Technical Notes

Divalent Rare Earth Activated 96% SiO_2 Glass

A. Wachtel

Westinghouse Electric Corporation, Bloomfield, New Jersey

Doping of porous 96% silica glass (1, 2) with organic dyes or transition metal ions, the latter followed by heat-treatment, is a well-known process for the preparation of color filters (3). Claffy, Ginther, and Arnold (4) reported on Ce, Sm, Mn, and Cu activated phosphors based on this material.

The present note describes the fluorescence of the divalent rare earths Eu^{2+}, Yb^{2+}, and Sm^{2+}, which is obtained only if Al^{3+} is also present. The glasses are therefore related to the high-SiO_2 form ("Phosphor I") of aluminosilicates which was described in an earlier publication (5), the principal differences in composition being only the B^{3+} content and the lower Al^{3+} content of the glasses.

The purpose of this note is twofold: (*i*) it shows that the effect of B^{3+} provides additional evidence concerning the nature of the Eu^{2+} activator center (5), and (*ii*) it attempts to explain the large effect of particle size on the spectral energy distribution of the Eu^{2+} emission in terms of optical cascade energy transfer.

Experimental

The raw material consisted of Corning No. 7930 glass ("thirsty Vycor") which contained 6.9×10^{-3} g atoms Al/mole. In the few instances where Al-free glass was required (Al = 0 points in Fig. 2), a raw material was prepared, in this laboratory, from 55 w/o (weight per cent) SiO_2-10 w/o Na_2O-35 w/o B_2O_3 glass by annealing at 575°C for 20 hr, and leaching in dilute HCl. The glasses were activated by impregnating with aqueous $RE^{3+}(NO_3)_3 + Al(NO_3)_3$ solutions of appropriate concentrations, followed by firing in a reducing atmosphere.

Fluorescence intensity of Eu-activated glass was measured by use of an integrating sphere in which specimens were excited through a 254 nm transmitting interference filter. Measurements were also taken on ground samples, using conventional powder plaques for which the intensity of 254 nm excitation was standardized with $CaWO_4$:Pb, NBS No. 1026. The detector used was the Spectra Brightness Spot Meter[1] set on "blue" ($\bar{z}$ sensitivity). Emission and excitation spectra were obtained as described by Thornton (6).

Results and Discussion

Figure 1 shows fluorescence intensity as a function of Eu for low or high Al concentrations. The former represent samples not intentionally doped with Al, *i.e.*, containing 6.9×10^{-3} Al/mole. The latter were prepared by impregnation, at 95°C, with fused salt mixtures $Al(NO_3)_3 \cdot 9H_2O + Eu(NO_3)_3 \cdot 6H_2O$. While fluorescence intensities of the samples prior to and after grinding are measured differently and are therefore not directly comparable, it can be seen that in both cases, maxima occur near 4×10^{-4} and 5×10^{-3} Eu. At approximately three times higher Eu concentrations, the samples acquired a yellow body color caused by a broad absorption band which is otherwise not present. At still higher Eu concentrations, the glasses devitrified. Note that the fluorescence intensity of unground specimens is highest at low Al and Eu concentrations, while the opposite holds true for powders.

Figure 2 shows fluorescence intensity, at three Eu concentrations, as a function of Al up to the highest

[1] Photo Research Corporation, Hollywood, California.

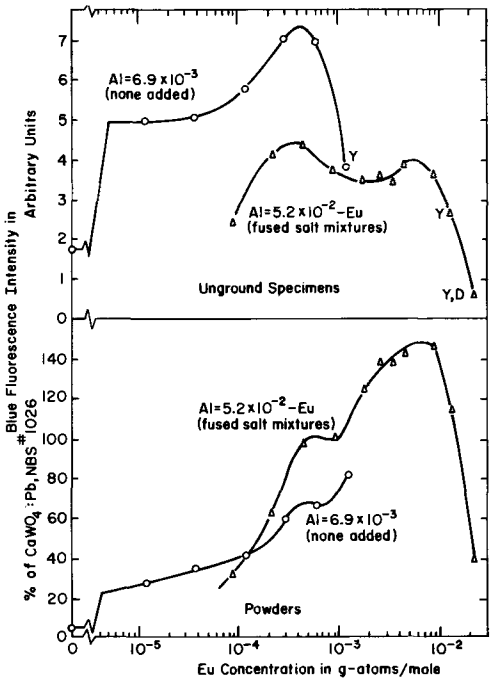

Fig. 1. Fluorescence intensity of 96% SiO_2 glass as a function of Eu^{2+} concentration. Y, yellow discoloration; D, devitrification.

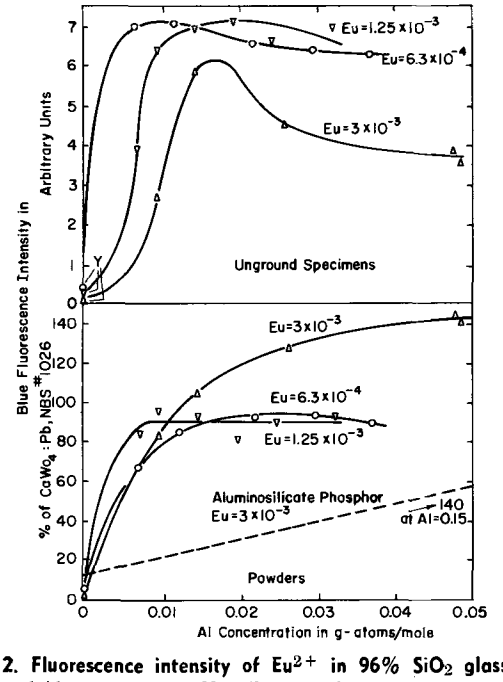

Fig. 2. Fluorescence intensity of Eu^{2+} in 96% SiO_2 glass as a function of Al concentration. Y, yellow discoloration.

attainable with the fused salt mixtures. In contrast to phosphors with varying Eu concentration (Fig. 1), single maxima are obtained; however, we note again that grinding shifts these to higher doping levels. The actual fluorescence intensity of powders prepared with 3×10^{-3} Eu becomes comparable to that of aluminosilicate phosphor I (5). It can be seen that in the powdered glasses, this fluorescence intensity level is obtained at somewhat less than 5×10^{-2} Al/mole, *i.e.*, at three times lower Al concentration than in the aluminosilicate phosphor,[2] and the shape of the curve suggests that at still higher Al concentrations, it would not be appreciably increased. At lower Eu concentrations, maximum fluorescence intensity in powders is obtained within the concentration range employed, but again, the fluorescence increases rapidly with increasing Al concentration. At Al = 0, the data were obtained on samples prepared with the Al-free raw material. These samples were essentially nonluminescent and showed a yellow body color even at the lowest Eu concentration.

A search for crystalline inclusions (mullite) which, in the case of the aluminosilicate phosphor, were proposed to be instrumental in the luminescence process, was unsuccessful. Even highly doped glasses failed to show distinct x-ray reflections or revealed significant inhomogeneities in electronphotomicrographs taken by transmission through thin edges.

The principal differences between the present glasses and the aluminosilicate phosphor, therefore, are the B^{3+} content of the glasses, and the lower Al^{3+} concentration which is required to produce the same fluorescence intensity observed in the aluminosilicate phosphor. The relatively large Eu^{2+} ion is a network modifier and therefore occupies interstitial sites. Charge compensation of network modifiers in silicate glasses by Al^{3+} or B^{3+} leads to formation of network forming (substitutional) $[AlO_4]$ or $[BO_4]$ tetrahedra (7-9). Each Eu^{2+} ion then requires two M^{3+} according to $2M^{3+} + Eu^{2+} = 2Si^{4+}$. The present experimental evidence, however, indicates that the activator center involves network modifying (interstitial) $[AlO_6]$ groups. This evidence may be summarized as follows: (*i*) Boron does not give rise to Eu^{2+} luminescence. Unlike Al^{3+}, it enters the SiO_2 network only substitutionally, an excess over low-valence modifiers forming triangularly coordinated $[BO_3]$ groups (9, 10). It is likely, therefore, that Eu^{2+} charge-compensated by substitutional Al^{3+}, is also nonluminescent. (*ii*) At low concentrations, Al^{3+} normally tends to occupy substitutional sites; in the presence of B^{3+}; however, some of the Al is displaced into interstitial sites (11, 12). The more rapid rise of fluorescence intensity with Al concentration in the (B-containing) glasses, as compared with the aluminosilicate phosphor, can therefore be explained by the more rapid rise in concentration of interstitial Al. (*iii*) Even in the glasses, maximum fluorescence intensity obtains at Al/Eu ratios which are substantially higher than the 2/1 ratio suggested by charge compensation. Again, such excess Al is known to occupy interstitial sites (9, 12, 13).

These arguments suggest that the luminescence center in the (homogeneous) glasses is basically no different from that proposed for the heterogeneous aluminosilicate phosphor in which Eu^{2+} replaces Al^{3+} at a mullite surface, and is charge compensated by Si^{4+} at the adjacent amorphous SiO_2 phase (5). In both cases, Al is a cation, and only the size of $[AlO_6]$ aggregates and the degree of crystalline order of interstitial aluminosilicates is different.

Emission spectra consist of bands with widths at half maximum averaging 77.1 nm in unground, and 75.6 nm in ground glasses. Variations in Eu concentration primarily affect the peak emission wavelengths as seen in Fig. 3. This figure shows the same low and high Al series shown in Fig. 1. In both cases, it can be seen that at high as well as low Eu concentrations, the emission spectra are independent of particle size. At moderate Eu concentrations, however, differences become pronounced, particularly in the high Al glasses. At 2.7×10^{-3} Eu, this difference is at a maximum of 10 nm. A displacement of the emission band is also observed by shifting the excitation of powders to longer wavelengths, as shown in Table I. Here it can be seen that in going from 254 to 405 nm excitation, the emission peak is shifted to longer wavelengths by 15.6 nm. The table also shows that the width at half maximum does not decrease (as expected by lack of emission below 405 nm), but actually increases by 2.2 nm.

Figure 4 shows the emission of the 2.7×10^{-3} Eu glass under 254 nm excitation. The excitabilities of the

[2] In ref. (5), Al was expressed as Al_2O_3 with the optimum at 0.075, *i.e.*, 0.15 Al.

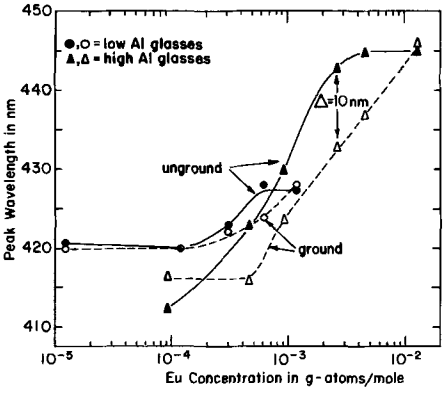

Fig. 3. Peak emission wavelength of 96% SiO_2 glass, under 254 nm excitation, as a function of Eu^{2+} concentration.

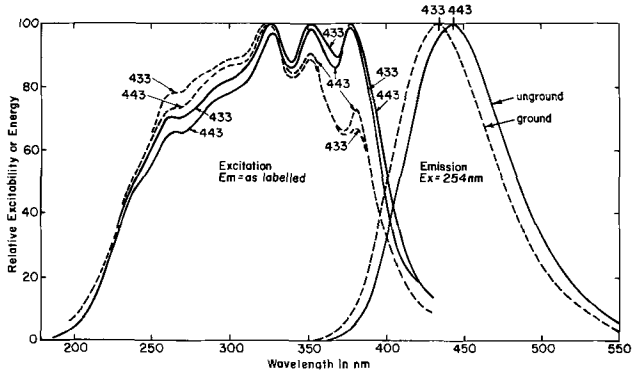

Fig. 4. 254 nm—excited emission spectra, and excitation spectra of 96% SiO_2 glass containing 2.7 x 10^{-3} Eu^{2+}/mole. Numbers in figure denote wavelength of measured emission.

two peak emission wavelengths, shown by the numbers in the figure, are also included. The relative heights of these are seen to vary with the observed emission wavelengths in the direction one would expect, and even more strongly with the particle size. In the latter case, the displacement is in the direction of greater excitability of powders at shorter wavelengths.

The 10 nm shift to longer wavelengths of the emission of the unground glass, as compared to that of the powder, is not due to self-absorption alone, since the emission band width is not narrower. It is therefore caused by excitation energy at longer wavelengths which is present in addition to the 254 nm radiation employed. Figure 4 shows that this energy originates from the 254 nm-excited emission of the glass, and that radiation near 400 nm (the center of overlap between the excitation and emission spectra) is primarily responsible for this process. Since pure 405 nm excitation of the powder caused a shift of 15.6 nm (Table I), it follows that in the present case, the shift should be smaller. The observed value of 10 nm, therefore, indicates that about 2/3 of the emission of the unground glass originates from optical cascade energy transfer. A detailed treatment of powder-optical processes which contribute to the present discussion is given by Melamed (14).

Table I. Emission properties of powdered 96% SiO_2 glass doped with 4.9 x 10^{-2} Al^{3+} and 2.7 x 10^{-3} Eu^{2+}

Excitation wavelength, nm	Emission peak wavelength, nm	Emission width at half maximum nm
254	433.0	76.0
365	435.5	75.2
405	448.6	78.2

96% silica glass (as well as the aluminosilicate phosphor) can also be activated by Yb^{2+} or Sm^{2+}, although these elements proved to be more difficult to reduce to the divalent state than Eu. Figure 5 shows excitation and emission spectra of an unground specimen of glass doped with 4.4 x 10^{-3} Al + 2.2 x 10^{-3} Yb/mole and fired in H_2 for 20 hr. The excitation spectrum, taken with Hg lines, is corrected for equal quanta of exciting radiation, but may contain more detail than indicated in Fig. 5. Nevertheless, it appears that there may be four excitation bands in addition to the pronounced increase in excitability towards short wavelengths. The broad emission band is unproportionally high on the short wavelength side, and therefore may consist of a number of unresolved bands. Figure 6a shows excitation and emission spectra of a glass doped with 4.4 x 10^{-3} Al + 2.2 x 10^{-3} Sm, fired in air, and Fig. 6b shows the same glass fired in H_2 for 20 hr. The excitation spectra in Fig. 6a and 6b were taken with a continuous source of uv, and are also corrected for equal quanta of exciting radiation. It can be seen that at 77K, neither the excitation nor the emission spectra of Sm^{2+} are significantly better resolved, although the vibronic side bands are markedly decreased. In this respect, the emission line widths of Sm^{2+} in the glasses differ from those in many crystalline matrices (15-19) where usually, broad bands are observed at room temperature. It should also be noted that the emission of the H_2-fired glass includes weak lines at 602 and 649 nm due to Sm^{3+}; with 254 nm excitation (not shown) these are considerably enhanced. This is caused by incomplete reduction in spite of the prolonged firing, and due to the relatively high reduction potential of Sm (20). For this reason, optimum doping with Sm (or Yb) is somewhat higher than with Eu, and detailed measurements of fluorescence as a function of actual Sm^{2+} or Yb^{2+} concentration have not been carried out.

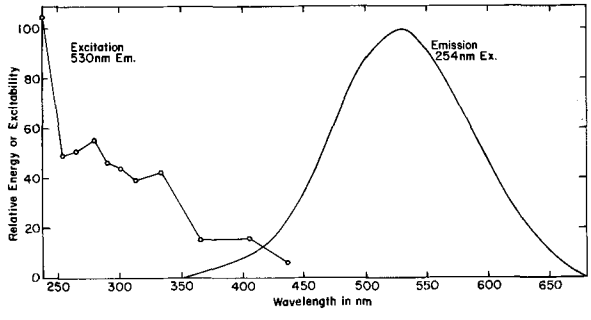

Fig. 5. Excitation and emission spectra of 96% SiO_2 glass doped with 4.4 x 10^{-3} Al + 2.2 x 10^{-3} Yb/mole, fired in H_2 at 1150°C for 20 hr.

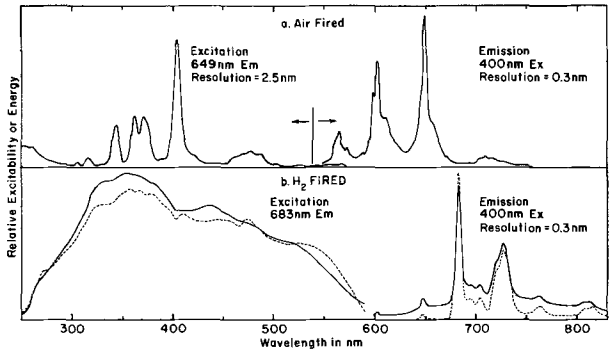

Fig. 6. Excitation and emission spectra of 96% SiO_2 glass doped with 4.4 x 10^{-3} Al + 2.2 x 10^{-3} Sm/mole; a, fired in air at 1150°C for 3 hr; b, fired in H_2 at 1150°C for 20 hr. Solid lines = spectra at room temperature; broken lines = spectra at 77K.

Acknowledgments

The writer wishes to thank Miss I. Walinski for sample preparation and measurements, and W. A. Thornton, N. T. Melamed, W. B. White, and C. Hirayama for spectra and helpful discussions. E. P. Riedel kindly determined the spectra of the Sm activated glasses.

Beryllium as an Acceptor in Silicon

E. A. Taft and R. O. Carlson

General Electric Research and Development Center, Schenectady, New York

The high oxygen content of Czochralski grown silicon crystals is well known (1), and some study has been made of the reactions of group III acceptors with this oxygen (2). The high free energy of formation and great thermal stability of BeO is also well established (3). The possibility of beryllium combining with oxygen in liquid or solid silicon to form a stable, electrically inactive impurity led to our investigation.

Experimental

Beryllium has been added to 500 ohm-cm silicon to be pulled from quartz crucibles. Single-crystal material was difficult to grow by this method because of nucleation from oxides on the melt surface, but specimens which could be studied were obtained. A beryllia crucible was also found to be suitable for use in pulling doped single-crystal silicon. However, the reaction of molten silicon with the crucible wall supplied the dopants, and the amount of dopant obtained could not be controlled. Also beryllium was diffused into oxygen-containing n-type and p-type silicon wafers at 1170°C for times up to 16 hr. It was found that consistent results could be obtained only if the beryllium metal was not directly exposed to the quartz walls of the furnace. The silicon test sample was, therefore, enclosed with beryllium in a cavity of silicon while the diffusion proceeded. In addition, float-zoned crystal of 1 ohm-cm beryllium doped oxygen-free silicon was made available by R. J. Mulligan. These variously doped crystals were then studied in infrared absorption, resistivity, Hall effect, and heat treatment.

Results

The oxygen content of undoped silicon crystals pulled from small quartz crucibles is typically 10^{18} atoms/cm^3. The oxygen is readily determined by infrared absorption (1). Beryllium doped crystals pulled from similar quartz crucibles typically contained 10^{17} atoms/cm^3 of oxygen, a moderate reduction. There is possibly some gettering of oxygen by beryllium in the melt, but, more likely, the formation of a beryllium silicate on the quartz crucible wall reduced the reaction rate of molten silicon with quartz. Crystals pulled from beryllia crucibles were found to contain oxygen in amounts comparable to that found for the beryllium doped crystals pulled from quartz crucibles. This oxygen level does not approach the concentrations of 10^{15} atoms/cm^3 found in float zoned silicon.

The distribution coefficient, k, of Be in silicon was obtained for a number of crystals pulled from quartz crucibles. The impurity concentration, C_S, of acceptors was obtained from traveling probe resistivity data at room temperature (4). (Most of the acceptors are ionized at the low concentrations obtained.) C_S is plotted against the atom fraction, g, of the initial charge solidified in a pulled crystal in Fig. 1. The curve $C_S = kC_L/1 - g$ contains the initial concentration, $C_L = 3.2 \times 10^{19}$ atoms/cm^3 of beryllium in the liquid obtained from the initial weighed charges of beryllium and silicon. For best fit to the points, k was selected at 1.3×10^{-4}. The consistency in results for several crystals measured, and the excellent fit to the curve, indicate that the dopant losses during the crystal growth were not significant. All crystals were "p" type showing values between 1.3 and 1.6×10^{-4} for k.

N-type silicon of 50 ohm-cm and of 0.06 ohm-cm was converted to p-type after Be was diffused at 1170°C for up to 16 hr, indicating the acceptor nature of the Be center. As the resistivity of these crystals was no longer changing with time of diffusion, the silicon appeared to be saturated with Be after this treatment. The resistivity *vs.* temperature for one of these crystals, Be 3, is shown in Fig. 2. Also in this figure are the data for K-97, a Be-doped crystal pulled from a quartz crucible. These p-type crystals prepared by different methods show the same deep-lying acceptor level of Be. The carrier concentration derived from Hall effect data for these same two crystals is given in

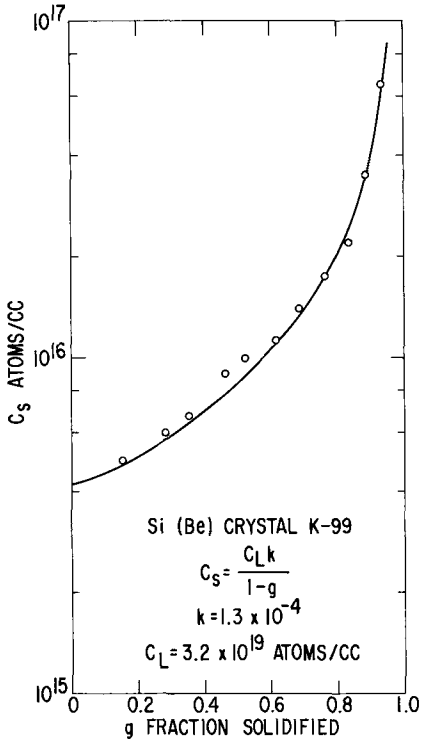

Fig. 1. Distribution coefficient of beryllium in silicon; k is chosen for best fit to the data points.

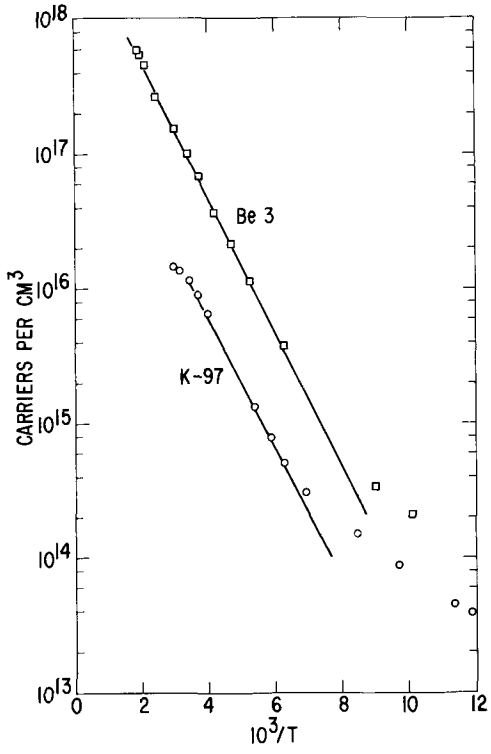

Fig. 3. Temperature variation of hole concentration in beryllium doped silicon derived from Hall effect data.

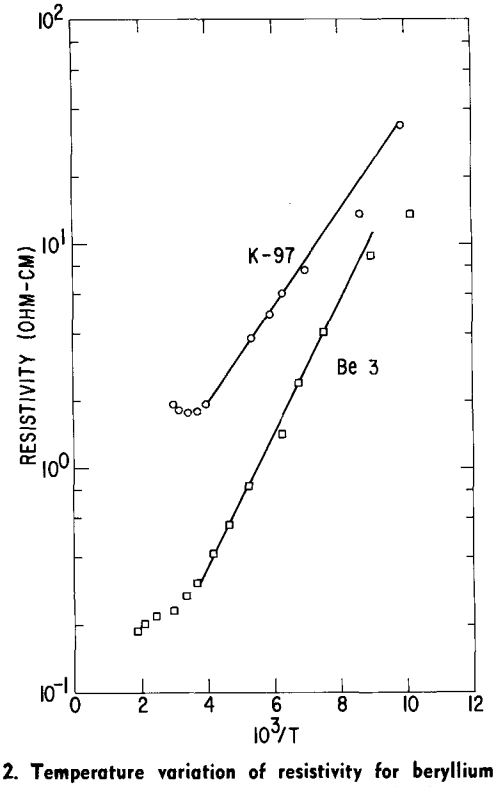

Fig. 2. Temperature variation of resistivity for beryllium doped silicon. K-97 is a grown crystal containing Be; Be 3 is a Be diffused silicon sample.

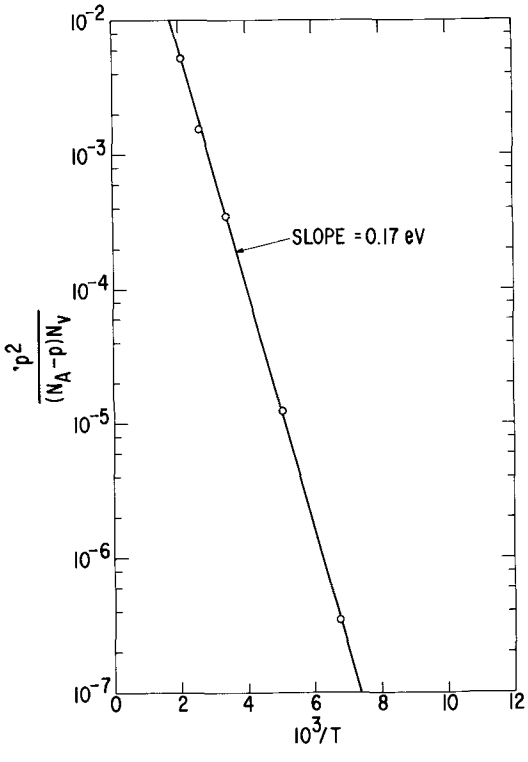

Fig. 4. Acceptor level determination from Hall effect data using corrections for total acceptor sites and for temperature variation of valence band density of states.

Fig. 3. A room-temperature mobility of 230 $cm^2\ V^{-1}\ sec^{-1}$ with an exponential temperature dependence of -2.4 for Be 3 shows that this crystal exhibits reasonable behavior for doped silicon. K-97 also exhibits normal mobility values.

Further analysis of the Hall effect data, such as that used by Hutson (5), yields the curve of Fig. 4. All crystals analyzed were similar in showing an activation energy of 0.17 eV for the Be acceptor center. Following Hutson, the intercept of Fig. 4 can be used to estimate the degeneracy of the Be center. As Fig. 4 was derived from a crystal with $< 10^{14}$ donor centers, compensation was negligible and the simpler equation is used.

$$\frac{p^2}{(N_A - p)N_V} = \left(\frac{m}{m}\right)^{*3/2} D^{-1} \exp\left(\frac{-E_o}{kT}\right)$$

The intercept is 0.25, $(m/m)^{*3/2}$ is 0.45 for holes in silicon leaving a degeneracy factor $D = 1.8$ or closely 2.

The possibility that Be contributes two levels in silicon has been considered but not investigated. The chemically similar element, zinc, is known to give two levels (6). If beryllium is considered to be a well-behaved solute in silicon, the distribution coefficient can be used to estimate the solid solubility at any temperature (7). Our coefficient of 1.3×10^{-4} would give an equilibrium concentration of 5×10^{17} Be atoms/cm^3 at 1170°C. As the data of the diffused sample Be 3 of Fig. 3 do not show a saturation of carriers, the room-temperature value has been utilized. Assuming an acceptor level of 0.17 eV in silicon, the number of acceptors needed to get the 10^{17}/cm^3 room-temperature carriers observed in Fig. 3 is calculated in the usual textbook approach. The value of 1.2×10^{18}/cm^3 acceptors obtained is higher than, but in reasonable agreement with, the value obtained from the distribution coefficient. Our data are not considered to be of sufficient accuracy to deduce an arguable meaning, such as two energy levels, from these differences in acceptor concentration.

Further trying to take advantage of the affinity of beryllium for oxygen, some of the crystals were subjected to heat treatment at 1000°C. The crystals contained initially 10^{16} atoms/cm^3 of Be and 10^{17} atoms of O_2 as determined from resistivity and from infrared absorption, respectively. The room-temperature resistivity of the samples rose by a factor of over 100 after only a few hours of heating. The Be was no longer active electrically and only background impurities of $< 10^{14}$/cm^3 were in evidence. The oxygen content changed little, if at all, but the oxygen was of course in great excess relative to the beryllium. A short heat treatment at 1300°C did not return the resistivity to the original value as is the case for the more usual dopants upon interaction with dissolved oxygen (8). The beryllium was thus not available for redissolution (9). In this case, it is not clear whether the Be actually left the crystal by means of diffusion to the surface or whether a Be-O combination is too tightly bound to be dissociated to any extent at 1300°C.

A 2 mm thick piece of oxygen-free beryllium doped ($\sim 10^{16}$/cm^3) crystal was heated in argon at 1050°C for 1 hr. The room-temperature resistivity doubled after this treatment, the Be presumably going to the surface to react with the surface oxide. From this result, we have an estimate of the diffusion coefficient of Be in silicon at 1050°C of $\sim 10^{-7}$ cm^2/sec. In this case, it is clear that the Be is leaving the silicon and not reacting with dissolved oxygen as could be expected with the pulled crystal samples. Diffusion or clustering of O_2 is not significant for these short times and low temperatures.

To sum up, beryllium in silicon is a fast diffuser giving an acceptor level at 0.17 eV. The distribution coefficient is 1.3×10^{-4}. A Be-O combination has not been observed.

Acknowledgment

We wish to acknowledge the interest and encouragement of the late F. H. Horn who suggested this study.

High-Surface-Area Electrodeposited Aluminum

Richard J. Roethlein

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Aluminum was electrodeposited from a nonaqueous organic hydride electrolyte, $AlCl_3$ and $LiAlH_4$ in ethyl ether, which produced aluminum deposits ranging from smooth compact to rough and highly porous. Formation of high-surface-area Al substrates has been obtained by the application of high current densities. High-capacity values are explained on the basis of fine particle formation incurred under these plating conditions. Current-voltage curves for the anodic and cathodic reaction are indicative of a diffusion-controlled process.

The preparation of high-surface-area aluminum electrodes for electrolytic capacitors has always been a major concern in order to obtain the maximum capacitance values per unit geometric area or volume. Increasing the surface area of aluminum has been done for the most part either by chemical or electrolytic etching. Recently, however, large surface gains have been reported (1) through the electrodeposition of aluminum.

By means of an organic aluminum plating solution (2) and varying current density, aluminum dendritic growths have been reported to produce a surface gain factor over smooth aluminum of one to two orders of magnitude, depending on the formation voltage of the sample. Due to the possible advantages such a method may have in producing high-surface-area aluminum substrates, an investigation was undertaken to determine the feasibility of electrodepositing aluminum.

The formation of dense compact aluminum deposits has received considerable attention in the literature (2-7); however, highly dispersed porous aluminum deposits which would produce maximum surface roughness have been avoided. Parameters were therefore studied which would affect the nature of the aluminum deposit and tend to produce high-capacitance values. Electroplating was carried out in a nonaqueous electrolyte on aluminum wire electrodes.

Experimental

Due to the detrimental effects moisture has on aluminum plating baths, all experiments were carried out in a dry box containing an atmosphere consisting of 9 parts N_2 and 1 part H_2. Reagent-grade anhydrous materials used in the plating solutions were weighed inside of the dry box to avoid contact with water vapor in the atmosphere. The aluminum plating bath was an organic electrolyte (5, 6) which was operable at room temperature and consisted of an ethyl ether solution of 3M $AlCl_3$ and 0.4M $LiAlH_4$. The addition of anhydrous ether to the alkali halides must be done slowly, otherwise foaming and undesirable side reactions occur which affect properties of the plating solution. The plating cell consisted of a cylindrical Pyrex glass vessel 6 in. in length formed from a 60/50 joint; the top portion consisted of an array of equally spaced 10/30 joints which served as inlet ports for the study, reference, and counter electrodes. The study electrode was a section of 47 mil diameter aluminum wire, 99.99% purity, which was sealed to a section of Pyrex tubing by means of heat shrinkable Flo-tite[1] Teflon[2] tubing. The aluminum electrode, with an exposed geometric area of approximately 0.5 cm^2, could then be adjusted in the plating cell by means of a 10/30 Teflon gland. The counterelectrode consisted of a spiral section of either aluminum or platinum wire which provided an even current distribution on the study electrode. A Luggin capillary was sealed to one of the 10/30 joints into which a section of platinum wire was inserted which served as the reference electrode.

Aluminum electrodes were precleaned by the following sequence: immersion into acetone, rinsed, concentrated solution of 85% H_3PO_4-15% HNO_3 at 85°C for 2 min, rinsed, 1N-NaOH 2 min, rinsed, then dried at 90°C. After immersion into the plating solution, it was necessary to preanodize the electrode at a high current density, 200 mA/cm^2, for about 1 min; failure to preanodize the electrode in the plating solution produced nonadherent deposits. After anodization was complete, the current was immediately reversed to the appropriate cathodic plating current.

Both capacitance and RC product values were measured with a conventional a-c bridge having a few millivolts' signal. The electrodeposited wire was suspended in a cylindrical glass tube, the sides of which were lined with a platinum black counterelectrode. The measuring electrolyte had a resistivity of 12 ohm-cm and was used previously by Burger and Cheseldine (8). Oxide formations were carried out in a solution of 17% ammonium pentaborate in ethylene glycol. Values of the capacity measured at "zero voltage" were taken on the unformed wire which has a thin natural oxide on its surface.

Results

The use of this organic aluminate plating solution provides uniform adherent electrodeposits of Al and has the added advantage of being operable at room temperature. Conductometric studies (9) have shown that an ethereal solution of $AlCl_3$ will increase in conductivity with addition of $LiAlH_4$ up to approximately 17% equivalence. The formation of ionized species,

[1] Trade-mark, Pope Scientific Company.
[2] Trade-mark, Du Pont Corporation.

$Al_2Cl_5^+ + AlH_4^-$, has been postulated to produce this conductivity maximum; further addition of the hydride causes a destruction of the ionic species and lowering of the conductivity. A contrary view has been held by several authors (13, 14) in that the presence of excess $AlCl_3$, or the formation of $AlHCl_2$ or trichlorodialane $AlH_2Cl \cdot AlHCl_2$ is considered more favorable. Recent studies (15) have postulated the existence of several chemical species present in the plating solution and the possibility that the plating current is carried by three or four different ions. They conclude that an anion containing hydride exists and that the Li etherate is the principal current-carrying ion. The exact nature of the ionic species in solution has still, however, not been definitely proved.

In the presence of moisture, oxygen, and carbon dioxide the bath rapidly deteriorates; hydrogen gas is liberated at both electrodes during electrolysis, but to a much greater extent at the anode. Brenner (6) concluded that the bath was not regenerative due to a different ionic species formed during the dissolution of aluminum. More extensive studies (15) of bath life, extending over an 8 month period, have shown that the Al anode does dissolve to some extent in a manner which replaces the deposited aluminum. We have found that reproducible plating results can be maintained by a periodic addition of solid $AlCl_3$ and $LiAlH_4$ to the plating solution.

Surface roughness of the electrodeposited material can be varied to a considerable extent by variations in the plating current density. Generally, a current density less than 50 mA/cm² tends to give a smooth deposit. As the current density is increased the deposits tend to become nodular, and for values greater than 100 mA/cm² dendritic growth becomes rapid. At current density values greater than 300 mA/cm², a black powdery-like deposit forms on the electrode surface. Values of the capacity showed a large variation with changes in the surface morphology of the electrodeposited aluminum.

A series of aluminum electrodes having an apparent geometric area of 0.5 cm² were electroplated at various cathodic current densities both at constant cathodic charge (Q), and also for varying periods of time with current density constant. For electrodes plated at current densities ranging from 50 to 300 mA/cm², capacity measurements taken at zero formation voltage fell into a limited range from 4 to 15 μfd/cm². Depending on the amount of charge passed, deposit thickness for these electrodes ranged from 1 to 10 mils, the thicker deposits exhibiting the higher capacity values.

Larger values of the capacity were not realized until the plating current density was increased to values greater than 300 mA/cm². At these extremely high current densities, a black deposit forms on the electrode surface accompanied by gas evolution. Capacity measurements gave values in excess of 150 μfd/cm² on the unformed wire, and plots of the reciprocal of capacity *vs.* formation voltage were linear (Fig. 1). Microscopic inspection of the dark deposit at magnifications up to 500X show the growth of crystals. Spectrographic comparison of the electrodeposited material and an Al wire showed traces of B, Si, Fe, and Cu to be present in both samples. Lithium, which is one of the constituents of the plating solution, was not detected in the sample of electrodeposited aluminum using a method accurate to 10 ppm. Photomicrographs taken on a cross section of an Al wire that was electroplated at a current density of 500 mA/cm² for 7 min are shown in Fig. 2. The photos show that electrodeposited material consists of a highly porous deposit, 3-4 mils in thickness, containing dendritic growths of varying diameter.

Figure 3 is a plot of capacity/cm² *vs.* formation voltage comparing the results we obtained for a wire electrodeposited at 300 mA/cm² for 5 min with that reported by Muhlhausser (1). In the low-voltage region, <10V, Muhlhausser's data indicate a considerable increase in capacitance over what we have found on

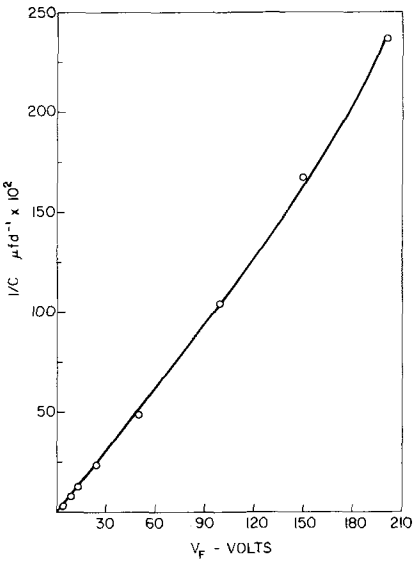

Fig. 1. Reciprocal capacity vs. formation voltage: electrodeposited Al, 300 mA/cm², 5 min.

electrodeposited wires; at higher formation voltages, the capacities he reports are considerably less than what we have observed.

The capacity of unformed wire was studied for Al deposits obtained at several high current densities for varying periods of time. Figure 4 indicates a sharp rise in capacitance with the amount of Al deposited

which tends to level off as the charge increases. The capacity also seems to be a function of the plating current density, the highest values being obtained for a current density the order of 500 mA/cm². The lower capacity values obtained at higher plating current density are due to a lack of adherence of the depositing material which becomes increasingly worse as the current density is raised. Adherence of the electrodeposited Al at high current density can be somewhat enhanced if a periodic short current reversal is applied during the plating sequence, *e.g.* 5 sec anodic/60 sec cathodic. During current reversal, the species formed could be aluminum hydride (16).

Values of the capacity measured as a function of formation voltage for three different deposit thicknesses (Fig. 5) indicate less of a capacity loss is incurred at higher formation voltages for thicker electrodeposits of aluminum. This does not contradict the previous findings, for if the samples used in Fig. 4 were formed at a higher formation voltage a more linear rise in capacity with charge increase would be observed.

Steady-state current voltage curves for the deposition and dissolution of aluminum were taken galvanostatically, potential differences being measured between the study electrode and a platinum reference electrode. A linear relationship exists between current and potential for both the anodic and cathodic electrode process; polarization values are similar to

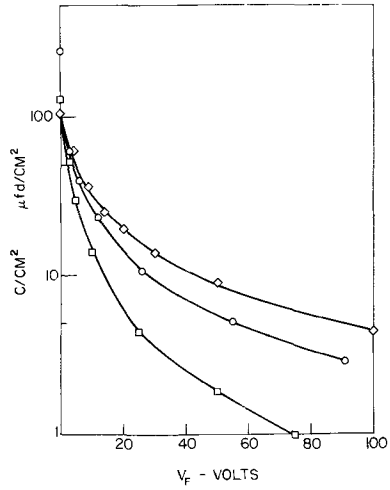

Fig. 5. Capacity/cm² vs. formation voltage as a function of deposit thickness. ◇—9 mils, 300 mA/cm², 20 min; ○—3 mils, 300 mA/cm², 5 min; □—1 mil, 300 mA/cm², 1 min.

those reported by Hayashi (10). A semilog plot, Fig. 6, gives a low value of the slope for the linear portion of the curve between 5 and 10 mV/decade. The low value of the slope eliminates the possibility of activation control and indicates that the reaction is most probably diffusion controlled. Measurements of the difference in potential between the extended linear portion of the curve and the potential observed at a certain current density gave a constant value for the resistance, $\Delta E/I$, over the range of currents studied. Although the shape of the curve indicates a limiting current region, most of the polarization is due to an ohmic drop incurred through the electrolyte. This is further emphasized by the small decrease in polarization that was observed when the electrolyte was stirred. For the concentrations used in these experiments, a true limiting current is not observed until current densities from 200 to 300 mA/cm² are reached.

Discussion

Since the largest capacity increases were observed for aluminum electrodeposits obtained at high current densities, the discussion is concerned mainly with that region of the experimental results. The formation of very fine crystals or powder metals by electrolysis is well known in the powder metallurgy industry, and these forms have been prepared from a wide variety of metals in both aqueous and nonaqueous systems (11). These deposits often appear black because of the very small size of the particles. The structure of these deposits depends strongly on the formation of new nuclei and the rate of growth of the already existing crystals. If the rate of nucleation is

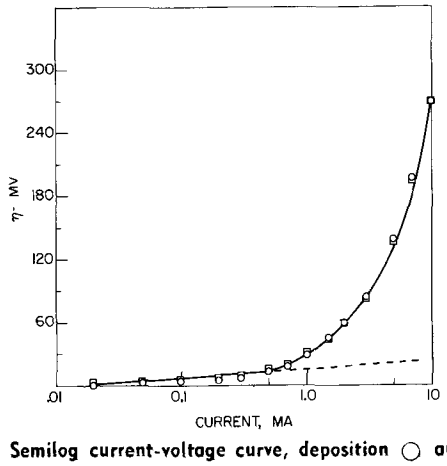

Fig. 6. Semilog current-voltage curve, deposition ○ and dissolution □ of Al.

large and crystal growth is inhibited, the formation rate of powder metals will be increased. Those factors that tend to reduce interfacial concentration, such as increased current density or decreasing metal ion concentration, will favor a high nucleation rate. As the concentration of metal ions in solution approaches zero, at limiting current, the onset of powder deposition begins.

We have observed experimentally that, upon application of a current sufficiently high to cause powder deposition, a black deposit does not begin to form until after a few seconds' time have elapsed. This lag is due to the time necessary to reduce the concentration of Al ions to near zero at the electrode solution interface. Initially, a bright metal deposits on the electrode but, as the concentration of Al ions at the interface approaches zero, a black powder begins to form. Consequently, those factors (current density, temperature, rate of stirring) that influence mass transport phenomena influence the formation of both powder deposition and particle size. After the onset of a black powdery deposition, we have observed that for current densities between 300-500 mA/cm^2 the deposits tend to become metallic again after several minutes of plating. This is probably due to an increase in the surface area of the electrode which in turn reduces the true current density. Thus, the Al ion concentration at the surface is increased favoring the deposition of larger metallic aluminum particles. This view is supported by the photomicrographs in Fig. 2 which show that larger particles tend to grow as the thickness of the electrodeposit increases.

The aluminum deposits we have studied in this work which have exhibited high capacities are a combination of very fine black Al particles overgrown by a porous dendritic deposit. Aluminum deposits grown at current density below the formation of powdered Al exhibit capacities that are an order of magnitude lower even though they are dendritic in nature and of the same or greater thickness. Capacity measurements for the deposition of copper (12) have also shown that a steep rise in capacity occurs with the onset of powder formation at limiting current.

The adhesion of these powder deposits is favorable for current densities below approximately 500 mA/cm^2; for higher current density values, the black particles fall off the electrode easily. It is therefore necessary to maintain a current density in the region where the particles will adhere to the aluminum substrate; this can be enhanced to some extent by a periodic reversal of current for a short duration.

Conclusions

1. A nonaqueous organic plating solution has been used successfully in electrodepositing aluminum to obtain high-surface-area Al electrodes.
2. The increased capacity values observed for these deposits have been related to the formation of fine black Al crystals which are obtained in the region of limiting current density.
3. Current-voltage curves indicate that the electrodeposition of Al from this electrolyte is probably diffusion controlled.

Electrodeposition of Resin

S. Mercouris and W. F. Graydon

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The electrodeposition, under constant voltage, of an emulsion of a polyacrylic resin is studied. The coulombic yield of the process is examined at different voltages and for different deposition times. The coating is analyzed for iron, and the iron content/coulombs relationship was found to be linear. An addition of a small amount of Cl^- in the bath highly increased the iron content of the coating. The role of the electrodissolved anodic metal is examined by comparative deposition on steel and platinum. The water content of the coating was studied and the "gassing" effect at the anode was related to the resistance of the resulting film.

Electrocoating, as a method of applying primers or finishes on metalic surfaces, has attained wide application in recent years. Several patents cover the use of different electrocoating baths and conditions of deposition. However, in spite of the numerous publications in this field, the actual mechanism of the electrodeposition process is not yet clearly understood, and the continuous operation of the electrocoating tanks still involves many problems.

The composition of an electropainting bath is very complex. It may consist of resin, pigment, extenders, and a crosslinking agent as well as other compounds

which give specific properties to the coating. All those constituents must be deposited at the same rate or special care must be taken to keep the composition of the bath constant. The problem is solved mainly by special formulation of the bath, so that equal rates of deposition are attained.

Due to the complexity of the electropainting bath, and the fact that a knowledge of behavior under simple conditions is a prerequisite to the understanding of complex technological problems, a relatively simpler system of an emulsion of a polyacrylic resin was studied. Moreover, the resin undergoes all the reactions leading to the deposition of the paint. The resin was solubilized in water by use of triethylamine and the suspended particles of the emulsions were aggregates of polymeric molecules charged by the ionization of some carboxyl groups of the molecules located on the surface of the particle.

Tawn and Berry (1) discussed the application of the theories of Pauli and Helmholtz to the above systems and they stressed the difficulties in studying them in terms of fundamental physicochemical properties alone. Following their ideas in the present work, the relationship among some of the less fundamental variables of the electrodeposition process was studied. The rest of the variables had to be kept constant and this caused some problems when the degree of dispersion was to be kept constant. In the emulsion of the resin, there is a wide distribution of particle sizes and size/charge ratios. This distribution cannot be exactly reproduced and, even for a given solution, changes with time. This difficulty can be easily overcome in many cases by taking all the measurements within a short time interval, but nothing can be done in the case where the concentration of the resin is the independent variable. The dependent variable then does not depend only on the given concentration, but also on the degree of dispersion of the prepared emulsions. Consequently, a higher variance is expected.

This can be clearly demonstrated in Fig. 5. Each point of the three lines is the mean of two measurements with a mean deviation less than 1% and all the points of each line come from measurements taken in a short time interval. However, the repetition of the same experiment, using the same emulsion on three different days, produces three distinct curves and this must be attributed to the change in the degree of dispersion of the emulsion since all the other variables can be considered reproducible.

Electrode reactions.—The species moving toward the anode by the applied electrical field are negatively charged colloidal particles of resin (colloid-R) COO^- and OH^-. It is generally accepted that the deposition is not due to the immediate discharge of the colloidal particles at the anode, and the main arguments are as follows:

1. Deposition can take place on diaphragms interposed between the anode and the emulsion which do not permit immediate contact between the colloidal particles and the anode [Fink and Feinleib (2)].
2. If deposition were due to immediate discharge of the particles, we would not be able to explain the deposition after the first layer is formed, since the particles cannot reach the anode any more [Finn and Mell (3)].
3. Tawn and Berry (1) reported a delay period before deposition could be observed and a progressive increase of the concentration of resin in the film adjacent to the anode (dipped film) during this period. This cannot be explained if the particles are immediately discharged and deposited.
4. Immediate discharge of the particles should be followed by a Kolbe Electrolytic Synthesis producing a condensation of the resin ions with an evolution of carbon dioxide. Gloyer, Hart, and Cutforth (4) have not detected either carbon dioxide evolution at the anode or significant reduction in acid value of the deposited resin.

It is generally accepted in literature that deposition is due to the following reactions.

$$(\text{Colloid-R})\text{COO}^- \xrightarrow{Fe^{2+}} [(\text{Colloid-R})\text{COO}]_2\text{Fe} \quad [1]$$

$$(\text{Colloid-R})\text{COO}^- \xrightarrow{H^+} (\text{Colloid-R})\text{COOH} \quad [2]$$

Fe^{2+} come from electrodissolution of the anode, and H^+ come from a local drop of the pH after the discharge and consequent removal of the OH^-.

Fink and Feinlieb (2) and, later, Olsen (5) proved that the iron is dissolved in the form of Fe^{2+} by adding thiocyanate or ferricyanide ions in the bath. The same was proved in this work more quantitatively by analyzing the coating for Fe^{2+} and Fe^{3+}.

May and Smith (6) tried to calculate the ratio of the amounts deposited, according to reactions [1] and [2], from the ratio of the electrical charges involved in each of them. The number of coulombs used for reaction [1] was calculated from the amount of iron determined by analysis of the coating. The charges involved in reaction [2] were calculated from the weight of the deposited coating and the acid number of the resin. The sum of the two numbers, as above calculated, was less than the total number of coulombs used for the deposition. They called this difference "unaccounted current."

Results and Discussion

Iron content of the coating.—A spectrophotometric method was used to analyze the coating for iron after dissolution with alcohol. The iron was determined in alcoholic solutions and in the presence of the resin. The number of coulombs used for the deposition was calculated from the area under the current/time curve obtained by the use of a recorder.

The lower curve of Fig. 2 shows the weight deposited *vs.* coulombs relationship, for different deposition times. A straight line, followed by a downward curve at higher deposition times (*i.e.*, beyond 4 min), is obtained. The slope of the straight line represents the coulombic yield of the deposition. A very small increase of the coulombic yield was observed with increasing concentration of the bath and a number 8-12 mg/coulomb was obtained for concentrations of 2-12% solids.

The amount of iron *vs.* the number of coulombs relationship for different times of deposition is linear as shown in Fig. 1. Since the coulombic yield is constant for different deposition times, a constant concentration of iron for different deposition times must be concluded. This concentration of iron was calculated to be of the order of 0.006%; the bath had a concentration of 2% solids. The relationship between the amount of iron and coulombs was also found to be linear for a solution of 12% solids and a similar iron concentration was calculated.

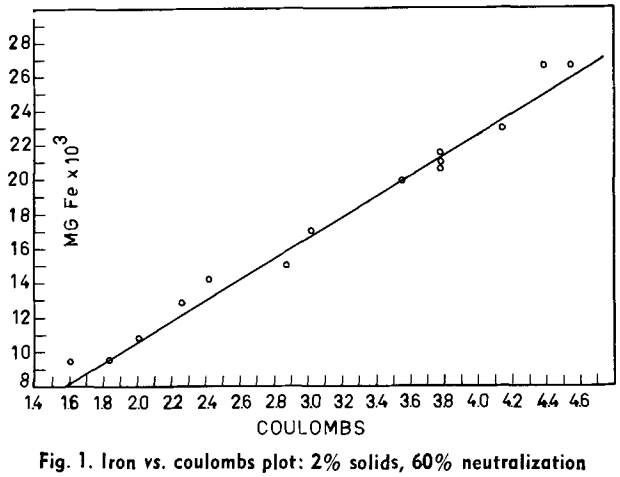

Fig. 1. Iron *vs.* coulombs plot: 2% solids, 60% neutralization

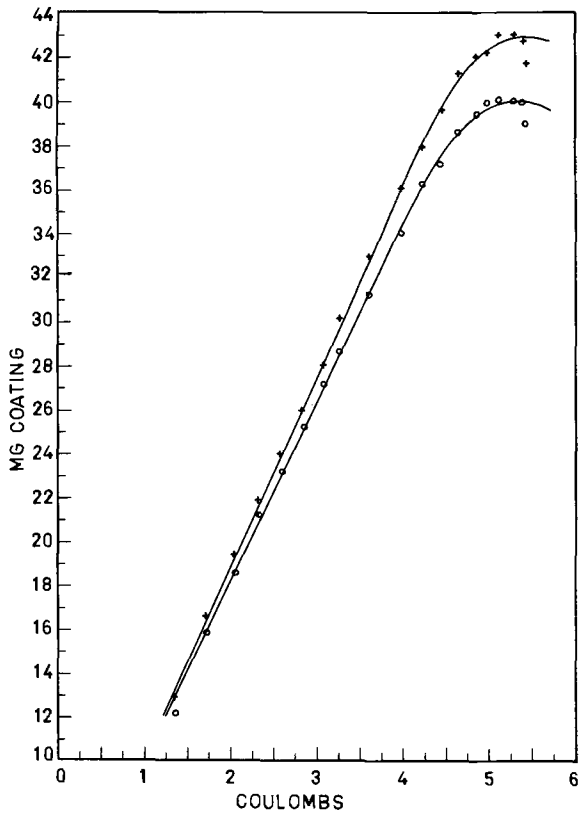

Fig. 2. Weight vs. coulombs plot: 2% solids, 60% neutralization. ○, Weight of baked coating; +, weight of unbaked coating.

The effect of the contamination of the bath with foreign anions was studied by adding a small amount of NaCl (50 mg/liter). The iron/coulombs relationship was again linear, but the concentration of iron was highly increased from 0.006 to 2%. The high concentration of iron is quite evident by the brown color of the coatings obtained.

Comparative deposition on iron and platinum was studied under identical conditions. The rates of deposition were found to be the same and identical coulombic yields were obtained. The equality of the coulombic yields is demonstrated in Table I. A pair comparison of the tabulated values must be considered (Fe-Pt), since the values for each pair are the result of experiments conducted under identical conditions (in a short time interval).

Role of iron in the electrodeposition process.—The percentage of the total current used to dissolve the iron can be calculated from the previous data. Table II shows the results for different runs.

Table I. Comparison of the coulombic yields for deposition on Fe and Pt

Conditions: 2% solids (+ 50 mg NaCl/liter)
60% neutralization
110V
3 min deposition time

Run No.	Coulombic yield Fe	Pt
1	8.24	8.30
2	7.83	7.61
3	7.25	7.55

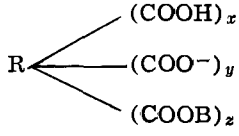
Table II. Percentage of coulombs used to dissolve the iron

	% Coulombs for iron
2% solids, 60% neutralization	2.07
12% solids, 60% neutralization	1.86
2% solids, 35% neutralization	3.37
2% solids (+ 50 mg/liter NaCl), 60% neutralization	72.8

The percentage of the current used for the iron dissolution seems to be independent of the concentration and has a higher value for a lower degree of neutralization.

From the acid number of the resin and the weight of the coating, the percentage of the current used to deposit the resin, according to reaction [2], can be calculated. This method of calculation, however, is not correct for the following reasons. The emulsion used for the electrodepositions consists of colloidal particles formed by aggregates of polymeric molecules. The charge of the particles is due to ionization of some carboxyl groups of molecules which are at the surface of the particle. However, there is a large number of other carboxyl groups which, being in the mass of the particle, are not ionized. Consequently, they do not take part in the electrodeposition reactions, but are deposited because of the deposition of the whole particle.

Tawn and Berry (1) represented the deposited species in the form



where B represents the neutralizing base.

x, y, and z can have different values depending on the ionization constants of the carboxyl groups and the base. Water insolubility or coagulation will result from an increase in the value of x, with a corresponding decrease in y, and will also be promoted by loss of base, *i.e.* fall in z. The above discussion shows that a particle can be deposited even when some of the carboxyl groups are still ionized or are neutralized with an equivalent amount of base.

It would be expected, thus, that by adding the percentage of the current used to dissolve the iron plus the percentage of the current calculated by counting all the carboxyl groups of the resin a number much higher than 100 would be obtained.

This was not verified by the experiments for they gave a sum much lower than 100. The difference from 100 is the unaccounted current reported by May and Smith (6).

Using an average value for the coulombic yield equal to 10, the percentage of the coulombs for the resin is calculated as being equal to 19. The unaccounted current, having been calculated equal to 79%, shows a very bad efficiency for reactions [1] and [2].

In the case of the bath contaminated with chlorides, the percentage of electrochemical equivalents for the iron was found equal to 72.8 (Table II). This is much higher than the percentage of the electrochemical equivalents of the resin calculated in the previous paragraph. That means that the amount of iron in the coating is much higher than the one required from the stoichiometry of reaction [1], even if we assume that this is the only deposition reaction. Consequently, questions arise as to the form in which the rest of the iron exists in the coating.

The results shown in Table I proving equal coulombic yields for deposition on iron and platinum cannot be explained by the previous theory. In the case of deposition on platinum, a large amount of current is used to discharge the chlorine ions producing chlorine gas. This amount of current does not result in any deposition. In the case of deposition on iron, the discharged chlorine ions dissolve the anode, producing iron ions, which deposit a certain amount of resin. Consequently, a higher coulombic yield for deposition on iron would be expected.

Sullivan (7) explains the existence of iron in the coating as being due to the formation of stable iron oxides by the reaction of the ferrous and ferric ions with the hydroxyl ions traveling toward the anode.

$$Fe^{+2} + 2\,OH^- \rightarrow Fe(OH)_2 \qquad [3]$$

$$Fe^{+3} + 3\,OH^- \rightarrow Fe(OH)_3 \qquad [4]$$

The main reaction explaining the deposition of resin in all cases is reaction [5].

$$(\text{Colloid} - \text{R})\text{COO}^- + \text{H}^+ \rightleftarrows (\text{Colloid} - \text{R})\text{COOH} \quad [5]$$

This reaction must be considered as having the form of equilibrium, and deposition occurs when $[(\text{Colloid}-\text{R})\text{COO}^-]\,[\text{H}^+] > k$, where k is the ionization constant of the resin. The drop of the *p*H close to the anode cannot be local, as often reported in literature, and a concentration gradient from the anode up to the bulk of the solution must be considered. Due to this concentration gradient, a large number of H^+ do not take part in the deposition reactions but are transferred to the bulk of the solution. This is a possible explanation of the "unaccounted current" since the current used to produce the above H^+ does not lead to any deposition.

Tawn and Berry (1) reported a higher concentration for the resin in the dipped film. An immediate discharge of the particles, as was already discussed, cannot be accepted. Consequently, a similar concentration gradient to H^+ for resin must be considered.

The delay period reported by Tawn and Berry (1) can be explained as the time required for the above two concentration gradients to build up. Deposition starts when the product $[(\text{Colloid-R})\text{COO}^-]\,[\text{H}^+]$ becomes greater than k. This also explains the progressive increase of the concentration of resin in the dipped film during the delay period reported by the same authors and the decrease of the delay period with an increase of the applied voltage reported by Yeates (8). The higher the voltage, the faster the formation of the two concentration gradients.

Finally, the curvature of the weight/coulombs curve after a long time of deposition, shown in Fig. 2, can be explained by the above proposed scheme. After a long time of deposition, the anode is almost isolated and there is a large potential drop through the film. The remaining potential difference is not sufficient to maintain the above concentration gradients. Thus, $[(\text{Colloid-R})\text{COO}^-]\,[\text{H}^+] < k$, and dissolution of the film occurs instead of deposition.

Water content of the coating.—The investigations of the water content of the film and the gassing effect, which will be discussed later, are of great technological importance since the studied variables are directly related to such qualities of the coating produced as appearance and resistance. For example, the higher the water content of the film, the higher the possibility of getting pinholes in the coating because of the escape of water bubbles during the baking process.

The water content of the film was calculated as the difference between the weight of a baked and an unbaked film under identical conditions. The unbaked film was dried by putting it in a desiccator under vacuum conditions.

Figure 2 shows the weight/coulombs plot of the baked and unbaked film for different times of deposition for a 2%-solids bath. It is interesting to note that even the weight of the unbaked film changes linearly with the number of coulombs. A problem arising here is that the difference in the weight of the unbaked and baked film, which gives the amount of water in the film, can be of similar magnitude as the variance of the distributions of the two numbers used for the subtraction. Consequently a great variance for the distribution of the water content is expected, making the results inconclusive.

The above problem was solved by drawing the regression lines and taking the differences between corresponding points. Each point of the regression line represents the mean of the distribution of the individual measurements, whose variance is eliminated in this way. A large number of points were used for the construction of the two regression lines in order to have a higher degree of confidence.

The values of the water content of the film at different times of deposition were calculated from Fig. 2.

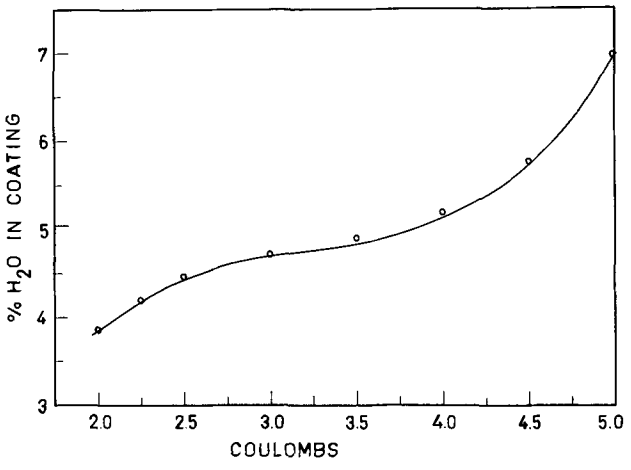


Fig. 3. Water content *vs.* coulombs plot: 2% solids, 60% neutralization.

The plot of the water content *vs.* the number of coulombs is shown in Fig. 3. An increase in the water content of the coating is observed with an increase in the number of coulombs at different deposition times.

The same work was repeated using a 12%-solids bath. The same increase of the water content was observed with increasing deposition time, but the actual numbers were higher (almost double).

The conclusion from the above results is that a film with lower water content can be obtained by using a lower concentration of resin and a shorter deposition time.

Gassing effect.—Tasker and Taylor (9) and, more recently, Curtis, Pugh, and Taylor (10) reported a peak in their resistance of the film/weight deposited plots. The experiment was conducted under constant current conditions. They examined the film with the aid of a microscope and proved that the peak occurred at the point at which the film originally laid down disrupted in order to allow the trapped anodic gas to escape.

Similar peaks were observed in the current/time curves under constant voltage conditions, as shown in Fig. 4. The peaks are inverted since the current is inversely proportional to the resistance.

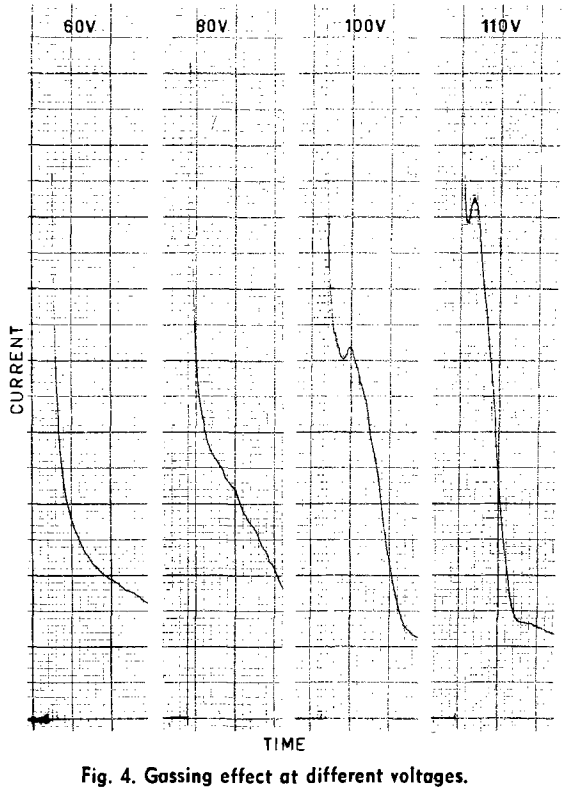

Fig. 4. Gassing effect at different voltages.

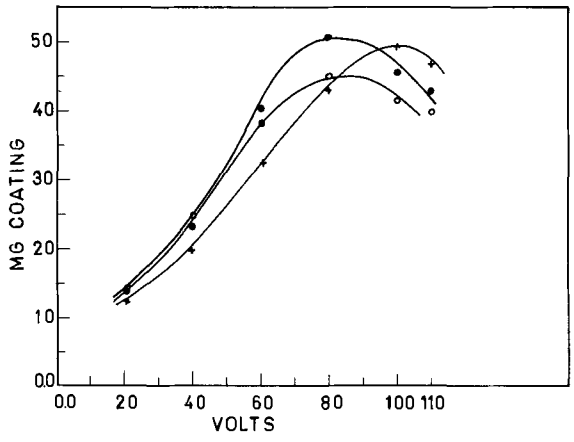

Fig. 5. Weight vs. voltage for 3 min deposition time: 4% solids, 60% neutralization. ○, First day; ●, second day; +, third day.

In Fig. 5, the weight of coating is plotted *vs.* the corresponding voltage of deposition for 3 min deposition time. The three curves represent three runs at three different days. An almost linear increase for each curve is observed followed by a curvature at 80-110V. This curvature of the weight/voltage plots starts almost at the same voltage at which the resistance "peaking" starts to appear. Possibly, there is a connection between the two phenomena.

After about 90V, a higher voltage deposits a lower weight for the same deposition time (3 min). That means that the higher the voltage, the higher the resistance of the deposited film. This can be considered a justification for the high voltages used in technical applications (100-300V). In the above experiment, a 4%-solids solution was used. For lower concentrations the above gassing effect was not observed, whereas for higher concentrations it was even more clearly evident (Fig. 5).

Conclusions

The coulombic yield of the electrodeposition was found to be constant for different voltages and at different deposition times. Almost constant coulombic yield was found for different concentrations of resin and for deposition on different metals. The iron content of the film, for deposition on steel, was proved to be almost constant for different concentrations of resin and different deposition times.

The electrochemical current used to dissolve the iron was proved to be a small percentage of the total current. The iron content of the film and the percentage of the total current used to dissolve the iron were highly increased after a small contamination of the bath with chlorides. The role of the ferrous and ferric ions in the electrodeposition reactions is not as yet clearly understood. More work must be done in order to elucidate the exact form of iron in the coating.

A small amount of water was found in the film. This increases with deposition time and is higher for higher concentrations of resin.

A rupture of the film due to the escape of trapped anodic gas was observed at a certain time during the deposition. This rupture occurred for higher concentrations and voltages greater than 80. In addition, an increase in the resistance of the film obtained was observed with a voltage greater than 80.

Preparation and Evaluation of Spreading Resistance Probe Tip

E. F. Gorey, C. P. Schneider, and M. R. Poponiak

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York

ABSTRACT

The spreading resistance technique used to evaluate various types of silicon structures is dependent primarily on the probe point. Data are presented on point preparation and loading of different point materials. A method for preparation and evaluation of point characteristics for effective use on thin silicon structures is described.

The spreading resistance technique (1-3) is the most versatile technique used to characterize impurity profiles of multilayered structures.

An improved spreading resistance probe (4) which utilized balance beam probe arms, weight loading, and controlled velocity of impact emphasized contact reproducibility as one of its most important parameters. It has been implied in the previous papers that a spreading resistance probe will function properly if a particular type of probe point is used.

The most critical part of the technique is the probe point. It must have the capability of making thousands of measurements without deteriorating and must maintain certain characteristics that make it useful in measuring both n- and p-type silicon structures.

This paper describes a method of preparing and evaluating a probe point for its use in the spreading resistance technique.

Probe Point Characteristics

A good probe point has the following characteristics: the effective penetration of the probe into the silicon surface must be kept to a minimum, and the spreading resistance measured in the forward and reverse

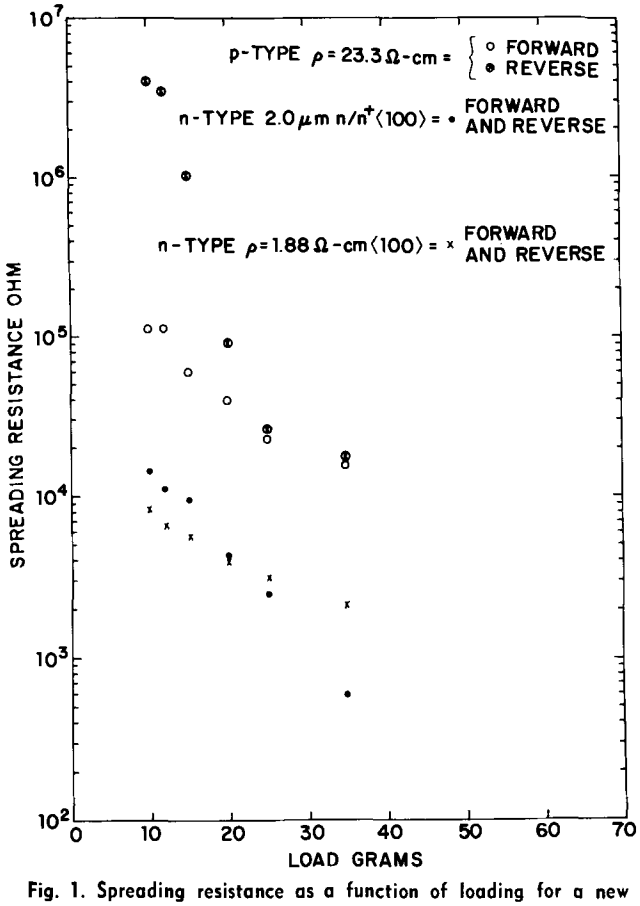

Fig. 1. Spreading resistance as a function of loading for a new K-75 point as received from vendor.

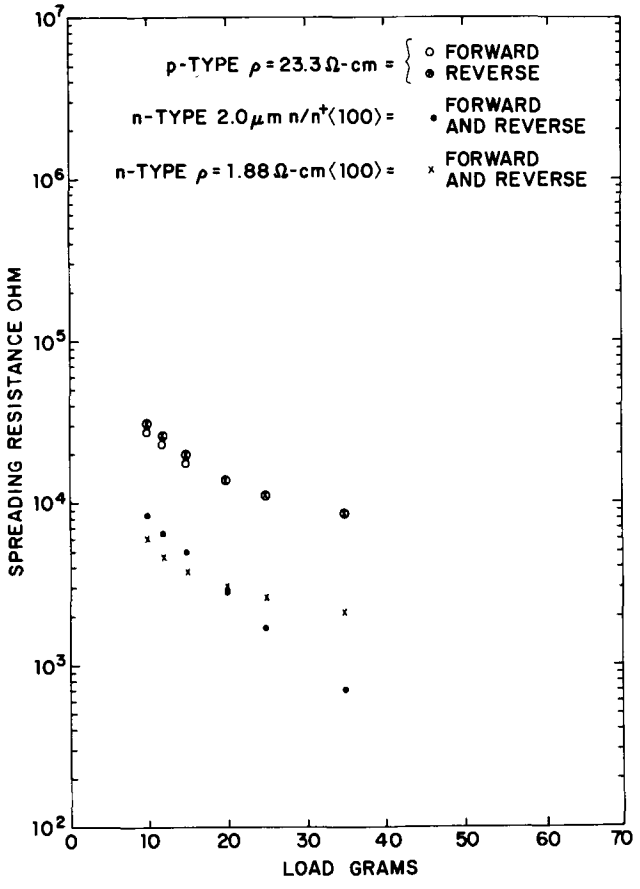

Fig. 2. Spreading resistance as a function of loading for a K-75 point prepared by 3 sec abrasion.

direction of current must not differ by more than 5% of the average. Experimental data indicate that a probe can function on n-type silicon but can give inconsistent results on p-type.

An experiment designed to study these characteristics and the behavior of n- and p-type silicon wafers was performed on 3 wafers. A 23.3 ohm-cm p-type mechanical polished bulk wafer was used to indicate when good contact was achieved. Good contact exists when the spreading resistance in the forward and reverse direction of current is within 5% of the average. A 1.88 ohm-cm n-type bulk wafer was used as a control wafer. A 3.0 ohm-cm n-type epitaxial layer of 2.0 μm thickness on a 0.001 ohm-cm n-type substrate was used to indicate effective probe penetration. In the range of loading where the ratio of the spreading resistances of the epitaxial wafer to the n-type bulk wafer remains constant, no effective penetration is considered to exist.

Spreading resistance was plotted as a function of probe point loading. All measurements were made utilizing the spreading resistance apparatus described in Ref. (4). Figures 1 through 4 show the results obtained from tungsten-ruthenium probe points with tip radius of 0.0007 in.

Figure 1 represents the results of a point as received from the vendor.[1] From 10 to 15g loads, bad contact is made on the p-type wafer. Good contact is made on both n-type wafers and no effective penetration exists. At 20g, the ratio of the two n-type wafers now changes and effective probe penetration is observed. The difference between the forward and reverse spreading resistance from the average on the p-type sample is 40%. Greater effective probe penetration of the epitaxial layer and good contact on the p-type wafer is observed at 25g loading. Deep effective penetration of the thin epitaxial layer and good contact on the p-type wafer was observed at 35g loading. From results obtained, it can be seen that at no one loading of the probe point did the point exhibit good contact and no effective penetration.

The probe in Fig. 2 was prepared by an abrasive blasting of 3 sec. The spreading resistance probe point is prepared by an abrasive blasting technique in the following manner. A series of probe points to be prepared are positioned in a holder with their points exposed. An air abrasive unit is then used to abrade the point with 27.5 μm aluminum oxide with a 50 psi pressure. The unit has a 1/16 in. nozzle orifice.

The nozzle of the unit is placed approximately 1 in. from the probe points. After abrading, each probe is immersed in trichlorethylene for 5 min. The probes are then wiped with cotton swabs saturated with acetone. This procedure gives the probe tips the proper finish to make good contact to the sample.

It was evident that the abrasive blasting technique changes the results significantly. Good contact was made on the p-type wafer with only 10g loading. This probe point will operate properly if used between 10-15g loading.

Figure 3 shows the results of abrading for 5 sec. Effective penetration starts at 15g. The probe point represented in Fig. 4 was the result of abrasion for 10 sec. In Fig. 3 and 4, the tips exhibited large spikes due to the abrasion which caused deep effective penetration.

Figure 5 shows the results of an osmium alloy probe point with a tip radius of 0.0007 in.[2] Effective penetration did not occur until 35g, but poor contact was made to the p-type wafer. This point will not meet all the requirements of a good point. Figure 6 represents a ruthenium alloy probe point with a tip radius of 0.0007 in.[3] which exhibited characteristics similar to the osmium point.

A convenient method to insure a good probe point is as follows. Measurements are made on 3 wafers: No. 1, a thin ($\sim$ 2.0 μm thick) n-type epitaxial layer of

[1] Fidelitone K-75 PIVOT, tungsten ruthenium alloy.

[2] Fidelitone #741 PIVOT, osmium alloy.

[3] Fidelitone #347 PIVOT, ruthenium alloy.

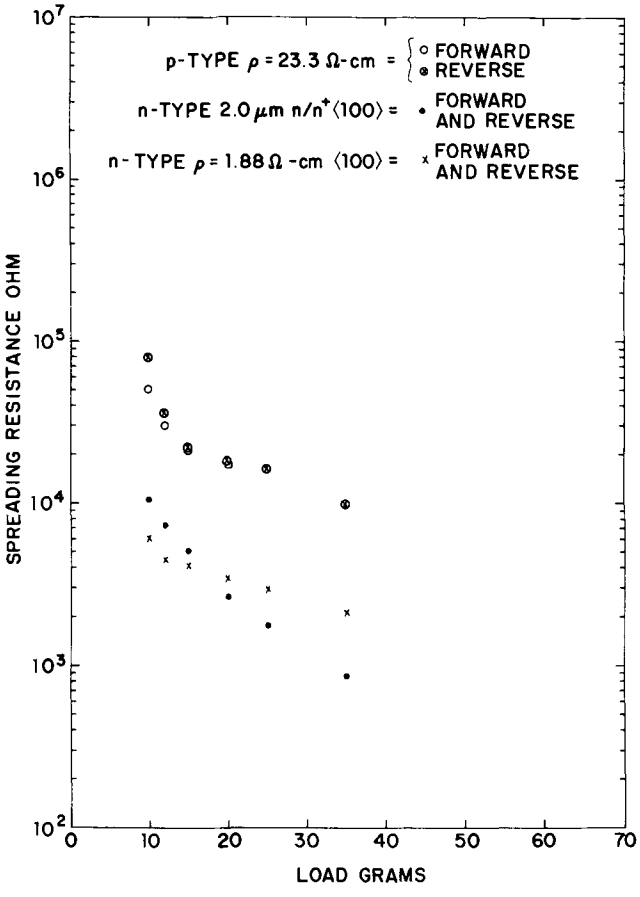

Fig. 3. Spreading resistance as a function of loading for a K-75 point prepared by 5 sec abrasion.

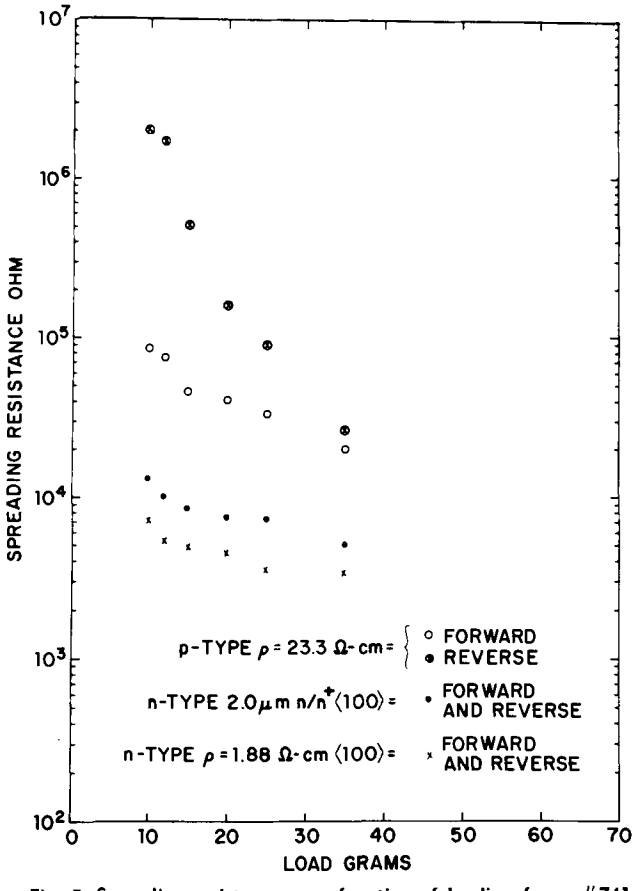

Fig. 5. Spreading resistance as a function of loading for a #741 osmium alloy point.

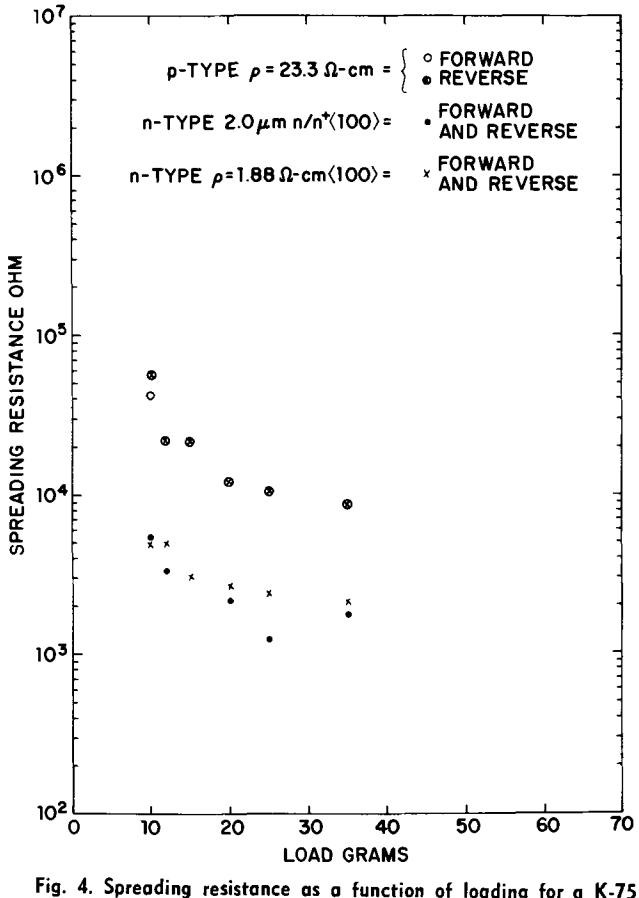

Fig. 4. Spreading resistance as a function of loading for a K-75 point prepared by 10 sec abrasion.

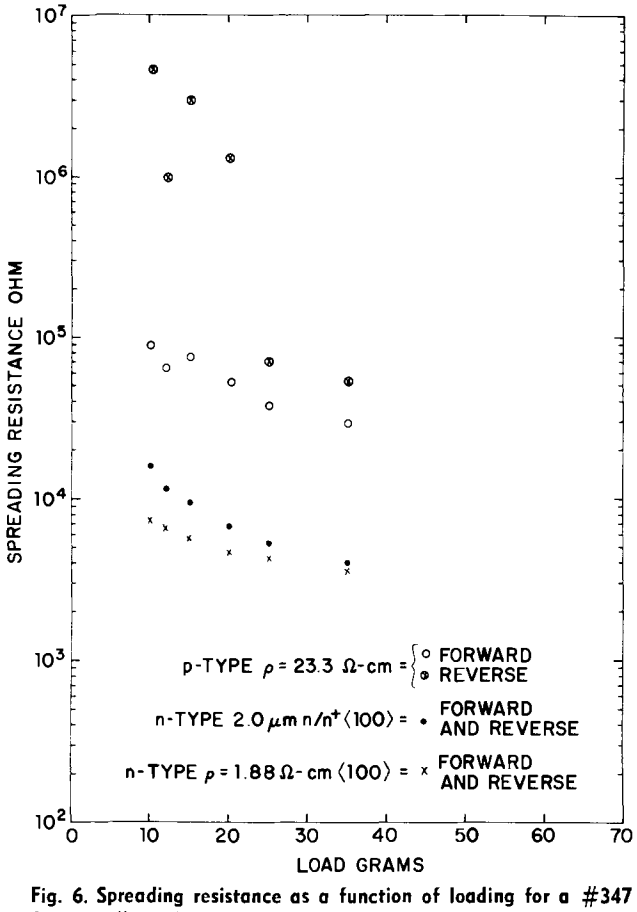

Fig. 6. Spreading resistance as a function of loading for a #347 ruthenium alloy point.

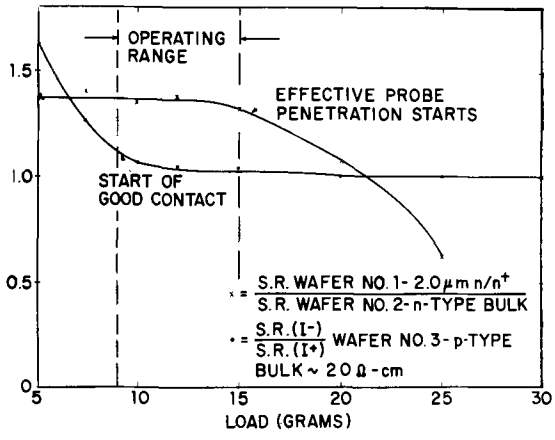

Fig. 7. Ratios of spreading resistances of n/n+ to n-type bulk wafers and spreading resistances in the reverse direction to the forward direction of current as a function of loading for a typical prepared K-75 probe point.

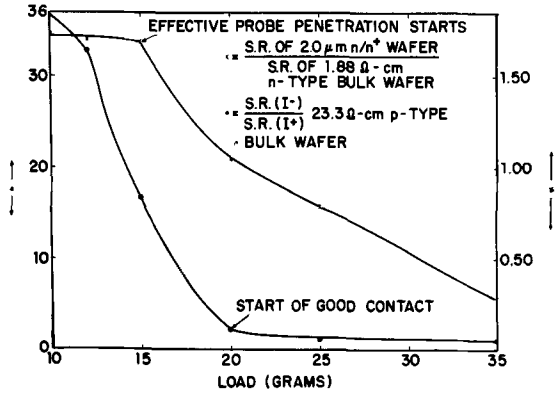

Fig. 8. Ratios of spreading resistances of n/n+ to n-type bulk wafers and spreading resistances in the reverse direction to the forward direction of current as a function of loading for an unprepared K-75 probe point.

some ρ on an N+ substrate exhibiting a certain spreading resistance; No. 2, an n-type bulk wafer with approximately the same spreading resistance as wafer 1; and No. 3, a p-type mechanical polished bulk wafer of ~ 20.0 ohm-cm. Starting with a probe point loading of 5.0g, the ratios of the spreading resistances of the n/n+ wafer to the n-type bulk and the spreading resistances in the reverse direction of current to the forward direction of current of the p-type wafer are plotted as a function of loading.

Figure 7 represents a probe point which will be operable in the range of 9-15g loading. The selection of the load for proper operation is limited to the regions where both ratios have a slope of 0. For comparison, Fig. 8 presents the same ratios for the probe point used in Fig. 1. In this case, the regions where the slopes are 0 do not coincide for any loading of the probe point indicating that the point cannot be used effectively in a spreading resistance apparatus.

At this point, the loading should be set at the midpoint of the operating range. Previous experience indicated that final conditioning of the point required repeated use under operating conditions to insure stability. Experimental data showed that a minimum of 250 measurement cycles are required to stabilize the probe point. Stabilization is a wearing-in process that removes probe point spikes that are not strong enough to withstand repeated operations. These manifest themselves by rapid changes in the spreading resistance.

Figure 9 is a test profile of a n/n+ epitaxial wafer. The wafer was beveled at a 1° angle and spreading resistance was measured on the bevel at intervals of

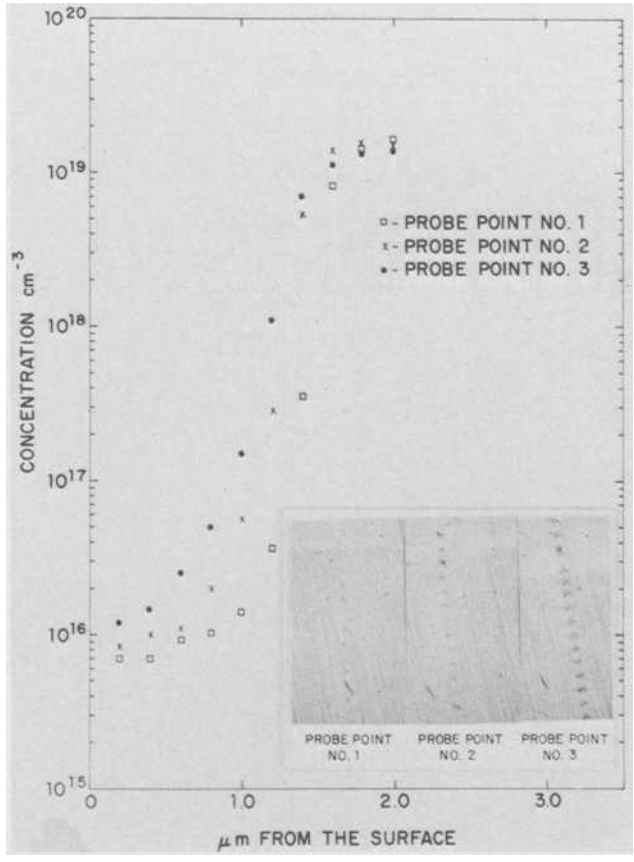

Fig. 9. Concentration *vs.* depth profile of a thin n/n+ epitaxial layer measured with three different K-75 probe points.

0.0005 in. resulting in depth increments of 0.20 μm. Three probe points, using the apparatus described in Ref. (4), were used to determine concentration *vs.* depth profiles. Probe point 1 was considered to have minimal effective penetration and probes No. 2 and 3 had increasing effective penetration, respectively. Visual inspection of the photographs of the three points' indentations on the bevel corroborate this finding. Probe point No. 1 was the only probe that would qualify as a good point using the method described previously.

Discussion

The method has been developed that produces probe points to be used in the measurement of spreading resistance of silicon with good precision. The requirements that a probe point must have are little effective penetration and good contact. A probe point with, and only with, these characteristics enables concentration *vs.* depth profiles of thin layers of any type structure to be measured.

Technical Note

Electrical Properties of Flash Evaporated Thin Film CdSe-CdTe Alloys

Tung H. Weng

School of Engineering, Oakland University, Rochester, Michigan

The work described in this paper was undertaken to determine the feasibility of forming thin film solid solutions of CdSe and CdTe by means of flash evaporation techniques and evaluate their electrical properties. One of the outstanding features of this alloy is the continuous variation of energy band gap and electrical properties with the composition of the constituent compounds. This means that a semiconductor with specific properties can be prepared simply by changing the composition. Such a wide range of properties would undoubtedly widen the scope of application which could not be achieved otherwise with a simple compound semiconductor.

Film preparation.—The apparatus used for flash evaporation is similar to that suggested by Müller (1), but with different design in the part of the powder feeder assembly as shown in Fig. 1. Instead of using mechanical vibration as in Müller's system, the powder is fed into the evaporator by a relay-operated plunger. When the relay is energized or de-energized by a variable square wave generator, the plunger strikes the reservoir so that the powder falls through a small opening located at the bottom of the reservoir into the funnel of the evaporator. This method provides a continuous and uniform rate of feeding which is essential if a homogeneous film with the original composition is to be obtained. One of the advantages of this system is that the rate of feed, and hence the rate of deposition, can be easily controlled by merely changing the frequency of the generator when the other physical settings, such as the diameter of the opening and the weight of the plunger, remain unchanged. This is desirable because it provides a simple means for controlling the crystalline structure as well as the properties of the deposit which is known to depend heavily on the deposition rate.

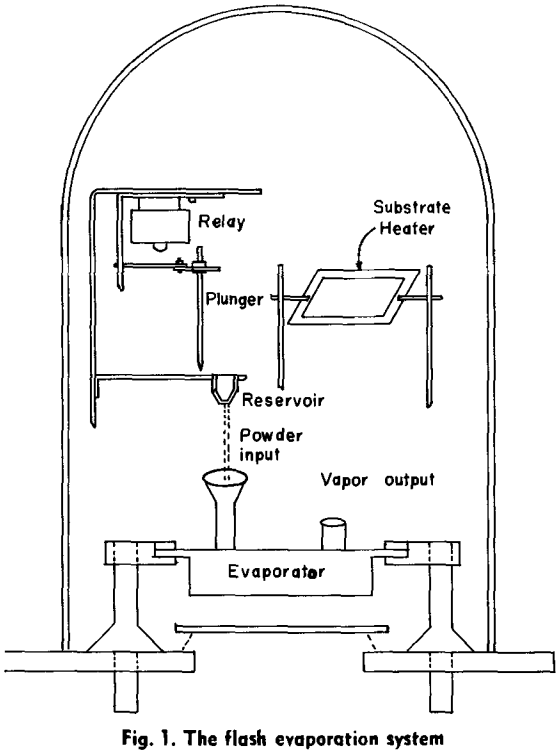

Fig. 1. The flash evaporation system

A folded molybdenum sheet was used as substrate heater. The glass substrate was inserted between the two sheets and clamped to the heater by metal screws. A Chromel-Alumel thermocouple for measurement of substrate temperature was placed adjacent to the substrate heater and made direct contact to the glass. The substrate was located about 8 in. from the evaporator with the hope that such a large distance between substrate and evaporator would minimize the heating effect generated by the heat radiating from the evaporator and produce a uniform thickness of the deposit. The vacuum system used is a 4 in. diffusion pump system with a liquid nitrogen trap. The pressure was maintained at 5×10^{-6} Torr during the entire evaporation. The evaporator which was designed specifically for the flash evaporation of compound semiconductors was kept at 1200°C. This assures a rapid and complete evaporation of each grain of the CdSe-CdTe powder which reaches the heater source.

CdSe and CdTe powders having a purity of 99.999% were supplied by Semi-elements, Inc. These powders were well mixed and sieved through a 0.088 mm opening before being put into the reservoir of the powder feeder assembly. For a given physical setting of the assembly, the rate of feed was approximately 10 mg/min which produced a 5 Å/sec deposition rate. A lower rate was also used, but the film resistivity was substantially higher than those obtained at 5 Å/sec. This is presumed to be caused by the absorption of oxygen during the crystal growth even though the vacuum pressure was in the 10^{-6} Torr range. In order to obtain a wide range of solid solutions, the composition used in this investigation varied from 10 to 90% of CdSe by weight. The substrates used were Corning's Type 7059 glass with dimensions of 3 in. x 1 in. x 0.048 in. Microslides with the same dimensions as the 7059

glass were also used. It was found that no significant difference in the characteristics of the deposited films was observed when these two types of glasses were interchanged. The substrates were cleaned, baked, and preheated to the designated temperature before evaporation took place. A set of four films with different substrate temperatures ranging from 50° to 200°C was prepared at a single pump down. This was intended to reveal the properties of the films as a function of the substrate temperature without being affected by other parameters which could conceivably have a pronounced effect on the properties of the deposits. A lower substrate temperature could not be obtained because of the heat radiating from the evaporator even with the substrate located far from the heater source. At higher substrate temperatures, however, the film resistivity was so high that the electrical measurement became increasingly difficult to perform and in many cases a thicker film could not be obtained. This is believed to be due to either re-evaporation or to a low sticking coefficient at a higher temperature.

Film properties.—The lattice type and constants of the CdSe-CdTe films were determined using x-ray diffraction. The diffractometer patterns were taken at room temperature and the output showed a single peak with a Bragg angle which varied with the composition of the constituent compounds. No trace of either CdSe or CdTe was detected regardless of their composition and preparation conditions. Since the as-deposited films showed a strong preferred orientation which would not give the information needed for an accurate result, the diffraction of randomly oriented powder was then performed. This was done by first stripping the films from their substrates and then pulverizing them before x-ray data were taken. Based on diffraction from various [hkl] planes, it was possible to determine their crystal type and lattice parameters rather accurately. The results are tabulated in Table I, and are similar to those obtained by Stucks and Farrell (2) for pure CdSe-CdTe alloys. The film containing 50 w/o (weight per cent) of CdTe could not be positively identified. This presumably was due to the presence of both hexagonal and cubic structures as reported elsewhere (2). There were no notable changes between the interplanar distance for a given composition when the substrate temperature was changed from 50° to 200°C. The relative intensity distributions for the powdered CdSe-CdTe alloys were estimated by measuring the peak heights directly on the diffractometer tracings. These data showed that the intensities for [002] (hex.) and [111] (cubic) directions are stronger than other reflections. These were also the preferred orientations of the films as deposited where a single peak was observed.

Table I. Lattice type and constants of thin film CdSe-CdTe alloys

Percentage of CdSe in CdSe-CdTe alloys	Hexagonal structure a Å	c Å	Cubic structure a Å
100	4.290	7.010	
75	4.352	7.146	
60	4.390	7.200	
50			
40			6.301
25			6.336
10			6.387
0			6.471

The carrier mobility and conductivity of CdSe-CdTe films with thickness of about 2000Å were determined using the Hall effect measurements. The dimensions of the Hall sample were 3/16 in. x ⅜ in. with evaporated indium films as ohmic contacts. All films regardless of their composition were N-type with carrier mobility and concentration varying with both composition and substrate temperature. In general, both mobility and carrier density decreased with increasing substrate temperature and varied appreciably from one set of films to another. Since reproducible properties of these films cannot be obtained without strict control of the preparation conditions, no attempt was made to pin down their electrical properties as a function of the preparation conditions. However, the mobilities of the films containing 25-50 w/o of CdSe prepared at the substrate temperature around 50°C were in the vicinity of 30 cm^2/V-sec. This figure is comparable to those of pure CdSe films (3).

On the basis of experimental results, one concludes that the flash evaporation technique can indeed be used to form polycrystalline thin film solid solutions of CdSe and CdTe and similar alloys (4). This technique offers simplicity and could be easily adopted for epitaxial growth of these alloys onto various single-crystal substrates, provided that suitable growth condition could be established. One of the immediate applications of these thin film alloys is in the area of thin film transistors. These have been fabricated successfully (5) and showed similar characteristics as CdSe and CdTe insofar as the stability and frequency response are concerned.

Brief Communication

Porosity in Electrodeposited Gold-Alumina Alloys

E. S. Chen and F. K. Sautter

U. S. Army Watervliet Arsenal, Watervliet, New York

Porosity is an important factor which affects the properties of all materials. In recent years, the emphasis of many investigations was on the effect of ductility (3, 4) of materials. However, it is frequently overlooked that test materials inherently contain pores as a consequence of the fabrication process. This is

alloys regardless of whether the manufacturing process is one of powder technique or electroforming. This report presents the results of a study on the porosity in electroformed Au-Al_2O_3 alloys before and after high-temperature heat treatment and the attending implications of porosity in the creep strength of these alloys.

Experimental

Electrodeposited Au-Al_2O_3 alloys were prepared from solutions containing

$KAu(CN)_2$	10 g/liter
KCN	10 g/liter
α-Al_2O_3 (1.0μ)	2-25 g/liter

using the techniques reported by Sautter (5). The plating was conducted at a pH of 10.5, current density of 3.5 mA/cm^2, and temperature of 60°C using pure gold as soluble anodes and electropolished copper tubings, 0.4 cm diameter, as cathodes. The solutions were agitated by Teflon-coated magnetic stirrers. Only one plate was prepared from each solution. For a cathode with a total surface area of 10 cm^2, the thickness of the deposit was on the average 180μ after 16 hr of plating. Tubular Au-Al_2O_3 alloy samples are obtained on removing the copper substrate by dissolution in 50% HNO_3.

The porosity in our electroformed alloys was studied through density measurements since such studies are commonly used to measure residual porosity in sintered materials and are also applicable to studying porosity in dispersion-hardened alloys (6). The density of Au-Al_2O_3 samples weighing 1.5g each were determined with an immersion technique using an analytical balance with a sensitivity of 0.1 mg. The immersion solution was doubly distilled water with added Triton X-100 surfactant to lower the surface tension to 35 dynes/cm thereby reducing solution damping effects. The precision of the density measurements is better than ±0.03 g/cm^3. The density for each sample was determined at room temperature before and after annealing for 1 hr at 1000°C in air. The Al_2O_3 content in the alloy specimens was determined gravimetrically.

In the course of preparing the alloy samples for density measurements, the observation was made that all annealed samples show permanent length increases. This unique behavior in the electrodeposited Au-Al_2O_3 alloys was further investigated with a Leitz dilatometer, using a heating rate of 2°C/min.

Results

Typical results of the density measurements as a function of Al_2O_3 content are shown in Fig. 1. The upper curve shows the density of the as-plated alloy to be a linear function of oxide volume per cent (v/o) and that the measured densities would superimpose on the theoretical values (not illustrated) predicted by the rule of mixtures using the densities of pure gold and aluminum oxide as 19.3 and 3.97 g/cc, respectively. The lower curve shows the effect of the heat treatment. The initial decrease in density is very pronounced up to an oxide concentration of 1.5 v/o at which point the density appears to vary linearly with further increases in oxide content. Figure 2 shows the expansion behavior typical of the Au-Al_2O_3 alloys tested. The curve shows the linear expansion *vs.* temperature of an alloy specimen 1.0 cm long containing 10.5 v/o 1μ Al_2O_3 particles against a 5.0 cm pure gold reference. Distinct discontinuities in the expansion-temperature curve were observed at 240°, 330°, and 450°C, indicating the release of different gas impurities from the metal matrix as well as adsorbed impurities from the surface of the oxide particles. Impurity analysis using mass spectrometry showed that the composition of the evolved gas was mainly hydrogen and water and that gas evolution commences at about 300°C.

Discussion

The difference between the densities of the plated alloys before and after heat treatment can be attributed to the presence of adsorbed impurities on the surface of the oxide particles. These impurities may be water, hydroxyl groups, or organic additives present in the plating electrolyte and are codeposited with the

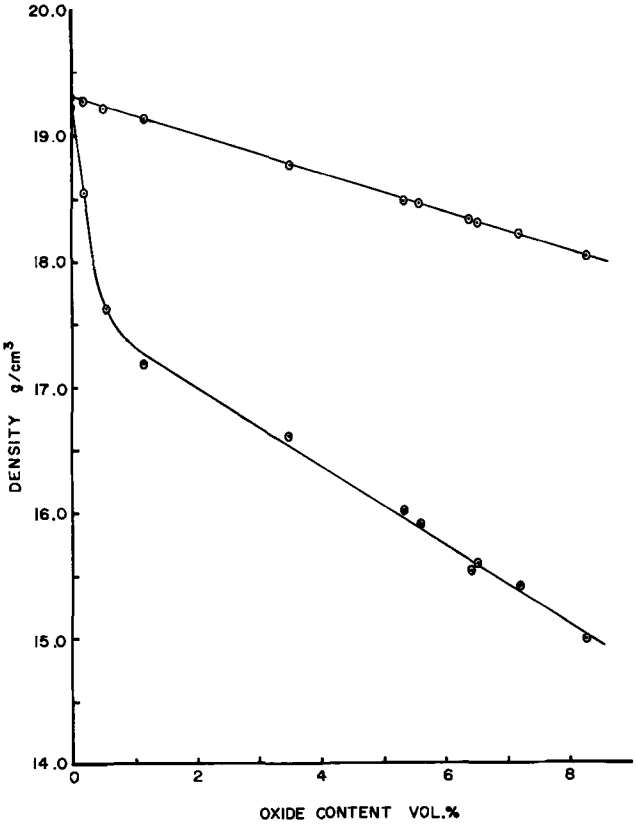

Fig. 1. Density as a function of volume per cent oxide in Au-Al_2O_3 (1.0μ) alloys. (Upper curve—as-plated alloys; lower curve—annealed alloys, 1 hr at 1000°C.)

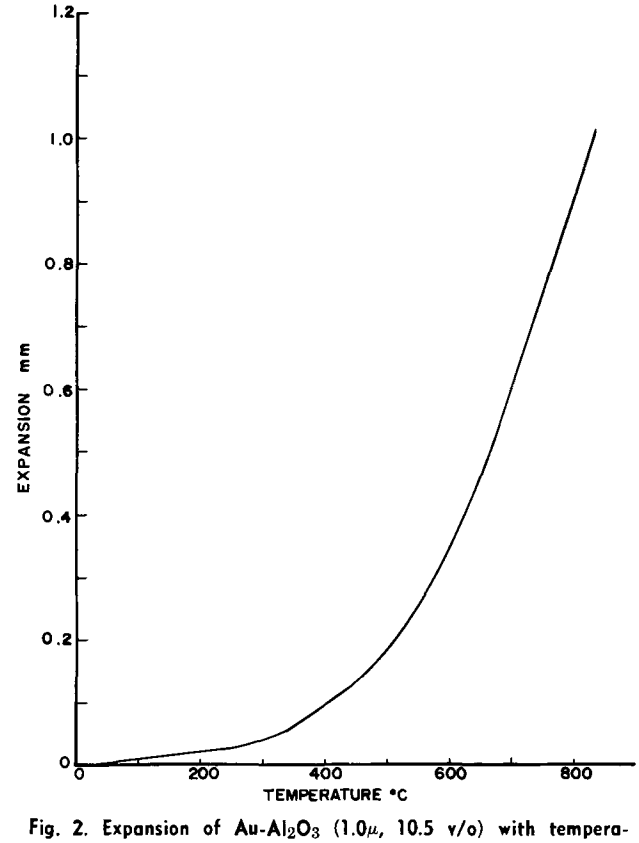

Fig. 2. Expansion of Au-Al_2O_3 (1.0μ, 10.5 v/o) with temperature for a heating rate of 2°C/min.

oxide particles. It has been calculated that an adsorbed monolayer on powders with a specific surface area of 100 m^2/g represents an impurity level of 5-10 v/o (7). The adsorbed monolayer occupies little volume in the condensed state. As such, the as-plated density should not deviate from the theoretical value; however, gasification of the impurities at high temperatures introduces porosity resulting in a subsequent decrease in alloy density. A simple calculation can illustrate this point more clearly. Consider an alloy sample containing 8 v/o oxide that is annealed at 950°C. The 1μ Al_2O_3 powder has an estimated specific surface area of 2 m^2/g. At 950°C, the gasified impurities build up sufficient pressure to cause irreversible deformation in the alloy. The resulting pore volume can be estimated by neglecting the effects of surface energy and assuming the ideal gas law holds. Using the pressure $P = 72$ psi or 4.9 atm which is the stress at zero strain (threshold stress for creep deformation) for a gold alloy containing 8 v/o oxide (8), $T = 1223$°K, $R = 82$ cc atm/°mole and 0.00016/18 moles of water, the pore volume is estimated to be 0.18 cc or 18 v/o. This compares favorably with our experimental value of 16.4 v/o measured at a slightly higher temperature of 1000°C. In view of the crude nature of the foregoing calculation, the significance of the illustration should not be attached to the agreement obtained but rather to the probability of pore formation proceeding in this manner. The initial sharp decrease in density of the heat-treated alloys is difficult to interpret without further investigation; however, one possible explanation is that should the relative degree of oxide particle agglomeration in the plating solution be greater when the solution is less concentrated in oxide, the resulting electrodeposit will also contain more agglomerated particles. Because occluded electrolyte is more prevalent in the agglomerated case, such system will show more porosity when the alloys are heat treated. Optical microscopic examination of polished alloy specimens indicates that a difference in degree of agglomeration does exist in the electrodeposits prepared from plating solutions of varying oxide concentrations. To eliminate the effects of particle agglomeration entirely, we are currently conducting experiments whereby electrodeposits are prepared under ultrasonic agitation to achieve optimum oxide dispersion.

The amount of porosity in the electrodeposited Au-Al_2O_3 alloys as calculated from our density measurements was as high as 16.5 v/o. A similar but smaller increase in porosity was observed after heat treatment of extruded and drawn Au-Al_2O_3 samples prepared by powder metallurgy. Furthermore, we have qualitatively studied alloy samples which were heat treated to produce porosity followed by cold working, extruding, and wire drawing whereby the density approached 99.9% of the theoretical value only to find that subsequent annealing will restore the porosity. This effect is a consequence of residual gases which can be eliminated only by completely melting the sample. In terms of high-temperature properties, the important criterion is therefore no longer the nucleation but the growth of existing pores that will determine the creep strength of these dispersion strengthened alloys. The presence of nonassociated pores anchored by uniformly distributed oxide particles will require creep deformation to be accompanied by the growth of these pores. Thus any gaseous impurities which can lower the internal metal surface energy must also be considered. The gasification of impurities, particularly that of water, at the indicated temperatures is in general agreement with the findings of other investigators (9), who deduced that surface hydration does occur on suitable parts of the α-Al_2O_3 surface and that ignition to 400°C results in the dehydration of physically bound water, while ignition above 400°C eliminates chemically bound water. Additional work is in progress using differential thermal analysis techniques to gain insight on the dehydration and gasification of adsorbed impurities in these alloys.

ABSTRACT

The diffusion coefficient for protons moving in the hydrated nickel hydroxide lattice has been determined using a potential step technique. It was found to have the value about 3.1 x 10^{-10} cm^2 sec^{-1} during charging and 4.6 x 10^{-11} cm^2 sec^{-1} during discharging for the nickel hydroxide structure usually found in the nickel electrode of the nickel-cadmium battery. The temperature dependence of the coefficient has been determined, and it has been concluded that the proton moves in the lattice by thermal diffusion. The enthalpy of diffusion was found to be 2.2 kcal deg^{-1} $mole^{-1}$ during charging and 2.3 kcal deg^{-1} $mole^{-1}$ during discharging of the electrode.

In previous work (1) the approximate diffusion coefficient for proton diffusion during oxidation of an α nickel hydroxide[1] electrode was found by a potential sweep technique. This procedure required the use of a semi-infinite diffusion model which entailed extrapolation from the experimental data. In the present work a new approach was used. A potential step was applied to the electrode and the data were analyzed using a finite diffusion model. Values of the diffusion coefficient for α and β nickel hydroxide during oxidation and reduction have been determined. The coefficient for β nickel hydroxide has also been found as a function of temperature.

Theoretical Considerations

The oxidation of the nickel hydroxide electrode is believed to proceed by a reversible one electron transfer step at the nickel ion site in the nickel hydroxide lattice. This produces a Ni^{III} ion and releases a proton. The proton diffuses from the oxidation site to the electrode-electrolyte interface where it reacts with an hydroxyl ion to form a water molecule. Electron conduction through the lattice is believed to be rapid in comparison to the rate of proton diffusion. It is also assumed that charge balance is maintained in the lattice at all times.

For the purposes of a quantitative description of the diffusion process we regard the initial concentration of protons in the lattice as constant at the value C° through the depth of the film and zero everywhere else. This is illustrated in Fig. 1. The electrodes used in this work were planar and therefore the diffusion problem is one dimensional.

This problem is the familiar heat transfer problem and has the solution (2)

$$C = \frac{4C^\circ}{\pi} \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \exp - \left\{ \frac{D(2n+1)^2\pi^2 t}{4h^2} \right\} \cos \frac{(2n+1)\pi x}{2h} \qquad [1]$$

where D is the diffusion coefficient and t is the time from the start of the diffusion process.

The experimentally measured quantity is the current as a function of time. This is expressed as

$$i_{diff} = n_e \mathbf{F} A D \left(\frac{\partial C}{\partial x} \right)_{x=h} \qquad [2]$$

$$i_{diff} = \frac{n_e \mathbf{F} A D 2C^\circ}{h} \sum_{n=0}^{\infty} \exp \left[- \frac{D\pi^2(2n+1)^2 t}{4h^2} \right] \qquad [3]$$

where n_e is the number of positive charges on the diffusion species, $\mathbf{F}$ is the Faraday, and A is the area of the electrode. A semilog plot of Eq. [3] is shown in Fig. 2 for typical values of D and h. This series, Eq. [3], which is valid for the finite boundary value problem, converges rapidly even for small times if the ratio D/h^2 is sufficiently large. C° is assumed to be equal to the concentration of nickel sites in the nickel hydroxide lattice, since one proton is released at each nickel site, and is expressed in mole/cm^3. It is found by dividing the molecular weight by the density of the nickel hydroxide layer. The molecular weight used in the calculations was that for α-$Ni(OH)_2 \cdot 2/3\ H_2O$ and the density was the x-ray value (4) for this material (2.5 g/cm^3).

In order to determine the diffusion coefficient D, the value of the diffusion length h must be known. This

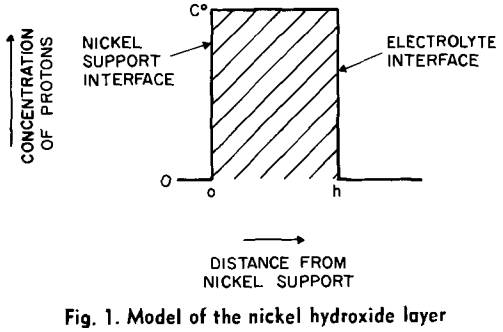

Fig. 1. Model of the nickel hydroxide layer

* Electrochemical Society Active Member.

[1] See ref. (1) for an explanation of the use of α and β.

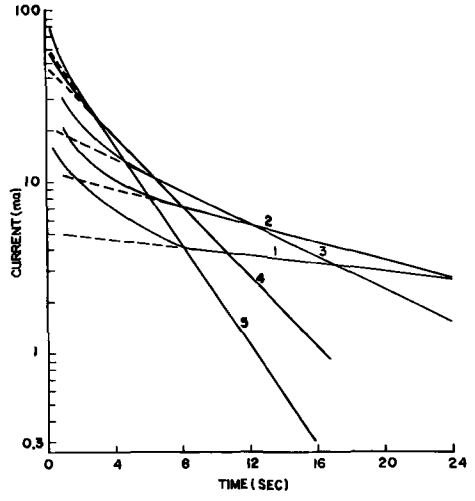

Fig. 2. Calculated diffusion currents $h = 1.0 \times 10^{-4}$ cm curve 1, $D = 1 \times 10^{-10}$; 2, $D = 2.5 \times 10^{-10}$; 3, $D = 5 \times 10^{-10}$; 4, $D = 1 \times 10^{-9}$; 5, $D = 1.5 \times 10^{-9}$.

may be found by noting that for sufficiently long times only the term with $n = 0$ in the summation of Eq. [3] will be significant and on extrapolating to zero time the current intercept has the value $n_e\mathbf{F}AD2C^\circ/h$ in which all the variables are known except D/h. The ratio of the slope of the straight line (on a semilog plot) in this region to the intercept has the value $\pi^2/8n_e\mathbf{F}AC^\circ$ $(1/h)$ and therefore

$$h(\text{cm}) = 5.318 \times 10^{-4} \times \frac{\text{intercept (A/cm}^2\text{)}}{\text{slope (sec}^{-1}\text{)}} \quad [4]$$

As a check on the results h may then be compared to the thickness of the film.

The thickness (l) of the film may be found from the expression

$$l = \frac{ItM}{n\mathbf{F}d} \quad [5]$$

where I is the current used to electroprecipitate the film, t the time of deposition, M the molecular weight of α nickel hydroxide, $n\mathbf{F}$ the number of electrons transferred per mole of nickel hydroxide deposited, and d the density of nickel hydroxide. A current deposition efficiency of 100% is assumed in the calculation. This has been found to be true for films of the thickness used in this work.

The total current measured upon the application of a potential step to the electrode is the sum of the diffusion current and the current required to charge the double layer at the electrolyte interface. This is expressed as

$$i = i_{\text{diff}} + i_{\text{cap}} = i_{\text{diff}} + C\left(\frac{dE}{dt}\right)$$

$$= i_{\text{diff}} + \frac{E_2 - E_1}{R} \exp - \left\{\frac{t}{RC}\right\}$$

where the symbols have the following meaning: E_1 is the starting potential of the electrode; E_2 is the potential to which it is shifted; C is the surface capacitance per unit area; and R is the uncompensated resistance between the reference and working electrodes of the electrolysis cell. We note that corrections for surface capacitance are important if D/h^2 and $1/RC$ are comparable. The value of D/h^2 lies between 10^{-1} and 10^{-2} sec^{-1}.[2] The surface capacitance of the nickel electrode is unusually large (5). The uncompensated resistance in the working electrode circuit is small however so that for typical values of the capacitance and resistance (3000 μf/cm^2 and 0.1 ohm), $1/RC$ is about 3000 sec^{-1}, four orders of magnitude larger than D/h^2, and the capacitance correction will be insignificant.

[2] From the experimental results.

Two possible mechanisms for the diffusion process are:

1. The proton may jump from one oxygen ion in the lattice to another as it diffuses toward the electrolyte interface. This hopping process is expected to have an appreciable activation energy since partial chemical bonds must be broken. As a result, this diffusion process will have a considerable temperature dependence. For instance, if the activation energy is 23 kcal/mole as given by Feitknecht and coauthors (3) at temperatures above 100°C, then the rate of the reaction room temperature quadruples for a 10°C rise in temperature.

2. Once released the proton may simply diffuse without any further chemical interaction with the lattice. This process is expected to have a small temperature dependence.

Besides these two extreme examples there is the possibility of intermediate processes some of which could include hydrogen bonding. It is evident, however, that the temperature dependence of the rate can give some insight into the physical nature of the diffusion process.

Experimental

The electrolysis cell has been described elsewhere (1). The working electrode was a film of hydrated nickel hydroxide electrochemically precipitated onto a 1 cm^2 disk of high-purity Inco 270 nickel that had been hand-polished with several grades of emery paper, the last being 4/0, washed with 10% HCl, and rinsed with distilled water immediately before the precipitation step. The electrochemical precipitation step consisted of immersing the electrode (wet with distilled water) into a beaker of 0.5M reagent $Ni(NO_3)_2$ solution and making it cathodic at a current density of 2 mA/cm^2 for 4 min. It was removed, washed with running tap water and distilled water, and then (still wet) placed in the electrolysis cell which contained about 300 ml of solution.

In earlier work (1) it had been found that the diffusion coefficient was independent of the concentration of electrolyte. In this work all measurements were made in 1M KOH (except where 1M LiOH was used). This solution was chosen because the electrode was more stable in the dilute solutions yet the solution was sufficiently concentrated that concentration polarization effects would be minimized.

The diffusion coefficient was determined by applying a potential step to a Wenking fast rise time model 61RS potentiostat and measuring the current as a function of time. Electronic compensation for solution resistance between the working electrode and the reference electrode was incorporated into the circuit. The potential step function was applied through a summing operational amplifier to the potentiostat. The base potential could be preset to any value.

Current was determined by measuring the voltage drop across a precision 5-ohm resistor in the working electrode circuit. It was recorded on either a Tektronix 564 oscilloscope (short times) or a Houston Instruments HR95 X-Y recorder (longer times).

For the diffusion experiments the electrolysis cell was immersed in a water bath which was held at constant temperature ± 0.1°C. The reference electrode, Hg/HgO (1M KOH), was at room temperature (25°C) for all experiments. Junction potentials for the solutions at different temperatures were considered small enough to be neglected.

The procedure for preparing the electrodes for the potential step experiments was to cycle the electrode three times in the solution using a potential scan. For the α nickel hydroxide experiments the electrode was then used immediately. To prepare the β structure the electrode was subsequently held at 0 volts (*vs.* Hg/HgO) for 16 to 24 hr and then potential stepped.

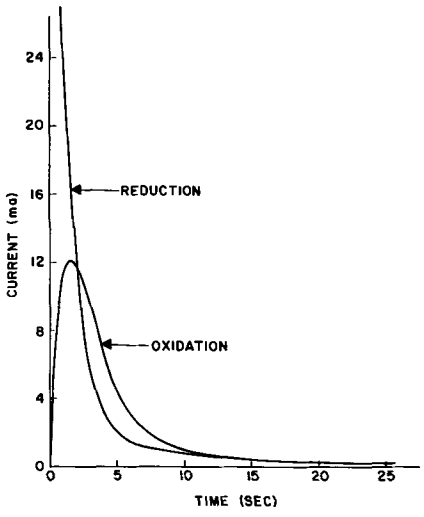

Fig. 3. Typical diffusion currents found on stepping the β nickel hydroxide electrode (40°C).

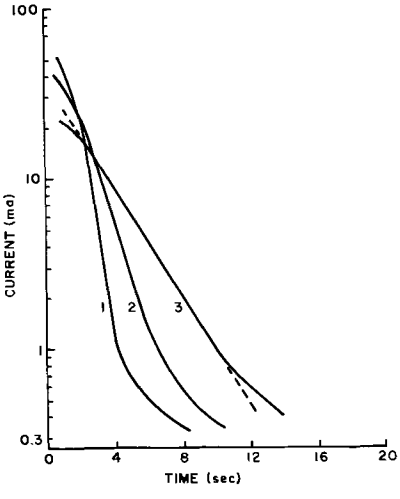

Fig. 4. Dependence of the oxidation currents on the potential of the applied step, β nickel hydroxide. Initial potential was 0.25V stepped to 0.51 (curve 1) to 0.49 (curve 2) to 0.475V (curve 3).

Results and Discussion

A typical plot of the current during stepped charge and discharge of a β nickel hydroxide electrode is illustrated in Fig. 3.[3] During charge (oxidation) of the electrode, the current increases over a period of about 2 sec before it begins to show the exponential decay. This behavior is unexpected. It may be that the poor conductivity of the reduced material limits the current flow until enough oxidized material has been produced to provide sufficient conductivity. On the other hand the current in the first second during reduction is larger than expected. This phenomenon may be related to the unusually large surface capacitance observed for this electrode and may reflect a surface layer in a higher state of oxidation than the bulk material.

The semilogarithmic plots of the oxidation and reduction currents are shown in Fig. 4 and 5, respectively. These may be compared to the curves in Fig. 2. The results agree with the theory in all respects except two. (*a*) A dependence of the oxidation current on the height of the potential step was found, and (*b*) the current during reduction was smaller than expected at long times.

The potential dependence of the oxidation current is shown in Fig. 4. The curve had the longest linear section for the smallest applied potential step. The higher potential step functions apparently were introducing added complications, perhaps from the formation of a higher surface oxidation state and from the competing oxygen evolution reaction. It was decided, therefore, that the data at the lower potentials were more representative of the conditions used to derive Eq. [3], and these were used in the calculations.

[3] Data plotted on the graph have been corrected for the residual oxygen evolution current.

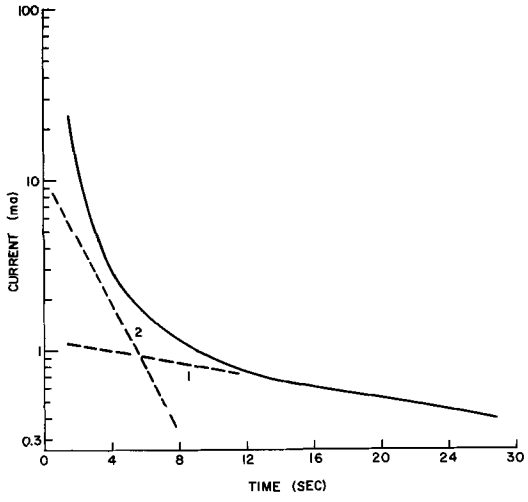

Fig. 5. Typical reduction current. Initial potential was 0.52V stepped to 0.36V.

The low currents observed on reduction suggested that a two step process occurs on reduction. Initially a rapid reduction was thought to occur and then a slower diffusion limited process. Examination of Eq. [3] reveals that the second term of the expansion has a coefficient in the exponential that is nine times larger than the coefficient in the first term. That is, the line representing the second term (line 2 in Fig. 5) should have a slope nine times greater than the line representing the first term (line 1). It was found that in all cases the slope of line 2 was in the range 8-10 times the slope of line 1 suggesting that there is no change in the diffusion process. Unless the initial reduction were very rapid it would probably be detected by this procedure. A more likely explanation for the failure of all the material to reduce in the time of the experiment now appears to be the formation of a poorly conducting layer as suggested in a previous paper (1). The currents on reduction were independent of the size of the potential step.

The diffusion lengths and diffusion coefficients found from the various experiments are included in Tables I and II. It was found that the diffusion length was consistently about 0.55 x 10^{-4} cm during oxidation and 0.15 x 10^{-4} cm during reduction. These values may be compared to the calculated (Eq. [5]) film thickness of 1.0 x 10^{-4} cm. This value is calculated assuming uniform planar distribution of the active material. This is not likely to be the case and surface

irregularities would be expected to result in shorter diffusion paths. A diffusion path of about one half the estimated film thickness, as found during oxidation, is reasonable. The smaller diffusion length found during reduction comes from the small reduction currents and is probably in error since it appears unreasonable that the diffusion length should change on going from oxidation to reduction. For this reason it appears preferable to use the diffusion length found on oxidation in the reduction calculations. The last column in Table I and II lists the diffusion coefficients found using the average diffusion length of 0.55×10^{-4} cm. At room temperature the coefficient on oxidation is about one seventh of the value found previously (1). This is satisfactory agreement since the earlier value was considered to be only an order of magnitude estimate.

Oxidation currents for an α nickel hydroxide electrode at three potentials are shown in Fig. 6. The dependence on the height of the potential step was similar to that for β nickel hydroxide, but more pronounced. As before, the reduction current was not dependent on the size of the potential step. The diffusion coefficient found for the α nickel hydroxide was not greatly different from that found for the β structure suggesting that the proton diffusion process is not dependent on the amount of water of constitution in the structures.

The diffusion coefficient found for the electrodes cycled in LiOH electrolyte also was not appreciably different from the other values. This experiment was done because of Tuomi's (5) description of a lithium nickelate phase that forms on cycling in the lithium electrolyte.

The temperature dependence of the diffusion coefficient for β nickel hydroxide is plotted in Fig. 7. These values were obtained on a single electrode because the temperature variation was so small that it did not greatly exceed random variation among the electrodes.[4]

[4] This appeared to be a result of changes in the structure of the electrodes as they aged at the different temperatures. The conversion from α to β $Ni(OH)_2$ was so rapid in fact at the higher temperatures that it was impossible to take measurements on α $Ni(OH)_2$.

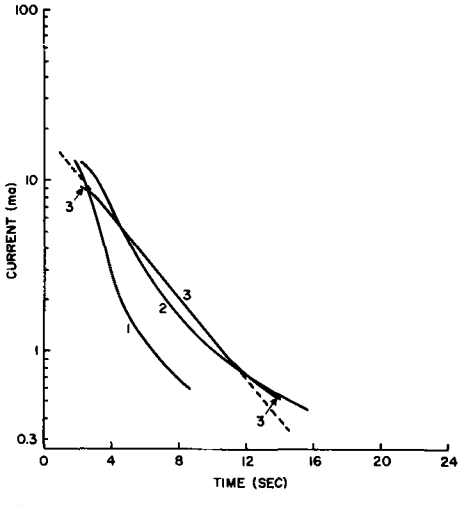

Fig. 6. Oxidation currents for α nickel hydroxide at 40°C. Initial potential 0.25V stepped to 0.50 (curve 1) to 0.48 (curve 2) to 0.46V (curve 3).

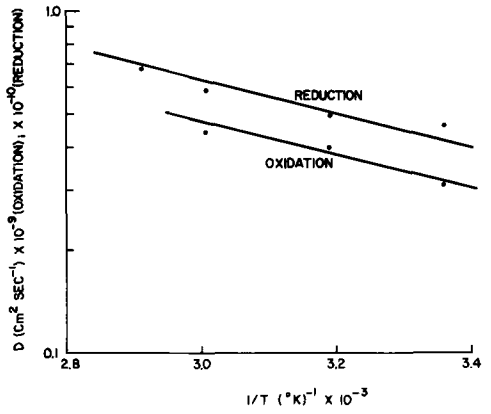

Fig. 7. Temperature dependence of the oxidation and reduction diffusion coefficients.

Electrodes were aged at 40°C by cycling them several times and then potentiostating them at 0 volt *vs.* Hg/HgO for about 24 hr. The first measurement following this procedure invariably showed a diffusion coefficient much lower than normal. This possibly is the result of excessive dehydration of the electrode during the forced discharge. The second and subsequent measurements however were reproducible and consistent. Measurements were taken on the same electrode in the order 40°, 25°, 55°, and 70°C with a 2-hr stand at each temperature for equilibration. This time period apparently was short enough that further structural changes did not take place since the measurements gave consistent results.

A least squares fit was used to draw the lines in Fig. 7. From the slope of the lines and using the expression

$$D = D_o \exp \frac{-\Delta H}{RT}$$

the enthalpy of diffusion (ΔH) for the protons diffusing in oxidized material (charging process) was 2.2 kcal deg^{-1} $mole^{-1}$ and for protons diffusing in reduced material (discharging process) was 2.3 kcal deg^{-1} $mole^{-1}$. The respective values for D_o were found to be 1.3×10^{-8} and 1.9×10^{-9} cm^2 sec^{-1}. The small temperature dependence of the diffusion coefficient clearly demonstrates that the protons move through the lattice by a simple diffusion process rather than by a jumping from one oxygen atom to the next.

Feitknecht (3) and coauthors measured the diffusion coefficient of protons in the $Ni(OH)_2$ lattice by a radiotracer technique. They found that, at temperatures above 100°C, the enthalpy of diffusion was about 23 kcal deg^{-1} $mole^{-1}$ and D_o was about 2×10^{-7} cm^2 sec^{-1} although the latter value could be wrong by several orders of magnitude since the data showed considerable scatter. These values were obtained by measuring the rate of exchange of hydrogen with water vapor. When they tried to measure the rate of exchange with water at lower temperatures, they found no temperature dependence. (It may be that the discrepancy in the results arises from a change in mechanism which generates the proton defects.) These authors clearly were measuring ΔH_f which is the sum of the enthalpy of formation of a proton defect and the enthalpy of diffusion of the proton. In the present experiments only the enthalpy of diffusion was measured since the electrode reaction generated the proton defects.

Acknowledgments

An Ellipsometric Study of Surface Films on Copper Electrodes Undergoing Electropolishing

M. Novak,[1] A. K. N. Reddy,[2] and H. Wroblowa[3]

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

Simultaneous current-potential and *in situ* steady-state ellipsometric measurements were carried out in order to study the electropolishing of vertical copper electrodes in a 65% aqueous solution of phosphoric acid. A technique was developed for displacing the visible, viscous film with glycerol and examining whether a second film was sandwiched between the copper surface and the viscous film. By using this technique, it was demonstrated that the electropolishing process involves the formation of two films on the electrode: (*i*) an adherent sandwiched solid film at least 40Å in thickness, and (*ii*) a displaceable viscous layer of highly concentrated electrolyte about 2000-3500Å thick. The solid film was either completely or partially destroyed when the electrode undergoing polishing was removed from the electrolyte, washed, and dried.

Theories concerning the mechanism of electropolishing of metals [cf. Hoar (1) and Jacquet (2) for reviews] have invoked the presence of either one or two layers in the immediate vicinity of the electrode. In the case of metals forming colored ions, a viscous liquid layer can be detected visually. This viscous liquid layer has been considered to be in contact with film-free metal (3-6), with metal covered with an adsorbed layer of oxygen or anions (7-9), or with metal covered with oxide or salt layers varying in thickness from about one monolayer to several tens of angstroms (10-21), according to the references quoted. This controversial situation has arisen most probably because the particular *in situ* methods used hitherto (impedance measurements, coulometry, current-potential curves) are not capable of yielding direct evidence about the thickness and nature of the film or films present. Direct methods such as electron diffraction suffer from a distinct disadvantage because they necessitate removal of the electrode from solution, followed by washing and drying.

What is required, therefore, is a technique which permits direct and *in situ* examination of the surface of an electrode undergoing electropolishing. Since the technique of ellipsometry is such a direct and *in situ* technique, it was used to study the electropolishing of copper.

Experimental

Procedure.—The copper electrode was mounted in a Teflon block, polished mechanically, rinsed with distilled and conductivity water, and placed vertically in the 65% phosphoric acid saturated with Cu^{++} ions. It was then potentiostated at the desired potential, until steady-state values were obtained for current (i) relative phase retardation (Δ), and relative amplitude reduction (ψ). The same steady-state values of the above parameters were obtained when the electrode was first potentiostated in the etching region of potentials to ensure a film-free metal surface, and then brought to the desired potential. The latter procedure, however, requires much longer periods of time, because the surface becomes rougher during dissolution and time is needed to smooth it in the region of potentials corresponding to polishing.

The presence of the viscous liquid film introduces an experimental difficulty which comes in the way of establishing the existence of a second film sandwiched between the metal and the liquid layer and of determining the nature and thickness of this sandwiched film. Thus, it is not clear whether the Δ and ψ values recorded from an *in situ* examination of the electrode are contributed to by one or two films. Under these circumstances, the following experimental procedure was adopted: (*i*) after the attainment of steady-state polishing conditions and the recording of the i, Δ, and ψ values, the electrolyte was displaced by an organic liquid of surface tension lower than that of the electrolyte; (*ii*) during this replacement of the electrolyte, the electrode was held potentiostated at the same potential as in the presence of the electrolyte. The following were the results of this procedure: first, the viscous liquid film present during electropolishing was removed; second, the inert organic liquid effectively stopped the anodic current without cessation of potential control; third, at no stage does the electrode become exposed to the atmosphere. Consequently, it may be assumed that after replacement of the electrolyte with the organic liquid, the viscous liquid film has been removed without destroying or altering any underlying film which may be present. In this "frozen" condition, the electrode was subject to ellipsometric measurements.[4]

The organic liquid usually used was glycerol. At several potential values the whole experiment was re-

[4] Since the experimental procedures adopted here permit ellipsometric measurements to be made in the presence and absence of the viscous layer, it is not necessary to make an *a priori* assumption that the viscous layer is liquid in nature. Even if it were a film of loose precipitate, the present experimental approach would still be valid.

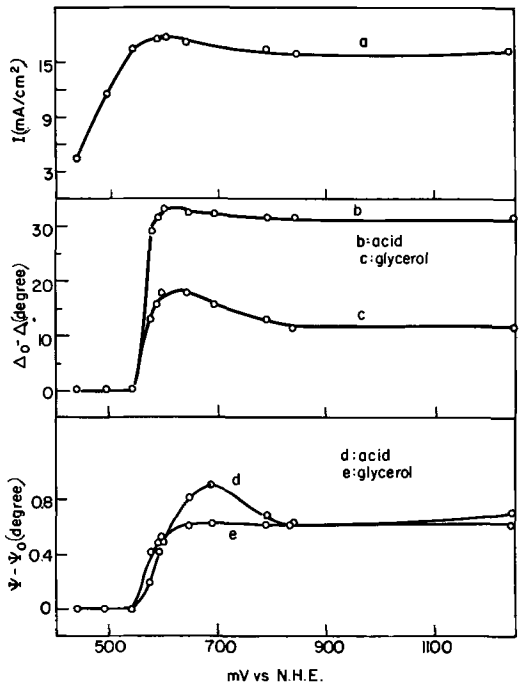

Fig. 1a. Steady-state current-potential relation; Fig. 1b. decrease of Δ with potential: b, for the total film, c, for the adherent film; Fig. 1c. decrease of ψ with potential: d, for the total film, e, for the adherent film.

peated using two new electrodes with two other organic materials: glycol and ethyl-octanol. Within the experimental error, the results obtained were identical with those in glycerol. It follows, therefore, that the same layer (be it the assumed viscous liquid layer, or a precipitated loose film) was removed by the displacing action of the organic fluids.

A new electrode-electrolyte system was used for each potential at which measurements were carried out.

Materials.—Polycrystalline blocks of Cu cut out of 99.9% pure Cu; 85% Baker phosphoric acid A.R.; Baker's Spectroscopically pure glycerol; Baker A. R. glycol; Airco FD ethyl-octanol; Baker A. R. copper oxide; conductivity water were used in experiments.

Apparatus.—1. Ellipsometer: D. C. Rudolf & Sons, Inc., Model 437-200E was used with the adjustable polarizer and analyzer positions and a fixed quarter-wave plate set between the polarizer and metal surface at $-45°$ to the plane of incidence. The source of light was a zirconium arc, followed by a mercury green filter (λ = 5461Å). Suitable corrections were made for nonnormal incidence of light. Accuracy of measurements was 0.05°. Reproducibility of results in the polishing region was $\pm 0.1°$.

2. Electrometer: Keithley, 610A.

3. Potentiostat: Wenking, 1A output current.

4. The cell (5 x 5 x 2.5 cm) was made of synthetic fused quartz with optically flat and homogeneous walls. Electrodes used were a saturated calomel reference electrode and a bright Pt sheet as a counterelectrode.

Results

The potential-dependence of the steady-state current density i, of $\Delta° - \Delta$,[5] and of $\psi - \psi°$ values is shown in Fig. 1a. (top), b (center), c (bottom), respectively. Curves b and d correspond to results obtained in phosphoric acid, curves c and e to results obtained after replacement of the electrolyte with glycerol. The angles of incidence, ϕ_1, were 69.34° and 70.04° in phosphoric acid and glycerol, respectively.

[5] $\Delta°$ and $\psi°$ refer to the values for reflection from a film-free metal surface in the particular medium under discussion.

Analysis of Results and Discussion

Qualitative description of the electrode surface at various potentials.—In the potential region up to 540 mV (*vs.* NHE), there is dissolution of the copper electrode (*cf.* the anodic current of Fig. 1a) without any change in Δ and ψ (*cf.* Fig. 1b and 1c). Since Δ and ψ remain at the values $\Delta°$ and $\psi°$, characteristic of a film-free copper surface, it must be concluded that there is no film formation in this domain of the current-potential curve which is known to be associated with visible etching and not with electropolishing. It is of significance to the technique of ellipsometry that the changes in Δ and ψ which may result from roughening of the surface during etching are less than the measurement accuracy of 0.05°.

In the range of potentials between 540 and 590 mV, four observations should be stressed: (*i*) there is an arrest in the current-potential curve (Fig. 1a); (*ii*) there is a visible brightening of the surface of the copper electrode; (*iii*) there is an abrupt change in the optical parameters (Fig. 1b and 1c), particularly in Δ which decreases by about 30° in the phosphoric acid electrolyte; and (*iv*) the change in Δ decreases by about 17° to about 13° after replacing the electrolyte with glycerol. Observations (*i*) and (*ii*) are customarily associated with the onset of the electropolishing process; observation (*iii*) must be interpreted in terms of the formation of one or two films necessary for electropolishing, and observation (*iv*) indicates that even after removal of some loose, nonadherent layer (either a viscous liquid layer or a loose precipitate), the electrode is covered with an adherent film. Thus, even without a quantitative analysis of the ellipsometric data, the present experiments have established that the electropolishing process is associated with the formation of two films, a loose, displaceable film and a second film adhering to the electrode.

The variation of Δ and ψ between about 540 and 840 mV (curves c and e) shows that the properties of the adherent sandwiched film undergo changes. These properties, however, remain constant from 840 to about 1300 mV, as indicated by the constancy of Δ and ψ.[6]

Quantitative characterization of films on copper electrodes undergoing electropolishing.—Adherent film on the electrode.—The experimental values of Δ and ψ obtained for each potential were compared with the sets of Δ and ψ values calculated by the IBM 7040 computer programmed with the exact equation for reflection from the film covered surface

$$\tan \psi \, e^{i\Delta} = R^p/R^s \qquad [1]$$

where

$$R^v = \frac{r_{12}^v + r_{23}^v e^{-i\delta}}{1 + r_{12}^v r_{23}^v e^{-i\delta}}$$

where v = p (parallel) or s (vertical) component of the polarized light, r's are Fresnel's reflection coefficients; subscripts 1, 2, 3 correspond to the bulk liquid medium, film and metal, respectively; $\delta = 4\pi \bar{n}_2 \cos \bar{\phi}_2 L/\lambda$

$\bar{n}_2$ = $(n_2 + i\kappa)$ = complex refractive index of film
n_2 = real part of the refractive index of the film
κ = absorption coefficient
$\bar{\phi}_2$ = angle of refraction in the film
L = film thickness
λ = wavelength *in vacuo* of the incident light (5461Å).

The value of $\bar{\phi}_2$ was expressed as a function of $\bar{n}_2$ by means of Snell's law included in the computer program

$$\sin \bar{\phi}_2 = n_1/\bar{n}_2) \sin \phi_1$$

[6] No experimental points are shown in the figure for the latter potential range, since all the measurements carried out in this range (in about ~50 mV intervals) practically coincided with each other and are denoted on nomograms and in Table I by No. 8.

where n_1 = refractive index of glycerol = 1.466; ϕ_1 = angle of incidence = 70.04°.

Since the two measurable quantities, Δ and ψ, are related to three unknown properties, L, n_2, and κ, of the film by two equations only, an infinite number of solutions are possible. Nevertheless, by adopting the procedure described below, the lower limit of film thickness at each potential was obtained without any assumptions and solely from the ellipsometric data.

Nomograms of n and κ were plotted on the $\Delta - \psi$ plane for various constant values of film thickness L. An example of a nomogram for a film thickness of 55Å is given in Fig. 2. In these nomograms, the "iso-κ" lines run from top to bottom and are bounded by the $\kappa = 0$ line at the extreme right. Since negative values of κ are physically meaningless, this 55Å nomogram must be considered inapplicable to experimental $\Delta - \psi$ points falling outside (*i.e.*, to the right of) the boundary defined by the $\kappa = 0$ line. To illustrate this argument, points 5, 6, and 8 have been inserted in Fig. 2 to show that they cannot correspond to $\kappa \geqq 0$ values, and that, therefore, they cannot be interpreted with the 55Å nomogram. Fortunately, such points (*e.g.*, 5, 6, and 8 of Fig. 2) can be made to fall within the $\kappa \geqq 0$ domain by trying nomograms for other film thickness. This is because the $\kappa = 0$ lines shift with increasing thickness toward the right, *i.e.*, toward higher ψ values (Fig. 3). Thus, experimental points lying to the right of the $\kappa = 0$ line in a nomogram for a particular thickness, L, must correspond to a film of a thickness $L' > L$. By applying nomograms for various thicknesses to the experimental $\Delta - \psi$ points obtained at various potentials, the lower limits of the thickness of the adherent sandwiched film were determined as a function of the relative potential of the electrode undergoing electropolishing (cf. Fig. 4).

It is of significance to the mechanism of electropolishing that, at a potential of only 40 mV more positive than 540 mV (which marks the limit of the etching region), the film formed on the surface of the electrode undergoing electropolishing has a thickness of not less than 40Å. This film which is sandwiched between the electrode and the viscous film persists on the electrode up to the potential of 1300 mV at which potential it has a thickness of not less than 55Å. Thus it must consist of a multilayer solid phase.

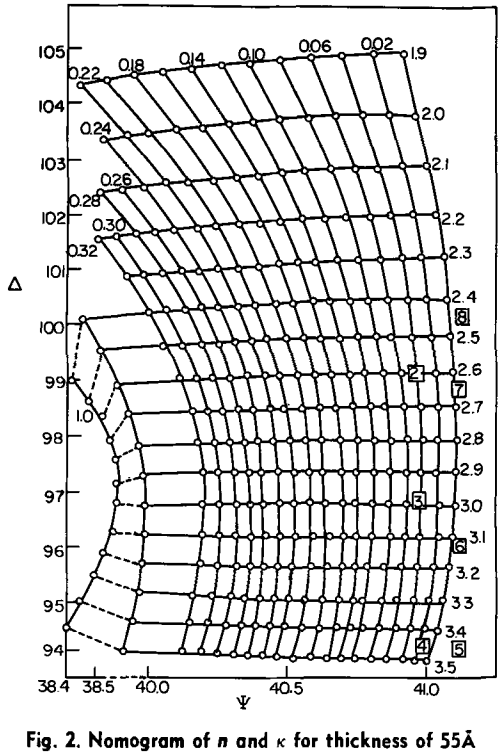

Fig. 2. Nomogram of n and κ for thickness of 55Å

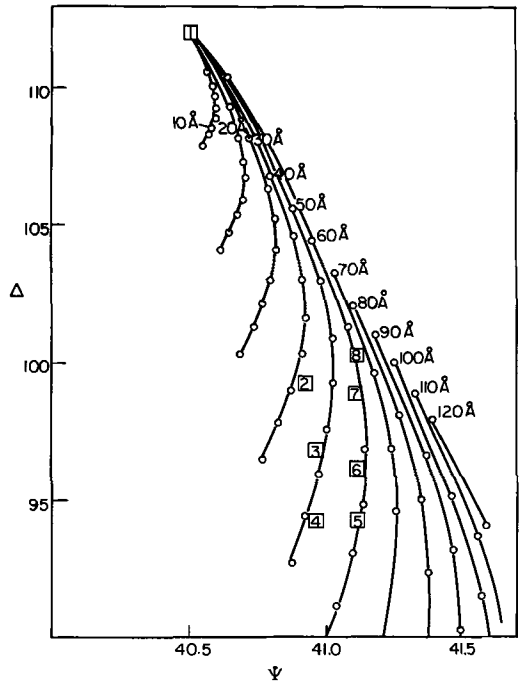

Fig. 3. Nomogram of $\kappa = 0$ lines for varying thicknesses of the film.

To advance from a determination of the lower limit of thickness of the sandwiched film to a characterization of its thickness and properties (*i.e.*, to a determination of the values of L, n_2, and κ), certain assumptions and additional arguments must be invoked.

The compounds constituting the solid film are most probably oxides or phosphates of copper. The refractive indices of copper oxides and phosphates are 2.7-2.8 (22) and 1.8 to 1.9,[7] respectively. These values are for bulk compounds, but one would not expect the values for a film to be lower. Hence, the refractive index of the sandwiched film can be argued to be not less than 1.8. It was found, however, that nomograms for thickness greater than 120Å force the experimental $\Delta - \psi$ points to correspond to films with a refractive index less than 1.8. In this way, it can be taken that the upper limit of the thickness of the sandwiched film is 120Å.

By restricting the thickness of the sandwiched film to a lower limit of 40Å and an upper limit of 120Å, the experimental $\Delta - \psi$ results were further analyzed in the following way. Using the nomogram for a particular thickness, the n_2 and κ values corresponding to a particular $\Delta - \psi$ point (obtained at a particular potential) were noted down. (It is obvious, for example, that the $\Delta - \psi$ point 2 in Fig. 2 corresponds to $n_2 = 2.6$ and $\kappa = 0.04$ in the 55Å nomogram.) For this same $\Delta - \psi$ point, the procedure was repeated with nomograms for different thicknesses. When a similar approach was adopted for all the experimental $\Delta - \psi$ points, Table I was constructed. From this table, it is seen that a particular $\Delta - \psi$ point corresponds to n_2 and κ values which are constrained to lie within certain limits. From these limits and the variation of the limits with potential, the following conclusions can be drawn.

1. In the potential range 0.580-0.840V, the absorption coefficient κ of the sandwiched film would have to change with potential if the refractive index is assumed constant and the film refractive index would have to vary with potential, if κ is assumed constant. Hence, either the refractive index or the absorption coefficient or both of them change with increasing anodic potential in the range just mentioned. That is, between 0.580 and 0.840V, the sandwiched film undergoes structural changes.

[7] Calculated from the Lorentz-Lorenz equation for $Cu(H_2PO_4)_2$.

2. The absorption coefficient of the final film (0.840-1.300V) has a very low value between zero and 0.02. The κ values at the potential 0.785V are also limited to this range.

3. The final film has a refractive index limited to the 1.8-2.4 range, indicating that it consists of copper phosphate or of a "mixture" of the latter and cuprous oxide (n_{Cu_2O} = 2.7-2.8 (22), $n_{Cu(H_2PO_4)_2}$ = 1.8-1.9).[8]

4. Winterbottom (23) quotes the value of κ_{Cu_2O} as 0.0086, obtained by measuring the attenuation of light (5451Å) by thin cuprous oxide disks. Thus, if the sandwiched solid film consists of phosphates with refractive index 1.8-1.9, its adsorption coefficient would be (*cf.* Table I) 0.01; and if it consists of cuprous oxide, its absorption coefficient would be 0.0086. Any mixture of the phosphate and oxide would most probably have an absorption coefficient of the same magnitude, *i.e.*, κ = 0.01.

It can be assumed, therefore, that $\kappa \leq 0.01$ and that higher values of κ can be rejected. This conclusion is supported by the electrochemical evidence contained in the current-potential curve (Fig. 1). Whereas the current-potential curve for electropolishing resembles that generally observed for anodic passivation in the initial rise of current with increasing anodic potential followed by a fall to a plateau in which the current is virtually independent of current, the plateau current for electropolishing ($\sim$ mA/cm^{-2}) is orders of magnitude greater than the plateau current ($\sim \mu$A/cm^{-2}) for passivation. In both cases, the potential is not sufficiently anodic for significant oxygen evolution to occur; hence the current must be utilized by some other process. If the solid film is an electronic conductor, as implied by Bockris *et al.* (24), then ionic transport through this film becomes prohibitively difficult, *i.e.*, the metal dissolution current becomes negligible. The large dissolution currents passing during electropolishing may, therefore, be taken to mean that the sandwiched solid film is not an electronic conductor, but an ionic conductor, in which case it would have an absorption coefficient very close to zero unless it is absorbing the 5461Å light used in the ellipsometer.

Since, in the light of these arguments, the absorption coefficient can be assigned a value ≤ 0.01, the thickness and refractive index of the solid film on the electrode surface can be assigned values as shown in Fig. 4. This is the best possible solution to the ellipsometric problem of recovering unique values of the thickness, refractive index, and absorption coefficient from the measurement of Δ and ψ in the absence of independent and direct knowledge of one of the three unknowns. It must be stressed, however, that no uncertainty exists with regard to the lower limit of thickness of the solid film which has been established to be 40-55Å.

Mention must be made at this stage of the fact that sensitive non-*in situ* methods, *e.g.*, electron diffraction, do not reveal the presence of this thick (40-55Å) film of copper phosphate/oxide on the electrode. To resolve this contradiction, the following experiment was performed. A copper electrode was immersed in the 65% phosphoric electrolyte and potentiostated at a potential of 1V until the polishing current assumed a steady value. Instead of displacing the electrolyte with glycerol and revealing a solid film of 60Å on the electrode, the latter was removed from the electrolyte, washed, dried, and then subjected to ellipsometric measurements in air. The thickness of the film did not exceed 20Å. This indicates that the 60Å solid film on the electrode does not survive the treatment of removal from the electrolyte, washing, and drying: it is either completely destroyed with the $<$ 20Å film being the result of atmospheric oxidation of a bared copper surface or it is partially dissolved with the $<$ 20Å film being a residue of the thick electropolishing film. It is understandable, therefore, that electron diffraction examination of a copper electrode removed from the polishing solution, washed with water and then with isopropyl alcohol, and dried, reveals the existence of a very thin ($< \sim$ 10Å) film of copper oxide. Thus, non-*in situ* methods used without special precautions designed to preserve the solid film on the electrode cannot lead to an elucidation of the electropolishing process.

Displaceable, nonadherent film.—An attempt to assess the properties of the viscous layer, displaceable by organic material, was made using a double film computer program (25) and an IBM 7090 computer. For both the first film on the copper surface and the second film, the value of κ was assumed to be zero.

The solutions for the experimental $\Delta - \psi$ values obtained in phosphoric acid fell into two distinct types. The first type of solution corresponds to a thin (0-10Å) internal film on the copper surface and an external film of about 60Å thickness and refractive index ~3, inconsistent with the 40-55Å lower limit of thickness previously established. In contrast, the second type of solution indicated an internal sandwiched film of about 40-70Å thick with a refractive index within the >2.4-3.6 range; this is virtually the same range of thickness as that established for the solid film observed on the electrode surface after displacing the external film.

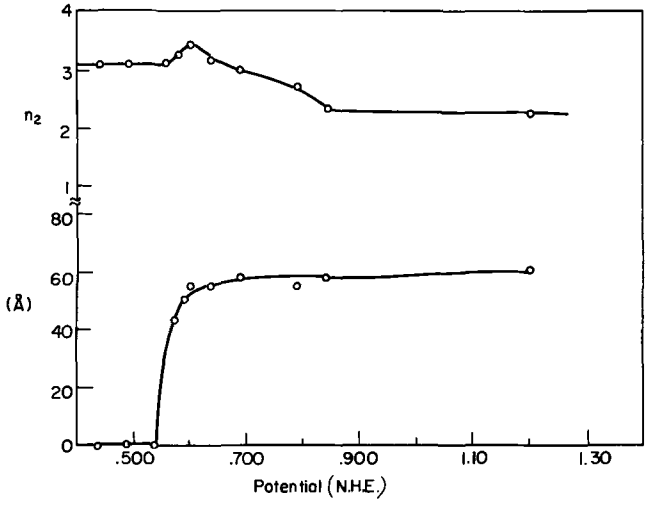

Fig. 4. Refractive index (n_2) and thickness (Å) of the adherent film as a function of potential, assuming the lowest limit of the film's thickness.

[8] *Cf.* footnote 7.

The range of n_2 includes the values corresponding to the latter film. The double-film computer program assumes that the films are sharply defined; in other words, it assumes that, at the external film-electrolyte interface, there is a discontinuous change in the refractive index. It is reasonable, however, to expect that, instead of a sharp interface, there is in fact an interphasial region in which the refractive index changes smoothly from a value characteristic of the displaceable film to one characteristic of the bulk electrolyte. If one ignores the existence of an interphasial region and considers a sharply defined displaceable film, then the second type of solution for the experimental $\Delta - \psi$ values indicates a film which has a thickness of 2000-3500Å and a refractive index very close to that of the bulk electrolyte. In other words, the ellipsometric measurements indicate that the displaceable layer observed during electropolishing is a thick, liquid film and not a loose precipitate.

The mechanism of electropolishing.—The present results support the views of Hoar (11), according to which the polishing can occur only if the metal dissolves randomly, and not preferentially as happens during the etching process. This randomness can be ensured only by dissolution of the metal into random vacancies arriving at the metal surface. Thus, polishing can occur only if a film is formed at the surface, through which cationic vacancies created at the film-electrolyte interface by the film's dissolution can migrate to the metal surface and accept the dissolving metal ions. (In molten salts, electropolishing could occur without a presence of such a film, since random holes are already present in the electrolyte itself.)

The film existing in the region 0.840-1.300V does not change its properties, nor thickness with potential, as evidenced by the constancy of Δ and ψ values (cf. Fig. 1 and 2). This fact contradicts the interpretation of impedance measurements given by Hoar (1), according to which the film's thickness increases linearly with potential. This, according to Hoar (1), was due to the fact that the rate of ionic migration through the film, v_m, has to be equal in the steady state to the rate of film's dissolution. The latter, being diffusion-limited, is constant and potential independent, and thus v_M must be potential-independent. Since v_M is proportional to the field across the film, $X = v/L$, it can be constant only if the film's thickness increases linearly with potential.

However, it seems that the vacancy mechanism of metal dissolution may lead to a different conclusion.

Since on arrival at the metal-film interface cationic vacancies are immediately filled in the fast process of metal dissolution into them, their concentration at the metal-film interface is always equal to zero and thus metal dissolves under limiting conditions determined by the rate of creation of vacancies at the film-solution interface, *i.e.*, by the rate of the film dissolution, which is potential-independent.

Thus in the potential region where the properties of the film remain constant with increasing potential (in this case, 0.840-1.3V), its thickness would also remain constant, since the film cannot be formed at the metal-film interface faster than it dissolves into the electrolyte.

The above suggestion, according to which the mechanism of electropolishing is that proposed by Hoar (1), however with a different rate-determining step, requires further verification in view of contradictory experimental findings, *i.e.*, thickness of the film (*a*) increasing with potential, as found by impedance measurements (1), or (*b*) constant, as found by ellipsometric evidence.

Film Formation and Reduction on Zinc Electrodes in Concentrated Potassium Hydroxide Solutions

M. W. Breiter*

General Electric Research and Development Center, Schenectady, New York

ABSTRACT

Anodic films were formed under potentiostatic conditions at three characteristic potentials in unstirred 6M KOH + 0.25M ZnO at 25°C on polycrystalline zinc electrodes, arranged either in a horizontal or vertical position. The film formation was followed as a function of time by determining the charge equivalent of the films by a method employing cathodic potential sweeps at 0.33 mV/sec. At each of the potentials, film formation occurred more rapidly on the horizontal than on the vertical electrode. The efficiency of film formation decreased from values above 50% at 250 sec to values around 20% on the horizontal electrodes. It stayed below 6% for the vertical electrodes.

The formation of anodic films on horizontal zinc electrodes was recently studied (1) in concentrated potassium hydroxide solutions either by taking photomicrographs of the electrode surface *in situ* at different potentials during a slow anodic voltage sweep or by measuring the two components of the electrode impedance with a small signal of superimposed 1000 Hz a.c. In agreement with earlier investigations (2-4), the course of the passivation was found to depend strongly on the convective conditions in the electrolyte near the zinc electrode. A loose, flocculent film, designated as type I, formed by precipitation from a supersaturated zincate solution near the surface in the absence of stirring. When the conditions of supersaturation were largely removed by stirring, the formation of a thin, more compact film, designated as type II, could be observed. The type II film, which is considered responsible for the passivation of the zinc electrode, appears to grow directly at the surface rather than by precipitation. It was also detected (5) beneath the type I film on horizontal electrodes in unstirred solutions. The different shape of voltammetric current-potential curves, measured on horizontal or vertical electrodes in unstirred solutions, was attributed to the influence of the convective conditions. While both type I and II film are produced in the absence of stirring on horizontal electrodes, the formation of type II film is predominant on these electrodes in stirred solutions and on vertical electrodes in unstirred solutions because of the effect (6) of natural convection.

New results concerning the formation of anodic films at constant potential are presented in this communication. Three characteristic potentials (−1.3V, −1.1V, −0.90V *vs.* an Hg/HgO reference electrode in 6M KOH) were chosen for the study. The potentials of −1.3 and −1.1V are close to the potentials of peaks in voltammetric current-potential curves on horizontal electrodes and vertical electrodes respectively of polycrystalline zinc in unstirred 6M KOH + 0.25M ZnO at 20° ± 1°C. The potential of −0.9V is located in the passive region. The film formation was followed by determining the charge Q_{Film} required for the reduction of the film. The efficiency of film formation was obtained from the ratio Q_{Film}/Q_{total}. Here Q_{total} designates the anodic charge consumed at constant potential U in time t.

Experimental conditions differ greatly from those of the recent coulogravimetric investigation (7) of the zinc electrode in potassium hydroxide. With regard to previous work on anodic films at zinc electrodes, the reader is referred to the comprehensive bibliography in ref (1).

Experimental Procedure

The electrodes were cut from rolled zinc sheet, designated as Mix 60 by the New Jersey Zinc Company, with a purity of 99.99%. They were polished by dipping them for a short time in concentrated nitric acid. Polishing was followed by a thorough rinsing in a stream of distilled water. The electrodes were mounted and immediately put into the vessel. They stayed at open circuit for 30 min in 6M KOH + 0.25M ZnO, saturated previously with purified nitrogen, before the desired potential was applied by the potentiostat. Nitrogen flowed at a large rate above the solution during the measurements. Throughout the study the electrode potential was measured against and is referred to a mercury-mercuric oxide electrode in 6M KOH. The solutions were prepared from reagent grade chemicals and distilled water. They were either made up freshly before the experiments or stored under argon with the exclusion of air.

The Teflon polymer vessel with the vertical arrangement of the electrode was described (1, 8) previously. The apparent surface area was 0.79 cm^2. For the horizontal arrangement the zinc electrode was pressed against a Teflon polymer block with a rectangular hole (2.5 cm long, 1 cm wide, 3 cm high) by a suitable Teflon polymer holder. The rectangular hole served as test electrode compartment and was connected with the counterelectrode compartment by another hole, drilled into the Teflon polymer block at a distance of 2 cm from the electrode surface. Visual observation of the electrode surface was feasible. A fine hole in the block, 0.05 cm from the surface, led to a separate reference electrode compartment. The counterelectrode was a hydrogen-diffusion electrode of the Niedrach-Alford type (9). It was verified that, under anodic polarization, the potential of the diffusion electrode did not differ by more than 0.1V from the value in the absence of polarization. Since platinum does not dissolve (10) at such potentials in alkaline solutions, side effects (11) originating from traces of platinum in the electrolytic solution were eliminated.

After applying a potential step by turning the switch of the Wenking 6 ITRS potentiostat, the anodic current was measured as a function of time on the meter of the instrument. The first reliable measurement of the current was feasible after about 10 sec. It took several seconds in the case of large initial currents before a constant potential was established. The procedure proved satisfactory since long-time experiments were involved. Short-time recording of the current during potentiostatic potential steps is worthless since the changing iR_{El} drop distorts the attempted potential step.

After the desired time of anodic polarization the potentiostat was turned off, leaving the zinc electrode at open circuit. The electrode potential became more negative and reached values close to −1.33V within 30 sec. The potentiometer of the potentiostat was adjusted to the value of the open-circuit potential. Po-

*Electrochemical Society Active Member.

tentiostatic control was turned on again, and a cathodic voltage sweep at 0.33 mV/sec, supplied by the Type 255 Exact function generator, was started by the manual triggering of the generator. The time required for the operations between the switching-off of the anodic polarization and the start of the voltage sweep was always 130-150 sec. The voltammetric I-U curves were recorded on a Mosley Model 136A X-Y recorder.

After the zinc electrode reached a potential at which hydrogen evolution was indicated by the current-potential curve, the potentiostatic circuit was disconnected. The open-circuit potential of the test electrode moved to values close to −1.36V. The potentiometer of the potentiostat was adjusted to this value. Potentiostatic control was switched on, and a second cathodic sweep was applied at 0.33 mV/sec. A time of about 150 sec elapsed between the stopping of the first cathodic sweep and the start of the second one.

The zinc electrode was removed from the vessel at the end of the second cathodic sweep. The procedure (anodic polarization, open circuit, first cathodic sweep, open circuit, second cathodic sweep) was always started with a fresh, chemipolished electrode.

Experimental Results

The anodic current density i is plotted as a function of time for the horizontal and vertical electrodes at the different potentials in Fig. 1 and Fig. 2. A double logarithmic plot was chosen to accommodate most of the data.

Some of the voltammetric i-U curves obtained in the described manner on horizontal electrodes are shown in Fig. 3. The solid curves on the left side of Fig. 3 were measured after an anodic polarization of 250 sec and the curves on the right side after 4500 sec at −1.3, −1.1, and −0.9V, respectively. The dotted curves result from the second cathodic sweep on the respective electrode (a' after a, etc.). Voltammetric curves on the vertical electrodes are similar to curves

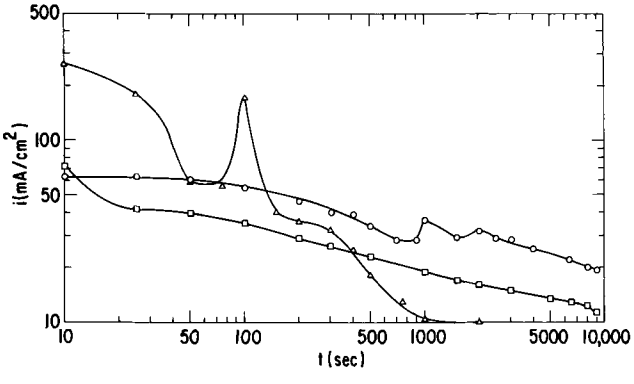

Fig. 1. Current density during the oxidation of horizontal zinc electrodes at −1.3V (○), −1.1V (△), and −0.9V (□).

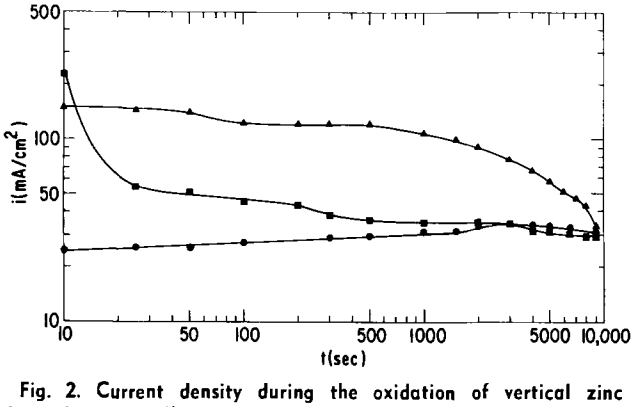

Fig. 2. Current density during the oxidation of vertical zinc electrodes at −1.3V (●), −1.1V (▲), and −0.9V (■).

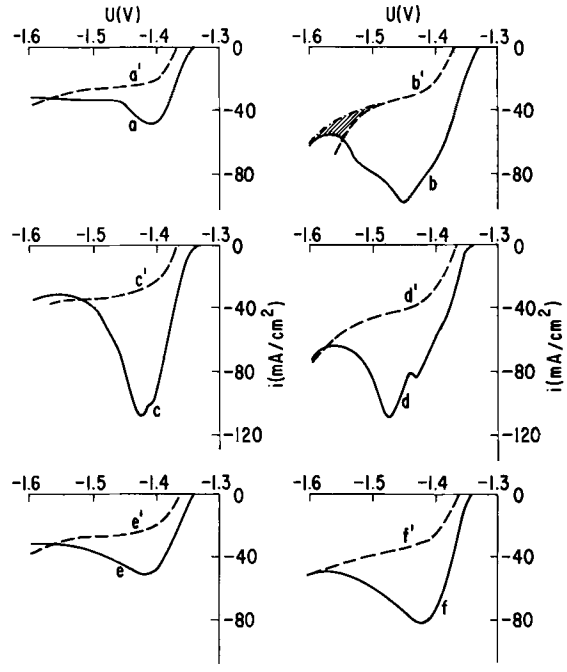

Fig. 3. Voltammetric *i-U* curves obtained at 0.33 mV/sec during cathodic sweeps after anodic polarization at −1.3V (a,b), −1.1V (c,d), −0.9V (e,f) for 250 sec (a,c,e) or 4500 sec (b,d,f) on the horizontal electrode. Dotted curves resulted from the second sweep on the respective reduced electrode.

a and e. The dotted curves, especially at shorter times of anodic polarization, are closer to the solid curves on vertical than on horizontal electrodes.

The charge Q_{Film} for the reduction of the film on the zinc electrode was evaluated in an approximate way

$$Q_{\text{Film}} = \int_{U_1}^{U_3} i\,dt - \int_{U_2}^{U_3} i\,dt \qquad [1]$$

Here U_1 and U_2 designate the starting potentials for the first and second cathodic sweep. U_3 is the potential where the solid and dotted curve intersect. The Q_{Film} values are plotted in Fig. 4 as a function of time of anodic polarization for the three different potentials. Open symbols belong to measurements on horizontal electrodes. Solid symbols refer to measurements on vertical electrodes. The Q_{Film} values were found equal to zero within the error limits for the different times of oxidation of the vertical electrode at −1.3V. The total charge consumed during time t of anodic polarization of the zinc electrode at constant potential was

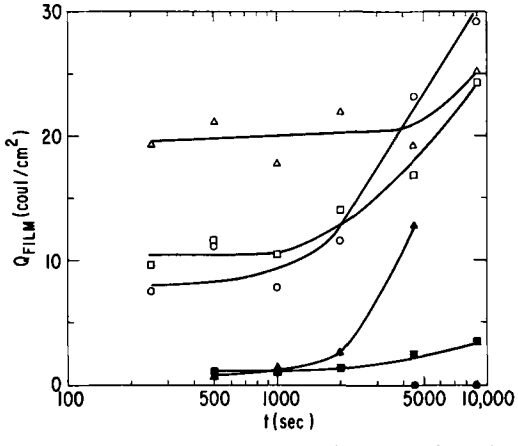

Fig. 4. Charges for the reduction of films, formed anodically on horizontal (○, △, □) and vertical (●, ▲, ■) electrodes as a function of time of anodic polarization. ○, ●, −1.3V; △, ▲, −1.1V; □, ■, −0.9V.

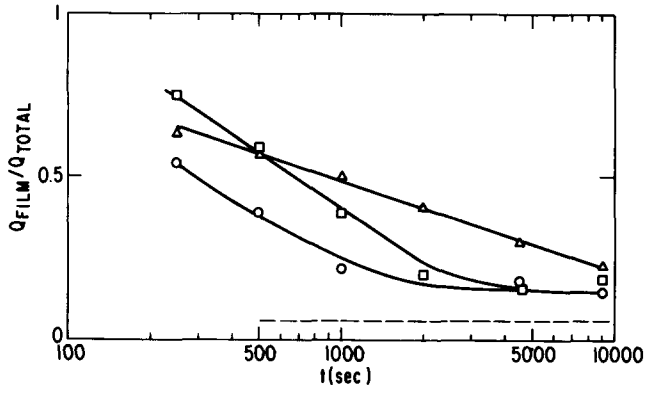

Fig. 5. Efficiency of film formation as a function of time for the horizontal electrodes (○: −1.3V, △: −1.1V, □: −0.9V). The efficiency stayed below 6% for the vertical electrodes.

determined by graphical integration of the i-t curves in a linear plot

$$Q_{\text{total}}(U,t) = \int_0^t i(\tau)d\tau \qquad [2]$$

The ratio $Q_{\text{Film}}/Q_{\text{total}}$ of the charges represents the efficiency of film formation and is plotted in Fig. 5 by open symbols for the horizontal electrode as a function of oxidation time. Here Q_{total} and Q_{Film} are values that result from three successive measurements. Since the error in the determination of Q_{Film} values is large, only the upper limit of 6% is shown for the ratio $Q_{\text{Film}}/Q_{\text{total}}$ on vertical electrodes in Fig. 5.

Discussion

General features of film formation.—The formation of anodic films and of dissolved zincate occur simultaneously at constant potential. The i-t curves display peaks within relatively narrow time intervals and steps in somewhat larger intervals (see Fig. 1 and Fig. 2). In agreement with previous results (1) this behavior is ascribed to the nonuniform film formation. Visual observation of the horizontal electrodes confirmed that the films started to grow in distinct patches on certain parts of the surface. The patches spread over the surface with time and grew in thickness. The initial patches appeared after shorter times when the potential became less negative. Wide vertical pores leading to uncovered areas of the zinc surface were visible as bright spots for at least 1000 sec.

The film formed at −1.3V on horizontal electrodes looked dark and sometimes contained white stripes in contrast to its whitish appearance (1) on the (0001) plane of zinc single crystals. Since it possessed the same properties (flocculence, loose adherence) as the type I film on the (0001) plane otherwise, the film at −1.3V is designated as type I film for polycrystalline surfaces. It forms by precipitation from the supersaturated zincate solution near the electrode surface.

At −0.9V a large part of the surface of the horizontal electrode assumed a goldish look after 200 sec. The goldish look darkened in the first 1000 sec. The formation of the compact type II film is observed. Patches of a grayish film, possibly type I film, appeared on top of the goldish film after about 1000 sec and spread with time.

The horizontal and vertical electrodes display a different long-time behavior. The current at a given potential decreases more rapidly with time on the horizontal electrode than on the vertical electrode (see Fig. 1 and Fig. 2). The different behavior will be correlated to the film formation in the discussion of Fig. 5. Since a steady-state current is not reached at constant potential on the zinc electrodes after 9000 sec, the shape of anodic current-potential curves on zinc in concentrated potassium hydroxide solutions depends strongly on the time intervals in which the potential is changed from one value to the next one.

Reduction of the film and determination of Q_{Film}.—The following processes may occur simultaneously during a cathodic potential sweep, starting at −1.33V after the preceding polarization of the zinc electrode at −1.3, −1.1, or −0.9V:

1. Reduction of the film.
2. Deposition of zinc from 6M KOH + 0.25M ZnO.
3. Hydrogen evolution.

Attempts to eliminate the zinc deposition by carrying out the reduction in 6M KOH failed because the loosely adherent type I film was partly removed from the surface during the replacement of 6M KOH + 0.25M ZnO by 6M KOH. Fast potential sweeps proved (12) useful for the determination of adsorbed carbonaceous species in the presence of large bulk concentrations of fuel on smooth platinum metal electrodes. However, the anodic films possess a porous structure on zinc. The application of fast sweeps or galvanostatic pulses would introduce additional problems because of the poor response (13) of porous systems.

The technique used in this investigation was already described under Experimental Procedure. It is based on a number of assumptions:

(*A*) After the film formation the specimen is at open circuit for 130-150 sec before the cathodic sweep is initiated. Autoreduction during this time has to be small.

(*B*) The charge consumed by the processes 2 and 3 is the same during the first and second cathodic sweep.

The error introduced by assumption *A* is not large for porous films (type I) on top of solid films (type II) because the processes which occur inside the pores are slow. Reduction of the type II film which was formed on vertical electrodes in 6M KOH takes place with a noticeable shift of the peak of the reduction wave toward more negative potentials with increasing sweep rate. The reduction of type II film is a hindered process, leading to a relatively small rate of autoreduction at open circuit within 130-150 sec. While assumption (*B*) is not strictly fulfilled, its application leads to acceptable errors in the present study for the following reasons.

(*a*) After short times of anodic polarization ($t \leq$ 250 sec) the dotted curves coincide within the experimental reproducibility with the curves of the first cathodic sweep, started at the open-circuit potential on fresh zinc electrodes in the horizontal or vertical arrangement. The maximum contribution of process 2 which is controlled by mass transport at $U < -1.4$V is given by curves a', c', and e' in Fig. 3 for a flat surface. The solid and the dotted curves are reasonably close on horizontal or vertical electrodes at potentials more negative than the potential U_{in} at which they intersect. Thus the position of the intersection which is largely determined by process 3 is not critical.

(*b*) The area under the dotted curve, as defined by the second integral in Eq. [1], increases with the time of anodic polarization for $t > 250$ sec (compare curves b', d', f' in Fig. 3). This increase reflects the fact that the zinc electrode became porous. The shape of the dotted curve did not change when the time between the end of the first cathodic sweep and the start of the second cathodic sweep was increased from 150 to 1000 sec. Thus each of the dotted curves represents the maximum contribution of process 2 at $U \leq -1.5$V on the porous electrode in question. The position of the intersection was not critical after anodic polarization at −1.1 and −0.9V on the horizontal electrode (see curve d' and d and curves f' and f in Fig. 3) because of the reasonable closeness of solid and dotted curve. The ascending branches of the dotted and solid curves at $U < -1.5$V were not found close any more on horizontal electrodes after larger times of anodic polarization at −1.3V. Hydrogen evolution starts earlier during the second sweep (see curve b' in Fig. 3) than

during the first sweep (curve b). The possible error may be estimated and is indicated by the shaded area between curves b and b' in Fig. 3. It is not large. A similar reasoning applies to the results on vertical electrodes whenever the solid and dotted curves are not reasonably close at $U < U_{in}$.

The error in the determination of Q_{Film} was estimated to be less than 10% for horizontal electrodes. Since the reproducibility is worse, this appears satisfactory for horizontal electrodes. For vertical electrodes, the error is larger than 10% because the anodic film is thin in most cases. Since an error estimate is difficult, the respective results on the vertical electrodes are of a more qualitative nature.

The solid curves c, b, and d in Fig. 3 display peaks. These peaks are connected with the reduction of the film since they are not eliminated by the point-wise subtraction of curve c' from curve c for instance. More about the origin of the peaks is not known at present.

Efficiency of film formation.—The points, representing the charge Q_{Film} at a given potential as a function of time of anodic polarization, scatter considerably in Fig. 4. The scattering reflects the fact that the film does not grow in a reproducible way on the different electrodes. It is less noticeable for the vertical electrodes because the same scale was used as for the horizontal electrodes.

In general Q_{Film} (U, t) is larger for the horizontal electrodes than for the vertical ones. The charge Q_{Film} increases with time in agreement with the visual observations on horizontal electrodes. When removing vertical electrodes after anodic polarization at −1.1V, preferential attack by big etch pits in the upper half of the circular surface was noticed. A wide hole shaped like a bird's wing penetrated the whole electrode (thickness 0.5 mm) after 9000 sec. The sudden increase of Q_{Film} with time between 1000 and 4500 sec at −1.1V may reflect preferential film formation in etch pits where the natural convection is not so strong than on the rest of the vertical surface.

The ratio Q_{Film}/Q_{total} decreases with time at each of the three potentials and reaches values between 0.15 and 0.23 after 9000 sec on the horizontal electrodes. The charge for zincate production is much larger than that for film formation. On the vertical electrodes the ratio Q_{Film}/Q_{total} remained below 0.06. Only this maximum value is indicated by the dotted line in Fig. 5 for the vertical electrodes.

More than 90% of the total current on vertical electrodes goes into zincate formation. The decrease of the net current with time at −1.1 and −0.9V (see Fig. 2) is largely due to an inhibition of the zincate production by the anodic film on vertical electrodes. A similar conclusion may be drawn at −1.1 and −0.9V for the horizontal electrodes at times between 2000 and 9000 sec (see Fig. 5). It is likely that the decrease of the rate of zincate production is caused by the gradual closing of pores when the films grow thicker with time. The peaks in the i-t curves result from the sudden opening and closing of pores. The gradual disappearance of the bright spots which reflect the presence of wide vertical pores ending at the metal surface, confirms the role of wide pores.

Electrolytic Determination of Porosity in Gold Electroplates

I. Corrosion Potential Measurements

Ronald J. Morrissey*

Research Division, AMP Incorporated, Harrisburg, Pennsylvania

ABSTRACT

The porosities of gold electroplates on copper may be determined by measuring the corrosion potentials of the specimens *vs.* a suitable reference electrode in an electrolyte which serves as a mild corrodant for the exposed basis metal. The corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl electrolyte are shown to vary with the exposed area fraction of copper according to an expression derived by Stern. It is possible to calibrate the technique so that values of the exposed basis metal area fraction in electroplated specimens can be estimated to a reasonable approximation. The method is simple and offers very high sensitivity, particularly at low porosities. Operational considerations and sources of error are discussed.

Chemical and electrographic test procedures for the determination of porosity in electrodeposits have been reviewed and evaluated in the literature (1-4). Such procedures are in most cases destructive and in general have not proven highly suitable for process control applications. Electrolytic techniques offer the promise of rapid and relatively nondestructive means of determining electroplate porosities with great sensitivity. Such techniques have therefore been of considerable interest.

In 1938, Hoar (5) suggested that the corrosion potential of a specimen coated with a porous electroplate could serve to indicate the degree of porosity. In 1951, Shome and Evans (6) reported the determination of porosities in electrodeposits of nickel and cobalt on steel by measuring the cell currents (leakage currents) passed when the specimens were connected, in an electrolyte of 3% NaCl plus 0.1% Rochelle salt, to a large copper gauze which served as an auxiliary cathode. No reference electrode was used. They reasoned that, if the copper gauze were made sufficiently large, the cell current would be limited only by the rate of anodic dissolution and would therefore be directly proportional to the exposed area of bare steel. This technique was subsequently extended by Ehrhardt (7) with the addition of an external power supply with which the potential between the specimen and the auxiliary cathode could be controlled. Again, no reference electrode was employed. Using an electrolyte of 5% H_2SO_4, and with a potential of 0.75V maintained between the specimen and the auxiliary cathode, Ehrhardt measured porosities in gold electroplates on copper. A variation of the leakage-current technique has been employed by Kamm, Willey, and co-workers (8) to determine the continuity of the iron-tin alloy layer in electrolytic tinplates on steel.

Clarke and Britton (9) considered the pore channels in an electrodeposit as an array of minute electrical resistances in parallel, and devised a technique for estimating the sum of these resistances (and hence, a measure of the porosity of the electrodeposit) by measuring the slope dV/dI of the anodic polarization curve of the specimen at potentials within approximately 100 mV of the corrosion potential. These authors also noted that the corrosion potentials of electroplated specimens appeared to vary with the porosity of the electrodeposit, but did not pursue the matter further. Using an electrolyte of 5% Na_2SO_4 plus 0.1% Rochelle salt, Clarke and Leeds (10) have applied the dV/dI technique to measurements of the porosities of gold electroplates on copper.

Relation of the Corrosion Potential to Electrodeposit Porosity

A series of experiments was undertaken to investigate the possible usefulness of corrosion potential measurements for determining porosity in gold electroplates on copper. OFHC copper sheet of 1 mm thickness was stamped to form a series of circular coupons of 25 mm diameter, each having a small punched tab at one edge. The geometric surface area of each specimen thus formed was 10.8 cm^2. Following stamping, the specimens were cleaned, degreased, and then rack-plated with Temperex HD gold[1] to a thickness of 100 μin. (2.54μ). Temperex HD is an unbrightened gold which yields deposits with a density approaching the bulk density of pure gold. Following plating, the specimens were rinsed in demineralized water, dried, and retained in a desiccator over dried silica gel prior to testing.

Corrosion potentials of the plated specimens were determined *vs.* that of a saturated calomel reference electrode in a solution of 0.1M KCl. A Pyrex resin kettle of 2 liters capacity served as the reaction vessel. This was fitted with a Plexiglas cap through which the electrodes could be immersed into the bath. Experiments were performed at room temperature, which varied from 22°-25°C. Solutions were made up using demineralized, boiled water, the specific resistance of which was typically 140,000-160,000 ohms. Analytical Reagent grade chemicals were employed throughout.

The reference electrode employed was a Beckman No. 39170 saturated calomel electrode having a fiber junction. For convenience, this was located in the electrolyte bath at a distance of 5 cm from the test specimen, which was itself suspended in the electrolyte by means of a 99.99% gold wire.[2] It had been shown in previous work (9) that the position of the reference electrode is of negligible influence in determining corrosion potentials of specimens coated with porous electrodeposits. Prior to each experiment, the potential of the saturated calomel electrode was checked against that of a Beckman No. 41236 silver-silver chloride electrode which was reserved as a standard.

Potentials were determined using a Keithley Model 610A electrometer. The output of this instrument was relayed to a strip-chart recorder, so that slow changes in the observed emf could be discerned easily. It was

noted that after a gold-plated copper specimen was immersed in the electrolyte its potential, measured *vs.* that of the reference electrode, would drift for a period of 10-30 min in a generally negative direction until a steady value was attained. The steady values, once attained, were observed to be stable for periods of several hours duration. It was further found that on repeated testing of the same sample the steady corrosion potentials observed were ordinarily reproducible to within ±2 mV.

Further experiments were conducted to obtain comparative indications of porosity in electroplated specimens from corrosion potential measurements and also by means of the ammonium persulfate—ammonium hydroxide etch technique described by Frant (11). Corrosion potentials of gold-plated OFHC copper specimens prepared as outlined previously were determined *vs.* SCE in 0.1M KCl solution. Following this, the specimens were rinsed in demineralized water, dried, and then individually subjected to the ammonium persulfate-ammonium hydroxide etch technique, the apparent porosities being indicated as parts per million of cupric ion in the resulting solutions. In order to minimize undermining of the gold platings by the rather aggressive etchant, etching times were restricted to 5 min/specimen. Analysis of the resulting solutions was performed by emission spectrography, using a rotating disk technique with radio-frequency spark excitation.

The results of this series of experiments are shown plotted in Fig. 1. It was found that the steady-state corrosion potentials obtained for the specimens in 0.1M KCl solution were proportional to the logarithms of their apparent porosities as determined by the chemical etch technique. Agreement of the experimental points to the line in Fig. 1 was found to be within the limits of precision of the emission spectrographic technique employed. Porosity in these specimens was found to occur most prominently at rack marks (thinly plated areas) in the area of the punched tab. These tended to be rather irregular among the various specimens, accounting for the observed dispersion in porosity values obtained.

Relation of the Corrosion Potential to Basis Metal Area Fraction

Experimental Considerations

The evidence of Fig. 1 leads one to speculate that the corrosion potentials of gold-plated copper specimens might perhaps be related to the logarithm of the exposed area or area fraction of copper. This is not without precedent. Stern (12) had shown that for binary galvanic couples controlled by activation polarization the corrosion potential was given by

$$\eta_{corr} = -\frac{E_A\beta_C}{\beta_A+\beta_C} - \frac{\beta_A\beta_C}{\beta_A+\beta_C}\log A_A i_{o_A} + \frac{\beta_A\beta_C}{\beta_A+\beta_C}\log A_C i_{o_C} \quad [1]$$

where η_{corr} is the corrosion potential of the couple, measured with respect to the equilibrium potential of pure cathode material in the same electrolyte, which is taken as zero. E_A is the corrosion potential of pure anode material in the electrolyte, again measured with respect to the equilibrium potential of pure cathode material taken as zero. β_A and β_C are the Tafel slopes of the logarithmic polarization curves for the anodic and cathodic processes, respectively. A_A and A_C are the respective area fractions of anode and cathode materials in the actual couple (such that $A_A + A_C = 1$), and i_{o_A} and i_{o_C} are the exchange current densities for the anodic and cathodic processes.

Here we may note that for a given base metal-noble metal couple in a given corrodant bath, the electrochemical parameters E_A, β_C, β_A, i_{o_C} and i_{o_A}, as well as the equilibrium potential of pure cathode material, are constants. Further, for the case of base metal specimens coated with noble metal electroplates of moderate to low porosity, $A_C >> A_A$. In this case, A_C approaches unity, and the term in ($\log A_C i_{o_C}$) may be considered a constant. It thus becomes possible to rearrange expression [1], combining and substituting terms to obtain a simplified expression of the form

$$V_{corr} = K_1 - K_2 \log A_A \quad [2]$$

where V_{corr} is the corrosion potential as measured *vs.* a suitable reference electrode, K_2 is equal to ($\beta_A\beta_C/\beta_A+\beta_C$), and K_1 incorporates the remaining constant terms resulting from the rearrangement of expression [1].

Establishment of Calibration Curves

Experiments were undertaken to determine the change in corrosion potential with basis metal area fraction in galvanically connected gold-copper couples of known geometric area relationships. 1 mm gold sheet of 99.9% purity[3] was stamped to form a circular coupon of 25 mm diameter, having a small punched tab at one edge. This was used as the gold specimen in all determinations. Its geometric gross surface area was 10.8 cm^2. Prior to each experiment, this specimen was cleaned by rinsing in acetone, soaking for 30 min in 1.0M HCl, and then rinsing with demineralized water. The specimen was then suspended in the electrolyte by means of a 99.99% gold wire.[2]

Formvar-insulated copper wire in No. 20, No. 30, and No. 36 gauge sizes[4] and in No. 47 gauge size[5] was chemically stripped and cut into short lengths. The cut ends were then ground approximately flat on an abrasive wheel. Spectrographic analysis indicated that these samples were of 99.99+% purity. Prior to each experiment, the copper specimen was cleaned by rinsing with acetone, soaking for 30 min in 1.0M NH_4Cl, and rinsing with demineralized water. The specimen was then suspended in the electrolyte by means of an adapter attached to the shaft of a micrometer head which could be mounted in the cap of the reaction vessel. Electrical contact to the copper specimen was effected by means of a lead connected to the micrometer barrel. Use of this arrangement allowed the immersed area of copper to be varied, during the course of a given experiment, over several orders of magnitude. The immersed area of gold was maintained constant at 10.8 cm^2 in all experiments.

[5] Obtained from Bridgeport Insulated Wire Company.

Some representative plots of measured corrosion potential (*vs.* SCE) *vs.* immersed area fraction of copper for gold-copper couples in 0.1M KCl solution are shown in Fig. 2. Figure 2 summarizes the results of two experiments, one using a No. 20 copper wire specimen and the other using a No. 36 copper wire specimen. The area fractions shown here are calculated on the basis of geometric areas. In determining the true immersed areas, one must consider the surface roughness factors of the various specimens. For purposes of this work, we have assumed that the roughness factor for a given wire specimen should be fairly consistent along its length. The straightness of the plots obtained would appear to indicate that this is true. The continuity of the plots obtained using No. 20 and No. 36 copper wire specimens would indicate that the surface roughnesses of these two specimens were comparable.

Deviations from linearity are observed in Fig. 2 at both large and small values of the immersed copper area fraction. At large copper area fractions, this is in accordance with the expression [1], for then (log $A_C i_{oC}$) can no longer be considered a constant. At small area fractions of copper, the deviations are caused experimentally by withdrawal of the wire specimen through the topmost layers of the electrolyte, giving rise to differential aeration and other interface effects at the meniscus. These effects can be eliminated by the use of metallographically mounted and sectioned wire specimens, or alternatively by the use of wire specimens which have been heavily gold plated and then perpendicularly sectioned according to the method of Ehrhardt (7). Additionally, the range of measurement may be extended by the use of a larger gold specimen and/or finer copper wire specimens.

Prolonged immersion in 0.1M KCl solution produces a visible film on copper. While this did not appear to affect the corrosion potentials of gold-copper couples, further experiments were performed using 0.1M NH_4Cl electrolyte, which exhibits a slight solvency for copper oxides. A plot of corrosion potential *vs.* immersed area fraction of copper for gold-copper couples in this electrolyte is shown in Fig. 3. The two lowermost points in this illustration were obtained using No. 47 copper wire specimens which were plated with Temperex HD gold to a thickness of 1 mil (25.4μ) and then perpendicularly sectioned so as to expose only the cross-sectional area of the copper wire substrate. Each such specimen, after cleaning by brief immersion

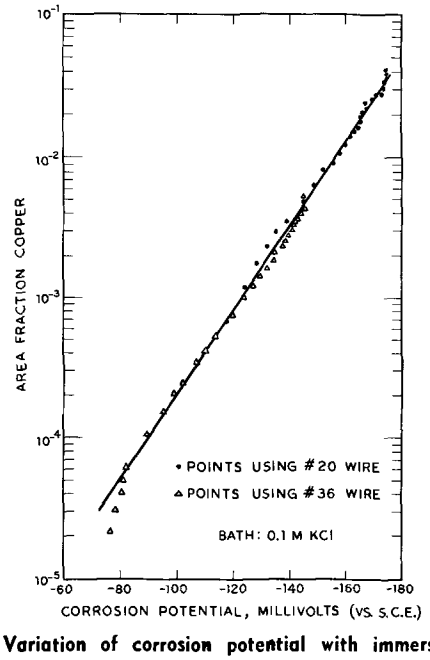

Fig. 2. Variation of corrosion potential with immersed copper area fraction.

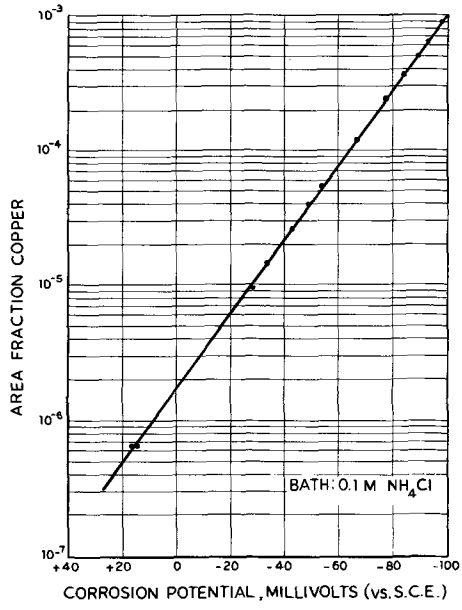

Fig. 3. Variation of corrosion potential with immersed copper area fraction.

in 6M HCl and rinsing in demineralized water, was introduced into the electrolyte via the micrometer device and immersed to a depth of 1 cm. Coupling of the plated and sectioned wire to the gold specimen and determination of the corrosion potential of the couple were then accomplished as previously outlined. In this fashion, interface effects were successfully avoided. The remainder of the data points in Fig. 3 were obtained using a bare No. 47 copper wire specimen prepared and immersed as outlined previously. The slope K_2 of this plot, calculated using common logarithms, is 0.0357V. This is in excellent agreement with the value of 0.0329V calculated for K_2 from the observed values for β_C of gold (0.0935V) and β_A of copper (0.0507V) in this electrolyte. The slope of Fig. 2 is 0.0335V, indicating that the Tafel slopes of gold and copper in 0.1M KCl solution are probably quite similar to those obtained in 0.1M NH_4Cl.

The range of measurement in Fig. 3 is extended by two orders of magnitude from that of Fig. 2. It was noted that corrosion potentials of gold-copper couples of a given immersed area fraction of copper in 0.1M NH_4Cl solution were more positive by approximately 25 mV than those of corresponding couples in 0.1M KCl solution.

Validation of the Calibration Curves

The expression [1] was derived for the case of binary galvanic couples controlled by activation polarization. It would thus be expected that the curves shown in Fig. 2 and 3 could serve as calibration curves for specimens coated with porous electrodeposits only if conditions were such that the effects of concentration and resistance polarization are small, and that accumulation of solid corrosion products in the pore channels is minimized or prevented entirely.

Two series of experiments were performed in an attempt to assess the validity of the calibration curves for specimens coated with porous electrodeposits. The first such series involved an attempt to simulate a porous specimen, again using a gold-plated copper wire. A No. 47 copper wire (diameter = 0.003 cm) was heavily plated with Temperex HD gold, the final diameter after plating being 0.0089 cm. The plated wire specimen was then perpendicularly sectioned, mounted in the micrometer device, cleaned as outlined previously, and immersed into the electrolyte. The corrosion potential of the plated wire specimen was then determined *vs.* SCE at various depths of immersion in the 0.1M NH_4Cl test electrolyte, and indicated

values of the immersed copper area fraction (obtained from the corrosion potentials by reference to Fig. 3) were compared to the values calculated geometrically from the immersion depths and the known cross-sectional parameters. Pertinent data are shown in Table I.

Agreement between the indicated and calculated values of the immersed copper area fraction was excellent at small values of the area fraction, becoming poorer as the specimen was progressively withdrawn from the electrolyte. Microscopic examination of the specimen at 25X magnification immediately after the experiment revealed that the copper wire substrate had been etched back slightly during the course of the experiment. It is felt that the deviations observed in the final readings may have been due in part to crystallographic changes occurring at the copper surface during etching, or to concentration polarization and diffusion effects arising from partial entrapment of soluble corrosion products within the confines of the gold tubulus thus formed. Additionally, withdrawal of the specimen through the topmost layers of the electrolyte would be expected to introduce differential aeration and other interface effects such as had been experienced in preparation of the calibration curves. Throughout the range investigated, agreement between the indicated and calculated values of A_A was within a factor of two.

The second series of experiments involved measuring the change in corrosion potential occurring when a copper specimen coated with a porous gold electroplate was galvanically coupled, in a solution of 0.1M NH_4Cl, to a large plate of pure gold and then decoupled, so that the exposed area fraction of copper, whatever its value, could be varied by a constant and calculable factor. The specimens employed were small OFHC copper electrical terminals, each of 2.5 cm^2 gross geometric surface area. These were barrel plated in small lots with Temperex HD gold to thicknesses of 100, 200, and 400 μin. (2.54, 5.08, and 10.16μ). In addition, several circular OFHC copper coupons of 25 mm diameter similar to those previously described were rack-plated with Temperex HD gold to a thickness of 50 μin. (1.27μ). These specimens each had a gross geometric surface area of 10.8 cm^2, but again owing to the incidence of rack marks in the area of the punched tab, this area was not immersed in the test electrolyte. The total immersed geometric surface area of each of these specimens was calculated to be 10.2 cm^2.

The gold specimen employed was a rectangular panel of 99.9% purity having a gross geometric surface area of 102.09 cm^2. This was then plated with Temperex HD gold to a thickness of 200 μin. so as to give it a smooth matte surface finish approximately comparable to that of the plated copper test specimens. Cleaning and preparation of this specimen was accomplished as previously indicated.

The experimental procedure was as follows. After cleaning, the gold panel was suspended in the 0.1M NH_4Cl test electrolyte by means of a 99.99% gold wire. Its corrosion potential was then determined *vs.* SCE. Typically, this was in the range +0.200 to +0.215V. The test specimen was then suspended in the electrolyte by means of a 99.99% gold wire and connected shuntwise to the gold panel and the electrometer voltmeter. The corrosion potential of the coupled specimens was then determined, after which the gold panel was decoupled from the specimen and the electrometer, and the corrosion potential of the test specimen alone was determined.

For the plated electrical terminals, coupling to the gold panel produces an increase in gross gold surface area by a factor of approximately 42. Since the exposed area of base copper is unchanged, its effective area fraction is diminished by the same factor. Inspection of Fig. 3 reveals that a change in A_A of this magnitude would yield a change in corrosion potential of approximately 59 mV. For the circular coupons, the change in effective copper area fraction is by a factor of approximately 11. Again from Fig. 3, the change in corrosion potential corresponding to such a change in effective area fraction is approximately 39 mV. The results of this series of experiments are shown in Table II.

In all cases, changes in corrosion potential observed in these experiments are equal to, or quite close to, the predicted values. The effect of increasing thickness of gold plating appears to be negligible in the range investigated, which is taken to indicate that in this range the effects of concentration and resistance polarization are small. Interestingly, the rack-plated coupons of 50 μin. gold thickness show less apparent porosity than the barrel-plated terminals of 200 μin. gold thickness. This is attributed both to the different conditions of plating and to the more complex shape of the barrel-plated terminals, which have significantly greater lengths of edge in relation to their surface areas than do the circular coupons.

The results of these series of experiments are felt to indicate that the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl electrolyte are adequately described by an expression of the form of Eq. [2], and that calibration curves of the type shown in Fig. 2 and 3 can be employed to obtain the apparent basis metal area fraction of such specimens to a reasonable approximation, probably within a factor of two or smaller.

Factors Affecting Corrosion Potentials

The corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl solution are affected both by the *p*H of the electrolyte and by accumulation of cupric ions at concentrations in excess of 4×10^{-6}M. Figure 4 shows the effect of electrolyte *p*H on the corrosion potential of a gold-plated copper specimen in 0.1M NH_4Cl. In this experiment, the corrosion potential of an OFHC copper electrical terminal (area = 2.5 cm^2) plated with 200 μin. of Temperex HD gold was determined *vs.* SCE in a bath of 500 ml of 0.1M NH_4Cl. A 5 ml aliquot of 1.0M HCl was then added to the electrolyte, and the solution back-titrated in small steps with 1.0M NH_4OH. Solution *p*H was monitored using an Instrumentation Laboratory, Inc. Model 175 *p*H meter. The effect of electrolyte *p*H on the corrosion potentials of gold-plated copper specimens in this system is of the order of 10 mV per *p*H unit, which is relatively small.

The effect of cupric ion accumulation on the corrosion potential of a gold-plated copper specimen in 0.1M NH_4Cl solution is shown in Fig. 5. In this experiment,

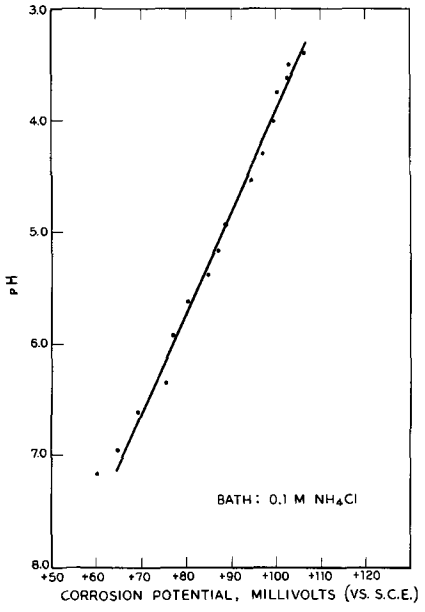

Fig. 4. Effect of electrolyte pH on corrosion potential

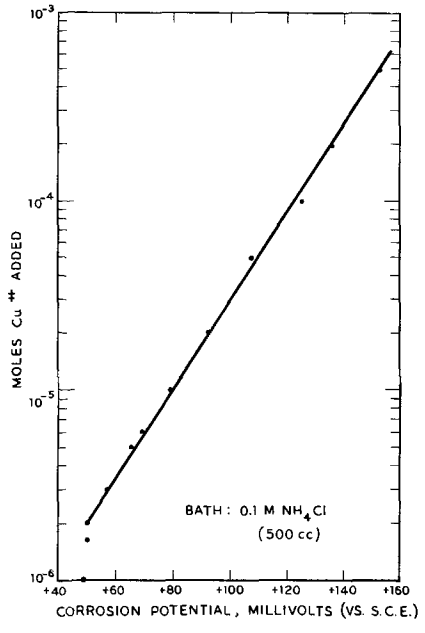

Fig. 5. Effect of cupric ion accumulation on corrosion potential

the corrosion potential of a circular OFHC copper coupon (area = 10.8 cm^2) plated with 100 μin. of Temperex HD gold was determined *vs.* SCE in a bath of 500 ml of 0.1M NH_4Cl. The bath was then titrated in small increments with 0.1M $CuCl_2$. No effect on the corrosion potential was noted until the indicated cupric ion concentration exceeded 4 x 10^{-6}M, after which the corrosion potential was observed to shift in a positive direction by approximately 43 mV per order of magnitude of cupric ion concentration. Due to the very limited solubility of cuprous salts in water, titrations involving cuprous ion were not attempted.

Provided that the electrolyte is changed at reasonable intervals, there would appear to be little danger of erroneous corrosion potential readings due to cupric ion accumulation in the bath. Assuming an exposed copper surface area of 10^{-5} cm^2 per test specimen and a steady corrosion current density of 1 mA/cm^2 of exposed copper (a value obtained from polarization resistance determinations in this electrolyte), it can be calculated that testing of several thousand specimens for periods of 1 hr each would be required to raise the cupric ion concentration of one liter of 0.1M NH_4Cl from zero to 10^{-6}M.

Parallel experiments were conducted in which the corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl electrolyte were monitored during titration of the electrolyte with solutions of 0.01M $NiCl_2$ and 0.01M $ZnCl_2$. No effect on the corrosion potentials was observed. It is conceivable that under proper conditions such a system might be calibrated to serve as a specific-ion electrode for cations of the basis metal.

Discussion

The corrosion potential technique represents a particularly simple means for determining electroplate porosities, and it would seem likely that with a suitable choice of electrolyte the method should prove applicable to a fairly wide variety of noble metal electroplates on base metal substrates. Less obviously, perhaps, inspection of Fig. 2 and 3 reveals that the sensitivity ($\Delta V_{corr}/\Delta A_A$) of the technique increases as A_A decreases. As far as is known, this feature is unique, and it would appear that for gold electroplates of low porosity on copper the method represents the most sensitive liquid-phase test technique yet devised. With a proper choice of the test electrolyte, the method is relatively nondestructive. From polarization resistance measurements, the corrosion current densities of gold-plated copper specimens in 0.1M NH_4Cl electrolyte are calculated to be of the order of 1 mA/cm^2 of exposed copper.

Limitations in applicability of the method as a porosity test are encountered at both large and small values of A_A. Regarding the upper limit, it was shown previously that in preparing the calibration curves of Fig. 2 and 3, deviations from linearity were observed at values of A_A larger than about 10^{-2}. The value of A_A at which deviations from linearity are first noted in the calibration curve represents the upper limit of A_A for which the approximate expression [2] is applicable to the system under investigation. At values of A_A larger than this, the method fails rapidly. A plot of corrosion potential *vs.* A_A yields, according to the general expression [1], an S-shaped trace, the center of which, in the systems examined in this work, is found experimentally to be quite flat. Thus, for gold-copper couples in 0.1M NH_4Cl solution, variation of A_A in the range of 5-95% or so is accompanied by only a negligibly small change in the corrosion potential, and in this range the method fails entirely.

In the lower limit, it has been shown by previous authors (13, 14) that liquid reagents often do not penetrate very fine or very deep pores in electrodeposits. This effect represents a limitation in detectability inherent in any porosity test method employing a liquid phase. The addition of a surfactant to the test electrolyte might serve to alleviate this effect somewhat, although Clarke and Britton (14) reported no significant improvement in pore penetration in similar experiments employing a surfactant.

Specific experiments have not been performed in this work to determine the effect of dissolved oxygen on the corrosion potentials of gold-copper couples. In the bulk solution, one might infer from the results of Fig. 4 that the magnitude of this effect would probably be rather small. In the topmost layers of the electrolyte, however, and particularly at the meniscus, the situation is complicated by the possibility of oxygen and other interface effects occurring simultaneously. It was mentioned previously that with certain refinements in specimen preparation techniques it is possible to avoid these latter effects in establishing calibration curves, and this was done in the preparation of Fig. 3.

Finally, it is noted that the time required after immersion of a plated specimen until a steady corrosion potential is achieved varies with the apparent porosity of the electroplate and with the chemical reactivity of the electrolyte employed. In 0.1M NH_4Cl solution,

equilibration times are of the order of 10-100 min, being generally greatest for specimens of lowest apparent porosity. The use of a more aggressive electrolyte, such as a solution of 0.05M H_2SO_4 + 0.1M NaCl, reduces equilibration times to the order of 1-2 min. This latter electrolyte has been found suitable for porosity determinations in gold electroplates on nickel as well as on copper, but the corrosion rates of the plated specimens are rather high. It has been pointed out in review that the addition of a surfactant to the test electrolyte might affect a significant reduction in equilibration times. Further work in these areas is indicated.

Summary

A method is presented for the determination of electroplate porosity by measuring the corrosion potential of the plated specimen *vs.* a suitable reference electrode in an electrolyte which serves as a mild corrodant to the exposed basis metal. It is shown that for gold-plated copper specimens in 0.1M NH_4Cl electrolyte the corrosion potential varies with the exposed area fraction of copper according to an expression derived by Stern. It is possible to calibrate the technique so that the exposed basis metal area fractions of plated specimens can be estimated to a reasonable approximation. Porosity values obtained from corrosion potential determinations are in fairly good agreement with those obtained using a chemical etch technique described by Frant.

The corrosion potential technique offers the advantages of great simplicity and very high sensitivity, particularly at low porosities. The corrosion potentials of gold-plated copper specimens in 0.1M NH_4Cl electrolyte are affected by the pH of the electrolyte and by accumulation of cupric ions at concentrations in excess of 4×10^{-6}M. In common with other liquid-phase porosity test techniques, a limitation in detectability is imposed by the ability of the electrolyte to penetrate very fine or very deep pores.

An Interrupter Technique for Measuring the Uncompensated Resistance of Electrode Reactions under Potentiostatic Control

J. D. E. McIntyre* and W. F. Peck, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A simple interrupter technique is described which permits the uncompensated resistance, R_u, in an electrochemical cell to be measured while the test electrode is under potentiostatic control. The ohmic potential drop, IR_u, can be monitored continuously as a function of the cell current, I, the d-c bias potential, and/or time.

In studies of the kinetics of electrode processes by modern potentiostatic techniques, a loss of control of the electrode potential can result from the ohmic potential drop associated with the flow of cell current, I, through the "uncompensated resistance" of the system (1). This uncompensated resistance, R_u, consists of the resistance of the electrolyte between the working electrode and the equipotential surface in the solution at which the Luggin capillary tip of the reference electrode is situated. It includes as well the resistance of the electrode itself and that of the lead connecting it to the potentiostat.

In measurements made with a constant or slowly varying d-c bias potential, the ohmic potential drop, IR_u, produces a distortion of the steady-state current-voltage (I-E) curves which, if uncorrected, will yield erroneous values of the characteristic kinetic parameters of the electrode reaction. The effects are even more serious for transient techniques such as rapid linear-scan or cyclic voltammetry since the I-E curves

* Electrochemical Society Active Member.

are further distorted by alteration of the voltage scan rate. In a-c measurements, the series combination of R_u and the double-layer capacity, C_{dl}, produces a phase shift between the actual electrode potential and the applied modulating voltage.

Several methods have been devised to correct for these undesirable effects. These include: (*i*) direct measurement of R_u by a-c bridge (2) or potential- or current-pulse techniques (3, 4) and subsequent correction of steady-state *I-E* curves; (*ii*) direct compensation by use of a resistance-bridge (5) or phase-reverter (6) circuits; (*iii*) direct compensation by means of positive feedback circuits (7-11); (*iv*) correction via electronic simulation and subtraction (12). The a-c bridge method is very accurate and properly takes into account the effects of shielding by the reference electrode probe; it is somewhat inconvenient to use. Positive feedback circuits automatically compensate for the ohmic potential drop, regardless of the magnitude of the current passed through the cell. The correct feedback setting can only be made, however, when there is negligible current flow through the cell. If the current distribution is nonuniform or varies with applied potential, the compensation is then only approximately correct. This method also fails when R_u changes with time as is the case for the dropping mercury electrode (DME). Further difficulties arise when cells with appreciable stray capacitance to ground are employed. In this case the additional phase shift can cause the potentiostat to burst into oscillation at a degree of positive feedback well below that required to compensate properly for R_u. For certain types of cells, overcompensation is possible (13).

Interrupter techniques, although widely used in the past to measure resistive overpotentials in galvanostatic experiments (14), have not been commonly employed for measurements on electrodes under potentiostatic control. For solid electrodes, they offer the possibility of measuring R_u and the ohmic potential drop directly as a function of applied potential. Changes in R_u can be ascribed to a variation of the current distribution on the surface or to the formation or removal of a surface film. In polarography, the variation in R_u can be detected as the mercury drop grows with time. When positive feedback circuitry is employed, the interrupter provides a convenient check on the degree of feedback required to compensate the ohmic potential drop correctly. In the present communication we describe the use of a simple potentiostatic interrupter technique which monitors IR_u continuously during the recording of a steady-state *I-E* curve.

Potentiostatic Interrupter Circuit

Figure 1 illustrates the circuit employed to interrupt the cell current momentarily. This circuit is a simple adaptation of a novel high-speed electronic switch devised by Warner and Schuldiner (15) to change from potentiostatic to galvanostatic control. In the present modification, the cell current is momentarily interrupted by applying a pulse of a few microseconds duration to the potentiostat input. The sign and magnitude of this pulse are such that the output of the control amplifier is driven to a voltage level sufficient to reverse-bias the diode, D1, connected in series with the counterelectrode. When the diode becomes nonconducting, the cell is isolated from the potentiostat control amplifier and is effectively "open-circuited." The voltage follower, *V*, detects the instantaneous change in potential, ΔE, caused by the removal of the ohmic potential drop, IR_u. This instantaneous change is followed by a much slower decay due to the discharge of C_{dl} through the Faradaic impedance of the electrode reaction. Knowing the cell current, *I*, and the potential change, ΔE, corresponding to the applied d-c bias potential, the value of R_u can be determined as a function of potential and/or time.

At the end of the pulse, diode D1 is restored to a conducting state, current flows again through the cell,

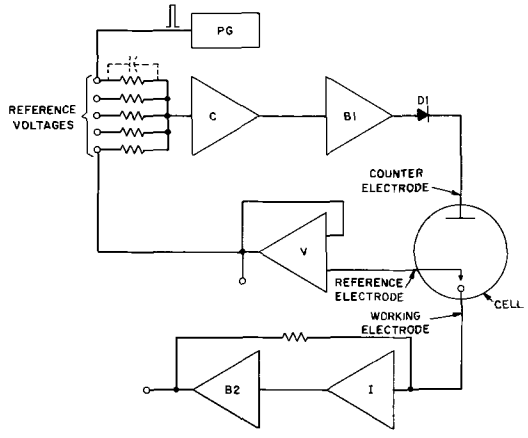

Fig. 1. Electrochemical cell and potentiostat with interrupter: C,I, Philbrick P45A operational amplifiers; V, Philbrick P25 operational amplifier; B1,B2, Booster amplifiers; D1, Western Electric 458A diode; PG, Tektronix Type 114 pulse generator.

and the potentiostat regains control. If the voltage pulse is sufficiently short, the decay of the electrode potential within its duration is very small, and the steady-state conditions of the reaction are not perturbed.

Faster "switch-off" times can be obtained by injecting a voltage pulse directly at the input of the booster amplifier, B1, as shown in Fig. 2. Amplifiers B1 and B2 consist of complementary pairs of npn and pnp transistors connected in a common emitter configuration (16) illustrated in Fig. 3. With this method, the pulse

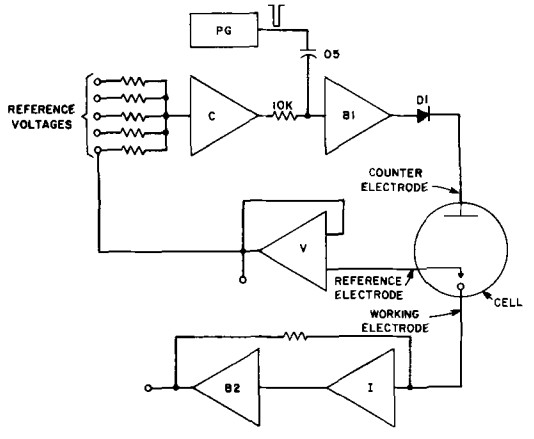

Fig. 2. Electrochemical cell and potentiostat with interrupter. Components are the same as in Fig. 1. Injection of pulse at input of B1 gives faster switch-off and recovery times.

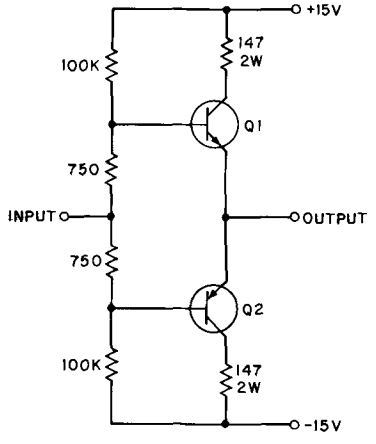

Fig. 3. Transistor booster amplifier: Q1, Western Electric 30A (npn); Q2, Western Electric 31A (pnp).

used must be larger and of polarity opposite to that employed with the circuit of Fig. 1. The pulse generator is isolated from the output of operational amplifier C by a blocking capacitor and series resistor.

The principal advantage of the second method is that the "switch-off" time is not dependent on the rise time of the summing amplifier. During the voltage pulse, the output voltage of "off-balance" amplifier C rises in an attempt to restore current through the cell. The output voltage of C thus remains positive and sufficiently high to restore D1 to its forward-biased state instantaneously when the pulse is removed. The potentiostat "recovery" time is thus shortened.

Anodic currents can be interrupted by a simple reversal of the diode and pulse-voltage polarity. The performance of the circuit of Fig. 2 is discussed below.

Circuit performance.—Figure 4 illustrates a network which simulates impedances found in a working electrochemical cell. Figure 5 shows the form of the potential relaxation observed at the output of voltage follower V when, with $R_u = 20$ ohms, a "cathodic" d-c current of 10.0 mA flowing through this circuit is interrupted by applying to the input of B1 a negative-going pulse of *ca.* −5V amplitude and 5 μsec duration. The initial rapid fall in potential represents the switch-off time of the system, *ca.* 0.2 μsec. The bottom flat section of the waveform represents the potential at point Y (Fig. 4), which decays with a time constant of 400 μsec. At the end of the pulse, the voltage at X rises rapidly, overshooting its initial value, and then decays back to its steady-state level. By substituting for R_u a series of standard resistors ranging from 1 to 100 ohms, it was ascertained that the value of the uncompensated resistance could be determined by this method with an accuracy of ~1%. To achieve this accuracy, the pulse repetition frequency must be low enough to allow amplifier ringing to decay completely after each pulse is applied.

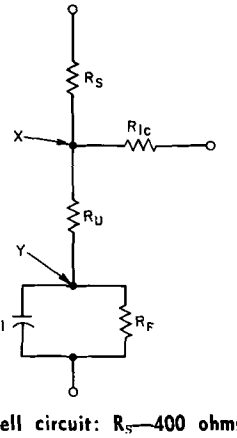

Fig. 4. Equivalent cell circuit: R_s—400 ohms; R_{lc}—20 kohms; C_{dl}—4 μF; R_F—100 ohms.

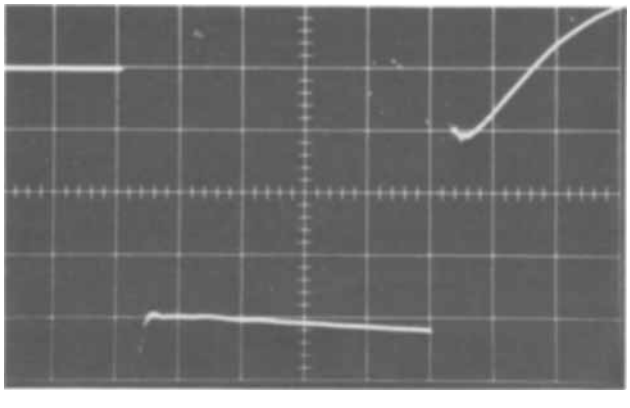

Fig. 5. Potential-relaxation waveform for equivalent cell circuit: I—10.0 mA, R_u—20.0 ohms; Y-axis, 50 mV/div; X-axis—1 μsec/div.

Figure 6 shows the form of the potential-relaxation waveform observed with an actual electrochemical cell. The working electrode was a gold rotating-disk electrode (RDE) of 0.32 cm^2 area immersed in oxygen-saturated 0.1*N* KOH. The platinum counterelectrode was isolated in a separate compartment by a fritted-glass disk, while the Hg/HgO reference electrode was isolated by a Teflon stop-cock. To avoid disturbance of the hydrodynamic streamlines at the RDE, the tip of the Luggin capillary was positioned *ca.* 0.75 cm below its surface. With the bias potential and rotational speed adjusted to give a limiting current of 1.00 mA, the value of the uncompensated resistance in this cell was found to be 17 ohms.

Although the design of this cell is far from optimal for rapid transient measurements, the switch-off time of this system is only 0.2 μsec. Best results are obtained by minimizing the length and capacitance of the shielded coaxial cable connecting the reference electrode to the voltage-follower input of the potentiostat. The effects of cable capacitance can be reduced by using a guard circuit to hold the shield at the same potential as the inner conductor, *i.e.*, at the reference electrode potential. This is conveniently accomplished by using a BNC connector with an isolated "ground" terminal (Dage Electric Co., Inc., Franklin, Ind., Model No. 4890-1) driven by the voltage-follower output. A significant reduction in recovery time and increased electronic stability was obtained by use of an auxiliary platinum-wire counterelectrode, positioned within a few centimeters of the working electrode and a.c.-coupled through a capacitor to the potentiostat output. This electrode affords a low-impedance by-pass path for transient currents and reduces the over-all time constant of the system. The response time of the system is the same regardless of whether or not the current follower is used. To avoid attenuation of the waveform amplitude, the resistance of the reference electrode probe arm should be made as small as possible. Luggin capillaries with closed isolating stop-cocks tend to act as low-pass filters for electrical signals.

No effect of the current interruption is observable in the recordings of the steady-state *I-E* curves measured with an RDE if the pulses are short and the time interval between pulses is longer than the sum of the pulse duration and the recovery time. Pulse durations of 5-10 μsec and a pulse repetition frequency of 0.1-1 kHz are generally suitable. The method can be used in a single-shot mode if a storage oscilloscope is employed.

The value of IR_u can also be monitored continuously as the direct current is altered. In Fig. 7, the vertical distance between the two traces represents the value of IR_u in the electrochemical cell; distance along the horizontal axis corresponds to the cathodic direct current flowing through this network. The diagonal trace in this photograph was formed by repeatedly interrupting the direct current as the latter was slowly

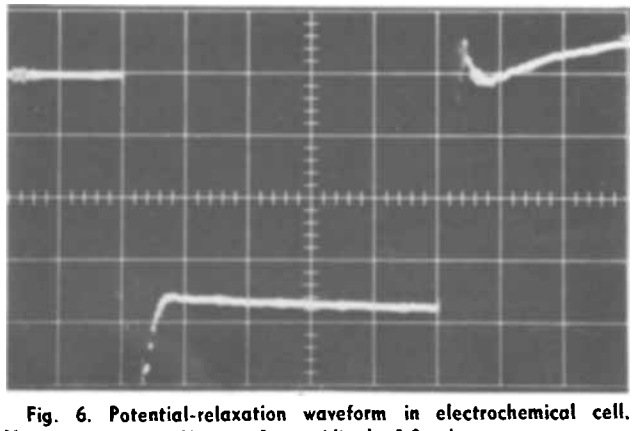

Fig. 6. Potential-relaxation waveform in electrochemical cell. Y-axis—5 mV/div; X-axis—1 μsec/div. I—1.0 mA.

varied from 0 to 1 mA. The oscilloscope beam intensity was simultaneously enhanced for the duration of each current interruption. Only the "flat" sections of the voltage pulses at the output of follower V exhibit sufficient intensity on the oscilloscope screen to register on the film. The slow variation in the d-c electrode potential is not recorded if the oscilloscope is a.c.-coupled to the output of V. A convenient horizontal reference trace is then obtained as shown in Fig. 7. At low current levels ($\sim$100 μA), the forward-biased diode resistance is too high for the potentiostat to maintain proper control and oscillation occurs. The instability of the potentiostat at low currents precludes the use of this technique at present for monitoring R_u in polarographic studies.

Discussion

The potentiostatic interrupter technique described in the preceding sections is particularly useful in studies of the kinetics of electrode reactions by the RDE method. Relatively high current densities can be attained with this method at high disk angular velocities. Since it is not desirable to position the reference electrode probe close to the surface of the RDE, ohmic potential drops can easily amount to 50-100 mV in solutions of moderately good conductivity (*e.g.*, 0.1M). The distortion of the steady-state I-E curves can readily be removed by analog simulation (12) or when the experimental data are subjected to computer analysis.

When appreciable overpotentials exist at the electrode surface due to activation or concentration polarization, the current distribution differs significantly from the primary distribution determined by the spreading resistance of the electrode (16). The equipotential contours in the electrolyte close to the electrode surface are distorted to force a higher current flow to the center of the disk. For electrode potentials in the limiting current region, the current distribution on the disk is uniform. The potential at the disk center is then 27% higher than the uniform surface potential associated with the primary current distribution, while the potential at the disk periphery is 18% lower. An intermediate situation exists when there is appreciable activation polarization. The possibility arises, therefore, of detecting a nonuniform current distribution by means of the potentiostatic interrupter technique.

In an experimental test, the value of R_u was measured at the quarter, half, and three-quarter wave points and in the limiting-current region of the steady-state I-E curve for oxygen reduction on a gold RDE. The probe tip was positioned 0.75 cm below the RDE surface. The value of R_u was observed to be constant over the entire I-E curve within the experimental precision of the measurements (*ca.* 2%). This apparent constancy of R_u is shown by the linearity of the diagonal trace of Fig. 7, which was obtained by continuously monitoring the values of IR_u and I as the potential was scanned through the wave.

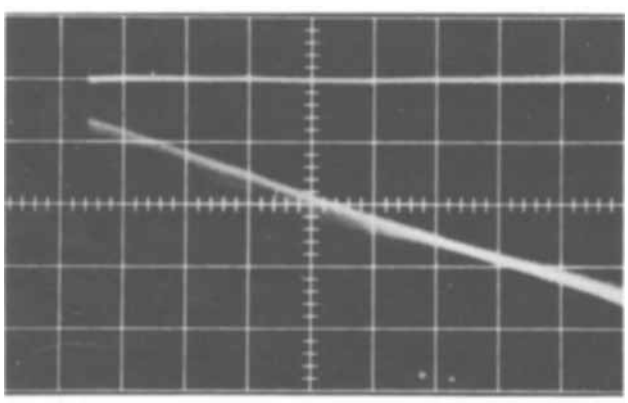

Fig. 7. Variation of ohmic potential drop in electrochemical cell with current. Y-axis—5 mV/div; X-axis—0.1 mA/div.

The observed constancy of R_u in the above experiment cannot, however, be taken as evidence of a uniform current distribution throughout the entire I-E curve. For the two extreme cases of the primary current distribution (uniform potential in the solution at the outer boundary of the diffusion layer) and the limiting-current distribution (uniform current density on the disk), significant differences in the measured ohmic potential drop to the center of the disk can only be detected when the probe tip is located at a distance within *ca.* 0.5 r_o of the disk surface, where r_o is the radius of the disk (17, 18). For the 0.25 in. diameter electrode employed, this would necessitate placing the probe tip at a distance less than 1.5 mm below the disk. This separation is independent of the electrolyte conductivity and so small as to cause distortion of the hydrodynamic and electrical current streamlines by geometric screening. Further, instability of the control system is likely to result when R_u becomes very small (19). In order to detect nonuniform current distribution on an RDE by this method, use of a large diameter disk ($r_o \geq 0.5$ in.) is indicated.

A second phenomenon will prevent detection of any alteration in R_u, however. Newman (20) has pointed out that if the potential across the surface is not uniform, the double-layer capacity is nonuniformly charged. When the direct current is interrupted, a transient current flows through the electrolyte from one section of the disk to another until the surface potential and charge become uniform. The relaxation time for this process is

$$\tau = r_o C/\kappa$$

where C is the specific double-layer capacity and κ is the specific conductivity of the electrolyte. With $r_o = 0.125$ in., $C \approx 20$ F cm^{-2} and κ (0.1N KOH) $= 0.024$ ohm^{-1} cm^{-1}, we have $\tau \approx 0.3$ msec, a time much longer than the duration of the interrupter pulse. As a result, the initial potential drop corresponds to the value of R_u associated with the primary current distribution, regardless of the actual current distribution on the disk before interruption. It is also this value of R_u which is measured by rapid pulse and high-frequency a-c methods as well as by positive feedback circuitry. The interrupter technique offers certain advantages over pulse or sinusoidal a-c methods since the latter require an accurate measurement of the transient current and are sensitive to the value of C_{dl} and the rise times of the pulse generator and potentiostat. The interrupter technique is not sensitive to these factors and requires only an accurate measurement of the d-c cell current.

Very brief current interruption times must be employed if perturbation of fast electrode reactions is to be avoided. With fast-rise potentiostats, amplifier ringing persists for 1 μsec or less. Interruption times of 5-10 μsec are then of sufficient length to permit the ohmic potential drop to be determined. The shorter the interruption time, the more rapid is the recovery of the potentiostat. Perturbation times associated with the voltage and current pulse methods are in general considerably longer. Interrupter measurements can only be made, of course, when there is an appreciable direct current flowing through the cell. This procedure should also be useful for potentiostats having relatively slow response times.

ABSTRACT

The temperature dependence of the electrolytic hydrogen-deuterium separation factor, S_D, was studied on bright platinum bead electrodes as a function of overpotential in 1.2*N* HCl-10% D_2O over the temperature range of 2°-80°C. As expected, S_D decreased with increasing temperature at a given overpotential. At each temperature, S_D increased as the overpotential corrected for *IR*-drop, η_{corr}, increased from $|-25$ mV$|$ to about $|-300$ mV$|$; from -300 mV to about -500 mV, the experimental limit, (which corresponds to $\eta_{appl} = 1.2$V) S_D remained constant within the ±5% reproducibility of the measurements. This behavior is attributed to a possible change in the mechanism of the hydrogen evolution reaction as $|\eta|$ is increased. The temperature coefficient of S_D is independent of η_{corr} within the experimental error. The Arrhenius activation energy difference between the hydrogen-deuterium and the hydrogen producing reactions, ΔE_A, is positive; ΔE_A decreases as $|\eta_{corr}|$ increases, but reaches a plateau value for $\eta_{corr} \geq |-300$ mV$|$. Conversely, the Arrhenius pre-exponential factor ratio, A_{H_2}/A_{HD}, increases over the same range of overpotentials before reaching a plateau value for $\eta_{corr} \geq |-300$ mV$|$. Comparison with published work is made.

The electrolytic hydrogen-deuterium separation factor, S_D, is defined as the atomic ratio of hydrogen to deuterium in the evolved gas divided by the atomic ratio of hydrogen to deuterium in the electrolyte. S_D has been studied as a function of temperature by several workers (1-5) on different cathode metals and in different electrolytes, usually with the aim of elucidating the mechanism of the much studied hydrogen evolution reaction. These studies were all carried out using constant current.

More recently, some workers have investigated the electrolytic hydrogen-deuterium separation factor as a function of the overpotential (6-10). As previously reported (11) we have studied S_D on bright platinum bead electrodes in 1.2*N* HCl-10% D_2O electrolyte as a function of the applied as well as the corrected overpotential, the latter quantity being equal to the applied overpotential minus the ohmic potential drop (henceforth called the *IR*-drop) due to the electrolyte resistance between the tip of the Luggin capillary and the cathode. It was clearly demonstrated that S_D is a function of the corrected overpotential under carefully controlled experimental conditions.

The present work was undertaken to determine if the temperature dependence of S_D was a function of the corrected overpotential, and to see if the Arrhenius activation energy difference for the H_2 and HD producing reactions was comparable to the theoretical maximum predicted by Rowland (1) on the basis of free atom reactions. It was also hoped that the Arrhenius pre-exponential factor ratio would possibly indicate the presence or absence of proton tunneling (12-15).

The Arrhenius factors may be evaluated from a temperature study of S_D as follows. In relatively dilute deuterium solutions (up to about 10% D_2O) the main species which undergo reduction in 1.2*N* HCl are H_3O^+ and H_2DO^+, and the main products are H_2 and HD. On this basis, Conway and Salomon (16, 17) have shown that

$$S_D = \left(\frac{D}{H}\right)_s \cdot 2\frac{[H_3O^+]}{[H_2DO^+]} \cdot \frac{f_{H_2DO^+}}{f_{H_3O^+}} \cdot \frac{f_{H_2}^{\dagger}}{f_{HD}^{\dagger}} \quad [1]$$

for the slow atomic hydrogen recombination or cata-

Key words: hydrogen, deuterium, separation factor, isotope separation, effect of temperature on, electrolysis, water, heavy water.

lytic mechanism (16) *viz.*

$$\left.\begin{aligned} &M-H+M-H \rightarrow H_2 \\ &M-H+M-D \rightarrow HD \end{aligned}\right\} \quad [2]$$

where M denotes the metal adsorption site for H or D and

$$S_D = \left(\frac{D}{H}\right)_s \cdot \frac{[H_3O^+]}{[H_2DO^+]} \cdot \frac{f_{H_2DO^+}}{f_{H_3O^+}} \cdot \frac{f_{H_2}^{\dagger}}{f_{HD}^{\dagger}} \quad [3]$$

for the slow atom-ion or electrochemical mechanism (16) *viz.*

$$\left.\begin{aligned} &M-H+H_3O^+ + e \rightarrow M + H_2O + H_2 \\ &M-D+H_3O^+ + e \rightarrow M + H_2O + DH \\ &M-H+H_2DO^+ + e \rightarrow M + H_2O + HD \end{aligned}\right\} \quad [4]$$

and for the slow proton discharge mechanism (17) *viz.*

$$\left.\begin{aligned} &M + H_3O^+ + e \rightarrow MH + H_2O \\ &M + H_2DO^+ + e \rightarrow MD + H_2O \end{aligned}\right\} \quad [5]$$

In Eq. [1] and [3], $(D/H)_s$ is the atom ratio of deuterium to hydrogen in the bulk solution (1.111 for 10% by volume D_2O), $[H_3O^+]/[H_2DO^+]$ is the concentration ratio of the H_3O^+ and H_2DO^+ ions in the solution, and the f-terms represent the appropriate partition functions of the indicated species, *e.g.*, $f_{H_2}^{\dagger}$ is the partition function for the activated complex leading to H_2 production. Since

$$k_{H_2}/k_{HD} = f_{H_2DO^+} f_{H_2}^{\dagger}/f_{H_3O^+} f_{HD}^{\dagger} \quad [6]$$

then Eq. [1] and [3] become

$$S_D = \left(\frac{D}{H}\right)_s 2\frac{[H_3O^+]}{[H_2DO^+]}\frac{k_{H_2}}{k_{HD}} \quad [7]$$

and

$$S_D = \left(\frac{D}{H}\right)_s \frac{[H_3O^+]}{[H_2DO^+]}\frac{k_{H_2}}{k_{HD}} \quad [8]$$

respectively; k_{H_2} and k_{HD} are the electrochemical rate constants for the H_2 and HD producing reactions respectively. Equations [7] and [8] can further be simplified, since

$$\left(\frac{D}{H}\right)_s = \frac{[HDO]}{2[H_2O] + [HDO]} \doteqdot \frac{[HDO]}{2[H_2O]} \quad [9]$$

i.e., $2[H_2O] >> [HDO]$. Therefore

$$S_D \doteqdot K_b\, k_{H_2}/k_{HD} \quad [10]$$

for the slow atomic hydrogen recombination mechanism, and

$$S_D \doteqdot K_b\, k_{H_2}/2\, k_{HD} \quad [11]$$

for the slow atom-ion and the slow proton discharge mechanisms, where K_b is the equilibrium constant for the reaction

$$H_2O + H_2DO^+ \rightleftharpoons HDO + H_3O^+ \quad [12]$$

i.e.

$$K_b = f_{HDO}\, f_{H_3O^+}/f_{H_2O}\, f_{H_2DO^+} \quad [13]$$

K_b can be evaluated from the partition function ratios as will be shown later, and therefore k_{H_2}/k_{HD} may be calculated once S_D has been measured. Using the well-known Arrhenius equation for the rate constant we obtain

$$\log_{10}\frac{k_{H_2}}{k_{HD}} = \log_{10}\frac{A_{H_2}}{A_{HD}} + \frac{\Delta E_A}{2.3\,RT} \quad [14]$$

after taking logarithms to the base 10. In Eq. [14], A_{H_2} and A_{HD} are the Arrhenius pre-exponential factors for the H_2 and HD producing reactions, respectively. The Arrhenius activation energy difference, ΔE_A, is defined as

$$\Delta E = E_A^{HD} - E_A^{H_2} \quad [15]$$

where E_A^{HD} and $E_A^{H_2}$ are the Arrhenius activation energies for the HD and H_2 producing reactions respectively. R and T have their usual significance. Both A_{H_2}/A_{HD} and ΔE_A are readily evaluated from a plot of $\log_{10}(k_{H_2}/k_{HD})$ *vs.* T^{-1} in the usual manner.

Experimental

The cell.—The cell and its operation for separation factor measurements have been described in detail in a previous paper (11). The following changes in the procedures reported there were made:

All data were obtained using the hydrogen reference electrode situated about 20 cm from the cathode and the smooth platinum bead cathodes described in (11). The reference electrode was effectively placed 1 mm from the cathode by means of a Luggin capillary. The pretreatment of the cathodes (geometric surface area $\simeq$0.06 cm^2) was changed for some experiments by eliminating the extraction of the cathode with warm electrolyte overnight in a Soxhelet extractor. For these experiments, the cathodes were placed in the cell as soon as possible after the hydrogen reduction step. No change in the reproducibility of the results was noted. On the contrary, the number of runs which produced spurious results decreased significantly to the point where only about one in twenty experiments had to be abandoned.

The second change involved the hydrogen reduction step of the cathode pretreatment. Instead of evacuating the oven before the cathode was allowed to cool to room temperature, the hydrogen atmosphere was maintained in the oven while the cathode cooled. In order to remove any hydrogen sorbed on the cathode, the assembly was evacuated for several hours to 10^{-6} mm Hg. This change did not affect the reproducibility or the absolute value of S_D measurements. All other procedures remained as described in (11) for the platinum bead cathodes, including the leaching-distillation pretreatment of the cell.

Anode.—The anode consisted of a strip of platinum gauze, 15 cm long and 4.5 cm wide (Johnson, Matthey and Mallory Unimesh No. Q2050, 48 mesh x 0.006 in.). This strip was wound into a roll, 0.5 cm in diameter and 4.5 cm wide, to which a platinum wire, 0.127 cm in diameter, was fastened at one end.

Chemicals.—The 1.2N HCl-10% D_2O electrolyte was prepared as described previously (11). The specific conductance of this electrolyte was 0.399 ohms^{-1} cm^{-1}.

Potential control.—For most of the results reported here, the applied overpotential, η_{appl}, was controlled by manually adjusting the current supplied by a galvanostat (Northeast Scientific Corporation, Model RI-234) to the cell while monitoring the reference electrode-cathode potential difference on a digital voltmeter (Fairchild, Model 7050). The current density based on the geometric surface area of the cathode varied from about 2 mA cm^{-2} at $\eta_{appl} = -25$ mV to about 3 A cm^{-2} at $\eta_{appl} = -1.0$V.

In practice, electrolysis was allowed to proceed until the current reached a steady state before the evolved hydrogen isotopes were collected for a separation factor measurement. A few minutes were necessary before this steady state was reached; once reached only minor, if any, current adjustments were found necessary to keep the desired applied overpotential constant during an electrolysis which lasted anywhere from 1 to 60 min depending on the applied overpotential. This procedure was found necessary because we have not yet been able to design a satisfactory transistor switch for obtaining IR-drop measurements using a potentiostat for potential control. Furthermore, it became apparent, as will be shown, that IR-drop measurements should accompany S_D measurements. The above procedure together with a transistor switch designed in our laboratory permitted the acquisition of *IR*-drop data immediately after a separation factor

determination. In fact, the electrolysis was terminated with the *IR*-drop meaasurement.

For comparison, however, some results based on potentiostatic control of η_{appl} as outlined previously (11) are included.

Temperature control.—The temperature of the cell was controlled to ±0.1°C by a circulating water bath. To prevent excessive liquid carry-over into the gas collection system during collection of the gas mixture (liberated hydrogen isotopes and argon sweep gas) a water cooled condenser was fitted onto the cathode compartment head. The temperature was monitored during several experiments by means of a platinum-10% rhodium 90% platinum thermocouple, placed about 2 mm from the cathode.

H/D *analyses.*—All gas samples were analyzed in triplicate on a CEC (Consolidated Electrodynamics Corporation) Model 21-130 mass spectrometer with a reproducibility better than ±1% in the H/D ratio.

IR-drop measurement.—To measure the *IR*-drop between the tip of the Luggin capillary and the working electrode a switch with an extremely rapid break time is ideal. The point where the potential decay due to double layer discharge and/or Faradaic discharge begin and where the *IR*-drop ends can then be readily determined. Existing solutions to this type of problem have generally involved mercury-wetted relays that have extremely rapid break times, but whose operate times of about 3-6 msec make it difficult to reduce switch times below 1 msec.

The switch used (Fig. 1) operates on a single pulse or continuous mode with a toggle frequency of about 5 MHz over the current range 0-800 mA and potential range 0-60V. The theoretical frequency response of the switch is 250 MHz which corresponds to a break time of 4 nsec. The practical response was about 200 nsec in the circuit shown schematically in Fig. 1.

Operation of the circuit depends on the fact that one state of the bistable or flip-flop circuit consisting of C_1, C_2, D_1, D_2, and E_3 turns on the transistors, Q_1 and Q_2, and the other state of the bistable circuit turns them off. When the transistors are conducting, the current source is short circuited to ground, but diodes D_3, since they will then be back biased, prevent the cell from also being short circuited. When the transistors are not conducting, current readily flows through the cell because diodes D_3 are then forward biased. In theory, micrologic elements E_1 and E_2 are not required, but in practice were found necessary to drive Q_1 and Q_2 completely to ground. E_1 and E_2 thus serve as buffer elements and ensure that enough current is supplied to Q_1 and Q_2. The micrologic elements are powered by two mercury batteries in series (B_1 and B_2) *i.e.*, by 2.7V. R_1 serves to isolate the bistable from the pulse generator.

The bistable was triggered by a Datapulse Type 101 pulse generator which is particularly suitable because it has a variable delay line built into one output channel. Thus, the Tektronix Type 581 oscilloscope with a Type 1A1 plug-in (rise time = 13 nsec at a sensitivity of 5 mV/division) could be triggered first and the applied overpotential recorded on the first part of the oscillogram before the current to the cell was switched with the delayed pulse to the bistable. The next pulse turns the transistor off and current to the cell is restored.

By operating the switch in the single pulse mode, it was possible to measure the *IR*-drop with a 1 μsec/division sweep rate and to terminate a given electrolysis simultaneously.

Results and Discussion

S_D as a Function of η_{appl} and T.—The main result of our experiments concerning the effect of temperature on the relation between the separation factor, S_D, and η_{appl} on platinum electrodes immersed in 1.2*N* HCl-10% D_2O aqueous electrolyte, is that, as the temperature is increased from 2° to 80°C, the separation factor decreases fairly evenly over the range of applied overpotentials, $|-50\text{ mV}| \leq \eta_{appl} \leq |-1200\text{ mV}|$. Figure 2 shows this effect of temperature on the dependence of S_D on η_{appl} where η_{appl} was controlled potentiostatically (closed symbols), and where η_{appl} was controlled by manually adjusting the current output from a galvanostat (open symbols) as described in the experimental section. Within experimental error both methods produced the same values. The potentiostatic results at 25°C (closed circles) are those reported previously (11). All the results in Fig. 2 are within a ±5% reproducibility range, although the reproducibility was poorest at 2°C, possibly due to a greater influence of impurity sorption effects at the electrode-electrolyte interface. It is also interesting to note that on several occasions considerable dissolution of platinum occurred at the anode at 80°C and when platinum ions were allowed to reach the cathode where they were readily plated out, the separation factor decreased; at the same time the results became much less reproducible. Such results were discarded.

That S_D appears to decrease as $\eta_{appl} \geqq |-500\text{ mV}|$ for the 2° results we believe is due to local heating of the cathode and/or the electrolyte immediately adjacent to it. An increase in the effective temperature

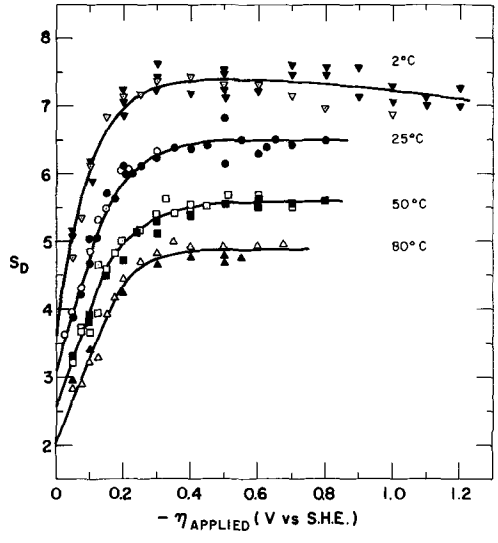

Fig. 2. Temperature dependence of the H/D separation factor as a function of the applied overpotential. Open symbols refer to galvanostatic control of the applied overpotential; closed symbols refer to potentiostatic control of the applied overpotential.

of 7°C can account for the observed drop in S_D from 7.35 at the maximum to 7.05 or about 4%, and in any case is within the limit of the reproducibility of the measurements. Nevertheless, it should be pointed out that a temperature measurement within about 2 mm of the cathode only showed an increase in temperature of a few tenths of a degree over the entire range of η_{appl}.

IR-drop measurements.—A typical oscillograph of the *IR*-drop between the cathode and the Luggin capillary is shown in Fig. 3. The *IR*-drop was measured from the horizontal line at the top, representing η_{appl} just before the anode-cathode circuit was broken, to the lower curve extrapolated back to where the potential difference fell. The small oscillations in the lower line are due to internal reflections in the coaxial lead cables which were kept as short as possible to minimize this effect. A 1 μsec/division sweep rate was used for all *IR*-drop measurements reported here. In this way *IR*-drops were readily measured at the end of an electrolysis to within ±3% for a given electrode in a given aliquot of electrolyte.

The *IR*-drop results are summarized in Fig. 4 in which η_{corr} is plotted as a function of η_{appl}. Because the results at different temperatures correspond to different cathode-Luggin capillary distances (about 1 mm), different cathodes, and different aliquots of electrolyte, some variation in the *IR*-drop would be expected. Evidently this variation is sufficiently large to mask completely the expected decrease in the *IR*-drop with increasing temperature due to an increase in conductivity of the electrolyte. Nevertheless, Fig. 4 clearly shows the importance of the *IR*-drop corrections at $\eta_{appl} \geq |-75\ mV|$ since these corrections approach 50% at $\eta_{appl} = -1000$ mV.

The effect of the *IR*-drop on the reproducibility of the separation factor-overpotential relationship is illustrated in Fig. 5 in which the closed and open triangles represent the applied and corrected overpotentials respectively. The importance of obtaining an *IR*-drop measurement for each specific S_D determination is shown clearly by the points 7 and 8 for example; for both, $\eta_{appl} = -300$ mV but $\eta_{corr} = -200$ mV and -150 mV, respectively. With the appropriate *IR*-drop correction, both S_D values fall on the smooth curve well within the estimated experimental error; as a function of the applied overpotential, they differ by about 7%. Points 1 and 2 further illustrate the advantage of obtaining *IR*-drop measurements coincident with S_D determinations as in this case the order in the magnitudes of the respective overpotentials is reversed when the *IR*-drop corrections are applied.

Although the *IR*-drop correction can be large, its effect on the dependence of S_D on overpotential is relatively small as seen in Fig. 6 (cf. Fig. 2) because S_D reaches a plateau. In Fig. 6 for reasons already stated, the 2°C curve is treated according to the dotted line.

Calculation of K_b.—Before the Arrhenius parameters can be obtained it is necessary to evaluate K_b (see Eq. [13] and *cf.* Eq. [10], [11], and [14]) as follows:

By applying the rule of the geometric mean (18) it can be shown that

$$f_{H_2DO^+}/f_{H_3O^+} = 3(f_{D_3O^+}/f_{H_3O^+})^{1/3} \qquad [16]$$

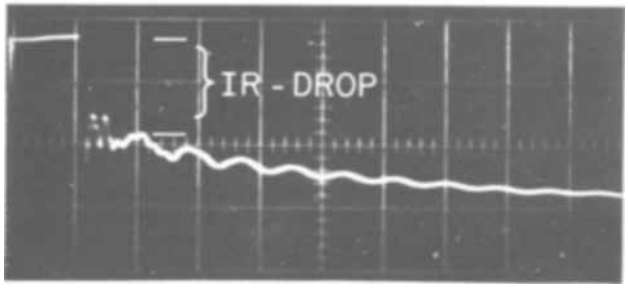

Fig. 3. Oscillograph of IR-drop for $\eta_{appl} = -680$ mV using the galvanostat; *IR*-drop = 300 mV and $\eta_{corr} = -380$ mV; ordinate = 200 mV/division; abscissa = 1 μsec/division.

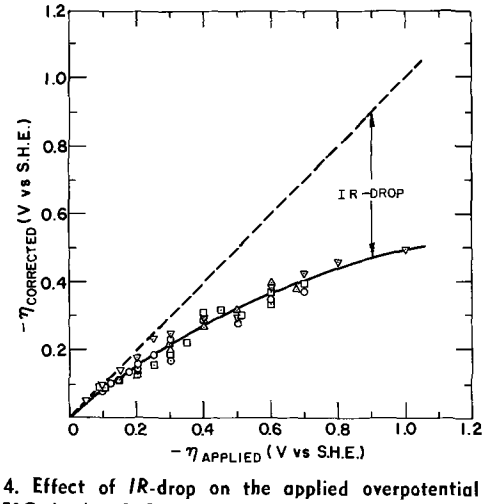

Fig. 4. Effect of *IR*-drop on the applied overpotential at 2°C (▽), 25°C (○), 50°C (□), and 80°C (△), respectively; ----, slope = 1.

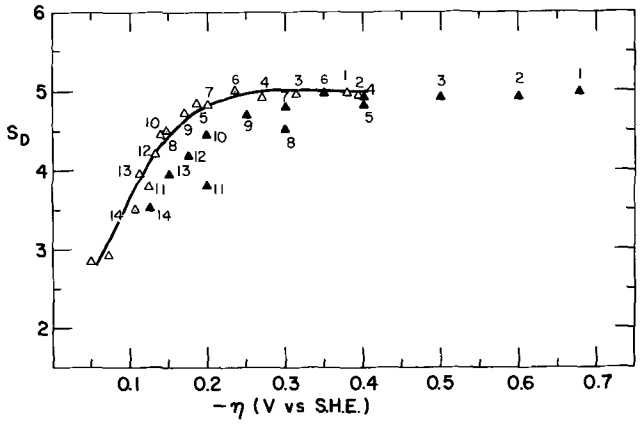

Fig. 5. Effect of *IR*-drop on the reproducibility of the H/D separation factor-overpotential relationship for 80°C. △, corrected for IR-drop; ▲, not corrected for IR-drop. Corresponding pairs of points have the same number.

Calculation of K_b (see Eq. [13] and *cf.* Eq. [10], [11], and [14]) as follows:

By applying the rule of the geometric mean (18) it can be shown that

$$f_{H_2DO^+}/f_{H_3O^+} = 3(f_{D_3O^+}/f_{H_3O^+})^{1/3} \qquad [16]$$

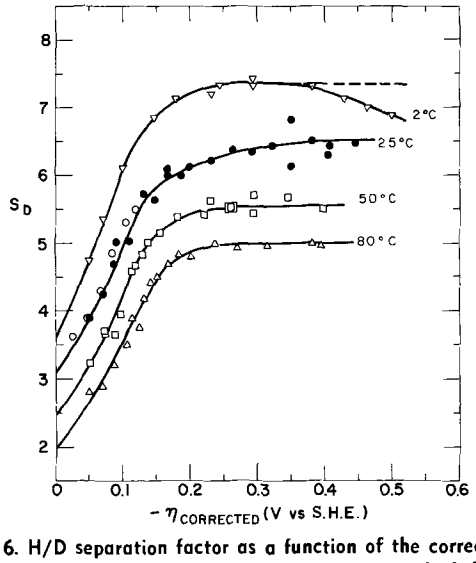

Fig. 6. H/D separation factor as a function of the corrected overpotential. Open symbols refer to galvanostatic control of the applied overpotential; closed symbols refer to potentiostatic control of the applied overpotential.

McIntyre and Salomon (19) have calculated f_{D3O+}/f_{H3O+} as well as f_{D2O}/f_{H2O} for the liquid phase as a function of temperature. Now consider the equilibrium

$$D_2O + H_2O \rightleftharpoons 2HDO \qquad [17]$$

for which the equilibrium constant for the liquid phase, K_w, is

$$K_w = f^2_{HDO}/f_{H2O}f_{D2O} \qquad [18]$$

so that

$$f_{HDO}/f_{H2O} = (K_w f_{D2O}/f_{H2O})^{1/2} \qquad [19]$$

K_w has recently been measured (20, 21) as a function of temperature. We have used $K_w = 3.76$ over our temperature range (2°-80°C) since the temperature dependence of K_w was found to be within the experimental error of the measurements (20). The values of K_b at 2° and 80°C were obtained by interpolating and extrapolating McIntyre and Salomon's data (19) for the temperature range 0°-75°C, respectively. The data are summarized in Table I.

Arrhenius parameters.—The Arrhenius plot for the activation energy difference between the hydrogen and the hydrogen-deuterium producing reactions[1] is shown in Fig. 7 as a function of the overpotential. Although the estimated errors are large (about ±10% for $\eta = 0$ and ±8% for the others) they are not shown in the interest of clarity. From the graph, it is obvious (*a*) that the positive slope, corresponding to a positive activation energy difference, becomes smaller as the cathodic overpotential increases and (*b*) that for $\eta_{corr} \geq |-300$ mV|, this difference remains constant. These facts are shown more clearly in Fig. 8 which is essentially a plot of the slopes of the lines in Fig. 7 as a function of η_{corr}.

Since the activation energy difference is positive and decreases as $|\eta_{corr}|$ increases, then, according to Eq. [15], the activation energy for the evolution of HD must be larger than that for the evolution of H_2 as expected, but must be decreasing relatively as $|\eta_{corr}|$ increases until $\eta_{corr} \geq |-300$ mV| where the activation energy difference becomes independent of overpotential. On the basis of the activation energy difference, therefore, S_D would be expected to decrease as $|\eta|$ is increased up to about |−300 mV| (see Eq. [10], [11], and [14]). Experimentally, the reverse is true. The explanation lies in the Arrhenius pre-exponential factor ratio.

If we extrapolate the curves in Fig. 7 to zero, *i.e.*, infinite temperature, we can estimate the behavior of the Arrhenius pre-exponential factor ratio, A_{H_2}/A_{HD}, for the H_2 and HD producing reactions, respectively, as a function of the corrected overpotential. As Fig. 9 shows, the pre-exponential factor ratio increases in an analogous manner as S_D itself. This increase more than offsets the tendency of the activation energy difference to decrease S_D as $|\eta|$ is increased, the net result being that S_D increases as $|\eta|$ increases up to about |−300 mV| for each temperature studied.

[1] For electrolytes of 10% D_2O content or less, the amount of D_2 liberated is negligible compared to HD.

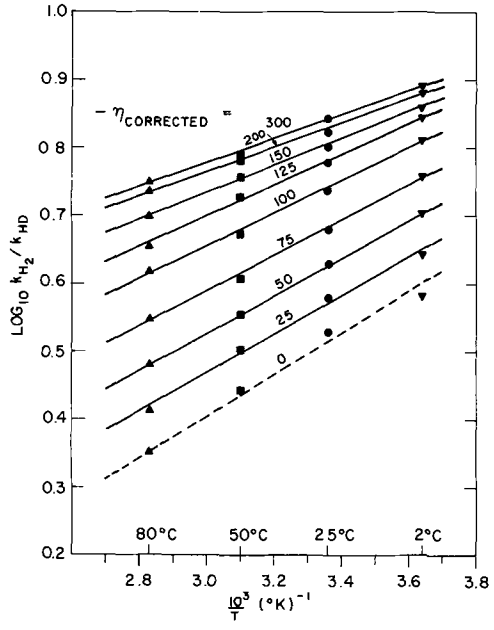

Fig. 7. Arrhenius plot as a function of the corrected overpotential on bright platinum bead electrodes in 1.2*N* HCl-10% D_2O for the temperature range 2°-80°C. - - - -, based on values of S_D extrapolated in Fig. 6.

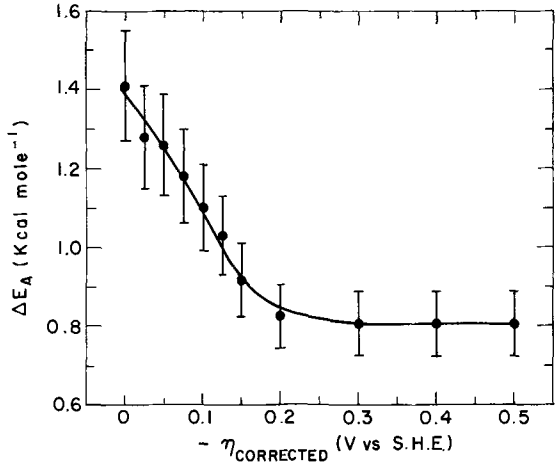

Fig. 8. Plot of the Arrhenius activation energy difference between the HD and the H_2 producing reactions as a function of the corrected overpotential (see Eq. [15]).

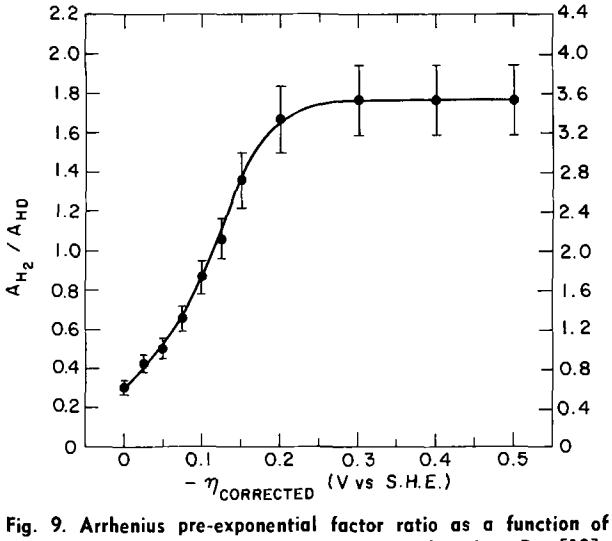

Fig. 9. Arrhenius pre-exponential factor ratio as a function of the corrected overpotential. Left-hand ordinate based on Eq. [10]; right-hand ordinate based on Eq. [11].

The fact that A_{H_2}/A_{HD} is less than unity for $0 \leq |\eta| \leq 110$ mV (see Fig. 9) based on the slow H-recombination mechanism and for $0 \leq |\eta| \leq 50$ mV based on the slow atom-ion and discharge mechanisms, may be interpreted as evidence for some proton tunneling in the proton discharge step according to Christov's theory (15). But in these overpotential regions the Tafel slope at 25°C (11) is −29 mV which conflicts with Conway's (12) theoretical prediction that the Tafel slope should be anomalously large (2 to 3) if proton tunneling is significant. We have found such high Tafel slopes (11), but for $|\eta| \geq 150$ mV where $A_{H_2}/A_{HD} > 1$ for which it is not necessary to invoke quantum effects. However, the authors do not intend to discuss the merits of the various proton tunneling theories; for this purpose the reader is referred to ref. (22).

Comparison with published results.—The fact that S_D increases as $|\eta|$ is increased and then reaches a plateau for each temperature studied may be due to a change in the mechanism, a change in the rate-determining step, or both (23). Our results at 25°C compare favorably with the theoretical calculations that include proton tunneling corrections (24). For 25°C Bockris and Srinivasan obtained $S_D = 3.0$ for the slow proton discharge followed by fast H-recombination mechanism while for the fast proton discharge followed by slow atom-ion desorption mechanism, $S_D = 5.5$. The experimental values are 3.2 ± 0.3 and 6.5 ±0.33 at $\eta = 0$ and $\eta > |-300$ mV|, respectively.

However, if we assume proton tunneling is absent, then it is possible to assign at least one other mechanism (24) for $\eta \to 0$. This mechanism is linked proton discharge-atom-ion desorption with either rate determining for which $(S_D)_{calc.} = 3.4$ based on 100% coulombic energy for all interactions and 3.6 based on 20% coulombic energy for M-H and H^+-OH_2, and 15% for H-H interactions. But, whether one argues for or against proton tunneling, a change in the mechanism as the cathodic overpotential is increased can account for the observed dependence of S_D on η.

Alternatively, the Tafel slope of −29 mV for $|\eta| \leq 75$ mV (11) has been attributed to slow H-recombination (25, 26), and this conclusion has been supported by Salomon and Conway's calculations (16). The fact that our Tafel slope approached $-\infty$ where S_D reached a plateau (11) may be indicative of a rate-controlling H-recombination step under Langmuir type adsorption when the hydrogen coverage approaches unity (26). Thus we have presumably explained the Tafel behavior based on a single mechanism and rate-determining step over an overpotential range where S_D about doubles before reaching a plateau. Therefore it is necessary to assume that the change in S_D results from changes in the relative adsorption-combination rates leading to H_2 and HD, respectively, as a function of total coverage of H and D which must be potential dependent to explain the results. This hypothesis is difficult to accept under Langmuir adsorption conditions where the adsorption energy is assumed to be independent of coverage. Tafel slopes alone may therefore be misleading in determining the mechanism of the hydrogen evolution reaction.

Within the experimental error of the measurements the temperature coefficient, dS_D/dT, of S_D is independent of η_{corr} as well as temperature. These results are presented in Table II along with those of Walton and Wolfenden (5) and those of Raman *et al.* (2) for alkaline solutions. The agreement between the three sets of results is good in view of the large errors and the different experimental conditions used. Our results suggest that perhaps dS_D/dT decreases as the temperature increases while those of Raman *et al.* suggest just the opposite. In both cases, the trends are within the experimental errors themselves. Although both the Arrhenius activation energy difference and the ratio of the pre-exponential factors are functions of η_{corr}, the net effect on the temperature coefficient is negligible since these dependencies are in opposite directions.

Table II. Comparison of temperature coefficients of S_D on platinum

Electrolyte	Temperature range, °C	$\frac{\Delta S_D}{\Delta T}$, deg^{-1}	Ref.
0.2 to 0.5N H_2SO_4 30 to 50 vol % D_2O	20-85	−0.028	(5)
1.2N HCl	2-25	−0.041 ± 0.019	This work
10 vol % D_2O	25-50	−0.030 ± 0.008	
	50-80	−0.019 ± 0.007	
15% KOH	30-40	−0.027	
10 vol % D_2O	40-50	−0.028	(2)
	50-60	−0.039	

Our results can be described by the following limit lines

$$k_{H_2}/k_{HD} = 0.30 \exp(1380 \text{ cal}/RT) \text{ at } \eta = 0, \text{ and}$$
$$k_{H_2}/k_{HD} = 1.77 \exp(815 \text{ cal}/RT) \text{ at } |\eta| \geq 300 \text{ mV}$$

based on the slow H-recombination mechanism (Eq. [10])

$$k_{H_2}/k_{HD} = 0.61 \exp(1380 \text{ cal}/RT) \text{ at } \eta = 0, \text{ and}$$
$$k_{H_2}/k_{HD} = 3.54 \exp(815 \text{ cal}/RT) \text{ at } |\eta| \geq 300 \text{ mV}$$

based on the slow atom-ion and proton discharge mechanisms (Eq. [11]). If we assume that K_b is about one (see Table I) over the whole temperature range, then the above limit lines for the slow H-recombination mechanism may be compared with Rowland's theoretical datum (maximum S_D) line 1 based on the postulate of free atoms at the electrode-electrolyte interface, and given by the expression: $S_D = 0.53 \exp(1840/RT)$. Certainly at the higher cathodic overpotentials our experimental activation energy difference is smaller than Rowland's theoretical one. Also, the theoretical value of the pre-exponential factor ratio is included in the experimental ones for the slow H-recombination mechanism but not for the slow atom-ion and proton discharge mechanisms.

Finally, it should be mentioned that our results at all temperatures disagree with those of Bockris *et al.* (23) at room temperature for the H/T separation factor, S_T. These authors claim that S_T on platinum in 1.0*N* HCl is independent of overpotential in the range −45 to −190 mV. This is precisely the range where S_D varies the most according to our results. Roy (3) found a linear correlation between the H/D, H/*T*, and D/*T* separation factors in alkaline solution on iron cathodes in good agreement with the theoretical predictions of Bigeleisen (27). Intuitively, it seems reasonable to expect a similar relationship for acid solutions and platinum cathodes since separation factors are ratios and not absolute quantities. To explain this discrepancy we have to assume that their electrode surfaces and/or experimental techniques were radically different from ours. It is difficult to assess this possibility since Bockris *et al.* give no experimental details or references for their HCl results on platinum.

Conclusions

1. Carefully controlled experiments yield reproducible (±5%) S_D values on smooth platinum electrodes in 1.2*N* HCl-10% D_2O.

2. In our system, *IR*-drops at a given applied overpotential could vary with time on the same electrode in the same aliquot of electrolyte. The reason for this behavior is not clear. Accordingly, the *IR*-drop was measured for each individual S_D determination.

3. The Arrhenius parameters are a function of overpotential. Agreement between our Arrhenius parameters and the theoretical ones based on Rowland's theory (1) is not too good. The pre-exponential factor ratio, A_{H_2}/A_{HD}, was less than unity for small cathodic overpotentials which may be indicative of some proton tunneling.

4. Experimentally, S_D increased as the cathodic overpotential was increased, and then reached a plateau at about $|\eta| \geqq 300$ mV at all temperatures. This behavior is best interpreted on the basis of theoretical calculations (24), as indicative of a change in the mechanism from slow proton discharge followed by fast H-recombination at $\eta \doteqdot 0$ to fast proton discharge followed by slow atom-ion desorption.

5. Within the experimental error dS_D/dT is independent of overpotential as well as temperature and agrees with other work.

Acknowledgments

The authors remain indebted to Dr. M. Salomon for many helpful criticisms of the manuscript. They are also most grateful to Mr. E. B. Selkirk who designed the transistor switch and to Mr. J. G. Wesanko who constructed the electrolysis cell.

Oxidation and Adsorption of Ammonia on a Platinized Platinum Electrode

Kazuo Sasaki and Yoshiro Hisatomi

Department of Applied Chemistry, Hiroshima University, Hiroshima, Japan

ABSTRACT

The electro-oxidation and adsorption of ammonia in aqueous alkaline solution on a platinized platinum electrode has been investigated by using the potentiodynamic technique. For comparison, the oxidation of hydroxylamine as well as potassium nitrite was also studied. It was concluded that the primary step of ammonia oxidation involves one electron. The primary product was relatively stable, indicating that the rate-determining step is one of the later steps of the net reaction. Pavela's method was used in conjunction with the potentiodynamic technique to study the adsorption of ammonia. The adsorption was found to be in accord with Temkin's isotherm, and the surface coverage of adsorbed ammonia was found to be about 0.3 at saturation.

It is generally accepted that many organic amino compounds adsorbed on a metal surface inhibit corrosion (1). Little is known, however, about the adsorption of ammonia, the simplest amino compound, on a metal surface from aqueous phase. In the present paper, the oxidation and adsorption of ammonia on a platinized platinum electrode in a potassium hydroxide solution has been studied.

Experimental Description

Aqueous 1M potassium hydroxide solution was the base solution throughout the experiments. All reagents were used without further purification. A cylindrical glass cell with a volume of 50 ml was used as the electrolytic cell. Electrodes were platinized platinum wires. In contrast to the ordinary cell system, a dummy electrode of a size similar to the working electrode was installed to start the potential sweep from any desired potential (Fig. 1).

In an actual experiment, the potentiostat was connected initially to the dummy electrode, and the potential sweep was run with this electrode. When the potential of the dummy electrode reached the desired value, the circuit was switched rapidly to the working electrode by a relay, leaving the dummy electrode at open circuit.

Measurements usually were made at 20°C. Potential values in this paper are referred to a "dynamic hydrogen electrode" (2) in 1M potassium hydroxide solution. Solutions were deaerated by bubbling nitrogen.

In order to determine the amount of ammonia adsorbed, Pavela's method (3) was used in conjunction with the potentiodynamic technique. The working electrode was first subjected to alternate cathodic and anodic polarization in the base solution to clean the surface. This pretreatment was continued until the shape of the current-potential curve no longer changed. The sweep was finally stopped at 0.5V in an anodic half cycle, where the electrode surface is free from both adsorbed hydrogen and oxygen. The electrode thus obtained was immersed in a solution containing the adsorbent. After a given time, the electrode was withdrawn from this bath and washed to minimize the amount of adhering solution. After washing, the test electrode was put into the electrolytic cell containing fresh base solution in order to study the electrochemical behavior of the ad-species.

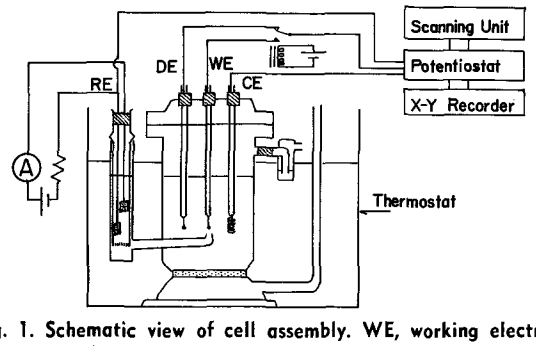

Fig. 1. Schematic view of cell assembly. WE, working electrode; RE, reference electrode; CE, counterelectrode; DE, dummy electrode.

The amount of adsorbed species was determined from the difference between the anodic charges which were obtained from current-potential curves measured with and without adsorption. After transferring the test electrode from the adsorption bath to the electrolytic cell, three kinds of potential sweeps were employed: (*i*) sweep started at 0.5V toward more positive potentials, (*ii*) sweep started at 0.5V toward more negative potentials, and (*iii*) anodic sweep started, with the aid of the dummy electrode, from the negative end of the hydrogen wave at 0.15V.

Using sweep (*i*), it was possible to find the total charge required to oxidize the adsorbed species. From sweep (*ii*) information on the oxidation state of the adsorbed species was gathered. Finally, with the aid of sweep (*iii*), the surface coverage of the adsorbed species was obtained from the decrease of the hydrogen wave. In actual experiments, combinations or modifications of these three sweeps were frequently employed.

After studying the effect of the washing time on the anodic stripping of adsorbed ammonia, the washing procedure was standardized as follows. After drawing the electrode out of the adsorption bath it was washed for 1 min by pouring a large quantity of the base solution over it and then rinsed for 2 min in a fresh base solution stirred with nitrogen.

Results and Discussion

Anodic oxidation of ammonia.—Cyclic current-potential curves in solutions with and without ammonia are shown in Fig. 2. An anodic current peak (Pa) appears prior to the formation of platinum surface oxide, and a sharp cathodic current peak (Pc1) appears in the potential range of hydrogen adsorption in the presence of ammonia. In contrast to the regular curve in solutions containing no ammonia (dashed line), the cathodic current peak for the reduction of platinum surface oxide is suppressed significantly by the presence of ammonia. The current peaks at Pa and Pc1 were found not only with ammonia but also with solutions containing either hydroxylamine (Fig. 4) or potassium nitrite (Fig. 5). Both peaks, Pa and Pc1, were proportional to the square root of the sweep rate indicating that the rate of reaction at these potentials is limited by diffusion (4).

Current-potential curves obtained at various potentials of sweep reversal are shown in Fig. 3. It is inter-

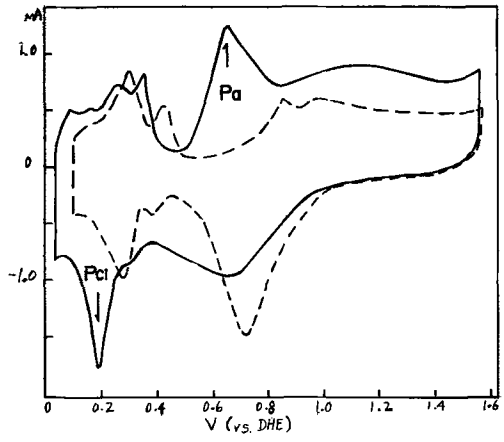

Fig. 2. Cyclic current-potential curves with and without ammonia. Solid line, with solution containing $1x10^{-2}$M ammonia; dashed line, 1N KOH base solution; sweep rate, 50 mv/sec.

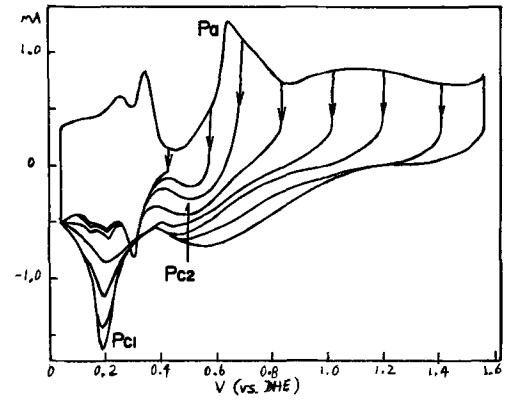

Fig. 3. Cyclic current-potential curves at various potentials of sweep reversal. Concentration of ammonia, $1x10^{-2}$M; sweep rate, 50 mV/sec.

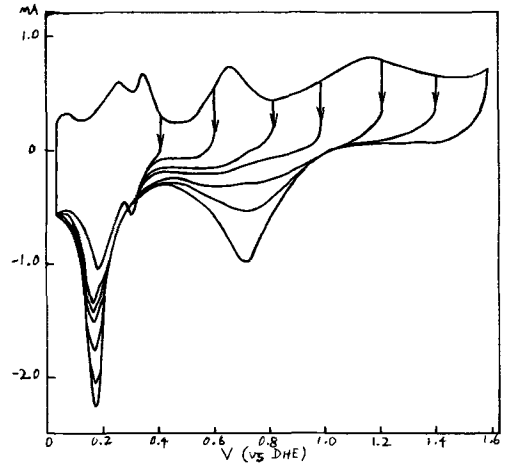

Fig. 4. Cyclic current-potential curves in a hydroxylamine solution. Hydroxylamine, $1x10^{-2}$M; sweep rate, 50 mV/sec.

esting to note that a characteristic cathodic peak, Pc2, is observed. Although this peak is not particularly sharp, it is suggested that the peak represents the reverse reaction of the one at Pa. This is illustrated in Fig. 6. The cathodic and anodic potentials of sweep reversal were fixed at 0.55 and 0.75V, respectively, in the potential range of Pa. The quantities of electricity during the anodic and cathodic half cycles changed with the sweep rate. The ratio of these two quantities, $Q(Pa)/Q(Pc2)$, decreased from 4.45 at 25 mV/sec to 1.25 at 200 mV/sec, suggesting that the ratio converges to unity at higher sweep rates. Values of the charge ratio are given in the caption of Fig. 6.

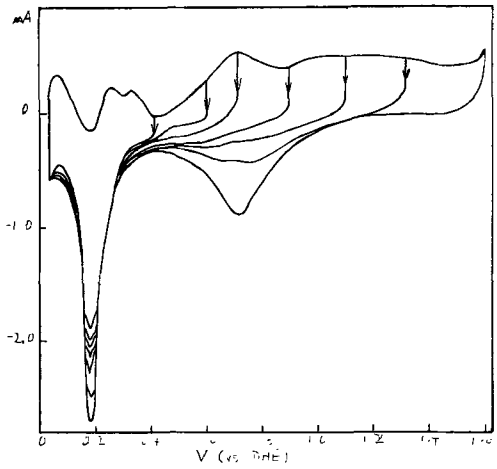

Fig. 5. Cyclic current-potential curves in a potassium nitric solution. Potassium nitric, $1x10^{-2}$M; sweep rate, 50 mV/sec.

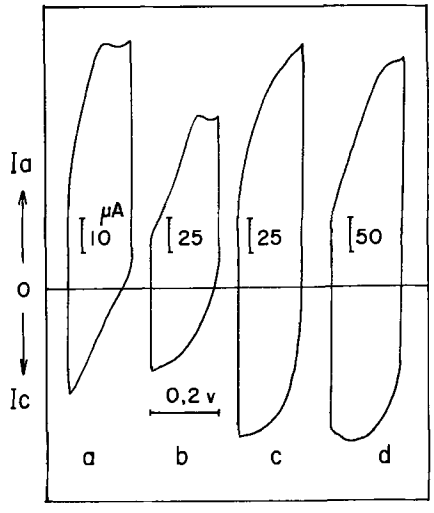

Fig. 6. Cyclic current-potential curves in an ammonia solution when cycle was repeated in potential range of Pa at various sweep rates. Area of electrode estimated from hydrogen wave was 5.45 cm^2. Concentration of ammonia was $5x10^{-3}$M. Sweep rates were 25, 50, 100, and 200 mV/sec for curves a, b, c, and d, respectively. Corresponding values of charge ratio, Qa/Qc, were 4.45, 1.93, 1.55, and 1.23, respectively.

The peak, Pc2, was characteristic of ammonia solution. When hydroxylamine or potassium nitrite were used instead of ammonia, the cathodic peak corresponding to Pc2 was no longer present (Fig. 4 and 5). This is more clearly illustrated in Fig. 7[1] where the effect of sweep rate on the shape of current-potential curves in a hydroxylamine solution is shown. In contrast to ammonia, the primary oxidation product of hydroxylamine undergoes further oxidation and no cathodic current is observed at sweep rates lower than 100 mV/sec. In addition, the peak height of the cathodic current in the hydrogen wave, Pc1, increased markedly with increasing potential of reversal (see Fig. 3). The cathodic current in this region was also observed as a strong peak with solutions containing either hydroxylamine or potassium nitrite (Fig. 4 and 5). With solutions of hydroxylamine, the peak was found even when a cathodic sweep was started from the positive end of the hydrogen wave, where hydroxylamine could not be oxidized to any degree. Several conclusions can be drawn from these observations:

[1] Although the electrode used to obtain the results in Fig. 6 and 7 was the same, having a geometric area of 0.014 cm^2, the real areas were different from each other owing to the aging of platinum black. The roughness factors of the electrode surface estimated from the hydrogen wave were 418 and 57.4 for the experiments of Fig. 6 and 7, respectively.

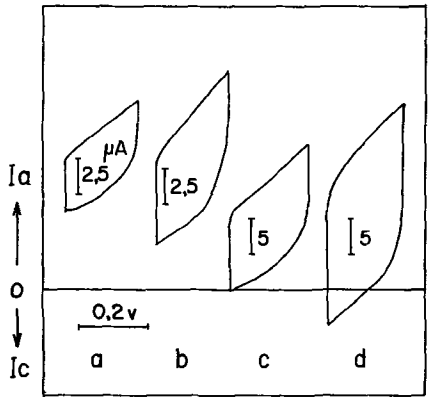

Fig. 7. Cyclic current-potential curves in a hydroxylamine solution at various sweep rates. Sweep range was fixed in potential range of Pa. Concentration of hydroxylamine, 5.10^{-3}M. Sweep rates were 25, 50, 100, and 200 mV/sec for curves a, b, c, and d, respectively. Area of electrode, 0.803 cm^2.

(*i*) The oxidation of ammonia is not complete, and some intermediates such as hydroxylamine or nitrite are produced partly and diffuse into the solution under the condition of cyclic voltammetry. (*ii*) Hydroxylamine as well as nitrite anion are reduced at potentials of the hydrogen region. (*iii*) The species responsible for the reaction at Pc2 is different from hydroxylamine, which is the reduction product of ammonia by a two-electron process; it is more likely to be an intermediate produced from ammonia by a one-electron process.

If the species responsible for Pc2 is the one-electron product then the charge ratio, $Q(\text{Pa})/Q(\text{Pc2})$, should vary, depending on the stability of the Pc2 species. The ratio must become larger than two when the Pc2 species is relatively unstable because the successive steps proceed at a faster rate than the initial one-electron step. The results summarized in Fig. 6 show that the ratio is less than two when the sweep rate exceeds 50 mV/sec and approaches unity. An extrapolation indicated that the ratio becomes unity when the sweep rate exceeded 400 mV/sec, suggesting that the life time of the primary oxidation product is in the order of 1 sec.

Undoubtedly, however, the primary product is not extremely stable, and actual oxidation proceeds further. Nitrogen was evolved when the oxidation was subjected to a prolonged treatment even at the potential range of Pa. Katan and Galiotto (6) and Wynveen (7) established the following net reaction

$$NH_3 + 3\,OH^- \rightarrow 1/2N_2 + 3H_2O + 3e$$

Based mainly on the analogy to the gas phase reaction, Oswin and Salomon (5) proposed the following sequence of reactions

$$NH_3 + M + OH^- \rightleftarrows M - NH_2 + H_2O + e \quad [1]$$

$$M - NH_2 + OH^- \rightarrow M = NH + H_2O + e \quad [2]$$

$$M = NH + OH^- \rightarrow M \equiv N + H_2O + e \quad [3]$$

$$M \equiv N + M \equiv N \rightarrow 2M + N_2 \quad [4]$$

According to this mechanism, reaction [2] is rate determining, and the primary step [1] is in quasi-equilibrium. This is in accordance with the present results.

Adsorption of ammonia.—When the cyclic potential sweeps were applied in solutions containing ammonia, the current peak corresponding to the oxidation of ammonia was always greater in the first sweep than the successive cycles. Probably this indicates that a finite amount of ammonia adsorbed on the platinum surface during the waiting time before the measurements. In order to confirm this, a series of experiments based on Pavela's method were conducted. Adsorption was carried out in a separate bath containing different concentrations of ammonia, and the stripping was carried out in a fresh base solution.

A typical example of the anodic stripping of adsorbed ammonia is shown in Fig. 8 by the curve represented by the solid line. The presence of adsorbed ammonia is clearly indicated by an anodic current peak located in the potential region of Pa and also by a decrease of the height of the hydrogen waves. The anodic peak was found unaffected by agitating the stripping solution with nitrogen. The peak disappeared, however, during an anodic sweep preceded by a cathodic one in stirred solution. This fact suggests that the adsorbed species was not ammonia itself, but had a certain oxidation state which could be reduced cathodically to ammonia.

It was found that the adsorption is proportional to the logarithm of the adsorption time. Adsorption was, in accordance with Temkin's isotherm, also proportional to the logarithm of the concentration of ammonia in the adsorption bath. As evident from Fig. 9, the maximal coverage (saturation) is observed at 10^{-4} to 10^{-3}M. The amount of adsorbed ammonia was approximately 78 $\mu coul/cm^2$ at saturation, and this corresponds to a fractional coverage of 0.3.

As shown in Fig. 8, the decrease of the area under the hydrogen wave is almost equal to the area of Pa. This indicates that the oxidation of the ad-species requires one electron per site.

In order to see the composition of the ad-species in more detail, the charge required for the cathodic reduction (Qc) of the ad-species was compared with that required for the anodic stripping (Qa). If the reaction sequence proposed by Oswin and Salomon is assumed to be correct, the following values of Qa/Qc can be expected for the respective intermediates

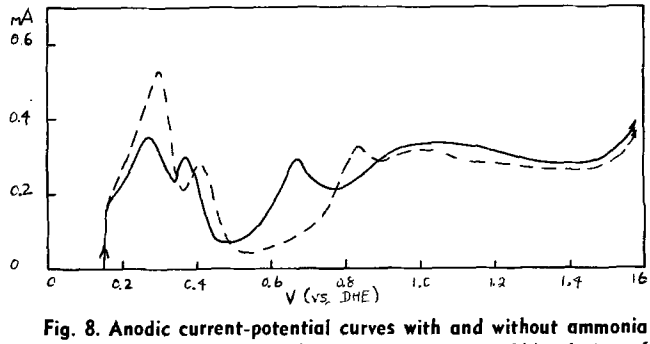

Fig. 8. Anodic current-potential curves with and without ammonia adsorption. Solid line, after 10 min adsorption in a 1M solution of ammonia. Dashed line, after 10 min immersion in a fresh base solution.

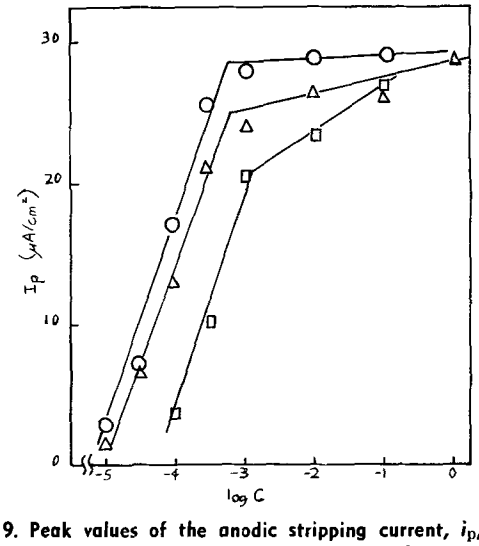

Fig. 9. Peak values of the anodic stripping current, i_p, vs. logarithm of concentration of ammonia in adsorption bath. Duration of adsorption treatment: □, 1 min; △, 5 min; and ○, 10 min.

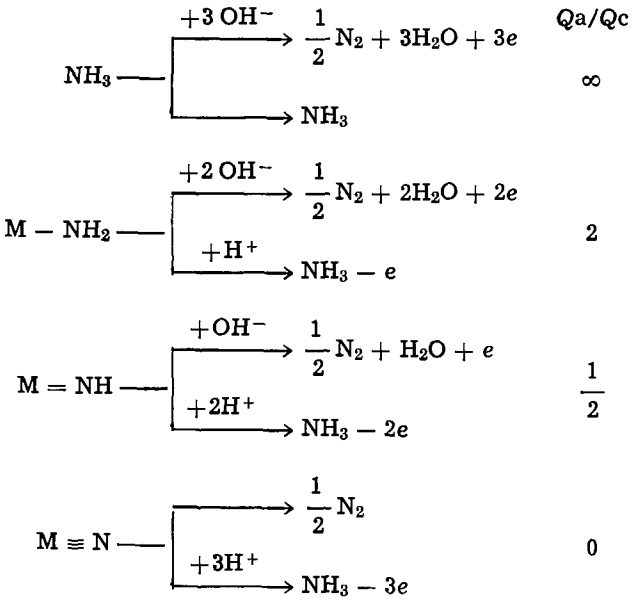

Actual values observed with ammonia were scattered from 1/2 to unity, and with hydroxylamine the values were from 1/5 to 1/2. Probably the actual composition is a mixture of these species. Furthermore, the presence of some oxygenated ad-species, which have often been reported in the case of organic compounds (8)[2] may not be ignored.

Effect of surface oxide on adsorption of ammonia.— In order to see the effect of the electrode potential on the composition of the ad-species, the following experiments were carried out. The test electrode was previously oxidized in the base solution at a given constant potential. In addition, the same potential was also applied to the test electrode during the time of adsorption.

The potential sweep in the stripping experiment was started in the cathodic direction from the potential at which the adsorption was carried out. Several examples of the current-potential curves are shown in Fig. 10. The sharp rise of anodic current at the starting point (see curves A and B) was found to represent the oxidation of sites on the platinum surface neither covered adsorbents nor the surface oxide. Similarly, the narrow cathodic current peak in curve C represents the rapid reduction of the surface oxide. The curves in Fig. 10 demonstrate that the cathodic current peak for the reduction of the surface oxide decreased with the decrease of the potential at which the adsorption took place. The oxidation peak during the subsequent anodic sweep increases in the sequence A, B, C. Figure 11 represents results of the same type in which the potential of the adsorption was at 0.9V and the duration of the adsorption was varied. The increase of the cathodic current at about 0.5V is pronounced for longer times of adsorption.

It is concluded from these results that ammonia still adsorbs on the platinum surface even at the potential where the surface oxide forms. The ad-species accumulates and the surface oxide diminishes at least at the potential of 0.9V. The appearance of the characteristic peak, Pc2 in Fig. 10 and 11, suggests that the major part of the ad-species consists of the same species as the primary product of the anodic oxidation. At higher potentials, however, the adsorbed amount decreases with increasing potential, indicating that species with higher oxidation state are unstable on the surface.

[2] Hydration of reacting species was not considered in the mechanism expressed by Eq. [1]-[4]. Both ammonia and hydroxylamine exhibit a cathodic current peak at Pc1, where the nitrite anion is reduced, and the peak becomes larger with increasing anodic potential of reversal. This seems to suggest the formation of some oxygenated compounds.

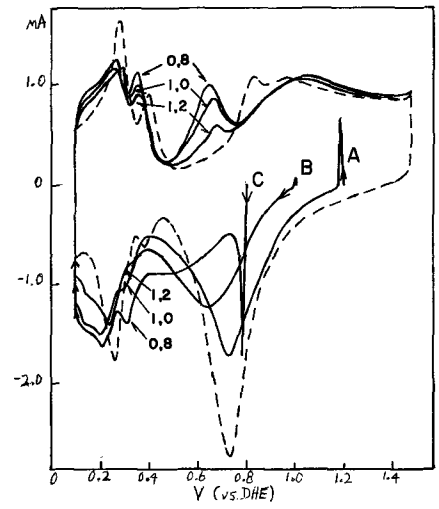

Fig. 10. Influence of electrode potential during adsorption. Numerical figures attached to each curve indicate electrode potential at which adsorption was carried out. Dashed curve represents current-potential curve observed in base solution. Concentration of ammonia in adsorption bath, 2×10^{-3}M. Sweep rate, 50 mV/sec.

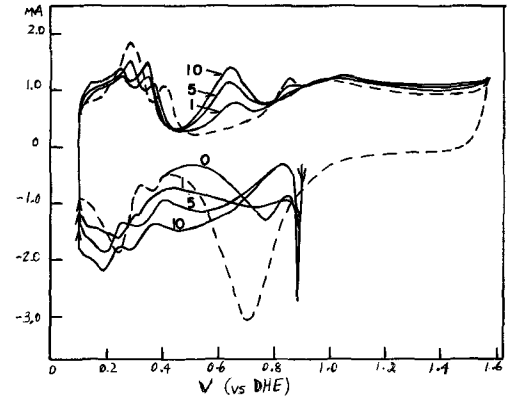

Fig. 11. Influence of adsorption time on stripping current. Adsorption was carried out at a constant potential of 0.9V. Numbers indicate time in minutes.

Summary

The anodic oxidation and adsorption of ammonia in alkaline solutions have been studied on a platinized platinum electrode. Ammonia is anodically oxidized at about 0.65V in 1M potassium hydroxide solutions. The rate of oxidation was, as a whole, diffusion limited. Under the condition of cyclic voltammetry, it was found that the primary product of the anodic oxidation is relatively stable. The life time was estimated to be in the order of 1 sec. When hydroxylamine was examined in place of ammonia, a stable intermediate was not detected. These results are in accordance with the mechanisms reported previously.

Adsorption was studied by employing Pavela's method. It was found that ammonia adsorbs on a platinum surface in accord with Temkin's isotherm and that the surface coverage is about 0.3 at saturation. It is suggested that the major species in the ad-layer is the primary product of ammonia oxidation.

The Mechanism of the Cadmium Electrode

K. E. Heusler and L. Gaiser

Max-Planck-Institut für Metallforschung, Stuttgart, Germany

ABSTRACT

Measurements of current-potential curves with solid cadmium in solutions of cadmium perchlorate and barium perchlorate under stationary and transient conditions indicate that the electrode reaction proceeds via two consecutive charge transfer steps with adsorbed monovalent cadmium as the intermediate. The rate constants and their dependence on potential and coverage were calculated from the experiments.

The kinetics of dissolution and deposition of solid cadmium in sulfate solutions has been investigated by Lorenz (1, 2). Results were in apparent agreement with the assumption that the rate-determining step is the charge-transfer reaction of Cd^{2+}-ions with a charge-transfer valence $z = 2$ and a cathodic transfer coefficient $\alpha = 0.45$. The results have been quoted as a clear verification of the theoretical relationships derived for such a simple transfer reaction (3, 4). However, the verification may have been only accidental due to the limited experimental evidence.

A mechanism involving two consecutive transfer reactions cannot be excluded, namely

$$Cd^{2+} + e \underset{k_1^+}{\overset{k_1^-}{\rightleftharpoons}} Cd_{ad}^{+} \qquad [1]$$

$$Cd_{ad}^{+} + e \underset{k_2^+}{\overset{k_2^-}{\rightleftharpoons}} Cd \qquad [2]$$

Indeed, an analogous mechanism with monovalent metal in the adsorbed state has been deduced from the kinetics of the solid zinc electrode in perchlorate solutions (5). Furthermore, measurements (6-12) at cadmium amalgam electrodes that yielded transfer coefficients close to $\alpha = 0.25$ assuming $z = 2$ point toward the mechanism [1], [2]. In addition, Lorenz (2) found $\alpha = 0.25$ from measurements of transition times for the deposition of solid cadmium at high current densities.

In an attempt to achieve a clearer understanding of the mechanism of the cadmium electrode, the present study focused experimentally on measurements of current-potential curves over a potential range greater than 0.5V, variation of the concentration of cadmium salt at constant ionic strength of the solution between 0 and 1.3M, and measurements of the time dependence of the polarization. It is significant that all the experimental facts on the kinetics of the cadmium electrode from the present investigation as well as those of Lorenz (1, 2) are consistent with the consecutive mechanism [1], [2]. Thus, a theoretical treatment of an electrode reaction with two consecutive charge-transfer steps is developed taking into account adsorption of the intermediate by generalizing the approach of Gerischer and Mehl (13). The treatment includes earlier considerations (3, 14-16) of the consecutive mechanism as limiting cases.

Experimental

The electrodes were made from cadmium wire with $<$ 1 ppm of metallic impurities. The wire was insulated with Teflon except for the part which served as the electrode. The nearly hemispherical electrodes with an area of about 1 mm^2 were renewed by heating the Teflon to about 200°C, pulling out the wire, and breaking it with tweezers without touching the electrode region. The electrode contained only very few grains. The reference electrode for fast pulse polarizations and the counterelectrode were made from the same cadmium wire. The potential of the reference electrode was measured against a saturated calomel electrode (SCE) at room temperature. A saturated sodium chloride solution separated the potassium chloride from the perchlorate solutions in the cell.

Perchlorate was chosen because this anion does not form complexes with the cadmium ion. Moreover the activity of the cadmium salt can be made much higher than for example in sulfate solutions, and no specific interaction of the anion with the metal surface is expected. The supporting electrolyte usually was a 1M barium perchlorate solution prepared from A. R. grade barium hydroxide, perchloric acid and water triply distilled from a dilute potassium permanganate solution. By adding a 1M cadmium sulfate solution, barium ions were partially replaced by cadmium ions. The solutions were centrifugated in order to remove barium sulfate. The ionic strength was kept constant (with the exception of the 1.3M cadmium perchlorate solution). Usually the solutions were slightly acidic at $pH = 2$ to 4. Sodium perchlorate solutions were also used in some experiments.

Measurements were performed at 0°C in a cell forming a loop in which the solution was rapidly circulated with a magnetic stirrer. The working electrode was polarized under galvanostatic or potentiostatic conditions. A pulse generator and a potentiostat with rise times $\leq 10^{-7}$ sec were used. The pulse heights and the signals from the electrode were measured with a dual-beam oscilloscope.

Results

Current-potential curves were obtained by polarizing the cadmium electrode from its rest potential or equilibrium potential to other potentials by potentiostatic pulses. After switching on the pulse, a current transient with an almost potential-independent decay time of $\tau' \lesssim 15$ μsec was observed. This decay corresponds to the charging of the double layer capacity (17, 18) of 20 to 30 $\mu F/cm^2$ through the effective electrolyte resistance $R_E \leq 0.55$ ohm cm^2 between the working electrode and the reference electrode. Values of C_D and R_E were measured independently by applying constant current pulses and observing the po-

tential transients. All the potentials given below are corrected for $R_E \cdot j$ using the respective experimental values of the electrolyte resistance and of the current density.

The double layer capacity did not change with the height of the current pulse. When hydrogen evolution was the only faradaic process, the transients were well described by the relationship of Roiter *et al.* (3, 19, 20). No significant frequency dispersion of C_D has been observed which might be caused by the roughness of the electrodes (21).

When dissolution or deposition of cadmium occurred, under potentiostatic conditions a slower current transient followed after the first transient. The characteristic time, τ, of the slower transient was in the order of 10^{-3} to 10^{-5} sec depending on experimental conditions. The limit for the separation of the two transients experimentally is given by the condition that $\tau' < \tau$. After the decay of the second transient the current remained constant for times of about 100τ. If the duration of the pulse was made longer than about 100τ, the current increased until a new steady state was attained.

Such long polarization was found to change the effective surface area, leaving the mechanism of the electrode reaction unaltered. These changes of the effective surface area are produced by depositing or dissolving layers of cadmium with an average thickness of the order of 1 μm. The steady-state surface morphology is finally determined by processes of positive or negative crystallization (22, 23), that in this paper will not be discussed further.

On the other hand, current-potential curves measured at times $3\tau < t < 100\tau$ correspond to steady states of the electrode reaction on a surface of constant morphology. In Fig. 1, steady-state current potential curves are shown for different cadmium salt concentrations. The potentials at zero current were found to shift by $\partial\epsilon/\partial \log c_{Cd2+} = 27$ mV/decade indicating that the equilibrium between cadmium and cadmium ions was established. The equilibrium was not appreciably disturbed by hydrogen evolution at $pH \geqq 3$ and $c_{Cd2+} \geqq 10^{-3}$M. Current-potential curves did not change with the pH-value of the solution. The anodic curve was independent of the cadmium salt concentration at overvoltages >60 mV. At high current densities a constant Tafel slope of about 108 mV/decade was found for both anodic and cathodic polarizations.

The reaction order, y_{Cd2+}, with respect to the cadmium ions was obtained from current-potential curves in solutions containing various concentrations of cadmium salt. An approximate value $y_{Cd2+} = 1$ was taken from those parts of the cathodic curves in which the currents were much smaller than the current limited by the diffusion of cadmium ions but much higher than the exchange current at the equilibrium potential. After correcting for diffusion polarization which yielded substantial contributions only for $c_{Cd2+} < 0.1$M, the more exact currents of Fig. 2 were obtained. Within the limits of reproducibility, the reaction order was found to be $y_{Cd2+} = 1.0$ for $c_{Cd2+} < 10^{-1}$M, but for $c_{Cd2+} > 10^{-1}$M the reaction order appeared to drop to about $y_{Cd2+} \approx 0.85$. There was no dependence of the dissolution rate of cadmium on the concentration of cadmium salt.

The anodic current-potential curve was measured down to very low current densities in solutions free of cadmium salt. The low current densities changed more rapidly with the potential than the high current densities. Tafel lines with slopes of 40-50 mV/decade may be assigned to the experimental points shown in Fig. 3. The cathodic Tafel lines in Fig. 3 with a slope of

about 115 mV/decade are due to hydrogen evolution with the rate being nearly proportional to the hydrogen ion activity.

For a quantitative analysis of the potentiostatic transients following the charging of the double layer the differences between the current densities, $j(t)$, at different times and the stationary current density, $j(\infty)$, were plotted logarithmically against the time as shown in Fig. 4. An exponential decrease of the excess current density, $j(t) - j(\infty)$, with time was only observed when $j(t)$ differed from $j(\infty)$ by 10% or less. The current decay was faster than exponential for large excess current densities. The effect is not caused by interference with the charging of the double layer, since it was observed even when the decay was very slow. It was also present for small excess current densities for which no significant corrections due to the electrolyte resistance, R_E, were necessary. Actually, any correction for $R_E \cdot j$ would enhance the effect.

For both cathodic and anodic overpotentials the stationary state was approached from higher current densities. The characteristic times, τ, taken from the final exponential decay of the excess current density on the cathodic side decreased for more negative potentials and on the anodic side for more positive potentials by about 108 mV/decade. The times of decay were measured at overvoltages between about 0.1 and 0.25V in a region where corrections due to the reverse reaction, to concentration polarization, ohmic drop, and interference with the charging of the double layer capacity were rather small. The dependence of the cathodic times of decay at constant potential upon the concentration of cadmium salt are plotted in Fig. 5 on a double logarithmic scale. The decay times decreased almost proportional to the cadmium perchlorate concentration.

At low cadmium perchlorate concentrations the charging of the double layer capacity was so much faster than the subsequent decay of the current that the faradaic currents at times $t \to 0$ after changing the potential could be measured. The corresponding transient current-potential curves were found to be symmetrical with respect to the equilibrium potential. The transient exchange current densities were about 0.5 A/cm². The absolute accuracy of such large values is low due to the high $R_E \cdot j$-correction. However, it was possible to compare the transient exchange current densities for different cadmium perchlorate concentrations by measuring at the same electrode without changing the geometry. A very small concentration dependence of the transient exchange current densities was observed as shown in Fig. 7.

Discussion

Considering the steady-state current-potential curves, Vetter (3) has given the following individually sufficient criteria for the appearance of consecutive charge transfer reactions: (a) extrapolation of the anodic and cathodic Tafel lines toward the equilibrium potential leads to two different current densities; (b) the Tafel line changes its slope $\partial\epsilon/\partial \ln j$ from a small value at low overvoltages to a large value at high overvoltages; and (c) the sum of the apparent anodic and the cathodic transfer coefficients $\alpha' = RT\partial/n\mathbf{F}\partial\epsilon$ does not add up to the number n of electrons transferred in the over-all reaction (15), *e.g.*, $n = 2$ for the cadmium electrode. The experiments show that not only one but all three criteria are fulfilled, except for specific experimental conditions. Thus, it is safe to conclude that a consecutive mechanism is operating. Additional information on the mechanism may be derived from the following theoretical treatment.

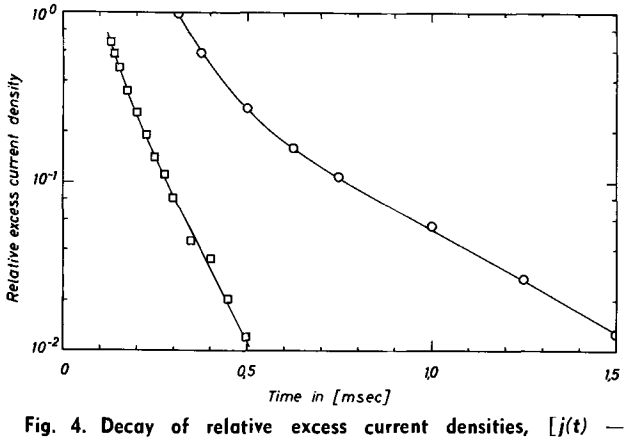

Fig. 4. Decay of relative excess current densities, $[j(t) - j(\infty)]/j(\infty)$, with time after switching from the equilibrium potential to negative overvoltages. (○), $\epsilon = -0.895$V vs. SCE in 0.014M $Cd(ClO_4)_2$ + 0.99M $Ba(ClO_4)_2$, (□), $\epsilon = -0.848$V vs. SCE in 0.15M $Cd(ClO_4)_2$ + 0.85M $Ba(ClO_4)_2$.

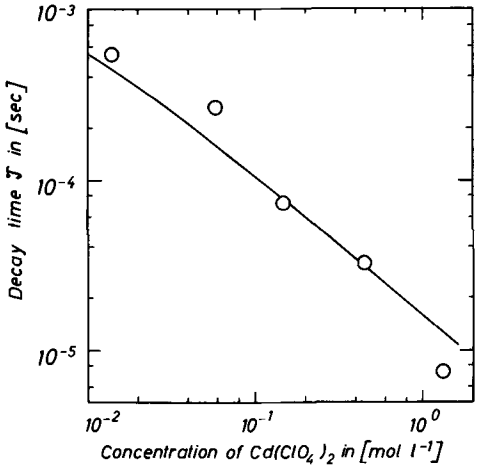

Fig. 5. Cathodic decay times at $\epsilon = -0.85$V vs. SCE as a function of the concentration of $Cd(ClO_4)_2$ in solutions of constant ionic strength at 0°C.

A consistent quantitative interpretation of the experiments is impossible without considering the adsorption of the intermediate. In deriving the following general relationships it is taken into account that the monovalent cadmium can only exist in the adsorbed state. The rates of the charge transfer reactions [1] and [2] in terms of current densities are given by

$$j_1 = k_1^+(\epsilon) \cdot f(\theta) - k_1^-(\epsilon) \cdot a_{Cd2+} \cdot g(\theta) \quad [3]$$

and

$$j_2 = k_2^+(\epsilon) \cdot g(\theta) - k_2^-(\epsilon) \cdot f(\theta) \quad [4]$$

with the rate constants $k_{1,2}^+(\epsilon) = k_{1,2}^+ \cdot \exp[\alpha_{1,2}\mathbf{F}\epsilon/RT]$ and $k_{1,2}^-(\epsilon) = k_{1,2}^- \cdot \exp[-(1-\alpha_{1,2})\mathbf{F}\epsilon/RT]$ and the transfer coefficients α_1, α_2 of the two steps [1] and [2]. The potential ϵ refers to a constant reference electrode like the SCE.

The influence of the relative surface coverage, θ, by the intermediate on the rates is expressed by the functions

$$f(\theta) = \theta \cdot \exp[-b(1-\theta)] \quad [5]$$

and

$$g(\theta) = (1-\theta) \cdot \exp[-a\theta] \quad [6]$$

The desorption of monovalent cadmium proceeds at a rate proportional to the coverage θ. It is assumed, consequently, that the rate of adsorption is proportional to the part $(1-\theta)$ of the surface not yet covered. Another effect to be considered is the dependence of the rate constants upon coverage. To a first approximation, there is a linear dependence of the activation energies of the charge-transfer reactions on the coverage as suggested by Temkin (24). For the activation energy E_a of adsorption one writes

$$E_a = E_a^0 + a\,RT\,\theta \quad [7]$$

and for the activation energy E_d of desorption

$$E_d = E_d^0 + b\,RT\,(1-\theta) \quad [8]$$

There are two reactions of adsorption, anodic reaction [2] and cathodic reaction [1]. It is assumed that [7] holds for both reactions with the same potential-independent interaction coefficient, a. The analogous assumption concerning the coefficient, b, follows from the fact that the coefficient, $A = a + b$, must be independent of the particular reactions [1] or [2], because A describes a thermodynamic quantity, namely, the change of the adsorption enthalpy with coverage at the equilibrium of the cadmium electrode.

The rates of dissolution or deposition of cadmium are given by

$$j = j_1 + j_2 \qquad [9]$$

The stationary state is characterized by $j_1 = j_2$. After elimination of either $f(\theta)$ or $g(\theta)$ two equivalent equations for the steady state current density, $j(\infty)$, are obtained

$$j(\infty) = 2\,g(\theta) \cdot \frac{k_1^+(\epsilon) \cdot k_2^+(\epsilon) - k_1^-(\epsilon) \cdot k_2^-(\epsilon) \cdot a_{Cd2+}}{k_1^+(\epsilon) + k_2^-(\epsilon)} \qquad [10]$$

and

$$j(\infty) = 2\,f(\theta) \cdot \frac{k_1^+(\epsilon) \cdot k_2^+(\epsilon) - k_1^-(\epsilon) \cdot k_2^-(\epsilon) \cdot a_{Cd2+}}{k_1^-(\epsilon) \cdot a_{Cd2+} + k_2^+(\epsilon)} \qquad [11]$$

The adsorption isotherm describing the dependence of the steady-state coverage on potential and cadmium ion activity follows from [5], [6], [10], and [11]

$$\frac{\theta}{1-\theta} \exp\left[a\theta - b(1-\theta)\right] = \frac{k_1^-(\epsilon) \cdot a_{Cd2+} + k_2^+(\epsilon)}{k_1^+(\epsilon) + k_2^-(\epsilon)} \qquad [12]$$

At large positive potentials both anodic rate constants become much larger than the cathodic rate constants. Then, as one can easily show, the potential dependence of the rate is given by $\partial/\partial = RT/\alpha_1\mathbf{F}$ if $k_1^+(\epsilon) << k_2^+(\epsilon)$ or by $\partial/\partial = RT/\alpha_2\mathbf{F}$, if $k_1^+(\epsilon) >> k_2^+(\epsilon)$. For $k_1^+(\epsilon) \approx k_2^+(\epsilon)$ and $\alpha_1 \neq \alpha_2$ the slope of the Tafel line depends on the potential. Analogously, at large negative potentials the Tafel slope is $\partial\epsilon/\partial \ln j_- = RT/(1-\alpha_1)\mathbf{F}$ for $k_1^-(\epsilon)\,a_{Cd2+} >> k_2^-(\epsilon)$ and $\partial\epsilon/\partial \ln j_- = RT/(1-\alpha_2)\mathbf{F}$ for $k_1^-(\epsilon)a_{Cd2+} << k_2^-(\epsilon)$. The earlier statement (3, 14, 15) that the Tafel slopes at high overvoltages are determined by the transfer coefficients of the respective preceding reaction step does not hold when considering adsorbed intermediates. Experimentally, it was found that $\partial \ln j_\pm/\partial = 2\mathbf{F}/\mathrm{RT}$ on both the cathodic and anodic sides. One concludes that $\alpha_1 = \alpha_2 = 0.5$ within the limits of experimental accuracy of at least $\pm 10\%$.

If at $a_{Cd2+} \to 0$ the cathodic current density for the deposition of cadmium becomes negligible, at negative potentials $k_2^-(\epsilon)$ must become large compared to $k_1^+(\epsilon)$. In this case, the equilibrium [2] is not appreciably disturbed by the anodic dissolution of cadmium; the coverage, θ, depends strongly on the potential; and the Tafel slope is $\partial\epsilon/\partial \ln j_+ = RT/(1+\alpha)\mathbf{F}$. This behavior is in good agreement with the anodic current-potential curve of Fig. 3.

On the other hand, it follows from [12] that for $a_{Cd2+} \to 0$ the coverage approaches $\theta_- \to 0$ at negative potentials, and therefore $g(\theta_-) \to 1$. As long as the activity of cadmium ions is small enough, $[1 - g(\theta_-)] << 1$, and the current density, j_-, at constant potential stays proportional to the activity, a_{Cd2+}, as is deduced from [10]. The current density, j_-, increases less than proportional to the activity of cadmium ions as soon as $g(\theta_-)$ deviates from unity appreciably. For very high activities the coverage may approach its limiting value $\theta_- \to 1$, or $[1 - f(\theta_-)] << 1$. Under this condition, the rate of deposition is independent of the activity, a_{Cd2+}, according to [11].

The activities and the concentrations of the cadmium ions are proportional to each other, since the experiments were done at constant ionic strength and since the activity coefficients of cadmium perchlorate and barium perchlorate solutions are nearly equal. For the purpose of the following numerical calculations it suffices to refer to concentrations.

From the measurements at low concentrations Fig. 2 yields the rate constant $k_1^- = j_-(\infty)/2c_{Cd2+}$. Extrapolating to high cadmium salt concentrations, one obtains $g(\theta_-) = j_-(\infty)/2k_1^- \cdot c_{Cd2+}$. At the highest concentration $c_{Cd2+} = 1.3\mathrm{M}$ a value of $g(\theta_-) \approx 0.5$ was found. A definite value of the interaction coefficient, a, cannot be calculated from such small deviations of $g(\theta_-)$ from unity. One finds that, qualitatively, $k_2^- > k_1^- \cdot c_{Cd2+}$ up to the highest concentrations.

An important step in calculating the six unknown parameters a, b, $k_{1,2}^\pm$, is the consideration of the dependence of the cathodic decay times on the concentration, c_{Cd2+}, shown in Fig. 5. Generally, the transient currents flowing after switching from the equilibrium potential to another constant potential are given by [9] inserting [3] and [4] and the change of coverage with time which may be calculated from [13]

$$Q \cdot d\theta/dt = \left[k_1^-(\epsilon) \cdot a_{Cd2+} + k_2^+(\epsilon)\right] g(\theta) - \left[k_1^+(\epsilon) + k_2^-(\epsilon)\right] f(\theta) \qquad [13]$$

where Q is the charge necessary to cover the bare cadmium surface completely with monovalent cadmium. Equation [13] describes how the steady state of [12] is approached from the equilibrium coverage θ_0 at $t \to 0$. Due to the complicated nature of the functions $f(\theta)$ and $g(\theta)$ an exponential decay of the current is generally not to be expected. The decay should be faster than exponential as long as θ changes rapidly at small times after a potential step. Such a behavior was observed experimentally. However, if either θ or $(1-\theta)$ are close to unity or if θ is close to its steady-state value, the variation of the exponential terms of [5] and [6] with θ can be neglected. The coverage then changes, as if the isotherm were of the Langmuir-type. The excess current densities decay almost exponentially according to the solution derived by Gerischer and Mehl (13)

$$\frac{j(t) - j(\infty)}{j^* - j(\infty)} = \exp -\frac{t}{\tau} \qquad [14]$$

The current density, j^*, is obtained by extrapolation to $t \to 0$ of the exponential decay, but it is not the true transient current density for $t \to 0$. The decay time, τ, is given by

$$Q/\tau \approx \left[k_1^-(\epsilon) \cdot a_{Cd2+} + k_2^+(\epsilon)\right] \exp\left[-a\theta\right] + \left[k_1^+(\epsilon) + k_2^-(\epsilon)\right] \exp\left[-b(1-\theta)\right] \qquad [15]$$

In [15], the rate constants are corrected for their dependence on the coverage. By definition, the rate constants, k_1^+ and k_2^-, correspond to $\theta = 1$ and the rate constants, k_1^- and k_2^+, to $\theta = 0$.

The reciprocal, cathodic and anodic decay times at high overvoltages were found to change with the potential in the same way as the rate constants, in agreement with [15]. Decay times are determined by the fastest of the rate constants. Cathodic decay times are expected to be independent of the activity, a_{Cd2+}, at low activities and proportional to the activity at high activities. From Fig. 5, it follows that $k_1^-(\epsilon) \cdot c_{Cd2+} \cdot \exp\left[-a\theta\right]$ apparently surpasses $k_2^-(\epsilon) \cdot \exp\left[-b(1-\theta)\right]$ even at relatively low concentrations, c_{Cd2+}. On the other hand, rather small deviations of $g(\theta_-)$ from unity are calculated from Fig. 2. Both the experiments of Fig. 2 and 5 are compatible, only if $b > a$. However, a whole set of interaction coefficients does agree with the two experiments almost equally well.

The ambiguity is completely removed by considering the interdependence of the cathodic and the anodic rate constants. Thermodynamics requires $k_1^+(\epsilon) \cdot$

$k_2^+(\epsilon) = k_1^-(\epsilon) \cdot k_2^-(\epsilon) \cdot a_{Cd2+}$ at the equilibrium potential, $\epsilon = \epsilon_o$. A second condition to be fulfilled is that from its constant value at positive potentials, $f(\theta_+)$ must begin to drop rapidly as soon as the potential gets more negative than about $\epsilon = -0.6$V *vs.* SCE, because of the increasing steepness of the anodic current-potential curves shown in Fig. 1 and 3. The two conditions can be fulfilled with a well-defined pair of interaction coefficients only. The selection of a pair of interaction coefficients with a large value of $A = a + b$ leads to a large rate constant, k_2^-, and a large product, $k_1^+(\epsilon_o) \cdot k_2^+(\epsilon_o)$. From the Tafel line at high anodic overvoltages and constant coverage, θ_+, the individual values of $k_1^+(\epsilon)$ and $k_2^+(\epsilon)$ are obtained. In the case of too large values of A, the calculated anodic current-potential curves are found to increase their slope at too negative potentials.

By successive approximation the parameters for optimal description of the experiments were obtained. The resulting interaction coefficients are $a = 0$ and $b = 10$. This indicates that the lateral interaction of the adsorbed monovalent cadmium only affects the activation energy of desorption. The rate constants at $\epsilon = -0.7$V *vs.* SCE are $k_1^+ = 10^{-3}$ [A/cm^2], $k_1^- = 38$ [A cm/mol], $k_2^+ = 1.7$ [A/cm^2], and $k_2^- = 8.0$ [A/cm^2]. Using these parameters the solid lines in Fig. 1, 2, 3, and 5 were calculated.

With slightly more divergent interaction coefficients such as $a = -1$ and $b = 12$, a good fit of the concentration dependence of the cathodic decay times is also obtained. However, the rate constants are left almost unchanged by such small changes, and there is very little effect on the general form of the current-potential curves.

The current-potential curves measured by Lorenz (2) for overvoltages <0.1V coincide with the calculated curves as well as the measurements in Fig. 1. However, the current densities observed in the earlier work are displaced to lower current densities by a factor of about two. This may be due to an inhibiting effect of the sulfate solutions as compared to the perchlorate solutions (11). The inhibiting effect of sulfate should be even larger than just estimated: the measurements of Lorenz (2) were performed at 20°C, the present ones at 0°C. According to the present results, the apparent symmetry of the current potential curves at potentials between $\epsilon = -0.6$V and $\epsilon = -0.8$V *vs.* SCE is due to the similar influences of k_2^- on the anodic rate and of k_2^+ on the cathodic rate.

From the rate constants one may evaluate the coverage as a function of the potential using (12). The coverage changes between the potential independent values, θ_+ at very positive potentials, and θ_- at very negative potentials, with the equilibrium coverage, θ_o, in between. The coverages, θ_- and θ_o, depend on the concentration of cadmium perchlorate as shown in Fig. 6. The coverage, θ_-, is almost proportional to the concentration for $\theta_- < 0.1$ corresponding to $c_{Cd2+} < 10^{-2}$M. The equilibrium coverage is almost proportional to the logarithm of the concentration in the range plotted in Fig. 6. The coverage, θ_+, naturally is independent of the concentration and has a value close to unity because $k_1^+ << k_2^+$. From the equilibrium coverage, the steady-state exchange current densities, $j_o(\infty)$, were calculated using [16]

$$j_o(\infty) = 2 f(\theta_o) \frac{k_1^+(\epsilon_o) \cdot k_2^+(\epsilon_o)}{k_1^-(\epsilon_o) \cdot a_{Cd2+} + k_2^+(\epsilon_o)} \quad [16]$$

or any other of the four equivalent equations to be derived from [10] and [11] for $j(\infty) = 0$. In Fig. 7, the steady-state exchange current densities are plotted as a function of the concentration, c_{Cd2+}, along with Lorenz's experimental results (2) derived from the equilibrium polarization resistance. The slopes of the two lines are exactly the same. The displacement by a constant factor is the result of the different experimental conditions, as mentioned above.

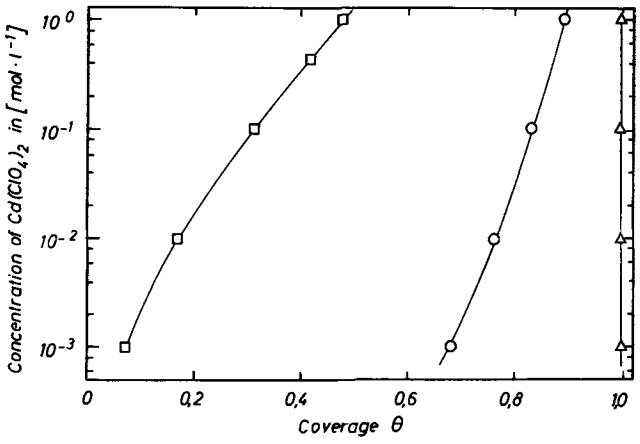

Fig. 6. Relative coverages with adsorbed monovalent cadmium, [△], at very positive potentials, θ_+; [□], at very negative potentials, θ_-, and [○], at equilibrium, θ_o, calculated from the experiments for different concentrations of $Cd(ClO_4)_2$.

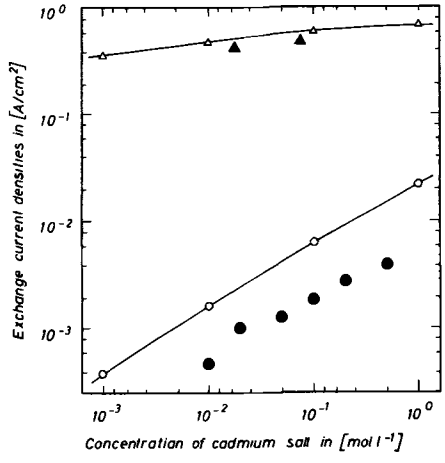

Fig. 7. Steady-state and transient exchange current densities, $j_o(\infty)$ and $j_o(0)$, for different concentrations of cadmium salt at constant ionic strength. [○], $j_o(\infty)$; [△], $j_o(0)$ calculated from the experiments; and [▲], $j_o(0)$ by direct measurements in perchlorate solutions at 0°C; [●], $j_o(\infty)$ from measurements of the equilibrium polarization resistance by Lorenz (2) in solutions containing $CdSO_4$ + 1.5M K_2SO_4 at 20°C.

At the equilibrium of the cadmium electrode the two steps [1] and [2] with two different exchange current densities are also in equilibrium. The exchange current densities of each step are obtained from [3] and [4] with $j_1 = 0$ or $j_2 = 0$. By comparison with [16] one deduces the relationship

$$2/j_o(\infty) = (1/j_{1,o}) + (1/j_{2,o}) \quad [17]$$

Under transient conditions, $j_1 \neq j_2$, but [9] is still valid. A transient current-potential curve measured for the time $t \to 0$ after switching from the equilibrium potential to other potentials should yield Tafel lines with a slope of 2 RT/F at high overvoltages. The extrapolation of the anodic and cathodic Tafel lines to the equilibrium potential should lead to a common transient exchange current density which is the sum of the exchange current densities of the two steps

$$j_o(0) = j_{1,o} + j_{2,o} \quad [18]$$

The transient exchange current densities are determined by the fastest step. On the other hand, the steady-state exchange current densities are determined by the slowest step. Since $j_{2,o}$ exceeds $j_{1,o}$ for all possible concentrations, c_{Cd2+}, the transient current densities are always larger than the steady-state current densities. Such a behavior is not generally expected but more probable than $j(0) < j(\infty)$, because

$$\frac{j(0)}{j(\infty)} = \frac{1}{2}\left[\frac{f(\theta_o)}{f(\theta_\pm)} + \frac{g(\theta_o)}{g(\theta_\pm)}\right] \quad [19]$$

as derived earlier (5). The transient exchange current densities obtained by direct measurement and indirectly by calculation from the other experiments are in excellent agreement, which can be considered as another proof for the validity of the proposed mechanism.

The first order rate constants of step [2] in both directions of the reaction are always larger than the rate constants of step [1] even at the highest cadmium perchlorate concentrations. Therefore, one might consider step [1] to be rate determining. This does not mean that step [2] is always in equilibrium. At high overvoltages the respective reverse reactions of both steps do not have any influence on the rate of the overall reaction. Although the rate constants of step [2] are relatively high, the electronic interaction between the cadmium metal and the adsorbed monovalent cadmium is still very weak. The kinetics can be explained with transfer coefficients of $\alpha = 0.5$ for both steps and with a well-defined monovalent intermediate. Therefore, the monovalent cadmium with the center of its charge in the Helmholtz layer must be separated from the metal. The obvious model is to assume that the monovalent cadmium is bound to the metal by a water bridge. Thus, step [2] is a metal/ion reaction (3) with the charge being transferred by the metal ion. On the other hand, step [1] is a typical redox reaction with electrons carrying the charge across the Helmholtz layer.

The comparatively low rate constants of step [1] may be assigned to drastic differences in the solvation sheets of cadmium ions in the solution and of adsorbed monovalent cadmium, according to the theory of redox reactions recently reviewed by Levich (25). Therefore, one may suppose that only small rearrangements of the solvation sheets of the completely discharged metal in the surface and of the adsorbed monovalent metal are left for the further reaction of step [2] resulting in a relatively large rate.

Film Formation on Copper and Alpha Brass in Aqueous Cupric-Ammonia Systems

L. H. Jenkins* and R. B. Durham

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee

ABSTRACT

Reaction rates of single crystalline copper and α-brass surfaces exposed to solutions of $Cu(NH_3)_x(OH)_2$ in ~15M aqueous ammonia have been investigated. Composition of the precipitated films formed on the surfaces was investigated and attempts made to correlate film texture and composition with the mode of attack on the metal surfaces. An estimate of the activity coefficient of NH_3 in concentrated aqueous NH_4OH could be made from the copper system data, and it is shown that film formation on brass occurred outside the limits defined in a general model of relative interfacial concentrations in the system. Also, it was observed that a thin film developed on α-brass prior to tarnish formation. Nonhomogenous breakdown of this initial film, which was more protective than the tarnish layer, occurred by means other than mechanical rupture. Some applications of the data to stress related corrosion phenomena are discussed.

Ammoniacal solutions of copper sulfate have been employed by Mattson (1), Forty and Humble (2), and McEvily and Bond (3) to investigate stress related corrosion phenomena of α-brass. The tendency of such solutions slowly to form precipitates over long periods of time somewhat affected the reproducibility of experimental results and introduces some uncertainty and difficulty in attempts to understand associated chemical phenomena. To circumvent this difficulty, Pugh, Montague, and Westwood (4) used solutions of $Cu(NH_3)_x(OH)_2$ in either 15M or 1M aqueous NH_3 in studying the role of aqueous complex ions of copper in the cracking of α-brass. Further studies by Pugh and Westwood (5) in 15M aqueous ammonia containing predominantly $Cu(NH_3)_5(OH)_2$ were interpreted to indicate two mechanisms of stress corrosion cracking, one in the presence of a tarnish layer and another in its absence. Also, they concluded that behavior was strongly influenced by the concentration of the complex cupric ion $Cu(NH_3)_5^{++}$. Recently Bertocci (6) proposed a model reaction mechanism whereby the reaction rates observed by Pugh *et al.* were explained in terms of enhanced transport of the oxidizing agent across the diffusion layer. The model assumed that immediately at the metal-solution interface the total concentration of cupric species was zero, having all been reduced to cuprous by the act of oxidizing the metal. In the case of copper metal in the systems reported here the cuprous concentration at the interface would be simply twice that of the bulk cupric concentration. For brass, the relative concentrations of zinc and cuprous ions at the interface would be determined by the composition of the alloy. However, uncertainties still exist regarding the exact nature of the films observed by Pugh and co-workers and the relationships between structure of the substrate, composition of the films, and composition of the solution. The following report concerns data collected in attempts to define these relationships.

Experimental Data

Materials and methods.—All data reported here were collected on coin shaped single crystalline metal specimens approximately 2.5 cm diameter x 0.7 cm thick. Prior to use the copper specimens were electropolished in an acid copper phosphate bath and rinsed in dilute solutions of H_3PO_4. Crystals of α-brass [70 w/o (weight per cent) Cu-30 Zn] were chemically polished using a solution after Mitchell (7) on a flat, soft cloth surface. Following rinsing, washing, and drying, the flat, polished surfaces were then spring-mounted with gentle pressure to a Viton O-ring of 1.6 cm ID at the end of a glass tube of the same dimensions. In this manner the orientation to be studied was isolated within a container and also served as the bottom of the chamber into which the test solution was introduced. The glass tube was ~ 15 cm long.

Solutions of varying copper content were prepared by dissolving Cu_2O in air-saturated aqueous solutions of ~ 15M NH_3. The air served to oxidize the cuprous ions to cupric so that the final test solutions consisted of air saturated solutions of soluble complex cupric hydroxides: $Cu(NH_3)_x(OH)_2$. Most observations were recorded in systems initially containing either 0.95, 1.90, or 3.80 g/l total copper (0.015, 0.03, 0.06M and hereafter referred to as test solutions II, III, and IV, respectively). However, some data also were obtained from ammoniacal solutions 0.015M in $Cu(NH_3)_x(OH)_2$ and 0.09M in KOH (hereafter referred to as test solution IIa). In all experiments the volume of test solution was 15 ml so that, following introduction of solution into the chamber formed by the metal surface and glass cylinder and closing the open tube end, a volume of air equal approximately to that of the solution was enclosed within the system.

At the conclusion of the tests, solutions were decanted and analyzed by spectrophotometric means for metal content. Sample surfaces were rinsed in distilled water and dried carefully in a gentle air stream in a manner which would not disturb any films present on the surface. Surfaces were then examined and photomicrographs taken. In some cases films cracked on drying revealing the substrate such that it was possible to measure average film thickness directly. (In a few instances the thickness of semitransparent, very thin films also could be measured.) The films were then dissolved in solutions of 50% by volume aqueous ethylenediamine, which subsequently were analyzed for metal content and the results correlated with measured film thicknesses. The clean metal substrate was then examined and again photomicrography used to record the observations. Films were stripped from certain other representative samples and examined by electron diffraction techniques in order to establish more accurately the components of films formed in typical solutions.

Copper metal-ammonia systems.—Compositions of test solutions II, III, and IV are within the limits of concentrations termed ranges II, III, and IV, respectively, by Pugh and Westwood (5), who reported the following observations for α-brass reacting under an

* Electrochemical Society Active Member.

applied stress within these ranges of concentration: In range II fracture occurred in both a trans- and intercrystalline manner after the formation of a brown, loosely adherent film. In range III failure occurred before visible surface films were formed. Range IV specimens were coated with the characteristic tarnish layer, and fracture was largely intercrystalline.

Test solutions II, IIa, III, and IV were used in the manner previously described to study the effects of solution composition and crystallographic orientation on the rate of dissolution of copper as a result of the following reactions

$$Cu(NH_3)_x^{+2} + Cu^o \overset{NH_3}{\leftrightarrows} 2Cu(NH_3)_2^+ \quad [1]$$

$$2Cu(NH_3)_2^+ + 1/2\,O_2 + H_2O \overset{NH_3}{\leftrightarrows} 2Cu(NH_3)_x^{+2} + 2\,OH^- \quad [2]$$

Although often thick by microscopic standards, from an analytical viewpoint the total material contained in a film over a copper substrate in all cases was insignificant as compared with the total material removed from the specimens and dissolved in the solution in which the film formed. Therefore, the rate of increase of copper in solutions shown in Fig. 1 indicates that the rate of weight loss of copper single crystals was independent of both crystal orientation and composition of the test solutions. The latter observation was unexpected for while, in general, films were not detected on copper in type II test solutions, exposure to solutions IIa, III, and IV caused immediate film formation.

In type II test solutions film formation was observed only after the copper content of the solution had increased to ~ 2 g/l (after ~ 90 hr reaction) due to the occurrence of reactions [1] and [2]. The onset of precipitation at this concentration suggested a means of estimating the activity coefficient of NH_3 in these systems. Although the equilibrium constant for the reaction

$$Cu^{++} + Cu^o \leftrightarrows 2Cu^+ \quad [3]$$

is $\sim 10^{-6}$, the stability constants for cuprous and cupric ammonia complexes is such that equilibrium is established in solutions of concentrated NH_3 only when reaction [3] is shifted almost completely to the right. In a series of experiments equilibria were established in different solutions initially containing varying amounts of $Cu(NH_3)_x(OH)_2$ in ~ 15M aqueous NH_3 exposed to copper metal in a closed system. It was determined that the limit of Cu_2O solubility (shown by the presence of a "tarnish" film at equilibrium) and

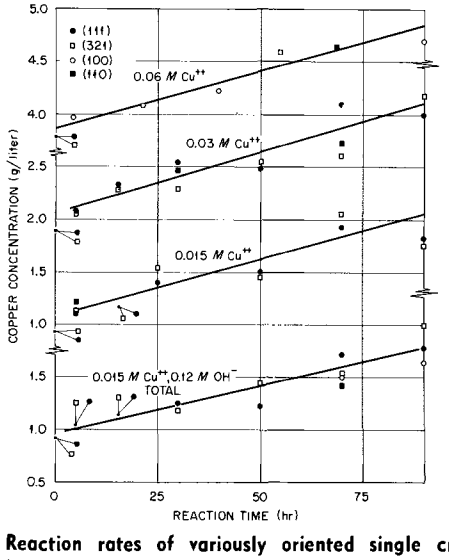

Fig. 1. Reaction rates of variously oriented single crystalline copper surfaces as a function of exposure time and solution composition in cupric-ammonia solutions.

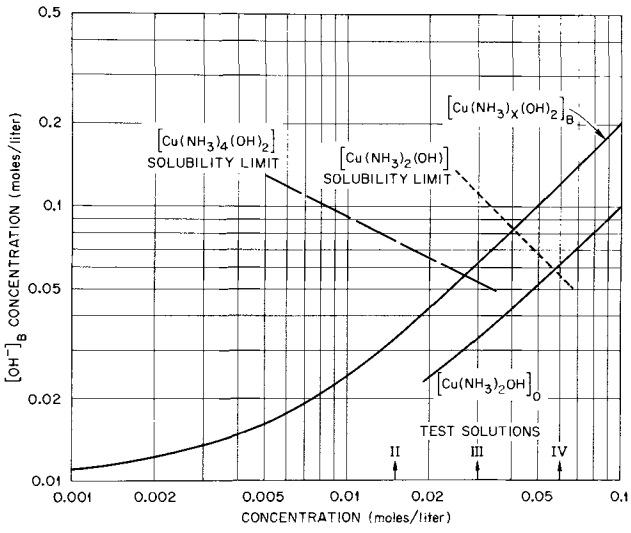

Fig. 2. Hydroxyl ion concentration in ~ 15M aqueous ammonia shown as a function of the concentration of $Cu(NH_3)_x(OH)_2$ in the system. Compositions of test solution types II, III, and IV also are indicated. Subscripts "B" and "O" refer to bulk and interfacial concentrations, respectively, when a copper surface is exposed to the solutions. Values of $[Cu(NH_3)_2OH]_0$ are calculated, of course, and are simply twice the corresponding bulk cupric concentrations.

the complete conversion of all cupric ions to cuprous (as demonstrated by the change from the characteristic deep blue color of cupric ammonia complexes to the colorless cuprous form) occurred simultaneously only in solutions initially containing ~ 1.90 g/l (0.03M) copper as soluble $Cu(NH_3)_x(OH)_2$. Therefore, the solubility limit of $Cu(NH_3)_2OH$ in ~ 15M aqueous ammonia was ~ 0.06M.

Using this value it is possible to estimate the activity coefficient for NH_3 in these concentrated systems: From the relationship

$$\frac{[NH_3]}{[OH^-]} = [NH_4^+]\ 5.5 \times 10^4 \ ^1 \quad [4]$$

it is readily seen that any contribution to the total hydroxyl ion concentration from the NH_4OH inevitably present must be small compared with the ~ 0.06M concentration associated with the cuprous complex, and may be neglected at this concentration. Then assuming that at this composition activity coefficients for all components other than NH_3 are unity, from the relationship

$$[Cu^+]\,[OH^-] = 1.26 \times 10^{-15} \quad [5]$$

and the stability constant of the cuprous ammonia complex

$$[NH_3]^2 = \frac{[Cu(NH_3)_2^+]}{[Cu^+]} \times 1.38 \times 10^{-11} \quad [6]$$

an activity coefficient of ~ 0.4 can be calculated for NH_3 in ~ 15M aqueous ammonia.

Using this value in Eq. [4] it is possible to determine the relationship illustrated in Fig. 2 between the total hydroxyl ion concentration, due to the presence of NH_4OH as well as $Cu(NH_3)_x(OH)_2$, and the concentration of the latter dissolved in concentrated aqueous ammonia. It is seen that at concentrations of $Cu(NH_3)_x(OH)_2 \gtrsim$ 0.03M practically all hydroxyl ions are furnished by the copper salt, while at lower concentration of the cupric complex significant contribution is made by the ammonium hydroxide present in the system. Figure 2 also illustrated another interesting feature of these solutions. From the relationships

$$[Cu^{+2}]\,[OH^-]^2 = 1.52 \times 10^{-20} \quad [7]$$

[1] See ref. (8) for the origin of all constants quoted here.

and

$$\frac{[Cu^{++}]\,[NH_3]^4}{[Cu(NH_3)_4{}^{++}]} = 2.35 \times 10^{-13} \qquad [8]$$

by using the previously indicated values for activity coefficients, it is possible to calculate the solubility limit of $Cu(NH_3)_4(OH)_2$ in the system. The figure shows that in ~ 15M aqueous NH_3 the solubility of $Cu(NH_3)_4(OH)_2$ could not exceed ~ 0.027M. Therefore, the primary effect of the formation of a $Cu(NH_3)_5{}^{++}$ complex ion, which Pugh *et al.* (4) reported to be the predominant complex cupric species in these systems, is to increase the total amount of copper which can be dissolved in such solutions. The calculations show that a saturated solution of $Cu(NH_3)_4(OH)_2$ could not generate sufficient cuprous ions at a copper interface to exceed the solubility of $Cu(NH_3)_2OH$ and form a tarnish film.

Also, the solubility limit of $Cu(NH_3)_2OH$ calculated from [5] and [6] is shown, as well as the maximum possible concentration of this species at a copper metal-solution interface when it is assumed that, as in the model proposed by Bertocci, at the interface all cupric ions have been converted to cuprous by the occurrence of reaction [1]. The calculations indicate that for interfacial concentrations which correspond to $Cu(NH_3)_x{}^{+2}$ bulk concentrations greater than ~0.028M, solubility of $Cu(NH_3)_2OH$ should be exceeded at the metal solution interface. This is in excellent agreement with the observed onset of film formation whenever the concentration of the cupric complex increased to ~ 0.03M in type II test solutions. Further agreement was indicated by immediate film formation on copper specimens when exposed to solution types IIa and III. The bulk hydroxyl ion concentration in the former solution totaled 0.12M and the cupric complex 0.015M. Using 0.4 for the activity coefficient of NH_3, Eq. [5] and [6] can be used to show that concentrations are such that conditions are established in which the solubility of $Cu(NH_3)_2(OH)$ is just exceeded at a copper metal interface immediately upon immersion in either type IIa or III solutions. Type IV solutions, of course, produced a great excess of cuprous species at the interface over that necessary to exceed the solubility of $Cu(NH_3)_2OH$.

Despite differences in composition, the type, as well as the rate, of film growth on copper surfaces was precisely the same in these three test solutions. In early growth stages (< ~ 15 hr exposure) a semitransparent film was formed through which features of the substrate often could be seen. The film appeared brown when wet, but a mottled green-yellow-red when dry. It was firmly adherent, compact, and possibly bore some epitaxial relationship to the single crystal substrate. After longer reaction times the films appeared blue-black when wet, and only slightly lighter in color when dried. Average film thicknesses gradually increased from ~ 2μ at 30 hr to ~ 8μ at 50 hr, although film growth did not always occur in a uniform manner for occasionally some areas were covered by a slightly thicker film than others. When dried the black film occasionally cracked or flaked away from the metal surface, and infrequently wet films did not adhere well to the substrate. Chemical analysis of the early tarnish film indicated it to be extremely porous, containing only about 20% of the theoretically possible Cu_2O. After still longer reaction times (50-90 hr) the films did not undergo further changes in appearances; nor did they grow much thicker, for the thickest films measured only ~ 10μ after 90 hr reaction. However, they did become much more dense and compact, and analysis revealed these films contained ~ 80% of the Cu_2O theoretically possible. Also, they adhered quite firmly to the substrate.

Electron diffraction measurements revealed that in all cases the films consisted primarily of Cu_2O. It seems, therefore, that differences in appearances, color, etc., arose from causes other than major differences in composition. No effects of orientation on film types were detected. However, for any given set of conditions, films on the copper (111) adhered better than on other orientations, although only slightly better than on the (100).

Reaction in type II solutions produced metal surfaces free of visible films, but greatly etched and faceted as illustrated in Fig. 3. Removal of equal amounts of material in type III solutions through thick oxide films on the surfaces resulted in a much more uniformly attacked surface substrate, as is also illustrated. Furthermore, the greater the supersaturation of CuOH produced at the interface, the more uniform was the surface attack as is illustrated in the figure. The appearance of the (100) substrate after prolonged reaction in the two types of test solution not shown in Fig. 3 are illustrated in Fig. 4. It is clear that test solutions III and IIa react in a very similar manner, but do not cause as uniform an attack as observed with type IV solutions.

The influence of oxide formation on reaction at a twin boundary is shown in Fig. 5. Since, as previously noted, reaction rates were the same in all test solutions, the different reaction times illustrated in Fig. 5 are directly proportional to the amount of material removed. Note that less material was removed preferentially at the boundary in every case where reaction occurred through a thick film covering the surface. Only after 70 hr in test solution III was boundary attack equivalent to that after only 2 hr in type II solution. To examine further the effects of grain boundaries on reactivities, polycrystalline copper specimens also were exposed to the test solutions. Typical results are illustrated in Fig. 6. Attack in type II solutions produced the normally heavily etched surface containing pits, etc., but type III solutions caused drastic alterations in surface appearances. As illustrated, in the latter case certain areas apparently reacted very little while others reacted to a greater extent. Comparison of these two illustrated surfaces indicated little relationship between grain boundary structure and the reactive areas on the film-covered polycrystal surface, although possibly the least reacted areas originally resulted from an epitaxial relationship between the film and substrate. On the illustrated surface obtained in type III solutions the areas of deepest attack were ~ 5μ, and as shown, reaction in these areas was more or less uniform on a large scale and no deep crevices or other evidence of preferential grain boundary attack was observed.

Brass-cupric ammonia systems.—With the exception of a few samples ~ 9° from the (111), the data were obtained from α-brass surfaces oriented (111). At the termination of reaction, solutions were analyzed for both copper and zinc content. In solution types II, IIa, III, and IV there was an initial decrease in copper content of the solutions so that part of the film concomitantly developed on the brass surface formed from copper initially in solution; and although the presence of zinc in solution could be detected, the zinc analysis was not sufficiently sensitive at low concentrations to conclude that its increase corresponded to the decrease in copper content. Therefore, little comparison can be made of the initial rates of reaction with those of copper, nor of the ratio of zinc/copper concentrations in solution. However, as reactions proceeded, the bulk copper concentrations in solution increased such that original concentrations were exceeded, and of course zinc concentrations increased with time.

When exposed to test solutions II, IIa, III, and IV films immediately began to form and grow on the brass surfaces. (It should be recalled that films on copper surfaces exposed to test solution II were not observed until after about 90 hr reaction time when the composi-

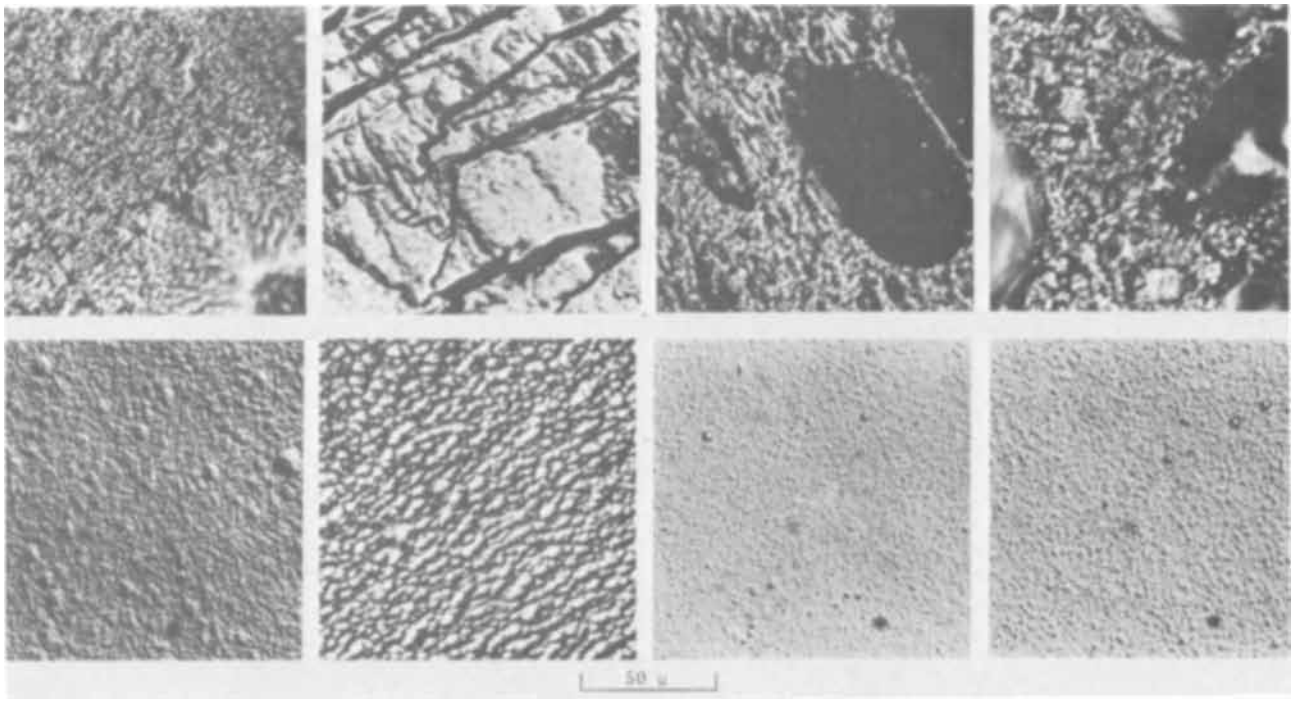

Fig. 3. Effects of orientation and solution composition on surface appearances. Top left to right: (111), (321), (110), and (100) after 90 hr exposure to type II solutions without visible film formation. Bottom illustrates the same orientations as above, but are photographs of metal substrates after "tarnish" film removed following 90 hr reaction in type III solutions for the (111) and (321), and the same length of exposure to type IV solutions for the (110) and (100). Although surfaces were film covered during the entire exposure to type III and IV solution, approximately the same amount of material had been removed from each of the eight surfaces illustrated.

tion of the solution had changed to approximately that of type III test solutions.) Like the copper systems, the rate and type of film growth on brass was approximately the same in all these test solutions. In the earliest stages ($< \sim 2$ hr) a relatively thin, more-or-less transparent film through which features of the substrated were discernible formed over the surface in an apparently homogenous manner. Interference colors were seen, and the film appeared firmly attached to the substrate. At exposure times greater than 2 hr it became obvious that further reaction did not proceed in a uniform manner over the entire surface. On portions of the surface the film appeared relatively unchanged from earlier appearances, but in other areas the film became opaque and darkened to a brown hue. When completely freed of all films it could be observed that the areas under dark film patches were more deeply etched than those portions of the surface which had been covered by the transparent film. With time the brown areas of the film changed to a dark blue-black color, and the regions covered by dark film islands increased at the expense of the less reactive areas under the thin transparent film. After approximately 70 hr, the mottled appearance vanished as the surfaces were entirely covered with the familiar "tarnish" film. But even on removal of the tarnish film formed during 70 or more hours reaction time, examination of the substrate revealed that attack had occurred in the described manner, for although all areas had reacted extensively, some had reacted to a much greater extent than others. All these observations are illustrated in Fig. 7 which shows the growth of island areas and concomitant changes in the structure of the substrate.

Direct measurements of tarnish film thicknesses could not be made. However, in general they appeared to fill the etched crater containing them and not to protrude significantly above the surface covered by the transparent film. Since the thicker films were contained in what was effectively an enormous etch

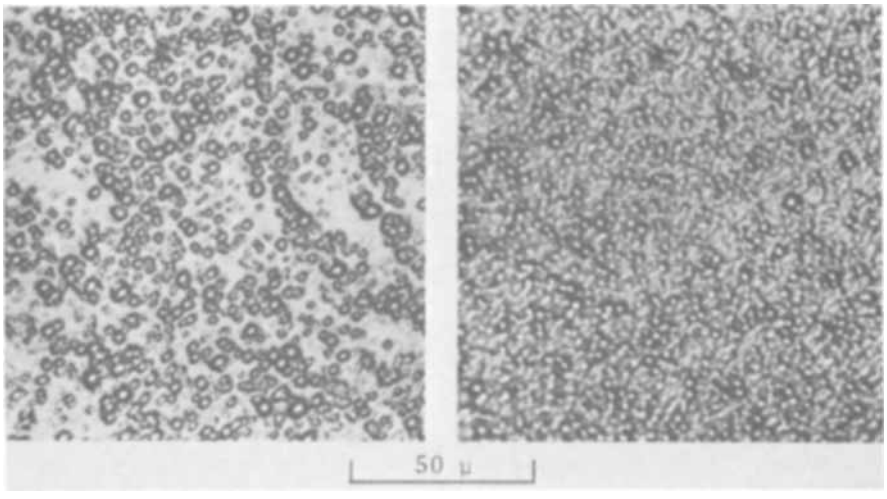

Fig. 4. Metal substrates of (100) after film removed following 90 hr reaction in solution type IIa (left) and III (right). Total reaction at these surfaces was the same as for those illustrated in Fig. 3.

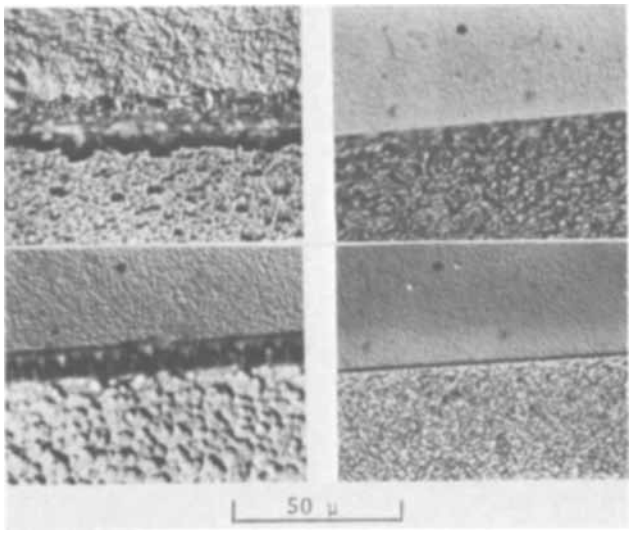

Fig. 5. Effects of reaction time, orientation, and solution composition on a bicrystal surface. In each photograph the top surface illustrated is a (111) and the bottom a (511). Top left: after 2 hr in type II solution without visible film formation; top right; metal substrate following film stripping after 2 hr reaction in type III solution; bottom left: metal substrate following film stripping after 70 hr in type III solution; bottom right: metal substrate following film stripping after 15 hr reaction in type IV solution.

pit with extremely rough and irregular features, they appeared reasonably adherent. Certainly once the tarnish film had developed over the entire surface the films appeared extremely compact and adherent.

Electron diffraction was used to establish that the tarnish films consisted of Cu_2O, ZnO, and Cu. Whether the slight traces of copper metal detected had their origin in the metal or in the solution is not known. However, the former is considered more likely since analysis indicated the tarnish films to be $\sim$ 80% Cu_2O and 20% ZnO so that no evidence for selective zinc dissolution was found in thick films. The traces of metallic copper possibly were inclusions of metal detached with the film during the stripping process.

In order to confirm the observations of Pugh and Westwood that film formation occurred in $\sim$ 15M aqueous ammonia with $Cu(NH_3)_x(OH)_2$ concentrations less than $\sim$ 0.01M, brass specimens were exposed to concentrated solutions of ammonia 0.005M and 0.007M in the soluble cupric hydroxide complex. Film formation was observed on surfaces in these solutions within 2 hr, and after 4 hr the unmistakable beginnings of nonhomogenous attack of the type illustrated in Fig. 7 were observed.

Discussion

At this point it is interesting to use Bertocci's model for interfacial and diffusion layer processes to construct a diagram of the bulk and interfacial concentrations of various components in a system of α-brass (70% Cu-30% Zn) reacting in cupric-ammonia systems. The results are shown in Fig. 8. For purposes of comparison, the corresponding concentration ranges of Pugh and Westwood are also indicated on the graph. The solubility limits of cuprous and zinc species are shown, as are their calculated maxima interfacial concentrations. Zinc relationships were calculated from the values

$$[H^+]^2\,[ZnO_2^{2-}] = 10^{-29} \qquad [9]$$

$$[Zn^{2+}]\,[OH^-]^2 = 10^{-17} \qquad [10]$$

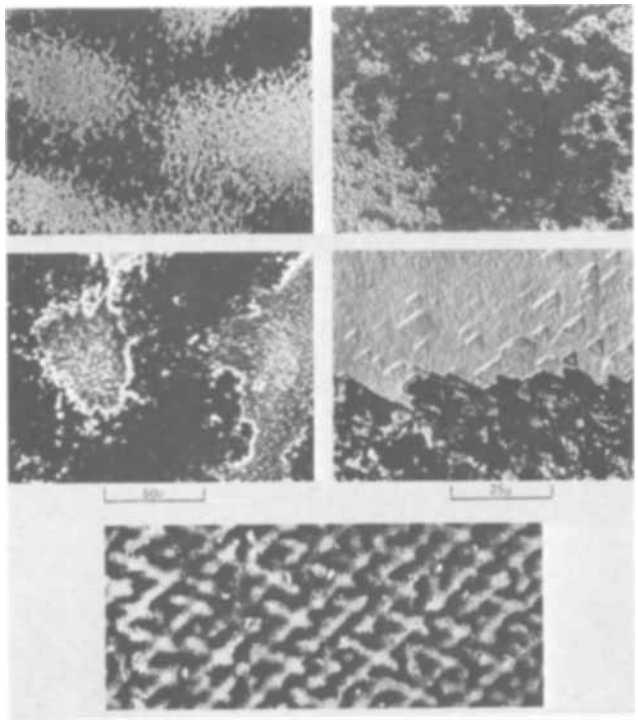

Fig. 7. α-brass surfaces oriented (111) after exposure to various test solutions. Top: after 4 hr in test solutions containing 0.005 g/l Cu (1/3 type II solution concentration), film covered surface (left), and substrate after film dissolved (right), magnifications as indicated. The dark aspect of the film is due to the presence of the "brown" appearing oxide. The substrate appears dark even when the brown film is removed because vestiges of the film remain and also because the area is heavily faceted. Middle: after 20 hr in type IV solution; surface illustrated at left was completely film covered and dark areas correspond to tarnish film, the lighter to the thin semitransparent film; the substrate after the film was dissolved away is illustrated at the right, and the highly local nature of the attack is emphasized. The bottom photograph is a low magnification picture of a brass substrate (originally completely covered with "tarnish" after 90 hr in type II solution) following dissolution of the film in aqueous ethylenediamine. The dark areas reflect the heavy faceting underlying the thick tarnish, the light areas reacted much less extensively. Note the geometric nature of the attack on this unstressed surface oriented $\sim$ 9° from the (111).

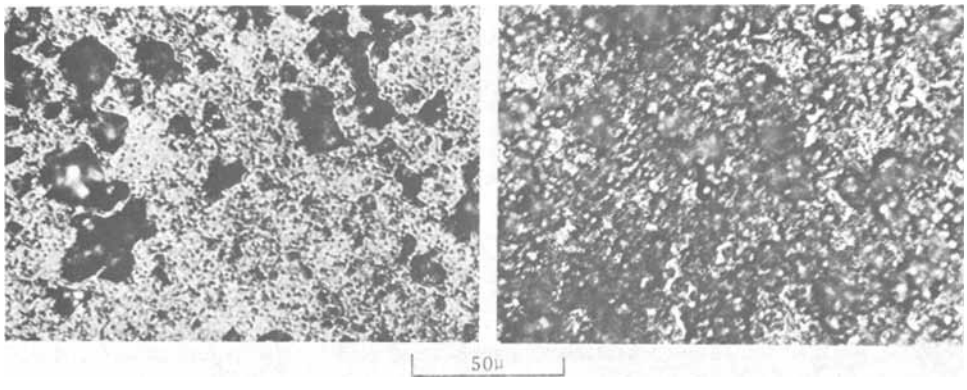

Fig. 6. Polycrystalline copper surfaces after 5 hr exposure to type II solution (left) and 70 hr to type III (right).

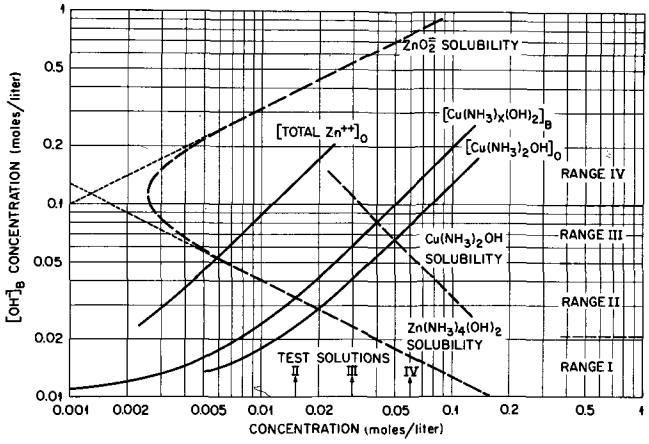

Fig. 8. Concentrations and solubility limits of various species in systems of α-brass exposed to solutions of ~ 15M aqueous ammonia containing the indicated concentrations of $Cu(NH_3)_x(OH)_2$. The subscripts B and O refer respectively to bulk concentration and those at the α-brass-solution interface.

$$\frac{[Zn^{2+}]\,[NH_3]^4}{[Zn(NH_3)_4{}^{2+}]} = 10^{-9} \qquad [11]$$

As Bertocci pointed out, Zn exhibits a solubility minimum in the system due to its existence in solution in two forms. However, note that under the conditions reported here, as well as those of Pugh and Westwood, zincate ions could not have been formed in quantities sufficient to alter interfacial hydroxyl ion concentrations to any significant extent. According to the model, complete reduction of cupric ions to cuprous produces zinc and cuprous ions at the interface in quantities proportional to the composition of the brass. The calculations shown in Fig. 8 indicate $Zn(OH)_2$ should precipitate slightly before the solubility of CuOH was exceeded. Moreover, they also indicate that no precipitate should form at the interface until the bulk concentration of $Cu(NH_3)_x(OH)_2$ exceeded ~ 0.025M (test solution type III; Pugh and Westwood range III). Since film formation on α-brass is reported here, as well as by Pugh and Westwood, at much lower bulk cupric complex concentrations, it is apparent that experimental observations in α-brass systems do not agree with the proposed model.

It could be assumed that initial reaction occurred by the selective oxidation of zinc without dissolution of copper from the metal, and that cupric ions in solution were reduced to the metallic state. Such an occurrence would produce the maximum possible interfacial zinc ion concentration in that it would exactly equal the bulk cupric ion concentration. Even so, Fig. 8 shows $Zn(OH)_2$ should not precipitate at cupric ion concentrations less than ~ 0.015M, although film formation was observed at concentrations smaller by a factor of three. Despite this discrepancy, the values of the constants used in [9], [10], and [11] probably are not sufficiently accurate to justify absolute rejection of the possibility of initial selective zinc oxidation.

The most obvious reason for film formation on single crystalline α-brass surfaces outside the limits established by Bertocci's model could be assumed to result from locally higher concentrations than allowed in the model which presupposes a uniform attack. Such events might account satisfactorily for thick films over reactive regions, but not for the thin films always observed over the remaining surface areas. At any rate it is apparent that Bertocci's model of interfacial phenomena adequately defines suitable conditions for film growth to occur, but it does not define the limiting conditions for film formation in the α-brass system. Moreover, it should be realized that the model has limited application to the systems reported here and to those of Pugh and Westwood since in deriving the model consideration was restricted to conditions in which films were not formed.

The rather periodic occurrence of areas of excess reactivity over the surface of brass single crystals (see Fig. 7) suggests that such areas did not develop because of the defect structure of the substrate or film. Surface appearances imply that the initial semitransparent film on brass was essentially of a protective nature. Apparently at random locations on the surface the film was penetrated, and further reaction of a highly local nature occurred in these areas. Meanwhile, nearby areas reacted to a very limited extent. Obviously the more reactive areas were influenced by the orientation of the brass since reaction proceeded along preferred crystallographic directions. The data do not suggest that the passive areas played an active role in the dissolution process, and it is highly doubtful that reduction of cupric ions, for example, occurred at these locations. Had this happened the tarnish film should have grown at these sites immediately on exposure to the more concentrated type IV solutions since the solubility of $Cu(NH_3)_2(OH)$ would have been exceeded at the interface. As this did not occur, it seems reasonable to suppose that, due to the fact Cu_2O is a p-type and ZnO an n-type semiconductor, perhaps the thin oxide films covering brass were composed of a mixture of these two oxides such that electron conduction became difficult.

Application to Stress-Corrosion Phenomena

While all the data reported here were gathered from unstressed specimens, the observations do have some applicability to similar systems in which stress related phenomena were observed, particularly those of Pugh and Westwood. The chemical system of Forty and Humble and of McEvily and Bond was slightly different from that employed in these studies, but the chemistry of films formed in all these systems is sufficiently similar to give some validity to reasonable comparisons.

Information from both copper and brass systems indicates that the dark, tarnish film is of a protective, but not of a passivating nature. On copper the reaction rate was not hindered by the formation of very thick oxide layers, and clearly the tarnish on brass formed over the more reactive areas. This is not to conclude that the thin passive films on brass differed greatly in composition from the tarnish film. While this might well be true, it could not be demonstrated, and comparison with films over copper serves as a reminder of the possibility that the differences could have been only of density and texture.

Since brown films on α-brass actually only represent the early stages of tarnish film formation, it appears highly unlikely that "brown" and "tarnish" films functioned in different manners during stress-corrosion processes in the studies Pugh and Westwood conducted in concentrated aqueous ammonia. Tarnish formation seems primarily indicative of the breakdown of an initial passive film and a reaction rate sufficient to permit more rapid film growth. Then, since highly local attack was observed on these unstressed brass surfaces, it appears that mechanical rupture of the tarnish film in similar stressed systems is a sufficient, but not a necessary, condition for nonuniform reaction to occur. As a matter of fact, the observations reported here would suggest that in the absence of truly passive films there is little effect of substrate structure, and that interfacial processes conductive to tarnish formation are not compatible with those necessary to maintain the passive film on α-brass. Of course this does not invalidate the observations of others indicating a relationship between cracks generated in the tarnish film by flexing and subsequent attack and crack formation in the brass substrate. Even if no other effects were obtained by

such procedures, the beneficial influence on reaction rates by diffusion in solution contained within a crack rather than through an amorphous oxide film is apparent. Also, McEvily and Bond have pointed out that although Forty and Humble's specimens were deformed to such an extent that slip bands were formed, while such massive deformation was certainly sufficient to establish a correspondence between cracks in the tarnish and in the metal substrate, cracking of the metal could occur at much lower stresses.

Occurrence of reaction on unstressed single crystal brass surfaces in an enhanced manner along <110> crystallographic directions, as illustrated in Fig. 7, suggests an explanation for inter- or transgranular cracking in these systems. If solution composition is such that extensive reaction occurs before a film is formed, it is reasonable to expect a certain degree of intergranular attack as a result of enhanced reactivity at grain boundaries. Conversely, if solution compositions are such that films are formed immediately, transgranular cracking should increase as selective attack at grain boundaries is decreased and the structure of individual metallic grains becomes more important. As a matter of fact, a reasonable argument can be made that it is not always necessary to postulate surface layer embrittlement and film rupture associated with applied stress to understand stress related corrosion phenomena. As on the unstressed specimens reported here, film penetration (without mechanical rupture) could occur on stressed specimens in a random manner. Reaction progressing along preferred directions occasionally could encounter dislocation pile-ups. Alternatively, film penetration could occur coincidentally through unstressed film covering areas of dislocation pile-ups in the metal substrate.

Conclusions

1. Reaction rates at copper surfaces were independent of the presence, thickness, or appearances of films formed on the metal surfaces.

2. The activity coefficient for NH_3 in 15M aqueous ammonia is $\sim$ 0.4.

3. The significance of $Cu(NH_3)_5^{2+}$ formation in concentrated aqueous ammonia apparently is to permit greater total cupric complex concentrations than can be achieved with the less soluble $Cu(NH_3)_4^{2+}$ form.

4. Visible films formed on copper surfaces always consisted primarily of Cu_2O, even though vastly different in appearances due to conditions of formation and growth.

5. The model proposed by Bertocci for diffusion layer phenomena and interfacial concentrations is useful in defining conditions for film growth, although not necessarily the limiting conditions for film formation.

6. A thin, colorless film formed on α-brass acted as a truly passive film, but tarnish films were not as protective. The composition of the passive film could not be determined, but tarnish films were composed primarily of Cu_2O and ZnO in approximately the proportions the metals were contained in the brass specimens.

7. Mechanical rupture was not a necessary condition for penetration of the passive film in α-brass. Once film breakdown had occurred, highly local reaction proceeded along crystallographically preferred directions in unstressed specimens.

On the Correspondence between Electrochemical and Chemical Accelerated Pitting Corrosion Tests

B. E. Wilde* and E. Williams

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

For some years now, many workers have been active in the development of a stainless steel that is resistant to pitting and crevice corrosion in halide media. Electrochemical techniques combined with statistical multiple-regression analysis have beeen used to derive a relationship between pitting susceptibility and chemical composition. Recent publications in the literature have suggested, however, that the use of electrochemical accelerated tests for pitting corrosion studies leads to erroneous conclusions about the pitting susceptibility of alloys. This paper describes the results of a program designed to investigate the above reports and firmly establish whether indeed electrochemical techniques can be used as valid accelerated tests in pitting-corrosion studies.

Extensive experimental investigation in 1*M* sodium chloride on Type 430 stainless steel have shown an excellent correlation between electrochemical and chemical techniques, both in visually observed pitting susceptibility and metal weight loss data. Further, data obtained in 1*M* sodium chloride containing different dissolved gases have indicated why other authors failed to obtain any correspondence between electrochemical and chemical accelerated pitting tests. Values of the critical breakdown potential were found to vary from -0.035 V_{SCE} to -0.185 V_{SCE} for the same steel in 1*M* NaCl saturated with oxygen and hydrogen, respectively.

Controlled potential chemical tests have shown, that although pitting can occur at potentials active to the breakdown potential, the corrosion potential in a given redox system rises to values more noble than this latter potential, as a necessary prerequisite for pit initiation.

Electrochemical techniques have been used extensively in the study of passivity breakdown and the development of alloys resistant to pitting corrosion. Brennert (1), Mahla and Nielson (2), and Kolotyrkin (3) have employed measurements of the "critical breakdown potential for passivity," E_c, to predict the resistance of alloys to pitting corrosion in halide media. Streicher (4) has successfully employed an electrolytic test to assess the pitting resistance of a number of alloys to chloride containing environments. The unique feature in these techniques is that they greatly accelerate the corrosion process, and thereby greatly facilitate laboratory studies (5-13). We have used the breakdown technique in our laboratory as a screening tool in alloy development programs, on the premise that, if we can raise E_c (by alloy chemistry changes) to potentials more noble than the corrosion potential of the alloy in the intended environment, we would get no pitting.

Recently, however, articles have appeared in the literature in which the validity of using E_c as an index of pitting corrosion in the above manner, has been questioned. France and Greene (14) report a lack of correlation between electrochemical and chemical exposure tests on AISI Type 430 stainless steel and zirconium in halide media. These authors argue that an electrostatic build-up of aggressive chloride ions at the metal interface occurs during electrochemical polarization, which does not necessarily occur at a freely corroding interface thereby leading to differing behavior. Steigerwald (15) has reported that although E_c relates to pitting performance in some manner, he has observed pitting to propagate at potentials active to E_c, for Fe/Cr alloys in acidified $FeCl_3$.

In view of the apparent conflict between the above reports and numerous laboratory tests, we undertook a study to demonstrate the correspondence between accelerated electrochemical and chemical pitting tests, no attempt being made to extend this correspondence to long term corrosion behavior. This paper describes the results of this study and an attempt to explain the discrepancies noted above.

Materials and Experimental Work

Effort was made as far as possible to duplicate the conditions reported by France and Greene (14) to be certain that the experimental technique was not a variable. Cylindrical electrodes of AISI 430 and 304 stainless steel were machined (0.25 in. diameter by 0.75 in. long) from solution-annealed stock having the composition shown in Table I. The electrodes were abraded through 2.0 emery paper, washed in detergent, rinsed in distilled water, and dried. Polarization experiments were conducted in a glass cell with bright-platinum

auxiliary electrodes. The specimens were mounted on a Stern-Mackrides-type holder (16).

The corrodent was reagent grade 1*M* sodium chloride, dissolved in distilled water (6.3 meg ohm cm^{-1}), to give a final *p*H of 6.3 at 25°C. Tests were conducted under thermostatic control at 25° ± 1°C. All potentials were measured with reference to a saturated calomel electrode connected to the cell with a Luggin Haber probe. No effort was made to correct for liquid junction potentials. Polarization measurements were conducted potentiodynamically by using equipment and procedures described elsewhere (17, 18) at a sweep rate of 0.600 V/hr similar to the traverse rate used by France and Greene in their step technique. The continuous scan procedure was adopted in the interests of better reproducibility (18).

Accelerated chemical exposure tests were conducted in: (*a*) 1*M* sodium chloride solution containing 178 g/l $K_4Fe(CN)_6$ and 2.23 g/l $K_3Fe(CN)_6$ to give a final corrosion potential at −0.100 V_{SCE} on a Type 430 stainless steel electrode, (*b*) the standard "ferric chloride test" (19), that is, 108 g/l $FeCl_3 \cdot 6H_2O$, with the *p*H adjusted to 0.9 with HCl.

All solutions, unless otherwise stated, were saturated with hydrogen gas at a flow rate of 1.5 l/min, giving a dissolved oxygen content of 0.076 ppm.

Results and Discussion

Polarization measurements and environmental variables.—Potentiodynamic anodic polarization curves for the two steels in hydrogen saturated 1*M* sodium chloride are shown in Fig. 1. The electrolyte volume in each test was regulated to 600 ml, and the curves were constructed by exposing the specimen to the corrodent for 60 min, followed by scanning in the noble direction. In contrast to data reported elsewhere (14) no active-passive transitions were observed, and the corrosion potentials on Type 430 stainless steel were slightly more noble having a value of −0.492 V_{SCE}. Clear breakdown potentials were observed however on both steels, the value on Type 430 stainless steel coinciding closely with that published previously (14), (−0.185V). The value of E_c on Type 304 stainless steel was −0.050 V_{SCE}. Prolonged exposure to potentials more noble than E_c resulted in severe pitting corrosion, as shown in Fig. 2. Although not shown in Fig. 2, no evidence of crevice corrosion was observed on any sample, and each polarization curve was reproducible to ± 10 mV with respect to E_c on repeat runs.

Since previous accelerated chemical test data were obtained using oxygen as the oxidizer (14), anodic polarization curves were obtained for the two steels in oxygen saturated 1*M* sodium chloride, at a flow rate of 1.5 l/min, to see if the oxidizer affected the passive state. Typical curves are shown in Fig. 3, from which

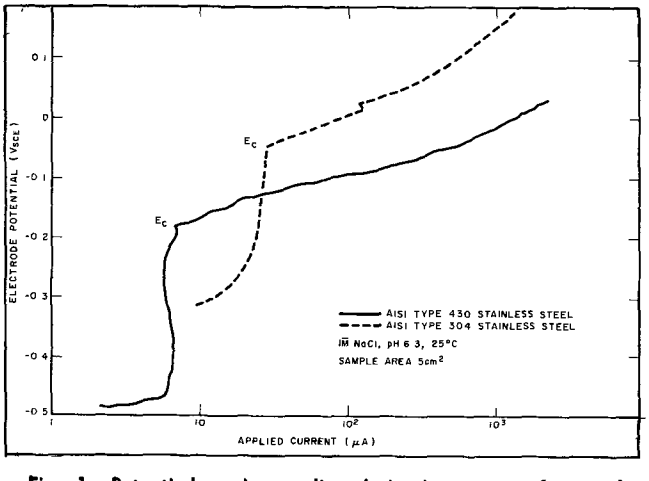

Fig. 1. Potentiodynamic anodic-polarization curves for steels exposed to hydrogen-saturated 1M NaCl sweep rate, 0.600 V/hr.

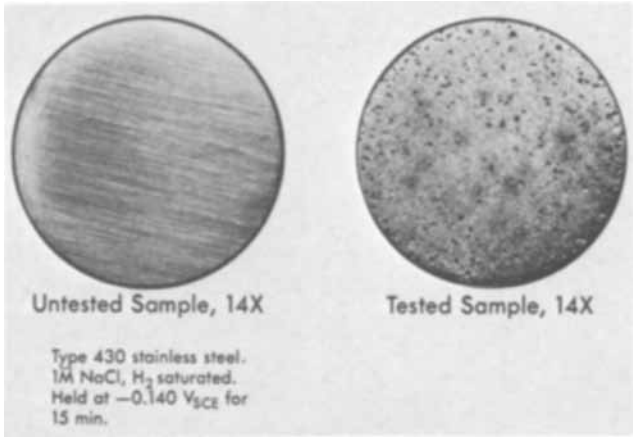

Fig. 2. Macrophotographs of AISI Type 430 stainless steel samples before and after polarization at potentials noble to E_c.

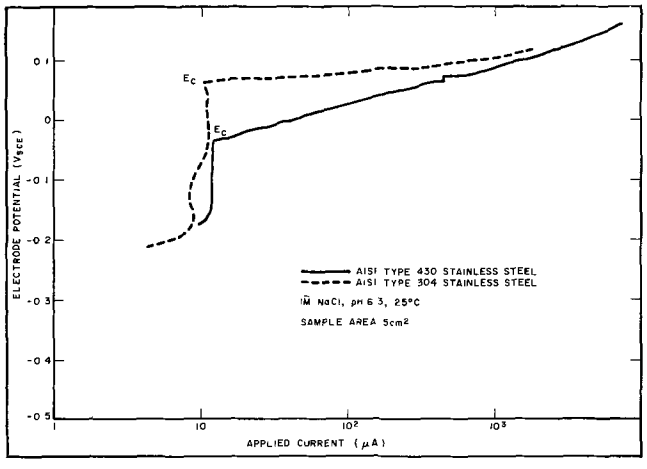

Fig. 3. Potentiodynamic anodic-polarization curves for steels exposed to oxygen-saturated 1M NaCl sweep rate, 0.600 V/hr.

it is clear that both steels evidenced a value of E_c considerably more noble than that recorded in hydrogen saturated solutions. It is interesting to note that the passive current for Type 430 stainless steel is not significantly affected by the presence of oxygen in the electrolyte, whereas that for Type 304 stainless steel is decreased. In view of the influence of oxygen on E_c, several other gases were used during polarization to see if any effect could be noted. The results of these experiments have been reported elsewhere (20), but are briefly summarized in Table II. It is evident from Table II, that E_c varies considerably with the nature of the stirring gas, which we treat as significant and not experimental artifacts in view of the stated reproducibility of our curves. Since nitrogen and argon are nonionic and do not participate in any electrode process, we do not at this time have any explanation of the effect. We might suggest however, that these gases may be involved in an adsorption process on the surface and, in this way, impede the adsorption of chloride ions that appears to be necessary for pit

Table II. Variation in E_c with the nature of the dissolved gases (20) in 1M NaCl at 25°C

Gas	$\frac{E_c}{V_{SCE}}$ Type 430 stainless steel	Type 304 stainless steel
Hydrogen	−0.185	−0.050
Nitrogen	−0.130	−0.020
Argon	−0.100	0.050
Oxygen	−0.035	0.065

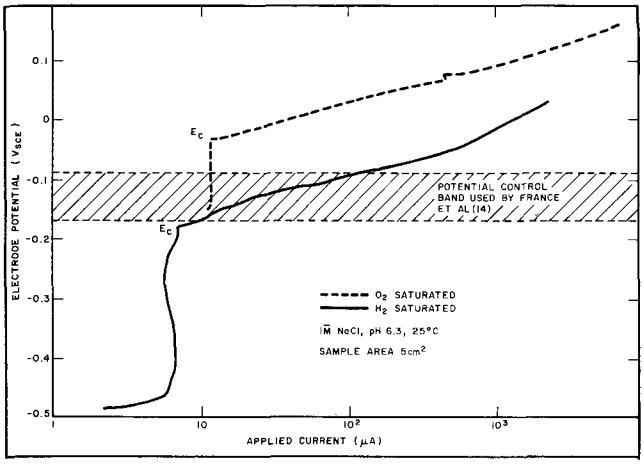

Fig. 4. Semischematic presentation of why previous authors (14) failed to pit AISI Type 430 stainless steel in chemical pitting tests with oxygen.

initiation (4, 21) to a degree varying with the nature of the gas. The important fact, however, is that E_c is not a unique function of alloy composition and is dependent markedly on environmental variables.

To explore the possible dynamic nature of this effect a Type 430 stainless steel was exposed to a solution of oxygen saturated 1*M* sodium chloride. The steady-state corrosion potential, E_{corr}, was -0.140 V_{SCE} in close agreement with that observed previously (14). Although on the basis of E_c obtained in hydrogenated solutions the sample should have pitted, no pitting was observed over a period of 100 hr. The sample was then connected to a potentiostat, and the applied potential regulated at -0.140 V_{SCE} for a further 100 hr, over which time no pitting was observed. At this point, without interrupting the applied potential, the oxygen flow was stopped and replaced by hydrogen at 1.50 l/min, and after 16 hr pronounced pitting occurred with a rapid increase in applied anodic current. These data clearly indicate the protective influence of oxygen with regard to passivity breakdown, and also that this influence can be destroyed merely by aspirating oxygen out of solution with hydrogen. Further they indicate the extreme caution which must be exercised when using breakdown data to predict pitting corrosion susceptibility.

On the basis of the above data, we can satisfactorily explain the reasons why France and Greene (14) did not get any correspondence between electrochemical and chemical accelerated pitting tests for Type 430 stainless steel as summarized in Fig. 4. It will be shown in a following section, that when controlled potential chemical tests are conducted with an oxidizer that does not interact with the passive film on the sample, complete agreement between the tests is obtained.

Accelerated chemical exposure tests.—The breakdown potentials of a series of alloys was determined, as previously described, in nitrogen-saturated 1*M* sodium chloride. The alloys were so chosen as to have a wide range of values of E_c, as shown in Table III. Each alloy was exposed to the "standard ferric chloride test" (19), for periods of 20 and 72 hr. Sheet specimens, (0.060 x 1 x 3 in.) were exposed, suspended in the solution by Teflon tape threaded through a hole in the top of the sample. At the same time, electrodes of each material were immersed and the potential/time behavior recorded. This corrodent contains chloride ions at a normality of 1.185 and is therefore similar to the 1*M* sodium chloride used to determine E_c, except that the redox potential on bright platinum was 0.555 V_{SCE} due to the presence of trivalent iron. In this solution, alloys whose corrosion potential went more noble than the breakdown potential should evidence pit initiation. Visual inspection after 20 and 72 hr indicated all the alloys had pitted except Hastelloy C as shown in Fig. 5. The potential transients are shown in Fig. 6, and are characterized by a relatively rapid (over 15 min) increase in E_{corr} to values between 0.220 and 0.525 V_{SCE}. On all samples except Hastelloy C, the corrosion potential then decreased in an oscillatory manner to values often much more active than E_c, and in certain cases to values approaching those reported by Steigerwald (15) on similar material, *e.g.*, -0.150 V_{SCE} for the 18 w/o Cr Type 304 stainless steel, and -0.300 V_{SCE} for

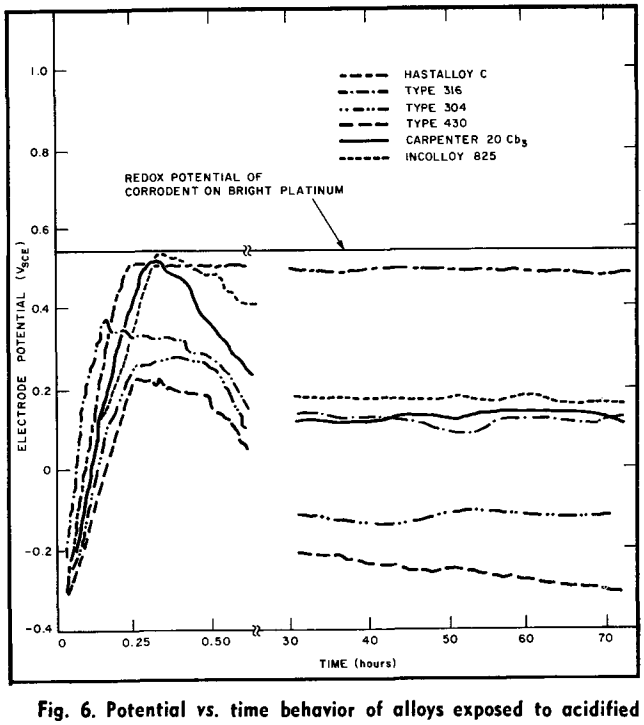

Fig. 6. Potential vs. time behavior of alloys exposed to acidified $FeCl_3$ solution.

the 17 w/o Cr Type 430 stainless steel. It is clear from inspection of Fig. 6 and Table III, that pitting did indeed occur at potentials more active than E_c for Types 304 and 430 stainless steel. However, it should be noted that at small times, all the samples except Hastelloy C, exhibited corrosion potentials more noble than their respective E_c and would therefore be expected to initiate pits. The initial passivation process, where the E_{corr} increases to values close to the solution redox potential, can be quite rapid as shown in the next section, where pit initiation occurred in less than 60 sec after immersion, followed by propagation at potentials more active than E_c, thus, both confirming and explaining Steigerwald's finding.

To further emphasize this point that E_c relates specifically to the pit initiation process and not to the propagation process, a series of controlled potential measurements were made. A schematic of a typical "cyclic" polarization curve (22) for Type 430 stainless steel in nitrogenated 3.5 w/o NaCl is shown in Fig. 7, to indicate the potential regions where pits once initiated, will propagate. Pits were initiated anodically at potentials noble to E_c in area A, then the applied potential was switched to those shown in areas B and C. It was clear that propagation occurred in area B, (*i.e.*, active to E_c) over a period of 100 hr, whereas no propagation was noted in area C. Pourbaix (22) has used such plots to develop the concept of the "protection potential E_p," which represents the potential more active than which pit propagation cannot be sustained and repassivation occurs.

From the above data, two significant factors emerge: (*i*) that there is complete correspondence in predictions of pitting susceptibility between electrochemical polarization data and exposure data obtained in an accelerated chemical test, and (*ii*) that although pitting corrosion can be sustained at potentials active to E_c, a necessary prerequisite in this process is that the corrosion potential of the sample at some time must become more noble than E_c to initiate pits. This latter process can occur quite rapidly in solutions of oxidizers and may be missed if a continuous potential check is not made, leading to the erroneous conclusion that pitting corrosion can initiate at potentials active to E_c.

Controlled potential chemical pitting tests.—It was shown above that oxygen stabilized the passive state with regard to breakdown by chloride ions, *e.g.*, values of E_c obtained in oxygenated solutions were considerably more noble than those obtained in hydrogenated solutions. On this basis it is understandable why no correspondence was obtained between controlled potential pitting tests conducted potentiostatically in H_2 saturated solutions and with oxygen as the oxidizer (14) in 1*M* sodium chloride solutions. To demonstrate further the correspondence between electrochemical and chemical pitting tests, a Type 430 stainless steel sample was exposed to a hydrogen saturated solution of 1*M* NaCl containing $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$ to give a corrosion potential of -0.100 V_{SCE}. Selection of the ferro- and ferricyanide salts for a redox system was made on the premise that being large anions they would be less likely than oxygen to be involved in adsorption processes which stabilized the passive state. Within 60 sec after immersion, pit nuclei were clearly visible because the Fe^{2+} corrosion product formed a patch of "Prussian blue" at the pit site, as reported by Stoffel *et al.* (22). Continued exposure resulted in an oscillatory shift of E_{corr} in the active direction as observed in the $FeCl_3$ tests. Equivalent tests on the same material, conducted potentiostatically at -0.1 V_{SCE} in hydrogen saturated 1*M* sodium chloride, resulted in distinct pit nuclei after approximately 45 sec. These tests were conducted for 24 hr and a comparison made of the weight loss behavior and general appearance in both the electrochemical and chemical test. These data are shown in Table IV, from which it is seen that excellent agreement was observed between both tests.

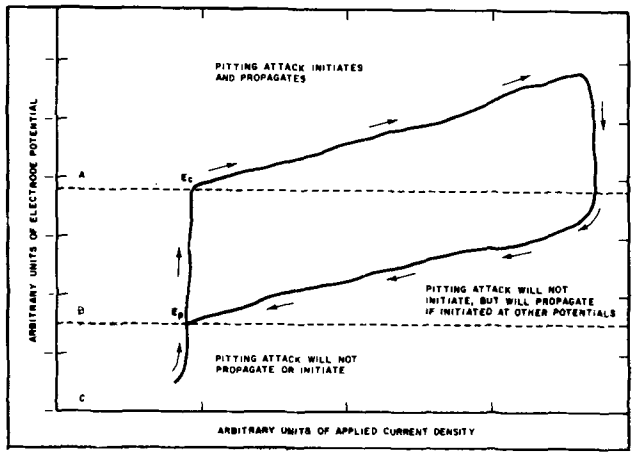

Fig. 7. Schematic presentation of data to support the argument that pit propagation can continue at potentials more active than E_c.

Initial pH	6.3	6.7
Final pH	8.3	6.9
Type of corrosion	Pitting	Pitting

Conclusions

Evidence has been presented which demonstrates the complete correspondence between the pitting corrosion behavior of Type 430 stainless steel in accelerated electrochemical and chemical tests. On the basis of polarization measurements and controlled potential corrosion studies, discrepancies previously reported between the two test methods can be satisfactorily explained.

The specific relation of the critical breakdown potential to pit initiation and not to pit propagation has been demonstrated, along with confirmation of the previously reported fact that pit propagation may proceed at potentials active to the breakdown potential.

It has been shown that extreme caution must be used when utilizing E_c as an index of pitting corrosion susceptibility, since the absolute magnitude of E_c has been demonstrated to vary not only with the well-documented environmental and experimental variables, but also with the nature of the gases dissolved in the corrodent.

Technical Notes

Diffusion Coefficients in Propylene Carbonate, Dimethyl Formamide, Acetonitrile, and Methyl Formate

J. M. Sullivan,[1] D. C. Hanson, and R. Keller*

Rocketdyne, A Division of North American Rockwell Corporation, Canoga Park, California

Diffusion coefficients in aprotic solvents are of interest for estimates of transport limitations in nonaqueous lithium batteries. Integral diffusion coefficients of $LiClO_4$ and some other solutes were measured in four aprotic solvents, and viscosity data were obtained.

The solvents propylene carbonate (PC), dimethyl formamide (DMF), and acetonitrile (AN) were distilled, and were analyzed by a vapor phase chromatographic technique employing a Porapak Q column. Solvent batches were used that contained 40 ± 20 ppm water and less than 60 ppm organic impurities according to this analysis; impurity contents were somewhat higher in the case of methyl formate (MF), namely, about 100 ppm water and 500 ppm methanol.

High grade commercial products were analyzed and used without further purification as solutes, except for vacuum drying of the lithium compounds. Lithium hexafluoroarsenate was supplied in a methyl formate stock solution by Honeywell's Livingston Electronic Laboratory, Montgomeryville, Pennsylvania.

A method that involves determining the weight change of a porous disk filled with the solution to be tested was employed for measuring diffusion coefficients. This method is described in detail in ref. (1) and was first used by Schulze (2). It has been revived by Wall *et al.* who studied its application to measure diffusion coefficients for aqueous electrolyte solutions (3), diffusion coefficients of polymers in aqueous environment (4), and in various nonaqeuous solutions (5). In this present work, the method has been applied to measure diffusion coefficients in aprotic electrolyte systems.

A porous disk was filled with the solution to be studied and suspended in a large volume of pure solvent. The apparent weight is measured as a function of time, and an average or integral diffusion coefficient, D, determined from equation

$$\log[W(t) - W(\infty)] = \alpha Dt + b \qquad [1]$$

where $W(t)$ is the apparent weight of the suspended disk at time t, and $W(\infty)$ the weight after equilibrium has been reached; α is an apparatus constant.

The recommended Micro-Porous Filter Disks (2-in. diameter, ¼-in. thick, porosity No. 10) were obtained from the Selas Corporation of America. They were evacuated, filled with the solution to be studied, and allowed to soak overnight. Each disk was suspended by a fine wire from the arm of an analytical balance in about 1½ liters of pure solvent. The solvent container was placed in a constant temperature mineral oil bath maintained at 25.00° ± 0.02°C. A flow of nitrogen was swept over the solvent. An aqueous 1.5M KCl solution was used for the determination of the frit constant α [in accordance with ref (1), the differential diffusion constant for one-half of the initial KCl concentration in the frit was employed, *i.e.*, $D = 1.87 \times 10^{-5}$ cm^2 sec^{-1} at 25°C].

The results of diffusion coefficient measurements are given in Table I; the estimated accuracy is 1-2%.

Viscosities were determined by a conventional technique involving measurement of the efflux time of the solutions through a capillary. Results are given in Table II.

There was direct correlation between the diffusion coefficient and the solvent viscosity. If the products of these two values, $D \times \eta_{(solvent)}$, are formed, they deviate not more than ±16% from the average for the reported values (the consistency is significantly smaller if the viscosity of the solution rather than of

Solution (solvent)	Viscosity, millipoises
PC	24.8
1M $LiClO_4$/PC	70.8
DMF	7.93
1M $LiClO_4$/DMF	18.9
AN	3.36
1M $LiClO_4$/AN	6.60
MF	3.38
1.1M $LiAsF_6$/MF	8.06

the solvent is considered). It may be tentatively suggested to estimate diffusion coefficients for other, similar solutions based on the solvent viscosity. It should be noted, however, that the values given here were all for solutes containing lithium ions at a concentration of 1M; diffusion coefficients of other solutes which do not contain the strongly solvated lithium ion with its low ion mobility are expected to be somewhat greater. The diffusion coefficient of 1M LiCl/DMF, incidentally, is believed to be slightly lower than the diffusion coefficient for 1M $LiClO_4$/DMF because of ion pair formation.

Acknowledgments

This work was supported by the NASA Lewis Research Center, under Contract NAS3-8521. The efforts of Dr. J. N. Foster in analyzing starting materials are gratefully acknowledged.

Liquidus Curves for Aluminum Cell Electrolyte

V. Representation by Regression Equations

E. W. Dewing*

Alcan Research and Development Limited, Arvida, Quebec, Canada

Previous reports from this laboratory (1-4) have given liquidus curves for a wide range of aluminum reduction cell electrolytes based on cryolite. The object of this note is to rationalize the results in the form of equations which may be used to predict the freezing point of any composition likely to be encountered in practice.

The typical pseudo-binary diagram for the system (cryolite + additives)-alumina shows a cryolite liquidus and an α-alumina liquidus meeting in a eutectic. For small additions of all additives except NaF and AlF_3 (the constituents of cryolite) the lowering of freezing point of cryolite should be linear and additive; for higher concentrations nonlinear terms may need to be introduced in order to obtain a good fit. For NaF and AlF_3 the linear terms are absent (since the freezing point is a maximum at the cryolite composition and small additions do not affect it) and only squared and higher order terms are needed. The equation for the cryolite liquidus to be tried is thus of the type

$$t = t_o + a(Al_2O_3) + b(Al_2O_3)^2 + c(CaF_2) + d(CaF_2)^2$$

$$+ e(CaF_2)(AlF_3) + f(AlF_3)^2 + \ldots\ldots\ldots\ldots$$

where (Al_2O_3), etc., represent weight per cent (w/o). [Note that (AlF_3) and (NaF) are quantities in excess of the cryolite composition and not total quantities.]

The unknown constants t_o, a , b, etc., in this equation were determined by a step-wise least-squares regression analysis program which accepted only those terms which were statistically significant. Most of the higher order terms were rejected. Three separate equations were generated; one for the normal range of cell operation (CaF_2 up to 12 w/o, AlF_3 up to 16.67%), one for the additives NaF, AlF_3, Al_2O_3, CaF_2, MgF_2, Li_3AlF_6, and NaCl to a maximum freezing point depression of 100°, and the third for depressions of up to 200°. The respective standard deviations of the experimental values from the equations are 2.1° (51 points), 2.9° (112 points), and 3.5° (133 points). Since the experimental accuracy is certainly not better than 1° this is satisfactory. Table I shows the coefficients in the equations.

Developing an equation for the alumina branch of the liquidus has to be done on empirical grounds since the concentrations are high and there is no useful limiting law to act as a guide. After several trials a general power series of the type

$$t = t_o + a(AlF_3) + b(Al_2O_3) + c(AlF_3)(Al_2O_3) + d(Al_2O_3)^2 + \ldots$$

was used. No terms in (NaF) were employed since, if it is present in any substantial amount, β-Al_2O_3 instead of α-Al_2O_3 is the stable phase.

The earlier experimental values (1-3) were obtained by visual observation of the onset of crystallization, while later ones (4) were obtained by an

equilibration method and gave higher temperatures for a given composition. To clarify the picture more equilibration measurements were made in the Na_3AlF_6-Al_2O_3 system and in the Na_3AlF_6-AlF_3-CaF_2-Al_2O_3 system. In the course of the regression analysis it was shown that the equilibration results were higher than the visual ones by 16°, with a standard error of ±1.2°. There was no indication that the difference varied with composition, and all the old results have been corrected upward by that amount.

Only one set of coefficients was generated to cover the whole range of composition; it gave a standard deviation of 5.3°C (125 points) or 4.2°C for the 58 points in the normal range of composition (Table II). The accuracy is poorer than for the cryolite liquidus; this is partly because the experimental methods are not so precise and partly because of the inadequate form of the equation used.

Several points call for comment:

1. Since the correction of 16° has been applied to the visual results, the equations given here are more accurate than the diagrams in the original papers (1-3).
2. The possible importance of various combination terms, *e.g.* (AlF_3) (MgF_2), has not been assessed since no results were available in which those constituents were added simultaneously. No data from other sources have been used. This is not to imply that they are inferior, but simply because of the danger that, if systematic differences between sources do exist, the regression analysis is liable to attribute them to the effect of the combination of additives. Since the combination terms are in general not very important it has been considered safer to ignore them than to risk having them seriously distorted.
3. With the aid of these equations computer programs can readily be written to determine liquidus and eutectic temperatures for a given composition, alumina solubilities for a given composition and temperature, etc.

The Standard Potential of the Silver-Silver Chloride Electrode in N-Methylformamide at 25°C

M. L. Berardelli, G. Pecci, and B. Scrosati*

Istituto Elettrotecnico, Università di Roma, Rome, Italy

In the last few years there has been a renewed interest in nonaqueous solvents because of their use to develop high energy battery systems. Particular attention has been focused on the amides and their alkyl derivatives.

The values of standard potential of reference electrodes in formamide (1-6), dimethylformamide (7), dimethylacetamide (8), and N-methylacetamide (9), have been reported.

In this work we extended the series to report the behavior of the silver-silver chloride electrode in N-methylformamide (NMF) at 25°C with respect to the standard hydrogen electrode using the following cell

$$Pt, H_2 \mid HCl\ (m)\ in\ NMF \mid AgCl, Ag \qquad [1]$$

N-methylformamide (NMF) (C. Erba RP product) was purified by storing it over CaO for two days and then by fractional distillation under reduced pressure. The final product had a specific conductance of 3×10^{-6} ohm^{-1} cm^{-1} in good agreement with the value reported in the literature (10).

The HCl gas was obtained by dropping concentrated H_2SO_4 on reagent grade NaCl and passing the evolved gas first through concentrated H_2SO_4 and finally through two traps at dry ice temperature.

The solutions used in cell [1] were prepared by passing HCl gas into NMF. The concentration of HCl was determined according to the technique described by Berardelli, Pistoia, and Polcaro (11).

The cell was an all-glass type of the design recommended by Ives and Janz (12). Particular care was taken in the preparation of the silver-silver chloride electrodes since their behavior in NMF depends to a great extent on the method and accuracy of preparation. The thermal electrolytic type electrodes, prepared according to the procedure described by Ives and Janz (12), were not reproducible in NMF. For the electrolytic type of electrodes, prepared by the method described by Brown (13) and Ives and Janz (12), the adherence of the AgCl films was very poor in NMF, and therefore the electrodes failed in short periods of time, as was previously found by Case and Parsons (14). Apparently the anodically formed silver chloride layer is easily dissolved by the solvent.

In this work the silver-silver chloride electrodes were of the thermal type, prepared according to the method described by Keston (15) and Ives and Janz (12). This method, when properly used, yields elec-

Key words: silver-silver chloride electrode, standard potential in nonaqueous solvent, N-methylformamide.

trodes which possess remarkable advantages over the electrolytic types, *i.e.*, less sensitivity to light and the absence of any occlusion or absorption of electrolyte during the preparation (12). This circumstance becomes very important for electrodes to be used in amides which can be decomposed by traces of water, the amide decomposition being catalyzed by hydrogen chloride (16). The electrodes were made by covering a platinum spiral of about 1.5 mm diameter, sealed in a glass tube, with a paste of 90% Ag_2O and 10% $AgClO_3$, to form a sphere of about 4 mm diameter. The electrodes were slowly heated to 100° and then to 650°C and maintained for about a half-hour at this temperature. The electrodes were then cooled slowly in the furnace (12). The preheating up to 100°C is critical and was made slowly to avoid crackings on the surface of the electrodes. The coating of the sphere by the paste, and the subsequent heating cycle were repeated until the surface of the electrode was completely uniform. The electrodes were stored in NMF and rinsed several times in the cell solutions before use. The silver-silver chloride electrodes, prepared and stored as described, were stable and reproducible in NMF for several hours, showing bias potentials of 0.1 mV or less. Hydrogen electrodes were prepared in the usual manner (12).

The emf measurements were made at 25.00° ± 0.05°C by a differential Keithley 662 voltmeter. EMF readings were taken 30 min after starting the hydrogen flow. The time to achieve equilibrium was about 3 hr, and was considered to have been obtained when the emf's remained constant, generally within ± 0.0005V, for 2 or more hours. Readings taken 24 hr later gave emf's 0.007-0.008V higher than the equilibrium values. This slow increase of the emf with time is probably due to a slight decomposition of the NMF solvent by traces of water when the cell remained for long periods of time in the water thermostatic bath. This reaction, which is catalyzed by hydrogen chloride, has been already observed in the case of emf determinations in formamide by Mandel and Delcroly (1) and by Agarwal and Nayak (2).

The emf's of cell [1], corrected to unit fugacity of H_2, are given in Table I, column 2, as a function of HCl molality. The molal standard potential of the silver, silver chloride electrode at 25°C was determined by plotting the function E' *vs.* the HCl molality m where E' is given by the equation

$$E' = E + \frac{2(2.303)\,RT}{F} \times \log m - \frac{2(2.303)\,RT}{F}\alpha\sqrt{m}$$

$$= E^\circ - \frac{2(2.303)\,RT}{F}\beta m \quad [2]$$

where the Debye-Hückel constant α for NMF at 25°C is 0.159 calculated using for the dielectric constant of NMF the value 171 reported by Weeda and Somsen (17).

Figure 1 shows the values of E' *vs.* the HCl molality. Extrapolation to zero molality by the method of least squares gives the standard potential of the Ag,AgCl electrode in NMF at 25°C, as $E^\circ = +0.208 \pm 0.003$V

Table I. Emf data at 25°C

m, HCl	E, V	E', V	$\gamma_\pm$
0.0100	0.450	0.211	0.979
0.0122	0.434	0.206	0.978
0.0213	0.406	0.206	0.980
0.0238	0.408	0.213	0.981

0.0684	0.347	0.204	1.011

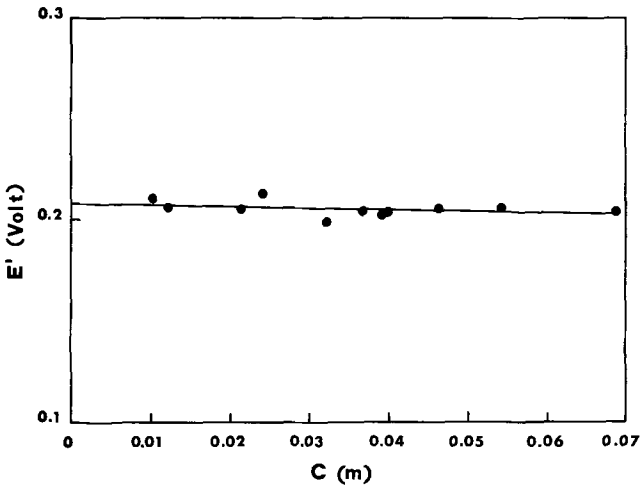

Fig. 1. E' as a function of HCl molality at 25°C

(Gibbs-Stockholm-I.U.P.A.C. convention). The decomposition of the solvent, which may occur to a different extent in each case, even in the freshly prepared solutions, is probably responsible for the scatter of the experimental points.

The best fit of the data corresponds to a straight line with a slope of −0.08 comparable with the −0.03 value found for a similar plot in N-methylacetamide (9). The value of β in Eq. [2] is then 0.676.

The mean molal activity coefficient $\gamma_\pm$ of HCl in NMF at 25°C may be calculated by the equation

$$\log \gamma_\pm = -\alpha\sqrt{m} + \beta m \quad [3]$$

Values of $\gamma_\pm$ obtained from Eq. [3] are listed in Table I.

Studies on the properties of the silver-silver chloride and other reference electrodes in other nonaqueous solvents are in progress in this laboratory.

Surface Active Agents as Corrosion Inhibitors for Aluminum

D. A. Vermilyea, J. F. Brown, Jr., and D. R. Ochar

General Electric Company, Schenectady, New York

Recent studies (1, 2) of the reaction between aluminum and water have shown that the mechanism involves the formation of amorphous Al_2O_3, the dissolution of the Al_2O_3 to form soluble species, and the precipitation of AlOOH from the solution. The AlOOH layer provides deposition sites close to the surface for dissolved species and hence allows the reaction to proceed at a high rate despite the very low solubility of Al_2O_3 in neutral solutions. Inorganic inhibitors function by becoming adsorbed on the oxide and preventing the nucleation and growth of the hydroxide layer (2).

This report is concerned with the use of several surface active agents as inhibitors. It is found that the most effective inhibitors are those which contain a strongly inhibiting inorganic group attached to a hydrocarbon. At least one of these is a better inhibitor, especially in acid solutions, than any of the inorganic ions previously studied.

Experimental

Previous studies (1, 2) showed that substances which retarded the attack of water on anodic Al_2O_3 films were corrosion inhibitors for aluminum, and the majority of the work reported here involved such anodic films. Anodic Al_2O_3 films were formed on evaporated aluminum films at 175V in a 1% ammonium borate solution at 25°C; the exact formation technique has been described in an earlier report (1). The principal means of measuring the rate of attack on the Al_2O_3 films was the measurement of electrical capacitance, although infrared absorption measurements and weight changes were also employed. All techniques have been fully described previously (1, 2).

The reaction medium was usually a solution containing the inhibitor at 10^{-3} M/1 or 0.01 v/o with the *p*H adjusted to 5 by additions of NaOH or $HClO_4$. A *p*H of 5 was selected because tests showed maximum inhibition at that pH. Some of the surface active agents used were proprietary compounds obtained from General Aniline and Film Corporation. Table I contains a list of such compounds and a description of their composition. Dodecyl acid phosphate was obtained from Hooker Chemical Corporation as an approximately equimolar mixture of monoalkyl and dialkyl phosphates. We found that part of this mixture was insoluble and separated the soluble part by repeatedly heating an aqueous slurry to 100°C, filtering, cooling to 5°C, and refiltering. We assume that the dialkyl derivative was more insoluble and that we retained mainly the monoalkyl phosphate. After this treatment the solution was entirely clear at 100°C. Of the other compounds tested some were obtained from chemical suppliers and some were made in our laboratory using standard techniques.

Table I. Proprietary surface active agents

Designation	Type	Description
Gafac RS-710	Anionic	Sodium salt of complex phosphate ester
Igepal CO-880	Nonionic	Nonylphenoxypoly (ethyleneoxyethanol)
Katapol VP-532	Cationic	Polyoxyethylated alkylamine

Results

Figures 1 and 2 show the capacitance data as a function of time. The initial change of capacitance is usually a decrease both because of a change of dielectric constant of the oxide on heating and because of the deposition of a layer of organic material on the surface. As the Al_2O_3 film is dissolved the capacitance increases. In order to avoid a sign change and to be able to plot data on a logarithmic scale we have added 2.0 to each measured change of AC^{-1} (area times reciprocal capacitance). In order to express changes of AC^{-1} in angstrom units of Al_2O_3 it is only necessary to multiply by 80. Large errors may result from such calculations when the change in capacitance is small.

The data of Fig. 1 show that nonionic and cationic substances are less effective than anionic substances. The Al_2O_3 film is probably slightly positive to its point of zero charge at *p*H 5, so that anions tend to be more strongly attracted. The nonionic CO-880 becomes more effective with time, probably due to entrapment in pores of the AlOOH layer.

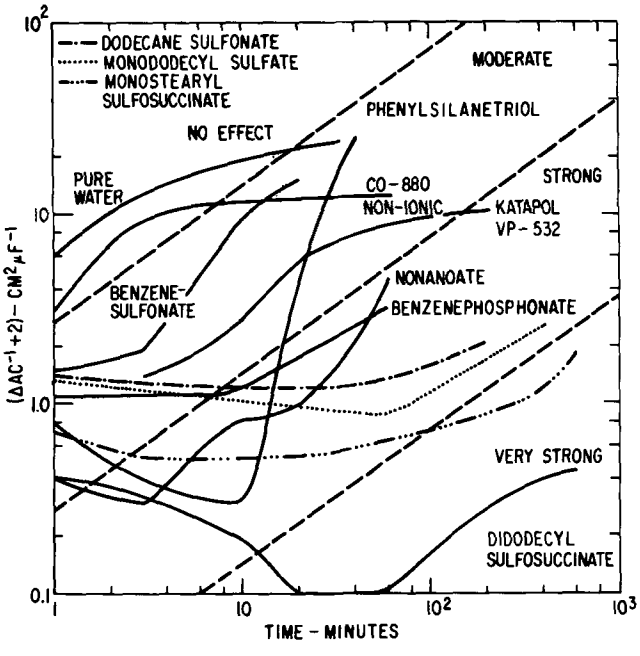

Fig. 1. Capacitance changes during reaction of anodic Al_2O_3 films with boiling solutions of various inhibitors at *p*H 5.

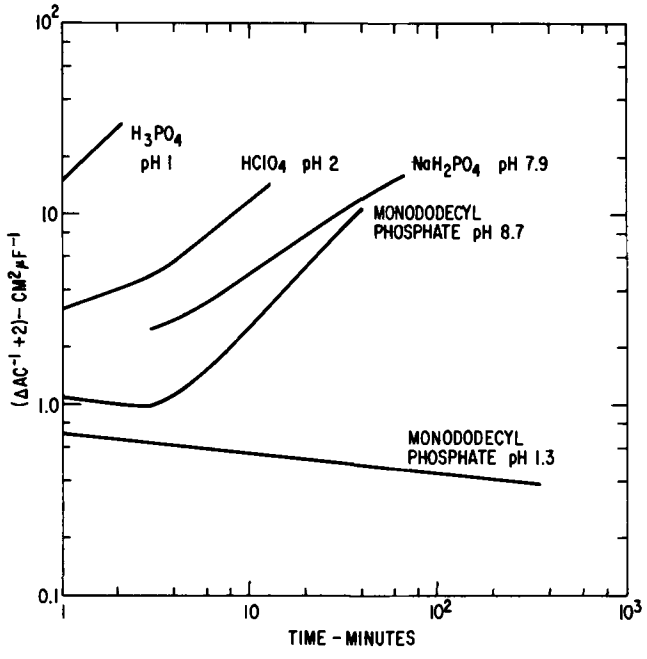

Fig. 2. Capacitance changes during reaction of anodic Al_2O_3 films with boiling solutions at various pH.

The anionic inhibitors all produced more or less hydrophobic surfaces on the Al_2O_3, showing that the ions were oriented with the inorganic group next to the oxide. The best inhibitors gave surfaces that were extremely hydrophobic. A comparison of data for benzenesulfonate and benzenephosphonate shows that the phosphonate group is much more effective than the sulfonate group. The comparison of data from straight chain hydrocarbon surface active agents shows that the order of effectiveness is $PO_4^{-3} > SO_4^{-2} > COO^{-1}$. With monododecyl phosphate and Gafac RS-710 at pH 5 no detectable attack on the oxide film occurs, and the data are not plotted in Fig. 1. Absence of attack was verified by infrared, which showed that the Al_2O_3 absorption was unchanged. An idea of the effectiveness of monododecyl phosphate ion can be obtained from Fig. 2, where results at lower pH are plotted. At pH 1.3 monododecyl phosphate entirely prevents attack on the oxide, while inorganic acids readily dissolve the Al_2O_3 (see $HClO_4$, Fig. 2) and phosphoric acid itself attacks the film at an even greater rate. Monododecyl phosphate is not effective at high pH, however, perhaps in part because the surface charge on the oxide changes sign as the pH is increased.

A few of these substances produced rather thick layers on the surface; all such substances were phosphates. At pH 5 Gafac RS-710, monododecyl phosphate, and monolinolenyl phosphate produced hydrophobic layers which resulted in large capacitance decreases (ΔAC^{-1} about 10). If it is assumed that the dielectric constant of the deposited material is 2, then such capacitance changes are equivalent to a layer roughly 200Å thick, so that multilayer films are evidently deposited. Infrared measurements confirmed the presence of aliphatic C-H on the surface. Such films could not be removed with organic solvents, but were slowly removed (in about one day) on exposure to pure water at 100°C, so that "permanent" protection by deposition of such a layer was not possible.

The phenylsilanetriol, produced *in situ* by the addition of an acetone solution of phenyltrichlorosilanetriol, was very effective for the first 10 min, producing an extremely hydrophobic surface, but apparently soon disappeared from the solution and hence ceased to protect. A second specimen treated in the same solution behaved as it would have in pure water. Possibly the silanetriol became attached to the surface of the vessel, or it may have undergone polycondensation (3).

Discussion

We believe that a reasonable interpretation of our data is that anionic surface active agents become attached to the Al_2O_3 surface by the inorganic group, forming a hydrophobic surface, preventing access of water to the surface and hence preventing dissolution of the Al_2O_3 and precipitation of AlOOH. The nature of the inorganic group is of primary importance, and phosphate, the most effective inorganic inhibitor, is also the most effective inorganic group in anionic surface active agents. Silicate is similarly effective as long as it remains in solution. Sulfate, while only weakly effective alone, becomes very effective when present attached to an organic molecule. The result with monododecyl phosphate at pH 1.3 confirms that these compounds can often be very much more effective than the inorganic ion itself.

We were not able to obtain anionic surface active agents based on other strongly inhibitive inorganic anions such as arsenate, periodiate, tungstate, sulfite, phosphite, tellurate, vanadate, antimonate, and selenate. It would be very interesting to synthesize and test such substances.

Vapor Deposition and Etching Open Tube Kinetics under Diffusion Controlled Conditions

F. A. Kuznetsov and V. I. Belyi

Institute of Inorganic Chemistry,
Siberian Department of the Academy of Sciences of the USSR, Novosibirsk, USSR

ABSTRACT

A quantitative method for treating chemical deposition and etching open tube processes is described. The method is based on the gas dynamic theory of boundary layer and on the similarity of mass- and heat-transfer phenomena. For the conditions Le=Sc=Pr=1, the equation for the rate of the process is

$$R_t = \rho_e u_e b S t$$

This equation is applied for the calculation of the rate of Ge and Si crystals deposition and etching. A good agreement of calculated and experimental values is obtained.

Chemical decomposition and etching in gas or vapor streams, the so-called open tube method, is often used for semiconductor crystal and device technology. As has been frequently pointed out in the literature, the best conditions for both chemical deposition of epitaxial layers and chemical vapor etching of single crystals in flowing systems at high temperatures correspond to diffusion control in the vapor phase.

Some analytical methods based on one-dimensional diffusion model have been used for calculation of the rate of these processes (1, 2). While useful for evaluation of the average rate, these methods could not take into account a very important feature: changing of the local rate of the deposition or etching along the direction of the gas stream. This nonuniformity of local rates very often can be observed in chemical vapor growth and etching processes and reflects nonuniformity of conditions of mass transfer along the gas flow direction.

In our calculations we have tried to make use of a method based on a model for the laminar boundary layer commonly employed in gas dynamic problems (3).

Let us consider a scheme of the boundary layer over a flat plate which is created as a result of chemical reaction between the plate and a gas stream parallel to it (Fig. 1). L on Fig. 1 is the length of the plate. Thickness of the boundary layer, schematically depicted by the curve OB, is the distance $\delta(x)$ along the direction normal to the plate surface, where the main change in gas species concentration, due to reaction at the plate, takes place. $\delta(x)$ is increasing along the direction of gas flow and is equal to zero at the front edge of the plate.

Mathematical expressions used for describing mass transfer across the boundary layer become much simpler if the interaction between the gas flow and plate is considered as transfer of the plate substance, E, from the solid phase to the gaseous solution or *vice versa*, and the concentration of the plate material E in gas phase is expressed by weight fraction, K, which can be calculated as

$$K = \frac{\sum_i P_i L_i A}{\sum_\lambda P_\lambda M_\lambda} \qquad [1]$$

where P_i is the partial pressure of i gaseous species containing the plate material atoms, L_i is a number of these atoms in i species, A is atomic weight of the plate substance, P_λ is the partial pressure of any gaseous species, and M_λ is the molecular weight of these species. We will assume below that the concentration of E just near the plate surface, K_w, is constant and equal to the equilibrium one, $K_w = K_{eq}$.

The concentration of E at the upper limit of boundary layer (OB curve) and above, K_e, is equal to that of initial gaseous solution.

The vector diagram on Fig. 1 shows variation of the concentration across the boundary layer along the y-axis.

Mass transfer at any point inside the boundary layer can be described by the following equation

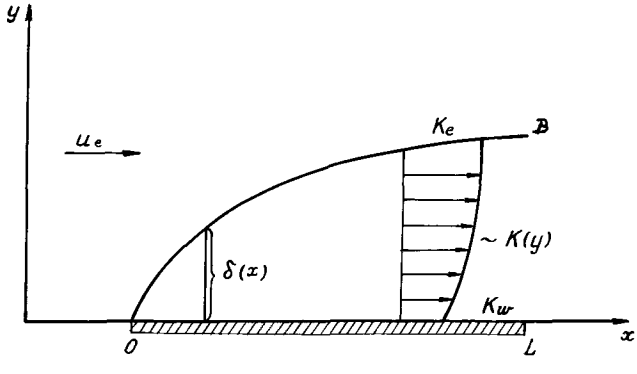

Fig. 1. Scheme of the boundary layer.

$$\rho u \frac{\partial K}{\partial x} + \rho v \frac{\partial K}{\partial y} = \frac{\partial}{\partial y}\left(\rho D \frac{\partial K}{\partial y} \right) \quad [2]$$

where ρ is gas mixture density, D is the diffusion coefficient, and u and v are components of the linear velocity of the gas stream in perpendicular and parallel directions in respect to the plate surface plane.

When integrated for the region of the boundary layer adjacent to the plane surface for a distance where a magnitude of the derivative $\partial K/\partial x$ becomes very close to zero, Eq. [2] gives

$$(\rho v)_w = (\rho v K)_w - \left(\rho D \frac{\partial K}{\partial y} \right)_w \quad [3]$$

where the subscript, w, indicates values corresponding to the region described above. Subscript, e, denotes parameters of the main flow outside the boundary layer.

The left-hand side of Eq. [3] is the mass flux of E per unit area in the direction normal to the plate surface. It is equal, evidently, to the local rate, R_t, of a heterogeneous process at steady state. The right-hand side is composed of two terms corresponding, respectively, to convective and diffusion contributions to the over-all rate.

Dependence of R_t on K_e, K_w, D, temperature and linear velocity of a gas stream, u_e, can, in principle, be obtained by the integration of Eq. [3].

The problem will be simplified if one considers the similarity theory for mass, heat, and momentum transfer phenomena. For this, we recall first that in flowing systems of the type considered in this paper, not only concentration but thermal and momentum boundary layers are formed over the surface of the plate. Without going into great detail, we may recall[1] that under the condition[2]

$$Le = Pr = Sc = 1 \quad [4]$$

all of these three layers have the same shape. That is to say, the thicknesses of the layers are equal to one another at any distance along the gas stream.

Under condition [4], concentration, enthalpy, and momentum fields over the plate are similar, and differential equations for diffusion, energy, and momentum all have the same form (as Eq. [2] does) (4). The similarity of the concentration and the enthalpy fields enables us to write

$$\frac{K - K_w}{K_e - K_w} = \frac{h - h_w}{h_e - h_w} \quad [5]$$

where h is steady motion enthalpy.

Equation [3] can be rearranged by substituting the derivative $(\partial K/\partial y)$ obtained from Eq. [5] by differentiating with respect to y.

By employing a usual expression for the Stanton number

$$St = \frac{1}{\rho_e u_e (h_e - h_w)} \left(\rho_e a \frac{\partial h}{\partial y} \right)_w \quad [6]$$

and remembering that $D/a = Le = 1$, one can transform Eq. [3] into

$$(\rho v)_w = \frac{(K_e - K_w)}{1 - K_w} \cdot \rho_e \cdot u_e \cdot St \quad [7]$$

Replacing $(\rho v)_w$ by R_t, the processes rate (per unit area), and the dimensionless ratio $(K_e - K_w)/(1 - K_w)$ by b, the mass transfer parameter, one can finally write

$$R_t = \rho_e \cdot u_e \cdot b \cdot St \quad [8]$$

One can see that the last equation consists only of values not too difficult to estimate.[3] The Stanton number used in Eq. [8] can be presented as a function of other dimensionless parameters, the Reynolds and the Prandtl numbers

$$St = f(Re, Pr) \quad [9]$$

Specific form of the relationship depends on geometry of the flowing system.

Assuming similarity of the viscous and enthalpy fields, one can use the following expression for the Stanton number for the case of parallel streamlining of flat surfaces (5)

$$St = 0.322\ Re_{(x)}^{-1/2}\ Pr^{-2/3} \quad [10]$$

Here a magnitude of St varies along the stream direction due to coordinate dependence of $Re_{(x)}$

$$Re_{(x)} = \frac{u_e x}{\nu} \quad [11]$$

where x is a distance along the plate equal to zero at the front edge of the plate. Thus, Eq. [8] with St given by Eq. [10] enables local rates of the process to be calculated.

An average value of the process rate can be calculated from Eq. [8] by employing for the Stanton number

$$St = 0.664\ Re_{(L)}^{-1/2} \cdot Pr^{-2/3} \quad [12]$$

where $Re_{(L)}$ is to be calculated from Eq. [11] by using L, the whole length of the plate, in place of x.

For a case of normal flow, with respect to the surface, the Stanton number magnitude is to be obtained (6) from

$$St = 0.47 \cdot Re_{(L/2)}^{-1/2}\ Pr^{-2/3} \quad [13]$$

where $Re_{(L/2)} = u_e \cdot (L/2)/\nu$. L is the width of the plate.

If a cold gas mixture reacts with a hot substrate (i.e., a substrate which is R.F. heated), an empirical coefficient $(T_w/T_e)^{-0.11}$ should be introduced (8) in Eq. [8]. This results in

$$R_t = \rho_e u_e b\ St \left(\frac{T_w}{T_e} \right)^{-0.11} \quad [14]$$

where T_w and T_e are plate and incoming gas stream temperatures, respectively. Values of density, ρ_e, and velocity, u_e, are now those in the incoming gas stream.

We have assumed so far that the surface concentration, K_w, is equal to the equilibrium one, K_{eq}. This makes the mass-transfer parameter, b, used in Eq. [8] and [14] easy to calculate. In cases where surface kinetic limitations are not negligible, this approach becomes unworkable, and the real surface concentration should be taken into calculation.

In general, this problem is very complicated, but for first order surface processes it can be solved. In this case, a relationship including both surface kinetic and mass-transfer limitation has the following form (7)

$$R_t = \frac{k \cdot \beta}{k + \beta} P_e \quad [15]$$

where k is surface reaction rate constant, β is the mass-transfer coefficient, and P_e is a partial pressure of gaseous species reacting with the surface in the main flow (outside the concentration boundary layer).

For practical use of Eq. [15], the rate constant, k, must be known. The mass-transfer coefficient, β, can be calculated as follows: rate of a process under purely diffusion controlled conditions can be described by the equation

$$R_t = \beta (P_e - P_{eq}) \quad [16]$$

where P_{eq} is the equilibrium pressure of the species of interest. Another expression for R_t is, for example, Eq. [8]. Combining Eq. [8] and [16], we obtain

$$\beta = \frac{\rho_e u_e b\ St}{P_e - P_{eq}} \quad [17]$$

[1] For more detail, see, for example (3, 4).

[2] $Le = a/D$ is the Lewis number (a is the thermal diffusivity), $Pr = \nu/a$ is the Prandtl number (ν is the kinematic viscosity), $Sc = \nu/D$ is the Schmidt number.

[3] An example of calculation based on Eq. [8] is given in the Appendix.

Table I. Systems considered and experimental conditions

Si-H_2-Cl_2	Growth	↓ ↓	Nonisotherm	1250-1300	32.7	[14]	(1)
Ge-H_2-Cl_2	Growth	⟶|	Nonisotherm	800-900	1.5 at −850°C	[14]	our data (13)

* ↓ ↓ denotes parallel position of the plate surface in respect to direction of gas stream, ⟶| corresponds to the perpendicular position.

Equations [8], [14], and [15] have been employed for a number of semiconductor crystal vapor growth and etch rate calculations. The calculations were performed for processes for which experimental kinetic data were obtained in our investigations or were available in the literature.

Table I contains information about systems considered and experimental conditions taken into consideration. Figures 2a and 2b give a comparison of calculated and experimental data for etching and growth processes, respectively. Logarithmic coordinates are used because of considerable variation of the rate values of different processes.

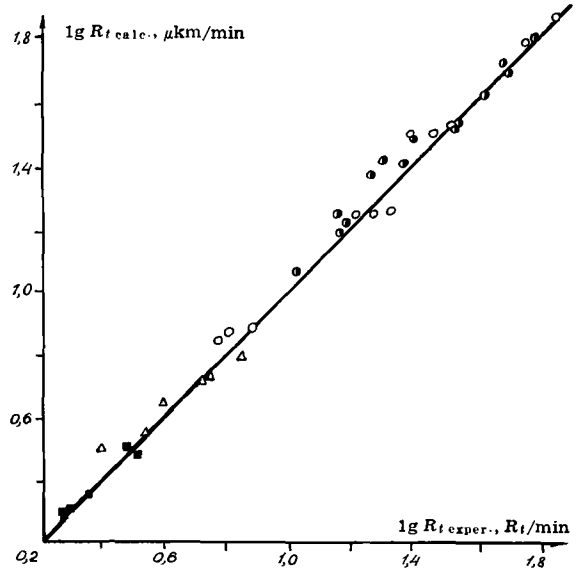

Fig. 2a

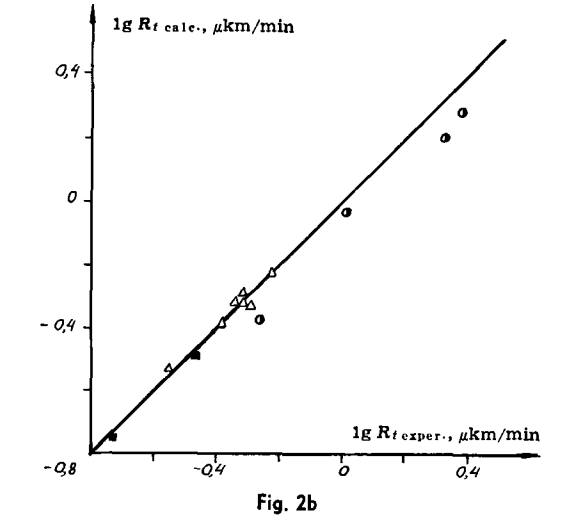

Fig. 2b

Fig. 2. Comparison of calculated and experimental rates: *(a)* Etching processes: ◑, our data (11), ○, Reisman and Berkenblit (9), △, Reisman and Berkenblit (10), ■, our data presented in the Appendix. *(b)* Growing processes: ◑, Shephard (1), △, Seki and Araki (12), ■, our data (13).

As can be seen, agreement is quite satisfactory. The difference between calculated and experimental results in the majority of the cases is not greater than 5-10%. Thus it can be concluded that for the processes considered, the method described above gives accuracy commensurate with the reproducibility of experimental results. Because of a number of simplifying restrictions used the method cannot, unfortunately, be regarded as a universal one, and experimental control should be undertaken for a few points when one employs the method for any particular process.

Manuscript submitted Nov. 18, 1968; revised manuscript received Feb. 18, 1970. This was Paper 76 presented at the Boston Meeting of the Society, May 5-9, 1968.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

APPENDIX

1. Physical parameters of gas phase are calculated under the assumption that it can be considered as a perfect gas mixture.

Density, ρ_e, (g · cm^{-3}) of a gas mixture can be obtained from

$$\rho_e = \sum_i n_i \rho_i$$

where n_i is the mole fraction of i species and ρ_i is its density.

Gas stream velocity, u_e, (cm · sec^{-1}) is calculated from

$$u_e = \frac{V_{To}}{S} \frac{T_{sub.}}{T_o}$$

where V_{To} is the flow rate (cm^3 · sec^{-1}) (measured at temperature T_o, °K), S is the cross section of a reactor (cm^2), and $T_{sub.}$ is temperature in the reaction zone.

Kinematic viscosity of a gas mixture, V, (cm^2 · sec^{-1}) is obtained from

$$\nu = \frac{1}{\sum_i n_i/\nu_i}$$

where ν_i is the viscosity of i gaseous species at pressure equal to its partial pressure in the mixture.

An example of calculation based on Eq. [8] is shown here for the case of Ge etching with H_2 + HI mixture. Our experimental results obtained for this process in a horizontal reactor with the substrate perpendicular to the gas flow direction have been used for comparison with calculated data.

Table II. Equilibrium partial pressure of gaseous species

P_H / P_I	Gaseous species	Partial pressure, atm 800°C	850°C	900°C
151.1	GeI_2	$2.08 \cdot 10^{-3}$	$2.09 \cdot 10^{-3}$	$2.10 \cdot 10^{-3}$
	HI	$8.50 \cdot 10^{-3}$	$8.59 \cdot 10^{-3}$	$8.68 \cdot 10^{-3}$
	H_2	$9.89 \cdot 10^{-1}$	$9.89 \cdot 10^{-1}$	$9.89 \cdot 10^{-1}$
48.4	GeI_2	$1.04 \cdot 10^{-2}$	$1.04 \cdot 10^{-2}$	$1.04 \cdot 10^{-2}$
	HI	$1.91 \cdot 10^{-2}$	$1.89 \cdot 10^{-2}$	$1.88 \cdot 10^{-2}$
	H_2	$9.69 \cdot 10^{-1}$	$9.69 \cdot 10^{-1}$	$9.69 \cdot 10^{-1}$

Table III. Calculated values of several parameters

P_H/P_I	Temperature, °K	$\rho \cdot 10^5$ (g · cm^{-3})	u_e cm · sec^{-1}	ν cm^2 · sec^{-1}	$Re_{L/2}$	$Re_{L/2}^{1/2}$	St	$K_w \cdot 10^2$	$b \cdot 10^2$	R_t calc μmk · min^{-1}	R_t exper. μmk · min^{-1}
151.1	800	4.10	18.3	7.40	0.98	0.99	0.55	3.98	4.21	1.85	1.74
	850	3.90	18.9	8.00	0.95	0.97	0.56	4.03	4.19	1.94	1.79
	900	3.80	19.8	8.60	0.92	0.96	0.57	4.04	4.20	1.99	1.86
48.4	800	7.80	18.3	5.20	1.41	1.19	0.46	9.69	10.8	7.80	8.21
	850	7.60	18.9	5.70	1.34	1.16	0.47	9.70	10.7	8.05	8.50
	900	7.30	19.8	6.10	1.30	1.14	0.48	9.75	10.7	8.35	9.10

Values of the system parameters, used both in the experimental study and in calculations, were the following

$$S = 0.785 \text{ cm}^2, \quad V_{H_2} = 235 \text{ cm}^3 \cdot \text{min}^{-1} \text{ (at 300°K)}$$

$$V_{HI} = \frac{2 V_{H_2} \cdot P_{I_2}}{760 - P_{I_2}} \text{ cm}^3 \cdot \text{min}^{-1} \text{ (here } P_{I_2} \text{ is V.P. of iodine at the I source)}$$

$$V_{To} \text{ (total)} = V_{H_2(To)} + V_{HI(To)}, \frac{L}{2} = 0.4 \text{ cm}$$

Table II shows computed equilibrium partial pressure of gaseous species for two values of hydrogen to iodine ratio, P_H/P_I, used both in the experiment and calculations. These data were employed for surface concentration, K_w, and parameter b calculations.

The parameter b was calculated from relationship $b = (K_e - K_w)/(1 - K_w)$. For the process under consideration $K_e = 0$ because the incoming gas mixture does not contain germanium compounds.

It has been assumed that the process at 800°-900°C is purely diffusion controlled so that the surface pressures could be considered as equilibrium ones.

Table III presents calculated values of several parameters used in the rate of process calculation. Value of the Pr needed for the St number calculation was taken equal to 0.8 as for diatomic gas mixtures. The last two columns show calculated and experimental values of the rate of process.

Buckling of Anodic Coatings

R. J. Block

Department of Chemical Engineering and Materials Science, The University of Oklahoma, Norman, Oklahoma

ABSTRACT

Anodic coatings on aluminum substrates undergoing tensile deformation have been observed to buckle. In general, buckling is a result of circumferential shrinkage of the surface. The buckling process is discussed, and an expression for the surface shrinkage of single crystals deforming on one slip system is derived.

The behavior of anodized coatings on aluminum undergoing plastic deformation has been studied by a number of investigators (1-3). However, one of the several mechanisms by which the coating accommodates the deformation of the substrate has not been described in the literature. Edeleanu and Law (4) and Bubar and Vermilyea (5) presented micrographs which showed buckling of anodic coatings but did not discuss the process.

Experimental

The present experiments consisted of extending monocrystals and polycrystalline aluminum wire in 0.4M boric acid solution brought to a pH of 5.5 with ammonium hydroxide. The aluminum had been electropolished, stripped of residual films, and both anodized and extended in the boric acid. The treatments produced barrier-type anodic coatings.

Results

Thick coatings accommodate deformation of the substrate by circumferential cracking after about 2% extension (6) and later by longitudinal buckling as shown in Fig. 1. Buckling is evidenced by the short vertical structures shown in the figure. The interference fringes apparent at each of the buckles indicate that the coating has indeed been lifted from the substrate. Figure 2 is a micrograph of an anodized polycrystalline wire showing buckling of the coating in one grain and general circumferential cracking. It should be noted that here as with the single crystal, both cracking and buckling are independent of slip plane traces in the substrate. A coating of intermediate thickness, 420Å, sometimes cracked along slip plane traces as shown in Fig. 3. When this occurred, short circumferential cracks were always associated with

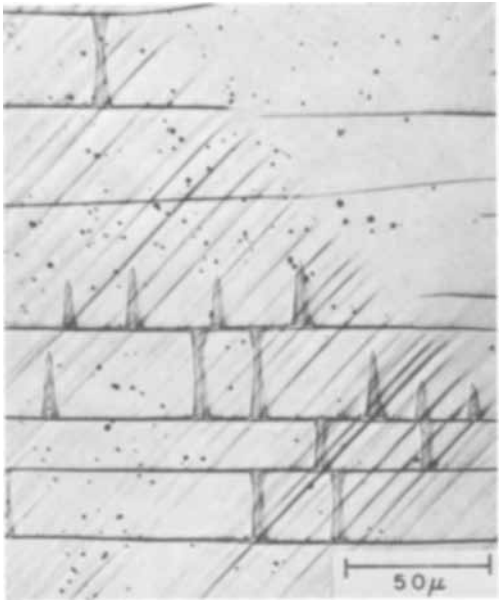

Fig. 1. Aluminum single crystal anodized at 90V and extended 14%. Tensile axis is parallel to vertical direction. Cracks in coating run horizontally. Wide vertical structures resulted from buckling of coating. Slip lines in matrix and in a kink band are visible beneath coating.

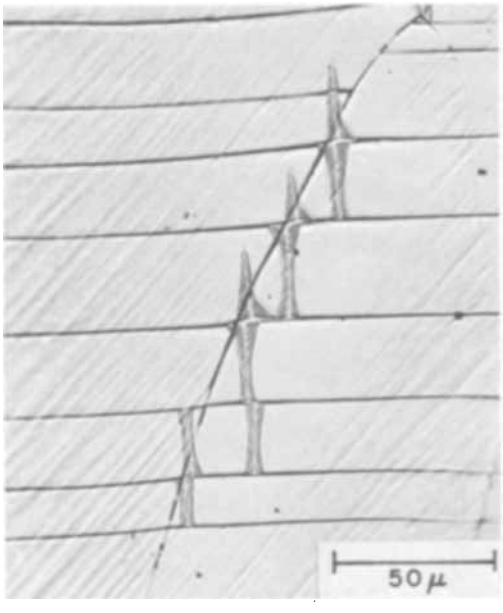

Fig. 2. Polycrystalline aluminum wire anodized at 90V and extended 3.7%. Extension was sufficient to cause general cracking of coating. However, buckling occurred only in isolated grains and at a few regions of singularity such as grain boundary shown.

the sites where buckling had occurred. Very thin coatings (approximately 100Å) showed only slip plane traces and were never observed to buckle. Presumably, their adherence exceeds their ability to support a significant load. The following discussion considers the behavior of thick coatings as illustrated in Fig. 1.

Discussion

Cracking of anodic coatings.—It is obvious that circumferential cracking results from substrate extension which is too great to be accommodated by the coating. The equivalent situation has been discussed by Edeleanu and Law (4) who invoked an interfacial slip mechanism to allow for stress relief between cracks

Fig. 3. Aluminum single crystal anodized at 30V and extended 11%. Cracks in coating formed along some of slip plane traces. In addition short circumferential cracks can be observed where buckling has occurred.

in the coating. Recently Grosskruetz and McNeil (7) also discussed the case of regularly spaced cracking of brittle coatings. There is some evidence from the present work that detachment of the coating ahead of the propagating crack permits partial stress relaxation in the coating.

Buckling of anodic coatings.—Buckling of the coating is due to shrinkage in the circumference of the substrate which results from extension. With specimens which should deform homogeneously, such as heavily cold worked wires, the circumferential shrinkage which produces buckling may be calculated directly from the extension, using a constant volume approximation. As the result of an experiment using as-swaged wire anodized at 90V, it was found that a circumferential shrinkage of 3.2% was required to initiate buckling of the coating. The problem of calculating the surface shrinkage of monocrystals deforming on a single slip system may also be solved in a fairly direct manner.

Surface shrinkage during single slip.—During single slip an initially circular specimen cross section becomes elliptical. According to the analysis of Schmid and Boas (8) the major axis of the ellipse is generally greater than the original specimen diameter while the minor axis is obviously reduced. Figure 4 represents this change in cross sectional shape, where R, the radius of the circle, is one half the original diameter, A is the major semiaxis of the ellipse, and B is the minor semiaxis. Assuming a coating on the specimen surface is broken into short cylindrical sections by circumferential cracks, then a point, (x, y), on the original surface at an angle, θ_0, to the major axis, becomes the point, (x', y'), at the angle θ_1 on the deformed crystal surface. The ratios of the axes, A/R and B/R, are p_1 and p_2 respectively, where p_1 and p_2 are the positive roots of Schmid and Boas' equation

$$p^4 + p^2\left[\frac{2\cos(\lambda_0 - \lambda_1)\sin\lambda_1}{\sin\lambda_0} + \frac{\sin^2(\lambda_0 - \lambda_1)}{\sin^2\chi_0}\right] + \frac{\sin^2\lambda_1}{\sin^2\lambda_0} = 0 \quad [1]$$

and λ_0 and λ_1 are the angles between the tensile axis and slip direction before and after extension and χ_0 is the angle the tensile axis makes with the slip plane. The transformation of a point on the circle to the cor-

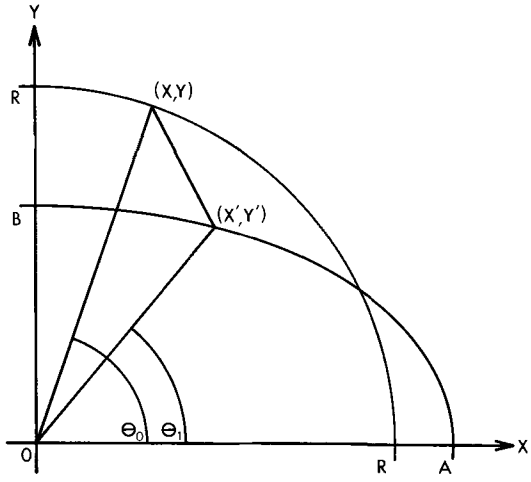

Fig. 4. Change in cross section of a cylindrical specimen undergoing single slip, diagram shows displacement of a point on surface of coating.

responding point on the ellipse is given by

$$x' = p_1 x \quad [2]$$

and

$$y' = p_2 y \quad [3]$$

From the equation of the circle and the transformation equations one obtains

$$dy = -\cot\ \theta_0\ dx \quad [4]$$

$$dx' = p_1 dx \quad [5]$$

and

$$dy' = -p_2 \cot\ \theta_0\ dx \quad [6]$$

The perimeter elements of the circle and the ellipse, dS_c and dS_e, are obtained from

$$dS_c^2 = dx^2 + dy^2 \quad [7]$$

and

$$dS_e^2 = dx'^2 + dy'^2 \quad [8]$$

Substituting in the above one obtains for the ratio of perimeter elements at a point on the circle and the corresponding point on the ellipse

$$\frac{dS_e}{dS_c} = \left[\frac{p_1^2 + p_2^2 \cot^2 \theta_0}{1 + \cot^2 \theta_0} \right]^{1/2} \quad [9]$$

One may now consider a few specific cases. When θ_0 is zero, the perimeter ratio, dS_e/dS_c, is p_2 and $0 \leq p_2 \leq 1$. The surface shrinkage, $1 - (dS_e/dS_c)$, always will be positive. When θ_0 is 90°, the perimeter ratio becomes p_1, where $1 \leq p_1 < (\sin \lambda_0 / \sin \chi_0)$. In this case the surface shrinkage is always zero or negative implying an expansion of the surface during deformation. Due to the limitations on the extent of single slip, one could expect only about 5% as the practical upper limit to circumferential surface expansion. This will be obtained for orientations of the tensile axis near [122].

For a given tensile extension there will be a point on the perimeter which has undergone neither shrinkage nor expansion. The angle, θ_1^*, to that point on the elliptical cross section is given by

$$\theta_1^* = \tan^{-1} \left[\frac{p_2}{p_1} \left(\frac{1 - p_2^2}{p_1^2 - 1} \right)^{1/2} \right] \quad [10]$$

A final case which might be worth noting is obtained when the crystal orientation is such that the tension axis, slip direction, and slip plane normal are coplanar, *i.e.*, $\lambda_0 = \chi_0$. Then the equation yielding the perimeter ratio assumes a particularly convenient form

$$\frac{dS_e}{dS_c} = \left[\frac{1 + \left(\frac{1}{1+\delta} \right)^2 \cot^2 \theta_0}{1 + \cot^2 \theta_0} \right]^{1/2} \quad [11]$$

where δ is the tensile extension.

The shrinkage at a point on the surface is thus a function of the extension and its direction relative to the slip vector for a crystal of a given orientation. In general the perimeter shrinkage increases from approximately zero for points near the surface through which pure edge dislocations exit the crystal, to its maximum near points on the surface through which pure screws egress.

Figures 5 and 6 illustrate the extremes in the behavior of the coating which was observed at various positions on a crystal in which $\lambda_0 \approx \chi_0$. The specimen shown had been deformed well into stage II, however, the regions associated with the "edge" and "screw" surfaces are still clearly defined. Longitudinal buckling characteristic of proximity to the "screw" face (Fig. 1 and 5) is never observed near the edge surface. In contrast, the appearance of the edge surface is shown in Fig. 6. Here, the coating has become detached and raised as a result of conjugate slip on planes whose

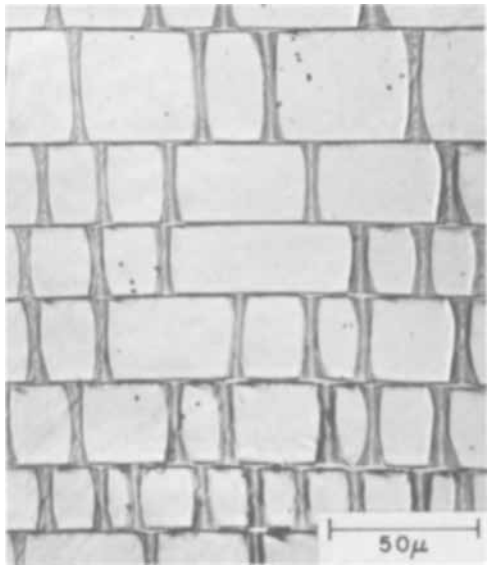

Fig. 5. Film buckling on "screw" surface of aluminum single crystal shown in Fig. 1.

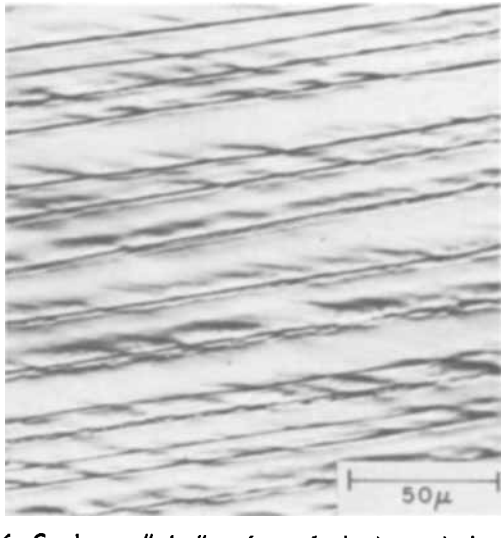

Fig. 6. Cracks on "edge" surface of aluminum single crystal shown in Fig. 1. Film has been lifted as a result of shear on intersecting slip planes, however, no buckling of coating has occurred.

traces intersect cracks which have formed earlier in the deformation. This phenomenon has already been described in the literature (4).

Acknowledgments

The author wishes to express his gratitude to Dr. J. H. Christensen for the many valuable discussions during the preparation of this paper, and to Mr. Parviz Mehdizadeh who prepared the specimens. This work was sponsored by the U.S. Atomic Energy Commission (Contract AT-(40-1)-3401) whose support is gratefully acknowledged.

Photosensitization of Terbium Fluorescence by Europium in CaF_2

Robert L. Amster[1]

Bayside Research Center of General Telephone & Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

Eu^{2+} sensitizes the fluorescence of Tb^{3+} in CaF_2. Furthermore, Tb^{3+} emission is sensitized by energy transfer from Eu^{3+}-O^{2-} complexes which possess intense broad ultraviolet absorption bands. The energy transfer from Eu^{2+} to Tb^{3+} is believed to occur by means of an exchange mechanism.

The fluorescence peak of Eu^{2+} in calcium fluoride is observed at 430 nm ($\sim$ 23,200 cm^{-1}) and corresponds to a transition from the lowest $4f^65d$ level, designated as $^8P_{5/2}$ or $4f^6(^7F_0)5d$ (e_g), to the $^8S_{7/2}$ ground state (1-6). When CaF_2 is activated with Tb^{3+}, an absorption line is observed at 487 nm ($\sim$ 20,500 cm^{-1}) which corresponds to the Tb^{3+} $^7F_6 \rightarrow {}^5D_4$ transition (7). An energy separation of only 2700 cm^{-1} between these Eu^{2+} and Tb^{3+} transitions suggests that one might observe nonradiative energy transfer from Eu^{2+} to Tb^{3+} in CaF_2. This nonradiative process would probably occur via a nonresonant transfer similar to that discussed by Van Uitert and Johnson (8). In such a case, the approximately 2700 cm^{-1} difference in energy between the ionic transitions would be transferred either to the ground state multiplet of a second Tb^{3+} ion or would be converted into lattice energy.

Nelson and co-workers (9) have observed energy transfer from Eu^{2+} to Tb^{3+} in fused silica. In silica containing only Tb^{3+}, the authors observed that 260 nm excitation yielded terbium fluorescence from both the $^5D_3$ and $^5D_4$ levels. When silica was doubly activated with Eu^{2+} and Tb^{3+}, they observed Tb^{3+} emission from only the $^5D_4$ level. They, therefore, concluded that Eu^{2+} selectively transferred energy to the $^5D_4$ level of Tb^{3+}.

In the present investigation CaF_2 has been doubly activated with Eu^{2+} and Tb^{3+}. Radiationless energy transfer from Eu^{2+} and within $(Eu^{3+}, Tb^{3+}, -O_2)^{2+}$ complexes to Tb^{3+} has been inferred. The results are discussed and models for the transfer processes are derived.

Experimental

The rare earth trihalides used were obtained from the Lindsay Division of American Potash Company and were reported to be 99.95% pure with respect to rare earth content. Calcium fluoride was Fisher Certified Reagent Grade. CaF_2:Eu^{2+}, CaF_2:Tb^{3+}, and CaF_2:Eu^{2+}, Tb^{3+} were produced by blending anhydrous EuF_3 and TbF_3 as required with CaF_2 and heating these mixtures for 2 hr at 1050°C in a hydrogen atmosphere. The starting materials were contained in alumina boats or crucibles and were held in a quartz tube through which hydrogen was continuously passed. The quartz tube, in turn, was inserted into a tube furnace initially heated to 500°C. The Eu^{2+} concentration in CaF_2:Eu^{2+} was varied between 0.001 and 0.035 g-atom/mole CaF_2. For the CaF_2:Tb^{3+}, the terbium concentration was generally 0.064 g-atom/mole CaF_2. In CaF_2:Eu^{2+}, Tb^{3+}, the Eu^{2+} concentrations were in the range 0.0025 to 0.05 g-atom/mole CaF_2 while Tb^{3+} concentrations ranged from 0.004 to 0.10 g-atom/mole CaF_2.

The emission and excitation spectra obtained were corrected in terms of energy *vs.* wavelength using a technique previously reported (10).

Results

The emission and excitation spectra of CaF_2:0.035 Eu^{2+} are shown in Fig. 1. Excitation at 390 nm yields a broad band fluorescence with a maximum at 430 nm. Excitation bands correspond to direct absorption by Eu^{2+}. Eu^{3+} emission is observed above 500 nm indicating that europium is incompletely converted to the divalent form even under strong reducing conditions. The relative emission intensities over a range of europium concentrations are as follows:

Eu^{2+} concentration, g-atom/mole CaF_2	Relative intensity of Eu^{2+} fluorescence
0.001	100
0.006	93
0.01	50
0.035	33

It is obvious from the data that increasing Eu^{2+} concentration in the range studied results in quenching of the divalent europium fluorescence.

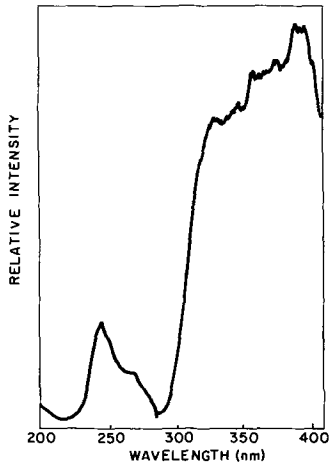

Fig. 1b. Excitation spectrum of CaF_2:0.035Eu^{2+} for emission at 430 nm.

CaF_2:Tb^{3+} emits very weak fluorescence from the $^5D_4$ level when excited with ultraviolet radiation; the most intense emission is observed at 542 nm corresponding to a $^5D_4 \rightarrow {}^7F_5$ transition (Fig. 2a). The excitation spectrum (Fig. 2b) consists of a number of sharp lines between 300 and 400 nm characteristic of Tb^{3+} absorption and a band extending from 300 nm into the far ultraviolet. The latter band corresponds to the absorption of Tb^{3+} from the $4f^8$ to $4f^75d$ configuration (11) plus contributions from OH^- and O^{2-} ions (12) which are present as a result of the initial presence of adsorbed water on the calcium fluoride. Oxide ion serves to charge compensate the excess positive charge introduced into the CaF_2 lattice when Tb^{3+} replaces a Ca^{2+} ion (13).

When CaF_2:Eu^{2+}, Tb^{3+} was excited by 390 nm radiation, Eu^{2+} emission was observed near 436 nm (Fig. 3a) corresponding to a shift of about 6 nm to longer wavelength relative to the emission from CaF_2:Eu^{2+}. (Although this shift is not apparent in the reduced figures, the shift is real, reproducible, and is readily observed in original spectra.) Intense terbium fluorescence was observed corresponding to emission from the $^5D_4$ level. The excitation spectra for both Eu^{2+}

and Tb^{3+} emission possess a broad band with a maximum near 390 nm corresponding to Eu^{2+} absorption (Fig. 3b). The fine structure of this band is similar for both CaF_2:Eu^{2+} and CaF_2:Eu^{2+}, Tb^{3+} and may be

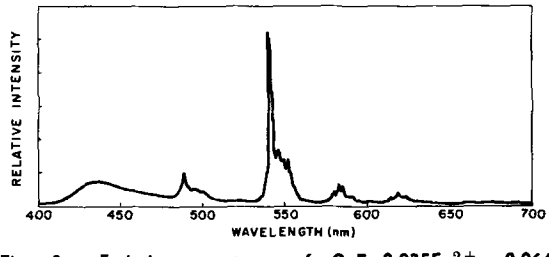

Fig. 3a. Emission spectrum of CaF_2:0.035Eu^{2+}, 0.064Tb^{3+} excited at 390 nm.

identified with transitions from the $^8S_{7/2}$ ground state to crystal field split sublevels of the excited $^8P_{5/2}$ state of Eu^{2+}. Although direct excitation of Tb^{3+} ions in CaF_2:Eu^{2+}, Tb^{3+} undoubtedly occurs, the Tb^{3+} excitation lines are probably obscured by the intense broad bands observed in the 200-400 nm region. A comparison of emission spectra of CaF_2:0.035 Eu^{2+}, 0.064Tb^{3+} with CaF_2:0.035 Eu^{2+} (Fig. 4) indicates that addition of Tb^{3+} to CaF_2:Eu^{2+} results in appreciable quenching of the entire Eu^{2+} fluorescence band. Furthermore, the presence of Eu^{2+} in CaF_2:Eu^{2+}, Tb^{3+} leads to considerable enhancement of Tb^{3+} emission relative to that in CaF_2:Tb^{3+} (Fig. 4). It is evident that nonradiative energy transfer occurs from Eu^{2+} to Tb^{3+} ions. Since the Tb^{3+} $^7F_6 \rightarrow {}^5D_4$ absorption is quite weak, the enhancement of terbium emission by addition of Eu^{2+} cannot be ascribed to a radiative transfer process. Rare earth ion concentrations of several mole per cent are required for the observation of $Eu^{2+} \rightarrow Tb^{3+}$ energy transfer. This indicates that short-range interactions are involved in the transfer process and suggests the possibility that the transfer occurs via an exchange mechanism (14).

In addition to the 390 nm band, the excitation spectrum for Tb^{3+} emission contains an intense structured band peaking at 310 nm (Fig. 3b). In a paper (10) concerning the emission and excitation spectra for CaF_2:Eu^{3+}, a similarly broad fluorescence excitation band was identified as a Eu^{3+}-O^{2-} charge transfer band. This was in turn associated with a $(Eu_2\text{-}O_2)^{2+}$ complex in which two nearest neighbor Eu^{3+} ions were bridged by two oxide ions. The oxide ions served to compensate the excess positive charges of trivalent europium substituted for divalent calcium in CaF_2. Forrester and McLaughlin (15) have proposed similar pair formation for Tm^{3+} in CaF_2: they concluded that Tm^{3+} ion pairs are bridged by two charge compensating O^{2-} ions when CaF_2 is reacted with Tm_2O_3. Eu^{3+} emission has been observed in CaF_2:Eu^{3+}, Tb^{3+} indicating that trivalent europium is present in this material. It is possible then that $(Eu^{3+}\text{-}O^{2-})_2{}^{2+}$ complexes and $(Eu^{3+}, Tb^{3+}\text{-}O^{2-})_2{}^{2+}$ complexes exist in CaF_2:Eu^{2+}, Tb^{3+}; the oxide ions would have been formed during reaction upon the high-temperature hydrolysis of the calcium fluoride with previously adsorbed water (13). The 310 nm band observed in the Tb^{3+} fluorescence excitation spectrum of CaF_2:Eu^{2+}, Tb^{3+} may be ascribed to charge transfer absorption by Eu^{3+}-O^{2-} in $(Eu^{3+}, Tb^{3+}\text{-}O^{2-})^{2+}$ followed by an intracomplex energy transfer with subsequent Tb^{3+} emission. That this band is not observed in the Eu^{2+} fluorescence excitation spectrum would indicate that either oxide ion bridged Eu^{3+}-Eu^{2+} complexes do not form or that there is no energy transfer within such complexes that can lead to Eu^{2+} emission.

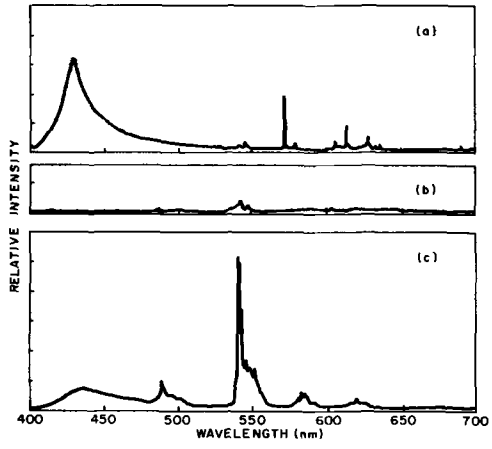

Fig. 4a. Emission spectrum of CaF_2:0.035Eu^{2+} excited at 390 nm; Fig. 4b. emission spectrum of CaF_2:0.064Tb^{3+} excited at 250 nm, all spectra recorded under identical conditions; Fig. 4c. emission spectrum of CaF_2:0.035Eu^{2+}, 0.064Tb^{3+}, excited at 390 nm.

Two alternative explanations may be given for the appearance of the 310 nm Tb^{3+} excitation band. It is known that the wavelength positions of divalent europium absorption bands are sensitive to the Eu^{2+} environment and may be observed near 300 nm. Thus, the 310 nm band might be ascribed to a Eu^{2+} ion in a lattice site differing somewhat from that of Eu^{2+} which is excited at 390 nm. One may assume that such Eu^{2+} ions, although transferring energy to Tb^{3+} ions, would yield some fluorescence like the Eu^{2+} ions absorbing at 390 nm. However, as noted previously the excitation spectrum for the only observed Eu^{2+} emission contains no 310 nm excitation band. It is, therefore, considered unlikely that the 310 nm band is a result of Eu^{2+} absorption.

The second alternate explanation for the 310 nm band is that it should be ascribed to the $4f^8 \rightarrow 4f^75d$ absorption in Tb^{3+} which is shifted to lower energy by the addition of europium (Eu^{2+} or Eu^{3+}) to CaF_2:Tb^{3+}. In no case has there ever been reported a Tb^{3+} f $\rightarrow$ d transition band in the 300 nm region. It appears quite unlikely that the presence of europium should have such an unusual effect on Tb^{3+} as to produce such a large shift in f $\rightarrow$ d absorption band wavelength. Additional support for the identification of the 310 nm excitation as a band associated with europium are the results of two other studies (17). In one case there was observed a 310 nm excitation band for Tb^{3+} fluorescence in $CaO\cdot 6Al_2O_3$:Eu^{2+}, Tb^{3+} and in another case for Mn^{2+} emission in $K_2O\cdot 6Al_2O_3$:Eu^{2+}, Mn^{2+}. In both studies the band was not observed when europium was not present. Clearly, this suggests that the 310 nm band is not to be identified with Tb^{3+} f $\rightarrow$ d absorption.

There is further precedent for associating the 310 nm band with Eu^{3+}-O^{2-} charge transfer. The presence of an oxide ion in the immediate vicinity of Eu^{3+} has given rise to charge transfer bands in the absorption and fluorescence excitation spectra of several activated materials. Blasse and Bril (18) have observed broad uv bands in the fluorescence excitation spectra of $NaGdO_2$:Eu^{3+} which they attribute to charge transfer from O^{2-} to Eu^{3+}. Similarly, Jørgensen (19) developed a theoretically founded explanation for such bands for Eu^{3+} in basic oxide solvents. It is reasonable to ascribe a similar identification to the 310 nm excitation band in CaF_2:Eu^{2+}, Tb^{3+}.

It must be recalled here that earlier studies reported nonradiative energy transfer from Tb^{3+} to Eu^{3+} in oxyanion salts (20). The transfer was considered to arise from a long-range electric dipole-electric dipole interaction. In the present study, the author explicitly suggests that the Eu^{3+}-Tb^{3+} interaction is short range and actually takes place via an intracomplex energy transfer. This is quite distinct from the earlier work where isolated Tb^{3+} ions were reported transferring to Eu^{3+}. One can best look on the transfer process in CaF_2 as arising from an absorption of energy by a $(Eu^{3+}, Tb^{3+}\text{-}O_2{}^{2-})^{2+}$ complex with the absorbed energy initially localized at a Eu^{3+}-O^{2-} band. The energy is subsequently relocalized at the Tb^{3+} ion by an intracomplex migration with resultant Tb^{3+} emission. In its simplest form, it is the Eu^{3+}-O^{2-} pair which is considered as the sensitizer of Tb^{3+}. Since it possesses an energy above ground (corresponding to 310 nm) greater than the $^7F_J \rightarrow {}^5D_4$ separation of Tb^{3+} it is possible for the $(Eu^{3+}\text{-}O^{2-})^+$ to Tb^{3+} transfer to occur. It must be repeated that such a model is in no way inconsistent with long range energy transfer from Tb^{3+} to Eu^{3+} in other host lattices.

Conclusion

It has been shown that Tb^{3+} emission can be photosensitized by nonradiative energy transfer from Eu^{2+} in CaF_2. It is further suggested that the appearance of

a 310 nm band in the Tb^{3+} excitation spectrum for $CaF_2:Eu^{2+}, Tb^{3+}$ indicates that energy can be absorbed by a $(Eu^{3+}, Tb^{3+}\text{-}O_2{}^{-2})^{2+}$ complex with the energy eventually becoming localized at the Tb^{3+} ion with resultant Tb^{3+} fluorescence. Such a model is supported by observations and is not inconsistent with earlier work where Tb^{3+} to Eu^{3+} energy transfer was reported.

Photoluminescence of ZnS:TbF_3 Thin Films

Y. S. Chen, J. C. Burgiel, and D. Kahng

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Photoluminescence from ZnS:TbF_3 evaporated films of approximately 1μ thick has been studied at room temperature as a function of the fluoride concentration. The excitation or pumping wavelength varies from 4880 to 2600Å, while the Tb^{3+} ($^5D_4 \rightarrow {}^7F_5$) emission transition at 5425Å is monitored at the output. For pumping photon energies below the ZnS forbidden gap, the excitation spectra resemble that of the pure TbF_3 film or single crystal. For this case, the conversion efficiency with 4880Å ($^7F_6 \rightarrow {}^5D_4$) pumping in samples that contain 0.86% TbF_3 is close to 100% as compared to 0.8% for pure TbF_3. With pumping energies above the ZnS gap, photoluminescence presumably due to energy transfer from electron-hole pairs has also been observed; however, such a process yields conversion efficiency generally in the 10^{-5}-10^{-6} range. These results support the model that electroluminescence in devices using similar films arises from direct excitation of Tb^{3+} levels by hot electrons as proposed by one of the authors.

The subject of photoluminescence (PL) in solids has been widely studied for the purpose of understanding impurity levels, energy transfer mechanisms, the effect of crystal field on transitions, as well as electroluminescent (EL) device mechanisms. In recent years, rare earth ions have been introduced into a number of host lattices (1), since it is possible to obtain emission lines corresponding to the orbital transitions of these ions. More recently, Anderson (2, 3) and also Razi and Anderson (4) reported EL and PL results of trivalent rare earth Tb^{3+} ion in ZnS single crystals. They have shown that the energy transfer mechanism is similar to that of the ZnS:Mn system (5), namely, resonant energy transfer resulting from electron-hole pair recombinations.

In this paper, we report the room temperature PL results of a new material system in which the rare earth fluoride molecules are incorporated within a host lattice. The particular system studied in this work is ZnS:TbF_3 thin films. Such films have been used in EL devices reported by one of us elsewhere (6). Our main purpose is to study the energy transfer mechanisms together with the efficiencies of such processes. We have also studied the emission and excitation spectra as a function of the fluoride concentration. A brief discussion is given at the end of this paper to relate the PL results to the proposed model for EL given in ref. (6).

Experimental

The system used for measuring the photoluminescence is given in Fig. 1. The excitation source consists of a 900W d-c Xe arc lamp, a 90-cycle chopper, and a Bausch & Lomb high intensity grating monochromator with interchangeable u.v. and visible gratings. The resolution used for excitation is 100Å.

The critical part of the system is the parabolic reflector in the sample chamber. The excitation beam travels through the window at the center of the reflector and is focused on the sample, which at the same time is positioned at the focal point of the reflector such that the PL signal generated can be efficiently collected. A Spex 3/4 meter spectrometer is used to analyze the PL spectra (resolution used is 10Å). Filters of appropriate characteristics were placed at the exit slits of the two monochromators to minimize the presence of scattered light from the excitation source.

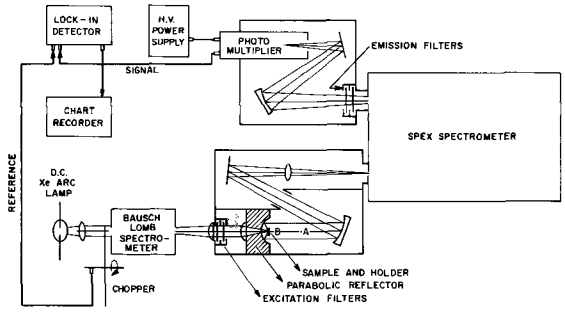

Fig. 1. Experimental setup for photoluminescence measurement

Sample preparation.—To determine quantitatively the conversion efficiency (defined as power emitted over power absorbed) of the PL signal generated in a thin luminescent film, it is necessary to know the excitation spectrum characteristic to the material and to know how much of the excitation power can be coupled to the film in the presence of interference phenomena. The problem of interference can be avoided by matching the indices of refraction of the film and the substrate which should be very thick and have slightly nonparallel surfaces. Such a sample geometry is depicted in Fig. 2. The aluminum mirror on the back of the substrate is provided to maximize the coupling between excitation and emission and to make sure that the reflected portion of the excitation beam can escape through the window in the parabolic reflector without suffering scattering onto the wall of the reflector.

We have prepared thin film samples of TbF_3 [n = 1.57 in the visible (7)] on quartz [n = 1.5 in the visible (8)] substrates and also thin film samples of ZnS [n = 2.3 at 5000Å (9)] with various TbF_3 concentration on $KTaO_3$ [n = 2.3 at 5000Å (10)] substrates. The samples were all prepared by evaporation or co-evaporation near 1000°C from separate sources onto a cold substrate. The optical properties of the thin TbF_3 film were found to be very close to that of the bulk TbF_3 single crystal. The concentration of TbF_3 in ZnS was determined by x-ray fluorescence and chemical analysis on the Tb content. The film thicknesses were determined optically (9).

PL efficiency and absolute power measurement.—To measure the absolute excitation and PL power, the following experimental steps were taken:

i. The power of the excitation beam, P_{ex}, was directly measured by a calibrated thermopile placed at B (see Fig. 1).

ii. The same excitation beam after a known amount of attenuation, X1, was measured by a photomultiplier (EMI No. 9558Q with S-20 response) placed at A in Fig. 1. The signal strength is $S(\lambda_{ex}, \Delta\lambda_{ex})$, where λ_{ex} is the wavelength of the excitation beam and $\Delta\lambda_{ex}$ is the bandwidth.

iii. The PL signal is measured by the same PM with a sample placed at B. The signal strength is $S(\lambda_o, \Delta\lambda_o)$, where λ_o is the emission wavelength and $\Delta\lambda_o$ is the bandwidth formed by appropriate filters. These filters attenuate the signal by X2. We have chosen $\Delta\lambda_o$ to embody the strongest line of the Tb^{3+} emission, namely the $^5D_4 \rightarrow {}^7F_5$ transition near 5450Å. Furthermore, since we are dealing the inner orbital transition of the rare earth ion, the emission spectra remain essentially fixed with respect to the variation of excitation wavelength and the total power content of emission is therefore proportional to the power content within $\Delta\lambda_o$.

iv. The proportionality contant, C, was determined by (*a*) taking the emission spectrum, (*b*) correcting the spectrum with the spectral response of the PM, (c) integrating out the areas of the entire spectrum and that within $\Delta\lambda_o$ and, finally (*d*) the ratio of the two areas is then the constant C.

v. The total power content of emission is then

$$P_{PL} = \frac{S(\lambda_o, \Delta\lambda_o) \cdot X1}{S(\lambda_{ex}, \Delta\lambda_{ex}) \cdot X2} \cdot P_{ex} \cdot C \cdot \epsilon$$

where ϵ is the relative PM response at λ_{ex} and λ_o (with $\Delta\lambda_{ex}$, $\Delta\lambda_o << \lambda_{ex}$, λ_o). The accuracy of the absolute power measurement was held to within ± 10%.

To determine the conversion efficiency of PL it is necessary to know the amount of power absorbed in the film. Such information is available from the absorption spectrum of TbF_3 single crystal, the ZnS reflection and transmission data above the energy gap, and the concentration of TbF_3 in ZnS.

In the weakly absorbing films such as TbF_3 pumped between 2500 and 4900Å and ZnS pumped well below the ZnS gap ($\lambda > 3600$Å), the relative amount of power absorbed can be expressed as (the sample geometry is given in Fig. 2)

$$\frac{\Delta I}{I} = \alpha \cdot 2d \qquad [1]$$

if

$$\alpha d << 1$$

and

$$\alpha d << \frac{1}{R} - 1$$

where I is the intensity of the incident light, ΔI is the loss of incident light due to the absorption, α is the absorption coefficient of the film, d is its thickness and R is the air-sample interface reflectivity and is equal to $([1 - n]/[1 + n])^2$ with n being the refractive index of the film (and the substrate). The substrate is assumed to be nonabsorbing in Eq. [1]. In Eq. [1], we have ignored the loss of the incident light due to the finite scattering in the film; this step is justified as long as the scattering process does not contribute to the emission process.

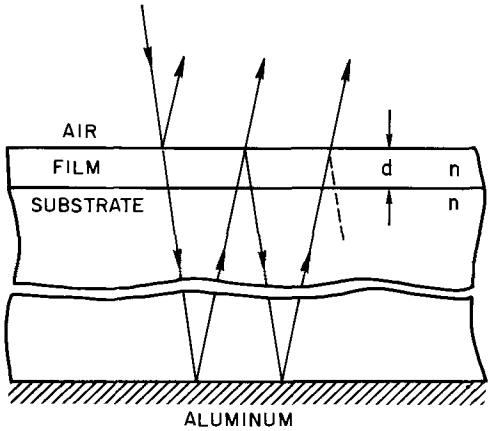

Fig. 2. Sample geometry used in photoluminescence measurement

Results

Three samples were investigated in this work: a TbF_3 film of 0.825μ in thickness, and ZnS:TbF_3 (3.3% and 0.86%) films of 1.17 and 1.66μ in thickness, respectively. The PL spectrum of a TbF_3 single crystal and those of the film samples under 2840Å pumping are given in Fig. 3. Notice that the fine structures appear in the spectrum of the TbF_3 crystal only. Understandably, excess strain and lack of symmetry in the film would cause the line broadening. To compare the results of PL in these film samples the $^5D_4 \rightarrow {}^7F_5$ (5300-5600Å) transition was monitored, while the excitation wavelength was varied from 2600 to 4880Å. This range of wavelength spans across the band edge of ZnS (~ 3200Å). No emission was observed under the excitation of 4700-3800Å; this means that the energy loss of the excitation beam due to the inevitable finite scat-

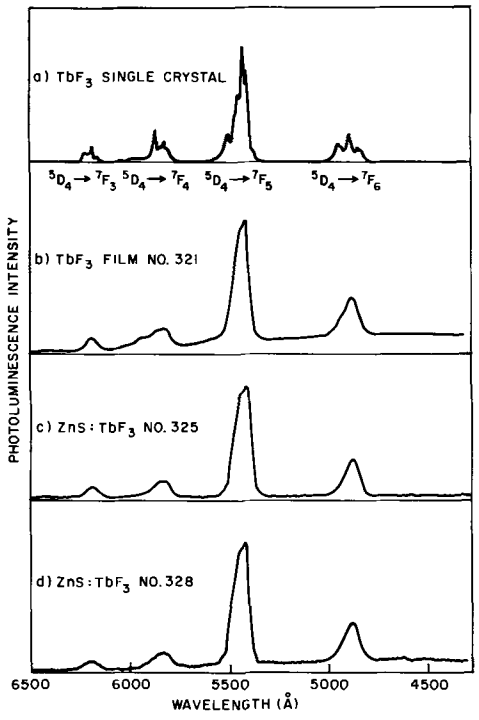

Fig. 3. Photoluminescence spectra at RT pumped with 2840Å light. (a) TbF_3 single crystal, (b) TbF_3 film 0.825μ thick (No. 321), (c) ZnS:TbF_3 (3.3%) film 1.17μ thick (No. 325), and (d) ZnS:TbF_3 (0.86%) film 1.66μ thick (No. 328).

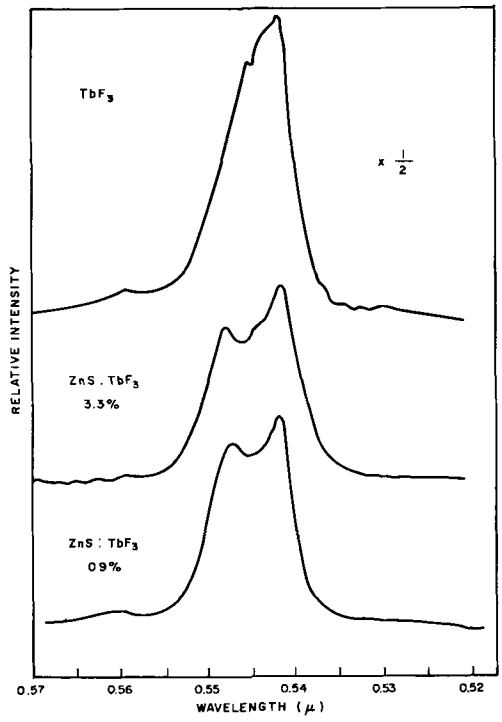

Fig. 4. Room temperature photoluminescence spectra near 5500Å of TbF_3, ZnS:TbF_3 (3.3%), and ZnS:TbF_3 (0.86%) films pumped at 4880Å.

tering in the film is not coupled to any energy transfer mechanism leading to the excitation (and the emission) of the Tb^{3+} ions. Thus the scattering loss, if any, can be treated the same as the reflection loss and can be ignored in the efficiency calculation of the energy transfer mechanisms. The results are given in Table I (columns I to III).

The 4880Å pumping was chosen in order to detect the direct excitation of Tb^{3+} in ZnS:TbF_3 as it is possible to have the combination of $^7F_6 \rightarrow {}^5D_4$ ($\sim$ 4880Å) up and $^5D_4 \rightarrow {}^7F_5$ down transitions. It is important to notice that the host ZnS at this wavelength is non-absorbing. The PL spectra of the film samples near 5500Å with 4880Å pumping are given in Fig. 4. Notice there is some difference between that of TbF_3 and those of ZnS:TbF_3; this difference could be due to the effect of host crystal field on the incorporated molecular centers.

The absorption band of the $^7F_6 \rightarrow {}^5D_4$ transition in TbF_3 single crystal has a bandwidth of 100Å and the absorption coefficient at the peak was measured to be 10 cm^{-1}. From Eq. [1] we have found the conversion efficiency for TbF_3 with 4880Å pumping is 0.8%. Under the assumption that the absorption by TbF_3 centers is proportional to the concentration and is independent of the medium in which they are situated (11), it was further found that the conversion efficiencies with 4880Å pumping are 12 and 32% for the 3.3 and 0.86% doped samples, respectively. These observed data clearly indicate the existence of a strong concentration quenching of the Tb^{3+} $^5D_4 \rightarrow {}^7F$ emission.

Notice that the power conversion efficiency of PL by direct excitation is near unity at a concentration level [$\sim$ 1 m/o (mole per cent)] much higher than the reported solid solubility of bare Tb^{3+} in ZnS ($\sim$0.01 m/o) (2, 12).

The conversion efficiencies for pumping above the ZnS gap are typically 10^{-5}-10^{-6}, as shown in column V of Table I. This is because the absorption coefficient α is typically of the order of 10^5 cm^{-1} in ZnS. In other words, most of the pumping energy is consumed to create electron-hole pairs. It is of interest to see if there exists, while pumping above the ZnS gap, a mechanism to transfer energy from the electron-hole pair recombination to the excitation of TbF_3 centers in addition to the direct excitation intrinsic to these centers. Such a mechanism can be referred to as lattice-coupled excitation. To investigate this, it is necessary to know the penetration depth δ ($= 1/\alpha$) of incident light into the ZnS film and the measured values are given in column IV of Table I. The value of δ determines the volume in which the energy transfer due to the direct excitation takes place. The ratio $\mathcal{R}$ of PL due to lattice coupled excitation over that from direct excitation can be defined as

$$\mathcal{R} = \left[\frac{PL_{ZnS}(\lambda)}{PL_{ZnS}(\lambda_o)} \cdot \frac{2d}{\delta}\right] \Big/ \left[\frac{PL_{TbF_3}(\lambda)}{PL_{TbF_3}(\lambda_o)}\right] - 1 \quad [2]$$

where $PL_{ZnS}(\lambda)$ and $PL_{TbF3}(\lambda)$ are the PL intensities pumped above ZnS energy gap, $\lambda_o = 4880$Å, and d is the thickness of ZnS:TbF_3 film. The results are given in column VI of Table I. Indeed there exists some noticeable lattice coupled excitation although only 10^{-5} of the excitation energy is converted into PL. Furthermore, the sudden increase of $\mathcal{R}$ near 3300Å is further evidence that lattice coupled excitation takes place. The absolute magnitude of $\mathcal{R}$ was found to vary slightly from sample to sample because of variations in the competing nonradiative processes.

Discussion

Our results can be summarized as follows:

1. The molecular center, TbF_3, in ZnS can be pumped directly and efficiently at levels below the energy gap of ZnS. This is true presumably for any host lattice and any rare earth fluoride dopant. The conversion efficiency, which is enhanced greatly in a dilute system, can be close to 100%.

2. The same centers can be excited via energy transfer from electron-hole recombination if pumped at energies above the forbidden gap of the host lattice. The efficiency for this process (lattice coupled excitation) is very poor and is in the range of 10^{-5}-10^{-6}.

There is very little data in the literature concerning PL in thin films to compare with our results. Efficiency of resonant transfer in ZnS:Ag powder sample has been reported as high as 21% (13) and rare-earth ions in a tungstate system gives efficiency near 1% (1).

When the ZnS:TbF_3 film is used in the electroluminescence device as described in ref. (6), the external power efficiency is about 10^{-4} (corresponding to an internal efficiency of $\sim 10^{-3}$ due largely to total internal reflection). The ionization coefficients for pair production in insulating ZnS single crystals and films, using conventional methods (14), were found by us to be 5×10^2 cm^{-1} at 10^5 V/cm and less than 10^4 cm^{-1} at 10^6 V/cm. Therefore, the efficiency for pair production from the injected carriers in the EL device is at best 5×10^{-2} for a 1000Å ZnS:TbF_3 film. The over-all power efficiency of EL emission, if lattice coupled excitation is the dominant mode, would be at best in the range of 10^{-6}-10^{-7}, which is clearly too small compared to the observed value. On the other hand, if the Tb^{3+} ions in ZnS:TbF_3 are impact excited directly, one would merely require an impact excitation coefficient of 200 cm^{-1} at 10^6 V/cm for these centers to achieve the observed efficiency in the EL devices. Thus we believe, from our PL results, direct impact excitation of the Tb^{3+} ions in ZnS:TbF_3 films is indeed the most likely mechanism for observed electroluminescence as proposed by one of the authors (6).

Acknowledgments

The authors wish to thank M. V. DePaolis for designing the PL sample chamber and many other technical assistances. They are also indebted to E. W. Chase for preparing the samples and to S. M. Vincent for analyzing the fluoride concentrations of the ZnS:TbF_3 samples.

Manuscript submitted Nov. 7, 1969; revised manuscript received Feb. 25, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

Some Aspects of Optical Measurement of Luminescence

W. A. Thornton

Advanced Development Department, Lamp Division,
Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Five aspects, all of which lead toward simplification of measurement, are discussed. It is shown that: (*I*) Slit width and resolution have no effect on the proper measurement of a line-plus-continuum spectrum; *i.e.*, the proper energy ratios are obtained independent of resolution as long as point-by-point analysis is used. (*II*) Calculated chromaticity of line-plus-continuum spectra such as those of fluorescent lamps is constant to ½% for slit width (line width at half-maximum) as great as 15 nm. Simpler analysis of lines as triangular area is as accurate and precise. (*III*) Differences in calculated characteristics of line-emitting phosphors are negligible at slit widths up to at least 8 nm. (IV) Spectrum broadening by nonzero slit width amounts, for example, to 1-2% for a slit-width/band-width ratio of 0.2. (V) A rough method of fluorescent lamp analysis by unequal slits and 10 nm intervals results in chromaticity accurate to 1% or better.

Accurate optical measurement of the spectral energy distribution (SED) of lamps or phosphors is at best difficult, particularly when line emission, or line emissions plus continuum, are present. Five aspects of such measurement are discussed, with the objectives of simplification without loss of necessary accuracy and of clarifying the advantages and validity of certain simplifying procedures.

Dispersing instruments used for analyzing the spectral energy distribution of a light source, as a function of wavelength, generally allow variation of resolution, usually by adjustment of the width of one or more slits at focal planes in the instrument. In this paper, resolution is specified as the width in nanometers, at half-height, of the apparent SED of actual line emission of zero width. For example, the 436 nm emission line from a mercury vapor discharge serves reasonably well as a source by which to measure the resolution, thus defined, of a dispersing instrument. Many research problems in luminescence require the best resolution attainable; that is the narrowest possible apparent SED of actual line emission. The reader is reminded that there are, however, numerous and important problems in luminescence for which excellent resolution is not only not required, but of no actual advantage, and thus in fact wasteful of time and effort in analysis. Examples are chromaticity, lumen output, and color rendering index of lamps, and chromaticity, quantum efficiency, mean wavelength, and luminosity of the emission of phosphors. The determination of most of these characteristics requires only moderate resolution simply because the tristimulus or color matching functions of human vision are involved multiplicatively, and these functions are comparatively structureless. Analysis of the SEDs of lamps or phosphor emission is simpler the broader the resolution of the dispersing instrument used; that is, the necessary sampling interval in point-by-point analysis becomes larger the broader the resolution, and fewer points suffice to analyze a given spectrum. One of the central considerations of this paper is the influence of this breadth on accuracy of analysis.

Effect of Slit Width or Resolution on Proper Measurement of a Line-Plus-Continuum Spectrum

It has been suggested by some that whether or not one obtains the proper relationship between the energy contents, for example, of a narrow line and of a continuum present in the same spectrum, depends on the slit width and resolution of the instrument used. The purpose of this section is to show that there is no basis for this proposal, and that in fact there is no range nor combination of slit widths (resolution) which in itself causes error.[1] We assume throughout that point-by-point analysis of experimental spectra is performed, in the manner now used by NBS (1), and that the attempt is not made as in past years (2, 3) to use some sort of relationship between peak heights and pass-bands.

Slit widths much smaller than the width of any component of the spectrum.—In this case, the spectrum of the source will be laid down in the exit plane with its correct spectral energy distribution. Scanning by an exit slit of the same width as the entrance slit, or larger or smaller, will yield the correct spectral energy distribution as long as the width of either slit is very small compared to the structure of the spectrum, as assumed. Hence the integrated energy in any component of the spectrum will bear the proper relationship to the integrated energy in any other component.

Slit widths much larger than the width of some component(s) of the spectrum.—Assume an actual spectral distribution, as shown in Fig. 1A, consisting of a broad continuum and a superposed very sharp

[1] Of course, one must retain sufficient resolution not to introduce significant errors due to wavelength-dependent correction factors, but this is a separate consideration, and such correction curves are also comparatively structureless.

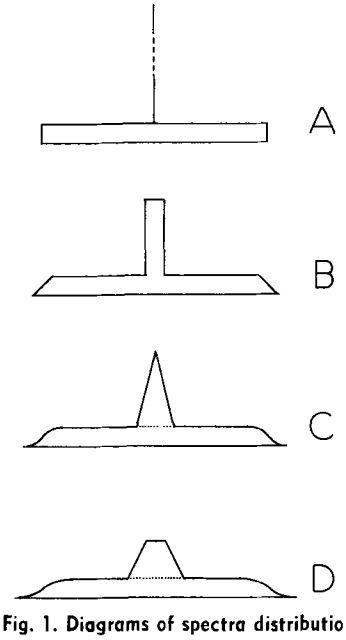

Fig. 1. Diagrams of spectra distribution

line of arbitrary height (intensity); the abscissa in Fig. 1A can be considered to be linear in wavelength, but in the following figures the abscissa will represent only the direction along which dispersion takes place, and the ordinates will represent proportional intensity in some units.

Figure 1B represents the way the spectrum of Fig. 1A is laid down in the exit plane by a dispersing instrument with entrance slit equal to one division. The entrance slit, however wide, is assumed to be filled with diffuse radiation, or at least that it and the entrance aperture are filled; any other arrangement will introduce source geometry as a factor, although it will be shown later that this is also unimportant to the question at hand. Note that the abscissa of Fig. 1B is no longer simply in wavelength units since the one-division-wide pedestal atop the continuum now represents essentially a single wavelength. Figure 1B indicates that the spectrum consists of 12 units in the continuum and 4 units in the line, and the question is, "Does this ratio apparently change with slit width?" Figure 1C represents the apparent spectral distribution as the spectrum 1B is scanned by an exit slit equal to one division. The "gain" convention used throughout this section is that when the exit slit is filled by and only by the continuum the output signal is equal to the actual intensity of the continuum. The continuum-line ratio remains 3 for this condition of equal slits. Figure 1D represents the apparent spectral distribution as the spectrum 1B is scanned by an exit slit equal to two divisions. The continuum-line ratio remains 3 for this condition of unequal slits.

The inference is that a slit width much wider than the width of the line emission in a line-continuum spectrum nonetheless yields the correct proportion of integrated energies in the line and continuum; again it is clear that entrance and exit slit widths need not be equal.

Slit widths comparable to the width of some component(s) of the spectrum.—It could be assumed that if no trouble arises in the cases given in the two previous sections that all should be well in the case of comparable widths also, and this is shown by the following. Let Fig. 2E represent an actual spectral energy distribution consisting of a continuum (20 units) and a "line" (4 units) which is two units wide at its base. If the entrance slit is two divisions wide, Fig. 2F represents the way the actual spectrum of Fig. 2E will be laid down in the exit plane; the 20/4 area ratio of course still holds. Figure 2G represents the apparent spectral distribution as the spectrum 2F is scanned by an exit slit equal to two divisions. The shaded areas were plotted on a larger scale and were found equal to one part in 300. This is taken as proof that slit widths comparable to line widths can still, in themselves, cause no error in point-by-point analysis of areas under the different components. One additional case was considered: that where slit width is several times line width. Again, Fig. 3H represents the actual distribution, Fig. 3J the distribution in the exit plane by a four-division entrance slit, and Fig. 3K the result of scanning 3J with a four-division exit slit. The area ratios are the same in H, J, and K. No problem exists within the scope of this discussion in obtaining the proper intensity relationship between "line" emission and a continuum in the same spectrum. It is suggested that the reader convince himself by drawing and integrating areas in the manner of Fig. 1-3. Since it has been shown that entrance and exit slit widths need not be equal, and it is apparent that failure to fill the entrance aperture will not affect the layout of the spectrum in the exit plane, it follows that it is irrelevant how the source radiation is introduced into the instrument.

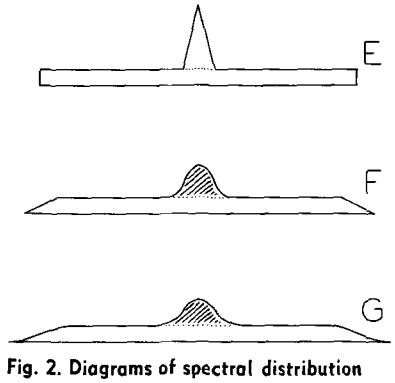

Fig. 2. Diagrams of spectral distribution

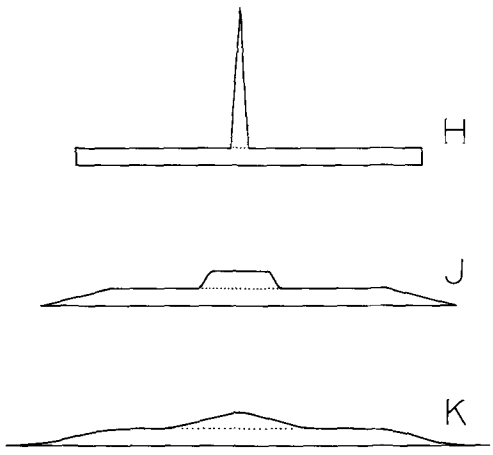

Fig. 3. Diagrams of spectral distribution

An experimental verification was done by analysis of a 365 nm mercury line superposed on the continuum due to calcium tungstate phosphor; the same ratio of energies in the line and continuum was obtained, within experimental error, over an 8X range of slit width (1.5-12 nm width at half-maximum of the apparent SED of the 365 nm Hg line).

Fluorescent Lamp Chromaticity vs. Slit Width and Method of Analysis of SED

A method for determining chromaticity of fluorescent lamps, which is both as simple and as accurate as possible, is of course needed wherever lamp color is rigidly specified. The usual colorimeter has a long history of difficult, if not excruciating, problems mainly because its good precision is limited to light sources which are very similar indeed in SED to the carefully calibrated standard lamp which must ordinarily be used. Therefore, NBS in September 1965 (1) changed "from a visual to a spectroradiometric basis for calibrating fluorescent lamp chromaticity coordinates." That is, lamp chromaticity would henceforth be determined from the SED of the lamp. The NBS method is a point-by-point (wavelength-by-wavelength) comparison of fluorescent lamp output to that of a standard incandescent lamp. The NBS paper (1) by Hammond quotes the following errors:

Repeatability of x and y by new method[2,3]:	0.002
Agreement with old method:	0.003
Range of values by three laboratories[3]:	0.004

On this basis, "the NBS therefore has decided that the accuracy of the spectroradiometric measurements is now sufficient to permit the calibration of fluorescent-lamp chromaticity standards from such measurements" (1).

A brief comparison of experimental procedure follows. NBS: Wavelength-by-wavelength comparison of outputs of unknown fluorescent and standard incan-

[2] NBS, GE, and Durotest are the three laboratories quoted as using the new method.

[3] A more recent NBS fluorescent lamp round robin (analysis completed in September 1969) showed an average deviation in x and y among five laboratories of 0.0025.

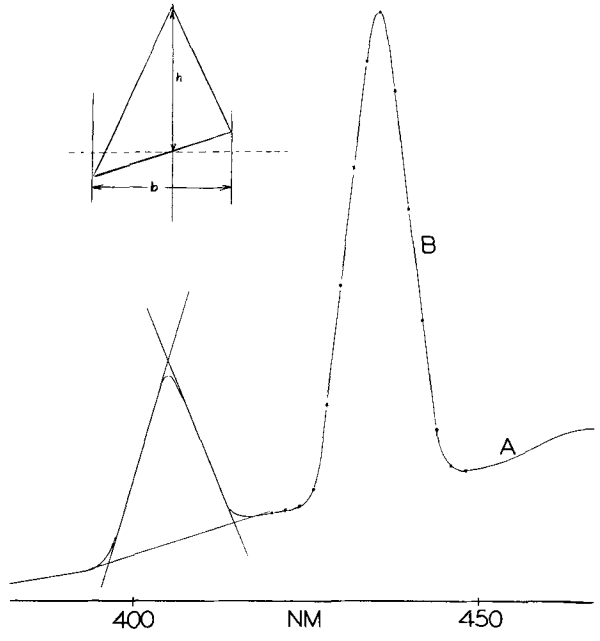

Fig. 4. Portion of SED of 40W 3500K white lamp

descent lamps. Here: Run raw SED, correct, and calculate by computer from stored data from standard incandescent lamp. Measurement time: NBS: About 40 min. Here: About 40 sec. Both: Accept light from a short section of the fluorescent lamp. Here: Also can use an integrating enclosure containing both fluorescent lamp and incandescent standard (only one of which is operating at one time) and from which the monochromator samples the integrated emission. Both: Entrance and exit slits equal; passband equal to about 6 nm, normally. Both: use EMI 9558 photomultiplier and anode amperes less than 10^{-6}.

Our method of analysis is illustrated in Fig. 4, which is a portion of the raw SED of a 40W 3500K White lamp, using 3 mm slits, which lead to a line width at half maximum of roughly 9 nm. The objective was to see (*a*) whether calculated chromaticity of a particular lamp varied with slit width or (*b*) whether the line emission was analyzed as areas of the triangles or point-by-point analysis, at various wavelength intervals, over the trace of the line emission. Both methods are illustrated in Fig. 4. When the mercury line emission was measured as triangular[4] areas (nm times vertical units), the phosphor emission continuum A was measured at 10 nm intervals. When the line emission was measured point-by-point (as, for example, in 2 nm intervals at B) the continuum was measured at the same or different intervals, as convenient. Obviously it is much simpler to measure the continuum from end to end at large (here 10 nm) wavelength intervals and then to add the triangular areas at the center wavelengths of the mercury lines; it turned out that this is just as accurate as the point-by-point method.

The results are given in Table I. Chromaticity varies by at most 0.002 with (*a*) variation in slit width (resolution) over a factor of five, or (*b*) analysis of mercury lines simplified to triangular areas rather than analyzed point-by-point at sufficiently small intervals, *i.e.*, the two methods pictured in Fig. 4.

It is concluded that any convenient slit width up to a resolution (line width at half-maximum) of at least 15 nm may be used without degrading chromaticity results beyond the 0.002 repeatability level experienced by NBS (1). The simpler triangle method of analysis, which allows measurement of the continuum as a whole and at wide wavelength intervals, and avoids

[4] The reader is reminded that the area of a skew triangle is half the height times the projected base; see sketch in Fig. 4.

Table I. Calculated chromaticity x, y in 1931 CIE color space, of a single 3500K white 40W fluorescent lamp, as a function of method of analysis of lamp SED

7.	2.5-6	7.5-18	0.4054	0.3953	Point by point, all 10 nm

* Entrance slit, then exit slit. Grating monochromator.
** Interval used to analyze mercury lines.

point-by-point analysis of mercury lines, is as accurate and as precise as the latter. This conclusion applies, of course, to SEDs other than those of fluorescent lamps. On the other hand, where great accuracy is called for, as in the case of fluorescent lamp standards, these approximate methods must be used with caution since the presently achieved precision of 0.002 in chromaticity must be improved.

Integrated Optical Characteristics of Line Emitters

Because of their interest in transitions among many discrete, closely spaced energy levels, some researchers like to measure their emission spectra at resolutions at least as high as 0.1-0.3 nm. On the other hand, because such spectra, when they consist of several or many lines, become prohibitively difficult to analyze accurately point-by-point, some workers purposely reduce resolution; this makes analysis simpler, although it is still arduous to analyze, for example, a many-line-emitting phosphor like yttrium oxide:Eu^{3+}.

At the higher resolutions used, even though the spectra are nominally corrected by some device, one has to be content with rather approximate relative line heights and (if two or more lines are unresolved) very little idea of the total energy in a composite group. By reducing resolution and using point-by-point analysis to obtain a rather precisely corrected spectral energy distribution (from which total energy, total photons, total lumens, quantum efficiency, chromaticity, mean wavelength, luminosity, etc. can be calculated), we attain a precision which is of the order of one MPCD (minimum perceptible color difference) in chromaticity, for example.

The question is: How much accuracy is forfeited by reducing resolution to this extent? That is, will the broadened SEDs give appreciably different, and erroneous, values of chromaticity, lumen output in blends, and the like? The SED of yttrium oxide:Eu^{3+} (YOE) was simplified to three lines as indicated in Fig. 5. Then this SED was altered by broadening the lines to Gaussian energy distributions 8 nm wide at half-height. Total energy under the SEDs remained constant, although this is not indicated in Fig. 5. Chromaticity, mean wavelength, and luminosity factor were computed for the SEDs. They were then combined by computer in blends with other phosphors and lumen output and color rendering index computed.

Table II lists chromaticity x, y, mean wavelength $\bar{\lambda}$ in nm, luminosity factor η, total lumen output of the blend including discharge in a 40W LPMV fluorescent lamp, color rendering index, and correlated color temperature of the blend SEDs. These tabulated quantities differ, for the most part, by two parts per thousand or less. In the case of chromaticity, the difference amounts to less than one minimum perceptible color difference.

It is concluded that the differences in calculated characteristics of SEDs of a single line-emitting phos-

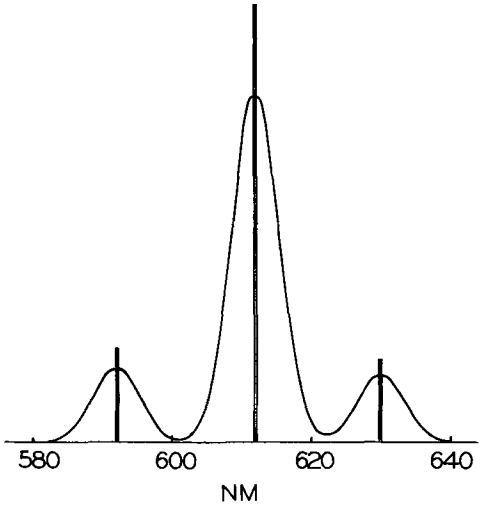

Fig. 5. Simplified SED of yttrium oxide:Eu^{3+}

phor, or of a complete lamp containing that phosphor in a blend, are completely negligible if resolution in terms of half-width in nanometers falls in the range 0-8 nm.

SED Broadening by Finite Slit Width

The true "natural" width of line or band emission is always apparently somewhat broadened by the use of nonzero slit width. It is sometimes useful to know the magnitude of this apparent broadening given the resolution of the dispersing instrument, either to know whether the apparent broadening is appreciable, or to be able to correct for it and thus obtain the true width of the emission.

Given a Gaussian distribution as the model SED, calculations were made of the apparent broadening by entrance and exit slits of various widths, both equal and unequal. The procedure was the same as that used in the section on Effect of Slit Width; the Gaussian distribution was scanned by a slit (pass-band) of a given width in units of the abscissa, the resulting "signal" was plotted and that distribution scanned again by a slit of the same or different width (pass-band). The width at half-maximum of the final distribution was then compared to that of the original distribution. The results for equal slits are plotted in Fig. 6 as fractional apparent increase in band width *vs.* the ratio of slit width (*i.e.*, equivalent resolution in wavelength units) to true band width. A range of ratios from about 0.02 to about 2.0 was covered. For example, the cross in Fig. 6 might represent a slit width of 8 nm (that is, a resolution equivalent to a broadening of line emission to 8 nm width at half maximum; this might result from an actual slit width of 2-3 nm in a given monochromator) analyzing an SED like that of zinc silicate:Mn of 40 nm width at half-maximum true band width. Thus the ratio will be 0.2, and we can expect a broadening of less than 2%. At very high ratios (broad slits, narrow emission) the broadening will be equal to the slit width, both in units of the true emission width; hence the asymptote of slope unity. Experimentally, at least for the monochromators[5] used in the present work,

[6] 500 mm, concave mirror, reflection grating.

Table II. Characteristics of the phosphor SEDs alone and in blends

Line width, nm	x	y	$\bar{\lambda}$	η	Blend L_0 (%)	Blend CRI	Blend CCT
0	0.6591	0.3406	611.4	0.4877	100.1	77.7	4062K
8	0.6580	0.3417	611.4	0.4881	100.0	77.8	4068K
	0.005	0.002	(1 MPCD)				

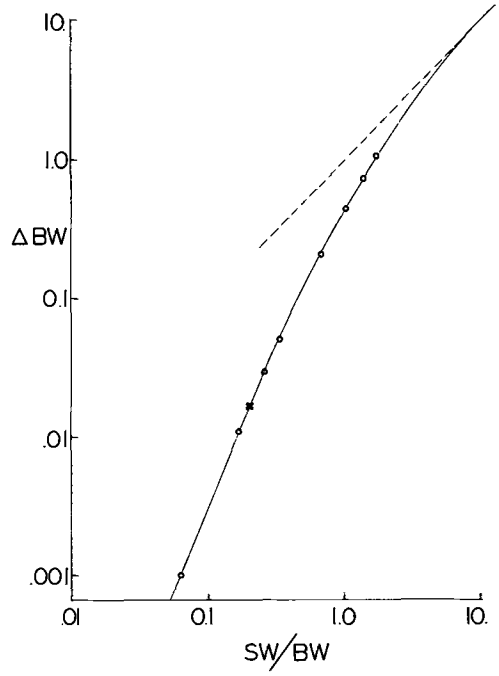

Fig. 6. Results for equal slits plotted as fractional apparent increase in band width *vs.* ratio of slit width to true band width.

observed broadening due to slit width is always less than predicted, presumably because other factors slightly broaden the apparent SED and prevent determination of the exact "true" width even at very small slit widths. Unequal slits cause broadening relatively 10-20% greater than that due to equal slits of the average value, but much less than that due to equal slits of the greater value.

Rough Method of Analysis of Fluorescent Lamps

The line emission of fluorescent lamps is a little work to analyze even if triangular areas are substituted for the lines as discussed in the section on Fluorescent Lamp Chromaticity. Slits can be widened so as to smear the SED to the point where 10 nm intervals are sufficiently closely spaced to sample adequately the SED. It happens, however, that the more important visible mercury line emissions fall near 5 nm multiples in wavelength. Hence it seemed likely that a certain choice of unequal slit widths would cause these line emissions to appear as trapezoids with corners falling

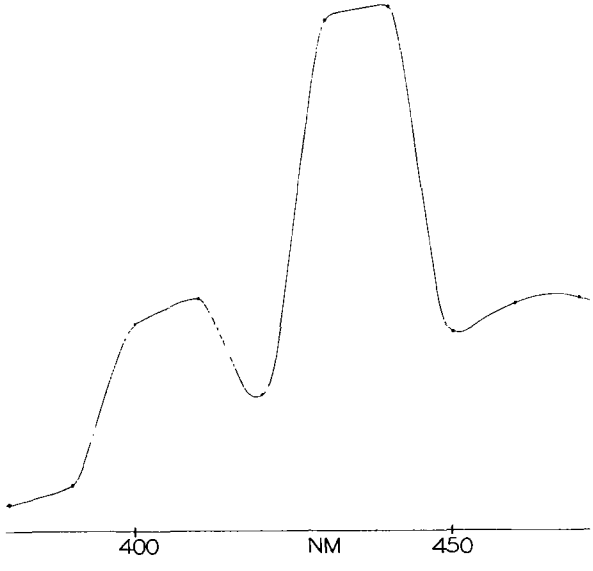

Fig. 7. SED of white (3500K) Standard fluorescent lamp

approximately at 10 nm multiples. In this way, 10 nm intervals would be expected to lead to more accurate evaluation of fluorescent lamp SEDs than if the necessarily greater broadening by wider, equal slits were resorted to.

Figure 7 is the SED of the same White (3500K) Standard fluorescent lamp, obtained with unequal equivalent slit widths (resolutions) of about 10 and 20 nm, corresponding roughly to 3 and 6 mm slits in the monochromator used. Calculated characteristics analyzed at 10 nm intervals are compared in Table I to those of the same lamp measured in the more conventional manner with equal slit widths and analyzed in narrow intervals or by the use of triangular areas as already described. Actually, since the computer can as easily use 10 nm intervals such as 401, 411, 421, etc., the mercury lines could be considered as centering on 366, 406, 436, 546, 576 nm and an even more accurate trapezoidal trace could be obtained for each line. This was not done here.

Conclusion

Even this rough approximation to the true fluorescent lamp SED, allowing simpler analysis than the triangle method, leads to a difference of about 0.004 in x and no detectable difference in y. Presumably a bit more finesse would allow even this simplest method to provide the 0.002 accuracy obtained by more difficult procedures.

The Glazing of Vacuum-Evaporated Gold-Chromium Films with a Lead-Containing Glass at 775°C

R. H. Buck[1]

United Kingdom Atomic Energy Authority, Aldermaston, Berkshire, England

ABSTRACT

The glazing of vacuum-evaporated gold-chromium duplex films on alumina substrates at 775°C using a lead-containing glass has been investigated. This process forms a part in the construction of a multilayer hybrid circuit. A detailed examination of a unique glazing defect using electron beam analytical facilities has led to the identification of a fine needlelike deposit associated with the defect as single crystals of the compound Pb_2CrO_5.

Examination of the other characteristic features of the defect, a central black spot and a porous gold film, has involved a study of the thermal stability of gold-chromium duplex films under nonglazing and glazing conditions. From the nonglazing experiments it is concluded that the chromium content of the needlelike deposit results from grain boundary diffusion of chromium through the gold film to be followed by oxidation at the gold/air interface during the heating cycle of the glazing schedule. The resistivity changes observed to occur in Au-Cr films at 400°C appear qualitatively consistent with this view. The cohesion and adhesion of gold chromium films of various thickness ratios were found to be maintained or improved after heating at 775°C for 2 hr. Glazing the as-deposited film gives rise to attack of the gold film by the lead constituent of the glass causing the black spot and a porous gold film.

In order to accommodate the high density circuitry required to meet the future needs of the computer industry it has been found necessary to adopt a multilayer structure comprising a ceramic substrate base with alternating planes of electrical conductors interspersed with glass or polymer insulating layers (1, 2). This approach, involving the use of commercially available materials as far as possible, poses novel problems in the construction of reliable arrays. Quite often situations are met, that rarely, if ever, have occurred in the more traditional applications of these materials, *e.g.*, the ability to be able to glaze over gold conductors with the requirements of the glaze layer to be more stringent electrically and in geometry than has been demanded hitherto.

Vacuum evaporation of the metal, followed by conventional photoresist and etching techniques, may be used to define the conductor geometry closely. Thus the question of the stability of the evaporated conductor arises if it is to be subjected to the temperatures and times involved in the glazing schedule. Contemporary applications of vacuum-deposited metal usually limit its use to low temperatures (generally below 200°C) and smooth substrate surfaces, *e.g.*, as metallization for active devices, thin-film circuitry on glass substrates and in optics. Less is understood and known about its use and properties at temperatures in the range 700°-800°C and on rougher surfaces. Therefore part of the investigation described below is to gain information on the behavior of vacuum-deposited metal films at high temperatures and the effect, if any, of the glazing process on them.

Experimental

In order to examine the effect of glazing, test specimens were prepared according to the procedure

[1] Present address: 9 Three Acre Road, Newbury, Berkshire, England.

adopted in constructing one part of a multilayered module.

Chromium was first evaporated onto a 2 x 1 in. alumina substrate to give a layer 300-400Å in thickness. The substrate material was AlSiMag 772 from the American Lava Corporation and had a 10 μin. CLA surface roughness (Talysurf measurement). This was followed by evaporation of a layer of gold, 5000-6000Å thick, from a molybdenum boat. A layer of glass, whose compositional analysis is presented in Table I, was subsequently screen-printed over the gold to give a pinhole-free, smooth, clear, layer 50μ thick after firing. The glass was obtained from C. E. Ramsden Company Ltd., of Stoke-on-Trent, and was designated F1169. It is a high lead silicate glass, not normally used in commercial glazing operations but in more specialized applications requiring a low working temperature and good flow properties. It was incorporated, as supplied, into a commercial screen-printing vehicle available from Blythe Colours Ltd., also of Stoke-on-Trent, to form a paste. The glaze-firing schedule involved placing the specimen in a muffle furnace at room temperature, raising its temperature to about 775°C and, after holding at this temperature for 1½ hr, allowing the furnace to cool to room temperature before withdrawing the specimen.

On examination of the substrate it was usually found that crawling back of the glaze had occurred at the edges and, on some substrates, circular, nonglazed regions appeared on firing. Figure 1 shows part of a substrate exhibiting this effect. Obviously this layer would not meet the demands of an acceptable insulating layer since the gold conductor layer is left bare. The majority of the areas have a black spot in the center suggesting that this is associated with the nonwetting behavior.

As this particular commercial glass possessed properties (3) that were otherwise very desirable for the construction of the multilayered circuit such as good flow properties leading to very smooth surfaces for subsequent conductor deposition, and as an alternative would not be easily available, it was decided to investigate the cause of this defect in more detail in an effort to understand and perhaps avoid its occurrence.

Examination of the defect.—The characteristic features of one of the areas illustrated in Fig. 1 is shown in Fig. 2 in greater detail. Long thin needles of approximately equal length may be seen radiating out from the black central spot like the spokes of a wheel. For the purpose of clarification these characteristic features may be described as the following: (*a*) the needles; (*b*) the black spot; (*c*) the gold film. The detailed investigation of these features, taken individually, was possible with the aid of electron beam, as well as optical, analytical techniques. The interrelationship of these features became clearer as the investigation proceeded.

Fig. 1. Nonwetted areas of a glazed gold-covered alumina substrate. 3.3X.

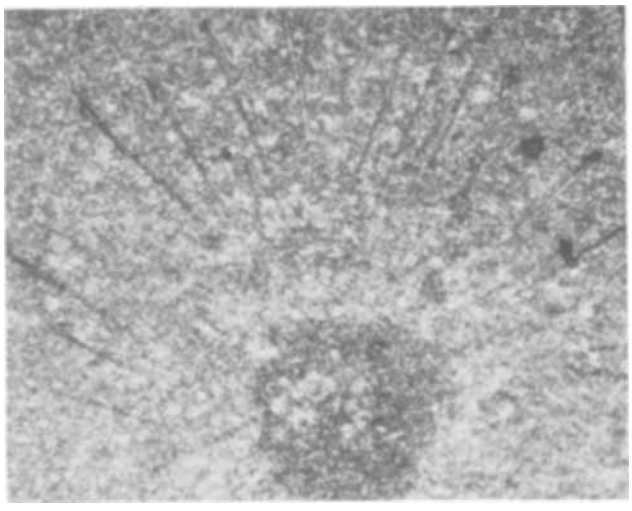

Fig. 2. Microscopical features of the majority of the nonwetted areas shown in Fig. 1. *ca.* 100X.

The needles.—The needles are very regular in shape. Figure 3 shows the needles enlarged. In the example of Fig. 2 they are about 0.4 mm long, between 2-6μ wide and 1-2μ high. That they were a precipitate lying on top of the gold film was proved by scratching them with the tip of a lightly loaded microhardness indenter and exposing the gold film underneath. They were found in regions wherever the glaze had crawled back, *e.g.*, at the edges of the substrate, and were oriented roughly perpendicular to the edge of the retreating glaze. When viewed in white light in a microscope they appeared red in color. In order to obtain more detailed information the electron beam microprobe and electron diffraction were used.

Microprobe examination.—Accurate microprobe analysis of the needles is complicated by their small dimensions and their shape above the level of the gold film (4). The probe is not normally used for such thin specimens, and a special technique was developed to keep the penetration depth of the electron beam in the specimen to a minimum by the use of low beam accelerating voltages. In addition, a traversing technique was adopted to ensure that x-rays from the needles only and not from their surroundings were analyzed since the needles were comparable in width to the electron beam spot size. Qualitative analysis was

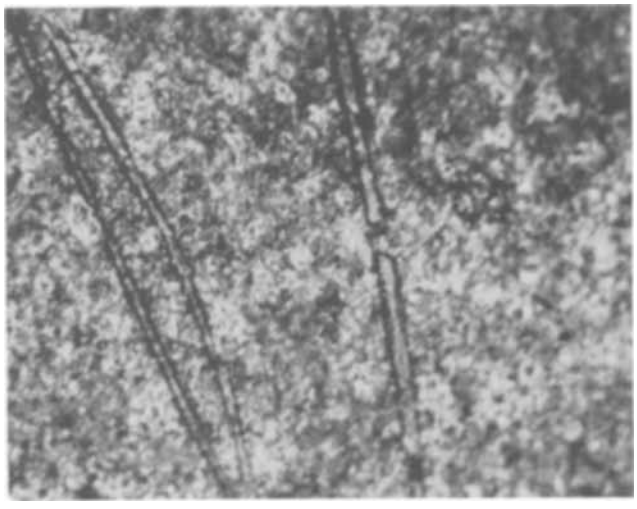

Fig. 3. Needlelike precipitates of Fig. 2. 360X

performed to determine what elements were present, as well as quantitative analysis to determine the amount of each element present in the needles.

After applying the usual corrections to the raw count data the final result was that the needles contained 70.4 w/o Pb and 9.2 w/o Cr and, as no other elements were found, the rest was presumed to be oxygen. Figure 4 shows the most recent PbO-Cr_2O_3 phase diagram (5) which gives all the possible compositions between pure lead oxide and chromium oxide. These are Pb_5CrO_8, Pb_3CrO_6, and Pb_2CrO_5. The latter compound, to judge from its melting point, may be the most stable. The compositional data gave good agreement with a compound of the formula Pb_2CrO_5.

Electron diffraction.—To confirm the above result, the needles were extracted using plastic replicas and analyzed by electron diffraction. It was necessary before extraction to dissolve the gold film in the vicinity of the needles using an etchant based on iodine and potassium iodide to lessen the adherence of the needles. The etchant did not appear to attack them chemically. The result was to show that the needles were of one composition, were crystalline (and not a glass for example), and were single crystals.

The electron diffraction pattern correlated well with x-ray data from the monoclinic compound Pb_2CrO_5, prepared by the direct fusion of PbO and $PbCrO_4$ in the correct proportions (6).

Needle pattern.—The reasons why the needles in the defect areas should adopt the pattern described are interesting, and perhaps not too much importance should be placed on the fact that they generally appear perpendicular to the glaze edge.

From microscopical studies of the needles in the circular defect areas and at the edge of the substrate, there did not appear to be any correlation between the orientation of the individual needles and the retreating glaze edge. That the needles appear as radiating out from the centers of the spots may only be a consequence of the initial growth nuclei being formed in or near the central black spot region when the glaze is beginning to crawl back from that area. If the nuclei are randomly oriented, needle growth can proceed in all directions out from the black spot center. The circle of glass outlining the defect gives the pattern of needles the appearance of spokes.

Similarly, where the glaze edge was straight, *i.e.*, at the substrate edges, a small but sufficient number of needles were found to lie parallel to the edge, to assume that the needles are the result of growth from randomly oriented nuclei.

The black spot.—Figure 5 is an optical micrograph of the black spot region taken with transmitted light. The black, opaque islands are of practically pure gold. Microprobe analysis could detect only very small amounts of Cr in the islands (of the order of 1/10 of 1% by weight) and no lead. A transparent section of a needle overlies this area.

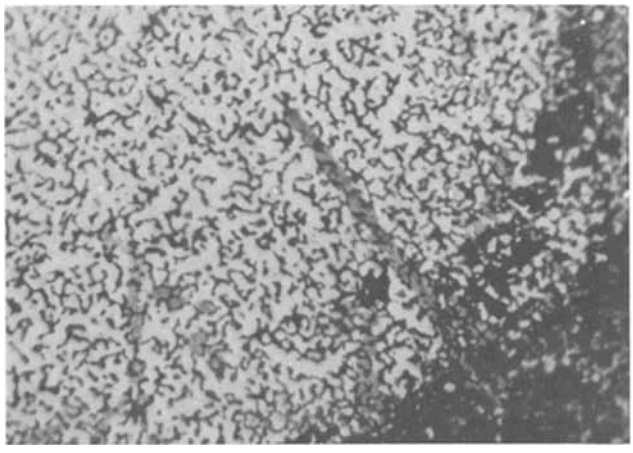

Fig. 5. Micrograph of a spot by transmitted light. 332X

Observations by scanning electron microscopy (SEM) showed that the islands possessed smooth, rounded forms, suggesting that, at some stage in the glazing process, the gold metallization had coalesced and may have been part of a molten system. In this manner, breakup of the gold film had occurred leading to the formation of the black spots which, in turn, became responsible for the nonglazing of the gold film at these points.

The interisland material, which is colored black, is probably a very thin interaction layer on the alumina substrate. It was bereft of gold, but seemed to be electrically conducting to judge from its behavior on microprobing since it allowed analysis of the islands without causing charging-up effects.

The gold film.—The gold film was examined in places where it was exposed, using SEM, and compared with the duplex film in the as-deposited state and after subjecting the film to the heat-treatment involved in the glaze firing schedule but without the presence of glaze.

The as-deposited films merely replicate the underlying alumina surface. In Fig. 6, on top of the individual alumina grains the gold film is smooth because the underlying grains themselves have smooth as-fired surfaces. The gold surface shown in Fig. 7, however, is very roughened as the result of the glazing treatment and contains pores of micron size.

That lead-containing glasses may attack gold and cause the roughened appearance is probable for, in the manufacture of ruby glasses (7), gold salts are dissolved in high-lead glasses. There is also the possibility that metallic lead, freed during the heating portion

of the glazing cycle by reducing atmospheres that may be present, *e.g.*, due to carbonization of the screen-printing vehicle, will also attack the gold.

In a separate investigation (8), however, no lead particles could be found in the glass after firing. The glass was etched for various times, and any particles in the glaze were extracted using carbon replicas and examined by electron microscopy and diffraction.

Effect of heat-treatment on duplex gold-chromium films.—SEM and electron microscopy were used to examine the duplex films that had been heat-treated in air as for glazing but without the presence of glass. A visible change in the appearance of the gold surface takes place after heat-treating at 775°C in that the surface darkens. In contrast, the unglazed areas on a glass-coated specimen appear as gold or green-gold. Figure 8 shows a direct view of the surface. The film is not porous as after glazing. There are no black spot defects, and it remains adherent as shown on the basis of a simple "Scotch Tape" test. There is a network pattern visible on the gold within the areas encompassed by the underlying alumina grains whose meshes have similar dimensions to grain size one would expect (9) for a film of this thickness (of the order of a micron diameter). It suggests that chromium has reached the surface by grain boundary diffusion through the gold and is removed from solid solution in the gold by oxidation at the gold/air interface. The network we thus

5	4000	150	27	No	Yes	Darkened Gold
6	3000	100	30	Yes	Yes	Darkened Gold

* Using a "Talystep" machine, the thicknesses were measured by employing concurrent deposition onto glass slides.

observe is formed by a pattern of chromium oxide nuclei outlining the gold grain boundaries.

The results obtained by testing for adhesion by the Scotch Tape test after heat-treatment at 775°C for 2 hr are shown in Table II for various gold/chromium thickness ratios.

Two significant conclusions may be drawn from these results: for all specimens the gold film remained adherent and coherent and the heat-treatment leads to an improvement in adhesion where previously the gold had not, or only partially, shown adherence. The green appearance of specimen 1 was obviously due to the oxidation of the chromium content of the film which was high.

Evidence of chromium being transported completely through the gold film is provided by the results of Bingham *et al.* (10) and Schnable and Keen (11) who measured change of the resistance of heated gold films on glass substrates with time. Figure 9 shows some of Bingham's results for films of different total thicknesses heated at 400°C. In each case the thickness of chromium was 400Å. The independent measurements of Whitcomb *et al.* (12) for films of different gold/chromium ratios baked at 450°C have been added, and tentative curves have been drawn through the few experimental points shown. The greatest changes in resistance occur within the first 4 hr at temperature, and the initial and final resistance values after periods of time greater than 12 hr are identical. The former behavior is qualitatively consistent with two competing processes: one involving the increase in resistance due to penetration of chromium atoms into the gold lattice and the other involving a decrease in resistance due to withdrawal of chromium atoms from the gold by oxidation at the gold surface. The similarity in the initial and final

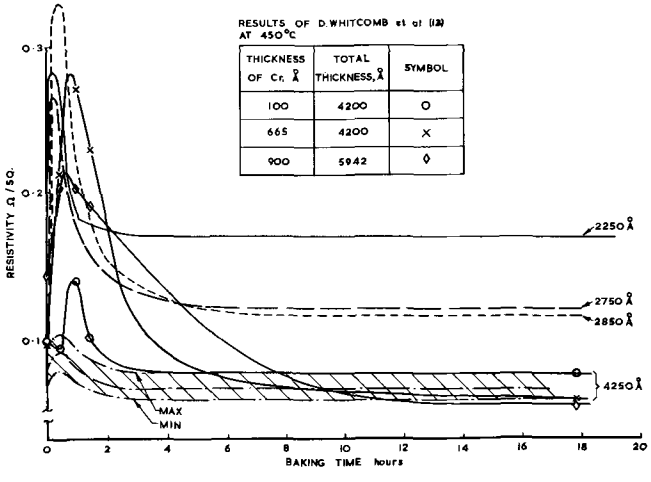

Fig. 9. Changes in resistivity of gold-chromium duplex films of varying gold thicknesses with time at 400°C (9). The result of Whitcomb *et al.* (12) for films of differing gold-chromium thickness ratio, baked at 450°C have been superimposed.

resistance values reflects the fact that these measurements have been made on virtually pure gold. In line with this argument, careful measurements made with the electron microprobe analyzer in the course of this work also failed to detect any chromium in the exposed gold film of the glazed samples.

Whitcomb *et al.* (12) noticed that the thickness of the chromium underlay affected the change with time of the resistivity. This has been made more obvious by plotting his results in Fig. 9. On the basis of the present description this dependence would arise simply because more chromium is available as a source material for diffusion through the gold overlay, followed by oxidation at the gold surface.

An alternative mechanism giving rise to the observed pattern is possible if it is assumed that bulk diffusion of chromium occurs with nucleation of the oxidized chromium at the gold grain boundaries. However, the work of Kenrick (13, 14) would seem to indicate the importance of the grain boundary in the transport of chromium atoms to the surface of the gold at lower temperatures than those used with present work. He examined films annealed up to 300°C on glass substrates and found evidence of early topographical changes at the gold grain boundaries due to chromium transport.

In bulk metals, grain boundary diffusion plays a significant part in the diffusive transfer of material at low temperatures, *i.e.*, below about 0.6 T_M where T_M is the absolute melting point of the metal. During glazing it probably occurs during the heating up period. Hence the grain pattern is established early on in the process and persists even at the peak glazing temperature of 775°C (0.78 T_M). This implies that stress-relieving processes such as grain growth and secondary recrystallization may have been inhibited by the presence of the chromium in the grain boundaries of the gold. Some evidence for this viewpoint comes from investigations of monolithic films where it has been found (15, 16) that grain boundary self-diffusion plays an important part in stress relief by acting to produce hillock growth. Modification of the grain boundaries, *e.g.*, by alloying, leads to modification of the mode of hillock growth.

Discussion

As a result of the investigation of the features of the defect, the needles, the gold film, and the black spot, the relationship between these features may now be established.

Having concluded that the needles are single crystals of a lead-chromium-oxygen compound we are now in a position to see how they were formed. During heating of the duplex film chromium diffuses through the gold film, primarily by a grain boundary mechanism. Since the specimen is fired in air oxygen is present at the surface, and lead results from reduction of the lead glass. The reacting species combine to form the most stable compound of the PbO-chromium oxide system, Pb_2CrO_5, which is solid at the glazing temperature. The reactants are brought together by transport over the surface of the exposed gold film.

The formation of the needles may then be visualized as a two-dimensional precipitation process with the reactants present at the gold surface. It is necessary to propose a nucleation and growth mechanism to account for the small number of nuclei present coupled with a fast growth rate in certain crystallographic directions in order to produce needles. Low supersaturations produce small numbers of nuclei. It can arise in this case since only small amounts of chromium are present in relation to the other elements, lead and oxygen. The high growth rate directions and reasons why these are preferred, however, may be resolved by studies of the structure of Pb_2CrO_5 which are presently being carried out (6) and will be reported on later.

The establishment of chromium as present in a concentrated form in the needles brings additional proof of the diffusion of Cr through the film and its removal at the surface. Given this knowledge alone, the practical consequences may have been expected to be twofold: (*a*) the conductivity of gold film conductors in a multilayer assembly remain substantially the same before and after heat-treatment, and (*b*) some loss of adhesion of the gold film to the alumina substrate may result.

The former consequence is advantageous, and successful working multilayer modules having the designed electrical properties have been produced using glasses other than F1169 (1). Contrary to the expectation (*b*), there is no noticeable lack of adhesion of the gold films after heating to 775°C in air for 2 hr without the glass layer. In fact the adhesion is enhanced. This treatment gives rise to the network pattern of chromium oxide. The duplex film remains intact and adherent even though this heat-treatment would be generally expected to be severe for such a film. Microns-thick, single-layer gold films, for example, on a metal surface such as cobalt are reported to coalesce completely on heating in vacuo at 400°C (17). The apparently remarkable ability of chromium in maintaining the adherence of a gold film even after heating in air has also been noted by Haq, Behrndt, and Kobin (18) who examined the adhesion of Au/Ta, Au/Si, Au/Ge, and Au/Cr combinations. They observe that "in contrast to all other systems, Au/Cr combinations exhibit no noticeable deterioration of adhesion, even after heat treatment at 450°C in air for several hours . . . ." A major contributing factor in the high-temperature stability of the duplex film must therefore be the presence of the chromium in maintaining both the adherence and coherence of the gold film.

On the other hand, when the glass coating is applied, black spots appear and the gold film becomes porous. Coalescence of the gold film to produce the black spots occurs before or during the time the glass is molten, since it is only possible for crawling back of the glass to take place at this time.

In the case of the film porosity, as with the formation of the black spots, it is difficult to isolate any one cause as solely responsible on the basis of the work described. The porosity in the film is not only present in the area of the defect, but extends over the whole of the metal film on the substrate. In the study of the etching behavior of this glass (8) it was noticed under the glass layer as well as adjacent to it in an area of coated substrate which, deliberately, had not been glazed.

In view of the fact that the lead constituent of lead glasses may easily be reduced to elemental lead and attack the gold film it was attempted to simulate this process by vacuum-depositing stripes of lead, 1 cm wide and 1μ thick, on to alumina substrates which had been precoated with gold-chromium layers of the thicknesses used in this work and subjecting these substrates to the glazing heat treatment schedule. A roughened porous film with the gold or green-gold appearance typically seen on substrates that had been glazed, resulted with isolated areas where the gold film had coalesced and produced black spots similar to those observed in the center of the glazing defect. These experiments provide some evidence that the film is capable of being attacked chemically by any lead that may be present during glazing. In addition, the attack is likely to be aided by any stresses in the film arising from thermal mismatch and chromium diffusion as already discussed.

The glaze defect is thus seen to be due to the break-up of the gold film at isolated, random points to form a surface discontinuity in the form of the black spot. The presence of the spot, which may be formed during

heating of the film or at the peak glazing temperature, especially if free lead is formed by reduction in the glaze, is at once made obvious by the crawling back of the molten glass.

The crawling back of glaze at surface discontinuities such as edges, steps, and holes is a well-known phenomenon in the practice of glazing and it is not always easy to define the causes (19). The amount of crawling depends largely on the wetting of the substrate by the glass, and in some of the samples used in this study where the glass had covered both gold and alumina on the same substrate, the crawling back was always more pronounced on gold. This effect above all precluded the use of this glass as a glaze insulator over patterned gold conductors where there were many gold/substrate discontinuities.

Conclusions

The pursuit of the reasons for the hitherto unexplained and unique type of defect arising on glazing gold-chromium duplex films was justified by producing a better understanding of the materials and processes involved, *e.g.*, of glasses and glazing and the interaction with processes affecting the stability of duplex thin films.

The obvious conclusion that this and allied glasses may not be employed in the glazing of patterned gold films has been drawn exclusively from a detailed examination of the defects where the small dimensions of the characteristic features, a deposit of red needles arranged around a central black spot region and a porous film, required the use of electron-beam analytical tools.

The red needles were found to be single crystals of the compound Pb_2CrO_5. The formation of their pattern in the defect has been described as a two-dimensional precipitation process with the reactants present at the gold surface.

The duplex gold-chromium films employed can withstand heating at the time and temperature required for the glazing process. The presence of the lead-glass, however, degrades the film by giving rise to isolated regions (black spots) where the glass does not adhere and a porous film. Attack by the lead glass of a stressed film appears responsible for this behavior.

Although the glaze adhered well to the gold it tended to be sensitive to surface discontinuities. The presence of these was exaggerated by pronounced crawling back of the glaze. In this manner the formation of the black spot regions by coalescence of the gold film caused the circular defects to appear in the glaze.

Phosphorus Diffusion in Silicon Using Phosphine

Y. W. Hsueh*

General Instrument Corporation, Microelectronics Division, Hicksville, New York

ABSTRACT

A study of phosphorus diffusion into silicon has been made by using an open tube diffusion system and phosphine in nitrogen as the impurity source. For constant doping gas and oxygen concentrations, the sheet resistance and junction depth were exponential functions of the reciprocal of absolute temperature. A linear relationship was obtained between junction depth and the square root of the diffusion time. Also, the experimental results showed the independence of mean conductivity, ($\bar{\sigma} \equiv 1/x_j\rho_s$) with diffusion time and temperature. The diffusion coefficient for phosphorus in silicon was calculated to be $6 \times 10^{-6} \exp(-1.90/kT)\,cm^2/sec$.

Phosphorus is used extensively as an n-type impurity material in silicon semiconductor device technology. Generally, open tube systems have been adopted for the diffusion process because of their operational simplicity over sealed tube diffusion methods. The impurity sources have usually been red phosphorus, phosphorus pentoxide (P_2O_5), or phosphorus oxychloride ($POCl_3$) (1).

As mentioned in a previous paper (2), the disadvantages of solid or liquid source diffusion systems are the control of the dopant concentration in the car-

* Electrochemical Society Active Member.

rier gas, difficulty in maintenance due to the complexity of the diffusion system, and reproducibility of results. For instance, Nassibian and Whiting (3) pointed out that the surface concentration could be increased by three orders of magnitude by raising the source temperature of red phosphorus from 260° to 320°C. Similarly, if $POCl_3$ is used as the diffusion source, the product of sheet resistance and surface concentration should be vapor pressure dependent. Nassibian's results showed that a change in source temperature from 20° to 28°C increased the surface concentration by a factor of two while the sheet resistance decreased by about 70%. It is therefore preferable to use a gas phase source, with known impurity concentration, if it gives increased reproducibility in the diffusion process.

The phosphine system has been discussed previously by Smith and Donovan (4), McLouski (5), and Heynes and van Loon (6). This paper describes the diffusion system characteristics and the process parameters in detail. Special emphasis is placed on more shallow diffusion processes than those reported in other published results.

Experimental Procedure

The diffusion system and material preparation were similar to those reported in a previous paper (2). A 50 mm diameter quartz tube was connected to a stainless steel gas supply system. The silicon wafers were (111) oriented, 10-40 ohm-cm p-type, boron doped, and mechanically and chemically polished. The doping gas was 1% phosphine in argon. Nitrogen was used as the carrier gas.

The sheet resistance was measured by the four point probe technique, and the average value was taken of several measurements made on each slice. The variation across a slice and from slice to slice in a single batch was less than 5% unless otherwise specified. Usually, the sheet resistance variation in either case was within 2%.

For calculations, the impurity distribution was assumed to follow the complementary error function distribution for the deposition process, and the Gaussian distribution for redistribution. The surface concentration was calculated by using Irvin's curves (7) after the junction depth was obtained by the standard angle lapping and staining method.

Result and Discussion

Diffusion system.—Oxygen is used in the phosphine diffusion process to provide phosphorus as the local diffusion source at the material surface according to the equations

$$2PH_3 \xrightarrow{450°C} 2P + 3H_2 \qquad [1]$$

$$2PH_3 + 4\,O_2 \longrightarrow P_2O_5 + 3H_2O \qquad [2]$$

In the absence of oxygen, reddish phosphorus appeared on the tube wall as a result of the reaction shown in Eq. [1]. In this case, it was found that the diffusion of phosphorus did not occur. However, when oxygen was used in the system, the phosphine was reduced to P_2O_5, and this acted as the local diffusion source. The diffusion mechanism was therefore similar to a system using P_2O_5 or $POCl_3$. Additional empirical analysis showed that large variations in deposition sheet resistance occurred when the concentration of phosphine in the carrier gas was less than 200 ppm. Also, abnormally high concentrations of phosphine caused phosphite precipitation, and the formation of electrically inactive phosphorus was detected. A fixed value of 300 ppm for phosphine concentration was used for all the following experimental work.

Oxygen was detrimental to the process only when present in high concentrations. No phosphorus deposition was observed on the system end cap even when the oxygen concentration was as low as 0.3%. Also for a given diffusion temperature, the diffusion parameters were not appreciably affected by variations in oxygen concentration between 0.5 and 4%. However, the sheet resistance increased by a factor of 2 when the oxygen concentration was increased from 4 to 8%, and the rate of increase of sheet resistance with oxygen concentration was very rapid for oxygen concentrations above 8%. The high sheet resistance obtained with high oxygen concentrations was caused by an apparent decrease in diffusion rate. Excessive growth of silicon dioxide in high oxygen concentrations partially masked the diffusion of phosphorus. For this reason, an oxygen concentration of 1% was used for these experiments.

Variations in total gas flow rate will give nonuniform deposition, and it was empirically determined that a total flow rate between 1100 and 1400 cc/min gave the best uniformity for this system. In addition, it was observed that other variations in sheet resistance sometimes occurred. These variations could not be correlated with low diffusion temperatures, low phosphine concentration processes, or diffusion times, and they were independent of surface concentration. This effect was eventually attributed to depletion of phosphorus from the heavily doped diffusion tube and was investigated experimentally.

The tube was saturated with phosphorus by a continuous phosphine flow. The phosphine supply was then turned off and wafers were then inserted for given periods of time. The sheet resistances obtained are shown in Fig. 1. The top curve shows the variation in sheet resistance for the wafer near the gas inlet, while the bottom curve indicates the average sheet resistance of wafers 12 in. further along the tube. The sheet resistance for wafers near the gas inlet was much higher than for those further down the tube, as predicted. The surface concentrations obtained were approximately 10^{20} at./cm^3 for a 1-hr period.

In addition, an experiment was carried out to investigate the rate of depletion of phosphorus from the tube. First, the sheet resistance was measured on wafers diffused for a given period of time after predoping the tube for 40 min. Second, material was diffused under identical conditions except for a delay of 45 min between the tube doping cycle and the diffusion process. The results showed a 35% difference in measured sheet resistance for the two processes. It can therefore be concluded that, the background doping from the tube must be taken into account in order to obtain good

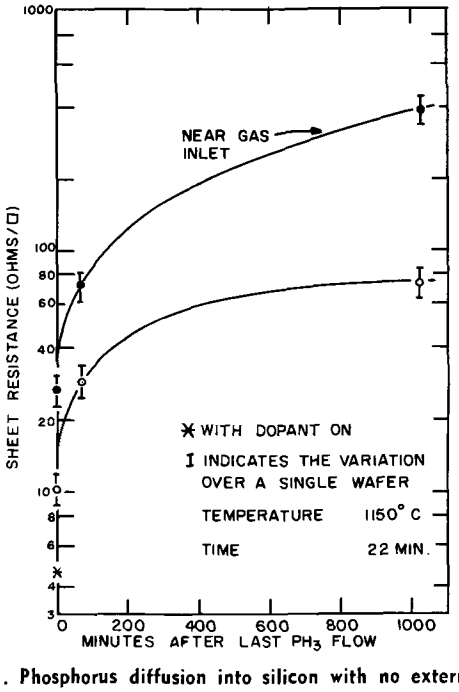

Fig. 1. Phosphorus diffusion into silicon with no external source fed into the diffusion system.

control over the diffusion process. It has been found that predoping of the tube for half an hour at the beginning of a working day is sufficient for high concentration processes, *i.e.*, $>10^{19}$ at./cc. Appropriate time intervals can be determined empirically for low surface concentration processes.

Diffusion time and temperature.—The relationship obtained between diffusion time and sheet resistance is shown in Fig. 2. The sheet resistance decreases slowly as the deposition time increases. For low temperatures and short deposition times, these values can fluctuate as described previously.

In Fig. 3, sheet resistance is shown as a function of the reciprocal of absolute temperature. The gradients of these curves are approximately constant for temperatures above 1000°C, but below 1000°C they increase as the temperature decreases. It has been shown (2) that sheet resistance can be expressed by the following equation

$$\rho_s = C \exp\left(\frac{E}{2kT}\right) \qquad [3]$$

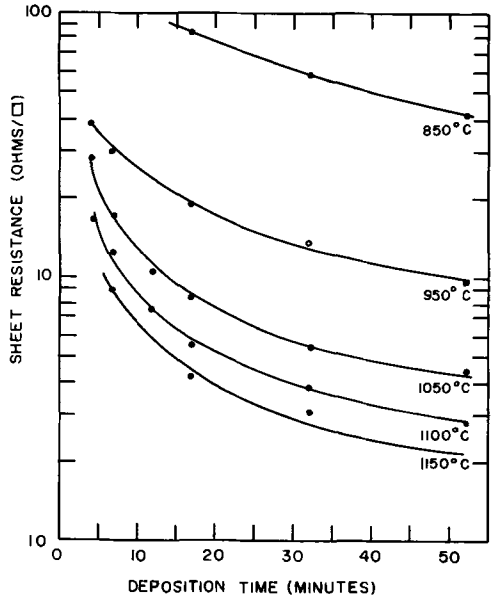

Fig. 2. Sheet resistance as a function of deposition time

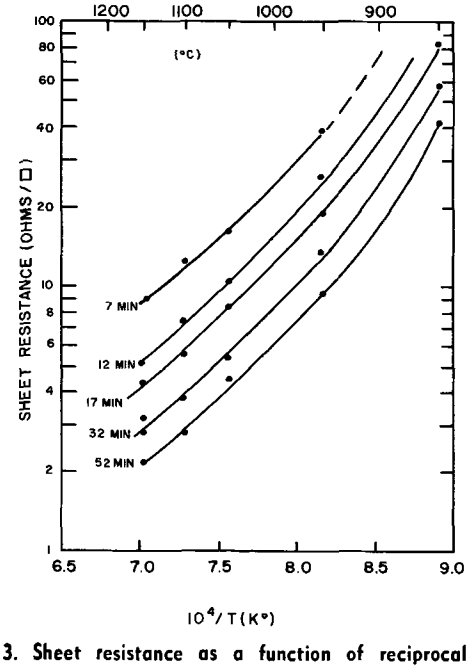

Fig. 3. Sheet resistance as a function of reciprocal absolute temperature.

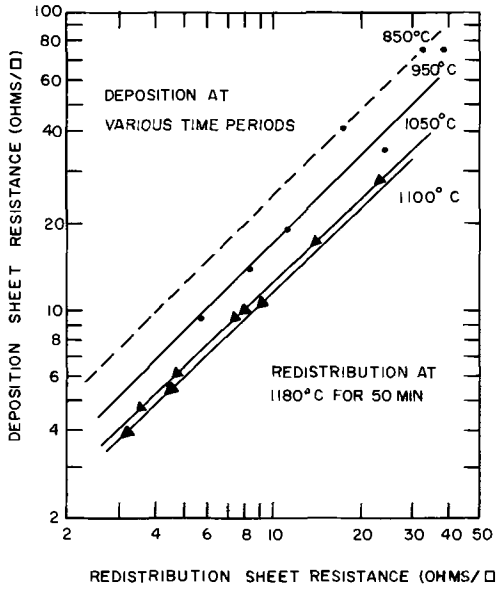

Fig. 4. Relationship between deposition and redistribution sheet resistances.

where E is the activation energy in eV, k is the Boltzmann constant, and

$$C = \frac{1}{q\mu}\frac{1}{2N_0}\left(\frac{\pi}{tD_0}\right)^{1/2} = \text{constant}$$

Thus, it is possible to determine the activation energy, E, from results shown in Fig. 3. This was calculated to be 2.11 eV in the temperature range 1000°-1150°C, 2.71 eV at 950°C, and 5.84 eV at 850°C. This temperature dependency of activation energy appears to be connected to the maximum solid solubility (8) of phosphorus at a given temperature. However, values for the activation energy calculated here are less than those obtained by MacKintosh, (9), and far less than those shown in Fuller's (10) results. This may mean that the activation energy depends on the oxidation rate at the silicon surface since the diffusion rate here was partially retarded.

Figure 4 shows that a straight line relationship exists between deposition and redistribution sheet resistance over the whole experimental range. This agrees with the results reported by MacKintosh (9) in which a closed tube system and a phosphorus pentoxide source were used.

The linear relationship in Fig. 4 can be expressed by

$$\rho_{dep} = a(\rho)^{b}{}_{redist} \qquad [4]$$

where a and b are constants for a given set of diffusion parameters. The values of a and b for various diffused temperatures were calculated and listed in Table I. These were again different from the values quoted by MacKintosh (9). Allowing for experimental error, the index b can be assumed to be unity. The constant a, therefore, becomes the ratio between deposition and redistribution sheet resistances. Apparently, this is temperature dependent up to 1000°C and is directly related to the solid solubility of phosphorus in silicon.

No apparent variation in the redistribution process was observed for different oxidizing conditions. Typical

Table I. Values of a and b for diffused temperatures

			Dry	1.5	9.2	3.0-3.3
10.7	1180	60	Wet	10	8.3	4.2
			Dry	3	8.4	3.9-4.2

results are listed in Table II. The junction depth after deposition was 1.0μ. The process normally involves the removal of the phosphorus glass by etching prior to redistribution. For nonetched wafers, the final oxide thickness was approximately 5% thicker and the sheet resistance 5-10% lower than for etched wafers, while the measured junction depths were almost equivalent. The similarity of these results can be explained by the high segregation coefficient (11) of phosphorus in silicon dioxide causing phosphorus to accumulate at the silicon-silicon dioxide interface. The depletion of phosphorus caused by the oxidation process must therefore be negligible compared with the total amount of diffused impurity.

Although the silicon dioxide growth rate under wet redistribution conditions is much faster than the growth rate in dry conditions, the faster diffusion rate of phosphorus under wet conditions must compensate for the added depletion which occurs. The difference between the two redistribution processes for shallow diffusion requirements is negligible.

Junction depth and surface concentration.—Junction depth is usually a function of diffusion time for constant process conditions. For constant diffusion temperature and carrier gas impurity concentration, a linear relationship was obtained between junction depth and the square root of diffusion time. The results for temperatures in the range 850°-1150°C are given in Fig. 5. Extrapolation of the curves for diffusion temperatures of 850°, 950°, and 1050°C gives a positive intercept for deposition time at zero junction depth. This infers that the maximum solid solubility limit is not obtained immediately, and the time lapse for the diffusion process to begin is approximately 1 min.

The diffusion equation states that

$$N(x_j, t) = N_0 \operatorname{erfc}\left(\frac{x_j}{2(Dt)^{1/2}}\right) \qquad [5]$$

where $N(x_j, t)$ is the concentration at a depth x_j and time t; (in this case the background concentration N_b); N_0 the surface concentration; x_j the diffusion junction depth; t the diffusion time; and D the diffusion coefficient of phosphorus in silicon. Therefore the curves in Fig. 5 represent a constant surface concentration diffusion condition, and the gradient of each curve is given by $2(D)^{1/2}\ \operatorname{erfc}^{-1}\ (N_b/N_0)$.

By using Irvin's curves, the surface concentrations were estimated from the sheet resistance and junction

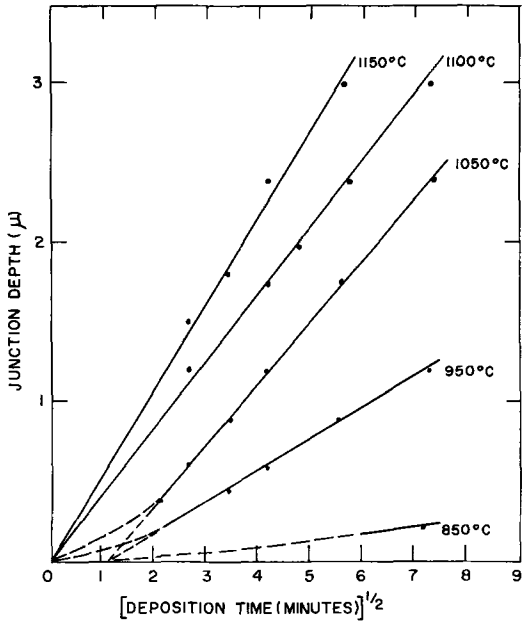

Fig. 5. Relationship between the junction depth and square root of time for various diffusion temperatures.

depth measurements. The results are temperature dependent and are listed in Table III. The surface concentrations obtained are higher than those reported by MacKintosh, and a correspondingly higher value for the solid solubility of phosphorus in silicon is therefore obtained. However, difficulty in measuring shallow junction depths accurately means that results for short diffusion times or low diffusion temperatures are liable to large errors.

Diffusion coefficient.—The diffusion process was assumed to follow the complementary error function except for those processes in which a redistribution step was used. The diffusion coefficient calculated on this model is useful for practical purposes. Some typical values are shown in Table III. The diffusion coefficient was also plotted against the reciprocal of absolute temperature. These results are shown in Fig. 6. Some previously published data are also included. For low diffusion temperatures, a large error can be introduced into these results by the inaccuracy in measuring shallow junction depths. The activation energy for the phosphine process based on a wide range of results is 1.90 ± 0.13 eV.

Assuming a value of 1.90 eV for the activation energy, the diffusion coefficient can be calculated from the following expression

$$D = 6 \times 10^{-6} \exp\left(\frac{-1.90}{kT}\right) \text{ cm}^2/\text{sec} \qquad [6]$$

The values obtained for D_0 are smaller than those re-

ported by Fuller. Values for D_0 are very sensitive to activation energy, and the activation energies of 3.7 and 2.4 eV obtained by Fuller and MacKintosh respectively are higher than those obtained here.

From Eq. [5] and the expression $D = D_0 \exp(-E/kT)$, the junction depth can be expressed by

$$x_j = C' \exp(-E/2kT) \quad [7]$$

where $C' = 2(D_0 t)^{1/2} \operatorname{erfc}^{-1}(N_b/N_0)$. This is constant if the diffusion time t, background concentration N_b, and surface concentration N_0 are kept constant. Figure 7 plots ln x_j against $1/T$. The activation energy based on the data from this figure varied from 1.77 to 2.01 eV. These values increase rapidly as the diffusion temperature decreases. The relatively close agreement between the three calculated values for the activation energy verifies the consistency of the results presented in this work.

From Eq. [3] and [7], it can be shown that the product of sheet resistance and junction depth is time and diffusion temperature independent. The data shown in Table III agree quite well with this conclusion except for very short diffusion times and shallow junction processes.

Conclusion

The results obtained for a phosphorus diffusion process based on phosphine showed that the junction depth and sheet resistance varied exponentially with reciprocal temperature, the junction depth varied with the square root of time, and the sheet resistance varied with the inverse of square root of time. Also, the product of sheet resistance and junction depth was independent of diffusion time and temperature. The activation energy for the process was calculated to be 1.90 eV. These results are based on the assumption that the diffusion process follows a complementary error function distribution.

Dopant Transfer in Heteroepitaxial Si Layers on Sapphire Substrates

J. Mercier

Section Physique des Couches Minces,
Laboratoire d'Electrostatique et de Physique du Métal, Grenoble, Gare, France

ABSTRACT

The contribution of hydrogen only to the impurity redistribution in heteroepitaxial silicon layers is analyzed. It is clearly demonstrated that a chemical reaction between H_2 and the sapphire substrate occurs at high temperature. Unequivocal evidence of the aluminum transfer is given. The rear of the substrate is the prevailing dopant source during the over-all process in our experiments.

P-type autodoping in epitaxial silicon layers, grown on sapphire substrates by pyrolysis of silane, has been reported extensively (1-7).

However, the understanding of this redistribution process is somewhat obscured by the following conditions:

1. Various doping sources are potentially possible. Their location, as well as their chemical nature, must be considered because the exact redistribution process depends on them.

2. The physical properties of the layers depend not only on the impurity concentration we wish to determine, but also on the high crystalline defect density that they contain. This affects to a large extent, for example, the carrier mobility and the impurities diffusion coefficient (2).

The major p-type dopant introduced in these layers is aluminum. It can obviously be supplied by the sapphire substrate, but it may be freed by a physical (outdiffusion) or a chemical process (reduction), and the physical location of the dopant source may be the rear or the front of the sapphire substrate. If a chemical reaction is assumed, the reducing species may be hydrogen or silane itself (8).

All these difficulties lead us to a separate analysis of the influence of the various chemical species involved. We began with hydrogen, but this does not imply that it has the prevailing effect on the redistribution process. Nevertheless, it fulfills several functions in the over-all process, which may take part in this autodoping. It is not only used as a carrier gas but also as a chemical agent. It has been proven that high-temperature prefiring of the substrate in hydrogen after mechanical polishing is the most reliable way to remove work damage. Figure 1 shows an x-ray surface topography of a $(01\bar{1}2)$ oriented substrate after such a heat-treatment. The crystalline quality is good, but preferred etching along [100] is clearly seen. This result can be considered as direct evidence of a chemical surface reaction between hydrogen and the sapphire substrate. The following reaction has been suggested (1)

$$Al_2O_3 + 2H_2 \rightleftarrows Al_2\overset{\nearrow}{O} + 2H_2\overset{\nearrow}{O}$$

Other steps may give rise to such a chemical reaction. Hydrogen remains in direct contact with sapphire (*a*) before complete coverage of the upper surface is achieved, and (*b*) during the growth step, with the rear face, which is only ground, not polished, to afford better thermal contact, and which allows the penetration of hydrogen. It must also be remembered that the temperature there is higher than anywhere else.

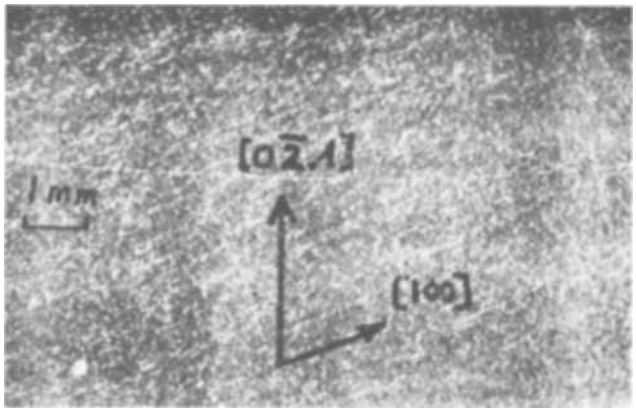

Fig. 1. X-ray surface topography of the sapphire substrate after H_2 etching at 1300°C.

Experimental Conditions

At any time, hydrogen flows in the reaction chamber. Unless otherwise specified, only heat-treatment in hydrogen in the reactor is performed on two kinds of substrates. Under normal conditions, the substrate has two bare faces, but for the sake of comparison some substrates are covered on their backside by a 10-μm thick, polycrystalline silicon layer. This layer has a p-type conductivity of the order of 0.1 ohm^{-1} cm^{-1}, but no conclusion can be drawn about its impurity concentration because of the unknown mobility.

Preliminary experiments must ascertain: (*a*) a sufficiently low residual contamination level from the system, afforded by the tubing, carrier gas or susceptor used. In fact, heat-treatment in H_2, of a lightly doped silicon wafer (5 to 10 ohm-cm n-type) at 1300°C, has no detectable effect on the conductivity type or resistivity of this sample. (*b*) The purity of the silane itself. It can be checked by growing an epitaxial silicon film on a silicon substrate of the same characteristics as indicated above. The layer resistivity is currently higher than 100 ohm-cm n-type, with this undoped silane.

In the following experiments, in order to remove the uncertainty arising from the influence of structure imperfections on the properties of these heteroepitaxial layers, a bulk silicon substrate is used as a check sample of the autodoping. Its initial characteristics are known, for example, the relation between resistivity and impurity concentration (9), the impurity diffusion constant (10). This wafer lies on the upper surface of the sapphire substrate. If its conductivity is n-type, the autodoping, when it occurs, can be measured by the characteristics (conductivity $\bar{\sigma}$ and diffusion depth x_j) of a p-type diffused layer produced at its surface.

Experimental Results

Heat-treatment with sapphire substrates only.—At a given temperature, when an inversion layer occurs in the n-type silicon sample, we have found that the layer

Table I. Dopant transfer from the substrate

T, °C	Back coating	Inversion	$\bar{\sigma}$, ohm^{-1} cm^{-1}	C_S, cm^{-3}	X_j, μm	λ, μm	D, cm^2/s
1050	Yes	No	—	—	—	—	—
	No	Yes	0.3	1.6×10^{16}	1.0	0.67	8.5×10^{-13}

	Yes	Yes	1.2	1×10^{17}	2.1	1.05	1.5×10^{-12}
1150	No	Yes	4.0	8×10^{17}	5.3	2.2	6.7×10^{-12}
	Yes	Yes	2.2	2.7×10^{17}	5.0	2.1	6.0×10^{-12}

Table II. Dopant transfer from sapphire with an epi layer

Epi layer type	Inversion	$\bar{\sigma}$, ohm^{-1} cm^{-1}	C_S, cm^{-3}	X_j μm	λ, μm	D, cm^2/s
p	Yes	1.5	1.5×10^{17}	1.4	0.67	1.2×10^{-12}
n	Yes	0.8	6×16^{16}	0.8	0.41	4.5×10^{-13}

depth x_j increased with time, as

$$x_j \propto \sqrt{t}$$

This means that some diffusion process occurs. Therefore we can deduce from Irvin's curves (9) the surface concentration C_S of the diffused layer, when x_j, the initial impurity concentration C_B, and the layer conductivity, $\bar{\sigma}$, are measured.

Assuming an ERFC profile, we determine the diffusion length λ and the diffusion coefficient D of the assumed dopant impurity from: $\lambda = 2\sqrt{Dt}$ (Table I).

The autodoping level (C_S) increases as T increases.

The back coating of the substrate reduces this level for a given set of conditions, so much so that at 1050°C no inversion layer is observed.

The calculated D have nearly the same values, whether the substrate is back coated or not. This result is consistent with the reasonable assumption that the same impurity is involved in both cases.

Using an Arrhenius plot of log D *vs.* $1/T$ (°K) and comparing with published results for B and Al in bulk silicon (10), it can be deduced unambiguously that aluminum is the transferred dopant by such an interaction, involving only hydrogen and sapphire.

No doubt such a situation is met at least for the prefiring treatment which supplies a large quantity of aluminum.

Impurity transfer from a substrate covered with an epitaxial silicon layer.—In order to test a possible barrier effect of an epitaxial layer against the impurity transfer, the same heat-treatments are performed, at a given temperature, $T = 1100$°C, but using a sapphire substrate on the upper surface of which an epitaxial silicon layer was previously grown.

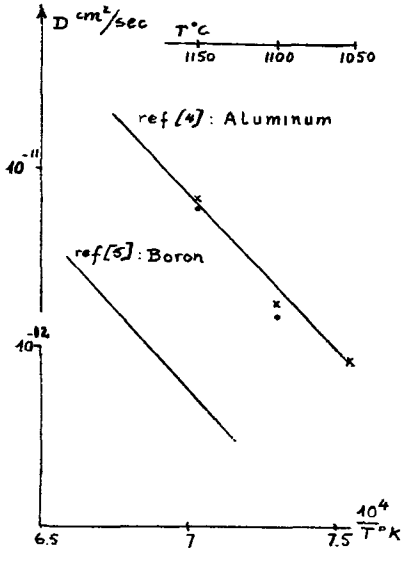

Fig. 2. Plot of log D (cm^2/sec) *vs.* $10^4/T$(°K). Solid curves, ref (10); experimental points: x unprotected substrate, o back coated substrate.

The comparison is made with two layers, (*a*) a 10 μm thick — 0.7 ohm-cm p-type layer (autodoped), and (*b*) a 6 μm thick — 8.7 ohm-cm n-type (deliberately doped with phosphorus) (Table II).

A somewhat surprising result is the occurrence of a diffused p-type layer, regardless of the epitaxial silicon conductivity type. This can be explained by (*a*) an electrical compensation existing in the n-type layer, which should contain phosphorus and aluminum; this result is reported elsewhere (11), and (*b*) a prevailing contribution of the rear of the substrate.

Both reasons are likely to be true because (*a*) on the one hand the high resistivity of the n-type layer may be the result of two large impurity concentrations of opposite type, but having two different transfer characteristics, and (*b*) on the other hand, the diffused layers have similar properties, for the same experimental conditions but for the presence of an epi layer, as it is apparent from Table III, gathering the comparative experiments reported in Tables I and II (at 1100°C, no back coating p-type layers).

The slightly smaller values in case II can account for some barrier effect, but the order of magnitude being the same, this indicates the importance of the rear surface.

It is therefore not surprising to find a fairly good agreement between the calculated diffusion coefficient when a p-type layer is involved. On the contrary, with the n-type layer the discrepancy is noticeable. The likely occurrence of phosphorus and aluminum diffusion precludes the validity of the assumptions made in the calculation of D.

Dopant transfer during growth.—The purpose of this experiment is to determine quantitatively the differences in the redistribution conditions during a heat-treatment or an actual epitaxy process.

The growth temperature is again $T = 1100$°C which is our optimum temperature (12), and we compare the properties of layers of different thicknesses (Table IV). Usually this layer thickness is of the order of 5 μm (reference conditions). Co is the impurity surface concentration in the layer. It is deduced from MOS capacitance measurements (13).

Table III. Comparison of diffused layer characteristics, heat-treatment $T = 1100$°C, no back coating

Condition	$\bar{\sigma}$, ohm^{-1} cm^{-1}	C_S, cm^{-3}	X_j, μm
I	1.7	2×10^{17}	2.6
II	1.5	1.5×10^{17}	1.4

Table IV. Autodoping in epitaxial growth at $T = 1100°C$

Back coating	Thickness, μm	ρ, ohm-cm	Co, cm^{-3}
No	5.2	0.7	7×10^{15}
No	1.5	0.135	1.5×10^{17}
Yes	1.4	0.64	3×10^{16}

Obviously, and this constitutes a weakness of our reasoning, the doping is not characterized by the same properties when growth or heat-treatment conditions are considered. But it is interesting to notice that Co has the same order of magnitude for thinner layers, as the surface concentration C_S of the diffused layer (1 to 2 x 10^{17} cm^{-3}) for the heat-treatment experiment.

The dependence of the layer resistivity on its thickness is apparent.

The contribution of the rear surface is also confirmed by a comparison of results on ρ and Co.

Some semiquantitative results can be deduced from the preceding figures, about the carrier mobility. Assuming (*a*) a weak dependence on the impurity concentration of this mobility for a given layer, and (*b*) a direct relation between the mean impurity concentration in the layer and Co, we can introduce a mean carrier mobility $\bar{\mu}$ taking into account the dependence on the layer depth of the electrical characteristics and write

$$\bar{\mu} \propto (\rho\ Co)^{-1}$$

Using the subscripts 1, 2, 3 for the three cases reported in Table IV, we have approximately

$$\frac{\bar{\mu}_1}{4} \simeq \frac{\bar{\mu}_2}{1} \simeq \frac{\bar{\mu}_3}{1}$$

We generally find for $\bar{\mu}_1 \sim$ 150-200 cm^2/V sec [measured values (12)] and therefore obtain

$$\bar{\mu}_2 \sim \bar{\mu}_3 \sim 40\text{-}50\ \text{cm}^2/\text{V sec}$$

It can be seen, comparing these results with measured (not calculated) figures reported by (7), that for thin layers, we get the same order of magnitude for $\bar{\mu}$ and $\bar{\mu}$ is weakly dependent on the impurity concentration. This implies reasonably that the mobility figures are limited for thinner layers rather by crystalline defects than by impurities.

Interesting experimental observations are made during the silicon growth on a back coated substrate.

In general, when silicon deposition begins, a decrease of the surface temperature (read with an optical pyrometer on the wafer) is observed, until a steady-state value is reached. But for a given set of conditions (H_2 flow, temperature), the transient time as well as the magnitude of this temperature decrease are different when protected or unprotected substrates are used. For example the following figures are typical

Substrate	Uncoated	Back coated
Transient time, min	5	1
$-\Delta T$, °C	30	10

Furthermore, the magnitude of the temperature gradient, observed between the edge and the center of the wafer during the steady state is reduced from 30° to 10°C, respectively.

All these observations are obviously related to the different thermal behavior of α Al_2O_3 and Si (infrared absorption, thermal conduction). It can be assumed, and we are now studying this point, that different nucleation conditions are achieved in both cases.

Conclusion

From the above, the following conclusions can be drawn:

1. Hydrogen is a powerful transport agent for aluminum. The need for a high-temperature gaseous etching of the sapphire substrates in H_2 makes a certain redistribution in the layers unavoidable.
2. The rear surface of the substrate is a prevailing doping source for aluminum during the prefiring stage as well as during the epitaxy process itself.
3. The back coating of the substrate offers a partial solution against the dopant transfer into the epitaxial layers.

Analysis of the High Temperature Electrical Properties of Wustite

M. S. Seltzer and A. Z. Hed

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio

ABSTRACT

A model is proposed to interpret the electrical conductivity and the Seebeck coefficient of wüstite. The methods for evaluating the concentration of charge carriers as a function of temperature and oxygen partial pressure were developed earlier from an analysis of thermogravimetric data. A hopping type mechanism of conduction is assumed. Thus, the mobility of the charge carriers is proportional to the jump probability which is assumed to be influenced by two factors. These are a blocking factor, which renders a fraction of the sites neighboring a charge carrier unavailable for occupancy, and a self-screening parameter which partially negates the blocking.

In a previous publication (1) the deviation from stoichiometry of wüstite has been computed on the basis of a defect structure model involving complex defects. The defects were assumed to be composed of two iron vacancies on octahedral sites and an iron interstitial on a tetrahedral site.

The model enables one to calculate the concentration of free charge carriers and therefore the electrical conductivity and the Seebeck coefficient. As is shown below, however, a straightforward calculation does not yield the observed experimental values obtained for the electrical conductivity. Furthermore, no model exists which can explain the observed change in sign of the Seebeck coefficient, Q.

In this paper we present an attempt to analyze the experimental data on the basis of the model proposed in ref. (1), with the inclusion of some parameters affecting the mobility of the charge carriers at high concentrations. Since these parameters affect the probabilities of occupancy of sites, they affect the Seebeck coefficient by changing the density of available states.

Vallet and Raccah (2) have proposed that their thermogravimetric data and high temperature x-ray studies of $Fe_{1-x}O$ may be explained only by assuming three different phases in the wüstite homogeneity range. In a recent publication, Fender and Riley (3) suggest that the high temperature electrolytic cell studies of the thermodynamic properties of $Fe_{1-x}O$ within the compound homogeneity range supports the existence of three different phases in wüstite. It has been proposed that the occurrence of different phases are due to differences in the ordering of the defects. The identification of these phases is, however, still an open question and is based on the fact that plots of emf values *vs.* temperature at constant composition consist of three linear regions. Rizzo *et al.* (4) have recently made similar measurements and have found a simple nonlinear relation over the whole range. The problem can be reduced simply to the question of whether these data are best fit by three different straight lines with different slopes or a single nonlinear line. We show in the following that a rather simple model can account for the nonlinearity of the observed properties at high temperature.

It has been suggested (6) that the negative thermal emf observed for wüstite at high deviations from stoichiometry is due to the appearance of negative charge carriers. This suggestion cannot be accepted as may be seen below.

The conductivity, σ, of a solid can be calculated from the general formula $\sigma = (n\mu_n + p\mu_p)\, e$, where n and p are the respective concentrations of negative and positive charge carriers, μ_n and μ_p their respective mobilities, and e their charge. At a given temperature p and n are related by $p \cdot n = n_i^2$, where n_i is an intrinsic concentration. It can be shown (5) that if positive and negative charge carriers participate in the conduction, a minimum in the isothermal conductivity occurs when $n\mu_n = p\mu_p$. Also, the transition from positive to negative thermal emf should occur at p/n ratios very close to $n/p = \mu_p/\mu_n$, or near the same concentration where minimum conductivity is observed.

No minimum in the isothermal conductivity of wüstite has been reported when the composition is changed from $Fe_{0.95}O$ to $Fe_{0.84}O$. This indicates that the condition $n\mu_n = p\mu_p$, is never attained. We therefore conclude that the model proposed by Hillegas (6) cannot account for the observed electrical conductivity in wüstite. To further substantiate the argument that only positive charge carriers contribute to the conductivity, consider the fact that the conductivity increases monotonically with increasing deviation from stoichiometry, even when the thermal emf changes sign. If, as Hillegas suggests, the decrease in thermal emf is due to the appearance of negative charge carriers, the conductivity should decrease throughout the minimum rather than increase.

We therefore assume that only one type of charge carrier, namely, holes, are contributing to the conductivity. The conductivity then is given by

$$\sigma = pe\mu_p \qquad [1]$$

To calculate the conductivity it is necessary to compute p, the concentration of holes. In ref. (1) it was suggested that the defects consist of the following complex ($V_{Fe}Fe_iV_{Fe}$), *i.e.*, two iron vacancies associated with an iron interstitial. The creation and ionization of these defects may be written as

$$Fe_{Fe} + V_i + \frac{1}{2}O_2 = Fe_c^x + O_O \qquad [2]$$

$$Fe_{Fe} + Fe_c^x = Fe_c' + Fe_{Fe} \cdot e^+ \qquad [3]$$

Fe_c^x and Fe_c' are neutral and singly ionized complex defects respectively, where the prime refers to negative charge, V_i represents an interstitial (tetrahedral) site available for occupancy by the complex defect, and Fe_{Fe} is a divalent Fe atom on a normal site (octahedral), $Fe_{Fe} \cdot e^+$ is an Fe^{+++} ion on an octahedral site with one extra electron hole (a trivalent iron cation), and O_O is an oxygen ion on an oxygen lattice site.

With the neutrality condition

$$p = [Fe_{Fe} \cdot e^+] = [Fe_c'] \qquad [4]$$

and expressing the concentration of the defects in molar fraction y, the deviation from stoichiometry, is given by

$$y = [Fe_c^x] + [Fe_c'] = \alpha + \beta \qquad [5]$$

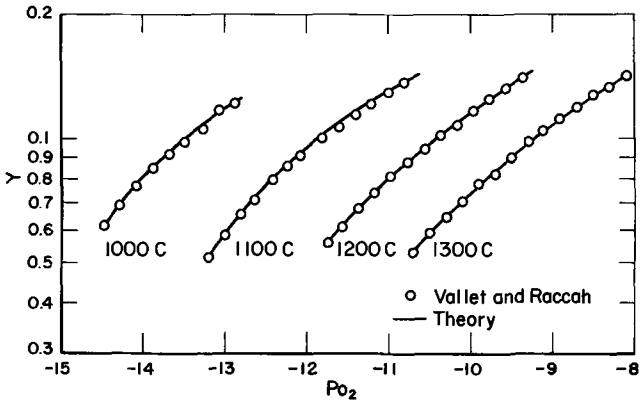

Fig. 1. Nonstoichiometry in wustite, y in $Fe_{1-y}O$, as a function of temperature and partial pressure of oxygen. Experimental results after Vallet and Raccah (2).

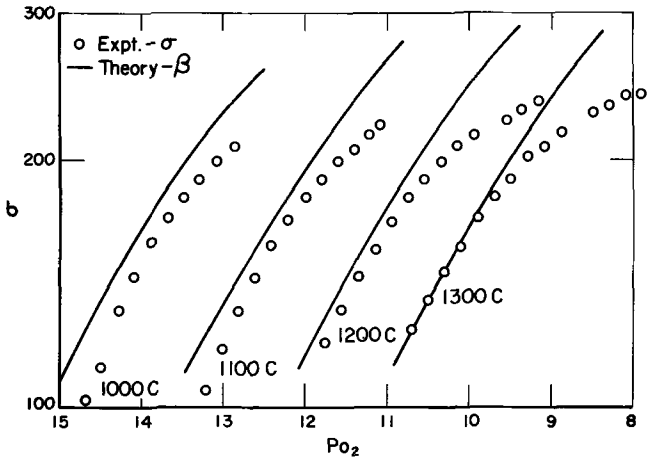

Fig. 2. Electrical conductivity as a function of oxygen partial pressure for several temperatures. Solid lines are obtained using Eq. [1]. Experimental data is after Hillegas (6).

where α is the concentration of unionized complex defects and β is a concentration of ionized defects and is also equal to p, the concentration of free charge carriers.

Due to the large concentration of defects, the concentration of regular octahedral sites and of empty tetrahedral sites cannot be assumed to be constant. It has been shown in ref. (1) that

$$[Fe_{Fe}] = 1 - \beta - 2y \qquad [6a]$$

and

$$[V_i] = 2 - 7y \qquad [6b]$$

With these values for the activities of octahedral sites and tetrahedral sites, the law of mass action applied to Eq. [2] and [3] yields

$$y - \beta = K_1 (2 - 7y)(1 - \beta - 2y)\, p_{O_2}^{-1/2} \qquad [7]$$

and

$$\beta^2 = K_i (y - \beta)(1 - \beta - 2y) \qquad [8]$$

Solving these equations, we obtain for β

$$\beta = \frac{-K_i(1 - y) \pm [K_i^2(1 - 3y)^2 + 4K_i y(1 - 2y)]^{1/2}}{2(1 - K_i)} \qquad [9]$$

and for p_{O_2}

$$p_{O_2} = \left[\frac{K_1 (1 - 2y - \beta)(2 - 7y)}{y - \beta} \right]^{-2} \qquad [10]$$

These equations have been solved numerically in ref. (1).[1] With the expressions $K_1 = 1.75 \times 10^{-9} \exp(79{,}400/RT)$ and $K_i = 0.13 \times 10^2 \exp(-17{,}900/RT)$ we calculated the deviation from stoichiometry as a function of p_{O_2}. The results are presented in Fig. 1 with the experimental results of Vallet and Raccah (2). Excellent agreement of theory with experiment is apparent. The values of β as a function of temperature and oxygen partial pressure were then used to calculate the conductivity using Eq. [1]. The mobility is assumed to be a constant of temperature and is calculated from the conductivity at the smallest deviation from stoichiometry separately at each temperature. The conductivity at all y has been calculated from these values of μ, and the results are shown in Fig. 2. We see that the conductivity as calculated deviates markedly from the measured conductivity even at relatively small values of y. This is not surprising since the concentration of charge carriers is extremely high and one would expect that the mobility would be a function of this concentration.

From the experimental results and the known concentration of charge carriers one can, however, estimate an approximate value for the mobility $\mu \cong 1$ cm²/V sec.[2] Such a small mobility is typical of solids where small polaron hopping is the operative mode of conduction (7). In this case the mobility is proportional to the jump probability of a charge carrier from site to site. If the concentration of charge carriers is very high, it is highly probable that one of the nearest neighbor sites will already be occupied by a charge and therefore hopping to this site will be prohibited. The probability of a jump will therefore be decreased by a factor $1 - \gamma\beta$, where γ represents a blocking parameter describing the availability of sites for charge motion. This term is similar to the blocking term on the tetrahedral site (Eq. [6b]), and we assume that each octahedral site occupied by a charge carrier blocks half the neighboring octahedral sites and its own site. Therefore, γ is equal to 4 in our calculations. Since the concentration of charge carriers is extremely large, it is quite probable that some of the blocked sites calculated in this manner are blocked twice. To allow for this effect we tried to accommodate in the model different screening parameters. Usually, self screening is proportional to the 1/2 or 2/3 power of the concentration of charge carriers. We found the former to better fit the results and we therefore used 1/2 for calculating the conductivity. The following expression for the mobility is therefore used

$$\mu = \mu_0 \beta^{1/2} (1 - 4\beta) \exp \frac{-E_a}{kT} \qquad [11]$$

The activation energy E_a is the heat of motion for the charge carriers themselves and it has been taken to be 0.01 eV. This is determined from the temperature dependence of the lowest conductivity values at each temperature where the influence of the blocking parameters is minimal. Also the deviation from stoichiometry at this part of the phase diagram does not change much with temperature and is about 5%. Using Eq. [1] and [11] the conductivity has been calculated. The results of these calculations are shown in Fig. 3 and are compared with the experimental results of Hillegas (6). Apart from a slight decrease in the conductivity with increasing concentration of charge carriers at the high oxygen pressure part of the phase, the fit of the calculated σ with the experimental values is very good. Later we discuss possible sources for the deviations at high concentrations of charge carriers.

One would like, however, to check the validity of the model proposed here on an independent set of experimental results. The Seebeck coefficient may serve

[1] Unfortunately, in ref. (1) a typographical error occurred in the pre-exponential values of K_1 and K_i; furthermore, to obtain better agreement with thermogravimetric results, the constants have been slightly varied in the present work.

[2] At the temperatures in question, this value alone is not by itself a sufficient consideration to apply the hopping model. Measurement at lower temperatures suggests, however, a mobility which strongly decreases with temperature and on this basis the hopping assumption is made.

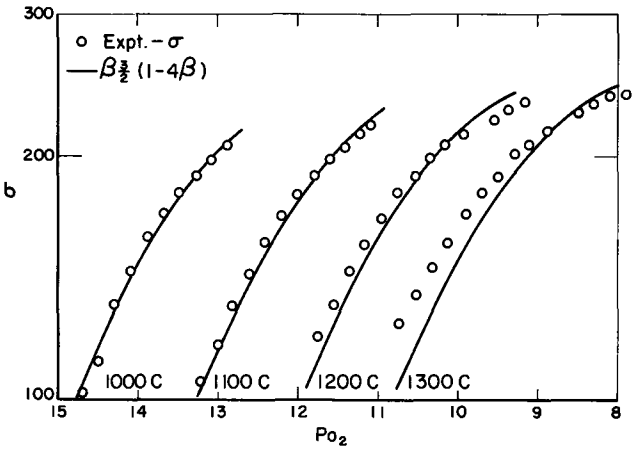

Fig. 3. Electrical conductivity as a function of oxygen partial pressure for several temperatures. Solid lines are obtained using Eq. [1] and [11]. Experimental data is after Hillegas (6).

as a tool for this purpose since it is, theoretically, simply related to the concentration of charge carriers.

The Seebeck coefficient is given by the expression

$$Q = \frac{k}{e}\left\{ \ln\frac{N_v}{c} + A \right\} \qquad [12]$$

where N_v is the density of states, c the concentration of charge carriers, and A a kinetic term. When the charge carriers are localized, N_v is assumed to be the concentration of available sites. From our discussion above this should be $N_v = \beta^{1/2}(1 - 4\beta)$. With $c = \beta$, we therefore obtain for Q

$$Q = \frac{k}{e}\left\{ \ln\frac{(1-4\beta)}{\beta^{1/2}} + A \right\} \qquad [13]$$

In Fig. 4 we plotted these values together with the experimental results of Hillegas (6). The kinetic term here equals −0.89. It is seen that good correlation is found between the experimental results and the theoretical curves which were obtained from the same model used to explain the conductivity data. A possible explanation of the negative kinetic term is presented below.

Discussion

We have presented here a model which has been used to interpret three sets of experimental data which are dependent on temperature and oxygen pressure. These data are deviation from stoichiometry, the electrical conductivity, and the Seebeck coefficient. The parameters of the theory are K_l and K_i which are temperature dependent in a well-determined way, and the blocking and screening effects.

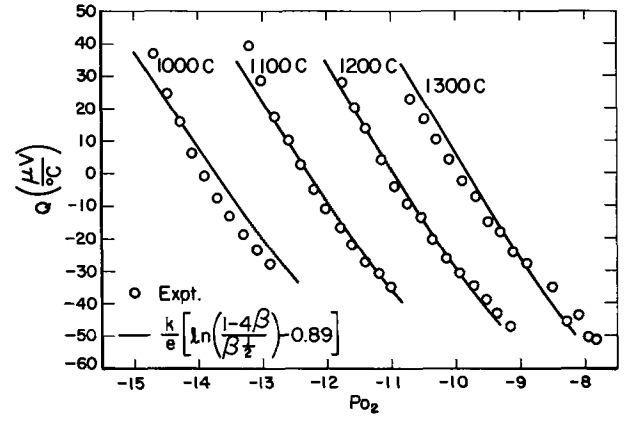

Fig. 4. Seebeck coefficient as a function of oxygen partial pressure for several temperatures. Solid lines are obtained using Eq. [13]. Experimental data is after Hillegas (6).

The blocking and screening parameters have been chosen in a manner consistent with physical reality. K_l and K_i were determined to fit the experimental thermogravimetric data alone. K_l was determined from the deviations from stoichiometry at low values of y, while K_i was estimated from the high y portions of the phase diagram. The fact that a very good fit for three independent experimental variables obtained over a wide range of temperatures and oxygen partial pressures, could be calculated using parameters derived to fit a single set of values,[3] points up the fact that the defect structure proposed and the form of the mobility bear a close relation to the actual properties of wüstite.

One of the conclusions from this treatment is that the nonlinearity observed in thermogravimetric data obtained using solid state electrolytic cells and in measurements of electrical conductivity does not warrant the introduction of three different phases in wüstite. This does not rule out the possibility of the existence of a long-range order as discussed by Koch and Cohen (8). However the macroscopic properties of wüstite would be influenced only to a minor degree even if such a long-range order did indeed exist.

The model presented here does have, however, some intrinsic limitations. We have seen that at very high concentrations of charge carriers the theoretically obtained values of the conductivity do deviate from the experimental ones. Assuming that the experimental values are correct one asks himself where the theory could be improved to account for these deviations. The parameters K_l and K_i and their temperature dependence have been calculated using the experimental thermogravimetric data. K_i however determines the ratios of β to y. (It describes the ionization of the complex defects.) The thermogravimetric data are by their nature less accurate than electrical conductivity data and less sensitive to K_i. Slight changes in K_i could influence the calculated conductivity to a larger degree than the deviation from stoichiometry. It is possible, therefore, that a better value of K_i could improve the theoretical values of the conductivity.

It is not impossible, however, that the screening coefficient $\beta^{1/2}$ changes slightly with β itself. We tested this idea, and for high β a screening coefficient $\beta^{2/3}$ does fit the results better than $\beta^{1/2}$. This would be a plausible result since the concentrations of charge carriers do increase by a factor of 3. Such a procedure will, however, render the relative simplicity of the model useless, and may involve the fitting of the experimental results to theory with too many parameters.

The exact form of the kinetic term in the Seebeck coefficient is still uncertain. Heikes *et al.* (9) show that for hopping charge carriers $A = \beta E_\mu/kT$ with $\beta = 1$ or $0 < \beta < 1$. To our knowledge no theoretical work predicts $\beta < 0$.

This behavior has, however, been observed before in CoO (10) and the question arises as to whether or not this is a general property. One speculation to explain this peculiar effect is that we have here a case of a "negative phonon drag." The A term in the thermoelectric power describes the temperature dependence of the scattering mechanism in the transport of charge carriers. In most cases, this is also the temperature dependence of the mobility. The phonon drag is however associated with an anisotropic scattering of phonons by the charge carriers, yielding an extra thermal energy in the direction of the charge motion. In the case of hopping, the charge motion is phonon assisted and one could interpret this as scattering of electrons by phonons and therefore a lowering of the thermal energy

[3] It should be noted that the fact that the temperature dependence of K_l and K_i must be of a given form does limit the choice of parameters, and a good agreement of the theoretical value to the thermogravimetric data is by itself a good indication of the usefulness of the model chosen.

of the system in the direction of motion. The occurrence of this negative A term in CoO, in some spinels, and in wüstite warrants a deeper theoretical study of this effect. It may be noted in this context that 0.89 is approximately E_μ/kT in this temperature range, and this also is very similar to the expression observed in CoO.

Acknowledgments

The authors are grateful to Dr. Hillegas and Professor J. B. Wagner for supplying us with their detailed experimental results.

Technical Note

Heats of Fusion of the $A_2^{V}B_3^{VI}$ Compounds

As_2S_3, As_2Se_3, As_2Te_3, and Sb_2S_3

M. B. Myers and E. J. Felty

Research Laboratories, Xerox Corporation, Rochester, New York

The nonoxide group V-VI, A_2B_3 compounds are of interest because of their semiconducting and photoconductive properties. Further, the particular compounds of the present study are in a very interesting class of materials referred to as chalcogenide glass formers. Because the active interest in these materials is a relatively recent one, there are little data with respect to their thermodynamic properties. This paper reports measurements of the heats of fusion and the corresponding melting points for As_2S_3, As_2Se_3, As_2Te_3, and Sb_2S_3.

Experimental

The materials were prepared by reaction of Gallard Schlesinger 99.9999% pure elemental components in silica glass ampoules at 600°C for 24 hr and air cooling to room temperature. The As_2Te_3 and Sb_2S_3 melts crystallized on cooling, whereas As_2S_3 and As_2Se_3 formed glasses. Suitable As_2Se_3 crystals were prepared from the glassy material by sublimation in sealed silica glass ampoules. Difficulty in obtaining completely crystalline As_2S_3 necessitated the use of natural crystals of the mineral orpiment.

The identity of the compounds was checked by x-ray diffraction, and the stoichiometry of their major constituents was determined to be within ± 1.0 a/o (atomic per cent) of the desired composition by electron microprobe analysis. The absence of any observable eutectic reactions during the thermal analyses further verified the accuracy of the compound compositions.

Calorimetric determinations were carried out with two different types of apparatus depending on the melting temperature of the compound. A Perkin-Elmer DSC-1B differential scanning calorimeter (1, 2) was employed in the analyses on As_2S_3, As_2Se_3, and As_2Te_3, whereas, the calorimeter accessory (3) for the Du Pont 900 DTA was used for Sb_2S_3.

The Perkin-Elmer calorimeter read out temperatures were corrected by calibrating the instrument using the melting points (4) of In, Sn, Pb, Zn, Cd, and Te. The Du Pont instrument potentiometrically recorded temperature with chromel-alumel thermocouples, and calibration with appropriate melting points indicated no additional corrections were required. The accuracy of the temperature measurement is ± 1°C. However, the uncertainty of the melting points is greater as indicated because of the difficulty in discerning the exact onset of melting. A comparative analysis on materials with well established melting points indicated a preference for an extrapolated onset technique for the DTA and a point of first departure from baseline for the DSC-1B.

The heats of fusion were determined by a comparison of the areas of the melting endotherms of the unknowns to those of standards with melting peaks in the same temperature range. The areas of the melting peaks were enclosed by drawing a straight line from the point of first departure from the baseline of the thermogram trace to the point of return. The area of each endotherm was measured ten times with a planimeter, and ten analyses were made on each unknown and standard.

The standard employed for the As_2S_3 determination was Pb, and the standard for the As_2Se_3 and As_2Te_3 determinations was Zn. These calibrations were checked by employing them for the measurements of the heats of fusion of Cd and Te. Comparison of the mean values of these determinations with literature values indicates a difference of 2.0 and 3.6%, respectively. The primary calibrant for the determination on Sb_2S_3 with the Du Pont apparatus was Bi_2Te_3. Because of the marked temperature dependence of the calibration factor in the temperature range of interest, the

Table I. Melting points, heats of fusion, and entropies of fusion of $A_2^VB_3^{VI}$ Compounds

Compound	Melting point, °C		ΔH fusion kcal/g at. (kcal/mole)		ΔS fusion cal/g at.° (cal/mole°)	
	Present study	Literature	Present study	Literature	Present study	Literature
As_2S_3	~315	307 (7)	1.37 ± 0.06 (6.85 ± 0.30)	0.91 (7)	2.33 (11.65)	1.6 (7)
As_2Se_3	368 ± 4.0	360 (12)	1.95 ± 0.06 (9.75 ± 0.30)		3.04 (15.20)	
As_2Te_3	374 ± 1.0	362 (13)	2.67 ± 0.07 (13.35 ± 0.35)		4.13 (20.65)	
Sb_2S_3	549 ± 4.0	547 (8)	2.29 ± 0.12 (11.45 ± 0.60)	1.12 (8)	2.79 (13.95)	1.37 (8)

secondary calibrants Cd, Zn, and Te were employed to establish a temperature coefficient for the factor. The error in the determination of the heat of fusion of Sb_2S_3 with the calibration is approximately 5%.

The heating rates for all of the analyses were 10°C/min, and depending on the gram-atomic weight of the sample, 1-10 mg of material were analyzed. The sample holders employed were Perkin-Elmer sealable aluminum containers for volatile samples. The inhibition of free vaporization was most important for As_2Te_3 and Sb_2S_3 near the melting point. Reaction with the sample container was only noted for Sb_2S_3 and was eliminated by forming a thicker oxide coating on the container by anodization.

Discussion and Results

The heats of fusion, melting temperatures, and computed entropies ($\Delta S_f = \Delta H_f/T_f$) obtained in this investigation are summarized in Table I and are compared in Fig. 1 with the literature values for Sb_2Se_3 (5), Bi_2S_3 (5), Sb_2Te_3 (6), and Bi_2Te_3 (6). The literature values for ΔH_f of As_2S_3 (7) and Sb_2S_3 (8) were determined by the pressure dependence of the melting point and by cryoscopic measurements, respectively. Comparison with the values of this study indicates fair agreement for As_2S_3 and poor agreement for Sb_2S_3. The determination of ΔH_f by cryoscopy requires assumptions concerning the nature of the liquid solution which are difficult to verify. It is believed that the calorimetrically determined value of the present study is the more accurate parameter for Sb_2S_3.

There is a great deal of experimental evidence indicating that ΔH_f is proportional to T_f for certain classes of crystal structures (9, 10). However, a constant entropy relationship between ΔH_f and T_f is not found for any of the groups of isostructural compounds appearing in Fig. 1. This lack of proportionality is also demonstrated for the isostructural elements Se and Te (8) included in Fig. 1 for comparison.

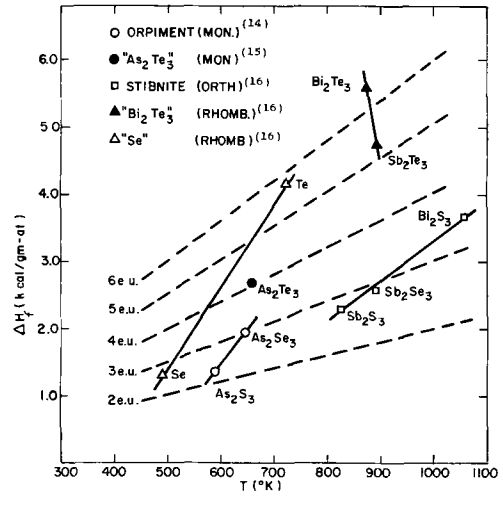

Fig. 1. Relationship between the heat of fusion and thermodynamic melting point. The isostructural compounds, connected by solid lines, are identified as to structural type in the upper left quadrant of the diagram. The broken lines indicate constant entropy values.

In order to evaluate the relative differences quantitatively in the entropy of fusion for these compounds, all the sources of entropy change require consideration. These contributions can arise from the volume change, molecular orientation randomization, and random mixing of elemental components. The importance of these factors vary according to the degree of dissociation of the compound in the melt.

Unfortunately, neither the ΔV_f nor detailed structural information of the melts are available to assess their relative contributions to ΔS_f. However, it is possible to qualitatively relate the differences in ΔS_f to variations in the constitution of the melt by comparing the ΔS_f's with the change in cohesive energy with fusion. The change in cohesive energy is assumed to be reflected by the ratio of the gram-atomic heat of fusion to the gram-atomic heat of atomization. The heats of atomization are not experimentally available; however, they can be estimated (11) from

$$\Delta H_a = 1/5\,[-\Delta H^\circ_{F(A_2B_3)} + 2\Delta H_a^\circ{}_{(A)} + 3\Delta H_a^\circ{}_{(B)}]$$

where ΔH°_F is the heat of formation of the compound, and ΔH_a° is the heat of atomization of the elements.

The data in Fig. 2 do indicate for both isostructural groupings and for these A_2B_3 compounds in general that the increase in the entropy of fusion is associated with a greater relaxation of bonding energy on fusion. This observation suggests that the progressive increases in the ΔS_f's observed in Fig. 2 are associated with greater structural change on fusion. The resulting melts would be characterized by increased dissociation and randomization. This trend is consistent with the observed decrease in glass forming tendencies and melt viscosities found for the higher gram-atomic weight compounds.

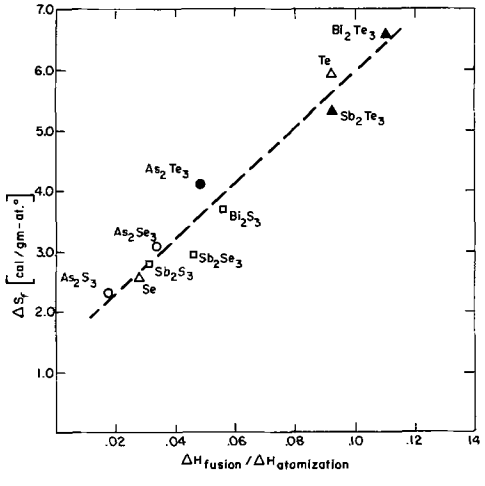

Fig. 2. Relationship between ΔS_f and the decrease in average bonding energy. Isostructural compounds are denoted as in Fig. 1.

Changes in the State of the Zinc Anode during Discharge of Leclanche Dry Batteries

K. Miyazaki*

Mitsui Mining and Smelting Company, Central Research Laboratories, Mitaka-shi, Tokyo, Japan

ABSTRACT

Microanalytical and x-ray diffraction examination of cross-sectional areas of discharged zinc anodes has been carried out together with the measurement of the extent of metal dissolution using typical fabricated zinc cans. The behavior of zinc as a dry cell anode, including the generation of discharge products, is very dependent on the degree of discharge and the capacity, even for batteries incorporating identical anodes. Manganese occurrence at the zinc-electrolyte interface is observed in particular cases of discharge. This is associated with the generation of enlarged micropores in the MnO_2 particles contained in the cathode cake.

This paper deals with an experimental study of zinc anode behavior in actual Leclanché dry cells. It is ordinarily recognized that the reaction of zinc anodes during discharge in Leclanché cells exhibits the following general features: (*a*) dissolution of the metal, (*b*) change in the crystalline orientation, and (*c*) generation of discharge products. However, these changes seem to have been overlooked in many cases, partly because a major portion of the technology in this field has long been in a border area between the zinc supplier and the dry cell producer and partly because the zinc is the "consumed electrode" and therefore provides few opportunities for investigation.

In recent years, much attention has been devoted to the nature of the zinc anode and its participation in some electrode processes. Among the basic studies on zinc behavior, McMurdie (1) related the discharge products including $ZnCl_2 \cdot 4Zn(OH)_2$, and $ZnCl_2 \cdot 2NH_3$. Cahoon (2) mentioned the occurrence of $ZnCl_2 \cdot 2NH_3$ and $ZnCl_2 \cdot 4NH_3$, and Drotchmann (3) and Bell (4) discussed the corrosion problem of the zinc plate in the Leclanché electrolyte. Most of the published data, however, have been limited to discussions of the results of rather "static experiments" with test pieces immersed in cell electrolytes, and a recalculation is required when applying them to the characterization of zinc anodes with "dynamic discharge reactions" in actual dry cells. It is often observed that the behavior of zinc in actual dry cell service deviates significantly from what might be expected from a separate immersion test with zinc pieces.

Because of the importance of the contribution of zinc ions to Leclanché dry cell reactions as seen in the previous work (5), an effort has been made in the present paper to observe where, and to what extent, the zinc anode will react to function as the counter-electrode of the MnO_2 during discharge of a Leclanché cell. It is well known that the cathode cake and paste formulation has a major influence on zinc anode performance; even with the same species of zinc anode, the performance of cells is largely governed by the way they are made. In the present study, utilizing this phenomenon and selecting some of the parameters in cell fabrication, a number of laboratory dry cells were constructed with a typical impact-extruded zinc can. These cells, prepared with several modifications, were then discharged on heavy and light loads. The resultant anodes have been examined by means of x-ray diffraction and electron probe microanalysis. The purpose here is to reveal how the three general features, (*a*), (*b*), and (*c*), mentioned above manifest themselves with a typical fabricated zinc can under actual service conditions and how they are described in terms of discharge characteristics of the cell.

Experimental

Anode zinc can.—A typical impact-extruded zinc can for commercial D-size cells in Japan was used for constructing the test cells. The weight was 14g and the chemical analysis was: Fe 0.01%, Pb 0.12%, Cd 0.06%, Cu 0.004%, and Zn the balance. This can was manufactured through the three main steps according to the common practice; *i.e.*, (i) metal ingot before rolling, (ii) "coins" obtained from the rolled sheet and ready for impact-extrusion, and (iii) impact-extruded can.

Figure 1 shows the x-ray diffraction pattern for each stage. At stage (i), the most intense peak was (101) being characteristic of the metallic zinc. The relative intensities of the (002) and (004) peaks became stronger at stage (ii), showing that the hexagonal zinc unit cells had slipped along the basal planes (6) through the rolling operation. After impact-extrusion, at the final stage (iii), the (002) peak remained stronger and the (103) peak was also intensified, while the (004) peak was comparatively reduced.

Construction of the cells.—The standard formulation in the previous work (5) was used in constructing laboratory cells with the above zinc cans. To provide a series of varied discharge characteristics, the following parameters were selected and varied; the source and activity of manganese dioxide, mixing ratios in the cathode mix, pH of the electrolyte, aging time of the mix, wrapping and unwrapping of cathode bobbin, and

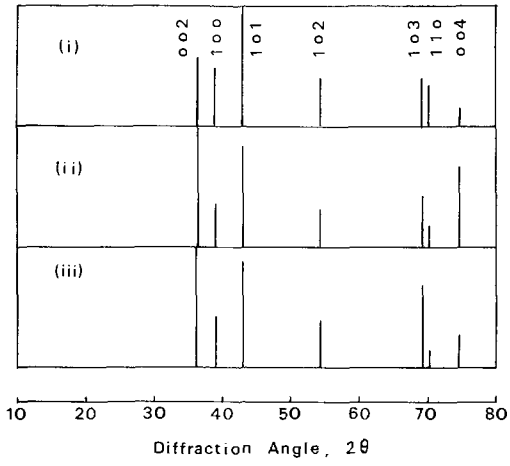

Fig. 1. X-ray diffraction examination of the zinc can at the main production stages: (i) the zinc ingot, (ii) rolled sheet, and (iii) impact-extruded can.

composition of the paste, thus giving 20 kinds of experimental fabrication processes. Mercury was always added to the paste in the form of $HgCl_2$ solution. Forty experimental cells in all, two cells for each fabrication, were obtained. They were hand pressed, containing 22g of manganese dioxide per cell.

In terms of present-day technology, our formulation and fabrication are probably outdated and perhaps naive. However, they did give us first-hand experience with some of the basic qualities of zinc when functioning as anode in actual working dry cells.

Discharge of the cells.—The two cells for each formulation were discharged, one on a relatively heavy load, 4 ohms for 30 min/day and 5 days a week, and the other on a relatively light load, 40 ohms for 4 hr/day and 5 days a week, to a cut-off voltage of 0.75V, respectively. Intermittent discharges were employed considering the fact that the daily usage of dry batteries is mostly intermittent.

Separation of discharged zinc anodes.—The discharged dry batteries were disassembled and the residual zinc anodes were separated, quickly rinsed with water, and then with acetone. Acetone facilitated the removal of the water and was itself removed at 20°C in air.

Care was exercised in removing some of the constituent materials of the residual cell, including the paste, from the consumed zinc electrode. Preliminary tests showed that the residual materials were removed from the developed anode surface by the brief rinse with water, and the film of zinc compounds formed on the immediate interior wall was satisfactorily stable and not affected by this treatment if the water was successively replaced with a volatile solvent such as acetone. Acetone was conveniently employed because it readily escaped from the surface at the room temperature of 20°C without any harmful effect to the consumed electrode.

When the rinsing procedure was not followed after disassembling the discharged dry cells, three undesirable effects took place: (i) the weight of the residual zinc anode was erroneous due to the wet paste, (ii) the bulk of the paste adhering to the electrode dried during the x-ray examination process and secondary compounds were formed other than the primary discharge products to be examined, and (iii) the wet paste interfered with mounting the specimen in the resin matrix used for the EPMA device and with examining it under the electron bombardment in vacuo.

There still remains a problem that this separation procedure may not be entirely satisfactory for a soluble discharge product such as polyammines, if any. However, the scope of the present study does not attempt to cover all the discharge products occurring in the cell, but concentrates on the changes in the state of the impact-extruded zinc metal from x-ray aspects. Among several ways tested for paste removal, the procedure described above was the best for the purpose of the present study.

Examination of discharged zinc anodes.—The discharged zinc anodes were examined as follows: (i) decrease in weight as an approximate measure of zinc dissolution, (ii) x-ray diffraction pattern of the developed interior surface using Cu K_α radiation for discharge products, and (iii) electron probe microanalysis for the Zn, Pb, and Mn distribution across vertical sections by scanning for the individual characteristic K_α x-rays.

Among the elements indicated in the chemical analysis of the zinc anode, Cd, Fe, and Cu were too small in amounts to be examined with the EPMA method, their images being overshadowed with the level of background. On the other hand, mercury which had been added to the paste in the form of $HgCl_2$ during assembly could be observed because it formed a layer of amalgam on the interior surface of the zinc anode.

In the case of Hg examination, however, the L_α ray instead of the K_α was employed due to the fact that the maximum accelerating voltage of the EPMA device with a LiF spectrum crystal was 50 kV, while the excitation voltage for Hg K_α ray is about 83 kV and that for Hg L_α is about 15 kV. Care was also extended to examine the background intensity of the Hg L_α image, because it was different from the one in the conventional cases of K_α images. A usual practice in the EPMA technique was followed in this case; a slight shift in the detecting angle from the wavelength of the Hg $L_{\alpha 1}$ ray, which is 1.23863Å, provided the background intensity of the Hg $L_{\alpha 1}$ itself, there being no interfering elements in the specimen that correspond to any wavelength in the shifted range.

The counting sensitivity of the x-ray detector of the microanalyzer was adjusted higher for the Pb, Mn, and Hg elements by a factor of 100 than for Zn because of their minor amounts. The other EPMA conditions were similar to the one described in the previous work (5).

Pore distribution measurement for MnO_2.—Pore size distributions were measured for the MnO_2 before and after discharge to determine changes that occurred as it functioned as a source of Mn^{+2} ions during discharge. The Barrett, Joyner, and Halenda method was used on the basis of nitrogen gas adsorption-desorption curves in a range of $p/p_o = 0.03$ to 0.97 obtained with a BET apparatus.

Results and Discussion

Dissolution of zinc.—The decrease in weight of the anode during discharge *vs.* the discharge hours are plotted in Fig. 2 and 3. The zinc anode dissolved in a larger quantity during the light discharge than during the heavy. The dissolution of the zinc is observed to be approximately proportional to the discharge duration in the former case, while not in the latter.

Changes in x-ray diffraction pattern.—The 40 residual zinc cans obtained, 20 each from the heavy and the light discharges, were roughly classified into four types of x-ray diffraction patterns as shown in Fig. 4. After the heavy discharge there was observed either a type that produced a number of the peaks of $ZnCl_2 \cdot 4Zn(OH)_2$ [Fig. 4(a)] or of $ZnCl_2 \cdot 2NH_3$ (b). After the light discharge, the zinc anode mainly produced the basic chloride rather than the diammine and the degree of generation was in some cases small (c), and in other cases considerable (d). While type (d) retained some of the stronger residual peaks of zinc, type (c) on the contrary possessed only smaller peaks of the metal.

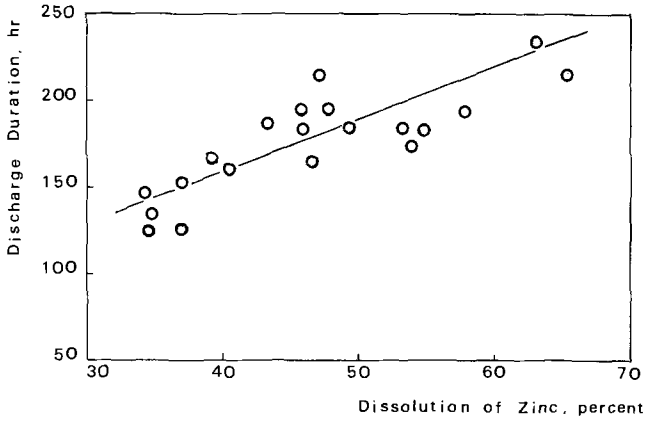

Fig. 2. Relationship between discharge duration and dissolution of zinc during the light discharge.

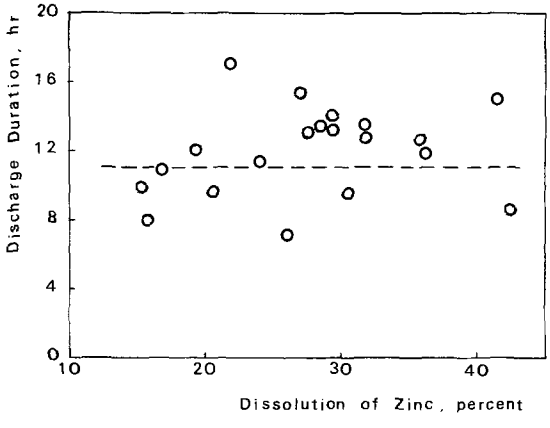

Fig. 3. Discharge duration vs. dissolution of zinc during the heavy discharge.

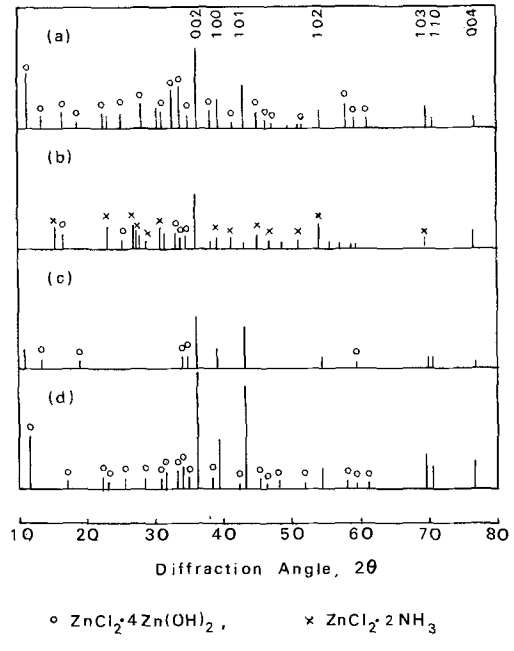

Fig. 4. Typical x-ray diffraction pattern of the zinc can after discharge: (a) and (b) after the heavy discharge, and (c) and (d) after the light discharge.

Figure 5 shows that the reduction of the intensity of the (002) peak is an approximate indication of the light discharge duration. It follows from Fig. 2 and 5 that the closest packed plane may be comparatively insensitive to dissolution during discharge, just analogous to the cases of heterogeneous catalysis with some metals where the closest packed planes are also

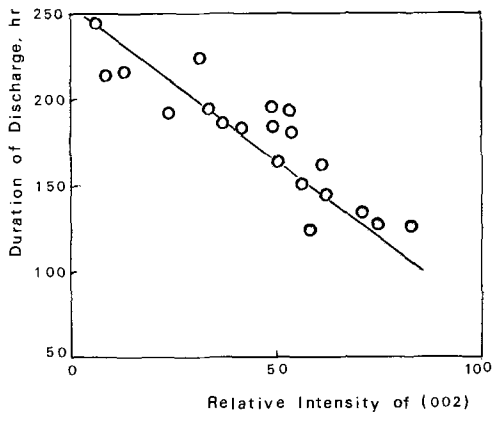

Fig. 5. A parallelism between the light discharge duration and the reduction of intensity of the (002) peak of the zinc anode after discharge.

the most inactive (7). This change was not pronounced in the case of the heavy discharge, probably because many other mechanical stresses would exist latent in the fabricated zinc can. Effects of these may overlap those of crystal orientation in determining changes during high rate drainage. Figure 6 is another indication that the basal planes of the hexagonal zinc lattice (00n), where n = 2 and 4 in the diffraction diagram of Fig. 1 (iii), are slower in the metal dissolution during the light discharge.

Discharge products and performance of dry cells.— An arbitrary rating for the degrees of generation of $ZnCl_2 \cdot 4Zn(OH)_2$ and of $ZnCl_2 \cdot 2NH_3$ was made on the basis of x-ray diffraction charts obtained with the residual zinc anodes. Five ratings were assigned from 1 through 5 for the basic chloride—for instance, the ones such as (a) in Fig. 4 were rated 5, while those such as (b) or (c) were 1. The diammine generation was likewise rated from zero through 3, being zero because a few examples did not produce any appreciable amount of the diammine as in the cases of (a), (c), and (d) in Fig. 4.

Figure 7 was obtained in this way showing that the more the zinc anode dissolved during the light discharge, the less basic chloride was generated. This observation indicates that the migration of zinc ions from the anode penetrates far into the cathode containing MnO_2 during discharge with the better performing batteries. It is therefore implied that most of the zinc precipitating as the basic chloride may come from the zinc chloride in the electrolyte and not from the zinc anode.

Figure 8 shows how the diammine generation is related to the initial voltage of cells; the lower the initial voltage, the more the diammine was generated during the discharge. If the ammonia radical to constitute the diammine is liberated by the oxidation reaction of ammonium ions (8, 9) at an initial stage of

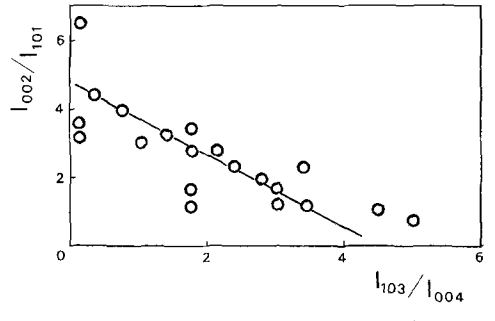

Fig. 6. Relationship between I_{002}/I_{101} vs. I_{103}/I_{004}, two specific intensity ratios of x-ray diffraction peaks, for residual zinc anodes after the light discharge.

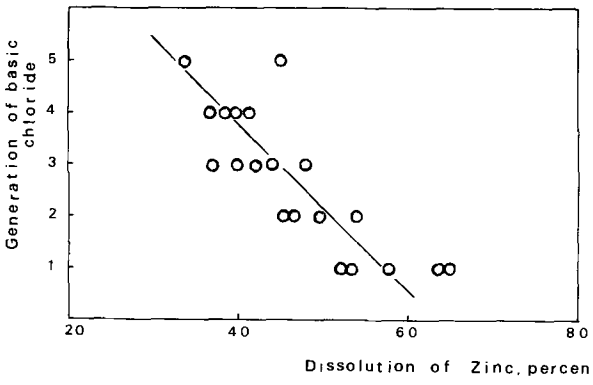

Fig. 7. Metal dissolution from the anode during the light discharge *vs.* the basic chloride generation.

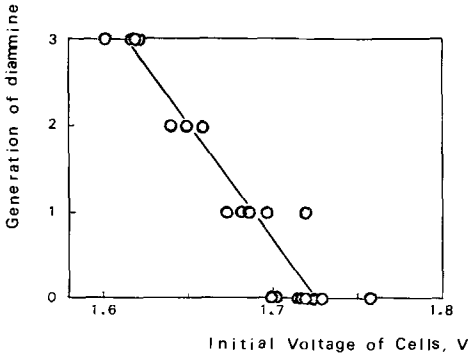

Fig. 8. Diammine generation during the heavy discharge *vs.* the initial voltage of cells.

discharge, the depolarizing power of MnO_2 may more or less participate in giving the relationship in Fig. 8.

$$2MnO_2 + 2NH_4^+ + 2e \rightarrow Mn_2O_3 \cdot H_2O + 2NH_3 \quad [1]$$

$$ZnCl_2 + 2NH_3 \rightarrow ZnCl_2 \cdot 2NH_3 \quad [2]$$

When the MnO_2 used is highly oxidative and its initial voltage is high, an excessive amount of ammonia may be supplied by Eq. [1], and the polyammines can be successively formed through the capture of the ammonia as follows (9, 10).

$$ZnCl_2 \cdot 2NH_3 + 2NH_3 \rightarrow ZnCl_2 \cdot 4NH_3 \quad [3]$$

$$ZnCl_2 \cdot 4NH_3 + nNH_3 \rightarrow ZnCl_2 \cdot (4 + n)NH_3 \quad [4]$$

The polyammines thus formed are rather soluble in a weakly alkaline atmosphere in the Leclanché cathode bobbin during discharge (8, 9, 11). However, when the MnO_2 used is mild in its activity and of low initial voltage, the liberation of ammonia at the initial stage of discharge may be low and just enough for the formation of the diammine; thus, the transformation of diammine to the polyammines may be limited in this case.

The relationship such as plotted in Fig. 8 was not found after the light discharge, probably due to a possible dissolution or transformation of the diammine, if any occurred, during the longer periods of discharge.

Transverse section of zinc anodes before and after discharge.—Figure 9 is a vertically sectioned area of zinc anode before discharge typically observed with the EPMA technique, while Fig. 10 and 11 show typical transverse aspects after the heavy and the light discharges, respectively.

It is interesting to note in Fig. 9(b) and (c) that the lead, which is usually alloyed with the zinc in a small quantity in order to improve the fabrication properties of the metal (12), is distributed in a rather homogeneous fashion together with the zinc base across the transverse section of the can wall. Figure 9(d) for

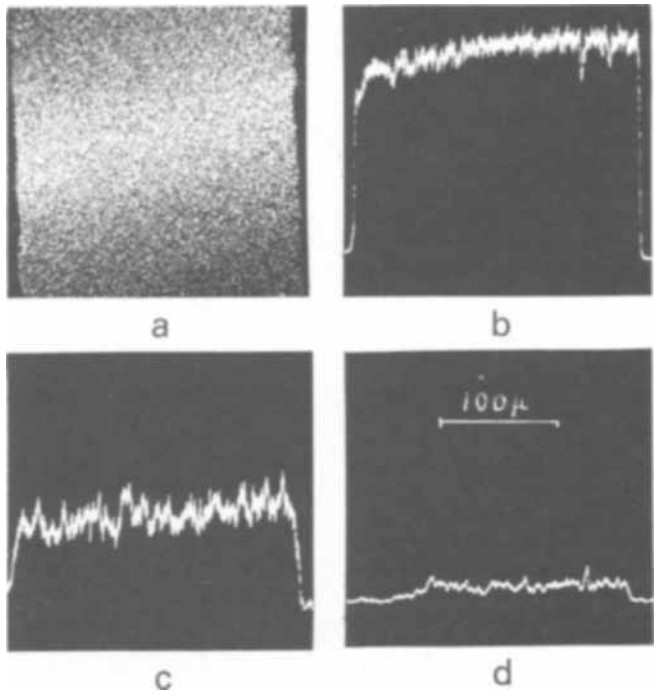

Fig. 9. Typical EPMA images from a vertically sectioned zinc anode before discharge: (a) Zn K_α distribution image, (b) Zn, (c) Pb, and (d) Mn line profiles.

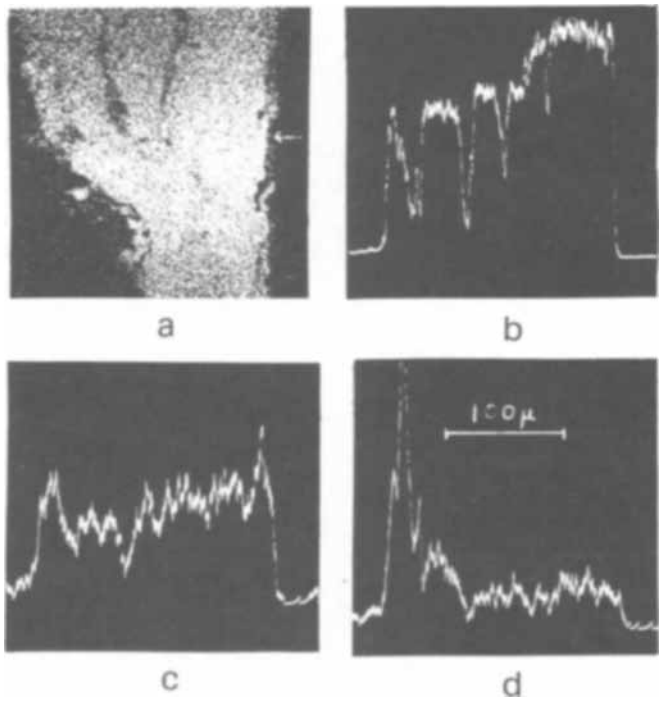

Fig. 10. Typical EPMA images from a vertically sectioned zinc anode after the heavy discharge: (a) Zn K_α distribution image, (b) Zn, (c) Pb, and (d) Mn line profiles.

manganese, although not an additive element to the zinc, was photographed as a blank test of the line profile for observing the movement of this element from MnO_2 after discharge.

After the heavy discharge, it is seen from Fig. 10(a) of the Zn K_α distribution image that the inside of the can (to the left side of the photograph) has been irregularly corroded as a result of the discharge. The line profiles for Zn, Pb, and Mn were obtained across the can at the position indicated with an arrow in Fig. 10(a) and are shown in Fig. 10(b), (c), and (d).

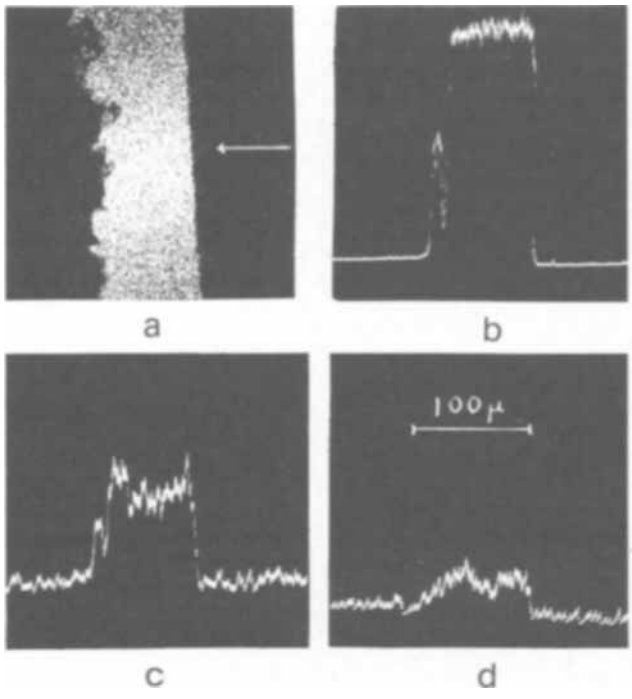

Fig. 11. Typical EPMA images from a vertically sectioned zinc anode after the light discharge: (a) Zn K_α distribution image, (b) Zn, (c) Pb, and (d) Mn line profiles.

A diluted zinc distribution toward the left side in (b) indicates that this element in this region may exist as a compound such as $ZnCl_2 \cdot 4Zn(OH)_2$ or $ZnCl_2 \cdot 2NH_3$ and not as the metal. Although the lead in (c) has come to distribute in a lightly zigzag pattern, a notable local concentration has not occurred.

The manganese line profile in (d), however, possesses an intense peak at the inside of the residual anode after the heavy discharge showing a local deposition of this element. This indicates that the manganese, which was practically absent before discharge as shown in Fig. 9(c), has moved onto this area during the discharge from the anode cake—the only manganese source across the electrolyte paste of the cell.

In the case of the light discharge, the situation is quite different from Fig. 10 as shown in Fig. 11, where the zinc seems to have dissolved rather homogeneously [(a) and (b)]. The lead shows no particular segregation along the transverse region (c) as in the case of the heavy discharge. It is interesting to note that no significant manganese occurrence is seen at the inside wall of the residual anode here (d), except that the background pattern somewhat differs depending on the metal zone and the surrounding resin matrix. It is generally observed as shown in (c) that the thickness of the residual can has become thinner in the light discharge than in the heavy.

Figure 12 shows the mercury line profiles, (a), (b), and (c), together with the backgrounds, (d), (e), and (f), where the pair (a) and (d) is a transversal section before discharge, (b) and (e) the one after the heavy discharge, and (c) and (f) after the light discharge, respectively. The line profiles were obtained with the 1.23863Å Hg $L_{\alpha 1}$ ray. As for the backgrounds, the continuous x-rays at a slightly longer wavelength by 0.016Å from the wavelength of Hg $L_{\alpha 1}$ ray were used by shifting the detecting angle of the microanalyzer by 30 min in angle from the position for the Hg $L_{\alpha 1}$. In this case, overlap of several other elements such as Ge, Sm, W, Yb, Xe, Re, Sb, and Tm would have to be taken into consideration if any of them were present in the specimen, because they could radiate their own characteristic x-rays in the range of 0.016Å shifted from 1.23863Å. However, it is most improbable that these

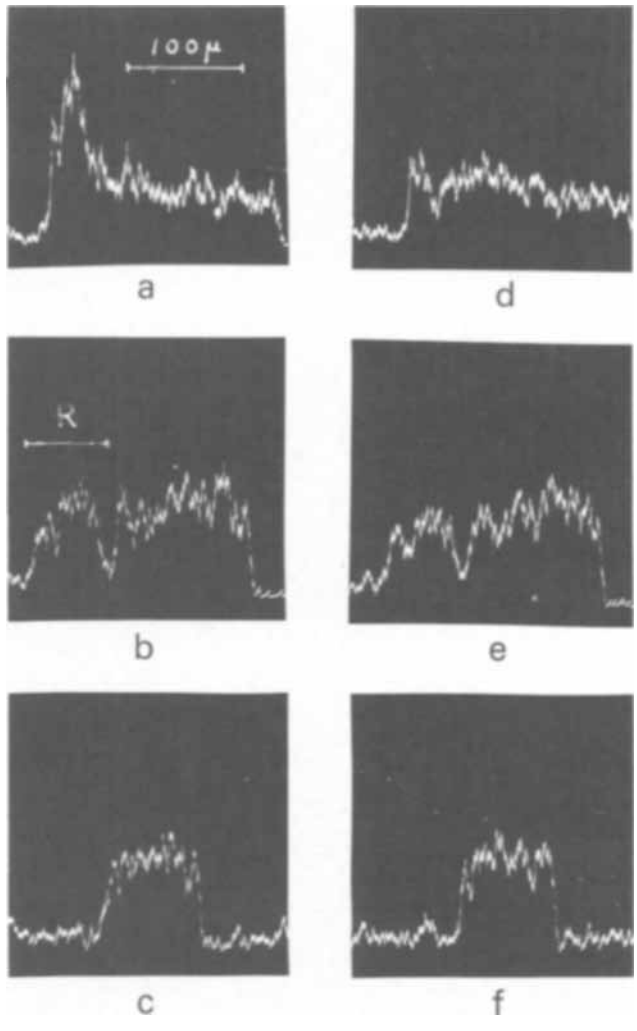

Fig. 12. Typical line profiles of Hg from a vertically sectioned zinc anode before and after discharge: (a) Hg $L_{\alpha 1}$ line profile before discharge with background image (d), (b) Hg $L_{\alpha 1}$ line profile after the heavy discharge with background image (e), and (c) Hg $L_{\alpha 1}$ line profile after the light discharge with background image (f), respectively.

elements exist to any extent in the zinc can used. Therefore, the images of the continuous x-rays taken by means of this technique [(d), (e), and (f)] secures the level of background for the mercury line profiles [(a), (b), and (c)] in Fig. 12.

In Fig. 12(a) and (d), it is observed that mercury was present in the anode wall in the order of 70-80μ deep from the inner surface which was in contact with the electrolyte before discharge. It is to be noted from Fig. 12(b) and (e) that the intensity of the Hg line profile of the region "R" is slightly higher than that of its background, which actually shows that a very small portion of mercury is retained in the discharge products on the surface during the heavy discharge. This is not the case during the light discharge [(c) and (f)]. It is indicated in general that the amalgamated film of the anode dissolved during an earlier period of discharge and the outer electrode regions having no mercury were left at the later stages of discharge.

Migration of manganese onto the zinc anode.—To consider the source of the above manganese deposit, although its chemical formula has not yet been established due to the small amount, the pore size distribution after discharge was measured for the MnO_2 particles taken from the discharged anode mixes of the cells corresponding to Fig. 10 and 11. As illustrated in Fig. 13, the heavily discharged MnO_2 possessed a dis-

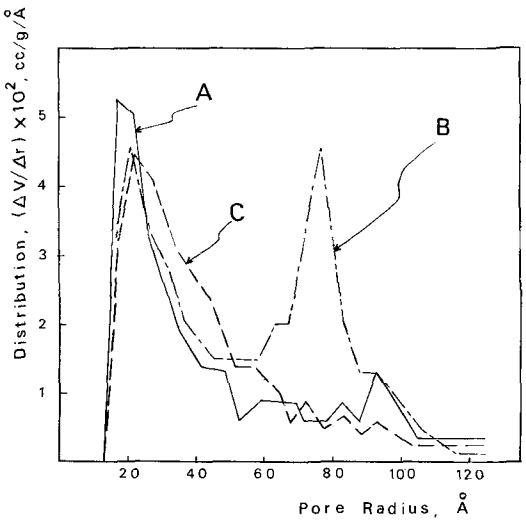

Fig. 13. Shifts in pore distribution in the typical MnO_2 after discharges: (A) before discharge, (B) after the heavy discharge, and (C) after the light discharge, where the X-axis represents the pore size in Angstroms and the Y-axis the distribution of pores expressed in terms of cc/g/Å by using the Barrett, Joyner, and Halenda equation.

tinctly double-headed pore distribution curve (B), one around 20Å and the other around 80Å in size. The initial pore openings distributed around 20Å before discharge (A), and this situation did not change much after the light discharge, only a minute enlargement of the average pore diameter having occurred (C). It should be pointed out that the additional pore openings around 80Å were generated to contribute to the heavy discharge output from the surface region of the MnO_2 particles, while the light discharge proceeded gradually along the paths of initial micropores of the interior. Many earlier workers (13-15) described the formation of Mn^{+2} ions as one of the discharge products of MnO_2. It has been shown here that a part of the Mn^{+2} ions formed can be transported across the dry cell compartments to reach the anode surface, particularly in the case of the heavy discharge.

The above observation will also be understood from the result of the preceding work (5) in which the discharge of MnO_2 particles was found to proceed through two processes, one from the surface and the other along the micropores or cleavages inside of the particles. At the same time, it is to be noted that the movement of the two ions, zinc and manganese, may extend to a greater distance toward their opposing electrodes during discharge of dry cells than has hitherto been expected.

Summary and Conclusions

Experimental study of the behavior of the zinc anode has shown that the mode and extent of its reactions are closely related to battery performance in actual service. The zinc anode dissolved to a greater extent during the light discharge than during the heavy. During the light discharge, the dissolution of the zinc was observed to be approximately proportional to the discharge duration, and the amount of zinc that dissolved was related inversely to the amount of the basic chloride, $ZnCl_2 \cdot 4Zn(OH)_2$ that formed. Although the anodes before use exhibited an intense (002) orientation, the intensity of this peak was reduced by an amount proportional to the light discharge hours. During the heavy discharge, a generation of the diammine, $ZnCl_2 \cdot 2NH_3$, was characteristic when the initial voltage of the dry battery was low. Before discharge, mercury was seen to be present in the anode to a depth of about 70-80μ from the inner surface which had been in contact with the cell electrolyte. It was observed that the inside wall of the anode with the amalgamated film dissolved at an early stage of discharge and the outer electrode regions having no mercury were left after discharge. Manganese ions were observed to have partly migrated from the cathode onto the anode just as the zinc did from the anode to the cathode. The heavy discharge produced additional pores in the MnO_2 that were larger in diameter than the original micropores. It is implied from a technical point of view that developing means of facilitating the mutual transportation of these ions during discharge will be one of the major concerns for improving the discharge performance of Leclanché dry batteries.

Acknowledgments

The author wishes to thank his colleagues, N. Sasaki, for the x-ray diffraction, T. Kobayashi, for the electron probe microanalysis, and M. Yamamoto, for helpful discussions during the course of this investigation.

Effect of Atmospheric Exposure on the Contact Resistance of Selected Tin Alloys

Sidney L. Phillips[*,1,2] **and Christian E. Johnson**

National Bureau of Standards, Washington, D. C.

ABSTRACT

Atmospheric exposure of plated specimens in a rural outdoor location showed that both tin-zinc and tin-cadmium alloy coatings on steel maintained a lower contact resistance than did equal thicknesses of tin, tin-lead, or tin-antimony alloys. After exposure for over 2 months, the contact resistances under a 50g load for 5-38 μm thicknesses of tin-zinc and tin-cadmium ranged between 10-100 mohms, although both coatings rapidly lost their luster. The tin-lead alloy maintained the lowest contact resistance of all the coatings tested, although it failed to provide corrosion protection as good as equal thicknesses of tin-zinc or tin-cadmium.

The metal coatings plated onto the structural materials used in the electronics industry sometimes have a dual function (1). On one hand, the coating must provide corrosion protection to the basis metal when exposed to a variety of atmospheric conditions. In addition, the same coating may also be required to present a low contact impedance when joined to another metal which is acting as an electrical conductor. Ficchi has discussed in detail the importance of good electrical bonding between structural surfaces both to provide low impedance paths to ground, and to prevent the accumulation of undesirable static charges at poorly conducting interfaces (1). From the viewpoint of machine design, a low impedance across a region of contact between conductors will also permit joined parts to be considered as a continuous conductor so that calculations can be simplified. In the present work, we report the results of a study which was focused on finding metal coatings that could be plated onto structural steel and meet these two criteria.

Work has been reported on the atmospheric corrosion of metals that were evaluated for use as coatings on the separable electrical conductors used in the electronics industry (2-8). These studies were primarily concerned with metals and alloys that would maintain low interfacial resistances under conditions of sliding contact between the metal parts. It was found that, if the load exceeds about 25g, such metals as gold, tin, rhodium, platinum, and tin-lead alloy maintain contact resistances in the range 1-10 mohms under a variety of exposure conditions for several years (2-5). The precious metals do not appear to be economically feasible either singly or in a duplex coating for structural materials, so that tin or tin-lead alloy would be of greater interest. For this reason, the work described here centers mainly around tin and some selected tin alloy coatings.

Experimental

In the present work, the conditions of exposure included both indoor and outdoor atmospheric exposure and the water-sulfur accelerated aging test (4). The criterion used to rank the various coatings was the change in electrical contact resistance when the metals were exposed to various environments. The measurements of contact resistance were carried out using a procedure similar to that reported in other work (2-8). Of interest also was the degree of rust products observed on the surface of the various coatings, and qualitative observations are included here.

Key words: corrosion, contact resistance, metal plating.

Contact resistance of tin and selected tin alloy coatings.—As noted, tin or tin-lead alloy coatings will maintain contact resistance values in the low milliohm range under a variety of environmental conditions, provided the load exceeds about 50g (4, 5). In addition to the published data on tin and tin-lead alloy, we were able to obtain similar measurements on alloy specimens of tin with cadmium, nickel, and zinc which were kindly furnished by The Tin Research Institute. For the most part, these specimens had been plated in the 1950's and were then stored under different conditions in their laboratory. The various coatings which they furnished together with coating thicknesses, storage conditions, and contact resistance are recorded in Table I. Included also in this table are data obtained for a specimen of tin-zinc which had been plated onto steel by M&T Chemicals, Incorporated, and gold and nickel coated specimens which had been plated at the National Bureau of Standards.

From this table, it can be seen that only the tin-nickel alloy consistently gave the highest and least reproducible readings under all aging conditions. In addition, contact resistance values were less reproducible and comparatively higher for tin-zinc alloy specimens which were passivated with chromic acid prior to storing. This effect can no doubt be traced to the presence of a poorly conducting film on the alloy surface which is difficult to shear so that the formation of metal-to-metal conducting paths is prevented (9). Some of the specimens had been stored in a washroom for 1 yr prior to further storage in the laboratory. In this case, the washroom had an atmosphere which was usually humid and polluted by the gases from the flue of a gas-fired water heater. The pollutants were not identified, but the result was to cause a marked increase in the contact resistance of the exposed samples. Nonetheless, the specimens plated with the tin-zinc alloy coating still gave much lower values than the tin-nickel alloy which had been exposed in a similar manner.

It should be noted that the relatively low values obtained for the tin, tin-zinc, and tin-cadmium alloys are due almost entirely to the softness of the coatings (5). If the load exceeds about 0.1g, the probe tip can shear through surface films and make contact with metal beneath the film so that the measured resistance is lowered considerably (9). Some surface rearrangement took place on the soft coatings when the measurements were made in this work, because shiny spots were observed on an otherwise matte finish at the circle of contact between the probe tip and the plated metal.

In addition to the contact resistance, the current flow through plated finishes at radio frequencies is of interest for electronic applications (1, 10). Contact imped-

ance measurements covering the frequency range 10 kHz to 30 MHz were obtained on specimens selected from Table I, and results are recorded in Table II. The presence of poorly conducting films was demonstrated by rotation of the probe tip under a sufficient load during contact, which had the effect of shearing through surface films so that metal-to-metal contact was established (4, 9). In the present work, the probe was rotated 15° and the usual result was a lowering of the contact impedance as shown in Table II. The decrease in contact impedance was especially marked for the specimen coated with tin-zinc alloy, which had been polished and stored in the washroom before final laboratory storage. The initial contact impedance fell between 840-923 mohms as compared with 20-190 mohms after rotation. Similar decreases were also obtained for all but one of the specimens coated with tin-nickel alloy, thus showing an important difference between sliding and static modes of electrical contact.

Other alloys of tin with bismuth and antimony were prepared by melting and mixing the pure metals under an argon atmosphere, and contact resistance values were obtained before and after atmospheric exposure tests including the sulfur-water accelerated aging test (3, 4). Although the alloy surfaces were discolored after exposure, the contact resistance values were only 4-20 mohms.

Based on the above results, it was concluded that tin and some tin alloys could provide corrosion protection to steel while also maintaining a low contact impedance under various conditions of exposure. Tin, and selected tin alloys were plated onto steel specimens for investigation in the atmospheric tests.

Preparation and plating of test specimens.—The test specimens were cut from sheets of cold rolled No. 3 finish steel, SAE 1010, one side of which had been polished bright, with a No. 4 temper. Each specimen was numbered near one corner using a steel die, and a narrow strip was cut halfway across the top, then turned over at a right angle to serve as a hanger (11). A hole was drilled in the center of this hanger, and the specimen was screwed to a plating rack. The rack held ten 3.4 x 7.6 x 0.09 cm specimens arranged in two rows of five each. The specimens were cleansed using conventional electrolytic methods, rinsed and washed with water, and finally dipped into 10% hydrochloric acid. The absence of a water break after this last dip was taken as the criterion for a clean metal surface.

Plating followed conventional procedures, with both the bath formulations and the plating conditions used being based on published data (12, 13). For each coating, three thicknesses were plated to include the ranges 2-5, 7-12, and 20-39 μm. Before exposing to the atmosphere, the surface of each specimen was finished by manually polishing with wet 600 grit silicon carbide paper. The hanger then was cut out of each specimen, and the area around the cut was painted over with stopoff lacquer.

Atmospheric exposure.—Individual specimens were placed in position on porcelain knob insulators screwed into place at predetermined positions on an aluminum

rack (11). The knobs held the specimens about 2 cm above the aluminum frame so that there was no metal-to-metal contact that could result in formation of an electrolytic cell. To minimize stress corrosion, the specimens were free to move slightly, but they could not be dislodged by a strong wind or a sharp blow. For outdoor exposure, the rack was inclined at about a 45° angle from the horizontal, and the specimens were placed so that the edge with the lacquer pointed down. The specimens undergoing exposure indoors were not inclined and lay flat in a horizontal plane. Both sets of specimens were observed at intervals to follow the effects of corrosion, and to measure any changes in contact resistance.

After 65 days of exposure indoors, there was neither a significant change in contact resistance nor observable rust products on any of the specimens. After the same length of exposure outdoors, only the three specimens coated with tin-zinc and the two specimens coated with the thicker tin-cadmium did not show any significant rust products. These outdoor specimens were tarnished so that the original metallic luster was replaced by a dull grayish color, while all the other specimens showed surface rust products. As might be expected, the amount of surface rust products was less marked for the specimens with thicker plated coatings.

The data obtained from the outdoors exposure test are given in Table III, where observations with the unaided eye of the extent of corrosion, and measurements of the contact resistance, are recorded as a function of time. Included also in this table are the times when corrosion was initially observed, and the times at which corrosion or corrosion products were judged to cover better than 50% of the surface of the metal coating. Rusting around the edges was discounted somewhat when recording data for this table, and a greater weight was assigned to the extent of rusting away from the edges. The enhanced corrosion caused by accumulation of moisture at points where contact was made between the edges of the specimen and the porcelain knobs was also discounted to some extent. Measurements of the contact resistance were discontinued on specimens which showed rust and rust stains over better than 50% of the surface. In these cases, values of the contact resistance depended on the portion of the surface which made contact with the probe tip, and the readings ranged between low milliohms and high ohms.

The specimens coated with tin-zinc alloy and those coated with the two thickest tin-cadmium alloy have been the outstanding performers in the outdoor exposure tests. While the surfaces of these specimens were dulled and covered by oxide films and particulate matter such as dust, there was no visible rust on the surface, including the edges and places where contact was made with the porcelain knobs. Three weeks after the original specimens were exposed, 2.5 μm thick coatings of both the tin-zinc and tin-cadmium alloys were exposed outdoors along with duplicates of the other three thicknesses of tin-zinc. In agreement with the earlier results, the 2.5 μm tin-cadmium coating showed appreciable rust within 7-10 days. On the other hand, the 2.5 μm coating of tin-zinc did not show any environmental effects for about 30 days, after which slight rusting around the edges and at a spot on the surface was observed. On the basis of these results, the tin-zinc alloy coating has provided somewhat better corrosion protection to steel when exposed outdoors than has the tin-cadmium coating. For both coatings, the contact resistance was less than 10 mohms on surfaces not covered by rust or rust products.

From measurements of the contact resistance of the specimens obtained from The Tin Research Institute, results of the water-sulfur environmental tests, and the exposure data obtained to date, we conclude that tin-zinc and tin-cadmium alloy coatings will best maintain a low contact resistance for long periods of time.

Acknowledgments

The Tin Research Institute furnished the steel specimens coated with tin alloys, and M&T Chemicals, Incorporated, furnished a tin-zinc coated specimen. Abner Brenner, Vernon Lamb, Eugene Damm, and Fielding Ogburn provided guidance during the course of the project, and Art Bunch furnished the contact impedance measurements.

The Structure of Ferric Compounds Introduced into Layers of Electrolytically Formed Aluminum Oxides

Z. Alexan, M. Bornaz, A. Calusaru, G. Filoti, A. Gelberg, and E. Romas

Institute of Atomic Physics, Bucharest, Rumania

ABSTRACT

By means of Mössbauer effect, x-ray, and infrared methods, we have studied samples of electrolytically formed aluminum oxide in which a ferric compound was introduced by immersion in ferric chloride solution. Two kinds of thin films were obtained: (*a*) with brown color and (*b*) with yellow color. At room temperature, both samples show a quadrupole splitting. At liquid nitrogen temperature, the Mössbauer spectrum has two lines in the first case and six in the second. After heating at 673°K, the spectra of both samples were taken at 77°K. They display a magnetic splitting, but the effective field value is different for each sample. The characteristic parameters of the spectra show that the ferric compounds are not in a simple oxyhydroxide form on the aluminum oxide surface, but that some combination with aluminum oxide had occurred.

The method of electrolytic oxidation is particularly important in the case of aluminum (1) due to the properties of Al_2O_3 layers formed on the metal surface, which have a high adhesion and an expansion coefficient close to that of metallic aluminum. The improvement of the properties of aluminum oxide would be of practical importance due to the large-scale use of electrolytic oxidation of aluminum in industry. By extension of chemical combinations, particularly the combination of aluminum oxide with nickel oxide, new properties can be obtained, *e.g.* higher compactness, increased endurance to external agents, or a new color. The purpose of the present work is to study the iron and aluminum oxide combination from the standpoints of both preparation method and chemical structure. Structure studies were made using Mössbauer spectroscopy of ^{57}Fe.

Experimental

In the case of aluminum and iron oxide layer preparation, we can distinguish two stages: (*a*) electrolytic oxidation leading to Al_2O_3 layers and (*b*) aluminum oxide combination with ferric compounds.

1. The aluminum oxidation was carried out using a classical method (2); the electrolyte was 30% H_2SO_4 solution at room temperature, 2 A/dm^2 current density, and an oxidation time of 30 min. The aluminum foil of 0.1 mm thickness had a purity of 99.99%.

2. The aluminum oxide combination with ferric compounds was carried out by immersion of the oxide layer in a ferric chloride solution. The anodic oxide was first washed in distilled water, in concentrated ammonia, and again in distilled water. A ferric chloride concentration of 100 g/liter was employed, at 98°C, with an immersion time of 1 min for each sample. The *p*H of this solution was not controlled, but neither $FeCl_3$ concentration nor solution *p*H caused differences in results.

Two kinds of layers can be obtained by this procedure: one yellow and the second brown, but it was not possible to establish the experimental conditions needed to obtain only one or the other.

3. Measuring techniques. The x-ray spectra were measured using conventional apparatus, the Mössbauer spectra were obtained by means of a sinusoidal velocity drive (3), and the infrared spectra with a Zeiss spectrometer. The ^{57}Co source was embedded in a copper lattice. The thermal treatment was carried out in a Pt Mössbauer oven. The temperature was maintained at 673° ± 2°K. The spectra at 80°K were recorded by means of a simple nitrogen cryostat.

Results

X-ray diffraction.—The aluminum oxide layers containing ferric compounds were scraped from the aluminum support and the powder was analyzed by x-ray diffraction using the Debye-Scherrer method. The 11 lines were compared with data from literature (4). Their structure was found to be close to that of β-FeOOH, γ-FeOOH, or α-Fe_2O_3 structure, because all these forms of iron compounds give similar patterns. Therefore, we can conclude that x-ray diffraction cannot give a reliable answer concerning the chemical structure of the layers.

Mössbauer spectra.—The Mössbauer spectra were taken of both yellow and brown samples at the treatment temperatures, *viz.* 80°, 298°, and 673°K. The temperature of 673°K was the upper limit for treatment due to the aluminum backing.

The brown sample spectra show a quadrupole splitting both at room and 80°K temperature before thermal treatment, and display a magnetic splitting at 80°K after thermal treatment (Fig. 1, a and e).

The yellow sample at 80°K shows a magnetic splitting both before and after thermal treatment, but at room temperature shows only a quadrupole splitting (Fig. 2, a and e). Each thermal treatment was carried out for 1 hr.

Infrared spectra.—In order to establish more precisely the composition of ferric compounds in the aluminum oxide layers, we recorded the infrared spectra for both yellow and brown samples. In Fig. 3, a comparison is made between infrared spectra of β-FeOOH

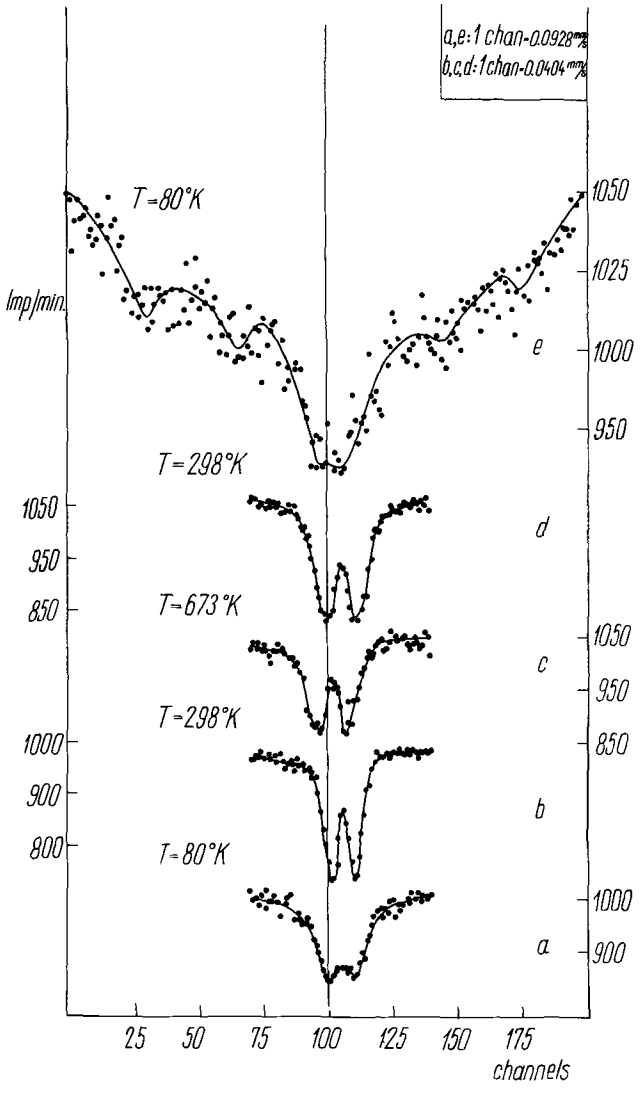

Fig. 1. Mössbauer spectra of brown sample (A)

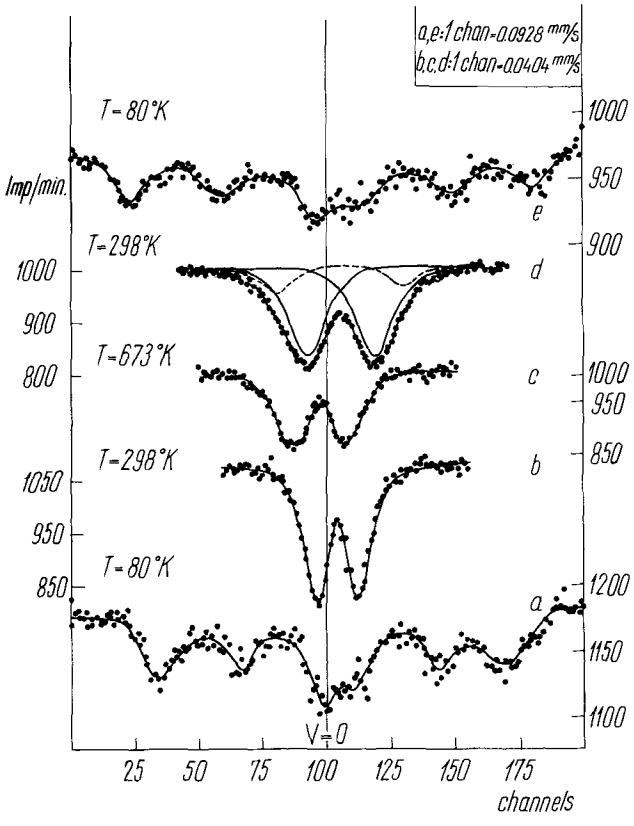

Fig. 2. Mössbauer spectra of yellow sample (B)

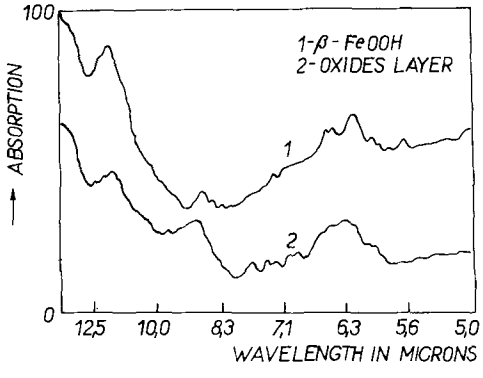

Fig. 3. Infrared spectra of both brown and γ-FeOOH samples

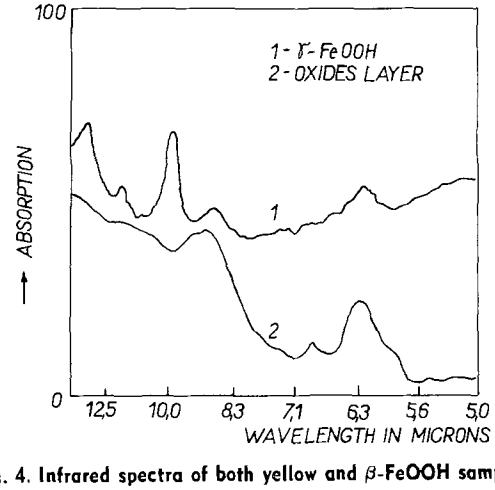

Fig. 4. Infrared spectra of both yellow and β-FeOOH samples

and of the yellow sample. There is some degree of correspondence between these substances and it seems reasonable to propose that the yellow sample is a β-FeOOH compound. These results agree well with the Mössbauer spectra. The peaks corresponding to the oxide layer are more flattened owing to the presence of aluminum oxide in the sample.

The same comparison between infrared spectra of γ-FeOOH and the brown sample is given in Fig. 4. It is possible to observe some peaks in both spectra at the same wavelength, for instance at 8.9 and 6.2μ, but there are other peaks existing in the spectra of the γ-FeOOH sample only. This fact may indicate some analogies in the structure of both compounds. However, it seems difficult to conclude that the samples are identical.

Discussion

The ferric compounds, formed by immersion of aluminum oxide layers into ferric chloride, could either be an iron compound by itself or a chemical combination between iron and aluminum oxides. These possibilities may be described by the following reactions:

$$2\,FeCl_3 + y\,Al_2O_3 + z\,H_2O = (Fe_2O_3)_x\,(H_2O)_z\,(\text{ads.})\,(Al_2O_3)_{y-x} + 2x\,AlCl_3 \quad [1]$$

$$2\,FeCl_3 + y\,Al_2O_3 + z\,H_2O = (Fe_2O_3)_x\,(Al_2O_3)_{y-x}\,(H_2O)_z + 2x\,AlCl_3 \quad [2]$$

The problem is to establish which type of compound is formed.

As it was shown, x-ray diffraction cannot distinguish between several iron oxides and oxyhydroxides, so that other methods had to be used in order to decide which of the two reactions takes place in our case. Mössbauer spectroscopy is able to establish the structure of compounds with general formula FeOOH or Fe_2O_3. In the

Table I

5	Treated	77		15.73	+0.15

case of FeOOH type combinations (5), the α-form presents magnetic splitting both at room temperature and at 110°K, the β-form shows a quadrupole splitting at room temperature and a magnetic one at 110°K, and the γ-form displays at both room temperature and at 110°K only a quadrupole splitting. Obviously, the corresponding Mössbauer spectra indicate characteristic values for both quadrupole splitting and isomer shift.

It seems at first sight from the Mössbauer spectra that the brown sample belongs to a compound of γ-FeOOH. The spectra at both room and 80°K temperatures present a quadrupole splitting, but their characteristic values were different from literature values. Indeed, the infrared spectra show that the brown sample is not identical to γ-FeOOH. In this case, it may be possible that a combination between γ-FeOOH and Al_2O_3, as indicated by the second proposed reaction, is formed. The formation of such a compound explains the difference of the quadrupole splitting and isomer shift between the present spectra (Table I) and the other known data (5). After thermal treatment, the resulting compound had completely new characteristics which were considerably different from those of the initial compound.

The yellow sample, without thermal treatment, presents a 80°K spectrum with a Zeeman splitting superimposed on a quadrupole spectrum. At room temperature, only a quadrupole splitting is left with a value different from that of the brown compound.

The values of the quadrupole splitting both at room and 80°K temperature differ from the values corresponding to β-FeOOH by about 15-20% (Table II).

The infrared spectra (Fig. 3) show a close analogy between β-FeOOH and the yellow sample. In this case, no combination with Al_2O_3 is formed, the ferric compound being adsorbed only on the aluminum oxide surface.

After thermal treatment, the spectra are strongly different from the corresponding one obtained with untreated samples (Fig. 2, d and e). The room-temperature spectra (Fig 2d) of the two wide lines can be decomposed in two doublets. The quadrupole splitting values are larger than those obtained before treatment. At 80°K, there also was an increase in the distance between the extreme lines *vs.* the same spectrum taken before the thermal treatment: Fig. 2a.

In addition, the yellow sample was subjected, for 16 hr, to thermal treatment to see if it was transformed into α-Fe_2O_3 configuration (7). This treatment brought about no modification of the structure, and this is additional proof that the spectrum corresponds to a more complicated compound.

Gold-Alloy Electrodeposits—Phase and Microstructural Changes Induced by Heat Treatment as Revealed by X-Rays

A. F. Mohrnheim

Metallurgical Research and X-Ray Laboratory, University of Rhode Island, Kingston, Rhode Island

ABSTRACT

Changes in composition and microstructure of gold-alloy electrodeposits caused by thermal treatment at relatively low temperatures, 100°-500°C, are revealed by semiquantitative x-ray diffraction analysis. The metallurgical characteristics of gold-nickel and gold-cobalt plates deviate from known equilibria shown by the temperature-composition or phase diagrams of the thermally alloyed systems. The plates as deposited are essentially single phase, metastable supersaturated, solid solutions. Thermal treatment of the Au-Ni plate causes precipitation of a Ni-rich phase; the precipitates of the Au-Co plate are practically pure, allotropic modifications of Co.

In general, electroplaters are concerned with: (*a*) the composition of the plating bath, (*b*) the conditions of the electrodeposition process, and (*c*) the resulting chemical and physical properties of the metal deposit. This report deals exclusively with the metallic structure of the deposit which naturally determines its physical properties. The bath and the process are not dealt with in detail because the plates were submitted as plated from proprietory baths containing metal chelates. We believe that such baths can be bought from a number of supply sources. Of course, no guarantee can be given that similar baths will reproduce exactly what has been found from the intensive study of electroplates from three commercially available bath formulations.

Previous Investigations

In a recent comprehensive treatise on electrodeposition of alloys by Brenner (1), it is stated: "The only reference to the structure of (gold-nickel) electrodeposited alloy is that of Raub (2). His x-ray diffraction examination showed that in alloys containing up to 6% nickel the lattice constant of gold was unchanged and that of nickel was expanded about 2%. Apparently the alloy was not a single phase like the equilibrium thermal diagram."

Our x-ray study leads to different conclusions. This difference, however, does not prove that these previous findings are erroneous since they were obtained from alloys plated from baths of different composition. Russian investigators (3) have reported that cobalt does not codeposit with gold. "However, Raub and Bihlmeier (4), mentioned obtaining deposits that contained from 0.4 to 0.8% of cobalt. Since there is some doubt that the deposit contained cobalt, their hardness must be attributed to their small grain size and perhaps to the presence of inclusions (1)."

Results of our x-ray studies, obtained from samples plated in baths containing complexing agents, differ from the above and were published in a preliminary detailed research report (5). Additional analytical data and supporting facts are presented in the following. The previous paper also reported observations and a semiquantitative analysis of preferred orientation in Au electrodeposits which, therefore, are not further discussed.

Theory

The angular position of x-ray diffraction peaks or lines (2θ-degrees), as expressed in Bragg's law, is a function of the interplanar spacing. Using this law and basic space relations, the lattice parameter, a (edge length of unit cell), can be computed. Since a varies in solid solutions (S.S.) with the concentration of the solute, changes in a can be related to changes in phase composition induced by heat treatment. Using Vegard's fundamental law (6), information can be gained about phase equilibria and phase changes by precipitation from supersaturated S.S. Vegard's law states that, in continuous S.S. of ionic salts, the lattice parameter of the solution is directly proportional to the atomic per cent (a/o) of solute present. Though this relationship is not strictly obeyed by metallic S.S., it is widely used for comparison. Complicating factors, limitations, and supporting evidence justifying the application of this method in this work are discussed later.

Changes in angular 2θ position and in the shape or profile of the x-ray diffraction peak caused by heat treatment can be interpreted as changes in the sample's microstructure. This is true because the height and breadth (width) of a recorded peak is influenced by residual microstresses, fine particle (grain) size smaller than 10^{-5} cm, and lattice imperfections. By systematically following changes in height and breadth of a diffraction peak due to heat treatment, the temperature range where recovery or grain growth occurs can be determined by plotting sample temperature *vs.* x-ray diffraction data.

Samples

Each of the Au electroplated specimens investigated measures 5 x 2.5 x 0.3 cm with a highly reflective surface on one side only. This side has been used for x-ray measurements. The samples as received have a Au deposit of about 10 μm (0.4 mils) electroplated on pure Cu mostly with a Ni interliner electroplated on top of the Cu surface before the Au deposition.

The electroplates have been deposited from three different commercial baths (7). Acidic bath A deposited bright, industrially pure Au with little Co. Acidic bath B deposited bright, industrially pure Au with little Ni. Both baths are operated at 32°C (90°F) with agitation, at 5 A/ft^2 current density, having 7.5 g/liter (1 oz/gal) Au with Co or Ni chelates and brighteners as additives. Bath C, a low cyanide bath (pH 8-10), deposits a bright Au deposit with about 1 w/o Ag and is operated under the same conditions as the other baths except at a slightly higher bath temperature, 38°C.

Since deposits from the Au-Ag bath, as previously reported (5), do not show changes in angular position of the diffraction peak nor in the peak profile due to heat treatment, they have been used as a control and for comparison. X-ray data for plates from this bath are shown in this article only in the "as-plated" condition.

In order to investigate the possible influence of the Cu substrate on the deposit, one Au-Co sample has been plated directly on the Cu without a Ni interliner. This sample indeed behaves differently due to early diffusion of the Cu atoms into the Au alloy plate at a relatively low-temperature heat treatment, as is shown later.

Experimental Procedures

The Au-plated samples have been treated and investigated as shown in the stepwise scheme below:

1. Scan samples as received.
2. Heat samples in air for a certain time in an oven at constant temperature.
3. Cool samples in air to room temperature (R.T.).
4. After cooling, scan samples and record x-ray diffraction peak on strip chart.
5. Compare peak profile and derive characteristic data before and after every heat treatment.
6. If there are changes in peak location and/or profile, reheat to the same temperature extending the time of thermal exposure.
7. If no further change is observed by the last treatment, increase the temperature, heat for a certain time, and repeat from No. 3 above.
8. Record and evaluate all changes, plot temperature *vs.* x-ray data, and find the temperature where the changes are most pronounced.

The time duration for the 1st heat treatment at a certain temperature had been 1 hr; most of the 2nd treatments at this temperature were 2 hr duration, that is, a total of 3 hr at the same temperature. If no distinct changes were observed after the last heat treatment, the experiments were continued at the next higher temperatures. The chosen temperatures (R.T., 100°, 175°, 200°, 240°, and 380°C) have been based on preliminary experiments and the ranges of available heating ovens. Slightly different temperature intervals, as will be indicated, have been chosen for duplicating experiments with other samples of Au-alloy plates.

Methods of Analysis

The *ideal* x-ray diffraction pattern of pure Au powder (8) has been considered the standard for comparing samples. A pure Au powder which has been prepared by the author and the Au-Ag deposit from bath C were found to produce almost identical diffraction patterns in contrast to the Au-Co and Au-Ni electroplates. All samples have been scanned under the same x-ray operating condition.

The diffraction patterns of the Au alloy electroplates as received, when compared with the standards, show striking differences of relative peak intensity [based on the strongest diffraction (111) of pure Au, $I/I_1 = 100\%$], peak profile (height and width), and peak location (diffraction angle, 2θ).

Significant differences in x-ray line characteristics between standards and Au-alloy deposits can be interpreted by differences in microstructure and in chemical composition, as is discussed later.

A definite proof of the presence of the alloying elements in the deposits has been obtained by the detection of the characteristic fluorescent radiation of Co and Ni recorded by conventional x-ray spectrographic techniques. For the detection of Ni in the deposit, the possible contributing Ni radiation from the Ni underplate and Ni impurities in the x-ray tube have been checked and are found to be insignificant in comparison with the intense Ni radiation from the electroplate.

The applied instrumental conditions for the x-ray diffraction analysis are shown in the Appendix. For control purposes, the whole x-ray diffraction pattern has been recorded on a strip chart. For expediency and reasons discussed later, the semiquantitative data for the (422) diffraction peak have been selected for tabulating and plotting the relatively large effects due to phase and microstructural changes caused by heat treatment.

Control measurements have been indicating satisfactory alignment and functioning of the x-ray equipment; they also confirm the assumed purity of the standards used. The approximate lattice parameter, a, as derived from the measured diffraction angle 2θ of the (422) peak has been compared with the *precise* parameter for pure Au powder, $a_0 = 4.0786$Å (Angstroms, 10^{-8} cm). The (422) diffraction angle of the pure Au electroplate and of the powder both show $a = 4.078$Å. The third decimal figure obtained by this method is usually considered unreliable but has been checked and verified by more precise methods as will be shown and discussed in detail.

The procedure for the semiquantitative x-ray analysis of the (422) peak of Au before and after each heat treatment was as follows:

1. Record the (422) peak on the strip chart.
2. Locate the approximate peak maximum on the chart.
3. Define 2θ by finding I max, maximum intensity (in c/sec = pulse counts per second), by counting for 1 min at three selected points near the peak. For broad peaks, determine the apex by fitting a parabola through the selected points (9).
4. Establish on the chart a base line with a ruler by joining the beginning and the end of the peak. Measure h max (in cm) and b (peak breadth) at ½ h max (in cm).
5. Count *I.I.* (integrated intensity), a measure of the area under the peak (in counts, c).
6. Tabulate the obtained data and plot temperatures *vs.* x-ray measurements.

The experimental method described above of measuring the changes in lattice parameter, a, is fairly easy. Simply by selection of a high angle line on the pattern, one usually obtains an accuracy of 0.01Å or about 0.4%. Most of the thermal effects observed in the following experiments are larger. In order to check on the method and the significance of the data obtained, several experiments have been duplicated using the time-consuming measurements of several high reflection angles and determining a for each line by assigning the proper wavelength and employing an electronic computer. By plotting the obtained values of a against $\cos^2\theta$ and extrapolating the curve to $\cos^2\theta = 0$, the "precise" a_0 is obtained. The accuracy is thus increased to 0.001Å, or about 0.04%. The extrapolation has been carried out by applying the method of least squares, that is, an objective, analytical method of finding the line which best fits the data. Most data shown in this report carry five decimal figures for computation only. The extrapolated a_0 (Tables IV, V, and VI) shows the fourth decimal figure in parenthesis for rounding a_0 to three significant figures, *i.e.*, 10^{-3}Å $= 10^{-11}$ cm.

As will be shown, the refined method of determining a_0 does not invalidate the first simple experimental method but confirms the first approximations by the addition of more significant figures.

Effects of Experiments

For convenient comparison, the scanned diffraction peaks have been traced from the back of the chart paper and superimposed, in order to show the difference between the original profile of the diffraction peak and its shape after heat treatment at different temperatures (Fig. 1-3). The peaks have been traced after those heat treatments that show significant changes in peak location and profile. Heating at 100°C for 2 more hr does not produce further changes. After heating for 1 hr at 175°C, further changes are observed and measured [Fig. 1(a) and 2(a)]. The effects of heat treatment at higher temperatures are shown in Fig. 1(b), 2(b), and 3.

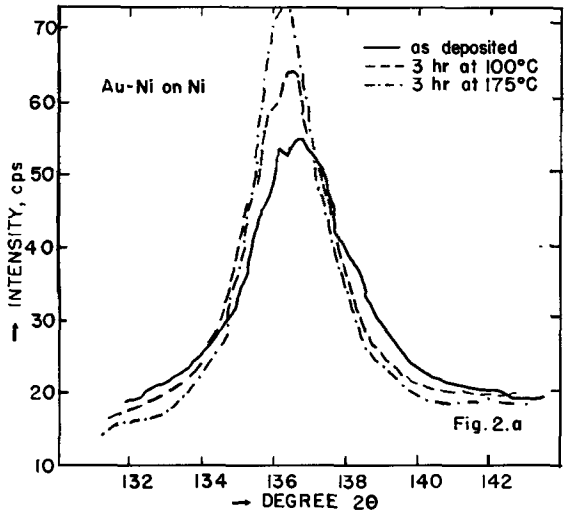

Fig. 2a

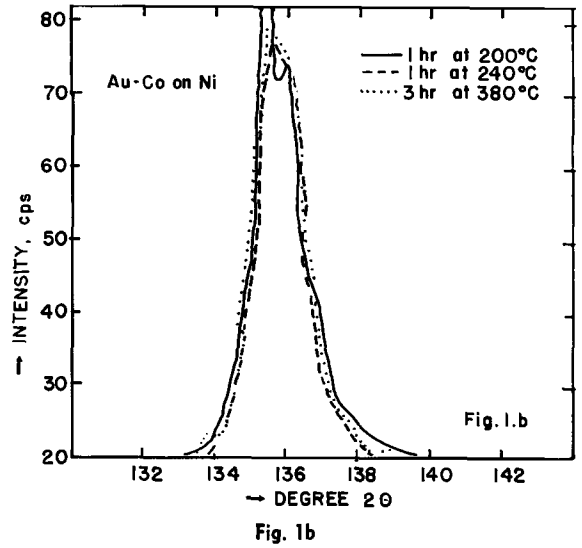

Fig. 1b

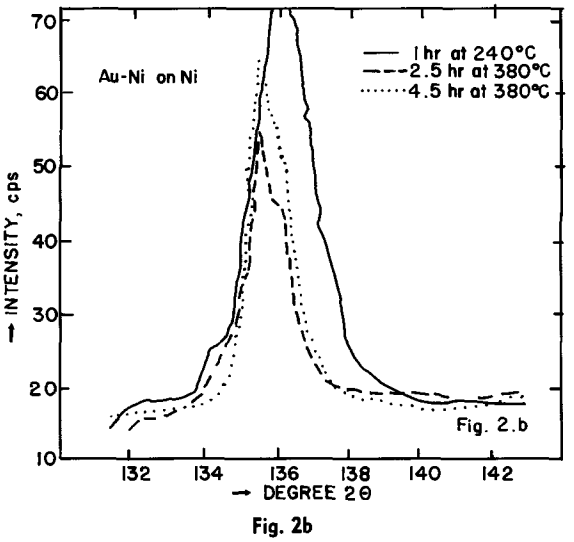

Fig. 2b

Fig. 1 (a and b). Heat treatment of Au-alloy electroplates. Superimposed (422) XRD peaks recorded after shown durations at temperatures.

Fig. 2 (a and b). Heat treatment of Au-alloy electroplates. Superimposed (422) XRD peaks recorded after shown durations at temperatures.

Comparison of the peak profiles from heat-treated Au-Co on Cu, having no Ni interliner (Fig. 3) with Au-Co on Ni [Fig. 1(b)] reveals obvious differences due to Cu diffusion and Au-Co-Cu alloying which is discussed later.

The XRD (x-ray diffraction) measurements (Tables I and II) show an angular shift of the (422) peak induced by heat treatment for four different Au-alloy samples. The corresponding, increasing parameter, a, expresses lattice growth. When heat-treating temperature is plotted *vs.* a, then rate changes in growth are indicated by the slope changes of the four curves (Fig. 4). Au-Co on Cu, having no Ni interliner (Sample No. 1) shows a considerable increase in a by heat treatment at 175° and 200°C, similar to the other samples. After heat treatment at 380°C, its cell edge, a, decreases drastically. Diffusion of the Cu atoms from the substrate at 240°C interferes with the growth of a. At this temperature, the Au color of the sample surface is changed to deep blue. At 380°C, the deep blue changes first to brick red (cuprous oxide, Cu_2O) and then to black (cupric oxide, CuO).

Sample No. 2, Au-Co on Ni, shows a distinct and steep increase of a at 200°C when it becomes practically equal to the a of pure Au. Like sample No. 1, this sample turns pale blue at 240°C and deep blue at 380°C; it does not turn red at 380°C. The slight surface oxidation can be wiped off.

				350°C	135.6	α_1	4.076
				400°C	135.4	α_1	4.078

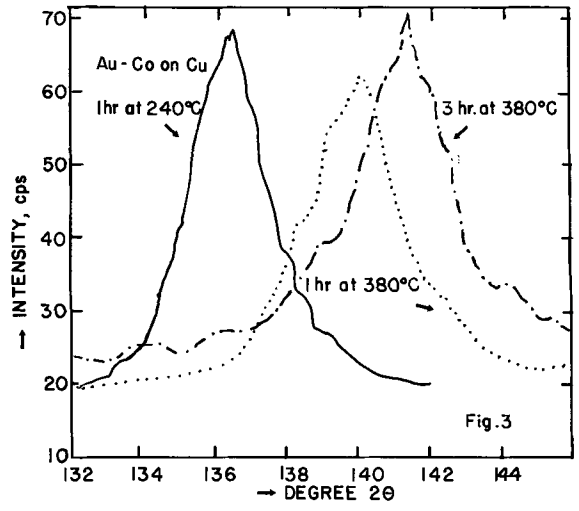

Fig. 3. Heat treatment of Au-alloy electroplates. Superimposed (422) XRD peaks recorded after shown durations at temperatures.

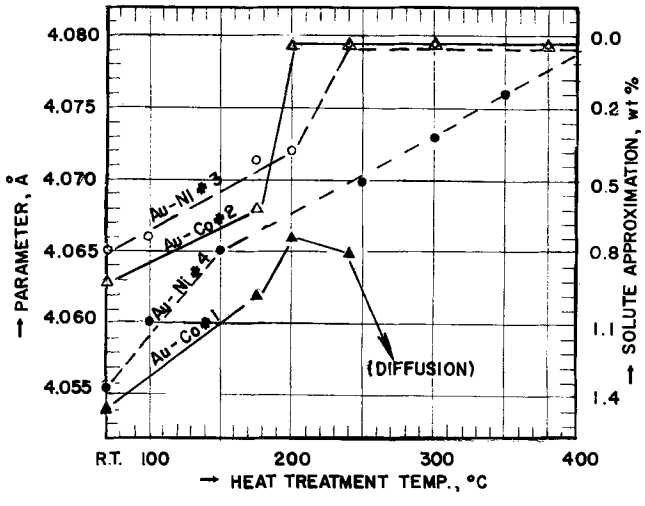

Fig. 4. Growth of lattice parameter with heat treatment of four Au alloy electroplates. For orientation, the concurrent change in concentration of the alloying element in S.S. is shown at the right ordinate. Sample No. 1, having no Ni interliner, breaks down at 240°C.

All samples differ in a in the condition "as plated." Samples No. 3 and 4 (both Au-Ni on Ni) also show a distinct difference in the growth rate of a. Similar to sample No. 2, sample No. 3 shows a steep growth of a up to the value of pure Au, except at a higher temperature (240°C). In contrast, the a of sample No. 4 with a relatively small initial value (more Ni atoms in the Au lattice) increases a rather rapidly at the temperatures 100° and 170°C, and then grows uniformly at 250°, 300°, and 350°C. Finally, a reaches the value of pure Au at 400°C. Further heat treatment for 1 hr at 450°C does not produce further change in a. The color of the Au-Ni samples turns gray (250°C), then increasingly dark (300°, 350°, 400°C) to almost black (450°C) because of increasing surface oxidation and diffusion.

The measured changes in peak profile as induced by heat treatment of samples No. 3 and 4 are expressed as *I.I.*, I max, h max, and b at 1/2 h max (Table III). Their plots against heat-treating temperatures (Fig. 5) show the rate of changes; most curves show distinct differences between the peak characteristics "as plated" and after heat treatment at 100°C. Up to and including heat treatment at 175°C, the rate of change of the slope of the curves is rather gradual. However, at 200°C, the Au-Co sample changes its peak profile drastically. No further large changes in peak profile can be observed after further heat treatment.

Table III. Changes in profile characteristic of the XRD peak (422) of Au-alloy electroplates induced by heat treatment

Treatment	*I.I.*, c	I max, c/s	h max, cm	b at ½ h max, cm
	Au-Co Sample No. 2			
As plated	4000	32	7.8	3.8
100°C	4000	34	8.6	3.6
175°C	4300	37	10.5	2.0
200°C	4600	79	15.3	1.9
240°C	4700	82	15.3	2.0
380°C	4600	75	15.3	2.1
	Au-Ni Sample No. 3			
As plated	4500	42	8.7	3.8
100°C	4600	49	11.8	2.8
175°C	4650	61	14.2	2.8
200°C	4700	62	14.7	2.5
240°C	4500	62	14.1	2.4
380°C	2700	60	12.5	1.6

Slope changes of the Au-Ni sample are not quite as steep as with the Au-Co sample. The peak breadth, b at ½ h max, drops distinctly at 100°C and decreases then rather uniformly. Maximum peak height is observed at 200°C. At 380°C, the peak characteristic of this sample becomes quite similar to that of pure Au standards (not shown).

Duplicate and control data for different Au-alloy electroplates and heat treatments (Tables IV and V) have been plotted, graphically extrapolated (Fig. 6 and 7), and analyzed by the method of least squares. As an example and for orientation, the four XRD peaks of the Au-Co "as plated" (Table IV) render a_0 = 4.051Å, shown by the intercept of the lowest dashed curve (Fig. 6), the slope = 0.0034 and the drift constant = 0.00014; the latter is a measure of the total systematic error involved in this determination.

Au-Co on Ni shows that a_0 has become largest and close to "pure" Au at 450°C. The considerable decrease of a_0 at 500°C suggests alloying of the Au-Co plate with atoms from the substrate by the process of diffusion. The same effect but at a lower temperature (400°C) is observed with the samples Au-Co without Ni interliner. Similarly, the control measurements for a_0 of Au-Ni alloy and pure Au electroplate support the

previous findings observed by measuring semiquantitatively the shifts of the (422) diffraction peak only.

The growth of a_0 from the "as-plated" condition to the a_0 of practically pure Au by heat treatment can be explained, according to Vegard's law, by a concurrent decrease of solute content. Figure 4 shows corresponding, derived, approximate percentages of solute in S.S.

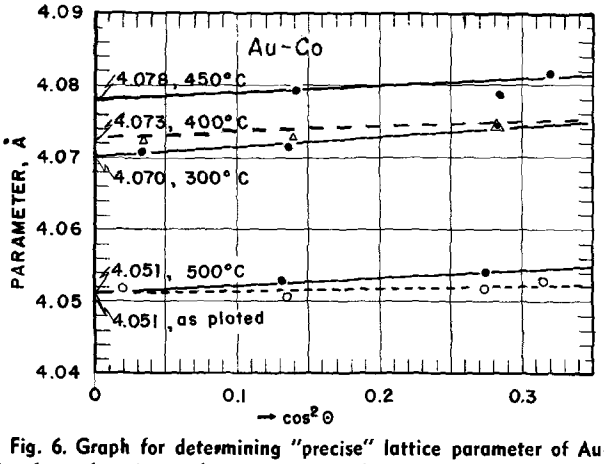

Fig. 6. Graph for determining "precise" lattice parameter of Au-Co electrodeposit as plated and after different heat treatment.

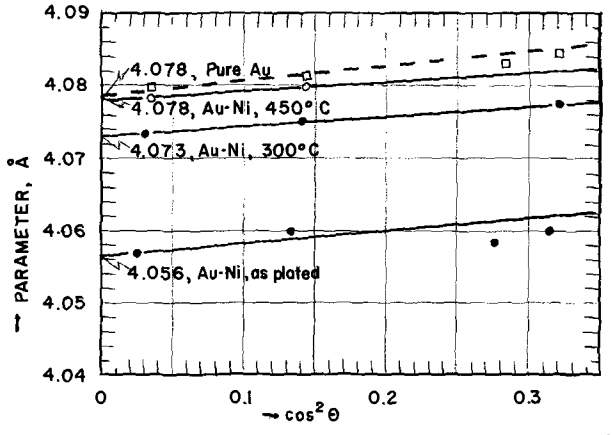

Fig. 7. As Fig. 5 for Au-Ni electroplate. The square symbols show measured data for a pure Au deposit, for orientation.

Vegard's Law and Atomic Absorption Analysis

The concentration of the solute, that is, Co and Ni in S.S. of the Au-alloy electroplates, as derived from the unit cell parameter, a_0 (Tables IV and V), as mentioned before, is based on the assumption that Vegard's law holds. Deviation from Vegard's law when it occurs is usually greatest about the middle of the composition-lattice parameter diagram. Since this study is concerned only with small amounts of alloying elements, a linear relationship between a/o and a can be assumed for approximating the solute content in the Au-alloy plate.

In order to check the x-ray computation of a and the applicability of Vegard's law for approximating the alloying element content in the plate, the electrodeposits were stripped and Co and Ni determined by AA (atomic absorption) analysis. While the results differ between plates, reasonable agreement is found for the same sample between AA analysis and the results from a measurements and computations. The x-ray computation and Vegard's law, of course, are based on the assumption that the alloying element in the "as-plated" Au alloy is present in a single-phase, supersaturated, substitutional S.S. which is discussed later.

Results and Discussion

The analysis of the semiquantitative XRD data (Table III) shows increasing h max and decreasing b at ½ h max; that is, "recovery of profile broadening" by heat treatment of the samples (Fig. 5). The peak profile approaches the appearance of the relatively high and narrow peak of pure Au standards. Small profile changes have been observed after heat treatment for 1 hr at 100°C. The progressive peak recovery by sharpening and narrowing of the profile is practically completed after heat treatment for 1 hr at 200°C for Au-Co and at 240°C for Au-Ni. Extra peak width, according to x-ray theory, could be caused by very fine particle or grain size smaller than 10^{-5} cm, lattice defects (dislocations), and/or microstrains. The *I.I.* (area under the peak) does not change much during heat treatment except for Au-Ni after the last treatment (Table III).

The steep slope changes of the curves with the concurrent minimum of b at ½ h max for Au-Co and the maxima for I max and h max (Fig. 5) suggest that the heat treatment causes gradual recovery from lattice faults, relief from microstrains (stresses), and/or grain growth. Though the latter is possible, it seems less likely since the beginning of the profile change for these "alloys" was observed at the relatively low temperature of 100°C, and no steep profile changes occur at 200° or 240°C. Also, x-ray back-reflection photographs of the samples after heat treatment at 400°C do not show Laue spots (10) which would indicate coarse grain growth.

Since heat treatment increases a to the value of pure Au, the alloying elements are assumed to have been codeposited in S.S. with the Au and to be precipitated by heat treatment as a separate phase. Under favorable conditions, one might expect to find diffraction peaks from the precipitated phase. By careful search for new diffraction lines as evidence for the precipitation, weak additional peaks were detected after heat treatment at 400°C. The analysis of the XRD measurements by the method of least squares (Table VI) and Vegard's law suggest a FCC, Ni-rich S.S. containing 97 a/o Ni. This value is in good agreement with the composition of the thermal alloy at equilibrium, 96 a/o Ni at 450°C, as determined by Wise (11).

Similarly, the Au-Co plate after heat treatment at 450°C shows six additional diffraction peaks. Their x-ray data (Table VII) suggest that the two allotropic forms of Co are present; that is, beta Co (FCC) which is said to be stable above 450°C (10), and the alpha or epsilon Co (HCP) which is said to be stable at lower temperatures (12). The derived $a = 3.549$Å for the Co beta precipitate is practically equal to pure Co, $a_0 = 3.552$Å, that is, containing little or no Au in S.S. This finding is also in good agreement with the known constitutional diagram for the binary system Au-Co at equilibrium (13). Attempts to discern precipitates under the microscope were unsuccessful.

Shifts in angular position of the peaks, in general, can be caused by applied uniaxial macrostrains, lattice imperfections, and/or change in lattice parameter. The following circumstantial evidence points to the latter:

(a) AA analysis of the stripped Au alloy plates for Co and Ni content check satisfactorily with the results from the x-ray determinations, that is, the computed alloying content derived from a_0 of the sample as plated and Vegard's law, suggesting that the Au alloy as plated consists of a single-phase S.S.

(b) The recorded diffraction pattern of the samples as plated shows only peaks for the Au-rich S.S.; no other peaks for the alloying elements can be detected. After prolonged heat treatment, however, several weak additional peaks can be positively identified as deriving from precipitated phases. This suggests that the plates as deposited are single-phase, supersaturated S.S. and that equilibrium is produced by precipitation caused by the heat treatment.

(c) During heat treatment, a of the samples increases to the value of pure Au and, excluding diffusion, remains constant upon further heat treatment (Fig. 4). This suggests that the originally supersaturated S.S. as plated approaches equilibrium as a result of heat treatment and that the phase mixture in the electroplate thus becomes stable (13).

Conclusions

1. The Au-alloy plates contain Co and Ni, respectively, as proven by x-ray spectrographic analysis.

Table VI. Precipitate in Au-Ni electroplate after heat treatment at 400°C—XRD measurements and derived lattice parameter, a_0

2θ (deg)		hkl	$\cos^2\theta$	a,Å	a_0,Å

Table VII. Precipitate in Au-Co electroplate after heat treatment at 400°C—XRD measurements and lattice parameter approximation

Measurements 2θ, deg	I/I_1	hkl	Co-phase	a, Å
42.2	w	100	α (HCP)	—
47.7	m	002	α	—
51.5	vw	200	β (FCC)	3.55
84.5	m	100	α	—
92.2	w	311	β	3.548
97.6	m	222	β	3.549

2. The alloying elements in the plates as deposited are in a single-phase, Au-rich metastable S.S. which is affected by heat treatment for 1 hr at 100°C.

3. The alloying element content varies between plates as approximated by Vegard's law and checked by AA analysis.

4. For Au-Co, the phase equilibrium is approached by heat treatment at 200°C. Nearly pure α- and β-Co is precipitated from the primary supersaturated S.S., thus forming a phase mixture where almost pure Au is the matrix.

5. For Au-Ni, the phase equilibrium is approached by heat treatment for 1 hr at 240°C. A secondary phase is precipitated from the primary supersaturated S.S., thus forming a two-phase alloy. The precipitate is a Ni-rich S.S., about 96 a/o Ni, in an almost pure Au matrix.

6. Recovery of the x-ray diffraction peak profile begins at 100°C and continues as temperature increases. This peak recovery is most pronounced for Au-Co and is practically completed after heat treatment for 1 hr at 200°C. The changes can be considered as caused by recovery from microstructural lattice defects in the plate, relief from residual microstrains (stresses), and/or possible grain growth.

7. Discoloring of the Au alloy plates after heat treatment for 1 hr at 240°C indicates surface oxidation.

8. Alloying by the process of solid-state diffusion of Cu from the substrate when there is no Ni interliner is shown by the x-ray data after heat treatment for 1 hr at 200°C; that is, before surface oxidation can be observed.

9. The noble character of the Au deposit surfaces is obviously lost after heat treatment in air for 1 hr at 380°C.

Acknowledgments

Thanks are due to Dr. Edward A. Parker, Vice President of Technic, Incorporated, Cranston, Rhode Island, for stimulating discussions and for supplying the samples, and to Mr. Tarek El Heneidy, research assistant, for making the measurements.

Manuscript submitted Sept. 12, 1969; revised manuscript received *ca.* Dec. 19, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1970 JOURNAL.

APPENDIX

The equipment and the instrumental conditions used for the x-ray diffraction analysis were: General Electric XRD-5; tube target Cu; take-off angle 4°; 23.5 kVp; 15 mA; beam slit 3°; Soller slit MR; detector slit 0.1°; Ni filter, 2 X 0.00035 in.; counter tube SPG-6 (Xenon); chart range 100 Hz; time constant 2.0 sec, linear response; scan 2°/min; chart speed 30 in./hr.

An Optical Study of Cathodic Hydrogen Evolution in High-Rate Electrolysis

Dieter Landolt,*,[1] Raul Acosta,* Rolf H. Muller,* and Charles W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory and Department of Chemical Engineering, University of California, Berkeley, California

ABSTRACT

Hydrogen bubbles evolved cathodically under conditions encountered in electrochemical machining have been studied by stop-motion photography. Constant current densities up to 150 A/cm^2 and flow rates up to 2500 cm/sec have been employed with an experimental flow channel of 0.5 mm gap width. The observed bubble size decreased strongly with increasing flow rate and increased with increasing current density. At flow rates above 800 cm/sec, the bubble size was always below 20μ, the smallest diameter resolved by the optical arrangement used. Less gas was evolved in nitrate than in chloride electrolytes under otherwise identical conditions. The hydrogen bubbles were usually confirmed to a region near the cathode. Voltage oscillations and electric breakdown coincided with the appearance of a new type of bubble.

In electrochemical machining, metals are dissolved anodically at current densities in the order of 100 A/cm^2 or higher. Hydrogen gas is formed cathodically and must be transported away from the reaction zone by the electrolyte stream. This hydrogen may affect the electrolytic process in several ways: It may increase the ohmic resistance of the electrolyte, resulting in higher cell voltage and different local current distribution. It may be oxidized at the anode and, thus, decrease the current efficiency of the metal dissolution process. It may form a continuous gas blanket at the cathode and, thus, lead to sparking. It may accumulate in large bubbles, which extend over the entire interelectrode gap, and, thus, drastically affect mass-transfer conditions at the anode. In order to obtain a better understanding of the relative importance of such phenomena, a photographic study of cathodically generated gas bubbles was initiated. During the course of this pursuit, somewhat related work has appeared in the literature (1, 2). In the present investigation, a more sophisticated optical arrangement has been employed and a better control and wider range of critical variables, such as current density and flow velocity, have been employed in addition to the use of a well-defined flow system.

Experimental Technique

The apparatus used has been described before (3). It consisted of a rectangular flow channel cell of 8 mm width and 0.5 mm height. Its sidewalls were made of flat glass plates, which provided for the optical observation of the interelectrode gap. The total channel length was 8.5 cm; the center of the electrodes was positioned 1 cm from the downstream end. The design of the flow cell provided for fully developed velocity profiles at the electrodes. Flow rates up to 2500 cm/sec were employed, corresponding to inlet pressures in the order of 10 atm. Since most of the pressure drop occurs in the entrance length of the flow channel, the absolute pressure at the electrodes, even at the highest flow rate employed, was only about 2 atm. Although under these conditions the effect of pressure on the gas volume has to be taken into account, at flow rates up to 1000 cm/sec, where most observations were made, the absolute pressure at the electrodes was only 1 to 1.3 atm, and its effect on bubble size was negligible within the accuracy of the present measurements. The copper electrodes were 3.17 mm long in the flow direction and 0.53 mm wide. Before experiments, the electrode surfaces were mechanically polished with 1μ diamond paste, cleaned with aqueous detergent and acetone, and degreased by hydrogen evolution in aqueous caustic.

The optical arrangement is shown schematically in Fig. 1.[2] A commercial flash light source (A) of 0.5μ sec flash duration[3] was used for illumination of the gas bubbles generated in the flow cell (B) in transmitted light mode. A camera (H) with open shutter and high speed film[4] was attached to a microscope tube containing a 2x objective (C) (f = 48 mm, N.A. = 0.08) and a 10x eyepiece (E). A small circular aperture (D) of 1.6 mm diameter, located in the rear focal plane of the objective (C) served as a telecentric stop (4). The purpose of this device is to avoid variations in the apparent size of bubbles due to differing distances from the objective and to increase the depth of field. Unfortunately, the telecentric stop also reduces the speed and resolution of the objective, the latter being about 20μ. In order to obtain a photographic distinction between the electrode surface and an adjacent, dense

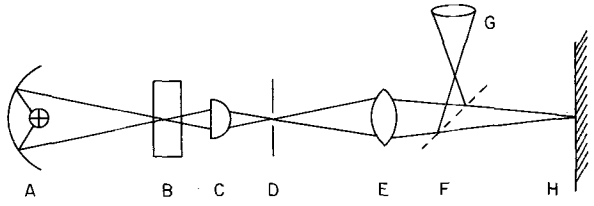

Fig. 1. Optical arrangement for high-speed photography of gas bubbles: A—light source (flash), B—flow channel cell, C—microscope objective, D—telecentric stop, E—microscope eyepiece, F—beam splitting prism, G—magnifier for visual observation, H—camera film plane.

layer of gas bubbles, a pre-exposure in the absence of bubbles was made at reduced light intensity. In a typical experimental run, constant current was applied to the cell for a short period of time by switching the output of a constant current supply[5] from a dummy circuit to the cell circuit. A mercury relay, actuated by a pulse generator, was used for the switching. The circuit also served to trigger the flash light source after a preset time, which was chosen to correspond to the passage of 12 coulombs/cm^2. The current was switched back to the dummy load automatically after the total passage of 15 coulombs/cm^2. The charge passed between the start of an experiment and the moment the picture was taken resulted in the evolution of about 1.5 cm^3 hydrogen (1 atm, 298°K) per cm^2 electrode. This was considered sufficient to establish steady-state conditions with respect to gas evolution. During the experiments, current and potentials were recorded by means of a light beam oscillograph.

Experimental Results

Bubble size.—Typical photographs obtained in 2*N* KCl solution at different flow rates and current densities are given in Fig. 2 to 4. Figure 2 illustrates the influence of flow rate and cathode orientation on bubble size for a current density of 50 A/cm^2. An estimate of the size distribution of the bubbles for the same experiments is given in Fig. 5. These distributions were obtained by measuring the diameter of all the bubbles which were individually discernible in the whole interelectrode gap, and determining the fraction in each size bracket of 25μ width. The quantitative validity of the distributions given in Fig. 5 is limited for several reasons: (*a*) The number of measured gas bubbles (27-60) represent only part of the total gas volume, and the differentiation between discernible and not discernible bubbles is subject to personal interpretation. (*b*) The variability of results in successive experiments probably requires a more sophisticated statistical evaluation. (c) Bubbles close to the cathode surface were usually not individually discernible and could, therefore, not be included in the count. (*d*) Bubbles smaller than 20μ in diameter were below the optical resolution. Qualitatively, however, Fig. 5 illustrates not only the order of magnitude of cathodically generated bubbles, but it also shows the decrease in size with increasing flow rates: the median bubble diameters are 99, 69, and 35μ for flow rates of 100, 200, and 400 cm/sec, respectively. It should also be noted that, at the lower flow rates (below 400 cm/sec), a few large bubbles often existed in addition to a large number of smaller ones. It was observed during the experiments that these large bubbles were sticking to the cathode surface for prolonged periods of time while the smaller bubbles detached from areas in between. Figure 5 also shows that the orientation of the cathode, *i.e.* whether it is facing up or down, has no systematic effect on size distribution, except at the lowest flow rate.

Figure 3 illustrates gas evolution at high flow rates. The size of the generated bubbles decreases rapidly with increasing velocity in this range and the size distribution becomes narrower, so that the previously

Total number of bubbles measured 31, 43, and 50, respectively, for cathode facing up (- - -) and 27, 32, and 60, respectively, for cathode facing down (———). (Counts incomplete in range 0-25μ, due to lack of resolution below 20μ.)

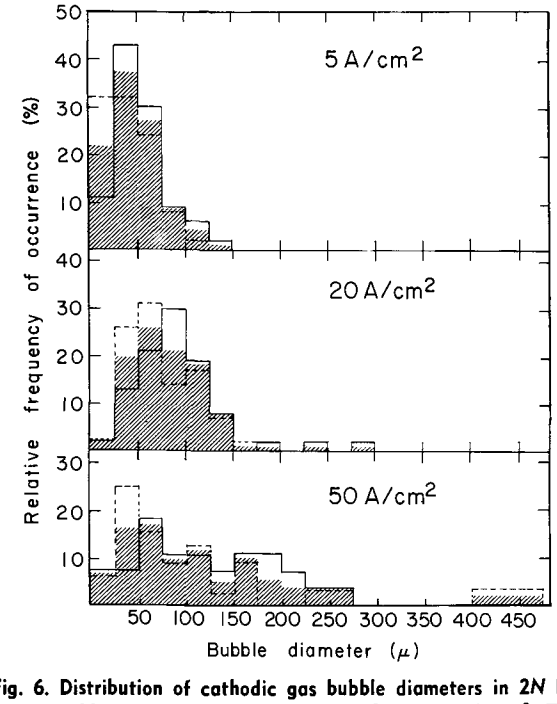

Fig. 6. Distribution of cathodic gas bubble diameters in 2N KCl. Flow rate 100 cm/sec, current density 5, 20, and 50 A/cm². Total number of bubbles measured 47, 47, and 31, respectively, for cathode facing up (- - -) and 37, 42, and 27, respectively, for cathode facing down (———). (Counts incomplete in range 0-25μ, due to lack of resolution below 20μ.)

observed coexistence of few large bubbles with smaller ones disappears. At flow rates of 800 cm/sec or higher, all individual bubbles were too small (below 20μ) to be resolved photographically.

The effect of current density on bubble size is illustrated in Fig. 4 and 6. A clear increase in bubble size is observed with increasing current density under otherwise identical conditions: the median bubble diameters are 56, 78, and 99μ for current densities of 5, 20, and 50 A/cm², respectively. These observations are in marked contrast to findings reported by Venczel (5), who studied gas evolution at vertical electrodes in stagnant solutions and reported a decrease in bubble size with increasing current density. The discrepancy might possibly be explained by the different modes of convection. A bubble may be assumed to detach from the surface when external forces, such as gravity or friction with the moving liquid, become larger than the normal component of the surface tension. Since in a stagnant solution the rate of stirring is increased when more gas is generated, higher current densities may lead to an earlier detachment of gas bubbles. In our experiments, on the other hand, local stirring was mainly due to the hydrodynamic flow and was, therefore, almost independent of current density. A decrease, rather than an increase, in bubble size with increasing current density would also be expected from the work of Kabanov and Frumkin (6). They showed that the contact angle, which determines the normal component of surface tension, depends on electrode potential. For very slow hydrogen evolution on mercury, smaller contact angles and, hence, smaller bubbles were observed at increasingly negative potentials.

Force balances have been applied to the prediction of bubble size in forced convection boiling (7). Such a force balance for an individual bubble may be formulated as

$$F_\sigma = F_i + F_b \qquad [1]$$

where F_σ is the surface tension force which holds the bubble on the electrode, F_i is the inertia force of the electrolyte acting on the bubble, and F_b is the buoyancy force of the bubble. The latter can be neglected at high flow velocities. According to Tong (7), a model of this kind predicts a decrease in bubble size with the square of the flow velocity. Such a dependence is at least qualitatively consistent with the present results. Relation [1] does, however, not account for the influence of current density and the wide distribution of bubble diameters observed at low flow rates. This distribution is at least partly due to the fact that the presence of other bubbles on the surface leads to locally varying flow conditions. Considering the fact that not even the dynamics of a single bubble growing in a laminar velocity field has been analyzed, no attempt has been made here to give a more detailed account of the vastly more complex case of multiple bubble dynamics in turbulent flow. Additional experimental studies should include the time dependence of bubble growth for a more detailed description of gas evolution under the present conditions in turbulent flow. Glas and Westwater (8) have investigated electrochemical gas evolution in stagnant solutions by high-speed cinematography. They found two growth stages: an early rapid growth period, associated with bubble diameters of up to about 50μ, followed by a slow period. Theoretical aspects of growth mechanisms have been discussed by Cheh (9), who applied mass transfer considerations to predict growth rates in the slow (asymptotic) growth period. No theoretical models exist at present which predict growth rate in the rapid growth period. Since, in our study, the bubble size was often smaller than 50μ, growth rate and residence time on the cathode surface could not be estimated on theoretical grounds.

Thickness of two-phase region.—Figures 2-4 illustrate the observation that the gas bubbles are not dispersed uniformly throughout the gap, but usually occupy a region near the cathode. At flow rates above 100 cm/sec, the thickness of this two-phase region is the same whether the cathode faces up or down. This behavior is to be expected, since at higher flow rates a gas bubble, unless it is very large, is swept away from the interelectrode gap too fast to be affected by

buoyancy. From Stoke's law, which may be applied to bubbles of less than 1 mm diameter (10), the steady-state velocity due to buoyancy can be described by Eq. [2]

$$v = \frac{g \rho d^2}{18\eta} \qquad [2]$$

where g = gravitational constant, ρ = difference in density of gas and liquid, d = bubble diameter, η = viscosity of liquid. Assuming an electrolyte flow velocity of 400 cm/sec and a bubble diameter of 50μ, the vertical distance traveled by the bubble due to gravity during the time needed to pass over a 3 mm long electrode is only 1.2μ.

In order to account for the observed thickness of the two-phase region, unusually high velocities perpendicular to the flow direction are required. In Fig. 3c for example (100 A/cm^2, 1000 cm/sec), bubbles are found up to a distance of approximately 0.3 mm from the cathode surface. A bubble moving steadily outward from the leading edge of the electrode would need an average velocity perpendicular to the cathode of 100 cm/sec to reach this position at the downstream end of the electrode. This motion away from the cathode surface is aided by the turbulence in the liquid. Such an effect is suggested by the irregular shape of the two-phase region, which can show large variations in local thickness (Fig. 3). It is interesting to note, however, that the average thickness seems to increase little downstream from the middle of the cathode. If turbulent mixing were the only mechanism determining the spreading of the two-phase region, we would rather expect a steady increase of its average thickness in the flow direction. It is, therefore, possible that other mechanisms contribute to the dispersion of gas bubbles. An example is the "rapid fire mechanism" mentioned by Glas and Westwater (8), who observed that in stagnant solution bubbles were frequently ejected from the electrode at a high velocity. This phenomenon is, at present, not well understood. The relatively smaller increase of the two-phase region in the downstream part might also be ascribed to a lower current density in this region, caused by the higher gas fraction and the associated higher ohmic resistance in the electrolyte. Dissolution of gas in the electrolyte furnishes another possible explanation for the same phenomenon. Indeed, a simple estimation shows that, under most conditions, all the gas generated could be dissolved in the total electrolyte volume passing through the gap. For example, assuming a current density of 100 A/cm^2, 8 x 10^{-6} moles of hydrogen are produced per second in our cell, while, at a flow rate of 1000 cm/sec, 40 cm^3 of electrolyte are flowing through it. A homogeneous dissolution of all the generated hydrogen would result in a concentration of 2 x 10^{-4} moles/liter, which is of the same order as the saturation concentration of hydrogen in potassium chloride solutions (11). However, the direct dissolution of all cathodically generated gas without the formation of bubbles is, in general, not likely because the concentration gradients available under typical flow conditions are too small to account for the transport of dissolved hydrogen by convective diffusion. This is the case even under the assumption of a 1000-fold supersaturation at the electrode surface.

A rapid dissolution of initially formed gas bubbles could provide an alternate route to a homogeneous solution. This process would also affect the measured gas bubble diameters. Such a redissolution of gas bubbles would be similar to the behavior of vapor bubbles generated in a supercooled liquid under forced convection. Gunther (12) has shown that such bubbles became smaller and eventually disappeared upon moving downstream. The time required to dissolve 50% of the volume of a bubble of 50μ diameter can be estimated as follows: If we assume saturation concentration of the gas at the gas-liquid interface under constant pressure, and zero gas concentration in the bulk solution, the concentration difference driving force will be given by the saturation concentration, say 5 x 10^{-4} moles/liter. For a constant mass flux per unit area of a spherical bubble, the decrease in volume may then be expressed by Eq. [3]

$$\frac{dV}{dt} = -A\, k\, C_{sat}\, V^{2/3} \qquad [3]$$

with $A = (RT/P)\ 4\pi\ (3/4\pi)^{2/3}$, C_{sat} = saturation concentration, k = mass transfer coefficient (cm/sec), V = bubble volume. Integration leads to Eq. [4]

$$3(V^{1/3} - V_o^{1/3}) = A\, k\, C_{sat}\, t \qquad [4]$$

where V_o = initial bubble volume. The time $t_{1/2}$ in which the volume is reduced to ½ V_o is

$$t_{1/2} = \frac{2.38\, V_o^{1/3}}{A\, k\, C_{sat}} \qquad [5]$$

With an arbitrarily assumed mass transfer coefficient of 10^{-1} cm/sec,[6] one obtains $t_{1/2} \approx 1$ sec for 1 atm, 298°K. This time is almost four orders of magnitude larger than the residence time of a bubble moving at 1000 cm/sec between the electrodes (3 x 10^{-4} sec). The redissolution of gas is, therefore, too slow to produce a homogeneous gas solution within the length of the present electrode gap or even to affect measurably the diameter of bubbles in our photographs.

Influence of electrolyte.—Figure 7 illustrates the surprising observation that less gas was produced at the cathode in KNO_3 than in KCl solutions, under otherwise identical conditions. The relative volume of the two-phase region in the interelectrode gap, shown in Fig. 8, has been obtained by planimetry of the areas occupied by the dispersed gas in the photographs. Since the solubility of hydrogen is about the same in both electrolytes (11), the observed difference must be due to other than differences in solubility. For example, the same amount of hydrogen could appear to be smaller in nitrate solutions due to a more finely dispersed form. A more likely explanation is that, due to the reduction of nitrate at the cathode, only part of the current is used for hydrogen evolution. In the present flow apparatus, the total amount of evolved hydrogen could not be determined, but some experiments were performed in stagnant solutions of KNO_3 and KCl at 5 A/cm^2. They confirmed that a much smaller volume of hydrogen was produced in nitrate than in chloride solution. A quantitative investigation of cathodic reactions in nitrate solutions has been initiated. The effect of different electrolytes on the amount of cathodically formed gas was further investigated by use of chlorate and sulfate solutions. Both the photographs taken in the flow system and the volumetric measure-

[6] Since the relative motion between bubble and solution is not known, the mass transfer coefficient k has to be assumed arbitrarily. The value chosen is a maximum guess. It corresponds to the figure estimated for the electrode-solution interface at the highest flow rates employed (3).

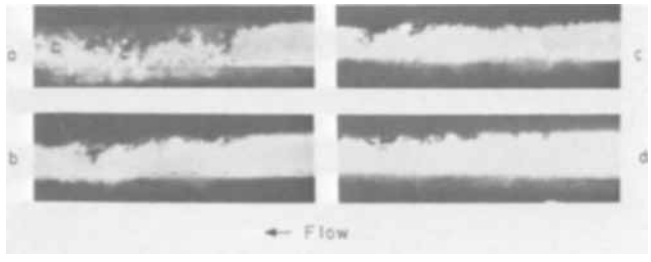

Fig. 7. Cathodic gas evolution at 100 A/cm^2 in 2N KNO_3 and 2N KCl, cathode facing down: a—KCl, flow rate 400 cm/sec; b—KCl, flow rate 800 cm/sec; c—KNO_3, flow rate 400 cm/sec; d—KNO_3, flow rate 800 cm/sec.

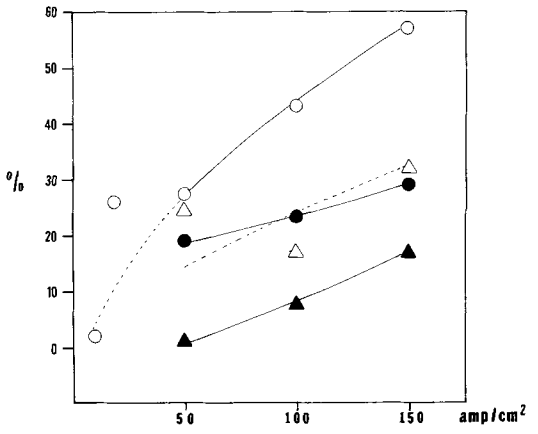

Fig. 8. Apparent volume fraction of interelectrode gap occupied by two-phase region (gas-electrolyte mixture): ○—2*N* KCl, 400 cm/sec; ●—2*N* KCl, 800 cm/sec; △—2*N* KNO_3, 400 cm/sec; ▲—2*N* KNO_3, 800 cm/sec.

ments in stagnant solutions indicated that, within the experimental accuracy, the same amount of gas was generated in these electrolytes as in the chloride solution.

Potential measurements under high current density conditions are dominated by large ohmic drops in the electrolyte between the working electrode and the tip of the reference electrode capillary (3). The apparent cathode potentials, thus determined at constant current density, provide an indirect measure of electrolyte conductivity and, consequently, gas volume fraction. Apparent cathode potential measurements are given in Fig. 9. It can be seen that a rapid increase of potential with decreasing flow rate, indicating the presence of a substantial volume fraction of gas in the electrode gap, occurs at a higher flow rate in chloride than in nitrate solutions. This shift is consistent with the evolution of a larger gas volume in the first electrolyte.

Discussion

Ohmic resistance.—Since one of the purposes of this study was to define the effect of cathodically generated gas on the electrolyte resistance, the question remains under which conditions this effect is significant. For the controlled current operation of these experiments, an increase in the ohmic resistance of the electrolyte results in an increase in over-all cell voltage. A marked increase in cell voltage, which is observed with decreasing flow rate in 2*N* KCl (Fig. 10), can be attributed primarily to cathodic phenomena, since anode potentials did not vary by more than 1-4V for different flow rates. This increase in cell voltage occurs at flow rates which rise with increasing current density and parallels the onset of voltage fluctuations. Although the qualitative influence of gas bubbles on cell voltage is thus strongly indicated, it has not been possible to derive a simple quantitative relation between the gas volume fraction and the cell voltage, which would hold for different current densities. The difficulty may, in part, be due to the fact that the gas was not homogeneously dispersed, neither in the direction normal nor parallel to the electrodes. The bubbles which have been observed to stick to the cathode surface at flow rates below 400 cm/sec further complicate the situation. Cole and Hopenfeld (1) have also investigated the influence of gas bubbles on cell voltage under ECM conditions. They accounted for the effect of the dispersed gas on the ohmic resistance of the electrolyte by using a relation given by De La Rue and Tobias (13). By making certain simplifying assumptions about the two-phase region and by adjusting one empirical parameter, they obtained agreement between theoretical and experimental results. The present study suggests, however, that such a simple treatment is not valid for the range of conditions employed here.

Sparking.—The formation of continuous gas blankets on vertical wire electrodes in sulfuric acid, at current densities of 6-8 A/cm², has been described by Kellogg (14). The formation of his gas blanket coincided with a drastic increase in surface temperature and a sharp drop in current. A similar phenomenon also is known to occur in heat transfer under forced convection conditions, where formation of vapor films leads to a sharp reduction in heat flux (burn out, critical heat flux) (15). It was, therefore, of interest to see whether, under ECM conditions, similar gas films are formed and whether they may lead to sparking and electrical breakdown. As long as a sufficiently high flow rate was maintained, no such phenomena were observed in the present experiments, even at current densities much higher than those employed by Kellogg. Upon decreasing the flow rate, however, large voltage fluctuations and eventual sparking occurred. These fluctuations, indicated by the broken lines in Fig. 10, soon became so large as to impede any measurement upon further re-

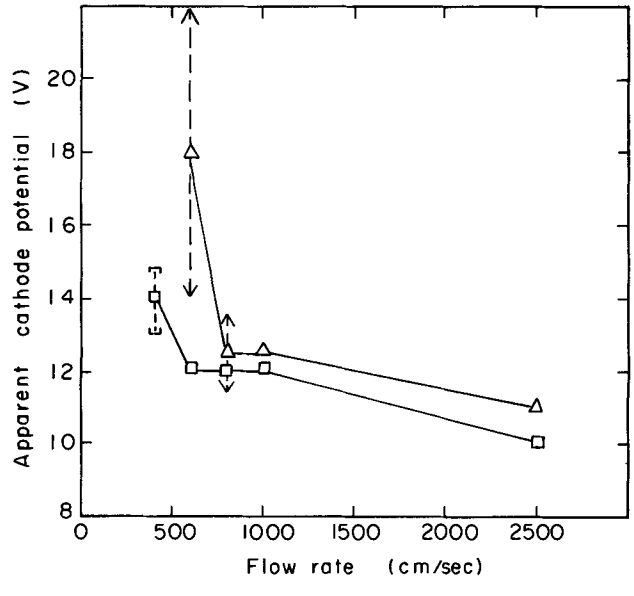

Fig. 9. Effect of gas evolution in different electrolytes on apparent cathode potentials, measured *vs.* sat. calomel with capillary upstream from the electrode. Current density 100 A/cm², cathode facing up. △—2*N* KCl, □—2*N* KNO_3. - - - amplitude range of voltage fluctuations.

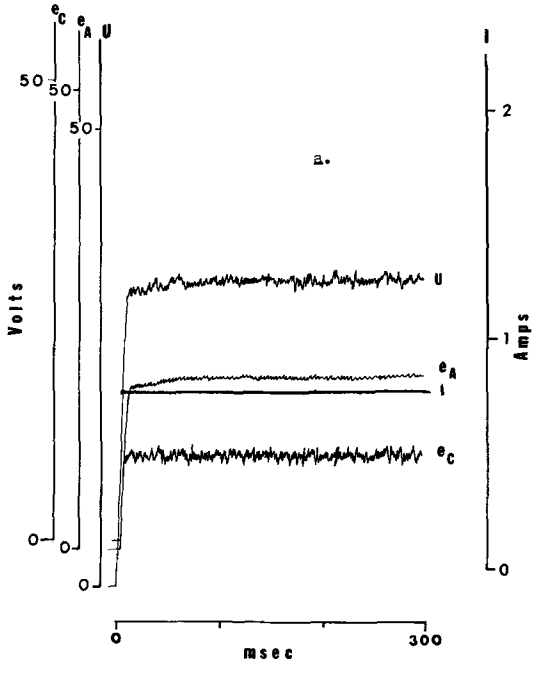
duction of flow rate. A close parallelism between oscillations in cathode potential and cell voltage confirmed the cathodic origin of the oscillations. The onset of these fluctuations coincided with the appearance of a different type of gas bubble characterized by a large size and odd shape. Picture (a) in Fig. 3 is typical for this situation. It appears that, under these conditions, small individual bubbles are no longer generated and continuous gas pockets may cover a sizeable fraction of the cathode surface. Although an actual sparking event could not be photographed, it is possible that such a breakdown coincides with an instantaneous complete coverage of the cathode. The gas volume fraction, at which uncontrolled fluctuations set in, has been estimated on the basis of current density and flow rate (neglecting gas dissolution) to be approximately 0.2 at 100 and 150 A/cm².

Anode reactions.—Voltage oscillations in constant current electrolysis may also originate at the anode. While a detailed discussion of such phenomena is beyond the scope of the present report, it is interesting to note that the anodic oscillations have been observed under certain conditions with several electrolytes, most notably sodium chlorate. Figures 12a to c illustrate how the anodic contribution to fluctuations in over-all cell voltage U increases in the electrolyte series, chloride, nitrate, chlorate, while the cathodic contribution remains about the same (except for a slight reduction in nitrate, due to the smaller gas volume). Of particular interest are the usually well behaved periodic oscillations which originate at the anode (as indicated by the apparent anode potential e_A in Fig. 12c) in chlorate solution. The frequency of these oscillations depended primarily on current density and was only slightly



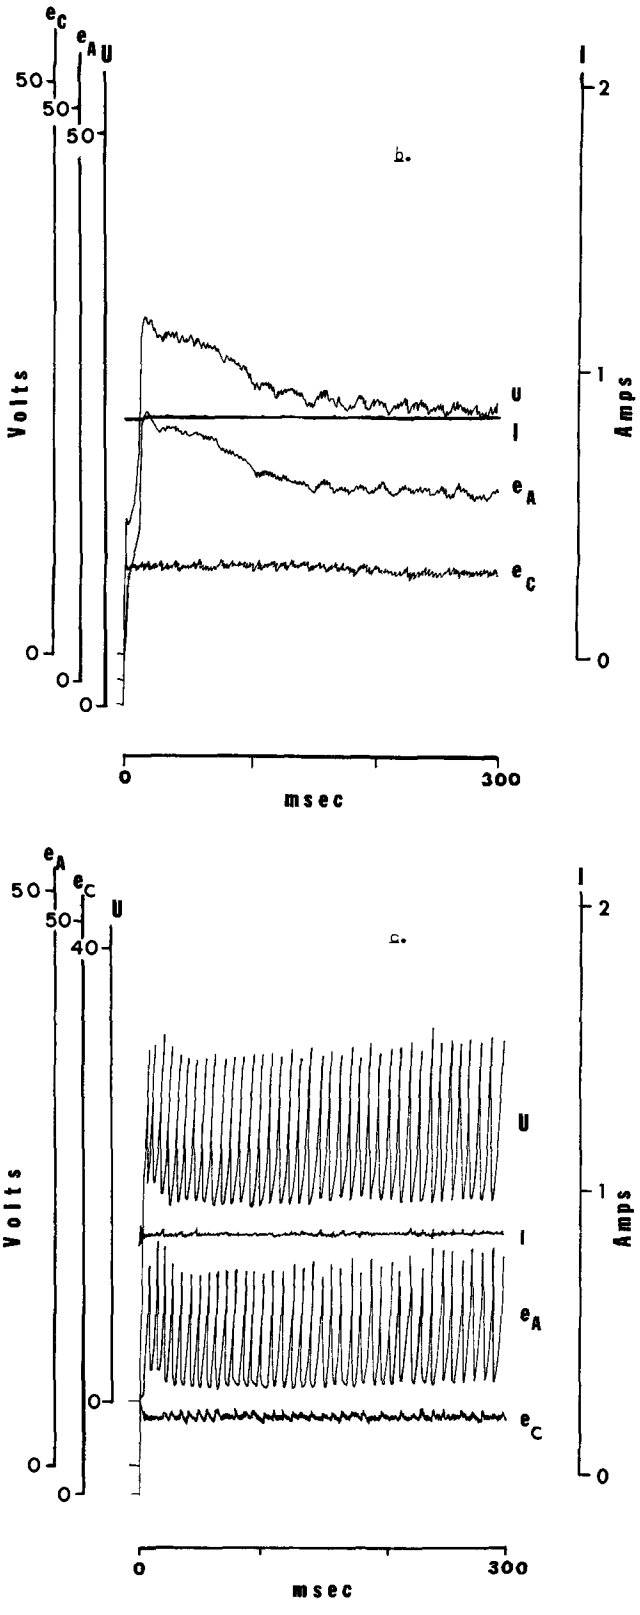


Fig. 12. Typical recorder traces of cell voltage U, current I, apparent anode potential e_A, and apparent cathode potential e_C; 50 A/cm², 400 cm/sec. a—2*N* KCl, b—2*N* KNO_3, c—2*N* $NaClO_3$.

affected by changes in flow rate. Typical frequencies were 130 and 300 Hz at 50 and 100 A/cm², respectively. The voltage fluctuations which originate at the cathode were irregular. Their frequency was much higher (mostly over 2000 Hz) and the amplitude depended strongly on flow rate as well as current density. Periodic phenomena at the anode can be related to the formation of solid films (3, 16), and Fig. 11 shows indeed how solid dissolution products are being re-

moved from the anode surface (together with a small amount of gas). Similar, but less pronounced, shedding of solid reaction products has been observed in sulfate and nitrate solutions.

The photographic pictures obtained in this study also demonstrate that, under the conditions of a previous investigation of anodic phenomena (3), gas bubbles were usually confined to the vicinity of the cathode. In view of the low solubility of hydrogen gas, it can be concluded that any fraction of the total anodic current possibly used for the oxidation of hydrogen has been negligible. The distribution of gas bubbles in the interelectrode gap gave no indication of the occurrence of plug flow phenomena, which could drastically affect mass transfer at the anode.

Summary and Conclusions

The present study was aimed at providing visual information on cathodic gas evolution during high rate metal dissolution, in order to determine the importance of cathodic phenomena on ohmic electrolyte resistance, anode reactions, and sparking. Qualitative rather than quantitative conclusions can be drawn from the results obtained in a flow channel cell with short electrodes.

1. The size of cathodically generated gas bubbles depends on current density as well as flow rate. At flow rates above 400 cm/sec, only very small (few microns in diameter) or no recognizable bubbles were generated.

2. A substantially smaller gas evolution in nitrate than in chloride solutions has been observed. It indicates the occurrence of cathodic reactions other than hydrogen evolution in the former solution.

3. The influence of cathodically generated gas bubbles on the ohmic cell resistance was very small at flow rates above approximately 1000 cm/sec for all current densities employed (up to 150 A/cm^2). At lower flow rates, this influence can be substantial. Models which are based on a uniformly distributed two-phase region and, among other simplifications, neglect the residence time of gas bubbles on the cathode surface, did not predict valid cell voltages.

4. No plug flow phenomena seem to have been induced by the gas evolution under the conditions employed in the present study.

5. The influence of cathodic gas evolution on anodic processes such as mass transfer and current efficiency was usually very small.

6. At insufficient flow rates, strong fluctuations in cell voltages were observed, which coincided with the formation of gas patches at the cathode and which eventually led to electric breakdown. The effect was more pronounced in chloride than nitrate solutions, in agreement with the fact that less gas was generated in the latter solutions under otherwise identical conditions.

7. In the absence of a theoretical model describing even the most simple single bubble dynamics in a flow field, additional experimental observations are needed to gain even a qualitative insight into the factors which determine growth, detachment, and dispersion of gas bubbles generated at high current densities and electrolyte flow rates in narrow gaps.

Technical Note

Capacitor Discharge Current for Thin-Film Alloy Deposition

Herman E. Austen

Process Research & Development, The National Cash Register Company, Dayton, Ohio

There are numerous articles in the literature on the use of thin films (less than 1000Å) of iron-nickel alloy for computer memories (1-5). These thin-film memory elements switch either by Néel wall movement or, preferably, coherent rotation. The rotational switch is faster and switching time is inversely proportional to the difference of the applied field and the coercive force.

Thin films of iron-nickel have been produced by sputtering, vacuum deposition, and electrodeposition.

Maintaining a constant composition from initial deposit to final thickness is difficult in electrodeposition of thin films because equilibrium conditions must be established in the cathode film and this requires an appreciable time. In the thinnest films (~ 500Å, or less), the total thickness may be deposited by the time equilibrium has been reached. The resultant change in composition will exert an appreciable influence on magnetic properties up to 1000Å, or more, thickness (15-17).

Several investigators have analyzed deposits as a function of thickness and have tried to obtain uniformity by the use of varying currents instead of direct current (6-14). Improvement has been obtained but none of the methods have produced a constant composition.

A method is herein described for varying the current to obtain a nearly constant coercive force from initial deposit to any desired thickness. In plots of coercive force *vs.* thickness using constant current, it had been found that the coercive force increased logarithmically with decreasing thickness. Various investigators had made analyses of thin deposits of iron-nickel (6-8), showing a similar increase in iron concentration of the deposit with decreasing thickness.

Since increasing the current density increases the nickel concentration, it was felt that a current which started high and decayed logarithmically to some d-c value would counteract the composition change. The curves of composition *vs.* thickness, or time, are similar to the decay current of a capacitor through a resistor. Although it has been shown that composition varies as $t^{-1/2}$ (14), for the short times involved in deposition of very thin films, variation of the current with log t is probably a close enough approximation and can be more easily obtained. The effect of such a current on the magnetic properties of iron-nickel deposits was investigated.

The simplest form of circuit is a power supply, capacitor, and DPDT switch as shown in Fig. 1(a). However, there is little flexibility in this circuit. One which provides for plating various thicknesses on cathodes of various configurations and sizes is shown in Fig. 1(b).

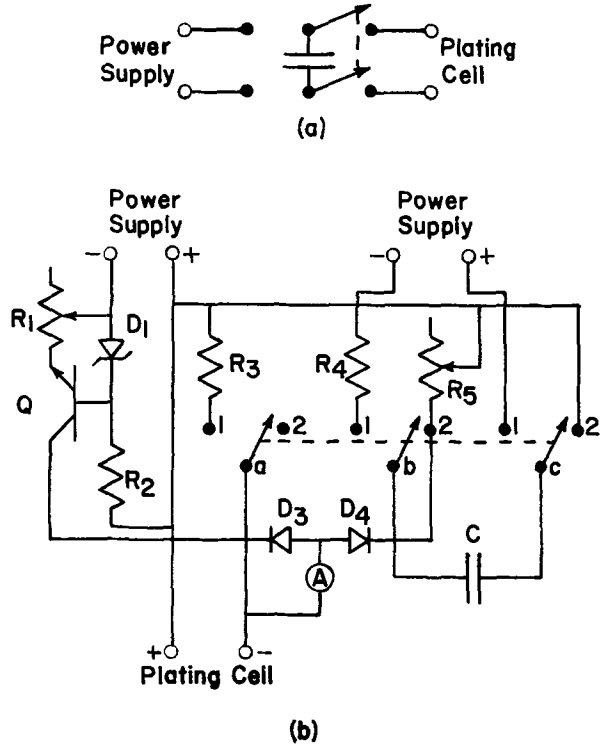

Fig. 1. Capacitor discharge circuits: (a) simplest form; (b) as used in experimental work.

Table I. Circuit values used in obtaining Fig. 2

R_1	500 ohms
R_2	750
R_3	22
R_4	22
R_5	5
D_1	V_z – 7.5V
C	0.35f
Plating cell impedance	300 ohms

Resistors R_1 and R_2, transistor Q, and Zener diode D_1 form an adjustable constant current circuit for the d-c plating current. When the gang switch is in position 1, the resistor R_3 acts as a load and allows presetting of the current and also acts to provide a bias against solution potential when the cathode is being placed in the solution. Also, with the switch in position 1, the capacitor is being charged through the current limiting resistor R_4.

When the switch is thrown to position 2, the capacitor is connected to the plating cell and resistor R_5 in parallel. Diode D_3 prevents capacitor current from flowing into the constant current circuit and, when the current from the capacitor drops to the preset constant direct current, the current flow comes from the constant current part of the circuit and diode D_4 prevents this current from flowing into the capacitor part of the circuit. Resistor R_5 adjusts the rate of decay of the capacitor. The resistance of R_5 is much less than the impedance of the plating cell and the capacitor charge is much larger than that required to deposit the iron-nickel. These conditions allow some variation in plating resistances without appreciable effect on the capacitor discharge time.

The values of the components as used for depositing on samples 1.8 cm in diameter are shown in Table I. Both power supplies provided 15V. These adjustments for optimum results were found by trial and error, using magnetic properties as the criteria. Undoubtedly, the optimum values of these components will vary with solution composition, temperature, and other operating variables. Satisfactory methods of analysis were not available and the samples were complicated as to analysis because the iron-nickel was deposited over a nonmagnetic chemical nickel deposit on a platinum substrate.

A composition of approximately 20% iron-80% nickel was assumed when a low coercive force and nearly zero magnetostriction were obtained. The shape of the

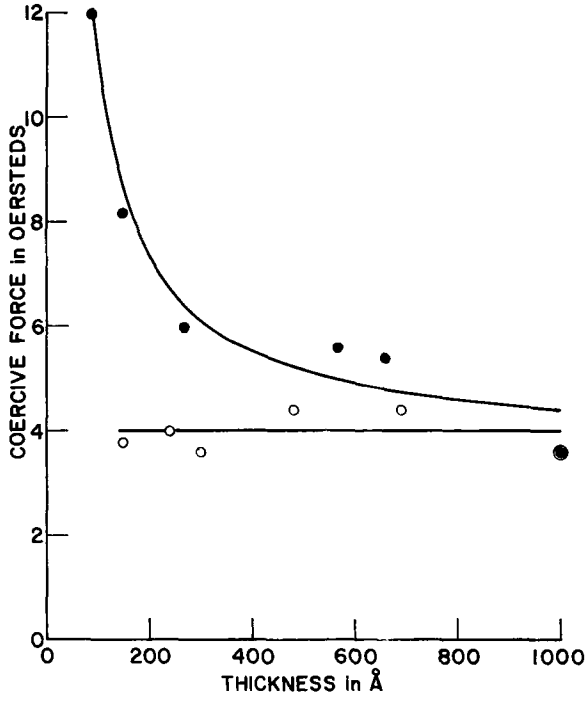

Fig. 3. Comparison of coercive force of d.c. and capacitor discharge plated films: ●, d.c.; ○, capacitor discharge.

hysteresis loop also suggested a constant composition when the sides were straight and the knees square. A typical current-time curve is shown in Fig. 2.

A comparison of coercive force *vs.* thickness curves for d-c plated samples and capacitor discharge plated samples is shown in Fig. 3. These samples were deposited on a platinum foil substrate which was stripped and re-used so that the epitaxial effect was the same for each sample. Also, a plating solution volume of 2 liters was used so that compositional, impurity, and pH variations were minimized. The platinum was not bright and thus a higher coercive force was obtained than would have been the case on a mirror-smooth substrate. On smooth copper, a coercive force of 5 oersteds was obtained at a thickness of only 65Å and an iron-nickel-molybdenum film deposited on copper had a coercive force of 4.5 oersteds at only 13Å thickness. These thicknesses were estimated from flux densities and charge used in deposition.

Experiments with pulsed current, a-c superimposed on d-c, and an initial high voltage strike have shown the capacitor discharge to be much better in obtaining the desired uniformity of thin-film deposits.

Some Aspects of the Mechanism of the Anodic Dissolution of Zinc in Sulfamic Acid-Formamide Solutions

I. A. Menzies, G. W. Marshall, D. Gearey, and G. B. Griffin

Corrosion Laboratories, Department of Chemical Engineering, University of Manchester Institute of Science and Technology, Manchester, England

ABSTRACT

The anodic behavior of zinc has been studied in sulfamic acid-formamide solutions as a function of sulfamic acid concentration, temperature, and water content of solutions. It has been shown that anodic polarization curves for Zn are typical of polishing systems, and it has been found that linear relationships exist between limiting current densities and the reciprocal viscosities of the solutions. The processes in solution are controlled by diffusion of cations or of solvent species. Film formation occurs at the onset of polishing as shown by a-c impedance studies, and this film is either highly soluble or unstable in the presence of considerable amounts of water. The over-all conclusion is that the mechanisms of polishing in sulfamic acid-formamide solutions are in agreement with those proposed by Hoar for anodic polishing in other environments.

The present work is a continuation of previous studies (1-3) of the anodic behavior of metals in organic electrolyte solutions. It has been shown that Fe, Cd, Sn, Ti, Zn, Pb, Ag can be electropolished in 1M sulfamic acid-formamide solutions and that typical anodic polarization curves are obtained under potentiostatic conditions. Furthermore similar, although less clearly defined, cell polarization curves have been obtained under galvanostatic conditions. However, these studies have been of a general nature, and the mechanisms involved in such anodic processes have not been examined in any great detail. Zinc appeared to be one of the more stable systems and hence perhaps the most promising of metals for such studies, and in the present work the role of sulfamic acid concentration, solution temperature, and the effects of water additions have been studied in relation to the anodic behavior of zinc in formamide. Alternating current measurements have also been made to study general aspects of the etching-polishing transition in this system.

Experimental

General techniques for the handling of anhydrous organic electrolyte solutions have been described elsewhere (1, 3) as have many of the experimental procedures. Only essential information will be given here.

Materials and polarization studies.—Formamide was purified by the method of Verhock (4) and had a specific conductance of 2 x 10^{-4} ohm^{-1} cm^{-1} at 25°C. Microanalytical grade sulfamic acid was used without further purification after storage in a vacuum desiccator. Zinc of 6*N* purity was used as the anode throughout. Zinc sulfamate hydrate was prepared by the reaction of zinc carbonate and sulfamic acid, the Zn sulfamate being crystallized out of the filtrate by evaporation of the solution under reduced pressure at 40°-50°C.

The cell used for polarization measurements has been described elsewhere (1, 3). The working electrode was placed between two Ta counterelectrodes, and the potential of the working electrode was measured against a $Cd/CdCl_2$ electrode in a KCl (satd.)-formamide solution prepared as described by Pavlopoulos and Strehlow (5) and contained in a separate compartment. The working electrode was a zinc rod machined to fit tightly into PTFE tubing so as to expose approx. 0.75 cm^2. The PTFE tube was fitted tightly into a glass tube and the Zn connected to a copper wire via a mercury contact as described previously (3). The Zn electrodes were prepared metallographically to 600 grade SiC paper, vapor degreased, etched in 10% HNO_3, and washed in distilled water, then formamide before use.

The polarization curves were measured galvanostatically using an electronically stabilized galvanostat (E.M. Wareham Measuring Instruments Ltd., Type C 220) having a variable output of up to 1A at 80V. A Millivac d-c Multimeter (Type MV 77B) was used to measure the potential between reference and working electrodes. During polarization measurements the galvanostatic current was increased in a stepwise manner (2.5-7.5 mA) and the potential of the working electrode determined 15s after each step. All measurements were carried out at 25° ± 0.1°C.

Measurement of solution densities and viscosities at 25° ± 0.1°C.—Densities were determined using a graduated pycnometer of 5 ml size, and viscosities were determined using British Standard U-tube viscometers sizes A and B. Double distilled water boiled for 30 min and quickly cooled immediately before use was used for calibration of both the pycnometers and U-tube viscometers, and the measurements of densities and viscosities were made in accordance with the Institute of Petroleum standard methods (6). For cali-

bration purposes the density and viscosity of water were taken to be 0.99704 g/cm³ and 0.8937 cp at 25°C, respectively (7).

A-C impedance measurements.—The bridge network is shown in Fig. 1. The 10 kHz sine wave input was controlled at 10 mV amplitude to prevent interference with the d-c process. A screened and balanced transformer input (T_1) was used, the supply thus being balanced to earth. The resistive ratio arms R_1, R_2 were maintained at equal values if possible to maintain best the advantages of the balanced input. The unknown was measured as a series resistance/capacitance combination.

The d.c. was applied across the diagonal of the bridge to avoid any possibility of shunting the a.c. from the unknown; a battery supply was used in order to minimize noise and earthing problems. A choke in the d-c circuit blocked a-c from d-c circuit when the bridge was unbalanced and the capacitor C_b blocked the d-c path through the diagonal. Bridge imbalance was detected with a tuned amplifier coupled to the bridge through the screened transformer T_2.

A special electrode was constructed for a-c measurements (Fig. 2). A strip of Zn, ~1 mm², was soldered to the end of the copper connecting wire and the specimen sealed into the glass tube with Araldite. Before use the base of the electrode was ground flat exposing ~1 mm² of metal surface to the electrolyte. The electrode was lightly pickled in 10 v/o HNO_3, washed and dried with acetone in a stream of warm air before use. This electrode was made the anode and surrounded by a large Ta cathode. The prepared anode was lowered into the solution in the cell in an atmosphere of dry oxygen-free nitrogen and the bridge balanced alternately for resistance and capacitance. Various current densities were then applied (0.1-1.0 mA/mm²) and the corresponding resistance and capacitance recorded.

Results

Density and viscosity measurements.—The densities and viscosities of the solutions used in the present investigation are given, with other data, in Tables I-III. The viscosities of solutions of sulfamic acid in formamide varied with sulfamic acid concentration in accordance with the expression $\log \eta = \log \eta_o + Zc$ where η and η_o are the kinematic viscosities of the solution and pure formamide, respectively, c is the concentration of sulfamic acid in moles/liter, and Z is a constant (Fig. 3.). It is also clear that there was a change in the slope of the function at concentration of 0.6-0.7M w.r.t. sulfamic acid (curve A). In sulfamic acid-formamide-water solutions similar relationships hold in formamide solutions with water concentrations up to 5M and in solutions containing >50 v/o water, *i.e.*, >26M, curve B.

Anodic polarization of zinc in sulfamic acid-formamide solutions.—The overpotential-current density relationships obtained in sulfamic acid-formamide solutions all exhibited reasonably well-defined limiting current densities. Typical curves are shown in Fig. 4; the values of the limiting current densities are given in Table I. In general the reproducibility of the curves and the limiting current densities was excellent (±2%), but at high overpotentials corresponding to the upper end of the limiting current density plateaus some scatter was observed. This made accurate measurement of the overpotential range corresponding to the limiting current density somewhat difficult. It is however clear that the overpotential range corre-

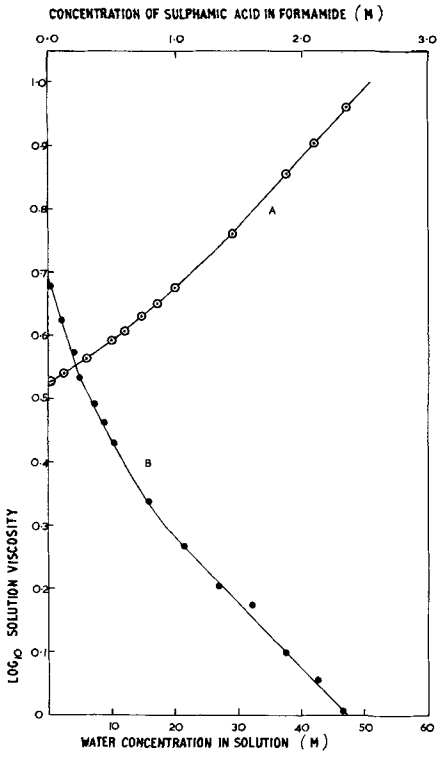

Fig. 3. Relationship between concentration and solution viscosity at 25°C (A) sulfamic acid in formamide, (B) H_2O concentration in 1M sulfamic acid-formamide solutions.

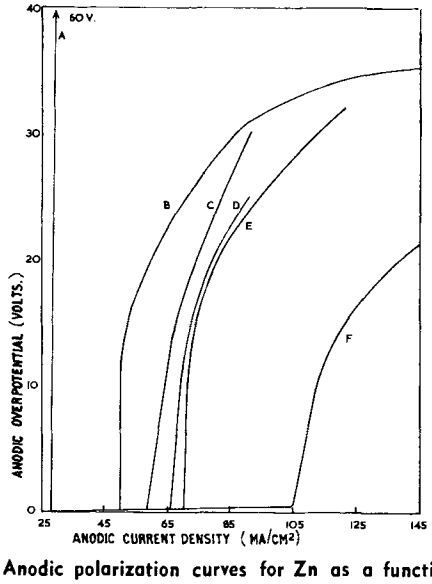

Fig. 4. Anodic polarization curves for Zn as a function of sulfamic acid concentration at 25°C: A, 2.6M; B, 1.0M; C, 0.75M; D, 0.5M; E, 0.25M; F, 0.1M.

sponding to the limiting current density increased with increasing sulfamic acid concentration from ~22V in 0.1M solutions to ~60V in 2.6M solutions. The limiting current density (Table I) decreased with increasing sulfamic acid concentrations, *i.e.*, with increasing solution viscosity. In fact (Fig. 5) there was a linear relationship between the limiting current density and the reciprocal of viscosity for sulfamic acid concentrations of from 0.25 to 2.6M.

The polarization curves obtained in 1M sulfamic acid-formamide solutions were similar at higher temperatures to curve B in Fig. 4 except that at 55°C there was a greater increase in current density with potential for potentials >7V than at other temperatures. The limiting current density increased with increasing temperature, and again there was a linear relationship

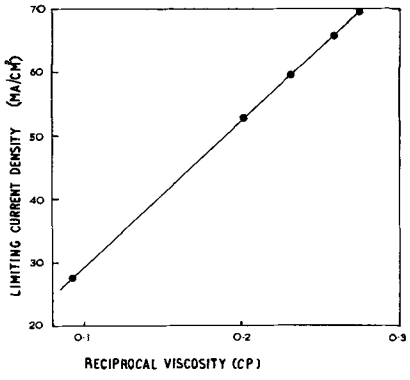

Fig. 5. Relationship between limiting current density and reciprocal viscosity as a function of sulfamic acid concentration at 25°C.

between limiting current density and reciprocal viscosity (curve A, Fig. 6).

Anodic polarization of zinc in 1M sulfamic acid-formamide-water solutions at 25°C.—The overpotential-current density curves obtained in 1M HSO_3NH_2-formamide solutions containing various proportions of water are shown in Fig. 7 and 8. The limiting current density was well defined at water concentrations up to ~31.9M (Fig. 7) whereas at higher water concentrations the limiting current density became decreasingly well defined as the water concentration increased. In general etching was observed at all current densities below the limiting current density and bright polishing at current densities equal to or greater than the limiting current density in solutions where these were reasonably well defined. It is clear from Table II that the solution viscosity decreased with increasing water concentration and this coincided with an increase in the observed values of limiting current density. For water concentrations up to 10.4M there was a linear relationship between the limiting current density and the reciprocal of solution viscosity (Fig. 8). This relationship did not however hold for higher water concentrations.

Anodic polarization of zinc in a 1M sulfamic acid-formamide-water (8.1M) solution at 25°C with Zn sulfamate additions.—Zinc sulfamate hydrate was not readily soluble in this solution and less so in sulfamic acid-formamide solutions in the absence of water. Hence only a limited investigation was carried out.

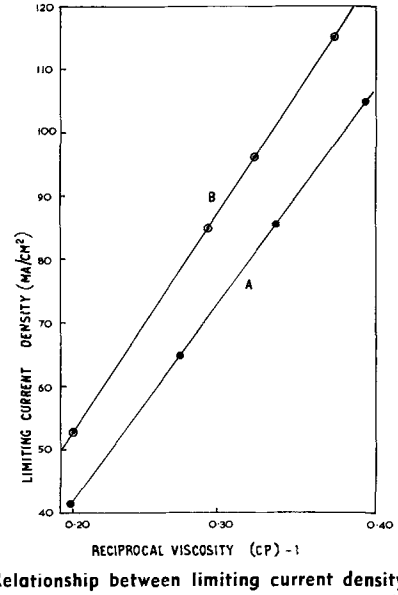

Fig. 6. Relationship between limiting current density and reciprocal viscosity as a function of (A) temperature and (B) water concentration in 1M sulfamic acid-formamide solutions.

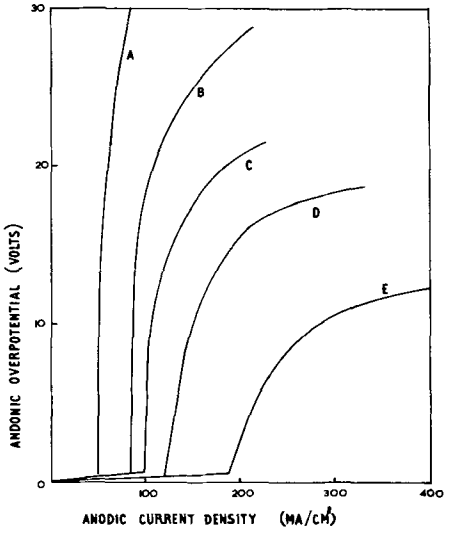

Fig. 7. Anodic polarization curves for Zn in 1M sulfamic acid-formamide-water solutions at 25°C as a function of water concentration: A, no H_2O; B, 4.07M; C, 8.1M; D, 10.4M; E. 15.7M.

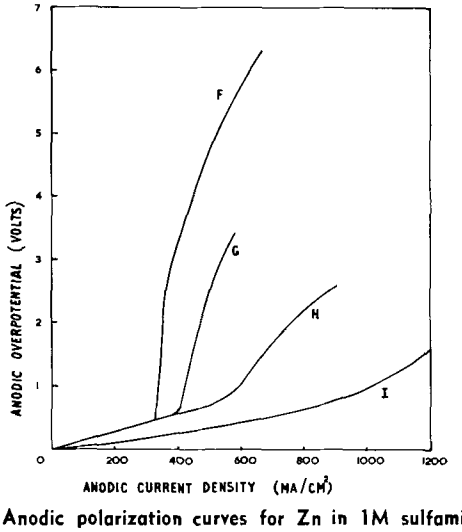

Fig. 8. Anodic polarization curves for Zn in 1M sulfamic acid-formamide-water solutions at 25°C as a function of water concentration: F, 26.8M; G, 31.9M; H, 37.4M; I, H_2O only.

The polarization curves were all similar to the corresponding curve in the absence of Zn sulfamate additions (C in Fig. 7) and showed well-defined limiting current densities typical of electropolishing systems. Again etching and polishing of zinc occurred in the appropriate regions of the curves. As can be seen in Table III, the solution viscosity increased with increasing zinc sulfamate concentration. This may have caused the decrease in the limiting current densities observed at higher sulfamate concentrations. However there appears to be relatively little effect of Zn ion concentration.

A-C impedance measurements in 1M sulfamic acid-formamide solutions at 25°C.—The variation of resistance and capacitance (measured as a SERIES combination) with current density is shown in Fig. 9A, 9B. Increase in current density toward i_{lim} resulted in small changes in resistance (a few per cent in the zero current value of 3.5 ohm cm²) and approximately a fivefold increase in capacity to 50 μF/cm² as the potential controlled conditions in the interphase changed. For current densities greater than i_{lim} the resistance and capacitance changed rapidly (<1 sec) to R values of 180 ohm cm² and C values of 0.2 μF/cm².

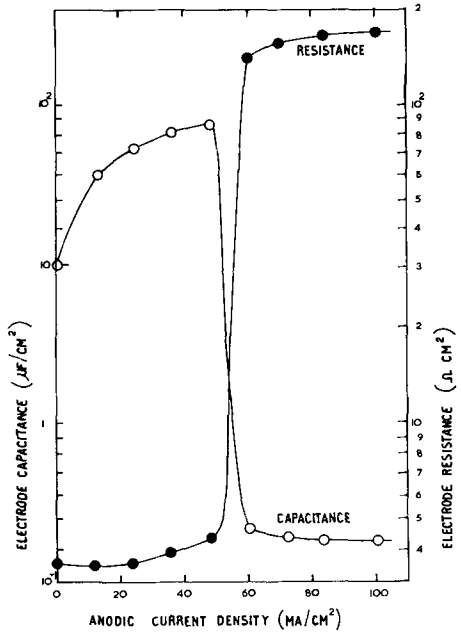

Fig. 9. Electrode resistance and capacitance as a function of current density during anodic polarization at 25°C in 1M sulfamic acid-formamide solutions: A, resistance; B, capacitance.

Interpretation and Discussion

The present results are an extension of previous studies of electropolishing (1-3, 8) and give a more detailed picture of a number of aspects.

The diffusional nature of the limiting currents is indicated by the linear $i_{lim}v \cdot 1/\eta$ relationship on varying the viscosity either by change of temperature (curve A, Fig. 6) or of sulfamic acid concentration (Fig. 5). Water content also affected viscosity and resulted in a linear $i_{lim}v \cdot 1/\eta$ relationship (curve B, Fig. 6) for water concentrations <10M where i_{lim} was still well defined. At higher water contents i_{lim} was ill defined probably due to increased solubility of the solid products of the dissolution reaction or to the water taking over as "acceptor" as discussed later.

The exact nature of the diffusing species is less certain. The values of i_{lim} obtained in this work are at the lower end of those found in aqueous polishing solutions (20 mA/cm²-several A/cm²) and this is in agreement with the larger solvodynamic unit expected in formamide. The over-all diffusion coefficient is nevertheless of the same order of magnitude as in aqueous solutions, and this suggests strongly that the diffusing species is a relatively simple species and is not a complex polymerized structure.

The diffusional situation appears then to be analogous to that in other environments reviewed by Hoar (9). Briefly, limiting currents are controlled either by (*i*) diffusion of metal ions away from the electrode surface the surface metal ion concentration $(M^+)_s$ being controlled by precipitation of a solid compound or (*ii*) diffusion of "acceptor" species (10-12) from the bulk solution.

The absence of effect of metal ion concentration (Table III), except in a possible viscosity effect, on i_{lim} might be thought to eliminate metal ion diffusion. However the diffusional flux is proportional to the concentration gradient $[(M^+)_s - (M^+)_b]/\delta$ where $(M^+)_b$ is the metal ion concentration in the bulk solution and δ is the diffusional layer thickness. If the maximum value of $(M^+)_b << (M^+)_s$ change in $(M^+)_b$ will not affect i_{lim}.

This might result from a high degree of supersaturation in the interphase (it seems likely that high field conditions in the double layer would encourage this) or simply from a rather soluble solid reaction product which permits a high value of $(M^+)_s$ before precipitation. An attempt was made, in the present work, to in-

vestigate the latter possibility and at the same time the variation of i_{lim} with $(M^+)_b$ by using a likely solid product zinc sulfamate as the source of $(M^+)_b$. Unfortunately only the hydrate salt was available, and its solubility was limited. Although little effect of i_{lim} with $(M^+)_b$ was noted this cannot be considered conclusive evidence against metal ion diffusion control of i_{lim}. It is intended to use anhydrous sulfamate and also other sources of metal ion to investigate this problem further; other sources of metal ion will of course entail introduction of foreign anions whose effect will need to be monitored.

The lack of effect of sulfamate ion bulk concentration $(sulf)_b$ on i_{lim} except as a viscosity effect (Fig. 5) does appear to eliminate sulfamate ion diffusion, because the diffusional flux would be approximately proportional to $(sulf)_b$ which is directly controlled. Other "acceptors" are available however which could control metal ion dissolution; the solvent itself either as a neutral species or as $HCO\ NH^-$ might be so involved. Such a mechanism could be correlated with the destruction of i_{lim} by water addition at higher concentrations (Fig. 8) as the faster diffusing water takes over the acceptor role. Thus although the diffusional nature of the limiting currents is clear, the diffusing species cannot be conclusively identified from a study of the limiting current behavior.

Perhaps the outstanding feature of the experimental results is the extremely high anode potentials (up to 60V) obtained. The appearance of these high potentials is accompanied by a rapid rise in a-c resistance and corresponding drop in series capacitance (Fig. 9). The resistance value is considerably larger than typical resistance measured in aqueous solutions (~100 ohm. cm^2 compared with ~10 ohm cm^2). It is considered that these observations can only be explained in terms of solid film formation for the following reasons:

1. The very rapid rise in a-c resistance and anode potential at currents of the order if i_{lim} is not typical of diffusion layer build up.
2. The fall in series capacitance is indicative of a thin film (~ several hundred Å).

Formation of a relatively thick viscous layer would be expected to result in a resistive increase only. The two cases are illustrated schematically below.

this results in R values ~400 ohm cm^2 and C values ~0.1 $\mu F/cm^2$ in the parallel mode. Using $C = (\epsilon/4\pi t)$ esu (9×10^{11} esu = 1F) where ϵ is the dielectric constant and t is film thickness and assuming $\epsilon = 10$ the value for $t \approx 10^{-5}$ cm.

3. If the resistance increase were due to a viscous layer in the region 0.05 cm thick (a typical probe/surface distance) the specific resistance would need to be 10,000 ohm cm^{-1}. Walton (13) measured specific resistances of simulated anodic diffusion layers in copper ion/phosphoric acid/glycerol solutions and found a maximum value of only 133 ohm cm^{-1}.

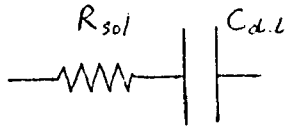
Epelboin *et al.* (14, 15) have also reported high anode potentials during Al polishing in ethanolic solutions of Mg $(ClO_4)_2$. They suggest a close packed anhydrous layer of adsorbed ClO_4^- ions to account for the high potentials. This appears unlikely. If specifically adsorbed layers were responsible for such potentials, then the phenomenon would have been observed in the numerous studies of the effect of specific adsorption on double layer structure (16). Hoar (9) has also criticized the close-packed layer idea on account of its lack of lateral stability.

It is considered more likely that the high anode potentials are simply a result of a more resistive than normal solid film, about 1000Å in thickness as indicated by the a-c impedance measurements. Further impedance measurements with potentiostatic control of the direct component are planned to confirm this hypothesis. The Zn system is ideal for such an investigation because of the large voltage and the high film impedances. The exact nature of the film also awaits further results.

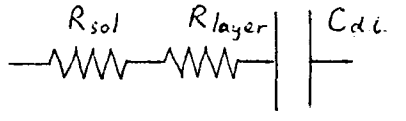
The anodic behavior of zinc in these solutions can then be explained on the solid film theory of polishing (9, 17); a solid film in close contact with the metal surface suppresses etching by ensuring that random vacancies occur at the metal/film interface. This film is more resistive than normal aqueous polishing films. High anode potentials are a direct result of this resistance. The over-all process of dissolution is diffusion controlled in the solution phase. The nature of the diffusing species is uncertain. It is possible to combine the inward diffusion of an "acceptor" species with the film theory in a very similar way to the more conventional metal ion diffusion from the surface. A

PATHS

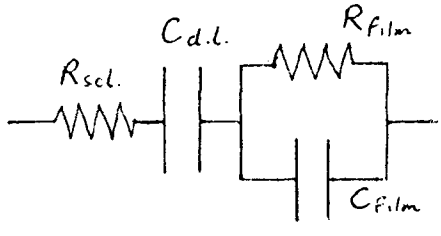
10 kHz. No film. Faradaic paths of minor importance. Impedance becomes series combination of solution resistance and double layer capacitance.



Thickish viscous layer. Capacitive impedance >> resistive impedance across layer. Layer appears as resistance only. Change in series resistance only.



Thin solid film. Capacitive and resistive impedances of film are reasonable alternative paths. Change in total series R and C expected.



Moreover, in the present case, the film impedance is considerably larger that the other impedances, *i.e.*, solution resistance and double layer capacitance, and impedance measured can sensibly be attributed to the film. Series/parallel transformation is necessary to identify the resistive and capacitive film components—

choice between the two diffusion mechanisms (*i*) solvent diffusion from the bulk solution and (*ii*) metal ion diffusion from the surface cannot therefore be made at this stage. Water additions probably increase the film solubility or stability thus reducing anode potentials attainable and also decrease solution viscosity

resulting in an increase in i_{lim} values. The work of Epelboin (14, 18) in which refrigeration of the electrode increased the anodic potentials suggests that an increase in i_{lim} might in itself be responsible for film breakdown as a result of increased Joule (i^2R) heating. The effect of decreasing sulfamate concentration (Fig. 4) in increasing i_{lim} and decreasing the anode voltages can be similarly explained.

Acknowledgments

The authors wish to thank Professor T. K. Ross for the provision of research facilities and the Science Research Council for their support and interest in this work.

Electrical Properties of Manganese Dioxide and Manganese Sesquioxide

P. H. Klose*, [1]

Union Carbide Corporation, Electronics Division, Greenville, South Carolina

ABSTRACT

Measurements of electrical properties of MnO_2 and Mn_2O_3 were carried out on material obtained by pyrolysis of $Mn(NO_3)_2$. From resistivity data, it is proposed that the conduction process is due to oxygen forming a donor level at 0.044 eV. In Mn_2O_3, oxygen vacancies might be acting as an acceptor level with an activation energy of 0.30 eV. Resistivity measurements were used to establish the MnO_2-Mn_2O_3 transition temperature at 545°C. The Hall mobility of MnO_2 was measured at 25°C. For resistivities of 0.1-100 ohm-cm, the mobility depends on the resistivity. This was taken as an indication that impurity scattering is the dominating process in this region. The voltage-current characteristic was measured for samples from 0.1 to 10^5 ohm-cm. The material showed ohmic behavior for fields from 10 mV/cm to 100 V/cm. The Seebeck coefficient was investigated over the temperature range 25°-125°C. A response of 0.6 mV/°C was found in high-resistivity n-type MnO_2, and 0.37 mV/°C in p-type Mn_2O_3.

The electrical properties of MnO_2 have been investigated previously by several experimenters. A survey of the results reported in the literature suggested that material preparation as well as type and technique of the measurements on MnO_2 might have affected the result, thus leading to apparent contradictions. Sasaki and Kojima (1), Glicksman and Moorehouse (2), and Brenet (3) measured the electrical resistivity of MnO_2 samples which were obtained by pressing pellets out of ground MnO_2 powder. The values reported for the resistivity ranged from about 30 to 300 ohm-cm. Bhide and Damle (4) investigated the properties of MnO_2 samples cut from naturally occurring pyrolusite. In their work the values quoted for the resistivity ranged from about 10 to 1000 ohm-cm. An entirely new approach to the preparation of experimental samples of MnO_2 was chosen by Wiley and Knight (5). Their samples were prepared by pyrolytic decomposition of chemically pure $Mn(NO_3)_2$. (A process commonly used to form the counterelectrode in tantalum capacitors). Wiley and Knight report a resistivity of about 0.1 ohm-cm for their material. In addition to the resistivity measurements by the above authors the differential thermal analysis of the MnO_2-Mn_2O_3 system carried out by Kozawa (6) offered an interpretation of the system from an entirely different point of view. His results indicated the possible existence of a low-temperature phase transition as well as the well-known high-temperature phase transition for MnO_2-Mn_2O_3 at about 580°C. Furthermore his results show a difference in the high-temperature phase transition temperature for pyrolusite which Kozawa refers to as β-MnO_2 and electrolytically formed MnO_2 which he designates γ-MnO_2. With the ample but divergent results reported in the literature the experimental work reported in this paper was, therefore, undertaken in an effort to find answers to some of the questions posed by the earlier experimental results.

Experimental

Sample preparation.—The experimental samples were produced by following the technique suggested

* Electrochemical Society Active Member.

Key words: resistivity, Seebeck coefficient, Hall coefficient.

by Wiley and Knight. Reagent grade manganous nitrate solution (50%) was pyrolized in a Pyrex test tube. The tube was filled repeatedly until a sufficiently thick layer had formed on the bottom of the tube. It was noted that the geometry of the test tube, *i.e.*, the ratio of diameter to the depth, affected the porosity of the deposit. To explore this effect material was pyrolized under various conditions by changing the geometry of the container. At the one extreme the container consisted of a flat dish which was repeatedly moistened with $Mn(NO_3)_2$ and then returned to the pyrolysis temperature. The other extreme condition was generated by carrying out the pyrolysis in a Pyrex vessel enclosed in an autoclave. This condition might be encountered on the inside of the porous structure of a tantalum capacitor. A small hole was provided in the autoclave to permit escape of the water vapor and other reaction gases. The reaction rate and the vent hole were adjusted so that only a small pressure gradient existed between the inside and the outside of the autoclave. Following the time schedule of Wiley and Knight sufficient reaction time was allowed in all cases to continue pyrolysis until the resistivity of the material became constant. The material was then cut with a carborundum saw in the shape of a rectangular parallelepiped with the approximate dimensions of 2 x 5 x 20 mm. Samples used for density measurements were mounted on a fixture and ground with 600 mesh alumina to a dimensional accuracy of about 1%. To obtain the different resistivities used in the various measurements high density ($\approx$4.7 g/cm^2) samples were baked for 16 hr in air. This period was found sufficient to establish resistivity equilibrium in all cases. Several different techniques had to be used to apply electrical contacts to the samples to accommodate the requirements of the various measurements. In the temperature range from $-50°$ to 125°C the resistivity was measured by applying small dots of silver paint to the side of the parallelepiped. These dots served as voltage probes. Silver paint was also used for the large current contacts at both ends of the sample. Between 125° and 625°C large area carbon pressure contacts held in place by tungsten springs gave reproducible and noise free results.

To measure the Seebeck coefficient the hot junction was formed by a lead point contact of about 0.1 mm^2. The cold junction consisted of a large area water-cooled lead contact. Silicone oil was used to improve the thermal coupling between the lead and the sample.

Density

The theoretical density of MnO_2 is given as $\rho = 5.026$ g/cm^3 (7). In their experiments Wiley and co-workers prepared essentially void-free MnO_2 with a density of 4.0 g/cm^3 by pyrolizing $Mn(NO_3)_2$. In an attempt to reproduce this result in our laboratory it became apparent that the shape of the reaction tube affected the resistivity and density of the end product. Repeated filling of a flat dish, *e.g.*, produced material with a density of 2.5 g/cm^3 and a resistivity of about 1 to 10 ohm-cm. If the pyrolysis was carried out at the same temperature as before but inside a standard Pyrex test tube, the density increased to about 4.0 g/cm^3 and the resistivity was reduced to 0.1 ohm-cm. The partial pressure of the reaction products over the solid was further increased by placing the Pyrex tube into a steel autoclave. The vent hole in the autoclave was adjusted to permit escape of water and other gases so as to generate only a small pressure differential inside the autoclave. Again the test tube was filled repeatedly until a sufficient amount of MnO_2 was collected at the bottom of the tube. The material pyrolyzed in the autoclave had a density of 4.7 g/cm^3 $\pm$1% and a resistivity of 0.0028 ohm-cm. From these results it appears that the partial pressure of the reaction products has a strong effect on the resistivity and the density of MnO_2. Since the complex pyrolysis process would require considerable more experimentation than could be carried out in connection with this work it was, therefore, only regarded as a tool to prepare suitable samples.

Resistivity and Activation Energy

The temperature dependence of the resistivity of MnO_2 has been investigated previously from various points of view (1-3). Our objective was to find regions of extrinsic, intrinsic, and mixed conduction in MnO_2 and Mn_2O_3 and, if posible, to identify the impurity associated with the activation energy of the resistivity. Assumptions about the structure and the stoichiometry of MnO_2 and Mn_2O_3 produced in our laboratory are based on the gravimetric and structure analysis reported by Wiley and Knight (5). As starting material for the resistivity measurements in most cases MnO_2 with a density between 4.0 and 4.7 g/cm^3 was selected. The oxygen content of the sample was gradually reduced by baking the material in air. A holding time of 30 min at the baking temperature was found to be sufficient to establish the oxygen equilibrium in the specimen as indicated by the resistivity. A family of resistivity *vs.* temperature curves generated by heating a sample (curve 1) to 450°C (curve 2), 525°C (curve 3), 540°C (curve 4), and 541°C (curve 5) is shown in Fig. 1. The temperature range of $-50°$-125°C was selected so that the temperature dependence of the resistivity could be expressed by the equation $\rho = \rho_0 \exp -\Delta E/kT$. Curve 1 was measured on the sample in the "as pyrolized" or "unbaked" condition. As the resistivity was increased through baking at successively higher temperatures the activation energy calculated from the slope of the resistivity curve went through a maximum of $\Delta E = 0.044$ eV at a room temperature resistivity of 0.5 ohm-cm. Curve 5 clearly deviates from an exponential dependence on inverse temperature. At this resistivity the impurity level seems to be exhausted, and mixed conduction arising from extrinsic plus intrinsic carriers determines the shape of the resistivity *vs.* temperature curve. For this resistivity (100 ohm-cm) Wiley and Knight give an oxygen to manganese ratio of 1.96. Further loss of oxygen by baking the sample at 542° $\pm$ 5°C results in a drastic change in structure (6), resistivity (5), and activation energy. No intermediate region could be found within the experimental accuracy of setting the baking temperature. The resistivity changes by about three orders of magnitude from 10^2 ohm-cm (MnO_2) to 10^5 ohm-cm Mn_2O_3. The activation energy for the impurity level in Mn_2O_3 as calculated from the temperature dependence of the resistivity is $\Delta E = 0.30$ eV. The two curves shown in Fig. 2 were obtained by heating the material to 542°C (6) and 545°C (7), respectively. At the low-temperature side of the graph the presence of another, much lower energy level may be noted. Measurements of the Seebeck coefficient indicated that conduction in Mn_2O_3

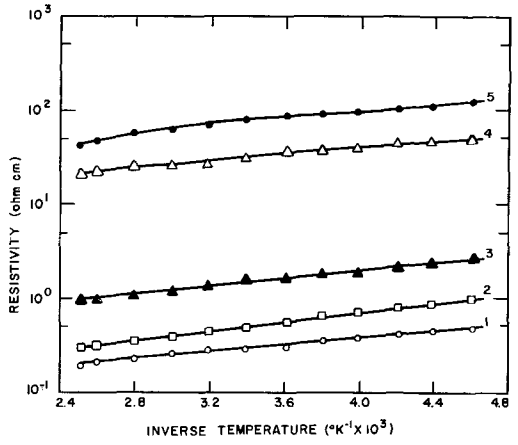

Fig. 1. Temperature dependence of the resistivity of MnO_2 for various anneal temperatures. Curve 1 represents a typical sample in the "as pyrolyzed" state. Samples 2 through 5 are heated in air at 450°, 525°, 540°, and 541°C, respectively.

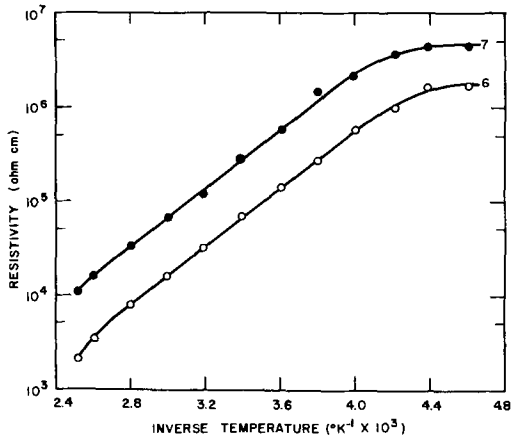

Fig. 2. Temperature dependence of the resistivity of Mn_2O_3 heated in air at 542°C, 6, and 545°C, 7.

is p-type. Apparently in Mn_2O_3 the observed impurity level is again controlled by the oxygen concentration, but in this case acting as acceptor. In the next experiment the intrinsic part of the temperature dependence of the resistivity was explored. Figure 3 shows resistivity measurements taken in the temperature region from 25° to 625°C. Material produced in the autoclave was used in this experiment. The sample had an initial resistivity of 0.0028 ohm-cm and an activation energy $\Delta E = 0.0066$ eV. The resistivity *vs.* temperature curves shown in Fig. 3 were obtained by continuously recording resistivity as a function of temperature as the sample was alternately heated and cooled. The temperature indicated on the various curves represents the maximum temperature to which the sample has been exposed. At this temperature the sample was held for 30 min to establish equilibrium before being cooled down again. The heating and cooling rate was kept linear at about 10°C/min. The slope of the high-temperature portion of the high resistivity MnO_2 sample was used to calculate the energy gap of the MnO_2 lattice $E_g = 0.37$ eV. Similarly for Mn_2O_3

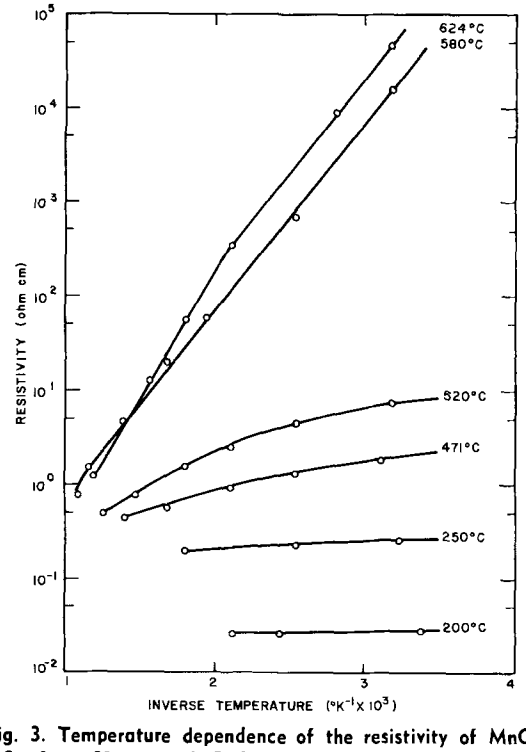

Fig. 3. Temperature dependence of the resistivity of MnO_2 and Mn_2O_3 from 23° to 650°C. The individual curves were recorded during the cooling cycle after each 30-min heat-treatment at the various temperatures indicated on the graph.

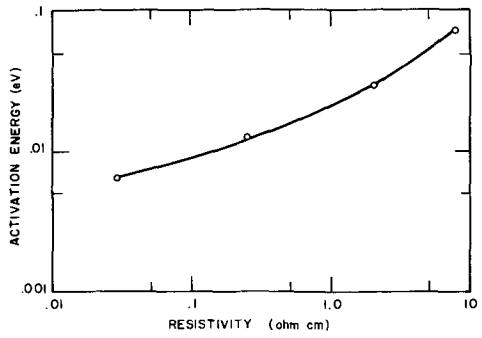

Fig. 4. Activation energy of MnO_2 as a function of the resistivity at 23°C. The activation energy was calculated from the resistivity in the temperature interval 57°-225°C.

$E_g = 1.08$ eV is found. The "growth" of the intrinsic region in Mn_2O_3 can be observed as the maximum anneal temperature of the sample is changed from 580° to 624°C (Fig. 3).

In the extrinsic-intrinsic region, a gradual increase in the activation energy as a function of resistivity is noted. This feature we believe is generally found in semiconductors. The temperature where it is observed depends on the material and the doping level. Resistivity measurements on gallium doped germanium reported by Fritzsche (8), *e.g.*, show this gradual change of the "activation energy" in the temperature region from 3° to 10°K. For every particular system a graph can be prepared which relates resistivity and activation energy in the appropriate temperature region. Hence it becomes possible to find the resistivity without knowledge of the geometry by measuring the temperature dependence of the resistance. Figure 4 shows the results for the MnO_2 system in the temperature interval 57°-225°C. Previously reported measurements which have been carried out over this temperature range roughly follow this relationship, *i.e.*, higher resistivity samples also tended to have higher activation energy.

It is interesting to note the close agreement between the high resistivity MnO_2 sample shown in Fig. 1 and the equivalent sample in Fig. 3. Both are of the order of 10 ohm-cm although one sample had an initial resistivity of 0.0028 ohm-cm and the other an initial resistivity of 0.2 ohm-cm.

In addition to the positive resistivity changes generated by heating MnO_2 in air at relatively high temperature a negative change of resistivity was consistently observed during the first heating cycle of a virginal sample to a temperature of about 120°C. This decrease in the resistivity of MnO_2 is usually of the order of 5-10% and is accompanied by a decrease in the activation energy as well.

Results of differential thermal analysis of the MnO_2-Mn_2O_3 system reported by Kozawa (6) indicate the possibility of a phase change at this temperature.

Hall Mobility

Results of Hall measurements reported by Das (9) established MnO_2 as an n-type semiconductor with a Hall mobility of the order of 10 cm²/V sec. Our measurements were carried out on MnO_2 samples with resistivities ranging from 0.23 to 115 ohm-cm. The temperature was kept constant at 23°C. The magnetic field was 1900 gauss. Results are summarized in Table I. The strong dependence of the Hall mobility on the re-

Table I. Hall coefficient of MnO_2 as a function of anneal temperature

Hall coefficient cm³/coul	Resistivity, ohm-cm	Hall mobility, cm²/V sec	Anneal temp, °C
−0.95	0.23	4.2	250
−2.6	0.63	4.1	350
−10.2	0.70	14.5	475
-2.4×10^3	115	21.0	540

sistivity leads to the conclusion that impurity scattering is most likely the dominant scattering mechanism in this temperature range. From the results we can estimate the intrinsic carrier concentrations. Using $\rho_i = (2\ n_i e_i \mu_H)^{-1}$ where ρ_i, n_i, e_i, and μ_H are the intrinsic resistivity, carrier concentration, electronic charge, and Hall mobility, respectively, we find $n_i = 8 \times 10^{14}$ cm^{-3}.

Voltage Current Characteristics

Bhide and Damle in their extensive work (4) with MnO_2 measured the V-I characteristic of naturally occurring pyrolusite. Their results showed an exponential relationship $I = C \exp. V$. In our measurement, as before, the material was prepared by pyrolysis of $Mn(NO_3)_2$. It was found that pressure contacts of tungsten or carbon lead to an exponential V-I characteristic as observed by Bhide and Damle.

However, the material showed ohmic behavior if large area silver paint contacts were applied to the samples. Figure 5 shows the results of these measurements. The electric field was varied from 10 mV/cm to 100 V/cm. The various curves shown in Fig. 5 represent samples of different resistivities obtained, as before, by baking in air. The deviation from linearity observed on one of the samples at fields higher than 20 V/cm is probably due to heating of the sample. Since the current density is considerably higher for the low-resistivity samples, it seems possible that this condition, compounded by an inhomogeneity in the material could give rise to undesirable heating effects or other nonohmic behavior of reversible and irreversible nature.

Seebeck Coefficient

Since the measurement of the Hall coefficient proved to be experimentally quite difficult for the high resistivity Mn_2O_3 material, the Seebeck coefficient and resistivity were measured on the samples covering this range of resistivities to establish the sign of the carrier and also to define better the temperature regions of extrinsic, intrinsic and mixed conduction. In Fig. 6 the Seebeck voltage is graphed as a function of the temperature differential of MnO_2 and Mn_2O_3. The results were obtained by holding the cold junction constant at 14°C while the hot junction was varied from 14° to 125°C. Trace 1 is typical for MnO_2 in the virginal state (as pyrolyzed). Traces 2 through 5 were measured on MnO_2 after heating in air to 525°, 535°, 540°, and 541°C, respectively. This group represents MnO_2 with decreasing oxygen content down to a ratio of oxygen to manganese of about 1.96. Traces 6 and 7 are intrinsic and high resistivity Mn_2O_3 obtained at baking temperatures

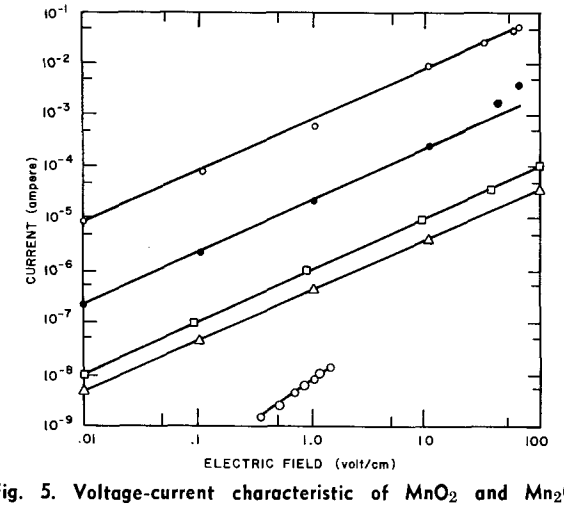

Fig. 5. Voltage-current characteristic of MnO_2 and Mn_2O_3. Curves 1, 2, and 3 are MnO_2 with resistivities of 0.4, 0.7, and 100 ohm-cm; curve 4 is typical for Mn_2O_3 with a resistivity of 10^5 ohm-cm. The short piece of V-I curve at the bottom of the graph shows a typical result of an earlier investigation (4).

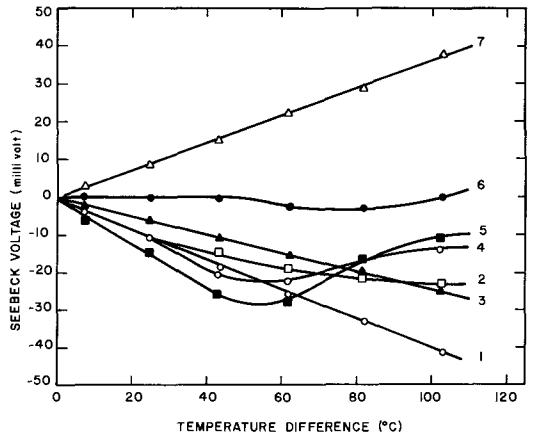

Fig. 6. The Seebeck voltage of MnO_2 and Mn_2O_3 in the temperature interval 14°-125°C. Curve 1 is typical for MnO_2 as pyrolyzed; curves 2 through 5 are obtained by heating MnO_2 at 525°, 535°, 540°, and 541°C. Curves 6 and 7 are Mn_2O_3 obtained by heat-treatment of MnO_2 at 542° and 545°C, respectively.

of 542° and 545°C, respectively. We note that the Seebeck coefficient reaches a maximum of −0.6 mV/°C in MnO_2 with a room temperature resistivity of about 50 ohm-cm. The Seebeck coefficient goes to zero at about 70°C and then turns positive in the region dominated by intrinsic conduction. From this one might conclude that the hole mobility is equal or greater than the electron mobility as has been observed in other semiconductors. Trace 2 and 3 represent an intermediate condition which does not seem to fit the over-all pattern. It seems possible that inhomogeneity of the oxygen concentration at the surface of the material gave rise to the anomalous behavior. Trace 6 indicates essentially zero Seebeck coefficient over the entire temperature range. From resistivity measurements we conclude that this material is already Mn_2O_3. Further baking at 545°C clearly establishes the p-type conduction shown in trace 7 with a Seebeck coefficient of +0.37 mV/°C.

Discussion

Wiley and co-workers have shown that high density low resistivity MnO_2 can be produced by pyrolysis of manganous nitrate. The material produced in the autoclave in connection with our work reinforces their findings. By varying the geometry of the reaction vessel we were able to observe extreme conditions which might be considered analogous to the condition commonly encountered in the manufacture of tantalum capacitors. Pyrolysis in the autoclave simulates the conditions found on the inside of the porous structure of a capacitor; pyrolysis in the flat dish relates to the condition on the outside skin. The many orders of magnitude of difference in the resistivity found in our measurements are expected to have a strong effect on the dissipation factor and the frequency response of such a device. Through the measurements of the electrical resistivity as a function of temperature it became evident that the activation energy is a sensitive tool suitable to distinguish between MnO_2 and Mn_2O_3 as long as the appropriate temperature range is selected. In the region of mixed conduction, *i.e.*, near room temperature and above, the variation of the resistivity *vs.* temperature slope might be helpful in finding the resistivity without knowledge of the geometry; this is a useful technique to monitor the pyrolysis process. From the measurements of the resistivity of MnO_2 in the extrinsic region it appears that loss of oxygen through baking gradually creates a sufficient number of vacancies in the lattice until it shifts to the Mn_2O_3 configuration. We find that, while the resistivity increases, the Hall mobility also shows an increase. This might be an indication that oxygen acting as an impurity is the major contributing factor to the scatter-

ing process in this temperature region. The activation energy $\Delta E = 0.044$ eV found in MnO_2 is tentatively ascribed to oxygen acting as a donor. The acceptor level found in Mn_2O_3 with activation energy $\Delta E = 0.30$ eV also was found to be controlled by the oxygen concentration. However, since further reduction of Mn_2O_3 finally leads to MnO with low p-type resistivity one might be inclined to associate this level with manganese vacancies. Further work in this area is needed to answer these questions. The apparent difference between the ohmic V-I characteristic of MnO_2 measured in this laboratory and the exponential dependence found for pyrolusite by Bhide *et al.* are most likely due to the large area silver contacts used in our experiment. In addition, however, one must consider the possibility that naturally occurring pyrolusite has different electrical properties than the MnO_2 prepared by pyrolysis of $Mn(NO_3)_2$ solution. Kozawa in his work on differential thermal analysis of pyrolusite and electrolytically prepared MnO_2 finds that pyrolusite has its phase transitions at a higher temperature than the MnO_2 prepared by electrolysis. The MnO_2-Mn_2O_3 phase transition temperature (545°C) found by Wiley using the gravimetric technique is in agreement with Kozawa's findings for electrolytic MnO_2. Since the transition temperature established by the resistivity measurement in this laboratory are also in agreement with Kozawa's results we are inclined to follow the suggestion of Kozawa to treat pyrolusite as a separate phase of MnO_2 produced by other than natural means. Our measurements of the Seebeck coefficient are essentially in agreement with the results published earlier by Das (9). Since the measurements reported here cover a large range of resistivity for MnO_2 as well as Mn_2O_3 the results can be used to assign temperature regions where extrinsic, intrinsic, and mixed conduction are to be found.

Although the foregoing information helps to clarify many aspects of the published information on the resistivity and activation energy of MnO_2 and Mn_2O_3, more work is needed to establish without doubt the origin of the impurity levels in MnO_2 and Mn_2O_3.

Acknowledgments

It is a pleasure to acknowledge the help and advice of Dr. J. Piper, of Union Carbide Corporation, and of Dr. E. Fagen and Mr. R. Neale, of Energy Conversion Devices, Inc., in the preparation of this manuscript. The author also wishes to acknowledge gratefully the help of Mrs. Ruth Skinner in the preparation of the material and in carrying out many of the electrical measurements.

Anodization of Tantalum Over the Temperature Range 0° to 250°C

R. J. Dreiner* and T. B. Tripp

Research and Development Center, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Tantalum was anodized at constant current in an aqueous electrolyte over the temperature range 0°-250°C. The voltage build-up was linear up to a voltage at which crystallization of the oxide occurred. The "crystallization voltage" decreased with increasing temperature. The change of the voltage build-up rates (dV/dt) with temperature was not compatible with the single barrier law for high field ionic conduction. In spite of the extended temperature range, it was not possible to distinguish between ionic current (i)-field (F) relations of the form $\ln i \propto F^{1/2}$ and $\ln i \propto F + F^2$. Current efficiencies were determined from charge and optical film thickness. The current efficiencies were (a) essentially constant up to a formation temperature of about 170°C and (b) decreased by about 30% between 170° and 250°C. Capacitance and loss angle of "equal charge" films increased with anodization temperatures higher than about 180°C. Oxygen dissolution in the tantalum substrate was suggested as the likely cause.

In recent literature (1-6) the three equations

$$i = i_1 \exp [(q\,a\,F - W_1)/kT] \quad [1]$$

$$i = i_2 \exp [(\gamma\sqrt{F} - W_2)/kT] \quad [2]$$

$$i = i_3 \exp [(q\,\alpha + \beta F)F - W_3)/kT] \quad [3]$$

have been applied to describe the field, F, dependence of the ionic current, i, during anodic oxide growth. Equation [1] expresses that a single barrier of width, $2a$, and height, W, is rate determining. The charge on the moving ion is q and the action of the electric field on the ion reduces the barrier height by $q \cdot a \cdot F$. The model (2) that the potential energy of an ion due to the applied field is modified by the coulomb attraction of large trapping centers within the oxide, leads to Eq. [2], which is similar to the Schottky relation for the field supported emission of electrons from metals. The exponent of the third equation is quadratic in the field. Christov and Ikonopisov (7) showed that the quadratic term arises if it is assumed that the applied

* Electrochemical Society Active Member.

field does not only modify the barrier height, but also shifts its position.

Combining Eq. [1], [2], or [3] with Faraday's law

$$d = \eta\lambda \int_o^t i^* dt \qquad [4]$$

yields the following relations for the voltage build-up rate (dV/dt) during constant current anodization

$$\frac{dV}{dt} = \eta\lambda i^* \left[\frac{W_1}{qa} + \frac{k \ln (i^*/i_1)}{qa} \cdot T \right] \qquad [5]$$

$$\frac{dV}{dt} = \eta\lambda i^* \left[\frac{W_2}{\gamma} + \frac{k \ln (i^*/i_2)}{\gamma} \cdot T \right] \qquad [6]$$

$$\frac{dV}{dt} = \eta\lambda i^* \left[-\frac{\alpha}{2\beta} \pm \frac{W_3 + kT \ln (i^*/i_3)}{\alpha\beta} \right] \qquad [7]$$

where d is the oxide film thickness. λ is equal to the ratio of the equivalent weight of tantalum oxide over the product of the Faraday number, the density of Ta_2O_5, and the area of the sample. The ionic current, i, and the external current, i^* are related as $i = \eta i^*$. The current efficiency, η, has been assumed to be independent of time, but might depend on temperature. The current efficiency has been neglected in the log terms. This can readily be done since the pre-exponential terms, i_1, i_2, i_3, which are of the order of 10^8 A/cm^2 (1, 2, 5), are much larger than i^* and because the current efficiency is not affected strongly enough by temperature as will be shown.

Plots of (dV/dt) and the square root of (dV/dt) *vs.* temperature should allow a distinction between the single barrier relation or the Schottky type Eq. [2]. No such straightforward evaluation is possible if Eq. [3] is valid. The exponents of Eq. [1] and [3] are parts of a series expansion of the exponent of Eq. [2], as shown in the Appendix. It is, therefore, rather difficult to distinguish between these three relations, which will become clear from the following.

The investigation of the high field ionic conduction during the anodization of tantalum in aqueous electrolytes is restricted to a limited field range and, if no special equipment is used, to a limited temperature range as well. The field changes by only about 30% if, at constant temperature, the formation current density is varied from 1 μA/cm^2 to 10 mA/cm^2. The upper current limit more or less assures that no excessive or uncontrolled heating of the sample occurs, and the lower limit is essentially set by time. It takes, for instance, about 10^3 sec to grow an oxide layer of 5Å on tantalum if the formation current is 1 μA/cm^2. Furthermore, at these low current levels the ionic current is not necessarily equal to the externally applied one, since the electronic current through the oxide may become an appreciable fraction of the total. Normally, the temperature range is set by the freezing and boiling points of the aqueous electrolyte, which is used when one wants to minimize incorporations of anions in the anodic oxide film (8). The formation field changes, again only by about 30%, if the temperature is varied between 0° and 100°C during anodizations at a constant current.

Individual values of the voltage build-up rate (dV/dt) can be determined quite accurately from constant current anodizations, but the scatter from sample to sample is such that it is almost impossible to make the necessary distinction in the trend of (dV/dt) over the temperature range 0°-100°C. The following should give an indication of the experimental accuracy needed to distinguish, *e.g.*, between Eq. [1] and [3]. Values for (dV/dt) were calculated at 10°C intervals between 0° and 100°C using Eq. [3] and the constants reported by Young (1). An equation of the form $(dV/dt) = a + bT$ was fitted to these points by least square analysis and (dV/dt) values were determined over the temperature range 0°-250°C, using this linear relationship. The data from this linear approximation are compared with values predicted by Eq. [3] and Young's constants in Table I. The percentage column in Table I is an indication of the experimental accuracy needed in order to distinguish between the linear approximation, which would mean that Eq. [1] is valid and Eq. [3]. Between 0° and 100°C, the precision has to be better than 1%, and to our knowledge this has not been achieved with voltage build-up measurements.

Table I. Comparison of calculated voltage build-up rates

Temp, °C	A (dV/dt)* in V/sec	B (dV/dt)** in V/sec	(A-B)·100/A in %
0	0.372	0.370	0.5
50	0.328	0.329	0.3
100	0.290	0.288	0.7
150	0.257	0.248	3.5

The results of a study by Draper and Jacobs (5) are of interest in connection with this discussion. These authors anodized Ta in 0.1*N* H_2SO_4 [0°-100°C], 100% H_2SO_4 [2°-50°C], and 40% H_2SO_4 [−65°-90°C] over the temperature ranges indicated in the brackets. They found (*i*) agreement with the single barrier theory, Eq. [1], when evaluating the data obtained from experiments over the smaller temperature ranges and (*ii*) deviations from Eq. [1] over the larger temperature range of about 150°C. The latter result could have been influenced by anion incorporation which is known to depend on formation temperature and electrolyte concentration.

In this work, the temperature range of anodizing tantalum in dilute aqueous electrolytes was extended up to 250°C by using an autoclave. In addition to reporting new data, which were obtained from the anodizations of tantalum in an aqueous electrolyte above 100°C, an attempt is made to distinguish between the ionic current-field relations.

Experimental

Samples were cut from 99.9% pure 10 mil tantalum sheet, and 70 mil diameter tantalum wire was spot welded to the tabs. The foils were degreased, electropolished in a 9:1 by volume mixture of concentrated nitric acid and HF, and then vacuum annealed at 2100°C, $<10^{-4}$ Torr. Just prior to use, each sample was immersed for 5 sec in 48% HF and thoroughly rinsed with distilled water.

The anodization cell was constructed from 303 stainless steel, and its configuration is shown schematically in Fig. 1. Electrical contact to the foil was made with

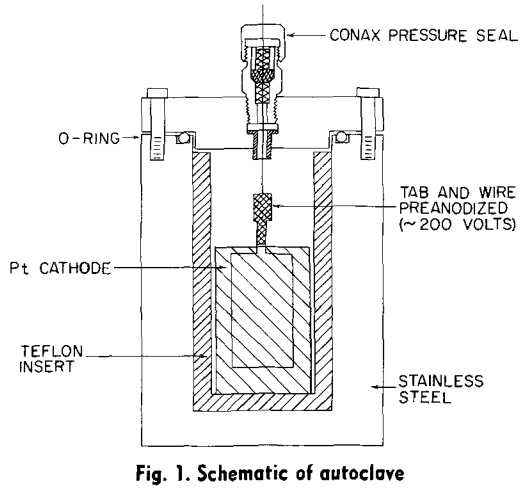

Fig. 1. Schematic of autoclave

the tantalum wire, which passed through a Connex PL power lead pressure seal. This seal is so designed that the wire is only in contact with Teflon and ceramic sleeves, thus assuring good electrical insulation from the cell. The tab of the foil and the wire were preanodized to 200V or higher if necessary. The 0.01M K_2SO_4 electrolyte was contained in a Teflon cup and was stirred with a Teflon covered magnetic stirring bar. The cathode was platinum foil. The cell was placed in a temperature-controlled, vertical tube furnace and rested on a stirring hot plate. The temperature of the cell was measured with a Chromel-alumel thermocouple, which was inserted into a small diameter hole drilled into the wall of the cell. The temperature of the system was at equilibrium for at least 15 min prior to a formation. As indicated by the thermocouple, the temperature fluctuated less than 1° during this period and the subsequent anodization.

All anodizations were carried out at a constant current density of 1.0 mA/cm^2. The voltage build-up was monitored with a Keithley 610-A Electrometer combined with an Esterline-Angus Recorder. Capacitance and loss angle were measured at 120 cps in a 40 w/o (weight per cent) H_2SO_4 solution at 25°C. The time of measurement after anodization varied from ½ to 3 hr depending on the anodization temperature and the corresponding time necessary to cool the cell to room temperature. The thickness and refractive index of the anodic oxide films were estimated by ellipsometry using the mercury line of wavelength 5461Å.

Results

A typical voltage-time curve, which was recorded during a constant current anodization at 214°C, is shown in Fig. 2. As seen, the voltage rose linearly with time to a peak voltage, V^*, then declined by ΔV^* to a minimum and after that increased again to a higher plateau. This higher voltage plateau was associated with film breakdown, since oscillations were observed in the voltage time recording. The period between the moment when the voltage reached V^* and the time when the potential again attained this value, during the second voltage rise, was designated t^*. Some values for V^*, t^* and ΔV^* are compiled in Table II. No data are listed for anodizations at temperatures below 100°C, since severe breakdowns occurred in the oxide film at the air-electrolyte interface. It was not possible to preanodize the tabs of the tantalum samples to sufficiently high voltages and, therefore, the breakdowns could not be prevented.

Similar voltage time curves as in Fig. 2 have been reported by Lakhiani and Shreir (9), who investigated the anodic oxidation of niobium over the temperature range 25°-95°C. These authors found, using electron diffraction, that films formed at 90°C to the lower voltage plateau or beyond were crystalline. Furthermore, electron micrographs revealed (*i*) that the niobium oxide films started to crack at the peak voltage V^* and (*ii*) that crystalline Nb_2O_5 appeared underneath the amorphous oxide on further anodization.

Table II. Effect of formation temperature on the peak voltage, V^*, which is related to the onset of oxide crystallization. See Fig. 2 for explanation of t^* and ΔV^*.

The tantalum samples, which had been anodized to the start of the lower voltage plateau, did not exhibit the usual bright and uniform interference colors over the whole sample area. Inspection under the microscope indicated small regions which looked similar to the ones described by Vermilyea (10) as "crystalline areas." These crystalline regions covered the whole area of samples which had been formed beyond the lower voltage plateau. Therefore, it is thought that the lower plateau is caused by the crystallization of the oxide film and that crystalline tantalum oxide is formed when samples are anodized to higher voltages.

Most of the tantalum samples were anodized by passing a constant charge of 3.33 coul, which corresponded to a formation time of 180 sec. Within this period, the potential rose to about 36V during formations at 250°C. Even at this temperature, this is well below the peak voltage V^*, see Table II, which is related to the onset of crystallization. To limit the formation times to 180 sec assured that no or only very little crystallization occurred at the higher formation temperatures during this time period.

The capacitances and loss angles of the samples were measured at 120 Hz and are plotted *vs.* the formation temperature in Fig. 3. As seen, there is a significant increase in the dielectric parameters of films grown

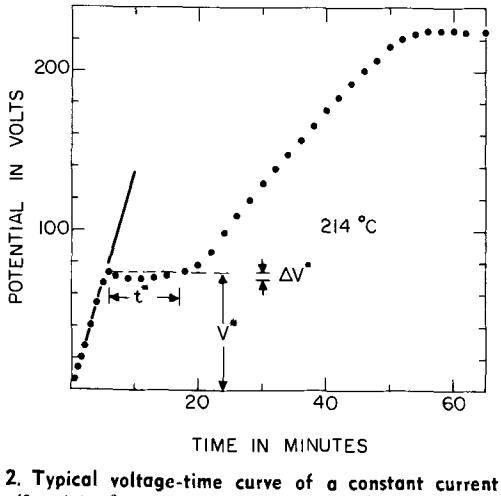

Fig. 2. Typical voltage-time curve of a constant current anodization (1 mA/cm^2) of tantalum at 214°C in 0.01M K_2SO_4 electrolyte.

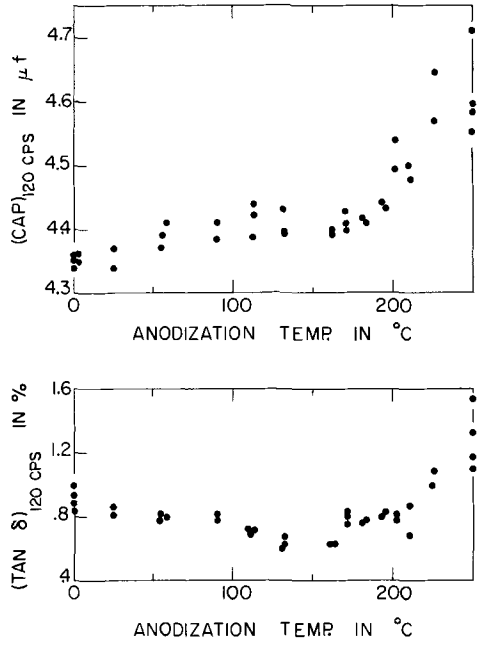

Fig. 3. Variation of capacitance and loss angle with anodization temperature. Measurements were made in 40% H_2SO_4 electrolyte at 25°C.

above about 180°C. It has been shown by Smyth *et al.* (11) (*i*) that the tantalum substrate extracts oxygen from the anodic oxide film when annealed at temperatures of 200°C and higher, and (*ii*) that the oxygen deficient layer adjacent to the tantalum substrate causes capacitance and loss angle to increase. The anodic growth of tantalum oxide occurs at the metal-oxide and oxide-electrolyte interfaces, since both the oxygen and metal ions are mobile (12). The dissolution of oxygen in the tantalum substrate during high-temperature anodizations should result in a lower current efficiency, but not cause an oxygen deficient oxide layer, as the oxygen is replenished by the formation process. However, the anodization cell did not cool down rapidly after formations had been terminated, and maybe the sample remained sufficiently long at a high enough temperature for some additional oxygen to dissolve in the tantalum substrate. This would cause an oxygen deficient layer located at the tantalum-tantalum oxide interface and thus give rise to higher capacitances and loss angles.

Voltage build-up rates (dV/dt) were determined from least square lines through voltage-time data evaluated from the recorder plots at 10-sec intervals over the first 180 sec of the formations. The variation of the voltage build-up rates with temperature is shown in Fig. 4. The data would be very well represented by a straight line over the first 100°C, but deviations from linearity are apparent when the fit is made over the entire temperature range. This then excludes Eq. [1], the single barrier relation. The solid line in Fig. 4 was calculated using Young's (1) data, which were obtained from runs at various current densities over the temperature range 0°-94°C. Young (1) found it justified to take the current efficiency as being equal to unity. The excellent agreement between the extrapolated curve of Young's data and our experimental results might, therefore, suggest that the current efficiency was unity over the whole temperature range 0°-250°C. However, this was not necessarily the case, as will be shown later.

We have plotted the square root of the voltage build-up rate *vs.* the formation temperature and from the least square analysis we obtained.

$$\sqrt{dV/dt} = (0.786 \pm 0.006) - (0.660 \pm 0.007)10^{-3}T \quad [8]$$

with T in °K. The correlation coefficient, which is one for a perfect linear relation, was 0.997. From the intercept at $T = 0$, we calculated 0.33 x 10^4 $(V/cm)^{1/2}$ for the ratio (W_2/γ), which compares very favorably with 0.335 x 10^4 $(V/cm)^{1/2}$ as reported by Young and Zobel (2). Hence, the data are represented very well by the Schottky-type Eq. [2]. On the other hand, the results are also in very good agreement with Eq. [3], as seen by the excellent fit of the calculated curve to the experimental data in Fig. 4. Thus, we were unable to distinguish between the ionic current field relations 2 and 3 in spite of the extended temperature range.

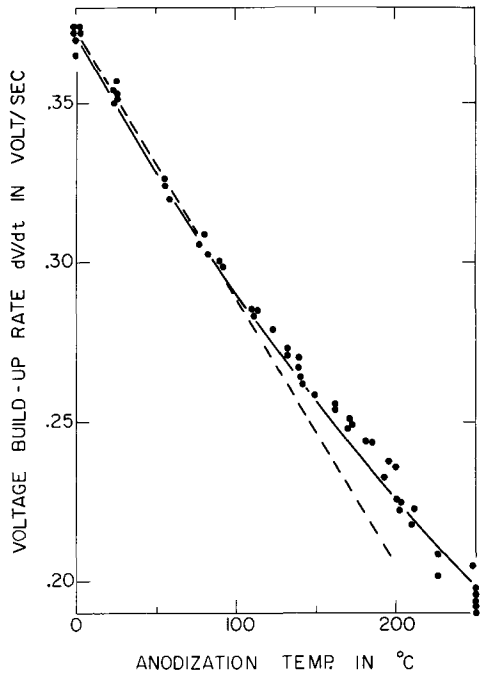

Fig. 4. Change in voltage build-up rate *(dV/dt)* with anodization temperature. Solid line was calculated using quadratic relation and Young's (1) data. Dashed line is least square fit to the 0°-100°C data.

The optical film thicknesses were determined assuming a homogeneous oxide layer from ellipsometer measurements, which were made under two angles of incidence. Results are summarized in Table III for a sample anodized at 202°C. The computer determined approximate values of the refractive index and the film thickness from analyzer and polarizer readings, designated (exp.) in Table III. Next, the exact analyzer and polarizer positions (calc. in table) were calculated using the refractive index and the film thickness previously determined. Then, the computer tried to minimize the differences (*a*) between the film thickness obtained from different angles of incidence and (*b*) between the experimental and calculated analyzer and polarizer positions. For the case demonstrated in Table III, the refractive index of 2.55 and the average film thickness of 891Å were selected.

Film thickness and refractive indices, obtained in this way, were plotted *vs.* anodization temperatures in Fig. 5 and 6. Both quantities are quite independent of anodization temperature up to about 170°C, and over this range the refractive index compares well with the one reported by Young (14). Above 170°C, the thickness of the "equal charge" films decreased and the refractive index increased. The colors of the "equal charge" films were compared with a color gauge con-

sisting of tantalum samples, which had been anodized to different voltages (in steps of 5V) at 34°C. The color variation between films formed at room temperature and at 250°C was small and corresponded to a potential difference of about 5V. The optical path, the product of thickness times refractive index, should, therefore, be approximately the same. This is the case as may be estimated from Fig. 5 and 6.

The rise of the refractive index with anodization temperature is not understood. Masing *et al.* (13) reported that the index increased by about 0.06% per 10°C rise of formation temperature. This was observed over the range 0°-100°C. The effect is too small to explain the steep rise of the refractive index of about 180°C, Fig. 6. Values for the index of some crystalline modifications of Ta_2O_5 are quoted by Young (14), and none exceed 2.37. Hence, the increase of the refractive index is unlikely to have been caused by some crystallization of the oxide, which might have occurred during higher temperature anodizations without affecting the voltage build-up. Regardless of anodization temperature, the same optical constants of the tantalum substrate were used for the evaluation of the ellipsometric data. It was speculated that these parameters were not true constants over the whole temperature range, but the following test indicated otherwise. Using the same optical constants for the substrate, the average optical thickness of four films anodized at room temperature remained unchanged after annealing in air at 200°C for 1 hr and after an additional 1-hr annealing in air at 300°C.

Thinner films and, therefore, lower current efficiencies are caused by oxygen dissolution in Ta substrate as has been discussed earlier. Current efficiencies (η) were calculated from Eq. [4] and are plotted *vs.* formation temperature in Fig. 7. It was assumed that the film density was uniform and independent of tempera-

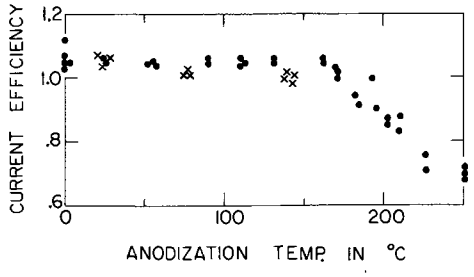

Fig. 7. Variation of current efficiency with anodization temperature of equal 3.33 coul charge (•) and 90V (x) formations.

ture. The efficiencies were approximately constant up to about 170°C. The average value was 1.04. A value larger than unity is partially due to the fact that the optical thickness includes the air-oxide film. Furthermore, the density (here 7.93 g/cm^3) (14) and sample area enters into the calculations of η and their combined uncertainty is hardly less than 4%.

The dielectric constant was calculated from optical thicknesses and capacitances and, as seen from Fig. 8, its value dropped drastically above anodization temperatures of 180°C.

The temperature dependence of the voltage build-up rates (dV/dt) has to be adjusted if the current efficiencies vary with temperature. This was done and Fig. 9 shows that up to ~170°C, the produce of voltage build-up rate times reciprocal current efficiency is not

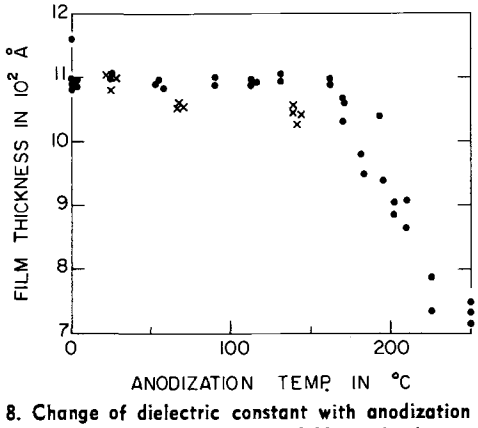

Fig. 8. Change of dielectric constant with anodization temperature. Oxide films formed to equal 3.33 coul charge (•) and 90V (x).

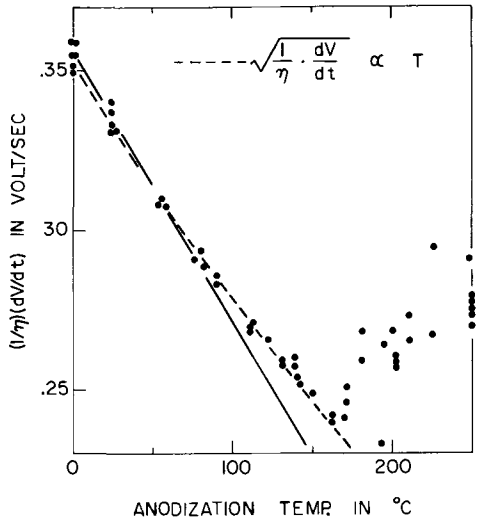

Fig. 9. Change of the adjusted voltage build-up rate $(1/\eta)(dV/dt)$ with anodization temperature. (η) is the current efficiency. Solid line is a linear approximation through the low-temperature points.

a linear function of anodization temperature. The broken line was calculated from the equation

$$\sqrt{(1/\eta)\,(dV/dt} = (0.770 \pm 0.066) - (0.646 \pm 0.099) \cdot 10^3 \cdot T \quad [9]$$

which was obtained from least square analysis. T is in degrees Kelvin. Equation [9] indicates that the Schottky-type current field relation is valid over the range 0°-~170°C. However, as shown in the Appendix, the difference between relations [2] and [3] is rather small and, therefore, the data are equally well represented by the current-field relation of which the exponent is quadratic in the field. The increase of the adjusted voltage build-up rates $(1/\eta)\,(dV/dt)$ with anodization temperatures above about 170°C implies that the formation field rose with temperature. It is not known why this should be the case.

Summary

Tantalum was anodized at a constant current of 1 mA/cm² in an aqueous electrolyte over the temperature range 0° to 250°C. The initial voltage build-up was linear. The linear range was limited essentially by crystallization of the oxide film, which occurred at lower voltages as the temperature increased. The change of the voltage build-up rates (dV/dt) with temperature was not compatible with the single barrier law for high field ionic conduction. In spite of the extended temperature range, it was not possible to distinguish between ionic current (i)—field F relations of the form $\ln i \propto F^{1/2}$ and $\ln i \propto F + F^2$. A reason for this was discussed. However, a recent publication by Dignam and Gibbs (15) showed (i) that there is extensive theoretical justification for the quadratic field term and (ii) that a statistical analysis of available experimental data arrived at a smallest standard deviation when the quadratic field term was included.

Current efficiencies were determined from charge and optical film thickness. The current efficiencies were (a) essentially constant up to a formation temperature of about 170°C and (b) decreased by about 30% between 170° and 250°C.

Capacitance and loss angle of "equal charge" films increased with formation temperatures higher than about 180°C. Oxygen dissolution in the tantalum substrate was suggested as the likely cause.

Acknowledgments

The authors gratefully acknowledge the contributions of Dr. M. Ghezzo and Mr. E. Burdick with respect to the ellipsometric measurements. Dr. Ghezzo set up the computer program for the evaluation.

APPENDIX

Expanding the square root term in the exponent of Eq. [2] and neglecting higher terms than the cubic one yields

$$F^{1/2} = F_o^{1/2} + \frac{1}{2} F_o^{-1/2} (F - F_o) - \frac{1}{8} F_o^{-3/2} (F - F_o)^2 + \frac{1}{16} F_o^{-5/2} (F - F_o)^3$$

Let the first three terms on the right side be $f(F)$. The error is of the order of the third term if $F^{1/2}$ is replaced by $f(F)$ and the relative error is

$$[F^{1/2} - f(F)]/F_o^{1/2} \simeq (F - F_o)^3/16\, F_o^3$$

The voltage build-up rate (dV/dt) is directly proportional to the field during constant current anodizations. With the following values from Fig. 4 ($T = 0$°C, $dV/dt = 0.373$ V/sec and $T = 125$°C, $dV/dt = 0.273$ V/sec) one obtains for the relative error: 0.31×10^{-2}. This means the maximum error is about 0.3% if, over the whole temperature range of 250°C, the square root term is replaced by a quadratic relation. Thus, within this limit, Eq. [2] can be expressed in the form of Eq. [3], with the constants adjusted accordingly.

The Nucleation, Growth, and Structure of Electroless Copper Deposits

Richard Sard*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

An electron microscopic investigation has revealed that the electroless deposition of copper occurs by repeated three-dimensional nucleation at catalytic sites on a substrate. The nature of the catalytic sites formed by immersion in the standard stannous and palladium chloride solutions was observed and found to influence the structure of the subsequently deposited metal. Initially, copper nuclei about 25Å in diameter form aggregates an order of magnitude larger. As the autocatalytic reduction reaction continues the aggregates increase in size until they become energetically unstable; then recrystallization occurs. The resulting continuous copper films exhibit a heterogeneous microstructure with grain size variations of more than an order of magnitude and also numerous twin faults.

There exists at present a considerable and rapidly growing interest in the electroless deposition of metallic films onto nonconducting substrates. Although many chemical systems for metal deposition have been developed (1), relatively little is known about the mechanisms which govern the behavior of these complex systems. Recently, however, some progress toward this goal has been made by Okinaka (2) and Paunovic (3) who employed electrochemical methods to study the kinetics of the electroless copper plating reaction.

An important property of electroless systems is their ability to deposit metals selectively. This property, which depends critically on the structure of the sensitized substrate, has been demonstrated by Sharp (4), who desensitized portions of a surface with u.v. radiation, and also by Turner (5), who used a printing technique to apply a sensitizer selectively.

A fundamental aspect of this type of deposition, about which very little is known, concerns the basic structural mechanisms responsible for the nucleation and growth of metallic films. These factors are important because they will ultimately determine the properties and consequently the technological usefulness of the films. Interest in magnetic thin films has led to several studies dealing with the structure of electroless nickel (6-8) and cobalt (9-12) deposits that were chemically reduced from solutions containing hypophosphite. However, there appears to be virtually no data available on the growth and structure of other electroless deposits including copper, which is of considerable technological importance. Also, there is very little direct evidence (6, 9) concerning the structures which exist prior to the formation of a continuous metal deposit. One reason for this lack of direct evidence is that electron microscopes capable of resolving information on the order of 10Å are needed. While such instruments are available, they have not yet been employed to study the process of electroless deposition.

The present study has been primarily concerned with the nucleation and growth of electroless copper deposits. However, some of the results, particularly those pertaining to the sensitization and activation treatments which precede metal deposition, are undoubtedly of a more general nature and can therefore be applied to other electroless deposition systems.

Experimental

Four aspects of the over-all process of electroless deposition were investigated: first, the influence of the substrate; second, the sensitization of the substrate with stannous chloride; third, the activation of the sensitized substrate with palladium chloride; finally, the deposition of a metallic copper film. The formulations of the various solutions are given in Table I. Initially, solutions were prepared using distilled water of conventional purity. Subsequently, however, deposition experiments were carried out with a higher regard for purity. For example, these experiments were conducted in a laminar flow work station and solutions were prepared with water[1] that was twice distilled in a quartz apparatus. The water used for the rinsing operations after each stage of the process was of the same type used for solution preparation. Reagent grade chemicals were used without further purification.

The electron microscopic techniques which were used to investigate the structures present at each

[1] An analysis carried out by D. L. Malm, of Bell Telephone Laboratories, using spark source mass spectroscopy indicated that this water contained from 1 to 10 atomic ppm of total residual impurities.

Table I. Solution formulations

Constituents	Quantity	Concentration
Sensitization*		
A. $SnCl_2 \cdot 2H_2O$	16 g/l	0.07 M
Conc. HCl	30 ml/l	0.82 M
B. $SnCl_2 \cdot 2H_2O$	30 g/l	0.13 M
Conc. HCl	10 ml/l	0.27 M
Activation*		
A. $PdCl_2$	0.1 g/l	0.0006 M
Conc. HCl	8 ml/l	0.22 M
B. $PdCl_2$	0.75 g/l	0.004 M
Conc. HCl	10 ml/l	0.27 M
Electroless Copper		
A. Saubestre's solution (22)	170 g/l	0.60 M
$KNaC_4H_4O_6 \cdot 4H_2O$ (Rochelle salt)	50 g/l	1.25 M
NaOH	35 g/l	0.14 M
$CuSO_4 \cdot 5H_2O$	30 g/l	0.28 M
EDTA	10 g/l	0.03 M

stage of the process were bright-field and dark-field imaging combined with selected-area electron diffraction, as well as direct carbon or two-stage surface replicas shadowed with a Pt-Pd alloy. These investigations were carried out with a Siemens Elmiskop instrument operated at 100 kV.

In order to study the initial stages of the process, prior to the formation of a continuous, self-supporting deposit, an electron-transparent substrate is required. Evaporated carbon films, about 200 to 400Å thick, were used, and suitable substrates were prepared by conventional techniques employing either plastic-coated microscope grids or glass slides as the original substrate materials.

Continuous copper films, 500-1000Å thick, were deposited onto glass slides, evaporated carbon, Kapton (a polyimide film), and freshly cleaved mica substrates. The structures of these films were studied by the electron microscopic techniques mentioned previously, which required stripping of the deposits from all but the carbon substrates. Continuous copper deposits were also examined by reflection electron diffraction while they were still adherent to their substrates in order to determine whether the different substrates exerted any influence on their orientation and structure.

Results and Discussion

Sensitization.—Evaporated carbon substrates were immersed in stannous chloride solutions, rinsed in distilled water, dried, and examined electron microscopically.[2] It was found that the product of this sensitization treatment exists as particulate matter on an extremely fine scale. Particles of the order of 10Å were resolved, and these tended to agglomerate into dense clumps an order of magnitude larger. High resolution bright-field and dark-field micrographs which illustrate these results are shown in Fig. 1a and 1b, respectively.

Figure 1a represents the structure present after immersion of a carbon substrate for 3 sec in stannous chloride solution A. The darker regions are in diffraction contrast and correspond to the deposited material. These regions appear to be clumps that are about 100-250Å in size and are comprised of smaller particles about 25Å in size. The coverage in this field of view is apparently less than 25%. In dark-field micrographs at higher magnifications (Fig. 1b) the smallest resolvable particles are approximately 10-20Å in size. Images of this type reveal only a portion of the deposited material as most of the diffracted electrons are stopped by the objective aperture.

The electron diffraction pattern shown is Fig. 2 is typical of those observed after sensitization in either solution for periods up to 1 min and water rinsing. This pattern corresponds to the oxide phase, SnO_2 (ASTM Data Card 5-0467). The analysis[3] of numerous similar diffraction patterns confirmed this result. It is important to remember, however, that these experiments were not performed *in situ* and the deposits were exposed to an air environment for at least 10 min prior to examination, during which time oxidation undoubtedly occurred.

The breadths of diffraction lines, as determined from microdensitometer traces, yielded an independent calculation of the particle size. Both the integral breadth and the peak width at half maximum were determined from several typical patterns. Breadths of 1 to 2 x 10^{-3} radians were found, which correspond to calculated values of the particle sizes in the range from about 30 to 15Å, to a first approximation (14).

[2] One series of these experiments was carried out in collaboration with R. D. Heidenreich using a modified Siemens Elmiskop that is capable of 2Å resolution under optimum conditions (13). It is unlikely, however, that features smaller than 10Å could be resolved in the present samples due to the background "noise" from the substrates.

[3] These measurements were facilitated by graphically recording many of the patterns with a Jarrell Ash microdensitometer. Evaporated TlCl was used for a calibration standard.

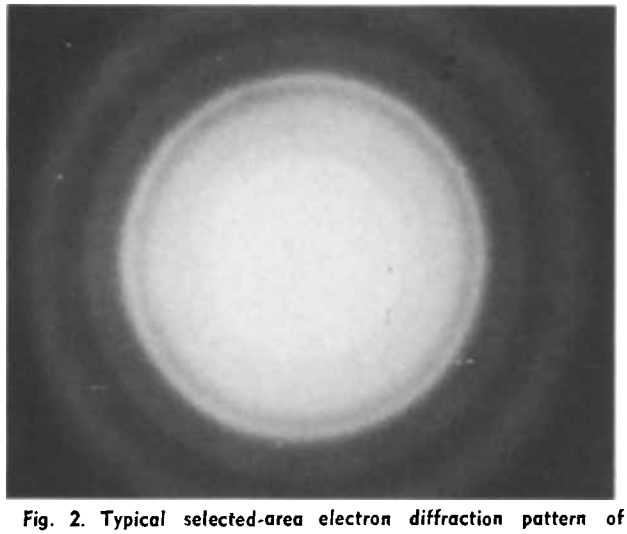

Fig. 2. Typical selected-area electron diffraction pattern of sensitized carbon substrate.

Increasing either the concentration of stannous chloride or the immersion time resulted in an increased coverage of the adsorbed sensitizing species. However, on a microscopic scale the coverage was heterogeneous, particularly when distilled water of ordinary purity was used. The results obtained from high-purity solutions showed a marked improvement with respect to uniformity and reproducibility. Figure 3 illustrates the effect of increasing the immersion time from 5 to 30 sec, as coverage increases from ap-

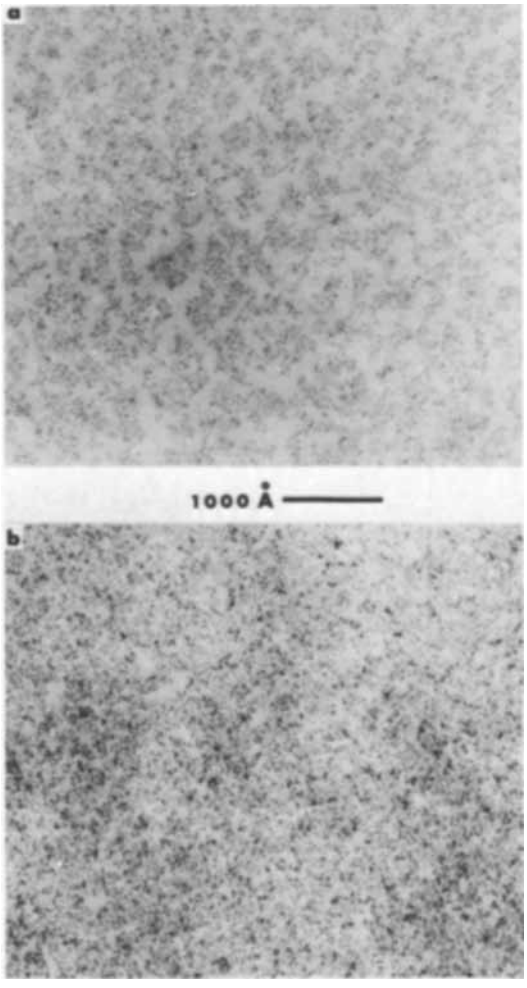

Fig. 3. Effect of time on sensitization of carbon substrates in $SnCl_2$-A (high purity): a (top) 5 sec immersion, b (bottom) 30 sec immersion.

proximately 30 to 75%. Although these fields of view are representative and appear to have uniform coverage, the results must be considered qualitative as other samples subjected to similar treatments occasionally exhibited different configurations. Hence, a considerable amount of statistical data would have to be obtained and analyzed, together with measurements on a more macroscopic scale, in order to describe and interpret the adsorption kinetics of this system quantitatively.

The above results confirm some of the deductions which were made recently by other workers who have studied the nucleation, growth, and structure of electroless nickel (6) and cobalt (9, 10) deposits. Marton and Schlesinger (6) were unable to resolve the products of stannous chloride sensitization, prior to activation and nickel deposition. By extrapolating a plot of particle size *vs.* time (back to $t = 0$) for growing Ni-P islands, assuming a constant microscopic growth rate, the catalytic sites were estimated to be less than 10Å in diameter. On the basis of the present results, it appears that the most important sites for further nucleation and growth are the densest regions of the deposit.

Several important aspects regarding the sensitization with stannous chloride solutions require further study. Although the presence of SnO_2 is indicated by electron diffraction, this analytical method is obviously not well suited to a direct study of hydrolyzed species and therefore cannot identify which of the many possible (15,16) stannous or stannous chlorohydroxides, oxyhydroxides, or hydrated oxides forms at the surface. In this regard, the *p*H at the surface is an important factor which has been found (4) to determine which compounds are formed. Recent work by Sharp and co-workers (4) has shown that tin must be present as Sn^{+2} and not Sn^{+4}, otherwise activation and electroless deposition will not occur. Diffraction patterns indicating the presence of the bivalent oxide, $(SnO)_{16}O$ (ASTM Data Card 13-111) were observed on samples subjected to a very mild rinse, *i.e.*, 10 sec immersion without turbulence. Although no systematic study of rinsing was conducted, this treatment influenced the structure observed during activation and electroless deposition.

Activation.—A surface containing only an adsorbed sensitizer is inactive in an electroless solution(17). Hence, the presence of a suitable catalyst is essential if that surface is to receive an electroless deposit. Palladium chloride solutions are most frequently used to provide the catalyst. The reaction mechanism for this process is generally thought (24) to be: $Sn^{+2} + Pd^{+2} \rightarrow Pd^0 + Sn^{+4}$, which means that the adsorbed stannous ions provide the sites and electrons for the adsorbing palladium ions. When excess sensitizer is dragged through into $PdCl_2$ solutions due to inadequate rinsing, the reduction to metallic Pd occurs adjacent to the interface and in the bulk of the solution. In such cases, metallic Pd particles, 50-100Å in size, become adsorbed on the surface. The set of arrows shown in Fig. 4 refers to corresponding regions in bright and dark-field micrographs where these particles are clearly seen.

The manner in which rinsing was carried out after the sensitization and activation treatments was found to affect the configuration of the adsorbed material. In contrast to the previous results for relatively mild rinsing by immersion, the structure shown in Fig. 5

resulted from a more severe rinse, *i.e.*, holding the carbon-coated glass substrate under running distilled water. The transmission micrograph in Fig. 5a indicates that the active material covers only a relatively small fraction of the surface in an island network. The morphology of this structure is visible in carbon replicas (Fig. 5b). Based on the shadowing geometry and Fig. 5b, these islands are estimated to be approximately 40Å in elevation.

The structures and diffraction patterns observed after activation of sensitized surfaces that received adequate rinsing were quite similar to those obtained prior to the activation treatment. The network-like clumps of adsorbed sensitizer persisted and the diffraction patterns became more diffuse which suggests that the activation process consists of the adsorption of very small amounts (probably less than about 20Å) of Pd onto the sensitized regions. Direct evidence of metallic Pd in diffraction patterns of these samples was observed when electron-beam induced recrystallization resulted in particles 100-150Å in size. Also, regions exhibiting dense coverage frequently gave diffraction patterns with extra lines corresponding to PdO.

The following qualitative results on the effect of the deposition variables were obtained. Increased concentration (solution B) resulted in increased Pd coverage. With respect to activation time, it appeared that most of the sensitized regions became covered after about 10-20 sec and that prolonged immersion had little effect. These effects were only observed when other factors, such as rinsing, did not interfere.

Electroless copper deposition.—The electroless deposition of copper from solution occurs only at catalytic regions on a surface. The initial stage in this process is represented by Fig. 6, which corresponds to a 3-sec immersion in solution A. The copper particles, which appear dark in Fig. 6a, nucleated at the most favorable catalytic sites. These sites correspond to the densest regions of the active material, which appear in gray contrast in Fig. 6a against the lighter, inactive regions on the substrate. It is interesting to note that the copper particles, which range up to about 300Å in size, are not single crystals but consist of aggregates of smaller crystallites. This observation is confirmed by the dark-field micrograph (Fig. 6b), which shows that the larger aggregates contain randomly oriented crystallites that are less than 50Å in diameter. The streaks associated with the bright, diffracting crystallites in Fig. 6b are due to spherical aberration, *i.e.*, the objective aperature was positioned off the optical axis, and are without structural significance. The feature denoted by the letter "T," which consists of two regions in diffraction contrast separated by a small dark band with parallel sides, is believed to represent a twinning fault. The formation of twins during electroless copper deposition is an important part of this process and is discussed below.

As the process continues autocatalytically, copper deposits on the originally formed nuclei. After about 10 sec in solution A, the largest aggregates exceed 500Å in size, yet all of these features consist of smaller crystallites as seen in Fig. 7. Crystallites as small as 25-50Å across are resolved, although some coherently diffracting regions larger than 100Å are plainly visible. Close examination of this as well as numerous similar samples revealed that the twin fault density at this stage is about 10^{10} cm^{-2} which corresponds to approximately 1% of the deposited nuclei. The diffraction patterns obtained from these deposits indicate that the copper is randomly oriented and possesses the lattice parameter of bulk material. It appears, therefore, that the deposition process from solution is random with respect to orientation. Thus, the formation of twin faults can occur whenever adjacent crystallites are in twin orientation across a common {111} boundary.

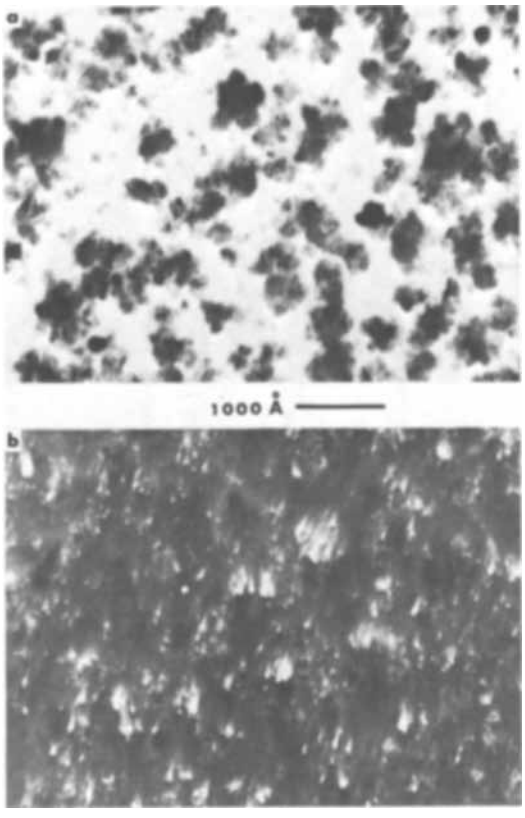

Fig. 7. Copper deposit after 10 sec in solution A. Carbon substrate sensitized and activated for 10 sec each in $SnCl_2$-A and $PdCl_2$-A. a (top) Bright-field image, b (bottom) dark-field image of same region.

Several important aspects of the electroless deposition of continuous films are illustrated in Fig. 8, which represents the structure formed when an activated substrate similar to Fig. 5 was plated for 1 min in solution A. The bright and dark-field pair of transmission micrographs (Fig. 8a and 8b, respectively) reveal that the grain size of this structure varies by more than an order of magnitude. The largest grains are 800-1000Å across, which corresponds to the estimated film thickness. It is noted that these larger grains tend to form continuous chains that are separated by regions consisting of much finer crystallites. The surface morphology of this deposit (Fig. 8d) confirms the existence of large elevated chains separated by regions where the film is thinner. The large-grained regions undoubtedly correspond to the active sites on the substrate where copper deposition originated.

With the exception of the chainlike network of larger grains, the basic structural features that are visible in Fig. 8 were common to all continuous deposits regardless of pretreatment. The microstructures were all qualitatively similar with respect to the grain-size variations and the existence of numerous twin faults. (The parallel fringes which extend across many of the larger grains in Fig. 8a are due to microtwin faults.) Typically, twin fault densities in excess of 10^{10} cm^{-2} were observed.[4] Moreover, all deposits were randomly oriented. This result was determined from transmission patterns (*e.g.*, Fig. 8c) of detached films and confirmed from reflection patterns of deposits still adherent to their substrates. The substrates activated for use in the reflection experiments were glass, freshly cleaved mica, and the polyimide material, Kapton.

The rate of electroless copper deposition is dependent on the nature of the catalytic surface as well as the composition of the solution. Solution A, which is relatively unstable, deposits copper at an average rate of 25 μ/hr (70 Å/sec), whereas solution B, which is more dilute and contains a stabilizer, is slower by a factor of about twenty. Despite this difference, it was found that both solutions yielded deposits with similar structural characteristics. In fact, by altering the catalyst coverage and immersion times it was possible to obtain virtually identical deposits. Figure 9 illustrates this point. The deposit in Fig. 9a received a 5-sec sensitization and activation prior to electroless deposition for 10 sec in solution A. When solution B was used with the same pretreatment relatively few nuclei were deposited and these required several minutes to grow into large aggregates. However, increasing the pretreatment times to 30 sec prior to deposition in solution B for an equivalent duration resulted in the structure shown in Fig. 9b.

Several stages in the development of a copper deposit from solution B when the surface concentration of catalyst is low can be seen in Fig. 10. In these experiments glass slides were used as substrates and ultrasonic agitation during rinsing reduced coverage to between 10 and 20%. The copper deposits together with their evaporated carbon supports were removed from the glass in 10% HF. This treatment accounts for the replicalike effect in Fig. 10a, where the outline of the deposit present at 30 sec is visible although the copper has dissolved and also accounts for the undercutting on the 1-min deposit (Fig. 10b). The other bright-field micrographs in Fig. 10c and 10d represent the structures developed after deposition for 3 and 5 min, respectively. The deposits obtained under these conditions, *i.e.*, low catalyst concentration and stabilized solution, differ from the one in Fig. 9b in that there are fewer aggregates and these grow to several thousand angstroms in size before encountering other similar features. The dark-field image (Fig. 10e) and diffraction pattern (Fig. 10f) confirm that the basic microstructural characteristics of these deposits

[4] Similar twin fault densities have been observed for both single crystal (18) and polycrystalline (19) copper electrodeposits and also for evaporated films (20).

are no different from those discussed previously.

The above results indicate that the structure of continuous electroless copper deposits is a direct consequence of the nucleation and growth phenomena which occur during the initial stages of the process. Initially three-dimensional nucleation occurs at catalytic sites on a surface. These nuclei form aggregates which become larger due to the continued depositon of material from solution until they become energetically unstable. At this stage a recrystallization process occurs which eliminates the interior boundaries and transforms the unstable aggregates into larger, single grains. Therefore, the conventional descriptions of metal deposition processes wherein nucleation is followed by two-dimensional growth via surface diffusion are not applicable to electroless deposition due to the chemical reduction reaction at the surface. The mechanism of this reaction is of great importance and has recently been studied using electrochemical techniques (2, 3). It appears that a detailed understanding of both the physical and the chemical aspects of this complex system will have to be obtained before a complete quantitative description can be given.

Summary

High resolution electron microscopy provides an extremely powerful method for elucidating the structural phenomena associated with the electroless process for metal deposition on nonconducting substrates. Application of this method has resulted in the following description of this process.

The products of the standard stannous chloride sensitization treatment exist as adsorbed clumps of material that are several hundred angstroms across and are comprised of particles 10 to 30Å in size. Activation with palladium chloride results in the adsorption of catalytic material onto the sensitized regions. The configuration of these active regions can be altered by rinsing. This alteration is reflected in the structure of the subsequently deposited metal.

The structural mechanisms which govern the electroless deposition of copper were deduced by following the stepwise development of metallic films. This process proceeds by repeated three-dimensional nucleation from solution at catalytic sites on the surface. The copper nuclei, which are about 25Å in diameter, form aggregates an order of magnitude larger. Since the reduction reaction is autocatalytic, the size of the aggregates increases during growth until they become energetically unstable. Then a recrystallization process takes place and the unstable aggregates are transformed into relatively large grains several hundred angstroms across. Continuous copper films obtained by this process exhibit a heterogeneous microstructure with grain size variations of more than one order of magnitude. This variation is attributed to the repeated nucleation and recrystallization process. These deposits also contain numerous ($>10^{10}cm^{-2}$) twin faults. Twin faults can form whenever adjacent nuclei are in twin orientation and possess a common {111} boundary. This situation apparently occurs quite frequently during the initial stages of the process when the randomly oriented copper nuclei form on the substrate.

An important first step toward the goal of elucidating the physical aspects of electroless copper deposits has been achieved. However, a more quantitative description encompassing both the physical and chemical aspects of the system is urgently needed.

Acknowledgment

Thanks are due to R. D. Heidenreich who made the electron microscope facilities available to the author and also assisted in the high resolution study of the sensitization process which resulted in Fig. 1a and 1b. The efforts of G. W. Kammlott who obtained the re-

flection diffraction patterns are also acknowledged. Finally, considerable insight regarding the chemistry of the electroless process was provided by Y. Okinaka, who, along with D. R. Turner participated in helpful discussions during the course of this work.

Manuscript submitted Jan. 19, 1970; revised manuscript received March 13, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Electrochemical Method to Measure the Copper Ionic Diffusivity in a Copper Sulfide Scale

A. Etienne

Department of Metallurgy, University of British Columbia, Vancouver, British Columbia

ABSTRACT

Copper sulfides have been grown on a copper anode from an acidic solution saturated with H_2S under a constant current. A theoretical model for the scale growth has been derived for steady-state conditions. From the set of experimental data, the cuprous ionic diffusivity of chalcocite and digenite in the scale have been calculated in the range of temperature from 30° to 73°C. The measured diffusion coefficient of cuprous ion in low chalcocite was found to be

$$D_{Cu+} = 8.1 \times 10^{-3} \exp\left(-\frac{5870}{T}\right) \text{ (cm}^2\text{ sec}^{-1}\text{)}$$

and in low digenite

$$D_{Cu+} = 3.6 \times 10^{-2} \exp\left(-\frac{6100}{T}\right) \text{ (cm}^2\text{ sec}^{-1}\text{)}$$

The calculation of the activation entropy for diffusion in both phases is attempted.

Copper sulfides can be grown on a copper anode from an acidic solution saturated with H_2S. If the operation is conducted at constant current, different sulfide layers of decreasing copper activity are built as the oxidation proceeds. If equilibrium is established, the successive phases should be, according to the phase diagram (1) (Fig. 1): copper, chalcocite, djurleite digenite, covellite, and sulfur. The reaction occurring at the anode is

$$y\text{Cu} + \text{H}_2\text{S} \rightarrow \text{Cu}_y\text{S} + 2\text{H}^+ + 2e$$

The electrochemical potential of such an electrode (Stockholm convention) is given by the following relationship

$$E = E_o - \frac{RT}{2\mathbf{F}} \ln \frac{A_{Cu^y} A_{H_2S}}{A_{Cu_yS} A_{H^+2}} + E_a \qquad [1]$$

The copper activity at the solid-liquid interface reflects the conditions imposed on the system and the transport properties of the scale being built. The sulfide activity is taken as unity. In defined geometric and stirring conditions, under a constant current, the hydrogen sulfide and hydrogen ion activities are constant in the vicinity of the electrode. In steady-state conditions, the activation overvoltage for a given sulfide is a constant. Therefore, the electrode potential variation with time follows the evolution of the copper activity according to the relationship [2] derived from [1].

$$\frac{dE}{dt} = -\frac{RT}{2\mathbf{F}} \frac{d}{dt} \ln A_{Cu^y}$$

$$\frac{dE}{dt} = -y \frac{RT}{2\mathbf{F}} \frac{d}{dt} \ln A_{Cu} \text{ if } y = \text{constant} \qquad [2]$$

If the sulfide scale grows uniformly on the electrode surface, the copper activity at the liquid-solid inter-

Key words: copper sulfides, diffusion coefficient, anodic film.

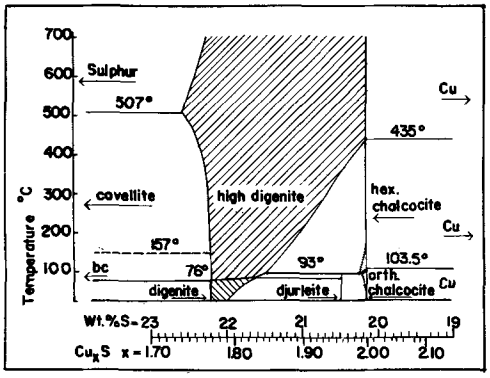

Fig. 1. Portion of the phase diagram of the system Cu-S from Roseboom (1).

face can be directly linked to the transport properties of the sulfide layer.

Theoretical Anode Model

In the copper sulfides, the sulfur ion mobility is considered negligible in comparison with copper ion mobility (2). In the case of high-temperature phases (αCu_2S, βCu_2S) there is experimental evidence (3, 4) to support this. It is also reasonable for the low-temperature phases in view of the relatively large size and associated immobility of the anion.

The copper sulfides have a good electronic conductivity. Chalcocite is a p-type semiconductor, its conductivity increases notably with copper deficiency ($\sigma = 10^{-2} \rightarrow 50$ ohm^{-1} cm^{-1} at room temperature) (5, 6). Digenite and covellite are almost metallic in character ($\sigma = 2 \times 10^4$ ohm^{-1} cm^{-1} at room temperature) (5, 7).

The phenomenological equations for diffusion relate the particle flux to the forces responsible for their motion. If the interaction effects are neglected, unidimensional transport in a two component system in the presence of a low strength electric field can be equated by

$$J_{Cu+} = - M_{Cu+}\left(\frac{d}{dx}\mu_{Cu+} + q_{Cu+}\frac{d}{dx}\Phi \right) \quad [3]$$

$$J_e = - M_e\left(\frac{d}{dx}\mu_e + q_e\frac{d}{dx}\Phi \right) \quad [4]$$

The electrical potential gradient can be derived from Eq. [4] and substituted in Eq. [3].

$$J_{Cu+} - \frac{q_{Cu+}}{q_e}\frac{M_{Cu+}}{M_e}J_e = - M_{Cu+}\left(\frac{d}{dx}\mu_{Cu+} - \frac{q_{Cu+}}{q_e}\frac{d}{dx}\mu_e \right) \quad [5]$$

Chemical potentials of ion and electron are not experimentally accessible values but are related through the measurable quantity, μ_{Cu}

$$\mu_{Cu} = \mu_{Cu+} + \mu_{e-}$$

Equation [5] is then simplified

$$J_{Cu+} + \frac{M_{Cu+}}{M_e}J_e = - M_{Cu+}\frac{d}{dx}\mu_{Cu} \quad [6]$$

As reported earlier, the copper sulfides are electronic conductors, their electronic conductivity being much larger than their ionic conductivity, and Eq. [6] can be reduced to

$$J_{Cu+} = - M_{Cu+}\frac{d}{dx}\mu_{Cu} \quad [7]$$

The Onsager coefficient M_i is directly related to the conductivity, diffusivity, and mobility of the particle i

$$\sigma_i = M_i q_i^2$$

$$\sigma_i = B_i C_i q_i^2$$

$$\sigma_i = \frac{D_i}{RT} C_i q_i^2$$

Equation [7] can be expressed in terms of any of these four parameters.

$$I_{Cu+} = - \frac{\sigma_{Cu+}}{\mathbf{F}}\frac{d}{dx}\mu_{Cu} \quad [8]$$

If the sulfide scale grows uniformly and continuously over the whole electrode surface, the sample thickness at any time is proportional to the number of coulombs passed through the electrolytic cell during that time

$$x - x_o = \frac{I_{Cu+}(t - t_o)}{y\mathbf{F}}\left(\frac{M}{d}\right)_{Cu_yS} \quad [9]$$

Combining Eq. [2], [8], and [9], yields Eq. [10].

$$I_{Cu+}{}^2\frac{1}{2\mathbf{F}}\left(\frac{M}{d}\right)_{Cu_yS} = + \sigma_{Cu+}\frac{dE}{dt} \quad [10]$$

which permits the calculation of the ionic conductivity of the sulfide scale formed under steady-state conditions from the slope of the recording of the electrode potential as a function of time.

Experimental

The anode was made of copper rod (99.995% purity) 0.905 cm in diameter, mounted in acrylic resin (Koldmount), and polished so that only one plane was in contact with the solution. The solution, 0.2M in Na_2SO_4 and 0.2M in H_2SO_4, was saturated by continuously bubbled H_2S. A strong convection pattern was brought about by a magnetic stirrer. The system was held at constant temperature by a regulated water bath. A 21V Ni-Cd battery unit provided current to the system through a set of appropriate resistors. The electrode potential was measured *vs.* a saturated calomel electrode by a Keithley 153 voltmeter which fed the signal to a Sargent SRG recorder.

Series of experiments have been carried out at temperatures between 30° and 73°C (below the digenite transition temperature) and under selected current densities between 1.9×10^{-4} A cm^{-2} and 1.55×10^{-3} A cm^{-2}.

The sulfide layer shows a uniform thickness over the electrode surface (Fig. 2) which ranged from 50 to 380μ depending on experimental conditions and the period of oxidation. The reaction products were identified by x-ray diffraction on a powder sample. The scale

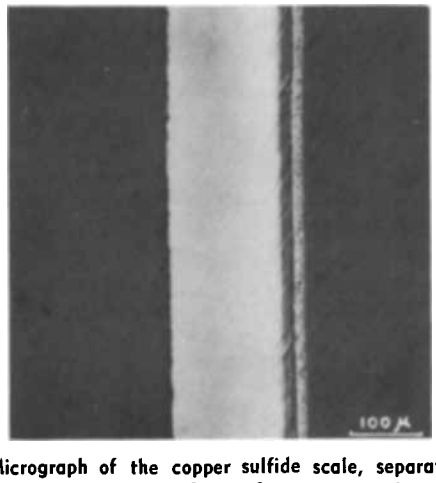

Fig. 2. Micrograph of the copper sulfide scale, separated from its Cu substratum. The Cu-Cu_2S interface was on the right side of the specimen. Digenite and djurleite are the only two phases to remain present. The band structure results from differences in the scale morphology emphasized by polishing.

structure and morphology could not be investigated by microscopy, electron diffraction, or microprobing. The three-sulfide assembly is not in equilibrium, and in the absence of an electric current one phase disappears during the time required for the sample preparation according to the reaction

$$0.8\ Cu_2S + 0.2\ Cu_{1.8}S \rightarrow Cu_{1.96}S$$

Results and Discussions

So far, three sulfides have been identified, chalcocite, djurleite, and digenite. No evidence, either direct or indirect, for the appearance of covellite was obtained in these experiments.

The sulfide growth model, analyzed earlier in this paper, is valid only in steady-state conditions, that is, when the cationic and total electric currents are constant. These conditions are satisfied when the first sulfide layer (Cu_2S) is deposited. The stoichiometry range of low chalcocite is smaller than 0.5% of its copper content (1), and, during Cu_2S formation, the ionic current virtually equals the total electric current (Fig. 3).

When a new sulfide starts to grow on the anode, the copper flux reaching the solid-liquid interface is changed according to the Cu^{++} to Cu^+ ratio in the new phase. If the digenite composition is approximated by $Cu_{1.8}S$ the reaction occurring at the liquid-solid interface at the stage of digenite growth can be represented by Fig. 4 and the correspondingly cationic (I^b_{Cu+}) and electronic ($I_e{}^b$) currents are equal to 90 and 10% respectively of the total current (I). The boundary between two solid phases is characterized by a thermodynamically fixed value of copper activity or electrochemical potential; therefore the potential drop in each sulfide layer is a constant. Consequently, the abrupt change in cuprous current at the onset of growth of a new phase initiates an unsteady-state process during which each sulfide layer adjusts its thickness to the new current conditions. The solid-state transformations accompanying the phase boundary motion are believed to generate stresses in the specimen because the scale always breaks away from the copper before CuS growth is apparent.

So far, the digenite stoichiometry range has been ignored. The digenite composition is reported (1) to extend from $Cu_{1.765}S$ to $Cu_{1.79}S$ at room temperature. Although the Cu poor limit is not affected by temperature, the Cu-rich limit changes to $Cu_{1.83}S$ at 83°C where digenite inverts to high digenite. During the digenite layer growth there is a continuous change in the Cu current flowing through the scale, but this variation is only 1.75% of the total current and is smaller than the accuracy of the measurement method.

From the set of experimental data, the cationic diffusivity of the chalcocite and digenite in the scale has

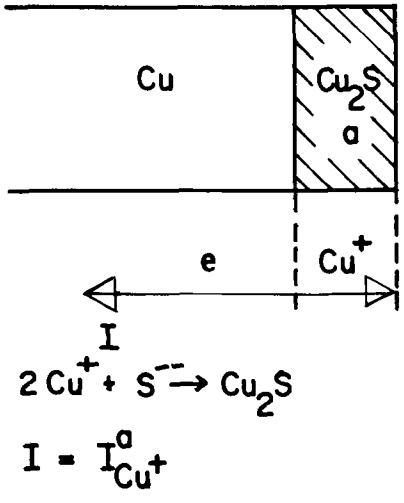

Fig. 3. Model of the Cu_2S film growing on the Cu anode

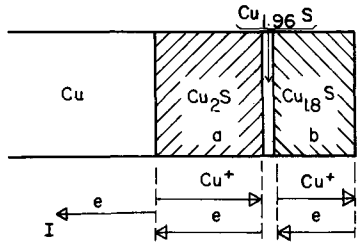

$$1.8\ Cu^+ + S^{--} \longrightarrow Cu_{1.8}S + .2e$$

$$I = I^b_{Cu^+} + I^b_e = I^a_{Cu^+} + I^a_e$$

$$I^b_{Cu^+} = 9I^b_e \qquad I^a_{Cu^+} = I^b_{Cu^+} + X$$

$$I^b_{Cu^+} = .9I \qquad I^a_e = I^b_e - X$$

$$I^b_e = .1I \qquad .1I \geq X \geq 0$$

Fig 4. Model of the copper sulfide scale at the stage of $Cu_{1.8}S$ growth.

been calculated in a range of temperature going from 30° to 73°C. Although djurleite was present in every sample, the ionic conductivity value could not possibly be derived from the experimental curve. This phase probably does not extend over enough atomic layers to allow a steady state to be established.

The measured ionic conductivity of digenite was independent of the current density used. In the chalcocite case, however, there was a current density value above which the experimental results became inconsistent. This limiting current density was increasing sharply with temperature. The dependence of the apparent ionic conductivity on the current density raises the problem of the morphology of the sulfides grown electrolytically.

It is usual practice to classify anodic films into continuous and noncontinuous films. In most of the cases reported in the literature, the distinction between continuous and noncontinuous films is based on the nature of the resistance opposed by the film to the current flow. It is characteristic of noncontinuous film to exhibit an approximately constant and low resistance (a few ohms) to the current flow during the growth of the scale (8). The smooth copper anode and the one plane electrode surface prevent introducing stresses which might lead to the cracking of the film. There is no solid-state transformation when the useful measurements are made, say when steady-state conditions prevail. The film growth is kinetically controlled by the copper ion diffusion through the solid, which mechanism favors the formation of a continuous, uniform scale. A decrease of the ionic strength of the solution (0.1 Na_2SO_4, 0.1 H_2SO_4) did not affect the experimental results.

The measured diffusion coefficient of cuprous ion in low chalcocite was found (Fig. 5) to be

$$D_{Cu+} = 8.1 \times 10^{-3} \exp\left(-\frac{5{,}870}{T}\right) \text{cm}^2\ \text{sec}^{-1}$$

$$D_{Cu+} = 1.1 \times 10^{-10}\ \text{cm}^2\ \text{sec}^{-1} \text{ at } 50°\text{C}$$

The measured diffusion coefficient of cuprous ion in low digenite was found (Fig. 6) to be

$$D_{Cu+} = 3.6 \times 10^{-2} \exp\left(-\frac{6{,}100}{T}\right) \text{cm}^2\ \text{sec}^{-1}$$

$$D_{Cu+} = 2.4 \times 10^{-10}\ \text{cm}^2\ \text{sec}^{-1} \text{ at } 50°\text{C}$$

In the temperature range studied, cuprous ions diffuse about twice as fast in digenite as in chalcocite. The ac-

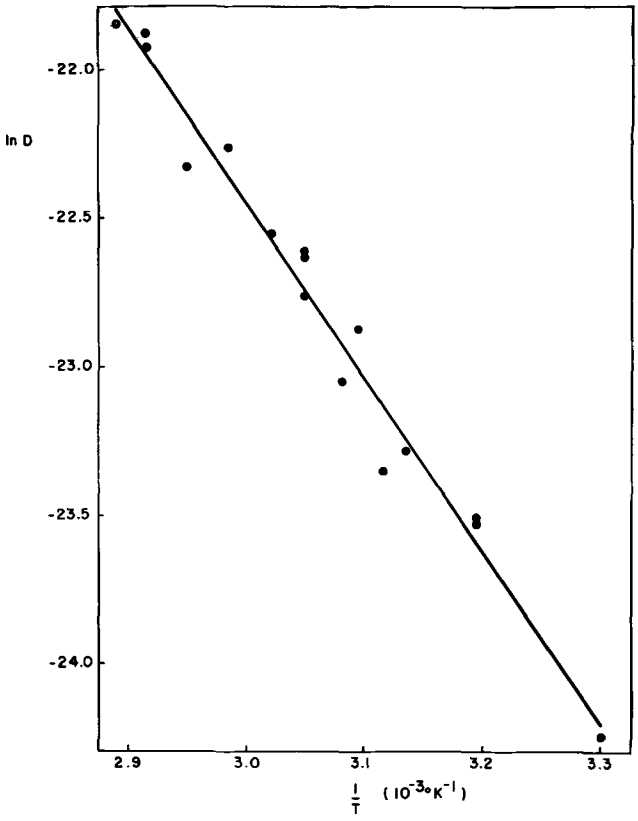

Fig. 5. Temperature dependence of the cuprous ion diffusion coefficient in chalcocite:

$$D_{Cu+} = 8.1 \times 10^{-3} \exp\left(-\frac{5{,}870}{T}\right) (cm^2\,sec^{-1})$$

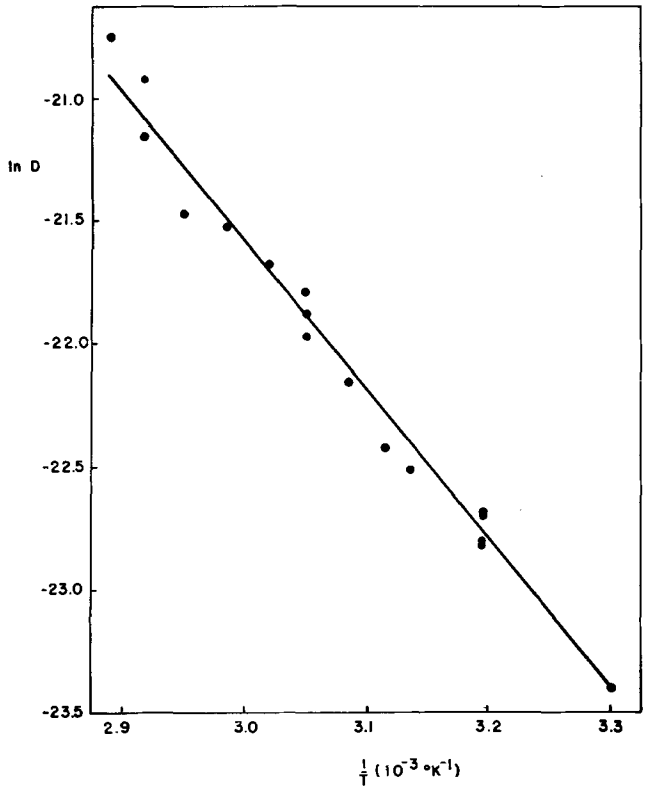

Fig. 6. Temperature dependence of the cuprous ion diffusion coefficient in digenite:

$$D_{Cu+} = 3.6 \times 10^{-2} \exp\left(-\frac{6{,}100}{T}\right) (cm^2\,sec^{-1})$$

tivation energy for diffusion is 11.7 ± 1 kcal mole^{-1} for chalcocite, and 12.1 ± 0.8 kcal mole^{-1} for digenite, respectively.

If an activation entropy for diffusion is to be calculated, the nature and concentration of diffusing defects must be known. The diffusion in ionic type crystals is often associated with the migration of Schottky or Frenkel type defects. X-ray investigations have suggested that in some ionic type crystals metallic ions were distributed virtually at random among a large number of nearly equivalent lattice sites [αAg_2S(9), αAgI(10), αCu_2S(4)]. In the case of low chalcocite and digenite which have relatively ordered copper lattices, an interstitialcy mechanism (the cations being equally mobile) may account for the cuprous ion diffusion. This is supported by the experimental observation that no significant variation of the diffusion coefficient has been observed with deviation from stoichiometry. Therefore, the equation of zeolitic diffusion is applicable (11).

$$D = \lambda^2 \frac{kT}{h} \exp\left(\frac{\Delta S}{R}\right) \exp\left(-\frac{\Delta H}{RT}\right) \quad [11]$$

The activation entropy for diffusion is then 1.9 e.u. for chalcocite and 1.3 e.u. for digenite, respectively. These low values are consistent with a mechanism which introduces little disordering in the lattice.

Conclusion

The thickening of a copper sulfide film on a copper anode at low electric field strength has been accounted for by electrolytic transport in the scale. The diffusion coefficients of cuprous ion in low chalcocite and low digenite have been measured in the temperature range of 30°-73°C during the growth of the anodic film. The phase boundary reactions did not appear to be too irreversible to interfere with these measurements.

Similar processes take place during the direct leaching of chalcocite minerals. This experiment supports the view that solid-state diffusion is a rate-controlling mechanism in the leaching of these minerals (12).

Theory of the Separation in Displacement Electrophoresis

G. Brouwer and G. A. Postema

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven-Netherlands

ABSTRACT

Displacement electrophoresis is a method of separating ions. After completion of this separation a qualitative and quantitative analysis of the sample composition can be made. In this report the separation process is investigated. It is shown that the sample introduces a transient system of homogeneous zones which are finally reduced to zones containing only one component of the sample. Starting from such basic equations as electroneutrality, current-continuity, and conservation of ionic species, equations are derived which permit the calculation of all quantities of interest, such as local field strength, composition of a particular zone, and speed of zone boundaries. In the case of a two-component sample the separation time can be calculated exactly; for the case of a multicomponent sample an approximate expression is given.

Displacement electrophoresis is an analytical technique which separates and orders ions in an electrical field according to their mobilities. A complete analysis of a sample is obtained with this method. If one is interested in, *e.g.*, separation of cations, the sample which has to be analyzed is placed in a column between a leading solution containing cations with a higher mobility than that of any of the cations in the sample, and the trailing solutions containing cations with a lower mobility than that of any of the cations in the sample. Electrodes are placed in the leading and trailing solution, and when an electrical field is applied the separation process starts and the cations move toward the cathode. After some time all cations will have the same counter-ions as these are moving in the opposite direction. Between the leading and trailing solutions the sample components have finally ordered themselves into consecutive zones according to increasing mobilities in the direction of migration. The same principle applies to the separation of anions.

Originally the method was employed as a separation method. In this way Kendall (1-4) in 1925 separated rare earth ions. Vestermark (5) and Eriksson (6) used this technique to isolate and concentrate certain substances from, *e.g.*, beet juice. Martin and Everaerts (7, 8) used its qualities for quantitative analyses. Independently Konstantinov, Fiks, and Oshurkova (9-12) arrived at similar observations.

This article emphasizes the separation process. It is shown that this process is governed by a number of simple equations. In the case of a two-component sample the time required for complete separation can be calculated as a function of the various parameters involved. For a multicomponent sample all quantities of interest can be calculated and an estimate of the separation time can be given.

Key words: boundary velocity, concentration boundary, concentration relations, conservation of ionic species, continuity of current, diffusion, dissociation, electroneutrality, electrophoresis, field-strength relations, heat production, homogeneous zones, ions, ion mobility, ion separation, leading solution, multicomponent sample, qualitative analysis, quantitative analysis, separation boundaries, separation time, trailing solution, transition region.

Theory of the Separation Process

General considerations.—Before application of the electrical field the sample is placed between the leading ion solution A and the trailing solution X. The concentrations of A and X are known; the concentrations of the various components in the sample are unknown

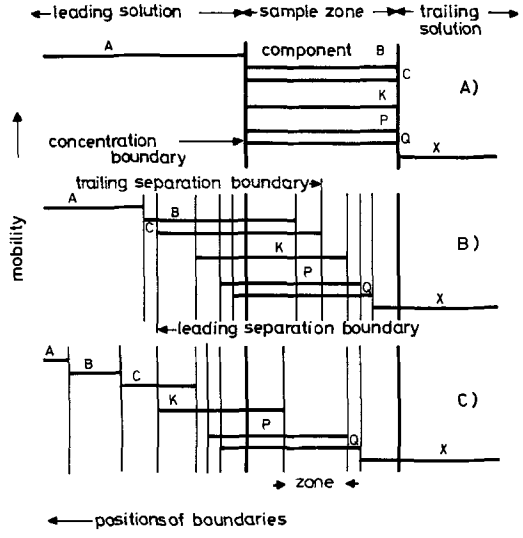

Fig. 1. Development of the zones and the positions of the components at the start (A), after application of the electrical field (B), and after some time has elapsed (C).

but well defined. This situation is schematically represented in Fig. 1A where only one type of ions is considered, say the cations A, B, C, ... K, . . . , P, Q, X. For simplicity it is assumed that there is only one common anionic species Z. The presence of certain ions is indicated by the position of horizontal lines. The levels of these lines indicate the mobilites of the cations. The original sample zone divides the column into three separate regions, marked by heavy vertical lines. After application of a constant current a new situation develops (Fig. 1B). The faster components of the sample have occupied leading positions whereas the slower ones are falling behind. The thin vertical lines represent zone boundaries. These indicate the limits of the sample components and the occurrence of fairly abrupt concentration changes of other sample components. Adjacent to the leading solution a zone is present containing the fastest component only. Heading the trailing solution is a zone containing the slowest sample component. After a sufficient time the number of zones decreases as the tails of the faster components pass the fronts of the slower components (Fig. 1C). Finally the sample components are separated, and consecutive zones containing only one component proceed to the cathode with a uniform speed, characteristic of displacement electrophoresis. As the apparent mobility of an ion is the product of the degree of dissociation of the ion and the mobility at complete dissociation, it will be preferable to choose optimal conditions. In order to control the degree of dissociation of weak electrolytes a particular choice of counter ions must be made. If the sample contains a weak acid the counter ion should be derived from a base, preferably a weak one to limit the hydroxyl ion concentration. Both groups mutually become charged by proton transfer. The degree of dissociation depends on the sum of both pK values. A more detailed treatment is postponed to a future paper.

At a certain stage of the separation a number of homogeneous zones is assumed to be present. A number of interzonal relations can be derived which determine the process completely. When the solvent is at rest, and the uniform field strength of zone j is called E_j (V cm^{-1}), an ion K with a mobility μ_K (cm^2 V^{-1} sec^{-1}) travels at a speed (cm sec^{-1})

$$v_{Kj} = \mu_K E_j \qquad [1]$$

A uniform cross section of the capillary tube results in a constant current density i (A cm^{-2}) in any zone. If the Faraday constant is $\mathbf{F}$ (C g-equiv.$^{-1}$) and the concentration of ion K in zone j is C_{Kj} (g-equiv. cm^{-3}), the following current density equation is valid

$$i/\mathbf{F} = E_j \sum_K (\mu_K + \mu_Z) C_{KJ} \qquad [2]$$

The ions K are neutralized by an equal amount of Z ions; the current contributions of both ions are proportional to the individual mobilities. Within a zone the ions of the same kind move with uniform velocities. In order to retain homogeneity an observer moving with the boundary should see a nondivergent flow of ions. For ions K passing the boundary between zones j and k this leads to

$$C_{Kj}(\mu_K E_j - v_{jk}) = C_{Kk}(\mu_K E_k - v_{jk}) \qquad [3]$$

where v_{jk} is the speed of the boundary between the zones j and k with respect to the solvent. Equation [3] results in

$$v_{jk} = \mu_K(C_{Kj}E_j - C_{Kk}E_k)/(C_{Kj} - C_{Kk}) \qquad [4]$$

There are as many ways to express v_{jk} as there are cationic species. Before any conclusions are drawn from this formula a survey is made of the various possible boundaries.

Types of boundaries.—Two types of boundaries can be distinguished (*a*) the separation boundaries, where one particular component is present on only one side of the boundary, *e.g.*, $C_{Kj} = 0$ and $C_{Kk} \neq 0$; in that case Eq. [4] results in

$$v_{jk} = \mu_K E_k \qquad [5]$$

and (*b*) concentration boundaries, which will be shown to be immobile and where all components are present on both sides. Equation [2] can be applied to zone j as well as to zone k. Subtracting these equations results in

$$\sum_K (\mu_K + \mu_Z)(C_{Kj}E_j - C_{Kk}E_k) = 0 \qquad [6]$$

Provided $v_{jk} \neq 0$ it is legitimate to divide each individual term of the sum [6] by v_{jk}. The assigned way to reduce the resulting expression is to select the particular cation of the term under consideration to evaluate v_{jk} from [4]. Then the following result is obtained

$$\sum_K \alpha_K C_{Kj} = \sum_K \alpha_K C_{Kk} \qquad [7]$$

where

$$\alpha_K = (\mu_K + \mu_Z)/\mu_K \qquad [8]$$

This relation can be applied repeatedly to consecutive zones separated by separation boundaries. As the concentrations of the leading and trailing solutions can be chosen at the beginning of the separation process and the concentrations of components in the sample are arbitrary, Eq. [7] is not satisfied at the original sample boundaries. This leads to the conclusion that these boundaries are immobile as only the condition $v_{jk} = 0$ can invalidate Eq.[7]. From [4] one can derive in this case

$$C_{Kj}/C_{Kk} = E_k/E_j \qquad [9]$$

When the sample is completely separated and the zones contain only one component, Eq. [7] is still valid and permits a quantitative analysis. In this restricted form the relation was given by Kohlrausch (13).

Two types of separation boundaries have to be distinguished: (*a*) the leading separation boundary between consecutive zones where zone j contains the components G, H, ... K, ... P and the following zone k the same but, in addition, the slower component Q; the latter is separated out as it is not transferred from k to j. (*b*) the trailing separation boundary between the zones k and l, in which case zone k contains the components G, H, ... K, ... Q whereas zone l contains the same components with the exception of the fastest ion G, which is separated out. Though Eq. [2], [4], and [9] permit the calculation of all unknown quantities, the elimination problem is tedious. A more convenient approach is given below.

Interzonal field strength relations.—To derive a relation for the ratio of the field strengths on both sides of a separation boundary case (*a*) will be considered first. As $C_{Qj} = 0$ Eq. [3] yields for K = Q

$$v_{jk} = \mu_Q E_k \qquad [10]$$

If we define β_{jk} as

$$\beta_{jk} = E_j/E_k \qquad [11]$$

Eq. [3] results by substituting [10] and [11] in

$$C_{Kj} = C_{Kk}(\mu_K - \mu_Q)/(\mu_K\beta_{jk} - \mu_Q) \qquad [12]$$

When both zones are not separated by an immobile concentration boundary, application of [12] to Eq. [7] results in

$$\sum_{K=G}^{P} \alpha_K C_{Kj} = \sum_{K=G}^{Q} \alpha_K C_{Kk} = \sum_{K=G}^{P} \frac{\alpha_K C_{Kk}(\mu_K - \mu_Q)}{\mu_K\beta_{jk} - \mu_Q} \qquad [13]$$

The last sum can be extended to K = Q because this final term equals zero. Equating the second expression

of [13] and the extended third one leads to

$$(\beta_{jk} - 1) \sum_{K=G}^{Q} \frac{\alpha_K C_{Kk}}{\beta_{jk} - \mu_Q/\mu_K} = 0 \qquad [14]$$

The solution $\beta_{jk} = 1$ has to be ruled out because substitution in [12] renders all concentrations equal except C_Q. This is in violation with Eq. [7] because of an excessive term $\alpha_Q C_{Qk}$. This leads to the restriction $\beta_{jk} < 1$.

Hence [14] results in

$$f(\beta_{jk}) = \sum_{K=G}^{Q} \frac{\alpha_K C_{Kk}}{\beta_{jk} - \mu_Q/\mu_K} = 0 \qquad [15]$$

This is a function from which only one root yields positive concentrations for all values C_{Kj} obtained by inserting C_{Kj} in [12]. From Eq. [12] it follows that for positive values of C_{Kj} the value $\beta_{jk} > \mu_Q/\mu_P$ and therefore

$$\mu_Q/\mu_P < \beta_{jk} < 1 \qquad [16]$$

The qualitative behavior of $f(\beta_{jk})$ is shown in Fig. 2. The function has poles at the values $\beta_{jk} = \mu_Q/\mu_K$. It is evident from the graph that only one root satisfies [15] and [16].

The conditions for a trailing separation boundary when the fastest component is separated out can be derived similarly. When we define

$$\beta_{kl} = E_k/E_l \qquad [17]$$

it results in

$$\sum_{K=G}^{Q} \frac{\alpha_K C_{Kk}}{\mu_G/\mu_K - \beta_{kl}} = 0 \qquad [18]$$

for

$$1 < \beta_{kl} < \mu_G/\mu_H \qquad [19]$$

Starting from a defined zone such as the sample zone all quantities of interest of the preceding one can be calculated. Primarily Eq. [15] determines the field strength ratio and Eq. [12] yields the various concentrations. The zone following the sample zone can be treated in a similar way by application of Eq. [18] and [12]. This process can be repeated until in all the zones all quantities are known. The concentration on opposite sides of a concentration boundary are linked by Eq. [9]. The system is completely determined as all conditions that can be imposed are obeyed. This also justifies the assumption of homogeneous zones. The field strength increases from zone to zone with a possible exception at the immobile boundaries.

Example.—In Fig. 3 the various stages of a separation process are illustrated. In this particular case the solvent is moved with a constant speed equal but opposite to the speed of the leading zone. The positions of various zone boundaries are plotted horizontally and the time vertically. After some time the number of zones is reduced until finally five zones each containing one sample component are formed. The concentration barriers, immobile with respect to the solvent, move backward with the speed of the solvent.

Influence of diffusion.—For discontinuous concentration variations diffusion should be taken into account. Because of the electrical field on the one hand and diffusion on the other hand a steady state is obtained. MacInnes and Longsworth (14) derived a relation for the transition width κ_{KL} (cm) between two zones, one containing only component K and the other one containing only component L in the moving boundary electrophoresis. When the limits of the transition are arbitrarily defined by the extremes

$$-2 \leq \ln (C_K/C_L) \leq 2 \;,\; \kappa_{KL} = \frac{4RT}{F v_{KL}} \frac{\mu_K \mu_L}{(\mu_K - \mu_L)} \qquad [20]$$

where R (J °K^{-1}) is the universal gas constant, T (°K) the absolute temperature, and v_{KL} the speed of the boundary concerned. In experimental conditions κ_{KL} will not exceed a few tenths of a millimeter. This value is comparable to the accuracy with which a boundary can be detected.

Separation time.—In order to evaluate the possibilities of analyzing a sample with the aid of displacement electrophoresis, a reasonable estimate of the separation time must be made. This is done by starting with a case of a two-component system which leads to a simple expression. From this an approximate value can be obtained for multicomponent samples.

In the simplest case the sample contains two components and, moreover, both leading and trailing solutions are adapted to the sample according to Eq. [7]. Therefore no concentration boundaries are required. The solvent is kept immobile. This case is illustrated in Fig. 4A where the positions of the boundaries are plotted along the horizontal axis against time along vertical axis. The original sample length is called λ_1 and the concentrations C_{B1} and C_{C1}. Inspection of Fig. 4A shows that the width of zone BC gradually diminishes as the confining boundaries converge with a differential velocity, given by the product of the local potential gradient and the difference in mobility of the species B and C. As the zone BC is on the verge of disappearing the separation is complete and the time elapsed, τ (sec), is given by

$$\tau = \lambda_1/(\mu_B - \mu_C) E_{BC1} \qquad [21]$$

The above case is merely fortuitous, and a more realistic one can be constructed by concentrating the sample by a factor γ. The sample length has to be reduced by the very same factor when the total amounts of B and C are kept unchanged. Two concentration boundaries appear in this case as is shown in Fig. 4B.

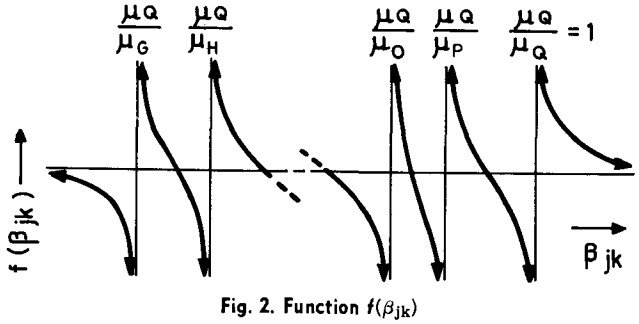

Fig. 2. Function $f(\beta_{jk})$

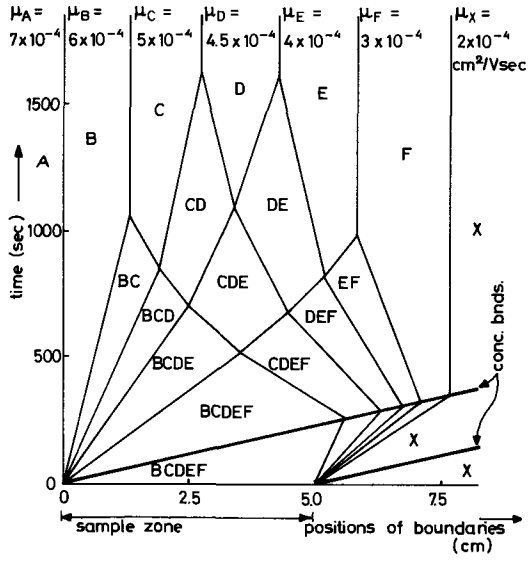

Fig. 3. Development of the various zones in the case of a five-component sample. In this arithmetical example: $C_A = 10^{-5}$ gEq. cm^{-3}, $C_B = C_C = C_D = C_E = C_F = 2.5 \times 10^{-6}$ g-equiv. cm^{-3} in the original sample zone, and $E_A = 30$ V cm^{-1}.

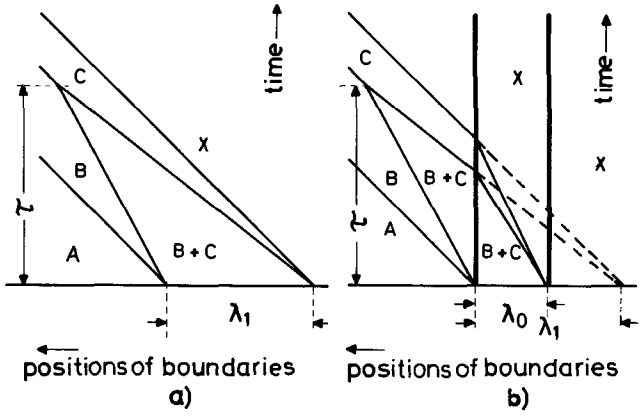

Fig. 4. Diagram of the separation of a two-component sample. Horizontally the positions of the boundaries are plotted, vertically the time. In case (a) the concentrations are all mutually adapted, and case (b) is the general one.

When the same current density is conserved the field strength, E_{BCO}, in the sample is lowered by a factor γ with respect to the previous case or, with respect to the part of the sample zone that has crossed the concentration boundary already. The time required by zone BC to leave the original sample region is the same as before because not only is the distance over which the boundary (BC,C) has to travel reduced by the factor γ, but its velocity as well. For comparison the simplest case is drawn in dashed lines. It can be concluded that the separation time is not affected by concentration boundaries.

A reduction of τ can be achieved by raising the potential gradients. The heat production per unit volume, P_m (W cm^{-3}), occurring in the adapted trailing solution puts a restriction on the system. Long separation times are found when $\mu_B \approx \mu_C \approx \mu$. Optimal conditions have to be chosen in order to limit τ to a reasonable value. Consider an example in which the sample length is λ_O whereas the concentrations are C_{BO} and C_{CO}. When a comparison is made with the adapted quantities the conservation of ionic species requires

$$\lambda_1(C_{B1} + C_{C1}) = \lambda_O(C_{BO} + C_{CO}) \qquad [22]$$

As it was shown that concentration boundaries do not affect the separation time

$$\tau = \lambda_O/(\mu_B - \mu_C)E_{BCO} \qquad [23]$$

Introduction of the zonal conductivities σ_A (ohm^{-1} cm^{-1}), σ_{BCO} and σ_X in Eq. [2] leads to

$$\sigma_A E_A = \sigma_{BCO}E_{BCO} = \sigma E_X = i \qquad [24]$$

As the conductivity is lowest in the adapted trailing zone, the local heat production, P_m, is a limiting factor, given by

$$P_m = \sigma_X E_X^2 \qquad [25]$$

When the system is operated under optimal conditions, it is possible to calculate a close approximation of τ by combining Eq. [8], [9], and [22] through to [25]

$$\tau \approx \lambda_O\sigma_{BCO}\mu_A^{1/2}/(\mu_B - \mu_C)\,(\sigma_A P_m \mu_X)^{1/2} \qquad [26]$$

In this formula all quantities are known with the exception of σ_{BCO}, which can be determined by a conductivity measurement, and $(\mu_B - \mu_C)$. The latter can either be predicted or be considered as a minimum value if the pair is to be separated in the time τ.

In order to arrive at the separation time of a multicomponent sample, a suggestion by Martin (private communication) is followed. Usually the bottleneck of the process is formed by the separation of a single obstinate pair which consumes so much time that the prelude to this stage can be neglected. In that case Eq. [26] again gives a reasonable estimate.

Conclusions

The separation process of displacement electrophoresis can be described adequately by equations for the system of homogeneous zones which are generated from the sample zone. Finally only zones containing one sample component remain, and they move with uniform speed. With the aid of relation [7] their concentration can be calculated as a function of the concentration of the leading electrolyte. In the solvent immobile concentration boundaries are situated at the original boundaries of the sample zone. The column which is preferably capillary, is thus divided into three regions in each of which Eq. [7] is valid. The changes of concentration at the immobile boundaries have a fixed ratio, and Eq. [9] gives the relation between the field strengths on both sides of this boundary. From a zone with known concentrations and field strength the field strength of an adjacent zone can be calculated by applying [15] or [18] and its composition by applying Eq. [12]. By repeating this process the potential gradient and the composition of all occurring zones can be calculated. Boundary speeds follow from [3] while the optimal separation time is given by [26].

Purification of Potassium Chloride Solutions

Voltammetric Criteria

Murray Rosen,*[1] Henry H. Bauer,*[2] and Philip J. Elving*

The University of Michigan, Ann Arbor, Michigan

ABSTRACT

Impurities of heavy metal and surface-active types can be removed readily from solutions of reagent grade potassium chloride by electrolysis at a graphite electrode; the surface-active material is also largely removed by column chromatography over charcoal. Operational approaches for monitoring the purity are described.

To obtain pure aqueous solutions, *e.g.*, of the alkali metal halides, for electrochemical studies, one may consider purifying the salt, the prepared solution, or even both. Purification of the salt can often be accomplished by growing crystals under carefully controlled conditions or by recrystallization. Purification of the solution would appear to be a more direct approach and, consequently, two procedures based on the types of impurities found in solutions of potassium chloride, are described; these involve column chromatography using charcoal and pre-electrolysis with a graphite electrode.

The purification of alkali metal halides has been frequently discussed in the literature. For example, before applying square wave polarography to solutions that had been pre-electrolyzed at mercury for removal of reducible species, Barker (1) found it necessary to contact these solutions with an inert adsorbent to remove surface-active substances. Berezina and Nikolaeva-Fedorovich (1a) monitored surface-active substances in water purified by various methods through observation of polarographic maxima of the second kind. Recent voltammetric studies of the background current at the pyrolytic graphite electrode (PGE) and the dropping mercury electrode (DME) in aqueous solutions of potassium chloride, revealed the presence of two types of impurities, which were found even in spectroscopic grade KCl. Type I impurity is polarographically active at the DME, *i.e.*, a catalytic peak (Fig. 2) is seen at -1.1V in 0.5*M* KCl solutions between *p*H 0.85 and 3, suggestive of the presence of a surface-active substance; in addition, it seems to be electrochemically reducible. Type II impurities definitely result in faradaic processes, *i.e.*, deposition waves or stripping peaks are seen at the PGE, indicating that they are probably heavy metals.

Removal of the two types of impurities has been investigated in terms of operational tests for the efficiency of the purification process. Since the absence of surface-active impurities is a frequent necessity in electrochemical and other investigations, the results of the present study should be of general interest.

In general, the electrolytic purification procedure is recommended over the charcoal treatment, even for the removal of surface-active impurities in potassium chloride solutions, *e.g.*, *p*H changes and concentration adjustments which generally accompany use of charcoal can be avoided (*c.f.* subsequent discussion). In addition, electrolytic purification can be used *in situ* and can be duplicated more easily in other laboratories. Moreover, the same procedure that is used to purify the solution can often be used to check impurity levels and to repurify the solution, if necessary, without essentially disturbing the main experiment. The electrolytic purification procedure described here is an adaptation of stripping analysis and, therefore, lends itself to quantitative interpretation if desired.

Experimental

Reagents.—Reagent grade hydrochloric acid (du Pont), potassium hydroxide pellets (Baker & Adamson), potassium chloride (J. T. Baker), spectroscopic grade potassium chloride (Hilger), Darco G-60 decolorizing charcoal (Atlas Chemical), and double-distilled water were used. The charcoal was purified as specified by the manufacturer (2); a suspension of it in 2*M* HCl was boiled and then filtered and washed on a Buchner funnel. Nitrogen (oil pumped grade), used for oxygen removal, was passed successively through two gas bubblers containing ammonium vanadate solution reduced by zinc amalgam in hydrochloric acid (3), gas bubblers contain calcium hydroxide solution and, finally, one containing double-distilled water.

Cells.—The working compartment (1.2-liter capacity) of the all-glass unjacketed cell used (Fig. 1) is fitted with a Teflon plug stopcock on the side near the bottom and can be closed with a No. 7 stopper; the two connecting bridges can be closed with No. 00

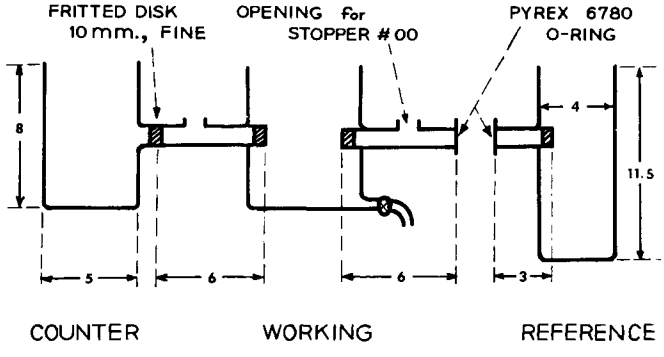

Fig. 1. All-glass three-compartment pre-electrolysis cell. Dimensions shown are in cm. The stopcock on the working compartment is perpendicular to the plane of the drawing.

stoppers. The working and counterelectrode compartments, which constitute a single unit, are joined to the reference electrode compartment by clamping the O-ring joints together. This arrangement enables the working cell to be cleaned without affecting the reference electrode.

The connecting bridges, which are bounded by glass-fritted disks and are stoppered to minimize mixing of solutions, are filled with background electrolyte solution when the cell has been assembled. This arrangement minimizes migration of undesired ions between compartments and is essential in preventing mercury ions from diffusing from the reference electrode compartment, *e.g.*, an early observation of an anodic stripping peak just positive of zero volt, when using an ordinary H-cell, was traced to the presence of mercury ions.

Electrodes.—A 1 x 12 in. strip of Grafoil self-bonded tape (Union Carbide), served as the working or purification electrode. Voltammetric analysis of solution purity was done with a shielded electrode (19.6 mm^2) made from pyrolytic graphite rod (General Electric) (4).

Apparatus.—A Sargent Model XV polarograph was used for the polarographic analyses. Voltammetry was carried out with a three-electrode system and operational amplifier circuits (5); voltammograms were recorded on a Moseley 7001A(S) X-Y recorder, using a Model 17106 filter to prevent saturation of the recorder amplifiers by a-c noise (no attenuation of the signal was noted). A Wenking potentiostat (100 mA output) provided the potential control for the pre-electrolysis. The Leeds & Northrup Model 4776 *p*H meter used was standardized with Beckman standard buffer solutions. All potentials were measured and are reported *vs.* the saturated calomel electrode (SCE).

The 1-in. diameter glass column used for chromatography, contained 3 to 24 in. of premoistened, purified charcoal with premoistened angelhair as a filter and plug at the bottom. To aid in replacement of the charcoal, the stem of the column was fitted with a Pyrex 6780 O-ring joint, which was mated to another joint attached to a Teflon stopcock. The solution to be purified is fed from a 2-liter, round-bottom flask joined to the top of the column. The stopcock tip is connected to a suction flask, to which an aspirator is attached.

Results

Type I impurity.—This impurity manifests itself by producing a catalytic wave with a peak at −1.1V at the DME in 0.5*M* KCl solutions of *p*H 1.4; the height of the wave varies between 2 and 45 μA and, for a given sample, reaches a maximum at *p*H 1.5 (Fig. 2). Drop-time (*t*) *vs.* potential (*E*) (electrocapillary) curves show no unusual dips or distortions, neither at the electrocapillary maximum nor at −1.1V.

The fact that the wave is decreased by about 85% on bubbling nitrogen through the solution while the latter is in contact with a mercury pool indicates that the impurity either reacts chemically with mercury or is adsorbed from solution.

Attempts at plotting adsorption isotherms for the impurity on the charcoal used in purification (2) did not yield a reproducible value for *n* in the Freundlich adsorption isotherm. However, the results indicated that at least two stages of charcoal treatment are necessary to remove 85-90% of the impurity. On column chromatography, results were generally as expected, *i.e.*, the longer the charcoal column the purer would be the resulting solution, but a longer time was needed and quite often the *p*H change was greater. Since an exhaustive study of the correlation of all of the possible parameters with solution purity was not attempted, only relative trends can be described. For a 6-in. charcoal column, removal was about 50-60% effective, and the resultant solution had a *p*H of about 8. A 24-in. charcoal column removed nearly 90% of the impurity; however, the resultant solution *p*H was often as high as 10, and generally 2 hr were required to draw two liters of solution through the 24-in. column via the aspirator. Barker (6) also noted that charcoal treatment caused a slight rise in solution *p*H during purification of 0.5*M* KCl.

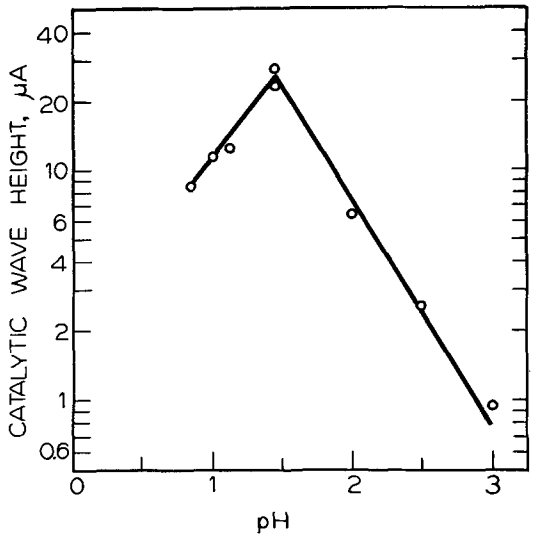

Fig. 2. Variation of catalytic wave height at DME with *p*H in 0.5*M* KCl solution.

Use of charcoal gives, at best, 90% removal of the impurity. Whether this effectiveness could be improved by recycling or by a batch-column arrangement was not tested since the same effectiveness could be achieved by electrolytic purification. It is possible that had Barker (1) used a carbon-type electrode for pre-electrolysis, further "cleaning" would not have been necessary. Since he does mention that his "cleaning" by charcoal treatment was effective in producing solutions in which the double-layer capacitance did not vary by more than 2% in about 20 min, it is possible that the 90% achieved here might have been adequate for his work.

Some exchange process occurs because the *pH* always increases after treatment. Since premoistened charcoal has to be used, the KCl solution to be purified has to be more concentrated than the final desired value, and the solution coming off the column has to be titrated and then diluted to the proper concentration. Another disadvantage in the use of charcoal is that the charcoal itself requires a lengthy and messy purification.

The electrocapillary (*t-E*) curve for a solution of the charcoal-treated material (diluted to 0.5*M* KCl) is not altered but is slightly displaced to lower drop times over the entire potential range.

Type II impurity.—The principal advantage of purification by electrolysis is in being able to plate out impurities on an electrode under conditions duplicating those used for subsequent voltammetric studies themselves.

In preliminary tests, 0.5*M* KCl solutions of *p*H 1.4, 6.4, and 12 were electrolyzed at a 5-mm diameter PGE at −0.8*V* for 10 min; without opening the circuit, the potential was then scanned to a more positive value. The resultant stripping peaks in the potential range of −0.8 to −0.2V. (Fig. 3) were largest at *p*H 1.4, indicating that impurities are most effectively removed at this *p*H. Stripping peaks observed between 0.2 and 0.7V are not due to the presence of the impurities, but are associated with the PGE surface (7).

The procedure for evaluating purity consists, then, essentially of electrolysis for 10 min at −0.8V, followed by scanning to 0.8V. During an electrolytic purification, *ca.* 1 liter of *p*H 1.4 potassium chloride solution is placed in the cell and its initial purity is

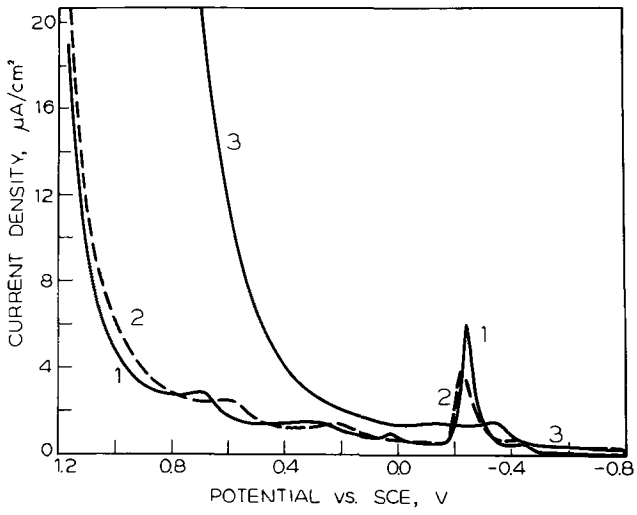

Fig. 3. Voltammograms for evaluating effectiveness of removal of type II impurities from 0.5M KCl solutions of pH 1.4 (curve 1), pH 6.4 (curve 2), and pH 12.7 (curve 3): stripping curves obtained after electrolysis at —0.8V for 10 min.

checked, using the 5-mm diameter PGE. After each 4 hr of electrolysis. the purity is rechecked. If further electrolysis is necessary, the Grafoil in the electrolysis cell is replaced by a fresh piece and the salt-bridge solutions are replaced by electrolyzed solution from the cell. Generally, at least 8 hr are necessary before stripping peaks are no longer observed in a solution-purity test. The electrolytic purification procedure does not appreciably alter the pH of the pH 1.4 solution used, because the amount of hydrogen ion gained or lost in 8 hr would be negligible. Purified solution can be drawn off via the Teflon stopcock whenever needed and brought to the desired pH by addition of acid or base.

Although at least three stripping peaks are observed, there is no way of determining whether any of them result from a type I impurity. Nevertheless, purification by pre-electrolysis also removes about 80 to 90% of the type I impurity, as measured operationally.

Acknowledgments

The authors thank Dr. Glenn Dryhurst, who first demonstrated the presence of the type I impurity, and the Atomic Energy Commission and the National Science Foundation for financial support of the work described.

Mathematical Study of Galvanic Corrosion

Equal Coplanar Anode and Cathode with Unequal Polarization Parameters

E. Kennard and J. T. Waber

Department of Material Science, Northwestern University, Evanston, Illinois

ABSTRACT

This paper gives a theoretical analysis of the distribution of potential and current density on the surface of a coplanar galvanic cell in which the polarization parameters for cathode and anode are unequal. The potential at any point can be represented as a Fourier series, in which the coefficients themselves are infinite series. It is shown that these Fourier coefficients can only be approximated by numerical methods. The potential distribution across the electrode at the electrode/electrolyte interface is shown to be dependent on both the anodic and cathodic polarization parameters and cannot be deduced from the potential distribution occurring when the anodic and cathodic polarization parameters are equal. As the cathodic polarization parameter is increased relative to that of the anode the potential shifts toward the open-circuit anodic voltage and both the potential and current distribution become more uniform. A parameter is suggested which characterizes the "microscopic" or "macroscopic" behavior of the cell. When the ratio between polarization parameters is large the behavior of the cell tends toward either anodic or cathodic control rather than the "mixed" control.

This paper gives a theoretical analysis of the distribution of potential for a galvanic cell in which the anode and cathode lie in the same plane. It is assumed that the slope of the current-potential curves has different values for the anodic and cathodic processes.

The distribution of potential in such a galvanic cell is determined by the current-potential relationship and the conductivity of the electrolyte solution. Wagner (1) formally proposed the name "polarization parameter" to represent the product of the conductivity and the slope of the polarization curve. The polarization parameter has the dimensions of length and it was shown by Waber (2) that the size of the cell in relation to the polarization parameter L could be used to determine whether the cell behaved in a microscopic or macroscopic fashion. In a microscopic cell the polarization parameter is large with respect to a characteristic dimension λ of the cell, and polarization

dominates to the extent that potentials are nearly uniform everywhere in the corroding liquid. If, on the other hand, the cell dimension is much larger than the polarization parameter, then the resistance drop through the electrolyte is controlling; this is a macroscopic cell, with large potential variations throughout the corrodent. The critical dimension λ of the cell is dependent on the configuration of the electrodes and electrolyte. Waber (3) showed that by using a linear approximation to the polarization curve the potential and current distribution could be calculated in terms of the polarization parameter, the equilibrium electrode potentials, and the geometric parameters of the cell. In this work the polarization parameter was assumed to be equal for the anodic and cathodic processes. The present work demonstrates the differences in potential which occur when the anodic and cathodic polarization parameters are unequal.

Description of Cell

In this work the model cell used is shown in Fig. 1. We choose the origin to lie in the plane at the midpoint of the anode. We assume both the anode and cathode to be infinite in the y-direction and of equal width c in the x-direction. The electrodes are covered by an electrolyte which is infinite in the $+z$-direction. A tangent approximation to the potential-current relationship is assumed. Figure 2 is a stylized representation of complex polarization curves such as reported by Ketcham and Haynie (3). Tangent lines are drawn to the polarization curves at some appropriate average current density. The intersections with the ordinate (E_a,E_c) are taken as the anodic and cathodic potentials for zero current. Of course these are in many cases very different from the true values. This method of linearizing a complex problem is equivalent to drawing a tangent to the enthalpy (H) curve for a two-component system in order to find the partial molar heats of mixing of the two components. In analogy one writes either

$$H^\alpha = H^\alpha{}_d + (\partial H/\partial x)\Delta x$$

for the enthalpy, or

$$E^\alpha = E_a + (\partial \Delta E_a/\partial J)J$$

for the polarization.

Mathematical Analysis

The polarized potential $P^*(x,z)$ in the cell must satisfy the two-dimensional Laplace equation

$$\partial^2 P^*/\partial x^2 + \partial^2 P^*/\partial z^2 = 0 \qquad [1]$$

and satisfy the boundary conditions

$$(\partial P^*/\partial x)_{x=0} = (\partial P^*/\partial x)_{x=c} = 0 \qquad [2]$$

$$P^*(x,0) = \begin{cases} E_a + L_a(\partial P^*/\partial z)_{z=0} & \text{for } 0 \leq x \leq c/2 \\ E_c + L_c(\partial P^*/\partial z)_{z=0} & \text{for } c/2 \leq x \leq c \end{cases} \qquad [3]$$

where L_a and L_c represent the anodic and cathodic polarization parameters.

The most general solution of Eq. [1] which satisfies the boundary Eq. [2] and which remains finite as z approaches either zero or infinity is

$$P^*(x,z) = A_0 + \sum_{n=1}^{\infty} A_n \cos(n\pi x/c) \exp(-n\pi z/c) \qquad \text{for } n = 1,2,3\ldots. \qquad [4]$$

The boundary conditions in Eq. [3] are used to determine the coefficients A_n of the series. The problem reduces to obtaining solutions of the infinite set of equations, for which A_i can now be regarded as the variable.

$$A_i = \sum_{j=0}^{\infty}{}' \alpha_{ij}A_j + \beta_i \qquad i = 0,1,2\ldots. \qquad [5]$$

where the prime on the summation indicates that the term $j = i$ is not included. The terms α_{ij} and β_i which enter as elements of the infinite determinant can be summarized as follows

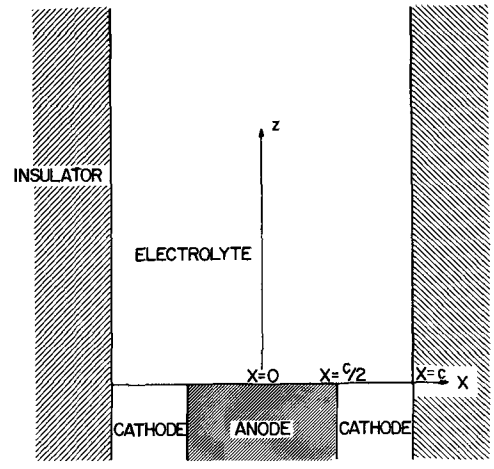

Fig. 1. Geometric arrangement of coplanar electrodes in model cell.

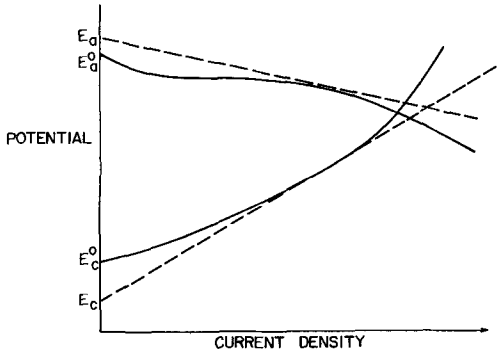

Fig. 2. Tangent approximation to the polarization curves. Extrapolated potentials E_a and E_c are not equal to the open-circuit potentials E_a° and E_c°.

Integers

i	j	Value of α_{ij}	Value of β_i
0	odd ≥ 1	$\alpha_{0j} = \dfrac{2(L_a - L_c)}{(L_a + L_c)} \sin(j\pi/2)$	$\beta_0 = \dfrac{(E_aL_c + E_cL_a)}{L_a + L_c}$
odd	even > 0	$\alpha_{ij} = \dfrac{-iL \sin(i\pi/2) \cos(j\pi/2)}{(a + bi)(j^2 - i^2)}$	$\beta_i = \dfrac{[(E_a/L_a) - (E_c/L_c)] \sin(i\pi/2)}{i(a + bi)}$
even	odd ≥ 1	$\alpha_{ij} = \dfrac{jL \sin(j\pi/2) \cos(i\pi/2)}{(a + bi)(j^2 - i^2)}$	$\beta_i = 0$
odd	odd	$\alpha_{ij} = 0$	
even	even	$\alpha_{ij} = 0$	

where the parameters L, a, and b are defined by

$$L = [(1/L_c) - (1/L_a)]$$

and

$$(a + bi) = \pi/4[(1/L_a) + (1/L_c) + 2i\pi/c]$$

The infinite set of simultaneous equations given by Eq. [5] possesses a unique solution which may be approximated using numerical methods. A discussion of the conditions under which a solution exists and a description of the numerical approximation is given in the Appendix.

The coefficients A_i were evaluated up to A_{100} for given parameters, L_a, L_c, voltages, E_a, E_c, and the electrode width c. The coefficients A were then substituted in Eq. [4] to obtain values for $P^*(x,z)$. The value of 100 was shown to be sufficient to ensure numerical convergence. The current density at the cathode was calculated using the dimensionless parameter

$$C_c(x) = \frac{P^*(x,0) - E_c}{L_c} \cdot \frac{2c}{E_a + E_c} \qquad c/2 \leq x \leq c$$

The anodic current density $C_a(x)$ is similarly defined Eq. [3]. It should be noted that the total current obtained by integrating $C_a(x)$ from 0 to $c/2$ is equal but opposite in sign to the similar integral of $C_c(x)$.

Results

The potential distribution at the electrode surface is shown in Fig. 3. These results were obtained by putting L_a equal to 1 cm and varying L_c from 0.1 to 10 cm. The total width c of the electrode was assumed to be equal to 1.0 cm.

Figure 4 shows the results obtained by setting $L_a = L_c = 10$ cm, and $L_a = L_c = 1$ cm. It is apparent that the behavior of the electrodes with unequal anodic and cathodic polarization parameters cannot be deduced from the separate curves obtained for equal polarization parameters.

Two curves are presented in Fig. 5 which represent the variation of the anodic current parameter $C_a(x)$ over the anode, and the cathodic current parameter $C_c(x)$ over the cathode; namely, the variation in current density as x ranges from 0 to 0.5c and from 0.5c to 1.0c. These two curves are drawn for a fixed value of L_a, namely 1 cm, but for two values of L_c. They illustrate the influence of L_c on the two current density parameters. In such circumstances, the anodic values are relatively uniform even though the cathodic values are not.

In order to assess the uniformity of corrosion attack, it is useful to construct the ratio of maximum to minimum current values. For the anode this is

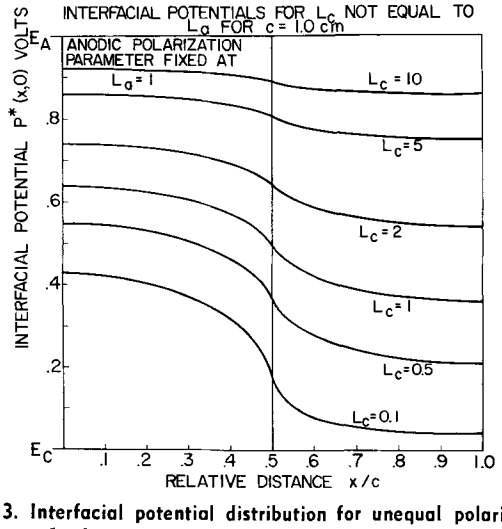

Fig. 3. Interfacial potential distribution for unequal polarization parameters, for $L_a = c = 1$ cm.

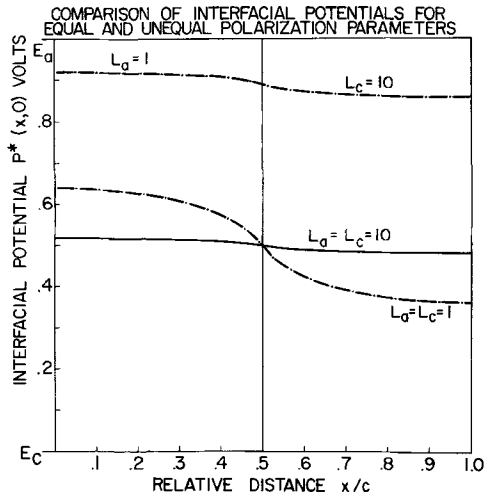

Fig. 4. Comparison of interfacial potential distribution for equal and unequal polarization parameters, presented as a function of (L_a/L_c) for fixed value of c.

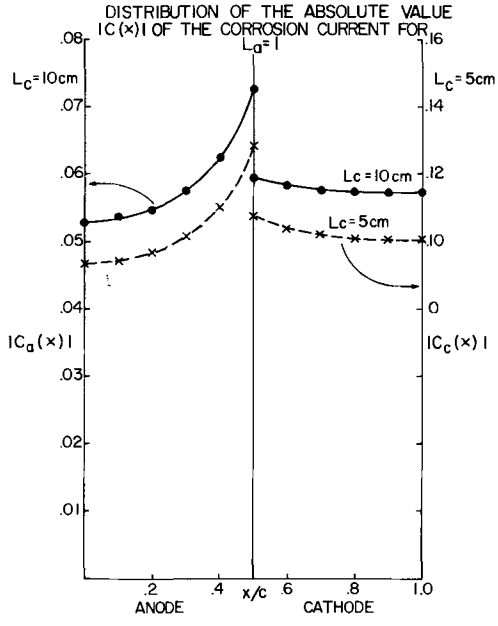

Fig. 5. Anodic and cathodic current densities for unequal polarization parameters, for $c = L_a = 1$ cm. Note that the gradients dC_a/dx and dC_c/dx in the vicinity of $x = c/2$ are inversely proportional to L_a and L_c, respectively.

$$\frac{\max C_a}{\min C_a} = \frac{C_a(x = 0.5c)}{C_a(x = 0)}$$

and similarly for the cathode

$$\frac{\max C_c}{\min C_c} = \frac{C_c(x = 0.5c)}{C_c(x = 1.0c)}$$

These two ratios are plotted as a function of the dimensionless parameter $2c/(L_a + L_c)$ in Fig. 6.

Discussion

In the majority of corrosion experiments one observes that the anodic and cathodic polarization parameters are approximately equal. However, in cases where the anodic reaction is strongly polarized, such as in a passive region, L_a is clearly much larger than L_c. The opposite situation might be encountered when the cathodic reaction is diffusion controlled. The present analysis is directed toward such situations. The question of the "microscopic" or "macroscopic" behavior of corrosion cells cannot be determined by the simple parameter (c/L). It can be seen from Fig. 3

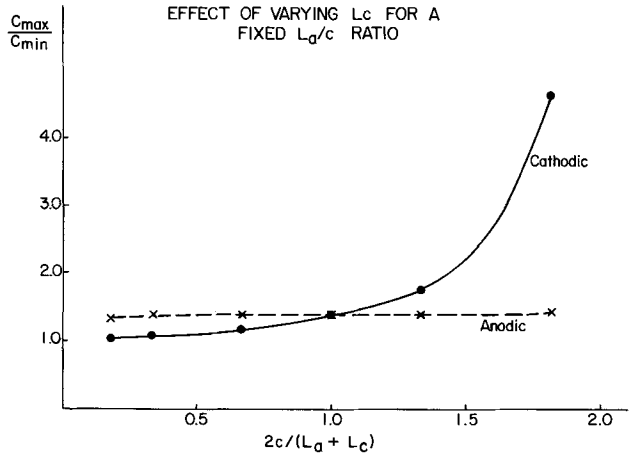

Fig. 6. Variation of the ratio of maximum to minimum current density with the parameter $2c/(L_a + L_c)$. Cathodic current full line, anodic current dashed line, for $c = L_a = 1$ cm. Small values of L_c are on the right-hand side.

that as the difference between the polarization parameters is increased the potential across the electrode becomes more uniform. We may thus replace the parameter (c/L) by $2c/(L_a + L_c)$ as the factor which determines whether the cell will behave "microscopically" or "macroscopically." When this ratio is small, the variation of current densities is small and the potentials are relatively uniform. These are the characteristics of a microscopic cell. In contrast, when the characterizing ratio is large, *i.e.*, when some cell dimension is much larger than both L_a or L_c, the cell can be regarded as "macroscopic." The variation of potential over the interface and the variation in current density is large. The ratio $2c/(L_a + L_c)$ represents what Waber (2) has defined as the characterizing size ratio (λ/L). Hence as the electrolyte is infinite the critical dimension λ is logically the electrode width c. It is reasonable to replace L by the average value $(L_a + L_c)/2$. Figure 6 thus shows that max C_a/min C_a increases rapidly as $2c/(L_a + L_c)$ exceeds unity. Since the total anodic current must be equal to the total cathodic current as L_c/L_a increases the anodic current is forced to decrease because the cathode is more effectively polarized. The net result of this is that there is a shift in both the anodic and cathodic potentials toward the open cell value of E_a and the distribution of potential over both anode and cathode becomes more uniform. This is illustrated in Fig. 3.

From Eq. [4] it can be seen that the potential of the specimen measured by a remote probe, *i.e.*, $P(x,\infty)$, is equal to A_o. The calculations show that A_o is equal to the mean of E_a and E_c for the case where L_a is equal to L_c. However, for $L_a > L_c$, A_o approaches E_c, and for $L_c > L_a$, A_o moves in the opposite direction toward E_a. The potential at a remote point $(z = \infty)$ is independent of x and has been named the potential of the composite electrode by Waber (5). One notes that the composite potential is dependent also on the ratio of the polarization parameters.

APPENDIX

A trial solution of Laplace's equation is

$$P(x,z) = A_o + \sum_{n=1}^{\infty} A_n \cos \frac{n\pi}{c} x \exp - \frac{n\pi}{c} z$$

which will be subject to the three boundary conditions

$$\frac{\partial P}{\partial x} = 0 \qquad \text{at } x = 0 \quad \text{and } x = c \qquad [1A]$$

$$P(x,o) = E_a + L_a \left.\frac{\partial P}{\partial z}\right|_{z=0} \qquad \text{for } 0 \leq x \leq c/2 \quad [2A]$$

$$P(x,o) = E_c + L_c \left.\frac{\partial P}{\partial z}\right|_{z=0} \qquad \text{for } c/2 \leq x \leq c \quad [3A]$$

Having defined $h \equiv \pi/c$, direct substitution of the series into boundary condition [2A] yields for $o \leq x \leq c/2$

$$A_o + \sum_{n=1}^{\infty} A_n \cos nhx = E_a + L_a \sum_{n=1}^{\infty} -nhA_n \cos nhx$$

Multiplying through by $\cos qhx$ (where q is an integer) and integrating with respect to (hx) from 0 to $\pi/2$, we obtain

$$\frac{A_o}{q} \sin (q\pi/2) + Aq\,\pi/4 + \sum_{\substack{n=1 \\ n\neq q}}^{\infty} \frac{A_n}{2} \left[\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q} \right] = \frac{E_a}{q} \sin q\,\pi/2 - L_a qh\, A_q\,\pi/4 - L_a \sum_{\substack{n=1 \\ n\neq q}}^{\infty} \frac{A_n}{2} nh \left[\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q} \right] \qquad [4A]$$

Similarly substituting into boundary condition [3A] and integrating from $\pi/2$ to π, we obtain

$$-\frac{A_o}{q} \sin q\,\pi/2 + A_q\,\pi/4 - \sum_{\substack{n=1 \\ n\neq q}}^{\infty} \frac{A_n}{2} \left[\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q} \right] = -\frac{E_c}{q} \sin q\,\pi/2 + L_c \sum_{\substack{n=1 \\ n\neq q}}^{\infty} \frac{nh}{2} A_n \left[\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q} \right] - L_c qh\, A_q \pi/4 \qquad [5A]$$

Dividing [4A] by L_a, [5A] by L_c and adding, one obtains

$$\frac{A_o}{q} \sin q\,\pi/2 \left[\frac{1}{L_a} - \frac{1}{L_c} \right] + (\pi/4)\, A_q \left[\frac{1}{L_a} + \frac{1}{L_c} \right] + \left[\frac{1}{L_a} - \frac{1}{L_c} \right] \sum_{\substack{n=1 \\ n\neq q}}^{\infty} \frac{A_n}{2} \left[\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q} \right] = \left[\frac{E_a}{L_a} - \frac{E_c}{L_c} \right] \frac{\sin q\,\pi/2}{q} - A_q (q\,h\pi/2) \qquad [6A]$$

For convenience, let us define two auxiliary factors

$$L \equiv \frac{1}{L_c} - \frac{1}{L_a}$$

$$a + bq \equiv (\pi/4) \left[\frac{1}{L_a} + \frac{1}{L_c} + 2qh \right]$$

Rearranging Eq. [6A] one obtains

$$A_q = \frac{A_o}{q} \frac{\sin q\pi/2}{[a+bq]} L + \frac{L}{[a+bq]} \sum_{\substack{n=1 \\ n\neq q}}^{\infty} \frac{A_n}{2} \left[\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q} \right] + \left[\frac{E_a}{L_a} - \frac{E_c}{L_c} \right] \frac{\sin q\,\pi/2}{q[a+bq]} \qquad [7A]$$

Defining the auxiliary function g as $g(n,q) \equiv$

$$\frac{\sin (n+q)\,\pi/2}{n+q} + \frac{\sin (n-q)\,\pi/2}{n-q}$$

The following four possibilities obtain

q	n	
odd	odd	$g(n,q) = 0$
odd	even	$g(n,q) = \frac{2}{n^2 - q^2}(-q \sin q\,\pi/2 \cos n\,\pi/2)$
even	even	$g(n,q) = 0$
even	odd	$g(n,q) = \frac{2}{n^2 - q^2}(n \sin n\,\pi/2 \cos q\,\pi/2)$

Substituting in [7A], we obtain when q is an odd integer

$$A_q = \frac{A_o}{q}\frac{\sin q\,\pi/2}{[a + bq]} \cdot L + \frac{L}{[a + bq]} \sum_{\substack{\text{even} \\ n}} A_n \left[\frac{-q}{n^2 - q^2}\right] \sin q\,\pi/2 \cos n\pi/2 + \left[\frac{E_a}{L_a} - \frac{E_c}{L_c}\right] \frac{\sin q\,\pi/2}{q[a + bq]} \quad [8A]$$

but when q is an even integer

$$A_q = \frac{L}{[a + bq]} \sum_{\substack{\text{odd} \\ n}} A_n \left[\frac{n}{n^2 - q^2}\right] \sin n\,\pi/2 \cos q\,\pi/2 \quad [9A]$$

Returning now to our boundary condition, we can also solve for A_o in the following way

$$0 \leq x \leq c/2$$

$$A_o + \sum_{n=1}^{\infty} A_n \cos nhx = E_a + L_a \sum_{n=1}^{\infty} -nh\, A_n \cos nhx$$

Integrating $P^*(x,0)$ with respect to (hx) from 0 to $\pi/2$

$$A_o\,\pi/2 = E_a\,\pi/2 - L_a h \sum_{n=1}^{\infty} A_n \sin n\,\pi/2 \quad [10A]$$

and separately from $\pi/2$ to π

$$A_o\,\pi/2 - \sum_{n=1}^{\infty} \frac{A_n}{n} \sin n\,\pi/2 = E_c\,\pi/2 + L_c h \sum_{n=1}^{\infty} A_n \sin n\,\pi/2 \quad [11A]$$

Dividing the first of this pair by L_a, and the second by L_c and adding, we obtain

$$A_o = 2/\pi \left(\frac{L_a - L_c}{L_a + L_c}\right) \sum_{\substack{\text{odd} \\ n}} \frac{A_n}{n} \sin (n\,\pi/2) + \left[\frac{E_a}{L_a} + \frac{E_c}{L_c}\right] \frac{L_a L_c}{L_a + L_c} \quad [12A]$$

Now make the variable change, $B_n = nA_n$ for $n = 1,2,\ldots\ldots$ and we obtain from Eq. [8A], [9A], and [12A], an infinite set of linear equations in the variables A_o and B_n which is of the form

$$B_j = \sum_i \alpha_{ij} B_i + \beta_j \quad [13A]$$

Specifically

$$q = 0 \qquad A_o = 2/\pi \left(\frac{L_a - L_c}{L_a + L_c}\right) \sum_{\substack{\text{odd} \\ n}} \frac{B_n}{n^2} \sin n\,\pi/2 + \left[\frac{E_a}{L_a} + \frac{E_c}{L_c}\right] \frac{L_a L_c}{L_a + L_c}$$

q an odd integer

$$B_q = A_o \sin q\,\pi/2 \frac{L}{a + bq} + \frac{Lq}{a + bq} \sum_{\substack{\text{even} \\ n}} \frac{-qB_n}{n(n^2 - q^2)} \sin q\,\pi/2 \cos n\,\pi/2 + \left[\frac{E_a}{L_a} - \frac{E_c}{L_c}\right] \sin \frac{q\,\pi/2}{a + bq} \quad [14A]$$

q an odd integer

$$B_q = \frac{Lq}{a + bq} \sum_{\substack{\text{odd} \\ n}} \frac{B_n}{n^2 - q^2} \sin n\,\pi/2 \cos q\,\pi/2$$

A set of equations of the form [13A] has a unique solution if certain convergency conditions are satisfied (4). These conditions are

$$(a) \quad \sum_i |\alpha_{ij}| < 1 \qquad j = 1,2,\ldots\ldots$$

$$(b) \quad |\beta_j| \leq K\left[1 - \sum_i |\alpha_{ij}|\right] \qquad K > 0$$

If these conditions are satisfied, then it can be shown that a bounded solution of the finite set of N equations

$$B_j = \sum_{i=1}^{N} B_i + \beta_j \quad [15A]$$

which we represent as $\{B_j^N\}$ is an approximation to the solution $\{B_j\}$ in the sense that $\lim_{N \to \infty} \{B_j^N\} = \{B_j\}$ and thus an approximation to B_j can be obtained by solving a finite set of simultaneous equations.

In order to prove the convergence of the equations given by [14A], we must thus consider the infinite sums

$$(i) \quad 2/\pi \left(\frac{L_a - L_c}{L_a + L_c}\right) \sum_{\substack{\text{odd} \\ n}}^{\infty} \left|\frac{1}{n^2}\right|$$

$$(ii) \quad \frac{Lq^2}{a + bq} \sum_{\substack{n \\ \text{even}}}^{\infty} \left|\frac{1}{n(n^2 - q^2)}\right|$$

$$(iii) \quad \frac{Lq}{a + bq} \sum_{\substack{\text{odd} \\ n}}^{\infty} \left|\frac{1}{n^2 - q^2}\right|$$

Considering first (i), it is easily shown that

$$\sum_{\substack{\text{odd} \\ n}} \left|\frac{1}{n^2}\right| = \frac{\pi^2}{8}$$

thus the infinite sum reduces to $\pi/4\ |L_a - L_c/L_a + L_c|$ and this is obviously < 1.

Turning now to Eq. (ii) and (iii), we must consider the infinite sums

$$\frac{q^2 L}{(a + bq)} \sum_{\substack{\text{even} \\ n}} \left|\frac{1}{n(n^2 - q^2)}\right|$$

and

$$\frac{qL}{(a + bq)} \sum_{\substack{\text{odd} \\ n}} \left|\frac{1}{n^2 - q^2}\right|$$

Without detailing the proofs, it can be shown that these sums are equal to

$$\frac{L}{a + bq}\left[1 + \log 2 + \left[1 + \frac{1}{2} + \frac{1}{3} \cdots \frac{2}{q-1}\right] - \left[\frac{1}{q+2} + \frac{1}{q+4} \cdots \frac{1}{2q-1}\right] - \frac{1}{2q}\right]$$

and $\frac{L}{a + bq} \sum_{n=1}^{q} \frac{1}{2n - 1}$, respectively.

It is not possible from these expressions to determine exactly the convergence for any arbitrary values of L_a, L_c, and c.

The convergence was investigated by selecting reasonable values for L_a, L_c, and c and numerically evaluating the expressions. These were found to be less than unity for the values of L_a, L_c, and c quoted in the section on "Results." The expressions were found to take on values greater than unity for either very large or very small ratios of L_a to L_c.

In a similar fashion, the convergence condition (*b*) concerning the magnitude of the free terms b_i was investigated by numerical evaluation. After the convergence conditions were tested in this fashion, the set of Eq. [15A] was solved for $N = 100$, and for given values of L_a, L_c, E_a, E_c, and c. The simultaneous set of equations was solved by direct substitution using a CDC 6400 computer.

Electrochemical-Chemical Synthesis of Methylene bis(Aluminum Dichloride)

Edward H. Mottus and Morris R. Ort

Monsanto Company, St. Louis, Missouri and Texas City, Texas, respectively

ABSTRACT

The electrochemical-chemical (EC) synthesis of methylene bis(aluminum dichloride), $Cl_2AlCH_2AlCl_2$, involves electrolysis of dichloromethane solutions using an aluminum anode and a passive cathode in an undivided cell. The aluminum anode is consumed during electrolysis. One gram-atom aluminum is lost per faraday. Suitable electrolytes are $AlCl_3$, $HOAlCl_2$, tetraalkylammonium chlorides, and, in general, salts that are sufficiently soluble in dichloromethane to give conducting solutions. The nature of the reactions and characterization of the products are discussed.

The electrochemical synthesis of organometallics usually involves the electrolysis of organometallic A to produce organometallic B or the reduction of a species

$$\text{(i.e., RX, RCR, } CH_2 = CHCN\text{, etc.)}$$

at a reactive cathode to form the organometallic of the cathode material (1). Some Kolbe reactions are reported to give direct reaction of an organic compound with a reactive anode (2). Chadwick and Kinsella (3) reported the preparation of methylaluminum diiodide by electrolysis of a solution of aluminum triiodide in methyl iodide with aluminum electrodes. We wish to report the EC synthesis of methylene bis(aluminum dichloride) ($Cl_2AlCH_2AlCl_2$) I.

Experimental

Electrolysis cells.—Small-scale electrolyses (100 ml total volume) were carried out in a tubular cell, 4 cm diameter and approximately 25 cm tall. The cell was fitted with ports for electrical leads and a condenser. An opening was provided at the bottom of the cell to allow introduction of gases into the electrolysis solution. The electrodes were constructed from 99.99% aluminum sheet 0.01 in. thick (Consolidated Aluminum Company of Canada) as concentric cylinders. The cathode was 2 in. high x ½ in. diameter, the anode was 2 in. high x 1 in. diameter, and they were held in place with Teflon spacers. In some experiments a platinum cathode was used. Stirring in the cell was with a magnetic stirring bar and by passage of gas through the electrolysis solution.

Larger-scale electrolyses were carried out in a 500 ml cell. In this cell a three-electrode concentric cylinder assembly was used. The dimensions of the cylinders were 1¾, 2¼, and 2¾ in. in diameter and 1 in. high. The inner and outer electrodes were cathodes, and the middle electrode was the anode.

Prior to use, the cell assemblies were dried in an air-circulating oven at 140°C. The cells were assembled hot and cooled under dry nitrogen.

Electrolyte solutions.—*Solvent.*—Dichloromethane (Matheson, Coleman and Bell or Fisher Scientific) was dried by passing through a 3 ft x 1 in. column packed with 3A molecular sieves (Linde).

Method A.—To 400 ml of dichloromethane under nitrogen was added 0.036 ml (0.002 mole) of water. The mixture was stirred until solution was complete and 0.267g (0.002 mole) of sublimed aluminum chloride added. The mixture was stirred overnight to give a clear, yellow solution. The solution was used as prepared or was heated under reflux to drive off by-product HCl.

Method B.—To 400 ml of dichloromethane under nitrogen was added 0.25g (0.002 mole) of ethylaluminum dichloride (Texas Alkyls Inc.). The solution was stirred and 0.036 ml (0.002 mole) of water added. The mixture was stirred overnight to give a clear, yellow solution of $HOAlCl_2$.

Method C.—A mixture of 0.267g (0.002 mole) of sublimed aluminum chloride and 400 ml of dichlorometh-

ane was refluxed under nitrogen overnight to a clear, light-yellow solution.

Methylene bis(aluminum dichloride).—The 500 ml cell was charged with 564g of electrolyte solution containing 5 millimoles/l of electrolyte with a 2.88 Cl^-/Al ratio. The electrolyte solution was saturated with ethylene and electrolyzed for 40 min at 0.5A with a steady-state voltage of 185-195V. Ethylene was continuously bubbled through the cell during electrolysis. After the electrolysis was complete, the solution was transferred to a 500 ml flask under nitrogen. The mixture was refluxed for about 30 min to drive off the excess ethylene and any HCl if present. During the electrolysis 12.21 m**F** of current were passed, and 0.3377g (12.51 mg atom) of aluminum was lost from the anode. This corresponds to 1.03 g atom of Al/**F**. The weight of the cathodes remained unchanged. Weight fractions of the solution were analyzed for Cl^-, Al-C bonds (4), and Al.

Anal. Calcd.—for $Al_2CH_2Cl_4$: Al, 0.10%; Al-C bonds, 12.51 meq; Cl^-, 30.75 meq. Found: Al, 0.09%; Al-C bonds, 12.01, 11.77 meq; Cl^-, 30.00, 30.00 meq.

The above Al and Cl^- analyses include the electrolyte in the solution of I. The chemical yield of I is $\sim$ 100%.

Alkylaluminum chloride etherates.—A RB flask equipped with a magnetic stirring bar and 3-way stopcock was charged with a known quantity of alkylaluminum chloride in dichloromethane or hexane solution. The solution was stirred and an excess of diethyl ether added. The excess ether and solvent were removed by distillation and the last traces of volatiles removed by pumping under 0.1 mm vacuum overnight. The alkylaluminum chloride etherates were diluted approximately 50% with dichloromethane for nmr studies.

Nmr.—The spectra were obtained on either a Varian A-60 or A-56-60. The internal standards were either TMS or dichloromethane. Where dichloromethane was used as the internal standard, the values were converted to TMS reference for comparison.

Results and Discussion

The EC synthesis of I involves the electrolysis of dichloromethane in the presence of an electrolyte at an aluminum anode in an undivided cell. The aluminum anode is consumed during the electrolysis. The over-all reaction is EC since 1g atom of the aluminum anode is consumed per faraday. If the reaction were truly electrochemical, 3 faradays/g atom of aluminum consumed would be required. The following sequence of reactions is postulated to account for the formation of I and by-products.

At cathode:

$$CH_2Cl_2 + e^- \rightarrow Cl^- + ClCH_2\cdot \quad [1]$$

$$CH_2Cl_2 + 2e^- \rightarrow 2Cl^- + CH_2: \quad [2]$$

If [1] is operative, the chloromethyl radical can dimerize.

$$2ClCH_2\cdot \rightarrow ClCH_2CH_2Cl \quad [3]$$

However, [2] is the most probable reaction, and the carbene formed undergoes typical carbene reactions.

$$2CH_2: \rightarrow CH_2 = CH_2 \quad [4]$$

$$CH_2 = CH_2 + CH_2: \rightarrow \begin{matrix} & CH_2 & \\ \diagup & & \diagdown \\ CH_2 & & CH_2 \end{matrix} \quad [5]$$

$$CH_2: + CH_2Cl_2 \rightarrow ClCH_2CH_2Cl \quad [6]$$

At anode

$$Cl^- \rightarrow e^- + Cl\cdot \quad [7]$$

$$Cl\cdot + Al \rightarrow AlCl \quad [8]$$

$$AlCl + CH_2Cl_2 \rightarrow Cl_2AlCH_2Cl \quad [9]$$

$$AlCl + Cl_2AlCH_2Cl \rightarrow \underset{\text{I}}{Cl_2AlCH_2AlCl_2} \quad [10]$$

Reactions [9] and [10] are postulated on the fact that AlCl is electronically analogous to carbene and probably undergoes the same type of reactions as carbene.[1]

The essential features of the anode reactions are, first, the oxidation of chloride to atomic chlorine and, second, the attack of atomic chlorine on the aluminum anode to give aluminum monochloride, the key intermediate in the synthesis of I.

The chemical reaction of aluminum and dichloromethane does not take place under standard conditions. Lehmkuhl and Schäfer (5) reported the synthesis of I in approximately 40% yield by the reaction of dichloromethane with aluminum shot-etched with dibromomethane or by using aluminum tribromide as an initiator.

The reaction in this case was through bromide followed by exchange of chloride for bromide.

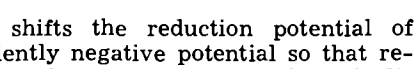
The basic reaction sequences presented here are believed to be general and will be further defined by us at a later date.

The conditions used during electrolysis played a large and unique role in the electrochemical synthesis.

If the electrolyses were carried out under nitrogen, Al (6) was deposited at the cathode via

$$AlCl_2^+ + 3e^- \rightarrow Al + 2Cl^- \quad [11]$$

Under these conditions the electrolyte was depleted and the conductance of the cell decreased with time.[2] However, if, under nitrogen, cyclohexene was added to the electrolysis solution, or ethylene was used as the blanketing gas instead of nitrogen, the deposition of Al at the cathode did not occur. Further, the conductance remained high throughout the electrolysis. The role of the olefin must be that of complex formation with the $AlCl_2^+$. Complex of the $AlCl_2$ cation with



[12]

olefin apparently shifts the reduction potential of $AlCl_2^+$ to a sufficiently negative potential so that reduction of dichloromethane becomes the only cathodic process.

The effect of the use of ethylene *vs.* nitrogen on the cell resistance is shown in Fig. 1. Shown in Fig. 1 are three electrolyses in which only the atmosphere has been changed. The cell resistances were calculated from the voltage and amperage at the experimental points. The sharp increase in cell resistance is immediately reversed by changing the atmosphere in the cell from nitrogen to ethylene (plot 3). Plot 2 shows that by carrying out the electrolysis for approximately 2 hr before the ethylene atmosphere is introduced most of the electrolyte has been depleted. Even though the electrolyte has been largely depleted, the introduction of ethylene has a significant effect on the cell resistance.

The use of ethylene or other olefins during electrolysis did not alter the composition of the product. Decomposition of the product solutions with CH_3OD gave mainly CH_2D_2 whether the electrolyses were carried out under nitrogen or ethylene. Deuterated ethane was never observed as a product of reaction with CH_3OD.

In some of our work the electrolysis was carried out under 6-11 psig ethylene pressure. Mass spectral analysis of gaseous atmosphere after electrolysis showed

[1] The referee questioned whether an attempt had been made to identify the intermediate Cl_2AlCH_2Cl as was postulated in Eq. [9]. The presence of small amounts of Cl_2AlCH_2Cl was indicated by mass spectral analysis of the gases obtained by decomposition of electrolysis solutions containing I with methanol. In all of the decomposition studies 0.5-0.7% CH_3Cl was observed which would only arise from Cl_2AlCH_2Cl. Since the postulated reactions occur at the metal surface the absence of larger amounts of Cl_2AlCH_2Cl is not surprising.

[2] The referee commented on the decline of conductivity under N_2 even though concentration of I was increasing and I is an electrolyte. I is a satisfactory electrolyte only in the presence of olefin. We propose that the olefin promotes ionization of I by complexing with the cationic species.

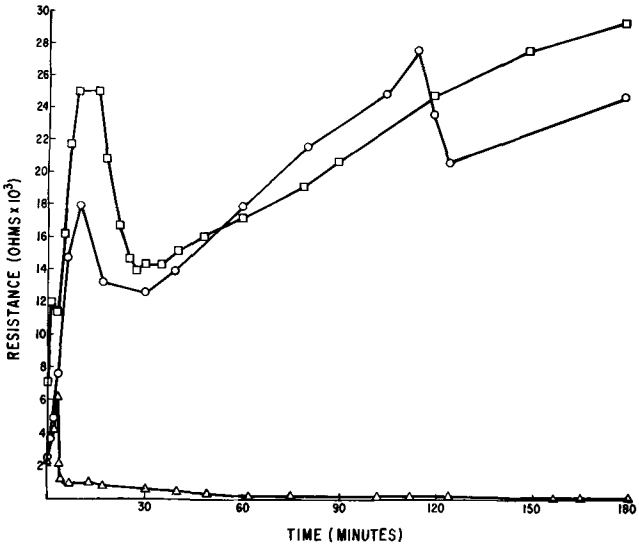


Fig. 1. Effect of ethylene on cell resistance: curve 1, □, electrolysis under nitrogen; curve 2, ○, electrolysis under nitrogen for 114 min, then under ethylene for 66 min; curve 3, △, electrolysis under nitrogen for 3 min, then under ethylene for 177 min.

the predominate product to have a mass of 42. For this specific experiment it was not determined if the product was propylene or cyclopropane. However, in subsequent work (to be reported by us at a later date) on a related reaction, the product with mass of 42 was identified as cyclopropane. By analogy we postulate that the reduction of dichloromethane is a 2-electron reduction to give carbene which adds to ethylene to give cyclopropane (see Eq. [5]).

In most of the studies the electrolyte was either $AlCl_3$ or $HOAlCl_2$, from the reaction of H_2O with $AlCl_3$ or $C_2H_5AlCl_2$. Other electrolytes investigated were tetraethylammonium chloride and manganese chloride. Both these were sufficiently soluble in CH_2Cl_2 to give conducting solutions and allow electrolyses to give I. Solutions of I in CH_2Cl_2 (at 2.5 x 10^{-3} mol/l) were also used as electrolyte.

The nature of product I has been established by decomposition studies, titration, and nmr. Decomposition of electrolysis solutions with CH_3OD yields mainly CH_2D_2, which can only arise from al-CH_2-al species. Titration with iodine yields one —C(Cl)—al— bond per Al lost from anode. Nmr spectrum of the etherate of I was compared with that reported for I prepared by Lehmkuhl and Schäfer. They isolated, characterized, and obtained the nmr spectrum of the dietherate of I. The al-CH_2-al protons were observed at τ, 11.01. When electrochemically prepared I was complexed with ether and the nmr spectrum obtained, two peaks were observed at τ, 11.14 and τ, 10.44. The peak at 11.14 corresponds to the dietherate of I; the one at 10.44 was of unknown origin.

Alkylaluminum chlorides are known to exchange rapidly to give equilibrium mixtures. For example, a solution of methylaluminum dichloride (25%) and dimethylaluminum chloride (75%) shows only a single sharp proton resonance signal both at room temperature and at —60°C (7).

It had been observed in long-term electrolysis that solid products began to precipitate toward the end of the electrolysis. If I underwent exchange reactions and the product of the exchange reaction was a solid, the equilibrium would be altered. Further, by complexing with ether the exchange should be stopped and both products observed by nmr. The exchange reaction is proposed as follows

$$2Cl_2AlCH_2AlCl_2 \rightarrow AlCl_3 + \underset{\text{II}}{Cl_2AlCH_2\overset{Cl}{\overset{|}{A}}lCH_2AlCl_2}(S) \qquad [13]$$

In order to determine if the peak at τ, 10.44 could be assigned to II, a series of alkyl aluminum chloride etherates was prepared in which the Al/CH_2 was varied. The influence of the aluminum on the methylene protons should vary as the Al/CH_2 ratio varies. The results are given in Table I.

In order to eliminate possible differences in the shielding of multiple ether complexing on the same molecule ethylaluminum dichloride, ethylaluminum dichloride etherate, I and I·diethereate were compared. The results are given in Table II.

The results in Table II indicate that the effect of adding ether is additive, and the contribution is the same for each aluminum etherate.

The results given in Table I indicate that the effect of aluminum on adjacent methylene protons is additive, and the peak at τ, 10.44 can probably be assigned to compound II. Further evidence that this assignment is correct is that, as the electrochemically prepared I was allowed to stand, more solids precipitated. When the etherate complex of the solution with an increased amount of solids present was prepared and the nmr spectrum obtained, the peak at τ, 10.44 increased at the expense of the peak at τ, 11.14.

Stable solutions of I in CH_2Cl_2 could be prepared by carrying out a series of electrolyses in which the electrolyte was the solution of I from the previous experiment. These solutions did not deposit solids (11) on standing. It is proposed that $AlCl_3$ or HCl in electrolysis solutions catalyzes the conversion I → II (Eq. [13]). The technique of successive electrolyses provides the means of obtaining solutions of I free from other Al species.

Summary

The electrochemical synthesis of methylene bis(aluminum dichloride) is an EC type involving electrochemical reduction of chloride to atomic chlorine, attack of atomic chlorine on the aluminum anode to yield aluminum monochloride. Reaction of this key intermediate with the solvent, dichloromethane, leads to the product. The cathodic products are postulated to arise from carbene, the two-electron reduction product of dichloromethane.

Estimation of Molecular Diffusivities in Liquids

R. O'Brien,* D. Quon, and C. R. Darsi

Department of Chemistry, University of Victoria, Victoria, British Columbia, Department of Chemical and Petroleum Engineering, University of Alberta, Edmonton, Alberta, and Chemcell Ltd., Edmonton, Alberta, respectively, Canada

ABSTRACT

A new experimental technique for measuring molecular diffusion through liquids, using microcell interferometry, is described. The main advantage is that an experiment can be performed in a few minutes. Aside from the saving in time, these short runs, which are inherently unsteady state, are more likely to be free of external effects. Concentration profiles are recorded on film at suitable time intervals. By analyzing the semidiscrete form of the diffusion equation and by a suitable linear transformation of the variables denoting the concentration profile, linear relationships are established between the logarithms of these transformed concentrations and time. This permits the determination of the diffusivity with maximum sensitivity. Conventional "least squares" curve fitting techniques are shown to be inadequate for analyzing the data from these experiments.

The present paper is concerned with (*a*) a description of the experimental techniques in which data on transient one-dimensional diffusion in a liquid are obtained by optical methods, and (*b*) a mathematical analysis of these data to determine diffusivities.

Experimental Techniques

The technique to be described involves microcell interferometry. Since a considerable amount of work in the fields of measuring diffusivities has been done in the past with a wide variety of apparatus, it is of some importance to show why a new technique should be introduced. The justification must be that either convenience or accuracy or both are better served.

Most diffusion apparatus in the past (1) has been large, with a long diffusion path, and relatively small concentration gradients. This has led to long experimental elapsed times and, hence, a difficulty in isolating the system from outside perturbations. In these measurements extremely good thermostatting arrangements have been necessary to avoid thermally induced convection, and great care must be taken to avoid mechanical agitation of any kind.

The advantages of the present cell is that experimental results are obtained very quickly, in only a few minutes. Better accuracies are to be expected since the outside perturbations are usually too slow to affect the results.

Furthermore, since the concentration gradient is produced electrochemically, a wide variety of gradients can be selected, including very steep ones, and the diffusion path is short.

Apparatus and procedure.—The main apparatus consists of an interferometer cell, its light source and the recording apparatus, in this case a motion picture camera.

The cell, shown in Fig. 1, has been described in some detail elsewhere (2). Briefly, it consists of a wedge-

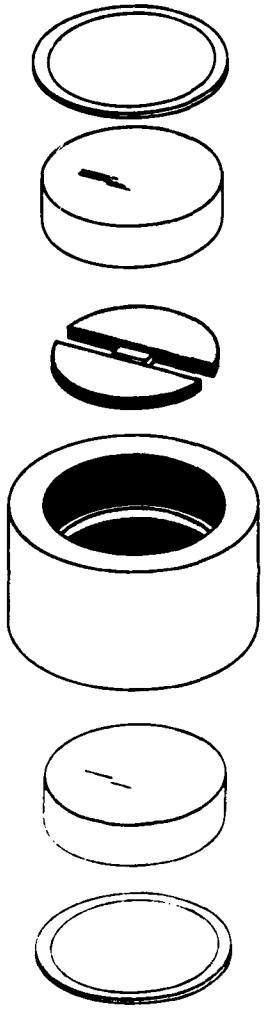

Fig. 1. Interferometric microcell

* Electrochemical Society Active Member.

type interferometer set up as an electrochemical cell. Copper blocks are sandwiched between glass flats which have partially reflecting dichroic coatings on the inner surfaces. Collimated sodium vapor light at near 90° incidence is made to interfere by beam intensity splitting at the reflecting coatings (Fig. 2) and a system of light and dark fringes at a spacing of about 3/mm is produced.

The experiments were carried out at two copper block spacings, 3 mm and 30 mm apart. These blocks, connected to a potential source, acted as parallel-faced horizontal electrodes with the cathode above the anode, separated by 0.1N $CuSO_4$ solution of pH 4.5. The electrical circuit was arranged to give a constant current of about 1 mA/cm^2. After approximately 3 min of electrolysis, the established concentration gradient (as shown by the bends in the interference fringes, Fig. 3) extended toward the center of the cell from both the anode and the cathode but left an unaltered volume of electrolyte in the center. The motion picture camera was started and the current switched off. Previous tests had confirmed that a linear relationship exists between concentration and refractive index. Hence, the shape of the interference fringes corresponds to the concentration profile existing in the cell. Figure 3 shows typical sets of fringes obtained at various times during the course of one run. For that particular magnification, the scale shows the relation between the concentration (in gram-moles/liter) and fringe displacement. Full details on how to interpret these fringes are given elsewhere (2). It was felt more desirable to study the decay portion of the curve, rather than the build-up portion, in order to avoid extraneous electrical effects. Since the camera speed was 8 frames/sec and about 5 min of the concentration gradient decay process were taken, only certain frames were analyzed (about 10). Further, in analyzing the fringes, each of which represents not only a refractive index contour but also a concentration contour, only certain fringes and certain points selected from these fringes were used. In fact, a fringe was selected which appeared to be representative and the same fringe was measured in each frame.

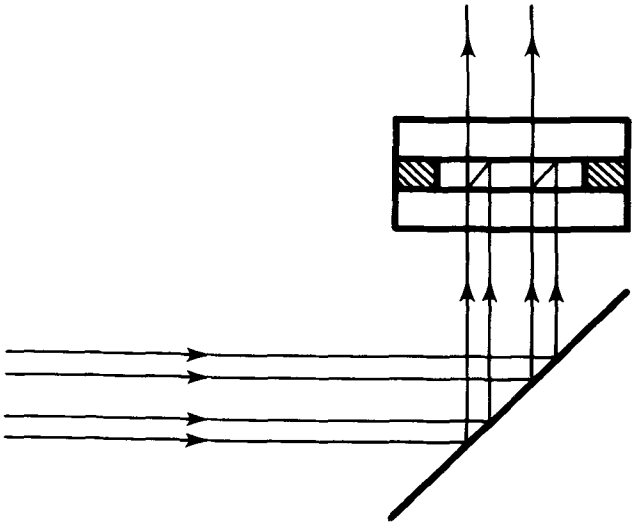

Fig. 2. Schematic diagram of light path

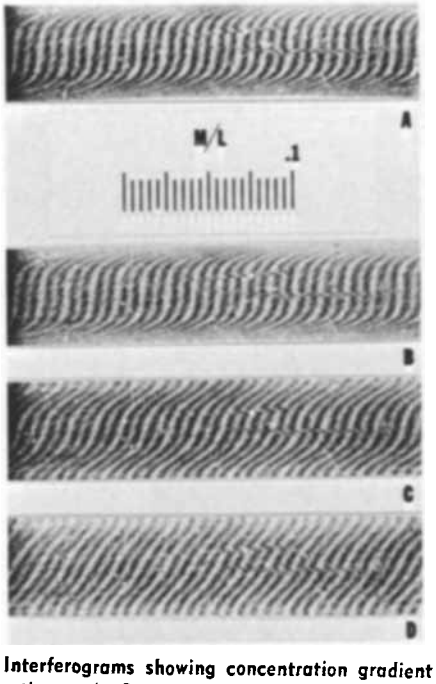

Fig. 3. Interferograms showing concentration gradient relaxation at various times: A, 0 sec; B, 1 sec; C, 60 sec; d, 30 sec.

Two methods of measuring were used. In some cases the fringe was projected on to rectangular coordinate graph paper at about 50X magnification, then sketched in with a pencil and the requisite values obtained by eye. In other cases, the film negative was placed in a flying spot digitalizer and computer punch cards made for various points on the selected fringe. These were then curve fitted on a computer and the values required found from an interpolation routine.

Mathematical Analysis

The general one-dimensional diffusivity equation with no internal source terms, is given by

$$\frac{\partial}{\partial x}\left(D\frac{\partial u}{\partial x}\right) = \phi\frac{\partial u}{\partial t} \qquad \begin{matrix} 0 < x < L \\ 0 < t \end{matrix} \qquad [1]$$

where u is the concentration, x distance, t time, D diffusion coefficient, ϕ the capacity factor, and L cell width.

For a typical boundary condition, one that corresponds to the experiments to be described later, the concentration is constant at the cell center and the gradient is zero at the walls. If the cell walls correspond to $x = 0$ and $x = L$, then these boundary conditions and any arbitrary but known initial condition are described by

$$\frac{\partial u}{\partial x} = 0 \qquad \text{at } x = 0,\ t > 0 \qquad [2]$$

$$u = u_c \qquad \text{at } x = L/2,\ t > 0 \qquad [3]$$

$$u = u_1(x) \qquad \text{at } t = 0,\ 0 < x < L/2 \qquad [4]$$

If D and ϕ are constant then the equation reduces to

$$\alpha\frac{\partial^2 u}{\partial x^2} = \frac{\partial u}{\partial t} \qquad [5]$$

where $\alpha = D/\phi$.

An analytical solution for the above problem is given by Carslaw and Jaeger (3) in the form of an infinite series, as follows

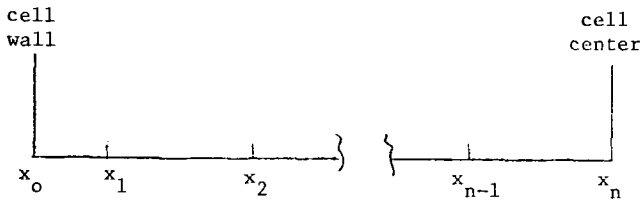
$$u = u_c + \frac{2}{(L/2)}\sum_{n=0}^{\infty}\exp\left[\frac{-\alpha(2n+1)^2\pi^2 t}{4(L/2)^2}\right] \cdot \cos\frac{(2n+1)\pi x}{2(L/2)}\left[\frac{2(L/2)(-1)^n u_c}{(2n+1)\pi} + \int_0^{L/2} u_1(x') \cdot \cos\frac{(2n+1)\pi x'}{2(L/2)} \cdot dx'\right] \qquad [6]$$

where x' is a dummy variable.

If data are available in discrete form, in which u is tabulated at various x's and t's but α itself is unknown, then presumably Eq. [6] can be used to calculate α. The best method appears to be a trial-and-error one, *i.e.*, guess a value of α, calculate u for a given x and t and compare this to the experimental value of u. One

could then use the least squares criterion to get the best fit value of α for the whole set of data. However, attempts to apply this technique to the experimental data from the test cells failed to yield useful results, for reasons which will be discussed later.

We have therefore set up an alternate mathematical model which permits a much more meaningful interpretation of the data. The space derivative in Eq. [5] may be discretized using the grid spacing shown below



where $x_{i+1} - x_i = \Delta x - h$ a constant $i = 2, \ldots, n$ and $x_1 - x_0 = \Delta x/2 = h/2$

Using central difference approximations, where appropriate

$$\frac{\partial^2 u_1}{\partial x^2} \simeq \frac{u_2 - u_1}{\Delta x^2}$$

$$\frac{\partial^2 u_i}{\partial x^2} \simeq \frac{u_{i-1} - 2u_i + u_{i+1}}{\Delta x^2} \qquad i = 2, \ldots, n-1$$

$$u_n = u_c \qquad [7]$$

This may be written in matrix form as

$$\frac{du}{dt} = \frac{\alpha}{h^2} Ku + b \qquad [8]$$

where u is the concentration vector, K the coefficient matrix, and b the boundary value vector (which is constant in this case).

If the potential vector u happens to fall along one of the characteristic directions of K (as represented by one of its eigenvectors, say u^*), we have the following equation

$$\frac{du^*}{dt} = \frac{\alpha}{h^2} \gamma^* u^* + b \qquad [9]$$

where γ^* is the eigenvalue corresponding to that eigenvector. This essentially decouples the system of equations, permitting a closed form analytical solution of Eq. [8]. Further, since any potential vector can be expressed in terms of the system eigenvectors or characteristic directions, a general solution may be obtained as follows.

Let Q be the matrix whose columns are the unit or normalized eigenvectors of K. By the nature of the equations, the coefficient matrix K is real and symmetric. This means (4) that there are: (*i*) n real eigenvalues and (*ii*) n mutually orthogonal and linearly independent eigenvectors; further, if the eigenvectors are chosen to be of unit length, the vectors are orthonormal. This also means that $Q^{-1} = Q^T$.

Define a new vector v by the equation

$$u = Qv \text{ and } v = Q^{-1}u = Q^T u \qquad [10]$$

Geometrically, the new variables v represent the same variables u with the coordinate system changed from the orthogonal cartesian coordinates to the orthogonal eigenvector system of coordinates. Substituting [10] in [8]

$$\frac{dQv}{dt} = \frac{\alpha}{h^2} KQv + b \qquad [11]$$

Premultiplying [9] by Q^T

$$Q^T Q \frac{dv}{dt} = \frac{\alpha}{h^2} Q^T K Q v + Q^T b \qquad [12]$$

But if Q is the matrix formed by the unit eigenvectors of K, the operation Q^TKQ is a similarity transformation which serves to diagonalize K, and produce a diagonal matrix Λ, whose diagonal elements are the eigenvalues of K (5), *i.e.*

$$Q^T K Q = \Lambda \qquad [13]$$

Also $Q^TQ = I$, the unit matrix; hence, [10] becomes

$$\frac{dv}{dt} = \frac{\alpha}{h^2} \Lambda v + c \qquad [14]$$

where $c = Q^T b$

In expanded form

$$\frac{d}{dt} \begin{bmatrix} v_1 \\ \cdot \\ \cdot \\ \cdot \\ v_n \end{bmatrix} = \frac{\alpha}{h^2} \begin{bmatrix} \lambda_1 & 0 & & \\ 0 & \cdot & & \\ & & \cdot & 0 \\ & & 0 & \lambda_n \end{bmatrix} \begin{bmatrix} v_1 \\ \cdot \\ \cdot \\ \cdot \\ v_n \end{bmatrix} + \begin{bmatrix} c_1 \\ \cdot \\ \cdot \\ \cdot \\ c_n \end{bmatrix} \qquad [15]$$

Each of these individual equations can be written as

$$\frac{dv_i}{dt} = \frac{\alpha}{h^2} \lambda_i v_i + c_i \qquad [16]$$

$$(i = 1, \ldots n)$$

The system of differential equations is now decoupled in terms of the modified variables, and there is no problem in integrating these equations separately.

The solution of [16] is

$$\frac{\lambda_i v_i(t) + c_i}{\lambda_i v_i(0) + c_i} = \exp\left(\frac{\alpha \lambda_i t}{h^2}\right) \qquad [17]$$

where $v_i(0)$ is the value of v_i at $t = 0$. Let the l.h.s. of [17] be referred to as $z_i(t)$ then,

$$z_i(t) = \exp\left(\frac{\alpha \lambda_i t}{h^2}\right) \qquad [18]$$

Therefore, plotting ln $z_i(t)$ *vs.* t should result in a straight line from whose measured slope α can be easily calculated.

Treatment of Experimental Data

Molecular diffusion of copper sulfate in water.—It was observed, as predicted from theoretical considerations, that the concentration at the mid-point of the microcell remained unchanged during the course of the experiments. The cell was divided into two five-point grids on either side of the center line, with the boundary conditions as designated by Eq. [2], [3], and [4].

It has been shown elsewhere (5) that a five-point grid is sufficient to give three-figure accuracy if the input data are known exactly. An appropriate interpolation formula was used to obtain the concentrations at the grid points and various elapsed times which are shown in Table I. The calculated values of $z_i(t)$ are given in Table II.

From the definition of the uncoupled variable vector $v(t)$, Eq. [10], it can be seen that the components $v_i(t)$ of this vector are the scalar products of potential vector $u(t)$ with the individual eigenvectors q_i ($i = 1$ to 5). Geometrically, these may be looked on as the projections of the potential vector $u(t)$ onto the individual eigenvectors q_i. If the initial condition vector u_0 happens to be colinear with one of the eigenvectors q_j, then it follows that v_j would have a finite value whereas the other v_i's ($i \neq j$) will have zero value and will continue to have zero values at subsequent times and these variables will contribute nothing to the analysis of data. In practice, the initial condition vector is "more colinear" with some eigenvectors than

the others; this is indicated by the relative magnitudes of the scalar products such as the ones shown in Table IIA.

The variables $z_i(t)$ are functions of $v_i(t)$, and are normalized values of v_i with respect to the initial value $v_i(o)$ and the modified boundary condition vector component c_i (Eq. [17] and [18]). Since these z_i's decay exponentially to zero with time (Eq. [18]), it follows that they are unity in numerical value at zero time, but displacement along the time axis will not affect the determination of α. Some of these z_i's decay faster than the others depending on the numerical value of the corresponding eigenvalue λ^*_i. Referring again to Table IIA, we notice that θ_2 is greater in magnitude than θ_1 or θ_3, but is less than θ_4 and θ_5. Since the eigenvalue λ^*_2 is about 4 times larger than λ^*_4 and about 35 times larger than λ^*_5, it follows that its decay is much faster than of z_4 and z_5. This is clearly seen by the relative size of numbers in Table IIB, columns 2, 4, and 5. The noise in the data has affected the accuracy of numbers in column 2 beyond 40 sec. Presumably, if more data were available between 0 to 30 sec, z_2 could be used along with z_4 and z_5 to calculate D. It must be remembered, however, that v_4 and v_5 (from which z_4 and z_5 were derived) had much better initial values.

These considerations have led us to use z_4 and z_5 only for the estimation of diffusivity of copper sulfate. They were separately fitted to a straight line (Fig. 4). The value of D using z_4 was 0.585 x 10^{-6} cm²/sec; using z_5 it was 0.602 x 10^{-6} cm²/sec. The average value (0.594 x 10^{-6} cm²/sec) is consistent with the reported literature value which ranges from 0.55 to 0.80 x 10^{-6} cm²/sec (6).

In order to compare the proposed procedure with the conventional "least squares" technique, the same data were analyzed, using a trial-and-error search procedure to find the minimum variance by substituting in various values of D, the diffusivity into Eq. [6].

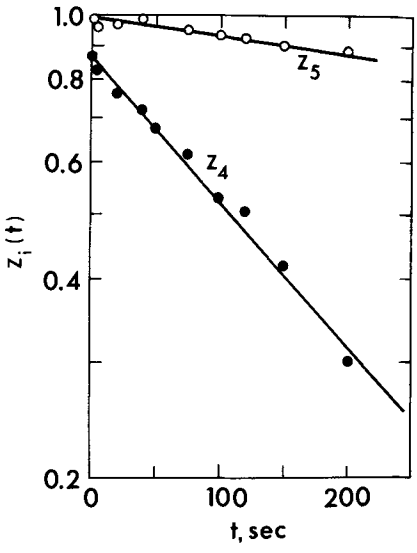

Fig. 4. Relations between transformed concentrations and time

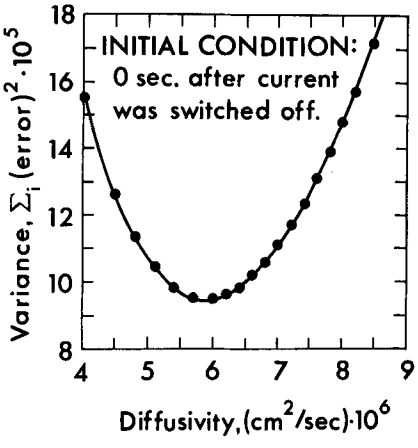

Fig. 5. Least squares analysis, initial condition A

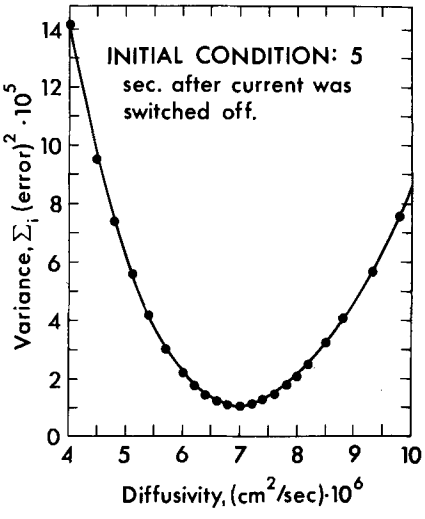

Fig. 6. Least squares analysis, initial condition B

The choice of an initial condition posed a problem; it was finally decided to carry out the calculations for two initial conditions, A and B, corresponding to 0 and 5 sec after the current was switched off. Results are shown in Fig. 5 and 6. As can be seen, it is most difficult to find the "best fit" value of α, the diffusivity, the two curves giving values of α that differ by more than 15%.

Conclusions

1. A combination of microcell interferometry and theoretical analysis provides a new means for rapid and accurate determination of molecular diffusivities in liquids.

2. The procedure outlined here is capable of yielding useful results even from rather "noisy" data. As better light sources and improved microcells are developed, the accuracy should be even better.

3. The "least squares" technique, besides using excessive computing time, failed to yield useful results. The variance, which is a measure of "best fit" is relatively insensitive to the value of α, the diffusivity. Furthermore, the method is predicated on a known initial condition; hence, much weight is placed on the correctness of these conditions. The proposed procedure, on the other hand, places approximately equal weight on all the data, which more truly reflects the experimental conditions.

Ion and Water Transport in Ion Exchange Membranes

J. H. B. George, R. A. Horne,[1] and C. R. Schlaikjer*[2]

Arthur D. Little, Inc., Cambridge, Massachusetts

ABSTRACT

Measurements have been made of the electrical conductivity of cation- and anion-permeable ion exchange membranes (Nepton CR-61 and AR-110) in a number of ionic forms at 10°, 25°, and 40°C and the corresponding Arrhenius activation energies calculated. Conductivity measurements have also been made on free solutions chemically analogous to the membrane systems and on membranes containing two mobile ions. Conductivities in the membrane are much lower than in free solution and the activation energies somewhat higher. In the case of mobile cations, but not anions, there is a very strong charge dependence. The observed conductivity phenomena are interpreted in terms of a general structural retardation of movement as a consequence of the enhanced water structure in the internal solution, and a more specific relaxation arising from the interaction of the mobile ions with the total coulombic field of their environment. Water transport measurements indicate that the ions moving in the membrane carry with them their primary hydration sphere, a sizable fraction of their total coulombic hydration atmosphere, and, especially in the case of larger species, entrained (or electro-osmotic) water as well.

Description of the Resin Systems

The membranes used in the present investigation were cation permeable Nepton CR-61 and anion permeable Nepton AR-110, both manufactured by Ionics, Inc. The manufacturer cooperated by taking particular pains to provide membrane samples as similar as possible with respect to properties such as capacity, water content, cross-linking, etc. The membranes are composed of divinyl-benzene-cross-linked polystyrene resins, the former with sulfonate, the latter with quaternary ammonium charge sites. They are quite highly cross-linked (30%) and, therefore, show relatively little water transport, a desirable feature in electrodialysis. The general aspect of the membrane then is of a porous, hydrophobic resinous matrix containing water and studded with hydrophilic charge sites.

Cross-linked resins sometimes exhibit a sieve effect, that is to say they mechanically exclude ions too large to pass through the available distribution of hole sizes [see Chap. 5 of Helfferich (1)]. Large ions such as $CH_3(CH_2)_2NH_3^+$, $(C_2H_5)_4N^+$, and $(CH_3)_3N(CH_2\phi)^+$ are mobile in the present membranes from which the conclusion can be drawn that there is an ample number of moderately large passages, *i.e.*, with diameters in excess of about 10Å. The "mesh width" of organic ion exchange resins ranges on the average from a few to about 100Å depending on the extent of cross-linking (1), and, inasmuch as the extent of cross-linking in a given membrane is highly variable, these numbers probably can be taken to represent the limits of pore sizes in a membrane. However, movement of species in the internal solution of the resin is not totally without mechanical restraint, thus water transport is markedly higher at low current densities (2) where the ions travel with accompanying water through the larger pores than at high current densities where the ions are forced through the smaller pores as well (3).

The membranes are roughly 30% water by weight. The water content (Table I) shows little dependence on the nature of the mobile ions present. But the water content of the anion permeable membrane appears to be consistently lower than that of the cation permeable membranes. Inasmuch as the relative water content of the cation-*vs.* anion-permeable membranes is just the opposite of what one would expect on the basis of hydration considerations, the difference is probably due to differences in the microgeometry of the two types of membranes and to the greater sul-

fonate concentration in the cation-permeable membrane than quaternary ammonium concentration in the anion-permeable membrane. The dehydration procedure was a mild one, drying to a constant weight at 110°C; hence these values probably represent only the water held weakly in the membrane. Characteristically colored hydrated ions, such as $Cu(H_2O)_4^{++}$, do not lose their coloration in the membrane on drying by this method; hence they must retain at least some of their waters of hydration. Similarly infrared studies on "dried" membranes in the La^{+++} form revealed quantities of water left. Then too, the membrane itself may retain some of its hydration crust.

The capacity of the cation-permeable membranes is about 1.47 meq/g (wet resin in the Na^+ form) and of the anion-permeable membranes 0.650 meq/g (wet resin of the Cl^- form). Little is known concerning the spatial distribution of the charge sites in the membrane. If coulombic forces dominate when the charge sites are synthesized, one would expect a more or less even spacing in order to achieve maximum charge separation; however, if hydrophobic forces are important, a clustering of charge sites would result. Furthermore the polymer condensation process results in considerable inhomogeneity of the degree of cross-linking, and this in turn also tends to concentrate the charge sites in clusters. The bulk of available evidence indicates that charge sites are usually very unevenly spaced (1). A crude estimate based on the capacities would indicate that on the average the distance between charge sites is of the order of magnitude of 10Å.

In order to avoid electrolyte invasion, in all of the measurements described here, unless otherwise stated, the concentration of the external solution was kept at 0.01*N*. To preserve electrical neutrality the concentration of the mobile ion in the internal solution is determined by the number of oppositely charged sites in the membrane and can therefore be calculated from the membrane's capacity and water content. The concentrations of mobile ions in the internal solution in the membranes thus calculated are about 4 and 2*N* for the cation-permeable and anion-permeable membranes, respectively.

As the concentration of the external solution is increased above 0.05*N*, invasion of the membrane by both ions of the external electrolyte commences. The internal electrolyte concentration becomes roughly proportional to the external concentration, and the proportionality factor increases as the charge of the ion increases, that is to say, the higher the charge of the ion the more readily it invades the membrane (Fig. 1).

Experimental Results

The major part of the experimental effort in the present studies was devoted to the measurement of

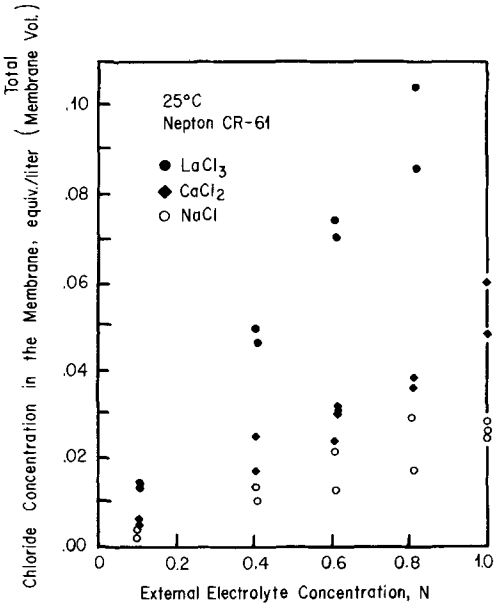

Fig. 1. Invasion of a cation-permeable membrane

the electrical conductivity of cation- and anion-permeable membranes containing different mobile ions. The conductivity cell used is shown in Fig. 2 with a membrane in place. The electrodes in the cell are parallel disks of platinized platinum. The equivalent circuit of the cell has been discussed by Feates, Ives, and Pryor (4), while further experimental details were given in a previous paper (2). Table II summarizes measured conductivities of the membranes containing

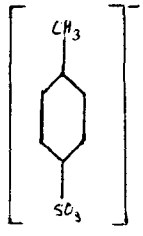
different mobile ions, λ_m. Also included in Table II are the limiting ionic conductivities of the ions in free solution λ^o_s and the Arrhenius activation energies in the membrane, $E_{a,m}$ calculated from data at 10°, 25°, and 40°C and for the free solution $E^o_{a,s}$ calculated from literature values of λ^o_s.

In order to test for any intrinsic tendency on the part of the species present in the membranes to form ion-pairs, conductivity measurements were made on the following systems which represented solution analogues of the membranes:

SOLUTION ANALOGUES OF THE CATION PERMEABLE MEMBRANE

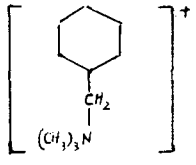
Li^+
Na^+
K^+
H^+
Mg^{++}
Ca^{++}
Ba^{++}
La^{+++}



p-toluenesulfonate (PTS)

SOLUTION ANALOGUES OF THE ANION-PERMEABLE MEMBRANE

Cl^-
I^-
$SO_4^=$



benzyltrimethylammonium (BTMA)

These measurements were made on solutions of concentration ranging from 0.001 to 2.5*N* at 10°, 25°, and 40°C. Some typical plots of the conductance *vs.* the square root of the concentration are shown in Fig. 3, while Table III summarizes measured conductivities and calculates activation energies of conductance of these systems.

The membrane conductivity studies were extended to embrace several series of more complex organic cations and anions and a few ammoniated metallic cations as mobile ions and the results are summarized in Table IV, while the results of studies on mixed electrolyte systems are presented in Fig. 4 and 5.

Table V summarizes the results of water transport measurements in the membranes at three different temperatures. The details of the experimental procedure have been described previously (2).

Discussion

The results in Table II present a number of interesting features. The two most striking of these are the great reduction of ionic mobility in the internal as compared to the external solution (last column)

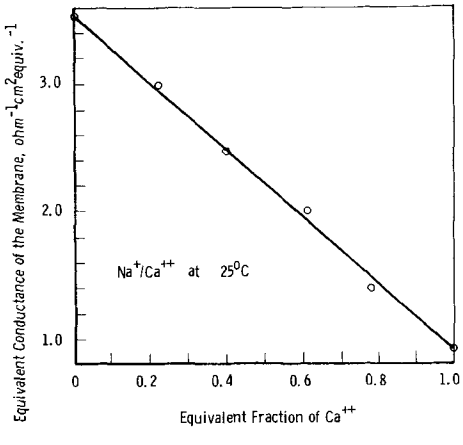

Fig. 4. Conductivity mixture effect in a cation-permeable membrane at 25°C for the system Na^+/Ca^{++}.

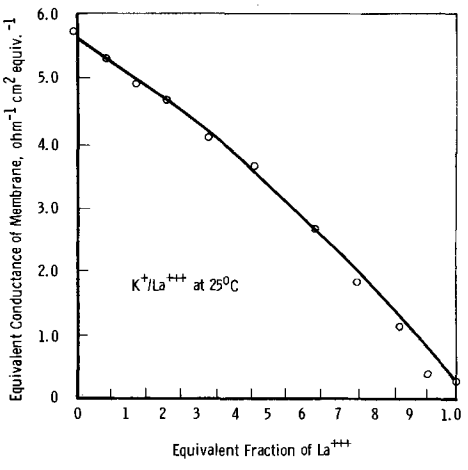

Fig. 5. Conductivity mixture effect in a cation-permeable membrane at 25°C for the system K^+/La^{+3}.

and the strong dependence of cationic mobility in the membrane on charge type. The strong charge dependence has been reported earlier by Heymann and O'Donnell (6), Rosenberg, George, and Potter (7), Spiegler and Coryell (8), and Grubb (9) and is in strong contrast with the free solution where the increase in hydration with increasing charge type tends to compensate for ion size and charge type, and results in surprisingly little variation in conductivities among different ions. The value of λ_m for anions shows no charge dependency and is more variable within a charge type than among charge types. In the case of the halide anions, however, there is a regular decrease in their mobility in the membrane with increasing ion size (crystal radius) and there is also, as might be expected, a regular increase in $E_{a,m}$, the Arrhenius activation energy of conductivity in the membrane. The ratio of the limiting conductivity of the mobile ion in free solution to the conductivity of the membrane containing that ion, λ^o_s/λ_m. is perhaps even more interesting: the value of this ratio is very nearly the same for all monovalent ions, both cations and anions, and for $SO_4^=$, falling in the range of about 14-20. The anions which do not obey this rule, F^-, I^-, and ClO_4^- are all anions which are notoriously eccentric in aqueous solution. presumably because of their peculiar effects on water structure. The only cationic exception to the rule, Cs^+, curiously enough has the same value of λ_s/λ_m as isoelectronic (and also anomalous) I^-, although this could be fortuitous. The doubly charged

[a] From ref. (2).

cations form a second family of similar λ^o_s/λ_m ratios. the value in this instance ranging from 60 to 85. To generalize, the values of λ^o_s/λ_m fall into the ranges of approximately 20.70:300 for singly, doubly, and triply charged cations.

Few systematic tendencies are evident in the activation energies of conductivity in the membrane. The $E_{a,m}$'s for conductivity in anion-permeable membranes tend to be in the majority of cases higher than for cation-permeable membranes, and this probably reflects differences in the mobile ions. As expected, save for a single exception, La^{+3}, the activation energy of conductance in the membrane is always higher than for the mobile ion in free solution. Inasmuch as E_a in free solution tends to decrease with increasing electrolyte concentration (10), the differences between the membrane and a free solution of comparable electrolyte concentration may be even greater.

A comparison of the results in Table II with those in Table III is also revealing. In the case of the monovalent ions the E_a's of the conductivity of the solution analogues of the membrane (Table III) fall between those of the membrane and of the ion in infinitely dilute free solution for both anions and cations. Mg^{++} and $SO_4^=$ are also intermediate. E_a for Ca^{++} PTS falls below the value of $E^o_{a,s}$, while the E_a's for Ba^{++}PTS and La^{+3}PTS fall very appreciably above both the corresponding $E_{a,m}$ and $E^o_{a,s}$. For the PTS solutions λ increases in going from Li^+ to Na^+ to K^+ (Table III) just as it did in the case of the membrane systems (Table II), and in all cases the value for the membrane analogue solutions is intermediate between λ_m and λ^o_s. E_a decreases with decreasing radius of the hydrated ion as expected. Heavily hydrated La^{+3} has a low Λ and a high E_a. Hydration increases with charge type; hence Λ decreases as E_a increases with increasing charge on the ion. Both Λ and especially E_a for BTMA salts show little systematic dependence on the nature of the anion.

Ion pair formation in the internal solution is commonly evoked in order to account for the observed differences between ionic mobilities in resins and in free solution. However, dilute solutions of each of the resin-analogue systems studied obeyed the Onsager limiting law (11), that is to say, plots of equivalent conductivity *vs.* the square root of the concentration were linear in the dilute solution range (Fig. 3). On the basis of this linearity, the conclusion can be drawn that none of the two ion systems examined showed any evidence for appreciable association in free aqueous solution, and from this, inasmuch as, apart from electrolyte concentration effects, there is no good reason for supposing that the dielectric constant is different in the internal than in the external solution, we can further conclude that these studies have given no reason for supposing that there is appreciable ion pair formation in the analogous resin systems. The strong dependence of Donnan exclusion on charge type is thus the consequence of ion field interaction rather than enhanced mobile ion-fixed ion association.

The classical theory of ionic conductivity takes as its model a charged sphere moving through a viscous continuum. As the concentration of electrolyte increases, the ions cease to move independently of one another, and the ion-ion interactions give rise to what is in effect a drag that reduces ion mobility. Hence conductivity equations such as the Onsager-Fuoss equation take the form of the limiting conductance Λ^o, minus subtractive terms for the drag effects.

$$\Lambda = \Lambda^o - (\phi_E + \phi_R)\sqrt{I} \qquad [1]$$

where I is the ionic strength, a concentration dependent parameter. In free aqueous solutions the first subtractive term, ϕ_E, represents the electrophoretic effect, the fact that an ion is moving, not in a stationary medium, but in a medium that is moving as a consequence of the motion (in the opposite direction) of

the waters surrounding the oppositely charge ions. Inasmuch as the charge sites in the membrane are more or less fixed, the movement of the mobile ion in the membrane should not be reduced by this phenomenon, unlike free solution. On the other hand, one might expect the relaxation effect, ϕ_R, to be more important in the membrane than in free solution. This drag effect arises from the restoring force when an ion is displaced in the coulombic field represented by its environment. In the membrane, because of the fixed locations of the charge sites, this field should be more resistant to alteration by the displaced ion than in free solution.

Meares (12) has derived a theoretical expression for the conductivities of ions in resins by consideration of the electrophoretic and relaxation effects. In the case of a resin, unlike free solution, the solvent flow is in the same direction as the movement of mobile ions, and the two effects are opposite. Here we wish to present a closely related but alternative analysis. We prefer to take the view that the immobility of the fixed charge site on the resin matrix makes the electrophoretic effect (ϕ_E in Eq. [1]) negligible[3] and the relaxation effect (ϕ_R) more important, and that the increased relaxational drag and the tightening of water structure in the membrane are the two principal factors responsible for the observed great reduction of ionic mobilities in the membrane as compared to free solution. Therefore, for membranes Eq. [1] can be rewritten

$$\Lambda_m = \Lambda^o_s/A_1 - \phi_{R,m}\sqrt{I} \qquad [2]$$

Since only the mobile ion contributes to the conductivity in the membrane λ^o_s is for the mobile ion only. The constant A_1 is a factor representing the reduction of species mobility by the "abnormal" water structure in the internal solution of the membrane and its value is probably in the neighborhood of 10. Also contained in A_1 is the "dilution" of the resin by the volume occupied by the nonconductive organic matrix. In free solution the relaxation term is given by (5)

$$\phi_{r,s} = \frac{2.8 \times 10^6 |z_1 z_2| q\, \lambda^o_s}{(\epsilon T^{3/2})(1 + \sqrt{q})} \qquad [3]$$

where q is $[|z_1z_2|/|z_1| + |z_2|]\ [(\lambda^o_1 + \lambda^o_2)/(|z_2|\lambda^o_1 + |z_1|\lambda^o_2)]$. Taking the charge of the resin, z_2, to be unity and its conductive parameters to be zero, we arrive at the following approximate expression for relating membrane conductivities to the charge of the mobile ion

$$\Lambda_m = \frac{\lambda^o_s}{10} - A_2 z_1 \sqrt{C(1 + z_1)/2} \qquad [4]$$

where z_1 is the charge of the mobile ion and C is its concentration (about $4N$ in the present case). Using the values in Table II we estimate that A_2 is somewhere in the range 0.8 to 1.2. The value of A_2 in free solution (25°C, $\epsilon = 78$) is 0.785[5] but inasmuch as A_2 contains $\epsilon^{-3/2}$ we expect this constant's value to be higher in the highly concentrated internal solution of the membrane. Thus an equation containing only a water structure factor and a relaxational term enables the semiquantitative estimation of the conductivity of mobile cations of any charge in a cation permeable membrane from the limiting conductivity of the cation in free solution. The calculated values for Λ_m, using $A_1 = 10$ and $A_2 = 1.1$, are 1.7, 2.8, 5.2, 5.6, 5.5, 5.2, 0.03, 0.67, 1.08, and negative [*sic*] for Li^+, Na^+, K^+, Rb^+, Cs^+, NH_4^+, Mg^{++}, Ca^{++}, Sr^{++}, Ba^{++}, and La^{+3}, respectively. Agreement with the observed values in Table II is good for monovalent ions and fair for divalent ions, but more important, Eq. [4] gives the right range of values for singly, doubly, and triply charged cations.

An expression of the form of Eq. [4] is not applicable to the conductivities of anions in anion-permeable membranes for they, as we have seen, exhibit no systematic charge dependency. In the case of anions, size, rather than charge, is clearly the important variable. For the smaller anions a structural retardation factor of a magnitude of 10-15 is still very much in evidence, but as the ion gets as large as Br^- or greater the retardation becomes even more severe as evidenced both by retardation factors of 20 and greater and higher energies of activation. Even more important, the relaxation term has ceased to be significant. This could be due to either the membrane or the mobile ion. The charge sites in cation-permeable membranes are coulombically hydrated whereas those in anion-permeable membranes with their CH_3 groups are hydrophobically hydrated. Generally speaking anions in free solution are less hydrated than cations, *i.e.*, anions interact coulombically more weakly with their environment. One reason for this is that their charge densities tend to be lower. Furthermore it is difficult to increase the charge on an anion without also increasing its size. Polyvalent anions stable in aqueous solutions are for the most part also polyatomic. This increase in size tends to diminish the effect of the increased charge so that anion charge densities are not as variable with charge type as cationic charge densities. The weakened capacity for coulombic interactions in the case of anions could very well greatly diminish the relative importance of the relaxation term.

Of particular current interest is the structural retardation factor, constant A_1 in Eq. [2]. Transport processes in clay minerals are retarded in a manner quite parallel to the present synthetic organic ion exchange materials; the activation energies are increased (and there is little ion-clay interaction contribution) and the apparent viscosity of the internal solution is anomalously high, and these observations have been attributed to a structuring of the water near the mineral surfaces (13, 14). Figure 6 compares schematically the probable differences in water structure in the internal and external solutions. Recently a new water form, "orthowater" has been discovered (15, 16) which reportedly has a viscosity 10 to 15 times that of "normal" water, in very good agreement with the present value of A_1. Whether orthowater and vicinal water (as in the resin) are synonymous or whether the former is peculiar to silica surfaces, which may catalyze its formation, remains to be seen (17).

It might also be noted that the diffusion of Na^+ in a Nepton membrane is 10 times slower than in free, dilute solution (8, 18).

The conductivities of tetra-alkylammonium cations, except for $(CH_3)_4N^+$ whose hydration still has considerable coulombic character (19), are very much lower than those of the simple monovalent ions in Table II; in fact, in the larger members of the series such as $(CH_3)N\text{-}CH_2\phi$ and $n\text{-}C_5H_{11}NH_3^+$ the values are comparable to those for triply-charged inorganic ions (Table II and IV). In addition to the importance

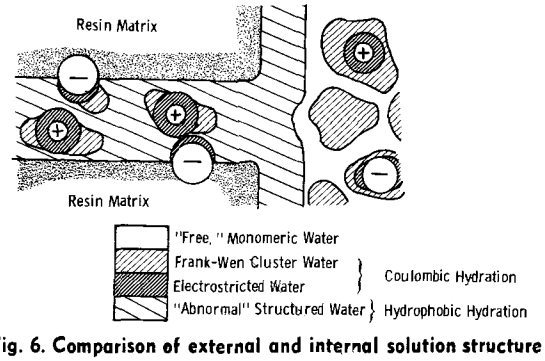

Fig. 6. Comparison of external and internal solution structure

[3] While the fixity of one ion makes the electrophoretic contribution to conduction (*i.e.*, the retardation of the movement of one ion by the oppositely directed movement of the solvent accompanying the second moving oppositely charged ion) negligible, it does not preclude the electrophoretic transport of solvent by the other moving and oppositely charged ion.

of ionic size, hydrophobic hydration may appreciably reduce the mobility of species in the internal solution, an hypothesis supported by the observation that, if these substances are made less hydrophobic by the addition of a second hydrophilic charge group, the conductivity increases so that, although doubly charged simple cations are less conductive than singly charged ones (Table IV), doubly charged diamine cations are much more conductive than isoelectronic singly charged monamines (Table IV) and the activation energies correspondingly lower. Within a given series the conductivity of the membrane decreases with increasing size of the mobile ion as expected.

In free solution the relatively high λ^{o}_{s} of $Co(NH_3)_6^{+++}$ (20) compared to La^{+3} (21) can be attributed to the weaker interaction of the former ion with the surrounding water. In the membrane the situation is reversed, and in the case of Cu(II) and Cr(III) the ammoniated cation is less mobile than the hydrated cation although paradoxically, the $E_{a,m}$'s are lower (Table IV). The reason for these abnormalities is not clear. The possibility of hydrolysis of these trivalent cations in the membrane casts severe doubt on the reality of the values. It is, however, reassuring to note that Λ_m for the trivalent ions of Co and Cr are comparable to the value listed in Table II for La^{+3}.

As before, the organic anions appear on the whole to be more mobile in the membrane than comparable cations, and again the differences between charge types, so obvious in the case of cations, has largely disappeared. The values of Λ_m tend to be lower than for simple anions (Table II) and decrease, as expected, with increasing size.

Mixed electrolytes.—In free aqueous solutions containing more than one electrolyte there are detectable deviations from the Kohlrausch principle of independent ionic mobilities and this "mixture effect" becomes more marked the greater the difference in the mobilities of the like-charged ions. For cations with a common anion Longsworth (22) has shown that the phenomenon depends only on the cations. Horne and Courant (23) have studied the effect of hydrostatic pressure on the mixture effect in free solution, and Mackay and Meares (24) examined the mixture effect for the system Na^+/H^+ in cation-permeable resin at 1 atm. Theoretical analysis of the conductivity of mixed electrolytic solutions (25, 26) predicts a mixture effect arising from the relaxation term. In the light of the apparent importance of relaxation in the internal solution of a membrane in determining ionic mobilities (see above), the conductivity of the asymmetrical systems Na^+/Ca^{++} and K^+/La^{+3} in Nepton CR-61 was examined. For their symmetrical system Na^+/H^+ Mackay and Meares (24) found a downward deviation from linearity, whereas the present results indicate that the Na^+/Ca^{++} system gives a nearly linear dependence of conductance on ionic composition (Fig. 4) and the K^+/La^{+3} system gives an upward deviation from linearity (Fig. 5).

The paper of Mackay and Meares (24), in addition to the mixture effect measurements, is of interest inasmuch as it contains two conclusions very similar to two of the crucial points that have emerged from the present study, namely that (*i*) specific ion pair and ionic association-type interactions are of minor importance, and (*ii*) the effective viscosity in the internal solution is anomalously high.

Water transport.—The question of how much of its hydration atmosphere a moving ion carries with it is of particular significance in desalination technology because the more water the solute transfers, the more difficult will be the separation of solute and solvent.

An ion moving in the internal solution of the membrane carries with it the more tightly bound electrostricted waters of hydration. The primary hydration number is not significantly different in the membrane than in free solution (3rd and 2nd columns, respectively, in Table VI). In addition it may also retain further waters of its total hydration atmosphere. If it is a large ion, water may also be transported as the result of ionic movement by entrainment in the ion's wake and/or by being pushed along the membrane passages in front of the moving ion.

Table VI. Primary hydration numbers of cations in an infinitely swollen sulfonated styrene-type cation exchange resin

Hg^{++}	4.5	5

Even though measurements were made at different current densities, the anions for the most part appear to transport less water than the cations (Table V) which is compatible with the generally greater hydration of cations. Except for Li^+, which is the most heavily hydrated of the alkali metal cations and Rb^+ and Cs^+, the amounts of water carried by all of the ions (multiplying the values of the multicharged ions by their charge) are remarkably similar. Among the anions, F^-, I^-, PF_6^-, and $Fe(CN)_6^{\equiv}$ appear to be exceptional. The hydration of F^- is considerably greater than that of its sister halides, hence the sizable number of waters it transfers is no surprise. Iodide ion, however, is at best only very weakly hydrated. It and PF_6^- may be sufficiently large to transport appreciable water by entrainment or pumping. The present experiments give little quantitative indication of the relative amounts of this electro-osmotic water and water of hydration. The qualitative expectation might be that for smaller ions the latter dominates and for larger ions the former becomes important. However, the situation is complicated by the fact that the most heavily hydrated ions are also commonly the largest. Electro-osmotic water transfer may tend to compensate for hydrated water sheared away as the ions press through the smaller passages.

The water transport value for $Fe(CN)_6^{\equiv}$ is negative, that is to say, the water moves in the direction opposite to that of the anion. This trivalent ion is taken up so strongly by the resin that it converts the membrane from an anion to a cation exchanger analogous to the conversion of a cation to an anion exchanger by Th(IV) complex ions (7) and of an anion exchanger to a cation exchanger by the absorption of oxalate (27). Values in Table V on the right are hydration numbers determined from membrane transport experiments by Rutgers and Hendrikx (28). Agreement is very good in the case of monovalent ions of both types, but they obtained values much higher than the present ones for divalent ions.

Figure 7 compares the temperature dependence of the number of water molecules transported by the alkali metal cations with the number of molecules of water in their total hydration atmospheres in free solution (29). The conclusions that can be drawn from this comparison are: (*i*) the ions in the membrane transport more water molecules than their primary hydration number (tightly bound electrostricted water) but less than their total hydration atmosphere in free solution; (*ii*) inasmuch as Li^+, the most heavily hydrated cation, retains more of its less strongly bound waters in the membrane its water transport has the largest temperature dependence. The other ions, being already stripped of many of their less strongly

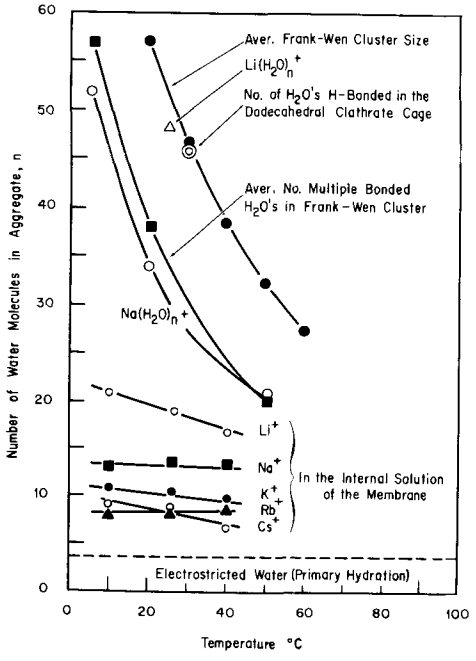

Fig. 7. Comparison of the water transport in the membrane with the total hydration atmosphere of the ions in free solution.

bound waters in the membrane, do not so readily lose further water molecules with increasing temperature.

Technical Notes

High Conductivity Solid Electrolyte System RbI-AgI

Boone B. Owens*[1] and Gary R. Argue*[2]

Atomics International, A Division of North American Rockwell Corporation, Canoga Park, California

There has been a considerable interest in solid electrolytes because of a large number of potential applications in electrochemical devices. However, such applications have been severely limited by the low conductivity of the available solid electrolytes (1). The conductivities of solid electrolytes at 25°C are in general many orders of magnitude smaller than those of electrolyte solutions, the former values being in the range of 10^{-12} to 10^{-6} (ohm-cm)$^{-1}$. Some progress has been reported in using compressed powders of AgI for which the observed specific conductivity at room temperature was of the order of 10^{-4} (ohm-cm)$^{-1}$ (2, 3). The conductivity of the solid electrolyte Ag_3SI at 25°C was reported to be 10^{-2} (ohm-cm)$^{-1}$ by Reuter and Hardel (4). Subsequent studies pertaining to the electrical conductivity and related devices of Ag_3SI were reported by Reuter and Hardel (5) and by Takahashi and Yamamoto (6-9).

The goal of obtaining solid electrolytes with conductivities (at ambient temperatures) comparable to those of electrolyte solutions was only recently accom-

Key words: conductivity, $RbAg_4I_5$, rubidium iodide, silver iodide, solid electrolyte.

plished. The solid electrolytes MAg_4I_5 (M = K, Rb, NH_4, and to a limited extent Cs) were reported to have unusually high ionic conductivities (10, 11). The values reported for the electrical conductivities of these materials differ by a factor of two to four. For example, the conductivity at 20°C of KAg_4I_5 was reported to be 0.050 (10) and 0.21 (ohm-cm)$^{-1}$ (11). In the present investigation the conductivity of the RbI-AgI system was investigated in greater detail and, in particular, the conductivity of the intermediate compound $RbAg_4I_5$ was studied.

Experimental

The compounds and intermediate compositions were prepared by the combination reaction

$$RbI + nAgI \rightarrow RbAg_nI_{n+1} \quad [1]$$

where n is the ratio of moles AgI to moles RbI. The indicated product is a single phase at 165°C for n = 0, ½, 4, and ∞, as may be readily deduced from the phase diagram (10). Other values of n yield two-phase products, in accord with the phase diagram. The compositions in the product were readily identified by x-ray diffraction analysis.

Mallinckrodt AgI and Research Organic RbI (99.9%) were used without any further purification. The reactants were melted together and then quenched; this product was then gound, compacted, and annealed under an argon atmosphere at a temperature of 165°C for 16 hr. The pulverizing, compaction, and annealing were repeated once. The annealing permitted any unreacted material to form the desired product and was not carried out to sinter the product *per se*.

The conductivity cells were of the type Ag foil/Ag, $RbAg_4I_5$/electrolyte/Ag,$RbAg_4I_5$/Ag foil in which a ½ in. diameter pellet was clamped between two Ag foil contacts. As indicated above, the pellet consisted of three layers, the two outer layers serving as Ag/Ag^+ contacts to the central electrolyte sample. The electrodes were prepared from intimate mixtures of Ag and $RbAg_4I_5$ containing nominally 20 w/o (weight per cent) of $RbAg_4I_5$. These mixtures were prepared by the *in situ* reduction of Ag_2O in a carbon-$RbAg_4I_5$ matrix to yield the indicated electrode powder. A cell was fabricated from the powdered electrodes and electrolyte samples by placing a ¼g of electrode powder into a ½ in. die, spreading the electrode powder with the piston, adding the electrolyte powder (1-5g), again forming the powder into a right cylinder, and then adding another ¼g of the electrode powder to form the second contact. The powder was then pressed to approximately 10,000 lb to form the pellet cell.

The cells for the composition dependence of the electrical conductivity were fabricated and tested under ambient conditions. Resistance measurements were carried out at 22°C. However, the cells for the temperature dependence of the specific conductivity of $RbAg_4I_5$ were fabricated in a dry box, under Ar atmosphere. The cells were placed in a controlled atmosphere chamber in which the temperature could be regulated to ±2°C. Cell resistances were measured with a 1 kHz conductivity bridge (ESI, Model 250 DA).

The specific conductivity σ was calculated in the conventional manner, from the sample resistance (corrected for contact resistance) and the sample geometry (diameter and length of right cylinder). The bulk density of these $RbAg_4I_5$ pellets at 22°C is 5.30 g/cm^3 as compared to the x-ray density of 5.38 g/cm^3 (13). No correction was applied for the temperature variation of the cell constant.

Results and Discussion

The effect of composition upon the conductivity is shown in Fig. 1 in which σ is plotted *vs.* m/o (mole per cent) AgI. The maximum value of 0.26 (ohm-cm)$^{-1}$ occurs at 80 m/o AgI which is the composition of $RbAg_4I_5$; this demonstrates the usefulness of composition-conductivity curves for phase diagram or possibly solid-state reaction studies (12). Values of 2 x 10^{-4} (ohm-cm)$^{-1}$ were observed for AgI and less than 10^{-8} for RbI and Rb_2AgI_3. The intermediate compositions were polyphase and had the intermediate σ values shown in Fig. 1.

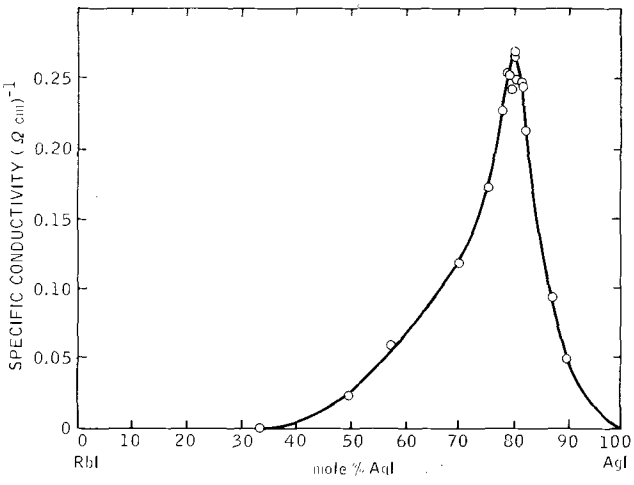

Fig. 1. Electrical conductivity of the system RbI-AgI at 22°C

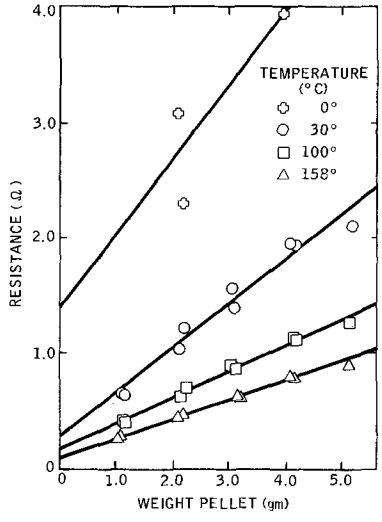

Fig. 2. Resistance of 1.27 cm diameter pressed powder pellets of $RbAg_4I_5$ as functions of sample weight.

The resistances of $RbAg_4I_5$ samples are shown in Fig. 2 for temperature values from 0° to 158°C. The contact resistance values reported in Table I are the intercepts of plots such as those shown in Fig. 2; from the slopes of these linear curves the values for the specific conductivities were calculated. The contact resistance increased considerably at the subambient temperatures, and there was greater scatter in the resistance values.

The Arrhenius plot of the specific conductivity is shown in Fig. 3. The plot is linear from 158° down to

Table I. Specific conductivity of $RbAg_4I_5$

T, °C	Contact resistance, ohm	Specific conductivity (ohm-cm)$^{-1}$
158	0.08	0.68
100	0.16	0.51
30	0.27	0.30
0	1.4	0.18
−55	3.4	0.087
−85	8	0.027

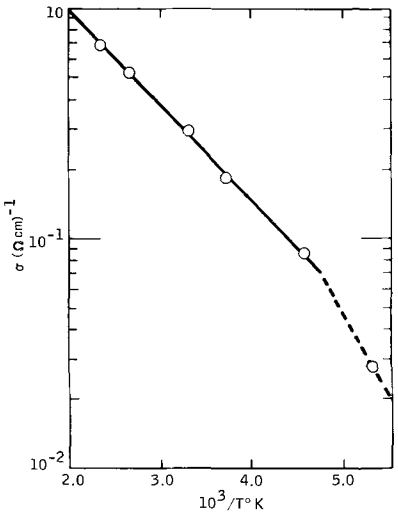

Fig. 3. Arrhenius plot of the electrical conductivity of $RbAg_4I_5$

−55°C; however, the −85°C value deviates from the linear curve. The Arrhenius activation energy for conduction is 1.7 kcal/mole over the temperature interval of at least 158° to −55°C. A low temperature reversible transition in $RbAg_4I_5$ has been observed by Geller (13); the transition temperature has been found to be −65°C, based on both optical measurements (14) and low-temperature calorimetry (15). However, no discontinuity in the conductivity was observed at this temperature although there is a conductance discontinuity at −155°C associated with a second reversible transition (11). The present conductivity values, when combined with prior results for lower temperatures, tentatively indicate that the solid phase existing between −65° and −155°C has an Arrhenius activation energy of 4 kcal/mole, with the approximate slope shown in Fig. 3 by the dashed line. The higher activation energy is associated with a structure in which the silver ions are in a more ordered state than in the highly disordered phase of $RbAg_4I_5$ existent at ambient temperatures (13, 15-17).

The mobile species in $RbAg_4I_5$ is the Ag^+ ion (18), and the low magnitude of the activation energy is consistent with the high ionic conductivity of the salt. The value of 1.7 kcal/mole is also in good agreement with the activation energy for the self-diffusion of Ag^+ ion in $RbAg_4I_5$; Bentle has reported the value of 1.99 kcal/mole (19).

The variations in the conductivity values previously reported for the MAg_4I_5 solid electrolytes (10, 11) are believed to be due to resistance contributions from the electrode contacts, as shown by the present investigation. In addition, the electrical conductivity of single crystal $RbAgI_5$ has been determined by Raleigh who observed a value of 0.268 $(ohm\text{-}cm)^{-1}$ at 24°C, with no orientation dependence (20). The value of σ at 24°C, based on the present investigation is 0.26 $(ohm\text{-}cm)^{-1}$, thus confirming the correlation of the high ionic conductivity of polycrystalline $RbAg_4I_5$ with the structure of the pure single crystal $RbAg_4I_5$ (12). The high mobility of the Ag^+ ion in $RbAg_4I_5$ is an intrinsic property of the pure crystal rather than a result of high surface mobility as has been suggested for powdered AgI (2, 3).

A Simple Apparatus for Controlling and Measuring Very Low Flow Rates through Porous Electrodes

A. P. Saunders

Institute for Direct Energy Conversion, University of Pennsylvania, Philadelphia, Pennsylvania

Steady-state electrochemical measurements at flow-through porous electrodes require a method of controlling and measuring flow rates which are often less than 10^{-2} ml/sec. A review of the literature failed to produce any information in this area and so a simple apparatus was devised (shown schematically in Fig. 1), based on a well-known method of obtaining a constant level, with which it is possible to maintain a constant (±1%) pressure behind the electrode, enabling mean flow rates through the electrode to be measured with

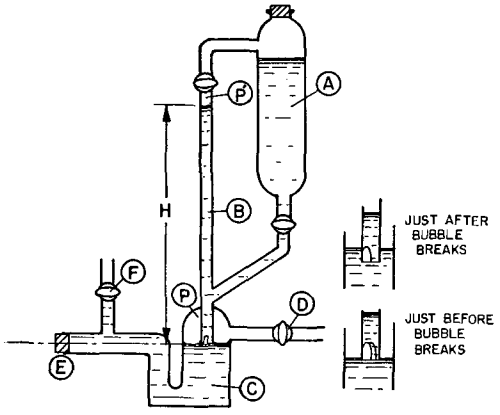

Fig. 1. Apparatus for controlling and measuring flow rates

a precision greater than 99%. A simple level controlling drain tube in the electrochemical cell (not shown) establishes a constant pressure drop across the electrode.

The apparatus, made of Pyrex glass, consists of an electrolyte reservoir (A), communicating via two Teflon stopcocks to an 0.8 cm ID calibrated precision bore tube (B), the bottom of which is notched and projects into the controlled level chamber (C). With the gas inlet (D) closed and the Teflon stopcocks open, electrolyte is flowed into the lower part of the apparatus, air or other chosen atmosphere being vented from the back of the electrode (E) by means of the stopcock (F). When the electrolyte level in (B) reaches a desired level, the Teflon stopcocks are closed and gas at a controlled pressure is admitted through (D), bubbling up the precision tube until an equilibrium is reached when

$$P\text{gas} + P'' = H\sigma g + P'$$

where P'' is a composite of a small head of electrolyte and meniscus forces, σ is the density of the electrolyte, and g is the acceleration due to gravity. Flow of electrolyte through the electrode deforms the annular meniscus in (C), creating a bubble which projects through the notch into the bottom of the precision tube. Eventually the bubble detaches and rises, displacing electrolyte from (B), which restores the level of the meniscus. The volume of ΔH is mainly controlled by the area of the annulus in (C) and the height of the notch. In this case, the two diameters of the annulus are 1.5 and 1 cm, the notch being approximately 5 mm wide and 3.25 mm high.

The system for regulating the gas pressure is shown in Fig. 2. The output (100 mV for a range of 0 to 5 psi) from an Ametek Model 58-5B/A-SS pressure transducer, 1, is varied by a potential divider and fed into a Moseley Model 680 recorder, 2. A limit switch on the recorder operates a solenoid valve, 3, between the gas supply cylinder and the system. As the limit switch has considerable dead band, it was only possible to control the pressure with fluctuations about a mean

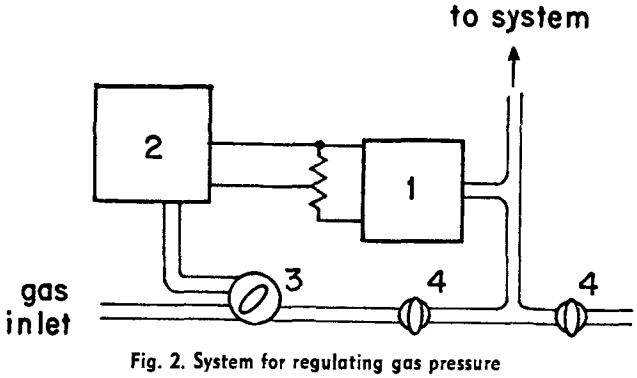

Fig. 2. System for regulating gas pressure

value. Judicial use of the fine needle valves, 4, on the inlet and outlet and the pressure regulator on the gas cylinder, enabled these fluctuations to be reduced to a uniform cycle with a frequency of 8 sec and an amplitude of less than 1% of the applied pressure, which ranged from 2 to 25 cm Hg.

It has been established by observation that just before the addition of electrolyte from (B), the meniscus in (C) falls to a constant level, rising sharply with the entry of electrolyte to a level which varies, corresponding to small variations of less than 5% in ΔH. Flow rates are therefore obtained by combining the volume of ΔH with the period of the meniscus rise in (C) which denotes the volume entering and exiting from the electrolyte at the back of the electrode. The meniscus in (B) occasionally moved slightly upward during the first 1 or 2 min following a level change before arriving at a stable position. In all cases, when measuring ΔH, the final stable position gave flow rates closer to the mean value than if the initial height (before the small upward movement) was used. Precision may be increased by using several successive increments of ΔH (*i.e.*, two, three or four bubbles entering (B)) with one time measurement. The apparatus will operate at the controlled pressure with the Teflon stopcocks open, the reservoir maintaining a constant supply of electrolyte to the electrode. These stopcocks should be closed when measuring flow rate, however, to keep the volume P' small and the apparatus less sensitive to changes in the ambient temperature.

Table I gives typical results using 2M KI electrolyte, and a ΔH of one, two, and three bubbles. Variations in flow rate with temperature (approximately 2%/°C), are clearly seen, the highest precision being obtained when the changes in ambient temperature were small. ΔH was measured with a cathetometer accurate to ±0.005 cm. Using a glass capillary to simulate a porous electrode giving the desired order of flow rate and pressure, measurements have been made with water and 3M KI electrolyte. The liquid was collected and weighed after passing through the capillary, the two methods agreeing to within 1%. The apparatus has been used through the range 2.5×10^{-4} to 1×10^{-2} ml/sec without loss of precision, but a high degree of dexterity is required when making measurements at the higher flow due to a bubble breaking every 30 sec, whereas the long period between bubbles at the low flow rate ($<10^3$ sec) causes some inconvenience. It is recommended, should flow rates in these regions be required, that changes be made in the annulus dimensions and notch height to provide a suitable time per bubble, *i.e.*, reducing the annular area and notch height to give a smaller ΔH at the 10^{-4} ml/sec range.

Should the pore characteristics of (E) be such that a low pressure of gas is required to obtain the desired flow rate, a controlled orifice, *i.e.*, a glass/Teflon needle

On the Anisotropy Observed During the Passivation of Nickel Monocrystals

C. J. Mauvais, R. M. Latanision,[1] and A. W. Ruff, Jr.

Metallurgy Division, Institute for Materials Research, National Bureau of Standards, Washington, D. C.

The passivation of polycrystalline nickel electrodes in acid solution has received much attention over the years (1-8). In many of these studies some particulars of the passivation mechanism have been deduced through the measurement of anodic polarization diagrams. It should be recognized, however, that such studies on ordinary polycrystalline specimens yield at best an average measure of processes which undoubtedly occur at different rates on the various exposed crystal faces. Indeed, significant anisotropy has been reported in the anodic dissolution of various metals (9) and in the growth of passive films on iron monocrystals (10).

In this study, we have potentiostatically measured the anodic polarization behavior of nickel surfaces parallel to low index crystallographic planes in 1*N* H_2SO_4 and found that a strong anisotropy occurs in the passive region.

Experimental

The two 99.999% nickel monocrystals used in this study were cut from a semicircular disk ⅛ in. thick × 5/16 in. radius with a [110] axis. Three low index faces {100}, {110}, and {111} were produced by spark machining and then chemically polished in an acetic acid-nitric acid solution to remove any damage. The orientation of each face, determined by the back-reflection Laue method, was within 1.5° of the selected orientation.

Potential measurements were made relative to a saturated calomel electrode by means of a salt bridge-Luggin probe assembly taking suitable precaution to avoid contamination of the electrolyte by Cl^-. The geometrical arrangement of the components of the electrolytic cell was in accord with the recommendations of Greene (11). The 1*N* H_2SO_4 electrolyte was prepared from double-distilled water and reagent grade acid. Steady-state polarization measurements were performed potentiostatically in solutions exposed to air at temperatures of 22°-23°C throughout. In each experiment, only the crystal face of interest was exposed to the solution, the remainder of the specimen being covered with a protective lacquer. There were no indications that the electrolyte penetrated the lacquer and thus complications arising from leakage currents were avoided. A reflection of the crystal symmetry of each surface is shown in the etch figures produced during these experiments, Fig. 1.

Results and Discussion

The anodic polarization behavior is shown for each of the exposed crystal faces in Fig. 2. It is clear that the current density in the passive region was not the same from one crystal plane to the next but decreased in the order: {100} > {110} > {111}. It is of interest to note that the relative rates of gaseous oxidation of the various crystal faces of nickel were reported (12, 13) to be in decreasing order: {100} > {110} > {111} when epitaxial oxide films were formed. In short, the degree of protection provided by the passive film as well as

Key words: polarization, nickel monocrystals, dislocations, passive film, surfaces.

by films developed in gaseous oxidation tends to be a maximum for the {111} face and a minimum for the {100} surface of Ni monocrystals.

Although NiO is generally the only stable oxide formed in air or oxygen (13), it has been suggested that the passive film on Ni in H_2SO_4 is not necessarily NiO, but may be a higher oxide (4) or a composite of oxides (2, 3, 14). Nevertheless, assuming that NiO is formed in at least some early stage of passivation, it should be noted that gaseous oxidation studies (15) have shown the existence of parallel orientations between NiO and Ni for the three low index faces, *i.e.*, {111}NiO||{111}Ni,{110}NiO||{110}Ni, {100}NiO||{100}Ni. Recognizing that the lattice parameters of NiO and Ni are unequal (misfit $\simeq$19%), we suggest that the orientation dependence of passivation observed in this work may be understood in terms of (*i*) the creation of a grid of dislocations at the Ni/NiO interface which accommodates the lattice misfit and (*ii*) boundaries developed within the passive film during its growth.

First, on the basis of Van der Merwe's theoretical treatment of oriented overgrowths (16), we expect that the oxide, when only a few monolayers thick, transforms from a pseudomorphic structure with the lattice parameter of the substrate to the (oriented) oxide structure having essentially the lattice parameter of the bulk oxide, the lattice misfit taken up principally by interfacial dislocations. The geometry and spacing of dislocations in the misfit network are expected to be a function of the orientation of the substrate [see, for example, ref. (17)]. If only pure edge dislocations are formed at the interface, one expects that the separation between the misfit dislocations on {111} is greater than on {100} surfaces. The strain fields of these dislocations may have an important accelerating effect on ionic diffusion and thus on the passivation process.

Second, it is known (15) that NiO occurs in both {111} and {100} orientations on {100}Ni surfaces. The first orientation relation has four different variants depending on the relative <110> orientations in the metal and oxide. If the passive film forms by nucleation over the original metal surface, it seems likely that the film would contain a mixture of the different variants. This would require misfit boundaries in the film oblique to the interface, which would affect the oxidation rate by providing additional rapid diffusion paths through the passive film. By comparison, {110} and {114}NiO orientations occur on the {110}Ni surface leading again to oblique misfit boundaries. Only {111}NiO films have been reported on the {111}Ni surface although two twin-related orientations are possible. The oblique twin boundaries formed in this instance should be less effective in increasing the reaction rate than those expected for the other two Ni orientations. In short, if the degree of protection in the passive region may be related to the availability of short-circuiting reaction paths one expects {111} to be better protected than {100}, as observed.

The present results thus indicate the heretofore neglected importance of considering the crystallography and defect structure of the film and the metal-film interface in understanding the mechanism and kinetics of passivation. Similar contributions to the kinetics of film growth in the gaseous oxidation of Ni and Cu monocrystals have been discussed by Cathcart and co-workers (18, 19).

Spectrophotometric Study of Electrogenerated Sulfur-Sulfide Solutions in Fused LiCl-KCl

F. G. Bodewig and James A. Plambeck***

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

During electrochemical investigations on chalcogen-chalconide systems in fused LiCl-KCl eutectic carried out in this laboratory (1, 2) it was noticed that a solution containing sulfide ions is blue in color if an excess of sulfur was present as a liquid pool floating on the melt (1). The blue color intensified when more sulfide was added to the solution, but disappeared when the sulfur was pumped off, indicating that it is not due only to a simple sulfide species. It appeared interesting to obtain the spectrum of this species and to investigate whether or not Beer's law is followed when it is generated by cathodization of a sulfur pool.

The spectrum of molten KSCN has been published (3) and the blue color observed has been ascribed to sulfur. An absorbance maximum was observed at 605 mμ between 250° and 450°C and below 250°C an additional one appeared at 415 mμ. The molar absorptivity for the 605 mμ maximum was estimated to be between 16,600 and 30,000.

A spectrum of molten LiCl-KCl eutectic containing sulfur has been published (4), and the blue color of the solution has been attributed to dissolved sulfur. The maximum absorbance was at about 600 mμ between 400° and 600°C. No value for the molar absorptivity was reported.

Experimental

Apparatus.—Spectra were recorded on a Cary Model 14 spectrophotometer. Potentials and currents were measured with a digital voltmeter (Model 3440A, Hewlet-Packard). Two 45V batteries in series were employed as a current source from which currents between 50 and 500 μA were drawn through a resistor network.

The spectrophotometric cell consisted of square Pyrex tubing (Vitro Dynamics) of inside dimensions 22 x 10 mm with a top connected to it by means of a 34/45 ground-glass joint. Four 10/30 ground-glass joints were blown on this top which were used to insert a thermocouple, a gold foil electrode, an isolation compartment with a tungsten electrode, and an inert gas inlet tube. The isolation compartments for the anode were made of Pyrex sealing tubes (5D; Ace Glass Inc.). Part of this cell is shown in Fig. 1. The cell path length was 10 mm.

After several attempts a furnace was constructed that operated satisfactorily and fitted into the Cary sample compartment (Fig. 1). Previously published oven designs (5, 6) did not allow insertion of the relatively large Pyrex cell used in the present study. Problems were also encountered in obtaining the uniform temperature necessary over a melt column of about 5 cm. The present design, which uses a large aluminum cylinder, accomplishes this; the temperature gradient in the unstirred melt was less than 2° over a vertical distance of 5 cm. The temperature of the oven was controlled by a Model 226 2-Mode solid state controller (API Instruments). The regulating thermocouple (not shown in Fig. 1) was placed close to the heating elements.

Materials.—The chemicals used have been described previously (1). Helium was used as inert gas. It was passed through three cold traps cooled with liquid nitrogen; the last cold trap contained activated carbon. After preparation of the melt as described previously (1) it was filtered through a Pyrex frit (B porosity; Ace Glass Inc.) before freezing and storage. A gold foil electrode (Johnson, Matthey & Mallory Ltd.) was used to generate the sulfide from a sulfur pool. The anode consisted of a tungsten spiral in an isolation compartment which prevented mixing of anode and cathode products.

Procedure.—The frozen eutectic was transferred to the cell and allowed to melt under a helium atmosphere. Once molten, the eutectic was again treated with chlorine gas after insertion of the isolation compartment and the Pyrex tube for the thermocouple. After 10-15 min the chlorine was removed by purging with helium which was also passed over the melt during the remainder of the experiment. The sulfide was generated with a gold electrode in a sulfur pool floating on the melt. The current used was about 100 μA. After each coulometric generation the solution was made uniform by stirring it with the isolation compartment. The temperature of the melt was 400° ± 2°C. Spectra were recorded with a scanning speed of 25 Å/sec. The concentration of the sulfide was calculated from the measured current, time of generation, and volume of melt obtained as before from a potentiometric chloride titration (1).

Results and Discussion

The spectrum of the solvent with a sulfur pool floating on it is the lower curve in Fig. 2. The zero

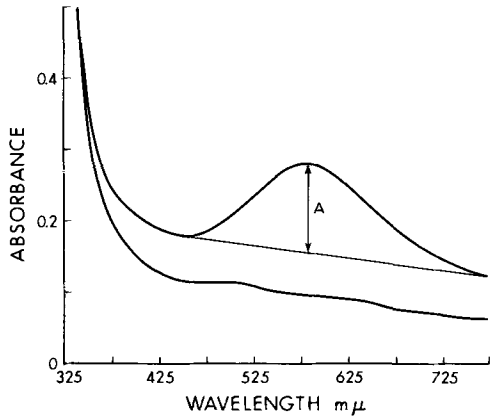

Fig. 2. Absorbance as a function of wavelength. Lower curve, fused LiCl-KCl with sulfur pool floating above it; upper curve; same following coulometric generation of sulfide.

point on the absorbance scale was taken arbitrarily since the reference light beam passed through air. It showed no peaks between 400 and 800 mμ, contrary to an earlier report by Greenberg, Sundheim, and Gruen (4). In the present work no blue color developed when care was taken in the purification of both the melt and the inert gas. Impurities present in the melt might have reduced enough sulfur to have produced the blue color observed in the earlier work (4). The spectrum after coulometric addition of sulfide to the melt is also given in Fig. 2. Only one maximum was observed at 585 mμ, not two as reported earlier (4).

Spectra of solutions with increasing sulfide concentrations were recorded at 400° ± 2°C. The absorbance at 585 mμ was measured as indicated in Fig. 2. For several experiments these absorbances were plotted as a function of time of coulometric sulfide generation at constant current. In all cases the extrapolated lines passed through the origin. This indicates that the linear background line drawn under the upper curve in Fig. 2 is the zero absorbance line. It should be noted that the "zero absorbance" line shifted from that of the solvent plus sulfur when sulfide was added to the solution. This was observed in all experiments.

A typical plot of absorbance as a function of sulfide concentration is shown in Fig. 3. Concentrations up to 2.2 x 10^{-5}M followed Beer's law accurately. Negative deviations occurred at higher concentrations. The cell path was measured as 1.00 cm. From this and the slope of the line of Fig. 3 the molar absorptivity of the absorbing species, calculated as $S^{=}$, was found to be 4600 1 $mole^{-1}$ cm^{-1} for sulfide concentrations up to 2.2 x 10^{-5}M. Lux and Anslinger (3) estimated the molar absorptivity to be 16,600 or higher, but this value was arrived at under the assumption that the absorbing species is S_2. Furthermore, it is not clear how these authors determined the zero absorbance line from which the absorbance was measured. The present value is therefore not strictly comparable with their value, especially in view of the fact that the fused salts used are significantly different.

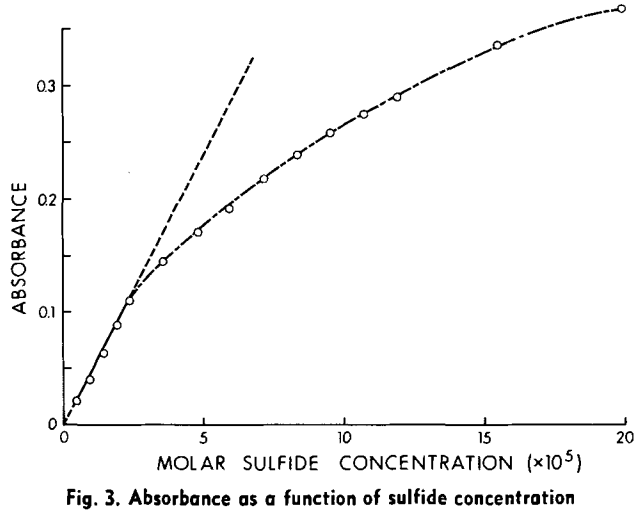

Fig. 3. Absorbance as a function of sulfide concentration

In the course of the present work several pure heavy metal sulfides have been added to the LiCl-KCl eutectic, in which they appeared to be very slightly soluble. These solutions were colorless until after sulfur was also added, when they turned the expected blue. This indicates that spectrophotometric measurements could be used to determine the solubility of metal sulfides in fused salts. However, suitable calibration curves would be required due to the pronounced deviations from Beer's law. Moreover, the solubilities measured would be those of metal sulfides in the presence of excess sulfur and could not *a priori* be assumed to be those which would be observed if the sulfur were not there. In spite of this, and the difficulty of preventing reduction of some of the sulfur by impurities, spectrophotometry may be a more practical approach than coulometry. Coulometric titrations of anodically generated Fe^{++}, Ni^{++}, Co^{++}, and Ag^{+} by reduction of a sulfur pool electrode produced potentiometric titration curves with breaks of 160-400 mV. These breaks consistently occurred a considerable, but not a reproducible, distance before the theoretical equivalence point.

Conclusion

The results reported here confirm the suggestion of our previous paper (1) that this absorption band and the blue color are due to one or more polysulfide species. It cannot be due to either sulfur or sulfide alone. The width of the band and the deviation from Beer's law suggest that multiple species may be involved. The present apparatus, however, permits no variation in the sulfur concentration and we have thus far been unable to test that suggestion.

The Polarization Correction in Conductance Measurements

R. P. T. Tomkins, G. J. Janz,* and E. Andalaft

Rensselaer Polytechnic Institute, Department of Chemistry, Troy, New York

To attain conductance data of highest precision, one finds that extrapolation of the measured resistances as a function of frequency is subject to various approaches and is not well documented in texts or the published literature. Two of the outstanding practices are due to Jones and Christian (1), *i.e.*, a graphical extrapolation based on the Warburg analysis of concentration polarization and to Fuoss (2), who introduced the inverse frequency extrapolation. With the recent increase of interest in nonaqueous electrolytes, where brightly polished or lightly platinized electrodes are generally used, the extrapolation techniques are reoccurring problems. Because of this uncertainty, alternate procedures such as measurements at frequencies up to 100 kHz (3), the use of electrodeless cells (4) and d-c bridge techniques (5, 6) have been used. Features specific for molten salts have recently been discussed elsewhere (7) and will not be mentioned here except to note that the basic problem, an extrapolation to correct for polarization effects, is encountered there as for aqueous and nonaqueous measurements. The conventional a-c conductance technique, nevertheless, is still the most generally and widely used method, largely because of its versatility and relatively simple instrumentation. The present note reports a critical evaluation of the limitations and applicability of the extrapolation procedures in most frequent use, and also redirects attention to the frequency dispersion errors that may arise if a conductance cell is used outside the range for which the calibration standard is applicable.

Experimental.—The purification of sodium iodide and acetonitrile have been described in a previous communication (8). Two Shedlovsky-type cells having constants of 16.8456 and 1.33735 were used for the concentrated and dilute solutions, respectively. The conductances of all solutions were measured with a Jones-Dike (9) a-c conductance bridge and accessories (Leeds & Northrup Company). A variable frequency audio signal generator (Eico, Model 377) and a tuned amplifier and null detector (General Radio, Model 1323-A) were used for the a-c signal and bridge circuit balance. The freqeuncy range was varied from 0.6-10 kHz.

L.S. to linear in f^{-1} σ	5750.4 0.6	0.017
L.S. to quadratic in $f^{-1/2}$ σ	5751.5 0.6	0.017
L.S. to linear in $f^{-1/2}$ σ	5745.6 1.2	0.101

† L.S., least squares analysis; σ, standard deviation.

Results and Discussion

The values of resistance as a function of concentration and applied frequency are in Table I and II. With the low cell constant (Table I), a considerable curvature in a plot of R *vs.* $f^{-1/2}$ is observed, and a satisfactory extrapolation (to infinite frequency, to gain the polarization-free value of R) cannot be advanced with certainty. On the other hand it is found that the graph of R *vs.* f^{-1} is linear; the thus extrapolated values for R at infinite frequency are in Table I. For more concentrated solutions (Table II), the extrapolation R *vs.* $f^{-1/2}$ is satisfactory.

As an alternative approach to gain R at infinite frequency, a least-squares analysis to quadratic or linear

Values in parenthesis indicate the per cent error in the measured value from that obtained by extrapolation to infinite frequency.

equations in f^{-1} was programmed. A comparison of the results with those of the preceding graphical extrapolations is in Table III. The agreement (both for f^{-1}) leaves little to be desired.

It is also informative to examine the results for the "per cent error" if the measurements are limited to one frequency only. Inspection of Table I and II shows that the per cent error depends on factors such as the cell constant, concentration, and frequency. The per cent error, thus introduced, is invariably larger than the limit of error (±0.02%) for meaningful theoretical interpretation of conductance data. It is also seen from Table III that the standard deviation provides a useful guide line for the selection of the "best" extrapolation technique.

An analysis of the frequency dispersion of the resistance, based on the results in Table I and II, is shown in Fig. 1. The curves indicate the limits of the concentration range where the slopes of the resistance-frequency plots are fairly constant when measurements with any one cell are being used over a range of electrolyte concentrations. The concentration dependence of $\Delta R/\Delta f^{-1/2}$ is illustrated in Fig. 2. Slopes A and B show the trends for dilute and concentrated solutions, respectively, whereas slope C is an attempt to curve-fit all the data points.

The equation advanced by Fuoss and Hsia (10) for KCl in water

$$\Lambda = 149.935 - 94.88C^{1/2} + 25.48\ C \ln C + 221 \cdot C^{3/2}$$

is in agreement with the Jones and Bradshaw demal standards at 0.01 and 0.1 within 0.11%, respectively, and is recommended for conductance cell calibrations.

While both Ives (11) and Fuoss (12) have advanced equivalent circuit models for the electrode/solution interface, the interpretation of the polarization correction remains incomplete, and from this viewpoint further discussion is best deferred. To summarize, both the $f^{-1/2}$ and f^{-1} graphical extrapolations are valid procedures providing due cognizance is taken of factors such as the cell constant, concentration, and range of frequencies. That extrapolation which gives a linear fit, or alternately the computer fitted equation having the least standard deviation is the "best" for the polarization correction but the justification remains largely empirical, namely that this is "what works."

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 116, No. 6, 8, 11, and 12, June, August, November, and December 1969.

Epitaxial Growth with Light Irradiation

M. Kumagawa, H. Sunami, and J. Nishizawa[1]
(Not published in the *Journal*)

This will acknowledge the receipt of a paper submitted for publication in this *Journal* entitled "Epitaxial Growth with Light Irradiation" in May 1967.

[1] Research Institute of Electrical Communication, Tohoku University, Sendai, Japan.

The paper was authored by M. Kumagawa, H. Sunami, and J. Nishizawa,[1] and described a technique for the enhancement of the low-temperature epitaxial growth of silicon with the aid of light irradiation. Unfortunately, the paper was not published in this *Journal* primarily because of the difficulty experienced by the authors in describing their work in current *Journal* style English, though the authors do not assent to the reason for rejection. Several months later, another paper was received for publication entitled "Low Temperature Silicon Epitaxy" by R. G. Frieser. By coincidence, the subject matter of this paper was very simi-

lar to that previously submitted by the Japanese authors. Since the paper by Dr. Frieser was well written and entirely acceptable in the opinion of several reviewers, it was published without delay and, of course, appeared before the paper by Kumagawa *et al.*, was completely revised. Those interested in the work of Kumagawa *et al.*, will find it in the November 1968 issue of the *Japanese Journal of Applied Physics.*

Effects of Oxidizable Anion Adsorption on the Anodic Behavior of Platinum

Sigmund Schuldiner (pp. 767-771, Vol. 116. No. 6)

T. Biegler[2]: In a recent series of papers[3-5] culminating in the work under discussion, Schuldiner has promulgated the views that there is negligible coverage of a platinum electrode by oxygen containing species up to at least 1.2V in the presence of hydrogen and 1.6V in the presence of formic acid and that, consequently, the retardation of hydrogen or formic acid oxidation at lower potentials is caused by anion adsorption. In criticizing these conclusions, Vetter and Schultze[6] have given an analysis of the kinetics of the partial reactions involved in the reduction of surface "oxide" by hydrogen or formic acid and have thereby shown the possibility of a steady coverage of "oxide" in the potential region where Schuldiner denies its existence. This appears to be an unnecessarily obscure way of attacking Schuldiner's assertions since the direct evidence for surface oxidation of platinum under these conditions is well established and well documented.

Will and Knorr[7] studied the effect of sweep rate on cyclic linear-sweep voltammograms in the presence of hydrogen. Even at quite low sweep speeds (1.6V sec^{-1}), the current-voltage curve approached the shape obtained in absence of hydrogen showing that formation and reduction of adsorbed oxygen (and hydrogen) layers occur more or less independently of the presence of bulk hydrogen. Direct comparisons of surface oxygen coverages in presence and absence of hydrogen,[8] formic acid,[9] and methanol[10,11] indicate that surface "oxide" formation is only slightly affected by the presence of these oxidizable species. In these cases, cathodic stripping was used to determine adsorbed oxygen and it seems unlikely that the association of the measured cathodic charge with surface "oxide" was in error. Furthermore, on the basis of reflectance measurements, Koch and Scaife[12] concluded that formaldehyde has no significant effect on oxygen coverage on platinum.

The published experimental evidence (the above list is not intended to be exhaustive) for adsorbed oxygen on platinum under these conditions is therefore strong. Nevertheless, in view of the amount of space being devoted to contrary assertions, it seems worthwhile to present a graphic and, I think, unambiguous demonstration of the presence of surface "oxide" during formic acid oxidation. No originality is claimed for the experiment and no quantitative data are extracted from it; indeed, results obtained by analogous methods already appear in the literature[8-11]. A platinum wire electrode in a deoxygenated solution of 1M formic acid, 1M sulfuric acid, is held at 0.18V (*vs.* reversible hydrogen electrode) to produce an "oxide"-free surface, then the potential is stepped to a value ϕ_{ox} for 10 sec after which a fast cathodic sweep (45V sec^{-1}) is started. At this sweep rate, the anodic current due to formic acid oxidation is swamped by the cathodic current

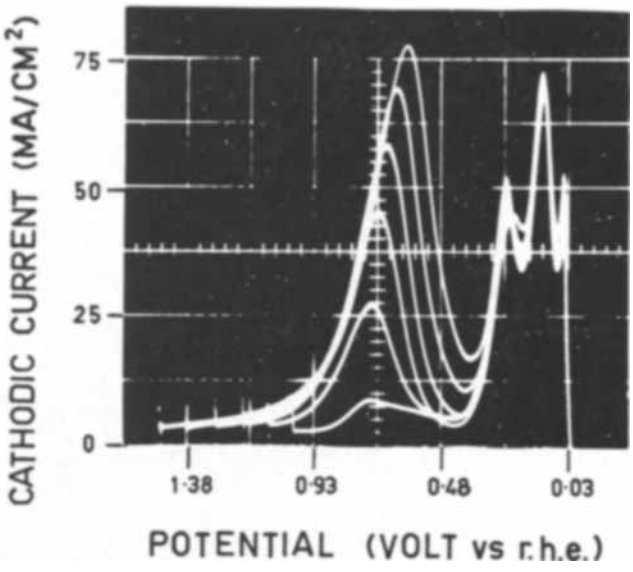

Fig. 1. Cathodic linear sweeps after 10 sec at various potentials in 1M HCOOH, 1M H_2SO_4. From left, curves start at 1.48, 1.38, 1.28, 1.18, 1.08, and 0.98V *vs.* r.h.e. Sweep rate 45V sec^{-1} (5 msec/graticule division).

arising from surface reduction processes. Figure 1 shows a series of sweeps for ϕ_{ox} ranging from 0.98 to 1.48V in 0.1V steps. The curves contain three cathodic peaks. The first increases with increasing ϕ_{ox} and its peak potential shifts cathodically; its behavior is analogous to that found in absence of formic acid[13,14] and it is therefore attributed to "oxide" reduction. The other maxima are the two well-known hydrogen peaks which show only a slight dependence on ϕ_{ox}, mainly due to a small overlap between "oxide" reduction and the first (more anodic) hydrogen peak.

These experimental results and their interpretation in terms of the presence of surface oxygen doubtless conform to the expectations of most electrochemists, especially as the work repeats that done in several other laboratories. Their publication is intended to counteract the wide circulation of incorrect notions concerning the surface behavior of platinum electrodes and to provide a challenge, in the simplest possible form, to explain the cathodic peak around 0.6-0.7V in terms of adsorbed species other than those containing oxygen.

S. Schuldiner: The communications gap between Biegler and myself is due to our very different concepts of the "steady state." Biegler evidently considers that stepping the potential to a given value for 10 sec brings the electrode to its steady-state condition. My measurements in formic acid,[15] formic acid + sulfuric acid,[15] and pure sulfuric acid[16,17] solutions showed that attainment of the steady state in the potential region of interest took many hours. My Fig. 1[15] typifies the current density *vs.* time relation found when a given potential is applied.

Using a rapid anodic charging method, Warner and Schuldiner[18] deposited a monolayer of what was considered to be oxygen atoms, O_{ad}, on a Pt electrode. Under open-circuit conditions, the Pt-O_{ad} reacted with H_2 in the sulfuric acid solution. As the reaction proceeded, a second anodic pulse was applied and the amount of O_{ad} formed to complete the monolayer was taken to be the amount of O_{ad} reacted at the time the second pulse was applied. Knowing the change in potential with time, we were able to determine a re-

lation between O_{ad} and potential (Fig. 4[18]). These transient measurements showed that when the potential decayed to about 0.9V the Pt surface was still covered by O_{ad}. However, my data[17] (see Fig. 2[17]) showed that under steady-state conditions at 0.9V only about one half of the adsorption sites on the Pt surface were covered with an adsorbate (which, under these steady-state conditions, I believe to be sulfate ion rather than O_{ad}). Recent work at this Laboratory,[19] also in H_2-saturated sulfuric acid solution further confirms that the amount of O_{ad} which can be deposited on a Pt electrode at potentials above 0.4V was time dependent. In summary, the point is that transient charging to an anodic potential may deposit O_{ad} on the Pt surface but, if the anodic potential is maintained, slow changes occur on the surface which result in a removal of O_{ad} by reaction with H_2 or formic acid and a deposition of sulfate ions.

I should like to point out at this time that charging curves can determine the number of coulombs of charge required to go from one potential to another and that ramp techniques can determine changes in current under potential sweep conditions, but the interpretation of what is occurring on the electrode surface is based more on consensus than on proof.

Concentration Changes in Operating Fuel Cells

T. J. Lundquist, Jr., and W. M. Vogel (pp. 1066-1069, Vol. 116, No. 8)

M. Beltzer[20]: T. J. Lundquist, Jr., and W. M. Vogel found large concentration changes in both strong acid and base electrolytes at high current densities ($\simeq$70 to 150 mA/cm^2) in their fuel cells, contrary to the results of Beltzer.[21] The authors claim that they cannot speculate as to the causes of the discrepancies. I suggest, however, that further analysis by the authors of their own experimental results would reveal the differences to be valid ones. Thus, they should not be considered discrepancies.

The major difference in the experiments of the authors and those of Beltzer lies in the properties of the matrices used. Consequently, it is necessary to examine the properties of matrices and their effect on mass transfer.

Although Lundquist and Vogel correctly state that the steady-state concentration difference (ΔC_∞) depends on matrix geometry, they completely ignore the retarding influence of the matrix to mass transfer. The effective mobility of ions traversing any matrix is invariably less than the mobility in bulk solution.[22-24] This results in larger steady-state concentration differences than would occur if the matrix were absent. This quantity (ΔC_∞) is also markedly dependent on the particular matrix used. For example, the authors used a Johns-Manville fuel cell asbestos matrix. Coleman *et al.*[25] have shown that the same electrode will exhibit substantially different performances when different asbestos matrices are used in the cell. The linear dependence of ΔC_∞ with matrix thickness and the near zero intercept (Fig. 6) certainly substantiates the authors' claim that the concentration gradients are confined solely to the matrix. Consequently, valid comparisons of results of different experimenters can be made only when these effects are accounted for.

Sample calculations using the authors' equations and data show how the particular matrix used can result in different concentration changes in cells operating at comparable current densities and employing essentially identical or similar electrodes.

Table I. Steady-state concentrations in H_2/O_2 cell filled with KOH, no matrix

I [mA/cm^2]	ΔC_∞ [mole/liter]	$(C_a)_\infty$ [mole/liter]	$(C_c)_\infty$ [mole/liter]
0	0	6.80	6.80
72	0.28	6.65	6.93
144	0.56	6.52	7.08

The effective diffusion coefficient of, *e.g.*, hydroxide ion in the matrix, is calculated from the authors' Eq. [7]

$$\Delta C_\infty = in_- l/DqF$$

where ΔC_∞ was determined experimentally, l is the matrix thickness, q the area, and n_- the transport number of hydroxide ion. I have used the authors' value of $n_- = 0.78$, an acceptable value in KOH solutions greater than 3 molar.[26] The relative mobilities of potassium and hydroxide ion in the matrix are most likely similar to that in solution so that the use of this value for the transference number in the matrix is justified.

Using the authors' case of the O_2/H_2 cell filled with 6.8M KOH (Table II), I have calculated an average diffusion coefficient based on the 72 and 144 mA/cm^2 discharge data of $D = 1.13 \times 10^{-5}$ cm^2/sec. The bulk value of D at 60°C is 5.05×10^{-5} cm^2/sec. This value was obtained using the 25°C value estimated by Austin[27] and a conductance activation energy of 2.4 kcal/mole.[28] This activation energy applies to KOH solutions ranging from 3 to 6 molar and is therefore applicable to the range of solutions used by the authors and myself.

Thus, if one did not use a matrix at all, the ΔC_∞ across a laminar section of the bulk solution having the same area and thickness as the matrix would be about only 1/5 of the matrix ΔC_∞. The calculated values of ΔC_∞, $(C_a)_\infty$, and $(C_c)_\infty$, the latter two quantities, the steady-state anolyte and catholyte concentrations in the absence of a matrix are tabulated in Table I of this discussion.

At 144 mA/cm^2 in the absence of a matrix, the concentration decrease in the anolyte would be only 0.28 moles/liter as opposed to 1.3 moles/liter with the matrix. The calculated concentration polarization resulting from this decrease is negligible

$$\eta = 0.066 \log \frac{6.80}{6.52} = 0.001\text{V}$$

This is in accord with the experimental results of Beltzer. Similar considerations apply to the catholyte and to both electrodes in strong acids as well. Negligible concentration polarizations at high current densities in acids and basic electrolytes have been demonstrated by Niedrach[29-30] and others.[31] Niedrach operated an anode at 400 mA/cm^2 in 6M KOH and encountered very little concentration polarization. He, too, did not use a matrix but employed free electrolyte in the interelectrode spacing.

In view of the foregoing, it is difficult to see how the authors can regard the results of others as contrary to theirs, when the differences are authentic ones, and the results of the different experimenters internally consistent.

I have an additional and admittedly minor point to make. The terms membrane and matrix are used interchangeably and the authors are not alone in this misuse of the terms. A membrane is a type of matrix but not all matrices are membranes. The operational definition of a membrane that is commonly accepted is that a membrane is a structure or phase which permits passage of material exclusively by molecular movement; *e.g.*, see Sollner.[32] I can only assume that Lundquist and Vogel did not use a true membrane because they took the trouble to orient the structure in a horizontal position to minimize liquid circulation through the "membrane." They also changed the relative positions of the anode and cathode so that the denser electrolyte (catholyte when KOH was used) is on the bottom. These manipulations would have been unnecessary if the matrix was a true membrane.

J. T. Lundquist, Jr., and W. M. Vogel: The discussion refers primarily to our Eq. [7] which is indeed incorrect if l and q are taken as the thickness and area of the matrix. By mistake, an essential sentence was omitted (not, however, in the Extended Abstract No. 335, ECS Meeting, Montreal 1968); namely, that the tortuosity and porosity of the matrix have to be taken into account. Thus, l and q are not the dimensions of the matrix as given in our Table II but are the latter multiplied by what is commonly called the matrix factor. Since this factor (approximately tortuosity/porosity) cannot be measured directly, we made no use of Eq. [7] *per se* but tested our theory using Eq. [13] which is free of this factor. The ratio of the bulk value for $D = 5.05 \times 10^{-5}$ (cm^2/sec) and the apparent value calculated by Beltzer is actually the matrix factor. This factor (4.4) is entirely reasonable for the kind of matrix used in our study.

We quite agree that if no membrane is used the concentration changes would be much smaller. However, in his original paper (see footnote 21) Beltzer describes his electrodes as being clad with a membrane (caption to Fig. 1 and 2 and other places). We understood this to mean that there was a porous body between the catalyst and the free electrolyte, in which case the discrepancy mentioned in our paper still exists.

Electrocapillary Measurements at the Interface Insulator-Electrolytic Solution

H. Dahms (pp. 1532-1534, Vol. 116, No. 11)

Ikram Morcos[33]: We note with interest the electrocapillary measurements at the insulator-electrolytic solution interface. We believe, however, that the interpretations given by the author are inapplicable for the experimental results. In this regard, we would like to point out the following.

Variation in the polyethylene/electrolytic solution interfacial tension cannot be calculated on the basis of the well-known equation

$$\gamma = \frac{rh\Delta\rho g}{2} \qquad [1]$$

This equation describes the relationship between the capillary rise and surface tension of liquids. The use of this equation for electrocapillary studies of liquid metals is justified because γ in such cases is also the liquid metal/electrolytic solution interfacial tension.

In the work of Dahms, we believe that the variation in the capillary rise of the solution inside the polyethylene tubing results from the variation in the contact angle between the solution and the polyethylene wall. This variation results from variation in the polyethylene/electrolytic solution interfacial tension according to the Young equation

$$\cos\theta = \frac{\gamma_{S/g} - \gamma_{L/s}}{\gamma_{L/g}} \qquad [2]$$

where θ is the contact angle and $\gamma_{S/g}$, $\gamma_{L/s}$, and $\gamma_{L/g}$ are interfacial tensions of the solid/gas, liquid/solid, and liquid/gas interfaces. Electrocapillary studies for solid electrodes based on the Young equation have already been reported in the literature[34-36].

In the case of a capillary tubing, the capillary rise or depression is a function of the contact angle as shown by the more general equation of capillary rise

$$h = \frac{2\gamma\cos\theta}{g\,r\,\Delta\rho} \qquad [3]$$

It has been reported by Zisman[37] that θ for the polyethylene/water system is around 100° and, accordingly, cos θ cannot be omitted from Eq. [3] on the basis of the assumption that the solution completely unwets the polyethylene wall with an angle of 180 as in the case of mercury. Under the effect of an electric field, $\gamma_{L/s}$ in Eq. [2] will decrease (as a result of charging the double layer and adsorption of ions) and, if we assume that $\gamma_{S/g}$ and $\gamma_{L/g}$ remain constant, cos θ should increase. This increase in cos θ should, according to Eq. [3] result in an increase in the capillary rise, h. Because the contact angle is more than 90°, this increase will be a decrease in the capillary depression as shown by Dahms. Again, with the assumption that $\gamma_{L/g}$* is constant, h should, according to Eq. [3], vary linearly with the variations in cos θ.

The use of capillary rise (or depression) *vs.* applied electric field plots to obtain surface charge or surface excess in the case of insulator electrolytic solution requires assuming the validity of Gibbs' equation. While such an equation has been used in the case of an ideally polarizable or reversible electrode,[38] it is questionable that the same applies for the insulator/electrolytic solution interface.

H. Dahms: The comments of I. Morcos appear to be concerned mainly with two points in my treatment of the electrocapillary data: the linear relationship between capillary depression, h, and the surface tension insulator/solution, which I have used, and the applicability of Gibbs' equation for this interface.

As indicated by the title of my communication, the electrocapillarometer which I have described is measuring the voltage dependence of the interfacial tension insulator/electrolytic solution, γ_{SL}. This phenomenon is certainly fundamentally different from the capillary depression or rise in a nonwetting or wetting capillary which is determined by the surface tension solution/gas, γ_{LG}. It can be seen that, independent of the contact angle, θ, there is a direct proportionality between h and γ_{SL}. By combining the general capillary rise equation with the Young equation (Morcos' Eq. [3] and [2]), we obtain

$$h = \frac{2\gamma_{SG}}{r\,\Delta\rho\,g} - \frac{2\gamma_{SL}}{r\,\Delta\rho\,g} \qquad [1']$$

Since only γ_{SL} will vary with the electric field while γ_{SG} remains constant, we can write

$$dh = -\frac{2}{r\,\Delta\rho\,g}\,d\gamma_{SL} \qquad [2']$$

This is the linear relation which I have used to obtain changes of surface tension from changes in capillary depression.

Concerning the applicability of Gibbs' equation, I agree readily that it cannot be directly used to obtain

surface charge from γ-voltage plots. For this purpose, the total applied electric field would have to be divided into the field acting across the bulk of the insulator phase and the field acting across the insulator/solution interface. This problem awaits further study. It will be noted that I have, therefore, avoided using Gibbs' equation to obtain surface charge. I think, however, that Gibbs' equation can be applied for obtaining the surface excess of a neutral species, n-butanol in my case, at the interface insulator/electrolytic solution. This treatment is based on the assumption that the voltage across the interface remains constant; *i.e.*, that the voltage distribution between insulator bulk and interface does not change with surface coverage by the neutral species, butanol. I think that this assumption is reasonable. The interface insulator/electrolytic solution can be considered to be an ideally polarizable interface in that there is, by definition, no current flow.

A Preliminary Investigation of Fluidized Bed Electrodes

J. R. Backhurst, J. M. Coulson, F. Goodridge, R. E. Plimley, and M. Fleischmann (pp. 1600-1607, Vol. 116, No. 11)

Richard Prober[39]: The development of fluidized bed electrodes, as reported by Backhurst, Coulson, Goodridge, Plimley, and Fleischmann, should stimulate considerable research interest directed toward optimization of electrode geometry as well as toward exploitation in large-scale electrochemical processes.

A fluidized bed electrode is a type of dispersed electrode, since the electrochemical reactions occur on the surfaces of suspended particles.[40] Heretofore, dispersed electrodes have used particles suspended by agitation or particles flowing as a slurry.[41] Fluidization of a bed of particles provides efficient contacting between the particles and the current feeder, and it consumes less power in suspending particles.

It is noteworthy that the reduction of m-nitrobenzene sulfonic acid on copper cathodes, which Backhurst *et al.* used as a test reaction system, is of the same class of reactions as the earliest application (to my knowledge) of dispersed electrodes.[42]

The data on the distribution of potential within a fluidized bed electrode (Figure 10) do, indeed, indicate that the bed is more effective near the current feeder than at points far away from it. This is evident upon replotting the data with cartesian coordinates in Fig. 10a and 10b. Both curves shown have a change of slope some 1.5-1.7 cm above the base of the bed. Above that point, the curves are linear with slopes that imply an effective resistance of 0.5 ohm cm of bed depth and an effective resistivity of 3.5 ohm-cm (*cf.* 2.5 ohm-cm for 1M sulfuric acid solution at 18°C). Thus, the upper part of the bed seems to be inactive unless the current feeder is located there.

John R. Backhurst: We would like to thank Dr. Prober for his comments on our paper on fluidized bed electrodes. It should be emphasized that we were reporting the preliminary results from this work, and more detailed experimental data has since been obtained. These experimental and theoretical conclusions will be published shortly.

In brief, they indicate, as Dr. Prober suggests, that in any fluidized electrodes of large dimensions in the direction of current flow there are regions of inactivity. However, these are not necessarily located in regions of the bed remote from the feeder. The distribution of activity shows a complex dependency on the many parameters which are used to describe the system; of these, the ratio of particulate to electrolyte conductivity appears at this stage to be most influential. In fact, if the feeder is located at the beginning of the bed away from the counterelectrode, the region of least activity for the reactions investigated so far is located in the center of the bed.

A Reversible Solid-State Battery with $RbAg_4I_5$ as Electrolyte

Mario De Rossi, Gianfranco Pistoia, and Bruno Scrosati (pp. 1642-1646, Vol. 116, No. 12)

Takehiko Takahashi[43]: On page 1643, Dr. De Rossi wrote that the electrolyte (Ag_3SI) cannot be used for battery purposes since it has high electronic conductivity, referring to the review written by Foley.[44]

The transference number of Ag^+ ion in Ag_3SI, t_i, was measured by Takahashi and Yamamoto to be 0.977 or 0.985.[45] But, when the transference number of the electron is small, $1 - t_i$ is not always considered to give an exact value of the electron transference number.

For this reason, Takahashi and Yamamoto also measured the electronic conductivity of Ag_3SI by Wagner's method to obtain 10^{-8} ohm^{-1} cm^{-1} at room temperature,[46] the value of which was, however, different from that obtained by the extrapolated figure of Reuter and Hardel's work ($10^{-4} \sim 10^{-5}$ ohm^{-1} cm^{-1}) as described in Dr. Foley's review.

The exact reason for this discrepancy has not been made clear, but it will be attributed to the preparation

procedure of Ag_3SI, the electronic conductivity of which is easily changed by changing the vapor pressure of sulfur when the reaction between AgI and Ag_2S is carried out to synthesize Ag_3SI. Thus, the electronic conductivity of 10^{-8} ohm^{-1} cm^{-1} at room temperature can easily be obtained by using a suitable vapor pressure of sulfur on synthesizing Ag_3SI without any change of ionic conductivity.[47]

Bruno Scrosati: The comment of Prof. Takahashi on this paper does not seem to need a precise answer since this answer is already included in the comment itself. Undoubtedly, some disagreements on the Ag_3SI electronic conductivity do exist in the literature, many of them due to different preparation procedures or to different determination techniques.

As to what the utilization of Ag_3SI as such in a solid state relates to, it may be definitive of the work of Owens and co-workers[48] on the Ag_3SI stability. In this work, it has been clearly proved that this solid electrolyte is not stable in the presence of iodine since it slowly degrades to AgI and S. It follows that the application of Ag_3SI in solid electrolyte cells is quite limited. Only low emf cells could be operative with all the related disadvantages, such as low power density, low emf., and kinetic restrictions.[48]

ABSTRACT

The physical and electrical properties of aluminum oxide films deposited on silicon by rf sputtering from an alumina target in an argon atmosphere were investigated as a function of sputtering power density in the range from 0.5 to 3 W/cm^2. The deposition rates ranged from 20 to 80 Å/min. The density, index of refraction, and dielectric constant of the films increased while the etch rate decreased with increasing power density. The surface charge at the aluminum oxide-silicon interface was typically larger than 10^{12} e/cm^2. This charge increased with increasing sputtering power density and could be reduced to 7-8 x 10^{11} e/cm^2 by annealing. The films exhibited trapping instabilities at room temperature but no polarization was observed under bias-temperature stress. The characteristics of composite layers of thermally grown silicon dioxide and sputtered aluminum oxide layers on silicon were also investigated and found to exhibit low surface charge densities, no hysteresis, and a "contact potential" as well as charge stored at the interface between the two insulators.

Dielectric films deposited on semiconductor substrates serve many functions in solid state devices. These functions include masking against diffusion of impurities during the formation of pn junctions, surface passivation, insulation in multilayer interconnections, fabrication of capacitor structures, and insulated-gate field-effect transistors (IGFET).

Amorphous silicon dioxide films have been used extensively in silicon device technology and are still the most commonly used dielectrics. However, silicon dioxide is structurally porous (as indicated by its low density) and permeable to ionic migration which reduce its effectiveness as a passivating layer. These disadvantages have prompted the investigation of other oxide and nitride dielectrics; among these is aluminum oxide.

The interest in aluminum oxide films stems from the following experimental observations: the ionic mobility of impurities (Na^+) is very low in these films (1), their radiation resistance is high compared to silicon dioxide films (2), and their dielectric constant is double that of silicon dioxide (3). These films are also of interest in double layer (SiO_2-Al_2O_3) structures where they act as effective junction seals (4) and also offer a possible method of controlling the threshold voltage of IGFET devices (5) due to the presence of a "contact potential" at the silicon dioxide-aluminum oxide interface.

Aluminum oxide films have been deposited on silicon by various methods. Chemical vapor deposition involving the hydrolysis of aluminum trichloride (6) or pyrolysis of organo-aluminum compounds (7) have been the most commonly used. The films prepared by these methods exhibit interface charge densities in the range 3-10 x 10^{11} cm^{-2} and this charge can be reduced to 1-2 x 10^{11} cm^{-2} when a thermally grown silicon dioxide interlayer is used between the silicon and the aluminum oxide (8). Both positive and negative interface charges have been reported in these films (7-11), the charge being strongly process dependent. DC reactively sputtered (12-14) aluminum oxide films have resulted in extremely low surface charge and surface state densities. Plasma anodized (2, 15) aluminum oxide films have also yielded extremely low surface charge densities. More recently, films have also been prepared by reactive evaporation (16), and yielded results similar to those obtained with chemically deposited films. Relatively little has been reported on the deposition of aluminum oxide by rf sputtering on silicon or other substrates (17, 18).

The purpose of this study is to investigate the physical and electrical properties of aluminum oxide films deposited on silicon by rf sputtering from an aluminum oxide target in an argon atmosphere and to evaluate the suitability of these films as passivating layers on silicon. This study also includes an investigation of the characteristics of sputtered aluminum oxide-thermally grown silicon dioxide double layers on silicon.

Experimental

The rf sputtering apparatus used in this work is shown schematically in Fig. 1. The dielectric target used was a sintered aluminum oxide (99.97%) disk 12.5 cm in diameter and 1 cm thick. It was metallized on one side and bonded using silver epoxy to a flat water-cooled aluminum disk which formed part of the vacuum chamber wall through a system of vacuum seals and an insulating ring. A metal shield surrounded the exposed areas of the water-cooled aluminum disk at a spacing of 0.5 cm in order to prevent sputtering from this region. The substrate supporting configuration was water-cooled.

A conventional rf generator operating at 13.56 MHz was used as the source of power which was coupled to the target electrode through a tunable network which insured matching between the coaxial transmission

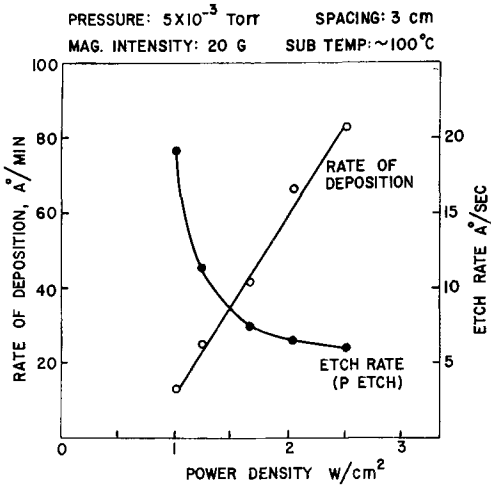

Fig. 2. Effect of power density on deposition and etch rates

line impedance and the sputtering system load impedance. The power delivered to the discharge was measured using a standing-wave power meter. A permanent magnet inside the vacuum system was used to provide a magnetic field (20 gauss) perpendicular to the dielectric target surface. This magnetic field caused a 20% increase in the deposition rate and helped to stabilize and confine the glow to the space between the two electrodes. Ultra high-purity argon (99.999%) was used as the sputtering gas and the pressure during sputtering was monitored by means of a cold cathode gauge. The system was evacuated by a 6 in. oil diffusion pump equipped with a water-cooled baffle and a liquid nitrogen trap. A Meissner trap was also fitted into the 18 in. glass bell jar to improve the ultimate vacuum.

In a typical run, the initial pressure in the system was 4×10^{-7} Torr. Prior to deposition, the target was cleaned by argon ion bombardment (with the substrates shielded) and the system was pumped down again to 4×10^{-7} Torr. Argon was then re-introduced in the system and the oxide deposition carried out under predetermined operating conditions. To minimize gas contamination the pumping system was not throttled during sputtering and liquid ntirogen was used in both traps. The argon pressure was kept at 5-7μ during most of the runs. At this sputtering pressure a 3 cm target to substrate distance was found to be compatible with a self-sustained uniform discharge and satisfactory deposition rates.

The nominal substrate temperature was measured using a thin (0.010 in.) chromel-alumel thermocouple prior to turning on and immediately after extinguishing the glow discharge. In most cases, the silicon slices were held on the substrate holder by means of a thin layer of gallium which provided good thermal contact and allowed deposition at low temperatures (~100°C). Depositions were also carried out with the substrates thermally isolated from the holder. The substrate temperature during these runs did not exceed 200°C and reached equilibrium within a few minutes after the discharge had been turned on (19).

Silicon used in this work was in the form of polished circular slices (Monsanto) 2.5 cm in diameter prepared by the Czochralski method. The dislocation count was specified to be less than 10^3 cm^{-2}. The slices used were n-type phosphorus doped, (111) orientation of approximately 10 and 0.01 ohm-cm resistivities. The high-resistivity slices were used for surface studies and the low-resistivity ones were used for investigations of the dielectric and optical properties of the aluminum oxide films. Prior to aluminum oxide deposition or silicon dioxide growth the polished silicon wafers were degreased, boiled in nitric acid, dipped in hydrofluoric acid, and then rinsed in deionized water. The silicon dioxide growth was carried out at 1100°C in dry oxygen in a horizontal resistively heated furnace provided with a quartz tube and mullite liner. The silicon dioxide was then annealed at the same temperature in nitrogen for 30 min. Both the oxygen and nitrogen gases were obtained from liquid sources.

After deposition the aluminum oxide films were annealed in nitrogen for 30 min at 300°C unless otherwise noted.[1] The heat treatments were restricted to a temperature below 320°C because of the possible occurrence of a new phase of aluminum oxide (γ') above this temperature (20).

The thickness of the films was measured using a Talystep (Taylor-Hobson) capable of ±20Å accuracy. The structure of the films was examined by electron microscopy. The density was determined by a differential weighing technique using a microbalance. The index of refraction was obtained from measurements on the interference pattern in the visible u.v. range by means of a Perkin-Elmer 450 spectrophotometer fitted with a 350 specular reflectance attachment. Knowing the film thickness from Talystep measurements, it was possible to estimate the index of refraction as a function of wavelength (21). The infrared spectra were obtained using a Perkin-Elmer 621 spectrophotometer fitted with two microspecular reflectance attachments.

Most of the electrical evaluations involved MIS (metal-insulator-semiconductor) structures. These were prepared by evaporating aluminum (99.999%) field plates, 1000Å thick, 500μ in diameter over the dielectric through a mask. Aluminum was also evaporated on the bare back-side of the silicon for contact. The evaporations were carried out from a resistively heated tungsten filament in a vacuum of 10^{-6} Torr. Electrical measurements were then carried out as described later in the paper.

Results and Discussion

For rf sputtering of insulating films on semiconductor substrates, the power density affects the rate of deposition, the etch rate, the density, the dielectric constant, the conductivity, and the surface characteristics of the semiconductor-insulator interface (22). Some of these effects will be considered in the following sections.

Physical Properties

The rate of deposition of aluminum oxide films as a function of power density is shown in Fig. 2. The deposition rate is a linear function of power density. The film thickness was uniform within 5% over the whole area of any one slice and films could be deposited over six slices simultaneously with a thickness uniformity of better than 10%. No cracks were observed in films ranging up to 5000Å in thickness.

The etch rate is a sensitive indicator of the structural properties of the film. The P-etch[2] rate for alu-

[1] Annealing at such low temperatures was found to have negligible effect on the densification of the layers.
[2] 15 parts 49% HF; 10 parts 70% HNO_3; 300 parts H_2O.

minum oxide films is shown in Fig. 2 and is seen to increase drastically at low power densities, indicating porous films. This fact was also confirmed by measurements of the density of the films as a function of power density. The low power depositions resulted in lower film densities as shown in Fig. 3. The density ranged from 3.5 g/cm^3 at a power density of 1 W/cm^2 to about 3.8 g/cm^3 at 2.5 W/cm^2.

The films examined by low-angle electron diffraction were found to be amorphous independently of the deposition power densities used in this investigation. The index of refraction of the films was found to increase with increasing power density ranging from 1.55 to 1.65 at 0.5μ. A typical infrared reflectance spectrum for an aluminum oxide film deposited on low-resistivity silicon is shows in Fig. 4. It exhibits a broad peak around 15μ, in general agreement with the data reported for α-aluminum oxide (23). No trace of water could be detected in the films from these infrared measurements. Relatively minor variations were observed in the physical properties of annealed films deposited on substrates held by gallium on the holder and those deposited on substrates thermally isolated from the holder.

Electrical Properties

Metal-aluminum oxide-silicon (MAS) structures.—Dielectric constant.—The dielectric constant of aluminum oxide films sputtered under the conditions described above were obtained from capacitance measurements of 1 kHz using a GR 1650B bridge. The values obtained ranged from 7 at a power density of 1 W/cm^2 to 8.5 at a power density of 2.5 W/cm^2. Values of 8.55 for sputtered aluminum oxide films have been reported by Pratt (18). The low dielectric constant observed at low power density is probably related to the low film density (24). The dissipation factor for these films ranged from 0.01 to 0.004.

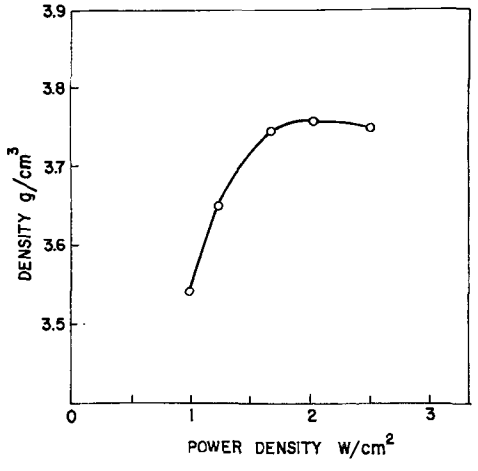

Fig. 3. Film density as a function of deposition power density

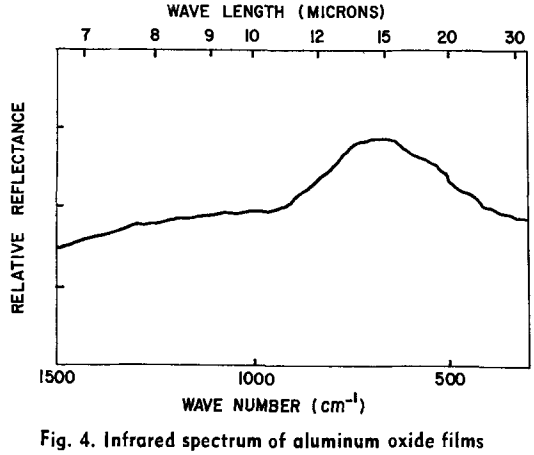

Fig. 4. Infrared spectrum of aluminum oxide films

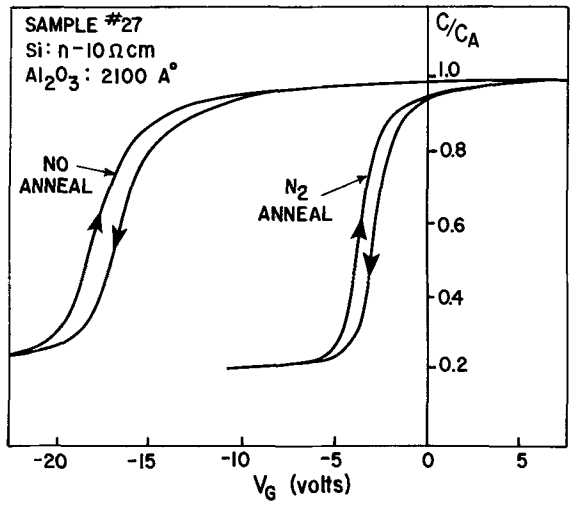

Fig. 5. Capacitance-voltage plots for a MAS device showing the effect of annealing. (C_A = aluminum oxide capacitance per unit area.)

Breakdown field.—The breakdown field of aluminum oxide films was measured by the method described by Worthing (25). A general correlation between power density and breakdown field was not possible and the measured breakdown values ranged fom 2 to 8 x 10^6 V/cm. These values agree with the ones reported by Pratt (18).

Surface charge.—The charge per unit area Q_{SA} stored in the aluminum oxide was determined from the capacitance-voltage characteristics (C-V) of the MAS structure. This method involves the determination of the flat-band voltage V_{FB} of the experimental C-V curve. The charge density Q_{SA} is then related to V_{FB} by the expression[3]:

$$V_{FB} = -Q_{SA}\left[\frac{x_a}{\epsilon_a}\right] + \phi_{MS} \qquad [1]$$

where ϕ_{MS} is the metal-semiconductor work function difference (26), and x_a, ϵ_a are, respectively, the thickness and dielectric constant of the aluminum oxide layer. The capacitance measurements were carried out at 1 MHz using a Boonton 71A capacitance meter.

As mentioned in previous sections, higher deposition power densities result in denser, higher quality films, however, a major detrimental effect in using high power densities is the deterioration of the silicon surface properties. The induced charge was measured as a function of deposition power density prior to annealing of the films. The charge induced was observed to increase with sputtering power density in agreement with the observations of Hu and Gregor (24). When the power density was below 1 W/cm^2 the induced charge was about 10^{12} e/cm^2. At power densities of 2.5 W/cm^2 and above the surface charge was 10^{13} e/cm^2 or larger. In all cases the effective charge stored in the oxide was positive. Annealing at 300°C for 30 min in N_2 prior to electrode deposition was found to reduce this charge in most cases to about 7-8 x 10^{11} e/cm^2. For initial (prior to annealing) charge densities higher than 10^{13} e/cm^2 N_2 annealing was found to have little or no effect and the charge stored in the oxide could not be significantly reduced. Figure 5 shows the C-V characteristics of a MAS sample prior to and after N_2 annealing. The increase in induced charge with increasing deposition power density can be attributed to an increase in the charge stored in the oxide due to structural differences between oxides deposited at various power densities and/or to bombardment induced surface damage during sputtering (24). Since the surface charge after annealing was approximately

[3] The charge Q_{SA} was assumed to be at the silicon-aluminum oxide interface.

constant for power densities below 2.5 W/cm^2, the reduction in surface charge can be due to annealing of radiation damage at the silicon-aluminum oxide interface. However, at higher power densities the surface charge is more likely to be associated with structural changes in the oxide or permanent surface damage which could not be annealed.

The distribution of oxide charge was studied as a function of distance in the oxide. The oxide charge, after annealing, was found to be located predominantly at or near the silicon-aluminum oxide interface. This observation was the result of a series of etching-annealing experiments. Aluminum oxide layers, 2000Å thick, were thinned by etching to produce oxide thicknesses ranging from 500 to 2000Å in several steps. The oxides were then annealed as described previously and the surface charge measured. In all cases the effective surface charge densities were of the order of 7-8 x 10^{11} e/cm^2 independent of oxide thickness. Similar results have been observed in sputtered silicon dioxide films on silicon (27).

A further observation which can be made regarding the C-V plots of Fig. 5 is the difference in the shape of annealed and unannealed samples. The slow transition in the C-V curve for the latter is probably related to a high surface state density which can be reduced by annealing.

Trapping.—Hysteresis is present in the C-V curves shown in Fig. 5. The sense of the hysteresis (flat-band voltage more negative after the maximum negative excursion) indicates charge interchange across the aluminum oxide-silicon interface. Hole emission from the silicon to the insulator or electron emission from traps in the insulator to the silicon could account for the observed sense of the hysteresis (28). An increase in hysteresis was observed when the bias-voltage swing about flat-band was increased. A displacement of the C-V curves was also observed at room temperature after application of a stress field exceeding a threshold of 1-2 x 10^6 V/cm. The direction of this displacement was opposite to that caused by polarization or ion migration and was temperature independent and dependent on previous bias history. Figure 6 shows the effect of stress voltage on the flat-band voltage of a MAS capacitor. Similar results have been observed on silicon nitride (28), (29), and vapor-deposited silicon oxide (30) on silicon. This instability is postulated to be associated with deep trapping centers in the dielectric coupled with charge transfer across the interface region between the dielectric and the semiconductor. The trapping instability and hysteresis could be caused by the presence of a very thin silicon dioxide layer (~20Å) which is usually present on silicon.

Polarization and ion migration.—Polarization and ion migration are characterized by a displacement of the C-V curves in a direction opposite to the polarity of the applied bias when the MAS sample is subjected to bias-temperature stress. The displacement is a function of applied bias and temperature. Annealed aluminum oxide layers were subjected to bias-temperature stress for 10 min at 250°C. The field applied during these experiments was smaller than the threshold field required for trapping (typically 1 x 10^6 V/cm). The resulting voltage shifts were typically less than 1V. Bias-temperature stress experiments with controlled Na^+ contamination indicated that Na^+ did not migrate appreciably through a 1000Å layer of aluminum oxide in agreement with the results of Tung and Caffrey (1). The above experiments indicate that polarization and ion migration in the sputtered films are negligible.

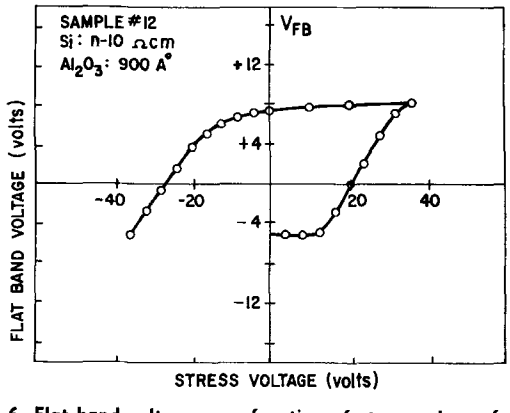

Fig. 6. Flat-band voltage as a function of stress voltage for MAS device.

Metal-aluminum oxide-silicon dioxide-silicon (MAOS) structures.—The electrical characteristics of aluminum oxide-silicon structures discussed above indicate that in spite of the absence of polarization and ion migration, the sputtered aluminum oxide films are not entirely satisfactory for passivation purposes because of the trapping instability associated with the insulator-semiconductor interface. Since thermally grown silicon dioxide on silicon does not exhibit charge instability, the properties of double layers of SiO_2 + Al_2O_3 were investigated.

Characterization of the insulator charge in MAOS structures was performed by C-V techniques. The analysis in this case is slightly complicated by the possible presence of a charge Q_{ii} at the silicon dioxide-aluminum oxide interface and a "contact potential" ϕ_{ii} at the same interface (4, 31). Taking these factors into account the flat-band voltage for the double layer is given by

$$V_{FB} = -Q_{SS}\left[\frac{x_o}{\epsilon_o} + \frac{x_a}{\epsilon_a}\right] - Q_{ii}\left[\frac{x_a}{\epsilon_a}\right] + \phi_{ii} + \phi_{MS} \quad [2]$$

where Q_{SS} is the fixed positive surface charge density at the Si-SiO_2 interface and x_o, ϵ_o are, respectively, the thickness and dielectric constant of the silicon dioxide layer. Distributed charge in the aluminum oxide and silicon dioxide has been neglected in the above equation (32).

In order to investigate the validity of Eq. [2] and to evaluate the magnitude of the various terms in that equation, four sets of samples having 1000Å of thermally grown silicon dioxide with overlayers of aluminum oxide ranging in thickness from 700 to 3000Å were prepared. The aluminum oxide layers were deposited at different power densities (ranging from 1 to 2 W/cm^2) for each set of samples. The double layers were then annealed at 300°C for 30 min in N_2 prior to electrode deposition. Figure 7 shows the C-V characteristics of one of the MAOS test samples. The C-V characteristics of the double layer do not exhibit hysteresis. Trapping is also absent in the double layer

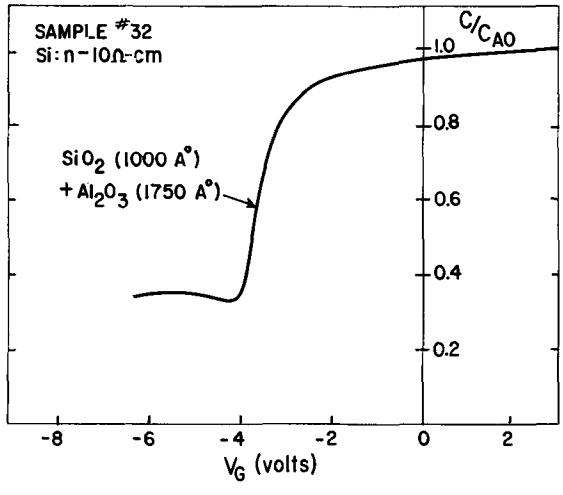

Fig. 7. Capacitance-voltage plot for a MAOS device. (C_{AO} = double-layer dielectric capacitance per unit area.)

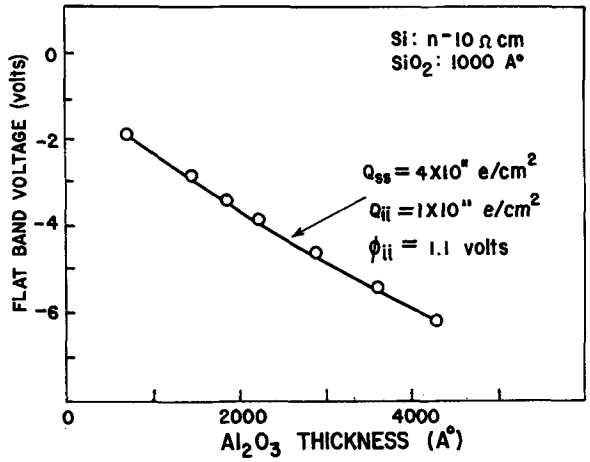

Fig. 8. Flat-band voltage as a function of aluminum oxide thickness in MAOS devices.

even for stress voltages up to the destructive breakdown of the dielectric layer. Similar results have been observed in Si_3N_4-SiO_2 double layers (29). Figure 8 shows a plot of the flat-band voltage of the double layer as a function of the aluminum oxide thickness for one set of samples. The aluminum oxide films in this case were deposited at 1.5 W/cm^2.

The constant parameters in Eq. [2] were estimated by curve fitting and found to be

$$Q_{SS} \sim 4 \times 10^{11} \text{ e/cm}^2 \text{ (positive)}$$

$$Q_{ii} \sim 1 \times 10^{11} \text{ e/cm}^2 \text{ (positive)}$$

$$\phi_{ii} \sim 1.1\text{V}$$

It should be noted that the intercept of the curve with the flat-band voltage axis for zero aluminum oxide thickness is not the value of ϕ_{ii}. This intercept depends on the values of Q_{SS}, x_o, ϵ_o, and ϕ_{MS} (-0.35V in this case). The magnitude of Q_{SS} in the annealed MAOS samples was found to be approximately the same as the one observed in MOS samples when the silicon dioxide was subjected to the same annealing. Wu and Formigoni (27) reported similar results on double layers of silicon dioxide sputtered on thermally oxidized silicon. The charge Q_{ii} was found to be positive for all the samples investigated and increased with increasing power density ranging from 1 x 10^{11} to 4 x 10^{11} e/cm^2. The charge Q_{ii} may be associated with charged traps at the interface. The density of these traps increases with increasing power density thus causing an increase in the stored charge. The origin of ϕ_{ii} is not completely understood (33), and it was found to range from 1 to 1.2V for the samples investigated. Both Q_{ii} and ϕ_{ii} have considerable effect on the threshold of IGFET's and the control of these parameters by deposition or annealing processes[4] may be required before the advantages of the double-layer structure can be fully realized.

Conclusions

Good quality aluminum oxide films can be prepared by rf sputtering of an alumina target in an argon atmosphere. The rate of deposition of the films is in the range 20-80 A/min for power densities ranging from 0.5 to 3 W/cm^2. The films were found to be amorphous and the etch rate, the density, the index of refraction, as well as the dielectric constant, were found to increase with increasing power density. In general, high power sputtering is preferred however, in this case surface charge becomes a problem. The initial surface charge after deposition was found to be larger than 10^{12} e/cm^2. After annealing this charge could be reduced to 7-8 x 10^{11} e/cm^2. The films deposited directly on silicon exhibited trapping instabilities at room temperature, but no polarization was observed under bias-temperature stress. Double layers of thermally grown silicon dioxide and sputtered aluminum oxide exhibited low-surface charge densities, no trapping instabilities, and a "contact potential" as well as charge stored at the interface between the two dielectrics. Both the interface charge and the contact potential were found to be process dependant and both will have to be controlled if full advantage is to be taken of characteristics of the double-layer structure.

[4] For double layers of aluminum oxide-silicon dioxide on silicon, Nigh *et al.* (4) have reported a positive ϕ_{ii} (of approximately the same value as the one reported here) but no Q_{ii}; Nishimatsu *et al.* (10) have reported the presence of both a negative Q_{ii} and a distributed charge in the Al_2O_3 films but no ϕ_{ii}; Kalter *et al.* (31) have reported a positive ϕ_{ii} but not Q_{ii}.

Photoluminescence of Eu(II) Activated $EuAlO_3$

Philip M. Jaffe*

Zenith Radio Corporation, Chicago, Illinois

ABSTRACT

$EuAlO_3$ activated with Eu(II) results in an efficient band emitting uv excited phosphor. From a study of the optical properties of $EuAlO_3$:Eu(III) and $EuAlO_3$:Eu(II) the following conclusions were reached: (*i*) there is little if any emission from Eu(III) because of concentration quenching; (*ii*) other than the trivial radiative energy transfer from Eu(II) to Eu(III) there is little interaction between Eu(II) and Eu(III); (*iii*) the excitation spectrum of Eu(II) emission can be explained in terms of crystal field theory.

In the last few years there has been much interest in divalent and trivalent Eu activated phosphors. This interest has been both theoretical and practical as evidenced by an examination of the recent phosphor literature as, for example, ref. (1) through (8). In these phosphors, other than those reported by McAllister (8), only one oxidation state of Eu was present. McAllister's work was with the complicated (Li, Ba, La, Eu)PO_4 in which Eu(II) and Eu(III) were present, simultaneously. A better phosphor in which to study interactions, if any, between Eu(II) and Eu(III) would appear to be $EuAlO_3$.

$EuAlO_3$ exists in two modifications, perovskite (cubic) and orthorhombic (9). The perovskite structure, which has the general form ABO_3, may be considered to be made up of layers of oxygen atoms (10). The large A ions are located in twelve-fold coordination and the smaller B ions in six-fold coordination. In $EuAlO_3$ the Eu(III) is in the A site. When Eu(II) is formed on reduction of Eu(III) it stays in an A site since no ion migration or rearrangement is necessary for its incorporation into the host lattice as may be necessary with McAllister's phosphors.

Experimental

The phosphors studied here were mixtures containing 80-90% of the cubic $EuAlO_3$, the balance being the orthorhombic modification. X-ray diffraction analysis has shown that $EuAlO_3$ can exist over the range of at least 0.1 g at. of excess Eu or Al using the substitution $Eu_{1\pm x}Al_{1\mp x}O_3$.[1]

The various compositions studied here were prepared by coprecipitating $Al(OH)_3$ and $Eu(OH)_3$ with ammonia from a hot solution of the nitrates. After digesting overnight, the precipitate was filtered, dried at 120°C, triturated, and fired in alumina crucibles at 1250°-1350°C.

Absorption, emission, and excitation spectra were obtained with a Jarrell-Ash ¼ meter monochromator fitted with a motor drive on the grating. The emission spectra were corrected for instrumental errors and for photomultiplier response. The excitation spectra are given relative to fluorescein above 3300Å and sodium salicylate below this wavelength. Absorption spectra were also taken on a Beckman DU spectrophotometer.

Firing in an O_2 atmosphere results in $EuAlO_3$ having a white body color. It is nonluminescent under uv excitation and shows a very weak red line emission under cathode rays. The spectrum consists of three groups of lines located at 589, 592, and 596 nm ($^5D_0 \rightarrow {}^7F_1$); 610, 614, 618, and 626 nm ($^5D_0 \rightarrow {}^7F_2$); and 655nm ($^5D_0 \rightarrow {}^7F_3$), respectively. The dominant line is at 614 nm. Firing in a reducing atmosphere (NH_3 was preferred) resulted in phosphors having a yellow-green band emission and a yellow-green body color. Figure 1 shows the emission spectrum from a typical NH_3 fired $EuAlO_3$ phosphor taken under uv excitation.[2] It consists of a broad band peaking at 510 nm. Examination of the recorded spectrum shows the absence of any line emission but the presence of some line absorption located around 520 to 540 nm.

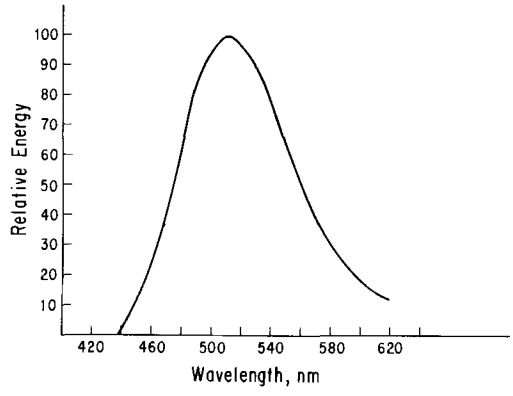

Fig. 1. Spectral distribution of the emission from $EuAlO_3$ fired in ammonia.

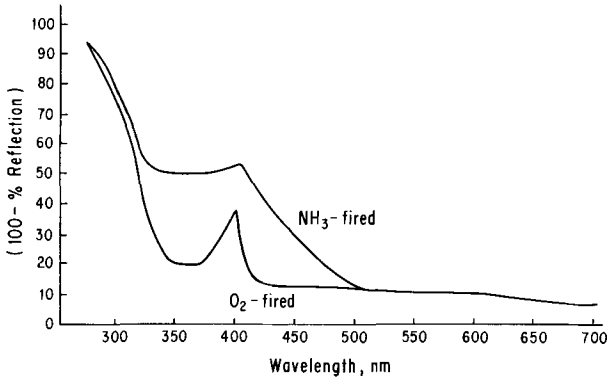

Fig. 2. Absorption spectra of $EuAlO_3$ fired in oxygen and in ammonia.

Figure 2 shows the absorption spectrum of near stoichiometric phosphors fired in O_2 and in NH_3, respectively. The oxygen-fired material shows a strong absorption band below 350 nm and a narrow, weaker band at 405 nm. The NH_3-fired phosphor shows a broad band extending from 330 to about 500 nm with a sharp peak at 405 nm. There is also a slight long wave broadening of the band below 350 nm. Superimposed on the absorption of the O_2- and NH_3-fired samples are several groups of absorption lines located around 360 to 400 nm, 525 to 550 nm, and 590 to 600 nm. These trivalent Eu absorptions are due to the

* Electrochemical Society Active Member.

[1] Increasing the Eu(III) or Al concentration above the stoichiometric 1:1 ratio results in an increase in the lattice parameter, a_o. Above 0.1 g at. Al, Al_2O_3 begins to appear whereas above 0.1 g at. Eu, the orderly lattice expansion of a_o becomes erratic. Firing in NH_3 results in the formation of $Eu(II)Al_2O_4$ at Eu concentrations above 0.1 g at.

[2] This system is difficult to work with and leaves much to be desired in reproducibility. The data presented are the average of several repeat samples.

transitions $^7F_0 \rightarrow {}^5D_{3\text{-}5}$, $^7F_0 \rightarrow {}^5D_1$, and $^7F_{0\text{-}2} \rightarrow {}^5D_0$, respectively. Corresponding lines in the two spectra are of about equal intensity. No absorption lines corresponding to the transitions $^7F_0 \rightarrow {}^5D_2$, 460 to 490 nm, were observed.

Using the substitution $Eu_{1\pm x}Al_{1\mp x}O_3$, samples were prepared over the stability range for excess Eu and Al, *ca.* 0.1 g at. Figure 3 shows the absorption spectrum of samples having $x = 0.1$ Al and 0.1 Eu; also shown for comparison is the spectrum of the near stoichiometric phosphor. Starting with an excess of Eu, increasing Al results in a progressive broadening of the two absorption bands plus an increase in the amplitude of the long wavelength band. The excitation spectra of these three phosphors are shown in Fig. 4. There are three distinct excitation bands located around 350, 310, and 260 nm. There might be a fourth band below 225 nm, but it could not be verified since measurements could not be made below 225 nm. The amplitude of the 310 nm band was invariant relative to the 350 nm peak while that of the 260 nm peak increases with increasing Eu. The brightness of these phosphors as a function of excess Eu or excess Al is shown in Fig. 5 for excitation into the three above-mentioned excitation bands. Starting with excess Eu, for all three excitations a progressive decrease in Eu, *i.e.*, increasing Al, results in a progressive increase in the brightness. In addition, the slope of the curves for 310 nm and 350 nm excitation are the same but different from the slope of the 260 nm excited curve. Incidentally, these phosphors are fairly efficient under 3650Å excitation. For example, the brightness of a good but nonoptimized near stoichiometric phosphor is about 60% of a (ZnCd)S:Ag phosphor of a similar color.

The temperature dependence of a near stoichiometric $EuAlO_3$ phosphor is shown in Fig. 6 for excitation into the three excitation bands. The curves are similar and show a temperature break-point around 200° to 220°K followed by a leveling off around 260° to 300°K.

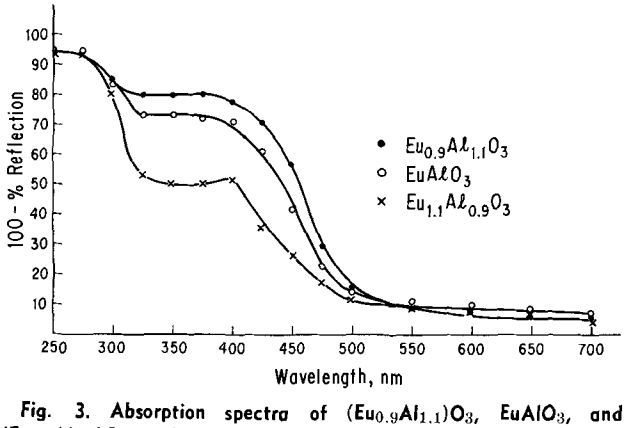

Fig. 3. Absorption spectra of $(Eu_{0.9}Al_{1.1})O_3$, $EuAlO_3$, and $(Eu_{1.1}Al_{0.9})O_3$ fired in ammonia.

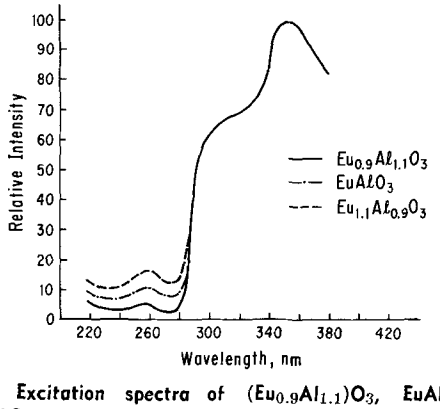

Fig. 4. Excitation spectra of $(Eu_{0.9}Al_{1.1})O_3$, $EuAlO_3$, and $(Eu_{1.1}Al_{0.9})O_3$ fired in ammonia.

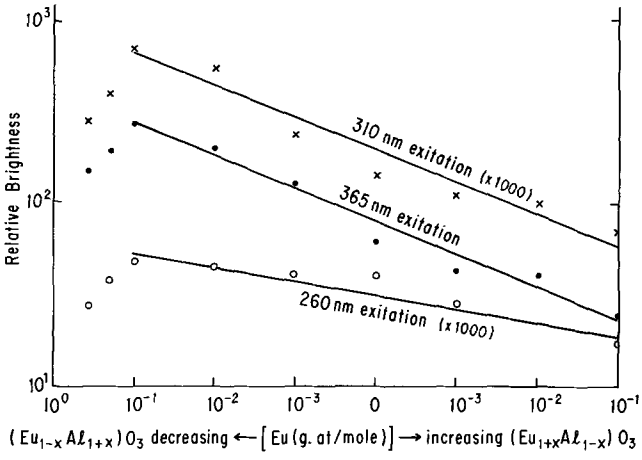

Fig. 5. Effect of an excess or deficiency of Eu on the brightness of $Eu_{1\pm x}Al_{1\mp x}O_3$. The stoichiometric composition is at the zero point on the abscissa. To its right, Eu is increasing; to its left it is decreasing. Excitation into the three excitation bands shown in Fig. 4.

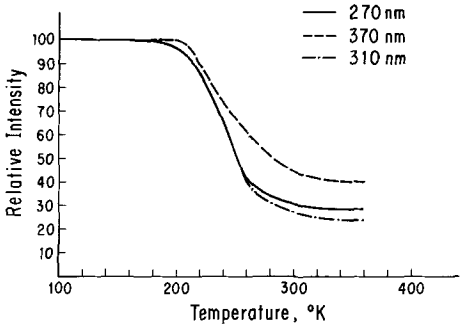

Fig. 6. Temperature dependence of the emission of a near stoichiometric $EuAlO_3$ fired in ammonia. Excitation into the three excitation bands shown in Fig. 4.

Attempts were made to measure the luminescence decay curves after excitation into the three excitation bands. Because the decay was very fast, the results are not conclusive. However, the decay appears to be the same for the three excitations, namely, an initial fast decay with a time constant less than 10 μsec followed by a slightly slower component.

Discussion

The green band emission obtained by firing $EuAlO_3$ in a reducing atmosphere is due to divalent Eu(11).[3] While trivalent Eu is present, it does not emit under uv excitation and only weakly so under cathode rays. This is most likely so because of concentration quenching.[4,5] However, the Eu(III) does absorb as evidenced by the superimposed line absorptions found in the absorption, excitation, and emission spectra. The Eu(II) emission is fairly efficient partially because of its low (unknown) concentration.

It is tempting to speculate that since Eu(II) replaces Eu(III), it would also be in the same site which is lacking a center of symmetry.[6] However, because the Eu(II) ion is larger than Eu(III), it is more easily polarized, thus affecting its environment

[3] Room temperature Mössbauer measurements show that divalent Eu is present and that its concentration increases with increasing Al content (16). This trend explains the results shown in Fig. 3 and 5, *i.e.*, the brightness and the absorption increase with increasing Eu(II) concentration.

[4] The weak luminescence under cathode rays and the lack of luminescence under uv indicates two things: one is that concentrating quenching is involved in both the excitation process and emission process, and two, that the excitation mechanism is somewhat different for the two modes of excitation.

[5] Van Uitert and Johnson found that for (Y,Eu)AlO_3, the optimum Eu concentration was about 5 a/o (12). The Eu(III) concentration in $EuAlO_3$:Eu(II) is considerably higher than this.

[6] The main line in the Eu^{+3} emission is at ~614 nm ($^5D_0 \rightarrow {}^7F_2$) which is due to an electric dipole transition indicative of an activator center lacking a center of symmetry.

so that its site symmetry may be quite different from that of Eu(III).

The fact that the 310 nm excitation band is invariant relative to the 360 nm band, Fig. 4, while the 260 nm band is not would indicate that there are two divalent Eu luminescent centers present. This is supported by the fact that the slope of the brightness *vs.* Eu concentration curve for 310 and 360 nm excitation are the same, but different from that of the 260 nm curve. Since the phosphors contain both cubic and orthorhombic phases, most likely one Eu(II) center is in the former phase and the other center is in the latter. Since in both centers the emission originates from a similar 5d excited level the luminescence decay would be expected to be similar as was observed.

We can account for the 310 and 350 nm excitation bands in the following way: the absorption of divalent Eu is due to the excitation of a 4f electron to a 5d level. Assuming cubic symmetry, this level is split by the crystal field into two main levels, t_2 and e (13). We can assign the 350 and 310 nm excitation bands to these two levels in the cubic perovskite as shown in Table I. The crystal field splitting parameter 10 Dq for these two lines is 3.7 kilo Kaysers, kK, which is in good agreement with similar data reported for other Eu(II) activated phosphors (14). If we assume that the 310 and 350 nm bands are associated with Eu(II) in the cubic (major) phase, then there should be two additional weaker levels due to Eu(II) in the orthorhombic phase. In this case, the 260 nm excitation band would then be the lower energy level of another 5d splitting. The 10 Dq value in this Eu(II) center is probably in the order of 4 to 10 kK. Using these values and assuming that the Eu(II) is still in a cubic field, then there should be a higher excitation level around 42 to 46 kK corresponding to a wavelength of 240-215 nm. There is an indication of a band in this region as shown in Fig. 4. The center of gravity for this level is around 40 to 41 kK whereas it was about 31 kK for the cubic phase.

Table I. Excitation bands and crystal field splitting of $EuAlO_3$ and other phosphors containing Eu(II)

Host	Excitation bands, $\times 10^3$ kilo Kaysers		10 Dq	Center of 5d level
$EuAlO_3$	28.6	32.3	3.7	30.8
CaF_2*	27.1	45.0	17.9	37.9
NaCl*	29.4	41.5	12.1	34.2
KBr*	29.7	38.1	8.4	33.1
$BaZrO_3$*	25.2	38.2	13.0	33.0

* Data taken from ref. (14).

The only interaction between Eu ions in the two oxidation states appears to be the trivial radiative energy transfer from Eu(II) to Eu(III). This is indicated by the weak absorption lines superimposed on the Eu(II) spectra. A similar conclusion has been reached by Blasse and Bril regarding energy interactions between Eu(II) and Eu(III) in SrY_2O_4 (15).

Distribution of Impurities in Zn,O-Doped GaP Liquid Phase Epitaxy Layers

R. H. Saul and W. H. Hackett, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A series of variously doped GaP liquid phase epitaxy (LPE) layers were analyzed to establish the distribution of Zn,O and residual impurities contributing to the net impurity gradient previously observed in the p-layer of high efficiency GaP LPE diodes. From these experiments we conclude that the net impurity gradient is primarily a consequence of a decreasing Zn concentration along the growth direction, and, to a lesser degree, an increasing residual donor concentration. The distribution of intentional and unintentional impurities was found to be independent of substrate doping level.

The effect of cooling rate on the various impurity distributions was also studied, covering the range 0.5°-18°C/min. Residual impurity levels and associated gradients were significantly reduced by decreasing the cooling rate which indicates that residual impurity incorporation is kinetically controlled, probably by slow diffusion of these impurities in front of the growing LPE layer. Similarly, the O level appears to be decreased by reduced cooling rate. In contrast, Zn doping was found to be independent of cooling rate which suggests that its incorporation was essentially under equilibrium conditions. Assuming this to be the case, we have shown that the observed Zn distribution is consistent with the temperature dependence of the Zn solid solubility. Using an equilibrium description for Zn incorporation, we have computed the near-junction Zn and O concentrations in the previously reported high efficiency diodes to be 6.7 x 10^{17} cm^{-3} and 2.7 x 10^{17} cm^{-3}, respectively. The corresponding level of residual impurities yields a net donor concentration of $\lesssim 3 \times 10^{16}$ cm^{-3}.

We previously reported (1) on the fabrication of efficient (~7%) red-light emiting GaP p-n junctions which were grown using a p-on-n liquid phase epitaxy (LPE) tipping process. In that work, the strong dependence of quantum efficiency η on Zn,O-doping in the p-type LPE layer was emphasized, and we noted that the (measured) impurity distribution was not uniform in the LPE layers. Ladany (2) observed a "spontaneous junction" or n-skin near the surface of his p-type LPE layers and suggested that impurity gradients existed in those LPE layers, although the impurity distributions were not determined. As illustrated in Fig. 1, the net impurity concentration at the surface of our p-layers is closely compensated, and thus generally leads to difficulty in providing a low-resistance ohmic contact to the p-layer since electrical contact is usually established at this surface. Consequently, the work described here was initiated to further the understanding of Zn,O and residual impurity distributions in LPE layers and how these are affected by cooling rate and substrate doping. These results have been used to determine the near-junction

Zn,O and residual impurity levels for high efficiency red-emitting diodes (1).

Experimental

LPE growth system.—The quartz capsule used for the sealed-tube LPE growth is illustrated in Fig. 2. The capsule, sealing plug, and boat were etched for 5 min in HF, rinsed in de-ionized water, and oven-dried just prior to loading. Polycrystalline GaP (Monsanto phosphine-synthesized material), sieved to 20-60 mesh and then etched in aqua regia, was added to Ga (99.9999+% purity obtained from Alusuisse Metals) to form the regrowth solution. Incorporation of Zn was accomplished by etching a crystalline needle (99.9999% purity obtained from United Mineral) to final weight and submerging this directly into the Ga. Powdered β-Ga_2O_3 (highest purity available from Alusuisse Metals) was added to the solution when O doping was desired. The Zn and Ga_2O_3 additions were 0.03 m/o (mole per cent) and 0.35 m/o, respectively, and correspond to the optimum doping levels found in our earlier work (1).[1] Undoped, Zn-doped, and Zn,O-

[1] In ref. (1), we noted that very large additions of Ga_2O_3 [~30 times larger than the solubility limit of Ga_2O_3 in Ga determined by Foster and Scardefield (3)] were required for efficient diodes. This was loosely attributed to kinetic effects characteristic of the LPE process. Transport of Ga_2O_3 (via Ga_2O) as a result of small thermal gradients which might exist within the capsule, together with the fact that the regrowth solution was not permitted to equilibrate at the maximum temperature, may account for the discrepancy between Foster's results and our own. In addition, the O solubility in the regrowth solution may be substantially different from that in Ga since the former is saturated with GaP.

doped LPE layers were grown on undoped solution grown (SG) crystals, Te-doped ($N_D - N_A$ = 0.3-5 $\times$ 10^{18} cm^{-3}) SG crystals or similar crystals on which Te-doped LPE layers had been previously grown.

The loaded capsules were evacuated ($<10^{-6}$ Torr), sealed by fusing the plug and capsule and loaded into a preheated (650°C) tiltable furnace which was then heated to ~1060°C at a rate of 20°/min. At the maximum temperature, LPE growth was initiated by simultaneously tipping the furnace and cooling at a programmed rate which could be varied from 0.5-18°/min. For most cases, cooling was interrupted and the crystal was annealed for 5 hr at 600°C followed by 17 hr at 500°C which for the Zn,O-doped layers, increases η by a factor of 3-4 (1). Heating, cooling, and *in situ* annealing cycle were programmed using a L&N Trend-trak control unit.

Determination of doping profiles.—A high resolution net impurity profile was obtained for each LPE layer by means of a series of surface-barrier capacitance measurements on an angle-lapped surface (4). Rectangular samples (50 x 150 mils) were lapped on a glass plate with Linde A to expose a surface lying 3° from the junction plane. Hot aqua regia was used to remove the resulting surface damage. The intersection of the junction plane and the lapped surface was delineated by etching for 1 min in a 1:1 solution of H_2O_2:HF under bright illumination (5). Schottky-barrier diodes were formed by evaporating an array of Au dots (100μ in diameter on 200μ centers) on the angle-lapped surface and alloying an ohmic contact to the top surface. Reverse bias C-V measurements on each Schottky-barrier diode yields, at the diode location, a net donor or acceptor concentration, $|N_D - N_A|$ (6, 7). This doping level was actually measured directly using an analog doping profiler (8). The resulting array of doping levels comprises a net impurity profile normal to the junction with an effective spatial resolution of 100μ · sin 3° = 5μ.[2]

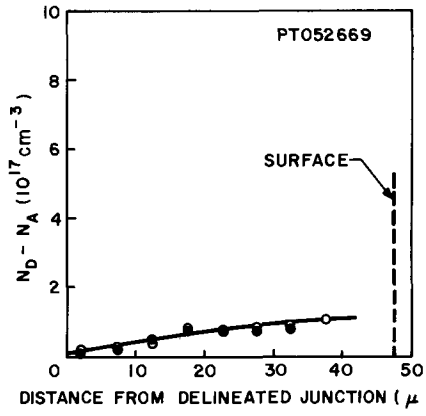

Fig. 3. Net impurity profile for an undoped LPE layer grown at a cooling rate of 10°/min. Open and solid circles designate measurements on different rows of Schottky-barrier diodes.

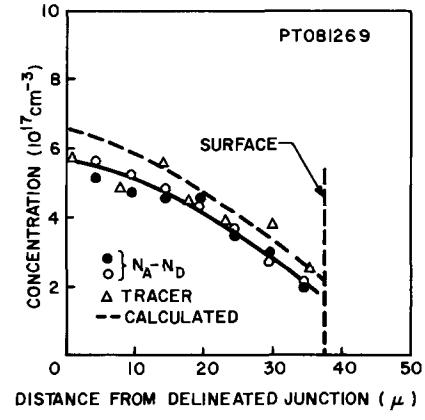

Fig. 4. Concentration profiles for a Zn-doped layer grown at 10°/min; see text.

Results and Discussion

Since the net impurity distribution in Zn,O-doped layers is the net result of various individual impurity distributions, we attempted to isolate these components by comparing impurity profiles for undoped, Zn-doped, and Zn,O-doped LPE layers. A cooling rate of 10°/min was used as in our earlier work (1). The results of these experiments are summarized in Table I.

Undoped LPE layers.—All undoped layers are n-type, the value of $N_D - N_A$ increasing with distance from the junction as in Fig. 3. This gradient is believed to result from a build-up of a slow-diffusing donor impurity, most probably Si, in front of the advancing solid-liquid interface. From the data of Table I, the residual impurity levels (and profiles) are apparently insensitive to Te concentration in the substrate; in fact, an undoped substrate (PTO61169) gave the highest net donor level at the junction. Thus, the LPE layers are not significantly autodoped by the substrate. The net impurity level at the junction is generally comparable to that observed in undoped SG crystals (~5 x 10^{16} cm^{-3}), although the latter are usually p-type. As shown later, this background impurity level is roughly an order of magnitude lower than the concentration of Zn and O. We note that, while the gradient in undoped layers is opposite from that of Zn,O-doped layers (Fig. 1), the distribution of residual impurities, by virtue of compensation, leads to a qualitatively similar net impurity profile. However, the residual impurity level is not large enough to account fully for the gradient in Fig. 1 which indicates that Zn and/or O are not uniformly distributed throughout the LPE layer.

Zn-doped LPE layers.—Figure 4 illustrates a net impurity profile (solid line) for an LPE layer doped

[2] The effective spacing between Schottky-barrier diodes was reduced to 100μ by staggering adjacent rows of Au dots.

Table I. Summary of dopant distribution in LPE layers[a]

Run	Dopant	Substrate doping level, $N_D - N_A$, cm^{-3}	LPE layer doping level, $N_A - N_D$, cm^{-3} Junction	Surface	LPE layer thickness, μ

[a] Layers grown with a cooling rate of 10°/min and subsequently annealed.
[b] Unannealed.

with Zn. As shown in Table I, layers grown on variously doped substrates yielded essentially identical profiles. From the above results, it is apparent that residual impurities also contribute to the (net) gradient evident in Fig. 4. This LPE layer was doped with radioactive ^{65}Zn, so that the Zn concentration profile could also be determined. Incremental layers were successively removed from this layer by etching and the Zn activity in each layer determined from the γ photon emission peak (1.11 MeV), characteristic of ^{65}Zn decay. The method of comparative standards was employed to obtain absolute values of Zn levels, and weight loss measurements were used to determine thickness of the incremental layers. From a comparison of the $N_D - N_A$ and tracer profiles (see Fig. 4), it is clear that the gradient in the Zn-doped layers is largely due to nonuniform Zn distribution. The scatter in the data, however, precludes meaningful determination of the residual impurity distribution, although it appears to be similar to that shown in Fig. 3.

Since the epitaxial layers were annealed in Ga for 22 hr after growth, it was necessary to determine if the nonuniform Zn distribution was a consequence of out-diffusion of Zn during the annealing treatment. An unannealed Zn,O-doped layer (PTO61669) was thus profiled but found to be similar to the annealed layers. (As indicated in the next section, O acts as a compensating donor and does not appreciably affect the net impurity gradient.) Thus out-diffusion of Zn (or in-diffusion of a donor impurity) during annealing is negligible,[3] and it is concluded that all observed profiles are established during epitaxial growth.

Since the distribution coefficient of Zn decreases as the temperature is lowered (10), one expects that as the Ga solution is cooled and the epitaxial layer thickens, the level of incorporated Zn should decrease along the growth direction as in Fig. 4. Using the GaP liquidus data of Rubenstein (11) and Hall (12), and the Zn solid solubility isotherms recently computed by Jordan (13), we have calculated the resulting Zn profile assuming that (*i*) layer growth and Zn incorporation are essentially equilibrium processes, and (*ii*) partitioning of rejected GaP between substrate and other competing surfaces (*e.g.*, the 2 m/o excess GaP present) is invariant for a given run. The first assumption is consistent with the results of the cooling rate experiments, as shown later. The second assumption effectively normalizes the calculated LPE layer thickness to the observed thickness. In view of the uncertainty in the thermodynamic data, the agreement between the calculated Zn distribution (shown as a dashed line in Fig. 4) and experimental data is quite good. These results imply that the observed Zn profile is a consequence of the LPE layer having been grown over a wide temperature range.[4] This view is supported by the observation that the Zn concentration at the junction is invariant while the surface concentration is independent of layer thickness and roughly constant (see Table I).

Zn,O-doped LPE layers.—Profiles of Zn,O-doped layers are independent of substrate doping and are essentially the same as for Zn-doped layers, with the former displaced to lower (net) acceptor concentrations, *cf.*, Fig. 1 and 4. This reduction in $N_A - N_D$, being the result of compensation of Zn acceptors by O donors, provides a direct measurement of the O concentration.[5] Thus from Table I, the apparent O concentration near the junction where the red luminescence occurs (14, 15) is typically $\sim 1.3 \times 10^{17}$ cm^{-3}. However, the concentration of Zn is comparable to the intrinsic carrier concentration n_i at the growth temperature (10); hence, the simultaneous incorporation of O is expected to affect the level of incorporated Zn. As shown below this leads to an underestimate of the O concentration.

The actual O concentration is readily estimated by considering the incorporation of Zn as described by the equations (10)

$$Zn(l) + V_{Ga} = Zn_{Ga}^- + e^+; K_1 = \frac{[Zn_{Ga}^-]p}{[Zn(l)][V_{Ga}]} \quad [1]$$

$$n + [Zn_{Ga}^-] = p \quad [2]$$

and

$$np = n_i^2 \quad [3]$$

Analogous equations result for Zn,O doping except that Eq. [2] becomes

$$n_o + [Zn_{Ga}^-]_o = p_o + [O_P^+] \quad [4]$$

where the subscript o is used to represent simultaneous Zn and O incorporation. At constant $[Zn(l)]$ and $[V_{Ga}]$ (constant in dilute solutions) it follows from Eq. [1] that

$$p[Zn_{Ga}^-] = p_o[Zn_{Ga}^-]_o \quad [5]$$

Combining Eq. [2]-[5], we have the desired result

$$[O_P^+] = [Zn_{Ga}^-]_o - ([Zn_{Ga}^-]_o - [O_P^+])$$

$$= A\left[\frac{A + (A^2 + 4n_i^2)^{1/2}}{B + (B^2 + 4n_i^2)^{1/2}}\right] - B \quad [6]$$

where $A \equiv [Zn_{Ga}^-]$ and $B \equiv [Zn_{Ga}^-]_o - [O_P^+]$ are the measured quantities. Note that Eq. [6] does not depend on the details of O incorporation, but simply makes use of the measured compensation resulting from O-doping. Taking $A = 5.3 \times 10^{17}$ cm^{-3}, $B = 4 \times 10^{17}$ cm^{-3} from Table I, and a computed (16) value of $n_i = 1.6 \times 10^{17}$ cm^{-3}, we obtain for the near-junction O concentration, $[O_P^+] = 2.7 \times 10^{17}$ cm^{-3}, which is somewhat greater than our earlier estimates (1). This numerical result is relatively insensitive to the chosen value of n_i.[6]

Since the electrical measurements do not distinguish between various donor species, we considered the possible incorporation of impurities in the Ga_2O_3, most notably S which has a rather large distribution coefficient (10). (Other donor impurities could not be detected by emission spectrography.) From combustion analysis (17) of the Ga_2O_3, the S concentration was estimated to be about 1 ppm. Using the solubility data of Trumbore *et al.* (10) and the amount of Ga_2O_3 added to the Ga solutions the S concentration in the Zn,O-doped LPE layers is expected to be $\lesssim 1 \times 10^{15}$ cm^{-3} which is well below the doping levels of interest. Hence, it is concluded that O is the compensating donor in these experiments.

Effect of cooling rate on dopant distribution.—Table II summarizes the results of experiments in which the cooling rate was varied between ~20 and ~0.5°/min. The residual impurity level in undoped layers is significantly reduced by diminishing the cooling rate. This result indicates that residual impurity incorporation is a rate dependent (nonequilibrium) process in which the effective distribution coefficient k increases as the cooling rate is increased. Such behavior is characteristic of impurities with $k < 1$ which diffuse slowly in the liquid (18). These experiments also suggest that the nonuniform impurity distribution in undoped layers is primarily a consequence of rapid growth as alluded to earlier.

The Zn-doped layers, on the other hand, appear to be unaffected by cooling rate within the range studied. Thus, Zn incorporation is not kinetically controlled

[3] This result is anticipated from the diffusion data of Panish and Casey (9).

[4] From the GaP liquidus data (11, 12), approximately 90% of the epitaxial layer has grown when the Ga solution has cooled 200°C from its maximum temperature.

[5] Actually, this is the concentration of electrically active (substitutional) O and may differ from the total O concentration which includes interstitial and other inactive forms [C. K. Kim, *Radiochem. and Radioannal. Letters*, 2, 53 (1969)].

[6] This follows from Eq. [6] except when $n_i >> A/2 = 2.6 \times 10^{17}$ cm^{-3}.

Table II. Effect of cooling rate on dopant distributions in LPE layers[a]

Run	Dopant	Cooling rate, °C/min	LPE layer doping level, $N_A - N_D$, cm^{-3} Junction	Surface
PT052669	—	~10	$\sim -3 \times 10^{16}$	-1.5×10^{17}
PT091869	—	4.4	$\sim -1 \times 10^{16}$	-9×10^{16}
PT091769	—	0.7	$\sim -5 \times 10^{15}$	$\sim -5 \times 10^{15}$
PT052169	Zn	10.0	5.3×10^{17}	1.2×10^{17}
PT091269	Zn	4.8	5.0×10^{17}	1.5×10^{17}
PT091569	Zn	0.5	5.0×10^{17}	1.5×10^{17}
PT061969	Zn,O	18.6	3.5×10^{17}	7×10^{16}
PT060969	Zn,O	10.5	4.0×10^{17}	7×10^{16}
PT081969	Zn,O	4.8	4.5×10^{17}	1.0×10^{17}
PT110369	Zn,O	1.0	4.6×10^{17}	1.6×10^{17}

[a] All layers were annealed.

which is, of course, a necessary condition for equilibrium incorporation. Since the Zn-doping in the LPE layers agrees closely with the computed equilibrium values (see Fig. 4), we conclude that our earlier assumption of equilibrium Zn incorporation is valid.

As the cooling rate is decreased, the Zn,O-doped layers exhibit a systematic increase in $N_A - N_D$ at the junction which we interpret as evidence of decreased O. This result is consistent with the very low distribution coefficient of O (3). The effective reduction in the value of k for O is not readily compensated by increased Ga_2O_3 in the regrowth solution because of the very low solubility of Ga_2O_3 in Ga.

Conclusions

The net impurity distribution observed in Zn,O-doped LPE layers results primarily from a nonuniform Zn distribution and, to a lesser extent, nonuniform distribution of residual impurities. The O distribution is more difficult to ascertain but appears to be relatively constant along the growth direction even though $k << 1$. While the build-up of slow diffusing residual donor impurities in front of the growing LPE layer accounts for the nonuniform distribution of residual impurities, the grading in Zn concentration is a manifestation of the temperature dependence of the Zn distribution coefficient. Thus the impurity grading in Zn,O-doped LPE layers can be minimized by employing slow cooling rates and restricting growth to a narrow temperature range. The latter might be accomplished by mechanically separating (tipping off) the Ga solution from the substrate before the solution has cooled 25°. Layers of sufficient thickness could be grown over a narrow temperature range by appropriate increase in the ratio of regrowth solution volume to substrate area, and by eliminating the excess (source) GaP which competes with the substrate crystal for the precipitating GaP.

Decreasing the cooling rate to a rather low value of ~0.5°/min reduced the unintentional impurity level ($N_D - N_A \simeq 5 \times 10^{15}$ cm^{-3}) which is desirable for minimizing nonradiative recombination centers which may be associated with such impurities. On the other hand, the level of incorporated O appears to decrease as the cooling rate is reduced which may be detrimental owing to the probable reduction in Zn-O complexes. The Zn concentration and distribution is independent of cooling rate in the range 0.5-10°/min which is consistent with equilibrium Zn incorporation. Using an equilibrium description for Zn incorporation, the near-junction Zn and O concentrations for the previously reported high efficiency diodes (1) are computed to be 6.7 x 10^{17} cm^{-3} and 2.7 x 10^{17} cm^{-3}, respectively.

Acknowledgments

The authors are indebted to Mrs. J. Armstrong for growing the epitaxial layers, T. E. McGahan for performing the surface-barrier capacitance measurements, and Miss K. B. Wolfstirn for performing the tracer analysis. They are particularly grateful to A. S. Jordan for helpful discussions concerning oxygen incorporation and for providing them with the solubility isotherms prior to publication.

A Stagnant Layer Model for the Epitaxial Growth of Silicon from Silane in a Horizontal Reactor

F. C. Eversteyn, P. J. W. Severin, C. H. J. v.d. Brekel, and H. L. Peek

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Flow patterns have been made visible in a horizontal water-cooled epitaxial reactor by injection of TiO_2 particles into the gas flow. From these experiments, a stagnant layer model has been developed with which the epitaxial growth of silicon from silane can be described. In the case of a nontilted susceptor, the model predicts an appreciable nonuniformity in thickness along the susceptor, whereas a small angle of tilting of the susceptor should yield a much better uniformity in thickness (2% over a length of 22 cm). Experiments agree very well with the theoretical predictions of the model.

Silane as source for the epitaxial growth of silicon has several advantages over $SiCl_4$ and $SiHCl_3$: lower deposition temperature, less autodoping from substrate, less outdiffusion, and no back etching. On the other hand, silane is rather unstable and will decompose also on the hot reactor wall. This means that, as far as the construction is concerned, reactors for SiH_4 and $SiCl_4$ or $SiHCl_3$ will be different. For the time being, the most popular type is the horizontal reactor. The construction is rather simple. A large number of slices can be grown in one charge and the reactor is easy to load and unload. For SiH_4, a water-cooled reactor is preferable, because otherwise silicon would be deposited on the reactor wall, which would make measurement of the temperature of the substrates with an optical pyrometer impossible.

In the past, several authors have described the process of epitaxial growth, though mostly in vertical reactors. Bradshaw (1) developed a boundary layer model with which he was able to explain the growth experiments in a vertical reactor. Here the deposition efficiency is low, so that the decrease in concentration of the silicon compound along the susceptor can be neglected. Shepherd (2) described the epitaxial growth of silicon from $SiCl_4$ in a small horizontal reactor, assuming a parabolic gas flow in the reactor and omitting the decrease in $SiCl_4$ concentration in the length direction of the reactor. For large horizontal reactors, the deposition efficiency is found to be about 35%. This means that the decrease in concentration of the silicon compound along the reactor cannot be neglected. Taking this into account, Rundle (3) investigated the epitaxial growth of silicon from $SiCl_4$ and $SiHCl_3$, assuming that the gas flow in the reactor has a velocity component only along the axis of the reactor and that the whole system is at a constant temperature, ignoring temperature gradients.

In this paper, it is shown that these assumptions cannot be justified. From gas flow pattern experiments, it is seen that there is a thermal convection in the reactor vertically *overturning* the main gas flow and resulting in complete mixing of the gas. Directly above the heated susceptor, the temperature then drops over a thin stagnant layer which is excluded from the main gas flow. These experiments are discussed and a model derived for the epitaxial growth in a horizontal reactor is analyzed. The rate of epitaxial growth is calculated in the case of a nontilted and tilted susceptor. It is shown that there is close agreement between the predictions derived from the model and the experiments.

Investigation of the Flow Pattern

Experimental arrangement.—To make the flow pattern in the reactor visible, TiO_2 particles are injected into the gas stream by means of the equipment shown schematically in Fig. 1 (4). The horizontal reactor used for these experiments is the same as is considered later for the epitaxial deposition of silicon from silane. It consists of a water-cooled quartz tube with a rectangular cross section (5 x 4 cm) and a graphite susceptor, 30 cm long, 4 cm wide, 8 mm thick, positioned in a quartz boat which fits in the reactor. In our case, the free space between a side wall of the reactor and the quartz boat is about 0.5 mm. The quartz boat rests on the floor of the reactor. The free height above the susceptor is 2 cm. Dry hydrogen and hydrogen containing water vapor flows into the reactor where the temperature of the susceptor is 1050°C. By switching two electromagnetic valves, the dry hydrogen can be passed over $TiCl_4$. Mixing of the water vapor-loaded and the $TiCl_4$-loaded hydrogen causes the formation of TiO_2 particles, resulting in a white haze. The flow pattern in the reactor can then be observed. Photographs of the gas flow patterns have been made through the window on the right-hand end of the reactor (see Fig. 1) and are discussed below.

Experimental results.—In Fig. 2, the streamline pattern is given for the water-cooled reactor with the susceptor at room temperature. It is seen from this

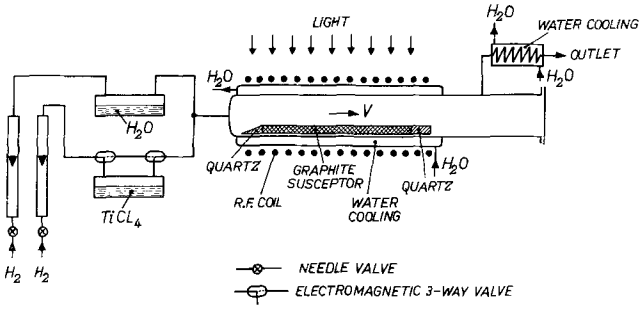

Fig. 1. Schematic view of the equipment to make gas flow patterns in the reactor visible.

Fig. 2. Streamline pattern above the nonheated susceptor ($T_S \approx 20$°C) with water-cooling around the tube (wall temperature approximately 10°C). Convective flow is visible under the influence of a small vertical temperature gradient. Rotation speed: about 1 rps.

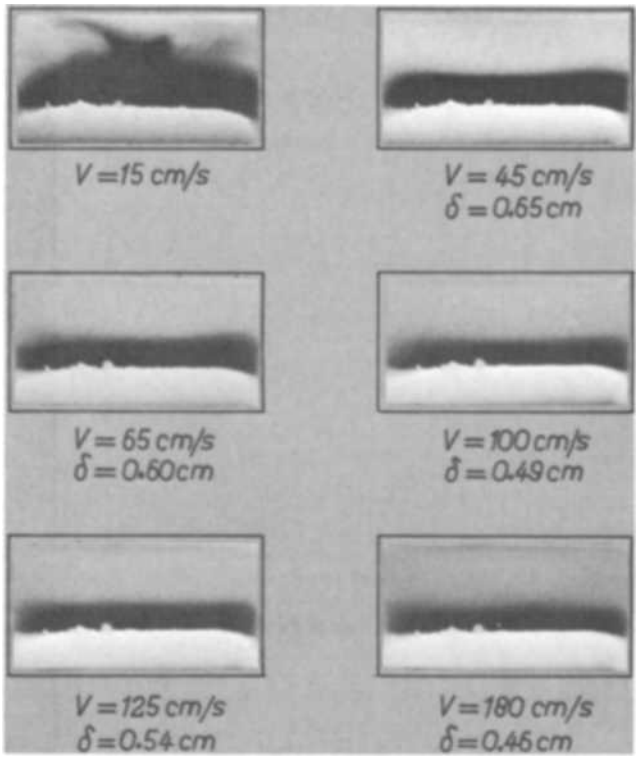

Fig. 3. Streamline patterns with TiO_2 at different gas velocities of hydrogen (corrected for heating up). Susceptor temperature 1050°C. Stagnant layer thickness decreases with increasing gas velocity.

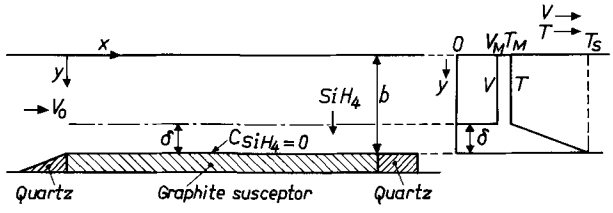

Fig. 5. Stagnant layer model for a horizontal reactor with a non-tilted susceptor.

photograph that, although the vertical temperature gradient is very small ($\Delta T \approx 10$°C over about 2 cm), a convection flow already exists which, combined with the net gas flow, results in a double screw flow pattern. When the susceptor is heated up, the vertical temperature gradient increases. Due to a buoyancy force, increased in this way, a higher rotation velocity of the spirals results and the separate streamlines mix. This is shown in Fig. 3 where hydrogen with different gas velocities flows through the reactor in which the susceptor is at 1050°C. In the case of low gas velocity the convection flow lines can be seen separately, but at higher velocity the streamline pattern is restricted to a region separated from the substrate by a dark layer. The latter is indicative of a region where the gas velocity is zero and the incoming TiO_2 particles will flow only in a region separated from the susceptor by a stagnant layer. The thickness of the stagnant layer depends on the gas velocity, as can be seen from Fig. 4. When the linear velocity in the reactor is increased, the stagnant layer thickness tends to decrease.

Epitaxial Growth with a Nontilted Susceptor

Calculations on the model.—From the experiments described above, a model has been developed with which the epitaxial growth in a horizontal reactor can be physically described and mathematically analyzed.

In Fig. 5, a schematic diagram of a horizontal reactor with a nontilted susceptor is drawn with the assumptions implied in the model for epitaxial growth. They are mainly based on the gas flow pattern experiments with TiO_2 and explicitly given below:

I. Due to vertical *overturning* caused by buoyancy forces in the gas (thermal convection), the velocity, V_m, and the temperature, T_m, are constant over the height ($b - \delta$) of the reactor tube.

II. The temperature of the gas (T_m) is taken to be constant in the length direction of the reactor. This assumption is valid for a water-cooled reactor.

III. In the stagnant layer, the gas velocity is zero and the temperature increases linearly with y from T_m to the susceptor temperature T_s: $T(y) = T_s - (T_s - T_m)(b - y)/\delta$.

IV. SiH_4 diffuses through the stagnant layer to the susceptor. At the surface of the susceptor, the SiH_4 concentration is assumed to be zero since the unstable SiH_4 reaching the susceptor decomposes immediately at the temperature considered (1050°C). Thus, the deposition rate of silicon is diffusion controlled.

With these assumptions, the rate of epitaxial growth in a horizontal reactor has been calculated and turns out to be described by the following expression (see Appendix A):

$$G(x) = 7.23 \times 10^6 \frac{D_0 T_s p_0}{R T_0^2 \delta} \exp\left(-\frac{D_0 T_s x}{T_0 V_0 b \delta}\right) \quad [1]$$

where G is the growth rate of silicon (μm/min); D_0, the diffusion coefficient at 300°K of silane in hydrogen ($D_0 = 0.2$ cm²/s); T_s, the susceptor temperature (°K); $T_0 = 300$°K; p_0, the partial pressure of silane (dynes/cm² $\approx 10^{-6}$ atm) at the inlet of the reactor; V_0, the mean velocity (cm/s) of the gas as calculated from the incoming gas flow and the free cross section of the tube; R is the gas constant (8.31 x 10^7 erg/°K). The free height above the susceptor is indicated by b (cm). The only unkown variable is δ, the thickness of the stagnant layer.

Experimental results.—Experiments were carried out on the epitaxial growth of silicon from silane in an atmosphere of hydrogen. Figure 6 shows an outline of the apparatus used for these experiments. Substrates were 0.01 ohm-cm (N- and P-type), polished slices of silicon single crystals. After etching the slices at 1200°C with HCl, the temperature of the susceptor is lowered to 1050°C, at which temperature the epitaxial growth is initiated by admitting a flow of hydrogen containing SiH_4. The temperature has been measured with an optical pyrometer and corrected for the emissivity of the silicon.

The growth rate, G, is obtained by measuring both the time of growth and the thickness of the deposited silicon layer. It has been verified that the growth rate, G, is a constant over the time of growth. The accuracy in the growth rate is affected by the accuracy with which the time of switching can be measured and by the accuracy of the thickness measurement method. The accuracy in time measurement amounts to ±0.2%.

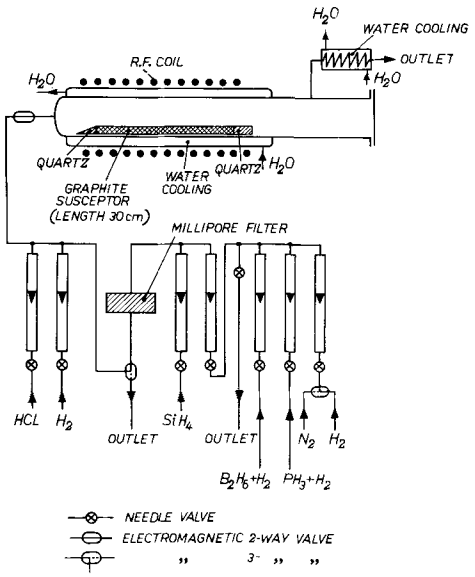

Fig. 6. Outline of the epitaxial growth equipment

The thickness has been measured by infrared multiple interference with a Hitachi EPI-G2 spectrophotometer. The data obtained allow for a final accuracy in thickness of ±0.5%. The evaluation technique used will be described by Severin (5).

According to Eq. [1], the growth rate is linearly dependent on the concentration of SiH_4 in the carrier gas. This was verified up to 10^{-1} vol % SiH_4 in a series of growth experiments. In each experiment, the slice was positioned at the same place in the reactor. The results of these experiments are given in Fig. 7. It is clear from this figure that growth rate varies linearly with the SiH_4 concentration.

Another series of experiments has been carried out to study the dependence of growth rate, G, on position x along the axis of the reactor. A typical result of these experiments is given in Fig. 8. It can be seen that, as required by Eq. [1] derived from the model, log G indeed decreases linearly with x.

Calculated and experimental values for the thickness of the stagnant layer.—From the slope of the line in Fig. 8 as well as from the value of G at $x = 0$ the thickness of the stagnant layer, δ, can be calculated. In Fig. 9, these values are given for gas flow rates (V_T) between 50 and 500 cm/s corresponding to V_o between 20 and 200 cm/s. This figure also shows the thickness of the stagnant layer as found by direct observation in gas flow pattern experiments with TiO_2 as shown in Fig. 3. Good agreement exists between these measured values of the stagnant layer thickness and the values of δ derived from $G(0)$. The values obtained from the slope turn out to be at variance. In order to proceed with the theory, a simple formal relation between δ and the velocity, V, is needed. A number of relationships have been tried but the relation:

$$\delta = \frac{A}{\sqrt{V_T}} - B \qquad [2]$$

with $A = 7$ cm$^{3/2}$ s$^{-1/2}$ and $B = 0.2$ cm appears to be the best compromise.

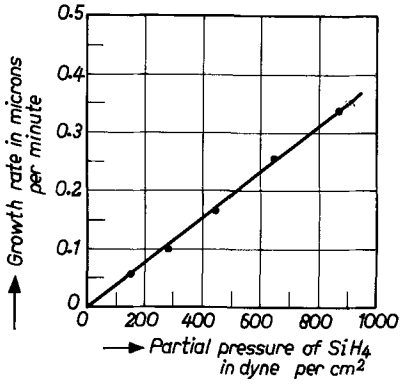

Fig. 7. Dependence of the growth rate on the partial pressure of silane (10^3 dynes/cm^2 relates to 0.1 vol % SiH_4).

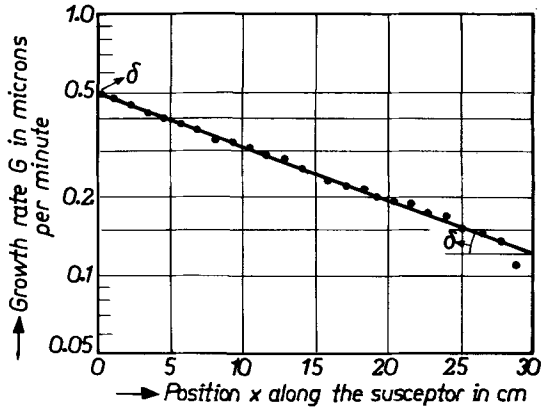

Fig. 8. Growth rate vs. position along the susceptor for V_o = 17.5 cm/s. Substrate temperature, 1050°C.

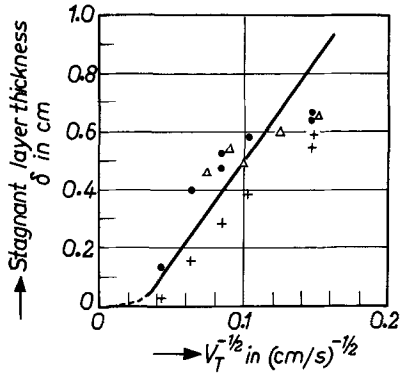

Fig. 9. Dependence of the stagnant layer thickness on the mean gas velocity in the reactor (corrected for heating up): △, from flow pattern experiments using TiO_2, + from the slope of the log $G(x)$-x curve; ●, from the growth rate at $x = 0$.

Theoretically and experimentally, the growth rate, G, decreases with increasing values of the position parameter, x. The magnitude of this effect depends on the gas flow rate. When Eq. [2] is inserted into Eq. [1], it follows that the slope of the log G *vs.* x curve as a function of V_o shows a rather flat minimum. This can be seen in Fig. 10. Some experimental data regarding this effect are also presented in this figure. It appears that the same trend is found in the experimental and in the calculated course of the slope of the log G *vs.* x curve as a function of the mean velocity, V_o. The differences in actual value of d log G/dx are due to the inaccuracies introduced by Eq. [2].

Increasing the gas flow rate from 9 to 34 cm/s results in a decrease of the slope of the log G *vs.* x curve. However, a further increase of the gas flow rate has no influence on the slope of the growth curve.

From these experiments and calculations, it is clear that it is impossible to get the same deposition rate in all positions on the susceptor. A smaller gradient in the thickness of deposited silicon should be obtainable with a stagnant layer thickness decreasing in the length direction of the reactor to compensate the effect of decreasing partial pressure of SiH_4. A gradually decreasing stagnant layer can be achieved by tilting the susceptor, as is dealt with below.

Reactor efficiency.—At this stage, it is interesting to consider the reactor efficiency, η, defined as the fraction

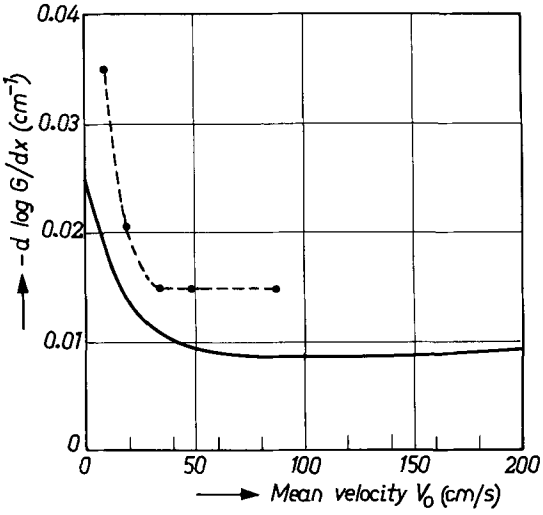

Fig. 10. Calculated values of the slope of the log $G(x)$-x curve from Eq. [1] and Eq. [2] at different values of the gas velocity (V_0). Some experimental values are also inserted into this figure (dotted line).

of the incoming SiH_4 decomposed on the hot susceptor. The reactor efficiency, η, can be expressed by

$$\eta = \frac{c\int_0^L J_y(x)\,dx}{n_0 V_0 b d} \cdot 100\% \qquad [3]$$

where L is the length of the susceptor, c the width of the susceptor, d the width of the reactor, $J_y(x)$ the molecular flux in the y-direction as a function of x, and $n_0 = p_0/kT_0$.

Integrating Eq. [3] yields

$$\eta = \frac{c}{d}\left\{1 - \exp\left(-\frac{D_0 T_s L}{b V_0 \delta T_0}\right)\right\} \cdot 100\% \qquad [4]$$

From Eq. [2] and Eq. [4], the dependence of the reactor efficiency, η, on the gas flow rate can be calculated. This is shown in Fig. 11. At low V_0, the efficiency, η, decreases with increasing V_0 and flattens up to the upper limit of the range of validity of Eq. [2]. Figure 11 also gives the experimental values of η, measured by gas chromatographic analysis of the incoming and outgoing gas. The experimental values are close to the calculated ones. As predicted, η decreases with increasing V_0 and tends to be constant at the right value of about 35%.

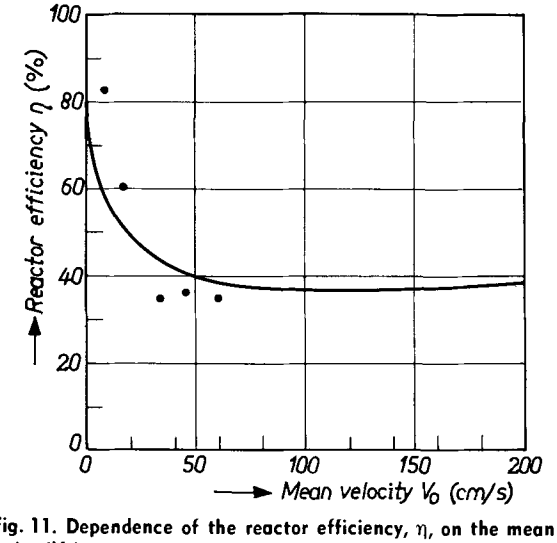

Fig. 11. Dependence of the reactor efficiency, η, on the mean gas velocity (V_0).

Epitaxial Growth of Silicon in a Horizontal Reactor with a Tilted Susceptor

Calculations on the model.—In Fig. 12, a schematic view is given of a horizontal reactor with a tilted susceptor. The assumptions for this model are the same as used for the nontilted susceptor. However, the decrease in stagnant layer thickness along the axis due to increasing gas velocity is taken into account. For this we use Eq. [2], which was found as a result of the experiments in a horizontal reactor with a nontilted susceptor. In the case of a tilted susceptor, the gas velocity is a function of x because of decreasing cross section of the free space above the susceptor

$$V_T(x) = \frac{V_0\, b\, T_m}{(b - x\tan\psi)\, T_0} \qquad [5a]$$

Of course, it has been avoided that the gas streams around and under the susceptor by filling up the space under and adjacent to the susceptor. The stagnant layer thickness, δ, and the temperature decay in the stagnant layer are supposed to be determined by the local velocity only and, hence, Eq. [2] and assumption III are modified to be a function of x

$$\delta(x) = \frac{7}{\sqrt{V_T(x)}} - 0.2 \qquad [5b]$$

and

$$T(x,y) = T_s + \frac{(T_s - T_m)\,(y - b + x\tan\psi)}{\delta(x)} \qquad [5c]$$

With these relations, the growth rate (μm/min) in a horizontal reactor with a tilted susceptor is found to be

$$G(x) = 7.23 \times 10^6 \frac{D_0 T_s p_0}{R T_0^2 \delta(x)} \exp\left\{-\frac{2 D_0 T_s T_m}{4 g T_0^2 \tan\psi}\left(\delta(0) - \delta(x) + 0.2 \ln\frac{\delta(0)}{\delta(x)}\right)\right\} \qquad [6]$$

This formula is derived in Appendix B.

Experimental results.—With Eq. [6], calculations have been carried out for a fixed angle of tilting of 2.9° and different gas velocities of 10-70 cm/s. This is shown in Fig. 13. It is seen that at low gas velocity (V_0 = 10 cm/s) the growth rate decreases in the length direction, while at a high gas velocity ($V_0 > 40$ cm/s) even an increase in growth rate is found. Between these two values, a region should exist where the growth rate is nearly independent of position x. Experiments carried out under the same conditions as those for which these curves have been calculated show a very good agreement with the calculations, as can be seen in Fig. 14. With a gas velocity V_0 = 18 cm/s a decrease in growth rate along the axis is found, while at 48.7 cm/s an increase in growth rate is obtained. With a gas velocity of 34 cm/s, the growth rate is constant within 2% over a region of 22 cm (≈80% of the susceptor length). Not only the predicted trends in the deposition rates are found experimentally, but also the experimental value of the growth rate in the case of nearly even deposition is close to the calculated value. As can be seen from Fig. 13, we obtain for p_0 = 1000 dynes/cm² and V_0 = 34 cm/s a growth rate G = 0.43 μm/min. This implies for p_0 =

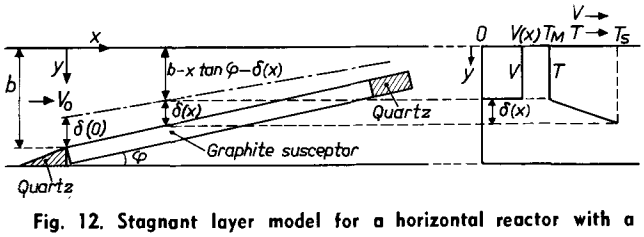

Fig. 12. Stagnant layer model for a horizontal reactor with a tilted susceptor.

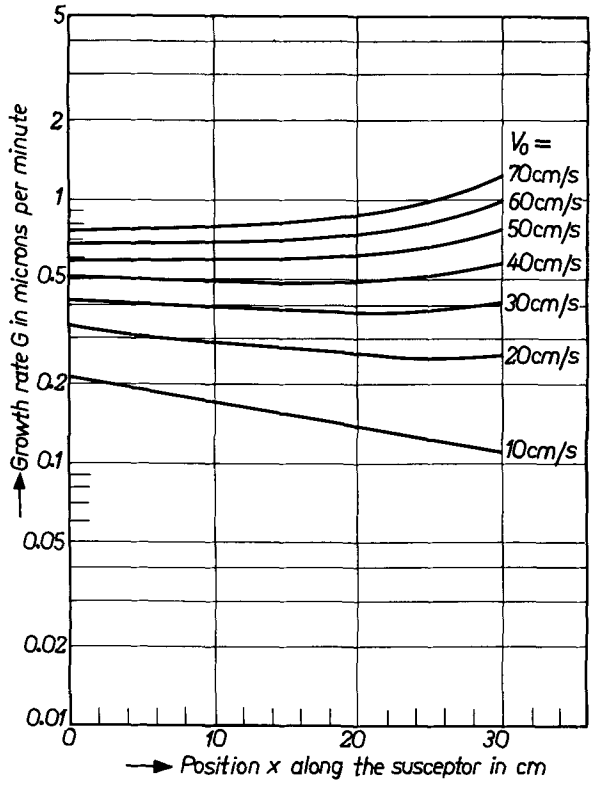

Fig. 13. Calculated values of the growth rate vs. position along the susceptor at different gas velocities for an angle of tilting of 2.9°. T_m = 700°K, T_s = 1350°K, b = 2.05 cm, p_o = 10^3 dynes/cm², D_o = 0.2 cm²/s.

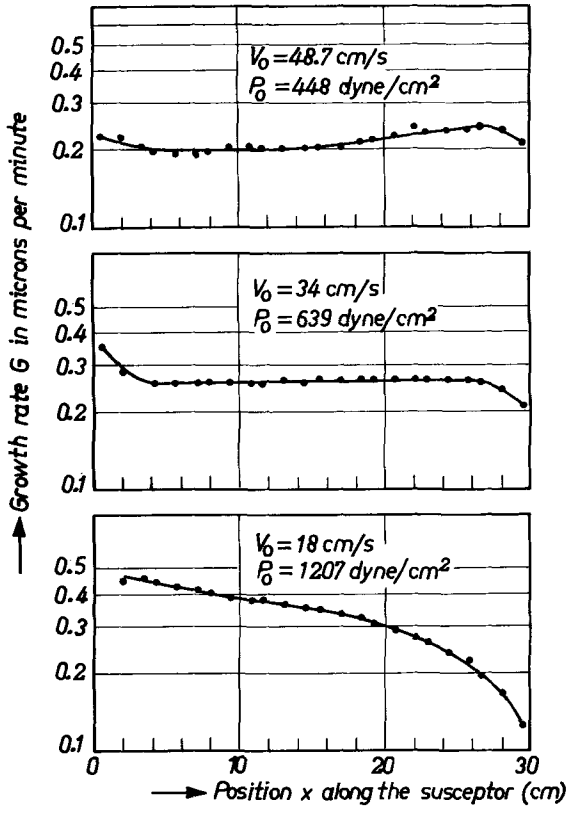

Fig. 14. Growth rate vs. position along the susceptor for an angle of tilting of 2.9° and V_o = 18, 34 and 48.7 cm/s, b = 2.05 cm, T_s = 1350°K.

639 dynes/cm² that G = 0.27 μm/min which agrees well with the experimental value G = 0.26 μm/min given in Fig. 14.

The decrease in growth rate at the end of the susceptor, as observed experimentally, is due to geometrical properties of the system where the flow and the temperature should match boundary conditions.

The uniformity in growth rate across the susceptor depends on how well the susceptor fits into the reactor. Variations in growth rate across the susceptor smaller than 5% have been found.

Discussion

From the experiments described in this paper, it is clear that the epitaxial growth of silicon from silane in a horizontal reactor can be adequately explained with a stagnant layer model. According to this model, above the heated susceptor a layer of stagnant gas is present in which the temperature gradient is very high (>100°C/mm). Above the stagnant layer the gas is vertically mixed by the high convection. When the vertical temperature gradient is small, the streamlines have been seen individually with a haze of TiO_2 and the rotation speed of the convection flow increases with the vertical temperature gradient. The experiment to which Fig. 2 refers yields for 5°C/cm a rotation speed of about 1 rps, as has also been calculated using an elementary theory in Appendix C. However, in the case of a heated susceptor, this temperature gradient is rather high resulting in so high a rotation speed that separate streamlines mix and that only a very small temperature gradient is left in the convective layer. In fact, we assume the temperature is uniform within this upper layer. This justifies the model as a whole.

The interpretation of the results presented in the sections on the experiments are based only on the equations of conservation of mass, which is expressed in the upper, convective, layer by the equation of continuity and in the lower, stagnant, layer by equating the silane diffusion flow to the growth rate of the silicon epitaxial layer, as shown in Appendixes A and B. The reactive species involved is supposed to be SiH_4.

We realize that a number of simplifying assumptions have been made in deriving the above results, particularly as regards the diffusion process. The diffusion of silane to the susceptor is rather complicated because several effects combine, which results in an effective diffusion coefficient of silane in hydrogen of 0.2 cm²/s at room temperature. In general, the temperature dependence of the diffusion coefficient is given by $D = D_o(T/T_o)^m$ with $1.75 \leq m \leq 2$. For mathematical convenience (see Appendix A), a value of m = 2 is used. However, a value of m = 1.75 would have been more reasonable because most gases diffuse in hydrogen with this m value (6). To obtain the same diffusion coefficient at high temperature (~1000°C), it is clear that the D_o value must be higher when m = 1.75 is used instead of m = 2.

Normally, thermal diffusion is neglected. In the case of a stagnant layer with a temperature gradient above 100°C/mm, this diffusion should be taken into account, as has been found by Bloem (7). Thermal diffusion results in a mass transport from the susceptor to the main gas flow and this diffusion flow is to be subtracted from the diffusion flow to the susceptor caused by a concentration gradient. The diffusion coefficient of silane in hydrogen due to a concentration gradient is not known, but on the basis of molecular weight a value of D_o = 0.6 cm²/s seems reasonable (2). The value of D_o = 0.2 cm²/s, with which the results described in this paper can be explained, should be considered as incorporating a correction for neglected thermal diffusion and the mathematically simplified temperature dependence of D.

APPENDIX A

As can be seen from Fig. 5, the space above the susceptor is divided into a convective and a stagnant layer. The derivation involves the equation of continuity in the convective layer and the diffusion equa-

tion in the stagnant layer. The solutions are coupled at the common boundary.

In an arbitrarily chosen point in the convective layer the equation of continuity should be satisfied, which reads, since only the stationary state is being considered and no decomposition of silane in the gas phase is assumed

$$\frac{\partial J_x(x)}{\partial x} + \frac{\partial J_y(x,y)}{\partial y} = 0 \qquad [A1]$$

Here, J_x is not a function of y, because due to convection all parameters concerned—temperature, T; density, n; partial pressure of silane, p; velocity, V—are uniform over the convective part of the cross section of the tube.

The second pertinent equation describes the diffusion process in the stagnant layer from the top surface to the substrate surface

$$J_y(x) = -D\frac{\partial n(x,y)}{\partial y} \qquad [A2]$$

According to elementary transport theory, $D \sim T^{1/2}/n(T)$ and a relation $D \sim T^{3/2}$ would be a reasonable assumption. Experimental evidence, however, is in favor of a $D \sim T^m$ relationship with $1.75 \leq m \leq 2$. We shall use here $m = 2$ for mathematical convenience so that $D = D_oT^2/T_o^2$.

Finally, we need the equation of state which, for the highly diluted silane, can be given by

$$p = nkT \qquad [A3]$$

where the temperature lapse rate in the stagnant layer is given by

$$T = T_s - (T_s - T_m)(b - y)/\delta \qquad [A4]$$

and $T = T_m$ in the convective part of the tube.

By straightforward calculation, it can be shown that Eq. [A2], [A3], and [A4] can be combined to give

$$J_y(x)T_o^2k\delta/D_o(T_s - T_m) = -T^2\frac{d\frac{p}{T}}{dT} \qquad [A5]$$

which can be integrated between $p = p(x,b - \delta)$, $T = T_m$ and $p(x,b) = 0$, $T = T_s$ to give

$$p(x) = J_y(x)kT_o^2\delta/D_oT_s \qquad [A6]$$

An alternative relation between $p(x)$ and $J_y(x)$ can be obtained by integrating Eq. [A1] over the cross section $0 < y < (b - \delta)$ and unit width, which yields, because J_y has a finite value only at the convective layer bottom surface and V and T are constant

$$J_y(x) = \frac{-(b - \delta)V}{kT_m}\frac{\partial}{\partial x}p(x) \qquad [A7]$$

When V, which is related to the inside parameters $(b - \delta)$ and T_m, is expressed in the corresponding outside parameters b and T_o as

$$V = V_obT_m/(b - \delta)T_o \qquad [A8]$$

Eq. [A7] can be written as

$$J_y(x) = \frac{-V_ob}{kT_o}\frac{d}{dx}p(x) \qquad [A9]$$

Eliminating $p(x)$ from the two solutions [A6] and [A9], we find

$$\frac{\partial}{\partial x}J_y(x) + \frac{D_oT_sJ_y(x)}{bV_oT_o\delta} = 0$$

which, with the boundary condition derived from [A6]

$$p(o) = \frac{J_y(o)kT_o^2\delta}{D_oT_s} \qquad [A10]$$

has the solution

$$J_y(x) = \frac{p_oD_oT_s}{kT_o^2\delta}\exp\left(-\frac{D_oT_sx}{bV_o\delta T_o}\right) \qquad [A11]$$

Using the density of silicon (2.33 g/cm^3) and the gas constant R instead of k, the growth rate of silicon in microns per minute can now easily be found to be

$$G(x) = 7.23 \cdot 10^6\frac{D_oT_sp_o}{RT_o^2\delta}\exp\left(-\frac{D_oT_sx}{bV_o\delta T_o}\right) \qquad [A12]$$

APPENDIX B

As has been made clear in the text, tilting the susceptor over a small angle, ψ, can be helpful to produce uniform thickness along the length of the reactor. As shown schematically in Fig. 12, the cross section varies both because of the tilting and because of the x-dependent stagnant layer thickness, $\delta(x)$. Equation [A8] should be written now as

$$V(x) = \frac{V_ob}{b - \delta(x) - x\tan\psi}\cdot\frac{T_m}{T_o} \qquad [B1]$$

where $V(x)$ is the velocity at high temperature in the reactor. From the experiments with a nontilted susceptor, the thickness of the stagnant layer, δ, has been found and plotted in Fig. 9 as a function of V_T where now

$$V_T(x) = \frac{V_obT_m}{(b - x\tan\psi)T_o} \qquad [B2]$$

and assuming a quasi-stationary state

$$\delta(x) = \frac{A}{\sqrt{V_T}(x)} - B \qquad [B3]$$

The temperature in the stagnant layer can be written as

$$T(x,y) = T_s + \frac{(T_s - T_m)(y - b + x\tan\psi)}{\delta(x)} \qquad [B4]$$

It can easily be verified that, apart from T being a function of x and y instead of y only, Eq. [A2], when combined with Eq. [A3] and [B4], yields the same Eq. [A5] and the same solution [A6]

$$p(x) = \frac{J_y(x)\delta(x)kT_o^2}{D_oT_s} \qquad [B5]$$

Under the actual conditions of the experiments, there is no decomposition on the wall. This means that the equation of continuity over the convective part of the cross section of the tube can be written as

$$J_y(x,b - x\tan\psi - \delta(x)) = -\frac{d}{dx}(b - \delta(x) - x\tan\psi)J_x \qquad [B6]$$

which yields for Eq. [B6] applying Eq. [A3]

$$-\frac{d}{dx}\frac{(p(x)V(x)(b - \delta(x) - x\tan\psi)}{kT_m} = J_y(x,b - x\tan\psi - \delta(x)) \qquad [B7]$$

or applying Eq. [B1]

$$J_y(x) = -\frac{V_ob}{kT_o}\frac{dp(x)}{dx} \qquad [B7a]$$

Eliminating $J_y(x)$ from Eq. [B5] and [B7a], it is found that

$$\frac{dp(x)}{dx} = -\frac{D_oT_sp(x)}{T_oV_ob\delta(x)} \qquad [B8]$$

which has the solution

$$p(x) = p(o)\exp\left[-\frac{D_oT_s}{T_oV_ob}\int_o^x\frac{dx}{\delta(x)}\right] \qquad [B9]$$

Hence, in terms of $J_y(x)$ from Eq. [B5]

$$J_y(x) = \frac{D_oT_sp(o)}{kT_o^2\delta(x)}\exp\left[-\frac{D_oT_s}{T_oV_ob}\int_o^x\frac{dx}{\delta(x)}\right] \qquad [B10]$$

It can easily be verified that for constant δ Eq. [B10] is equal to Eq. [A11], as it should be.

Integrating the exponent in Eq. [B10] with Eq. [B2] and [B3] yields the following rather cumbersome expression

$$J_y(x) = \frac{D_o T_s p_o}{kT_o^2 \delta(x)} \exp\left[-\frac{2D_o T_s T_m}{A^2 T_o^2 \tan\psi}\left(\delta(o) - \delta(x) + B \ln\frac{\delta(o)}{\delta(x)}\right)\right] \quad [B11]$$

Using the density of silicon (2.33 g/cm^3) and the gas constant R instead of k, the growth rate of silicon in microns per minute can now easily be found to be

$$G(x) = 7.23 \cdot 10^6 \frac{D_o T_s p_o}{RT_o^2 \delta(x)} \exp\left[-\frac{2D_o T_s T_m}{A^2 T_o^2 \tan\psi}\left(\delta(o) - \delta(x) + B \ln\frac{\delta(o)}{\delta(x)}\right)\right] \quad [B12]$$

APPENDIX C

In the experiments with small vertical temperature gradient (see Fig. 2), the TiO_2 particles were visibly moving upward along streamlines. This is a basic phenomenon in meteorology (8). The velocity y of the rising lump of gas can be assessed in the following way.

Denoting the vertical coordinate by y and the acceleration of gravity by g, the force experienced by a given parcel of gas, primed if not in equilibrium with the environment, increases with the deviation from hydrostatic equilibrium. This yields in a first order of approximation a force proportional to this deviation, or, since the unprimed quantities refer to equilibrium

$$\ddot{y} = -g\frac{\rho - \rho'}{\rho'} = -g\frac{\Delta T}{T} \quad [C1]$$

Integrating this equation, it is found that

$$y_o - y = \frac{g\Delta T t^2}{2T} \quad [C2]$$

which yields, when the height of the tube is b and the characteristic time to traverse this distance is τ

$$\tau = \left(\frac{2bT}{\Delta T g}\right)^{1/2} \quad [C3]$$

Numerically, this fits well: $b = 2$ cm, $\Delta T \approx 10°$K, $T = 300°$K, $g \approx 10^3$ cm/sec^2 yields $\tau \approx 1/3$ sec, which means, taking into account the lateral and downward motion, 1 rps. This has been observed experimentally.

NOMENCLATURE

x,	position on the susceptor
y,	position above the susceptor
$G(x)$,	growth rate at position x on the susceptor, μm min^{-1}
$J_x(x,y)$,	molecular flux of SiH_4 in the x-direction as a function of x and y, cm^{-2} s^{-1}
$J_y(x,y)$,	molecular flux of SiH_4 in the y-direction as a function of x and y, cm^{-2} s^{-1}
δ,	stagnant layer thickness, cm
$\delta(x)$,	stagnant layer thickness at position x on the susceptor, cm
$\delta(o)$,	stagnant layer thickness at $x = 0$, cm
c,	width of the susceptor, cm
d,	width of the reactor, cm
b,	free height of the reactor at $x = 0$, cm
L,	length of the susceptor, cm
T_m,	temperature of the gas in the convective part of the reactor, °K
T_s,	susceptor temperature, °K
$T(x,y)$,	temperature of the gas in the stagnant layer as a function of x and y
T_o,	300°K
$p(x)$,	partial pressure of silane at the position x, dynes cm^{-2}
p_o,	partial pressure of silane at the inlet of the reactor, dynes cm^{-2}
$V(x,y)$,	linear gas velocity in the reactor as a function of x and y, cm s^{-1}
V_o,	mean gas velocity in the case of a nonheated susceptor cm s^{-1}
V_m,	linear gas velocity in convective part of the reactor, cm s^{-1}
$V_T(x)$,	mean gas velocity in reactor as a function of x (corrected for heating up), cm s^{-1}
R,	gas constant (= 8.31 x 10^7 erg °K^{-1})
k,	Boltzmann constant (= 1.3 x 10^{-16} erg °K^{-1})
ρ,	gas density, g cm^{-3}
n,	number of silane molecules per unit volume, cm^{-3}
D_o,	diffusion coefficient for silane at 300°K (corrected value for thermodiffusion: 0.2 cm^2 s^{-1})
η,	deposition efficiency, %
t,	time, s
ψ,	angle of tilting of the susceptor
g,	acceleration of gravity, cm s^{-2}
τ,	characteristic time for convective flow, s

Thermodynamic and Experimental Aspects of Gallium Arsenide Vapor Growth

A. Boucher and L. Hollan

R.T.C.—La Radiotechnique-Compelec, Laboratoire E.R.G., 92—Suresnes, France[1]

ABSTRACT

The thermodynamics of the transport of GaAs by $AsCl_3$ in an open system has been investigated theoretically and a new approach taken to determine the maximum possible amount of GaAs that can be deposited. The results of the calculations have been checked experimentally, using hydrogen and argon as a carrier gas, by measurements of the amount of Ga (or GaAs) withdrawn from the source and also of total amounts of GaAs deposited. We show that in the range of temperatures of practical interest the experimental results can be accounted for by a simple theoretical analysis assuming a single dominant equilibrium reaction. The theoretical work and the experimental measurements have led to an exact knowledge of the chemical compounds involved and have been used as a basis for a preliminary investigation of the growth mechanisms. The problem has been approached by measurements not only of the total amount of deposit but also of the rate of growth on a GaAs substrate in the presence of various temperature gradients. A kinetic limitation of the growth rate appears clearly.

The epitaxial growth of GaAs by transport in the vapor phase in the presence of $AsCl_3$ is now one of the most widely studied transport reactions. Since the early work (1) there have been many publications on the subject, but the emphasis has been on the production of a material having useful properties. More fundamental work has been rather neglected, and a detailed knowledge of transport phenomena is still lacking in many ways. With respect to thermodynamic reactions Fergusson and Gabor (2) were the first to consider the system as a whole and to calculate, on a computer and from thermodynamic data taken either from tables or from empirical formulas, the most important factors which govern the transport. The corresponding experimental results are, however, very few and incomplete. Also, their work was limited to a consideration of equilibria over the source material. The same type of analysis has been carried out by Hurle and Mullin (3). A much more experimental approach has been taken by Seki *et al.* (4); these authors also gave a simplified theory which will be discussed later.

Problems arising in this field are very numerous: for instance, the influence of factors as important as rate of growth, temperatures of the source and of the deposit, and the temperature gradient is hardly known. As for the mechanisms which really control the growth, knowledge is even scarcer. Some experimental observations have been reported (5), but it is still impossible to predict the influence of such factors as the concentrations of different chemicals at each point in the reactor (*e.g.*, the ratio Ga/As in the gas phase), the amount of supersaturation, the crystallographic orientation of the substrate, etc. All those factors, however, must be controlled in order to reasonably predict the rates of introduction of dopants and vacancies into the crystal structure, which in turn determine the electronic quality of the resulting layers.

In order to improve our understanding of the mechanisms of the reaction we have therefore undertaken on the one hand a theoretical analysis, the results of which are then compared to the experimental results, and on the other hand systematic measurements carried out in the epitaxial reactors under precise experimental conditions.

[1] This laboratory has merged effective January 1st, 1970 with the Laboratoires D'Electronique et de Physique Appliquee, 3 avenue Descartes, 94- Limeil-Brevannes, France.

Computer Calculations

We have taken into account the same reactions as Fergusson and Gabor, neglecting however the partial pressures of Cl^- and Cl, namely

$$GaCl_3 \rightleftharpoons GaCl + Cl_2 \qquad [1]$$

$$2GaCl + \tfrac{1}{2}As_4 \rightleftharpoons 2GaAs_{(S)} + Cl_2 \qquad [2]$$

$$H_2 + Cl_2 \rightleftharpoons 2HCl \qquad [3]$$

$$As_4 \rightleftharpoons 2As_2 \qquad [4]$$

together with their associated relations

$$\log k_i = \frac{\Delta G_i}{RT} \qquad [5]$$

in which the ΔG_i's are evaluated either from the data given by Fergusson (1) or from those given by Hurle (3).

In practice, in this range of temperatures, since the partial pressure of arsenic is larger than the equilibrium partial pressure over saturated gallium, a thin GaAs crust develops on the gallium. After an initial saturation period, the thickness of this layer must become stationary. Thus, this same equation [2] may be used to describe the equilibrium either over a gallium arsenide source or (again in the range of parameters considered) over an arsenic-saturated gallium source.

The three relations which are required to make the system complete can be found by expressing the conservation of the total pressure of chlorine and of arsenic. Thus, we have in all cases

$$\Sigma p_i = 1 \text{ atm} \qquad [6]$$

where the p_i's are the partial pressures, and

$$p_{GaCl} + 3p_{GaCl_3} + p_{HCl} + 2p_{Cl_2} = 3p_{AsCl_3} \equiv 3p_o \qquad [7]$$

where p_o is used to denote the (constant) $AsCl_3$ partial pressure.

Since the flow of arsenic over an arsenic-saturated gallium source is conserved, we have in this case

$$4p_{As_4} + 2p_{As_2} = p_o \qquad [8a]$$

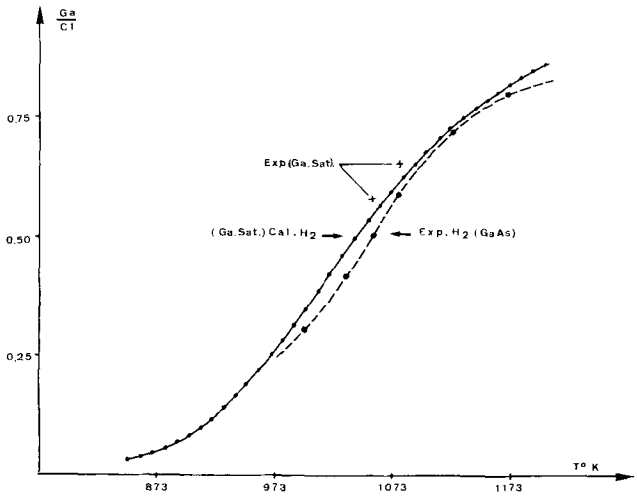

Fig. 1. Experimental and calculated curves of the Ga/Cl ratio vs. temperature at equilibrium with the source.

This equation is no longer valid[2] over the substrate (because of GaAs deposition) and must be replaced by

$$4p_{As4} + 2p_{As2} = p_o - (p^*_{GaCl} + p^*_{GaCl_3} - p_{GaCl} - p_{GaCl_3}) \quad [8b]$$

where the p^*'s denote the partial pressures over the source material, deduced from Eq. [1] through [8a].

Equation [8b] shows that equal amounts of arsenic and gallium have precipitated out of the corresponding gas phase, and the system of Eq. [1] through [7] together with Eq. [8b] characterizes the new equilibrium at any chosen temperature over a GaAs substrate farther down in the reactor, which would result if the substrate region were long enough to allow this equilibrium to be reached. This allows us to compute, by difference, the amount, ΔGaAs, of GaAs which it is thermodynamically possible to deposit, as a function of the temperature of the substrate for any given temperature of the source. The system of Eq. [1] through [8a] has been solved primarily to check our results against published ones as well as to provide the initial conditions p^*_{GaCl} and $p^*_{GaCl_3}$.

Results of Calculations

We show here only the most typical curves which were obtained from these calculations. In all cases, the $AsCl_3$ partial pressure p_o is taken to be 0.01 atm, and the ΔG_i's are those given by Fergusson and Gabor (2).

The theoretical curve of Fig. 1 (continuous line) shows the variation of the Ga/Cl ratio in equilibrium over an As-saturated Ga source in equilibrium with the incoming gas as a function of source temperature. The experimental curve on this figure will be discussed later.

The curves of Fig. 2 show the evolution of the partial pressures of the different compounds as a function of the deposition zone temperature, always assuming this zone to be infinitely long. The points on the right on each curve correspond to equilibrium over the source (which was taken to be at 1120°K). In agreement with Fergusson's results, we found the As_2 partial pressure to be quite negligible, and therefore we did not show it on Fig. 2. Other points worth noting are: (*i*) the partial pressure of $GaCl_3$ is also negligible above 1030°K. This implies that the theoretical curve of Fig. 1 can be interpreted directly in terms of the ratio p_{GaCl}/p_{HCl}; (*ii*) the decrease in p_{GaCl} is due principally to the reduction by hydrogen (formation of HCl) and not to disproportionation (p_{GaCl_3} is negligible for $T > 1030$°K; (*iii*) the limit to the reaction is due to the using up of the arsenic, as could be expected.

[2] Equation [8a] would not be valid either in the case of a true GaAs source, An approximate equation for this case will be given below, but the corresponding computer calculations have not been carried out.

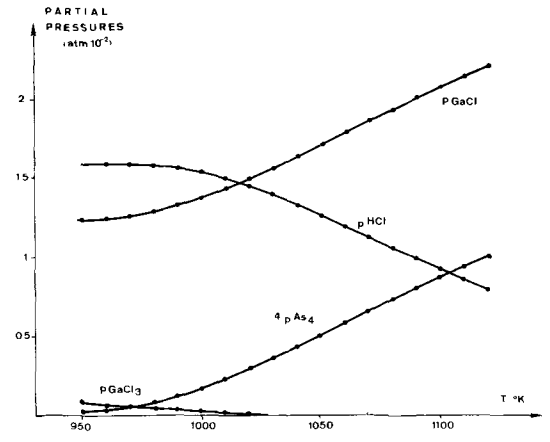

Fig. 2. Calculated equilibrium partial pressures of the chemical compounds vs. temperature.

The preceding remarks have led us to plot the curves shown in Fig. 3 in which the ratio Ga/As is shown as a function of deposition zone temperature (always assuming that equilibrium is reached) for different values of source temperature. The curves are of course limited to the right at the value of the source temperature corresponding to each curve, so that the dotted curve drawn through these points shows this same Ga/As ratio under conditions of equilibrium at the source as a function of source temperature. One can see that this ratio tends to become very large for a reasonable temperature difference between the source and the deposition zone, 100°C for instance.

Finally, the family of curves of Fig. 4 show the ratio of the amount ΔGaAs of "thermodynamically available" GaAs to the total arsenic content of the gas when it leaves the source, plotted as a function of deposition zone temperature with the source temperature as a parameter. Again, the curves are limited to the right at the value of source temperature corresponding to each curve. These curves enable us to calculate the degree of supersaturation of the gas phase over the substrate provided we measure the amount of deposit which has actually taken place on that substrate, under the condition that there has been no deposit farther up-stream.

Further discussions of the various theoretical curves will be given later.

Source Equilibrium Measurements

The purpose of this part of the work was to check the corresponding calculations, and particularly the values of the parameters ΔG_i, by carefully measuring the amounts of Ga or GaAs transported from an

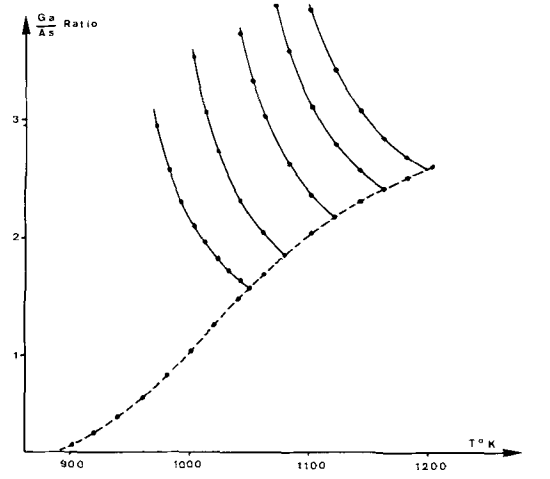

Fig. 3. Ga/As ratio at equilibrium in the reactor vs. temperature for different source temperatures.

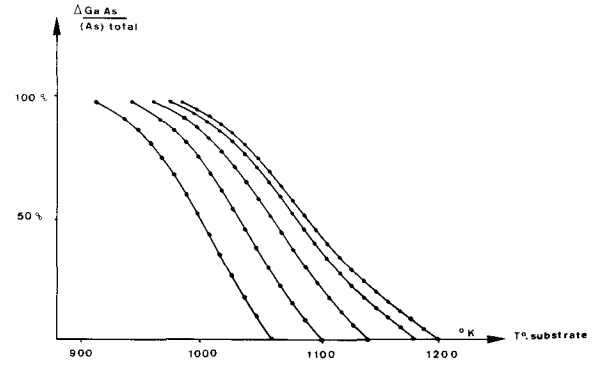

Fig. 4. Ratio of the amount of "thermodynamically available" GaAs to the total arsenic content of the gas when it leaves the source, plotted as a function of deposition zone temperature with the source temperature as parameter. Without deposit, this quantity is none other than the relative supersaturation.

arsenic-saturated source by a known amount of $AsCl_3$ as a function of source temperature. In order to know exactly the amount of $AsCl_3$ in the gas stream a determination of the saturated vapor pressure of this compound was necessary, as the data available in the literature are in disagreement with one another.

The vapor of boiling $AsCl_3$ is carried along by a hydrogen current through a thermostatically controlled distillation column. The gases then pass through washing flasks containing soda and leave the apparatus through a gas-meter. By measuring the weight of chloride formed with the soda in the washing flasks, and knowing the total gas volume, p_{AsCl_3} was determined as a function of temperature. By using different flow rates, we verified that our saturation system showed good reproducibility, and that saturated vapor tension was obtained for a wide range of flow rates. The results can be summarized by the formula

$$\log p_{AsCl_3}\ (\text{mm Hg}) = 8.7 - \frac{2300}{T}$$

which is in good agreement with Matthews' data (6).

The transport of gallium (or of GaAs) was carried out by passing the gas stream first through the saturation system described above, then over the gallium heated to the required temperature. The flow rate and also the geometrical conditions were determined so that equilibrium was reached. (This was checked as above by varying the flow rates in a reasonably wide range around the desired values.)

The transport lasted about 1 hr, the total flow integrated by the gas meter being about 10 1. The GaAs source was weighed before and after the run. In the case of a gallium source, the measurements are made more difficult by the fact mentioned above, that the gallium is not merely saturated by arsenic but is in fact covered by a thick film of gallium arsenide. Careful analyses of sources quenched after a long period of saturation have shown that the percentage of arsenic (which may be of the order of 5%) depends on the geometrical shape of the source and may vary with the temperature. It is, however, reasonable to assume that once the source is saturated the thickness of this film remains constant. The experimental procedure was then to saturate a source at a certain temperature, quench it, weigh it, and bring it back quickly to the same temperature before turning on the flow of $AsCl_3$. The source was quenched and weighed again after the run, and a first approximation of the amount of gallium transported was obtained from the weight loss. The difficulty with this procedure was of course that some evaporation of arsenic took place before equilibrium conditions could be reached over the source, and complementary experiments were necessary to determine the necessary corrective terms. Even then reproducibility was only fair, and more consistent results could be obtained with a GaAs source.

The results of these measurements are best summarized by the experimental curve of Fig. 1 (dashed line). The corresponding points represent the average of slightly scattered measurements, carried out at the same temperature, using a GaAs source. Because of the experimental difficulties described in the preceding paragraph, only two points (crosses on Fig. 1) have been obtained with a gallium saturated source; in this case also, the points represent the average of a number of measurements, but the scatter was definitely larger, so that more measurements had to be taken. The agreement between these two points and the theoretical curve calculated from Fergusson's parameters is good. The agreement when Hurle's parameters were used was definitely not as good. The discrepancy with the experimental curve corresponding to the case of a GaAs source is qualitatively explained by the decrease in arsenic partial pressure.

Interpretation of the Experimental Results

If Δm is the weight loss of Ga (or GaAs), ΔV the volume in liters under normal conditions of the carrier gas that has passed through the system, and p_o the saturated vapor pressure of $AsCl_3$, we have

$$\alpha \equiv \frac{n\ \text{Ga}}{n\ \text{Cl}} = \frac{22.4}{3M\ p_o} \cdot \frac{\Delta m}{\Delta V}$$

where M is the atomic mass of Ga (or molecular mass of GaAs), and α the ratio of the number of gallium atoms to that of Cl atoms in the gas.

Since the computer calculations show that in the presence of hydrogen the amount of $GaCl_3$ is negligible in the range of temperatures envisaged, we can assume that the predominant equilibrium is

$$2GaCl + H_2 + \tfrac{1}{2}As_4 \rightleftharpoons 2GaAs + 2HCl \qquad [9]$$

In the case of a gallium source, we have

$$3p_o = p_{HCl} + p_{GaCl} \qquad [10]$$

$$p_{As4} = \tfrac{1}{4}\, p_o \qquad [11]$$

we can then express the equilibrium constant K_1 relative to Eq. [9] as

$$K_1 = \frac{p^2(HCl)}{p^2(GaCl)\ p^{1/2}(As_4)} = \frac{2(1-\alpha)^2}{\alpha^2\, p_o^{1/2}}$$

In the case of GaAs source, Eq. [10] remains valid, but Eq. [11] is to be replaced by

$$p_{As4} = \tfrac{1}{4}(p_o + p_{GaCl}) \qquad [12]$$

whence

$$K_1 = \frac{2(1-\alpha)^2}{p_o^{1/2}\, \alpha^2 (1+3\alpha)^{1/2}}$$

where p_o is known and α is determined experimentally. If the logarithm of K_1 thus calculated is plotted against the inverse of the absolute temperature, the continuous-line curve of Fig. 5 is obtained. For temperatures higher than 1000°K, the linearity of the curve shows that the assumption is justified and that the predominant equilibrium which controls the group of reactions is indeed that expressed by Eq. [9]. Above 1000°K, a very good agreement is found between the values of K_1 determined experimentally and those calculated from Eq. [5] using Fergusson's parameters. The agreement is definitely not as good if Hurle's parameters are used (see dotted lines on Fig. 5). Below this temperature, the reaction

$$3GaCl + \tfrac{1}{2}As_4 \rightleftharpoons 2GaAs + GaCl_3 \qquad [13]$$

can no longer be neglected, and it is necessary to carry out a complete calculation in order to account for the experimental results (Fig. 1).

Another interesting verification was undertaken by using argon as carrier gas. We assume that equilibrium

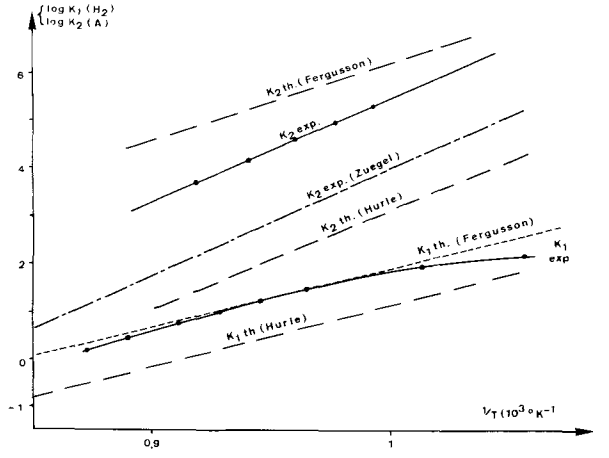

Fig. 5. Experimental and theoretical equilibrium constants vs. inverse temperature for equilibriums [9] and [13].

[13] is now the dominant one; the equilibrium constant is in this case

$$K_2 = \frac{p_{GaCl_3}}{p^3_{GaCl} p^{1/2}_{As_4}}$$

with

$$3p_o = p_{GaCl} + 3p_{GaCl_3}$$

If we set

$$p_{GaCl} = 3\,\alpha'\,p_o$$

we have, in the case of a gallium arsenide source, which was the only one used together with argon

$$p_{As_4} = \frac{p_o}{2}(1 + \alpha')$$

so that

$$K_2 = \frac{\sqrt{2}\,(1 - \alpha')}{27 p_o^{5/2}\,\alpha'^3\,(1 + \alpha')^{1/2}}$$

with α' being deduced from the experimental data by the formula

$$1 + 2\,\alpha' = \frac{22.4}{M_{P_o}} \cdot \frac{\Delta m}{\Delta V}$$

Log K_2 thus calculated is also plotted on Fig. 5 as a function of $1/T$. Here too, a good agreement with the starting assumption can be seen since a straight line is obtained. Further, the experimental curve lies between those calculated using the data of Fergusson and those of Hurle, the best fit being again obtained with the straight line corresponding to Fergusson's values. It is interesting to note the large difference between the two calculated sets of values, while the thermodynamic data are at first sight quite comparable

Fergusson: $\Delta G = -108{,}000 + 138.2T - 8.0\,T \log T - 3.2 \cdot 10^{-3}T^2$

Hurle : $\Delta G = -108{,}560 + 141.4T - 6.45T \log T - 3.2 \cdot 10^{-3}T^2$

We have also plotted on Fig. 5 the values of K_2 deduced from Zuegel's results (obtained under vacuum) (7). The agreement with our experimental results is quite acceptable.

Measurements Rate of Growth and Total Deposit

These measurements were carried out in order to investigate the extent to which a knowledge of the thermodynamics of the reactions involved would allow a prediction of these quantities.

The rate of growth was measured in a classical epitaxial system (8) with the two types of temperature gradients shown in Fig. 6. In both cases the growth was carried out under the same operating conditions, namely; flow rates, source temperature (1120°K), substrate orientation, etc. Several substrates were used in every run, the essential difference being that in the case of gradient 1 the substrates were at different temperatures; in the case of gradient 2 they were at the same temperature, but this temperature level could be varied at will without changing the source temperature nor the general shape of the curve. Typical results have been gathered on Fig. 7, which shows the growth rate as a function of the inverse of the absolute temperature.

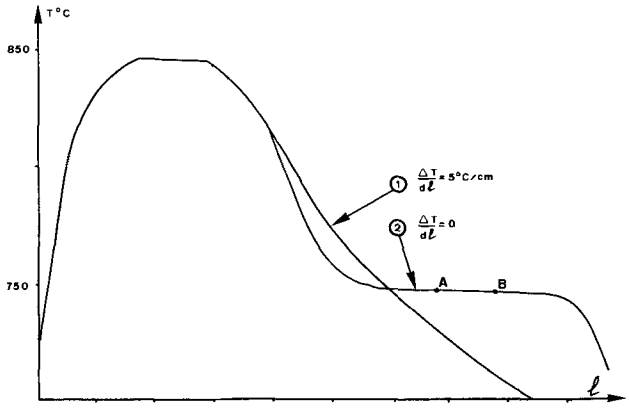

Fig. 6. Thermal gradients used in epitaxial growth

The initial results of growth rate measurements, when no special care was taken, were very widely scattered. A correlation was found however between the occurrence of low and widely scattered growth rates and the appearance of a sizable amount of deposit on the walls on the reactor. This led us to measure the total amount of GaAs deposited (on the substrate, the substrate holder, and the walls of a removable sleeve fitted inside the reactor).

It was found that reproducible growth rates would be obtained if and only if (*a*) there was no deposit except on the GaAs substrate, and (*b*) the total amount of deposited GaAs was lower than 10% of the "thermodynamically available" GaAs. If these conditions were not satisfied, low and widely scattered growth rates were obtained.

A plot of the reproducible growth rates *vs.* inverse temperature yields the solid curve of Fig. 7. The values measured are independent of the temperature gradient (type 1 or 2 of Fig. 6), of the substrate area (again provided that the total deposit remains low enough), and, in case of gradient 2, of the position of the substrate in the flat region of the curve (points A and B, Fig. 6).

These results do not agree with those obtained by Seki (4). By taking into consideration only the thermodynamic aspects of the deposition mechanism. Seki predicts that the growth rate should increase monotonically with decreasing substrate temperatures, and his results agree with this prediction. On the same

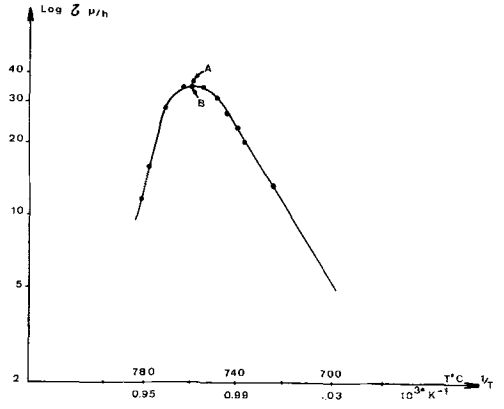

Fig. 7. Experimental growth rate vs. inverse temperature

basis, we would expect the same qualitative behavior, but our experimental data, like those of Shaw's (5), show that below 750°C the growth rate falls rapidly with decreasing temperature. The corresponding law can be characterized by a well-defined activation energy of 40 kcal/mole for a (100) substrate orientation. In view of the strong dependence of the growth rate on substrate orientation in this range of temperatures, it seems natural to assume that this activation energy corresponds to a surface reaction.

We have already noted that, when the conditions for reproducible growth rates are achieved, the total deposition rate is also low. Thus, in this case, a good approximation of the degree of the relative supersaturation and of the GaAs ratio over the substrate can be obtained from the curves of Fig. 3 and 4. These data may prove useful for an investigation of point defects, *e.g.*, vacancies, introduced in the epitaxy process.

On the other hand, when the growth rates are not very reproducible, it is impossible to obtain any correct theoretical estimate of these two parameters, or to deduce a reliable value of activation energy from the experimental data. A relative reproducibility may however be achieved, and the electrical quality of the deposits may be quite satisfactory; however, considerable experimental work is needed to find the proper operating conditions.

Summary and Conclusions

We have carried out a theoretical calculation of the amount of GaAs available for epitaxial growth in an open $AsCl_3$ system, using a more rigorous definition of this quantity than done by previous authors. We have checked the values of the relevant parameters by careful experimental measurements of transported material and have found the values given by Fergusson and Gabor (2) to give the best agreement with our measurements. These experiments were carried out under conditions very similar to those usually prevailing for actual epitaxial growth. They have shown that, in the temperature range usually involved (730°-880°C) the dominant equilibrium is

$$2GaCl + \tfrac{1}{2}As_4 + H_2 \leftrightharpoons 2GaAs + 2HCl$$

when hydrogen is used as the carrier gas. When the carrier gas is argon, the dominant equilibrium is

$$3GaCl + \tfrac{1}{2}As_4 \rightleftharpoons 2GaAs + GaCl_3$$

A comparison of calculated thermodynamic parameters with experimentally determined rates of epitaxial growth have shown that other mechanisms must be taken into account, namely a surface reaction with an activation energy of 40 kcal/mole.

The rate of epitaxial growth can be strongly affected by the occurrence of unwanted deposits on other parts of the reactor.

Growth and Characterization of Lead Telluride Epitaxial Layers

John W. Wagner and Alan G. Thompson

Electronic Materials Division, Bell & Howell Company, Pasadena, California

ABSTRACT

PbTe single-crystal epitaxial layers have been grown on PbTe substrates using the tipping technique. The layers were grown on {111} and {100} oriented substrates from lead-tellurium solutions containing from 0.01 to 0.20 atomic fraction tellurium. Cooling rates of from 0.2° to 1°C/min were used. The resulting layers were characterized using x-ray, optical, etching, and electrical techniques. Diodes were fabricated from several of the resulting materials, and their characteristics were found to be substantially improved over diffused PbTe diodes.

Lead telluride crystals which are grown from stoichiometric melts have hole concentrations of approximately 8×10^{18} cm^{-3} due to deviations from stoichiometry (1). The form of the lead-tellurium phase diagram close to the stoichiometric composition has been investigated by Brebrick and Allgaier (2), who showed that by annealing PbTe in the presence of lead or tellurium-rich vapor, the carrier concentration can be made n- or p-type and varied over a wide range. Thus, by annealing at a certain temperature the hole concentration can be lowered to the desired value; by lowering the temperature and annealing for a relatively short time an n-type layer can be diffused into the surface. The resulting p-n junction is suitable for photovoltaic detector and laser fabrication.

In the case of the $Pb_{1-x}Sn_xTe$ alloy the same process is followed. However, as the tin content of the alloy is increased, the anneals and diffusions must be performed at progressively lower temperatures, resulting in extremely long material preparation times. Work

performed previously in this laboratory (3) has shown that PbTe and $Pb_{1-x}Sn_xTe$ crystals pulled from metal-rich melts have carrier concentrations substantially lower than those pulled from stoichiometric melts.

Experience with the epitaxial growth of gallium arsenide from gallium solution has shown that high-purity layers can be prepared with a planar interface. We have therefore explored the possibility of growing epitaxial layers of PbTe from lead solution with the following advantages in mind (*i*) no lengthy annealing or diffusion procedures would be necessary, (*ii*) the possibility of more planar junctions than have been obtained by diffusion, and (*iii*) the possibility of higher purity layers.

In this paper we present results for PbTe grown from lead solutions. Metallurgical data are given and various electrical measurements are reported. The characteristics of the grown p-n junctions are compared with those of diffused junctions reported in the literature.

Growth Process

The PbTe layers were precipitated from solution on to single-crystal PbTe substrates using a tipping technique similar to that of Nelson (4). The apparatus is shown schematically in Fig. 1. A quartz boat was inserted into the quartz tube. The tube was placed in a horizontal resistance furnace which could be tilted in either direction with respect to the horizontal. The source material, which consisted of Pb (Asarco, nominal 6N) and PbTe, was placed in one end of the boat. A polished and etched seed wafer of PbTe was placed in the other end of the boat. The furnace was tilted so that the seed was higher than the source material, and the temperature of the furnace was raised while a stream of hydrogen was passed through the tube. The PbTe was seen to dissolve in the lead as the temperature was increased. After the PbTe had completely dissolved, the temperature was slowly lowered to find the liquidus point of the solution. This procedure was repeated several times until the initial freezing point had been established to within approximately 1°C. The temperature was then raised to slightly above the solidifying point and the system was allowed to stabilize. The furnace was then tilted so as to transfer the solution over the seed wafer. The temperature was then slowly lowered so that the PbTe would deposit as a single-crystal growth onto the wafer. After slowly cooling over the desired temperature interval (20°-100°C), either the system was allowed to rapidly cool to room temperature or the furnace was tilted to its original position, allowing the remaining solution to flow off the layer prior to cooling to room temperature.

Layers of PbTe were grown on single-crystal {111} and {100} oriented PbTe wafers using this tipping technique. Lead-tellurium solutions containing from 0.01 to 0.20 atomic fraction tellurium were used and the cooling rate was varied from 0.2° to 1.0°C/min. The resulting layers had thicknesses of from 50 to 300μ, and the epitaxial growth rate was qualitatively observed to follow the expected dependence on the solubility *vs.* temperature curve and on the cooling rate.

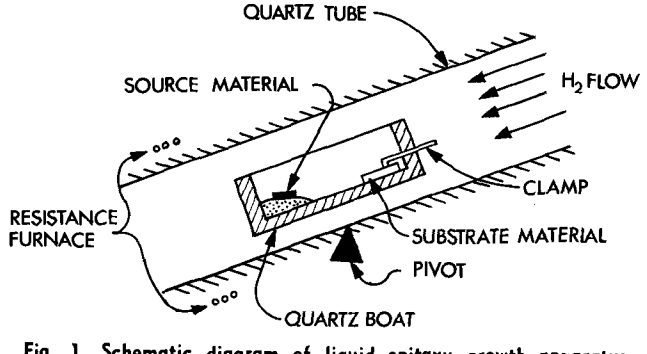

Fig. 1. Schematic diagram of liquid epitaxy growth apparatus [after Nelson (4)].

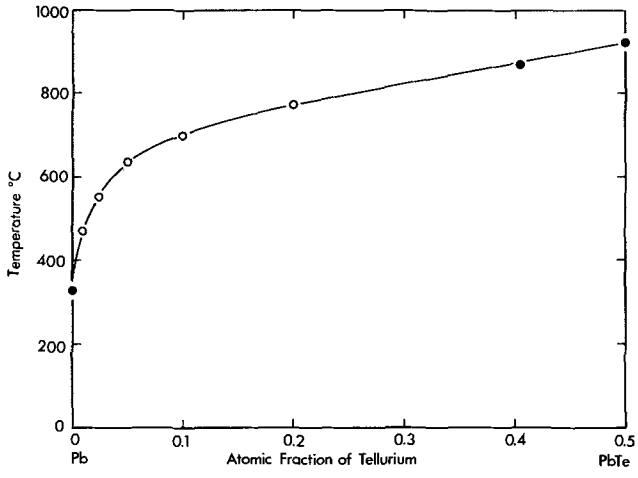

Fig. 2. Liquidus curve for the metal-rich portion of the lead-tellurium phase diagram. ●, Literature values [ref. (3, 5, 6)]; ○, present data.

The metal-rich portion of the liquidus curve of the lead-tellurium system is shown in Fig. 2. The melting points of lead, lead telluride and the p to n crossover composition were taken from the literature (3, 5, 6). The open circles are taken from the data obtained in the liquid epitaxy experiments, and are estimated to be accurate to ±5°C. Although a portion of the melt vaporizes during the stabilization period, its weight is very small in comparison with the total melt and it decreases with decreasing temperature. The accuracy of the atomic fraction of tellurium is better than ±0.005 for the higher values and probably ±0.001 for the more dilute solutions. The only other references on this portion of the liquidus are over 50 years old and are quoted in Hansen (7). These are not shown on Fig. 2 because of their large scatter and doubtful validity.

Characterization

Several techniques were used to characterize the as-grown layers: the most useful were x-ray, etching, optical, and electrical.

X-ray.—X-ray Laue photographs were taken of several of the epitaxial layers to verify their single-crystal nature and to obtain a qualitative indication of their perfection. Figure 3(a) shows a typical Laue pattern of a {100} oriented layer. The spots in these patterns were sharp and singular. Figure 3(b) is an unusual Laue photograph of a section of a {100} layer which contained a low-angle boundary. The spots are seen to be doubled with an angular separation of less than a degree; the small angle in this layer originated from a low-angle grain boundary in the PbTe substrate. It should be pointed out that these low-angle grain boundaries are very common in the lead salts,

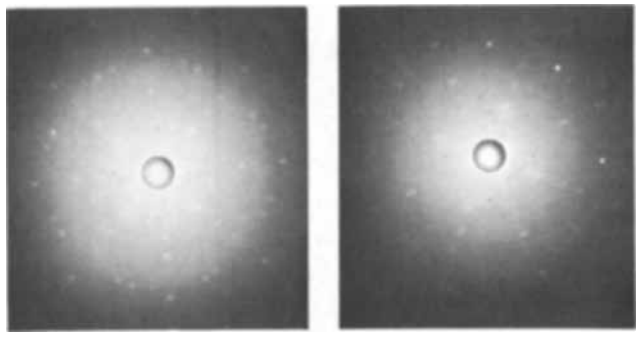

Fig. 3 (a). (left) Typical Laue pattern of {100} PbTe epitaxial layer; Fig. 3 (b). (right) Laue pattern of {100} epitaxial layer grown on a substrate containing a low-angle grain boundary.

and great care must be exercised during the preparation of bulk material to avoid them and obtain truly single-crystal ingots. Figures 3(a) and 3(b) were both taken on layers from which the solution had been tipped off prior to cooling to room temperature.

Optical.—Those layers which were cooled to room temperature with the lead-tellurium solution over the surface had to be etched in hot, concentrated HCl for several days to reveal the epitaxial layer. The HCl did not "attack" the PbTe layer, but the etching procedure did leave the layer with a dull gray appearance. Some interesting surface features were seen on {111} and {100} layers when the solution had been etched away. Figure 4(a) is a photograph of the as-grown surface of a {111} layer after removal of the Pb-Te alloy. The overlapping parallelopipeds have (100) cube faces. Figure 4(b) is a photograph of the as-grown surface of a {100} layer, again after etching away the alloy. This surface also consists of an overlapping growth structure dominated by (100) faces.

The overlapping growths shown in Fig. 4(a) and 4(b) were due to rapid growth which occurred when the solution was allowed to cool to room temperature while over the layer. Such growth was possible because the cooling process was still slow enough (a few degrees Centigrade per minute) to allow rapid precipitation from solution. Such precipitation can also occur in the epitaxial growth of other materials (such as GaAs) from solution when the solution is permitted to remain over the layer during the final cooling. The obvious answer to this problem is to remove the solution prior to the final cooling.

Those layers from which the Pb-Te solution was tipped off prior to final rapid cooling were found to be relatively flat and to have shiny, metallic surfaces. The surfaces exhibited none of the overlapping structure seen in Fig. 4, and a typical {100} layer is shown in Fig. 5. However, a few of the layers showed some interesting surface structure when viewed under an optical microscope. Figure 6(a) is a microphotograph of an as-grown surface of a {100} layer. The hillocks seen in the photograph occurred occasionally on several layers, and their height was typically a few microns. No determination was made as to the origin of these hillocks, but one can speculate that they arise around a lead precipitate or an impurity precipitate. Figure 6(b) is a photograph of a section of another {100} surface. The "waves" shown in the photograph were seen sparingly on a few of the layers and on only small portions of these layers, usually toward the edge of the substrate. These "waves" are apparently due to transient thermal gradients during the growth of the layers. It must be emphasized that the features shown in Fig. 6(a) and 6(b) were seen on only a few of the layers and then only on small portions of these layers.

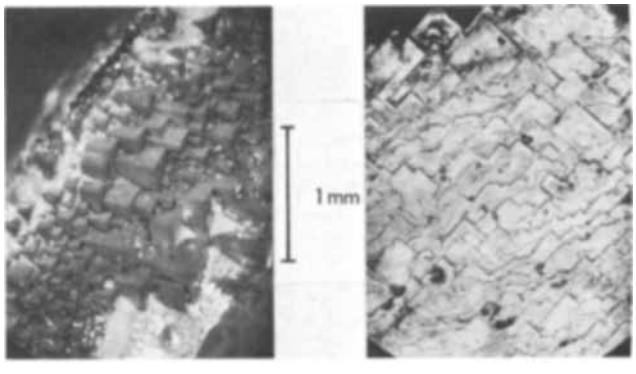

Fig. 4 (a). (left) Surface of PbTe epitaxial layer grown on a {111} oriented substrate with the melt over it during rapid cooling; Fig. 4 (b). (right) Surface of PbTe epitaxial layer grown on a {100} oriented substrate with the melt over it during rapid cooling.

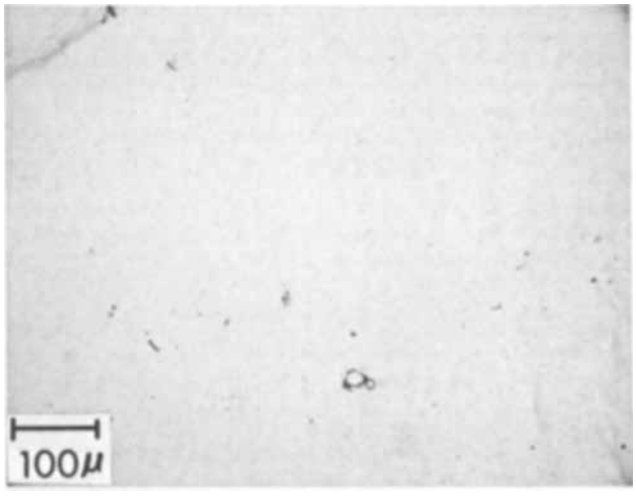

Fig. 5. Surface of a typical PbTe epitaxial layer grown on a {100} oriented substrate with the melt decanted before rapid cooling.

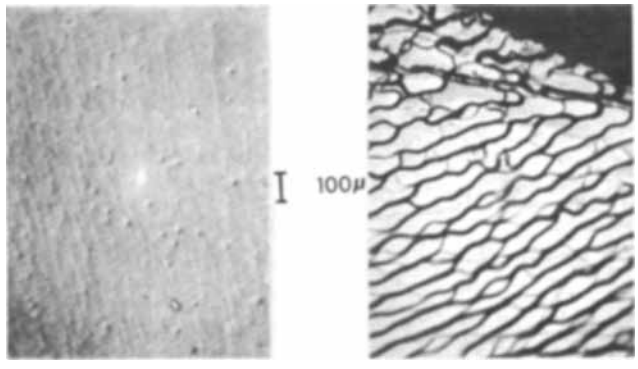

Fig. 6 (a). (left) Surface of a {100} epitaxial PbTe layer showing small hillocks; Fig. 6 (b). (right) Surface of a {100} epitaxial PbTe layer showing "waves."

Except for these features, the surfaces were quite smooth when viewed under the optical microscope, as in Fig. 5.

Etching.—Cross sections of the wafers were lapped and polished mechanically and were then polished and etched electrolytically [using an etch of Norr (8)] to reveal the growth junction. Figure 7(a) shows a typical junction; these junctions were relatively planar. Another view of the rapid growth which occurs during final cool down, if the solution remains over the layer, is shown in Fig. 7(b). The narrow straight line in this figure is the main junction formed between the substrate and the epitaxial growth. The ragged area above the epitaxial growth is the region where the rapid growth began during the final cooling phase.

Electrical.—The interface between the substrate and the layer can be appropriately termed a junction since the substrate was always p-type and the resulting layers were always n-type. This has been shown

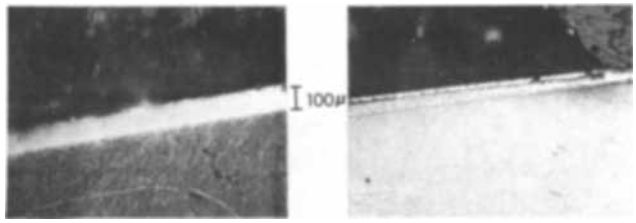

Fig. 7 (a). (left) Typical PbTe p-n junction grown by liquid epitaxy; Fig. 7 (b). "Double junction" in PbTe due to slow and rapid growths.

using a thermoelectric probe and Hall measurements. Hall measurements were performed at 77°K on the layers without attempting to remove the substrate. Such measurements assume that the layer is sufficiently isolated from the substrate so that the Hall data are characteristic of the layers. These measurements gave electron carrier concentrations ranging from 3×10^{17} to 7×10^{17} cm^{-3} for layers grown from 0.01 to 0.10 atomic fraction tellurium solutions, respectively; mobilities ranged from 30,000 to 10,000 $cm^2\ V^{-1}\ sec^{-1}$, respectively. One Hall measurement was performed on an exceptionally thick layer from which the substrate had been lapped off. The carrier concentration of this layer was measured to be 3×10^{17} cm^{-3} prior to lapping off the substrate and 4×10^{17} cm^{-3} after removal of the substrate. This reasonable agreement supports the belief that the layers are sufficiently isolated from the substrates when making Hall measurements at 77°K.

Diodes

Diodes have been fabricated from several of the epitaxial wafers. Mesas of approximately 10^{-2} cm^2 were etched into the n-type layers, and ohmic contacts were placed on the n-layer using Indalloy 5. Several different contacts were tried on the p-type substrate. Figure 8(a) shows an *I-V* curve of one of the diodes fabricated using Indalloy 2 as the contact to the p-face. The forward characteristics of this diode are rather poor and are dominated by contact resistance. The reverse characteristics are quite good. Figure 8(b) shows an *I-V* curve of a diode which had a gold contact to the p-side. The forward characteristics of this diode are vastly improved over the diode having the Indalloy contact but still exhibit substantial contact resistance. The reverse characteristics of this diode are still rather good.

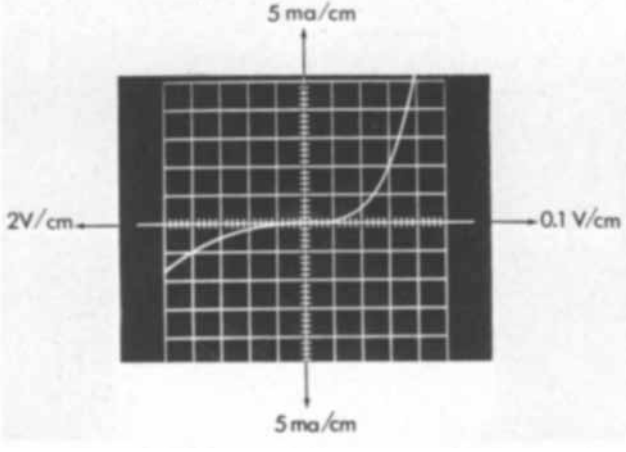

Fig. 8. (a). *I-V* curve for PbTe epitaxial diode, 2508-6A, Indalloy 2 contact to p-side; taken at 77°K.

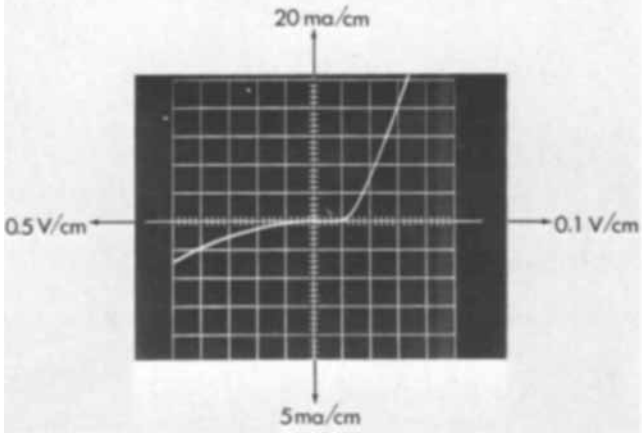

Fig. 8 (b). *I-V* curve for PbTe epitaxial diode, 2508-6A, gold contact to p-side, taken at 77°K.

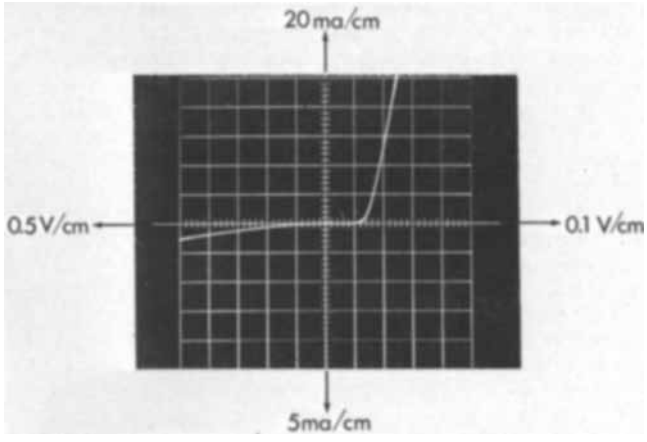

Fig. 8 (c). *I-V* curve for PbTe epitaxial diode, 2508-6B, gold-thallium contact to p-side; taken at 77°K.

We have found that a gold-thallium alloy (27:73 Au:Tl) gave the best contact to the p-side of the diodes. Figure 8(c) is a typical *I-V* curve of a diode with the Au-Tl contact. The forward characteristics of this diode are a factor of two improved over the diodes having gold contacts and are typical of those reported in the literature for diffused PbTe diodes (9, 10). The reverse characteristics are much better than those reported for diffused diodes. A few of the diodes we have fabricated using Au-Tl contacts to the p-side have had forward and reverse characteristics which were greater than a factor of two improved over the typical diode shown in Fig. 8(c).

Figure 9 is a semilogarithmic plot of the forward current-voltage characteristics of several PbTe diodes. The open squares are data from a diffused diode reported by Butler (9), while the open circles are data of Zoutendyk (10), also on a diffused diode. The solid squares are data from one of our diodes that had Indalloy 2 as the contact to the p-side. The early appearance of contact resistance is evident. The solid circles are data from one of the diodes fabricated using the Au-Tl alloy on the p-side. From the linear portion of the semilogarithmic *I-V* plots, one can calculate the *A* values for the diodes in the diode equation

$$I = I_0\, e^{qV/AkT}$$

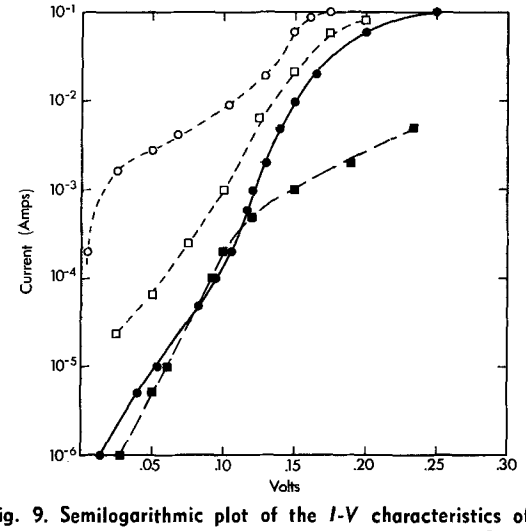

Fig. 9. Semilogarithmic plot of the *I-V* characteristics of PbTe diodes at 77°K, all having areas of the order of 10^{-2} cm^2. ○, Diffused diode [ref. (9)]; □, diffused diode [ref. (10)]; ■, liquid epitaxial diode, Indalloy 2 contact to p-side; ●, liquid epitaxial diode, gold-thallium contact to p-side.

Those diodes which we prepared using Au-Tl contacts to the p side had A values between 1.8 and 2.0.

Capacitance data were taken for several of the diodes. The capacitance was found to have a linear $1/C^2$ to $1/C^3$ dependence on the voltage, tending to follow the square law behavior for low voltage. The negative intercept of the extrapolated $1/C^2$ curves generally lay between 0.1 and 0.25V. Carrier concentrations determined from the differential capacitance measurements were in the range of 10^{16}-10^{17} cm^{-3}, corresponding to a movement of the space charge layer of 2 to 5μ. This is indicative of the region between the p substrate and n layer, where compensation would be expected because of slight melt back of the substrate and diffusion during layer growth. Any material melted and absorbed by the melt will not contribute impurities since the substrate carriers are due mainly to vacancies; this is not the case for the III-V compounds. The form of the $1/C^n$ curves substantiates this argument, since they indicate a sharp, but not discontinuous changeover from p- to n-type behavior.

Conclusion

PbTe single-crystal epitaxial layers have been grown from lead solutions on PbTe substrates using the tipping technique of Nelson; x-ray Laue patterns verified the single-crystal nature of the layers. Those layers which were cooled down to room temperature with the Pb-Te solution over the surface exhibited a region of rapid, overlapping growth due to rapid precipitation from solution. Such rapid precipitation is believed to occur in the liquid epitaxial growth of other materials when the solution is allowed to freeze over the layer. Layers from which the solution was removed prior to final cool down were relatively smooth and had shiny, metallic surfaces, with best growth on the {100} face. The growth junctions were revealed by electrolytic etching and were found to be essentially planar. The layers had majority carrier (n-type) concentrations of from 3 x 10^{17} to 7 x 10^{17} cm^{-3} and mobilities as high as 30,000 cm^2/V-sec. Diodes which were fabricated from the layers had forward characteristics which were as good as or somewhat better than those reported in the literature for diffused PbTe diodes. Their reverse characteristics were greatly improved over the reported diffused diodes. Thus, this method of p-n junction preparation shows promise for superior electrical properties because of the short time the material has to be held at a relatively high temperature and the planar interface which results.

Acknowledgments

We wish to acknowledge the assistance given by K. Schwartz in the electrical measurements, E. Masumoto for the x-ray measurements, and R. K. Willardson for helpful suggestions through the course of this work. This work was partly supported by the Naval Weapons Center, Corona, California, under Contract No. N00123-68-C-2131.

The Effect of Environment on the Fracture of Adhering Aluminum Oxide

J. C. Grosskreutz[1]

Midwest Research Institute, Kansas City, Missouri

ABSTRACT

The spacing of cracks in anodic layers grown on 1100-0 and 7075-T6 aluminum was measured as a function of the strain in the substrate and as a function of environment. The environments were distilled water, sea water, methanol, and dry air. In general, the cracks produced by a given substrate strain were densest in the materials exposed to distilled water and least dense in those exposed to dry air. An analysis is given whereby the fracture strength of the oxide, σ_f, can be derived from the minimum crack spacing observed, d_s. The result is $\sigma_f = (\tau/2t)d_s$, where τ is the interfacial shear stress between oxide and substrate, and t is the oxide thickness. Values of σ_f which are obtained in dry air approach those reported for sapphire whiskers. The effect of other environments is to reduce σ_f by 10-20% in methanol, 20-40% in sea water, and 30-40% in distilled water.

The mechanical and fracture properties of metal oxide films (Al_2O_3 in particular) have been treated in detail in a recent paper (1). It was shown that the fracture of films adhering to a strained substrate occurred as regularly spaced cracks at right angles to the tensile axis, provided that the oxide was sufficiently thick (> 1000Å for Al_2O_3). A phenomenological theory was described which accounted for the variation in crack spacing as a function of substrate strain. An interesting observation was that the crack spacing reached a minimum value, such that further straining of the substrate produced only a widening of the exist-

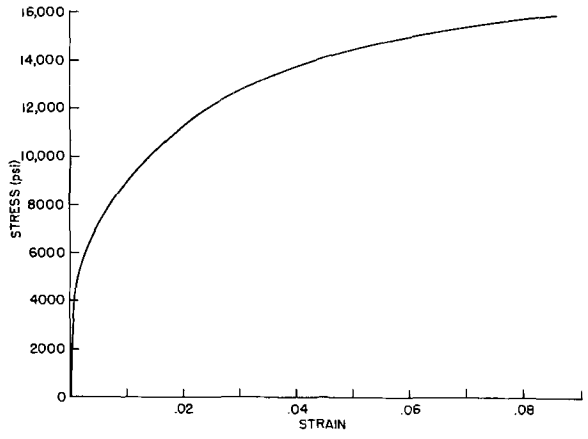

Fig. 1. Stress-strain curve for 1100-0 aluminum

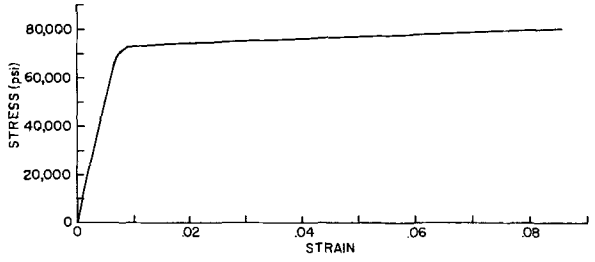

Fig. 2. Stress-strain curve for 7075-T6 aluminum

ing cracks. This minimum spacing was called the saturation spacing, d_s.

It is the purpose of the present paper to explore the effect of environment on the density of cracks in a strained Al_2O_3 oxide film and to show how the saturation spacing can be used to derive the fracture stress of the adhering oxide.

Experimental Details and Results

Anodic oxide films of a nominal thickness, 1400Å, were grown on 1100-0 and 7075-T6 aluminum substrates in a tartaric acid electrolyte (2). The substrate material was in the shape of a conventional, flat tensile specimen with a gauge length of 2 in. and a cross section of 1/32 in.^{2}. The anodized specimens were pulled to various values of strain and the density of cracks determined optically at 200X by a simple intercept method.

Control of the environment was achieved by means of a silicone rubber cup which was molded to surround a 1 in. section of the gauge length. For the case of liquid environments, the cup was simply filled and the top left open. For gaseous environments, the cup was entirely enclosed except for inlet and outlet ports. Four environments were chosen for study: distilled water, artificial sea water, methanol, and dry air (−60°C dew point).

The mechanical properties of the two substrate materials are summarized in Fig. 1 and 2 and Table I.

The results of the experiments to determine crack density as a function of substrate strain in the various environments are shown in Fig. 3 and 4. The values of the saturation (minimum) crack spacing are given in Table II.

Discussion of Results

The discussion of these results is facilitated by a simple consideration of the stresses which produce the saturation crack spacing.

Simple theory of saturation spacing.—Begin by assuming the existence of a regularly cracked oxide film, Fig. 5(a). Once cracking has started, the strains and displacements in the oxide are not the same as those in the substrate because the moduli in the two layers are

Table II. Values of the saturation spacing, d_s, in various environments

different (1). Hence, there are shear strains in the matrix near the interface and it is these strains which are responsible for transferring stress to the oxide coating. Figure 5(b) illustrates half of one segment of the oxide and shows the interfacial shear stress, τ, which is generally a function of x. If P is the load per unit width in the oxide (the width direction is perpendicular to the paper in the figure shown), and if the oxide is rigid with respect to shear, then the force, dP, acting on a slice of oxide, dx, is due entirely to the shear stress, τ, acting across the interfacial area of the slice. Hence

$$dP = \tau dx$$

or, in terms of the stress in the oxide segment

$$d\sigma = \frac{\tau}{t} dx$$

Thus

$$\frac{d\sigma}{dx} = \frac{\tau}{t} \qquad [1]$$

Equation [1] gives the distribution of stress in the oxide segment as a function of distance along its length.

In all cases of interest, the saturation spacing of cracks is reached after the substrate has begun to flow plasticly. Under this condition, τ never rises above the shear flow stress of the substrate. For practical purposes, we shall assume that τ is constant along the length of the segment[2] and is equal to the shear flow stress in the substrate. Equation [1] can then be integrated to give

$$\sigma = \left(\frac{\tau}{t}\right) x \qquad [2]$$

The critical spacing, d_c, will occur when the stress, σ, just rises to the fracture stress, σ_f, of the oxide at the midpoint of the section. Setting $x = d_c/2$, we have finally

$$d_c = \frac{2t\sigma_f}{\tau} \qquad [3]$$

The saturation spacing of cracks will range from about $d_c/2$ up to just less than d_c. Considering the approximations already involved in the calculation of d_c, we define the saturation spacing $d_s = d_c$.

Comparison of the results with the theory.—The difference between the spacings observed on the 1100 and 7075 substrates in a given environment can be accounted for in terms of the differences in the shear flow stress of these two materials. For a rough comparison, assume that the thicknesses and fracture strength of the oxide on the two substrates are identical; then the ratio of the saturation crack spacings should be in inverse proportion to the ratio of shear flow stresses. Substitution of the values for the dry air environment gives the result $d_s(1100)/d_s(7075) = 3.1$ and $\tau(7075)/\tau(1100) = 5.1$. While the agreement is not precise, the correctness of the interpretation does not seem to be in doubt.

Rewriting of Eq. [3] gives

$$\sigma_f = \frac{\tau}{2t} d_s \qquad [4]$$

Because t and τ are unaffected by environment, the relative values of the fracture strengths in the three aggressive environments with respect to dry air can be calculated from the d_s data, and the results are given in Table III, where σ_{fo} is taken as the fracture strength of the film in dry air.

If τ is taken as 0.577 times the tensile flow stress reported in Table I, an absolute value for σ_f can be calculated from Eq. [4]. These numbers are tabulated in the fourth column of Table III. The calculated fracture strengths of the oxide film on 1100-0 aluminum agree well with the fracture strength reported for unpolished sapphire whiskers (3), 300,000-500,000 psi. On the other hand, the calculated values for the film on the 7075 substrate are too high by at least a factor of 2. This discrepancy is further emphasized by the fact that the anodized layer on 7075-T6 aluminum contains a great many defects and voids in comparison to the layer on the 1100 aluminum (1). The difficulty here probably lies in the value assumed for τ, the interfacial shear stress at the surface of 7075 aluminum. It is well known that soft, precipitate-denuded zones exist along grain boundaries in this alloy and it is entirely possible that such a zone exists at the interface between the substrate and the anodic layer. In this case, the maximum shear stress developed in the interface would be much less than the bulk flow stress which was used in the calculation. In fact, the ultimate shear stress for 7075-0 (annealed condition) is about half that of 7075-T6, which could account for the discrepancy.

Another method for calculating σ_f makes use of the fact that the anodic layer on 1100-0 aluminum is purely elastic (1). Hence, $\sigma_f = \epsilon_f E_c$ where ϵ_f is the fracture strain in the oxide and E_c is the Young's modulus of the coating film. We take as ϵ_f that substrate strain at which significant cracks first begin to appear in the adhering oxide. In the case of the dry air environment, this strain is $\epsilon_f \sim 0.0175$. The value for E_c in dry air is 15×10^6 psi (1). These values lead to a calculated value of $\sigma_f = 262{,}500$ psi, about half that given in Table III.

These calculated fracture strengths are an order of magnitude higher than those previously reported for separated Al_2O_3 films (1) in dry air, *e.g.* ~ 43,000 psi. However, these latter fractures were dominated by the existence of defects in the oxide and the fracture, once started, grew catastrophically by a Griffith mechanism. In the case of an adhering oxide, however, this

Table III. The effect of environment on fracture strength of adhering aluminum oxide

Material	Environment	σ_f/σ_{fo}	σ_f (Calculated) (psi)
1100-0	Dry air	1.00	550,000
	Distilled water	0.56	312,000
	Sea water	0.74	410,000
	Methanol	0.76	415,000
7075-T6	Dry air	1.00	1,000,000
	Distilled water	0.65	660,000
	Sea water	0.60	605,000
	Methanol	0.92	920,000

[2] Clearly, this approximation neglects the fact that near the center of the segment the shear stress decreases, passing through zero at the center. However this fact does not seriously alter the value of σ in Eq. [2].

mechanism does not operate because of the constraint of the substrate and the effective fracture stress of the oxide apparently approaches that of sapphire whiskers.

Interpretation of the environmental effects.—In general (Fig. 3 and 4), distilled water is the most aggressive environment. The relative effect of this and the other environments on σ_f is best understood in terms of the elastic modulus of the oxide. This modulus decreases in the presence of water vapor (1) and, if the fracture strain is not appreciably affected, the decrease would account for the observed decrease of σ_f in distilled water. The slightly less harsh effect of sea water on the oxide grown on 1100 aluminum is not understood. The fact that sea water is more aggressive for the oxide grown on 7075 aluminum is likely due to localized attack at magnesium-, zinc-, and copper-rich sites which form in the oxide at undissolved second-phase particles on the surface of 7075.

The smaller effect of the methanol is attributed to the smaller amount of water available to the oxide in this environment. The fact that methanol had a smaller effect on the oxide grown on 7075 aluminum is difficult to explain. The experiments were conducted at the same time and the same source of methanol was used. So, if one assumes that the effect is real, the explanation must lie in the difference between the anodic films grown on the two substrates.

In summary, the data and the comparison with a simple theory of oxide fracture allow the following conclusions to be drawn:

1. The higher the shear strength of the substrate, the more dense the cracks in the adhering oxide.
2. Environment affects the fracture strengths of the adherent oxide films. σ_f becomes lower as the water content of the environment increases. The lowest fracture stresses occurred for distilled water environment.
3. The calculated values of the fracture stress in the various environments were of the order of 300,000-500,000 psi. Calculation of the fracture stress of the film adhering to a 7075 substrate is complicated by an apparent loss in the shear strength of the substrate near the oxide interface.

Acknowledgments

The author acknowledges with pleasure the continued support of ONR Metallurgy Branch through Contract Nonr-3908(00). I would also like to thank my colleague Dr. J. R. Hancock for calling my attention to the simple approach to calculating the oxide fracture spacing and to acknowledge the help of Mr. Sid Hamilton and Mr. Henry Moloney in determining the oxide fracture spacings.

Germanium Oxide Film Growth in $HF:H_2O_2$ Solutions

D. A. Kiewit

Hughes Research Laboratories, Malibu, California

The use of germanium oxide films to protect the semiconductor surface during processing or to electrically passivate the surface in the vicinity of p-n junctions has been suggested on several occasions (1-4). The use of SiO_2 films for these purposes in silicon planar technology is well known. Although germanium oxide films are not useful as diffusion masks because they reduce to the volatile oxide GeO at temperatures above ~600°C, it is worth considering their use in device fabrication schedules which do not involve such high temperatures, such as ion implantation, or to provide a passivating surface film that can be formed after all high-temperature stages in a process have been completed.

In the past several approaches to the problem of growing germanium oxide films on germanium surfaces have been attempted. Thermal oxidation of germanium has been used (3) to grow thin films of the hexagonal modification of GeO_2 on a bare Ge surface or beneath a pyrolytically deposited SiO_2 film (4). Anodization of germanium, especially in nonaqueous solutions, has been used by Wales (2) and others to grow GeO_2 films with resistivities as high as 10^{12} ohm-cm. Hexagonal GeO_2 films have also been formed (5) by the oxidation of germanium in nitric acid solutions more concentrated than 7*N*.

The growth of a glassy, hydrated germanium oxide film in aqueous $HF-H_2O_2$ solutions was first reported by Heidenreich (1), who recommended using the films to protect a germanium surface from contamination during processing.

Experimental

Germanium oxide films were grown on 1-40 ohm-cm n-type germanium wafers at room temperature in a variety of $HF-H_2O_2-H_2O$ solutions in which the HF concentration was varied between 100 and 300 g/liter and in which the H_2O_2 concentration was varied between 4.1 and 37.8 g/liter. B & A electronic grade HF and cp H_2O_2 and 15 Mohm deionized H_2O were used as reagents. The composition of the as-received H_2O_2 was determined with a $KMnO_4$ titration.

After the film was grown, part of it was masked with wax and the unmasked region was then stripped by a 5-10 sec immersion in aqua regia (this stripping procedure was found to remove less than 20Å from an uncovered germanium surface, and introduced a negligible error into the subsequent thickness measurement). The thickness of the germanium oxide film was measured with a Sloan M100 Fizeau-Tolansky type interferometer. The precision of the thickness measurement was about 10%.

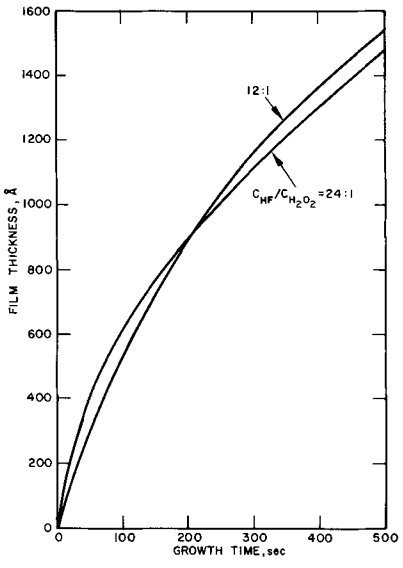

Fig. 1a. C_{HF} = 100 g/l

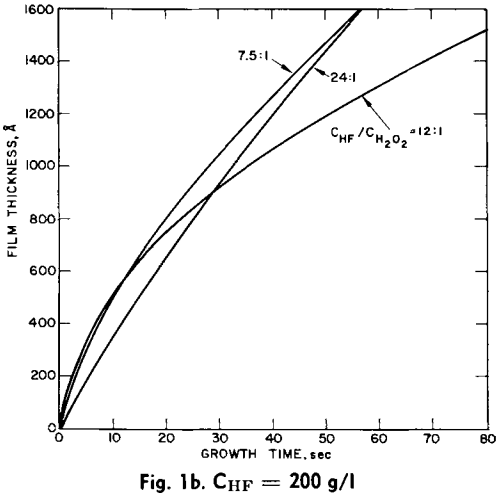

Fig. 1b. C_{HF} = 200 g/l

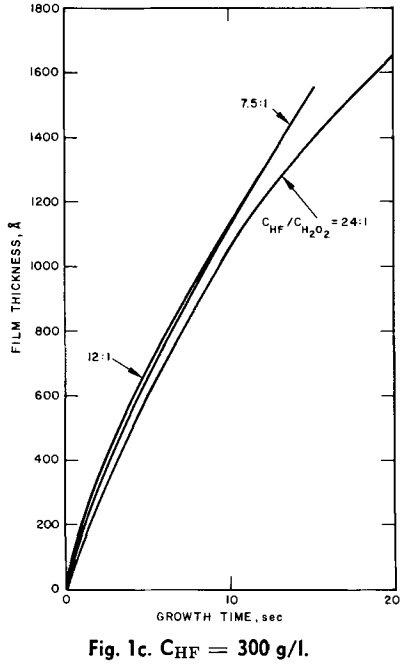

Fig. 1c. C_{HF} = 300 g/l.

Fig. 1. Growth of germanium oxide films in $HF-H_2O_2-H_2O$ solutions of various concentrations.

The thickness of germanium stripped from the wafer in the course of growing a film was measured gravimetrically using a Mettler balance accurate to 0.1 mg. The measured weight changes were generally at least 20 mg, indicating the measurement was precise to within 5%.

Neither the film growth rate nor the associated germanium etching rate depended on the sample resistivity. In the present investigation, mechanically polished surfaces were used for most of the measurements of film growth, but supplementary experiments on chemically polished germanium wafers indicated that the rate was not affected by mechanical damage introduced during polishing.

The growth of germanium oxide films in $HF-H_2O_2-H_2O$ solutions of various concentrations is described in Fig. 1. It is apparent from these data that varying the $HF:H_2O_2$ concentration ratio has little effect on the film growth rate in the investigated solutions, but that films are formed much more rapidly at higher HF concentrations.

Films less than about 400Å thick had pinholes which were clearly visible at 200X. At some other thickness, which depended on the solution, but which never exceeded 2000Å, the film began to crack. Between 400Å and the onset of cracking, the films were smooth, homogeneous, and uniform over the surface of a 2 cm wafer. After the onset of cracking, especially when a solution which grew films very rapidly was used, the film sometimes spalled off the germanium surface and a second film began to grow in its place. In addition, it was found that re-immersing a dried film in the growth solution led to a complete stripping of the film from the substrate before further film growth occurred.

The interference colors of these films agree closely with those predicted from Vasicek's (6) results for a film with a refractive index of 1.607. This value of the refractive index was reported by Kordes (7) for bulk amorphous GeO_2. The agreement between the colors observed in this work with those reported by Wales (2) for anodically grown GeO_2 is not quite as good.

Reflection electron diffraction studies indicate that the films that were grown were amorphous, and a decrease in thickness on heating to several hundred degrees centigrade indicated that they were hydrated. These observations agree with those of Heidenreich (1).

Studies of the rate of germanium etching associated with the film growth are summarized in Fig. 2. These data indicate that faster etching is associated with higher HF concentrations and a lower $HF:H_2O_2$ concentration ratio in the investigated solutions. The observation regarding the $HF:H_2O_2$ ratio must be regarded as tentative because of a lack of corroborative evidence. The lack of a saturation region in these curves indicates that the film does not effectively pro-

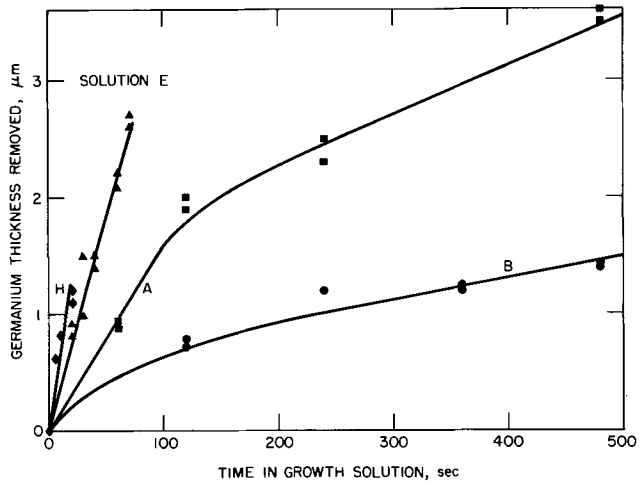

Fig. 2. Rate of germanium etching associated with film growth. A: C_{HF} = 100 g/l; $C_{HF}/C_{H_2O_2}$ = 12. B: C_{HF} = 100 g/l; $C_{HF}/C_{H_2O_2}$ = 24. E: C_{HF} = 200 g/l; $C_{HF}/C_{H_2O_2}$ = 12. H: C_{HF} = 300 g/l; $C_{HF}/C_{H_2O_2}$ = 12.

tect the surface from further etching. No inhomogeneity in etch rate was observed to be associated with the onset of cracking or spalling of the oxide films.

Summary

In view of the partial solubility of these germanium oxide films in HF, the faster growth rate in the solutions with higher HF concentrations was initially surprising. However, a comparison of the film growth rates and the germanium etching rates in the same solutions showed that the substrate is being removed 10 to 30 times more rapidly than the film is forming. Because of this disparity in the relative rates, the faster oxide growth at higher HF concentration is less surprising, as the rate of germanium removal is also higher at high HF concentrations. During growth the germanium oxide film is apparently readily permeable to the species involved in the reactions. This conclusion is supported by the high germanium etch rate both before and after the onset of oxide film cracking; the even, homogeneous etching of the germanium surface after the film has cracked or spalled; and the observed lack of agitation effects on film growth rate. This indicates that the etching and film growth reactions are not limited by mass transport through the films, and that the films do not provide a passivating layer against further chemical attack.

Since simultaneous reactions occurred at several interfaces, and since not all of the reaction products at the surfaces are known, no attempt was made to set up a quantitative model to describe the reaction kinetics. It is apparent, however, that the film growth is not diffusion limited. Hence, one of the steps in the competing processes of coalescence and dissolution of the glassy film must be rate-controlling.

The Estimation of Field Strengths in the Oxide during Conventional and Plasma Anodization

G. Olive, D. L. Pulfrey, and L. Young*

Electrical Engineering Department, The University of British Columbia, Vancouver, British Columbia, Canada

Most authors (1) have supposed that plasma anodization is analogous to conventional anodization in that the oxide film grows due to a process of ionic conduction at high fields, leading to an exponential dependence of ionic current density on field. To test this assumption one needs to be able to estimate the electrostatic field in the oxide from experimental data on oxide thickness and from measurements on the potential of the sample being anodized. The present work is concerned with the very real problems that arise in attempting to relate measurable quantities to the field in the oxide. These problems are only in part analogous to those that occur in the case of wet anodization, but our attempts to solve the problem in plasma anodization leads us to a reconsideration of the problem in wet anodization. As will appear, an important point is what account, if any, should be taken of the free energy of formation of the oxide. Our work is complementary to that of O'Hanlon (2) who has recently pointed out that the method used in much of the previous work on plasma anodization is inadequate and has suggested one approach to solving the problem.

As a start, it may be supposed that a probe is placed in the plasma very close to the oxide-coated electrode, which we take, for definiteness, to be tantalum. The probe could be an electrode evaporated onto a region of thicker oxide, *i.e.*, in the region in which the plasma is perturbed by the current being drawn by the tantalum electrode. Otherwise it could be a macroscopic electrode outside the sheath surrounding the tantalum. It is well known (3) that in some, but not all, plasma conditions the current-voltage characteristic of a probe (Langmuir probe) may be interpreted to give what is known as "plasma potential." Our understanding of this is that, when the probe registers plasma potential, the "macro" or "inner" potential in the plasma is constant near the probe or, at least, does not vary near the probe because of the current drawn by the probe. It would seem that, as regards points in the plasma, or, for that matter, in any phase other than absolute vacuum, potential in this sense does not mean an averaged potential but the potential corresponding through Poisson's equation with a space- and time-averaged space charge density. It is thus a property of a model not a thermodynamic quantity. The measurement of Langmuir's plasma potential corresponds to the same number of each species being removed by the probe as would cross from one side an imaginary plane replacing the probe. If the probe is very close to the tantalum, it is perhaps open to argument whether it could register plasma potential. However, if it could, or if the potential of a more distant probe could somehow be corrected for the systematic gradient of potential in the plasma due to the passage of current and for any potential drop across a perturbed sheath surrounding the tantalum, then the energy diagram of Fig. 1 would seem to apply and

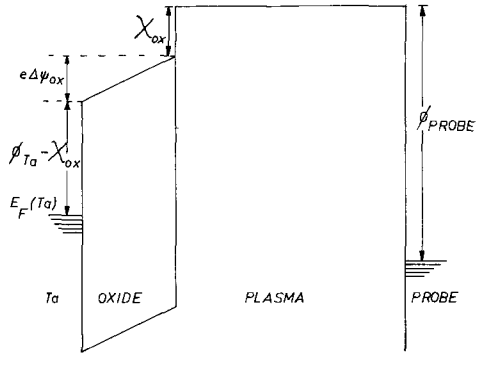

Fig. 1. Energy diagram

* Electrochemical Society Active Member.

$$\Delta\psi_{ox} = V \text{ (Ta-probe)} + \frac{1}{e}(\phi_{probe} - \phi_{Ta})$$

where $\Delta\psi_{ox}$ is the potential drop across the oxide; V(Ta-probe) is the measured (and for the more distant probe, corrected) voltage between the tantalum and the probe, *i.e.*, Fermi potential difference, and the ϕ's are work functions.

The problem may be avoided in part by taking current-voltage characteristics of the tantalum electrode at various oxide thicknesses with respect to some invariant probe which is sufficiently close that random variations in time in the potential gradient through the plasma are negligible. If the phenomena in the plasma sheath near the oxide may be assumed to be the same for a given current density independent of oxide thickness, then at least an incremental field in the oxide can be obtained associated with a given formation current. By starting with a very thin oxide the mean field $\bar{E} = \Delta\psi_{ox}/d$, where d is thickness, can be obtained to some approximation.

The question must now be considered as to whether some account should be taken of the free energy of formation of the oxide. In other words is the electrostatic field as thus estimated in fact the desired quantity for comparison with theory. We refer to standard works, such as Hauffe's (4), for discussion of how the free energy of formation corresponds to gradients of electrostatic potential and of concentrations of reactants through the film in the absence of applied fields. We suggest that if we are comparing experimental results with a model in which high field ionic conduction due to an electrostatic field is considered but in which diffusion is neglected, then we need to consider only the electrostatic field. In this case no account need be taken of the free energy of formation of the oxide. If diffusion or other effects due to concentration gradients need to be taken into account, then we are in further difficulties because the analogy with the wet system breaks down in that in plasma anodization we do not have a system at a uniform temperature; indeed the plasma species need not be even thermally distributed in energy (3). Also, it is quite possible that the reaction involves not neutral oxygen gas but some charged oxygen species in the plasma which are not in equilibrium with the neutral gas, or even at the same temperature. Hence the calculation of the free energy of reaction is to that extent uncertain.

The usual approach to the analogous problem in conventional anodization has been quite different. In this case a quantity which has been called "overfield" has been used. With the cell: Ta/oxide/solution H_2/Pt a hypothetical reversible emf may be calculated from thermal data. After elimination of ohmic potential drops in the solution, the overpotential may be defined as the excess of the cell voltage over the reversible value. The overfield was defined (5, 6) as the overpotential divided by the thickness of oxide. The close relation of the above to the method [proposed in an early paper by Vermilyea (7)] of adding in the "reaction voltage" has been discussed elsewhere (6). By "reaction voltage" is normally understood the hypothetical equilibrium voltage of the cell $Ta/Ta_2O_5/H_2O/H_2$/Pt.) At the reversible potential the overfield is zero but there is no reason why the electrostatic field in the oxide should be zero. Indeed, photovoltaic experiments have been interpreted as showing that the field in the oxide at this potential is such as to oppose the passage of ionic current in the direction causing growth (6). One advantage of the overfield is that it is at least well defined. It is also thermodynamically meaningful, *i.e.*, directly measureable. The other main reason for its acceptance as a useful way of describing experimental results is that it seems to work, in the sense that the overfield for tantalum and niobium (but not zirconium) has been found experimentally to be independent of thickness at constant ionic current density with some reservations about the significance of the data for very thin films (<200Å) (6). This may have been a delusion since one expects, not a constant field, but a transition with increasing thickness from Mott's interface control model to Verwey's model in which the ionic conductivity of the neutral bulk oxide controls the current. However, it seems to us that the argument as given above in respect to plasma anodization suggests that the overfield method works, if it works, by accident; the theoretical model involves only the electrostatic field and hence one should attempt to estimate this field (not overfield) in treating experimental data for the purpose of testing the model.

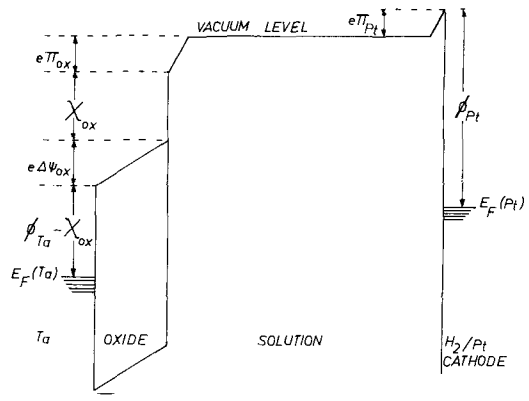

Fig. 2

Figure 2 shows one way of doing this. The difficulty of using the potential within the solution is avoided by using the vacuum level: the energy of an electron at rest just outside a hypothetical vacuum/solution interface. The electrical double layers on the platinum and oxide surfaces contribute π_{Pt} and π_{ox}, respectively. For the equilibrium situation the sum is expected to be constant, thus an equilibrium involving, say, OH^- across the oxide/solution interface would cause the interface pH-dependence of π_{ox} and π_{Pt} to cancel. Hence

$$\Delta\psi_{ox} = (1/e)(E_F(Pt) - E_F(Ta)) - (\pi_{ox} + \pi_{Pt}) + \frac{1}{e}(\phi_{Pt} - \phi_{Ta})$$

$$= V_{over} + V_{rev} - (\pi_{ox} + \pi_{Pt}) + \frac{1}{e}(\phi_{Pt} - \phi_{Ta})$$

where E_F is the Fermi energy, V_{over} is the overpotential for the production of Ta_2O_5, V_{rev} is the reversible cell emf (about 0.8V, tantalum negative). Approximating π_{Pt} by taking the zero charge point as corresponding to zero potential difference (*i.e.*, about 0.2V positive to the hydrogen potential in the same solution for pH about 0 or 1) and with recommended values (8) for the work functions ϕ_{Ta} and ϕ_{Pt} we have

$$\Delta\psi_{ox} = V_{over} - \pi_{ox} + (-0.8 - 0.2 + 5.3 - 4.1)\text{ V}$$

Perhaps the apparent success of overfield has been due to the cancellation of the terms following V_{over} on the right-hand side. The values of the work functions are, of course, uncertain, but, clearly, cancellation is likely to occur within a few tenths of a volt. A lack of cancellation would imply something about the magnitude of concentration changes of reactants across the oxide.

Acknowledgment

The authors thank the U.S. Air Force Avionics Laboratory, Wright-Patterson Air Force Base (Contract F33 615-68-C-1074) for their support for our work on plasma anodization.

Effects of Specimen Size and Configuration in Plasma Anodization

N. Ramasubramanian

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

In plasma anodization the potential of the specimen surface relative to the unperturbed plasma determines the charge carrier collection and hence the oxide growth (1,2). When anodizing a specimen which is large with respect to the mean free path of the plasma particles or is surrounded by a shield, the plasma in its vicinity is perturbed (3, 4). The purpose of this paper is to show that such plasma perturbations and edge effects influence the forming characteristics.

Experimental

A diagram of the Pyrex glass discharge tube and the various probes is shown in Fig. 1. A preoxidized zirconium wire and a cylindrical platinum foil formed the cathode and anode of the tube, respectively. The temperature in the vicinity of the specimens was monitored by a shielded chromel-alumel thermocouple. Oxygen pressures were in the range of 0.77 ± 0.03 Torr; accelerating voltages of 650-800V were used with a discharge current of 20 mA. With water circulating in the jacket the temperature close to the specimens was ~200°C.

The materials zirconium and Zircaloy-2 (Zr-1.5% Sn-0.1% Fe-0.1% Cr-0.05% Ni) were supplied by Wah Chang Corporation and tantalum by Fansteel Metallurgical Company. The specimens were disks of the dimensions shown in Table I. A wire of the same material was spot welded onto the disk. The combination was chemically polished using a nitric and hydrofluoric acid mixture (with or without sulfuric acid) after mechanical abrasion of the exposed face. The wire was insulated by a tight fitting ceramic capillary which in turn was housed in a Pyrex glass tube. In the case of type-B and -D unshielded samples, care was taken to expose a short piece of the wire so that the specimen was isolated from the space charge sheath on the insulation; the area of the exposed wire was a small fraction of the specimen area.

A Moseley X-Y_1-Y_2 recorder and Keithley electrometers were used to measure and plot the current and voltage. Anodization of at least two specimens could be followed simultaneously. In a typical experiment the current-voltage curve for the platinum wire probe was recorded. The floating potentials with the specimens were measured, a fixed anodizing voltage with respect to the tube anode was applied and current-time curves were followed. The platinum probe was cleaned between experiments.

Oxide thicknesses were estimated from a comparison of the capacitance data measured at 1 kHz using 1M NH_4NO_3 solution contacts with similar measurements on wet anodized films. Area/capacitance *vs.* thickness curves were constructed assuming 28 Å/V for zirconia (5) and 17 Å/V for tantalum oxide films (6). The interference colors of the plasma and wet anodized films having the same area/capacitance value were similar.

Key words: plasma perturbation, space charge sheath, diffusion sheath and edge effects.

Results

The potentials referred to are all relative to the discharge tube anode; V_p, specimen potential following anodization and V_w, floating potential of the specimen before anodization.

Specimen area.—Anodization characteristics were compared among specimens whose areas varied approximately in the ratio 1:2:20 (*c.f.* Table I). For specimens of areas 0.3 cm² or less the floating potentials, current decay and Å/V values were in close agreement. These quantities were all different for the large sized type-D specimen. Another observation with all large specimens was the obvious decrease in oxide thickness amounting to ~15% from the center to the edge. With smaller area specimens of type-A, -B, and -C the oxide film was more uniform. The oxide thick-

Type-A specimens of Zr, Zr-2 and Ta were wires 0.8 to 0.9 mm in diameter and 0.1 to 0.13 cm² in area.

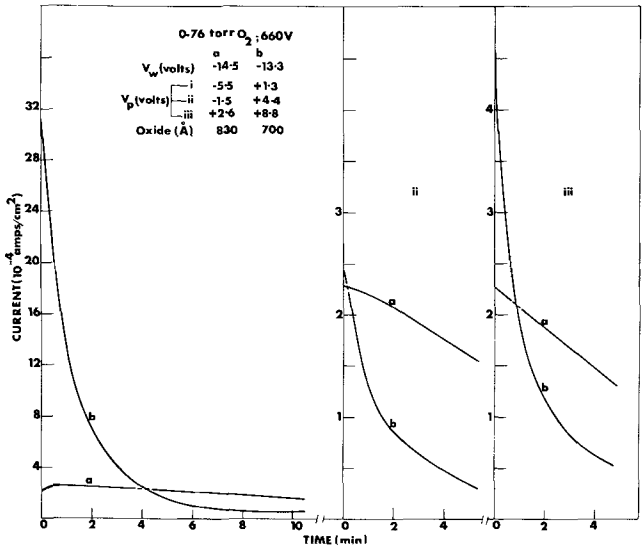

Fig. 2. Plasma perturbation effects; comparison of current-time curves obtained with zirconium samples; a, type-D, 3.56 cm² (perturbed) and b, type-B, 0.285 cm².

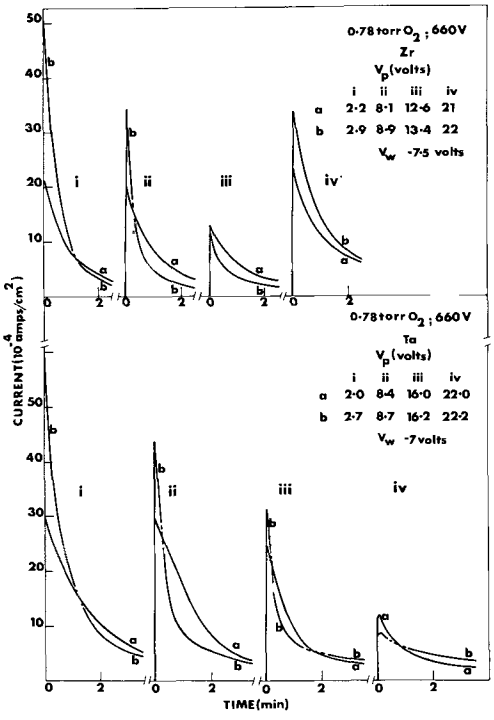

Fig. 3. Comparison of current-time curves; a, unshielded type-B and b, shielded, type-C specimens.

ness quoted here for large area samples is an average one.

Figure 2 shows a typical set of current decay curves and the experimental potentials for zirconium samples. The anodization was done in steps without interrupting the discharge; the curves a were obtained with the type-D large specimen 3.56 cm² in area and b with the type-B specimen 0.285 cm² in area. During the first step there was practically no oxide growth (judged by interference color) on the large specimen in the first few minutes. The current density was very low compared to the smaller area specimen and showed only a slight decrease with time. In the subsequent steps the current showed a considerable decrease with time, almost linear; but the rate of fall, especially in the initial stages, was very low compared to the smaller sized specimen. However, after the experiment the oxide on the large area specimen was thicker and $(V_p - V_w)$ apparently lower.

Edge effects.—The anodizing characteristics of type-C shielded specimens and the usual type-B unshielded specimens were followed simultaneously. In Fig. 3 are shown two sets of data obtained with zirconium and tantalum specimens. Similar results were obtained with Zircaloy-2 specimens. The current density in the case of the shielded specimen was higher when the anodizing voltage in the first step or the increment in it during the subsequent steps ii, iii, etc., was fairly large, about 6V or more. Under such circumstances in the initial stages the current density decreased more rapidly than for unshielded specimens. The oxide film thicknesses were zirconium B-810Å and C-775Å and tantalum B-590Å and C-560Å. In another series of experiments the oxide thicknesses were compared after the initial anodizing step. When the $V_p - V_w$ was ~9V or more the oxide thicknesses with shielded specimens were higher by about 15%. For example, voltages close to those shown in Fig. 3 gave oxide thicknesses for zirconium B-254Å and C-280Å and tantalum B-155Å and C-175Å.

Discussion

The perturbations resulting from the specimen size and presence of a surrounding shield are different in nature and are discussed under separate headings, specimen area and edge effects. There is a fundamental difficulty in applying the probe theory [a review of Langmuir and Mott-Smith's theory, assumptions involved and the technique is given by Loeb (7)] to oxygen plasmas, however, because they contain negative ions in addition to electrons and positive ions. The treatment presented here must therefore be regarded as only approximately correct.

Specimen area effects.—Waymouth (3) has given a detailed treatment of the problem and also reported experimental evidence supporting his theory (8). The conclusions can be stated in brief as follows. When probes of dimensions several times the mean free paths of electrons and ions are used the large drain of carriers leads to plasma perturbations in their vicinity. As a result (*i*) charge collection by the probe is determined by free fall space charge sheath and also a diffusion controlled presheath; (*ii*) in the perturbed region there is a large reduction in the density of carriers; and (*iii*) the plasma potential changes by ΔV at the sheath boundary; this change which is negative for probe potentials near floating potential, passes through zero, and becomes positive for probe potentials near plasma potential.

In order to compare the perturbation effects caused by the presence of various probes, it is convenient to treat them as spheres wtih the same surface areas (3). The electron mean free path in the present study is about 1.5 mm and therefore probes of area $>>0.3$ cm² introduce plasma perturbations. A schematic diagram of the changes in potential difference between the specimen surface and the plasma during constant voltage anodization for the unperturbed and perturbed cases is shown in Fig. 4. With increasing oxide thickness the specimen surface potential tends towards the floating potential V_w.

The results shown in Fig. 2 can be explained as follows. During the first anodizing step there is practically no oxide growth on the large area specimens because plasma perturbations result in a lowering of carrier density and a shift $+\Delta V$ in plasma potential which leads to only a small potential drop in the space charge sheath. In the subsequent steps with increase in the applied voltage this potential drop is larger than in the first step and anodization proceeds. The degree of perturbation decreases during anodization with the decrease in current and for comparable specimen surface potentials the potential drop in the space charge sheath is lower for the large sized specimen than that for the small area one. Therefore, in the former case

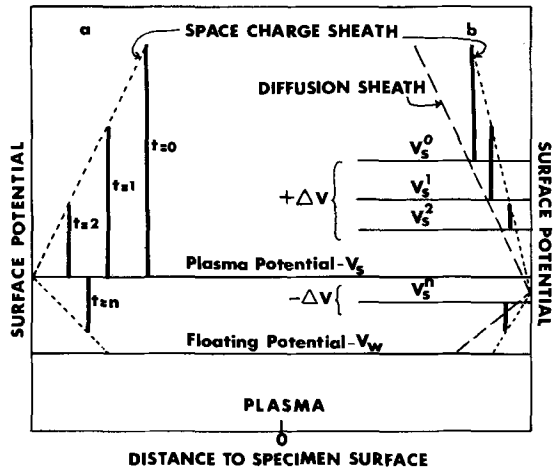

Fig. 4. Schematic diagram of changes in potential difference between the specimen surface and plasma (shown in solid vertical lines) during anodization; a, type-B specimen and b, type-D specimen (perturbed); t, time of anodization for type-B specimen; V_s^0 . . . . V_s^n, potentials of the perturbed plasma for specimen surface potentials at the respective t values

one would expect the occurrence of sputtering effects (1) to a less extent, and this might be one of the reasons for obtaining a higher Å/V ratio with the large sized specimens. In the perturbed and unperturbed plasmas the ratio of the electrons, negative ions and positive ions is also likely to be different.

Edge effects.—In plasma anodization evaporated metal specimens have been used in which the metal was surrounded by an insulating glass substrate (9,10). Such a structure is similar to the shielded specimens in the present study. The insulating shield operates at the floating potential and therefore has a negative field associated with it. One would expect a retarding influence on the negative carriers and thus a lowering of the charge collection by the shielded specimen (4). The Å/V ratio is seen to vary between the shielded and unshielded specimens depending on the size of the voltage increment for the anodizing step. However, the ratio is higher for the shielded specimens when the forming voltage in the initial step and the increment in it during the subsequent steps of anodization are large. It is suggested that ionization occurs in the space charge regions, resulting from the potential difference between the specimen surface and the insulating shield. As the anodization proceeds the specimen surface moves towards floating potential (2), the potential the shield is operating at and therefore the extent of the ionization process decreases. It should be mentioned here that the size of the Pyrex glass shield (OD 6 mm) is not large to introduce plasma perturbation effects discussed under "area effects."

Forming Voltage in Plasma Anodization

N. Ramasubramanian

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

The significance of the floating potential in determining the forming voltage in plasma anodization was reported by O'Hanlon (1). In order to estimate the surface potential of the anodized specimen it was suggested that a correction could be applied based on the i x V characteristics for the specimen obtained prior to anodization. The validity of such a correction is questionable on the following grounds: (*i*) the i x V characteristics of an anodizable specimen cannot be traced out at potentials positive to the floating potential without risking oxidation; (*ii*) plasma characteristics change with time of operation of the discharge tube; and (*iii*) work functions of the materials concerned are important in determining the various potentials measured and these differ and/or change during anodization.

Results

Aging of the discharge tube.—The experimental procedure has been described elsewhere (2). At constant gas pressure the acceleration voltage needed to maintain a constant plasma current increased with operating time of the discharge tube. The plasma characteristics were evaluated from the i x V curves obtained for the platinum wire probe; these changed with the aging of the tube. The values of V_w, floating potential, and V_s, plasma potential, become more negative, and T_-, the slope of the log i_- (negative carrier current), *vs.* potential plots decreased. In plasmas of electrons and positive ions $1/T_-$ is proportional to the electron temperature. After the discharge tube had been in operation for more than about 10 hr the presence of a film deposited on the platinum anode was detected by its interference color. This film was soluble in HF-HNO_3 mixture.

i x V Characteristics of the platinum probe.—Anomalous behavior was observed during current-voltage measurements with the platinum wire probe. At potentials slightly positive to V_w, the current showed an increase with time when the voltage was kept constant, and the i-V characteristic showed the presence of a negative resistance region. The probe characteristics changed completely after 10-15 min of standing in the

plasma. No anomalies were then detected in the current-voltage sweeps. Figure 1 shows the difference between current-voltage curves for the platinum probe obtained at the beginning and at the end of an experiment. Curves obtained with a type-B Zircaloy-2 specimen before and after anodization to an oxide thickness of 700Å are also included for purposes of comparison. The V_w measured with the platinum was closer to the Zircaloy values after the experiment. The similarity between the curves b and d should be noted. At potentials slightly negative to V_w the curves are concave to the voltage axis, and they show a gradual rise at potentials slightly positive to V_w.

If, after the experiment, the platinum probe was cleaned by dipping in a HF + HNO_3 mixture, the i-V characteristic reverted almost to that in curve a (small differences were due to changes in the plasma condition). The plasma characteristics were evaluated by analyzing curves a obtained at the beginning of experiments.

Anodization of zirconium, Zircaloy-2, and tantalum.— In a plasma the V_w values obtained with tantalum, zirconium, and Zircaloy-2 probes were more negative than those obtained with platinum, by about 5-7V. In a typical experiment, the first anodizing step was to polarize the specimens to potentials slightly positive with respect to the floating potentials obtained with them, but still negative with respect to the floating potential measured with a platinum probe. The data from two such experiments using type-B specimens are shown in Fig. 2; the values of the various potentials in volts are tabulated in the insert. Oxide thicknesses following the anodization were, case a Ta-80Å and Zr-170Å and in case b Zr-190Å and Zr-2-160Å. The $V_p - V_w$ values for Ta in set a and Zr-2 in set b were less than the respective ones for Zr, but the initial current densities were higher.

Discussion

In plasma anodization a knowledge of the plasma characteristics is essential because they determine the reactions occurring at the plasma-oxide interface

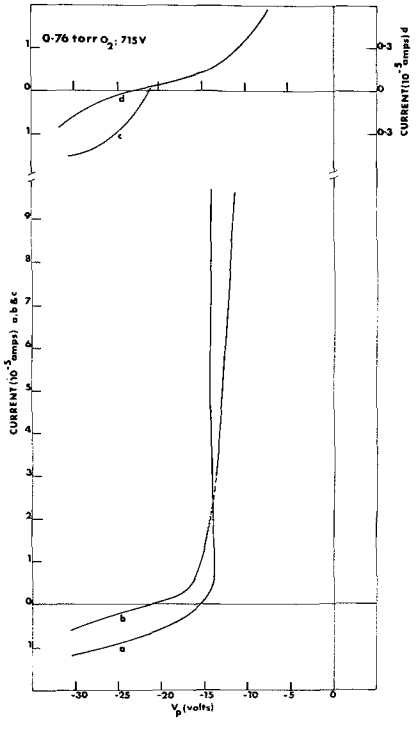

Fig. 1. Current voltage characteristics for the platinum probe (a and b) and Zircaloy-2 specimen (c and d); at the beginning of the experiment (a and c) and after anodizing Zircaloy-2 over a period of 15 min (b and d).

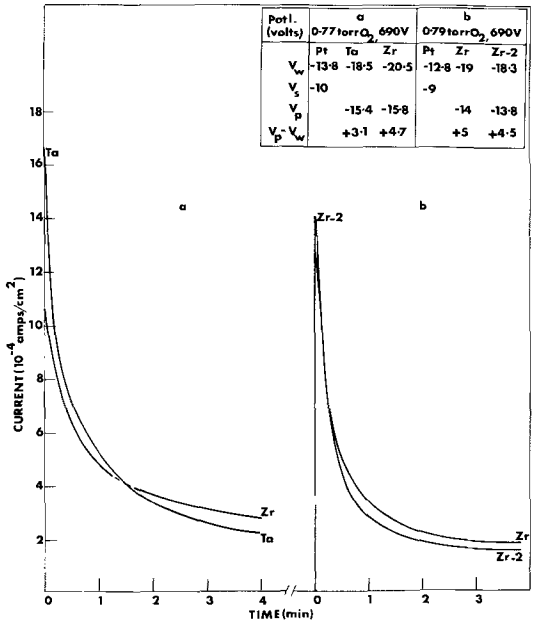

Fig. 2. Current-time curves for type-B specimens; specimen potentials negative to plasma potentials but positive to floating potential; floating potentials measured before anodization are quoted.

(1-3). The plasma characteristics can be evaluated from the i x V curves obtained for an inert probe. However, the potentials recorded during such measurements might be in error due to work function differences and/or changes in the work functions brought about by deposition of a sputtered film, ion bombardment, etc. (4). For example, in the cases of zirconium, Zircaloy-2, and tantalum the floating potentials measured were negative by 4V or more relative to that for platinum. Therefore, specimen potentials relative to a floating platinum probe do not give the true anodizing voltages as has been claimed (5), and the errors involved in such measurements are quite large.

The work function of platinum bombarded by positive oxygen ions has been shown to be higher by 1.2 eV than that of a clean surface (6). This may be responsible for the negative resistance anomaly observed in the current-voltage characteristics of the platinum probe. Then the actual difference between the plasma potential and floating potential would be higher by ~1.2V than the experimental values (*c.f.*, table inserted in Fig. 2), assuming that for a i-V sweep the V_w measured refers to positive ion bombarded and V_s determined refers to clean platinum surfaces. In the negative resistance region (cleaner platinum surface) the measured potential shifts to a more negative value. The deposition of material sputtered off the zirconium wire cathode is an additional process giving rise to changes in the platinum probe characteristics during an experiment and in the plasma characteristics with the aging of the discharge tube.

The variation of the plasma and wall potentials with the type of material used to measure them and the time of operation of the discharge tube is shown schematically in Fig. 3. It is seen that the higher the work function of the probe material the less negative are the measured potentials.

The errors in anodizing voltage measurements are due to (*i*) changes in the plasma characteristics during an experiment and (*ii*) work function differences between the anodized and unanodized specimens which is unknown. These can be eliminated to a large extent by taking the potential of the specimen relative to its floating potential (obtained from i x V measurements) at the end of the experiment. The specimen surface

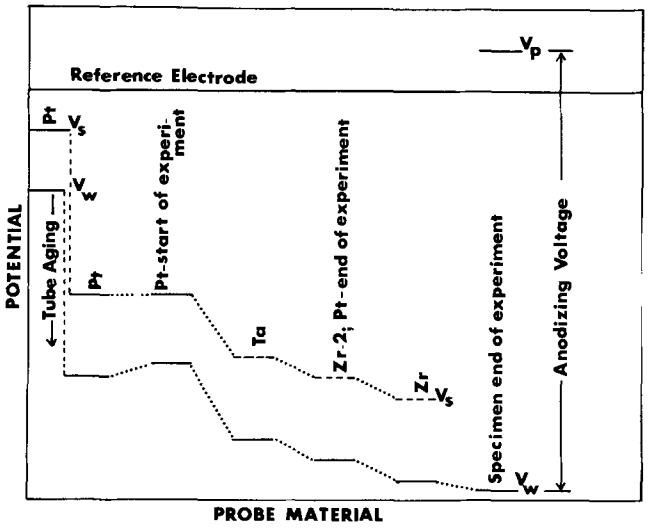

Fig. 3. Schematic diagram of the variation of plasma and floating potentials for a fixed plasma current and gas pressure with time of operation of the tube and the probe materials used.

potential would be closer to the floating potential of the plasma at the end rather than at the start of anodization.

The anodizing voltages, $(V_p - V_w)$ values given in the table in Fig. 2, are not very large compared to the corrected $(V_s - V_w)$ value for platinum. In the case of tantalum the anodizing voltage is less than the latter. It follows then that anodic oxide growth is observed at potentials negative to the plasma potential but positive to the floating potential; a conclusion which supports the model proposed by O'Hanlon (1). Therefore during i x V measurements at potentials positive to floating potential the specimen is likely to anodize; the measured potentials are thus not specimen surface potentials as assumed by O'Hanlon, but include a definite drop across the oxide grown during the measurements. The surface potentials would obviously be less than the measured potentials.

Response of Electroluminescent ZnS:Mn,Cu,Cl Films to Rectangular Pulse Excitation

John L. Plumb[1]

Department of Electrical Engineering, University of Connecticut, Storrs, Connecticut

and Robert F. Cotellessa*[1]

Department of Electrical Engineering, Clarkson College of Technology, Potsdam, New York

Zinc sulfide doubly activated with Cu and Mn is important as an electroluminescent phosphor in that it is responsive to excitation by a d-c field. The emission spectrum of such phosphors is due to the Mn activation and peaks at approximately 5850Å. The excitation of the Mn luminescence center is generally believed to occur without ionization of the center. The role played by the Cu activation in the excitation process is not completely understood.

Electroluminescence in evaporated ZnS:Mn,Cu,Cl films was first reported by Thornton (1). A number of investigators have studied the response of such films to d-c excitation (2-6). Vecht *et al.* (7) have reported quantum efficiencies greater than unity or brightness of 1000 ft-L with d-c excitation of electroluminescent panels containing a ZnS:Mn,Cu,Cl powder set in an organic binder.

When d-c voltage is applied to an evaporated film of ZnS:Mn,Cu,Cl, a change in film characteristics takes place. Thornton (2) reported a complex response to reversal of the polarity of applied voltage, with many seconds being required to reach equilibrium. The occurrence of an electroluminescence forming process on initial application of voltage was reported by Goldberg and Nickerson (3). Soeya (8) has further investigated these slow transient effects.

Comparatively little has been published relating to the response of formed electroluminescent ZnS:Mn,Cu,Cl films to repetitive unidirectional pulse excitation. Thornton (2) has observed a dependence of emission rise time on voltage-pulse amplitude and a dependence of emission decay time on voltage-pulse repetition rate. In this paper are reported the results of varying over wide ranges the duration, repetition rate, and amplitude of the voltage pulse excitation.

Film Preparation and D-C Characteristics

Films of ZnS:Mn,Cu,Cl, approximately 5μ in thickness, were formed by a two-step evaporation-firing process similar to that described by Thornton (9). Luminescent powder, activated with 1.0% Mn, 0.3% Cu, and 1.0% Cl by weight, was evaporated and deposited onto a warmed tin-oxide-coated glass substrate. The deposited film subsequently was baked at a temperature between 650° and 675°C in contact with luminescent powder. An aluminum electrode was deposited to complete a sandwich cell configuration.

[1] A major part of this work was done while the authors were with the Department of Electrical Engineering, New York University, Bronx, New York.
Key words: electroluminescence, zinc sulfide, phosphors, pulse excitation, manganese.

The cells were subjected to a thorough electrical forming process. With d-c voltage applied (the Al positive with respect to the tin oxide), the cell current decreased from its initial value with a simultaneous increase in light emission. The change was rapid at first and slowed to a very gradual change which continued over many hours. The formed cell was rectifying and light was emitted in the reverse direction of current flow (Al electrode positive).

The dependence of cell current on applied reverse voltage obeyed closely the exponential relation

$$I = a \exp b\sqrt{V}$$

where a and b are constants for a given cell. The dependence on voltage of the ratio of light emission to cell current was best described by the relation

$$L/I = A \exp (-B/\sqrt{V})$$

where A and B are constants for a given cell.

Pulse Excitation

Unidirectional rectangular voltage pulse excitation was applied to the electroluminescent cells, with the Al electrode positive with respect to the tin oxide electrode. The voltage rise time (to 90%) and fall time (to 10%) were 0.2 μsec or less. The current pulses were monitored. An initial peak occurred at the leading edge of the current pulse, due to a small cell capacitance, and this component of current decayed with a fall time of 1-2 μsec.

A 1P21 photomultiplier was used to detect light emission. To obtain a time-average of light emission, or integrated light output, the average of the photomultiplier current was measured. To observe the actual light pulse, or brightness waveform, the photomultiplier output was connected by a short cable to an oscilloscope. A variable shunt resistance permitted adjustment of the detector response time, which was reduced beyond the point where it had any effect on the shape of the light pulse.

One light pulse was emitted for every voltage pulse. At voltage-pulse durations or pulse widths of several milliseconds, emission was initiated at the leading edge of the voltage pulse and the brightness increased with a risetime of the order of 1 msec to an equilibrium value. Emission was extinguished at the trailing edge of the voltage pulse, and the brightness decayed to zero. At short pulse widths, the brightness continued to increase for a period of time following the trailing edge of the voltage pulse. The waveforms of the brightness for a pulse amplitude of 32V are shown in Fig. 1.

The decay time, to 1/3 of peak brightness, of the light pulses was 0.75 to 0.80 msec. This decay time was independent of voltage-pulse duration, repetition rate, or amplitude.

The dependence of average light emission on voltage-pulse duration, or pulse width, varied from an approximately linear relation to a dependence somewhat greater than linear (a power greater than one) from cell to cell. Log-log plots of light emission *vs.* pulse width for a typical cell are shown in Fig. 2 for several different voltage-pulse repetition rates, or frequencies. The linear character extends to pulse widths as low as 0.01 msec. It is also evident that the light emission is determined largely by the duty factor of the pulse excitation, *i.e.*, the fraction of a cycle in which nonzero voltage is applied. A semilog plot of light emission *vs.* pulse width at a constant duty factor of 0.2 is shown in Fig. 3 for two cells. The light emission passes through a broad maximum and does not change greatly as pulse width is varied from 2 to 0.02 msec. The same behavior was observed in all ZnS:Mn,Cu,Cl cells. At a pulse width of 0.01 msec, and a frequency of 2000 pps, the emission decreases with a decrease in pulse width and simultaneous increase in frequency. A pulse width of 0.01 msec is yet several times longer than the 0.001-0.002 msec fall time of the capacitive component of current.

The dependence of average light emission on frequency at constant pulse width was approximately linear. Log-log plots of emission *vs.* frequency for three different pulse widths are shown in Fig. 4 for a typical cell. Also shown in the figure is the measured emission with d-c excitation at a voltage equal to the voltage-pulse amplitude. At a frequency of approximately 1000 pps, the rate of increase of emission with frequency begins to fall off. At this frequency the ex-

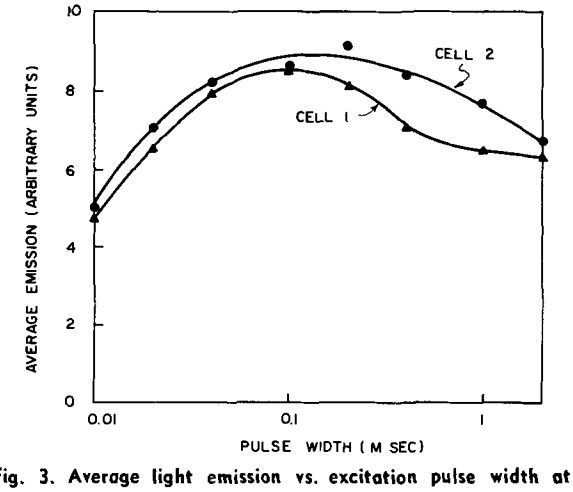

Fig. 3. Average light emission vs. excitation pulse width at a constant duty factor of 0.2 for cells 1 and 2.

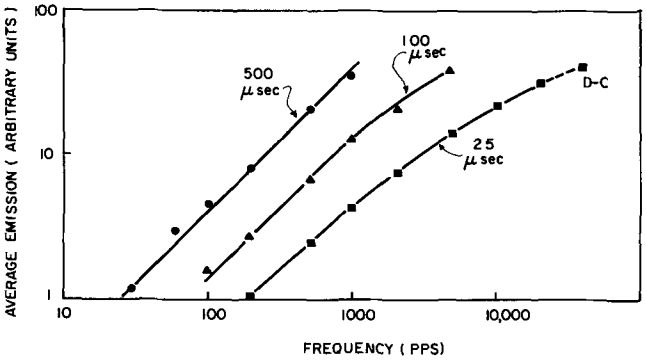

Fig. 4. Average light emission vs. excitation pulse repetition frequency at different pulse widths for cell 2.

citation period is 1.0 msec, *i.e.*, the approximate decay time of the light pulse.

The emission spectrum was recorded at room temperature for varying combinations of pulse width and frequency. No change was observed in the spectrum as pulse width or frequency were changed. The emission peak occurred at approximately 5850Å.

The dependence of average light emission on voltage-pulse amplitude appeared to be the same as the dependence on d-c voltage with d-c excitation. This relationship is shown in Fig. 5, in which the ratio of emission to cell current is plotted *vs.* the reciprocal of the square root of V_T, where V_T is the sum of pulse amplitude and d-c bias voltage. There was some enhancement of emission by this d-c bias voltage. The increase in light emission, obtained when the d-c bias voltage is increased, cannot be accounted for solely as d-c emission produced by the d-c voltage; the emission is enhanced to a significantly greater degree. The enhancement mechanism is possibly the same as that responsible for the enhanced electroluminescence resulting from the simultaneous application of a-c and d-c voltage to phosphor powder cells (10).

In some cells the Mn was omitted to obtain a ZnS:Cu,Cl film, and in others the Cu and Cl were omitted to obtain a ZnS:Mn film. The response to pulse excitation of the ZnS:Cu,Cl film, as determined by the effects of varying voltage-pulse duration, repetition rate, and amplitude, was the same as that of ZnS:

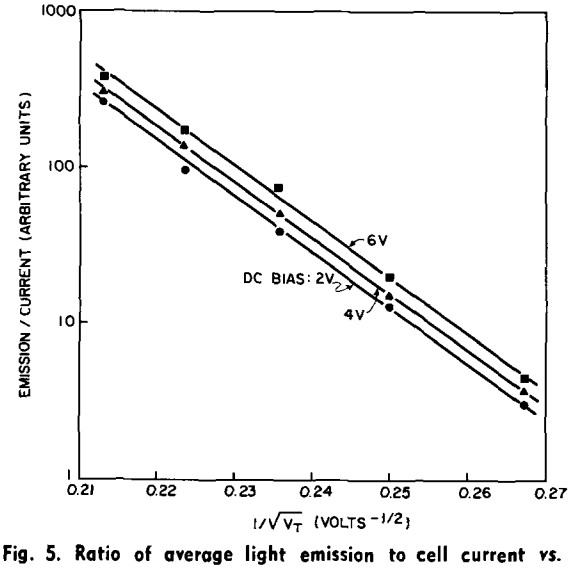

Fig. 5. Ratio of average light emission to cell current vs. the inverse square root of the sum of excitation pulse amplitude and d-c bias voltage for cell 2.

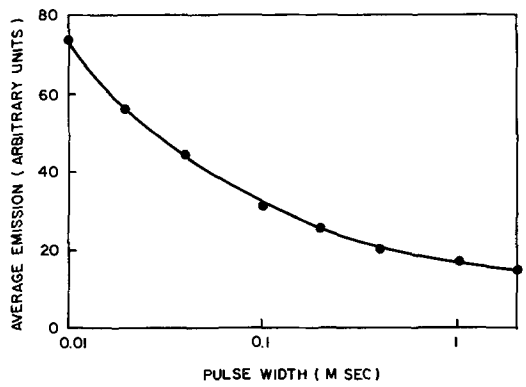

Fig. 6. Average light emission of a ZnS:Mn cell vs. excitation pulse width at a constant duty factor of 0.2.

Mn,Cu,Cl films. However, the light emission with either pulse or d-c excitation, was at least an order of magnitude less in the ZnS:Cu,Cl cells and contained shorter wavelength components.

The ZnS:Mn films did not require forming; the d-c resistance was high when voltage was first applied. Some films, of very high resistance, were not d-c electroluminescent. The emission with pulse excitation is plotted *vs.* pulse width at constant duty factor in Fig. 6. At constant duty factor, the light emission increases with increasing frequency and decreasing pulse width. This behavior is different from that of the ZnS:Mn,Cu,Cl films as demonstrated in Fig. 3. The emission apparently results partly from a-c electroluminescence that is more strongly dependent on the repetition rate of the voltage pulses than on their duration. The emission was three or more orders of magnitude less than in the ZnS:Mn,Cu,Cl cells.

Conclusion

The emission rise in ZnS:Mn,Cu,Cl phosphor films on application of a d-c field takes place in approximately 1 msec. The emission rise time and decay time are independent of duration, repetition rate, and amplitude of applied d-c pulses, as in the shape of the emission spectrum.

The excitation process does not exhibit the same slow response. The integrated light output with pulse excitation is approximately linearly dependent on pulse widths to values as low as 10 msec. It is approximately linearly dependent on frequency to values where the interpulse time approaches the emission decay time. The integrated light output is determined largely by the fraction of time voltage is applied.

Some Evidence for Duplex Film Structuring Within the Anodic Alumina Barrier Layer

G. A. Dorsey, Jr. (pp. 466-471, Vol. 116, No. 4)

Robert S. Alwitt[1]: It might be of interest that the secondary phase described by Dorsey is not always obtained upon anodization of aluminum in boric acid electrolyte at 90°C. We anodized chemipolished, etched, 99.99% Al at 1.7 mA/cm^2 in aqueous 100 g/liter H_3BO_3 at 90°C. Film formation was stopped and the specimen removed when the cell voltage reached 200V. The index of refraction and thickness of the oxide film were calculated from ellipsometric measurements made at two angles of incidence. For a homogeneous film, the calculated values will be independent of the angle of incidence while a duplex film will have apparent properties that vary with the angle of incidence. The following results were obtained:

Angle of incidence	Refractive Index	Thickness (Å)
50°	1.772	2534
60°	1.787	2501

The good agreement between the two sets of data is strong evidence for the absence of a duplex film.

The major differences between this experiment and those performed by Dorsey are the current density for film formation and the absence in our experiment of any final period at constant voltage. Perhaps the second factor is the important one. From the relation between current and time for barrier film growth at constant voltage,[2] it was estimated that, at the conditions used by Dorsey, the time to reach the final current at 90°C should have been about 30% longer than the time at 60°C. This compares with a fivefold difference in the observed times. Apparently some process occurred during this period at 90°C that interfered with barrier film formation.

Dorsey refers to the primary barrier layer as an aluminum oxide trihydrate, based on his earlier interpretations of *IR* spectra.[3,4] The most convincing evidence for such a composition would be a weight loss at an elevated temperature equal to the proposed water content. Dorsey has not shown this, presumably because he thinks the iodine-methanol or bromine-methanol solutions used to isolate the oxide may alter their apparent water content.[5] We would like to point out that Bernard and Randall used this technique to measure the water content of hydrated aluminum oxide films.[6] The results were the same as those obtained by an independent method. This technique was also found to permit quantitative recovery of anhydrous aluminum oxide films.[7] Thus, there is no evidence that these methanol solutions either remove or introduce into the oxide any volatile matter.

Several years ago, we reported results on the weight loss at 900°C of isolated aluminum oxide films.[7] Films formed to 200V in aqueous H_3BO_3 solution at 90°C had a weight loss of 1.2% after 2 hr at 900°C. Clearly, these films contained no significant amount of trihydrate. Recently, the *IR* spectra of aluminum oxide films have been interpreted in a way that is consistent with these results.[8]

G. A. Dorsey, Jr.: Considering that Alwitt's anodizing conditions (sevenfold higher current density and failure to allow current-voltage equilibrium) were such as to minimize any "secondary-phase oxide" barrier layer formation, it is not surprising that none was found. However, he presents only two pieces of data and apparently disregards the dependence of ellipsometric data on (*a*) depth of penetration effects and (*b*) angle dependence effects pertaining to the proper measurements of optical constants.[9]

A recent paper by Vol'fson and Pilyankevich[10] does, however, show the same primary-secondary phase barrier layer relationship, using electron-optical data: their term for the "secondary phase" is pseudo-barrier layer. Figures 2 and 5 of their paper, plus a composite drawing in their Figure 6, are in good agreement with the photomicrographs shown in the paper that is the subject of this discussion; their further discussion follows a close parallel with that paper and another published earlier.[11] But such evidence for duplex barrier layer structure is not without precedence. Brock and Wood[12] found at least four barrier layer regions of characteristic a-c resistivity with the outer *ca.* 20% of the coating generally permeable or porous. Grosskreutz and Shaw[13] found an "ultrastructure" at the barrier layer surface, also suggestive of duplex film formation.

Further, the apparent transition sequence from primary to secondary phase barrier layer (with subsequent porous layer formation) is indirectly suggested in the data of Hunter and Fowle,[14] who found that the effective thickness of the barrier layer decreased on sealing under conditions where dissolution of alumina should be negligible. Also, Diggle, Downie, and Goulding[15] found that changes in the effective thickness of the barrier layer (decreases) are a field-assisted process rather than one attributable solely to chemical dissolution.

Regarding Alwitt's reliance on the methanol-iodine film isolation technique, there is (contrary to his statement) ample evidence to at least point with caution toward this procedure. Erdey *et al.*[16,17] point out that halogen-containing metal solvents (they used methanol-bromine) also attack $Al(OH)_3$ and are not inert toward altering the original barrier layer structure. A comparison of their XRD and DTG data show that both amorphous and crystalline aluminum trihydrates are at least partially decomposed when that reagent is used to isolate a barrier layer film.

Alwitt's own paper[18] cites this film isolation procedure in connection with weight loss measurements

(water content) apparently obtained by re-weighing stripped films following a 2-hr bake at 900°C. He reports *ca.* 1.2 w/o (weight per cent) water content with this technique. However, it has long been recognized that aluminas should not be cooled and re-weighed until they have come to equilibrium using at least 1200°C.[19] Otherwise, low weight loss values will be found when the alumina takes up water again on cooling or, in the case of barrier layer oxides, on immediate re-exposure to atmospheric humidity.[20]

There is no substitute for good TGA/DTG data; convincing evidence for a possible trihydrate composition, as Alwitt states. Lacking good data to report, one can only point out that various other data are suggestive of a trihydrate composition. This laboratory still does not have the necessary equipment to obtain a thermogram showing the complete weight loss/water content of barrier layer oxides, although a substitute method (for partial water content) was devised.[20] However, we now feel compelled to release data that were obtained much earlier, but not reported since they were strictly of an exploratory nature. These data were obtained for us by the Perkin-Elmer Corporation, using their TGS-1 thermobalance with a 40°C/min heating rate, and reportedly with helium purging, to 650°C.

Sample	Weight loss ($\mu g/cm^2$) at equilibrium (650°C)		Theoretical weight loss ($\mu g/cm^2$)
	Sample A	Sample B	
100V barrier layer coating intact on alloy 1199 foil	10.8	13.5	13.1 Assuming 14Å/V with a density of 2.7 g/cm^3, and assuming a uniform trihydrate composition

These data should not be viewed as anything other than a cursory examination. By now, we had hoped to have the necessary instrumentation to prepare a thorough report that might have some value toward answering Alwitt's second comment: his criticism of a much earlier paper[21] where *IR* data suggested a hydrogen-bonded cyclic trihydrate barrier layer composition, and one that appeared to consist of two structural phases.

An examination of the literature will, however, reveal that this suggested composition is still within reason. Grunwald and Fong[22] favored just such a hydrogen-bonded cyclic trihydrate dimer/polymer structure for soluble alumina in acid solution, at least near pH3 (a condensed form of this, as with the barrier layer film, does not seem unreasonable). Regarding the composition itself, Erdey *et al.*[16,17,23] report XRD, DTG, and dissolution rate data to show that the anodic alumina barrier layer film consists of at least 35 w/o $Al(OH)_3$ (at least 25% amorphous trihydrate) plus up to 14% monohydrate, with the balance consisting of γ-alumina and presumably anhydrous. Bogoyavlenskii[24] and Shreider[25] also report trihydrates in the barrier layer.

Schwabe[26] found that hydrogen ion was forced from the alumina barrier layer on reanodization (equivalent to at least 18 w/o water), while Brock and Wood's data[12] suggested at least some hydration phenomena, which increased outward to the coating surface. And, since barrier layer oxides are often reported to be γ-alumina, it might be well to point out that David and Welch[27] found that a small proportion of combined water was essential to stabilize the spinel-type γ-phase of both Fe_2O_3 and Al_2O_3. Even with an ostensively nonaqueous electrolyte, Wood and Patrick[28] found that trace amounts of water exert an influence on film growth rate and appear to be necessary for uniform film growth of thick coatings.

This still provides only indirect and inconclusive evidence for the earlier speculation[21] regarding barrier layer composition and structure. Alwitt does, however, cite an excellent and generally thorough paper by Vedder and Vermilyea[29] within which the authors present yet another interpretation of the barrier layer 960 cm^{-1} *IR* absorption band. They attribute the absorption to a translational mode (lattice vibration or "liberation" mode) of anhydrous alumina: to an absorption that has been shifted upward to an abnormally high frequency by surface polarization effects. Their discussion is based on the work of Berreman[30] who showed such an effect for thin films of lithium fluoride. This is an interesting possibility, but necessarily contains assumptions (and is lacking in data) that seem to make this equally speculative with other interpretations. One might note that Barker[31] found such liberation modes in Corundum, but these were weak absorptions at longer wavelengths and were polarization-sensitive. Gamo,[32] however, attributed the 920 cm^{-1} band of $Al_2(SO_4)_3 \cdot 18H_2O$ as due to hydrogen-bonded water coordinated to aluminum, while Pliskin and Lehman[33] found that the Si-OH bending vibration is near 930 cm^{-1}, also in a hydrogen-bonded system.

Marker Techniques for Studying the Mechanism of Scaling of Metals Based on the Use of the $O^{18}(p,n)F^{18}$ Nuclear Reaction

J. B. Holt and L. Himmel (pp. 1569-1580, Vol. 116, No. 11)

A. Brückman, S. Mrowec, and T. Werber[34]: Investigations on the contribution of individual reactants in the over-all process of the transport of matter through scales formed on metals and alloys, as well as research works on the mechanism of these processes, have been developing for years our knowledge about the mechanism of gaseous corrosion of metallic materials. These investigations also bring valuable (and sometimes not obtainable by other methods) information about the type of defects present in crystal lattices of oxides and sulfides.

In view of the importance of this problem for the physics and chemistry of the solid state, many experimental and theoretical papers discussing the methods of investigations in this field have been published in recent years. This problem is also dealt with in the paper presented by Holt and Himmel. In it, the authors present a detailed analysis of methods used today in investigating the contribution of individual reactants in the process of scale formation with the aid of neutral and radioactive markers. On the background of these considerations, the authors present their own method consisting of the use of a stable and radioactive isotope of the oxydans in the process of two-stage oxidation of metal specimens. The method involves preliminary oxidation in a medium enriched in the active isotope and then in a normal medium. After having stopped the reaction, the distribution of the active isotope in the scale is determined autoradiographically. In view

of the lack of an appropriated radioactive isotope of oxygen, the stable isotope O^{18} is used and transformed into the radioactive isotope F^{18} according to the nuclear reaction $O^{18}/n,p/F^{18}$.

Holt and Himmel have applied their method—to check its applicability—in investigating the share of diffusion of individual reactants in the process of growth of oxide scales on Fe and Zr and on Fe-Pt alloys. On the basis of obtained results, Holt and Himmel came to several methodological conclusions and to conclusions concerning the mechanism of reactions under investigation. Several of them arouse some objections and some suggestions must be directly corrected.

According to the suggestion of Holt and Himmel, the isotope of the oxidizing element shall be used in the process of two-stage oxidation in such a way as to mark the primary formed of the reaction product, similarly as in the conventional marker method.

This method leads—as mentioned also by the authors—to unambiguous conclusions only in cases where the scale layer is compact on its whole cross section and adheres strongly to the metal surface. In cases of formation of scales which are built up of two layers with a porous inner one, the method proposed by Holt and Himmel is useless or leads to alternative conclusions only. Himmel and Holt are therefore suggesting that unambiguous results can be obtained from marker experiments (carried out by the conventional method or by the method consisting of use of radioactive isotopes) only in the case of compact monolayer scales characterized by a very good adhesion to the metal surface. This method is therefore principally useless in investigating the mechanism of heterophasic scale formation on metals and alloys. In conclusion, Himmel and Holt formulate the conditions which must be fulfilled in preparing the specimens for investigation if the formed monolayer scale is to be compact and adhere to the metal surface.

Himmel and Holt are doubtless right when they insist that the mobilities of individual reactants in the lattice of the oxidation product can be rationally determined by marker methods only in cases of monolayer scale formation. In this case, no other methods are needed, however, than those consisting of the conventional marking of the metal surface with neutral substances, as mentioned also by the cited authors in their paper.

On the other hand, the results of such investigations are interesting first of all from the point of view of solid-state physics and not of gaseous corrosion. It is well known that in the case of oxidation of metals and alloys the formation of multilayer scales prevails, the mechanism of scale growth being thereby very complex. The method proposed by Holt and Himmel gives no better possibilities to study these phenomena than the conventional marker method. The radioactive isotope of the oxidizing element can, however, be very useful in studying the mechanism of scale formation on metals and alloys under the condition it is employed in another way than that suggested by Holt and Himmel. Such a method has been used already for many years and the results of model investigations carried out by this method on metal-sulfur and alloy-sulfur systems have contributed to the development of the dissociative model of formation of multilayer scales on pure metals and on binary alloys.[35-44] Himmel and Holt do not mention these papers at all in their extensive dissertation. If they had made acquaintance with these papers, they would have avoided one-sidedness in treating this important problem.

The authors of these remarks have demonstrated that valuable information about the mechanism of mono- and multilayer scale formation on metals and alloys can be obtained by the method of two-stage oxidation but in another way than that proposed by Holt and Himmel. Namely, the radioactive isotope of the oxidizing element must be introduced into the medium in the second, and not in the first, stage of the reaction. The autoradiographs of cross sections of scales obtained in this way offer the possibility of formulating unambiguous conclusions not only in the case of monolayer scales. Figures 1 and 2 of this discussion show such autoradiographs of sulfide scale formed in the course of two-stage sulfurization on copper and on a copper-zinc alloy containing 15% zinc. Figure 1 demon-

strates that, in spite of formation of a two-layer scale (with a porous inner one) on flat surfaces of the specimens, the inner transport of the oxidizing agent is not observed. At edges, the radioactive sulfur isotope penetrated into the interior of the scale through microfissures situated perpendicular to the metal surface. The fissures can be clearly distinguished on the autoradiograph and on the microphotograph. The mechanism of fissure formation as well as the mechanism of scale growth in these different parts of the specimens are described in detail in our cited papers. It must be emphasized that application of radioactive and not active sulfur in the way proposed by Holt and Himmel, *i.e.* in the reversed sequence, would bring to such little illustrative picture as that reproduced in their Fig. 7 [*sic*]. Also, Fig. 2 of this discussion should be compared with Fig. 9 of the Holt-Himmel paper. In Fig. 2, the inward transport of the oxidizing element through microfissures, formed as the result of secondary dissociation processes and situated perpendicular to the core, can be clearly observed. Both scale layers can also be clearly distinguished. On the basis of the autoradiograph obtained by Holt and Himmel, no precise conclusions about the mechanism of scale formation on Fe-Pt alloy can be formulated. It must be emphasized that such good results as shown in Fig. 1 and 2 can be obtained not only in cases where the preparations can be relatively easily polished. Analogous results have been obtained in many other cases, especially in investigating the mechanism of sulfurization of nickel,[36,40] iron,[37,38] Ni-Cr-alloys,[45] and other systems.[46,47]

It should also be mentioned that the radioactive isotope of sulfur was used in the case of many model reactions[39,43,44,48] investigated by Wagner's pellet method.[49]

When the contribution of the inward lattice diffusion is to be unambiguously determined, an inert marker and additionally the radioactive isotope of the oxidizing element must be used simultaneously in a way described in the papers.[36,43]

It should also be said that our investigations carried out with use of the O^{18}-isotope (according to the nuclear reaction $O^{18}/\alpha,n/Ne^{21}$) lead to identical results as in the case of sulfurization.

Concluding, we must underline that in spite of Holt-Himmel's suggestion that radioactive S^{35}-isotope was widely used in our laboratory as well as by other authors[50,51] and has contributed to a better understanding of the mechanism of scale formation on metals and alloys. Some similar conclusions appear also in Holt-Himmel's paper, suggesting thus that they have been formulated for the first time as a result of their own investigations.

J. B. Holt and L. Himmel: We must confess that, at the time our paper was submitted to this *Journal*, we were not aware of the publications cited by the discussors, nor did we know that Professor Mrowec and his colleagues had been using S^{35} as a marker in the elegant manner they have described. The convincing illustrations which they have provided demonstrate that their technique is basically sound and that it has been applied with great skill in studying the mechanism of growth of sulfide scales on metals and alloys. While we have been remiss in not making mention of this important refinement in technique, we would like to point out that the contribution made by Professor Mrowec and his co-workers to the development of the dissociative model for the growth of duplex scale was specifically acknowledged in our paper.

The primary objective of our work was to show that the $O^{18}(p,n)F^{18}$ nuclear reaction could be used successfully to study the transport of oxygen in oxide scales formed on metals and alloys. To accomplish this, we employed O^{18} as a marker and, to provide the most direct comparison with inert marker techniques, we chose to mark the original interface between the metal and the gas by oxidizing first in O^{18} and then O^{16}. In no way have we excluded the possibility or, indeed, the desirability of reversing the oxidation sequence, as Brückman, Mrowec, and Werber recommend. In fact, in connection with our experiments on the scaling of zirconium as well as in the general discussion to our paper, we have pointedly emphasized the advantages that may be gained by reversing the order of oxidation, particularly when dealing with fissured or nonadherent scales. Furthermore, in other work on the mechanism of the oxidation of magnetite, to which we have referred in our paper, we found it expedient to oxidize first in normal oxygen and then in O^{18} even though dense, adherent Fe_2O_3 layers at least 1 mm thick could easily be produced on the Fe_3O_4 substrate.

Although we agree that the choice of the marking sequence to be employed in practice is not a trivial one and should be given careful consideration, we do not exclusively favor one marking sequence in preference to the other in all circumstances. If a choice must be made, we feel that this should be dictated not only by the structural characteristics of the scale and by which of the two reacting components is the faster diffusing species in the scale lattice, but also by the type of information being sought. Our experiments on the scaling of iron in H_2/H_2O atmospheres provide a case in point. The porosity observed in thick wüstite scales grown on cylindrical iron specimens (Fig. 8c and d) is of an entirely different nature from that which originates in the sulfide scales formed on Cu or Cu-Zn alloys (Fig. 1a and 2). The internal voids which are present in the scale are not interconnected and are located relatively deep below the external surface; moreover, cracks or fissures which would permit oxygen from the gas phase to penetrate freely into the interior of the scale do not appear to be present. Thus, if we had oxidized these specimens first in H_2O^{16} and then H_2O^{18}, the chances are we would merely have confirmed what we already knew; namely, that oxygen is virtually immobile in the wüstite lattice. In all probability, the O^{18} distribution would have failed to reveal that oxygen transport actually does take place in the interior of the scale by what we have concluded must be a dissociative mechanism.

For the most part, this also applies to the scaling behavior of Fe-Pt alloys. In this case, we have deliberately tried to destroy the adherence between the scale and the metal by introducing a more noble alloying element which tends to concentrate at the metal/scale interface during growth of the scale. With rectangularly shaped specimens, relatively direct access of oxygen to the interior of the scale might be possible if the gas can enter at the corners and edges of the sample and penetrate along the metal/scale interface. To check out this possibility, it would have been instructive to oxidize in the reverse sequence. However, it is doubtful whether this would have yielded a more enlightening result concerning the relative mobilities of iron and oxygen in the scale formed on Fe-Pt alloys. The outer portion of the scale does not contain platinum and hence a marker experiment carried out in the manner recommended by the discussors would again simply confirm that iron is the mobile species in Pt-free wüstite.

strates that, in spite of formation of a two-layer scale (with a porous inner one) on flat surfaces of the specimens, the inner transport of the oxidizing agent is not observed. At edges, the radioactive sulfur isotope penetrated into the interior of the scale through microfissures situated perpendicular to the metal surface. The fissures can be clearly distinguished on the autoradiograph and on the microphotograph. The mechanism of fissure formation as well as the mechanism of scale growth in these different parts of the specimens are described in detail in our cited papers. It must be emphasized that application of radioactive and not active sulfur in the way proposed by Holt and Himmel, *i.e.* in the reversed sequence, would bring to such little illustrative picture as that reproduced in their Fig. 7 [*sic*]. Also, Fig. 2 of this discussion should be compared with Fig. 9 of the Holt-Himmel paper. In Fig. 2, the inward transport of the oxidizing element through microfissures, formed as the result of secondary dissociation processes and situated perpendicular to the core, can be clearly observed. Both scale layers can also be clearly distinguished. On the basis of the autoradiograph obtained by Holt and Himmel, no precise conclusions about the mechanism of scale formation on Fe-Pt alloy can be formulated. It must be emphasized that such good results as shown in Fig. 1 and 2 can be obtained not only in cases where the preparations can be relatively easily polished. Analogous results have been obtained in many other cases, especially in investigating the mechanism of sulfurization of nickel,[36,40] iron,[37,38] Ni-Cr-alloys,[45] and other systems.[46,47]

It should also be mentioned that the radioactive isotope of sulfur was used in the case of many model reactions[39,43,44,48] investigated by Wagner's pellet method.[49]

When the contribution of the inward lattice diffusion is to be unambiguously determined, an inert marker and additionally the radioactive isotope of the oxidizing element must be used simultaneously in a way described in the papers.[36,43]

It should also be said that our investigations carried out with use of the O^{18}-isotope (according to the nuclear reaction $O^{18}/\alpha,n/Ne^{21}$) lead to identical results as in the case of sulfurization.

Concluding, we must underline that in spite of Holt-Himmel's suggestion that radioactive S^{35}-isotope was widely used in our laboratory as well as by other authors[50,51] and has contributed to a better understanding of the mechanism of scale formation on metals and alloys. Some similar conclusions appear also in Holt-Himmel's paper, suggesting thus that they have been formulated for the first time as a result of their own investigations.

J. B. Holt and L. Himmel: We must confess that, at the time our paper was submitted to this *Journal*, we were not aware of the publications cited by the discussors, nor did we know that Professor Mrowec and his colleagues had been using S^{35} as a marker in the elegant manner they have described. The convincing illustrations which they have provided demonstrate that their technique is basically sound and that it has been applied with great skill in studying the mechanism of growth of sulfide scales on metals and alloys. While we have been remiss in not making mention of this important refinement in technique, we would like to point out that the contribution made by Professor Mrowec and his co-workers to the development of the dissociative model for the growth of duplex scale was specifically acknowledged in our paper.

The primary objective of our work was to show that the $O^{18}(p,n)F^{18}$ nuclear reaction could be used successfully to study the transport of oxygen in oxide scales formed on metals and alloys. To accomplish this, we employed O^{18} as a marker and, to provide the most direct comparison with inert marker techniques, we chose to mark the original interface between the metal and the gas by oxidizing first in O^{18} and then O^{16}. In no way have we excluded the possibility or, indeed, the desirability of reversing the oxidation sequence, as Brückman, Mrowec, and Werber recommend. In fact, in connection with our experiments on the scaling of zirconium as well as in the general discussion to our paper, we have pointedly emphasized the advantages that may be gained by reversing the order of oxidation, particularly when dealing with fissured or nonadherent scales. Furthermore, in other work on the mechanism of the oxidation of magnetite, to which we have referred in our paper, we found it expedient to oxidize first in normal oxygen and then in O^{18} even though dense, adherent Fe_2O_3 layers at least 1 mm thick could easily be produced on the Fe_3O_4 substrate.

Although we agree that the choice of the marking sequence to be employed in practice is not a trivial one and should be given careful consideration, we do not exclusively favor one marking sequence in preference to the other in all circumstances. If a choice must be made, we feel that this should be dictated not only by the structural characteristics of the scale and by which of the two reacting components is the faster diffusing species in the scale lattice, but also by the type of information being sought. Our experiments on the scaling of iron in H_2/H_2O atmospheres provide a case in point. The porosity observed in thick wüstite scales grown on cylindrical iron specimens (Fig. 8c and d) is of an entirely different nature from that which originates in the sulfide scales formed on Cu or Cu-Zn alloys (Fig. 1a and 2). The internal voids which are present in the scale are not interconnected and are located relatively deep below the external surface; moreover, cracks or fissures which would permit oxygen from the gas phase to penetrate freely into the interior of the scale do not appear to be present. Thus, if we had oxidized these specimens first in H_2O^{16} and then H_2O^{18}, the chances are we would merely have confirmed what we already knew; namely, that oxygen is virtually immobile in the wüstite lattice. In all probability, the O^{18} distribution would have failed to reveal that oxygen transport actually does take place in the interior of the scale by what we have concluded must be a dissociative mechanism.

For the most part, this also applies to the scaling behavior of Fe-Pt alloys. In this case, we have deliberately tried to destroy the adherence between the scale and the metal by introducing a more noble alloying element which tends to concentrate at the metal/scale interface during growth of the scale. With rectangularly shaped specimens, relatively direct access of oxygen to the interior of the scale might be possible if the gas can enter at the corners and edges of the sample and penetrate along the metal/scale interface. To check out this possibility, it would have been instructive to oxidize in the reverse sequence. However, it is doubtful whether this would have yielded a more enlightening result concerning the relative mobilities of iron and oxygen in the scale formed on Fe-Pt alloys. The outer portion of the scale does not contain platinum and hence a marker experiment carried out in the manner recommended by the discussors would again simply confirm that iron is the mobile species in Pt-free wüstite.

In the growth of wüstite on high-purity iron, a local loss of adherence occurs between the scale and the metal at the corners and edges of plate-shaped specimens and at isolated regions around the circumference of cylindrical specimens. Despite this, we had no difficulty in establishing, unequivocally, that the mobility of oxygen in wüstite is negligibly small compared to that of iron. We therefore take exception to the statement that the marking sequence we have used will yield unambiguous results only when the scale is perfectly adherent and free from porosity. The scale need not remain firmly attached to the metal substrate over the entire specimen area in order that the diffusing component be positively identified. As Brückman *et al.* have correctly pointed out, difficulties in the interpretation may arise if the scale is completely nonadherent, just as they do when inert markers are employed. This is certainly true for the growth of thick sulfide scales on Cu but not apparently for the scaling of iron in air (Fig. 10). Thus, on an iron sample oxidized in air, the O^{18} distribution was basically the same on both sides of the specimen even though the scale on one side was adherent, while that on the other side was completely nonadherent. It, therefore, appears that the real problems in interpretation are caused not by the loss of adherence *per se* but by accompanying dissociative transport of the nonmetallic component.

So far, we have considered the information obtainable using only the nonmetallic constituent as a marker. It will be recalled, however, that the generalized marker approach which we suggested in our paper involves making use of both components of the system as markers wherever possible. If this is done, we feel confident that a reliable estimate of the relative mobilities in the scale lattice can be obtained even when dissociative transport mechanisms are operative. For scaling reactions in which the nonmetallic component is the faster diffusing species, it would seem particularly desirable to employ a radioisotope of the metal as a marker, as our experiments on the scaling of zirconium have indicated.

In summary, we doubt that a single recipe for carrying out marker experiments can be formulated which is at the same time simple, completely foolproof, and ideally suited to the study of all types of scaling reactions on metals and alloys. The rich variety of phenomena encountered even in a single system such as the reaction between iron and oxygen would seem to require that a combination of techniques be used if a complete understanding of the scaling process is to be achieved. Professor Mrowec and his colleagues have concentrated on one aspect of the over-all problem which we only briefly touched upon in our article, *i.e.* the mechanism of growth of nonadherent, duplex scales. We recognize the merit of their approach to this important and practical problem but we still believe that the techniques we have developed are also useful for their intended purpose.

Application of Preferential Electrochemical Etching of Silicon to Semiconductor Device Technology

M. J. J. Theunissen,* J. A. Appels, and W. H. C. G. Verkuylen

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Preferential electrochemical etching of epitaxial structures has been applied to the fabrication of semiconductor devices. Preparation of thin layer devices and isolated structures is described. As an introduction to these applications, the etching of various epitaxial structures is described. Consideration is given to the manner in which the etching behavior is influenced by thermal treatment, the presence of diffusion areas, and crystal imperfections.

Anodic dissolution of silicon in hydrofluoric acid has been described by several workers (1, 2). It was found by van Dijk (3) that electrochemical etching of epitaxially grown structures can be used to make thin silicon crystals. Using silicon slices of the n^+n or the n^+p type, the low-resistivity n^+ substrate can dissolve anodically and the etching process stops near the epitaxial boundary. Thin single crystals of silicon with a thickness down to 0.5μ were prepared by van Dijk.

This paper presents some applications of this electrochemical etching process to semiconductor technology. Before this is done, the etching behavior of homogeneously doped substrates and epitaxially grown structures will be considered in more detail. One application of the electrochemical etching process is the preparation of devices in thin silicon layers of high quality. These thin silicon layers can be advantageously used to make devices having improved performance. Similar devices may be made in thin silicon layers grown on sapphire, spinel, or other insulators. However, the crystal imperfections of these layers (often made by heteroepitaxial growing techniques), still limit the applications. Two new methods of preparing thin layer devices are described. In one method, lateral devices are fabricated in a thin silicon layer which is made on top of a polycrystalline silicon substrate with a SiO_2 layer in between. In the second method of making thin layer devices, diffusions are carried out in the initial epitaxially grown structures, then the slice is etched, leaving a device with vertical junctions only.

The electrochemical etching process can also be applied successfully in the preparation of isolated structures. A technique is presented for utilization of this process in the preparation of integrated circuits with dielectric isolation and beam lead air-gap isolation.

Experimental Procedure

The samples used consisted of homogeneously doped n- and p-type silicon slices and epitaxially grown slices with a highly doped substrate ($> 3.10^{18}$ atoms/cm^3) and an epitaxial layer with a dopant concentration lower than 2.10^{16} atoms/cm^3. Both (111) and (100) oriented slices were used; slice diameters were between 32 and 40 mm.

The homogeneously doped slices were chosen in the impurity concentration range from 10^{15} to 10^{19} atoms/cm^3. Prior to the electrochemical process, the slices were etched in HF (48%)-HNO_3 (65%) (1:10) etchant to remove work damage. Contact between the anode and the silicon was made by pressing a platinum strip (15 x 3 mm^2) pressed against the silicon slice near its edge with a perspex clamp, the resistivity of the slice disregarding. The slice, including the contact, was completely immersed in the electrolyte; if the silicon anode current was to be measured, the platinum strip was covered with an apiezon wax.

The n^+ substrates of the epitaxial slices were antimony doped, the p^+ substrates boron doped. The substrates were subjected to an appropriate etching and polishing procedure and, prior to the epitaxial growing process, to an HCl(1%) and H_2 treatment for 10 min at 1220°C. Epitaxy was carried out at 1220°C in a $SiCl_4$ and H_2 mixture (growth rate 0.5 μm/min; dopants for the n-type layers were phosphorus or antimony; the dopant for p-type layers was boron). In this way, n^+n, n^+p, p^+n, and p^+p epitaxial structures were grown. The mounting and beveling of the slices and the method of making contact between the n^+ silicon and the platinum strip have been described by van Dijk (3).

During the electrochemical etching process, the anode-cathode current was recorded as a function of the time. The etching process was stopped as soon as a constant current level was reached, indicating that the low-resistivity substrate had been dissolved (except a minor part shielded by the platinum strip).

The electrochemical etching conditions of both the homogeneously doped slices and the substrate of the epitaxial ones were the same, namely: $V_{anode\text{-}cathode} = 10V$; electrolyte: 5% aqueous HF; bath temperature 18°C; complete darkness; cathode: platinum gauze (10 x 10 cm^2); cathode parallel to slice at a distance of about 5 cm.

After anodic dissolution of the low-resistivity substrate of the epitaxial slice, chemical etching of the

* Electrochemical Society Active Member.

remaining epitaxial layer was performed in a freshly prepared etchant. The composition was: 50 ml HF (48%), 50 ml acetic acid (Merck 99% minimum purity), and 200 mg $KMnO_4$ (Merck 99% minimum purity). The etch rate was approximately 0.2 μm/min at 18°C.

The Sirtl etch technique (4) and optical microscopy were used to note surface defects.

The thickness of the thin layers was measured by multiple interference microscopy (Tolansky), or indirectly derived from the known depth of diffusion layers or etched grooves, which are revealed at the rear side during chemical thinning of the slice. In the case of thin silicon layers on oxide and polycrystalline silicon, thickness measurements were done using beveling (5) or infrared interference techniques (5).

Experimental Results and Discussion

Anodic etching of silicon samples.—Homogeneously doped samples.—In order to obtain more insight into the etching behavior of nonhomogeneously doped silicon samples, such as the epitaxially grown slices used for the thin layer devices, we subjected various homogeneously doped samples to the electrochemical etching process. Experiments on anodic dissolution of n-type silicon crystals, with a donor concentration ranging from 10^{15} to 10^{19} atoms/cm^3 under the conditions specified before, indicated that there are three concentration regions, each with a different etching behavior. Above 3 x 10^{18} donors/cm^3 (<0.01 ohm-cm), we found complete dissolution of the crystals. In the range between 3 x 10^{18} and 2 x 10^{16} donors/cm^3 (0.01-0.3 ohm-cm), only partial dissolution occurred with a decreasing rate at the lower donor concentrations. As can be seen in the lower part of Fig. 1(a), a part of the silicon crystal, extending from the electrolyte-silicon interface into the bulk crystal, has been converted to a brown porous structure. Infrared transmission spectra showed that the brown layer consisted mainly of pure silicon, which is similar to the brown layers reported by Turner (1) and Beckmann (6). At donor concentrations lower than about 2 x 10^{16} atoms/cm^3 (>0.3 ohm-cm), we found no visual evidence of attack when the etching time was shorter than about ½ hr. However, when etching was continued, the silicon anode current density increased (from less than 1 to more than 5 mA/cm^2) and the crystal surface became dull. Figure 1(b) shows a cross section of a 2 x 10^{15} n-type slice after a short treatment with Sirtl etchant. As can be seen, channels locally penetrate nearly 20 μm into the crystal; their direction appeared to be crystal oriented. The cause and the nature of the channels are not fully understood; the density and the length of the channels increased with the anodizing time.

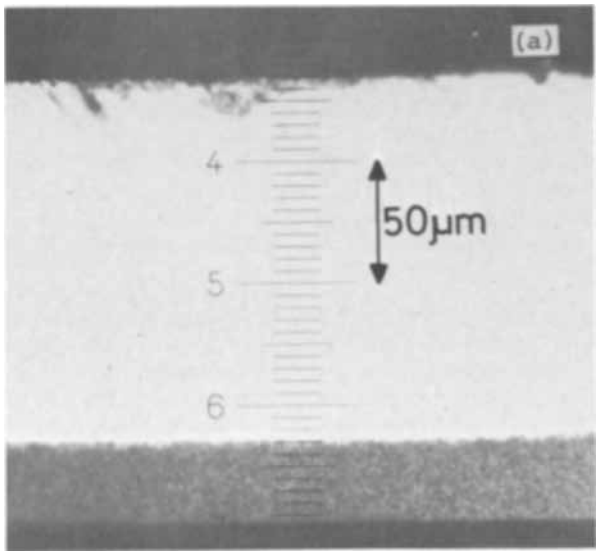

Fig. 1(a). Cross section of an n-type Si slice (N_D = 10^{17} donors/cm^3; (111) slice orientation) after an anodizing treatment of 1 hr.

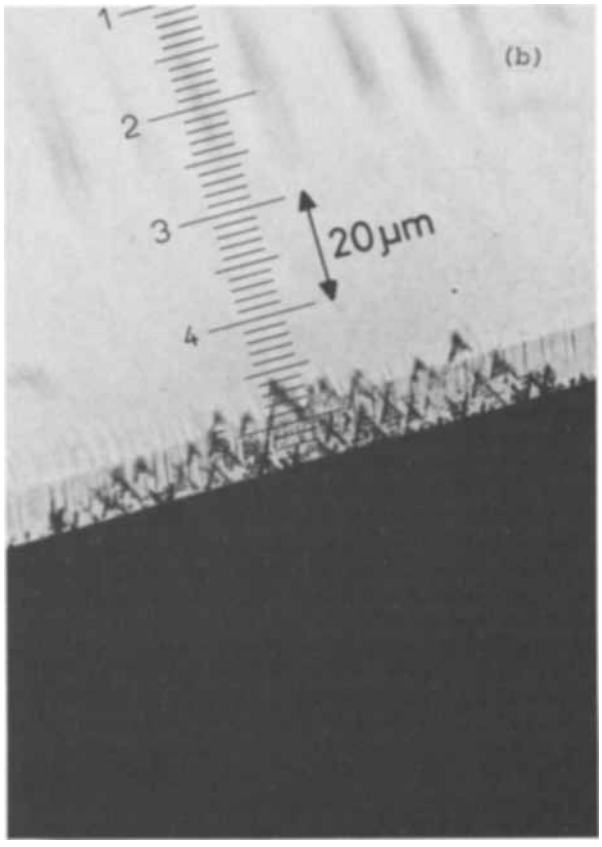

Fig. 1(b). Cross section of an n-type Si slice at a weak spot (N_D = 2.10^{15} donors/cm^3; (100) slice orientation) after an anodizing treatment of 1 hr followed by Sirtl etching.

Homogeneously doped p-type silicon samples were found to dissolve when the acceptor concentration was higher than about 5 x 10^{15} atoms/cm^3 (>3 ohm-cm). The dissolution rate of p-type silicon was found to increase with the acceptor concentration. At acceptor concentrations below 5 x 10^{15} atoms/cm^3, local attack around the platinum strips was often observed, while the other part of the slice was covered with a brownish deposit.

Epitaxially grown structures.—Figure 2 schematically shows, among other things, the profiles of the net impurity concentration as they will appear in n^+n, p^+n, n^+p, and p^+p epitaxial slices. Based on the experi-

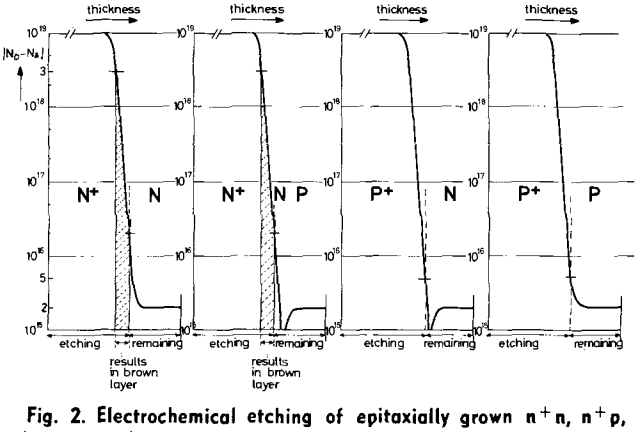

Fig. 2. Electrochemical etching of epitaxially grown n^+n, n^+p, p^+n, and p^+p structures under standard etching conditions as can be expected from the results of homogeneously doped n- and p-type crystals.

ments with homogeneously doped slices, the ranges have been indicated where etching, nonetching, and formation of a dark brown layer can be expected. More detailed considerations should probably take into account the generation and recombination of holes and electrons and their distribution at the silicon surface, combined with the nature of the electrochemical reactions. It is shown below that experiments done with epitaxial slices roughly agree with the indications as sketched in Fig. 1.

n^+n Structures.—Anodic dissolution of the n^+ substrate of an n^+n epitaxial slice resulted in a thin silicon crystal covered with a thin dark brown layer as predicted in Fig. 2. The thickness of this dark brown layer and the smoothness of the silicon under this layer appeared to depend on the slope of the net donor profile. A steep profile resulted in a smooth surface, whereas a gradual profile was characterized by an irregularly etched surface and a thicker brown layer.[1] It can be concluded that, for applications which require a smooth surface, outdiffusion of the n^+ substrate must be reduced as much as possible. Figure 2 predicts that after electrochemical etching of n^+n samples a very thin n-type layer with a higher donor concentration remains. This layer can be removed by chemical etching. This was done with the etchant indicated earlier in this paper. The etchant also appeared to be very suitable for removing the brown layer. There is another reason why chemical etching of the thin n-type layer is advisable. Sirtl etching of cross sections of the n-type crystals (thickness about 10 μm) revealed a high density of etch channels (about $10^8/cm^2$) extending a few microns (0-5 μm) from the "epitaxial" side into the n-type layer.

These channels are similar to those found for homogeneously doped n-type samples but their density was generally higher. They may originate at crystal defects at the epitaxial interface, although x-ray topography and Sirtl etching of cross sections of epitaxial n^+n slices showed no evidence of a poor interface structure. The depth of the channels appeared to increase with the distance from the platinum contact. This is due to the fact that electrochemical etching of epitaxial slices begins at the areas furthest from the platinum strip, so that these areas are longer exposed to the electrolyte.

n^+p.—Epitaxial n^+p slices showed an etching behavior similar to that of n^+n slices. The surface of the remaining thin crystal was covered with a thin dark brown layer. In addition, a thin n-type layer was found on top of the thin p-type crystal as predicted in Fig. 2. The thickness of the dark brown layer, the smoothness of the etched surface, and the thickness of the n-type layer were again found to be dependent on the amount of outdiffusion of the n^+ substrate.[2] Chemical etching was again used to reduce the thickness until a homogeneously doped p-type layer remained. No channels were observed in the p-type layer.

p^+n.—Anodic dissolution of the p^+ substrate in epitaxial p^+n slices resulted in a thin layer with a very irregularly etched surface. No brown layer was observed. Often small parts of the surface were found to be still p-type. There was a strong tendency of the n-type layer to dissolve completely around the platinum contact.

p^+p.—Electrochemical etching of p^+p epitaxial slices was found to give results similar to those of the p^+n slices, an irregularly etched surface, and a strong tendency for the p-type layer to etch completely around the platinum contact. It was not possible to smooth the thin p-type crystals by chemical etching.

The experiments with epitaxial slices show that thin n- and p-type crystals with a smooth surface can be made from epitaxial n^+n and n^+p slices with a rather steep profile. The donor concentration should preferably be higher than 3×10^{18} atoms/cm^3. The etching process stops where the donor concentration is about 2×10^{16} atoms/cm^3. When n^+n slices are used, channels are introduced in the high-resistivity n-type layer during the anodic dissolution of the low-resistivity n^+ substrate, which affects the crystallinity of the epitaxial layer. Chemical etching is necessary to remove that part of the thin epitaxial crystal in which the concentration deviates from that of the rest of the epitaxial layer or the crystal perfection is lower. High demands must be made on the quality of the epitaxial layers. These layers must be uniform in thickness and be homogeneously doped to insure that the variation thickness of the thin layer is small after chemical thinning. The crystal perfection must be high, because we observed that dislocations and stacking faults can result in etch pits and even holes in the thin layer during electrochemical etching. The substrate of the epitaxial slice must be free of striations. Electrochemical etching of substrates with striations often resulted in thin layers covered with substrate remnants arranged in the known striation circles. Most applications require a thin crystal with a smooth surface. For this reason n- and p-type layers made of p^+n and p^+p structures are less suitable for device applications.

Before the electrochemical etching process is carried out, diffusions can be done from the front side of the slice. To guarantee that the electrochemical etching process stops at the epitaxial boundary, a high-resistivity layer between the diffused layer and the substrate must always be present; *i.e.*, the diffusions are done in the top of the epitaxial layer, the rest of the epitaxial layer acts as a barrier against the anodic dissolution of the diffused areas. The quality of this barrier appeared to depend on the combination of its thickness and its free carrier concentration. It can be expected that the critical values of the thickness and the concentration are basically related to the etching mechanism. Thus, injection of holes from the diffused areas into the high-resistivity barrier (1) and avalanche breakdown (punch-through effects) of the depletion layer which is formed in the high-resistivity layer during anodic dissolution of the n^+ substrate promote the anodic attack of this barrier. The critical values of thickness and concentration of the intermediate layer appeared to be less stringent when the diffused area at the front side had been split up in local areas not interconnected by metallic leads; in practice, we used these local diffused areas. The n-type intermediate layer was between 8 and 15 μm, the resistivity ranged from 1 to 20 ohm-cm. The p-type barriers were from 5 to 10 μm, with a resistivity between 1 and 15 ohm-cm.

Applications.—Thin layer devices.—Thin monocrystalline silicon layers on insulating substrates like sapphire have gained much interest during the last few years, mainly because of the possibilities of making lateral devices, *i.e.* devices that are characterized by the presence of vertical junctions only, and which therefore have extremely low capacitances. They are made by diffusing impurities through the thin layer to the insulating substrate. Bonding pads can be made directly on the insulating substrate at places where the silicon layer is selectively removed by etching, thus lowering the metal-to-substrate capacitance. Integrated circuits can be provided with a complete isolation between the building blocks. Downing and Hagon (7) have described several lateral devices and circuits made in thin silicon layers on sapphire. Zuleeg and Knoll (8) made a lateral bipolar npn transistor

[1] This influence of the outdiffusion from the substrate was deduced from etching experiments on n^+n and n^+p slices, which had been subjected to various heat treatments; *i.e.*, $\sqrt{D_{Sb} \cdot t}$ varied from about 2×10^{-5} cm (heat treatment during epitaxy) to 10^{-4} cm. Etching experiments with n^+n type structures, made by diffusion of donors in homogeneously doped n-type samples, did not result in smooth surfaces either.

[2] Same note as footnote 1.

with promising high-frequency characteristics. The monocrystalline silicon layers on insulating substrates can also be used to make deep depletion or "junctionless" FET's in which the conduction of the thin n- or p-type layer itself is modulated by the gate potential. Heiman (9) describes an n^+nn^+ MOST, made in a silicon layer of 0.5-2.0 μm on sapphire. Excellent high-frequency behavior was shown by a Schottky gate FET made on a silicon substrate of 10-50 kohm-cm and a gate width of 1 μm as reported by Drangeid *et al.* (10). Combinations of lateral n^+pn^+ and deep depletion p^+pp^+ may be used in the fabrication of complementary MOS memory systems (11).

Despite the great amount of effort put into the fabrication of monocrystalline layers made by heteroepitaxial techniques, the fundamental electrical and physical parameters of these thin layers are in general inferior to those made by homoepitaxial techniques (Si on Si) (12, 13). The availability of the preferential electrochemical etching process makes it possible to prepare thin silicon layers of high quality of 0.5 μm and more in thickness. We now describe two methods of preparing thin layer devices. Both methods require epitaxial layers of uniform thickness and resistivity and a high crystal perfection.

In the first method, devices are made in a thin silicon layer (0.5-2.0 μm), which has been attached to a polycrystalline silicon substrate with an oxide layer in between (Fig. 3). In the experimental procedure, thermally oxidized slices of the n^+n or n^+p type, with an epitaxial layer of about 10 μm, were used. The thickness of the SiO_2 layer was usually 1 μm, but thicker oxide layers up to 5 μm, preferably made by a low-temperature process, may be used. This oxide layer serves as an insulating layer. On top of this oxide layer, polycrystalline silicon may be grown in an epitaxial reactor by hydrogen reduction of $SiCl_4$ or $SiHCl_3$ at temperatures of about 1000°-1150°C. An alternative method of making polycrystalline substrates which minimizes the total heat treatment is deposition of silicon by evaporation in accordance with the method described by Ploos van Amstel (14). In 5-10 min, layers of up to 300 μm are deposited at a substrate temperature of 900°C.

Electrochemical etching is now used to dissolve the monocrystalline n^+ substrate. The remaining thin monocrystalline layer is subjected to chemical etching to the desired thickness of, *e.g.*, 2 μm, followed by mesa etching as can be seen in Fig. 3. Devices are then made using conventional diffusion and photoetching techniques.

In the second method of making thin layer devices, diffusions are carried out first, followed by electrochemical and chemical etching of the slice to the desired thickness. In the case of junction devices, the horizontal part of the p-n junction is removed, leaving only the vertical p-n junctions with their small area. This method is illustrated in Fig. 4.

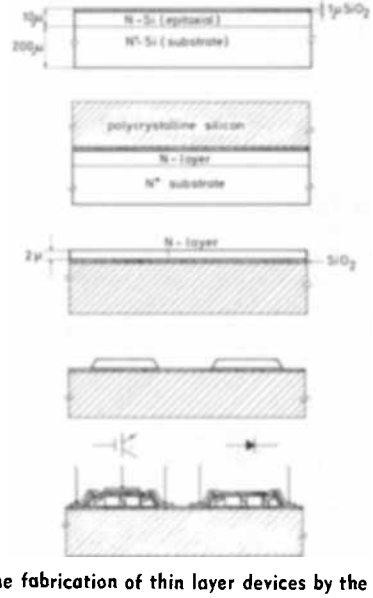

Fig. 3. The fabrication of thin layer devices by the first method

In the experimental procedure, epitaxial slices of the n^+n and n^+p type were used. In the example given in Fig. 4, discrete MOS devices of the p^+np^+ type and the n^+nn^+ type were made. A typical value of source and drain diffusion depth is 3 μm in a 12 μm thick epitaxial layer. After the metallization, grooves were etched in order to divide the thin slice into individual chips later on. The slice containing the MOS devices, each device being surrounded by a groove of 3 μm depth, was affixed "face down" on a temporary carrier (glass plate) by means of a wax. The low-resistivity n^+ silicon was then removed by electrochemical etching. The remaining epitaxial layer is thinned by chemical etching to, *e.g.*, 2 μm. During the last stage of the chemical etching process, the diffusion areas and the grooves were revealed as can be seen in Fig. 5. By the chemical etching process, the slice was divided into chips automatically. We found that the thin chips can be handled quite readily by a vacuum pipette. By means of a polymer (silicone resin), the chip can be attached to a ceramic substrate. Bonding can be performed using conventional thermocompression bonding techniques.

Comparing the two methods of preparing thin layer devices, it should be noted that in both methods the

electrochemical etching process was carried out after the epitaxial slices were subjected to high-temperature steps. As mentioned before, outdiffusion of the n^+ substrate can result in surface irregularities which seem to be the most critical in the first method because the diffusion and the photoetching steps are still to be done. Moreover, we found that the first method necessitated careful control of the deposition parameters of the oxide and of the polycrystalline silicon and of further processing; otherwise, warping of the slice (mainly due to the recrystallization of the polycrystalline silicon) would affect the accuracy in photomasking steps. An advantage of the second method is that normal processing can be used for making devices in normal epitaxial slices and, after electrochemical etching, the slice is subjected only to low-temperature steps. Furthermore, measurements of the device parameters before and after the thinning process can be done easily. Passivation of the upper and lower side surface was done by thermal SiO_2 in the first method; in the second method, passivation of the lower side was done by means of a silicone resin. In the first method, bonding pads were made upon the insulating layer (Fig. 3), whereas in the second method, these pads were made upon the thin silicon layer (Fig. 4), thus causing a metal-to-substrate capacitance. However, it is possible to provide the thin chips with beam leads which eliminates this parasitic capacitance.

Both methods were found useful for making thin layer devices. Discrete devices such as diodes, p- and n-channel MOS transistors, as well as deep depletion n^+nn^+ and p^+pp^+ MOS transistors were made.

It was found that the d-c characteristics of the devices made by the two methods were basically the same as for the thick slices. Leakage currents were found to be somewhat higher than the leakage currents of normal diodes. The capacitance reduction was considerable, as can be seen in Fig. 6. In Fig. 7, the d-c characteristics of an n^+nn^+ deep depletion MOST are shown. Deep depletion MOST's of the n^+nn^+ type with a partial gate structure showed a considerably better high-frequency power gain than a conventional n-channel MOST of the same geometry; this improvement is due to low output conductance (15).

The minority-carrier lifetime in the thin silicon layer was determined by the MOS transient response method (16), using p^+pp^+ type deep depletion MOS

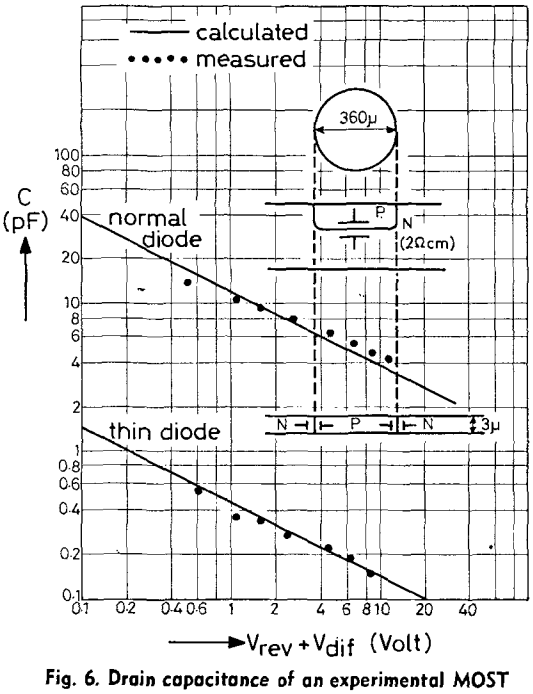

Fig. 6. Drain capacitance of an experimental MOST

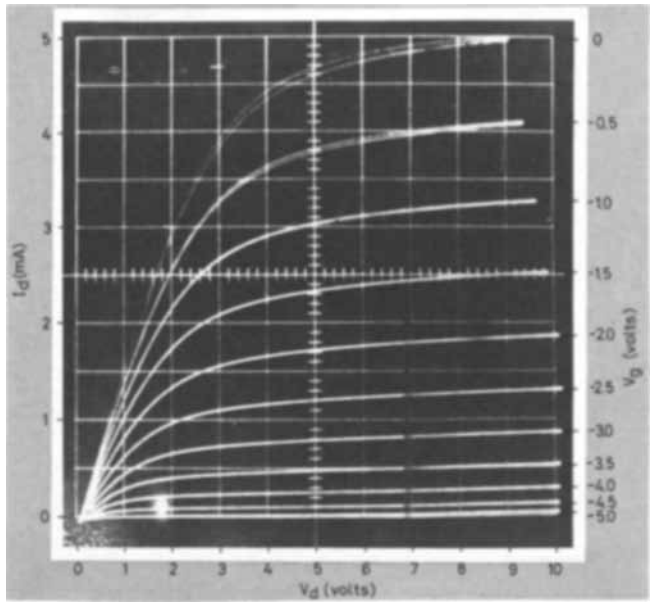

Fig. 7. Typical characteristics of an n^+nn^+ type deep depletion MOST in the depletion mode: $t_{ox} \approx 2000$Å; $t_{Si} \approx 2.5$ μm; $\rho_{Si} = 10$ ohm-cm and $W/L = 60$. (Note: In equilibrium, the maximum depletion region depth for 10 ohm-cm is about 1 μm but, due to the fact that the gate is pulsed (100 Hz), equilibrium is not reached; no inversion is built up at the oxide-silicon interface.)

transistors. The time constant, T, for a 2.5 μm thick p-type layer ($N_A = 1.6 \times 10^{15}$ acc/cm^3) was about 48 μsec, giving a lifetime τ of about 0.2 μsec. This value is quite normal for epitaxially grown silicon after processing.

Isolation techniques in integrated circuits.—The p-n isolation which is widely used does not give complete isolation. The main drawbacks are the substrate leakage and capacitance effects on the components and circuit operation. The desirability of a better isolation has resulted in several developments. The best known are the dielectric isolation process and the air gap isolation process. In the following we show that preferential electrochemical etching can advantageously be used in these processes.

Oxide isolation.—A description of this well-known technique is given in (17). A critical step in this process is lapping and etching just to the upper level of the oxide walls. Figure 8 illustrates the use made of the principle that, during preferential electrochemical etching of n^+n epitaxial slices, dissolution automatically stops at the n^+n interface. In the experimental procedure, epitaxial slices of the n^+n type with an epitaxial layer of 15 μm were used. Buried layers were made by diffusion in top of the epilayer, followed by etching of the isolation grooves which have to surround the active areas. These grooves were

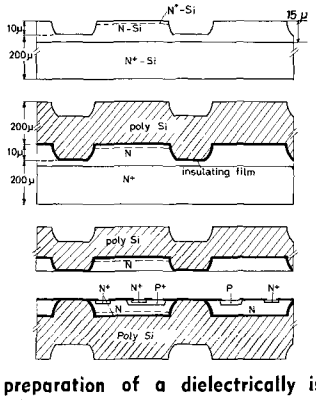

Fig. 8. The preparation of a dielectrically isolated structure starting from an n^+n slice.

etched in the n-type layer in such a way that, between the bottom of the grooves and the n^+n-interface, a high resistivity layer of about 5 μm remains. In order to accomplish this over a whole slice, epitaxial n^+n slices with well-defined and uniform layer thickness were needed. Thermal oxidation and deposition of the polycrystalline substrate have been described before.

Electrochemical dissolution of the n^+ monocrystalline substrate, followed by chemical etching of the n-type layer, reveals the top of the oxide walls of the isolation pattern. Chemical etching must be stopped at the right moment to prevent etching of the oxide and the underlying polycrystalline substrate. If chemically inert layers such as silicon nitride or aluminum oxide are used instead of silicon oxide, this problem is much less severe.

Figure 9 shows a cross section of an oxide isolated structure with diffused areas made by the preferential etching technique. Measurements done on such structures gave a resistivity of the polycrystalline silicon at 20°C of 5-10 x 10^5 ohm-cm, which is reduced to 2-4 x 10^4 ohm-cm at 100°C. Breakdown voltage of 1 μm SiO_2 > 1000V, leakage current <10 nA/cm^2 at 5V d.c., and a capacitance of 3000 pF/cm^2.

Beam lead air-gap isolation.—Beam lead air-gap isolated microcircuits were described by Lepselter *et al.* (18). Instead of diffused junctions, air gaps are used for electrical isolation of active areas. These areas are discrete silicon islands which contain the active devices. They are interconnected electrically and mechanically by metallic beams. In the fabrication of the air-gap isolated circuits, there are two important process steps in which etching can play an important role: first, the thinning of the slices from 200 to about 20 μm, usually done by chemical etching or lapping; second, the etching of the isolating air gaps. For this critical step, Rosvold *et al.* (19) used a low-temperature oxide for masking and alignment from the back of the slice of the air-gap pattern followed by anisotropic etching in KOH.

Preferential electrochemical etching can be used to reduce the slice thickness to, *e.g.*, 20 μm or even less. If buried layers are needed, multilayer structures like $n^+_{subst}nn^+n$ or n^+pn^+n can be used. Electrochemical etching may, however, be used for both etching steps. We found that the reduction of the thickness and the etching of the air gaps can be done simultaneously when a procedure is used as indicated in Fig. 10. In an epitaxial n^+n-type slice, n^+ isolation diffusions were done through the n-type layer up to the n^+ substrate. In the n-type "island" of high resistivity, devices were made and interconnected by etch-resistant metallization strips. Electrochemical etching resulted in an air-gap isolated circuit provided with beam leads. Figure

Fig. 10. Air-gap isolated beam lead integrated circuit

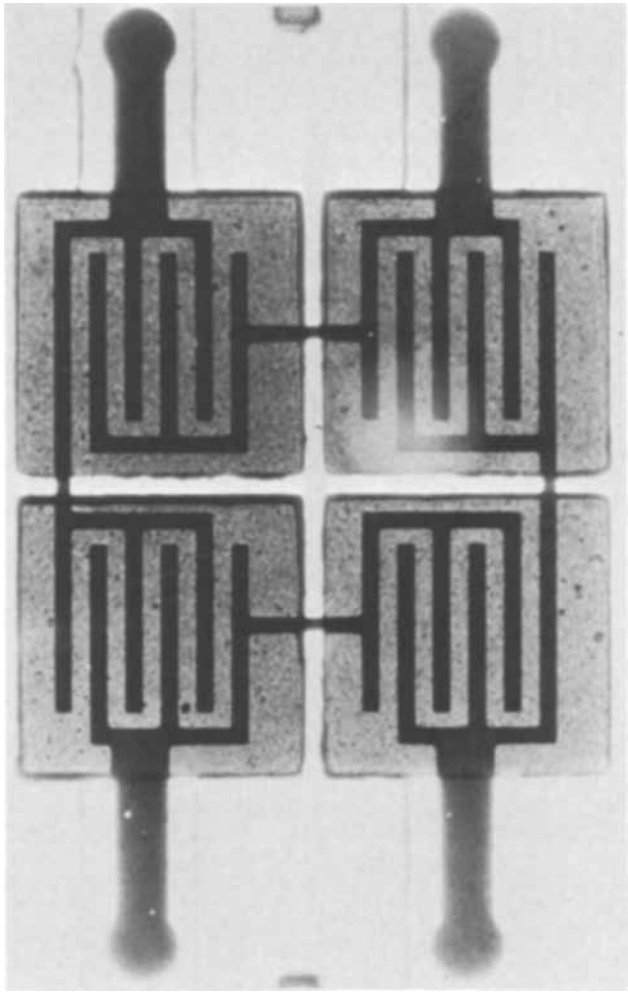

Fig. 11. A diode circuit, made using anodic dissolution of the n^+ substrate and the n^+ isolation diffusions, in transmitted light.

11 shows a simple diode circuit interconnected by thin aluminum leads. In the given example, aluminum oxide was used at those places where protection of the aluminum metal against the hydrofluoric acid was needed, *i.e.* under the air-gap interconnections and the beam leads. The width of the air gaps is defined by the width of the n^+ diffusions between the n-type "islands." It will be clear that in the case of thick epitaxial layers the lateral n^+ diffusion is considerable, thus causing the air gaps to be relatively wide. It may be added that the diodes can be made as lateral thin layer diodes by reducing the thickness of the n-type islands by chemical etching, followed by passivation of the p-n junctions.

Conclusions

Preferential electrochemical etching can be applied successfully in silicon device technology. The reduction of the thickness can be done easily and reproducibly, provided epitaxially grown slices of the n^+n and n^+p type are used as starting material for device fabrication; p^+n and p^+p are less favorable. Using standard etching conditions ($V_{anode\text{-}cathode}$ = 10V, 5% aqueous HF, bath temperature 18°C, dark), the sub-

strate concentration must be higher than 3 x 10^{18} donors/cm^3 in order to obtain completely controllable results. The etching process stops at the place where the donor concentration is about 2 x 10^{16} atoms/cm^3, but n^+n slices show channels in the high-resistivity n-type layer. The outdiffusion from the n^+ substrate must be reduced as much as possible; striations and crystal imperfections must be avoided. The electrochemical etching process has to be followed by a chemical etching process to obtain a thin homogeneously doped crystal of high perfection. The electrochemical etching process in combination with chemical etching allows the fabrication of thin layer devices with highly reduced capacitances and junctionless deep depletion devices in monocrystalline silicon of high quality. The diffusions in the epitaxial layer are not attacked during electrochemical etching if an intermediate high-resistivity layer of sufficient thickness is present; deeply diffused n^+ areas can be etched away together with the n^+ substrate. The latter has been used to prepare beam lead air-gap isolated structures.

Corrosion Problems in Decorative Chromium Plating

G. Kubach

Robert Bosch GmbH, Stuttgart, Germany

ABSTRACT

Microcracked chromium is by far more resistant to corrosion than crack-free chromium, especially if the work-piece is mechanically stressed. Corrosion with microcracked chromium penetrates bright nickel quite uniformly but it may soon reach the basis metal, provided no barricade like copper or semibright nickel is underlaid. Finally, corrosion pits increase to such a dimension that the surface is no longer decorative. Some correlations between the great loss of appearance and the nature of the underlying metal systems are described.

In an earlier series of experiments on the corrosion-preventive action of various decorative nickel-chromium coatings, we had found that microcracked chromium possessed a number of advantages over other types of chromium (*e.g.*, crack-free), but that a number of questions had still to be answered. The most important of these were the following:

Is the outstandingly good corrosion resistance of mechanically stressed nickel plated with microcracked chromium due to the lack of cracks in the nickel? Or, on the other hand, is it that cracking of the nickel is not harmful when microcracked chromium is present?

According to Völkel (1), bright nickel plated with microcracked chromium, with a crack density of 400-700 cracks/cm, is corroded to a depth of 1-3 μm in the first year of use.

However, we have observed corrosion of the basis metal, after only a few months' outdoor exposure, in steel parts coated with nickel to a thickness of 15 μm and with microcracked chromium according to specification.

Samples coated with microcracked chromium often appear very unattractive after long outdoor exposure, and we wished to establish how far this depended on the nature and thickness of the metal layer(s) under the chromium.

Mechanical stressing on nickel-chromium coatings.— To reproduce in static outdoor exposure the stress which occurs in automotive applications, we have introduced a method of treating chromium-plated samples with impacts prior to exposing them on the test stand. Test-pieces prepared in this way, with various nickel-chromium coatings, have been exposed to the very severe industrial atmosphere of Essen (Ruhr) for 19 months and then examined. Figures 1(a-d) show the damaged areas, slightly enlarged. It is readily seen that microcracked chromium performed much better than crack-free chromium. In Fig. 1(a) (crack-free chromium on bright nickel), it is clearly evident that of the many concentric cracks produced by the blow both the inner- and the outermost are more corroded than the others. This emphasizes the role of

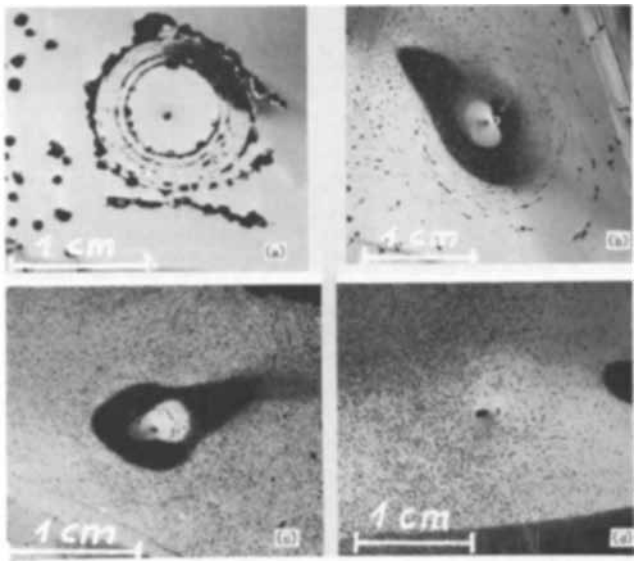

Fig. 1. Impact spots after corrosion: (a) c. 12 μm bright nickel, crack-free chromium; (b) c. 28 μm duplex nickel, crack-free chromium; (c) c. 16 μm bright nickel, microcracked chromium; (d) c. 25 μm duplex nickel, microcracked chromium.

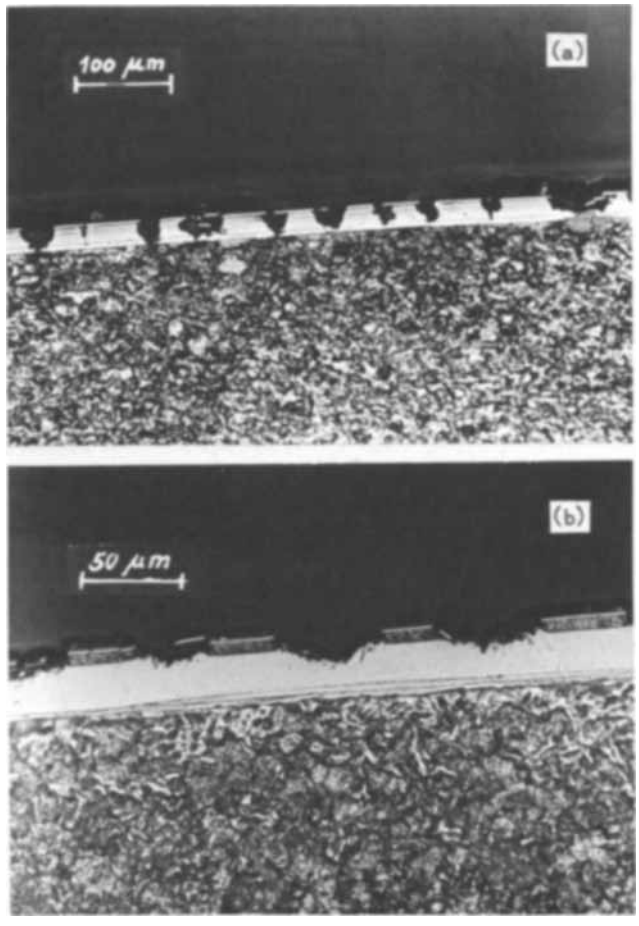

Fig. 2. Cross sections—corrosion on impact spots: (a) bright nickel, crack-free chromium; (b) duplex-nickel, crack-free chromium.

cathodic control of nickel corrosion in contact with chromium. Adjoining both these cracks there is a large unbroken area of chromium, so that these cracks have a larger cathodic area than the others.

The next two pictures [Fig. 2(a) and (b)] show sections of the samples with crack-free chromium. It is clear that in contrast to the bright nickel, which was penetrated completely by cracks, the duplex nickel system has resisted complete penetration of the cracks and has subsequently very effectively prevented penetration of the corrosion in depth. Obviously, however, the thin copper layer (about 3 μm) applied as first coating in all the test pieces with bright nickel has also considerably protected the basis metal.

These results are really only what was to be expected. It must still be asked, however, why microcracked chromium protects so well against corrosion, particularly mechanically stressed samples. Nohse (2) pointed out that damage to a microcracked chromium coating does not alter the ratio of the electrode areas, and hence also does not affect the corrosion behavior. Völkel (1), on the other hand, expected that in a microcracked chromium coating "the internal stresses should be so relaxed that no further cracks should occur in transport service, which would be propagated through the bright nickel layer beneath." Various experiments have already been made on the effect of bending of nickel-chromium coatings, and gave the fairly unanimous result that the tendency of bright nickel to crack is less under microcracked chromium than under normal chromium (3-5). We investigated the effect of individual impacts on the surface of a chromium coating. For this purpose, we plated plane panels, 10 x 5 cm, on one side with the following sequences of coatings:

1. 16 μm bright nickel, crack-free chromium.
2. 32 μm bright nickel, crack-free chromium.
3. 26 μm semibright nickel, 8 μm bright nickel, crack-free chromium.
4. 16 μm semibright nickel, 16 μm bright nickel, crack-free chromium.
5. As 3, but with fresh electrolyte for the semibright nickel.
6. 16 μm bright nickel only.
7. 16 μm bright nickel, microcracked chromium.

Masks were used in deposition, so that coatings of very uniform thickness were produced (±2 μm nickel). The plates were then laid, coated side up, in a simple holder and impact bodies of various masses, with a radius of about 3 mm at the point of impact, were dropped onto them from different heights. The support had a hole of 10 mm diameter in the middle, so that the samples could be bent by the blow.

Microscopic examination of the impact regions of the surface showed that, in all test pieces with crack-free chromium, concentric cracks had formed round the point of impact even when the blow was comparatively light. There was not a clear difference between bright nickel and duplex-nickel. The samples coated with bright nickel, but not chromium plated, remained free from cracks even after the strongest blows. The surfaces of the samples with microcracked chromium remained almost unchanged, but under the strongest blows (65g/60 cm or more), single cracks could clearly be seen widened at the areas of greatest deformation.

Sections of the impact regions then were prepared and examined under the microscope; the results are shown in Table I. It can be seen that all the chromium-plated bright nickel coatings, including those under microcracked chromium, have cracked in varying degrees. In particular, one can conclude that a somewhat heavier impact is necessary to crack through a thick bright nickel coating than through a thin one; and it is also clear that duplex-nickel tends to prevent cracking through to the basis metal, the more so the greater its portion of semibright nickel. Fresh electrolyte of the semibright nickel obviously produces better properties in this respect than old electrolyte.

Because bright nickel cracks under microcracked chromium even by impacts too weak to have produced any visible surface change (*see* above), it must be

Cr m = microcracked chromium.

assumed that stress cracks are particularly easily produced at the small notches of microcracked chromium.

To check the somewhat surprising result obtained with microcracked chromium, we made further experiments of the same type. The evaluation of the sections is shown in Table II. It can be seen that the results of the first experiment are largely confirmed.

In these sections, the microcracked chromium coatings showed, besides the cracks through to the basis metal, a relatively large number of cracks which had only very slightly penetrated into the nickel, but more so in the samples marked 1 than in the samples marked 2. The network of cracks in test piece 2 was, however, not as uniform as in 1, and consisted of a large number of small cracks and fewer large cracks. It may be concluded perhaps that, with nonuniform cracks, the fine ones are hardly affected by impact, but that the large ones, on the other hand, crack almost immediately through to the basis metal under the bright nickel. With a uniform crack network, however, the impact would be better distributed over all the cracks, so that many would be propagated into the bright nickel, but only a few penetrate to the semibright nickel or substrate surface.

Both experiments agree in showing that, even with microcracked chromium, impacts produce cracks through the bright nickel but not to the same extent as with crack-free chromium. This slightly greater crack resistance is not sufficient to explain the much better corrosion resistance of microcracked chromium. This latter property is due to the ratio of the cathode and anode area and that ratio, and therefore the corrosion rate, remains unaltered when the nickel cracks. If the crack penetrates to the basis metal, however, corrosion of the latter begins at once, and proceeds, according to Flint (5), preferentially.

Hence, even with microcracked chromium, duplex-nickel is advantageous for less noble metal substrates since the ductile semibright nickel cracks to the basis metal only after very strong impact. Other samples were not deformed by single impacts before exposure to corrosion, but were treated with falling sand. Corrosion of such test pieces with microcracked chromium was practically unaffected. With crack-free chromium on duplex-nickel, however (*see* Fig. 3), well-developed corrosion is seen only in the isolated pores in the outer sand-treated zone. In the center of this zone, however, where the pores are numerous, a corrosion picture very similar to that of microcracked chromium was produced. It thus seems possible, in principle, to transform crack-free or other chromium into microcracked by treatment with falling sand. This, however, is presumably effective only if duplex-nickel (copper-nickel?) is used. With bright nickel only, there is a considerable danger that a few large cracks will penetrate through to the basis metal and cause considerable corrosion. This did actually occur in all our test pieces of this type.

Corrosion mechanism in microcracked chromium.— In some experiments, steel parts coated with 6-8 μm bright nickel and microcracked chromium were covered with a thick layer of red rust after only a few months' outdoor exposure. Samples with a thin copper underlayer showed no rusting. This led to tests to determine if the corrosion of steel could be prevented, and if so to what extent, by intermediate layers of copper (or semibright nickel).

These tests (outdoor exposure) are still in progress, but we already can say that fairly thin layers of this type do, in fact, clearly retard the corrosion of steel. Formerly this has been reported for copper underlayers by Turner (6) and by Claus and Klein (7). Intermediate observations on the test pieces in this series of experiments led us to formulate a new hypothesis on the mechanism of corrosion in microcracked chromium.

Earlier microscopic examination of the surface of samples plated with microcracked chromium had shown that after long outdoor exposure there developed, on the one hand, heavily-corroded zones, often with areas in which the chromium had completely broken away, and also other regions in which, although the crack network was clearly recognizable, the individual cracks were almost uncorroded. The same observation has already been reported by Völkel (1).

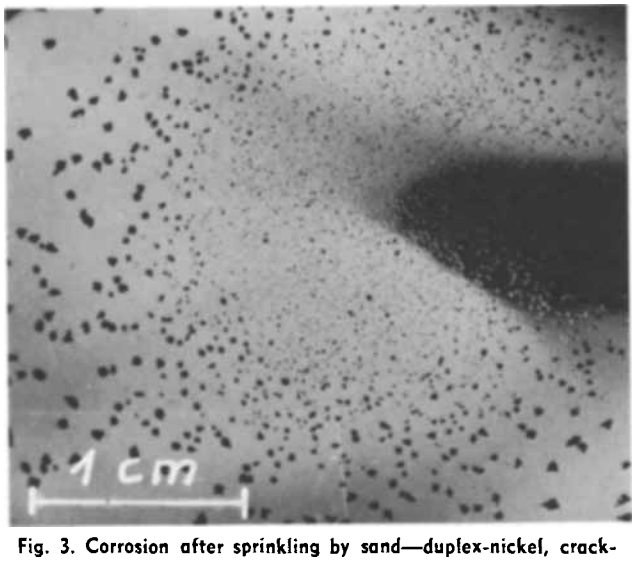

Fig. 3. Corrosion after sprinkling by sand—duplex-nickel, crack-free chromium.

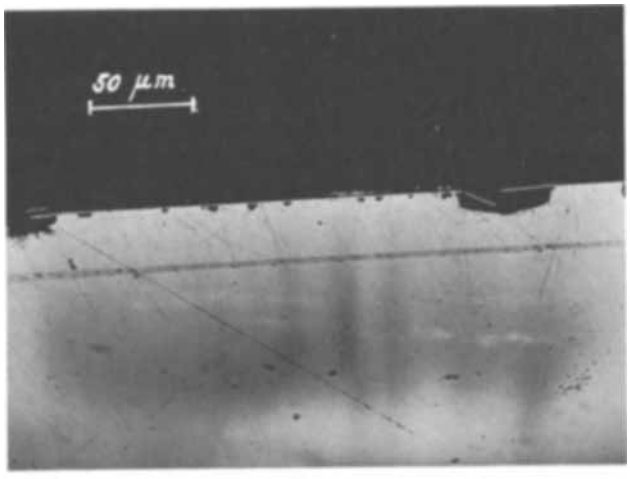

Fig. 4. Section—corrosion on microcracked chromium

Corrosion obviously does not penetrate uniformly into the nickel in these cases.

Now we prepared 5 sections of the above mentioned series, and on all samples between larger corrosion sites of various sizes we found very small ones, at which under the chromium crack only very little nickel had been corroded (Fig. 4). A quantitative evaluation of the sections for number and sizes of corrosion sites showed the following (*see* Table III). The fact that about 60% of all the corrosion sites, with good agreement among the 5 test pieces, were of the small, slightly corroded type leads us to suppose that their formation is particularly favored. It is, however, unlikely that corrosion at all these spots should have begun shortly before inspection. How are we to explain this large number of scarcely corroded cracks?

Raub (8) assumed that the fine cracks in microcracked chromium could be blocked by the corrosion products, and that the corrosion process in general was controlled by the high resistance of the electrolyte and by the resistance of the corrosion products in the narrow cracks. The other view, however, which is fairly generally accepted, is that the corrosion of nickel in contact with chromium is cathodically controlled. According to this view, the very small corrosion rate at each crack is due to the very small area of chromium available to function as cathode at each individual crack, or, in other words, because the anode surface (nickel) is large in proportion to the cathode surface (chromium) (9). We assume that this second mechanism does in fact obtain in principle, but that in microregions the corrosion can indeed be influenced by blocking the cracks, perhaps in the following way.

Corrosion begins at once at all microcracks which have penetrated to the nickel, but proceeds very slowly, because the small cathode area provided for each crack does not permit a high corrosion current. The cracks are very narrow, so that a crack easily can be blocked by the products of nickel corrosion. The electrolyte resistance rises and corrosion is retarded, or possibly completely inhibited.

The available cathodic surface for the neighboring cracks is correspondingly increased, and corrosion of these cracks will be accelerated if the resistance is small enough. At such sites, the underlying metal can be reached quickly. The small corrosion sites, however, which we found in such large numbers in the sections, are, on this basis, permanently blocked by corrosion products at an early stage. The fact that zones of strong corrosion are frequently found adjacent to almost corrosion-free areas can be explained on the assumption that, in regions where many cracks are blocked, the nickel in the few remaining cracks corrodes so strongly that larger areas of the coating are removed by the pressure of the corrosion products. This could be particularly true when the corrosion has penetrated to the basis metal. Figures 1(c) and (d) show that corrosion indeed can be completely inhibited by blocking or closing of the microcracks: The complete absence of corrosion in the center of the impact area is presumably due to pressing together the walls of microcracks at this point by the impact.

Table III. Corrosion sites after outdoor exposure

Part No.	Length of section (cm)	Total No. of corrosion sites	Small corrosion sites No.	Small corrosion sites % of total
B 90	2.25	648	391	60.5
B 92	2.05	526	296	56
B 94	2.22	604	376	62
B 96	1.82	356	188	53
B 98	1.82	534	338	63.5

The corrosion sites, which are very numerous, are statistically distributed over the surface and, if corrosion is not too far advanced, too small to be seen with the naked eye. Hence, corrosion through cracks in microcracked chromium can remain unnoticed for a long time and appear quite uniform but, in fact, it does not proceed uniformly in depth. Uniform penetration could be secured if it were possible to make corrosion proceed without hindrance in all cracks.

Turner (7), however, has established that the appearance of microcracked chromium is often considerably impaired after static outdoor exposure, but hardly after service. This can be explained in the following way.

In service, the chromium is continually subjected to impacts of sand, stones, *etc.*, causing formerly closed cracks to be reopened, and perhaps some open cracks may be closed. This should lead to a more uniform penetration in depth of corrosion of microcracked chromium in automotive service than in static corrosion testing. It is also possible that cracks which originally did not reach the nickel will completely penetrate, which would also increase the uniformity of corrosion.

Thus, the good corrosion preventive properties of microcracked chromium will be fully effective only under the mechanical stresses which occur in service.

Preservation of the decorative appearance; comparison of steel and brass substrates.—As mentioned, the decorative appearance of microcracked chromium is more or less impaired by long exposure to corrosive conditions, because the corrosion sites become visible to the naked eye. A further series of experiments showed correlations between this loss of decorative appearance and the nature and thickness of the layers under the chromium. The materials examined included bright nickel of various thicknesses, duplex-nickel, and a combination first suggested, as far as we know, by Rittner (10): a layer of bright nickel with a thin film of semibright nickel on top, which could be described as "inverted duplex-nickel." The basis metals used in our experiments were steel and brass. As usual in our laboratory, the microcracked chromium was applied as double-chromium with 400-600 cracks/cm.

After 16 months' outdoor exposure in Essen, differences between the various test pieces could be seen clearly. Results for the steel samples are shown in Table IV (not cleaned before examination). The uncleaned brass parts showed, on principle, the same appearance, except that the corrosion products naturally were much less conspicuous.

All the brass samples could easily be cleaned. Some of the steel parts gave difficulty in this respect, so that nitric acid had to be used. After cleaning, the parts could be ranked with respect to the remaining decorative effect, which was considerably different from the order of merit of the uncleaned ones. Figures 5(a-e) show the brass parts. It can be seen that the thinnest bright nickel and the "inverted duplex-nickel" still look best, while thicker bright nickel looks worse and

Table IV. Corrosion of steel parts

No.	Type of coating	Appearance
A22	7 μm Ni b	Completely covered with heavy red-brown rust
A58	18 μm Ni b	Covered with a thin yellow-brown rust layer
A94	30 μm Ni b	Nickel corrosion and thin rust film
A118	23 μm Ni d	Nickel corrosion, hardly any rusting
A143	10 μm Ni b with 6 μm Ni p on top	Nickel corrosion, extensive rusting on single sites

Symbols: Ni b = bright nickel.

Ni p = semibright nickel.

the normal duplex-nickel is even poorer, although this had the best appearance before cleaning.

The appearance of the steel parts was about the same, but with one marked difference [Fig. 6(a-e)]: the test piece with 7 μm bright nickel had a very poor appearance. However, in the regions of this sample in which corrosion had not produced too large a corrosion site, the surface is still largely intact.

These results are in accord with the valid theories on the process of corrosion in multilayer systems, which therefore need not be repeated in detail here. The impairment of the decorative effect of a microcracked chromium coating with time, is however, obviously determined by two factors:

1. The thickness of the topmost nickel layer. This determines the size of the corrosion sites when the next metal is reached.

2. The nature of the next layer, *i.e.* whether more or less noble than the nickel. If the top layer is less noble, the corrosion of the nickel layer proceeds more rapidly, inevitably sideways, the corrosion sites become larger and in the end clearly visible, but the next metal remains effectively protected. This is known to be the case with duplex-nickel. If, however, the next layer is less noble, it is preferentially attacked and the nickel layer above with its comparatively small corrosion sites remains largely intact. The decorative effect is impaired only when the corrosion of the next

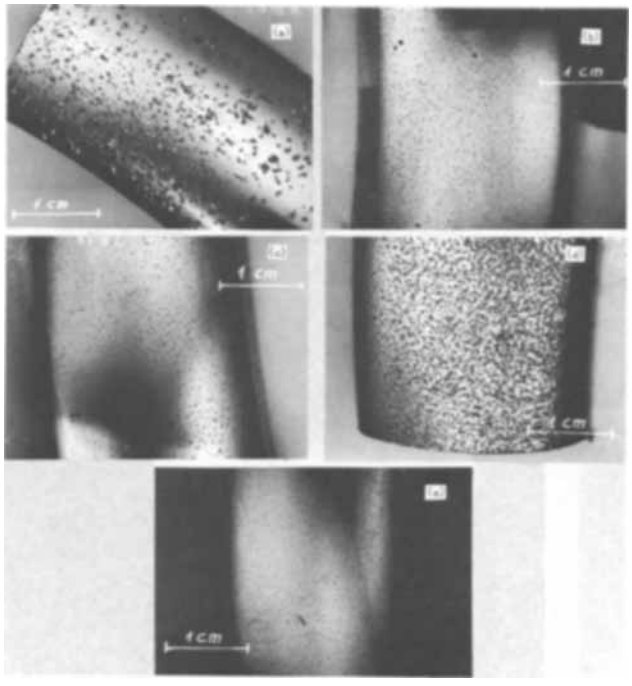

Fig. 6. Corrosion of steel samples plated with microcracked chromium over: (a) 7 μm bright nickel, (b) 18 μm bright nickel, (c) 30 μm bright nickel, (d) 23 μm duplex nickel, (e) 16 μm inverted duplex nickel.

or a subsequent layer is so strong that parts of the nickel layer are removed by the pressure of the corrosion products. This mechanical removal of the layer by the corrosion products seems hardly to occur with inverted duplex nickel as long as only the bright nickel is corroding, but to proceed rapidly when a very reactive basis metal, *e.g.* steel, is reached. Thus, a noble layer, such as semibright nickel or copper, should first be deposited on an iron substrate.

Brass as basis metal for microporous chromium plating.—The series of experiments discussed in the foregoing section confirm the finding of Seyb (11) that, with a brass substrate, even fairly thin bright nickel layers under microcracked chromium produce very good corrosion behavior. We have conducted further tests on this point.

Evaluation of polished sections.—We prepared two polished sections of each of the brass samples in the above series of tests and examined them for the number of corrosion sites, depth of penetration, and corroded surface area. The results are shown in Table V.

The fact that the number of corrosion sites penetrating to the substrate metal was smallest with duplex nickel, but very large with thin bright nickel and inverted duplex-nickel, was to be expected from

Table V. Corrosion of brass parts

Type of coating	Corrosion sites per cm Total	Corrosion sites per cm Penetrated to substrate	Corrosion sites penetrated to substrate (%)	Bright nickel corrosion per cm² section (10^{-2} mm²)
8 μm Ni b	180	56	31	3.1
6 μm Ni b	286	117	41	2.9
20 μm Ni b	175	13	7.5	3.7
18 μm Ni b	141	16	11.3	3.8
39 μm Ni b	200	1 (?)	<0.5	4.3
31 μm Ni b	168	1	0.6	4.6
31 μm Ni d	180	0	0	4.2
21 μm Ni d	150	0	0	7.0
21 μm Ni id	170	32	19	3.6
15 μm Ni id	265	84	32	3.6

Symbols: Ni b = bright nickel.
Ni d = duplex nickel.
Ni id = inverted duplex nickel.

the appearance of the test pieces. The extent of the corroded nickel in the sections (last column) shows a clear dependence on the structure of the coating; bright nickel was the most strongly corroded in the case of duplex nickel. This, again, was to be expected. The other test pieces, in which bright nickel was in direct contact with brass, showed less corrosion of the bright nickel; while more corrosion of the brass had occurred. Thus, under the conditions existing, brass behaved anodically toward bright nickel.

Contact corrosion of bright nickel and brass.—A brass plate of 42 cm^2 surface area was placed in a simple electrolytic cell, together with an electrolytically prepared bright nickel plate of the same size, and with a 1 ohm resistance in the circuit. As electrolyte, we used the solution prescribed for the acetic acid salt spray test (ASTM B 287-62): 5% aqueous NaCl, brought to a pH of 3.2 with CH_3COOH.

The quantities passing into solution in this cell in 7½ hr were:

22.5 mg Cu

13.3 mg Zn

4.3 mg Ni

It can be seen from the analysis that the brass plate was preferentially attacked, and that Cu and Zn dissolved in exactly the same ratio as that in which they were present in the brass.

In another experiment (brass and nickel in separate solutions of the above-described composition, without current), the quantities dissolved, under otherwise identical conditions, in 16 hr were:

3.25 mg Cu and 2.1 mg Zn

8.8 mg Ni

Further, the curves of current density against potential for bright nickel and brass in the neighborhood of the rest potential were plotted potentiostatically in the above solution. The size of the electrodes was 7 x 4.8 cm^2. The curves are shown in Fig. 7. The mixed potential against a saturated calomel electrode is −273 mV. Brass is the local anode; the corrosion current density is 9.2 mA/dm^2.

Analysis of the corrosion products.—The corrosion products deposited on the brass rings in the series of experiments last described were examined polarographically. For this purpose, they were dissolved from 4 cm^2 of the surface with 1N HNO_3; the time required for this was 1.5 min. This dissolution was carried out as many as 5 times on the same area, but from the 3rd dissolution onward only little nickel was removed. Table VI shows the result. The last column is particularly interesting. It can be seen that in no instance were copper and zinc found in the ratio of 63:37, corresponding to the composition of the brass; a greater proportion of zinc was always found. Further, this

Cr f = crack-free chromium.

excess of zinc was more pronounced with microcracked chromium than with crack-free chromium.

Investigation with the electron microprobe.—The investigations described led to the supposition that, in the contact corrosion of brass and nickel, the brass normally corrodes as a single substance but, in the presence of narrow cracks, and particularly in corrosion under microcracked chromium, the brass is de-zinc-ed. (The possibility of the corrosion products of copper being more easily washed away than those of zinc, which could have led to the same analytical results, may be ruled out on the basis of the solubilities of the salts concerned.)

To test more closely the question of zinc removal, we investigated sections of corrosion sites by the electron microprobe in brass under microcracked chromium. Figure 8 shows the result and, in fact, a zinc deficit is clearly apparent at the bottom of the corrosion pores in the brass, but with practically no loss of copper. Since, however, a fairly large amount of copper is present in the pores, copper must also be corroded.

Thus, either the zinc is preferentially attacked in the corrosion of brass, or copper and zinc are dissolved in the ratio in which they are present in the brass, namely 63:37, and then the copper is, to a certain extent, deposited by cementation in the narrow corrosion sites. It is difficult to find a reason for the great amount of copper in the pores, if indeed the zinc has been preferentially corroded, and therefore we think that brass corrodes as a single substance and copper is deposited in the corrosion sites by cementation.

The exposure taken with SKα-radiation shows, moreover, that the corroding medium contains a large amount of sulfur. This was to be expected, as, in outdoor exposure in the severe industrial atmosphere of Essen, SO_2 would be the main corroding agent.

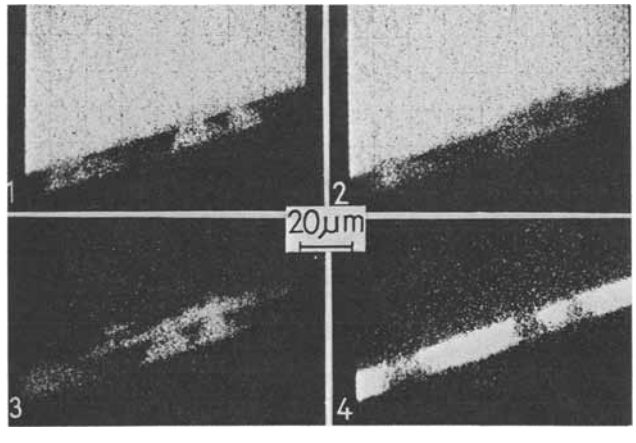

Fig. 8. Corrosion pores of bright nickel—microcracked chromium on brass—investigation of sections with the electron microprobe: 1—Cu Kα, 2—Zn Kα, 3—SKα, 4— Ni Kα.

Summary

The corrosion of nickel covered by microcracked chromium is cathodically controlled, as in the valid theories. But in static outdoor exposure, when samples plated with microcracked chromium are not mechanically stressed, many cracks are blocked, as has been shown. This results primarily from corrosion products which render such cracks ineffective for further corrosion. The result is that the neighboring, still-open cracks corrode more strongly, so that larger pores are formed at these sites and the next metal layer is reached comparatively soon. Thus, in static open-air exposure, uniform corrosion is not observed as is normally expected with microcracked chromium.

In service, however, when the part is continuously exposed to the action of sand and stones, cracks which have been blocked are repeatedly opened, and all cracks will contribute to the corrosion during its whole duration, even if periodically and to a different degree. Thus, for microcracked chromium, service conditions are not only harmless but actually beneficial. If this mechanism is right, it may be expected that microcracked chromium would behave better at exposed than at protected positions on a vehicle.

The resistance to penetration of a part plated with a microcracked chromium system also depends, of course, to a great extent on the nature and thickness of the intermediate layers. Thus, it has been shown that, with unfavorable basis metals such as steel (and probably also zinc), a ductile layer under the bright nickel is indispensable. This is primarily because bright nickel easily cracks through, even under microcracked chromium, when subjected to impact. In the absence of such a ductile layer, this will lead to immediate corrosion of the basis metal. The very ductile layer must, moreover, be more noble than the bright nickel.

Finally, it has been established that a sequence of coatings most effectively preventing corrosion of the basis metal does not necessarily also preserve the decorative effect longest. Therefore, the question of whether corrosion of the substrate metal is permissible or not should be considered in deciding the sequence of coatings. Corrosion of the substrate metal is not permissible with steel, but it is quite harmless with brass. The reason is that, in contact corrosion with nickel under microcracked chromium, brass is only slowly attacked, with preferential removal of zinc; the corrosion products are therefore inconspicuous and easily removed. Thus, for brass, a simple sequence of fairly thin bright nickel (10-15 μm) followed by microcracked chromium is adequate.

The decorative appearance could be very effectively preserved in our experiments by a thin semibright nickel layer between the bright nickel and the chromium. This sequence, namely bright nickel/semibright nickel/microcracked chromium, admittedly causes certain difficulties, particularly with the brightness and protection of the basis metal. If it is steel or zinc, therefore, a copper or semibright nickel layer must additionally be provided under the bright nickel. Such a system would, by the way, show some similarity with Tri-Nickel, which has already been used.

Acknowledgments

The author wishes to express his thanks to Robert Bosch GmbH for permission to publish this paper, and to his colleagues, particularly Mrs. Nemiroff, Mr. Binder, Dr. Fischer, Mr. Haas, Dr. Illenberger, and Mr. Pritsch, for their assistance with the experimental work, and Dr. Neumann for helpful discussions.

The Measurement of Specular Defects on Semiconductor Surfaces

J. M. Adley* and E. F. Gorey

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York

ABSTRACT

An apparatus and optical technique is described that allows the quantitative measurements of haze and other specular defects on silicon surfaces. The technique can be applied to any flat, polished specimen and yields information on the nature of the defect as well as the relative surface area covered. Data are presented for such defects as stacking faults, lapping damage, and scratches. The application of this technique to the study of epitaxial growth over steps on a silicon wafer is also described.

The most frequently used inspection in the processing of semiconductor devices is the visual inspection of silicon surfaces. Such inspection generally is made by an operator or inspector under a microscope light, on whose judgment a significant portion of the wafers inspected is often rejected. Such judgments are completely subjective and vary widely from operator to operator and day to day, even with the same operator. If such process control is to become less subjective, if valid comparisons of different wafer surfaces are to be conducted, or if any detailed study of the nature and causes of surface defects is to be made, then there exists a critical need for a more objective, quantitative technique of measuring the physical perfection of the wafer surface. Such an improved inspection technique must be at least as sensitive as the human eye, rapid,

nondestructive, and capable of observing the same features observed by the operator, but in such a way that a quantitative parameter is obtained.

Description of Technique

The basic principle of operation of this technique is that, when collimated light is normal to the surface, the light reflected at off-normal angles indicates surface defects. The light reflected to an off-normal position must be due to a surface defect face making some angle, α, with the surface: a scratch, for example, as shown in Fig. 1. A small mirror is placed next to the beam to collect the light reflected by the defects. The light incident on the mirror is focused through a telescope onto a photomultiplier tube. The wafer is then rotated using the incident beam of light as the axis of rotation. Upon rotation of the specimen such that a face of a surface defect is oriented so that it reflects light into the mirror, the photomultiplier output increases. If there are no facets oriented on the surface such that no light is reflected onto the mirror when the sample is at angle θ (Fig. 1), then only a "perfect surface" or residual signal will be seen. The photomultiplier tube output is plotted against the angle of rotation, θ, and the resulting graph contains information on the surface of the specimen under investigation. A scratch will thus produce two peaks, one corresponding to each face of the scratch. The location of the peaks reveals the angular orientation of the defect faces to each other and may give information on the type of defect; for example, a scratch or a scribe line on a silicon surface will produce two peaks 180° apart as shown in Fig. 2. The trace of the wafer before scribing, shown as the bottom line in Fig. 2, reveals a near-perfect surface free of defects as indicated by the very low minimum intensity and total absence of peaks.

The maximum-to-minimum intensity difference indicates the relative amount of a particular surface defect present, while the minimum intensity compared to a standard or reference value indicates general surface condition, in terms of surface roughness and cleanliness. The graph of a specimen having surface haze is shown in Fig. 3, where the high minimum value indicates that there is some reflection of the collected light in all directions. Correlation of the maximum-to-minimum intensity difference and the minimum intensity to surface haze "standards" reveals that increasing haze as seen by an operator is the result of increasing maximum-to-minimum intensity difference and increasing minimum intensity. Further study is under way to determine the relation of the two quantities to further processing. The two large peaks indicate that most of the defects causing the surface "haze" are oriented in the same direction, but the width of the peak indicates that not all the defects are exactly parallel. A graph of an epitaxially deposited silicon <111> wafer is shown in Fig. 4, showing the three facets of the pits at 30°, 180°, and 330°. A scribe line was placed on the wafer for the purpose of checking the orientation of the pits. The location of the peaks resulting from the scribe line reveals that the large peak at 180° is due to the long sharp edge of the pits as seen in the photograph.

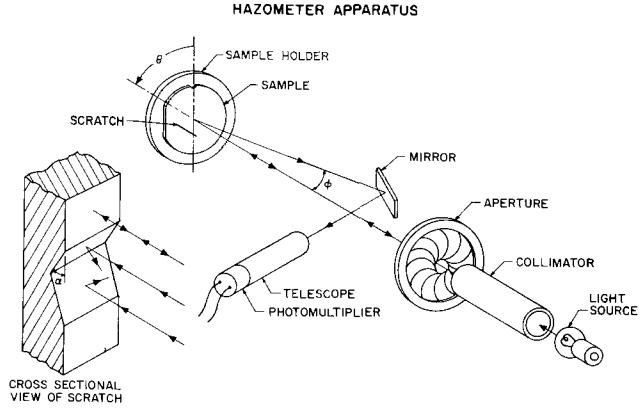

Fig. 1. Method of measuring specular defects. (The light reflected from the faces of the defect, here the scratch, is not reflected in all directions, but rather in two directions which have a component perpendicular to the surface edge of the defect face—perpendicular, that is, to the direction of the scratch here.)

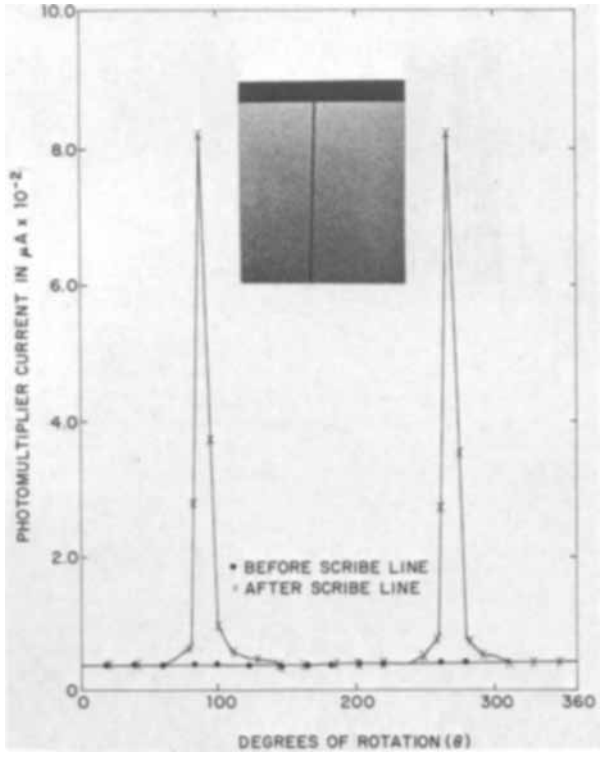

Fig. 2. Two peaks produced by single scribe line in silicon surface. (The scribe line area represented only 0.07% of the wafer area under observation and did not increase the minimum intensity value.)

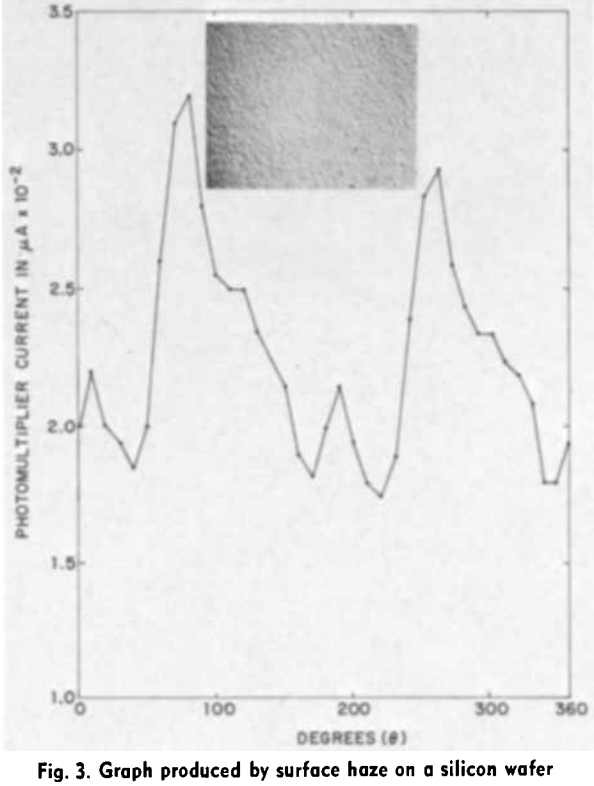

Fig. 3. Graph produced by surface haze on a silicon wafer

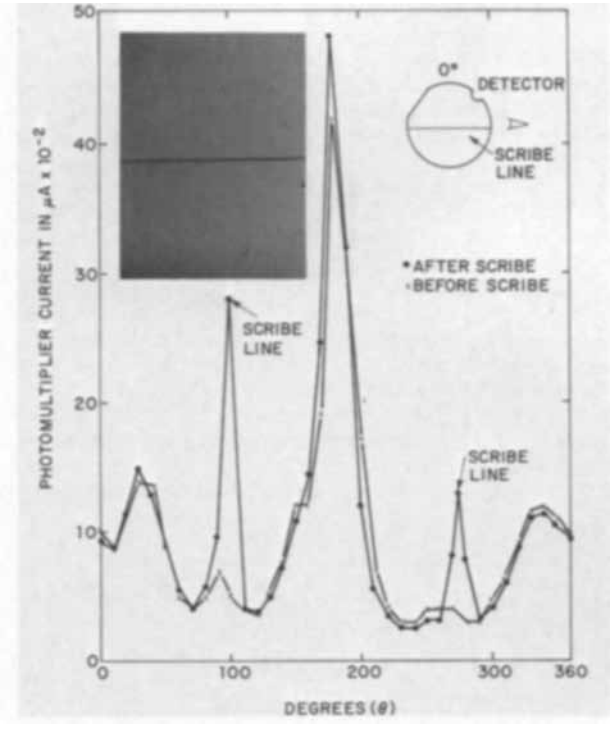

Fig. 4. Pitted, epitaxially deposited silicon <111> wafer

Dirt on the wafer has the effect of increasing the intensity value of the graph as shown in Fig. 5. Since the dirt is assumed to reflect light in all directions, the output intensity at all angles (θ) is expected to increase uniformly, thus increasing the peak and valley level by the same amount while preserving the information on the silicon surface defect given by the maximum-to-minimum intensity difference.

A mechanically polished wafer was expected to yield the same graph as the graph obtained for dirt; that is, it was assumed that the small surface scratches present from the polishing operations were completely random in orientation and would produce a constant high level output. However, as the graph in Fig. 6 reveals, the

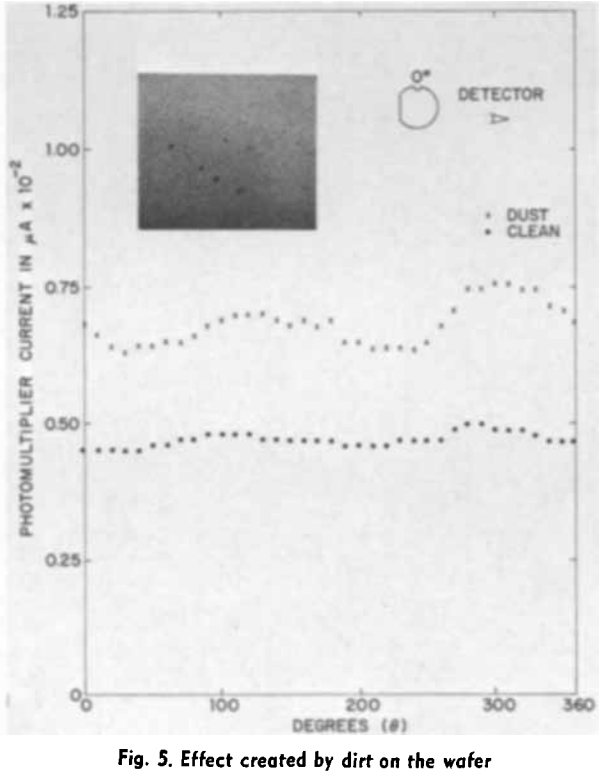

Fig. 5. Effect created by dirt on the wafer

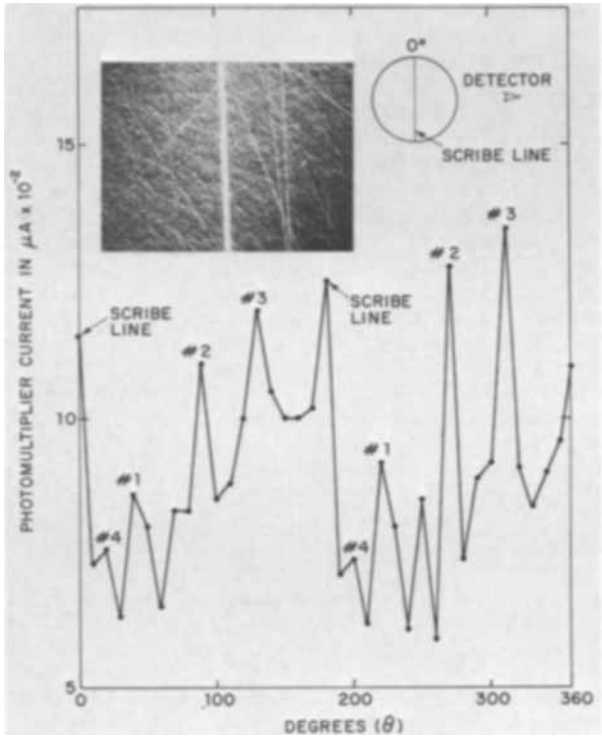

Fig. 6. Effect of scratches due to 0.25-μM grit mechanical polishing of silicon wafer.

lapping scratches show a definite structure of four preferred orientations, numbered 1-4, that are not apparent from the photograph of the surface also shown in Fig. 6. Thus, this technique is able to determine orientation dependence that is not readily apparent by any other technique.

The graph of a diffusion test square on a silicon wafer after epitaxial deposition is shown in Fig. 7. The four edges of the test square, which are of equal length, should produce equal intensity peaks; but, while three of the four peak intensities are nearly equal, one is significantly lower. The lower peak we assumed to be due to a change in the angle which that edge makes with the surface, an assumption that was verified by visual examination of similar structures

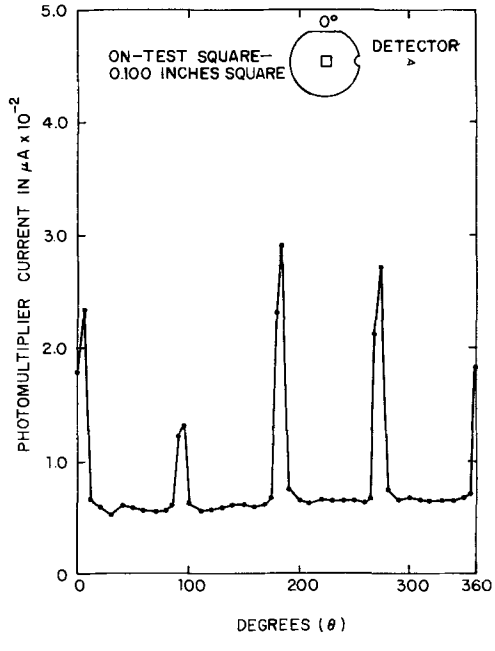

Fig. 7. The four edges of a test square on a silicon wafer after epitaxial diffusion.

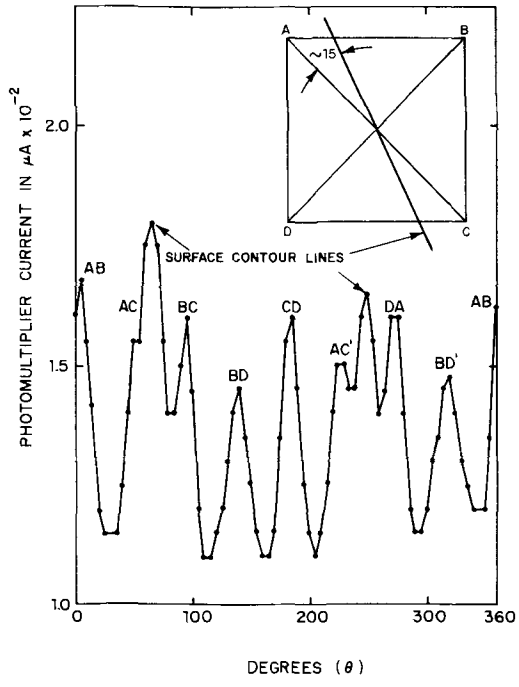

Fig. 8. Stacking fault edges, diagonals, and rolling contour lines ($\phi \approx 6°$).

under high magnification. Thus, this technique can be used to measure the angle between the defect face and the surface; in particular, the angle change of a step after epitaxial growth.

Observation of a low-temperature <100> epitaxial silicon surface produces the complex graph shown in Fig. 8. A diagram of the geometrical structure causing the peaks graphed is shown in the upper right-hand corner of the figure. The four sides of the upper right-hand figure are attributed to the four edges of the stacking fault, and the diagonals across the stacking faults appear in this specimen as four more peaks in between the four peaks due to the stacking fault edges. These edge and diagonal facets are shown in Fig. 9a, b, and c. In addition to the stacking fault structures, two additional peaks were seen on the graph that did not correspond to any possible stacking fault structure seen on the microscope photographs shown in Fig. 9a,

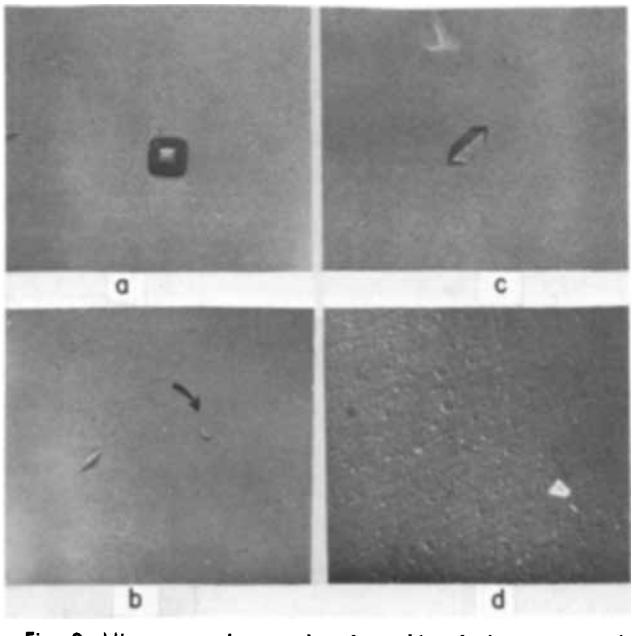

Fig. 9. Microscope photographs of stacking faults represented in Fig. 8.

b, and c. However, under Nomarski interference contrast observation, rolling contour lines were seen as shown in Fig. 9d, having the precise orientation needed to account for the two extra peaks on the graph. Thus, this technique of measuring surface defects appears to detect all geometrical features of a polished or smooth surface.

Observation of the epitaxial surface shown in Fig. 8 at larger angles of observation (ϕ in Fig. 1) will reveal the relative angle each group of facets makes with the surface. Normally the angle of observation (ϕ) is approximately 6°, but the graph in Fig. 10 was observed at approximately 11°. The intensity of the contour peaks has been greatly reduced indicating that these features are very shallow (α in Fig. 1 is small compared to the other features on the surface). The sample responsible for the graph in Fig. 11 was observed at a still larger angle (approximately 23°) and shows a further decline of the peaks due to the diagonals of the stacking faults and the contour line peaks, while the four edges of the stacking fault have in-

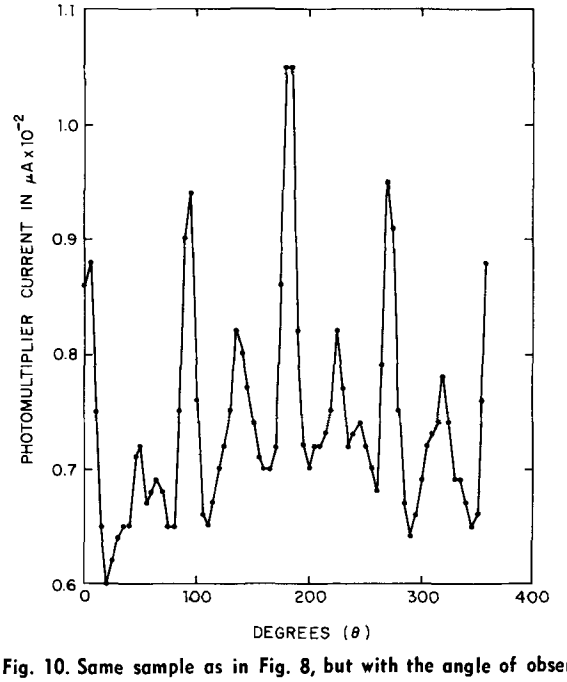

Fig. 10. Same sample as in Fig. 8, but with the angle of observation, ϕ, increased to ~11°.

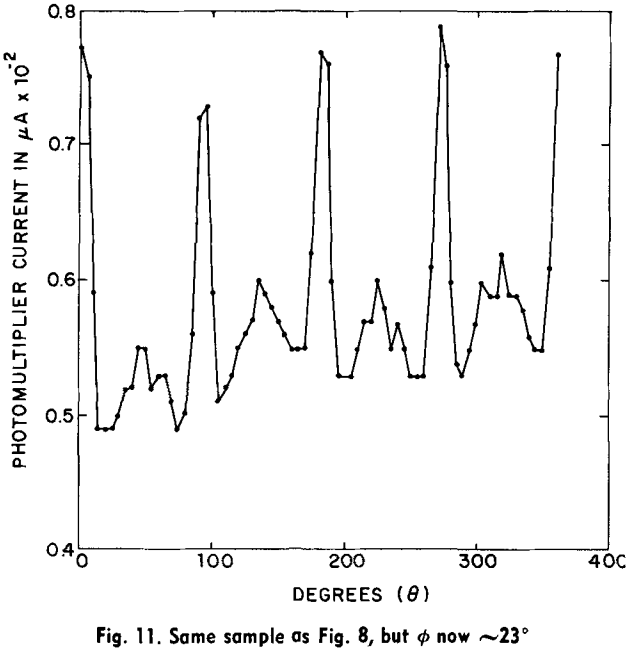

Fig. 11. Same sample as Fig. 8, but ϕ now ~23°

creased in relative intensity, thus indicating that these features make large angles with the surface.

Discussion

A technique has been developed for translating visual defects to electrical signals containing information on the nature and relative area covered by these defects. This technique allows either graphical presentation of the output as is now practiced, or allows possible future scanning of the output by computer. Because the technique can observe an entire wafer surface at once rather than by repeated scanning, this technique allows extremely rapid observation of wafers at rates possibly greater than 100 wafers per hour. But most important, this technique is operator-independent and does allow quantitative characterization of the wafer surface by using the maximum and minimum intensity difference and the minimum intensity value.

The question that must now be answered is what effect these new parameters have on subsequent processing steps. Which of the two parameters now available to characterize a surface is the more critical for further device processing and yield? Some wafers may have a very large maximum-to-minimum intensity difference but a low minimum intensity value, while others may have a small maximum-to-minimum difference and a high minimum intensity value. Studies are presently being conducted to gain some information on this question.

In summary, a quantitative measurement of surface defects has been developed and will be used to study the effects of wafer surface perfection on processing steps.

Acknowledgment

The authors would like to thank Gunar Paegle for his work in the design and building of the special sample holder. They would also like to thank all those who contributed the samples measured by this technique.

Technical Notes

Determination of the Ohmic Contribution to the Polarization of Fuel Cell Electrodes

D. Lucesoli, P. Degobert,* and E. Kochaniak

Institut Français du Pétrole, Rueil-Malmaison, France

While developing significant-size air electrodes (150 x 200 mm), having a three-layer hydrophobic structure (conductive current-collecting layer, catalytic layer, hydrophobic layer), we found high polarizations at current densities above 50 mA/cm^2. In order to determine the ohmic losses included in the polarizations, we developed a graphic method based on oscilloscope measurements. This method, when applicable, enables an optimization of the current-collecting layer properties (sintered nickel structure) in order to minimize ohmic drops.

Principle of the Method

The over-all polarization of a single electrode for a given current density is generally broken down into three distinct terms designated as:

- ohmic polarization
- concentration polarization
- activation polarization

In order to improve the performance of our electrodes, we tried to study separately the parameters influencing the total overvoltage (1) and to develop experimental procedures for studying every type of polarization.

The relaxation time, *i.e.* the time necessary to recover initial potential after a sudden interruption of the current applied to an electrode, enables the ohmic polarization to be separated from other types of polarization. The resistive component of the overvoltage disappears almost instantaneously (within about 10^{-5} sec), whereas other components decrease slowly, sometimes following exponential relationships.

Several publications have already described this method using a sudden interruption of the current to determine and eliminate ohmic polarization, both in Leclanché-type dry cells and in fuel cells (2-7).

In our case we applied this method to a half cell, measuring the actual potential compared with a reference electrode; and we tried to develop a graphical method to obtain, with sufficient accuracy, the values corresponding to the ohmic component, which are somewhat difficult to extract directly from the diagram shown on the oscilloscope screen. In order to avoid the possible limitations, which are mentioned by Niedrach and Tochner (8) (more particularly time constant of the measuring system too close to the time constant of the electrochemical system), we calculate by extrapolation the value corresponding to the interruption time zero, thus avoiding inclusion of nonlinear polarization values, in the final result. This

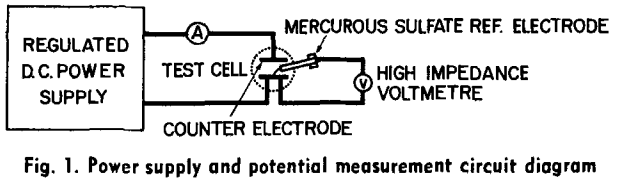

Fig. 1. Power supply and potential measurement circuit diagram

* Electrochemical Society Active Member.

graphic method allows the use of mercury-wetted switch relays which are commonly commercially available (Vynckier-France type 0612). Figure 3(a) shows the voltage drop pattern for a pure resistor, and Fig. 3(b) the same pattern for a composite overvoltage (actual fuel cell electrode).

Experimental Assembly

Measurements were made in half cells using the galvanostatic method. Potentials were measured through a Luggin capillary with mercuric sulfate reference electrodes. Figure 1 shows the experimental assembly, in which current at a constant intensity was supplied to the cell from a stabilized d-c source. Figure 2 shows the measurement circuit used to record the potential-time diagram on an oscilloscope screen immediately after the current is interrupted by an electronic switch allowing an interruption time of from 5 to 60 msec with a frequency of 1 Hz. By selecting the corresponding sweep frequency on the oscilloscope, we were able to measure the voltage drop pattern with great accuracy.

Graphic Method for Determining Ohmic Polarization

After interruption of the current, the shape of the voltage decrease on the oscilloscope screen should ideally be as shown in Fig. 3(a) (9); *i.e.*, ohmic polarization disappears before any concentration or activation polarization change can occur. In fact the actual path of the electron beam on the screen is as shown in Fig. 3(b), and accurate direct measurement of the ohmic drop is very difficult. By varying the interruption time of the electronic switch, we can have different patterns on the screen corresponding to every value of the interruption time [Fig. 4(c)]. Our graphic method consists of measuring the voltage decrease, $\Delta V_{(t)}$, for several interruption times, t, and of calculating the ohmic component from the values obtained.

Like Tvarusko (2) we can express the transient value of the voltage drop $\Delta V_{(t)}$ by relating the transient impedance, Z, to the Laplace transforms of voltage and current corresponding to the same phase angle (10)

$$\mathcal{L}\,\Delta V_{(t)} = \mathcal{L}\,I_t \cdot Z$$

By neglecting any inductive process in the measurement circuit (porous gas electrode, Luggin capillary filled with electrolyte, platinum wire) and assuming that the electrolyte conductivity remains constant throughout the Luggin capillary between the gas electrode and the platinum wire, in the equivalent electrical circuit we can take into account only a resistive component and a capacitance corresponding essentially to the double layer on the electrode. As for Leclanché type cells (2-4), the equivalent circuit consists (Fig. 5) of a pure ohmic resistance, R_o, connected in series with a polarization resistance, R_p, and in parallel with a capacitance, C. Resistance R_o is always linear, whereas under transient conditions R_p and C present nonlinear variations.

According to Tvarusko's study (2) which feeds the equivalent electrical circuit with a square-wave current (like our electronic switch), we can express the transient voltage response as

$$\Delta V_{(t)} = I\,R_o + I\,R_p\left[1 - \exp\left(-\frac{t}{RpC}\right)\right]$$

when a given intensity, I, is applied.

Transient impedance Z will be

$$Z = R_o + R_p\left[1 - \exp\left(-\frac{t}{RpC}\right)\right] \qquad [1]$$

where t is the interruption time.

For $t = 0$

$$Z_o = R_o \qquad [2]$$

We assume that the double-layer capacitance remains constant with varying potential and that the activation polarization and even concentration polarization decay exponentially with time.

The instantaneous voltage drop corresponds to the pure ohmic resistance but can be difficult to measure with accuracy from the oscilloscope pattern.

For $t = \infty$

$$Z_\infty = R_o + R_p \qquad [3]$$

If we call $L = R_o + R_p$ the asymptotic value of Z_∞, Eq. [1] may be written as

$$Z = L - R_p\left[\exp\left(-\frac{t}{RpC}\right)\right]$$

or as

$$\log_{10}(L - Z) = \log_{10} R_p - Kt \qquad [4]$$

with

$$K = \frac{\log_{10} e}{RpC}$$

Equation [4] gives a linear relationship between $\log_{10}(L - Z)$ and the interruption time, t. On a semilogarithmic diagram, as shown in Fig. 6, the intercept

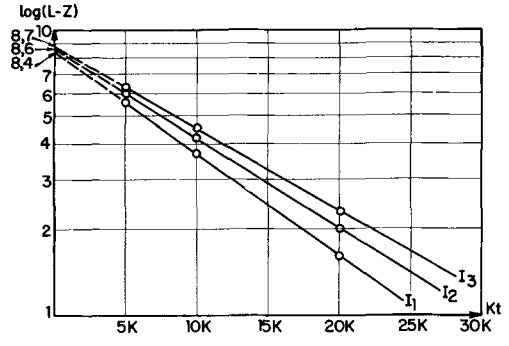

Fig. 6. Plotting equations No. 7 for different current densities

Table I

I (mA/cm²)	$I_1 = 20$				$I_2 = 40$				$I_3 = 60$			
t (msec)	5	10	20	60/80	5	10	20	60/80	5	10	20	60/80
ΔV_t (mV)	68	106	148	180	130	200	290	370	184	290	420	560
Z (ohm-cm²)	3.4	5.3	7.4	9.0	3.25	5.00	7.25	9.25	3.05	4.85	7.00	9.35
L-Z (ohm-cm²)	5.6	3.7	1.6	0	6.0	4.25	2.00	0	6.30	4.50	2.35	0
R_p (ohm-cm²)			8.4				8.6				8.7	
R_o (ohm-cm²)			0.6				0.65				0.65	

of the straight line with the $\log_{10}(L - Z)$ axis when $t = 0$ gives the value of R_p. R_o must be calculated from $R_o = L - R$, with L being determined experimentally when the over-all ohmic drop remains constant for increasing interruption times.

Table I, corresponding to Fig. 6, shows that in our case for interruption times greater than 60 msec the voltage drop reaches its asymptotic value, from which we determine that the limit for the impedance $Z = L$. Verifications were made for three different current densities.

In our case, where direct knowledge of the ohmic proportion in the over-all overvoltage is important, we can derive it by the direct plotting of

$$\log_{10}(\Delta V_\infty - \Delta V_t) = f(Kt)$$

where $\Delta V_\infty = \Delta V_{60} = \Delta V_{80}$ for $t \geq 60$ msec.

The intercept of the line when $t = 0$ gives ΔV_p (voltage drop for activation and concentration only) and

$$\eta\Omega = \Delta V_\infty - \Delta V_p$$

In the graphic method, the margin of error is less than 10%, an accuracy which is sufficient at present for development of our fuel cell electrodes. It must be mentioned that the pattern obtained for $\eta\Omega$ is valid for only one given point on the electrode surface, *i.e.* the point located at the tip of the Luggin capillary.

Application of the Graphic Method

The method was first used to study the influence of the specific properties of the current-collecting porous nickel layer on the over-all polarization, in order to choose the best suited type of porous support. Different electrodes made from several types of nickel plates were compared for their ohmic share in the over-all polarization. The same type and location of current-collecting wires was used on all the electrodes tested, and the Luggin capillary was located at the same point. Temperature was kept at 50°C.

Our porous metal support, made of sintered nickel, was drowned in the KOH electrolyte and behaved like a matrix filled with electrolyte. Its rheological properties (porosity, pore size, tortuosity) play an important part in the effective conductivity of the electrolyte inside the nickel support

$$\Psi_{eff} = \frac{\epsilon}{q}\Psi \qquad [5]$$

Ψ_{eff} = effective conductivity of electrolyte inside the porous matrix
Ψ = actual conductivity of the electrolyte (mho/cm)
ϵ = volume porosity of the porous support
q = tortuosity of the porous support

In particular, the ionic conductivity is proportional to the volume porosity of the matrix.

On the other hand, the electrical resistivity of the dry porous nickel support increases with the volume porosity (Fig. 7) for the same type of nickel plates, and when over 40% the increase in resistivity is more than linear.

Figure 8 gives the results of the apparent ohmic drop measured on electrodes of the same type, but with a nickel porous support having a different porosity although assumed to have about the same tortuosity. With a porosity of 20% to about 40% for the nickel support, the "apparent ohmic polarization" for different current densities decreases slowly, which corresponds to the increase of the effective electrolytic conductivity inside the porous matrix according to Eq. [5]. With a porosity of over 40%, the increase in electrical resistivity overcomes the decrease in ionic conductivity Ψ_{eff}. This study made on supports of the same thickness enabled the optimum porosity range (30-40%) to be chosen for the best power density in mW/cm². For 100 mA/cm², the apparent ohmic polarization, which reaches 80-85 mV for a porosity of 70%, decreases to 35-40 mV for a porosity of 40%. In terms of specific power density, this may represent 5 mW/cm² for each electrode, *i.e.* 10 mW/cm² for the cell or a 20% gain at an average power density of 50 mW/cm².

Whereas it is of great interest to decrease the volume porosity so as to improve the electrical conductivity of the support, care must be taken not to increase the weight-power ratio by using a heavier nickel support, because the specific weight of such a support increases proportionally when the porosity decreases at a con-

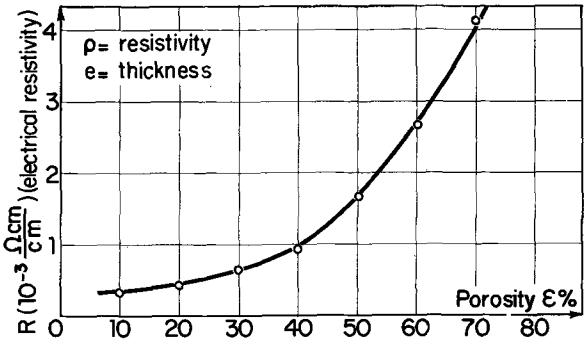

Fig. 7. Variation of electrical resistivity ($R = \rho/e$) with porosity

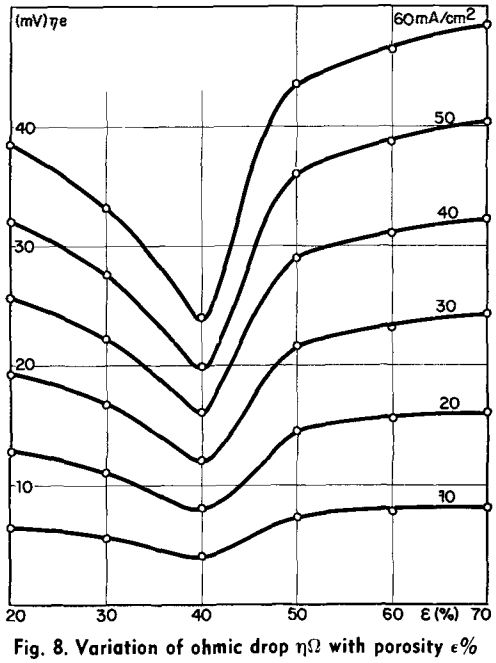

Fig. 8. Variation of ohmic drop $\eta\Omega$ with porosity ϵ%

stant thickness for the sintered plates. This conclusion leads us to replace our original 60-70% porosity plates about 0.4 mm thick by 40% porosity plates 0.25 mm thick so as to keep the same weight-power ratio, since the decrease in thickness does not significantly change the shape of the curve in Fig. 8.

Thus, the interruption technique for eliminating ohmic drop in the study of cells, combined with the graphic method described here, makes it possible to know with sufficient accuracy the value of the apparent ohmic polarization at every point of an electrode. In principle this requires four measurements at four different interruption times (with four other measurements at another current density to confirm the result). The method may be used for testing the performances of large electrodes by plotting the decay of ohmic polarization, particularly as a function of the location of the current collecting tabs. In order to improve the accuracy of our measurements, another electronic device allowing shorter interruption times (beginning at about 100 μsecs) is being developed in our laboratory. To speed up measuring, this device will be combined with electronic memories recording the values corresponding to given times after shutting off the current. Such an assembly will enable the values to be directly transferred to a digital computer which will give the values of the apparent ohmic drop directly through the corresponding program. A special test cell is now being developed to map the distribution of ohmic drop, polarization, *etc.*, on large electrodes, with the help of a digital computer. These devices and the corresponding results will be described in another paper.

Properties of Aluminum Nitride Derived from $AlCl_3 \cdot NH_3$

Daniel W. Lewis

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania

Aluminum nitride powder has been prepared by vaporization of aluminum in a nitrogen atmosphere at temperatures of 1800°-2000°C (1) and also by striking a d-c arc between high-purity aluminum electrodes in nitrogen gas (2). These powders have been well characterized as AlN and were found to be chemically and thermally stable high-temperature dielectric materials. Renner (3) prepared aluminum nitride by thermal decomposition of the $AlCl_3 \cdot NH_3$ complex. More recently, thin layers of aluminum nitride have been applied in the fabrication of semiconductor devices for surface passivation, as diffusion masks, and as dielectric layers (4). Vapors of $AlCl_3$ and NH_3 are the usual source materials in thin film electronic applications. However, thin films of aluminum nitride have also been deposited by chemical vapor transport techniques, using NH_4Cl or HCl as the transport agent (5). Very little is known of the composition and properties of the products prepared using $AlCl_3$ and NH_3 or their addition product as starting materials.

Present Work

We were interested in examining aluminum nitride as an electrical insulation for refractory conductors operating at 800°-1000°C and at frequencies and voltages likely to be encountered in aerospace applications. Since this required continuous layers 1-10 mils thick, a vapor deposition technique was employed, using the volatile $AlCl_3 \cdot NH_3$ complex as the source material. The equation representing the formation of aluminum nitride from the complex is

$$AlCl_3 \cdot NH_3 \xrightarrow{700°\text{-}1400°C} AlN + 3HCl$$

In preparing specimens for examination, ultrapure nitrogen was used to carry vapors of the complex over the hot substrate, which was usually molybdenum rods, plates, foils, or wire coils. The substrate temperature was varied from 700° to 1400°C and the pressure in the reaction system was in the range of 5-10 Torr. A quartz U-tube reaction chamber, as sketched in Fig. 1, was

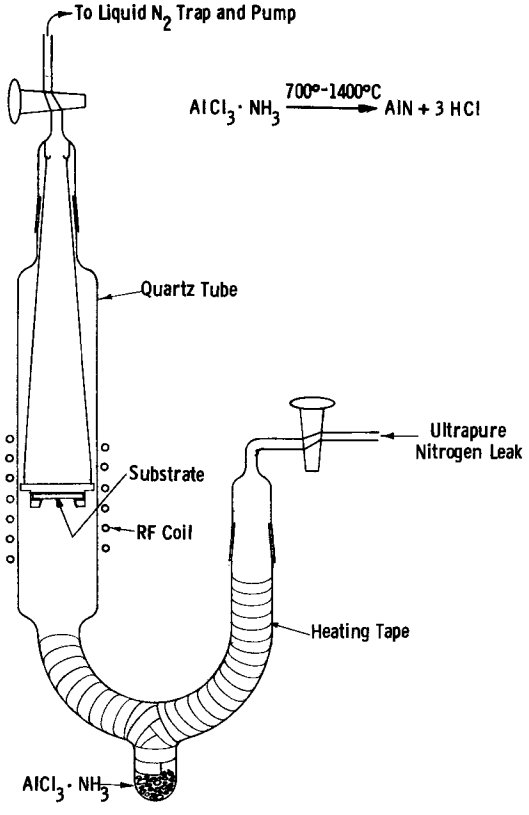

Fig. 1. Flow apparatus for vapor deposition of aluminum nitride

Key words: aluminum nitride, aluminum chloride, ammonia, pyrolytic films, dielectric properties, composition.

used and the substrate was heated by means of an external rf induction coil. Substrates were first given a heat cleaning and degassing at 1500°-1600°C and a pressure of 5-10μ. The substrate was then lowered to the desired temperature and the pressure was increased to 5-10 Torr by allowing ultrapure nitrogen to enter the system by way of a controlled leak. The cup containing the source material was heated by means of a small heating mantle. The rate of deposition was controlled mainly by the temperature to which the substrate and the source material were heated. At a substrate temperature of 1100°-1300°C, the rate of deposition was varied from 1 to 10 mils/hr by varying the source material temperature from 100° to 200°C. Films deposited in the substrate temperature range of 700°-800°C were smooth transparent electrical insulators. In the 1000°-1300°C deposition temperature range, opaque hard (8-9 on the mho scale) coatings were obtained. Using this system, it was not possible to deposit continuous films at greater than 1400°C. Either nothing deposited, or that which did was in the form of beads which made only a small area of contact with the substrate. Examples of these coatings on ½ in. diameter molybdenum rods are shown in Fig. 2.

Our aim was to determine the variation in properties of aluminum nitride films formed at various deposition temperatures. Films deposited at substrate temperatures of 800°, 1000°, and 1300°C were examined regarding their x-ray diffraction patterns, infrared spectra, hydrolytic stability, flexibility, oxidation resistance, and high-temperature electrical properties.

X-ray diffraction analysis.—Photographs of the x-ray diffraction patterns of material deposited at 800°, 1000°, and 1300°C are shown in Fig. 3. The pattern of the 800° material shows the presence of two crystalline phases. The sharp lines correspond to a crystal having the simple cubic NH_4Cl structure. Very diffuse lines of AlN are also visible. Ammonium chloride, which sublimes at about 335°C, at atmospheric pressure probably

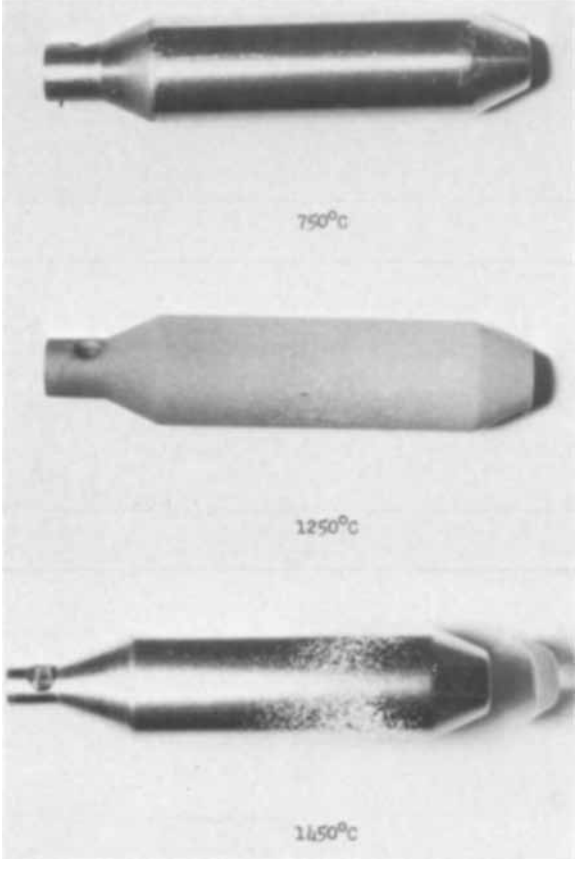

Fig. 2. Aluminum nitride deposited on molybdenum rods at 750°, 1250°, and 1450°C (1.5X).

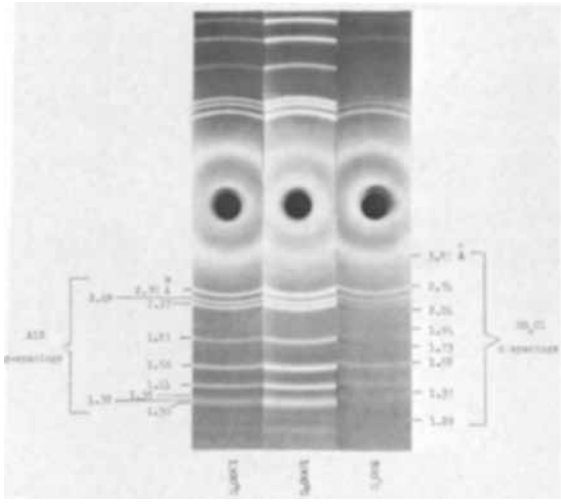

Fig. 3. X-ray diffraction patterns of aluminum nitride deposited at 800°, 1000°, and 1300°C.

was not present in the coating as deposited at 800°C, but could have been subsequently formed by hydrolysis of the powdered sample. No NH_4Cl lines are present in the patterns of the 1000° and 1300°C coatings; only the AlN structure is present. The lines in the pattern of the 1300° material are much sharper than in the 1000° deposit, indicating an increase in the crystallinity of the deposit as the deposition temperature increases.

Infrared spectra.—Infrared spectra were obtained on powdered samples of 800°, 1000°, and 1300°C aluminum nitride deposits using Nujol mulls between NaCl plates. These are shown in Fig. 4. Here, too, there is evidence of considerable amounts of ammonium chloride in the coatings deposited at 800°C. This is indicated by the sharp absorption at 7.2μ between the two Nujol peaks, and lesser NH_4Cl bands at 6.2, 5.8, 5.2μ, and several in the 3-3.5μ region. The very strong broad band centered at 14μ is characteristic of AlN. In the spectrum of the

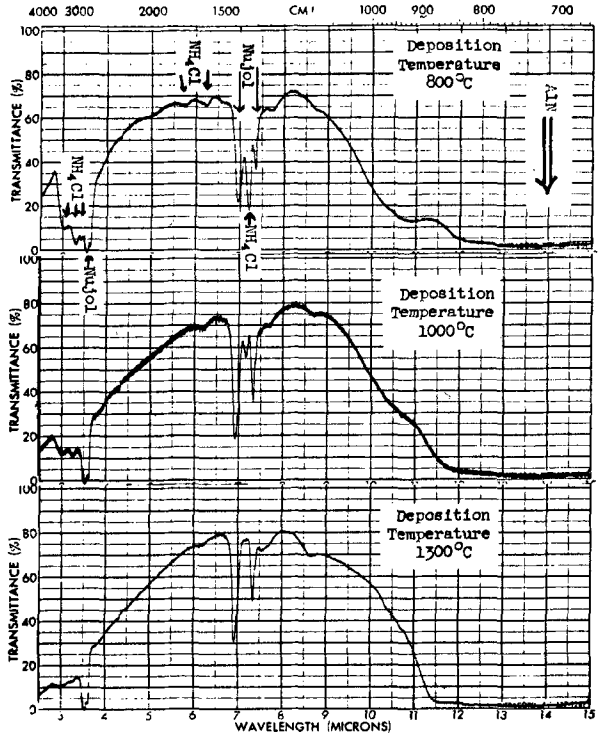

Fig. 4. Infrared spectra of aluminum nitride deposited at 800°, 1000°, and 1300°C (Nujol mull on NaCl plates).

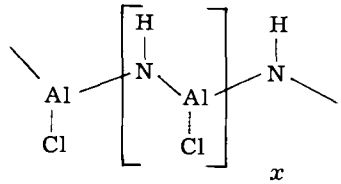
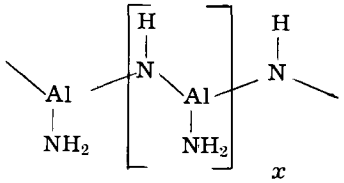
1000° material, the 7.2μ band and all of the lesser NH_4Cl bands are much weaker than in the 800° deposit. The AlN band in the 12-15μ region is still strong. In the spectrum of the 1300° deposit the 7.2μ band, as well as the other NH_4Cl bands, has disappeared leaving only the Nujol and AlN absorption.

Once again, these spectra do not necessarily point to the presence of NH_4Cl as such in the coating as deposited. It probably results from one, or more, incompletely condensed materials still containing hydrolyzable chlorine and nitrogen.

Hydrolyzability.—To check the hydrolysis theory, some of the 800° material was soaked in water in a stoppered vial. After standing for some time the vial was opened, releasing a definite ammonia odor. No odor was detected when 1000° and 1300° deposits were similarly treated. A more quantitative measurement was made by soaking weighed amounts of finely ground samples in deionized water in stoppered flasks. After 1 hr in water with intermittent shaking, aliquots for ammonia and chloride ion determinations were removed using a pipette fitted with a filter stick. Ammonia content was determined colorimetrically by the use of Nessler's reagent. Absorbance was measured at 4000Å using a Beckman Model DU spectrophotometer. The aliquot for chloride ion determination was diluted with a mixture of methanol and acetone and then acidified with 1:1 H_2SO_4. It was titrated with 0.0025*N* $AgNO_3$ using glass and silver electrodes. After 8½ hr, aliquots were again removed for ammonia and chloride determination. Results of these determinations are shown in Table I. It can be seen that coatings deposited at 800°C are more susceptible to hydrolysis than are the 1000° and 1300°C coatings. At lower deposition temperatures, the deposit very probably contains incompletely condensed hydrolyzable materials having the general composition



and



It should be noted that even though the very finely powdered samples of 1300° deposits showed some small amount of hydrolysis, 1 mil thick films of this same material could be isolated from molybdenum plates by soaking the coated plate in a mixture of HNO_3-HF. The 1/16 in. thick plate dissolved in 30-60 min with no apparent affect on the nitride film. As deposited on a molybdenum substrate, coatings appear gray, but when released from the substrate they are white or light tan.

Oxidation resistance of aluminum nitride coatings and protection offered to molybdenum.—The product of oxidation of aluminum nitride at high temperatures is alumina. Total conversion of the nitride to the oxide would result in a weight gain of 25%. To determine the extent of oxidation of a 4 mil film deposited at 1300°, it was heated in air at 1000°C for 115 hr. After 90 hr the sample stopped gaining weight. The total increase in weight during this heating was 4% which probably represents the conversion of the nitride surface to alumina.

Molybdenum rods and wire coils coated with aluminum nitride were heated in air at 700°C to determine to what extent the coating protects the metal against oxidation. Molybdenum metal begins to oxidize noticeably at 400°C and very actively at 600°C. Sublimation of the oxide layer begins at about 640°C. Judging from the oxidation resistance of the nitride film itself, a continuous nonporous film should protect molybdenum from oxidation up to 1000°C. A coil made from 40 mil molybdenum wire was coated with 0.2 mil of aluminum nitride. This coil along with an uncoated molybdenum coil of similar geometry was heated at 700°C for 16 hr. After this time, as shown in Fig. 5, there was very little left of the uncoated coil, but the coated coil was still intact. However, some attack occurred on this coil at the two points where it was found necessary to connect the coils ends to enable it to be heated inductively.

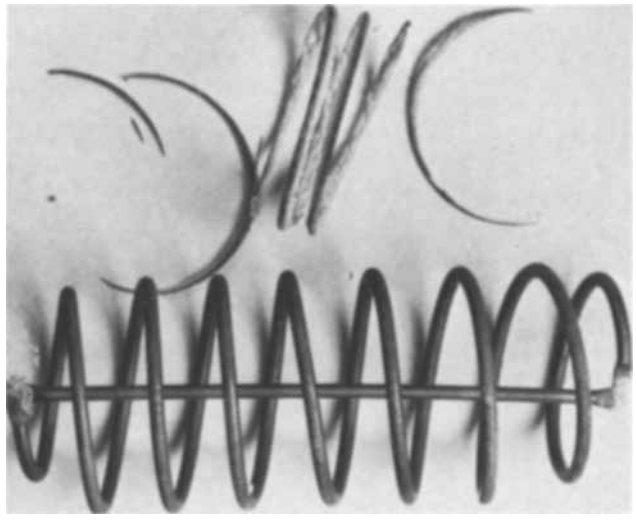


Fig. 5. Molybdenum wire coils, uncoated and coated with 0.2 mil aluminum nitride, after 16 hr at 700°C in air (2.5X).

Composition.—As noted earlier, x-ray diffraction of these deposits shows the presence of the hexagonal wurtzite structure which AlN is known to have. Infrared analysis also confirms its presence. The density of a 4.35g sample deposited at 1300° was found to be 3.13 g/cc. This compares with a value of 3.26 g/cc calculated using the cell dimensions, $a = 3.111$Å and $c = 4.980$Å. Results of elemental analysis of two separate depositions, in the 1250°-1300° range are given in Table II. It can be seen that these samples still contain about 0.3% chlorine impurity. The presence of this impurity is probably the reason why the electrical properties of the product derived from $AlCl_3 \cdot NH_3$ fall short of what is expected of high-purity AlN.

Flexibility.—Most of the aluminum nitride coatings deposited in this work, being 1 mil thick or greater, were very brittle. An attempt was made to evaluate

thinner coatings applied to 5 mil molybdenum foil. This was done by bending the coated foil over mandrels ranging from 3 to ⅞ in. in diameter. Increments between mandrels were ¼ in. A 0.2 mil film did not show evidence of cracking until bent around a 2¼ in. mandrel. No obvious cracking of 1μ films took place as the mandrel diameter was reduced to ⅞ in., but when examined under a microscope a few long cracks were evident.

Electrical properties.—High-temperature electrical properties of aluminum nitride coatings deposited at 800° and 1300°C are shown in Fig. 6, 7, and 8. At room temperature the d-c conductivity of these films is in the 10^{-15}-10^{-14} (ohm-cm)$^{-1}$ range, but as the temperature is increased this value increases rapidly. As might be expected from the foregoing properties of coatings deposited at 800°C, the conductivity and dissipation factor of this material are considerably higher than those of the 1300°C product. The d-c conductivity of the former at 300°C is 8×10^{-10} (ohm-cm)$^{-1}$. Since at this temperature the conductivity *vs.* temperature curve is becoming quite steep, measurements of this material were not made at higher temperatures. Electrical properties of the film deposited at 1300°C were measured up to 800°C. At a measuring temperature of 300°C, the d-c conductivity of the 1300°C material is lower by a factor of 10^4 than that of the coating deposited at 800°C.

These dielectric values compare very favorably with those reported (1, 6) for aluminum nitride crystals formed by a vapor phase reaction of the elements or by sublimation of an existing aluminum nitride source. Nevertheless they are somewhat inferior to similar properties of high-purity alumina or to what might be expected of high-purity aluminum nitride. It should be mentioned that, due to errors in the measurement of the thickness of some of the rougher coatings, these values may be in error by as much as 20%.

Summary

Aluminum nitride coatings were pyrolytically deposited on refractory metal substrates using the volatile $AlCl_3 \cdot NH_3$ complex as the source material. Deposi-

tion rates depended on the temperatures of the substrates and the source material, and can be as high as 10 mils per hour. At a deposition temperature of 800°C, the transparent, amorphous films were subject to some atmospheric hydrolysis. Coatings deposited at 1300°C were stable, very hard, brittle, opaque, crystalline, and very adherent on molybdenum or tungsten. They offered considerable high-temperature oxidation protection to these refractory metals, but complete coverage of irregular surfaces was difficult. Electrical properties of these coatings are poorer than what is expected for high-purity aluminum nitride.

Thin Tunnelable Layers of Silicon Dioxide Formed by Oxidation of Silicon

Alvin M. Goodman and James M. Breece

RCA Laboratories, Princeton, New Jersey

Although there is a considerable amount of information available about the thermal growth of relatively thick (200-90,000Å) SiO_2 films on Si as a function of time and temperature (1-8), there is comparatively little information published on the growth of thin tunnelable oxide layers at moderately elevated temperatures. The measurement of thin oxide layers by ellipsometry has been described by Archer (9), McCrackin *et al.* (10), Zaininger and Revesz (11), and Saxena (12). In addition, Archer (13) has described the growth of thin oxide films on Si in air at room temperature; these films continued to grow with time under room ambient conditions.

In the work described in this paper, a study was made of the growth of SiO_2 on freshly etched Si at 600°C in dry oxygen and in water vapor. The object of this work was to develop a technique for reproducibly fabricating thin tunnelable SiO_2 layers (on Si) and to determine the degree of thickness stability of these layers under room ambient conditions.

The layers described in this paper have been and are being used in MNOS memory capacitors and transistors of the tunneling-mode type described by Wallmark and Scott (14).

Layer Fabrication, Measurements, and Discussion

The oxidations were carried out in the center zone of a resistance heated 3-zone tube furnace. The center (flat) zone was maintained at 600° ± 1°C. For the dry oxidations, pure tank O_2 was passed through a Millipore Filter (0.2μ) and a dry ice trap into a quartz furnace tube (1.5 in. ID) at a flow rate of 80 cc/min (measured between the trap and the furnace). For the oxidations in water vapor, a quartz flask containing quadruple distilled water (maintained at 101°C) was connected to the furnace tube through quartz tubing. This quartz tubing was heated to prevent condensation on the inner walls. The vapor pressure over the water was 788 Torr (corresponding to 101°C). The vapor pressure at the sample is undoubtedly somewhat less although it is not accurately known. A region near the exit (open) end of the furnace was maintained at ~150°C; the use of this region will be discussed shortly.

The majority of the wafers used in the oxidation experiments were 6-13 ohm-cm, p-type with chemically polished 100 faces. A smaller number of "wet" oxidation experiments were carried out using wafers of different orientation and conductivity type; this is discussed later. All thickness measurements were made ellipsometrically.[1]

Our initial oxide growth results were not reproducible from day to day. A number of different wafer preparation procedures were tried before arriving at the following preoxidation wafer treatment.

Each wafer was: (i) cleaned in a solution of 4 parts distilled H_2O, 1 part H_2O_2 (30% stabilized), and 1 part NH_4OH (58%) by boiling for 5 min; (ii) triple rinsed in distilled H_2O; (iii) etched in concentrated HF for 2 min at room temperature; (iv) rinsed in distilled H_2O by diluting the HF and pouring off most of the diluted solution at least 5 times—*not allowing the wafer surface to be exposed to air until after the final dilution and rinse with H_2O*; (v) spun dry for 1 min in a clean Teflon spinner; and (vi) preheated in the 150°C region of the furnace for 2 min to drive off any remaining water (or other volatile contaminants).[2]

Each wafer was then placed in the 600°C zone of the furnace for the desired amount of time, after which the oxide thickness was measured as quickly as possible (within 2-3 min) and in some cases at various intervals thereafter.[3]

The results of the 600°C oxidations in dry oxygen are shown in Fig. 1, while the subsequent growth curves of three layers in room ambient are shown in Fig. 2.

[1] The thickness determinations were made using Saxena's correction [Fig. 2 of Ref. (12)] to the usual linear approximation (9, 11). Vedam (15) *et al.* have recently reported new values for the optical constants of silicon which are at variance with the generally accepted values (9, 11-13). If these new values had been used to obtain the film thicknesses from the ellipsometric measurements, the calculated film thicknesses would have been about 3.2% greater (16).

[2] When the furnace is connected to the water vapor source for the "wet" oxidations this step, of course, does not eliminate all water on the surface but instead brings it to a repeatable concentration before the oxidation at 600°C.

[3] The oxide thickness has also been checked at intermediate points in the preparation procedure. The oxide thickness measured (within 2-3 min) after the spin drying step has been found to be in the range 6-9Å. Similarly, the oxide thickness measured (within 2-3 min) after the preheating step has been found to be in the range 9-11Å.

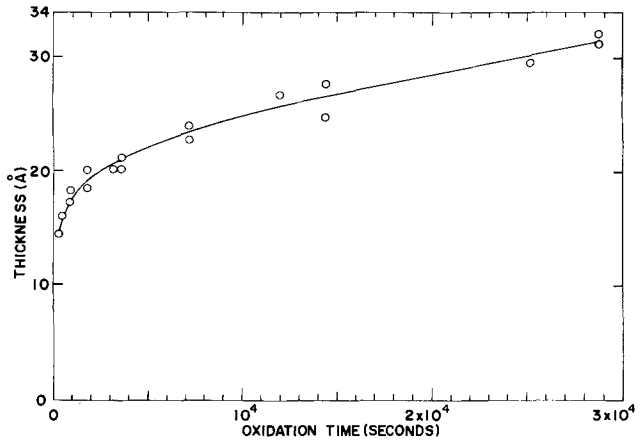

Fig. 1. Growth of silicon dioxide in dry oxygen at 600°C

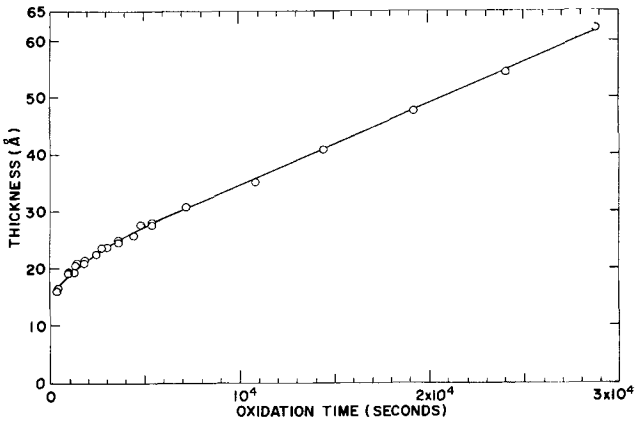

Fig. 3. Growth of silicon dioxide in water vapor at 600°C

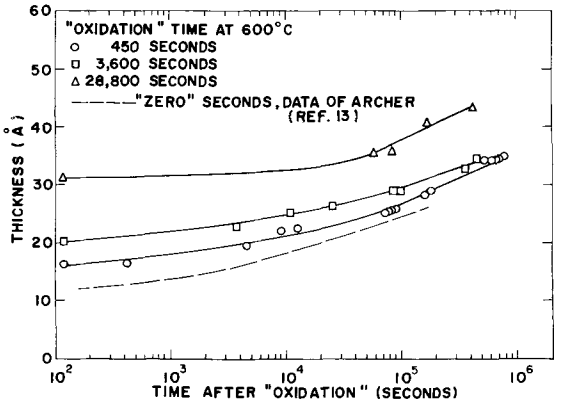

Fig. 2. Oxide growth in room ambient after "dry" oxidation at 600°C.

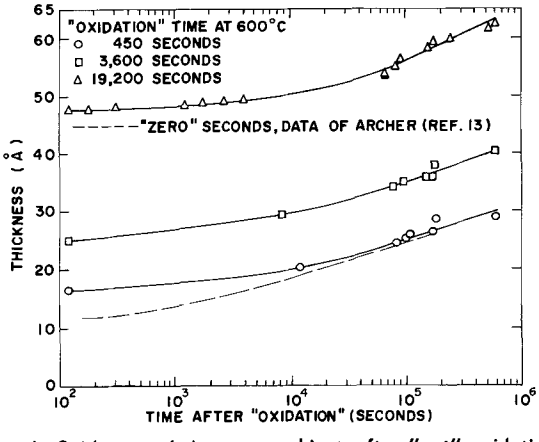

Fig. 4. Oxide growth in room ambient after "wet" oxidation at 600°C.

The room-temperature oxide growth found by Archer (13) is shown in Fig. 2 for comparison.

Only one of the experimental points in Fig. 1 lies more than 1Å off the smooth curve; it seems likely that this was due to a measurement error since a repeat oxidation for that time gave a thickness result within 1Å of the curve. It is apparent that there is a rapid initial growth region during which the growth rate diminishes with time. The growth becomes approximately linear with time for oxide thickness greater than about 25Å and the rate in this region is about 3.2×10^{-4} Å/sec. It is of interest to compare this rate with the values that can be extrapolated from the investigations of others at higher temperatures. From the dry oxidation work of Deal and Grove (3) (in the range 700°-1200°C), one would expect a growth rate of 5.5×10^{-5} Å/sec. Revesz and Evans (8) have investigated the dry oxidation of silicon both in an rf-heated system under "very clean" conditions in the range 900°-1300°C and in a resistance-heated alumina tube in the range 900°-1250°C. Their results were given in the form of values of the parameters a_o and Q_a where the rate constant a was given by $a = a_o \exp(-Q_a/kT)$. The resultant values of a at 600°C are 5.7×10^{-3} Å/sec for the rf-heated system and 2.4×10^{-4} Å/sec for the resistance-heated system.

The growth of the oxide layers after oxidation at 600°C, shown in Fig. 2, clearly indicates that the oxide thickness is not stable under room ambient conditions and that continued growth occurs at a rate similar to that for oxide growth on previously unoxidized Si wafers.

Figure 3 shows the results of the 600°C oxidations in water vapor; the subsequent growth of three "wet" oxide layers in room ambient is shown in Fig. 4. All of the data points in Fig. 3 are within ± 1Å of the smooth calibration curve. Other oxidations were carried out to check this curve and the resulting data points (not shown in Fig. 3) were also within ± 1Å of the smooth curve. Above an oxide thickness of about 25Å the growth rate is constant and equal to 1.4×10^{-3} Å/sec. This may be compared with the wet oxidation data of Deal and Grove (3) (in the range 900°-1200°C) from which one would expect a growth rate of $\sim 1.6 \times 10^{-3}$ Å/sec at 760 Torr of H_2O.

The wet oxidations of Revesz and Evans (8) were carried out in an alumina tube at a water vapor pressure of ~24 Torr; this was obtained by bubbling He through distilled water and then passing the "wet" He through the furnace tube. If one extrapolates their results (in the range 920°-1200°C) to 600°C, a linear rate constant of 7×10^{-5} Å/sec is obtained. If one assumes that the rate constant depends linearly on water vapor pressure, then this would be equivalent to a rate constant value of 2.2×10^{-3} Å/sec at 760 Torr. The agreement between these linear growth rates is better than one would expect considering the uncertainty of the water vapor pressure in each case and the fact that the growth rates for Ref. (8) and (9) are extrapolated to 600°C from experimental data at temperatures at least 300° higher.

Below an oxide thickness of about 25Å, the growth rate is higher than the linear value and not constant. A rapid initial growth phase of this type is usually observed in dry oxidations but has apparently not previously been observed in the case of oxidation in a wet ambient (17). A possible reason for this is discussed in the next section.

The growth of the "wet" oxide layers after oxidation at 600°C shown in Fig. 4 is similar to that found for the "dry" oxide layers in Fig. 2. In both cases the oxide thickness is not stable under room ambient conditions and continued growth occurs at a rate similar to that for oxide growth on previously unoxidized Si.

It is desirable for many purposes to reduce the interface state density by high-temperature annealing (18). Annealing of both "dry" and "wet" oxide layers in H_2 at 500°C for 1 hr produced no detectable growth.

Further Discussion—Oxidation Mechanisms

Deal and Grove (3) have explained the lack of observation of rapid initial growth in the wet oxidation case as follows. There is a rapid initial oxidation phase associated with the transport of an ionic species and such a phase is to be expected until the oxide thickness is large in comparison with the space-charge layer extent within the oxide. The extent of the space-charge region is characterized by the extrinsic Debye length

$$L_D = [(kT/e)(K\epsilon_0/2eC)]^{1/2}$$

where k is Boltzmann's constant, T is the absolute temperature, e is the magnitude of the electronic charge, K is the oxide relative dielectric constant (3.8 for SiO_2), ϵ_0 is the permittivity of free space, and C is the equilibrium concentration of the ionized oxidant in the oxide at the free surface. For "wet" oxidation at 1000°C, the value of C is about $3 \times 10^{19}/cm^3$ and L_D is ~6Å. Thus, the rapid initial oxidation phase would not have been observed using the multiple beam interferometric measurement technique [employed in Ref. (3)] with an accuracy of ± 25Å or any other measurement technique with a similar accuracy. On the other hand, for oxidation at 1000°C in dry O_2, they found that C is about $5 \times 10^{16}/cm^3$ and the resultant value of L_D is ~150Å. This corresponded well to their experimental observation of rapid growth of dry oxide in the region below about 200-300Å.

The temperature dependence of C in the range 900°-1200°C is very weak for both "wet" and "dry" oxidation and L_D does not vary greatly (3). If the same temperature dependence holds down to 600°C, the "wet" oxidation result observed in the present work (Fig. 3) is in accord with the explanation presented above. However, this would mean that the dry oxidation observed in the present work was still in the initial rapid growth region and a lower linear rate constant would be expected if the dry oxidation studies were extended to much greater oxidation times.

In addition to the work described in the previous section, some additional "wet" oxidation experiments were carried out using 7-11 ohm-cm p-type wafers with 111 faces and 7-13 ohm-cm n-type wafers with both 100 and 111 faces. The oxide layers grown during these experiments were all in the 16-32Å range; the resulting data were within ± 1Å of the smooth curve in Fig. 3. If the dominant rate-limiting step in the oxidation were at the $Si-SiO_2$ interface, one would expect the oxidation rate to be orientation-dependent (19). This is clearly not the case in the rather limited range studied here.

An examination of Fig. 2 and 4 shows that the growth of the oxide layers in room ambient after oxidation at 600°C is similar in character to the growth of oxide on freshly etched silicon reported by Archer (13). That is, the oxide thickness after long exposure to room ambient seems to be a logarithmic function of time. The logarithmic growth rate (Å/decade of time) varied from sample to sample but this is to be expected since the room ambient was not controlled. The variability of the room ambient is also the reason for the somewhat greater scatter of points in Fig. 2 and 4 than in Fig. 1 and 3. A variety of models exhibiting a logarithmic oxide growth law has been described by Kubaschewski and Hopkins (20); another model leading to this type of growth has been suggested more recently by Ritchie (21). We do not have sufficient information at this time to decide which (if any) of these models is applicable.

Conclusions

The results of the experiments described in this paper lead to the following conclusions:

1. It is possible to reproducibly grow thin tunnelable layers of SiO_2 on Si by both wet and dry oxidation at 600°C.
2. After the high-temperature growth period, the oxide layers continue to grow under room ambient conditions at a reduced rate.
3. The oxide layer thickness remains stable during annealing at 500°C in H_2 for 1 hr.

[1] Hydro-Québec Institute of Research, 75 Dorchester Blvd. West, Montreal 128, Que., Canada.

We would like to mention in this respect that, while working on a similar system involving bromide instead of iodide, we have obtained nearly identical results.

We, however, feel that it is worth mentioning the different conceptual approach that we used. First, we built the cell in the discharged state simply by making Ag/LiBr/Ag sandwiches. Electrolysis of the halide then insured the charging of the cell. We have then been able to observe several reproducible cycles of charges and discharges of the elementary cell.

A second difference consisted in the manufacturing of the cell. Instead of going into sophisticated vacuum deposition techniques, we simply dipped the silver electrodes into the molten halide. They were then pressed against each other after removal from the melt.

Errata

In the paper "Ultrafine Porous Polymer Membranes as Battery Separators" by J. L. Weininger and F. F. Holub which appeared on pp. 340-342 of the March 1970 issue of the JOURNAL, Vol. 117, No. 3, the last line of Table I, page 341, "Tortuosity Factor," should read "20 7.1 31" instead of "3.1 1.2 4.0."

In the paper "Study of the Behavior of Ethylene Carbonate as a Nonaqueous Battery Solvent" by Gianfranco Pistoia, Mario De Rossi, and Bruno Scrosati which appeared on pp. 500-502 of the April 1970 issue of the JOURNAL, Vol. 117, No. 4, there are several errors, corrections for which follow.

Page 500, column 1—In line 5 of paragraph 5, "Carbowax" should read "Charbowax." Column 2— In line 3, in the sentence beginning "The salts generally used . . . ," the last word should read "are" instead of "were." Table I—The last item in column 4 should read "2.0 (40°C)[c]" instead of "2.3 (40°C)[c]."

Page 501—In Table III, column 3 should read "11.84 (1.3m; 1.6*N*); 11.32 (1.0m; 1.2*N*); 7.87 (0.85m; 1.0*N*)" instead of "11.84 (11.3M; 1.6*N*); 11.32 (1.0M; 1.2*N*); 7.87 (0.85M; 0.89*N*)." In column 1, line 17 of text, "0.85M" should read "0.85m." In the third paragraph from the bottom of column 1, in lines 3 and 4, "1.3M, 1.0M, 0.85M" should read "1.3m, 1.0m, 0.85m." In the next to the last line of the next to last paragraph, "1M" should read "1m" and the comma at the end of the sentence should be replaced with a period. In the second line of the last paragraph, "(10 mA/cm^2)" should read "(5 mA/cm^2)." Column 2—In the first line of the caption for Fig. 2, "10 mA/cm^2" should read "5 mA/cm^2." In lines 6 and 18 of the text, "0.85M" should read "0.85m." In line 11, "CuF" should read "CuF_2."

Page 502—In the 1st line of the caption for Fig. 3 and the last line of Table IV, "0.85M" should read "0.85m." In Ref. (8), the correct title is "*Proc. Ann. Power Sources Conf.*"

Morphological Changes in the Lead Dioxide Electrode During Its Reduction and Reoxidation

A. C. Simon,* C. P. Wales,* and S. M. Caulder*,[1]

Naval Research Laboratory, Electrochemistry Branch, Washington, D. C.

ABSTRACT

The discharge and recharge of the PbO_2 electrode was followed by optical microscopy. During discharge the PbO_2 dissolved with simultaneous growth of relatively large $PbSO_4$ crystals. $PbSO_4$ nucleated at preferred sites on the PbO_2 and did not form a passivating film over other parts of the PbO_2 surface. The PbO_2 remaining at the end of discharge, however, had been encapsulated within $PbSO_4$ crystals grown during the discharge. During recharge these PbO_2 particles within the $PbSO_4$ crystals offered a conductive path through the highly resistive $PbSO_4$, and the formation of PbO_2 began within the encapsulating $PbSO_4$ crystals at the surface of these residual PbO_2 particles. PbO_2 thus formed grew rapidly toward the surface of the $PbSO_4$ crystals and, when reaching the surface, appeared to spread to surround the $PbSO_4$ crystals, encapsulating them in turn and leaving hollow shells as the $PbSO_4$ crystals dissolved.

The lead dioxide electrode has been, and still continues to be, the subject of considerable investigation. Despite this intensive study there still remains a number of unsolved problems concerning the behavior of this electrode, particularly when it is used as one electrode of the lead-acid storage battery.

Although numerous ingenious techniques have been developed to study the reactions taking place at this electrode during the charging and discharging of the battery, there has been surprisingly little effort made toward direct microscopic examination of the crystallogenesis in this electrode. This is remarkable since the physical condition of the electrode and its microstructure influence the degree of porosity, available reactive surface and reaction rate, and undoubtedly affect the efficiency of use of the reactive material present.

The process of charge and discharge at the electrode has been studied by Feitknecht and Gaumann (1) and also by Hisano (2), using electron microscopy. However, these studies were confined to the formation of passivating layers of $PbSO_4$ on the surface of soft lead and the subsequent further oxidation of these layers to lead dioxide. There still remained the question as to whether the PbO_2 of the active material would behave in a manner similar to that observed for the PbO_2 corrosion product of lead.

Koval and Barilenko (3) studied the charge-discharge process that occurred in the active material of actual battery plates, using optical and electron microscopy. However, their principal interest was in the effect caused by $BaSO_4$ which had been incorporated into the PbO_2 electrode. Moreover, although their photomicrographs show a definite change in the size of the $PbSO_4$ crystals formed in the presence and absence of the $BaSO_4$, there is very little additional information that can be obtained concerning the nature of the microstructure of the active material.

Further study of the actual crystallographic changes occurring in the active material during charge and discharge of the lead dioxide electrode therefore seemed to be necessary. Methods had been developed in this Laboratory (4) to study the actual microstructure of lead dioxide and other electrodes. Using these methods, numerous sections of charged positive battery plates had been examined in this Laboratory as well as a smaller number of discharged plates. In addition, a microscopic study had been made of the mechanism of electrolytic formation and the crystallographic changes that occurred in the positive electrode during the forming process (5).

Using these techniques and improvements of their own devising, Bagshaw (6) and Pierson (7) carried out further investigations of the process by which the PbO_2 electrode is electrolytically formed (oxidized) from an original mixture of PbO and basic lead sulfates. In addition, a very creditable cinematographic study of the actual electrolytic formation of the lead dioxide electrode has been prepared (8).

Despite these earlier successes, similar studies have not been made of the charge-discharge process at the PbO_2 electrode is electrolytically formed (oxidized) this process by similar techniques. Examination of completely charged or fully discharged plates gave no information of the mechanism by which the microstructural changes took place. Therefore, an experiment was set up to allow examination of sectional electrodes removed during intermediate stages of the charge-discharge process.

Procedure

The electrodes used in this investigation were commercial battery plates, received cured but unformed. The test cell consisted of two positive and three nega-

* Electrochemical Society Active Member.
[1] International Lead Zinc Research Organization Research Associate at the Naval Research Laboratory.

tive plates, and portions of the positive plate were removed at appropriate intervals during discharge and subsequent recharge. In order to insure that the test portions were of equal size and that there would be no distortion of the active material during removal of the portions, the plate was given a preliminary treatment before forming. This consisted of division of the plate into thirds by removal of the active material from between vertical grid bar rows at two locations and into sixths by the subsequent removal of active material from between horizontal grid bars midway between top and bottom of the plate. The apportioning was done in a manner to insure that the remaining pasted portions were of nearly equal area. In addition, a number of the horizontal and vertical wires were removed from the grid in the open rows, leaving just enough grid bars to give support and conductivity for the rates of charge and discharge used. This preparation of the plate made subsequent removal of portions very easy and rapid, and with minimal distortion to either the portion removed or that remaining.

The plates were formed in 1.11 sp gr acid. A current of 1.5A was used for 27 hr with the final potential reaching 2.34V. The current was then lowered to 1.0A and the cell was charged for an additional 20.3 hr to a constant potential of 2.42V. The forming acid was then replaced by 1.25 sp gr acid and the cell was on stand in this acid for 3.15 hr before the first discharge was commenced. The first discharge, which lasted for 19.3 hr, was made at the 1.0A rate but subsequent discharges were made at 3.0A. Discharge capacity declined from 18.3 A-hr at cycle 2 to 17.1 A-hr at cycle 8. All discharges were terminated at 1.80V. For identification purposes the initial forming and subsequent discharge are designated as the first cycle. All charges after the forming charge were done at 1.0A. At cycle 8, the usual charge at 1.0A was followed by a floating period at 2.25V for 72 hr.

At the beginning of the 9th cycle, after insuring that the cell was again in a fully charged state, a portion of one positive plate was removed for examination and the necessary adjustments were then made in cell current to compensate for the removal. Following this, a discharge was made at a rate equivalent to that used in the previous cycles and other portions of the plate were removed at five equal intervals based on the estimated capacity and a discharge terminating at 1.80V. With the removal of each portion the current was adjusted to compensate, so that the current density remained the same throughout the discharge.

One positive plate was thus investigated during its discharge and the other, which had been carried through the same discharge, was similarly removed in six portions during the subsequent recharge. The charge and discharge conditions and the points at which samples were removed are shown in Fig. 1.

The area of the negative plates remained greater than that of the positive throughout the experiment and there was also a large excess of electrolyte. Very little change from room temperature of 25°C occurred within the cell during the experiment.

Following removal, the various portions were immediately washed in running water, dried, and additional pellets punched out to obtain material for DTA and x-ray analysis. The remainder of each plate portion was then impregnated with a catalyzed polyester. After the hardening and curing of this resin each plate portion was sectioned and the individual sections were polished for examination by optical microscopy.

Observed Changes in Microstructure

The lead dioxide electrode in its oxidized or charged state was found by x-ray diffraction analysis to consist practically entirely of β-PbO_2, which had a microstructure that was cell-like or reticulate in nature. This was evident after cross sections had been made through the resin-impregnated electrode structure and

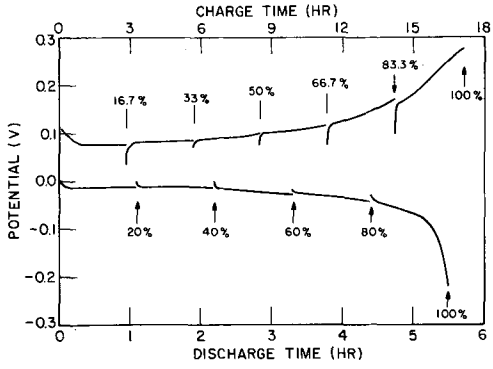

Fig. 1. Potentials of positive plate vs. $PbSO_4/PbO_2$ reference electrode, during 9th discharge (bottom) and subsequent recharge (top). At each arrow current was interrupted while a portion of the plate was removed. Numbers by the arrows indicate per cent that the plate had been discharged or charged.

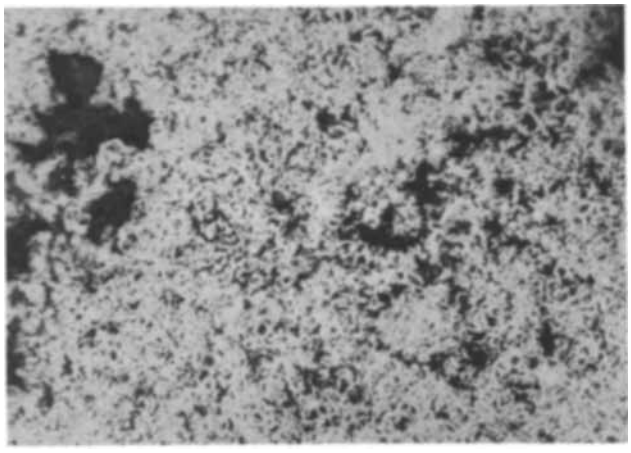

Fig. 2. Structure found in a fully charged plate. Unpolarized, vertically reflected illumination is used in this and subsequent photographs so that the reflective areas which appear bright in the photograph represent hard, dense PbO_2 particles, while the dark areas represent the voids of the plate. Note that, with the exception of a very few larger areas of porosity, the active material had a very uniform structure. The PbO_2 formed a nearly continuous cellular network, as in a sponge. Original magnification 400X.

these sections then suitably polished. An example of this type of structure is shown in Fig. 2. In this photograph the dark areas represent former voids in the plate which are now filled with the impregnating resin. The bright network represents a densely constituted PbO_2 structure which in actuality is dark brown or black. It appears white in the photograph because this and the following photographs were taken with vertical illumination of the polished surface. Under vertical illumination smooth and dense areas tend to reflect the light directly back through the eyepiece and such areas thus appear bright, or white in a photograph.

It can be noted that the lead dioxide in the network structure has an almost metallic luster, indicating a dense, hard material. If oblique lighting is used this white network is seen to be in relief upon the surface, which also indicates that the material of the network is hard, at least harder than the plastic with which the electrode material was impregnated.

Discharge process.—The initial nucleation and growth of $PbSO_4$ crystals was not observed. The first examination, when the electrode had been 20% discharged, showed that a number of crystals of normal lead sulfate, $PbSO_4$, had formed in a random fashion throughout the active material. These crystals had a reflectivity intermediate between that of the plastic and the PbO_2 so that they could be easily identified. In addition these crystals were almost invariably sur-

rounded by some void area, represented by the impregnating plastic, so that their visibility was increased. The distribution was truly random, with no greater concentration of the lead sulfate crystals in one area than another, such as at the surface or near the grid members.

The crystals were distinctly rectilinear and it was found that there was not much difference in the maximum crystal size when the 20% discharged plate was compared with that which had been 40% discharged. The total number of crystals, however, had noticeably increased in the 40% discharged electrode.

It seemed that the growth of the $PbSO_4$ crystals was slowed by some factor when the crystals reached a certain size so that growth practically stopped and new nuclei were necessary to allow the process to continue. Any of a number of factors could cause such a slowdown of crystal growth but the most probable is the depletion of one of the reacting ions at the surface of the growing crystal. The appearance of the 40% discharged plate may be estimated from Fig. 3.

At greater than 40% discharge the crystals were found to be larger. It seemed that, as sites for nucleation on the PbO_2 surface were depleted, the $PbSO_4$ crystals were crowded closer together and tended to grow upon one another so that agglomeration was increased. There was also probably continued slow growth of the earlier formed $PbSO_4$ crystals so that all of the crystals of $PbSO_4$ tended to merge together (Fig. 4). Nevertheless, their separate identity was distinguishable at high magnification.

The increase in size of the $PbSO_4$ crystals was, of course, at the expense of surrounding PbO_2, which was being dissolved at a rate proportionate to the growth of the $PbSO_4$ crystals. Comparison of Fig. 3 and 4 illustrates another characteristic of the discharge process. As the reduction of the PbO_2 to $PbSO_4$ continued, the amount of the bright shiny network of PbO_2 steadily diminished until at the end of the discharge it did not resemble a network but seemed to consist only of scattered individual particles of β-PbO_2. Although the specific volume of the $PbSO_4$ is greater than that of the PbO_2, the $PbSO_4$ forms as regular crystals that are more compact than the porous network structure of the original PbO_2. This compact form insures that the crystals of $PbSO_4$ continue to find space for growth, as can be seen in the photographs. The destruction of the PbO_2 structure during discharge is made evident by comparison of Fig. 5 and 6.

At the higher magnification of Fig. 4 it can be seen that practically all of the remaining PbO_2 particles are encapsulated within the large $PbSO_4$ crystals. It should be remembered that these photographs are of cross sections so that the white or mottled areas of PbO_2 seen surrounded by $PbSO_4$ at the surface of the section are in reality buried within the $PbSO_4$ crystals.

When polarized light was used in the examination of the sections, it was found that the $PbSO_4$ crystals did not show up well, particularly for the sections 20 or 40% discharged. At high magnification, using oil immersion it was found that as the extent of the discharge increased more of these crystals became visible, evidently because more became oriented so as to give reflections from lower surfaces. In every case, however, many more crystals were seen by vertical illumination with unpolarized light than with po-

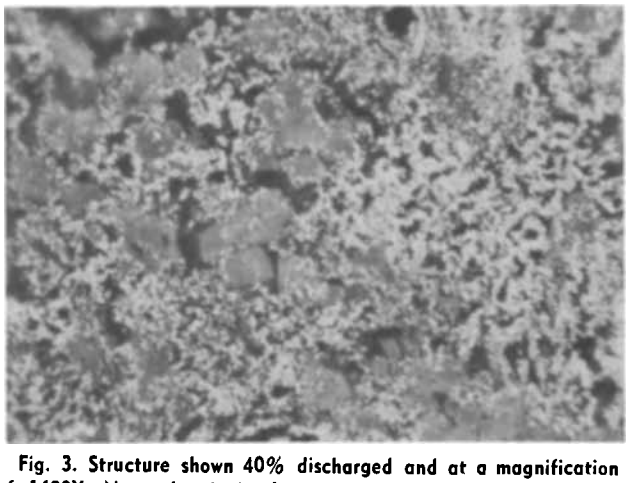

Fig. 3. Structure shown 40% discharged and at a magnification of 1600X. Note the distinctly rectilinear nature of the $PbSO_4$ crystals and that they seem to be present in small clusters.

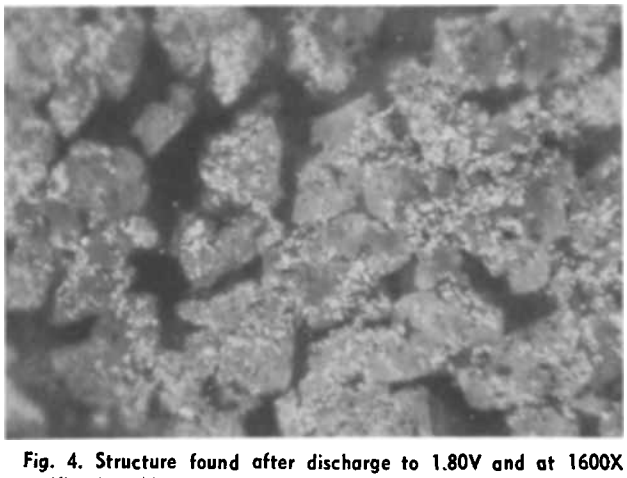

Fig. 4. Structure found after discharge to 1.80V and at 1600X magnification. Note particularly that access to remaining PbO_2 is not lost as a result of the $PbSO_4$ blocking the plate voids (still numerous), but that the PbO_2 has been rendered inaccessible by becoming encapsulated within the $PbSO_4$ crystals themselves.

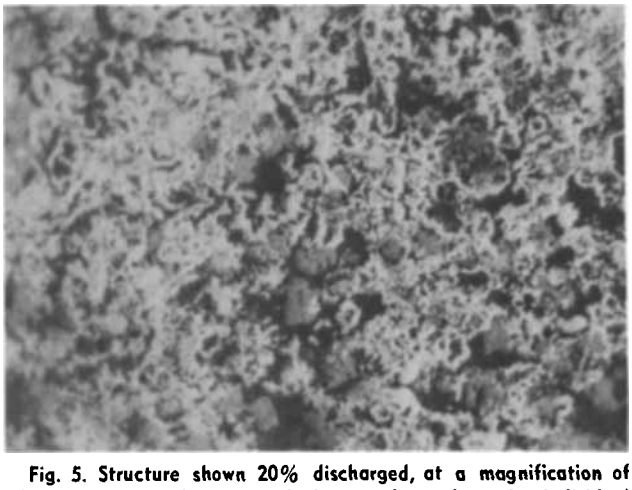

Fig. 5. Structure shown 20% discharged, at a magnification of 800X. This magnification is high enough to show the individual particles of PbO_2 and $PbSO_4$ and the field of view is sufficient to give an idea of general distribution of particles.

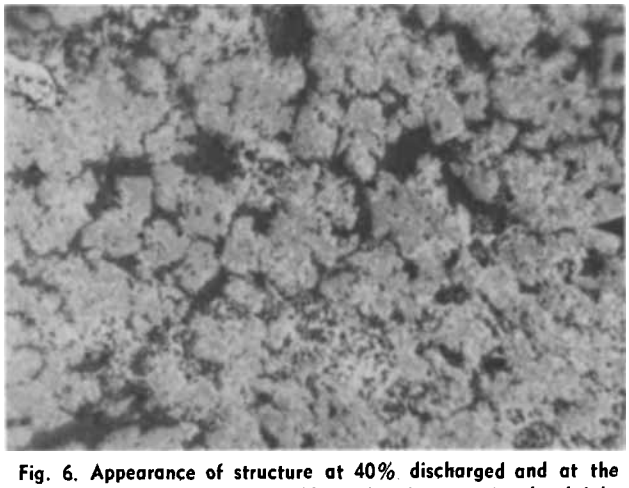

Fig. 6. Appearance of structure at 40% discharged and at the same magnification as Fig. 5. Note the decrease in the bright PbO_2 and the increase in the gray areas of lead sulfate.

larized. The crystals that could be seen by polarized light seemed to be colorless and to have a regular rectilinear form with few internal imperfections.

Another feature that was noted under polarized light was a small but distinct change of the PbO_2 to a lighter red color at the surface of the plate in those sections that had received one-half or more of the total discharge. This color change appeared only at the surface of the electrode and extended to a depth of not more than 10-20μ. It seemed that this color change took place within individual PbO_2 particles and that the color changed from a dark brown or red to a light red-orange. Examination of the surface of such electrodes after drying and before the plastic impregnation, and without the use of magnification or polarized light showed only a change from reflective black to dull brown during the course of the discharge.

Recharge process.—In many ways the oxidation or recharge of the electrode was a reverse replay of the changes that had been observed during discharge but there were some differences which at first appeared conflicting.

In examination at lower magnification it seemed that there was little change in the size or number of lead sulfate crystals as the recharge proceeded to 50%. At the same time there seemed to be a small increase in the amount of the PbO_2 network, evidenced by an increase in the bright network that had been present before discharge.

Comparing the samples at somewhat higher magnification also seemed to verify that the appearance of the $PbSO_4$ crystals was remaining practically unchanged between 17 and 50% recharged. Compare, for example, Fig. 7 and 8. The apparently unchanged $PbSO_4$ crystals and the small increase in the PbO_2 network up to the 50% recharged (Fig. 8) was puzzling, especially when compared with the considerable change that took place between 50 and 66% recharged (Fig. 9). These results made it appear that more PbO_2 was formed during the second half of the recharge than during the first half.

This inconsistency was explained, however, at the higher magnification of 1600X which revealed details that made evident what actually had occurred. In the electrode that was recharged up to 33% of the fully charged state it was found that the increase in the PbO_2 particles had occurred almost entirely within the lead sulfate crystals, with only a very few PbO_2 particles appearing at the $PbSO_4$ crystal surfaces. Thus, while a conversion of $PbSO_4$ to PbO_2 was occurring within the $PbSO_4$ crystals, their external size and form were not altered (Fig. 10). By the time that the electrode was 50% recharged the PbO_2 particles appearing at the surface of the $PbSO_4$ crystals had become quite numerous (Fig. 11) and with increasing recharge all the PbO_2 particles seemed to form at the surfaces of the remaining $PbSO_4$ crystals (Fig. 12).

Beyond 50% recharge, the $PbSO_4$ crystals definitely decreased in size while the PbO_2 now formed entirely at their surfaces and more completely encircled their dwindling masses. This caused the formation of hollow shells (Fig. 12), seen as circles in the cross section. Finally, all of the $PbSO_4$ was converted to PbO_2 and

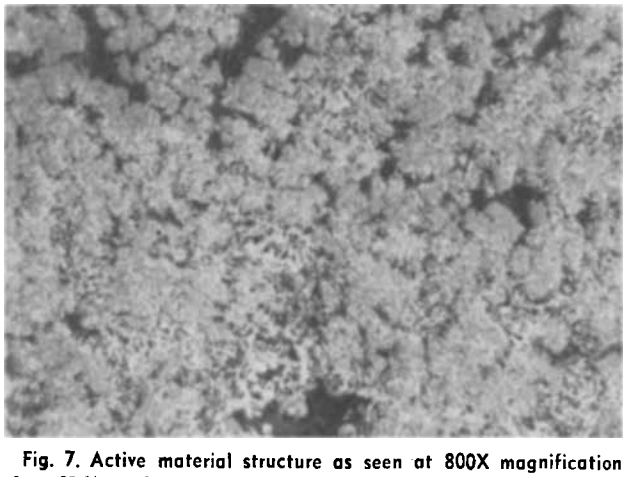

Fig. 7. Active material structure as seen at 800X magnification after 17% recharge. Notice the considerable amount of bright PbO_2.

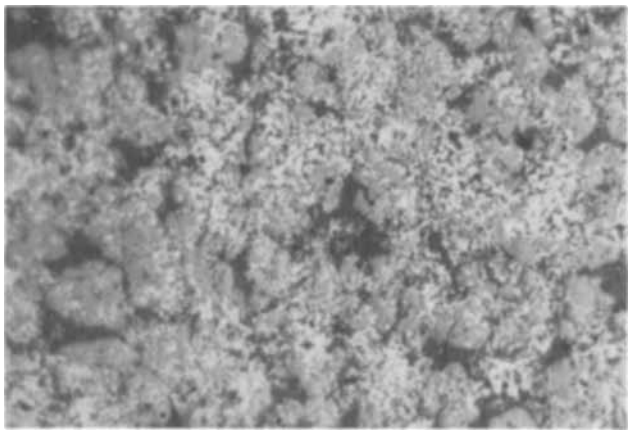

Fig. 8. Active material structure as seen at 800X magnification and after 50% recharge. Note comparatively unchanged appearance of the $PbSO_4$ areas in this photomicrograph as compared with Fig. 7. Also note that, while the amount of bright PbO_2 has increased in Fig. 8, the PbO_2 in both photographs is mainly within the $PbSO_4$ crystals and not at their surfaces.

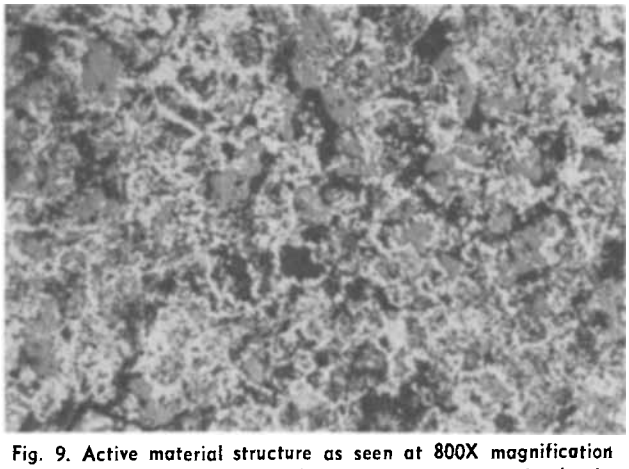

Fig. 9. Active material structure as seen at 800X magnification and after 66% recharge. Note the distinct increase in the bright PbO_2, and that this increase is now primarily at the surface of the $PbSO_4$ crystals.

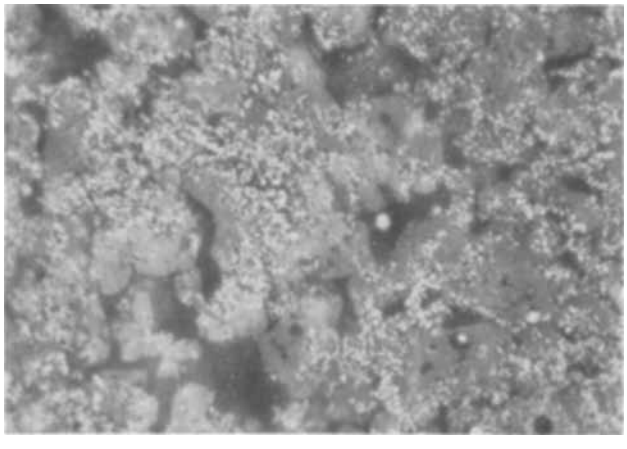

Fig. 10. Active material structure as seen at 1600X magnification and after 33% recharge.

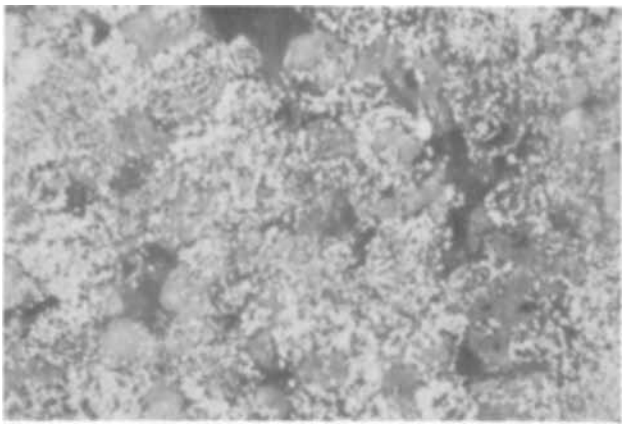

Fig. 11. Active material structure as seen at 1600X magnification and after 50% recharge.

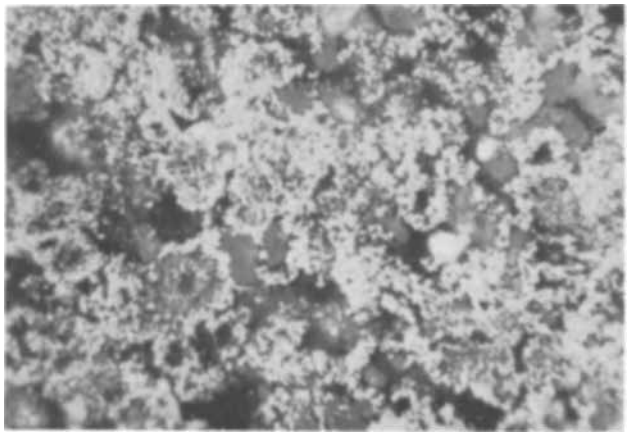

Fig. 12. Active material structure as seen at 1600X magnification and after 66% recharge.

the structure then assumed practically the same configuration as in Fig. 1. The size of the cells outlined by the PbO_2 and their configurations, do not necessarily follow that of the $PbSO_4$ crystals upon which they were formed. As previously stated, many of the $PbSO_4$ crystals contain residual PbO_2 upon which the PbO_2 of the recharge process nucleates and grows. This residual PbO_2 is itself assumed to be a connected network and the further growth of PbO_2 causes the formation of additional network within the $PbSO_4$ crystals. During its growth toward the surface this additional network subdivides the space from which the $PbSO_4$ crystal dissolves. This PbO_2 increase within, as well as at the surface of, the original $PbSO_4$ crystals causes the resultant PbO_2 structure to differ from that of the $PbSO_4$ crystals from which it was formed.

It had been observed that a thin surface layer of the active material changed from dark to light when the discharge was about half completed. This thin surface layer of lighter colored material remained during the subsequent recharge until the electrode was about one-half recharged, at which point the color became darker and indistinguishable from that of the rest of the electrode and no further change was detected throughout the remaining period of charge.

The series of samples from the discharge and subsequent recharge were also examined by x-ray and differential thermal analysis, but without uncovering any additional information. The x-ray analysis, as would be expected, showed increasing $PbSO_4$ and diminishing PbO_2 intensities as the discharge proceeded. This situation was reversed on the subsequent recharge. Plotting the relative intensities against the percentage of discharge or recharge revealed that the curve of intensities for discharge was almost exactly duplicated on recharge.

Discussion

From the above observations it would seem that the process of discharge began with the nucleation of $PbSO_4$ at various selected sites on the surface of the PbO_2, such sites always being adjacent to porous areas of the electrode. In other words the nucleation occurred at surfaces of the PbO_2 that were in contact with the electrolyte, either at the surface of the electrode or at the surfaces of the various pores and cavities within the electrode to which electrolyte had penetrated. Since PbO_2 is a relatively good conductor of electricity, differences in conductivity do not seem to be the reason for this process of nucleation occurring more frequently at one area of the electrode than at another. No noticeable difference was found in the extent of the $PbSO_4$ crystal growth near the grid or near the surface, as long as electrolyte was able to penetrate freely into the area.

Once the $PbSO_4$ crystals are nucleated further growth seems to depend on the continued dissolution of the PbO_2 crystals in the immediate vicinity, reaction between the Pb^+ and $SO_4^=$ ions, and redeposition as $PbSO_4$ upon the surface of the $PbSO_4$ crystals already present. There was no evidence that the $PbSO_4$ was forming any layer, passivating or otherwise, upon portions of the PbO_2 surface other than where nucleation had taken place.

As the discharge continued, further deposition of $PbSO_4$ was almost entirely upon already existing crystals so that these increased in size until many grew into a continuous mass containing more than one crystal. During this process of $PbSO_4$ formation, the amount of PbO_2 steadily decreased, as would be expected, until finally all PbO_2 that remained appeared to be encapsulated in the $PbSO_4$.

One assumes that initially the PbO_2 network was a continuous electrical circuit and that the electrolytic process that was making Pb^{++} ions available continued from all points of this surface except those actually covered by portions of growing sulfate crystals. Even if it is assumed that all PbO_2 particles are in contact and are part of the electric circuit of the plate at the beginning of the discharge, there is no certainty that all will remain so. Unequal solution of PbO_2 undoubtedly will remove a few PbO_2 particles from the circuit. In the path of the growing $PbSO_4$ crystals, supplied with $PbSO_4$ from other PbO_2 areas, such particles might become encapsulated and completely surrounded by $PbSO_4$. Alternatively, it is probable that at some points the continued growth of the $PbSO_4$ crystals in certain directions might cause them to grow around and encapsulate portions of the remaining PbO_2 network that yet might remain in the electrical circuit of the plate. The complexity of the PbO_2 structure insures numerous contacts between neighboring particles so that it is likely that most particles continue in the circuit even when a number of contacts have been lost. This seems to be indicated by the relatively complete conversion of the PbO_2 to $PbSO_4$. If it is assumed that the observed encapsulated PbO_2 is still in the electrical circuit of the plate several of the observed phenomena can be more easily explained, but there is, as yet, no definite evidence that such a circuit exists.

If a conductive network of PbO_2 does remain during and after the formation of the $PbSO_4$ crystals we have a ready explanation of how, in a material as nonconductive as $PbSO_4$, an electrical path is furnished both during discharge and the subsequent recharge. Because of the high electrical resistivity of $PbSO_4$ such a conductive network would be most beneficial.

The fact that in the initial stages of the recharge process PbO_2 was found to increase within the $PbSO_4$ crystals argues for a conductive network. The further observation that the recharge process changed to one where the $PbSO_4$ crystals reacted to form PbO_2 at the surface, when the internal growth of PbO_2 was extended to the surface, indicates that the process would

normally take place on the surface if it could. But the fact that it did not initially do so indicates that the process of oxidation must extend only slowly from one crystal to the next, made possible only by the conducting PbO_2 that is being formed by the process. The presence of a conducting internal network, on the other hand, makes it possible for oxidation to take place simultaneously at many crystals so that the slowness of the oxidation is not so readily apparent.

If there is a conducting network, then a $PbSO_4$ crystal can be considered as forming upon, rather than surrounding completely, the PbO_2. This means that at some point or points at the interface between $PbSO_4$ and PbO_2 the latter must extend to the surface of the $PbSO_4$ crystal. In the growth of the $PbSO_4$ crystal it is not likely that a perfect and electrolyte impervious seal was made with the PbO_2 surface that it is deposited upon and partially surrounds. It is a well known fact that corrosion processes are accelerated, or at least preferentially nucleated, at deep cracks and similar defects. Grain boundary penetration and the formation of PbO_2 has been detected in grid alloys, in sulfuric acid electrolyte and operating under similar conditions to those described here (10), which is presumably the result of microporosity and which causes greatly accelerated formation of PbO_2 deep within the metal. It seems logical to expect that the oxidation of $PbSO_4$ to PbO_2 might be similarly accelerated or stimulated at cracks. This would be particularly probable because PbO_2 is already present to nucleate the process and to form a conductive path leading into the discontinuity between the PbO_2 and $PbSO_4$ surfaces, and also because the lesser volume of the reaction product, PbO_2, would tend to enlarge the discontinuity and allow additional electrolyte to reach the area.

If, on the other hand, it is assumed that the encapsulated PbO_2 is present as separate, disconnected particles then it must also be assumed that most of these are completely surrounded by $PbSO_4$ and that the possibility of discontinuities extending to the surface is small. In this case there is no logical basis for assuming that reaction should begin in the interior. There is no access of electrolyte to the PbO_2 surface, there is a relatively very thick lead sulfate layer that probably prevents sufficient oxygen from diffusing to the reacting surfaces and there seems to be no reason to believe that a process facing these difficulties should take place within the crystal rather than at the surface.

The results of the x-ray and differential thermal analysis, as well as the optical examination, seemed to confirm that the discharge and recharge processes involved only dissolution and redeposition and that no solid state reactions were involved in going from one state of oxidation to the other. Solid state transformations would be expected to result in lattice changes detectable by x-ray analysis or by changes in thermal decomposition products, neither of which was observed. Berndt (9), among others, has also presented convincing arguments for the dissolution-reprecipitation mechanism over that of the solid state.

It is realized that the observations made in the present investigation might have been different if different current densities had been used. Berndt (9), Leibssle, Reber, Hermann, and Zehender (11), and Bode, Pasesar, and Voss (12) indicate that the reaction mechanism may be different at higher current density, while work of Metzler and Schwarz (13) indicates that the acid concentration used is also a very important consideration.

One of the puzzling features of the lead-acid storage battery has been its ability to function as efficiently as has been demonstrated when one of the reaction products is $PbSO_4$, a material of such high electrical resistivity.

The idea of a residual PbO_2 network which can provide electrical conductivity through the $PbSO_4$ of high electrical resistivity seems logical and has been supported by direct observation.

However, further investigation will be necessary to definitely confirm these observations and, if this confirmation is obtained, to determine the minimum amount of PbO_2 that must be so employed in obtaining maximum operational efficiency.

New Experiments on the Sensitization of Zinc Oxide by Means of the Electrochemical Cell Technique

K. Hauffe,* H. J. Danzmann, H. Pusch, J. Range, and H. Volz
Institut für Physikalische Chemie der Universität, Göttingen, West Germany

ABSTRACT

The "formal quantum yield" of the sensitization of the anodic photocurrent of zinc oxide by Rhodamine B has been determined by means of an electrochemical cell technique. Zinc oxide was used as a single crystal in the electrochemical cell

+ Indium | ZnO crystal | Electrolyte + Dye | Platinum −

in aqueous and methanol electrolytes. Simultaneously, the adsorption of the dye on zinc oxide powder has been measured. The influence of the solvent on the extent of the adsorption is significant. The important role of the cosensitizer on the sensitizing ability of the dye is discussed.

A decisive step in the electrophotographic process is the transfer of charge carriers through the interface, adsorbed sensitizer/zinc oxide. This transfer, however, is retarded in the dark as long as no redox systems are present with an electronic exchange level near the edge of the conduction band (1-3). Illumination with light of the optical absorption band of the sensitizer is necessary in order to supply the presupposition of an electron transfer toward zinc oxide. Electron transfer in the inverse direction occurs very easily. Furthermore, it should be mentioned that the excellent electrophotographic properties of zinc oxide are caused by the formation of electron exhaustion space-charge layers with high electrical resistance surrounding the highly conductive bulk of the zinc-oxide grains. These space-charge layers can be eliminated by illumination due to generation of charge carriers. Thus, it becomes understandable that one of the main problems is the investigation of the electronic processes and phenomena occurring between the above-mentioned interface and the space-charge layers.

Generally, for electrophotographic studies with zinc oxide, a negative charge is generated on a suitable zinc oxide-binder layer by means of a corona discharge (6). This surface charge is mainly represented by adsorbed O_2^- and O^- ions. Due to illumination with light of a wavelength $\leq$ 380 nm ($\equiv$ band gap for ZnO) electron-hole pairs are generated in the exhaustion space-charge layer near the surface of the ZnO grains. The holes recombine with the electrons trapped by the oxygen species which desorb and the freed electrons of the electron-hole pairs disappear via the grounded metal electrode. This mechanism, here only indicated, has been investigated by numerous authors (4-7). A more extensive representation and, particularly, a discussion about the participation of donors (*i.e.*, zinc ions in interstitial position) during the charging and discharging process have been given by Hauffe and Stechemesser (8).

In order to exclude the complications appearing with polycrystalline zinc oxide embedded in a resin as a binder, most of the experiments dealt with in this report have been carried out with single crystals of zinc oxide. In this paper, some results of our measurements, particularly on the charge transfer sensitized by organic dyes, are reported. As demonstrated by many authors (9-15), for the sensitization of the light-decay of electrically charged zinc oxide-resin layers, certain organic dyes with conjugated double bonds and charge resonance are especially effective. These experiments, however, have been performed mainly with polycrystalline zinc oxide. Under these experimental conditions, a quantitative evaluation of the sensitization measurements is scarcely possible because of the undefined irradiation caused, for instance, by an optical shielding of an unknown amount of ZnO crystallites in the layer. In this paper, we omit the often-discussed question as to whether or not sensitization is caused by an energy transfer or by an electron transfer, because often the two mechanisms cannot be distinguished. Markevich and Putzejko (16) found a maximum of the photovoltage with polycrystalline zinc oxide covered by various dyes at a coverage of about 50% of a monolayer.

It is our opinion, however, that optical shielding of the embedded ZnO powder, particularly at higher dye concentrations, cannot be excluded from consideration. Furthermore, since the intensity of the light responsible for the sensitization at the surface of the single grains can be only roughly estimated, we decided to perform sensitization measurements with single crystals. As discussed elsewhere (15), the single crystal was used as anode in the following electrochemical cell

+ Indium | ZnO single crystal
| Electrolyte + Dye | Platinum −

where an adsorption equilibrium with the dye in the electrolyte was established. Since in electrophotography, particularly, the behavior of dye mixtures and their mutual influence as adsorbed species is of significant interest, the interaction of two dyes and their influence on sensitization was also studied using single crystals. These experiments have been published elsewhere (17) and are continued with nonaqueous electrolytes. One of the first necessary requirements for a better understanding of the sensitization are quantum yield measurements.

Measurements of Spectral Sensitization and Adsorption

Experimental

Pretreatment of crystals and the measuring setup.— Pure single crystals of zinc oxide were supplied from the 3M Company in the form of platelets 1 mm in thickness with the (0001) face (= Zn^{++} face) and the $(000\bar{1})$ face (= $O^=$ face) perpendicular to the c-axis. These crystals were polished with diamond paste of grain sizes down to 0.25μ. In order to get a barrier-free electrical contact,[1] the $(000\bar{1})$ face was covered with

[1] The barrier-free contact of indium as electrode for zinc oxide is obviously caused by the increase of concentration of free electrons in zinc oxide near the interface In/ZnO due to the chemical exchange reaction.

$$2\ In + 3\ ZnO = In_2O_3 + 3\ Zn\ (dissolved\ in\ In) \quad [a]$$

with a subsequent dissolution of In_2O_3 into ZnO according to

$$Zn^{\cdot} + In_2O_3 = 2\ In|Zn|^{\cdot} + e' + 3\ ZnO \quad [b]$$

or by combination of Eq. [a] and [b]

$$2\ In + Zn^{\cdot} = 2\ In|Zn|^{\cdot} + e' + 3\ Zn\ (dissolved\ in\ In) \quad [c]$$

Here, $Zn^{\cdot}$ and e' denote zinc ions in interstitial positions and free electrons, respectively. Furthermore, $In|Zn|^{\cdot}$ denotes an indium ion in a zinc ion-lattice site and the dot and the prime the positive and negative excess charge, respectively. As can be seen from Eq. [c], the concentration of free electrons is increased by the incorporation of indium ions into the ZnO lattice.

* Electrochemical Society Active Member.

a translucent indium film. Then the prepared crystal was cemented with Apiezon W wax in a small window of the electrochemical cell so that usually the (0001) face was in contact with the electrolyte. If methanol electrolytes were employed, the Apiezon W wax was substituted by Teflon. The $(000\bar{1})$ face exhibited the same behavior; the sensitization, however, was only about half of the value of the other face. In Fig. 1, the experimental setup with a schematic sketch of the electrical circuit can be seen. A Wenking potentiostat served as voltage supply, and a picoammeter 417 and an electrometer 610 R from Keithley were used for current and voltage measurements, respectively. The cell was flushed with purified nitrogen. The light of a xenon high-pressure lamp was irradiated through the back side of the crystal. The employed wavelengths could be obtained by corresponding interference filters or by a monochromator. The light intensity was determined with a calibrated thermopile. Since the spectral transparency of the crystal was measured, the light intensity present at the interface ZnO/electrolyte could be determined.

The dye was dissolved in an electrolyte consisting generally of an m/10 KCl solution buffered with an m/10 acetate-acetic acid (pH = 4.6). Also a methanol electrolyte with 10^{-3} moles/liter KCl was employed. The average water content was smaller than 0.5 v/o. A noticeable change in the photocurrent was recognized only above 0.5 v/o H_2O. Experimental details can be obtained from the paper of Volz (18).

Adsorption measurements.—Since the knowledge of the amount of adsorbed dye is necessary for the determination of the effectiveness of the sensitization and since a direct measurement with single crystals is not possible, adsorption measurements have been performed with various ZnO powders. Such measurements have been carried out in our laboratory by Danzmann (19). These measurements were performed by adding an amount of 1g ZnO powder to 20 cm^3 of a dye solution of various concentration. In order to guarantee an adsorption equilibrium due to an intimate contact between the ZnO powder and the dye solution, all experiments have been carried out in a glass tube closed and assembled on a vibrating machine. The zinc-oxide powder was exposed to the solution for 2-3 hr in spite of the fact that, generally, after 1 hr no change in the dye concentration was detectable. All operations have been done under red light. The rest of the zinc oxide which remained in the dye solution was separated in a centrifuge. The change of the extinction of the solution was determined by means of a Zeiss DMR 21 spectrometer. The measuring technique corresponds to that used by Markevich and Putzejko (16). By additional adsorption experiments with a ZnO powder column, smaller amounts of adsorbed dyes also could be determined. A glass tube was filled with the corresponding ZnO powder. The dye concentrations of the various fractions of the solution passing the column have been measured until no further change in the concentration of the electrolyte was detectable. If the initial dye concentration is c and the concentrations of the fractions V_1, V_2 . . . V_n are c_1, c_2 . . . c_n, the surface concentration Γ of the adsorbed dye can be calculated according to

$$\Gamma = \Sigma(c - c_i)V_i/(\text{BET surface of the ZnO powder})$$

Results and Discussion

The sensitizing behaviors of Rhodamine B, Rose Bengale, Eosin, Fluorescein, and Methylene Blue have been studied by means of current-voltage curves in the above-mentioned electrochemical cell in the dark and under illumination (17-20). In this paper, the sensitizing ability only of Rhodamine B is dealt with in more detail. The wavelength dependence was studied in some cases, but mainly only light of the optical absorption maximum of the corresponding dye was used. While in the dark at anodic polarization of the ZnO electrode the current amounts to only 10^{-10} A/cm^2 due to the barrier action of the exhaustion space-charge layer, it can be increased by illumination to about 2-3 orders of magnitude depending on the light intensity. A typical voltage-current curve with a Rhodamine B sensitized ZnO electrode under irradiation with 545 nm light is represented in Fig. 2. Even at small voltages of about 0.5V measured *vs.* an Ag/AgCl electrode in m/10 KCl solution, a marked saturation region with a constant current is established. In this region, all electrons introduced by the sensitization step from the dye into the space-charge layer of the ZnO crystal will be exhausted by the applied electrical field to the grounded back side of the crystal. The remaining electronically unoccupied state of the adsorbed dye will be filled by an electron from the redox electrolyte or from an oxygen ion on the ZnO surface. At lower voltages, however, the current decreases. Therefore, the saturation current between 0.5 and 1V is a direct quantitative measure of the sensitizing ability of a dye.

As a suitable quantity for comparison among various measurements, particularly for the comparison of

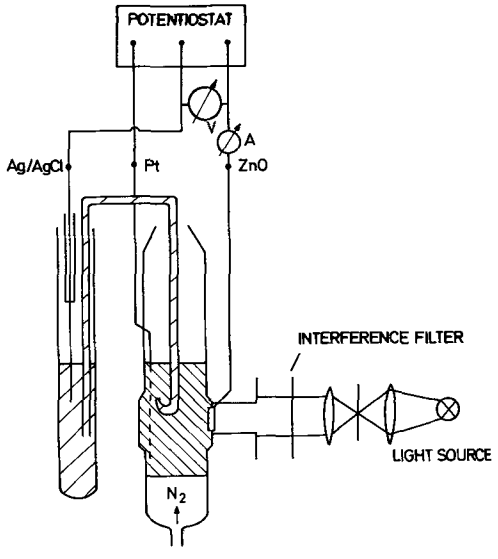

Fig. 1. Schematic representation of the electrochemical cell technique.

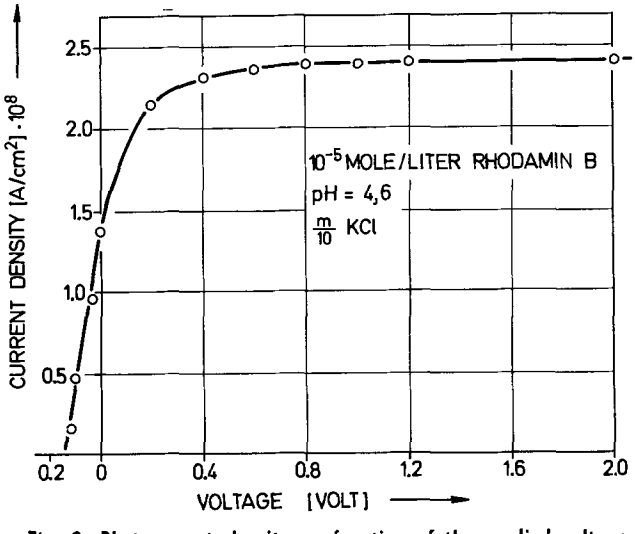

Fig. 2. Photocurrent density as function of the applied voltage under illumination with 545 nm light at room temperature. For all measurements, an m/10 acetate-acetic acid buffered aqueous m/10 KCl solution (pH = 4.6) was used. The concentration of Rhodamine B was here 10^{-5} moles/liter.

the data from electrochemical experiments with those from adsorption measurements, we introduced the "formal quantum yield" defined as the ratio of the number of flowing electrons to the number of incident photons per square centimeter and second. This quantity is readily accessible for measurement. It does not contain additional assumptions on the absorption probability of molecules as is usually the case for the determination of the direct quantum yield.

The precise proportionality of the photocurrent to the light intensity recognized in former investigations (15, 20) could be confirmed by the independence of the formal quantum yield from the light intensity, as may be seen from Fig. 3. On the basis of this result, sensitization data obtained at various light intensities can be compared. These results have been obtained not only in aqueous electrolytes but also in dye-containing methanol electrolytes. The measurements of the wavelength dependence of the photocurrents, represented in Fig. 4, 5, and 6, have been carried out by means of a monochromator with a resolution of 10 nm/mm slit width. The monochromator was used with a slit width of 0.5 mm. As can be seen, the wavelength dependence of the photocurrent for methanol (Fig. 4) and for aqueous dye solutions not too concentrated (Fig. 5) is in rather good agreement with the wavelength dependence of the extinction in Fig. 6 defined as log I_0/I. It should be noted that the curves of the spectral sensitization are shifted slightly to the longer wave range, especially for methanol solutions about 10 nm.

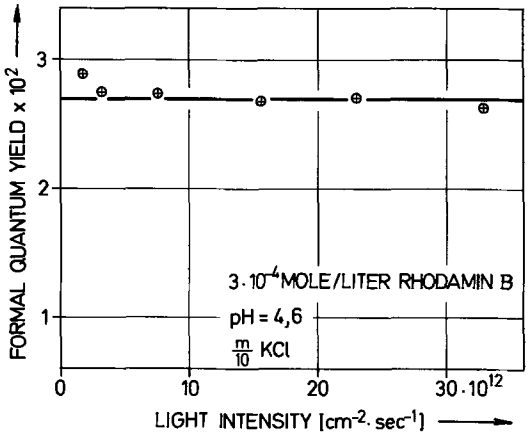

Fig. 3. The formal quantum yield as a function of the light intensity in the same electrolyte as in Fig. 2. The concentration of Rhodamine B, $c_{RhB} = 10^{-4}$ moles/liter.

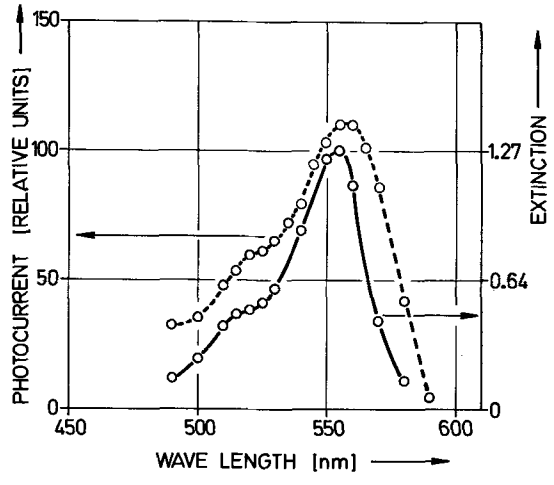

Fig. 4. Spectral sensitization of a ZnO single crystal (measured as photocurrent) and extinction of the dye-containing methanol solution as function of the irradiated wavelength in a 0.01m KCl-methanol solution with $c_{RhB} = 10^{-4}$ moles/liter.

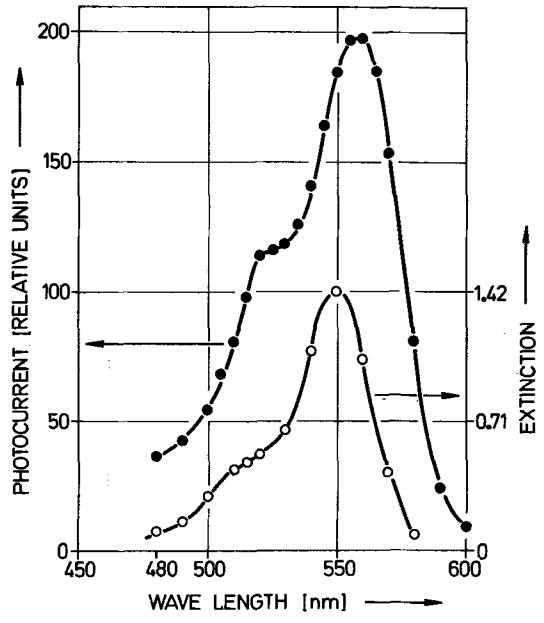

Fig. 5. Spectral sensitization of the anodic photocurrent and the extinction of Rhodamine B, aqueous electrolyte with $c_{RhB} = 10^{-5}$ moles/liter.

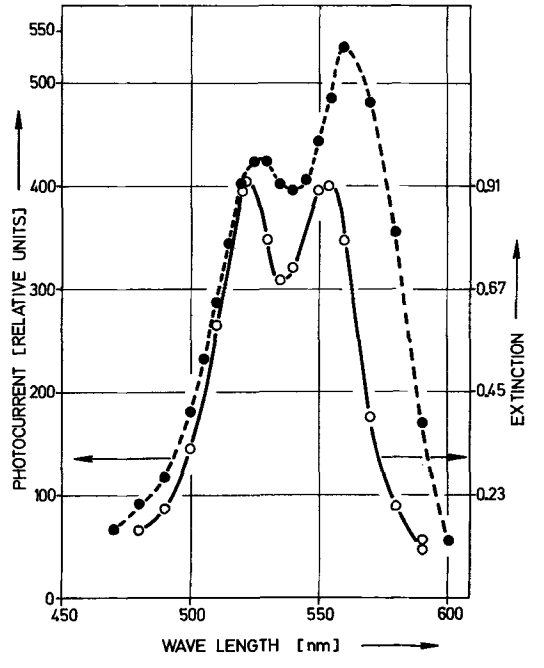

Fig. 6. Spectral sensitization of the anodic photocurrent and the extinction of Rhodamine B, aqueous electrolyte with $c_{RhB} = 2 \times 10^{-3}$ moles/liter.

Presumably, this shift is caused by the interaction between the adsorbed dye and the zinc-oxide surface resulting in a slight decrease of the excited state which is not significant if the adsorption occurs from a strong polar solvent like water. In aqueous solutions with rather large concentrations of Rhodamine B (see Fig. 6, $c_{RhB} = 2 \times 10^{-3}$ moles/liter), the extinction curve indicated the appearance of a dimer band at shorter wavelengths (21). The sensitization spectrum of the photocurrent, however, exhibits only a weak maximum in the dimer band. From this we may conclude that the sensitization by the adsorbed dimer must be poor. At present, it is unknown whether the poor sensitizing ability of the dimer is caused by a small adsorption or by a small quantum yield.

A further important result can be deduced from Fig. 7 and 8 where both the formal quantum yield and the photocurrent are plotted *vs.* the concentration of the dye in aqueous and in methanol solutions. If an aqueous electrolyte is employed, the formal quantum yield is increased continuously with increasing dye concentration. At higher concentration, however, the gradient becomes smaller. The curve corresponds roughly to an adsorption isotherm which, however, cannot be deduced, neither from a Langmuir type nor from a Freundlich type adsorption. A direct comparison with adsorption isotherms obtained on ZnO powders in a dispersion was not possible because this adsorption technique is not applicable at such high concentrations. In these cases, only adsorption measurements by means of ZnO powder columns are used. In Fig. 9, some orienting measuring points are plotted *vs.* the equilibrium concentration of the dye in the solution. The adsorption curve has a course similar to that of the curve for the formal quantum yield in Fig. 7. More precise measurements are projected. Due to the above-mentioned formation of dimers, the evaluation of the sensitization measurements becomes more difficult.

As we found, measurements with a methanol electrolyte exhibit other results. According to the course

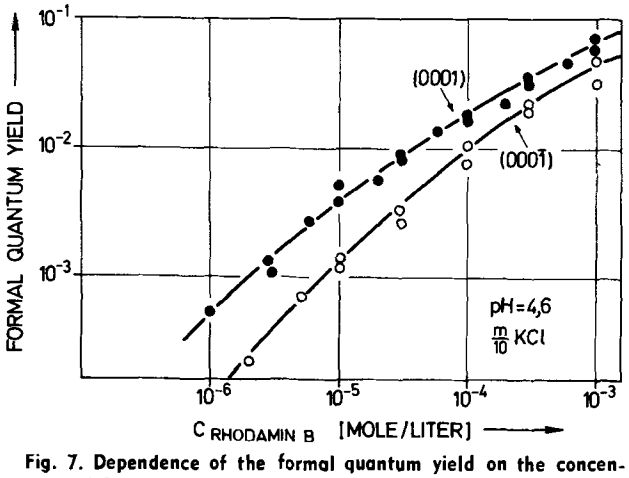

Fig. 7. Dependence of the formal quantum yield on the concentration of Rhodamine B in an aqueous electrolyte (0.1 molar KCl, pH = 4.7) at both crystallographic faces.

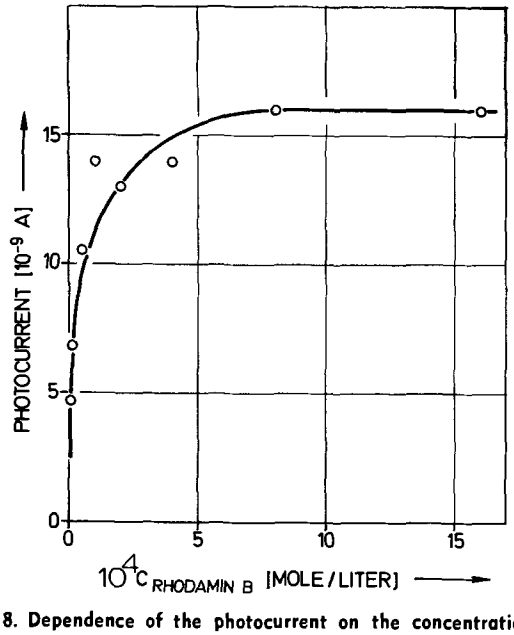

Fig. 8. Dependence of the photocurrent on the concentration of Rhodamine B in the methanol electrolyte. Here and in all other measurements, except in Fig. 7, only the (0001) face was used.

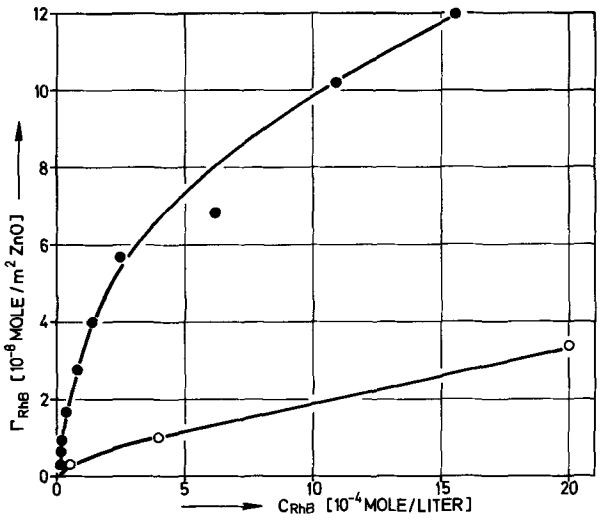

Fig. 9. Adsorption curves of Rhodamine B on zinc oxide: (a) from an aqueous solution by means of a chromatographic column technique (open circles), and (b) from a methanol solution after a classical method (solid circles) with various concentrations of Rhodamine B.

of the dependence of photocurrent on dye concentration in Fig. 8, a constant photocurrent is already established at rather low concentrations of Rhodamine B (at 2 x 10^{-4} moles/liter methanol). A maximum, as observed from photovoltage measurements with dyed polycrystalline zinc-oxide samples (16, 25), could not be detected. Furthermore, the course of the curve does not correspond to the expected one which was found by adsorption measurements represented in Fig. 9. An elucidating result is obtained if the ratio of the photocurrent obtained with a ZnO single crystal to the dye surface concentration of polycrystalline ZnO is plotted *vs.* the concentration of the dye solution. In spite of the lack of knowledge of absolute values concerning the amount of adsorbed dye on ZnO single crystals, it is allowable to apply the ratio of the relative values represented in the course of the adsorption curve for polycrystalline material to the single crystal. It results that the efficiency of sensitization becomes larger with decreasing dye concentration in the solution as can be seen from Fig. 10. This result is surprising since even at small surface concentrations the interaction of the adsorbed dye molecules in their excited state must be noticeable and, therefore, influences the efficiency of the sensitization.

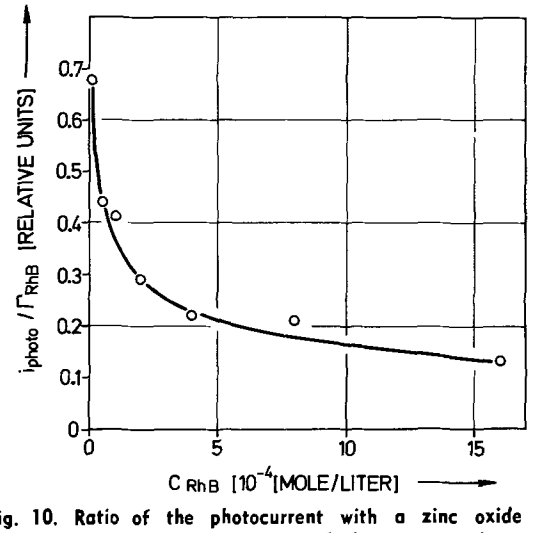

Fig. 10. Ratio of the photocurrent with a zinc oxide single crystal to the surface concentration of the dye on polycrystalline material as function of the dye concentration in the methanol electrolyte.

Further interesting information in the sensitization process is supplied by the change of the photocurrent with the time and by the bleaching rate of the dye. As can be seen from Fig. 11, at longer illumination time the photocurrent initially decreases rather sharply and later more gradually until a constant current is reached, the value of which is approximately 30% below the initial value. One has to assume that the molecules formed by the light oxidation of Rhodamine B must block the surface for the adsorption of new, undestroyed dye molecules. The decrease in the photocurrent cannot be explained by the decrease of the Rhodamine B concentration in the electrolyte since the change in the dye concentration is too small. This was demonstrated by measurements of the decrease of the dye concentration during the illumination. From simultaneous measurements of the dye concentration in the solution after various illumination periods and of the photocurrent, the very significant result was obtained that for every generated electron (*i.e.*, for every electron which has crossed the interface electrolyte/crystal) about five Rhodamine B molecules have been destroyed. If we have an open circuit, no noticeable destruction of the dye can be detected. This result leads to the conclusion that a radical mechanism must be responsible for the destruction reaction whereby the Rhodamine B molecule must give off its electron into zinc oxide. Therefore, for this reaction it is difficult to believe that an energy-transfer mechanism should govern. This result is in agreement with that of Gerischer and Tributsch (22, 23). These authors have further found that the destruction of the dye can be prevented by admission of a reducing compound into the electrolyte which can provide an electron to fill the unoccupied singlet state of the adsorbed dye. The protective compound for Rhodamine B was allylthiourea which was destroyed instead of the dye (23). By the addition of this reducing compound, the quantum yield of the sensitization process was simultaneously increased. A corresponding effect was obtained by us if the ZnO crystal was cathodically polarized before the sensitization experiments, whereby it is believed that zinc atoms have been generated on the surface of the crystal. This assumption is supported by the increase of the anodic dark current both in the absence and presence of dyes after a cathodic polarization period of the crystal. Furthermore, the difference of the sensitized anodic current and the dark current became larger. While the anodic dark current exhibited an increase of 2-3 orders of magnitude, the difference of the light and dark current became larger to a factor of 2-3.

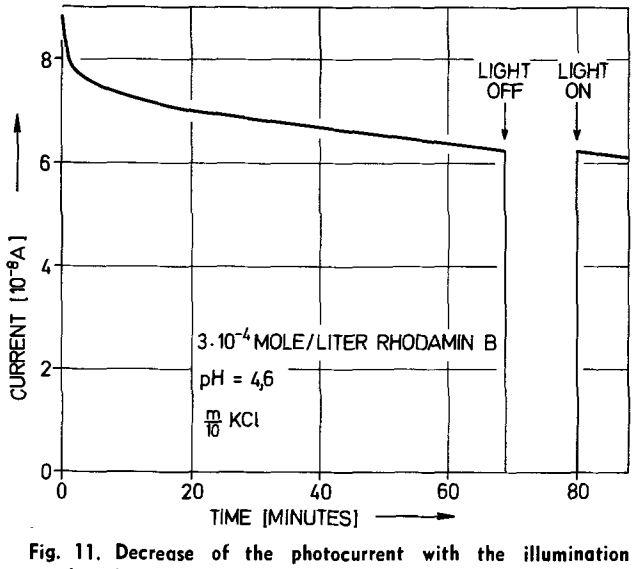

Fig. 11. Decrease of the photocurrent with the illumination time (an interruption of the illumination does not cause a recovery).

Conclusions and Final Remarks

As we discussed above, a quantitative evaluation of the sensitization experiments is possible only if simultaneous determinations are made of the quantum yield and the surface concentration of adsorbed dye molecules per unit area. With respect to further considerations, we assume that the probability of the optical absorption of a dye molecule is independent of whether the molecule is in the adsorbed or in the solved state. Under the assumption of a quantum yield of 1, 1/3, or 1/10, the number of adsorbed molecules/cm² can be calculated and compared with the data obtained from adsorption experiments. The following estimation, which is based on a correct value of absolute light intensity, was controlled by actinometric measurements of light intensity. The photocurrent generated by light of 365 nm wavelength was measured and corresponded to a quantum yield of about 0.85 which is in fair agreement with former experiments (24). As can be seen from Fig. 12, the calculated percentage of coverage of the zinc-oxide surface with the dye is much larger than the coverage obtained by adsorption experiments. For the calculation, the following formula was employed

$$1.6 \times 10^{-21} \epsilon\Gamma = \log_{10} [QY/(QY - FQY)]$$

where ϵ denotes the molar extinction coefficient and QY and FQY are the quantum yield and the formal quantum yield, respectively. Also with a quantum yield of 1, the discrepancy is still large. In the case of aqueous dye solutions, a reasonable comparison is possible only for rather small dye concentrations ($c_{RhB} = 10^{-5}$ moles/liter). Also under these experimental conditions, the surface coverage calculated from the data of the electrochemical cell experiments was larger by about a factor of 30 than that from adsorption measurements. For the evaluation of the electrochemical data, the geometrical surface area of the ZnO crystal has been used rather than the real surface area since the latter is unknown. However, the introduction of a large roughness factor is unlikely. Furthermore, the assumption of a photoadsorption (26) cannot remove this large discrepancy. Oster and Wassermann (26) have found, indeed, a photoadsorption of Fluorescein and of its halogenated derivatives on powdered zinc oxide. The speed of adsorption, however, was rather slow in contrast to our sensitization kinetic experiments. As can be seen from Fig. 13, the

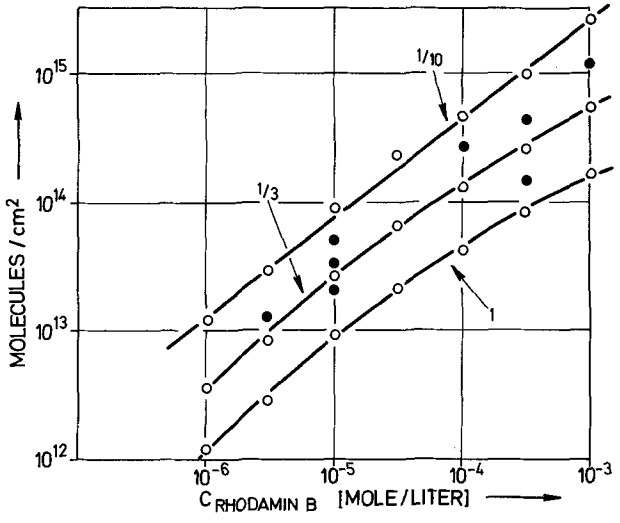

Fig. 12. Calculated coverage of the zinc-oxide surface with Rhodamine B per cm² geometrical surface in dependence on the dye concentration in an aqueous electrolyte under assumption of various formal quantum yield quantities, 1/10, 1/3, and 1 (the numbers at the curves denote the quantum yield) o—o calculated from the formal quantum yield, ●—● calculated from the current-time curves.

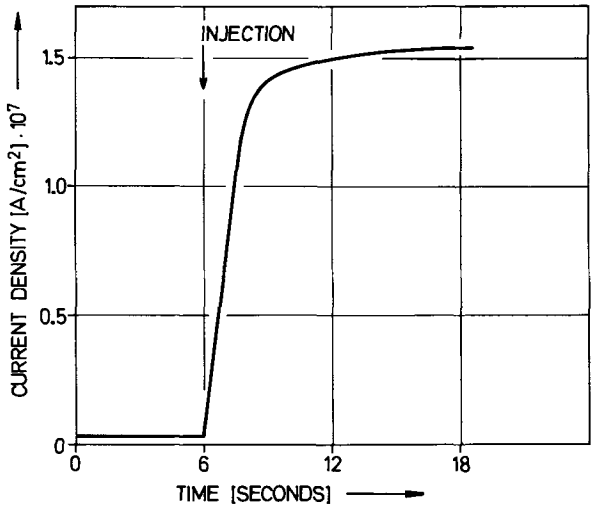

Fig. 13. Rise of the anodic photocurrent (aqueous electrolyte and 545 nm illumination) after injection of 5 cm³ of a 10^{-5} moles/liter Rhodamine B solution into 25 cm³ dye-free electrolyte.

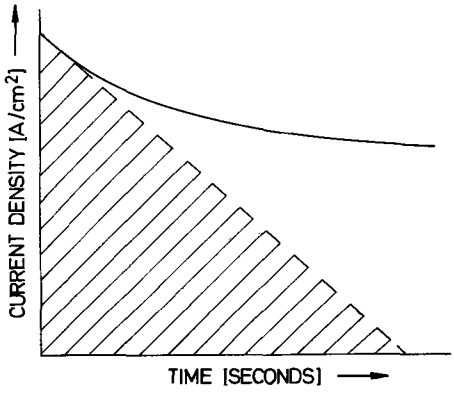

Figure 14. Evaluation of current-time curves concerning the dye coverage of a zinc-oxide surface. Schematic sketch for the calculation of the dye coverage.

photocurrent reached its final value in a few seconds after the injection of 5 cm³ of a 10^{-5} moles/liter Rhodamine B solution into 25 cm³ dye-free electrolyte. This rise time of the photocurrent caused by dye adsorption during illumination can be much shorter because the mixing in the electrolyte seems to be rate determining and depends on the stirring. Furthermore, the linear dependence of photocurrent on light intensity is not compatible with photoadsorption. Also, a significant change of the optical absorption probability of a dye molecule in the adsorbed state compared to that in the electrolyte cannot be assumed of the similarity of the sensitization spectrum to the optical absorption spectrum of the corresponding dye solution.

As can be concluded from the results in Fig. 12, the quantum yield of sensitization must be nearly 1 because a lower quantum yield would postulate a still higher coverage of the ZnO surface with dye (more than a monolayer) which should be scarcely possible. On the basis of quantum yield measurements, we may tentatively assume that preferably adsorbed dye molecules might sensitize the electron transfer since the amount of dye available from the surrounding electrolyte is too small for a noticeable contribution to the sensitization. Similar effects could be found in methanol electrolytes even if the quantities were different. At the same dye concentration of about 10^{-3} moles/liter, the anodic photocurrent through the cell with an aqueous electrolyte was twice as large as the current with methanol electrolyte. This means that the quantum yield of sensitization in an aqueous electrolyte must be significantly higher than that in a methanol solution, although the adsorbed amount of the dye from a methanol solution has been found three times larger than that of aqueous solutions. On the basis of these results, it may be concluded that the adsorption data with polycrystalline ZnO in aqueous solutions cannot be used for the evaluation of the single-crystal current experiments. Further investigations are running for the interpretation of this, at present, unknown phenomenon.

The calculations of the extent of the dye coverage in the presence of aqueous solutions will be confirmed further by an estimation by means of the current-time curves, and by measurements of the kinetics of the dye oxidation. If consideration is made of the initial gradient of the current decay extrapolated toward its intersection with the abscissa, and the destruction of five dye molecules per flowing electron, then the number of adsorbed dye molecules can be calculated from the area surrounded by the x-y axis and the tangent (see the schematic drawing in Fig. 14). The results, represented in Fig. 12, are in fair agreement with those obtained from the steady sensitization currents.[2]

The plotted measuring data are grouped near the curve estimated for a total quantum yield of 1/3. From the evaluated dye reaction, it may be concluded that the adsorbed dye molecules do inject their electron into zinc oxide during the sensitization step. By this mechanism, the increase of the quantum yield becomes understandable which was found either in the presence of partly reduced ZnO surfaces after a cathodic polarization, or in the presence of a reducing compound in the electrolyte, as for instance allylthiourea. In both cases, the regeneration of the unoccupied singlet ground state of the excited dye molecule occurs by recombination with the electron of reducing agent. This effect, called "supersensitization," is well known in the literature and the reducing compound is known as a "supersensitizer." According to this representation, however, the terminology is misleading. It is recommended that the first expression be eliminated entirely and that the second one be replaced by the term "cosensitizer," CS, which acts only as a contractor for electrons. Therefore, the general reaction scheme can be tentatively formulated as follows

$$\text{Dye(ads)} + h\nu \rightarrow \text{Dye}^*\text{(ads)} \quad [1]$$

and

$$\text{Dye}^*\text{(ads)} \rightarrow \text{Dye}^+\text{(ads)} + e'\text{(ZnO)} \quad [2]$$

or

$$\text{Dye}^*\text{(ads)} \rightarrow \text{Dye(ads)} + \text{energy} \quad [3]$$

In order to prevent the undesirable step [3] which decreases the quantum yield, the following one becomes effective in a presence of a cosensitizer, CS

$$\text{Dye}^*\text{(ads)} + \text{CS(aq)} \rightarrow \text{Dye(ads)} + \text{CS}^+\text{(ads)} + e'\text{(ZnO)} \quad [4]$$

and, also, the further oxidation of the dye, additionally

[2] The full circles in Fig. 12 are calculated under the following assumption. If Γ is the coverage of the surface and 5 molecules will be destroyed per flowing electron through the cell, it is obtained

$$d\Gamma/dt = 5 \times dn/dt$$

whereby

$$n = i/e$$

with i as the current density and e the elementary charge. If we use for small values of $d\Gamma$

$$\frac{d\Gamma}{\Gamma} = \frac{di}{i}$$

we get

$$\Gamma = \frac{d\Gamma/dt}{di/dt} i$$

and finally under consideration of Fig. 14

$$\Gamma = 5 \times \frac{F}{e}$$

where F is the area bordered by the x-y axis and the tangent.

responsible for the decrease in the quantum yield, will be significantly prevented. $e'(ZnO)$ denotes a free electron just injected into ZnO and the star denotes the electronically excited state. According to this sequence of reaction steps, the cosensitizer is oxidized and can again enter the electrolyte. If trapped electrons, for instance as O_2^- species, are available on the ZnO surface and if the electron-exchange level is not too high, then an electron-exchange reaction may occur as follows

$$CS^+(ads) + O_2^-(ads) \rightarrow CS(aq) + O_2^{\times}(ads) \quad [5]$$

Further experiments are in progress.

Electrochemical Characteristics of Iron in Acidic Solutions Containing Ring-Substituted Benzoic Acids

A. Akiyama[1] and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California

ABSTRACT

The electrochemical behavior of Armco iron in 1*N* H_2SO_4 in the absence and presence of ring-substituted benzoic acids have been investigated by the measurement of the corrosion potentials, open-circuit capacitances, potential-current polarization characteristics, potential transients, and corrosion rates. Anomalous behavior was observed for iron in the presence of para-hydroxybenzoic acid. The corrosion rates of inhibited Armco iron followed a LFER with an adsorption mode of inhibition. The adsorption correlation indicated that increasing the electron density at the adsorption center increased inhibition. Corrosion inhibition of Armco iron by ring-substituted benzoic acids increased in the following order: benzoic acid < m-OH < m-NH_2 < p-OH < p-NH_2.

Recently, a series of investigations on organic corrosion inhibitors have been carried out in this laboratory. In the first paper (1), the correlation between the inductive and resonance effects of organic compounds and their inhibitive properties was quantitatively discussed and stimulated this laboratory's experimental study of the structure-inhibition relationship for organic compounds.

Initially, aniline and substituted anilines were studied as corrosion inhibitors of iron and the experimental results have been reported in a previous paper (2). A discussion of the inhibition mechanism of organic substances has been made on the basis of the experimental results of anilines (3).

This paper is a continuation of the previous work by Donahue (2, 3) and is based on a study of the electrochemical behavior of Armco iron in 1*N* H_2SO_4 containing ring-substituted benzoic acids.

Experimental

The electrochemical cell and the instrumentation have been described previously (4, 5). All electrodes

* Electrochemical Society Active Member.
[1] Permanent address: Department of Applied Electrochemistry, Tokyo Institute of Technology, Tokyo, Japan.

were prepared from the same sample of a commercial Armco iron rod (0.5 in. diameter). The analysis of the Armco iron was 0.15% Cu, 0.13% C, Mn, P, S, Si, and 99.72% Fe. The electrodes were made as follows: (*a*) the rod was cut into cylinders, (*b*) a thin part of the cylindrical surface was milled off on a lathe, (c) degreased with hot benzene in a soxhlet column for several hours, (*d*) dried under vacuum, (*e*) annealed at 900°C for 1 hr under vacuum of 10^{-5} mm Hg, (*f*) degreased with hot benzene again, (*g*) dried under vacuum, (*h*) stored in a desiccator with silica gel, and (*i*) activated in 5*N* H_2SO_4 for 10 min just before an experiment.

All organic chemicals were recrystallized from water and dried at 80°C under vacuum. The purity was checked by melting point determination.

Iron corrosion in the presence of each of the selected ring-substituted benzoic acids at a concentration of 0.02M was studied. These organic compounds were benzoic acid, para- and meta-amino and hydroxy benzoic acids. In addition, experiments with phenol were conducted. The supporting electrolyte was 1*N* H_2SO_4 which was deaerated with prepurified nitrogen. Other organic compounds which were considered but whose solubility was not sufficient for this work were para- and meta-toluic acid, para- and meta-methoxy benzoic acid, para- and meta-chloro-benzoic acid, terephthalic acid, and isophthalic acid. Para-nitrobenzoic acid was also studied to some extent, but electrochemical reduction of this compound precluded further experimentation. However, a brief discussion of these results will be given later in this paper.

Electrode potentials were measured relative to the saturated calomel electrode (SCE). The d-c pulse technique was used to determine the differential capacitances. The electrolyte was maintained at room temperature which was 24° ± 1°C.

Results

Figure 1 compares the corrosion potential-immersion time behavior of iron in the presence of all the inhibitors studied. As shown the corrosion potentials of the inhibited iron shifted toward positive potentials with respect to the uninhibited iron. Previously (6), it had been reported that the shift of the corrosion potential of iron in the presence of sodium benzoate was in the positive direction. In this study, the corrosion potential of iron in the presence of benzoic acid shifted in the positive direction only about 15 mV. The benzoate ion has been regarded as a corrosion inhibitor of metals in neutral and alkaline solutions (6-8). However, the mode of inhibition of benzoic acid in an acidic solution is different than in alkaline solutions since in a low pH solution such as 1*N* H_2SO_4, the benzoic acid is undissociated.

The cathodic overpotential of both uninhibited and inhibited iron reached steady-state within 5 sec with the exception of para-hydroxy benzoic acid which required several minutes as shown in Fig. 2. The cathodic overpotentials for 1 mA/cm² are compared in Fig. 3. In general, the cathodic overpotentials at some specified polarization changed with immersion time but

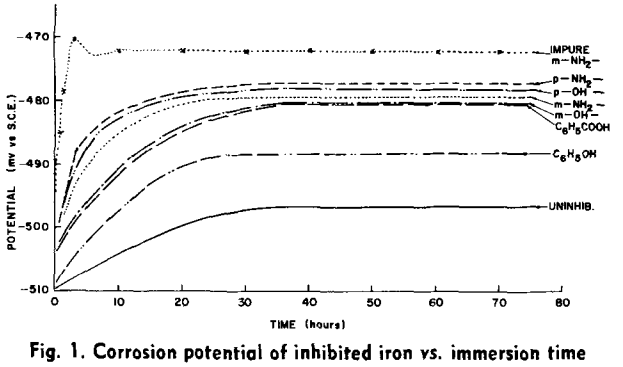

Fig. 1. Corrosion potential of inhibited iron vs. immersion time

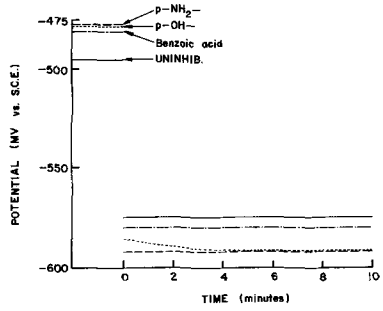

Fig. 2. Potential transient of inhibited iron during cathodic polarization of 1.0 mA/cm².

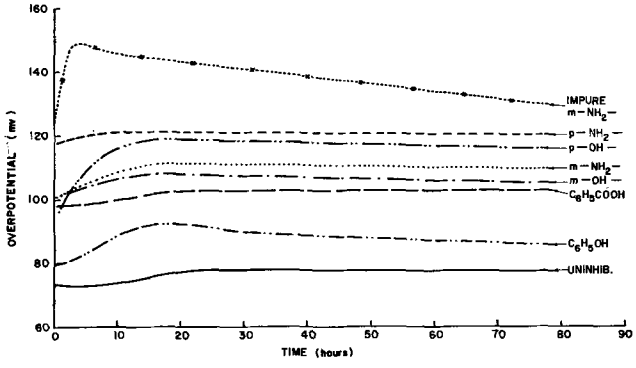

Fig. 3. Cathodic overpotential of inhibited iron at 1 mA/cm² (pulse duration = 5 sec).

were constant after about 30 hr. It is noted that iron in an acidic solution of impure meta-aminobenzoic acid was the exception. This organic compound exhibited the best inhibitor qualities.

The small positive shift in the corrosion potential and the increase in the cathodic overpotential of inhibited iron indicate that the benzoic acids studied in this investigation are mixed inhibitors (9). These results suggest that the organic compounds have a slightly greater effect on the electrodissolution of iron than on the hydrogen evolution reaction (HER).

The corrosion current was determined by extrapolation of the cathodic Tafel curves to the corrosion potential. Typical corrosion currents are plotted against immersion times in Fig. 4. The open and closed points represent different runs in order to demonstrate the reproducibility of the results. Corrosion currents (i_{corr}) and cathodic Tafel slopes (b_c), determined after an immersion time of 20 hr are given in Table I. The corrosion current reached a constant value at approximately an immersion time of 20 hr. The cathodic Tafel slopes for inhibited and uninhibited iron were essentially constant during the run.

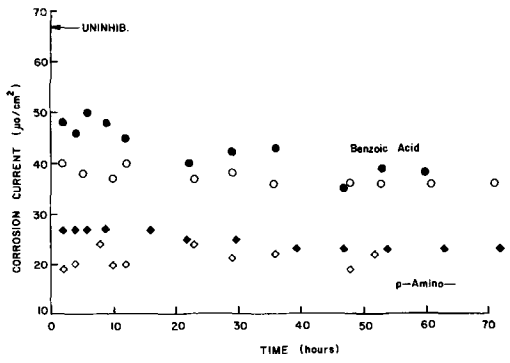

Fig. 4. Corrosion current of iron in the presence of benzoic acid and p-aminobenzoic acid.

Table I. Experimental data

(Concentration of inhibitors = 0.02M)

Inhibitor	ϕ_{corr}, mV	b_c, mV	i_{corr}, $\mu A/cm^2$	C_0, $\mu F/cm^2$	C_{50}, $\mu F/cm^2$
Uninhibited	−495	67	66	36	129
Benzoic acid	−480	71	38	35	86

* Estimated using mean cathodic Tafel slope of 72 mV.

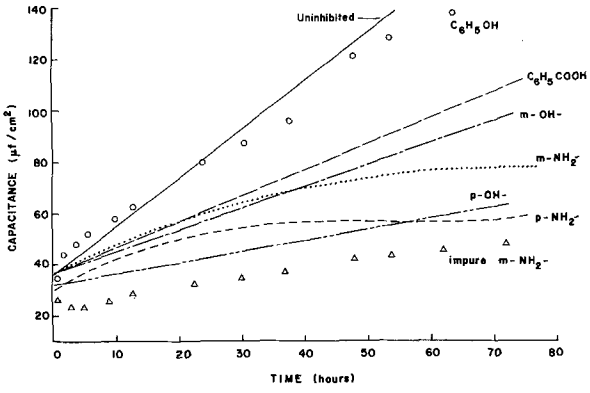

Fig. 6. Open-circuit differential capacitance of iron

Superpolarization (*i.e.*, maximum in the potential-time transient) was observed during a galvanostatic anodic pulse. The inhibited iron exhibited larger superpolarization values and attained the maximum at shorter times than the uninhibited iron. The potentials during a galvanostatic anodic polarization of 1.0 mA/cm^2 are plotted against the polarization time in Fig. 5. The steady-state polarization potentials of inhibited iron were shifted to more positive values than the uninhibited iron. As shown in Fig. 5, the positive shift of the polarization potential of iron in the presence of para-hydroxy benzoic acid was more substantial than iron in the presence of the other organic compounds.

Yamaoka and Fischer (10) studied the steady-state anodic polarization of iron in the absence and presence of inhibitors, o-phenamthroline or phenylthiourea, and observed that at high current densities, anodic polarization of inhibited iron approached that of uninhibited iron. They suggested that the superpolarization of inhibited iron during an anodic current pulse was due to the desorption of the inhibitor. Gatos (8) reported that benzoate ions did not inhibit iron corrosion when iron was coupled to gold (*i.e.*, during anodic polarization). On the other hand, he implied that inhibition of iron corrosion with benzoate ions was achieved when iron was coupled with zinc (*i.e.*, during cathodic polarization). However, further details of these results were not given.

The results of Yamaoka and Fischer (10) and Gatos (8) suggest that the larger superpolarization of iron in the presence of the benzoic acids observed in this investigation may be the manifestation of organic desorption during anodic polarization. Nevertheless, the open-circuit and cathodic polarization behavior of iron indicate that the benzoic acids inhibit anodic dissolution of iron at open circuit and small anodic currents.

The open-circuit differential capacitances (*i.e.*, at the corrosion potential) are plotted against immersion times in Fig. 6. The capacitance of uninhibited iron increased linearly with immersion time up to the end of the experiment. The capacitances of iron in the presence of benzoic acid and the hydroxybenzoic acids also increased approximately linearly with immersion, but were less than the capacitance of uninhibited iron.

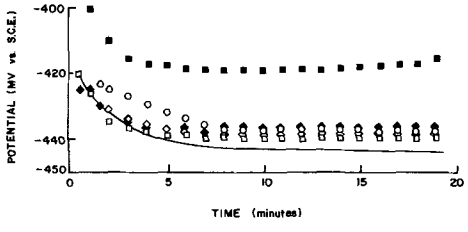

Fig. 5. Potential transient during anodic polarization of 1.0 mA/cm^2: solid line is for uninhibited iron, benzoic acid (○), m-hydroxybenzoic acid (□), p-hydroxybenzoic acid (■), m-aminobenzoic acid (◇), and p-aminobenzoic acid (◆).

On the other hand, the capacitance of iron in the presence of the aminobenzoic acids increased with immersion time, but approached a steady-state value. It should be noted that the initial open-circuit capacitances (within 2 hr immersion) were approximately 35 $\mu F/cm^2$ for inhibited and uninhibited iron. In Table I, C_0 represents the initial open-circuit capacitance. The capacitances of iron after 50 hr immersion, C_{50}, decreased in the following order as shown in Table I, phenol > benzoic acid > m-OH > m-NH_2 > p-NH_2 > p-OH.

The differential capacitance of both uninhibited and inhibited iron was not greatly affected by galvanostatic cathodic polarization indicating a low surface coverage of hydrogen atoms. On the other hand, the capacitance increased during anodic polarization as observed previously for iron in the presence of the substituted anilines (2). This increase in capacitance (adsorption pseudocapacitance) and the potential transient behavior during anodic galvanostatic polarization has been attributed to the increase in surface concentration of FeOH (11). The adsorption pseudocapacitance was approximately the same for inhibited and uninhibited iron except for para-hydroxybenzoic acid. The smaller adsorption pseudocapacitance of Armco iron in the presence of para-hydroxybenzoic acid was similar to the results obtained previously with para-toluidine (2).

In a previous investigation (2), it was shown that the electrochemical behavior of iron in 1*N* H_2SO_4 containing aniline was not significantly different than the uninhibited case. The behavior of iron in 0.02M phenol in 1*N* H_2SO_4 was examined since the effect of the hydroxy substituent on the inhibitor qualities of benzoic acid was a part of this investigation. Figures 1, 3, and 6 and Table I show that, of the inhibitors studied, phenol had the least effect on the electrochemical characteristics of iron.

Similar to results obtained previously for the impure aniline (2), impure meta-aminobenzoic acid inhibited the corrosion rate of iron more than the purified compound as shown in Table I. The impure organic compound was used "as-received," it was brownish colored. As shown in Fig. 6, the open-circuit capacitance of iron in the presence of impure meta-aminobenzoic acid was significantly lower than in the presence of the purified organic.

The impure, colored aniline and meta-aminobenzoic acid contain high molecular weight compounds which have long conjugated structures. The long conjugated structures are usually considered to enhance adsorption. From a practical point, further investigations on the identification of the impurities may be of considerable importance.

It was observed that the addition of sodium chloride (8.55 mM) to the corrosion environment containing para-aminobenzoic acid affected the electrochemical behavior of iron in the following way: the corrosion potential remained unchanged, the open-circuit capaci-

tance decreased from 56 to 42 $\mu F/cm^2$ with the addition of the sodium chloride, the corrosion current decreased from 22 to 11 $\mu A/cm^2$, and the cathodic Tafel slope remained unchanged. These results indicate that the addition of sodium chloride in modest amounts enhances the inhibition of iron with para-aminobenzoic acid. Such effects have been investigated by others as, for example, Hackerman *et al.* (12).

The reduction of para-nitrobenzoic acid on iron in 1*N* H_2SO_4 was observed for a saturated solution (~0.01M). The corrosion potential was shifted toward the positive direction by stirring the electrode, −428 mV for the stationary electrode and −417 mV for the electrode rotated with a tangential velocity of 8.5 cm/sec or with agitation of electrolyte. The capacitance at the corrosion potential was unusually large, 281, 346, and 735 $\mu F/cm^2$ for immersion times 1, 2, and 22 hr, respectively. Cathodic polarization of iron in the para-nitrobenzoic solution indicated that the reduction reaction was diffusion-controlled.

Discussion

The corrosion rates of iron in the presence of ring-substituted benzoic acids are plotted against the Hammett substituent constants in Fig. 7. For comparison, the corrosion rates of uninhibited and phenol inhibited iron are also given. It should be noted again that iron in 1*N* H_2SO_4 containing para-hydroxybenzoic acid did not achieve steady-state cathodic overpotentials as the other organics during a 5 sec pulse as shown in Fig. 2; several minutes were required. There are two data points given for the para-hydroxybenzoic acid in Fig. 7. The open point is the corrosion rate determined using the cathodic Tafel line of slope, 80 mV, obtained experimentally. The closed point is the corrosion rate estimated by the best fit of the overpotential data using a cathodic Tafel line of slope, 72 mV, which was the average value obtained with the other organic compounds.

The correlation of the corrosion rates of iron inhibited by ring-substituted benzoic acids indicate that increasing the electron density at the adsorption or reaction center by the addition of electron providing substituents on the ring increased inhibition. Furthermore, correlation was achieved by using the σ values of the free amine rather than the protonated amine for the aminobenzoic acids. In the bulk solution of the 1*N* H_2SO_4, the aminobenzoic acids should be protonated. Therefore, the correlation indicates that the adsorbed aminobenzoic acids were in the unprotonated state. This suggests that these organics were adsorbed in the flat position on the iron surface [see also p. 1013 of ref. (3)].

The anomalous anodic behavior of iron in the presence of para-hydroxybenzoic acid was manifest in the anodic transient data and the pseudocapacitance during these anodic transients. These results suggest that the para-hydroxybenzoic acid interacts with the surface intermediate formed during the electrodissolution of iron at polarization conditions of reasonably large displacement from the open circuit.

Anomalous behavior of iron in the presence of para-hydroxybenzoic acid was also observed during cathodic polarization. As shown in Fig. 2, steady-state conditions during cathodic polarization were not achieved for at least several minutes for iron in the presence of para-hydroxybenzoic acid, while less than 5 sec were required for iron in solutions containing the other organics. This cathodic behavior of iron suggests that the para-hydroxybenzoic acid interacts with the reaction intermediate during the HER.

The electrochemical polarization behavior of inhibited iron indicates that the para-hydroxybenzoic acid affects the reaction mechanism of both the electrodissolution and the HER. A mechanism was proposed previously (3) to take into account the active participation of an organic inhibitor in the electrodissolution of iron and can be used as a basis to interpret qualitatively the experimental results of this investigation including the para-hydroxybenzoic acid data. Similar mechanisms to account for the interaction between the organic compound and the reaction intermediate during the HER can also be readily devised. However, the primary purpose of this study was to investigate the possible linear free energy relationship (LFER) correlation of iron inhibition by ring-substituted benzoic acids.

To provide further information on the deviation of the para-hydroxybenzoic acid data (open point) from the correlation curve shown in Fig. 7, the cathodic overpotential of the inhibited iron was plotted *vs.* the substituent constants in Fig. 8. For all current densities, the correlation lines were drawn parallel. At low current densities, a good correlation was obtained indicating the simple adsorption mode of inhibition. However, at the higher current densities the para-hydroxybenzoic acid data substantially deviates from the correlation line and the deviation is shown to increase with increase in current density. As shown in Fig. 8, the rate of the HER on iron was less in the presence of para-hydroxybenzoic acid than in the presence of para-amino-benzoic acid at large polarization. This increase in polarization accounts for the observed larger cathodic Tafel slope of iron in the presence of para-hydroxy-benzoic acid.

It seems reasonable to assume that the closed data point for para-hydroxy-benzoic acid in Fig. 7 more closely approximates the electrodissolution rate at open circuit (*i.e.*, the corrosion rate), since it better

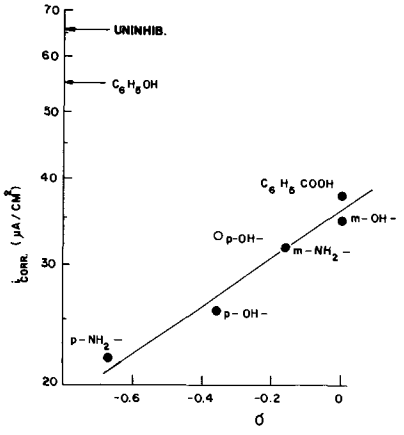

Fig. 7. Corrosion rates of inhibited iron *vs.* Hammett substituent constants.

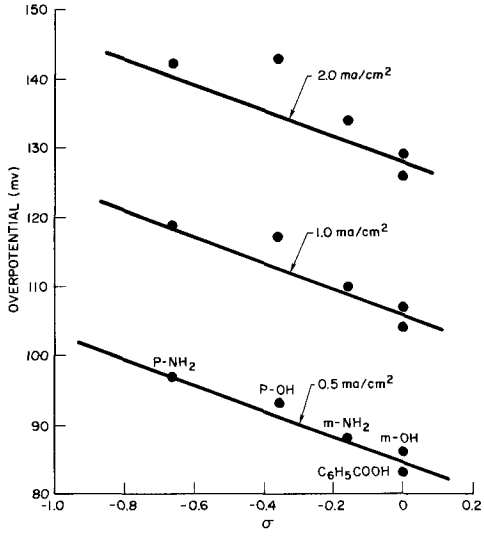

Fig. 8. Cathodic overpotentials of inhibited iron *vs.* Hammett substituent constants.

reflects the low polarization data. Therefore, it is concluded that corrosion inhibition of iron (at open circuit) by the ring-substituted benzoic acids studied is achieved by the simple adsorption mode. At larger anodic and cathodic polarization, the electrochemical behavior indicates that the para-hydroxybenzoic acid interacts with the adsorbed intermediates, FeOH and H, and thus, alters the reaction mechanisms of electrodissolution and the HER.

The Anodic Dissolution of Titanium in Sulfuric Acid

R. D. Armstrong, J. A. Harrison, H. R. Thirsk,* and R. Whitfield

Electrochemistry Research Laboratories, Department of Physical Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, England

ABSTRACT

The mechanism of titanium dissolution in sulfuric acid has been investigated using wire, rotating disk and platinum ring-titanium disk electrodes. Titanium dissolves directly as Ti^{3+}, without any solution soluble intermediates. The reaction is H^+ catalyzed (approximately first order). A possible mechanism is suggested.

The electrochemical behavior of titanium has frequently been investigated (1-10), particularly in relation to stress corrosion cracking. The mechanism of Ti dissolution has however rarely been inferred from the results obtained, and it was for this reason that the present work was undertaken.

Experimental

Titanium electrodes (99.9%) were investigated in the form of wires (diameter 1 mm) and disks (diameter 7.5 mm). A titanium disk-platinum ring electrode system was also used (r_1 = 3.18 mm, r_2 = 3.47 mm, r_3 = 4.77 mm).[1] Before use the Ti disks were mechanically worked with emery. The solutions used were prepared from AnalaR reagents and triply distilled water. They were all deoxygenated with N_2. The reference electrodes were H_2/H^+ in 1M H_2SO_4 to which all potentials are referred, after correction for liquid junction potentials. The solutions used together with the corrosion potentials of titanium in these solutions are shown in Table I.

Repetitive triangular sweep measurements were made using a function generator and a potentiostat at sweep speeds from 3 mV/sec to 1 V/sec. Square pulse potentiostatic measurements were also used. For the ring-disk electrode two potentiostats were used so that the potentials of the ring and disk electrodes could be separately controlled. All measurements were made at 70° ± 1°C, since at lower temperatures the current levels were found to be inconveniently small.

* Electrochemical Society Active Member.
[1] A smaller spacing was not practicable for use at other than ambient temperature.

gen evolution (I), active titanium dissolution (II), and passivity (III) can clearly be identified. The anodic and cathodic sweeps coincide at sufficiently slow sweep speeds. The dependence on sweep rate is shown in Fig. 2, as $dV/dt \rightarrow 0$, a convergence to a limiting *i-E* curve was found. The limiting *i-E* curves for different solutions are shown in Fig. 3 (active dissolution) and Fig. 4 (hydrogen evolution). If hydrogen evolution was maintained for some time, the electrode characteristics changed in that the rate of hydrogen evolution at fixed potential was markedly increased and the dissolution of the metal greatly suppressed (Fig. 5). We took this to be due to hydriding of the metal.

Current-potential curves on rotating disk electrodes.—Current potential curves on rotating disk electrodes showed no dependence on disk speed[2] between $\omega = 2.6$ and $\omega = 680$ rad/sec. This is shown in Fig. 6 for the active branch. The *i-E* relationships obtained coincided with those obtained from wire electrodes.

Ring-disk electrodes.—The *i-E* relationship obtained on the ring electrode while active dissolution was proceeding (Fig. 7) showed a single anodic wave before oxygen evolution. The ring current in the region of this limiting current is shown for various values of the disk potential (Fig. 8). For active dissolution

$$\frac{i_r}{i_d} = 0.13 \pm 0.01$$

Transient measurements.—Active to passive potentiostatic transient measurements showed a monotonically decreasing current with time (Fig. 9A, B), whereas passive to active transients (Fig. 10) were of a sigmoid form.

[2] In HCl there was also no dependence on rotation speed. In $HClO_4$ however there was a marked dependence which is probably associated with a homogeneous oxidation of Ti species.

Discussion

Thermodynamic requirements.—For Ti in sulfuric acid the following potentials have been quoted (11, 12) (at 25°C)

$$Ti = Ti(H_2O)_6^{3+} + 3e \qquad E°_H = -1.21V$$

$$Ti = Ti(IV) + 4e \qquad E°_H = -0.88V$$

The Ti/Ti(II) potential is uncertain since stable solutions of Ti(II) cannot be prepared in aqueous media (13), although recent estimates (14, 15) give

$$Ti = Ti(II) + 2e \qquad E°_H = -0.6V$$

Ti(III) complexes with OH^- as (16)

$$Ti^{3+} + OH = Ti(OH)^{2+}, \log K_1 = 12.71$$

while Ti(IV) is present in sulfuric acid largely as $Ti(OH)_3HSO_4$ (17).

Thus, thermodynamically, Ti could dissolve in the potential region under investigation as Ti(II), Ti(III), or Ti(IV). However the product of the reaction must be Ti(III) or Ti(IV) since Ti(II) is oxidized by water.

Mechanism of Ti dissolution.—The independence of the dissolution current on disk rotation speed shows that (*a*) surface processes are rate determining, and (*b*) that solution soluble intermediates are absent. It is not possible to deduce a Tafel slope from the composite *i-E* curves because of the relatively small potential region between hydrogen evolution and passivation. However the reaction is approximately first order with respect to H^+ at constant potential.

This is in agreement with previous observations on the effect of hydrogen ion concentration in sulfuric and hydrochloric acids (2, 8, 10).

The product of the reaction follows from the ring disk experiments. Since it can be oxidized it must be Ti(II) or Ti(III). The collection efficiency (*N*) estimated from Alberry and Bruckenstein's (18) tables is 0.40 which fits the experimental results if

at the disk $\quad Ti \rightarrow Ti^{3+} + 3e$

at the ring $\quad Ti^{3+} \rightarrow Ti(IV) + e$

Thus the dissolution of Ti appears to be H^+ catalyzed, in contrast to Fe (19) which is OH^- catalyzed. A possible mechanism is

$$Ti \rightleftharpoons Ti_{ads}^{2+} + 2e$$

$$Ti_{ads}^{2+} + H^+ \rightarrow Ti^{3+} + H_{ads}$$

$$H_{ads} \rightleftharpoons H^+ + e$$

which would require the reaction to be first order in H^+ and have a Tafel slope of ~34 mV/decade for the case of low coverage by adsorbed species.

Another possible explanation for the H^+ dependence of the dissolution rate is that OH^- is adsorbed in the region of Ti dissolution and reduces the rate of dissolution through a surface coverage effect.

Hydrogen evolution.—Current-potential curves for hydrogen evolution showed a Tafel slope of 172 mV/decade (at 70°C) and an order of unity with respect to H^+. This indicates the slow discharge of H^+ as the rate determining step. The present work is compared with previous work (20, 21) on hydrogen evolution on Ti in Table II. Thus Ti is a high overvoltage metal while Ti-H has a low overvoltage for hydrogen evolution.

Table II. Parameters for hydrogen evolution on titanium

Solution	Temperature	log i_o, A cm^{-2}	Tafel slope, mV/decade	Reference
1M H_2SO_4	70°C	−6.37	172	This work
1M H_2SO_4	Room temp	−8.15	119	20
0.5M H_2SO_4	Room temp	−6.01	135	21
1M HCl	Room temp	−6.30	130	21

Passivation of titanium.—The i-E curve for the active-passive transition in titanium shows no dependence on rotation speed. We consider this as evidence that the passivation of Ti does not involve an intermediate dissolution reaction followed by "precipitation" in the solution as has been proposed for Ni (22). The passive-active transients which are observed (Fig. 10) can be explained by assuming that the passivating film on titanium is removed by a mechanism involving the nucleation and growth of two dimensional holes. If the holes grow a velocity v cm sec^{-1} and nuclei are formed at the rate of A nuclei cm^{-2} sec^{-1} then the fraction of active surface (S) after a time t is

$$S = 1 - \exp\left[\frac{-\pi v^2 t^3 A}{3}\right]$$

The component which will be observed is then (23) (*i*) due to the active dissolution of Ti, i_1; (*ii*) due to the passive dissolution of Ti, i_2; (*iii*) due to hydrogen evolution on the active surface, i_3; (*iv*) due to hydrogen evolution on the passive surface, i_4 and

$$i_1 = i_{01}\left[1 - \exp\left(\frac{-\pi v^2 t^3 A}{3}\right)\right]$$

$$i_2 = i_{02}\exp\left(\frac{-\pi v^2 t^3 A}{3}\right)$$

$$i_3 = i_{03}\left[1 - \exp\left(\frac{-\pi v^2 t^3 A}{3}\right)\right]$$

$$i_4 = i_{04}\exp\left(\frac{-\pi v^2 A t^3}{3}\right)$$

while the observed current is

$$i = i_1 + i_2 - i_3 - i_4$$

which qualitatively agrees with the observed transients.

Acknowledgments

We would like to thank Mr. R. D. Giles for helpful discussions during the course of this work.

Mechanism of Electrodeposition of Manganese in Alpha and Gamma Modifications

N. Dhananjayan

National Metallurgical Laboratory, Jamshedpur-7, India

ABSTRACT

A mechanism of the deposition of manganese in alpha and gamma modifications, in the presence and absence of addition agents in the electrolyte, has been proposed based on experimental results and evidence. A flash layer of amorphous manganese is deposited from pure solutions, over which gamma manganese begins to build up in the absence of reducible sulfur or selenium compounds in the electrolyte. In the presence of sulfur dioxide, the amorphous nature continues to build up to an increasing thickness over which crystalline alpha manganese is obtained. Alpha manganese is obtained in the presence of sulfur, selenium, or tellurium when the cathode polarization together with the hydrogen content of the deposit is found to be increased. Likewise, the increase in current density increases the cathode polarization together with the hydrogen content of the deposit when hard brittle amorphous manganese is obtained. The low hardness and density of electrodeposited alpha manganese, compared to its annealed state, and the increase in hardness together with ductility on heating, suggest that a part of the discharged hydrogen ions assumes positions inside the lattice or forms a complex during the deposition of alpha manganese.

According to Dean (1,2), manganese is initially deposited to a few thousandths of an inch thick in gamma modification from all electrolytes, and in the presence of SO_2 in the electrolyte, this gamma gradually transforms to the alpha form, the transition proceeding outward from the cathode plate. When the alpha form reaches the surface, manganese will plate as macroscopic crystals of alpha manganese. Dean (1,2) has

Key words: electrodeposited manganese, structure, mechanism, cathode polarization, hydrogen.

based his above inference on the "duplex structure," as he calls it, of deposited manganese and the higher hardness of the manganese surface-facing cathode.

Schlain and Prater (3) obtained good deposits of gamma manganese on copper cathodes in the absence of SO_2 with current efficiencies of 62-72% on 5-12 hr runs, but their deposits on stainless steel were poor and porous. According to them, the addition of SO_2 prevents the formation of gamma manganese. The deposited gamma manganese takes about 238 hr at 25°C for half completion of the transformation to alpha manganese (4).

Bell's work (5) does not seem to support Dean's contentions. She plated manganese on aluminum, mild steel, and copper to 0.0005-0.0015 in. thick and found only the presence of alpha manganese, although there was no reducible sulfur compound present in the electrolyte. She had used a high current density of 23-27 A/dm^2 and had used electrolytic manganese flakes in the anolyte to make up the manganese content of the bath.

According to Moiseev and Popova (6,7) and Gorbunova (8), the deposits on copper, silver, and iron from manganese ammonium sulfate baths with or without addition of glycerol to a thickness of 10-60μ, at current densities of 30 A/dm^2, and at *p*H 3.8-4 showed only x-ray patterns similar to the one from the amorphous substances. They obtained gamma manganese, in some cases, in the deposit 10μ thick, on a silver cathode, in the absence of glycerol in the bath. At room temperature, it passed over to the alpha form in about 6 hr. The deposits obtained by Moiseev and Popova (6,7) with 0.3% SO_2 in the electrolyte, at current densities of 17-25 A/dm^2 and at *p*H 2.2-3.0, showed clear crystalline structure of alpha manganese with a texture, while deposits obtained at current densities of 25-30 A/dm^2 and at *p*H 3.8-4.2 showed only a pattern of the amorphous body.

This paper proposes a new mechanism on the deposition of manganese in alpha and gamma forms, on the basis of more recent data from an extensive study (9, 10), and attempts clarification of certain anomalies in the observations of earlier investigators.

Experimental

Considerable attention was paid in the preparation and purity of the electrolyte to ensure absence of colloidal or sulfide sulfur. Unless otherwise mentioned, the conditions of deposition were as follows.

Composition of electrolyte: 23-24 g/liter of manganese as manganese sulfate and 135-140 g/liter of ammonium sulfate; initial *p*H of catholyte and feed electrolyte: 7.2; electrolyte flow to the cell: 10 ml/min; cathode current density 4.2 A/dm^2; and temperature: 28°C

Each cathode had a vertically cut slit, 4 x 1 cm, in the center (see Fig. 1). The top of the slit was 1 cm below the solution level. A 0.25 mm thick wire of the cathode material was attached in the slit. The wires were cold drawn and annealed. They were then polished with metallographic paper 2/0. A portion was cut from the middle of this wire with deposited metal and the same was used as the specimen for x-ray studies. For back-reflection x-ray studies of deposits, cathodes, with deposited manganese from a small cell, were directly used as the specimen. For microstructure studies, the metastable gamma manganese or specimens containing both alpha and gamma were cold-mounted with plastic solution and powder.

The electrode potentials were determined with a view of studying the comparative differences in the values of the various forms of manganese in identical solutions under identical conditions. They were measured directly from 1*N* $MnSO_4$ solution, prepared from transformed gamma manganese, and contained no sulfur, selenium, or any dissolved gases. The recorded potential values from the moment the metal is placed in the solution to about 30 min were extrapolated to zero time and the potential at zero time was taken for comparison. It may be mentioned that the extrapolated values to zero time of two different specimens of each of the various forms of manganese examined were in very close ranges of ±0.003V. No correction has been made for the activity coefficient and the values cannot be taken as absolute standard potential values.

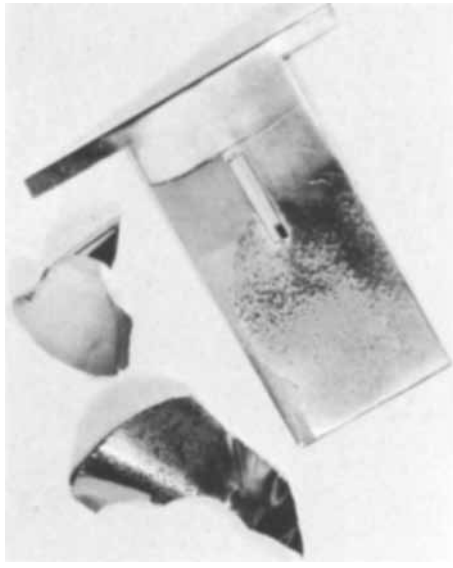

Fig. 1. Stainless steel cathode after stripping off deposited gamma manganese showing the amorphous undercoat of manganese.

The hydrogen content in deposited manganese was determined by vacuum extraction at 500°C as the solubility of hydrogen in manganese is minimum at that temperature. The order of reproducibility in the determination was about ± 5%/100g of metal.

Results and Discussion

Nature and growth of manganese deposits.—It can be seen from Table I that deposition of manganese on a stainless steel cathode in the absence of reducible sulfur or selenium compounds in the electrolyte results in a nonuniform amorphous deposit (Fig. 1) for

Table I. Structure of initial deposits of manganese from solutions in absence and presence of sulfur dioxide or selenious acid

Addition agent g/liter	Time of deposition	Structure of the deposit	
		On stainless steel cathode	On copper cathode
Nil	8 sec	Amorphous	Only diffraction pattern of copper substrate
Nil	30 sec	Gamma (diffraction line of 2.13Å only)	Only diffraction pattern of copper substrate

Nil	2 min	Gamma (diffraction line of 2.13Å only)	Amorphous (broad diffused halo at *d* value 2.08-2.15Å)
Nil	3 min	Gamma (diffraction line of 2.13Å only)	Amorphous (broad diffused halo at *d* value 2.08-2.15Å)
Nil	5 min	Gamma (all the diffraction lines of gamma)	Gamma (all the diffraction lines of gamma)
0.15 SO_2	2 min	Amorphous (broad diffused halo at low angle)	Amorphous (broad diffused halo at low angle)
0.15 SO_2	5 min	Amorphous (broad diffused halo at low angle)	Amorphous (broad diffused halo at low angle)
0.15 SO_2	10 min	Amorphous (broad diffused halo at low angle)	Amorphous (broad diffused halo at low angle)
0.15 SO_3	15 min	Alpha (all the diffraction lines of alpha)	Alpha (all the diffraction lines of alpha)
0.1 H_2SeO_3	1 min	Alpha (all the diffraction lines of alpha)	—

the first 8 sec over which gamma manganese begins to build up. Deposits on copper up to 1 min of deposition, under the same conditions, do not show any diffraction lines other than those of copper, which may perhaps be the period of alloy formation and/or diffusion, after which up to 3 min of deposition, in addition to the substrate pattern, a broad halo at a low angle indicating the amorphous nature of the growing deposit is noticed. At 5 min of deposition, all the diffraction lines of gamma manganese are noticed both on stainless steel and copper cathodes.

On the other hand, on addition of 0.15 g/liter of SO_2 to the same electrolyte under the same conditions, the deposits, both on stainless steel and copper, continue to show the initial amorphous pattern up to 10 min of deposition. At 15 min, both give a clear crystalline pattern of alpha manganese. No evidence of deposition of gamma manganese was found at any time on either cathodes in the presence of SO_2, although in its absence, gamma lines were distinguishingly clear at 5 min of deposition. The amorphous deposits show a hardness value of 652 DPN indicative of alpha manganese.

Beyond 15 min of deposition, crystalline alpha manganese is obtained on all cathodes in the presence of SO_2 or SeO_2 in the electrolyte and gamma manganese is obtained in their absence. The photomicrographs of alpha manganese, obtained in presence of S or Se, show a clear columnar structure, while those of gamma manganese, obtained in absence of these compounds, show a twinned structure as can be seen from Fig. 2a and 2b.

The surface of the alpha manganese-facing cathode, obtained in the presence of SO_2, immediately after deposition or after a period of four years of aging at room temperature, does not give any back-reflection x-ray pattern confirming that the particle size of the surface-facing cathode is below the range of diffraction by x-rays. Only after heating at 500°C for 2 hr in vacuum did this specimen give a sharp back-reflection pattern of alpha manganese.

Deposition of gamma over alpha manganese and vice versa.—Figure 3a and 3b show the photomicrographs of deposited alpha over gamma manganese and vice versa.

Back-reflection x-ray examination of the deposit obtained in 10 min, in the presence of selenium, over gamma manganese shows diffraction lines of alpha and gamma manganese, while the deposit in 10 min, in the absence of selenium, over alpha manganese shows diffraction lines of alpha manganese only. This later deposit, on x-ray powder pattern, shows a broad diffused halo at a d value of 2.10Å along with alpha manganese lines. This indicates that during deposition, from solutions containing no reducible S or Se compounds, over alpha manganese, an amorphous deposit forms initially because of which gamma deposited over alpha could be stripped off separately. On the other hand, alpha manganese deposited over gamma could not be stripped off, the entire deposit coming off together from the cathode.

Substrate influence.—Thus it can be seen that copper and manganese cathodes have some influence in the first few layers of the deposit. Beyond that, the sub-

No.	Nature of manganese metal	With respect to hydrogen electrode as zero, at 27°C, V: Electrode potential in 1N $MnSO_4$ solution (extrapolated value to zero time)	With respect to hydrogen electrode as zero, at 27°C, V: Cathode potential at a current density of 4.2 A/dm²*
1.	Pure alpha manganese containing no sulfur or selenium (deposited as gamma manganese and transformed to alpha by heating at 160°C for 1 hr in vacuum)	−1.058	—
2.	Gamma manganese (electrodeposited)	−1.085	−1.392
3.	Alpha manganese containing sulfur (electrodeposited from solutions containing 0.1 g/liter of SO_2)	−1.092	−1.399
4.	Alpha manganese containing selenium (electrodeposited from solutions containing 0.1 g/liter of H_2SeO_3)	−1.125	−1.408

* No correction has been made for the ohmic drop between the Luggin capillary and electrode surface.

strates have no directing influence on the structure of the deposit. The presence of reducible S or Se compounds alone in the electrolyte determines the ultimate structure. With all other conditions of deposition such as current density, pH, temperature, composition of electrolyte, and even cathode efficiency remaining the same on any substrates, gamma or alpha manganese can be deposited depending on the absence or presence of reducible compounds of S or Se in the electrolyte.

Standard and cathode potentials.—It can be seen from Table II that the standard electrode potential of pure alpha manganese containing no sulfur or selenium should be less negative than that of gamma manganese and that the two values differ only very slightly, which is in conformity with the standard free energy of each modification (11). It is also seen that the cathode potentials under the same current densities of deposition increase in the order of (*a*) gamma manganese, (*b*) alpha manganese containing sulfur, and (*c*) alpha manganese containing selenium, which is found to be in conformity with the order of electrode potential values.

Pure alpha manganese (transformed gamma manganese) is found to have a very low hydrogen overvoltage, while gamma manganese has a comparatively higher hydrogen overvoltage.

Addition agents, polarization, and hydrogen content.—It can be seen from Table III that electrodeposited gamma manganese contains 42-70 ml/100g of hydrogen, almost the same amount soluble in gamma manganese within its temperature ranges of stability (12). On the other hand, electrodeposited alpha manganese, in presence of sulfur or selenium, contains 230-260 ml/100g of hydrogen, while the absolute solubility of hydrogen in alpha manganese is only 21.6 ml/100g at 25°C (12). It is noticed that the presence of reducible S or Se compounds in the electrolyte increases the cathode polarization with a resultant increase in the hydrogen content of the alpha deposit obtained. Both these properties can be attributed to the negative catalytic activity of sulfur and selenium on the recombination of hydrogen atoms (13, 14) to form molecules.

While the negative catalytic agents of group VIB, viz., S, Se, and Te, facilitate the deposition of alpha manganese, negative catalytic agents of group VB, viz., P, As, and Bi, do not behave similarly. With tellurium the hydrogen content increases to 598 ml/100g and the deposit shows an amorphous pattern on x-ray studies.

Organic inhibitors in the electrolyte also increase the cathode polarization, but they neither yield alpha manganese nor introduce any high amount of hydrogen in the deposit. Experiments D and E in Table III show that only cathodically reducible sulfur compounds yield alpha manganese and that the effect of SO_2 is primarily not that of a reducing agent in the deposition of manganese (1).

Effect of conditions of deposition.—Cathode current density.—With all other conditions of deposition remaining the same, increase in current density from 4-5 to 30 A/dm² prevents the formation of gamma manganese from solutions containing no reducible S or Se compounds, and an amorphous brittle manganese with the hardness of alpha and with a hydrogen content of 550 ml/100g is obtained. Heating this amorphous deposit at 125°C in a vacuum of 10^{-3} mm of Hg gives a clear crystalline pattern of alpha manganese.

Table III. Addition agents, hydrogen content, and structure of deposited manganese

(Excepting for Expt. A—1, when copper cathode was used, all the other experiments were carried out with stainless steel cathode.)

During deposition at high current densities, at the top solution-air interface portion, where the current is blocked due to accumulation of hydrogen bubbles and where the cathode polarization is decreased, gamma manganese is obtained. Similarly if a cathode is bent at the projected side which is drawn nearer to the anode and where the current density is high, alpha manganese (amorphous) is obtained, and on the reverse side where the current density is low, gamma manganese is obtained.

Catholyte pH.—At catholyte pH around 2, in the presence of SO_2, deposits obtained show crystalline pattern of alpha manganese, instead of the amorphous deposits obtained up to 10 min of deposition at pH around 7 as mentioned earlier. This has to be attributed to the formation of hydrogen sulfide and its direct inhibitive action on the recombination of hydrogen atoms and to direct proton inclusion in the deposit (13,14).

Hardness and evolution of hydrogen in manganese.—Unlike other electrodeposited metals like Fe, Cr, Ni, etc., electrodeposited alpha manganese does not show a high hardness value compared to its annealed state. The electrodeposited alpha manganese has a hardness of 690 DPN, which increases to 1000 DPN on heating to 500°C in vacuum, when practically all the hydrogen is removed. The electrodeposited gamma manganese has a hardness of 100 DPN.

The electrodeposited alpha manganese left at room temperature is found to be less brittle with the passage of time. Most of the hydrogen in alpha manganese can be removed on heating to 300°C in a vacuum of 10^{-4} mm of Hg without significantly affecting the broadening of diffraction rings (Table IV). On heating to 500°C, the broadening disappears, the x-ray pattern is well resolved, and the hardness is also increased. Along with hardness, the ductility of the metal also increases.

The x-ray powder patterns obtained in this investigation of gamma and alpha deposits containing various amounts of hydrogen generally confirm Potter's (15) earlier finding that the broadening of the lines was highest with transformed gamma manganese. Potter (15) explains, on the basis that all the hydrogen is in interstitial solid solution, that the highest broadening with transformed gamma manganese is because of an uneven distribution of hydrogen in the unit cell of alpha manganese so formed. On the other hand, it is felt that the highest broadening observed with transformed gamma manganese should be attributed to the volume change associated with the transformation of gamma to alpha and the resultant stress. Second, the deposits containing more than 500 ml/100g of hydrogen obtained in this investigation were generally amorphous.

General discussion.—No evidence to support Dean's theory that manganese is initially deposited in gamma which subsequently transforms to alpha in presence of SO_2 was found from x-ray studies of the deposits. The experimental results in this investigation indicate that the particle size of the initial deposit, in presence of SO_2, should be less than 0.01μ, being below the range of diffraction by x-rays. Apparently the thin crystalline deposit toward the cathode, mentioned by Dean (1), seems to be this amorphous deposit. The higher hardness and the tarnish resisting brightness of the surface-facing cathode (1) can be explained by the finer grain size and orientation of the initial deposit.

Presumably the high current density of 23-27 A/dm^2 and the sulfur present in the electrolytic manganese flakes which were used directly in the anolyte to make up to the manganese content of the bath may be responsible for the absence of the gamma modification in the deposits that Bell (5) obtained in the absence of SO_2 in the electrolyte.

The gamma manganese obtained in this investigation took about 5 days for half completion of transformation to alpha at a temperature of 32°C, corroborating Potter's data (4). In this investigation, the addition of glycerol was not found to have any effect on the structure of deposited manganese compared to those obtained from pure solutions as reported by Moiseev (6, 7). However, this investigation corroborates Moiseev's (6, 7) findings that at a lower pH, crystalline alpha manganese is obtained instead of the amorphous deposits obtained initially at higher pH values in the presence of SO_2.

Table IV. Evolution of hydrogen from electrodeposited alpha manganese (pilot plant sample) during heating to various temperatures

Temperature, °C	Evolved hydrogen in 15 min at 10^{-4} mm of Hg (ml/100g)
75	11.58
100	15.45
200	106.90
300	154.50
400	16.73
500	2.57

Proposed Mechanism

The following mechanism is suggested in the deposition of manganese in alpha and gamma modifications, at current densities of the order of 4-5 A/dm^2 and at catholyte pH values around 7.

(*i*) (*a*) Barring the exceptions of a directing influence of an active substrate in the first few atomic layers of the deposit, manganese is initially electrodeposited from pure solutions of manganese and ammonium sulfate in an amorphous nature. This amorphous deposit resembles alpha manganese.

(*b*) Pure alpha manganese containing no S or Se and especially this amorphous deposit has a very low hydrogen overvoltage, and for this reason it cannot be electrodeposited from pure solutions to any appreciable thickness.

(*c*) As soon as an initial flash layer of such extremely fine grained (alpha) manganese is formed in about 8-10 sec, it facilitates hydrogen discharge and hydrogen evolution takes place. This discharge of hydrogen ions makes the vicinity of the cathode more alkaline when the potential for evolution of hydrogen is raised.

(*d*) The standard electrode potential of gamma manganese is only slightly more negative than that of pure alpha manganese, and the increase in polarization due to the discharge of hydrogen (as mentioned under (*c*) above) enables gamma manganese to be deposited. Due to the higher hydrogen overvoltage of gamma manganese, gamma manganese begins to build up.

(*ii*) (*a*) With an addition of 0.1 g/liter of SO_2 to the electrolyte, the amorphous nature of the initial deposit continues to build up to an increasing thickness, over which crystalline alpha manganese is obtained. This bears a close resemblance to the thick amorphous brittle manganese, having hardness of alpha, obtained at high current densities, viz., 27-30 A/dm^2, from solutions containing no reducible sulfur or selenium compounds.

(*b*) Addition of reducible compounds of sulfur or selenium to the electrolyte not only increases the cathode potential values, but simultaneously increases the surface concentration of hydrogen atoms, as in the case with high current densities of deposition from pure solutions.

(c) These indicate that alpha manganese begins to build up when the cathode polarization is raised, together with a high adsorption or absorption of hydrogen as noticed from the hydrogen contents of deposited manganese in presence of sulfur or selenium in the electrolyte, and also at high current densities of deposition from solutions containing no reducible sulfur or selenium.

(*d*) The strength of the bond between manganese and sulfur or selenium may be greater with a result of the adsorption of these particles, and their effect on the discharge of metal ions may also be greater.

(*iii*) (*a*) The low hardness and density of electrodeposited alpha manganese, compared to its annealed state, and the increase in hardness together with ductility on heating suggest the possibility that a part of the discharged hydrogen ions assumes positions inside the lattice or forms complex during the formation of alpha manganese.

(*b*) On the other hand, desorption characteristics of hydrogen in alpha manganese do not favor the view that all the hydrogen in electrodeposited manganese is inside the lattice.

(*c*) After the flash layer of amorphous (alpha) manganese of the first 8-10 sec, further deposition of manganese in alpha form has to be attributed to the properties mentioned before and has to be explained presumably on the basis that a part of the hydrogen atoms goes inside the lattice and remains as protons and that the electrons are not equally shared between different kinds of atoms in alpha manganese and that the structure is more similar to that of a compound than to a true element (16).

Microscopic Study of the Formation of Cathodic Films on Iron During Electrolysis of Chromium Plating Solutions at Various CrO_3:SO_4 Ratios

J. C. Saiddington and G. R. Hoey*

Corrosion Section, Extraction Metallurgy Division, Mines Branch, Department of Energy, Mines and Resources, Ottawa, Ontario, Canada

ABSTRACT

The formation of cathodic films was observed under the microscope during electrolysis of chromium plating solutions at various CrO_3:SO_4 ratios. The microscopic observations were correlated with galvanostatic and potentiostatic polarization data. It was found that an amorphous oxide film formed in chromic acid solutions. This film also formed, as a transient stage prior to chromium deposition, in solutions containing sulfate at CrO_3:SO_4 ratios ranging from 200:1 to 65:1. Chromium deposition was associated with transformations at the cathode surface that involved the breakup of the amorphous oxide film and the appearance of a viscous film. The nature and formation of these two types of cathodic films are discussed with reference to findings of other investigators.

Although the deposition of chromium from chromic acid solutions is an important industrial process little is known about its mechanism. Dubpernell (1) in a critical review of the available literature on the subject came to the conclusion that even the simplest questions about chromium plating cannot be answered with the present knowledge. A critical area of disagreement concerns the existence, role, and nature of cathodic films formed during electrolysis of chromic acid solutions in the presence and absence of sulfate.

The views regarding these films constitute two main schools of thought. One school maintains that pure chromic acid cannot be reduced to metal because a nonporous amorphous oxide film grows on the cathode surface and prevents all reduction processes other than that of hydrogen ion. The presence of sulfate alleviates the barrier-like conditions at the cathode

surface by one of the following processes: (*a*) penetration by sulfate resulting in partial disruption of the amorphous oxide film suggested by Muller (2), (*b*) partial chemical dissolution of the film in the presence of sulfate suggested by Weiner (3), (*c*) modification of the film into reducible compounds that serve as an intermediate reduction stage postulated by Reinkowski and Knorr (4) and by Okada and Yamamoto (5), and (*d*) inhibition of the film growth in the presence of sulfate assumed by Kappel and Gerischer (6).

The second school of thought, represented by the views of Vagramyan and Usachev (7), Solov'eva and and Vagramyan (8), and Shluger and Kazakov (9), maintains that the deposition of chromium is brought about by formation of an entirely different type of film in the presence of sulfate. This second type of film, in distinction from the amorphous oxide type of film (film of the first type), is considered to be a colloidal complex consisting of the products of the reduction of chromic acid to the trivalent state, together with Cr^{6+} and $SO_4^{=}$ ions. This film may be observed visually on cathodes extracted from plating baths with the current on (10, 11); it dissolves easily in dilute chromic and sulfuric acids, in the electrolyte in the absence of current, and even in distilled water. Its thickness may vary in accordance with the electrolyte composition and the conditions of electrolysis, but it is always macroscopic. The colloidal film does not form in pure chromic acid, whereas the amorphous oxide film forms and grows in pure chromic acid to a considerable thickness.

The formation of an amorphous oxide film, that is, a film of the first type, has been detected in the present investigation during electrolysis of both "pure" and sulfate-containing chromic acid solutions by *in situ* microscopic observations of the cathode surface. These observations were correlated with polarization characteristics. The observations reveal that the amorphous oxide film disintegrates when chromium deposition begins in conventional plating baths and cannot therefore be considered an intermediate stage in the chromium plating process, as proposed by some investigators (4, 5). In addition, the present work points indirectly to the formation in the plating bath of the second type of film prior to the establishment of the chromium deposition process. Microscopic observations indicate that, under the conditions investigated, this second type of film is in the form of a transparent viscous layer during chromium plating and that it does not form in pure chromic acid solutions. One can assume, therefore, that such a film has a faculty of bringing about the final reduction step to metal in agreement with the results of the Russian investigators (7-9). The unconventional nature of the second type of film is not surprising in view of many phenomena associated with chromium plating that are not encountered in other electrodeposition processes.

Experimental

The experimental setup used in the investigation is represented schematically in Fig. 1. The microscopic technique used was similar to the one described by Jones and Saiddington (12) but included increased resolution of the optical system. To remove the evolving hydrogen bubbles, which would otherwise interfere with microscopic observations, a constant flow of solution at approximately 1 cm/sec was maintained between the objective and the cathode surface. For comparison, duplicate experiments were performed with solution stationary at the cathode surface.

All solutions were prepared with 250 g/l of analytical reagent quality chromium trioxide, which contained 0.02% of sulfate as an impurity. Thus, in "pure" chromic acid the ratio of chromium trioxide to sulfate was 5000:1. In addition to pure chromic acid four other concentrations of sulfate at fixed CrO_3:SO_4 ratios of 200:1, 100:1, 75:1, and 65:1 were studied. In a number of experiments the CrO_3:SO_4 ratio was varied from

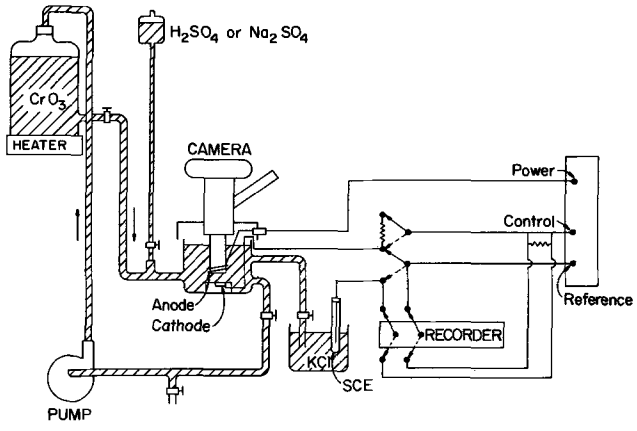

Fig. 1. Schematic diagram of the plating cell and accessories

5000:1 to 100:1 and subsequently to 400:1 or 500:1 while the electrolysis was in progress under galvanostatic or potentiostatic conditions. The variation of the CrO_3:SO_4 ratio was accomplished by increasing or decreasing the addition of H_2SO_4 or Na_2SO_4 to pure chromic acid solution passing continuously through the plating cell (see Fig 1).

An ANOTROL potential controller was used as a source of constant current and controlled potentials. Polarization curves were recorded by means of a potentiometric recorder with a ½-sec response over a full 9-in. grid and a 4-megohm input impedance off balance. Saturated calomel electrode was used throughout as a reference across a salt bridge that did not introduce significant ohmic drops at the currents employed.

Cathodes were prepared from iron rods, 3.96 mm diameter, with cross-sections polished metallographically to a fine finish. A 2-min immersion in the plating bath preceded by a thorough rinse with distilled water was the only chemical treatment employed.

All experiments were conducted at 50°C. Practically all microscopic observations were made at 100X magnification with 0.18 NA objective under conditions of dark field illumination with solutions flowing across the cathode surface. The visual observations are described in the text. Photomicrographic record is illustrated by a small number of selected photomicrographs.

Results

Electrolysis at constant current.—Voltage-time curves.—Voltage-time curves at a current density of 220 mA/cm² at CrO_3:SO_4 ratios of 5000:1, 200:1, 100:1, 75:1, and 65:1 obtained with the solution maintained stationary in the plating cell are shown in Fig. 2a. Similar curves obtained with the solution flowing across the cell at approximately 1 cm/sec are shown in Fig. 2b. The principal effect of the agitation thus introduced was a complete separation of curves 2 and 3 shown in Fig. 2b, while they coincided in the first part of their length in Fig. 2a.

The curves are considered in terms of five ranges of potential.

Potential range (*i*) is characterized by a rapid shift of potential from the value +0.85V *vs.* SCE, measured during the immersion of the electrodes in the plating cell before commencement of the electrolysis, to the potential of hydrogen evolution at −0.75V. Since the rate of the shift of the potential to this point was found more rapid than the response characteristics of the recorder, this part of the curve is shown in Fig. 2a and 2b as a straight line and can be considered, in the context of this investigation, to represent the process of charging the electrode from the potential of rest to the potential of hydrogen evolution. This range of potential was the subject of detailed studies by Okada, Nakamura, and Ishida (13).

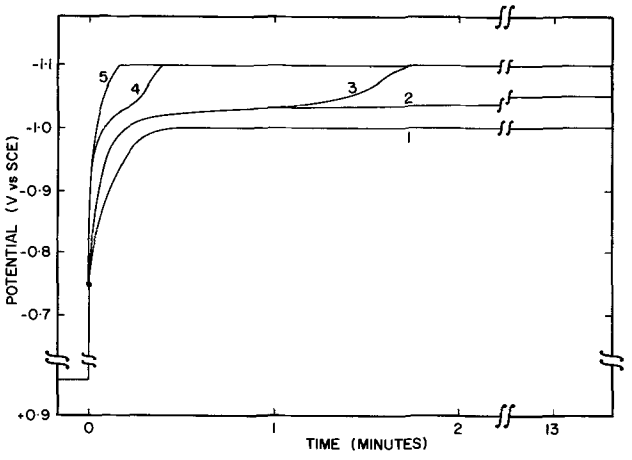

Fig. 2a. Polarization curves at a constant c.d. of 220 mA/cm^2 in stationary solutions. CrO_3, 250 g/l; temperature, 50°C. CrO_3:SO_4 ratios: curve 1, 5000:1; curve 2, 200:1; curve 3, 100:1; curve 4, 75:1; and curve 5, 65:1.

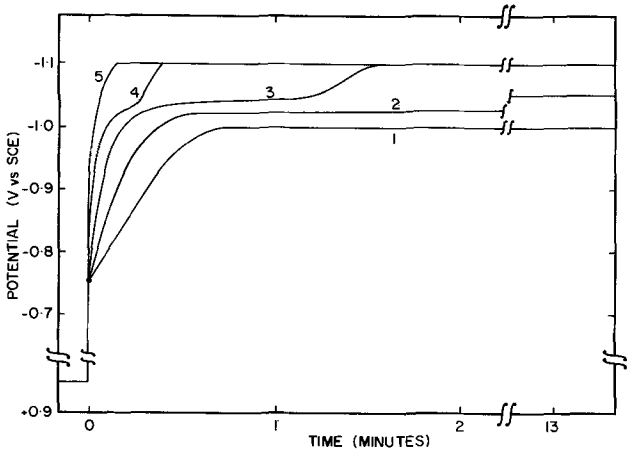

Fig. 2b. Polarization curves at a constant c.d. of 220 mA/cm^2 with a solution flowing across the cathode surface at approximately 1 cm/sec. CrO_3, 250 g/l; temperature, 50°C. CrO_3:SO_4 ratios: curve 1, 5000:1; curve 2, 200:1; curve 3, 100:1; curve 4, 75:1; and curve 5, 65:1.

Potential range (*ii*) starts with the evolution of hydrogen at −0.75V. This value is in good agreement with the potential of hydrogen evolution on iron, which, when calculated on the basis of Tafel parameters available in the literature (14-16), is −0.747 to −0.770V (*vs.* SCE) at *p*H −0.212, c.d. 0.220 A/cm^2, and temperature of 50°C. The fact that the potential of the initial hydrogen evolution was the same at all CrO_3:SO_4 ratios investigated suggests that sulfate concentration has no measurable effect on the initial discharge of the hydrogen ion. The fact that hydrogen evolution continued, from this stage onward, at potentials increasingly more negative is an evidence of the increase of the overvoltage values.

The appearance of the electrode immersed in the solution before commencement of the electrolysis is seen in Fig. 3a. Microscopic observations of the cathode surface during potential range, (*ii*) revealed always the presence of bright transparent gas bubbles against dark background as seen in Fig. 3b, taken during the experiment 3, Fig. 2b.

The end of the potential range (*ii*) was manifested by changes of the gassing pattern followed by formation of an amorphous oxide film easily observed under the microscope at about −1.00V.

Potential range (*iii*) is characterized by the formation of a visible (under the microscope) amorphous oxide film and a temporary arrest of the polarization between about −1.00 and −1.04V observed quite distinctly on the potential-time curves 1, 2, and 3 but appearing as an inflection on curve 4. In the case of 65:1 ratio no significant arrest of potential was observed, although the presence of the amorphous oxide film at the surface at about −1.00V was detected during a brief (3 sec) transition period. Since the duration of the potential arrest decreased with the decrease of the CrO_3:SO_4 ratio from 5000:1 to 75:1 one can assume that in the case of 65:1 ratio the polarization was too fast for the arrest to be resolved by the experimental technique employed.

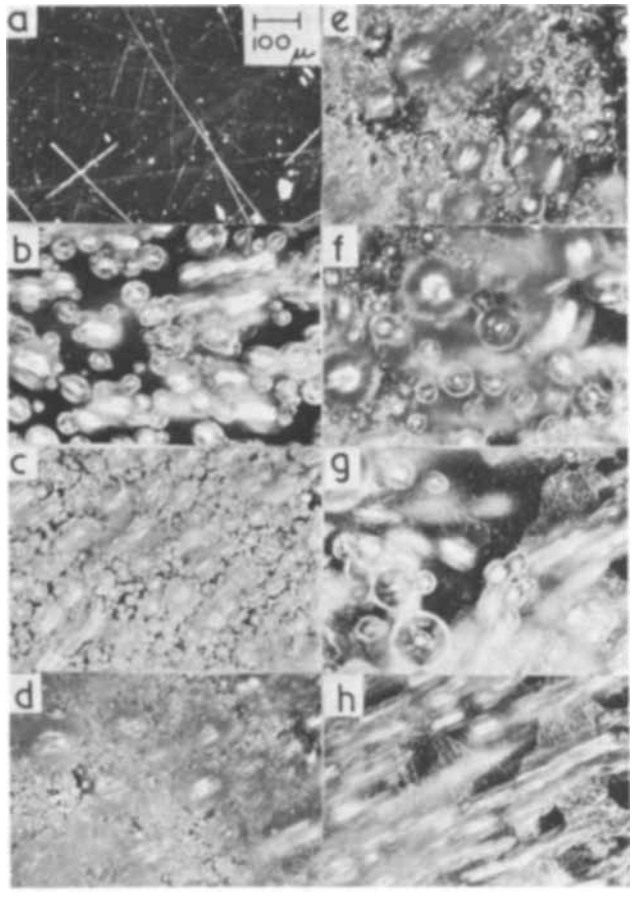

Fig. 3. Photomicrographs of the cathode surface during experiment No. 3 in Fig. 2b. Original magnification X100. Dark field illumination. Exposure 1/60 sec. a, Original surface before electrolysis; b, 10 sec; c, 55 sec; d, 70 sec; e, 75 sec; f, 85 sec; g, 90 sec; h, 100 sec.

The formation of the amorphous oxide film was always preceded by the changes of gas evolution from that seen in Fig. 3b to that seen in photomicrograph c, Fig. 3. The appearance of the cathode surface would then change gradually to that seen in photomicrograph d which shows the amorphous oxide film as a grayish background with gas bubbles moving away from the surface seen in the foreground, out of focus.

Potential range (*iv*) is characterized by further polarization from the end of potential range (*iii*) at about −1.04V to the potential of chromium deposition at steady-state conditions. The potential of chromium deposition varied with CrO_3:SO_4 ratio and is here designated, therefore, as potential range (*v*).

The shift of potential from range (*iii*) to range (*v*) is associated with certain transformations that create conditions favorable at the cathode surface for the deposition of chromium. Since chromium deposition does not take place at potential range (*iii*) the transition from range (*iii*) to range (*v*) is a step of fundamental importance.

In "pure" chromic acid the polarization would always end at about −1.00V. There was no further shift of potential, and there was no metal deposition. The

amorphous oxide film would continue to grow, flake off, then regrow, the process continuing indefinitely. In 200:1 solution, however, the potential kept on shifting gradually to more negative values until chromium deposition began at −1.05V.

In conventional baths the transition from range (*iii*) to (*v*) was observed to be rapid and quite distinct. It would always begin with an initial breakup of the amorphous oxide film followed by continuous rapid changes involving disintegration of the solid amorphous oxide film and an increase of the viscosity in the vicinity of the cathode surface, a condition that significantly reduced the mobility of the evolving hydrogen bubbles that began to become stationary and grow to larger sizes. The whole process would be completed in about 15 sec.

The beginning of the breakup of the amorphous oxide film is seen in Fig. 3e. The breakup is manifested by the appearance of dark areas representing the surface underneath. The condition at the surface 10 sec later on, when the disintegration of the amorphous oxide film is about half-way completed and the electrolyte next to (in the vicinity of) the cathode surface is more viscous, is seen in Fig. 3f. The surface is partly obscured by large gas bubbles that have just become detached from the surface and remain suspended in the viscous medium long enough to register in foreground out of focus.

Although in 75:1 and 65:1 solutions the transition from range (*iii*) to (*v*) occurred more rapidly it could still be traced through the formation and breakup of the amorphous oxide film, observed under the microscope.

The inference from these observations is that during the transition the amorphous oxide film was replaced by a viscous film which had physical and chemical characteristics distinctly different from those in the bulk of the solution. Once the film was established its existence could not be detected in the incident light unless agitation, preferably within the film itself, brought about changes in the angle of refraction across its boundary.

The ability to observe the presence of the second type of film at the cathode surface by direct observation of the electrode in the incident light was based, primarily, on the visibility of a ripple, (during hydrogen evolution) when the light was crossing media with different refractive properties near the cathode surface. Since the glass extension of the objective was immersed in the plating bath, no ripple was detectable when the evolution of gas bubbles took place in a uniform medium. If, however, gas-bubble formation occurred within or underneath a film having a composition different than that of the adjoining bulk of the solution, a ripple resulting from the stirring effect was easily recognizable as that caused by temporary intermixing of media with different consistencies. These observations, characteristic of the "schlieren effect" that indicates refractive-index changes due to composition variation, in conjunction with the evidence of the decreased mobility of the growing gas bubbles were interpreted as manifestations of increasing viscosity of the precathodic layer. The observational technique employed in the present work could not detect directly changes in viscosity. The term "viscous film" was adopted to emphasize the liquid-like properties of the second type of film in contrast with the solid "amorphous oxide film," the presence of which was associated with a different region of potential.

Potential range (*v*) is characterized by the deposition of chromium at steady-state conditions, that is, at a constant potential the value of which depended on CrO_3:SO_4 ratio. At ratios 100:1 to 65:1 it was −1.10V. In 200:1 solution the final stage of polarization reached the level of −1.05V.

The deposition of chromium from 200:1 solution is of special interest because it reveals certain details of the initial stages of deposition that could not be observed under rapidly changing conditions in other solutions. The electrolysis of 200:1 solution is discussed, therefore, under a separate heading.

The beginning of chromium deposition in the conventional plating bath is seen in Fig. 3g in the form of an epitaxial growth on the surface at the upper right hand corner of the photomicrograph. Figure 3h shows that the epitaxial growth, at various degrees of progress, has covered the whole surface area 10 sec later on. This stage of the electrolysis coincided with a new gassing pattern in the form of small mobile hydrogen bubbles.

Similar progress of initial chromium deposition was observed to occur more rapidly in 75:1 and 65:1 solutions.

Observations at CrO_3:SO_4 *ratio of 200:1.*—The observations made during electrolyses of solutions with CrO_3:SO_4 ratio of 200:1 (curve 2 Fig. 2b) merit separate discussion because they showed that the potential of chromium deposition at steady-state conditions (−1.05V *vs.* SCE) can be reached with the cathode surface completely covered by the amorphous oxide film.

The formation of the amorphous oxide film was observed to begin in 200:1 solution after about 3 min of electrolysis at potential range (*iii*). The appearance of the cathode surface covered with the amorphous oxide film about 1μ thick, is illustrated in the photomicrograph Fig. 4b. Photomicrograph a illustrates the evolution of hydrogen at potential range (*ii*) and during the initial part of potential range (*iii*), prior to the formation of the amorphous oxide film.

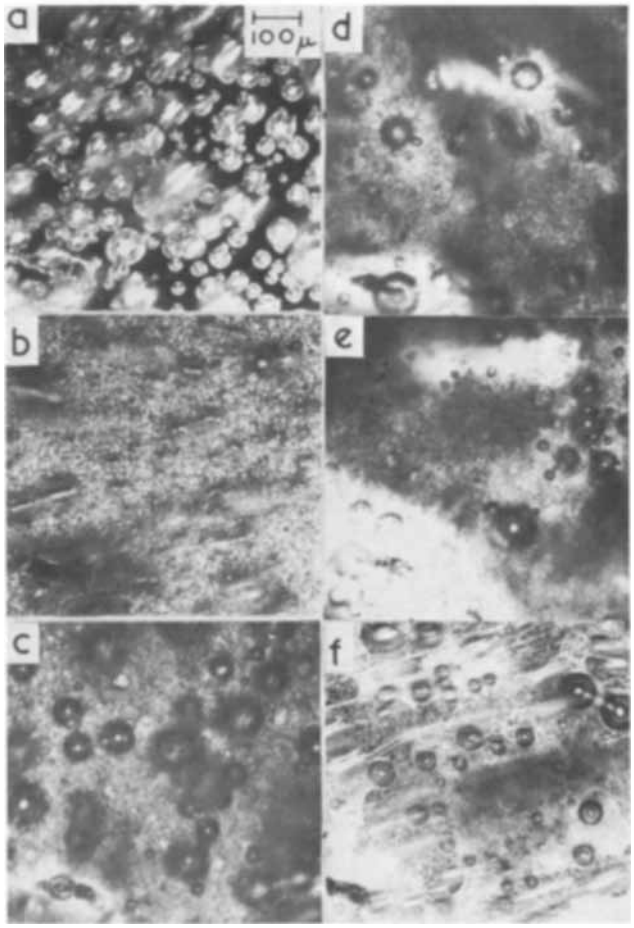

Fig. 4. Photomicrographs of the cathode surface during experiment No. 2 in Fig. 2b. Magnification and illumination as in Fig. 3. Exposure 1/125 sec. a, 1 min electrolysis; b, 6 min; c, 23 min; d, 31 min; e, 35 min; f, 38 min.

In 200:1 solution the potential kept shifting slowly to more negative values over a period of 10 min, while the amorphous oxide film remained on the surface. When the potential of −1.05V was reached in the 12th minute, permanent bright spots appeared on the cathode surface, indicating the beginning of chromium deposition at these spots, underneath the amorphous oxide film. A more advanced stage of this phenomenon is seen in Fig. 4c. The permanent bright spots could be distinguished easily from transient bright spots associated with images of gas bubbles that moved within the field of vision. The breakup of the amorphous oxide film, observed to begin around the bright nucleation spots, continued by fragmentary detachment from the surface. Partial detachment of the amorphous oxide film revealed small bright areas of chromium that can be easily seen in Fig. 4d, in contrast with the large dark areas corresponding to the overlaying oxide film. Figure 4e shows a more advanced stage of the same phenomenon when still larger portions of the chromium deposit are exposed. At this stage it was possible to observe quite distinctly the evolution of hydrogen within a viscous film in which remnants of the amorphous oxide film remained suspended for various periods of time before moving away from the cathode surface.

An example of a small portion of the amorphous oxide film suspended near the cathode surface in a viscous film is seen in Fig. 4f in the form of a small darker area in the center of the photomicrograph. Closer examination reveals that this remnant of the amorphous oxide film is slightly transparent showing small hydrogen bubbles inside or underneath. This is quite remarkable if one considers that, at this stage, the chromium deposition process has been already in progress for over 25 min.

The above observations demonstrate that the shift of potential from range (*iii*) to (*v*), at least in 200:1 solution, is not due to the breakup of the amorphous oxide film, as one could infer from interpretation of observations made in conventional plating bath, and that the breakup of the oxide film is not a process of gradual dissolution or gradual conversion into another type of cathode film, but rather a phenomenon of mechanical disruption of a redundant layer that has formed during the earlier stages of the electrolysis. Thus, the significant changes at the cathode surface that occur during the shift of potential from about −1.00 to −1.05V inhibit further growth of the amorphous oxide film and, at the same time, bring about the process of the reduction of chromic acid to metal. These fundamental changes can be attributed to the formation of a viscous film with unique characteristics that, at present, are not well understood, since they may be due to the formation of polynuclear species (17) in the form of olated polymer ions together with coordinated Werner-type complexes involving trivalent chromium (18, 19).

Effect of the addition of sulfate to "pure" chromic acid. —The transformations observed in conventional plating bath during transition from the potential range (*iii*) to (*v*) have also been observed during transitions induced by addition of sulfate to "pure" chromic acid when the cathode was kept polarized at a constant current density.

The effect of such an addition of sulfate is seen in Fig. 5 in the form of an increase of the polarization from the level of −1.00V to the level of −1.07V which, in this particular experiment, represents the potential of chromium deposition at range (*v*).

Potential range (*iii*) , as in other experiments, was characterized by the evolution of hydrogen and formation of the amorphous oxide film. The appearance of the amorphous oxide film after 20 min electrolysis of pure chromic acid is seen in photomicrograph Fig. 6a. The addition of sulfate to the solution entering the cell, marked in Fig. 5 by an arrow pointing upward, resulted in gradual changes of the CrO_3:SO_4 ratio from 5000:1 to 130:1. Simultaneously, the potential began to shift from −1.00 to −1.07V. The amorphous oxide film began to break up in a manner similar as in conventional bath. Before the breakup was completed the presence of viscous film was observed in the vicinity of the cathode surface. The transformations ended with a complete disintegration of the amorphous oxide film.

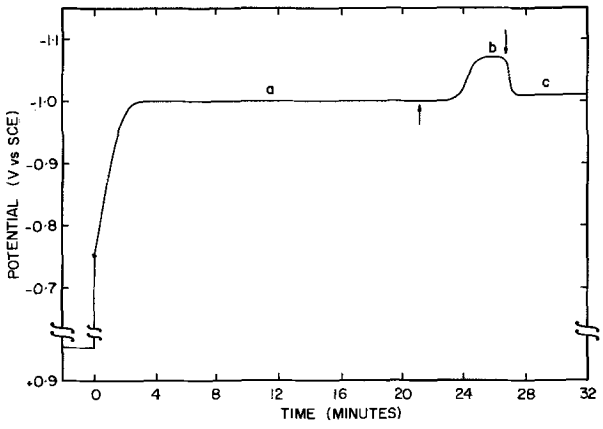

Fig. 5. Effect of increasing (arrow up) and decreasing (arrow down) the sulfate concentration at a constant c.d. of 175 mA/cm². Chromic acid solution 250 g/l of CrO_3; temperature, 50°C; solution flow across the surface 1 cm/sec (approx.). CrO_3:SO_4 ratios: a, 5000:1; b, 130:1; c, 500:1.

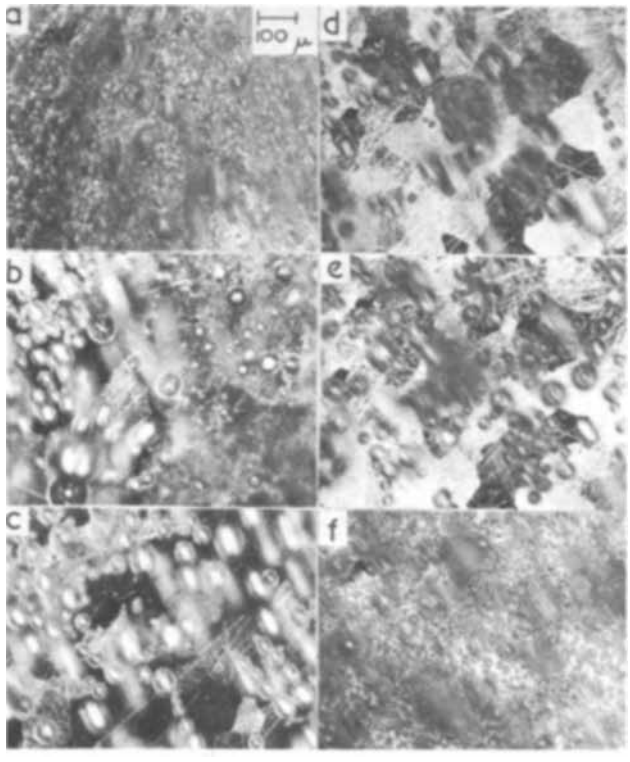

Fig. 6. Photomicrographs of the cathode surface during polarization shown in Fig. 5. Magnification X100. Dark field illumination. Exposure 1/125 sec. a, 20 min 45 sec, c.p. —1.00V; b, 25 min, c.p. —1.07V; c, 25 min 45 sec, c.p. —1.07V; d, 27 min, c.p. —1.01V; e, 28 min, c.p. —1.01V; f, 41 min. c.p. —1.01V.

The final stage of the disintegration is seen in Fig. 6b. Here, part of the surface is still covered with the amorphous oxide film. Stationary gas bubbles are observed to grow to larger sizes within a viscous film that restricts their mobility. The center and upper left hand corner of the photomicrograph shows an outline of a grain pattern indicating the presence of a coherent chromium deposit. Small mobile gas bubbles were ob-

served visually within this area. Fifteen seconds later chromium deposit, together with small bubbles overhead, was observed over the surface area as illustrated in Fig. 6c. This stage represents chromium deposition at steady-state conditions at potential range (*v*).

Effect of the withdrawal of sulfate from the plating bath.—The withdrawal of sulfate from the plating bath during electrolysis was accomplished by decreasing the addition of sulfuric acid (or sodium sulfate) to pure chromic acid entering the plating cell (see Fig. 1). This point is marked in Fig. 5 by an arrow directed downward.

As a result of the changes introduced, the CrO_3:SO_4 ratio started to increase from 130:1 to 500:1. This increase upset the steady-state process of chromium deposition shifting the potential back to the −1.00V level. As this new level of potential was being reached, amorphous oxide film began to form in certain restricted areas characterized by a very intense gassing.

The growing amorphous oxide film is seen in Fig. 6d as dark circular patches. Figure 6e shows that the formation of the amorphous oxide film extended eventually over the other parts of the surface. In the end, a uniform film covered the whole surface in a manner identical to that at the beginning of the electrolysis of pure chromic acid. This can be easily confirmed by comparison of photomicrographs a and f in Fig. 6.

The fact that the hydrogen evolution can be controlled during electrolysis of chromic acid solutions by the addition or withdrawal of sulfate, irrespective of the cathode surface, indicates that the inhibition of hydrogen ion discharge involves processes in which sulfate either interacts reversibly with the cathode surface itself or with the solution adjoining it, thus, forming an effective film barrier.

The formation of the amorphous oxide film is considered to be the result of lower hydrogen ion concentration at the cathode surface. This process is discussed in greater details under a separate heading.

Electrolysis at controlled cathode potentials.—Fixed CrO_3:SO_4 *ratios.*—Microscopic observations during electrolysis at controlled cathode potentials in solutions with fixed CrO_3:SO_4 ratios revealed the same sequence of events that was observed during electrolyses in constant current experiments, namely, initial evolution of hydrogen followed by the formation of the amorphous oxide film, its breakdown and replacement by a viscous film and a final stage consisting of the deposition of chromium at the steady-state conditions.

This preliminary study supported in all aspects the general observations on the formation and presence of cathodic films during chromium plating, made in galvanostatic investigations, and was, therefore, not pursued to completion.

Adjustable CrO_3:SO_4 *ratios.*—The results of the electrolysis at controlled cathode potentials and adjustable CrO_3:SO_4 ratios corroborate and amplify certain important features of the formation and breakup of the cathodic films observed under galvanostatic conditions and are, therefore, considered in more detail.

The effect of the addition and withdrawal of sulfate during polarization at controlled cathode potentials was investigated in a similar manner as during constant current electrolyses.

The cathodes were polarized initially in "pure" chromic acid solutions until steady-state conditions were established for a substantially long period of time (about 15 min). During this period the amorphous oxide film grew on the cathode surface to a considerable thickness. The addition of sulfate to the flowing solution was then started at a predetermined rate suitable for lowering the CrO_3:SO_4 ratio to the desirable level. When the metal deposition process was established, the addition of sulfate to the chromic acid entering the plating cell was decreased, thus increasing effectively the ratio to a new level.

Effect of the addition of sulfate to pure chromic acid.—Figure 7 shows current-time curves obtained at controlled cathode potentials of −1.10 and −1.00V *vs.* SCE. The addition of sulfate is marked by an arrow pointing downward. Prior to the addition of sulfate (region a), the cathodes were overlaid with the amorphous oxide film in a manner similar as in Fig. 5 at the potential arrest a shown in Fig. 6a.

The addition of sulfate at a predetermined rate resulted in a rapid drop of the over-all rate of electrolysis at −1.10V. The accompanying transition from the stage of hydrogen evolution and amorphous oxide film formation at a to the metal deposition at b was also very rapid and difficult to observe under the microscope in all the details.

At −1.00V, however, the transition from a to b was very protracted. The addition of sulfate was started at the 13th minute but no significant changes were observed until about the 17th minute, when the initial nucleation of chromium deposition in the form of bright spots at a number of sites became evident. The breakup of the amorphous oxide film started around such sites and continued by fragmentary detachment from the surface. The presence of a viscous film was detected at the cathode surface through a characteristic evolution of stationary hydrogen bubbles. By the time the lowest current-density value was reached (approximately 100 mA/cm^2) the cathode surface was entirely free of the amorphous oxide film and the process of chromium deposition was well established in the 24th minute.

Since all the above observations detected a sequence of events very much like the one observed during electrolysis of 200:1 solutions at constant current no photomicrographic record is included.

Effect of the withdrawal of sulfate from the plating bath.—The withdrawal of sulfate was started when it was ascertained that the process of metal deposition was established. In a number of experiments the addition of sulfate to pure chromic acid was then discontinued completely, thus allowing the CrO_3:SO_4 ratio to rise to 5000:1 level. At the 5000:1 level the chromium-plated cathode surface became completely covered with the amorphous oxide film. In the experiments represented by curves 1 and 2 in Fig. 7 the addition of sulfate was decreased sufficiently to allow the CrO_3:SO_4 ratio to increase to 500:1 and 400:1, respectively.

Curve 1 in Fig. 7 shows that such a restricted withdrawal of sulfate at the 21st minute, marked by an arrow pointing upward, resulted in a rapid increase of the over-all rate of reaction at −1.10V. The surface became partially covered with the amorphous oxide film by the time c level was reached.

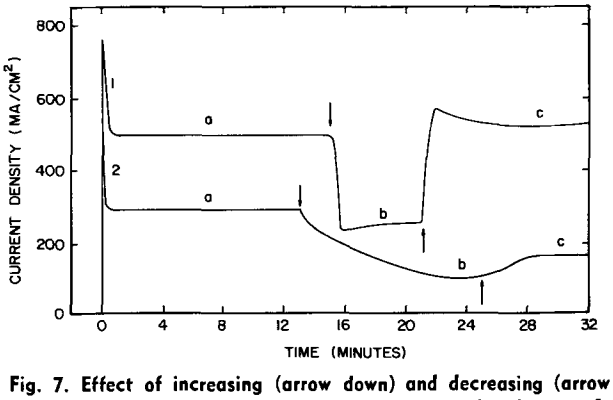

Fig. 7. Effect of increasing (arrow down) and decreasing (arrow up) the sulfate concentration at constant potentials of curve 1, −1.10V *vs.* SCE and curve 2 −1.00V *vs.* SCE. Ranges of CrO_3:SO_4 at curve 1, a = 5000:1; b = 100:1; c = 500:1; at curve 2, a = 5000:1; b = 150:1; c = 400:1.

At −1.00V (curve 2) the withdrawal of sulfate was started at the 25th minute of the experiment. Its effect was not observed immediately under the microscope. Figure 8a shows a selected area of the cathode surface 1 min-30 sec after the beginning of the withdrawal of sulfate, when the deposition of chromium was apparently still in progress in the presence of small very mobile hydrogen gas bubbles. Few seconds later on, between the time of taking photomicrographs a and b, very heavy gassing started at the site of an inclusion, seen as a dark dot in the upper part of the photomicrograph off center (marked by an arrow). The gassing and the accompanying growth of the amorphous oxide film kept spreading in a circular manner until it reached, in 2 min after withdrawal of sulfate, the size seen in Fig. 8b. The lateral growth of the amorphous oxide film (area *vs.* time) continued at a rate which was practically identical with the rate of the increase of the current density (c.d. *vs.* time). A more advanced stage of such a growth is seen in Fig. 8c, 2 min-45 sec after the withdrawal of sulfate.

Since the CrO_3:SO_4 ratio was not allowed to reach the range of pure chromic acid, the growth of the amorphous oxide film was not allowed to continue unchecked. Thus, both the increase of the current density and a further growth of the amorphous oxide film were arrested. Figure 8d shows the appearance of the film after the arrest of its growth when the gassing at the surface of the film began to decrease markedly. Figure 8e shows the same amorphous oxide film 11 min-30 sec after withdrawal of sulfate when larger stationary gas bubbles were observed to form at the surface and at the edge. Those hydrogen bubbles evolving at the edge revealed unmistakably the presence of a viscous film. The hydrogen bubbles evolving over the remaining surface area, where the deposition of chromium was observed to take place, were small and very mobile.

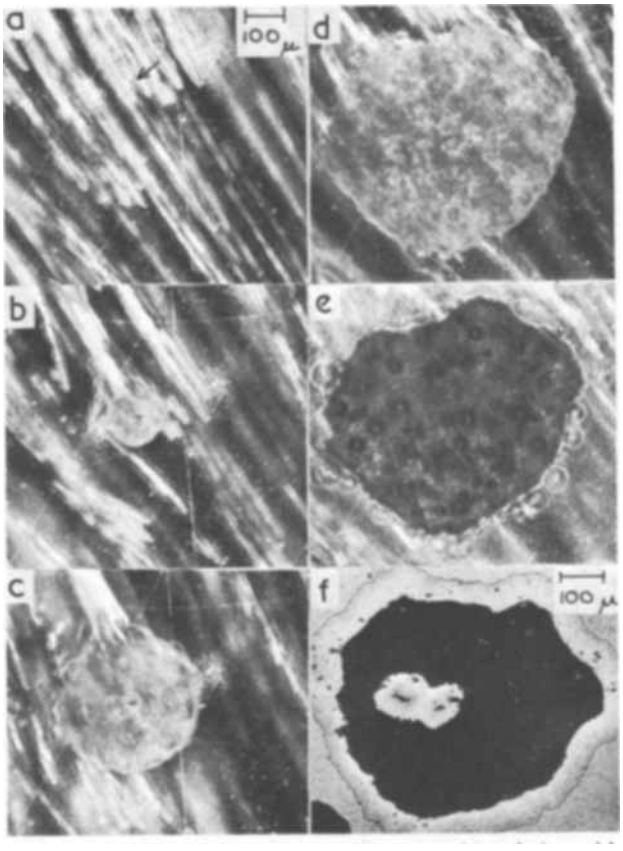

Fig. 8. Photomicrographs of the cathode surface during withdrawal of sulfate. Curve 2 in Fig. 7. a to e dark field illumination, magnification X 100. f bright field illumination, magnification X 110 (approximately). a, 26 min 30 sec, 113 mA/cm^2; b, 27 min, 121 mA/cm^2; c, 27 min 45 sec, 142 mA/cm^2; d, 29 min 30 sec, 155 mA/cm^2; e, 36 min 30 sec, 155 mA/cm^2; f, after completion of electrolysis (58 min).

The amorphous oxide film was reduced partially to metal at its edge and also around the inclusion sites. This is easily confirmed by examination of the same surface area after completion of the electrolysis shown in Fig. 8f. It is seen that during the additional 22 min of electrolysis after photomicrograph e was taken, a considerable portion of the amorphous oxide film was converted into chromium deposit. Photomicrograph f was taken under bright field illumination. The dark reddish amorphous oxide film could easily be observed then at low magnification even with the help of an ordinary magnifying glass. In the photomicrograph, the amorphous oxide film is seen as a dark area against a bright background of chromium deposit. The bright band (around the black area), corresponding to the original size of the amorphous oxide film before its reduction, appears to be superimposed over a base of coherent chromium deposit. This suggests that two reduction processes to metal proceeded simultaneously at the same surface area. In the steady-state case with the usual plating solution, this cannot occur since the amorphous oxide film begins to disintegrate below the potential at which plating occurs.

The experimental results during electrolysis at controlled cathode potentials show that the addition of sulfate to pure chromic acid brings about a drop of the over-all rate of reaction evidently due to inhibition of hydrogen evolution. Since the hydrogen evolution resumes at higher rates after withdrawal of sulfate, the inhibition is not likely due to adsorption of sulfate or its complexes at the cathode surface but rather due to the formation of a barrier in the solution adjoining the cathode surface.

The initial formation of the amorphous oxide film at inclusions, that is, at sites with low overvoltage characteristics, shows that the formation of such a film is related to higher *p*H environment. The lateral growth of the amorphous oxide film at rates parallel to the rates of current increase indicates the establishment of low hydrogen overvoltage conditions in the expanding areas.

Discussion

Interpretation of potential-time curves.—According to Dubpernell (1) there are four electrochemical reduction processes associated with cathodic polarizations in chromium plating solutions. The processes are as follows:

(I) Reduction of Cr^{6+} to Cr^{3+} involving $Cr_2O_7^=$ species.

(II) Reduction of Cr^{6+} to Cr^{3+} involving $CrO_4^=$ species.

(III) The evolution of hydrogen with a simultaneous reduction of Cr^{6+} to Cr^{3+}.

(IV) The deposition of chromium accompanied by the evolution of hydrogen and the reduction of Cr^{6+} to Cr^{3+}.

Processes (I) and (II) take place at potential ranges that vary with the type of basis metal and surface pretreatment (20), but always at values more positive than the evolution of hydrogen. Since both processes involve the formation of trivalent chromium at low current densities, their separation into distinct steps on a current-potential polarization curve is not always feasible.

The evolution of hydrogen with simultaneous reduction of chromic acid to trivalent chromium in the absence of chromium plating, that is, reduction processes (III), is sometimes not observed on metals with high hydrogen overvoltages, when the electrolysis proceeds directly from processes (I), (II) to processes (IV).

The beginning of reduction processes (I), (II), (III) on iron corresponds to about +0.50, −0.50, and −0.75V *vs.* SCE, but these potentials depend on surface prep-

aration. Chromium deposition does not start until the potential of −1.00V *vs.* SCE is reached, and this potential is not affected by the nature of the cathode surface (21).

The four reduction processes described above are used by some investigators as a basis for a division of the current-voltage curves into four branches. In the present investigation the division of potential-time curves into five ranges is more convenient and in better accord with well-defined stages of polarization observed chronologically under the microscope.

Potential range (i).—The first range of potential did not involve microscopic observations because, as mentioned before, it was too fast to be resolved by the recorder. This range of potential corresponds to processes (I), (II).

Okada, Nakamura, and Ishida (13) studied, by means of oscillographic techniques, charging curves during initial cathodic polarizations of gold and platinum electrodes at various current densities in pure and sulfate-containing chromic acid solutions. They found that in pure chromic acid the charging curves (potential *vs.* charge) from the potential of rest to the potential of hydrogen evolution were always the same irrespective of the current densities used. In the plating bath, at low current densities (50 mA/cm^2), there were current carrying reactions ($Cr^{6+} \rightarrow Cr^{3+}$) that prevented the charging of the cathode to the potential of hydrogen evolution. At higher current densities (200 mA/cm^2) the charging rates in the plating baths were the same as in pure chromic acid solutions. This means that at sufficiently high current densities the reduction of chromic acid to trivalent chromium in the presence of sulfate cannot support the over-all rate of electrolysis at potentials less negative than the evolution of hydrogen. It is justifiable, therefore, on the basis of this evidence to consider potential range (*i*), at high current densities, as predominantly a process of charging the electrode to the potential of hydrogen ion discharge.

Potential range (ii).—This range corresponds to the reduction processes designated (III). Although in the presence of sulfate the reduction of the chromic acid to trivalent chromium is assumed to account for part of the total charge transfer, the polarization rate during this range of potential is controlled by the hydrogen evolution reaction. Therefore, regardless of the presence of sulfate the shift of potential that constitutes range (*ii*) is a process sufficiently well defined to merit separate treatment. The increase of the rates of polarization with decreasing CrO_3:SO_4 ratios must be considered, therefore, in terms of increasing hydrogen overvoltages.

Potential range (iii).—This range also corresponds to the reduction processes (III). However, here the appearance of the amorphous oxide film observed clearly under the microscope together with distinct temporary arrest of the polarization at higher CrO_3:SO_4 ratios sets this range of potential apart from the previous one. The formation of the amorphous oxide film at various CrO_3:SO_4 ratios is discussed in the next section, under a separate heading.

Potential range (iv).—This is the transition range from the reduction processes (III) to (IV), that is, from the partial reduction of chromic acid ($Cr^{6+} \rightarrow Cr^{3+}$) and hydrogen evolution ($2H^+ \rightarrow H_2$) in the absence of chromium deposition, to the stage of chromium plating at steady-state conditions, in the presence of hydrogen evolution and Cr^{3+} formation.

Potential range (v).—Three reduction processes, namely, $Cr^{6+} \rightarrow Cr^{3+}$, $H^+ \rightarrow \frac{1}{2}H$, and $Cr^{6+} \rightarrow Cr^0$ occur simultaneously at steady-state conditions. Both the evolution of hydrogen and the reduction of chromate to Cr^{3+}, assuming that formation of Cr^{3+} is not due to side reactions, proceed at more negative potentials than at range (*iii*), that is, under conditions of higher voltage values. The remarkable thing is that this higher overvoltage condition exists only as long as there is adequate sulfate concentration in the plating bath. As soon as sulfate is removed the potential shifts to less negative values, the deposition of chromium ceases, and the amorphous oxide film forms rapidly on the surface.

Since the higher overvoltage during chromium plating is a phenomenon reversibly controlled by the presence of sulfate irrespective of the surface conditions, it is more likely that the overpotential is due to formation of a film which does not form a stable bond with the surface, rather, than due to a reversible adsorption of sulfate or its complexes.

There is no clear cut evidence what occurs during the transition range (*iv*).

Reinkowski and Knorr (4) postulated formation of intermediate reducible compounds containing complexes of divalent chromium. These compounds, adsorbed on the cathode surface, were considered to be involved in the final reduction step to metal.

Solov'eva and Vagramyan (8) explained the transition as a process of formation on the electrode surface of a colloidal film from the products of incomplete reduction of chromic acid, chromate and sulfate ions. According to these authors (22), a film, forming a continuous phase on the electrode surface, appears due to the accumulation of the $Cr^{6+} \rightarrow Cr^{3+}$ reaction products together with certain components of the solution. The colloidal film inhibits the reduction of chromate ions to the trivalent state and the discharge of hydrogen ion.

Okada and Yamamoto (5) assumed that the film that forms at potential range (*iii*) grows thicker gradually and, subsequently, the hydrogen overvoltage of the "filmed" electrode increases when the potential shifts to the potential range (*v*). They expressed a belief that the amorphous oxide film that forms at potential range (*iii*) in the presence of sulfate is an olated oxide compound of Cr^{3+} penetrated with sulfate anions. The rate of transition from potential range (*iii*) to (*v*) depends on the rate of the growth of the film formed at range (*iii*), according to these authors.

Present investigations show that the amorphous oxide film that forms at potential range (*iii*) begins to disintegrate when the potential shifts from range (*iii*) to (*v*) in a conventional plating bath. Thus, the increase of hydrogen overvoltage is not due to the thickening of the film formed at range (*iii*) as suggested by Okada and Yamamoto. Since potential range (*v*) can be reached with the cathode surface completely covered by the amorphous oxide film (at CrO_3:SO_4 ratio of 200:1), one cannot infer that the transition from potential range (*iii*) to (*v*) is due to the disintegration of the amorphous oxide film only.

The fact that during the transition the vicinity of the cathode surface becomes more viscous suggests formation of a viscous film, which, presumably, is the same film as the continuous phase film discussed by Vagramyan and Solov'eva. It appears that the viscous film forms independently of the amorphous oxide film, which, in turn, becomes superfluous once the potential shifts to the level of range (*v*).

Nature and the formation of cathodic films.—Amorphous oxide film.—Sysoev, Drobantseva, and Platonina (23) analyzed chemically cathodic films formed on copper and steel during electrolysis of pure chromic acid solutions. They concluded that the films consisted only of trivalent chromium apparently in the form of $Cr(OH)_3$.

Weiner and Schiele (24) examined films detached from cathodes polarized in pure and sulfate-containing chromic acid solutions. They found by electron diffraction methods that all films formed on Fe, Ni, Cr, Cu, Ag contain only Cr_2O_3. Films formed in plating baths also were found to contain traces of oxides of the cathode metal in addition to Cr_2O_3.

Since chromic oxide, presumably, at various stages of hydration, is practically the only constituent of the amorphous oxide film it is reasonable to assume that its formation will be affected by the availability of Cr^{3+} at the interface.

Trivalent chromium apparently is not produced in any measurable concentrations by direct electrochemical reduction of pure chromic acid (25). The electrolysis, in this case, consists of the evolution of hydrogen with practically 100% current efficiency. Snavely (26) has shown that chromic acid can be reduced to trivalent chromium by evolving hydrogen, but that the reaction is very slow. Thus, the low concentration of the trivalent chromium at the beginning of the electrolysis of pure or nearly pure chromic acid may account for the slow rate of the formation and growth of the amorphous oxide film observed in such solutions.

The reduction of chromic acid to trivalent chromium, that is, $Cr^{6+} \rightarrow Cr^{3+}$, is promoted by sulfate to proceed at potentials less negative than the evolution of hydrogen (27, 28). Hence, the initial stages of polarization, in the presence of sulfate, yield trivalent chromium that accumulates at the interface, before hydrogen evolution begins at potential range (*ii*). Intense hydrogen evolution lowers hydrogen ion concentration at the interface, creating conditions favorable for the formation of an oxide-type film, which, according to Pourbaix diagrams (29), can be avoided only by maintaining high degree of acidity in the catholyte.

Since the rate of $Cr^{6+} \rightarrow Cr^{3+}$ increases with sulfate concentration, the formation of the amorphous oxide film will be accelerated at lower CrO_3:SO_4 ratios. This is borne out experimentally. The formation of the amorphous oxide film was observed, for instance, to begin at 6th and 3rd minute in solution with ratios 5000:1 and 200:1, but its presence was visible already in 50th, 14th, and 3rd second in solutions with CrO_3:SO_4 ratios 100:1, 75:1, and 65:1.

Close association between hydrogen evolution and the amorphous oxide film formation is demonstrated in Fig. 8b to d. Whether the process of the film formation is entirely a chemical precipitation reaction or a reaction involving charge transfer at the interface cannot be decided on the basis of the evidence presented. The increase of the over-all rate of electrolysis during lateral growth of the amorphous oxide film indicates only an increase of the reduction rate within the expanding areas which may be entirely due to more intense hydrogen evolution.

The electron microscope examination of the amorphous oxide films by Weiner and Schiele (30) showed that there are two kinds of oxide films. One, very thin (0.02μ) and pore free, forms initially on the cathode surface. The other thicker (0.1μ) and fairly porous continues to grow over the thin one, with the line of demarcation not always distinguishable.

Presumably, the thin film forms during the initial shift of potential from -0.75 to -1.00V, that is, at potential range (*ii*), when its presence cannot be detected under the microscope and when its effect is manifested by higher rates of polarization at lower CrO_3:SO_4 ratios. The thicker film is apparently the one that is observed visually to grow at the potential range (*iii*).

The evidence of the reduction of the amorphous oxide film to metal (Fig. 8f) is in agreement with observations made by other investigators (31, 32). The process is not considered to be connected with the mechanism of chromium deposition at steady state conditions, because the amorphous oxide film is observed to break up into fragments at the onset of chromium plating.

Viscous film.—According to Kappel and Gerischer (6) the cathode is covered with mono- or bi-molecular oxide film, which serves as an intermediate stage for the final reduction step to metal. The role of sulfate is to limit the thickness of the film through a competitive dissolution reaction and, thus, to allow the release of oxygen during the reduction.

The presence of mono- or bi-molecular oxide films is difficult to detect by conventional methods. Electron diffraction examination of conventional deposits (5) did not reveal the presence of any films, although an oxide-type film has been observed together with the chromium deposit in dilute solutions (33). This is not unexpected because dilute solutions are considerably less acid and, therefore, provide an environment more favorable for the formation of the amorphous oxide film.

In conventional plating solutions the visible amorphous oxide film disintegrates when the potential of chromium deposition is reached. Whether a thin invisible amorphous oxide film remains on the surface during chromium plating cannot be resolved on the basis of the microscopic observations. The fact that the initial deposition of chromium starts underneath the amorphous oxide film during electrolysis of 200:1 solutions (Fig. 4) is an evidence pointing out to the contrary.

Shluger and Kazakov (9) investigated dissolution processes at the cathode surface after cessation of the electrolysis by observing the edge of the electrode under the microscope in transmitted light. An attempt by these investigators to observe the cathode surface in the incident light during plating was not successful because of copious hydrogen evolution. These authors concluded that there is a colloidal film present at the cathode surface during chromium plating, the dissolution of which is observed when the current is switched off.

In the present investigation microscopic observations of the cathode surface in the incident light at the termination of the electrolysis did not permit the differentiation between the dissolution of a cathodic film and the dissipation of a concentration gradient. No evidence is therefore available that the viscous film that seems to form during the transition from the potential range (*iii*) to (*v*) is still present at the cathode surface at the end of the plating process. Its existence can be detected only when the cathode surface is partially covered with the fragments of the amorphous oxide film when at least part of the evolving hydrogen originates within or underneath the viscous film, thus revealing its presence.

Whether the viscous film observed in the present investigation is the same film reported by Shluger and Kazakov is not absolutely certain. It is reasonable to assume that it is the same film since both microscopic observations were made at similar low-range magnifications which are unlikely to reveal the existence of two entirely different types of macrofilms. The viscous nature of the film does not exclude a colloidal suspension resulting from the disintegration of the amorphous oxide film.

The unconventional characteristics of the viscous film may account for a number of unusual phenomena such as: (*a*) preferential reduction of higher rather than lower oxidation states of chromium to metal (34), (*b*) inability to discharge cations during chromium plating at adequately negative potentials (35), (c) favorable environment for the reduction of anions of other metals (36, 37), and (*d*) the variation of current efficiency with current density, temperature, and electrolyte composition (38).

Conclusions

It is concluded that the amorphous oxide film itself is not involved in the mechanism of chromium deposition at steady-state conditions despite the evidence that it can be reduced electrolytically to metal. Its formation is a consequence of side-reactions facilitated by higher *p*H and higher trivalent chromium concentration.

The deposition of chromium is associated with the formation of an entirely different type of film which is

transparent and viscous in contrast with the opaque and solid nature of the amorphous oxide film.

The formation of the viscous film, which occurs only in the presence of adequate sulfate concentration, inhibits the evolution of hydrogen and the progress of other reactions that contribute to the formation of the amorphous oxide film.

A Study of Some Primary Processes in Electropolymerization by Cyclic Voltammetry of Phenyl-Substituted Ethylenes

B. Lionel Funt and Derek G. Gray[1]

Department of Chemistry, Simon Fraser University, Vancouver, British Columbia, Canada

ABSTRACT

Tetraphenylethylene, triphenylethylene, stilbene, 1,1 diphenylethylene, and styrene were utilized as model compounds. Cyclic voltammetry in tetrahydrofuran, NBu_4ClO_4, showed that the radical anions of these compounds were protonated in this medium and are therefore stronger nucleophiles than polycyclic aromatic hydrocarbons for which similar protonation does not occur. The stability of the initial ionic species produced increased with the number of phenyl substituents in this series of substituted ethylenes. The cyclic voltammetric data was examined critically to determine the reversibility of the electron transfer steps, the number of electrons added per step, and the stability or lifetime of transient substances formed. Reaction mechanisms are proposed and the relevance of the findings to electropolymerization processes is indicated.

The passage of an electrolytic current through a nonaqueous organic solution can produce a wide variety of reduction products at the cathode. These may include radicals, radical anions, carbanions, and other related intermediates (1).

In our previous work, we had shown that in the presence of a suitable monomer, polymerization could take place (2). The rate of polymerization was, in

[1] Present address: Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

general, controlled by the magnitude of the current, and the molecular weight, in many instances, could be regulated in absolute value (3) and in distribution of molecular weight by the current programmed through the solution.

The local environment, in terms of type of solvent and supporting electrolyte, can be chosen to determine a mechanism by which the polymerization will occur. Thus it is possible to conduct free radical, anionic and cationic (4) reactions induced electrolytically.

The technique of electropolymerization has many novel and interesting possibilities. It can provide a degree of control over the rate of the reaction which is not possible in thermally conducted or chemically initiated polymerization. The reaction can also be stopped readily or caused to proceed over a program of different rates as a function of time.

The purpose of this study is to elucidate the nature of the intermediates and their roles in polymerization reactions. Our primary interest was in the polymerization mechanism rather than in the electrode mechanism, and the focus of attention was on the chemical processes and their interrelationships rather than on the theory of electrode reactions.

The phenyl-substituted ethylenes provide a particularly interesting group of model compounds. One of the members of the series, styrene, is a very important and well-characterized monomer. Another member, stilbene, will copolymerize but not homopolymerize, while others, such as tetraphenylethylene, will not undergo polymerization in conventional systems due to steric hindrance (5-7).

Cyclic voltammetry was employed as these systems are particularly sensitive to trace proton donor impurities and an upper limit of 10^{-4}M, may be placed on the impurity level if "living" polymerization is to occur. Cyclic voltammetry between stationary platinum electrodes can be adapted for work under such conditions in vacuum systems.

Experimental

The experimental conditions employed have been reported previously (8).

All solvent transfers and electrolytic measurements were conducted under high-vacuum conditions. The planar working electrode was 0.07 cm^2 platinum wire sealed in glass, and a platinum disk served as counter-electrode.

A silver wire sheathed in a glass capillary proved adequate as a reference electrode (9). Tetrahydrofuran was the solvent, and tetra-n-butyl ammonium perchlorate was the supporting electrolyte.

Cyclic voltammograms were obtained by feeding a signal from a function generator through a potentiostat to the electrolysis cell and recording the output on an x-y recorder.

The effects of uncompensated iR resistance on the values of the peak potential were corrected by extrapolating to zero current. The deviation from strict linearity will be significant in any rigorous quantitative analysis of the data but has little importance in the mechanistic interpretation and comparisons which are our prime concern. The characteristics of the species produced on the cathodic scan were investigated using a more rapid reverse anodic scan. This technique has been shown to give anodic diffusion currents proportional to the surface concentration of the cathodic products (10).

Results

Some details of the cyclic voltammetry of phenyl-substituted ethylenes are presented in Table I.

Tetraphenylethylene.—Cyclic voltammograms for tetraphenylethylene at a series of scan rates are shown in Fig. 1. The most striking feature was a large anodic peak which indicated that the reduction product was relatively stable in solution. The cathodic peak height

** Scan rate, 0.15 V/sec.
† A value for $\Delta E_p/\Delta i_p$ of 20 ± 3 μA/mV is ascribed to uncompensated ohmic resistance for the solution and cell geometry used here and previously (8). Larger values are related qualitatively to irreversible charge transfers or subsequent chemical reactions.
‡ Apparent number of electrons in re-oxidation step. Determined by relative peak-height increase with scan rate.

was almost twice that obtained under identical conditions for the first reduction step of *trans*-stilbene [a known one electron reversible process (6)] and the peak height was sharper than that for *trans*-stilbene. The separation of cathodic and anodic peak potentials extrapolated to zero current was found to be 60 ± 4 mV. However, for a reversible two-electron transfer reaction, the peak height should be $2^{3/2}$ that for a single-electron transfer, and the peak separation should be 30 mV. Thus the process cannot be interpreted as a simple two-electron transfer. However, the discrepancy may be resolved by considering multi-step charge transfers. The experimental results obtained here coincide with those predicted for substances undergoing two successive reversible electron transfers at potentials separated by less than 0.1V. (11). Thus the reduction process may be written

$$(Ph)_2C=C(Ph)_2 + e = (Ph)_2C=\dot{C}(Ph)_2$$

$$(Ph)_2C=\dot{C}(Ph)_2 + e = (Ph)_2C=C(Ph)_2^{=}$$

Neither the radical anion nor the dianion appears to be protonated to any appreciable extent in the time interval between electron transfers. Thus this reaction differed from most two-electron reductions of aromatic hydrocarbons. Nevertheless, the appearance of the reverse peak on the cyclic voltammogram enables this unusual mechanism to be assigned with a high degree of confidence.

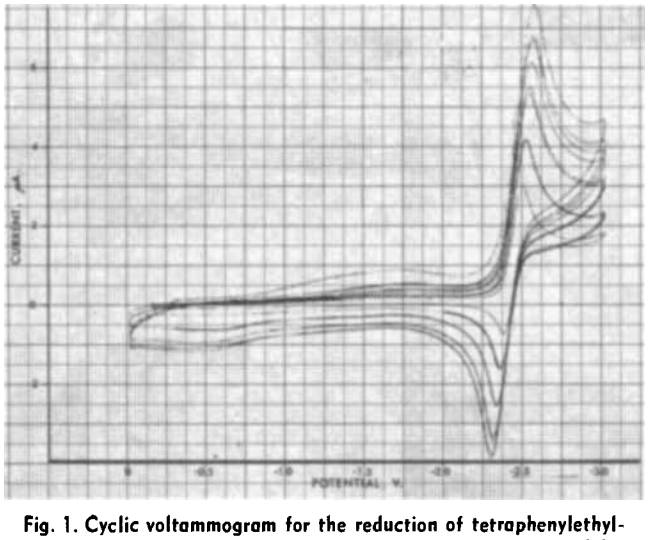

Fig. 1. Cyclic voltammogram for the reduction of tetraphenylethylene, 0.9 mM, in 0.1M $N(Bu)_4ClO_4$-THF solution. Scan rates: 0.06, 0.15, 0.30, 0.48, 0.60 V/sec.

Triphenylethylene.—The voltammetric peak height for triphenylethylene was also found to be about twice that expected for a one-electron transfer. However, no anodic peak was evident on the reverse scan and the peak was narrower and sharper than that found for reversible transfers. The results are shown in Fig. 2. The rate of potential shift with increasing current indicated an irreversible electrode process or a subsequent chemical reaction of the initial electrochemical product Two reaction paths appear plausible

$$(Ph)_2C = CHPh + e \rightarrow (Ph)_2C = CCHPh^{\cdot-} \quad [Ia]$$

$$(Ph)_2C = CCHPh^{\cdot-} + H^+ \rightarrow (Ph)_2\dot{C} - CH_2Ph \quad [Ib]$$

$$(Ph)_2\dot{C} - CH_2Ph + e \rightarrow (Ph)_2\underline{\underline{C}} - CH_2Ph \quad [Ic]$$

or

$$(Ph)_2C = CHPh + e \rightarrow (Ph)_2C = CHPh^{\cdot-} \quad [IIa]$$

$$(Ph)_2C = CHPh^{\cdot-} + e \rightarrow (Ph)_2C = CHPh^{=} \quad [IIb]$$

$$(Ph)_2C = CHPh^{=} + H^+ \rightarrow Ph_2\underline{\underline{C}} - CH_2Ph \quad [IIc]$$

The first mechanism was proposed by Hoijtink (12) for the reduction of aromatic hydrocarbon in the presence of proton donors. This author showed the molecular orbital theory predicted that the radical formed by protonation of the radical anion (reaction [Ib]) was reduced (reaction [Ic]) at lower potentials than that for initial electron transfers (Eq. [Ia]). However, this mechanism would require fast protonation of the triphenylethylene radical anion even when the only proton source in solution was the tetrabutylammonium salt. In view of the results obtained with the stilbene radical ion under identical conditions, it seemed unlikely that such reactions could occur.

The second reaction path is more likely. A second electron is transferred to the radical ion (Eq. [IIb]) at a potential close to that for the first transfer. The dianion formed is sufficiently basic to abstract a proton from a salt anion and produce a carbanion. The narrowness of the peak measured by the difference between the peak and half-peak potentials also supports a mechanism requiring two-electron reduction prior to protonation.

An attempt was made to detect the carbanion which both reaction mechanisms predicted as product. For this, the asymmetric scan technique was employed. The anodic peaks formed on varying the reverse potential scan rate was rather misshapen and indicated an irreversible reaction. However, by comparing the change of peak height with square root of scan rate for the forward and reverse reactions, the rate of peak increase for the reverse reaction was found to be about half that for the forward reaction

$$(Ph)_2\underline{\underline{C}} - CH_2Ph \xrightarrow{-e} (Ph)_2\dot{C} - CH_2Ph$$

Thus, two electrons were required for the reduction and only one for the oxidation The irreversibility of the oxidation reaction is due to the high reactivity of the free radicals formed. Unlike an anion radical, this intermediate is uncharged and therefore electrostatic repulsion does not hinder dimerization or disproportionation.

The carbanion oxidation mechanism may be assigned to the anionic peak for triphenylethylene on the basis of molecular orbital considerations (12).

Although the oxidation of carbanions derived from polycyclic aromatic hydrocarbons has been reported (13), we believe that experimental evidence for electrolytic oxidation of an ethylenic hydrocarbanion has not been found previously.

Trans-Stilbene.—This compound has been studied intensively by a number of workers who employed conventional polarography in dimethylformamide and found that *trans*-stilbene exhibited the behavior typical of polycyclic aromatic compounds (6, 14).

The cyclic voltammogram (Fig. 2) showed that the reduction occurred in two stages. If the potential scan was limited to 2.8V, the anodic and cathodic peaks were found to be of equal height and the other parameters also indicate clearly that a single reversible one electron reduction occurred. One can thus conclude that the radical ion of *trans*-stilbene is stable under these conditions

$$PhHC = CHPh + e \rightarrow PhHC = CHPh^{\cdot-}$$

The subsequent reduction at more cathodic potentials was also a single-electron transfer

$$PhHC = CHPh^{\cdot-} + e \rightarrow PhHC = CHPh^{=}$$

The absence of a corresponding anodic peak on reversing the scan indicated that the dianion had undergone further reaction. In this case, protonation by the salt cation was probable

$$PhCH = CHPh^{=} + H^+ \rightarrow PhC\underline{\underline{H}} - CH_2Ph$$

It should be noted that the product was again found to be a carbanion and an oxidation peak was formed at the potential expected.

In this case, the rate of growth of the peak height with scan rate was less than that expected for a one-electron transfer, and this may be due to further proton abstraction by the carbanion, thus reducing the amount available for oxidation on the reverse scan. Asymmetric scan data could not be employed successfully in this instance because of a small unexplained peak at −1.6V.

1,1 Diphenylethylene.—For this substance, a two-electron irreversible reduction was found. However, the peak was much broader than that found with triphenylethylene, and therefore a different mechanism is indicated. If one assumes that a radical anion is formed initially, then the absence of a phenyl substituent on one of the olefinic carbon atoms would be expected to decrease the steric hindrance toward proton abstraction from the salt cation. In this case, Hoijtink's mechanism would be expected

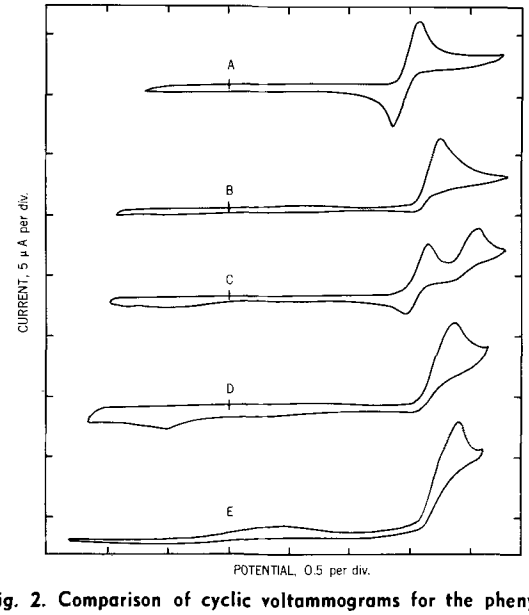

Fig. 2. Comparison of cyclic voltammograms for the phenyl-substituted ethylenes. A, Tetraphenylethylene (0.90 mM); B, triphenylethylene (0.87 mM); C, *trans*-stilbene (1.16 mM); D, 1,1 diphenylethylene (0.87 mM); E, styrene (1.44 mM). All voltammograms were obtained under similar conditions in 0.1M $N(Bu)_4ClO_4$-THF with a scan rate of 0.15 V/sec.

$$(Ph)_2C = CH_2 + e \rightarrow (Ph)_2C = \dot{C}H_2^-$$

$$(Ph)_2C = CH_2^- + H^+ \rightarrow (Ph)_2\dot{C} - CH_3$$

$$(Ph)_2\dot{C} - CH_3 + e \xrightarrow{\text{fast}} (Ph)_2\ddot{C} - CH_3^-$$

The carbanion formed was oxidized at 0.5V on the reverse scan. The asymmetric scan technique showed that the anodic peak increased at half the rate of the cathodic peak. This indicates a one-electron transfer oxidation

$$(Ph)_2\ddot{C} - CH_3^- - e \rightarrow (Ph)_2\dot{C} - CH_3$$

Unlike the corresponding stilbene carbanion, there was thus no evidence of protonation of the 1,1 diphenylethylene carbanion, presumably due to the steric effect of the two phenyl substituents at the nucleophilic site.

Styrene.—Cyclic voltammograms for styrene resemble those for 1,1 diphenylethylene except that the peak due to anodic oxidation of the carbanion was very much smaller than expected for the one-electron transfer. This behavior is consistent with the diminished steric hindrance in the styrene carbanion compared with the 1,1 diphenylethylene carbanion. Thus, the second protonation step may occur before electrolytic oxidation can take place

$$PhHC = CH_2 + e \rightleftharpoons PhHC = \dot{C}H_2^-$$

$$PhHC = CH_2^- + H^+ \rightarrow PhHC - CH_3$$

$$PhHC - CH_3 + e \rightarrow PhHC - CH_3^-$$

$$PhHC - CH_3^- + H^+ \rightarrow PhH_2C - CH_3$$

$$PhHC - CH_3 - e \rightarrow PhHC - CH_3$$

A comparison of the voltammograms of the phenyl-substituted ethylenes under similar conditions in 0.1M tetrabutylammonium perchlorate in tetrahydrofuran at a scan rate of 0.145 V/sec is shown in Fig. 2.

Discussion

A summary of the relative stabilities of the various species which we have assigned on the basis of interpretation of the numerical data and the cyclic voltammograms is shown in Table II.

The results for the phenyl-substituted ethylenes show that as expected from chemical considerations, the stability of the anionic species produced by electrolytic reduction increases with the number of phenyl substituents. This is clearly illustrated in Table I.

Cyclic voltammetry thus indicates the nature of electron transfer reactions with very little ambiguity and also permits the investigation of the carbanion electro-oxidation.

The data with 1,1 diphenylethylene are of particular interest. This compound was used as a model substance in the elegant pioneering studies on anionic polymerization conducted by Szwarc and his coworkers (15, 16). Using stop-flow techniques they found a very high rate of combination of the radical anions with a rate constant of 1-2 x 10^6 1 · $mole^{-1}$ sec^{-1}.

Table II. Summary of the relative stabilities of the anionic species derived from phenyl-substituted ethylenes under voltammetric conditions

Compound	Dianion, $R^=$	Radical anion, R^-	Carbanion, RH^-
Tetraphenylethylene	Stable	—	—
Triphenylethylene	Protonated	—	Stable
Stilbene	Protonated	Stable	Protonated
1,1-Diphenylethylene	—	Protonated	Stable
Styrene	—	Protonated	Protonated

Although the mechanism we propose involves proton abstraction rather than radical combination, this is not at variance with Szwarc's quantitative results. The concentration of the living anions in the reaction mixture is extremely low, while the concentration of tetrabutylammonium ions is relatively high. The latter are effective proton donors and cannot be used in systems in which a living anion concentration is maintained. The ratio of the concentrations of living ions to tetrabutylammonium ions must be at least a factor of 10^6, and thus protonation can be justified in competition with combination even on quantitative grounds.

The lifetime of the radical ions of 1,1 diphenylethylene has been claimed to be much longer by Evans and Evans (17), but the validity of their results have been questioned by Szwarc (16). These authors refute Szwarc's suggestion that the optical spectrum and the properties reported by them should be attributed to the benzophenone radical ion (17). Despite this, the dominant evidence in the literature favors Szwarc's quantitative results and mechanism.

The electrochemical data which we report for the diphenylethylene is based on the observation of a two-electron transfer. This observation is in keeping with a number of other investigations on phenyl-substituted ethenes. Studies by Wawzonek (6) and by Grodzka and Elving (7) indicate a single two-electron wave. However, the latter point out the difficulties in assigning an exact mechanism to the process.

A result of relevance to electropolymerization is that under the experimental conditions employed in voltammetry the ions of styrene and 1,1 diphenylethylene do not dimerize but undergo protonation and reduction. This indicates that the radical ions are more basic than those derived from polycyclic hydrocarbons, which undergo dimerization. It can be concluded that the tetrabutylammonium cations, which are the source of the protons, will be inefficient chain initiators in vinyl electropolymerization. This result also indicates clearly the importance of finding alternative electrolytes for electropolymerization studies. A number of suitable salt systems have been explored, but thus far those most suited for electropolymerization, for example sodiumtetraphenylboride, are not satisfactory for studies in cyclic voltammetry. Further exploratory work is required.

Thermodynamics of Liquid Copper-Silver Alloys by a Solid Electrolyte Cell

U. V. Choudary and A. Ghosh

Department of Metallurgical Engineering, Indian Institute of Technology, Kanpur, India

ABSTRACT

The reversible galvanic cell

$$\text{Cu(S), } Cu_2O\text{(S) // CaO-}ZrO_2\text{ // Cu-Ag(1), } Cu_2O\text{(S)}$$
electrolyte

was employed to determine the thermodynamic properties of liquid copper-silver alloys in the range of X_{Cu} from 0.1 to 0.8 and temperature from the liquidus to 1330°K. The activities of copper were found to be higher than the values reported by Hultgren *et al.* on the silver-rich side, whereas they agree well in the high-copper side. Values of F^E, obtained by extrapolation of the data of this study to 1400°K, agree well with those reported in literature. H^M, determined in this study, agree with the calorimetric results within the experimental uncertainty. Small values of S^E confirm the nearly regular behavior of the Cu-Ag system.

Thermodynamic properties of liquid copper-silver alloys have been determined in the past by employing three methods: calorimetry (1-3), vapor pressure measurements (4), and distribution equilibria (5). Phase diagram calculations have also been carried out (6). Hultgren *et al.* (6), in their thermodynamic compilation, have critically reviewed these studies and pointed out the need for more accurate determinations. Calorimetric measurements (2, 3) show mutual agreement. However, they do not, normally yield accurate values of activities. Direct activity measurements were done by Edwards and Downing (4) by the vapor pressure method. Their data contained large scatter and were also found to lead to some thermodynamic inconsistencies according to later analysis (6). The data of Koros and Chipman (5), obtained from measurements of distribution equilibria between liquid copper-silver and liquid iron-copper alloys were confined to a narrow range (0.01-0.12) of mole fraction of copper.

Therefore it was decided to make direct measurement of activities in this system and for this the solid electrolyte cell method was chosen. Various investigators (7-10) have demonstrated that emf measurements with the solid oxide electrolytes are capable of yielding results with good accuracy. In the present work, the cell was

$$\text{Cu(S), } Cu_2O\text{(S) // CaO-}ZrO_2\text{ // Cu-Ag alloy(1), } Cu_2O\text{(S)} \quad [I]$$
electrolyte

This type of cell has already been employed by some investigators (11-14) and is of the general type

$$\text{A, AO // Solid oxide // A-B alloy, AO} \quad [II]$$
electrolyte

Such cells yield values of activity of A in the alloy A-B directly from the cell emf's. In cell I, if $p_{O_2}{}^o$ and p_{O_2} are the partial pressures of oxygen on the left and right side of the cell respectively, then

$$E = \text{emf of the cell} = \frac{RT}{4F} \ln \frac{p_{O_2}}{p_{O_2}{}^o} \quad [1]$$

Again, 4 Cu(S or in alloy) + O_2(g) = 2 Cu_2O(S)
Therefore

$$K = \frac{a_{Cu_2O}{}^2}{a_{Cu}{}^4 \times p_{O_2}} \quad [2]$$

If Cu_2O is pure, then

$$p_{O_2} = \frac{1}{K \cdot a_{Cu}{}^4} \quad [3]$$

Taking the pure solid copper as the standard state and combining Eq. [1] and [3], we obtain

$$E = -\frac{RT}{F} \ln a_{Cu} \quad [4]$$

Other thermodynamic quantities also can be calculated, as shown later (Eq. [5]-[15]).

Accurate results can be obtained, provided the following conditions are satisfied. (*a*) The solid electrolyte is completely ionic in the range of p_{O_2} prevailing in the experiments. (*b*) The oxide of A is much more stable compared to the oxide of B. Moreover AO should be stoichiometric. (*c*) The solubilities of oxygen in A and in alloy A-B are small. (*d*) There are no side reactions, such as those between electrode and electrolyte, electrode and contact lead, and electrode and atmosphere to any significant extent.

The calcia-stabilized zirconia is a perfect ionic conductor (7-10) in the range of p_{O_2} prevailing during the experiments (greater than 10^{-10} atm). Cu_2O is much more stable compared to Ag_2O and exhibits little nonstoichiometry (15) in the range of temperature investigated. The Cu-O phase diagram (16) shows that the solubility of oxygen in solid copper in equilibrium with Cu_2O, below 1330°K, is negligibly small. Approximate calculations based on the model of Belton and Tankins (17), for the solubility of oxygen in binary alloys, reveal that liquid Cu-Ag alloys (X_{Cu} =

Key words: thermodynamics, copper, silver, solid electrolyte, emf.

0.15-0.9), when equilibrated with Cu_2O, dissolve oxygen to a maximum of 1 a/o (atom per cent) at 1300°K.

Experimental

Cell assembly.—Two types of cell, as shown schematically in Fig. 1a and b, were employed in the present work. In cell a, the electrolyte was a ⅜ in. I.D., ½ in. O.D., and 1 in. high crucible of 15 m/o (mole per cent) calcia-stabilized zirconia, obtained from the Zirconium Corporation of America. In cell b, laboratory-made crucibles from fully stabilized ZIRCOA-B powders, served as the electrolyte. The crucibles were slip-cast, presintered at 1200°C for one day, and finally sintered at 2000°C for 6 hr in a ZIRCOA pot furnace. The densities of the crucibles, after final sintering, varied between 5.5 and 5.9 g/cc. Thin copper foil was wrapped around the solid electrolyte crucible in the form of a close-fitting cup, and the annular gap was filled with Cu-Cu_2O mixture.

The furnace was globar-heated in order to avoid inductive emf's. The temperature was controlled by a Leeds & Northrup Electromax Signalling controller within ±1°C. The temperature of the cell was measured by a calibrated Pt-Pt/10% Rh thermocouple. The experiments were conducted under a flow of argon, purified by successively passing through a copper-gauze furnace, $CaCl_2$ and P_2O_5-towers, and finally through a magnesium-chip furnace. The emf's were measured by a Leeds & Northrup potentiometer with a sensitivity of 0.01 mV.

Calibration run.—Cell a was used in most of the runs. In order to make sure that there was no significant short-circuiting of the electrodes by gaseous transport via atmosphere and electronic conductivity in the electrolyte, a calibration run was taken with mixtures of Cu-Cu_2O and Ni-NiO as the two electrodes. Cu_2O and NiO powders were of Fisher Certified Reagent grade. Cu and Ni powders were obtained from Semi-Elements Inc. with a minimum purity of 99.9%.

The Cu-Cu_2O mixture was placed inside the electrolyte crucible, and contact was established by pressing a platinum disk, which was spot-welded to Pt and Pt/10% Rh wires, sheathed in a double-bore alumina tube. This served as lead as well as thermocouple. Platinum wire was wound round the electrolyte crucible and a moist paste of Ni-NiO was applied over it. The electrolyte crucible was contained in a recrystallized alumina crucible and Ni shot along with NiO powder were kept in the latter in order to provide a better environment.

The furnace chamber was first flushed with purified argon, evacuated at 150°C, and then was slowly heated to 900°C under flowing argon. Both the electrode mixtures were sintered *in situ*, establishing very good electrical contact. The duration of the run was one week and the temperature cycling was done two times in the range 1020°-1325°K. The measured emf was considered as steady, if it remained constant within ±0.2 mV for a minimum period of 6 hr. Moreover, the cell was left overnight and at times for one full day at arbitrarily selected temperatures. The emf's remained steady and the fluctuations never exceeded 0.5 mV. Reversibility of the cell emf was checked by polarization tests and by varying the gas flow rate. Table I compares or data with the most precise values available elsewhere (9, 18) and the agreement is excellent. Cell b was tested against cell a by measurements at the same compositions ($X_{Cu} = 0.5$). The emf's in these two arrangements agreed well (±1 mV).

Selection of contact lead for liquid alloy.—Dissolution of the lead by the liquid alloy is a problem in this kind of study. There are two ways to tackle it. First, one can use a lead which dissolves to a negligible extent and hence can be dipped continuously. Diaz and Richardson (19) immersed a chromium-alumina cermet continuously in liquid copper at 1100°C with success. If the lead material tends to be dissolved faster, it is immersed for a short time only, during the time of measurement of emf. Inconel, cermet, and Cu_2O were tried as leads. While the Inconel was dipped into the alloy during measurements only, the other two materials were kept immersed continuously. The cermets were hung by platinum wires, whereas Cu_2O was sintered on platinum wire for strength. Although all the above leads were found to be quite satisfactory during trials, the cermet was chosen because it gave the smallest scatter. Therefore most of the runs reported here have been taken with cermet-cermet combination, as shown in Fig. 1. The cermet was the same as that used by Diaz and Richardson (19).

Table I. Temperature dependence of emf for the calibration cell: Ni, NiO/CaO-ZrO_2/Cu, Cu_2O

	Temperature, °K	1020	1116	1150	1200	1273	1323

* Calculated values from temperature-emf relations of the investigators.

Emf measurements on copper-silver alloys.—The master alloys of Cu and Ag were prepared by melting the required amounts of copper (Semi-Elements Inc., U.S.A., purity 99.97%) and silver (American Smelting and Refining Co., U.S.A., purity 99.99%) shot either in an evacuated and sealed quartz tube or in a one-end open quartz tube under a stream of purified argon. The weight of each master alloy ranged between 7 and 10g. The alloys were taken in the recrystallized alumina crucible (cell a, Fig. 1) or in electrolyte crucible (cell b, Fig. 1) along with 1 to 2g of Cu_2O. The furnace chamber was first evacuated with the cell assembly in position, filled with purified argon, and then slowly heated to 1000°C. At this temperature, the cell attained a steady emf in less than 2 hr. Emf's were recorded at intervals of 30 min, and if the variation

was within ±0.1 mV in a period of 2 hr the emf's were considered to be steady. A minimum of 4 hr was allowed before a temperature change was effected. Each experiment was subjected to the tests for reversibility and reproducibility just as the calibration run. Even after heavy polarization (1 mamp for 3 min), usually a maximum of 30 min were enough for re-attainment of steady emf's. Additions of Cu or Ag in the form of small shot were made at 1050°C. Immediate changes in emf's were observed and steady emf's were attained in about 2 hr.

Chemical analysis of the alloys was not made. In order to be certain of the accuracy of compositions during the experiments, a few times the same compositions were obtained either from the master alloys directly or by additions. Emf's by these two procedures differed by less than 1 mV. This observation, coupled with the facts that the temperature cycling yielded reproducible emf's and that the emf *vs.* temperature plots were straight lines with standard deviations of less than 1 mV in all the experiments, pointed out that negligible compositional changes took place during the experiments either through evaporation of Ag or in any other manner.

Results

The measurements were confined in the range of X_{Cu} from 0.1 to 0.8 and in the temperature range $T_{liquidus}$ to 1330°K. A few measurements were made below the liquidus and above 1330°K. Figure 2 shows the least-square lines for the emf *vs.* temperature relation at each composition. Table II presents the results analytically along with the standard deviations and maximum deviations. The emf's could also be extrapolated to 1400°K, after correcting for dE/dT at the melting point of copper (1356°K). The cell emf's gave partial quantities for copper directly with solid copper as the standard state. Liquid copper was employed as the standard state, by making appropriate corrections for fusion values of copper, as noted below.

$$F^{M}_{Cu} = -EF - \Delta F_{fusion} = RT \ln a_{Cu} \quad [5]$$

$$S^{M}_{Cu} = F\frac{dE}{dT} - \Delta S_{fusion} \quad [6]$$

$$H^{M}_{Cu} = F^{M}_{Cu} + T S^{M}_{Cu} \quad [7]$$

where F^{M}_{Cu}, S^{M}_{Cu}, H^{M}_{Cu} are free-energy, entropy, and

heat of mixing of copper with liquid copper as the standard state.

The partial thermodynamic quantities for silver were determined using the following equations

$$\log a_{Ag} = \log X_{Ag} - X_{Ag}X_{Cu}\alpha_{Cu} + \int_{o}^{X_{Cu}} \alpha_{Cu} \cdot dx_{Cu} \quad [8]$$

$$F^{M}_{Ag} = 4.576\ T \log a_{Ag} \quad [9]$$

$$H^{M}_{Ag} = -X_{Ag}X_{Cu}\beta_{Cu} + \int_{o}^{X_{Cu}} \beta_{Cu} \cdot dx \quad [10]$$

$$S^{M}_{Ag} = (H^{M}_{Ag} - F^{M}_{Ag})/T \quad [11]$$

where

$$\alpha_{Cu} = \frac{\log \gamma_{Cu}}{(1 - X_{Cu})^2} \quad [12]$$

$$\beta_{Cu} = \frac{H^{M}_{Cu}}{(1 - X_{Cu})^2} \quad [13]$$

The integrals in Eq. [8] and [10] have been evaluated graphically from Fig. 3 and 4. From these partial values, integral and excess properties for Cu-Ag system were calculated. For the latter, the equations employed are noted below.

$$F^{E} = (1 - X_{Cu}) \int_{o}^{X_{Cu}} \alpha_{Cu} \cdot dx_{Cu} \quad [14]$$

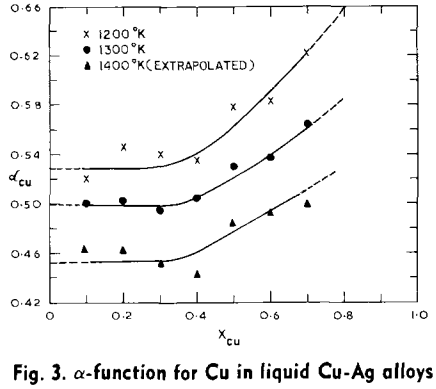

Fig. 3. α-function for Cu in liquid Cu-Ag alloys

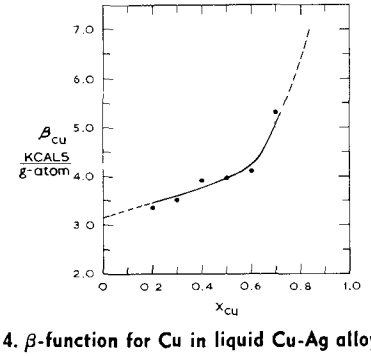

Fig. 4. β-function for Cu in liquid Cu-Ag alloys

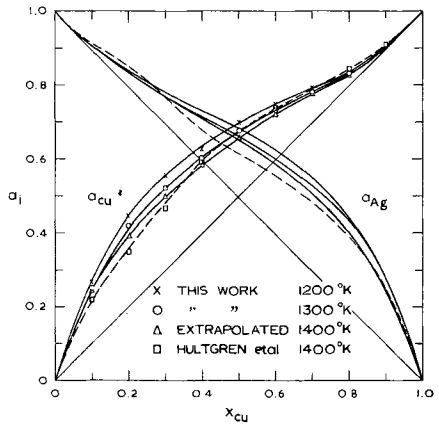

Fig. 5. Activity plots in liquid Cu-Ag alloys

$$H^E = (1 - X_{Cu}) \int_0^{X_{Cu}} \beta_{Cu} \cdot dx_{Cu} \qquad [15]$$

where the superscript E denotes excess property.

Discussion

Hultgren *et al.* (6) give a value of 0.96 ± 0.005 for the activity of copper at the eutectic temperature (1052°K). Emf data in this study at $X_{Cu} = 0.4$ and 0.7, yielded activity values of 0.953 and 0.965, respectively. This agreement is considered to be excellent. At $X_{Cu} = 0.1$, the liquidus was found to be 13°C higher than that given in the phase diagram. Repetition with another master alloy of the same composition yielded reproducible results. At $X_{Cu} = 0.2$ and 0.3, considerable supercooling (greater than 20°C) was observed. Even prolonged equilibration (12 to 18 hr) and stirring of the bath resulted in the same emf's. The dissolved oxygen could be the cause for lowering of the liquidus.

The activities of Cu and Ag at 1200°, 1300°, and 1400°K (extrapolated) are presented in Fig. 5 along with the values reported by Hultgren *et al.* (6). The standard states for both are pure liquid metals. For determination of the activity of Ag, an extrapolated value of α_{Cu} was employed only for $X_{Cu} = 0.8$, since at this composition γ_{Cu} is close to unity and a little error (0.5%) in a_{Cu} can lead to a large uncertainty in α_{Cu}. The values at 1400°K are 10 to 15% higher on silver-rich side and 3 to 5% lower on high copper side, compared to those of Hultgren *et al.* (6).

As Table IV shows, H^M_{Cu} obtained from the intercepts of emf *vs.* temperature plots, increase with decreasing X_{Cu}, except at $X_{Cu} = 0.1$, where H^M_{Cu} is unusually low. The change in solubility of oxygen with temperature could be causing this discrepancy. Quantitative explanation could not be given in the absence of oxygen solubility data in these alloys. If Cu_2O will dissolve in the liquid alloy according to the reaction

$$Cu_2O(S) = 2\underline{Cu} + \underline{O} \qquad [16]$$

it can lead to an increase in X_{Cu} by a fraction of few hundredths, which is enough to decrease the slope of emf *vs.* temperature plot and hence decrease measured H^M_{Cu} considerably. This process is reversible with respect to temperature and hence temperature cycling will not reveal any irreproducibility. Approximate calculations on the basis of the model proposed by Belton and Tankins (17), for the solubility of oxygen in binary alloys, confirms that oxygen solubility is at least 1 a/o at 1300°K for silver-rich alloys ($X_{Cu} = 0.1$). However, the consequent inaccuracy in the activity of Cu at $X_{Cu} = 0.1$, resulting from this departure in actual slope, is estimated to be less than 3% at 1300°K. For $X_{Cu} = 0.2$, the dissociation of Cu_2O will not cause appreciable compositional changes (less than 0.005 in X_{Cu}). Moreover, emf values for the alloys ($X_{Cu} \geq 0.2$) are much less sensitive to slight compositional changes, and the shift in H^M_{Cu} will be well within the experimental uncertainty. Even if an approximate correction for oxygen solubility is made in a_{Cu}, the present values are higher than those reported by Hultgren *et al.* (6). The molar free energies of mixing (F^E) of this work are compared with those of Hultgren *et al.* (6) in Fig. 6 and the agreement is quite good.

In Fig. 4, the curve of β_{Cu} *vs.* X_{Cu} has been extrapolated from the middle ranges of composition toward the terminal regions. For the low-copper side the reason for this extrapolation will be obvious from the preceding discussion. On the high-copper side, the values of $(1 - X_{Cu})^2$ becomes small, making β_{Cu} very sensitive to any error in H^M_{Cu}. Therefore extrapola-

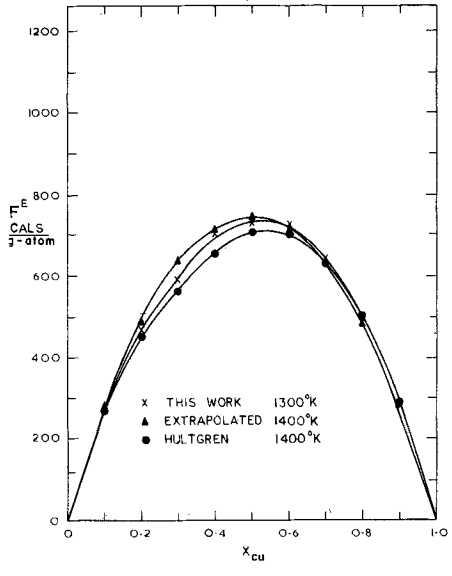

Fig. 6. Excess molar free energies of mixing in liquid Cu-Ag alloys.

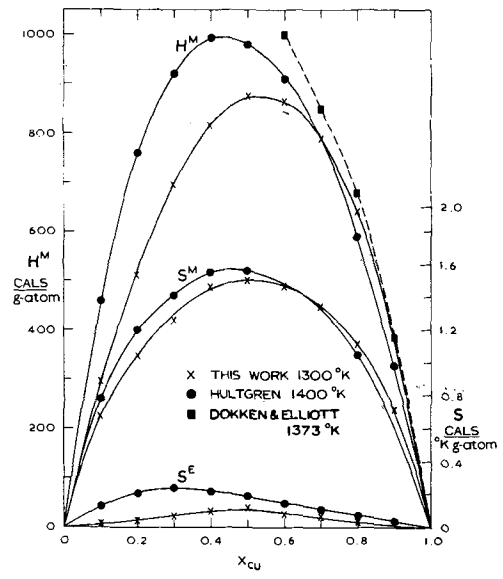

Fig. 7. Integral molar heats and entropies of mixing in liquid Cu-Ag alloys.

tion from the middle composition ranges was preferred. As Fig. 7 shows, the values for integral molar heats of mixing, H^M, agree well with the calorimetric determinations (2, 3) in the high-Cu range, whereas on the lower copper side, the values are somewhat lower. Considering the uncertainty of nearly 200 cal in H^M values of present work, the agreement is good.

Acknowledgments

The authors wish to thank Mr. P. J. Ray Chowdhury for his active help in the construction of apparatus and during experimentation; Mr. K. P. Jagannathan for his timely assistance in some of the runs. The authors are indebted to Mr. K. Thomas Jacob of Imperial College, London, for helpful discussions.

Supporting Electrolyte Effects in Electrochemistry: Copper and Mercury Acetylacetonates in Acetonitrile Solvent

J. N. Burnett,[1] L. K. Hiller, Jr.,[2,3] and Royce W. Murray*,[4]

Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina

ABSTRACT

The anodic mercury wave of acetylacetonate and the reduction of $Cu(acac)_2$ have been investigated in acetonitrile solvent. The electrochemistry of both species is substantially modified by the presence of lithium perchlorate in the tetraethylammonium perchlorate supporting electrolyte. The anodic mercury wave of acetylacetonate yields a stable mercury(II) acetylacetonate product in lithium-containing medium; the product complex undergoes rapid decomposition in the absence of lithium. A coordinative interaction of lithium ion with $Hg(acac)_2$ is postulated. The reduction of $Cu(acac)_2$ proceeds in a single two electron wave in Et_4NClO_4 electrolyte and in two single electron steps in $LiClO_4$-Et_4NClO_4 electrolyte. An interpretation resting on the instability of $Cu(acac)_2^-$ and the coordination of acetylacetonate by lithium ion, to give $Li_2(acac)^+$, is given to account for this behavior.

In acetonitrile solvent, the tetraalkylammonium enolate salt of 1,3-pentanedione (acetylacetonate, R_4N^+ $acac^-$) is, at most, weakly associated as an ion pair. When lithium or tetraalkylammonium acetylacetonate is dissolved in acetonitrile containing $LiClO_4$ electrolyte, the β-diketonate becomes coordinated in a stable dilithium complex, $Li_2(acac)^+$ (1). The cathodic electrochemistry of various metal acetylacetonates is sensitive to the presence of $LiClO_4$ electrolyte because of this lithium coordination. For instance, the one-electron reduction of *tris*(acetylacetonato)iron(III), $Fe(acac)_3$, in tetraethylammonium perchlorate electrolyte yields a stable $Fe(acac)_3^-$ complex. In lithium

perchlorate-tetraethylammonium perchlorate electrolyte, charge transfer is immediately followed by a poorly reversible abstraction of an acetylacetonate ligand by lithium ion to give $Fe(acac)_2$ and the dilithium complex (2). Investigation into the details of lithium electrolyte effects in acetonitrile has continued. Reported here are some further results on two electrochemical reactions: the anodic reaction at a mercury electrode in the presence of acetylacetonate and the reduction of *bis*(acetylacetonato)copper(II), $Cu(acac)_2$, at mercury.

Experimental

Acetonitrile solutions contained 0.1*M* tetraethylammonium perchlorate (Et_4NClO_4) as supporting electrolyte; various concentrations of lithium perchlorate were added to this. Acetylacetonate was added to lithium-containing solutions as Li(acac), forming $Li_2(acac)^+$, and to 0.1*M* Et_4NClO_4 solutions as the tetrabutylammonium salt, $Bu_4N^+acac^-$. The latter compound was prepared by a procedure provided by Posner *et al.* (3), in which acetylacetone is mixed with a solution of tetrabutylammonium hydroxide (Eastman) in methanol, the reaction mixture cooled, and ethyl acetate added to precipitate the white salt. This was recrystallized from methylene chloride, again using ethyl acetate to induce precipitation. All acetylacetonate solutions were used within a few hours of their preparation; solutions of $Li_2(acac)^+$ are quite stable, while those of Bu_4N^+ $acac^-$ give ultraviolet spectral indication of decomposition after about 10-12 hr. Standard $Cu(acac)_2$ solutions were prepared from J. T. Baker material recrystallized from benzene.

Working electrodes were either a DME or a hanging mercury drop electrode of the design of Shain *et al.* (4). Potentials reported are *vs.* an aqueous NaCl-SCE reference electrode isolated from the working electrode compartment with a Et_4NClO_4-acetonitrile salt bridge. Coulometry experiments on the anodic mercury wave of acetylacetonate were carried out with a micrometer thin layer cell (5) equipped with a mercury-coated platinum working electrode. The cell was calibrated by potential step coulometry of $Fe(acac)_3$ ($n = 1$) in 0.1*M* Et_4NClO_4-acetonitrile. A range of solution thicknesses were employed in both the calibration and thin layer determination of acetylacetonate n values. Instrumentation and other details are as cited earlier (2).

Results and Discussion

Anodic mercury wave of acetylacetonate.— Solutions of Bu_4N^+ $acac^-$ in Et_4NClO_4 electrolyte exhibit an anodic polarographic wave with $E_{1/2} = -0.242$V *vs.* SCE; those containing Li(acac) dissolved in $LiClO_4$-Et_4NClO_4 supporting electrolyte exhibit this wave at more positive, $[LiClO_4]$-dependent potentials (Table I). On Pt and Au electrodes, these solutions yield anodic waves at +0.3 and +0.9V, respectively. The anodic reactions on the solid electrodes are of demonstrably different properties and origin (6), however. The anodic reaction of acetylacetonate at mercury is assigned to an oxidation of mercury to yield a mercury acetylacetonate complex.

The anodic mercury wave of $Li_2(acac)^+$ [Li(acac) dissolved in $LiClO_4$-containing media] is considered first; various data are summarized in Table I. Polarographic ($i/h^{1/2}$), chronopotentiometric ($i\tau^{1/2}$), and potential sweep ($i_{p(a)}/v^{1/2}$) criteria establish diffusion control of the anodic reaction by $Li_2(acac)^+$. Stability of the mercury-containing anodic product, and its nonadsorption, is demonstrated by accord of cyclic voltammetric $i_{p(a)}/i_{p(c)}$, chronopotentiometric τ_f/τ_b, and thin layer coulometric Q_{anod}/Q_{cath} ratios with diffusion-only expectations.

The anodic mercury acetylacetonate product is anticipated to represent a mercury(II) species; mercury(I) acetylacetonates are unknown. The following results bear on the stoichiometry of the mercury(II)

Table I. Characteristics of the anodic mercury wave of Li(acac) dissolved in $LiClO_4$-0.1*M* Et_4NClO_4-acetonitrile solvent (dilithium acetylacetonate)

complex: Potential step thin layer coulometry gives a result of 0.83 electrons/acac. This result, n near unity, indicates a $Hg(acac)_2$ product, with perhaps some higher coordination, such as $Hg(acac)_3^-$, occurring as well. Proximity of the polarographic I_d constant, 2.69, with those of known one-electron metal acetylacetonate reactions in acetonitrile [I_d = 3.18, $Fe(acac)_3$; I_d = 3.06, $Co(acac)_3$ (2); I_d = 3.2, first wave of $Cu(acac)_2$, see below] is consistent with this observation. Verification of the 1:2 stoichiometry is provided by an amperometric (polarographic) titration of 0.5 m*M* $Hg(ClO_4)_2$ with a $Li_2(acac)^+$ solution [Li(acac) dissolved in 0.1*M* $LiClO_4$]. The initial mercury(II) wave is linearly attenuated (to zero current) and replaced with the more cathodic reduction wave of coordinated mercury(II) (rising to a maximum current), with an end point corresponding to a 1(Hg)/2(acac) mole ratio. An excess of acetylacetonate initiates precipitation of the fairly insoluble mercury complex and appearance of the anodic $Li_2(acac)^+$ wave. A polarogram of the "end point" solution (which contains 16 m*M* $LiClO_4$) shows that the cathodic $Hg(acac)_2$ wave has $E_{1/2} = +0.22$V, the same potential as that of the anodic $Li_2(acac)^+$ mercury wave at this $[LiClO_4]$ (Table I). The cathodic-anodic couple in a cyclic voltammogram of the $Hg(acac)_2$ solution exhibits a similar correspondence to one observed for a solution of $Li_2(acac)^+$.

The most interesting feature of the anodic $Li_2(acac)^+$ mercury wave is revealed by examination of the dependency of its $E_{1/2}$ on the concentration of dissociated lithium ion (to which $[LiClO_4]$ is nearly proportional, Table I). This examination, strictly speaking, can be semiquantitative only, owing to the imperfect reversibility of the reaction: $\Delta E_{peak} > 30$ mV. In solutions containing sufficient excess lithium ion that $[LiClO_4]_{x=0} \approx$ constant and that most of the acetylacetonate exists as the dilithium complex [>80% as $Li_2(acac)^+$ for $[LiClO_4] > 10$ mM, (1)], a plot of $E_{1/2}$ *vs.* log $[Li^+]_{free}$ should be linear with slope 0.059 m/n, where $n = 2$ and m is the number of lithium ions released by the anodic process. If two $Li_2(acac)^+$ reactants combine with mercury to give as product simply $Hg(acac)_2$, a slope of 118 mV is anticipated. The actual 58 mV slope of the linear plot of experimental results (of which those in Table I are a sampling of about one-third of those available) is

quite divergent from this simple expectation, and indicates retention of two lithium ions in the mercury(II) acetylacetonate product complex

$$2Li_2(acac)^+ + Hg \rightarrow Li_2Hg(acac)_2^{2+} + 2Li^+ + 2e \quad [1]$$

Accepting the result of the $E_{1/2}$ — $\log[Li^+]_{free}$ analysis as proof of mixed coordination of acetylacetonate to mercury(II) and lithium ion admittedly, owing to the reversibility factor, requires some caution. Two additional factors serve to add plausibility to a process such as reaction [1]. The first centers on previous chemical evidence. Among the metal β-diketonates, mercury(II) complexes apear to be unique in that the diketonate ligand bonds to the metal as an enolate (unidentate) ligand (as opposed to the usual cyclic geometry). Hammond and Nonhebel (7, 8) have shown this from arguments based on infrared and ultraviolet spectra and solubility and chemical reactivity (benzoylation) data. One oxygen site on an acetylacetonate ligand bound to mercury(II) is thus free for association with another metal ion. The acetylacetonate ligand is known, through demonstration (1) of the existence of $Li_2(acac)^+$, to be capable of bonding in an open chain form each of its oxygens to a metal ion. Postulation of a lithium ion $Hg(acac)_2$ association is, against this background of previous evidence, chemically reasonable.

The second argument centers on the behavior of the anodic reaction of $Bu_4N^+acac^-$ in 0.1*M* Et_4NClO_4 (lithium absent). The anodic acetylacetonate mercury wave in this medium has a polarographic $I_d = 4.00$, $E_{1/2} = -0.242$V, and is diffusion controlled in the polarographic experiment. The product of this anodic reaction, in contrast to that found in the presence of lithium ion, is quite unstable; cyclic voltammetric $i_{p(a)}/i_{p(c)} > 1$ and chronopotentiometric $\tau_f/\tau_b > 3$ ratios (poorly reproducible) both indicate extensive decomposition. Anodic thin layer charge-time curves exhibit only a poor inflection at an $n_{acac} = 1$ charge, and substantial further charge accumulation (exceeding edge diffusion and background values) occurs on prolonged electrolysis ($n = 14$ after ~15 min). Evidently the decomposition slowly leads to further oxidizable materials. Surface effects of the anodic product(s) are indicated by polarographic electrocapillary observations. The details of the decomposition reaction(s) of the mercury(II) acetylacetonate anodic product are unknown. It is quite clear, however, that the absence of such decomposition in solutions containing lithium ion provides additional circumstantial evidence for a coordinative interaction of lithium ion with $Hg(acac)_2$ such as that of reaction [1].

Reduction of $Cu(acac)_2$ *in acetonitrile.*—Several polarographic studies of $Cu(acac)_2$ in aqueous solvent and in aqueous mixtures with ethanol, methoxymethanol, dioxane, and methyl cellosolve (9, 12) have described a single, two-electron reduction wave. In a 50% aqueous-50% pyridine solvent mixture, on the other hand, Calvin and Bailes (13) report that $Cu(acac)_2$, and other copper(II) β-diketonates, are reduced in two one-electron waves, the second polarographic wave exhibiting the same reduction potential found for Cu(I) in this medium in the absence of acetylacetonate. The reduction pattern in Calvin and Bailes' solvent is interpretable as resulting from a combination of the greatly lessened stability of copper(I) β-diketonate in the presence of pyridine [its post-electron transfer decomposition shifting the potential of the Cu(II)/Cu(I) couple to more positive values], with the stabilization of the "free" copper(I) state by pyridine solvation (shifting the $E_{1/2}$ of the Cu(I)/Cu(0) reaction to more negative values), the combination removing the overlap between the potentials of the two couples.

The polarographic reduction of $Cu(acac)_2$ in acetonitrile solvent can proceed by either the one two-electron or the two one-electron wave pattern, depending on the supporting electrolyte employed. Independently, Hiller (2, 14) and Leddy (15) showed that the former pattern results when using Et_4NClO_4 electrolyte and the latter occurs with a $LiClO_4$ or a $LiClO_4$-Et_4NClO_4 electrolyte, and ascribed this effect to the coordination of acetylacetonate by lithium ion. To clarify the mechanistic details of this effect, the $Cu(acac)_2$ reduction has been examined further by polarographic, cyclic voltammetric, and chronopotentiometric experiments in these media.

Figure 1 shows polarograms of $Cu(acac)_2$ in acetonitrile containing Et_4NClO_4 and $LiClO_4$-Et_4NClO_4 supporting electrolytes. The single, diffusion-controlled ($i_d/h^{1/2}$ constant) wave in Et_4NClO_4 electrolyte is of two electron height ($I_d = 7.10$) and has the asymmetrical shape and $[Cu(acac)_2]$-dependent reduction potential [$E_{1/2} = -0.58$, -0.62V for 0.10, 0.50 m*M* $Cu(acac)_2$, respectively] expected for an electrode reaction involving three diffusing products [two $acac^-$ and one Cu^o (Hg)]. The polarographic wave is irreversible; an E *vs.* log $[(i_d - i)/i^3]$ plot is curved and of average slope ~130 mV. Addition of $LiClO_4$ to the Et_4NClO_4 supporting electrolyte splits this wave and causes a pronounced positive potential shift until, at >1:1 ratio of $[LiClO_4]/[Cu(acac)_2]$, two clearly defined reduction waves are evident. Both waves are diffusion-controlled and are approximately equal in height ($I_d = 3.2$, 3.5). In this medium the reduction clearly is resolved into its Cu(II)/Cu(I) and Cu(I)/Cu(0) steps. Increasing $[LiClO_4]$ shifts the $E_{1/2}$ of the first wave to continually more positive values, but the $E_{1/2}$ of the second wave is independent of lithium concentration for $[LiClO_4]/[Cu(acac)_2] > \simeq 4$. The $E_{1/2}$ of the second, nearly reversible, wave, -0.34V *vs.* SCE, is coincident with that reported for the reduction of "free" copper(I) in acetonitrile solvent (16).

These polarographic results can be interpreted in terms of the following reactions

$$Cu(acac)_2 + e^- \rightarrow Cu(acac)_2^- \quad [2]$$

$$Cu(acac)_2^- \rightleftarrows Cu^+ + 2(acac^-) \quad [3]$$

$$2(acac^-) + 4Li^+ \rightleftarrows 2Li_2(acac)^+ \quad [4]$$

$$Cu^+ + e^- \xrightarrow{-0.34} Cu^o(Hg) \quad [5]$$

Pertinent to this interpretation, which is analogous to that for Calvin and Bailes' experiment (13), is the literature observation (17) that the *mono*-acetylacetonate of copper(I) is quite unstable. The copper(I) *bis*-acetylacetonate resulting from the first charge transfer step (reaction [2]) is presumed to be also unstable and to undergo dissociation (reaction [3]) to the stable, "free" (acetonitrile-solvated) copper(I) ion.

In the Et_4NClO_4 electrolyte, the potential for the reduction reaction [2] remains, in spite of the following chemical process [3], more cathodic than that for the second charge transfer step reaction [5]. In this medium, then, the reaction sequence [2, 3, 5] occurs in a single, two-electron polarographic wave.

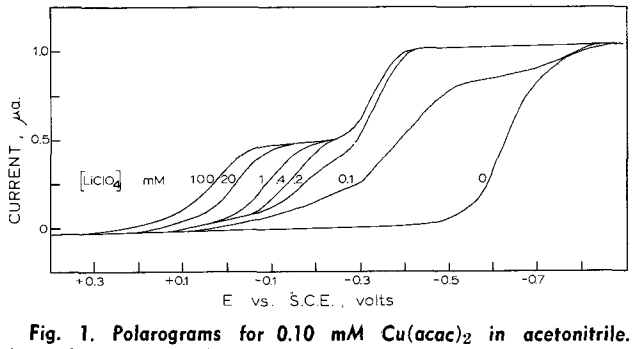

Fig. 1. Polarograms for 0.10 mM $Cu(acac)_2$ in acetonitrile. $[Et_4NClO_4] = 0.10M$, $[LiClO_4]$ indicated on figure.

In the presence of lithium ion (*i.e.*, in the $LiClO_4$-Et_4NClO_4 electrolyte), the dissociation reaction [3] is followed by lithium coordination to acetylacetonate (reaction [4]). This event can influence the potential at which the reaction sequence [2, 3] occurs only if the dissociation reaction [3], while lying far to the right, is nevertheless not chemically irreversible, or alternatively, if the lithium ion participates as a reactant in the dissociation process. Apparently one of these circumstances (it is thought to be the former) is the case, since the potential for reaction [2] is strongly dependent on the lithium ion concentration and can be shifted to a value less cathodic than that for the reduction of Cu^+ ion. Two one-electron polarographic waves result: reactions [2, 3, 4] and reaction [5].

The result of a cyclic voltammetric experiment in the $LiClO_4$-Et_4NClO_4 electrolyte is shown in Fig. 2. The two cathodic waves observed on the first potential sweep correspond to the polarographic steps observed at the same [$LiClO_4$]. The second of these, at −0.34V, exhibits an anodic partner, is nearly reversible electrochemically (ΔE_{peak} = 70 mV), and is completely reversible chemically ($i_{p(a)}/i_{p(c)}$ = 1.00), which is consistent with expectations (16) for reaction [5]. The first cathodic wave shows no reverse peak at any sweep rate examined (0.05-5.0 V/sec), which is consistent with the decidedly drawn-out polarographic shape of this wave. The reverse rate of reaction [3] and/or [4] must be quite slow. The residual $Li_2(acac)^+$ in the diffusion layer thus generates, on continuing positive potential sweeping, an anodic mercury wave with potential (E_{peak} = +0.28V) and reverse cathodic wave ($i_{p(c)}/i_{p(a)}$ = 1.0) precisely corresponding to that expected for reaction [1].

Chronopotentiometric experiments, shown in composite form in Fig. 3, produce the same pattern of waves observed by cyclic voltammetry. The chronopotentiometric constants for the two cathodic waves, $i\tau_1^{1/2}/AC^o$ = 263 ± 13 and $i\tau_2^{1/2}/AC^o$ = 650 ± 23 amp $sec^{1/2}$ cm/mole, are current-independent. Current reversal at time t_1 gives an anodic wave at the potential of reaction [1]. The experimental time ratio t_1/τ_3 = 1.33 is in accord with the theoretical prediction (18) of 1.25 for a one-electron-forward, two-electron-reverse chronopotentiometric reaction sequence. Current reversal at t_2 yields an anodic wave (τ_4) for the one-electron production of Cu^+ followed by the anodic mercury acetylacetonate wave. The theoretical $t_2/[\tau_4 + \tau_5]$ = 1.79 for a two-electron-forward, three-electron-reverse reaction sequence agrees quite well with the experimental 1.76 result.

At sweep rates >0.6 V/sec, cyclic voltammetry of $Cu(acac)_2$ in Et_4NClO_4 electrolyte yields, like the polarography, a single cathodic wave. This is followed on sweep reversal by a corresponding anodic wave (Fig. 4A). The couple is electrochemically irreversible (ΔE_{peak} = 0.21V) but, at these sweep rates, chemically reversible ($i_{p(a)}/i_{p(c)}$ = 1.0). (An analogous anodic-cathodic couple is observable at a copper amalgam electrode in a solution of $Bu_4N^+acac^-$ in the Et_4NClO_4 electrolyte.) Thus, in the absence of lithium ion, a sufficient population of the unstable $Cu(acac)_2^-$ species exists for the cathodic reaction sequence [2, 3, 5] to be quantitatively reversed.

Cyclic voltammetry of $Cu(acac)_2$ in Et_4NClO_4 at lower potential sweep rates produced an unexpected result, Fig. 4B. The anodic reversal wave at −0.52V becomes kinetically controlled; $i_{p(a)}/i_{p(c)}$ decreases with decreasing potential sweep rate. A result of the kinetic diminution of the extent of Cu^o(Hg) reoxidation at −0.52V is the appearance of a subsequent anodic wave at −0.25V. The oxidation of Cu^o(Hg) to Cu^+ (reverse of reaction [5]) and the oxidation of mercury in the presence of $acac^-$ both occur at this potential. A cathodic partner to this wave is visible (at −0.34V) only on prolonged cycling of potential (dashed curve). In the absence of a completely satisfactory explanation for the kinetic limitation of the anodic wave at −0.52V, attempt at further interpretation of the second anodic wave (−0.25V) does not seem worthwhile.

In summary, in both the anodic mercury wave of acetylacetonate and the cathodic electrochemistry of $Cu(acac)_2$, a more definitive understanding proved possible in the $LiClO_4$-containing medium. It is also clear that the mechanistic results for the reduction of $Cu(acac)_2$ in the $LiClO_4$-Et_4NClO_4 electrolyte were of utility in understanding some features of the reaction in the absence of lithium. A previous comment (2) that supporting electrolyte effects such as that of the lithium ion can allow interpretively useful perturbations can be reiterated here.

Hydrodynamic Potentiometry and Amperometry at Ring-Disk Electrodes

Barry Miller* and Stanley Bruckenstein*,[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

An electronically regulated speed control unit has been programmed to produce an $\omega^{1/2} = kt$ relation for disk and ring-disk electrodes. Besides automatic hydrodynamic amperometry (Levich plots), one can perform two new techniques of hydrodynamic potentiometry: (*a*) recording of disk potential (E_D) *vs.* $\omega^{1/2}$ at constant disk current (i_D); and (*b*) recording of E_D *vs.* i_D at constant surface concentrations of all species, obtained by holding $i_D/\omega^{1/2}$ constant while scanning i_D. The equations governing (*a*) are derived and the implications of (*b*) for measuring rate constants and/or uncompensated solution resistance are discussed.

The rotating ring-disk electrode geometry is particularly favorable for electrochemical studies in that it is possible to control the rate of mass transfer in addition to either potential or current. Advantages inherent in programmed control of the electrode rotation speed (ω) have not been exploited in the past. Ordinarily, (ring-) disk electrode experiments are carried out at constant ω, controlling either potential or current. Additional information contained in the ω-dependence can be obtained only by repeating the particular experiment at a series of different, constant ω's.

The purpose of this work is to develop the theory required to interpret data obtained when $\omega^{1/2}$ is varied continuously and to describe a method for programming ω while effectively retaining a hydrodynamic steady state (Levich equation conditions).

The functional form of the Levich equation

$$i = 0.62\, n\, A\, D_i^{2/3}\, \omega^{1/2}\, \nu^{-1/6}\, (C_i - C_i^s)$$
$$= nK_i\, \omega^{1/2}\, (C_i - C_i^s) \qquad [1]$$

indicates that it is of particular value to obtain a recordable voltage which is proportional to $\omega^{1/2}$. In Eq. [1], C_i and C_i^s are the bulk and surface concentrations of the i^{th} species and the other symbols have their conventional significance.

Creason and Nelson (1) have recently reported briefly on a method in which the square root of a voltage produced by a tachometer generator (geared to the rotator drive motor) is recorded *vs.* current. We have used an operational amplifier circuit containing a squaring module to program an exisitng electronically regulated motor speed controller (2) to produce, rather than compute, the desired $\omega^{1/2}$ dependence. This apparatus has been used to perform automatically

1. Hydrodynamic amperometry—plots of i *vs.* $\omega^{1/2}$ at constant E_D (disk potential) and constant bulk concentration C_i—Eq. [1].
2. Hydrodynamic potentiometry
   (*a*) plots of E_D *vs.* $\omega^{1/2}$ at constant i and C_i (Method HP1).
   (*b*) plots of E_D *vs.* i at constant C_i where the ratio $i/\omega^{1/2}$ is held constant (Method HP2).

The latter two techniques are new, to the knowledge of the authors. Method HP1 may be thought of as a translation of the chronopotentiometric experiment at stationary electrodes to the steady-state convective diffusion control regime where rotation speed replaces time as the third variable. Method HP2 has application to the measurement of exchange currents and the direct determination of solution resistance between reference capillary tip and disk.

Theoretical

Hydrodynamic Amperometry

The theoretical aspects of (ring-) disk experiments of this type are well developed and require no elaboration here [for a complete bibliography, see Ref. (3)].

* Electrochemical Society Active Member.
[1] Present address: Department of Chemistry, State University of New York at Buffalo, Buffalo, New York.

However, it is worth pointing out that the direct recording of i *vs.* $\omega^{1/2}$ at constant E_D, (*a*) generally produces greater reproducibility, (*b*) shortens the time of an experiment to a few minutes, and (c) makes obvious any deviations from the expected $\omega^{1/2}$ behavior such as those arising from kinetic or film-forming complications.

Hydrodynamic Potentiometry

E_D vs. $\omega^{1/2}$ at constant i and C_i, Method HP1.—The general shape of an E_D *vs.* $\omega^{1/2}$ curve can be deduced graphically from the conventional current-potential curve of a particular system. Consider a solution containing two species, A and C, which are reduced according to

$$A + n_1e \rightarrow B \qquad [2]$$

$$C + n_2e \rightarrow D \qquad [3]$$

with half-wave potentials of $E_1^{1/2}$ and $E_2^{1/2}$, respectively, where $E_2^{1/2} < E_1^{1/2}$.

Suppose that Eq. [2] and [3] represent reversible systems involving soluble species. Then a plot of $i/\omega^{1/2}$ *vs.* E_D, as shown in Fig. 1*A*, is constant for given C_A and C_C when uncompensated ohmic potential drops are ignored. The sigmoid curve in Fig. 1*A* is independent of the manner in which the ratio $i/\omega^{1/2}$ is established. In conventional practice, a series of $i - E_D$ curves would be obtained at different constant $\omega^{1/2}$ values. In hydrodynamic potentiometry, Method 1, i is held constant at a value I, ω is varied, and E_D is recorded *vs.* $\omega^{1/2}$. In Fig. 1*B* we have plotted $\omega^{1/2}/i$ *vs.* E_D simply by taking the reciprocal of the ordinate of Fig. 1*A* at all values of E_D.

Since it is not possible to have $\omega^{1/2}$ approach zero and maintain rotating disk transport assumptions, only part of the $\omega^{1/2}/i$ *vs.* E_D curve can be observed experimentally.

Sharp potential changes in the $E_D - \omega^{1/2}$ plot occur at potentials in the vicinity of the limiting current regions (4). If ω_1 represents the angular velocity when I corresponds to the limiting current for reaction [2] and ω_2 the angular velocity when I corresponds to the sum of the limiting currents for reactions [2] and [3], one can relate $\Delta\omega^{1/2}$ $(= \omega_1^{1/2} - \omega_2^{1/2})$ to the concentration of A and C in solution. The curves for these two angular velocities and an intermediate one are shown in Fig. 2.

We shall refer to ω_1 and ω_2 as transition velocities. In practice, transition velocities at a disk electrode are determined graphically from $E_D - \omega^{1/2}$ plots in a manner analogous to that used for transition times in chronopotentiometry. Alternatively, plots of ring currents *vs.* $\omega^{1/2}$ obtained at ring-disk electrodes may be more precise in defining the transition velocity for the $E_D - \omega^{1/2}$ data, particularly for irreversible systems, wherever such ring reactions are feasible.

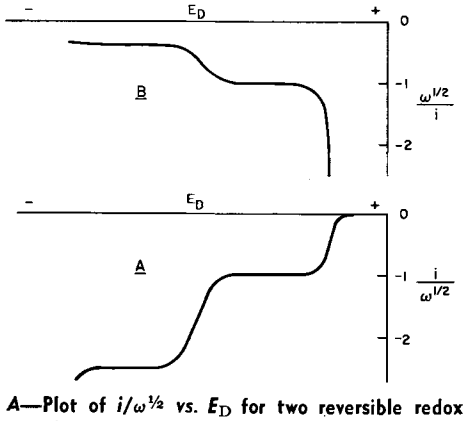

Fig. 1. *A*—Plot of $i/\omega^{1/2}$ *vs.* E_D for two reversible redox systems at a rotating disk electrode. Anodic currents are treated as positive and positive potentials increase from left to right. *B*—Plot of the reciprocal of the ordinate of *A* *vs.* E_D.

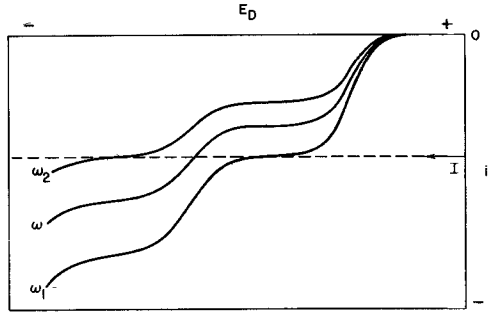

Fig. 2. Plot of the i-E_D curves for two reversible redox systems at three rotation speeds, $\omega_1 > \omega > \omega_2$; reaction [2] yields the first wave, the sum of reactions [2] and [3] contributes toward the second wave. At ω_1, I equals the limiting current of the first wave and, at ω_2, I equals the sum of the limiting currents of the first and second waves.

$\omega^{1/2}$-Concentration relations.—If a constant cathodic current, I, of appropriate magnitude is passed through a cell containing A and C which have the i-E curves in Fig. 2, the following limiting current relations may be written for ω_1 and ω_2, respectively (giving cathodic current a negative sign).

$$-I\omega_1^{-1/2} = K_An_1C_A \qquad (C_A^s = 0) \qquad [4]$$

$$-I\omega_2^{-1/2} = K_An_1C_A + K_Cn_2C_C \qquad (C_A^s = C_C^s = 0) \qquad [5]$$

At rotation speeds $\omega \geqq \omega_1$ the current efficiency for reaction [2] is essentially 100%, whereas at $\omega_2 < \omega < \omega_1$ both reactions [2] and [3] proceed. In the general case, at ω_2 both B and D are produced at limiting currents. For the special case of consecutive oxidation or reduction reactions of a single substance, $C_A = C_C$, $B \equiv C$, and the electrode reaction at ω_2 produces D exclusively (the $n_1 + n_2$ electron product of the starting substance, A).

From Eq. [4] and [5]

$$-I(\omega_2^{-1/2} - \omega_1^{-1/2}) = K_Cn_2C_C \qquad [6]$$

or

$$\frac{\omega_2^{1/2}\,\omega_1^{1/2}}{\Delta(\omega^{1/2})} = \frac{-I}{K_Cn_2C_C} \qquad [7]$$

If C_C is held fixed, and ω_1 and ω_2 determined from the $E_D - \omega^{1/2}$ plot for a series of constant currents, Eq. [7] predicts that the function $\omega_1^{1/2}\,\omega_2^{1/2}/\Delta(\omega^{1/2})$ is proportional to I with a slope from which the diffusion coefficient of C can be obtained.

On dividing Eq. [5] by Eq. [4], we have

$$\frac{\omega_1^{1/2}}{\omega_2^{1/2}} = \frac{K_Cn_2C_C + K_An_1C_A}{K_An_1C_A} \qquad [8]$$

which may be rewritten as

$$\omega_1^{1/2} - \omega_2^{1/2} = \Delta(\omega^{1/2}) = \omega_1^{1/2}\left(\frac{K_Cn_2C_C}{K_An_1C_A + K_Cn_2C_C}\right) \qquad [9]$$

or, on substitution of Eq. [4]

$$\Delta(\omega^{1/2}) = -I\left(\frac{K_Cn_2C_C}{K_An_1C_A}\right)\left(\frac{1}{K_An_1C_A + K_Cn_2C_C}\right) \qquad [10]$$

In the general case, both C_A and C_C are obtained from two equations, [4] and [5] or [7] and [10], in the manner of transition time-concentration relations in chronopotentiometry where τ_2 is dependent on τ_1 as $\omega_2^{1/2}$ is on $\omega_1^{1/2}$. If $C \equiv B$, as is the case in the step-wise reduction of A to D, we may set $C_A \equiv C_C$ and $K_A \equiv K_C$, yielding

$$\frac{\omega_1^{1/2}}{\omega_2^{1/2}} = \frac{n_1 + n_2}{n_1} \text{ and}$$

$$\Delta(\omega^{1/2}) = \left(\frac{-I}{K_AC_A}\right)\left(\frac{n_2}{n_1}\right)\left(\frac{1}{n_1 + n_2}\right) \qquad [11]$$

In the special case that $n_1 = n_2 = 1$ (Cu(II) → Cu(I) → Cu in 0.5M KCl), $\omega_1^{1/2}/\omega_2^{1/2} = 2$ and $\Delta(\omega^{1/2}) = -I/2\,K_A C_A$.

Potential-$\omega^{1/2}$ Curves

Two consecutive electrochemical reactions involving different substances.—If reactions [2] and [3] are assumed to occur at sufficiently separated potentials, they will yield a distinct $E_D - \omega^{1/2}$ step for [3].

$\omega > \omega_1$.—The $E_D - \omega^{1/2}$ curve for $\omega > \omega_1$ corresponds to the situation in which only B is produced at the electrode surface and, assuming Nernstian behavior, is obtained by substitution into

$$E_{A-B} = E^f_{A-B} + \frac{0.059}{n_1} \log \frac{C_A^s}{C_B^s} \quad [12]$$

from the appropriate expressions. E^f_{A-B} is the formal potential for the A-B couple in the medium being studied. Eliminating C_A from Eq. [1] when $i = -I$, using Eq. [4] yields

$$C_A^s = \frac{I}{n_1 K_A} (\omega_1^{-1/2} - \omega^{-1/2}) \quad [13]$$

The flux of A and that of B are of equal absolute magnitude, hence

$$I\omega^{-1/2} = n_1 K_B C_B^s \quad [14]$$

Eliminating C_A^s and C_B^s from [12] using [13] and [14] gives

$$E_{A-B} = E^f_{A-B} + \frac{0.059}{n_1} \log \left(\frac{D_B}{D_A}\right)^{2/3} + \frac{0.059}{n_1} \log \frac{(\omega_1^{-1/2} - \omega^{-1/2})}{\omega^{-1/2}} \quad [15]$$

since $K_B/K_A = (D_B/D_A)^{2/3}$. The half-wave potential, $E_{A-B}^{1/2}$, occurs at $\omega = 4\omega_1$ (unity value of the log argument) and would be observable only if starting the scan at $\omega \geq 4\omega_1$ were feasible for a given current level, I. The dimensions of $\omega^{-1/2}$ are time$^{1/2}$; the close parallel of both Eq. [15] and the $4\omega_1$ condition to the corresponding equation of chronopotentiometry and the $\tau_1/4$ point are obvious.

$\omega_1 > \omega > \omega_2$.—In this range of speed, both reactions [2] and [3] proceed. The current, I, may be written in terms of the fluxes of A and C and the Levich equation as

$$-I\omega^{-1/2} = n_1 K_A C_A + n_2 K_C [C_C - C_C^s] \quad [16]$$

The second term on the right-hand side of [16] may be expressed in terms of the flux of D, namely

$$-I\omega^{-1/2} = n_1 K_A C_A + n_2 K_D C_D^s \quad [17]$$

Since $C_C^s = 0$ at $\omega = \omega_2$ and $n_1 K_A C_A$ is given by Eq. [4], Eq. [16] may be written as

$$-I\omega_2^{-1/2} = -I\omega_1^{-1/2} + n_2 K_C C_C \quad [18]$$

and Eq. [17] as

$$-I\omega^{-1/2} = -I\omega_1^{-1/2} + n_2 K_D C_D^s \quad [19]$$

On substituting Eq. [18] and [4] into Eq. [16] to obtain C_C^s and solving Eq. [19] for C_D^s, one obtains

$$C_C^s = \frac{-I}{n_2 K_C} (\omega_2^{-1/2} - \omega^{-1/2}) \quad [20]$$

and

$$C_D^s = \frac{-I}{n_2 K_D} (\omega^{-1/2} - \omega_1^{-1/2}). \quad [21]$$

$$E_{C-D} = E^f_{C-D} + \frac{0.059}{n_2} \log \frac{C_C^s}{C_D^s} \quad [22]$$

whereupon substitution of Eq. [20] and [21] gives

$$E_{C-D} = E^f_{C-D} + \frac{0.059}{n_2} \log \left(\frac{D_D}{D_C}\right)^{2/3} + \frac{0.059}{n_2} \log \frac{(\omega_2^{-1/2} - \omega^{-1/2})}{(\omega^{-1/2} - \omega_1^{-1/2})} \quad [23]$$

The half-wave potential, $E_{C-D}^{1/2}$, occurs at $\omega^{-1/2} = \frac{\omega_2^{-1/2} + \omega_1^{-1/2}}{2}$.

In the case of a step-wise reduction where the second reaction is

$$B + n_2 e \rightarrow D \quad [24]$$

rather than [3], Eq. [17] remains valid. However, Eq. [16] must be replaced. We equate the flux of A to the sum of the fluxes of B and D, namely

$$n_1 K_A C_A = n_1 K_B C_B^s + n_2 K_D C_D^s \quad [25]$$

On substitution of Eq. [4] and [19] and rearrangement

$$n_1 K_B C_B^s = -I(2\omega_1^{-1/2} - \omega^{-1/2}) \quad [26]$$

The limiting current at ω_2 corresponds to that of the reaction $A + (n_1 + n_2)e \rightarrow D$ which is given by

$$-I\omega_2^{-1/2} = (n_1 + n_2) K_A C_A \quad [27]$$

Combining Eq. [27] and [4] yields

$$\omega_1^{-1/2} = \left(\frac{n_1}{n_1 + n_2}\right) \omega_2^{-1/2} \quad [28]$$

permitting the introduction of $\omega_2^{-1/2}$ into Eq. [26],

$$n_1 K_B C_B^s = -I \left(\frac{2n_1}{n_1 + n_2} \omega_2^{-1/2} - \omega^{-1/2}\right) \quad [29]$$

The $E_D - \omega^{1/2}$ curve for reaction [24], on combining Eq. [21] and [29] and assuming Nernstian behavior, is

$$E_{B-D} = E^f_{B-D} + \frac{0.059}{n_2} \log \left(\frac{D_D}{D_B}\right)^{2/3} \left(\frac{n_2}{n_1}\right) + \frac{0.059}{n_2} \log \left[\frac{\left(\frac{2n_1}{n_1 + n_2}\right) \omega_2^{-1/2} - \omega^{-1/2}}{\omega^{-1/2} - \omega_1^{-1/2}}\right] \quad [30]$$

$E_{B-D}^{1/2}$ is obtained for

$$\omega^{-1/2} = \frac{1}{2} \left[\left(\frac{2n_1}{n_1 + n_2}\right) \omega_2^{-1/2} + \omega_1^{-1/2}\right]$$

In the special case $n_1 = n_2$, the right-hand log terms of Eq. [23] and [30] are identical. When the n_2 electron transfer step produces a constant activity state (*e.g.*, metal deposition as in $CuCl_2$ reduction in 0.5M KCl), C_D^s is taken as 1 and Eq. [30] becomes

$$E_{B-D} = E^f_{B-D} + \frac{0.059}{n_2} \log (D_B)^{-2/3} + \frac{0.059}{n_2} \log \left[\frac{-I}{n_1 K_B} \left(\frac{2n_1}{n_1 + n_2} \omega_2^{-1/2} - \omega^{-1/2}\right)\right] \quad [31]$$

For the $CuCl_2$ case, $n_1 = n_2 = 1$, and Eq. [31] reduces to

$$E_{B-D} = E^f_{B-D} + 0.059 \log (D_B)^{-2/3} + 0.059 \log \left[\frac{-I}{K_B} (\omega_2^{-1/2} - \omega^{-1/2})\right] \quad [32]$$

As in the conventional i-E representation, the half-wave potential at $\omega^{1/2} = 4/3\ \omega_2^{1/2} = 2/3\ \omega_1^{1/2}$ for such a system depends on the current level, I.

Ring Current-$\omega^{1/2}$ Relation

The transition velocities may be determined by using a ring electrode for amperometric detection of one or more of the species A, B, C, or D in the general case, or of A, B, or D in the step-wise reduction. To illustrate calculating the ring current, i_r, in any specific case, consider detecting B in the step-wise re-

duction $A \rightarrow B \rightarrow D$ in the region $\omega_1 > \omega > \omega_2$ where both B and D are being formed. The surface concentration of B at the disk is given by Eq. [26] or [29]. The disk current, i_d, that may be assumed to be producing B with 100% current efficiency is related to C_B^s by $i_d = -n_1 K_B \omega^{1/2} C_B^s$, hence

$$i_d = I(2\omega_1^{-1/2} - \omega^{-1/2})\omega^{1/2}$$

$$= I\left[\left(\frac{2n_1}{n_1 + n_2}\right)\omega_2^{-1/2} - \omega^{-1/2}\right]\omega^{1/2} \quad [33]$$

The ring current is

$$i_r = \pm N \frac{n_r}{n_d} i_d \quad [34]$$

where $n_d = n_1$, the number of electrons in the B-producing disk reaction, n_r is the number of electrons in the ring reaction detecting B, N is the geometric collection efficiency, and $\pm$ refers to the sign appropriate to the direction of the ring reaction. Then ($\omega_1 < \omega < \omega_2$)

$$i_r = \pm N\left(\frac{n_r}{n_d}\right) I\left(\frac{2\omega^{1/2}}{\omega_1^{1/2}} - 1\right)$$

$$= N\left(\frac{n_r}{n_d}\right) I\left[\frac{2n_1\omega^{1/2}}{(n_1 + n_2)\omega_2^{1/2}} - 1\right] \quad [35]$$

At $\omega > \omega_1$, the ring current is constant at (n_r/n_d) N I since the entire cathodic current, I, is going to form B. At $\omega < \omega_2$, the ring current is zero as the reaction proceeds entirely to D. In the region $\omega_1 > \omega > \omega_2$, the ring current varies linearly with $\omega^{1/2}$.

Collecting the quantities in Eq. [35] that are constant in a particular experiment, and assuming $n_d = n_1 = n_2 = 1$ [$CuCl_2$ in 0.5M KCl, Cu(I) → Cu(II), oxidation at the ring requiring a minus sign] yields

$$i_r = \left(\frac{-N I}{\omega_2^{1/2}}\right)(\omega^{1/2} - \omega_2^{1/2}) \text{ for } \omega_1 \geqq \omega \geqq \omega_2 \quad [36]$$

E_D vs. i at constant C for $i/\omega^{1/2}$ ratio held constant. Method HP2.—If the ratio $i/\omega^{1/2}$ is held constant by suitable instrumentation while i is scanned at a rotating disk electrode, the surface concentration, C^s, corresponding to the ratio, $i/\omega^{1/2}$, remains constant under the conditions of Eq. [1]. Thus, for the anodization of a metal, the surface concentration of the dissolving species is fixed. For a soluble redox couple, the ratio of the surface concentrations of Ox and Red will be held constant. During the experiment, E_D is determined while i is scanned. If the solution resistance is negligible, the derivative $(\partial E_D/\partial i)_{Cs}$ can be obtained over a range of C^s and i values. The extrapolation of this partial derivative to zero current yields the polarization resistance and, thus, the exchange current at that particular surface concentration. Since the polarization resistance may be determined as a function of surface concentration, the method is of general application to electrode kinetic problems. A detailed discussion of this procedure for determining the d-c polarization resistance kinetic parameters will be forthcoming. The present paper is devoted to the experimental basis of this method, and only one particular theoretical aspect is developed here. The measurement of the solution resistance between rotating disk and reference electrode capillary, neglected in the above discussion, is considered below.

All determinations of the derivative $(\partial E_D/\partial i)_{Cs}$ contain the uncompensated part of the series resistance that always exists between the disk electrode and the Luggin capillary tip. For fast reactions and/or sufficient surface concentration of electroactive species, kinetic contributions to the polarization may become negligibly small compared to the IR drop, reversing the situation previously considered. This condition of negligible reaction polarization may be tested experimentally by determining $(\partial E_D/\partial i)_{Cs}$ at $i \rightarrow 0$ for several values of C^s, and observing whether or not a constant value of $(\partial E_D/\partial i)_{Cs}$ is found. In kinetic studies, the derivative will normally not be constant and the IR term must be corrected for, possibly using the approach to be outlined.

For any given value of $i/\omega^{1/2}$, the extrapolated value of E_D at $i = 0$ is the Nernst potential of the system for the particular fixed value of C^s, independent of kinetic parameters and IR drop. Any deviation of the actual value of $i/\omega^{1/2}$ from the programmed ratio will distort the i-E_D curve and introduce an error in the extrapolated Nernst potential. Such experimental problems are not serious. In the case of a reaction with a very high exchange current, for which $(\partial E_D/\partial C)_{Cs}$ at $i \rightarrow 0$ equals R, even a 5% variation in $i/\omega^{1/2}$ is equivalent to only a $0.6/n$ mV shift in the (reversible) disk potential, where n electrons are transferred in the potential determining reaction. In practice, the ratio of $i/\omega^{1/2}$ can be controlled to better than 1%, and this introduces no significant experimental errors.

Experimental

Figure 3 shows the $\omega^{1/2}$-scanning scheme. An operational amplifier integrator fed with a constant current produces a linear voltage ramp, $E_S = at$. Squaring this output produces a voltage, $E_o = a^2b^2t^2$, where b^2 is a constant introduced in the squaring operation. (A second integration instead of direct squaring would produce an equivalent result.) A tachometer generator attached directly to the disk electrode produces a d-c voltage, E_T, that is proportional to rotational speed, $E_T = \omega/c^2$. A fraction, R_s/R_g, of E_T is compared to the output of the squaring module and made equal to it by a control amplifier supplying the armature of the driving motor (2), causing the motor speed to vary according to $\omega = (a^2b^2c^2\ R_g/R_s)\ t^2$. The constants b and c are not adjustable and are characteristic of the squaring module and tachometer generator, respectively. Hence, it is necessary to divide the tachometer output with the divider network R_s/R_g (Fig. 3) to produce the desired relation between $\omega^{1/2}$ and E_S.

$$E_S = \left(\frac{R_s}{R_g}\right)^{1/2} \frac{\omega^{1/2}}{bc} \text{ and } \omega^{1/2} = abc\left(\frac{R_g}{R_s}\right)^{1/2} t$$

Driving the X axis of an X-Y recorder with E_S yields a calibrated, linear $\omega^{1/2}$ scale. In practice, a set of R_s values has been used to provide $\omega^{1/2}$ scans from 0-1000, 2500, 5000, and 10,000 rpm. In the apparatus used in this study, the manual speed adjustment within the original speed controller is still operative, so that the $\omega^{1/2}$ scans may be started at any arbitrary initial value of $\omega^{1/2}$ as well as zero.

Since the motor speed is actually being controlled to give $\omega^{1/2} = kt$, rather than being linearly scanned

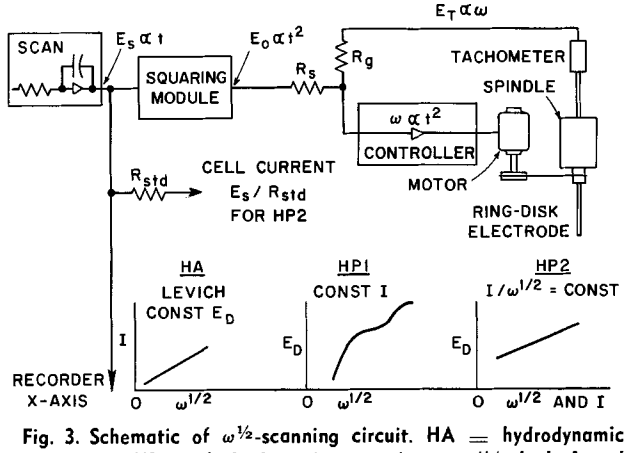

Fig. 3. Schematic of $\omega^{1/2}$-scanning circuit. HA = hydrodynamic amperometry, HP = hydrodynamic potentiometry (Methods 1 and 2). See text.

vs. time and the tachometer generator output voltage square rooted (1), the time derivative, $d\omega^{1/2}/dt$, is being held constant rather than $d\omega/dt$ (1). This allows one to scan wide ω ranges with increasing angular acceleration at the higher speeds, where it can be more readily tolerated. The transit time from disk to ring, for example, is inversely related to ω (5), as is the time required to reach a specified fraction of the steady-state limiting current at the disk in a potential jump experiment (6).

For the experiments in which $I/\omega^{1/2}$ is held constant, the output E_S is also used to provide, with the aid of an intermediary buffer amplifier equipped with a 0.5A booster, a cell current equal to E_S/R_{std}. R_{std} is a precision six-decade, 10-megohm resistance box (General Resistance Model DS166B). The X axis of the recorder is thus simultaneously calibrated in both $\omega^{1/2}$ and I units. The ratio, $I/\omega^{1/2}$, is fixed and given by $(R_s/R_g)^{1/2}$ $(1/R_{std}bc)$.

The linearity and calibration of the $\omega^{1/2}$-E_S relations depend on the squaring module accuracy (Burr Brown 9874/19, 0.1% full scale), the linearity of the tachometer-reference system in the controller, the R_g/R_s ratio for tachometer output division, and the amplifier bias at the summing point (the R_s-R_g junction in Fig. 3). With proper adjustment of the latter two factors, the $\omega^{1/2}$ scale was found to be linear with E_S (X axis) from 10-100 rpm$^{1/2}$ (high range, ω_{max} = 10,000 rpm) to within ±1%. The accuracy increases with speed where the bias adjustment is less critical. Calibration can be achieved by setting E_S = 1V, adjusting the amplifier bias until $\omega^{1/2}$ = 10 rpm$^{1/2}$ and then, at E_S = 10V, trimming the tachometer divider until $\omega^{1/2}$ = 100 rpm$^{1/2}$. This cycle is repeated until the accuracy is within the desired limit.

Rotation speeds were measured with a General Radio 1536A photoelectric pickoff and a Hewlett-Packard 5216A counter. All curves were recorded on a Honeywell 580 X Y Y' plotter.

The cell, electrode construction, and electronics have been previously described (7). A gold split ring-disk operated with shorted half-rings was employed for reduction experiments in 2 mM $CuCl_2$-0.5M KCl; the disk of the same electrode was used for experiments in 1M H_2SO_4 containing millinormal level Fe(III) and MnO_4^-. The Fe(III)-MnO_4^- solution was not analyzed, since the same solution was used to obtain both hydrodynamic potentiograms and conventional i-E curves. The comparison of these does not require knowledge of $C_{MnO_4^-}$ or $C_{Fe(III)}$. Solutions were prepared with triply distilled water. The geometrically calculated collection efficiency for the gold electrode was 0.349. The disk of a silver disk-graphite split ring electrode was used for anodic experiments in 1N $HClO_4$. The disk areas of both electrodes were 0.178 cm^2.

Mating of the motor scan electronics to the cell operational amplifier circuitry (7) requires further comment since Fig. 3 suggests that the motor controller employs a ground-referenced, operationally programmable power supply. The motor controller (2) actually used required a floating reference source in a bridge circuit, and therefore both controller and scan circuitry had to be isolated from ground by suitable transformers. Capacitive grounding of the low point in the controller circuit reduced the a-c level of the common return in the $\omega^{1/2}$-scan circuitry, with respect to power line ground, to about 2V. A unity gain difference amplifier referenced to power line ground was then used to convert E_S, measured between the integrator output and the isolated common, to a single-ended signal compatible with the existing ground referenced cell control electronics and recorder. Careful measurements with a 0.1% digital voltmeter (Hewlett-Packard Model 3430A) proved that no detectable errors were introduced into E_S by these manipulations. The constant speed regulation of this configuration, better than 1 ppt at 2000 rpm, is actually superior to that originally claimed (2) (0.5%).

Results and Discussion

Hydrodynamic Amperometry—Disk and Ring

The current-voltage curve for the gold disk electrode in a solution of 2 mM $CuCl_2$ in 0.5M KCl is shown in Fig. 4*A*. The ring current-voltage curve for a constant current producing Cu(I) at the disk is shown in Fig. 4*B*. The $\omega^{1/2}$-scanning device was tested by controlling the disk potential to give the limiting current of the Cu(II) → Cu(I) wave while controlling the ring potential to give the limiting current value for the oxidation of Cu(I) → Cu(II). The $\omega^{1/2}$-scan was made from zero to >8100 rpm. Because of inertia and the motor low speed limit of 15-20 rpm, the electrode does not begin to rotate until the X-axis deflection corresponds to ~30-40 rpm (the spindle gear ratio was 2:1). Once the motor begins to rotate, it rapidly reaches the *nominal* speed required by E_S. The rotation speed of the electrode is within 1% of the indicated X-axis value at 100 rpm when $d\omega^{1/2}/dt$ = 0.33 rpm$^{1/2}$-sec^{-1}. The entire Levich plot, obtained automatically under these conditions, along with the simultaneously recorded ring current, is shown in Fig. 5. It is satisfactorily linear (±1%) for ω > 300 rpm. If $d\omega^{1/2}/dt$ > 0.33 rpm$^{1/2}$-sec^{-1}, the speed at which i_d or i_r linearity with $\omega^{1/2}$ is reached becomes greater. The ring current plot is within ±2% of the best straight line in the region 300-8000 rpm and yields a collection efficiency (the negative of the ratio of the i_r- and i_d-

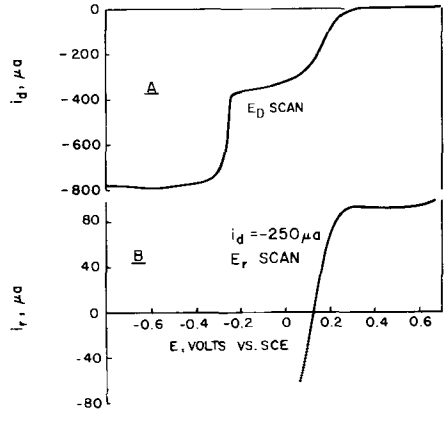

Fig. 4. *A*—Current-potential curve for the reduction of 2 mM $CuCl_2$ in 0.5M KCl at a gold disk; rotation speed 5000 rpm, potential scan 20 mV/sec. *B*—Ring current-potential curve for 0 < E_r < 0.7V for the above system when a cathodic disk current of 250 μA is applied.

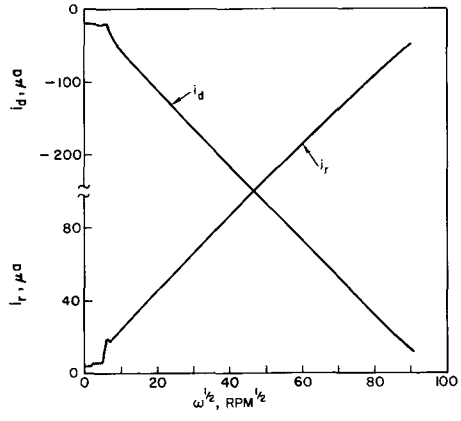

Fig. 5. Automatically recorded disk current and ring current as a function of $\omega^{1/2}$ for the 2 mM $CuCl_2$-0.5M KCl solution and the conditions E_D = −0.170V, E_r = +0.650V, and $\omega^{1/2}$ scan rate of 0.33 rpm$^{1/2}$ sec^{-1}. Scan started from ω = 0.

$\omega^{1/2}$ slopes) of 0.375. This experimental value of N is 7% larger than the calculated value of 0.349 for the gold ring-disk electrode, presumably because of Cu(I) produced during many previous $\omega^{1/2}$-scans in the same solution. The i-E curve of Fig. 4A also indicates a small second-wave enhancement of the same origin.

The ring current reaches a linear slope as rapidly as does the disk current when $d\omega^{1/2}/dt = 0.33$ rpm$^{1/2}$ sec^{-1}, indicating that no additional problems are introduced in collection studies with ordinary electrode geometries by $\omega^{1/2}$ scanning. For $d\omega^{1/2}/dt = 0.33$ rpm$^{1/2}$-sec^{-1}, a scan from 0-10,000 rpm takes 5 min. Starting at 1000 rpm, no deviation from linearity was observed when the speed was scanned to 8000 rpm in less than 90 sec. The value of D for Cu(II) calculated from the slope of the disk trace in Fig. 5 is 6.3 x 10^{-6} cm^2/sec.

Hydrodynamic potentiometry—Method HP1.—Cu(II)-Cu(I)-Cu system.—The hydrodynamic potentiogram for the $CuCl_2$-0.5M KCl system is shown in Fig. 6, along with the limiting Cu(I) → Cu(II) ring current. The E_D-$\omega^{1/2}$ curve can be related to Fig. 4A, the conventional i-E curve, by the transformation indicated in Fig. 1. However, it is to be noted that a nucleation overpotential peak for Cu deposition is visible in the E_D-$\omega^{1/2}$ curve. Such a peak cannot occur during a conventional controlled potential scan. The experiments were performed by adjusting $\omega^{1/2}$ to about 90 rpm$^{1/2}$, applying the desired constant current, and then scanning toward lower rotation speeds. Experiments were ended when the disk electrode potential reached the hydrogen evolution region, *i.e.* when the impressed current became greater than the limiting current for the complete reduction of Cu(II).

Fifteen runs similar to those shown in Fig. 6 were made using applied currents from 230 to 470 μA. Below 230 μA, the ω_2 transition [Cu(II) → Cu(0)] occurs at motor speeds too low for Levich conditions to apply and, above 470 μA, the limiting current of the Cu(II) → Cu(I) step is exceeded at the starting (high) motor speed. For the $\omega^{1/2}$ scans with currents between 230 and 470 μA, the $\omega_1^{1/2}$ and $\omega_2^{1/2}$ transitions were clearly defined. In order to determine these transition velocities, an arbitrary graphical procedure was adopted in which the linear regions on either side of ω_1 and ω_2 were extrapolated and the intersections used to define the value of $\omega_1^{1/2}$ and $\omega_2^{1/2}$.

The theoretical prediction of Eq. [7] is tested in Fig. 7, where the function $\omega_2^{1/2}\,\omega_1^{1/2}/\Delta(\omega^{1/2})$ is plotted *vs.* the impressed current. The plot is linear over the accessible current range and, within the experimental error, extrapolates to zero. A value for the diffusion coefficient of Cu(II) of 6.8 x 10^{-6} cm^2-sec^{-1} was obtained from the slope, compared to the 6.3 x 10^{-6} cm^2-sec^{-1} from the one electron Levich plot in Fig. 5, and 6.8 x 10^{-6} cm^2-sec^{-1} from a previous rotating disk determination (8) on the same system.

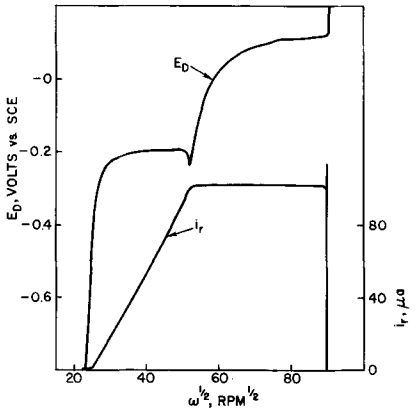

Fig. 6. (Upper trace) E_D as a function of $\omega^{1/2}$ for 2 mM $CuCl_2$-0.5M KCl at a constant cathodic current of 273 μA which was turned on at the upper right point. $\omega^{1/2}$ scan rate 0.33 rpm$^{1/2}$ sec^{-1}. (Lower trace) Ring current at +0.65V measured concurrently.

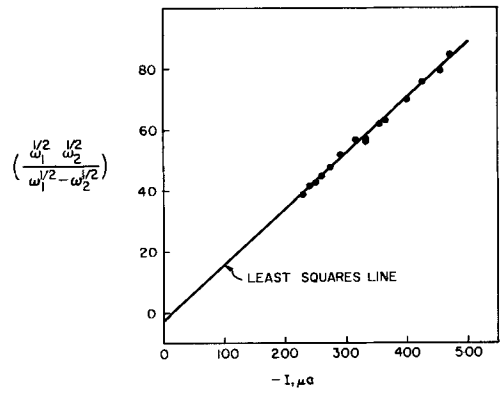

Fig. 7. Plot of the function $\frac{\omega_1^{1/2}\,\omega_2^{1/2}}{\Delta(\omega^{1/2})}$ *vs.* I from data of 15 hydrodynamic potentiograms as in Fig. 6 for the $CuCl_2$-KCl system.

According to Eq. [11], the theoretical value of $\omega_1^{1/2}/\omega_2^{1/2}$ is 2. The 15 curves from which Fig. 7 was constructed yielded an average value of 2.09 with a standard deviation of 0.04. The very slight positive bias is in the direction predicted if, as previously discussed, a small fraction of Cu(II) is assumed to have been converted to Cu(I) in the course of the experiment. Considering this factor, the experimental $\omega_1^{1/2}/\omega_2^{1/2}$ is in agreement with the predicted value.

In Fig. 6, the ring current $-\omega^{1/2}$ traces for the oxidation of Cu(I) to Cu(II) show constant collection efficiency until the rotation speed drops below ω_1, whereupon the disk current efficiency for Cu(II) → Cu(I) reduction becomes less than 100%. After copper metal nucleation occurs at the disk electrode, the ring current decreases linearly with $\omega^{1/2}$ to zero at the ω_2-transition velocity. The i_r-$\omega^{1/2}$ behavior is exactly that predicted in Eq. [36], and the intersections of the straight lines of the i_r-$\omega^{1/2}$ trace can be used to define the values of $\omega_1^{1/2}$ and $\omega_2^{1/2}$. This gives results in excellent agreement with the previously described method using the E_D-$\omega^{1/2}$ plots, which was feasible because the $dE_D/d\omega^{1/2}$ slopes were quite linear in our experiments. However, many disk electrode reactions can be extremely irreversible; *e.g.*, a drawn-out E_D-$\omega^{1/2}$ curve between the transition velocities would have been seen if the Cu(I) → Cu(0) reaction were very slow. Even in such an instance, the i_r-$\omega^{1/2}$ plots would still give well-defined $\omega_1^{1/2}$ and $\omega_2^{1/2}$ values since such plots depend only on current efficiency. As long as the steps in the i-E_D plot are separated by a limiting current region (as here for Cu(II) → Cu(I) → Cu at the disk), the i_r-$\omega^{1/2}$ plot ought not to be affected because of irreversibility at the disk electrode, provided an adequate limiting current region for the ring reaction exists. When two disk reactions slightly overlap in potential, instead of being separated by a clear limiting current region, the corresponding E_D-$\omega^{1/2}$ transition will be ill defined and i_r-$\omega^{1/2}$ intersections for suitable ring reactions will be rounded. However, the latter traces will be linear in the regions away from the theoretical intersection points and thus can readily be extrapolated to the transition velocity intersection. This is comparable to the general advantage of amperometric titrations, which have basically two linear regions, over potentiometric ones in end point definition.

An experimental equivalent of a ring electrode is of course absent in constant current stationary electrode techniques, *viz.* chronopotentiometry. In hydrodynamic voltammetry, the combination of constant IR drop at the disk electrode, and ring electrode-defined $E^{1/2}$-values may be of special value as compared to single-electrode techniques in situations complicated by irreversibility, potential overlap, and/or high re-

sistance, provided a suitable ring electrode reaction or sequence of reactions is available.

Fe(III)-Fe(II) and MnO_4^--Mn(II) Systems

The E_D-$\omega^{1/2}$ behavior predicted by Eq. [23] for a mixture of two different electroactive components was tested with a Fe(III)-MnO_4^- mixture in 1M H_2SO_4. In this experiment, the Fe(III)-Fe(II) potential is represented by $E_{C\text{-}D}$ in the region $\omega_1 > \omega > \omega_2$. In a conventional i-E curve of this system, a plot of E_D *vs.* log $(i_d - i)/i$ for the Fe(III) step is linear with a slope close to that characteristic of a reversible one-electron transfer, 59 mV/decade. From Eq. [23], the equivalent reversibility test using hydrodynamic potentiometry is a plot of E_D *vs.* log $[(\omega_2^{-1/2} - \omega^{-1/2})/(\omega^{-1/2} - \omega_1^{-1/2})]$. Such a plot should be linear and have a slope of $59/n$ mV/decade for an n electron reversible reaction.

The E_D-$\omega^{1/2}$ and i-E_D behavior of a gold disk for the Fe(III)-Fe(II) step in 1M H_2SO_4 solution containing both Fe(III) and MnO_4^- was found to be quite dependent on electrode pretreatment and direction of potential scan. In this work, we sought only to compare the log plot relationships for i-E_D and E_D-$\omega^{1/2}$ curves under electrode surface conditions as equivalent as possible. Brief anodization of the disk electrode at a constant current equal in magnitude to the cathodic current used in the E_D-$\omega^{1/2}$ experiment proved adequate, as did holding the disk electrode equally briefly at about 1.3V *vs.* SCE prior to the i-E_D experiments. Immediately after pretreatment, E_D was made to vary from − to + potentials, *i.e.* from H_2 evolution to more positive potentials by increasing $\omega^{1/2}$ during the E_D-$\omega^{1/2}$ experiment and by scanning E_D positively in the i-E_D experiment.

Two controlled potential i-E curves and one hydrodynamic potentiogram are shown in Fig. 8, as actually recorded on the same chart. The x-axis of the recorder was successively calibrated for current, and then for $\omega^{1/2}$.

The rotation speeds for the i-E_D plots were selected to give limiting currents for the sum of the two steps not very different from the constant 167 μA cathodic current used in the hydrodynamic potentiogram. The appropriate log analyses of the three curves are shown in Fig. 9. The two i-E_D plots yield slopes (60 and 62 mV) that are in experimental agreement with reversible behavior. The log function of Eq. [23] is also linear with potential and gives a slope in accord with the others (56 mV). If the electrode surface is not treated as described, the log functions have varying irreversible slopes (>59 mV). Each such plot, however, appears to be reasonably linear, as would be expected from the form of Eq. [23] after it had been properly modified by incorporating the effects of irreversibility into the pre-logarithmic factor.

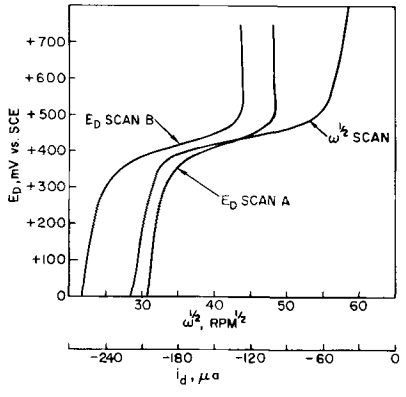

Fig. 8. E_D scans *A* and *B* are conventional 20 mV/sec potential scans vs. disk current at 835 and 1330 rpm, respectively. $\omega^{1/2}$ scan is E_D vs. $\omega^{1/2}$ hydrodynamic potentiogram at a constant 167 μA cathodic disk current. Solution is approximately millinormal Fe(III) and MnO_4^- in 1M H_2SO_4. $\omega^{1/2}$ scan rate 0.33 rpm$^{1/2}$ sec^{-1}.

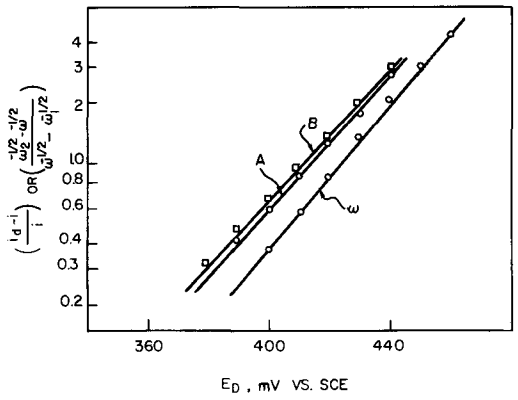

Fig. 9. Fe(III) → Fe(II) waves of Fig. 8 analyzed logarithmically. For E_D scans *A* and *B*, log $[(i_d - i)/i]$ is plotted vs. E_D and for the hydrodynamic potentiogram log $\left(\frac{\omega_2^{-1/2} - \omega^{-1/2}}{\omega^{-1/2} - \omega_1^{-1/2}}\right)$ is plotted vs. E_D.

The log function of ω in Fig. 9 is unity at +423 mV or, from the curve in Fig. 8, for $\omega^{-1/2} = 0.0246$ rpm$^{-1/2}$. The theoretical value of $\omega^{-1/2}$ at this point is, from Eq. [23], $(\omega_2^{-1/2} + \omega_1^{-1/2})/2$. Values of $\omega_2^{1/2}$ and $\omega_1^{1/2}$ were obtained from the intersections of linear extrapolations of the steepest and flattest parts of the E_D-$\omega^{1/2}$ curve, giving for the theoretical value, $(0.0176 + 0.0314)/2 = 0.0245$ rpm$^{-1/2}$, in excellent agreement with the result from the logarithmic plot. Furthermore, the experimental ratio of $\omega_1^{1/2}/\omega_2^{1/2}$ is 1.78, which, from Eq. [8], should be equal to the ratio of the total limiting current for Fe(III) + MnO_4^- divided by the MnO_4^- limiting current alone, when ω is constant. This ratio was found to be 1.82 by continuing i-E_D scans of the type shown in Fig. 8 anodically to the residual current level at the base of the MnO_4^- wave, again showing satisfactory internal consistency.

Hydrodynamic Potentiometry—Method HP2

Determination of uncompensated ohmic resistances.— As described in the Experimental section, recording i *vs.* E_D while scanning the current, i, through the disk electrode and holding the ratio, $i/\omega^{1/2}$, constant may yield information about the kinetics of the redox couple being studied. In the limiting case of a high exchange current when the polarization resistance is much less than the solution resistance between reference capillary and the disk, the slope of the i-E_D curve gives the solution resistance. This case was tested with a silver disk in 1*N* $HClO_4$. The plot of E_D *vs.* i obtained using a controlled, constant value of $i/\omega^{1/2} = 0.25$ mA-rpm$^{-1/2}$ is shown in Fig. 10. The slope of Fig. 10 yields a resistance of 3.2 ohms. This $i/\omega^{1/2}$ ratio corresponds to a Ag^+ surface concentration of

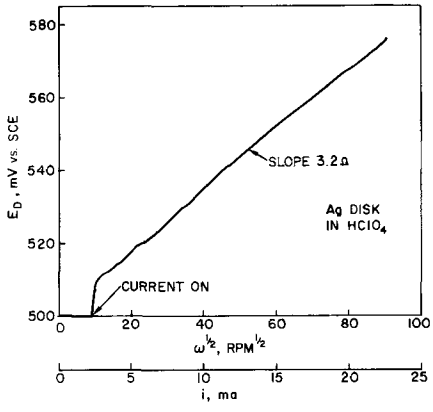

Fig. 10. Controlled $i/\omega^{1/2} = 0.25$ mA-rpm$^{-1/2}$ current and $\omega^{1/2}$ scan of a silver disk in 1*N* $HClO_4$. Disk potential plotted simultaneously against $\omega^{1/2}$ and anodic current, *i*.

0.054M, for which the exchange current is > 1 A/cm^2, according to Gerischer and Tischer (9). The corresponding polarization resistance is calculated to be less than 0.2 ohm for the electrode used. Hence, the value of 3.2 ohms should correspond to the solution resistance between the Luggin capillary tip and the disk electrode (about 1 cm).

Without altering the position of any of the components in the electrode cell, a potentiostatic interrupter method (10) was used to measure independently the uncompensated ohmic potential drop. The average of several measurements was 3.5 ± 0.5 ohms.

Further evidence that the i-E_D method was yielding solution resistance was obtained by lowering the reference capillary away from the disk electrode, which gave a slope of 3.5 ohms. Then a 10 ohm $\pm$ 0.05% resistor was inserted in series with the disk electrode, and the slope was found to be 14.0 ohms. The difference in the latter two values yielded 10.5 ohms for the resistance inserted in series with the disk, and is indicatve of the accuracy limits of this method for determining uncompensated ohmic resistance at that level, about 5%. The reproducibility of the i-E_D traces was considerably better than that obtained by the interrupter method using an oscilloscope.

Summary and Conclusions

The theoretical consequences of programming the rotation speed of (ring-) disk electrodes according to $\omega^{1/2} = kt$ have been successfully verified under three schemes of current, potential, and surface concentration control. The linearity of ring and disk currents with $\omega^{1/2}$ at constant E_D and E_r under Levich conditions confirms the expected features of considerably shortened experiment time, satisfactory reproducibility, and ready observation of deviations from i *vs.* $\omega^{1/2}$ behavior occurring at the electrode. Other particular benefits of a continuous $\omega^{1/2}$ scan and the consequent minimal ring and disk perturbation (shortened time and fewer coulombs passed) will depend on the experiment being done and need not be elaborated here.

Using hydrodynamic potentiometry, method HP1, satisfactory values of diffusion coefficients and agreement with theoretical behavior were obtained for the predicted

$$\omega^{1/2},\ \omega_1^{1/2}/\omega_2^{1/2},\ \frac{\omega_1^{1/2}\,\omega_2^{1/2}}{\Delta(\omega^{1/2})},\ \text{and}\ \frac{(\omega_2^{-1/2} - \omega^{-1/2})}{(\omega^{-1/2} - \omega_1^{-1/2})}$$

functions of ring and disk i-E parameters. Using method HP2, reliable solution resistance measurements have also been obtained. While these techniques might be carried out manually, such plotting in method HP1 would be tedious and as omissive of possible important detail as the equivalent procedure in conventional current-potential methodology. Similarly, our experience with method HP2 has shown that the precision of i-E_D data is significantly improved with the scanning technique as opposed to manual adjustment of both i and $\omega^{1/2}$ values with measurement of E_D point-by-point. This is of considerable importance when the total E_D excursion is only a few millivolts since the precise measurement of E_D is a limiting factor in determining the magnitude of the rate constants that can be handled in applications of the method to kinetic analysis (11).

Method HP1 with concurrent ring measurements can offer a substantial improvement in the experimental determination of transition velocities and in wave analysis. The precise location of apparent $E^{1/2}$ values in relatively resistive solutions, as in most organic solvents, and for irreversible reactions might make this technique the method of choice in those cases. The constant IR drop also simplifies analysis.

The motor speed scanning circuitry employs a squaring module to generate the $\omega^{1/2} = kt$ relation. For any other kind of rotation speed dependence, as might be required for kinetic studies, a log operator, a succeeding variable gain stage, and then an antilog conversion could be used to generate any required ω-power. The transformation of E-$\omega^{1/2}$ curves into i-E plots as outlined in Fig. 1 could be accomplished automatically using analog division of a constant voltage proportional to I by the E_S output proportional to $\omega^{1/2}$ and recording the quotient. The transformed plot is likely to have certain features different from the i-E plots done by either current or potential scanning. For example, in the $CuCl_2$ experiment, conventional potential scanning would miss the metal nucleation overpotential. Current scanning would show this feature but, along with the potential sweep, would suffer from a variable IR correction not present in the transformed HP1 data.

Circuit for Transient-Free Current-Potential Control Conversion

Stanley Bruckenstein*[1] and Barry Miller*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

A general technique for switching a closed loop control circuit from one function to another is described. A closed loop exists at all times, even during the switching operation. A potentiostat that can be switched to a galvanostat and *vice versa* in less than 10 μsec was built. No spurious potential or current transients were observed on test or real cells. This potentio-galvanostat has been tested with a conventional three electrode cell, with a ring-disk electrode, and as a potentiostatic interrupter.

The use of active circuit elements, *e.g.*, operational amplifiers, in closed loop configurations to control the potential of or the current through an electrode is commonplace today. In general, these circuits are far superior to ones involving only passive elements. However, the closed loop configurations that we are familiar with do not permit changing from one control situation to another and back again, without opening the loop and causing the controlling element to limit. Such limiting is sometimes fatal to the experiment. For example, in order to go from galvanostatic to potentiostatic control and back again, the various active and passive elements are rearranged by switching. In currently used configurations this requires opening the loop in one or both switching directions. A particularly ingenious method of this type described by Warner and Schuldiner (1) involves using a back-biased diode to open the loop. The same pulse that limits the potentiostat is used in the current mode as the voltage source to supply the current to the cell through a series resistance. This circuit functions well in transferring controlled potential control to a simple resistive current source, but potential overshoots occur on re-establishing potentiostatic control.

Any attempt to change the control function of a single closed loop operational amplifier circuit that opens the loop produces an unstable condition that is accompanied by undesirable electrical transients in the supposedly controlled system. In general, if a circuit is designed with two closed loop paths involving the same control amplifier, it is possible to make changes in control function, unaccompanied by conditions of instability. To our knowledge, this concept has not been previously applied to electrochemical studies. In such circuits, one control function exists when one loop is closed, while the second control function is imposed when the second loop is closed. This second loop simultaneously performs two functions. First, it negates the control function of the first loop and second, it establishes the desired control situation.

Negation of the control situation established by the first loop is accomplished by appropriate use of an inverting amplifier whose output is made the negative sum of every signal fed to the input of the control amplifier. The input of the inverter is taken from the same signal sources as those going to the negative input of the control amplifier and through identical impedances. The output voltage of the inverter is fed through an appropriate resistance to a single pole, single throw switch connected to the negative input of the control amplifier. If the various resistors associated with the inverting amplifier are properly chosen, closing the switch produces a zero output voltage and current at the control amplifier. In effect, the first closed loop has been opened since the output current of the control amplifier drops to zero.

Closing the switch can also establish the control function desired in the second situation. Any other signals fed to the same side of the switch as the inverter, or alternatively to the summing point of the inverter, will not be cancelled and can establish the second control situation. This situation will correspond to the required one if proper choice of the controlling parameters is made. Since only one control amplifier is used for both control loops and at least one closed loop always exists regardless of the switch position, control is maintained at all times.

The phase shifts of the two closed loop situations are slightly different. It is necessary to choose the passive components associated with the various active circuit elements to satisfy the less stable of the two configurations.

In this paper we describe one of the many possible circuits fulfilling the design principles outlined above which will function either as a potential or current controlling device. This circuit contains two closed loops with one common control amplifier, and no spurious potential or current transients are observed on switching from one configuration to the other.

Experimental

Chemicals and apparatus.—All chemicals were of reagent grade, and ordinary distilled water was doubly distilled from quartz.

The rotator for the ring-disk electrode was manufactured by the Pine Instrument Company of Grove City, Pennsylvania.

The ring-disk electrode had a platinum disk and a platinum ring and was insulated with Teflon. The disk radius was 0.2410 cm, the ring electrode outer radius was 0.4858 cm, and the ring width varied from 0.0053 to 0.0131 cm. The geometry of this particular electrode is such that the variation in ring width introduces a large uncertainty in the calculated value of the collection efficiency, *i.e.*, a change in inner diameter of the ring by 0.0010 cm changes N by $\sim$ 6%. For this reason N was determined experimentally using the oxidation of Br^- to Br_2 at the disk electrode and the reverse reaction at the ring electrode. The solution used in all experiments contained $3.6 \times 10^{-3} M$ NaBr and $0.2 M$ $HClO_4$. The value of N found was 0.078 ± 0.001. This mean N corresponds to a ring electrode inner radius of 0.4733 cm, which lies within the experimental measurements of this dimension.

The disk of this ring-disk electrode was also used for all experiments not involving a ring electrode.

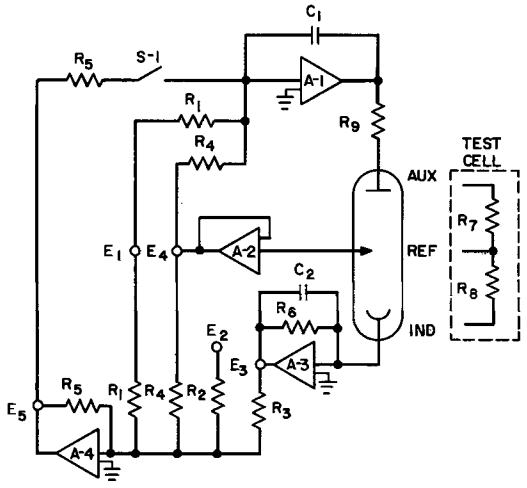

Fig. 1. Schematic circuit of potentio-galvanostat for transient-free switching from potential (S-1 open) to current (S-1 closed) control.

In the ring-disk experiment, two previously described instruments were used. Instrument 1 independently controls the potential of both ring and disk electrodes (2). Instrument 2 controls the current through the disk electrode while independently controlling the potential of the ring electrode and can also be switched to perform the function of circuit 1 (3). Potentiostatic control of the disk electrode is maintained in instruments 1 and 2 using the configuration of amplifiers A-1, A-2, and A-3 shown in Fig. 1. The disk potentiostats for both these instruments were modified according to Fig. 1 to provide disk current control on closing S-1.

Steady-state experiments were performed using the disk electrode potentiostats of instruments 1 and 2 modified according to Fig. 1, and with the original version of instrument 2 in which current control through the disk electrode was maintained using a more conventional single loop controlled current source. Nonsteady-state experiments were performed using the modified form of instrument 2. The amplifiers employed in obtaining the results displayed in Fig. 2-7 were all Burr-Brown amplifiers: Models 3072/15 (A-1 and A-3), 3013/15 (A-2) and 3003/15 (A-4)[2] (see Fig. 1.)

The ring electrode control circuits of instruments 1 and 2 do not interfere with experiments involving only the disk electrode.

All potentials are reported *vs.* the Ag/AgBr electrode in contact with the test solution, whose potential was −14 mV *vs.* SCE.

Switching.—Conventional mechanical switches bounce on closing, and these switching interruptions are visible in experiments analogous to those shown in Fig. 2 to 7 below. The use of a mercury wetted relay obviates this problem. We have used a Western Electric Model 276B relay with an 0.01 μF capacitor across the relay coil. However, energizing this relay coil can still induce a spurious pulse into the potentio-galvanostat circuitry unless care is taken in shielding and physically locating the relay. This problem is far more serious when a real electrochemical cell is used in place of the test cell.

Even more rapid bounce-free transfer was obtained using an electronic switch (Burr Brown 9859/15) as S-1. In this case the switching of the test cell (C_1, C_2, and R_9 all zero) between potentiostat and galvanostat was complete in less than 10 μsec in either direction with no trace of overshoot. The specified operating time of the switch itself is 3 μsec on, 5 μsec off. The logic pulse (+5V on, 0V off) operating the switch was obtained from an operational amplifier zero crossing detector caused to flip between its limits, with a blocking diode in one direction providing the zero volt condition. Any voltage step source would serve. Application of the pulse through a mechanical switch may be satisfactory (no bounces), depending on the quality of the switch, since the Burr-Brown FET device has a 0.5V noise immunity.

[2] Later experience of the authors indicates the lower offset of the chopper stabilized Model 3072/15 is preferable for the A-4 function.

Circuitry

Figure 1 is a schematic diagram of a circuit which permits switching from a controlled electrode potential to a controlled electrode current and *vice versa* without introducing spurious transients. When switch S-1 is open, the potential of the indicator electrode is controlled by amplifiers making up the closed loop, A-1 and A-2. A-3, the current follower, maintains the indicator electrode potential at virtual ground. In the commonly used version of this circuit, $R_1 = R_4$, and E_1 may be any function of time produced by a suitable signal generator. The current through the indicator electrode, i_D, is obtained from E_3 and R_6 using Eq. [1]

$$i_D = -E_3/R_6 \qquad [1]$$

For simplicity in the derivation given below, we assume ideal operational amplifiers of infinite open loop gain, zero input current, and zero error voltage between the positive and negative inputs.

The summing point restraint at the input of the inverting amplifier, A_4, requires that

$$\frac{E_1}{R_1} + \frac{E_2}{R_2} + \frac{E_3}{R_3} + \frac{E_4}{R_4} + \frac{E_5}{R_5} = 0 \qquad [2]$$

When the switch S-1 is closed, the summing point restraint condition at the negative input of the control amplifier A-1 yields

$$\frac{E_1}{R_1} + \frac{E_4}{R_4} + \frac{E_5}{R_5} = 0 \qquad [3]$$

Solving Eq. [1], [2], and [3] for the controlled cell current gives

$$i_D = \frac{E_2 R_3}{R_6 R_2} \qquad [4]$$

E_2 may also be any function of time supplied by an appropriate signal generator.

The transient and steady state behavior of the circuit shown in Fig. 1 is reported below. A purely resistive and a resistive-capacitive analog of an electrochemical cell were used in addition to an electrochemical cell in which a rotating platinum disk electrode served as the indicator electrode. The test (resistive) cell was required to study the circuit's transient response in the absence of electrode-solution processes. Under certain circumstances the electrochemical behavior of a real system prevents the circuit response from being studied. Such a situation occurs in two cases in an electrochemical cell:

(*i*) On switching from constant current control to constant potential control, the current follower potential limits; and (*ii*) on switching in the opposite direction the potential of the reference electrode follower A-2 relaxes in a relatively slow fashion after the initial uncompensated ohmic potential drop.

The circuit configuration shown in Fig. 1 will be referred to as a potentio-galvanostat since this combination of existing terminology implies the control functions of the circuit. The effect of the second control loop on the ring control circuits of instruments 1 and 2 was also studied.

Results and Discussion

Steady-state behavior. Controlled current mode.—Test cell.—The same signal source was used to supply

E_1 and E_2 with switch S-1 closed. The outputs of the current follower and of the voltage follower were recorded *vs.* E_2 on an X-Y-Y' recorder. Within the control limits of the operational amplifier, the slopes of these lines corresponded within ~ 0.2% (recorder limitation) to those which would be predicted from the resistance values listed in the legend to Fig. 2. The currents controlled varied from 10^{-7} to 10^{-2}A. Scanning E_1 along with E_2 had no effect on the controlled current, nor did stepping E_1 by ± 1V about any preset value of E_2.

The independence of the circuit performance on E_1 clearly demonstrates the negation of potentiostatic control in the loop A-1, A-2, and A-3 by the inverting amplifier, A-4, and transfer to current control on closing the second loop through S-1.

Ring-disk electrode.—Circuit 2 in the current-controlling (conventional single loop) configuration was used to determine N_{exp}, the experimental collection efficiency, in a solution containing 3.6 x $10^{-3}M$ NaBr and 0.2M $HClO_4$, scanning the anodic disk current from 0 to 0.500 mA. Next, the modified versions of circuits 1 and 2 in the current controlling mode were used to determine N_{exp} for disk currents of 0 to 0.500 mA. Again E_1 was set equal to E_2 in order to test the potentiostatic rejection property of the double loop configuration.

Values of N_{exp} obtained in all three experiments agreed within 1% with each other and were, within experimental error, indistinguishable from the theoretical value of N.

Transient behavior.—Test cell.—Resistors R_7 and R_8 (Fig. 1) simulated the simplest transient control situation required of the potentio-galvanostat. The response of amplifier A-2, the reference electrode follower, on opening and closing switch S-1 (mercury relay, see above) is shown in Fig. 2. For convenience, in this section, we shall refer to the negative of the reference electrode follower voltage, $-E_4$, as the indicator or disk electrode potential, (E_D). The indicator electrode potential changes between the required limits in about 2 x 10^{-4} sec, without overshooting either potential limit. The output potential of the current follower, E_3, changes between the values required by the constant current and constant potential situations on closing and opening switch S-1 in an equally satisfactory fashion, as shown in Fig. 3.

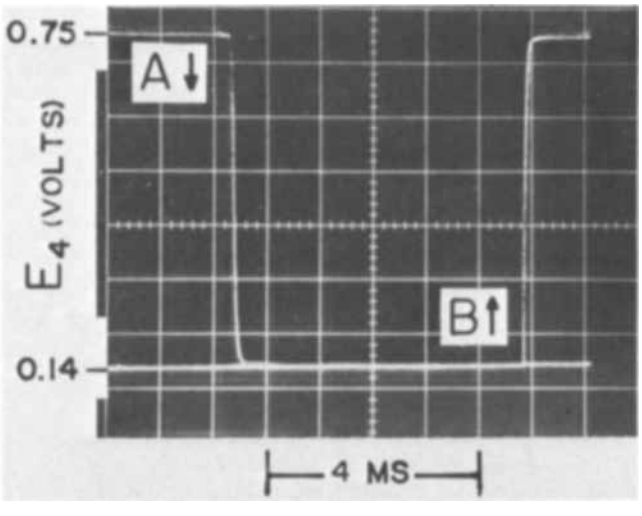

Fig. 2. Response of test cell reference potential E_4 between current and potential control. R_7 = 2K, R_8 = 1K in Fig. 1. Horizontal time scale 1 msec/major division. C_2 and R_9 = 0, C_1 = 100 pf. Trace A, start upper left with —0.75 mA constant current switching to —0.14V constant potential; trace B, start lower horizontal line (constant potential) switching to constant current, same values as trace A. Note: $E_4 = -E_D$, R_6 = 10K.

Electrochemical cell.—The transient behavior of the potentio-galvanostat was studied using a platinum rotating disk electrode. The auxiliary (counter) electrode was a large area platinum gauze electrode that was not separated from the disk electrode by a porous diaphragm. The reference electrode was a silver wire coated with silver bromide in a Luggin capillary filled with the solution in the cell. The resistance between the disk and auxiliary electrode was 14 ohms at 1 kHz.

The circuit in Fig. 1 tended to break into oscillation, whether S-1 was open or closed, unless the series resistance, R_9, was introduced between the output of the control amplifier, A-1, and the auxiliary electrode. In the work reported below R_9 = 1470 ohms. If the auxiliary electrode is separated from the disk electrode compartment, the total cell resistance becomes sufficiently large to make R_9 unnecessary under most conditions. The mercury relay was used for S-1.

Figures 4 and 5 illustrate the transient response of the disk electrode current follower (E_3) and that of the reference electrode follower (E_2) on closing

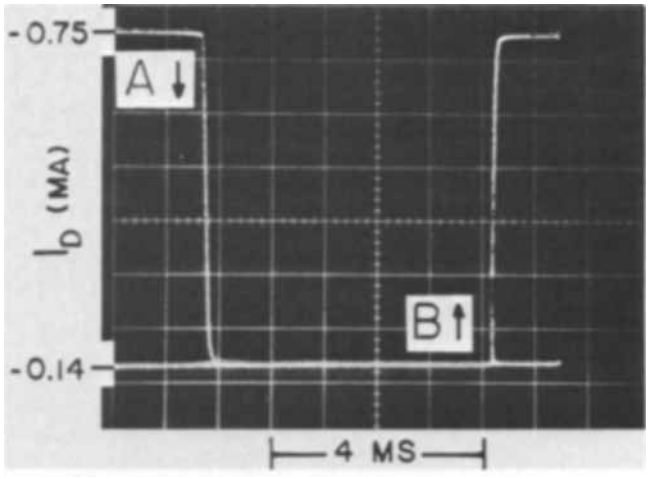

Fig. 3. Response of current follower A-3 for conditions of Fig. 2. Trace A, start upper left (constant current), switching to constant potential; trace B, start lower horizontal line (constant potential), switching to constant current.

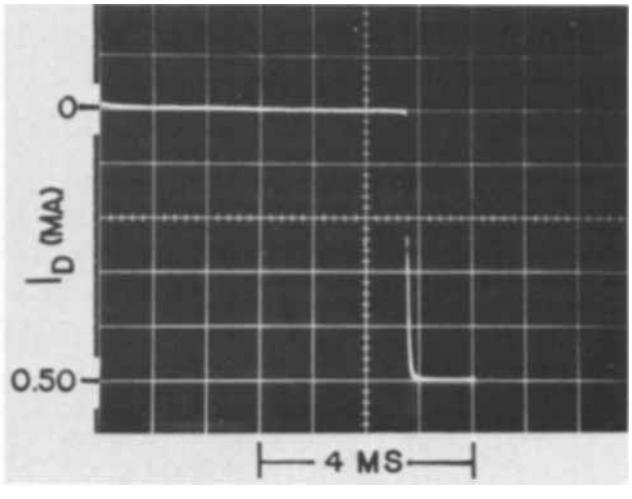

Fig. 4. Current follower (E_3) response during potential to current control switching on 2500 rpm disk electrode in 3.6 x 10^{-3}M NaBr, 0.2M $HClO_4$. Constant —0.10V E_D (upper left) switched to + 0.50 mA constant I_D (lower right). 1 msec/major div. horizontal axis. R_6 = 10K.

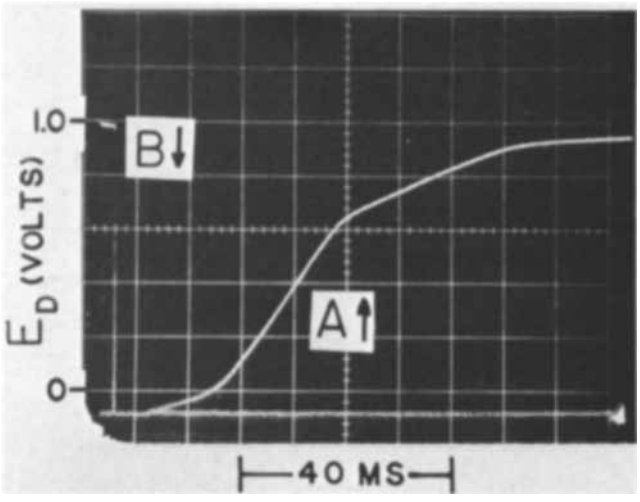

Fig. 5. Reference electrode (E_D) response during potential to current control switching under solution and rotation conditions of Fig. 4. 10 msec/major div. horizontal axis. Curve A, potential (−0.10V) to current (+0.50 mA); curve B, current (+0.50 mA) to potential (−0.10V).

S-1. The initial potentiostatic condition corresponded to $E_D = -0.10$V, while the final galvanostatic condition corresponded to $i_D = 0.500$ mA (anodic disk current). The limiting convective diffusion current for the oxidation of bromide to bromine at the disk electrode was 0.88 mA at 2500 rpm.

As can be seen in Fig. 4, the disk electrode current changes rapidly ($\sim 10^{-4}$ sec) and smoothly between practically zero current and 0.500 mA without any overshoot. The behavior of E_D (curve A, Fig. 5) is governed by surface and convective diffusion processes in solution. The relatively slow, sigmoid variation in E_D with time reflects the charge necessary to oxidize any hydrogen adsorbed at −0.10V, oxidation of the disk electrode, and the time required to establish steady-state surface concentrations of Br_2 and Br^- at the disk electrode. The potential variation is smooth and of the expected shape (4).

Curve B, Fig. 5 and Fig. 6 show the response of the disk electrode when S-1 is opened. Before opening S-1, $i_D = 0.500$ mA, and $E_D = 0.935$V. On opening S-1, E_D changes rapidly ($\sim 10^{-4}$ sec) to the preselected potential, −0.10V without overshooting. The disk-electrode current-follower potential, Fig. 6, shows a

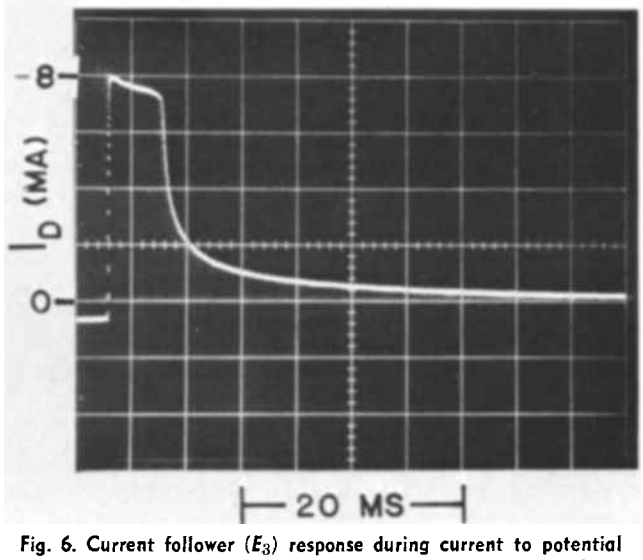

Fig. 6. Current follower (E_3) response during current to potential control switching under Fig. 4 conditions. 5 msec/major div. horizontal axis. From left, constant current (+ 0.50 mA) switched to constant potential (−0.10V).

relatively flat region for about 5×10^{-3} sec, followed by the expected current variation for a disk electrode potential step (5). The initial flat current region is caused by voltage limiting of the control amplifier, as was verified in three different ways. First, oscilloscopic observation of the output potential of amplifier A-1 demonstrated voltage limiting for about 5×10^{-3} sec. Second, halving the initial anodic current decreased the length of the initial flat region by ~30%. Third, the output of the control amplifier was biased 9V using a Kepco Precision Voltage Source in the sense required to overcome the external ohmic potential drop, and the experiment shown in Fig. 6 repeated. The length of the flat current region was reduced to $\sim 2 \times 10^{-3}$ sec.

Ring-disk electrode.—The potentio-galvanostatic circuitry in Fig. 1 was incorporated into circuit 2, which independently controls disk and ring electrode potentials. Ring electrode potentials and currents were observed on opening and closing S-1. The ring electrode potential was unaffected, and ring electrode currents had the expected nonsteady-state shapes (6).

Changing E_1 by a potential step of ± 1.1V produced no detectable changes in the potentials or currents at the ring or disk electrodes while S-1 was closed.

Interrupter application.—Switching the potentio-galvanostat from a controlled potential to a zero controlled current state produces the equivalent of a potentiostatic interrupter experiment. Hence it is possible to measure the true potential of the indicator electrode and calculate the uncompensated ohmic drop between the reference and indicator electrodes. The frequency and time of the interruption period are readily controlled by applying a suitable signal to the logic gate of the Burr-Brown FET switch. Such signals are readily obtained from a number of pulse generators and, in the interrupter experiment reported below, we have used a General Radio Model 1340 Pulse Generator.

The test-circuit of McIntyre and Peck (7) was employed to examine the interrupter performance of the potentio-galvanostat. This circuit differs from the test cell shown in Fig. 1, in that $R_7 = 420$ ohms and R_8 was replaced by a 50-ohm resistor, the uncompensated cell resistance, in series with a parallel *RC* network ($R = 100$ ohms, $C = 8.6$ μf), to simulate the equivalent circuit of a disk electrode. An additional 20 Kohm resistor was inserted in the lead to A-2 (Fig. 1) to represent the resistance of the Luggin capillary and reference electrode.

Approximately 80 μsec pulses, at a repetition rate of about 2270 Hz were used to gate the FET switch, thereby imposing a controlled potential of 1.50V or a zero current state at the indicator electrode. These conditions correspond to an uncompensated ohmic potential drop of 0.50V. The results of two pulses are shown in Fig. 7. The uncompensated ohmic drop was obtained from the intersection at 1.0V of the two stages of potential decay. The rapid potential change immediately after interruption is 5 divisions or 0.50V, in excellent agreement with the actual uncompensated ohmic potential drop in the test circuit. The slower potential change visible at longer times after interruption corresponds to the voltage decay within the *RC* circuit. Removal of the gate pulse switches the circuit back to potentiostatic control, with barely detectable potential overshoot. Depending on the application envisioned, pulse width and repetition frequency can be adjusted over very wide limits. The pulse width may, in many situations, be made narrow enough to make unimportant any relaxation of the electrode potential during the interrupt time interval. Thus, the circuit in Fig. 1 is well adapted to use as a repetitive interrupter for applications which require monitoring (or recording) of the true potential of an electrode.

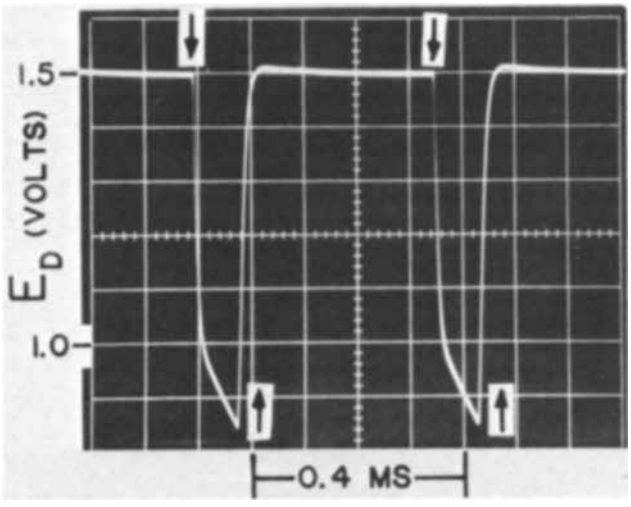

Fig. 7. Potentiostatic interrupter mode. 80 μsec gate pulse width, repetition rate 2270 Hz. Two interruptions shown; ↓ S-1 closed (switch to zero current), ↑ S-1 opened. Horizontal axis 100 μsec/major div. Vertical axis 0.10 V/major div. Cell description, see text.

It is to be kept in mind that test cell switching time is a property of the particular combination of logic pulse rise time, switch operating time, and amplifier slew rates. There is no reason to believe that, where required, the circuit principle cannot be extended to over-all switching times considerably better than those cited here (~ 10 μsec) by choice of faster operating components, either currently or soon to be available from a rapidly developing technology.

Conclusion

The potentio-galvanostat circuit described in this paper permits switching from a controlled electrode potential to a controlled electrode current situation and *vice versa* without introducing spurious potentials or currents in an electrochemical cell. The performance of the circuit in one state is identical to that of an individual potentiostat and in the other is comparable to that of a more conventional galvanostat. The general principle described may be used to switch other potentiostat configurations to galvanostats. Alternatively, a potentiostat may be added to an existing galvanostat using the second loop principle without loss of control during switching.

The potentio-galvanostat may also be used as a transient free interrupter by rapidly switching to a zero controlled current, if S-1 is a FET switch whose gate is driven by an appropriate signal.

An Experimental Study of Nonuniform Current Distribution at Rotating Disk Electrodes

Stanley Bruckenstein*,[1] and Barry Miller*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The theoretical predictions of Newman (1, 2) concerning the existence of a nonuniform current distribution at rotating disk electrodes have been verified in media containing insufficient supporting electrolyte. Measurements of the thickness of copper films deposited on a platinum disk yield results qualitatively of the form predicted by Newman. The primary current distribution is approached at currents corresponding to a small fraction of the limiting convective diffusion current in the absence of appreciable supporting electrolyte, while a uniform current distribution is found in the limiting current region. Nonuniform current distribution at a disk electrode has been found to have significant effects on the collection efficiency of a ring-disk electrode. These effects depend markedly on the geometry of the electrode. Similar behavior has been noted in the currents observed at "shielded" rings of ring-disk electrodes. Under conventional polarographic conditions in solutions containing fifty- to a hundred-fold excess of supporting electrolyte, no significant deviations from a uniform disk current distribution could be detected.

The theory of ring-disk electrodes has been developed assuming Levich's concept of uniform accessibility of the disk electrode. Recently (1,2), Newman has calculated the effect of the ohmic potential drop outside the diffusion layer of a disk electrode using Laplace's equation, considering the cases of (*a*) a single salt, and (*b*) a diffusing species present in excess electrolyte. In the absence of a large excess of supporting electrolyte, he concluded that there will not be a radially independent current density at a disk

electrode except for the limiting current region and discussed several generalized situations.

In the case where the current passed through the disk electrode is much less than the limiting current and the exchange current, we combine his (2) Eq. [30] and [36] to obtain

$$J = \frac{r_0}{k_0} \frac{di}{d\eta_s}\Big|_0$$

where k_0 is the specific conductance of the particular solution, r_0 is the radius of the disk electrode, $di/d\eta_s|_0$ is the slope of the disk current-overpotential curve at zero current, and J is a parameter used in Fig. 2 of Newman's paper (2). This figure shows that a uniform current density is approached only when $di/d\eta_s|_0$ is small. The initial slope is small only for irreversible reactions and will be higher for more reversible couples. In the limit, for a reversible couple, the current density at the center of the electrode is one half of the average current density, as is the case for the primary current distribution. Note that these conclusions hold only when concentration polarization may be ignored.

Newman has compared his theoretical calculations to an experiment involving copper deposition from 0.1*M* $CuSO_4$ at a rotating disk electrode, obtaining fair agreement between theory and experiment (2). Further experimental studies of the magnitude of this effect in the presence of varying amounts of supporting electrolyte seem to us to be quite important since it would be incorrect to use existing ring-disk theory in solutions which yield significantly nonuniform disk electrode currents. We have used three approaches.

First, thin copper deposits have been plated on a rotating disk electrode, and their thickness measured with the aid of a Talysurf surface roughness instrument (4). We find that the deposit thickness increases with the radial coordinate under Newman-type conditions and that it is independent of radius under Levich-type (uniformly accessible) conditions.

Second, we have used the novel approach of Albery and Ulstrup (5). They showed, theoretically, that the collection efficiency of a thin ring-thin gap ring-disk electrode reflects the concentration profile at the outer edge of the disk. Under Newman-type conditions the disk electrode current densities are higher at the edge than under Levich-type conditions; hence higher values of N should be observed when significant nonuniform disk electrode currents exist. Qualitatively, the same conclusions should hold for all geometries of ring-disk electrodes. However, Albery and Ulstrup's experimental study of NaBr-$HClO_4$ solutions yielded N-values in agreement with, or lower than those calculated using the assumptions of a uniform disk current (5). We have repeated some of their experiments with three different ring-disk electrodes of widely different geometries in NaBr-$HClO_4$ solutions, and, contrary to them, always find N-values equal to or greater than the geometrical N-value, as their theory for Newman-type conditions predicts. The Albery-Ulstrup approach has been used by us in two other experiments, involving electrochemical oxidation of a Cu disk in NH_3-$(NH_4)_2SO_4$ solutions and a Ag disk in $HClO_4$ solutions and collection of the metal ion at a ring electrode. Again we find N-values that are equal to or greater than the theoretical value.

Third, we have used ring-disk electrodes with insulating gaps of radically different thicknesses to determine the ring current for the oxidation of Br^- to Br_2 in solutions containing different concentrations of $HClO_4$. During this experiment the potential of the ring electrode was held at the instantaneous potential of the disk electrode. If a uniform current density exists at the disk electrode, the ratio $i_r/i_d = \beta^{2/3} - N$ (7), where $\beta = (R_3^3 - R_2^3)/R_1^3$, and R_3, R_2, and R_1 are the outer and inner radii of the ring and the disk radius, respectively. As $R_2 - R_1 \rightarrow 0$ and $R_3 - R_2 >>$ $R_2 - R_1$ (thin gap, thick ring electrode) $i_r/i_d \rightarrow (R_3^2 - R_2^2)/R_1^2$. This result is the equivalent of considering a thick ring-thin gap ring-disk electrode to be a disk electrode of radius R_3 for which it is possible to measure the current in the regions $0 \leq r \leq R_1$ and $R_1 \leq r \leq R_3$ separately.

Under Newman-type conditions, the current density increases across a disk as the radial distance grows larger. Hence the average current density in the region $R_2 \leq r \leq R_3$ (ring electrode) will be higher than that in the region $0 \leq r \leq R_1$ (disk electrode). Thus, for all ring-disk electrode geometries i_r/i_d should be greater than $\beta^{2/3} - N$ or greater than $(R_3^2 - R_2^2)/R_1^2$ at a ring-disk electrode with a thin gap and thick ring. As reported below, we have found this to be the case for the oxidation of Br^- in the presence of insufficient supporting electrolyte.

The use of a thick ring-thin gap ring-disk electrode to test for nonuniformity of current distribution has recently been suggested by Marathe and Newman (3), who propose comparing the ring and disk current densities when both electrodes are held at the same potential. As shown above, this is merely the limiting case in comparing values of $\beta^{2/3} - N$.

Experimental

Reagents.—All chemicals were of reagent grade. House distilled water was doubly distilled from quartz and collected in quartz.

Ring-disk electrodes and control circuitry.—Experiments involving the determination of the collection efficiency of copper in NH_3—$(NH_4)_2SO_4$ mixtures and of silver in perchloric acid solutions used epoxy-type electrodes and the circuit reported by Miller (6), while all other experiments used Teflon-type platinum ring, platinum disk electrodes (Pine Instrument Company, Grove City, Pennsylvania) and the circuit reported by Bruckenstein and co-workers (7). A Honeywell Model 580 X-Y recorder was used.

All electrodes were ground and polished using standard techniques. The final finish was produced using 0.3μ alumina.

All experiments were performed at room temperature (23°C).

Measurement of copper film thickness on disk electrodes.—The thickness of deposited copper films was measured using a Taylor-Hobson Ltd. Talysurf Model 4 stylus-type surface roughness instrument. The accuracy obtainable is of the order of 5% (4) and in our experiments seems to be determined primarily by the smoothness of the copper deposit. The Talysurf device conveniently measures step heights and its 0.3μ full-scale and 1.0μ full-scale ranges were used. These steps were produced in our copper experiments by covering exactly half the copper-plated platinum disk electrode with Scotch Brand electroplaters' tape and dissolving the unprotected copper with a few drops of concentrated nitric acid. The electrode surface was then immediately washed with water, the electroplaters' tape removed, and the entire electrode surface rinsed with acetone. The disk electrode was mounted on a micrometer stage positioned on the bed of the Talysurf instrument, and the stage adjusted so that the step between the copper-plated surface and the platinum surface was at right angles to the direction of travel of the diamond stylus. A 2 in. diameter aluminum rod of length equal to the disk electrode was also fastened to the micrometer stage. This rod was necessary to support the shoe affixed to the arm holding the diamond stylus of the Talysurf instrument. The center of the disk electrode was located using the micrometer stage to measure the diameter and setting the stage at the calculated position. Repetitive measurements indicate that the disk electrode center can be located to within 0.003 cm. Step heights

were determined at intervals of about 0.06 cm along the step.

Results and Discussion

Copper film thickness measurements.—The radial flux dependence across a disk electrode was determined by plating approximately 2.7 coulombs/cm^2 of copper metal at 900 rpm on a platinum disk electrode at specified fractions of the limiting current and measuring the film thickness using the Talysurf instrument. This charge corresponds to an average thickness of $\sim 10^{-4}$ cm.

Marathe and Newman (3) have discussed the importance of keeping the deposit thickness considerably less than the momentum boundary layer, and our deposit thickness corresponds to a smaller fraction of the momentum boundary layer than in their experiments. Copper was plated from a solution 3.0 m*M* in $CuSO_4$ and 0.2 m*M* in $HClO_4$ before and after adding known amounts of $NaClO_4$. The results obtained are shown in Fig. 1 in which L/L^0 is plotted *vs.* r/R_1. L^0 represents the thickness of the deposit at the center of the electrode while L represents the deposit thickness at a distance of r from the center of a disk electrode of radius R_1.

Within the experimental error, the thickness of the copper plate is independent of r if copper is plated on the convective-diffusion limiting current region in the solution containing no added $NaClO_4$. This result is in agreement with the predictions made by Newman (2). Marathe and Newman (3) were unable to perform an equivalent experiment because their deposit became powdery.

In this same solution, if the copper is plated at 20% of the limiting current, marked deviations from the uniform flux condition exist. The results of this experiment are indistinguishable from the theoretical curve derived assuming the primary current distribution first calculated at a disk electrode by Newman (1). Newman's result for the primary current distribution can be rewritten in the form

$$\frac{L}{L^0} = \frac{1}{(1 - (r/R_1)^2)^{1/2}}$$

and is the dashed line shown in Fig. 1.

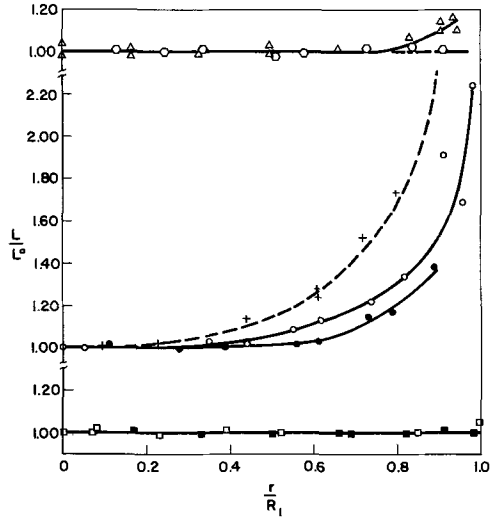

Fig. 1. Effect of supporting electrolyte on the radial dependence of the thickness of a deposited Cu film. 2 x 10^{-3}M $CuSO_4$ + 2 x 10^{-4}M $HClO_4$, platinum disk electrodes of $R_1 \simeq 0.394$ cm used. Rotation speed = 900 rpm (15.00 Hz). Average film thickness = 1.0μ. Key: □, on limiting current; +, 20% of limiting current; ○, 4.2 x 10^{-3}M $NaClO_4$ added, 20% of limiting current; ●, 4.2 x 10^{-2}M $NaClO_4$ added, 20% limiting current; △, 0.10M $NaClO_4$ (total) added, 20% of limiting current; ⬡, 50% of limiting current; ■, 0.40M $NaClO_4$ (total) added, 20% of limiting current.

As $NaClO_4$ is added to the original solution, the film thickness becomes more uniform, but it is only when as much as 0.4*M* $NaClO_4$ is present that a uniformly thick film of copper deposits at 20% of the limiting current. No significant deviations from a radially uniform deposit can be detected in 0.1*M* $NaClO_4$ solution at 50% of the limiting current.

If we neglect individual differences in ionic equivalent conductivities, the above results suggest that no appreciable deviation from Levich's assumption of uniform accessibility will occur provided at least a fifty-fold excess (on a normality basis) of supporting electrolyte is present and currents measured are in excess of 20% of the limiting current.

Collection efficiency measurements.—Oxidation of NaBr.—The collection efficiency at a platinum ring electrode for the reduction of Br_2 (produced by oxidation of Br^- at a platinum disk electrode) was studied in a 3.0 m*M* NaBr solution as a function of $HClO_4$ concentration using three different ring-disk electrodes. The collection efficiency was determined by scanning an anodic current, i_d, through the disk electrode linearly with time and measuring the ring electrode current, i_r, at 0 volt *vs.* SCE. i_d was plotted *vs.* i_r on an X-Y recorder. In all cases, this plot was a straight line and independent of scan direction provided, (*i*) the disk electrode potential did not become so positive that electrode oxidation occurred, and (*ii*) the electrode was briefly cathodized in the solution being studied to reduce thoroughly the platinum disk surface. If these precautions are not observed, $i_d - i_r$ plots become nonlinear at positive potentials, and the apparent collection efficiency becomes smaller than the theoretical value.

The results of the experiments are shown in Fig. 2 in which N_c/N is plotted *vs.* log C_{HClO_4}/C_{NaBr}. N_c is the observed value of N at c molar $HClO_4$, while N is the value observed when $C_{HClO_4}/C_{NaBr} > 100$. The latter value always agreed within a per cent or so of the theoretical value, N_{theor}, in our experiments and did not change detectably on adding excess perchloric acid.

With all three electrodes, $N_c/N \geqq 1$, as was predicted by Albery and Ulstrup but not observed by them when they performed this identical experiment. The reasons for the experimental discrepancy between our

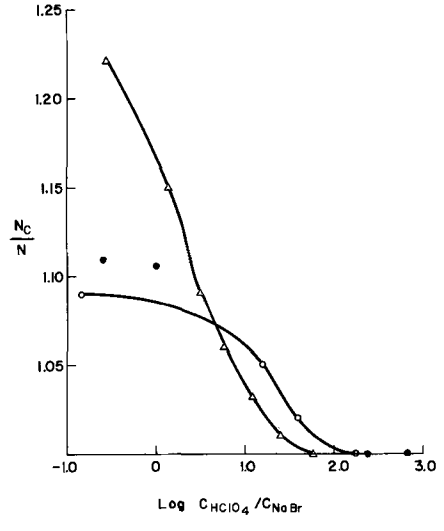

Fig. 2. Effect of C_{HClO_4} on the collection efficiency of ring-disk electrodes. Disk electrode reaction $2Br^- \rightarrow Br_2 + 2e$, ring electrode reaction, $Br_2 + 2e \rightarrow 2Br^-$. Key: △, $C_{NaBr} = 3.6 \times 10^{-3}$M, $N = 0.173$, and $\beta^{2/3} = 0.335$ (thin gap, thin ring electrode); ●, $C_{NaBr} = 3.6 \times 10^{-3}$M, $N = 0.399$, and $\beta^{2/3} = 1.16$ (thin gap, wide ring electrode); ○, $C_{NaBr} = 1.73 \times 10^{-2}$M, $N = 0.399$, and $\beta^{2/3} = 1.16$ (thin gap, wide ring electrode). Rotation speed = 2500 rpm (41.67 Hz).

results and those of Albery and Ulstrup is not clear; however, Albery and Hitchman (8) have confirmed that $N_c/N \geq 1$ on repeating one of our experiments.

The extent of deviation of N_c from N is a function both of the geometry of the ring-disk electrode and the amount of supporting electrolyte present. The largest deviation in 1 m*M* $HClO_4$ is observed with a thin gap, thin ring electrode, $N_c/N = 1.22$ (Δ in Fig. 2). The deviation is smaller for an electrode with a wider gap (○ and ● in Fig. 2). For an electrode with an extremely wide gap (N = 0.079 and $\beta^{2/3} = 0.73$) the value of $N_c/N = 1.02$ in a solution for which $C_{NaBr} = 3.6 \times 10^{-3}M$ NaBr and $C_{HClO_4} = 1.00 \times 10^{-3}M$. N_c/N *vs.* log C_{HClO_4}-data for the latter electrode are so close to 1.00 they are not plotted in Fig. 2. Thus, it appears that, for a given disk electrode radius, the wider the gap between the ring and disk electrodes, the more the concentration profile at the inside edge of the ring approaches the Levich situation. This result is seen by the simple analogy of fluid flowing in a tube into which a solute is injected upstream. The further downstream an observer is positioned, the less able he is to detect whether or not the solute was injected uniformly throughout a given upstream volume element.

On the basis of Fig. 2, it seems valid to conclude for ring-disk electrodes of the usual geometries that a fifty-fold excess of perchloric acid is sufficient to eliminate the possibility of detecting, through N, the effect of any nonuniform current distribution during the oxidation of Br^- at the disk electrode. Since the collection efficiency of a wide gap electrode is extremely insensitive to any nonuniform disk current distribution, such an electrode should prove quite valuable in situations where only the average flux leaving the disk need be determined.

Oxidation of metals.—A copper-disk, gold-ring electrode was used to study the collection efficiency of Cu(I) produced by oxidizing the copper disk in ammoniacal media. The current scanning technique used for the bromide studies was employed. The ring process was Cu (I) → Cu(II) + e and the ring current was proportional to the anodic disk current. As seen in Table I, $N_c/N_{theor} = 1.09$ in 0.1*M* NH_3 and is within a per cent of unity when $C_{NH_4^+} \geq 0.02M$.

A silver disk, graphite ring electrode was used to study the effect of C_{HClO_4} on N_c/N_{theor}. In these experiments silver dendrites grew very rapidly at the ring electrode, and the ring current for the reduction of silver increased with time at a constant anodic disk current. Therefore, N_c was obtained from the ring current extrapolated back to zero time. The results of these experiments are also shown in Table I. In 0.1*M* $HClO_4$, $N_c/N_{theor} = 1.00$ and does not change for $C_{HClO_4} = 1.0M$.

In both of these experiments, the electrode geometry is one that has been used fairly extensively in other studies. These electrodes are not overly sensitive to a nonuniform current distribution at the disk. The maximum disk current levels used in the above experiments correspond to disk electrode surface concentrations of 0.5 m*M* Cu (I) and 1.0 m*M* Ag (I). The appreciable positive effect in 0.5 m*M* $HClO_4$ for silver corresponds to the case in which the supporting electrolyte is not in excess of the surface concentration of the electrogenerated species. Supporting electrolyte concentrations approximately 50-100 fold larger than the surface concentrations were required to approach N_{theor} within 1%.

[b] $N_{theor} = 0.348$, silver disk, graphite split ring, split corrected for in calculating N_{theor}, $i_d = 100$ μA and 200 μA at each C_{HClO_4}. Average N_c/N_{theor} reported. Rotation speed = 2000 rpm (33.3 Hz). $R_1 = 0.227$ cm, $R_2 = 0.259$ cm, and $R_3 = 0.324$ cm.

Effect of supporting electrolyte on the ratio of ring and disk currents.—A plot of anodic ring electrode current *vs.* anodic disk electrode current was obtained for two ring-disk electrodes in 3.6×10^{-3} *M* NaBr solution containing 1.00 m*M* $HClO_4$. The ring potential was maintained equal to the disk electrode potential while the current through the disk electrode was scanned linearly with time. Next, sufficient concentrated $HClO_4$ was added to make the solution 0.2*M* in acid, and the previous experiment repeated. Both experiments yielded straight line plots, provided the electrode potential did not become so positive that platinum surface oxidation occurred. The slopes of these plots correspond to $\beta^{2/3}-N$ and are given in Table II, along with the theoretical values for $\beta^{2/3}-N$ calculated from the electrode geometry.

The higher current density at the ring electrode as compared to that at the disk electrode in the absence of excess supporting electrolyte is confirmed by the data in Table II.

The principal difference between the geometries of electrodes 1 and 2 (Table II) is in the width of the ring electrode. In such a situation, it is expected that the electrode with the narrower ring (electrode 1) should have the higher average current density arising from the nonuniform current density distribution caused by the absence of excess supporting electrolyte. This is the case, since the ratio of $\beta^{2/3}-N$ in the presence and absence of excess $HClO_4$ is greater for electrode 1, whose ring is about half the width of that of electrode 2.

Visual evidence for nonuniform current distribution.—A simple experiment can be performed which dramatically demonstrates the effects of a nonuniform current distribution at a disk electrode. First, copper is deposited on a rotating platinum disk electrode from a solution containing 3.0 m*M* $CuSO_4$ and 0.2 m*M* $HClO_4$ under conditions which yield a uniform deposit, *i.e.*, at a potential in the limiting current region. The amount of copper is not critical, and for demonstration purposes 5-10 min of deposition at 900 rpm produces a clearly visible deposit. Next, an anodic current equal in magnitude to the convective diffusion limiting current is passed through the electrode. As shown above by the collection efficiency studies involving the oxidation of copper and silver disks, the copper disk will be oxidized nonuniformly because of the lack of excess supporting electrolyte. Rather larger current densities are to be expected at the edge of the disk as compared to the center of the disk. Visual examination of the disk during the oxidation step produces the following observations which can only be explained by the more rapid oxidation of copper at the edge of the disk. First, immediately after starting the oxidation cycle, no visible change of the electrode

Table II. Effect of supporting electrolyte concentration on $\beta^{2/3}$-*N*

Solution	$\beta^{2/3}$-*N* for electrode 1[a]	$\beta^{2/3}$-*N* for electrode 2[a]
$3.6 \times 10^{-3}M$ NaBr + 1.0 m*M* $HClO_4$	0.45	1.25
$3.6 \times 10^{-3}M$ NaBr + 0.200*M* $HClO_4$	0.19	0.78
Theoretical value	0.17	0.76

[a] Rotation speed = 2500 rpm (41.67 Hz).

surface occurs. Then, a perfectly concentric band of platinum becomes visible at the edge of the disk, and the width of this band increases with time as the central area of the disk covered with copper shrinks. Ultimately the area covered by copper becomes zero. If the oxidation of the copper is interrupted some time after the outer platinum band becomes visible and the electrode is examined under 10X magnification, the border between the copper and platinum is seen to be very sharply defined. This result clearly demonstrates that the current density at the edge of the copper deposit is very much higher than the average current density.

Conclusions

Nonuniform current distribution effects at a rotating disk electrode, as predicted by Newman (2) and experimentally verified in a 0.1*M* $CuSO_4$-0.1*M* H_2SO_4 solution by Marathe and Newman (3), have been studied as a function of supporting electrolyte concentrations using a number of redox systems. A fifty-fold excess of supporting electrolyte is sufficient to produce a uniformly accessible disk surface during the deposition of Cu(II) from $NaClO_4$ media, provided the applied current exceeds 20% of the limiting current. The effects of nonuniform accessibility on the collection efficiency of a ring-disk electrode predicted by Albery and Ulstrup (5) have been observed and depend on the electrode geometry. Thin ring-thin gap electrodes are most sensitive to nonuniform current distribution effects, while extremely wide gap electrodes show barely detectable effects. The magnitude of the quantity $\beta^{2/3}$-N of a ring-disk electrode is also sensitive to nonuniform current densities at a disk electrode.

For practical purposes, results obtained with a ring-disk electrode in the presence of a 50 to 100-fold excess of supporting electrolyte may be assumed to be free of problems arising from nonuniform current density effects.

The Transient Regime of the Anodic Dissolution of a Three-Valent Metal Proceeding in Two Steps under Galvanostatic Conditions

I. H. Plonski*

Institute for Atomic Physics, Bucharest, Romania

ABSTRACT

The transient regime of the anodic dissolution of a three-valent metal, proceeding in two steps under galvanostatic conditions, is studied for the particular case when $z_1 = 1$, $z_2 = 2$ and $i_{01} > i_{02}$. It has been found in going from low to high current densities that the $\eta - t$ curve changes its shape, namely: for $i < i_{cr1}$, monotone increasing η toward the steady state; for $i_{cr1} < i < i_{cr2}$, peaked-shaped $\eta - t$ curves; for $i > i_{cr2}$, monotone increasing η toward the steady state again. Under particular conditions of $[M^+]_0$ values, the overvoltage peak may disappear for $i_{cr1} < i < i_{cr2}$. At the same time the $[M^+]_0 - t$ curves have shapes depending on the i and $[M^+]_0$ values. The steady-state value of the intermediate ion concentration increases with increasing current density, passes through a maximum, and then, for very high values of i, decreases toward zero. The decay curves do not display a peak. An apparent remanent overvoltage is noticed, especially for high values of $[M^+]_0$, when the decrease of $[M^+]$ toward $[M^+]_0$ is slow in comparison with the decrease of η toward zero.

In the present paper, the third of a series (1, 2) on the subject of the transient regime of two stepwise-proceeding electrode reactions, the case of the anodic dissolution of a three-valent metal is considered. The complete system of equations, describing the stepwise metal dissolution

and

$$\frac{d[M^{(z_1+z_2)+}]}{dt} = \frac{i_{02}}{z_2\mathbf{F}}\left(\frac{[M^{z_1+}]}{[M^{z_1+}]_0}\,e^{\alpha_{a2}\eta} - \frac{[M^{(z_1+z_2)+}]}{[M^{(z_1+z_2)+}]_0}\,e^{-\alpha_{c2}\eta}\right) + D_2\left(\frac{\partial M_2}{\partial x}\right)_{x=0} \quad [3]$$

Here, η is the overvoltage, t the time, C the double layer capacity, i the current density, i_{01} and i_{02} the exchange current densities for the first and second step, respectively, $\mathbf{F}$ the Faraday number, $[M^{z_1+}]$ and $[M^{z_1+}]_0$ the intermediate ion concentration, $[M^{(z_1+z_2)+}]$ and $[M^{(z_1+z_2)+}]_0$ the final ion concentration at the electrode surface at the time t and at equilibrium; z_1 and z_2 are the number of electrons involved in the first and second step, respectively, and α_{a1}, α_{c1}, α_{a2}, and α_{c2} are given by the expressions: $\alpha_{a1} = \beta_1 z_1\mathbf{F}/RT$; $\alpha_{c1} = (1-\beta_1)z_1\mathbf{F}/RT$; $\alpha_{a2} = \beta_2 z_2\mathbf{F}/RT$; $\alpha_{c2} = (1-\beta_2)z_2\mathbf{F}/RT$ with β_1 and β_2 the symmetry factors for the first and second step, respectively, R the gas constant, and T the absolute temperature; the M_1 and M_2 are the concentrations of the intermediate and final ion, respectively, in the bulk of the solution; the terms $D_1\left(\frac{\partial M_1}{\partial x}\right)_{x=0}$ and $D_2\left(\frac{\partial M_2}{\partial x}\right)_{x=0}$ represent the rate of the appearance (or disappearance) of the respective ion at the electrode surface due to mass transfer.

In order to investigate the behavior of the electron transfer in a first approximation, the final ion concentration is assumed constant and the mass transfer processes are neglected. Therefore, the system of equations reduces to Eq. [1] and [2] with $D_1\left(\frac{\partial M_1}{\partial x}\right)_{x=0} = 0$.

Also, the treatment of the two mechanisms, $z_1 = 1$, $z_2 = 2$ and $z_1 = 2$, $z_2 = 1$, each of them for $\frac{i_{01}}{z_1} > \frac{i_{02}}{z_2}$, $\frac{i_{01}}{z_1} = \frac{i_{02}}{z_2}$ and $\frac{i_{01}}{z_1} < \frac{i_{02}}{z_2}$ in both anodic and cathodic directions, would be interesting, but the computations are very laborious so we studied only the case of $z_1 = 1$, $z_2 = 2$, and $\frac{i_{01}}{z_1} > \frac{i_{02}}{z_2}$. We also take $\beta_1 = \beta_2 = 0.5$, i.e., $\alpha_{a1} = \alpha_{c1} = \alpha$; $\alpha_{a2} = \alpha_{c2} = 2\alpha$.

Steady State, the Moment of Switching on the Current, and Their Critical Values

Under steady-state conditions the values of $[M^{z_1+}]$ and η, marked by the index ∞, are given by (1)

$$\frac{[M^{z_1+}]_\infty}{[M^{z_1+}]_0} = \frac{\frac{z_2}{z_1}\frac{i_{01}}{i_{02}}\,e^{\alpha_{a1}\eta_\infty} + e^{-\alpha_{c2}\eta_\infty}}{\frac{z_2}{z_1}\frac{i_{01}}{i_{02}}\,e^{-\alpha_{c1}\eta_\infty} + e^{\alpha_{a2}\eta_\infty}} = \frac{2\frac{i_{01}}{i_{02}}\,e^{\alpha\eta_\infty} + e^{-2\alpha\eta_\infty}}{2\frac{i_{01}}{i_{02}}\,e^{-\alpha\eta_\infty} + e^{2\alpha\eta_\infty}} \quad [4]$$

and

$$i = \frac{z_1+z_2}{z_2}\,i_{02}\,\frac{e^{(\alpha_{a1}+\alpha_{a2}+\alpha_{c1})\eta_\infty} - e^{-\alpha_{c2}\eta_\infty}}{1+\frac{z_1}{z_2}\frac{i_{02}}{i_{01}}\,e^{(\alpha_{a2}+\alpha_{c1})\eta_\infty}} = \frac{3}{2}\,i_{02}\,\frac{e^{4\alpha\eta_\infty} - e^{-2\alpha\eta_\infty}}{1+\frac{i_{02}}{2i_{01}}\,e^{3\alpha\eta_\infty}} \quad [5]$$

Equation [4] is evaluated for different values of η_∞ and $\frac{i_{01}}{i_{02}}$. The results are given in Fig. 1, from which we can note the following:

1. The intermediate ion concentration increases with increasing η_∞, passes through a maximum value, and decreases then toward zero.
2. The maximum value of $[M^+]_\infty$ and the overvoltage or the current density at which it is attained increase with increasing of the ratio $\frac{i_{01}}{i_{02}}$.

By forming the derivative of Eq. [4] and equating it to zero we obtain the expression of $\eta_{\infty[M^+]_{\infty\,\max}}$

$$\eta_{\infty[M^+]_{\infty\,\max}} = \frac{1}{3\alpha}\ln\frac{\left(1-\frac{i_{02}^2}{2i_{01}^2}\right)+\sqrt{\left(1-\frac{i_{02}^2}{2i_{01}^2}\right)-\frac{i_{02}^2}{4i_{01}^2}}}{\frac{i_{02}}{2i_{01}}} \quad [6]$$

from which in conjunction with Eq. [4], we obtain the maximum value of $[M^+]_\infty$ attainable for a given system.

The value of η_∞ for which the steady-state value of $[M^+]$ equals its equilibrium value results from Eq. [4]

$$\eta_{\infty[M^+]_\infty} = [M^+]_0 = \frac{1}{\alpha}\ln\frac{i_{01}+\sqrt{i_{01}^2-i_{02}^2}}{i_{02}} \quad [7]$$

Transient Regime

Because the system is too intricate to be used in the discussion of the critical values of i and η_∞ from which the $\eta - t$ curves can change their shapes we consider for a moment, as in the previous paper (1), that the capacitive current density is negligible, that is

$$i_{\mathbf{F}} = i_{01}\left(e^{\alpha_{a1}\eta} - \frac{[M^{z_1+}]}{[M^{z_1+}]_0}\,e^{-\alpha_{c1}\eta}\right) + i_{02}\left(\frac{[M^{z_1+}]}{[M^{z_1+}]_0}\,e^{\alpha_{a2}\eta} - e^{-\alpha_{c2}\eta}\right) = i \quad [8]$$

and

$$\frac{d\eta}{dt} = \frac{(i_{02}\,e^{\alpha_{a2}\eta} - i_{01}\,e^{-\alpha_{c1}\eta})\,[(z_1+z_2)\,i_{01}i_{02}(e^{(\alpha_{a1}+\alpha_{a2})\eta} - e^{-(\alpha_{c1}+\alpha_{c2})\eta}) - i\,(z_2\,i_{01}\,e^{-\alpha_{c1}\eta} + z_1\,i_{02}\,e^{\alpha_{a2}\eta})]}{N} \quad [9]$$

where

$$N = z_1z_2\,\mathbf{F}[M^{z_1+}]_0\,\{(\alpha_{c1}+\alpha_{a1})i_{01}^2\,e^{(\alpha_{a1}-\alpha_{c1})\eta} + (\alpha_{c2}+\alpha_{a2})\,i_{02}\,e^{(\alpha_{a2}-\alpha_{c2})\eta} + i_{01}i_{02}[(\alpha_{c2}-\alpha_{c1})\,e^{-(\alpha_{c1}+\alpha_{c2})\eta} + (\alpha_{a2}-\alpha_{a1})\,e^{(\alpha_{a1}+\alpha_{a2})\eta}] - i(\alpha_{a2}\,i_{02}\,e^{\alpha_{a2}\eta} + \alpha_{c1}\,i_{01}\,e^{-\alpha_{c1}\eta})\}$$

It can be seen from Eq. [9] that $\left.\frac{d\eta}{dt}\right|_{t=0} = 0$ in two particular cases:

1. When the first round bracket is zero, that is for

$$\eta_{(0+\epsilon)} = \frac{1}{\alpha_{a2}+\alpha_{a1}}\ln\frac{i_{01}}{i_{02}} \quad [10]$$

where $\eta_{(0+\epsilon)}$ is the value of η which the electrode potential assumes when the current is switched on. Because the $\eta - t$ curve, determined by Eq. [9], has no maxima, minima, or inflection points, $\left.\frac{d\eta}{dt}\right|_{t=0} = 0$ implies that $\eta_{(0+\epsilon)} = \eta_\infty$, in other words the overvoltage, attains its steady-state value from the beginning. From this critical value of η_∞, denoted by $\eta_{\infty cr1}$ (which

corresponds, in accordance with Eq. [8], to a critical value of i, denoted by i_{cr1}), the $\eta - t$ curve will change its curvature.

2. When the second bracket is zero, which is satisfied for the steady state (1), *i.e.*, for $[M^{z_1+}] = [M^{z_1+}]_\infty$. It can be seen from Eq. [4] or from Fig. 1 that $[M^{z_1+}]_0 = [M^{z_1+}]_\infty$ in two particular cases, namely; for $\eta_\infty = 0$) (*i.e.*, $i = 0$) which is an uninteresting case, and for η_∞ given by Eq. [7]. For this reason we denoted η_∞ given by Eq. [7] by $\eta_{\infty cr2}$ and its corresponding i by i_{cr2}.

In conclusion, if $C = 0$, the $\eta - t$ curve can change its curvature twice.

The fact that the double-layer capacity is in parallel with the equivalent impedance of the electrode reaction implies $\eta_{(0+\epsilon)} = 0$, *i.e.*, any real $\eta - t$ curve begins from zero, even for $i \neq 0$, with $\left.\frac{d\eta}{dt}\right|_{t=0} > 0$.

On the basis of expressions [1] and [2], theoretical curves of $\eta - t$ (Fig. 2) and $[M^+] - t$ (Fig. 3) were computed for the special case of $C = 3 \times 10^{-5}$ (**F**), $[M^+]_0 = 5 \times 10^{-11}$ ($M/1$), $i_{01} = 1 \times 10^{-4}$(A), $i_{02} = 1 \times 10^{-5}$(A) and different values of i pointed out on the figures.

From Fig. 2 the following observations are made:

1. As expected from the discussion of the case of $C = 0$, as a consequence of the competition between the charging of the double layer and the transitory electron transfer process, the $\eta - t$ curves are peak-shaped between i_{cr1} and i_{cr2}.

2. The difference $\eta_{peak} - \eta_\infty$ increases at first, passes through a maximum value, then, for $i \to i_{cr2}$, decreases toward zero. The maximum value of this difference and the corresponding i may be computed.

3. It is generally valid that the time necessary to reach the steady state decreases with increasing of i, except for i_{cr2} when the steady state of η is attained sooner. If $[M^+]_0$ is great enough, no noticeable change in the intermediate ion concentration takes place. Consequently, for i_{cr2} the $\eta - t$ curve reflects the charging of the double layer, only.

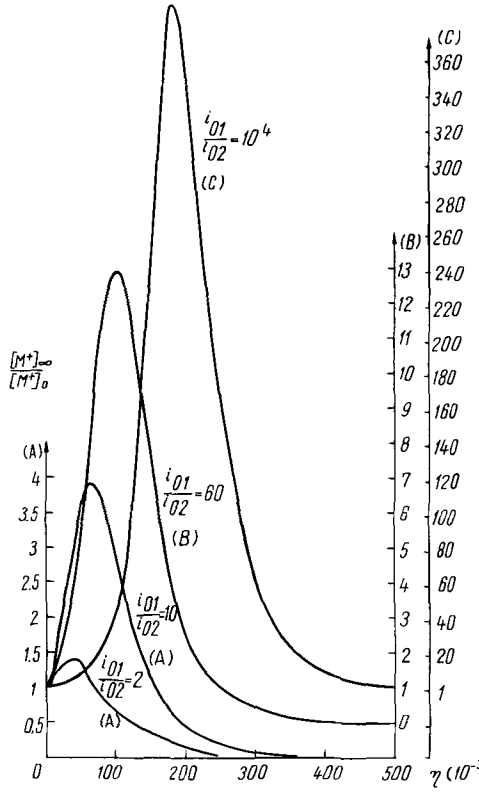

Fig. 1. Ratio between the intermediate ion concentration in the steady state and at equilibrium, $[M^+]_\infty/[M^+]_0$, as a function of steady-state overvoltage, η_∞, for different values of the ratio i_0/i_{02} written on the curves. (The capital letter on the curves indicates the ordinate.)

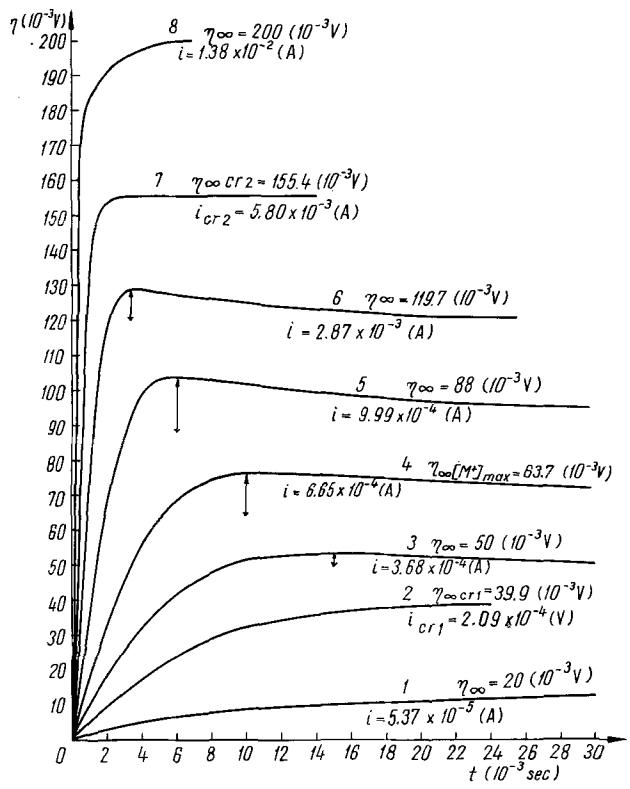

Fig. 2. Overvoltage, η, as a function of time, t, for different values of current density written on the curves. The arrows indicate the difference $\eta_{peak} - \eta_\infty$.

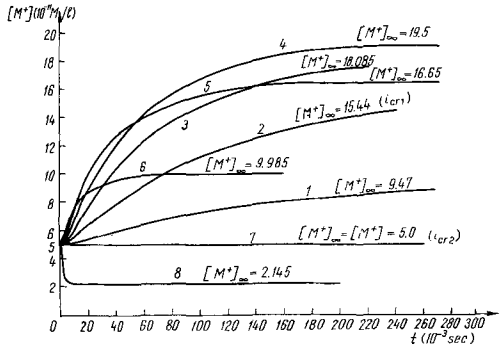

Fig. 3. Intermediate ion concentration, $[M^+]$, as a function of time, t, for the current densities corresponding to the same numbers as the curves in Fig. 2.

From Fig. 3A it may be noticed that for $i < i_{[M^+]_\infty max}$, the $[M^+] - t$ curves are S-shaped; for $i > i_{[M^+]_\infty max}$, these curves may be S-shaped or may have maxima, depending on the $[M^+]_0$ value. This is discussed later. Furthermore, the influence of the change of intermediate ion concentration at equilibrium is studied.

Due to the complexity of the expression for the production rate of the intermediate ion, $\frac{d[M^+]}{dt}$, it is difficult to discuss quantitatively the influence of the change of $[M^{z_1+}]_0$ on it, but it is known that this rate can vary between $\frac{2i_{01} - i_{02}}{2\mathbf{F}(i_{01} + i_{02})} i$ (the maximum value attainable at $t = 0 + \epsilon$ if $C = 0$) and zero (the rate at the steady state) (1).

On the other hand, it follows from Eq. [4] that the steady-state intermediate ion concentration is proportional to its equilibrium concentration.

The fact that $\frac{d[M^+]}{dt}$ cannot surpass the maximum value given before, but that $[M^+]_0$ can theoretically be as high as we desire means that the period of time necessary to attain $[M^+]_\infty$ and η_∞ increases with increasing $[M^+]_0$. This can be seen from Fig. 4A and 5A.

For large values of $[M^+]_0$ (curves c) there appears a disproportion between the period of time necessary to attain, say, 90% of η_∞ for η and the same proportion of $[M^+]_\infty$ for $[M^+]$, *i.e.*, the overvoltage increases rapidly to a value near η_∞ as $[M^+]$ changes very little.

For very low values of $[M^+]_0$ (curves a) $[M^+]$ also will have very low values; consequently, the change of the intermediate ion concentration does not affect the $\eta - t$ curves noticeably. In contrast, little changes of η lead to large changes in the $[M^+] - t$ curves, for example, the maxima presented by curves 5a and 8a.

It is interesting to notice the influence of the change of the intermediate ion concentration at equilibrium on the $\eta - t$ curves for $i_{cr1} < i < i_{cr2}$, *i.e.*, for the domain of possible peak-shaped $\eta - t$ curves. For very low values of $[M^+]_0$ (curve 4a, Fig. 4A), when the overvoltage attains for the first time the value of η_x, the intermediate ion concentration attains the $[M^+]_\infty$ value too, so that the steady state is established. In this case the peak disappears and the overvoltage at the plateau corresponds to η_x. For moderate values of $[M^+]_0$ (curves 4b, Fig. 4A) because at the very moment when η attains the value of η_∞ first, $[M^+]$ is far from its steady-state value, η increases continuously and then decreases to η_∞. The peak appears. The difference $\eta_\infty - \eta_{peak}$ increases with increasing $[M^+]_0$ approaching its maximum value given by the difference $\eta_\infty - \eta_{(0+\epsilon)}$. For very high values of $[M^+]_0$ (curve 4c, Fig. 4A), we have an apparent disappearance of the peak. The slope of the decrease of η from η_{peak} to η_∞ being very little, a pseudoplateau is established so that η_{peak} and η_∞ cannot be distinguished experimentally.

The effect of $[M^+]_0$ on the shape of $\eta - t$ curves will be explained clearly by means of an equivalent scheme which will be given elsewhere.

In addition to this, the following observations are made from Fig. 5A:

1. The $[M^+] - t$ curves have shapes depending on the value of $[M^+]_0$ besides the value of i.
2. For large values of $[M^+]_0$, the $[M^+] - t$ curves are only S-shaped (curves c).
3. For an intermediate value of $[M^+]_0$ (curves b) and $i > i_{[M^+]_\infty max}$, the $[M^+] - t$ curves may be S-shaped for lower values of i and may display maxima for larger currents.
4. For low values of $[M^+]_0$ and $i > i_{[M^+]_\infty max}$ all $[M^+] - t$ curves display maxima even for the case of $[M^+]_\infty = [M^+]_0$ (not given on the figure) or of $[M^+]_\infty < [M^+]_0$ (curve 8a). The maximum transition value of $[M^+]$, attainable in this case, is the greater the lower is the value of i, but can never surpass the maximal value of $[M^+]$ given by Eq. [4] in conjunction with Eq. [6].

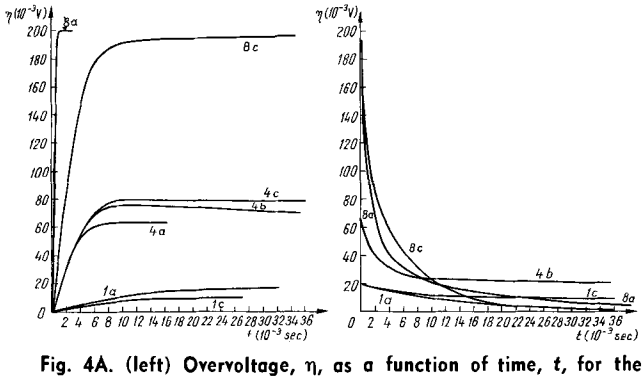

Fig. 4A. (left) Overvoltage, η, as a function of time, t, for the current densities corresponding to the same numbers as the curves in Fig. 2 and to the following values of initial intermediate ion concentration, $[M^+]_0$: curves a, $[M^+]_0 = 5 \times 10^{-13}$ M/l; curves b, $[M^+]_0 = 5 \times 10^{-11}$ M/l; curves c, $[M^+]_0 = 5 \times 10^{-10}$ M/l.

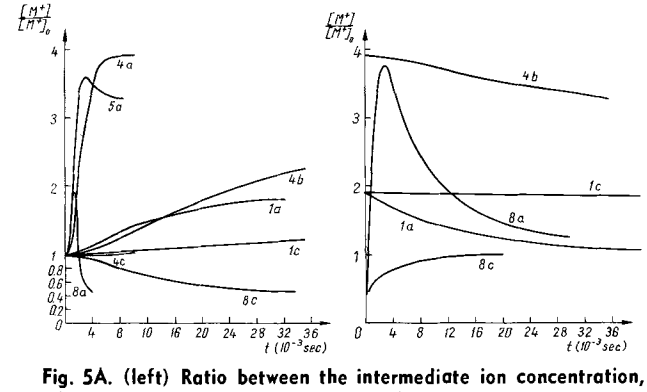

Fig. 5A. (left) Ratio between the intermediate ion concentration, $[M^+]$, and its value at equilibrium, $[M^+]_0$, as a function of time, t, corresponding to the curves in Fig. 4A. The upper abscissa is valid only for curve 8a.

Fig. 5B. (right) Ratio between the intermediate ion concentration and its value at equilibrium, $[M^+]/[M^+]_0$ as a function of time, t, corresponding to the curves in Fig. 5A.

Decay Curves

The decay curves were computed on the basis of Eq. [1] and [2] with η_∞ and $[M^+]_\infty$ as initial values of η, $[M^+]$, and $i = 0$, in other words we consider that the current is switched off after the reaching of the steady state. Some specific curves corresponding to the curves of Fig. 4A and 5A are given in Fig. 4B and 5B.

From Fig. 4B two observations are made:

1. The decay curves are monotone, η decreasing toward zero. No peak, which would imply transitory negative values of η, is noticed.
2. From a certain time, the decrease toward the steady state is slow so that an apparent remanent overvoltage may be noticed experimentally (curves 1c and 4b).

From Fig. 5B characteristic shapes of $[M^+] - t$ curves as functions of i and $[M^+]_0$ values result.

1. For $i < i_{cr1}$, curves 1, $[M^+]_0$ is monotonously decreasing. For high values of $[M^+]_0$, curve 1c, the decrease of the intermediate ion concentration is very slow, so that when the electrode potential approaches a pseudoplateau of η, $[M^+]$ is diminished very little.
2. For $i_{cr1} < i < i_{cr2}$, curve 4b, $[M^+]$ decreases following an S-shaped $[M^+] - t$ curve.
3. For $i > i_{cr2}$, $[M^+]$ increases to the equilibrium value following a simple monotonously increasing curve for high values of $[M^+]_0$, curve 8c, or following a peak-shaped curve for very low values of $[M^+]_0$.

Conclusions

1. The appearance of $\eta - t$ curves with peaks in a certain domain of i in the anodic dissolution of a trivalent metal may prove a stepwise mechanism in which $z = 1$, $z = 2$, and $i_{01} > i_{02}$.
2. The absence of $\eta - t$ curves with peaks does not prove that the dissolution is not proceeding stepwise. In this case attention must be given not to confuse η_∞ with η_{peak}.
3. The decay curves do not have peaks. Due to an apparent remanent overvoltage and $[M^+]$, attention must be paid not to apply a second current pulse too soon, because this second pulse would start with com-

pletely different initial values than the equilibrium values corresponding to the former pulse.

4. By anodic dissolution of a three-valent metal, proceeding in two steps which were dealt with above, intermediate ion concentrations higher than a critical value cannot be obtained.

Manuscript received Feb. 17, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1971 JOURNAL.

Faradaic Impedances: Diffusion Impedance and Reaction Impedance

Israel Epelboin* and Michel Keddam

Groupe de Recherche du C.N.R.S., "Physique des Liquides et Electrochimie," associé à la Faculté des Sciences, 9, quai Saint-Bernard, Paris 5°, France

ABSTRACT

Relative contributions of double-layer and faradaic impedances have been studied for two typical cases involving important electrochemical processes. The faradaic impedance has been interpreted quantitatively in terms of models which describe either the mass transport or the reaction mechanism at the electrode. The first case is the electrochemical reduction of the I_3^- ion at a rotating platinum disk in the presence of a supporting electrolyte (KI 0.1*N*). The mass transport impedance has been computed by means of a Laplacian transformation of the impulsional response of the system. It is shown that this impedance accurately follows an expression based on Nernst's hypothesis. The diffusion layer thickness, determined by means of impedance measurements, is in agreement with that deduced from hydrodynamic data. The second case is the anodic dissolution of iron in aqueous sulfuric acid at different pH's. The steady-state current-potential curves and the complex impedance in the whole frequency range, between 30 kHz and 10^{-5} kHz, have been interpreted in terms of a dissolution mechanism in two steps involving an adsorbed FeOH intermediate.

Despite the capacitive behavior of the over-all impedance of an electrode in the high-frequency range, separating the double-layer impedance from the faradaic impedance is very difficult, and often impossible, when rapid electrode reactions occur. For slow electrochemical processes, the theoretical justification of an *a priori* distinction between double-layer charging and charge transfer is still controversial (1), even in the presence of a supporting electrolyte (2) and in the absence of specific adsorption.

In this article, the problem has been approached from an experimental point of view, turning to account the complete analysis of variations of the impedance of the electrode up to its limit at zero frequency. For this purpose, we chose two markedly different electrochemical systems, the first having a diffusion impedance, the second a reaction impedance. The two examples are the polarographic discharge of the I_3^- ion at a platinum electrode, and the anodic dissolution of iron in an acidic medium, respectively. In both cases, exact determination of faradaic impedance is an effective method for testing the validity of models that describe mass transport or the succession of heterogeneous reaction steps at an electrode surface. In the first system, the presence of a supporting electrolyte and the limiting of the reaction rate by a slow process, *i.e.*, convective diffusion, are favorable conditions for distinguishing between double-layer capacity and faradaic impedance. On the other hand, neither of these conditions is satisfied in the second example, and separation seems more delicate.

Experimental

Compounds.—Water for electrolyte solutions was distilled and then treated on an ion exchange resin. Reagents such as I, KI, H_2SO_4, and Na_2SO_4 were analytically pure (Merck).

Electrodes and cell.—Platinum was provided by the Lyon-Allemand Laboratories (Paris) and iron, spectroscopically pure, by Johnson-Matthey Chemicals Ltd. (London). The disk electrode is made up of a cylindrical cross section whose surface is isolated by a polyolefinic thermoretractable sheath. The surface in contact with the electrolyte is treated with emery paper (600 grade), then polished with alumina or diamond paste (7 μm).

The rotation speed of the disk, driven by an asynchronous motor, is checked by a stroboscope and is stable to better than 1%. A double compartment saturated calomel reference electrode (SCE) is directly immersed in the cylindrical glass cell, maintained at 25° ± 0.1°C by water circulation. The counterelectrode is a coaxial platinum mesh having a large surface area.

Electronic set-up.—A detailed description of the potentiostatic apparatus, essentially a wide-band potentiostat (PZ1 Electronique Appliquée, Paris), has been given elsewhere (3, 4). Impedances have been determined by two methods: the one using a sinusoidal potential, the other an impulsion technique. For frequencies f greater than 0.01 kHz, measurements have always been carried out under sinusoidal conditions with an impedance meter giving the phase and modulus of the impedance (3). For frequencies below 0.01 kHz, different methods have been used in the two cases considered: (*i*) for I_3^- discharge, impedance is deduced from the response of the system to a small amplitude step by means of a Laplacian transformation in real terms. Impedances were electronically computed; (*ii*) for iron dissolution, impedance is determined by means of Lissajous' oscillographic method

Results and Discussion

Diffusion impedance: polarographic discharge of an ion.—The over-all electrochemical reaction in aqueous solutions is

$$I_3^- + 2e^- \rightarrow 3I^-$$

The presence of the supporting electrolyte KI (0.1*N*) allows us to neglect all coupling between layer charging and charge transfer. For the same reason, electrical migration does not contribute to transport of the I_3^- ion, which is solely due to convective diffusion. Use of a rotating disk electrode ensures that the diffusion layer is of uniform thickness at the electrode surface (uniformly accessible surface). Figure 1 shows a group of current-potential curves $I = f(V)$ obtained, for solutions 2.44 x 10^{-3} M in I_3^-, at different rotation speeds Ω (in rpm). We have checked that the limit currents are proportional to $\Omega^{1/2}$ under conditions of laminar flow, in conformity with hydrodynamic theory. Impedance diagrams in the complex plane $Z = R - jG$ have been recorded under the same conditions as for Fig. 1. An example is given in Fig. 2 for a potential of 0.25 V/SCE and a rotation speed Ω = 900 rpm. Diffusion impedance Z_d and transfer resistance R_t then have comparable values. The double-layer capacity C_d, in parallel with R_t, gives rise to the circular part of the

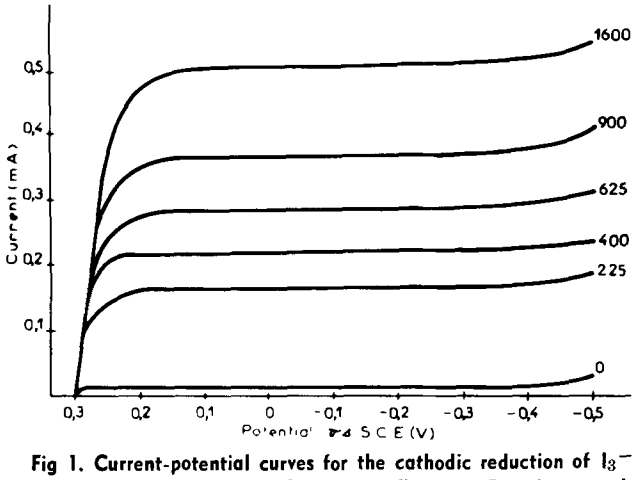

Fig 1. Current-potential curves for the cathodic reduction of I_3^- at a rotating platinum disk 0.4 cm in diameter. Rotation speeds Ω in rpm; $[I_3^-]$ = 2.44 x 10^{-3}M; [KI] = 0.1M; temperature, 25° ± 0.1°C.

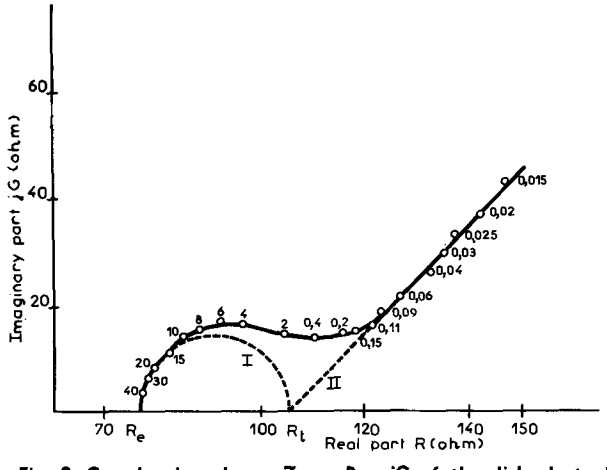

Fig. 2. Complex impedance $Z = R - jG$ of the disk electrode measured under the same conditions as for Fig. 1 (Ω = 900 rpm; V = 0.25 V/SCE). Experimental points correspond to frequencies in kHz. Dotted lines: I = C_d shunted by Z_f; II = Warburg's impedance (see Eq. [1]).

diagram between 40 and 0.2 kHz (line I, in Fig. 2). For this frequency range, C_d can be calculated as 8 μF · cm^{-2}. As well as the resistance of the electrolyte R_e, the capacity C_d is independent of the rotation speed of the disk, and hence of the concentration of I_3^- in the interface. After correcting the total impedance for the effect of C_d by assuming it to be of constant value (8 μF · cm^{-2}) in parallel with the faradaic impedance, we verify that this result is in agreement with the role of KI as supporting electrolyte. It is to be noted that the pretreatment of the electrode surface is of great importance: a diamond-polished disk gives a double-layer capacity almost three times as large as that for an alumina-polished disk.

After eliminating C_d, presumed to be in parallel with the faradaic impedance $Z_f = R_t + Z_d$, we verify that, for frequencies greater than about 10 Hz, the frequency dependence of the diffusion impedance can be expressed by Warburg's formula

$$Z_d = \frac{A}{\sqrt{j\omega}} \qquad [1]$$

where A = constant and $\omega = 2\pi f$. A straight line of slope unity (line II, in Fig. 2) corresponds to this equation.

Analysis of the variation of the diffusion impedance for frequencies below 0.01 kHz, measured by the method given in the experimental section, shows that Z_d no longer obeys Eq. [1], but can be accounted for satisfactorily by the analytical expression [2]

$$Z_d = \frac{R_d \operatorname{th} \sqrt{j\omega\, \delta^2/D}}{\sqrt{j\omega\, \delta^2/D}} \qquad [2]$$

based on the assumption (4, 5, 6) that transport is due exclusively to diffusion through an electrolyte layer of thickness δ and with a diffusion coefficient D (Nernst's hypothesis). It can be easily ascertained that for sufficiently high frequencies (th $\sqrt{j\omega\, \delta^2/D} \sim 1$), Eq. [2] becomes Eq. [1].

To illustrate the good agreement between theory and experiment, we list in Table I the values of δ_1 and δ_2 calculated from Eq. [2] at different rotation speeds, for two different frequency ranges; Table I also gives the thickness of the Nernst layer calculated from the hydrodynamic equation for a rotating disk, Eq. [3]

$$\delta_N = 1.61 \left(\frac{D}{\nu}\right)^{1/3} \left(\frac{\nu}{\Omega}\right)^{1/2} \qquad [3]$$

where ν denotes the kinematic viscosity of the solution. Table I shows that δ_1 and δ_2 values, obtained from diffusion impedance measurements, are indeed independent of frequency, which is in agreement with Eq. [2]. Furthermore, it can be seen from the last column of Table I that the thickness thus determined is accurately proportional to $\Omega^{-1/2}$.

Table I. Determination of the Nernst layer thickness, δ, by diffusion impedance measurements (diffusion coefficient D = 1.13 x 10^{-5} cm^2 sec^{-1}; kinematic viscosity ν = 0.00874 cm^2 sec^{-1})

Reaction impedance: anodic dissolution of iron.—The over-all anodic reaction in aqueous sulfuric acid is

$$Fe \rightarrow Fe^{2+} + 2e^-$$

The rate of this reaction increases with increasing electrolyte pH, as shown by the current-potential curves (Fig. 3). Curves 1 to 4 correspond to pH values of 0.03, 1.61, 2.68, and 3.50, respectively. The electrode rotation speed (2000 rpm) is sufficiently high to make all effects of mass transport on dissolution rate negligible, even for the highest anodic currents reached here. These curves have been corrected for ohmic drop, previously determined either by an interruptor method (7) or from the high frequency limit of the impedance. The current-potential curves tend, for high anodic potentials, to a common line, independent of pH. For lower anodic potentials, these curves become almost parallel; the reaction is then nearly first order in OH^-, as can be calculated from the following equation

$$\left(\frac{\partial \log I}{\partial pH}\right)_V = -\left(\frac{\partial \log I}{\partial V}\right)_{pH}\left(\frac{\partial V}{\partial pH}\right)_I$$

This result strongly supports one of the mechanisms proposed by Bockris, Drazič, and Despič (8) which implies the formation of an adsorbed FeOH intermediate. On the other hand, the hypothesis that FeOH acts as a catalyst, suggested by Heusler (9), which predicts a reaction order of 2 tending to 1 for high anodic polarizations (7), must be rejected. The mechanism proposed in ref. (8) involves the following steps

$$Fe + (OH^-)_{ads} \underset{K_1'}{\overset{K_1}{\rightleftharpoons}} (FeOH)_{ads} + e^- \qquad [I]$$

$$(FeOH)_{ads} \xrightarrow{K_2} (FeOH)^+ + e^- \qquad [II]$$

$$(FeOH)^+ + H^+ \rightleftharpoons Fe^{2+} + H_2O \qquad [III]$$

In step [I], the adsorbed hydroxyl gives an adsorbed $(FeOH)_{ads}$ intermediate. In step [II], iron would leave the lattice as a cation $(FeOH)^+$; then, in step [III], would pass into the solution as a Fe^{2+} ion. This reaction mechanism can be accounted for, if step [III] is neglected, by calculations similar to those already used in the case of hydrogen evolution (10) and iron dissolution (11). Steps [I] and [II] being simultaneous, we shall consider they occur on fractional electrode areas of $(1 - \theta)$ and θ, respectively; according to the Langmuir isotherm, the fraction θ is covered by a monolayer of FeOH. The relationship between current and potential can then be expressed (7) as

$$I = \frac{2FK_1K_2\beta\,[OH^-]}{K_1[OH^-] + (K_1' + K_2)\,\beta} \qquad [4]$$

where β denotes the maximum superficial density of $(FeOH)_{ads}$. The electrochemical rate constants K_1, K_1', and K_2 of steps [I] and [II] are supposed to follow Tafel's law

$$K_i = k_i \exp b_i V$$

where k_i is the pre-exponential rate constant and b_i the Tafel exponent.

If the anodic potential is sufficiently high, the rate constant K_1' of the reverse reaction in step [I] can be neglected in the denominator of Eq. [4]. If we define the partial currents I_1 and I_2, determined by the rates of reactions [I] and [II], as

$$I_1 = 2F\,K_1[OH^-] \qquad [5]$$

and

$$I_2 = 2F\,K_2\,\beta \qquad [6]$$

expression [4] then simplifies to

$$I = \frac{I_1 I_2}{I_1 + I_2} \qquad [7]$$

and the coverage coefficient can be expressed as

$$\theta = \frac{I_1}{I_1 + I_2} \qquad [8]$$

According to Eq. [7], when the potential increases steps [I] and [II] become successively rate determining, in an order which depends on the relative values of b_1 and b_2. These two coefficients can be determined by means of the curves in Fig. 3.

1. In a range from 4 to 100 mA, the form of the $I = f(V)$ characteristics is in agreement with Eq. [7] (4, 7).
2. When the anodic polarization is low, the curves tend toward the straight lines I_{1A}, I_{1B}, I_{1C}, and I_{1D} (Fig. 3, in dotted lines) which represent the variations of the current I_1, following Eq. [5], their common slope being $b_1 = 36V^{-1}$.
3. When the anodic polarization is very high, the curves approach a common asymptote I_2 (dotted line), which is in agreement with Eq. [6], its slope being $b_2 = 10.5V^{-1}$.
4. Below 4 mA, the experimental plot deviates from the I_1 lines, because of the influence of cathodic reactions (reverse reaction in step [I], reduction of dissolved oxygen, discharge of the solvated proton). Moreover, partial coverage by adsorbed hydrogen diminishes the effective area of the electrode (7).

Taking into account the sign of $(b_1 - b_2)$, it is found, from Eq. [8], that the degree of coverage by $(FeOH)_{ads}$ increases with increasing anodic potential, reaches 0.5 for $I_1 = I_2$ (points N_1, N_2, N_3, or N_4, in Fig. 3), then tends toward 1.

By studying the relaxation of θ, by analysis of the faradaic impedance Z_f, we should be able to confirm these first results. In fact, by assuming that the potential V undergoes sinusoidal oscillations of very small amplitude and of frequency f, we have deduced from Eq. [4] an expression for Z_f; this expression, already proposed elsewhere (4), can be simplified under conditions where K_1' is negligible (this is the case for $I >$ 4 mA), and becomes

$$\frac{1}{Z_f} = \frac{FK_1\,[OH^-]\,K_2\beta}{K_1\,[OH^-] + K_2\beta}\left[\, b_1 + b_2 + \frac{(K_2\beta - K_1\,[OH^-])\,(b_1 - b_2)}{j\,\omega\,\beta + K_1\,[OH^-] + K_2\beta}\,\right] \qquad [9]$$

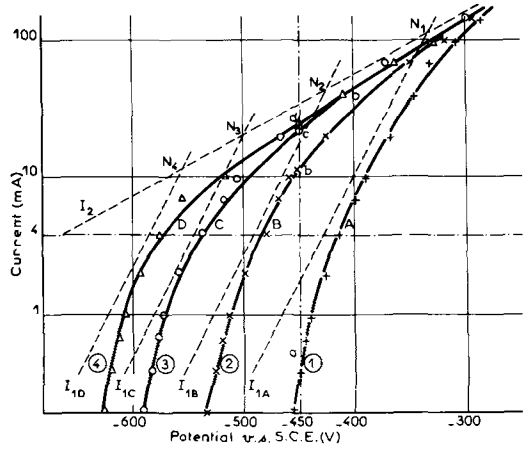

Fig. 3. Steady-state current-potential curves for the anodic dissolution of a rotating disk of Johnson-Matthey iron 0.5 cm in diameter. (Ω = 2000 rpm; temperature, 25° ± 0.1°C.) + Curve 1: H_2SO_4 1M, pH = 0.03; × curve 2: H_2SO_4 0.1M, Na_2SO_4 0.9M, pH = 1.61; ● curve 3: H_2SO_4 0.01M, Na_2SO_4 0.99M, pH = 2.68; △ curve 4: H_2SO_4 0.0012M, Na_2SO_4 1M, pH = 3.50. Continuous line = experimental curves; dotted line = partial currents deduced from Eq. [15] and [6].

In terms of Eq. [5], [6], and [7], Eq. [9] becomes

$$\frac{1}{Z_f} = \frac{I}{2}\left[b_1 + b_2 + \frac{(b_1 - b_2)(I_2 - I_1)}{2\mathbf{F}j\omega\beta + (I_1 - I_2)} \right] \qquad [10]$$

This expression, a rational fraction in $j\omega$, corresponds to an equivalent scheme whose elements are independent of frequency and depend on potential only through currents I, I_1, and I_2 defined above. Since $b_1 > b_2$, the reactive element of the scheme will be a capacity for $I_1 > I_2$ (*i.e.*, for potentials more anodic than those corresponding to points N_1, N_2, N_3, or N_4, in Fig. 3) and a self-inductance in the contrary case.

The four diagrams of Fig. 4, 5, 6, and 7 which correspond to this last case, have been recorded under the same conditions (of pH and polarization) as points A, B, C, and D in Fig. 3. We verified in all cases that the extrapolated impedance at zero frequency is equal to dV/dI.

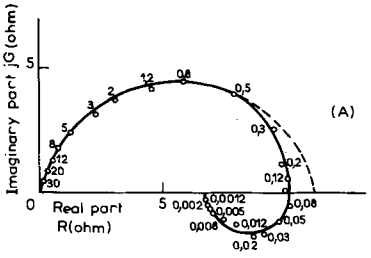

Fig. 4. Complex impedance $Z = R - jG$ for an iron anode under the same conditions as for Fig. 3. (A) represents the polarization point.

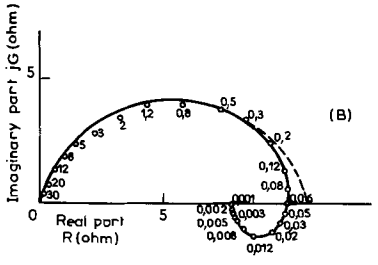

Fig. 5. Complex impedance $Z = R - jG$ for an iron anode under the same conditions as for Fig. 3. (B) represents the polarization point.

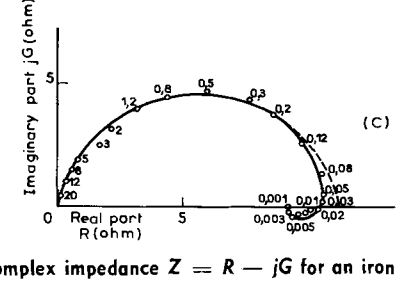

Fig. 6. Complex impedance $Z = R - jG$ for an iron anode under the same conditions as for Fig. 3. (C) represents the polarization point.

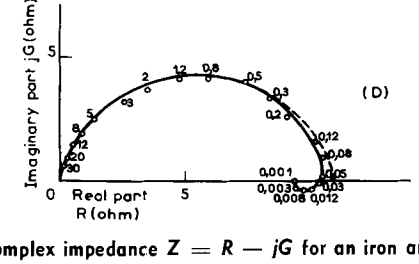

Fig. 7. Complex impedance $Z = R - jG$ for an iron anode under the same conditions as for Fig. 3. (D) represents the polarization point.

The variations of the experimental impedance with frequency are in agreement with the theoretical expression of Z_f (Eq. [10]), if the electrochemical double layer is taken into account. This layer introduces a capacitive contribution on the over-all impedance Z in the high-frequency range.

The inductive behavior of Z_f is shown in the $Z = R - jG$ diagrams by (*a*) a maximum of the real component R, and (*b*) a negative value of the imaginary component G.

Using these results, we tried to determine the equivalent circuit elements in order to compare them with values calculated by means of Eq. [10] which can also be expressed as

$$\frac{1}{Z_f} = \frac{1}{R_t} + \frac{1}{jL\omega + \rho} = \frac{1}{R_t} + \frac{1}{\rho(1 + j\omega\tau)}$$

where

the transfer resistance

$$R_t = \frac{2}{I(b_1 + b_2)} \qquad [11]$$

the faradaic resistance

$$\rho = \frac{2(I_1 + I_2)}{I(b_1 - b_2)(I_2 - I_1)} \qquad [12]$$

the faradaic time-constant

$$\tau = \frac{L}{\rho} = \frac{2\mathbf{F}\beta}{I_1 + I_2} \qquad [13]$$

A numerical analysis (carried out in collaboration with J. C. Lestrade) of the diagrams in Fig. 4 to 7 reveals that it is impossible to describe adequately the experimental results by assuming that the equivalent scheme of Eq. [10] is shunted by a constant capacity. We have therefore represented the observed systematic deviation by a distribution of the capacitive time-constant in the high frequency range, about a characteristic value τ_{HF}. For this purpose, two empirical relations, frequently adopted in dielectric relaxation studies, have been used. The first one, of a symmetrical type (12), leads to an expression of the over-all impedance of the electrolyte, including the resistance of the electrolyte

$$Z = R_e + \left\{ \frac{1}{R_t}\left[1 + (j\omega\,\tau_{HF})^{\gamma}\right] + \frac{1}{\rho(1 + j\omega\tau)} \right\}^{-1} \qquad [14]$$

The second one is of an asymmetrical type (13)

$$Z = R_e + \left\{ \frac{1}{R_t}(1 + j\omega\,\tau_{HF})^{\gamma} + \frac{1}{\rho(1 + j\omega\tau)} \right\}^{-1} \qquad [15]$$

where γ is a nondimensional number between 0 and 1.

Parameters R_e, R_t, τ_{HF}, γ, ρ, and τ have been determined by means of the least-squares method applied to nonlinear complex functions, in the same manner as for certain relaxation problems already studied in our laboratory (14). The calculations have been carried out on a IBM 360/75 computer. These results are presented in Table II, with their confidence interval calculated on the 10% level of significance (15). They indicate that the two resistances R_e and R_t are scarcely affected by the adopted distribution law, whereas the characteristic elements of low frequency behavior of the system, *i.e.*, ρ and τ, depend markedly on this law. The data in the third column are deduced from steady-state measurements, corresponding to Fig. 3, by means of Eq. [11], [12], and [13]. The value of β adopted in Eq. [13], *i.e.*, 3×10^{-9} cm^{-2}, corresponds to a FeOH layer on the plane (110) of the α-Fe crystal lattice. Agreement between measured (columns 1 and 2) and calculated (column 3) values is quite good except for τ. The differences observed in the case of the time-constant might be explained by the fact that the theory

based on the Langmuir isotherm assumes that all sites on the electrode surface are equivalent, a situation that cannot be realized because, among other reasons, of the polycrystalline structure of the electrode used.

Conclusions

Separation of the double-layer capacity and faradaic impedance, for the polarographic discharge of I_3^-, leads to the conclusion that the diffusion impedance at the surface of a rotating disk can be satisfactorily calculated in terms of the model of the Nernst layer and shows that the Warburg impedance is a limiting case.

The analysis of an iron anode impedance, in H_2SO_4 aqueous solutions, reveals that the double-layer impedance cannot be described as a constant capacity in parallel with the faradaic impedance. However, a partial separation of respective contributions of these two impedances, by means of empirical relationships, made it possible to compare the experimental data with a mechanism implying that dissolution occurs in two steps (8). Inductive impedances, quite comparable to that of an iron anode, are well-known in the case of certain biological systems involving membranes (16). As for the metal-electrolyte interface, evidence for such an impedance was obtained in our laboratory in 1952 (17). However, in the present article, an interpretation of inductance in terms of a faradaic process is given for the first time.

Technical Notes

Potential Oscillations of the H_2-CO System at Low CO Content

S. Szpak

Naval Weapons Center, Corona Annex, Corona, California

This communication considers the development of potential oscillations in a gas-diffusion electrode operating under galvanostatic conditions. Qualitatively, results seem to agree with those reported recently by Deibert and Williams (1). The essential difference appears in the frequency and the potential range in which they occur.

Present address: Chemical Laboratory, Mare Island Naval Shipyard, Vallejo, California 94542.

Experimental

The experimental arrangement was patterned after Will (2), except for details in the construction of the working electrode. Will's "inverted pore" was replaced by a "slit-electrode," assembled as follows: two platinized platinum foils, of equal areas by charging curve measurements, mounted in plastic frame were assembled to form a narrow slit (0.236 cm) configura-

tion. The extent of immersion of the electrode assembly, *i.e.*, the film length h, was determined by the use of a cathetometer. The electrode was operated at constant gas composition (99.7% H_2 + 0.3% CO) and pressure slightly higher than atmospheric and controlled by a needle valve in the exit stream.

To assure the reproducibility of results, the following procedure was adapted: totally immersed electrode was subjected to an anodic potential of +1.8V (*vs.* H_2 electrode in the same solution) followed by cathodic potential of −0.5V for 30 sec, each. Entrapped gaseous reaction products (O_2, H_2 respectively) were removed from the space between platinum foils by withdrawal of the electrode assembly from the solution. After exposure to the reactant for 10 min, the working electrode was immersed again, adjusted to the desired depth and equilibrated for at least 20 min. It is noteworthy that for pure hydrogen this procedure yielded results identical to those of an inverted pore.

Development of Potential Oscillations

The necessary condition for the development of potential oscillations are the existence of film of critical length, the presence of two component reactive gas mixture, and constant current from an external source within a rather narrow range of current. No potential oscillations were observed when the film length exceeded 0.3 cm, or when pure hydrogen, or hydrogen diluted with an inert gas, was used. The range of current necessary to initiate and sustain periodic behavior is proportional to the film length. For example, for h = 0.07 cm, $1.0 < i_{cr} < 2.0$ mA, while for h = 0.113 cm, $1.0 < i_{cr} < 3.0$ mA.

The V/t curves, shown in Fig. 1, exhibit two distinct branches prior to the initiation of periodic behavior. The initial portion, AB, is characterized by rapid growth in potential with time, and it is usually completed within seconds after closure of the switch. The second branch, terminating at C, requires substantially longer times; in some cases, more than 20 min. This induction time for the development of periodic behavior appears to be a complex function of impressed current and depth of immersion.

Discussion

Equivalent circuit.—The stability conditions for the electrode processes can be investigated, using the concept of an equivalent circuit (3). Such a circuit, shown in Fig. 2, consists of a combination of resistance R_1 and capacitance C in series, short-circuited by resistances $R_{2,1}$,$R_{2,2}$ . . . . Resistances R_1, $R_{2,1}$,$R_{2,2}$ are the faradaic discharge resistances, *i.e.*, essentially non-ohmic in character, and C is the adsorption pseudocapacitance arising from the potential dependent surface coverages (4). The film resistance, R_f, is assumed to operate in series with R_1. Taking$R_f >> R_1$, $R_{2,n}$, and $C_{dl} << C$, we have (by Kirchhoff's law)

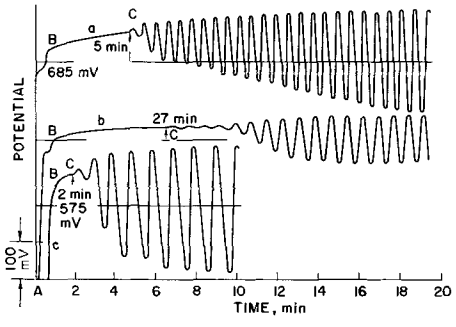

Fig. 1. Potential oscillations in gas-diffusion electrode. Electrolyte: 6 NH_2SO_4; gas composition: 99.7% H_2, 0.3% CO; pressure: 1 atm; temperature: room. Curve a: i_p = 2.0 mA, h = 0.113 cm; curve b: i_p = 1.5 mA, h = 0.113; curve c: i_p = 1.5 mA, h = 0.07 cm.

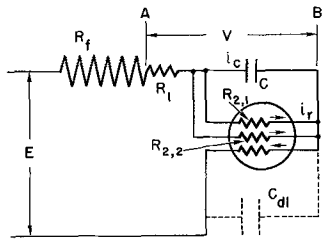

Fig. 2. Equivalent electric circuit. R_f = film resistance (ohmic); C = pseudocapacitance; C_{dl} = double layer capacitance.

$$E = R_f (i_c + i_r) + V \qquad [1]$$

where E is the time-independent potential operating across the cell and V is the experimentally measured potential. Replacing i_c and i_r by appropriate expressions containing V (*i.e.*, $i_c = C\,dV/dt$, $i_r = f(V)$) and solving for dV/dt, we get

$$\frac{dV}{dt} = \frac{1}{R_f C}[E - V - R_f f(V)] \qquad [2]$$

The conditions for potential oscillations are determined by the nature of $f(V)$ (5); this function must not be single-valued, and its derivatives at the points of stationary states (equilibrium) (6) must be positive.

Nature of $f(V)$ for H_2 + CO system.—The $i_r = f(V)$ curve is the usual steady-state potential/current relationship. For the gas-diffusion electrode, the steady-state $f(V)$ is identical with the potentiodynamic curve of $dV/dt < 100$ mV/min, and $V \leq +800$ mV, irrespective of the direction of potential sweep, as indicated by the dashed line in Fig. 3a. Considerably different behavior is observed when small amounts of CO were introduced into the hydrogen stream. Typical behavior for the latter case is shown by the solid line.

Evidently, the introduction of CO into H_2 stream resulted in non-single-valued $i_r = f(V)$ curve (ABCDA-curve in Fig. 3a). The details of this curve, for h = 0.113 cm, are shown in Fig. 3b. The characteristic points are: (*i*) if the potential sweep was reversed at $V \leq +700$ mV, the forward and reverse traces coincided; (*ii*) if the reversal of potential sweep was executed at $V > +700$ mV, a "hysteresis" was

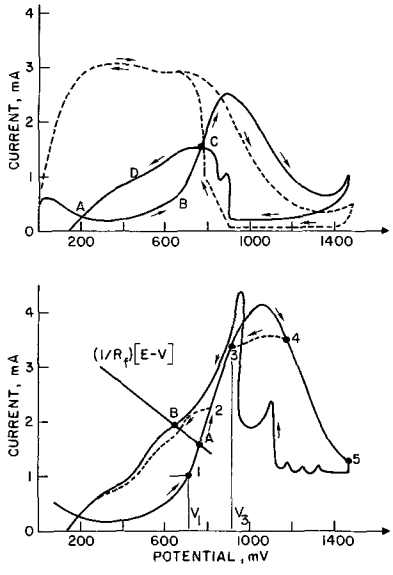

Fig. 3. Potentiodynamic i/V curves for gas diffusion electrode. (a, upper figure): dashed-pure hydrogen; solid-hydrogen containing carbon monoxide, with h = 0.07 cm, dV/dt = 75 mV/min. (b, lower figure): for hydrogen containing carbon monoxide with h = 0.113 cm, dV/dt = 75 mV/min.

observed. It is seen that the extent of hysteresis depends on the potential at which the reverse sweep took place, being essentially unaffected for $V > +900$ mV (points 3, 4, and 5 in Fig. 3b).

Assuming that the curve ABCDA (Fig. 3b) represents the required function, one seeks points of equilibrium; or, what is equivalent, the solution of [2] for $dV/dt = 0$, and determine the sign of $f'(V)$, at V_1, V_2, representing the roots of

$$\frac{1}{R_f}(E - V) = f(V) \qquad [3]$$

The simplest procedure is the graphical solution, since $f(V)$ is obtained in that form. The roots V_A, V_B are given by the intersection of a straight line $i = 1/R_f\ (E - V)$ with $i = f(V)$, as shown in Fig. 3b. It is seen that $f'(V)$ at V_1 and V_3 is positive, thus fulfilling the condition for oscillatory behavior.

Qualitatively, the above analysis is consistent with the observations, particularly with regard to the narrow range of impressed c.d., the effect of film length, and the potential range which is lower than reported by Deibert and Williams for higher CO content and different electrode geometry.

Mechanism of periodic behavior at low CO concentration.—Total constant current, i_p, can be split into the capacitance current i_c and reaction current i_r. The presence of two-component gas mixture suggests that i_r can be further split to represent the contribution due to oxidation of hydrogen and carbon monoxide. The contribution of each reaction is governed by the composition of gas mixture, the applied potential, the kinetics of individual reaction, and the effect of one reaction on the other.

The kinetics of hydrogen oxidation in a gas-diffusion electrode is limited by the transport of hydrogen across the electrolyte film (2). The kinetics of carbon monoxide oxidation is more complex. Its essential feature, as far as the development of potential oscillation is concerned, is that the oxidation rate is inversely proportional to the surface coverage, θ_{co}, and occurs at substantial rates at potential higher than +800 mV, but less than those where the formation of surface oxide exerts an inhibitive effect (7).

Assuming, as a first approximation, that the oxidation of hydrogen and carbon monoxide occurs independently, and taking into account the composition of the reacting gas (99.7% H_2, 0.3% CO), one can conclude that the reaction current is essentially due to hydrogen oxidation.

Evidently, two critical potentials exist along the ABC-curve, Fig. 3a. Below the lower critical potential, V_1, Fig. 3b, $f(V)$ is single-valued only if this potential is not exceeded on forward potential sweep. This implies that the electrode retains a steady-state surface concentration of CO, which depends on its concentration in the gas phase. As the potential is increased, the oxidation of adsorbed CO takes place, thus making additional electrode surface available for hydrogen oxidation. At sufficiently high potentials, where the oxidation of CO is controlled by diffusional transport (the upper critical potential V_3, Fig. 3b), the electrode operates essentially as a hydrogen electrode, and free from CO interference.

At intermediate points, *i.e.*, points located between the critical potentials, where the rate of CO oxidation is greater than CO adsorption, that is, where the number of "free sites" for hydrogen adsorption increases, lower potential is required to support the impressed constant current, i_p. As the potential is decreased, however, conditions favorable for CO adsorption reappear, thereby resulting in increase in potential to maintain the impressed constant current, until oxidation of CO can occur again. Thus, the cyclic process is realized.

Electrochemistry of Silver in Condensed Phosphoric Acid

David P. Lake*,[1] and John H. Kennedy

The University of California, Santa Barbara, California

Work in this laboratory (1) has demonstrated that condensed phosphoric acid [78 w/o (weight per cent) P_2O_5] is an excellent solvent for transition metal ions, and that solutions of these ions can be analyzed *in situ* by volumetric titrations with potentiometric end points. Condensed phosphoric acid offers several advantages as an electrochemical solvent, especially its wide range of operating voltage. The only electrochemical reactions taking place in the pure acid are the reduction of H^+ and the oxidation of water. The potential of H^+ reduction is slightly dependent on P_2O_5 concentration, but is at most 0.2V less than in water. However, the oxidation potential of H_2O is very dependent on P_2O_5 concentration, and the decomposition potential of 85% P_2O_5 is about 5V.

According to McMillan (2), Ag(II) is stable in strong acids for a few hours at 0°C. Davis and Lingane (3) successfully used Ag(II) as an electrolytically generated coulometric titrant in 5M HNO_3 at 0°C, but they found the other acids less successful. In light of the high stability toward oxidation exhibited by condensed phosphoric acid, a study of silver(I) oxidation was made in this electrolyte medium.

Experimental

The 78 w/o acid was prepared by adding analytical grade P_2O_5 to 85% H_3PO_4 (68 w/o P_2O_5) with heating and stirring. A liter of the acid was treated with a few drops of concentrated H_2O_2 and then heated to 300°C to decompose excess H_2O_2. The resulting water-clear solution was cooled and analyzed for P_2O_5 content. This solvent had a viscosity of 5000 centipoises at the ambient temperature of this study.

A known volume of the solvent was placed in an H-cell constructed from two 100-ml beakers connected with a tube containing a glass frit. Mounted on one side were the reference electrode, the working electrode, a silver sheet for generating Ag(I), and a magnetic spin bar. A platinum auxiliary electrode was in the other compartment. The working electrode consisted of a platinum sheet 0.226 cm^2 in area. The reference electrode was contained in an 8-mm diameter x 10 cm long glass tube with a wire sealed into the bottom end. Mercury was placed in the tube and condensed phosphoric acid poured over it. Some of the mercury was electrochemically oxidized until the acid became filled with white, solid mercury phosphate. One end of a 2 mm diameter Teflon tube filled with condensed phosphoric acid was placed inside the top of the glass tube, with the other end held with Teflon cord in the H-cell next to the working electrode. The Teflon tube was plugged with glass wool at both ends to prevent diffusion of electrochemically active ions into or out of the H-cell.

Ag(I) was generated in the stirred solution by electrochemically oxidizing the silver sheet with respect to the counterelectrode. The desired concentration was obtained by using a constant current for a predetermined time. The silver electrode was then disconnected, the platinum working electrode connected in its place, and the stirrer turned off. A Beckman Electroscan was used for constant current coulometry, chronopotentiometry and voltage sweeps.

Results and Discussion

Chronopotentiometry.—A chronopotentiometric wave, attributed to oxidation of Ag(I), was observed in solutions which were > 0.01M. For solutions containing 0.0995M Ag(I), $i\tau^{1/2}$ was 374 μA-sec$^{1/2}$ with a standard deviation of ± 2 μA-sec$^{1/2}$. The product $i\tau^{1/2}$ was reasonably constant in spite of the long transition time (385 sec) for the lowest current. Condensed phosphoric acid is sufficiently viscous that the usual problem of convective stirring was not encountered. $E_{\tau/4}$ increased from 1.45 to 1.53V with increasing current which may have been caused by the placement of the reference electrode probe, $E_{\tau/4}$ dependence on current for silver(I) oxidation cannot be ruled out. By plotting Ag(I) concentration *vs.* $\tau^{1/2}$, the diffusion coefficient was calculated to be 2.7 x 10^{-8} cm^2/sec from the slope.

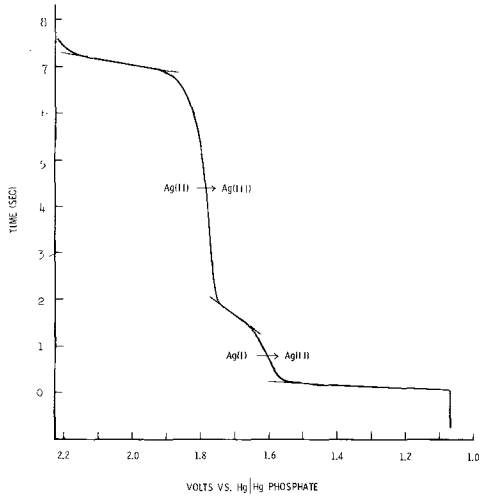

Fig. 1. Chronopotentiogram of 0.174M Ag(I) in condensed phosphoric acid. Current, 500 μA.

Reverse chronopotentiometric curves were taken, and the results are shown in Table I. The ratio τ_f/τ_r was close to three indicating a soluble product with a diffusion rate about equal to the reactant. The E° values from the forward and reverse waves compare very well, showing the reaction to be virtually reversible.

In solutions of 0.0995M Ag(I) a second wave appeared around 1.8V *vs.* Hg/Hg phosphate reference (Fig. 1). Assuming that the first wave corresponds to Ag(I) → Ag(II), the second wave could be attributed to further oxidation to Ag(III) or that either the reactant Ag(I), or the product Ag(II), exists in two forms. For example, one species may be adsorbed on the electrode. The chronopotentiometric data do not distinguish between these alternatives. Table II shows that τ_2/τ_1 for the two waves is 5-7, in poor agreement with the theoretical value of 3 for the simple process: Ag(I) → Ag(II) → Ag(III). However, the discrepancy may lie in an irreversible second reaction.

The E° values of the two electrode reactions were estimated to be $+1.47 \pm 0.02$V and $+1.70$V *vs.* Hg/Hg phosphate reference electrode from the $E_{\tau/4}$ values. However, reversibility of the second wave was not established, and thus, is only an estimate.

One other comment might be made regarding the chronopotentiometric data for the first wave. Since the ratio of τ_f/τ_r is nearly three (slightly greater), there is no fast decomposition of Ag(II). If a fast decomposition did occur, the ratio would be smaller because Ag(II) would be removed from the electrode by decomposition as well as by diffusion. Since no decomposition was indicated, Ag(II) should be reasonably stable in condensed phosphoric acid.

Scanning voltammetry.—Further information concerning silver(I) oxidation was sought from scanning voltammetry, and in particular, to identify the nature of the second oxidation step. Two anodic peaks were easily identified when solutions of Ag(I) were scanned from 1.2 to 2.1V. A typical scan is shown in Fig. 2, with data for various scan rates at two concentrations given in Table III. The value of $i_P/v^{1/2}$ was reasonably constant, even with the low scan rates because of the high viscosity of the solvent.

The separation of Ag(I) oxidation and Ag(II) reduction peaks was greater than the 58 mV theoretical value for a reversible case. However, the chronopotentiometric data for Ag(I) oxidation indicated a reversible process and for this reason it was of interest

to calculate D from the Ag(I) voltammogram peak. Values for the diffusion coefficient ranged from 2.7-2.9 x 10^{-8} cm²/sec, in excellent agreement with the value calculated from the chronopotentiometric data.

As mentioned in the section on the chronopotentiometry of Ag(I), one of the possibilities for explaining the second peak is adsorption of one of the silver species on the electrode. Wopschall and Shain, in a detailed treatment (4) showed that when the reactant was strongly adsorbed, a second peak appeared after the normal diffusion peak; and when the product was strongly adsorbed, a second peak appeared before the diffusion peak. In both cases the adsorption peak is symmetrical both in voltage and current when a triangular voltage sweep is applied.

The fact that the first peak obtained during oxidation of Ag(I) fits the theory for a diffusion-controlled process, rules out adsorption for that peak. The second peak, however, could be caused by adsorption of the reactant Ag(I). Figure 2 shows a triangular sweep with an unsymmetrical peak, indicating that it is not an adsorption peak. Wopschall and Shain also point out that a given concentration, the ratio of the adsorption peak to the diffusion peak increases with the scan rate. The data in Table III show the opposite. Thus, both tests show that the second peak is not an

adsorption peak. Since the second wave was not an adsorption peak, it is reasonable to conclude that the second oxidation step was the formation of Ag(III).

The $E°$ values of the two electrode reactions can be estimated from the peaks although strict reversibility was not established. For the first peak, this may result from some kinetic complications for the reduction of the stable Ag(II) species, since the oxidation of Ag(I) was shown to be reversible from chronopotentiometry. In any case, the estimated $E°$ values of +1.48 and +1.75V *vs.* Hg/Hg phosphate reference agree quite well with the values obtained from the chronopotentiograms.

Preparation of Ag(*II*).—In view of the indication that Ag(II) should be stable, an electrochemical preparation was carried out. A platinum electrode of about 10 cm² was placed in a 1.5 cm diameter tube. The bottom end, which was made of fritted glass, was placed along with the counterelectrode in a beaker of acid. Three cubic centimeters of 0.05M Ag(I) were placed in the tube, and oxidized with a 10V power supply. The whole apparatus was provided with a dry N_2 cover. After 1 hr there was a slight pink color near the electrode; after one week the entire solution was dark purple. The current efficiency was low because the high voltage applied also produced oxygen as a by-product.

A known volume of this solution was diluted with condensed phosphoric acid and placed in the H-cell. The voltage of the platinum working electrode was set at +0.8V, the stirrer was turned on, and the current resulting from the reduction of the purple solution was recorded. When the current had fallen to 2% of its original value, the total number of coulombs was calculated. Comparing this number with the number of moles of silver used for this coulometric titration showed that 0.94 electrons/mole participated in the reduction, thus indicating the presence of Ag(II). This solution of Ag(II) was stable at room temperature for at least several months.

The absorption spectrum (Fig. 3) showed a single band as expected for the d^9 configuration, and the molar extinction coefficient was 80 at 525 nm.

Conclusion

This study demonstrates that condensed phosphoric acid is a suitable solvent for electrochemical studies, and furthermore, the stability of Ag(II) showed the ability of this solvent to support species having a high oxidation potential. Electrochemical preparation of Ag(II) for spectral studies was accomplished, and this technique may be applied to other strong oxidants.

Earlier work (1) showed that the $E°$ of the Hg/Hg phosphate reference was +0.54V *vs.* SHE. The $E°$ values of Ag(II) and Ag(III) found in this work were +1.47 and +1.70V *vs.* Hg/Hg phosphate. When converted to the SHE scale, the Ag(I-II) and Ag(II-III) couples were +2.01 and +2.24V, respectively. Latimer (5) reports the aqueous value for Ag(II) as −1.98V

and estimates Ag(III) as about −2.1V (Latimer sign convention).

The Distribution Coefficient of Boron in Germanium

W. D. Edwards

Communications Research Centre, Ottawa, Ontario, Canada

ABSTRACT

The equilibrium distribution coefficient of boron in germanium was found to be 12.2. The variation with growth rate was interpreted in terms of a theory by Burton, Prim, and Slichter. As the growth rate was increased the width of the diffusion dominated layer initially increased followed by a later decrease. This was due to a change from a thermally produced melt flow pattern to a hydrodynamically produced pattern. The results show that a slow growth rate and a high rotation rate should be used to obtain equilibrium distribution coefficients.

The effective distribution coefficient of boron in germanium as a function of crystal growth rate has been measured by Bridgers and Kolb (1). The results were obtained for a particular crystal rotation rate of 60 rpm and an unspecified crystal growth direction. They were interpreted in terms of a theory proposed by Burton, Prim, and Slichter (2).

Boron in germanium is unusual in that the distribution coefficient is greater than one. A recent theoretical paper by Hurle and Jakeman (3) predicted anomalous results for systems with $k > 1$. Additional values of the effective distribution coefficient *vs.* growth rate for a 30 rpm rotation rate and specifically for the <111> growth direction are presented here. The departure of these results from those predicted by the theory is ascribed to the approximate equality of the thermal convection flow and hydrodynamic flow patterns at this rotation rate.

Experimental

The germanium crystals were produced by the Czochralski technique. The germanium melt was contained in a 48 mm diameter carbon crucible which was heated by a slotted carbon heater. Resistive heating gives a more massive system than is usual with induction heating. This reduces temperature gradients and gives better short term temperature stability. The furnace was evacuated and crystal growth took place in a vacuum of between 2 x 10^{-6} and 10^{-5} Torr. The seed was oriented in the <111> direction and the crystals were grown at a number of growth rates between 0.1 and 3 mm/min. A rotation rate of 30 rpm was used. Boron dissolves slowly in germanium and hence all melts were made from previously grown, boron-doped crystals. The seed to crystal joints were 2-3 mm in diameter and the growing crystals were expanded slowly so that the full diameter of ~2 cm was not reached until approximately 3 cm of crystal had been grown. The furnace gradients were such that the solid-liquid interface was slightly convex to the melt. On completion of growth the crystals were cooled to room temperature over a period of 2 hr.

Key words: germanium, boron in germanium, distribution coefficient of boron in germanium.

The completed crystals were removed from the furnace and a volume *vs.* length-grown measurement was made by liquid displacement. The crystals were then sectioned longitudinally to give parallelepiped samples suitable for two-probe resistivity measurements. Other, transverse, samples were cut so that Hall measurements could be made.

Results and Discussion

The incorporation of impurity atoms into single crystals during growth has been discussed by a number of authors (2, 4). For a liquid-solid system in equilibrium the ratio of the concentration of impurity in the solid, C_s, to that in the liquid at the interface, C_o, is defined as the equilibrium distribution coefficient, k_o. For the particular case of boron in germanium, k_o is greater than unity. Under the conditions of Czochralski crystal growth discussed here, there is a departure from equilibrium. As crystal growth proceeds boron is preferentially incorporated into the solid and, because of the limited stirring and the finite boron diffusion rate in the liquid, a boron concentration gradient is established in the liquid germanium adjacent to the liquid-solid interface. The result is less boron in the solid than expected. This departure from equilibrium may be expressed in terms of an effective distribution coefficient, k_{eff}, defined as C_s/C_l where C_l is the boron concentration in the bulk of the liquid. Burton *et al.* (1) have derived an expression relating k_{eff} to k_o in terms of the crystal growth parameters

$$k_{eff} = \frac{1}{1 + [1/k_o - 1] \exp - (\delta f/D)} \qquad [1]$$

where D is the solute diffusion coefficient in the liquid, diffusion in the solid is neglected, f is the crystal growth rate, and δ is the thickness of the diffusion dominated region in the liquid. δ itself is somewhat arbitrary and may be expressed as

$$\delta = bD^{1/3} \nu^{1/6} \omega^{-1/2} \qquad [2]$$

where ω is the crystal rotation rate, b is a constant, and ν the liquid viscosity. For the small solute concentrations considered here k_o is assumed independent of concentration.

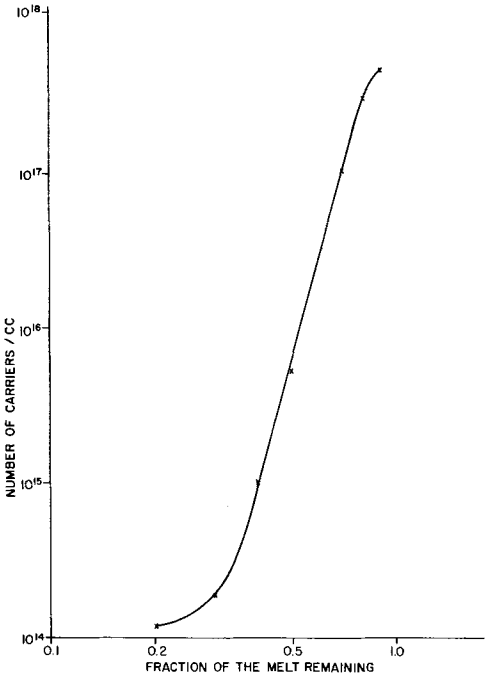

Fig. 1. Log-log plot of the carrier concentration in the crystal, C_s, as a function of (1 — x) the fraction of the melt remaining.

As a result of the preferential incorporation of the boron into the germanium the melt is steadily depleted of boron as crystal growth proceeds. The relationship (4) between the solute concentration in the solid and the fraction of the melt that is crystallized, x, is

$$C_s = k_{eff}\, C_l^o\, (1 - x)^{k_{eff}-1} \qquad [3]$$

If the crystal growth and rotation rates are kept constant then k_{eff} may be determined (1) from the slope of the curve obtained by plotting log C_s *vs.* log $(1 - x)$. A plot of this type was made for each crystal grown.

A set of experimental results for a growth rate of 0.33 mm/min are shown in Fig. 1 plotted as log C_s *vs.* log $(1-x)$. These points were obtained from the crystal volume *vs.* length and resistivity *vs.* crystal length plots. The concentration values were obtained from the resistivity values by using the curves published by Sze and Irvin (6). Concentration values calculated from Hall measurements made were used as checks only. The plot of Fig. 1 is seen to be linear with deviations at both high and low carrier concentrations. At high concentrations the crystal was still expanding and at the low concentration end of the plot the residual impurities, *i.e.*, other than boron, were becoming significant. Hence, only the linear portion of the plot was considered.

An effective distribution coefficient of 9.3 for a growth rate of 0.33 mm/min was determined from Fig. 1. In Table I are shown the effective distribution coefficients calculated in this manner for a number of growth rates. Equation [1] may be rearranged to give

$$1 - (1/k_{eff}) = [1 - (1/k_o)] \exp(-\delta f/D) \qquad [4]$$

A plot of ln $[1 - (1/k_{eff})]$ *vs.* f, the growth rate, should give a straight line with slope $-\delta/D$. The results of Table I are shown plotted in this form in Fig. 2. The results that Bridgers and Kolb obtained for a rotation rate of 60 rpm are also shown in Fig 2. From the probable intercept on the ordinate a value of

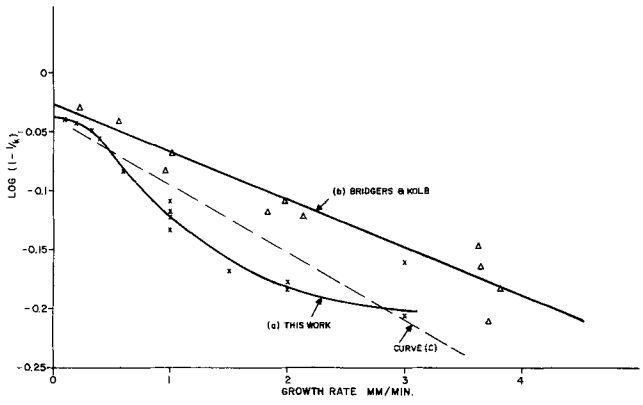

Fig. 2. Results of this work and those of Bridgers and Kolb plotted as a function of growth rate according to Eq. [4]. The slope, δ/D, for curve b is 56 sec/cm and for curve c is 79.2 sec/cm.

k_o of 12.2 is obtained, a figure which is definitely lower than the value of 17.4 ± 20% calculated by Bridgers and Kolb. The difference is most likely due to an orientation effect. The specific reference by these authors to the repeatability of their crystal growth without loss of boron and their use of a carbon crucible would appear to eliminate an explanation for the difference, based on an assumption of less boron oxidation, in the case of the present work. It has been shown that the oxidation of boron effectively removes the boron (7) as an electrically active dopant and consequently an oxygen leak into the crystal grower could give an apparent increase in k_{eff} as measured from a plot such as Fig. 1. The apparent disappearance of boron observed by Swiggard and Shenker (8) also raises the possibility that an equilibrium with a nonelectrically active boron (9) dope could be affecting such measurements.

Recently Hurle and Jakeman calculated the effect of temperature perturbations on the effective distribution coefficient. Where $k_o > 1$ they predict that the distribution coefficient measured, which is an average value when perturbations are present, will be less than the effective value expected from the Burton, Prim, and Slichter theory. In the particular case of crystal melt-back just failing to occur with the peak of each temperature fluctuation (the so-called marginal case) the measured k_{eff}^m will equal $k_{eff}/2$. Their calculated results are subject to several boundary conditions or restraints. The Hurle and Jakeman relationships for the marginal case and $k > 1$ have been evaluated for the experimental conditions used here. At the lowest growth rate used of 0.1 mm/min the maximum depression of k_{eff} due to fluctuations is 7% even for the marginal case. Growth took place in the < 111 > direction and the possible existence of facets would lead to delays between any driving perturbation present and the interface response. The concentration variations as a result of the temperature fluctuations would thus be reduced (10). Very little faceting is thought to have occurred because transverse resistivity plots did not reveal any evidence of resistivity coring. The Hurle and Jakeman calculations are not really applicable when facets are present.

It is also relevant that for part of the growth of the 0.1 mm/min crystal a small island due to a scum particle existed at the edge of the melt. Such islands accentuate temperature asymmetries leading to more definite striations (11). In this instance no irregularity

Table I. Values of k_{eff} for several crystal growth rates

Growth rate, mm/min	0.1	0.2	0.33	0.4	0.6	1.0	1.0	1.0	1.0	1.5	2.0	2.0	3.0	3.0

in the log C_s *vs.* log $(1 - x)$ curve was found. This point together with the observations of the last paragraph are taken as an indication that any temperature fluctuations present and particularly those due to the crystal rotation are not sufficient to cause a significant lowering of k_{eff} due to the mechanism discussed by Hurle and Jakeman. Closer comparison with the results of Bridgers and Kolb is not possible as they did not give some key growth information, *e.g.*, the doping levels used and the crystal growth direction.

From Eq. [4] it is seen that the slope of the plot of Fig. 2 gives a value for δ/D. The results obtained here give a nonlinear plot which has a greater average slope than a similar plot of Bridgers and Kolb's results. The increased slope is expected because of the reduced rotation rate. The relationship calculated from Eq. [2] and the Bridgers and Kolb δ/D value for 60 rpm is plotted as curve *C* in Fig. 2. It is necessary to consider the possible reasons for the nonlinearity.

The diffusion coefficient, *D*, is temperature dependent and the temperature gradient will vary with growth rate. However, the region over which *D* is considered is very small and the consequent variation in temperature across δ is very small compared with the actual temperature at the interface. The liquid-solid interface temperature is essentially fixed at the freezing point; hence *D* is practically constant and the cause of the nonlinearity is δ, the width of the diffusion dominated layer.

At the rotation rate used the amount of stirring that is induced is particularly sensitive to the relative magnitude of the thermally produced convection current and the crystal-rotation induced flow pattern (12,13). With the particular resistive heating arrangement used the melt rises at the sides of the crucible and falls at the center due to the effect of the cooled seed (Fig. 3). This picture is reinforced by the experimental observation that scum particles, once dislodged from the crucible, will travel inward toward the seed as would be expected from the flow diagram of Fig. 3.

The flow pattern due to the crystal rotation is the opposite of the thermally induced pattern, *i.e.*, the liquid rises at the center beneath the crystal and falls at the crucible sides (12-14). It has been shown that at crystal rotation rates of ~30 rpm the predominant stirring mechanism is changing from the thermally induced flow to the crystal-rotation induced flow. The diffusion layer thickness, δ, which depends on this flow pattern will be especially sensitive to the growth conditions at the crystal rotation rate of 30 rpm.

As the pull rate is increased for a given rotation rate the latent heat of solidification rejected by the growing crystals increases. If we ignore the radiation loss at the interface the heat balance equation is

$$f \rho L = K_s \frac{\delta T}{\delta z} - K_L \frac{\delta T}{\delta \gamma} \qquad [5]$$

where f is the growth rate, ρ is the density, L the latent heat of fusion, K_s and K_L the thermal conductivities in the solid and liquid, respectively, and $\delta T/\delta z$ and $\delta T/\delta \gamma$ the temperature gradients in the solid and liquid, respectively.

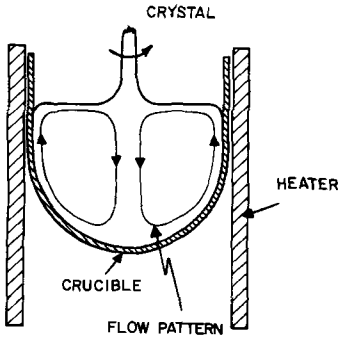

Fig. 3. Thermal flow pattern established in the melt for zero or low rotation rates.

An upper limit to the growth rate is reached when the heat flowing along the solid arises entirely from the latent heat of fusion. At quite modest growth rates the heat rejected is a significant fraction of that being conducted along the crystal. For example, if for germanium $K_s = 0.058$ cal cm^{-1} C^{-1} sec^{-1}, $\delta T/\delta z = 110°/cm$, $\rho = 5.32$ g/cc, and L = 114 cal/g, then for a growth rate of 3 mm/min the latent heat of fusion is contributing some 47% of the heat being conducted along the crystal. As may be seen from Eq. [5] this will reduce the temperature gradient in the liquid, *i.e.*, the cooling effect of the seed on the liquid is reduced and the over-all effect is a reduction in the effectiveness of the thermal convection flow pattern (Fig. 3).

The results shown in Fig. 2 support this premise. As the growth rate increases and the effectiveness of the thermal flow pattern is reduced the diffusion layer thickness, δ, initially increases, as was observed. An effect of this type was predicted by Robertson (13). At the higher growth rates the rejection of significant amounts of latent heat of solidification facilitates the establishment of the hydrodynamic flow pattern at the given rotation rate. Once again a definite flow pattern is established in the melt with a consequent reduction in the diffusion layer thickness, δ, as observed. There is a suggestion of this behavior, *i.e.*, an initial increase in δ and a later decrease, in the experimental results of Bridgers and Kolb, reproduced in Fig. 2. These workers used a higher crystal rotation rate of 60 rpm and the effect would therefore not be as great as for the 30 rpm of the present work. To eliminate effects due to a thermally induced flow pattern it is thus necessary to use even higher rotation rates, *e.g.*, >100 rpm. The growth system described here is limited to a maximum rotation rate of ~45 rpm because of mechanical stability problems.

Conclusion

The value of the distribution coefficient of boron in germanium was found to be 12.2. This is significantly lower than the value of 17.4±20% found by Bridgers and Kolb. It is not clear whether this difference arises because of an effect due to the crystal orientation, the ready oxidation of the boron, or the presence of boron in a nonelectrically active form.

The relationship between the effective distribution coefficient and growth rate agrees with that calculated by Burton *et al.* and the results of Bridgers and Kolb, if allowance is made for the particular growth conditions. An effect predicted by Robertson and due to a reduction in the degree of stirring in the melt with increase in growth rate has been observed.

A rotation velocity of at least 100 rpm and a small growth rate should be used to obtain values of k_0. A high rotation rate establishes a hydrodynamic flow pattern. A small growth rate minimizes thermal effects due to the latent heat of fusion and also reduces the amount of extrapolation necessary to obtain the value of k_0.

Acknowledgment

The author wishes to thank Mr. K. Gustafson for his help with the growth of the germanium crystals.

The S-Shift Curve Characteristics of Si-O Stretching Band of Amorphous Silica

Kenzo Sato

Musashi Works, Hitachi, Ltd., Kodaira-shi, Tokyo, Japan

ABSTRACT

The absorption profile of the Si-O stretching band of a silica layer was studied as a function of layer thickness. Behavior of the S-shift curve which relates the wave number of the reflection/absorption peak and the layer thickness was found to vary with the conditions of layer growth and thermal treatment. Tentatively, these effects were explained as related to the presence of two types of loosely bound lattice oscillators derived from the expression $(Si_xO_y)_n$, and they were considered to be present both on the surface and inside the silicon-silica interface layer.

The properties of a thin amorphous silica layer grown above a silicon wafer have been studied by many researchers for interest regarding its electrical characteristics as an insulator and for crystallographic interests (1-4) as well as the study of crystalline quartz (5-8). Also, much interest is concerned with the structural evaluation of the thin silica layer which was formed by the compound shown as $(Si_xO_y)_n$ by means of x-ray diffraction analysis and infrared absorption spectroscopy. Various network models based on x-ray diffraction data have been proposed (9,10) which suggest that the amorphous silica layer consists of an extended three-dimensional network lacking periodicity, the construction of which may be inhomogeneous and which would undergo modifications according to its growth and impurity inclusion. Especially, precise measurements of the lattice vibrational spectra by the infrared spectroscopical method in the 1-30μ region suggest many interesting optical properties which are seen as peculiar to thin films (11-14). For example, the O-H stretching band formed by wet oxygen gas visible in the 2.5-3.5μ region is apt to become modified by thermal treatment (11). Profile of the Si-O stretching band seen in the 9-10μ region and the bending band seen in the 21-23μ regions is sensitively modified by the conditions for layer growth and impurity inclusion (13).

Furthermore, wavelength of the peak of the Si-O stretching band and bending band is not always seen at definite points, and it is noticeable that the peak fluctuates according to the conditions of layer growth and that the conditions shift toward the longer wavelength side with layer thickness (12). This effect can be called a surface shift (S-shift), considered as caused by certain essential optical properties of very thin films, presumably due to the presence of loose bonds formed by unsaturated lattice oscillators.

In this paper, the main interest was concerned in studying the profile of Si-O stretching band characteristics because the band is considered as the most basic spectrum representing the properties of $(Si_xO_y)_n$ compounds in a silica layer. Especially the effect of the S-shift was studied experimentally, and the origins of this effect are considered related to the inhomogeneous structure of the silica layer.

Experiments

Considering the peculiar properties of the sample, its thickness is less than 1μ and characteristics of the thin layer are not always uniform, not only at the silicon-silica interface but also on the surface of the silica layer. Both the reflection and transmission methods were used to measure the step etched samples. The etchant used is shown as (NH_4F:HF = 6:1), and the layer thickness was measured by observing the surface color formed by interference. Accuracy is considered as within an error of ±200Å.

The infrared spectrophotometer used was a Hitachi EPI-2, double-beam type with NaCl optics whose resolving power is 2.5 cm^{-1}/mm in the 9μ region. The area of samples for the measurements was about 10 mm in diameter with an incident angle of 10 degrees for the reflection measurements.

The results of these measurements are summarized as follows:

Thermally grown and chemical vapor deposited silica (C.V.D.).—Shown in Fig. 1a, b, and c are some examples of measuring the silica layer which was grown thermally at 1100°C with a flow of wet oxygen gas (A sample) and chemically deposited silica at 800°C by decomposition reaction of tetra-etoxysilane by oxygen gas (B sample). In reflection measurements, sample A shows that the wave number of the reflection maximum of the Si-O stretching band is shifting continuously from 1100 to 1045 cm^{-1} with a variation of layer thickness from 7000Å down to 1200Å. Also, the transmission minimum shifts from 1080 cm^{-1} (at 7000Å) down to 1069 cm^{-1} (at 3300Å) and returns to 1075 cm^{-1} (at 1250Å).

These phenomena were commonly seen in the thermally grown silica layer, although the wave number somewhat fluctuates in the samples. On the other hand, concerning sample B which was deposited from tetra-etoxysilane, as shown in Fig. 1c, the S-shift curve of transmission measurements did not return to the shorter wavelength side even when the layer thickness became smaller than 3000Å.

Fig. 1a. Infrared reflection and transmission spectrum of silica layer.
The three parts of Fig. 1a show reflection and transmission spectra of silica layers.

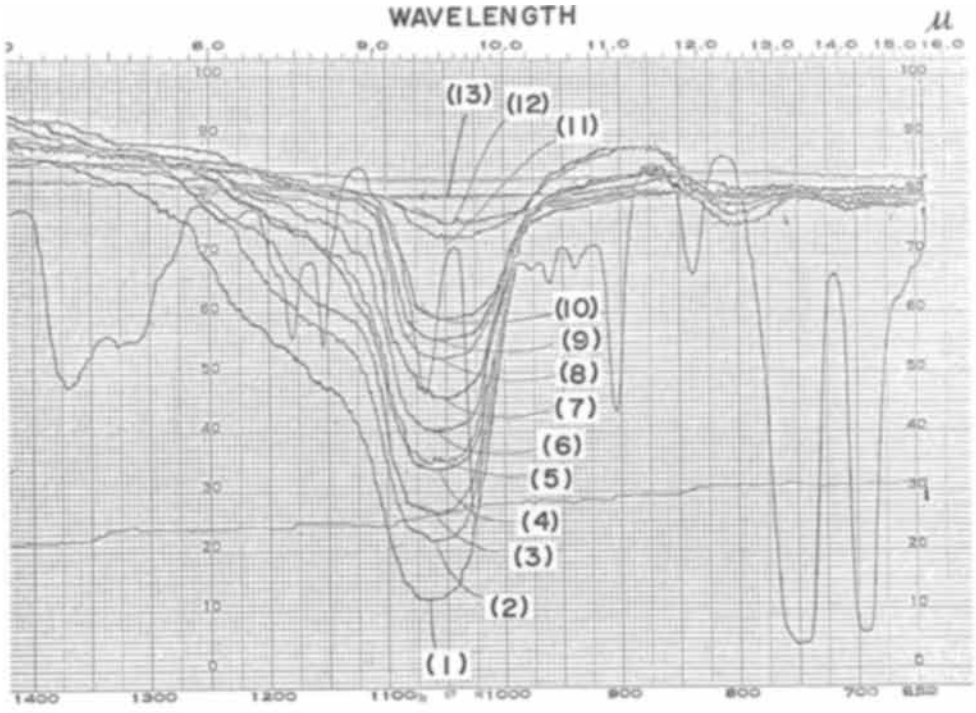

Fig. 1a(i). One example of absorption measurements of silica layer which was deposited by decomposition reaction of tetraethoxysilane using oxygen gas at 800°C. The thickness of step-etched sample corresponding to the running number is shown in the note. The absorption minima of Si-O stretching band is shifting continuously from 1065 to 1040 cm^{-1}, but Si-Si stretching band at 800 cm^{-1} is not shifting.

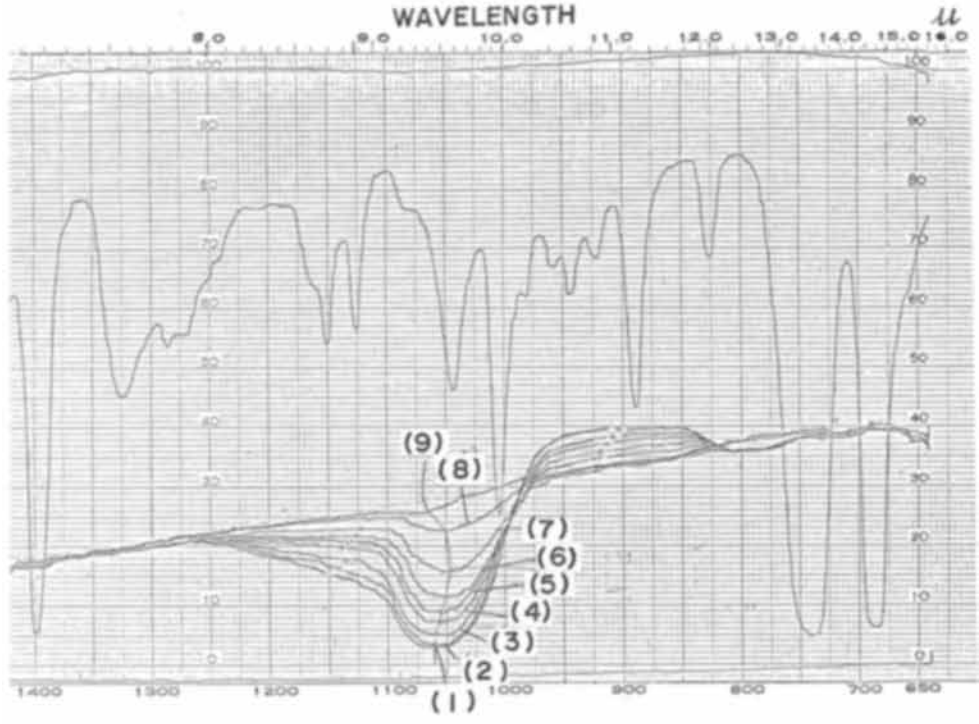

Fig. 1a(ii). One example of absorption measurements of silica layer which was grown thermally at 1100°C using wet oxygen gas. The thickness of step-etched sample corresponding to the running number is shown in the note. The absorption minima of Si-O stretching band is shifting from 1060 cm^{-1} (at 7200Å) to 1045 cm^{-1} (at 2750Å) and return to 1065 cm^{-1} (at 100Å).

As-grown layers.—In this case, also, properties of the S-shift curve were measured to the silica layers, their thickness in an as-grown state differing from each other. The two groups of samples which were grown thermally changed the duration time of the layer growth in wet oxygen gas, and the layer thickness in an as-grown state is 8000Å (C sample) and 3700Å (D sample), respectively. Also, deposited silica layers whose thickness in an as-grown state was 6000Å (E sample) and 3000Å (F sample) were used as samples and their S-shift curves were measured. The results are shown in Fig. 2, where the C sample reveals that the reflection maximum is shifting from 1103 cm^{-1} (at 8000Å) to 1055 cm^{-1} (at 1250Å; and in the D sample, from 1090 cm^{-1} (at 3800Å) to 1060 cm^{-1} (at 750Å). In these two curves, the wave number of the D sample is shifting toward the shorter wavelength side approximately 10 cm^{-1} from that of sample C. This effect can be termed as the P-shift (phase shift) of the as-grown layer.

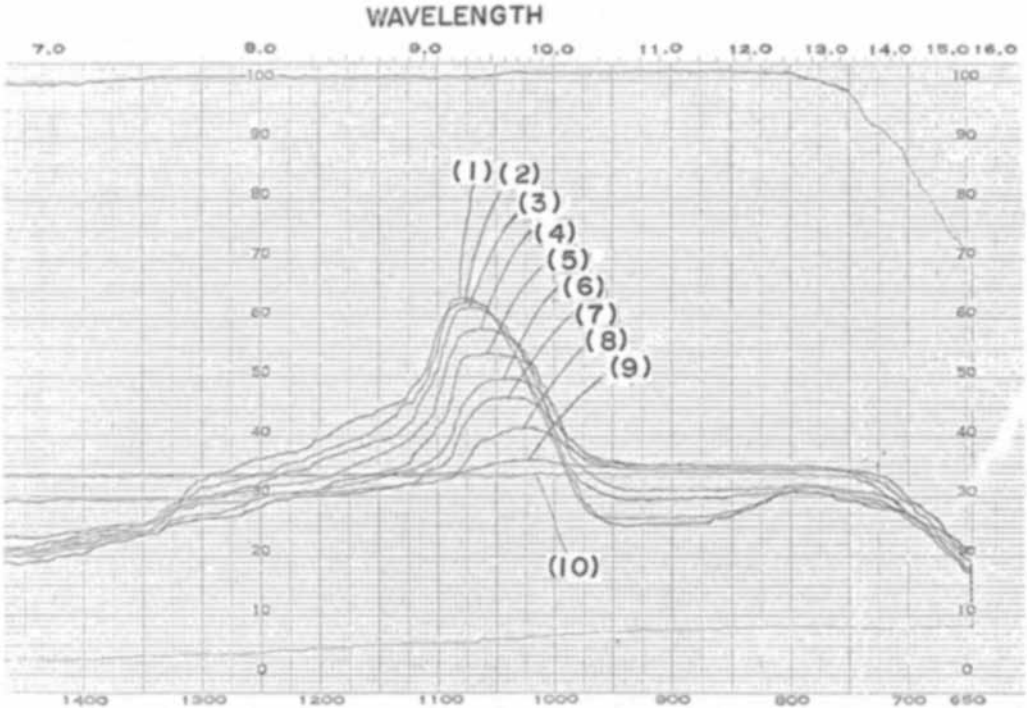

Fig. 1a(iii). One example of reflection measurements of silica layer which was grown thermally at 1100°C using wet oxygen gas. The thickness of the silica layer corresponding to the running number is shown in the note. The reflection maxima of Si-O stretching band is shifting continuously from 1075-1030 cm^{-1} but Si-Si stretching band at 775 cm^{-1} is not shifting.

Note: The thickness of step-etched samples corresponding to the running number in Fig. 1a (i), (ii), and (iii).

Sample No.	(i) Absorption, Å	(ii) Absorption, Å	(iii) Reflection, Å
1	6300	7200	6000
2	5200	6200	5500
3	4450	5400	4900
4	3650	4260	4200
5	3250	3650	3650
6	2750	2750	3050
7	2500	1600	2250
8	2000	600	1500
9	1500	100	850
10	1250	—	0
11	750	—	—
12	500	—	—
13	0	—	—

On the other hand, in the E sample, the wave number is shifting from 1070 cm^{-1} (at 6000Å) to 1036 cm^{-1} (at 1500Å); and in the F sample, it is shifting from 1050 cm^{-1} (at 3000Å) to 1030 cm^{-1} (at 1000Å). It is clear that the effect of the P-shift is not visible in the sample of the C.V.D. silica layer.

Thermal treatment.—In the third measurements, the effect of the S-shift was also studied on two kinds of samples. The G sample is thermally grown and the H sample is the C.V.D. silica layer.

Here, a sample wafer was divided into four pieces and these were heated at 700°C at duration times of 0, 3, and 6 hr, and their S-shift curves were measured. They are as shown in Fig. 3a and b.

In this figure, no special effect requiring consideration was observed in the G sample; but in the H sample, the S-curves shifted toward the shorter wavelength side with the duration of thermal treatments.

Discussion
