Influence of the initial oxide layer.—In order to get further insight in the phenomena induced by the presence on the sample surface of the initial oxide layer arising either from the polishing or from the spontaneous oxidation of the metal the shape of the growth laws near the origin was studied in more detail both in natural and in O^{18}-labeled solutions. As the shift of the curve $N_O = f(V_{ox})$ toward negative potentials was observed on polished aluminum samples for which the initial layer contains a relatively high quantity of oxygen, the growth laws were further studied on samples covered by an initial layer of similar oxygen content but of different origin. Unpolished aluminum was hence thermally oxidized in air at 520°C for 3 hr and then further oxidized anodically at constant potential in natural solutions. Figure 4 and Table I show the corresponding results. The growth of the anodic film starts at a potential V_1 much higher for thermally oxidized samples; nevertheless in spite of the presence of an about three times thicker initial layer, the growth law $N_O = f(V_{ox})$ shows no translation toward negative potentials.

Experiments in O^{18}-labeled solutions may give additional information on the role of the initial layers. Let $N_{O18} = g(V_{ox})$ be the growth law obtained in such solutions. In order to compare directly $N_{O18} = g(V_{ox})$ to $N_O = f(V_{ox})$, (obtained from unlabeled films) it is convenient to normalize the results to 100% enrichment of the electrolyte used. We shall call $\hat{N}_{O18} = \hat{g}(V_{ox})$ these normalized values. If the initial layer behaves like a barrier layer, and if, in addition, the oxygen atoms it contains remain in the film obtained after oxidation, undergoing no isotopic exchange (which, as we shall see, is the case), Eq. [3b] applies to N_{O18} with the following alteration

$$V_{ox} - V_{eq} = \eta_m + \eta_s + \lambda E_{ox}\hat{N}_{O18} + \lambda E_{ox}N_O^i \quad [3d]$$

for $V_{ox} > V_1$, where N_O^i is the oxygen content of the initial layer. It should be noted that the growth starting potential V_1 is equal to $\eta_m + \eta_s + \lambda E_{ox}N_O^i$ and hence slightly depends on J_i; the experiments shown here were all made at constant potential, *i.e.*, at low final current densities. Equation [3d] shows that the straight line $\hat{N}_{O18} = \hat{g}(V_{ox})$ differs from $N_O = f(V_{ox})$ only by a translation toward positive potentials. Any deviation from such a behavior indicates a more complicated role of the initial layer in the oxide growth than assumed.

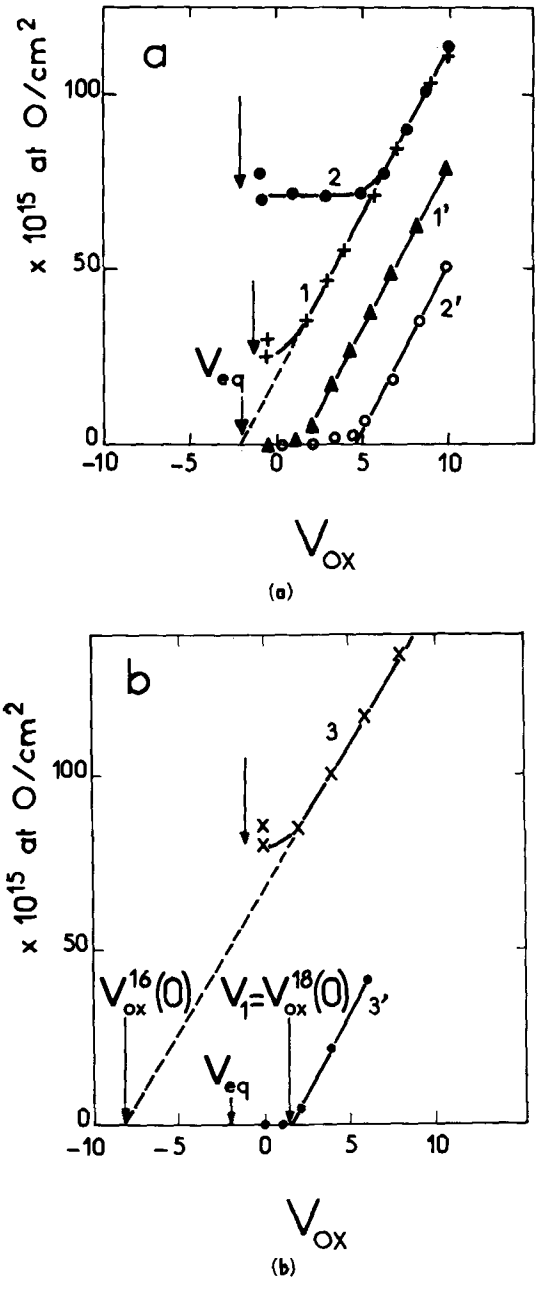

Fig. 4. Growth laws for aluminum at constant potential: (a) unpolished and (b) polished samples. Curves 1, 2, 3 represent $N_O = f(V_{ox})$, respectively, for unpolished; unpolished and thermally oxidized; polished samples. Curves 1', 2', 3' represent $\hat{N}_{O18} = \hat{g}(V_{ox})$ for samples of the safe type anodized in O^{18} enriched solutions.

Figure 4a shows $\hat{N}_O{}^{18} = \hat{g}(V_{ox})$ for unpolished aluminum, both thermally oxidized and not. It is clear that these curves strictly obey Eq. [3d], V_1 increasing with the oxygen content of the initial layer. Figure 4b shows the corresponding results for polished aluminum. We see here that, in spite of the presence of a thick initial layer, the starting potential V_1, as observed on $\hat{N}_{O18} = \hat{g}(V_{ox})$, remains small, near the value observed for unpolished aluminum.

The results of Fig. 4 and Table I suggest the following interpretation. The shift toward negative potentials of $N_{O16} = f(V_{ox})$ is not dependent on the oxygen content of the initial layer but on its nature. The initial layers of thermal origin behave like a barrier layer having no influence on the growth law and presenting no isotopic exchange of oxygen during further anodic oxidation, like anodic aluminum oxides, as shown in

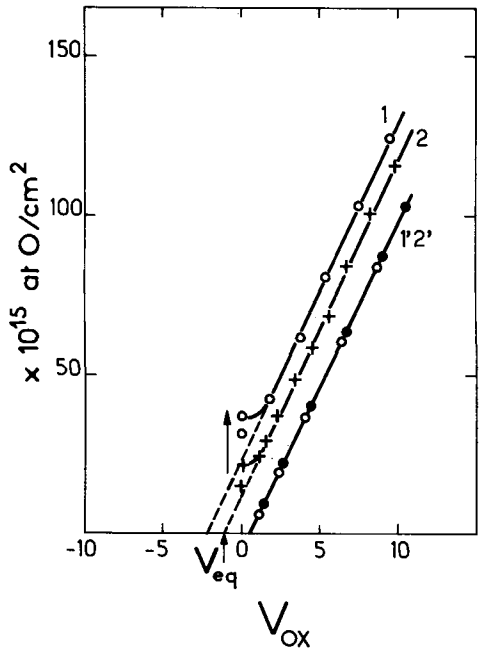

Fig. 5. Growth laws for tantalum at constant potential. $N_{O16} = f(V_{ox})$: curve 1, unpolished and curve 2, polished samples. $N_{O18} = g(V_{ox})$: curve 1', unpolished and curve 2', polished samples.

ref. (10). The initial layer on polished aluminum consists of two regions: (*a*) a region of high ionic conductivity responsible for the shift of $N_{O16} = f(V_{ox})$ by an amount $|V_{ox16}(0) - V_{eq}|$ and (*b*) a region of the barrier type responsible for the shift of $N_{O18} = g(V_{ox})$ by an amount $V_{ox18}(0) - V_{eq}$. This region has an oxygen content similar to that of the initial layer on the unpolished aluminum. The relative oxygen content of these regions is the ratio of these potential shifts, *i.e.*, 2.6 in this case. Moreover the layer of high ionic conductivity does not undergo isotopic exchange of oxygen during anodic treatment. These results indicate that the oxygen coming from the solution merely passes through the layer of high ionic conductivity, if we assume that the latter remains at the oxide-solution interface; in this case this layer would have a porous character (see Discussion).

Figure 5 shows the growth laws obtained on polished and unpolished tantalum in labeled and unlabeled solutions, and Table I shows the corresponding parameters. A translation of the curve $N_{O16} = f(V_{ox})$ toward negative potentials for unpolished tantalum seems to indicate the presence of a layer of high ionic conductivity in this case. It should be noted that the curves $\hat{N}_{O18} = \hat{g}(V_{ox})$ have the same intercept with the potential axis for both types of tantalum used.

Electric field of formation.—The values of E_{ox} were deduced from the oxygen growth laws by assigning well chosen values to λ in Eq. [3b]. It should be noted that in order to obtain a linear relation $N_O = f(V_{ox})$, when N_O^c is not vanishing, it is not necessary to require N_O^c to be a constant. In fact, if N_O^c itself varies linearly with V_{ox}, at least in a given range of potentials, the curve $N_O = f(V_{ox})$ remains linear. Such a behavior may change the value of the apparent field of formation E_{ox} as deduced from the slope of the curve $N_O = f(V_{ox})$. A decrease of N_O^c with V_{ox} may correspond to the gradual dissolution of an initial layer of high ionic conductivity or to pore-filling processes (32); an increase of N_O^c with V_{ox} may be caused by a partial formation of a hydroxide or of a porous layer during the anodic process (4). In the last case N_O^c may vanish at small V_{ox}, so that no shift of the intercept V_{ox} is observed. In what follows we shall calculate the apparent field E_{ox}; the effects of the various behaviors of N_O^c will be considered in the Discussion.

For aluminum the roughness factor was taken equal to unity; this assumption will be discussed later. Like Young (1) and Diggle *et al.* (33) we assume that the barrier layers of aluminum oxide have the formula Al_2O_3 and are amorphous. The density of such layers was measured by several authors in various conditions; the reported values range from 2.73 g/cm^3 (34) to 3.3 g/cm^3 (35). Van Geel and Schelen (36) measured 3.1 g/cm^3 for aqueous solutions; this value is near that of Bernard and Cook (5), 3.17 g/cm^3, measured in organic solutions. This is in agreement with ref. (37) in which it is assumed that barrier layers formed in organic and aqueous solutions are similar from this point of view. Our calculations were based on the value 3.17 g/cm^3.

For polished tantalum we shall take a roughness factor equal to unity in agreement with Young (1), who measured a density of 8.01 g/cm^3 for aqueous solutions; this figure was later confirmed by Schrijner and Middelhoek (38) to within 0.5% precision. We admitted here a density of 8 g/cm^3.

The calculated values of E_{ox} are listed in Table II. In order to compare our results to those of the literature, we also list in this table our values, recalculated with the densities used by the other authors quoted. For aluminum, E_{ox} is always larger on polished samples than on unpolished samples, the difference increasing with decreasing current density. Moreover our recalculated values on unpolished samples agree to within 2% with those of Harkness and Young (7), who did not use electrochemical polishing; our results on polished samples agree to within 5% with those of Bernard and Cook (5), who resorted to electrochemical polishing. These agreements might be fortuitous; nevertheless they are worthy to be noticed as Harkness and Young ascribed the difference between their values and those of Bernard and Cook to the influence of the different solutions used, whereas here the surface preparation seems to play a fundamental role. For tantalum there is excellent agreement with the values of Young (1) and good agreement for recalculated values with those of Vermilyea (39). The agreement with Young is natural for the values at high current density, as we too used coulometric measurements on tantalum to define our standard. At low current densities, where the faradaic efficiency might be less than 100%, the agreement is a good confirmation

Table II. Electric field of formation E_{ox} x 10^6 V/cm

of the value of Young, as our value, determined by nuclear microanalysis, is not influenced by the presence of an electronic current.

Components of the current.—The ionic current density in Eq. [4] may be in turn decomposed at the oxide-solution interface according to

$$J_i = J_{ox} + J_{dis} \qquad [5]$$

where J_{ox} is the part of the current which contributes to the film growth and J_{dis} the dissolution current J_{dis} includes the current density of direct dissolution of the cations as well as that equivalent to the dissolution of oxide already formed. The one to one empirical relation between J_i and E_{ox} may be written conveniently

$$J_i = A \exp B E_{ox} \qquad [6]$$

where, for a given system A and B are temperature-dependent parameters. According to various authors (1, 40) B may slowly vary with E_{ox}, this leading for example to a quadratic term in the exponential. In what follows, at constant temperature and in the range of current densities covered, we shall consider B as constant and estimate its value from Eq. [6].

The components of J_{ox} and J_{dis} may be separated if J_i is known. This implies an estimation of J_e in Eq. [4], which might be carried out as shown below. J_{ox} is in fact given directly by the nuclear measurements. By definition the number $N_O(t)$ of oxygen atoms per square centimeter in the layer at time t is

$$N_O(t) - N_O(0) = k \int_0^t J_{ox}(\theta)\, d\theta \qquad [7a]$$

$$= k \int_0^t R(\theta)\, J(\theta)\, d\theta \qquad [7b]$$

where $R(t)$ is the oxidation current efficiency at any instant

$$R = \frac{J_{ox}}{J} \qquad [8]$$

and where the constant k is equal to 0.312×10^{19} atoms of oxygen per coulomb, if we assume that the oxygen is fixed in the film in the state O^{--}.

For oxidations carried out at constant current, the precise measurement of the number Q of coulombs per square centimeter

$$Q = \int_0^t J(\theta)\, d\theta \qquad [9]$$

consumed during oxidation allows the determination of the oxidation current efficiency from the following relation, deduced from [7b]

$$R = \frac{1}{k} \frac{dN_O}{dQ} \qquad [10]$$

This quantity is easily measured and will be used to determine J_{ox} by using Eq. [8].

Measurements at constant current.—The oxidation of tantalum and aluminum at constant current (1 to 10 mA/cm²) in presence of a redox system yields an upper limit of the electronic component J_e: 1% of the current for polished Ta in agreement with ref. (9), 2% for polished Al, 5% for unpolished Al and Ta. By difference we obtain the minimum value of the ionic current density J_i. For each type of samples used it is thus possible to estimate the value of the constants A and B in the empiric relation [6]. The approximate values of A and B obtained, using the values of E_{ox} determined at 1 and 10 mA/cm² from Table II are listed in Table III. The agreements between our results and the literature are similar to those found in Table II.

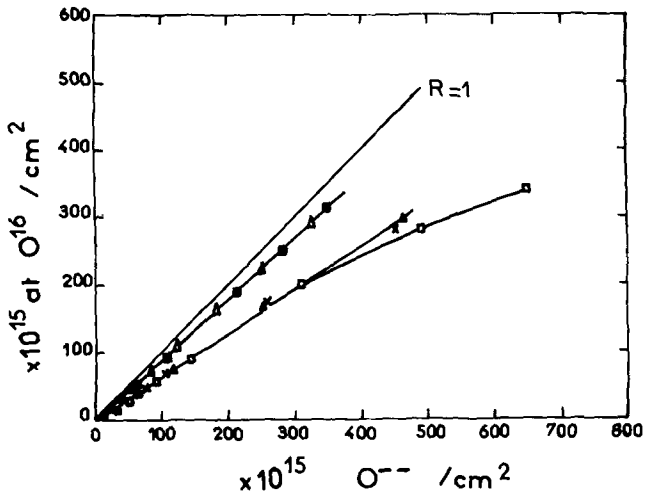

Fig. 6. Number of O^{16} atoms/cm² fixed on aluminum samples by anodic oxidation vs. electric charge consumed, expressed as a number of O^{--} anions/cm². △ polished Al, 10 mA/cm² and ■ 1 mA/cm²; ▲ unpolished Al, 10 mA/cm², × 6.6 mA/cm², and □ 1 mA/cm².

On Fig. 6 the number of O^{16} atoms per square centimeter fixed on the surface of aluminum samples by anodic oxidation at constant current (minus the initial layer) is plotted as a function of the number of coulombs per square centimeter used during formation of the film (this quantity being expressed in numbers O^{--}/cm²). The slope of the curves gives, by definition, the values of R. Here $R = 1$ for tantalum and is not considered.

For polished aluminum the current efficiency is independent of the current. For unpolished aluminum the decrease of the efficiency as the layer thickness increases and the current density decreases, is due to an increase in the dissolution current, as the electronic current is less than 5% of the total. Moreover R is much smaller for unpolished than for polished aluminum. The various components of the current as deduced from the values of J_e and R are listed in Table IV. The large values of J_{dis} found for aluminum, especially for unpolished samples, raise the question whether the dissolution currents are of chemical or electrochemical nature.

The equivalent chemical dissolution current density for aluminum oxide was measured by nuclear methods, without applied electric field (this being in fact proportional to $-dN_O/dt$); an estimated value of only about 0.3 μA/cm² for both polished and unpolished aluminum was found. It would therefore appear that the dissolution current during oxidation is purely electrochemical. This is in agreement with ref. (37). The dissolution current density on tantalum was not measurable, an estimated upper limit being 3×10^{-3}

Table III. Values of the constants A and B

Table IV. Components of the currents for aluminum at constant current densities

Surface preparation	V_{ox}, V	J, mA/cm²	Expressed in % of J J_e	J_i	Expressed in % of J_i J_{ox}	J_{dis}
Polished	0-50	$1 \leq J \leq 10$	≤2	98	92 ± 5	8
Unpolished	0-30	1	≦5	95	68 ± 4	32
		6.6	≦5	95	68 ± 4	32
		10	≦5	95	68 ± 4	32
	30-50	1	≦5	95	42 ± 3	58
		6.6	≦5	95	65 ± 5	35
		10	≦5	95	65 ± 5	35

The values of J_e and of J_{ox} were calculated directly from measurements; the value of J_i and J_{dis} were deduced by difference.

Measurements at constant potential.—These measurements were carried out at $V_{ox} = 50$V. At the low final current densities reached in this case the electronic current density J_e may be relatively high and the value of J_i cannot be inferred from that of J. However, J_{ox} may be estimated directly from the relation (see Eq. [7a])

$$J_{ox} = \frac{1}{k}\frac{dN_O(t)}{dt} \qquad [11]$$

We may in addition estimate J_i at any instant t, by using Eq. [6], in which E_{ox} is deduced from Eq. [3b] by inserting $N_O(t)$ and where A and B are assumed to have the same values as at higher currents (Table III). This procedure implies that the nature of the films formed at low final currents is the same as at high constant current, *i.e.*, that λ and $N_O{}^c$ remain constant throughout the treatment. The values thus found should satisfy the inequality

$$J_{ox} \leq J_i \leq J \qquad [12]$$

Violation of this equation would suggest that a film of different nature from the barrier layer is formed.

Results for oxidations for various durations are listed in Table V where the values for J_i should be considered as orders of magnitude whereas the errors on J_{ox} are less than 50%. It appears that condition [12] is always satisfied, within experimental error, for the anodic oxidation of tantalum. Furthermore after 10-min oxidation the growth of the oxide is already slow and its rate tends toward zero for long periods, whereas the electronic current may represent more than 90% of the total. For the oxidation of unpolished aluminum it is only after 50 min that a current density J of less than 10 μA/cm² is reached, the film continuing to grow slowly. With polished aluminum, on the other hand, the current density J decreases very rapidly and between 17 and 90 min J_{ox} is negligible. For both types of aluminum samples the inequality [12] is satisfied until 90 min. In this case the electronic current density may be estimated to represent about 90 and 60% of the total for polished and unpolished samples, respectively. Furthermore after 13 hr at constant potential with both types of aluminum, J_{ox} is larger by orders of magnitude than the calculated J_i and an appreciable growth of the oxide layer shows up. This may be ascribed to the formation of a layer of high ionic conductivity, *i.e.*, an increase of $N_O{}^c$, which, if not taken into consideration, leads by the use of Eq. [3b] to too small values of E_{ox}. This interpretation is supported by the fact that after 60 hr under potential the films are of porous character, as proved by the stain test with an organic dye. Hunter and Towner (28) and Hoar and Yahalom (29) made similar observations.

Isotopic exchange of O^{18}.—The ionic transfer reactions at the oxide-solution interface leading to oxide formation may be written as (9, 41)

$$M_{ox}{}^{++} + (H_2O)_s \rightleftarrows (MO)_{ox} + 2H_s{}^+ \qquad [13]$$

$$(H_2O)_s \rightleftarrows (OH^-)_s + H_s{}^+ \rightleftarrows O_{ox}{}^{--} + 2H_s{}^+ \qquad [14]$$

where the index "ox" stands for ions in the oxide, "s" in the solution. Reaction [13] describes cation transfer, the oxide being formed by precipitation; reaction [14] describes oxygen transfer. If at the interface there is only one type of reaction responsible for ionic transport, the classical theory of the overpotential can be applied (27, 41) relating the ionic current density J_i during oxidation to the electrochemical exchange current J_{ex} for the reaction as follows

$$J_i = J_{ex}\left[\exp\left(\frac{\alpha ZF}{RT}\right)\eta_s - \exp\left(-\frac{(1-\alpha)ZF}{RT}\eta_s\right)\right] \qquad [15]$$

where α, Z, $\mathbf{F}$, R, and T have their usual meaning.

O^{18} tracing allows a direct determination of J_{ex} by observing the rate of isotopic exchange of oxygen between the oxide and the solution, no external field being applied. This rate depends both on J_{ex} and on the self-diffusion of oxygen in the oxide. The theory of these processes was developed in detail in papers published by our group (27, 41, 43). The slope of the curve $\hat{N}_O18(t)$ at the origin gives the values of J_{ex} independently from the oxygen self-diffusion rate.

Table V. Oxide growth during the constant potential phase

Metal	Time of oxidation*	$N_O(t)$, 10^{15} at./cm²	J, μA/cm²	J_i, μA/cm² (calculated)	J_{ox}, μA/cm²

* After $V_{ox} = 50$V is reached, at 5 mA/cm² current density.

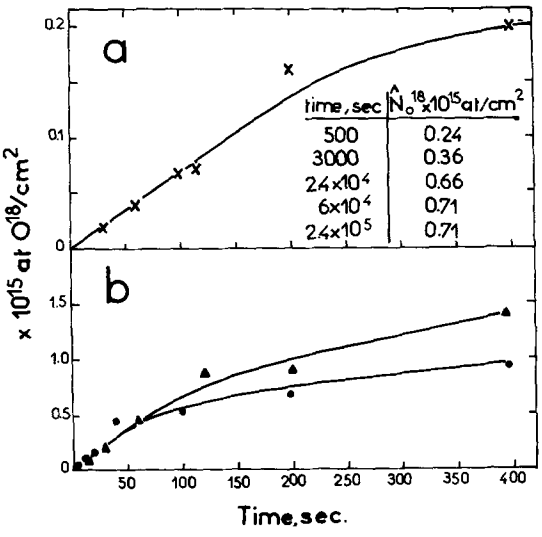

Fig. 7. Isotopic exchange in O^{18} enriched solutions as a function of time for oxides formed at 20V, 10 mA/cm^2 in O^{18} depleted solutions: a, tantalum; b, aluminum: ▲, unpolished; ●, polished samples.

The question arises whether under a high field, the growth of the anodic layer does in fact occur by transfer of oxygen at the oxide-solution interface. Comparison of the electrochemical exchange current J_{ex} of oxygen obtained by tracing with O^{18}, with the exchange currents calculated from Eq. [15] for various values of the ionic current allows the question to be elucidated. The experiments on isotopic exchange with no applied field were carried out on oxides initially formed at constant current (10 mA/cm^2) up to 20V in O^{18}-depleted water. The samples were then immersed in a solution enriched in O^{18} for increasing lengths of time t. The results are shown in Fig. 7.

In the case of tantalum, after a linear start, the exchange slows down and the saturation is reached after about 6 hr. The saturation value, 7 x 10^{14} at./cm^2 suggests that the exchange is confined to the first (or first few) molecular layer. This was confirmed by slightly dissolving the oxide. After about 15Å of oxide have been removed the O^{18} has completely disappeared. The slow dissolution of the oxide was obtained in a solution of 300g NH_4F/liter of concentrated HF as in ref. (9), according to a procedure used by Pringle (42). At 27.5°C a uniform dissolution rate of 62 ∓ 3 Å/min was observed (9, 43) in our experimental conditions. It must be verified that the observed phenomenon was not due to simple spontaneous growth of an oxide film in the enriched solution. The sample which had undergone isotopic exchange to saturation was hence immersed again in the depleted solution. The observed disappearance of O^{18} after several hours, which cannot be due to dissolution (as seen above), proved the reversibility of the phenomenon, characteristic of isotopic exchange. The observed saturation indicates a very low diffusion coefficient of oxygen in the oxide Ta_2O_5, in agreement with (43). The slope at the origin of the curve in Fig. 7a yields a value of the exchange current density of 0.3 μA/cm^2, with 15% precision.

Analogous results were obtained for aluminum for times below 10 min (Fig. 7b). For times of the order of an hour the O^{18} uptake goes on increasing slowly. Thus after 63 hr we found on polished and nonpolished samples, respectively, 15 x 10^{15} and 16 x 10^{15} at./cm^2. On the other hand a loss of the initial oxygen content of 62 and 69%, respectively, was observed, in agreement with the value of the dissolution current found above. The absence of a saturation effect on aluminum may be due to the corrosive attack of the solution; a high self-diffusion rate of oxygen in the barrier layer is unlikely taking into account the results of ref. (10). The slopes at the origin of the curves in Fig. 7b yield a value of the exchange current density of 3 μA/cm^2 with 30% precision.

From Eq. [15], using the experimental values of the overpotentials and of J_i, an order of magnitude of the electrochemical exchange current density of OH^- anions was deduced. As the sum of the overpotentials is statistically zero, we took for $\eta_m + \eta_s$ the corresponding standard deviations; this leads to lower limits for J_{ex}. These values and the results from the exchange experiments are listed in Table VI. The complete disagreement between the corresponding values of J_{ex} will be interpreted in the Discussion.

Discussion

Initial layers on aluminum samples.—The existence of an oxide layer of high ionic conductivity on the surface of polished aluminum samples clearly appears from the above results. Its presence and nature may account for some of the differences in the behavior of polished and unpolished aluminum during anodic oxidation, in particular the observed decrease of the slope dN_O/dV_{ox}, on polished samples. A first explanation could be that this layer is an unsoluble oxygen containing residue from the polishing bath. Preliminary experiments similar to that of ref. (10), using the Al^{27} $(p,\gamma)Si^{28}$ resonant reaction, indicate however that this layer has a high aluminum content. It seems therefore that the layer is a porous aluminum oxide film or perhaps a hydroxide; the use of O^{18} tracing and the localization of the O^{18} after various anodic treatments of the metal will give further insight in the nature of this film and in the mechanism of its influence on the anodic oxide formation. This conclusion may be related to the results of Hollo (16) who found by electron microscopy that electropolishing in a phosphoric acid-butyl alcohol bath yields a porous oxide film and to those of Welsh (44) who found similar results using various electropolishing baths.

Dependence of the oxygen growth law slopes on sample preparation.—The higher values of the slopes dN_O/dV_{ox} for unpolished than for polished aluminum could be explained by a corresponding difference in the roughness factor of the metal under the oxide. Under this assumption the difference would depend on the final oxidation current density J, and would be maximum for J equal to some μA/cm^2. Now, this value was reached after a stage at high current (5 mA/cm^2) at the end of which the slopes are not significantly different (Table I); hence neither are the roughness factors. It is difficult to imagine a mechanism which would lead to an increase in roughness factor during a phase at constant potential and low current. Hence we shall admit that the roughness factor of the metal backing was near unity.

Two possible explanations will now be considered:

(*i*) The anodic films formed on both polished and unpolished aluminum are pure Al_2O_3 oxides. The

Table VI. Oxygen exchange currents

Metal	$\eta_m + \eta_s$, mV	J, μA/cm^2	J_i, μA/cm^2	Minimal values of J_{ex} calculated from Eq. [15], μA/cm^2	J_{ex} deduced directly from the isotopic exchange of O^{18}, μA/cm^2
Polished tantalum	0 ± 80	10^4	~10^4	2 × 10^3	0.3 ± 0.05
Both polished and unpolished aluminum	0 ± 170	10^4	9.5 × 10^3	3 × 10^2	3 ± 1

smaller slope on polished aluminum would be due to the superposition of this oxidation mechanism and of the slow transformation of a part of the layer of high ionic conductivity initially present at the surface into a barrier layer. The growth law corresponding to unpolished aluminum would then be characteristic of barrier layer formation alone, (*i.e.*, yield the real E_{ox}). Similar assumptions may hold for tantalum. In the case of aluminum the transformation of the high ionic conductivity layer may be due to two types of mechanisms: those which do not lead to an increase of its oxygen content [for example, the transformation of $Al(OH)_3$ into Al_2O_3 by proton repulsion] and those which do (*i.e.*, pore filling process).

(*ii*) The growth law characteristic of barrier layer formation alone would correspond, according to this assumption, to polished aluminum. The higher slope for unpolished aluminum (*i.e.*, a lower apparent E_{ox}) would be due here to the simultaneous formation of a barrier layer and of a layer of high ionic conductivity (hydroxide or porous film). The ratio of the slopes would correspond then to the proportion of oxygen present in the barrier layer with respect to the total amount of oxygen in the film formed on unpolished aluminum. Polishing would appear as preventing such phenomena, the layer of high ionic conductivity remaining unchanged during treatment. This assumption cannot be applied to tantalum.

The real phenomenon could be a combination of these two mechanisms. In particular the second mechanism could play an increasing role with decreasing current densities as indicated by the porous oxidation phenomena which appear at low current densities. In any case the ratio of the slopes being close to unity, the proportion of the current J_{ox} which may contribute to the transformations of type (*i*) or (*ii*) is small.

Ion transfer at the oxide-solution interface.—The large value of the electrochemical dissolution current J_{dis} for aluminum in our solution indicates a considerable mobility of the cations at the oxide-solution interface. This is confirmed by the observations of Davies *et al.* (37) who directly determined the presence of the aluminum cations in the ammonium citrate solution. The relative values of J_{dis} with respect to J found by these authors on electrochemically polished aluminum differ from our results; in particular they found that this ratio depends on J, whereas no such dependence appears in Fig. 6. This discrepancy may be due to the different polishing procedure used and to the much higher potential V_{ox} applied (120V as compared to 50V in our case). It should be noted that these phenomena depend strongly on the solution used; in particular J_{dis} is negligible in organic solutions of the type used by Vermilyea (45).

The discrepancy by several orders of magnitude between the values of J_{ex} directly measured by isotopic exchange of oxygen without any applied field for both aluminum and tantalum and the values deduced from Eq. [15], as listed in Table VI, may be interpreted in the following way. We may define a cationic transfer current J_c at the oxide-solution interface by the relation

$$J_c = J_{dis} + \theta J_{ox}$$

where θ represents the proportion of the oxidation current J_{ox} due to cation transfer. The oxygen transfer current is hence $(1 - \theta)J_{ox}$. In what follows we shall try to estimate the values of θ.

(*i*) The large difference between the measured and calculated values of J_{ex} may be explained in two ways:

1. The two experiments are not comparable and the electrochemical exchange current of oxygen may be much greater during anodic growth than without an applied field. According to the literature (46) we can assume that the electric field will have the effect of creating oxygen vacancies which will appear at the oxide-solution interface. The presence of these oxygen vacancies will then increase the transfer current of oxygen at the interface which leads to a strong increase in the apparent electrochemical exchange current density of oxygen. This would explain the low values of the observed overpotentials and lead to $\theta \simeq 0$.

2. The low value observed for the overpotential in anodic growth may be explained by the transfer of cations predominating at the oxide-solution interface, ($\theta \simeq 1$). The chemical reaction in the double layer would be followed by precipitation thus contributing to film growth. Using relation [15] we may calculate in this hypothesis the apparent exchange current density J_{ex} for the transfer of Ta^{5+} or Al^{3+} cations. Taking $J_i = J_c = 10$ mA/cm^2 and $\eta = 0.1$V we get the minimal values of J_{ex} equal, respectively, to 0.45 and 24 μA/cm^2.

In the case of tantalum the high value of the cationic exchange current density calculated for $\theta = 1$ seems incompatible with the high chemical stability of the oxide, as well as with the observed absence of any dissolution current (Table V).

On the other hand the assumption $\theta = 1$ implies that the layer of high ionic conductivity present on polished aluminum samples should be rapidly buried in the oxide formed. If this layer is porous most of the current J_{ox} should contribute to its transformation into a barrier layer by pore filling; as seen above, this is not the case. If this layer is not porous, it should remain in contact with the metal; such a process seems unlikely. A definite conclusion may be reached only by localizing the final position of the initial layer by O^{18} tracing, an experiment which is in progress. All these considerations would appear to support the interpretation which implies that the growth of the oxide is achieved essentially by oxygen transfer at the oxide-solution interface, both for tantalum and aluminum.

(*ii*) The fact that the oxidation is chiefly due to oxygen transfer does not imply that J_c is small but only that $J_c = J_{dis}$. For aluminum the cationic transfer current density may hence be very large, up to 60% of the ionic current (Table IV) and there is no contradiction between our conclusions. The small probability of the oxide forming reaction by cation transfer might be explained by the decrease of the free energy of the cations in the oxide with respect to that in the metal, as suggested by Novakovski and Likhachev (47) in the case of iron passivity phenomena.

It should be emphasized that the fact that the growth of the oxide is mainly due to oxygen transfer at the oxide-solution interface does not imply that oxygen transport takes place in the bulk of the oxide. In fact cations migrating through the oxide, on arriving near the interface, would also create oxygen vacancies, leading to the oxidation reaction. The discussion of ion transport phenomena in the bulk of the oxide is beyond the scope of this work.

On the Deviations from Parabolic Oxidation of Co-25 w/o Cr at High Temperature

A. Z. Hed

Battelle Memorial Institute, Columbus, Ohio 43201

ABSTRACT

Large deviations from parabolic behavior have been observed during the oxidation of Co-25 w/o (weight per cent) Cr alloys. The rate-controlling process of the oxidation at high oxygen pressures is solid-state diffusion of cobalt through CoO channels in the inner layer; thus a model decribing the deviation from parabolic behavior in terms of time dependency of the mean cross section of these CoO channels is suggested.

In a previous publication (1), the oxidation behavior of Co-25 w/o (weight per cent) Cr in the temperature range 900°-1300°C, and oxygen pressure range 0.1-760 Torr, was described. Two mechanisms of oxidation were identified for this alloy. Their occurrence depends mainly on the ambient oxygen partial pressure and temperature. At high oxygen pressures, the oxidation involved the formation of a duplex scale, the inner layer being primarily the spinel $CoCr_2O_4$, the outer layer CoO. At low oxygen pressures, Cr_2O_3 was the dominant oxidation product on the flat surfaces, while at the edges of the specimen duplex structures consisting of an inner spinel layer and an outer CoO layer were found. In both cases, the initial oxidation rates deviated markedly from parabolic. The purpose of this treatment is to describe the deviation from parabolic rates in the high oxygen pressure range by a simple mathematical model, and interpret this model on the basis of physical processes. The experimental data used in the present analysis were reported in ref. (1).

[1] Present address: Israel Product Research Company Ltd., 34/36, Itzhak Sadeh St., Tel-Aviv, Israel.

Key words: oxidation, corrosion, cobalt alloys.

Analysis of the Results

In order to determine the nature of the deviations from parabolic behavior in the high oxygen pressure range the oxidation was assumed to obey a simple parabolic rate equation after very long oxidation times, as has been shown in ref. (1), Fig. 5 and 7. The linear part of a graph of $(\Delta W/A_T)^2$ *vs.* time was extrapolated to low values of time and the experimental values $(\Delta W/A_T)^2$ were subtracted from the extrapolated ones (see Fig. 1) where ΔW and A_T are the weight gain and area of the specimen, respectively. The differences between the experimental values and the straight line $(\Delta W/A_T)^2 = k_p t - B$ may be described as an exponential function of time. The experi-

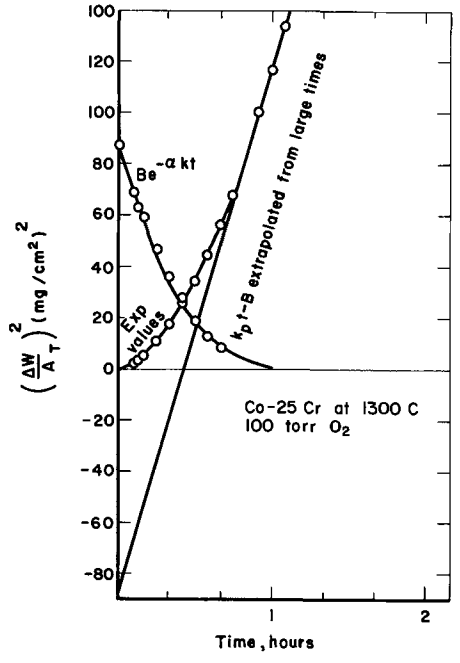

Fig. 1. Graphic representation of the calculation of the deviation from parabolic behavior for the oxidation of Co-25 w/o Cr at high oxygen pressures.

mental oxidation rate may therefore be expressed

$$\left(\frac{\Delta W}{A_T}\right)^2 = k_p t - B + Be^{-\alpha k t} \qquad [1]$$

where k_p is the "large times" parabolic rate constant, t, time, B a constant, α and k factors which will be discussed later. To test the exponential nature of the deviation from parabolic behavior the logarithms of the deviations were plotted *vs.* time for samples oxidized at 1100° and 1300°C in 100 and 760 Torr oxygen (Fig. 2). In all cases, including many not shown in this graph, a good fit to a straight line was obtained. Below a model is developed to interpret these deviations.

It has been shown (1) that the rate-determining process for the oxidation of Co-25 w/o Cr at high oxygen pressures is cobalt cation diffusion through a net-

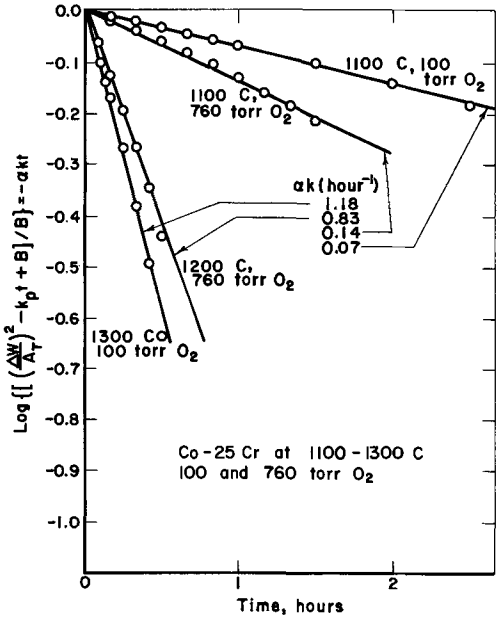

Fig. 2. Normalized deviation from parabolic behavior for Co-25 w/o Cr oxidized at temperatures between 1100° and 1300°C and high oxygen pressures.

work of CoO channels in the inner spinel layer. If the cross sectional area of this network parallel to the alloy surface is A_{eff} then the equation

$$\frac{dx}{dt} = \frac{k_p'(A_{eff}/A_T)}{x} \qquad [2]$$

describes the growth rate of the oxide scale, where k_p' is the parabolic rate constant associated with the oxidation of pure cobalt and is related to the measured k_p as discussed below. The (A_{eff}/A_T) factor is introduced to account for the fact that transport is confined to the area A_{eff} alone, the diffusion coefficient of cobalt in $CoCr_2O_4$ being three orders of magnitude smaller than in CoO (2, 3). A_{eff} is equal to the total area A_T minus the area A_s occupied by the spinel and the area $A_{Cr_2O_3}$. The experimental results suggest that A_{eff} is a function of time; however, it is sufficient to determine the variation of A_s with time.

In general, the rate of reaction for the production of spinel from Cr_2O_3 and CoO depends on the area of contact between the two oxides and the thickness of the spinel already created between the two oxides. In the case of a growing scale a gradient of cobalt cation vacancies is established from the alloy/scale interface to the outer scale/gas interface, thus creating a unidirectional movement of cobalt cations. Thus only the rate at which the cross section of spinel perpendicular to the cobalt migration path changes is important and this rate is primarily proportional to the cross section of the area occupied by Cr_2O_3. Thus as an approximation

$$\frac{dA_s}{dt} = kA_{Cr_2O_3} = k(A_o - \alpha A_s) \qquad [3]$$

where A_s = spinel cross section
$A_{Cr_2O_3}$ = Cr_2O_3 cross section
A_o = an initial cross section of Cr_2O_3 (mainly due to preferential oxidation of Cr during the holding time when the specimen is in an atmosphere ranging from 10^{-5} to about 30 Torr oxygen)
α = a factor that relates the effective cross-sectional area of the spinel formed to the cross-sectional area of Cr_2O_3 consumed
k = a surface rate constant for the formation of spinel.

By integrating Eq. [3] with the initial conditions $t = 0$, $A_s = 0$, the time dependence of A_s and $A_{Cr_2O_3}$ is found to be

$$A_s = \frac{A_o(1 - e^{-\alpha k t})}{\alpha}$$

$$A_{Cr_2O_3} = A_o - A_o(1 - e^{-\alpha k t}) = A_o e^{-\alpha k t} \qquad [4]$$

As pointed out above, the effective area for cobalt diffusion is given by $A_{eff} = A_T - A_s - A_{Cr_2O_3}$. Substituting for A_s and $A_{Cr_2O_3}$ the expressions given in Eq. [4], gives for A_{eff}

$$A_{eff} = A_T - \frac{A_o}{\alpha} - \frac{\alpha - 1}{\alpha} A_o e^{-\alpha k t} \qquad [5]$$

which in Eq. [2] produces

$$\frac{dx}{dt} = \frac{k_p'\left[\left(A_T - \frac{A_o}{\alpha} - \frac{\alpha - 1}{\alpha} A_o e^{-\alpha k t}\right) \Big/ A_T\right]}{x} \qquad [6]$$

and on integration yields

$$\frac{x^2}{2} = \frac{k_p'}{A_T}\left[\left(A_T - \frac{A_o}{\alpha}\right) t + A_o\left(\frac{\alpha - 1}{\alpha^2 k}\right) e^{-\alpha k t} + \text{const}\right] \qquad [7]$$

Where the integration constant may be calculated from the initial conditions: $t = 0$, $x = 0$, yielding $\text{const} = -\frac{\alpha-1}{\alpha^2 k} A_o$.

The weight gain, ΔW, and the thickness of the scale, x, are related by

$$\Delta W = x A_T \rho \quad [8]$$

where ρ is the mean density of the scale multiplied by the average weight fraction of oxygen in the scale, and was assumed to be constant with time. This is probably true since the ratio of the inner- to outer-layer thicknesses was constant with time [see Table I in ref. (1)].

Substituting for x gives

$$x^2\rho^2 = \left(\frac{\Delta W}{A_T}\right)^2 = \frac{2\rho^2 k_p'}{A_T}\left[\left(A_T - \frac{A_o}{\alpha}\right)t - A_o\left(\frac{\alpha-1}{\alpha^2 k}\right) + A_o\left(\frac{\alpha-1}{\alpha^2 k}\right)e^{-\alpha k t}\right] \quad [9]$$

Equation [9] has exactly the form of Eq. [1], where $k_p = 2k_p'\rho^2\left(1 - \frac{A_o}{A_T\alpha}\right)$ and $B = 2\frac{A_o k_p'\rho^2}{A_T}\left(\frac{\alpha-1}{\alpha^2 k}\right)$. We see that the square of the weight gain can be represented by the sum of a straight line, $k_p t - B$, and an exponential function, $Be^{-\alpha k t}$. Figures 1 and 2 show that this was the observed behavior.

Discussion

The analysis above describes an oxidation mechanism controlled basically by the solid-state diffusion of cobalt in CoO. An attempt was made here to account for the presence of phases in the scale which are impervious to cobalt migration, for all practical purposes, and whose morphology is time dependent. It must be emphasized that the treatment is a very simplified representation of the oxidation processes.

The basic advantage of this model is that it accounts for the decrease of the "long time" parabolic rate constants relative to those of pure cobalt, and the initial deviations from parabolic behavior. The measured parabolic rate constant at long times, k_p, is related to the theoretical rate constant, $2\rho^2 k_p'$ ($2\rho^2$ appears as a result of integration and transformation from "thickness" to "weight gain" expression of the rate equation), for the oxidation of pure cobalt by the factor $\left(1 - \frac{A_o/\alpha}{A_T}\right)$. Since A_o/α is the cross section of spinel after full reaction of Cr_2O_3 to spinel, the above weighing factor is the normalized portion of the scale able to tranport cobalt cations, after long times, as suggested in ref. (1).

This model is self-consistent but it has shortcomings related to the simplification of the parameters A_o, α, and k. These have been simplified for mathematical expediency although there is a great deal more known of their physical significance. A_o is defined as the initial cross section of Cr_2O_3; however, in the equation describing the growth rate, the cross section, A_o, should be an average over the whole of the inner layer rather than at a particular location in the layer. The surface reaction constant, k, should represent not only the effect of formation of spinel at a CoO/Cr_2O_3 interface, but also the diffusion through a $CoCr_2O_4$ interface layer, and more important, the rate of sintering of the product. Metallographic examination of the Cr_2O_3 scale at the alloy/scale interface revealed [ref. (1)] that this product is extremely porous, but the inner spinel formed is fully dense, indicating that some sintering occurred. The description of these mechanisms in a mathematical formulation is difficult and necessitates the simplified treatment.

It is theoretically possible for the constant B to be positive or negative. When $\alpha > 1$ ($B > 0$), the cross section of the resultant spinel is smaller than that of the parent Cr_2O_3 oxide, and the instantaneous parabolic rate constant will be an increasing function of time, until the CoO cross section stabilized as is found for Co-25 w/o Cr oxidized at high oxygen pressure. The fact that $\alpha > 1$ is explained by the presence of porous Cr_2O_3 and dense spinel. When $\alpha < 1$ ($B < 0$) the cross section of the resultant spinel is larger than that of the parent oxide and the instantaneous parabolic rate constant will be a decreasing function of time leading sometimes to the closing of the CoO channels and change in the oxidation mechanism to the preferential oxidation of chromium. The oxidation of Co-25 w/o Cr at low oxygen pressure could represent such a case, since we observed a decrease of the oxidation rate with time; however, further complication due to CrO_3 evaporation makes a full analysis difficult in terms of the present model.

Kinetics and Morphological Development of the Sulfide Scale on a Nickel-20 w/o Chromium Alloy in Hydrogen Sulfide-Hydrogen Atmospheres at 700°C

G. Romeo,[1] W. W. Smeltzer,* and J. S. Kirkaldy

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The sulfidation kinetics of a Ni-20 w/o (weight per cent) Cr alloy exposed to hydrogen sulfide-hydrogen atmospheres at 700°C have been determined as a function of the sulfur pressure. The morphology and phase composition of the duplex sulfide scale formed as a corrosion product have been investigated. The kinetics appear to be controlled by diffusion of the reactants through the scale. No significant dependence of the parabolic rate constant on the sulfur pressure has been determined within the wide range 8×10^{-8} to 2×10^{-2} atm. A correlation is presented for the growth kinetics and the structural features of the nickel and chromium sulfide constituents of the scales with the ternary nickel-chromium-sulfur phase diagram.

A recent review paper by Strafford (1) points out the increasing interest during the past few years on the role of sulfur in the high-temperature corrosion of metals and alloys. Due to the difficulty of purifying natural fuels from sulfur and sulfur compounds and the inherent aggressiveness of such reagents at high temperature, considerable problems may arise in plant operations and, in general, when metal parts have to work in such environments. Although several explanations have been proposed, the fundamental mechanism underlying sulfidation phenomena is not completely understood. Comparatively few data have been collected in this field with respect to the amount of work done in the field of oxidation with air, pure oxygen, or oxygen-supplying atmospheres.

Although the sulfidation of pure metals may possibly be described in terms of comparatively simple models, the situation becomes most complicated when dealing with alloys. In an attempt to gain a better insight into sulfidation properties, we selected for the present study a nickel-base type alloy. The strengh and the high-temperature corrosion resistance of these alloys make them suitable for special applications, like turbines, jet engines, heat-exchangers, *etc.* A control of sulfur corrosion is therefore of paramount importance for these alloys.

A comprehensive investigation on the sulfidation behavior of nickel-chromium alloys has been carried out by Mrowec and co-workers (2) by using pure sulfur at the constant pressure of 1 atm. The whole range of alloy compositions was studied. We thought that it would be of interest to establish the dependence between rate of sulfidation of nickel-chromium alloys and sulfur pressure, the latter being controlled by means of hydrogen sulfide-hydrogen atmospheres. Some work with these atmospheres has already been done by Hancock (3), Davin *et al.* (4), and Seybolt (5), but to our knowledge no systematic study has been made to establish the above correlation. At the same time, we intended to determine the equations governing the kinetics in the chosen conditions and the structure and composition of the phases formed as corrosion products, for the purpose of assessing a detailed mechanism of scale formation.

Experimental

The formation of a liquid phase in the Ni-Cr-S system is possible at temperatures above 600°C as shown by thermodynamic studies (6). After a few preliminary runs, we found it convenient to carry out experiments at 700°C, since the reaction was of the gas-solid type throughout the range of employed sulfur pressures. These could be determined from the equilibrium $H_2S = H_2 + \frac{1}{2}S_2$. If the equilibrium constant is known at the fixed temperature, a definite value of sulfur potential can be obtained, by adjusting the ratio p_{H_2}/p_{H_2S}. Values of the equilibrium constant are reported by Lewis and Randall (7). The assumptions are made that the only sulfur species present in the gas phase is the diatomic molecule S_2 (7) and that there is no influence of hydrogen on the sulfidation reaction. This last point however deserves further consideration, as pointed out recently by Zelouf and Simkovich (8).

The binary phase diagram for the Ni-Cr system (9) shows that an 80 Ni-20 w/o Cr alloy consists of a solid solution over a large range of temperatures, whereas lower contents of nickel may correspond to a two-phase structure. This, together with the technical properties mentioned in the introduction, led us to choose the above alloy for study. The impurity contents of the alloy are recorded in Table I.

Cold-rolled sheets of the Ni-20 w/o Cr alloy were sheared into plates approximately 1.50 x 0.5 x 0.1 cm and weighing ~0.7g. These dimensions fulfill the requirements suggested by Romanski (10) for a "specific area" of the specimen. However we did not apply, as proposed by the same author, corrections for the area consumed during the reaction, since the over-all consumption in all our experiments was well below 10% of the initial specimen area. A suspension hole was drilled in each plate, and the specimens were then batch annealed *in vacuo* for 3 days at 1000°C. They were then ground and metallographically polished down to 1μ diamond abrasive and finally stored in ace-

tone. The surface area of each specimen was computed by measuring its dimensions with a micrometer.

The apparatus used for the sulfidation experiments is shown schematically in Fig. 1. A gravimetric method was employed, in which the elongation of a McBain balance could be followed by means of a cathetometer. The assembly was similar to the one described previously by Morris and Smeltzer (11). The main modification consisted in the use of inert gas (helium or argon) for purging the upper portion of the reaction column, thus avoiding condensation of sulfur in the spring chamber. The equation $f = a/A\ F$, where f and F are, respectively, the volume flow rate of the inert gas and of the reaction mixture, and a and A the cross section areas of the small inert gas outlet and of the reaction tube, demonstrated that a low flow of inert gas did not dilute the hydrogen-hydrogen sulfide atmosphere. F was of the order of 0.5 liter/min. A corresponding linear flow rate in the reaction tube of 0.6-0.7 cm/sec prevented thermal segregation of the gases.

Rotameters supplied by Brooks Instrument Division were used for metering the components of the reaction atmospheres. They consisted of interchangeable tapered glass tubes and floats of different specific gravity and were calibrated by the soap film method. Ultra-high-purity grade hydrogen, hydrogen sulfide, and helium were supplied by Matheson Company. The assembly, which could be evacuated to about 10^{-4} Torr while the furnace was brought up to temperature, was filled with helium prior to starting an experiment. The composition of an atmosphere was adjusted and the specimen was then lowered into the reaction zone a few minutes after the reaction gases had entered from the bottom of the mullite tube. This prevented the formation of a liquid sulfide phase, which was likely to happen if the equilibrium pressure of sulfur in the hot zone was not reached. Weight gains were followed for average periods of 5 hr. At the end of the run, the specimen was winched into the upper portion of the column, where the temperature drop was sufficient for quenching it. The assembly was then flushed with a stream of nitrogen.

A modification of the assembly consisted in substituting for the spring chamber a similar column equipped with four winches and four quartz rods. To these, specimens were attached and sulfidation experiments could be carried out for intervals up to 15 hr. In these experiments, continuous weight gains could not be recorded but the scale growth could be easily studied, since the four specimens could be lifted and quenched at different convenient times.

Samples of the scale formed on the specimens were removed for subsequent analyses. Specimens were cold mounted in epoxy resin and cross sections were polished and examined metallographically, both in ordinary and polarized light. Some interesting features of the scales were also examined with a scanning electron microscope. Measurements of scale thickness were made with an optical microscope equipped with a micrometer drum.

Identification of the constituents in the corrosion product was carried out by x-ray analyses, mainly with the Debye-Scherrer powder method. Nickel-filtered copper radiation was employed. Information about phase compositions and the diffusion profiles of the components in the alloy and across the scale were obtained with a CAMECA MS-64 electron microprobe. Point counts were analyzed with respect to a set of standards and corrected for atomic number and mass absorption by means of a computer program.

Results

Kinetics and scale morphology.—Kinetic measurements have been done at sulfur potentials varying approximately from 10^{-7} to 10^{-2} atm. With the exception of an initial induction period lasting for 30-40 min, the sulfidation kinetics followed a parabolic dependence in the whole range of sulfur pressure studied. In Fig. 2, parabolic plots of kinetic data, $(\Delta m/A)^2$ *vs.* t, are shown corresponding to several values of sulfur pressure for periods up to 5 hr. In Table II, values of the parabolic constants, K_p, are reported as a function of sulfur potential. For some experimental conditions, the limits of reproducibility were not better than ±25%.

At all sulfur pressures, the corrosion product appeared as a duplex scale consisting of a yellow outer layer and a gray inner layer. Both layers appeared to be compact and adherent to each other and to the alloy substrate with the exception of widely dispersed regions, where small voids were found to occur at boundaries and within the sulfide layers. These features are exemplified in Fig. 3 and 4 for two specimens sulfidized at different sulfur pressures. In Fig. 5, the observation at comparatively high magnification in polarized light demonstrates that both layers are essen-

tially compact, although a considerable difference in hardness and crystal structure can be responsible for a higher amount of polishing artifacts in the inner layer than in the outer one. These differences are exhibited more strikingly in Fig. 6 and 7, corresponding to pictures taken by scanning electron microscopy, of the outer and inner surface of the scale, respectively, and of a fractured scale cross section. A large grain size of the outer layer is matched by a much finer

structure of the inner layer. In all cases, no evidence was found for internal sulfidation, as also reported by Mrowec and Zastawnik (12). The two layers in most cases appear to consist of one phase each, although minor features could be detected, as in Fig. 4 where a sublayer may be distinguished in the inner part of the outer layer of a scale formed in a 5% hydrogen sulfide atmosphere, and in Fig. 5 where groups of very small and preferentially oriented precipitates occur in the outer layer of a scale formed in a 50% hydrogen

A presentation of the scale growth at one sulfur potential is given in Fig. 8. Thicknesses were measured for both layers at 20 different points along the scale. The average values obtained by statistical treatment have been plotted *vs.* the reaction time up to 15 hr. Morphological irregularities were more pronounced in the outer than in the inner layer as shown by the amplitude of the errors bars, which are proportional to the probable error. It appears, however, that both layers follow the same growth kinetics. The ratio of thickness of the outer to the inner layer is constant with the time and roughly equal to 2/1.

Phase identification.—Mixed x-ray patterns for the sulfides in both the inner and outer layers were obtained by grinding samples of the scales and analyzing them with the Debye-Scherrer powder method. In all cases, it was possible to identify clearly, by comparison with ASTM cards, sulfides of nickel corresponding to the compositions NiS and Ni_3S_2, this stoi-

chiometry varying with the conditions of sulfur pressure for the reaction, as shown in Table III. Only a few faint lines were detected that could possibly be assigned to a sulfide of chromium. Attempts to gather better information by using a chart-recording x-ray diffractometer were not successful, since a too-small amount of corrosion product was available for analysis. Flakes of the scale, on the other hand, could be examined by reflection electron diffraction. The patterns obtained from the inner surfaces of these flakes could be indexed according to the ASTM card for CrS.

Information about the composition of the duplex scale could also be obtained with the microprobe. Very little nickel [2-3 a/o (atomic per cent)] was found in the inner layer and no chromium in the outer layer, while the sulfur content varied with the phase composition of the scale. This situation is exemplified by the micrographs in Fig. 9, where the distribution of the system components is shown by the images of the corresponding x-ray radiations. Figures 10, 11, and 12 correspond to plots of point counts taken scanning with the electron beam across the alloy and the scale. The specimens were also scanned parallel to the edges, but no different results were found. The three figures are related to the lowest, medium, and highest sulfur pressure used during the experiments. It can be seen that, while the outer layer corresponds entirely to a nickel sulfide the composition of which is in agreement with the data of Table III, the inner layer composition

positions of the scale layers can be related to the Ni-Cr-S ternary phase diagram, as discussed later.

Discussion

The parabolic plots shown in Fig. 2 for the over-all reaction kinetics demonstrate that sulfidation of the alloy proceeds by diffusion-controlled processes over

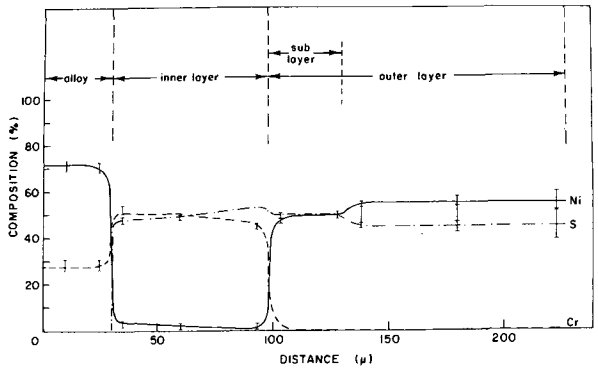

Fig. 11. Distribution profile after sulfidation in a 50% H_2S atmosphere for 5 hr.

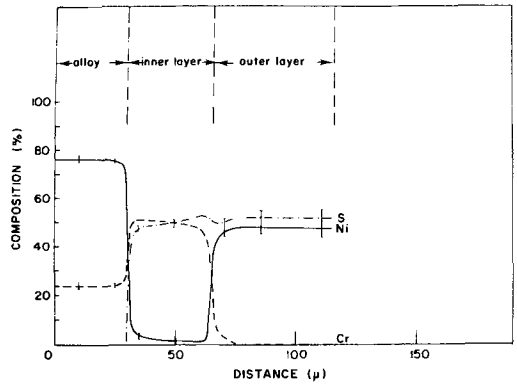

Fig. 12. Distribution profile after sulfidation in pure H_2S for 5 hr.

the whole range of sulfur potentials investigated, after a preliminary brief induction period. This result is in agreement with Mrowec's *et al.* (2) kinetic data for the sulfidation of nickel-chromium alloys with sulfur vapor. The presence, in our case, of hydrogen in the sulfidizing atmosphere has apparently not affected the basic kinetic law governing the sulfidation process. In fact, any influence of hydrogen on the defect structure of the scale would only affect the value of the parabolic rate constant. Figure 13 is a semi-logarithmic plot of K_p *vs.* sulfur pressure. One can see that the over-all variation of K_p with the sulfur potential in the range from approximately 10^{-7} to 10^{-2} atm is of the same order of magnitude as the experimental error. In other words, from a practical point of view there is no sensible dependence of the rate of sulfidation on the sulfur potential. Furthermore, Mrowec *et al.* (2) report a value of K_p equal to about 1 mg^2 cm^{-4} min^{-1} for an alloy of composition close to ours (21.8 w/o Cr) at a sulfur pressure of 1 atm. Taking this into account, we may infer that a variation of 7

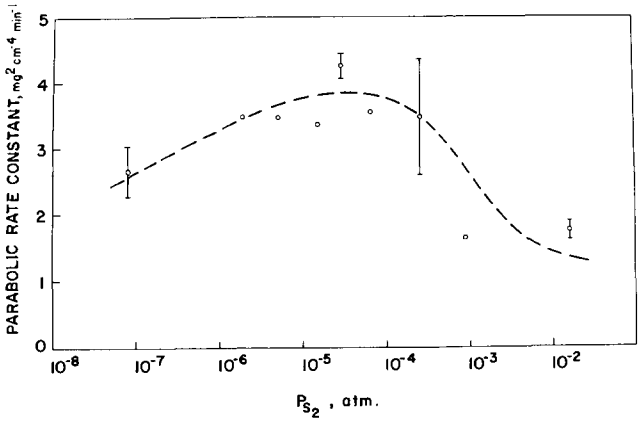

Fig. 13. Semilogarithmic plot of K_p vs. sulfur potential

orders of magnitude in sulfur potential does not have an appreciable effect upon K_p. However, the curve drawn through the experimental points shown in Fig. 13 exhibits a maximum in K_p at an intermediate sulfur pressure corresponding to a ratio of H_2S to H_2 in the atmosphere equal to 1. We ascribe this trend to the change in composition of the outer layer reported in Table III. At very low sulfur pressure (10^{-8} to 10^{-9} atm), a liquid phase is likely to be encountered. At higher sulfur pressures (10^{-7} atm), solid nickel sulfide forms with a composition corresponding to Ni_3S_2. Around 10^{-5} atm sulfur, it becomes possible to form a phase corresponding to NiS. In intermediate ranges of sulfur pressure 1-3 x 10^{-5} atm, the two solid nickel sulfide phases can coexist in a scale.

The morphology of the scale illustrated in Fig. 3 corresponds to the distribution profile of Fig. 10. The compact outer layer can be related to an atom ratio in the profile pertaining to the composition Ni_3S_2. The optically distinguishable sublayer in the outer layer of Fig. 4 appears to consist of NiS as demonstrated by the profile shown in Fig. 11. Figure 12 shows the distribution profile for a specimen which has reacted with pure hydrogen sulfide. The composition of the outer layer corresponds to NiS (no pictures of the specimen were exhibited in this case since the morphology corresponded essentially to the one shown in Fig. 3).

These findings are qualitatively consistent with thermodynamic data for the formation of nickel and chromium sulfides. Standard free energies of formation at 727°C have been reported by Rosenqvist (13), $\Delta G^\circ_{NiS} = -17{,}775$ and $\Delta G^\circ_{Ni_3S_2} = -42{,}450$ cal/mole. The standard states are the pure metal and S_2 vapor at 1 atm. For the formation of chromium sulfide, Hager and Elliott (14) propose that $\Delta G^\circ_{CrS} = -48{,}400 + 13.4\ T$ cal/mole, which is assumed to be valid in the range of temperatures 1375°-1570°K. However, extrapolating back to 700°C, we can roughly estimate the value $\Delta G^\circ_{CrS} = -35{,}360$ cal/mole, with the standard states chosen as above. No similar data have been found in the literature for higher chromium sulfides. Correspondingly, the following approximate equilibrium sulfur pressures can be derived

$$p_{S_{2(Ni_3S_2)}} = 5 \times 10^{-10} \text{ atm}, \quad p_{S_{2(CrS)}} = 1 \times 10^{-16} \text{ atm}$$

According to these values for sulfur pressures, chromium exhibits a much higher affinity for sulfur than nickel. Nickel, however, reacts more rapidly and forms concurrently a separate, thicker external layer of sulfide. Utilizing the values for the free energies of formation for NiS and Ni_3S_2, one can derive a value of $\Delta G^\circ_{NiS} = -10{,}875$ cal/mole for the reaction $Ni_3S_2 + 1/2\ S_2 = 3\ NiS$ at 727°C. This would equal an equilibrium pressure $p'_{S_{2(NiS)}} = 2 \times 10^{-5}$ atm which is within the intermediate sulfur pressure range of the diagram in Fig. 13. Thus it is possible that Ni_3S_2 and NiS may exist in a scale over appropriate sulfur potential ranges (see also Table III).

Although kinetic runs for the over-all sulfidation reaction were not followed for longer than 5 hr, results of scale growth experiments have demonstrated that the sulfidation mechanism remains basically unchanged for intervals up to 15 hr. Moreover, the same kinetic relationship controls the growth of both the inner and the outer layers. The average layer thicknesses from Fig. 8 are represented by parabolic plots in Fig. 14. It is evident that the rate of growth for both sulfide layers and the over-all reaction kinetics can be expressed by parabolic relationships. These findings are consistent with the scale morphologies shown in Fig. 3, 4, and 5, and with a prerequisite for a diffusion-controlled reaction, namely the formation of essentially compact reaction product layers within a scale. On this account, it would be possible to envisage a process for the transport of matter through the scale only in terms of lattice or grain boundary diffusion.

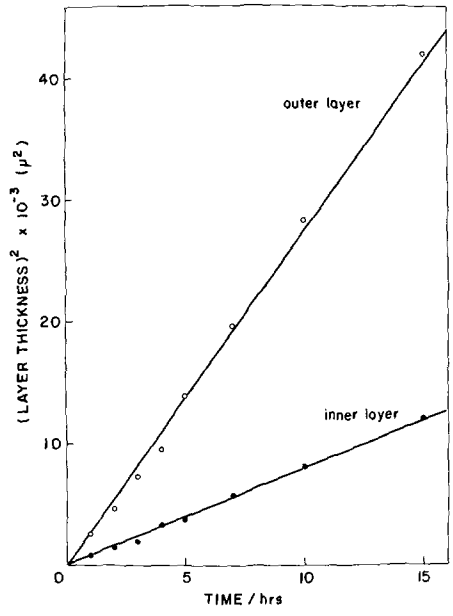

Fig. 14. Parabolic growth of the scale layers

The mechanism proposed by Mrowec *et al.* (2) for the growth of sulfide scales on nickel-chromium alloys is somewhat more complicated, since it advocates dissociation at the inner-outer layer interface, alternate building and healing of microfissures in the outer layer, and worsening of the contact between the scale and the alloy due to the growth of a chromium sulfide phase by inward sulfur transport with consequent onset of porosity. The main discrepancies between our findings and theirs consist in the relatively homogeneous and compact nature of the inner chromium sulfide layer in our case, as opposed to a pronounced porosity and the reported presence of a second phase (nickel sulfide stringers) in the inner layer in their case, for alloys of comparable composition.

The distribution profiles of Fig. 10-12 show a sharp variation in the concentration of nickel and chromium at the alloy-scale interface. Very little nickel (2-3 a/o) was found in the inner layer and no chromium in the outer layer, while the sulfur content varied with the phase composition of the scale. The outer layer was composed of Ni_3S_2 and NiS, the latter sulfide becoming predominant at sulfur pressures greater than 3 x 10^{-5} atm. A debatable point remains with respect to the stoichiometry of the chromium sulfide layer. Apparently, there is discordance in the literature on the relative stability of different chromium sulfide phases, as stressed recently by Viswanathan and Spengler (15). The compositions reported by Hancock (3), Mrowec *et al.* (2), and Seybolt (5) can vary, for instance, in the range CrS to Cr_2S_3. We mentioned earlier that in our case microprobe profiles seem to account for an average composition close to CrS. The phase diagram of Fig. 15 proposed by Bolze *et al.* (6) shows, moreover, that the chromium sulfide region may contain several chromium sulfide phases ranging from CrS to Cr_2S_3. Accordingly, the question remains open as to the exact number of phases present in the inner chromium sulfide layer.

We report in Table IV some numerical results of the microprobe analyses shown in Fig. 10-12. They refer to regions close to the interfaces present in the scale. At all sulfur pressures, the alloy is in contact with a chromium sulfide of composition close to CrS, in which about 3 a/o nickel is dissolved. The inner layer is, in turn, in contact with an outer layer corresponding closely to a composition for NiS at sulfur potentials greater than 10^{-5} atm. At lower sulfur potentials, the two nickel sulfides NiS and Ni_3S_2 may coexist in the outer layer. From the distribution profile of Fig. 11, corresponding to a sulfur pressure of about 10^{-5} atm,

Table IV. Electron microprobe analyses of sulfide scales

The table shows a set of average compositions (a/o) for the phases present in the corrosion product. The values have been determined from the corrected point counts for the different elements at the recorded distances from interfaces. The inner and outer regions correspond to distances of 5μ from the phase interfaces, represented by the vertical broken lines in Fig. 10-12. The asterisks indicate data that differ appreciably from the rest of the compositions reported for the outer region of the nickel sulfide layer.

v/o H_2S in the H_2-H_2S atmosphere	Chromium sulfide layer		Nickel sulfide layer	
	Inner region	Outer region	Inner region	Outer region
5	$Cr_{0.48}Ni_{0.03}S_{0.49}$	$Cr_{0.44}Ni_{0.06}S_{0.50}$	$Ni_{0.46}Cr_{0.01}S_{0.51}$	$Ni_{0.55}S_{0.45}$
50	$Cr_{0.51}Ni_{0.02}S_{0.49}$	$Cr_{0.45}Ni_{0.02}S_{0.53}$	$Ni_{0.48}Cr_{0.02}S_{0.50}$	$Ni_{0.54}S_{0.42}$
100	$Cr_{0.47}Ni_{0.02}S_{0.51}$	$Cr_{0.47}Ni_{0.01}S_{0.53}$	$Ni_{0.47}Cr_{0.02}S_{0.50}$	$*Ni_{0.48}S_{0.52}$
Average compositions of phases	$Cr_{0.93}Ni_{0.04}S$	$Cr_{0.82}Ni_{0.06}S$	$Ni_{0.66}Cr_{0.02}S$	$Ni_{2.5}S_2$ $*Ni_{0.93}S$

it appears that the inner region of the outer layer has a composition equal to NiS, whereas the region adjacent to the gas phase is closer to the formula Ni_3S_2, for which the ratio of sulfur to nickel is lower. The photomicrograph in Fig. 4 has illustrated that the NiS may appear as a distinct sublayer in the outer well-defined layer. This situation can be justified by the presence of a stabilizing content of chromium of about 2% in this sublayer.

The presence of the above chromium and nickel sulfide phases in the superficial scale is consistent with phase determinations for the ternary Ni-Cr-S phase diagram at 700°C (6). If the compositions shown in Table IV are superimposed on the phase diagram, tentative composition paths can be drawn, as shown in Fig. 15. In our case, tie lines have to be followed in the two-phase CrS-NiS region, because no precipitates are observed in the inner layer. Consequently, path A (1-2-3-4-5 in Fig. 15) would correspond to the formation of Ni_3S_2 (Fig. 3) or an intermediate sublayer of NiS beneath Ni_3S_2 (Fig. 4) at low and intermediate sulfur potentials, respectively. At high sulfur potentials, on the other hand, path B (1-2-3-4-6 in Fig. 15) would correspond to the presence of only NiS in the outer layer.

According to these arguments, the results of Mrowec and co-workers (2) could be described by a path similar to B, bearing in mind that a tie line has to be crossed in the region above points 3 and 4, to account for the presence of a second phase in the chromium sulfide layer. However, their experiments were carried out at a much higher sulfur pressure of 1 atm. Hence, according to the ternary phase diagram, higher sulfides both of chromium and nickel (Cr_2S_3 and NiS_2) could be present in the corrosion products, as indeed reported by these authors.

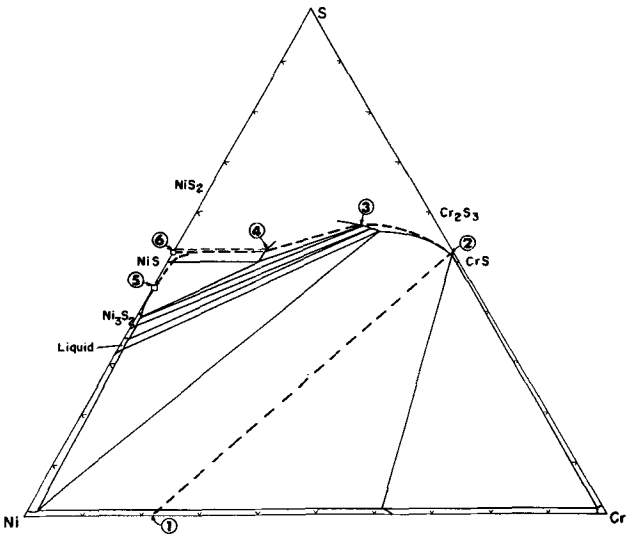

Fig. 15. Ternary phase diagram at 700°C for the Ni-Cr-S system. The dotted line represents tentative composition paths for the sulfidation process.

Conclusions

At 700°C, the sulfidation of a Ni-20 w/o Cr alloy in hydrogen sulfide-hydrogen atmospheres is governed by parabolic kinetic relationships when the reaction is entirely of the gas-solid type. The process for growth of the duplex scale is therefore diffusion controlled and, from measurements of the scale growth, one can assume that the mechanism does not vary for fairly long reaction times. A qualitative correlation can be made between parabolic rate constant and structure of the scale, although more accurate information has still to be collected about the composition of the nickel and chromium sulfide phases formed during the reaction.

Most qualitative features of the sulfidation process have been found consistent with the findings of other workers, except for the structure of the inner chromium sulfide layer of the scale. This polycrystalline layer on the nickel-20 w/o chromium alloy appears to be compact and may contain several chromium sulfide phases. An attempt has been made to correlate the microprobe analysis with the ternary phase diagram, in the form of tentative composition paths for the reaction.

Preparation and Properties of Pyrolytic Zirconium Dioxide Films

R. N. Tauber, A. C. Dumbri, and R. E. Caffrey*

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania 18103

ABSTRACT

Zirconium dioxide (ZrO_2) films in the thickness range of 500-8000Å have been prepared by chemical vapor deposition in the temperature range of 800°-1000°C. The films were identified as fine-grained (~325Å), nearly stoichiometric, monoclinic ZrO_2, using electron microprobe analysis, infrared absorption, and transmission electron microscopy. The films exhibited remarkable resistance to most aqueous acids and bases, although slight etching occurred in hot (220°C) phosphoric acid. The deposits had an index of refraction of 2.1 ± 0.1 at 546 nm and an optical energy gap of 5.12 eV. ZrO_2 deposited on silicon offered little resistance to Na diffusion at 600°C, while films deposited on thermal SiO_2 were a good barrier due to pile-up of the Na near the ZrO_2/SiO_2 interface. The current density, J, depended on the field, E, as $J = AE^n$, where n was 6 for the metal biased negatively and 2.75 or 5, depending on the magnitude of the field, for the opposite polarity. The dielectric constant in the frequency range of 5×10^2 to 1×10^5 Hz was relatively independent of frequency near 300°K and equal to approximately 18, however some dispersion was noted near 573°K. The a-c conductivity could be represented by $\sigma_{ac} = Cf^{\beta}$ where f is the measuring frequency and β a temperature dependent parameter, decreasing from ~1 at 300°K to ~0.5 at 573°K. The dielectric strength of the films varied between 1 to 2×10^6 V/cm, independently of thickness and polarity. High frequency (1 MHz) C-V measurements indicated the presence of negative surface charge, which varied between -6×10^{11} to -1×10^{12} cm^{-2}. The structures exhibited instability under negative bias, indicative of negative charge being injected into the insulator. C-V measurements on the double dielectric system (ZrO_2/SiO_2) showed that the presence of ZrO_2 caused a flatband voltage displacement ≈ +0.8V. In addition, the flatband voltage shifted as a function of time under negative bias and was found to obey the relationship $\Delta V_{FB} = K \log t$.

Recent developments in microelectronics, such as integrated circuit passivation and IGFET technology, have engendered extensive research in the preparation and characterization of insulating thin films (1). Much of the effort has been directed to SiO_2, Si_3N_4, and Al_2O_3. Recently, alternatives to these materials have been sought. TiO_2 (2) and Nb_2O_5 (3) have been investigated. It has been found that chemical vapor deposition (CVD) in the temperature range of 600°-1000°C produces films with the most desirable properties for the above applications.

A refractory oxide that has not been investigated in detail is zirconium dioxide (ZrO_2). This material is characterized by low electrical conductivity and extreme chemical inertness. Much of the information available on ZrO_2 has been obtained on relatively impure bulk, sintered material.

This paper reports on the preparation of ZrO_2 films by CVD, and a survey of the optical, chemical, electrical, and interfacial properties of the resulting films.

Film Preparation

The preparation of oxide films by CVD has been discussed by Powell *et al.* (4). The reaction chosen to produce the ZrO_2 films is written in over-all form as

$$ZrCl_4 + 2CO_2 + 2H_2 \xrightarrow{800°\text{-}1000°C} ZrO_2(s) + 2CO + 4HCl \quad [I]$$

which is conjectured to proceed in two steps

$$CO_2 + H_2 \rightarrow H_2O + CO \quad [a]$$

$$ZrCl_4 + 2H_2O \rightarrow ZrO_2(s) + 4HCl \quad [b]$$

where H_2O is formed near the heated substrate.

The deposition apparatus is shown schematically in Fig. 1. The substrate rests on a molybdenum susceptor, which is heated inductively. The gases are carefully metered through Brooks rotometers and are transported through stainless steel lines to the 50 mm quartz reaction chamber. The $ZrCl_4$ is transferred to the chamber by passing hydrogen through a heated saturator. A schematic of the stainless steel saturator is shown in the enlarged section of Fig. 1. The carrier gas is forced to take a tortuous path over six layers of $ZrCl_4$. All lines downstream from the saturator are heated approximately 20°C above the saturator temperature in order to prevent recondensation of the $ZrCl_4$ prior to its arriving at the heated substrate.

Successful depositions were made with substrate temperatures between 800° and 1000°C on various substrates. Most often, the depositions were done at 900°C on 3-7 ohm-cm, (100), n-type silicon using the following concentrations of reactants: $ZrCl_4$, 0.01%;

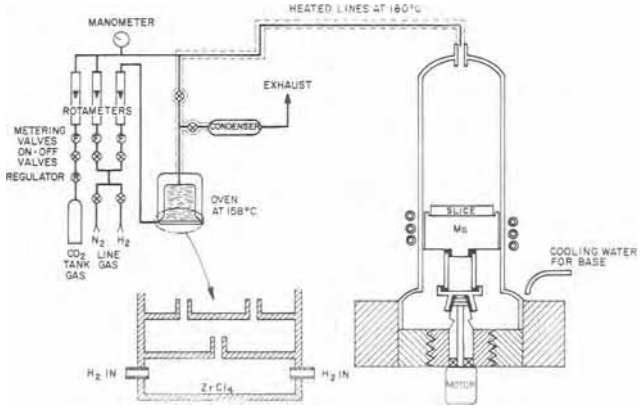

Fig. 1. Schematic representation of deposition equipment

* Electrochemical Society Active Member.

Key words: zirconium dioxide, chemical vapor deposition, dielectric properties, optical properties, insulator.

CO_2, 2.48%; the remainder hydrogen. Total hydrogen flow was ~ 3 l/min. Depositions were also made on 0.001 ohm-cm silicon, thermal SiO_2, and fused silica disks.

Identification and Structure of Films

The films were identified with respect to composition and structure using electron microprobe analysis, infrared absorption, and transmission electron microscopy.

The composition of the films was determined using a Materials Analysis Corporation Electron Microprobe at an accelerating potential of 5 kV and an x-ray emergence angle of 38.5°. The details of this technique have been described by Colby (5). Several specimens were studied at various times in the history of the experiment. A typical analysis indicated that the films consisted of 34.23 ± 0.50, 64.95 ± 0.52, and 0.81 ± 0.02 a/o (atomic per cent) zirconium, oxygen, and silicon, respectively. Silicon always appeared as an impurity. The films appeared to be slightly Zr rich, however this could be due to experimental error, since the Zr standard had a thin oxide film on its surface which would tend to cause one to overestimate the Zr concentration in the film.

The specimens for infrared absorption were prepared by depositing ZrO_2 to a thickness of 0.45 μm on 50 ohm-cm silicon slices approximately 0.63 mm thick. Spectra were taken on a Beckman IR-12 double beam spectrophotometer. A silicon slice similar to the substrate was placed in the reference beam. A typical spectrum is shown in Fig. 2. No peaks were observed at wavenumbers above 650 cm^{-1}, however six prominent peaks were observed. McDevitt and Baun (6) obtained infrared spectra from ZrO_2 pressed powders in Nujol and CsBr. The peaks shown in Fig. 2 are in good agreement with their results.

Samples were prepared for transmission electron microscopy by etching an 800Å ZrO_2 film deposited on silicon in 50:50 HF:H_2O_2 solution. The films cracked and floated free of the substrate, where they were picked up with a copper grid. The specimens were examined in a Philips 300 electron microscope at an accelerating potential of 100 kV. Figure 3 shows a transmission micrograph at 83,000 magnification. A well-defined equiaxed grain structure is observed with an average grain size of approximately 325Å. Figure 4 shows a diffraction pattern of the same area. The pattern indexes quite well to monoclinic ZrO_2 (baddeleyite) (7). Table I summarizes the indexing of the pattern shown in Fig. 4. Several weak lines were not resolved in the diffraction pattern.

The use of the electron microprobe, infrared absorption, and transmission electron microscopy has conclusively shown the films are a fine-grained, nearly stoichiometric, monoclinic ZrO_2.

Film Properties

General.—The deposits were clear, hard, crystalline films of ZrO_2 which formed a tenacious coating to the substrate. Films as thick as 8000Å did not show evidence of cracking either in the as-deposited state or after a liquid nitrogen quench and heating to room temperature.

The films did not etch appreciably in common aqueous acids and bases such as hot H_2SO_4, boiling HCl, hot HNO_3, boiling aqua-regia, 49% HF, saturated NaOH, and KOH. The HF tended to crack the films into a "river pattern" and subsequently lift them from the substrates. The films did etch slightly in boiling phosphoric acid. The removal rates were 3 Å/min, 6 Å/min, and 50 Å/min at 180°, 190°, and 220°C, respectively. The insensitivity of the ZrO_2 films to acids and bases may render it a useful coating material in a corrosive environment.

Optical Properties

Index of refraction.—The index of refraction, n, was measured on ZrO_2 films deposited on polished silicon using a Gaertner ellipsometer at a wavelength of 546 nm. Using the analysis developed by Archer (8), both the index of refraction and the thickness were obtained. The results of approximately 75 measurements on different deposits yielded an index of refraction of 2.1 ± 0.1. This result is in excellent agreement with single-crystal results which show indices of refraction of 2.13, 2.19, and 2.20 for the a_o, b_o, and c_o axes, respectively (9). Wilkens (10), studying infrared interference of anodic and thermal ZrO_2, obtained a value for the index of refraction of 2.00 ± 0.05 in the wavelength region of 1000-7000 nm.

Optical energy gap.—Specimens were prepared for energy gap measurements by depositing 0.52 μm of ZrO_2 on optically flat fused silica substrates. Absorbance *vs.* wavelength measurements were made on a Perkin-Elmer 202 UV-VIS double beam spectrophotometer in the wavelength region of 200-750 nm. No absorption peaks were observed except for a relatively sharp edge at approximately 240 nm. It was assumed that this edge was due to the fundamental energy gap absorption.

The average transmission, T, of optical energy through a medium of thickness, x, and absorption coefficient, α, can be written as

$$T_{AV} = (1 - R)^2/[\exp(\alpha x) - R^2 \exp(-\alpha x)] \quad [1]$$

where R is the reflectivity. The $R^2 \exp(-\alpha x)$ term arises from considerations involving multiple reflections. The absolute reflectivity was measured relative to a highly polished silicon surface and found to be less than 0.03. Considering the small value of R and the relatively large values of α in the absorption edge, Eq. [1] reduces to

$$T_{AV} = \exp(-\alpha x) \quad [2]$$

The spectrophotometer used in this investigation records in absorbance, A, which is related to transmission by

$$T = 1/10^A \quad [3]$$

The largest value of A that can be measured is 1.5 which corresponds to $T = 0.0318$. Using Eq. [2] and [3], and knowing the thickness, the absorption coefficient as a function of photon energy ($h\nu$) can be obtained from the A vs. λ curve. The values of absorption coefficient measured in the region of the edge were on the order of 10^4 cm^{-1}. These values are indicative of direct optical transitions. It has been shown by Fan (11) that, for the direct allowed transition, the absorption coefficient is related to the photon energy by

$$\alpha_{(direct)} = A(h\nu - E_g)^{1/2} \quad [4]$$

where A is a constant, and E_g is the direct energy gap. Figure 5 is a plot of α^2 *vs.* $h\nu$ for a ZrO_2 film. The linearity predicted by Eq. [4] is observed and extrapolation to $\alpha = 0$ yields an energy gap of 5.12 eV.

It has been shown by Vijh (12) that a correlation exists between the energy gap and the heat of formation per equivalent for many binary semiconductors and insulators. This is expressed as

$$E_g \pm 20\% = 2\,\Delta H_f^\circ/\text{equiv.} \quad [5]$$

where ΔH_f°/equiv. is the heat of formation per equivalent. Vijh (13) gives a value of ΔH_f° (ZrO_2) equal to −64.5 kcal/equiv. Substituting this value into Eq. [5] yields an energy gap of 5.5 eV. The experimental value of 5.12 eV is within the 20% limits. Doyle and Clark (14) measured the absorption of ultraviolet radiation in ZrO_2 and noted a rise in absorption at approximately 5.5 eV. This agrees well with the value of optical energy gap obtained in this investigation.

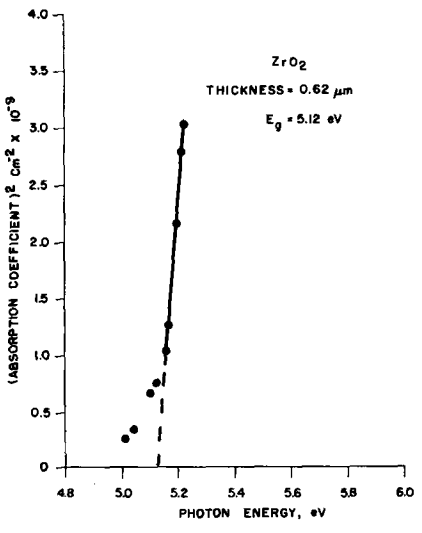

Fig. 5. (Absorption coefficient)^2 as a function of photon energy for ZrO_2.

Na *tracer diffusion.*—Radioactive sodium (Na^{22}) as NaCl along with normal NaCl was vacuum evaporated on ZrO_2 films deposited on silicon and on thermal SiO_2. The total Na was 220 times the radioactive Na^{22}. Diffusions were carried out in a forming gas atmosphere at 600°C for times of 22 and 200 hr.

After diffusion, the excess NaCl was rinsed off the surface and the Na^{22} activity measured as a function of film thickness. The thickness after each etching step was measured on an ultraviolet-visible spectrophotometer from reflectivity minima (15). Hot phosphoric acid (220°C) was used to remove ZrO_2 at a rate of 50 Å/min. The Na penetration was determined using the technique developed by Buck *et al.* (16).

Figure 6a and b are plots of Na^{22}/cm^3 *vs.* depth in angstroms for ZrO_2 on silicon, for diffusion times of 22 and 200 hr, respectively. It is apparent from these plots that ZrO_2 does not offer an appreciable barrier

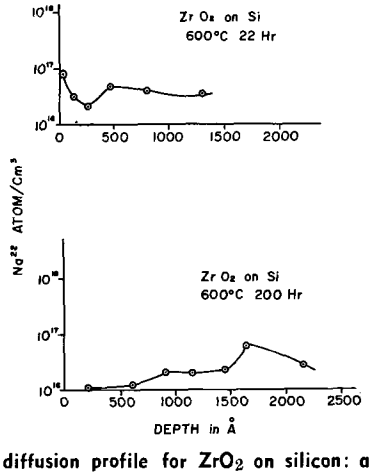

Fig. 6. Na diffusion profile for ZrO_2 on silicon: a (top), 22 hr; b (bottom), 200 hr.

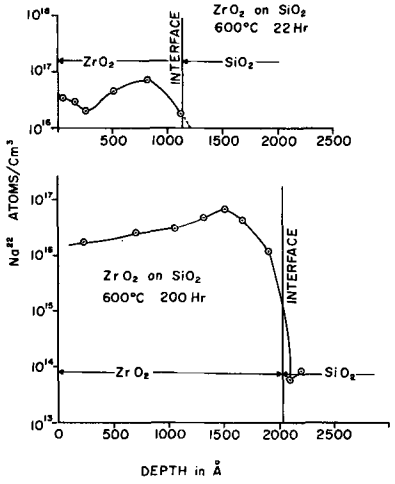

Fig. 7. Na diffusion profile for ZrO_2 deposited on thermal SiO_2: a (top), 22 hr; b (bottom), 200 hr.

to Na penetration at 600°C. For example, in the case of the 22-hr diffusion, removal of the initial 70Å of ZrO_2 leaves 91% of the Na, while similar diffusions in Si_3N_4 show only 3-10% of the Na remaining after removal of 50Å.

Figure 7a and b are plots of Na^{22}/cm^3 *vs.* depth for ZrO_2 deposited on approximately 1000Å of thermal SiO_2, diffused for 22 and 200 hr, respectively. The Na atoms show a strong tendency to pile up before the ZrO_2/SiO_2 interface. This is evidenced by the fact that 300Å from the interface, 35% of the Na remains, while at the interface, only 0.1% of the Na remains for the 200-hr diffusion.

This phenomenon of Na pile-up at a dielectric-dielectric interface has been observed by Tung and Caffrey (17) for the Al_2O_3/SiO_2 system. They describe several possible mechanisms for immobilization of the Na; however, none have been verified. A possible cause they did not consider may be the presence of a large stress gradient in the deposited dielectric, which either immobilizes the Na or serves as an effective barrier to further Na penetration. It has been shown by Tauber and Drum (18) that a large stress gradient ($\sim 2 \times 10^{15}$ dynes/cm²/cm) exists in pyrolytic Al_2O_3 deposited on thermal SiO_2 in the region of the observed Na pile-up. It is expected that a similar behavior exists in the ZrO_2/SiO_2 structure. Additional experiments are being performed to obtain better understanding of this phenomenon and to determine whether it is general to dielectric-dielectric interfaces.

Electrical Properties

The electrical measurements were performed on aluminum-zirconium dioxide-silicon capacitors fabricated by pyrolytically depositing ZrO_2 at 900°C on silicon and then filament evaporating aluminum in a vacuum of 4×10^{-7} Torr. The aluminum was evaporated through a mask in an array of dots having areas of either 2.01×10^{-3} cm² or 1.25×10^{-2} cm², depending on the particular experiment. A sheet of aluminum was evaporated on the back of the samples. The electrical properties of interest were: (*i*) d-c conductivity, (*ii*) dielectric constant, (*iii*) a-c conductivity, (*iv*) dielectric strength, (*v*) fixed surface charge, (*vi*) interface states, and (*vii*) ZrO_2-SiO_2 double dielectric layers.

D-C conductivity.—ZrO_2 films approximately 2000Å thick were deposited on $\sim$ 0.001 ohm-cm silicon. The current-voltage characteristics of the Al-ZrO_2-Si (MIS) structures were measured in a specially constructed test set. The specimen was held in place by means of a vacuum chuck and a copper probe was used to contact the aluminum dot. The specimen and probe were enclosed in a grounded copper box, which was flushed with dry nitrogen. Voltage was applied to the specimen by a Keithley Model 246 constant voltage power supply, and measured on a 610B electrometer. The current was measured by a second 610B electrometer, the output of which was connected to a time-base x-y recorder.

Several of the specimens investigated showed ohmic behavior at low voltages and had conductivities ranging from 10^{-12} to 10^{-14} (ohm-cm)$^{-1}$. A particularly resistive film having a low field conductivity of approximately 10^{-15} (ohm-cm)$^{-1}$ was investigated in detail. It was observed that the application of voltage produced a time dependent current which decayed to a steady-state value. The steady-state current was measured as a function of voltage for both the polarities (dot negative and dot positive).

The current decay was analyzed for the application of a voltage of −2.5V and found to obey the relationship (Fig. 8)

$$I(t) = At^{-0.45} \qquad [6]$$

for 20 sec $< t <$ 200 sec. It is obvious that [6] is not valid for very short, or very long times. This form of current decay has been observed previously by other investigators studying dielectric films (19) and they have related this behavior to a low frequency loss mechanism. This aspect is discussed in a later section.

Figure 9 is a plot of the current density, J, as a function of applied field, E. No ohmic behavior was observed at the lowest detectable currents ($\sim 10^{-13}$A). For the dot negative, the J-E dependence is represented by

$$J = AE^6 \qquad [7]$$

over five orders of magnitude of current. These data have been tested for a $J \propto \exp(E^n)$ dependence considering integral, fractional, positive, and negative values of n, however, no expression was found to fit as well as [7]. The data for the dot positive show considerably more scatter, however, two distinct regions are discernible. At the lower fields a $J = BE^{2.75}$ relationship was obeyed while at the higher fields a $J = CE^5$ relationship yielded the best fit.

Other investigators have observed high power dependence for various insulating films. Rand and Roberts (20) found $J \propto E^{13\text{-}15}$ for BN, while Argall and Jeacock (21) found linear, quadratic, and sixth power dependencies for anodized ZrO_2. Recently Argall (22) found linear, 3/2, and sixth power laws for anodized TiO_2.

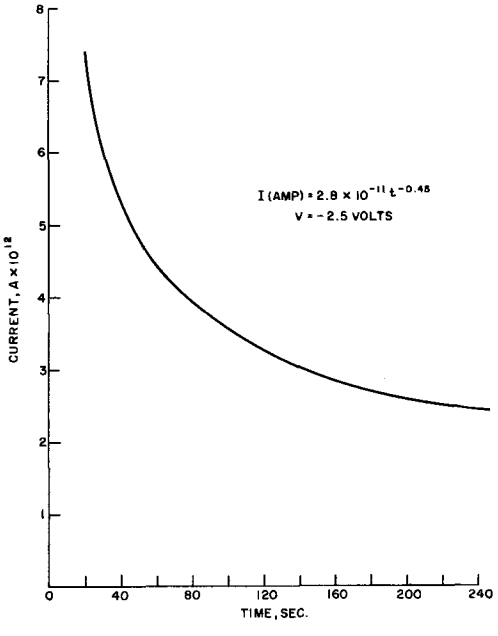

Fig. 8. Current decay for application of −2.5V

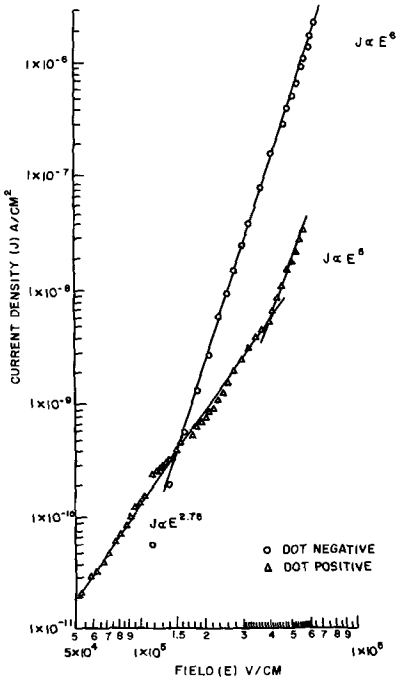

Fig. 9. Current density, J, as a function of applied field, E, for both polarities.

The present state of the theory of electronic conduction in insulators is not developed to the point where a mechanism can be assigned to a power dependence. A mechanism that may be responsible is some aspect of space charge limited conduction (SCLC). The theory of SCLC has been discussed by Lampert (23) and Rose (24). For the special cases of trap-free, or shallow trapped material, the current density is given by $J \propto E^2/l$ where l is the specimen thickness. Rose (24) has investigated the case of an exponential distribution of traps, and showed the current density is given $J \propto E^{t+1}/l^t$ where the parameter $t = T_t/T$, and T_t is a temperature characterizing the trap distribution. In the present investigation, a value of $t = 5$ is obtained which corresponds to a characteristic temperature of $T_t = 1500°K$.

The case of the reverse polarity was less amenable to analysis because of the two stages. It was observed, however, that if electrons were the conducting species, then the silicon was less injecting than the aluminum contacts.

Dielectric constant and a-c conductivity.—ZrO_2 films, approximately 2000Å thick, were deposited on ~ 0.001 ohm-cm silicon and contacted with 2.01 x 10^{-3} cm^2 area aluminum dots. The specimens were scribed, and portions were mounted on TO-18 headers. The specimens were placed in a resistance heated furnace. The capacitance and loss tangent were measured in the frequency range of 5 x 10^2 to 1 x 10^5 Hz and the temperature range of 300°-573°K. The measurements were performed on a General Radio Type 1610-B capacitance measuring assembly, using the three terminal mode at 0.7V peak-to-peak.

Dielectric constant.—The dielectric constant was determined from the film thickness and capacitance, where the thickness was determined from either ellipsometry (8) or reflectivity minima in the UV-VIS portion of the spectrum (15). Figure 10 is a plot of dielectric constant, ϵ, as a function of frequency at various temperatures. Near room temperature, ϵ was virtually independent of frequency, however, at elevated temperatures some dispersion was noted. Harrop, Wood, and Pearson (25), in a review of the a-c properties of dielectric films at room temperature, have shown that, in general, ϵ is not frequency dependent

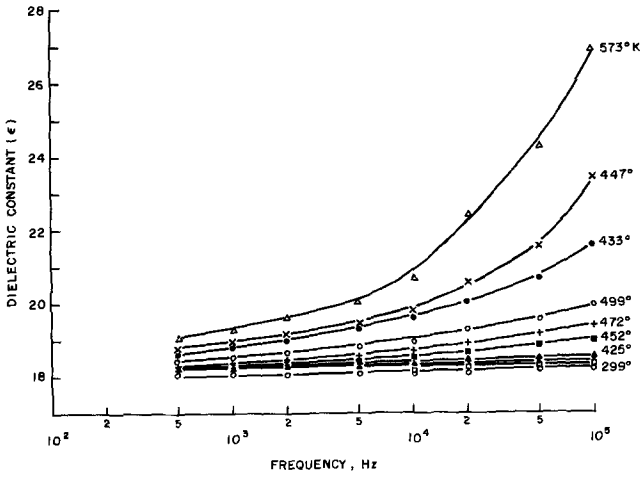

Fig. 10. Dielectric constant, ϵ, as a function of frequency with temperature as a parameter.

in the range of 10^2-10^5 Hz. Harrop and Wanklyn (26) measured the room temperature dielectric constant of single-crystal monoclinic ZrO_2 of unspecified orientation. They found a value of 22 ± 3 at 1592 Hz and observed a slight decrease with increasing frequency. We have made capacitance measurements on a Boonton capacitance bridge at 1 MHz and found a dielectric constant of 17 ± 0.5.

A-C conductivity.—The a-c conductivity was calculated from the loss tangent (tan δ), where tan δ was given by

$$\tan \delta = 1/2\pi f C_p R_p \qquad [8]$$

where f was the measuring frequency in Hz, C_p the parallel capacitance in farads, and R_p the parallel resistance in ohms. The conductivity, σ(ohm-cm)$^{-1}$, was related to the resistance and specimen dimensions by

$$\sigma = l/R_p A \qquad [9]$$

where l was the film thickness in centimeters and A the contact area in square centimeters. Combining [8] and [9]

$$\sigma = 2\pi f C_p (l/A) \tan \delta \qquad [10]$$

Figures 11 and 12 are plots of the a-c conductivity as a function of frequency over the temperature range investigated. The data over the whole temperature range can be represented by

$$\sigma = Cf^{\beta} \qquad [11]$$

where β is a temperature dependent parameter, approaching unity near room temperature and decreas-

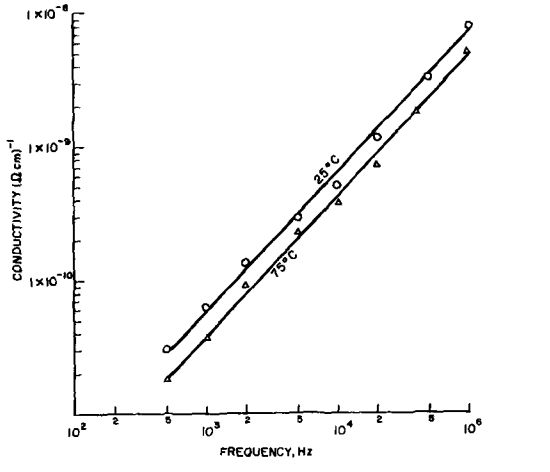

Fig. 11. A-C conductivity as a function of frequency, near room temperature.

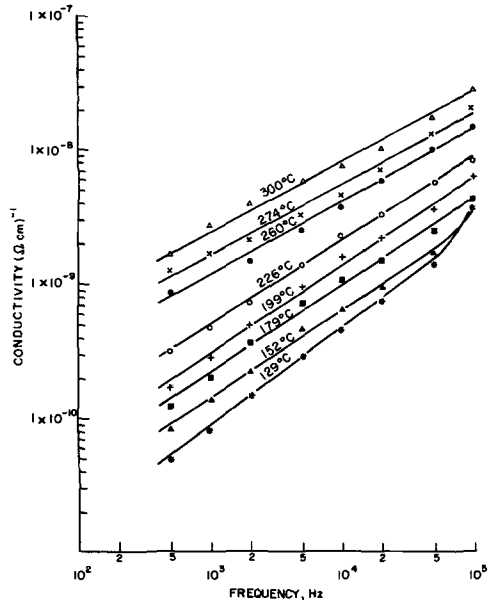

Fig. 12. A-C conductivity as a function of frequency, at elevated temperatures.

ing with increasing temperature to ~ 0.5 at 573°K. Similar conductivity behavior has been observed by Morley *et al.* (19) on vacuum deposited "silicon oxide" in the frequency range of 2 x 10^2 to 10^4 Hz and the temperature range of 273°-510°K. Argall and Jonscher (27) also found a similar behavior on evaporated "silicon dioxide" and anodized aluminum oxide films in the frequency range of 10^2 to 10^5 Hz and the temperature range of 77°-400°K. Above 10^5 Hz, they observed a $\sigma \alpha f^2$ relationship which they attributed to an electronic hopping process.

The conductivity results in the range of 10^3-10^5 Hz are not amenable to simple analysis. A possible explanation that may be considered is that the behavior results from the remanence of a low-frequency Debye-type loss mechanism. Morley *et al.* (19), when considering the Cole-Cole form of the Debye equation for frequencies greater than the relaxation frequency, have shown that the conductivity can be approximated by

$$\sigma \approx \epsilon_0(\epsilon_s - \epsilon_\infty)(2\pi)^\beta f^\beta/\tau_0{}^{1-\beta} \qquad [12]$$

where ϵ_0, ϵ_s, and ϵ_∞ are the permittivity of free space, the static, and the high frequency limits of the real part of the dielectric constant, respectively. τ_0 is the mean, or most probable relaxation time, and represents the width of the distribution of relaxation times. For a broad distribution of relaxation times, as would be expected at low temperatures, $\beta \to 1$, while as the temperature increases and the distribution narrows, $\beta \to 0$. Argall and Jonscher (27), using similar arguments concerning the remanence of a low frequency loss mechanism, have shown that a similar σ *vs.* f relationship should result.

During the course of this work, no low-frequency loss peak was observed, however, such behavior may be inferred from the current decay discussed previously. Morley and co-workers (19) in their work on silicon dioxide observed a similar current decay, except they obtained data at very short times where expression [6] is no longer applicable. Using the transform from d-c decay to dielectric loss factor, developed by Hamon (28), they showed that a loss peak should occur at 5 x 10^{-3} Hz. We can speculate that a similar behavior is applicable for the ZrO_2 films. The low-frequency dispersion is usually associated with interfacial polarization. Further measurements at lower and higher frequencies are necessary to firmly establish the conduction mechanisms in these films.

Dawson and Creamer (29) measured the temperature dependence of the a-c conductivity at 1592 Hz on anodic ZrO_2 films in the temperature range of 80°-290°C. They attempted to fit their data to an Arrhenius plot (log $\sigma \alpha 1/T$), however, except for a narrow temperature range (250° < T < 290°C), the agreement was poor. They extracted an activation energy of $\Delta E \approx 0.56$ eV from the high-temperature results. Argall (22), and Argall and Jonscher (27) have questioned the use of an Arrhenius plot for a-c conductivity. They showed that for "silicon oxide," aluminum oxide, and titanium oxide films the data can be better represented by log $\sigma \alpha T$, rather than log $\sigma \alpha 1/T$.

Figures 13 and 14 are plots of log σ *vs.* $1/T$ and log σ *vs.* T, respectively, for the ZrO_2 films for various frequencies. It is obvious from Fig. 13 that the

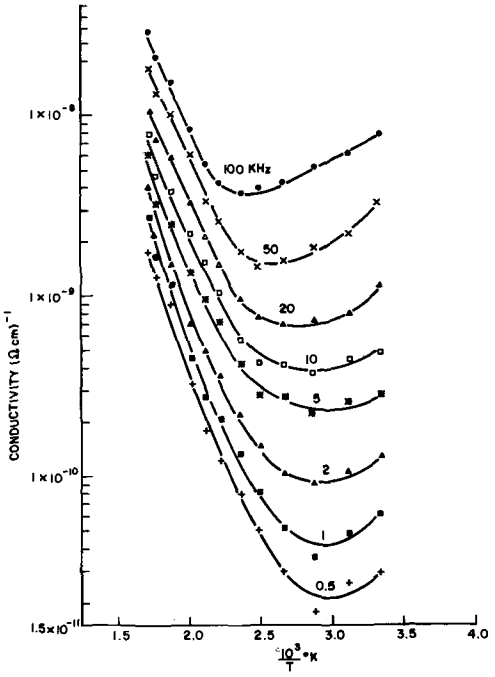

Fig. 13. Log a-c conductivity vs. reciprocal temperature

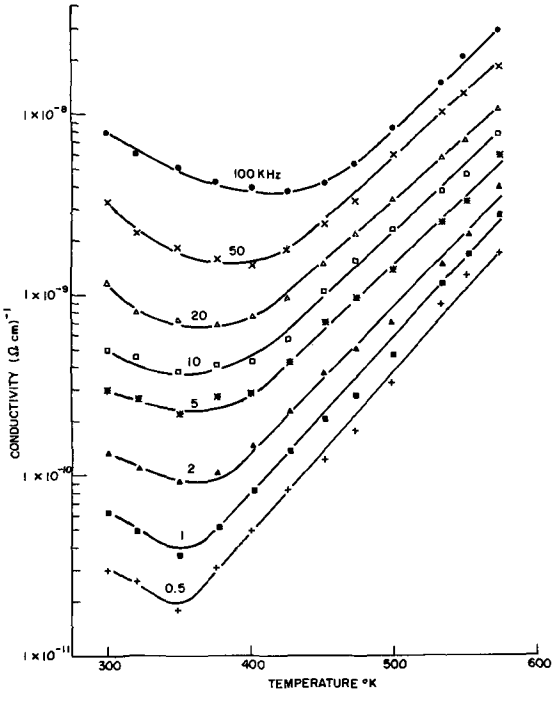

Fig. 14. Log a-c conductivity vs. temperature

data do not follow the log $\sigma \propto 1/T$ behavior below 2 x 10^4 Hz, while at higher frequencies, the Arrhenius behavior is approximated fairly well. Referring to Fig. 14 it is seen that the results can be expressed by log $\sigma \propto T$ above some temperature; the temperature at which this behavior is applicable increases with increasing frequency. At present, there is no interpretation available which readily explains the observed behavior.

The interpretation of the a-c conductivity results for ZrO_2 films prepared by CVD leaves several unexplained observations. It appears that, in general, the results are similar to those obtained from several other dielectric films prepared by various techniques.

Dielectric strength.—ZrO_2 films in the thickness range of 500 to 3600Å were deposited on 3-7 ohm-cm silicon and contacted with aluminum dots, 2.01 x 10^{-3} cm^2 in area. The breakdown voltage was measured on the capacitor structure in a capacitance-voltage (C-V) test set. A Boonton capacitance meter was connected to the y-channel of an x-y recorder, while the ramp voltage was connected to the x-channel. Voltage was increased on the metal dot at a rate of 1.5 V/sec, until an appreciable current ($\sim$ 1 μA) caused a voltage drop within the test set. The thickness of deposit under each dot tested was calculated from the accumulation capacitance.

The results of approximately 30 measurements on various slices yielded a dielectric strength varying between 1 and 2 x 10^6 V/cm, independently of thickness and polarity. This value is less than that which has been found for pyrolytic Al_2O_3, Si_3N_4, and SiO_2 (5-7 x 10^6 V/cm).

Metal-Insulator-Semiconductor (MIS) Properties

High frequency (10^6 Hz) room temperature C-V measurements were made on pyrolytic ZrO_2 deposited on 3-7 ohm-cm (100) silicon and contacted with 2.01 x 10^{-3} cm^2 aluminum dots. The resulting capacitor exhibited extreme instability with a negative bias on the field plate. To minimize the effect of the instability, the C-V traces were made between 0 and 4.8V. Figure 15 shows a C-V plot for a typical ZrO_2 deposit. In this case the film thickness was 2030Å and the flatband voltage (V_{FB}) 1.08V.

The relationship between V_{FB} and fixed surface charge density N_{FC}, is given by

$$V_{FB} = \varphi_{MS} - \frac{N_{FC} q\, l}{\epsilon \epsilon_0} \qquad [13]$$

where φ_{MS} is the work function difference between the metal and the semiconductor, q is the charge on the electron, the other quantities have been defined previously. Figure 16 shows the V_{FB} dependence on thickness, where the data were obtained on a single slice exhibiting a thickness gradient. The straight-line dependence predicted by [13] is observed. Values of

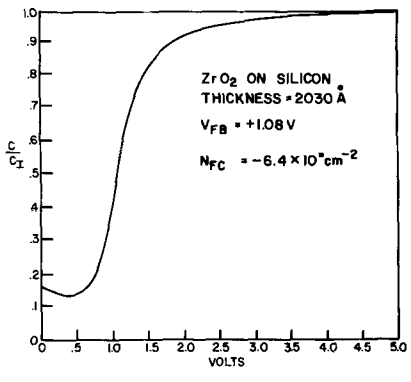

Fig. 15. Normalized capacitance as a function of applied voltage (0-4.8V).

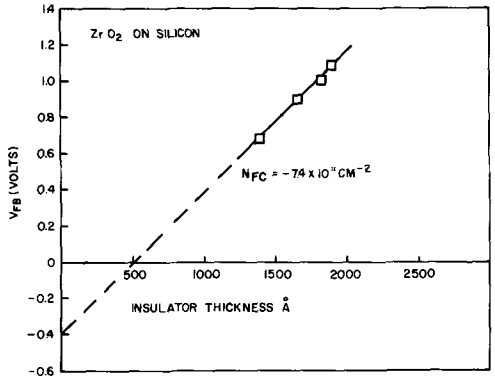

Fig. 16. Flatband voltage as a function of insulator thickness

φ_{MS} and N_{FC}, obtained from the least squares fit of the data, are −0.41V and −7.4 x $10^{11}/cm^2$, respectively. The value of φ_{MS} is in reasonable agreement with the theoretical value (−0.32V) for the silicon substrate-aluminum contacts used. Other ZrO_2 deposits resulted in values of N_{FC} ranging from −6 x 10^{11} to −1 x $10^{12}/cm^2$.

As mentioned previously, the instability under negative bias was extremely pronounced. For a field of −4 x 10^5 V/cm, the V_{FB} shifted approximately + 4V in 3 min. The direction of the shift indicates the presence of more negative charge near the interface and probably results from the trapping of injected charge in the insulator.

The distribution of interface states in the band gap was measured using the quasi-static technique developed by Kuhn (30). Figure 17 is a plot showing the distribution of interface states (N_{ss} in cm^{-2} eV^{-1}). Near the band edges the values are on the order of 10^{12} cm^{-2} eV^{-1}, while near mid-gap they approach 10^{11} cm^{-2} eV^{-1}. This is comparable to results obtained for Nb_2O_5 deposited by CVD on silicon (3). We cannot be certain that these interface states are the result of the interface between the silicon and the pyrolytic ZrO_2. They may be due to the silicon-native SiO_2 interface.

Double Dielectric (MIOS) Properties

C-V measurements, similar to those described previously, were made on sandwiches of aluminum-pyrolytic ZrO_2 ($\sim$ 2000Å)-thermal SiO_2 ($\sim$ 1000Å) and silicon (MIOS).

Values obtained for V_{FB} on this structure were approximately 0.18V. It has been well documented (31) that thermal SiO_2 grown in this laboratory and annealed in hydrogen at 900°C has a fixed charge of: $N_{FC} \approx 4 \times 10^{10}/cm^2$. Considering SiO_2 and ZrO_2 as a single insulator, and accounting for the differences

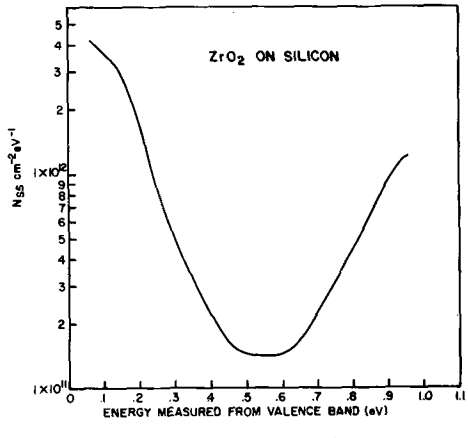

Fig. 17. Interface state density as a function of position in silicon band gap.

in ϵ, this fixed surface charge should correspond to a value of V_{FB} of ~ -0.6V. Thus, we observe a displacement in V_{FB} of 0.8V due to the presence of the second insulator. A similar displacement has been observed for Al_2O_3 deposited on SiO_2 (31). Possible causes of this displacement have been discussed by Nigh (31):

1. A sheet of negative charge near the insulator-insulator interface.
2. A contact potential or barrier energy at the insulator-insulator interface.
3. Changes in the metal-insulator barrier height when ZrO_2 is substituted for SiO_2.

It is attractive to invoke mechanism 1 to explain the observed behavior, since a sheet charge of $-1 \times 10^{12}/cm^2$ near the ZrO_2-SiO_2 interface, for a 2000Å ZrO_2 film, would account for the displacement. It has been shown by Adda and Nigh (32), from etching experiments on the Al_2O_3-SiO_2 system, that mechanism 1 cannot completely account for the behavior. It is noteworthy that the flatband displacement phenomenon is not peculiar to Al_2O_3, but occurs for other insulators as well.

The double dielectric system exhibited an instability of the V_{FB} with application of negative bias to the field plate. For an initial field of 1.7×10^5 V/cm across the ZrO_2, the V_{FB} increased $\sim$ 2.0V in 10^3 min. The V_{FB} shift depended on cumulative time at bias as

$$\Delta V_{FB} = K \log t \qquad [14]$$

Charging the MIOS capacitor to saturation at the same field, and discharging with the front and back contact shorted resulted in a discharge rate of approximately 10% of the charging rate.

Conclusions

1. A fine-grained ($\sim$ 325Å), near stoichiometric, monoclinic ZrO_2 can be produced by CVD in the temperature range of 800°-1000°C utilizing the reaction

$$ZrCl_4 + 2CO_2 + 2H_2 \rightarrow ZrO_2 + 2CO + 4HCl$$

The films were resistant to attack by most aqueous acids and bases.

2. The index of refraction of the films was 2.1 ± 0.1 at 545 nm and the optical energy gap was equal to 5.12 eV.

3. The d-c conductivity was investigated and the J-E dependence was represented by $J \propto E^n$. It is hypothesized that the behavior results from a form of SCLC with the insulator containing an exponential distribution of traps.

4. The a-c conductivity depended on frequency in the range of 5×10^2 to 1×10^5 Hz, as $\sigma \propto f^\beta$ where $\beta \approx 1$ at 300°K and $\beta \approx 0.5$ at 573°K. This behavior may result from the remanence of a low-frequency loss mechanism.

5. C-V measurements indicated that the films contained a density of interfacial negative charge which varied between -6×10^{11} and -1×10^{12} cm^{-2}. Double layer (ZrO_2/SiO_2) measurements indicated the presence of the ZrO_2 shifted the V_{FB} approximately + 0.8V.

6. The 1 MHz dielectric constant was found to be 17 ± 0.5 and the dielectric strength varied between 1 and 2×10^6 V/cm.

Acknowledgments

The authors thank J. W. Colby and D. R. Wonsidler for their assistance with the microprobe analysis and J. Drobek for his assistance with the electron microscopy. The authors also acknowledge the helpful discussions with H. E. Nigh and J. J. Curry.

Manuscript submitted Sept. 8, 1970; revised manuscript received Dec. 14, 1970. This was Paper 116 presented at the Los Angeles Meeting of the Society, May 11-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

ABSTRACT

The ternary subsolidus phase equilibria has been determined for that portion of the system containing less than 50 m/o (mole per cent) P_2O_5. Limits of solid solution along the orthophosphate join were determined for $Ca_3(PO_4)_2$, $Mg_3(PO_4)_2$, and $Ca_3Mg_3(PO_4)_4$. The 3:3:2 compound had a rapid, reversible inversion at 1104°C and melted incongruently at 1175° ± 5°C. $CaMgP_2O_7$ melted incongruently at 1120° ± 5°C. The Eu^{2+}- and Tb^{3+}-activated emission of $Ca_3Mg_3(PO_4)_4$ and associated solid solutions were examined under 2537 and 3650Å excitation, and the Mn^{2+}-activated emission of $CaMgP_2O_7$ was examined under cathode-ray excitation.

The binary compounds in the systems $CaO-P_2O_5$ and $MgO-P_2O_5$ have been reported by various authors to exhibit impurity-activated luminescence. This investigation was therefore undertaken to study the subsolidus equilibria in the system $CaO-MgO-P_2O_5$ and to explore for possible phosphor hosts among the ternary compounds and solid solutions.

A large volume of literature has been published on the $CaO-P_2O_5$ (1-7) and $MgO-P_2O_5$ (8-12) systems. Seven compounds, which can be prepared by solid-state reaction, have been reported for the $CaO-P_2O_5$ system and three have been reported for the $MgO-P_2O_5$ system. A convenient summary of these compounds, their various polymorphs, and symmetry data are listed in Table I.

Doman *et al.* (13) found that the CaO-MgO system was a simple eutectic type with small regions of solid solution (s.s.) at both ends, the CaO s.s. being approximately twice as extensive as the MgO s.s.

The orthophosphate join was investigated by Ando (14) and by Slawski (15). They both reported an intermediate compound $Ca_3Mg_3(PO_4)_4$, which melted incongruently at 1175°C. Ando reported a phase diagram which indicated solid-solution regions about $Ca_3Mg_3(PO_4)_4$ and at both ends of the join. The solidus line between $Ca_3(PO_4)_2$ s.s. and $Ca_3Mg_3(PO_4)_4$ s.s. was at 1175°C and that between $Ca_3Mg_3(PO_4)_4$ s.s. and $Mg_3(PO_4)_2$ was at 1120°C. With increasing amounts of magnesium, the $\beta \rightarrow \alpha$-$Ca_3(PO_4)_2$ transition temperature was raised, and the β form was stabilized. These solid-solution regions were also reported by Slawski, but, in addition, he reported two polymorphic transitions of $Ca_3Mg_3(PO_4)_4$, $\gamma \rightleftarrows \beta \rightleftarrows \alpha$, with transition temperatures of 1006° and 1104°C, respectively.

The pyrophosphate join was investigated by Bobrownicki and Slawski (16) and by Slawski (17). Bobrownicki and Slawski reported an intermediate compound, $CaMgP_2O_7$, which melted incongruently at 1127°C. The solidus line between $Ca_2P_2O_7$ and $CaMgP_2O_7$ was determined to be 1116°C and that between $CaMgP_2O_7$ and $Mg_2P_2O_7$ to be 1127°C. No data were reported for the region 90 to 100 w/o (weight per cent) $Mg_2P_2O_7$, although a $Ca_2P_2O_7$ solid solution was claimed to extend to approximately 2 w/o $Mg_2P_2O_7$. The x-ray diffraction data which were given for $Ca_2P_2O_7$ corresponded to that of the α form, which indicated that as the magnesium content increased, the α or high-temperature form was stabilized. This was just the reverse of the situation for the orthophosphate where a low-temperature form was stabilized. Slawski (17) later reported the intermediate compound to be $Ca_4Mg_2P_6O_{21}$ which melted incongruently at 1140°C. He also reported solid-solution regions at both ends of the join, the $Ca_2P_2O_7$ s.s. (7% at 1140°) being about three times as extensive as the $Mg_2P_2O_7$ s.s. (2% at 1126°). The join $Ca_3Mg_3(PO_4)_4$-$Mg_2P_2O_7$ contained a eutectic at 1056° and 24 w/o $Mg_2P_2O_7$. The composition and temperature of two ternary eutectics were given.

The fluorescence of Eu^{2+} in $Ca_3Mg_3(PO_4)_4$ has been described by Wanmaker and ter Vrugt (18). They reported an emission peak which varied between 440 and 460 nm and attributed this to the presence of more

than one activator site. Quantum efficiency of their material was 52%, and good brightness was maintained up to 200°C. They did not indicate that they were aware of the $Ca_3Mg_3(PO_4)_4$ solid solutions.

Experimental

Phase equilibria studies.—Reagent grade $CaCO_3$, $MgCO_3$, and $(NH_4)_2HPO_4$ were used in preparing the compositions listed in Table II. The starting materials were thoroughly mixed with acetone and then heated to 300°, 500°, 700°, and 900°C in platinum crucibles. Compositions containing 50 m/o (mole per cent) P_2O_5 or more were heated to 100°, 200°, 300°, and 500°C. The samples were remixed with acetone after each heat treatment. Pellets of ½ in. diameter were pressed to approximately ¼ in. thickness and heat treated at various temperatures and times. Several compositions containing 40 m/o or more of P_2O_5 were melted and then recrystallized at various temperatures and times.

Routine phase identification was determined by a Norelco x-ray diffractometer using nickel-filtered CuKα radiation and a scanning rate of 1° 2θ/min. For the solid-solution studies a scanning rate of 1/4° 2θ/min and silicon external standard were used.

A Model 6000 Griffin-Telin hot-stage microscope with an argon atmosphere was used to determine the melting points of the two ternary compounds and as a check for rapid, reversible polymorphic inversions.

Luminescence.—Starting materials for phosphor preparation included luminescent or reagent grade $CaHPO_4$, $CaCO_3$, basic magnesium carbonate, $(NH_4)_2HPO_4$, Eu_2O_3, Tb_4O_7, and $MnCO_3$, and especially prepared $MgNH_4PO_4$.

The compositions which contained europium were mixed in acetone and air fired in fused silica crucibles, followed by a reducing heat treatment in forming gas.

Spectral distribution curves were obtained on a direct reading spectroradiometer corrected for photocell response. The procedures for excitation and emission measurements have been previously described (19).

Results and Discussion

Phase equilibrium relationships.—The data presented in Table II were used to construct the subsolidus phase diagram given in Fig. 1. The orthophosphate and pyrophosphate joins were investigated in more detail than the remainder of the system because of the presence of the two ternary compounds.

Orthophosphate join.—The results of the present investigation agree qualitatively with the previous results of Ando (14) and Slawski (15) about the existence of solid solutions in the neighborhood of the compound $3CaO \cdot 3MgO \cdot 2P_2O_5$ (3:3:2). However, quantitatively there is considerable disagreement. Ando's diagram showed only calcium-rich solid solutions, and Slawski claimed solid solutions in the range 50-54.13

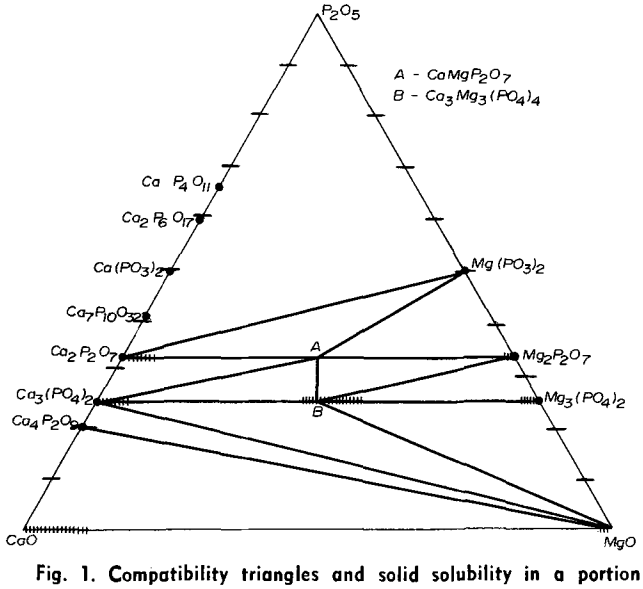

Fig. 1. Compatibility triangles and solid solubility in a portion of the system CaO-MgO-P_2O_5.

m/o $Ca_3(PO_4)_2$. It has now been shown that the solid solutions extend approximately twice as far in the direction of $Mg_3(PO_4)_2$ as in the direction of $Ca_3(PO_4)_2$. Very accurate 2θ measurements obtained by slow scanning on solid solutions along the join using silicon standardization indicated the following regions of solution:

1. 0.0 to ≈3.0 m/o CaO at 1020°C

[~0-4.0 m/o $Ca_3(PO_4)_2$]

2. ≈30.0 to ≈40.0 m/o CaO at 1020°C

[40-53.3 m/o $Ca_3(PO_4)_2$]

3. ≈70.0 to 75.0 m/o CaO at 1100°C

[~93.4-100 m/o $Ca_3(PO_4)_2$].

It should be emphasized that scanning at 1/4° 2θ/min did not reveal differences between the d spacings of these orthophosphate solid solutions and the parent compound. This is not infrequently the case in oxide systems. The limits of solid solubility were estimated rather closely by the appearance of a second phase in x-ray diffraction patterns and by the optical microscope, the latter being a more sensitive indicator in this particular system.

One polymorphic transition reported by Slawski (15) for the 3:3:2 compound was confirmed at 1104° by DTA, and it was found by quenching methods to melt incongruently at 1175° ± 5°.

Pyrophosphate join.—The data reported by Bobrownicki and Slawski (16) for the pyrophosphate join were confirmed. However, the presence of an intermediate compound with the composition $Ca_4Mg_2P_6O_{21}$ reported by Slawski (17) seems highly unlikely. The data given in Table II show that the intermediate compound was present in all the compositions. However, a change in the composition of the second phase from β-$Ca_2P_2O_7$ to β-$Mg_2P_2O_7$ occurred between the compositions containing 35.0 and 33.3 m/o CaO. The latter composition is $CaMgP_2O_7$, and all compositions near it contained large amounts of the intermediate compound, whereas the composition corresponding to $Ca_4Mg_2P_6O_{21}$ (44.5 m/o CaO, or 66.7 m/o $Ca_2P_2O_7$) was in a region where the compositions contained lesser amounts of the intermediate compound. The melting behavior of these compositions also indicated that the intermediate compound was $CaMgP_2O_7$ and not $Ca_4Mg_2P_6O_{21}$. Just above the solidus, microscopic examination showed that the compositions ranging from 60.0 to 33.3 m/o CaO contained liquid and needle-shaped crystals. The proportion of crystals increased with increasing amounts of magnesium, and the composition $CaMgP_2O_7$ yielded only crystals. Thus it was concluded that the intermediate compound had the composition $CaMgP_2O_7$. No region of solid solution surrounding $CaMgP_2O_7$ was indicated by the x-ray diffraction data, and the incongruent melting was confirmed at 1120° ± 5°C. The solidus temperatures between β-$Ca_2P_2O_7$ and $CaMgP_2O_7$ and between $CaMgP_2O_7$ and β-$Mg_2P_2O_7$ were determined to be 1115° and 1120°C, respectively, in agreement with those reported by Bobrownicki and Slawski. No attempt was made to check the extent of solid solution in $Ca_2P_2O_7$ or $Mg_2P_2O_7$. Compositions containing 50 m/o CaO or less formed glasses easily, whereas the composition containing 60 m/o CaO could not be quenched to a glass on the microscope stage. X-ray diffraction data on the ortho- and pyrocompounds are given in Table III.

Metaphosphate join.—Only cursory experiments were made in this region, and two unknown phases (X and X′) were found. One (X) was present in every composition, but it was especially prominent in the compositions containing 35.0 and 30.0 m/o CaO. The other unknown phase (X′) occurred only in the composition containing 35.0 m/o CaO which was recrystallized from a glass at 400°/24 or 850°C/24 hr. If this glass composition was recrystallized at 600°C/24 hr, it yielded the unknown phase (X) identical with that seen in compositions which were prepared by solid-state reaction. Two compositions, one on either side of the metaphosphate "join," were prepared by solid-state reaction and by recrystallization from a glass in an attempt to locate the unknown phases, but no success was achieved. All the compositions along the metaphosphate "join" were slightly hygroscopic except those containing less than 15 m/o CaO. Although the temperatures of initial melting listed in Table II are somewhat erratic, they do indicate a gradual increase in melting temperature with increasing amounts of magnesium. All these data indicated that the metaphosphate "join" was not a true join or a binary section similar to the ortho- and pyrophosphate joins and that at least one other ternary compound may exist in the system in the region near 35 m/o CaO, 18 m/o MgO, and 47 m/o P_2O_5. A major effort would have to be made to clarify the phase relations in this portion of the system, but this was not considered to be within the scope of the present work.

Luminescence.—The two compounds in the system were prepared with known activators such as Mn^{2+}, Eu^{2+}, Sn^{2+}, U^{6+}, Tb^{3+}, Dy^{3+}, Eu^{3+}, and several combinations for double activation. Of these, Eu^{2+} and Tb^{3+} in the orthophosphate and Mn^{2+} in the pyrophosphate were found to be the most efficient. Compound formation and the absence of second phases were always verified by x-ray diffraction.

$Ca_3Mg_3(PO_4)_4$:Eu^{2+}.—The emission spectrum peaks in the blue region and changes slightly in position and half-width as the composition varies between the solid-solution limits. Figure 2 shows the spectral distribution of two phosphors with compositions at either end of the solid-solution region. Compositions were prepared by firing at 1100° for 6 hr, followed by a treatment at 1050°-1100° in a reducing atmosphere of about 2.5% H_2 in N_2.

Figure 3 shows the shift of the emission peak with a variation of the Ca^{2+} content in the solid solution (Eu^{2+} at 0.06 mole or lower), compared with the emission of the end member compounds. The shift is linear between $Ca_{3.00}Eu_{0.06}Mg_{2.94}(PO_4)_4$ and $Ca_{2.34}Eu_{0.06}Mg_{3.60}(PO_4)_4$. Beyond these limits, the spectra showed no shift other than that which could be attributed to the presence of the binary end member, indicating that the solid-solution limits determined by this method are in good agreement with those obtained by the phase equilibrium studies. If the Eu^{2+} is increased at the expense of Ca^{2+}, the peak emission is shifted to longer wave lengths and the half-width is increased. In both types of formulations, the absolute peak intensity decreased as the half-width increased, as shown in Table IV.

The increase in half-width is the result of an asymmetric spectral distribution, skewed toward longer wavelengths, which probably indicates that several different site symmetries are available to the Eu^{2+}

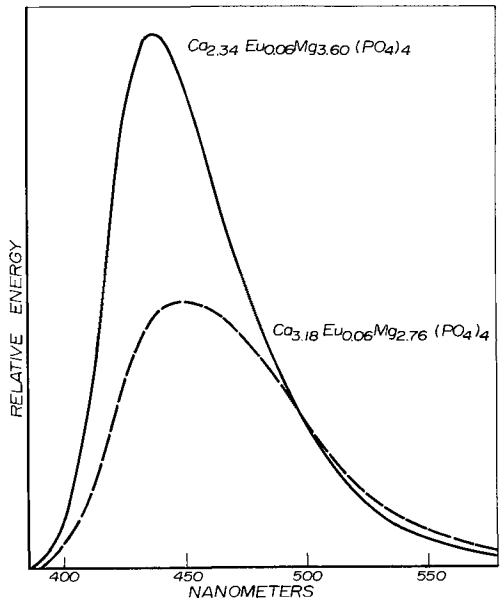

Fig. 2. Emission spectra for $Ca_{2.34}Eu_{0.06}Mg_{3.60}(PO_4)_4$ and $Ca_{3.18}Eu_{0.06}Mg_{2.76}(PO_4)_4$ under 2537Å excitation.

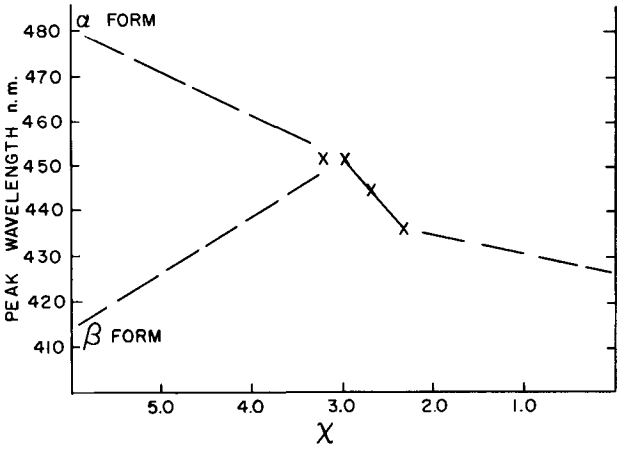

Fig. 3. Peak wavelength of $Ca_{6-x}Eu_{0.06}Mg_x(PO_4)_4$ series compared to end member orthophosphates (2537 excitation).

activator. As the sites are occupied by Eu^{2+}, broadened spectra and concentration quenching occur. The minimum Eu^{2+}-Eu^{2+} interaction occurs at the high Mg end, where considerable substitution of Mg^{2+} (radius 0.67Å) has occurred in Ca^{2+} sites (radius 0.99Å). The incorporation of Eu^{2+} (radius 1.12Å) for Ca^{2+} could occur in sites largely surrounded by the smaller Mg cations, permitting some compensation for the large size differences in the structure, and minimizing the Eu^{2+}-Eu^{2+} interaction.

Good agreement was found with the emission spectra for α-$Ca_3(PO_4)_2$:Eu^{2+} and β-$(Ca,Mg)_3(PO_4)_2$:Eu^{2+} previously reported by Wanmaker and ter Vrugt (18). The fluorescence of $Mg_3(PO_4)_2$:Eu^{2+}, with a weak emission at 425 nm, has been reported by Lagos (20), who found that the orthophosphate was the only magnesium phosphate compound which would accept Eu^{2+}.

Table IV. Spectral data for orthophosphate compositions

Composition	Intensity	Peak (nm)	½ width (nm)
$Ca_{2.00}Eu_{0.40}Mg_{3.60}(PO_4)_4$	55	450	84
$Ca_{2.20}Eu_{0.20}Mg_{3.60}(PO_4)_4$	70	443	65
$Ca_{2.30}Eu_{0.10}Mg_{3.60}(PO_4)_4$	98	440	61
$Ca_{2.34}Eu_{0.06}Mg_{3.60}(PO_4)_4$	100	439	60
$Ca_{2.35}Eu_{0.02}Mg_{3.60}(PO_4)_4$	93	433	56
$Ca_{2.94}Eu_{0.06}Mg_{3.00}(PO_4)_4$	60	452	85
$Ca_{3.18}Eu_{0.06}Mg_{2.76}(PO_4)_4$	45	452	85

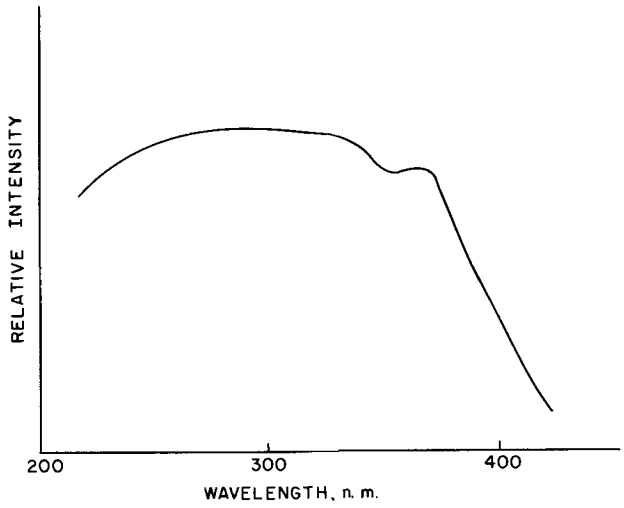

Fig. 4. Excitation curve for $Ca_{2.34}Eu_{0.06}Mg_{3.60}(PO_4)_4$ against sodium salicylate standard, detected wavelength is 440 nm.

About 4% $Ca_3(PO_4)_2$ is soluble in $Mg_3(PO_4)_2$, and apparently $Eu_3(PO_4)_2$ can also be incorporated in minor amounts.

An approximation of the quantum efficiency at 62% was made by comparing the spectra shapes of the phosphor and sodium salicylate, using a QE of 64% for the latter. The phosphor is responsive to both 2537 and 3650 excitations, as shown in Fig. 4. The optimized phosphor was tested in 40W lamps, as shown in Table V.

$Ca_3Mg_3(PO_4)_4$:Tb^{3+}.—Calculated as a substitute for Ca^{2+}, Tb^{3+} was found to require the formation of cation vacancies with the general formula $Ca_{6-x-3y}Tb_{2y}\square_yMg_x(PO_4)_4$. When charge compensation with an alkali was tried, (Na, Li, K, Rb), the brightness decreased substantially. The optimum brightness was again obtained at the magnesium end of the solid-solution range, $x = 3.60$ and $y = 0.05$ in the above formula. Emission intensities varied with Tb^{3+} concentration, and the emission from the $^5D_3$ level (blue) is quenched relative to $^5D_4$ levels (green) as the concentration is increased. This effect was found when changing the Tb^{3+} content on the magnesium end of the solid solution by increasing the value of y and also by increasing the value of x from 2.40 to 3.60 at a constant Tb concentration, which would increase the Tb^{3+}-Tb^{3+} interaction.

The absolute brightness of this phosphor is quite low, with a peak intensity of 50% of sodium salicylate, under 2537Å excitation. The excitation curve (Fig. 5) shows very poor response to the 2537Å radiation, but it is about ten times as efficient under 215 nm excitation when absorption can occur directly into the 5d band of Tb^{3+}. The phosphor is considerably more efficient under cathode-ray excitation, but the material is unstable and decreases in intensity with time. Attempts to obtain a brightness evaluation or even to record the spectra were unsuccessful due to the rapid change in the phosphor.

$CaMgP_2O_7$:Mn^{2+}.—When activated with Mn^{2+}, this phosphor responds to cathode-ray excitation, emitting in the orange-red region, with a moderately long afterglow. Partial substitution of up to 15% Zn for Mg increased the brightness. Decay measurements were made in comparison with the known phosphor

Relaxation Phenomenon at Turnover in Point Contact Silicon Devices

Takashi Agatsuma* and Kiyoshi Miyake

Semiconductor and Integrated Circuits Division, Hitachi, Ltd., Kodaira-shi, Tokyo, Japan

ABSTRACT

Studies were made of the point contact breakdown or the turnover using samples of NN^+ type. Single voltage ramp with high amplitudes was applied in the reverse direction. Initially, the voltage increased with time at a constant rate corresponding to the rising slope of the voltage ramp until the voltage reached the onset of the flat part of the voltage ramp where the turnover occurred. Relaxation process was observed associated with the turnover. The relaxation process of the voltage consisted of two stages. The first stage was characterized by an exponential decay having a time constant in the range $10^{-6} \sim 10^{-3}$ sec depending on the temperature and the amplitude of the voltage ramp. The second stage was a slow process toward a steady state. The initial rate of the relaxation and the temperature dependence of the time constant suggested that the relaxation process, *i.e.* the turnover, is due to the internal field emission of electrons from shallow slow states into the conduction band of Si. A qualitative model of the emission process is discussed in terms of the rate of change in the density of occupied slow states which involves the interaction of electrons between slow states and the conduction band. A comparison of the model with experimental data showed that the slow states must be located at the energy level ~0.15 eV from the conduction band edge.

When a high voltage pulse with a short pulse width is applied in the reverse direction of a point germanium contact diode, a turnover mode different from the one observed by applying d-c or a-c voltage from a 50 Hz source is observed. Hunter (1) reported that the turnover voltage obtained by using the high-voltage pulse becomes higher than that of d-c voltage. Billig (2), Lempicki and Wood (3), and Kikuchi and Tarvi (4) also discovered that the turnover characteristic was affected by the amplitude and the wave form of the applied voltage. According to these reports, the turnover current begins to move forward with a delay of "a certain time" after the occurrence of the turnover, and this time delay varies with the amplitude and the wave form of the applied voltage.

A self-heating hypothesis has been proposed to account for this phenomenon. The idea was that, when the temperature of the point contact is increased to

* Electrochemical Society Active Member.
Key words: breakdown, point contact, semiconductor.

a certain level, a heating effect occurs followed by an emission of the current carriers. The physical significance of this model is, however, still unclear. The present author and others (5) have pointed out that the phenomenon can be understood as a relaxation effect caused by the transfer of the current carriers between surface states at the point contact and the bulk of the semiconductor. This paper describes the experiments and the qualitative analysis of the relaxation phenomenon observed for point contact silicon devices.

Experimental Samples and Procedures

An N-type silicon slice with a thickness of 5 ~ 6 mm and a specific resistivity of 0.5 ~ 10 ohm-cm and an NN^+ silicon wafer were prepared. The NN^+ silicon wafer was composed of the N^+ layer, a phosphorus-diffused layer with a high concentration and about 100μ in thickness, and the mirror-polished N layer with a specific resistivity of 13 ~ 14 ohm-cm and a thickness of 20 ~ 90μ. The wafer was separated into pellets of 2 x 2 mm. The pellet was soldered on the silver base using the gold-silicon eutectic alloy. Before the measurements, pellets were dipped into hydrofluoric acid for 1 min cleaned with deionized water, and spin dried.

The tungsten probe with a diameter of 1.0 mm was electrochemically etched to a diameter of 15-20 $\mu\phi$ at the point. The point of the tungsten probe was attached on the N layer surface with the loading pressure of $3 \times 10^6 \sim 10^7$ g/cm^2.

The arrangement of the measuring circuit has been described previously (6). The applied voltage consists of a rising part and a following flat part. The slope of the rising part was varied from 2×10^4 to 7×10^6 V/sec, and the amplitude, Va, of the flat part from 0 to 500V. The voltage was applied one time in the reverse direction through a current-limiting resistance, R_L.

Experimental Results

Figure 1 shows typical relaxation characteristics of the voltage observed on the N-type silicon slice. The voltage rises steeply with the rising slope of the applied voltage and then decreases at the rate of an exponential function characterized by a relaxation time constant, τ. This process is the first stage of Fig. 1. The voltage decreases gradually after the first stage until it almost stops to decrease and approaches a constant value, V_S, which is the second stage. The relaxation characteristic of the current was exactly equivalent to that of voltage, and the current increases with the time constant, τ, up to a constant value.

The onset of the turnover corresponds to the point where the voltage begins to decrease at the rate of an exponential function from the initially raised voltage; that is, the voltage relaxation starts. Thus, the initially raised voltage becomes the turnover voltage, V_T. As shown in Fig. 1, the turnover voltage and the relaxation time constant vary with the amplitude of the applied voltage. When the applied voltage becomes low enough to make V_T almost equal to V_S, no turnover occurs.

Figure 2 shows the relationship between the initial rate of the relaxation of the voltage $dv/dt|_{t=0}$ and the reciprocal F_{SO}^{-1} of the initial electric field strength at the point-contact surface, with W_N as a parameter. The sample used is an NN^+-type silicon device. The initial rate of the relaxation was obtained from the slope of the relaxation curves at the onset of the turnover. The initial surface field strength, F_{SO}, was calculated from the turnover voltage assuming that the depletion layer formed by applying the reverse voltage was equal to the one made by the Schottky-type junction.

The logarithm of the initial rate of the relaxation, as shown in Fig. 2, had an almost linear relationship with F_{SO}^{-1}, and the linear curves of the $dv/dt|_{t=0}$ *vs.* F_{SO}^{-1} tend to shift toward the larger portion of F_{SO}^{-1} with decreasing thickness in the N layer. This means that the turnover is initiated at the lower voltage as the thickness is decreased.

It was also found that the relaxation time constant changes largely with the ambient temperature. Figure 3 shows the effect of ambient temperature on the time constant, τ, in terms of τ *vs.* $10^3/T$, in which case the amplitude of the applied voltage was a fixed constant during measurements. In this case, the time constant, τ, was obtained by assuming that the first stage of the voltage relaxation curve was approximately repre-

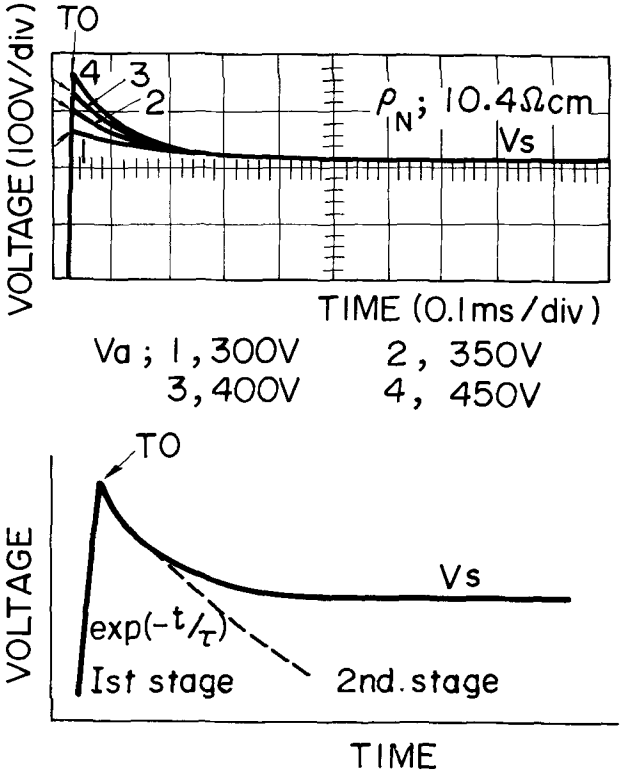

Fig. 1. Typical characteristics of voltage relaxation

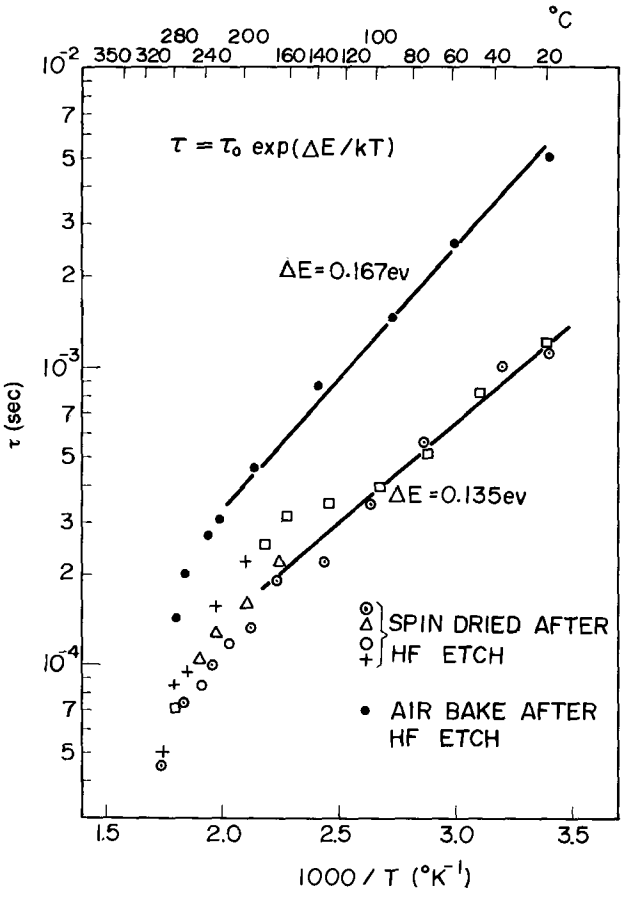

Fig. 3. The effect of ambient temperature on the relaxation time constant.

sented by the following formula

$$V = V_T \exp(-t/\tau) \qquad [1]$$

As seen in the figure, the logarithmic value of τ was approximately represented by a straight line having a slope against $1/T$, namely

$$\tau = \tau_0 \exp(\Delta E/kT) \qquad [2]$$

where k is the Boltzmann constant and ΔE is the activation energy. ΔE was slightly different from the surface treatments of the samples and was estimated on the order of 0.13-0.16 eV.

Discussion and Conclusion

As shown in the previous section, the turnover appearing in the reverse direction of the point contact silicon diode was characterized by the relaxation phenomenon of voltage and current, and the relaxation characteristic was varied by such factors as the field strength, ambient temperature, and surface treatments. This phenomenon could not be fully understood by a simple heating model. Another model of the "charge transfer mechanism between the slow surface states in the silicon dioxide and the silicon bulk" was provided in view of a close similarity of the relaxation phenomenon to the longitudinal field effect for the surface of silicon (7).

Consider the case where an electric field is applied in a form whose polarity is such that the tungsten is made negative and silicon is made positive. The energy diagram under the application of the voltage for the tungsten-silicon dioxide film-silicon system is shown in Fig. 4. The conduction electrons of the N-type silicon near the point contact will be affected by the applied electric field to repel from the N-layer surface and form a depletion layer. In this case, however, electrons trapped at the slow surface states would not be moved but frozen, and this resulted in a nonequilibrium state of electrons inside the tungsten-silicon dioxide film-silicon system. Then the relaxation phenomenon could be understood as a process of transfer of electrons from a nonequilibrium state to an equilibrium state.

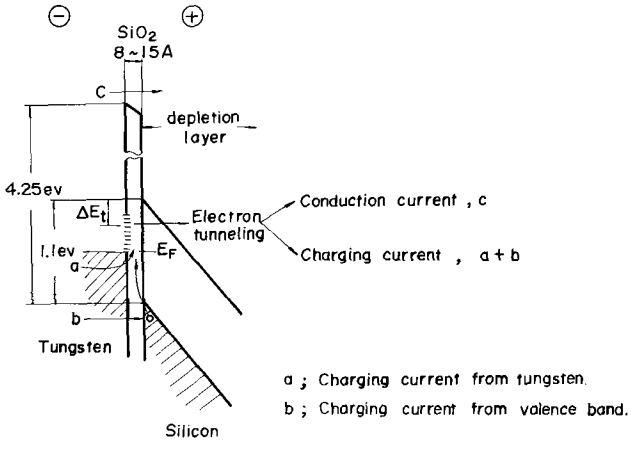

Fig. 4. The energy diagram of tungsten-silicon dioxide film-silicon during the relaxation.

With regard to the above, Rupprecht gave the time constant, τ, as a function of temperature, and Many and Goldstein (9) provided a method of solving this phenomenon by using field strength and presented a tunnel effect model. Taking into consideration the results shown in Fig. 2 and 3, however, one introduces the equation involving both temperature effect and field effect.

Thus, the relaxation process of the voltage can be expressed in terms of the rate of change in the density of occupied slow states, n_t, as follows

$$\frac{dn_t}{dt} = -C_n n_1 \{\exp(-\alpha/F_S)\} n_t + C_p p_1 (N_t - n_t) + J_t/q \qquad [3]$$

where

$$\alpha = \frac{4\sqrt{2m_e^*}}{3qh}(E_c - E_t)^{3/2} \qquad [4]$$

where q is the electronic charge, h is Planck's constant/ 2π, and m_e^* is the effective mass of electrons, being taken as the smallest mass in the conduction band (0.19 m_0, m_0: free electron mass)

$$N_t = N_0/\{1 + \exp(E_t - E_F)/kT\} \qquad [5]$$

N_t is the initial density of occupied surface states which are able to emit an electron. N_0 is the density of the slow surface states, and E_F is the Fermi-level of metal-silicon dioxide film-silicon system.

In this case, the slow surface states are assumed to consist of single charged center having the energy E_t. The temperature involves both the ambient temperature and the temperature rise induced by self-heating.

$$n_1 = N_c \exp\{-(E_c - E_t)/kt\}$$
$$p_1 = N_v \exp\{-(E_t - E_v)/kT\} \qquad [6]$$

n_1 and p_1 are the density of electrons and holes, respectively, which would be present in the oxide for the case where the Fermi level is at the level of E_t. E_c and E_v are the energy level of the edge of the conduction band and the valence band, respectively. N_c and N_v are the effective density of states for the conduction band and the valence band, respectively. C_n and C_p are the capture coefficients, the probabilities per unit time of electrons and holes, respectively, which are captured by the unoccupied slow surface states.

The first term in the Eq. [3] represents the net rate of emission of electrons from the slow surface states to the conduction band of silicon. In this case, the tunnel probability of the electrons crossing the forbidden

band of the silicon dioxide film is considered as unity, because the thickness of the silicon dioxide is in the range of 8 ~ 12Å (10). The second and third terms also represent the charging rate at which electrons are provided from the valence band and the tungsten, respectively, to fill the slow surface states being unoccupied. From its similarity to the second term, the third term may be substituted as follows

$$J_t/q = A_t(N_t - n_t) \qquad [7]$$

When the exponential term in Eq. [3] is considered as unity and the second and third terms are neglected, Eq. [3] becomes

$$\frac{dn_t}{dt} = -C_n n_1 n_t \qquad [8]$$

Equation [8] represents the thermal emission of electrons from the fast surface states into the conduction band at low temperatures and coincides with Eq. [3] given by Rupprecht (8). On the other hand, under high fields at low temperatures, Eq. [3] changes into

$$\left.\frac{dn_t}{dt}\right|_{t=0} \propto \exp\left(-\alpha/F_S\right) \qquad [9]$$

This equation corresponds to Eq. [2] presented by Many *et al.* (9).

The electrons emitted from the slow surface states will form currents, one part of which will constitute a conduction current in the conduction band of silicon bulk and the other part of which will become a charging current for the slow states being unoccupied. Accordingly, the current density may be expressed as

$$i(t) = q(N_t - n_t)^{3/2}\mu_e\bar{F} + q(N_t - n_t)C_pP_1 + J_t \qquad [10]$$

where the first term is the conduction current, in which μ_e is the electron mobility and $\bar{F}$ is the mean value of the field strength in silicon bulk. The second and third terms are the charging current from the valence band and the tungsten, respectively. The components of these currents are shown schematically in Fig. 4.

The surface field strength, F_S, observed after the turnover may be expressed as a function of time.

$$F_S^2 = F_{SO}^2 - I(t) \cdot K \cdot R_L \qquad [11]$$

where $I(t)$ is the current given by $\pi b^2 \cdot i(t)$, where b is the radius of the contact surface. K is the constant value for converting the voltage into the surface field strength, and given as $K = 4 \times 10^8/\rho_N \cdot 0.53^2$ where ρ_N is the resistivity in the N layer, and R_L is the external resistance.

Figure 5(a) and (b) show the numerically calculated curves of F_S from Eq. [3], [10], and [11] under the initial condition $t = 0$, $n_t = N_t$. Figure 5(a) and (b) are for the cases of $T = 300°K$ and $T = 400°K$, respectively. In these calculations, the following values were used; $N_o = 10^{15}$ cm^{-2}, $E_c - E_t = 0.15$ eV, $\mu_e = 4.0 \times 10^9 \cdot T^{-2.6}$ cm^2/V-sec, $C_n = C_p = 5 \times 10^{-8}$, 5×10^{-9} cm$^3 \cdot$ sec^{-1}, $\bar{F} = 200$ V/cm, $A_t = 10^{-5}$, 10^2, 10^5 sec^{-1}. A voltage relaxation curve for the silicon block with ρ_N of 10.4 ohm-cm are shown in the figures as experimental data.

In Fig. 5(a), a comparison was made between the calculations and the experimental curve by providing $C_n = 5 \times 10^{-9}$ cm$^3 \cdot$ sec^{-1}. In this case the two curves coincided for short periods of time regardless of the value of A_t, but as the time was postponed, these two curves could be matched by giving $A_t = 10^2 \sim 10^5$ sec^{-1}. In Fig. 5(b) the same condition, $C_n = 5 \times 10^{-9}$ cm$^3 \cdot$ sec^{-1}, was also provided. In this case both curves were exactly superimposed by giving $A_t = 10^{-5}$ sec^{-1} during times shorter than 2×10^{-5} sec, but no agreement of the two curves was obtained for a longer duration of time than this.

The values of physical quantities such as N_o, $E_c - E_t$, C_n, $\bar{F}$ and A_t used for the calculations mentioned above were determined as shown from the following discussion.

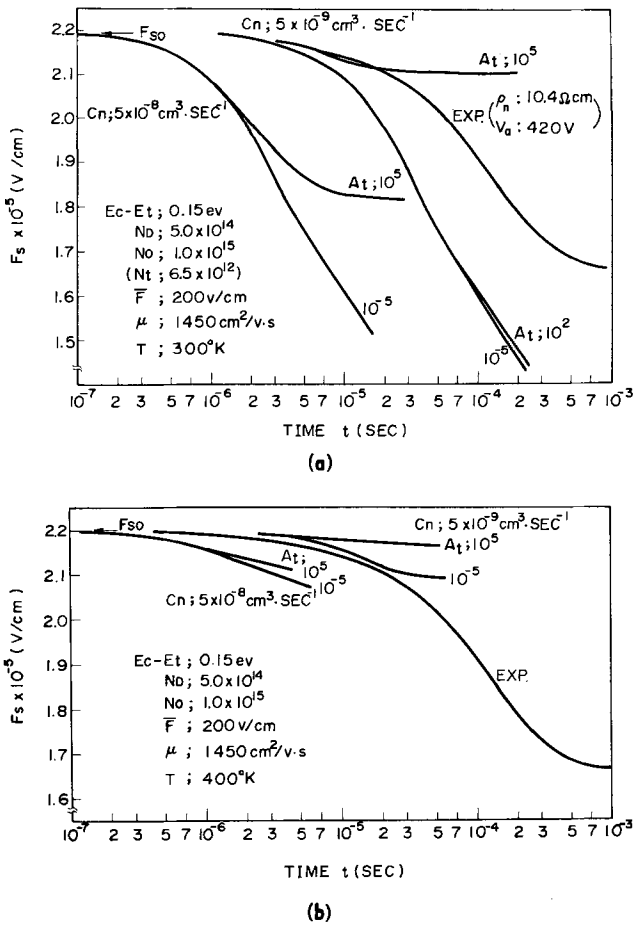

Fig. 5 (a), (b). Computed curves of F_S as a function of time

The slow surface state used in the present model were of the donor type, thus capable of emitting electrons. As the relaxation phenomenon observed quite distinctively for the samples which were cleaned in deionized water after hydrofluoric acid etching, the vapor molecules adsorbed on the silicon surface are considered to have an important role in forming the donor-type slow surface states. According to Sochanski and Gatos (11), when the vapor molecules are chemically adsorbed on the semiconductor surface, the electrons are transferred from molecules to the semiconductor, and the electrons thus transferred constitute slow surface states of the donor type. It could be deduced that, as the number of adsorption sites on the semiconductor surface is of the order of $10^{14} \sim 10^{15}$ cm^{-2}, the density of the slow surface state N_o is in the range of $10^{14} \sim 10^{15}$ cm^{-2}.

As mentioned previously, Fig. 2 and 3 describe the experimental results of the behavior of the relaxation characteristic. Figure 2 deals with this matter by using only the electric field as a responsible factor and neglecting the effect of temperature, and Fig. 3 just the opposite. Therefore, Fig. 2 may be understood by the model using Eq. [9]; Fig. 3, the model using Eq. [8]. As a result, $E_c - E_t = 0.19$ eV was obtained from the former case and, from the latter case in which $\Delta E = 0.13 \sim 0.16$ eV was previously obtained as shown in Fig. 3, these values of ΔE may be interpreted as $E_c - E_t$. As seen from the above, surface states responsible for the relaxation phenomenon have the relatively shallow energy level of the order of 0.15 eV.

This estimation of 0.15 eV as the value for $E_c - E_t$ may not deviate greatly from other reported results because in the study using an MOS-type device (12), the maximum value of the density of the interface states in the Si-SiO_2 system was found in a range as

high as 0.1 ~ 0.15 eV from the bottom of the conduction band.

According to Sclar *et al.* (13), the capture coefficient for hydrogen-like impurities in silicon and germanium was confined in the range of $10^{-9} \sim 10^{-8}$ $cm^3 \cdot sec^{-1}$. This value, applicable to slow surface states, was used for the present calculations, and F and A_t were suitably selected so that the calculation curves might not diverge from the experiment curve.

As seen from Fig. 5, the perfect matching of the calculation curves on the experiment curve was difficult to achieve because the physical quantities, such as N_o, $E_c - E_t$, and T used in Eq. [3], [10], and [11], were all dependent on a wide range of arbitrary selections. Should such a complete fit be made between the two curves, it would not be possible to decide whether the values given to physical quantities were really pertinent.

Thus it may be concluded from the above discussion that the relaxation phenomenon is due to the internal field emission of current carriers from the slow surface states in the oxide which must be located at a shallow energy level (~0.15 eV) from the conduction band edge.

N Layer Thickness Dependence of Second Breakdown in Point Contact NN^+ Si Devices

Takashi Agatsuma* and Kiyoshi Miyake

Semiconductor and Integrated Circuits Division, Hitachi, Ltd., Kodaira-shi, Tokyo, Japan

ABSTRACT

The second breakdown phenomenon in point contact Si devices was studied using NN^+-type Si pellets having different heat sinks, where the thickness of the N layer was varied from 20 to 90μ, and the resistivity in the N layer was 13 ~ 15 ohm-cm, while the resistivity and the thickness in the N^+ layer were kept constant. Single voltage ramp was applied in the reverse direction of the devices through the current limiting resistance, R_L. The second breakdown characteristics, P_M *vs.* t_d, were found to vary depending on the thickness in the N layer and also the thermal coupling at the contact between the pellets and heat sinks. The thermal model presented showed that the second breakdown characteristics can be explained assuming that the second breakdown occurs when the temperature at the interface of N and N^+ layers reaches an initiating temperature. The initiating temperature was found to vary with the thickness of the N layer and was lowered as the thickness was reduced.

In a previous paper (1) it was shown that the turnover phenomenon observed in the reverse direction of the point contact silicon device may be caused by an injection of current carriers due to the electric field emission. In this case, however, it is predictable that, since a large amount of power is dissipated at the point contact area, the device, when held at turnover for longer periods, is subject to such a second breakdown as is seen in the P-N junction diodes, transistors, and other N^+ NN^+ devices (2).

Anupyl'd (3), who found a second breakdown phenomenon in point contact germanium diodes, has commented briefly on the frequency dependence of the applied voltage and the changes caused by the surface treatments of the device. Agatsuma (4) used point contact silicon NN^+ devices and attempted to clarify the phenomenon. The present paper is intended to describe how the delay time associated with the second breakdown varies depending on the thickness of the N layer and the thermal coupling between the pellet and the heat sink, thereby explaining this breakdown as a heat conduction phenomenon for the longitudinal direction of the device.

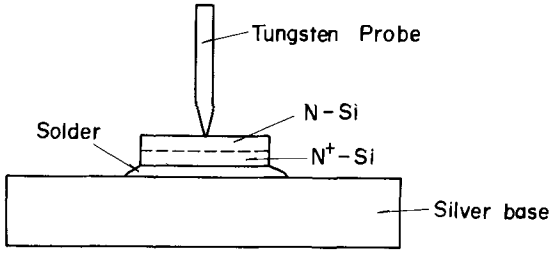
Key words: breakdown, point contact, semiconductor.

Experimental Samples and Procedures

NN^+-type silicon wafers were prepared composed of the N^+ layer, a diffused layer of phosphorus with a surface concentration of over $10^{20}/cm^3$ and the thickness of 100μ, and the mirror-polished N layer with the specific resistivity of 13-15 ohm-cm and the thickness ranging from 20 to 90μ. The wafers were broken into small pieces (pellets) of a rectangular form to prepare the samples. The N^+ layer of pellets was attached on the heat sink (silver base) by one of the following three soldering methods. Figure 1 shows simple illustrations of the samples used.

(*a*) Vacuum-evaporate a thin layer of Mo-Ni-Ag alloy on the surface of the N^+ layer, then being welded to a silver base of 3 mm thickness through 2-5μ thick solder form.



(a) Sample having heat sink of silver base

(b) Sample under thermally insulation

Fig. 1. Schematic drawing of the samples for the experiments

(b) Insert a gold pellet between the N^+ layer and the silver base, and heat them all to form an Si-Au eutectic alloy, thus soldering the pellet on the silver base with the thickness of eutectic layer in the range of 30-50μ.

(c) Place the pellet in a vacuum of 10^{-4} mm Hg, using a cryostat to provide the condition that the N^+ side is under thermal insulation. Before the measurements, the sample was immersed in hydrofluoric acid for 1 min, rinsed in deionized water, and spin dried.

The tungsten probe with a diameter of 1.0 mm was electrochemically etched to a diameter of 15-20 $\mu\phi$ at the point. The tungsten probe was positioned to the N side with a pressure of 3 x 10^6-10^7 g/cm^2. The arrangements of the measuring circuit are the same as in a previous paper (1). The applied voltage consisted of a rising part with a rising slope and a following flat part. The rising slope was continuously varied from 2 x 10^4 V/sec to 5 x 10^7 V/sec and the amplitude V_a of the flat part was also changed from 0 to 500V. The single voltage was applied in the reverse direction through the current limiting resistance, R_L.

Experimental Results

Figure 2 shows the typical characteristics of voltage and current transients with V_a as a parameter when a high voltage pulse is applied in the reverse direction of the device. Initially both voltage and current increased with time as shown in the figure. Then, the voltage curve arrived at its maximum value, V_T where it stopped increasing further and the current curve reached a point, I_p, where it changed the course of its progress. V_T and I_p are the turnover voltage and current, respectively (1).

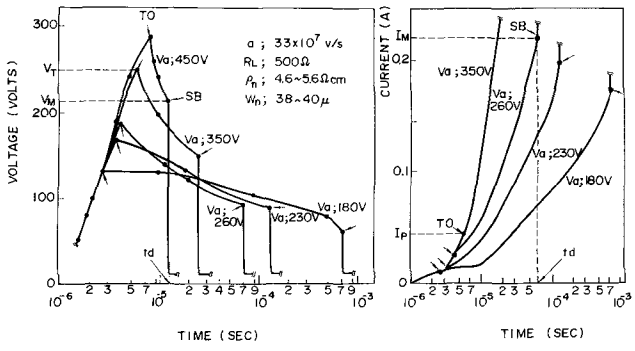

Fig. 2. Typical characteristics of voltage and current transients

After the voltage curves continued to decrease with a certain time constant, and the current curve kept on increasing, both of the curves came across a point where "the voltage reduced abruptly and the current increased suddenly." This is the occurrence of a second breakdown to which P-N junction diodes and transistors are subjected. The voltage, current, and delay time, all of which play their roles in characterizing the secondary breakdown, are defined as V_M, I_M, and t_d, respectively.

Figures 3(a) and (b) show the variations of the second breakdown characteristics with the thickness in the N layer. In the experiments, the rising slope was held at a constant value of 5.5 x 10^7 V/sec. The voltage-time and current-time characteristics were first observed and, then, the power, P_M, which is I_M multiplied by V_M and the delay time, t_d, were measured. The values of P_M and t_d were determined for each value of the applied voltage, V_a. In this manner, P_M *vs.* t_d curve for the sample with a given thickness in the N layer was obtained. This procedure was followed for all samples having the N layer ranging from 20 to 90μ. Thus, P_M *vs.* t_d curves were obtained with the thickness of the N layer as a parameter.

Figure 3(a) illustrates P_M *vs.* t_d characteristics using the soldering method mentioned previously, *i.e.* the method of soldering the surface of the N^+ layer to the silver base with Mo-Ni-Ag alloy. In the thicker samples, as seen from the figure, t_d decreases gradually with increasing P_M, while, in the thinner samples, t_d shows an appreciable decrease with no further increase in P_M.

Figure 3(b) represents the variation of P_M *vs.* t_d characteristics with the soldering methods (*a*), (b), and (c). As the delay time, t_d, became longer (in the order of ~msec), P_M *vs.* t_d characteristics were greatly changed depending on the soldering methods. For example, for the samples of 90μ thickness, the value of P_M for the constant value of t_d decreased in the sequence: Mo-Ni-Ag silver base, Au-Si silver base, and the thermally insulated sample. In the case of Mo-Ni-Ag silver base, t_d increased rapidly with no further increase in P_M. When P_M approached 40W, t_d became so long that the second breakdown was actually unobserved, while, in the case of the insulated sample, t_d did not display a saturation such as in the above case, but only a gradual reduction with the decrease of P_M. This behavior, however, became less pronounced for thinner samples.

It is to be noted that, for a range of shorter delay times, any choice of the soldering methods did not affect P_M *vs.* t_d characteristics.

The behavior mentioned above is also understood from the voltage-time characteristic and the current-voltage characteristic (relaxation curves), as shown in Fig. 4(a) and (b). As seen in Fig. 4(a), for the sample with the Au-Si eutectic silver base the voltage showed no appreciable decrease during the sweep time exceeding ~1 msec, and the second breakdown was observed at a point along the curve of this time characteristic. On the other hand, the insulated sample showed a gradual reduction of the voltage even after

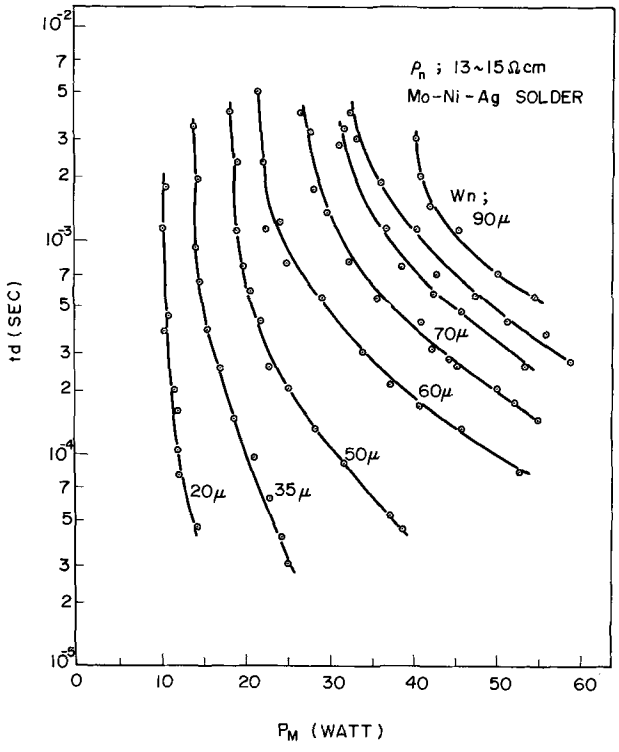

Fig. 3 (a). The dependence of P_M vs. t_d characteristics on the thickness in the N layer.

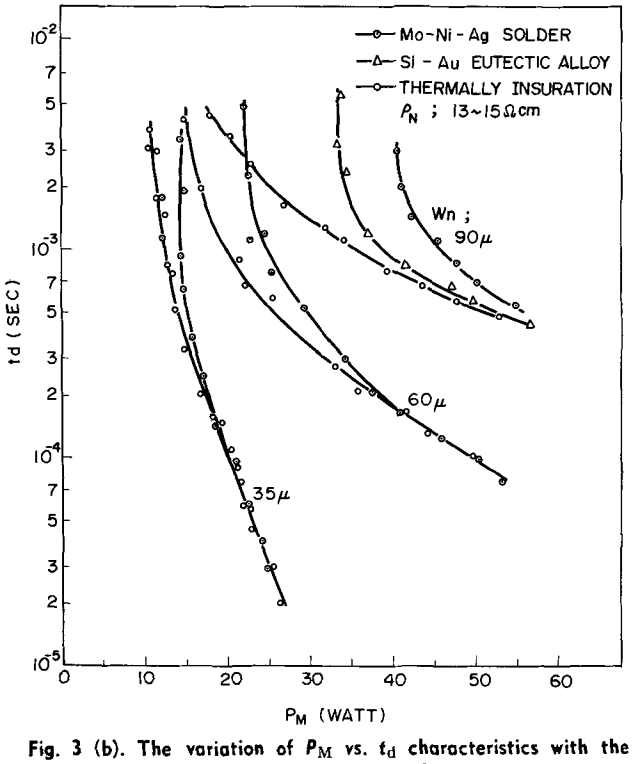

Fig. 3 (b). The variation of P_M vs. t_d characteristics with the thermal coupling between pellets and heat sinks.

the sweep time became greater than ~1 msec, and the second breakdown occurred at some point along this curve. The numbers on the curves shown in Fig. 4(b) indicate the time during which the operating points move along relaxation curves. As seen from the figure, in the case of the silver-base sample the operating point stayed at a high-power level for a long duration of time, but in the case of the insulated sample the point quickly passed over such a high-power region and reached a lower-power level where it remained for a long period of time.

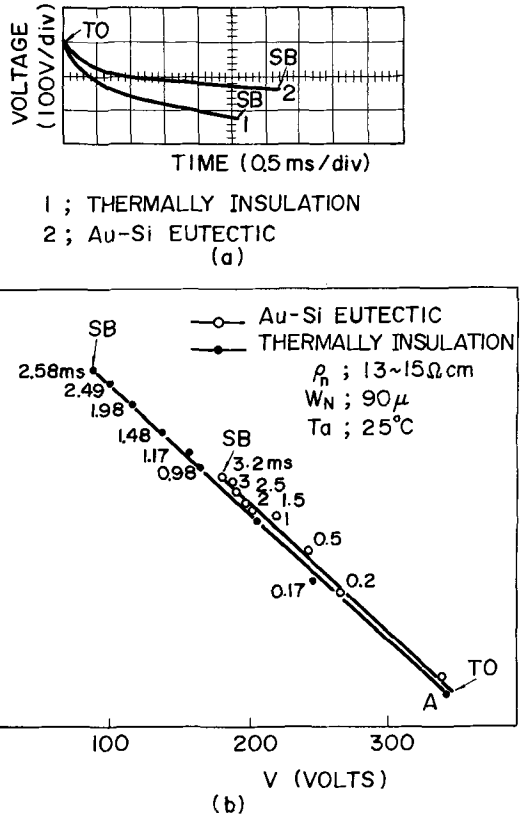

Fig. 4. The comparisons of voltage-time (a), and voltage-current characteristics (b) between samples with Au-Si eutectic silver base and under thermal insulation.

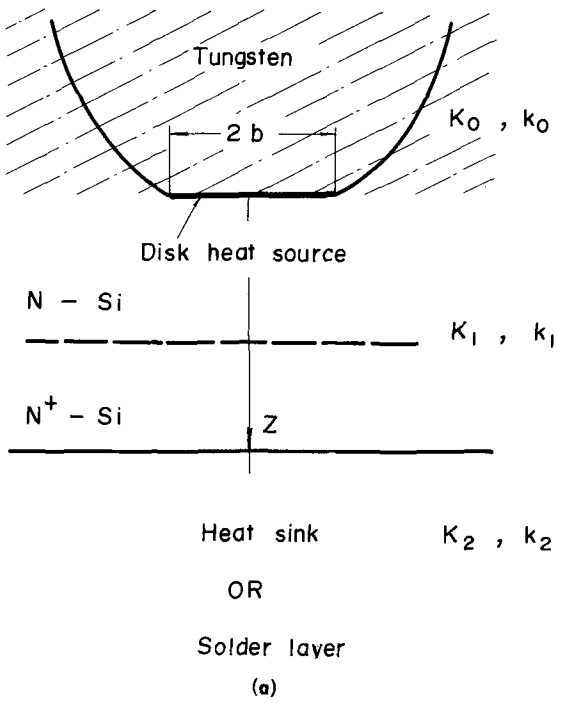
Discussions and Conclusion

As seen in the previous section the second breakdown occurred when the device was subjected to staying at the turnover for the duration of delay time, t_d. Then, the thermal model was proposed as shown diagrammatically in Fig. 5(a). This model consisted of a disk heat source having a radius b, the N-type silicon and the heat sink both extending in the direction of Z axis, and a tungsten probe. The disk heat source is positioned on $Z = 0$ plane, the surface of the contact between a tungsten point and the N-type silicon. Let us assume that the power is spread uniformly over the disk, and no heat is generated inside the N-type silicon. The heat generated may be conducted in two directions of $\pm Z$ axes, one advancing through the N-type and N^+-type silicon layers toward the heat sink and the other moving along the tungsten probe.

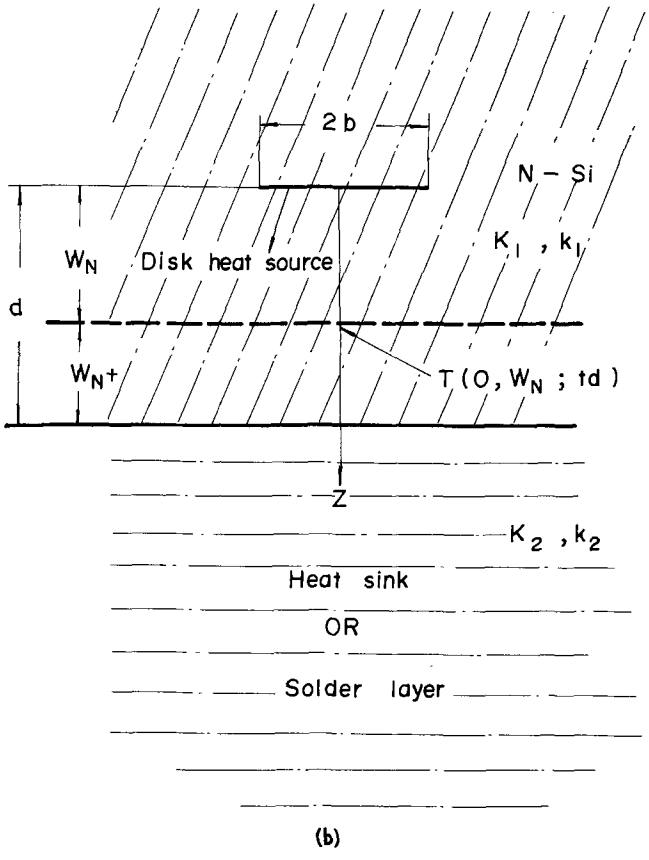
We consider, for simplicity, that as shown in Fig. 5(b) the whole device comprises the silicon and the heat sink, each extending to infinity, and that the heat disk is located at a distance d from the heat sink. The effect of the tungsten probe is made as a correction for this simple model.

Attention was paid to the temperature at a point of $r = 0$, $Z = W_N$, namely the boundary between the N and N^+ layers immediately under the tungsten point. Let the initial conditions be that $t = 0$, $T = 0$ and that the power $P(t)$ is dissipated from the moment of $t = 0$ to $t = t_d$. Then, the temperatures developed at the time of t_d at the point of $r = 0$, $Z = W_N$ are given by the following equation (5)

$$T(0,W_N;t_d) = \frac{1}{2\rho_1 C_1\sqrt{\pi k_1}} \left[\int_0^{t_d} \frac{P(t)}{t^{1/2}} e^{-W_N^2/4k_1t}\,(1 - e^{-b^2/4k_1t})\,dt + \left(\frac{1-K}{1+K}\right) \int_0^{t_d} \frac{P(t)}{t^{1/2}} e^{-(W_N+d)^2/4k_1t}\,(1 - e^{-b^2/4k_1t})\,dt\right] \quad [1]$$



(a)



(b)

Fig. 5 (a), (b). The thermal models used

where

$$K = \frac{K_2}{K_1} \cdot \left(\frac{k_1}{k_2}\right)^{1/2}$$

$$k_{1,2} = \frac{K_{1,2}}{\rho_{1,2} \cdot C_{1,2}} \qquad [2]$$

where $K_{1,2}$, $k_{1,2}$, $\rho_{1,2}$, and $C_{1,2}$ represent the thermal conductivity, the diffusivity of heat, the density, and the specific heat, respectively, and suffix 1 refers to the silicon and suffix 2 to the heat sink. W_N and W_{N+} are the thicknesses of the N layer and N^+ layer, respectively, d is the distance between the disk heat source and the heat sink, namely the thickness of the pellet. In Eq. [1] and [2], $K = 1$ corresponds to the case where the entire region of the device was constituted by the silicon and $K = 0$ to the case where the N^+ side is under thermal insulation.

Figure 6 shows the results numerically calculated from Eq. [1] for $P(t) = P_0$ ($\equiv$ constant) as a function of P_o/T $(0, W_N; td) \cdot 2\sqrt{\pi} \cdot k_1^{1/2} K_1$, with W_N as a parameter. In this case, b is 8μ, and $K = 0$, 1, 6 are taken for each value of W_N, where $K = 6$ corresponds to the Mo-Ni-Ag silver base. As shown in Fig. 6, t_d *vs.* P_o/T curves vary depending on W_N, and these curves are slightly affected by the values of the heat sink as long as t_d is kept below 10^{-4} sec, but once t_d exceeds 10^{-4} sec, t_d *vs.* P_o/T curves are influenced by the factor of the heat sink, splitting to the different curves depending on the values of K.

The values of k_1 (=0.51 cm²/sec) and K_1 (=0.84 W/cm · deg) are constant determined for the silicon. Therefore, if it is assumed that the second breakdown occurs when the temperature $T(0, W_N; t_d)$ reaches some constant temperature T_i $(0, W_N; t_d)$, then the value of $T(0, W_N; t_d) \cdot 2\sqrt{\pi} \cdot k_1^{1/2} K_1$ can be regarded as a constant. In this connection, P_o may be identified as the power, P_M, required for the initiation of the second breakdown. Thus, Fig. 6 can be considered to represent the relationship between the power, P_M, and the delay time, t_d, in the event of the second breakdown. It is therefore considered that the calculation curves shown in Fig. 6 qualitatively explain the W_N dependency and the variations with the heat sink of the second breakdown characteristics.

The above discussion has been made on the basis of the assumption that the thermal model consisted of

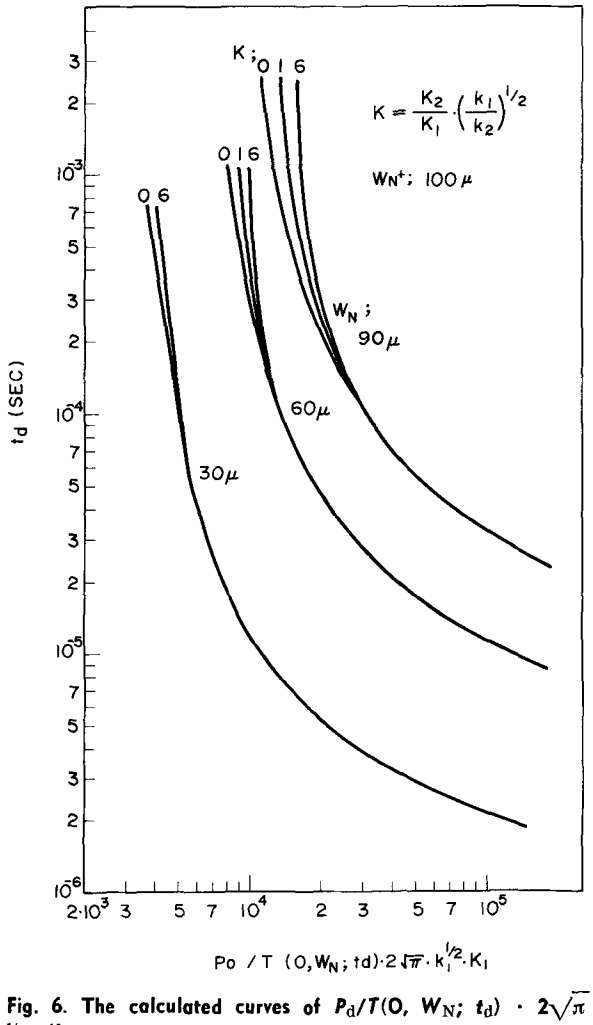


Fig. 6. The calculated curves of $P_d/T(0, W_N; t_d) \cdot 2\sqrt{\pi} \cdot k_1^{1/2} \cdot K_1$ *vs.* t_d.

the silicon extending infinitely in the $+Z$ direction and the heat sink stretching endlessly in the $-Z$ direction and that the disk heat source was embodied at the $Z = 0$ plane in the silicon. However, in the actual devices as shown in Fig. 5(a), the disk heat source was located on the surface where the tungsten probe came into contact with the N-type silicon layer. Therefore, for the quantitative estimation of the temperature of the second breakdown, it is necessary to take into consideration the effect of the tungsten probe.

The correction can be made by providing the coefficient (6), which is given by

$$\lambda = \frac{K_1 k_0^{1/2} - K_0 k_1^{1/2}}{K_1 k_0^{1/2} + K_0 k_1^{1/2}} \qquad [3]$$

where K_0 is the thermal conductivity of the tungsten and k_0 its thermal diffusivity. Using $K_1 = 0.2$ cal/cm · S · deg, $k_1 = 0.51$ cm^2/S, $K_0 = 0.346$ cal/cm · S · deg, and $k_0 = 0.56$ cm^2/S, the calculated value of λ becomes $-1/4$. This shows that the calculation values of the temperature for the thermal model as shown in Fig. 5(a) may be obtained by subtracting a 25% portion from the calculation values of the thermal model shown in Fig. 5(b).

It is to be noted that Fig. 6 represents calculation curves for the case in which the power P_0 is considered to be unchanged with time. But, in the present experiments, it was observed that the power dissipated changes considerably with time. When the sample of W_N below 80μ with a heat sink was used, the power dissipated continued to increase with a duration of time, and the second breakdown was initiated when the power reached its peak value. On the other hand, for the thermally insulated sample, as already shown in Fig. 4(b), the power dissipated was boosted during the early stage of its advancement and then reduced slowly, and the second breakdown appeared when the power was decreased to its minimum value. For the sample having a heat sink and W_N of 90μ, however, the power dissipated was almost constant at all times and the change with time was only a slight one.

Then, for a sample of 90μ in W_N thickness the estimations of T_i (0, 90μ; t_d), the initiating temperature for the second breakdown can be made from the above considerations by using calculation curves shown in Fig. 6. If we put $W_N = 90\mu$ and $t_d = 5.7 \times 10^{-4}$ sec in Fig. 3(b), P_M is read as 54W corresponding to $P_0 = 2.68 \times 10^7$ W cm^{-2}, and the value of 396°C was obtained as T_i (0, 90μ; t_d) by substituting the values of P_0, K_1 and k_1 into the equation; $P_0/\{T_i$ (0, 90μ; t_d) · $2\sqrt{\pi}$ · $k_1^{1/2}$ · $K_1\} = 1.6 \times 10^4$ sec$^{1/2}$. Considering the spread of the thickness in the N layer from 90 to 95μ, the temperature calculated becomes 370°-396°C. When the correction factor of λ is introduced, and considering that the measurements were carried out at room temperature, the initiating temperature is found to be in the range of 297°-316°C, being near the intrinsic temperature of silicon used.

For the case of the samples below 90μ, the power dissipated was observed to increase with time as mentioned previously. Then, the initiating temperature for this case was estimated by putting the average values of the power over time t_d equal to P_0. The temperatures obtained for the samples having W_N of 80, 70, 60, 50, and 20μ were 280°, 252°, 225°, 202°, and 192°C, respectively. In these estimations the calculations were made for the range of t_d below 10^{-4} sec in order to remove the effect of the heat sink on the second breakdown characteristics as shown in Fig. 3(b).

From the above discussion it may be concluded that the W_N dependence of the second breakdown and its variations with the heat sinks can be explained on the basis of the assumption that the second breakdown occurs when T (0, W_N; t_d), *i.e.* the temperature at the interface of the N layer and the N^+ layer reaches an initiating temperature. It was found that the initiating temperature varied depending on the thickness of the N layer, and was lowered as the value of W_N is reduced. When W_N is in the range of $90 \sim 80\mu$ this temperature was nearly the same as the intrinsic temperature of N-type silicon used.

The results that the initiating temperature decreases with W_N would not be explained on the basis of the thermal model. When W_N is lowered, the depletion layer associated with the reverse voltage passes through the N layer and reaches the N^+ layer. In such a case, the field effect must be added on the thermal effect, although this has yet to be studied more thoroughly.

Selective Etching of Gallium Arsenide Crystals in H_2SO_4-H_2O_2-H_2O System

Shinya Iida and Kazuhiro Ito

Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

Selective etching of GaAs in the H_2SO_4-H_2O_2-H_2O system was studied as a pretreatment to selective deposition. Flat-bottomed holes were obtained in low H_2SO_4 solutions, whereas nonplanar holes were obtained in high H_2SO_4 solutions. Differences between both cases are considered from the etching behaviors under nonselective conditions. Using low H_2SO_4 solutions, selective etching was conducted on substrates with different crystallographic orientations. Asymmetrical holes were observed in all cases except for holes on the {001} substrate with rectangular windows held parallel to the <001> direction. The possibility of the revealed planes being the wall in the hole is discussed.

Electronic devices have been developed such as the Gunn oscillator (1) and the millimeter wave diode (2) using an epitaxially grown crystal. According to their development, the requirement of integrated circuit technology in GaAs is increasing. The importance of selective deposition as an integrated circuit technology has been realized. This technique involves selective etching on a substrate. Selective etching was effected by a chemical solution consisting of the H_2SO_4-H_2O_2-H_2O system, most commonly used as a surface polishing etchant. The various etching behaviors are observed with various composition ranges in the above-mentioned system.

In this paper are described a correlation of the etching behaviors and the composition of the solution under nonselective etching conditions, favorable etching conditions to obtain flat-bottomed selective holes, and the orientation effects on hole structure.

Experimental

The substrate surfaces used here were the {001}, {111}, {110}, {112}, and {113} planes. These were sliced within 1° from the above-mentioned principal orientation and polished to a mirror-like finish.

Etching rates were measured from a step height between an etched face and a wax-coated original face, using an interference microscope. Chemical etching was accomplished in 10 ~ 60 sec and the temperature was maintained at 0 ~ 100° ± 1°C.

In selective etching, an SiO_2 mask 1000 ~ 2000Å thick was deposited on the substrate by a pyrolysis of tetraethoxy silane, and circular or rectangular windows were cut into the mask.

Structures of the holes were observed on the {110} cleavage plane perpendicular to the substrate surface under an optical microscope and under a goniomicroscope.

Etching solutions used here consisted of 98 w/o (weight per cent) sulfuric acid, 30 w/o hydrogen peroxide, and deionized water. In the following section, the volume ratios of these agents are used (35 H_2SO_4: 65 H_2O_2 means 35% by volume of 98 w/o H_2SO_4 plus 65% by volume of 30 w/o H_2O_2).

Etching Behaviors under Nonselective Conditions

Temperature and composition effects of the solutions on the etching.—Etching rates were studied on the {001} surface by varying each composition in the H_2SO_4-H_2O_2-H_2O system. The etching rates at 0°C are shown in Fig. 1 as a ternary diagram. In this case, a peak was obtained at the point of 35 H_2SO_4: 65 H_2O_2 and no etching was observed on the line of H_2SO_4-H_2O and H_2O_2-H_2O members. The etching rates were decreased by increasing H_2O at a constant ratio of H_2SO_4 and H_2O_2.

Key words: gallium arsenide, etching, semiconductor.

The diagram is roughly divided into four regions by the etched surface state. In the A region (high concentration of H_2SO_4 and H_2O_2), the etched surface became cloudy above 20° ~ 30°C. In the C (high H_2O_2) and D (high H_2SO_4) regions, mirror-like surfaces were obtained within the experimental ranges (0 ~ 70°C). In the B (high H_2O) region, a cloudy surface was frequently observed, the cloudy phenomenon due to small pits which may have been influenced by crystalline defects of the substrate.

The etching studies at various composition in the system were studied at temperatures ranging between 0° ~ 100°C. Composition ratios of the etching solutions used were as follows:

a. 1 H_2SO_4 : 4 H_2O_2 : 0 H_2O

b. 1 H_2SO_4 : 1 H_2O_2 : 1 H_2O

c. 5 H_2SO_4 : 1 H_2O_2 : 1 H_2O

d. 5 H_2SO_4 : 1 H_2O_2 : 20 H_2O

e. 40 H_2SO_4 : 1 H_2O_2 : 1 H_2O

In all cases the etching rates exponentially increased with elevating etching temperatures as shown in Fig. 2. From the slopes of the figure, the activation energies were determined to be 6 ~ 11 kcal/mole. In the high H_2SO_4 solutions, lower energies (6 ~ 8 ± 0.1 kcal/

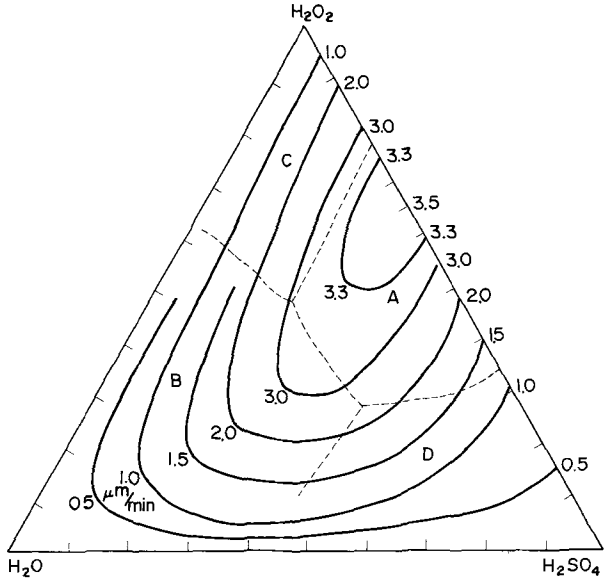

Fig. 1. Constant etching rate contours in the system of H_2SO_4-H_2O_2-H_2O obtained at 0°C. The triangle was divided into four zones (A, B, C, and D) by the etched surface state.

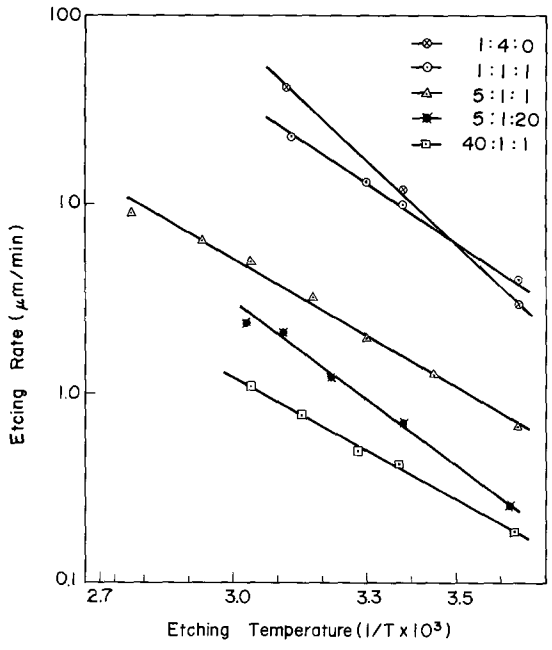

Fig. 2. Plot of the log etching rate vs. $1/T$ in various composition ratios of the solutions.

mole) were obtained, whereas larger energies ($8 \sim 11 \pm 0.1$ kcal/mole) were obtained in the low H_2SO_4 solutions. These facts may suggest that the controlling factors affecting both solutions are different.

Further, stirring effects were examined by adding ultrasonic vibration while etching. Shift of the etching rates occurred only in the high H_2SO_4 solutions. Representative data are shown in Fig. 3. It was confirmed that etching rates were invariable with carrier concentrations and impurities in the substrates.

Orientation effects on the etching rates.—Etching experiments were also conducted on the substrate with some different orientations under the same conditions. The etching solutions used here were a high H_2SO_4 solution ($8\ H_2SO_4 : H_2O_2$) and a low H_2SO_4 solution ($1\ H_2SO_4 : 8\ H_2O_2 : 1\ H_2O$), and the etching temperatures were maintained within $0 \sim 40° \pm 1°C$. Representative data are shown in Fig. 4. Etching rates are similar on the different substrates except for the {111}A plane in the former solutions; however, the etching rates depend on the substrate orientations in the latter.

Further, in depending on temperature of the etching rates on several substrates with other orientations, the slopes in the former are smaller than those in the latter, these behaviors similar to those on {001}. Under all conditions the etching rates on the {111}A surface were the slowest of all, and the etched surfaces were not shiny. For this reason, the {111}A surface was not employed as the substrate of selective etching in this work.

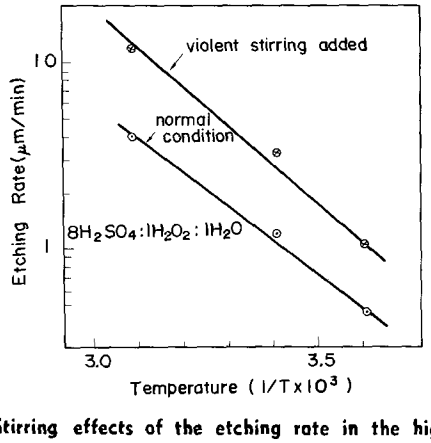

Fig. 3. Stirring effects of the etching rate in the high H_2SO_4 solutions.

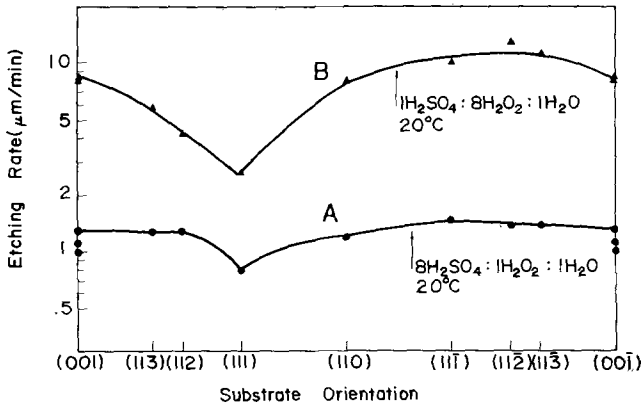

Fig. 4. Orientation dependence on the etching rates in the high H_2SO_4 (A) and in the low H_2SO_4 (B) solutions.

Selective Etching

Flat-bottomed hole on the {001} substrate.—An exposed GaAs surface bounded by an SiO_2 mask was etched by the solution in the H_2SO_4-H_2O_2-H_2O system. Flatness of the hole bottoms was examined with an interference microscope. Hole bottoms obtained by high H_2SO_4 solutions such as $8\ H_2SO_4 : 1\ H_2O_2 : 1\ H_2O$ became uneven due to deep etching near the frame of the window; while flat-bottomed holes were obtained by low H_2SO_4 solutions such as $1\ H_2SO_4 : 8\ H_2O_2 : 1\ H_2O$ or $1\ H_2SO_4 : 1\ H_2O_2 : 8\ H_2O$ solution. Representative cross sections are shown in Fig. 5. It was found from additional experiments that etching solutions with an H_2SO_4 content below one-third in overall volume were useful in obtaining flat-bottomed holes. These results agreed with those on the other substrate orientations.

Asymmetry structures of the holes.—When a side of a rectangular window was set parallel to the <110> direction and chemically etched on the {001} surface, dissimilar hole structures were observed at a right-angled intersection of two {110} cross sections perpendicular to the substrate surface as shown in Fig. 6. Thus, on one cross section, a trapezoidal structure with its short side at the bottom was formed (Fig. 6, A); whereas a trapezoidal structure with its long side at the bottom was formed on another cross section (Fig. 6, B). This difference could be explained by the remainder of the {111}A planes (Ga side), the slowest in the etching rate, although it was departing from being a precise {111}A plane.

When the side of the rectangular window was set parallel to the <100> or <010> direction, symmetrical walls were obtained (Fig. 7). These four walls were determined to be {100} planes since they were nearly perpendicular to the (001) surface, and no {111}A plane existed in these zones. These holes are available for the selected deposition described elsewhere (3).

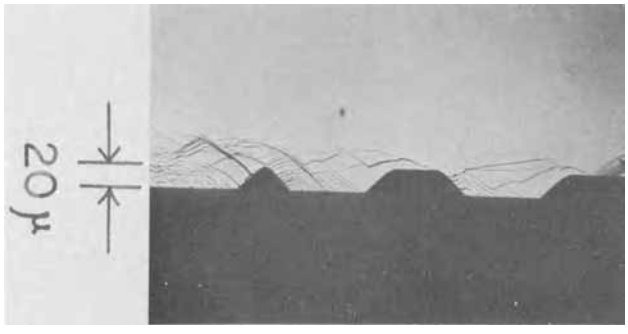

Fig. 5. Representative cross section of the flat bottomed hole

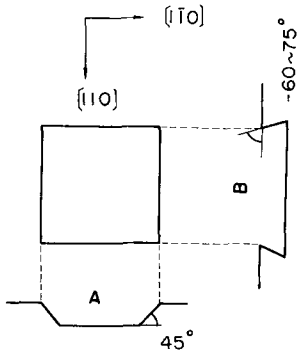

Fig. 6. Schematic hole figures on the {110} cross section on the {001} substrate with <110> rectangular window direction.

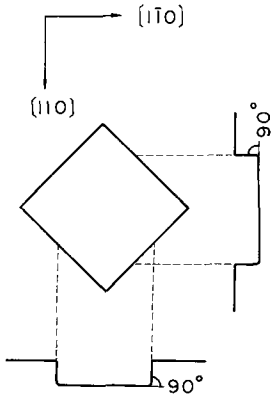

Fig. 7. Schematic cross section of the hole on the {001} substrate with <001> rectangular window direction.

Hole structures on the substrates with other crystallographic orientations.—Selective etching was carried out on the {111}B, {110}, {112}A, {112}B, {113}A, and {113}B planes in addition to the {001} previously described. An edge of the rectangular windows was set parallel to the <110> direction. Observed angles between the walls in the holes and the substrate surfaces on the vertical cross sections of the {110} cleavage plane and the plane which makes a right angle with the {110} plane are listed in Table I. In all cases, the walls in the holes show asymmetrical patterns on the right and left sides on the {110} cleavage planes, although symmetrical hole structures were observed on another cross section which was vertical to the {110} cleavage plane and perpendicular to the substrate surface. On this cross section, one could not observe the walls under a goniomicroscope in the {112}A and {113}A substrates since the hole structures displayed a trapezoidal pattern with the long side at the bottom.

Discussion

Shaw reported that the etchants most commonly used for chemical polishing of GaAs such as 5 H_2SO_4 : 1 H_2O_2 : 1 H_2O and 1000 CH_3OH: 1 Br_2 produced holes which had a nonplanar bottom (4). This was attributed to surface diffusion of the etchant molecules absorbed on the protective mask (diffusion rate-limited process). In our work, similar results were obtained by using high H_2SO_4 solutions. Facts disclosing no orientation effects on the etching rate and smaller activation energies (5) of the etching rate in the high H_2SO_4 solutions strongly support Shaw's conclusions.

While in the low H_2SO_4 solutions which produced flat-bottomed holes, the etching rates are clearly varied with different substrate orientations, and the activation energies are larger than those in the former solutions. These experimental results may suggest that the etching process in the latter is chemical reaction rate-limited, but not the diffusion rate-limited process, because a decrease of the H_2SO_4 content effects a drop in viscosity. When similar etching was done under the condition of additional ultrasonic vibration, it was recognized that the etching rate and the activation energies were increased in the high H_2SO_4 solutions, whereas no changes of etching behavior appeared in the low H_2SO_4 solutions within our experimental ranges shown in Fig. 3. Those facts reveal that a diffusion rate-limited process changes to

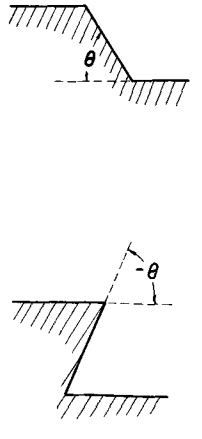

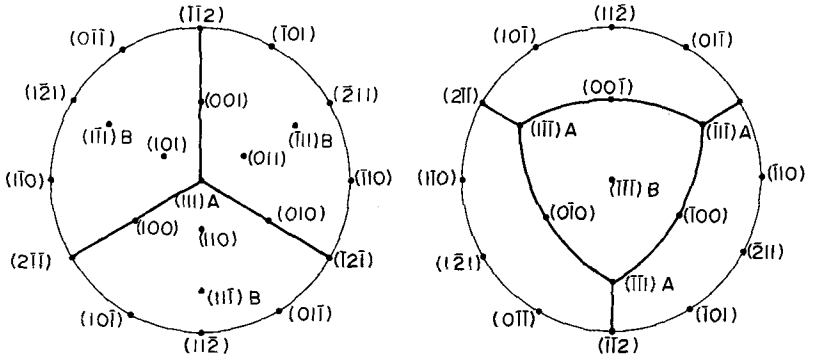

Fig. 8. Plot of possible wall planes in the hole in standard stereo projection. Revealed planes are only on the lines (great circle) connected with the four {111}A planes.

a reaction rate-limited process in chemical etching through violent stirring.

Hole structures in the rectangular selected area parallel to the <110> direction show asymmetrical patterns on the substrates of the {001}, {111}, {110}, {112}, and {113} planes except in the case of the rectangular window with a <100> direction on the {001} substrate. This phenomenon is due to the fact that the wall planes are revealed by the rule, and these planes are not present in symmetrical position.

The first plane to appear is the {111}A plane as the wall, because of its having the slowest etching rate of all. If the {111}A plane is not contained in the zone around an axis, which agrees with the side of the rectangular window, the plane appears—strongly affected by {111}A planes existing near it. In other words, the revealing plane is the intersection between the great circle through the nearest two {111}A planes, and the great circle through the substrate orientation and the parallel planes to a side of the window in standard stereo projection. From the above-mentioned interpretation the {223}A, {335}A, {112}A, {113}A, {115}A, {117}A, and {001} planes are considered as possible low-index planes, these planes all being Ga side planes with the exception of {001}. Thus these planes are always on the six arcs connected with four {111}A planes as shown in Fig. 8.

Comparing the measured angles with the predicted angles considered from the above-mentioned presumption, both cases agree well. The gaps of the angles between both cases are probably due to an uncertainty of orientation in preparing the rectangular window and substrate and/or experimental errors.

Conclusion

Selective etching was conducted on GaAs crystal surfaces with several crystallographic orientations in the H_2SO_4-H_2O_2-H_2O system. Nonplanar-bottomed holes were obtained in high H_2SO_4 solutions, whereas flat-bottomed holes were obtained in low H_2SO_4 solutions. Experimental facts show that the etching process in the former is the diffusion rate-limited process, and the latter is the chemical reaction rate-limited process.

Hole structures in the selective etching on the substrates display an asymmetrical pattern. Symmetrical holes were observed only on the {001} with <001> directional rectangular windows. These facts are well explained by the remains of the {111}A planes which constitute the slowest among the etching rates and their effects.

Epitaxial Growth of Al_2O_3 on Al_2O_3 Substrates by Chemical Vapor Deposition

Donald R. Messier and Philip Wong

Army Materials and Mechanics Research Center, Materials Research Laboratory, Watertown, Massachusetts 02172

ABSTRACT

The growth of Al_2O_3 on single-crystal and polycrystalline Al_2O_3 substrates via the net chemical reaction $2AlCl_3(g) + 3H_2O(g) = Al_2O_3(s) + 6HCl(g)$ was investigated in the temperature range from 1400° to 1600°C. Deposits that were obtained varied from polycrystalline at lower temperatures to single crystal at higher temperatures. Use of a 60° oriented substrate resulted in a higher quality, faster growing deposit compared to deposits on 0° and 90° oriented substrates.

The chemical vapor deposition (CVD) technique has several advantages that make it attractive as a method of growing single crystals of ceramic materials. Some of these advantages are: (*a*) growth occurs under isothermal conditions, the crystals obtained are thus relatively unstrained and require no annealing; (*b*) single crystals can be grown at temperatures several hundred degrees below the melting point, an advantage over melt growth techniques; and (c) because purification results from the vaporization process, the crystals obtained are of higher purity than those grown by other low-temperature methods such as hydrothermal or flux growth. A disadvantage of the CVD method is the slowness of growth rates; this is at least partially offset, however, by the fact that large crystals grown more rapidly by melt techniques are often highly strained and require long anneals.

The investigation reported here is a successor to a previous one (1) concerned with the formation of polycrystalline alumina by CVD. The only previous investigation of the growth of large single crystals of alumina by CVD that has been published in the open literature is that of Schaffer (2). He employed the reaction $2\ AlCl_3\ (g) + 3\ H_2\ (g) + 3\ CO_2\ (g) = Al_2O_3\ (s) + 3\ CO\ (g) + 6\ HCl\ (g)$, at temperatures of 1550° and above to grow single crystals weighing up to 80g. Under his conditions, the reaction rate was negligible at the lowest temperature investigated, 1550°C. A report by Schaffer (3) contains additional data on the growth of large crystals by CVD. Parker and Harding (4) reported the use of an apparatus and technique similar to Schaffer's to grow bicrystals of alumina at temperatures about 1700°C.

Earlier work at our laboratory (1) indicated that significant growth rates could be obtained via the net reaction $2\ AlCl_3\ (g) + H_2O\ (g) = Al_2O_3\ (s) + 6\ HCl\ (g)$, at temperatures considerably lower than had been previously reported. One purpose of this study was therefore to establish a low-temperature limit for the growth of single crystals at significant rates; there are numerous advantages in power and materials requirements if it is possible to work at temperatures below 1600°C. Another purpose of this investigation was to establish more clearly the effect of the crystallographic orientation of the substrate on the rate of growth and character of the resulting deposit.

Experimental Procedures

The substrates that were used in the CVD studies included both polycrystalline alumina and single-crystal sections cut to the desired orientations from Verneuil ruby and sapphire and from Czochralski sapphire. A typical substrate was 1.6 cm long x 1.6 cm wide x 0.2 cm thick. The orientations that were used were 0° ("c") corresponding to the (0001) plane, 90° ("a") corresponding to the $(11\bar{2}0)$ planes, and 60° corresponding approximately to either the $(10\bar{1}2)$ or the $(2\bar{1}\bar{1}3)$ planes[1] (see Fig. 5 for reference). The surfaces of some of the substrates were prepared by polishing with 1-5 μm diamond grit with a lead lap. Other substrates were simply used as-cut with a 220 grit diamond cutoff wheel. No obvious differences were observed between deposit layers obtained on substrates prepared in either manner.

The apparatus that was used is described in detail elsewhere (1). The furnace has a molybdenum winding and the muffle tube and all components used in the hot zone are aluminum oxide. The aluminum chloride gas is generated by the chlorination of aluminum metal. The water vapor is formed by the reaction of hydrogen and oxygen gases. Figure 1 shows the details of the rectangular box that serves as the reaction chamber. Combination of the hydrogen and oxygen to form water vapor occurs after exit of the gases from the nozzle.

Before a run, the substrates that are to be used are cemented with alumina cement to the removable floor of the reaction chamber. The system is then assembled, evacuated, and heated to the desired temperature. The reaction is begun by starting the flow of the reactant gases. The total system pressure was held at 0.5 Torr for all of the runs. Gas flow rates were maintained constant at 0.77 lpm for hydrogen, 0.57 lpm for oxygen, and 0.08 lpm for chlorine. The temperatures that were used were 1400°, 1500°, and 1600°C and run times were 6 hr. At the conclusion of a run, the system was cooled under vacuum. The specimens were removed by simply breaking them away from the floor of the reaction chamber.

Results

Kinetics of deposition.—Table I summarizes the results of deposition rate measurements on single-crystal substrates of various orientations at 1400°, 1500°, and 1600°C. Rates were determined by measuring the thickness of deposit obtained in a 6 hr run. It should be noted that the rates given are for growth on only one side of a substrate; they could easily be doubled by use of an arrangement that allowed simultaneous deposition on both sides. The maximum linear growth rate listed in Table I (60° substrate at 1500°C) is equivalent to a mass rate of 50.4 mg/cm^2 · hr. This rate compares favorably to the maximum value of 90.4 mg/cm^2 · hr quoted by Schaffer (2) for growth at 1750°C in an arrangement that allowed simultaneous deposition on all surfaces of the substrate.

Considering the complexity of the reaction mechanism and experimental difficulties, the apparent lack of temperature dependence of the reaction is not sur-

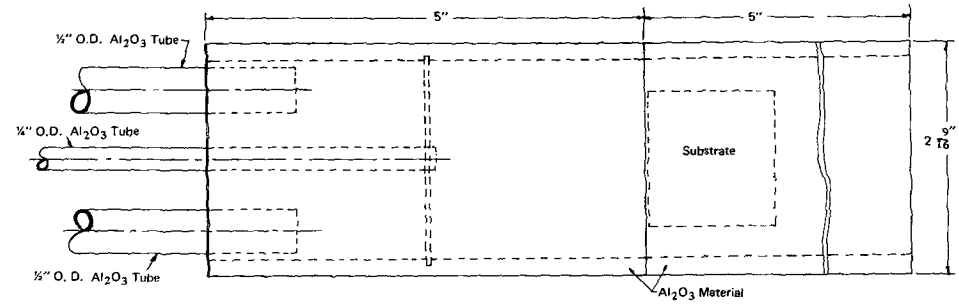

Fig. 1. Chemical vapor deposition nozzle and substrate system.

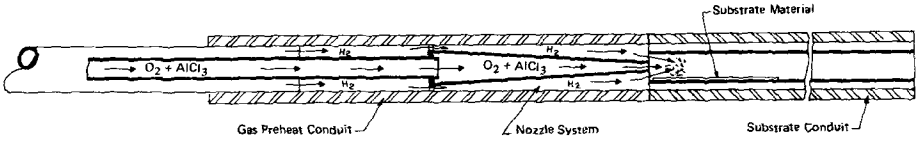

prising. That the rates are lower at 1600°C is believed to be partially a result of leakage of the reaction chamber caused by sagging of its top panel at this temperature. From a practical standpoint, the results indicate that, under our experimental conditions, close temperature control is unnecessary to obtain uniform deposits.

Characterization of deposits.—Microstructure.—The polycrystalline deposits formed at 1400°C showed interesting microstructural features that aid in their characterization. Most of the deposits formed on single-crystal substrates at 1500°C and above, however, were single crystal, and generally showed no microstructure at all. The latter were clear transparent, and indistinguishable microscopically from the underlying substrate.

Figure 2 shows a cross section of a typical deposit formed on a polycrystalline substrate at 1400°C.[2] The usual columnar grained structure with pronounced grain boundaries is clearly evident. Also notable is the considerable porosity near the interface.

Figure 3 shows deposits that formed on single-crystal substrates at 1400°C. Although further evidence shows that these deposits are still polycrystalline, the interface between deposit and substrate is cleaner, and the microstructure better than the deposit on a polycrystalline substrate. The presence of columnar grains, however, indicates that the substrate did not completely control the growth of the deposit; such grains must have resulted from nuclei formed on the single-crystal surface.

Figure 4 shows a cross section, under crossed Nicols in transmitted polarized light, of the deposit formed on a 60° oriented single-crystal substrate at 1400°C. All areas that show the same extinction behavior have the same crystallographic orientation. It is evident from the figure that certain of the columnar grains mushroom out and eventually join to form a deposit that appears single crystal. These observations are corroborated by the fact that grain boundaries were not visible in the top part of this specimen under reflected light. As far as microstructure is concerned, it thus appears that a deposit that is more nearly single crystal is obtained at 1400°C on a 60° oriented substrate than on those of the other orientations tested.

X-ray diffraction.—Figure 5 is a stereographic projection of the poles of the only five sets of plane corresponding to peaks on x-ray diffractometer traces of the surfaces of polycrystalline deposits. Various combinations of these peaks were found on material formed on single-crystal substrates (0° and 90° orientations) at 1400°C, and on polycrystalline substrates at 1400° and 1600°C. Reflections from prismatic planes and the basal plane were notably absent. Although none of the preferred orientations was observed on all of the specimens, all of the orientations occurred with about the same frequency. Furthermore, there was no apparent correlation between the orientation of the single-crystal substrates and the preferred orientation of the deposit.

The microstructural observations and x-ray diffraction data indicate that the polycrystalline deposits comprise columnar grains growing in certain preferred directions. That the directions shown in Fig. 5 are the fast growth directions for alumina follows from a discussion by Buckley (5) of the analogous case of solidification from the melt. Buckley shows that this type of microstructure results when the grain growing

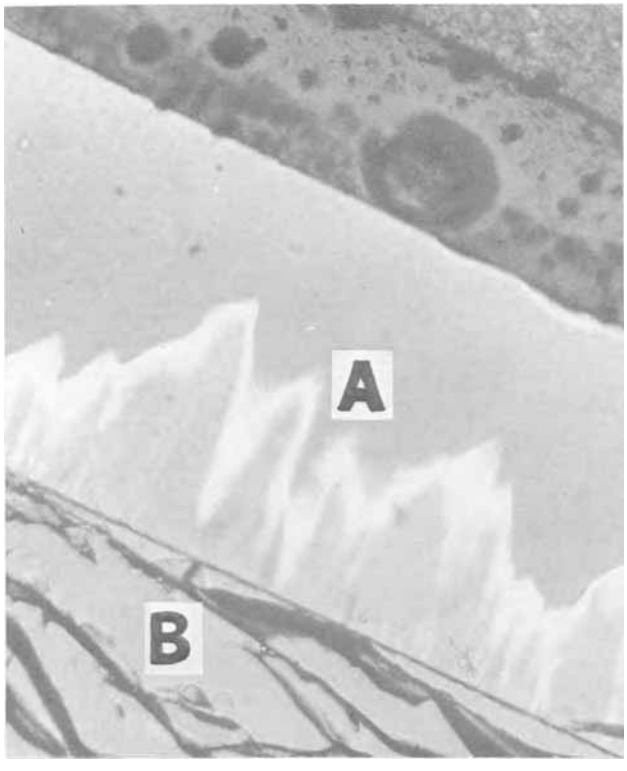

Fig. 4. Photomicrograph (175X, polarized light) of a thin section of a deposit (A) formed at 1400°C on a 60° oriented sapphire substrate (B). The deposit became virtually single crystal as it grew away from the substrate.

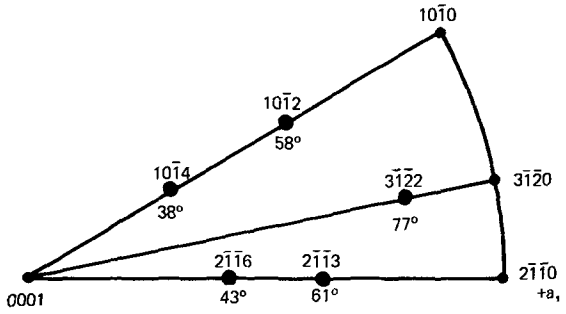

Fig. 5. Stereographic projection of poles of planes that are parallel to the surface of polycrystalline alumina deposits.

from nuclei oriented in the fast growth directions eliminate the slower growing ones. His explanation also accounts for the peculiar columnar-grained structures shown in Fig. 2-4.

The Laue back-reflection x-ray technique was used to evaluate the quality of the deposits formed on single-crystal substrates. In cases where single-crystal deposits were obtained, their orientations were the same as those of the underlying substrates. The absence of significantly misoriented subgrains on single-crystal deposits was confirmed by repeat Laue patterns on several areas of specimens and by optical microscopy using polarized light.

All of the deposits formed at 1400°C, except that on the 0° substrate showed a high degree of preferred orientation. The deposit on the latter substrate gave a polycrystalline Laue pattern. Figure 6 shows Laue patterns of deposits obtained on single-crystal substrates of several orientations at 1500°C. The substrates that were used were all cut from the same boule and run at the same time; the results should therefore reflect the influence of substrate orientation alone. The deposit on the 60° oriented substrate is single crystal and that on the 0° substrate is polycrystalline. The splitting of the spots in the pattern obtained on the 90° deposit indicates that some subgrain structure exists in this material. Deposits obtained on single-crystal substrates of all orientations tested were single crystal at 1600°C.

Dislocation density measurement.—Dislocation densities were determined on basal plane sections of the CVD deposits by an etch pit technique. The technique was that described by Sahagian (6) as a refinement of the early ones given by Alford and Stephens (7) and Scheuplein and Gibbs (8). It involved chemical polishing in orthophosphoric acid at 425°C for 2 min, followed by etching for about 5 min in the same reagent at 320°C.

Figure 7 shows an etched basal plane section of a deposit formed on a 60° substrate at 1600°C. This figure illustrates clearly the single-crystal nature of the deposit and the almost perfect match between deposit and substrate; only a partially complete line of etch pits delineates the interface between them. The distribution of dislocations in the deposit is uniform parallel to the interface and the dislocation density decreases as the distance from the substrate increases.

Another indication of the good quality of the crystal is that subgrain boundaries are absent. The dislocation densities given, 1.7×10^5 and $2.5 \times 10^5/cm^2$ for deposit and substrate, respectively, are averages of counts from several photographs including hundreds of etch pits for the areas shown in Fig. 7. The dislocation density measured on a deposit formed on a 0° substrate at 1600°C ranged from $5.5 \times 10^4/cm^2$ to $6.0 \times 10^5/cm^2$. These dislocation density values compare favorably to those of from 10^4 to $10^6/cm^2$ quoted by Sahagian (6) for basal plane sections of single crystals grown by a number of techniques.

Discussion of Results

The results concerning the dependence of the quality of the crystal on the orientation of the seed are con-

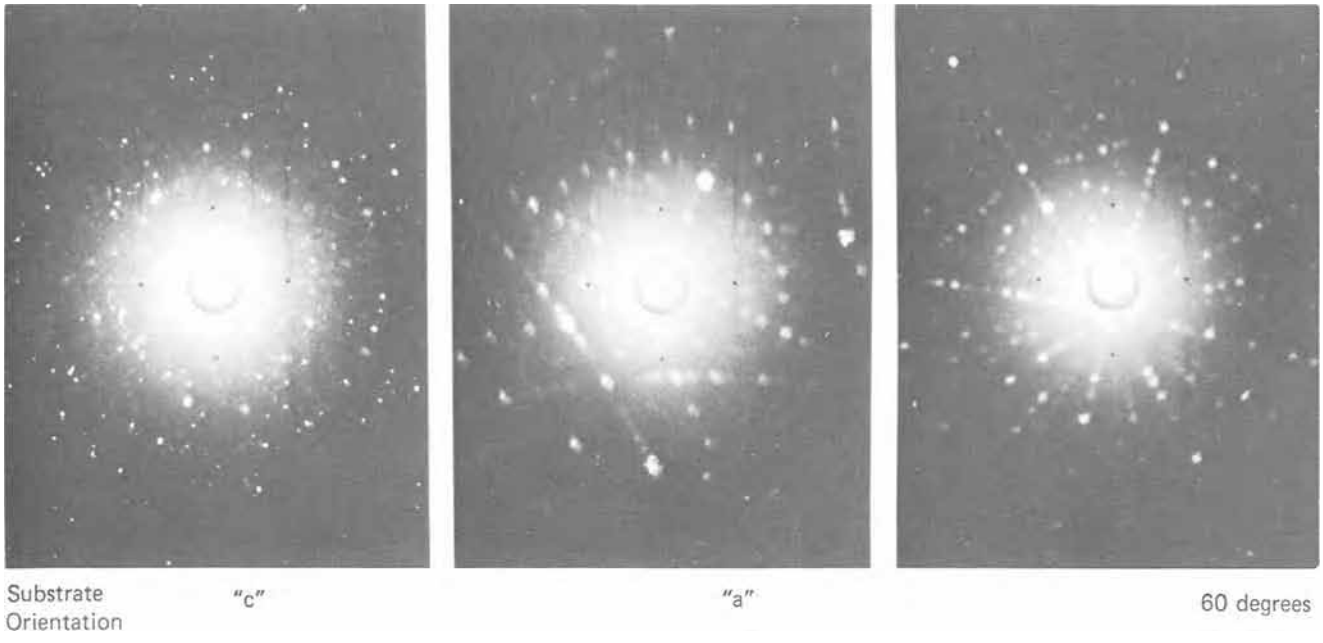

Fig. 6. Back-reflection Laue patterns of material deposited at 1500°C showing the higher perfection obtained by use of a 60° oriented substrate.

sistent with results of investigations of the growth of alumina single crystals by other techniques (9, 10). For example, Beliustin (9) found that flame-fusion single crystals grown from 60° seeds had less mosaic structure than crystals grown from seeds of other orientations. Our x-ray results indicate that the same is true for crystals grown by CVD. Beliustin states that growth is more uniform when one of the habit faces of the crystal is perpendicular to the geometric axis of the boule, and when there are other possible faces close to that face in orientation; the 60° orientation satisfied these conditions better than any other orientations we tested. The reason given by Beliustin for the lesser amount of substructure in crystals grown in this orientation is that the proximity of other faces produces growth steps that are less pronounced than they are, for example, on a 0° orientation. The latter orientation is considerably farther from possible habit faces than is the former. That a better crystal formed on the 90° seed than on the 0° seed is also consistent with this argument, for the former is closer to other potential faces than the latter.

Stephens and Alford (10) obtained results similar to ours concerning dislocations in alumina single crystals. Their specimens were crystals grown in various orientations by flux and flame-fusion techniques. They found, as did we, that growth orientation did not affect dislocation density. In addition, they observed that 0° crystals contained more substructure than 60° ones, and that 90° crystals contained the least substructure of all. Our results concur with the former observation, but not with the latter.

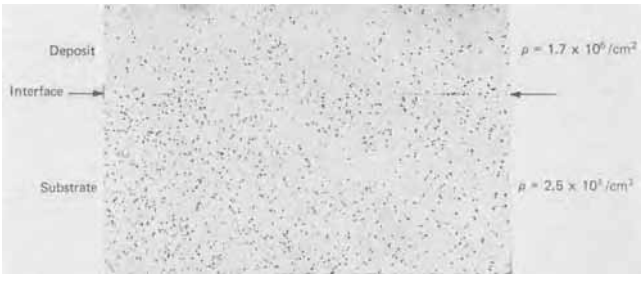

Fig. 7. Photomicrograph (48X) of an etched basal plane section of a single-crystal deposit grown on a 60° oriented sapphire substrate at 1600°C. The deposit shows a lower density of dislocation etch pits than does the substrate.

The indexes of the fast growing planes are the same as those of faces occurring on natural crystals of alumina (11). The two planes near 60° (Fig. 5) correspond to common faces and the other three planes to less common ones. Although basal and prismatic faces predominate on both natural and synthetic alumina single crystals (3, 11), our results indicate that neither face is a fast growing one. This is entirely consistent with Buckley's (5) explanation that the faces seen on a single crystal after long growth times are the slower growing, low index ones. In normal growth, the faster growing, high index faces soon grow themselves out of existence. It should be recalled, however, that the results shown in Fig. 5 pertain to the growth of columnar grained, polycrystalline deposits. For that type of growth, the fast growth directions prevail.

Consideration of phenomena involved in the CVD process leads to some qualitative conclusions about the kinetics of crystal growth. Among the phenomena involved are nucleation and growth of new material on the substrate, gas phase transport, and chemical reactions at the surface of the growing crystal.

That single-crystal deposits were obtained on single-crystal substrates of all orientations tested at 1600°C indicates that nucleation is unimportant at this temperature. The deposits merely grow on the substrates. At 1500°C, however, only the 60° deposit was single crystal. The misoriented, columnar grained deposits formed on other single-crystal substrates at and below this temperature must have resulted from nuclei formed at their surfaces. It thus appears that deposition kinetics at 1500°C and below are complicated by nucleation phenomena, and that an evaluation of growth rate as a function of substrate orientation is meaningful only for the 1600°C data.

The data on the rate of growth of the deposits at 1600°C (Table I) correlate nicely with the x-ray data on fast growing directions. Fastest growth occurs on the 60° substrate which, as seen in Fig. 5, is close to several such directions. Growth is second fastest on the 30° seed, one that is also oriented close to several favorable directions. The 0° and 90° substrates, still further from fast growth directions, yield equally slow growth rates.

The results also yield some information concerning possible rate-controlling steps in the CVD process. That the growth rate depends on the orientation of the substrate indicates that it is not solely controlled by the rate of supply of reactants, *i.e.* gas phase transport. When one considers also that gas phase nucleation is not observed, one concludes that a surface reaction of some sort is at least partially rate controlling. Although this surface process probably is some sort of surface catalyzed decomposition and oxidation of the aluminum chloride, formulation of a detailed reaction mechanism requires more data than are available at present.

In summary, it may be concluded that:

1. Single crystals of aluminum oxide can be grown by CVD at significant rates at a temperature of 1500°C, 550°C below the melting point.
2. There are five approximately equal fast growth directions for aluminum oxide, all of which lie between the basal (0001) plane and $(2\bar{1}\bar{1}0)$ and $(10\bar{1}0)$ prismatic planes.
3. Growth rate and crystal quality are both enhanced by use of a 60° substrate rather than a 0° or 90° one.

Chemical Vapor Deposition of Iron Oxide Films for Use as Semitransparent Masks

J. B. MacChesney, P. B. O'Connor, and M. V. Sullivan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Iron oxide films have been prepared by thermal decomposition of iron pentacarbonyl vapor in an oxidizing atmosphere. Optical spectra show these to be opaque in the ultraviolet but partially transparent to visible light. The nature of these deposits was studied by electron and x-ray diffraction, electron microscopy, and the Mössbauer effect. It was found that deposition at low temperatures resulted in a partially crystalline film, while films formed at higher temperatures were composed of αFe_2O_3 crystallites. The chemistry of the deposition process was considered in light of mass spectrometer analyses of species present during deposition.

Photolithographic processes for the manufacture of integrated circuits require a mask to define images on photoresist materials used to form circuit patterns. Conventional silver emulsion or chromium film masks have disadvantages. The former are easily scratched and the latter opaque to visible light, thus inhibiting registration of successive patterns. It is desirable to have a durable mask which is at least partially transparent to the visible, but opaque to ultraviolet, light used for photoresist exposure. To this end, Sinclair, Sullivan, and Fastnacht (1) considered a number of transition metal oxides suitable for mask fabrication, but settled on mixtures of vanadium and iron oxide as best able to satisfy the requirements of this mask. These they defined as: transmission of less than 1% below 4000Å, transmission of greater than 30% at 5890Å, and etchability in reagents compatible with photolithographic processing so as to provide resolution of lines separated by no more than 2μ.

Initially, our intentions were to duplicate their work using films prepared by chemical vapor deposition techniques. However, it soon became apparent that pure iron oxide films prepared by this technique differed from the sputtered films prepared by Sinclair *et al.* The principal difference was that chemically deposited films could be etched, whereas sputtered films could not. Therefore, the present study was primarily directed toward the preparation and characterization of iron oxide films prepared by chemical vapor deposition.

Key words: Fe_2O_3 (iron oxide) thin films, photolithographic masks, iron pentacarbonyl, vapor deposition.

Deposition

Iron pentacarbonyl, $Fe(CO)_5$, was selected as the source of iron in these experiments. This compound is desirable because its properties combine high vapor pressure which facilitates transport in the vapor phase and low decomposition temperature. For these reasons, use of $Fe(CO)_5$ for deposition of iron films or preparation of highly pure iron powder is well known. However, it appears to have been little used for preparation of iron oxide films, although its use is mentioned by Powell (2) and films prepared by its decomposition in microwave plasma are reported by Secrist and MacKenzie (3).

In the present studies, films were prepared using the apparatus shown in Fig. 1, which consists of a dep-

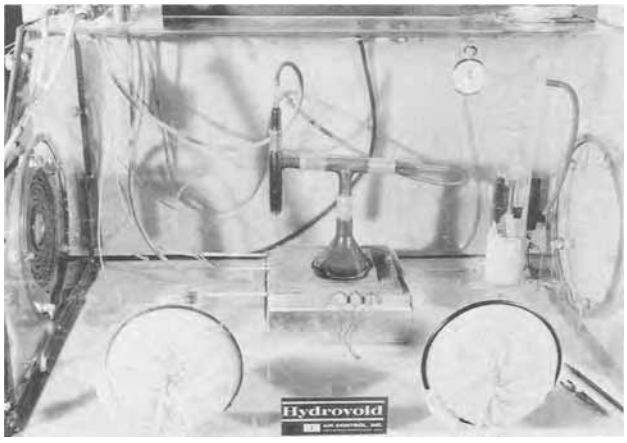

Fig. 1. Photograph of deposition apparatus as described in the text.

osition chamber resting on a hot plate. Iron pentacarbonyl vapor, generated by bubbling argon through the liquid contained in a side-arm test tube, is transported to a "T" junction where it is mixed with oxygen or other gases prior to entering the deposition chamber. Film deposition occurs by thermal decomposition of the carbonyl vapor on the surface of the heated substrate. Exhaust gases exit around the base of the deposition chamber. The apparatus was contained in a glove-box which was continuously exhausted to remove potentially toxic or explosive products.

Electronic flow meters (Hastings Raydist Model LL100) were used to monitor the flows of the different gases. Temperatures were measured by Chromel-Alumel thermocouples embedded in the plate supporting the substrate and these were recorded using a multipoint recorder. The substrate for photomask usage was a 2 x 2 x 1/16 in. soda lime glass plate which had been degreased, detergent washed, boiled in H_2O_2 (30%), blown dry, and baked. Thicknesses of iron oxide films were measured using a Tallysurf.[1]

Characterization of these deposits was accomplished by optical and Mössbauer spectra, scanning electron microscopy, electron microscopy, electron microprobe analysis, x-ray, and electron diffraction. The suitability of deposited films for mask purposes was determined by etching studies on patterned and unpatterned surfaces.

A systematic survey of deposition conditions was carried out using various flow rates, reactive gases, and deposition temperatures. These results are summarized by Fig. 2. The diagrams of this figure compare deposition rates for different flow rates of carrier gas at substrate temperatures of 120°, 140°, 160°, 180°, and 200°C in atmospheres of argon, carbon dioxide, oxygen, and oxygen-water. It is observed [Fig. 2(a)] that in an argon atmosphere little apparent change in deposition rate is occasioned by either increase in temperature or increased carrier flow. In order to check whether this behavior would occur with other nonoxidizing gases, CO_2 was introduced into the deposition chamber in addition to the argon carrier. The resulting deposition rates are shown by Fig. 2(b). Although only one flow rate was used, the similarity with the pure argon atmosphere is evident.

A dramatic change in deposition rates resulted when oxygen was used as the reactive gas [Fig. 2(c)]. Here it was observed that deposition rates, at all but the lowest temperature, were as much as an order of magnitude greater than in previous experiments. Further, these rates were approximately proportional to the carrier gas flow, *i.e.* iron pentacarbonyl concentration, and were not believed to be temperature dependent above 140°C. The final diagram of the series, Fig. 2(d), compares rates observed for oxygen-water mixtures

[1] A product of Taylor-Hobson Company, Limited.

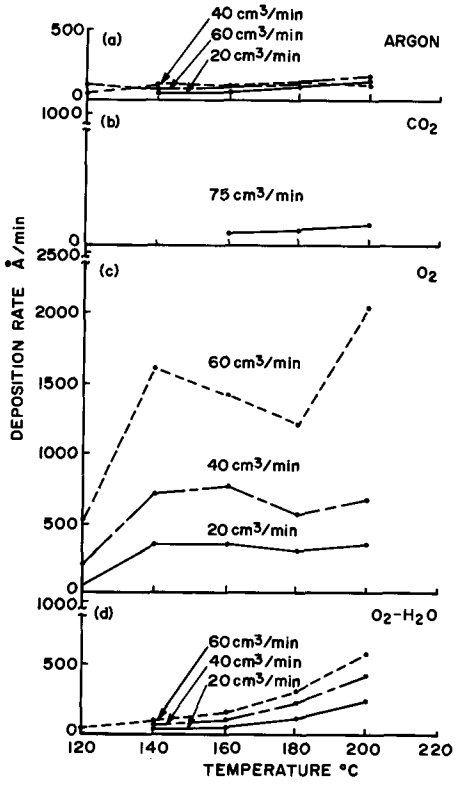

Fig. 2. Deposition rate (Å/min) vs. temperature (°C): (a) deposition in argon at carrier flows of 20, 40, and 60 cc/min; (b) deposition in CO_2 with carrier flow Ar of 75 cc/min and CO_2 flow 60 cc/min; (c) deposition on O_2, carrier flow (Ar) 20, 40, and 60 cc/min, and O_2 flow 60 cc/min; (d) deposition in O_2-H_2O, carrier flow (Ar) 20, 40, and 60 cc/min, O_2 bubbled through water at 25°C.

which were prepared by bubbling the gas through a column of water at 25°C. Although the vapor pressure of water is only 23.7 mm, this addition drastically retarded deposition, below even that of argon at the lower temperatures. The deposition rate appeared to be more temperature dependent in this case than in those where argon or CO_2 was used as a carrier.

These results can, for the most part, be rather easily summarized. When, as in the case of argon or CO_2 atmospheres, the quantity of oxygen is limited to that present as an impurity in the inert gas, to back diffusion into the deposition chamber, or desorption from the walls of the apparatus, deposition rates are low. When the supply of oxygen is plentiful, the deposition rates are high, and proportional to the quantity of iron being transported into the chamber. The role of water vapor, however, is less obvious. Even when large quantities of oxygen are supplied with it, deposition rates are low. These rates, unlike those described previously, are temperature dependent and suggest a thermally activated process. Thus, clearly either the reaction or the kinetics involving the decomposition of iron pentacarbonyl is different in a water-containing atmosphere. This point is discussed more extensively in a later section.

Etching Studies

Preparation of semitransparent photomasks requires that films with the appropriate optical spectra be etched in solvents compatible with photoresist processing materials. Furthermore, in order to achieve the desired resolution of the etched films, it is necessary that solution be accomplished uniformly without significant undercutting. Sinclair *et al.* (1) had found sputtered iron oxide films to be extremely resistant to normal etchants, and when etched they provided unsatisfactory resolution. Some of our films behaved similarly, but others could be successfully etched in

diluted HCl at temperatures between 25° and 50°C. This difference could be associated with the deposition temperatures. Films deposited below approximately 160°C could be satisfactorily etched, while those deposited at higher temperatures could not.

Optical Spectra

This observation posed the question: What is the essential difference between these two types of films? Initially, it was thought that optical spectra would provide valuable clues. Thus, extensive absorption spectra in the region between 3000 and 7000Å of films deposited under a variety of conditions were obtained using a Cary recording spectrophotometer (Model No. 14). However, for the purpose intended, this approach proved disappointing since no significant differences were observed. The point is illustrated by optical spectra (Fig. 3) of films deposited in oxygen using a carrier flow of 60 cc/min. This plot of optical density *vs.* wavelength is essentially similar for the spectra of films prepared at different temperatures, except that a somewhat sharper cutoff is exhibited by films formed at higher temperatures.

Although not particularly revealing for the purpose of characterizing the iron oxide films, these spectra do show that iron oxide films meet the criteria for semi-transparent photomasks. They are highly absorbing in the spectral range used for photoresist processing and are reasonably transparent in the visible. A typical film for photomask usage would be about 1800Å thick and would have an optical density of 2 at 4000Å and of 0.3 at 6000Å.

Scanning Electron Microscopy

A more powerful tool for the characterization of these films proved to be the scanning electron microscope. Micrographs were obtained at 10,000-20,000X using a Cambridge Stereoscan II apparatus operating in the secondary mode. The films were sufficiently conducting, $\rho \approx 10^9$ ohms/sq, so that no surface coating was needed. The resulting micrographs clearly reveal a distinction between the surface morphologies of the two types of films. Figure 4(a) shows a typical surface of a high-temperature film. Here, deposition occurred

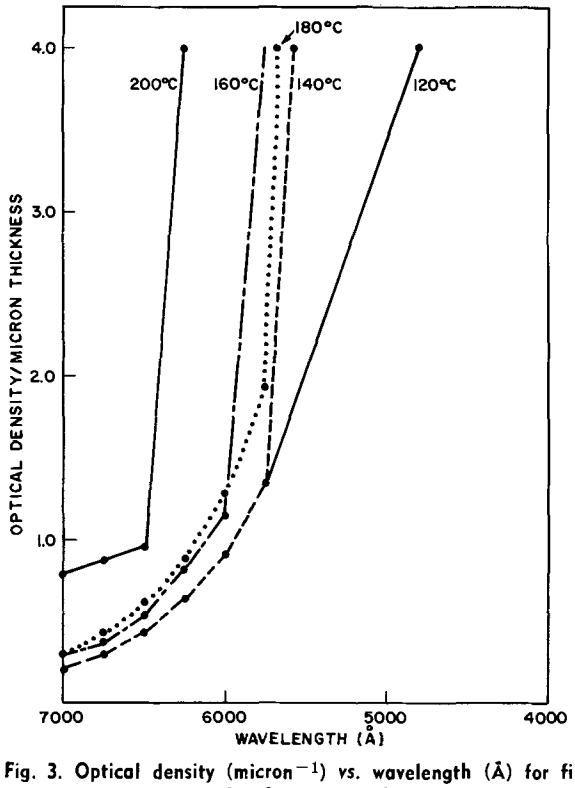

Fig. 3. Optical density (micron^{-1}) *vs.* wavelength (Å) for films formed at temperatures of 120°, 140°, 160°, 180°, and 200°C in an atmosphere of carrier (Ar) 60 cc/min, O_2 60 cc/min.

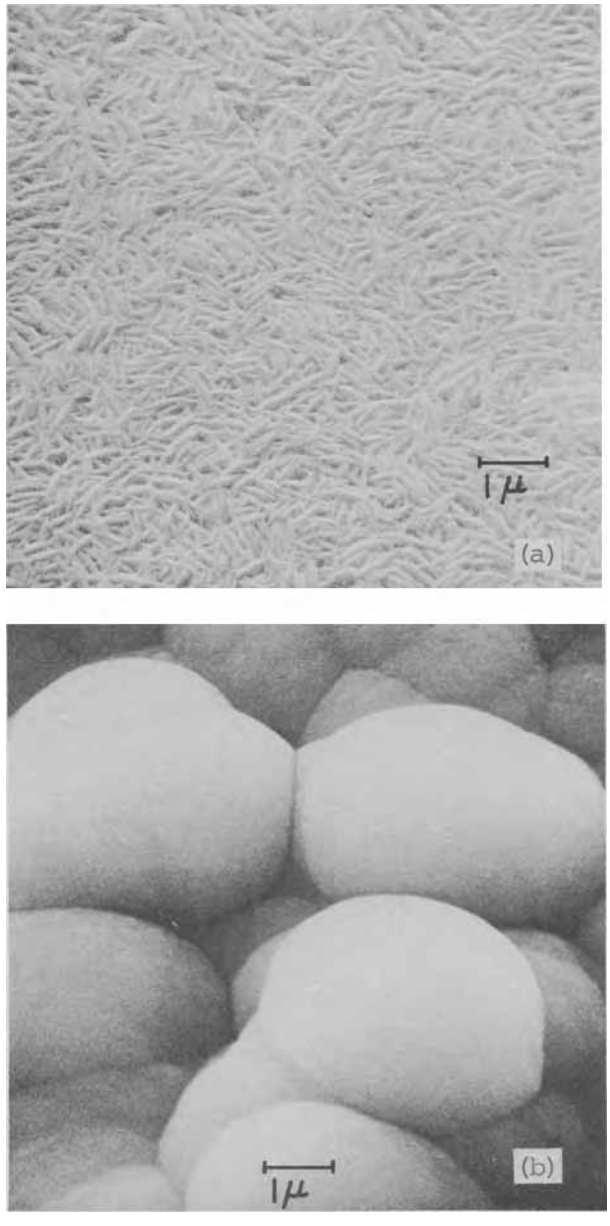

Fig. 4. Scanning electron micrographs of the surfaces of films deposited in an oxygen atmosphere carrier Ar and O_2 40 cc/min and 60 cc/min, respectively: (a) high-temperature morphology deposited at 210°C, (b) low-temperature morphology deposited at 160°C.

at 210°C in oxygen where the carrier and oxygen flows were, respectively, 40 and 60 cc/min. It is seen that the film consists of well-developed acicular crystallites with dimensions of approximately 0.1 x 0.1 x 1.0μ. A quite different appearance is observed for films formed under similar flow conditions but deposited at 160°C. An example is shown in Fig. 4(b). Component particles of this film are large, approximately 4μ in diameter, and have a rounded appearance with an absence of well-developed crystal faces. The morphology of this film is reminiscent of the reniform (4) habit frequently displayed by one variety of naturally occurring hematite. The development of this habit is associated with a low-temperature (sedimentation) process. When contrasted with the well-formed crystallites observed in the films formed at higher temperatures, it was reasonable to suspect that the difference between the two types of films involved the degree of crystallinity attained by each.

X-Ray Diffraction and Mössbauer Spectroscopy

There was little difficulty in establishing that films formed at the higher temperatures were crystalline

Table I

and that their structure was that of αFe_2O_3. X-ray diffractometer patterns, obtained using CrKα radiation, gave reflections characteristic of this phase. In addition, Mössbauer spectra of characteristic films were obtained by methods described previously (5). One such spectrum was obtained from a 6μ film which had been deposited at 206°C and subsequently removed from the substrate. This consisted of six lines characteristic of magnetically ordered materials. Its isomer shift, obtained from the centroids of the peaks, was +0.21 mm/sec relative to ^{57}CoPd and its effective magnetic hyperfine field was 512 kOe. Both values are typical of the αFe_2O_3 phase.

Analysis of the low-temperature deposits proved more difficult. Here, x-ray diffraction, and electron diffraction as well, proved worthless. No reflections could be obtained from these films even when films several microns thick were scanned. At the same time, it was found extremely difficult to remove these deposits from glass for Mössbauer spectroscopy. However, it had been observed that films deposited on steel panels at similar temperatures had morphology identical to those deposited on glass and could thus be assumed comparable. One such film, deposited at 160°C, was removed using diluted HCl and a portion of it was retrieved from the acid for analysis. The Mössbauer spectra of this film revealed the presence of both magnetically ordered and paramagnetic-trivalent iron. The hyperfine split spectra revealed an effective field of 512 kOe similar to that observed previously. The isomer shift of the paramagnetic iron was +0.19 mm/sec. Although somewhat less than that observed previously, this value is still typical of trivalent iron. Thus, it was concluded that the low-temperature phase was composed of trivalent iron, a portion of which was present in a crystalline environment, while the remainder was either amorphous or incorporated in a phase not magnetically ordered at room temperature. It appears likely that the film was composed of crystallites having a wide range of sizes, the smaller of which were superparamagnetic and thus exhibited a range of blocking temperatures (6).

Analysis

Electron probe microanalysis was obtained from films deposited on silicon wafers. One film was deposited at 155°C using a flow of 85 cc/min argon and 80 cc/min O_2 and yielded a film 4750Å thick. A second film was deposited at 200°C to a thickness of 2250Å using an argon flow of 70 cc/min and oxygen of 50 cc/min. The mean chemical composition and two sigma limits based on 12 analyses of these films are shown in Table I.

These analyses indicate that the compositions of both films approximate that of Fe_2O_3 but are iron deficient with possible minor concentrations of carbon and silicon. This suggests the possible presence of goethite ($Fe_2O_3 \cdot H_2O$), the hydroxide $Fe(OH)_3$ or, as evidenced by the presence of carbon, a carbonate or carbonyl.

Chemistry of Iron Oxide Film Formation

The decomposition of iron pentacarbonyl in the pure state or in an inert gas atmosphere appears to be reasonably well understood. Decomposition takes place according to the over-all reaction: $Fe(CO)_5 = Fe + 5CO$. Carlton and Oxley (7) have studied equilibrium decomposition via this reaction and find that it is thermodynamically favorable, in the pure state, at temperatures above 60°C. However, the rate is limited by kinetics below approximately 200°C and by diffusion above this temperature. The rate-limiting step at lower temperatures is the decomposition of adsorbed carbonyl on the deposition surface. The activation energy for this reaction is 20 kcal/mole, but iron pentacarbonyl is only weakly adsorbed on the reaction surface ($\Delta H_{ads} = 5$ kcal/mole). Carbon monoxide, on the other hand, is quite strongly absorbed ($\Delta H_{ads} = 22$ kcal/mole). Thus, the presence of carbon monoxide in the reaction atmosphere, either as an addition or resulting from the deposition, strongly depresses the decomposition, while argon and helium which are not strongly adsorbed have little effect on the reaction rate.

In order to better understand the decomposition of iron pentacarbonyl in oxidizing atmospheres, we arranged to pass its vapor together with the argon carrier and the oxidizing gas into a CEC[2]-621 mass spectrometer. In one instance, the oxidizing gas was pure oxygen and, in another, oxygen saturated with water at 25°C. Argon (carrying the pentacarbonyl) was mixed with either of these atmospheres in the ratio of 40:60 (per cent by volume) and passed into a Pyrex manifold connected to the mass spectrometer. This was so arranged that the gas mixture could be fed directly into the instrument or first passed through a furnace packed with glass wool. Samples were analyzed for argon, oxygen, carbon monoxide, carbon dioxide, nitrogen, and iron pentacarbonyl. The results of these analyses are given in Table II. The three columns on the left give the results of direct passage into the spectrometer, while the remainder show the

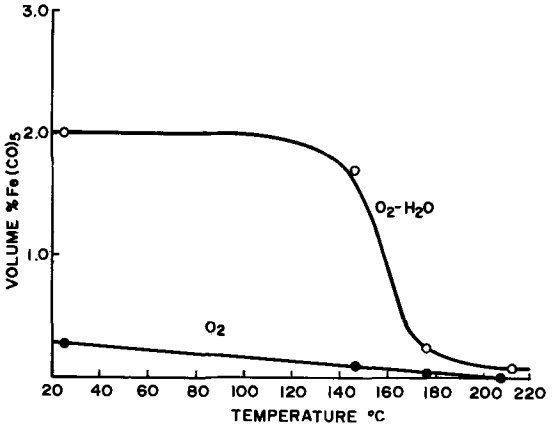

Fig. 5. Curves showing % $Fe(CO)_5$ vs. temperature (°C) obtained from mass spectrometer analyses. Mixtures of $Fe(CO)_5$ vapor, argon, and O_2 or O_2-H_2O were passed through glass wool packing before entering mass spectrometer.

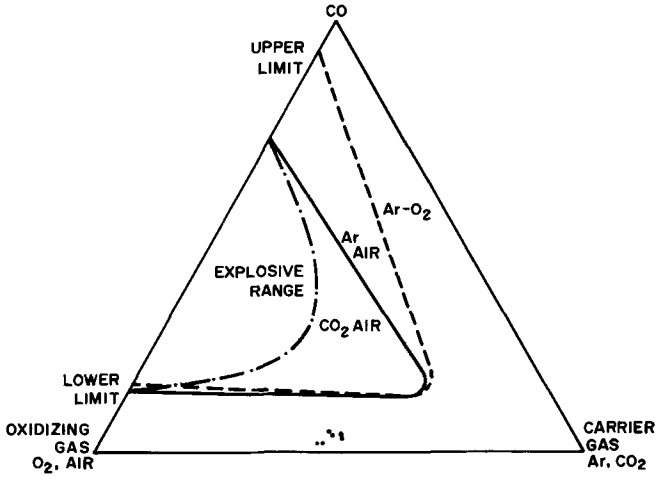

Fig. 6. Curves showing explosive ranges of various ternary gas mixtures: solid curve, CO-air-Ar; dashed curve, CO-O_2-Ar; dash-dot curve, CO-air-CO_2. Points in lower center of diagram represent analytically determined compositions of postdeposition atmospheres.

effects of passage through the glass wool. It is evident that even at low temperatures the glass wool, presumably because of its large surface area, causes decomposition of iron carbonyl. This is severe with pure oxygen but insignificant when oxygen and water are both present. These results are compared by curves of % $Fe(CO)_5$ *vs.* T (°C) in Fig. 5.

These data, combined with those derived from the deposition rate experiments represented in Fig. 2, clearly show that water inhibits the decomposition of iron carbonyl. We suggest the following rationale to explain this phenomenon: The decomposition of iron pentacarbonyl to iron oxide proceeds by a surface-catalyzed reaction. However, both oxygen and water are strongly adsorbed on the reaction surface. The heat of adsorption of oxygen on oxides is approximately 20 kcal/mole (8) and that of water on αFe_2O_3 is reported to be between 14.2 and 18.7 kcal/mole (9) at 150°C. Thus it is reasonable to think that, under the conditions of film formation, both oxygen and water compete for surface sites. In this regard, it might be mentioned that the data of Fig. 2(d) which represents deposition rates for oxygen-water mixtures, when plotted as ln R (Å/min) *vs.* $1/T(°K^{-1})$, yield a straight line whose slope is equivalent to an activation energy of 12.7 kcal/mole. This value is in reasonable agreement with that of the heat of adsorption of water on iron oxide.

The carbon monoxide concentrations determined in these analyses raise another point deserving consideration. In a process of this kind, where CO is present in an atmosphere rich in oxygen, there is the possibility of approaching the explosive range of these gas mixtures. Fortunately, the literature abounds with data on the explosive limits for mixtures of CO with O_2 and air in the presence of inert gases. From these data, we have constructed Fig. 6 which shows by means of a ternary diagram the explosive range of mixtures of CO with air or oxygen and an inert gas. The solid line of this diagram is drawn on the basis of data by van Heiningen (10) and shows the explosive range of CO-air-Ar. The range for CO-O_2-Ar is also known (11) and is represented on this diagram by the dashed curve.

In the lower center of this diagram, a series of dots are used to represent the compositions of gas mixtures tabulated in Table II. It is seen that these lie safely outside of the explosive limits. Nevertheless, the concentration of CO in deposition atmospheres could become of concern should the iron pentacarbonyl concentration, either by intent or accident, be raised significantly. In order to avoid the explosive region, the concentration of the argon carrier could be raised to greater than 60%. Alternatively, CO_2 could be substituted for argon. This causes the explosive range to shrink appreciably (12) as shown by the dash-dot curve of Fig. 6. Thus, with appropriate flow of air as the oxidizing gas and CO_2 as the carrier, the explosive range can be avoided completely.

Conclusions

This study shows that iron oxide films having optical characteristics suitable for semitransparent photomasks can be conveniently and easily prepared by decomposition of iron pentacarbonyl in an oxygen atmosphere. The substrate temperature at which the deposition is carried out is important in determining the resistance of the film to etching agents. Satisfactory films could be prepared at temperatures below approximately 160°C. These were composed of partially crystalline αFe_2O_3.

Acknowledgments

The authors are indebted to many colleagues who have provided the analytical data on which the characterization of these films is based. We are particularly grateful to G. W. Kammlott for scanning electron microscopy, P. K. Gallagher for Mössbauer spectra, G. W. Colby for microprobe analysis, F. V. DiMarcello for aid on thickness measurements, and F. Gollob, of the Gallob Analytical Service, Berkeley Heights, New Jersey, for mass spectrometer analyses. In addition, we wish to acknowledge useful discussions with W. J. Schreibeis and D. W. Johnson, and to thank W. R. Sinclair and M. D. Rigterink for both encouragement and advice, and P. A. Turner for critical reading of the manuscript.

Manuscript submitted June 19, 1970; revised manuscript received Nov. 30, 1970. This was Paper 126 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

The Solid Solubility Isotherms of Zn in GaP and GaAs

A. S. Jordan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The solid solubility isotherms for Zn in GaP and GaAs have been calculated as a function of Zn concentration along the Ga-P-Zn and Ga-As-Zn liquidus isotherms over a wide temperature range. These calculations were based on a critical evaluation of the available solubility data, assuming regular ternary solution behavior in both ternary melts. The solubility isotherms are not only in agreement with the published data, but are also in accord with recent experimental results on the incorporation of Zn in GaP grown by liquid-phase epitaxy and liquid encapsulation pulling. In addition, the Zn surface concentrations in GaP and GaAs arising from ternary source diffusion have been estimated as a function of temperature. Finally, the enthalpies for the incorporation of Zn in GaP and GaAs according to $Zn(l) + V_{Ga} = Zn_{Ga}$ are given as approximately -2.16 and -2.29 eV, respectively.

Zinc is one of the most frequently used p-type dopants in GaP and GaAs. In particular, Zn plays a pivotal role in the formation of Zn-O complexes in red emitting electroluminescent GaP diodes (1). Several recent investigations have been devoted to the study of Zn solubility in GaP and GaAs. Most of these studies have not only provided a limited amount of solubility data at certain temperatures, but have also contributed to the present understanding of the incorporation mechanism of Zn in GaP and GaAs.

The major objective of this paper is to calculate the complete solid solubility isotherms for Zn in GaP and GaAs as a function of Zn concentration along the Ga-P-Zn and Ga-As-Zn liquidus isotherms over a wide temperature range. The temperature dependent equilibrium constants for the incorporation of Zn in these crystals required to perform the calculations are obtained by a critical analysis of the published solubility data in combination with Zn, P, and As activities taken from recent work (2). It is further shown that the approximate enthalpies of Zn incorporation are in good agreement with an independent theoretical estimate. In addition, the Zn surface concentrations as a function of temperature in GaP and GaAs resulting from ternary source diffusion are evaluated. Finally, it is demonstrated that the Zn solubility isotherms in GaP at both low and high temperatures are in accord with recent experiments on the incorporation of Zn in GaP grown by liquid-phase epitaxy and liquid encapsulation pulling.

Analysis of the Solubility Data

Trumbore *et al.* (3) have determined the solid solubility of Zn in GaP crystals, grown at about 1040°C from Ga-rich solutions by a thermal gradient technique. These authors (3) were able to relate the Zn solubility in the solid to the Zn concentration in the melt by means of a simple model, assuming the incorporation of singly and completely ionized Zn acceptors on vacant Ga sites. More recently, Panish and Casey (4, 5) and Casey *et al.* (6) have considered in some detail the ionization of Zn in GaAs and GaP and pointed out that the accepted theories for impurity incorporation, based on Fermi-Dirac statistics, required the presence of a significant amount of neutral Zn at higher concentrations. However, when the effects of high impurity concentrations on the density of states were taken into account, they have found that the merger of the localized impurity level with the valence band resulted in the total ionization of Zn.

Therefore, the incorporation of Zn in GaP or GaAs can be given by the following defect equilibria

$$O = V_{Ga} + V_P \quad [1a]$$

$$P(l) + V_P = P_P \quad [1b]$$

$$Zn(l) + V_{Ga} = Zn_{Ga} \quad [1c]$$

$$Zn_{Ga} = Zn_{Ga}^- + e^+ \quad [1d]$$

$$P(l) + Zn(l) = Zn_{Ga}^- + P_P + e^+ \quad [2]$$

where the left-hand side of Eq. [1a] represents the normal occupation in the lattice and Eq. [2] by summing over Eq. [1a] through [1d] describes the over-all incorporation process. Consequently, the equilibrium constant, K, for Eq. [2] takes the form

$$K = [Zn_{Ga}^-]\gamma_h[e^+]/a_{Zn}a_P \quad [3]$$

where the brackets signify the concentration of the enclosed species, γ_h is the activity coefficient of holes, as introduced by Panish and Casey (6), and the functions a_{Zn} and a_P are the Zn and P activities in the liquid phase in equilibrium with Zn-doped GaP. The standard states for the activities are the respective pure liquids. In writing Eq. [3] it has been assumed that the activity coefficients for $[Zn_{Ga}^-]$ and $[P_P]$[1] as well as $[P_P]$ itself are constants (Henrian and Raoultian regions, respectively). By the use of the electroneutrality condition, $[Zn_{Ga}^-] + [e^-] = [e^+]$, and the mass action relation for electrons and holes, $\gamma_h[e^-][e^+] = n_i^2$,[2] where n_i is the intrinsic concentration, one can eliminate $[e^+]$ from Eq. [3] and obtain the following relationship

$$\frac{C^{s2}_{Zn}\gamma_h}{2}\left[\sqrt{1+\left(\frac{2n_i}{C^s_{Zn}}\right)^2\frac{1}{\gamma_h}}+1\right] = Ka_{Zn}a_P \quad [4]$$

Key words: III-V compounds, doping, electroluminescent materials, semiconductor phase equilibria.

[1] The Raoultian behavior of the activity coefficient for $[P_P]$ is not seriously affected by $\gamma_h \neq 1$ as the Gibbs-Duhem equation is approximately obeyed when $[e^+]/[P_P]$ is about 10^{-3} or smaller.

[2] Note that $\gamma_e = 1$ because for Zn-doped GaP as well as for Zn-doped GaAs $[e^-] << [e^+]$.

It should be noted that in Eq. [4] the complete ionization of Zn has been introduced; thus $[Zn_{Ga}^-]$ was replaced by C^s_{Zn}, the total concentration of substitutional Zn, expressed, as usual, in units of atoms/cc.[3] Replacing the symbol P by As, Eq. [1] through [4] also hold for Zn-doped GaAs. Of course, the K's have different values for GaAs and GaP.

In determining K by Eq. [4], one must know the activities in the liquid phase, *i.e.*, $a_{Zn} = \gamma^l_{Zn} x^l_{Zn}$ and $a_P = \gamma^l_P x^l_P$ (or $a_{As} = \gamma^l_{As} x^l_{As}$), where γ^l_i and x^l_i are the activity coefficient and atom fraction of the designated component in the ternary melt, respectively. The evaluation of a_{Zn}, a_P, and a_{As} is based on work reported in ref. (2), where the liquidus data for Zn-doped GaAs and GaP in equilibrium with Ga-As-Zn and Ga-P-Zn ternary melts are fitted by means of a liquidus equation in four parameters, assuming regular solution behavior. It is demonstrated therein that the calculated ternary liquidus isotherms and component partial pressures are in good agreement with the available liquidus and pressure data. Therefore, if at a particular temperature C^s_{Zn} as a function of x^l_{Zn} has been determined, then at any x^l_{Zn} the calculated liquidus isotherm yields the corresponding x^l_{As} or x^l_P and the activity equations for regular ternary solutions provide the appropriate activities (8).

In addition, the evaluation of K from Eq. [4] also requires a knowledge of n_i and γ_h. Tabulated temperature dependent values of n_i for GaAs and GaP are available from the unpublished works of Ermanis and Casey (9) and Casey and Focht (10), respectively. Moreover, the calculated variations of γ_h on $[e^+]$ for GaAs-Zn at 700°, 800°, 900°, and 1000°C and for GaP-Zn at 1000° and 1100°C, based on the analysis of diffusion data, have been presented by Casey *et al.* (6) and Panish and Casey (4), respectively. According to these authors, γ_h departs from unity for Zn-doped GaP above $[e^+] = 3 \times 10^{19}$ and for Zn-doped GaAs above $[e^+] = 6 \times 10^{19}$. Indeed, a preliminary analysis of the extensive 1000°C Zn solubility data for GaAs of Panish and Casey (5) and Casey *et al.* (6) below this limit (where $\gamma_h = 1$ holds) by logarithmic least-squares, a method to be presented next, shows that the calculated K in combination with Eq. [4] is unable to describe the solubility isotherm in the 10^{20} range unless the γ_h of Casey *et al.* (6) is introduced. However, a similar analysis of the Zn solubility measurements of Trumbore *et al.* (3) and Panish and Casey (4) at 1040°C indicates that the experimental results, including the 10^{20} range are well represented by taking $\gamma_h = 1$ throughout. Hence, only the calculations involving Zn-doped GaAs will take into account the proposed departure of γ_h from unity at high carrier concentrations.

Since most of the experimental solubility data show a considerable scatter, it was decided to evaluate K from Eq. [4] by the method of logarithmic least squares whenever isothermal C^s_{Zn} was obtained by an investigator at more than one value of x^l_{Zn}. Briefly, by denoting at each C^s_{Zn} the logarithms of the left-hand side and $a_{Zn}a_P$ in Eq. [4] by η_i and ξ_i, respectively, one can transform this equation into

$$\eta_i = \ln K + \xi_i$$

Then, applying the method of least squares, one obtains $\ln K$ in the form

$$\ln K = \left(\sum_{i=1}^{n} \eta_i - \sum_{i=1}^{n} \xi_i \right) \Big/ n \qquad [5]$$

where n is the number of solubility determinations at a given temperature by one of the investigators.

The reported measurements of Trumbore *et al.* (3) and Panish and Casey (4) at 1040°C and Foster and Scardefield (11) at 1144°C for C^s_{Zn} in GaP as a function of x^l_{Zn} are suitable for a direct application of Eq. [4] and [5]. Likewise, the solubility data of Casey *et al.* (6) and Panish and Casey (5) at 900° and 1000°C for Zn-doped GaAs can be analyzed readily by means of the same equations. Log K *vs.* reciprocal temperature plots calculated from the above sources are shown in Fig. 1.

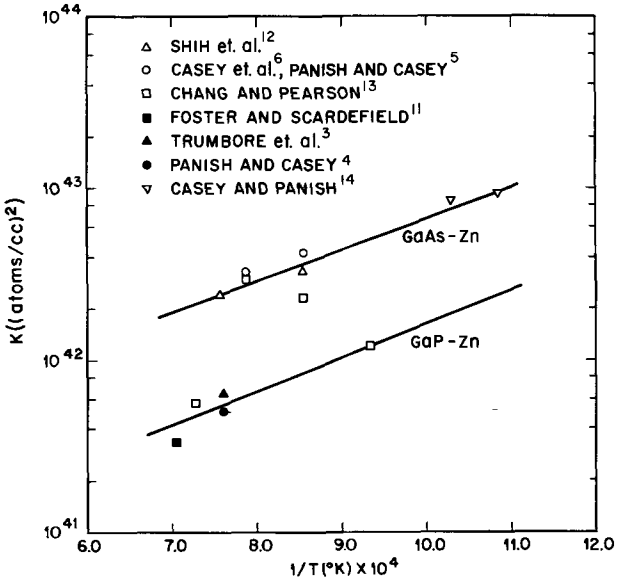

Fig. 1. Equilibrium constant *vs.* reciprocal temperature for the incorporation reactions.

$$Zn(l) + P(l) = Zn_{Ga}^- + P_P + e^+$$

and

$$Zn(l) + As(l) = Zn_{Ga}^- + As_{As} + e^+$$

Several additional K values, derived from the diffusion studies of Shih *et al.* (12), Chang and Pearson (13), and Casey and Panish (14), are also illustrated in Fig. 1. Shih *et al.* (12) have determined the surface concentrations of Zn in GaAs crystals at 900° and 1050°C, diffused from a radioactive Zn^{65} source in sealed tubes also containing an excess of As. These authors (12) have estimated the partial pressures of As, p_{As_4}, corresponding to the liquid concentrations along the ternary liquidus isotherm resulting from the presence of various known amounts of Zn^{65} and As in the ampoules. The calculation of p_{As_4} was accomplished by the use of an equation due to Furukawa and Thurmond (15) in combination with the published liquidus isotherms (16) and the earlier pressure measurements of Shih *et al.* (17).

However, to evaluate K the required variables are x^l_{Zn} and the activities instead of p_{As_4}. Therefore, these variables were derived from the raw data of Shih *et al.* (12) by a procedure completely consistent with the previously mentioned liquidus isotherm and partial pressure calculations (2), and also taking into account the presence of As_2 in addition to As_4 in the gas phase. When GaAs is heated in contact with As and an impurity in sealed tubes, ternary liquid and gas phases are formed. Since only a negligible amount of Ga is transferred into the gas phase, the total number of moles of As in the liquid (l) and gas (v) phases can be written (15) in the form

$$n^a_{As} + n^l_{Ga} = n^l_{As} + n^v_{As} \qquad [6]$$

where n^a_{As} is the number of moles of added As. Allowing for the presence of As_2 and As_4 in the gas phase and assuming the validity of the ideal gas law for the gaseous species, one has $n^v_{As} = 4n^v_{As} + 2n^v_{As_2}$ and Eq. [6] can be transformed into

[3] Consequently, the unit of K is $(atoms/cc)^2$. It can be shown that K is related to the dimensionless thermodynamic equilibrium constant, K_a, by the constant factor $K \simeq (5 \times 10^{45}/k) K_a$ where k is the activity coefficient of $[Zn_{Ga}^-]$ in the Henrian limit.

$$\frac{RT}{V}\frac{w^{a}_{As}}{M_{As}}+\frac{RT}{V}\frac{w^{a}_{Zn}}{M_{Zn}}\frac{(x^{l}_{Ga}-x^{l}_{As})}{x^{l}_{Zn}} \equiv f_1+f_2\frac{(x^{l}_{Ga}-x^{l}_{As})}{x^{l}_{Zn}}=4\left(p_{As_4}+\frac{p_{As_2}}{2}\right)+p_{Zn}\frac{(x^{l}_{Ga}-x^{l}_{As})}{x^{l}_{Zn}} \quad [7]$$

where V is the sample volume and w^{a}_{i} and M_i are the added weight and molecular weight of the designated species, respectively. For every value of C^{s}_{Zn}, the w^{a}_{i}'s and V have been given by Shih *et al.* (12); hence, f_1 and f_2 are known. Moreover, at each x^{l}_{Zn} along the Ga-As-Zn ternary liquidus isotherm x^{l}_{As} and x^{l}_{Ga} and the corresponding p_i's are available from previous work (2) is graphical and also tabulated form. Thus, for every fixed value of f_1 and f_2 a unique x^{l}_{Zn} satisfying Eq. [7] as well as a_{Zn} and a_{As} were obtained. Finally, the K's at 900° and 1050°C were evaluated from Eq. [4] and [5].

In earlier work, Chang and Pearson (13) determined the solubility of Zn in GaP and GaAs at 800° and 900°C, respectively, as a function of Zn concentration in radioactive Zn^{65}-Ga liquid alloys, used as diffusion sources. In addition, at several temperatures both compounds were diffused from a pure Zn^{65} source and the surface concentrations measured. In all cases the appropriate ternary x^{l}_{Zn} was located by intersecting the calculated liquidus isotherm, plotted on an equilateral triangle, by the straight line connecting the reported Zn composition of the source, situated on the Ga-Zn axis, with the composition representing GaP or GaAs. The evaluation of the K's from the C^{s}_{Zn} data and the derived x^{l}_{Zn} and activities followed the previously performed procedure.

It should be noted that below about 1040°C for GaP and 900°C for GaAs the liquidus composition corresponding to the pure Zn source is in equilibrium not only with solid GaP or GaAs (doped with Zn) but also with solid Zn_3P_2 or Zn_3As_2 (16, 18, 19). Therefore, in view of the uncertainty involved in locating the x^{l}_{Zn} and the activities at which both solid phases are in equilibrium with the melt, and the possibility of precipitation of Zn_3P_2 or Zn_3As_2 in the GaP or GaAs, the solubility data obtained under the above conditions were not utilized.

Recently, Casey and Panish (14) diffused Zn into GaAs at 650° and 700°C from an invariant ternary source. The composition of this source was such that at these temperatures three solid phases GaAs, Zn_3As_2, and ZnAs were in equilibrium. At both temperatures the magnitude of the solid solubility, obtained from the diffusion profile, indicates extrinsic conductivity in the crystal ($n_i << C^{s}_{Zn}$); hence Eq. [4] reduces to

$$\frac{C^{s2}_{Zn}\gamma_h}{a_{Zn}a_{As}}=K \quad [8]$$

The calculation of the $a_{Zn}a_{As}$ product is based on thermodynamic data for the decomposition of $ZnAs_2$ and Zn_3As_2, extensively discussed in a recent communication (20). Lyons (21) has shown that between 612° and 740°C $ZnAs_2$(s) dissociates according to

$$ZnAs_2(s) = 1/3\ Zn_3As_2(s) + 1/3\ As_4(g) \quad [9]$$

with the accompanying free energy change, ΔG^{o}_{1}

$$\Delta G^{o}_{1}(\text{kcal}) = 18.8 - 18.5T \times 10^{-3} \quad [10]$$

In addition, Jordan (20) has derived the free energy change, ΔG^{o}_{2}, between 328° and 478°C for the reaction

$$Zn_3As_2(s) = 3Zn(g) + \tfrac{1}{2}\ As_4(g) \quad [11]$$

Extrapolating ΔG^{o}_{2} to the mid-temperature range of Lyons (≈680°C), one has

$$\Delta G^{o}_{2}(\text{kcal}) = 136 - 95.9T \times 10^{-3} \quad [12]$$

Adding $\Delta G^{o}_{1}/4$ to $\Delta G^{o}_{2}/3$, one obtains the free energy change, ΔG^{o}_{As}, for the reaction

$$\tfrac{1}{4}\ Zn_3As_2(s) + \tfrac{1}{4}\ ZnAs_2(s) = Zn(g) + \tfrac{1}{4}\ As_4(g) \quad [13]$$

in the form

$$\Delta G^{o}_{As}(\text{kcal}) = 50.1 - 36.4T \times 10^{-3} \quad [14]$$

Since the activities of the pure solid phases in ternary source diffusion are unity, the equilibrium constant for Eq. [13], K_{As}, which can be calculated from Eq. [14] is given by

$$K_{As} = e^{-\Delta G^{o}_{As}/RT} = p_{Zn}p^{1/4}_{As_4} \quad [15]$$

Dividing Eq. [15] by the product $p^{o}_{Zn}p^{o1/4}_{As_4}$, where p^{o}_{Zn} and $p^{o}_{As_4}$ denote the vapor pressure of pure liquid Zn and As, respectively, one obtains the activity product

$$a_{Zn}a_{As} = \frac{p_{Zn}}{p^{o}_{Zn}}\left(\frac{p_{As_4}}{p^{o}_{As_4}}\right)^{1/4} = \frac{K_{As}}{p^{o}_{Zn}p^{o1/4}_{As_4}} \quad [16]$$

The pressures p^{o}_{Zn} and $p^{o}_{As_4}$ were evaluated from equations presented by Kubaschewski *et al.* (22) and Nesmeyanov (23), respectively. It should be noted that although no liquid phase exists at the conditions of these ternary source diffusion experiments, the use of pure liquid pressures in Eq. [16] is necessitated by the previous choice of referring the activities, employed in the calculation of K by Eq. [4], to the pure liquid standard states. Thus, the activities in Eq. [16] are those of a hypothetical supercooled liquid solution.

Substituting values of $a_{Zn}a_{As}$ at 650° and 700°C, obtained from Eq. [16], into Eq. [8] and taking γ_h for Zn-doped GaAs from the 800°C curve of Casey *et al.* (6) (instead of the somewhat less reliable 700°C results), K's at both temperatures from the known C^{s}_{Zn}'s of Casey and Panish (14) were derived.

Observing the positions of the discrete K values in Fig. 1 for Zn-doped GaP and GaAs, calculated by the preceding critical assessment of the available experimental data, one concludes that it is reasonable to fit them by the customary straight-line relationship between ln K and $1/T$. Therefore, using the method of least-squares the following equations were obtained for the K's

$$-RT \ln K \times 10^{-45} = -8980 + 21.7T \text{ (cal)} \quad [17]$$

for Zn-doped GaP and

$$-RT \ln K \times 10^{-45} = -8530 + 18.4T \text{ (cal)} \quad [18]$$

for Zn-doped GaAs. These lines of best fit are also shown in Fig. 1. The enthalpy changes for the GaP and GaAs incorporation reactions according to Eq. [2] are given by the constant terms in Eq. [17] and [18] (divided by 23,060 (cal)/eV) as −0.39 and −0.37 eV, respectively. These enthalpies are approximately equal which is perhaps not surprising in view of the common dopant and the similarity of the two compounds.

Calculation of the Solubility Isotherms

Solving Eq. [4] for C^{s}_{Zn}, one finds that the solid solubility of Zn in GaP and GaAs in terms of K and the activities is given by

$$C^{s}_{Zn} = \sqrt{\frac{Ka^{2}_{P}a^{2}_{Zn}}{\gamma_h\left(\frac{n^{2}_{i}}{K}+a_{P}a_{Zn}\right)}} \quad [19]$$

Therefore, substituting K from Eq. [17] or [18] into Eq. [19], one can evaluate C^{s}_{Zn} in both compounds at any temperature if the activities in the external phase are known.

In previous work (2) the liquidus isotherms and the partial pressures for Ga-As-Zn and Ga-P-Zn ternary melts in equilibrium with Zn-doped GaAs and GaP were obtained between $x^{l}_{Zn} = 10^{-6}$ on the Ga-rich sides and $x^{l}_{Zn} = 10^{-6}$ on the As and P-rich sides. As mentioned before, calculation of the pressures required a knowledge of the activities. Hence, at any

temperature for each value of x^l_{Zn} in the Ga-P-Zn or Ga-As-Zn ternary solution, C^s_{Zn} for Zn-doped GaP or GaAs in equilibrium with its respective melt can be determined.

In Fig. 2 and 3 calculated curves for C^s_{Zn} in GaAs as a function of x^l_{Zn} are presented between 600° and 1200°C in 100°C intervals and also at 1050°C, together with the previously analyzed solid solubility data. The error limits given in Fig. 2 with the 1000°C data of Panish and Casey (5) and Casey *et al.* (6) were taken from the authors.

For large values of C^s_{Zn} at 1000°C two curves are shown in Fig. 1. One of them, the dashed line, calculated in this range by setting $\gamma_h = 1$ does not, as mentioned earlier, describe the experimental results. On the other hand, the solid line obtained by substituting the 1000°C γ_h data into Eq. [19] is in good accord with the measured values. Thus, the solubility isotherms for Zn-doped GaAs were evaluated at and below 800°, at 900°, and at and above 1000°C by the use of the 800°, 900°, and 1000°C γ_h *vs.* carrier concentration curves of Casey *et al.* (6), respectively.

The lower and upper segments of the solubility isotherms describe C^s_{Zn} for a crystal in equilibrium with a Ga-rich and an As-rich liquid, respectively. To avoid crowding of the curves, only the lower segments are shown below 900°C. These isotherms are terminated at the approximate liquid composition where the secondary solid phase Zn_3As_2 appears (2, 16, 19).

The calculated solubility isotherms for Zn-doped GaP are illustrated in Fig. 4 and 5 between 600° and 1400°C in 100°C intervals and also at 1040°, 1144°, 1460°, and 1465°C. The experimentally determined solubility data, utilized in the preceding analysis, are also shown.

It has been previously indicated that for Zn-doped GaP the 1040°C isotherm even for large values of C^s_{Zn} can be described by taking $\gamma_h = 1$. Comparing the solid curve calculated by equating γ_h to unity in Eq. [19] and the dashed curve obtained by a combination of the same equation with the γ_h of Panish and Casey (4), one notices that at high Zn concentrations a somewhat better agreement with the experimental data is achieved if $\gamma_h = 1$. Therefore, all the isotherms for Zn-doped GaP were evaluated from Eq. [19] by assuming that γ_h does not depart from unity in the entire composition range.

At and above 1040°C both the lower and upper segments of the isotherms are shown. In the interest of

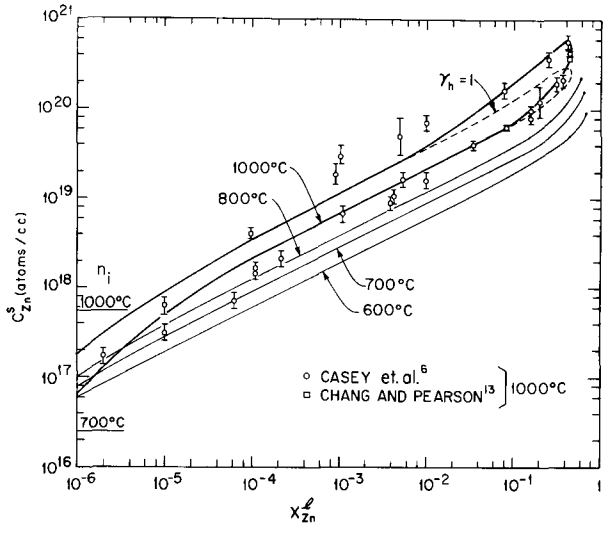

Fig. 2. Zn concentration in GaAs *vs.* x^l_{Zn} along the 600°, 700°, 800°, and 1000°C liquidus isotherms in the Ga-As-Zn system. The isotherms at 800°C and below are terminated at the approximate liquid compositions where Zn_3As_2, a secondary solid phase, appears.

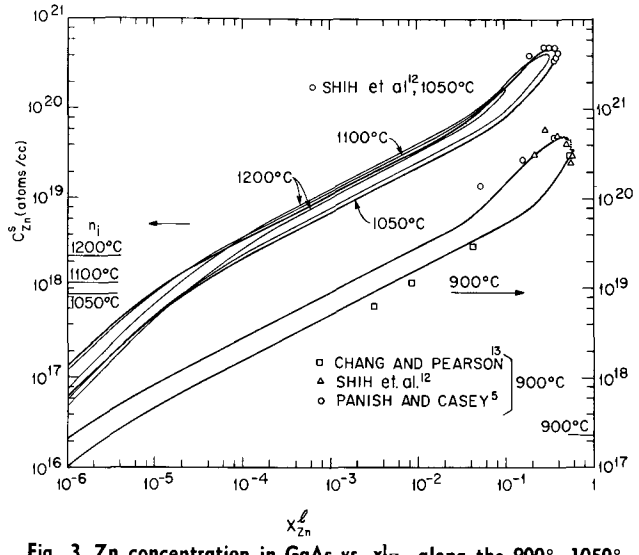

Fig. 3. Zn concentration in GaAs *vs.* x^l_{Zn} along the 900°, 1050°, 1100°, and 1200°C liquidus isotherms in the Ga-As-Zn system.

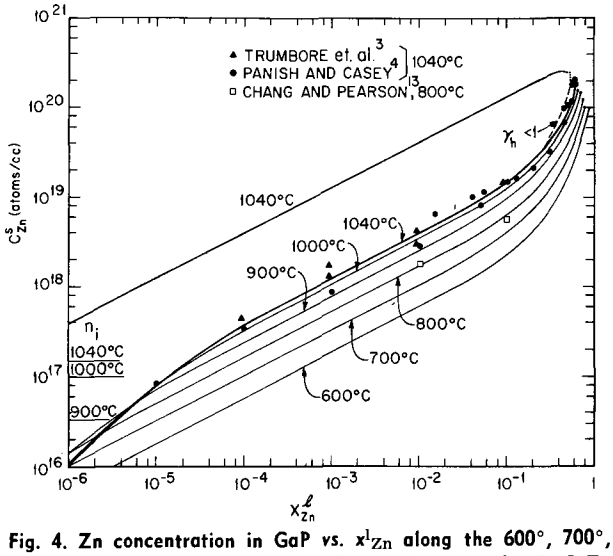

Fig. 4. Zn concentration in GaP *vs.* x^l_{Zn} along the 600°, 700°, 800°, 900°, 1000°, and 1040°C liquidus isotherms in the Ga-P-Zn system. All but the 1040°C isotherms are terminated at the approximate liquid compositions where Zn_3P_2, a secondary solid phase, appears.

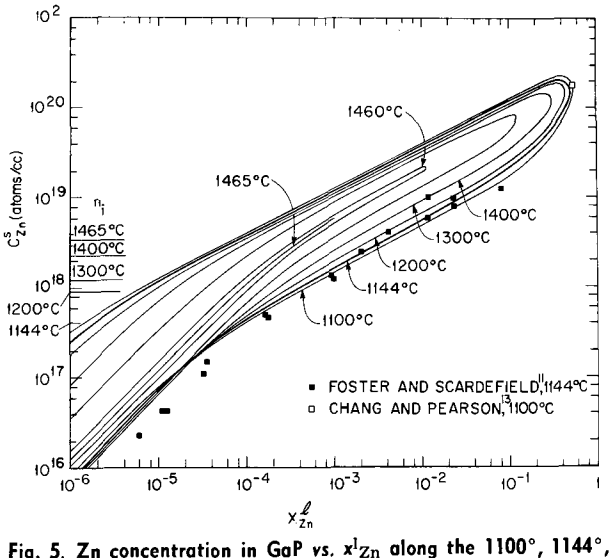

Fig. 5. Zn concentration in GaP *vs.* x^l_{Zn} along the 1100°, 1144°, 1200°, 1300°, 1400°, 1460°, and 1465°C liquidus isotherms in the Ga-P-Zn system.

clarity below 1040°C only the lower segments are presented. These isotherms were terminated at the approximate liquidus composition where the secondary solid phase Zn_3P_2 appears (2, 18).

At most temperatures, in Fig. 2 through 5, n_i for GaAs (9) and GaP (10) are also given at the edge of the diagrams. Above 800°C Fig. 2 through 5 clearly show the intrinsic region ($[e^+] \approx n_i$) with a unit slope as well as the extrinsic region ($[e^+] = C^s_{Zn}$) with a slope of 0.5. The calculated solidus isotherms for Zn-doped GaAs and GaP are generally in good agreement with the available solid solubility data.

Whenever the ternary liquid is in equilibrium only with the primary solid phase, Zn-doped GaAs or GaP, at a fixed temperature a whole range of solid solubilities is allowed as a function of x^l_{Zn}. However, if for example Zn-doped GaAs is in equilibrium with two additional solid phases, namely, Zn_3As_2 and $ZnAs_2$, as is at the surface in the case of ternary source diffusion, then at a constant temperature C^s_{Zn} is an invariant. By a combination of Eq. [8], [16], and [18], this uniquely defined surface concentration of Zn in GaAs was evaluated as a function of temperature and is presented in Fig. 6. The solid line calculated on the basis of the γ_h data of Casey *et al.* (6) agrees well with the measured surface concentrations of Casey and Panish (14). At lower temperatures and solubilities it merges with the dashed line obtained by setting $\gamma_h = 1$.

Furthermore, it is possible to estimate the C^s_{Zn} of GaP diffused from a ternary source. The composition of this source is located in a region where the three solid phases ZnP_2, Zn_3P_2, and GaP are in equilibrium. The calculation of C^s_{Zn} was accomplished by a combination of Eq. [8], equating γ_h with unity, and Eq. [18], evaluating the product $a_{Zn}a_P$ from an equation similar to Eq. [16]. This product is given by

$$a_{Zn}a_P = \frac{p_{Zn}}{p^o_{Zn}}\left(\frac{p_{P4}}{p^o_{P4}}\right)^{1/4} = \frac{K_P}{p^o_{Zn}p^{o1/4}_{P4}} \qquad [20]$$

where K_P is the equilibrium constant for the reaction

$$\tfrac{1}{4}\,Zn_3P_2(s) + \tfrac{1}{4}\,ZnP_2(s) = Zn(g) + \tfrac{1}{4}\,P_4(g) \qquad [21]$$

and the meaning of the other symbols is self-evident.

The free energy change, ΔG^o_P, for Eq. [21], obtained by adding the free energy change for the Zn_3P_2 analogue of Eq. [11], reported by Schoonmaker *et al.* (24) to the ZnP_2 analogue of Eq. [9], estimated by Jordan (20), is of the form

$$\Delta G^o_P(\text{kcal}) = 53.4 - 40.3T \times 10^{-3} \qquad [22]$$

The vapor pressure of pure liquid P was evaluated by the third-law method from data given in the JANAF tables (25).

The estimated C^s_{Zn} for GaP in contact with a ternary source is shown in Fig. 6. It is apparent from Fig. 6 that the carrier concentrations resulting from ternary source diffusion would be too high for red electroluminescent diode applications.

Discussion of Results

In the previous section the solubility isotherms for Zn in GaAs and GaP were presented between 600°C and temperatures near the respective melting points. As the measured solubilities utilized in the evaluation of the equilibrium constants for Zn-doped GaP were obtained in a somewhat restricted temperature interval, it seems desirable to show with the aid of independent information that the extrapolation over a wide temperature range is justified.

Recently, Verleur (26) has grown Zn-doped GaP crystals by liquid encapsulation pulling from a melt containing $Zn(PO_3)_2$, a glassy low melting point dopant (27) first used in liquid-phase epitaxy. The room temperature hole concentrations from Hall measurements on the seed and tail ends of these crystals were determined as a function of various $Zn(PO_3)_2$ additions to the GaP melt. It is possible to estimate the C^s_{Zn} values corresponding to these hole concentrations by means of the experimental curves of Casey *et al.* (28), relating Hall data to absolute temperature for several GaP crystals doped with a known amount of Zn[65]. In Fig. 7 the results obtained by Verleur (26) and the estimated C^s_{Zn} of the seed *vs.* x^l_{Zn} are shown for three GaP ingots. Values of x^l_{Zn} for each melt were calculated by assuming the incorporation without loss of the total amount of Zn present in the $Zn(PO_3)_2$. Figure 7 also illustrates the theoretical solubility isotherm for GaP at 1465°C, in the immediate vicinity of

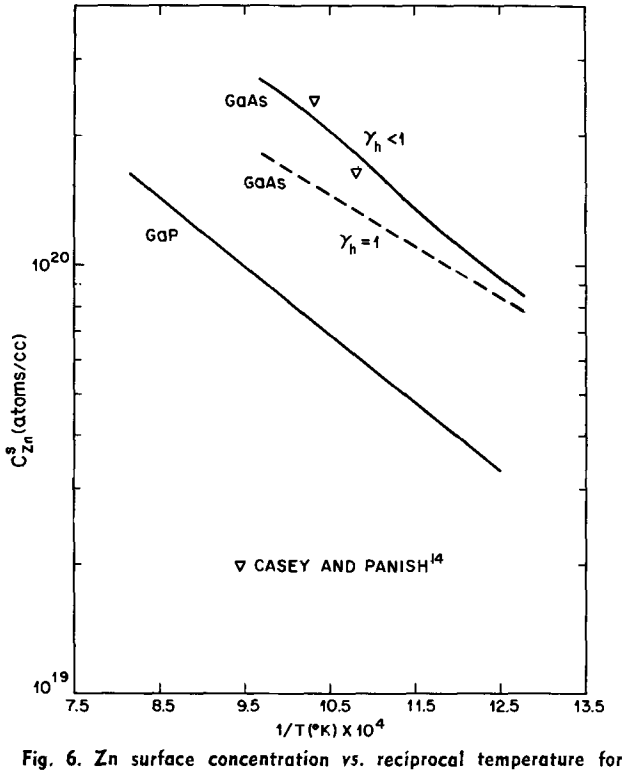

Fig. 6. Zn surface concentration *vs.* reciprocal temperature for GaAs and GaP crystals diffused from invariant ternary sources.

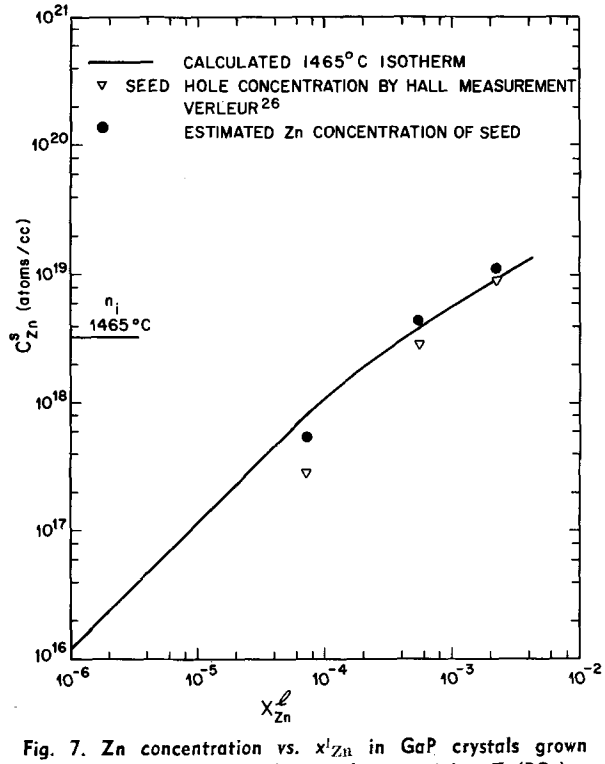

Fig. 7. Zn concentration *vs.* x^l_{Zn} in GaP crystals grown by liquid encapsulation pulling from melts containing $Zn(PO_3)_2$.

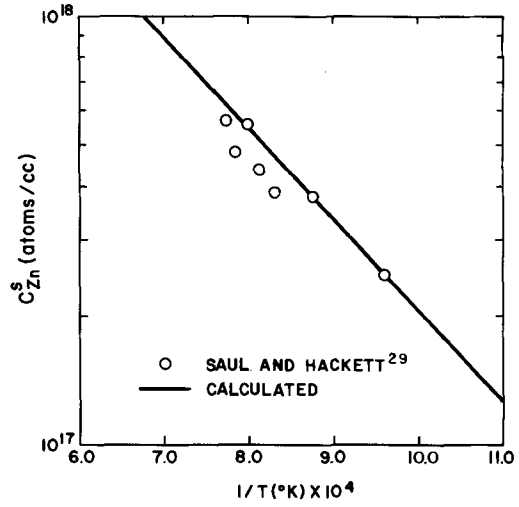

Fig. 8. Zn concentration vs. reciprocal growth temperature for a GaP layer grown by liquid-phase epitaxy from a solution containing $x^l_{Zn} = 3 \times 10^{-4}$. Only the Zn^{65} tracer data of Ref. (29) are shown.

the melting point.[4] It is seen that the calculated and experimentally derived C^s_{Zn} are in good accord.

Additional evidence to confirm the essential correctness of the low temperature isotherms is provided by the recent data of Saul and Hackett (29) on Zn incorporation in GaP, grown by liquid-phase epitaxy from an initial growth temperature of 1025°C and from a solution containing $x^l_{Zn} = 3 \times 10^{-4}$. It has been shown by these authors that the Zn solubility in GaP, obtained by surface capacitance measurements and Zn^{65} tracer analysis, decreases from the growth interface (1025°C) to the surface (≈770°C). Furthermore, Saul and Hackett (29) have demonstrated by means of a detailed analysis that their experimental Zn distribution data (C^s_{Zn} *vs.* distance from interface) compare favorably with the theoretical Zn profile calculated on the basis of the isotherms in Fig. 4. An alternative representation of the measurements of Saul and Hackett and of the calculated C^s_{Zn} can be accomplished in terms of a more commonly used thermodynamic variable by introducing equivalent growth temperatures instead of distances from the interface. Thus, it is shown in Fig. 8 that the theoretical C^s_{Zn} at $x^l_{Zn} = 3 \times 10^{-4}$, presented as a function of reciprocal temperature, provides a very good description of the tracer data of Saul and Hackett (29). The equivalent temperatures required in plotting the experimental results were obtained from Saul (30).

It should be noted that the ratio C^s_{Zn}/x^l_{Zn} divided by 4.94×10^{22} and 4.43×10^{22} atoms/cc for GaP and GaAs, respectively, yields the commonly defined distribution coefficient. In general, the distribution coefficient varies extensively along a solubility isotherm. Hence, any measurement of the variation of the distribution coefficient with temperature is meaningful only at a constant x^l_{Zn}. In particular, dividing C^s_{Zn} in Fig. 8 by the constant value $4.94 \times 10^{22} \times 3 \times 10^{-4}$ gives the temperature dependence of the distribution coefficient at $x^l_{Zn} = 3 \times 10^{-4}$, illustrating its decrease with decreasing temperature.

It can be readily seen by differentiating Eq. [8] that in the extrinsic region the sign of $d \log C^s_{Zn}/d\,1/T$, indicating whether C^s_{Zn} is increasing or decreasing with increasing T, depends on the size and sign of the temperature coefficients of the activities and K. If for different dilute solutes in GaP or GaAs the enthalpies corresponding to Eq. [2] are assumed to be roughly equal, then for a fixed dopant concentration in the melt the sign and magnitude of the derivative $d \log \gamma_{dopant}/d\ 1/T$ in the Ga-dopant binary liquid determines the sign of the temperature derivative of the distribution coefficient.

[4] At the exact melting point C^s_{Zn} approaches zero.

Having demonstrated that the temperature dependent equilibrium constants given in Eq. [17] and [18] describe the available information on the solubility of Zn in GaP and GaAs, one can estimate some other thermodynamic quantities relevant to the chemistry of Zn incorporation. Although the K's yield the enthalpy change for the over-all incorporation reaction according to Eq. [2], the energetics for the dissolution of Zn in GaP and GaAs following the defect mechanism represented by Eq. [1c] are not known. However, it is possible to estimate the enthalpy change for Eq. [1c], H_{1c}, by subtracting the enthalpy changes for Eq. [1a], [1b], and [1d], denoted by H_{1a}, H_{1b}, and H_{1d}, respectively, from that of Eq. [2], H_2. Thus, one has

$$H_{1c} = H_2 - H_{1a} - H_{1b} - H_{1d} \qquad [23]$$

Values of H_{1d} for GaP and GaAs were taken from Casey *et al.* (28) and Hill (31), respectively. In the absence of data for H_{1a} and H_{1b}, most of these enthalpies were estimated by comparison with similar quantities for Ge and Si. In order to estimate H_{1a}, the ratio of H_{1a} to the heat of atomization of GaAs and GaP into the monatomic gaseous components, H_s, was set at 0.56 and 0.52, respectively. The choice of these ratios is based on the recognition that H_{1a}/H_s are relatively constant for the covalent semiconductors Ge, Si, and CdTe (7). Hence, the ratios for GaAs and GaP were equated with those of Ge and the average of Ge and Si, respectively. Then, using the H_s data of Arthur (32) and Thurmond (33) for GaAs and GaP, respectively, the H_{1a}'s were obtained.

H_{1b} for GaAs was calculated by combining the heat, H_V(As), associated with annealing experiments of Potts and Pearson (34) according to $\frac{1}{4}\ As_4(g) + V_{As} = As_{As}$ with the heat of vaporization of As(l) (23). H_{1b} for GaP was evaluated by adding the heat of vaporization of P(l) (25) to H_V(P), estimated by the expression $H_V(P) = H_V(As)/H_V(Ge)\ [H_V(Si) + H_V(Ge)]/2$. H_V(Si) and H_V(Ge) were obtained from the known enthalpies of sublimation (35) and neutral vacancy formation (7) for these elemental semiconductors. The results of the above calculations are summarized in Table I.

The estimated enthalpies of Zn incorporation in GaP and GaAs represented by Eq. [1c] are −2.16 and −2.29 eV, respectively. The negative sign of these energies indicates that as the impurity is condensed on a Ga vacancy, as expected, heat is liberated.

An independent estimate of H_{1c} can also be derived by an adaptation of a method due to Weiser (36), previously applied to impurities in Ge and Si. Briefly, the atomistic interpretation of Eq. [1c] is based on the removal of Zn from a liquid reservoir via evaporation and its condensation on a gallium vacancy. Hence, H_{1c} is given by

$$H_{1c} = \Delta H_{vap} - E_b + E_s \qquad [24]$$

where ΔH_{vap} is the known heat of vaporization of Zn(l) (35) and E_b and E_s are the bond and strain energy contributions to the energy released by the dopant atoms upon condensation into the vacancies.

It is possible to estimate the E_b's by Allen's method (37) from the heats of vaporization of P(s), As(s), and Zn(s). The explicit expressions of E_s for Si and

Table I. Estimated enthalpies for Zn incorporation in GaP and GaAS

	GaP	GaAs
From Eq. [23]		
H_{1a} (eV)	3.84	3.77
H_{1b} (eV)	−2.13	−1.88
H_{1d} (eV)	0.06	0.03
H_2 (eV)	−0.39	−0.37
H_{1c} (eV)	−2.16	−2.29
From Eq. [24]		
ΔH_{vap} (eV)	1.20	1.20
E_b (eV)	3.91	3.72
E_s (eV)	0.38	0.13
H_{1c} (eV)	−2.33	−2.39

Ge, given by Weiser (36), are of the form $E_s = k_i(\Delta r)^2$ where k_i is a constant specific to the host (Ge or Si) and Δr is the difference in tetrahedral radius between host and impurity. Using k_{Ge} and $k_{Ge} + k_{Si}/2$ for GaAs and GaP, respectively, and taking Δr for As and Zn and also P and Zn from Pauling (38), one can find approximate values of E_s for both Zn-doped compounds. Some details of these calculations are shown in Table I. The resulting H_{1c}'s for GaP and GaAs are -2.33 and -2.39 eV, respectively, in surprisingly good agreement with the previous estimates of -2.16 and -2.29, respectively, which were partially based on the equilibrium constants.

Acknowledgments

The author expresses his gratitude to H. C. Casey and F. A. Trumbore for many fruitful discussions. Thanks are also due to H. W. Verleur and R. H. Saul for the permission to use some of their unpublished results.

Manuscript submitted July 31, 1970; revised manuscript received Jan. 11, 1971. This was Paper 145 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

ABSTRACT

Thermogravimetric measurements of the compositional phase diagram of MnO_{1+x} were made as a function of temperature from 1000° to 1500°C and as a function of oxygen partial pressure over most of the stable phase field. The values of x in MnO_{1+x} are presented as a function of temperature and oxygen pressure both numerically and graphically. The pressure dependence of the vacancy concentration at constant temperature was found to obey a relation of the form $x = \text{const}\ P(O_2)^{1/4}$ for $x < 0.02$. The enthalpy of solution of oxygen in this composition range is about -0.3 eV. At larger departures from stoichiometry, a sharp transition to a different defect structure is observed in the log x *vs.* log $P(O_2)$ plots, and the enthalpy of oxygen dissolution for $x > 0.02$ is $\Delta H = -0.70$ eV. Comparison of the experimental data with oxygen activities in the oxide calculated for several different defect models suggests that, for $x < 0.02$, any pairwise interaction between vacancies is less than 0.025 eV and the vacancies can be considered to be noninteracting. The behavior observed for $x > 0.02$ is believed to be due to a transition to a more complex defect at high defect concentrations and not to a change in degree of ionization of the metal vacancy. The influence of carbon dissolution, from the CO_2-CO mixtures used, on these measurements is discussed.

The iron group monoxides, MnO, FeO, CoO and NiO, exist as stable solid solutions over various ranges of metal deficiency. Small deviations from stoichiometry, at oxygen partial pressures $P(O_2) \leq 1$ atm, are found in NiO_{1+x}, where $x \leq 0.001$ (1-3), and in CoO_{1+x}, where $x \leq 0.013$ (4-6). In FeO_{1+x}, on the other hand, the departure from stoichiometry is within the range $0.045 \leq x \leq 0.19$ (7-10), and the stable phase field does not include the stoichiometric composition. In NiO_{1+x} and CoO_{1+x} the excess oxygen has been found to be incorporated primarily by the formation of either singly or doubly ionized, isolated metal vacancies (1-3, 11,12). In FeO_{1+x}, on the other hand, a more complex defect structure involving both metal interstitials and metal vacancies has been proposed on the basis of neutron diffraction studies (13) and thermodynamic considerations (14). This complex defect structure in FeO_{1+x} is plausible, in view of the large departures from stoichiometry that give rise to very large concentrations of point defects.

Unlike the foregoing iron group monoxides, MnO_{1+x} can exist over a wide range of compositions extending continuously from values of x very near zero to an oxygen excess as high as about $x \simeq 0.15$ (5, 15-19). This oxide is, therefore, an interesting material in which one might look for a transition from simple defect structure models, based on infinitely dilute concentrations of point defects, to the more complex defect structure models that can be anticipated at higher defect concentrations.

Pope and Simkovich (20) have recently reported that a considerable amount of carbon can be dissolved in MnO_{1+x} from CO_2-CO mixtures in contact with the oxide at elevated temperatures. Since CO_2-CO mixtures were used in the present study to establish the desired partial pressures of oxygen, the amount of carbon dissolution present is also considered.

Experimental Phase

In the present work, the oxygen excess in MnO_{1+x} was determined thermogravimetrically in the temperature range 1000°-1500°C at oxygen partial pressures $10^{-14} \leq P(O_2) \leq 1$ atm, using a Cahn RG electrobalance. The oxygen partial pressures used were produced by introducing constant flows of CO_2-CO or O_2-Ar mixtures into the furnace. The oxygen partial pressure, $P(O_2)$, established by the reaction

$$CO_2 \leftrightharpoons CO + \tfrac{1}{2}O_2 \qquad [1]$$

was generally calculated from the relation

$$P(O_2)^{1/2} = K_{CO_2}\,[P(CO_2)/P(CO)] \qquad [2]$$

where K_{CO_2} is the dissociation constant for Reaction [1] and is given by Wicks and Block (21), and $P(CO_2)/P(CO)$ is given by the ratio of the CO_2 and CO flows introduced into the furnace at atmospheric pressure and room temperature. In the case of very large CO_2/CO ratios, a correction must be made for the influence of the dissociation of the CO_2 on the CO_2/CO ratio actually present in the hot zone of the furnace. In this case, the oxygen partial pressure is calculated from the relations

$$P(O_2)^{1/2} = K_{CO_2}\frac{P(CO_2)}{P(CO)}\,\frac{1-\alpha}{1+\dfrac{P(CO_2)}{P(CO)}\,\alpha} \qquad [2a]$$

and

$$P(O_2) = \frac{\dfrac{\alpha}{2}\,\dfrac{P(CO_2)}{P(CO)}\,P}{1+\dfrac{P(CO_2)}{P(CO)}\left(1+\dfrac{\alpha}{2}\right)} \qquad [2b]$$

where α is the fraction of CO_2 dissociated and P is the total pressure in the furnace.

A polycrystalline sintered MnO sample, prepared from spectroscopically pure Johnson Matthey[2] Mn_2O_3 powder, was used for the majority of the measurements. Measurements were also made on a single-crystal disk, 1 cm in diameter and 2 mm thick. The agreement between the data obtained on the polycrystalline and single-crystal specimens was within experimental error. The mass spectrographic analyses of the single crystal and a representative polycrystalline specimen are shown in Table I.

	Li	Na	Mg	Al	Si	Ca	Ti
Single crystal	2	20	20	50	200	200	15
Polycrystal			<10	20	50	10	
	Cr	Fe	Co	Ni	Cu	Mo	La
Single crystal	100	500	200	100	2	3	1000
Polycrystal		10		10	30	50	

The sample was suspended from the balance into an alumina tube furnace by means of a sapphire fiber. All weight change measurements were made at a total pressure of 200 Torr in order to minimize thermal fluctuations of the balance beam. The gas was admitted into the bottom of the furnace at a flow rate which corresponded to a linear velocity of 10 cm/sec in the vertical tube. After the sample was equilibrated in the flowing atmosphere, the flow was terminated and the weight, w, was recorded in the static atmosphere. The departure from stoichiometry, x, was calculated from the relative weight change, $w - w_0$ (the w_0 value being the indicated balance weight of the "stoichiometric" specimen, measured at 800°C in a gas mixture of the ratio $CO_2/CO = 1$), by the relation

$$x = \frac{M_{MnO}}{M_O} \frac{w - w_0}{w_s} \qquad [3]$$

where w_s is the true weight of the "stoichiometric" sample, and M_{MnO} and M_O are the molecular weight of MnO and the atomic weight of oxygen, respectively.

The balance sensitivity, at the temperatures and gas flow rates used, was about 4 μg and the reproducibility of the weight change measurements was within ± 10 μg. Evaporation was observed at high temperatures, $T > 1200$°C, especially at low oxygen pressures. The measured weight changes were corrected for the effect of evaporation by assuming the evaporation rate to be constant at constant temperature and CO_2/CO ratio. The evaporation rates at 1500°C, under the conditions of these experiments, were about 3 μg/min. The influences of buoyancy and thermomolecular flow effects were evaluated by measurements on an inert sapphire disk having the same geometry as the MnO samples used. Under the experimental conditions of this study, the required corrections for these effects were found to be less than 15 μg.

The extent of carbon dissolution in MnO as a result of high temperature exposure to CO_2-CO mixtures was evaluated on a number of polycrystalline disks. The disks, weighing approximately 7g each, were pressed from Mn_3O_4 starting powder and were sintered in air at 1200°C for 8 hr. They were then heated in CO_2-CO mixtures (where they were rapidly converted to MnO) for 8 hr, and then were quenched in the same CO_2/CO atmosphere. Low CO_2/CO ratios were used, lower in fact than those employed in the gravimetric studies, in order to have a high carbon activity. The carbon contents were then determined by combustion to CO_2 and gas chromatographic analysis. Two sintered Mn_3O_4 disks, unexposed to CO_2/CO mixtures, were analyzed as controls on the starting powder. The results for all these measurements are shown in Table II. The carbon contents of the sintered Mn_3O_4 specimens preclude any conclusions about the actual amount of carbon introduced into the MnO specimens by the CO_2-CO atmospheres or its dependence on the CO_2/CO ratio. This amount could not, however, exceed about 50 ppmw. Although any carbon introduced might influence the electrical properties near stoichiometry or in the n-type region, as suggested by Pope and Simkovich (20), it should not influence the gravimetric measurements in the composition range reported here, where

* CO_2/CO ratio calculated from Eq. [2] using $P(O_2)$ calculated from Eq. [2(a)] and [2(b)].

** O_2-Ar mixture. Equivalent CO_2/CO ratio is calculated from Eq. [2].

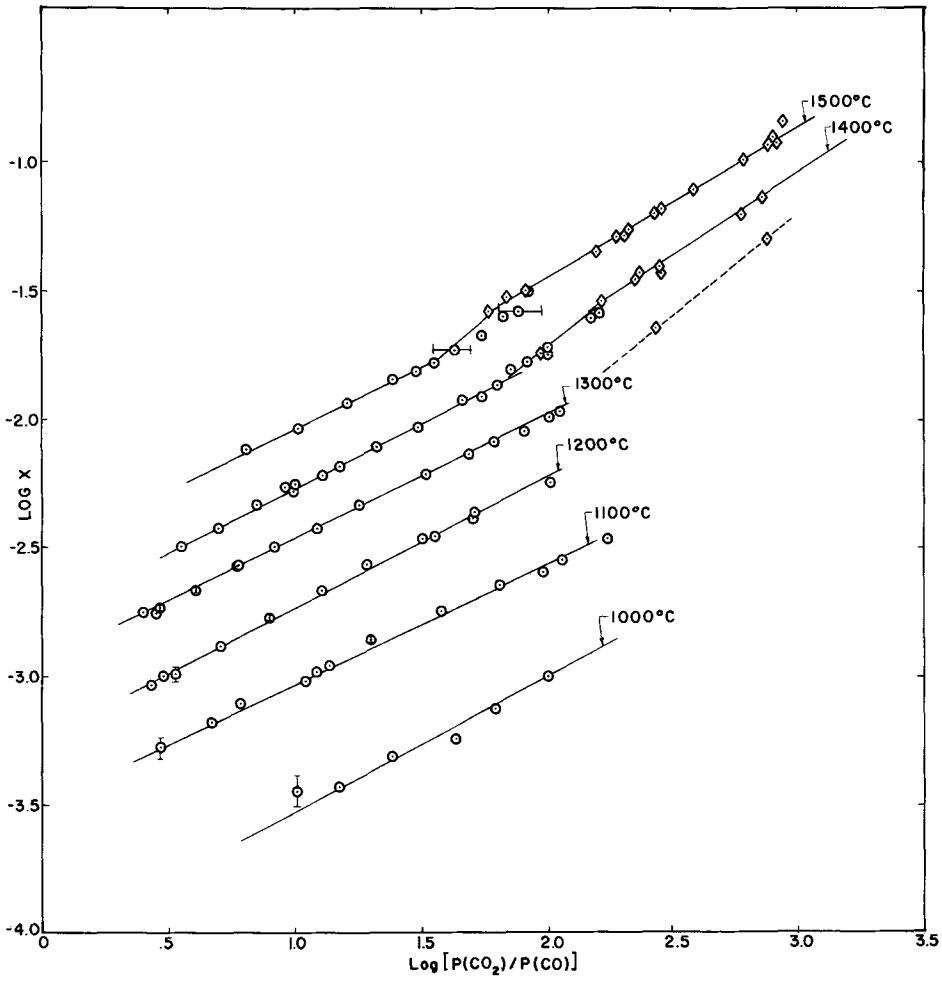

Fig. 1. Departure from stoichiometry, x in MnO_{1+x}, as a function of the CO_2/CO ratio. Extreme error bars are shown for log $\frac{P(CO_2)}{P(CO)}$ and for log x: ⊙, CO_2-CO mixtures (CO_2/CO ratios calculated from Eq. [2] using $P(O_2)$ calculated from Eq. [2a] and [2b]; ◆, O_2-Ar mixtures (equivalent CO_2/CO ratios calculated from Eq. [2]).

the departures from stoichiometry are generally very much larger than several hundred ppm.

Results

The measured departure from stoichiometry, x in MnO_{1+x}, is given in Fig. 1 as a function of the CO_2/CO ratio. The measured values are given in Table III. The total probable error in x is estimated, from the variances of the quantities appearing in Eq. [3], to be ± 0.0002. In the temperature range measured, the vacancy concentration at temperature was found by least square analysis to obey the relation

$$x = \text{const} \left[\frac{P(CO_2)}{P(CO)} \right]^{1/2.1 \pm 0.1}_{T=\text{const}} \qquad [4]$$

at small departures from stoichiometry, $x \lesssim 0.02$. At high temperatures and large departures from stoichiometry, a sharp transition to a stronger pressure dependence is observed. This transition occurs at the end of the range of experimentally accessible CO_2-CO mixtures. Its independence of the method by which the oxygen partial pressure was established, however, is demonstrated by the overlap of the data measured in CO_2-CO and O_2-Ar mixtures. The breaks observed in the log x *vs.* log $P(CO_2)/P(CO)$ plots of Fig. 1 at $x \simeq 0.02$ were observed in several polycrystalline samples as well as in the single crystal. The temperature dependences of the electrical conductance and departure from stoichiometry in constant CO_2/CO and O_2/Ar mixture ratios are given in Fig. 2. The slopes of these plots for $CO_2/CO = 22.8$ and 99, mixtures for which $x < 0.02$, are 1.30 ± 0.15 eV. The slope of the log x *vs.* $10^3/T(°K)$ plot at $P(O_2) = 10^{-3.73}$ atm (obtained in an O_2-Ar rather than a CO_2-CO mixture), for which $0.03 \lesssim x \lesssim 0.05$ over the measured temperature range, corresponds to a value of -0.70 eV.

Discussion

The departure from stoichiometry in MnO_{1+x} on the oxygen excess side may be attributed either to metal vacancies or to oxygen interstitials. Diffusion (18, 19), oxidation (22), and combined electrical conductivity and thermogravimetric studies (5, 16) support a manganese vacancy model. It is clear from Fig. 1 and Eq. [2] that at low defect concentrations, *i.e.* for $x \lesssim 0.02$,

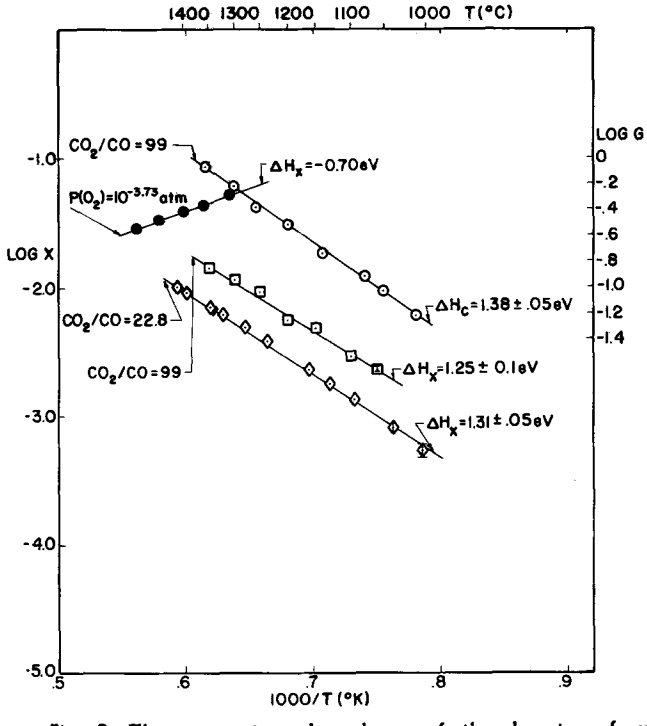

Fig. 2. The temperature dependence of the departure from stoichiometry, x, and the electrical conductance, G, in constant CO_2/CO and O_2/Ar ratios.

$$x = C(T)[P(CO_2)/P(CO)]^{1/2} = C'(T)P(O_2)^{1/4} \quad [5]$$

This is consistent with the pressure dependence expected of singly ionized metal vacancies produced by the reaction

$$\tfrac{1}{2}O_2 \rightleftharpoons O^x_O + V'_M + h^+ \quad [6]$$

where, in the usual Kroger and Vink (23) notation, the superscripts denote charge state, the subscripts denote position in the lattice, and h^+ represents an electron hole. The $P(O_2)^{1/4}$ dependence of the hole concentration is obtained by applying the mass action law to Reaction [6], approximating defect activities by defect concentrations, and assuming the charge neutrality condition

$$[V'_M] = p \quad [7]$$

For large departures from stoichiometry, the approximation of defect activities by concentrations is not satisfactory and the actual activities should be calculated.

The oxygen activity in MnO_{1+x} may be calculated by essentially the same procedure as that used by Libowitz (14) for FeO_{1+x}. Assuming that the predominant defects present are singly ionized metal vacancies and electron holes, obeying the charge neutrality condition of Eq. [7], and assuming a simple Bragg-Williams interaction between metal vacancies (*i.e.*, a pairwise interaction between nearest neighbors), then the free energy of the MnO_{1+x} crystal can be written in the form

$$G = N\mu_{MnO} + N_V g_V + N_V I_h + \frac{z}{2}\frac{N^2_V}{N}\epsilon - kT \ln \frac{N!}{(N_V!)^2 (N - 2N_V)!} \quad [8]$$

where N is the total number of Mn sites in the lattice, N_V is the number of Mn vacancies, μ_{MnO} is the free energy of an MnO formula unit in the ideal lattice, g_V is the free energy of neutral metal vacancy formation, I_h is the ionization energy of the Mn vacancy (for the removal of one positive hole), z is the coordination of the Mn site, and ϵ is the energy of interaction of the Mn vacancies. The oxygen activity in the oxide, a_O, can be calculated from Eq. [8] and the relations

$$\mu_O = \frac{\partial G}{\partial N_O} = kT \ln a_O \quad [9]$$

and

$$N = N_O = N_V + N_{Mn} \quad [10]$$

where μ_O is the chemical potential of oxygen in the MnO_{1+x} crystal and N_O and N_{Mn} are the number of oxygen and manganese atoms in the crystal, respectively. In our experiments, where a given specimen is oxidized or reduced, N_{Mn} is constant and therefore $\partial N_V/\partial N_O = \partial N/\partial N_V = 1$. The oxygen activity is obtained from Eq. [8-10]. Using Stirling's approximation and noting that the value of x in MnO_{1+x} is given by

$$x = \frac{N_O}{N_{Mn}} - 1 \quad [11]$$

the oxygen activity in MnO_{1+x} can be written as

$$kT \ln \left[a_O \left(\frac{1 - x^2}{x^2} \right) \right] = \mu_{MnO} + g_V + I_h + \frac{z}{2}\epsilon \left[\frac{2x}{1+x} - \left(\frac{x}{1+x} \right)^2 \right] \quad [12]$$

For small departures from stoichiometry, Eq. [12] can be approximated by

$$x^2 = K_{V'_M} a_O \quad [13]$$

where

$$K_{V'_M} = \exp\left[-(\mu_{MnO} + g_V + I_h + z\epsilon x)/kT \right] \quad [14]$$

Since $a_O \propto P(O_2)^{1/2}$, Eq. [13] yields the same result as Eq. [5] when $\epsilon = 0$. Equation [13] is a good approximation up to relatively large values of x, since the difference between the exact form of the oxygen activity in the crystal, given by Eq. [12], and the approximate form in Eq. [13] is less than 1% for $x < 0.1$. From Eq. [12] and a plot of $\ln [a_O(1 - x^2/x^2)]$ as a function of x, shown in Fig. 3 for data obtained at 1300° and values of $x \leq 0.01$, an upper limit for the interaction energy can be set at about $|\epsilon| \leq 0.025$ eV. This region, $x \leq 0.01$, can therefore be assumed to be a region of noninteracting defects.

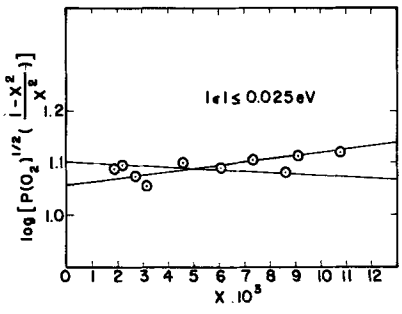

Fig. 3. Evaluation of the interaction energy $|\epsilon|$, from a plot of $\ln [P(O_2)^{1/2}((1-x^2)/x^2)]$ vs. x at 1300°C.

The oxygen activity in MnO_{1+x} was calculated from Eq. [12] at several fixed temperatures, using a value for the combined energies obtained by fitting to one experimental datum point. The resultant curves, labeled "simple," and the measured data are shown for two temperatures, 1300° and 1500°C, in Fig. 4 and 5, respectively. The oxygen activity was also calculated using an expression based on a defect complex model, involving association of two metal vacancies and a metal interstitial, derived by Libowitz (14) to fit thermodynamic data for FeO_{1+x}. The resultant curves, labeled "complex," are also shown in Fig. 4 and 5. The isolated defect and defect complex models give essentially the same results for $x < 0.02$. In this range of small departures from stoichiometry, the isolated, noninteracting, singly ionized metal vacancy model is believed to be more reasonable for MnO_{1+x} than the defect complex model, however, since no change in behavior with increasing temperature is observed even to 1500°C. If defect complexes were present, one would expect to see the effects of dissociation at high temperatures.

The enthalpy of dissolution of oxygen in the oxide, $\Delta H_{V'_M}$, in the region $x < 0.02$, can be found using Eq. [2, 13, 14] from the relation

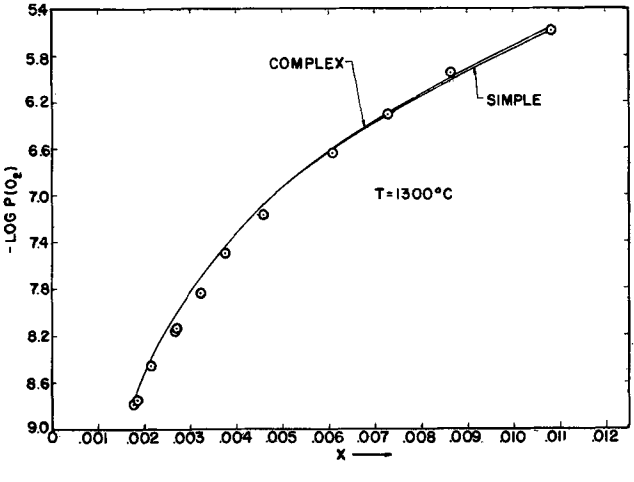

Fig. 4. Comparison of calculated oxygen activity for simple and complex defect structures with experimental data at 1300°C.

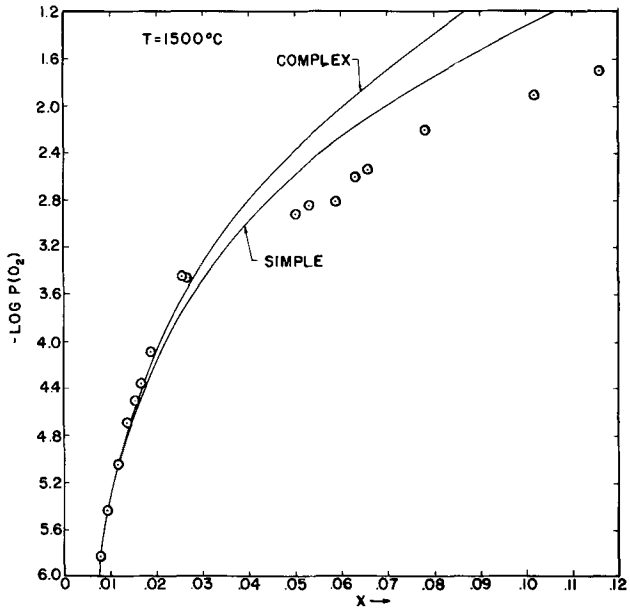

Fig. 5. Comparison of calculated oxygen activity for simple and complex defect structures with experimental data at 1500°C.

$$\Delta H_{V'_M} = -\frac{d \ln K_{V'_M}}{d(kT)^{-1}}\Bigg]_{P(O_2)=\text{const}}$$

$$= \frac{d \ln K_{CO_2}}{d(kT)^{-1}} - 2\frac{d \ln x}{d(kT)^{-1}}\Bigg]_{P(CO_2)/P(CO)=\text{const}} \quad [15]$$

The first term on the right, $[d \ln K_{CO_2}]/[d(kT)^{-1}]$, varies very little in the temperature range measured and is given by Wicks and Block (21) as −2.91 eV. The second term, $[d \ln x]/[d(kT)^{-1}]$, is found from Fig. 2 to be -1.3 ± 0.1 eV, and is found to be independent of the $P(CO_2)/P(CO)$ ratio in this range. Therefore, $\Delta H_{V'_M} \simeq -0.3$ eV. The enthalpy of dissolution of oxygen in MnO_{1+x} decreases sharply at larger departures from stoichiometry. At a given partial pressure established by an O_2-Ar mixture, $\Delta H_{V'_M}$ is given directly by $d \ln x/d(kT)^{-1}$. It may be noted in Fig. 2 that at $P(O_2) = 10^{-3.73}$ atm, $\Delta H_{V'_M} = -0.70$ eV.

The $P(O_2)^{1/3.3}$ dependence of x, found for $x > 0.02$ in Fig. 1, could be interpreted in terms of the singly ionized, noninteracting metal vacancies present at low defect concentrations associating, at higher defect concentrations, to form divacancy complexes. The formation of such complexes would be described by the reaction

$$O_2 \rightleftharpoons 2\,O^x_O + (V_M V_M)'' + 2h^+ \quad [16]$$

where $(V_M V_M)''$ denotes the complex. If the charge neutrality condition is given by $2[(V_M V_M)''] = p$, then the oxygen pressure dependences of the defect concentrations and of x are given by

$$2[(V_M V_M)''] = p = 2x = K_c P(O_2)^{1/3} \quad [17]$$

where $K_c \propto \exp(-\Delta G_c/kT)$ and ΔG_c is the free energy change for Reaction [16]. To a first approximation

$$\Delta G_c \simeq 2(\mu_{MnO} + g_V + I_h) - g_{int} \quad [18]$$

where g_{int} is the free energy of interaction of the complex $(V_M V_M)''$ and, therefore, the enthalpy of interaction of the complex, h_{int}, would be given by $h_{int} \simeq (\Delta H_c)_{x>0.02} - 2(\Delta H_{V'_M})_{x<0.02} = -0.1$ eV.

Our recent data, and that of earlier investigators (12), for CoO_{1+x} show similar behavior. The oxygen pressure dependence of the electrical conductivity of CoO_{1+x} increases from $P(O_2)^{1/4}$ at low pressures, corresponding to $x < 0.008$, to $P(O_2)^{1/3.6}$ at $P(O_2) = 1$ atm. Since the transition in oxygen pressure dependence in CoO_{1+x} occurs at about $P(O_2) = 10^{-1}$ atm, it would be experimentally very difficult to see as much of the higher defect concentration range as is visible in MnO_{1+x}. If complexes are indeed responsible for the behavior at high defect concentrations in MnO_{1+x} and CoO_{1+x}, they are more likely to be of the two-vacancy type than the two-vacancy–cation interstitial type suggested for FeO_{1+x} (13, 14). Formation of the latter type by the reaction

$$\tfrac{1}{2}O_2 + Fe^x_{Fe} \rightleftharpoons O^x_O + (V_M Fe_i V_M)' + h^+ \quad [19]$$

would lead to a pressure dependence of the hole concentration of the form $p \propto P(O_2)^{1/4}$. A higher degree of ionization of the complex or a correction based on the use of activities at high defect concentrations (14) would only decrease the oxygen pressure dependence. To observe a stronger pressure dependence, as in MnO_{1+x} and CoO_{1+x}, one would need higher order complexes if cation interstitials are involved.

It should be noted that a transition to a stronger pressure dependence, as seen in Fig. 1 for $x > 0.02$, can also be caused by a change in the ionization state of the metal vacancy. In this case, it could be due to the increasing concentration of neutral metal vacancies. In the extreme case, when the neutral metal vacancy is the predominant defect present, the oxygen activity is given by

$$\frac{x}{1+x} = K_o a_O \quad [20]$$

where $K_o = \exp[-(\mu_{MnO} + g_V)/kT]$ and, for small deviations from stoichiometry, a $P(O_2)^{1/2}$ dependence would be expected. A transition from the pressure dependence characteristic of singly ionized metal vacancies to that characteristic of neutral metal vacancies would, however, extends smoothly over a number of orders of magnitude of oxygen pressure. For example, if we define the limits of the transition region as the $P(O_2)^{1/3.85}$ and $P(O_2)^{1/2.15}$ dependences, then the transition region would extend over about seven orders of magnitude of oxygen pressure. The change in pressure dependence of x at about $x \simeq 0.02$ in Fig. 1, therefore, has more of the character of a phase transition. Similar breaks in behavior, interpreted as phase transformations, have been observed in FeO_{1+x} (8). The origin of the transition in MnO_{1+x} cannot be asserted without further x-ray and neutron diffraction study.

Reduced Dislocation Densities in Liquid Phase Epitaxy Layers by Intermittent Growth

R. H. Saul

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

GaP liquid phase epitaxy (LPE) layers grown using an interrupted cooling rate to induce intermittent growth, exhibit an abrupt reduction in dislocation density ρ which coincides with the interface between growth increments. Constant cooling rates interrupted by partial melt-back (heating) of the LPE layer or by isothermal annealing are both effective in reducing ρ, typically by factors of 3-6. Successive reductions in ρ could be achieved by employing several interruptions in cooling rate. These results are discussed in terms of proposed mechanisms for dislocation elimination in crystals.

A variety of liquid regrowth techniques, including liquid phase epitaxy (LPE) (1), traveling solvent method (TSM) (2), and partial back-melting (PBM) (3), are frequently employed for the fabrication of multilayer semiconductor structures. Crystals grown by these methods generally contain fewer dislocations than the substrates upon which they are grown. This improvement in crystalline perfection has been observed by etch pit or x-ray topography techniques in GaP (4, 5), GaAs (6), and GaSb (7, 8). The reported reduction in dislocation density ρ is typically by factors in the range of 3-10, and in all cases the reduction is abrupt, occurring at the initial growth interface. Because of the likelihood of slight dissolution of the substrate for LPE and TSM growth, the mechanism of dislocation elimination in these cases is probably the same as for PBM growth where the substrate is deliberately partially melted. In this paper it is shown that, in addition to the above-mentioned decrease in ρ, the dislocation density can be further (abruptly) reduced within a LPE layer by interrupting the cooling rate to induce intermittent or incremental growth. Proposed mechanisms of dislocation elimination are discussed in terms of these results and the feasibility of several step reductions in ρ is demonstrated.

Experimental Phase

The GaP LPE layers employed in this work were grown (9) from Ga-GaP solutions containing 0.01 a/o Te which provided an initial[1] doping level essentially equal to that of the Te-doped Czochralski substrates ($N_D - N_A \simeq 3 \times 10^{17}$ cm^{-3}). The layers were 25-150μ thick and were grown on a chemically polished P{111} surface. The various cooling cycles which were employed are schematically illustrated in Fig. 1. Cooling cycle I provides a constant cooling rate from A to D; cooling cycle II additionally employs a partial melt-back of the LPE layers[2] from B to C; and cooling cycle III employs a 2-hr isothermal arrest from B′ to C. The interruptions in cooling rate used in cycles II and III profoundly affect ρ as discussed below.

Each LPE layer was etched (11) on a {110} cleavage plane, normal to the growth plane, to reveal the substrate-LPE layer interface and metallurgical junction associated with the programmed changes in growth for cooling cycles II and III. Utilizing a model (10) for LPE growth which has been shown to describe adequately LPE layers similar to those used in the present work, it is readily shown that for a layer of

Key words: GaP, liquid phase epitaxy (LPE), intermittent growth, interrupted cooling, reduction in dislocations by interrupted cooling of LPE layers.

[1] The Te concentration in these layers increases along the growth direction as discussed elsewhere (10). This Te gradient is not expected to influence the effects observed in this study.

[2] This is not to be confused with the PBM method (3) in which the substrate is back-melted.

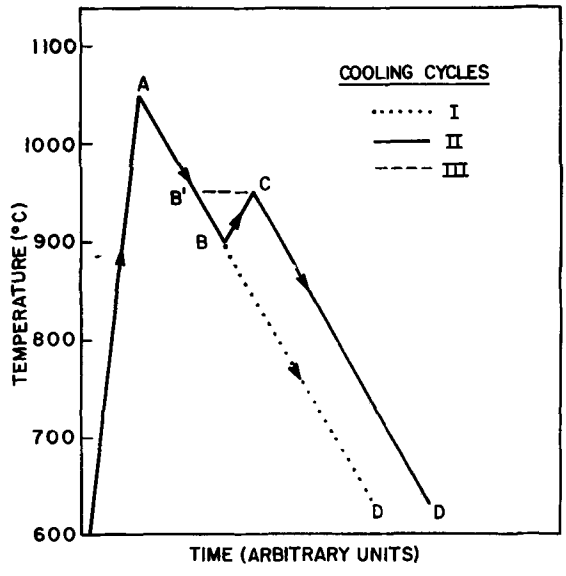

Fig. 1. Schematic representation of cooling cycles used for growth of LPE layers. Except for the initial heating rate (~20°/min), heating and cooling rates were 1°/min.

thickness t, the separation of the initial growth interface (corresponding to point A in Fig. 1) and that corresponding to point C in Fig. 1 is αt where $\alpha \lesssim 0.4$. Thus α is that fraction of the layer thickness corresponding to growth along the path ABC or AB'C. The actual value of α was determined from the cleavage-face delineation. No junction was evident in LPE layers grown using cooling cycle I. The crystals were subsequently polished at an angle of 3° to the growth surface, and the dislocation density distribution was determined by etching (4). The reduction in ρ at the substrate-LPE layer interface could not be conveniently determined in this manner because of the large disparity in etching rates of the substrate and LPE layers; however, cleavage-face x-ray topography (12) generally indicates about a 5- to 10-fold reduction in ρ over a distance less than 3μ for layers grown using cooling cycle I. Similar reductions are expected for all the cooling cycles used in this work.

Results and Discussion

Table I summarizes the results for layers grown using the various cooling cycles. For layers grown without interrupted cooling (cycle I) the dislocation density is uniform throughout the thickness of the layer, in agreement with previous observations (4-8). However, for layers grown with partial melt-back of the LPE layer (cycle II), ρ is initially constant, *i.e.*, independent of distance from the initial growth interface, but is precipitously reduced within the layer at a position coincident with the metallurgical junction delineated at a thickness αt.

Figure 2 illustrates the delineated metallurgical junction and corresponding step reduction in ρ for a layer (NT 021070) in which ρ is reduced by a factor of ~6. The rough agreement between the measured values of α (see Table I) and the value computed from the programmed cooling cycle ($\alpha < 0.4$) demonstrates conclusively that the reduction in ρ occurs at the commencement of growth (C in Fig. 1) following the partial melt-back. The last entry in Table I indicates that interrupted cooling without deliberate melt-back (cycle III) is also effective in reducing ρ. Thus it appears that the reduction in ρ is not attributable to melt-back *per se*, but rather the result of a stationary liquid-solid interface; however, the occurrence of slight melt-back resulting from thermal fluctuations during the 2-hr isothermal annealing cannot be precluded.

Table I. Effect of cooling cycle on dislocation density in LPE layers

Sample	α	ρ (initial) (10^5 cm^{-2})	ρ (final) (10^5 cm^{-2})	Cooling cycle
NT 102169-3	—	0.8	0.8	I
NT 102369-1	—	5.6	5.6	I
NT 021070	0.38	5.0	0.8	II
NT 022570	0.36	2.8	0.8	II
NT 031370-Q	0.33	2.5	0.65	II
NT 033170	0.30	4.5	1.0	II
NT 042270	0.44	6.4	2.3	III

The above results imply that the reduction in ρ within the LPE layers is a phenomenon associated with the liquid-solid interface and obviously not the result of the latter part of the epitaxial layer having been grown under conditions of reduced thermal and/or mechanical stress as previously suggested for PBM growth (7). Although it is apparent that regrowth under severe stress conditions will introduce new dislocations, it is not obvious that growth under conditions of reduced stress provides a driving force for the removal of dislocations. On the contrary, the driving force is provided by the "excess" free energy associated with these defects; dislocations are not equilibrium defects, i.e., the "equilibrium" number of dislocations in a crystal at any temperature is zero. The removal of dislocations is a problem of geometric termination, either within the crystal by mutual annihilation (formation of half-loops or networks) or at a surface by reorientation of dislocations into directions nearly normal to the growth direction (formation of partial-loops) (8).

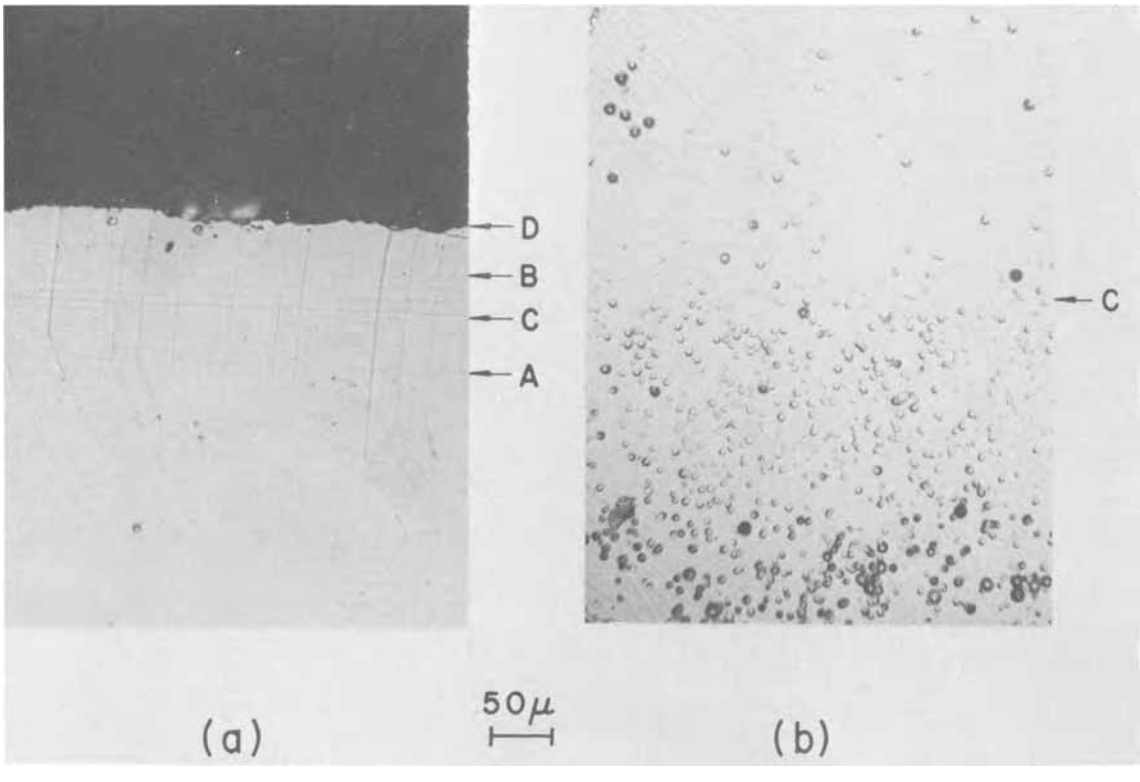

Fig. 2. Revelation of various junctions on a cleavage face (a) and dislocation etch pits on a surface lying 3° from the growth face (b) for a LPE layer grown using cooling cycle II. The arrows in the figure locate the positions corresponding to the changes in cooling rate shown in Fig. 1. (No junction is delineated at B.)

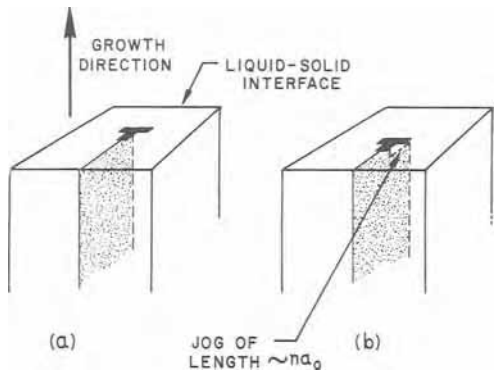

Fig. 3. Schematic illustration of an edge dislocation penetrating a liquid-solid interface (a). The shaded area represents the extra half-plane and the dashed line denotes the dislocation line. The absorption of n vacancies at the dislocation core results in a jog lying within the interface (b). (See text.)

The formation of both half-loop and partial-loop configurations requires high dislocation mobility and, for an AB compound semiconductor, climb of edge components involving both A and B vacancies (or A and B interstitials). It is postulated that the very high disorder at a liquid-solid interface provides an efficient source of the necessary point defects, and a quasi-stationary interface (which in Fig. 1 occurs in the vicinity of point B or along the path B'-C for cooling cycles II and III, respectively) provides sufficient time for reorientation of dislocations. The improvement in crystalline perfection generally observed at the initial growth interface for LPE, TSM, and PBM crystals is believed to occur by a similar mechanism.

The formation of loop or network configurations is enhanced by the tendency for dislocations to lie normal to the growth direction as discussed below. Since the dominant dislocations observed in III-V semiconductors are the so-called 60° dislocations that have substantial edge character and because we are mainly concerned about dislocations propagating along the growth direction, we consider, for simplicity, edge dislocations which are parallel to the growth direction. (The Burgers vector is thus contained in the growth plane which in practice coincides with an {hkl} glide plane.) At a stationary liquid-solid interface, the high concentration of vacancies results in dislocation climb normal to the Burgers vector so that if n vacancies are absorbed at the dislocation core, the resulting jog length is $\sim na_o$,[3] where a_o is the lattice parameter as schematically represented in Fig. 3. As the interface slowly advances, the total jogged length (and hence length of dislocation lying normal to the growth direction) is $\sum_i n_i a_o$, where n_i is the number of vacancies absorbed in each of the i "molecular" layers which have grown. One can envision rather long jogged lengths, *e.g.*, if this process occurs over a growth thickness of 1000Å and $n_i \sim 100$, then for the resulting sawtooth configuration the length of dislocation lying parallel to the growth plane is 10μ. Interaction among impinging dislocations results in network or loop formation which is confined to the region where the liquid-solid interface is quasi-stationary; the reduction in ρ occurs (abruptly) at this position.

Two questions immediately arise: (*i*) Why are not all the (removable) dislocations eliminated at the initial growth interface (point A in Fig. 1)? and (*ii*) Can further stepwise reductions in ρ be achieved? The elimination of dislocations is dictated by the random statistics of thermally induced climb and glide, and not all dislocations can be expected to terminate at the initial commencement of growth. Subsequent establishment of a stationary liquid-solid interface via interrupted cooling enables additional dislocations to terminate.

[3] A 60° dislocation can be represented by a (double-layered) {111}-oriented extra half-plane which is adjacent to the {111} slip plane containing the dislocation line and Burgers vector (13). Within this framework, climb occurs along the <110> direction lying 60° to both the dislocation line and Burgers vector. Hence, the corresponding jog length is $\frac{\sqrt{2}}{2} na_o$.

Table II. Variation of dislocation density in an incrementally grown layer

Incremental layer	Temperature range, °C	Average dislocation density (10^5 cm^{-2})
1	1060-1030	6.8
2	1030- 995	4.2
3	995- 955	3.1
4	955- 915	1.1
5	915- 600	1.3

Successive step reductions in ρ were attempted using a cooling cycle with four interruptions, with a 10-min thermal arrest between each growth increment.[4] The temperature range for each interval (see Table II) was chosen to give incremental layers of approximately the same thickness. Four nearly equispaced junctions were observed on the etched cleavage-face of a crystal grown in this manner. However, the incremental layers were so narrow that the corresponding step reductions in ρ were not apparent on the etched angle-lapped surface; rather ρ appeared to continually decrease. The value of ρ corresponding to the half-thickness of each incremental layer is given in Table II. The dislocation density appears to be reduced in all but the last of the growth increments where the thermal arrest occurred at the lowest temperature. The over-all reduction in ρ for this layer is comparable to the largest reduction observed in a single-step layer (NT 021070); however, it is believed that longer periods between growth increments may result in greater reductions in dislocation density.

The ultimate reductions in ρ that can be achieved by intermittent growth is not known, but it is likely to depend on the extent of dislocation entanglement and other factors limiting dislocation mobility rather than simply the number of these defects. The character and morphology of dislocations that can terminate at a stationary liquid-solid interface remains to be clarified.

Acknowledgment

The author is indebted to Mrs. J. Armstrong for growing the LPE layers, to G. A. Rozgonyi for topographic analysis of several of the layers, and to L. J. Varnerin for suggesting that isothermal annealing might be an alternative to partial back-melting. Helpful suggestions by W. H. Hackett, Jr., and W. A. Brantley are gratefully acknowledged.

Manuscript submitted Sept. 1, 1970; revised manuscript received Dec. 11, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

[4] A longer thermal arrest resulted in a highly irregular surface which hampered identification of the various metallurgical junctions.

Study on the Lithium Oxide-Nickel Oxide System

II. Thermodynamics of the Concentrated Solid Solutions

S. Pizzini,*,[1] G. Monari,[2] and R. Morlotti*

Reactor Material Laboratory, Thermochemistry Group,
Commission de la Commonauté Europeenne, CCR Euratom, Petten, Nederland

ABSTRACT

Thermodynamic activity measurements of dissolved lithium oxide in NiO-Li_2O solid solutions have been carried out within the homogeneity range to the solubility limit (about 33 a/o lithium). The measurements have been carried out by means of suitable galvanic cells, of the type

$$Pt/NiO\text{-}Li_2O\,(x_2)//\text{intermediate electrolyte}//NiO\text{-}Li_2O\,(x_1)/Pt$$

where α-Li_2SO_4 and β-spodumene have each been used as the intermediate electrolyte.

In a previous paper (1) and in a short note (1 bis), we dealt with the thermodynamics of the dilute solid solutions of lithium oxide in nickel oxide [from about 0.1 to 7 a/o (atom per cent) lithium]. In this range of concentrations the solution is known to be of the substitutional type, where lithium enters cationic positions and electroneutrality is maintained via an equivalent number of electron holes

$$0.5\,Li_2O\,(NiO) + 0.25\,O_2 \rightarrow Li_{Ni}' + h^\bullet + O_O^x \quad [1]$$

$$K_1 = [Li_{Ni}'][h^\bullet]/[Li_2O]^{1/2}\,p_{O_2}{}^{1/4}$$

and

$$[Li_{Ni}'] = [h^\bullet]$$

$$h^\bullet + Ni_{Ni}^x \rightarrow Ni_{Ni}^\bullet \quad [1\text{ bis}]$$

where it is assumed that electron holes are localized at nickel sites and Li_2O is considered as dissolved in NiO. At low partial pressures of oxygen, lithium enters the lattice with a different mechanism which involves, according to Deren and co-workers (2-5), either nickel vacancies

$$Li_2O + 2\,V_{Ni}'' + 2\,h^\bullet \rightarrow 2\,Li_{Ni}' + 0.5\,O_2 \quad [2]$$

at concentrations not higher than 0.01 a/o lithium, or interstitial positions

$$Li_2O \rightarrow Li_i^\bullet + Li_{Ni}' + O_O^x \quad [3]$$

at concentrations intermediate between 0.01 and 0.1 a/o lithium.

A new representation of the feature of this system was also given in ref. (1) by means of the phase diagram of Fig. 1, which shows the homogeneity region of the solid solutions along the line joining the NiO corner to the compound $LiNiO_2$. It is this line which expresses the stoichiometric 1:1 ratio between the substitutional lithium and the electron holes localized at Ni^{3+} sites.

In the same paper it was experimentally shown that the emf of concentration cells, like the following one

$$Pt/Li_2O\,(x_2)\;NiO/\alpha\text{-}Li_2SO_4/Li_2O\,(x_1)\;NiO/Pt \quad [4]$$

(operated with both electrodes under a pressure of 1 atm of oxygen) follows the Nernst law

$$\Delta E = \frac{RT}{F}\ln\frac{x_1}{x_2} \quad [5]$$

(where x_2 and x_1 are the atomic ratios of lithium in solution) up to about 2 a/o lithium, whereas at higher concentrations the departure from pure Nernstian behavior is no longer negligible.

A very general equation for the emf of cell [4] might be obtained when considering cell [4] as a double cell, with the intermediate electrolyte acting as a gas-tight diaphragm, so that the oxygen pressures above both solid solutions are those corresponding to the stoichiometry. With the electrolyte working as a pure lithium conductor, the emf of a single cell

$$Pt(O_2),\,Li_2O\;(a)/\alpha\text{-}Li_2SO_4/Li$$

could be written

$$E = E^\circ + \frac{RT}{2F}\ln\frac{a_{Li_2O}}{a^2_{Li}p_{O_2}{}^{0.5}} \quad [6]$$

being the single-cell reaction ($z = 2$)

$$0.5\,O_2 + 2\,Li \rightarrow Li_2O\;(soln) \quad [7]$$

By taking into account the equilibrium constant of reaction [1], one obtains, for the emf of cell [4]

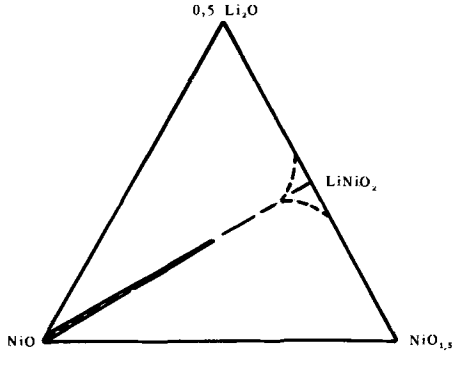

Fig. 1. Phase diagram (schematic) of the system Li_2O-Ni_2O_3-NiO. The homogeneity range lies between 0 and 33 a/o lithium.

* Electrochemical Society Active Member.
[1] Present address: Istituto Elettrochimica, Università di Milano, Via Venezian 21, Milano, Italy.
[2] Present address: Istituto di Ricerche Donegani, Novara, Italy.
Key words: activities, galvanic cells, electrical conductivity, point defects, nickel oxide.

$$\Delta E = \frac{RT}{F} \ln \frac{[Li_{Ni}']_1[Ni_{Ni}^{\cdot}]_1}{[Li_{Ni}']_2[Ni_{Ni}^{\cdot}]_2} - \frac{RT}{2F} \ln \frac{p°_1}{p°_2} \quad [8]$$

where $p°_1$ and $p°_2$ are the partial pressures of oxygen in equilibrium with the stoichiometric solutions.

In the total range of concentrations investigated, one could expect two extreme situations to occur: (*a*) the solution is a system in which both kinds of defects (*i.e.*, lithium in substitutional positions and electron holes at nickel sites) are randomly distributed, so that in the absence of interactions Eq. [8] becomes

$$\Delta E = \frac{RT}{F} \ln \frac{x_1^2}{x_2^2} - \frac{RT}{2F} \ln \frac{p°_1}{p°_2} \quad [8 \text{ bis}]$$

and (*b*) the solution is a system where only lithium is randomly distributed, whereas electron holes are localized at one of the 12 neighbor nickel ions (which form the cationic co-ordination shell of a lithium ion in the fcc lattice of the solid solution) and form stable ion pairs.

By taking into account the association reaction

$$Li_{Ni}' + Ni_{Ni}^{\cdot} \rightleftarrows [Li_{Ni}' \cdot Ni_{Ni}^{\cdot}]x \quad [9]$$

which formally accounts for the pairing of defects, one obtains

$$\Delta E = \frac{RT}{F} \ln \frac{x_1}{x_2} - \frac{RT}{2F} \ln \frac{p°_1}{p°_2} \quad [8 \text{ ter}]$$

It is worth remarking that in both cases, and independently of the degree of association, the pressure dependence of the emf is of the type

$$\Delta E = \frac{RT}{F} f\left(\frac{x_1}{x_2}\right) - \frac{RT}{F} \ln (p_{O_2}^{1/2})_1/(p_{O_2}^{1/2})_2 \quad [10]$$

The preference for one or the other situation depends on the configurational energy terms of the particular type of lattice. It has been demonstrated by means of mechanical and electrical relaxation measurements (6) that, at least at low temperatures, dilute solutions consist entirely of isolated dipoles ($[Li_{Ni}' \cdot Ni_{Ni}^{\cdot}]x$ pairs) whereas it is very likely that more concentrated solutions contain increasing concentrations of a different configuration, consisting of two neighboring lithium ions, both compensated by an electron hole at a nickel position.

Experimental results reported in the previous paper seem to confirm the van Houten and Bosman (6) view about the presence of isolated dipoles in the dilute solution and of more complex configurations in which electron holes are delocalized (or sheared with more than one nickel ion) as the lithium concentration increases.

The present paper is an attempt to extend the use of purely configurational factors when discussing the deviations of both entropy and free energy terms from ideality, in the range of more concentrated solutions.

Experimental

Electrolytes for emf measurements.—α-Li_2SO_4, which was successfully used in the range of dilute solutions (1), was shown to fail at a lithium level in the electrodes higher than 15 a/o.

Although lithium substituted β-alumina (7-9) should be a suitable electrolyte, we focused our efforts on SiO_2-base electrolytes which appear very promising[3] and which have been successfully used (12-13) for thermodynamic activity determinations.

Silica glasses[4] have been used, after a suitable doping, as intermediate electrolytes. The doping process consists of making a sandwich of three pellets (the intermediate being the silica glass and the other ones, lithium-doped NiO or Li_2SO_4) and heating it at 700°-800°C for some days. After a subsequent annealing of the SiO_2 disk at 600°C, the electrolyte is ready for operation. Analysis reveals an increase of the lithium content of about two orders of magnitude whereas the sodium content remains constant.[5]

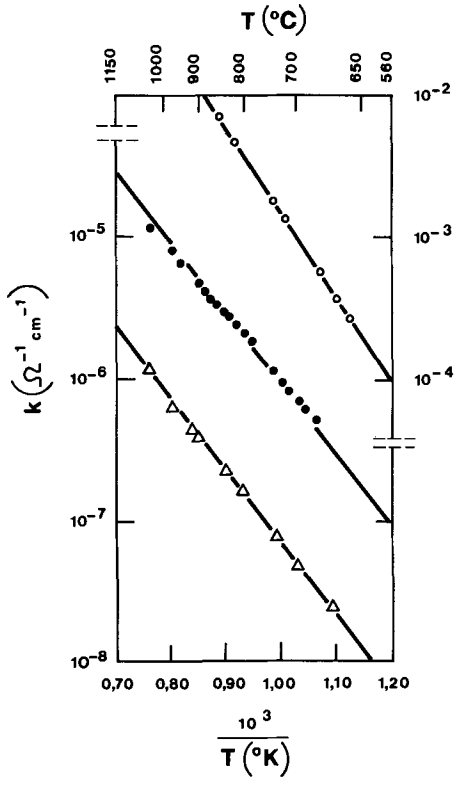

Fig. 2. Electrical conductivity of Pursil silica (△), lithium-doped Pursil silica about 100 ppm (●), and β-spodumene (○).

When comparing the results obtained with cells fitted with α-Li_2SO_4 and lithium-doped SiO_2 (see next paragraph) one recognizes that such an electrolyte could be satisfactorily used only for very dilute solutions to about 2-3 a/o lithium. A small attack of the electrolyte, at the side in contact with the more concentrated solution, is always present, and we suppose that only because of the very low reaction rate can we obtain sufficiently good results when the electrodes consist of dilute solutions.

β-spodumene (a member of a family of silico-aluminates with a composition $Li_2O \cdot Al_2O_3 \cdot 4\ SiO_2$, which expresses a one to one ratio between the aluminum and lithium) has particularly attractive structural properties (14-17) that should enhance ionic conduction. It presents channels of about 3Å diameter that run parallel to the a and b axes, similar to those present in zeolites. Along these channels lithium ions should move relatively freely when subjected to a convenient electric field. Moreover, β-spodumene is endowed with cation exchange properties, probably limited to Li^+ and H^+ (17), as with zeolites. β-spodumene was prepared by mixing SiO_2, Li_2CO_3, and Al_2O_3 in the appropriate proportions, firing the mixture and pressing it to pellets of 12 mm in diameter and finally by sintering at about 1400°C. Some a-c[6] electrical conductivity measurements have been made (18) on undoped and doped silica samples as well as on β-spodumene to have a preliminary rough idea of the carrier concentration and mobility in such a SiO_2-base compound.

The results are given in Fig. 2 as log K *vs.* $1/T$ plots which illustrate that the activation energy remains approximately constant[7] in spite of the large variation of

[3] For their ion exchange properties and purely ionic conductivity (10, 11).

[4] Pursil 453 Quarz & Silice with a total alkali content of about 20-40 ppm.

[5] A typical analysis, before and after the treatment is Li 1.4 ppm, Li 96 ppm.

[6] Carried out with a General Radio impedance bridge, Model 1608 A.

[7] 23.12 kcal/mole (pure silica), 23.32 kcal/mole (100 ppm Li-doped silica), 26.9 kcal/mole (β-spodumene).

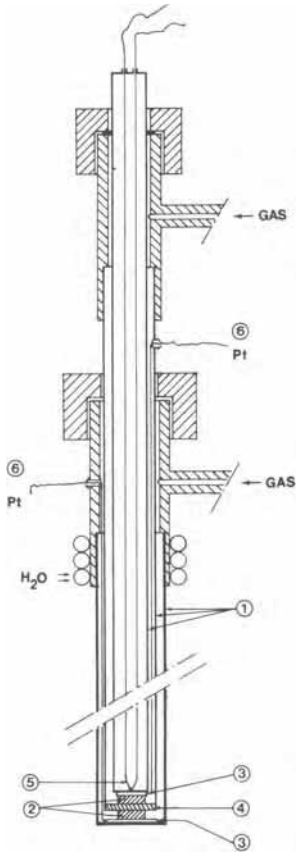

Fig. 3. Cell with separate compartments: 1, silica glass tubes; 2, electrodes; 3, platinum electrodes; 4, lithium-doped Pursil silica glass which serves as an intermediate electrolyte; 5, Pt-Pt, Rh thermocouple; 6, Pt wires to the electrodes.

the lithium concentration, whereas the absolute value of the conductivity depends on the total alkali content (and changes of about four orders of magnitude for a concentration change of the same order of magnitude). We therefore argue the same hopping mechanism as in doped silica, but with a very high level of free carriers.

Results of experiments carried out in cells of the type [1] with lithium-doped silica and β-spodumene serving as intermediate electrolytes, are illustrated in the next paragraph.

Emf measurements.—Emf measurements on solid galvanic chains of type [4] have been carried out in cells of conventional design as illustrated in previous papers (1, 19, 20) as well as on a cell with separate compartments, which is shown in Fig. 3. This cell was designed to perform measurements of emf as a function of the partial pressure of oxygen. With such a cell we should be able to determine the deviations from stoichiometry as a function of the oxygen pressure as well as the dissociation pressure of the solid solution as a function of the lithium concentration.

The requirements this cell should fulfill are the following:

1. A very limited volume of one of the two electrode compartments, to avoid sensible variations in the sample concentration due to large amounts of oxygen evolved when the external pressure is made lower than the decomposition one.
2. An intermediate electrolyte which allows a gas-tight separation between the electrode compartments.

The first requisite is satisfied by the design of the cell where the ID and OD of the silica tubes are chosen to leave the minimum dead volume.

The second requisite could be satisfied only when using lithium-doped silica glass, because the β-spodumene we prepared presents problems of gas tightness due to its relatively high porosity. One optically polished disk of Pursil silica was welded at the bottom of a silica tube (doped according to the directions given above) and used in the cell of Fig. 3. The cell is operated with two electrodes having about the same composition ($\sim$ 1 a/o lithium); one compartment is filled with pure oxygen, the other one (after a preliminary outgassing at room temperature under a vacuum of 10^{-2} Torr) is successively filled with different mixtures of oxygen-nitrogen (mass spectrometrically controlled for the oxygen content) and brought to the desired temperature under a continuous gas flow. The temperature was controlled to $\pm$ 0.1°C with a proportional temperature controller and the emf and temperature measured and recorded by a digital voltmeter and digital recorder (Hewlett & Packard, Dymec System).

Results

Comparison of the different electrolytes.—The results obtained when fitting cell [4] with lithium-doped silica, β-spodumene, and α-Li_2SO_4 at 800°C, are reported in Fig. 4. Similar results were obtained at lower temperatures. It appears that results obtained with different electrolytes fit the same curve, within experimental error, over the concentration range 0.5-7 a/o. At higher concentrations only β-spodumene works successfully. Examples of E *vs.* T curves obtained with β-spodumene are given in Fig. 5.

Cells with separate compartments.—The results of experiments carried out at 766°C with cells fitted with two electrodes containing about 1 a/o lithium are

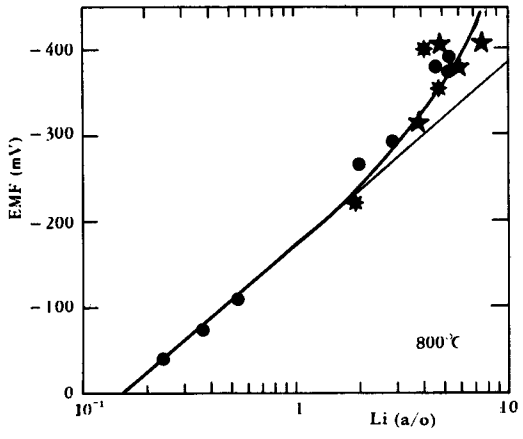

Fig. 4. EMF *vs.* concentration (in lithium atoms per cent) at 800°C: ●, α-$LiSiO_4$ as intermediate electrolyte; ✲, lithium-doped silica; ★, β-spodumene.

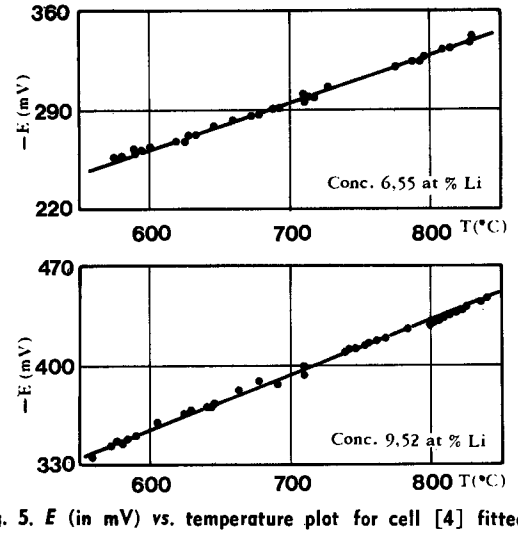

Fig. 5. E (in mV) *vs.* temperature plot for cell [4] fitted with β-spodumene as intermediate electrolyte.

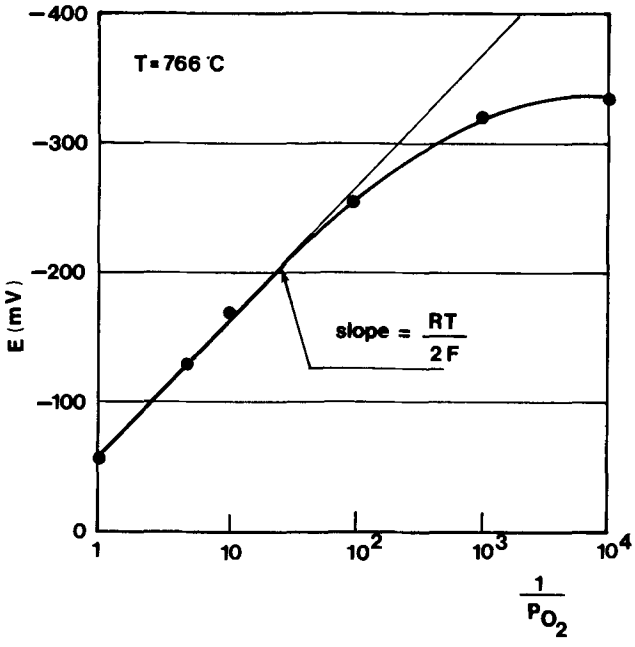

Fig. 6. EMF vs. partial pressure of oxygen plot for cell [1] fitted with lithium-doped silica glass and separate compartments.

shown in Fig. 6. The experimental points (which are an average of about 60 points printed down in more than 48 hr at each pressure investigated) present a mean square deviation of 4.05 mV and fit a curve having a slope of 104 mV.

Measurements on isobaric cells.—Results of experiments carried out on isobaric cells of type [4], when using β-spodumene as intermediate electrolyte, are reported in Table I (see also Fig. 4 and 5). This table gives the parameters which express the linear temperature dependence of the emf at different concentrations of lithium. The average number of (E, T) points used for computing the "a" and "b" values is 100. The concentration ratios quoted here have been normalized to a reference compartment concentration of 0.365 a/o lithium and correspond to concentration values iodometrically determined after completion of each high temperature experiment.

Table I. Experimental values of emf of cell [1] for different $LiNiO_2$ concentrations

$\frac{Li(a/o)_1}{Li(a/o)_2}$	E (mV) = a + b T
1.013/0.365	E = 49.37 + 0.087T
3.575/0.365	E = 46.29 + 0.287T
4.357/0.365	E = 144.64 + 0.230T
4.804/0.365	E = 2.51 + 0.379T
8.55/0.365	E = 60.96 + 0.335T
9.52/0.365	E = 120.13 + 0.390T
16.41/0.365	E = 135.65 + 0.634T
18.41/0.365	E = 11.63 + 0.691T
22.06/0.365	E = 39.05 + 0.653T
28.48/0.365	E = −1.79 + 0.772T
31.73/0.365	E = −9.46 + 0.762T

The equations reported in Table I have been used for plotting the emf isotherms of Fig. 7, 8, and 9. Here, the molar fraction ratio $x/(1-x)$ [where $(1-x)$ is the molar fraction of the NiO solvent or of the Ni_{Ni}^{x}

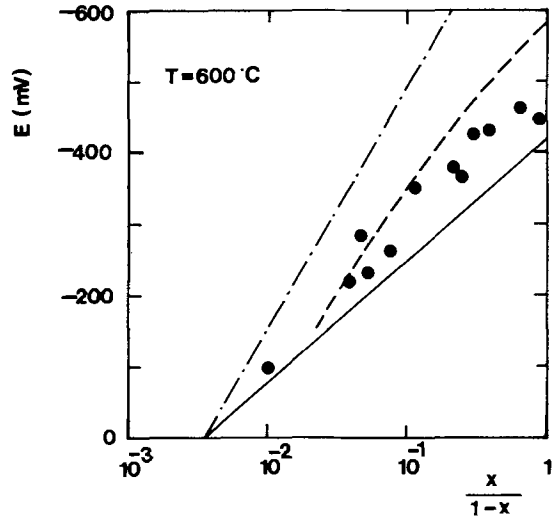

Fig. 7. Plot of the emf cell [4] fitted with β-spodumene vs. the ratio x/(1—x) of the molar fractions.

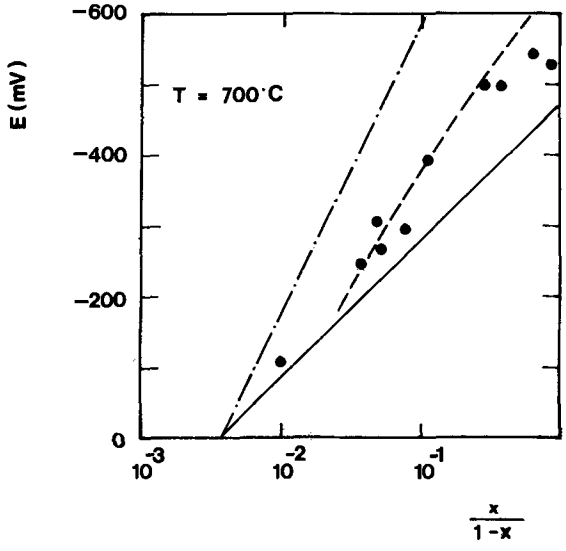

Fig. 8. Plot of the emf of cell [4] fitted with β-spodumene vs. the ratio x/(1—x) of the molar fractions.

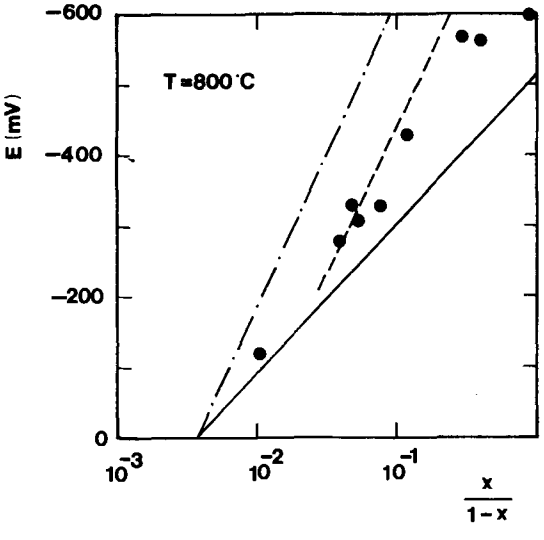

Fig. 9. Plot of the emf of cell [4] fitted with β-spodumene vs. the ratio x/(1—x) of the molar fractions.

ions] accounts for the fact that in the range of concentrated solutions, the concentration of Ni_{Ni}^{x} is no longer constant (see Eq. [1 bis]). The straight lines appearing in the same figures have been plotted according to the equations

$$\Delta E = \frac{RT}{F} \ln \frac{x_1}{1 - x_1} \Big/ \frac{x_2}{1 - x_2} \qquad [11]$$

and

$$\Delta E = \frac{RT}{F} \ln \frac{x_1^2}{x_2^2} \Big/ \frac{1 - x_1}{1 - x_2} \qquad [12]$$

where the former accounts for the theoretical emf of a solution in which pairing is 100% (solid line), and the latter for that of a solution in which pairs are 100% dissociated (dashed-dotted line).

Discussion

In the first paper of this series we discussed the thermodynamics of the dilute Li_2O-NiO solutions as that of binary system where the components are $LiNiO_2$ and NiO. In the same paper we stressed the influence of ion pairing on the thermodynamics of the solution. However, we emphasized that the use of pair concentrations (or other kind of associated species) as a measure of the $LiNiO_2$ activity does not mean that we identify a particular array of ions in the lattice with a chemical species, such as $LiNiO_2$. Nevertheless, if we do identify the activity of ion pairs with that of $LiNiO_2$, the fact that the Nernst equation holds to a deviation of less than 1 mV for $0.0015 \leq x_{LiNiO_2} \leq 0.01$, leads to the conclusion that, over this concentration range, the activity coefficient of $LiNiO_2$ is unity.[8]

Deviations from such an ideal behavior which have been observed at $x > 0.01$ were explained by considering that the statistical probability of finding configurations containing more than one lithium ion increases with the increasing of lithium content, thus affecting the entropy of the system. These entropy changes were shown to account for the over-all change of the free energy of the solution, as the enthalpy changes are, within the limits of experimental accuracy, inappreciable.

In order to avoid any possible mistake between species, coming from the different defect reactions postulated in the first part of this paper according to Eq. [1], [1 bis], and [9], and chemical components of the solution, we discuss here our present experimental results only in terms of a defect model involving ionic species, defects, and associated defects.

Measurements on cells with separate compartments show that the dependence of emf on the oxygen pressure is of the type (see Experimental section and Fig. 6)

$$\Delta E = \text{const} - \frac{RT}{2F} \ln \frac{(p_{O_2})_1}{(p_{O_2})_2} \qquad [10 \text{ bis}]$$

where the first term is essentially independent of the partial pressure of oxygen and the slope of the experimental curve equals $RT/2F$ within a few millivolts.

It is apparent that the experimental emf has the right oxygen pressure dependence required by the chosen defect model (Eq. [10]) and that the concentration of defects is not affected by the oxygen partial pressure, up to 10^{-2} atm, the first term being a constant.

This behavior indicates that the 1:1 ratio between substitutional lithium and Ni^{3+} does not appreciably change when changing the partial pressure of oxygen within the indicated range of pressures and, furthermore, that nickel vacancies, arising from reaction

$$0.5\, O_2 \rightarrow O_O + V_{Ni} \qquad [13]$$

do not play any significant role in the thermodynamics of the solution.

[8] As the standard state for NiO, the hypothetically pure and stoichiometric NiO under an oxygen pressure of 1 atm is chosen.

At the lowest partial pressures ($<10^{-2}$ atm) the deviation from linearity and the approximate independence of the emf with respect to the external pressure, indicate that the actual oxygen pressure in the electrode compartment remains constant, due to the buffering action of a decomposition reaction, that might be written as

$$[Li_{Ni}' \cdot Ni_{Ni}^{\cdot}] + 2\, O_O^x \rightarrow 0.25\, O_2 + 0.5 Li_2O + NiO \qquad [14]$$

and the system turns to be invariant.

A dissociation pressure between 10^{-2} and 10^{-3} atm, which might be inferred from Fig. 6 at 766°C, is in agreement with a figure of about 8 Torr at 800°C, reported by Hauffe (23) as the lowest pressure at which the electrical conductivity still remains independent of the pressure, for a sample of NiO doped with 1 m/o (mole per cent) lithium.

Other electrical conductivity measurements (21, 22) show that the electrical conductivity is independent of the partial pressure of oxygen. [Hauffe (23) interpreted this independence by considering that it is the chemical potential of the dissolved lithium oxide which varies with the oxygen pressure, whereas the concentration of the substituted lithium as well as of the electron holes does not.]

In order to check whether purely configurational factors account for the composition dependence of both emf and isothermal temperature coefficient of isobaric cells, we shall first consider how the entropy term should depend on the composition. When neglecting other terms but the configurational ones, the calculation of the configurational entropy of mixing could be carried out first for the two limiting situations recognized above, and corresponding to the cases: (*I*) of a mixture in which Li^+ and Ni^{3+} are associated to give stable pairs and, (*II*) of a mixture in which Li^+ and Ni^{3+} are randomly distributed.

In the first case, by using trivial statistical calculations, it could be demonstrated that the entropy of mixing results as

$$\Delta S = -R(n_{Li+} \ln x_{Li+} + n_{Ni2+} \ln x_{Ni2+}) \qquad [15]$$

and the partial molar entropy of the solute is found by differentiation to be

$$\bar{S}_{Li} - S^{\circ}_{Li} = -R \ln x_{Li} \qquad [16]$$

In the second case, the entropy of mixing could be obtained by assuming that both Li^+ and Ni^{3+} are independently arranged on N sites of the cation lattice, so that one finds

$$\Delta S = -2R(n_{Li} \ln x_{Li} + n_{Ni2+} \ln x_{Ni2+}) \qquad [15 \text{ bis}]$$

and

$$\bar{S}_{Li} - S^{\circ}_{Li} = \bar{S}_{Ni3+} - S^{\circ}_{Ni3+} = -2R \ln x_{Li} \qquad [17]$$

In Fig. 10 the straight line corresponds to the partial entropy differences (in μV/°C units) calculated from the equation

$$-\epsilon F = R[\ln x_2 - \ln (1 - x_2) - \ln x_1 + \ln (1 - x_1)] \qquad [18]$$

for the concentration cell [4] and one remarks that the experimental isothermal emf coefficients closely fit[9] the theoretical plot only in the dilute solution region. For more concentrated solutions, where deviations from the ideal behavior are apparent, it is always possible to find empirical equations which give the entropy of mixing, by replacement of the molar ratios with other suitable concentration parameters.

Then the equation for the entropy of mixing takes the form

$$\Delta S = -R(n_A \ln g_A + n_B \ln g_B) \qquad [15 \text{ ter}]$$

where $g_A + g_B = 1$.

In the case of polymer solutions (24) it has been shown that g_A and g_B are well described by the volume

[9] Thus indicating that the dilute solution is entirely constituted of undissociated pairs.

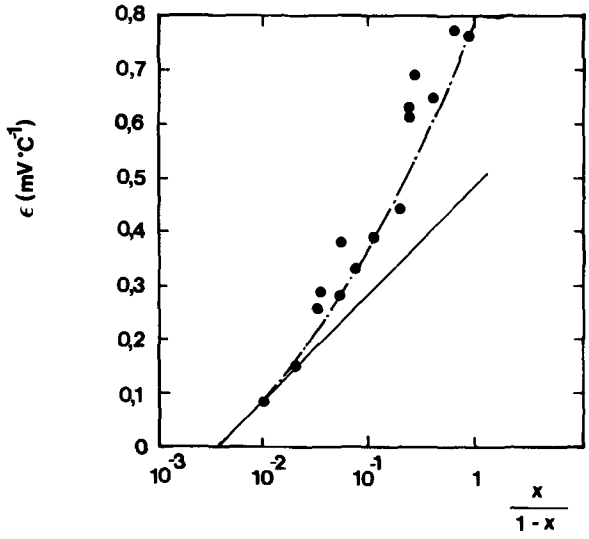

Fig. 10. Plot of the isothermal temperature coefficients of the emf vs. $x/(1-x)$. Straight line corresponds to the calculated entropy differences according to Eq. [18] and the dashed-dotted line to the entropy differences calculated according to Eq. [18 bis].

ratios ϕ_1 and ϕ_2 whereas, in our present case, it could be shown that g_A coincides with the relative statistical probability of finding those configurations containing more than two solute atoms within the nearest neighbors of a solvent atom.

Such a configurational function $g(n_i,r)$ accounts for the deviations from ideality only due to the increasing number of the contacts between like atoms as the concentration of the solute increases.

Numerical calculation of the g_A and g_B terms of Eq. [15 ter] could be accomplished by considering that in the rocksalt structure the coordination number z of cations is 12 and that each individual term $g(n_i,r)$ in the sum

$$g = \sum_{r}^{z} g(n_i,r) \qquad [19]$$

(where n_i is the number of atoms of species i in the mixture and r is the fraction of z sites occupied by cations of type i) could be calculated by the expression [see also ref. (1)]

$$g(n_i,r) = \frac{n_i!\,(N-n_i)!}{N!} \cdot \frac{z!\,(N-z)!}{r!\,(n_i-r)!\,(z-r)!\,(N-n_i-z+r)!} \qquad [20]$$

It is apparent that g_A in Eq. [15 ter] corresponds to the sum

$$g_A = \sum_{2}^{12} g(n_i,r)$$

Equation [18] could therefore be rewritten as

$$-\epsilon\mathbf{F} = R[\ln g_2 - \ln(1-g_2) - \ln g_1 + \ln(1-g_1)] \qquad [18\text{ bis}]$$

Equation [18 bis] is plotted in Fig. 10 as the dashed-dotted line and one can see that this configurational function closely fits the experimental points.

When we use, as has been done in the first paper, the values of the statistical probabilities $\sum_{r=2}^{12} g(n_i,r)$ as a measure of the activity of the solute and the values of $1 - \sum_{r=2}^{12} g(n_i,r)$ as a measure of the activity of the solvent, the calculated emf according to Eq. [11] results as

$$\Delta E = \frac{RT}{\mathbf{F}} \ln \frac{\sum_{r=2}^{12} g(n_i,r)}{x_2\left(1 - \sum_{r=2}^{12} g(n_i,r)\right)} \qquad [11\text{ bis}]$$

when substituting the molar ratios with the ratio of the statistical probabilities.

Results obtained are plotted in Fig. 7, 8, and 9 as dashed-dotted lines and show that this function accounts for the experimental results only in the range of intermediate concentrations as has been already shown (1).

We suggest, as a conclusion that the solid solutions of lithium oxide in nickel oxide are well described, in the range of dilute and intermediate concentration solutions, by a model which has the following important features:

1. Dilute solutions[10] ($0.1 \leq x \leq 2$ a/o lithium) consist entirely of undissociated [Li_{Ni}' $Ni_{Ni}^{\cdot}$] pairs. The electron holes are fully localized. This view agrees with the experimentally observed high values of the activation energy for the electrical conductivity in the same range of concentrations and are not conflicting with Deren's results reported in ref. (2, 3, 5), which show very low values of the activity coefficient of Li_2O in the same range of concentrations.[11]

2. In solutions lying in the intermediate concentration range ($2 \leq x \leq 10$ a/o lithium) interaction between like atoms leads to an apparent dissociation of ion pairs, corresponding presumably to a partial delocalization of electron holes. The entropy of the solution is always lower than the ideal one and is accounted for when calculating the (statistical) contacts between like ions. Also the activity of the components of the solutions could be approximately calculated by taking into account only statistical factors.

At the highest concentrations, however, the solution is no longer describable with the simple model illustrated in this present work.

Acknowledgments

The authors are greatly indebted to Dr. H. Rother, Professor G. Bianchi, Dr. V. Wagner, and Dr. A. Bonomi for helpful discussions and to Miss L. Oud for her kind cooperation.

This work was performed in cooperation with the Istituto di Elettrochimica, Università di Milano, and represents a part of the dissertation presented by G. Monari for the degree of chemistry at the University of Milano.

Manuscript submitted Nov. 19, 1969; revised manuscript received Jan. 5, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

[10] In our previous paper we used the operative definition of "ideal solution" for those dilute solutions in which lithium and nickel[111] are fully associated in pairs. Note that we have used a definition which could give rise to confusion when compared with the current use of "ideality," viz., in electrolytic solutions, where "ideality" corresponds to the absence of any specific interaction between ions.

[11] In ref. (2) we have however stressed that, due to the use of electrodes consisting of a mixture of nickel metal and the solid solution, the concentrations given by Deren result in much lower concentrations of [Li_{Ni}' $Ni_{Ni}^{\cdot}$] pairs.

Diffusion of ^{51}Cr in NiO Single Crystals

M. S. Seltzer

Metal Science Group, Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio 43201

ABSTRACT

The diffusion of ^{51}Cr into NiO single crystals has been investigated as a function of temperature in the region 1100°-1250°C and under oxygen partial pressures from one to 10^{-4} atm. At high chromium concentrations the diffusion is concentration dependent, probably as a result of self-doping by the trivalent chromium cations. At 1 atm of oxygen the concentration independent diffusion coefficients can be represented by $D_{Cr}^{NiO} = 9.36 \times 10^{-5} \exp(-47.0 \text{ kcal}/RT)$. At 1150° and 1250°C chromium diffusivities decrease with decreasing oxygen partial pressure.

While self-diffusion of Ni in NiO has been studied by a number of investigators (1-8) there have been only two studies of impurity tracer migration in this compound (8, 9). Experimentally observed activation energies for nickel self-diffusion in NiO vary from 44 to 63 kcal/mole. The higher values are taken to represent diffusion in relatively pure crystals where native defects predominate over those introduced by cation impurities having valence different from the host cation, nickel. In these cases the experimentally measured activation energies include the energy of formation for the defects by which nickel migrates, as well as the energy to move the diffusing species from one equilibrium position to an adjacent site. The lower activation energies then represent only the migration energy where the concentration of defects is fixed by the impurity concentration over the temperature range investigated.

In the temperature range 1100°-1400°C, both Volpe and Reddy (7) and Crow (8) have found that nickel diffusivities decrease with decreasing oxygen pressure in the region 1 atm $> p_{O_2} > 10^{-7}$ atm, with the pressure dependence varying with temperature and p_{O_2}. The results were interpreted in terms of nickel diffusion via both singly and doubly charged nickel vacancies.

Studies of cation impurity tracer diffusion in NiO have been limited to measurements of ^{60}Co (8) and ^{55}Fe (8, 9) migration. Crow (8) found that activation energies for ^{60}Co in polycrystalline NiO containing 0.002 atom fraction chromium were about 41 kcal/mole, independent of p_{O_2} in the range 1-5 x 10^{-5} atm over the temperature range 1100°-1400°C. Diffusivities decreased slightly with decreasing oxygen partial pressure. For diffusion of ^{60}Co in "pure" NiO single crystals, activation energies of 53.1 and 52.8 kcal/mole were measured in 1 atm and 5 x 10^{-5} atm, respectively. The lower activation energies found in the doped crystals are taken to represent values for migration under conditions where the vacancy concentration is controlled by the trivalent chromium addition.

Key words: point defects, nonstoichiometry, defect pairs, vacancies.

Measurements of iron diffusion in NiO single crystals (8, 9) suggest that this species acts as a self-dopant, yielding activation energies indicative of impurity controlled diffusion. Thus Crow found that diffusion rates for ^{55}Fe in NiO were nearly independent of p_{O_2}, particularly at 1100°C, while activation energies decreased from 46 to 41 kcal/mole as the oxygen pressure decreased from 1-5 x 10^{-5} atm. Variations in the pre-exponential compensated for the activation energy changes to give the p_{O_2} diffusion independence at 1100°C. Richards and Wagstaff measured an activation energy of 44.5 kcal/mole for ^{55}Fe in nickel oxide. This value, determined in air in the temperature range 1000°-1400°C, is in excellent agreement with the values reported by Crow.

The objective of this investigation was to determine diffusion coefficients for ^{51}Cr in NiO as a function of chromium concentration, oxide composition, and temperature, in order to provide additional information necessary for an understanding of impurity migration in oxides. Such information is essential for proper interpretation of experimental results of the oxidation of alloys, sintering of oxides, and creep of scales formed during alloy oxidation.

Experimental Procedures

The NiO single crystals used in this study were obtained from Argonne National Laboratory. They were grown by the Verneuil process in an arc-image furnace. A typical analysis in ppm is Co, 200; Ag, 80; Al, 10; Cr, 30; Fe, 60; Mn, 30; K and Na, 6; Si, 10; and

Ta, 20. Several preliminary experiments were performed on single crystals grown by Marubeni-Iida. These crystals had a typical analysis in ppm of Mg, 110; Ca, 85; Co, 20; Fe, 30; Al, 10; Ti, 10; others, 15. Diffusion specimens, 4 x 4 x 2 mm were prepared by cleaving {100} parallelepipeds from the large boules and polishing parallel surfaces using 600 grit metallographic paper.

In order to obtain specimens with a desired composition prediffusion equilibrations were conducted in a platinum-rhodium wire wound resistance furnace. Equilibrations of up to two weeks duration were performed at the desired temperature with the oxygen partial pressure fixed by using premixed argon-oxygen gas mixtures in the range $1\text{-}10^{-4}$ atm p_{O_2}.

The ^{51}Cr labeled chromium was produced by neutron irradiation of high purity iodide chromium metal in the Battelle Research Reactor. In order to prepare the chromium for irradiation, approximately 1g of metal was sealed in a quartz vial under a helium atmosphere. The quartz vial was then sealed in an aluminum capsule which also contained a helium atmosphere. The chromium was irradiated for 48 hr in a thermal flux of 1×10^{13} n/cm^2/sec, which produced a specific activity of $\sim$ 100 mci/g of chromium. A gamma ray spectra was taken to check the 0.32 meV peak of ^{51}Cr.

The irradiated chromium was deposited on one side of the NiO specimens by vapor deposition using a vacuum evaporator operated at 1×10^{-6} mm Hg. The chromium was vaporized by resistance heating in a tungsten boat. The depositions were performed in three or four evaporation steps of about 30 sec each, which provided an adherent layer. The weight of chromium deposited on the specimens was 40-60 μg/cm^2 which resulted in layers about 700-900Å thick. The quantity of chromium on the diffusion specimens was determined by comparison of the ^{51}Cr activity to that of a sample of irradiated chromium of known weight.

Two chromium-plated specimens were then sandwiched into a spring-loaded Vycor specimen holder and placed in the diffusion furnace under conditions of temperature and oxygen partial pressure similar to those used in the prediffusion anneal. On completion of the diffusion anneal, side faces of the diffusion specimens were cleaved off to remove activity from rapid diffusion down the sides of the specimens. Diffusion profiles were obtained by a sectioning method (13) and by counting the residual surface activity after each sectioning step (14). Sectioning was performed by grinding the specimen on 600 grit metallographic paper which was impregnated with kerosene. For the grinding operation the specimen was glued to a stainless steel insert which fit into a micrometer-driven stainless steel grinding block. Approximate values for the thickness removed could be estimated from the micrometer settings. After the grinding operation the mounted specimen was placed in an electronic height gauge to determine more exactly the thickness removed. In this manner cuts of 3-4μ could be taken $\pm$ 0.1μ. The mounted specimen could then be placed in a counter to measure the residual activity, while the kerosene impregnated metallographic paper on which grinding had been performed was placed in a glass vial for counting the activity in the sections removed.

An end-window, gas flow proportional counter was used to radioassay the diffusion specimen after removal of each layer. The detector was operated at 1750V using P-10 counting gas. A modular scaler was used to accumulate the pulses from the detector. The efficiency of this system for counting ^{51}Cr is about 2%. A sufficient number of counts were taken to reduce counting errors to less than 1% for each section removed.

Experimental Results and Discussion

For the experimental conditions of this investigation an infinitely thin layer of ^{51}Cr can be said to have been deposited on a semi-infinite solid. For such conditions the gradient of tracer concentration C at distance x beneath the original interface is given by

$$\delta \ln C/\delta x^2 = -1/4Dt \qquad [1]$$

where D is the diffusion coefficient in square centimeters per second and t is the time in seconds. Diffusion coefficients can be obtained by plotting the logarithm of the activity against the square of the distance from the initial interface, and setting the slope of the straight line so obtained equal to $-1/4Dt$. Data obtained from diffusion anneals conducted at 1100° and 1250°C under 1 atm of oxygen are plotted in Fig. 1 as counts per minute, cpm *vs.* x^2, microns squared. Similar results were obtained using data from either the sectioning method or the residual activity technique (which were used in Fig. 1). It is seen that the initial portions of these penetration profiles do not yield straight lines. These portions of the profiles may represent concentration dependent diffusion, resulting from self-doping due to diffusing chromium ions. As the concentration of nickel vacancies due to the trivalent chromium addition drops below the concentration due to impurities already in the NiO, the diffusivities for chromium become independent of chromium isotope concentration, as represented by the latter portions of the penetration profiles in Fig. 1.

Diffusivities obtained from the straight line portions of Fig. 1 are plotted as log D *vs.* reciprocal of absolute temperature, $1/T$, in Fig. 2. A straight line can be fit to these data using the method of least squares to get the Arrhenius type equation

$$D = 9.36 \times 10^{-5} \exp\left(-\frac{47.0 \pm 3.0 \text{ kcal}}{RT}\right) \frac{\text{cm}^2}{\text{sec}} \qquad [2]$$

The activation energy of 47.0 kcal/mole is similar to the values obtained for diffusion of ^{55}Fe in NiO single crystals by Crow (8) and by Richards and Wagstaff (9). Under 1 atm of oxygen Crow reported an activation energy of 46.0 kcal/mole for iron diffusion in the temperature range of 110°-1400°C. As pointed out

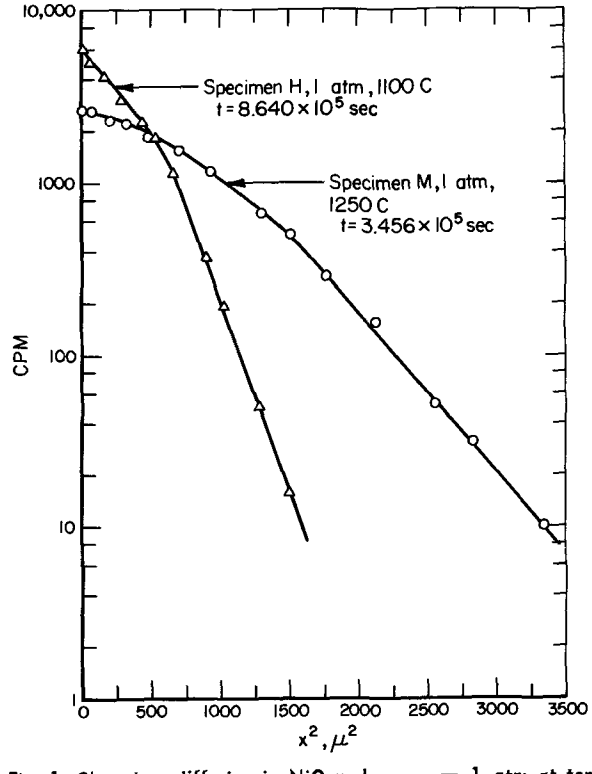

Fig. 1. Chromium diffusion in NiO under $p_{O_2} = 1$ atm at temperatures of 1100° and 1250°C. Activity in cpm vs. penetration as microns squared.

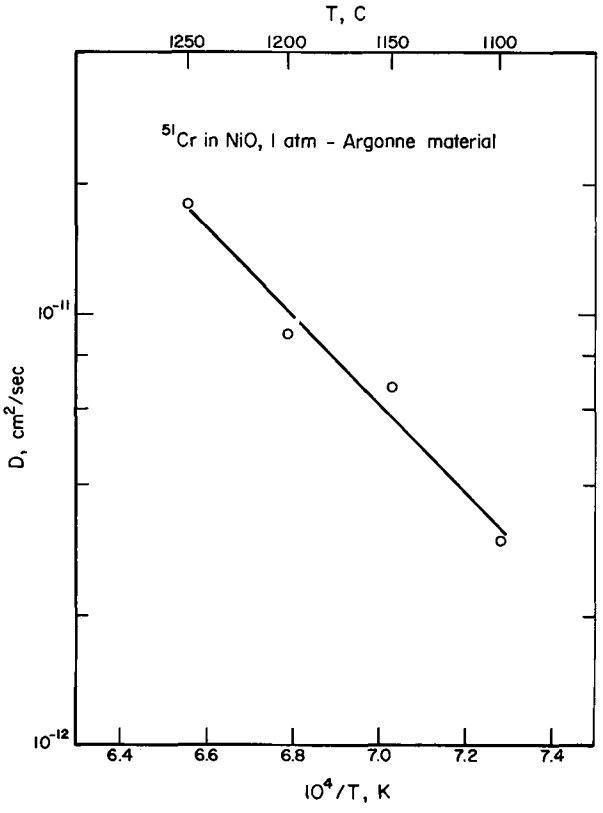

Fig. 2. Temperature dependence for diffusion of chromium in NiO at 1 atm oxygen. Log *D* vs. 1/*T*.

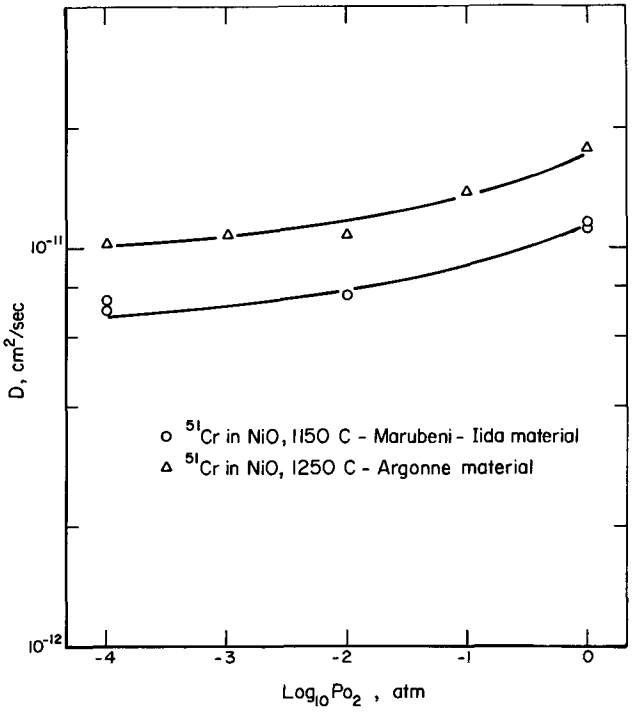

Fig. 3. Diffusion coefficients *vs.* oxygen pressure for chromium in NiO at 1150° and 1250°C.

by Crow, and discussed further below, these activation energies, which are somewhat lower than the values found for cobalt and nickel diffusion in NiO, can probably be attributed to the trivalency of the chromium and iron cations in the divalent cation host lattice.

The dependence of ^{51}Cr diffusivities on oxygen partial pressure at 1150° and 1250°C is shown in Fig. 3 as log D *vs.* log p_{O_2}. The data do not appear to be linear with log p_{O_2}. It is likely that they should be fit by curves whose slopes increase with increasing oxygen partial pressure. The diffusivities obtained from Marubeni-Iida crystals are a factor of two greater than the values determined from Argonne material (compare diffusion coefficients from Fig. 2 and 3 at 1150°C and 1 atm oxygen pressure for the two kinds of material). This may result from the fact that the net concentration of trivalent impurities is greater in the Marubeni-Iida crystals than in the Argonne material. Since trivalent additions are expected to increase the nickel vacancy concentration while monovalent impurities decrease the native vacancy concentration, the over-all effect is higher diffusivities in the NiO obtained from Marubeni-Iida.

Although the data obtained in this investigation are insufficient to develop a detailed model for the operative diffusion mechanism some suggestions can be made based on the information available.

The first possibility is that chromium diffusion occurs by a vacancy mechanism, similar to self-diffusion of nickel in NiO. The activation energy for chromium diffusion of 47 kcal/mole is, however, considerably lower than that for intrinsic self-diffusion of nickel in NiO, even where the chromium diffusivities are calculated from the concentration independent portions of the penetration profiles. It is of course likely that the NiO specimens used in this study have a high enough background concentration of electrically active impurities so that an activation energy representative of extrinsic diffusion has been obtained. In this case the penetration profiles indicate concentration independent diffusion once the chromium concentration falls below the over-all impurity level in the diffusion specimens. The similar activation energies for ^{55}Fe and ^{51}Cr in NiO could then be attributed to extrinsic diffusion where the energies for migration of iron and chromium in NiO are fortuitously similar. Crow (8) has shown that the oxygen partial pressure dependence may be expected to decrease with decreasing p_{O_2}, as is shown in Fig. 3, as the vacancy concentration becomes impurity controlled at low oxygen partial pressures. In this case the activation energy for diffusion might be expected to increase with increasing p_{O_2} as the nickel vacancy concentration becomes independent of impurity level. For ^{55}Fe in NiO Crow indeed found the activation energies to increase from 41 to 46 kcal/mole as the oxygen partial pressure increased from 5 x 10^{-5} to 1 atm. However, the value of 46 kcal/mole is still well below the value of 54.7 kcal/mole found by Crow for Ni in NiO at 1 atm.

An alternative diffusion mechanism, involves migration via an impurity-vacancy complex, in this case presumably a chromium ion-nickel vacancy pair. The theoretical basis for such a mechanism of impurity diffusion in ionic crystals has been developed by Lidiard (10), and the mechanism has been invoked to interpret experimental results for systems such as ^{109}Cd diffusion in AgBr (11).

Under the conditions of this investigation the chromium concentration over the straight portion of the penetration profile is assumed to be small in comparison with the nickel vacancy concentration, but D_{Cr} is proportional to p where p is the degree of association of the impurity. The degree of association is given (12) by the mass action equation

$$p/(1-p) = (12\,v/N^+)\exp(\Delta G/kT) = v\,K \quad [3]$$

where v is the concentration of unassociated nickel vacancies, N^+ is the concentration of nickel ion sites, ΔG is the association energy, K is an equilibrium constant, k is Boltzmann's constant, and T is the absolute temperature. Rearranging Eq. [3] gives

$$D_{Cr} = C_p = C\left[\frac{v\,K}{1+vK}\right] \quad [4]$$

where C is a constant. In this case D is seen to be nearly independent of oxygen pressure and of chromium concentration if K is large.

Acknowledgments

The author wishes to thank J. E. Howes and the late R. D. Tenaglia for invaluable assistance with various aspects of this investigation. The NiO crystals used were kindly provided by Dr. M. L. Volpe of the Argonne National Laboratory. The research was supported by the Columbus Laboratories, Battelle Memorial Institute.

Manuscript submitted July 16, 1970; revised manuscript received Jan. 11, 1971. This was Paper 149 presented at the Atlantic City Meeting of the Society, Oct. 4-9, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Liquid Phase Epitaxial Growth of $InAs_{1-x}Sb_x$

G. B. Stringfellow and P. E. Greene†

Solid State Laboratory, Hewlett-Packard Company, Palo Alto, California 94304

ABSTRACT

Single-crystal epitaxial layers of $InAs_{1-x}Sb_x$ have been grown using a steady-state, liquid phase epitaxial growth technique. In the range of $0 < x < 0.35$ they were grown on InAs substrates from liquid compositions on the pseudobinary phase diagram and also from liquids in the In-rich corner of the ternary phase diagram at temperatures between 580° and 720°C. In the range of $0.89 < x < 1$ they were grown on InSb substrates from In-rich liquids with growth temperatures ranging from 480° to 520°C. The grown crystals are homogeneous in the region more than 4μ from the substrate. The optical absorption edges are sharp, similar to the InAs absorption edge. The 300°K energy band gap as a function of composition may be described by the following expression

$$E = 0.35 - 0.771x + 0.596x^2 \text{ eV}$$

The electrical properties of the $InAs_{1-x}Sb_x$ alloys with $x < 0.35$ are similar to those of pure InAs, *i.e.*, when $n = 2 \times 10^{16}$ cm^{-3} typical mobilities are 30,000 cm^2/V-sec at 300°K and 50,000 cm^2/V-sec at 77°K. For alloys with $x = 0.89$ typical mobilities are 67,000 cm^2/V-sec at 300°K and 50,000 cm^2/V-sec at 77°K. Incorporation of Sn during growth of $InAs_{0.92}Sb_{0.08}$ from the pseudobinary liquid at 720°C was found to give n-type doping. Under these conditions the distribution coefficient was determined to be 0.01.

$InAs_{1-x}Sb_x$ alloys are interesting semiconductor materials for two main reasons: (A) The energy band gap covers the range from 3-12μ (1) which is a range of practical interest for infrared emitting diodes and detectors. (B) They offer the prospect of having higher mobility than any presently known semiconductors (2).

The properties of $InAs_{1-x}Sb_x$ alloys were first investigated by Woolley and co-workers. They established the InAs-InSb miscibility (3), the pseudobinary phase diagram (3), and they investigated the variation of fundamental properties such as band gap (1, 4) and effective mass (5-7) with composition. Sirota and co-workers (8-10) and Kudman and Ekstrom (11) also investigated the properties of $InAs_{1-x}Sb_x$ alloys. All of the above measurements were performed on polycrystalline samples of $InAs_{1-x}Sb_x$. Basov *et al.* (12) reported the growth of single crystalline $InAs_{0.98}Sb_{0.02}$ by the Czochralski technique and the fabrication of laser diodes in this material. Neither the growth of $InAs_{1-x}Sb_x$ single crystals with $x > 0.02$ or the epitaxial growth of single crystals of the alloys have been reported in the literature, although Tietjen *et al.* (13) have grown polycrystalline layers of $InAs_{1-x}Sb_x$ with $x < 0.95$ by vapor phase chemical deposition. The electrical and optical properties, which are very dependent on structural imperfections, particularly grain boundaries, have not been investigated using single crystals.

The purpose of this paper is to describe the epitaxial growth of $InAs_{1-x}Sb_x$ ($x < 0.35$ and $x > 0.89$) single crystals and to briefly report some of their chemical, structural, optical, and electrical properties.

Crystal Growth

The In-As-Sb phase diagram which is necessary for the growth of $InAs_{1-x}Sb_x$ alloys has been calculated (14) and has been verified experimentally during the course of the present work. The calculated liquidus isotherms and experimental data obtained by solu-

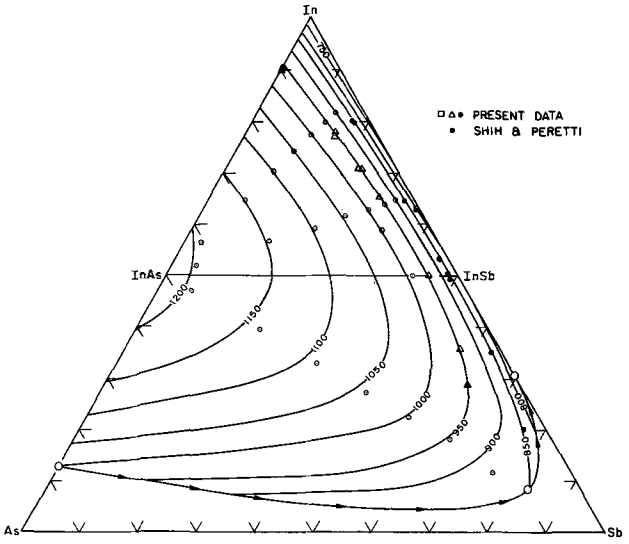

Fig. 1. Calculated liquidus isotherms for the system In-As-Sb compared with data of Shih and Peretti (21) (○) and data obtained from solubility measurements of InAs in In-Sb melts (●, △, □).

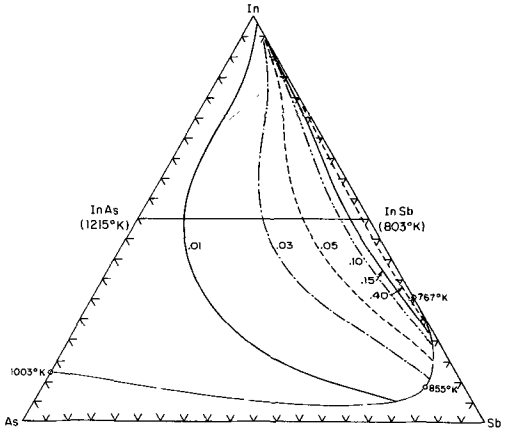

Fig. 2. Calculated iso(solid concentration) curves for the In-As-Sb system. Each curve representing the liquid compositions in equilibrium with a single solid compositon is labeled X_{InSb}.

bility measurements of InAs in In-Sb liquids are presented in Fig. 1. By comparing this with Fig. 2, which illustrates calculated iso(solid concentration) lines one can see that a solid alloy of a given composition can be grown from any liquid on the iso(solid-concentration) line but the highest growth temperature is obtained on the InAs-InSb pseudobinary. The pseudobinary, presented in Fig. 3, illustrates many of the problems encountered in the growth of single-crystal layers of $InAs_{1-x}Sb_x$ alloys:

1. The solid composition is strongly temperature dependent in the range $x > 0.1$. Thus any thermal excursion occurring during the growth of the crystal produces a large composition gradient in the grown crystal.

2. The growth temperatures are very low especially with $x > 0.2$. In fact, if InSb substrates are used, the temperature must be below 530°C.

3. The As distribution coefficient is very large causing severe kinetic problems such as constitutional supercooling during the growth of $InAs_{1-x}Sb_x$ crystals.

4. The lattice parameter of InSb is 7% larger than that of InAs, which causes difficulty in epitaxial growth of alloys of intermediate composition on either InAs or InSb especially in liquid phase epitaxial growth where compositional tapering is difficult.

These crystal growth problems necessitate a somewhat unique crystal-growth technique. During steady-

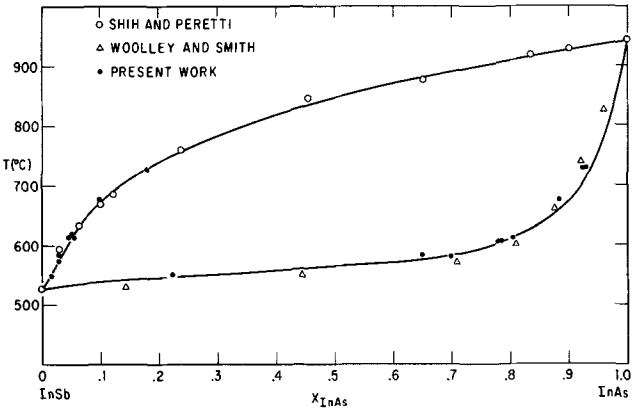

Fig. 3. Calculated pseudobinary phase diagram for the InAs-InSb system. Liquidus data points were obtained by solubility measurements of InAs in In-Sb solutions (●) and from the results of Shih and Peretti (20) (○). The solidus points were obtained by growing crystals at near equilibrium conditions. The results of Woolley and Smith (2) are presented as triangles (△).

state liquid phase epitaxial (SSLPE) growth the substrate temperature is held constant. A temperature gradient maintained in the liquid phase between the substrate and the source material acts as a driving force for the crystal growth, controls the growth and nucleation rates, and acts to stabilize the interface, thus minimizing the constitutional supercooling in the melt. The substrate may be either InAs or InSb. The source should, in principle, have the same composition as the growing epitaxial layer. Because of the large As distribution coefficient, however, the solid phase is always much richer in As than the liquid from which it is growing; thus in a system where the melt is much larger than the crystal grown, a source of As is all that is required to avoid appreciable depletion of the melt except for the growth of nearly pure InSb. InAs, a convenient source of As, was used throughout the crystal growth experiments. The apparatus for the steady-state liquid phase epitaxial growth of $InAs_{1-x}Sb_x$ is illustrated schematically in Fig. 4.

Experimental

Crystal growth was carried out in a high purity graphite crucible purged with H_2 purified by diffusion through a palladium-silver alloy membrane. The source and substrate were prepared by standard lapping and polishing procedures followed by a chemical etch in 1% Br in methanol just prior to introduction into the crystal growth apparatus. The melt was prepared by weighing appropriate amounts of 6-9's In and Sb into the graphite crucible along with polycrystalline InAs. The crucible was then heated to the

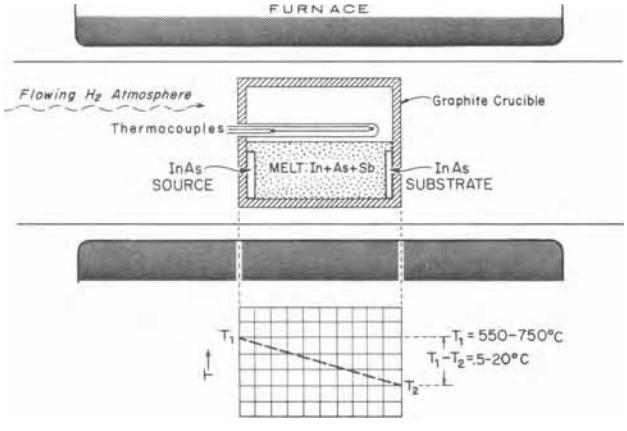

Fig. 4. Schematic diagram of the apparatus used to grow crystals of InAs-InSb alloys by the steady-state liquid phase epitaxy technique.

growth temperature for several hours to dissolve the InAs and saturate the melt. The substrate and source were then introduced into the melt by rotating the crucible. The growth was terminated by rotating the crucible again to remove the source and substrate from the melt.

The liquidus data were obtained as above using only a pure InAs substrate with no source wafer and no temperature gradient. The solubility was determined by weighing the substrate before and after the experiment, wherein the substrate was immersed in the liquid for several hours in order to completely saturate the melt. The solid compositions were determined by growing crystals using very low ΔT and, hence, low growth rates to insure that the crystal growth occurred at near-equilibrium conditions. The solid composition was found to be uniform within ± 1 a/o (atomic per cent), facilitating the determination of the phase diagram data. The alloy compositions were obtained from the lattice parameters determined from Debye-Scherrer x-ray powder diffraction patterns, using the a_0 *vs.* x data of Woolley *et al.* (3). The results are accurate to ± 0.01 in x which is equivalent to the half width of the x-ray diffraction lines.

Crystals of a given composition may in principle be grown from any of an infinite number of temperature-liquid composition pairs. In practice, the choice of the growth conditions is governed by three principles:

1. The growth temperature must be lower than the melting temperature of the substrate.
2. The As vapor pressure must be low enough to avoid appreciable loss of As from the melt during growth.
3. The growth temperature should be the highest possible which will satisfy 1 and 2 above. The highest growth temperature for a given solid is from a liquid on the pseudobinary phase diagram.

A brief summary is presented in Table I of the growth conditions used for the successful growth of $InAs_{1-x}Sb_x$ epitaxial crystals of several compositions. For growth of solids with $x = 0.04$ from liquids on the pseudobinary phase diagram the temperature-composition coordinates are such that As was lost rapidly from the melt. Crystals with $x = 0.04$ were successfully grown at 720°C from an In-rich liquid. For $x = 0.08$, 0.15, 0.20, and 0.31 the optimum growth conditions were found to be on the pseudobinary phase diagram. Crystals with $0.89 < x < 1$ were grown on InSb substrates at temperatures slightly below 530°C, the melting point of InSb. The liquid compositions were in the In-rich portion of the phase diagram.

Crystals were grown using temperature differences of 2°-15° between source and substrate. Large temperature differences of 7°-15° were usually necessary for growth with the flat liquid-solid interface necessary to avoid trapping of the melt.

Results

The experimental In-As-Sb liquidus data is plotted along with calculated results in Fig. 1. The experimentally determined solid compositions in equilibrium with a given liquid are presented in Table II for comparison with experimental results. The rms deviation of the experimental from the calculated results is 0.01, which is equal to the experimental uncertainty in x.

Photographs of typical epitaxial layers grown using the conditions set forth in Table I are presented in Fig. 5. These photographs illustrate the excellent surface morphology obtained for $x < 0.16$, which degrades as x is increased. Attempts to grow crystals with $x > 0.25$ on InAs substrates produced only polycrystalline material. The range of compositions was extended to $x = 0.35$ by growing the final epitaxial layer on a previously grown epitaxial layer having an intermediate value of x.

729	0.500	0.410	0.090	0.93	0.935	0.005

Electron microprobe scans were made of the epitaxial layers along cleaved edges in a direction perpendicular to the growth plane. A typical result is presented in Fig. 6. The composition of the epitaxial layer changes from InAs to 8% InSb in the first 4μ of growth after which the composition is nearly constant. The position $d = 0$ in Fig. 6 is the InAs substrate surface before growth. There was no evidence of substrate dissolution prior to the growth.

Another test of the homogeneity of the epitaxial layers is the width of the large angle Debye-Scherrer powder x-ray diffraction lines. Figure 7 shows the 731 and 642 lines for an $InAs_{0.92}Sb_{0.08}$ alloy and pure InAs. The alloy lines are no broader than those of pure InAs indicating that the alloy layers are homogeneous to within $\pm$ 0.01 in x.

The fact that the alloy layers were single crystalline and epitaxial was verified by Laue x-ray diffraction patterns.

Optical absorption was measured on $InAs_{1-x}Sb_x$ samples of various compositions. The transmission measurements were made using the standard sample in-sample out technique. Absorption coefficients were calculated using the relation

$$\frac{I}{I_0} = \frac{(1-R)^2}{e^{\alpha d} - R^2 e^{-\alpha d}}$$

which takes into account multiple internal reflections. Reflectivity data are not available for the alloys, so a value of $R = 0.3$, which is appropriate for pure InAs, was used for all alloys. The experimental results are plotted in Fig. 8. The absorption edge can be described using the empirical expression

$$\alpha = A \exp (h V/kT_0)$$

which has been found to describe the absorption in pure III-V compounds (15). The value of T_0, which indicates the steepness of the edge, was found to be 80°K for pure InAs and the alloys with $x < 0.20$ and

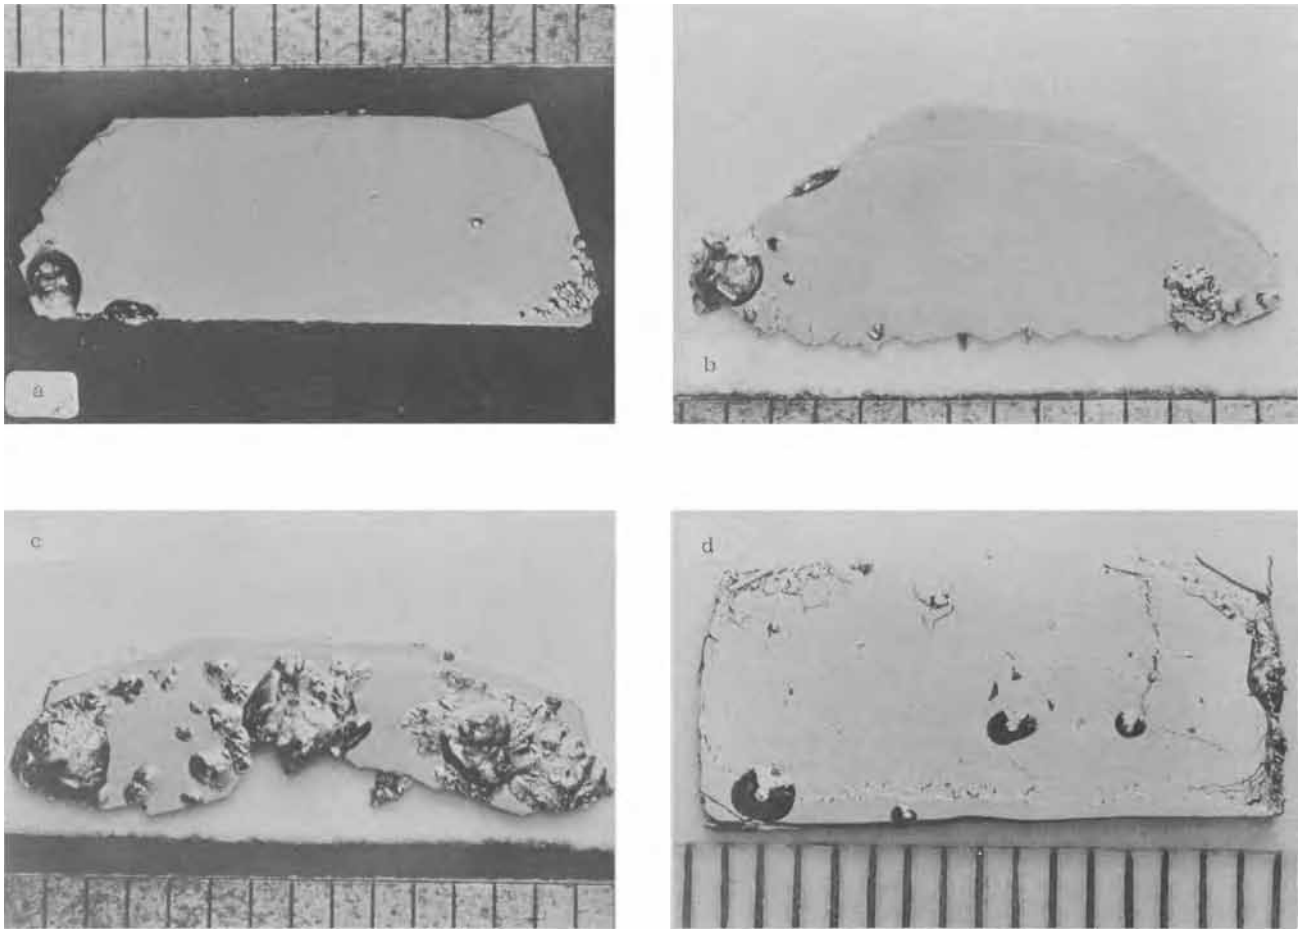

Fig. 5. Photographs of as-grown surfaces of typical epitaxial layers of $InAs_{1-x}Sb_x$ grown by SSLPE technique: (a) $x = 0.08$, (b) $x = 0.15$, (c) $x = 0.31$, (d) $x = 0.89$.

$x = 0.89$. When $x > 0.25$ the edge is slightly less sharp, with $T_o = 110°K$. It is not clear whether this is an intrinsic property of the alloys or is due to the possible slight sample inhomogeneities, within the ± 0.01 detectability limits, or within the size limits of the 1μ microprobe spot.

The band gap was determined from the absorption data as the point at which $\alpha = 300$ cm^{-1}, which gives the correct band gap for InAs and InSb. In order for absorption data to give a correct value for the energy band gap of the alloys there must be no extraneous absorptions broadening the band edge and no Burstein shift. The Burstein shift for the samples measured can be estimated from the carrier concentration data presented below, knowing the conduction band density of states. The samples measured were degenerate at room temperature; but the Fermi level was never more than 0.025 eV above the bottom of the conduction band; which is less than the value of $4\ kT$, *i.e.*, 0.1 eV necessary to produce a Burstein shift at room temperature (16). Thus, the absorption data give a reliable determination of the band gap.

The band gap *vs.* composition is plotted in Fig. 9. These results on single-crystal epitaxial layers with controlled carrier concentration are seen to agree well with earlier data of Woolley (1) obtained on poly-

crystalline samples with higher carrier concentrations.

Conductivity and Hall effect measurements were made on single-crystal samples of $InAs_{1-x}Sb_x$ of various compositions. Hall samples of the standard rectangular parallelopiped geometry were made from $InAs_{1-x}Sb_x$ layers with the InAs substrates removed. Ohmic contacts were made by soldering indium spheres to the bar. The measurements were made using standard d-c potentiometric techniques at temperatures of 300° and 77°K. The results are presented in Table III. The carrier concentrations in undoped material can be controlled in the range $n = 2 \times 10^{16}$ cm^{-3} for all compositions. The room temperature mobilities of the alloys with $x < 0.35$ are approximately the same as for the pure InAs. The liquid nitrogen mobilities range from 20,000 to 50,000 cm^2/V-sec for undoped samples. The mobilities measured for $x = 0.89$ are 67,000 cm^2/V-sec at 300°K and 50,000 at 77°K.

The mobilities obtained are disappointingly low for samples with $x = 0.20$-0.35 and $x = 0.89$. Mobilities

* Sn doped.
† Intrinsic at 300°K.

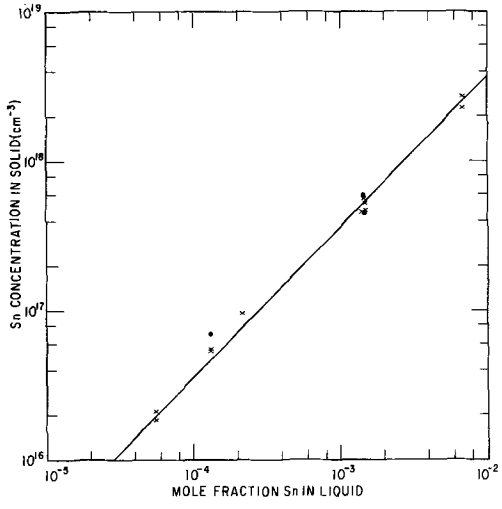

Fig. 10. Sn concentration in $InAs_{0.92}Sb_{0.08}$ solid vs. Sn concentration in the In, As, Sb liquid. Sn concentrations in the solid were obtained by Hall effect (x) and emission spectrographic analysis (●). The crystals were grown at 720°C from the pseudobinary liquid. Under these conditions the distribution coefficient is 0.01.

for $x = 0.35$, $n = 2 \times 10^{16}$, were calculated assuming a combination of polar optical and ionized impurity scattering to be 85,000 cm^2/V-sec at 300°K and 65,000 at 77°K. The low mobilities measured are probably due to imperfections in the grown crystals similar to those which cause mobilities of InAs grown on GaAs substrates to be much lower than InAs grown on InAs substrates (17).

N-type doping of $InAs_{0.92}Sb_{0.08}$ was investigated by introducing Sn during crystal growth from the pseudobinary liquid at 720°C. The Sn concentration in the solid was measured by measuring the carrier concentration and by emission spectrographic analysis. The results shown in Fig. 10 indicate the incorporated Sn is electrically active and non-self-compensating in the range of 1×10^{16} to 3×10^{18} cm^{-3}. The distribution coefficient was found to be independent of composition and equal to 0.01 under these growth conditions.

One other important method of evaluating the material is to fabricate diodes and study their properties. Wong *et al.* (18) have successfully fabricated high efficiency diodes from the $InAs_{1-x}Sb_x$ described in this paper, and reported on their properties.

Discussion

A comparison of Table 1 with Fig. 5 illustrates that the growth of $InAs_{1-x}Sb_x$ becomes increasingly difficult as x increases. The surface morphology was found to degrade, even though ΔT was increased in order to increase the growth rate and stabilize the flat interface. This seems to be due to the increasing lattice parameter mismatch as x increases. As noted above, it was not possible to grow single-crystal epitaxial layers of $InAs_{1-x}Sb_x$ with $x > 0.25$ on pure InAs substrates. A stepwise taper implemented by growing the final epitaxial layer on a previously grown epitaxial layer having an intermediate value of x resulted in successful growth of single-crystal epitaxial layers with x as large as 0.35. This indicates that the lattice parameter mismatch is the factor limiting the range of composition over which single-crystal epitaxial layers may be grown.

The free energy of a growing nucleus is increased by constraining it to stretch to fit the lattice of the substrate upon which it is growing. For this reason the lowest energy growth is in the form of columns, or, to minimize surface free energy, faceted platelets. Applying a large temperature gradient in the liquid tends to reverse this tendency and make the growth flat, but when the lattice parameter mismatch is too large, the crystals continue to grow as platelets. The

result is polycrystalline layers. The strain energy term, in addition to the chemical free energy, also perturbs the composition of the solid in equilibrium with a given liquid toward the composition of the substrate. This effect may explain the taper of composition from the substrate composition to the final chemical equilibrium composition over 4μ as seen in Fig. 6. For the growth of $Ga_{1-x}Al_xAs$ on GaAs substrates, where there is no lattice parameter mismatch, Woodall (19) reported an abrupt change in solid composition at the interface which could not be resolved using the 1μ microprobe beam size.

It should be noted that the band gaps of the alloys successfully grown by SSLPE growth on InAs substrates span the region from 0.35 eV (pure InAs) to 0.14 eV which is below the band gap of InSb. This is a region of considerable practical importance for infrared emitting diodes and detectors. These results plus the successful growth of $InAs_{1-x}Sb_x$, $x > 0.89$, indicate that the best way to cover a large range of band gaps is to grow alloys with $0 < x < 0.3$ on InAs substrates for the range 3 to 7.3μ and alloys with $1 > x > 0.6$ on InSb substrates for the range from 7.3 to 12μ.

Conclusions

Single-crystal epitaxial layers of $InAs_{1-x}Sb_x$ with $0 < x < 0.35$ and $0.89 < x < 1$ have been grown on InAs and InSb substrates, respectively, by steady-state liquid phase epitaxial growth. The crystals were found to have the following properties:

1. The solid composition remains constant after the first 4μ of crystal growth.
2. The undoped alloys have optical absorption edges as sharp as the undoped InAs edge.
3. The composition dependence of the energy band gap agrees with data of Woolley for polycrystalline $InAs_{1-x}Sb_x$.
4. The residual doping level of the undoped alloys is typically less than 2×10^{16} cm^{-3}.
5. The electron mobilities for undoped alloys range from 30,000 ($0 < x < 0.35$) to 67,000 (cm^2/V-sec) ($x = 0.89$) at 300°K and from 30,000 to 50,000 cm^2/V-sec at 77°K for all alloy compositions investigated.
6. $InAs_{0.92}Sb_{0.08}$ was Sn doped to give an electron concentration in the range 2×10^{16} to 3×10^{18} cm^{-3}. The Sn distribution coefficient at 720°C was determined to be 0.01.

Technical Note

The Effect of a Barrier Oxide on Evaporation of Water from a Hydrous Aluminum Oxide Film

R. S. Alwitt*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts 01247

Bernard and Randall (1) have shown that a smaller weight loss results when a hydrous aluminum oxide film is heated while still in contact with base metal than when an isolated film is heated. This was found to be due to reaction of some of the water in the film with substrate aluminum to produce more oxide. There are no published results to indicate whether a barrier oxide layer between the hydrous film and the metal would block the diffusion of water to the substrate. This is of importance in analyzing thermogravimetric and differential thermogravimetric data obtained with

250	1933	173	585	174	164	0.948
250	1786	199	673	156	186	0.924

anodized aluminum. Such data have been used to determine the amounts of different component oxides [*e.g.*, amorphous $Al(OH)_3$, boehmite] in the anodic film with the assumption that no liberated water reacted with metal substrate (2, 3).

Experimental Procedure

Aluminum foil samples of 99.99% purity were lightly etched by immersion in 1*N* NaOH for 2 min at room temperature. The specimens were then anodized at room temperature in an electrolyte of 30% ammonium pentaborate in ethylene glycol at a current density of 1.4 mA/cm^2. Anhydrous, amorphous, barrier films are formed in this electrolyte at 100% current efficiency (4). Films were formed with thicknesses equivalent to 90, 150 and 250V. The specimens were then immersed in boiling water for 3 min to convert an outer portion of the films to hydrous oxide (5). The samples were then heated in air at 600°C for 2 hr. The quantities measured were the charge passed during anodization, the weight before and after the water reaction, and the weight after heating.

The weight of anodic oxide was calculated from the charge assuming 100% current efficiency. The amount of oxide that reacted with water was calculated assuming the hydrous oxide contained 22.8% water. This composition was determined from data of Bernard and Randall (6). The final barrier thickness was calculated from the weight fraction of the initial oxide that did not react with water.

Results and Discussion

The results are listed in Table I. The weight loss at 600°C is the sum of water evaporated and hydrogen evolved from any reaction of water with metal substrate. Some water may be trapped in the barrier oxide while diffusing toward the substrate and may not be released at 600°C (7) so it is not possible to unequivocally determine from these data the amount of water that reacted. But the entries in the last column clearly show that even a 160V film is not a sufficient barrier to permit quantitative recovery of water.

It might be noted that the capacitance of a 150V specimen was measured before and after reaction with water, and the voltage supported by the film after the water reaction was measured. Both of these measurements indicated a 60V barrier film. This agreement with the weight data indicates that hydration proceeded uniformly over the surface.

It is clear that before thermogravimetric data obtained on oxide films *in situ* can be interpreted, it is necessary to determine whether water can react with the substrate under the test conditions. Alternately, one can work with isolated films obtained by dissolving the metal in 10% bromine-methanol. It has been demonstrated that this technique permits the quantitative recovery of pseudoboehmite (1) and amorphous anodic oxide (7). Erdey *et al.* (2) reported that this treatment partially decomposed hydrargillite, but they did not give the conditions or extent of attack. It would be worthwhile to study the effect of this reagent on other forms of aluminum oxide to determine under what conditions it may be used.

Hydrogen-Air/Lead Battery Hybrid System for Vehicle Propulsion

K. V. Kordesch*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Parma, Ohio 44129

ABSTRACT

The high energy density of a fuel cell battery and the peak current capability of a secondary battery are combined in the power plant of an electric car. The four-seat vehicle weighs 2000 lb and is powered by a 7 kW (20 kW peak) d-c motor. The 6 kW hydrogen-air fuel cell battery is connected in parallel with a 4 kWhr lead battery (84V); 660 ft^3 of hydrogen are stored in six lightweight cylinders (180 lb total weight) equivalent to 33 kWhr of actually available electric energy. The design of the fuel cell battery was aimed at very long life expectancy on intermittent duty, fast automatic starting and shutdown, reliable safety features, and use of available commercial accessories. The operation of the car is not more difficult than driving a conventional auto; the range is over 200 miles. The refilling of the hydrogen cylinders takes only a few minutes from a 2000 psig supply. The acceleration is similar to that of a small car with a combustion engine. Top speed is 55 mph.

Advantages and shortcomings of electric cars for urban transportation have been discussed extensively, mainly from the standpoint of pollution control (1). Military vehicles powered by fuel cell systems have been investigated for reasons of fuel efficiency (2). Pilot production of small electric cars with lead batteries has started in Japan, and the development of heat engine-battery hybrids has been seriously considered in the United States and Germany. For use in the vehicle which has no chance to recharge for hours and cannot have a motor generator on board (*e.g.*, taxies or "city cars" driven up to 200 miles/day), the fuel cell/secondary battery hybrid seems to offer a possible solution.

To take one more step into the future (fuel cells are not ready for production today), the *fuel* should not be derived from coal or oil for reasons of conserving fossil fuels.[1] Hydrogen seems to be a suitable energy source (compressed, liquid, or derived *in situ* from ammonia or other inexpensive chemicals), since it is the only reactant which can be easily used in high power fuel cells. The lowest present cost estimate for the noble metal catalyst requirement is $50/kW, but improved technology could eliminate or reduce this considerably. Air must be the oxidizing agent; no noble metal catalysts are needed for carbon-air cathodes.

The author has selected an alkaline fuel cell system for experimentation because, technically, it is the most advanced. Oxygen would be necessary to achieve peak performance from the fuel cell power plant (3). However, with a hybrid system, the overload capability is provided by the secondary battery and air is sufficient. The hydrogen-air/lead battery system was chosen as the most practical solution (4, 5).

The project of building a small electric car for urban transportation was actually started in 1966 by remodeling an Austin A-40 for electric propulsion by utilizing 14 lead acid batteries (84V) as the power source. The resulting vehicle (2000 lb) performed very much as predicted by many surveys made then and at later dates (6).

In 1968-1969, the car was partially converted to "fuel cell power." A 90V hydrogen-air battery replaced the seven lead-acid batteries in the rear compartment, while the seven front batteries remained as before.

No special efforts have been made to optimize components. Commercially available accessories (pumps, blowers, *etc.*) were used throughout the system. The fuel cells were hand built with electrodes of the type described in several publications (7, 8) by the author and his co-workers.

Improvements in electrode technology during the years 1967-1969 were not included because the earlier electrodes could not be mixed with the later ones for the sake of uniformity of the complete power plant, but it should be noted that the later electrodes would have allowed a design center of 100 A/ft^2 current density rather than 50 A/ft^2 (9).

This improvement was achieved by reversing the electrodes so that the porous nickel layer (nonwetproofed) faced the electrolyte, while the carbon faced the gas side, unobstructed and not subject to nitrogen blockage. The porous nickel served as an air blow-through barrier. However, due to the reduction in fuel cell activities at Union Carbide Corporation (mainly because no commercial application in the near future could be visualized), such electrodes found only limited use in hydrazine-air batteries built for the U. S. Army (10).

The experimental car, as it now exists, will have the role of a test vehicle in discovering any inherent maintenance problems, battery life expectancy, and establishing feasibility of further design improvements

* Electrochemical Society Active Member.

Key words: electric automobile, fuel cell operated vehicle, high energy density battery system, low pollution power source, parallel connected battery systems, saving of fossil fuels.

[1] At present, most of the commercial hydrogen is derived from fossil fuels, but this may change with the advent of nuclear power plants.

Fig. 1. Electric car powered by a hydrogen-air/lead battery hybrid power system.

as well as durability of materials and accessories. The vehicle is provided with safety features which should prevent any trouble due to accidental improper handling. The transportation rules governing compressed flammable gases have been carefully observed (11).

A photograph of the vehicle is shown in Fig. 1. The fuel cell system is mounted in the rear compartment together with all of the necessary accessories for automatic start-up and shutdown, including nitrogen purging. The lead battery is situated in the front next to the motor. For simplicity, the original four-gear shift transmission with clutch has been retained (it proved very beneficial for up-hill driving). "Gas pedal"-type speed control is achieved by field-winding switching.

The Hybrid Battery Concept Applied to an Automobile

The use of a fuel cell for vehicle propulsion poses problems relative to safe handling, short start-up time, avoidance of overloading and cell reversal, automatic controls in case of operating failures (electrolyte loss, overheating, *etc.*), and shutdown procedures.

Several of these problems disappear if a fuel cell battery is operated in parallel with a secondary battery. The start-up time can be stretched to several minutes while the equipment (or vehicle) is operated during that time from the secondary battery. Overloading is effectively prevented because the secondary battery takes over at the minimum voltage determined by the fuel cell characteristics. Figure 2 shows the principal wiring diagram of the hybrid automotive power plant. Seven 12V lead-acid batteries are connected in series (42 cells), and this bank is connected in parallel with a hydrogen-air fuel cell battery consisting of 15 eight-cell modules in series (120 cells). At low load levels, the fuel cell battery reaches a higher voltage than the lead-acid battery and is therefore able to charge the secondary battery. However, when the fuel cell battery is not in operation, it contains no hydrogen and has a far lower voltage than the lead-acid battery. The latter would now electrolyze water at the fuel cell electrodes and thereby cause wasteful and harmful operation. To prevent this, a diode is inserted into the connecting leads to permit current to flow only in one direction. This is one of the innovations permitting shutdown of the fuel cell battery and emptying of gases (and electrolyte) during nonoperating periods. This feature prolongs the lifetime of the fuel cells.

During start-up, however, hydrogen reaches the cells at different times and causes the activated cells to reverse the still inactive cells. This results in permanent damage to the "driven" or reversed cells. The reversed cells can be "righted" only by individually applying a pulse current (in the charging direction), a very time-consuming procedure. The difficulty can be avoided simply by applying the lead-acid battery voltage to the fuel cell battery (while the anode compartments are filled with nitrogen) by means of a resistor to bridge the diode during that period causing a small charge current to flow, which "polarizes" the cells in the "right" direction.

The nitrogen gas supply added to the fuel cell system to blanket the anodes when required can also be used for safety protection in cases of an emergency.

The Hydrogen-Air Fuel Cell System

Figure 3 shows the block diagram of the hydrogen-air fuel cell power plant as used in the automobile (the nitrogen supply is not shown).

The hydrogen-air battery contains 120 single H_2-air cells of the "duplex" or "bicell" construction. Eight such cells are arranged into a module. Figure 4 gives details of the construction of this basic 6V unit. The gas supply entry slits are on top of the batteries and the exit slits are on the bottom. Cross flow is desired. Plastic separators (network of fibers) represent the main flow resistance in the cell. The electrolyte enters

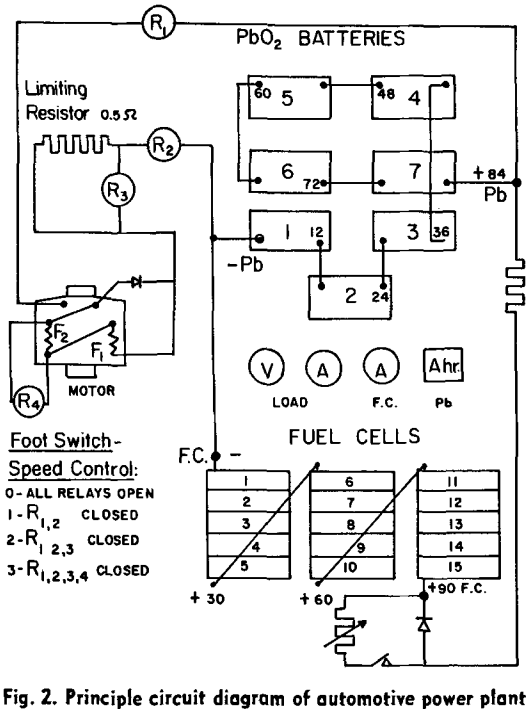

Fig. 2. Principle circuit diagram of automotive power plant

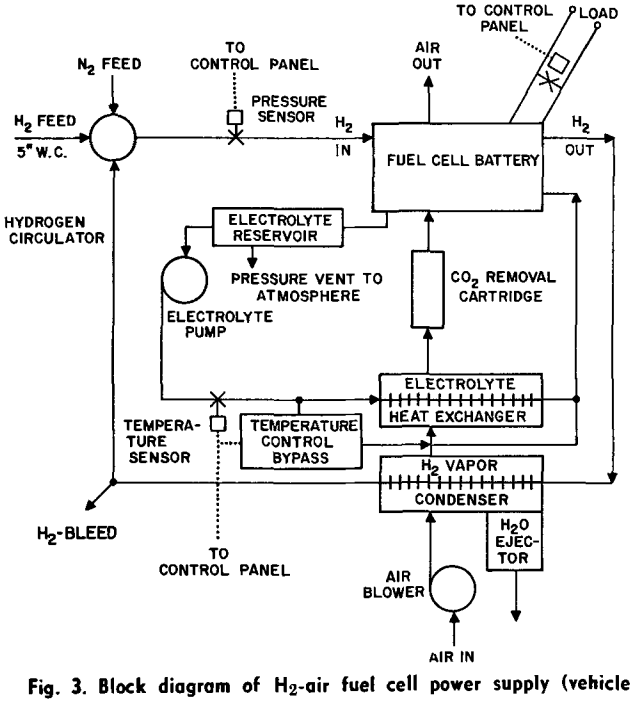

Fig. 3. Block diagram of H_2-air fuel cell power supply (vehicle concept).

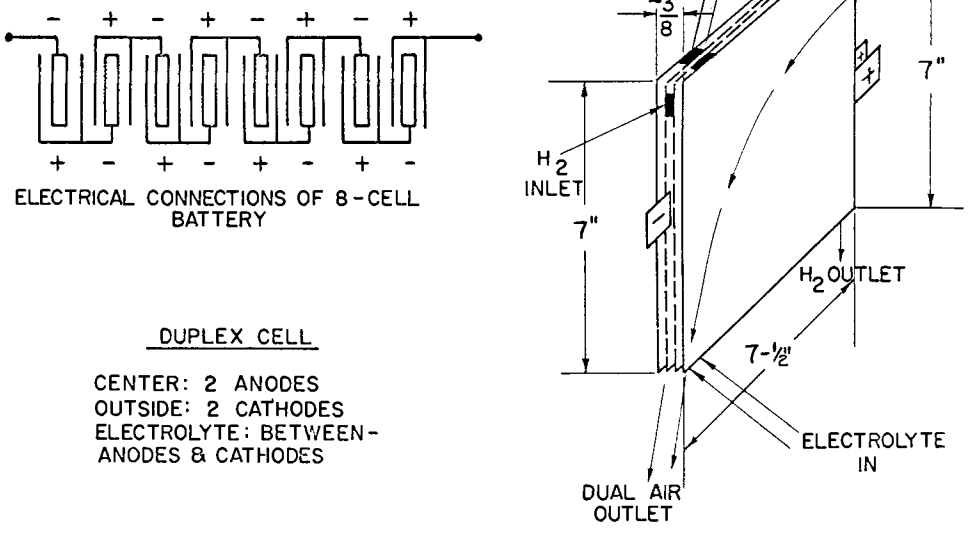

Fig. 4. Electrical connection and construction of "duplex" cell batteries.

through eight thin tubes on the bottom (not shown in Fig. 4) and leaves through two overflow tube arrangements on top. The tubing presents a relatively high electrical resistance, thus reducing parasitic current flow between cells and modules. From gas-use measurements on open circuit, it is estimated that this method of electrolyte connection reduces waste current to a level of 1-2% of the rated output. Five of such modules are connected to a "battery block," representing a power package of 2 kW at high level (100 A/ft^2) performance.

Three blocks are connected to one another by manifold networks for electrolyte, hydrogen, and air. The arrangement of the electrolyte flow pattern is critical in that it determines the magnitude of the parasitic current flow *via* the KOH conductance. The position of gas inlet and outlet ports influences the uniform distribution of the gas flow. The entire battery is mounted on a hinge so that it can be turned up to permit easy access to the bottom manifolds and electrical connections.

Figure 5 is a photograph of the modules of the hydrogen-air battery (in the turned-up position).

Figure 6 shows the battery in normal position (view from the rear of the car).

Hydrogen is stored as compressed gas in six cylinders on top of the car. The cylinders are made by the Pressed Steel Tank Company (Model No. 8RC 1500T). These lightweight tanks are made for aircraft use, scuba diving, and similar purposes.

The gas regulator and the manifold parts are standard and are fitted with the required heat and overpressure safety plugs on the cylinder valves. At the main regulator (outside the car), the pressure is reduced to 30 or 50 psig and the gas is piped through the main solenoid valve to the low-pressure regulator which delivers hydrogen at a pressure range of 2-12 in. water column (w.c.) at a high flow rate. Stainless steel traps placed after the battery collect any water before the hydrogen returns to the circulator pump; this pump is able to produce a 1 in. w.c. differential pressure across the stacks at 10-20 times the theoretical gas circulation rate at the 3 kW level (60 ft^3/hr). This amount of circulation is sufficient to remove all the water produced at 50 A/ft^2 when the battery is operating at 65°C temperature and the cooling system at 25°C.

A hydrogen-bleed value (adjustable between 0 and 5 ft^3/hr) serves as a constant inert removal device. It is usually set at from 1 to 1½ ft^3/hr hydrogen. A rapid bleed valve is activated during the start-up and shutdown sequences to exchange the battery atmosphere rapidly (N_2 for air, H_2 for N_2, and N_2 for H_2). The maximum gas flow-through rate is ~15 ft^3/min at a 10 in. w.c., which allows the exchange atmosphere to sweep the manifolds in a very short time should an emergency arise.

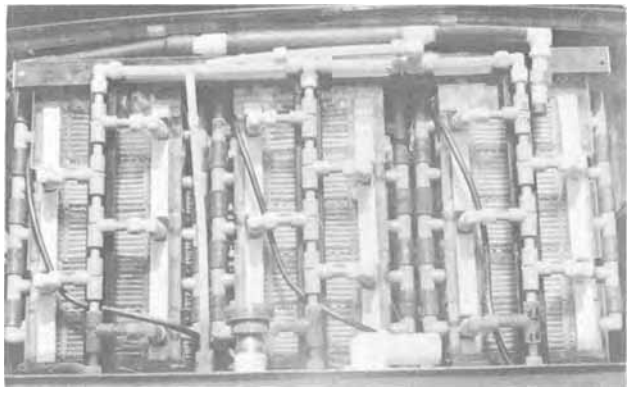

Fig. 5. Bottom view of complete 6 kW battery showing electrolyte distribution manifolds and electrical connections.

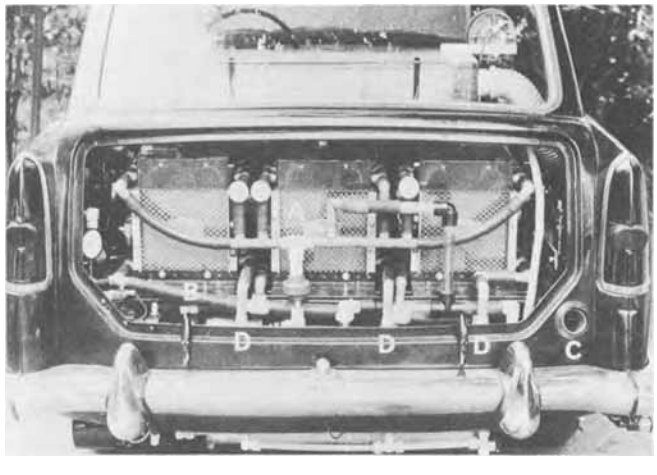

Fig. 6. Complete battery in normal position (view from rear of the car): A—electrolyte outlet manifold leading into filter, B—air outlet manifold, C—air exhaust (from water trap), D—hydrogen outlet manifold.

The hydrogen passes through a heat exchanger (water cooled) before it returns to the circulator pump (see Fig. 2). There, water vapor condenses out and passes through an automatic drain valve into the water collector tank (10 liter capacity) located under the car.

Nitrogen is stored in a cylinder mounted under the battery. The tank is of the same type as the hydrogen cylinders, but smaller (40 ft^3), and can be filled from the right rear side of the car. Nitrogen flow control is achieved by means of a solenoid valve which is energized from the dashboard sequence switch.

Air Supply System

Air is moved through the battery by a vacuum cleaner-type blower. The air intake is in the car but the blower is underneath (outside) the car to reduce noise. The pressure side of the blower is connected to the CO_2 scrubber (mounted on top of the battery) with a 3 in. flexible hose. From the CO_2 scrubber, the air is directed into three air-intake manifolds, one for each battery block. The moisture-laden air is exhausted to the outside. The blower speed is changed by depressing the footswitch in accordance with needed power requirements. With a 1 in. w.c. backpressure across the stacks, the blower can deliver 30-50 ft^3/min of air (maximum on full voltage). This is ten times the stoichiometric requirement on high level load (60A). However, to conserve the CO_2-scrubber capacity, it is normally run from lower voltage taps (24 and 32V) while still satisfying the average load of 30A and at the same time removing water vapor to such an extent that the H_2-water removal circuit has only to carry 50% of its designed capacity. This versatility assures that a satisfactory KOH normality will be maintained under all conditions (high outside temperature and high humidity are the most unfavorable conditions).

The feature of taking the air from the inside of the car and exhausting it to the outside of the car is an important safety feature because it reduces the danger of small hydrogen leaks.

The CO_2 scrubber is filled with 20 lb of soda lime; it should last at least 500 miles of average driving according to laboratory tests. Additions of Baralyme and layers of indicating Lithadsorb in the compartments close to the battery end serve as a booster and warning indicator. Intermittent driving modes seem to permit far better bed utilization than earlier continuous tests have indicated. It is interesting to note that fuel cells pick up CO_2 from the air with "inefficiency" after about 80% of the CO_2 has been removed. This becomes even more pronounced when the electrolyte dilutes under 9*N*.

The air scrubber is mounted horizontally, and five vertical buffer plates prevent bypassing of unscrubbed air when the soda lime has settled. The best particle size seems to be the 3-5 mesh range to combine low back pressure with satisfactory scrubbing.

Electrical Control Circuits

The complete start-up and shutdown procedure is sequenced by a six-position switch on the dashboard:

Position 0, System OFF

Position 1-3, STARTING

1. Open N_2 valve; bleed system rapidly.
2. Start electrolyte and air blower when pressure is sensed on the out-flow side of the fuel cells; the H_2 valve is opened; the bleed valve is also opened.
3. Connect resistor across diode; bleed reduced to small fraction of use rate.

Position 4, Normal OPERATING position of switch

All accessories are energized (but controlled by thermal switches, *etc.*)

Position 5, SHUTDOWN

De-energize everything; open N_2 valve; bleed system rapidly.

Position 6 (Same as Position 0), Fuel cell battery OFF

Since any small amount of H_2 remaining in the cells would create a reduced pressure in the anode compartments as long as the electrodes are wet and the intercell electrolyte connections are still conducting (*via* the wet manifolding), a separate negative pressure-sensitive diaphragm (−1 in. w.c.) will send nitrogen into the battery until all of the H_2 has been used up.

Control lights indicate conditions of the battery and functioning of accessories.

It is not possible to operate all circuits from the 12V accessory battery because the drain would be too high. The best solution for maintaining a separate ground is to charge the accessory battery from the fuel cell system by means of a d-c—d-c inverter with an 84-90V input and a 12-15V output.

The Lead-Acid Battery

The seven 12V batteries are all located under the hood, two in front of the motor and five above it. The batteries used were commercially available batteries manufactured by Globe Union Corporation:

Dimensions: 10¼ in. x 6¾ in. x 8¼ in. (height)
Weight: 47 lb each (329 lb total)
No. plates: 78 plates total (13 in each cell) in each battery
Capacity: 84 A-hr (20 hr rate)

Figure 7 shows a photograph of the front end of the car.

Test Results

Performance of the H_2-air battery in the laboratory.— All of the 6V modules were tested in the laboratory for at least 1 week (about 200 hr) to make sure that there were no defective cells present. If no leakage or poor intercell contacts were observed after the 5 day heat cycling (from room temperature to 70°C each day), the mechanical qualities were also considered satisfactory.

Actually, this type of battery has had a long testing history, dating back to 1966. At that time, Union Carbide Corporation tested H_2-air batteries consisting of eight Duplex cells in series, built exactly like the automobile batteries but smaller in size (4 in. x 6 in) (12).

The electrodes used in the batteries consisted of a wetproofed porous nickel layer as the backing (gas side), with a sprayed-on (plastic bonded) carbon layer on the electrolyte side (7).

The next two figures present polarization and life data for the condition that the batteries were being kept filled with electrolyte all of their life. No shut-

Fig. 7. Front-end view of the car

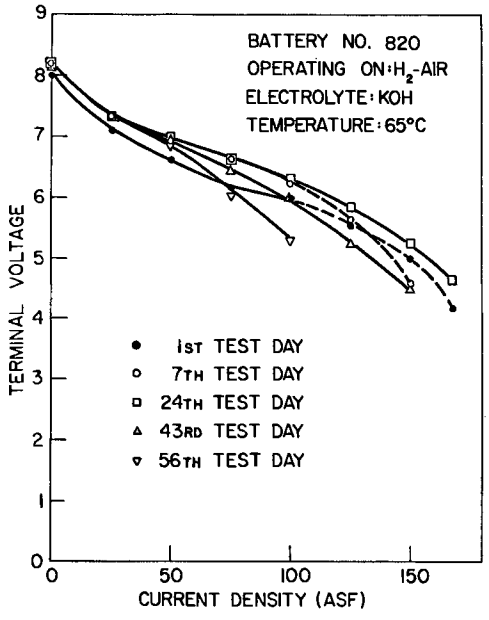

Fig. 8. Effect of aging—Battery No. 820

down procedure (as is now practiced) was used because we did not yet know of its advantages.

Figure 8 shows the performance of the 6V battery (No. 820). The effect of aging on the polarization curve should be noted.

Figure 9 gives the life history of Battery No. 820. As we now know, the capability of the battery to continue to operate after the first cell failure (after 56 days of operation) when the battery was shut down, washed with water, and restarted was very significant.

A very extensive study of water transportation as a function of gas flow, temperature, and KOH concentration was also made at that time (12). These data and others concerning mass transport and heat transfer in fuel cells (13) were very helpful in designing the automobile power plant.

Data accumulated during 1967-1969, when batteries had to be shut down on purpose (storage tests), showed that intermittent use of the batteries increased their lifetime. Note: 2000 hr continuous service is a little over 2 months; 2000 hr intermittent service may correspond to 60,000 miles driving over a three year period.

Performance of the automobile.—The hydrogen-air batteries produced over the time period 1968-1969 were washed and dried after their initial 1 week tests and were stored without any special precaution. In May 1970 the system was finished and activated for the first time as a 120 cell power plant.

Determination of polarization curves from points actually recorded during tests has been attempted in Fig. 10.

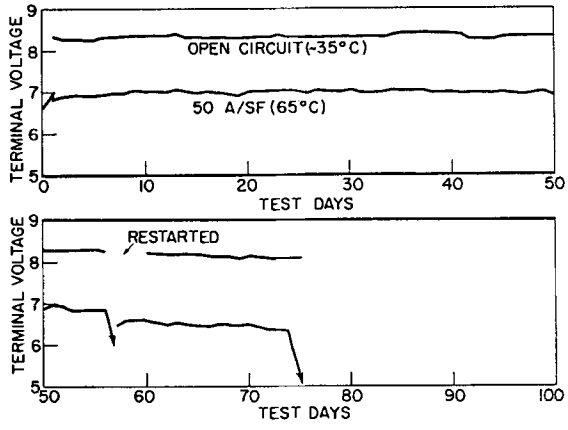

Fig. 9. Life history of Battery No. 820

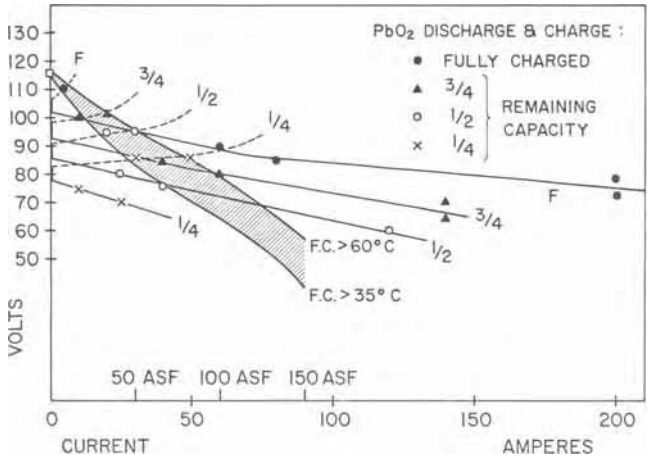

Fig. 10. Test polarization curves

Table I was compiled from instrument readings while the vehicle was moving. Road performance (acceleration and speed) and total capacity (driving range) can be readily estimated from checking its columns.

Fuel consumption.—As closely as can be estimated today, the hydrogen consumption rate is closely following that predicted (*viz.*, 1000 psi drop of tank pressure for 100 miles) for driving at mixed speeds (suburban mode). This also includes short test runs without moving the car. Since this pressure drop is about half of full pressure and the total available hydrogen volume is 660 ft^3, the figure for hydrogen consumption is therefore 330 ft^3/100 miles.

The hydrogen consumption per mile is expected to be lowest at a steady (40 mph) speed for a long uninterrupted distance. Under such conditions, about 75A

4.2	85	50	¼	0	50	

Note: 60A from fuel cell = 100 A/ft^2 current density.

current (at 80V) are required, to which the fuel cell contributes approximately 1/2 to 2/3 until the lead batteries drop below 25% remaining capacity in their state of charge. Such a situation will be encountered if more than 2 hr of continuous driving are planned. If there is then no recharge pause available, the fuel cells will have to supply nearly all of the power (6 kW).

The parasitic (electrolytic) current within the fuel cell battery can be determined from open-circuit gas consumption measurements. These are in the order of 2 ft^3/hr, which is approximately 1½% of the 100 A/ft^2 consumption of 120 ft^3/hr. The hydrogen-bleed rate (at present set at 2 ft^3/hr) adds another 1½% waste for a total of nearly 3% of the high-level output of 6 kW. The voltage of 0.95 V/cell (7.6 V/module, or 114V for the entire battery) confirms the low parasitic current flow of about 2 A/ft^2 on open circuit. Altogether, the accessories have a power consumption of about 250-300W, or nearly 4-5% of the 100 A/ft^2 output of the fuel cell battery.

Conversion efficiency.—The fuel cell battery operates at about 0.8 V/cell. This means that the electrochemical efficiency (0.8/1.23) is 60% based on $H_2 \rightarrow H_2O$ (liquid), and the thermal efficiency (83% of this) is about 50%.

Operating costs.—The figure of 330 ft^3 H_2/100 miles is only a tentatively proposed estimate for city driving. On this basis, the cost per mile of driving is ½¢/mile if we assume that the cost of hydrogen in large quantities is 30¢/lb (220 ft^3). Liquid hydrogen storage may be considered.

Hydrogen delivered in steel cylinders, of course, is more expensive (up to ten times) than hydrogen at the plant or at large filling stations. The automobile could also be operated on liquid ammonia plus a catalytic converter. The reduction in weight would also be favorable by comparison. A 15 min time limit for getting the converter on "full stream" seems technically feasible. Only one cylinder instead of six would be needed.

Secondary battery life.—Frequent deep discharge cycles are *at present* not recommended for lead-acid batteries, but considerable improvements are expected. Of course, Ni-Cd batteries would be more suitable, but the price is high.

Conclusions

The purpose of this project was to demonstrate (*a*) that an electric automobile could be powered by a fuel cell/lead-acid battery hybrid system and retain the advantages of both battery types, and (*b*) that such a system can be easily started and shut down and is no more complicated than any other assembly of batteries with such common accessories as pumps, motors, and simple electrical circuits.

These facts were demonstrated and the electric automobile showed in driving tests that it behaved essentially like the gasoline-engine-powered automobile, except that its top speed was somewhat limited.

Summarizing the pertinent energy and power density figures, the following data are listed:

Power and energy-per-weight-figures:

Fuel cell system—6 kW (at 100 A/ft^2) output; weight, 370 lb (~60 lb/kW); 33 kWhr (actual) capacity; 90 Whr/lb; efficiency of conversion, ~50%

Lead-acid batteries—16 kW peak output; weight, 330 lb (~20 lb/kW); 3.4 kWhr (actual) capacity (at 50A); 11 Whr/lb.

Manuscript received Oct. 19, 1970; revised manuscript received *ca.* Jan. 20, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

A Logarithmic Throwing Index for the Measurement of Throwing Powers

Der Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A new and simple method is presented for expressing the result of throwing power measurements of electroplating solutions in terms of a logarithmic throwing index," defined as the ratio of the logarithm of linear ratios (L) to that of the metal distribution ratio (M). Graphically it is the reciprocal of the slope of a straight line obtained when M is plotted against L on log-log coordinates. The limitation of a linear throwing index method found in the literature and the advantages of the method proposed here are discussed with published results from use of the Haring-Blum cells.

In electroplating, throwing power is a measure of the extent to which a plating bath deposits a coating of uniform thickness on different parts of a cathode surface. For practical purposes, a simple and direct measurement, allowing rapid comparison of various plating solutions and operating conditions, is the use of a Haring-Blum cell (1). This device is a rectangular electrolytic cell having two metal cathodes of equal size placed vertically at either end. Between the cathodes is a flat, perforated anode having different distances from each cathode. The ratio of the anode distance from the far cathode to that from the near cathode is called the linear (or primary current distribution) ratio, L; the ratio of the rate of metal deposition on the near cathode to that on the far cathode is called the metal distribution ratio, M. The throwing power of a plating bath at a given operating condition is normally calculated from one of the following formulas:

Haring-Blum equation (1)

$$\text{Throwing power} = \frac{L - M}{L} \times 100 \qquad [1]$$

Heatley-Pan equation (2, 3)

$$\text{Throwing efficiency} = \frac{L - M}{L - 1} \times 100 \qquad [2]$$

Field equation (4)

$$\text{Throwing power (BSI)} = \frac{L - M}{L + M - 2} \times 100 \qquad [3]$$

Objection against using these equations has been raised by Jelinek and David (5) for the following reasons: first, the use of different equations would result in different numerical values for a plating bath at constant operating conditions; and second, the throwing powers computed by these equations vary appreciably with linear ratios. It is, therefore, desirable to have a single number that characterizes the throwing power of a bath over a range of linear ratios.

Jelinek and David have suggested a throwing index (5) obtained by plotting the metal distribution ratio *vs.* linear ratio on arithmetic coordinates. A straight line passing a common point ($L = 1$, $M = 1$) is drawn through the data points, and the reciprocal of the gradient of the line is taken as the throwing index. In this way a single value is obtained for a range of linear ratios which can be used to show variations of throwing power with changes in current density, temperature, and bath compositions. Since the method implies that there is a linear relationship between the metal distribution ratio and the linear ratio, a throwing index obtained this way will be called the linear throwing index in this paper. As will be shown, the linear throwing index, however, has inherent shortcomings.

This paper presents a new and simple method in terms of the logarithmic throwing index, which has all the advantages of the linear throwing index, and gives better descriptions of the characteristics of throwing power over a wide range of linear ratios.

Limitation of Linear Throwing Index

Since the linear throwing index is defined as the reciprocal of the slope of a straight line passing through the common point ($L = 1$, $M = 1$), and the experimental data in the L-M plot, there should exist the following relationship between the metal distribution and the linear ratios

$$M = 1 + \frac{1}{a}(L - 1) \qquad [4]$$

where a is the linear throwing index of a bath at constant plating conditions. Substituting this equation into the Heatley-Pan equation for the "throwing efficiency," one has

$$\text{Throwing efficiency} = \frac{L - 1 - \frac{1}{a}(L - 1)}{L - 1} \times 100$$

$$= \frac{(L - 1)\left(1 - \frac{1}{a}\right)}{L - 1} \times 100$$

$$= \left(1 - \frac{1}{a}\right) \times 100 = \text{const}$$

Similarly, by putting Eq. [4] in place of M in the Field equation, one can show that

$$\text{Throwing power (BSI)} = \frac{1 - 1/a}{1 + 1/a} \times 100 = \text{const}$$

Thus, the use of the linear throwing index results in a constant throwing efficiency and a constant "throwing power (BSI)" independent of linear ratios. This contradicts the experimental evidence, since the throwing power measurements expressed by the Heatley-Pan and the Field equations vary with linear ratios (3, 6). Apparently, the linear correlation given in Eq. [4] is not sufficient to describe the variation in the metal distribution ratios with changing linear ratios. A better relationship is therefore needed.

Logarithmic Throwing Index

In this laboratory we have made a regressional analysis for the throwing power data taken from the works

* Electrochemical Society Active Member.

Key words: throwing power, throwing index, logarithmic throwing index.

Table I. List of simple relationships that would give M = 1, when L = 1

Binomial	$M = 1 + \frac{1}{\alpha}(L-1)^{\beta}$
Exponential	$M = \exp\left\{\frac{1}{\alpha}(L-1)\right\}$
Linear	$M = 1 + \frac{1}{\alpha}(L-1)$
Parabolic	$M = 1 = \frac{1}{\alpha}(L-1) + \beta(L-1)^2$
Power	$M = L^{1/\alpha}$

Note: α and β are the regression coefficients.

of Pan (3), Jelinek and David (5), Gardam (6), and Wesley and Roehl (7). A number of functions that would give $M = 1$ when L equals unity were tested with the help of a digital computer. Table I is a partial list of the functions.

It is found that among the functions tested, the following relationship gives the best fit to the experimental data and still retains the characteristics of a single valued parameter for the measurement of throwing powers:

$$M = L^{1/A} \qquad [5]$$

The coefficient, A, in the exponent is a constant for a plating bath at constant operating conditions and will be called the logarithmic throwing index.

Accordingly, a plot of log M *vs.* log L should result in a straight line passing through the origin (0, 0). The logarithmic throwing index can be evaluated directly by taking the reciprocal of its slope. A solution with ideal throwing power would produce a horizontal line at log $M = 0$ and would therefore have a value of logarithmic throwing index equal to infinity. On the other hand, a solution with extremely poor throwing characteristics would give a vertical line at log $L = 0$, and its logarithmic throwing index equals zero.

To show the validity of this method, some of the experimental data are plotted in a log-log fashion as shown in Fig. 1. It is seen that Eq. [5] holds true for a wide variety of plating baths. Table II lists values of the logarithmic throwing index calculated from the

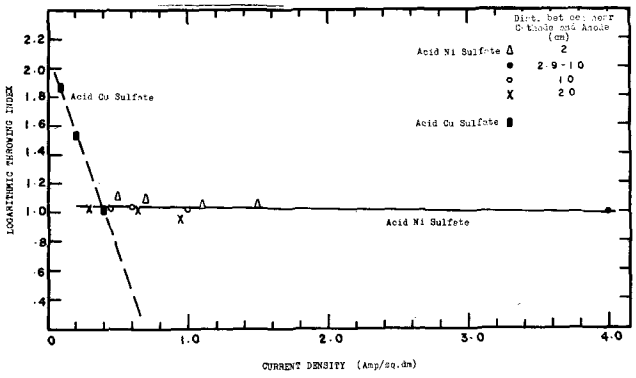

Fig. 2. Effect of current density on the logarithmic throwing index.

published results (3, 5-7) by means of regressional analysis of the linear transformation of Eq. [5]. In Fig. 2, the logarithmic throwing index of two baths in Table II is plotted against plating current densities. The dash (acid Cu sulfate) and the solid (acid Ni sulfate) curves are the regressional lines showing the tendency for the logarithmic throwing index to decrease with increasing current density.

For comparison, values of linear throwing index computed from the same data by means of regressional analysis of Eq. [4] are also given in Table II. Some of the linear and the logarithmic indexes listed are then used to calculate throwing powers in terms of Eq. [1]-[3] as functions of linear ratios. The results are compared with the values computed from the original data of metal distribution measurements. Such comparisons are shown in Fig. 3-5 for Cd-cyanide, acid-Cu-sulfate, acid-Ni-sulfate, and acid-Zn-sulfate baths. The dotted lines in the figures are the values of throwing powers calculated by replacing M in its appropriate equations with the linear throwing index and its linear relationship, Eq. [4]. The solid lines are computed by substituting into the equations, the logarithmic throwing index and Eq. [5]. The original data are indicated by the symbols ○, □, x, and △. It is seen that the calculation agrees with the previous discussion in which the use of linear throwing index would lead to a constant throwing efficiency (Fig. 4) and a constant throwing

for the results expressed in terms of the Haring-Blum equation, which has thus far been omitted from the discussion, the logarithmic throwing index describes the experimental data better than the linear throwing index (Fig. 3).

Conclusions

Based on the previous discussion, it can be concluded that the logarithmic throwing index is a better tool for expressing the results of throwing power measurements of the Haring-Blum cells. For practical electroplating studies, it can be conveniently computed (by taking common logarithms on both sides of Eq. [5] from

$$\text{Logarithmic throwing index } (A) = \frac{\log L}{\log M}$$

If several experimental points are made, an average value can be assigned to a plating bath to reduce the experimental error. In this way only a single number is obtained, which represents the characteristics of a plating solution at constant operating conditions and can be used to indicate the variation of throwing powers with changes in bath temperature, composition, current density, etc.

The method is proposed principally as an empirical tool to minimize the experimental effort required for electroplating studies. It is felt that further theoretical study is necessary to clarify why the throwing power of plating baths follows the logarithmic fashion as suggested by Eq. [5].

ABSTRACT

In the fabrication of surface wave devices, standard photoresist-chemical etching techniques often provide a very low yield even at moderate resolutions, frequently cause a degradation of the substrate finish, and in many cases are incompatible with substrates of interest. A photolithographic technique is described in which metalizing is done after a photoresist image is produced on the substrate, thereby circumventing most of the problems inherent in chemical etching. It is shown by means of electron micrographs of photoresist profiles that intimate mask-substrate contact is essential. Devices with line widths of 1 μm can be produced with high yield.

This paper describes a technique of photolithography which is especially suited to the fabrication of surface elastic wave devices. In contrast to the usual technique of producing a photoresist image on a thin metallic film and etching the unprotected metal either chemically or by ion bombardment, the present technique produces the desired pattern by evaporation of the metal onto a photoresist image prepared directly on the substrate surface. The unwanted metal is separated when the photoresist is subsequently removed by organic solvents. This technique, which is depicted schematically

Key words: photoresist, surface waves, ultrasonics, photolithography, piezoelectric, scanning electron microscope, transducers.

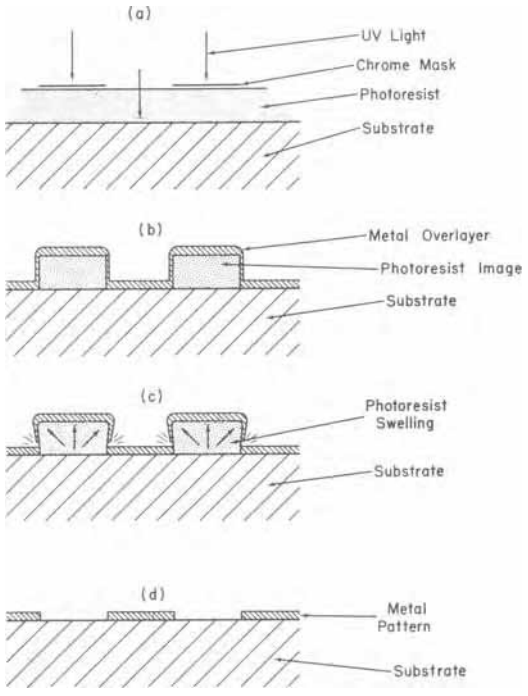

Fig. 1. Schematic representation of the steps involved in the photolithographic process.

in Fig. 1, has some distinct advantages whenever substrates present special materials processing problems, or when high resolution is required. In concept it is not new; however, published accounts either provide insufficient details (1, 2), or are not relevant to surface wave devices (3, 4), or both. In this paper, we describe the technique in detail and illustrate, by means of electron micrographs of photoresist profiles, certain critical aspects.

Photolithographic materials and techniques originally developed for use in chemical micromilling and printed-circuit board fabrication have been greatly refined and improved for use in microelectronics. However, the techniques used in microelectronics are predicated on the availability of low-cost inert substrates and selective etches. Thin film microelectronic circuits are generally formed on substrates such as ceramics or glass, and the resistive and conductive films are etched using chemicals that will attack one film but not the other and will not attack the substrate. Similarly, silicon device technology requires etches that will attack the interconnect metalization but not the oxide or the silicon, and etches that will attack the oxide but not the silicon, and *vice versa*. For microelectronic circuits involving complex patterns at line widths below about 15 μm, the availability of large numbers of essentially identical substrates at low cost is an important factor in obtaining a good yield of devices through standard photoresist-chemical etching techniques. Good yield generally requires that all the crucial process parameters (resist thickness, exposure time, baking temperature, etchant concentration, etching times and agitation, *etc.*) be optimized, and this in turn implies that many substrates are processed and many failures are discarded.

In surface elastic wave studies (5-7), typical substrates are materials such as lithium niobate, bismuth germanium oxide, lithium iodate, zinc oxide, cadmium sulfide, quartz, gallium arsenide, indium antimonide, YAG, and YIG. They are chosen for their desirable piezoelectric or acoustic loss properties, or as interesting piezoelectric semiconductors. They are specially grown, cut, and oriented (sometimes to 1/10 deg) and polished to a high tolerance. By the time a substrate is ready to be made into a device by photolithographic techniques, its preparation represents a considerable investment of time, effort, and expense. In contrast to the inexpensive and mass-produced substrates of the microelectronics field, surface wave substrates cannot generally be discarded because of a failure in the photolithographic process; they must be cleaned and reprocessed. It has been observed in this laboratory that the optically polished surfaces of many of the above-mentioned substrates are especially susceptible to degradation from such repeated processing. Scratches and pits present or nascent on the surface become augmented or revealed by the sequence of metalizing followed by chemical etching, thus requiring that the substrate be polished anew. Because optically polished surfaces do not generally have as smooth a finish as do chemically polished or glazed surfaces, one finds that surface wave device fabrication is troubled with special problems of unpredictable and nonuniform etching. Even if all process parameters are optimized, the yield of surface wave devices by chemical etching is quite low and goes down rapidly with an increase in pattern complexity and resolution. As a rule of thumb, for metal thicknesses in the 1000-2000Å range, chemical etching yields are unacceptably low for patterns involving a large number of lines and spaces of 5 μm or less in width. Sputter etching (8, 9) is capable of good yield at higher resolution but is fraught with other problems. It is difficult to control or monitor, it risks sputter etching of the substrate, and it sometimes makes the photoresist difficult to remove.

Many substrates with desirable acoustic or piezoelectric properties are incompatible with the usual metal etchants and photoresist stripping agents, and this incompatibility is intensified when such materials are in the form of polycrystalline thin films. Thus, extensive chemical compatibility tests must sometimes be performed for each desired metal-substrate combination. The technique described here does not expose the substrate to the hostile environment of chemical etching and is thus better suited for chemically reactive or easily degraded surfaces.

In surface wave work, one is frequently confronted with the problem of producing a device on a "one of a kind" substrate, a very demanding requirement for chemical etching even if chemical compatibility is no problem. The process described here provides a surprisingly high device yield in this "one of a kind" situation, even for patterns involving line widths of 1 μm.

Processing Techniques and Discussion

Figure 1 illustrates the steps of the technique. Obviously, the key element is to produce a distinct break in the metal film at the point where it leaves the substrate and begins to form a bridge over the photoresist relief pattern. To insure this, we have found that it is essential to produce a sharp vertical profile in the photoresist and to carry out the metal deposition so that atoms impinge at near normal incidence. In this way, the metal on the sides of the photoresist relief patterns is considerably thinner than the metal film on the substrate and the top of the photoresist, and the required removal of unwanted metal is readily effected by swelling the photoresist in an organic solvent.

The character of a photoresist profile depends critically on the exposure conditions, primarily on the avoidance of diffraction effects and to a lesser extent on the exposure time. In all cases, we have used contact printing rather than projection exposure (3) because of the critical focusing problems inherent in the latter and the convenience, reproducibility, and economy inherent in the former. Our masks are chromium images on Corning 0211 glass, approximately 0.2 mm thick, which are made by contact printing from 6.4 mm thick master plates. The master plates are exposed on a Model 1795[2] Photorepeater (9). In contact printing, the mask is pressed onto a substrate's photoresist coating using mechanical probes as is depicted in Fig. 2.

[2] D. W. Mann Company, Burlington, Massachusetts.

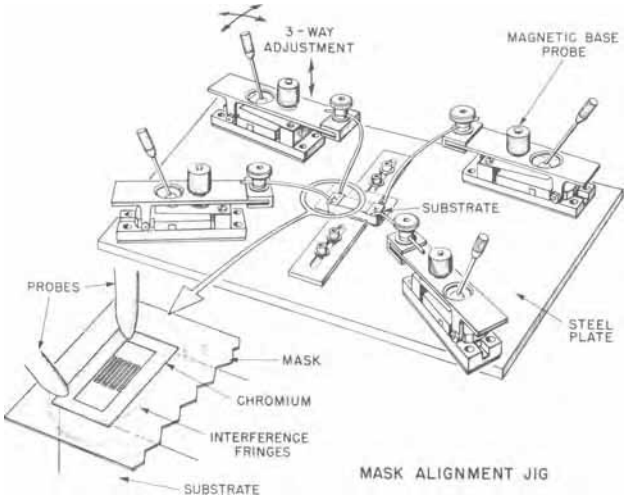

Fig. 2. Fixture for mask alignment and obtaining intimate contact.

The thin glass is quite flexible and readily deforms to the contours of the substrate or around the occasional dust particle. This work is done under yellow safelights and, when the separation between the mask and the photoresist film is reduced below about 2 μm, strong interference fringes are observed. It is a fairly simple matter to adjust the forces applied and the positions of the probes to achieve intimate or "optical" contact in the areas of the patterns. In practice, "optical contact" can be achieved quite easily over large areas without risk of damaging the substrate, the mask, or the photoresist film. The bond between mask and substrate which frequently results can be broken either by immersion in water or by peeling back the flexible mask.

Figure 3 shows that sharp vertical profiles, and in some cases undercut profiles, are obtained with the positive photoresists AZ1350[3] and AZ1350H[3] whenever intimate contact is provided. On the other hand, a marked rounding occurs even for relatively small mask-to-substrate separation. Such rounding usually makes it impossible to remove the metal bridge unless perhaps the substrate is subjected to high-power ultrasonic agitation for long periods of time, a treatment which usually damages surface wave substrates and degrades metal structures. Rounding of the profile of a photoresist pattern is of little or no concern in the case where it would be used as a chemical etching resist, and it is for this reason that the usual practice of photolithography in microelectronics does not demand such intimate contact except in the case of 1μ resolution structures (9, 10). It is noteworthy that intimate contact is necessary regardless of the resolution of the desired pattern, and this plus the care necessary to obtain intimate contact simultaneously with pattern alignment can be viewed as disadvantages of the technique. However, our experience is that these disadvantages are not significant, particularly when only a small number of prototype laboratory devices is desired.

The process did not work with negative photoresists, and this failure is attributed to a rounding of the photoresist profile. In fact, the very exposure conditions that in the case of a positive photoresist lead to the ideal undercut profile lead in the case of the negative photoresist to rounding. Moreover, since the mask must be in intimate contact with the photoresist film, standing waves are set up in the film even for nonmonochromatic exposure sources. At the nodal planes, there is insufficient exposure to cross-link the photoresist, and the subsequent development causes sections of the film to float away and redeposit elsewhere on the substrate. This phenomenon has been discussed by Altman and Schmitt for the case of projection exposure (11).

[3] Shipley Company, Incorporated, Newton, Massachusetts.

Metal deposition is carried out in an electron beam evaporator at a source-to-substrate distance of about 44 cm in order to insure that evaporated atoms arrive at the substrate at near-normal incidence. We have had some success with standard thermal evaporation from extended sources at about 20 cm source-to-substrate distance, but generally the device yield is considerably smaller than with the electron beam unit, especially for the higher resolution devices. To verify the assertion that the deposited metal must arrive at the substrate at near normal incidence, experiments were conducted in which an rf sputtering unit substituted for the electron beam evaporator. It was found that, even in the case of a very thin metal film (300-500Å of chromium), it was impossible to separate away thoroughly the unwanted metal by solvent techniques.

At the present time, in this laboratory the photolithographic process described in this paper is used for all surface wave device fabrication irrespective of pattern resolution or substrate material. For the production of interdigital electrode transducers in the range of line widths from 10 to 1 μm for $LiNbO_3$ delay lines, the following procedure is used. The substrates are thoroughly cleaned, the final rinse being in 12-18 megohm resistivity water, and dried in a jet of filtered dry nitrogen. Next, they are spin-coated with AZ1350 positive photoresist to a thickness of about 5000Å, or AZ1350H to a thickness of about 20,000Å, the choice depending on pattern resolution and the metal thickness desired. AZ1350H works quite well, at least down to 2 μm line widths. From Fig. 3, it can be readily inferred that the deposited metal thickness should not exceed about 1/3 to 1/2 of the photoresist height. Although we have not explored experimentally the limits on the metal thickness, it seems reasonable that AZ1350H would permit thicker metal films than AZ1350.

After baking in an air oven at 80°C for 10 min, the desired pattern is produced in the photoresist by contact printing using a collimated high-pressure mercury lamp and the 0.2 mm thick chromium-on-glass mask. The photoresist is developed in an aerated spray of AZ Developer for 30 sec using a nitrogen-powered artist's air brush and the recommended dilution of 1 to 1 with water. Substrates are then rinsed in high-purity water and blown dry with filtered dry nitrogen. At this point, the photoresist pattern can be inspected under a microscope for possible resist defects or residues in the open areas. If desired, the photoresist can be removed using acetone and the substrate reprocessed without fear of degradation of the surface finish. This is seldom necessary.

The photoresist is not baked after pattern development because it is not required by the process and runs the risk of rounding the photoresist profile through plastic flow. For the same reason, the substrates are not heated in the electron beam evaporator prior to the metal film deposition. The softening point of AZ1350 is about 130°C so some preheating or glow discharge cleaning to enhance metal adhesion is permissible. We have chosen to forego these in favor of double-layer metal films, the first chosen for its superior adhesion. The electron beam apparatus conveniently permits the sequential evaporation. For most surface wave devices, we deposit 300Å of titanium or chromium and 1000 to 2000Å of aluminum, the thicknesses being precisely monitored on a quartz crystal oscillator. We have substituted gold for the aluminum, on occasion used aluminum without the interface film, and in fabricating the flexible masks by this process used films of chromium or titanium 500-1000Å thick. The process works equally well for these cases. Probably any metal or combination which satisfies adhesion requirements can be used, but it has been speculated that the brittleness of the metal film and stress at its junction with the photoresist relief structure may be important factors.

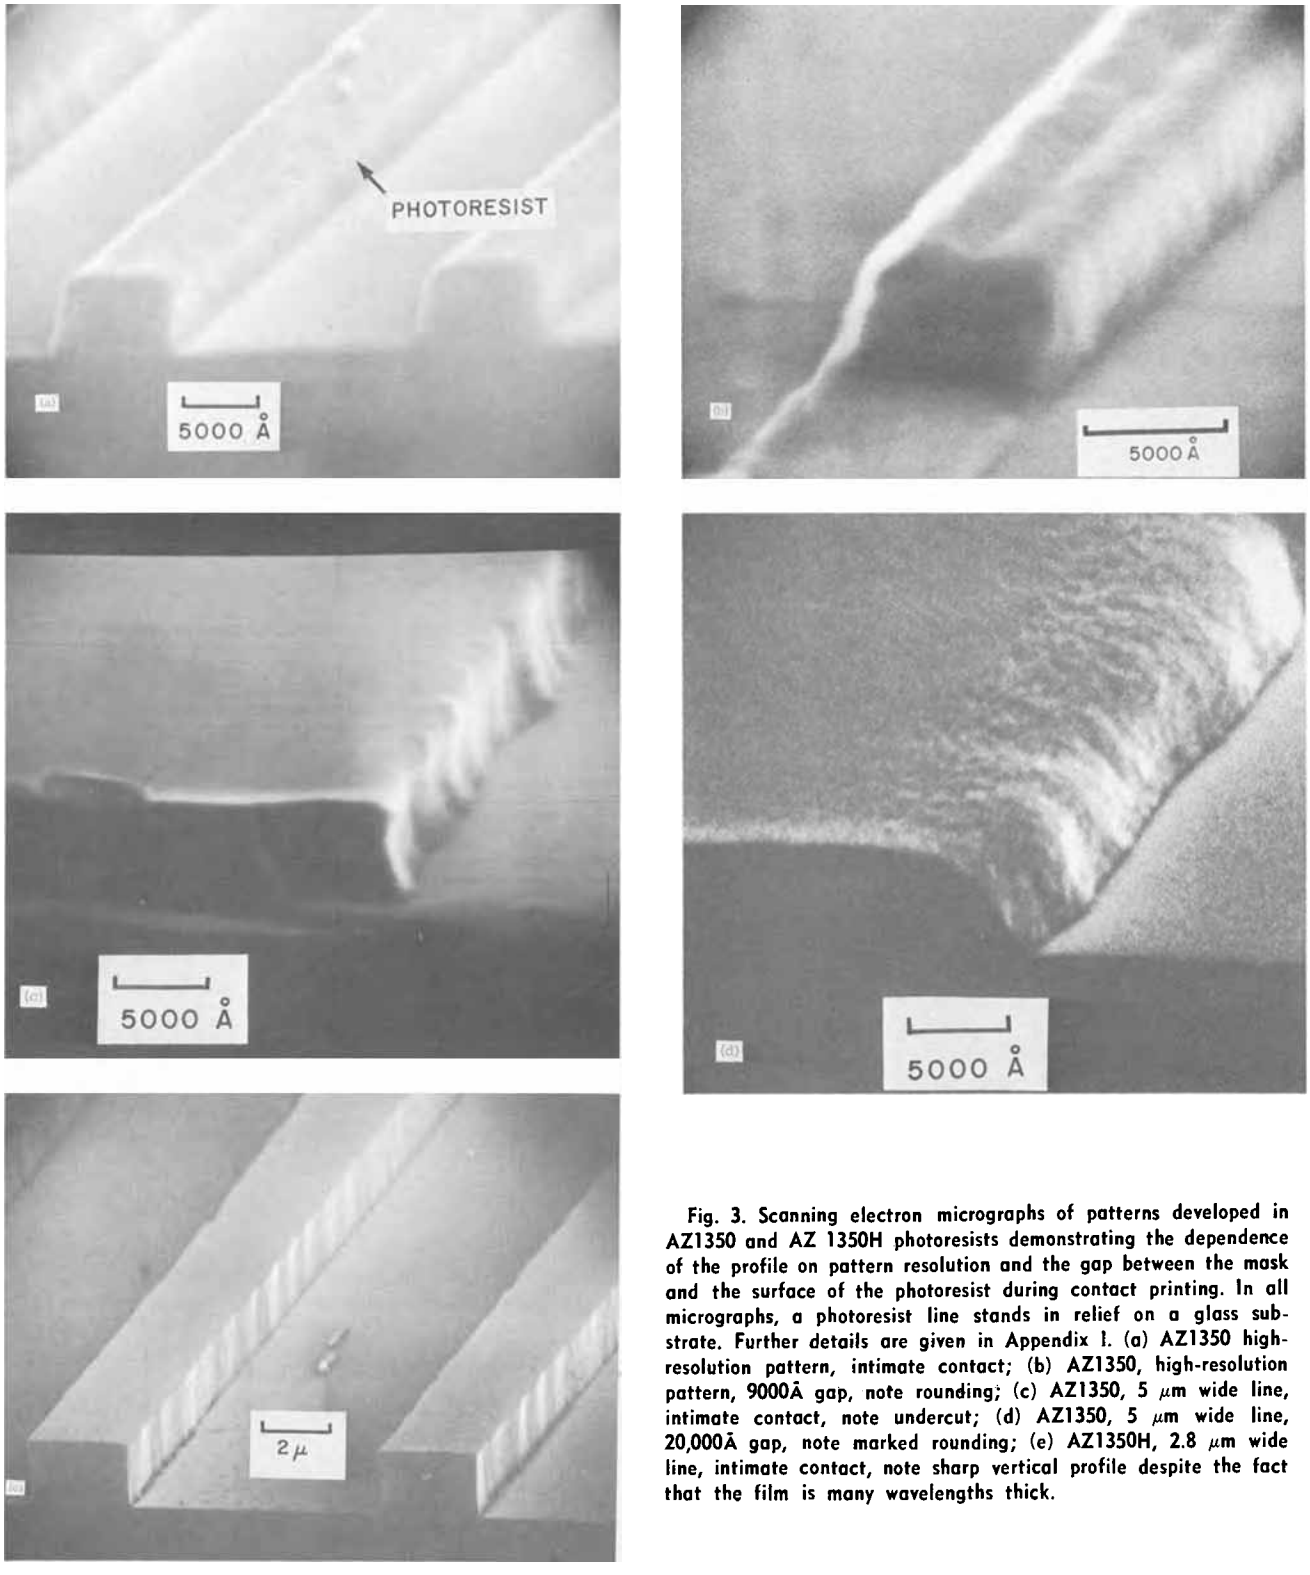

Fig. 3. Scanning electron micrographs of patterns developed in AZ1350 and AZ 1350H photoresists demonstrating the dependence of the profile on pattern resolution and the gap between the mask and the surface of the photoresist during contact printing. In all micrographs, a photoresist line stands in relief on a glass substrate. Further details are given in Appendix I. (a) AZ1350 high-resolution pattern, intimate contact; (b) AZ1350, high-resolution pattern, 9000Å gap, note rounding; (c) AZ1350, 5 μm wide line, intimate contact, note undercut; (d) AZ1350, 5 μm wide line, 20,000Å gap, note marked rounding; (e) AZ1350H, 2.8 μm wide line, intimate contact, note sharp vertical profile despite the fact that the film is many wavelengths thick.

After metal deposition, it remains only to swell the photoresist and remove the unwanted metal from the substrate. An aerated acetone spray was found to be most effective especially for 1μ resolution periodic structures. However, this is extremely hazardous because of the risk of explosion or fire and must be carried out with appropriate safety precautions.

When the procedure described above is followed, metal patterns are obtained which exhibit very nearly the same degree of edge acuity as the photoresist pattern. Figure 4 shows an interdigital electrode transducer with 1¼ μm line widths.

For substrates which have naturally rough or pitted surfaces, such as the sintered piezoelectric ceramics and some thin films, the technique described is especially valuable. There seems to be very little degradation of the edge acuity of metal patterns because of surface roughness. In contrast, when chemical etching is used on such substrates, ragged edges and discontinuities are frequently encountered.

The photolithographic technique described is similar in principle to the electron beam fabrication technique developed by Hatzakis and Broers (12, 13). They showed that an undercut profile was obtained with an electron degradable polymer film as a natural consequence of electron scattering, and that there was no continuity between evaporated metal on the substrate

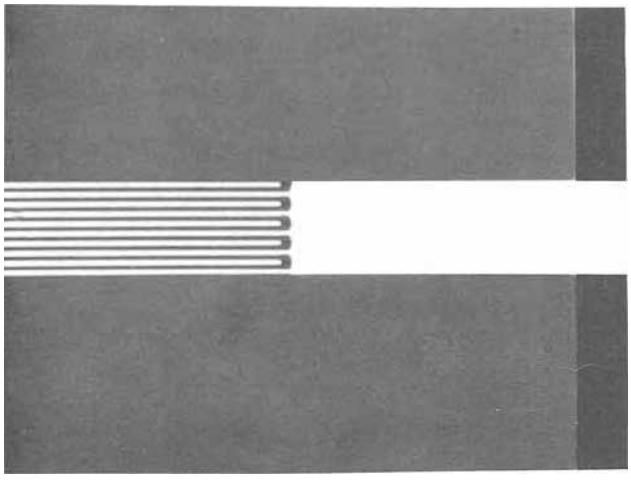

Fig. 4. Interdigital electrode transducer with 2½ μm separation between centerlines of adjacent fingers.

and metal on top of the polymer film. Our work indicates that photoresists present a more difficult problem.

Acknowledgments

The authors wish to thank R. Gray and R. Reinhard for their assistance in preparing the electron beam evaporated films.

APPENDIX I

A series of experiments were conducted on the influence of exposure time, mask-substrate separation, and pattern resolution on photoresist profiles, and the effect this had on the success or failure of the photolithographic process described in this paper. Aluminosilicate glass plates 0.15 cm thick which had been scribed on the back side were chosen as test substrates. Photoresist patterns were developed on the front sides of the glass plates opposite the scribe lines. The application of a relatively small flexural force caused the glass and the photoresist to fracture cleanly along the scribe line. Two types of interdigital electrode transducer patterns were used as masks for the experiments. Both patterns had a total of 14 fingers. The distance between centerlines of adjacent fingers was 10 μm for one pattern and 2½ μm for the other.

After coating the substrates with photoresist and baking them, the interdigital electrode patterns were exposed and developed on the substrate. The placement of the patterns was such that, when the plates were fractured in two, each half contained half of the interdigital electrode pattern. One half of the original glass plate was coated with approximately 200Å of gold so that it could be inspected in a scanning electron microscope. The other half was coated with 300Å of chromium and 1000Å of aluminum in the electron beam evaporator and then processed to remove the unwanted metal.

The exposure time and the separation between mask and substrate were varied over wide ranges, the latter being determined from the interference fringes. Referring back to Fig. 3, metal patterns with extremely sharp edge acuity, free of breaks or shorts between adjacent lines, were obtained with the other halves of the substrates in Fig. 3(a), (c), and (e). With the substrates corresponding to 3(b) and 3(d), it was impossible to separate away the unwanted metal. The rounded profile resulted in a continuous metal bridge over the photoresist. Obviously, the intimacy of mask-substrate contact is the essential element.

The range of acceptable exposure times is quite broad. We found that the threshold of complete exposure could be exceeded in many cases by a factor of 2 without any deleterious effects.

On the Czochralski Growth of GaP[1]

E. A. Miller, L. R. Weisberg,* and W. K. Liebmann[2]

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

A high-pressure, magnetic Czochralski apparatus was built for the growth of GaP. Various operating problems were successfully overcome, such as seed-holder vibrations, poor visibility, explosions, control of solid-liquid interface shape, efficient coupling of rf power into the melt, and correcton of large temperature gradients. Experiments were carried out demonstrating the large effects of gaseous pressure on the temperature gradients. At 35-atm pressure, the autoclave behaved as if it were filled with a liquid and not a gas, both with respect to visibility and heat flow. Coarse-grained polycrystalline ingots were grown, with grains limited in size to 1 cm^3 because of spurious nucleation of new grains.

The utilization of the liquid encapsulation technique has considerably simplified the Czochralski growth of GaP (1). Prior to this, its high melting point (1470°C) and dissociation pressure (35 atm) (2) had made the growth of large single crystals a very difficult task. Several years ago (3), we had carried out experiments using the magnetic Czochralski technique (4) for GaP in an autoclave, which resulted in the preparation of coarse-grained polycrystalline ingots, with grains as large as 1 cm^3. This work should be of interest to workers in this field for three reasons.

Key words: gallium phosphide, crystal growth, high-pressure growth, Czochralski growth.

First, the liquid encapsulation is not necessarily a universal technique, since compounds might exist where suitable liquid escapsulants cannot be found. For such materials, the magnetic Czochralski technique would be preferred. Second, the liquid encapsulation technique suffers in that the volatile species, here phosphorus, continually escapes from the melt, which can cause a continual change in stoichiometry. The magnetic Czochralski technique does not have this difficulty. Third, results found here can give further insight to crystal growth under high pressure, including the liquid encapsulation technique.

For people who are accustomed to crystal growth under atmospheric pressure, two main problems are encountered at 35 atm pressure: poor visibility due to convection effects, and unusual temperature gradients. Both of these problems can be "visualized" by assuming that the autoclave is filled with a liquid and not a gas. Data are given below concerning these and other problems and methods are presented to avoid them.

Experimental Apparatus

The apparatus was a standard magnetic Czochralski growth system operating within a autoclave, as shown in Fig. 1. The autoclave design was based on similar units used by Fischer (5), and was actually a predecessor of the autoclave shown by Fischer in his Fig. 10. The autoclave is divided into three sections. The crucible containing the GaP melt and the rf heating coil are located in the bottom section. The rf leads are introduced into the autoclave through a coaxial high-pressure seal which is electrically insulated from the autoclave so that, during operation, the autoclave can be grounded. The inert gas is supplied to the apparatus through a high-pressure valve. The magnet assembly for the control of the seed holder motion is located in the upper part of the autoclave. The center section contains the viewing port, which is aimed into the center of the crucible, and lines up with the viewing port on the quartz ampoule. The drive mechanism for the vertical and rotational motions of the magnets is mounted directly on top of the autoclave, and the pulling rod passes through a multiple o-ring seal. There is also a pressure safety release valve on the top of the autoclave. The walls and the lid of the autoclave are watercooled. All the controls for the furnaces and for the seed holder motion are located in a central panel which is not shown in the figure.

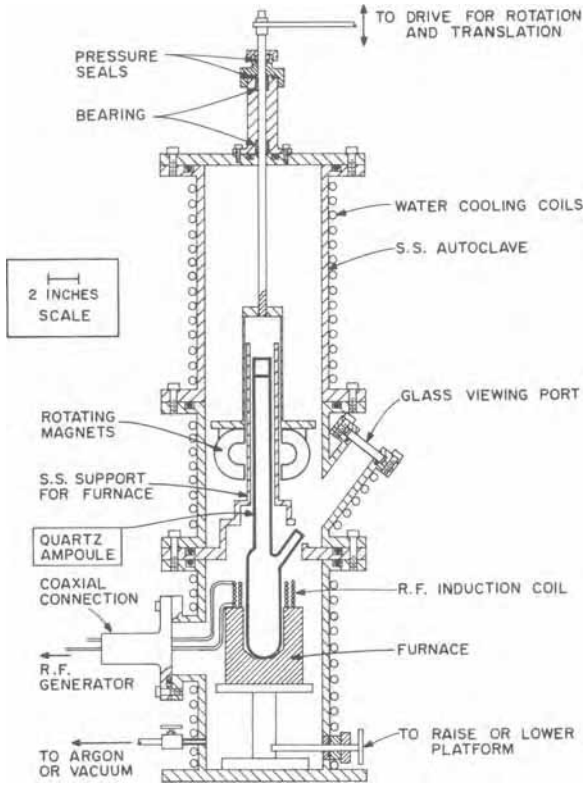

Fig. 1. Cross-sectional view of the high-pressure, magnetic Czochralski apparatus. S.S. denotes stainless steel.

Figure 1 also shows the quartz growth ampoule in the center of the autoclave, which is supported and held in position by a stainless steel piece. This support also divides the whole container into separate sections to reduce convection currents. The phosphorus reservoir is located at the bottom of the growth ampoule, and is surrounded by a furnace. Thermocouples are located at various points for temperature control. The upper section of the growth ampoule is kept at a temperature exceeding the condensation temperature of the phosphorus.

Four permanent magnets are suspended from a rod passing through the top of the autoclave, and these magnets couple to Permendur pieces within the seed holder. The weight of the seed holder is approximately 200g. The driving mechanism for the magnets is located outside the autoclave, providing a constant rotation of 16 rpm while the pulling rate is variable between 0 and 10 mm min^{-1} in a continuous fashion. The autoclave can withstand at least 60 atm internal pressure, and is also vacuum tight.

The rf generator was a 10 kW, 450 kHz unit, manufactured by the Lepel Company.

To vacuum seal the growth ampoule, a special ampoule construction was used with a side arm to contain the small lumps of red phosphorus. This allowed the entire ampoule to be vacuum baked at 600°C, including the gallium, without heating the phosphorus. Subsequent to bake-out, and without breaking the vacuum, the phosphorus was moved from the side arm into the ampoule. The ampoule was then sealed under vacuum. Directly prior to growth, the GaP was synthesized in the crucible, so that no separate synthesis step was required. The amount of phosphorus was calculated so that, during operation, all of the phosphorus was in the vapor form of P_4 molecules, which simplified determination and control of the phosphorus vapor.

Attempts were made to roughly balance the phosphorus pressure within the ampoule and the argon pressure surrounding the ampoule. However, pressure was usually maintained a few atmospheres above the phosphorus pressure within the ampoule, since it was found in separate tests that well-designed quartz ampoules could withstand implosion up to at least 40 atm of excess external pressure.

Results

Seed holder vibration.—The design of the quartz seed holder (6) is shown in Fig. 2. The Permendur slugs are sealed within and protected by the seed holder. The seed holder and attached quartz rods rotate within two BN disks, which in turn can slide up and down within the ampoule. Original problems of excessive vibration and erratic motion of the seed were virtually eliminated by constructing all the moving parts of the seed holder with high precision, including the use of precision-diameter quartz rods in the bearings, and a precision-bore quartz tube for the upper member of the ampoule. The bearings were machined from BN, with allowance in the design for differential thermal expansion.

Coupling of rf into melt.—To provide good coupling between the rf coil and the melt, it was found that an rf coil wound in a continuous double-concentric shape provided the best results. The coil is shown surrounding the ampoule in Fig. 2. The coil is easily wound into the shape without any shorting by placing quartz Fiberglas sleeving over the copper tubing.

Melt temperature control.—In this system, it was difficult to place a thermocouple into close proximity with the crucible. Also, deposition of GaP on the walls

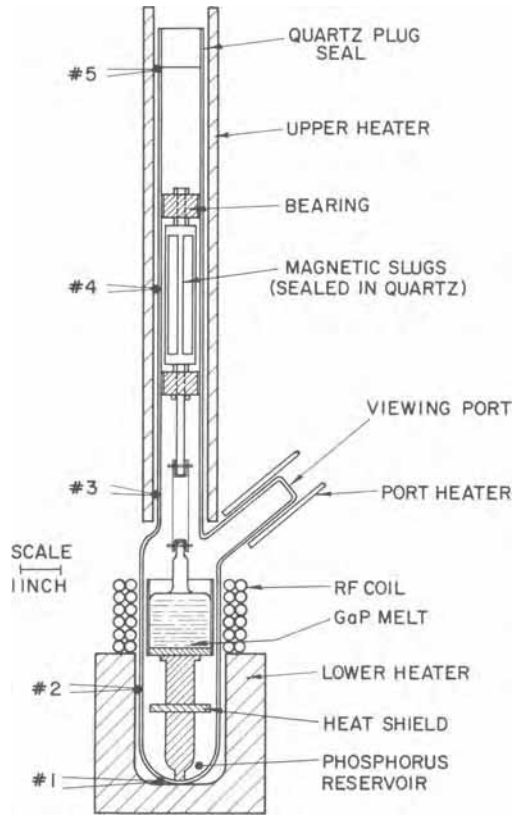

Fig. 2. Cross-sectional view of the growth ampoule for GaP, including the seed holder, crucible, rf coil, and upper and lower heaters. The numbers on the left indicate thermocouples.

prevented the use of optical temperature sensors. Instead, adequate temperature control of the melt was achieved by controlling the rf power output. A pickup coil was placed next to one of the rf input leads to the autoclave. The resulting signal was rectified and fed into a standard thermocouple control unit, which in turn regulated the saturable core reactor control in the rf generator.

Visibility problems.—Visibility can be impaired for two reasons. First, GaP can deposit on the quartz walls surrounding the crucible. Second, the fluctuations and convection currents in the argon gas give a shimmering and unsteady view of the crucible, such as the appearance of an object at the bottom of a swimming pool.

The first problem was successfully overcome by placing a side arm on the growth ampoule, as shown in Fig. 2. This is surrounded by a heater, and the temperature of the heater is held at about 1000°C. This visibility port remains clear for hours under growth conditions.

The problem of turbulence was minimized by eliminating much of the optical path through the gas with the use of a fused quartz rod acting as a light-pipe. Both ends of the quartz rod must be polished. Quartz rods were easily selected that were free of significant distortion. The quartz rod extended between the viewing port and the side arm of the ampoule, thus providing a clear view of the solid-liquid interface.

Explosion problems.—There were found to be two main causes of explosions (or implosions). The first was the formation of a "lid" of solid GaP on the top of the melt. Once this formed, as the melt was heated further, the crucible would crack and spill its contents onto the quartz ampoule, thus causing the explosion. This problem was easily avoided by keeping the phosphorus cool while first heating the gallium in the crucible to about 1500°C, and then slowly increasing the phosphorus pressure to the desired value (35 atm). Then, any GaP that forms remains molten.

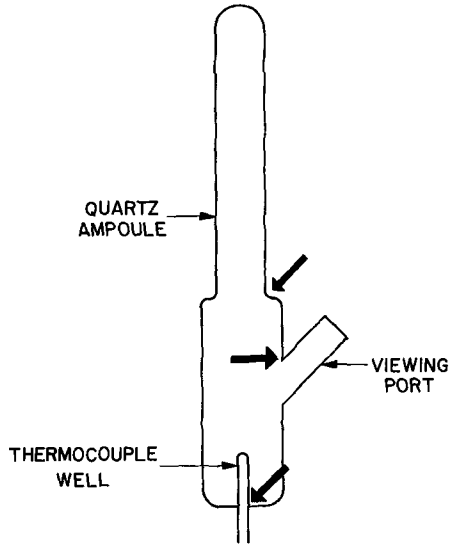

Fig. 3. Cross-sectional view of an ampoule subject to explosion. The arrows indicate weak points of construction which should be avoided.

The second and more severe problem concerned the construction of the quartz ampoule. Needless to say, the ampoule must be fully annealed after construction. However, it is also important to eliminate all sharp bends in the ampoule. Examples of a poorly designed ampoule with the weak points identified is shown in Fig. 3, in contrast to the successful design shown in Fig. 2. Using the ampoule shown in Fig. 2, explosions were reduced to roughly one in 15 runs, from the original incidence of one in two explosions.

It is noteworthy that, even in the most severe explosions, there was no damage outside of the autoclave, nor was there any damage to the large glass viewing port.

Solid-liquid interface shape.—Although direct couping of the rf energy into the melt was efficient, the resulting solid-liquid interface was invariably concave into the melt, which can be detrimental to crystal growth. In a series of experiments, the phosphorus pressure was varied between 30 and 50 atm, but no improvement was noted in either the shape of the interface or the crystallinity of the grown ingots.

Next, we tried several experiments with susceptors surrounding a crucible. In the first, a cylindrical susceptor was employed surrounding and touching the BN inner crucible. Molybdenum was unsatisfactory since it reacted with phosphorus at roughly 1300°C. Tungsten failed marginally since it reacted with phosphorus above 1500°C when gallium was present (in phosphorus vapor alone no reaction was seen). When the melt was placed in a graphite crucible, a black deposit, believed to be carbon, formed on the walls and blocked visibility, even in the side arm. However, it was found that both graphite and vitreous carbon were suitable as susceptors when a BN inner crucible was used to contain the melt.

The use of the carbon susceptors was found to change the shape of the solid-liquid interface to convex into the melt. Hence, this arrangement provided another control over the growth parameters.

Crucible materials.—Several crucible materials were tested, including quartz, SiC, graphite, vitreous carbon, and hot-pressed BN. Of those tested, the last was superior, especially because of its machinability. However, hot-pressed BN is not pure, since a binder is added, and contains B_2O_3. Extensive vacuum bake-out (over 16 hr) was used for the BN until no further deposits on the walls of the bake-out chamber were observed. Nevertheless, residual impurities in the BN might have been detrimental to the crystal growth, and pyrolytic BN is probably superior.

Insulation at high pressures.—The results on heat flow were the most unexpected feature of these crystal growth studies, especially for a person familiar with the Czochralski growth of Ge, Si, or GaAs.

We first considered the effect of insulation at elevated pressures. We performed an experiment in which a hollow tubular heater was placed vertically at the center of the autoclave, with one thermocouple inside the heater, and with thermocouples placed at various distances away. The outer diameter of the heater was about ½ in. The heater was held at 1150°C, and the temperature was measured as the argon pressure was increased. The measurements were carried out first in the absence of insulation, and again after the autoclave was filled with Fiberfrax insulation, normally considered to be an effective insulator.

Typical results are shown in Fig. 4 for one thermocouple located 1½ in. from the surface of the heater. It can be seen that the insulating effect of the Fiberfrax decreases rapidly with increasing pressure. It acts as if the autoclave is filled with a liquid, and not a gas, with the Fiberfrax floating around, doing almost nothing. Thus, at high pressures, one must use much denser insulators, such as brick insulators.

Unusual temperature gradients.—Another surprising feature of heat flow concerned temperature gradients within the growth ampoule. For example, we grew GaAs single crystals in this same apparatus as a test. When the GaAs melt was heated to above 1250°C, the reservoir below the crucible overheated, *i.e.* increased to over 600°C. In contrast, when we grew GaP at 35 atm, even when the melt was heated to 1500°C, the reservoir below the crucible remained well below 600°C.

Tests were carried out to demonstrate the effects of gas pressure on the vertical thermal gradients. A "dummy" quartz ampoule was used, containing no Ga or P, but with small holes to allow argon gas to enter. A graphite cylinder was used in place of the crucible, and the seed holder was placed in its usual position. Seven thermocouples were placed along the ampoule, five in the positions indicated in Fig. 2, and one next to thermocouples 1 and 5, but in the interior of the ampoule. The graphite was heated to 1350°C, but no power was supplied to either the upper or lower heaters.

Little difference was seen between the interior and corresponding exterior thermocouples at any pressure.

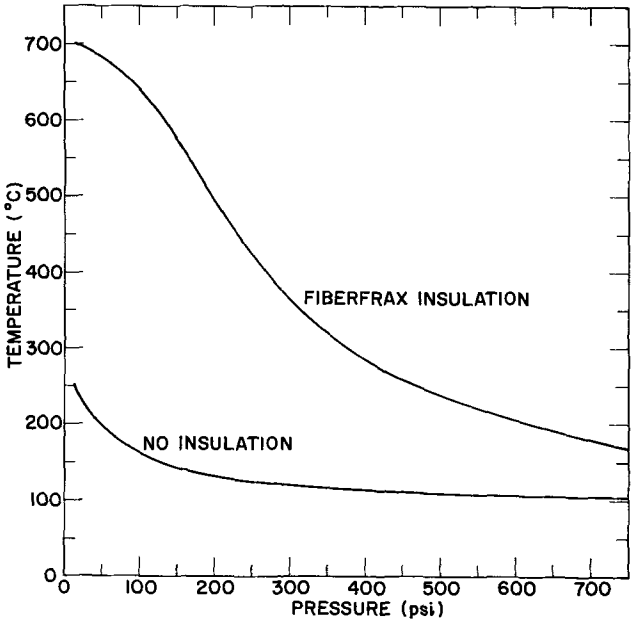

Fig. 4. Variation of temperature with pressure of a thermocouple placed 1½ in. away from the surface of a heater maintained at 1150°C.

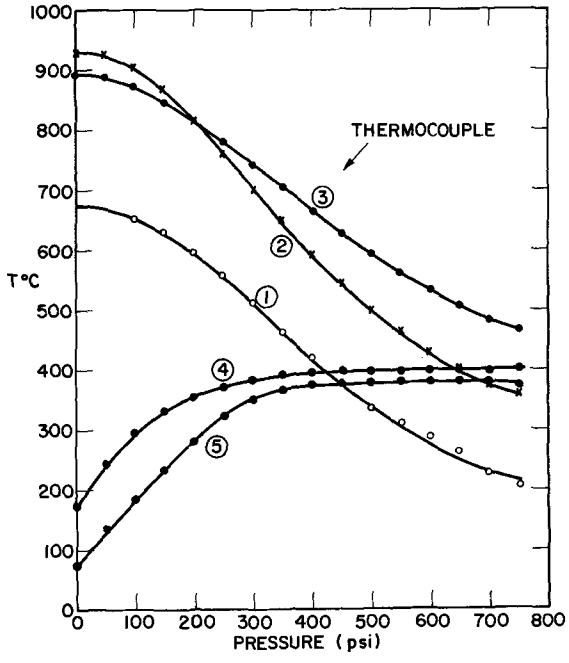

Fig. 5. Variation of temperatures along the ampoule with increasing argon pressure. Refer to Fig. 2 for the thermocouple positions. Crucible held at 1350°C, but no power supplied to upper and lower heaters.

However, the temperatures along the ampoule varied greatly with increasing pressure, as shown in Fig. 5. Thermocouples 1, 2, and 3, which at low pressures were heated mostly by radiation, dropped several hundred degrees centigrade. Thermocouples 4 and 5, in contrast, were heated probably by the convection currents in the gas. It is particularly surprising that thermocouples 2 and 3 ended up nearly 1000°C cooler than the crucible, even though they were both quite close to the crucible.

Before this effect was understood, sections of the ampoule (such as close to thermocouple 3) were below 600°C, and served as a sink for the phosphorus. In turn, this explained why, in early runs, ingots were frequently gallium rich. Proper use of solid-type insulators served to correct this problem in later runs.

GaP growth and properties.—After including the above improvements in the apparatus, coarse-grained GaP could be grown, with grains as large as 1 cm^3. GaP crystals grown in the apparatus in 1964 are shown in Fig. 6. The smoothness of these crystals shows the good temperature and mechanical control achieved. The material was always n-type as grown, with an electron concentration usually in the 10^{16} cm^{-3} range, and an electron mobility of about 150 $cm^2/V\text{-}sec$. The material grown was quite pure, although special ef-

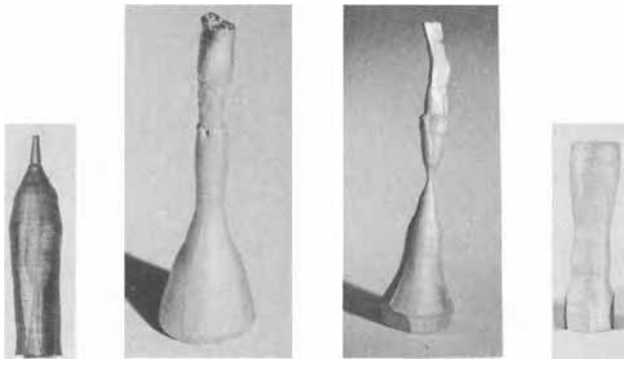

Fig. 6. GaP crystals grown in the high-pressure, magnetic Czochralski apparatus. Typical diameters of crystals at the bottom are ½-¾ in. Large single crystalline grains can be seen.

forts to maintain purity were not made. A typical emission spectrographic analysis was (ppm): Cu(<1), Si(0.1), Mg(1), B(30). The boron was probably from the BN crucible.

Large ingots of GaP could also be cast in the crucible. This cast material was close to stoichiometry, with little free gallium visible, and was very clear, with transparency possible through pieces exceeding 3 cm in thickness.

Cross-sectional examination of the pulled GaP crystals revealed that nucleation of additional grains continually occurred during growth. This occurred both at the interior and at the surface of the crystal. It was this factor that prevented the growth of larger single crystals.

The cause of this spurious nucleation was never ascertained. Single crystalline seeds were used, and the crystals were necked down after the initiation of growth. The obvious crystal growth parameters such as pulling speed, rotation rate, solid-liquid interface shape, and phosphorus pressure were all varied and optimized, but the nucleation persisted. Perhaps impurities from the hot-pressed BN crucible contaminated the melt, or maybe surface nucleation occurred due to severe fluctuations in convective heat losses at the solid-liquid interface. (Note that when liquid encapulation is used, the melt-solid interface is protected from convection heat losses.) However, the experiments were terminated because it was very time consuming to obtain data. A single run, starting from the loading of an ampoule and ending with the cleaning of the autoclave, consumed close to a week's time.

Acknowledgments

The authors are grateful to Dr. A. Fischer for valuable advice concerning construction and operation of the autoclave, and to Dr. D. Richman for important discussions during the course of the work.

Performance Domain Analysis of Primary Batteries

R. Selim and P. Bro*

P. R. Mallory & Company Incorporated, Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

The performance of primary batteries is generally given in terms of discharge curves or discharge tables for a discrete set of operating conditions. This is satisfactory for many applications, but it leaves unanswered the question of the performance of batteries under operating conditions other than those specified.

The Peukert equation (1, 2) has been used to describe the discharge of secondary batteries, and it appears to be reasonably good for this purpose. We have found that the Peukert equation can also be used for primary batteries, but only at moderate and high rates. It is not satisfactory for primary batteries at low rates.

Analyses of the discharge of cells and batteries under a variety of conditions have led to a new capacity-current correlation for primary batteries that is satisfactory for high, low, and intermediate discharge rates. In addition, the new correlation leads to the definition of a performance domain for a battery. The performance domain is a useful tool for the description of battery performance and for the analysis of the effects of design changes on battery performance.

Empirical Correlation

The search for a useful capacity-rate correlation was guided by the results of analyses of resistive network models of porous electrodes. Generally, they lead to expressions containing hyperbolic functions. It is characteristic of primary batteries that they deliver a limiting capacity at low rates, not necessarily the stoichiometric capacity, and the choice of a suitable hyperbolic function for the capacity-rate correlation should reflect this characteristic. Trial and error work with experimental data and various mathematical expressions led to the following best description of the battery performance

$$q = q_o \frac{\tanh (i/R)^{1/A}}{(i/R)^{1/A}} \qquad [1]$$

where i = battery current, mA
q = realized battery capacity, mAhr
q_o, A, R = empirical parameters

This correlation exhibits the proper capacity-rate relationship, and it approaches the Peukert equation at high rates.

The definition of the useful capacity of a battery is somewhat arbitrary, but we have found the correlation to be satisfactory for a variety of criteria defining the useful capacity provided consistency is maintained. The parameters are calculated most conveniently from the experimental data by the method of least squares applied to nonlinear expressions (3) using discharge data obtained over the entire range of discharge rates,

including low, intermediate, and high discharge rates (360 BASIC program available on request).

The empirical correlation has been tested for a wide variety of batteries: lead acid batteries, Leclanche cells of many sizes, alkaline manganese batteries, nickel-cadmium batteries, silver-cadmium cells, silver-zinc cells, and alkaline mercury cells, using performance data available from the manufacturers, e.g. (4), and a satisfactory fit was obtained in all cases. An illustration of a typical fit is shown in Table I where the observed and calculated data are compared for the discharge of 930-S Zn/HgO cells. It may be seen that the correlation fits reasonably well over the entire range of discharge rates.

The Performance Domain

The parameters q_o, A, and R can be represented graphically by a point in a three-dimensional coordinate system, and a unique prismatic region surrounding this point can be defined by the standard errors in q_o, A, and R as shown in Fig. 1. This volume is the performance domain of the battery, and it characterizes the range of battery performance to be expected due to the intrinsic variations between the cells.

Each of the three parameters that define the performance point has a simple physical interpretation. The quantity q_o is the maximum capacity obtainable from the battery. It is referred to as the standard capacity of the battery, and the deliverable capacity at any particular rate of discharge can be obtained from it using Eq. [1].

The quantity R has the dimension of current, and it is referred to as the standard rate of the battery. It is the rate of discharge beyond which the performance

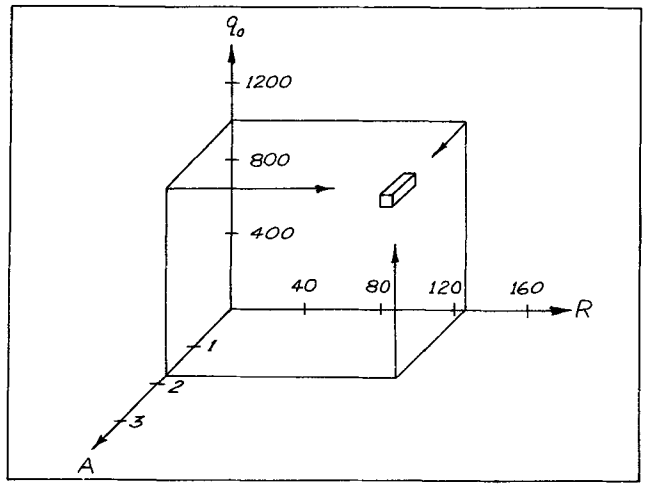

Fig. 1. Performance domain diagram of 930 S Zn/HgO cells at 25°C.

begins to become significantly rate limiting as distinct from capacity limiting. The delivered capacity is 76% of the standard capacity at the standard rate. At higher discharge rates, the delivered capacity begins to decrease appreciably.

The quantity A is the accommodation coefficient of the battery. It measures how readily the battery can accommodate high discharge rates without appreciable losses in efficiency. A small A indicates a rapid loss of efficiency above the standard rate, and a large A indicates that the battery can be operated efficiently above the standard rate. The quantity A is, therefore, a significant characteristic of the rate capability of a battery.

Discussion

The specification of the standard capacity, the standard rate, and the accommodation coefficient of a battery represents a rational and an informative means of rating battery performance that is preferable to the common practice of assigning a somewhat arbitrary rate and capacity to a battery. A table of the performance points of various batteries in conjunction with a nomograph of Eq. [1], Fig. 2, can replace bulky performance manuals.

The performance point provides an analytical tool for the evaluation of the effect of design changes on battery performance. When a design change is introduced a new performance point is established. If it

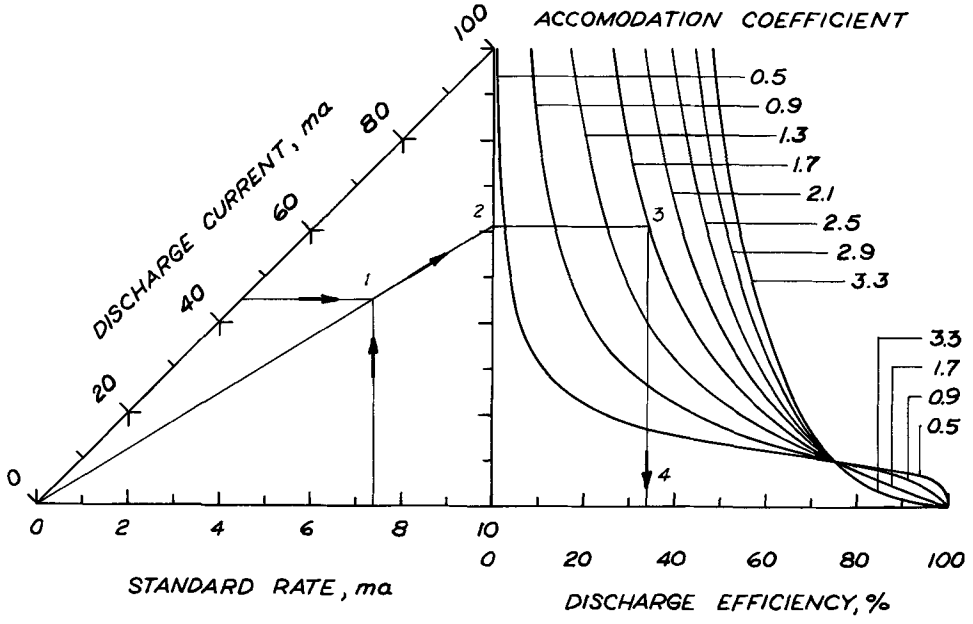

Fig. 2. Nomograph of rate-capacity relationship, Eq. [1].

falls inside the performance domain the effected change is probably of no significance. And conversely, if a significant change is obtained, the direction of change to the new performance point establishes the nature of the significant effect, whether it be a change in the standard capacity, the standard rate capability, or the accommodation capability or in a mixture of them.

The performance points of batteries also provide a means for comparing different battery systems in either the same or different structures, and the performance parameters make it possible to establish their relative merits in quantitative terms for a wide range of operating conditions.

The performance domain centered at q_o, R, and A is defined in extent by the standard errors in q_o, R, and A. For a specific batch of batteries of a particular kind and size the volume of this domain is a measure of the "quality" of the batch or what may be called the manufacturing consistency of the batch. The smaller the domain volume of a particular type of battery, the smaller the variability within the batch and the higher the quality. The qualities of different kinds of batteries may be compared in terms of the dimensionless domain volumes defined by $\Delta q/q_o$, $\Delta R/R$, and $\Delta A/A$.

The performance correlation, Eq. [1], is presented in a nomographic form in Fig. 2, and it applies to any battery. In order to use it for a particular battery it is necessary to obtain the performance parameters of the battery first. Then, the discharge efficiency can be read from the nomograph for a wide range of discharge rates.

The nomograph is independent of the mode of discharge selected by the user provided consistency is maintained in specifying the discharge rate and the standard rate. Thus, constant current or constant load or pulse load discharges may be used to any desired cutoff voltage, and the efficiency may be determined from Fig. 2, provided that q_o, R, and A were determined for the same type of discharge regime. The quantity (i/R) is dimensionless and independent of how the current or discharge rate is specified. The left-hand part of the nomograph simply performs the division (i/R), and the nomograph is equally valid if both the standard rates and the discharge rates shown in Fig. 2 are divided or multiplied by the same number or if the rates are expressed in terms other than milliamperes.

Electrochemical Machining: A Note on the Throwing Power of Electrolytes

D. T. Chin* and A. J. Wallace, Jr.

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

Owing to the increasing use of hardened metals in recent years, electrochemical machining (ECM) has had a great impact on the metal removal process. One of the major problems encountered in ECM is how to obtain satisfactory dimensional control of a desired cutting geometry. To achieve this, one needs information regarding the performance of an electrolyte at various operating conditions. Such information is desirable in designing the shape of tools that would produce a desired shape on the machined work piece.

In a recent article, Brook and Iqbal (1) have suggested using the concept of throwing power to evaluate the extent of dimensional control that an electrolyte could give under constant operating conditions. They describe a modified Haring-Blum cell for measuring the throwing power of ECM electrolytes and present data obtained at a relatively low current density of 15 A/in.^{2}. The cell, in effect, is not suitable for the measurement at high current densities (300-1200 A/in.^{2}) normally used in electrochemical machining. It consists of two parallel anodes located at different distances from the cathode with no adjustment of the gap spaces while cutting is in progress. Using a normal ECM current density of 500 A/in.^{2}, for instance, experience with concentrated $NaClO_3$ indicates that for the near anode a gap space initially set at 0.01 in. will be widened to about 0.05 in. at the end of a 2-min period of machining. The cutting rate on the far anode is usually not as fast as that of the near anode; consequently, this causes a decrease of linear ratios during the experimental runs. If the initial gap for the far anode is 0.05 in., the linear ratio, as estimated from Brook and Iqbal's data, would vary from an initial value of 5 to approximately 1.2 at the end of the machining. Such a great variation in linear ratios presents a serious limitation for the accurate measurement of throwng power at high current densities.

We have developed a simple and reliable method for measuring throwing power at normal ECM operating current densities. The method consists of measuring the anode-cathode gap space as a function of time and expressing the result in terms of a logarithmic throwing index. An intense and comprehensive investigation of this new concept is being carried out at the General Motors Research Laboratories. This paper describes the results of some of these studies. A summary on the rationale of this dynamic approach is given below, and the experimental data obtained from an ECM flow cell is then presented for the sodium chlorate electrolyte.

Theoretical Background

Consider an anode and a stationary parallel cathode having an initial gap space δ_o in. The rate of cutting, r (in./sec or in./min), at any point on the anode surface is equal to the rate of increase in gap space, $d\delta/dt$

$$\frac{d\delta}{dt} = r \qquad [1]$$

where δ is the local gap space at time t after starting machining. The initial condition for the differential equation is: at $t = 0$, $\delta = \delta_o$, and $r = r_o$, where r_o is the initial cutting rate at the point where the gap is

* Electrochemical Society Active Member.

Key words: electrochemical machining, throwing power, throwing index.

measured. Introducing new variables

$$L \text{ (linear ratio)} = \frac{\delta}{\delta_o}$$

and

$$M \text{ (metal distribution ratio)} = \frac{r_o}{r}$$

Eq. [1] becomes

$$\frac{dL}{dt} = \frac{r_o}{\delta_o}\frac{1}{M} \qquad [2]$$

To solve the equation, one needs to replace M with a known function of L. A regressional analysis (2) of published throwing power data obtained from the Haring-Blum cell for various plating baths has shown that the metal distribution ratio, M, can be correlated to the linear ratio, L, by

$$M = L^{1/A} \qquad [3]$$

where A is the logarithmic throwing index and is constant for a given electrolyte at constant operating conditions. In electroplating, the metal distribution ratio is defined as the ratio of the metal deposition rates on two equipotential plane cathodes located at different distances from the anode. In ECM, however, the definition has been changed to the ratio of the rate of dissolution on the near plane anode to that on the far plane anode. Since the metal dissolution is the reverse process of electroplating, we may assume that Eq. [3] is also valid for the case of electrochemical machining. Substituting Eq. [3] into Eq. [2] and making use of the initial condition (at $t = 0$, $L = 1$), we have

$$\int_1^L L^{1/A}\,dL = \frac{r_o}{\delta_o}\int_o^t dt \qquad [4]$$

Equation [4] can be integrated to give the following expression describing the time-variation of local gap space between the anode and the cathode

$$t = \frac{\delta_o}{r_o\left(\frac{1}{A}+1\right)}\,(L^{1/A+1} - 1) \qquad [5]$$

Accordingly, if a set of L *vs.* t data is plotted in the form of t against $L^{1/A+1}$, one should obtain a straight line having a slope equal to $\delta_o/r_o(1/A + 1)$ and an intercept equal to $-\delta_o/r_o(1/A + 1)$. To find the proper exponent of L, a trial-and-error method is required: (*i*) assume a value of $1/A$, (*ii*) plot the data points in the form of t *vs.* $L^{1/A+1}$, and (*iii*) repeat steps *i* and *ii* until the data points fall on a straight line having a slope equal in magnitude to its intercept. From the slope of the straight line and the exponent of L, the initial cutting rate, r_o, and the logarithmic throwing index, A, (and thus the throwing power) can be calculated for an electrolyte at given operating conditions.

An alternative way to find r_o and A is via the graphical differentiation of the L *vs.* t curve. This can be seen if we rearrange Eq. [2] (after replacing M by $L^{1/A}$) or differentiate Eq. [5] with respect to L

$$\frac{dt}{dL} = \left(\frac{\delta_o}{r_o}\right)L^{1/A} \qquad [6]$$

This equation suggests that a straight line is obtained if log (dt/dL) is plotted against log L. The slope of the straight line is $1/A$, and its intercept equals log (δ_o/r_o). It should be noted, however, that the graphical differentiation of the L *vs.* t curve is generally not very accurate. The accuracy may be very seriously impaired by small errors in the experimental data. Unless there is a large number of data points available, this method is not recommended for the direct evaluation of the logarithmic throwing index.

Experimental Procedure

The experimental setup is similar to the flow cell system described in an earlier electrolyte study (3) with slight modifications. It consisted of a centrifugal pump, a solution reservoir, and a Lucite cell cavity. The cell and the solution reservoir were incorporated as one unit as shown in Fig. 1. The cathode was a circular copper tube, 0.251 in. OD and 0.176 in. ID, fixed on the bottom of the cell. The anodes were flat 1008 steel panels, 1 × 3 × 0.025 in., which were held in place above the cathode. The initial spacing between the anode surface and the cathode tip was 0.01 in.

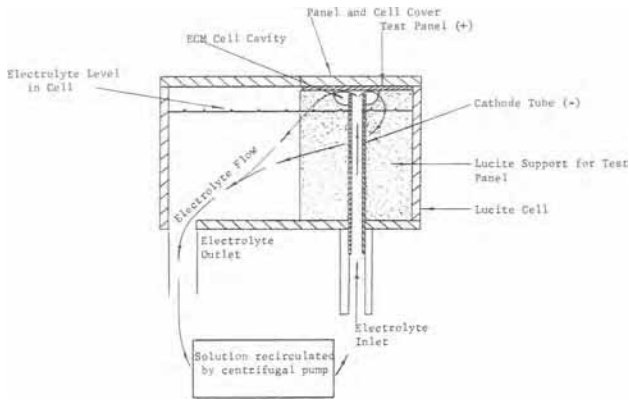

Fig. 1. Schematic illustration of the ECM test apparatus

In this study, the throwing power measurement was performed for sodium chlorate electrolytes. For each run the cell voltage was kept at 17.5V, and the electrolyte was fed through the cathode tube into the cell with a flow rate of 2.5 liters/min. The duration of machining varied from 10 to 60 sec. At the end of each test, the resulting gap space was measured as the depth of metal removed plus the initial gap space.

Result and Discussion

Figure 2 is a set of measurements of gap space expressed in the form of L *vs.* t for 320 g/liter $NaClO_3$ electrolyte at a cathodic current density of 610 A/in.^{2}. The electrolyte temperature was maintained at 18°C. It was found (using the method of trial and error) that a straight line having a slope of 8.0 sec was obtained if the data are replotted as t *vs.* $L^{1.9}$ as shown in Fig. 3. Thus the logarithmic throwing index, A, of the chlorate solution becomes

$$A = \frac{1}{1.9 - 1} = 1.11$$

For a given linear ratio, the metal distribution ratio, M, can now be computed from Eq. [3] with the known value of the logarithmic throwing index. Figure 4 is

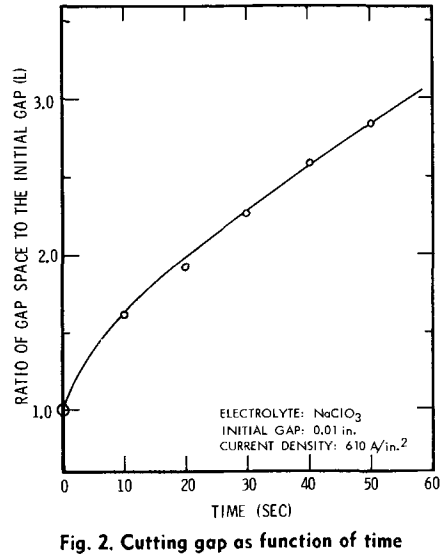

Fig. 2. Cutting gap as function of time

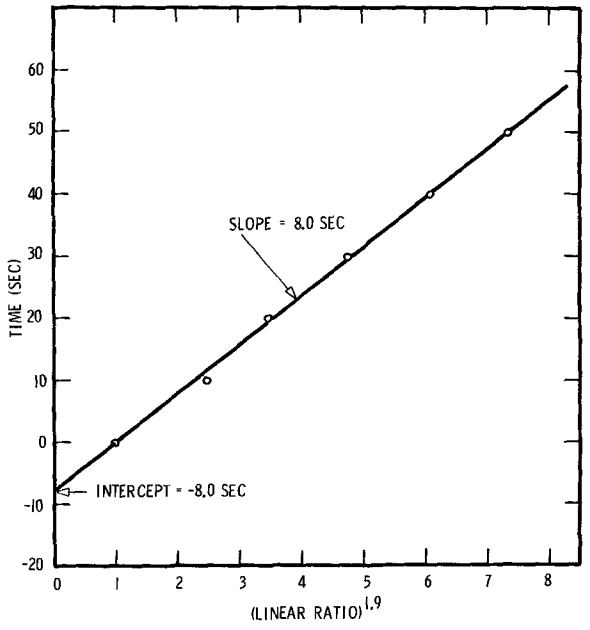

Fig. 3. t vs. $L^{1.9}$

a log-log plot of M *vs.* L for the sodium chlorate electrolyte at the above operating conditions (solid line). For comparison, Brook and Iqbal's chlorate data obtained at 15 A/in.^{2} is also plotted in the figure as circular dots. It is seen that the present measurement gives a straight line passing through the common point represented by the linear ratio equal to 1 and the metal distribution ratio equal to 1. Brook and Iqbal's data, on the other hand, also gives a reasonably straight line as shown by the dashed line; it, however, would extend to the point ($L = 1$, $M = 0.2$) instead of ($L = 1$, $M = 1$). This obviously contradicts the fact that two equipotential anodes located at the same distance from the cathode should have equal rates of metal dissolution; the deviation is probably due to the variation of linear ratios during their measurement with the modified Haring-Blum cell.

Furthermore, the present method also enables one to find precisely the initial cutting rate, r_o, corresponding to the initial gap space. For the case presented here, it can be calculated from the logarithmic throwing index and the slope of the straight line given in Fig. 3

$$r_o = \frac{0.01}{8.0 \times 1.9} \times 60 = 0.039 \text{ in./min}$$

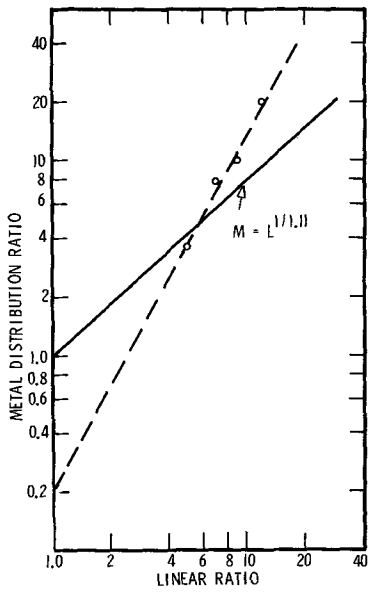

Fig. 4. Log-log plot of metal distribution ratio vs. linear ratio. The dark line is the result of present measurement from a 320 g/liter $NaClO_3$ electrolyte at a current density of 610 A/in.^{2} The circular dots connected by the dashed line are Brook and Iqbal's chlorate data at 15 A/in.^{2}.

In summary, the measurement of time variation of gap space provides simple and efficient means for obtaining the throwing power data of electrolytes under ECM operating conditions. The information thus obtained can be used directly for the tool design and in ECM practices for determining the optimum tool feed rate to maintain a constant gap space.

Pulse Electroplating of High-Resistance Materials, Poorly Contacted Devices, and Extremely Small Areas

C. A. Burrus

Bell Telephone Laboratories, Incorporated, Crawford Hill Laboratory, Holmdel, New Jersey 07733

Electroplating is an accepted method of applying many metallic coatings to low-conductivity surfaces. Plating by means of current *pulses* rather than the commonly used direct current has been proposed for certain applications and a number of advantages have been reported for the pulse-deposited coatings (increased density, increased purity, reduced hydrogen embrittlement, *etc.*) (1). However, the method seems to have been little used, probably due to the added complications of providing pulsed power supplies.

Key words: pulse electroplating, semiconductor contacts.

We have employed a simple form of high-voltage pulse plating for more than 10 years in the small-scale fabrication of experimental semiconductor devices, largely to overcome the problems associated with plating high-resistance or nonuniform-resistance surfaces of small areas. Our usage has involved the plating of extremely small areas (tips of 0.003 cm wires), relatively poor-conductivity surfaces (moderately doped semiconductors), materials with poor electrical contacts (n-type GaAs held with tweezers), *etc.*—materials which, partly because of difficulties in plating

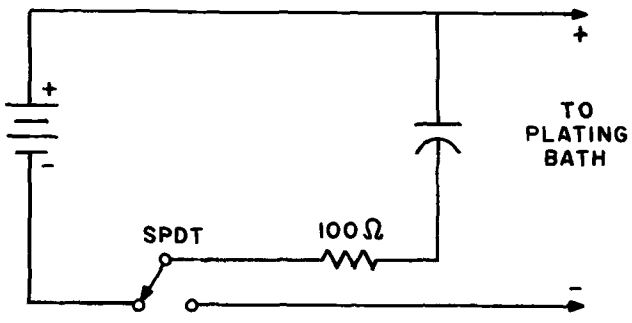

Fig. 1. Simplest form of pulse-plating circuit

by direct current, normally are coated by vacuum evaporation. This pulse-plating technique has proved to be so rapid and convenient in small-scale applications, compared to vacuum evaporation, that we wish to describe it briefly.

The plating circuit in its simplest form is shown in Fig. 1. A capacitor is charged from a battery through a normally closed SPDT microswitch. When the microswitch button is pressed, the battery is disconnected and the capacitor is discharged through the plating bath, providing a "pulse" of plating current. As a practical matter, it is convenient to provide a variable-voltage power supply and a number of capacitors which can be switched in and out of the circuit in parallel. The total charge per pulse delivered to the plating bath then can be controlled by adjusting the charging voltage and the value of the capacitance. The total metal transferred in the plating can be adjusted, additionally, by varying the number of pulses applied.

Use of such a capacitor discharge, or of a more sophisticated pulse generator, allows the starting voltage applied to the plating solution to be many times that normally used (tens of volts rather than 1-3V) but at the same time conveniently restricts the rate of charge transfer so that "burning" of the plate does not occur. The relatively high voltage aids in overcoming problems of starting a plate due to poor contacts to the object to be plated, high resistance of the object itself, thin insulating films on the surface, the presence of higher- and lower-resistance areas in parallel, and irregular shape of the surface; it often permits use of a plating solution at room temperature which normally would plate satisfactorily only at elevated temperatures; it conveniently permits plating of a surface which can be contacted only through a rectifying junction; and it easily permits the plating of extremely small areas without burning.

Wide variations in conditions have been found to be permissible, and at least two dozen different metals and metal mixtures have been plated at one time or another. A few examples which illustrate the use of the technique are listed below. Representative examples of devices fabricated with its aid can be found in the references.

1. *Very small areas.*—Plating of a dopant metal onto a pointed wire for formation of a pulse-alloyed p-n junction. For a 0.01 cm length of 0.003-0.005 cm wire: 5 μf charged at 5-7V, 3-5 pulses (2,3).

2. *Poor conductivity surface, and room-temperature use of solution normally used hot.*—Plating of tin at room temperature onto n-type GaAs for alloying as an ohmic contact, 1 cm^2 area: 80 μf, 35V, 50-100 pulses (4-6).

3. *Surface with poor electrical contact.*—Starting a gold plate on n-type GaAs held with tweezers, 1 cm^2 area: 80 μf, 45V, 20-30 pulses (4-6).

4. *Many small areas in parallel.*—Plating gold into array of 2-3 μm diameter windows on n-type GaAs to form Schottky-barrier diodes, array 1 cm on edge: 20-40 μf, 45V, groups of 5-7 pulses until desired buildup obtained (6).

5. *Surfaces in series with rectifying junction.*—Plating gold into array of p-type surfaces diffused in micrometer-diameter windows on n-type semiconductor, array 1 cm on edge: 40 μf, 45V, groups of a few pulses until desired thickness obtained (4,7).

6. *High- and low-conductivity materials in parallel* —Starting plating on p- and n-side of semiconductor chip bonded to metal stud, with metal and semiconductor immersed: 20-40 μf, 20-50V, 10-20 pulses (5).

7. *Bridging of thin insulating layer.*—As in No. 6, but semiconductor chip electrically separated from stud by thin SiO_2 layer: 80-120 μf, 50V, 30-40 pulses (5).

Some of these applications make use of the pulse-plating method to create an equipotential layer on surfaces whose conductivity is poor or nonuniform (items 2, 3, and 6) and the plating can be completed by conventional methods. Other applications (as illustrated in items 1, 4, and 5) may require that the entire job be done by the pulse technique. In all applications, use of an electronic pulse generator speeds the operation.

Method for Producing Graded Composition Epitaxial Layers by Vapor Deposition

L. G. Bailey and G. G. Rogers

Texas Instruments Incorporated, Materials Science Research Laboratory, Dallas, Texas 75222

In recent years vapor phase epitaxial growth techniques have been used extensively for the preparation of III-V compounds for solid-state device applications. Solid-solution alloys of many of these compounds have also been produced to obtain materials with intermediate properties. The formation of graded composition alloy films, however, has received relatively little study, although such films have been considered for special device applications and for reducing the effects

Key words: $Ga_xIn_{1-x}As$ alloys, semiconductors, III-V compounds.

of lattice mismatch between substrates and heteroepitaxial layers (1, 2).

To produce graded composition epitaxial layers with chemical transport systems, the composition of the reacting vapor can be changed as a function of time by altering the relative input rates of fixed composition gases into the deposition chamber. Although this method offers the flexibility for producing any desired composition profile within the layer by suitable flow rate programming, it is difficult to execute simply if reproducible results are to be obtained. The control of very low flow rates ($\leqq$ 20 cm^3/min) is usually required during part of the growth for at least one of the input gases, and manual or even motor drive operation of needle valves to change flows is difficult at these levels because of inconsistencies in delivered flow as a function of angular rotation of the valve control shaft. In addition, techniques for accurate flow rate measurement are difficult at these levels. These problems multiply when the control of two or more flows must be coordinated to obtain a smoothly varying deposit composition.

The method reported here employs the filling and emptying characteristics of reservoirs to produce gas mixtures of changing composition at constant flow rate. The method is simple, depends on an easily reproducible physical process, and utilizes fixed gas flows at levels which are simple to measure and control. Although Tietjen and Amick have mentioned the use of a ballast vessel to smooth fluctuations in gas flows and compositions (3), their graded $GaAs_xP_{1-x}$ deposits were prepared by changing the flow rates of the input gases (2).

Experimental Procedure

A reactor of the design reported by Conrad *et al.* (4) was used to prepare epitaxial layers of $Ga_xIn_{1-x}As$ alloys on GaAs substrates. Three separate source holders were used, containing elemental arsenic, elemental gallium, and an alloy of indium and gallium. Arsenic was transported by sublimation into a carrier stream of purified hydrogen, while the group III elements were transported as chlorides by high-temperature reaction with HCl carried in hydrogen. Deposit compositions between GaAs and an alloy determined by the composition of the indium-gallium alloy were prepared by adjustment of the concentrations of HCl in hydrogen at constant flow rate entering the source holders. A gas-handling system shown in Fig. 1 was used to supply time-varying concentrations of HCl to each of these sources. This system consisted essentially of an $AsCl_3$ saturation bubbler-reduction tube combination to generate HCl-H_2 gas mixtures and a gas reservoir. This system could deliver either an increasing concentration (reservoir initially filled with hydrogen and a HCl-H_2 mixture introduced during operation) or a decreasing concentration (reservoir initially filled with a HCl-H_2 mixture and flushed during operation with pure hydrogen).

A 3-liter reservoir was used for the indium-gallium alloy source and a 0.6-liter reservoir was used for the gallium source. Flow rates of hydrogen through both systems were 50 cm^3/min, and a hydrogen flow of 33 cm^3/min was passed through the arsenic source held at 427°C. Additional flows of 39 cm^3/min and 18 cm^3/min were added to the reservoir outputs for the indium-gallium source and the gallium source, respectively. The growth temperature was 740°C, and the group III sources were held at 844°C. Growth rates were typically in the range of 15 to 25 μm/hr.

A series of tests was performed to determine directly the reservoir delivery characteristics under the same conditions of flow rate and HCl concentration as were used in the growth experiments. Gas composition was measured with a thermal conductivity cell–Wheatstone bridge combination, and its output was displayed on a strip chart recorder.

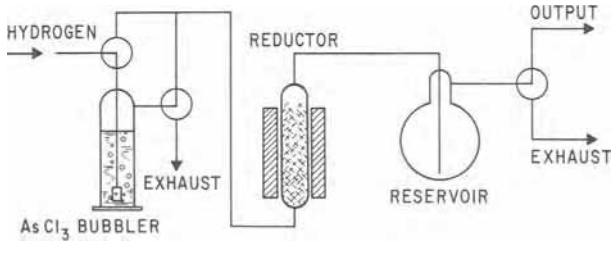

Fig. 1. System for producing time-varying concentration of HCl in hydrogen.

Results and Discussion

The reservoir delivery tests showed that both reservoirs closely followed exponential filling and emptying behavior. Figure 2 presents typical semi-log plots of gas composition *vs.* time for emptying of both reservoirs. Similar results were obtained for reservoir filling. These results indicate that under the specified operating conditions the reservoir delivery characteristics can be fairly accurately described with simple theory. Specifically for reservoir emptying, beginning with an initial concentration, C_0, of HCl in hydrogen, the output of the reservoir with time is:

$$C_t = C_0 \exp(-Ft/V) \qquad [1]$$

where C_t is the concentration at time t, F is the flow rate through the reservoir, and V is the reservoir volume. This relation follows from the assumptions of (*a*) complete reservoir mixing and (*b*) the rate of HCl loss from the reservoir as proportional to its instantaneous concentration and the gas flow rate through the reservoir.

It should be noted that the slopes of the curves in Fig. 2 will be equal to $-F/V$ if the reservoir delivery is described by Eq. [1]. Using the value of flow rate employed during the tests, the calculation of reservoir volumes yielded 3.17 and 0.60 liters which are in excellent agreement with those determined by direct measurement of water capacity, namely 3.03 liters and 0.59 liter respectively.

Figure 3 shows the variation of deposit composition with distance through a graded $Ga_xIn_{1-x}As$ epitaxial deposit formed on a (100) oriented GaAs substrate. Deposition time was 210 min, producing a layer 89 μm thick with a final composition at the surface of 46 m/o InAs. The data presented were obtained by electron microprobe analysis across a five-degree beveled section of the sample.

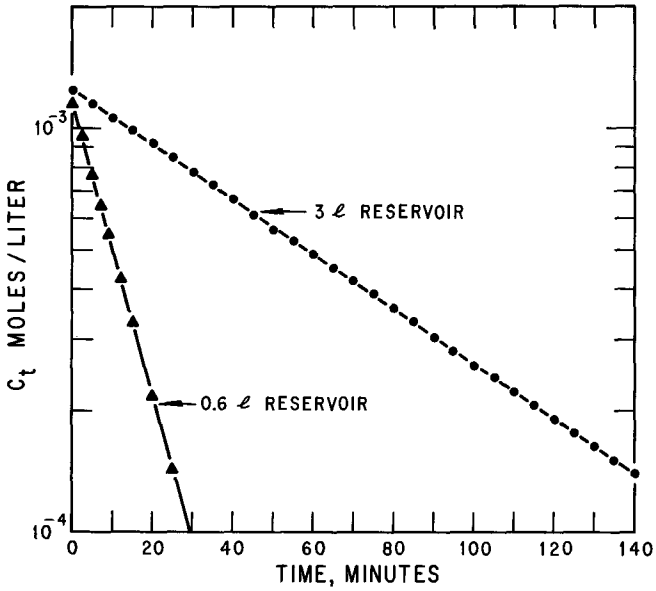

Fig. 2. Output concentration of HCl in hydrogen as a function of time for reservoir emptying.

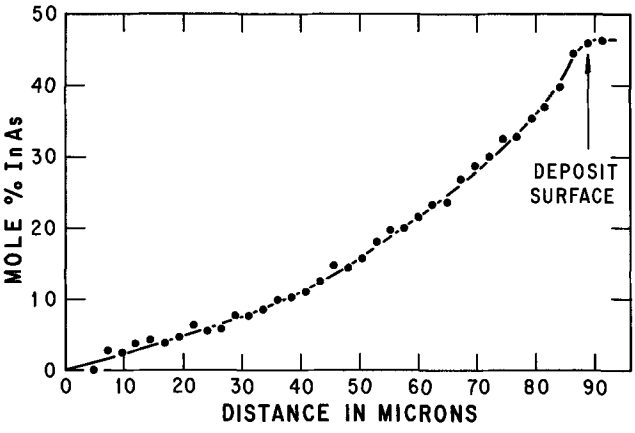

Fig. 3. Variation of $Ga_xIn_{1-x}As$ composition with depth in epitaxial deposit.

The composition of vapor-deposited $Ga_xIn_{1-x}As$ alloys is very sensitive to the relative proportions of indium and gallium chlorides in the reacting gas stream. Gallium segregates into the growing layer, and the ratio of gallium to indium in the deposit is approximately five times the ratio of the halides in the vapor for alloys in the range of 0 to 50 m/o GaAs. This phenomenon increases the difficulty of obtaining reproducible, uniformly graded layers in this alloy system, especially near pure InAs. However, as can be seen in Fig. 3, the use of an indium-gallium alloy source to fix the final deposit composition and gas reservoirs to produce slowly changing gas inputs to the group III sources has given good control on deposit composition, and the grading is very uniform.

Although the use of gas reservoirs for producing time-varying concentrations of HCl in hydrogen for grading the composition of $Ga_xIn_{1-x}As$ alloys has been discussed specifically here, we expect the technique to be a general one and applicable to many combinations of gases and alloy systems. For example, graded layers of $GaAs_xP_{1-x}$ could be prepared by using reservoir filling to increase the concentration of PCl_3 and decrease the concentration of $AsCl_3$ entering separate gallium sources.

Acknowledgments

The authors wish to thank W. W. Gartman for his assistance in preparing the epitaxial layers and Dr. J. P. Smith for his electron microprobe analysis of the beveled samples.

ABSTRACT

The kinetics of the Zn^{2+}/Zn(Hg) electrode reaction were investigated in binary mixtures of water and n-propanol. The apparent cathodic transfer coefficient increases from 0.25 in water to 0.39 in 0.04 mole fraction n-propanol, then gradually decreases to a value of about 0.3 as further alcohol is added. The apparent exchange current decreases sharply from 18 mA/cm² in water to about 1 mA/cm² in 0.04 mole fraction n-propanol, then gradually increases as the concentration of n-propanol increases. Above 0.9 mole fraction alcohol, the apparent exchange current rapidly increases as the water concentration falls below the concentration of the excess $LiClO_4$ electrolyte. These variations are interpreted in terms of specific adsorption of n-propanol on the electrode surface and preferential solvation of the Zn^{++} ions in solution by water molecules and by a change to a reaction mechanism involving $ZnClO_4^+$ as water molecules become unavailable for the preferential solvation.

Many investigations of the Zn^{2+}/Zn(Hg) electrode reaction in aqueous solutions have been made (1-6). Although the existence of Zn^+ as an intermediate in the reaction mechanism has been proposed (6-9), it is generally accepted that the charge-transfer reaction kinetics can be best described with a single two-electron step (10-12).

$$Zn^{2+} \cdot aq + 2e^- \rightleftharpoons Zn \qquad [1]$$

Since solvation and desolvation processes represent the main energy barriers in such electrode reactions, it is of interest to investigate the effect of the solvent on this reaction. The primary purpose of this study is to investigate the behavior of the apparent anodic and cathodic transfer coefficients and the apparent exchange current for the Zn^{2+}/Zn(Hg) electrode reaction in binary mixtures of water and n-propanol.

Experimental

Solutions and chemicals.—Bi-distilled water and chromatography grade n-propanol were used in preparing the binary solvent. The electrolyte concentrations were always 0.0083M $Zn(ClO_4)_2 \cdot 6H_2O$, 1.0M $LiClO_4$, and 0.02M $HClO_4$. The water content of these solutions was determined by Karl Fischer titrations. Bubbling purified nitrogen through the solutions removed dissolved oxygen. The zinc concentration in the amalgam was maintained at about 0.7M (0.01 mole fraction zinc).

Galvanostatic measurements.—Details of galvanostatic or constant current pulse measurements can be found elsewhere (13-14). The glass cell used was similar to one described previously (1) except that measurements were made with the amalgam drop hanging directly from the capillary and the current was conducted through the capillary to the drop. A magnetic hammer controlled by an adjustable timing device tapped the capillary at intervals of about 2 sec, dislodging the amalgam drop. The measurement on the fresh amalgam drop was made 1.5 sec later by delivering a short pulse of constant current to the amalgam drop and following the change in potential with time by means of an oscilloscope (14). An amalgamated zinc rod was used as the reference electrode.

A major experimental difficulty present in the galvanostatic method is the elimination of the resistance polarization, η_Ω, from the initial value of the overvoltage, $\eta(O)$, in order to obtain the charge-transfer overvoltage, η. The resistance polarization can be determined from the extremely rapid potential jump at the start of the constant current pulse. The electrolyte resistance, $R_\Omega = \eta_\Omega / i$, was found to be related to the specific conductance, k, of the solution by the expression

$$R_\Omega = 35 \text{ ohms} + 2.4 \text{ cm}/k \qquad [2]$$

Equation [2] is for experiments where the amalgam drop weighs 2.6 mg at the instant of measurement, or, assuming spherical shape, has a surface area of 0.016 cm². This size of the amalgam drop was maintained constant for all measurements. The 35 ohms was found to be the internal resistance of the closed circuit, most of this being the resistance through the amalgam thread in the capillary. As the mole fraction of n-pro-

panol increases, it becomes increasingly more difficult to determine R_Ω directly, hence all calculations are based on values of R_Ω obtained from Eq. [2] using experimental values of k. The second term in Eq. [2] agrees favorably with the theoretical value calculated from the expression $R_\Omega = r \cdot A^{-1}k^{-1}a(r + a)^{-1} = 2.1$ cm/k where r is the radius of the amalgam drop, A is its surface area, and a is the distance between the surface of the drop and the reference electrode (15). For our case, $r = 0.036$ cm and $a = 0.5$ cm. Shielding by the capillary tip reducing the effective area by 12% accounts for the slightly larger experimental value of 2.4 cm.

Coulostatic measurements.—The coulostatic method used is, in principal, similar to that reported by Delahay (16-17) and details will be given elsewhere (18). A 1.0 μsec pulse of constant current charges the electrode, and the overvoltage-time curve resulting from the discharge of the double layer by the electrode reaction is recorded. By keeping the initial overvoltage small ($|\eta| < 5$ mV), linear $\log|\eta|$ *vs.* time plots are observed from which the apparent exchange current and differential double layer capacity can be determined. For all galvanostatic and coulostatic measurements, the temperature was maintained at 25° ± 0.2°C.

Results

Tafel plots of the galvanostatic measurements allow the anodic transfer coefficient, α, and the cathodic transfer coefficient, β, to be determined independently. The exchange current was determined by both extrapolation of the Tafel lines to $\eta = 0$ and determination of the charge-transfer resistance at low overvoltages. No corrections were made for the potential of the diffuse double layer; hence apparent transfer coefficients and apparent exchange currents are obtained. The variation in the apparent transfer coefficients as a function of the mole fraction of n-propanol is shown in Fig. 1, and Fig. 2 shows the apparent exchange current density as a function of mole fraction of n-propanol.

Due to the decreasing conductivity with increasing mole fraction n-propanol (Fig. 3), the effect of the resistance polarization, η_Ω, and therefore the experimental error, becomes greater as the alcohol concentration increases. The larger anodic transfer coefficient, α, is more sensitive to error introduced by η_Ω than is β. For mole fractions of n-propanol greater than 0.3, $\alpha \simeq 0.7 \pm 0.1$ and $\beta \simeq 0.3 \pm 0.05$. For high concentrations of n-propanol, $\eta_\Omega >> \eta$, and results become suspect.

The coulostatic method does not require elimination of η_Ω since there is no current flow during measurement other than the faradaic current resulting from the discharge of the double layer. The apparent exchange current densities obtained from coulostatic measurement are in excellent agreement with those determined from galvanostatic measurements (Fig. 2).

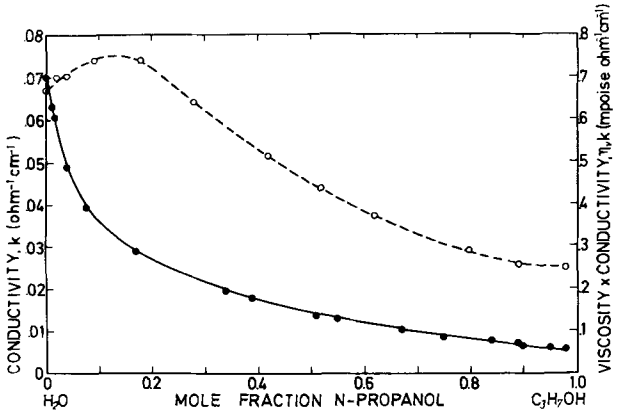

Fig. 3. Variation of the specific conductivity, k, and the product of viscosity x conductivity, $\eta_v \cdot k$, with mole fraction n-propanol at 25.0°C. ●, conductivity measurements; ○, experimental $\eta_v \cdot k$ product.

The variation of the differential capacity of the double layer with mole fraction n-propanol, as determined from the coulostatic measurements, is shown in Fig. 4.

The apparent transfer coefficients can also be obtained from coulostatic measurements using the relationships

$$\alpha = \left(\frac{\partial \ln i_o}{\partial \ln a_{Zn^{2+}}}\right)_{a_{Zn}} \quad \text{and} \quad \beta = \left(\frac{\partial \ln i_o}{\partial \ln a_{Zn}}\right)_{a_{Zn^{2+}}} \qquad [3]$$

However, undissociated $ZnClO_4^+$ or $Zn(ClO_4)_2$ in alcohol solutions may affect the determination of α. For accurate coulostatic measurements, it was experi-

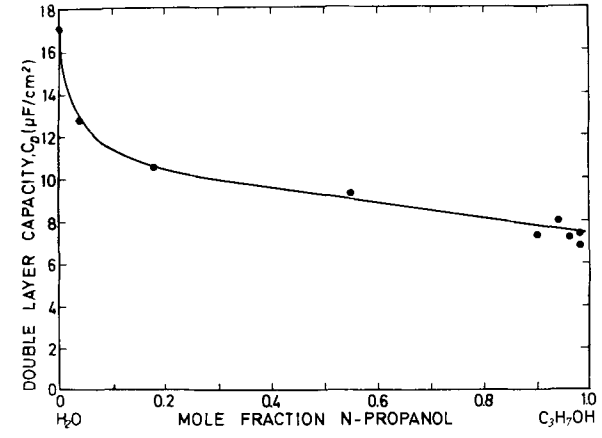

Fig. 4. Variation of the double layer differential capacity with mole fraction n-propanol at 25.0°C. The potential is the equilibrium potential of the zinc electrode.

mentally determined that the concentration of Zn in the amalgam must be between about 0.05M and 2M. Coulostatic determinations of the apparent transfer coefficients in 0.98 mole fraction n-propanol yielded approximate values of $\alpha = 0.6 \pm 0.1$ and $\beta = 0.3 \pm 0.1$, in agreement with results from Tafel plots of the galvanostatic measurements.

The equilibrium potential of the amalgamated zinc rod reference electrode was measured in the various solutions against the normal calomel electrode (NCE) using a 1M KCl salt bridge. The equilibrium potential was found to vary linearly with the mole fraction n-propanol, from −1.11V in aqueous solution to −0.84V in 0.98 mole fraction alcohol. From the Henderson equation, the liquid junction potential is estimated to be less than 5 mV for all solvent compositions.

Using the rapidly dropping mercury electrode method, the potential of zero charge, Epzc, was determined to be −0.55 *vs.* NCE in 1.0M KCl aqueous solution, while for 1.0M $LiClO_4$ in n-propanol, Epzc = −0.31V *vs.* NCE and for 1.0M $LiClO_4$ in methanol, Epzc = −0.36V *vs.* NCE. Although the addition of 0.01 mole fraction Zn to the mercury may shift Epzc about 0.2V more negative (19-20), it still appears that all measurements were made at potentials negative to Epzc. In fact for pure Zn in aqueous solution, Epzc is about −0.9V *vs.* NCE (20), or about 0.2V positive to the $Zn^{++}/Zn(Hg)$ rest potential.

A few measurements were made in methanol-H_2O and ethanol-H_2O solutions. The apparent transfer coefficients were found to be $\alpha \simeq 0.7$ and $\beta \simeq 0.3$ in these solutions. In the methanol solutions, the apparent exchange current density decreases much more gradually with mole fraction alcohol than found for n-propanol, reaching a minimum of $i_o = 3$ mA/cm² at about 0.5 mole fraction methanol.

Discussion

The $Zn^{2+}/Zn(Hg)$ electrode reaction can be described by a single two-electron step over the entire concentration range of n-propanol. The apparent exchange currents calculated from the charge-transfer resistance at low overvoltages and from coulostatic measurements assuming a two-electron step agree with the values obtained by extrapolating the Tafel plots to zero overvoltage. No assumption regarding the number of electrons involved is required in determining the exchange current from the Tafel extrapolations. Furthermore, the expected value of unity is obtained for the sum of the anodic and cathodic transfer coefficients determined from the Tafel relationship when a two-electron step is assumed, although this sum is about two if a rate-determining step involving a single electron is assumed. Similar results supporting a two-electron transfer step were found by Jaenicke and Schweitzer in other organic solvents (12).

The effect of the addition of n-propanol on the apparent transfer coefficients and apparent exchange current density (Fig. 1 and 2) may result from specific adsorption of the alcohol on the electrode surface, from changes in the potential, ϕ_2, of the diffuse double layer, or from changes in the charge-transfer reaction mechanism. Apparently all three effects are present in this complex system.

Considering the effect of the potential, ϕ_2, of the diffuse double layer, the relationship between the total current, i, and the change-transfer overvoltage, η, is

$$i = i_t^o \cdot e^{(n\beta - z)\frac{F}{RT}\phi 2} \cdot \left[e^{\frac{\alpha_t n F}{RT}\eta} - e^{\frac{-\beta_t n F}{RT}\eta} \right] \quad [4]$$

where i_t^o is the true exchange current, n is the number of electrons involved in the electrode reaction, z is the ionic valence of the oxidized species, α_t and β_t are the true anodic and cathodic transfer coefficients, respectively, and **F**, *R*, and *T* are as usual (21).

For small ϕ_2 potentials occurring in a large excess of indifferent electrolyte, $\phi_2 - \phi_2(\eta = 0) \simeq (C_D/C_d) \cdot \eta$ where C_D is the capacity of the total double layer (Fig. 4) and C_d is the capacity of the diffuse double layer (22), and Eq. [4] becomes

$$i = i_o \cdot \left[e^{\frac{\alpha n F}{RT}\eta} - e^{\frac{-\beta n F}{RT}\eta} \right] \quad [5]$$

where α and β are the apparent transfer coefficients and i_o is the apparent exchange current at $\eta = 0$. The relationship between the experimental apparent transfer coefficient, β, and the true value, β_t, is

$$\beta = \beta_t + \left(\frac{z}{n} - \beta_t \right) C_D/C_d = 1 - \alpha \quad [6]$$

In aqueous or near aqueous solutions where $Zn(H_2O)_x^{++}$ is the oxidized species, $n = z = 2$, hence

$$\beta = \beta_t + \alpha_t \cdot C_D/C_d \quad [7]$$

The correction factor, $\alpha_t \cdot C_D/C_d$, is usually less than the experimental error (5%) in aqueous solutions containing a large excess of indifferent electrolyte (22).

According to Eq. [7], the initial increase in the apparent cathodic transfer coefficient, β, upon adding n-propanol (Fig. 1) represents either an increase in the true transfer coefficient, β_t, or an increase in the correction factor $\alpha_t \cdot C_D/C_d$. Figure 4 shows a sharp decrease in C_D on adding n-propanol, probably due to specific adsorption of n-propanol on the electrode which lowers the dielectric constant of the Helmholtz double layer (23) and hence the Helmholtz capacity, C_H. In the presence of the 1.0M excess $LiClO_4$ electrolyte, the effect of the alcohol on the diffuse double layer capacity, C_d, will be small compared with the effect on C_H. An unreasonable 5- to 10-fold decrease in C_d to a value of about 50 μf/cm² is required to explain the initial increase in β in terms of the correction factor $\alpha_t \cdot C_D/C_d$. Therefore, it is concluded that the initial changes in the apparent transfer coefficients upon adding n-propanol (Fig. 1), reflect the changes in the true transfer coefficients. This is contrary to previous reports that the transfer coefficients of the $Zn^{2+}/Zn(Hg)$ electrode reaction are unaffected by the presence of alcohol (2, 12). However, it is interesting to note that values for β_t obtained by Jaenicke and Schweitzer (12) in water-tetrahydrofuran mixtures change with addition of the organic solvent very similarly to the change in β observed using n-propanol. The correction factor used by Jaenicke and Schweitzer (12) for the effect of the diffuse double layer can be shown to be equivalent to the correction factor in Eq. [7].

The increase in the true cathodic transfer coefficient, β_t, upon addition of n-propanol indicates that the transition state has moved closer to the electrode surface. In mixed water-alcohol solvents, the metal ion is preferentially solvated by water (24-26) while the alcohol tends to be specifically adsorbed on the amalgam electrode surface (2, 12, 23). In the cathodic reaction, the water molecules in the solvent shell of the Zn^{++} ion are exchanged for alcohol molecules as the Zn^{++} ion passes into the adsorbed alcoholic layer, whereupon desolvation follows as the Zn^{++} ion proceeds to the electrode surface (12). It is reasonable that the transition state occurs closer to the electrode surface in the presence of specifically adsorbed alcohol than in the case of pure aqueous solutions where only simple desolvation of Zn^{++} is involved. Figure 1 indicates that this effect relaxes as the increasing alcohol concentration reduces the contrast between the solvent composition at the electrode surface and in the bulk solution. Fundamental changes in the reaction mechanism may also occur as the solvent composition changes which may affect β_t.

The potential dependence of the electrochemical transfer coefficients (27) must also be considered in any interpretation of the behavior of β. In the cathodic

potential region where β was determined, the transfer coefficients for $Zn^{2+}/Zn(Hg)$ electrode reaction do not show any significant dependence on the potential (5, 28). In the anodic potential region where α was determined, it is reported that α tends to decrease with increasing potential (5, 28). Figure 1 does show that many experimental α values do tend to be smaller than expected, but this result is not entirely outside the experimental error.

The product of viscosity and conductivity, $\eta_v \cdot k$, shown in Fig. 3 indicates the extent of ion association in these solutions since $\eta_v \cdot k$ is roughly proportional to the ionic concentrations (12). Figure 3 indicates that about 60-70% of the salts present are undissociated in solutions with high n-propanol concentrations.

Plotting the equilibrium potential ϵ_o, *vs.* $\log[LiClO_4]$ in 0.98 mole fraction propanol gives a slope of about -30 mV (Fig. 5), suggesting from the Nernst equation that the net electrode reaction in this solution is $ZnClO_4^+ + 2e^- \rightleftharpoons Zn + ClO_4^-$, assuming that the activity of ClO_4^- is proportional to $[LiClO_4]$.

The electrochemical reaction order, P, for the ClO_4^- ion in the cathodic reaction can be determined from the relationship (29)

$$\frac{\partial \ln i_o}{\partial \ln a_k} = P + \frac{\alpha_t n\mathbf{F}}{RT}\frac{\partial \epsilon_o}{\partial \ln a_k} + (n\beta_t - z)\frac{\mathbf{F}}{RT}\frac{\partial \phi_2^e}{\partial \ln a_k} \quad [8]$$

where a_k represents the activity of the ClO_4^- ion and ϕ_2^e represents the value for ϕ_2 at $\epsilon = \epsilon_o$. The term involving ϕ_2^e is usually neglected when a_k represents some species other than the excess electrolyte. Figure 5 shows the variation of i_o *vs.* $\log[LiClO_4]$ in 0.94 mole fraction alcohol as determined from coulostatic measurements. Using the approximate relationship (30) $\partial \phi_2/\partial \ln a_k \simeq RT/\mathbf{F}$ (taking the positive sign since the Epzc measurements indicate $\phi_2 < 0$) and the relationship $z = n - P$ converts Eq. 8 to

$$\frac{\partial \ln i_o}{\partial \ln a_k} \simeq 2P - n + n\beta_t + \frac{\alpha_t n\mathbf{F}}{RT}\frac{\partial \epsilon_o}{\partial \ln a_k} \simeq 2P - 2 \quad [9]$$

where various terms were evaluated using $n = 2$ and $\beta_t = 0.3$ and estimating $\partial \epsilon_o/\partial \ln a_k$ from Fig. 5. Assuming $a_k = [LiClO_4]$ to evaluate $\partial \ln i_o/\partial \ln a_k$ from Fig. 5 yields, using Eq. [9], $P \simeq 0.75$ for $[LiClO_4] < 0.8M$ and $P \simeq 1$ for $[LiClO_4] > 0.8M$.[2] This suggests that at high $LiClO_4$ concentrations in the alcohol-rich solutions, the rate-determining step is primarily

$$ZnClO_4^+ + 2e^- \rightleftharpoons Zn + ClO_4^- \quad [10]$$

while for low $LiClO_4$ concentrations there is likely to be a parallel reaction involving the solvated Zn^{++} ion. It is interesting to note that the slope of the $\log i_o$ *vs.* $\log[LiClO_4]$ plot (Fig. 5) changes where $[LiClO_4] = [H_2O] = 0.8M$. At higher $LiClO_4$ concentrations, due to the shortage of water molecules, some of the Li^+ or Zn^{++} ions must remain completely dehydrated in the solution.

The apparent exchange current, i_o, is related to the true exchange current, i_t^o, by the expression

$$i_o = i_t^o \cdot e^{(n\beta_t - z)\frac{\mathbf{F}}{RT}\phi_2} \quad [11]$$

where $\phi_2 < 0$ since measurements are made at potentials negative to Epzc. For discharge of either $Zn^{++} \cdot solv$ or $ZnClO_4^+ \cdot solv$, $n\beta_t < z$, hence $i_o > i_t^o$. The sharp decrease in i_o upon adding n-propanol (Fig. 2) may be attributed either to a decrease in i_t^o or to ϕ_2 becoming less negative. Probably both effects are present.

Aramata and Delahay (2) showed that addition of n-amyl alcohol produces a sharp decrease in i_o for $Zn^{2+}/Zn(Hg)$ electrode reaction which they account for by ϕ_2 becoming less negative with addition of the alcohol and by the decrease in the effective surface area resulting from coverage of the electrode by the n-amyl alcohol. Their results are for 0.05M $Mg(ClO_4)_2$ electrolyte. In 1M $LiClO_4$ electrolytes, the ϕ_2 effect on the apparent exchange current will be much less.

A decrease in i_t^o upon addition of the alcohol can be attributed to the discrepancy between the solvent composition at the electrode and in the solvation shell of the Zn^{++} ion. In pure aqueous solutions, the major energy barrier to the discharge of the Zn^{++} ion is probably dehydration of the $Zn^{++} \cdot aq$ ion. With alcohol specifically adsorbed on the electrode, the dehydrated Zn^{++} must also compete with the alcohol for adsorption onto the electrode surface which increases the energy barrier. Similar arguments for an increased energy barrier upon adding an organic solvent are proposed by Jaenicke and Schweitzer (12). Their reported exchange currents are also apparent exchange currents since their corrective term for the diffuse double layer, $\eta \cdot C_D/C_d$, becomes zero at $\eta = 0$.

The steep increase in i_o above 90% alcohol (Fig. 2) probably results from complete replacement of water in the solvation shell of the Zn^{++} by propanol molecules. Calculations show that at 0.9 mole fraction alcohol there is only one water molecule available for each Li^+ and Zn^{++} ion in the solution. Both ions tend to be preferentially solvated by the water (24), hence competition for the water molecules becomes intense. As the alcohol concentration increases beyond 90 mole per cent (m/o) n-propanol, the Zn^{++} or $ZnClO_4^+$ ions may tend to become solvated solely by the alcohol. The energy barrier for desolvation of the alcoholic Zn^{++} ion is likely much less than for the aqueous Zn^{++} ion, hence i_t^o and i_o increase rapidly in this region. As the

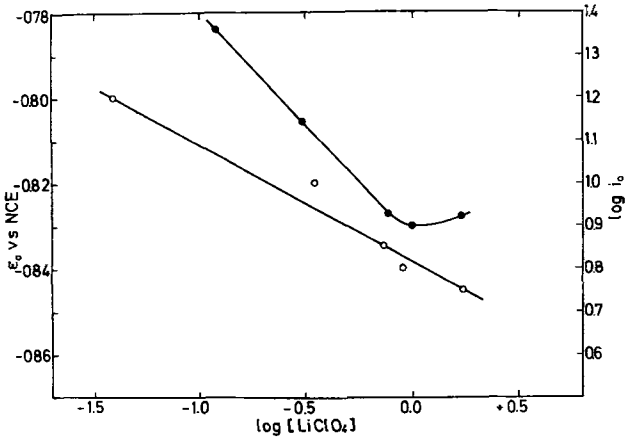

Fig. 5. Variation of the equilibrium potential, ϵ_o, and apparent exchange current density, i_o, for the $Zn^{2+}/Zn(Hg)$ electrode reaction with $\log[LiClO_4]$ at 25.0°C. The ϵ_o values were determined in 0.98 mole fraction n-propanol while the i_o values are for 0.94 mole fraction n-propanol. ○, ϵ_o measurements. ●, i_o measurements.

[2] Using the relationship $a_k = c_k\gamma$ where c_k and γ are the concentration and activity coefficient, respectively, of species k, Eq. 9 may be written

$$\frac{\partial \ln i_o}{\partial \ln c_k} = 2P - n\alpha_t + \frac{\alpha_t n\mathbf{F}}{RT}\frac{\partial \epsilon_o}{\partial \ln c_k} + (2P - n\alpha_t)\frac{\partial \ln \gamma}{\partial \ln c_k}$$

From Fig. 5, $\frac{\alpha_t n\mathbf{F}}{RT}\frac{\partial \epsilon_o}{\partial \ln c_k} = -n\alpha_t/2$. Letting $y = \frac{\partial \ln i_o}{\partial \ln c_k}$ and $x = \frac{\partial \ln \gamma}{\partial \ln c_k}$ and solving the above equation for the reaction order, P, gives

$$P = \frac{n\alpha_t(3/2 + x) + y}{2(1 + x)}$$

From the mean activity coefficient of $LiClO_4$ in aqueous solutions, generally $|x| < 0.1$. In alcohol solutions, indications are that γ decreases more markedly with salt concentration than in aqueous solutions which would give larger values for $|x|$. Nevertheless, the value of P is fairly insensitive to tne actual value of x for x values greater than -0.5. For example, using $y = 0$ from Fig. 5, P varies from only 1.4 to 0.9 in 1M $LiClO_4$ for x values ranging from -0.5 to $+0.5$. At the higher salt concentrations, $|x|$ likely decreases and approaches zero as γ approaches a minimum value. A more exact analysis awaits the actual measurement of the mean activity coefficient of $LiClO_4$ in these solutions.

remaining water molecules in the Zn^{++} ion are replaced by n-propanol molecules, the reaction mechanism probably shifts to that of Eq. [10] involving $ZnClO_4^+ \cdot solv$.

The gradual increase in i_o between 0.1 and 0.8 mole fraction n-propanol (Fig. 2) is probably due to ϕ_2 gradually becoming more negative from decreasing dissociation of the salts (Fig. 3). As long as water molecules are available, the Zn^{++} ion will apparently remain preferentially solvated by the water molecules (24-26). Partial exchange of water molecules for n-propanol molecules in the solvation shell of the Zn^{++} ion at the higher alcohol concentrations would likely contribute to this increase in i_o.

Summary

Galvanostatic and coulostatic measurements of the apparent exchange current and apparent transfer coefficients for the $Zn^{2+}/Zn(Hg)$ electrode reaction in binary mixtures of water and n-propanol are reported.

The observed changes in these quantities can be interpreted in terms of changes in the potential across the diffuse double layer, specific adsorption of the alcohol on the electrode surface and preferential solvation of Zn^{++} ions by water, and by a change to a reaction mechanism involving $ZnClO_4^+$ as the concentration of n-propanol increases.

Acknowledgment

The authors wish to thank D. Laupheimer for valuable technical assistance in the coulostatic measurements. Dr. Melvin H. Miles expresses appreciation for a NATO postdoctoral research fellowship which made this work possible.

An Electrochemical Oxygen and Sulfur Vapor Gauge with Pyrex as Solid Electrolyte[1]

D. Yuan* and F. A. Kröger*

Department of Materials Science, University of Southern California, Los Angeles, California 90007

ABSTRACT

Electrochemical cells W,Na|Pyrex|Pt,O_2; Pt,O_2|Pyrex|Pt,O_2; and W,Na|Pyrex|C,S_2 are found to give emf's following the Nernst formula. The emf is attributed to the formation of Na_2O or Na_2S in the glass near the glass-gas interface. After strong polarization in either direction, the cell emf returns to the value for the unperturbed system. Energies and entropies of solution of Na_2O in Pyrex are shown to be close to the corresponding values for the formation of Na_2SiO_3. Pyrex cells can be used as O_2 or S_2 pressure gauges.

Glass has been used as solid electrolyte in the cell H_2|glass|O_2 for measuring the emf's due to the formation of water from oxygen and hydrogen (1-3). Pyrex, a borosilicate glass (4), has been used as a sodium ion specific membrane in contact with molten sodium salts (5) or liquid sodium alloys (6) to measure sodium activities. The Na^+ conductor Na-βAl_2O_3 has been used as a solid electrolyte in a cell based on the reaction $Na(l) + S(l) \rightarrow Na_2S$ (7). It is of interest to see whether Pyrex can also be used to measure the oxygen and sulfur pressure in gases. To this end, emf measurements were carried out on cells of the types

$$W, Na(l) |Pyrex|Pt, O_2(g) \quad [1]$$

$$W, Na(l) |Pyrex|C, S_2(g) \quad [2]$$

and

$$Pt, O_2(I) |Pyrex|Pt, O_2(II) \quad [3]$$

The reactions underlying a possible emf are

* Electrochemical Society Active Member.

Key words: oxygen pressure gauge, sulfur pressure gauge, Pyrex, gas cell.

$$2Na(l) + \tfrac{1}{2}O_2(g) \rightarrow Na_2O \text{ (glass)}; G^\circ (Na_2O, \text{glass}) \quad [4]$$

$$2Na(l) + \tfrac{1}{2}S_2(g) \rightarrow Na_2S \text{ (glass)}; G^\circ (Na_2S, \text{glass}) \quad [5]$$

and

$$O_2(p_{O_2})_I \rightarrow O_2(p_{O_2})_{II} \quad [6]$$

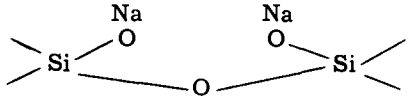
Na_2O (glass) and Na_2S (glass) indicate the state of the compounds as they are present in the glass at the glass-gas interface. If the activity of Na_2O in the glass is a_{Na_2O}, then the free enthalpy of Na_2O in the glass is

$$G^\circ (Na_2O, \text{glass}) = G^\circ (Na_2O) + RT \ln a_{Na_2O} \quad [7]$$

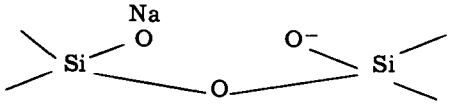
$G^\circ(Na_2O)$ being the standard free enthalpy of $Na_2O(s)$. A similar expression holds for G° (Na_2S, glass). A value of $a_{Na_2O} \neq 1$ must be expected to result partly from the heat and vibrational entropy of solution of Na_2O in the glass ($G_{exc.\ ox.} = H_{exc.\ ox.} - TS_{exc.\ ox.}$) and partly from configurational entropy due to the distribution of the Na_2O or its components in the glass ($a_{Na_2O,\ config.}$)

$$RT \ln a_{Na_2O} = RT \ln a_{Na_2O,\ config.} + G_{exc.\ ox.} \quad [8]$$

For simple solution behavior, $a_{Na_2O} = x^n_{Na_2O}$, n depending on the atomic structure of the solution. We expect $n = 1$ for incorporation of Na_2O in a manner in which only one defect is formed, the two Na's being close together

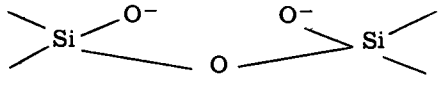


$n = 2$, if two defects are formed in concentrations larger than the native disorder



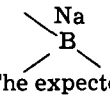
$+ Na_i^+$

and $n = 3$ if three defects are formed



$+ 2\ Na_i^+$

Alternatively, we may have configurations involving boron



$(n = 1)$, or 
$+ Na_i^+$ $(n = 2)$

The expected emf's are for cell [1]

$$-E_1 = \frac{1}{2F}[G^\circ (Na_2O) + G_{exc.\ ox.} + RT \ln a_{Na_2O,\ config.}\, p_{O_2}{}^{-1/2}\, a_{Na}{}^{-2}] \quad [9]$$

a_{Na} being the activity of Na in the melt at the left hand side, and p_{O_2} the oxygen pressure in the gas at the right-hand side.

Similarly, for cells [2]

$$-E_2 = \frac{1}{2F}[G^\circ (Na_2S) + G_{exc.\ sulf.} + RT \ln a_{Na_2S,\ config.}\, p_{S_2}{}^{-1/2}\, a_{Na}{}^{-2}] \quad [10]$$

Cells [3] should follow the Nernst expression

$$-E_3 = \frac{RT}{4F} \ln \frac{(p_{O_2})_{II}}{(p_{O_2})_I} \quad [11]$$

Since $G^\circ = H^\circ - TS^\circ$ and $G_{exc.} = H_{exc.} - TS_{exc.}$, Eq. [9] and [10] can be rewritten as

$$-E_{ox.} = \frac{1}{2F}\left[[H^\circ (Na_2O) + H_{exc.\ ox.}] - T\left[S^\circ (Na_2O) + S_{exc.\ ox.} + R \ln \frac{a^2_{Na}\, p_{O_2}{}^{1/2}}{a_{Na_2O,\ config.}}\right]\right] \quad [12]$$

and

$$-E_{sulf.} = \frac{1}{2F}\left[[H^\circ (Na_2S) + H_{exc.\ sulf.}] - T\left[S^\circ (Na_2S) + S_{exc.\ sulf.} + R \ln \frac{a^2_{Na}\, p_{S_2}{}^{1/2}}{a_{Na_2S,\ config.}}\right]\right] \quad [13]$$

If we neglect the temperature dependence of H and S, [12] and [13] indicate that the emf's of cells [1] and [2] are of the form $E = E_o - BT$. A plot of the emf as a function of temperature is a straight line, with E_o, the intercept at $T = 0°K$, equal to $-(H^\circ_{Na_2O} + H_{exc.\ ox.})/2F$ and the slope B, equal to $-\frac{1}{2F}\left(S^\circ + S_{exc.\ ox.} + R \ln \frac{a^2_{Na}\, p_{O_2}{}^{1/2}}{a_{Na_2O,\ config.}}\right)$ with similar expressions for the sulfur case.

Experimental

Sealed sodium-filled glass cells were made as indicated in Fig. 1. The sodium was Mallinckrodt pro analysis sodium, used without further purification. As electrodes and leads, pure tungsten wires were used at the Na side, Pt wire and Pt paste at the oxygen sides (cells [1] and [3]), and graphite yarn and graphite powder at the sulfur side (cell [2]).

The sodium cell was placed inside another Pyrex tube which serves as a protection against the outside atmosphere, and the combination was mounted inside a furnace. Temperature fluctuations were kept within ±2°C by operating the furnace on a constant voltage transformer. A Chromel-Alumel thermocouple was used in measuring the temperatures. The cell emf's were measured by a Cary 31CV vibrating reed electrometer which serves as a high impedance voltmeter. When different electrode materials were used, the emf values were corrected for the small thermoelectric power of the couples these materials constitute. In the polarization experiments, outside voltages were supplied by constant voltage dry batteries and currents were measured with a Simpson meter. A digesting period is necessary for each measurement at the desired temperature in order to reach a steady state. Several gases were used to establish different oxygen activities, such as $N_2 + 10^{-5}$ atm O_2 and Ar + 10^{-7} atm O_2. For lower oxygen activities, CO/CO_2 and H_2/H_2O buffer systems were used. For the H_2/H_2O system, tank hydrogen gas is passed through water at known temperature so that the hydrogen gas is saturated with water vapor at that temperature. For the CO/CO_2 sys-

tem, tank nitrogen (containing 10^{-5} O_2) is passed over graphite which transforms the oxygen into a mixture of CO and CO_2 (8). The graphite was in a Pyrex tube inside another furnace. Different ratios of CO/CO_2 can be established by keeping the graphite at different temperatures. The "$N_2 + H_2$" mixture point was achieved by passing N_2 (containing 10^{-5} O_2) and H_2 in a 1:1 ratio through a liquid air trap to remove water, and then through a furnace at 700°C to transform the oxygen into water vapor. The oxygen pressure can be calculated from the H_2/H_2O ratio, the latter being known if it is assumed that all the O_2 in N_2 is turned into H_2O. In all cases but the latter, the oxygen pressure was determined with the aid of a cell with calcia-stabilized zirconia as solid electrolyte. For "$N_2 + H_2$," the O_2 pressure falls outside the range where the electrolyte has an ionic transference number equal to one, and therefore we have to rely on the calculated pressure. In the sulfur cells, sulfur pressures were established by various methods. In a first set of experiments, solid or liquid sulfur was present in the outer compartment of the cell and the temperatures of the sulfur and the cell were the same. In a second set of experiments, the sulfur and the cell were at different temperatures. Use of two separately controlled sections of the furnace makes it possible to vary the temperature of the sulfur source and the cell independently; *i.e.*, we can study the properties of the cell at constant T under varying sulfur pressures. In order to transfer the sulfur vapor from one compartment to the other, pure argon was used as a carrier gas. Finally, in a third series of experiments, H_2S and mixtures of $H_2 + H_2S$ were used to establish low sulfur activities.

Results and Discussion

Oxygen cells.—Figure 2 shows the emf of the oxygen cells at 500°C as a function of the oxygen activity. All the points except the "$N_2 + H_2$" point are close to the line showing the O_2 pressure dependence required by Eq. [9]. This indicates that the interpretation of the cell emf as being based on the formation of Na_2O is correct: formation of Na_2O_2 would give a dependence $\propto p_{O_2}$. In order to find the reason for the deviation of the "$N_2 + H_2$" point, let us consider the theoretical low-pressure limit for the operation of the cell. This limit is different for buffered and for nonbuffered gases. For the former, this limit is set by the oxygen pressure at which liquid sodium with $a_{Na} = 1$ is formed. In this case the cell [1] becomes identical with a cell Na(l) |Pyrex|Na(l) with $E = 0$. Extrapolation of the Nernst line in Fig. 2 to $E = 0$ gives $(p_{O_2})_{\text{limit, buffer}} = 10^{-60}$ atm—well below the 10^{-40} value of the "$N_2 + H_2$" point. In nonbuffered gases, we expect the cell to be limited by the dissociative evaporation of Na_2O

$$Na_2O\ (\text{glass}) \rightarrow 2Na(g) + \tfrac{1}{2}O_2(g); \quad G^\circ_{\text{evap. ox.}} \quad [14]$$

$$p_{Na}^2\, p_{O_2}^{1/2} = \exp\left(-G^\circ_{\text{evap. ox.}}/RT\right) \quad [15]$$

with $G^\circ_{\text{evap. ox.}} = -G^\circ(Na_2O, \text{glass}) + 2G^\circ(Na_{1\rightarrow g})$. $G^\circ(Na_2O, \text{glass})$ is given by the emf $E_1 = 2.52$V of cell [1] with pure Na(l) on one side and 1 atm O_2 on the other at 500°C: $G^\circ(Na_2O, \text{glass}) = -2FE_1 = -116.2$ kcal mole. $G^\circ(Na_{1\rightarrow g}) = 25.7$ kcal/mole (9) and, thus, $G^\circ_{\text{evap. ox.}} = 167.6$ kcal/mole and $\exp(-G^\circ_{\text{evap. ox.}}/RT) = 2.7 \times 10^{-48}$ $\text{atm}^{5/2}$. At the sublimation point, $p_{Na} = 4p_{O_2}$; then [15] leads to $(p_{O_2})_{\text{limit, unbuffered}} = 3.1 \times 10^{-20}$ atm. This is much larger than the value $\approx 10^{-38}$ atm the Nernst line indicates for the "$N_2 + H_2$" point and shows that the H_2/H_2O buffer is still active. This is to be expected. Since only reaction of H_2 and O_2 is involved, this H_2O-poor buffer should perform as well as the mixtures with more water. The deviation of the $N_2 + H_2$ point can therefore not be explained by a deviating oxygen activity in the gas phase, but must be due to a different chemical reaction having become potential determining—possibly nitride formation. Further work is necessary to solve this problem. In any case, the cell is shown to be reliable down to a pressure of 10^{-32} atm O_2.

In order to check the stability and reproducibility of the cell, it was polarized for several hours with a voltage of 12V with a Na electrode either positive or negative. Figure 3 shows the relaxation of the cell emf measured after removal of the polarizing field. For

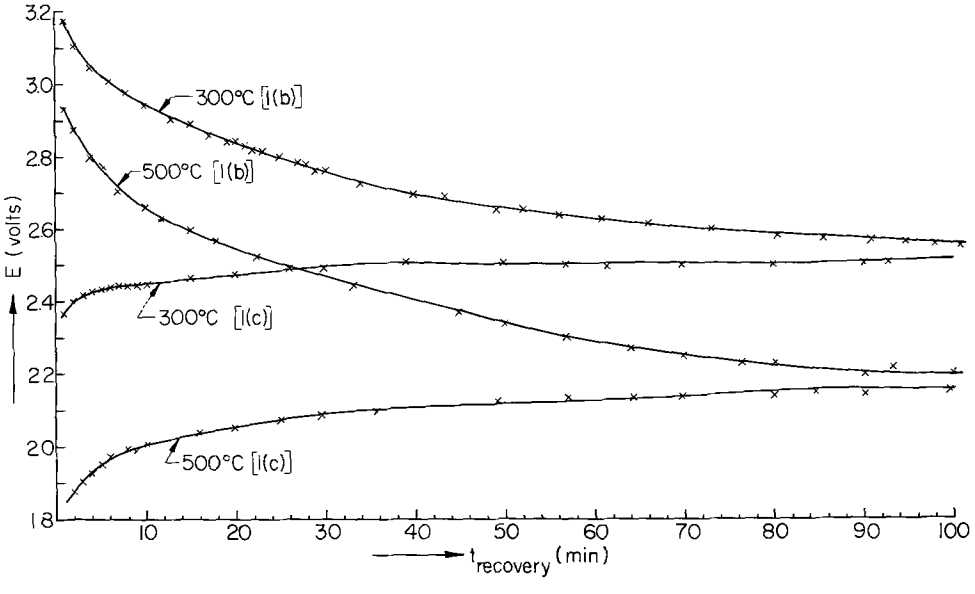

Fig. 3. Variation of the emf with time for an oxygen cell after polarization.

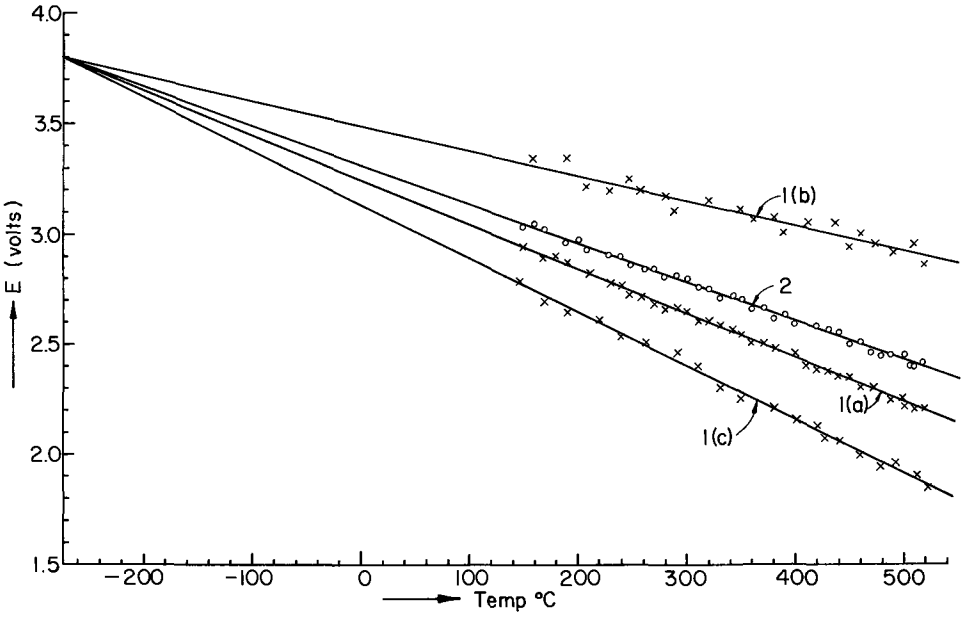

Fig. 4. Emf as $f(T)$ for a cell W, Na(l) | Pyrex | Pt, O_2, 1(a)—$p_{O_2} = 10^{-5}$ atm; unpolarized. 1(b)—As (a), but polarized (Na^+ pulled inward). 1(c)—As (a), but polarized (Na^+ pulled outward). 2—$p_{O_2} = 1$ atm.

both directions of polarization, the cell returns to its original emf in 1.5-2 hr.

Figure 4 shows the emf of the oxygen cells as a function of temperature. The lines 1(a) and 2 represent the equilibrium emf's for $N_2 + 10^{-5}$ atm O_2 and pure O_2, respectively. Lines 1(b) and 1(c) are obtained after polarization with a field of 12V at the corresponding temperature for several hours until the readings did not change with further polarization. For 1(b), the Na-side of the cell was negative; *i.e.*, sodium ions were removed from the outer surface. For 1(c), the same voltage was applied in the opposite direction; *i.e.*, sodium ions were drawn to the outer surface. In both cases the final values, taken approximately 30 sec after removal of the polarizing field, are independent of the time of polarization and the voltage used for polarization. This independence suggests for 1(b) that electrolysis has taken place with formation of a new phase (Na_2O or Na_2SiO_3) at the outer surface. Yet, as shown in Fig. 3, the original emf is restored in a comparatively short time, which suggests that true polarization, without second-phase formation, has occurred or, at least, that the formation of a second phase does not affect the emf. This is also indicated by the fact that 1(b) and 1(c) extrapolate to the same $T = 0$ value in the equilibrium lines. For all four cases [though with considerable scatter for 1(b) and 1(c)], the emf is a linear function of T: $E = E_o - BT$. The equilibrium lines 1 and 2 fit the relation

$$E = 3.80 - 1.75 \times 10^{-3}T - \frac{RT}{2F} \ln a^2_{Na}\, p_{O_2}{}^{1/2} \quad [16]$$

Interpretation of $E_o = 3.80$V on the basis of Eq. [12], neglecting the temperature dependence of H and S, leads to $H^\circ_{Na_2O} + H_{exc.\ ox.} = -173$ kcal/mole; with $H^\circ_{Na_2O,\ 298} = -100.6$ kcal/mole (10), this gives $H_{exc.\ ox.} = -72.4$ kcal/mole,[2] somewhat more negative than the enthalpy effect of the reaction

$$Na_2O + SiO_2 \rightarrow Na_2SiO_3;\ H^\circ_{298} = -56.5 \text{ kcal/mole (11)},$$

$$\Delta S = -40 \text{ cal/deg mole (11)} \quad [17]$$

The slope B for cell [2] is 1.75 x 10^{-3} V/°K. The quantity $2FB = 80.7$ cal/deg mole can be identified with $-[S^\circ(Na_2O) + S_{exc.\ ox.} - R \ln a_{Na_2O,\ config.}]$. For Na_2O made from Na(l), $\Delta S^\circ(Na_2O)_{298} \cong -37$ cal/deg mole (10); then $S_{exc.\ ox.} - R \ln a_{Na_2O,\ config.} \cong 43.7$ cal/deg mole. $S_{exc.\ ox.}$ should be close to ΔS of reaction [17].

[2] Since we neglect the temperature dependence of H and S in the interpretation of E_o and B, there is no point in distinguishing between H°_{298} and H°_0 and ΔS_{298} and ΔS°_0.

Therefore, $R \ln a_{Na_2O,\ config.}$ must be very small. Figure 5 shows the emf measurements of cell [3], with oxygen at different pressures at the two sides. The readings of the emf's have an uncertainty of ±5 mV, the flow of gas through the cell making the temperature somewhat unsteady. The readings, however, are close to the calculated values of Eq. [11].

It may be concluded that Pyrex glass cells may be used as an oxygen activity sensor. Since the large value of E_o for the sodium cell introduces a considerable source of error, it is preferable to use a cell of type [3], provided temperature effects can be eliminated. The sodium-oxygen cell can also be used to determine the Na_2O activity in sodium glasses.

Sulfur cells.—Figure 6 shows the emf of sulfur cells of type [2] as a function of the temperature of the cell for various sulfur pressures. The curve for saturated sulfur vapor corresponds to the case that the sulfur source and the cell are at the same temperature. For the other curves, the sulfur source was at temperatures different from that of the cell. When sulfur vapors, produced by evaporation of S(l) at a total pressure determined by the source temperature, reach the cell compartment with its higher temperature, the total pressure remains the same but the partial pressure of the molecular species S_2, S_3 . . . S_7, S_8 is changed. The pressure of a particular species, *e.g.* S_2, is related to those of all other species by known equilibrium constants of reactions such as $3S_2 \rightarrow 2S_3$, $2S_2 \rightarrow S_4$, *etc.* (12), and, for a given total pressure, the pressures of the various species can be calculated. Figure 7 shows the partial pressure of S_2 at different temperatures with the sulfur source at 200°, 250°, 300°, and 350°C.

By combining Fig. 6 and 7, we can construct the emf of cells of type [2] as a function of p_{S_2} at different temperatures (Fig. 8). The emf can be represented by

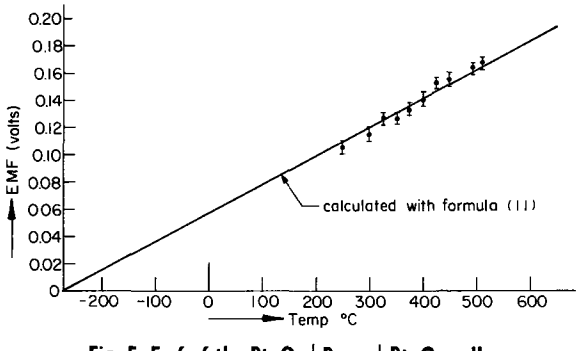

Fig. 5. Emf of the Pt, O_2 | Pyrex | Pt, O_2 cell

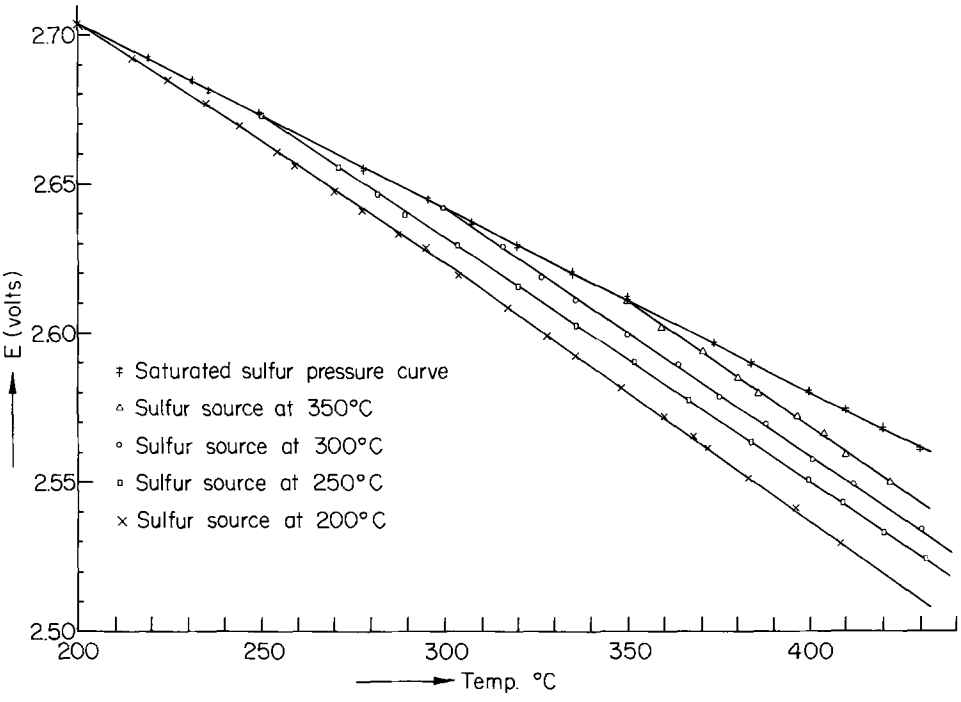

Fig. 6. Emf as function of temperature for the sodium-sulfur cell with saturated and non-saturated sulfur vapor.

$$E = E_0 - BT = 3.32 - \left(1.03 \times 10^{-3} + \frac{R}{2F} \ln a_{Na} p_{S_2}^{1/2} \right) T \quad [18]$$

The sulfur pressure dependence indicates that sulfur is incorporated at the glass surface as single ions $S^=$, as is to be expected if Na_2S is formed.

The intercept at $T = 0$ is $E_0 = 3.32$V, or $-(H^\circ_{Na_2S} + H_{exc.\ sulf.}) = 153$ kcal/mole for this reaction. As $H^\circ_{Na_2S} \cong -93$ kcal/mole (10), $H_{exc.\ sulf.} \cong -60$ kcal/mole, somewhat smaller than in the oxide case. It should be not too different from the unknown enthalpy of the reaction $Na_2S + SiO_2 \rightarrow Na_2S \cdot SiO_2$. Further, we find $S_{exc.\ sulf.} \cong -17$ cal/deg mole $+ R/2F \ln a_{Na_2S,\ config.}$

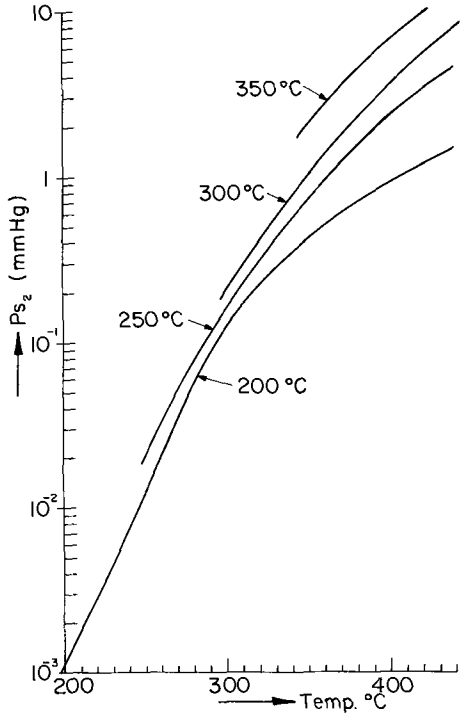

Fig. 7. Partial pressures of S_2 as a function of the temperature of overheating for sulfur vapor generated by heating sulfur at various temperatures (indicated at the curves).

The four lines in Fig. 8 fit the relation of Eq. [13]. With low sulfur pressures established with the aid of H_2S and mixtures $H_2S + H_2$, cells of type [2] give the emf as shown in Fig. 9. The reaction $H_2S \rightleftarrows H_2 + \frac{1}{2}S_2$ leads to

$$K_p(T) = \frac{p_{H_2} \cdot p_{S_2}^{1/2}}{p_{H_2S}} \quad [19]$$

with (13)

$$\log K_p(T) = -\frac{4.57 \times 10^3}{T} + 2.35 \quad [20]$$

Using Eq. [19] and [20] we can calculate values of p_{S_2} as $f(T)$, both for pure H_2S and for mixtures $H_2 + H_2S$. Then using Eq. [13] we can calculate the expected values of E of our cells and compare these to the observed emf's. There is good agreement for $T > 330$°C, but discrepancies are found for pure H_2S at $T < 330$°C. As shown in Fig. 9, these discrepancies are removed by assuming that the tank H_2S used contained an excess of sulfur equivalent to $(p_{S_2})_{extra} = 10^{-4}$ atm. This extra sulfur may have originated from persulfide ions present in the material used to generate the H_2S.

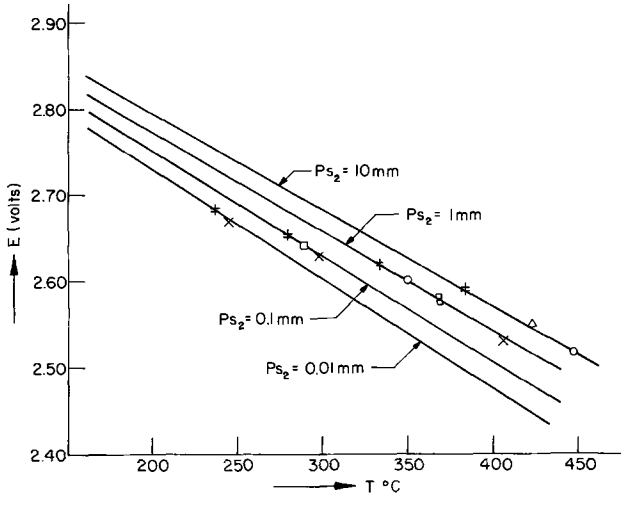

Fig. 8. p_{S_2} isobars of the sodium-sulfur cell with experimental points deduced from the data of Fig. 6.

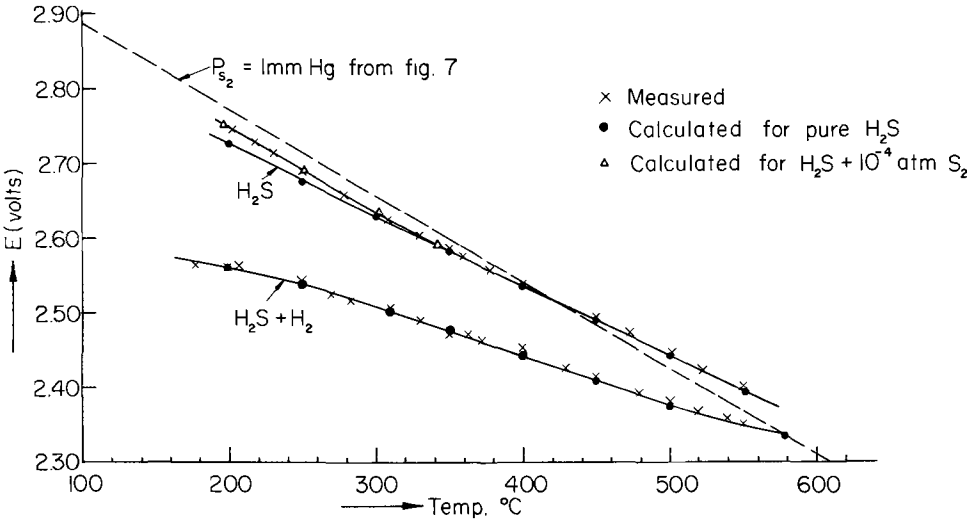

Fig. 9. Emf measurements of the sodium electrode in H_2S and an equimolar $H_2 + H_2S$ mixture compared with values calculated for pS_2 produced by pure H_2S and by $H_2S + 10^{-4}$ S_2.

It may be concluded that Pyrex glass cells may be used to measure the sulfur activity in the gases. In order to reduce errors connected with a large value of E_o, it is advisable to use cells Pt, O_2(g) |Pyrex| C, S_2(g) rather than cells [2].

Ionic Conductance in Solids

I. Compounds Formed between Silver Iodide and the Cyanides of Metals of Group IA

G. W. Mellors and D. V. Louzos*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

Compositions whose conductance is essentially ionic have been prepared in the KCN-AgI and RbCN-AgI systems. The maximum conductance is attained at a ratio of silver iodide to alkali cyanide of four to one. For example, KCN-4AgI has a conductance of 1.4×10^{-1} ohm^{-1} cm^{-1} at 25°C. The conductance has been measured as a function of temperature for KCN-4AgI and of composition for the general system. X-ray patterns and thermal analyses indicate that these new compounds are unique materials and not mixtures of their constituents.

Interest in solids that display high ionic conductance at or near room temperature arises from the fact that these materials when employed as battery electrolytes would avoid some of the difficulties associated with the conventional aqueous systems. Such shortcomings include limited shelf life, cell leakage, restricted temperature range of operation, and the difficulty of making miniaturized systems.

* Electrochemical Society Active Member.
Key words: solid electrolyte, silver iodide, conductance, KAg_4I_4CN, potassium cyanide.

It is not intended here to embark on an extensive review of the field; should the reader so desire, he may refer to a number of excellent articles (1). Very few solid materials are known possessing a specific conductance, purely ionic in nature, as high as $10^{-1} \sim 10^{-2}$ ohm^{-1} · cm^{-1}. Conductance of at least this magnitude is probably required so that cells of low internal resistance, able to deliver appreciable power, may be constructed.

The solid-state conductance of AgI (2), Ag_2HgI_4 (3), Ag_3SI (4, 5), and of the *M*I-4AgI series where *M* may

be K^+, Rb^+, or NH^+_4 (6, 7) have been reported. More recent work (8) has shown the conductance of $RbAg_4I_5$ to be 0.279 ohm^{-1} cm^{-1}, rather than the lower value of 0.21 ohm^{-1} cm^{-1} originally reported.

It was thought of interest to examine the compounds of silver iodide with the alkali cyanides and this paper describes the preparation and properties of alkali cyanide-silver iodide materials. The compounds KAg_4I_4CN and $RbAg_4I_4CN$ possess high ionic conductances very similar to those of KAg_4I_5 and $RbAg_4I_5$.

Experimental

Materials.—Silver iodide was obtained from Mallinckrodt Chemical Works. Potassium and sodium iodides and cyanides (ACS certified) were obtained from Fisher Scientific Company. Rubidium, lithium and cesium iodides, barium and silver cyanides were obtained from City Chemical Corporation. Silver metal and potassium argentocyanide were obtained from I. Miller, Incorporated, Cleveland. Argon, helium, and nitrogen were obtained from the Linde Division of Union Carbide Corporation.

All materials were stored in a dry box and wherever practicable were in addition fused and ground prior to use.

Apparatus.—Samples were made by melting together the components under argon or nitrogen in Pyrex test tubes (6 in. x 1 in.) with side arms. Pellets of samples were prepared between appropriate electrodes in a Carver Laboratory Press, Model B, and the resistance was measured with a 1000 cycle conductance bridge (Industrial Instruments, Model 216B2).

The dry box was a controlled-atmosphere laboratory Model 2C380-28R built by Kewaunee Manufacturing Company.

Differential thermal analyses were made using a Du Pont series 900 Differential Scanning Calorimeter.

Results

Preparation.—KAg_4I_4CN was prepared by melting together potassium cyanide [6.49 w/o (weight per cent)] and silver iodide (93.51 w/o) in an atmosphere of dry argon.

The procedure was as follows. The dried powders were well mixed and placed in a Pyrex tube which was flushed with dry argon for about 2 hr. After an overnight (≈16 hr) hold at 180°C, the temperature was raised to 495°C, maintained for 1 hr, and finally the tube was quenched to room temperature in a blast of cold air while the contents were protected by an argon atmosphere. (An alternative and satisfactory method of quenching was simply to pour the molten salt into liquid nitrogen.)

The material as prepared was a gray-green mass. The tube and contents were then sealed off and transferred to a dry box where the material was powdered in an agate mortar and pestle.

KAg_4I_4CN may also be prepared by heating together either KI (1 mole), AgCN (1 mole) and AgI (3 moles) or $KAg(CN)_2$ (1 mole), KI (1 mole) and AgI (7 moles). In both these cases, a material identical in all respects to that produced by the original preparation was obtained.

$RbAg_4I_4CN$ was prepared either by the reaction of RbCN (1 mole) with AgI (4 moles) or by heating a mixture of RbI (1 mole), AgCN (1 mole) and AgI (3 moles) to 400°C and quenched to room temperature. The procedure was much the same as that described previously: the reaction tube was flushed with dry nitrogen for 1 hr, heated to 130°C and held overnight, finally heated to 400°C, and quenched by plunging the tube and its contents into liquid nitrogen. The resultant solid was ground to a cream-yellow powder in a dry box.

The corresponding sodium compound was made by heating together sodium cyanide (4.96 w/o) and silver iodide (95.04 w/o). The homogenized melt was quenched from about 400° ~ 420°C to room temperature under an argon atmosphere and the material powdered in a dry box. It was dark gray-green in color.

Because of the unavailability and general difficulty of preparation of lithium cyanide, the alternative preparation starting with lithium iodide[1] (1 mole), silver cyanide (1 mole) and silver iodide (3 moles) was employed. A procedure identical to that used in the preparation of $RbAg_4I_4CN$ above was followed and the resultant compound was dark brown in color.

It should be possible to prepare $NH_4Ag_4I_4CN$ by a similar procedure but, to date, three preparations by fusing together NH_4I (1 mole), AgCN (1 mole) and AgI (3 moles) have led to gray-green solids with conductances considerably poorer than the rubidium and potassium compounds. Two preparations in sealed tubes have yielded materials of similar poor conductance.

One sample of CsCN-4AgI was made by fusion of CsI (1 mole), AgCN (1 mole) and AgI (3 moles) under argon.

One sample of the mixed potassium-rubidium compound $RbKAg_8I_8(CN)_2$ has been prepared. It is a gray solid of high conductance (see Table I). The starting materials were RbI (1 mole), $KAg(CN)_2$ (1 mole) and AgI (7 moles) and the usual heating and quenching procedures were followed.

Samples of $Ba(CN)_2$-2AgI, $Ba(CN)_2$-4AgI and $Ba(CN)_2$-8AgI were prepared by fusing together the components at 500°C under argon and quenching, still under an inert atmosphere, to room temperature. These were yellow solids of indifferent conductance (≈10^{-5} ohm^{-1} cm^{-1}).

Several compositions in the AgI-$KAg(CN)_2$ series were prepared by the above procedure with the upper temperature being in the 420°-480°C range. These materials, upon grinding in a dry box, were green-yellow powders. For conductance data on these materials, see Table I.

Table I. Conductance of cyanide-iodide materials

Material	Sp conductance (ohm^{-1} cm^{-1} at 25°C)
KCN · 4AgI	0.14
RbCN · 4AgI	0.18
NaCN · 4AgI	3.3×10^{-5}
LiCN · 4AgI	1.38×10^{-5}
NH_4CN · 4AgI	3.20×10^{-6}
CsCN · 4AgI	9.09×10^{-4}
KCN · RbCN · 8AgI	0.15
$Ba(CN)_2$-2AgI	6.6×10^{-6}
$Ba(CN)_2$ · 4AgI	1.4×10^{-5}
$Ba(CN)_2$ · 8AgI	1.3×10^{-5}
2AgI-$KAg(CN)_2$	2.9×10^{-2}
3AgI-$KAg(CN)_2$	6.7×10^{-2}
4AgI-$KAg(CN)_2$	1.2×10^{-1}
9AgI-$KAg(CN)_2$	3.8×10^{-2}
19AgI-$KAg(CN)_2$	4.5×10^{-3}

Conductance measurements.—Pellets were formed in the laboratory press at 2000 and 3000 kg/cm^2 and measured at the same pressure. It was noted that the resistance of the sample under examination decreased up to about 1000 kg/cm^2 and then remained almost constant up to the highest pressure employed (~10,000 kg/cm^2). Either platinum or silver foil electrodes were employed. The pellet was usually about 1 cm in length and 1 cm^2 in cross-sectional area; thus, the reading obtained was approximately equal to the specific resistance (or the reciprocal of the specific conductance). It was assumed that contact resistances were negligible.

Table I shows the values of the specific conductance determined for fifteen iodide-cyanide materials. From this it can be seen that the potassium and rubidium compounds possess conductances that approximate those of the MAg_4I_5 (where M is Rb, K, or NH_4) compounds previously cited (6, 7). However, the sodium and lithium versions, as in the pure iodide systems, are relatively poor conductors differing but little from silver iodide itself in this respect. Remarks on the prepa-

[1] Used as received.

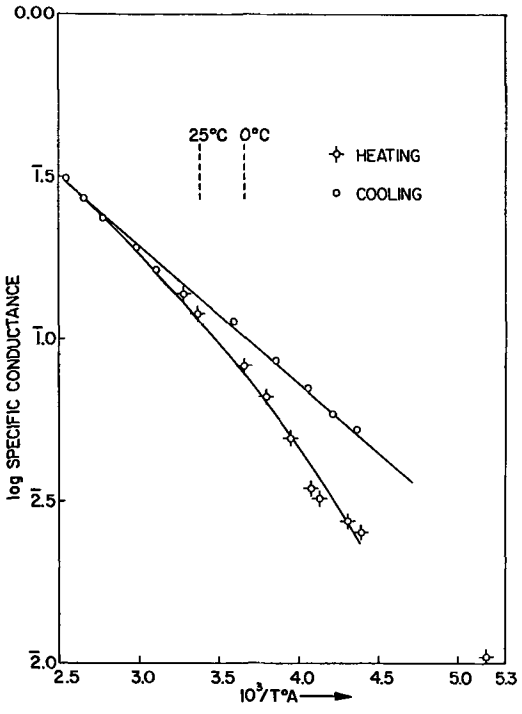

Fig. 1. Conductance of KAg_4I_4CN

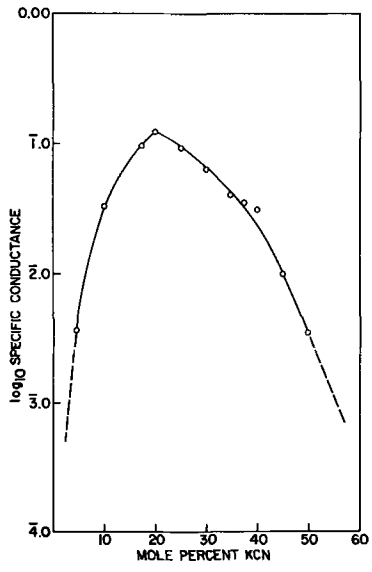

Fig. 2. Conductance as a function of composition for the KCN-AgI system at 25°C.

rations of ammonium derivative appear in an earlier section (*v.i.*) and it would appear (as yet of only one sample) that CsCN-4AgI is a borderline case vis-à-vis conductance.

In Fig. 1, the variation of conductance with temperature for KAg_4I_4CN is presented. From this graph of the logarithm of the specific conductance *vs.* the reciprocal of the absolute temperature, one may compute an apparent energy of activation of 1.94 kcal · $mole^{-1}$. Some remarks on these data are in order.

The conductance was measured at room temperature and the specimen and press were then cooled to −44°C in a large refrigeration chamber with a number of arrests, to permit attainment of equilibrium, at intermediate temperatures. Conductance measurements were obtained on the cooling cycle. During heating to 117°C, which was accomplished with a small furnace enclosing the sample, further measurements were obtained but, on the second and subsequent heating and cooling cycles, the data fell along the upper straight line of Fig. 1. It is likely that the first heating cycle causes annealing or, in general, changes to which the conductance is sensitive. Be it noted that inflections around room temperature were absent in this "annealed" material.

The conductance at 25°C of various compositions in the KCN-AgI system is shown in Fig. 2.

Nature of conductance in cyanide-iodide compounds.—It is important that the conductance of a material to be used as a solid electrolyte be essentially ionic in nature and this may be proved by demonstration of the validity of Faraday's laws.

Both KAg_4I_4CN and $RbAg_4I_4CN$ were electrolyzed under pressure between weighed silver electrodes at room temperature. In the case of the potassium salt in a run of 1 hr duration at 10 mA/cm^2 current density, anode and cathode current efficiencies of 100% were obtained. In a second experiment conducted over a 16½ hr period at 2 mA/cm^2 current density, efficiencies of 95% on the anode and 90% on the cathode were obtained. These relatively small deviations from the theoretical are probably caused by the difficulty in collecting all the cathodically deposited silver rather than by actual deviation from Faraday's laws, and for this reason it has been found preferable to weigh anode loss rather than cathode gain. The measurement of coulombs was less accurate than would have been the case had a coulometer been employed.

Measurements to determine whether a small fraction of the conductance is electronic in nature have not yet been made. It is recognized that a very small contribution ($t_e \approx 10^{-4}$) could adversely affect the behavior of the material. The deviations observed from theoretical can probably be accounted for mainly by experimental difficulty and only secondarily by an electronic contribution. Within the accuracy of the Faradaic experiments, the conductance is essentially ionic.

Although direct measurements of electronic conductance were not made, it may be inferred from the following experiment that the contribution of electrons to the total conductance is small. The emf of the cell $Ag/KAg_4I_4CN/I_2$ was 0.683V at 25°C, compared with the theoretical value of 0.687V for $Ag/AgI/I_2$ calculated from thermal data (9).

In a later experiment, electrolysis of $RbAg_4I_4CN$ between weighed silver electrodes at 0.52 mA/cm^2 current density for 94½ hr resulted in anode and cathode efficiencies of 99.7%.

X-ray patterns of iodide-cyanide materials.—Chemical analysis of the material prepared by fusion of 1 mole KCN and 4 moles AgI shows 42.65% Ag, 49.42% I, 2.33% CN and 4.1% K, compared with the theoretical values of 42.97% Ag, 47.03% I, 2.58% CN and 3.9% K. The AgI:KCN ratio of this material is computed at 3.97, and the I/CN ratio at 4.34.

The x-ray pattern of this material shows very great similarity to that observed by Bradley and Greene (6d) for $RbAg_4I_5$ and a comparison of "d" values and intensities for several of these cyanide-iodide materials and β-AgI is made in Table II.

Although certain lines are found in both the $RbAg_4I_5$ and AgI patterns, the occurrence of strong lines at "d" values of 3.74, 3.37, and 2.19 suggest that the KCN · 4AgI complex is not simply a disordered or contaminated AgI but rather a separate unique material with structure similar to the general MAg_4I_5 type of structure. However, the presence of a small impurity of AgI cannot be ruled out.

Annealing of the KCN · 4AgI complex at 190°C appears to reduce the crystallinity of the material as evidenced by the broadening and reduction in height of the x-ray peaks. This contrasts with $RbAg_4I_5$ in which annealing leads to more perfect crystallinity (and also to a higher electrical conductance). Since Raleigh (8) found no effect of annealing $RbAg_4I_5$, the material we prepared was undoubtedly not identical with his in crystallinity.

* These "d" spacings and intensities calculated by Bradley & Green (6d) and not observed experimentally.
** Patterns unavailable for high-temperature β-AgI. Data for β-AgI from *NBS Quarterly*, 8, 539 (1958).
*** "d" Values averaged from four patterns.

The "d" spacings of $RbAg_4I_4CN$ are shown in the fourth column of Table II. In general, these bear great similarity to those of KAg_4I_4CN and $RbAg_4I_5$ and again it is to be noted that the medium-strength 3.99 peak, present in both KAg_4I_4CN and $RbAg_4I_4CN$, is absent in $RbAg_4I_5$, the latter having only a weak peak at 3.94.

Also included in Table II are the "d" spacings of $RbKAg_8I_8(CN)_2$. On the other hand, in Table III the x-ray pattern of NH_4CN-4AgI shows only lines ascribable to β-AgI, while the pattern of CsCN-4AgI shows AgI together with some lines ascribable to the "MAg_4I_5" general structure. Refinements in the preparation of the ammonium complex may yield a material with the characteristic structure, but it is evident that at this stage the CsCN-4AgI material shows more promise.

Differential thermal analysis.—Experiments were run, on both heating and cooling cycles, with KAg_4I_4CN, $RbAg_4I_4CN$, and, for comparison, with KAg_4I_5 and $RbAg_4I_5$. Table IV shows the temperatures of solid-state decomposition and of the eutectic in each system. The differences in the incongruent melting points clearly demonstrate that the cyano iodides and iodides are indeed different materials.

$RbAg_4I_4CN$	216	181
$RbAg_4I_5$	285	200

Discussion

At the outset of this work, it was thought that the pseudohalogenic properties of cyanide might make the addition of compounds containing this ion to silver iodide a worthwhile pursuit. However, if ionic size be the only critical factor, the CN^- ion, which has an effective freely rotating radius of 1.92Å, intermediate between that of Cl^- (1.81Å) and Br^- (2.00Å) and smaller than I^- (2.16Å) (10), might not be too interesting since mixtures of KBr(0.2)-AgI(0.8) have conductances of 1×10^{-4} ohm^{-1} cm^{-1}.

That size alone is not the overriding factor may be concluded from the highly conducting properties of KAg_4I_4CN and $RbAg_4I_4CN$. In the absence of complete structural data for these compounds analogous to that gathered for $RbAg_4I_5$ by Bradley and Greene (6d) and by Geller (11), it can only be inferred from the close similarity of the x-ray patterns that the cyanide-iodide and the pure iodide compounds have rather similar spatial distribution of component atoms.

If the aforementioned assumption is made that the CN^- ion is freely rotating thereby acquiring spherical symmetry, and that the effective radius is 1.92Å, the distance in the alkali cyanides may be computed as follows:

LiCN	2.52Å
NaCN	2.87Å
KCN	3.27Å
RbCN	3.40Å
CsCN	3.61Å
NH_4CN	3.40Å

It is known that LiCN · 4AgI and NaCN · 4AgI do not conduct, while the corresponding compounds of K and Rb are good conductors. Experiments involving Cs and NH_4 cyanides have shown tentatively that NH_4CN · 4AgI is a rather poor conductor and that CsCN · 4AgI, though more conducting than the NH_4CN · 4AgI material, is still considerably poorer than the K or Rb compounds.

Obviously, the assumption of spherical symmetry for the cyanide ion is not correct; but, as a first approximation, it is clear that a mole of cyanide can substitute for a mole of iodide in the MAg_4I_5 structure and hence will not impede the high mobility of the silver ions. More importantly, the resultant field induced by the different charge density of the CN^- ion is changed very little from that of an iodide ion coupled with K^+, Rb^+, or NH_4^+ ions.

That these materials are unique compounds and not previously prepared materials contaminated with impurities is shown by the reproducible nature of the incongruent melting points and eutectic temperatures

and by the difference of these values from those for the previously known iodide compounds. While difficulties of preparation have been met resulting in the presence of small amounts of unreacted silver iodide, there is no indication from thermal data that impurities in KAg_4I_4CN and $RbAg_4I_4CN$ consist of KAg_4I_5 or $RbAg_4I_5$.

In a series of experiments, the compositions $Ba(CN)_2 \cdot 4AgI$, $Ba(CN)_2 \cdot 8AgI$, and $Ba(CN)_2 \cdot 2AgI$ were prepared and their conductances measured. The Ba^{2+} ion was chosen because, although its ionic radius (1.35Å) is very similar to that of potassium (1.33Å), the charge density is considerably different. The conductances of all three compositions were about 10^{-5} ohm^{-1} cm^{-1}.

These materials are poor conductors and approximate the values obtained for the mixtures of AgI with LiCN or NaCN. Probably the higher charge density of the Ba^{2+} ion "tightens" up the structure reducing the mobility of the Ag^+ ion and, although structural data are lacking, it may well be that such materials do not possess the characteristic "MAg_4I_5" structure but crystallize in another form.

While as yet the only cations found useful have been K^+ and Rb^+, there is apparently considerable latitude in the cyanide-to-iodide ratio in the vicinity of that composition which gives maximum conductance. Consideration of the ionic conductor $KAg(CN)_2 \cdot 4AgI$ leads to the important observation that, although the alkali metal:cation ratio has now become 1:6, the x-ray pattern shows "d" spacings and intensities extremely similar to those of the molecularly more simple $KCN \cdot 4AgI$ compound. This would suggest that the general skeleton of these compounds based on I^- ions has a very loose structure, amenable to extensive substitution, and this additional "degree of freedom" is under investigation in more detail, since the conductance might conceivably be maximized by an altered CN/I ratio. Further it should be realized that a material which retains conductive properties despite changes in the ratio of its constituents may be valuable in a battery system where such changes may occur during service.

The stability of these highly conductive materials with respect to water vapor has been investigated both by x-ray diffraction and by differential thermal analysis and will be discussed in a later paper.

Conclusion

It may be concluded that the binary mixtures $KCN \cdot 4AgI$ and $RbCN \cdot 4AgI$ together with the ternary $KCN \cdot RbCN \cdot 8AgI$ are essentially ionic conductors. The maximum value of conductance is attained when the components are present in the ratio of 1 mole alkali cyanide to 4 moles silver iodide. The specific conductance of either binary compound, while smaller in magnitude, nonetheless approaches that for members of the family 1M Ag_4I_5 (where M is Rb, K, or NH_4) that were reported earlier (6, 7).

Acknowledgments

The authors would like to express their thanks to S. Senderoff, G. E. Blomgren, T. A. Reilly, and J. A. van Lier for enlightening discussions and to M. Soldat, G. W. Sheffield, and K. K. Maszczynski who performed much of the experimental work.

Manuscript submitted Aug. 31, 1970; revised manuscript received Jan. 22, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Ionic Conductance in Solids

II. The Phase Diagram of the KCN-AgI System and Some Observations on the Stability of Cyanide-Iodide Compounds

G. W. Mellors, D. V. Louzos,* and J. A. van Lier

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

ABSTRACT

Some 25 compositions varying from pure AgI to pure KCN were examined. The phase diagram has an incongruent compound at the composition 4AgI-KCN with an incongruent melting point of 230°C. A eutectic occurs at the composition 45KCN-55AgI at a temperature of 200°C. The stability of KAg_4I_4CN has been examined by differential thermal analysis, conductance, and emf measurements. The effect of water vapor on both the potassium and rubidium compounds has been determined by DTA or x-ray methods.

The work of Bradley and Greene (1, 2), Owens and Argue (3), and Topol and Owens (4) on the phase relationships in the alkali iodide-silver iodide systems has shown that the conducting compounds of general formula MAg_4I_5 (where M = Rb, K, or NH_4) are incongruently melting compounds, stable with respect to temperature between about 250°C and room temperature. This present paper describes the determina-

* Electrochemical Society Active Member.

Key words: solid electrolyte, silver iodide, phase diagrams, KAg_4I_4CN, potassium cyanide.

tion of the phase relationships in the KCN-AgI system, which has been reported by the present authors (5) to contain compositions of high ionic conductance.

Experimental

Materials.—Silver iodide (99.5% pure) was obtained from Mallinckrodt Chemical Works. Potassium cyanide (98.8% pure) was obtained from Fisher Scientific Company (ACS certified). This material was fused under argon and crushed and stored in a dry box prior to use. Argon (99.996% pure) and helium were obtained from the Linde Division, Union Carbide Corporation.

Apparatus.—The compositions for thermal analysis were contained in Morganite recrystallized alumina crucibles, size XN 100. The samples were stirred by purified argon, bubbled into the melt *via* an alumina tube. The temperature was measured by a Chromel-Alumel thermocouple, encased in an alumina thermowell, provided with an external (0°C) cold junction.

The crucible and contents were placed inside a larger, deeper alumina crucible and were confined under an argon atmosphere with a Pyrex or Inconel outer vessel. Figure 1 shows the general layout of the system.

Procedure.—Each sample was about 30g in weight and the complete, sealed apparatus was flushed with argon for several hours prior to a run. The cell was then heated to a temperature about 100°C above the liquidus of the composition under examination and held at that temperature with stirring for several hours to homogenize the melt. The furnace power was switched off and a cooling curve obtained on a recorder chart, after which the temperature was again raised and the cooling curve repeated, when, if all was well, agreement with the previous inflections to about ±1°C was usually obtained. A Du Pont series 900 Differential Thermal Analyzer together with a Differential Scanning Calorimeter attachment were used in parallel determinations of the thermal inflections.

Results

The literature values for the melting points of the pure salts were reproduced to ±1°C, *viz.* 558°C for silver iodide and 634.5°C for potassium cyanide (6).

The phase diagram drawn conventionally as a binary is shown in Fig. 2 and in general aspect it appears very similar to those of the binaries of AgI with either RbI, KI, or NH_4I. An incongruently melting compound appears at the molar composition 20KCN-80AgI, the transition temperature being 230°C, and a eutectic occurs at 200°C at the molar ratio 45KCN:55AgI. The horizontal line at 146°C at the silver iodide-rich end of the diagram represents the $\alpha \rightleftharpoons \beta$ transition in this material. On the cyanide-rich side of the diagram, a maximum melting point appears to be reached at the composition 66KCN-33AgI, followed by a sharp rise of the liquidus curve from a second eutectic around 72 ~ 75KCN to the melting point of pure KCN (634.5°C).

Problems were encountered in examining compositions between 65 and 100 m/o (mole per cent) KCN, in that it proved difficult and in some cases impossible to obtain meaningful inflections. It at first appeared that there was some break in the continuity of the liquidus between 65 and 70 m/o KCN which suggested the presence of perhaps a second incongruently melting compound, possibly 2KCN · AgI or $K_2AgI(CN)_2$.

Both the RbI-AgI and KI-AgI systems contain compounds 2RbI · $AgI(Rb_2AgI_3)$ and 2KI · $AgI(K_2AgI_3)$, the former being an incongruently melting compound and the latter formed by solid-state transition below about 125°C. These are nonconductors and it became pertinent to ask whether a compound 2KCN · AgI [*i.e.*, $K_2AgI(CN)_2$] might not exist in the cyanide-iodide system. Accordingly, the composition 2KCN-AgI was made up by standard techniques, quenched, and powdered in a dry box. The x-ray pattern indicated perfect matching of "d" spacings and intensities for a mixture of $KAg(CN)_2$ and KI. It must be concluded that the following reaction had occurred

$$2KCN + AgI \rightarrow KAg(CN)_2 + KI$$

the final result being an equimolecular mixture of potassium iodide and potassium argentocyanide. A 2KCN-AgI specimen made up and slowly cooled over a 16 hr period showed an identical x-ray pattern.

In general, as the concentration of cyanide ion is increased, the greater will be the tendency to form $KAg(CN)_2$ and KI. At compositions where the KCN:AgI mole ratio exceeds 2:1, the three materials KI, KCN, and $KAg(CN)_2$ will coexist and thus the system could be represented in the most general case as a reciprocal system of KI-KCN-AgI-AgCN. However, in view of the exceptional stability of $KAg(CN)_2$ with respect to the other components of this system, it can also be considered as a pseudobinary of AgI and the (1:1) mole mixture of KI and $KAg(CN)_2$ if one wishes.

In fact, the reaction product of 0.1 mole KI, 0.1 mole $KAg(CN)_2$, and 0.7 mole AgI is equivalent in ap-

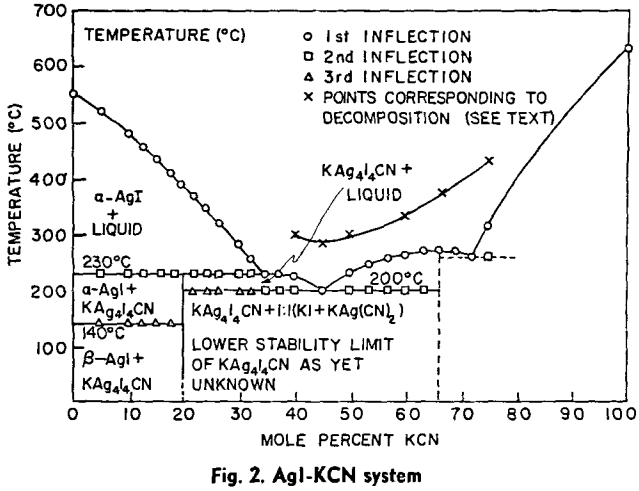

Fig. 2. AgI-KCN system

pearance, x-ray pattern, and conductance to the reaction product of 0.2KCN and 0.8AgI.

There are, it must be conceded, problems in obtaining reproducible data in this system, particularly in the KCN-rich compositions. In Fig. 2 (labeled X) are shown a number of points, corresponding to inflections consistently obtained in DTA and cooling curves. In the first instance, these were thought to represent a liquidus line, but at present it is believed that they are associated with the thermal decomposition or the products of such decomposition of the initially formed compounds on prolonged heating above the melting point. As the proportion of KCN increases, so also does that of $KAg(CN)_2$. This latter is unstable (melting point 370°C) with respect to prolonged high-temperature treatment and, as a result, silver metal appears in the melt with the probable release of cyanogen and residual KCN.

It is intended to consider, in a later publication, the detailed reactions in the KCN-AgI system and in other closely related systems. The present diagram must therefore be considered as substantially correct with respect to major solidus and liquidus lines, though in the cyanide-rich region, the nature of the true equilibrium phases has not yet been established.

Discussion

Stability of cyanide-iodide compounds.—The diagram as presented in Fig. 2 is fairly straightforward and the areas of stability of the various materials appear sharply delineated. An important point remaining unresolved by the phase diagram work is that of the lower temperature of stability of the compound KCN · 4AgI. However, this instability reaction which, in the iodides, takes the form

$$2MAg_4I_5 \rightleftharpoons M_2AgI_3 + 7AgI$$

is extremely slow and therefore difficult to determine by thermal methods. Bradley and Greene (1) in their investigation of the KI-AgI system reported that differential thermal analysis showed only a broad and indistinct peak, but that conductance measurements with a slower rate of temperature increase showed the existence of a distinct temperature (38° ± 2°C) for the onset of the above reaction. Another approach taken by these authors was to measure the emf's of the cells:

Cell I, $Ag/AgI/I_2$, the reaction for which was assumed to be

$$Ag(c) + \frac{1}{2}I_2\ (c) \rightarrow \beta\text{-}AgI\ (c) \qquad [1]$$

and Cell II, Ag/K_2AgI_3, KAg_4I_5/I_2, the reaction for which was assumed to be

$$Ag\ (c) + \frac{1}{2}I_2\ (c) + \frac{1}{7}K_2AgI_3\ (c) \rightarrow \frac{2}{7}KAg_4I_5\ (c) \qquad [2]$$

On subtracting reaction [1] from reaction [2] one obtains

$$\beta\text{-}AgI\ (c) + \frac{1}{7}K_2AgI_3\ (c) \rightarrow \frac{2}{7}KAg_4I_5\ (c) \qquad [3]$$

the free energy change for which is

$$-(E_{\text{Cell II}} - E_{\text{Cell I}})/F$$

When these emf's were plotted as a function of temperature, the straight lines intersected at about 40°C, with the quantity $(E_{\text{Cell II}} - E_{\text{Cell I}})$ positive above this temperature and negative below it. This demonstrated that if reactions [1] and [2] are the correct reactions for Cells I and II, then reaction [3] goes spontaneously to the right above 40°C and to the left below this temperature.

Cells analogous to those set up by Bradley and Greene (1) involving the KAg_4I_4CN compound would be

Cell I, $Ag/AgI/I_2$

and

Cell IV, $Ag/[KAg(CN)_2 + KI\ (1:1)]$, KAg_4I_4CN/I_2

the reaction for which was assumed to be

$$\frac{1}{7}KAg(CN)_2\ (c) + \frac{1}{7}KI\ (c) + Ag\ (c) + \frac{1}{2}I_2\ (c) \rightarrow \frac{2}{7}KAg_4I_4CN\ (c) \qquad [4]$$

On subtracting reaction [1] from reaction [4], one obtains

$$\beta AgI\ (c) + \frac{1}{7}KAg(CN)_2\ (c) + \frac{1}{7}KI\ (c) \rightarrow \frac{2}{7}KAg_4I_4CN\ (c) \qquad [5]$$

the free energy change for which is

$$-(E_{\text{Cell IV}} - E_{\text{Cell I}})/F$$

The emf's of these cells were measured and are shown in Fig. 3. It can be seen that $(E_{\text{Cell IV}} - E_{\text{Cell I}})$ is negative over the full temperature range. If reaction [4] is the correct assumption for the reaction of Cell IV, then it would appear that reaction [5] goes spontaneously to the left at all temperatures. However, while a metastable material may exist almost indefinitely at room temperature, it should convert to the stable form when heated to a reasonably high temperature. It has been found that prolonged heating of KAg_4I_4CN at 150°C does not produce any additional free AgI. It therefore seems more reasonable to conclude that reaction [4] is not the potential-determining reaction of Cell IV in the solid state.

Whereas in the experiments of Bradley and Greene (1) only one solid material, K_2AgI_3, was employed, in the present work a mixture of KI and $KAg(CN)_2$ constituted the solid phase and the presence of two solids, even though mixed intimately, may render reaction by diffusion more difficult.

In the case of the pure iodide compounds MAg_4I_5, the instability reaction involved the compounds identified in the phase diagram, *viz.* $2MAg_4I_5 \rightarrow M_2AgI_3 + 7AgI$ and, therefore, one might be tempted to conclude from Fig. 3 that the dissociation reactions in the cyanide compounds would be

$$2KAg_4I_4CN \rightarrow 7AgI + KI + KAg(CN)_2$$

or

$$KAg_4I_4CN \rightarrow 3AgI + KI + AgCN$$

but the emf experiments neither confirm nor deny this hypothesis.

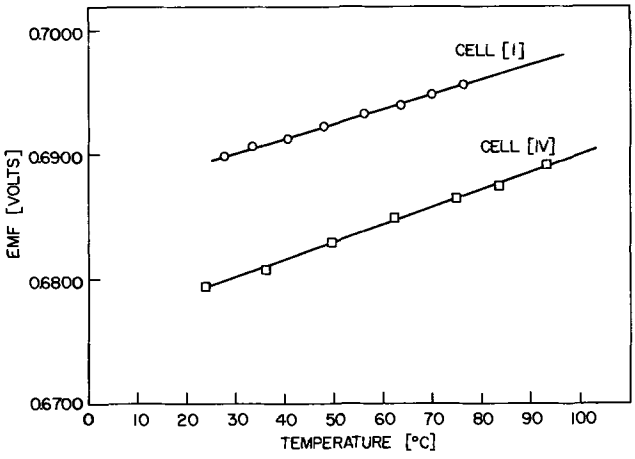

Fig. 3. EMF of silver cells

The measurement of the conductance of KAg_4I_4CN as a function of temperature has been presented in the first paper of this series and shows an absence of inflection at or around room temperature. This indicates that, if a structural change or decomposition does occur in the vicinity of room temperature, it can only be extremely small in extent and hence not readily detectable by conductance measurements.

The DTA experiments extended from room temperature up to about 300°C. Figures 4 and 5 show a typical trace obtained for KAg_4I_4CN and $RbAg_4I_4CN$ and indicate an absence of thermal arrests up to 147°C. The presence of an endothermic inflection at 147°C which is characteristic of silver iodide (Fig. 6) raises the question as to whether the source of such silver iodide is by decomposition of KAg_4I_4CN or $RbAg_4I_4CN$. Such decomposition might be an inherent property of these iodide-cyanide materials but alternative explanations are those of (*a*) incomplete reaction between the components, or (*b*) inadvertent contamination by moisture producing AgI during the course of the DTA or during transfer to the apparatus.

Since DTA is generally considered to be a sensitive indicator of structural change, it was thought worthwhile to examine KAg_4I_5 and $RbAg_4I_5$ where studies have indicated instability of the complex below 38° and 27°C, respectively. A thermogram free of inflections up to about 240°C (approximately the position of the eutectic in the KI-AgI system) was obtained from the former system, and in the latter system no significant inflections were obtained until about 200°C.

The apparent conflict between the DTA and the aforementioned thermodynamic work (4) should not be taken to indicate that water vapor was admitted inadvertently during the latter measurements. Rather it should show that the instability at 27°C in $RbAg_4I_5$ in the absence of moisture can be observed only by thermodynamic measurements and that it is too slow a process to observe in a kinetic experiment even by a method as sensitive as DTA. It should be noted that the infinitesimally slow rate of the decomposition reaction in the absence of moisture is very desirable from the viewpoint of battery "shelf life."

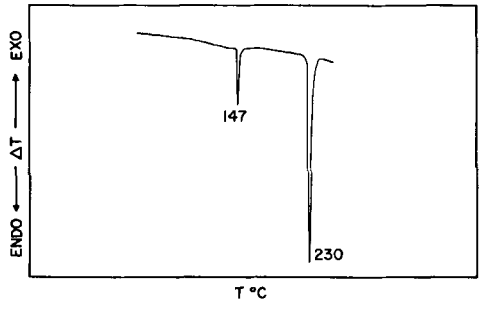

Fig. 4. DTA of KAg_4I_4CN

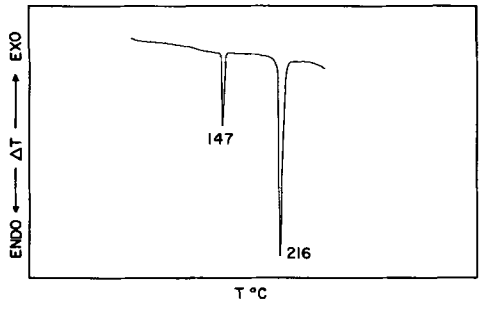

Fig. 5. DTA of $RbAg_4I_4CN$

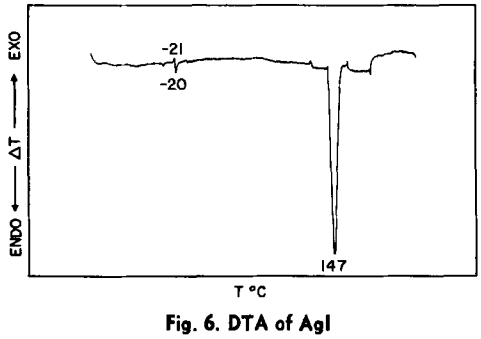

Fig. 6. DTA of AgI

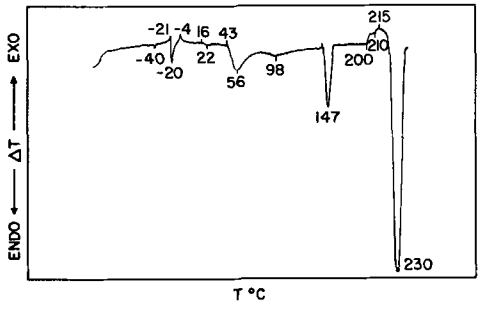

Fig. 7. DTA of KAg_4I_4CN exposed to water vapor

Some qualitative observations on the reactions of KAg_4I_4CN and $RbAg_4I_4CN$ with moisture might be made here. If either of these materials is exposed to moisture (the normal 35% humidity of the laboratory being more than adequate) for a period of time, thermograms are obtained that now show endothermic inflections between 0°C and about 150°C. These inflections vary with the amount of water and the time of exposure and Fig. 7 shows a typical result on KAg_4I_4CN. Additional evidence for the undesirable effects of water vapor is obtained from the fact that a specimen previously showing the characteristic x-ray pattern of KAg_4I_4CN, after exposure to this medium, predominantly shows lines assignable to AgI.

Qualitatively, $RbAg_4I_4CN$ would appear to possess greater stability with respect to moist air than KAg_4I_4CN. The DTA measurements show that, even after exposure to laboratory air for 12 days, additional endothermic peaks do not develop in the region of interest (approx 0°-100°C) in contrast to KAg_4I_4CN. Whereas KAg_4I_4CN on exposure to laboratory air for 24 hr gains weight and displays significant changes in its x-ray pattern, $RbAg_4I_4CN$ retains its characteristic diffraction pattern even after 6 weeks' exposure under similar conditions.

Acknowledgments

The authors wish to thank G. E. Blomgren, S. Senderoff, and T. A. Reilly for interesting and enlightening discussions; G. W. Sheffield, M. S. Soldat, P. A. Pleban, and K. K. Maszczynski who performed much of the experimental work; and S. C. Maszczynski for the x-ray diffraction data.

The Corrosion Behavior of Cu and Naval Brass in 0.5M NaCl Solutions at Ambient Temperature

A. H. Taylor

Tyco Laboratories, Inc., Bear Hill, Waltham, Massachusetts 02154

ABSTRACT

The rotating ring-disk technique was used to obtain insight into the corrosion mechanisms of pure Cu and naval brass in deaerated 0.5M NaCl at ambient temperature. The potential regions for the reactions: $Cu^{2+} \rightarrow Cu^{+}$, $Cu^{2+} \rightarrow Cu$, $Cu^{+} \rightarrow Cu^{2+}$, and $Zn^{2+} \rightarrow Zn$ have been explored to permit analysis of the products of dissolution processes occurring during galvanostatic corrosion of these materials. Pure Cu corrodes only via Cu^{+} over the range $\sim 2.5 \times 10^{-6}$ to $\sim 900 \times 10^{-6}$ A/cm^2 corrosion current (0.19 cm^2 area). No evidence is found for Cu^{2+} species or for film forming reactions. Naval brass [60.54 w/o (weight per cent) Cu, 38.70 w/o Zn, and 0.76 w/o Sn] corrodes solely via Cu^{+} and Zn^{2+} up to $\sim 450 \times 10^{-6}$ A/cm^2 corrosion current. No Cu^{2+} species are found. Experiments indicate that selective dissolution of Zn does not occur. No evidence can be found for a Cu redeposition mechanism. Data suggest the occurrence of a homogeneous solution reaction in which soluble Cu^{+} species produced on corrosion of the alloy undergo hydrolysis before reaching the zone of the ring electrode. No evidence is found for formation of CuOH or Cu_2O directly on the corroding surface.

Work described here is based on part of a program sponsored by the Office of Saline Water, United States Department of the Interior, aimed at more clearly defining the corrosion mechanisms of Cu-based alloys in saline environments. The present paper deals with preliminary work on Cu corrosion and naval brass corrosion under closely controlled conditions, subsequently outlined.

Lu *et al.* (1) has investigated the dissolution rate of Cu in H_2SO_4 at 25°C using a rotating Cu cylinder. He reports a rate-controlling step via oxidation of cuprous ion at the solution/copper interface. Thermodynamic aspects of Cu corrosion along with kinetic and electrochemical studies are reported by Ives *et al.* (2) in water containing various salts (including NaCl). Simultaneous dissolution of Cu and film growth, predominantly as Cu_2O, are indicated in the presence of O_2 and CO_2. Cl^{-} ions alter the dissolution kinetics and film growth processes causing more localized attack. Cu_2O dissolves more rapidly in Cl^{-} media. Similarly, May (3), in a study of the mechanism of pitting corrosion of Cu, noted the formation of CuCl and Cu_2O in the early stages of the process in saline solutions. Rotating ring-disk studies (4-7) by Miller (7) on a Cu electrode in NaOH solution showed that low current density dissolution proceeded via Cu^{+} with concurrent Cu_2O formation. Above 400 μA/cm^2, Cu^{2+} species were found.

Much attention has been paid to the mechanisms of brass dissolution in a range of environments and in particular on the occurrence of preferential and simultaneous dissolution. Studies have been aimed at distinguishing between dezincification by a selective dissolution mechanism as compared to an ionization-redeposition mechanism. The inhibitive effects of small As additions on the dezincification of a number of brass alloys, has also been of particular interest (8-14). A wide range of techniques have been brought to bear on this problem, ranging from x-ray (8, 11, 15-17) electron diffraction (18, 19) and metallographic observations (20) of corroded surfaces to more recent rotating ring-disk studies (21-23) of the corrosion mechanisms.

Stillwell and Turnipseed (15) used x-ray diffraction in a study of η-brass dissolution in dilute HCl and concluded that the dissolution was selective. Polushkin and Shuldener (16) observed twinning in the Cu crystals in dezincified α-brass and concluded that the Cu was residual. Lucey (11), however, observed twinning in Cu crystals redeposited from CuCl solution. He inferred from his data that simultaneous dissolution of Cu and Zn occurs followed by Cu redeposition (on α- and β-brass alloys). Bengough and May (8) found that the crystalline form of Cu produced by dezincification bore no resemblance to that in the original alloy. A Cu redeposition process was thus inferred.

Pruna *et al.* (17) and Hashimoto and Ogiva (18) both found evidence for a brass dissolution/Cu redeposition mechanism. Further support for this came from the work of Joseph and Arce (20) on 63/37 brass and Sugawara and Ebiko (19) on α- and $\alpha + \beta$-brass alloys in Cl^{-} media. The latter workers also found Cu_2O or CuCl in the early stages of corrosion. Higher Zn content alloys were more subject to dezincification.

The work of Pickering *et al.* on a wide range of alloys is of interest. Rotating ring-disk techniques (21) revealed the absence of an ionization-redeposition mechanism of preferential dissolution in a 30 a/o (atom per cent) Zn alloy in sulfate medium. Feller's rotating disk studies (22) indicated that preferential dissolution of Zn occurred more readily in the higher Zn content alloys (~80 a/o Zn) than in the Cu-rich alloys. More recently, Pickering and Byrne (24) measured partial currents during Cu and/or Zn dissolution from γ-, ϵ-, and α-brass alloys in sulfate medium. Various modes of dissolution were found depending on the potential. The ϵ-alloy (86 a/o Zn) yielded only Zn^{++} on dissolution. The γ-alloy (65 a/o Zn) dissolved first as Zn^{++} solely, followed by a potential region where dissolution proceeded in the ratio 10:1 Zn/Cu. The α-brass (30 a/o Zn) gave first of all Zn^{++} followed by an intermediate potential region where Zn and Cu dissolved to differing extents and finally in a 1:1 ratio. They also measured partial currents as a function of time during dissolution at constant potential and found a decrease in rate with time. The rate of decrease of the partial current from Zn dissolution was greater than that from Cu dissolution. X-ray examination of γ- and ϵ-brass alloys by Pickering (25) indicated a volume diffusion mechanism for preferential dissolution of these alloys.

Miller's rotating ring-disk studies (23) on 70/30 brass in Mattson (26) type solutions (~pH 7) are of interest. No evidence was found for Cu_2O film formation, in contrast to results (7) for Cu in NaOH. At low current densities (<5 mA/cm^2) corrosion proceeded

Key words: dezincification, galvanostatic corrosion, rotating ring disk.

via Cu^+ and Zn^{++} solely. Above this Cu^{++} species were produced (and no Cu^+).

Consideration of these data reveals that there is scope for further work in the field. As pointed out by Stillwell and Turnipseed (15) and Fink (9) both dezincification mechanisms can occur depending on the circumstances. It is clear also, that the composition of the alloy has a very important bearing on the mode of corrosion.

Our studies were aimed at examining the mechanism of brass dissolution and film formation in 0.5M NaCl media, the latter since we were also interested in anodically protecting the alloys in high-temperature saline solutions. Preliminary work is reported on pure Cu and naval brass corrosion in these solutions. Following the work of others (7, 21-23) this investigation has been carried out using a rotating ring-disk setup, the advantages of which have been admirably outlined by Miller (7, 23). Essential details of equipment and experimental procedures are given in the following sections.

Experimental

The rotating ring-disk assembly used in these studies was purchased from R. Disantis (Willowick, Ohio). Speed control was achieved using an electric motor (B2410) and Minarik Control unit (SL-32), Reserve Electric Company, Cleveland. This assembly was capable of rotation from 300 to 6000 rpm and was calibrated using a stroboscope. Disk materials of pure Cu (99.99%) and naval brass (60.54% Cu, 38.70% Zn, 0.76% Sn) were concentric with, but separated from, Au ring electrodes via Teflon insulating gaps. The materials were ~1/16 in. thick and were replaced as required. In a number of experiments the rings were amalgamated with Hg for reasons stated later.

Before and following each corrosion experiment, the electrodes were mounted on a lathe and polished with 600 grit silicon carbide paper followed by 5μ alumina with a polishing cloth. The electrodes were thoroughly rinsed with distilled water before use.

A concise diagram of the electrochemical cell employed is shown in Fig. 1. In the cell free rotation (up to 2000 rpm) of the electrode assembly was achieved while preventing any O_2 from contacting the solutions —the latter since O_2 is reduced at some of the potentials of interest and is particularly deleterious on an amalgamated ring (Hg/Au) in the region of Zn^{++} reduction. We employed a rotation speed of 500 rpm in most of our experiments. Solutions were flushed before use (~30 min) to remove O_2 using tagged N_2 (~4 ppm O_2 in the gas phase) in conjunction with a millipore filter (Millipore Filter Corporation, Bedford, Massachusetts) to remove extraneous dust, etc. During experiments a constant flow of N_2 was passed over the solutions. In this way no problems were found from O_2 during our measurements.

Solutions were made from an ultrapure grade NaCl (0.5M, Brinkmann Instrument, Inc., Westbury, New York). When required, the Au ring was lightly amalgamated using triply distilled Hg. This Hg/Au amalgam electrode was held at $\leq$0V *vs.* SCE at all times. In practice, solutions were replaced with new ones, suitably deaerated, prior to each new experiment.

Two sets of data are reported here. In the first case, we required information on the diffusion limited potential regions within which the various possible dissolved species, *i.e.*, Zn^{++}, $Cu,^+$ and Cu^{++} could undergo further reaction, either oxidative or reductive. To this end we used 0.5M NaCl solutions 10^{-6} to 10^{-3}M in Zn^{++} or Cu^{++} ions and scanned the ring and/or disk (0.03 V/min and 0.60 V/min) at various rotation speeds. Current/potential data were recorded on an X-Y recorder (Houston Omnigraphic Corporation, Bellaire, Texas). For these experiments an Au ring/Au disk or Hg/Au amalgam ring-disk electrode was employed. To examine the region where Cu^+ is oxidized to Cu^{++}, a different technique was used which is described in subsequent sections.

Corrosion experiments in which an Au or Hg/Au amalgam electrode was employed with a Cu or naval brass corrodible disk, were obtained in a different manner. As pointed out by Miller (7) corrosion and film formation on a rotating disk can readily be analyzed by using a constant disk anodization current to control the coulombs passed rather than sweeping the potential. In addition, such galvanostatic experiments do not require the more sophisticated electrochemical control equipment used by Bruckenstein (27) and Miller *et al.* (7, 23, 28). A conventional Wenking potentiostat, Model 61 TRS (Brinkmann Instruments Inc.) was used here to control the potential of ring or disk during cyclic scanning experiments. For corrosion measurements, the ring potential was held at the potential of interest and the disk corroded with a series of constant currents from 0.5 to ~85 μA (disk area ~0.19 cm^2). Ring currents as a function of each disk corrosion current were then measured on a Griebach milliammeter (Griebach Model 500, ½% accuracy; Griebach Instruments, New Rochelle, New York). Currents at times <2 sec are not accurate due to this method of measurement.

Collection efficiencies (29) (N) for each electrode were calculated from measurements of the various ring and disk radii using a microscope. Theoretical values were 0.3822 for Au/Au, 0.3762 for Cu/Au, and 0.3973 for naval brass/Au. Experimental and theoretical values for the Cu/Au electrode agreed to within 1%.

Results and Discussion

Cu *oxidation and reduction on* Au *in 0.5M* NaCl.— The reactions of Cu species have been well characterized in the past using rotating ring-disk systems (7, 23, 27). Typical voltage scans on the Au ring of a Au/Au ring-disk electrode in 0.5M NaCl solution containing 10^{-3}M Cu^{++} are illustrated in Fig. 2. The figure shows two plateau regions extending from 0 to −0.26V *vs.* SCE and from −0.35V to beyond −0.60V *vs.* SCE.

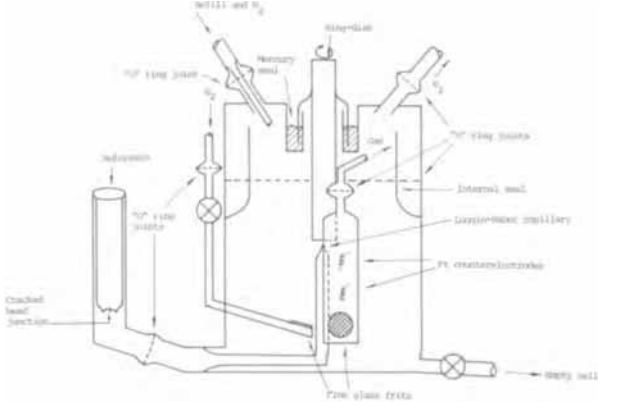

Fig. 1. Electrochemical cell for rotating ring-disk corrosion studies in "O_2-free" 0.5M NaCl at ambient temperature.

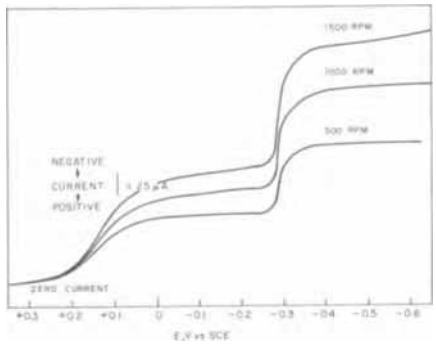

Fig. 2. Typical cyclic scans at ambient temperature on a rotating Au ring electrode in 0.5M NaCl solution containing 10^{-3}M Cu^{2+} (scan speed = 0.6 V/min).

Using reported values for the Cu^{++} diffusion coefficient (27) and a value for the kinematic viscosity (30) of KCl, a calculation of the limiting diffusion current (29) to the rotating ring electrode confirms that the first plateau corresponds to reduction of Cu^{++} to Cu^{+} and that the second plateau corresponds to reduction of Cu^{++} (and Cu^{+}) to Cu. These plateau regions were shown not to be significantly altered when the concentration of Cu^{++} in solution was reduced to 10^{-6}M and the scan rate lowered to 0.03 V/min.

Since CuCl is relatively insoluble in 0.5M NaCl, a slightly different approach was used to establish the region where Cu^{+} can be oxidized to Cu^{++} on an Au electrode under these conditions. Here, as before, the salt solution was made 10^{-3}M in Cu^{++} ions. The latter were reduced to Cu^{+} on an Au disk held at close to -0.20V by a constant current of -68.5 μA (the limiting current in 10^{-3}M Cu^{++} solution when the disk was potentiostated at -0.20V). Disk-produced Cu^{+} species were then swept into the zone of the Au ring for further oxidation back to Cu^{++}. This oxidation current should then reach a plateau level at NI_d where N is the collection efficiency of the electrode and I_d is the disk current arising from reduction of Cu^{++} to Cu^{+} (in this case -68.5 μA). At potentials less positive than those required for Cu^{+} oxidation, smaller ring currents should be observed.

Ring oxidation currents were corrected for background which was insignificant in most cases. Currents were time independent in all cases. Results plotted as ring current *vs.* ring potential are shown in Fig. 3. A plateau region was found from $\sim +0.35$ to >0.60V *vs.* SCE corresponding to oxidation of disk-produced Cu^{+} species. Moreover, this oxidation current varied from 26 to 27 μA (0.35 to 0.60V) which compared very favorably with a value of 26.0 μA calculated from the applied disk current of 68.0 μA (corrected for background) and the Au/Au ring-disk theoretical collection efficiency of 0.3822. We conclude that Cu^{+} species are oxidized to Cu^{++} at $\geq$0.35V vs. SCE in these solutions on an Au electrode.

In summary, we find that Cu^{++} is reduced to Cu^{+} between 0.00 and -0.26V *vs.* SCE and to Cu at ≤ -0.35V *vs.* SCE as detected on an Au ring electrode. Also on a Au ring, Cu^{+} is oxidized to Cu^{++} at $\geq +0.35$V *vs.* SCE. These results agree very well with those found by Napp *et al.* (27) on a Pt electrode in 0.5M KCl containing 10^{-3}M Cu^{++}. Similar data are reported by Miller also (7, 23).

Zn^{++} *reduction on an* Hg/Au *amalgam in 0.5M* NaCl. —Since the reversible potential for Zn^{++} reduction is well below that at which H_2 is evolved on an Au electrode, we amalgamated our Au ring with Hg. Cyclic scan experiments were then carried out between the limits 0.0 and -1.6V *vs.* SCE. Scan speed was varied, as was the concentration of Zn^{++} in the electrolyte ($ZnCl_2$, Baker Analyzed Grade).

In 10^{-3}M Zn^{++} solution, a plateau was observed at < -1.0V *vs.* SCE which depended on rotation speed,

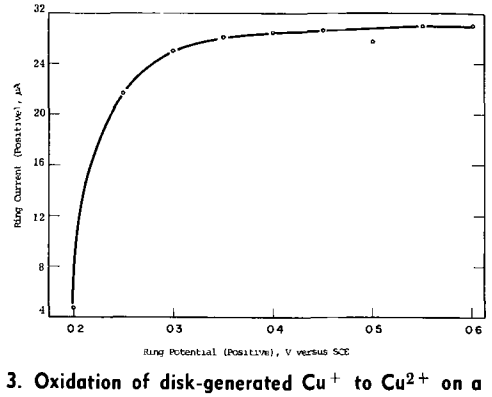

Fig. 3. Oxidation of disk-generated Cu^{+} to Cu^{2+} on a rotating Au ring electrode (500 rpm) as a function of ring potential in deaerated 0.5M NaCl containing 10^{-3}M Cu^{2+}.

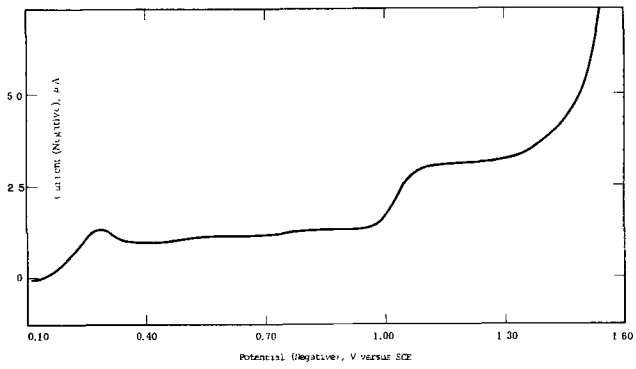

Fig. 4. Reduction of 10^{-5}M Zn^{2+} on a rotating Hg/Au amalgam ring electrode in 0.5M NaCl at ambient temperature (scan speed = 0.03 V/min).

increasing with increase in ω. Plateau currents plotted against $\omega^{1/2}$ according to the limiting diffusion equation (29) showed a straight line behavior extrapolating through the origin. Experimental and calculated currents assuming D_{Zn++} equals D_{Cu++} (the diffusion coefficients for the two species) and assuming a two-electron transfer process ($Zn^{2+} \rightarrow$ Zn), agreed very well.

Only a slight shift ($\sim$0.10V) in the potential region of the plateau current with scan speed and Zn^{++} concentration, was observed. Figure 4 shows a typical scan (0.03V/min) in 10^{-5}M Zn^{++}. The current is small to near -1.0V where a sharp increase is obtained. This levels out to a plateau at -1.1V and stays constant to -1.36V when H_2 evolution causes a sharp increase in current. The plateau current on this figure, corrected for the relatively large background value, also agreed with the calculated value.

We conclude from these data that Zn^{++} can be detected on an Hg/Au amalgam electrode at $-1.1\text{V} \geq E \geq -1.36$V *vs.* SCE which is not dissimilar from Miller's results (23) is neutral ammoniacal media.

Having confirmed these various potential regions in our solutions, we were now in a position to investigate the corrosion mechanisms of Cu and naval brass disks using Au and Hg/Au ring electrodes as detectors.

Corrosion of Cu *in 0.5M deaerated* NaCl.—Measurements were carried out at 500 rpm in unbuffered 0.5M NaCl (*p*H $\sim$ 6.5) deaerated as described. The Cu ring was normally held at $+0.60$V, -0.20V, and -0.60V to detect Cu^{+}, Cu^{++}, and both of these, respectively. The Cu disk (and ring) were polished before use as described. Disk corrosion current was varied from $+0.5$ to $+180$ μA. The disk area was 0.19 cm^2 and the theoretical collection efficiency (N) of this assembly was 0.3762.

Generally in this and in all other similar experiments, the assembly was immersed in the NaCl solution and deaeration commenced. After $\sim$30 min when the disk potential was normally constant, N_2 was passed over the solution, and the ring potentiostatted at the potential of interest. After $\sim$30 min a constant background current was observed at all potentials. The disk was then corroded and the ring current followed with time on a milliammeter. Disk potential measured in a separate experiment varied from -0.28 to -0.17V as the applied corrosion current was varied from 2.25 to 180 μA. When constant values for ring current were obtained, generally within 10 sec, the disk current was switched off and ring current followed with time. Normally this fell rapidly to its background value within 10 sec. The solution *p*H on commencement of these experiments (and those on naval brass) was $\sim$*p*H 6.5 and generally fell to $\sim$*p*H 4.7 on completion of the experiments. A typical sequence of the above events at -0.60V is shown in Fig. 5.

This indicates a sharp increase in I_r at all values of I_d. A 2-sec offset from zero time is apparent due to the cumulative effects of double-layer charging, transit time of dissolution species from disk to ring, and sim-

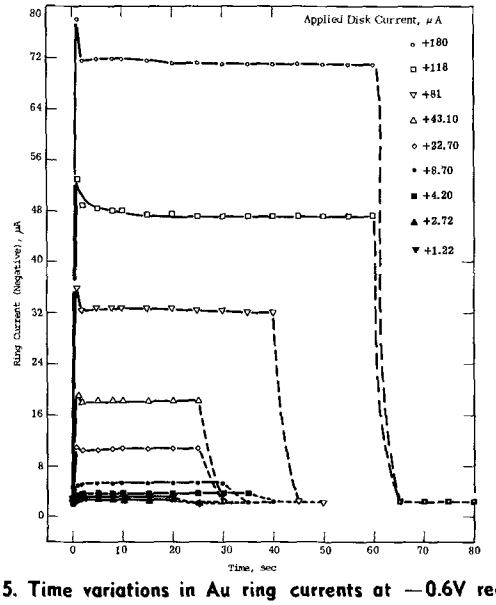

Fig. 5. Time variations in Au ring currents at −0.6V reduction of Cu^+ produced from a Cu disk during corrosion in deaerated 0.5M NaCl at ambient temperature.

ple mechanical measurement error due to overshoot in the milliammeter when first switched on. Currents, after stabilizing out to steady values in about 2 sec, were constant thereafter. When I_d was switched off, background ring values were relatively constant within 5 sec. In practice, the final background ring value was sometimes slightly larger than its initial value, especially at high I_d. This was a negligible effect here. Background ring currents were constant in the region of 2.1 μA. This is a large correction factor at small I_d, however, it was constant and as just noted, was corrected for using the value read 10 sec after each measurement. No noticeable variations in results were observed, even when the background current varied by a factor of as much as 5.

Figure 6 summarizes the results of Fig. 5 together with similar data with the ring at +0.60V *vs.* SCE both corrected for background and plotted against I_d. A linear relationship is apparent over the entire disk corrosion range. The theoretical plot assuming dissolution

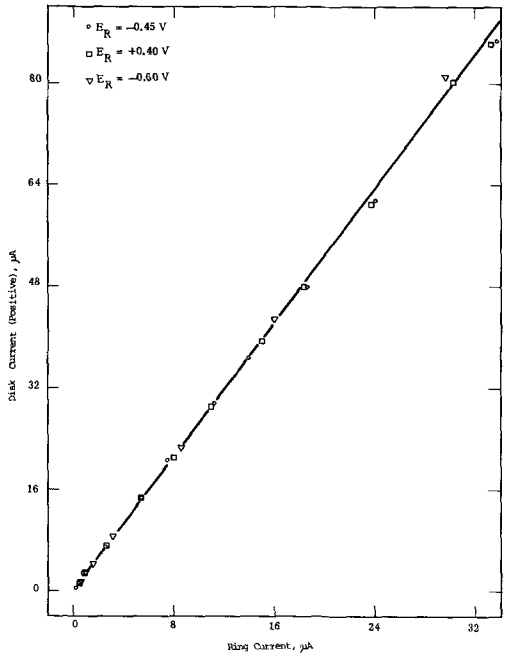

Fig. 6. Background corrected Au ring currents as a function of Cu disk corrosion currents in deaerated 0.5M NaCl at ambient temperature.

as Cu^+ solely and a value for N of 0.3762 agrees with the experimental plot exactly.

A further point may be made. Since the results at +0.60 and −0.60V (SCE) are mirror images of each other then obviously no Cu^{2+} is formed on corrosion. This was substantiated further by corroding the disk and measuring I_r with the ring at −0.20V *vs.* SCE. No increase in ring current was observed up to 180 μA I_d.

We conclude from the foregoing that in our solutions, Cu corrodes solely via Cu^+ up to ~900 μA/cm² disk corrosion current. No film formation or homogeneous solution reactions are observed.

Miller's results (7) on 70/30 brass in neutral NH_3-NH_4 salt solutions were shown to correspond to the *p*H region where Cu^{2+}-NH_3 couples begin to etch Cu (and Zn) with Cu^+-NH_3 complexes as product (31, 32). Low currents produced Cu^+ and high currents (>5 mA/cm²) produced Cu^{2+}, the polarization being a function of free NH_3 concentration and therefore of *p*H. Cu_2O formation was not observed although its possible formation was noted under less vigorous mass transport conditions. In contrast to this, Cu_2O was found during Cu corrosion in more basic, NH_3 free, 1*N* NaOH solutions (23). No film free dissolution occurred in 1*N* NaOH even at the lowest current density employed (~10 μA/cm²). Above 400 μA/cm², Cu^{2+} species were produced after the Cu_2O passivation step.

The latter observations are in accordance with the published Pourbaix (33) diagrams for Cu in aqueous solutions. Hence it is apparent from the diagrams that at sufficiently noble potentials (high anodic polarization currents) dissolution of Cu takes place as Cu^{2+} and not Cu^+. At less noble potentials (lower anodizing currents) Cu_2O formation is also indicated especially in more basic solutions. In the present experiments, as outlined above, no Cu^{2+} was found and film free dissolution of the metal occurred as Cu^+. Separate measurements showed that at each corrosion current, a single potential plateau for the metal was established immediately which had a value of < -0.17V *vs.* SCE even at the highest current employed (~900 μA/cm²). It seems unlikely that under these conditions of potential, *p*H, and salinity any Cu_2O or Cu^{2+} would be expected (33). As noted by Bertocci (34), in solutions containing halide ions, the activity of Cu^+ ions is depressed by the complexing reaction

$$Cu^+ + 2Hal^- \rightleftharpoons CuHal_2^-$$

This would then serve to facilitate dissolution of the metal via Cu^+ as is indeed observed.

The results illustrate the usefulness of the ring-disk electrode in corrosion studies. The extension of these techniques to a more complex dissolution process involving naval brass is described below.

Corrosion of naval brass in 0.5M deaerated NaCl.—More substantial data on a naval brass disk were obtained in an exactly similar manner to that for pure Cu. In this case, interpretation of the results was complicated by the dissolution of Zn^{++} also from the alloy necessitating the use of the Hg/Au amalgamated ring. Measurements in unbuffered 0.5*M* NaCl solutions are described. A theoretical value for N of 0.3973 was used in this case.

In all of these experiments the alloy potential increased linearly with the logarithm of applied current. Only a single time independent plateau was observed at each current. The disk potential, measured in a separate experiment, varied from −0.336 to −0.22V as the disk corrosion current was varied from 1.4μ to 89 μA.

Typical I_r *vs.* time curves before and after disk corrosion for a ring potential of −0.60V *vs.* SCE followed the general trends observed with pure Cu. Figure 7 summarizes the results of these data and also others at +0.60V, all corrected for background, and plotted as I_d *vs.* I_r. As with pure Cu, results at the two potentials are mirror images and fall on the same line indicating that no Cu^{++} is formed under these circumstances.

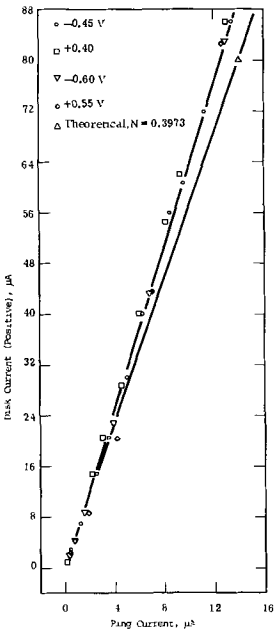

Fig. 7. Background corrected Au ring currents as a function of naval brass disk corrosion currents in deaerated 0.5M NaCl at ambient temperature.

This was further verified by results at −0.20V *vs.* SCE where no reduction of Cu^2 to Cu^+ was observed at the ring during disk corrosion.

The composition of the alloy is 60.54 w/o Cu, 38.70 w/o Zn, and 0.76 w/o Sn. Neglecting the small Sn content this corresponds to 61.15 a/o Cu and 38.85 a/o Zn. Assuming alloy dissolution in this atom per cent (a/o) ratio, *i.e.*, simultaneous dissolution of both components, we would expect that the fraction of the applied disk corrosion current (I_d) resulting in the production of Cu^+ species would equal

$$\frac{\text{a/o Cu}}{(1 \times \text{a/o Cu}) + (2 \times \text{a/o Zn})} I_d \qquad [1]$$

The calculation assumes no selective Zn^{++} dissolution, Cu^+ redeposition or film forming reactions (and of course, no dissolution as Cu^{++} as we have already shown). In addition, for a ring collection efficiency of $N = 0.3973$, the observed ring current from further ring oxidation to Cu^{2+} of corroded Cu^+ species, if dissolution proceeds in the stated a/o ratio should be

$$\frac{\text{a/o Cu}}{(1 \times \text{a/o Cu}) + (2 \times \text{a/o Zn})} \times 0.3973\, I_d \qquad [2]$$

or

$$0.1749\, I_d \qquad [3]$$

Based on the above, a theoretical line is shown also in Fig. 7 which is clearly different from the observed value. Hence at 80 μA I_d, I_r observed is 12.6 μA compared to I_r calculated of 14.0 μA, *i.e.*, 1.4 μA lower. Though this is not a large value of current, it is nevertheless almost 10% lower than the calculated value and was experimentally reproducible. It is interesting to note that the partial current for Cu^+ corrosion from the brass plotted as a function of disk potential, agreed quite well with the Cu^+ polarization curve for the pure metal. That is Cu corrosion from the alloy occurs at the same rate as in the pure metal. Similar results are reported by Pickering and Byrne (24) for γ- and α-brasses.

To examine the causes for the discrepancy between calculated and experimental Cu^+ corrosion currents, *e.g.*, selective dissolution of the Zn in the alloy, we amalgamated the ring as described and carried out exactly similar experiments, this time with the ring potentiostated at −1.3V *vs.* SCE. Here all dissolved species are plated out at the ring. I_r should therefore equal

$$0.3973\, I_d \qquad [4]$$

This holds true in the event that any preferential dissolution of Zn occurs by redeposition of Cu^+.

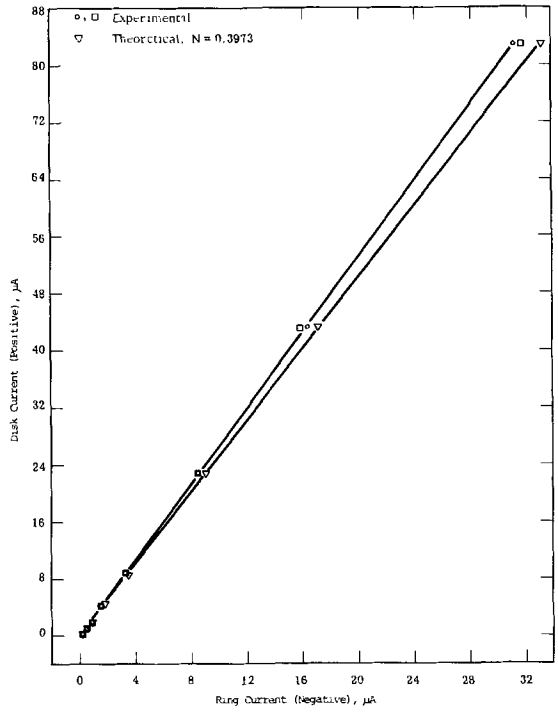

Fig. 8. Background corrected Hg/Au amalgam ring currents at −1.3 V as a function of naval brass disk corrosion currents in deaerated 0.5M NaCl at ambient temperature.

A typical I_r *vs.* time plot followed the trends outlined earlier (Fig. 5) during and after disk corrosion for a ring potential of −1.3V *vs.* SCE. The current levels were higher here as expected. Figure 8 shows the results of this experiment and a repeat of the same illustrating the I_r *vs.* I_d relationships. Also shown is a theoretical line according to Eq. [4]. Clearly, again, the data do not coincide but deviate by 1.6 μA at an I_d value of 80 μA. The calculated increase in ring current (due to $Zn^{++} \rightarrow Zn$) at a disk corrosion current of 80 μA when the ring potential is moved from ±0.60 to −1.3V, is 17.7 μA. The measured increase is 17.4 μA. This suggests that the discrepancy in the data is due to the Cu in the alloy undergoing some further reaction either at the disk or in transit to the ring and also eliminates the supposition that Zn^{++} is selectively corroded from the alloy or that Cu^+ redeposition occurs. This is in accord with Pickering (24) and Feller's (22) results which show that preferential dissolution of Zn from Cu-Zn alloys occurs more predominantly with Zn-rich than with Cu-rich alloys.

Most likely, a homogeneous solution reaction involving a fraction of the corroded Cu^+ species can account for the discrepancy between calculated and observed ring currents. Soluble CuCl can readily hydrolyze (to Cu · OH) before reaching the ring electrode and will not then be picked up there. Again, the hydrolysis product may well redeposit nonelectrochemically on the alloy surface in a manner similar to that outlined by May (35) during pitting corrosion and film formation on Cu and its alloys in Cl^- media. The second possibility is of course that some film formation, possibly Cu_2O, occurs directly on the corroding surface. In further experiments where the electrode was rotated more rapidly (2000 rpm) and the measurements repeated at −1.3V *vs.* SCE, the theoretical and experimental lines now coincided. This then substantiates the homogeneous reaction theory. In the event that a film is found on the surface, it can only be deposited there by a nonelectrochemical deposition of insoluble hydrolysis products formed from soluble corroded Cu^+ species.

It is more difficult to explain the occurrence of this phenomenon in the brass alloy as compared to pure Cu under exactly similar conditions. The explanation may be in the fact that the alloy surface offers more

favorable redeposition sites as compared to a pure Cu surface. The suggestion is very tenuous however, and the effect requires detailed experimentation in these and more basic NaCl solutions. Preliminary results in the latter media do reveal significant film forming reactions. These data and results on other alloy systems at increased temperatures will be reported subsequently.

Summary and Conclusions

1. The rotating ring-disk system has been used to investigate pure Cu and naval brass corrosion in saline solutions. The various diffusion-limited potential regions for oxidation and/or reduction of Cu^+, Cu^{2+}, and Zn^{2+} in these environments on Au and/or Hg/Au amalgam electrodes are reported.

2. The technique has been shown to be amenable to corrosion investigations. Dissolved disk species are readily identifiable at the rotating rings potentiostatted at predetermined potentials. Homogeneous and film forming reactions can also be distinguished readily.

3. Over the range $\sim 2.5 \times 10^{-6}$ A/cm^2 to $\sim 900 \times 10^{-6}$ A/cm^2 pure Cu corrodes solely via Cu^+ in 0.5*M* NaCl solutions at ambient temperature. No Cu^{2+} species are found nor is any evidence presented for film formation or homogeneous reactions of any kind.

4. Over the range $\sim 1.4 \times 10^{-6}$ A/cm^2 to $\sim 450 \times 10^{-6}$ A/cm^2, naval brass corrodes readily via Cu^+ and Zn^{2+} in these solutions. No Cu^{2+} species are found. No preferential dissolution by selective dissolution of Zn or a Cu^+ redeposition mechanism is indicated. Some evidence for a homogeneous reaction is found. Any films formed are caused by a nonelectrochemical redeposition process involving homogeneously produced species rather than direct film formation on the surface.

A Study of the Anodic Oxidation of Vanadium

B. H. Ellis, M. A. Hopper*,[1] and D. J. De Smet*

Department of Physics, University of Alabama, University, Alabama 35468

ABSTRACT

The anodic oxidation of vanadium in acetic acid-sodium tetraborate solutions containing small amounts of water has been studied over a potential range of 100V using the open-circuit transient analysis technique. An anodic layer which showed bright uniform interference colors was found to grow on the metal surface. Results of these experiments indicate that the dependence of the oxidation current density, i, on the formation potential, V, is expressible in the form $i = i_0 \exp(V/V_0)$, where i_0 and V_0 are parameters determined from the data analysis. The parameter i_0 is found to depend on the applied current density, while the parameter V_0 varies directly with the formation potential during galvanostatic oxidation. A result in this form implies that the electric field in the oxide is a function of the applied current density. These results show similarities to results previously obtained by others for the anodic oxidation of bismuth, tantalum, and iron.

Even though the anodic oxidation of several metals has been extensively studied (1), vanadium has received little attention. One reason for this has been the difficulty in forming an anodic film on vanadium. A study by Johansen, Adams, and Van Rysselberghe (2) of a number of metals, including vanadium, in an aqueous boric acid-ammonia solution at 25°C indicated that no anodic film would form on vanadium under these conditions. Young (1) suggests, but does not verify, that an anodic film might be formed on vanadium if a partly nonaqueous electrolyte were used. In 1965, Keil and Salomon (3) successfully formed an anodic oxide film on vanadium in acetic acid-sodium borate-water solutions. By using this almost completely nonaqueous electrolyte they overcome the problem, experienced in the past by others, of the solubility of the anodic oxide product in aqueous solutions. In a later work (4), they studied some of the chemical and electrical properties of the vanadium anodic oxide film. From these studies they concluded, among other things, that the oxidation state of the vanadium was not a function of the potential to which the vanadium was oxidized, the anodic film was V_2O_4, and, for constant current growth, a linear dependence of the growth rate on the current density necessitated that the electric field in the oxide layer be constant.

The intentions of the present study were to determine the electrical properties of vanadium oxide films by use of open-circuit transient analysis and to identify other physical properties of the oxide film. The open-circuit transient analysis technique has been used in the study of the anodic oxidation of several metals (5-10). Its use in the study of the vanadium oxide film, and a comparison of these results with results found in the studies of other metals, will help to determine the general properties of the anodic oxidation of metals.

Experimental

The samples used in this study were high-purity (99.98%) vanadium, ¼ in. diameter rods of varying lengths, purchased from Materials Research Corporation. Each sample was drilled along its axis, mechanically polished, and mounted between Teflon washers in an electrode assembly similar to the one detailed by Feller and Osterwald (11). This assembly was then immersed in a solution of 25% sulfuric acid, 70% orthophosphoric acid, and 5% nitric acid for about 30 sec. After rinsing with distilled water and drying, each sample was anodically oxidized to a potential of 50V, then the oxidation product was dissolved by immersing the electrode assembly in distilled water. This anodic oxidation and removal of the oxide was repeated several times prior to using a sample for actual measurements in order to insure reproducibility.

The electrical circuitry used was identical to that described by De Smet and Hopper (5). Current densities were calculated by dividing the applied current by the exposed macroscopic surface area of the vanadium sample. A Sanborn 7700 strip chart recorder was used to record potentials and open-circuit transients.

The electrolyte solution used in this study was similar to that described by Keil and Salomon (4) with a reduction of the water content. Nineteen grams of $Na_2B_4O_7 \cdot 10\ H_2O$ were added per liter of glacial acetic acid, this solution was heated to 60°C, and just sufficient water was added to dissolve all the salt (31 ± 1.5 ml of water per liter of acetic acid). Other nonaqueous solvents, including formamide and ethylene glycol (with various added salts), were tried but these would not sustain the formation of a vanadium oxide film. The solutions were bubbled with argon prior to and throughout the experiments.

A jacketed five-necked flask was used for the cell. The electrode assembly, a coiled platinum wire cathode, a platinum wire reference electrode, a thermometer, and a gas dispersion tube were fitted through the standard taper joints of the cell.

Preliminary experiments indicated that the vanadium anodic oxide film exhibits a photoeffect (or photoeffects) at visible wavelengths; therefore, all experiments were conducted in a darkened room, and the cell was draped with a black cloth to preclude light from reaching the cell.

The effect of temperature on the layer was also studied. The acetic acid-sodium tetraborate solution freezes at 12°C, which marks the lower temperature limit. Other experiments were conducted at temperatures of 24°, 35°, and 40°C. For experiments conducted near or above room temperature, temperatures were controlled by a Haake Model F constant temperature circulator, which circulated water through the jacket of the cell. For experiments conducted at 12°C, the electrolyte was cooled by immersing the cell in an insulated container filled with shaved ice. After the immersion, the temperature fell from 24° to approximately 10°C, then rose to 12°C. Once the temperature stabilized at 12°C, in a period of about 30 min the solution froze solidly.

Although the vanadium oxide film would not form on a clean surface using the low current densities which we were interested in investigating, a low current density will sustain growth once some oxide is present on the surface. For this reason, the following procedure was used to study the growth of the oxide at low current densities: vanadium oxide was formed on

* Electrochemical Society Active Member.
[1] Present address: Department of Physics, University of Waterloo, Waterloo, Ontario, Canada.
Key words: vanadium oxide, anodic oxide.

the clean surface at a high current density (about 500 μA/cm^2), then the current was switched to the required lower current density (10, 30, or 100 μA/cm^2) after an initial oxide film was formed. This procedure allowed open-circuit voltage decay experiments to be performed from desired current densities and formation potentials.

Results

If one considers an oxide film on a metal surface to be equivalent to a capacitor with a dielectric medium (which in some manner carries a small current) located between the capacitor plates, then the differential equation describing such a circuit is given by

$$C\,dV/dt + i = i_e \qquad [1]$$

where i is the current density through the film, i_e is the externally applied current density, V is the potential across the layer, and C is the capacitance per unit area of the layer.

The initial portions of the experimental open-circuit transients obtained for vanadium fit an expression of the form

$$V = k - V_o \log(t + \theta) \qquad [2]$$

very well. Here V_o, k, and θ are parameters which depend on the particular transient and its initial conditions. It follows, by differentiating Eq. [2] and substituting into Eq. [1], with $i_e = 0$, that the expression for the current density through the film may be written as

$$i = i_o \exp(V/V_o) \qquad [3]$$

where i_o and V_o are experimental parameters with the same dimensions as i and V, respectively. This derivation includes certain assumptions which have been discussed previously (5, 8). As the potential decays when the circuit is opened, a point in potential or time is reached where these assumptions no longer apply; hence, Eq. [2] will not describe the potential decay beyond this point. Basically, Eq. [3] is a high-field ionic conduction relation and would thus not be expected to describe the entire open-circuit potential decay, especially when the potential drop across the oxide approached zero.

Each open-circuit transient was recorded and analyzed graphically by plotting V *vs.* $\log(t + \theta)$, which was found to be a straight line for a properly chosen value of θ. Transients fit the expression of Eq. [2] over at least 1½ decades of time, corresponding to approximately a 90% decay in the potential at current densities of 100 μA/cm^2 and a 65% decay in the potential at current densities of 10 and 30 μA/cm^2. This type of analysis of open-circuit transients was described by Grahame (12), and has been used in studies of the anodic oxidation of several metals (5-10).

A series of open-circuit potential decays was recorded at intervals during galvanostatic oxidation. These transients were then analyzed to determine values for V_o and θ. To avoid confusion in terminology, we designate the current density immediately prior to the opening of the circuit as the formation current density. Also, the term formation potential designates the overpotential at which the open-circuit transient was initiated.

Figure 1 shows the values of the parameter V_o obtained from several typical sets of transients as a function of the formation potential at room temperature for three values of the formation current density: 10, 30, and 100 μA/cm^2. For each formation, current density V_o increases with formation potential and each plot is linear, at least to a formation potential of 50V (within experimental error). All lines pass through the zero of formation potential. For the largest value of the formation current density, 100 μA/cm^2, the plot of V_o *vs.* formation potential shows a noticeable change in slope at about 60V. The differences in the slopes for these three values of current density are readily apparent.

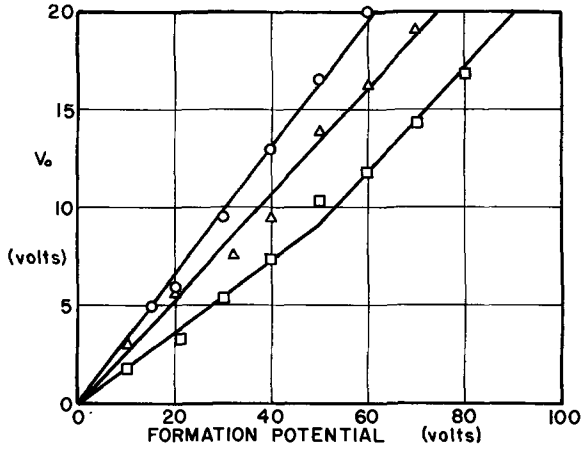

Fig. 1. Dependence of V_o on formation potential for vanadium at room temperature. The formation current density was 10 μA/cm^2 for the data represented by the circles, 30 μA/cm^2 for the data represented by the triangles, and 100 μA/cm^2 for the data represented by the squares.

A plot of the reciprocal capacitance *vs.* formation potential for current densities of 30 and 100 μA/cm^2 is shown in Fig. 2. The reciprocal capacitance is calculated from the relation $1/C = V_o/(i_e \cdot \theta)$, obtained from the boundary conditions of Eq. [1]. This result shows that the reciprocal capacitance varies with formation potential, and there are two distinct changes in slope occurring at approximately 40 and 60V. Since the parameter θ found for the open-circuit transients on vanadium can be obtained only within 10%, this error will show up directly in the reciprocal capacitance. As a result, the reciprocal capacitance-potential plots have only qualitative significance.

The plots of formation potential *vs.* time were much the same as those reported by Keil and Salomon (4) at room temperature, with the same three distinct regions of time rate of change of formation potential. This experiment conducted at various temperatures indicates a dependence of dV/dt on temperature above an overpotential of 10V. Figure 3 shows the results for a formation current density of 500 μA/cm^2 at temperatures of 12°, 24°, and 35°C. The slopes of the lines for these temperatures are 0.084, 0.075, and 0.0625 V/sec, respectively. Figure 4 shows dV/dt (above a potential of 10V) *vs.* formation current density for the same temperatures and supports the dependence of dV/dt on temperature.

The effects of visible light on the formation potential of the vanadium anode while undergoing galvanostatic oxidation is shown in Fig. 5. During galvanostatic

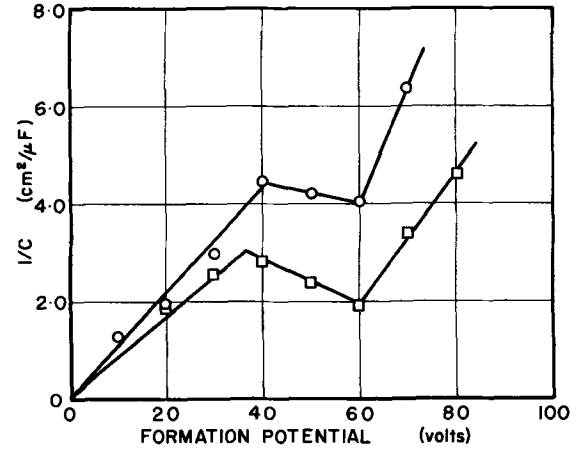

Fig. 2. Dependence of the reciprocal capacitance on formation potential. The formation current density was 30 μA/cm^2 for the data represented by the circles and 100 μA/cm^2 for the data represented by the squares.

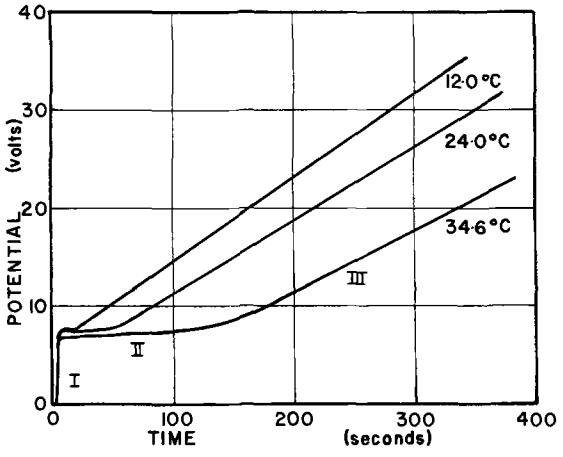

Fig. 3. Potential vs. time at a constant current density of 500 μA/cm^2 at the indicated temperatures. The vanadium sample was clean at the beginning of each experiment.

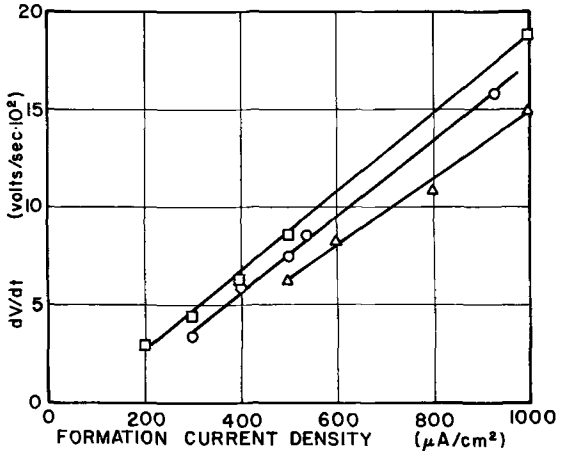

Fig. 4. The rate of change of potential (above a potential of 10V) as a function of the formation current density. The temperature was 12°C for the data represented by the squares, 24°C for the data represented by the circles, and 35°C for the data represented by the triangles.

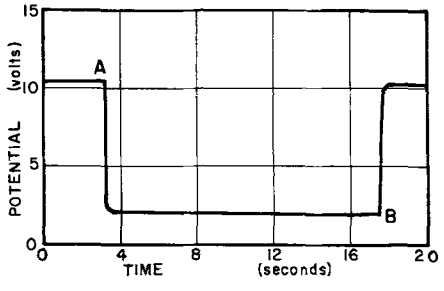

Fig. 5. Potential vs. time with an applied current density of 3 μA/cm^2. At point A the electrode was illuminated with visible light, and at point B the light was removed.

oxidation with an applied current density of 3 μA/cm^2, a high-intensity light was shone on the electrode. The light produced a sharp decrease in the potential, which returned to its original value upon removal of the light. Several experiments of this kind showed an increase of the photoeffect (that is, the voltage drop) with an increase in the formation potential under galvanostatic conditions and a decrease in the photo effect with increasing formation current densities. At a fixed current density, the per cent voltage drop when the electrode was illuminated was approximately constant. No attempt was made to vary the intensity of the illumination.

In order to facilitate the discussion which follows, a potential transient in which the applied current

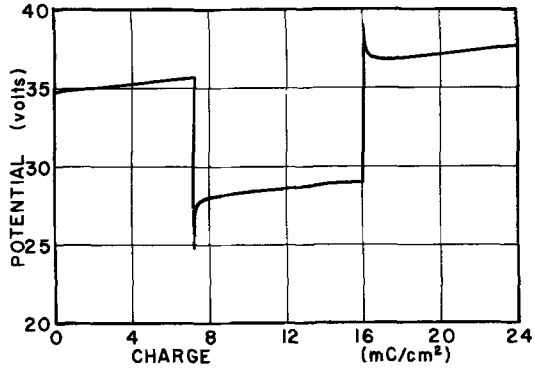

Fig. 6. Potential vs. charge for a transient in which the current density was switched from 500 to 100 μA/cm^2 and then back to 500 μA/cm^2.

density was switched from 500 to 100 μA/cm^2 and then back to 500 μA/cm^2 was recorded and is shown in Fig. 6. The speed of the strip chart recorder was slowed by a factor of five when the current density was lowered, and then switched back to its original speed when the current density was returned to its original value, thus giving a plot of potential *vs.* charge. This figure shows a potential overshoot when the current density is abruptly changed. This type of overshoot is typical of many materials undergoing anodic oxidation (1, 5, 6, 8).

Discussion

Several authors (1) interpret the theoretical relation for an exponential dependence of the current density through the anodic oxide film on the formation potential as an activation energy-controlled process. For the high-field case, this relationship is given as

$$i = 2\,anv \exp -\,(W - \lambda eaE/kT) \qquad [4]$$

where a is the half barrier width, n the density of charge carriers, ν the ion oscillation frequency, W the activation energy for the process, λ the valence of the charge carrier, and E the electric field at the activation barrier. The average electric field in the layer is the formation potential divided by the thickness of the layer (5-10). Taking the electric field at any barrier (*i.e.*, the local electric field at the barrier) equal to the average electric field in the layer, then Eq. [3] and [4] yield

$$V_0 = (kT/\lambda ea)\,D \qquad [5]$$

where D is the thickness of the layer. Therefore, if one uses this model, V_0 is directly proportional to the thickness of the oxide layer, D, assuming λ and a are constants, independent of current.

The data displayed in Fig. 1 support this type of model by showing that the values of V_0 vary directly with the formation potential for any value of the constant current density. For different values of formation current densities, the slopes of the data differ, indicating that the field in the layer depends on the formation current density. Another estimate of the thickness of the oxide layer can be seen in the data presented in Fig. 2, which shows the reciprocal capacitance proportional to the formation potential, at least for potentials below 40V. Assuming that the oxide layer acts like a parallel plate capacitor, this indicates that the capacitance of the layer is proportional to the layer thickness, as might be expected.

In Fig. 3, the data show that the potential growth pattern falls in three distinct regions, labeled I, II, and III, as reported by Keil and Salomon (4). The first region is an almost instantaneous potential rise from the zero current value to a potential value that is dependent on several factors, including the type of electrolyte used and the formation current density. This region can most likely be attributed to the ohmic voltage across the electrolyte. A second region follows

and is distinguished by a slow time rate of change of the potential. Also, the length of region II is found to depend on the formation current density and the temperature of the electrolyte. The work of Keil and Salomon (4) shows that most of the charge passed in region II goes into the production of V^{+4} ions in solution. This type of behavior is completely analogous to the active state region on the passive metals such as iron, *etc.* [see Ref. (1)], and its length is known to depend on the applied current density, the solution concentration and temperature, *etc.* This region appears to exist until the potential reaches a certain value, called the transition potential by Keil and Salomon, which is also dependent on the aforesaid factors. Once the potential reaches this value, the time rate of change of potential becomes much greater and remains at this value for the rest of the oxide layer growth.

Experiments were conducted with the photoeffects to attempt positive identification of the different types of photoeffects present in the vanadium system. Figure 5 indicates that photoconductivity is present during visible light irradiation of the oxide film. Using an accepted definition of photoconductivity as a change in the conductivity of the oxide layer due to the absorption of radiation, and using the results of Gudden and Pohl's experiments in photoconductivity as reported by Bube (13) which show photoconductivity to be a volume effect, our data clearly indicate its presence in this study. The data shown in Fig. 5 and similar data taken at varying formation potentials show the photoeffect to be dependent on the thickness of the oxide film, thus a volume effect. Similar data were reported for the photoeffect on bismuth anodic oxide films by De Smet and Hopper (5). This change in conductivity of the oxide layer is probably an electronic current added to the normal ionic current in the oxide layer. We believe that other photoeffects, perhaps including surface effects, may also be present in this system, but attempts to verify this have not been successful.

Figure 4 shows the dependence of dV/dt on the formation current density at three different temperatures. These results show that dV/dt varies approximately linearly with formation current density. This figure does not, however, imply that the electric field within the layer is independent of the formation current density. Figure 7 shows the same data as Fig. 4, this time presented in a somewhat different manner. Here we have assumed that the current efficiency of layer growth is 100%, that is all of the charge passed into layer formation (a conclusion of Keil and Salomon) and calculated $dV/dQ = (1/i) \cdot (dV/dt)$. This quantity should be proportional to the electric field within the layer. In Fig. 7, this quantity is plotted as a function of the formation current density and it is clear that dV/dQ is not a constant, independent of current density. [In Fig. 7, the lines have been drawn in merely to show the trend of the data and do not necessarily imply an exactly linear relation between dV/dQ and $\log(i)$.]

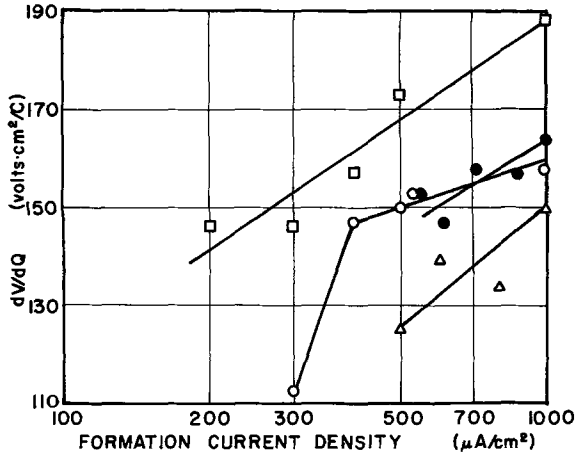

Fig. 7. Dependence of dV/dQ on the formation current density. The data represented by the squares were taken at a temperature of 12°C, the open circles at 24°C, and the triangles at 35°C. The data represented by the filled circles were taken from Ref. (4).

Figure 6, which shows potential *vs.* charge as the formation current density is switched from one value to another, demonstrates the same point. First, if the electric field were independent of formation current density, then the slopes of the linear portions of the curves at different currents would be identical. In fact, the slope of the linear portion of the curve at the lower current density is slightly smaller than that at the higher current density. Second, when the current density is lowered, the potential falls (even if the potential overshoot is ignored and the linear portion of curve is extrapolated to the point where the current was switched) and, since there is no decrease in the layer thickness, the electric field in the layer must decrease. A similar argument holds for an increase in the electric field when the current density is increased.

Until this point, we have not mentioned the parameter i_o other than to say that it has the same dimensions as i. Values of i_o for vanadium can be calculated from Fig. 1 and Eq. [3]. It is difficult to give exact values for i_o for vanadium, since the errors in individual values of i_o may be 25% or more. Nevertheless, it has been found that i_o does tend to increase with increasing formation current density. This type of dependence of i_o on formation current density has been found for several other materials, and it has been suggested that it may be possible to account for the potential overshoot such as that shown in Fig. 6 by considering the manner in which i_o changes when the formation current density is changed (5, 7,8). Similar arguments may be advanced for vanadium. We feel that the physical cause of the potential overshoot, when the current density is abruptly changed, is also the cause of the changes in i_o.

The results of the present study show many features which are strikingly similar to the results of studies of anodic films on several other metals (5-10). Experiments on the anodic oxidation of bismuth (5), iron (6, 7), and tantalum (8) show that the decays of overpotential during open-circuit transients all fit the form of Eq. [2], implying a relation between current and potential in the form of Eq. [3]. All these systems also show the same type of dependence of V_o on the formation potential fixed formation current density. The slopes of V_o *vs.* potential all depend on the formation current density. All these materials (and many others which form anodic oxide films by a high-field ionic conduction process) show potential transients similar to Fig. 6 when the current density is abruptly changed. These general features must be properties of the anodic oxidation process itself and are independent of the particular system under investigation.

Anodization of Vanadium

R. G. Keil*,[1] and K. Ludwig

Department of Chemistry, University of Dayton, Dayton, Ohio 45409

ABSTRACT

A study was made of the relationship between ion current migrating through anodic oxide films on vanadium and the electrostatic field across the dielectric over a potential range of some 100V utilizing the open-circuit transient method. The results show that the relationship between the formation current density, i, and the formation potential, V, is of the form $i = i_0 \exp(V/V_0)$, where i_0 and V_0 are parameters resulting from analysis. V_0 was found to be a linear function of the formation voltage. The quantity, θ, was found to be essentially equal to zero, a result which departs from results previously reported for other metals, for example tantalum, iron, and bismuth.

We have previously reported (1, 2) that an anodic vanadium tetroxide film, which exhibits interference colors, can be grown on vanadium metal when it is subjected to anodic polarization. An anodization solution composed of glacial acetic acid, borax, and water was used. The water concentration was not critical when below 5M (molar). These results showed that the film was vanadium IV oxide formed at 100% current efficiency at the anode. Other results suggested the film was probably porous.

In this present work, we desire to study the electrical properties of this vanadium oxide film by use of open-circuit transient analysis, a method pioneered by Grahame (3) and used in the study of the anodic oxidation of several metals (4-6). Previous experimental results indicated that the anodic vanadium oxide film was porous. We were curious during this study, therefore, to determine if θ might have an abnormal value. Ord (5) has found its value to be unity. This point and the relationship between the ion current density and the electrostatic field during film growth were the main objectives of this study.

Experimental

High-purity (>99.94%), single-pass, zone-refined vanadium rods (⅜ in. diameter) purchased from Materials Research Corporation was used for this work. The electrode was mounted and prepared for anodization by methods previously described (2). Just prior to anodization, the electrode was etched in a 1:1 water-nitric acid (70% assay) solution. The electrode was then washed, first with distilled water, then with absolute ethanol, dried, and immersed in the anodization bath.

The cell used was basically the one previously used but modified to accept a saturated calomel reference electrode in contact with the anodizing solution *via* a Luggin capillary of potassium nitrate. At extremely low water and/or sodium tetraborate concentrations, films formed showed the existence of nonhomogeneous electrostatic fields as was evidenced by nonuniform interference colors across the electrode surface. In this work, we found an acetic acid solution 2.0M in water and 0.02M in sodium tetraborate was best. This solution had a conductivity of 79 micro-(ohm-cm)$^{-1}$. These studies were all carried out at 25°C. An inert ambient of argon was maintained in the reaction flask and the anodizing solution was degassed prior to use.

An anodic film did not form on the vanadium metal surface at low current densities. Therefore, the following procedure was adopted to study the film growth at low current densities. Vanadium oxide was formed on the clean metal initially at about 1500 μA/cm^2 until the overpotential exceeded 20V. Then the current was decreased in successive steps until the desired current density (32, 71, or 352 μA/cm^2) was reached. This allowed the open-circuit transients to be obtained from desired current densities and formation voltages.

A schematic of the electrical circuitry used is shown in Fig. 1. High-input-impedance differential operational amplifiers (Philbrick SP102) were used for the galvanostat and follower. These amplifiers operate over a range of ±100V. Potentials and open-circuit transients were recorded on an oscillographic recorder (Sanborn 7701B). All potentials were recorded relative to the saturated calomel reference electrode. Overpotentials were calculated from observed voltages by subtracting the value of the open-circuit potential. Apparent current densities were obtained by dividing the applied current by the macroscopic surface area of the anode.

Results

The oxide film can be considered to be the dielectric medium of a capacitor whose plates are composed of the substrate metal and the anodizing solution. While forming, say under galvanostatic conditions, the film carries current in some manner. The external current throughout the circuit must equal the sum of the current passing through the film, plus capacitance charging. The differential equation which relates the current density through the film, i, the overpotential, V, and the external circuit current, i_e, is given by

$$i + C\,dV/dt = i_e \qquad [1]$$

Information concerning the relation between quantities in Eq. [1] can be obtained by utilizing the "open-circuit transient" method. Transients of this type (voltage *vs.* time) have been used to study the kinetics of a number of anodic oxide film systems (4-6). During an open-circuit transient, $i_e = 0$ and the differential equation describing the system becomes

$$i + C\,dV/dt = 0 \qquad [2]$$

If one can measure the change in the potential with time, the current through the anodic oxide may be determined, assuming a value for C is available.

For vanadium, the experimental voltage transients fit an expression of the form

$$V = k - V_o \ln(t + \theta) \qquad [3]$$

The quantities θ, V_o, and k are parameters which are determined by the particular transient and its initial conditions. The transient can be analyzed graphically by plotting the overpotential during open-circuit decay *vs.* $\ln(t + \theta)$ on graph paper. For each transient, θ is varied (by making a judicious choice) until a straight line is obtained for V *vs.* $\ln(t + \theta)$. This operation was performed with the aid of a digital computer. The computer was fed voltage *vs.* time data. It then performed the following functions: (*a*) it chose from a very large selection the value of θ which produced a minimum standard deviation of all data points when the data was subjected to a linear least square analysis, and (*b*) it printed out the values of k, θ, V_o, and the standard deviation. Differentiating Eq. [3] with respect to time, one obtains

$$\frac{dV}{dt} = \frac{-V_o}{(t + \theta)} \qquad [4]$$

Solving Eq. [3] for the quantity $(t + \theta)$ and substituting into Eq. [4] yields

$$\frac{dV}{dt} = -V_o \exp(-k/V_o) \exp(V/V_o) \qquad [5]$$

Substituting Eq. [5] into Eq. [2] yields the final result, an equation of the form

$$i = i_o \exp(V/V_o) \qquad [6]$$

where $i_o = CV_o \exp(-k/V_o)$. The point is that an equation of this form is the mathematical consequence of the differential equation describing the system and the experimental voltage-time profile. Here, i_o and V_o are experimentally determined parameters whose dimensions are the same as i and V, respectively. If time zero equals the commencement of the transient, the transients fit Eq. [3] for times corresponding to 80% of the potential decay at a current density of 352 μA/cm^2 and 60% of the potential decay at 32 and 71 μA/cm^2. Figure 2 shows the relationship between the parameter V_o and the formation potential. For a given formation current density, V_o is a linear function of the formation potential and all lines pass through the origin. The slope of each line is obviously a function of the formation current density and decreases with increasing current density. Studying anodization processes in a nonaqueous medium like glacial acetic acid affords one the rare opportunity of studying the effect of water concentration on the process. Figure 3 shows clearly that the quantity V_o is, for a formation current density of 71 μA/cm^2, definitely a function of the anodizing solution at a given formation potential.

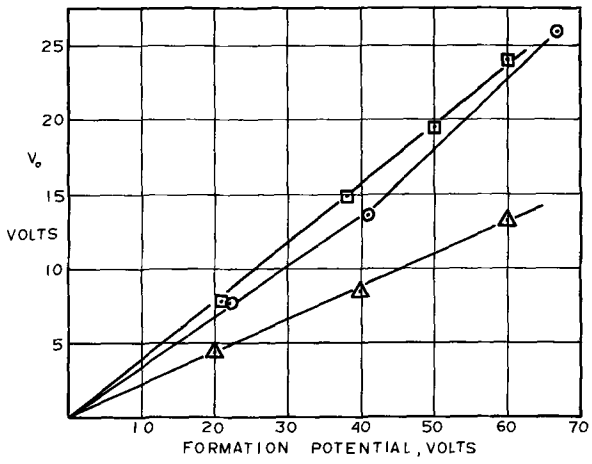

Fig. 2. Dependence of V_o on formation potential for vanadium in anodizing solution. The formation current density was 32 μA/cm^2 for the data represented by squares, 71 μA/cm^2 for the data represented by circles, and 352 μA/cm^2 for the data represented by triangles.

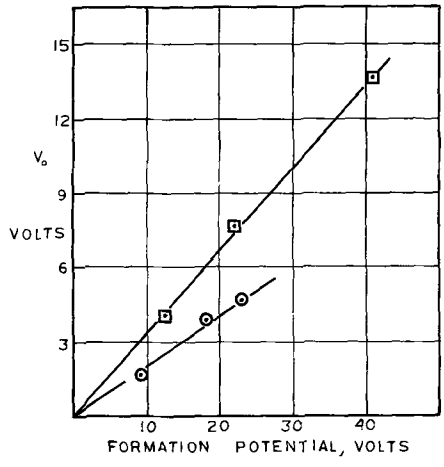

Fig. 3. Formation potential *vs.* V_o for vanadium anodized at 71 μA/cm^2 in 0.02M $Na_2B_4O_7$, 2.0M H_2O, $HC_2H_3O_2$ (squares), and 0.02M $Na_2B_4O_7$, 0.75M H_2O, $HC_2H_3O_2$ (circles) at 25°C.

From data analysis, we learned that the value of θ required to fit the transient data to Eq. [3] is quite small, with values ranging from essentially zero to as high as 0.1. A typical value is 0.02. Generally, θ increases with the formation potential of the film. Figure 4 shows the relationship between the reciprocal capacitance and the formation potential. The reciprocal capacitance is related to θ by the equation $1/C = V_o/i_e\theta$.

Discussion

An exponential dependence of the current density through the oxide film on the overpotential can be interpreted in terms of an activation-energy-controlled process (7). The theoretical relation for such a process, in the high-field case, is given in its simplest form by

$$i = 2anv \exp(-U/kT) \exp(qaE/kT) \qquad [7]$$

where a is the half-jump distance of the activation barrier, n the density of charge carriers, ν the frequency of the oscillating ions, U the activation energy for the process, q the effective charge on the mobile ions, and E the electric field at the activation barrier. The other symbols have their usual meanings. Assuming the field at the activation barrier is equal to the average electric field, a comparison of Eq. [6] and [7]

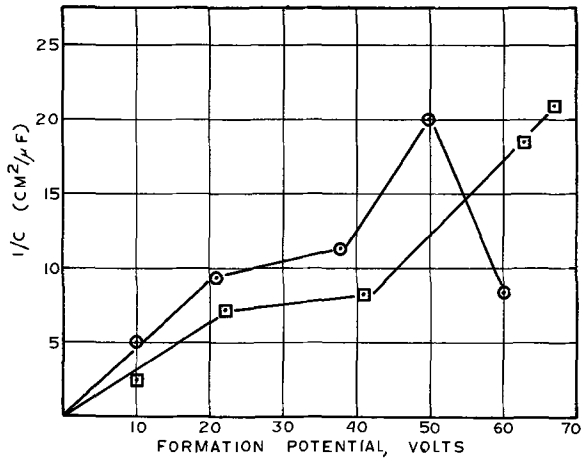

Fig. 4. Dependence of the reciprocal capacitance on formation potential. The formation current density was 32 μA/cm^2 for the data represented by the circles and 71 μA/cm^2 for the data represented by the squares.

may be made which yields the relationship

$$V_0 = (kT/qa)D \quad [8]$$

Thus, V_0 is proportional to the thickness of oxide layer, D.

The experimental data presented here verified a model of this type. Figure 2 shows that the values of V_0 are linearly proportional to the formation potential for a given formation current density over a wide range of values and that the lines intersect the origin. This result indicates that a high-field conduction process limits the current through the layer. Data taken for different formation current densities fall on lines of differing slopes, indicating that the field in the layer and i_0 both depend on the formation current density. The field in the dielectric may increase with increasing formation current density because of an increase in the ion jump distance at higher formation current densities.

As mentioned earlier, the values of θ required to linearize Eq. [3] are unusually small compared to results obtained with other metals by other investigators. We interpret this to mean that films formed in glacial acetic acid solutions containing 0.02M $Na_2B_4O_7$ and 2.0M H_2O are porous compared to those formed on, say, tantalum. These results are not at all inconsistent with our previous findings.

In an earlier work (2), we reported results which supported the existence of a porous anodic layer. First, infrared measurements showed that acetic acid, incorporated into the film during film growth, is removed from the film on standing after a very short time. Second, the final leakage current density, 0.15 μA/cm^2, was some 1000 times larger than that found for other valve metals (8). The comparative speed with which the acetic acid evaporated suggested that it might have been located along channels in the film. The onset of a porous "channel" structure during early stages of film growth would account for these experimental results. One is able to combine the values of θ, i_e, and V_0 to calculate the reciprocal capacitance through the relation, $1/C = V_0/i_e\theta$. Figure 4 shows the relationship between formation potential and $1/C$ is only roughly linear. Perhaps this is due to random defect structures like channels within the forming oxide film.

Finally, we look at Fig. 3 which shows that V_0 is, for a given formation potential, very much a function of the anodizing media. It is interesting to note that the solution containing the greater amount of water (2.0M *vs.* 0.75), yields larger values of V_0 for a given formation potential, a fact which suggests that the film formed in the solution containing the greater amount of water is thicker [recall $V_0 = (kT/qa)D$]. Perhaps this is quite correct since we reported (2) previously that film breakdown potential appears to decrease with increasing water concentration in the anodizing solution.

The results of this investigation are similar to those obtained by others studying other oxide film systems (4-6). All systems to date have shown the same type of dependence of V_0 on formation potential. The unusual results found in this study are the small values of θ necessary to linearize the transient relationship. This is believed to be due simply to the nature of the anodic oxide on vanadium.

Identification of Gold Islands on Copper-Plated Wire Surfaces by Cyclic Voltammetry

M. W. Breiter* and F. E. Luborsky

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

Periodic potentiostatic current-potential curves have been used to demonstrate the existence of gold islands on a copper substrate. The samples of smooth and rough copper substrates were prepared in a continuous wire plating system with an average thickness of the gold deposit of from 0 to 1400Å. Time-dependent changes in the potentiostatic curves were qualitatively explained in terms of the respective electrode reactions.

During studies concerned with the preparation of Permalloy films on wire (1), it was discovered that the application of a very low current in the gold-plating bath during the wire preparation resulted in substantial improvements in the performance of the wire as a nondestructive read-out (NDRO) element. This wire preparation and the magnetic results are described separately (2).

In this paper, we describe periodic potentiostatic measurements on the wires, without the magnetic film, which were used to obtain qualitative information about the "coverage" of the copper by the gold deposit. This technique differs from the determination of porosity of gold deposits based on measurements of the corrosion potential (3) and is sufficiently sensitive to detect the small amounts of gold present on the copper. The corrosion potential measurements were insensitive to the small amounts of gold encountered in this work. It is shown that the substrates which produce magnetic films with superior properties do contain some gold and that this gold is in the form of islands covering only a fraction of the copper substrate surface.

Experimental

The wires were prepared in the continuous wire-plating line (1, 2) by sequentially depositing a "smoothing" copper layer, a "rough" copper layer, and then a gold layer. The remainder of the plating system was not used so as to prevent contamination of the surface; *i.e.*, the NiFe cell was open, the anneal furnace "off," and the mercury removed from the test jig contact cups. Samples of various combinations of copper and gold were prepared as shown in Table I. Optimum magnetic properties, in subsequent processing, were obtained with substrates of the type represented by samples G and H. The current-voltage characteristic for the gold deposition cell is given in Fig. 1. The average gold thicknesses were determined by wet chemical analysis for samples down to 11Å. Each sample was assembled as an electrode and immersed in the 1M KOH electrolyte in a conventional cell of Pyrex glass. The electrolyte was flushed free of oxygen before use and kept agitated with the nitrogen during the measurements.

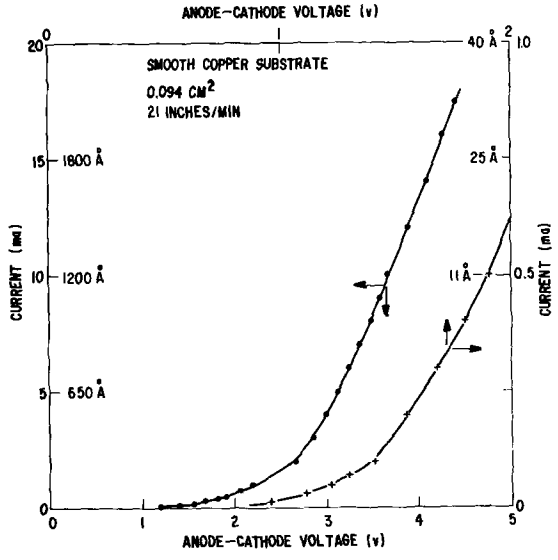

Fig. 1. Current-voltage characteristic for gold deposition in continuous plating line. Thicknesses obtained by chemical analysis. Upper and right coordinates are an expanded scale of the initial portion of the curve.

A Wenking 61TRS potentiostat and Type 255 Function Generator from Exact Electronics were used to apply periodic potential sweeps at different rates to the test electrode. The current was measured as a voltage drop across standard resistors and the current-potential curve displayed on a Tetronix 302 Oscilloscope. Potentials were measured *vs.* a hydrogen elec-

trode in 1M KOH. Measurements were all at room temperature.

Results

As in previous work (4, 5) concerning the surface composition of heterogeneous platinum-gold alloy wires, we have attempted to obtain information on the composition of the surface from characteristic waves in voltammetric current-potential curves. Preliminary work showed that the application of periodic potential sweeps between 0.2 and 1.2V at small rates (<1 V/sec) led to the fairly rapid destruction of the surface of some of our samples because of copper dissolution from copper patches between the gold islands. Judging only from the absence of any short-time destruction of samples made with an average thickness of the gold deposit of about 1200Å, it can be said that much thinner gold deposits do not cover the copper substrate uniformly. For the studies of the surface composition, a sweep rate of 100 V/sec was chosen. At this rate, the effect of copper dissolution is much smaller. A few results obtained at small sweep rates are mentioned later since they support the conclusions from measurements at 100 V/sec.

Voltammetric current-potential curves measured at 100 V/sec at a solid copper wire and on a smooth copper substrate are replotted in Fig. 2. The curves represent early cycles before a destructive effect was noticeable, but not the initial cycle. The shape of the I-U curves is nearly the same and the areas enclosed by the two curves are directly proportional to their apparent surface area given in Table I. The copper substrate on which the gold film was deposited in other experiments (see Table I) is uniform and thick enough to display the properties of bulk copper. The area under the anodic wave is equal to that under the cathodic wave within the experimental error (±10%). Only the anodic formation (6, 7) and cathodic reduction (6, 7) of copper oxides

$$2Cu + 2OH^- = Cu_2O + H_2O + 2e^- \quad [1]$$

$$Cu_2O + 2OH^- = 2CuO + H_2O + 2e^- \quad [2]$$

take place at the high sweep rate. A separation of the two reactions is not possible on the basis of the present results.

Voltammetric I-U curves taken in 1M KOH on a smooth gold wire at 100 V/sec are represented by curves in Fig. 3. The curves are practically symmetrical to the potential axis at U ≤ 1.1V, indicating the presence of a nearly reversible process. The formation and reduction of the oxygen layer occurs only to a small extent and is recognizable at the right side of the curves. The nature of the nearly reversible process became clear when $CuSO_4 \cdot 5H_2O$ was added in increasing amounts to the electrolyte. The height of the peaks at about 0.85V increases with the copper ion concentration (compare curves a to b). The addition of Cu^{++} in tests on the solid copper wire showed no change in the curves and no peak near 0.85V. It is suggested that the cathodic formation of absorbed copper atoms, Cu_{ad}, or of $(Cu_2O)_{ad}$ is observed during the cathodic sweep and its stripping away during the anodic sweep

$$CuO_2^{--} + 2H_2O + 2e^- = Cu_{ad} + 4OH^- \quad [3]$$

or, more likely,

$$2CuO_2^{--} + 3H_2O + 2e^- = (Cu_2O)_{ad} + 6(OH)^- \quad [4]$$

An absorbed layer of a copper-containing species is formed at potentials less positive than that for deposition of thick copper layers with bulk properties. This layer may have properties like a copper-gold alloy, but it still has to be formed on the gold substrate. The situation is similar to that encountered on platinum (8). Reactions [3] and [4] are so fast on gold that small traces of copper ions in the reagent-grade KOH can be detected. The presence of an impurity having the electrochemical properties of the Cu^{++}/Cu^+ couple was established (9) in a similar way for 0.5M HCl. The occurrence of reaction [3] which requires the presence of gold atoms is used subsequently in a qualitative way as evidence for the existence of gold patches on the surface of copper substrates. The gold patches were obtained by deposition of gold.

Three I-U curves, taken at 100 V/sec in 1M KOH with increasing average thickness of the gold deposit on top of the copper films, are replotted in Fig. 4. The conditions for the gold deposition are given in Table I. The curve for sample I in Fig. 4 with the thick gold deposit has a shape similar to curve a for the solid gold wire in Fig. 3. The gold deposit is uniform and covers the copper substrate essentially completely (except for random porosity). The enclosed areas during the anodic and cathodic sweep are about equal and proportional to the apparent surface area. The middle and the left I-U curve in Fig. 4 displayed one broad anodic wave and two cathodic waves. The cathodic wave between about 0.6 and 0.2V can be ascribed to the reduction of copper oxides, as a comparison with the curves on copper in Fig. 2 demonstrates. The narrower cathodic wave at about 0.8V appears at about the same potential as the cathodic wave of curve b in Fig. 3 and has a similar shape. It is attributed to reactions [3] and [4]. The height of this wave is a qualitative measure for the total area of the gold patches on top of the copper substrate. As expected, the height is larger for sample H with the thicker gold deposit. The presence of the cathodic wave between 0.6 and 0.2V in samples G and H represents evidence that a part of the underlying copper substrate is not covered by the gold film. This part participates in reactions [1] and [2] and, to a smaller extent, in copper dissolution.

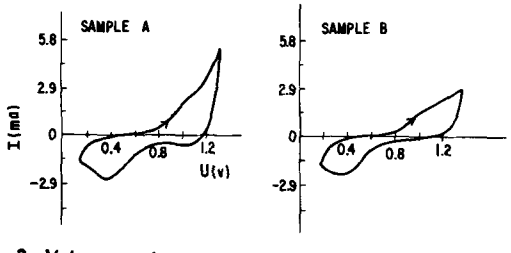

Fig. 2. Voltammetric current-potential curves at 100 V/sec on solid copper wire (sample A) and a smooth copper substrate (sample B).

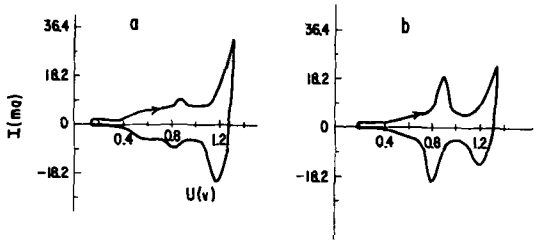

Fig. 3. Voltammetric I-U curves on solid gold wire, J, in 1M KOH + XM $CuSO_4 \cdot 5H_2O$ at 100 V/sec. Curve a: $X \approx 0$. Curve b: $X = 10^{-5}$.

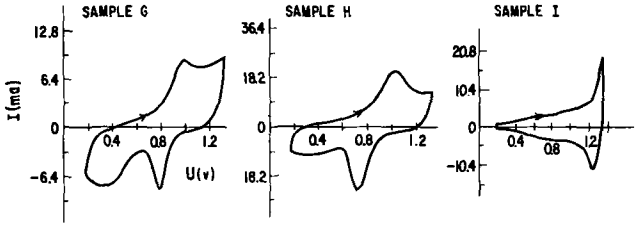

Fig. 4. Voltammetric I-U curves at 100 V/sec on 1M KOH on copper films with increasing average thickness of the gold deposit.

The occurrence of copper dissolution is evidenced by an increase with time of the height of the cathodic wave for gold at 0.8V.

It was not possible to obtain a quantitative measure for the coverage of the copper substrate with gold because thin gold films, like that on sample G, disappear from the surface during the cycling. The I-U curve of sample G was traced about 20 sec after connecting it to the potentiostatic circuit. During extended cycling, the cathodic peak at 0.8V becomes smaller and finally disappears. Then the I-U curve looks like curve b of the copper substrate in Fig. 2. The removal of the thicker gold film sample H was much slower than that of sample G. It is not known at present if the gold film is removed by anodic dissolution or by mechanical breakage because of anodic dissolution of the underlying copper substrate.

A qualitative confirmation of the preceding results is derivable from I-U curves measured at small sweep rates. The curves at 1 mV/sec have the form recently reported (10) for solid copper in 1M NaOH. The large anodic wave appearing at about 0.85V during the anodic sweep masks any other effect. However, the height of this wave increases with decreasing average thickness of the gold deposit, indicating that more copper areas become exposed to the electrolyte and participate in the anodic copper dissolution.

Conclusions

It has been demonstrated that periodic current-potential curves can be used to obtain qualitative information on the relative surface areas of copper and gold on composite samples. Differences between gold on smooth or on rough copper substrates could not be observed because of the qualitative nature of the measurements.

Acknowledgments

The authors wish to thank R. Skoda and B. J. Drummond for the preparation of the samples.

A New Technique for Investigating the Electrochemical Behavior of Electroless Plating Baths and the Mechanism of Electroless Nickel Plating

N. Feldstein* and T. S. Lancsek

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

The electrochemical potential of electroless nickel and electroless cobalt plating baths can be altered by the addition of a variety of chemical compounds to the baths. At the same time, the metal-to-phosphorus ratio in the deposit is altered. This behavior has been studied for a series of baths using typical accelerators including thiourea, glycine, and formate; each of these represents a different type of accelerator characteristic. A Tafel-like behavior was observed to apply for the deposition of nickel (or cobalt) and also for the deposition of phosphorus. Therefore, given a suitable reference point, the plating rate and metal-to-phosphorus ratio can be predicted from the measured potential. A model based on a modified hydride mechanism is proposed for the electroless deposition of nickel-phosphorus. With the help of this model, the hydrogen evolved during deposition can be quantitatively accounted for.

Since the discovery of the electroless plating process by Brenner and Riddell (1), many commercial processes have been developed employing this plating technique. In particular, the deposition of nickel layers by electroless techniques is widely used in the electronics industry. Although the actual structure (2-4) of nickel-phosphorus deposits formed with these baths is still unresolved, the phosphorus content in the deposit is of importance. Typical chemical and physical properties (5, 6) which are dependent on the phosphorus content are: resistivity, hardness, internal stress, corrosion resistance, magnetic moment, and electrical contacts to semiconductor material. It is thus important to control the phosphorus content through control of those parameters which affect its deposition rate.

In examining prior literature on the phosphorus content of nickel deposits, there is a general agreement on the following trends.

1. The per cent phosphorus increases with increasing temperature of operation.
2. The per cent phosphorus increases with increasing hypophosphite concentration.
3. The per cent phosphorus increases with decreasing pH of the bath.

Although considerable effort has been devoted to the study of the role played by major components of the bath (buffers, complexing agents, reducing agents, *etc.*), little attention has been focused on the possible effect(s) of stabilizers (7) and accelerators (8-10) on the phosphorus content of the deposit.

* Electrochemical Society Active Member.

Key words: electroless plating, electrochemical behavior and mechanism, role of accelerators.

In a recent investigation (11), it was demonstrated that inhibitors (stabilizers) alter the electrochemical parameters at the electrode solution interface and at the same time change the nickel-phosphorus ratio in the deposit. In the present investigation, it was decided to examine the effect(s) associated with some typical accelerators, since the use of such additives is highly desirable in practical plating. The accelerators chosen in this investigation were typical, each representing a specific class of accelerator.

Experimental Procedures

Chemicals.—All chemicals used in preparing the plating solutions were reagent grade. The water used was deionized and then distilled.

Rate.—For comparison of the relative effect(s) of the various accelerators, standard 2 in. x 2 in. alumina substrates (American Lava Corporation 614 plain) having a 40 μin. surface roughness were used. Volume of solutions was held at 200 cc unless otherwise stated. Electroless plating on these substrates was carried out using a conventional tin-palladium sensitization and activation sequence; the weight gain during plating was recorded. In most cases, initiation of plating was apparent within 30 sec; however, for solutions having the highest thiourea concentration, the initiation was sluggish. No agitation was provided during the plating.

The plating time in all cases was chosen as 10.0 min except in the case of bath C in which the deposition time was taken as 20.0 min. All plating temperatures were maintained within ±0.5°C; *p*H values were maintained within ±0.02 *p*H units at the corresponding operating temperature with the help of a Corning *p*H-controller, Model 10c. No agitation was provided during the plating cycle. In the current work, electroless Ni-P and Co-P plating baths shown in the Appendix were employed.

Subsequent to the plating, the deposits were analyzed for their nickel and phosphorus (or cobalt and phosphorus) content employing both x-ray fluorescence spectroscopy and conventional wet chemical analysis. For the wet chemical analysis, a gravimetric technique based on dimethylglyoxime was used for nickel (or cobalt), while the phosphorus was determined colorimetrically with molybdenum blue. In the x-ray technique, the net x-ray intensity (counts per second) was monitored for PKα and NiKα lines, respectively. Hydrogen evolved in the course of plating was collected by a simple displacement apparatus.

Potential measurements.—Potential measurements were carried out using a recording potentiometer (John Fluke Manufacturing Company, Model 825A). All steady-state potentials (mixed potentials) and equilibrium potentials were obtained using freshly deposited nickel or cobalt electrodes against SCE at the operating temperatures. Potential measurements were made as the concentration of the additives was varied. All reported values are within ±1 mV.

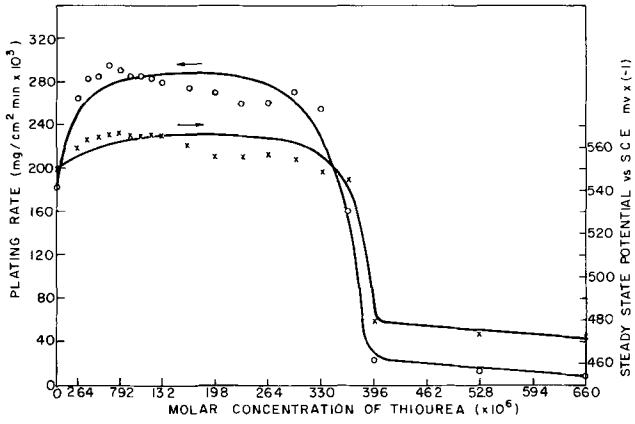

Fig. 1. Effect of thiourea on a nickel-plating bath (bath A)

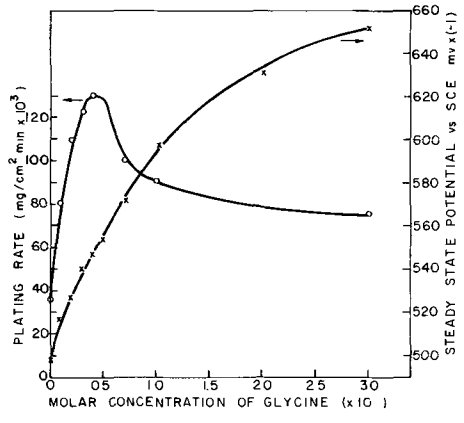

Fig. 2. Effect of glycine on a nickel-plating bath (bath B)

Results and Discussion

In examining the kinetic results shown in Fig. 1-4, the effect(s) of the accelerators may be divided into three distinct classes.

AI class (accelerator-inhibitor).—The over-all behavior of this class is demonstrated in Fig. 1 and 4. Initially, there is an increase in plating rate leading to a maximum. Further increases in additive concentration lead to inhibition of the plating rate, due to an adsorption-poisoning type mechanism. Typical materials in this class are thiourea and thiocyanate.

API class (accelerator with partial inhibition).—For this class, the over-all behavior is shown in Fig. 2. Following the initial acceleration in deposition rate, there is an inhibited range. However, the degree of inhibition is not complete; a plateau is reached at the higher accelerator concentrations. The plateau level achieved can either be below or above the initial level in the absence of additive.

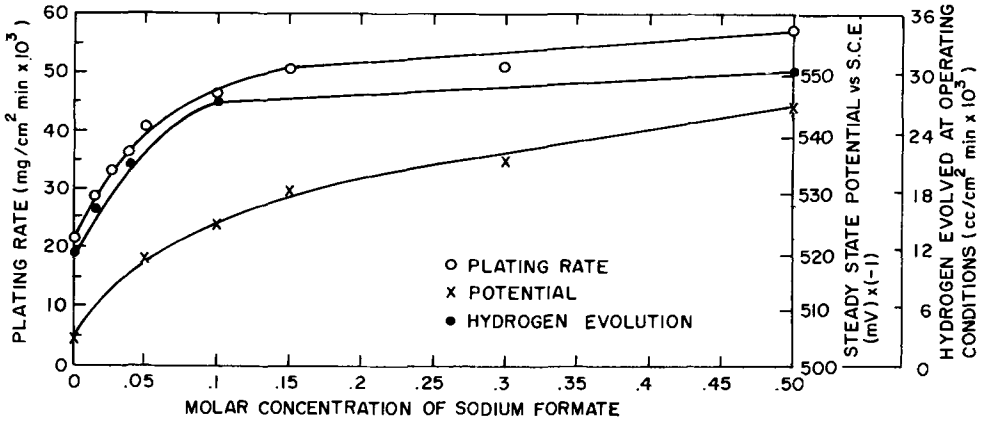

Fig. 3. Effect of formate on a nickel-plating bath (bath C).

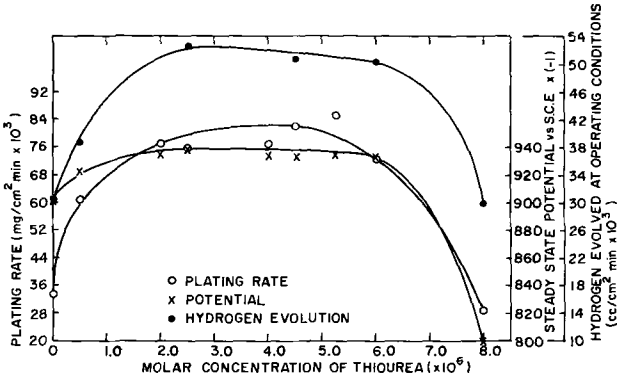

Fig. 4. Effect of thiourea on a cobalt-plating bath (bath D)

AO class (accelerator-only).—For this class, the over-all behavior is illustrated in Fig. 3. Contrary to the behavior in the above two classes, the plating rate approaches a maximum value asymptotically as the additive concentration is increased. It should be noted that the additives in this class generally do not form complexes with the metallic cation in bulk solution. Besides formate, similar behavior was noted with fluoride ion.

As reported by DeMinjer and Brenner (7), the incorporation in the bath of thiourea in low concentrations gives an accelerating effect on the plating rate. Figure 1 (bath A) shows the manner in which the plating rate and steady-state potential vary as the thiourea concentration is modified. Variations in both the plating rate and steady-state potential are similar; *i.e.*, corresponding increases or decreases in each take place as thiourea is added to the bath. It should be noted, however, that, although thiourea is known to accelerate plating from some acidic electroless nickel baths, there are cases (12) (acid-type bath) in which this anticipated acceleration does not take place. Examination of the deposits with respect to their elemental composition (Table I) shows distinct acceleration in the formation rate of both the nickel and phosphorus. At the same time, the per cent phosphorus in the deposit decreases during the acceleration part of the curve. Due to the high operating temperature, no collection of hydrogen was attempted.

In Fig. 2 (bath B), the effect of glycine on the plating rate and the steady-state potentials is demonstrated. The plating rate characteristics are in excellent agreement with the work by Holbrook and Twist (8). Furthermore, they have reported that the molar ratio of hydrogen to nickel (nickel plus phosphorus) is constant over the entire glycine range, and this determination has not been repeated in the current work. It is further demonstrated in Fig. 2 that the steady-state potential gradually increases toward more cathodic values upon the addition of glycine and leveling occurs at the higher glycine concentrations. As the glycine content varies, the equilibrium potential for the nickel redox system is altered in a regular fashion. Specifically, −384 mV *vs.* SCE and −445 mV *vs.* SCE were measured for this system in the absence of hypophosphite for 0 and 0.3M glycine, respectively. Although the potential curves for the glycine system do not follow the same characteristics as shown in Fig. 1, 3, and 4, this behavior is not surprising since glycine can complex the nickel with a *p*K value of about 5 (13). However, in view of the variations of steady-state potential with added glycine, it is not surprising to find (Table II) that both the nickel and phosphorus formation rates are altered. In addition, deposits having a different phosphorus-nickel ratio are obtained.

As seen from Fig. 3 (bath C), upon the addition of formate to the electroless nickel bath, acceleration in plating rate takes place. The plating rate, the rate of hydrogen evolution, and the steady-state potential all increase gradually leading to a plateau. As demonstrated in Table III, both the nickel and phosphorus deposition rates increase with formate addition. There is also a net decrease in the phosphorus concentration in the deposit as the formate concentration increases. Furthermore, from the data of Fig. 3 and Table III, the molar concentration of hydrogen to nickel was found to be 1.4 over the entire formate concentration range examined.

Examination of the equilibrium potential for the nickel system in the absence of hypophosphite resulted in a constant value of −383 ±4 mV. *vs.* SCE at 75°C and *p*H of 4 over the entire formate concentration range. This result, along with absorption measurements in the uv-visible range, suggests that there is no complex formation between the formate and the nickel ions in solution.

While in Fig. 1-3 electroless nickel plating baths were examined, Fig. 4 (bath D) shows the influence of thiourea on a typical electroless cobalt bath. In examining the results of Fig. 4, it is apparent that initially there is an increase in the plating rate, the rate of hydrogen evolution, and the steady-state potential with added thiourea. Further addition of the thiourea leads to a decrease in these dependent variables and the eventual cessation of the plating process. This general course of behavior closely resembles the results shown in Fig. 1. In Table IV it is clearly shown that both the cobalt and phosphorus and their respective plating rates are enhanced, however in a manner in which the per cent phosphorus is decreased in the

acceleration part of the curve. Examination of the equilibrium potential for the cobalt system in the absence of hypophosphite resulted in a constant value of -726 ± 2 mV *vs.* SCE for thiourea concentrations of 0-4.5 x 10^{-6}M. This behavior is exactly analogous to that exhibited by the nickel system shown in Table I. Analysis of the gaseous product evolved as related to the cobalt deposited shows that in all cases the molar concentration of the gaseous product to cobalt is in the range of 4:1 to 3:1 without any specific trend with thiourea addition. Furthermore, it was found mass spectrometrically that a substantial portion of the gas phase is ammonia.

Replotting the results of Fig. 1, 3, and 4 (and their corresponding tables) shows the manner by which the net plating rates for nickel and cobalt vary with the steady-state potentials (Fig. 5). Since the deposits formed in this work are generally quite thick, it is reasonable to assume that composition is uniform throughout the bulk of the cross section. Although in Fig. 5 the plating rate for the metals is plotted *vs.* potential, by suitable transformation (using Faraday's law) these plating rates can be converted to "deposition currents." As seen in all three cases, the logarithm of the plating rate (or deposition current) is a linear function of the potential. This behavior is characteristic of Tafel plots (14). From relating the slopes of Fig. 5 to the theoretical Tafel slope, the transfer coefficients (α) were evaluated (assuming $n = 2$). The theoretical Tafel slope is

$$-\frac{n\alpha RT}{\mathbf{F}} = \frac{d\ln i}{dE}$$

where n = number of electrons in charge transfer step
α = transfer coefficient
R = gas constant
T = absolute temperature
$\mathbf{F}$ = Faraday constant

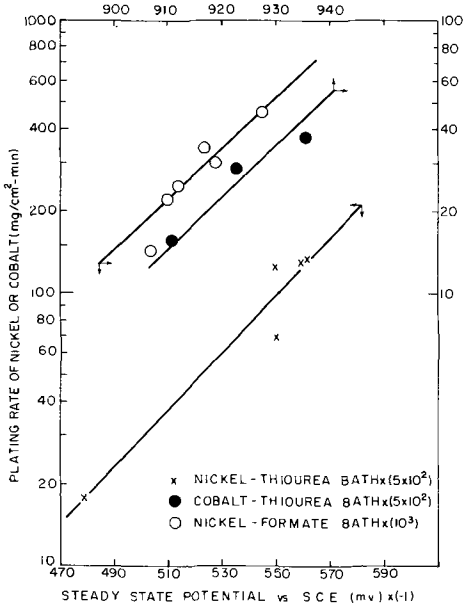

Fig. 5. Plating rate of nickel and cobalt *vs.* steady-state potential.

Specifically, the following transfer coefficients were found: 0.5 for the nickel-formate and cobalt-thiourea baths, and 0.4 for the nickel-thiourea case.

Since the Tafel type equation appears to fit the observed data, a charge transfer step can be assumed to be the slow step in the reduction of the metallic cations. Furthermore, from earlier work, this slow charge transfer step is probably due to a slow electron exchange or a slow chemical change during the course of the anodic oxidation of hypophosphite.

Figure 6 was prepared from data on the phosphorus deposition rate. As seen in all three cases, a linear relationship exists which again resembles a Tafel plot. From the slopes of Fig. 6 and the theoretical Tafel slope (n assumed to be unity), the corresponding charge transfer coefficients were found

0.71 for cobalt-thiourea bath
1.1 for nickel-thiourea bath
1.1 for nickel-formate bath

It is thus concluded that the electrochemical reduction of hypophosphite to phosphorus is also charge transfer controlled and that the kinetics of deposition may be described by the Tafel equation. However, since by definition α may have values only in the range 0-1, the value of n must be greater than 1 in the electrochemical process leading to the formation of phosphorus.

It is thus postulated that reduction of hypophosphite itself is not involved in the formation of phosphorus. Rather, another intermediate having phosphorus in a formal valence state greater than one is probably involved. This species is probably formed from hypophosphite during oxidation step(s). This intermediate species is postulated to be a metaphosphorus acid (HPO_2), which, although short-lived, could lead to the formation of either elemental phosphorus by reduction or orthophosphorus acid (H_3PO_3) by hydration.

Wieland and Winkler (15) postulated, on the basis of organic analogies, that a metaphosphorus acid is formed during the catalytic dehydrogenation of hypophosphorus acid. Based on Wieland and Winkler's postulate, Goldenstein *et al.* (2) proposed metaphosphorus acid as an intermediate in the oxidation of hypophosphite. It is interesting to note that in their work (2) the metaphosphorus acid is formed as part of an atomic hydrogen transfer mechanism rather than the hydride-type mechanism accounted in this investigation.

7. $H_2PO_2^- + OH^-$	$\longrightarrow HPO_3^= + H_2$	CHEMICAL

Fig. 7. A modified hydride transfer mechanism. For alkaline condition, X represents a catalytic site, and M represents nickel or cobalt.

In view of the results of the current investigation, and the arguments presented by Lukes (16), it is believed that a modified hydride-type mechanism (16) best accounts for general characteristics of Ni-P and Co-P type baths. Figure 7 shows the basic steps which occur in this modified hydride transfer mechanism. Reaction 1 is the rate-controlling step resulting in the charge transfer control behavior observed for reactions 3 and 6. No attempt is made in this investigation to distinguish between the two isomeric forms of hypophosphite (17). At the same time, the hydrogen evolved during the course of plating is the sum total of reactions 4, 5, and 7 (Fig. 7). Reaction 7, however, should occur only at high temperatures and in alkaline media (18). From the experimental data for the hydrogen evolved from baths B, C, and from recently reported data on an alkaline room-temperature bath (11), excellent agreement was found between the hydrogen measured and that expected, based on the composition of the deposit. Specifically, it was found that the following correlation holds fairly rigorously

$$\frac{d}{dt}[H_2] = \frac{d}{dt}[Ni] + 1.5\frac{d}{dt}[P]$$

This correlation is consistent with the over-all mechanism proposed in Fig. 7 and suggests that reaction 5 plays a minor role for the baths under examination. Furthermore, due to the competitive nature of reactions 2 and 6 with respect to PO_2^-, it can be anticipated that reaction 2 will become more important in alkaline media. This is consistent with the observation of several investigators that the phosphorus content in the deposit is lower as the *p*H is increased.

Based on the results of this investigation and the consistency of the values for the transfer coefficient (α) for nickel (or cobalt) and phosphorus, the following practical results are envisioned, all leading to greater simplicity and better control of the composition of the deposit.

1. Based on (*a*) the value found for α (transfer coefficient), (*b*) at least one deposition rate measurement, (*c*) the corresponding steady-state potential, and (*d*) the composition of the deposit, a complete deposition rate for nickel (or cobalt) and phosphorus as a function of potential may be calculated. The potential can be changed for a given bath by, *e.g.*, adding an accelerator so that a complete plating rate *vs.* accelerator concentration curve can be constructed (for class I and III only). From these data, precise bath compositions may be selected to yield the desired alloy composition and plating rate.

2. Although in the current investigation an analysis for a binary system (Ni-P or Co-P) was made, it is believed that a similar analysis can be made for ternary systems.

3. The use of thiourea in electroless plating is highly desirable since it accelerates, as well as stabilizes, such baths. There is, however, a basic limitation in the use of this material because its concentration decreases with time, due to hydrolysis and sulfur codeposition. It is thus highly desirable to have a simple analytical technique for low thiourea concentrations. Based on the potential variations (Fig. 1 and 4) with thiourea concentration, a simple potentiometric technique (19) has been conceived for the determination of thiourea in electroless plating baths.

Conclusions

In the acceleration of electroless nickel and cobalt deposition from hypophosphite-based media, three distinct classes of accelerators are observed

AI (accelerator-inhibitor)
API (accelerator with partial inhibition)
AO (accelerator-only)

In all cases, there are distinct potential changes for the bath and compositional variations in the deposit as the accelerator concentration is increased. Detailed analysis of classes I and III accelerators shows that the nickel (or cobalt) and phosphorus deposition kinetics satisfy a Tafel-like equation. This correlation with the Tafel equations implies that the electroless deposition reactions may be treated by simple electrochemical principles. From our earlier work (11), it is known that the anodic oxidation of hypophosphite is the rate-controlling step.

The hydrogen evolved is due to several chemical reactions taking place simultaneously. In acid media (or low-temperature alkaline media), we observe that the moles of hydrogen gas evolved are the sum total of the moles of nickel deposited plus 1.5 $\times$ the moles of phosphorus deposited. This leads to the hypothesis that the phosphorus originates from a short-lived intermediate such as metaphosphorus acid, rather than from the parent hypophosphite molecule. These observations are consistent with the modified hydride mechanism proposed to account for the findings of this investigation.

Voltammetric and Coulometric Studies of the Mechanism of Electrohydrodimerization of Diethyl Fumarate in Dimethylformamide Solutions

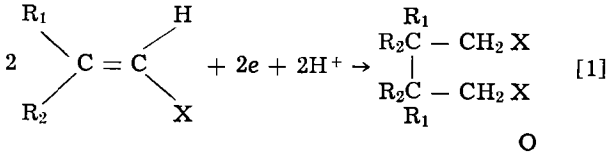
ABSTRACT

The reduction of diethyl fumarate (DEF) in tetra-n-butylammonium iodide (TBAI)-dimethylformamide (DMF) solutions at a platinum electrode has been studied by cyclic voltammetry, double potential step chronoamperometry, and controlled potential coulometry. The chronoamperometric response for several possible mechanisms of electrohydrodimerization has been obtained by digital simulation techniques, and a method for distinguishing among the mechanisms suggested. Results of double potential step chronoamperometric experiments strongly support a mechanism where the electrochemically generated anion radicals undergo a second-order dimerization reaction. Controlled potential electrolysis results give evidence for a bulk polymerization reaction in the absence of proton donor; protonation in the presence of hydroquinones; and good efficiency to the hydrodimer product in the presence of lithium perchlorate trihydrate.

The study of electrohydrodimerizations (or electrolytic reductive couplings) of activated olefins and related substances, by an over-all reaction shown in Eq. [1] has been the subject of numerous investigations, most recently especially



[1]

X = electron-withdrawing group, *e.g.* —CN, —C(=O)—OEt

by Baizer and co-workers [see (1-3) and references contained therein]. The reduction on acrylonitrile ($R_1 = R_2 = H$, X = CN) has been the subject of most of the investigations because of the commercial importance of the hydrodimerized product, adiponitrile. Relatively few studies have been concerned with a kinetic analysis of the mechanism of the process, however. The first papers, generally on the basis of product distribution, viewed the process as occurring with an initial two-electron reduction to the dianion, which then attacked the parent molecule to produce coupled products. Beck (4), based on an analysis of current-potential curves for the reduction of acrylonitrile, proposed a rate-determining step involving one electron and one water molecule to form a neutral radical, which is immediately reduced further to the protonated carbanion. Recently Petrovich, Baizer, and Ort (2, 3) carried out polarographic, cyclic voltammetric, and macroscale electrolysis studies of a number of diactivated olefins in N,N-dimethylformamide (DMF) solutions and concluded that dimeric products were formed by either attack of an electrochemically generated anion radical on the parent unreduced olefin, followed by further electroreduction and protonation, or by protonation of the anion radical, followed by further reduction to an anion and subsequent attack on the olefin. An alternate pathway to the dimer, that of coupling of the anion radicals, was deemed less likely.

The research described here was undertaken to investigate the mechanism of the hydrodimerization reaction using a variety of electroanalytical techniques,

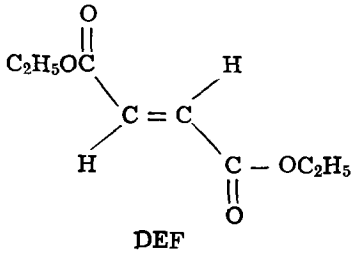
including double potential step chronoamperometry, cyclic voltammetry, and controlled potential coulometry. Other investigations of the mechanism by rotating ring disk electrode voltammetry and electron spin resonance spectroscopy will be reported elsewhere. The compound selected for study was diethyl fumarate (DEF), since



DEF

previous studies (2, 3) have shown that the following reactions of the initially formed radical anion are sufficiently slow to allow rather easy application of electroanalytical techniques.

Experimental

Materials.—Dimethylformamide (DMF) was purified as previously described (5). Tetra-n-butylammonium iodide (TBAI) was the polarographic grade supplied by Southwestern Analytical Chemicals, Austin, Texas. Diethyl fumarate (DEF) (K and K Laboratories, Inc., Plainview, New York) was used without further purification, since preliminary experiments with distilled samples showed identical behavior to that of unpurified samples.

Apparatus.—The cell used in coulometric experiments is shown in Fig. 1. It is comprised of four compartments (auxiliary, intermediate-buffer, working, and reference,) four electrodes (auxiliary, micro, macro, and reference), and a freeze-pump-thaw (F-P-T) chamber. The F-P-T chamber is used for degassing the solution by freezing at liquid nitrogen temperature, pumping to about 10^{-5} Torr, and then thawing to room temperature (with the pump off). This procedure is repeated three to five times (5).

A silver wire isolated in a compartment closed with a fine sintered glass disk was used as a reference electrode. It was found to be stable (with less than a 10 mV drift) in our TBAI-DMF systems for at least 48 hr. The reference electrode was positioned in the current path between the auxiliary and macroelectrode so that the macroelectrode would not overshoot the controlled voltage because of iR drops in coulometry experiments.

The microelectrode used for chronoamperometry and voltammetry was an 0.16 cm diameter platinum disk in glass. It was pretreated by soaking briefly in nitric acid, rinsing, and drying. The macroelectrode was two thicknesses of fine platinum gauze, 2 cm high by 10 cm long, formed into a "C." It was attached with a pin socket for easy cleaning and assembly. The auxiliary electrode was 20 cm of coiled 18 gauge platinum wire. Stirring was accomplished with a Teflon-coated stirring bar (5/16 in. diameter by 1/2 in. long). Some chronoamperometric meaurements were performed in a cell similar to the one shown in Fig. 1, but with only two large compartments (F-P-T and working), with the auxiliary electrode housed in a fritted chamber similar to that used with the reference electrode described above, but having a medium, rather than fine, sintered glass disk on the bottom.

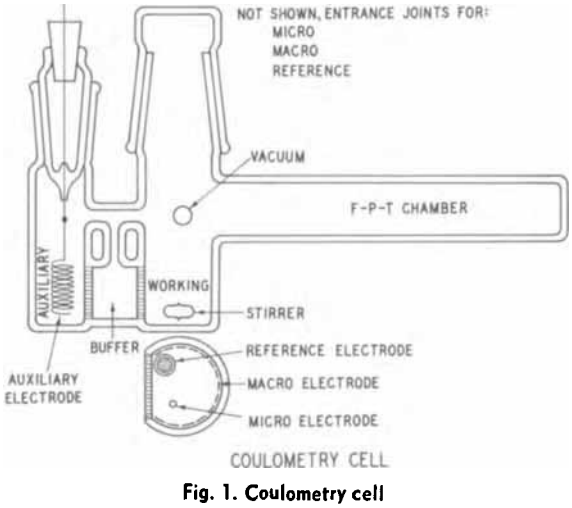


Fig. 1. Coulometry cell

Electrochemical experiments were carried out with a PAR Model 170 Electrochemistry System (Princeton Applied Research Corporation, Princeton, New Jersey). Positive feedback was generally used for resistance compensation in voltammetric experiments. In some high current situations during macroelectrolysis at high concentrations compensation was not complete because of limitations in the instrument. This does not affect the results, however, since it resulted in actual potentials less negative than those set. The various functions of the instrument were checked and calibrated periodically.

Some chronoamperometric data were also taken using a Wenking Model 61-RH potentiostat in conjunction with a Wavetek Model 114 function generator and associated switching and triggering circuitry.

Most of the chronoamperometric and chronocoulometric data were recorded using a PDP-12A computer (Digital Equipment Corporation, Maynard, Massachusetts) for data acquisition. Signals for current and coulombs from the PAR-170 system were interfaced to the analog-to-digital converters of the PDP-12A through appropriate operational amplifier followers, sense line triggers, etc. Data points were taken every 50 μsec. Techniques employed were generally similar to previous applications of digital data acquisition techniques in chronocoulometric experiments [see (6, 7) and references contained therein].

Typical experimental procedure.—A solution of DEF in DMF was prepared in a 50 ml volumetric flask. When lithium perchlorate was to be added to the electrolysis solution, a weighed amount of $LiClO_4 \cdot 3H_2O$ was added to the F-P-T chamber and 4.00g of TBAI was placed in the bottom of the working electrode compartment along with the stirring bar. The TBAI could not be mixed with the $LiClO_4$ at this stage, as lithium iodide will air oxidize to give iodine.

The cell was set up with the F-P-T chamber vertical and the DEF-DMF solution was poured in. The cell was then assembled by inserting the electrodes, closed and evacuated, and the F-P-T cycles were carried out. It was then manipulated to mix the TBAI and liquid (50 ml of DMF solution and 4.00g TBAI result in a volume of 53.0 ml).

The cell was then righted, the levels in the different compartments adjusted roughly by sloshing, and then the cell was set on a flat, stable surface and allowed to equilibrate thermally and hydrostatically; this took about 2 hr. In this cell 42% of the solution was in the working electrode compartment, as determined by removing the contents of each chamber and weighing them. The reference compartment was filled by means of a small hole just above, and a larger hole about 2 cm above, the electrolyte level. All electrochemical experiments were performed with the solution under reduced pressure. During coulometry the cell was maintained at 20°-25° and was stirred continuously. To prevent condensation in the remote portions of the cell, the liquid had to be kept cooler than the dry portions of the cell as transport through the vapor space was rapid at the reduced pressure.

Results

Cyclic voltammetry.—Cyclic voltammetric experiments were undertaken to determine the potentials for the potential-step experiments, to provide qualitative and semiquantitative information for use in

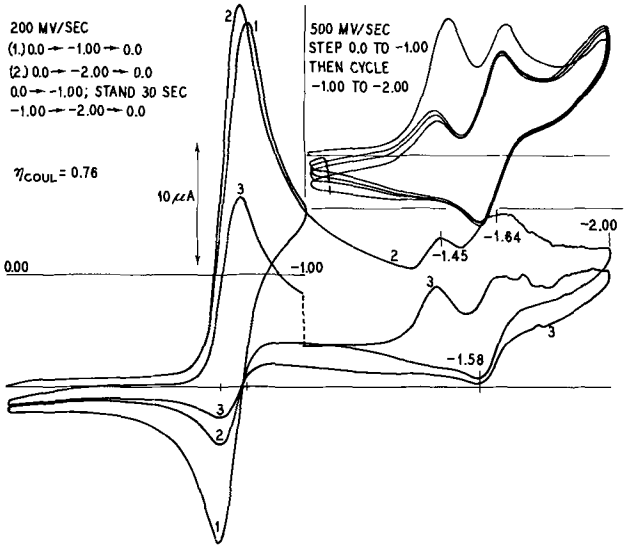

Fig. 2. Cyclic voltammograms for DEF in 0.44M TBAI-DMF solution. Potential programs and sweep rates as shown.

determining the effects of different additives (water, $LiClO_4$), and for following macroscale electrolyses. Typical cyclic voltammograms of DEF in anhydrous DMF containing 0.44*M* TBAI are shown in Fig. 2. The first peak occurs at a cathodic peak potential, E_{pc}, of −0.80V *vs.* the Ag reference electrode (Ag-RE). In all of the solutions studied the range of the peak potential was −0.78 to −0.81V with sweep rates of 100-200 mV/sec (and with positive feedback used for resistance compensation). Half-peak potentials were typically 60 mV positive of E_{pc}; $E_{pc} - E_{pa}$ values were typically 65-67 mV. Baizer and co-workers (3) gave −1.54V *vs.* an aqueous saturated calomel electrode (SCE) for the polarographic $E_{1/2}$ of the first wave in DMF −0.1*M* tetraethylammonium perchlorate (TEAP) solutions—both anhydrous and containing 1*M* water. Smaller waves following the first occur at about −1.45 and −1.64V *vs.* Ag-RE. Baizer and co-workers (3) found that a current decrease was noted during polarographic reduction of DEF at potentials about 0.6V past the $E_{1/2}$ of the first wave in anhydrous DMF. They ascribed this behavior to formation of the dianion at these potentials which reacted with incoming parent molecules in a polymerization reaction. In DMF solutions containing 1*M* H_2O a second wave, somewhat smaller than the first wave, at −2.27V *vs.* SCE, was observed. Typical data for the variation of the cathodic peak current, i_{pc}, of the first reduction with scan rate, v, and concentration, C, are given in Table I. Baizer and co-workers (3) mention a similar decrease of $i_{pc}/v^{1/2}$ C with increasing v for DEF and related compounds.

Table I. Typical cyclic voltammetric data for first reduction wave of diethyl fumarate[a]

[a] The solution was 0.1*M* TBAI in DMF. The platinum working electrode area was 0.11 cm². The value of $i_{pc}/v^{1/2}C$ for the reduction of azobenzene in these solutions at this electrode was 8.2, and was independent of scan rate. Experimental results of V. Puglisi.

Double potential step experiments.—To measure the rate at which the radical anion produced during the first reduction wave reacts and from these data elucidate the mechanism for the reaction, double potential step chronoamperometric experiments were undertaken. These methods, which have been used previously for reactions involving following first-order reactions (EC-mechanism) (8, 9), involve measuring the current as a function of time when the potential of the working electrode is changed.

Experimentally, the potential is first stepped to E_1, where the reaction $R + e \rightarrow R^{\cdot -}$ occurs at a mass transfer controlled rate. At a time T_F, the potential is stepped to E_2 where only the reaction $R^{\cdot -} \rightarrow R + e$ occurs. In chronoamperometric experiments, the current is measured just before T_F (I_F) and just before $2T_F$ (I_B). The ratio I_B/I_F has a value of 0.2928 in the absence of kinetic perturbations regardless of the length of T_F (8). If $R^{\cdot -}$ reacts to form nonoxdizable species, then the ratio I_B/I_F is perturbed, and will be a function of T_F. The order and rate of the perturbing reaction can be found from the variation of this ratio with T_F and concentration.

Chronocoulometric experiments are similar, except that Q_F and Q_B are measured at T_F and $2T_F$, respectively, with the unperturbed ratio Q_B/Q_F equal to 0.4142 (9).

Because the potential is stepped to values where the electrode reactions (either reduction of R or oxidation of $R^{\cdot -}$) occur at diffusion controlled rates, the measurement is unaffected by the rate of the electron transfer step. Moreover, when an adequate potentiostat and positive feedback compensation of uncompensated resistance are employed, the measurements are relatively unperturbed by double layer charging effects. These are decided advantages of these techniques over cyclic voltammetric investigations of the mechanism. Moreover, digital simulation of the different cases involving kinetic complications are somewhat easier for potential steps than for potential sweeps.

Five different reaction schemes were considered as possible in the hydrodimerization reaction scheme:

I. First order EC:

At E_1: $R + e \rightarrow R^{\cdot -}$ $\quad R^{\cdot -} \xrightarrow{k_1} X$

At E_2: $R^{\cdot -} \rightarrow R + e$

II. First order ECE

At E_1: $R + e \rightarrow R^{\cdot -}$ $\quad R^{\cdot -} \xrightarrow{k_1} R^{\cdot -\prime}$; $R^{\cdot -\prime} + e \rightarrow X$

At E_2: $R^{\cdot -} \rightarrow R + e$

III. Second order EC

At E_1: $R + 2e \rightarrow R^{2-}$ $\quad R^{2-} + R \xrightarrow{k_2} R_2^{2-}$

At E_2: $R^{2-} \rightarrow R + 2e$

IV. Second order ECE

At E_1: $R + e \rightarrow R^{\cdot -}$

$R^{\cdot -} + R \xrightarrow{k_2} R_2^{\cdot -}$; $R_2^{\cdot -} + e \rightarrow R_2^{2-}$

At E_2: $R^{\cdot -} \rightarrow R + e$

(For IVA: $R^{\cdot -} \rightarrow R + e$ and $R_2^{\cdot -} \rightarrow$ products + e)

V. Second order dimerization

At E_1: $R + e \rightarrow R^{\cdot -}$ $\quad 2R^{\cdot -} \xrightarrow{k_2} R_2^{2-}$

At E_2: $R^{\cdot -} \rightarrow R + e$

Schemes III, IV, and V represent possible alternate paths to the hydrodimer. It is assumed that R_2^{2-} is protonated rapidly, so that oxidation of R_2^{2-} at the

electrode at E_2 need not be considered. Similarly, the results would be the same in say V, if R^- first protonated in a fast reaction and then the protonated species coupled to R_2H_2. Scheme II represents the case of, for example, protonation of R^- followed by further reduction to lead to the two-electron product RH_2. Scheme I has been treated previously (8, 9) and was included here to compare with the other cases and also to serve as a check on our digital simulation procedure.

The digital simulation procedures for obtaining theoretical I-time (t) and Q-t curves generally followed methods described in detail before (10, 11). For simplicity, the diffusion coefficients of all species were taken as equal. The results are changed only slightly for reasonable differences in diffusion coefficients (*e.g.*, $D_{R^-} = 2D_{R_2^{2-}}$, etc.). The normalized currents or coulombs are determined as functions of the dimensionless parameter k_jTC^{j-1} (when $k_jT_FC^{j-1} = 1.0$), where j is the order of the reaction consuming R^- ($j = 1$ for cases I and II and $j = 2$ for cases III, IV, and V) and C is the bulk concentration of R (Fig. 3). Variations in $k_jT_FC^{j-1}$ result in variations in the ratio I_B/I_F and Q_B/Q_F for each mechanism. As a result of several simulations with other values assigned to the parameter $k_jT_FC^{j-1}$, the ratios shown in Table II were obtained. From these tabulated data the working curves for the different mechanisms are drawn. To simplify evaluation of experimental results and to establish criteria that might distinguish between the proposed mechanisms, the working curves are plotted using the dimensionless ratio I_B/I_F, normalized by dividing by 0.2928, which we will call R_I, the normalized current ratio. This ratio will vary from 1.0 in the absence of kinetic complications to zero for large values of $k_jT_FC^{j-1}$. Similarly, the Q_B/Q_F ratio is normalized to yield an R_Q which varies between zero in the absence of kinetic perturbations to 1.0 in the limit of fast kinetics. (Where comparisons with previous theoretical treatments based on solution of the partial differential diffusion equations under appropriate boundary conditions are possible, excellent agreement is obtained.) The horizontal axis is given in units of $t_{1/2}$, the real time at which $R_I = 0.5$ (Fig. 4). This value of $t_{1/2}$ can be used to calculate the rate constant of the reaction, once the mechanism is established, by the expressions given in Table II. The different mechanisms can be distinguished by comparing the shape of experimental R_I or R_Q *vs.* $t_{1/2}$ curves with the theo-

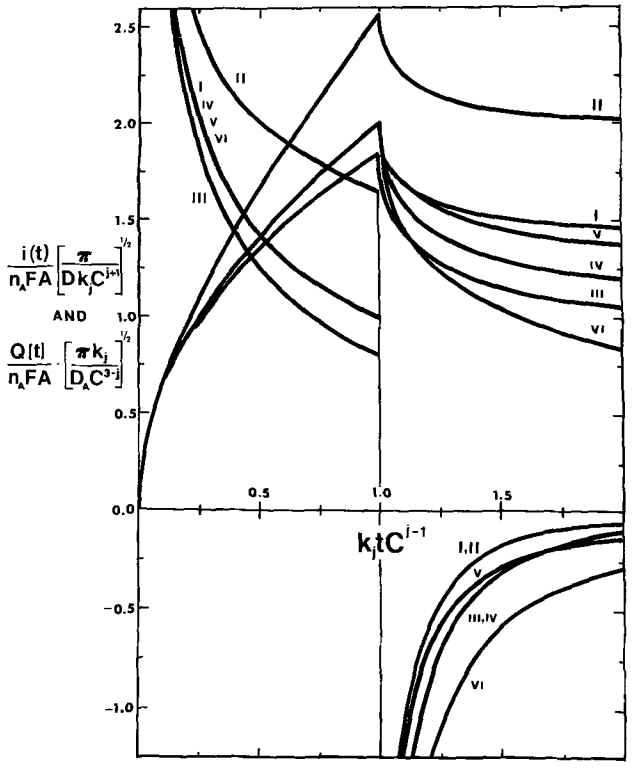

Fig. 3. Variation of current and coulombs with k_jtC^{j-1} for different mechanisms in text for double potential step chronoamperometry and chronocoulometry. VI represents system with no kinetic complications.

[a] From ref. (8).
[b] From ref. (9); note, however, that a computational error appears to have been made computing the final results from the correct derived equation. The results in this column have been recomputed (J. Phelps, University of Texas at Austin, 1968).
[c] Rate constants can be calculated from the measured $t_{1/2}$-value by the following equations:

Mechanism	Rate constant
I	$k_1 = 0.406/t_{1/2}$
II	$k_1 = 0.273/t_{1/2}$
III	$k_2 = 0.922/t_{1/2}C$
IV	$k_2 = 0.690/t_{1/2}C$
V	$k_2 = 0.830/t_{1/2}C$

where $t_{1/2}$ is the value of T_F at which $R_I = 0.5$.

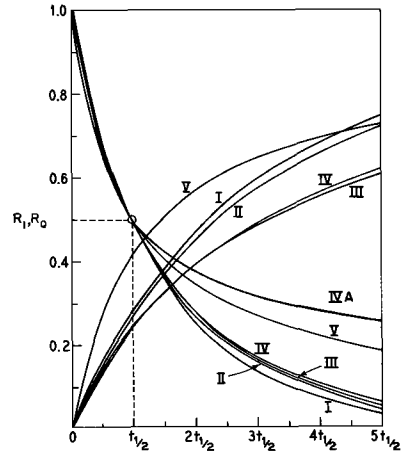

Fig. 4. Variation of normalized current and coulomb parameters as functions of $t_{1/2}$ for the different mechanisms in the text.

retical ones of Fig. 4. The following conclusions can be made about the possibility of distinguishing among mechanisms I through V: (*i*) the R_I and R_Q *vs.* T_F behavior for V is sufficiently different from the others to be distinguished; (*ii*) since I and II are independent of concentration, they may be distinguished from III and IV; (*iii*) it would be difficult to distinguish between III and IV only on the basis of potential step data; however, other information, such as the number of electrons involved in the electrode reaction determined at small times and low concentrations, or the establishment of the existence of intermediate radical ions by ESR can be used.

Double potential step chronoamperometric experiments were performed with several concentrations of DEF in DMF-TBAI solutions containing different amounts of water; typical results are given in Fig. 5 and Table III. The points shown in Fig. 5 fall along a theoretical curve characteristic of mechanism V, values of the rate constant for dimerization of the radical anions, k_2, are given in Table III. Note that the data do not fit the R_I *vs.* t behavior characteristic of the other mechanisms, particularly for times greater than several half-lives. For example, for mechanism IV, at a $T_F = 5\ t_{1/2}$, R_I is less than 0.07, whereas experimentally, R_I values of about 0.19 are found. Within the framework of mechanisms considered, the type involving formation of radical ions and then coupling of these gives the best agreement with theory. Addition of water increases the rate of this coupling reaction, but does not appear to alter the over-all mechanism.

[a] Added water to give $[H_2O]/[DEF] = 6.5$.
[b] [DEF] = 1 mM.
[c] [DEF] = 16.8 mM.

Coulometric experiments.—Table IVA shows the results of controlled potential coulometric reduction of DEF in anhydrous DMF, for various DEF concentrations. In all cases the apparent number of faradays per mole of DEF, n_{app}, is appreciably less than the value of 1.00 expected for electrohydrodimerization. The electrolysis times for exhaustive electroreduction were short (less than 1000 sec) and during electrolysis the working compartment solution turned yellow, while the middle compartment solution did not change color. Cyclic voltammograms taken during the exhaustive electrolysis showed that the first DEF reduction peak (Fig. 2) and the peak at −1.45V diminished with time and had disappeared by the end of the electrolysis. The peak at −1.64V persisted and at conclusion it showed a peak current of 7 μA compared to an initial peak current of 30 μA for the first reduction wave of DEF.

Effect of addition of lithium perchlorate and other substances.—As an aid in the elucidation of the mechanism of the reaction, a few preliminary experiments involving the addition of alkali metal ion salts or hydroquinone were carried out.

Table IV lists coulometric n_{app}-values obtained for reduction of solutions containing different amounts of lithium perchlorate trihydrate in addition to TBAI in DMF, for DEF of about 1 mM. These data are shown graphically in Fig. 6. As the ratio of $LiClO_4 \cdot 3H_2O$ to DEF approaches about 2.0, the n_{app}-value increases to the value of 1.0 expected for the hydrodimerization reaction as the sole reaction. For ratios of about 2.0 and

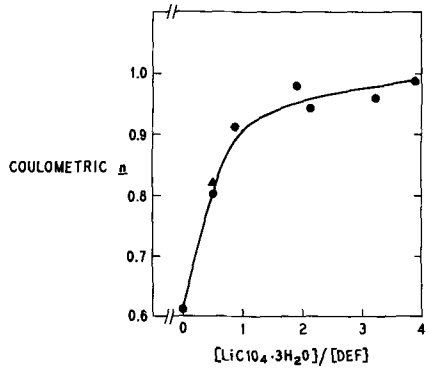

Fig. 6. Coulometric n_{app}-values for the reduction of DEF in solutions containing various ratios of lithium perchlorate trihydrate to DEF. The solutions contained 10 mM DEF. The point marked △ contained additional water to give $[H_2O]/[DEF] = 6.5$.

greater the total electrolysis times were typically 4000 sec as compared to shorter electrolysis times in anhydrous-DMF, or for low $LiClO_4 \cdot 3H_2O$/DEF ratios. The solution after reduction was water white for higher amounts of $LiClO_4 \cdot 3H_2O$, as compared to the yellow solutions characteristic of solutions containing no or low amounts of this salt. In one experiment at a $LiClO_4 \cdot 3H_2O$/DEF ratio of 0.50, water was added to give a water to DEF ratio of 6.5. This corresponds to the amount of water present in solutions with $LiClO_4 \cdot 3H_2O$/DEF ratios greater than 2.0. If the role of the lithium ion was only to catalyze a reaction with water, the coulometric n_{app} should approach 1.0. Experimentally, the n_{app}-value found was not significantly different from those found in solutions containing no additional water.

The cyclic voltammetric behavior of DEF is also altered by the presence of $LiClO_4 \cdot 3H_2O$ (Fig. 7). For $LiClO_4 \cdot 3H_2O$/DEF ratios of 1.9 or higher, no back current is observed for the oxidation of the reduction product of the first wave, for scan reversal at potentials of −1.0 to −1.7V *vs.* Ag-RE. Filming of the electrode occurs when the reduction scan is carried out to potentials beyond about −1.5V; evidence for this filming is the greatly decreased reduction currents on second and subsequent cathodic scans following reversal at these potentials. Normal (nonfilming) behavior for subsequent cathodic scans is observed for scans reversed at potentials up to −1.0V. At lower $LiClO_4 \cdot 3H_2O$/DEF ratios, some reversal current is observed after the first wave.

Controlled potential coulometry results for the addition of sodium iodide, and sodium iodide and water (Table IVC) show that lithium ion has a specific effect. The n_{app}-values with both NaI and H_2O are very close

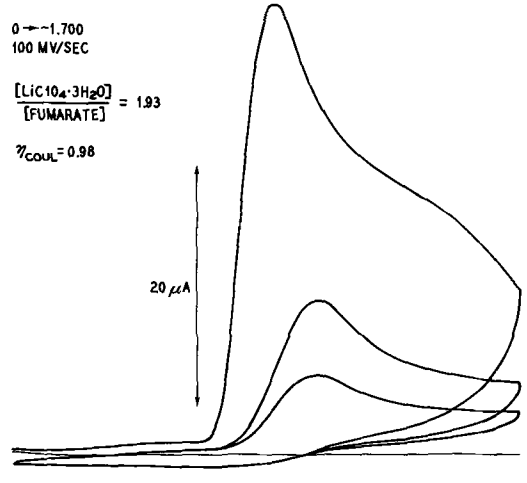

Fig. 7. Cyclic voltammograms for DEF solutions containing lithium perchlorate trihydrate.

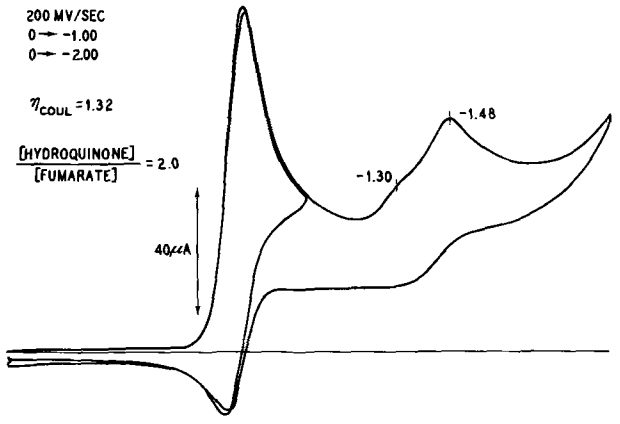

Fig. 8. Cyclic voltammograms for DEF solutions containing hydroquinone.

to those in anhydrous DMF. Cyclic voltammograms with NaI, however, are very similar to those with $LiClO_4 \cdot 3H_2O$ (Fig. 7); they show the distortion following the fumarate reduction, the absence of back current on reversal following the first reduction wave, and the apparent filming of the electrode when cycled beyond −1.5V.

When hydroquinone is added as a proton donor in a coulometric experiment, an n_{app}-value larger than one is obtained. Cyclic voltammetry in the presence of hydroquinone (Fig. 8) as compared to that in its absence (Fig. 2) shows that the peak at −1.64V is absent, the peak at −1.45V persists and may show some reversibility, and a small peak at −1.30V is clearly detectable. The peak anodic current following reversal at −1.0V is smaller for solutions containing hydroquinone at the same DEF concentrations, while the cathodic peak current for the first reduction wave is about 12% larger.

Discussion

In agreement with Baizer and co-workers (3), we find the first step of the reduction to be a one-electron transfer to form the anion radical of DEF ($R \cdot^-$). Evidence for this includes the cyclic voltammetric $i_p/v^{1/2}$ C-value, which is very near that for the reduction of azobenzene in DMF, a known one-electron reduction (12). Moreover, electron spin resonance spectra of $R \cdot^-$ have been observed (13, 14). The double potential step experiments suggest that dimerization of these radical ions is the major path to the hydrodimer for DEF. Rejection of this dimerization step in the previous study (3) was based primarily on the rather large decrease of $i_p/v^{1/2}$ values with increasing v, which the authors felt favored an ECE-type reaction. However, the particular type of ECE-reaction which might occur (a second order ECE, mechanism IV) is different from the more usual first order ECE reaction (mechanism II) in that $n_{app} = 1$ at the limit of both very large and very small values of k_2 for mechanism IV, (whereas n_{app} varies between 1 and 2 as k_1 increases, for mechanism II). Several theoretical papers on linear potential sweep and cyclic voltammetry have recently appeared (15-18) which pertain to these mechanisms. In particular they show that the dimerization mechanism (scheme V) shows a decrease of $i_p/v^{1/2}$ of up to 18% with increasing v (15, 17), while the second-order ECE mechanism (scheme IV) shows a small increase in this function with increasing scan rate. An excellent comparison of these two mechanisms can be seen in Fig. 6 of the paper of Saveant *et al.* (17). Hence, the cyclic voltammetric data in this paper and in ref. (3) are in better agreement with the dimerization mechanism, although more detailed cyclic voltammetric experiments are required to test the extent of agreement quantitatively. The free energy of activation of the coupling process was determined from the measured rate constants at 25° and 0°C to be about

−4.5 kcal/mole of R_2^{2-} formed. This rather low value may also be indicative of a radical anion coupling reaction. Dimerizations of anion radicals are known in the case of vinyl and vinylidene monomers (19) and also for ketyl anion radicals in the formation of pinacols (20). Wiemann (21) also postulated the coupling of radical anions in the hydrodimerization of esters. The relative contribution of mechanisms IV and V to the over-all hydrodimerization path must depend on the structure of the activated olefin.

We have also investigated mechanism IV including the possibility of $R_2\cdot^-$ being electroactive and oxidized at E_2. Computer simulations of this mechanism (IVA) yield an R_I curve which lies significantly above V (Fig. 4). The possibility of $R_2\cdot^-$ having diffusion coefficients significantly different from the other species was also simulated. For example, curve IV is even higher above V when D_{R_2-} is smaller than D_R, so that mechanism IVA does not agree with our experimental data.

In agreement with Baizer and co-workers (3), we find that water increases the rate of disappearance of the anion radicals. This occurs without apparently causing a change in mechanism. Although this could be ascribed to fast protonation of $R\cdot^-$ to RH· followed by dimerization, this seems unlikely, since RH· should also be reduced at the electrode (or by $R\cdot^-$) in an ECE reaction (mechanism II) and no evidence for the involvement of this reaction is observed, even in coulometric experiments. Since the amounts of water which affect the reaction are too small to change the bulk dielectric constant appreciably, the rate increase may be due to specific solvation of the anion radicals by water. Hydroquinone, a better proton donor than water, does show a contribution of the first-order ECE mechanism both in voltammetric and coulometric experiments.

Polymerization, probably by reaction of R with R_2^{2-}, can account for the low n_{app}-values in coulometry. This reaction may not be important in the potential step experiments, since the solution in the vicinity of the electrode is relatively depleted in R. Lithium ion decreases the extent of this polymerization, perhaps by increasing the rate of protonation of R_2^{2-}.

ABSTRACT

Equations were derived for calculating the local and average limiting current densities for an electrode located on the wall of a rectangular channel. The validity of the equation for the average limiting current density was checked experimentally by the deposition of Hg^{2+}. The equation expressing the local limiting current density as a function of the length and width of the electrode was verified by the deposition of Ag from an electrolyte labeled with ^{110m}Ag.

For a short electrode located on the wall of a cylindrical tube, the mass transfer rate can be evaluated using the Léveque equation (1)

$$\mathrm{Nu} = 1.62\ (\mathrm{Re\ Sc}\ D/L)^{1/3} \qquad [1]$$

where the Nusselt, Reynolds, and Schmidt number are given by

$$\mathrm{Nu} = [\bar{i}/(n\mathbf{F})]D/[D_1(c^0_1 - c^s_1)] \qquad [2]$$

$$\mathrm{Re} = \bar{u}\,D/\nu \qquad [3]$$

$$\mathrm{Sc} = \nu/D_1 \qquad [4]$$

Equation [1] is an asymptotic solution of the Graetz problem (2). Sieder and Tate (3) evaluated an empirical equation of the form

$$\mathrm{Nu} = 1.86\ (\mathrm{Re\ Sc}\ D/L)\ (\mu/\mu_s)^{0.14} \qquad [5]$$

where the factor $(\mu/\mu_s)^{0.14}$ represents a correction for the deformation of the velocity profile due to variable liquid viscosity.

Limiting current distribution on the infinite, parallel plane electrodes is well known (8). For that system, current distribution controlled simultaneously by ionic transport, ohmic drop, and electrode polarization was calculated recently by Parrish and Newman (9).

Mass transport to short electrodes located on the opposite sides of the rectangular channel has not yet been analyzed quantitatively and, therefore, is dealt with in the present paper.

Model System

An electrode of a length L and of a width $2d$ is embedded in the wall of a rectangular channel with dimensions $2b$, $2c$. The origin P(O,O,O) of the coordinates x, y, z is located in the center of the leading edge of the electrode. A counterelectrode is located symmetrically on the opposite side of the channel (Fig. 1). The electrolyte flow is laminar and fully developed; constant physical properties of the electrolyte are assumed. The concentration of the electroactive ion "1" on the whole surface of the electrode is equal to c^s_1. In the inlet solution, the concentration of the ion "1" is equal to c^0_1. Only solutions containing an excess of supporting electrolyte or single salt solutions are considered.

Velocity and Concentration Profiles in the Channel

The velocity profile for steady-state laminar flow in a rectangular channel was calculated by Love (4); the resulting equation for the velocity u in the x direction reads (5)

$$u/\bar{u} = \left\{1.5 - 1.5(y/b)^2 - 6(2/\pi)^3 \sum_{n=0}^{\infty} (-1)^n\,(2n+1)^{-3}\,[\cosh(pz/c)]\,(\cosh p)^{-1} \cos(py/c)\right\} \times \left\{1 - 6(b/c)\,(2/\pi)^5 \sum_{n=0}^{\infty} (2n+1)^{-5} \tanh p\right\}^{-1} \qquad [6]$$

where

$$p = (2n+1)\ (\pi c/2b) \qquad [7]$$

and $\bar{u}$ is average linear velocity in the channel. Equation [6] was derived for the coordinate system with the origin Q(O,O,O), see Fig. 1; the equation is valid for systems where the mass flow due to diffusion and migration is relatively small in comparison to the convective flow of electrolyte in the channel. Owing to the high Schmidt number in the electrolyte solutions (Sc $\geqq$ 1000), the diffusion layer is very thin. Hence, for the flow near the wall, the velocity profile can be considered linear inside the diffusion layer. The velocity is then given by the equation

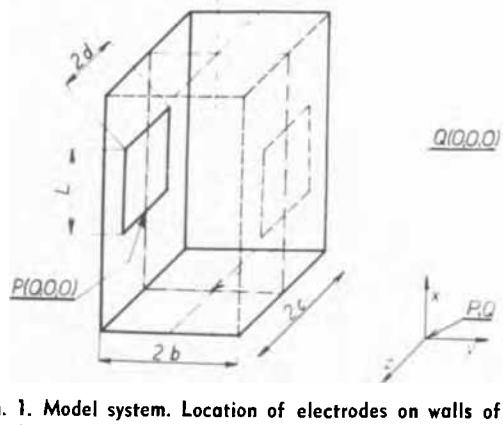

Fig. 1. Model system. Location of electrodes on walls of rectangular channel. $2b$, $2c$: channel dimensions; $2d$: width of electrode; L: length of electrode; P(O,O,O), Q(O,O,O): origins of coordinate systems; x,y,z: coordinates.

$$u/\bar{u} = \left(\frac{du/\bar{u}}{dy/b} \right)^s y/b \qquad [8]$$

where

$$\left(\frac{du/\bar{u}}{dy/b} \right)^s = 3f \qquad [9]$$

Substituting $u/\bar{u}$ from [6] into [9] yields the equation for f which is a function of z/c and b/c

$$f = \left\{ 1 - 2(2/\pi)^2 \sum_{n=0}^{\infty}{}' (2n+1)^{-2} \cosh(pz/c)(\cosh p)^{-1} \right\} \times \left\{ 1 - 6(b/c)\ (2/\pi)^5 \sum_{n=0}^{\infty}{}' (2n+1)^{-5} \tanh p \right\} \qquad [10]$$

It is apparent from Eq. [10] that $f \to 1$ for the flow between infinite parallel plates ($b/c \to 0$). The values of f are given in Table I.

The velocity profile can be substituted into the equations of convective diffusion

$$\vec{v} \cdot \nabla c_1 = D_1 \nabla^2 c_1 \qquad [11]$$

with boundary conditions

(*i*) $c_1 = c^s{}_1$ for $y = 0, 0 < x \leqq L$, and $0 \leqq z \leqq d$

(*ii*) $c_1 = c^o{}_1$ for $x = 0$ and $y > 0$

(*iii*) $c_1 = c^o{}_1$ for $0 < x \leqq L$ and $y \to \infty$

Equation [11] can be rewritten in the form

$$u(\partial c_1/\partial x) = D_1(\partial^2 c_1/\partial x^2 + \partial^2 c_1/\partial y^2 + \partial^2 c_1/\partial z^2) \qquad [12]$$

It can be shown by an analysis of the relative order of second derivatives at the right-hand side (6) that $\partial^2 c_1/\partial y^2 >> \partial^2 c_1/\partial x^2$. It can be also shown that diffusion in the z direction can be neglected in comparison to that in the y direction for electrodes of width d smaller than the width c of the channel (see Appendix for a detailed analysis).

After the substitution for u from [8] and [9], the equation of convective diffusion [12] is

$$\bar{u}3f(y/b)(\partial c_1/\partial x) = D_1(\partial^2 c_1/\partial y^2) \qquad [13]$$

Equation [13] can be solved by a method used in similar asymptotic cases. Introducing dimensionless variables η and C defined by

$$\eta = y[\bar{u}f/(3xbD_1)]^{1/3} \qquad [14]$$

and

$$C = (c_1 - c^s{}_1)/(c^o{}_1 - c^s{}_1) \qquad [15]$$

into Eq. [13], we obtain the differential equation

$$-3\eta^2(dC/d\eta) = d^2C/d\eta^2 \qquad [16]$$

with boundary conditions

(*i*) $C = 0$ for $\eta = 0$

(*ii*) $C = 1$ for $\eta \to \infty$

The solution of Eq. [16] is

$$C = \left[\int_0^{\eta} \exp(-\eta^3)\, d\eta \right] \Big/ \left[\int_0^{\infty} \exp(-\eta^3)\, d\eta \right] \qquad [17]$$

where

$$(dC/d\eta)_{\eta=0} = \left[\int_0^{\infty} \exp(-\eta^3)\, d\eta \right]^{-1} = 1/\Gamma(4/3) = 1/0.893 \qquad [18]$$

For calculating the local current densities at the electrode, we obtain

$$i^s/(n\mathbf{F}) = D_1(\partial c_1/\partial y)^s = D_1(c^o{}_1 - c^s{}_1)\ 0.893^{-1}\ [\bar{u}f/(3xbD_1)]^{1/3} \qquad [19]$$

Equation [19] gives the values of local current densities as a function of the x and z coordinates. The values of f needed in the calculation of i^s are given in Table I for several values of z/c and b/c.

The integration of Eq. [19] over the whole surface of the electrode yields

$$\mathrm{Nu} = 1.85\,\phi\,(\mathrm{Re\ Sc}\ D/L)^{1/3} \qquad [20]$$

where

$$D = 4bc/(b + c) \qquad [21]$$

and

$$\phi = (1 + b/c)^{-1/3}\,(c/d) \int_0^{d/c} f^{1/3}\, d(z/c) \qquad [22]$$

The values of ϕ can be found in Table II. Equation [20] represents an analogy to the Léveque equation for rectangular channels.

Experimental

Equation [20] was tested by measuring the limiting current density for the deposition of Hg^{2+} on an electrode (d = 1 cm, L = 8 cm) situated on the wall of a rectangular channel (b = c = 2.15 cm). The experiments were performed at 25°C and a Hg^{2+} concentration of 1.87 x 10^{-7} mole/cm^3, using 1*N* KOH for supporting electrolyte. The Reynolds number varied from 82 to 383. The diffusion coefficient of Hg^{2+} was determined by the Cottrel method (D_1 = 7.6 x 10^{-6} cm^2/sec) and the value of the kinematic viscosity of the electrolyte (ν = 9.66 x 10^{-3} cm^2/sec) was taken from earlier published data (7); hence, the Schmidt number was 1271.

The results of the experiments are collected in Table III. The experimental values of the Nusselt number fall into the range (−2%, +6%) as compared with the theoretical values.

The dependence of i^s on x and z was verified by the deposition of Ag from an electrolyte labeled with ^{110m}Ag. The dimensions of the channel were b = 0.5 cm and c = 1 cm; the electrode covered the entire width of the channel wall (d = 1 cm and L = 10 cm). The temperature was kept at 25°C.

Silver was activated in the thermal neutron flux of a nuclear reactor. The activated ^{110m}Ag was used for the preparation of both the silver cyanide electroplating bath and the solution used in actual mea-

surements (~0.001m $AgClO_4$, 1m $NaClO_4$, 0.001m $HClO_4$). The silver cyanide bath served for the preparation of standards, *i.e.*, silver plates (1 mm thick) covered with a gradually changing deposit of active silver. For each standard, the weights of active Ag per cm² were known. A thin silver layer (0.2 mm) deposited on a plate 1 mm thick was also prepared using the silver cyanide bath. This silver plate served as an anode in the cell.

During the measurement, the cell voltage was kept at a constant value (*ca.* 300 mV) corresponding to the limiting current density. After finishing the electrolysis, the electrode was dried and its surface was covered with a 1 μm thick layer of polymethylmethacrylate (by mean of a chloroform solution). The electrode surface was then pressed against the AF-3 autoradiography film (ORWO Company, Wolfen, G.D.R.). The optical density of the developed film emulsion defined as log [(incident light intensity-background intensity)/(transmissed light intensity-background intensity)] was evaluated photometrically by means of a microdensitometer. The relationship between optical density and weights of ^{110m}Ag per cm² was obtained making use of the aforementioned standards; this relationship was linear.

By this method, limiting local current densities of silver deposition were obtained for $z/c = 0$ and $0 < x/L < 1$ (Fig. 2) and for $0 < z/c < 1$ and $x/L = 0.35$ (Fig. 3), 0.65, and 0.95.

For $z/c = \text{const}$, *i.e.*, for $f = \text{const}$, the relationship between i^s and x/L is of the form

$$i^s = \text{const}\ (x/L)^{-1/3} \qquad [19a]$$

For $z/c = 0$, this equation was fitted within the interval of ±6% (see Fig. 2).

For $x/L = \text{const}$, the relationship

$$i^s/i^s_{z=0} = (f/f_{z=0})^{1/3} \qquad [19b]$$

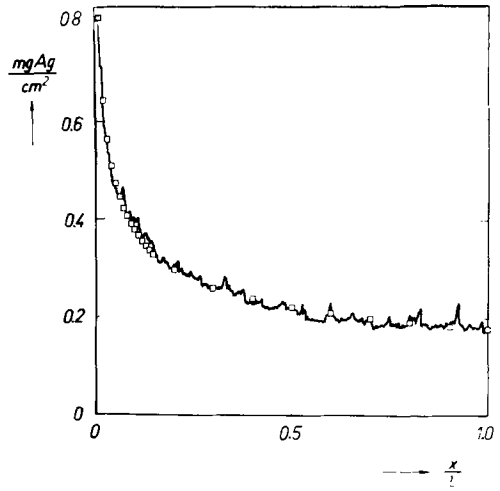

Fig. 2. Limiting local current densities (represented by mg Ag/cm²) as a function of the length of electrode for $z = 0$, $b = 0.5$ cm, $c = 1$ cm, $L = 10$ cm, $d/c = 1$, Re = 200. (Deposition of Ag^+, $c^o_1 = 10^{-5}$ mole Ag^+/cm^3, supporting electrolyte 1*N* KNO_3). □, Theoretical (Eq. [19-a]); ———, experimental.

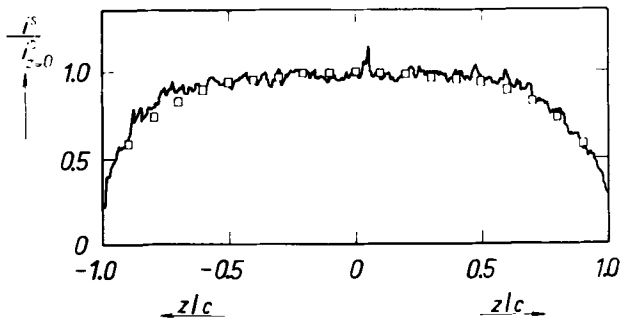

Fig. 3. Relative local current densities as a functon of width of electrode for $x/L = 0.35$, $b = 0.5$ cm, $c = 1$ cm, $L = 10$ cm, $d/c = 1$, Re = 200. (Deposition of Ag^+, $c^o_1 = 10^{-5}$ mole Ag^+/cm^3, supporting electrolyte 1*N* KNO_3.) □, Theoretical (Eq. [19-b]); ———, experimental.

was fitted within the interval of ±10% for x/L equal to 0.35, 0.65, and 0.95, respectively (see Fig. 3). The experimental lines on Fig. 2 and Fig. 3 were obtained using a microdensitometer.

Conclusions

By the asymptotic solution of the convective diffusion equation, the explicit expressions for calculating the average and local limiting current densities on the electrode embedded in the wall of a rectangular channel were derived. The expressions were checked experimentally. The agreement between experimental and theoretical average limiting current densities (Eq. [20]) was good for the system with an electrode not covering the entire channel width $d < c$. Similarly, the experimental verification of Eq. [19] for the local limiting current densities yielded good results for the region of z/c, where diffusion in the z direction can be neglected (see Appendix). For $z/c \to 1$, the difference between the predicted and experimental values increased. Therefore, Eq. [20] would give approximate values of Nusselt number for the systems with $d = c$.

APPENDIX

Concerning the validity of Eq. [13], the question is for what condition it is possible to disregard the term $\partial^2 c_1/\partial z^2$ in comparison to $\partial^2 c_1/\partial y^2$.

Concentration gradients in the z direction can be caused by the change of f values along the z axis. It follows from Table I that for the given b/c ratio, the region of z/c exists, where f decreases very slowly; therefore, in this region, mass transport in the z direction can be neglected in comparison to mass transport in the y direction. In order to investigate this point further, we shall calculate mass flows in y and z direction (averaged along the length of electrode) for the given z/c, using the solution of Eq. [13]

$$\bar{j}_y = (1/L)\int_0^L j_y\,dx = -(3/2)D_1(c^o_1 - c^s_1)\,0.893^{-1}\,[\bar{u}f/(3bLD_1)]^{1/3} \qquad [A\text{-}1]$$

$$\bar{j}_z = (L\bar{\delta}_N)^{-1}\int_0^L\left(\int_0^\infty j_z\,dy\right)dx = -(3/16)\{(1.5046/0.893^2)\,D_1\,(c^o_1 - c^s_1)\,[\partial f/\partial\,(z/c)]/(fc) \qquad [A\text{-}2]$$

In these equations, 1.5046 is the gamma function of 5/3, j_z is the local mass flow in the z direction, and $\bar{\delta}_N$ is the thickness of diffusion layer averaged along the length of electrode

$$j_z = -D_1\,(\partial c_1/\partial z) = -(1/3)\,D_1\,(c^o_1 - c^s_1)\,\eta\,(dC/d\eta)\,[\partial f/\partial\,(z/c)]/(fc) \qquad [A\text{-}3]$$

$$\bar{\delta}_N = (2/3)\,0.893\,[3bLD_1/(\bar{u}f)]^{1/3} \qquad [A\text{-}4]$$

The ratio $\bar{j}_z/\bar{j}_y$ for the given z/c is then

$$\bar{j}_z/\bar{j}_y = 0.3037\,[bLD/(c^3 Re\ Sc)]^{1/3}\,[\partial f/\partial(z/c)]/f^{4/3} \qquad [A\text{-}5]$$

Values of $[\partial f/\partial(z/c)]/f^{4/3}$ as a function of b/c and z/c are summarized in Table A-I.

Equations [A-1] to [A-5] were derived from the solution of the equation of convective diffusion [13], where the term $\partial^2 c_1/\partial z^2$ was neglected. Therefore, the values of $\bar{j}_z/\bar{j}_y$ calculated from Eq. [A-5] are only approximate; the purpose of this equation is to find the maximum value of z/c for which the ratio $\bar{j}_z/\bar{j}_y$ is sufficiently low.

As an example, the values of $\bar{j}_z/\bar{j}_y$ according to Eq. [A-5] were calculated for the geometrical and flow parameters corresponding to the deposition of Ag from the labeled electrolyte. It can be seen from Table A-II that in this case, the value of $\bar{j}_z$ can be neglected in comparison to $\bar{j}_y$ in the region $0 < z/c < 0.85$. Therefore, in this region, Eq. [20] for the Nusselt number is valid with sufficient accuracy. For the electrodes covering the entire channel width, Eq. [20] will give approximate results.

Manuscript submitted June 22, 1970; revised manuscript received Jan. 7, 1971. This was Paper 259 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

LIST OF SYMBOLS

- $2b$ dimension of channel (distance between electrodes), cm
- $2c$ dimension of channel (parallel to width of electrode), cm
- c_1, c^o_1, c^s_1, concentration of electroactive ion in boundary layer, in inlet electrolyte, and at electrode surface, mole/cm^3
- C dimensionless concentration, see Eq. [15]
- $2d$ width of electrode, cm
- D diameter of cylindrical tube or hydraulic equivalent diameter of rectangular channel, see Eq. [21], cm
- D_1 diffusion coefficient of electroactive ion or of binary electrolyte, cm^2/sec
- f see Eq. [10]
- $\mathbf{F}$ Faraday's constant, 96,496 coulomb/equiv
- $i^s, \bar{i}$ local and average current density at electrode surface, A/cm^2
- $j_y, \bar{j}_y, j_z, \bar{j}_z$ local and average mass flow in y and z direction, respectively, see Eq. [A-1] to [A-3,], mole/cm^2 sec
- L length of electrode, cm
- Nu Nusselt number, see Eq. [2]
- n number of electrons produced per one reactant ion or molecule
- P(O,O,O), Q(O,O,O) origins of the coordinates, see Fig. 1
- Re Reynolds number, see Eq. [3]
- Sc Schmidt number, see Eq. [4]
- $u, \bar{u}$ local and average electrolyte velocity in x direction, cm/sec
- $\vec{v}$ electrolyte velocity, cm/sec
- x,y,z length in coordinate direction, cm
- $\Gamma(4/3) = 0.8930$, $\Gamma(5/3) = 1.5046$, gamma function
- $\bar{\delta}_N$ see Eq. [A-4]
- η dimensionless coordinate, see Eq. [14]
- ϕ see Eq. [22]
- μ dynamic viscosity, poise
- ν kinematic viscosity, cm^2/sec

Intersolvent Potentials and the Reversible Nitrate and Sulfate Electrodes

L. G. Boxall*,[1] and K. E. Johnson*

Department of Chemistry, University of Saskatchewan Regina Campus, Regina, Saskatchewan, Canada

ABSTRACT

The standard potentials for the cells Ag/AgCl in (Li,K)Cl//$AgNO_3$ in (Li,K)NO_3/Ag at 400°C and Ag/AgCl in (Li,K)Cl//Ag_2SO_4 in (Li,Na,K)$_2SO_4$/Ag at 550°C are 0.687 and 0.718V, respectively, on the mole fraction scale. The cells Ag/$AgNO_3$ in (Na,K)NO_3//(Na,K)NO_3/NO_2, O_2, Pt, or Au and Ag/Ag_2SO_4 in (Li,Na,K)$_2SO_4$//(Li,Na,K)$_2SO_4$/SO_3, O_2, Pt show reversible behavior and good Nernstian response on variation of the partial pressures of the gases by means of a versatile gas-flow system. The standard free energy of formation of $AgNO_3$ was found to agree with published data for the range 250°-400°C. For the reaction $2Ag + SO_3 + \frac{1}{2}O_2 = Ag_2SO_4$, $\Delta G°$ was found to be -26.6 ± 0.1 kcal mole^{-1}.

One stage in the development of a unified emf series for several molten salt solvents is the measurement of the emf's of cells of the type M/MX in AX//MY in BY/M. This has already been reported with M = Ag for the cases where (*a*) X = NO_2, Y = NO_3, and A = B = Na (1) and where (*b*) X = CO_3, Y = SO_4, A = Li, Na, and B = Li, Na, K (2). In this paper we present further data for such cells with (c) X = Cl, Y = NO_3, A = B = Li, K and (*d*) X = Cl, Y = SO_4, A = Li, K, and B = Li, Na, K again using Ag as the metal of the electrodes.

In chloride melts, the chlorine electrode is of prime thermodynamic significance and its potential and stability have been established for LiCl-KCl (3). The NO_2, O_2/NO_3^- electrode has received attention for molten silver nitrate (4, 5) but not for alkali nitrate melts. We include therefore some studies of the NO_2, O_2/(Na,K) NO_3 electrode and the hitherto undeveloped SO_3, O_2/(Li,Na,K)$_2SO_4$ electrode. Of the other relevant gaseous electrodes, the CO_2, O_2/(Li,Na)$_2CO_3$ electrode has been shown to function reversibly (2) and, in the course of this study, the $NO_2/NaNO_2$ electrode has been shown not to operate reversibly.

Experimental

The preparation of the solvents has been described elsewhere (1,6,7) except that high-purity sodium pyrosulfate for use in clearing the sulfate melt was prepared according to a method described by Hotz (8) involving the controlled decomposition of copper sulfate and the absorption of the sulfur trioxide evolved by sodium sulfate. Analytical procedures for anions were as described by Ayres (9) whereas silver was determined by atomic absorption spectrophotometry (10) using a Techtron AA100 instrument. The apparatus for silver concentration cell measurements was similar to that described previously except that a double fritted compartment was used to separate the nitrate melt from the chloride.

For the gas electrodes the design and mode of operation were quite critical so will be described in some detail.

Gas electrode design.—The final design consisted of a piece of 8 mm glass tubing with a roll of platinum or gold gauze sealed in one end.

The top ¼ in. of a piece of ¾ in. x 3 in., 50 mesh platinum wire gauze (Johnson, Matthey and Mallory, Ltd.) was folded over to double the thickness. Platinum wire, 26 gauge, was then coiled in a zig-zag fashion across the upper half of the gauze and the whole rolled lengthwise. The upper portion of the gauze containing the platinum lead wire was sealed into the glass leaving approximately ¼ in. of gauze exposed below. The heavier platinum wire served to create small channels for the passage of gas.

The vertical adjustment of the electrode was made by a micrometer electrode holder (1.5 mm traverse per per dial revolution). It was placed in a compartment inserted through the central part of the 3-necked flask used for the cell. It was essential to start the flow of gas (initially nitrogen) before inserting the electrode in the melt to a point just above that needed to produce bubbling. The top of the gas electrode and the delivery tube from the gas control system were wrapped with heating tape to obtain better temperature equilibration. The gases could be readily flushed out through the tap at the top to a dry ice trap and water aspirator.

Gas control system.—Tank nitrogen was purified by passage over copper mesh at 325°C and through molecular sieve (Type 5A). Oxygen was dried by passage through molecular sieve. Liquid nitrogen tetroxide (Matheson of Canada Ltd., 99.5%) was used as supplied as was liquid sulfur trioxide (E. H. Sargent and Company).

The flows of nitrogen, oxygen, and nitrogen dioxide were controlled using stainless steel microflow valves (Matheson of Canada Ltd., Model 151) and measured using pressure differential flowmeters with n-butyl phthalate in the manometers. Flowmeters were connected in series with an open-ended n-butyl phthalate manometer to measure the excess pressure above atmospheric. The nitrogen and oxygen flowmeters were calibrated with a bubble meter and the nitrogen dioxide flowmeter, which was thermostated at 65°C, was calibrated by collecting the gas in half saturated KOH solution and back-titrating the excess base with hydrochloric acid. At the temperature of the emf measurements, the N_2O_4 is completely dissociated into NO_2 so that the calculation of partial pressures is a formality.

Since none of the normal manometric fluids is inert to sulfur trioxide, a mixture of nitrogen and oxygen of known composition was passed at a known rate from the flowmeters through liquid SO_3 in a boiling flask maintained at about 10°C hotter than the subsequent U-tube condensing column. The temperature of the latter was varied to give the desired effluent rate of SO_3, any excess SO_3 condensing in a small bulb at the bottom of the U-tube. All the tubing (1 mm ID) through which SO_3 passed was kept above 50°C by the use of heating tape or infrared lamps. The partial pressure of SO_3 was obtained from the expression

$$\log (760\, p_{SO_3}) = 10.022 \frac{-2269.4}{T}$$

* Electrochemical Society Active Member through the Faraday Society.
[1] Present address: Department of Chemistry, Colorado State University, Fort Collins, Colorado.
Key words: chloride, sulfate, nitrate, gaseous, electrode, melt.

where T°K is the temperature of the condensing column (11). The SO_3 content of the effluent gases was checked by condensing it and weighing: for four trials the calculated and experimental weights differed by 2.0%, −1.5%, −2.2%, and 0.7%.

In the cells involving gas electrodes a correction was required for the silver-platinum thermopotential. Therefore in a separate experiment the thermoelectric power of a silver-platinum thermocouple was measured using a calibrated chromel-alumel thermocouple and a sodium-potassium nitrate melt in a thermostat. The emf fitted the expression

$$E(\text{mV,Ag+}) = 0.0004 + 5.11 \times 10^{-3}t + 2.09 \times 10^{-5}t^2 - 9.74 \times 10^{-9}t^3 \quad (t \text{ in °C})$$

with values such as 0.14 mV at 25°C, 2.71 mV at 270°, and 7.51 mV at 550°C, the reference junction being 0°C. In the gas electrode studies the reference temperature was 25° ± 3°C. Thus +2.57 mV was added to the measured potential of the cell

$$\text{Ag/Ag(I) in (Na,K)NO}_3\text{/NO}_2\text{, O}_2\text{, Pt}$$

at 270°C.

Results

Chloride//nitrate potential.—The Ag(I)/Ag electrode was studied by concentration cell measurements in (Li,K)Cl and (Li,K)NO_3 (Li:K = ratio of 0.59:0.41 in each case) at 400°C and ideal Nernst behavior was observed for the concentration range 0.001 to 0.1 molal (M). The corrosion problem, encountered in activity coefficient measurements (12) did not arise here since the starting silver ion concentrations were about 10 times greater and the contact time between silver and dilute silver nitrate solutions much less.

The emf of the cell

$$\text{Ag/Ag(I) in (Li,K)Cl//Ag(I) (0.03}M\text{) in (Li,K)NO}_3\text{/Ag}$$

was determined at several temperatures as a function of silver chloride concentration. Figure 1 shows the results at 400° ± 2°C and these are summarized in column (c) of Table I. In the calculation of $E°_N$ the activity coefficients used were $\gamma_{N=0} = 2.04$ (13) for silver chloride and $\gamma_{N=0} = 1.91$ (12) for silver nitrate. The densities were taken from Janz (14) or measured separately (15).

The temperature dependence of the cell emf over the range 365°-450°C (the upper limit was dictated by nitrate decomposition) had the value

$$\frac{dE°}{dT} = (4.7 \pm 1.2) \times 10^{-4} \text{ volt deg}^{-1}$$

M, M, and N refer to molal, molar, and mole fraction scales.
* The previous value referred to Ag(I) not Ag_2SO_4 and Ag_2CO_3.

Chloride//sulfate potential.—The Ag(I)/Ag electrode was studied by concentration cell measurements in the individual solvents (0.59 LiCl, 0.41 KCl, and 0.78 Li_2SO_4, 0.085 Na_2SO_4, 0.135 K_2SO_4) at 550°C and ideal Nernst behavior was observed for the concentration range 0.001-0.1M. The use of the ternary rather than a binary sulfate obviated the expense of silica apparatus and permitted direct correlation with the carbonate studies at 550°C.

The emf of the cell

$$\text{Ag/Ag(I) in (Li,K)Cl//Ag(I) (0.015}M\text{) in (Li,Na,K)}_2\text{SO}_4\text{/Ag}$$

at 550° ± 2°C is shown as a function of silver chloride concentration in Fig. 2 and the results are summarized in Table I. In the calculation of $E°_N$, $\gamma_{N=0}$ = 1.76 was used for silver chloride (16) but $\gamma_{N=0}$ for silver sulfate was assumed to be unity for lack of data {$\gamma_{N=0} = 0.85$ for Ag_2SO_4 in (0.8 Li_2SO_4, 0.2 K_2SO_4) (17)}. Again, densities were taken from ref. (14) or measured separately (15).

Nitrogen dioxide/nitrite electrode.—The cell Ag/Ag(I) in $NaNO_2$//$NaNO_2$/NO_2, Pt was studied at 270° ± 2°C. It was found that the cell emf was affected by the flow rate of gas and the time that the platinum electrode had been in the melt. No resemblance to Nernstian behavior was observed.

Nitrogen dioxide, oxygen/nitrate electrode.—The cell Ag/Ag(I) in (Na,K)NO_3//(Na,K)NO_3/NO_2, O_2, Pt was studied over the range 250°-325°C. The substitution of gold for platinum did not change the results. It was found that gas flow rates above 10^{-4} mole minute^{-1}

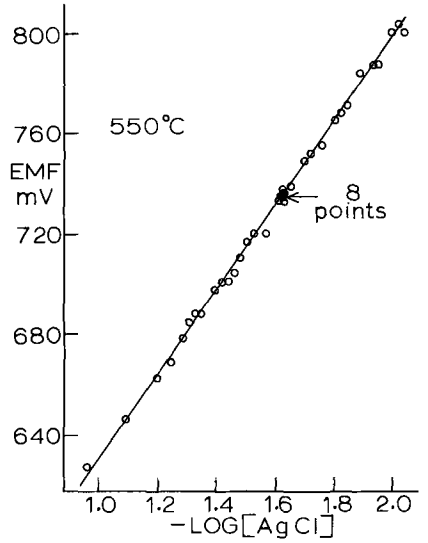

Fig. 2. Nernst plot at 550°C for the cell Ag/Ag(I) in (Li,K)Cl//Ag(I) (0.015M) in (Li,Na,K)$_2$ SO_4/Ag.

Table II. Potentials of the Pt, NO_2, O_2/NO_3^-

Number of cells	Total gas flow rate, moles minute^{-1} x 10^4	Slope of Nernst plot, V	E°, V
1	3.0	−0.0903	0.667 ± 10
1	2.0	−0.0995	0.586 ± 5
2	1.5	−0.1089	0.588 ± 3
3	1.0	−0.1102	0.552 ± 2

affected the slope of the Nernst plot and the derived standard potential, as illustrated in Table II. In subsequent runs the flow rate was kept below 10^{-4} moles minute^{-1}.

The cell potential was measured as a function of the Ag(I) concentration and the partial pressures of nitrogen dioxide and oxygen at several temperatures. The Nernst equation, corrected to a common Ag(I) molality of 0.030 takes the form

$$E = E^\circ_M - \frac{RT}{F} \ln \frac{\gamma_M\, 0.030}{p_{NO_2}\, p_{O_2}^{1/2}}$$

The activity coefficients of silver nitrate were taken from ref. (12). The data for 270°C are presented in Table III and Fig. 3 and those for five temperatures are summarized in Table IV. dE°_N/dT had the value of -0.00203 volt deg^{-1}.

Sulfur trioxide, oxygen/sulfate electrode.—The cell Ag/Ag(I) in (Li, Na, K)$_2SO_4$//(Li, Na, K)$_2SO_4/SO_3$, O_2, Pt had its emf at 550° ± 2°C measured as a function of sulfur trioxide and oxygen partial pressures. Flow rates up to 3 x 10^{-4} moles minute^{-1} gave the same potentials. The gaseous electrode required 15-30 min to stabilize after each change in gas composition and for a fixed composition remained constant to ±3 mV for 5 hr. After shorting for 5 sec, the electrode potential was reestablished within 2 min. The results are depicted in Fig. 4 and summarized in Table V.

The chloride//nitrate cell reaction is the transfer of silver ions from a nitrate to a chloride environment. From the standard chemical potential, E°_N of 0.668 ± 0.002V at 400° ± 2°C we calculate $\Delta G^\circ = -15.4 \pm 0.05$ kcal mole^{-1}. Likewise, the chloride//sulfate cell reaction is the transfer of silver ions from a chloride to a sulfate environment with ΔG°_{873} of -17.5 ± 0.05 kcal mole^{-1}.

In Ref. (1) it was suggested that the reaction for the nitrite//nitrate cell was $NaNO_2 + AgNO_2 = AgNO_2 + NaNO_3$ with E°_M corresponding to -5.30 ± 0.07 kcal mole^{-1} a 309°C. However, we should consider the standard states as the pure silver salts. In this case the meaningful quantity is E°_N (-5.05 ± 0.07 kcal mole^{-1}) but there are *no* alkali metal salts left in the reaction since they are accounted for by the activity coefficients

Table V. Standard potentials for the cell Ag/Ag(I) in (Li, Na, K)$_2SO_4$//(Li, Na, K)$_2SO_4$/SO_3, O_2 Pt

Temperature	550° ± 2°C	Partial pressure ranges:
$E°_M$ (measured), V	0.767 ± 0.002	SO_3: 0.390 to 0.842 atm
E_{Ag-Pt}, V	0.0074	O_2: 0.036 to 0.577 atm
$E°_M$ (chemical), V	0.774 ± 0.002	
$E°_M$ (chemical), V	0.827 ± 0.002	
$E°_N$ (chemical), V	0.575 ± 0.002	

(12). The $E°_N$ values are then related to the free energies of silver ions in the respective salts.

In Table IV we see very good agreement between $E°_N$ for the silver nitrate formation cell and the $E°$ value calculated for the reaction

$$Ag + NO_2 + \tfrac{1}{2} O_2 = AgNO_3$$

from published thermodynamic data (18-21). The dissociation of NO_2 into NO and O_2, although thermodynamically favored, is confirmed to be too slow (22, 23) to be of consequence in the experiments which involved short contact times between NO_2 and the melt. It should be pointed out that the results of Ketelaar and Dammers-de Klerk (4) for pure silver nitrate were also in agreement with the thermodynamic data; however the experimental arrangement used in this study was more versatile, permitting the complete testing of the Nernst equation through independent variation of the partial pressure of each gas.

Using the solid at 600°C, Hauffe and Hoeffgen (24) reported $E° = 0.555$V for the formation potential of silver sulfate

$$2Ag + SO_3 + \tfrac{1}{2} O_2 = Ag_2SO_4$$

which compares well with the value of 0.575V at 550°C (Table V) which in turn leads to a value for $\Delta G°_{823}$ of -26.6 ± 0.1 kcal mole^{-1}. We note also that $E°_M$ at 0.774V lies in the region predicted by voltammetric studies of (Li,K)$_2SO_4$ (25) and (Li,Na,K)$_2SO_4$ (26). The failure of the NO_2/NO_2^- electrode is in keeping with the findings of Topol *et al.* (27) and McCormick and Swofford (28) that the two components, as well as undergoing reversible electroreduction and electrooxidation, respectively, also react with each other thus

$$NO_2 + NO_2^- = NO_3^- + NO$$

Linear Sweep Voltammetry of Ni(II), Co(II), Cd(II), and Pb(II) at Glassy Carbon Electrodes in Molten Lithium Chloride-Potassium Chloride Eutectic

Wishvender K. Behl*

Power Sources Division, Electronic Components Laboratory, United States Army Electronics Command, Fort Monmouth, New Jersey 07703

ABSTRACT

The reduction of Ni(II), Co(II), Cd(II), and Pb(II) was studied at glassy carbon electrodes in molten lithium chloride-potassium chloride eutectic at 450°C using the technique of linear sweep voltammetry. Peak-shaped voltammograms were obtained at scan rates of 10 mV to 1 V/sec. Linear dependence of peak currents on metal ion concentration and the square root of voltage scan rate was obtained for all the cations studied. The diffusion coefficients of Ni(II), Co(II), Cd(II), and Pb(II) were calculated from the experimental data and found to be 1.26, 1.02, 0.98, and 1.29 x 10^{-5} cm^2/sec, respectively.

The polarographic method has been extensively applied to a study of the solute species dissolved in molten salts. These studies have been carried out both at dropping metal electrodes (mercury, bismuth, lead) and solid (platinum, tungsten, graphite) microelectrodes. The subject has been thoroughly covered in a number of reviews (1-4). At elevated temperatures, the polarographic method suffers from the use of large polarization times so that it is extremely difficult to completely eliminate the convective transport of the electroactive species to the electrode surface. Further, the metal ions which result in the deposition of a solid metal at the solid microelectrodes show an "increasing limiting current phenomenon" (1, 2, 5, 6) due to an increase in the electrode area. These difficulties can be eliminated by using the techniques of chronopotentiometry or linear sweep voltammetry (oscillographic polarography) where polarization times of only a few seconds or less are employed. The chronopotentiometric method has been widely used (1, 2) in molten salts in the past whereas the technique of linear sweep voltammetry has attracted attention only recently.

Mamantov *et al.* employed this technique to study the voltammetry of several cations in molten fluorides (7-12) at platinum wire, pyrolytic graphite, or glassy carbon electrodes and in molten $NaNO_3$-KNO_3 eutectic (13) at platinum wire electrodes. Francini *et al.* used the dropping mercury electrode to study the voltammetric behavior of several cations (14, 15), halide ions (16) and oxygen and its ions (17) in low melting nitrates. The reduction of Ag(I) at platinum wire electrodes was studied by Hills, Oxley, and Turner (18) in molten LiCl-KCl eutectic and by Kawamura (19) in mixtures of molten $NaNO_3$-KNO_3. Behl and Gaur (20) studied the reduction of Ag(I) and Pb(II) at platinum wire electrodes in molten $NaNO_3$-$Ba(NO_3)_2$ eutectic. Naryshkin and co-workers studied the reduction of several cations at platinum microelectrodes and determined their diffusion coefficients in molten NaCl-KCl (21) and LiCl-KCl (22) eutectic. They also used this method to study (23) the temperature dependence of diffusion coefficients in the latter solvent.

It was the purpose of this study to examine the applicability of the theory (24, 25) of linear sweep voltammetry to the reduction of Ni(II), Co(II), Cd(II), and Pb(II) at glassy carbon electrodes in molten lithium chloride-potassium chloride eutectic at 450°C. Since cadmium and lead metals are both liquid at the working temperature and are known (26-30) to be soluble in their halide salts, it was also of interest to see if the reduction of Cd(II) and Pb(II) was similar to the reduction of Ni(II) and Co(II) which results in the deposition of solid metals at the electrode surface.

Experimental Procedure

Reagent grade chemicals (Fischer Scientific Company) were used. The lithium chloride-potassium chloride (59:41 mole per cent [m/o]) eutectic solvent was purified by usual treatment with hydrogen chloride gas. Briefly stated it was heated at 130°C in a flowing atmosphere of hydrogen chloride gas for about 24 hr. The temperature was then slowly raised to 100 degrees above the melting point (352°C), and the bubbling of hydrogen chloride continued for another 4-6 hr. This was followed by bubbling the molten eutectic with chlorine gas for 2-3 hr. The treatment with chlorine helped to remove the black organic matter usually found in the melt after treatment with hydrogen chloride gas. The temperature was then lowered and the anhydrous eutectic so obtained was stored in an inert atmosphere of argon gas until used. Anhydrous cadmium chloride, nickel chloride, and cobalt chloride were obtained from the corresponding hydrates by heating in a flowing atmosphere of hydrogen chloride gas. Lead chloride was dried by heating under vacuum at 130°C.

The cell assembly is shown in Fig. 1. The cell consisted of a 64 mm outer diam Pyrex tubing (16 in. long) closed at the bottom and having a ground glass flange at the top. The eutectic solvent was contained in an inner Pyrex cup (57 mm outer diam and 4 in. long) and compartmented by use of Pyrex tubes (10 mm diam) with fritted-glass bottoms. The top of the cell was sealed, using an Apiezon wax, to another Pyrex flange joint assembly consisting of four standard tapered joints (19/38 $). These were used to insert the different electrodes, thermocouples, and a gas bubbling tube. The use of Teflon Swagelok fittings to introduce the electrodes into the cell helped to isolate the melt from the atmosphere. The cell also had a side arm tube with a ball joint which could either be connected to a vacuum system or to the gas outlet.

The cell assembly was heated at 450°C under vacuum for 3-4 hr before use and allowed to cool slowly to the room temperature. The top of the cell was then

* Electrochemical Society Active Member.

Key words: linear sweep voltammetry, lithium chloride-potassium chloride eutectic, nickel (II), cobalt (II), cadmium (II), lead (II), glassy carbon electrode, diffusion coefficients.

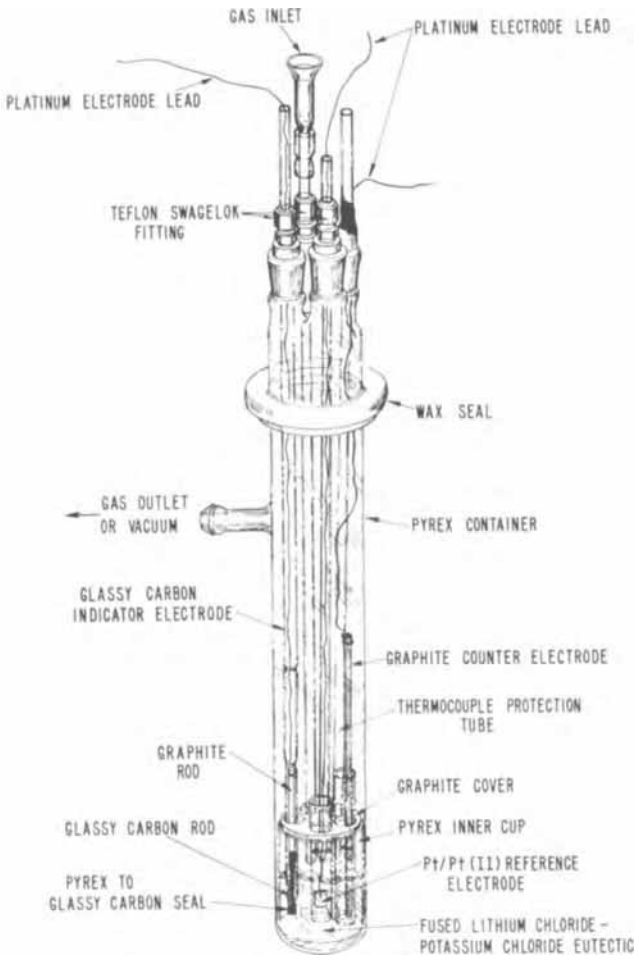

Fig. 1. Cell assembly

removed and a 100-125g solid sample of the purified eutectic transferred to the inner Pyrex container. The cell was then quickly reassembled and evacuated. The temperature was slowly raised to 450°C over a period of 10-12 hr. The eutectic melted and seeped into the Pyrex fritted disk compartments. The vacuum was then released by argon gas and a flowing atmosphere of argon maintained throughout the duration of the experiment.

The metal ion concentration in the eutectic was obtained by adding, with a small platinum scoop, weighed amounts of anhydrous salt into the main body of the eutectic (Fig. 1). Pt(II) concentration in the reference fritted disk compartment was generated *in situ* by the anodic dissolution of platinum foil at small current densities using a graphite rod in another fritted disk compartment as the counterelectrode. The exact metal ion concentration was determined at the end of each experiment by weighing the eutectic in each compartment and expressed in moles/liter. The density value (31) of 1.648 g/ml at 450°C was used for this purpose.

A three-electrode system was used for all measurements. The Pt/Pt(II) system was used as the reference electrode and a graphite rod as the counterelectrode. The indicator electrodes were made from 1.5 mm diam glassy carbon rods. A small length (3 in.) of the glassy carbon rod was tightly fitted into a ⅛ in. diam graphite rod in which a 1.5 mm hole had been previously drilled. The joint between the glassy carbon and graphite was then cemented using a Union Carbide C-9 carbon cement and the seal matured by baking in an inert atmosphere of argon gas. The electrical contact was made by tying a platinum wire around the graphite rod. The glassy carbon rod was sealed into a Pyrex tubing under vacuum and the end ground flush with the seal so as to expose the cross section of the rod. The electrode was polished to a mirror finish. The diameter of the exposed cross section was measured with an optical micrometer and the area of the electrode, unless otherwise stated, was 0.0174 cm^2.

A wire wound cylindrical furnace was used to heat the cell and the temperature of the cell was maintained at 450° ± 2°C using a SCR proportionating temperature controller (API Instruments Company). The temperature was measured with a Chromel-Alumel thermocouple.

The voltammetric scans were performed with a Tacussel Model PIT-2A potentiostat coupled with a GSTP-2 function generator. The current flowing through the cell was measured across a precision resistor in the counterelectrode circuit. The i-V curves were recorded on a Tektronix (Type 564) storage oscilloscope and photographed using a Polaroid (Type 107) film. Sweep rates were calibrated with a Tektronix (Type 184) time marker and were known with a precision of ±2%.

Results and Discussion

The theoretical treatment of linear sweep voltammetry for the electrode processes involving the reversible deposition of a soluble or insoluble product is available (24). The equations for the reversible deposition of a soluble product in the electrode or the solution were first independently derived by Randles (32) and Sevcik (33) and later rederived by Matsuda and Ayabe (34). Berzins and Delahay (35) treated the case where the reversible charge-transfer resulted in the deposition of an insoluble product. From their treatment, it can be shown that the peak current for the reversible deposition of an insoluble metal at 450°C is given by the equation

$$i_p = 236\, n^{3/2} A\, C\, V^{1/2} D^{1/2} \qquad [1]$$

where i_p is the peak current (amperes), n is the number of electrons in the charge transfer step, A is the area of the electrode (cm^2), C is the concentration (moles/liter), D is the diffusion coefficient (cm^2/sec), and V is the voltage scan rate (V/sec).

Assuming that the activity of the deposited metal is equal to unity, the peak potential, E_p, is related to the metal chloride concentration (C) by the equation (24, 35)

$$E_p = E^\circ + \frac{RT}{n\mathbf{F}} \ln f\, C - \frac{0.854\, RT}{n\mathbf{F}} \qquad [2]$$

where E° is the standard electrode potential, f is the activity coefficient of the metal chloride in solution and RT and $\mathbf{F}$ have their usual thermodynamic significance.

A similar relation can also be derived for the half-peak potential, $E_{p1/2}$, and is given by the equation (9)

$$E_{p1/2} = E^\circ + \frac{RT}{n\mathbf{F}} \ln f\, C - \frac{0.0815\, RT}{n\mathbf{F}} \qquad [3]$$

It is seen from Eq. [2] and [3] that both the peak and half-peak potentials would shift to more positive values as the metal chloride concentration is increased. Thus, at 450°C, the plots of E_p or $E_{p1/2}$ *vs.* log C would result in straight lines with a slope equal to 2.303 $RT/n\mathbf{F}$ or 0.0717V at 450°C for a two electron process.

Combining Eq. [2] and [3], the difference (ΔE) between the peak and half-peak potential is given by

$$\Delta E = E_p - E_{p1/2} = \frac{-0.7725\, RT}{n\mathbf{F}} \qquad [4]$$

Thus the difference (ΔE) is independent of the concentration as well as the scan rate.

Typical voltammograms for the reduction of 31.02, 27.32, 51.55, and 35.49 millimolar solutions of $NiCl_2$, $CoCl_2$, $CdCl_2$, and $PbCl_2$, respectively, at a scan rate of 0.095 V/sec are shown in Fig. 2. In each case, peak shaped voltammograms were obtained and on reversing

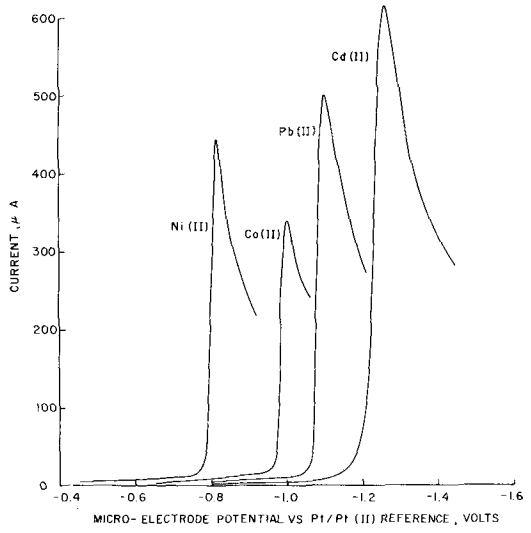

Fig. 2. Typical voltammograms for the reduction of 31.02, 27.32, 51.55, and 35.49 mM solutions of $NiCl_2$, $CoCl_2$, $CdCl_2$, and $PbCl_2$ at glassy carbon electrodes at a scan rate of 0.095 V/sec.

the direction of polarization, sharp anodic stripping peaks were observed. The potential of the working electrode was held at −0.2V *vs.* Pt/Pt(II) reference for a few minutes and the solution stirred before taking the next voltammogram. Several voltammograms were recorded at each scan rate between 10 mV to 1.0 V/sec and at several metal chloride concentrations.

The reduction of Ni(II) and Co(II) results in the deposition of an insoluble substance (solid metal) at the electrode surface at the working temperature of 450°C. Thus, the peak and half-peak potentials for the reduction of both Ni(II) and Co(II) would be given by Eq. [2-4]. The reduction of Cd(II) and Pb(II), on the other hand, results in the deposition of liquid metals at 450°C. These metals are known to dissolve in their chlorides according to the equations

$$Cd + CdCl_2 \rightleftharpoons Cd_2^{++} + 2\,Cl^- \quad (36\text{-}38) \qquad [5]$$

$$Pb + PbCl_2 \rightleftharpoons Pb_2^{++} + 2\,Cl^- \quad (39, 40) \qquad [6]$$

Thus if the deposition of cadmium and lead metals at the electrode surface is followed by their dissolution in dilute solutions of cadmium chloride and lead chloride, respectively, the activity of deposited metal will neither be equal to unity nor remain constant. The peak and half-peak potentials will, therefore, not be given by Eq. [2-4] but would instead obey the equations (24, 25, 34) for the deposition of a soluble product.

The peak and half-peak potentials of the recorded voltammograms for the reduction of Ni(II), Co(II), Cd(II) and Pb(II) were measured at all concentrations and scan rates and the data for one concentration in each case are summarized in Table I. The difference, ΔE, between the peak and half-peak potentials was found to be of the order of 20-30 mV as compared to the theoretical value of 24 mV predicted by Eq. [4] for the reversible deposition of insoluble substance at the electrode surface involving a two electron change at 450°C. Further, the peak and half-peak potentials, in each case, shifted to more positive values with increase in metal chloride concentration and the plots of $E_{p1/2}$ *vs.* log *C* resulted in straight lines with theoretical slopes predicted by Eq. [3]. Typical $E_{p1/2}$ *vs.* log *C* plots for the reduction of Ni(II), Co(II), Cd(II), and Pb(II) at a scan rate of 0.205 V/sec are shown in Fig. 3. The solid lines have the theoretical slope equal to 2.303 *RT*/2**F** or 0.0717 at 450°C and the circles represent the experimental points. Similar plots were obtained at other scan rates.

The standard electrode potentials, $E°$, for the metal ion-metal couples can also be calculated by use of

Eq. [2] or [3] and compared with the reversible standard electrode potentials determined by Laitinen and Liu (41) in lithium chloride-potassium chloride eutectic at 450°C. In practice the $E_{p1/2}$ *vs.* log *C* plots shown in Fig. 3 were extrapolated to 1.0M (molar) concentration (standard state on molarity scale) of the metal chloride and the $E_{p1/2}$ values so obtained were substituted in Eq. [3] to obtain the $E°$ values for the metal ion-metal couples *vs.* the used platinum reference (≈ 5-20 mM). It was assumed that the activity coefficient of the metal chloride remains constant over the concentration range studied and the activity coefficient term in Eq. [3] is included as a constant in the $E°$ value. The $E°$ values were then converted to 1.0M platinum reference using the Nernst equation and compared with the literature values (41). The data are summarized in Table II. The standard electrode potentials obtained in the present study are within 14-59 mV of the equilibrium values determined by Laitinen and Liu (41). In view of the obvious errors involved in determining the $E°$ values from the recorded voltammograms on a Polaroid film, the above agreement is considered quite satisfactory.

Since the peak and half-peak potentials for the reduction of Ni(II) and Co(II) as well as Cd(II) and Pb(II) closely obey Eq. [2-4], it can be concluded that the reduction of these ions results in the deposition of the metal in such a way that the surface of the glassy carbon electrode is completely covered with a layer

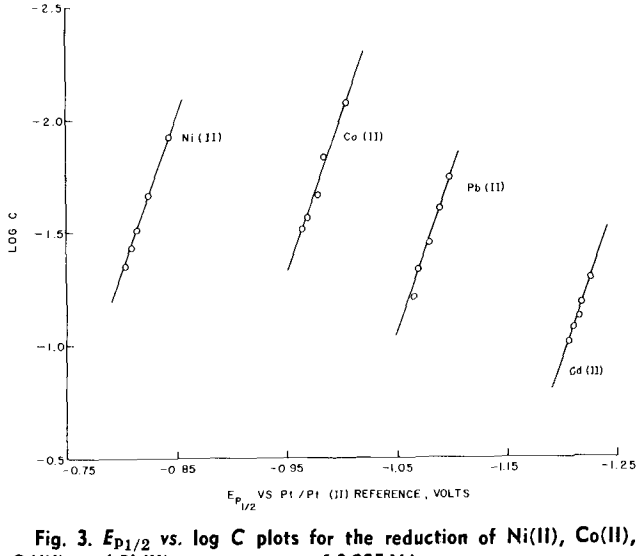

Fig. 3. $E_{p1/2}$ *vs.* log *C* plots for the reduction of Ni(II), Co(II), Cd(II), and Pb(II) at a scan rate of 0.205 V/sec.

[a] Voltage scan rate 0.205 V/sec.
[b] H. A. Laitinen and C. H. Liu, Ref. (41).

of the metal and its activity remains constant and equal to unity. At the scan rates used, the dissolution of the liquid metals (cadmium and lead) into the dilute solutions of their respective chlorides is probably very small and slow so that the electrode is always completely covered with a thin film of the metal. Thus, on reversing the direction of polarization after the peak, a sharp anodic peak is always observed due to the dissolution of the metal film on the electrode surface. The reverse voltammograms were not studied in detail as a study of the oxidation of the thin electrodeposited metallic layers of nickel, cobalt, cadmium, and lead in molten and solid lithium chloride-potassium chloride eutectic is available in literature (42).

It was also shown by Mamantov *et al.* (9) that for the reversible deposition of an insoluble metal at the electrode surface (assuming that the activity of the deposited metals remains constant), the plots of the microelectrode potential, E, *vs.* log $(i_p - i)$ approach linearity in the range (0.5-0.9) i_p with a slope equal to $RT/2.2\ nF$ or 0.014 for a two-electron process at 450°C. Such plots for the voltammograms presented in Fig. 2 are shown in Fig. 4. Again the solid lines have the theoretical slope and the circles represent the experimental points. As expected, these plots approach linearity only in the approximate range of (0.5-0.9) i_p. Similar plots were obtained for the other voltammograms at all concentrations and scan rates.

The reduction of Ni(II), Co(II), Cd(II), and Pb(II) at glassy carbon electrodes in molten lithium chloride-potassium chloride eutectic, therefore, occurs reversibly and leads to the deposition of a metal (solid or liquid) virtually at unit activity at the electrode surface and is similar to the deposition of an insoluble substance (24, 35). The peak currents would, therefore, be given by Eq. [1]. The peak currents for the reduction of ions studied were obtained by extrapolating the residual part of the voltammograms to the peak potential and measuring the height between this base line and the peak of the voltammograms. The

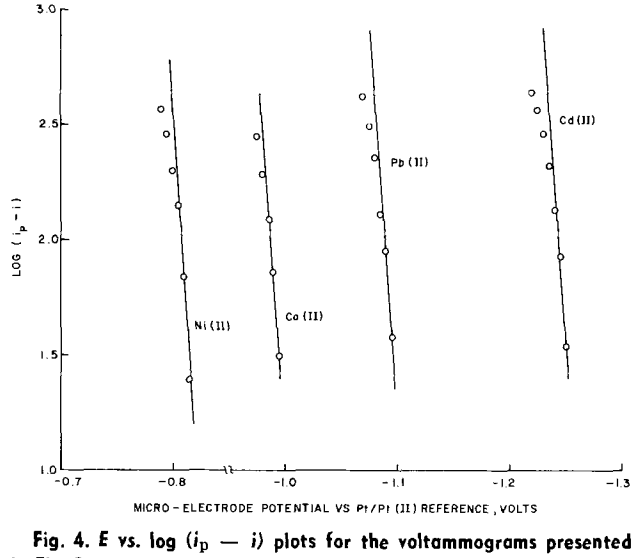

Fig. 4. E vs. log $(i_p - i)$ plots for the voltammograms presented in Fig. 2.

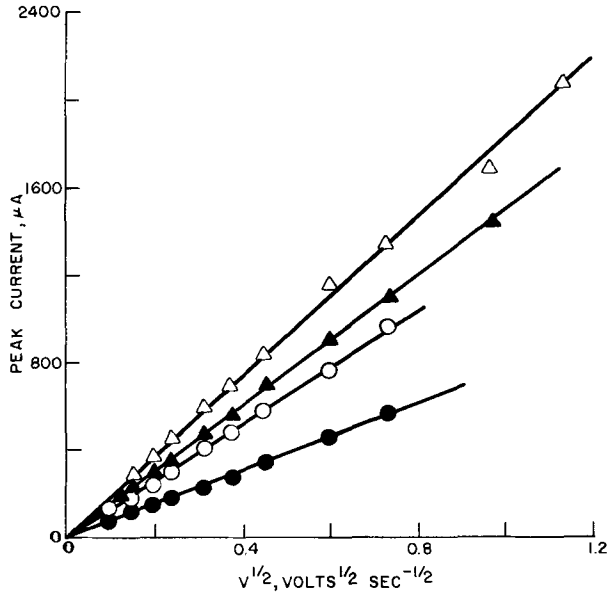

Fig. 5. i_p vs. $V^{1/2}$ plots for the reduction of 21.70 (●), 31.02 (○), 35.49 (▲), and 51.55 (△) mM solutions of cobalt chloride, nickel chloride, lead chloride, and cadmium chloride, respectively.

peak currents increased with increasing metal chloride concentration and square root of voltage scan rate and obeyed Eq. [1]. Thus, plots of peak current (i_p) *vs.* the square root of voltage scan rate ($V^{1/2}$) resulted in straight lines passing through the origin. The linear relation was observed up to an approximate scan rate of 0.8-1.0 V/sec and at higher scan rates, the peak currents tended to be lower than those predicted by Eq. [1] and showed negative deviation from the straight line plot. The typical i_p *vs.* $V^{1/2}$ plots for the reduction of 31.02, 21.7, 51.55, and 35.49 millimolar solutions of $NiCl_2$, $CoCl_2$, $CdCl_2$, and $PbCl_2$, respectively, are shown in Fig. 5. Similar plots were obtained at other concentrations.

At each concentration, the $i_p/V^{1/2}$ values were obtained from the slopes of the linear i_p *vs.* $V^{1/2}$ plots and substituted in Eq. [1] to calculate the peak current constants ($K_p = i_p/V^{1/2}\ AC$) as well as the diffusion coefficients (D) of the ions studied. These data are summarized in Table III. For most of the present work, glassy carbon electrodes with area equal to 0.0174 cm^2 were used. In case of the reduction of Co(II), an electrode of area equal to 0.0533 cm^2 was also employed and K_p values obtained with this electrode agreed very well with K_p values obtained with the former electrode. The constancy of the K_p values presented in Table III clearly demonstrates the linear dependence of peak currents on the metal chloride concentration and the electrode area as predicted by Eq. [1]. The average peak current constants (K_p) for the reduction of Ni(II), Co(II), Cd(II), and Pb(II) were respectively found to be 2.37, 2.12, 2.09, and 2.39 (10^3 A $sec^{1/2}\ V^{-1/2}$ cm per mole).

The diffusion coefficients obtained in the present study are compared in Table V with those obtained by other workers in lithium chloride-potassium chloride eutectic at 450°C by chronopotentiometry at platinum microelectrodes (43-45), polarography at dropping bismuth electrode (46) and linear sweep voltammetry at platinum microelectrodes (22). In general, the diffusion coefficients determined in the present studies are somewhat lower than the previously reported literature values for Ni(II) (22), Co(II) (44), Cd(II) (22, 43-46), and Pb(II) (22, 44, 46). However, there is a good agreement between our value for the diffusion coefficient of Co(II) and the value reported by Naryshkin *et al.* (22) and between our value for the diffusion coefficient of Pb(II) and the value found by Thalmayer, Bruckenstein, and Gruen (45).

Summary and Conclusion

The reduction of Ni(II), Co(II), Cd(II), and Pb(II) at glassy carbon electrodes was shown to occur reversibly in molten lithium chloride-potassium chloride eutectic by the technique of linear sweep voltammetry. The reduction of Cd(II) and Pb(II), which results in the deposition of liquid metals at the working temperature of 450°C, was found to be similar to the reduction of Ni(II) and Co(II) which results in the deposition of solid metals at the electrode surface. The peak currents showed linear dependence on concentration as well as the square root of voltage scan rates in the range of 0.01 to 1.0 V/sec. The experimental results showed close agreement with the theoretical equations for the deposition of an insoluble product at the electrode surface. The diffusion coefficients for the ions Ni(II), Co(II), Cd(II), and Pb(II) were calculated and found to be 1.26, 1.02, 0.98, and 1.29 x 10^{-5} cm^2/sec, respectively.

Technical Notes

The Self-Discharge Mechanism of the Li/LiI/AgI Solid Electrolyte Cell

Charles C. Liang*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Burlington, Massachusetts 01803

Investigations have been conducted in this laboratory on various high-voltage, solid-electrolyte battery systems with lithium anodes and lithium iodide electrolytes. A variety of iodine-based cathode materials such as iodine (1), metal polyiodides (*e.g.* CsI_3, RbI_3), and ammonium and organic ammonium polyiodides (*e.g.* NH_4I_3, $N(CH_3)_4I_3$) were used in the solid electrolyte cells. The initial performance of these cells was satisfactory. The cells exhibited the expected open-circuit voltages and could deliver short circuit currents of 300 $\mu A/cm^2$ at room temperatures. However, after a storage period of a few days, the internal impedance of these cells showed sharp increases indicating the diffusion of iodine through the electrolyte to react with lithium producing more resistive lithium iodide. Furthermore, the corrosive nature of the iodine-based cathodes made the selection of a satisfactory current collector and cell housing material extremely difficult.

In view of these difficulties, a metal iodide, AgI, was selected as the cathode material for the solid-electrolyte system. In addition, thin film–multilayer cell structures were designed to obtain useful discharge currents (2). The fabrication processes and the discharge characteristics of the thin film Li/LiI/AgI cells were reported in a previous publication (3). Further studies on the system revealed that the maximum discharge efficiency of the Li/LiI/AgI thin film cells was only 50% even under a drain rate as low as 5 $\mu A/cm^2$. Furthermore, the Li/LiI/AgI system was unstable. The thin film cells failed to operate after a storage period of two to four weeks at room temperatures.

The present investigation was undertaken in an attempt to determine the self-discharge mechanisms of the Li/LiI/AgI cells.

Experimental

Foote Mineral $LiI \cdot 3H_2O$ was dehydrated according to the processes reported previously (3). Mallinckrodt AgI was dried at 160°C overnight before use. Powder mixtures of anhydrous lithium iodide and silver iodide were ground in a Fisher mechanical grinding apparatus for about 1 hr. Immediately after the grinding, x-ray diffraction patterns of the mixtures were obtained at room temperatures using conventional techniques with CuKα radiation.

Pellets of lithium iodide on silver iodide were prepared by pressing prepressed lithium iodide and silver iodide pellets together under a pressure of 50,000 psi in a 7/16 in. diam steel die. These pellets were stored in individual brown glass bottles at ambient temperatures (26° ± 2°C) in a Vacuum Atmospheres Model HE-453-2 dry box. After the pellets had been stored for a predetermined period of time, they were placed in the holder of a small lathe and the silver iodide side was sectioned. The lithium content of each section was determined flame photometrically.

Results and Discussion

The x-ray diffraction patterns were obtained of the lithium iodide-silver iodide mixtures with lithium iodide contents of 20 mole per cent (m/o), 50 m/o, and 80 m/o, respectively (Table I). The diffraction pattern of the mixture containing 20 m/o of lithium iodide

showed only the silver iodide lines indicating a complete dissolution of the 20 m/o of lithium iodide in silver iodide. Both lithium iodide and silver iodide were evident in the diffraction patterns of the mixtures containing more lithium iodide. However, no third component was detected from these x-ray diffraction patterns. These results showed clearly that solid solutions were formed under the present experimental conditions.

The lithium iodide on silver iodide pellets were stored at 26° ± 2°C for three months before analysis. Figure 1 shows the lithium iodide contents in the silver iodide layers at various distances from the interface after three months. A curve was not drawn in Fig. 1 because the reproducibility of the results was poor. There were times that a variation of ±20% was observed with two similar samples. The poor reproducibility may be due to a variety of causes such as the uncertainty of the determination of the distance from the interface and the perpendicularity of the layer depth to the surface of the sample. Nevertheless, the results did show that the interdiffusion of the lithium and the silver ions did occur and occurred with rather high rates even at room temperatures.

It is known that interdiffusion of lithium and silver ions occurs when lithium iodide and silver iodide are in close contact at high temperatures. The coefficients of interdiffusion at temperatures between 200°C and 370°C are in the order of 10^{-5} cm²/sec (4). Results from this investigation showed that the interdiffusion of the cations took place in silver iodide/lithium iodide even at a temperature as low as 26° ± 2°C.

The interdiffusion of the lithium and the silver ions in the electrolyte and the cathode would result in a direct short circuit between the anode and the cathode in the Li/LiI/AgI cell, and we attributed the cell failure upon storage to the interdiffusion process.

Manuscript submitted Nov. 30, 1970; revised manuscript received March 3, 1971. This was Paper 20 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Electromigration of Fe and Cr in Liquid Bi[1]

S. G. Epstein[2] and J. R. Weeks

Brookhaven National Laboratory, Upton, New York 11973

The electromigration behavior of Fe and Cr in liquid Bi was investigated as part of an experimental study of the electronic phenomena that occur during the corrosion of low alloy steels in liquid Bi. The purpose of this note is to present the results obtained and to suggest their possible significance in explaining observed corrosion phenomena.

[1] This work was performed under the auspices of the United States Atomic Energy Commission.
[2] Present address: The Aluminum Association, 750 Third Ave., New York, New York 10017.
Key words: electromobility, apparent diffusion, diffusion coefficients of chromium and liquid bismuth.

Electromigration experiments were performed using the capillary-reservoir technique, which has been previously described in detail (1). Since the solubilities of Fe (2) and Cr (3) in liquid Bi are quite low (15 and 44 ppm, respectively, at 500°C), the sensitivity of this technique was put to a test. In essence, several fused quartz capillaries, normally 1 mm ID and 5 cm long with W electrodes sealed in one end, were filled in a reservoir containing liquid Bi alloyed with small amounts of either Fe or Cr. A d-c current was passed through two of the capillaries; the others sampled the

alloy. Previously irradiated Fe and Cr were used in preparing the alloys, and their migration behavior was determined by radiochemical analysis. This technique is sufficiently sensitive to allow detection of the few ppm of radioactive tracer element present and precise enough to determine the actual concentration to within ±10% at these levels.

In the first experiments with Bi-Fe alloys, single capillaries with sealed-in tungsten electrodes were submerged in the liquid alloy, and a second electrode was inserted into the reservoir to complete the circuit. The results of these experiments—all performed at about 500°C—are given in Table I. In the capillaries which contained the anode, an average of only about 9 ppm Fe was found after a current of 250 A/cm² was passed for one to two days. However, in the capillaries that contained the cathode, well over 100 ppm Fe was found in the contained alloy after the current was passed. Furthermore, a greater current passed through the cathode capillary resulted in a higher concentration of Fe in the contained alloy. The neutral capillaries were intended to be samples of the melt, which should have contained a saturated solution of Fe (15 ppm). These results indicate a tendency for Fe to migrate toward the cathode, against the electron flow. Since more Fe was originally added to the charge than the 15 ppm soluble at 500°C, some particulate Fe is expected to have been present, and autoradiography revealed the presence of several large particles of Fe in the cathode and in one of the neutral capillaries. These could have formed in the capillaries because electromigration supersaturated the Bi in the capillaries with Fe so that precipitation occurred *in situ*, or they may have formed in the bath and have been carried into the capillaries by the current.

More quantitative data were obtained for Cr migration in Bi due to its somewhat greater solubility. Experiments were performed at temperatures from 310° to 605°C. The results are given in Table II. In each experiment current flowed through two of the capillaries, one containing the anode and the other the cathode. Average values of the electric mobility (U) and the coefficient of electron drag (P) were calculated from the Cr concentration changes in both current-carrying capillaries in each experiment. The scatter in data at 310°C and 405°C may be attributed to the low solubilities of Cr in Bi at these temperatures (≈2 ppm at 310° and 10 ppm at 405°). The abnormally high Cr concentration found in both capillaries at 310°C may be analogous to the high Fe concentrations in the cathode-containing capillaries in Table I. At the higher temperatures the values of U [defined in Ref. (1)] for Cr in Bi are similar to those reported (4) for Ni in liquid Bi.

In previous papers (5, 6), one of the authors has concluded that electromigration in liquid metals results from an interaction between the electron stream and the metal ions. This interaction is described by the parameter, P [defined in Ref. (6)], equal to the number of solute atoms passing through the capillary orifice per electron passing through the contained alloy.

The positive values of P indicate that Cr ions in Bi scatter electrons more strongly than the Bi ions and therefore receive a greater fraction of the momentum of the electrons. Hence, Cr is preferentially transported to the anode, displacing Bi to the cathode. Belashchenko (7) has summarized various arguments why transition metals in alloys should scatter electrons strongly, and, in addition to chromium, Ni, Co, Zr, Pd, and U have been observed (4, 7) to migrate to the anode in liquid Bi. Iron ions apparently scatter the electrons less strongly than liquid Bi and migrate to the cathode.

In a second series of experiments, the diffusion and electrodiffusion of radioactive Cr were measured from a reservoir of the Bi-Cr alloy into capillaries previously filled with pure Bi, in the apparatus shown in Fig. 1. At the desired temperature the alloy was stirred and sampled. The capillary cluster was then lowered into the pure Bi under vacuum; the capillaries were filled by pressurizing the system with purified He, removed from that reservoir, and immediately rotated and lowered into the alloy without allowing the contained Bi to solidify. Direct current was passed through two of the capillaries for a predetermined time. The capillary cluster was then removed from the reservoir and quenched by a stream of liquid nitrogen-cooled helium. The capillaries were sectioned and the contained alloy weighed and dissolved into measured amounts of acid solutions and the solutions counted for Cr^{51}. Diffusion coefficients were calculated by the average concentration technique described by Crank (8). The results of a typical experiment are given in Table III. The apparent diffusion of Cr in Bi is seen to have been enhanced approximately 3 to 4 times by the passage of 1000 A/cm² at 515°C.[3]

Any relation between these results and the selective leaching of chromium or selective attack of Cr-rich alloys during corrosion of steels in liquid bismuth is speculative at best at the present time. Preliminary

[3] Values of U and P cannot be conveniently calculated from the experiment in Table III since the boundary conditions were not those needed for these calculations.

data suggest that potentials of the order of a few microvolts may exist between Cr-rich steels as the cathode and Cr-poor steels as the anode when immersed in liquid bismuth. If these potentials are substantiated, the eddy currents that possibly result from them would tend to increase the rate of dissolution of chromium and decrease the rate of dissolution of iron. Data of sufficient accuracy to demonstrate the validity of this suggestion, however, are not available at the present time.

Acknowledgments

The laboratory assistance and patience of J. E. Rutherford, Jr., in making the electromigration measurements was invaluable to this program. The work was performed under the general supervision of D. H. Gurinsky.

Manuscript submitted Nov. 15, 1968; revised manuscript received Jan. 14, 1971.

A Bipolar Current Interrupter for Electrochemical Measurements

P. M. Schwartz

RCA Laboratories, Princeton, New Jersey 08540

There have been some recent papers (1, 2) on the current interrupt technique as an approach to measuring and correcting for ohmic potential drops in electrochemical cells. The method introduced by McIntyre and Peck (2) is a good one, but it lacks the flexibility of being simultaneously usable with both anodic and cathodic currents. This situation is inconvenient in a-c experiments such as controlled double potential step experiments. A circuit has been introduced by Bruckenstein and Miller (3) which may be used for bipolar current interrupt measurements. Their circuit, however, establishes the zero current condition by applying the proper voltage to the cell in a feedback loop. This zero current condition is thus susceptible to errors arising from drifts in the amplifiers. In what follows, a current interrupter is described which works with both polarities of current and which establishes the zero current by switching a large resistance in series with the cell. The circuit described below also appears to have a slightly higher switching speed than the circuit of Bruckenstein and Miller.

Key words: ohmic potential measurement, double potential step, voltammetry, polarography.

In Fig. 1 a circuit is shown which works with both polarities of current. This circuit uses a field-effect transistor as the switching element to interrupt the current. In this application, the field-effect transistor operates as a voltage-controlled resistor switching from a typical resistance of >10M at cutoff to about 200 ohms at zero bias. A limitation inherent in the use of a field-effect transistor as the isolating element is that the current supplied by the circuit is limited to the saturation current of the transistor which is typically 10-30 mA for the type used. Should it be necessary to drive more current, several transistors may be used in parallel. There is also an advantage in using a field-effect transistor instead of a diode as the isolating element. McIntyre and Peck have noted that the high resistance of the diode at low current causes their circuit to oscillate when placed in a potentiostatic control circuit. This problem does not exist with the field-effect transistor since it maintains its low resistance down to zero current. Therefore, this interrupter circuit should be very useful in polarography.

The operation of the circuit is quite simple. When a negative pulse is applied to the gate input, Q_5 applies

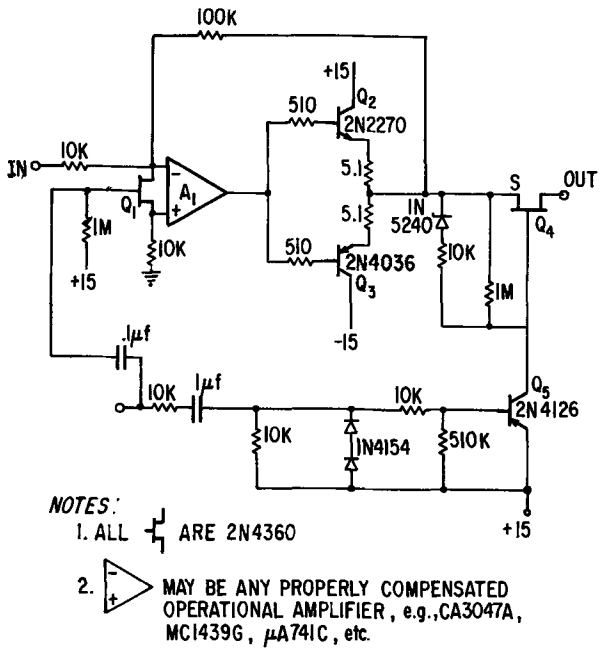

Fig. 1. Circuit diagram of the current interrupter

a large positive bias to the gate of Q_4. This action puts a large resistance in series with the electrochemical cell and prevents any current flow to the cell. The gate pulse also reduces the bias on the gate of Q_1 which shorts the inputs of the operational amplifier. This is especially necessary when the interrupter is part of a feedback loop in a potentiostat circuit for controlling electrode voltages in polarography and voltammetry, since in this case the amplifier would saturate and disturb the bias on Q_4 if Q_1 were not present. This interrupt process is quite rapid, being limited by the switching time of the transistor. In a practical configuration that included ample cable capacitance, the interrupt time was ~1 μsec.

When the gate pulse turns off, Q_5 turns off, and the bias resistors of Q_4 and Q_1 charge the gate-source voltages of those transistors to the quiescent values. Thus, Q_4 returns to the low-resistance state and Q_1 to the high-resistance state. This returns control of the output voltage to the operational amplifier. The recovery of the circuit is more complicated than the interrupt action. First, there is the time necessary to discharge the gate-source capacitance of the field-effect transistors. For the low-frequency transistors used in this circuit, that time is $\lesssim$20 μsec. Second, there is the response time of the operational amplifier. With a typical slew rate of 2.5 V/μsec, the amplifier recovery time for a typical electrochemical application would be only a few microseconds. The recovery time of the circuit was found to be ~20 μsec. This time could be improved by using higher-frequency transistors with a smaller gate-source capacitance or by decreasing the bias resistors.

The performance of the interrupter when it is acting like a voltage amplifier is shown in Fig. 2 and 3. Figure 2 shows an oscilloscope trace of the current through an electrochemical cell due to a constant applied voltage that is reversed every 13 msec. The interruptions are generated by a variable delay pulse generator (*e.g.*, Hewlett-Packard 214A) that is triggered by the voltage switching transients. Figure 3 shows, on an expanded time scale, the shape of an interrupted current pulse and the electrode voltage as measured by a reference electrode in the cell. Both the voltage and current have a recovery time constant of ~20 μsec while the fall of the current to zero takes ~1 μsec. In this mode of operation, interrupt pulses spaced as close as 200 μsec have applied without altering the over-all current waveform.

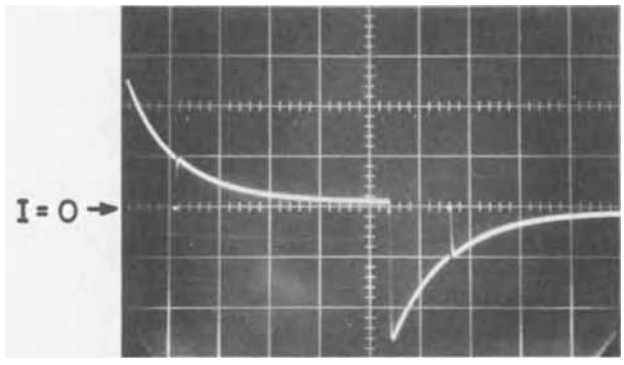

Fig. 2. Twenty-microsecond interruptions of positive and negative currents with interrupter applying a constant voltage to a cell: vertical scale 1 mA/div; horizontal scale 2 msec/div.

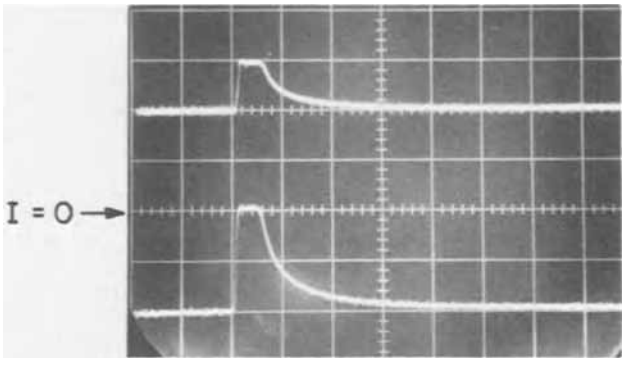

Fig. 3. Details of an interrupt pulse: upper trace—electrode voltage, 0.2 V/div; lower trace—cell current 0.4 mA/div; horizontal scale 20 μsec/div.

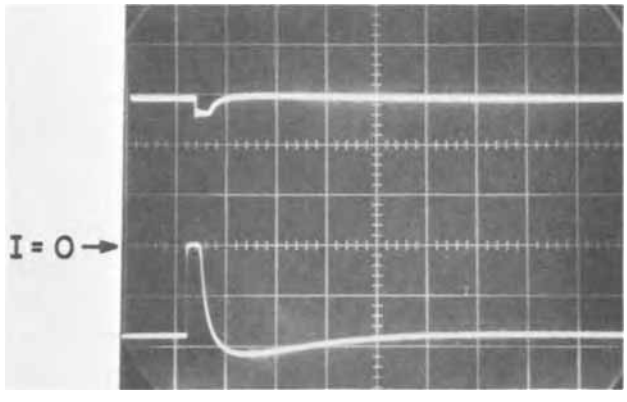

Fig. 4. Interrupt pulses in a controlled potential mode: upper trace—electrode voltage 0.5 V/div; lower trace—cell current 1 mA/div; horizontal scale 50 μsec/div.

The performance of the interrupter in controlled potential applications has also been examined. For this purpose the reference electrode potential, buffered by a voltage follower, and the signal voltage were summed at the inverting input of A1 and the 100K resistor in the feedback loop was replaced by a 0.001 μf capacitor. The results of a current interruption are shown in Fig. 4. We note that the recovery and settling time of the current has been extended to ~200 μsec. With the information provided in Fig. 4, the "uncompensated resistance" (2) in the controlled potential experiment is readily evaluated.

Acknowledgment

The author wishes to thank R. A. Blakeley for his assistance in the construction of the interrupter.

Brief Communication

A New Method of Preparation of $RbAg_4I_5$ Solid Electrolyte

Bruno Scrosati*

Istituto di Chimica Fisica, Università di Roma, Rome, Italy

$RbAg_4I_5$, silver rubidium iodide (SRI) solid electrolyte, has been so far prepared by melting a stoichiometric mixture of AgI and RbI and then quenching it (1, 2).

Recently we have discovered that SRI is soluble in acetone and in a number of other organic polar solvents and that it can be recrystallized from solutions (3). Furthermore, in a paper published in 1913 by Marsh and Rhyme, it is reported that a "rubidium silver iodide RbI,AgI" is obtained when RbI and AgI are dissolved in acetone and the solution evaporated in dry air (4).

This evidence encouraged us to suppose that SRI could simply be obtained by crystallization from a solution prepared by dissolving in acetone a mixture of silver and rubidium iodides. To test this, a known amount of AgI was added to acetone, followed by subsequent addition of RbI to the same solution. AgI, which as such is practically insoluble in acetone (see Table I), readily dissolved in the presence of RbI. The complete dissolution was obtained for an AgI/RbI molecular proportion of about 2 to 1.

The complete dissolution of the AgI-RbI mixture in acetone, however, was followed by a spontaneous precipitation of a white compound (this latter material was then identified, by x-ray powder analysis, as RbI). The acetone solution was then filtered and slowly evaporated. The resulting crystallized salt was dried at 100°C in an oven and analyzed by x-ray. The results are reported in Table II, which also includes the patterns of SRI, calculated and found by Bradley and Greene (7). All the lines of SRI are present in the acetone-crystallized compound indicating that the compound is indeed $RbAg_4I_5$.

The remaining lines found, all very weak in intensity, could probably be attributed to some impurities present in the starting materials. In fact RbI and AgI, commercial products, have been used without any further purification. This hypothesis may be confirmed by the value of the ionic specific conductivity of $RbAg_4I_5$ crystallized by acetone solution which was found to be 0.1 $(ohm\text{-}cm)^{-1}$ at 25°C. This conductivity value is somewhat inferior to that of pure $RbAg_4I_5$, which is about 0.24 $(ohm\text{-}cm)^{-1}$ at 25°C (8).

It is reasonable to suppose that starting with high purity compounds, a more conductive $RbAg_4I_5$ could also be obtained by the crystallization method described here. On the other hand it has to be considered that when SRI is used as electrolyte in a solid-state battery, its resistance represents only a small fraction of the over-all cell resistance, the major contributions being the electrode-electrolyte polarizations. Therefore, $RbAg_4I_5$ prepared by crystallization from an acetone solution of commercial AgI and RbI, may also be used as electrolyte in solid-state batteries. A difference of 0.14 $(ohm\text{-}cm)^{-1}$ in specific conductivity will affect the total resistance only by fractions of ohms.

Key words: $RbAg_4I_5$ solid electrolyte, preparation of.

On the basis of the reported evidence, the AgI-RbI mixture solution reaction could be tentatively represented as

$$4AgI + 2RbI \xrightarrow{\text{acetone}} 4AgI \cdot 2RbI \rightarrow RbAg_4I_5 + RbI\downarrow \quad [1]$$

To have a clearer picture of the solution mechanism, however, a more detailed study of the species in solution is necessary. This study is in progress in our laboratory.

The described new method of SRI preparation appears to be of a certain technological importance for the following reasons:

a) It is well known that the SRI decomposition, which takes place according to the reaction

$$2RbAg_4I_5 \rightarrow Rb_2AgI_3 + 7AgI \quad [2]$$

is favored by the presence of moisture. With the crystallization method of preparation in which dry acetone and pure starting materials are used, it is theoretically possible to prevent the decomposition and, ultimately, obtain a very pure material.

b) The possibility of obtaining SRI by crystallization from acetone solution allows the growing of single crystals and the deposition of thin layers of electrolyte. At the present, SRI single crystals have only been grown from nonstoichiometric melts, using the Czochralski technique (9). This method, however, is not of very easy application and presents technical problems. Single crystal growth from solution is certainly a much easier and faster procedure. In fact we have grown small octahedral SRI crystals by simple evaporation of the solutions (3). The feasibility of obtaining thin layers of film of electrolyte is also of considerable importance since it allows the development of low resistance, miniaturized solid-state batteries.

c) Finally, the solution procedure described in the case of the SRI preparation, is general and it can be applied, varying the starting materials and the solvent, for the preparation of a series of a new compound and new electrolytes. In fact at the moment a number of new solid electrolytes crystallized from solutions are under study in this laboratory.

Acknowledgments

The author would like to thank Dr. P. Cignini for the x-ray work.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 117, No. 10 and 12, October and December 1970.

The Approach to Limiting Current in a Stagnant Diffusion Cell

L. Hsueh and J. Newman (pp. 1242-1245, Vol. 117, No. 10)

L. Nanis[1]: For precise application of the stagnant diffusion cell, the authors should take into account the contribution to the over-all ohmic drop associated with the sudden change in cross section of electrolyte at the open end of the capillary. This so-called "constriction" resistance is in series with the capillary resistance given in the authors' Eq. [6]. It is of interest to note that the constriction resistance is of importance to a number of related technologies which involve the thermal and electrical resistance at metal interfaces such as electrical contacts, spot welding, and also end effects in the early definition of the ohm based on the resistance of a specified mercury column. The constriction resistance is discussed in several texts.[2-4] Calculation of the resistance of an idealized circular cross section is accomplished by solution of the Laplace equation for the field near a circular conducting opening in an otherwise insulating plane bounding the semi-infinite conducting medium. From the gradient of potential, the flux or current density normal to the disk opening is obtained, permitting application of Ohm's law to yield the resistance. The field solution for disk geometry was worked out as early as 1832 by Green[5] and in 1873 by Weber.[6] More recently, the resistance for disk geometry has also been verified by Newman.[7] By adding the end effect or constriction resistance to the resistance of the electrolyte within the capillary, the authors' Eq. [6] may be revised as

$$\Delta\phi_{ohm} = \frac{I}{\kappa_\infty a}\left[\frac{L}{\pi a} + \frac{1}{4}\right] \quad [1]$$

where I is current (A) and a is capillary radius (cm). (Remaining notation same as used by Hsueh and Newman.) According to Eq. [1] above, the end effect may be considered negligible if the capillary length to radius ratio is sufficiently large, *i.e.* $L/\pi a >> 1/4$. For vanishingly short capillaries, Eq. [1] gives the potential drop for the disk alone (cf. Eq. [9] of footnote 7). The authors report various capillary lengths, *i.e.* 7, 10, and 15 cm; and, from an electrode (and capillary) area given as 0.178 cm^2, a radius of 0.25 cm may be considererd as typical. Using these figures in Eq. [1], the ohmic potential will be consistently underestimated if the end effect is ignored, giving a 2.7% error for the 7 cm long capillary and 1.3% error for

the 15 cm capillary. Clearly, the end effect becomes increasingly more important only for capillary lengths smaller than those reported by the authors. However, the constriction resistance should be taken into account where the capillary length (or L/a) is reduced in order to decrease time required for experiments (cf. authors' Eq. [17]).

It should be mentioned that the term ¼ in Eq. [1] is based on a boundary condition of constant potential on the disk surface.[7] An upper limit to the end effect term may be considered on the basis of uniform current density over the disk surface at the capillary opening.[8,9] Is this case, the term ¼ in Eq. [1] is replaced by $8/3\pi^2$. Since the actual capillary (open) end condition is not known, the limiting cases of constant potential and constant current density provide a lower and upper bound. The end correction term for the resistance of electrolyte in the capillary given in Eq. [1] may thus be considered as somewhat uncertain but at least bounded between 0.25 and 0.27. Finally, it should be noted that the end-effect resistance calculations relate to a capillary of infinitely large extent in the radial direction. However, from the range of the potential field,[8] the correction terms may be considered as valid for a capillary outside radius which is five to six times the inside radius or greater.

On the Relation between Standard Potentials and Activity of Interstitial Silver Ions in AgCl and AgBr

A. Hoffman (pp. 1525-1527, Vol. 117, No. 12)

F. A. Kroger[10]: In this paper, Hoffman attempted to prove that the difference in the standard potentials of Ag/AgCl and Ag/AgBr can be ascribed to the difference in activity of interstitial silver ions, Ag_i, in the respective silver halides. This would imply that the individual standard potentials depend strongly on the activity of interstitial silver and, if true, would make the standard potentials sensitive to the presence of small concentrations of aliovalent impurities and would seriously decrease their usefulness. As we shall see, this is not the case.

The potential difference under discussion is essentially due to the exchange reaction

$$AgBr + Cl^-(aq) \rightarrow AgCl + Br^-(aq) \qquad [1]$$

$Cl^-(aq)$ and $Br^-(aq)$ representing Cl^- and Br^- in aqueous solution under standard conditions. As shown in Table I of this Discussion, this reaction gives a value of $\Delta E = \Delta G^\circ/F \approx 149.2$ mV; the small difference from $\Delta E = 222.2 - 71.3 = 150.9$ mV[12] cited in the discussed paper is due to the use of slightly different values for the standard free energies.

Reaction [1] depends on the chemical potentials of the silver halides, and these in turn are equal to the sum of the chemical potentials of the basic structure elements Ag_{Ag} and Br_{Br} and Cl_{Cl}. Writing X for Cl or Br

$$\mu(AgX) = \mu(Ag_{Ag}) + \mu(X_X) \qquad [2]$$

The latter in turn depend on the concentrations (expressed as site fractions) through

$$\mu_j = \mu_j^\circ + RT \ln [j] \qquad [3]$$

j representing Ag_{Ag} or X_X.

As long as the silver halides are reasonably pure, $[Ag_{Ag}] \approx [X_X] \approx 1$, and the chemical potentials of the structure elements Ag_{Ag} and X_X are close to their standard values.

Interstitials, vacancies, and foreign impurities play a role only insofar as they affect $[Ag_{Ag}]$ and $[X_X]$; their effect is negligible as long as their site fraction is small compared to 1, say $<10^{-3}$ or 10^{-4}. Electrodes based on pure and weakly doped halides will give standard potentials differing no more than corresponds to the impurity concentration. Doping with divalent cations, on the other hand, has a marked effect on the concentration of $Ag_i^\cdot$ and V'_{Ag}. For AgBr and AgCl, the concentrations of these defects if determined by Frenkel disorder are, respectively, $\approx 10^{-8}$ [13] and 2×10^{-9}.[14] Aliovalent impurities present in concentrations larger than these values will affect the concentrations of the native defects; *e.g.*, the presence of 10^{-4} divalent cations such as Ca or Cd will increase $[V'_{Ag}]$ to this value and decrease $[Ag_i^\cdot]$ to 10^{-12} in AgBr and 2×10^{-13} in AgCl. It is very doubtful that materials used to prepare standard electrodes have ever been pure to the order 10^{-8}. Therefore, Hoffman's assumption of defect concentrations determined by Frenkel disorder is unrealistic. A more fundamental objection against the analysis as presented by this author lies in the identification

$$RT \ln [Ag_i^\cdot]_{AgBr}/[Ag_i^\cdot]_{AgCl} = \Delta\mu(Ag_i^\cdot) \qquad [4]$$

(Hoffman's Eq. [16]).

Since $\mu(Ag_i^\cdot) = \mu^\circ(Ag_i^\cdot) + RT \ln [Ag_i^\cdot]$, [4] is correct only if $\mu^\circ(Ag_i^\cdot)_{AgBr} = \mu^\circ(Ag_i^\cdot)_{AgCl}$. There is no reason why this should be so. The correspondence between the observed value of ΔE and $\Delta E = \Delta\mu(Ag_i^\cdot)/F$ as calculated in Hoffman's Eq. [18] must be fortuitous. In fact, there is no corespondence if we use more recent values for the G° of Frenkel disorder in AgCl and AgBr[14] $(G^\circ_{AgCl} - G^\circ_{AgBr})/2 = (1032 - 885)/2 = 74$ mV.

Table I. Standard free energies of reaction for various processes related to the Ag/AgX electrode potentials[11]

	Reaction	ΔG° (kcal/mole)
1	$AgBr(s) \rightarrow Ag(s) + \frac{1}{2}Br_2(l)$	22.91
2	$\frac{1}{2}Br_2(l) \rightarrow Br^-(aq) + e^-(Pt)$	−24.595
3	$Ag(s) + \frac{1}{2}Cl_2(g) \rightarrow AgCl(s)$	−26.22
4	$Cl^-(aq)\ e^-(Pt) \rightarrow \frac{1}{2}Cl_2(g)$	31.345
5	$AgBr(s) + Cl^-(aq) \rightarrow AgCl + Br^-(aq)$	3.44 (+)

A. Hoffman: The effect of impurities on the concentration of interstitial silver ions, (Ag^+i), is an important consideration. A plot of log ionic conductivity versus the reciprocal of temperature, reveals a break in the curve at lower temperatures for silver halides[15,16]. The temperature at which the break in the slope of the curve occurs has been used as a check on the purity of the specimens. The break reflects the condition where the concentration of impurity ions becomes significant compared to the number of thermally generated defects.

Lehfeldt[15] has shown that the break for various specimens of AgBr occurs at temperatures below room temperature. Consequently at room temperature, the uncontrolled concentration of impurities has not apparently effected the concentration of Ag^+i. For single crystal silver chloride [having a lower value of (Ag^+i) than AgBr], the break in the slope occurs well above room temperature.[16] With highly purified single crystals, the break approaches but does not reach room temperature.[16] Thus, uncontrolled impurities do effect the value of (Ag^+i) in single crystal AgCl at room temperature. The amount of uncontrolled impurities present that can effect (Ag^+i) will, of course, depend

on the method of preparation. (Electrolysis, which is often used to prepare standard electrodes, might generate silver halides with lower concentrations of, for example, Cd^{++} than the procedures used in growing single crystals.)

Clearly, the extent of the effect of impurities on the value of (Ag^+i) is hard to evaluate unless the type and the concentration of these impurities are known. This represents an uncertainty in our argument.

I agree that there is no *a priori* reason why $\mu^o_{(Ag^+i)AgBr}$ should be equal to $\mu^o_{(Ag^+i)AgCl}$. I have just attempted to show that the suggestion of Awad,[17] using the model developed by Honig[18] (that the silver halide lattice can be looked upon as a solvent containing the solute cations-Ag^+i, and solute anions-silver ion vacancies) is consistent with the available data, if the assumption is made that the solvent effect can be neglected (*i.e.* that $\mu^o_{(Ag^+i)AgBr} = \mu^o_{(Ag^+i)AgCl}$).

It is possible that the correspondence between $E_2^o - E_1^o$, and $RT/n\mathbf{F} \ln {}^X(Ag^+i)_1/{}^X(Ag^+i)_2$ is fortuitous but the results for AgI suggest otherwise. I have submitted a manuscript to the *Journal*, which shows that the above equation seems to hold, within the error limits of the experimental data, for AgI also. Since AgI has a higher value of (Ag^+i) than AgBr, the break in the slope of the conductivity versus temperature should occur at even a lower temperature than that for AgBr; and hence, the effect of impurities should be more insignificant. This paper will also point out that the presence of Cd^{++} ions has a significant effect on the characteristic potential of silver halides, as determined chronopotentiometrically.

Andre J. de Bethune[19]: F. A. Kroger's critique of Hoffman's paper can, itself, be subjected to a number of objections of a formal nature. Electrochemistry, and physical chemistry to which it is intimately related, are, if anything, *algebraic sciences, i.e.* sciences based on the correct usage and manipulation of algebraic quantities. Benjamin Franklin[20] in 1752 adopted the algebraic signs (+) and (−) to represent the two physically distinct electricities discovered in 1733 by Charles Dufay: the *vitreous electricity* produced by friction in glass, porcelain, hair of animals, and wool; and the *resinous electricity* in amber, silk, thread, paper, sealing wax, and sulfur, respectively.[21]

Other areas of electrochemistry and physical chemistry have their own algebraic sign conventions.[22] Alternative "European" and "American" (so-called) conventions have been provided for the handling of "half-cell emf's." Nevertheless, the 1953 I.U.P.A.C. Stockholm convention, reaffirming a usage which goes back to Ostwald (1887) and Gibbs (1899), defines the *electrode potential* in an algebraically invariant way, *e.g.* Zn NEG, Cu POS to standard hydrogen, corresponding to the observed d-c polarities of these metals as determined from Franklin's choice of POS and NEG.

Notwithstanding these various algebraic conventions, some of them over 200 years old, Kroger brushes algebraic considerations aside and makes several statements which are in error, unless reinterpreted by the reader. Kroger's reaction Eq. [1], the displacement of Br by Cl in AgBr, has a positive Gibbs free energy change, $\Delta G^o = +3.44$ kcal $= +14.39$ kJ $= +0.1492$ volt-faradays (Kroger's Table I). The cell corresponding to reaction [1] would be, according to the 1953 I.U.P.A.C. Stockholm conventions[23]

$$(+)\ Ag/AgCl/Cl^-//Br^-/AgBr/Ag\ (-) \qquad [A]$$

where the cell voltage E(cell) is to be calculated as V(right) − V(left), and the V's are defined as in Gibbs.[24] For cell [A], therefore

$$E\ (\text{cell A}) = -\Delta G^o/(1\mathbf{F}) = -149.2\ \text{mV} \qquad [1]$$

a value very close to the difference of the electrode potentials[25]: V(right) − V(left) $= (+71.3) - (+222.2) = -150.9$ mV, as pointed out by Kroger. This writer omits several minus signs from his discussion which is, as a result, algebraically erroneous as presented by him.

The present formal critique does not affect the substance of the points in controversy between Professor Kroger and Dr. Hoffman.

Carelessness in the handling of the algebraic signs of electrochemistry causes our science incalculable harm.

The Influence of an Air-Formed Film on the Nucleation and Morphology of Etch Pits in Pure Iron

G. M. Spink[1] and M. B. Ives

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Annealing pure iron in hydrogen, followed by etching in a hydrogen atmosphere is shown to develop etch features at defects in the metal itself, rather than those of an oxide film. These features are contrasted with those reported for the same etchant on unreduced samples. The influence of an air-formed film in controlling etch morphology is discussed.

The etch pitting of crystalline materials is now a well established method for pinpointing dislocations and following their movements under stress. Although much of the early work was confined to nonmetals, well authenticated examples do exist in the literature where researchers have produced etch pits at dislocation sites in metal single crystals; for example, the classical work of Livingston on copper (1) and Hibbard and Dunn on silicon iron (2). Later work included the etching of bismuth (3), tungsten (4), nickel (5), molybdenum (6), zinc (7), cadmium (8), and niobium (9). A recent review of etching methods and etchants used has been made by Robinson (10).

Subsequent research on polycrystalline metals, notably iron and iron alloys, indicated that an aging treatment was necessary in order to "decorate" the line defects with small quantities of an impurity or trace element. Suits and Low (11), for example, have shown that aging is necessary for etch pitting of dislocations in an Fe-3% Si alloy and that carbon is the principal segregating impurity. Pickering (12), again working with polycrystalline Fe-3% Si, found that a one-to-one correspondence between etch pits and dislocations is only possible when the dislocation density is below a critical value which cannot be displaced upwards by increasing the carbon content. He observed pitted areas in etched thin foils directly under the electron microscope, and saw that fresh dislocations introduced by plastic deformation were never pitted whereas aged dislocations were attacked to a degree depending on the carbon level. Pickering concluded that for a one-to-one correspondence to exist the amount of carbon in solution must be (*a*) equal to, or above, the level which is necessary to produce sufficiently large carbon atmospheres at every dislocation present in the alloy during aging; and (*b*) below that level which, by the formation of random clusters or precipitates during aging, is sufficient to cause two-dimensional nucleation of etch pits not associated with dislocations.

More recently etchants have been developed which produce etch pits without an aging treatment. Liss (13) developed etch pits in iron in what appear to be glide bands. Pelessini and Alessandrini (14), also working on iron, demonstrated the increasing density of pits with work hardening, without intermediate aging treatment, on grains of all orientations.

It is often difficult to interpret the results of etch pitting of polycrystalline metals because of the much increased density of dislocations, compared with single crystals. The processes of slip and twinning are more complex and dislocations exist in bands or tangled networks rather than as discrete defects. The pits themselves are shallow and irregular in outline and, if the dislocation density is high enough, they overlap giving an effect more like over-all surface dissolution than surface pitting.

Thus far, investigators working on polycrystalline metals have set out to show that their particular etchant will produce pits having a one-to-one correspondence with dislocations intersecting the surface etched. Sometimes this is not convincingly done, mainly because of the confusion created by the factors outlined above. No one appears to have considered the possibility that a surface film might influence the nucleation and subsequent growth of an etch pit. Yet one important difference between the surface of a nonmetallic crystal and a metallic one is the usual occurrence of an air-formed oxide film on the latter.

The present work was devised to determine how the presence or absence of an air-formed oxide film affects the nucleation and growth of etch pits in pure iron, using the etching system developed by Taoka *et al.* (15). Normally the pits produced are bounded by faces parallel to {100} and {110} planes. Each pit reflects the symmetry of the grain in which it lies, and by measuring the angles between the pit facets and the surface of the grain in a goniomicroscope the orientation of the grain can be determined.

A detailed study of the pits and the mechanisms controlling pit morphology has been discussed elsewhere (16). While the same etchants have been used here, the conditions were designed to reduce any air-formed film which might otherwise exist on the iron surface prior to etching. A significant modification in etch pit morphology was observed.

Experimental

Samples of "Ferrovac E" iron were subcritically annealed in hydrogen to reduce any surface film and

[1] Present address: Central Electricity Research Laboratories, Materials Division, Leatherhead, Surrey, England.

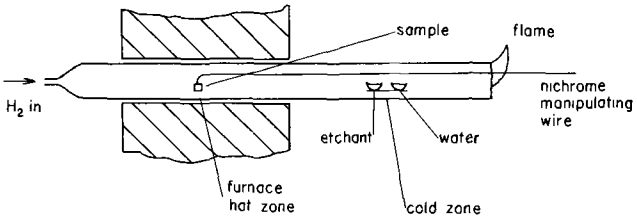

Fig. 1. Apparatus for preparing and etching oxide-free iron surfaces.

then were etched under hydrogen atmosphere in a solution containing 1 part HCl, 5 parts H_2O_2, and 100 parts H_2O. The apparatus is shown in Fig. 1. Small specimens, ½ in. diameter and ⅛ in. thick were given a standard mechanical and chemical polishing treatment and, attached to the end of nichrome wire, were pushed into the furnace hot zone through the hydrogen flame. Several investigators (17-19) have studied the reduction of oxide films on the surface of pure iron, checking for the presence or absence of a film by x-ray and electron diffraction methods. They consider that several minutes at 750°C in hydrogen is sufficient to reduce any film present. In the present experiments a standard reduction treatment of 30 min at 875°C was adopted. After reduction, the specimen was drawn back into the cold zone where its temperature eventually dropped to no more than 10 degrees above ambient.

To etch the sample in its reduced condition, two small polythene vessels fixed to a copper base plate were fed through the flame into the cold zone. One vessel contained the etchant and the other, distilled water for washing. The sample was immersed in the etchant, then washed and returned to the reduction zone to remove the reddish-brown oxide layer produced during etching. This normally took 1 hr at 875°C.

The pits produced by this technique were different both in distribution and morphology to those obtained during "normal" etching (16). Figures 2 and 3a show typical areas of a sample which before reduction had been lightly deformed in a direction parallel to its prepared surface. Two types of pits are present: (*a*) shallow depressions of irregular shape with ill-defined edges (Fig. 2b), and (*b*) conical pits having a well-defined rounded form (Fig. 3a).

In addition (Fig. 2) the shallow pits form continuous or semicontinuous grooves along slip lines. As would be expected in a body centered cubic polycrystalline metal the slip lines are "wavy" in nature and may pass through several grains, ending abruptly at the boundary of a grain unfavorably oriented for slip, to begin again on the other side of that grain.

The effect of etching time is apparent in Fig. 3 which shows the same area after etching for (a) 2 sec and (b) 4 sec. Obviously, the sample had to be removed from the apparatus for photomicroscopy, then reduced before etching a further 2 sec to obtain Fig. 3b. The pits in the two photographs demonstrate a one-to-one correspondence.

It is apparent then that the pits nucleate and grow at well-defined singularities in the surface structure. Pit counts on samples having various mechanical and thermal histories (Table I) indicate that pit densities are similar to those which would be anticipated if pits were formed at dislocation sites.

Of course, all dislocations would necessarily be in the "aged" condition, and the samples to some degree, in the annealed state, because of the reduction treatment

Table I. Pit counts

Condition of oxide free surface	Average pit density
Annealed	$0.25 \times 10^6/cm^2$
Mechanically polished surface	$0.60 \times 10^6/cm^2$
Deformed by Rockwell "brale" indenter	$0.90 \times 10^6/cm^2$

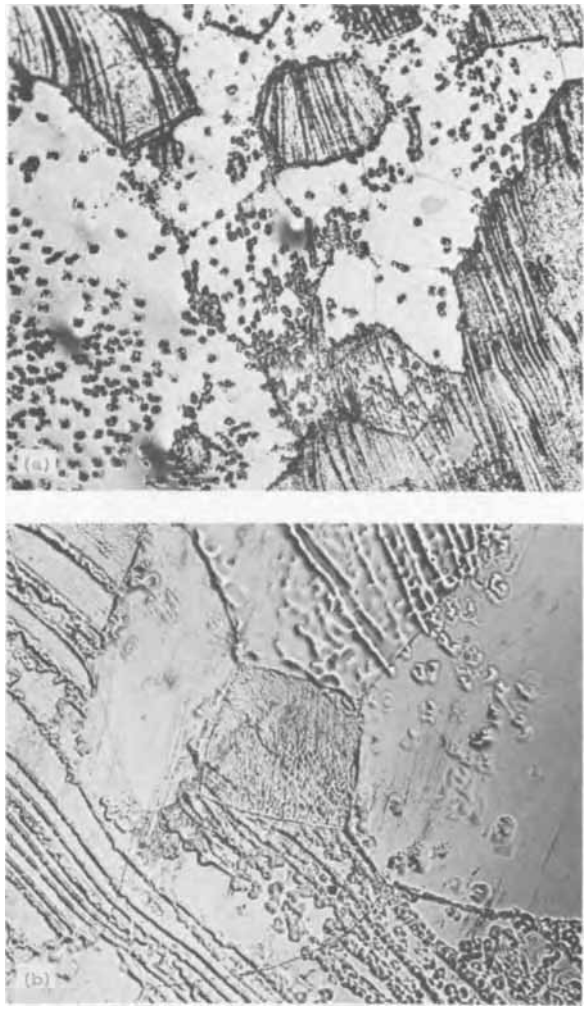

Fig. 2. Lightly deformed iron surface etched for 2 sec in oxide free condition (a) 200 X, (b) 500 X.

required before etching. In one experiment a sample was deformed *after* reduction, but prior to etching, while still in the furnace cold zone. This was achieved by allowing a pointed lathe tool, clamped to a quarter-inch diameter steel rod, to fall from a height of ¾ in. onto the surface of the sample. The impressions made on the surface were of similar size to those produced by a microhardness indentor. No increased density of pits was observed near the indentations. This suggests that the dislocations must be aged before etching will reveal their presence.

On all samples, etching for times greater than 5 sec developed crystallographic facets on the deep conical pits, identical to those on pits produced by etching in air (16). In the case of the shallow pits the rapid over-all surface dissolution seemed to overtake pit growth and they gradually faded out.

After long etching times, the appearance of the pits on oxide free surfaces was similar to that of pits produced by etching in air, followed by the reduction treatment (16). The two conditions could be distinguished by the observations that on an oxide free surface: (*a*) number of pits was independent of time, (*b*) grain boundaries were continuously attacked, and (c) there was a wide variation in pit sizes and extent of facet development.

The pits in Fig. 3b can be seen to be already developing a definite crystallography.

Discussion

Under normal metal etching procedures pits probably form at defects in the oxide film, which may or may not be related to the underlying metal. The fact that pit densities are proportional to etching time rules

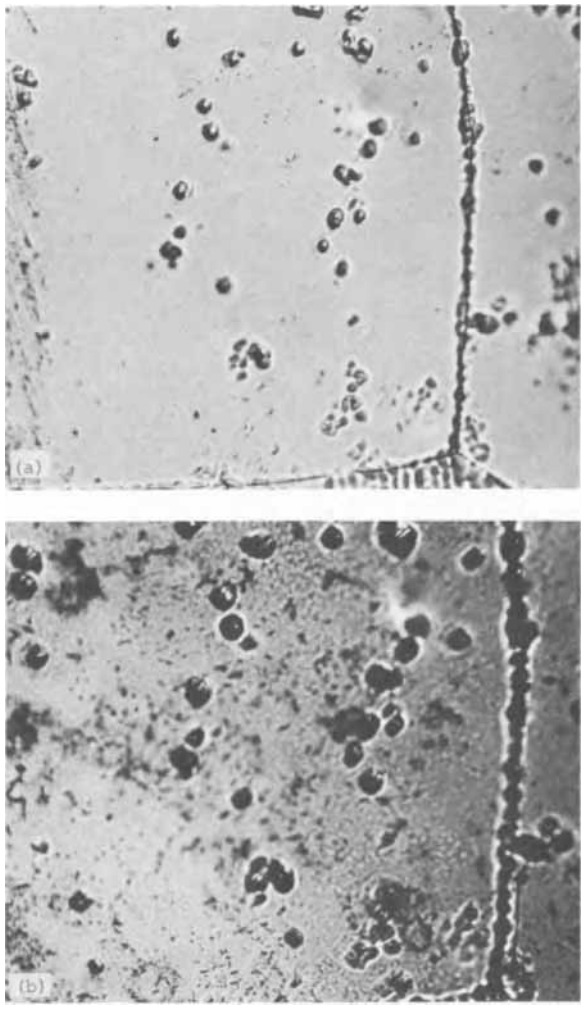

Fig. 3. (a) Annealed iron surface etched for 2 sec in oxide-free condition, 500X. (b) Same field, etched for a further 2 sec in oxide-free condition, 500X.

out a possible one-to-one correspondence with dislocations. Stresses in the film may generate flaws at which conditions for electrochemical attack are more favorable than elsewhere. Pits occasionally nucleate at grain boundaries. If the oxide film is related in orientation to the iron substrate (18) a film discontinuity may be created where the base becomes discontinuous, *e.g.* at grain boundaries.

The pits obtained by etching an oxide-free surface presumably are nucleated at defect sites in the metal. Such pit densities are independent of etching time and are similar to dislocation densities expected for annealed iron. Densities do increase with plastic deformation but this effect tended to be masked in this work because of the high-temperature reduction treatment required prior to etching. Deformation after reduction, but prior to etching, did not produce increased pit densities, indicating that an aging treatment is however necessary to decorate the dislocations.

Slip lines etched out in continuous shallow grooves, similar to those observed by Brandon and Nutting (20) and by Low and Guard (21). The "wavy" nature of the slip lines results from the ability of the screw components of dislocations to move off the glide plane easily and from the large number of slip systems. Certain arrays, presumably composed of edge dislocations, remain confined to straight lines despite the complex stress patterns which exist in polycrystalline materials.

If a dislocation network lying parallel to and just below a surface has an impurity atmosphere, and the rate of dissolution is high in the impure region, an etch groove can form along the network. The grooves observed by Low and Guard (21) were decorated with carbon. Alternatively, the local elastic strain associated with a dislocation lying parallel to and just below a surface could cause the observed differential etching effect.

It was observed here that etching an oxide-free surface produces two different types of pit. The relatively deep conical pits of Fig. 3a were never found in slip bands and constituted the majority of pits in a well-annealed, undeformed sample. They are most likely formed at aged dislocations of edge character which intersect the grain surface at a high angle. As Fig. 3b suggests, these defects extend well below the surface.

The other type of pit, however, is shallow, irregular in shape and ill-defined (Fig. 2b). Some of the slip bands in Fig. 2b are not continuous and are seen to be strings of individual pits of this type. The shallow pits are of the same nature then as the "grooved" slip lines. Cross slip of the screw component of a dislocation loop lying on or just below the surface would result in the irregular shapes observed (21).

Perhaps the most convincing evidence that the shallow pits and slip line grooves are caused by individual dislocations, dislocation loops or tangled networks parallel to and just below the surface, is the fact that after etching for 4 sec they have all but disappeared. At longer times they vanish completely, leaving only the deep pits which have started to develop crystallographic facets.

Conclusions

1. Reduction of the air-formed oxide film from the surface of iron was observed to cause a complete change in etching behavior. Instead of pits nucleating at flaws in the film, they nucleate at singularities in the base metal structure.

2. Two types of etch features are formed on a reduced surface. One is deep with conical sides and appears to be formed at the sites of intersection of aged dislocations with the surface. The other is shallow, irregular in shape and outlines slip lines. This type is probably caused by either the segregated impurity atmospheres of, or the strain fields associated with, dislocation networks lying parallel with, and just below, the surface.

The Oxidation of Iron-Aluminum Alloys from 450° to 900°C

William E. Boggs*

U. S. Steel Corporation, Applied Research Laboratory, Monroeville, Pennsylvania 15146

ABSTRACT

The oxidation behavior of a series of iron-aluminum alloys (to 8% Al) containing up to 0.1% carbon has been investigated over the temperature range 450° to 900°C. The oxidation rate increases and then decreases with increasing aluminum content and also with increasing temperature as the result of changes in the oxide composition. The composition of the oxide is also influenced by the carbon content of the alloy, water vapor in the atmosphere, and the partial pressure of oxygen. Perforation of the protective Al_2O_3 films that form at the higher temperatures results in the formation of scattered nodes of iron oxide. The amount of nodular oxide increases with temperature, carbon content, and water vapor and decreases with increasing aluminum concentration.

It is well known that aluminum additions greatly increase the oxidation resistance of steel (1). For example, a 6% aluminum-iron alloy has about the same oxidation resistance as a 16% chromium-iron alloy at 890°C (2). Production difficulties, that is, poor hot and cold workability and fabricating difficulties when the aluminum content exceeds about 8% have limited the technological application of these alloys. In spite of these difficulties, the superior oxidation resistance of the material has prompted several investigations of the mechanisms of oxidation of iron-aluminum alloys.

The variety of experimental conditions, particularly of temperature, aluminum concentration, and oxygen pressure, under which these studies were conducted has led to a profusion of somewhat conflicting data. The pertinent investigations are those of Miyake (3), Hickman and Gulbransen (4), Scheil and Kiwit (5), Kornilov (6), Nakayama (7), Schmahl, Baumann, and Schenck (8), and Saegusa and Lee (9).

In addition, nodular oxide formation, often a limiting factor in the usefulness of oxidation-resistant alloys, has been studied in iron-aluminum (9) as well as in other ferrous alloy systems (10-15). According to Wood (16), the Cr_2O_3 layers that form on iron-chromium alloys and stainless steels in oxygen from 800°C up become detached from the alloys in random areas and tend to arch outwards because of the stresses that develop during oxide growth. Cracking of this oxide then exposes areas of chromium-depleted surface to oxygen, and iron-rich nodules begin to form. When the cavity under the lifted Cr_2O_3 film becomes filled with growing oxide, the roof could crack off and allow unimpeded growth of the nodular oxide.

In the present investigation, the effects of temperature, oxygen pressure, water vapor, and alloy composition on the oxidation of iron-aluminum alloys have been studied. Special attention has been given to factors influencing growth of iron oxide nodules on these alloys at the higher temperatures.

Key words: oxidation resistance, nodular oxide, internal oxidation.

Materials and Experimental Work

The compositions of the iron-aluminum alloys used in this study are given in Table I. These alloys were vacuum-induction melted using high purity raw materials. The alloy ingots were hot- and cold-rolled to 0.15 to 0.30 mm thick sheet. This material was then vacuum-annealed at 950°C for 4 hr and cooled to room temperature at 2°C per min. Electropolished specimens were inserted in the vacuum microbalance (17), and reduced in hydrogen at 400°C for 1 hr. After evacuation to about 2×10^{-7} Torr, the oxidation experiments were begun.

The hydrogen treatment at 400°C reduces the iron oxides but not the aluminum oxides that unavoidably form during the brief manipulation of the specimen in air after electropolishing. However, the aluminum oxides apparently do not form a complete cohesive film at the start of oxygen exposure or the phenomena discussed herein could not occur.

The oxidation experiments were conducted in pure oxygen at pressures of 10 and 700 Torr, flowing water vapor at 22 Torr, or in flowing oxygen at 678 Torr saturated with water vapor at 22 Torr. The reactions were studied in the microbalances at 450° to 900°C. Additional experiments were conducted in laboratory air in muffle furnaces at 900° and 1093°C.

Alpha cyanoacrylate, an adhesive which is resistant to methanol, was used to support thin oxide films during stripping in 5 to 7% bromine in absolute methanol. Thicker films did not require a supporting layer.

Results and Discussion

The effect of aluminum concentration.—The oxidation rate of iron at 500°C in oxygen at a pressure of 700 Torr increased with increasing aluminum concentration to a maximum at about 0.092% aluminum. This may be an example of the Wagner-Hauffe effect wherein Al^{+++} replaces some Fe^{++} causing an increase in the cation vacancy concentration and thereby the rate of diffusion of iron ions through the Fe_3O_4 lattice (18).

The oxidation rate at 0.50 to 0.72% aluminum dropped to about the same as the oxidation rate of "pure" iron (0.003% Al). Further increases in aluminum concentration continued to decrease the oxidation rate under the experimental conditions used. An isometric projection of the weight-gain data obtained from the oxidation of the iron-aluminum alloys at 500°C in oxygen at a pressure of 700 Torr is shown in Fig. 1.

Two-phase scales consisting of Fe_3O_4 on the inside and αFe_2O_3 on the outside were formed on the low-aluminum alloys at 500°C (Fig. 2A) whereas three-phase scales were formed on the higher aluminum alloys (Fig. 2B). The three oxide phases were hematite (αFe_2O_3) on the outside, magnetite (Fe_3O_4) in the middle, and hercynite ($FeAl_2O_4$) next to the metal. The hercynite layer appears to develop at the expense

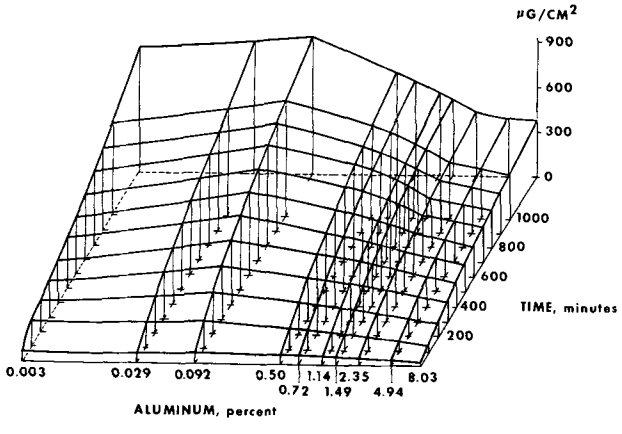

Fig. 1. Effect of aluminum concentration on the oxidation of Fe-Al alloys at 500°C in oxygen at 700 Torr.

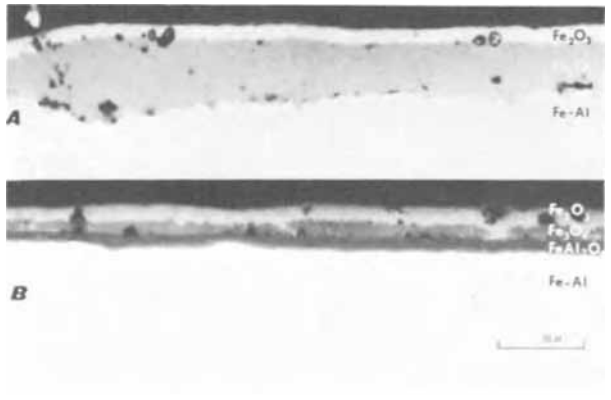

Fig. 2. Oxide formed on Fe-Al alloys in 3900 min at 500°C in oxygen at 700 Torr. (A) Fe-0.5% Al, (B) Fe-4.94% Al.

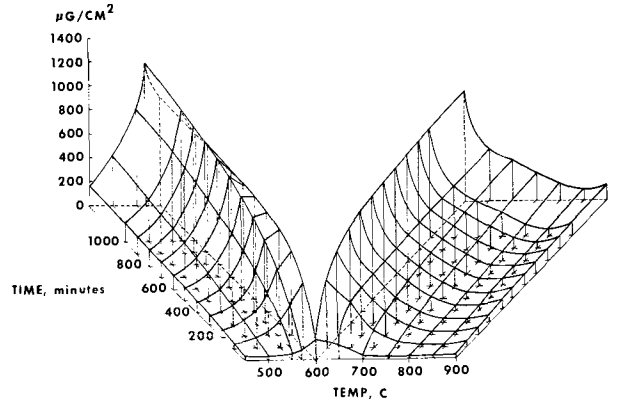

Fig. 3. Effect of temperature on the oxidation of an Fe-4.94% Al alloy in oxygen at 700 Torr.

of the magnetite layer. Whereas about 75% of the scale formed on the low-aluminum alloy shown in Fig. 2A was Fe_3O_4, less than 25% of the scale formed on the high-aluminum alloy (Fig. 2B) was Fe_3O_4. This indicates a reduction in the outward flow of iron ions. Thus, the spinel (18), $FeAl_2O_4$, constitutes a barrier to the diffusion of iron and thereby contributes to the observed oxidation resistance.

The effect of temperature.—The data obtained from the oxidation of the iron-4.94% aluminum alloy in oxygen at 700 Torr and a temperature range of 450° to 900°C are shown in Fig. 3. The time axis for temperatures up to 600°C is projected to the left and the time axis for temperatures above 600°C is projected to the right. The first data points plotted on the figure are at 10 min. The oxidation rate increased with temperature to a maximum at about 570°C and then decreased to a minimum at about 850°C. The temperature at which the maximum oxidation rate was observed, 570°C, coincides with the temperature at which FeO becomes stable (19).

The x-ray diffraction patterns from these scales indicate that the three oxide phases discussed above (hematite, magnetite, and hercynite) are formed up to 570°C in oxygen at 700 Torr. As the reaction temperature was increased above 570°C, the cubic aluminum oxide γAl_2O_3, began to appear. Concurrently, the hercynite, $FeAl_2O_4$, began to disappear. Sections of the oxide obtained at 600°C showed only two layers of oxide, αFe_2O_3 and mixed $FeAl_2O_4$-γAl_2O_3. Only a single layer can be distinguished in the sections of oxide formed at higher temperatures (Fig. 4).

It appears that the observed effect of temperature on the oxidation of the iron-aluminum alloys at 700 Torr is due to the preferential oxidation of aluminum at the higher temperature. Up to about 570°C, $FeAl_2O_4$ forms in a layer at the oxide-metal interface. The increase in oxidation rate with increasing temperature up to 570°C is probably associated with a temperature-dependent increase in iron ion diffusion rate through the hercynite layer. Above 570°C the reactions producing aluminum oxide begin to predominate. Initially the iron oxides and hercynite may form on the surface as well, when there is insufficient aluminum in the surface layer to form a complete alumina film. Subsequently aluminum atoms diffuse to the oxide-metal interface and form additional alumina by the displacement reactions with $FeAl_2O_4$ and the iron oxides. Thus, as the temperature is increased, and the mobility of aluminum atoms in the metal increases, more and more of the protective aluminum oxide is formed, less and less iron oxide and hercynite remain, and the over-all oxidation rate drops.

Two aluminum oxides have been identified in the films formed at temperatures above 600°C. These are the cubic oxide, γAl_2O_3, and the hexagonal oxide, αAl_2O_3. The γAl_2O_3 was always observed as large crystals in apparent epitaxial association with the substrate,

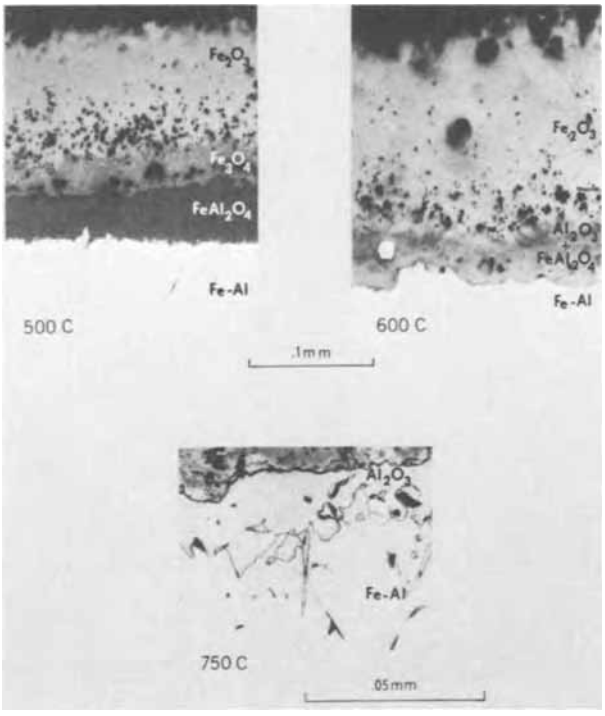

Fig. 4. Effect of temperature on oxide composition in oxygen at 700 Torr. Fe-4.94% Al (taper sections).

whereas the αAl_2O_3 was always observed as very small crystals in completely random orientation. It appears that the αAl_2O_3 results from the recrystallization of the γAl_2O_3.

The effect of oxygen pressure.—Figure 5 is an isometric projection showing the effect of oxygen pressure on the oxidation of the iron-4.94% aluminum alloy at 500°C. From 10 to 50 Torr there was only a slight increase in rate. Between 50 and 160 Torr there was a marked increase in rate. Increasing the oxygen pressure from 160 to 700 Torr produced little further increase in oxidation rate.

Several differences have been observed between the oxides formed in the two oxygen-pressure ranges. The outer layers of the films formed at 10 Torr up to about 570°C could be stripped mechanically whereas no part of the oxide formed at 700 Torr could be similarly removed. The oxide formed at 10 Torr appeared to consist of large single-crystal plates, whereas the oxide formed at 700 Torr consisted of very small randomly oriented crystals (Fig. 6). The portion of the film that could be stripped mechanically from the surface of specimens oxidized in oxygen at 10 Torr consisted mainly of αFe_2O_3. The whole film stripped chemically from specimens oxidized in oxygen at 700 Torr contained $FeAl_2O_4$, Fe_3O_4, and αFe_2O_3 but no Al_2O_3. These observations suggest that film separation occurred during oxidation of the iron-aluminum alloys at 10 Torr, but that the oxide remained in contact with the substrate at 700 Torr. This pressure-dependent phenomenon has been observed with the oxidation of pure iron, and various explanations have been proposed (20, 21).

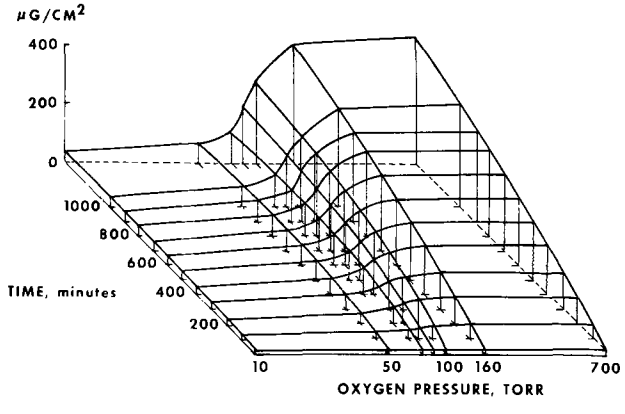

Fig. 5. Effect of oxygen pressure on the oxidation of an Fe-4.94% aluminum alloy at 500°C.

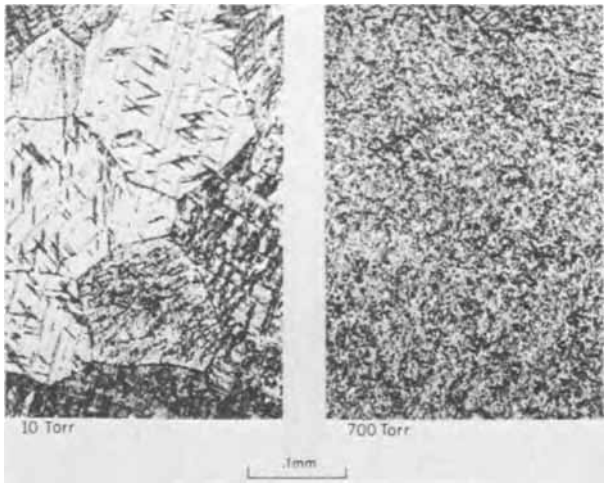

Fig. 6. Effect of oxygen pressure on crystal morphology of oxide formed on an Fe-4.94% Al alloy in 3900 min at 500°C.

It appears that the oxides of iron comprise the first major components of the films that form on the iron-aluminum alloys at temperatures up to 570°C. If the oxide is in intimate contact with the substrate, aluminum diffuses to the oxide-metal interface and reacts with the Fe_3O_4 to form a layer of $FeAl_2O_4$. When the initial oxide layer has separated from the substrate, the iron oxide in this layer is converted to αFe_2O_3. Oxygen, at reduced pressure, may enter the cavity under the separated layer and sustain oxidation of the substrate at a much reduced rate. The reduced oxidation rate allows aluminum time to diffuse from the substrate so that the concentration of aluminum in the new oxide is much higher than in scales that have formed without film separation. This argument is supported by the data given in Table II for the average iron and aluminum concentrations in some typical films. The aluminum-to-iron ratio of oxide formed at 10 Torr where separation occurs is always higher by at least a factor of 3 than the aluminum-to-iron ratio of oxide formed at 700 Torr where oxide separation apparently is not so extensive.

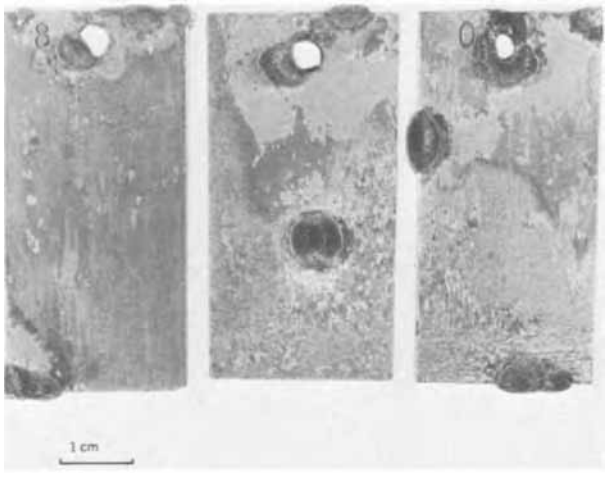

Fig. 7. Nodular oxide formed on commercial Fe-5.54% Al steel in air at 1093°C.

Nodular oxide.—Localized oxidation of iron through the protective aluminum oxide film that forms at the higher temperatures leads to the growth of corn-like nodes of iron oxide such as are shown in Fig. 7. These nodules were formed on an iron-5.54% aluminum steel in air at 1093°C for 192 hr. Nodular oxide also can occur on iron-aluminum alloys under milder conditions. Microscopic iron oxide nodules were grown on the Fe-8% Al alloy at 600°C in dry oxygen at 10 Torr.

The effect of nodular oxide growth on the over-all oxidation kinetics.—The influence of nodular growth on the over-all kinetics of oxidation of an iron-4.94% aluminum alloy in dry oxygen at 700 Torr is illustrated in Fig. 8. The oxidation rate decreases continuously at 600° and 700°C with the formation of $FeAl_2O_4$ in competition with Al_2O_3. However, at 800° and 900°C, the rate decreases for about 200 min during the growth of the protective alumina film and then increases to a maximum during the growth of iron oxide nodules before decreasing again. Examination of the surface of the alloy after the rate has begun to fall off shows that the nodules actually occupy only a small proportion of the total surface (Fig. 9). This observation, together with the decrease in oxidation rate, suggest that some mechanism operates to slow the growth or limit the size of the nodules and that new nodules do not continue to form. In general, the ultimate size seems to depend mainly on the oxidation temperature.

The morphology of nodular oxide.—A section through a typical corn-like oxide node is shown in Fig. 10. The hard outer shell is almost pure hematite, αFe_2O_3. The porous interior contains Fe_3O_4, FeO, and αAl_2O_3. (A crack through to the surface has admitted oxygen to form a hematite shell around the central cavity. Sometimes hercynite, $FeAl_2O_4$, is also detected in this region.) The metal in front of the alloy-

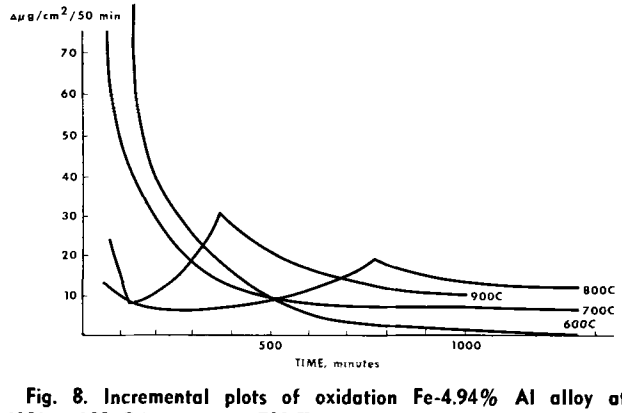

Fig. 8. Incremental plots of oxidation Fe-4.94% Al alloy at 600° to 900°C in oxygen at 700 Torr.

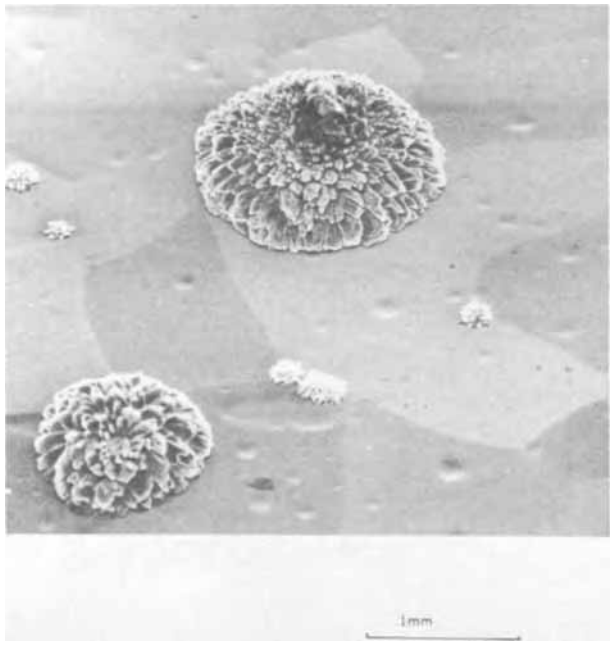

Fig. 9. Nodules formed on Fe-4.94% Al alloy in 1300 min of 800°C in oxygen at 700 Torr.

nodule interface polishes in relief indicating that this region is harder than the bulk of the alloy. Optical and microprobe images of an example of this region of relief polish are shown in horizontal section in Fig. 11. The oxygen image indicates a high concentration of oxygen in the relief-polished area of metal surrounding the oxide of the nodule. Aluminum is also shown

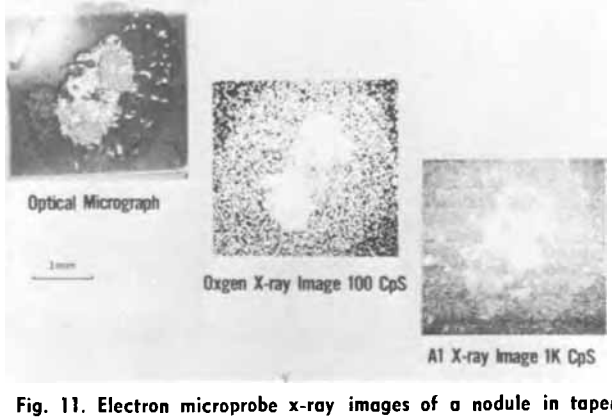

Fig. 11. Electron microprobe x-ray images of a nodule in taper section.

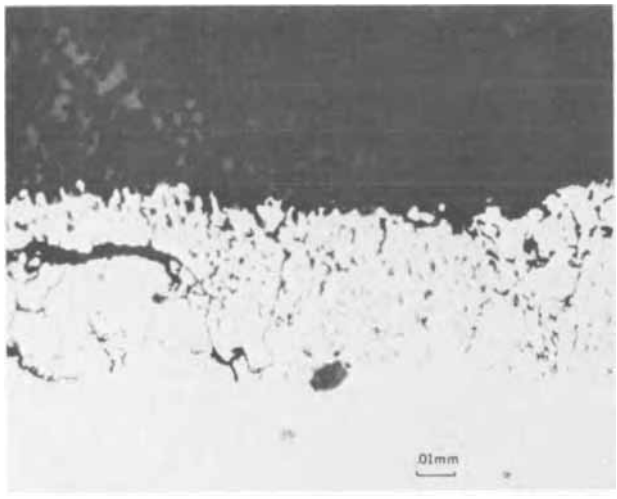

Fig. 12. Section through a nodule formed on commercial Fe-5.54% Al steel in air for 192 hr at 1093°C.

to be in higher concentrations in this area. A high magnification optical micrograph of a perpendicular section (Fig. 12), shows that the relief-polished area ahead of a nodule contains a second phase, a dispersion of small particles. The electron microprobe evidence of Fig. 11 indicates that this dispersed phase is aluminum oxide.

The nodules are apparently a localized manifestation of iron oxidation. The formation of the protective alumina film on the surface of this alloy depletes the alloy of aluminum in the region adjacent to the oxide so that this region becomes iron rich in comparison with the bulk of the alloy. When a break occurs in the alumina film, oxygen comes in contact with this iron-rich layer and nucleates an iron oxide nodule. Oxygen can diffuse through the iron oxide of the nodule into the substrate, where it then reacts with aluminum to form the dispersed alumina phase. This internal oxidation process precludes the diffusion of aluminum to the nodule-alloy interface that would be necessary to heal the crack in the original protective film.

Some oxide nodules are easily popped out of the substrate by using a sharp needle. The resulting pits contain a layer of white material found by x-ray diffraction to be αAl_2O_3. Since iron diffuses outward through the iron oxide phases that form the interior of a nodule, it seems reasonable to believe that the dispersed phase, αAl_2O_3 formed by internal oxidation, may accumulate and be compacted in sufficient quantity at the nodular oxide-metal interface during growth of the nodule to eventually isolate it from the metal substrate.

The effect of water vapor.—When oxidation experiments were conducted in the presence of water vapor, oxidation rates were substantially increased (Fig. 13), and there appeared to be little or no induction period before the beginning of nodule growth. There is relatively little difference in the oxidation kinetics in pure water vapor and in oxygen containing water vapor at 22 Torr in spite of the great difference in oxygen pressures.

Well-developed nodules could be detected with the scanning electron microscope after as little as 10 min at 800°C in the presence of water vapor. Incremental plots of the data from wet and dry oxidation experiments are shown in Fig. 14. In contrast to the behavior in dry oxygen, the oxidation rate increased continuously in the presence of water vapor, at least for the duration of the experiments. Estimates of the amount of surface containing nodules (per cent dark) after oxidation at 800°C for periods of 5 to 1000 min in oxygen dry or saturated with water vapor were made by using an Autoscan Reflectance Microscope. These

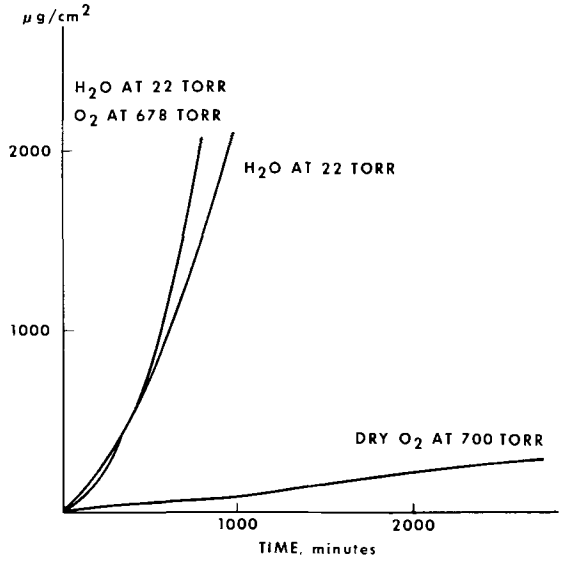

Fig. 13. Effect of water vapor on the oxidation of an Fe-4.94% Al alloy at 800°C.

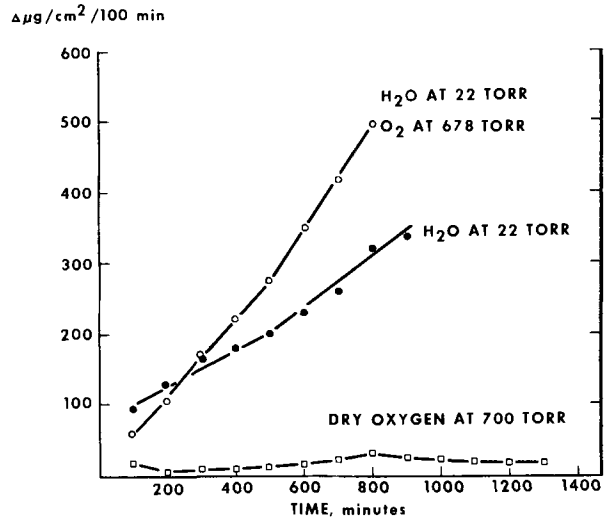

Fig. 14. Incremental plots of oxidation of an Fe-4.94% Al alloy at 800°C in water vapor and in wet and dry oxygen.

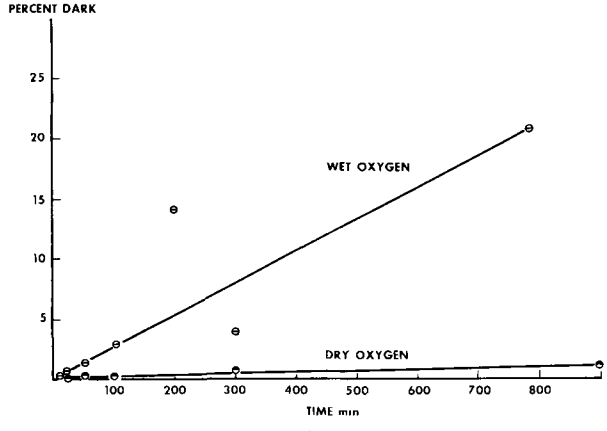

Fig. 15. Fractions of an Fe-4.94% Al alloy covered by nodular oxide at 800°C in wet and dry oxygen.

data are plotted in Fig. 15. If the data points for 200 and 300 min in wet oxygen are disregarded, the areal coverage by the nodules approximates to a linear relationship for at least the first 790 min. After 790 min at 800°C in wet oxygen, the proportion of surface involved was 20.6%. In contrast, after 1000 min in dry oxygen, the proportion of surface represented by nodules was only 1.14%.

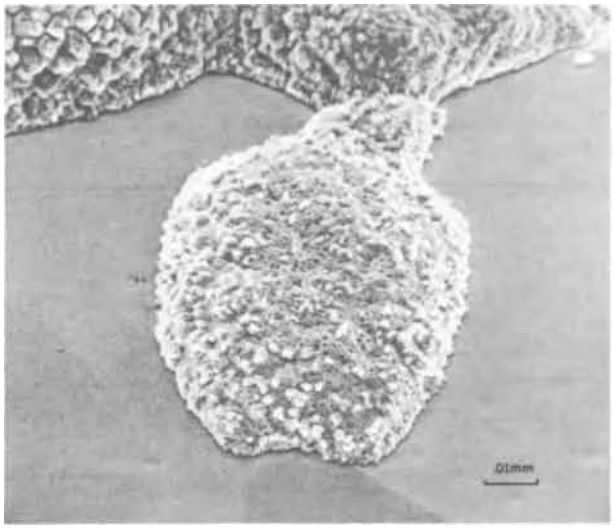

Fig. 16. Nodules formed on an Fe-4.94% Al alloy in 790 min at 800°C wet oxygen.

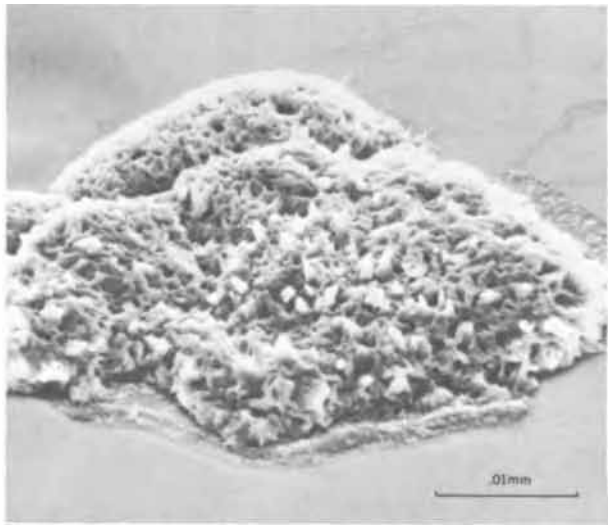

Fig. 18. Nodule formed on an Fe-4.94% Al alloy in 300 min at 800°C in wet oxygen.

Both the composition and the morphology of the oxide nodules are affected by water vapor. The major component of the nodular oxide formed in dry oxygen (Fig. 9) was cubic oxide (Fe_3O_4, γFe_2O_3, and/or $FeAl_2O_4$). The minor component was αFe_2O_3. In oxygen saturated with water vapor (Fig. 16), the major component of the nodular oxide was αFe_2O_3 and the minor component was cubic oxide. This change in composition probably resulted from penetration by oxygen deeper into the oxide nodules. Fujii and Meussner (22) have suggested that hydrogen from the dissociation of water vapor can act as a carrier to move oxygen across voids in oxide scale. A similar mechanism may account for the increase in the amount of hematite formed in wet oxygen, but it is difficult to explain the extremely high oxidation rate.

Examples of the nodular oxide formed in pure water vapor are shown in Fig. 17. The major component of these nodules was $FeAl_2O_4$, hercynite, and the minor component was cubic oxide. A nodule formed in 300 min at 800°C in water-saturated oxygen is shown in Fig. 18. This nodule is surrounded by a disturbed area that appears to result from plastic deformation of the substrate and the Al_2O_3 film to accommodate the increased subsurface volume of the oxide nodule.

At present, we have no clear explanation for the increased nucleation and growth of nodules in the presence of water vapor. The diffraction patterns of the oxides formed in wet oxygen at 800°C were more difficult to identify than the diffraction patterns from the aluminum oxides formed in dry oxygen. A hydrated form of aluminum oxide which is more easily cracked or separated from the substrate may be involved.

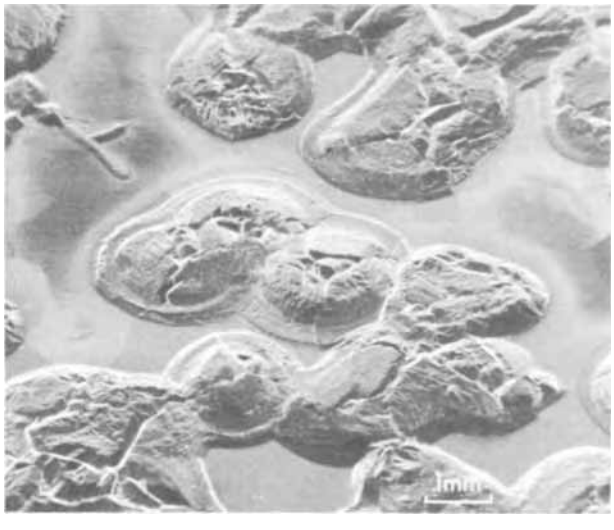

Fig. 17. Nodules formed on an Fe-4.94% Al alloy in 960 min at 800°C in pure water vapor.

The effect of carbon.—The behavior of iron-5.5% aluminum alloys containing up to 0.10% carbon at 500°C in oxygen at 10 Torr was similar to that of the iron-5% aluminum alloys. The oxide films apparently lost contact with the substrate resulting in a virtual halt of oxidation. The oxidation rate of the Fe-5.99Al-0.10C alloy was intermediate between the (low) rate of the Fe-4.94Al alloy and the (high) rate of the Fe-0.11C alloy. At the 0.1% carbon level, there are apparently enough vacancy sinks in the substrate to prevent the accumulation of vacancies at the oxide-metal interface, and the oxide remains in more intimate contact with the substrate. Carbon concentration had little effect on the oxidation rate at 700 Torr as the higher oxygen pressure prevented film separation (20, 21). The same three oxide phases, Fe_2O_3, Fe_3O_4, and $FeAl_2O_4$, that were formed on the Fe-4.94Al at 500°C were also formed on the iron-aluminum-carbon alloys under these conditions.

Above about 700°C the evolution of gas from the reactions between carbon and the iron oxides may interfere with the formation of a protective oxide film on iron-base alloys containing appreciable amounts of carbon (23). The effect of carbon concentration on the oxidation of the iron-carbon-aluminum alloys at 800°C is shown in isometric projection in Fig. 19. A sharp increase in oxidation rate with increasing carbon content is clearly evident. Microscopic examination of oxidized specimens revealed that a thin passive alumina film covered most of the surface of the alloys but that the frequency with which iron oxide nodules disrupted this film increased with increasing carbon concentration (Fig. 20). Most of the weight gain shown in Fig. 19 reflects the growth of nodular oxide, not film.

There appear to be two ways in which carbon can interfere with the protective alumina and allow nodular iron oxide to nucleate. The direct oxidation of carbon at random sites in competition with iron and aluminum might leave holes in the film at which nodules might nucleate. Alternatively, carbon from the substrate can react with iron oxides in the initial film to produce high pressure CO pockets which burst through the film and allow oxygen to reach the substrate, nucleating the nodular oxide.

Summary

As the aluminum concentration in iron-base alloys was increased from 0.003 to 0.09%, the oxidation rate

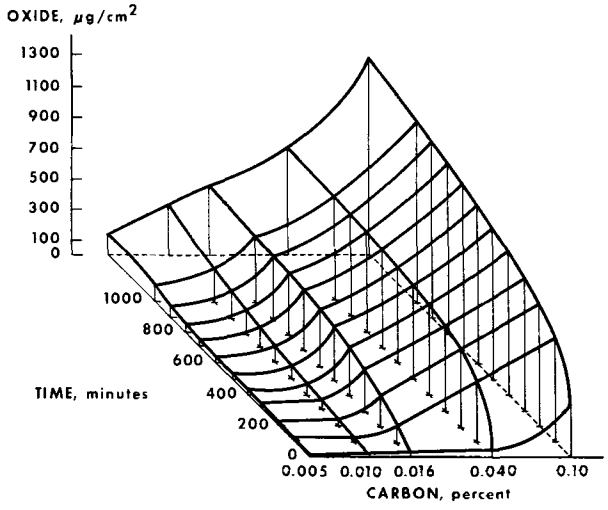

Fig. 19. Effect of carbon concentration on the oxidation of Fe-5.5% Al-C alloys at 800°C in oxygen at 700 Torr.

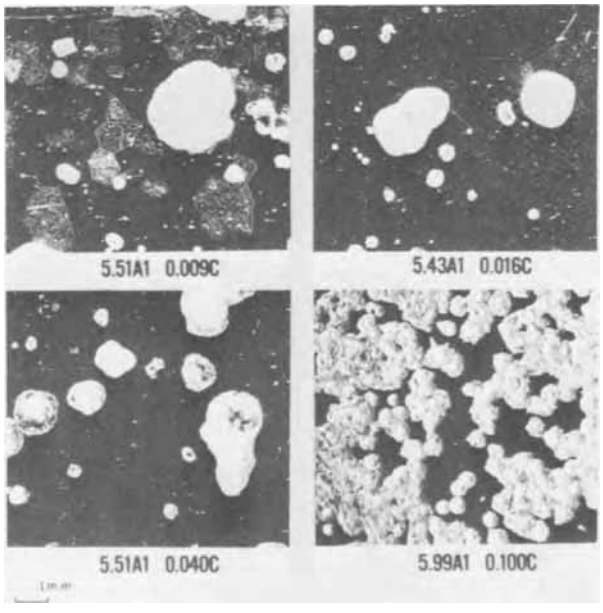

Fig. 20. Dark field optical micrographs showing effect of carbon concentration on the amount of nodular oxide formed on Fe-Al-C alloys in 1300 min at 800°C in oxygen at 700 Torr.

also increased. Above about 0.09% aluminum, the oxidation rate decreased with increasing aluminum concentration.

Up to 0.09% aluminum and at temperatures up to 570°C the scale consisted of two phases, αFe_2O_3 on the outside and Fe_3O_4 next to the metal. Above 0.09% aluminum a third phase, $FeAl_2O_4$, was found between the Fe_3O_4 and metal. This phase, hercynite, imparts oxidation resistance to the alloy.

Above 570°C, γAl_2O_3 began to appear in the scale and the oxidation rate decreased with increasing temperature. At 800° to 850°C the film was almost pure alumina and the oxidation rate was at its lowest.

As the oxygen pressure was increased at 500°C there was a slight increase in oxidation rate up to 50 Torr, a sharp increase between 50 and 160 Torr, and only a slight additional increase in rate between 160 and 700 Torr. Apparently, the initial oxide film tends to separate from the substrate during oxidation at pressures up to about 50 Torr. This creates cavities in which aluminum is preferentially oxidized to form a barrier layer under the outer iron oxide. Above 160 Torr, film separation did not appear to be a factor in the growth of the oxide, and consequently, oxidation rates were higher.

Localized oxidation of iron through the protective aluminum oxide film that forms on iron-aluminum alloys at the higher temperatures leads to the growth of corn-like nodes of iron oxide. The amount of nodular oxide increases with increasing temperature and increases in the presence of water vapor, but decreases with increasing aluminum concentration.

In dry oxygen, an initial period of γAl_2O_3 film formation precedes the increase in oxidation rate that accompanies the growth of nodular iron oxide. It is believed that the formation of an alumina film on the surface of an iron-aluminum alloy tends to decrease the concentration of aluminum in the zone near the oxide-metal interface. Any cracks or faults that may develop in the protective oxide film alloy oxygen to react with unprotected iron to form nodules. Internal oxidation ahead of the node-metal interface precipitates aluminum oxide dispersed in the iron matrix thereby preventing the healing of the protective oxide skin.

Water vapor increases the growth rate and alters the morphology and composition of the nodular oxide. Dry-formed nodules consist of an outer shell of Fe_2O_3 and a porous interior of Fe_3O_4, FeO and some αAl_2O_3. Nodules formed in wet oxygen contain a greater proportion of αFe_2O_3. The major component of the nodular oxide formed in pure water vapor is hercynite, $FeAl_2O_4$.

A three-phase scale consisting of αFe_2O_3, Fe_3O_4, and $FeAl_2O_4$ develops on Fe-Al-C alloys at 500°C. The innermost layer, $FeAl_2O_4$, causes a reduction in the oxidation rate compared with that of pure iron. Carbon at concentrations less than about 0.10% permitted film separation in oxygen at 10 Torr thereby causing abnormally low oxidation rates. Film separation did not occur at carbon level of 0.10%, and more nearly normal oxidation rates were observed. Carbon had no apparent effect on the oxidation at 500°C in oxygen at 700 Torr.

The oxidation rate of the Fe-Al-C alloys increased with increasing carbon concentration at 800°C. The thin protective film of alumina that formed on the binary Fe-Al alloy at 800°C also formed on the ternary Fe-Al-C alloy. Most of the observed weight gain was due to the growth of nodular iron oxide through this film. The frequency with which the nodules penetrated the passive alumina layer increased with increasing carbon concentration. Carbon apparently interferes with the integrity of this film so that oxygen can react with the iron in the substrate to form nodular oxide.

Manuscript submitted Oct. 12, 1970: revised manuscript received ca. Jan. 21, 1971. This was Paper 125 presented at the Atlantic City Meeting of the Society Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Characterization of Silicon Dioxide Films by the Electron Probe

B. Swaroop*

Kelsey-Hayes Research and Development Center, Ann Arbor, Michigan 48105

ABSTRACT

The morphological and compositional characterizations of thermally grown silicon dioxide films on a silicon substrate have been conducted exclusively by the use of the electron probe. The linear increase of oxygen x-ray intensity with the thickness of the films (<2000Å) demonstrates the feasibility of a quick method of finding the unknown thickness. The range of penetration of electrons in the oxide films shows 3/2 power low dependence with the accelerating potential of the beam. The quantitative analysis of oxygen content in thin as well as thick films has been obtained by using the appropriate absorption and atomic number corrections.

Silicon dioxide films have drawn great attention as dielectric in the semiconductor technology. The effectiveness of these films over the devices is very much dependent upon their purity, porosity, stoichiometry, and conductivity. Therefore, quick analysis of these films with respect to their mass thickness, contamination, stoichiometry, and valence state of their constituents is very desirable. The present investigation dealt with the compositional as well as the morphological characterization of silicon dioxide films with the use of an electron probe.

Theory

In the electron probe instrument, high energy electrons (5 to 50 keV) are brought into focus to the required diameter size of the beam spot (>1μ) on the surface of the material to be analyzed. The characteristic x-rays emitted from the sample are monochromatized by curved crystal and detected by the proportional counter. The measured x-ray intensity for a characteristic peak is used to determine the amount of the element present in a given sample. The details of the techniques involved in such measurements are elaborately given elsewhere (1, 2).

An electron beam is excited at potential energy V (keV) impinging normally on a thick specimen, as shown in Fig. 1a, and produces the characteristic x-ray until the electron energy reduces to less than excitation potential (E_c) of the given element. However, from the total number of electrons impinged on the surface, a small fraction are backscattered as shown by mode 1 (Fig. 1) and the rest of them, as shown by mode 2, are responsible for producing the x-ray. During the traverse of electrons in the specimen, the total number of ionizations (N) produced before the electron energy reduces to less than E_c is given by (3-6)

$$N_{(A)} = \frac{C_{(A)}N_0}{A} R_{(A)} \int_{E_c}^{V} (\phi_A/S_{(A)}) \cdot dE \qquad [1]$$

where C_A is the concentration of element "A" in the given compound or alloy, N_0 is the Avogadro number, A is the atomic weight, $R_{(A)}$ is the remaining fraction of ionizations when the loss due to backscattering is removed (4, 6), $S_{(A)}$ is the specific deceleration power for electrons (6), and ϕ_A is the x-ray ionization cross-section of atoms "A". The subscript (A) defines that each term corresponds to an alloy or compound.

A similar expression can be obtained for a number of ionizations obtained from pure bulk element "A". Thus, in the absence of x-ray absorption and fluorescence effects, the ratio $K_{(A)}$ is given by

$$K_A = I_{(A)}/I_A = C_{(A)}R_{(A)} \int_{E_c}^{V} (\phi_A/S_{(A)}) \cdot dE \Big/ C_A R_A \int_{E_c}^{V} (\phi_A/S_A) \cdot dE \qquad [2]$$

where $I_{(A)}$ and I_A are the observed intensities of element "A" in a given compound and in pure standard respectively. However, if pure solid standard is not available, *e.g.* oxygen in the case of silicon dioxide, then $I_{(A)}$ would be compared with a similar compound of known concentration (C_s). In the latter case, the above expression will become simply

$$I_{(A)}/I^s_{(A)} = C_{(A)}/C_s \qquad [3]$$

The above Eq. [3] is only true if compound standard is exactly of the same composition as that of unknown. Otherwise Eq. [2] still must be used but replacing C_A with C_s.

Key words: thickness, stoichiometry, x-ray, thin films.

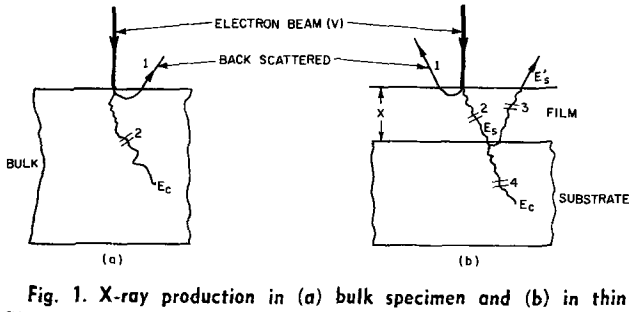

Fig. 1. X-ray production in (a) bulk specimen and (b) in thin films.

When the electrons are impinging on a thin film (7), as shown in Fig. 1b, the energy of the electrons at the interface of the substrate reduces to a value of E_s ($E_s > E_c$). In such a situation, further contributions to ionization are produced by two extra modes (modes 3 and 4 as shown in Fig. 1b). Mode 3 is due to backscattered electrons from the substrate. The number of backscattered electrons depends upon the backscattered yield (η) of the substrate. The ionization will be produced by this mode as long as the energy of the electron is above E_c potential of the given element. The fourth mode is contributed due to the penetration of electrons in the substrate, provided the element "A" is present in the substrate. Following the treatment of Colby (7) the observed x-ray intensity for element "A" is given by

$$I_{(A)} \propto C_{(A)} \left[R_{(A)} \int_{E_s}^{V} (\phi_A/S_{(A)})\,dE + \eta R_{(A)} \int_{E'_s}^{E_s} (\phi_A/S_{(A)}) \cdot dE \right] + C'_A\,(1-\eta)\,R_S \int_{E_c}^{E_s} (\phi_A/S_S) \cdot dE \quad [4]$$

where, R_s and S_s are usual terms for the substrate as explained earlier. The lower limit E'_s in one of the integrals is the exiting electron energy after producing the ionization by mode 3. When the substrate does not contain the analyzed element, the observed intensity is contributed only from the first two integrals of Eq. [4]. Such is the case for the analysis of oxygen in silicon dioxide films on the silicon substrate.

In order to calculate $C_{(A)}$ from the K ratio, the observed intensities are to be corrected for x-ray absorption, atomic number, and fluorescence effects in the sample as well as in the standard. The expressions [1], [2], and [4] given above include the atomic number effect, *i.e.* the use of terms R and S with each ionization.

In the present investigation for the determination of oxygen and silicon content, the amorphous silica and silicon dioxide films were used. The experiment results were corrected by using modified Philbert's absorption correction (8, 9) and Poole-Thomas electronic interaction correction (5) for thick films. For thin films, atomic number correction was calculated according to the treatment given by Colby (7). The modified Philbert's absorption correction is given by

$$f(\chi) = (1+h)/(1+\chi/\sigma_c)\,[1+h(1+\chi/\sigma_c)] \quad [5]$$

where, $\chi = (\mu/\rho)$ cosec θ; (μ/ρ) is the mass absorption coefficient, θ is the x-ray emergence angle, $h = 1.2\bar{A}/\bar{Z}^2$, $\bar{A}$ is the mean atomic weight, Z is the mean atomic number, and σ_c is the modified Lenard coefficient as given by Heinrich (10)

$$\sigma_c = (4.5 \times 10^5)/(V^{1.67} - E_c^{1.67}) \quad [6]$$

The mass absorption coefficient (μ/ρ) for OK_α and SiK_β emission lines are taken from the values given by Henke *et al.* (11). For thin specimen, the absorption is taken into account by replacing E_c in Eq. [6] with E_s.

Experimental Procedure

The amorphous silicon dioxide films were grown on silicon substrate as described elsewhere (12). The silicon substrate was approximately 0.012 in. thick and the thickness of the films range between 200 and 15,000Å. The thickness of the films were measured mainly by the Tolansky method (13) which gave an accuracy of ±10Å in the measurements.

The electron probe was operated between 5 and 30 keV at 0.8 x 10^{-7}A specimen current for amorphous silica and with a beam diameter of 15μ. The intensity measurement for OK_α and Si emission bands were obtained using lead stearate crystal in vacuum. A thin window flow proportional counter with flowing gas mixture of 75% methane and 25% argon at atmospheric pressure was used. The measured intensities were as the peak intensity minus the off peak background count. The spectrometer was peaked for the characteristic line of unknown films as well as standards in order to avoid the effects of wavelength shift. All counts were accumulated for a given period of time. The observed intensities were corrected for dead time of the counting circuit.

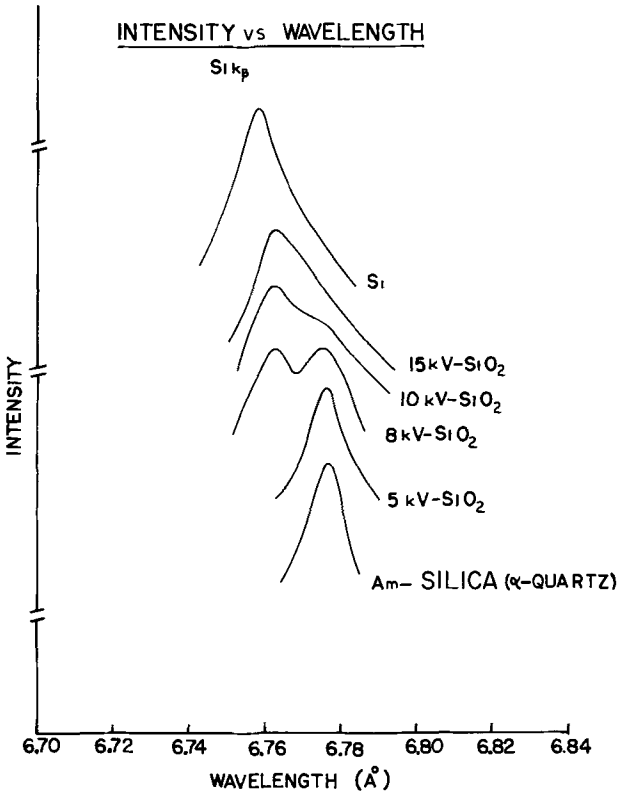

Fig. 2. Silicon (K_β) emission bands from pure silicon, amorphous silica and silicon dioxide films.

Results and Discussion

The SiK_β emission bands were first observed from bulk amorphous silica, α-quartz and 1700Å thick silicon dioxide film on the silicon substrate. Figure 2 summarizes the data obtained at various exciting potentials of the electron beam. The silicon peak position in pure silicon and amorphous bulk silica are observed at 6.758 and 6.776Å respectively. Similarly, the peak from α-quartz indicated the position very close to that of bulk silica. These emission wavelengths were observed to be almost independent of accelerating potential between 5 and 30 keV. At excitation potential of 5 keV, the peak position in the oxide film is almost coinciding with that from bulk silica; this indicates that electrons do not reach the substrate with sufficient energy to ionize the photons from the substrate. At 8 keV beam potential, there were observed two peaks of nearly equal intensities suggesting that electrons arrive with sufficient energy to excite the silicon photons from the substrate. However, at 10 and 15 keV, the silicon peak positions are close to that of pure silicon. Thus, the main contribution to the x-ray intensity is from photons being excited from the silicon substrate. These observations are very similar to that reported by Knausenburger *et al.* (14). From this data it was inferred that in order to use SiK_β emission band for analyzing the valence state of thin oxide films, or to use SiK_α peak for stoichiometric analysis of these films, one ought to work at low accelerating potentials (*i.e.* between 5 and 8 keV) so that x-rays are not excited from the substrate. On the other hand, OK_α emission band should be used in order to avoid $(1-\eta)$ substrate correction as given in expression [4]. Another important inference that can be drawn from

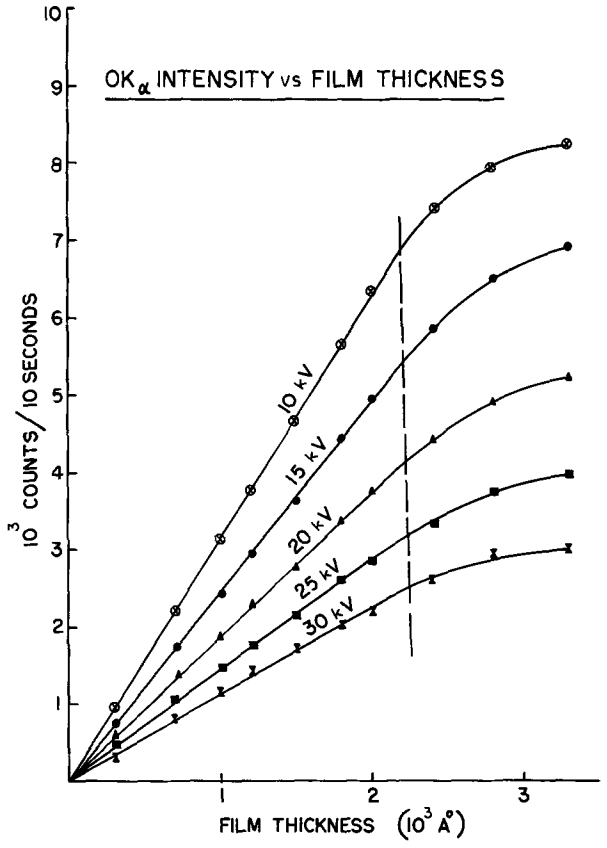

Fig. 3. Oxygen (K_α) intensity from various thicknesses of silicon dioxide films at given accelerating potentials.

these peak positions (Fig. 2) is that oxide films under investigation are essentially free from elemental silicon and that silicon is in a divalent state.

On the basis of the above analysis, the x-ray intensity for the OK_α peak from various thicknesses of the oxide films at beam potentials of 10, 15, 20, 25, and 30 keV were investigated. As shown in Fig. 3, the plots at various potentials are almost linear in the film thickness ranging from 0 to 2000Å. The intensity count rate increases linearly with the thickness. Such a linear relationship really offers a quick method of finding an unknown thickness of a given film (<2000Å) provided a calibration curve has been obtained at any given accelerating potential.

The x-ray intensity (I_F) observed from the films can also be written in terms of absorption attenuation as opposed to the atomic number effect alone as given by Eq. [1] and [4]. Such an expression is given by

$$I_F \propto \int_o^{\rho x} \phi_A(\rho x')\, e^{-\chi \rho x'} \cdot d(\rho x') + \eta \int_o^{\rho x} \phi_A(\rho x - \rho x')\, e^{-\chi \rho x'} \cdot d(\rho x') \quad [7]$$

where ρx is the mass thickness of the film, and χ is the x-ray absorption parameter. The other terms of this equation have been explained earlier. For the second integral in Eq. [7] it has been assumed that back scattered electrons are near normal to the substrate. For thin films, the x-ray excitation function $\phi_A(\rho x')$ may be approximated as (15)

$$\phi_A \approx 1 + \delta \rho x, \text{ for } \delta \rho x < 1 \quad [8]$$

where the parameter δ is the measure of electron diffusion within the film material. This parameter increases rapidly with decreasing accelerating voltage and much more slowly with increasing atomic number. The value of δ can be calculated from the initial slope of x-ray excitation curves (16) as shown in Fig. 5, or from theoretical calculations using various electron scattering theories, or from curve fitting of accurate thin film data. After substituting Eq. [8] into Eq. [7], integrating and expanding for $\delta\rho x$ and $\chi\rho x$ each being less than 1, the following expression is obtained

$$I_F \propto (1+\eta)\,\rho x\left[1 + \rho x\left(\frac{\delta}{2} - \frac{\chi}{2}\right) - (\rho x)^2\left(\frac{\delta\chi}{2} - \frac{\chi^2}{6}\right) + \ldots\right] \quad [9]$$

$$\propto \sum_1^{\infty} (1+\eta)\,(\rho x)^n\,(-1)^n \left[\frac{\delta\chi^{n-2}}{(n-1)!} - \frac{\delta\chi^{n-2}}{n!} - \frac{\chi^{n-1}}{n!}\right]$$

Relation [9] indicates that x-ray intensity is directly proportional to the mass thickness of the film as long as δ is approximately equal to χ. However, if $\delta <$ or $> \chi$, then the deviation from the linearity will be observed.

Figure 4 compares the computer analysis of expression [9] with that of obtained data. It is found that as long as $\delta \approx \chi$,the linear relationship between measured intensity and mass thickness of the films is observed. Beyond the film thickness of (50-55) 10^{-6} g/cm^2 the deviation from the linearity is evident. An excellent fit between the computer analysis and experimentally obtained data is shown in Fig. 4. For this analysis, the value of δ and η (15) were used as 1.8 x 10^4 cm^2/g and 0.16 respectively. Further, Eq. [9] predicts the negative and positive deviation for $\delta < \chi$ and $\delta > \chi$ respectively. It appears that the negative deviation is observed for silicon oxide films at all the accelerating potentials (Fig. 3 and 4).

The ratio of measured oxygen intensities from the films (I_F) to that of bulk silica (I_B) at various thicknesses of the films are shown in Fig. 5. These plots are for various accelerating potentials. Similar to that observed in Fig. 3, the normalized intensity rose linearly in the beginning. At higher thicknesses the ab-

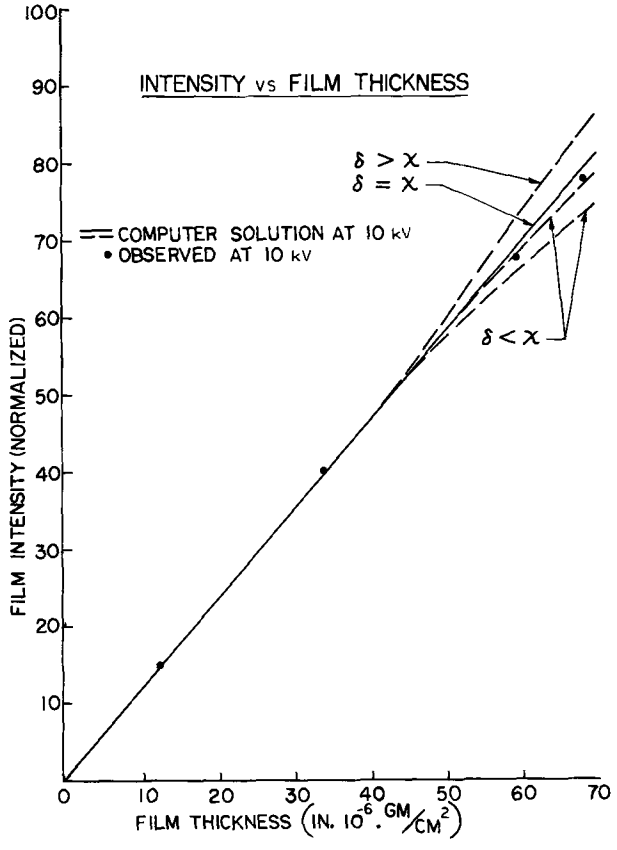

Fig. 4. Comparison between observed oxygen intensity and that calculated from the computer for various thicknesses of the films.

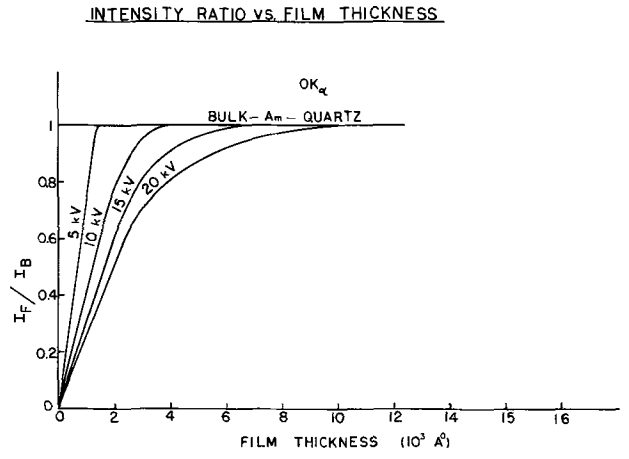

Fig. 5. Ratio of measured oxygen intensity from the films to that of bulk silica.

sorption effect, as indicated by Eq. [7], comes into play and thus an exponential rise is observed. At the thickness, where the measured intensity from the films is nearly the same as that of the bulk, the electrons are exciting the photons only from the film. In such a case, the energy of electrons before reaching the substrate reduces to less than E_c, the excitation potential of the oxygen. Therefore, this thickness level, where $I_F \approx I_B$, is then the effective penetration of electrons at the given accelerating potential. Figure 6 shows such thickness levels of oxide films at various accelerating potentials. A straight line relationship of the type

$$R_x = CE^p \qquad [10]$$

is observed, where the exponent p is found to be 1.5 and C is a characteristic constant. Cosslett and Thomas (17) have also shown that the mean as well as the extrapolated range follow the 3/2 power law. Similar dependence has also been observed by Colby (7) for various dielectric films.

The determination of the range in Eq. [10] is very important in order to calculate the energy of electrons at a given depth (x) in the films or at the interface of the substrate and film or at zero thickness when electrons are exiting with energy greater than E_c, *i.e.* via mode 3 in Fig. 1b. The simple modification of Eq. [10] in terms of energy of electrons and film thickness can be written as (17)

$$x = \frac{C'\bar{A}}{\rho\bar{Z}} V^{1.5} \qquad [11]$$

where, x is film thickness in Å, ρ the density in g/cm³, $\bar{Z}$ the mean atomic number, $\bar{A}$ is the mean atomic weight, V the accelerating potential of the electrons in keV, and C' the instrument constant which is 195 for silicon dioxide films.

Figures 7 and 8 show the measured as well as corrected OK_α intensities respectively for 3300 and 1500Å thick films at various accelerating potentials. The observed intensities in both the cases indicate decrease with increase in accelerating potential. This effect is mainly due to absorption attenuation of the x-ray and decrease in efficiency of producing photons with increase in accelerating potentials because of relatively constant volume of excitation in thin films. When these raw intensities were corrected for absorption and atomic number effects, the corrected intensities are much higher and they increase with accelerating potential. Further, it is worth noting that above 1500Å thick films (Fig. 7 and 8) the observed as well as corrected intensities show a linear relationship with accelerating potential. However, in thin films ($\leq$ 1500Å), such a linear relationship tends to show a curvature, probably owing to electrons straggling or noticeable fluorescence effect at high working potentials.

Figure 9 shows the corrected OK_α intensities for bulk amorphous silica and for oxide films of 12,000 and 2000Å thicknesses. It should be noted that the intensities for bulk and 12,000Å thick film are almost equal (within 1 to 2%) in the range of 10 to 20 keV. As observed in Fig. 5, at these potentials the 12,000Å thick film is within the penetration range of electrons. Thus, for quantitative analysis of oxygen in these films, the

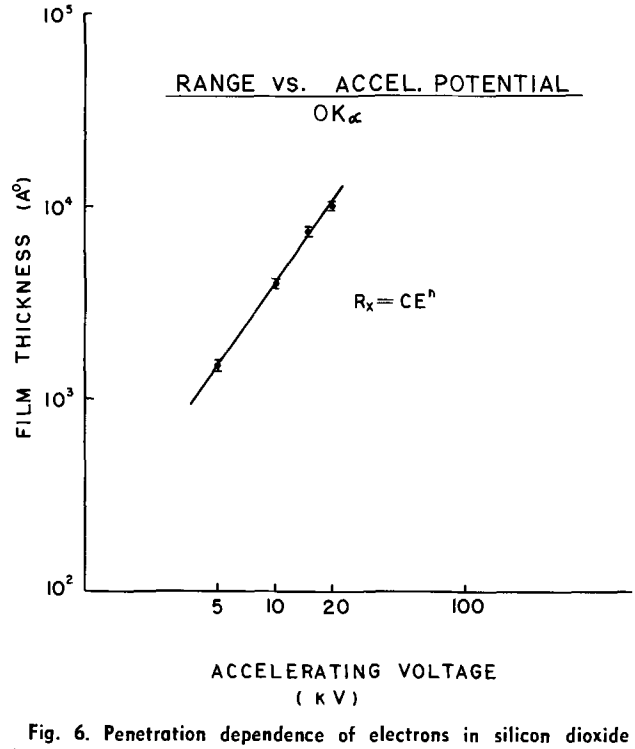

Fig. 6. Penetration dependence of electrons in silicon dioxide films at various accelerating potentials.

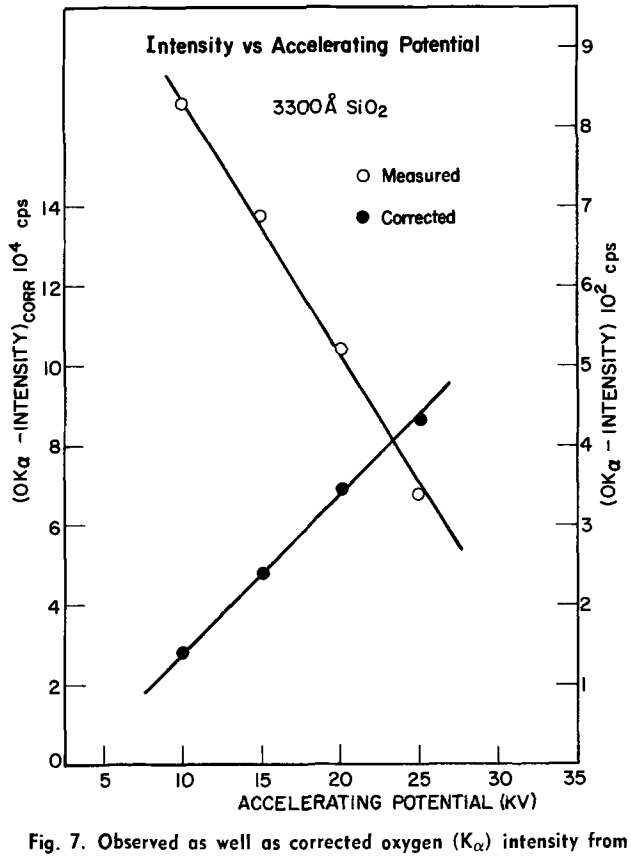

Fig. 7. Observed as well as corrected oxygen (K_α) intensity from 3300Å thick oxide film.

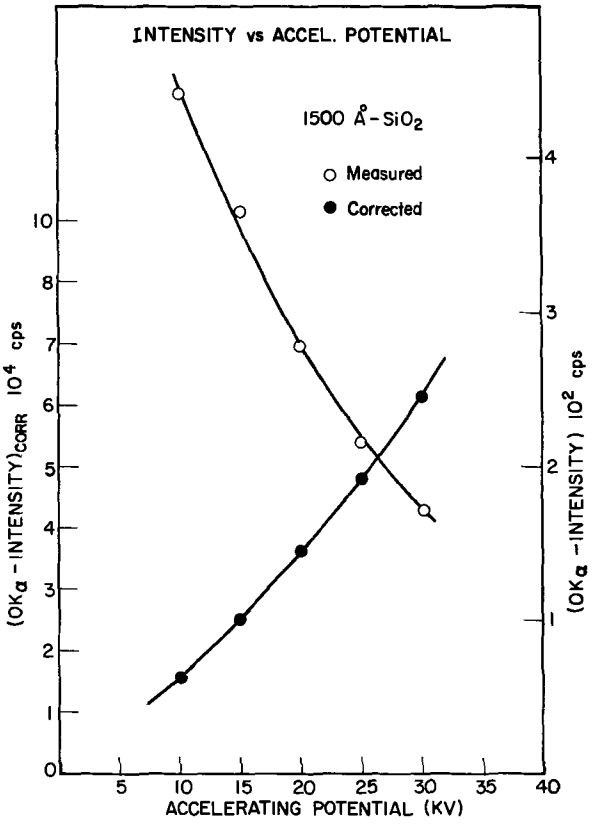

Fig. 8. Observed as well as corrected oxygen (K_α) intensity from 1500Å thick oxide film.

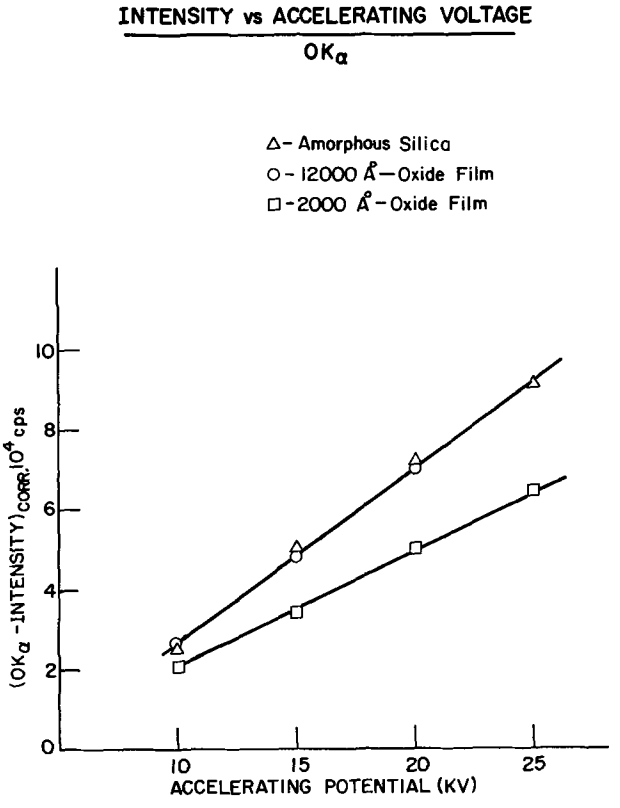

Fig. 9. Corrected oxygen (K_α) intensities from bulk silica and from oxide films (12,000 and 2000Å) at various accelerating potentials.

η-substrate correction (Eq. [4] and [7]) is not required. However, for 2000Å thick film, the actual K ratio has to be calculated after having considered the excitation of x-ray by mode 3 (Fig. 1b). Further, at any given accelerating potential, the observed intensity for 2000Å thick film is less than that of 12,000Å thick film. This is so only because in thin films the total electron energy has not been used for excitation of oxygen photons.

Table I gives the typical quantitative analysis of oxygen content in various silicon dioxide films. In arriving at the observed mass concentration given in column 4, Eq. [1] to [10] have been used. The observed mass concentration of oxygen has been found to lie within 1-2% of the theoretical mass concentration. Similarly, the silicon content of these films can also be evaluated (18). However, for thin films analyzed at high accelerating potential, the additional $(1 - \eta)$ term as given in Eq. [4] has to be considered. For the quantitative calculations the IBM 1130 computer was used.

Figure 10 shows the OK_α x-ray scan of oxide area which contains an intentionally created step of 500Å. The bright area represents the oxide thickness of 700Å and the less bright area is approximately 200Å. Such a variation in intensities could be visualized to a minimum difference in thickness of 200Å. However, to obtain a photograph of such an area containing a small difference in thickness, the scanning, pulse height, and photographic conditions have to be optimum.

Conclusions

From the present investigation it may be concluded that characterization of silicon dioxide films or other dielectric films (19) with respect to their morphology as well as composition can be achieved by the use of the electron probe. These films may either be grown or deposited on a substrate. The mass thickness of thin films of silicon dioxide in the range of 100 to 2000Å can routinely be measured once the calibration curve has been obtained. However it should be emphasized that simultaneous determination of thickness and composition is not possible by the use of probe alone. Either one has to be supplemented by some other method. Such measurements offer a quick nondestructive method for finding the thickness, variation in thickness, and stoichiometry of the films. These techniques as explored by the use of the electron probe can be of utmost significance in semiconductor technology.

Cathodoluminescence of Ce^{3+}- and Eu^{2+}-Activated Alkaline Earth Feldspars

K. R. Laud, E. F. Gibbons, T. Y. Tien,* and H. L. Stadler*

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The compounds $MAl_2Si_2O_8$, where M = Ca, Sr, or Ba, were synthesized. Compositions in the three binary systems were also prepared. Cathodoluminescence of these compositions activated with Ce^{3+} and Eu^{2+} was studied. It was found that the Ca and Sr feldspars formed complete solid solutions. In the systems Ba-Ca feldspars and Ba-Sr feldspars, only partial solid solutions are formed. The solid solubility limits are

$SrAl_2Si_2O_8$ to $Sr_{0.6}Ba_{0.4}Al_2Si_2O_8$
and $BaAl_2Si_2O_8$ to $Ba_{0.8}Sr_{0.2}Al_2Si_2O_8$
$CaAl_2Si_2O_8$ to $Ca_{0.9}Ba_{0.1}Al_2Si_2O_8$
and $BaAl_2Si_2O_8$ to $Ba_{0.6}Ca_{0.4}Al_2Si_2O_8$

Both the Ce^{3+}- and Eu^{2+}-activated phosphors give broad emission bands under cathode-ray excitation. The peak positions of the emission for Ce^{3+}-activated phosphors are

$CaAl_2Si_2O_8$ — 355 and 490 nm
$SrAl_2Si_2O_8$ — 530 nm
$BaAl_2Si_2O_8$ — inert

and those for Eu^{2+}-activated phosphors are

$CaAl_2Si_2O_8$ — 470 nm
$SrAl_2Si_2O_8$ — 465 nm
$BaAl_2Si_2O_8$ — 375 and 500 nm

The peak position of the cathodoluminescent emission of the solid solutions for both Ce^{3+} and Eu^{2+} as activators depends on the major alkaline earth cation in the host. No significant shift from the pure compound was observed.

C^{3+}- and Eu^{2+}-activated phosphors are known to give broad-band emission under cathode-ray excitation (1). The emission peak depends on the host and is found to occur from the near ultraviolet to the yellow-red region of the spectrum. A solid solution series of isostructural end members with slightly different sized cations as hosts would be an ideal system to study the effect of crystal chemical variation

* Electrochemical Society Active Member.

Key words: phosphors, luminescence, cathodoluminescence, feldspars, cerium, europium, aluminosilicates.

on the luminescence of Ce^{3+} and Eu^{2+} ions. Moreover, it offers the possibilities of finding useful phosphors for commercial applications.

The alkaline earth aluminosilicates (known as alkaline earth feldspars) $MAl_2Si_2O_8$ (where M = Ba, Sr, Ca) crystallize in network structures and are known as stuffed derivatives of silica. The ionic radii of these alkaline earth ions are comparable to those of the Ce^{3+} and Eu^{2+}. The tabulated ionic radii (Pauling's) are Ca^{2+} = 0.99Å, Sr^{2+} = 1.13Å, Ba^{2+} = 1.35Å, Eu^{2+} = 1.12Å, and Ce^{3+} = 1.11Å. The sites available to the activators, therefore, should be those of the alkaline earth ions, since the fourfold sites in this structure are too small for the ions having a size larger than 1Å. The sites for 1Å size ions are the hexagonal structural holes in the feldspar network.

Reference to luminescence in feldspars was made as early as 1939 (2, 3). However, luminescence in binary alkaline earth feldspar systems has not been reported previously. Subsolidus phase relations in the three mutual binary systems of $CaAl_2Si_2O_8$, $SrAl_2Si_2O_8$, and $BaAl_2Si_2O_8$ have not been studied prior to this work. One would expect an extensive series of solid solutions in the three binary systems $CaAl_2Si_2O_8$-$SrAl_2Si_2O_8$, $SrAl_2Si_2O_8$-$BaAl_2Si_2O_8$, and $BaAl_2Si_2O_8$-$CaAl_2Si_2O_8$ because of the similar feldsparlike structure of the compounds and also because of the close ionic radii of the cations. These solid solutions would enable one to study the variation of cathodoluminescent emission spectra with composition.

Structural Information on the Hosts

The feldspars are a group of mineral structures based on an infinite three-dimensional silicon-oxygen framework. In alkaline earth feldspars, half of the tetrahedral positions in the framework are occupied by Al^{3+} and the other half by Si^{4+} so that, for every two Al^{3+}, one divalent Ca^{2+}, Sr^{2+}, or Ba^{2+} is introduced to neutralize the negative charge of the $(Si,Al)O_2$ framework. These large cations take the interstitial positions. The ratio of (Si + Al) to O must always be 1:2 since every Si or Al is surrounded tetrahedrally by four oxygen atoms and each of these is common to two tetrahedral groups. The silicon-oxygen framework for all of the alkaline earth feldspars is essentially the same; however, there are differences in crystal symmetries which are due to the difference in the size of the cations around which the framework closes in. Alkaline earth feldspars are $CaAl_2Si_2O_8$ (anorthite), $SrAl_2Si_2O_8$, and $BaAl_2Si_2O_8$ (celsian). According to Wyckoff (4), in anorthite ($CaAl_2Si_2O_8$) the Ca-atom has six or seven close oxygen neighbors at distances between 2.28 and 2.82Å. In celsian ($BaAl_2Si_2O_8$), the Ba-atom has nine oxygen neighbors at distances between 2.667 and 3.135Å, as well as a tenth somewhat more distant at 3.421Å. Both Ca and Sr feldspar have triclinic symmetry and the Ba feldspar is monoclinic. There are other polymorphs of these feldspars; however, they are either metastable or the stability region is outside of the temperature of preparation for this study. The polymorphs dealt with in this paper are the high-temperature phases. A brief discussion of these polymorphs follows.

Eskola (5) prepared both strontium and barium feldspars by heating oxides to 1400°C with $Sr(VO_3)_2$ and $Ba(VO_3)_2$ as fluxes and characterized the products using a petrographic microscope. He also found that a homogeneous mixture of 50 w/o (weight per cent) $SrAl_2Si_2O_8$ and 50 w/o $CaAl_2Si_2O_8$ has indexes of refraction the same as those of $CaAl_2Si_2O_8$. He postulated that Sr-feldspar formed a complete series of solid solutions with Ca-feldspar.

Davis and Tuttle (6) reported two crystalline phases of $CaAl_2Si_2O_8$ composition. One phase had a feldsparlike structure (that of anorthite). The second phase, which was metastable, had a hexagonal structure.

Sorrell (7) prepared strontium and barium feldspars in the solid state using mixtures of kaolin-type clays and Ba- or Sr-sulfates. The barium compound showed a metastable hexagonal phase which was very persistent and required prolonged heating to convert it to stable celsian (feldspar). The strontium compound also showed a hexagonal phase which was unstable and detectable only during continuous x-ray investigation. He suggested that the hexagonal phase is not a high-temperature polymorph of feldspar, but rather a metastable form produced as a result of rapid crystal growth. The stable phase of the barium feldspar had monoclinic symmetry and the strontium feldspar was triclinic.

Ito (8) determined the crystal structure of hexacelsian (a hexagonal form of $BaAl_2Si_2O_8$) and found it to consist of a double sheet of silica-alumina tetrahedra with common apexes, held together by barium ions in 12-fold coordination.

More recently Lin and Foster (9), during an investigation of $BaAl_2Si_2O_8$ polymorphism, concluded that there are four polymorphs of $BaAl_2Si_2O_8$ (*viz.*, paracelsian, orthorhombic form, hexacelsian, and celsian). Monoclinic celsian was stable from room temperature to 1590°C, where it inverted sluggishly to hexacelsian. The latter, stable to the melting point (1760°C), persisted metastably on cooling below 1590°C and inverted to the orthorhombic form through 300°C. Naturally occurring paracelsian was found to be a metastable phase which changed monotropically through hexacelsian to celsian at temperatures as low as 500°C.

Experimental

The starting materials used for the preparation of batches were $CaCO_3$, $SrCO_3$ $BaCO_3$, CeO_2, Eu_2O_3, aluminum hydroxide, and silicic acid. Except for CeO_2 and Eu_2O_3, which were phosphor grade, reagent-grade chemicals were used.

In all compositions, Ce^{3+} and Eu^{2+} concentrations were maintained at 1 and 2 m/o (mole per cent), respectively. Prior to formulation, weight loss factors for aluminum hydroxide and silicic acid were determined. Since Ce^{3+} was substituted for Me^{2+} (Me^{2+} = Ca^{2+}, Sr^{2+}, or Ba^{2+}), charge balance was accomplished as follows: for $MeAl_2Si_2O_8$:Ce, the formulation was 99 parts $MeAl_2Si_2O_8$ and 1 part $CeAl_3SiO_8$.

Weighed batches were mixed under acetone, air dried, calcined in platinum crucibles to 800°C, remixed, and finally fired at 1400°C for 24 hr. The products were ground and placed in alumina boats which were heated in an atmosphere of nitrogen with 3% hydrogen at 1100°-1200°C for 18 hr. Samples were cooled to room temperature in the reducing atmosphere.

Crystalline phases were identified by a Norelco x-ray diffractometer using a scanning rate of 2θ = 1 deg/min as a routine. For precise "d" spacing and lattice parameter measurements, a slow scanning rate of ¼ deg/min and silicon as an external standard were employed. The lattice parameters were calculated using at least 10 diffraction lines by the least-squares method using a computer program.

The cathodoluminescence (C.L.) data were obtained in a demountable electron beam gun system operated at 3 kV. Samples were mounted at the focal point of an optical system which then refocused the emitted light on the entrance slit of a ¾m Czerny-Turner spectrometer. The output from a photomultiplier (P.M.) tube, located at the exit slit of the spectrometer, was amplified by means of a synchronous detector and displayed on an x-y recorder. The required periodic signal for the P.M. tube was obtained by applying a 13 Hz square wave to the horizontal deflection plates of the electron beam gun, thus providing a 50%

excitation duty cycle on the sample. The same square-wave generator provided the reference signal for the synchronous detector.

The excitation spectra were taken in a system utilizing a xenon light source focused through a mechanical light chopper onto the entrance slit of a ¾m spectrometer. The emission from the sample, located at the exit slit, was recorded by means of a photomultiplier tube, the output of which was amplified by means of a synchronous detector and displayed on an x-y recorder. Appropriate filters were used in front of the sample and the P.M. tube and the spectra shown were corrected for system response.

Results

The compounds $CaAl_2Si_2O_8$, $SrAl_2Si_2O_8$, and $BaAl_2Si_2O_8$.—Calcium and strontium feldspars were easily prepared at 1400°C. The powders were well crystallized and produced well-defined x-ray diffraction patterns. In $CaAl_2Si_2O_8$ and $SrAl_2Si_2O_8$ compositions, Ca-feldspar and Sr-feldspar were the only phases identified. No trace of the metastable hexagonal phases was detected in each of these.

After 24 hr at 1400°C, hexacelsian was the only phase identified in the $BaAl_2Si_2O_8$ composition. Heating for 3 days at 1400°C did not convert the material to celsian, which was brought about after firing for 5 days. It is obvious, therefore, that hexacelsian when made with pure starting materials appears metastably at 1400°C and is very persistent.

The cell dimensions of the Sr- and Ba-feldspars were calculated using the least-squares method. Table I summarizes the results of this work and those reported previously. In $BaAl_2Si_2O_8$, there is good agreement between the lattice parameters calculated in this work and those reported by Sorrell (7) in the ASTM Data File. In $SrAl_2Si_2O_8$, the axial parameters *a*, *b*, and *c* of the triclinic cell agree very well with previously reported data. However, the angular parameters were somewhat different. In the ASTM File, the angle gamma (94.10°) is larger than alpha (89.43°). This work found alpha (90.18°) to be slightly larger than gamma (89.27°). A very small difference was apparent in the angle beta. The previous data for $CaAl_2Si_2O_8$ were obtained using a natural specimen of unknown chemical composition. Since anorthite is generally found to contain albite, *etc.* (10), the difference in the data presented could be due to such impurities.

The cathodoluminescent emission spectra of Ca-, Sr-, and Ba-feldspars activated by each of Ce^{3+} and Eu^{2+} are shown in Fig. 1A and 2A, respectively. Ce^{3+}-activated $CaAl_2Si_2O_8$ gave two emission peaks. The peak emission in the ultraviolet region occurred at 355 nm.

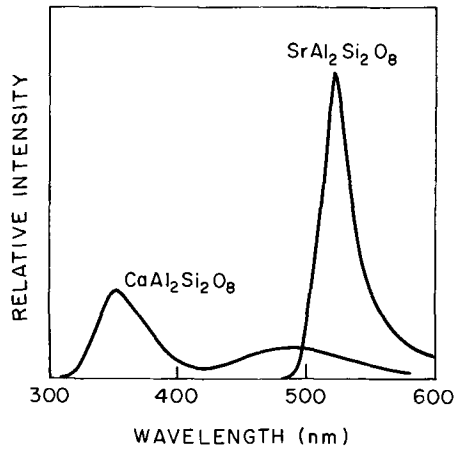

Fig. 1A. Emission spectra of Ce^{3+}-activated $CaAl_2Si_2O_8$ and $SrAl_2Si_2O_8$ due to C. L. excitation.

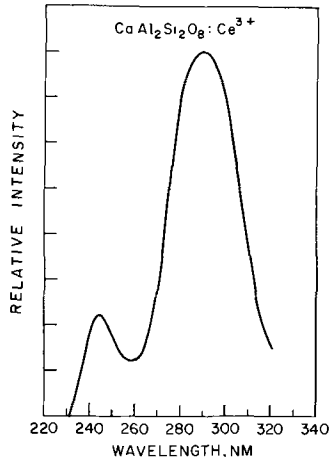

Fig. 1B. Excitation spectra of Ce^{3+}-activated $CaAl_2Si_2O_8$

Emission in the visible region was broad with a peak at 490 nm in the blue-green region. Ce^{3+}-activated $SrAl_2Si_2O_8$ gave a peak emission at 530 nm in the green region. Excitation spectra are shown in Fig. 1B and 2B. $SrAl_2Si_2O_8$:Ce^{3+} is very weakly excited by ultraviolet; only one small excitation band could be observed around 265 nm. Ce^{3+}-doped $BaAl_2Si_2O_8$

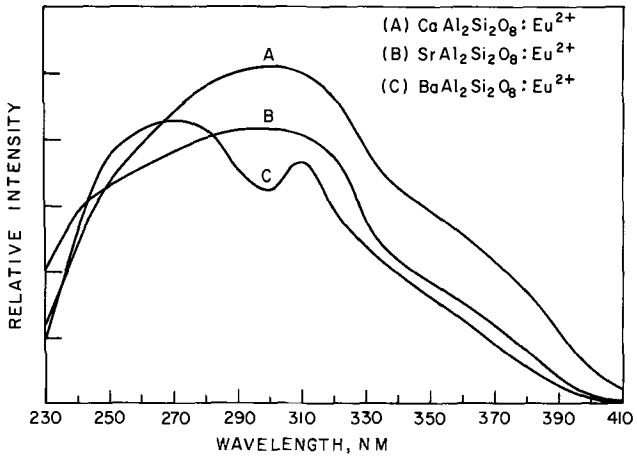

Fig. 2B. Excitation spectra of Eu^{2+}-activated feldspars

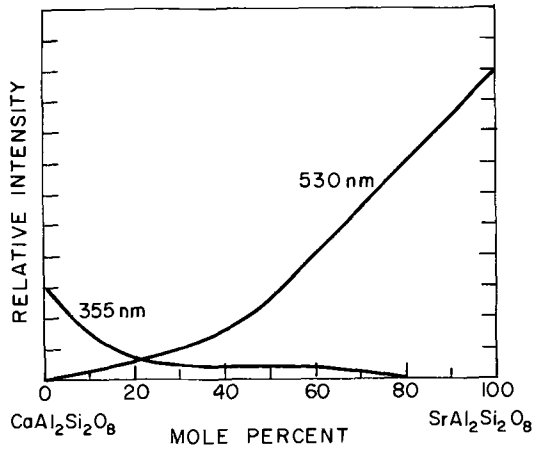

Fig. 4. A plot of relative intensity vs. composition of emission peaks in the system $CaAl_2Si_2O_8:Ce^{3+}$-$SrAl_2Si_2O_8:Ce^{3+}$ due to C.L. excitation.

(celsian) and hexacelsian were inert to C.L. excitation.

The emission of Eu^{2+}-activated $CaAl_2Si_2O_8$ and $SrAl_2Si_2O_8$ due to C.L. excitation occurred in the blue region with peak emission at 470 and 465 nm, respectively. The emission peaks were broad and there were no significant differences in their positions. The emission of Eu^{2+}-activated $BaAl_2Si_2O_8$ due to C.L. excitation occurred in the ultraviolet region and very weakly in the blue-green region with peak emission at 375 and 500 nm, respectively.

The system $CaAl_2Si_2O_8$-$SrAl_2Si_2O_8$.—Five phosphors prepared in this system were completely reacted after 24 hr at 1400°C. Only the feldspar phase was identified in each composition. X-ray diffraction patterns showed complete solid solution series between the end members. A plot of observed "d" spacing as a function of composition, shown in Fig. 3, is in good agreement with the concept of complete solid solubility.

In Ce^{3+}-activated phosphors prepared in a series of solid solutions, one frequently finds a continuous shift in the C.L. emission peak positions from one end member to the other. The Ca-feldspar and Sr-feldspar system, however, shows no such shift in the peak position. On the contrary, emission peaks of both the end members were present in the solid solution series. The 490 nm emission peak for $CaAl_2Si_2O_8$ decreases considerably at $Ca_{0.8}Sr_{0.2}Al_2Si_2O_8$ and then ceases beyond this limit. Figure 4 gives a plot of relative intensity (by peak height measurement) of emission peak as a function of composition. The peak intensity of the emission characteristic of Ca-feldspar decreases as the concentration of Sr^{2+} increases in the solid solutions. Similarly, the peak intensity of Sr-feldspar emission decreases with an increase in Ca^{2+} concentration.

Since the C.L. peak emission of Eu^{2+}-activated Ca- and Sr-feldspar occurs at 470 and 465 nm, respectively, no shifts in the positions of peak emission were anticipated in the solid solution series. The peak emission of phosphors prepared in the solid solution region occurred in the blue region at 470 nm as did those of the end members. The relative intensity (by peak height measurement) of the emission peaks as a function of composition is plotted in Fig. 5. Unlike Ce^{3+}-activated phosphors, these solid solutions have higher intensity than the end members. The phosphor with 75% Ca- and 25% Sr-feldspar has maximum intensity in the emission peak.

The system $SrAl_2Si_2O_8$-$BaAl_2Si_2O_8$.—Six compositions were prepared in this system. X-ray diffraction patterns indicated that Sr-feldspar accepted 60 m/o Ba^{2+} for Sr^{2+} in solid solution. Ba-feldspar accepted only 20 m/o Sr^{2+} for Ba^{2+}. Cell dimensions of the compositions in the system were calculated by the least-squares method. The parameters obtained, as a function of composition, are plotted in Fig. 6A and 6B. The *a*, *b*, and c parameters of $SrAl_2Si_2O_8$ all increase with the substitution of Ba^{2+} for Sr^{2+}. This linear relationship is evident up to 60 m/o Ba^{2+} beyond which the slope of the plot for $BaAl_2Si_2O_8$ solid solution region is different. Similarly, the angular parameters alpha and gamma of $SrAl_2Si_2O_8$ approach 90 deg at 60 m/o Ba^{2+}. Thereafter, they become 90 deg in the $BaAl_2Si_2O_8$ solid solution region. Between 60 and 80 m/o $BaAl_2Si_2O_8$, there exists a two-phase region.

The relative intensity (by peak height measurement) of the 530 nm peak emission *vs.* composition of Ce^{3+}-activated phosphors in the system is plotted in Fig. 7. The peak emission of $SrAl_2Si_2O_8$ increased in intensity with the substitution of Ba^{2+} for Sr^{2+} up to 40 m/o Ba^{2+} and then it dropped slowly up to 60 m/o Ba^{2+},

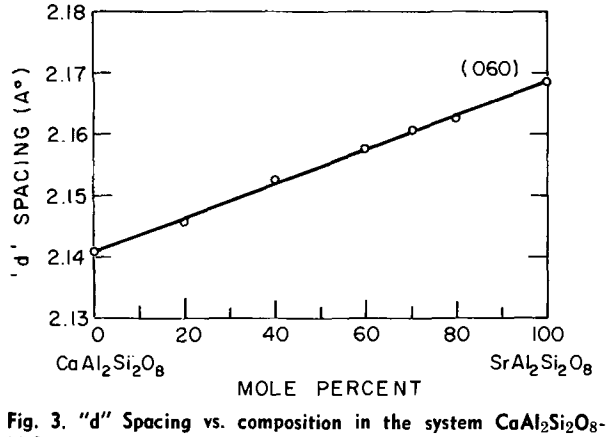

Fig. 3. "d" Spacing vs. composition in the system $CaAl_2Si_2O_8$-$SrAl_2Si_2O_8$.

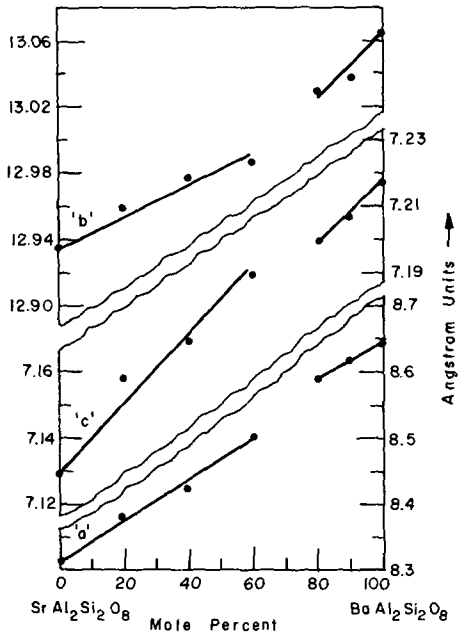

Fig. 6A. Lattice parameter vs. composition in the system $SrAl_2Si_2O_8$-$BaAl_2Si_2O_8$.

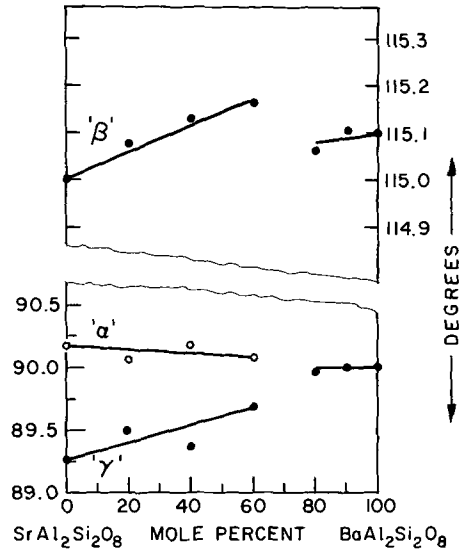

Fig. 6B. Lattice parameter vs. composition in the system $SrAl_2Si_2O_8$-$BaAl_2Si_2O_8$.

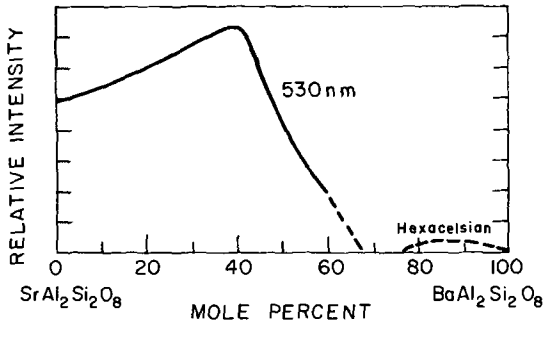

Fig. 7. Relative intensity vs. composition of emission peak in the system $SrAl_2Si_2O_8$:Ce^{3+}-$BaAl_2Si_2O_8$:Ce^{3+} due to C.L. excitation.

beyond which the luminescence ceases. Ce^{3+}-doped $BaAl_2Si_2O_8$ is inert to C.L. excitation and its solid solutions are also found to be inert. Similar results were obtained in the Eu^{2+}-activated system. Figure 8 shows a plot of the relative intensity of the 465 nm emission peak as a function of composition. The relative intensity increases with Ba^{2+} concentration up to 35 m/o Ba^{2+} and then slowly decreases up to 70 m/o Ba^{2+}. Beyond this limit, the luminescence almost ceases. The intensity of the 375 nm emission peak of $BaAl_2Si_2O_8$ decreases with increasing Sr^{2+} concentration up to 20 m/o Sr^{2+} and then ceases.

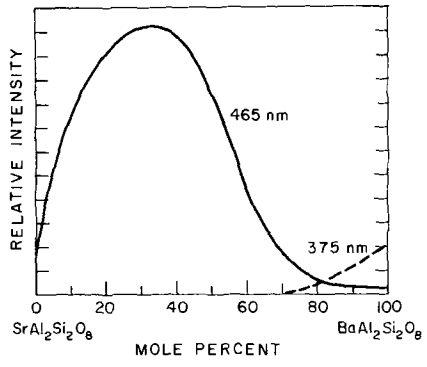

Fig. 8. Relative intensity vs. composition of emission peak in the system $SrAl_2Si_2O_8$:Eu^{2+}-$BaAl_2Si_2O_8$:Eu^{2+} due to C.L. excitation.

The system $CaAl_2Si_2O_8$-$BaAl_2Si_2O_8$.—Six compositions were prepared in this system. X-ray diffraction patterns indicate that $CaAl_2Si_2O_8$ can accept only up to 10 m/o Ba^{2+} for Ca^{2+} in solid solution. However, the $BaAl_2Si_2O_8$ solid solution is very extensive. Up to 60 m/o Ba^{2+} can be replaced by Ca^{2+} in $BaAl_2Si_2O_8$ solid solution. Between 10 and 40 m/o Ba^{2+}, Ca-feldspar and Ba-feldspar were both identified as coexisting phases. $BaAl_2Si_2O_8$ and its solid solutions were found to be inert to cathode-ray excitation when doped with Ce^{3+} and to be only very weakly excited when activated by Eu^{2+}. Therefore, the extensive solid solution of $BaAl_2Si_2O_8$ with $CaAl_2Si_2O_8$ was of no interest for luminescence studies. Since $CaAl_2Si_2O_8$ solid solution was very limited ($\leq$ 10 m/o Ba^{2+} for Ca^{2+}), it was not investigated further.

Discussion

The Ce^{3+}-activated $CaAl_2Si_2O_8$ shows two distinct peaks in the excitation spectra occurring at 34.5 x 10^3 cm^{-1} and 41 x 10^3 cm^{-1} (see Fig. 1B). These peaks are assumed to be caused by the crystal field splitting of the Ce^{3+} ion as has been previously suggested (1a). Two peaks separated by approximately 8160 cm^{-1} are also observed in the emission spectrum. In $SrAl_2Si_2O_8$:Ce, only one very weak excitation peak around 38 x 10^3 cm^{-1} could be identified. Because of inefficient pumping of the material by photons, the existence of other excitation bands cannot be ruled out. The emission spectrum also shows only one peak occurring at 18.9 x 10^3 cm^{-1}.

In forming the solid solution series between the Ca and Sr end members, the lattice parameters varied continuously as a function of composition; however, the position of the Ce^{3+} emission appears not to be affected. Instead, the emission for the solid solution samples appeared to be a combination of the two types of spectra. This would imply that the Ce^{3+} ion is probably occupying two different kinds of sites in the solid solution in which the activator environment is essentially the same as that in the end members. This may indicate that the local environment of the activator ion remains virtually unchanged, even though there is a long-range change in the crystal which is reflected in the lattice parameter variations. The decrease in the Ce^{3+} emission in the single-phase solid solution region proceeding from Sr toward Ba is also probably due to the Ce^{3+} ions occupying two sites, with the alkaline earth ion site in $BaAl_2Si_2O_8$ being inert.

With Eu^{2+} activation, both the $CaAl_2Si_2O_8$:Eu^{2+} and $SrAl_2Si_2O_8$:Eu^{2+} samples showed a broad emission throughout the visible with the peak of the band occurring at 465-470 nm. The general character of the

emission band did not change as a function of composition across the solid solution series. However, it is interesting to note that the maximum intensity occurs at a point in between the two end members. It is not known whether this increase is caused by an increased efficiency of the Eu^{2+} ion (a decrease in radiationless energy loss) or by an improvement in the energy transfer mechanism between the host and activator. A similar variation of the intensity of the 465 nm band is also observed in the Sr to Ba solid solution samples.

The $BaAl_2Si_2O_8$:Eu material shows two peaks in the emission spectra separated by approximately 6670 cm^{-1}. Again, the presence of these two bands may be caused by a splitting of the 5d level of the Eu^{2+}.

Acknowledgments

The authors are grateful to R. G. DeLosh for helpful discussion and to D. R. Peacor for the computer program for lattice parameter calculation of the triclinic crystals.

Phase Equilibria and Tin-Activated Luminescence in the System $Ca_3(PO_4)_2$-$Ba_3(PO_4)_2$

Eric R. Kreidler

Lighting Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio 44112

ABSTRACT

The phase diagram for the system $Ca_3(PO_4)_2$-$Ba_3(PO_4)_2$ has been determined in detail. Although no intermediate compounds were found in the system, two extensive solid solution regions having the α-$Ca_3(PO_4)_2$ and β-$Ba_3(PO_4)_2$ structures were found to exist. Beta-$Ba_3(PO_4)_2$ is a newly discovered polymorph stable above 1390°C. The divalent tin-activated luminescence of various phases in the system was studied. The most efficient phosphor was α-$Ca_{2.50}Ba_{0.45}Sn_{0.02}(PO_4)_2$ which had properties similar to those of $Ca_{10}(PO_4)_6F_2$:Sb. The performance of α-(Ca, Ba)$_3(PO_4)_2$:Sn in fluorescent lamps was evaluated.

The alkaline earth orthophosphates serve as host structures for efficient luminescence and have been studied extensively in this regard. As a result of the interest in luminescence, a number of alkaline earth orthophosphate phase diagrams have been determined. The system $Ca_3(PO_4)_2$-$Ba_3(PO_4)_2$ has received some attention (1) but has not been examined in detail. Prior to the present study, two compounds, having the compositions $Ca_2Ba(PO_4)_2$ and $Ba_2Ca(PO_4)_2$, were reported to occur in the system (1, 2). These phases are found to be members of two distinct solid solution series, and no discrete compounds exist within the calcium orthophosphate-barium orthophosphate system.

The tin-activated luminescence of β- and α-$Ca_3(PO_4)_2$ and of $Ba_3(PO_4)_2$ was reported by Butler (3) in 1951. Both forms of calcium phosphate have efficient visible emissions when excited by 254 nm radiation. Under the same conditions, barium orthophosphate shows only a weak ultraviolet fluorescence. The temperature dependence of the luminescence in α-$Ca_3(PO_4)_2$:Sn and β-$Ca_3(PO_4)_2$:Sn as well as the effects of magnesium additions in β-$Ca_3(PO_4)_2$:Sn were studied by Wanmaker and Radielovic (4). Lendvay (5) speculated on the nature of the luminescence centers in β-$Ca_3(PO_4)_2$:Sn and assigned the red emission band to Sn^{2+} ions replacing Ca^{2+} ions and the green band to interstitial Sn^{2+} ions. Besides tin, many other activators have been examined in the alkaline earth orthophosphates; among these are Ce (6), Tl (7), Cu (8, 9), Sb (10), Eu (11), and Tb (12). In this study, only tin-activated luminescence is discussed.

Key words: phase equilibria, calcium-barium orthophosphates, phosphors, tin, luminescence.

Experimental

Samples were prepared by reacting mixtures of reagent-grade $CaCO_3$, $BaCO_3$, and $(NH_4)_2HPO_4$ in the solid state at temperatures of 500°, 800°, and 1050°C for times of 4, 15, and 15 hr, respectively. Between heat treatments, the samples were thoroughly remixed under acetone in glass mortars. The materials used for the phase equilibrium studies were free of tin, and were formulated to have the orthophosphate stoichiometry (*i.e.*, [Ca + Ba]/PO_4 = 1.5). Tin-activated luminescent materials were prepared by one of two methods and were intentionally made deficient in cations to facilitate incorporation of the activator. In the first method, mixtures of SnO_2, $CaCO_3$, $BaCO_3$, and $(NH_4)_2HPO_4$ were reacted in the solid state as described above. In order to obtain tin in the divalent state, these materials were then heated for 1 hr at 1050°-1100°C in a flowing atmosphere of 1% hydrogen and 99% nitrogen. In the second method, mixtures of

$Sn_2P_2O_7$ and pre-reacted $(Ca, Ba)_3(PO_4)_2$ were sealed into evacuated, fused silica capsules and heated for 2-4 hr at 1150°-1200°C. Both methods of preparation gave efficient phosphors.

The phase relationships were studied by several methods. Slow reactions were studied by the quenching technique (13) and, when possible, the equilibrium conditions were approached from two directions. Fast reactions were studied by the DTA method with a Du Pont 600 Thermoanalyzer. High-temperature x-ray diffraction measurements were done in a TemPres x-ray diffraction furnace. Phase analyses of the products were carried out on a General Electric XRD-5 diffractometer using nickel filtered copper radiation. For routine phase indentification, the diffractometer was scanned at 1 deg theta/min, but for more precise measurements the diffractometer was scanned at 0.1 deg theta/min, and the peak positions were corrected by reference to an internal aluminum standard. Index of refraction measurements were by the oil immersion method. Temperatures were measured to an accuracy of ±2°C with calibrated platinum/platinum-10% rhodium thermocouples.

Excitation and emission spectra of the phosphors were measured as described by Hoffman (14). These spectra are automatically corrected for instrumental errors and represent true relative energy per wavelength interval. The reflectance of pure α-$Ba_3(PO_4)_2$ was measured, relative to Kodak high-purity $BaSO_4$, with a McPherson Model 225 vacuum spectrometer.

Phase Equilibria

The results of the phase equilibrium study are summarized in Fig. 1. The phase diagram was constructed on the basis of quenching experiments (Table I), differential thermal analysis (Table II), and precise measurements of x-ray "d" spacings as functions of composition and temperature (Table III). The data in Tables II and III are based on multiple observations and serve to refine the approximate phase boundaries derived from the data in Table I.

Contrary to previous reports, no intermediate compounds exist within the system $Ca_3(PO_4)_2$-$Ba_3(PO_4)_2$. However, two extensive series of solid solutions do occur, and their structures correspond to those of the high-temperature polymorphs of calcium and barium orthophosphate. The compound, $CaBa_2(PO_4)_2$, reported by Lagos (2) is a member of the β-$Ba_3(PO_4)_2$ solid solutions. The x-ray pattern of $Ca_2Ba(PO_4)_2$ reported by Bobronicki *et al.* (1) is a poor approximation of the pattern of the limiting α-$Ca_3(PO_4)_2$ solid solution.

Polymorphism of $Ca_3(PO_4)_2$.—The phase transitions in pure calcium orthophosphate have been examined

on numerous occasions, but some disagreement over the inversion temperatures is evident in the literature. For example, the correct temperature of the $\beta \rightleftarrows \alpha$ inversion is 1130°C (15, 16), but one still finds the temperature quoted as 1180°C in the literature on luminescence. The $\alpha \rightleftarrows \alpha'$ inversion temperature was originally reported as 1430°C by Nurse *et al.* (17), but a subsequent determination by Tromel and Fix (18) gave a value of 1470°C. The temperature of the $\alpha \rightleftarrows \alpha'$ inversion was redetermined by DTA (Table II) and found to be 1475° ± 7°C which is in excellent agreement with the value of Tromel and Fix. The inversion was rapid reversible and showed neither supercooling nor superheating effects when traversed at 50°C/min. The melting point of $Ca_3(PO_4)_2$ was not determined in this study and the value used in Fig. 1 was taken from Tromel and Fix (18). The incongruent melting behavior of $Ca_3(PO_4)_2$, reported by Welch and Gutt (15), has been discussed elsewhere (19) and concluded to be an incorrect result. The low-temperature phase transitions suggested by Koelmans *et al.* (20) were not studied.

$Ca_3(PO_4)_2$ solid solutions.—The α-calcium orthophosphate solid solutions have a maximum barium concentration of 28 m/o (mole per cent) at 1000°C. All members of the solid solution series [including pure α-$Ca_3(PO_4)_2$] may be obtained metastably at room temperature by removing the samples from the furnace and allowing them to cool in air. A sintered sample of α-$Ca_3(PO_4)_2$, containing 5 m/o $Ba_3(PO_4)_2$, was examined under the microscope and found to have biaxial positive optic character. The optic character is in agreement with Mackay's observation of a monoclinic unit cell (21). The low symmetry helps explain the changes observed in the x-ray diffraction patterns as the α-solid solutions are traversed. Aside from the normal displacement of the diffraction peaks due to dilation of the lattice, one observes what are apparently single peaks splitting up into three or more separate peaks. One also observes large relative intensity changes among the peaks. These effects can be attributed to different rates of expansion of the crystal axes and perhaps also to a change in the monoclinic β-angle as the barium concentration increases. It is also possible that the structure becomes triclinic as barium is added. In any case, the diffraction patterns of the limiting solid solution and of pure α-$Ca_3(PO_4)_2$ are so different in appearance that, if only these two patterns were compared, they very likely would be attributed to two different compounds. However, if x-ray patterns are taken at 5 m/o intervals, a gradual change of the pure α-$Ca_3(PO_4)_2$ pattern into that of the limiting solid solution is observed. Microscopic analysis of the samples showed them to contain only one phase whose average refractive index varied with composition as shown in Table IV.

The phase boundaries of the α-solid solutions were determined by observing the points at which the x-ray "d" spacings ceased to vary as a function of composition. The details of the method are outlined by Cullity (22). The samples used for these determinations were in the form of pressed pellets (2 mm high by 10 mm diameter), which were equilibrated for several days at the temperatures indicated in Table III.

The change in the $\alpha \rightleftarrows \alpha'$ inversion temperature as a function of composition (Fig. 1) indicates considerable solid solubility of $Ba_3(PO_4)_2$ in α'-$Ca_3(PO_4)_2$ at high temperatures. The α' solid solutions rapidly revert to the α-form on cooling, and even quenching into water from 1500° is insufficient to preserve them.

The solid solubility of $Ba_3(PO_4)_2$ in β-$Ca_3(PO_4)_2$ was determined by x-ray measurements to be less than 2 m/o at 880°C.

Polymorphism of $Ba_3(PO_4)_2$.—In 1963, the author investigated the thermal behavior of $Ba_3(PO_4)_2$ by DTA and high-temperature x-ray diffraction methods. A

0.20	1.597

* Measured for NaD line at 25°C. These samples were equilibrated at 1200°C/20 hr. Birefringence of the crystals was low, ~0.002.

strong, sharp endotherm was observed at about 1360°C and the high-temperature x-ray study showed the presence of a new phase at 1400°C. These results were unreported except for a brief reference by McCauley and Hummel in 1968 (23). Since 1968, more precise DTA studies have been carried out and the inversion temperature has been revised to 1390° ± 15°C. The heating and cooling rates were found to influence the inversion temperature, indicating that the transition is somewhat sluggish. At 50°C/min, the inversion occurred at 1410° on heating and at 1241°C on cooling. The corresponding temperatures observed at heating and cooling rates of 15°C/min were 1404° and 1380°C. The latter results bracket the inversion temperature to within 25°C.

Although β-$Ba_3(PO_4)_2$ can undergo considerable supercooling, this phase cannot be obtained at room temperature by rapidly quenching it into water. To the author's knowledge, the high-temperature or β form of barium orthophosphate has not been discovered previously. An x-ray pattern of β-$Ba_3(PO_4)_2$ taken at 1450° ± 10°C is given in Table V.

$Ba_3(PO_4)_2$ solid solutions.—The β-$Ba_3(PO_4)_2$ solid solutions are unstable below 890°C (the eutectoid temperature) and decompose to a mixture of α-$Ca_3(PO_4)_2$ ss and α-$Ba_3(PO_4)_2$. However, β-solid solutions having compositions between 50 and 80 m/o $Ba_3(PO_4)_2$ can be obtained metastably at room temperature by removing samples from the furnace and allowing them to cool in air. Solid solutions having compositions between 80 and 95 m/o $Ba_3(PO_4)_2$ can be preserved by water quenching. The phase boundaries of β-$Ba_3(PO_4)_2$ were determined from precise "d" spacing measurements of nine diffraction lines. The samples were in the form of cylindrical pellets and were equilibrated at the temperatures and for the times shown in Table III. The eutectoid composition, determined by extrapolation of the phase boundaries, is 63 m/o $Ba_3(PO_4)_2$ and 37 m/o $Ca_3(PO_4)_2$.

A sample of composition $(Ba_{0.6}Ca_{0.4})_3(PO_4)_2$ was crystallized from the melt and examined microscopically. This member of the β-solid solution series was biaxial negative with a small optic axial angle. The low symmetry precluded indexing of the x-ray powder patterns. Representative powder patterns of the β-solid solutions are given in Table V.

The solid solubility of calcium orthophosphate in α-$Ba_3(PO_4)_2$ was less than 2.5 m/o over the temperature range 880°-1200°C. This value was determined from precise x-ray measurements.

** Only the visible emissions are listed. Intensity is relative to sodium salicylate peak heights of 100.

Melting Behavior

The melting behavior within the system was studied by the technique of differential thermal analysis. The DTA curves obtained for samples having 0-25 m/o $Ba_3(PO_4)_2$ had no distinguishable melting peaks, and those obtained for samples having 25-50 m/o $Ba_3(PO_4)_2$ were complex and difficult to interpret. Well-defined DTA peaks attributable to melting were observed for compositions having 50-90 m/o $Ba_3(PO_4)_2$ (Table II). The departure points of the DTA curves from the base line were taken as the solidus temperatures and the peaks of the DTA curves were taken as the liquidus temperatures. Considerable supercooling of the melts in this system was observed and instantaneous crystallization often occurred near or somewhat below the solidus temperatures. For this reason, only the heating curves were used in constructing the phase diagram. Although the liquidus and solidus curves in Fig. 1 were not located with high precision, their configuration is probably correct as shown.

Luminescence

The phosphors listed in Table VI were prepared and their properties measured. The phases present in the phosphors were as expected on the basis of the phase diagram, and the small amount of tin present caused no appreciable changes in the phase relationships. Of the phosphors studied, only those based on the α-$Ca_3(PO_4)_2$ structure were efficient enough for practical use. The composition of the α-$Ca_3(PO_4)_2$:Sn phosphors was optimized, and fluorescent lamp tests were made on two such phosphors. The intensity scales on all emission spectra are expressed as percentages of the peak intensity of sodium salicylate,[1] and the intensity scales on all excitation spectra are normalized to 100.

α-$Ba_3(PO_4)_2$ phosphors.—The excitation and emission spectra of α-$Ba_3(PO_4)_2$:Sn are given in Fig. 2. The emission spectrum consists of a single, nearly Gaussian band[2] centered at 426 nm. The excitation spectrum consists of two well-resolved bands at 230 and 245 nm and a broad feature extending from 215 nm to shorter wavelengths. The absorption edge of unactivated α-$Ba_3(PO_4)_2$ occurs at about 165 nm (Fig. 3) so that all features in the excitation spectrum are due to transitions involving tin.

Barium orthophosphate has two inequivalent barium positions in its structure (24) and, assuming that tin replaces barium, one might expect two emission bands. The simplicity of the excitation and emission

[1] Merck U.S.P.
[2] When plotted as a function of energy, the spectrum is Gaussian within ±2 σ of the mean, but small positive deviations from a Gaussian shape are apparent outside these limits—especially on the low-energy side of the band. According to Dexter (25), the low-energy side of an emission band is not necessarily Gaussian in shape.

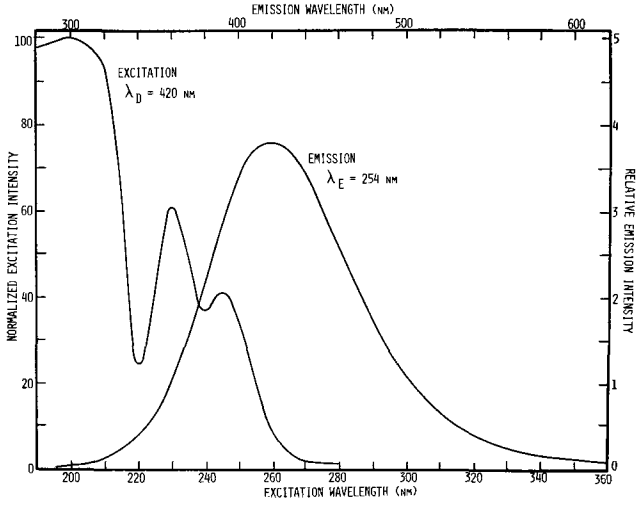

Fig. 2. Emission and excitation spectra of α-$Ba_3(PO_4)_2$:Sn. λ_D = detection wavelength, λ_E = excitation wavelength.

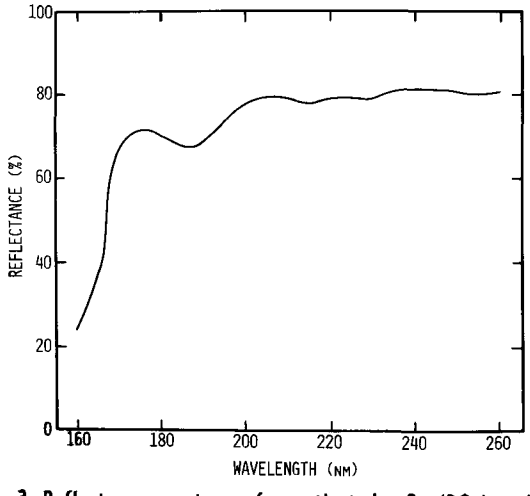

Fig. 3. Reflectance spectrum of unactivated α-$Ba_3(PO_4)_2$ relative to $BaSO_4$.

spectra indicates, however, that only one kind of luminescence center is present. The exact nature of this center cannot be determined from the data available at present. Although transitions can occur to several excited states of the stannous ion, emission apparently occurs only from the lowest excited state. A schematic configuration coordinate diagram which accounts for the observed spectra is given in Fig. 4.

β-$Ba_3(PO_4)_2$ phosphors.—The emission spectra of several β-phosphors, excited by 254 nm radiation, are shown in Fig. 5. These phosphors are inefficient and not of interest as practical materials. The emission spectra are complex and consist of bands at 300, 410,

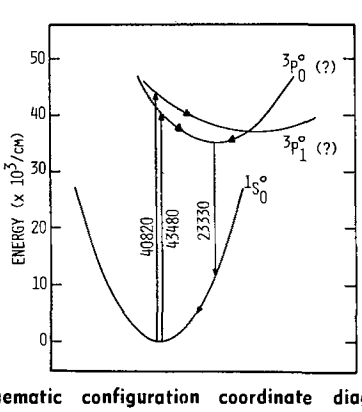

Fig. 4. Schematic configuration coordinate diagram for α-$Ba_3(PO_4)_2$:Sn.

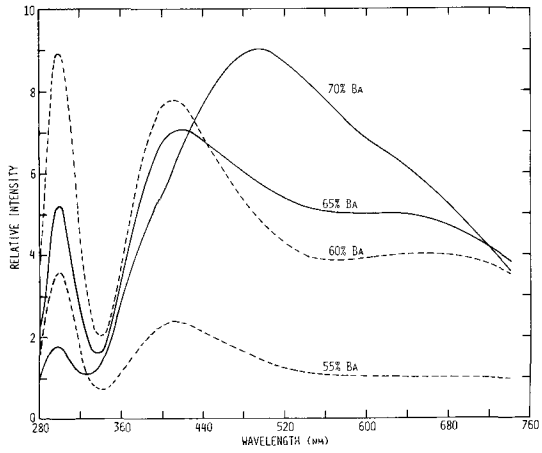

Fig. 5. Emission spectra of β-(Ba, Ca)$_3(PO_4)_2$:Sn phosphors as a function of composition. Barium concentrations are in mole percentages. Excitation = 254 nm radiation.

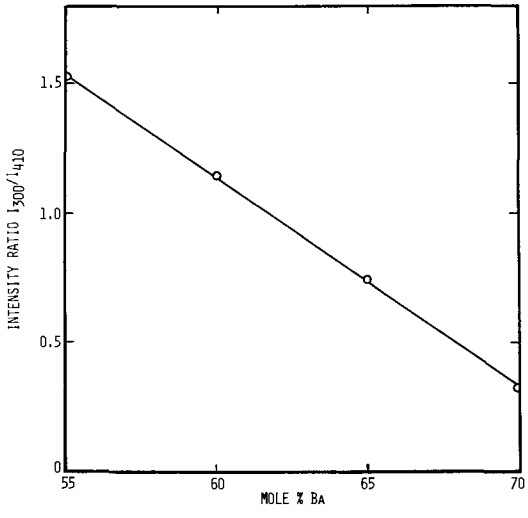

Fig. 6. Change in relative intensity of the 300 and 410 nm emission bands in β-(Ba, Ca)$_3(PO_4)_2$:Sn as a function of composition.

490, and 660 nm. The relative intensities of the bands change as a function of composition as shown in Fig. 6. This fact is taken as an indication that at least two, and possibly more, kinds of lattice positions are occupied by luminescent tin ions. The relative intensity changes can then be interpreted as due to a redistribution of tin ions over the various positions as the barium concentration is increased.

The excitation spectrum of the 490 nm emission band is shown for the most efficient β-phosphor in Fig. 7. The excitation spectrum contains at least five bands located at 205, 230, 243, 287, and 340 nm. All of these bands could be due to crystal field splitting of the J levels of the ^3P and ^1P states of the stannous ion (a maximum of 12 levels is possible). However, the emission bands at 410 and 660 nm overlap the 490 band and it is likely that the excitation spectrum has features due to these other bands.

α-$Ca_3(PO_4)_2$ phosphors.—The emission spectra of two α-$Ca_3(PO_4)_2$:Sn phosphors are shown in Fig. 8. In agreement with Butler (3), two emission bands located at 340 and 500 nm were observed. Both bands are shifted to shorter wavelengths and broadened upon incorporation of barium into the phosphor. The intensity[3] of the 340 nm band relative to that of the 500 nm band is independent of the barium concentration and has a value of 0.23. The excitation spectra of the 340 and 500 nm bands (Fig. 9) are considerably different. This might indicate that two kinds of tin centers, having

[3] Based on the areas under the bands. The areas were obtained by application of Simpson's rule.

different electronic energy structures, are present in the phosphor. However, this interpretation is at variance with the expectation that, if two centers were present, their relative emission intensities might vary as a function of composition. The question of the origin of the two emission bands in α-$Ca_3(PO_4)_2$ cannot be answered with certainty and, until such an answer is available, it is useless to attempt any interpretation of the spectra.

Optimization of α-$Ca_3(PO_4)_2$.—Suitable α-$Ca_3(PO_4)_2$:Sn phosphors can be prepared either by the sealed tube method or by the reduction firing method (see Experimental section). However, at barium concentrations lower than 5 m/o, the preparation of efficient phosphors by the reduction firing method becomes difficult due to high volatility losses of tin at the high temperatures necessary to obtain the α-$Ca_3(PO_4)_2$ structure. The phosphors low in barium were best prepared by the sealed tube method, a procedure not amenable to the production of large quantities of phosphor. The phosphors tended to have a gray body color which became darker as the limiting barium concentration was approached. Considering ease of preparation, phosphor efficiency, and phosphor appearance, the optimum barium concentration is near 15 m/o.

The efficiency of the phosphor as a function of formulated tin concentration was determined (Fig. 10). The optimum tin concentration is near 0.33 m/o, but somewhat higher values lead to only a slight loss in phosphor efficiency.

An important feature of any phosphor intended for practical application is how well it maintains its brightness as a function of operating temperature. The temperature dependence of two phosphors (Fig. 11) was measured by packing them into heated plaques and taking emission spectra at specific temperatures. The phosphor brightness is not affected by temperature up to about 150°C but thereafter brightness decreases slowly with increasing temperature. At 300°C, the phosphors are about 80% as bright as at room temperature. These results are in good agreement with those of Wanmaker and Radielovic (4). Insofar as temperature dependence is concerned, the α-$Ca_3(PO_4)_2$:Sn phosphors are well suited for application in fluorescent lamps (operating temperature ~40°C) and somewhat less well suited for use in high-pressure mercury vapor lamps (operating temperature ~300°C).

Two samples of phosphor, based on $Ca_{2.50}Ba_{0.45}(PO_4)_2$:$Sn_{0.02}$ as the optimum composition, were prepared in kilogram quantities and evaluated in 40W fluorescent lamps. These lamps are compared to a lamp made with blue halophosphate phosphor in Table VII. Although the α-calcium orthophosphate phosphors had initial powder brightnesses equal to that of blue halophosphate, when processed into lamps, they were considerably less efficient. The loss in efficiency is probably due to partial reoxidation of tin during lampmaking. In

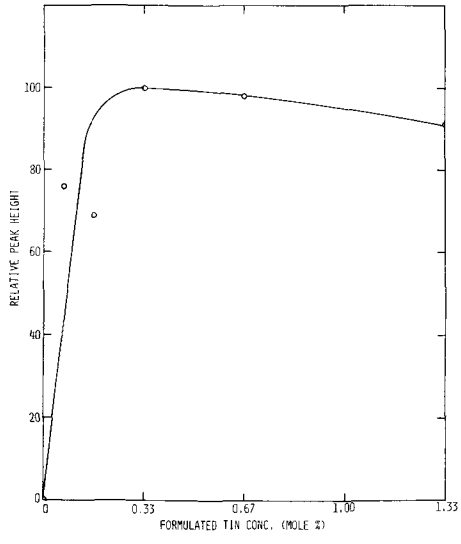

Fig. 10. Visible luminescence as a function of tin concentration in α-$Ca_{2.52-x}Ba_{0.45}Sn_x(PO_4)_2$. Mole per cent tin = 100x/3. Excitation wavelength = 254 nm.

terms of 500 hr maintenance, the α-calcium orthophosphate phosphors were as good as blue halophosphate. The color of the lamps remained stable over the duration of the tests.

Acknowledgments

The writer wishes to thank his colleagues who contributed to this work. Samples were prepared by Barbara Press and Larry Haydu. X-ray diffraction data were collected by Miss Jeannette Cooper and her staff. The measurements of optical spectra were made by Ralph Hewes, Tom Davis, and staff. Lamp tests were run by Tom Vincent.

Optical and Electrical Properties of $SrAl_2O_4:Eu^{2+}$

Victor Abbruscato[1]

Bayside Research Center of General Telephone & Electronics Laboratories, Incorporated, Bayside, New York 11360

ABSTRACT

It has been shown that the optical and electrical properties of $Sr_{0.95\pm x}Eu_{0.05}Al_2O_{4\pm x}$ depend on composition. A composition with excess alumina was found to have the highest CR efficiency, photoconductivity, and a long-lasting persistence. A mechanism is proposed which assigns the delayed luminescence to a process involving the conduction of charged particles. Evidence is presented which indicates that holes are trapped at lattice defects and the Eu^{2+} emission is associated with thermal deactivation of these traps.

Since the introduction of $YVO_4:Eu^{3+}$ as an important commercial phosphor, there has been an increasing interest in the mechanism of transfer of energy absorbed by a host to a rare earth activator. In the ZnS and SrS systems, it has been shown that the energy transport can take place *via* electron and hole transfer (1, 2). This mechanism can also occur in fluoride hosts. For example, Banks and Schwartz (3) have shown that in the $CdF_2:Eu^{3+}$ system the Eu^{3+} acts as an electron trap, forming Eu^{2+}. On thermal deactivation of the Eu^{2+} to Eu^{3+}, the Eu^{3+} is reformed in an excited state and, as a result, the characteristic luminescence of Eu^{3+} is observed. The mechanism for thermoluminescence in the $CaF_2:Ce^{3+}$ system has also been shown to be of a charge-transfer type, involving the reduction and reoxidation of Ce^{3+} under x-ray irradiation (4). In the case of rare earth ions in oxide systems, the mechanism of transfer has been presumed to be predominantly of the multipolar type (5).

The phosphors MAl_2O_4 (M = Ba, Sr, Ca, Mg) activated by Eu^{2+} have been reported by Palilla *et al.* (6) and also by Blasse and Bril (7). The phosphor $SrAl_2O_4:Eu^{2+}$, prepared by firing Al_2O_3, $SrCO_3$, and Eu_2O_3 in H_2 at between 1400°-1700°C, has a green emission peaking at 520 nm. This phosphor has a fast decay of 10 μsec to 10% of initial brightness. The luminescent properties depend to a large extent on the conditions and stoichiometry under which the phosphor is prepared. For example, Blasse and Bril (7) prepare the phosphor by firing at 1450°C in a N_2-H_2 atmosphere and report a CR efficiency of 1.5%. Palilla *et al.* (6) fire a composition containing excess alumina at 1700°C in a H_2 atmosphere and estimate a CR efficiency of approximately 7% (8). In addition to an initial rapid decay, a high-level persistence which lasts for seconds is also observed in their samples. Since the decay of the transitions within the Eu^{2+} ion is found to be in the 10-100 μsec range (9), it was decided to investigate the electrical and optical properties of this material to determine if the long persistence is due to a trapping mechanism involving electrons or holes, and to determine to what extent this phenomenon is involved in the over-all luminescence process.

Experimental

The compositions of the samples prepared were $Sr_{0.85}Eu_{0.05}Al_2O_{3.9}$ (excess alumina), $Sr_{0.95}Eu_{0.05}Al_2O_4$ (one to one), and $Sr_1Eu_{0.05}Al_2O_{4.05}$ (excess strontium oxide). The phosphors were formed by firing the appropriate mixtures of SrC_2O_4, Al_2O_3, and Eu_2O_3 in H_2 at 1700°C for 3 hr. The products were checked using x-ray diffraction analysis and had the $SrAl_2O_4$ structure, which is distorted stuffed tridymite.

The luminescent emission spectra were recorded with a ¾m Jarrell-Ash scanning spectrometer and corrected for instrumental response.

The reflectance spectra were determined with the use of a Cary 14 spectrometer equipped with a diffuse fluorescence attachment.

The photoconductive excitation spectra were recorded with the use of a sandwich conductive cell. The front side of the sandwich was a quartz slide which had a thin conducting layer of tin oxide on the inside surface, and the back side of the cell was a thin copper plate. The cell was placed in the sample compartment of a Cary 14 spectrometer, which was used as a pulsed excitation source. The photocurrent produced a potential across a precision resistor and this voltage was measured using a PAR Model 121 lock-in amplifier tuned to the frequency of the source.

The relative conductivity measurements under long uv radiation were recorded using a gap cell, which consisted of a gold strip evaporated on a quartz slide. The gap across the strip was 20μ. In order to avoid undesirable effects resulting from differences in particle size, the distribution of particle size was established by sieving the samples. Magnified photographs showed the particles of the three samples to be of uniform size. Each sample was redeposited five times and the average value taken as the photoconductive response. The d-c voltage applied across the gap was 400V.

The Hall measurement was determined using a sintered sample of $SrAl_2O_4:Eu^{2+}$ which had an excess of alumina.

For the glow curve measurements, the phosphor was deposited on a copper plate which was then fitted into the slot of a metal block Dewar. Liquid nitrogen was introduced into the Dewar, the sample was irradiated (366) for 1 hr, and then allowed to warm up. The rise of the temperature between −125° to −75°C was linear at a rate of 0.08 deg/sec. The temperature was measured with a copper-constantan thermocouple which was in contact with the copper plate.

The long luminescence persistence and photoconductive decay times were measured simply by switching off the exciting sources while monitoring the signal from the amplifier with a H.P. 7100B strip chart recorder.

Results

The optical and electrical measurements have shown that the $SrAl_2O_4:Eu^{2+}$ high alumina sample, as compared to the other samples, has a higher luminescent intensity under uv and CR excitation, and, also, that this sample has a much higher persistence level and photoconductive response. This is shown by data in Table I.

The excitation spectra and diffuse reflectance spectra of the excess alumina, one to one, and excess SrO samples are shown in Fig. 1. The latter two correspond to the spectra previously published (5, 7), while the excess alumina sample shows a greater relative excitation response in the visible region. Figure 2 shows the glow curve spectra for the three samples, using 366 nm excitation. The photoconductive excitation spectrum of the high-alumina sample in the visible region is

Key words: fluorescence, phosphorescence, photoconductivity, rare earth luminescence.

Table I

	Excess alumina $Sr_{0.85}Eu_{0.05}Al_2O_{3.9}$	One to one $Sr_{0.95}Eu_{0.05}Al_2O_4$	Excess strontium oxide $Sr_1Eu_{0.05}Al_2O_{4.05}$
% Persistence after 1.0 sec	0.70	0.085	0.080
Relative brightness, 366 nm excitation	100	55	61
Relative brightness, CR excitation	100	84	76
Relative photoconductive response, 366 nm excitation	100	13.1	17.3

shown in Fig. 3 and is compared to the reflectance curve for this sample. It was also observed that the samples were photoconductive under long and short uv and x-ray excitation. The Hall effect measurements showed qualitatively that holes were the conducting species under uv excitation. The decay times of the persistence and photoconductivity are similar (Fig. 4), which would indicate that the same charged species, in this case holes, is responsible for both phenomena.

Attempts were made to oxidize the Eu^{2+} activator to Eu^{3+} in portions of these samples by firing in wet oxygen at 800°C for 20 hr. These attempts met with complete success only in the high-alumina sample, while the other samples still exhibited a broad-band emission centered at 520 nm, due to Eu^{2+} (Fig. 5). It was also noted that, in the case of the high-alumina sample, the x-ray pattern showed a distinct change. The pattern changed from the distorted stuffed tridymite to very nearly "ideal stuffed tridymite," a more symmetrical structure. Therefore the Eu^{3+} emission lines in the high-alumina sample [Fig. 5(a)] are sharp and well defined, while in the one-to-one sample [Fig. 5(b)] the Eu^{3+} emission lines are broader and less defined.

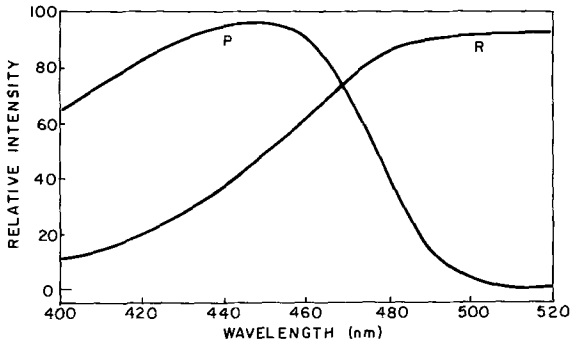

Fig. 3. The photoconductive excitation spectrum (P) and the diffuse reflectance spectrum (R) of the high-alumina sample in the visible region.

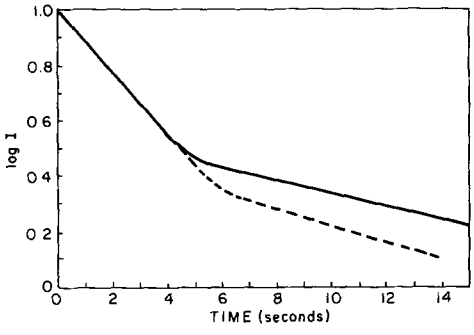

Fig. 4. The decay times of the persistence (solid line) and photoconductivity (dotted line) under 366 excitation.

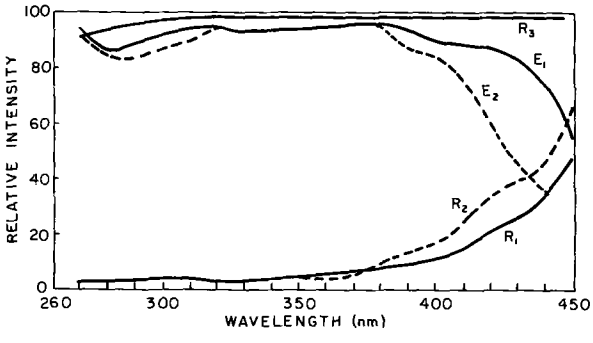

Fig. 1. Excitation spectra and diffuse reflectance spectra of $SrAl_2O_4:Eu^{2+}$ phosphors of various compositions. E_1 and E_2 represent the excitation spectra for the excess alumina and one-to-one sample, respectively. R_1, R_2 represent the diffuse reflectance spectra of the excess alumina and one-to-one phosphors, respectively. R_3 shows the diffuse reflectance spectrum of unactivated $SrAl_2O_4$ and unactivated $SrAl_2O_4$ with excess alumina, which are similar. Curve for the excess strontium oxide sample are the same as the one-to-one phosphor.

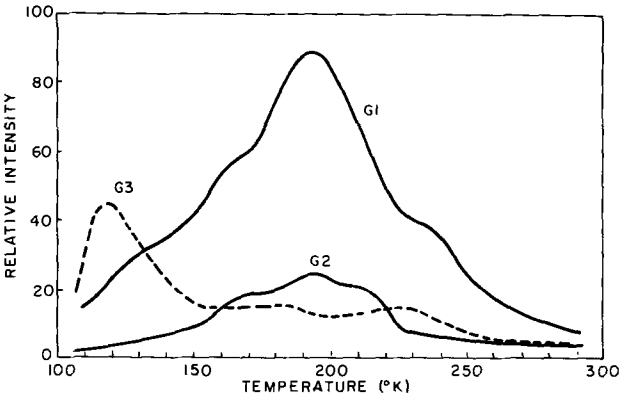

Fig. 2. The glow curves for the three samples, G1, G2, and G3 represent the glow curves for the excess alumina, one-to-one, and excess strontium oxide phosphors, respectively.

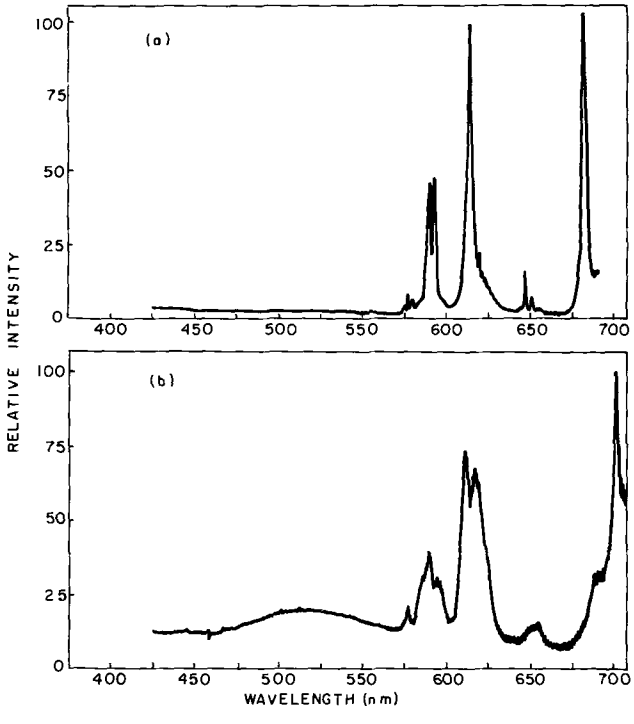

Fig. 5. The emission spectra of the reoxidized sample: (a) the excess alumina sample, exhibiting only sharp-line Eu^{3+} emission; (b) the one-to-one sample, exhibiting Eu^{2+} broad-band (520 nm) emission and Eu^{3+} emission.

Discussion

The model that is proposed to explain these results and the differences between the excess alumina sample and the other samples follows. The excess alumina incorporated into the $SrAl_2O_4$ host introduces a defect in the lattice. This defect has the property of being a hole donor, as was shown by the Hall measurement. The exact nature of this defect is not known, but it is associated with the incorporation of Eu^{2+} into the lattice, since the photoconductive absorption bands are not introduced into the $SrAl_2O_4$ host unless it is activated with Eu^{2+} (Fig. 1 and 3). The hole can migrate until it recombines or is trapped. The recombination of the charged species can cause luminescence of the Eu^{2+} ion, as shown by the fact that the photoconductivity and the Eu^{2+} luminescent persistence decay at the same rate (Fig. 4).

The glow curves show that hole trapping levels are present and are composition dependent with the high-alumina sample showing the highest concentration of traps (Fig. 2). High-alumina samples can either incorporate the alumina interstitially as Al^{3+} plus O^{2-}, or Sr^{2+} vacancies can be produced. These Sr^{2+} vacancies can be compensated by oxide vacancies or partially filled by Al^{3+} (*i.e.*, $2Al^{3+}$ for $3Sr^{2+}$). We feel that the hole traps described above are probably associated with Sr^{2+} vacancies. The ease of oxidation of Eu^{2+} in the high-alumina sample (Fig. 5) is evidence for the production of Sr^{2+} vacancies rather than the incorporation of alumina interstitially. Interstitial Al^{3+} and O^{2-} will not promote oxidation of Eu^{2+}. On the other hand, either of the Sr^{2+} vacancies described above will promote oxidation of Eu^{2+} because of the presence of O^{2-} vacancies or Al^{3+} occupying Sr^{2+} sites.

The possibility of the Eu^{2+} also acting as a hole trap was considered. This would be analogous to Eu^{3+} acting as an electron trap in the CdF_2 system (3). The high-alumina sample at liquid nitrogen temperature was irradiated for 1 hr with uv light. The emission spectrum was then recorded as the sample was irradiated at 325 nm and showed no traces of the main Eu^{3+} emission lines between 600 and 625 nm. Since Eu^{3+} would exhibit a detectable emission spectrum in $SrAl_2O_4$ (Fig. 5), it was concluded that the Eu^{2+} is most likely not acting as a trapping center.

It is therefore proposed that the charge transfer mechanism of excitation in the high-alumina sample involves the generation of a hole in the valence band. These holes can either recombine or be trapped in a lattice defect, probably a Sr^{2+} vacancy. The Eu^{2+} persistence is associated with the thermal deactivation of these traps and subsequent recombination. This mechanism of energy transfer can be an important factor in the emission intensity under CR and uv excitation. If it is assumed that the slowly decaying emission (persistence) results from a trapping phenomenon and that the initial rapidly decaying emission results from Eu^{2+} ions in an excited state, then the relative contribution of the trapping mechanism to the total emission can be obtained by an analysis of the decay curve. By comparing the areas under the curves of persistence and the total luminescence, it is estimated that in the high-alumina sample approximately 99% of the total luminescent intensity is due to activation by conducting holes.

A mechanism involving the conduction of charged species may also be operative in other rare-earth activated phosphors. For example, Pfahnl (10) has shown that, with P16 ($Ca_2MgSi_2O_7$:Ce^{3+}) ($CaAl_2Si_2O_8Ce^{3+}$) fast decay phosphors, aging under CR excitation causes the intensity and decay times to decrease. It was also shown that the decay is nonexponential in the low light level region. It is quite possible that the persistence of these phosphors is due to a trapping phenomenon. When the phosphor is aged, the probability of transfer of energy from the host to the Ce^{3+} *via* a charged species is decreased, causing a decrease in luminescence, and also a decrease of the persistence level. In another investigation, it was pointed out by Gomes de Mesquita and Bril (11) that, with certain Ce^{3+}-activated phosphors, the initial rapid decay of the Ce^{3+} luminescence is followed by an afterglow of relatively long duration. A quantity δ was defined as the percentage of cathodoluminescence 80 μsec after the end of the exciting pulse. It was found that δ could be as high as 5-10% for various gehlenite samples. When the samples were cooled down from room to liquid nitrogen temperature, δ-values increased for some samples and decreased for others. This behavior could not be explained by the authors. However, if one assumes that a trapping mechanism is responsible for the delayed luminescence, these results are easily explained. At low temperature, $kT << E_T$, (E_T = thermal energy of trap), δ will have a low value since a trap that is filled will not thermally deactivate and therefore will not contribute to an afterglow. At high temperatures, $E_T << T$, δ will again have a low value since a filled trap will rapidly deactivate, leading to a very rapid decay. Therefore, δ as a function of temperature should follow one of the hypothetical curves shown in Fig. 6; δ will decrease or increase on cooling below room temperature, depending on the depth of the trap in relation to room temperature. It is quite possible within the same host, depending on preparative and composition conditions, to have a different distribution and concentration of trapping levels.

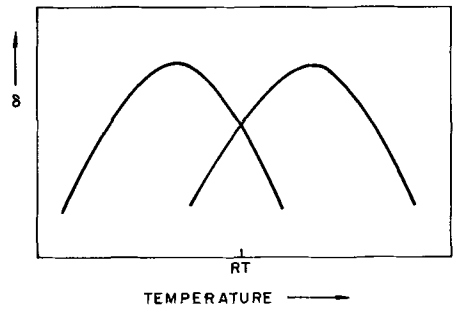

Fig. 6. Delta as a function of T

Conclusions

The optical properties of $SrAl_2O_4$:Eu^{2+}, such as efficiency under CR and uv excitation, have been shown to be dependent on composition. These differences have been correlated to the electrical properties of the phosphor. It has been shown that in this oxide system, the method of excitation of Eu^{2+} under uv and Cr excitation is predominantly of the charge transfer type.

Acknowledgments

The author is greatly indebted to V. D. Meyer for helpful discussions and to J. Ragusin for his assistance in the experimental part of the work.

Alkaline Earth Aluminum Fluoride Compounds with Eu^{+2} Activation

Mary V. Hoffman*

Lighting Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio 44112

ABSTRACT

The systems MF_2-AlF_3 (M = Ca, Sr, or Ba) were investigated and the compounds and their fluorescence with Eu^{+2} were determined. In these compounds, Eu^{2+} activation results in two distinct types of emission, a band emission from 5d to 4f transitions typically found for Eu^{+2} in other matrices and line emissions from 4f to 4f transitions, similar to those of the isoelectronic Gd^{+3}.

The binary systems MF_2-AlF_3 (M= Ca, Sr, or Ba) have all been reported in the literature. The Ca system was first reported by Holm (1), and later by Ravez and Hagenmuller (2) and by Shore and Wanklyn (3). The Sr system was reported by Ravez and Hagenmuller (2) and the Ba system by Ravez (4, 5). Some fluorescence work with Mn^{+2} and other activators in the Ca and Sr systems has been reported by Smith (6) and by Wilke *et al.* (7), but these did not define the compounds in the systems.

Experimental Procedures

Two general methods were used to prepare these materials, a solid-state procedure and a precipitation method. The solid-state method is used for the calcium compounds and Sr_2AlF_7 and the precipitation procedure can be used for all barium compounds and $SrAlF_5$. For the solid-state method, AlF_3 was prepared by firing "Linde 'A' " Al_2O_3 in anhydrous HF. The alkaline earth fluoride was prepared by coprecipitation with Eu as the carbonate, followed by conversion to the fluoride by firing in anhydrous HF or by reaction with aqueous HF. The alkaline earth fluoride and AlF_3 were then combined in the stoichiometry required and fired. This method has the disadvantages of slow reaction rates and the high volatility of AlF_3 at temperatures approaching the melting points of the various compounds.

The precipitation procedure used consisted of combining the stoichiometric amounts of the alkaline earth, Eu and Al in 0.3M nitrate solutions. The pH was adjusted to 4.5-5.0 with NH_4OH and the solution heated to 80°C. A 0.3M solution of $NH_4F \cdot HF$ was added to the nitrate solution, equivalent to 95-100% of the stoichiometric amount. The resulting precipitate was heated and stirred for several hours before filtering, washing, and drying.

The firing procedure for either method consisted of a reduction firing, followed by a firing in anhydrous HF. The first firing at 750°C was in porcelain boats in an atmosphere of 1% H_2 in N_2 to reduce the activator to Eu^{+2}. The second firing was in anhydrous HF carried by N_2, utilizing a platinum tube furnace. Temperatures for this firing ranged from 700° to 900°C for 2-4 hr.

Measurements

The emission spectra were taken on a spectroradiometer previously described (8). Spectral band widths (SBW) used were 5 and 0.5Å. The detailed methods of measuring excitation and decay utilized to define the optical transitions in these phosphors have been described elsewhere (9). Quantum efficiency measurements were made by comparison of spectra with sodium salicylate, using a value of 64% for this standard. DTA measurements were made on a Du Pont Model 900, on samples which were sealed in platinum tubing, in an N_2 atmosphere. With the exception of $SrAlF_5$, all DTA measurements were made on samples containing 2 m/o (mole per cent) Eu^{+2}.

Results, Compound Formation

The binary compounds as reported in the literature and determined in this work are summarized in Table I.

CaF_2-AlF_3.—All references reported a compound at $CaAlF_5$ and found that an inversion $\alpha \rightarrow \beta$ occurs, but the exact temperature was not in agreement. The in-

vestigations by Ravez and Hagenmuller (2) were done in sealed tubes but with no mention of atmosphere control used. The other works were done in air. As prepared under conditions used in these tests, the α- and β-$CaAlF_5$ were confirmed and a second compound at Ca_2AlF_7 was found which melted at 829° ± 3°C.

SrF_2-AlF_3.—Ravez and Hagenmuller (2) reported two compounds, $SrAlF_5$ and Sr_2AlF_7, with no inversions. These were confirmed in this work.

BaF_2-AlF_3.—This system was reported by Ravez to have the compounds $BaAl_2F_8$, α- and β-$BaAlF_5$, β-$Ba_3Al_2F_{12}$, $Ba_5Al_2F_{16}$, and $Ba_9Al_2F_{24}$ (4, 5). This work was done in sealed tubes but no atmosphere control was mentioned. Identification of the compounds was both by x-ray diffraction and IR absorption (5).

In this work, utilizing an HF atmosphere, the compounds α- and β-$BaAlF_5$, α-$Ba_3Al_2F_{12}$, and $Ba_9Al_2F_{24}$ were confirmed, but the compounds $BaAl_2F_8$ and $Ba_5Al_2F_{16}$ were not found. The structure reported as β-$BaAlF_5$ was found to be metastable at room temperature, but could be quenched by rapid cooling. $Ba_5Al_2F_{16}$ was found when firing in an atmosphere containing some oxygen, but not when fired in HF. The reported $\alpha \rightarrow \beta$ inversion in $Ba_3Al_2F_{12}$ was detected by DTA at 865°C but could not be obtained by quenching. The melting point was found at 883° ± 5°C, which was reported as the inversion temperature by Ravez. No additional heat effects were found when the sample was heated to 970°C, the reported melting point.

EuF_2-AlF_3.—Ravez and Dumora (10) reported a compound at $EuAlF_5$, isostructural with $SrAlF_5$, and a solid-solution region from EuF_2 to $Eu_{0.7}Al_{0.3}F_{2.3}$. The compound was confirmed in this work, and the solid-solution region was not investigated.

Results

Eu^{+2} *emission.*—With Eu^{+2} incorporation in the alkaline earth site, the compounds in these systems give emission of two distinct types, the broad band emission associated with the 5d to 4f transition in Eu^{+2} and line emission usually found in 4f to 4f transitions of the trivalent rare earths. Some structures gave both emissions. The spectral data for these compounds are summarized in Table II. Excitations for both types of emission are broad, unstructured bands, as shown in Fig. 1.

Band emission.—All of the structures in the CaF_2-AlF_3 system and the compound Sr_2AlF_7 gave band emission of moderate efficiencies. Typical emission curves are shown in Fig. 2. The compound $Ba_9Al_2F_{24}$ also gave weak band emission, but was not investigated in detail.

Line emission.—In these systems, line emission was found in the compounds $SrAlF_5$, α- and β-$BaAlF_5$, and α-$Ba_3Al_2F_{12}$. The emission contains a band resulting from the 5d to 4f transition, with a narrow group of

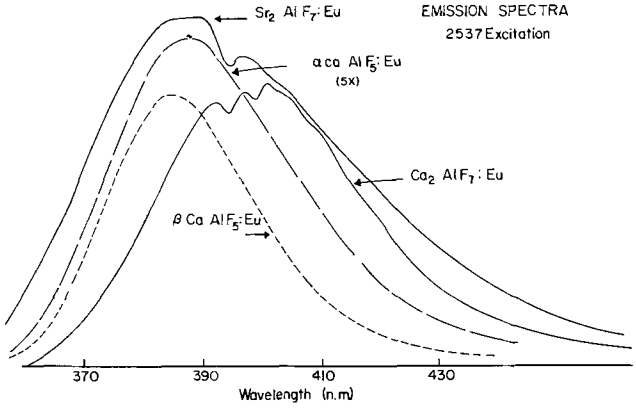

Fig. 2. Spectra of Eu^{+2} band emission, 2537Å excitation

lines superimposed on the band. The relative intensity of the band is highest in $SrAlF_5$, equaling about half of the total peak height, and is very weak in several of the barium compounds. The line emission is attributed to transitions in the 4f-4f level of Eu^{+2}, which is isoelectronic with Gd^{+3}. The major lines, which fall between 358 and 361 nm, are due to $^6P_{7/2}$ to $^8S_{7/2}$ transitions with a lesser amount of emission occurring near 355 nm from the $^6P_{5/2}$ to $^8S_{7/2}$ transition.

The number and positions of these lines are dependent on the particular structure of the compound. Spectral distribution curves are shown in Fig. 3-6, in

which α-$BaAlF_5$, β-$BaAlF_5$, and α-$Ba_3Al_2F_{12}$ are shown in expanded scale to include only the lines of the $^6P_{7/2}$ to $^8S_{7/2}$ transitions. When recorded on a resolution of 5Å SBW, the emission of β-$BaAlF_5$ cannot be distinguished from α-$BaAlF_5$ except by intensity. When recorded at 0.5Å SBW, each structure is shown to be distinctive. The peak heights shown in Table II are as recorded at 5Å SBW on the best materials obtained. The quantum efficiencies shown in the table of the three line emitters were obtained by comparing spectra taken at several different resolutions and can be considered only approximate.

The $SrAlF_5$ compound is the only line emitter which has a congruent melting and can be grown as a single crystal from the melt. Work is in progress by J. P. Meehan of this laboratory on obtaining single crystals of both unactivated and activated materials, and has provided crystals for structure analysis. The initial work has shown that the structure is more complex than reported by Ravez. The number of sites available for Eu^{+2} substitution has been confirmed as four. $SrAlF_5$ has two families of Sr^{+2} sites, one in eight-fold coordination and one in seven-fold coordination. Each family has two slightly differing arrangements (11). The number of lines in the $^6P_{7/2}$ to $^8S_{7/2}$ transition should be 16, resulting from four lines per Eu^{+2} site. Fifteen of these lines have been found. A more complete description and assignment of the lines in this and several other of these compounds was published elsewhere (9).

Substitutions of Eu^{+2} up to 30 m/o have been prepared with no change in the spectral distribution. Above about 2 m/o substitution, the emission intensity varies little with concentration. Since $EuAlF_5$ is isostructural with $SrAlF_5$, complete substitution is probable.

The extent of Eu^{+2} substitution in the barium compounds is considerably less than in $SrAlF_5$. α-$BaAlF_5$ will accept only about 12% Eu^{+2}. No change in spectral distribution has been found with increasing activator content, and above about 0.5% Eu, the intensity varies little. The β-$BaAlF_5$ form has been obtained by rapidly cooling the sample from just above the transition point, such as 800°C. The absolute intensity of the β form is highly dependent on the heating and quenching conditions. When $BaAlF_5$ is cooled from a firing temperature closer to the melting point, such as 850°C, the structure reverts to a poorly crystallized α-$BaAlF_5$, with some retention of another unknown structure. The presence of this form, which has been referred to as the γ form [ref. (9)] is detected by the addition of emission lines on the high wavelength side of the $^6P_{7/2} \rightarrow {}^8S_{7/2}$ transitions by measurements at 0.5Å SBW. The phase relations and structural changes which result in this modification have not been identified.

In $Ba_3Al_2F_{12}$, the Eu^{+2} substitution is limited to about 2%. Beyond this, the phase relations are such that α-$BaAlF_5$ and EuF_2 (or EuF_3) are stable. Ravez reported a β form, and included x-ray diffraction data, but no evidence of this structure has been found by quenching samples from an HF or N_2 atmosphere.

Solid solutions—Solid solution of Ba and Ca in the $SrAlF_5$ was determined by the shift in d spacing of the line at d = 1.959 (Fig. 7). The substitution of Ba can be made to a composition of $Sr_{0.15}Ba_{0.85}AlF_5$, and with Eu^{+2} activation, the spectral distribution changes as shown in Fig. 8. The line emission is reduced in intensity, and several additional 5d to 4f emission bands are introduced with increasing substitution. A similar change in spectral distribution is found with calcium in solid solution, which was found to extend to $Sr_{0.6}Ca_{0.4}AlF_5$ range. The presence of additional bands may indicate preferential substitution of Ba or Ca in the four Sr sites. In $BaAlF_5$, the substitution of Sr is limited to about 2%. The effect on Eu^{+2} emission is seen in increased intensity of the line emission, but no change in the 5d to 4f emission was detected when measured at 5Å SBW.

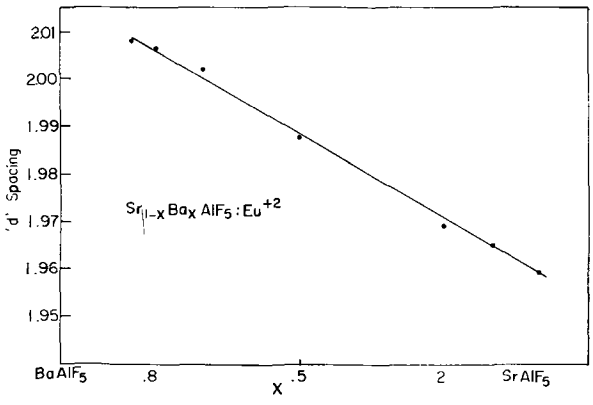

Fig. 7. Change in d spacing with Ba substitution in $SrAlF_5$

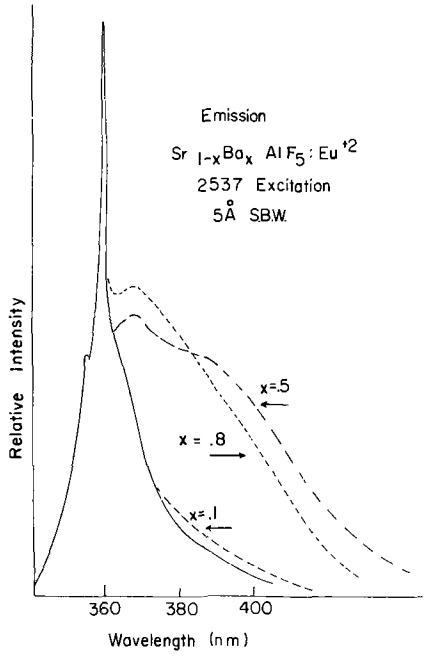

Fig. 8. Change in emission spectra of Eu^{+2} bands in solid-solution region of (SrBa)AlF_5.

Summary

The determination of compounds existing in the system aluminum fluoride-alkaline earth fluoride has disclosed structural types which result in a new type of emission from Eu^{+2}. This narrow line emission is sufficiently intense at 25°C to be potentially useful as an ultraviolet source. Spectral measurements at high resolution have shown that for a single compound, the number, position, and relative intensities of the lines are consistent, but the phase relations are such that preparative conditions can readily affect the phase purity of the material. These conditions affect the quenching of metastable phases and also possibly the volatility of the component fluorides, so that the characterization of all line-emitting compounds has not been completed.

Acknowledgments

The author is pleased to acknowledge the work of Dr. R. A. Hewes and Dr. J. P. Meehan of the Laboratory, and Dr. R. Newnham of Pennsylvania State University in contributing to this work. The optical measurements were made by Miss E. J. Wilson, and the preparative and measurements were done by Mrs. L. Funaro, Mrs. B. Burts, and Miss L. Wichert.

Manuscript submitted Dec. 2, 1970; revised manuscript received Jan. 15, 1971. This was Paper 358RNP presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Mechanism of Flux Action in the Thermal Recrystallization of Zinc Sulfide

R. A. Brown*

RCA Electronic Components, Lancaster, Pennsylvania 17604

ABSTRACT

Electrical conductivity and electron microscopic studies on ZnS:0.015% Ag containing 2% NaCl or 10% NaCl suggest chemical interaction between zinc sulfide and flux at about 620°C. In these systems the rate of increase in particle size at 750° to 1250°C followed $D^3 = kt$, where D is the average particle diameter at a firing time t. Activation energies for particle growth were 29 ± 2 kcal at 750°-1000°C, and 58 ± 4 kcal at 1000°-1250°C. Thermal recrystallization in zinc sulfide without additives commenced at 1050°C. From 1100° to 1250°C particle growth in ZnS also obeyed $D^3 = kt$, with an activation energy of 61 ± 4 kcal. These results can be interpreted in terms of material transport by diffusion processes.

There are numerous reports in the literature regarding the effect of a fluxing agent on the thermal recrystallization and luminescent properties of zinc sulfide phosphors. Earlier workers (1-3) suggested that the purpose of the flux is to provide a liquid phase in which the zinc sulfide is soluble, so that transport of material can easily occur. Apparently, no experimental evidence has been offered in support of this hypothesis. The work of Houben (4) cast some doubts on the classical concept of the mechanism of particle growth. In studies on the ZnS-NaCl system this worker found no zinc sulfide in the fused sodium chloride phase.

Earlier studies (5-7) showed that ZnS is precipitated from aqueous solution in the form of relatively large, irregularly shaped aggregates which are made up of very fine (submicron) grains of zinc sulfide. More recently Brown (8), following previous work by Bodi and Tufts (9), has investigated changes in the particle size and morphology of zinc sulfide phosphors during the early stages of firing. These investigations demonstrated that on heating in the presence of sodium chloride as flux, the fine grains of material coalesce and grow rapidly within the aggregate, so that during the first few minutes each agglomerate becomes a single particle of zinc sulfide. Subsequently, thermal recrystallization proceeds by the growth of large particles at the expense of smaller ones.

The objectives of the present study were: a) to determine the minimum temperature at which recrystallization occurs in zinc sulfide and zinc sulfide containing sodium chloride as flux; b) to investigate the possibility of the formation of a liquid phase at temperatures below the normal melting point of the flux; c) to suggest possible mechanism(s) for the particle growth processes.

Investigation of chemical interaction and liquid phase formation between the zinc sulfide and flux was carried out by electrical conductivity methods, following the procedure of Cypres and van Ommeslaghe (10). For the particle size measurements a Coulter Counter was employed. This instrument analyzes particle size distribution by noting the change in resistance of an electrolyte caused by the volumetric change in an orifice as each particle passes through it. The rate of increase in particle size was interpreted in terms of an expression of the form $D^n = kt$ (11, 12), where D represents the average particle diameter at a firing time t. This expression is discussed more fully in the Appendix. It should be pointed out that the thermal effects depend on factors such as sample size, configuration of the firing vessel, duration of heating, and the rate of cooling. Consequently, the results obtained should be regarded as relative rather than absolute. Note that compositions are given in terms of per cent by weight.

Experimental

A detailed account of the preparation of zinc sulfide from aqueous zinc sulfate solution with hydrogen sulfide has been given previously (7). For the present work, zinc sulfide was obtained by precipitation at 25°C from 2 liter of 1M zinc sulfate solution using a hydrogen sulfide flow of 0.82 liter/min. After filtration through a Buchner funnel and washing with deionized water the precipitate was subsequently dried at 100°C for 6 hr.

For the electrical conductivity experiments, 0.6g specimens of zinc sulfide containing 2% sodium chloride were pressed into cylindrical compacts at a pressure of 800 kg/cm². The disks were placed between two

* Electrochemical Society Active Member.

Key words: phosphors, particle growth, zinc sulfide-sodium chloride, zinc diffusion in zinc sulfide.

pieces of platinum foil, to provide electrodes, and heated at a rate of approximately 10°C/min to 900°C in a stream of oxygen-free nitrogen having a flow rate of 30 cc/min. During heating, electrical conductivity of the specimens was measured at regular intervals of time by means of an Industrial Instruments Model RC 16 B conductivity bridge. For comparison, specimens of pure sodium chloride and pure zinc sulfide were pressed into disks and their electrical conductivity measured, as above.

Initially, recrystallization experiments were carried out by firing 5.5g samples in covered "Vitreosil" crucibles for various lengths of time at temperatures between 550° and 800°C in air. Systems investigated included ZnS:0.015% Ag with 2% NaCl flux, zinc sulfide without additives, ZnS containing Ag, Al, or Cu each at the level of 0.015%, and zinc sulfide containing 2% sulfur. Subsequently, specimens were examined by electron microscopic and x-ray powder diffraction methods, for the determination of particle size, morphology, and crystal structure.

For more prolonged particle growth experiments the following method was employed to prevent oxidation of the samples, and maintain a stoichiometric composition of the zinc sulfide, during heating. Test samples of 10g were placed in covered "Vitreosil" crucibles, located in a larger crucible, surrounded with zinc sulfide, and covered with a lid. Specimens were fired at temperatures in the range 750°-1250°C for periods of 1 to 10 hr. Compositions studied included ZnS:0.015% Ag with 2% or 10% sodium chloride flux, and zinc sulfide without additives. Subsequently, the materials were examined by scanning electron microscopic, x-ray powder diffraction, and Coulter Counter methods.

Results

Some representative results obtained in the initial firing experiments are given as Fig. 1 and 2. Figure 1(a) shows the appearance of the zinc sulfide precipitate after firing at 800°C for 2 hr. On heating zinc sulfide for 2 hr at 800°C in the presence of 0.015% Ag, Al, or Cu, or with 2% sulfur, there was no noticeable change in either aggregate size or morphology. This absence of change is demonstrated in Fig. 1(b) which gives only the typical result obtained for ZnS:0.015% Ag. X-ray powder diffraction data for both pure ZnS and zinc sulfide containing the various additives showed a sharpening in the diffraction patterns at firing temperatures of 700° and 800°C. Consequently, in the absence of a flux heating to 800°C apparently leads to an amorphous → crystalline lattice rearrangement, but does not give any visible change in the size or morphology of the aggregates. Figure 2 shows the influence of temperature on ZnS:0.015% Ag with 2% NaCl flux. At 550°C [Fig. 2(a)] and 600°C [Fig. 2(b)] there is no evidence of particle growth after heating for 2 hr. On firing for 2 hr at 650°C some slight coalescence occurs, as demonstrated in Fig. 2(c). Recrystallization proceeded rapidly at 700°C. Coalescence of the fine grains commenced at about 4 min [Fig. 2(d)]; after firing for 2 hr a particle size of approximately 2μ was attained, as shown in Fig. 2(e).

A plot of electrical conductivity as a function of temperature for (*a*) sodium chloride, (*b*) zinc sulfide containing 2% sodium chloride, and (*c*) zinc sulfide is given as Fig. 3. Zinc sulfide shows a gradual, slow increase in conductivity with rise in temperature. In the case of sodium chloride there is a pronounced increase in electrical conductivity at 800°C, which corresponds with the normal melting point of 801°C. Contrast these results with the behavior of the ZnS, 2% NaCl system which shows a large increase in conductivity at 620° to 720°C, followed by a further rise in the region of 800°C. This suggests the occurrence of a liquid phase or chemical reaction at temperatures as low as 620°C. Figure 4 shows the behavior of the electrical conductivity of ZnS, 2% NaCl during heating and cooling. Since the curve obtained on cooling does not follow that given during heating, it is suggested that the electrical conductivity may be due to chemical reaction, rather than a simple melting.

Results obtained in the particle growth experiments were plotted in the form of log D *vs.* log t, where D represents the average diameter of the phosphor particles (median point by weight of particles based on Coulter Counter measurements) at a firing time t. The derivation of these log D — log t plots is developed in the Appendix. Typical sets of curves, in which log D is plotted against log t at different firing temperatures, are given in Fig. 5 for ZnS:0.015% Ag, 2% NaCl, and in Fig. 6 for ZnS:0.015% Ag, 10% NaCl. These graphs show that a linear dependence does, in fact, exist. Since the measured slope of these lines is 0.33, particle growth in zinc sulfide containing sodium chloride as flux can be described by the expression $D^3 = kt$. Note that in this system an increase in the flux content leads to enhanced particle growth.

Arrhenius-type activation energy plots were derived from the data of Fig. 5 and 6, with the use of an arbitrarily chosen constant D of 10μ, and are given as Fig. 7. These plots show the occurrence of two activation energy values. In the ZnS:0.015% Ag, 2% NaCl system the results obtained were 29 ± 2 kcal at 750°-1000°C and 58 ± 4 kcal between 1000° and 1250°C. For ZnS:0.015% Ag, 10% NaCl activation energies for particle growth were 29 ± 2 kcal at 750° to 950°C and 59 ± 4 kcal at temperatures in the range 1050°-1250°C. Activation energies were calculated by means of a regression and correlation analysis carried out by G. M. Ehemann of this laboratory with the use of an RCA Spectra 70 computer program.

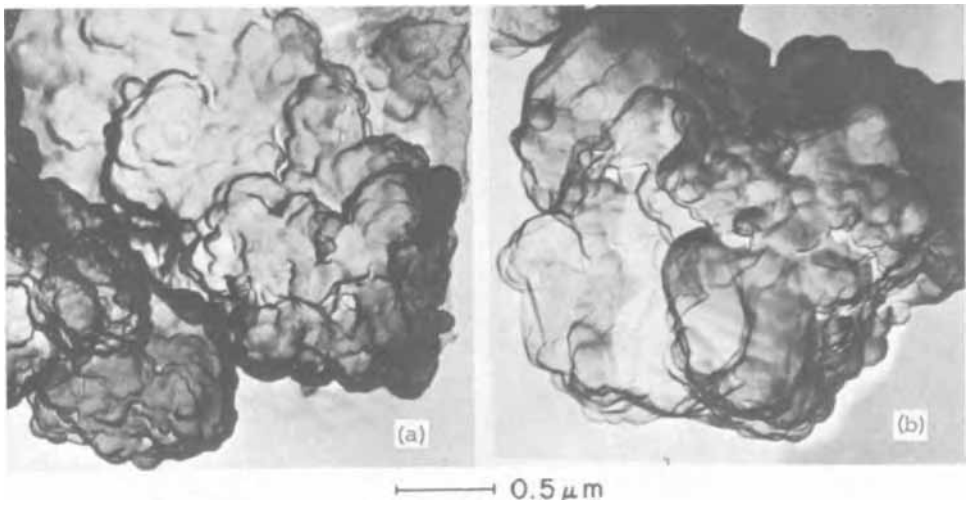

Fig. 1. Firing sequence at 800°C for 2 hr: (a) ZnS, (b) ZnS:0.015% Ag.

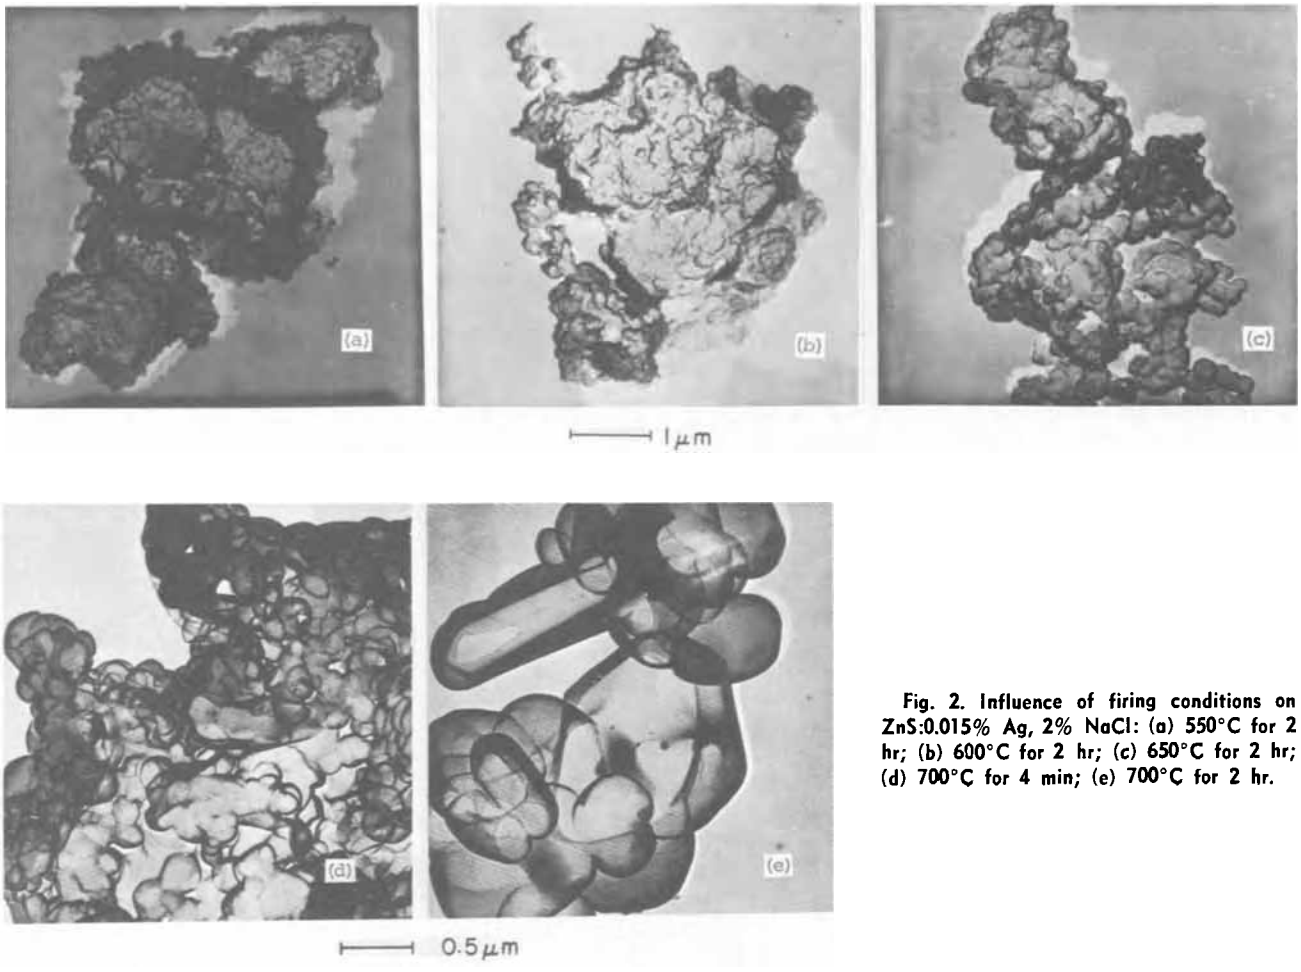

Fig. 2. Influence of firing conditions on ZnS:0.015% Ag, 2% NaCl: (a) 550°C for 2 hr; (b) 600°C for 2 hr; (c) 650°C for 2 hr; (d) 700°C for 4 min; (e) 700°C for 2 hr.

Figure 8 gives the relationship between log D and log t for zinc sulfide without additives. In this case, there was no measurable increase in particle size on heating for up to 6 hr at 800°-1000°C. Only the typical results obtained at 800° and 1000°C are given in Fig. 8. Some increase in particle size was observed at 1050°C. Between 1100° and 1250°C plots of log D *vs.* log t were linear with a slope of 0.33. Consequently, the relationship $D^3 = kt$ is also followed in zinc sulfide without flux, at temperatures above 1050°C. An Arrhenius plot was derived from the data of Fig. 8 and is given as

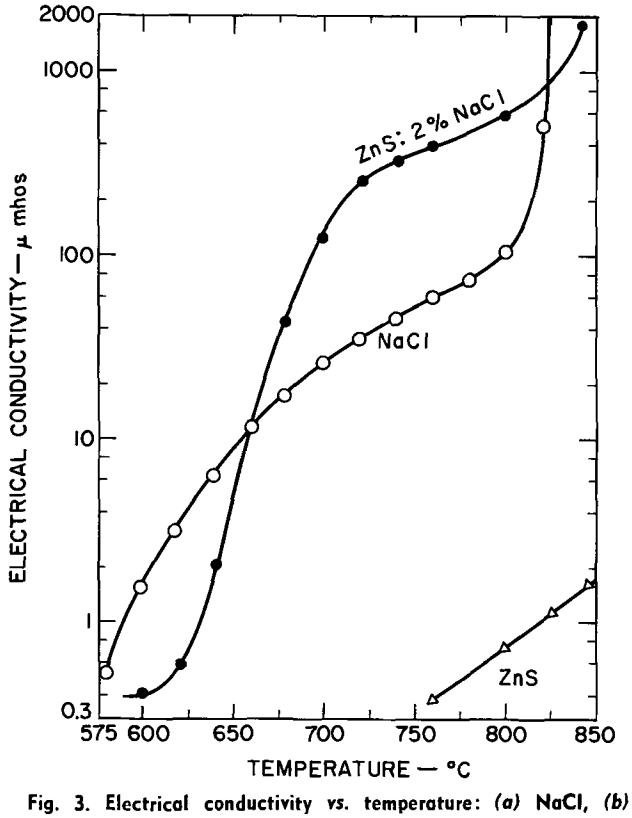

Fig. 3. Electrical conductivity *vs.* temperature: *(a)* NaCl, *(b)* ZnS-2% NaCl, *(c)* ZnS.

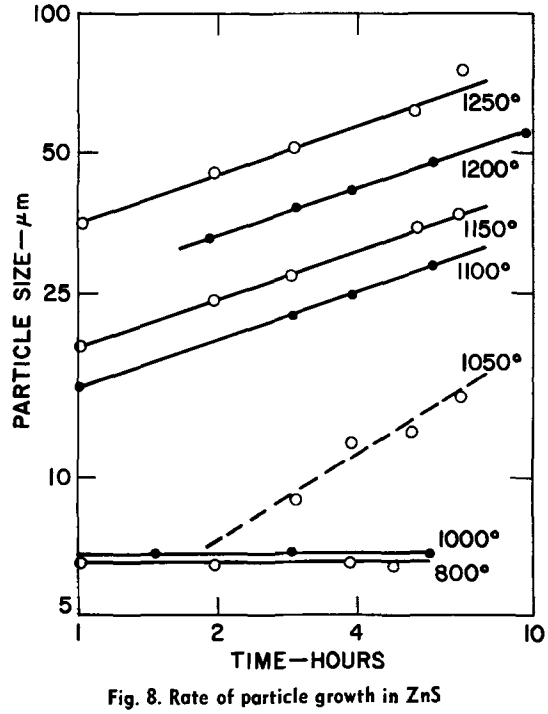

Fig. 8. Rate of particle growth in ZnS

Fig. 9. From this plot, the activation energy for thermal recrystallization in zinc sulfide at 1100° to 1250°C was calculated to be 61 ± 4 kcal.

Scanning electron photomicrographs of (*a*) unfired zinc sulfide precipitate, (*b*) zinc sulfide heated for 1 hr at 800°C, and (*c*) zinc sulfide fired at 1000°C for 1 hr are given in Fig. 10. These confirm that in the absence of a flux there is very little change in the appearance of the zinc sulfide aggregates on heating at temperatures up to 1000°C. On the other hand, these photomicrographs appear to show that some growth of the fine zinc sulfide grains occurs within the aggregate.

Discussion

On the basis of the electrical conductivity and electron microscopic studies, the onset of thermal recrystallization is suggested to occur by the following sequence of events. Heating zinc sulfide with sodium chloride to about 620°C leads to chemical interaction between the zinc sulfide and flux with the formation of a liquid phase, and the consequent introduction of defects in the zinc sulfide lattice. This sequence would explain the marked rise in electrical conductivity at 620° to 720°C. If the behavior of zinc sulfide is comparable with that of zinc oxide (13) then it is possible that the electrical conductivity may result from the presence of interstitial zinc. Other workers (14, 15)

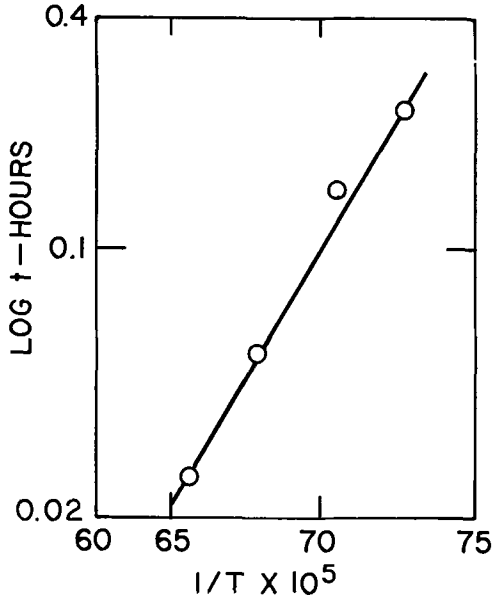

Fig. 9. Arrhenius plot for particle growth in ZnS

have established the occurrence of a chemical interaction by showing that when zinc sulfide phosphors are prepared in the presence of a metal chloride flux zinc chloride is formed according to the reaction

$$ZnS + 2MCl \rightarrow ZnCl_2 + M_2S$$

where M represents an alkali metal, such as Na. This finding was confirmed in the present study by the detection of zinc chloride in the wash water from typical phosphor preparations. Following the chemical reaction at 620°C, thermal recrystallization commences at about 650°C. Note that this temperature is considerably below the normal melting point of 801°C (16) given for the sodium chloride flux.

For ZnS:0.015% Ag with 2% NaCl or 10% NaCl the activation energy for particle growth at 750° to 1000°C was 29 kcal, whereas at 1000° to 1250°C a value of 58 kcal was obtained. Several workers (17-19) have studied the self-diffusion of atoms in polycrystalline zinc sulfide and have found movement of zinc to be the rate determining step in the diffusion processes. On the basis of radioactive tracer studies, Secco (17) gave a value of 29 kcal for the interstitial diffusion of zinc, that is movement of zinc through interstitial channels in the zinc sulfide lattice. An activation energy of 61.5 kcal was obtained by Secco (17) for the lattice diffusion of zinc, that is the movement of zinc through normal zinc sites in the zinc sulfide lattice. A similar value for a lattice diffusion mechanism was given by Bansagi and co-authors (19). The results obtained in the present study are in very good agreement with the activation energy values given by Secco (17). Consequently, particle growth in zinc sulfide containing sodium chloride is suggested to occur as follows. Chemical interaction between the host material and flux leads to the introduction of chloride into the host lattice at low temperatures (20). Although the exact nature of the resultant defects is not fully understood, several workers (21, 22) have suggested that interstitial zinc may be formed. Since the activation energy of 29 kcal is in excellent agreement with the value of 29 kcal given by Secco (17) for an interstitial diffusion mechanism, it appears that particle growth in ZnS:Ag with NaCl flux at 750°-1000°C occurs by the direct interstice-to-interstice diffusion of zinc (valency unspecified). At temperatures between 1000° and 1250°C the energy of activation of 58 kcal agrees with the value of 61.5 kcal given by Secco for a lattice diffusion process. Apparently, at higher temperatures there is sufficient thermal mobility for transport of material to occur by the lattice diffusion of zinc (valency unspecified). Note that these growth processes do not involve a solution-reprecipitation mechanism, and would require only small quantities of chloride in the zinc sulfide lattice. This conclusion is in accord with the finding of Houben (4) that fused sodium chloride does not dissolve zinc sulfide to an appreciable extent.

In the absence of a flux zinc sulfide showed no appreciable changes in aggregate size or morphology on heating at temperatures up to 1000°C. From 1100°-1250°C an activation energy of 61 kcal was obtained for the growth processes. This result suggests that at higher temperatures particle growth in zinc sulfide occurs by the same mechanism as in ZnS with NaCl flux, namely, lattice diffusion of zinc. The onset of thermal recrystallization in zinc sulfide, and perhaps also the change in mechanism for zinc sulfide with a flux, may be initiated by the cubic-hexagonal phase transformation which occurs at approximately 1020°C (23). This finding is in keeping with an observation by Morgan (24).

For both zinc sulfide and ZnS-NaCl the rate of increase in particle size can be represented by the expression $D^3 = kt$. Shionoya and Amano (25) found that a similar equation can be used to describe particle growth in ZnS:Cu and ZnS:Cu containing either 4% or 10% NaCl at 1000° to 1150°C. These workers obtained an activation energy of 30 kcal for particle growth in ZnS:Cu containing sodium chloride, and showed that the value was independent of the amount of flux used. This result is in accord with the value of 29 kcal calculated in the present study for ZnS:0.015% Ag with NaCl at lower temperatures, and again suggests an interstitial diffusion mechanism. An activation energy of 80 kcal was given by Shionoya and

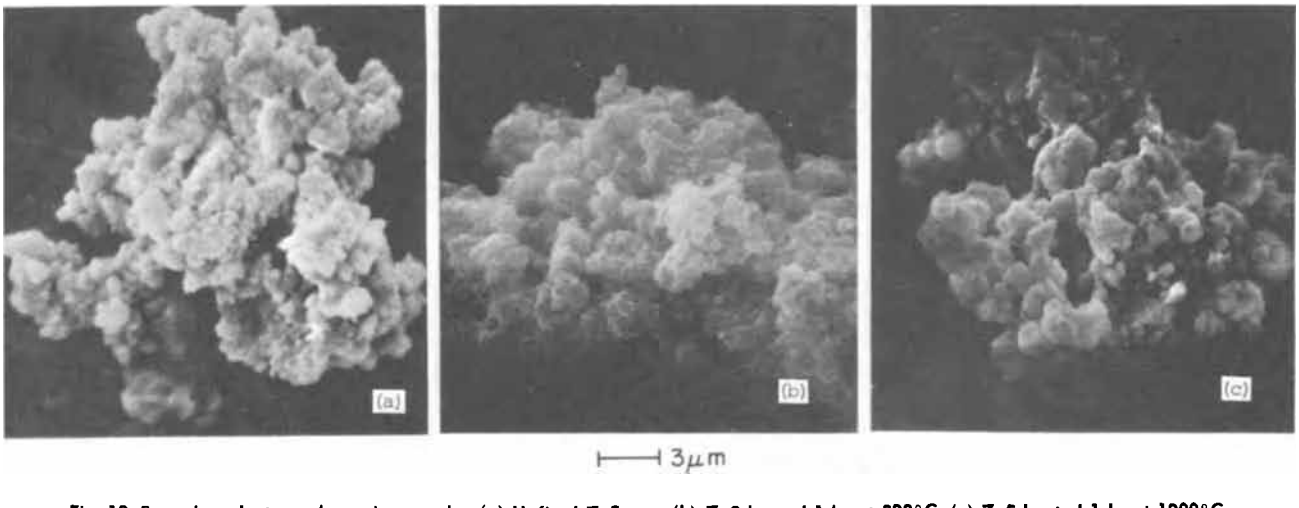

Fig. 10. Scanning electron photomicrographs: (a) Unfired ZnS ppt, (b) ZnS heated 1 hr at 800°C, (c) ZnS heated 1 hr at 1000°C

Amano for thermal recrystallization in ZnS:Cu. This value is somewhat higher than the 61 kcal found in the present work for zinc sulfide without additives.

In summary, this work has shown that chemical reaction between zinc sulfide precipitate and sodium chloride flux occurs at approximately 620°C. This temperature is considerably below the normal melting point of the flux. Subsequently, thermal recrystallization in ZnS:Ag containing sodium chloride commences at 650°C and becomes rapid at 700°C. The rate of increase in particle size of zinc sulfide or ZnS:0.015% Ag with NaCl follows the expression $D^3 = kt$, where the symbols have the meanings given above. Results obtained in the thermal recrystallization experiments can be interpreted in terms of material transport by diffusion processes. This finding is in contrast with the classical concepts of flux action, which postulated that particle growth in zinc sulfide phosphors occurred by a dissolution-reprecipitation phenomenon.

Acknowledgments

The author expresses his gratitude to E. W. Bomgardner for assistance with the preparatory work, also to Mrs. E. M. Rineer and Mrs. J. N. Shenk for providing the Coulter Counter measurements. For valuable discussions and suggestions especial thanks are due to Dr. A. L. Smith.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

APPENDIX

Particle Growth Dependence

Various workers have shown that the rate at which grain growth occurs in metal or ceramic systems is inversely proportional to some power of the average grain diameter, *i.e.*

$$\frac{dD}{dt} = \frac{k}{D^m}$$

or, on integrating

$$D^{m+1} - D_0^{m+1} = kt \qquad [1]$$

where D = the average diameter of a grain at a firing time t
D_0 = the grain diameter at $t = 0$
k = a rate constant

Equation [1] is usually written in the form $D^n = kt$, or as

$$D = k^{1/n} t^{1/n} \qquad [2]$$

where $n = (m + 1)$ and when $D >> D_0$. Thus, on plotting log D as a function of log t a straight line of slope 1/n is obtained. Frequently the value of 1/n lies between 0.1 and 0.5.

An activation energy for grain growth can be obtained conveniently from the log D/log t plot by measurement of the time, t', required to reach an arbitrarily chosen constant value of grain size. The reciprocal of this time value is directly proportional to the rate constant for grain growth. Consequently, the relationship between log t' and $1/T$ is, in effect, an Arrhenius plot of slope $E/2.303R$, from which the activation energy E can be evaluated.

In the present study the expressions developed for grain growth in porous compacts are applied to particle growth in zinc sulfide phosphors. Note that Eq. [2] is valid only for $D >> D_0$. This assumption is justified in the present study since the initial size of the zinc sulfide crystallites is approximately 0.02μ [ref. (7)], whereas the particle size of the fired phosphors is in the range 5μ to 50μ. For convenience, t' is taken as the time required to reach a particle size of 10μ.

The Influence of the Amorphous Phase on Ion Distributions and Annealing Behavior of Group III and Group V Ions Implanted into Silicon

Billy L. Crowder*

International Business Machines Corporation, Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A study has been made of room-temperature implantations of group III and group V ions into amorphous Si layers prepared by the previous implantation of Si ions into crystalline Si substrates. Neutron activation combined with anodic oxidation and HF stripping techniques was used to determine the profiles of the implanted ions for Ga^{71} and Sb^{121}. Electrical evaluation of the implanted layers by Hall effect and sheet resistivity measurements in conjunction with layer removal techniques yielded profiles of the net electrically active species and the depth variation of mobility after annealing for 30 min in the temperature range 600°-900°C. The ion species studied were B^{11} (60-200 keV), Al^{27} (200 keV), $Ga^{69\&71}$ (140 and 280 keV), P^{31} (100-280 keV), As^{75} (280 keV), $Sb^{121\&123}$ (120 and 260 keV), and Bi^{209} (240 keV). The epitaxial regrowth of the amorphous phase at 600°C causes most of the implanted ions within this region to become electrically active and uncompensated for the ion species B, P, As, Sb, and Bi even for peak ion concentrations in excess of 10^{20} cm^{-3}. For Al and Ga implants, the number of carriers was less than the number of implanted ions. The profiles obtained for these implantations into amorphous Si were compared with predictions based on the theory of Lindhard, Scharff, and Schiott.

A dominant feature frequently observed in the annealing behavior of the electrical properties of ion-implanted Si produced at or below room temperature is the presence of a marked annealing stage at 600°C (1-4). This annealing stage has been attributed to the epitaxial recrystallization of a continuous amorphous phase onto the underlying Si substrate, a process which occurs between 550° and 600°C (5, 6). The present investigation represents a systematic study of the annealing effects that this amorphous phase has on the electrical properties of Si implanted with group III and V elements in the energy range 60-300 keV. A broader view of the electrical behavior of ion-implanted Si may be found in the article by Baron *et al.* (1) or in the review contained in the monograph by Mayer, Eriksson, and Davies (7).

For relatively high-dose implantations of heavy ions (*e.g.*, greater than 10^{15} ions cm^{-2}) at room temperature or below, most of the ions impinge on amorphous Si. Table I presents the dose required to produce a continuous amorphous surface layer as computed from a simple model (8) for the common group III and V ions in Si for very low-temperature implantations (D_0) and for room-temperature implantations (D_{300}), and as observed experimentally at room temperature (9). For light ions and/or low doses, a question arises as to whether implantation in a "random" direction is equivalent to implantation in amorphous material. Dearnaley and co-workers, who employed the convenient radiotracer P^{32}, determined that the profile for 120 keV P^{32} in amorphous Si (produced by Ne bombardment) was different from 120 keV P^{32} implanted in a "random" direction (10). The profile in amorphous Si exhibited a peak concentration at a depth 20% deeper than the profile obtained in crystalline Si in a "random" direction and no evidence of channeling. A second aim of the present investigation is to determine the ion profiles obtained in amorphous Si for several group III and V ions and to compare such profiles with the theoretical predictions of Lindhard, Scharff, and Schiott (LSS) (11).

Table I. Ion dose required to produce a continuous amorphous Si layer (8)

Ion	D_0, cm^{-2}	D_{300}, cm^{-2}	D_{300} [measured (9)], cm^{-2}
B	9×10^{14}	4×10^{17}	$>2 \times 10^{16}$
P	2×10^{14}	8×10^{14}	$>5 \times 10^{14}$
As	1×10^{14}	2×10^{14}	2×10^{14}
Sb	6×10^{13}	1×10^{14}	1×10^{14}
Bi	4×10^{13}	6×10^{13}	5×10^{13}

Experimental Procedure

Implantations were conducted with the 300 kV accelerator used in our previous studies (3, 4, 6). The focused ion beam, after electromagnetic separation, was rastered electrostatically to provide a uniform implantation over a 2 x 2 cm^2 area. The total dose was determined by integrating the ion beam current. Dose rates employed in the present investigation ranged from 0.1 to 1.0 μA cm^{-2}, typically being 0.5 μA cm^{-2}. The substrates were wafers cut from Czochralski-grown crystals with a resistivity of 1 ohm-cm. These wafers were etch polished to provide a damage-free surface.

Hall effect and sheet resistivity measurements were made using the van der Pauw configuration previously employed. The van der Pauw pattern, defined by mesa etching, utilized contact pad regions produced by diffusion. Ions were implanted into substrates of opposite conductivity type to form p-n junctions, which provided the electrical isolation necessary for investigating the electrical properties of the implanted layer. In profiling experiments, anodic oxide growth, removal of an oxide by dilute HF, and electrical measurements were accomplished in a sample holder previously described (4).

Ion profiles were determined for P^{31}, As^{75}, Sb^{123}, and Ga^{71} by using neutron activation analysis in conjunction with layer removal by anodic oxidation and HF stripping as previously described (12). In this technique, liquid scintillation counting on the solution resulting from dissolving the anodic oxide provided the

necessary radiochemical assay. Annealing of samples was accomplished in a tubular furnace under a flowing nitrogen atmosphere.

Amorphous Silicon

A few comments are in order as to what constitutes a continuous amorphous Si phase. Investigations by Brodsky and co-workers on amorphous Si produced by several techniques provide a convenient frame of reference with which to work. These authors have determined some of the material properties associated with amorphous Si (13). Our previous investigations have demonstrated that the surface layers of Si which have received a "saturation" dose of energetic heavy ions exhibit the same optical properties and the characteristic ESR signal associated with amorphous Si (14) [the term "saturation" is used since the strength of the characteristic ESR signal increases linearly with dose (for fixed dose rate) until a critical dose[1] is reached beyond which only a small change with increasing dose is observed]. It is reasonable to conclude that such layers are completely amorphous Si.

The amorphous Si phase was produced by bombardment with 280-300 keV Si^{28} ions. For substrates maintained at or near room temperature during implantation, a dose of 3 x 10^{15} ions cm^{-2} was sufficient to produce an amorphous surface layer 0.5-0.6μ deep. In this paper, the term "amorphous Si" refers to such a surface layer.

One problem associated with the use of Si^{28} is the possible contamination of the ion beam with singly ionized molecular nitrogen. The source gas used was SiF_4, and the ratio of mass 28 to 29 to 30 was used to verify that no large amount of N_2 contamination was present. In the present experiments, the possible incorporation of relatively small concentrations of N^{14} seemed preferable to the use of large doses of "inert" species such as Ne^{20} or Ar^{40}. The use of Ar^{40} to produce amorphous Si has a deleterious effect on the annealing behavior of the electrical characteristics of Si implanted with P, even for an annealing temperature in excess of 900°C. A sample which was damaged with Ar (280 keV, 3 x 10^{15} cm^{-2}) prior to an implantation of P (280 keV, 3 x 10^{15} cm^{-2}) had, after a 600°C, 30 min anneal, a sheet resistivity of 550 ohms/sq compared to 80 ohms/sq observed after similar annealing for a control sample implanted only with P. This sample still exhibited a high sheet resistivity (160 ohms/sq) after annealing at 915°C for 30 min.

Interpretation of Hall Effect Measurements

The interpretation of Hall effect measurements obtained from ion-implanted layers has been adequately covered by a number of authors (1, 7). We briefly review some of the assumptions involved in interpreting the types of experiments presented in this paper.

The electrical measurements yield values for the sheet Hall coefficient, R_S, and the sheet resistivity, ρ_S. In experimental evaluation of the efficacy of annealing treatments, these parameters are often converted to the number of carriers per square centimeter, N_S, and the effective mobility, μ_{eff}

$$N_S = r/R_S e$$

$$\mu_{eff} = R_S/\rho_S$$

where e is the charge on the electron and r is the Hall factor expressing the ratio of Hall mobility to conductivity mobility. In most cases, the assumption is made that $r = 1$. We shall return to this point later in this section. It should be noted that both N_S and μ_{eff} are weighted averages over the impurity distribution (1, 7). In general, N_S is smaller than the true number of carriers per square centimeter since carrier mobilities are higher with lower impurity concentration. Because of this fact and the fact that the annealing behavior may differ in different portions of the ion distribution, the data obtained by isochronal annealing studies of the parameters, N_S and μ_{eff}, are only semiquantitative.

A more accurate picture of the implanted ion distribution may be obtained by combining sheet resistivity and sheet Hall coefficient measurements with layer removal techniques (1, 7). From such differential measurements, one can compute the resistivity of the ith layer, ρ_i

$$d_i\,(\rho_i)^{-1} = (\rho_S)_i^{-1} - (\rho_S)_{i+1}^{-1}$$

the mobility, μ_i, of the ith layer

$$\mu_i = \left[\frac{(R_S/\rho_S^2)_i - (R_S/\rho_S^2)_{i+1}}{(\rho_S)_i^{-1} - (\rho_S)_{i+1}^{-1}}\right]$$

and the carrier concentration, n_i, for the ith layer

$$n_i = (e\mu_i\rho_i)^{-1}$$

where d_i is the thickness of the ith layer. In this manner, a profile of the depth distribution of carrier concentration, carrier mobility, and layer resistivity can be derived.

A basic assumption involved in the above analysis is that the ratio of the Hall mobility to the conductivity mobility is unity. For lightly doped Si ($\lesssim 10^{16}$ cm^{-3}), the experimentally determined ratio is 1.2 to 1.3 for electrons and 0.7 to 0.8 for holes (15, 16). In n-type specimens, the Hall ratio, r, tends to unity for concentrations in excess of 10^{18} cm^{-3}; thus, for properly annealed n-type layers doped by ion implantation, the experimentally observed electron mobility is very nearly that determined for uncompensated bulk Si of comparable carrier concentration (1, 4). In such cases, the use of bulk data [*e.g.*, Irvin's curves (17)] in conjunction with differential sheet resistance measurements would yield a reasonable approximation to the impurity distribution.

The value of r for high concentrations of acceptors in Si is not at all well known. Irvin's data for p-type Si indicate mobility values which are significantly lower than those observed in other studies in the range 10^{17} to 10^{19} cm^{-3} (16). Furthermore, a determination of the Hall mobility in ion-implanted layers (Al, Ga implantations) (1) indicated deviations from bulk mobility values for concentrations in excess of 5 x 10^{17} cm^{-3}. Figure 1 presents a compilation of the observed Hall mobilities as a function of layer resistivity for a number of "well-annealed," boron-implanted Si wafers. Implantations were conducted at room temperature at energies of 30-200 keV. The samples were subsequently annealed for 30 min at 900°-950°C prior to stripping

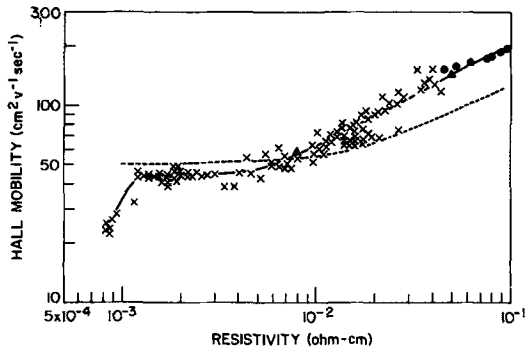

Fig. 1. Hall mobility vs. layer resistivity for B^{11} ion-implanted Si. Implantations were conducted at room temperature with ion energies between 30 and 200 keV, and the wafers were annealed for 30 min at 900°-950°C. The crosses represent data obtained for ion-implanted layers, the dashed line corresponds to the conductivity mobility of bulk Si from Irvin's curves [Ref. (17)], the triangles are Hall mobility measurements in bulk Si from Morin and Maita (Ref. 15), and the circles are Hall mobility data from Wolfstirn [Ref. (16)].

[1] The critical dose determined in this manner agrees well with published values obtained from Rutherford backscattering experiments (Table I).

for profiling. The triangles represent the Hall mobility determined in bulk Si (B-doped) by Morin and Maita (15), while the closed circles indicate the Hall mobility of Ga-doped Si given in Wolfstirn's study (16). The observed Hall mobility in these ion-implanted layers agrees well with that observed in bulk Si. In the concentration range 10^{17} to 10^{19} cm^{-3}, this agreement is an indication that the value of r is 0.7. The dashed line represents the conductivity mobility determined from Irvin's curve of resistivity as a function of impurity concentration (17). Irvin's data in the lower concentration range deviate markedly from experimental observations. The observed Hall mobility does approach a constant value in the concentration range 10^{19} to 10^{20} cm^{-3}, which is consistent with a constant conductivity mobility from Irvin's bulk data. If his bulk data in this concentration range are correct, a value of r of 0.8-0.9 would be consistent with the observed Hall mobility. For concentrations in excess of 10^{20} cm^{-3}, only limited experimental information was obtained. At concentrations greater than 1.5 x 10^{20} cm^{-3}, the observed Hall mobility decreased sharply with increasing concentration.

In interpreting the measurements of Hall effect in this paper, the assumption is made that the ratio of Hall mobility to conductivity mobility is unity. In well-annealed samples, the results discussed above indicate that such an assumption introduces errors of less than 30% in carrier concentration profiles in the range 10^{17} to 10^{20} cm^{-3}, the error being in the direction of indicating too many carriers in p-type samples and too few carriers in n-type samples.

Experimental Results and Discussion: Group III Elements

Boron.—The effect of the amorphous phase on the annealing behavior of room-temperature boron implantations is summarized in Fig. 2, which depicts the variation of N_S and ρ_S with 30 min isochronal annealing at temperatures 600°-900°C. The samples were implanted with 120 keV B^{11} ions in a "random" direction (1 x 10^{15} cm^{-2}, open triangles) or into amorphous Si (1 x 10^{15} cm^{-2}, closed circles; 1 x 10^{16}, open circles)

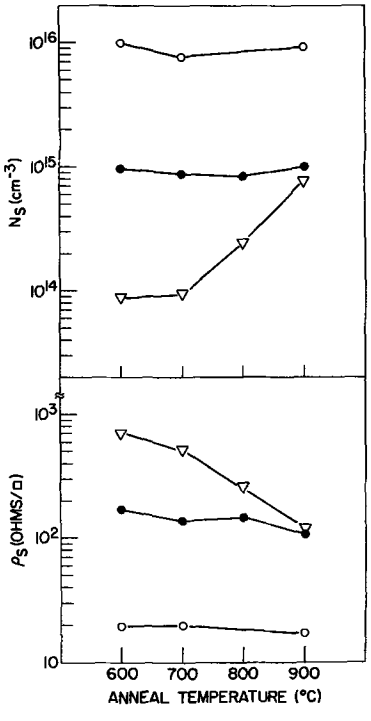

Fig. 2. N_S and ρ_S vs. annealing temperature for 120 keV B^{11} implanted into amorphous Si (circles) and into crystalline Si in a random direction (triangles). The implanted B dose was 1 x 10^{15} ions cm^{-2} (closed circles, open triangles) and 1 x 10^{16} (open circles), and implantations were conducted at room temperature. The duration of annealing was 30 min.

prepared by a sufficient dose of 300 keV Si^{28} ions (1 x 10^{16} cm^{-2}) to render the substrate amorphous from the surface to a depth of 0.6μ. The presence of the amorphous phase, which regrows epitaxially onto the Si substrate at 550°-600°C, greatly increases the number of implanted species which are electrically active and uncompensated, as previously observed by a number of authors (2, 18).

An experiment designed to establish clearly the association between the location of the amorphous phase and the region in which most of the ions are rendered electrically active and uncompensated after a low-temperature anneal was performed as follows. Damage by 300 keV Si^{28} ions was used to produce an amorphous region of a known thickness (0.53μ as determined from interference fringes in the optical absorption spectrum). This wafer was then implanted with B^{11} ions of such an energy that roughly half the ions were within this surface amorphous region and half were deeper within the crystal (*e.g.*, 200 keV ions). After annealing to recrystallize the amorphous phase, the wafer was profiled. The results of this experiment are presented in Fig. 3, which shows the depth distribution of the hole concentration and the hole mobility of 5 x 10^{15} 200 keV B^{11} ions cm^{-2} implanted under the above conditions. The carrier concentration shows a marked drop near the point at which the amorphous-crystalline interface occurs. Beyond this depth, the carrier concentration is markedly lower than the implanted ion concentration as shown by the solid line which represents the profile obtained in an annealed sample which had been implanted at 100°K with the same dose of 200 keV B^{11} ions. Implantation of B at such low temperatures produces a continuous amorphous surface layer; *cf.* Table I and Ref. (2).

The carrier mobility, on the other hand, is representative of that observed in uncompensated bulk Si of comparable carrier concentration (given by the dashed line in Fig. 3 which was derived from the experimental

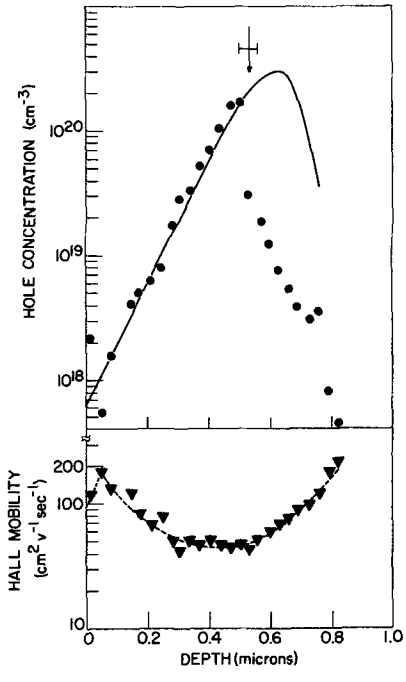

Fig. 3. Depth variation of the hole concentration and Hall mobility for 5 x 10^{15} keV B^{11} ions cm^{-2} implanted into Si with an amorphous surface layer. The depth of the amorphous layer was determined by interference fringes in the optical absorption spectrum to be 0.53μ as shown by the arrow. After implantation, the wafer was annealed at 800°C for 30 min prior to profiling. The dashed line represents the Hall mobility as determined from the solid line in Fig. 1 and the layer resistivity. The solid line is a profile obtained from a well-annealed sample implanted at 100°K with 5 x 10^{15} 200 keV B^{11} ions cm^{-2}.

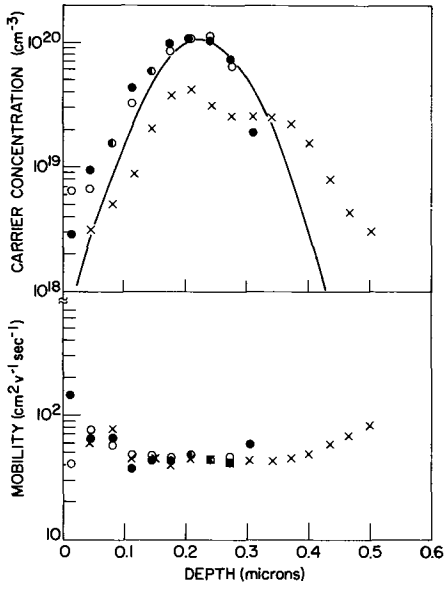

Fig. 4. Depth variation of the hole concentration and Hall mobility for 60 keV B^{11} ions implanted into amorphous Si (circles, 1.5 x 10^{15} cm^{-2}) and into crystalline Si in a random direction (crosses, 1 x 10^{15} cm^{-2}). In the latter sample, the Si was rendered amorphous to a depth of 0.5-0.6μ after B implantation by Si ion damage. The samples were annealed at 800°C for 30 min before profiling. The solid line represents a gaussian approximation to the amorphous implanted profile.

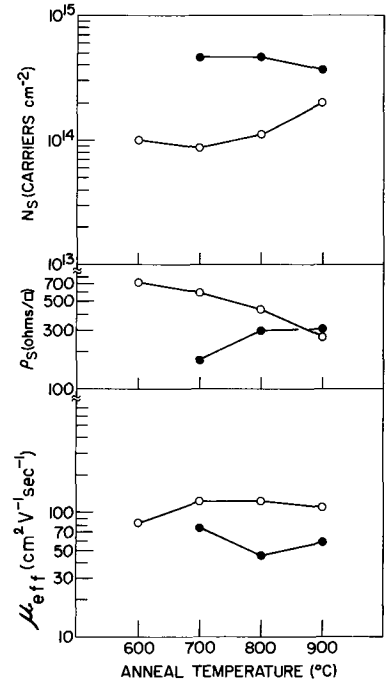

Fig. 5. Variation of N_S, ρ_S, and μ_{eff} with 30 min isochronal annealing temperature for 1 x 10^{15} 200 keV Al ions cm^{-2} implanted at room temperature into amorphous Si (closed circles) and into crystalline Si in a random direction (open circles).

layer resistivity and the data presented in Fig. 1) even in the region in which the hole concentration is markedly lower than the number of implanted B ions. This behavior is typical of B implantations (19) and indicates that nonsubstitutional B and/or compensating defect centers are neutral species.

The profile obtained by implanting into crystalline Si in a "random" direction and that obtained by implanting into amorphous Si are markedly different, as evident in Fig. 4 which presents the carrier concentration profile and variation of Hall mobility with depth for three Si wafers implanted with B and annealed at 800°C for 30 min prior to profiling. In two wafers, 60 keV B^{11} ions (1.5 x 10^{15} cm^{-2}) were implanted into amorphous Si (open and closed circles). In the third wafer (crosses), 1 x 10^{15} 60 keV B^{11} ions cm^{-2} were implanted into crystalline Si in a "random" direction (7 deg off <100>). This wafer was then damaged by Si ions to produce an amorphous phase prior to the post-implantation anneal. Implantation into amorphous Si produces a profile which is asymmetric, falling off sharply on the deep side (the value of N_S after 0.32μ was removed was only 8 x 10^{12} cm^{-2} for the sample represented by the closed circles in Fig. 4). This distribution is distinctly different from that obtained by implanting in a random direction (crosses in Fig. 4); *e.g.*, the value of N_S after 0.32μ was removed was 3 x 10^{14} cm^{-2}. The solid line in Fig. 4 is a gaussian approximation to be discussed in more detail in a later section.

Aluminum.—Isochronal annealing studies of Si implanted with Al ions are depicted in Fig. 5, which presents the annealing behavior of N_S, ρ_S, and μ_{eff} for two implantations of 1 x 10^{15} 200 keV Al ions cm^{-2}. In one case (closed circles), implantation was conducted into amorphous Si prepared by Si damage. In the other case (open circles), implantation was into crystalline Si in a "random" direction. Although the substrate in the latter case was nominally at room temperature, this dose of Al ions was not sufficient to produce a visible surface amorphous layer. The recrystallization of the amorphous phase again results in a relatively large fraction of the implanted ions being electrically active and uncompensated. In these Al implantations into the amorphous layer, however, increasing the annealing temperature decreases N_S and increases ρ_S, indicating that Al acceptors are being compensated and/or removed from substitutional sites. At this energy, a dose of 1 x 10^{15} ions cm^{-2} corresponds roughly to a peak ion concentration of 5 x 10^{19} cm^{-3} which is in excess of the solubility of Al in Si (2 x 10^{19} cm^{-3} at 1100°C). It should also be noted that previous investigations of Al implantations at significantly higher doses (1 x 10^{16} cm^{-2}) indicated that markedly higher sheet resistivities were obtained for such high doses after annealing (700°-900°C) than were obtained for 1 x 10^{15} ions cm^{-2} (19), again indicating that concentrations of substitutional Al markedly exceeding the solid solubility are not obtained by ion implantation after annealing. The behavior of 200 keV Al implanted into crystalline Si is very similar to that observed at lower energies by other authors; N_S increases smoothly with annealing temperature, while μ_{eff} approaches a constant value above 700°C (1, 19).

The profiles of carrier concentration and Hall mobility obtained for 200 keV Al implantations into amorphous Si after a 30 min anneal at 800°C (open circles and triangles) and 900°C (closed circles and triangles) are presented in Fig. 6. The observed carrier profile exhibits a "tail" relative to a gaussian approximation (dashed curve). Near the peak concentration, the observed Hall mobility is markedly lower than that expected for uncompensated bulk Si of comparable carrier concentration (the dotted line was computed from bulk mobility data and the solid line in Fig. 6). The low mobility indicates the presence of many scattering centers in addition to the implanted Al ions.

Figure 7 presents the profile obtained from implanting 1 x 10^{15} keV Al ions cm^{-2} into crystalline Si in a "random" direction and following the isochronal annealing sequence shown in Fig. 5. This profile exhibits a very long tail (channeling and/or interstitial diffusion during annealing). For the corresponding implantation into amorphous Si (closed circles, Fig. 6), the value of N_S after 0.6μ was removed was 7 x 10^{12} cm^{-2} and the value of μ_{eff} was 160 cm^2 V^{-1} sec^{-1}. The corresponding values after 0.6μ was removed for the specimen whose profile is given in Fig. 7 were 4 x 10^{13}

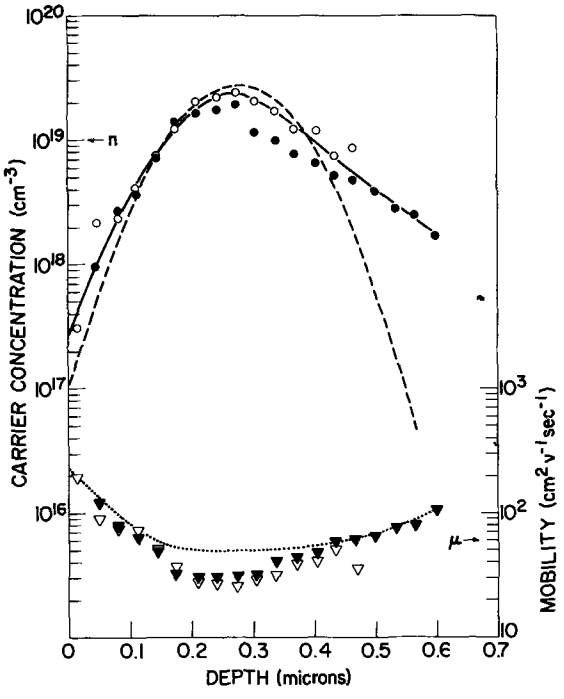

Fig. 6. Depth variation of the hole concentration and Hall mobility for 1 x 10^{15} 200 keV Al ions cm^{-2} implanted into amorphous Si. The samples were annealed for 30 min at 800°C (open points) or 900°C (closed points) prior to profiling. The dotted line corresponds to the mobility computed from the carrier concentration as given by the solid line and the bulk Hall mobility data presented in Fig. 1. The dashed line represents a gaussian approximation to the implanted profile.

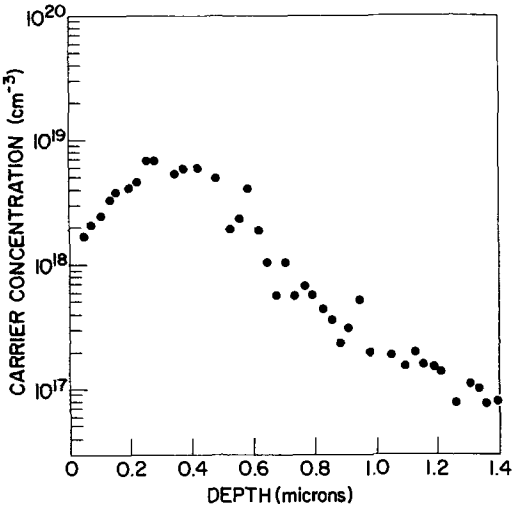

Fig. 7. Depth variation of the hole concentration for 1 x 10^{15} 200 keV Al ions cm^{-2} implanted into crystalline Si in a random direction after a 30 min, 900°C anneal.

cm^{-2} and 180 cm^2 V^{-1} sec^{-1}; *i.e.*, over five times as many carriers were present beyond 0.6μ in the "random" implant as compared to a comparably annealed amorphous implant.

At lower doses (*e.g.*, 1 x 10^{14} 200 keV Al ions cm^{-2}), the profile observed after annealing samples implanted in a "random" direction at 900°C was almost flat (7-9 x 10^{17} cm^{-3}) to a depth of 0.6μ and the mobility observed was comparable to that for bulk Si. This behavior was also noted for 30 keV Al implantations by Baron and co-workers (1) after 800°C annealing, which suggests that diffusion of Al does occur during the annealing process.

Gallium.—The isochronal anneal behavior of 280 keV Ga^{71} implanted into Si in a "random" direction is presented in tabular form in Table II. In all cases, the

Table II. Isochronal annealing behavior of 280 keV Ga^{69} implantations*

Dose (cm^{-2})	Annealing temp (°C)	ρ_s (ohms/sq)	N_s (cm^{-2})	μ_{eff} (cm^2 V^{-1} sec^{-1})
3 x 10^{15}	590	500	0.6 x 10^{15}	20
	700	412	0.27 x 10^{15}	60
1 x 10^{15}	590	215	0.44 x 10^{15}	67
	700	260	0.24 x 10^{15}	100
3 x 10^{14}	590	860	0.1 x 10^{15}	67
	700	940	0.1 x 10^{15}	60

* Duration of isochronal anneals was 30 min. Implantations were conducted at room temperature into Si substrates oriented 7 deg off the <100> axis.

dose of Ga was in excess of that required to produce a continuous amorphous surface layer (approximately 2 x 10^{14} cm^{-2}; see Table I). The value of N_s is observed to decrease with increasing annealing temperature, as observed by previous authors for 40 keV Ga (1, 20). Implanting concentrations of Ga much in excess of the solid solubility observed at high temperatures (3.5 x 10^{19} cm^{-3} at 1100°C) results in layers with a markedly higher sheet resistance than that observed for lower implantation doses (*e.g.*, compare the values for 1 x 10^{15} cm^{-2} and 3 x 10^{15} cm^{-2} in Table II). Such behavior was also noted for 40 keV Ga by Bulthuis and Tree (20). In this respect, Ga and Al behave in much the same fashion.

Since Ga^{71} is a convenient isotope for neutron activation, profiles of the Ga ion concentration as a function of depth were obtained by layer removal techniques in conjunction with radiochemical analyses. Two such profiles are presented in Fig. 8, which depicts the Ga^{71} concentration as a function of depth for implantation of 1 x 10^{15} Ga^{71} ions at 280 keV (open circles) and 140 keV (closed circles). The solid and dashed lines represent gaussian approximations to the implanted profiles. One would expect similar ranges and range straggles for Ga^{71} and As^{75}, which is indeed experimentally observed [*cf.* Fig. 10 and Ref. (12)]. One significant difference, however, is that the Ga profile shows a more pronounced tail on the distribution; the deviation from a nearly gaussian profile occurs at an order-of-magnitude-higher concentration level than that observed for As implantations [see Fig. 4 in Ref. (12)]. Since channeling is curtailed by relatively low damage levels and since one would expect the rate of damage production by 280 keV Ga^{71} and As^{75} to be comparable, this tail may be evidence

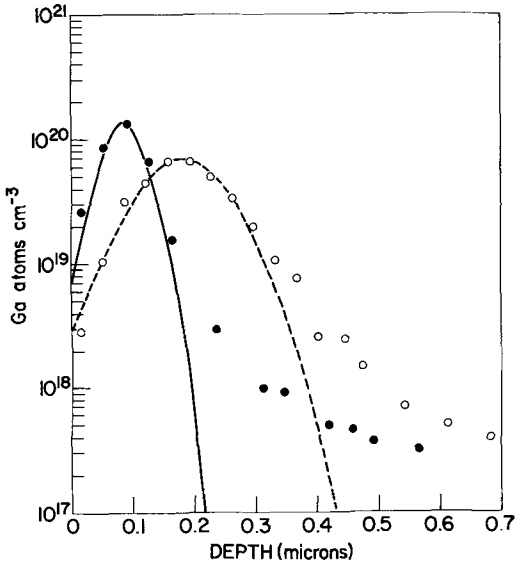

Fig. 8. Depth variation of Ga^{71} ion concentration as determined from neutron activation analysis stripping experiments for Si wafers implanted in a random direction with 1 x 10^{15} Ga^{71} ions cm^{-2} at 140 keV (closed circles) or at 280 keV (open circles).

for interstitial diffusion of Ga during implantation, neutron activation, or the 600°C, 30 min anneal which follows neutron activation.

Experimental Results and Discussion: Group V Elements

Phosphorus.—Figure 9 represents the carrier concentration profile and variation of mobility with depth of two wafers implanted at room temperature into amorphous Si with 3 x 10^{14} 280 keV P^{31} ions cm^{-2}. After implantation, the wafers were annealed for 30 min at 600°C. Prior to annealing, the location of the amorphous-crystalline interface, shown by the arrow in Fig. 9, was determined from interference fringes in the infrared optical absorption spectra of these wafers. The shape of this profile agrees quite well with that previously determined by neutron activation analysis and stripping for high-dose implantations (in which the majority of implanted P ions were actually incident on Si rendered amorphous by the damage produced by initial P ions) (12). The recrystallization of the amorphous phase does incorporate most of the implanted P ions on substitutional sites and removes most of the radiation damage defects in this region. The Hall mobility observed in this region is essentially that of bulk Si of comparable resistivity (the conductivity mobility of correspondingly doped bulk Si is shown by the solid line in Fig. 9) (17). A notable feature of these implantations is the fact that there is a transition region, as shown in Fig. 9, in which the sheet resistance and sheet Hall coefficient remained constant as layers were removed, indicating that this region is of relatively high resistivity. As the final layers were removed in this "transition region," the sheet resistance and sheet Hall coefficient actually decreased (possibly because of space charge effects). After this region was passed, layer removal resulted in normal behavior in which removing material resulted in an increase in sheet resistance and Hall coefficient. In this transition region, defects which compensate the implanted P ions are still present after a 600°C, 30 min anneal.

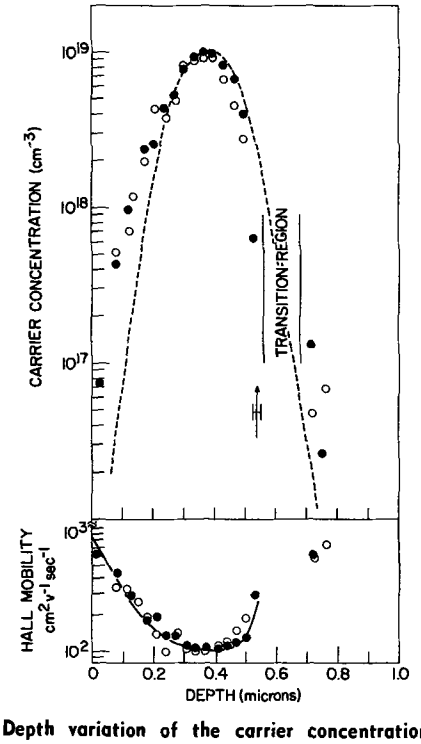

Fig. 9. Depth variation of the carrier concentration and Hall mobility for amorphous Si implanted with 3 x 10^{14} 280 keV P^{31} ions cm^{-2}. The depth of the amorphous Si layer was determined by interference fringes in optical absorption spectra as shown by the arrow. After implantation, the wafers were annealed at 600°C for 30 min. The dashed line represents a gaussian approximation to the ion profile. The solid line represents the mobility computed for bulk Si of comparable resistivity.

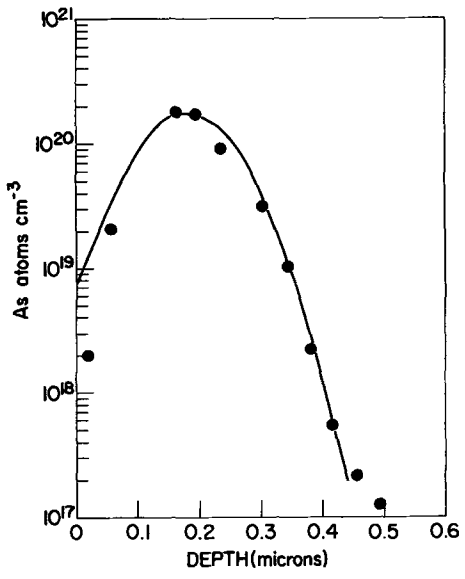

Fig. 10. Depth variation of As^{75} concentration for 280 keV As^{75} implantation into amorphous Si at room temperature as determined by neutron activation analysis. The As ion dose was 3 x 10^{15} cm^{-2}. The solid line represents a gaussian approximation to the profile.

The dashed line in Fig. 9 is a gaussian approximation to the profile. The experimental profile is asymmetric, exhibiting a larger concentration gradient (absolute value) at depths beyond the peak than at depths more shallow than that of the peak concentration.

Arsenic.—As^{75} is a sufficiently heavy ion that implantations of moderate doses (*i.e.*, greater than 3 x 10^{14} cm^{-2}) at room temperature will produce a continuous amorphous phase overlapping most of the implanted ion distribution as shown by previous studies (5, 6). Again, recrystallization of this amorphous region at 550°-600°C is the dominant factor in the observed annealing behavior (5, 6). Figure 10 presents a profile obtained by neutron activation analysis in conjunction with layer removal techniques for 3 x 10^{15} 280 keV As^{75} ions cm^{-2} implanted into amorphous Si at room temperature. This profile is essentially identical to that obtained by implanting a dose of 3 x 10^{15} 280 keV As^{75} ions cm^{-2} into crystalline Si wafers, except that channeling, which occurs during the initial stages of implantation, is not present [cf. Ref. (12)]. The solid line in Fig. 10 represents a gaussian approximation to the implanted profile.

Mayer and co-workers reported that the ratio of N_s to the implanted As dose was approximately 0.5 even after annealing to temperatures as high as 900°C (21). In that study, a low energy (20 keV) and a high dose (1 x 10^{15} cm^{-2} or higher) were employed, resulting in peak As concentrations of the order of 10^{21} cm^{-3}. At such high As concentrations, there is not a 1 to 1 correspondence between conduction electrons (measured at room temperature) and the As concentration. For example, a room-temperature implantation of 1 x 10^{16} 280 keV As ions cm^{-2} results in only 0.5 x 10^{16} carriers cm^{-2} after a 600°C, 30 min anneal. A room-temperature implantation of 3 x 10^{15} 280 keV As ions cm^{-2} results in 3 x 10^{15} carriers cm^{-2} after such an anneal. The upper limit on As concentrations at which the integrated carrier concentration equals the implanted dose is approximately (3 ± 1) x 10^{20} cm^{-3}.

Antimony.—A profile of the Sb^{123} concentration obtained by neutron activation of a sample implanted with 1 x 10^{15} 120 keV Sb^{123} ions cm^{-2} at room temperature in a direction nearly parallel to <111> is presented in Fig. 11. Implantation was started into crystalline Si, but most of the Sb ions were incident upon amorphous Si due to damage incurred from the ener-

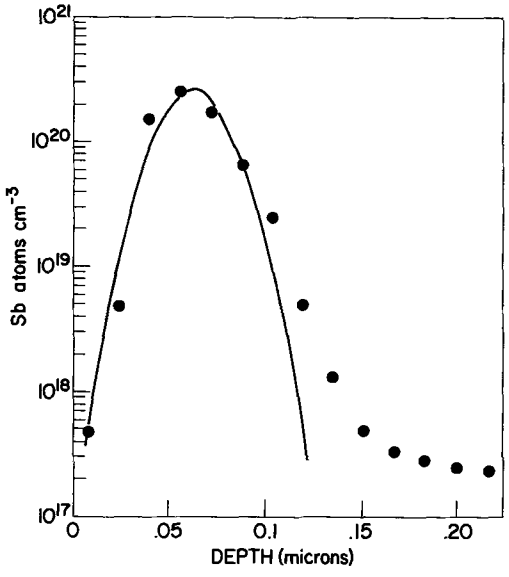

Fig. 11. Depth variation of Sb^{123} concentration in Si ion implanted with 1 x 10^{15} 120 keV Sb^{123} ions cm^{-2} as determined by neutron activation analysis. The solid line represents a gaussian approximation to the profile.

getic Sb ions in the initial stages of bombardment. The long "tail" presumably is due to channeling which occurred during that initial period before the damage density was sufficiently high to curtail it. The solid line represents a gaussian approximation to the implanted profile.

In a previous letter, we reported that the presence of the amorphous phase produced effective annealing at 600°C of even high concentrations of implanted Sb, but that implanting under conditions which prevented the formation of such an amorphous phase (*e.g.*, by heating the substrate to 500°-600°C during implantation) resulted in only a fraction of the implanted Sb as electrically active and uncompensated (3). The carrier concentration profile and depth variation of mobility for these two experimental conditions are presented in Fig. 12; the open circles and triangles were obtained from Si implanted with 3 x 10^{15} 260 keV Sb^{121} ions cm^{-2} at room temperature and annealed for 30 min at 600°C, while the closed circles and triangles represent data from a Si substrate (<111> orientation) maintained at 500°C during the implantation of 3 x 10^{15} 260 keV Sb^{121} ions cm^{-2}. The half-open circles represent "smoothed" data; the actual Hall data in this region were very noisy because of experimental difficulties. The measured sheet resistivity and an assumed mobility of 28 cm^2 V^{-1} sec^{-1} were used to compute these points.

Annealing a room-temperature implantation at 600°C, which recrystallizes the amorphous phase, results in a majority of the Sb being electrically active and uncompensated with mobilities near that of bulk Si of comparable resistivity, as shown by the dashed line in Fig. 12. The integrated carrier concentration observed in Sb implanted into Si at 500°C is about 30% of the implanted Sb, and the carrier mobility is markedly lower than that expected for bulk Si of comparable resistivity, indicating the presence of large numbers of scattering centers which limit carrier mobility. The carrier profile also indicates that implanting under these conditions results in a large fraction of the implanted ions being channeled and/or undergoing enhanced diffusion. Although no experiments were conducted to determine which process was occurring in these Sb implantations, previous research on high-temperature As implantations indicated that the largest effect was due to channeling in that the observed distribution was dependent on substrate orientation (4). The solid line in Fig. 12 represents a gaussian approximation to the Sb profile.

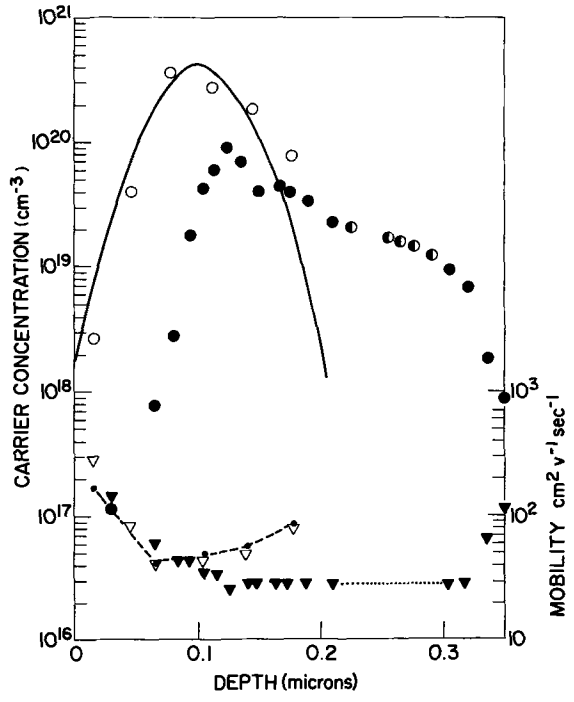

Fig. 12. Depth variation of the carrier concentration and Hall mobility of silicon implanted with 3 x 10^{15} 260 keV Sb^{121} ions cm^{-2} at room temperature followed by a 600°C anneal (open points) or 500°C anneal (closed points). The half-open points represent carrier concentrations calculated from the observed layer resistivity and an assumed constant mobility of 28 cm^2 V^{-1} sec^{-1} for the latter sample. The solid line is a gaussian approximation to the ion profile. The dashed line represents the mobility determined from bulk Si data and the observed carrier concentration in the room temperature implant.

Bismuth.—The implantation of doses of Bi^{209} in excess of 10^{14} cm^{-2} should result in the formation, at room temperature, of a continuous amorphous region, which should provide effective annealing at 600°C. This behavior is indeed observed as summarized in Table III for two different doses of 240 keV Bi^{209} ions. Table III presents the values observed for N_s and μ_{eff} as well as the integrated number of carriers per square centimeter obtained from profiling measurements and the ratio between this number and the implanted dose. For such high-energy implantations, a relatively large fraction of the implanted Bi dose can be obtained electrically active and uncompensated, in contrast to the reported behavior for 20-50 keV Bi implantations (22). For the heavy element Bi, a 20 keV implantation in Si produces a distribution with a peak concentration only slightly over 100Å from the sample surface, which may be responsible for the observed compensation at such low energies. In the 1 x 10^{15} 240 keV Bi ions cm^{-2} implantation, the peak carrier concentration was 1.2 x 10^{20} cm^{-3}, a value much in excess of the solid solubility of this species at 1100°C (2 x 10^{17} cm^{-3}).

Figure 13 presents the carrier concentration and mobility profile obtained by stripping the 3 x 10^{14} 240 keV Bi^{209} ions cm^{-2} implant. The carrier mobility is appreciably lower than that expected for bulk Si of com-

parable resistivity as shown by the dashed line. The solid line is a gaussian approximation.

A Comparison of Profiles in Amorphous Si with Lindhard Theory

It is of interest to compare the experimentally determined profiles obtained in this study for implantations into amorphous Si with the predictions of Lindhard, Scharff, and Schiott (LSS) (11), or, more specifically, with the tabulation "Projected Range Statistics in Semiconductors" by Johnson and Gibbons (23). An estimate will thereby be available as to the validity of such tables when applied to other amorphous semiconductors.

Profiles obtained by neutron activation reflect accurately the ion distribution, e.g. P^{31}, As^{75}, Sb^{123}, Ga^{71}. Profiles obtained from carrier concentration profiles are less reliable, but, when a majority of the implanted species are electrically active and uncompensated, the correspondence between carrier concentration and ion concentration should be good; e.g., the assumption that the correspondence is 1 to 1 should be good for B^{11}, reasonable for Bi^{209}, and less reliable for Al^{27}.

A basic assumption involved in applying the LSS theory in its simplest form is that the ion distribution is gaussian. This assumption was tested by comparing the observed profile with a gaussian distribution with the same peak position and a range straggle chosen so that this distribution and the observed distribution had the same full width at half maximum. The gaussian curves in Fig. 4, 6, 8, and 9-13 were determined in this manner. For light ions, e.g. B^{11} and P^{31}, the ion distribution is definitely skewed and exhibits a sharper gradient beyond the peak than before the peak[2]. The distributions observed for heavy ions implanted into amorphous Si are more nearly gaussian in shape.

[2] For such cases, the ion energies employed in the present investigation are sufficiently high so that electronic stopping becomes a significant factor in the energy loss of these ions. The additional straggle associated with this energy loss mechanism would be expected to produce a skew in the ion distribution toward the surface, since this energy loss mechanism is most important at high energies (i.e., near the substrate surface). For very light ions, wide angle scattering, which is neglected in simple LSS theory, may also distort the ion profile.

[1] LSS calculations from Johnson and Gibbons' tabulation [Ref. (23)].
[2] The experimental errors in these parameters are approximately ± 10%.
[3] Ref. (10).

The LSS theory provides a model from which one can compute the distance an ion travels in an amorphous material before coming to rest (the range, R) and the projection of this distance onto the direction of incidence of the incoming ion (the projected range, R_p). This theory is also used to compute the second moments or standard deviations associated with the quantities R and R_p, *i.e.* ΔR and ΔR_p. A compilation of the parameters characterizing the gaussian approximations as described in the previous paragraph for implantations into amorphous Si from this study, together with the values calculated from the LSS theory by Johnson and Gibbons for R, R_p, ΔR, and ΔR_p (23), is presented in Table IV. Also included in this table are the data obtained by Dearnaley and co-workers (10) for 120 keV P^{32} implanted into amorphous Si produced by Ne bombardment. The agreement between the observed range and the projected range is, in most cases, within the experimental errors inherent in these stripping experiments (±10%). Simple LSS theory does provide a reasonable estimate for this quantity.

The situation with respect to ΔR_p is not as clear. For very heavy ions (*e.g.*, Sb or Bi implanted in Si), for which the range and projected range are nearly equal, one would believe intuitively that ΔR and ΔR_p would be comparable (11). Surprisingly, the computations of Johnson and Gibbons indicate that, for such species, the value of ΔR_p is only about half that of ΔR (23), a result which strongly suggests that these authors made an error somewhere in their numerical analysis. Since their tabulations agree rather well with other calculations based on the LSS theory for ions lighter than the target atoms [see, *e.g.*, Ref. (24)] the origin of the error is not obvious. The error lies in the manner in which approximations were introduced into the LSS theory in order to facilitate numerical computations (see Appendix I).

Experimentally (see Table IV), it appears that the calculated values of ΔR are indeed in better agreement with the observed distribution widths than are the calculated values of ΔR_p, except for ions which are much lighter than Si (*e.g.*, B^{11}). If one adopts the simple rule of thumb that the larger of ΔR and ΔR_p should be used in estimating a gaussian approximation to an ion implantation profile, then the observed distribution widths near the peak concentrations agree with Johnson and Gibbons' LSS tabulation for B, Al, P, Sb, Bi, As, and Ga implantations into amorphous Si to within better than 30%.

Summary

In this investigation, we have demonstrated that the LSS theory does provide a reasonable estimate for the

most probable projected range of group III and group V ions in amorphous Si. The observed distribution widths, however, indicate that the detailed calculations of Johnson and Gibbons (23), although based on the LSS theory (11), erroneously predict values of ΔR_p which are much too small for heavy ions. The experimental results favor the use of their ΔR rather than ΔR_p as a reliable estimate for all but very light ions. A convenient rule of thumb is to use the larger of ΔR or ΔR_p when using these tables to estimate ion distributions.[3]

The distributions obtained in amorphous Si and in Si oriented in a random direction are not necessarily equivalent [*e.g.*, B and Al in the present study, P^{32} as observed by Dearnaley and co-workers (10)]. For heavy ions, the observed distributions in amorphous Si tend to be gaussian in shape. For light ions such as B or P, the observed distributions in amorphous Si are definitely asymmetric.

We have provided further evidence for the importance of the amorphous Si phase in determining the annealing characteristics of ion-implanted Si. The following observations are pertinent.

1. Elements with low solid solubility: For group III and V elements which have a low solid solubility at elevated temperatures (*e.g.*, Sb, Bi, Al, Ga), the maximum fraction which can be obtained electrically active for moderately high doses (*e.g.*, 1×10^{15} ions cm^{-2}) is achieved by annealing at temperatures near 600°C where the epitaxial regrowth of the amorphous phase occurs. Higher annealing temperatures tend to reduce the maximum electrical activity obtainable for these ion implanted species.

2. Group V elements: For P, As, Sb, and Bi, the epitaxial regrowth of the amorphous phase renders a majority of the implanted ions in this region electrically active and uncompensated. Peak concentrations in excess of 10^{20} electrons per cubic centimeter can be readily obtained from such species ($2\text{-}4 \times 10^{20}$ cm^{-3} observed for P, As, and Sb). Provided these peak values are not exceeded, the correspondence between the ion distribution and the electron distribution is nearly 1 to 1 for P and As and close to 1 to 1 for Sb and Bi for the atoms which lie within the region occupied by the amorphous phase before recrystallization. The discrepancy between the results reported in this work for 240 keV Bi and those reported for 20-50 keV Bi(21) probably results from the proximity of the ion distribution to the sample surface in the lower energy implantations.

3. Group III elements: No evidence of a marked increase in solubility over the solid solubility observed at high temperatures as a result of the epitaxial regrowth of the amorphous phase was obtained for ion-implanted group III ions. Only B could be obtained electrically active and uncompensated at high concentrations ($2\text{-}4 \times 10^{20}$ cm^{-3}) after implantation into amorphous Si and annealing at 600°C. The results obtained for Al implantations into amorphous Si suggest that, after 800°C annealing, charged compensating defects are present near the peak carrier concentration (reduced carrier mobility relative to bulk values). The shape of the profiles obtained for Al and Ga implantations into amorphous Si suggests that diffusion of these species may be occurring in the temperature range 600°-800°C.

4. The production of an amorphous phase by ion bombardment always results in a "transition region" composed of heavily damaged Si which is partially crystalline and partially amorphous. Annealing at 600°C does not remove all of the radiation damage defect centers in this region, and the remaining defects result in compensation and/or reduced mobility for n-type layers in this transition region.

[3] There is theoretical justification for using the larger of ΔR and ΔR_p from these tabulations. Details are given in Appendix I.

Acknowledgments

The author gratefully acknowledges the contributions of J. M. Fairfield and G. Jung in providing the neutron activation profiles, and the capable technical assistance of W. N. Hammer, N. A. Penebre, and R. A. Fiorio. The author is also indebted to W. S. Johnson for his discussion about the anomaly in the computer tabulations contained in Ref. (23).

APPENDIX I

The author contacted William S. Johnson regarding the apparent anomaly in the computer range calculations by James F. Gibbons and him contained in Ref. (23). This Appendix is a nonmathematical condensation of his private communication kindly provided to the author.

The quantity of interest, ΔR_p, can be considered to arise from two sources:

(*a*) The straggle associated with R, ΔR, projected in an appropriate fashion.
(*b*) The additional straggle associated with the uncertainty in the angle of deflection of the ions.

For very heavy ions incident upon a light substrate (*i.e.*, for those cases in which μ, the ratio of the mass of the target atom to the mass of the ion, approaches zero), one would expect that the contribution from (*b*) should tend to zero, because the angular deflection approaches zero. In this case, ΔR_p should tend to approach ΔR, as mentioned in the text. However, the tabulated values of ΔR_p contained in Ref. (23) tend to approach zero as μ approaches zero and are thus in error. The question thus arises, "What went wrong with the computer calculations?"

The origin of the discrepancy is the following. The computer calculations are based on integral equations derived from the LSS theory by applying a Taylor series expansion, keeping only first-order terms. Johnson has found that introducing this same Taylor expansion at the same point in deriving equations for the full range parameters leads to the result that, to first order, ΔR is zero! The use of higher-order terms in the Taylor expansion is thus necessary to evaluate ΔR correctly. By analogy, one may argue that it is necessary to consider second-order terms in correctly evaluating ΔR_p, particularly for those cases in which the ion is heavier than the target atoms. In a crude sense, the computer calculations of ΔR_p contained in Ref. (23) represent contributions from (*b*) to the straggle and ignore contributions from (*a*). In this case, the use of ΔR as a good approximation to ΔR_p for μ less than 1 is justified. In addition, the importance of contribution (*b*) for light ions (*i.e.*, μ greater than 1) dominates the observed straggle so that the tabulated values of ΔR_p in Ref. (23) should be reasonable estimates for this situation. This argument is certainly not conclusive but does provide some basis for using the larger of ΔR or ΔR_p as suggested in the text.

Growth of Wide, Flat Crystals of Silicon Web

ABSTRACT

The temperature field and heat flow about the solidification interface of web crystals was modified by use of shaped radiation sinks. As a result, web was grown as wide as 3 cm and flat to less than 2.5 μm in 100 μm thick sheet. A qualitative extension of thermal models in dendrite growth applied to web morphology satisfactorily explains the experimentally observed results.

Silicon web growth is a modification of the controlled dendritic solidification process (1-3) in which a thin ribbon of silicon, bounded by two thicker dendrites, is pulled directly from a melt (Fig. 1). Growth is initiated by immersing a twinned [$2\bar{1}\bar{1}$] dendrite seed into an undercooled melt. Initially, growth is lateral giving the seed an inverted "T" shape; when pulling is commenced, a dendrite propagates into the melt from each end of the "T." As the solidified dendrite bridge emerges from the melt, a thin film of liquid is drawn up by surface tension between the button and the two dendrites. As growth proceeds, the dendrites grow apart, widening the web until finally a quasi-steady state is reached where the web width is constant. Web growth thus consists of seeding, widening, and finally steady-state growth during all of which the dendrites solidify slightly below the melt surface and the web section solidifies slightly above the original unperturbed melt level.

O'Hara and Bennett (3) proposed that web flatness, or rather lack of flatness, is governed by two-dimensional nucleation at the liquid meniscus-web interface so that a localized reduction in undercooling should reduce the rate of nucleation and promote flatness. Furthermore, O'Hara (4) and Tucker and Schwuttke (5) have noted that low or dislocation-free web could be grown. Our primary interest was to determine the relationships between heat sources and sinks and the crystallographic factors that determine web morphology and perfection.

There was also a practical reason for this work. We wished to determine what thermal conditions were necessary to grow wide web with flat surfaces and low dislocation content suitable for direct use in fabricating devices. Although web has been produced (6) several meters in length and a centimeter or so in width, this material must be grown wider, flatter, and of low dislocation content to be really interesting to the device fabrication industry. Greater width is desirable, for many power devices are larger than 1 cm in diameter and, while large-area rectangular-shaped web was available, this shape is not compatible with present industry tooling. In addition, photomasking requires a surface flat to 10 μm, and, although web in thin section has been reported within this tolerance (7), many devices require a thicker substrate material. Finally, dislocations which generate in the supporting dendrites accumulate within thicker web during growth (4, 7),

often reaching densities of 10^3-10^5 dislocation pits/cm^2. A reduction in dislocation density is essential to preparation of good device-grade web material.

In our experiments, we have altered the temperature fields about the growth interface in a controlled manner. We were able to obtain web crystals 3 cm over-all width and flat to within 2.5 μm on 100 μm thick material, with dislocation densities near 1000 cm^{-2}. We describe the experiments which resulted in these improvements and postulate crystal growth mechanisms that may be operative.

Apparatus

The apparatus used to pull web crystals is shown in Fig. 2. This system consists of a shallow quartz crucible which nests within larger molybdenum susceptors; 450 kHz, 10 kW rf heat is supplied the susceptors through a quartz furnace tube. A rapid flow of argon from the bottom of the tube and out a slot through which the crystal is pulled at the top of the system protects the melt. Pulling was accomplished by winding a leader and subsequently grown web on a large (34 in.) diameter reel. Growth rates of 1-5 cm/min could be achieved by driving the reel with a variable-speed d-c motor, regulated to about $\pm$0.01 mm/min.

The temperature of the melt was controlled by sensing radiation from a deep hole in the molybdenum support just below the melt with a sapphire light pipe and a Leeds & Northrup "Radiomatic" thermopile. The thermopile output was used to control the output of the rf generator and, although actual temperature variations within the melt were not determined, the control point variation was estimated at $\pm$0.2°C. The quality of the over-all control is indicated by our ability to grow great lengths of very small dendrites (0.1 mm diameter) without variations in size or thickness.

Maintenance of proper temperature gradients within the melt was the single most important aspect of web growth. The area of solid web crystal in contact with the melt was small and, although the heat released from the solidifying crystal must certainly dominate isotherms close to the interface, small asymmetric variations in the temperature of the surrounding melt greatly affect the growth. To maintain reproducible thermal conditions, we encased the rf coil in a castable ceramic and mounted the cast coil rigidly on a milling head positioner which could be moved in a vertical "z" direction, and the "xy" plane with respect to the susceptor. Displacements as small as 2.5 mm had marked effects on crystal growth.

As shown in Fig. 2, a slotted lid was used to cover the top of the system through which the web was pulled. The shape of this slot had much to do with defining the region of melt undercooling. Measurements showed the outer edge of the melt to be hotter than the center, thus preventing spontaneous nucleation at the melt-quartz interface, while the center region of the melt surface was undercooled as a result of radiation loss through the shield slot. Positioning the web crystal within the melt was achieved by a combination of adjustable molybdenum guide fingers and a movable flat steel plate above the slot in the lid. Proper control of the web position with respect to the undercooled center of the melt was essential to satisfactory crystal growth.

Temperature measurements in the melt were made with shielded Pt-PtRh thermocouples in fine closed-end quartz capillaries. Mechanically, it was difficult to accommodate these during web growth; thermally, their presence near the interesting region, the interface, cannot be tolerated. As in previous quantitative work (9), we were forced to rely on a melting point calibration at the melt center using a fine dendrite, and a set undercooling below this using the system's controller. The principal experimental parameter was the disposition of heat sources and sinks about the melt; and the controlled variable was the response of web growth to these.

Experimental

We altered heat flow and temperatures near the solid-liquid interface in several ways. First, we put quartz-covered, 40W resistance heaters, 0.3 cm diameter and 2.5 cm long, close to or below the melt surface and 0.2-0.3 cm away from the center of each side of the web sheet. By turning these on and off, we grew web which was thinner when heat was supplied. Since no other parameter was varied, we conclude that the undercooling of the melt near the web face was reduced and that the thinner web was a consequence of a reduction of at least the crystal growth rate and probably the nucleation rate as well, confirming the O'Hara and Bennett model (3). We were unable, however, to control the heaters sufficiently well to grow flat web surfaces and we abandoned these in favor of radiation sinks.

We modified the crucible with two kinds of radiation sinks. The simple slot in the lid (Fig. 3A) was changed by pinching in its center and by cutting out round holes at its ends (Fig. 3B). This "dog bone" slot was intended to reduce radiation loss from the center of the web and the nearby liquid, while increasing losses

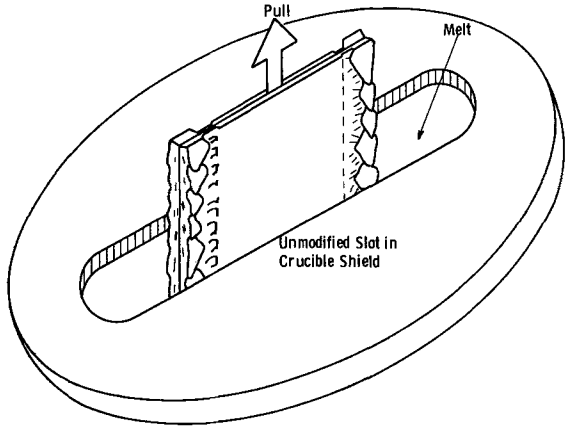

Fig. 3A. Crucible lid radiation shield showing relationship of slot shape to the crystal during pulling.

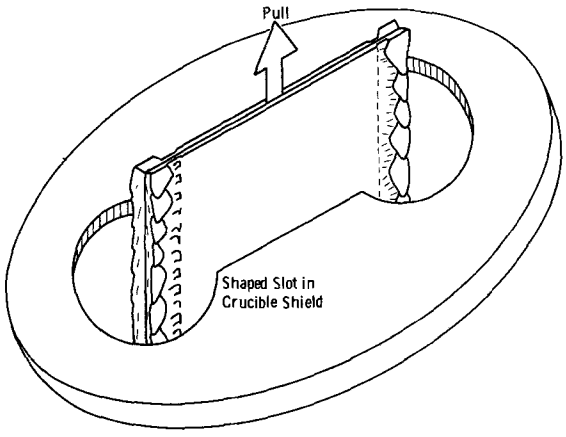

Fig. 3B. Shaped shield slot used to heat the web region while cooling the dendrite regions.

around the dendrites. For the same undercooling at the dendrites (as measured by the same dendrite size and growth velocity), the web center must be relatively hotter and growth or nucleation rates there lower.

A second and even more successful technique for radiation control is shown in Fig. 4. Two radiation ports were drilled through the bottom of the molybdenum susceptor. Each was estimated to radiate about 10W through the quartz crucible, cooling the melt beneath the dendrites. So effective was this additional cooling that solid silicon occasionally nucleated on the quartz over the ported area. Using this modification, we were able not only to improve surface flatness but also to increase greatly the initial web width and subsequent widening rate. There was one serious difficulty. Dislocations were rapidly generated and the web quickly became polycrystalline. A final modification (Fig. 5) consisted of a pair of heat shields which were put above the slot in the lid parallel to the web faces. Their function was to reduce further the temperature gradients in the web and adjacent melt by reducing radiation losses from the web after it has been pulled through the slot. This aftershield on the two-hole ported crucible was the most successful apparatus used. In it we grew the wide, flat webs of Fig. 6.

Results

Crystal width.—At constant undercooling and pull velocity, the dendrites diverge from the [$2\bar{1}\bar{1}$] growth axis and each other and the web slowly widens. The rate is sensitive to apparatus changes, and a convenient way to characterize it is to plot over-all width

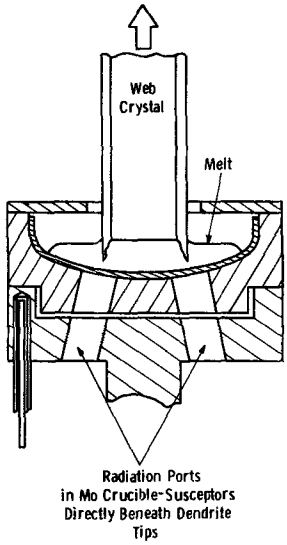

Fig. 4. Two radiation ports in crucible whereby the melt directly beneath the two dendrites is cooled.

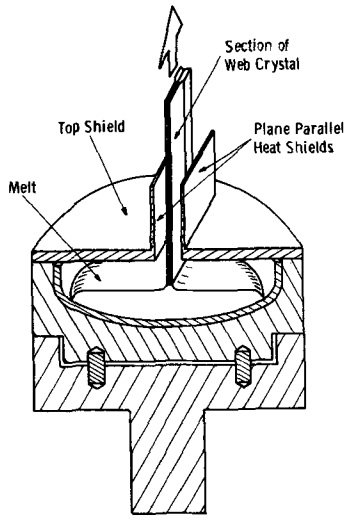

Fig. 5. Heat shields positioned parallel to the (111) web face reducing the rate of heat loss by radiation from the solidified crystal.

as a function of length, Fig. 7. The three curves are averaged data of at least six crystals from each of the three furnace modifications. The first is that of Fig. 3A, the second, Fig. 3B, while the third is like the first but with the ports of Fig. 4. The widening rates increased with each change, from 0.04 to 0.1 mm/cm of length. In the ported crucible design, the limiting width was not set by approach to steady state as in the unmodified crucible but rather by the 3 cm outer diameter of the

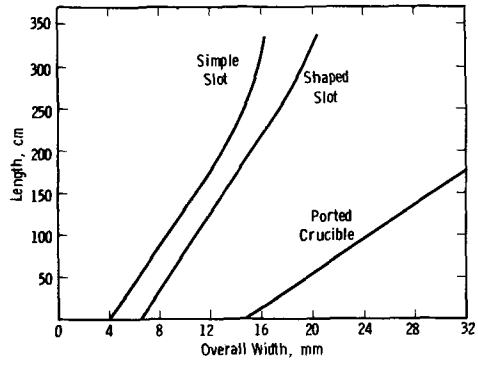

Fig. 7. Over-all crystal width as a function of web length. The widening rate in the ported crucible is about twice the simple or shaped slot rates.

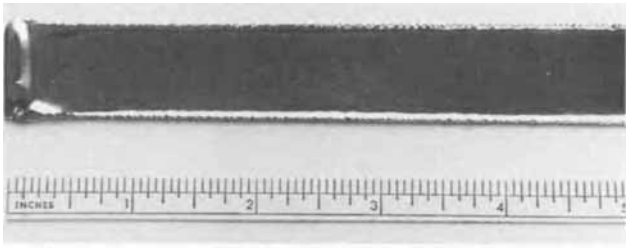

Fig. 8. Web crystal in which the initial seed button was widened to 2 cm prior to pulling. A 0.02 cm dendrite seed (not shown) was used to seed this crystal.

melt. The web was as wide as the melt. Had there been more silicon, we believe greater width could have been achieved.

These modifications changed the initial seeded width as well as widening rate. The initial widths increased from 0.4 through 0.6 to about 1.4 cm, suggesting a very real effect of apparatus upon the undercooling at the melt surface. Figure 8 shows an extreme case. The first web grown was over 2 cm wide. The seed dendrite (not visible) was about 0.02 cm diameter. Great skill was required to do this. For example, if the rf heating coil was not well positioned or if the seed was not put into the center of the undercooled region, the growth from the seed would be asymmetrical. On pulling, the tiny seed would bend under the lopsided load with subsequent loss of the meniscus and web. Although we cannot specify a detailed mechanism, we believe that the initial width and the widening rate are related to the extent to which the undercooled region was modified by the introduction of radiation sinks.

Web flatness.—Using a microscope with a calibrated micrometer eyepiece, we measured cross sections cleaved normal to the $[2\bar{1}\bar{1}]$ growth direction (Fig. 9) The distance from the intersection of the twin planes with the cleavage faces (a reference trace) to the web faces was determined at 2 mm intervals across the width to obtain the surface profile. Profiles were taken at 1 ft intervals along the web length, since both thickness and flatness vary slowly with length (providing growth conditions were not varied). The microscope measurement, referred to the twin plane trace, was sensitive not only to surface flatness but also to thickness, to bow, and to taper.

In Fig. 10, the surface profiles are plotted relative to the twin planes using a magnified and displaced vertical scale to demonstrate deviation from flatness. The total average thickness of the web was constant. The average standard deviation from flatness, σ, is shown for each profile trace. By moving the web during growth, the distance of the twins to the surface could be varied. The data shows a relationship between the flatness of the surface and its distance from the twin planes; Fig. 11 quantitatively shows this to be a linear function, with σ increasing at a rate of 10 μm for each 100 μm increase in distance from the twin plane. At a given total thickness, the closer the twin planes are to one surface, the flatter it will be but only at the expense of the reverse side. For this reason, we use the averaged standard deviation of both sides to measure web surface quality. In summary, surface flatness deteriorates as web widens. It is relatively better on whichever face is nearest to the twin planes.

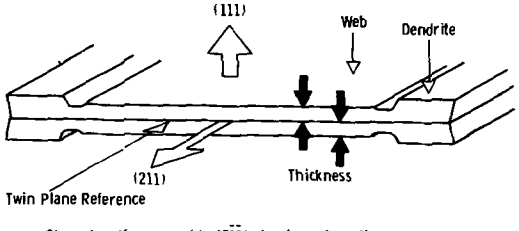

Fig. 9. Schematic cross section of web crystal normal to $(2\bar{1}\bar{1})$ showing the supporting dendrites and adjacent fillet regions. Web thickness and deviation from flatness was microscopically measured using the twin plane trace as a reference plane.

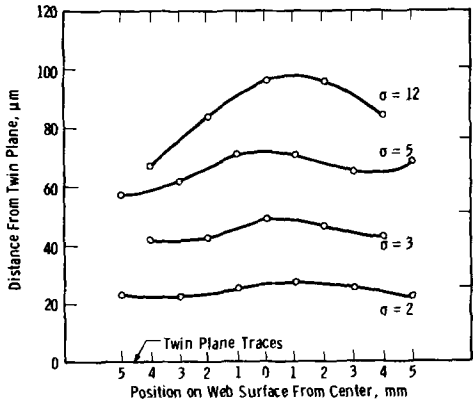

Fig. 10. Magnified profiles of web surfaces showing increased deviation from flatness (σ) with distance (thickness) from twin plane reference.

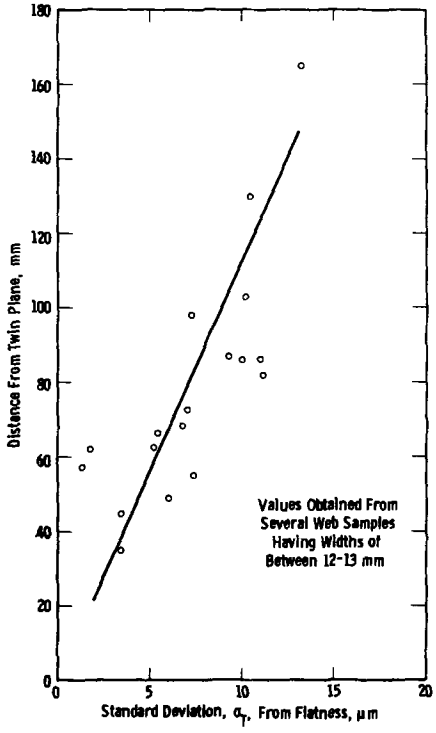

Fig. 11. A linear increase of about 10 μm deviation from flatness (σ) occurs for each 100 μm increase in thickness.

We now describe experiments with several crucibles. Figure 12 shows least-square line fits of average σ as a function of width for the three crucibles described earlier and a ported crucible with the aftershields. The flatness at given width improved regularly as the apparatus was successively modified. The web from the ported crucible with aftershields is much the flattest, even at widths greater than we could grow in others. The deviation is always less than 10 μm which is adequate for photomasking. These data confirm the efficiency of controlled heat flow in determining overall web flatness despite the observed effects of interface width and the influence of the twins.

Discussion

We can derive insight into web growth behavior by qualitative extensions of known thermal models of

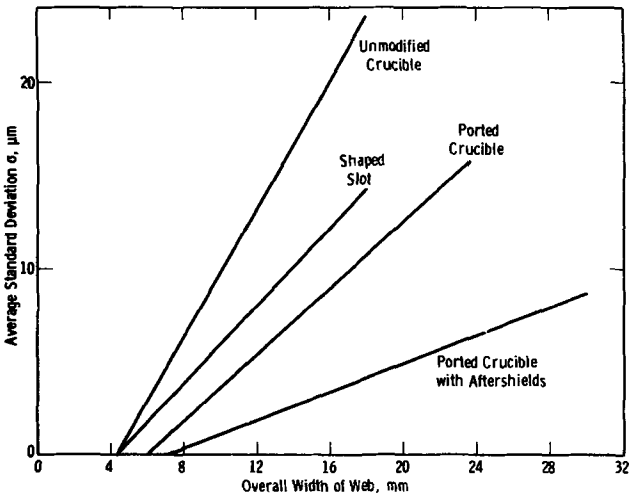

Fig. 12. Averaged values of flatness deviation are shown here as a function of over-all web width for different crystal-pulling arrangements. The ported crucible with aftershield arrangement yielded web flat to within 10 μm at 3 cm over-all width.

dendritic growth. The tip morphologies of semiconductor dendrites (8) and the theories that successfully account for their growth (9, 10) show that the thermal gradients about these are large and have almost rotational symmetry about the [2$\bar{1}\bar{1}$] growth axis. Imagine two dendrites, with a coplanar twin structure, growing side by side in an undercooled melt. Temperatures at some constant depth in the melt will in general be higher between the dendrites than at other points equidistant from one or the other dendrite. Heat flow will stagnate across the plane containing the twins. Temperature gradients thus favor growth away from the common [2$\bar{1}\bar{1}$] growth direction and the dendrites diverge. If the dendrites are joined by web, this tendency to diverge should be further increased, and the web widens. If effective heat sinks are added outside the dendrites, the widening rates will become larger. This is indeed what we observed with our lid and crucible designs. The limiting width is apparently set by the melt diameter.

The flatness of web is certainly affected by interactions with the dendrites. For example, when the dendrites are close together and the web is narrow, its middle is thin for the dendrites always dominate the heat flow about the web immediately adjacent to them. But when the dendrites are far apart, the center of the web is less influenced by them and becomes increasingly responsive to other heat sources and sinks within the system. Unfortunately, some of these other sources and sinks, the melt, the crucible, and susceptor are of overriding rotational symmetry. If only these rotationally symmetric fields were present and no attempt was made to compensate for them, the web would become round like a [211] Czochralski crystal. It is thus plausible that, when wide, web should grow thicker at its center. Since when web is narrow it is thinnest at the center, there must be some particular width at which web is flattest. As the width increases beyond this point, there should be a degradation in surface flatness. When heat sinks are added which relieve the rotational symmetry, the quantitative relationship between flatness and width should become more favorable, and the width at which the surface is flattest will become greater. The slopes of the lines in Fig. 12 show the former, and their intercepts on $\sigma \equiv 0$ the latter.

There is a correlation between surface flatness and the distance of that surface from the twin planes. Since the whole web-dendrite structure is more or less flat, there should be near the interface a stagnation plane across which no heat flows. This must also be more or less flat and certainly should be within the projection of the thickness (the [211] section) of the crystal, for the solid liquid interface is, after all, nearly isothermal. For an isolated dendrite, any plane containing the tip normal is a stagnation plane and the plane of the twins is one of these. For two coplanar dendrites the twins uniquely define it, and in our crystals it is probable that the stagnation surface will be near the twins in the web as well. Thus, if web is growing with one face near the twin planes, this face and not the other should lie nearer this surface of thermal stagnation. It is plausible that this face should be flatter, for temperatures close to the stagnation plane should be higher and nucleation and growth rates correspondingly lower after the mechanism proposed by O'Hara and Bennett (3). Thus, flatness and the distance to the twins can be plausibly related. Similarly, reversing the argument, the other side of the web should become less flat. As one side improves, the other degrades.

Dislocations.—Silicon web has a reputation for its high dislocation content, a reputation well earned for it often contains 10^3 to 10^5 dislocations/cm^2. In our web, the majority of dislocations were generated in bursts at melt entrapment centers on the dendrite surfaces (4, 7). These dislocations may slip into the web sheet and then turn and propagate in the [2$\bar{1}\bar{1}$] growth direction. If there is a sufficient number of these bursts, dislocations accumulate in the web center until eventually the web becomes polycrystalline.

In contrast to this, Tucker and Schwuttke (5) have described the growth of dislocation-free web. This web was relatively narrow, thin (45μ), and was grown with melt temperatures within 5°C of the silicon melting point. We have also grown thin web under low undercooling conditions and have confirmed that the crystal was dislocation free. Like Tucker and Schwuttke, we observed a few dislocation bursts in the dendrites, but the web was so very thin it did not intercept them and the dislocations could not propagate. However, thicker web is necessary for most conventional semiconductor devices and, hence, dislocations generated in the dendrites can and do intercept the web sheet. In the web, dislocations can be partially

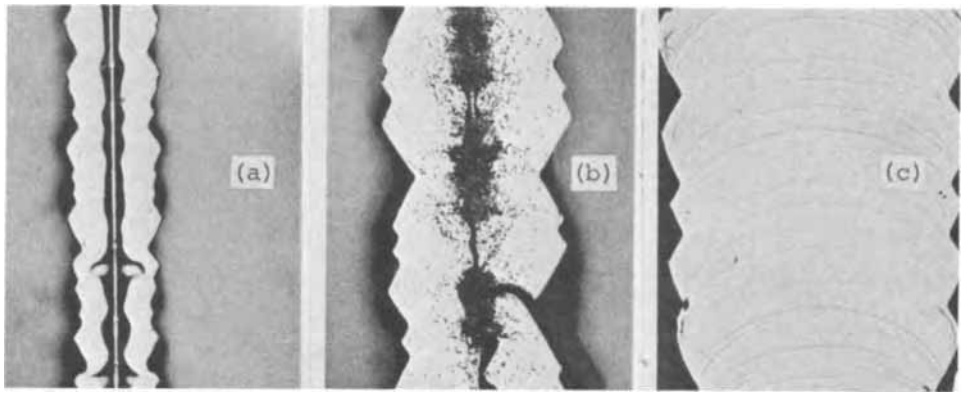

Fig. 13. Silicon dendrites grown at different depths of penetration beneath the melt surface, etched (90X).

eliminated by "necking down," or thinning the web. The dislocation density was not affected at all by the curvatures of the interface, either concave up or down to the melt. We therefore studied the formation of dislocation bursts in the dendrites and attempted to develop a technique to minimize them.

At a given undercooling, a variable pull rate can be used to produce dendrites of constant thickness but differing widths. At fast rates they are narrow, with the {111} surfaces characterized by a medial trough [Fig. 13(a)]. At lower rates, the dendrite grows deeper in the melt and the trough is partially filled [Fig. 13(b)]: Note the dislocations. At slowest rates and deepest penetration the trough is completely filled, producing good {111} surfaces without dislocations [Fig. 13(c)]. The great bursts of dislocations characteristic of the second morphology each arise at a core of silicon pushed above the adjacent {111} surface, clear evidence of both entrapment of liquid after a surface chill and subsequent deformation.

We introduced the plane parallel aftershields described earlier to slow down the freezing of any liquid droplets caught in the dendrite surfaces and also to reduce thermal strain; we also found that they forced the dendrites to grow more deeply under the melt surface as in Fig. 13(c). Using this geometry, the burst density was greatly reduced although not completely eliminated. With aftershields, the wide flat crystals previously described could be grown with a dislocation density near $10^3/cm^2$. Without these aftershields, the number of dislocation bursts was large and web from the ported crucible grew polycrystalline within a few feet.

In addition to dislocation generation in the dendrites, it was frequently observed that dislocations grew into the web from the seed button. By use of a small dendrite seed, by seeding at low undercooling, and by initially pulling at a very slow rate, we were able to minimize this source. An additional technique of "necking" was often used to advantage near the start of web growth. This was done by increasing the pulling speed for a short time until the web was thinned to about 1 mil; dislocations near the sheet surface then terminated. Those dislocations located next to the twin planes (in the last mil of web) could not be eliminated without losing the web as well. Although dislocation-free web was not grown thicker than about 100μ, careful technique and use of aftershields did result in growth of long pulls of thick, wide, flat web having low dislocation counts.

The Influence of Methane on Twin Formation During the Vapor Growth of Silicon Crystals

Lawrence D. Dyer*

Chemical Materials Division, Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Single crystal silicon layers were deposited by the vapor reduction method onto <111> silicon rods with various concentrations of methane in the deposition gases. Twins appeared only at CH_4 concentrations of 100 ppm and above. In contrast to the results in the case of oxygen addition, twins were found on both $\{\bar{2}11\}$ and $\{1\bar{1}0\}$ faces; and the density of twins on the $\{\bar{2}11\}$ face increased as the 6.7^{th} power of the methane concentration. The general dependence of twin density on the methane concentration suggests that agglomerates of five to seven carbon atoms are responsible for the twin formation. A possible mechanism by which carbon or SiC chains containing less than seven atoms can cause twinning on the $\{\bar{2}11\}$ face is presented.

The growth of silicon single crystal ingots by the pyrolytic reduction of halosilane vapor (1-3) is a means of shortening the process by which single crystal silicon is obtained. One of the main problems with the growth of silicon by vapor deposition is the formation of twins in the growing material. For the <111> and <100> axial orientations that are commonly used, the size of the twins increases with the layer thickness (3); and, one twin starting from a ¼ in. diameter seed will ruin more than a 1 in. long section of a 1 in. diameter silicon rod grown from that seed. A major source of twins is impurities in the input *halo*silane-hydrogen mixture.

In a previous study oxygen was found to cause twins on $\{\bar{2}11\}$ faces if the oxygen concentration was 200 ppm or greater; but, no twins formed on $\{1\bar{1}0\}$ faces (4). The twins were attributed to the substitution of oxygen atoms in growth ledges, which causes

* Electrochemical Society Active Member.

Key words: vapor growth of silicon, twin formation, defects in Si from methane.

enhancement of the probability of deposited silicon atoms being in the twinned position. The purpose of the present study was to investigate the influence of methane on the formation of twins during vapor growth.

Experimental Procedure

Epitaxial deposition was carried out on ¼ in. diameter silicon rods, each having a <111> axis, in a manner similar to that described by Allegretti *et al.* (2), and Sirtl and Spielmann (3) using trichlorosilane as the silicon source. The rod temperature during deposition was 1250°C, and the growth rate was 2.6 μm/min. Within the first hour of deposition, the shape of the rod changed from circular to dodecahedral with the development of six {$\bar{2}11$} and six {$1\bar{1}0$} faces. The {$1\bar{1}0$} faces then gradually became narrower while the {$\bar{2}11$} faces increased in width as growth continued (2, 3).

Silicon deposition was carried out for 2 hr. Methane was then diverted into the reaction chamber at the desired concentration—either 72, 107, 143, or 453 ppm. By delaying the introduction of the methane, any {$\bar{2}11$} twins that began at the original seed crystal could be distinguished by size from those caused by the methane (4). Deposition times after the introduction of methane ranged from 1.5 to 11.0 hr. The 453 ppm run was terminated at 1.5 hr because the numerous twins on the {$\bar{2}11$} faces would have overlapped and made counting difficult.

After each run the rod was removed from the reactor, and defects were counted under an optical microscope on each of the faces {$\bar{2}11$} and {$1\bar{1}0$}.

After examination portions of the carbon-containing epitaxial layers of each rod were cut off and analyzed for total carbon by a combustion method (5). Sample size was approximately 1g. The detection limit was 10 ppm, and the accuracy was ± 10% at the 100 ppm level and above.

Results

Three main results were obtained:

1. Twins and defects were produced on the {$\bar{2}11$} and {$1\bar{1}0$} faces by the influence of methane during epitaxial growth.
2. The carbon concentration in the epitaxial layers was approximately the same as it was in the vapor phase.
3. There exists a quantitative relationship between density of twins and methane concentration.

Morphology and appearance of twins and associated defects on {$\bar{2}11$} and {$1\bar{1}0$} faces.—The defects can be divided into three categories: (*a*) twins on the {$\bar{2}11$} faces, (*b*) twins on the {$1\bar{1}0$} faces, and (*c*) chevron-shaped defects on the {$1\bar{1}0$} faces.

Twins on {$\bar{2}11$} faces.—A top view of a typical twin on the {$\bar{2}11$} face is shown in Fig. 1. (Such twins are not to be confused with those having vertical (111) twin boundaries, as shown by Faust and John (6) and Mendelson (7). The crystallography has been worked out by Sirtl and Spielmann (3). An independent check by x-ray back-reflection confirmed their results. In the figure the twin (A) is bounded on one end by the sloping coherent twin boundary (B) and on the other end by microtwin lamellae (C), which fill two trough-shaped gaps between {111} planes of the parent crystal and {111} planes of the twin crystal.

Twins on {$1\bar{1}0$} faces.—A typical twin structure on the ($1\bar{1}0$) face is shown in Fig. 2. It consists of two twins, one on the ($1\bar{1}1$) face, and one on the ($1\bar{1}\bar{1}$) face, meeting each other at a central boundary.[1] A similar twin structure is shown in Fig. 3 where two oppositely situated stacking fault tetrahedra intersect. An etched (111) cross section through this defect (A-A in Fig. 3a) is shown in Fig. 3b. The etching texture within the regions presumed to be twins is different from that outside these regions.

[1] The author is indebted to Professor Gareth Thomas at the University of California for this suggestion.

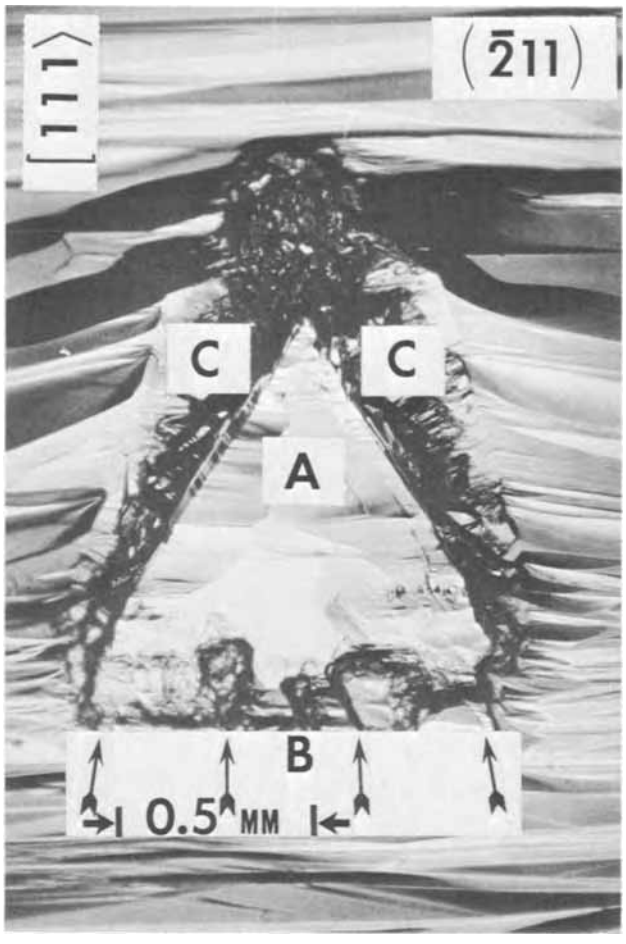

Fig. 1. Typical twin structure on ($\bar{2}11$) face

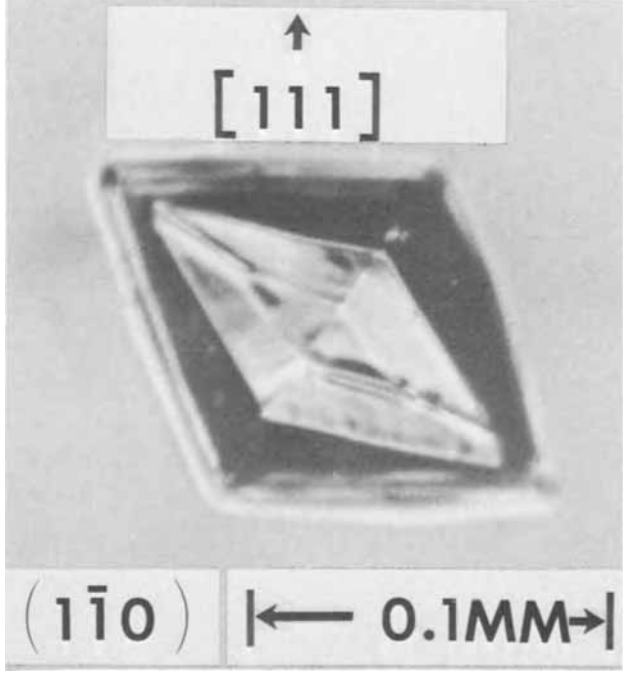

Fig. 2. Twin structure on (110) face

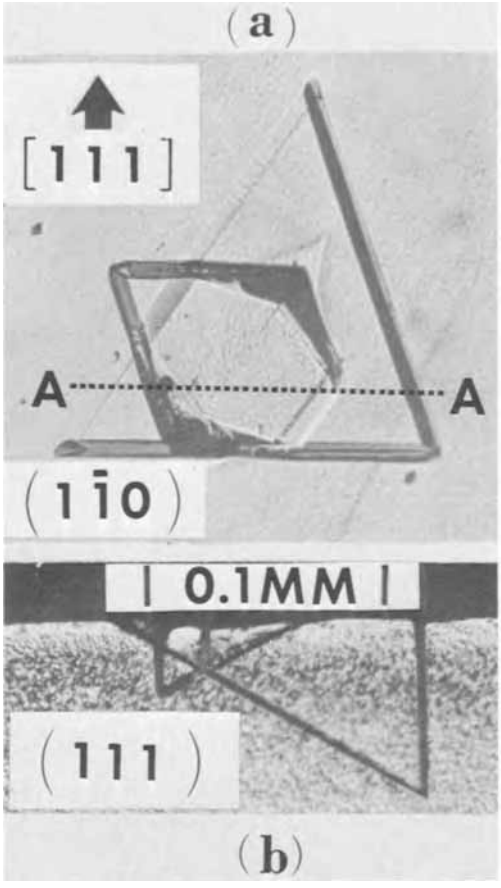

Fig. 3(a). Twin structure at intersection of two oppositely oriented stacking fault tetrahedra on (1$\bar{1}$0) face. (b). (111) Cross section of twin structure on (1$\bar{1}$0) face through A-A.

From the foregoing microscopic studies, the crystallography of the twin on the (1$\bar{1}$0) face was deduced and is shown in Fig. 4. The calculated and observed angles between the [$\bar{3}$52] and [110] directions in the twin and the parent crystal are 71.56° and 71° ± 1°, respectively.

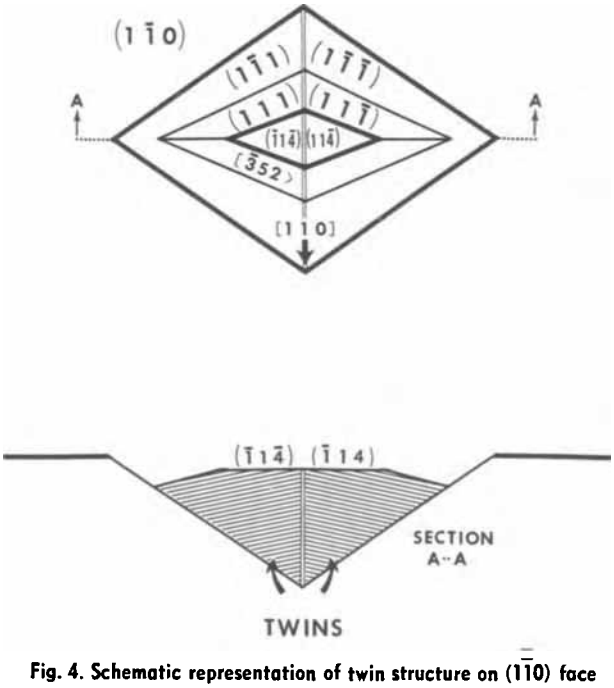

Fig. 4. Schematic representation of twin structure on (1$\bar{1}$0) face

Chevron-shaped defects on {1$\bar{1}$0} faces.—Micrographs of the layers deposited on {1$\bar{1}$0} faces at methane concentrations of 72, 107, 143, and 453-ppm are shown in Fig. 5a, b, c, d, respectively.

Several defects are evident in Fig. 5b. We have called these defects "chevrons" because their most characteristic feature is the meeting of two faults at an obtuse angle. Very often the faults are found closed into a lozenge shape, as shown in Fig. 6. A (111) cross section (B-B) of such a lozenge is given in Fig. 7, showing it to consist of vertical faults. The material enclosed by the lozenge defect is still correctly oriented, as can be seen from the dislocation etch pits in Fig. 6.

There is some connection between the chevron or lozenge faults and the twin structures because most twin structures have lozenges associated with them (8). The most likely interpretation of the chevron faults at present is that they are microtwin lamellae (9-12). As a temporary assignment the {1$\bar{1}$0} defects were counted as twins if a dark pit was seen at the apex of the chevron. Otherwise, the defects were counted as chevrons although the individual faults may actually consist of thin lamellar twins.

Defect density vs. carbon content.—Twin counts and carbon contents are given in Table I. The carbon contents in ppm were found to be approximately the same in the condensed phase as in the vapor phase. The results on twin densities are given on a time basis because of the different deposition times and because twins are produced during the entire time of exposure to methane. A defect density of 0.02 cm^{-2} hr^{-1} corresponds to 1 twin on a 20 cm rod in 2 hr.

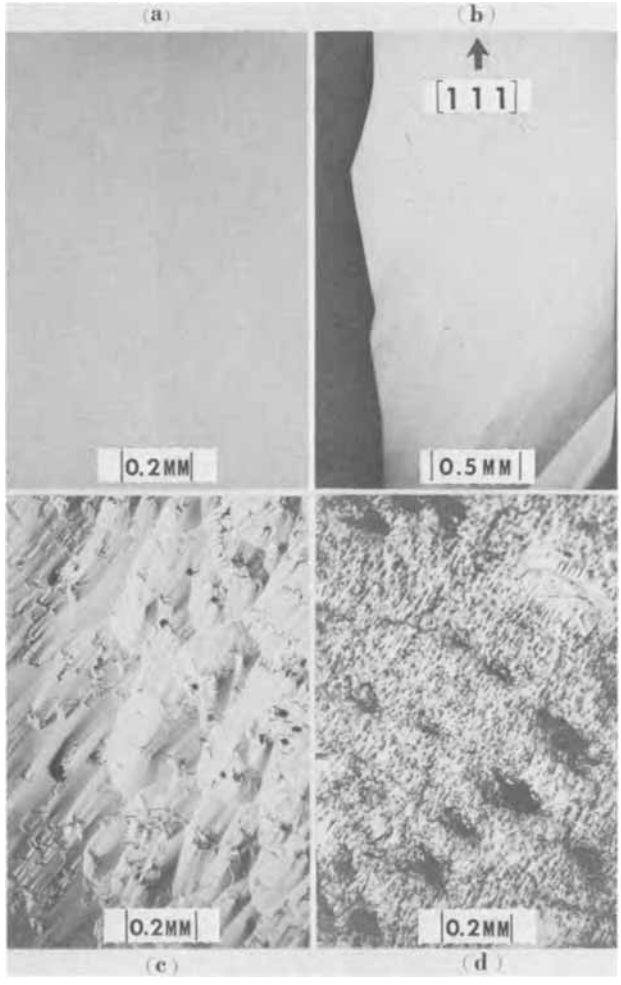

Fig. 5. {1$\bar{1}$0} Surfaces grown in the presence of methane. (a) 72 ppm, (b) 107 ppm, (c) 143 ppm, (d) 453 ppm.

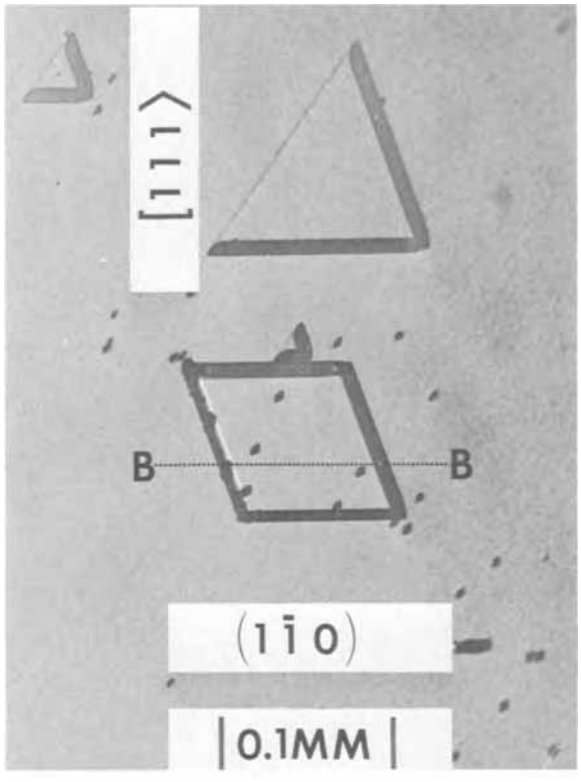

Fig. 6. Lozenge-shaped defect on (1$\bar{1}$0) face

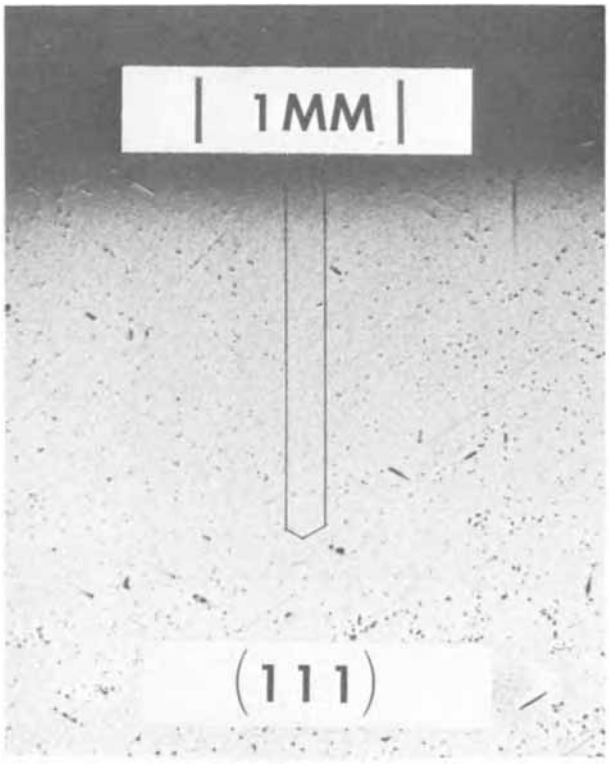

Fig. 7. (111) Cross section of defect shown in Fig. 6

From the table it appears that there is a nonlinear relationship between the density of defects and the methane concentration. Somewhere between the concentrations 72 and 143 ppm the density of each kind of defect rises significantly. The {1$\bar{1}$0} chevron defects are more numerous than the {1$\bar{1}$0} twin defects, and both are more numerous at each concentration than {2$\bar{1}$1} twins.

Table I. Twin count and carbon content at various methane concentrations

CH_4 added, ppm	Defect count/cm²/hr {211} Twins	{110} Twins	{110} Chevrons	Carbon content of layer, ppm
0	0	1.0	0.4	<10
72	0.0015	0.027	0.05	97 ± 10
72				122 ± 10
107	0.035	0.47	3.5	Not measured
143	1.2	1440	1.2×10^4	167 ± 15
453	533	Very large	Very large	395 ± 40

Figure 8 shows a plot of the twin density generated per hour on the {2$\bar{1}$1} face *vs.* the negative logarithm of the carbon or methane mole fraction. The experimental points give a slope m of 6.7 ± 0.2. Thus, we can write the empirical relationship

$$\frac{d}{T} = kC^{6.7}$$

where d is the twin density, T is the time, k is a constant, and C is the methane or carbon concentration.

Discussion

Carbonaceous contaminants have previously been found to give twinned growth centers on the {111} face during epitaxial growth (9, 13, 14). Also, twins have been shown before in epitaxial layers on the {2$\bar{1}$1} face (2, 3), and electron diffraction evidence has shown twins in {1$\bar{1}$0} epitaxial layers (15).

In the present study, a quantitative relationship between twin density and carbon content was found and should be accounted for.

There is no doubt that we could be dealing with the beginnings of the precipitation of carbon in some form. The solid solubility of carbon in silicon at 1250°C has been given as 6×10^{17} (16) and $< 3.5 \times 10^{17}$ (17) atoms/cc, whereas our 100 ppm apparent

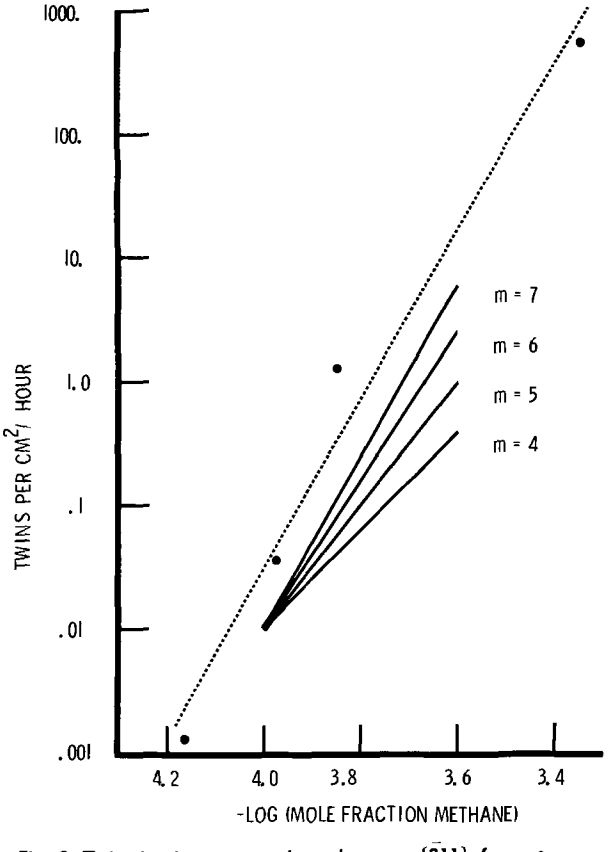

Fig. 8. Twin density generated per hour on {2$\bar{1}$1} face *vs.* negative log of methane concentration.

threshold concentration corresponds to 5 x 10^{18} atoms/cc. However, the carbon in each atom layer may not have time to aggregate to any great extent before it is covered up.

Miller *et al.* (9), and Inoue (14), attribute the twins found on {111} faces in epitaxial layers to packing effects from two extra SiC (0001) planes inserted into the crystal. While this manner of forming twins is indeed possible, it is a more stringent requirement than is necessary because of the large number of carbon atoms involved. In the present study the twin density on the $\{\bar{2}11\}$ face was proportional to the total carbon concentration to the 6.7^{th} power. This result can be interpreted to mean that only a few carbon atoms are required to come together simultaneously to cause a twin, whether 6-7 on the basis of the law of mass action, or 5-6 on the basis of the relationship derived by Walton (18). A mechanism was sought which could result naturally in the formation of a twin on the $\{\bar{2}11\}$ face and still involve the aggregation of only a small number of carbon atoms. Such a mechanism was found possible if carbon or silicon carbide groupings were in the form of chains in the $\{\bar{2}11\}$ surface in directions parallel to the $<01\bar{1}>$ ledges in each face. Twins can form when the groupings are long enough to create a mismatch between the normal silicon position and the substituted silicon position at the end of the chains sufficient to allow a twinned pair of atoms to be fixed in position in the growing row. Subsequent addition of atoms would produce the same orientation and shape of twin that were shown in Fig. 1. The smallest groupings that can create such an accumulated mismatch are chains containing three or four carbon atoms. Figure 9 shows two ways in which a twin nucleus may be formed from a silicon carbide chain of four carbons.

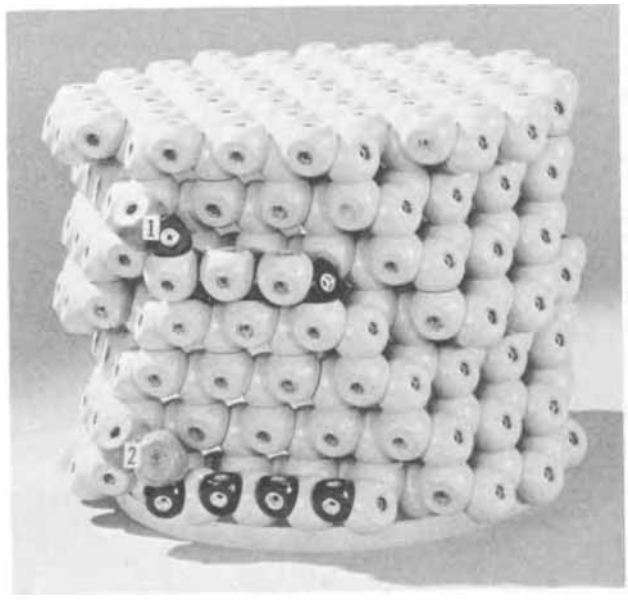

Fig. 9. Atom model of $\{\bar{2}11\}$ face showing two mechanisms by which twins would be formed by chains of carbon or SiC in $<01\bar{1}>$ steps.

Conclusions

Methane has been found to cause twins in silicon during vapor growth.

Methane causes twins on both the $\{\bar{2}11\}$ and $\{1\bar{1}0\}$ faces, in contrast to oxygen which does not form twins on the $\{1\bar{1}0\}$ face up to 600 ppm.

The density of twins on the $\{\bar{2}11\}$ face varies as the 6.7^{th} power of the methane concentration, while the density of defects on the $\{1\bar{1}0\}$ face increases even more rapidly with concentration. The formation of twins is attributed to a row growth mechanism made possible by C or SiC chains a few atoms long.

Properties of Low-Temperature Heteroepitaxial Thin Silicon Films Grown in Helium Atmosphere

J. Mercier

Section Physique des Couches Minces, Laboratoire d'Electrostatique et de Physique du Métal, Centre National de la Recherche Scientifique, Grenoble, Gare, France

ABSTRACT

Epitaxial Si layers grown by pyrolysis of silane on sapphire substrates in a He atmosphere are analyzed by x-ray diffraction, scanning electron microscopy, and the sputter-ion microprobe. Their properties are compared with those of layers grown in hydrogen at higher temperatures. A marked decrease in epitaxial temperature is observed, which is related to nucleation characteristics of the freshly deposited Si atoms. The growth rate limitations are discussed. Qualitative analysis by sputter-ion probe provides some promising results concerning impurity incorporation.

Structure defect formation and impurity incorporation are common plagues in heteroepitaxial Si films grown at high temperatures by pyrolysis of silane. It is expected that decreasing the epitaxial temperature should minimize these undesirable phenomena.

The lower epitaxial temperature in the usual silane and hydrogen system is 1025°C (1) and we succeeded in growing high-quality layers at 1030°C. Figure 1 shows an electron diffraction pattern of a 2.4 μm thick layer, the crystalline quality of which is indicated by the occurrence of Kikuchi lines. A further decrease of the temperature is hindered by the decrease of both crystalline quality and growth rate of the layer.

Obviously, hydrogen limits the silane dissociation rate (2) and is efficient in impurity transfer (3). From this standpoint (but we see later that this is not the major reason), its replacement by an inert gas is desirable.

Helium, owing to its expected high purity and good thermal conductivity, is an attractive choice. Furthermore, promising results are reported for Si growth on Si (4).

Its use, instead of hydrogen, in principle involves no major change of the deposition technique. However, in practice even the purest available He (given as 99.9995%) contains sufficient amounts of water vapor and oxygen to require further purification. Molecular sieves and liquid N_2 traps are not sufficient means, especially because of the extreme oxidizability of silane. Though special inert gas purifiers can now be purchased, they were not available when the present work started.

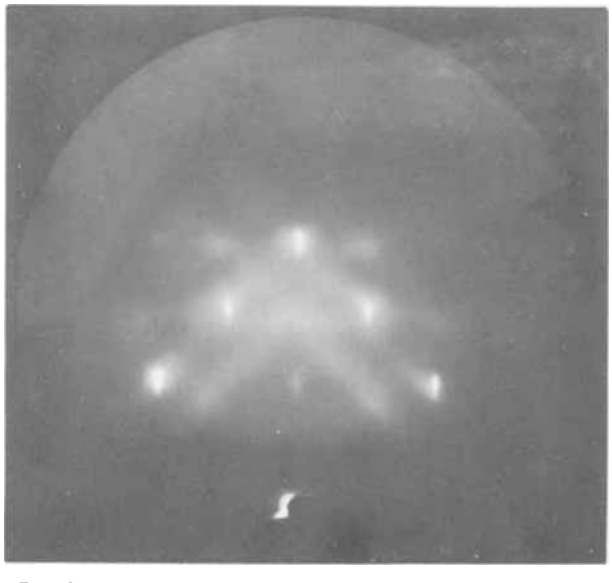

Fig. 1. Electron diffraction pattern of a (001)-Si layer grown in H_2 at 1030°C.

Expecting some balance of this oxidation reaction, we also tried experiments in a He-H_2 mixture.

Characterization Methods

These methods were chosen according to the aims of our study. We were especially interested in growing thinner layers (1-2 μm) than in our previous work and in obtaining more physical insights into interfacial processes.

Nucleation studies and chemical analyses were therefore required, using suitable techniques: scanning electron microscopy, electron replica microscopy on the one hand, and sputter-ion microprobe analysis (5) on the other, were selected.

This last method being relatively new and unusual, some comments are in order. First, infrared spectroscopy previously used by us (6) reaches its sensitivity and resolution limits for such thicknesses. The choice was to be made between the sputter-ion microprobe and the electron microprobe, but the former affords decisive advantages:

(a) A localized area to be analyzed (250 μm diameter).
(b) No limitation in atomic number of the elements, owing to the mass-spectrometry analysis.
(c) The crucial resolving power in depth (of the order of 100Å).
(d) A high sensitivity, in the 10^{-6} to 10^{-9} range of relative mass concentration.
(e) For each element, an ionic distribution image recorded on a photographic plate, resolving areas in the 1 μm range.

However, some drawbacks are also obvious:

(a) The method is destructive.
(b) Insulating layers require a metallic electrode on their surface in order to remove electric charges during sputtering.
(c) The secondary ionic current of a given element is not merely proportional to its total concentration in the matrix, but depends on several properties of this matrix. Therefore, comparative experiments are valuable.

Nucleation Experiments

Standard conditions for Si films grown in H_2 are defined as follows:

α-Al_2O_3 boules grown by the Czochralski method are cut, mechanically polished, and etched in H_2 at 1300°C for 15 min prior to epitaxy (6).
The crystalline orientation of the substrate is (01.2).

Table I. Experimental data at $T = 1100°C$

Growth conditions		Islands' properties		
Carrier gas	Time (min)	Density (cm^{-2})	Diameter (μm)	Contact angle
H_2	1	10^9	0.2-0.4	>90°
H_2	4	3×10^7	1-2	>90°
He	1	3×10^8	0.3-0.5	<90°
He	4	Continuous layer		

Silane flow rate: 5 cm^3/min.
Total flow rate: 10 liters/min.
Epitaxial temperature: $T = 11700°C$.

The nucleation steps are defined by a 1 or 4 min deposition time.

The same conditions are applied in comparative experiments, except for the replacement of H_2 as a carrier gas, during growth, by the He-H_2 mixture.

Scanning electron microscopy provides an easy measurement of the size and density of the Si islands, Fig. 2, a and b. After breaking the slice, the contact angle between the Si balls and the substrate is determined, Fig. 3, a and b.

The corresponding data are given in Table I.

Discussion.—The general trends, along with the use of He, are:

(*a*) An increase of the net reaction rate, as shown by the faster complete coverage of the substrate.
(*b*) Striking modifications of the nucleation properties—increase of the size, decrease of the density of the islands, at a given time, contact angle less than 90°.

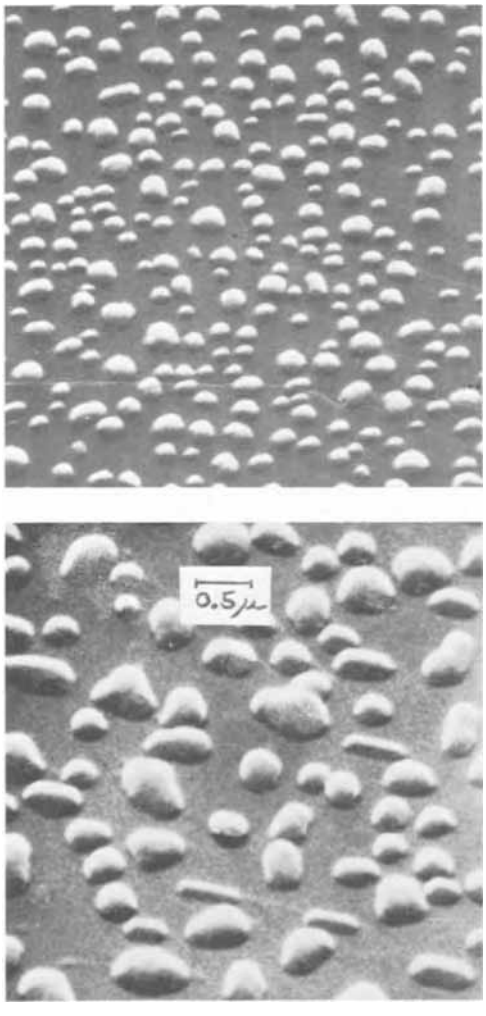

Fig. 2. Density and size of Si islands (scanning electron microscope): a (top)—ambient H_2, time 1 min (X11,000); b (bottom)—ambient He, time 1 min (X20,000).

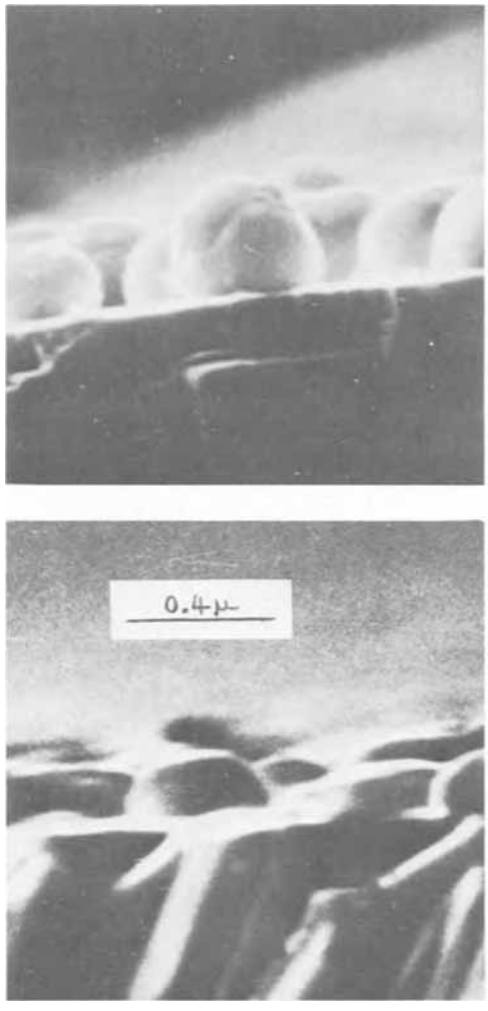

Fig. 3. Shape of Si islands: a (top)—ambient H_2, time 4 min (X26,000); b (bottom)—ambient He, time 4 min (X65,000).

These features are generally considered to be favorable to epitaxy. The contact angle value, especially, is related to defect formation during coalescence when it exceeds 90°.

Low-temperature Epitaxy

The crystalline orientation of thicker layers grown in He was checked by x-ray diffraction; a Cu-K α-radiation diffractogram is given in Fig. 4. The magnification factor is indicated for the various planes, and it is apparent that multiple orientations are found [particularly (001), as expected, and (111) orientations].

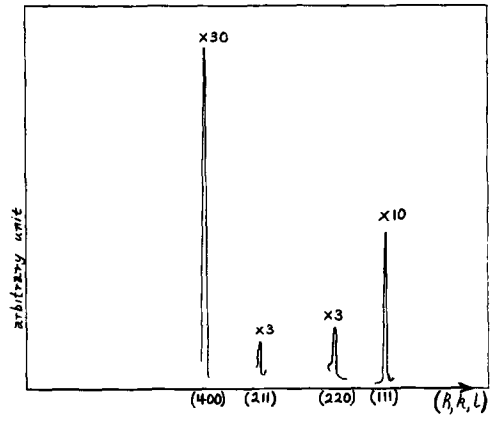

Fig. 4. X-ray diffracted intensities of a high-temperature layer grown in He. The relative height must be multiplied by the factor given at the top.

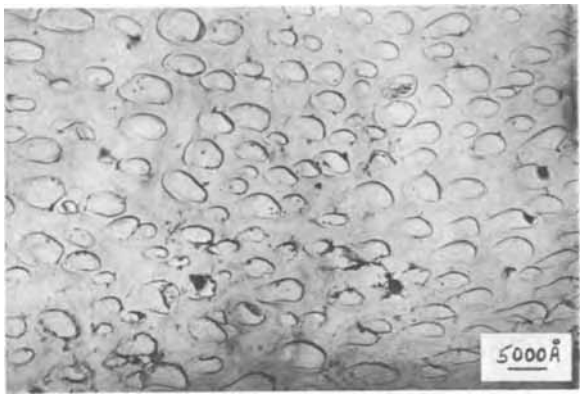

Fig. 5. Electron microscope replica of the sapphire substrate after etching the Si islands shown in Fig. 2(a) (X13,000).

Although they are not completely satisfactory, these preliminary results allow experiments at lower temperatures.

Monocrystallinity could not be achieved unless all flow rates were decreased. Ultimately, the following conditions were selected:

$T = 900°C$.
Carrier gas: He + H_2 (20% parts/volume).
Total flow rate: 2 liters/min.
Silane flow rate: 2 cm^3/min.

The decrease of total flow rate was needed because:

(a) Keeping it at its previous value gives a very different distribution of the deposit along the reaction tube. When T is decreased, the deposition area is more and more confined upstream, unfortunately in a nonuniform temperature region. This shift can be offset by decreasing the total flow rate.

(b) The crystalline quality increases, presumably due to less impurity incorporation *via* the vapor phase (see chemical analysis).

Summing up some characteristics of such films:

(a) Continuous layers are grown very rapidly, in less than 1 min.

(b) The growth rate at 900°C in helium is nearly equal to that measured at 1100°C in hydrogen (typical value: 0.1 μm/min).

(c) Non-purposely doped layers are slightly N-type and highly resistive ($\rho > 100$ ohm-cm).

(d) X-ray diffraction indicates that a quasi single orientation is achieved, but the strongest line is given by a (220) reflection instead of the expected (400) reflection. Thus, we confirm the tendency to grow (110) Si films at low temperature irrespective of the ambient, since we reported this in (6) for Si growth in H_2.

Table II. Properties of the layers to be analyzed

Layer	Growth conditions: Ambient	Growth conditions: T, °C	Thickness, μm	ρ, ohm-cm	Conductivity type	Orientation
H	H_2	1100	0.8	0.1	P	(001)
L	He	900	1.2	>100	Slightly N	(110)

Impurity Incorporation into the Films

Before describing the sputter-ion experiments, it is interesting to report direct evidence of the interaction between the substrate and the impinging Si at the early stages of the Si deposition. The method has been applied before (7) for Si grown on spinel.

Silicon islands are deposited in H_2 at 1100°C for 1 min, as shown in Fig. 1. Selective etching removes these islands only and an electron microscopy replica reveals depressed pits, outlining the previously present islands (Fig. 5).

Using He, we have also performed experiments similar to those we reported with H_2 (3) and have found aluminum transfer at a comparable level in the same high-temperature range. However, the results were not easily reproducible and were more difficult to interpret in terms of a simple diffusion process. This difficulty may be ascribed to the less pure ambient which can modify the surface conditions.

Sputter-ion Analysis

A reference is needed for this case also. A relatively thin layer is grown under standard conditions, as defined previously. Its properties are then compared with those of a layer grown in He at 900°C. The first layer is referred to as the *H* (High *T*) layer and the second as the *L* (Low *T*) layer. Their properties are given in Table II.

Prior to sputtering, a thick gold layer was evaporated in an ultrahigh vacuum system on the Si top surface.

We ascertained that no gold was incorporated into the film by selecting Au^+ ions at first. In any case, this film prevents any precise study of the Si surface itself.

We also determined that phosphorus was not detected in the *L*-layer even though it is N-type.

Aluminum (Al^+) and oxygen (O^-) were selected for the analysis since they were found previously (6) by other methods.

Silicon (Si^+) was also measured because it provided an interesting comparison with bulk material.

The three profiles (Al, O, Si) are plotted on one graph for each layer in Fig. 6, a and b.

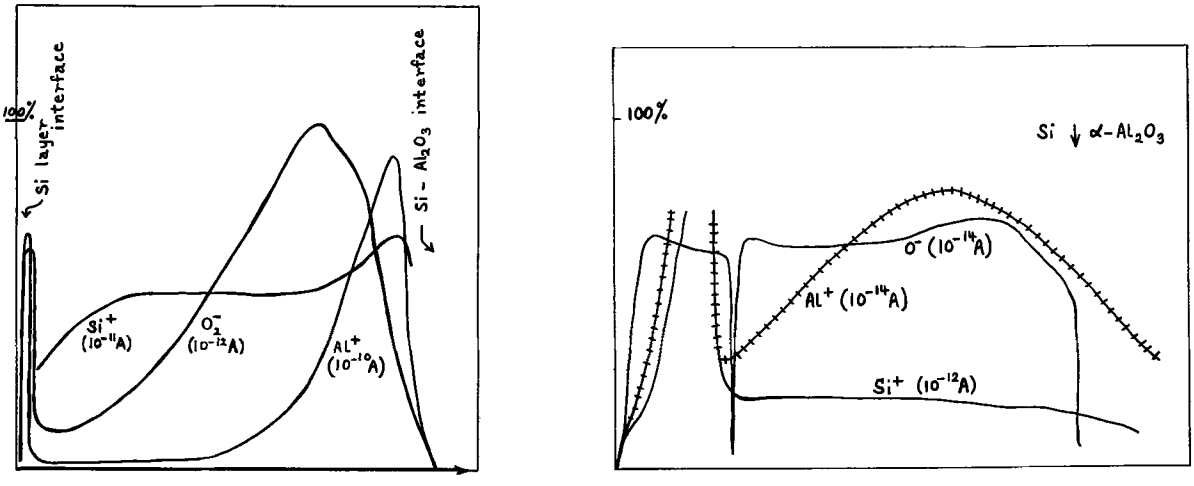

Fig. 6. Impurity profiles: a(left)—*H*-layer; b (right)—*L*-layer. The full scale (100%) corresponding to the given ionic current range is also shown.

Discussion.—As previously mentioned, the free surface properties are difficult to ascertain. In all cases, and for all elements involved, surface peaks appear. These may be explained by the phenomenon of chemical emission (8) associated with the presence of oxygen. The dip in the impurity profile of oxygen in the *L*-layer is clearly and repeatedly found and is obviously limited to the surface layer.

The outlines are somewhat different. A true diffusion profile is found in all cases (Al and O) except for the oxygen distribution in the *L*-layer, which is rather constant with depth. The O-profile, compared to the Al profile in the *H*-layer, is satisfactory because it is known that oxygen diffuses faster into Si than Al.

We conclude qualitatively that solid-state diffusion is important at high temperatures, but that oxygen incorporation *via* the vapor phase predominates at low temperatures.

Quantitatively, the results are not so understandable. To confirm the influence of the matrix, we must point out the difference between the two Si^+ secondary currents: bulk Si gives rise to a Si^+ ion current in the range of 10^{-11}A, corresponding also to that of the *H*-layer. On the contrary, the Si^+ current for the *L*-layer is only in the range 10^{-12}A. In fact, a full study must consider the influence of various parameters: the crystalline orientation, crystal perfection, and the numerous possible Si ions.

As an example, we have found that the etch rate is influenced by the crystalline perfection (9)

Bulk Si	250-300 Å/sec
Hetero Si in He	200 Å/sec
Hetero Si in H_2	80 Å/sec

Another very important point to remember is the difference in the ionization efficiency according to the chemical nature of the element; for example, bulk aluminum (Al^+ is the only ionized species) gives rise to a 10^{-10}A ionic current. However, Si and Al have almost the same atomic number, but their chemical bondings are, in fact, very different.

Taking this point into account and keeping in mind only relative figures, it is likely that:

(a) The Al content in the *L*-layer is about 10^{-4} less than in the *H*-layer.
(b) The oxygen content, likewise, is about two orders of magnitude less in the *L*-layer.
(c) Near the Si substrate interface of the *H*-layer, comparable Al-O-Si concentrations are found, which may imply a compound formation.

Some difficulties will be met in accurately defining the end of the film sputtering, especially for positively ionized species. The profile presents a long tail; by means of the specimen viewer, attached to the apparatus, we ascertained that a secondary ionic current is measured long after the primary beam reaches the bottom of the film. It is likely that, for insulating layers and due to specimen biasing, the primary ion beam shifts and etches an extended area. This hampers any firm relationship between impurity concentration and secondary current corresponding to that tail.

Last but not least, information is provided by the ionic distribution images for Al and oxygen into the *H*-layer. The apparatus records an image of a small etched region (150 μm in diameter) during sputtering, corresponding to a specific element. It therefore provides a true distribution of this element over the etched area. The difference between oxygen and Al distribution (Fig. 7, a and b) is striking: except for a small number of localized spots, the O-pattern appears uniform; conversely, Al presents a spotty pattern suggesting a localized distribution, presumably at dislocation sites. This result can be related to the beautiful photoconductivity experiments (10) on similar structures, indicating space charge distributions.

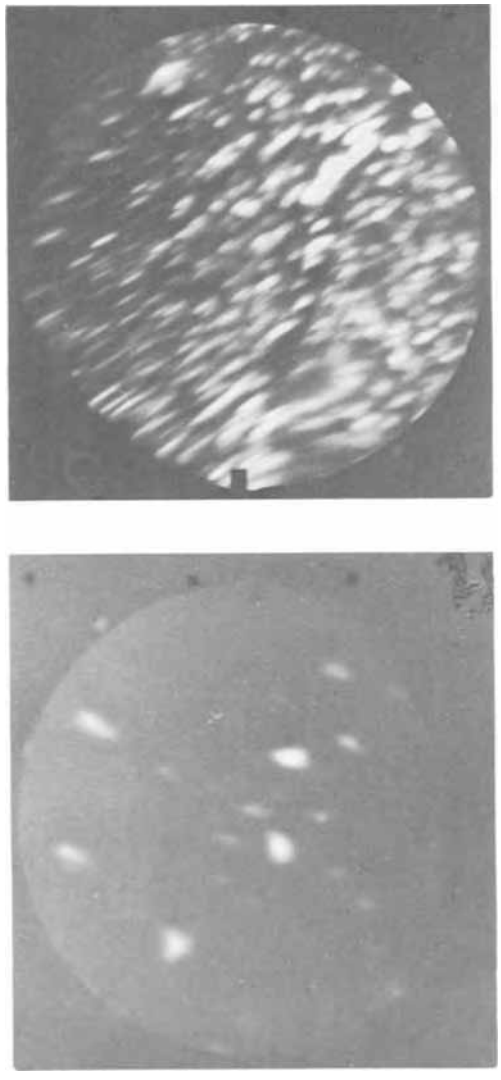

Fig. 7. Ionic distribution image (*H*-layer) of: a (top)—aluminum, b (bottom)—oxygen.

Conclusion

These first experiments were very fruitful and the main results can be summarized as follows.

1. Compatibility of low-temperature epitaxy and the He process is demonstrated.
2. Autodoping is therefore minimized.
3. The sputter-ion technique is a very promising tool for chemical analysis of such layers.

However, much work remains to be done. Several basic problems must be solved: understanding the trend toward (110) orientation, quantitative interpretation of the ion probe measurements, and, accordingly, understanding of impurity incorporation processes.

Practical problems concerning the applicability of this general technique depend on:

1. Purification conditions in order to make the layer growth procedure easier. For example, it is necessary to pump the whole system 2 days before an experiment starts.
2. Electrical characteristics (especially for doped layers). Since doping and growth conditions are related, their compatibility must be checked.

Acknowledgments

I am grateful to Professor L. Néel for allowing this research to be undertaken in his laboratory, and to Dr. B. K. Chakraverty for valuable discussions.

I express my deepest gratitude to Dr. G. Blet and his group of the L.R.G. Thomson-C.S.F. for their con-

stant scientific cooperation (IR, x-ray electron microscopy experiments). It is a pleasure to emphasize local cooperation with several laboratories of the Nuclear Center at Grenoble (C.E.N.G.). My particular thanks are addressed to Dr. Cornu in charge of DPC.SIS, who allowed the ion probe measurements. I am indebted to Dr. Blanchard for carrying out these experiments and for many interesting discussions.

Manuscript submitted June 8, 1970; revised manuscript received Dec. 17, 1970. This was Paper 197 (with the added sputter-ion analysis) presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Ionic Contamination and Transport of Mobile Ions in MOS Structures

M. Kuhn and D. J. Silversmith

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

A fast, simple and very sensitive technique has been developed to determine the extent of ionic contamination of oxides in MOS capacitors. The method is capable of detecting better than 10^9 mobile ions/cm^2 and is based on the measurement of the displacement current response to a slow linear ramp voltage at elevated temperatures. This yields an ionic displacement current peak whose area is proportional to the total mobile ionic space charge. The method is expected to be very useful for routine process and quality control applications. This technique has been used to study positive mobile charge behavior in silicon dioxide. The voltage dependence of the ionic displacement current indicates that trapping of ions occurs at the metal-oxide interface and that ionic transport from the metal to the silicon interface is controlled by trap emission. Ion transport from the silicon to the metal interface is characterized by a single, bulk-limited transport mechanism below 300°C with an activation energy that appears concentration dependent. Above 300°C an additional transport mechanism is observed which is slow in comparison to the primary transport mechanism.

Trace amounts of ionic contamination in thermally grown SiO_2-Si MOS structures and insulated gate field effect transistors (IGFET) are a source of instability because of ionic drift under action of an electric field. Extensive work (1-4) has traced the major source of this ionic drift instability to the presence of sodium. The extent and distribution of sodium contamination has been determined both destructively [by neutron activation analysis (5) and flame photometry (6)] and nondestructively by capacitance measurements of bias-temperature aged MOS capacitors (1-4). Flame photometry and neutron activation analysis are complicated experimental methods which are not practical for routine analysis and which lack sensitivity for sodium levels below 10^{12} atoms/cm^2. The usual high-frequency C-V measurements under bias-temperature stress indicate sodium contamination by observing shifts in the flatband voltage. These measurements are uncertain because flatband voltages are influenced by changes in the surface charge and surface state density under bias-temperature stress. Such changes make unambiguous ion concentration determinations difficult for concentrations less than 1-2 x 10^{10} ions/cm^2.

The limitations mentioned above are largely overcome if one measures the ionic displacement current in an MOS capacitor driven by a slow linear voltage ramp (7). This measurement is made at elevated temperatures, and the ionic motion is revealed by a current peak near zero bias. The total mobile ionic charge is proportional to the area of this peak, and the ionic species can be readily measured down to 10^9 ions/cm^2. The method is rapid and simple, in addition to being sensitive and independent of changes in interface properties.

The ramp method has been used to study mobile charge drift in various SiO_2-Si and Al_2O_3-SiO_2-Si MOS structures with ion concentrations spanning a range from above 10^{13} ions/cm^2 to fewer than 10^9 ions/cm^2 (8). The fraction of ionic species that is mobile depends exponentially on temperature over a range between 100°-400°C, and the shape of the ionic displacement current indicates that ionic trapping occurs at the metal-insulator interface. This suggests that ionic transport is characterized by at least two processes: a fast process at lower temperatures and a slow process at temperatures above 300°C.

This method has been independently developed by Kerr (9) and Chou (10) who have tested and confirmed its validity using the simpler and electrochemically symmetrical Si(poly)-SiO_2-Si(100) MOS structure.

Key words: ion transport, mobile ions in insulators, MOS characterization.

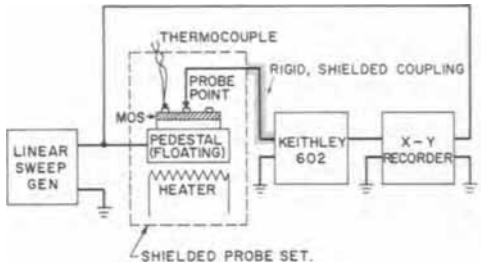

Fig. 1. Schematic diagram for mobile ion drift test set

Apparatus

The experimental test set for performing mobile ion drift measurements is shown schematically in Fig. 1. The apparatus consists of a shielded probe set containing an electrically isolated pedestal heated with a shielded resistance heater to temperatures up to 400°C and a movable probe point. The pedestal is driven with a slow linear voltage ramp obtained from an operational amplifier integrator or a slow triangular wave function generator (HP-3310A) to provide sweep rates typically 5-100 mV/sec. The displacement current flowing through the MOS capacitor on the pedestal is monitored through the probe point and is measured using a Keithley 602 electrometer operating in the "fast" mode. In this way the electrometer functions as a high gain operational amplifier, reducing the input voltage drop essentially to zero and also minimizing the response time. The output from the electrometer (unity gain) and the applied voltage ramp are recorded on an X-Y plotter to display a plot of displacement current *vs.* voltage. As typical displacement current levels are about 10^{-11}A, careful electrostatic shielding is required, and the Keithley input connector from the probe point should be kept as short and as rigid as possible to minimize stray capacitance and vibrational noise.

Analysis

The response of an MOS capacitor to a slow linear voltage ramp in the absence of any mobile charged species has been discussed (7); it was shown that under quasi-static conditions, low frequency C-V characteristics are obtained. When the oxide contains ionic impurity species which are mobile under the influence of electric field at elevated temperatures, these mobile ions contribute an additional component to the displacement current. This ionic component may be analyzed to yield the quantity of mobile ions present and may provide some additional information on their transport properties, as will be shown by the following analysis.

We consider an MOS capacitor with space charge density $\rho(x)$ in the insulator as shown below the energy band diagram of Fig. 2. The charge $Q(V)$ induced at the semiconductor surface when a voltage V volts (measured with respect to the bulk semiconductor) is applied to the field plate is given by

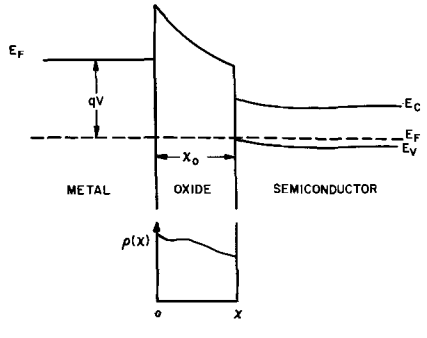

Fig. 2. Electron energy diagram of an MOS structure in accumulation. The band bending is characteristic of a P-type semiconductor. A hypothetical charge density in the oxide is shown.

$$Q(V) = -\int_0^V C(V)dV + Q_{FB} \qquad [1]$$

where $C(V)$ is the low frequency differential MOS capacitance and Q_{FB} is the induced charge necessary to establish the flatband condition. Q_{FB} may be expressed in terms of the metal-semiconductor work function difference Φ_{MS}, the space charge distribution $\rho(x)$ per unit area and the oxide-capacitance per unit area, C_{ox}, as (7)

$$Q_{FB} = C_{ox}\Phi_{MS} - \int_0^{x_o} \frac{x}{x_o}\rho(x)dx \qquad [2]$$

x is the distance into the oxide measured from the metal-oxide interface, x_o is the oxide thickness. The displacement current flowing out of the metal field plate, when the applied voltage varies with time and the space charge density is mobile, can be expressed as

$$i = -\frac{dQ(V,t)}{dt} = \frac{d}{dt}\int_0^V C(V)dV + \frac{d}{dt}\int_0^{x_o}\frac{x}{x_o}\rho(x,t)dx \qquad [3]$$

Furthermore, if we choose a linear time dependence for the applied voltage, $V = \pm\alpha t$ and using $d/dt = \pm\alpha\, d/dV$, the displacement current becomes

$$i(V) = \pm\alpha C(V) \pm \alpha\frac{d}{dV}\int_0^{x_o}\frac{x}{x_o}\rho(x,V)dx \qquad [4]$$

This expression for the displacement current as a function of applied voltages is valid under conditions of quasi-static equilibrium, that is, under sweep conditions so slow that the ionic charge distribution $\rho(x, V)$ can continuously equilibrate with the externally applied voltage. This quasi-static equilibrium may be expected to apply at elevated temperature, in the range above 150°C at sweep rates less than 100 mV/sec. Under these conditions the entire shape of the charging curve can be determined, in principle, by calculating the equilibrium charge distribution as a function of applied voltage from a solution of Poisson's equation and the general transport equations and using these to calculate the second term in Eq. [4]. We would expect these detailed calculations to yield information about the line shapes and their relation to the ionic transport properties, which might lead to a useful method for ionic spectroscopy.

It remains to show explicitly that the mobile ionic charge density is obtainable from the displacement current. This follows directly when we consider the integral of the ionic displacement current Eq. [4])

$$\int_{-V_o}^{+V_o}[i(V) - \alpha C(V)]dV = \alpha\int_0^{x_o}\frac{x}{x_o}\rho(x,+V_o)dx - \alpha\int_0^{x_o}\frac{x}{x_o}\rho(x,-V_o)dx \qquad [5]$$

This equation shows that the integral of the ionic component of the displacement current between two bias limits is equal to the difference in the weighted space-charge distribution, provided that the charge distribution is allowed to equilibrate. The mobile ionic charge density is obtained directly if the initial and final conditions are chosen so that all the mobile charge is located at an interface. For example if $-V_o$ and V_o are chosen so that $\rho(x, -V_o) \simeq \rho_o\delta(x)$, and $\rho(x, +V_o) \simeq \rho_o\delta(x - x_o)$ Eq. [5] becomes

$$\int_{-V_o}^{V_o}[i(V) - \alpha C(V)]dV = \alpha\rho_o \qquad [6]$$

In practice, at elevated temperatures, $C(V) \simeq C_{ox}$ over the entire bias range, and a practical formula for the determination of mobile ionic charge density is

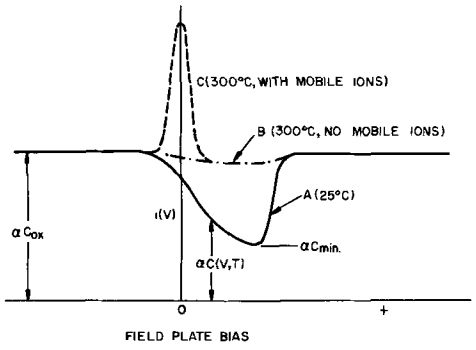

Fig. 3. Displacement current of a typical MOS capacitor (P-type substrate) in response to a d-c ramp. Curve A (25°C) and B (300°C) show the characteristic dip in capacitance near $V = 0$ due to majority carrier depletion at the Si-SiO_2 interface. Curve C (300°C) shows a peak at $V = 0$ due to the transport of mobile ions from the oxide bulk to an interface.

$$\rho_0 \simeq \frac{1}{\alpha}\int_{-V_0}^{V_0}[i(V) - \alpha C_{ox}]dV \qquad [7]$$

The mobile charge concentration is proportional to the area between the displacement current curve and the line corresponding to the oxide capacitance in a displacement current *vs.* voltage characteristic.

The idealized displacement current response as a function of the applied voltage with and without mobile ionic space charge is shown in Fig. 3. At room temperature the displacement current is proportional to the low frequency differential MOS capacitance as shown in curve A. In the absence of mobile ionic space charge an increase in the ambient temperature results primarily in an increase of C_{min}/C_{ox} until, at temperatures typically above 300°C, the displacement current is nearly constant and equal to the oxide capacitance. This behavior is a consequence of the rapid increase of the intrinsic carrier concentration with temperature which results in silicon surface capacitance much larger than C_{ox}. Such a response at elevated temperature (300°C) is shown in curve B. When ionic space charge is present in the oxide, then as the temperature is raised, redistribution may occur as a function of bias, resulting in an ionic displacement current peak near zero applied voltage; this ionic displacement current peak is superimposed on the MOS *C-V* characteristic as shown in curve C. Generally, this ionic peak is readily separable from the electronic displacement current. Therefore, this provides a simple, rapid, convenient and highly sensitive method for the investigation of ionic space charge concentrations, with the additional advantage that the method is largely independent of any of the variations in MOS interface properties ($Q_{ss} + N_{ss}$) which limit both accuracy and sensitivity of the conventional method of measuring flatband voltage shifts after bias-temperature aging. The changes in Q_{ss} and N_{ss} limit the resolution in measurement of the flatband voltage shift, and therefore limit the accuracy to no better than 10^{10} ions/cm^2.

Experiment

The experimental technique described above has been used to study ionic transport in a wide variety of MOS structures. Both P and N substrates in (100) and (111) orientations have been used with dopant concentrations ranging from 10^{14} to 10^{17}/cm^3. Oxides have been grown to thicknesses of 800-2500Å in both a plasma oxidation (8) system and a dry 1150°C oxidation furnace. Various annealing procedures after growth have been attempted, but no measurable changes in ion transport have been seen. These measurements have indicated positive ion (sodium) concentrations from below 10^9 to more than 10^{13} ions/cm^2 and give substantially the same ion concentrations as determined from flatband voltage shifts after bias aging.

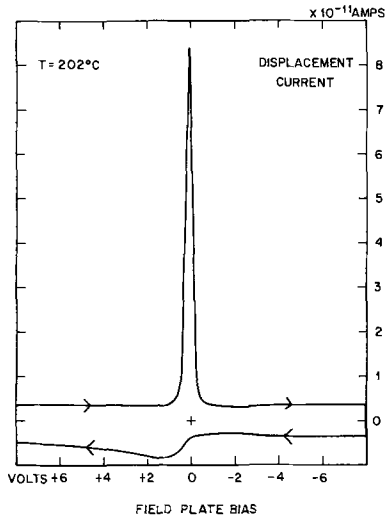

Fig. 4. Displacement current response for a heavily contaminated oxide at 200°C. The substrate consisted of a 5μ N-type, 1 ohm·cm, (111) epitaxial silicon film grown on an N-type wafer. The oxide is 1000Å thick, and is grown in an oxygen plasma system. The field plates are 15 mil dots of 200Å Cr and 2000Å Au. The sweep rate of the d-c ramp is 77.5 mV/sec.

A typical ramp response curve for a heavily contaminated oxide is given in Fig. 4. The sweep from field plate positive to negative (left to right) yields the response shown in the upper curve, while the voltage sweep from negative to positive is the lower curve. This d-c ramp *C-V* MOS measurement was taken at 202°C, and the peak above the C_{ox} baseline corresponds to 2.5 x 10^{12} mobile ions/cm^2 in the oxide. The peak is well defined with respect to C_{ox}, and the shape agrees with the model proposed earlier in this paper. During this sweep positive ions are expected to move from the Si-SiO_2 interface to the metal-SiO_2 interface, and the resulting capacitance peak, suggests that no interface trapping occurs at the Si-SiO_2 interface.

The most striking feature of these curves is the strong asymmetry of the ionic displacement current in the two sweep directions. The response when sweeping from the field plate negative to field plate positive is distorted and broadened over the entire positive voltage range, resulting in a very broad peak as shown in the lower trace of Fig. 4. This clearly indicates that ion transport is sluggish as may be expected of a transport mechanism limited by emission from ionic traps located at the metal-SiO_2 interface. Similar measurements on many MOS structures have indicated that the area under the peak and the dip are equal (with respect to the upper and lower C_{ox} baselines), showing that all the ions transported to the metal-oxide interface can be brought to the silicon-oxide interface by changing the polarity of the voltage ramp. As expected from quasi-equilibrium arguments, the area under the peak is independent of sweep rate, as long as the rate is sufficiently slow to establish the boundary conditions which approach delta functions (as described in the previous section).

The temperature dependence of the ionic displacement response is given in Fig. 5. The ionic peak does not saturate but continues to increase with temperature. At low temperature the sweep from field plate negative to positive (right to left) yields a broadened structure, resulting from the trapping-emission mechanism at the metal-oxide interface. At higher temperatures this peak sharpens and approaches more closely the ideal shape (or the shape of the peak for the opposite sweep) as expected if emission of ions from traps is more rapid at higher temperatures. Furthermore, an additional structure is observed above the C_{ox} baseline at elevated temperature ($T > 300$°C), as shown in the upper trace of Fig. 5. This structure typically takes

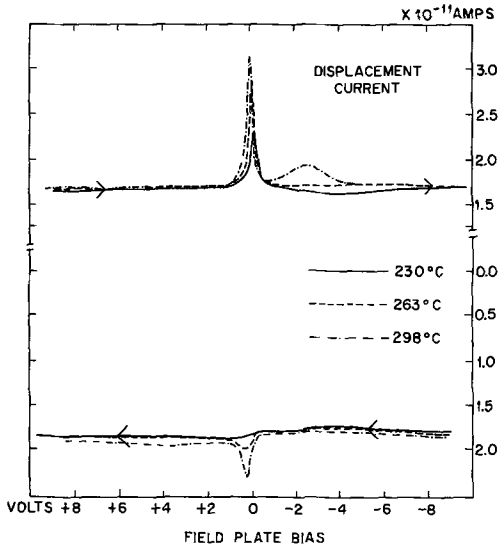

Fig. 5. Displacement current response of an MOS capacitor at 230°, 263°, and 298°C. The substrate consisted of a fresh N-type, 1 ohm·cm, (100) expitaxial film. The oxide was 2000Å thick, and was grown in a dry oxidation furnace at 1150°C. After growth, the sample was annealed in Ar at 1150°C for 30 min. Fifteen-mil dots of 200Å Cr and 2000Å Au were deposited for field plates. The sweep rate of the d-c ramp was 42.3 mV/sec.

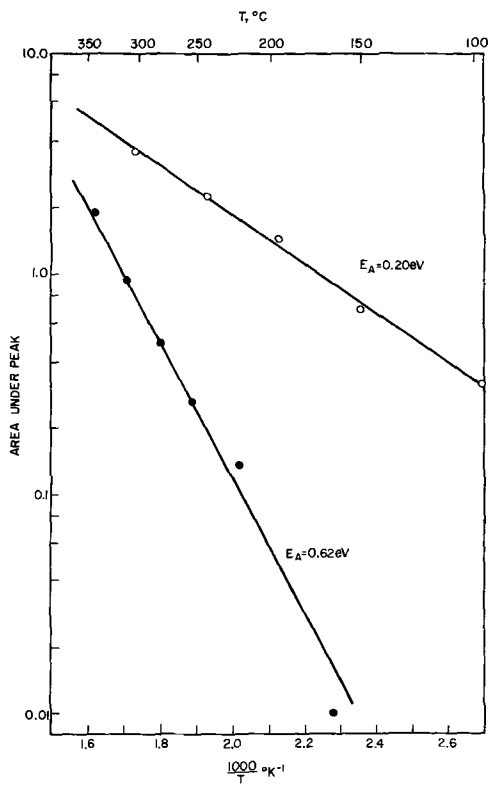

Fig. 6. Temperature dependence of the displacement current peak. The total area under the displacement current peak, above the C_{ox} baseline, is plotted on the ordinate. The open dots are data from an MOS capacitor with the same specifications as those described in the caption for Fig. 4. The closed dots are from a device fabricated on 10 ohm·cm, (100) P-type silicon. The oxide was 2000Å thick, and was grown in a dry oxidation furnace at 1150°C. After growth, 15 mil dots of 200Å Cr and 2000Å Au were deposited for field plates.

the form of a second broadened peak displaced by approximately −2V from the mobile ion peak. This may be evidence for the onset of an additional high temperature field dependent transport mechanism.

No saturation of the ionic peaks with temperature was observed. The area under the mobile ion structure increased exponentially with temperature to the limit of the experiment (370°-400°C). In Fig. 6 the temperature dependence of the area under the mobile ion structure has been plotted for two similar devices. If one can assume that the number of available mobile ions at a particular temperature can be described in terms of an activation formalism, then activation energies can be determined by plotting the area under the displacement current peak above the C_{ox} baseline *vs.* $1/kT$ where T is the measurement temperature. Applying this analysis to our experimental results we find that the activation energy, E_A, is a function of ionic concentration and is lower for higher ionic contamination. For example, a device containing about 10^{13} sodium ions/cm^2 at 300°C has an activation energy of 0.20 eV; whereas a similar device with 10^{11} sodium ions/cm^2 at 300°C has an activation energy of 0.62 eV. The increase in activation energy with decreasing ionic contamination agrees with our observation that ionic transport effects can be seen at lower temperatures only with high ionic contamination. The activation energy, E_A, is clearly a function of the impurity concentration, but no model for this behavior can be proposed at present. However, this result suggests that sodium transport in silicon dioxide may be complicated by concentration effects and may be inadequately described by a simple noninteracting single carrier model, that is, the diffusion coefficient and mobility may be concentration dependent.

As indicated in Fig. 5, we consistently observe a strong asymmetry in the shape of the ionic displacement current for a bias sweep from positive to negative voltage (silicon to metal) compared with the shape of current for a negative to positive voltage (metal to silicon) sweep. The sweep from field plate positive to negative voltage results in a sharp well-defined (fast) ion current peak near zero bias in contrast to a very broad (sluggish) ionic response associated with trap emission for the opposite sweep direction. The response of the mobile species to the voltage ramp ("fast" or "slow") appears to be independent of ramp rate below 100 mV/sec. In an electrochemically symmetric Si(poly)-SiO_2-Si(100) structure, however, the ionic displacement current is essentially independent of the sweep direction (10). Therefore, we conclude that ionic traps are associated with the metal-oxide interface and the mobile ionic species is positively charged.

The displacement current-voltage characteristic typically observed at 350°C is shown in Fig. 7. The upper curve corresponds to ion transport from the silicon to the metal interface and shows a well-defined broad peak at −2V in addition to the sharp peak structure observed alone below 300°C. After the appearance of this broad peak at 300°C (Fig. 5), the initial sharp structure saturates, and for higher temperatures the area above C_{ox} increases only under the broad peak. The total mobile charge (corresponding to the area under both peaks) follows an activation law behavior, and no change in the slope of an activation energy plot has been observed. The metal-to-silicon ionic transport above 300°C is characterized by the same sequence of mechanisms as shown in the lower curve of Fig. 7: Near zero volts a fast saturated peak is observed, and at a higher magnitude of voltage in the sweep, a slow and broad, unsaturated peak is seen. This result strongly suggests that the same positively charged ion is responsible for both peaks in the high-temperature transport. The two peaks further suggest two possible states for sodium or two transport mechanisms in SiO_2.

Discussion and Conclusions

The response of MOS capacitors to slow linear voltage ramps at elevated temperatures provides a simple, rapid, convenient, and highly sensitive method for the measurement of ionic contaminants in the oxide of the MOS structure, which is compatible with routine

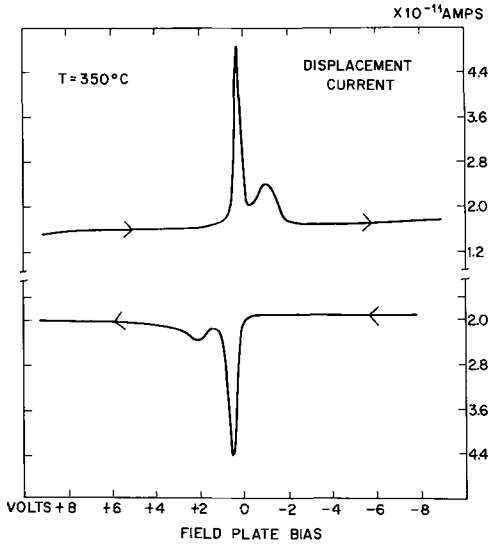

Fig. 7. Displacement current response at 350°C. The substrate of the MOS capacitor was a fresh P-type, 1 ohm·cm, (100) epitaxial film. The oxide was 2000Å thick, and was grown in a dry oxidation furnace at 1150°C. After growth, the sample was annealed in Ar for 30 min. Fifteen-mil dots of 200Å Cr and 2000Å Au were deposited for field plates. The sweep rate of the d-c ramp was 42.3 mV/sec.

process control. The method is capable of measuring ion concentrations below 10^9 ions/cm^2 and has the advantage of being largely independent of any variations in MOS interface properties (Q_{ss} and N_{ss}) with temperature. The temperature dependence of interface properties has limited both the accuracy and sensitivity of conventional methods of measuring flatband voltage after bias-temperature aging. The sensitivity of the method discussed in this paper increases with increasing oxide thickness because the ionic displacement current is superimposed upon a reduced oxide capacitance level. Using the methods of flame photometry and atomic absorption spectroscopy (6), good correlation was obtained for sodium concentrations measured by flame emission and by the high-temperature voltage ramp method discussed here.

Earlier studies by Snow *et al.* (1) on sodium ion migration in SiO_2 (using flatband shift and ionic polarization measurements after application of a positive step voltage) were interpreted in terms of a bulk-limited diffusion model and were used to extract activation energies associated with the bulk diffusion of sodium ions in SiO_2. The results presented in the previous section indicate that mobile ion transport from the metal-to-silicon interface is trap-emission controlled with the ion traps located at or near the metal-oxide interface. More recent experiments by Chou (10) have indirectly verified that the transport of mobile ions from metal to silicon is trap controlled. A comparison of our results with Chou's clearly indicates that Snow's diffusion analysis is not applicable to the sodium ion polarization measurement under positive step voltage conditions and that activation energy measurements obtained therefrom will relate to trap emission mechanisms rather than to bulk diffusion.

In contrast to ion transport from the metal-to-silicon interface, ion transport from the silicon-to-metal interface does not appear emission limited but appears controlled by bulk transport processes. Two modes of transport have been observed. A "fast" transport is observed above about 150°C and an additional "slow" transport is seen above 300°C. This observation is generally in agreement with those of Hofstein (2) who has also observed two transport modes in MOS structures heavily contaminated with sodium. Hofstein observes the onset of the "slow" transport at 200°C with a somewhat higher activation energy. Additional, more detailed studies of the mobile ion response using both the ramp and step response methods may provide the detailed information necessary to yield a correct understanding of the transport of mobile ions in MOS structures.

A Self-Consistent Method for Estimating Non-Step Junction Doping Profiles from Capacitance-Voltage Measurements

R. B. Fair

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania 19604

ABSTRACT

The use of the step-junction approximation for calculating the net doping density from C-V measurement data can lead to serious errors in the resulting profiles for sequentially diffused structures. Non-step junction behavior can be accounted for if the equation for the effective doping density is multiplied by a correction factor. Two approximate methods of estimating this correction factor are discussed in which the net ionized impurity density on the high side of the junction is assumed to change either linearly or exponentially with incremental changes in depletion layer depth. For both of these approximations, the net ionized impurity density on the low side is assumed to change parabolically. These net distributions of charge, which are iteratively determined in a self-consistent fashion, yield the best approximations for this functional form of the profile, according to the C-V measurements made on the junction. Comparisons between experimentally obtained doping profiles and profiles computed *via* the techniques described in this paper show good agreement.

Proper knowledge of the net impurity profiles in p-n structures is essential for the design of diodes and transistors, especially microwave transistors where the performance is limited by the net doping in the base region. High side impurity distributions can be obtained fairly accurately by carrying out anodic sectioning of the semiconductor material, and by taking resistivity measurements of the exposed surface (1). The low side doping profile of a p-n junction is usually determined by assuming a step junction, and by calculating the net ionized impurity distributions with data obtained from the diode capacitance-voltage method (2, 3). However, it is well known that in p-n junctions the depletion region extends into the high concentration side of the junction. Attempts to account for this phenomenon have resulted in analytical expressions for the symmetrical step junction, the moderately unsymmetrical step junction, and the linearly graded junction (4, 5). Experimental evidence has shown that, for a low voltage bias, the linearly graded junction yields a reasonably accurate approximation to the total depletion region thickness ($C \propto V^{-1/3}$). Conversely, as was first shown by Pritchard (6), observation of a $V^{-1/3}$ variation of capacitance is not a reliable indication of linear grading. Decker (7) has been able to determine the doping *vs.* depth in epitaxial layers in which the profile of the high side doping is assumed to be a complimentary error function. The low side doping can be determined from capacitance-voltage measurements, and from numerical integration of the assumed high side profile.

None of the aforementioned methods can be used to describe adequately nonideal doping distributions associated with shallow diffusions or implantations, while taking into account the space charge sweep into the highly doped side. Interactions between sequentially diffused impurities and incomplete ionization cause actual doping profiles to deviate from analytically assumed profiles.

In this investigation, the equation for the effective doping density, as determined by the C-V relationship, is modified for the determination of low side doping, $N_2(x)$, by the inclusion of the multiplicative factor $(1 - dx_1/dx_2)$; dx_1/dx_2 (negative) denotes the rate of change of the high side sweep-out distance with respect to the low side. Two approximate methods of determining dx_1/dx_2 are discussed in which the net ionized impurity concentration on the high side of the junction is made to change either linearly or exponentially with incremental changes in junction bias. For both of these approximations, the net ionized impurity distribution on the low side is assumed to change parabolically (see Fig. 1). The linear-parabolic and the exponential-parabolic distributions were selected because they approximate the actual net profiles in sequentially diffused structures. These net distributions of charge, which are iteratively determined in a self-consistent fashion, yield the best approximations of this type for the determination of dx_1/dx_2, according to the C-V measurements made on the junction.

Key words: C-V measurements, transistors, doping profiles.

Two-Sided Depletion Layer Sweep-Out

For an arbitrary profile on each side of a p-n junction, the relationship between the effective doping density, $N_T(x_d)$, and the net doping densities, $N_1(x_1)$ and $N_2(x_2)$, at the edges of the depletion layer is (8)

$$\frac{1}{N_T(x_d)} = \frac{1}{N_1(x_1)} + \frac{1}{N_2(x_2)} \qquad [1]$$

where x_d is the depletion layer width expressed as $x_d = (x_2 - x_1)$ (Fig. 1). $N_T(x_d)$ is a function of capacitance and voltage and is defined as

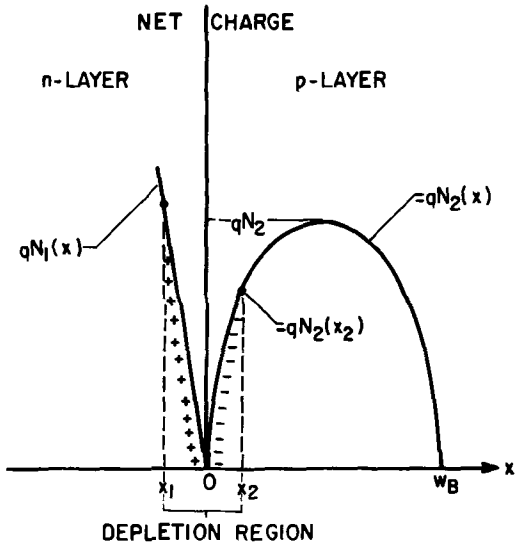

Fig. 1. Illustration of the way in which the space charge is assumed to change with applied junction voltage (linear scales). The signs of the ionized impurities in the depletion region are indicated.

$$N_T(x_d) \equiv \frac{\left(\frac{C}{A}\right)^3}{q\,\epsilon_0\epsilon_r}\left[\frac{-dV}{d\left(\frac{C}{A}\right)}\right] \qquad [2]$$

A is the area of the junction, and C is the capacitance given by the expression

$$C = \frac{\epsilon_0\epsilon_r A}{x_d} \qquad [3]$$

It can be seen from Eq. [1] that, for C-V measurements made on a particular p-n junction, it is impossible to determine uniquely the net profiles $N_1(x)$ and $N_2(x)$ which yielded these measurements. However, if the complete net profile on one side of the junction is assumed, such as $N_2(x)$, then it is possible to solve for $N_1(x_1)$ and x_1. Thus, the correctness of the estimation of the actual $N_1(x_1)$ is dependent on the correctness of the assumed profile, $N_2(x)$. In this paper, $N_2(x)$ is assumed to be parabolic, and the general form of $N_1(x)$ is either linear or exponential.

If Eq. [1] is rearranged, the net low side doping density, $N_2(x_2)$, becomes

$$N_2(x_2) = \frac{\left[1 + \frac{N_2(x_2)}{N_1(x_1)}\right]\left(\frac{C}{A}\right)^3}{q\,\epsilon_0\epsilon_r}\left[-\frac{dV}{d\left(\frac{C}{A}\right)}\right] \qquad [4]$$

Using the fact that equal quantities of charge must reside on the two sides of the junction, Eq [4] can be rewritten as

$$N_2(x_2) = \frac{\left[1 - \frac{dx_1}{dx_2}\right]\left(\frac{C}{A}\right)^3}{q\,\epsilon_0\epsilon_r}\left[-\frac{dV}{d\left(\frac{C}{A}\right)}\right] \qquad [5]$$

Therefore, for the net doping profiles which have been assumed (linear-parabolic and exponential-parabolic), it is possible to solve for the ratio $N_2(x_2)/N_1(x_1)$ (or dx_1/dx_2) for given C-V measurements. In this way a correction to the effective doping density, $N_T(x_d)$, is made which yields an estimate of the net low side doping, $N_2(x_2)$. The assumed profiles which are used in determining dx_1/dx_2 are iteratively adjusted so that the estimate of dx_1/dx_2 is self-consistent.

The Linear-Parabolic Junction

In order to calculate x_1, x_2, and hence, dx_1/dx_2, it is assumed that the change in the high side net charge density with increments of voltage is linear with distance from the junction. Thus, the charge on the high side, Q_h, is given by

$$Q_h = q\int_{x_1}^{0} m_1 x\,dx \qquad [6]$$

where m_1 (negative) is the grade constant. If the charge distribution on the low side of the junction is assumed to be parabolic with distance from the junction, then the charge on the low doped side, Q_l, is given by

$$Q_l = \frac{4q}{w_B{}^2}\int_0^{x_2} N_2(w_B x - x^2)\,dx \qquad [7]$$

where N_2 is the height of the parabola (ion/cm^3), w_B is the width of the parabola, and x_2 is the distance to the space charge edge. By setting $Q_h = Q_l$, and using the fact that

$$N_2 = \frac{N_2(x_2)w_B{}^2}{4x_2(w_B - x_2)} \qquad [8]$$

then

$$x_2{}^3 + x_2{}^2\left[w_B - x_d - \frac{2N_2(x_2)}{3m_1}\right] + x_2\frac{N_2(x_2)}{m_1}\left[\frac{4}{3}x_d - w_B\right] + \frac{N_2(x_2)x_d}{m_1}\left[w_B - \frac{2}{3}x_d\right] = 0 \qquad [9]$$

for which

$$\frac{dx_1}{dx_2} = -\frac{N_2(x_2)}{x_1 m_1} \qquad [10]$$

for charge balance at the junction.

In order to solve Eq. [9] for x_2, prior knowledge of dx_1/dx_2 and $N_2(x_2)$ is required. Thus, for each pair of C-V measurements, an iteration procedure must be performed on dx_1/dx_2 and m_1, starting with $dx_1/dx_2|_0 = -0.5$ and m_1 equal to the grade constant of the linearly graded junction. $N_2(x_2)$ can then be determined from Eq. [5]. Using these values in Eq. [9], x_2 can be determined by inverse interpolation, and then Eq. [10] can be solved for the next better value of dx_1/dx_2. This iterative process of calculating $N_2(x_2)$, x_2, and the corresponding improved estimate of the true value of dx_1/dx_2 proceeds until

$$\left.\frac{dx_1}{dx_2}\right|_{i+1} - \left.\frac{dx_1}{dx_2}\right|_i \simeq 0 \qquad [11]$$

where i refers to the i^{th} iteration.

When the condition expressed in Eq. [11] is satisfied, $N_2(x_2)$ is still not necessarily an accurate estimate of low side doping, since x_2 is not accurately known. The initially assumed value of grade constant, m_1, must be adjusted until the calculated charge distribution about the junction has associated with it a capacitance that is equal to the measured value. Thus, the calculated capacitance, $C_n{}^1$, associated with n^{th} C-V measurement can be written as

$$C_n{}^1 = \frac{(q_n - q_{n-1})A}{V_n - V_{n-1}} \qquad [12]$$

where q_n is the charge residing on the low side of the junction for the n^{th} value of bias, V_n. For the parabolic, low side profile

$$q_n = \frac{q\,N_2(x_2)\left[\frac{w_B}{2} - \frac{x_2}{3}\right]x_2}{(w_B - x_2)} \qquad [13]$$

If $C_n{}^1 \neq C_n$, where C_n is the n^{th} measured junction capacitance, then m_1 can be adjusted so as to bring $C_n{}^1$ closer in value to C_n. For each newly adjusted value of m_1, the iteration procedure for dx_1/dx_2 must be repeated and a new $C_n{}^1$ computed until

$$C_n{}^1 - C_n \simeq 0 \qquad [14]$$

Figure 2 shows the way in which the final values of m_1 (which caused Eq. [14] to be satisfied) varied as a function of applied junction voltage for a particular diode. The reference value of m_1, about which these final values of m_1 are distributed, was obtained from the C-V data as the slope of $1/C^3$ *vs.* V.

The above-mentioned procedure for calculating dx_1/dx_2 and then $N_2(x_2)$ from Eq. [5] can be performed on a computer. For each pair of C-V measurements, these iterative computations are performed with the result that each calculated point on the low side profile is adjusted to the extent that $[1 - dx_1/dx_2]$ modifies the step junction approximation.

The Exponential-Parabolic Junction

If the change in the net high side charge with voltage is approximated by an exponential curve, then the charge balance at the junction can be written as

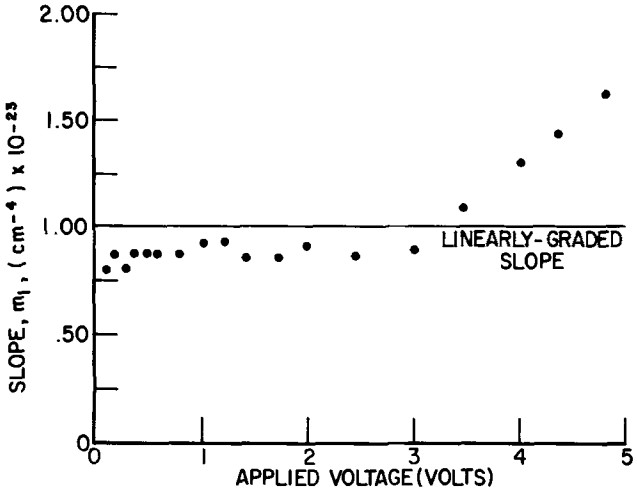

Fig. 2. Calculated values of the grade constant which give correct capacitance values for the linear-parabolic junction.

$$N_1\left[-\frac{1}{k^1}+\frac{e^{-k^1x_1}}{k^1}+x_1\right]=\frac{N_2(x_2)x_2\left[\frac{w_B}{2}-\frac{x_2}{3}\right]}{(w_B-x_2)} \quad [15]$$

where

$$N_1(x)=N_1(e^{-k^1x}-1) \quad [16]$$

k^1 is a parameter which is adjusted so that Eq. [16] initially approximates the net high side profile, and N_1 is the value of doping at which the net impurity concentration approaches the singly diffused high side concentration. dx_1/dx_2 for the exponential-parabolic junction is

$$\frac{dx_1}{dx_2}=\frac{N_2(x_2)}{N_1(1-e^{-k^1x_1})} \quad [17]$$

Figure 3 illustrates the way in which $N_1(x)$ (Eq. [16]) approximates an actual net high side profile with $N_1 = 10^{19}$ and $k^1 = 0.56 \times 10^5$. $N_1(x)$ is shown as a dashed curve (curve 3), and curve 2 represents the net high side profile which was obtained by subtracting the two singly diffused total doping profiles of opposite conductivity type (curve 4 from curve 1). Also shown is the net low side doping distribution, $N_2(x)$, (curve 5) which was calculated from Eq. [5] in conjunction with C-V measurements made on this p-n structure. The estimation of $N_2(x_2)$ and x_1 for each pair of measurements using the exponential-parabolic approximation is carried out by applying inverse interpolation to Eq. [15] for each iterated value of dx_1/dx_2. When the condition of Eq. [11] is satisfied, the capacitance associated with the calculated charge distribution can be determined from Eq. [12]. If $C_n^1 \neq C_n$, then k^1 can be adjusted so as to being C_n^1 closer in value to C_n. For each newly adjusted value of k^1, the iteration procedure for dx_1/dx_2 must be repeated until Eq. [15] is satisfied. Thus, the M data points for the computed net low side profile are modified again by the M iterated values of $(1 - dx_1/dx_2)$, which are computed from M exponential-parabolic charge profiles.

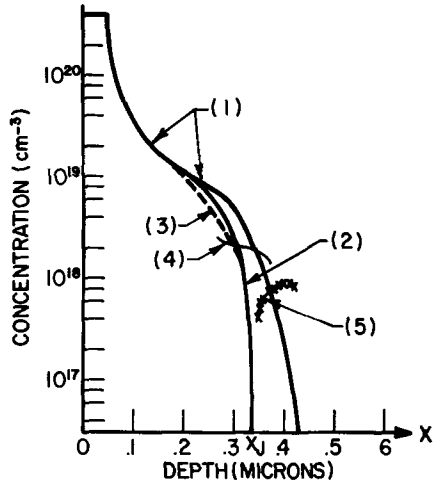

Fig. 3. Illustration of the exponential approximation to the high side net doping: (1) experimental total doping curve (phosphorus diffusion); (2) high side net doping (curve 4 from curve 1); (3) exponential approximation, $N_1(x)$; (4) experimental total doping curve (boron diffusion); (5) calculated net doping, $N_2(x)$. Curves 5 and 4 should coincide at $x = 0.42\mu$ when the compensation from the high side doping becomes negligible.

Experimental

Figure 4(a) shows the calculated net ionized impurity distributions on both sides of the junction of a sequentially diffused p-n structure (net profile symbols are on the figure). Figure 4(b) is an enlarged view of the junction region. A comparison is indicated between the net profiles which result when dx_1/dx_2 is computed from the linear-parabolic, the exponential-

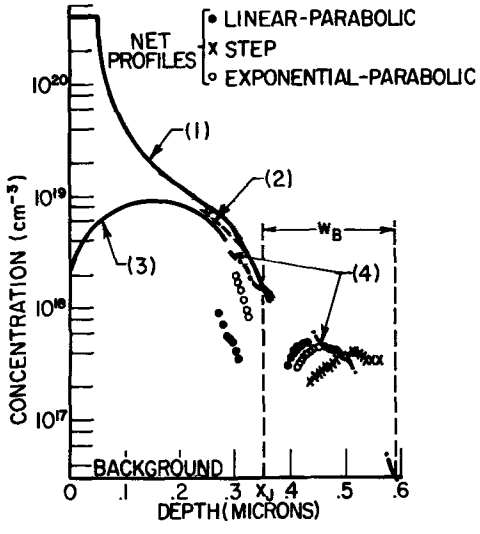

Fig. 4(a). Comparison of the calculated profiles. The $N_1(x_1)$ and $N_2(x_2)$ data points as computed from the approximations to dx_1/dx_2 are indicated by the symbols. (1) Experimental phosphorus profile (singly diffused); (2) boron profile obtained by subtracting linear-parabolic data points from (1); (3) experimental boron profile (singly diffused); (4) boron profile obtained by subtracting exponential-parabolic data points from (1).

parabolic, and the step junction ($dx_1/dx_2 = 0$) approximations. Curve 1 is a singly diffused emitter profile (phosphorus), and curve 3 is a singly diffused base profile (boron). Curves 2 and 4 show the calculated total base doping when the base and the emitter are diffused sequentially. Curve 2 was obtained by subtracting the linear-parabolic data points from the total emitter doping profile (curve 1). Curve 4 was obtained by subtracting exponential-parabolic data points from curve 1. Because of the "emitter push-out" effect, the accuracy of the parabolic methods cannot be checked by comparing the calculated profiles with the superposition of the singly diffused emitter and base profiles. Nevertheless, it is possible to see that there is continuity on the high side between the measured singly diffused base profile (curve 3) and the calculated total doping profiles (curves 2 and 4).

Emitter push-out can be reduced by diffusing arsenic from a doped-oxide source for the emitter, and by implanting the base region with boron ions. Figure 5 shows the calculated net doping on both the high and low sides of the emitter-base junction. For this structure, dx_1/dx_2 was computed using the exponential-parabolic approximation. It can be seen that the calculated net high side doping indicates that the impurity gradient of the arsenic profile is very large in the junction region. The measured gradient from Fig. 5 is approximately 2.5 x 10^{25} cm^{-4}, which closely agrees with the value of the gradient as determined by computer simulation of the arsenic diffusion.

Curve 1 in Fig. 5 is the predicted implant profile (9). Curve 2 was drawn by subtracting the n-background doping level from the $N_2(x_2)$ data points. Good agreement with the predicted implant profile can be seen. It should be noted that the step-junction approximation ($dx_1/dx_2 = 0$) to this p-n structure would yield virtually the same values of $N_2(x_2)$ as the exponential-parabolic approximation because of the steep high side profile gradient.

Figure 6 shows the way in which dx_1/dx_2 varies with the depletion region width for the structure of Fig. 4. The values of dx_1/dx_2 which were used to plot these curves were obtained by performing the iterations required to make the charge changes with bias equal on both sides of the junction. The non-step and nonlinearly graded behavior of the linear-parabolic and the exponential-parabolic junctions can be seen ($dx_1/dx_2 = 0$ for a step junction, and $dx_1/dx_2 = -1$ for linear grading). Also shown in Fig. 6 is the fact that the dx_1/dx_2 values for the two approximations differ. Reference to Eq. [10] and [17] indicates that

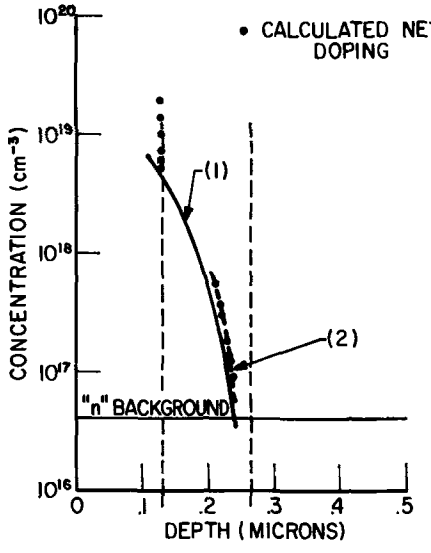

Fig. 5. Comparison of predicted and calculated profiles. (1) Predicted total implant doping, 30 keV, 1 x 10^{14} ions/cm^2, boron beam; (2) calculated total implant doping using the exponential-parabolic approximation for dx_1/dx_2.

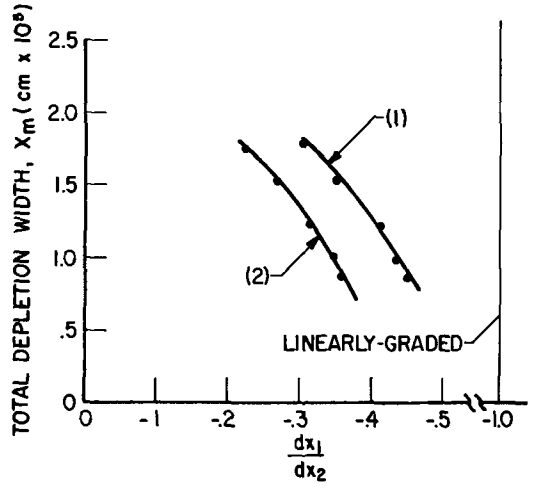

Fig. 6. Variation of dx_1/dx_2 with depletion layer width. (1) Linear-parabolic approximation; (2) exponential-parabolic approximation.

this difference is due to the functional form of the charge distributions on the high side of the junction.

Conclusion

The self-consistent methods developed here can be used for estimating doping profiles in the vicinity of the junctions of sequentially diffused or diffused-implanted structures. The linear-parabolic approximation for the determination of dx_1/dx_2 accounts for non-step junction behavior in structures for which a grade constant can be estimated. The exponential-parabolic approximation gives an improved estimate of net doping if some information can be obtained concerning the singly diffused low and high side profiles. However, because of the self-adjusting nature of these approximations, uncertainties in grade constant, m_1, or exponential constant, k^1, should not affect the precision of the computed profiles.

The accuracy errors associated with any C-V measurement technique occur in the measurement of dC and A, the area of the p-n junction, in the determination of the junction locations, and in the assumption of the form of the high side profile. While the self-consistent parabolic approximations described here do not improve on the first three sources of errors, a best fit of an assumed functional form of $N_1(x)$ can be obtained for a given pair of C-V measurements, providing that the parabolic approximation to the low side net doping is valid. Once this best fit is obtained, the correction factor ($1 - dx_1/dx_2$) can be determined so that the effective doping density, multiplied by ($1 - dx_1/dx_2$), yields the net low side doping density, $N_2(x_2)$ (Eq. [5]). This procedure is then repeated for each pair of C-V measurements. While it has not been ascertained which is the more accurate approximation (linear-parabolic or exponential-parabolic), each is clearly an improvement over the step approximation for shallow, sequentially diffused junctions.

ABSTRACT

Diffusion of tin into GaAs from a doped SiO_2 source layer has produced average carrier concentrations twice as high as those previously reported in the literature for diffusions from such films. The average carrier concentration in the diffused layers was 6 to 8 x 10^{18} cm^{-3} for junctions 1 to 2 μm deep. The surface concentration appears to be nearly constant during the first hour of diffusion at 1050°C and decreases due to source film depletion. Carrier concentrations in the diffused layers were measured with both Hall effect and infrared reflectivity techniques.

High concentration n-type diffusion into GaAs is of considerable importance in the development of certain devices. Tin is a convenient n-type dopant for GaAs since it can be diffused from tin-doped SiO_2 films as suggested and carried out by von Muench (1). In addition to acting as a source of tin during diffusion, the SiO_2 films serve to protect the GaAs surface from erosion during processing at high temperatures. However, von Muench (2) found that the carrier concentration, that is, the electrically active donor tin concentration, was limited to 3 x $10^{18}/cm^3$ in diffused layers obtained using either the doped oxide film or pure tin as a diffusion source. Fane and Goss, who diffused tin into GaAs from tin deposited on the GaAs surface by electroplating, have reported that sheet resistance readings indicate about 10^{19} carriers/cm^3 were present in the resulting tin diffused layers (3).

In the present work tin diffusions into GaAs from tin-doped SiO_2 films were carried out using a different procedure from that used by von Muench. Tin-diffused layers having average carrier concentrations of 6-8 x $10^{18}/cm^3$, as measured with Hall effect apparatus, were achieved.

In the system utilized by von Muench the doped SiO_2 source film was deposited from a carrier gas which passed through a mixture of ethylorthosilicate (EOS) with 0.04 volume per cent (v/o) tetraethyl stannane (TET). In the system applied by the present authors the doping of the source solution was 2 v/o of tetramethyl stannane (TMT). TMT was used in an attempt to increase the concentration of tin in the deposited oxide. Although little information is available on the vapor pressure of TET and TMT, TET has a vapor pressure of only 10 mm at 73°C and TMT boils at 78°C (4), indicating that TMT probably has a higher vapor pressure in the room temperature source solution. The diffusions by von Muench were done in a closed ampoule with 1 atm of As pressure. During the work described in this paper diffusions were done in an open tube in forming gas (85% N_2-15% H_2).

Experimental Procedure

The GaAs substrates used were Zn-doped, p-type with hole concentrations of either 5 x $10^{16}/cm^3$ or 1 x $10^{18}/cm^3$. The doped oxide films were deposited on the substrates in a horizontal tube furnace. Forming gas was bubbled through a flask which contained the solution of TMT in EOS at room temperature and passed into the furnace tube where pyrolytic deposition occurred on the slices at 500°C. The oxide films were made as thick as possible to avoid source depletion during the diffusion. In the present cases, 5000-6000Å were deposited; oxides thicker than this could not be used because cracking of the oxide coating appeared after deposition. The diffusions were done at 1050°, 950°, and 850°C in a loosely closed quartz box which was held in a flowing forming gas atmosphere. The quartz box contained a few grams of crushed GaAs to provide some arsenic in the atmosphere and to further protect the diffusion slice from surface damage.

After drive-in the oxide source was removed from the slice with HF, the back was lapped, and Hall effect measurements were carried out on the As-diffused wafer. The Hall effect measurements were made at room temperature in the dark; the specimens were held in the fixture shown in Fig. 1. Contact to the diffused layer was made through tinned phosphor-bronze wires; the contact was formed by a high-voltage pulse from a tesla coil. On most of the specimens the contacts to the diffused layers were checked to be certain that proper rectifying properties were obtained with a fifth electrode attached to the back as a ground connection. The data were analyzed according to the technique of van der Pauw (5). The specimens were then angle lapped, and the junction depth was determined by staining with a solution of $CuSO_4$ containing a trace of HF. Some of the scatter in the data to be presented is related to difficulties in accurately measuring the junction depth. The reproducibility of a given junc-

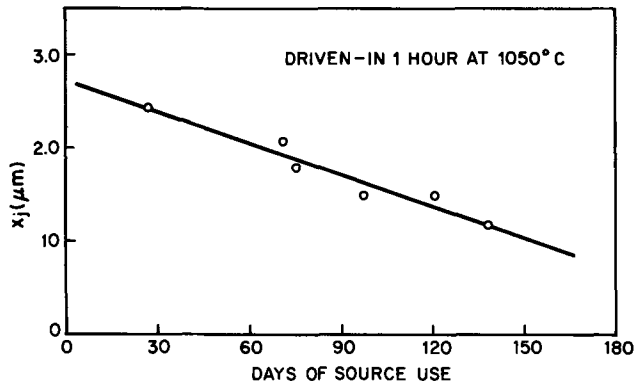

Fig. 2. Depletion of TMT from EOS source as indicated by decrease in junction depth for constant drive-in conditions after various times of source operation.

tion depth in consecutive lapping and measuring cycles is about $\pm 0.15\mu$.

One of the problems with using TMT as a dopant in EOS is that EOS has a vapor pressure of only 12 mm at 60°C and hence appears to be much less volatile than TMT which as previously noted boils at 78°C (4). Therefore, TMT probably evaporates at a higher rate than EOS in all but the most dilute solutions. This causes a slow decrease in the dopant concentration in the EOS source solution and thus in the deposited diffusion source films. Figure 2 shows the junction depths obtained for constant time and temperature diffusions from films deposited from a given 2% TMT source solution as a function of the length of time after the source was mixed. The source was being used at an approximately constant rate during the time covered. The diffusions reported herein were done over a period of approximately six weeks; thus an additional source of scatter in the results presented is due to this source solution differential evaporation effect.

Results and Discussion

Selection of source solution composition.—Doped oxide diffusion source films were deposited from EOS source solutions containing a range of TMT concentrations up to 10 v/o in an effort to optimize the source composition with respect to surface concentration. The junction depth, which should increase with increasing surface concentration since the diffusion conditions are kept constant, increases monotonically with increasing TMT dopant concentration. However, for source concentrations significantly above 2% TMT in EOS the surface of the GaAs was attacked by the doped oxide film. For this reason the 2% solution was chosen for further investigation.

Junction depth vs. time measurements.—In Fig. 3 and 4 the junction depth, x_j, is plotted *vs.* the square root of diffusion time, t, for the p-type substrates of the high and low carrier concentrations. The "error bars" in this and following graphs indicate the range of results obtained from all the specimens having the given value of the abscissa variable, and the average value of all these is the plotted point. The data in Fig. 3 indicates that x_j is roughly proportional to $t^{1/2}$ for times ranging from about 1 hr at 1050°C to 10 hr at 850°C. Beyond this time, the junction depth increase slows down markedly.

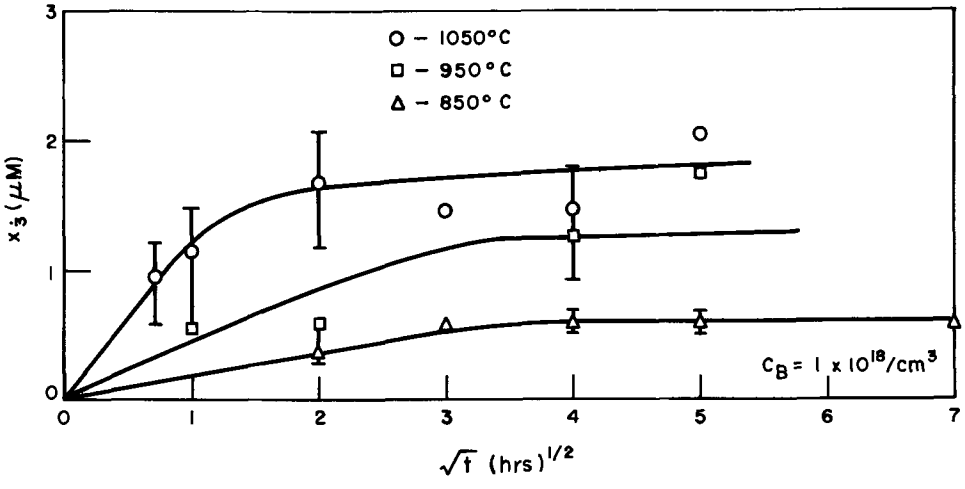

Fig. 3. Junction depth as a function of the square root of time in substrates with carrier densities of $1 \times 10^{18}/cm^3$.

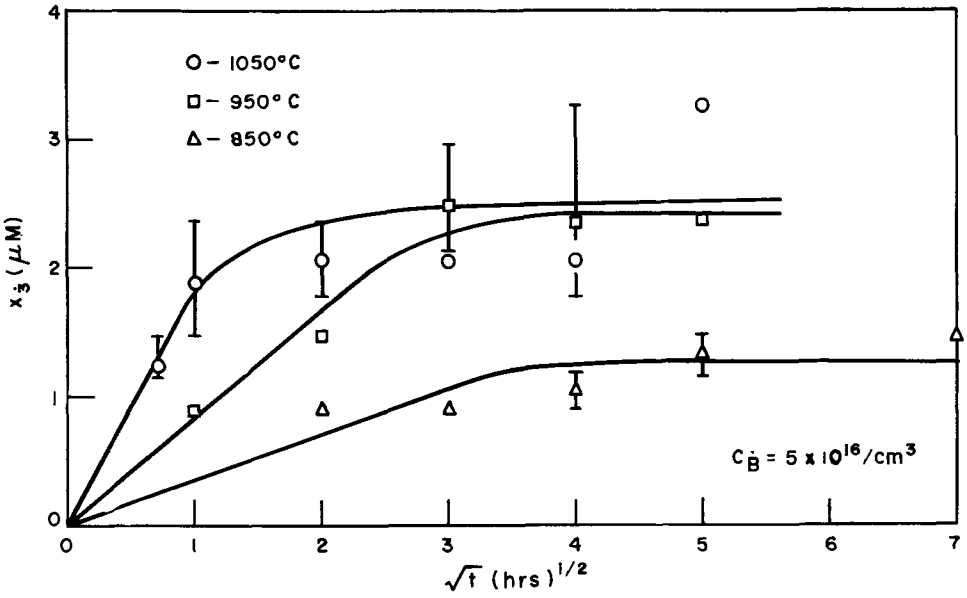

Fig. 4. Same as Fig. 1 in substrates with carrier densities of $5 \times 10^{16}/cm^3$.

This initial behavior is consistent with the presence of a constant surface concentration of tin, C_s. This would be true even if the diffusion coefficient, D, was a function of tin concentration, C, as long as this dependence could be expressed as a function of C/C_s (6). It would also not be affected by the possibility that the number of active tin donors is not equal to the chemical concentration of tin, as may be the case (2). Thus even if the diffusion coefficient of tin was a function of concentration and the active tin donor concentration was not equal to the total tin concentration, a constant C_s diffusion could give x_j proportional to $t^{1/2}$. This suggests that the doped oxide at first supports a constant surface concentration in the GaAs; then since the source is finite, it begins to deplete, and this leads to a leveling off of the x_j *vs.* $t^{1/2}$ curve.

For a finite thin film source, the long-term behavior approaches that of an instantaneous source or Gaussian diffusion (7). If this is the case, then for a Gaussian distribution

$$\frac{x_j^2}{t} = 4D \ln\left(\frac{Q}{C_j\sqrt{\pi D}}\right) - 2D \ln t \qquad [1]$$

should hold, where Q is total number of diffusing ionized tin atoms and C_j is the base carrier concentration. D here is assumed to be constant; even if D is not a constant for long diffusion times, the reduction in concentration variation across the diffused layer and the generally lower concentration throughout the layer may make Eq. [1] approximately correct with D interpreted as an effective, or average, diffusion coefficient. Thus the quantity x_j^2/t should be constant as a function of time up to the point in Fig. 3 and 4 where the curve breaks away from an approximately straight line relationship between x_j and $t^{1/2}$. For longer times x_j^2/t should become proportional to ln t as seen in Eq. [1].

Figures 5 and 6 show plots of $-x_j^2/t$ *vs.* ln t for the highest and lowest diffusion temperatures studied. It should be pointed out that the scatter at shorter times and shallower junction depths is related to the fact that the x_j values, which are already uncertain to $\pm 0.15\mu$, must be squared. The behavior predicted is fairly well obeyed for the longer times. The values of the effective diffusion coefficients for Sn in GaAs taken from the slopes of the tails of the curves are 5×10^{-13} cm^2/sec at 1050°C and 3.5×10^{-14} cm^2/sec at 850°C.

It will be noticed that particularly in the data for the slices having the lighter base carrier concentrations ($C_j = 5 \times 10^{16}$/cm^3) there is an apparent discontinuity or transition region which must be introduced between what has previously been interpreted as the constant surface concentration and depleting source regions of Fig. 5 and 6. Although the presence of this discontinuity is not well understood, it could arise if the apparent diffusion coefficient were a strong function of concentration, especially if it decreased with decreasing average concentration in the layer, finally reaching some constant value for long diffusion times and low average carrier concentrations.

Hall effect measurements.—In addition to the junction depth determinations, Hall effect measurements were also made on the diffused slices. The carrier concentration, $\bar{n}$, obtained from the Hall effect measurements is approximately the average concentration of carriers over the entire diffused layer; this corresponds to the average concentration of ionized tin donors in the layers. (Actually, some of the donor tin is compensated by zinc acceptors in the substrate and does not contribute to the carrier concentration; thus a number equal to the substrate carrier concentration should be added to $\bar{n}$ to obtain the tin donor concentration.)

Of course, this does not correspond necessarily to the total (chemical) concentration of tin in the layer; in fact, it is known to deviate from the total concentration in some cases (2). If we assume that the fraction of the total tin that is active as donors is independent of concentration of tin and that D is constant, then two limiting cases of the dependence of $\bar{n}$ on time can be considered. For a constant surface concentration, a complementary error function profile is generated and $\bar{n}$ would be constant. For a depleting source or Gaussian profile

$$\bar{n} = \frac{Q}{x_j}\,\mathrm{erf}\,\frac{x_j}{2\sqrt{Dt}} \qquad [2]$$

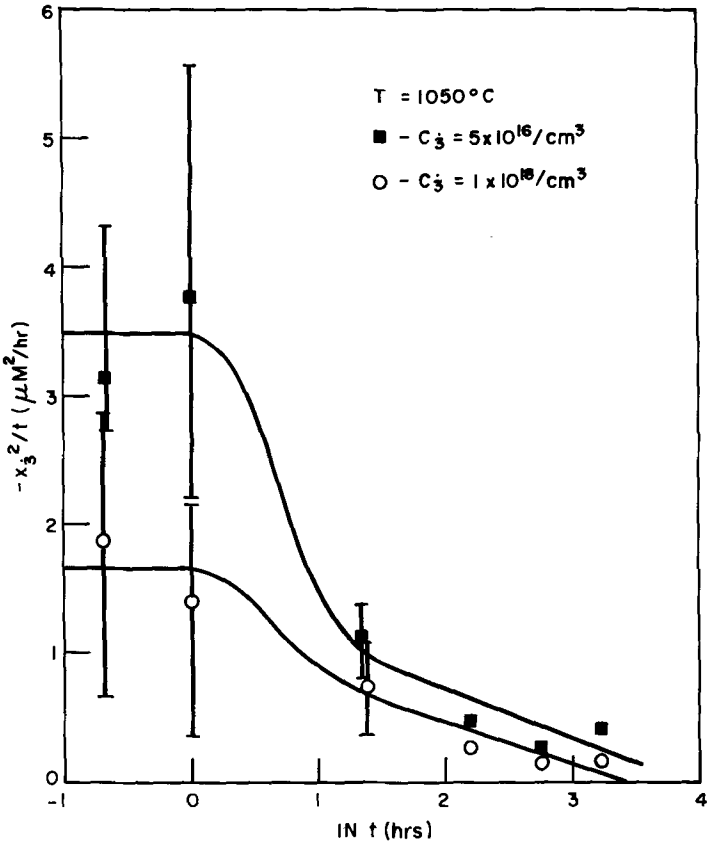

Fig. 5. Ratio of junction depth squared to diffusion time as a function of ln (diffusion time) at 1050°C.

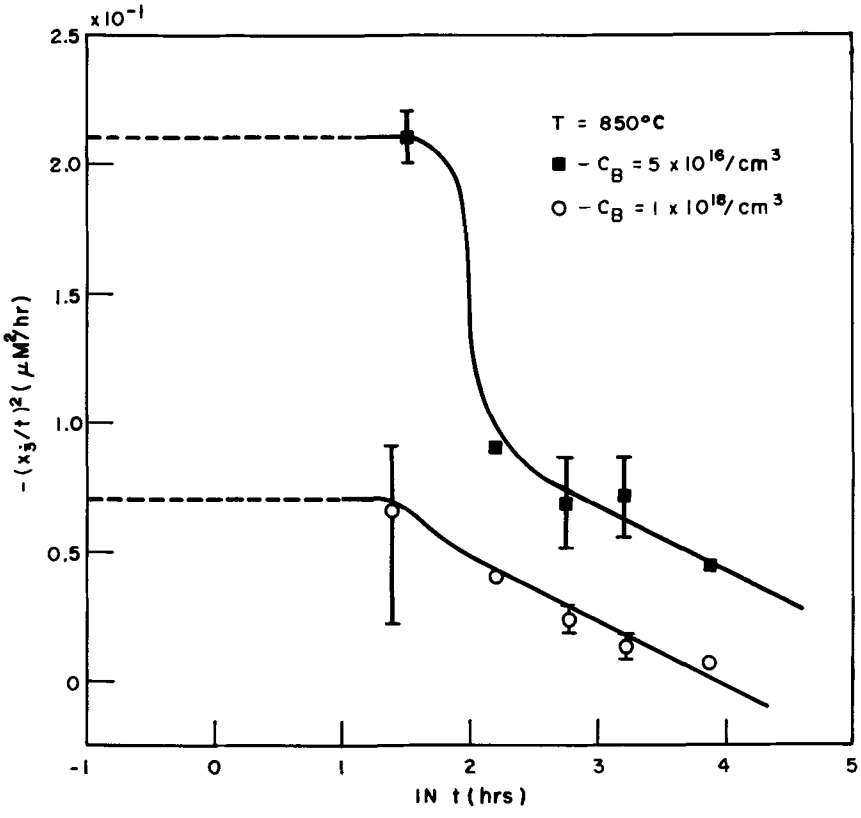

Fig. 6. Ratio of junction depth squared to diffusion time as a function of ln (diffusion time) at 850°C.

For values of $(x_j/2\sqrt{Dt})$ less than one the error function can be approximated by its argument with a maximum error of about 15%. Hence

$$\bar{n} \simeq \frac{Q}{2\sqrt{D\bar{t}}} \qquad [3]$$

For periods of 10 hr or longer this condition holds at 1050°C in the present diffusions, if the D value calculated from the slope in Fig. 5 is used in calculating $(x_j/2\sqrt{D\bar{t}})$. Figure 7 shows a plot of average tin donor concentration, $\bar{n}$, as a function of the inverse square root of time at 1050°C; also shown is similar data for a freshly prepared TMT:EOS source. The data can be fitted reasonably well with a straight line over the entire time range even though the $t^{-1/2}$ relationship was expected to hold only for longer times. The scatter in the data probably masks a change in slope of the curve at shorter times. In any event, for short diffusion times, average carrier concentrations—which are presumed to be equal to uncompensated donor tin concentrations—as high as 6-8 x 10^{18}/cm³ can be seen to be present in the diffused layers.

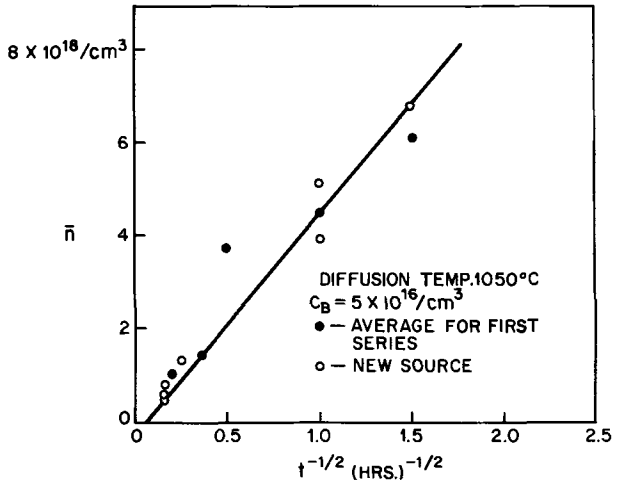

Fig. 7. Average carrier concentration in a tin diffused layer as a function of the inverse square root of the diffusion time for diffusions done at 1050°C.

Infrared measurements of surface concentration.— The surface concentrations in some of the diffused layers have also been measured by the infrared reflectivity technique (8). The positions of the reflectance minima from which these concentrations are determined are characteristic of the maximum carrier concentrations in the diffusion profiles (9). [For a complete discussion of the use of infrared reflectivity for determining surface concentrations in diffused layers, see Abe and Nishi (10).] The surface concentration data as determined from the infrared technique along with the average carrier concentrations measured with Hall effect apparatus are presented in Table I for slices diffused for 0.5 and 1 hr at 1050°C. The slice listed as having a base hole concentration of 2 x 10^{17}/cm³ is one of a few that type diffused along with the slices previously discussed. The infrared measurements support the observation that carrier concentrations in the range of 6 to 8 x 10^{18}/cm³ are present in the diffused layers, but they also indicate that the surface concentrations are equal to or no more than a factor of two larger than the average carrier density measured by the Hall technique. In particular, the fact that the average carrier concentration in the diffused layer for the slice diffused 0.5 hr is approximately equal to the surface concentration suggests that the carrier distribution may be relatively flat near the surface for the most heavily diffused layers. This would be the case if either the diffusion coefficient or the fraction of the tin ionized were appropriate functions of concentration.

In summary, regardless of the exact nature of the diffusion kinetics, the data presented in the preceding

Table I. Surface concentrations from IR reflectivity

Subst. doping (no/cm³)	Diff. time (hr)	Avg carrier conc from Hall effect (no/cm³)	C_s from IR (no/cm³)
5 × 10^{16}	0.5	8 × 10^{18}	7.4 × 10^{18}
5 × 10^{16}	1.0	3 × 10^{18}	4.8 × 10^{18}
5 × 10^{16}	1.0	3 × 10^{18}	5.9 × 10^{18}
2 × 10^{17}	1.0	4 × 10^{18}	6.0 × 10^{18}

sections indicate that the oxide source begins to deplete soon after diffusion starts. The fact that higher carrier concentrations (6-8 x 10^{18}/cm^3) were achieved in this work than had previously been observed is probably related in part to the recognition that, with an oxide source, depletion effects make short-time. shallow diffusions mandatory if high concentrations are to be obtained.

Conclusions

1. Diffusion of tin from tin-doped SiO_2 films deposited on p-type GaAs by pyrolytic decomposition of ethylorthosilicate containing tetramethyl stannane yields n-type diffused layers having average carrier concentrations of 6-8 x 10^{18}/cm^3 for short (0.5-1.0 hr) diffusion times.

2. The diffusion source appears to yield a constant surface concentration initially and then depletes. In order to obtain the high average carrier concentrations short diffusion times must be used to avoid depletion effects.

Preparation and Properties of $Mg_xZn_{1-x}Te$[1]

S. G. Parker,* A. R. Reinberg, J. E. Pinnell, and W. C. Holton

Texas Instruments, Incorporated, Dallas, Texas 75222

ABSTRACT

The pseudo-binary alloy system $Mg_xZn_{1-x}Te$ has been investigated for $0 = x \leq 0.8$. Compositions containing less than 53 mole per cent (m/o) Mg have a cubic structure with expanded lattice spacings of ZnTe. For Mg concentrations of 0.53-0.80 m/o the alloys have a hexagonal structure with contracted lattice spacings of MgTe. The bandgaps, as determined by electron beam bombardment, vary linearly with composition within the crystalline structure.

Numerous attempts have been made to form solid solutions from semiconductor compounds to obtain variable bandgap materials, with the aim of producing a light emitting diode whose output wavelength was thereby adjusted. Growth of solid solutions among the III-V compounds for this purpose has been rather successful; however, efficient light emission from diode structures is limited to wavelengths longer than 6000Å by the fact that at higher energies the bandgap becomes indirect. Since the II-VI compounds, principally the zinc and cadmium chalcogenides, retain a direct bandgap for the entire series, it should be possible using alloys of these, to obtain efficient light emission to wavelengths as short as the near ultraviolet. Diodes emitting in the visible have been made using ZnSe-ZnTe heterojunctions (1) and from solid solutions of $ZnSe_xTe_{1-x}$ (2). Recently solid solutions of $Mg_xCd_{1-x}Te$ were reported with light emitting diodes having been made from these alloys (3-5). This paper reports the preparation and light emitting properties of $Mg_xZn_{1-x}Te$.

Experimental

Mixtures of ZnTe, Mg and Te were melted together to give various values of x for the pseudo-binary $Mg_xZn_{1-x}Te$. Compounding was done in carbon coated quartz tubes of 8-13 mm ID by heating at 1200°C for 16-20 hr in a rocking furnace. The growth tube containing the charge was outgassed at 10^{-5} Torr and 200°C for 1 hr before sealing off for compounding. The molten charge was quenched at 50°-60°C/min to the solid state to prevent segregation (6) into solid solution of variable composition. To quench the boules the furnace power was shut off and a blast of air directed over the quartz tube. Various quench rates were obtained by changing the air flow.

The ZnTe was made by fusing 99.9999% pure Zn and Te together in He ambient while contained in a carbon-coated quartz boat. Unreacted material was removed by heating at 500°C under a vacuum of 10^{-3} Torr. The Mg metal, which was 99.99% pure, was etched with Br_2-methanol to remove oxides and carbonates from the surface and placed immediately in the compounding tube under a He ambient. The Te was 99.9999% pure and was degreased in boiling trichloroethylene before use. After compounding the quartz tube was cracked to recover the $Mg_xZn_{1-x}Te$ boule. There was no wetting of the quartz if the Mg were well-etched and if a crack-free carbon coat was obtained on the quartz tube. The boules containing Mg $\geq$ 5.0 m/o were stored in kerosene or under a vacuum to prevent reaction with H_2O or O_2. The exact composition of the material after compounding was determined by microprobe. Sometimes the compounded material was reloaded into a carbon coated quartz tube, and the Bridgman technique was used to grow large single crystals up to 1 cm on an edge. The system was heated and outgassed before sealing off as for the compounding operation.

* The composition of the boules was not the same.
** Composition determined by microprobe.
† Boules were 8 mm in diameter and 6 cm in length.

MgTe for use as a reference was compounded by the same procedure used for the MgTe-ZnTe system except the ZnTe was omitted. A temperature of 1300°C was used for compounding with no quenching. The compounding tube was broken under kerosene so that the MgTe was not exposed to O_2 or H_2O. Samples of MgTe were taken from the kerosene bath and quickly sealed under vacuum for x-ray and DTA studies. ZnTe reference samples were obtained by vapor transport in a He ambient.

The composition of the alloys was determined by microprobe analysis using a Material Analysis Company Model 400 Electron Probe Microanalyzer. A Mg-Sn alloy was used as the Mg standard while ZnTe was used as the Zn standard. Samples were embedded in a cold, self-setting plastic and lapped in oil to expose the sample surfaces. These sample surfaces were then degreased with trichloroethylene and placed immediately in the microprobe apparatus where a vacuum of 10^{-5} Torr was pulled. An accelerating voltage of 20 kV was used for the electron beam. The precision was ±1% while the accuracy was ±2%.

Differential thermal analysis of the alloy samples was made with a Du Pont 900 Differential Thermal Analyzer. The sample size was about 25 mg and consisted of four to five chips of the material being studied. The material was removed from the kerosene storage jars or the vacuum dessicator, rinsed in boiling trichloroethylene and placed in quartz tubes, which were evacuated to 10^{-5} Torr then sealed off. Alumina powder was used as the standard reference. The thermocouple was platinum-platinum 13% rhodium. Heating rates of about 10°C/min and cooling rates of 5°C/min were used. The onset of melting was taken as the solidus temperature during heating while the liquidus points were determined by the onset of freezing during the cooling. At least two DTA runs were made for each alloy composition with a reproducibility of ±2%. Supercooling occurred occasionally but usually was not greater than 5°C.

X-ray diffraction patterns were obtained by the Debye-Sherrer method. Samples were ground to about 200 mesh under kerosene, degreased with trichloroethylene placed in a capillary tube then pumped to 10^{-3} Torr and sealed off. Copper K_α radiation for 6 hr was used to obtain the diffraction patterns.

For estimation of bandgap the luminescence stimulated by an electron gun was used. Samples of different alloy compositions prepared by the technique described above were mounted on the cold finger of a cryostat which shared a common vacuum system with a high-power electron gun. The electron gun was capable of producing pulses with a beam current of 20 mA, at a voltage up to 50 kV ranging in width from 15 to 200 nanosec at a repetition rate of 60 Hz. The recombination radiation was collected by a mirror system and focused onto the entrance slit of a ¾ meter grating spectrometer. A sampling oscilloscope was used to time resolve the observed spectra and present the data as luminescence intensity *vs.* wavelength on a recorder.

Physical Properties of the Material

Homogeneity as a function of quench rate is illustrated in Table I. It can be seen that the homogeneity, as determined by microprobe analysis of randomly selected spots in a cross sectional slice, was rather good for a quench rate of ≧20°C/min. This table also gives a comparison of the homogeneity for slices from the first and last portions to freeze. Unless freezing was rapid there was much segregation. Although rapid quench rates gave better homogeneity, coring and blow holes resulted at the higher quench rates. Above a quench rate of 75°C/min the boule was so badly cored that it was useless. Boules cooled at 20°C/min or less were not cored and did not contain blow holes, but these boules were very inhomogeneous.

The quenched material was polycrystalline but did contain single crystals up to 3 mm on an edge. The size of the single crystals decreased as the Mg content increased. Tellurium, which was determined by microprobe measurements, collected at many of the grain boundaries to make the material opaque to visible light. The amount of Te at the grain boundaries was reduced by adding 10 m/o excess Mg during compounding; this was necessary because some of the Mg was usually not available for reaction because it existed as MgO or $Mg(OH)_2$. The remainder of the Te could be removed by heating the $Mg_xZn_{1-x}Te$ in molten Zn at 850°C for several hours; this Zn treatment produced transparent material. The color of the $Mg_xZn_{1-x}Te$ varied from red-brown for low values of x to colorless for material rich in Mg. Material containing 50 m/o Mg or greater reacted with H_2O or methanol. Typical impurities present are shown in Table II.

From the differential thermal analysis results, a partial phase diagram for the MgTe-ZnTe system showing liquidus and solidus curves was constructed as shown in Fig. 1. This phase diagram indicates that solid solutions exist over a wide range for values of x in $Mg_xZn_{1-x}Te$. Linear changes in d-spacings with composition as shown by x-ray diffraction gave additional evidence that solid solutions are formed in both hexagonal and cubic structures. A pseudobinary with a cubic structure exists for Mg concentrations of 0-53 m/o. This cubic material is very similar to ZnTe with the d-spacings being expanded as the Mg concentration is increased. Table III illustrates that the d-spacings for $Mg_{0.6}Zn_{0.4}Te$ are clearly related to those for MgTe. The phase diagram is unknown in the range 0-20 m/o ZnTe since no compounds were made in this region. X-ray diffraction showed that two different hexagonal phases exist at $Mg_{0.82}Zn_{0.8}Te$ with one of these phases being similar to that for MgTe. The phase diagram in the transition region between the cubic and hexagonal structures, as bounded by the dashed

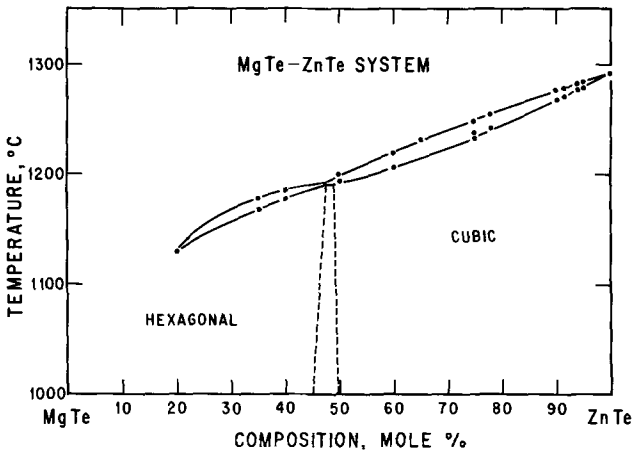

Fig. 1. Phase diagram for MgTe-ZnTe system

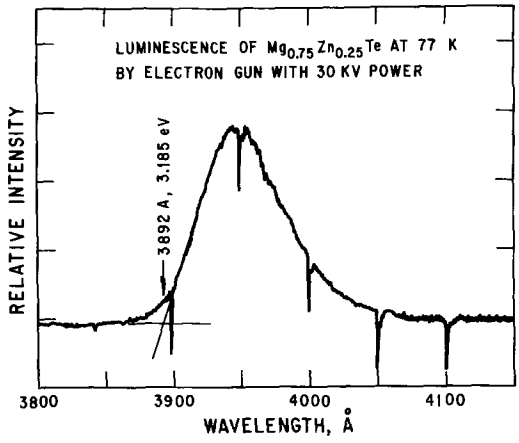

Fig. 2. Typical luminescence curve obtained by electron beam bombardment.

lines, is unknown. X-ray diffraction data did not clearly define what structures were present. Phase diagrams are based on equilibrium conditions. Because we were working with quenched samples, equilibrium conditions probably did not prevail.

It is rather difficult to explain the existence of two hexagonal phases for the composition $Mg_{0.82}Zn_{0.18}Te$ and not for MgTe. Additional study is necessary to completely determine the system in the range of 0-25 m/o ZnTe. The melting point of MgTe which is 1200° ± 5°C has not been reported previously; DTA indicates a possible phase transition in MgTe at 1170° ± 5°C. X-ray diffraction showed the MgTe to be hexagonal in agreement with work of others. It is obvious that the composition of the solid in equilibrium with the melt would be different from that of the melt; thus, Bridgman-type crystal growth would not produce material of uniform composition.

Some indication that solid solutions existed with the MgTe-ZnTe system were obtained from band edge luminescence at 77K using electron beam bombardment. A typical luminescence curve is shown in Fig. 2. Only a single luminescence line was observed which was in the region of the unexpected bandgap. Typical line widths were approximately 0.05 eV at 77K. In addition to this line, samples which had been post annealed in liquid zinc at 800°C for 24 hr exhibited a strong broad luminescence at longer wavelengths which was typically 0.250 eV in width. The broad luminescence could also be distinguished from the sharper band edge line by time resolution. That is, the sharp band edge line decayed very rapidly essentially following the electron beam current. The broad, impurity line, on the other hand, had a considerably longer decay time, typically several microseconds.

Values for the energy bandgap were estimated from the sharp, fast luminescence. We have arbitrarily chosen the high energy limit of this line as the value for the energy gap. At least in the case of pure ZnTe this gives a value of 2.37 eV which is within 0.025 eV of the accepted value for 77K. Since the sample did tend to vary somewhat in composition in a given boule and the microprobe determination of alloy composition was subject to an error of approximately 5%, it was not felt that a more careful determination would be meaningful. Figure 3 shows how the bandgap corresponding to the band edge luminescence varies with composition over the range of x = 0-80 m/o for $Mg_xZn_{1-x}Te$. A break is indicated at the region where the structure changes from cubic to hexagonal because the bandgap is expected to vary with structure. It is observed that the wavelength corresponding to the bandgap varies almost linearly, within experimental error, up to about 0.53 m/o Mg. For 0.53 to 0.80 m/o Mg the bandgap also varies linearly but with a different slope than for the smaller Mg concentrations. The

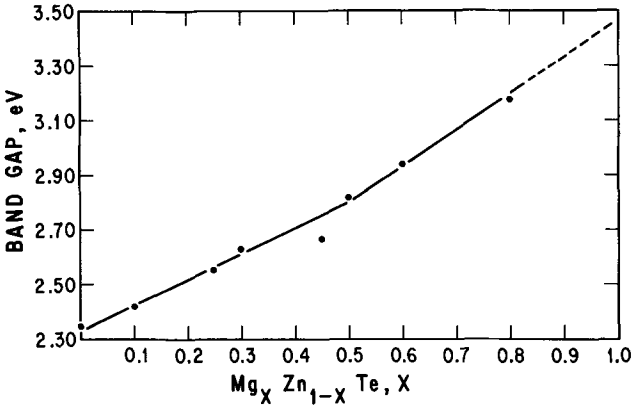

Fig. 3. Band gap as a function of composition by electron beam bombardment.

extrapolation to pure MgTe, however, leads to a value for the emission edge of 357 μm (3.47 eV) which is considerably lower energy than the value 4.7 eV previously reported (5, 7, 8).

The reference for the 4.7 eV bandgap of MgTe given by Itoh is R. H. Bube's "Photoconductivity of Solids" (7). Bube presents a table of bandgap energies of some 128 compounds including the selenides and tellurides of Mg, Sr, and Ba. Since no further references are given in this table a search was made of the literature for a primary source. The only reference to the bandgap of MgTe that could be uncovered was a measurement of the optical absorption of thin films reported by Saum and Hensley. Although these data show a maximum in the absorption coefficient occurring at about 4.7 eV, it is questionable as to whether it is appropriate to associate this value with an expected peak in band edge recombination radiation. Several sharp peaks below the maximum absorption value for the other alkaline earth chalcogenides have been tentatively identified as due to excitons. For MgTe an analogous peak is observed at 3.6 eV as reported by Saum and Hensley (8). It is possible that oxygen or H_2O reacted with the $Mg_xZn_{1-x}Te$ to form oxygen compounds which would influence the bandgap values obtained. In the absence of further detailed analysis of absorption and luminescence in these compounds it is not possible to predict where the recombination radiation should occur although it has been observed in the alkaline oxides that the cathodoluminescence generally occurs well below the fundamental electronic optical absorption (9).

Optical absorption measurements on the (Mg,Zn)Te alloys gave values for the absorption edge which were less than the bandgap values obtained by electron bombardment. This indicates that impurities or other defects caused absorption within the bandgap. The sample slices for absorption measurements were lapped to a thickness of 1 mm or less and polished.

Efforts were made to grow single crystals of (Mg,Zn)Te by the gradient freeze technique and by iodine chemical transport. Boules containing large, single crystal regions about 1 cm on an edge were obtained by the gradient freeze method while only small single crystals that were 3-4 mm on an edge were obtained by I_2 chemical transport. The homogeneity of crystals grown by both methods is illustrated in Table IV. It can be seen that the crystals grown by both methods were not very homogeneous. There was also considerable segregation of Mg and Zn in the first and later to freeze portions of the gradient freeze process. Thus, it was obvious that homogeneous crystals were not to be obtained using the gradient freeze method. Although the crystals grown by I_2 transport were rather homogeneous throughout their bulk, additional work would be needed to establish the conditions for growing larger, more uniform crystals. The chemical transport was similar to that used for growth of ZnSe crystals (10). X-ray diffraction of $Mg_xZn_{1-x}Te$ crystals grown by both methods showed that the material was cubic in structure. The compositions of these crystals ranged from $x = 0.05$-0.3.

The (Mg,Zn)Te material as produced was always p-type with resistivity of 10^4-10^5 ohm-cm. An effort was made to decrease the resistivity and to produce n-type material by doping. Aluminum metal, which was introduced during the compounding step, was used to produce n-type $Mg_{0.25}Zn_{0.75}Te$. The aluminum concentration in the (Mg,Zn)Te as determined by emission spectroscopy was 500-1000 ppm, while the resistivity was 10^7-10^8 ohm-cm. Therefore, the n-type material was probably compensated. An n-type layer was produced in (Mg,Zn)Te by diffusion of Al into the material. In the diffusion experiments Al metal was evaporated onto the surface of a (Mg,Zn)Te slice then heated at 850°C for 16 hr in the presence of Al and Zn vapors. The surface where the Al had been evaporated was n-type and could be lapped away to reveal p-type material. The resistivity of the n-type, Al diffused layer was about 10^5 ohm-cm. Attempts to measure Hall mobility both in the dark and with light were unsuccessful.

Diodes were made by diffusing Al into p-type $Mg_{0.25}Zn_{0.75}Te$ and contact to the n-type surface was made by alloying the In-Ga, while Au evaporated onto a $LiNO_3$ treated surface was used for contact to the p-type surfaces (11). The diode action was only slight, showing 1 x 10^4 ohms in the reverse direction. No light was emitted from the diode up to a breakdown voltage of 120V. Several unsuccessful attempts were made to obtain visible light from $Mg_xZn_{1-x}Te$ diodes of various composition.

Summary

The Mg-Zn-Te system produces pseudobinary alloys of $Mg_xZn_{1-x}Te$ for values of $x = 0$-0.80. Compositions containing up to approximately 53 m/o Mg have a cubic structure with expanded lattice spacings of ZnTe. Compositions richer in Mg crystallize in the hexagonal MgTe structure. Bandgaps corresponding to band edge recombination as determined by electron beam stimulation showed a linear variation with composition. The material was compounded by reaction of ZnTe, Mg, and Te in a carbon coated quartz tube at 1200°C. If quenched rapidly from the melt the boules were homogeneous but polycrystalline. The material was p-type with resistivity of 10^4-10^5 ohm-cm; aluminum diffusion produced n-type material.

The Total Vapor Pressure of Tin Telluride under Equilibrium and Nonequilibrium Conditions

E. E. Hansen and Z. A. Munir

Department of Materials Science, School of Engineering, San Jose State College, San Jose, California 95114

ABSTRACT

The sublimation pressures of tin telluride were measured under equilibrium and free-surface conditions over the temperature range 785°-970°K. The expressions for the total sublimation pressures measured under these conditions are $\log P(\text{atm}) = (7.892 \pm 0.195) - (1.134 \pm 0.017)10^4/T$ and $\log P(\text{atm}) = (7.233 \pm 0.155) - (1.075 \pm 0.013)10^4/T$, respectively. Calculations of the thermodynamic properties associated with the reaction SnTe(s) = SnTe(g) gave, respectively, second-law ΔH_{298} and ΔS_{298} of 54.7 ± 1.3 kcal/mole and 40.8 ± 1.4 eu for the equilibrium condition, and 51.6 ± 1.1 kcal/mole and 37.4 ± 1.2 eu for the free surface condition. Third-law $\Delta H°_{298}$ associated with the equilibrium sublimation is 52.8 ± 0.5 kcal/mole. From these results, it appears that the sublimation coefficient is one in the temperature range covered in this work.

Total sublimation pressures in equilibrium with tin telluride have been measured by Knudsen cell methods (1-3), and the sublimation mode of this compound has been analyzed by mass spectrometric and optical absorption techniques (3, 4). Colin and Drowart's mass spectrometric investigation (3) has shown SnTe(g) to be the predominant species resulting from the sublimation of tin telluride. Their Knudsen cell measurements gave total sublimation pressures which are appreciably (40-70%) higher than those reported earlier by Nesterova *et al.* (1) and Hirayama *et al.* (2). Aside from this uncertainty in the published equilibrium pressures, information regarding the free-surface pressures of this compound appears to be totally lacking. In view of the desirability of such information, especially in current research efforts associated with the synthesis and control of properties of this thermoelectric material, this study was conducted for the purpose of determining both the equilibrium and free-surface sublimation pressures by means of the torsion method.

Experimental

The method and apparatus used in this work have been described in previous publications (5-8). Graphite torsion cells used in the present study had geometric designs similar to those described earlier (7, 9). Pertinent cell dimensions, reported in Table I, along with correction factors (10) and angular deflections of the cells, were used to calculate the sublimation pressure at any given temperature.

Temperatures were measured by means of a calibrated Pt-Pt/10% Rh thermocouple positioned inside a "dummy" cell which was situated about 2 cm below the torsion cell. The latter, which was suspended in the middle portion of a tungsten-mesh heating element, contained the sample to be sublimed. Thermocouple calibration techniques, as well as other calibration experiments aimed at establishing confidence in the results obtained in the present apparatus, have been discussed previously (8, 11).

Key words: tin telluride, sublimation pressure, heat of sublimation, free-surface sublimation.

Table I. Geometric characteristics of torsion cells

Langmuir-2	31.7	31.7	8.7	8.7	—	—

* This quantity corresponds to the orifice area of the torsion-effusion cells and to the sample surface area in the torsion-Langmuir experiments.

The purity of the tin telluride samples used in this work was established by x-ray analysis. Similar analytical methods were also employed in order to establish the congruency of sublimation of this compound. Debye-Scherrer diffraction patterns of sublimated samples which had lost up to 40% of their initial weight were identical to those obtained from unsublimated samples. However, in view of published results concerning the stoichiometry of tin telluride (12), the present x-ray results do not exclude the possibility of the existence of metallic tin in the heated samples. Within the limits of reliability of the x-ray techniques employed in this investigation, the concentration of any free tin is not likely to exceed about 3 a/o (atomic per cent). Compositional deviations toward the Te-rich end of the homogeneity range of SnTe were assumed not to have occurred since they would have resulted in

a significant change in the lattice parameter of the heated samples (13). For the torsion-Langmuir portion of this study, approximately 2 mm thick wafers were cut from tin telluride ingots which were the product of an attempt to grow single crystals. X-ray examinations of the wafers showed them to consist of a relatively small number of grains (single crystals). Because of technical difficulties, however, it was not feasible to isolate a sufficiently large single-crystalline sample for the purpose of determining its sublimation rate.

An oil diffusion pump, aided by a liquid nitrogen trap, maintained the ambient pressure inside the torsion apparatus at or below 2 x 10^{-5} Torr during all measurements.

Results

The equilibrium and free-surface sublimation pressures of tin telluride measured over the temperature range 785°-970°K are shown in Fig. 1. The least-squares expression for the equilibrium pressure covering the range 871°-970°K is

$$\log P(\text{atm}) = (7.892 \pm 0.195) - (1.134 \pm 0.017)\,10^4/T \quad [1]$$

where T is the temperature in degrees Kelvin and the shown errors are the standard deviations. Calculations of the second-law heat and entropy of sublimation at 298°K utilizing the available Cp value for SnTe(g) (14) and an assumed one for SnTe(s) (2), were based on the reaction

$$\text{SnTe(s)} = \text{SnTe(g)} \quad [2]$$

Because of lack of Cp data for solid tin telluride, the corresponding value for PbS(s) (14), an isoelectronic compound having an identical crystal structure and approximately the same molecular weight, was assumed to hold true for SnTe(s). These calculations gave the following values for $\Delta H°_{298}$ and $\Delta S°_{298}$: 54.7 ± 1.3 kcal/mole and 40.8 ± 1.4 eu, respectively.

Third-law $\Delta H°_{298}$ values for the sublimation process of Eq. [2] under equilibrium conditions, which were based on calculated free-energy functions (2) and the experimentally determined pressures, are shown in Table II. The average $\Delta H°_{298}$ value is 52.8 ± 0.5 kcal/mole.

Table III lists the free-surface sublimation pressures of SnTe. The least-squares expression for these pressures in the temperature range 785°-924°K is

$$\log P(\text{atm}) = (7.233 \pm 0.155) - (1.075 \pm 0.013)\,10^4/T \quad [3]$$

Employing Cp data cited above, changes in enthalpy and entropy accompanying the free-surface sublimation of tin telluride were calculated by the second-law method. The corresponding results at 298°K are 51.6 ± 1.1 kcal/mole and 37.4 ± 1.2 eu.

Discussion

In agreement with published studies on the sublimation of a number of tin and lead chalcogenides (11, 15-17), the present work indicates that the sublimation coefficient of tin telluride is essentially unity in the temperature range investigated. This conclusion is made on the basis of the reasonable agreement between the pressures obtained under equilibrium and free-surface conditions (Fig. 1). The agreement between the values of the second-law ΔH_{298} calculated from the results obtained under these two conditions, within about 6%, is considered reasonable in view of the susceptibility of this method of calculation to experimental errors at either end of the range covered (18). However, because of the normal scatter in the measured pressures, the present results cannot be interpreted so as to exclude the possibility of a sublimation coefficient, α, slightly less than one, *e.g.* $0.9 < \alpha < 1.0$. Closer examination of the torsion-Langmuir results indicates that these pressures are slightly higher than those measured by the torsion-effusion method. It is believed that this discrepancy may be attributed to a temperature effect commonly referred to as evaporation-cooling (19). At a total pressure of 10^{-5} atm the temperature calculated from Eq. [3], the torsion-Langmuir results, is about 1°C less than that calculated from Eq. [1], that representing the torsion-effusion results. Similar calculations show that at a total pressure of 10^{-6} atm the corresponding temperature difference is about 4°C. Thus it is likely that, as a consequence of sublimation, the wafers used in the torsion-Langmuir experiments may have experienced a reduction in temperature, which may be, at least in part, responsible for the discrepancies cited above.

The validity of the assumed correspondence between the torsion-effusion results obtained in this work and the true equilibrium pressure values associated with the sublimation of SnTe is based on the relative lack of dependence of the values reported here on both the orifice size and the mean free path. Results obtained

with cells differing by a factor of about 4 in their orifice areas show no significant dependence on the size of the orifice. The average third-law $\Delta H°_{298}$ values calculated from the results of each of the three cells differ by only 0.2 kcal, or 0.4%. Furthermore, the present torsion-effusion results agree well with results reported in the literature based on equilibrium measurements. The third-law $\Delta H°_{298}$ value obtained in this work, 52.8 ± 0.5 kcal/mole, is in good agreement with the value reported by Hirayama *et al.* (2), 53.1 ± 1 kcal/mole which was based on identical free-energy functions. Third-law treatment of the results of Colin and Drowart (3) and of Nesterova *et al.* (2) using the free-energy functions employed in this work gave $\Delta H°_{298}$ values of 52.4 ± 0.4 kcal/mole and 53.2 ± 1.2 kcal/mole, respectively. The former authors (3) reported a value of 52.1 ± 0.4 kcal/mole based on free-energy functions which used a slightly different Cp value for SnTe(s).

The question of the existence of molecular flow conditions inside the cells, and hence the suitability of the effusion method for measuring pressures in the range reported here, is examined in light of the results listed in Table II. These results show no significant systematic increase in the measured pressures down to relatively low ratios of the mean free path-to-orifice diameter, λ/d. Earlier studies (16, 20, 21) have shown that, for molecularly subliming solids, the lower limit of λ/d in the molecular streaming range can be much less than the generally accepted value of one.

With reference to the work of Brebrick and Strauss (4), the present results indicate that, if deviations from stoichiometry in the SnTe samples utilized did exist, they would most likely be toward the Sn-rich end of the relatively narrow field of stability of SnTe, about 1 a/o (22-24). The mass-spectrometric investigations of Colin and Drowart (3), which presumably utilized Sn-rich samples, showed SnTe(g) to be predominant species in the vapor phase over a temperature range approximating that investigated in the present study. In addition to SnTe(g) and aside from gaseous species resulting from fragmentation, small concentrations of Sn_2Te_2, Te_2, $SnTe_2$, and Te were also detected. Using appropriate ionization cross sections (3), the relative partial pressures $P_{Sn_2Te_2}/P_{SnTe}$, P_{Te_2}/P_{SnTe}, and P_{SnTe_2}/P_{SnTe} were calculated to be 6.1×10^{-3}, 4.2×10^{-3}, and 4.7×10^{-3}, respectively. Although no calculations were made for Te(g), the partial pressure of this species is similarly insignificant when compared with the major component, SnTe(g). Finally, the authors of Ref. (3) indicated that, at sublimation runs where the sample had sublimed completely, small amounts of metallic tin (about 1% of the initial sample) were left behind. In view of this and other considerations regarding the nonstoichiometry of SnTe(s), it is concluded here that the total pressures measured in this work are essentially those corresponding to the maximum partial pressure of SnTe(g) which results from the incongruent sublimation of SnTe(s). Contributions of Sn(*l*) are believed to be insignificant with respect to SnTe(g). Support for this assumption comes from the observation that angular deflections, measured under the experimental conditions described above, remained constant at any given temperature for prolonged periods of time.

ABSTRACT

The field-assisted transport of sodium ions through phosphosilicate glass-SiO_2 composite films on silicon substrates has been investigated. The effects of P_2O_5 concentration (in the 0 to 8 mole per cent [m/o] range), sodium contamination level (between 10^{11} and 10^{15} Na^+ ions/cm^2), field, temperature, and time have been quantitatively determined. For a limited quantity of transported sodium, this quantity is approximately proportional to the square root of biasing time; exponentially dependent on temperature and field, increases linearly with the initial sodium contamination level; and decreases drastically with increasing P_2O_5 concentration. For example, seven more orders of magnitude of time are required to drift a given number of Na^+ ions through a PSG (3.5% P_2O_5 — 125Å)/2025Å SiO_2 composite layer than through a 2150Å thick layer of pure, thermally grown SiO_2. The results are consistent with a model based on the emission of Na^+ ions from traps in the phosphosilicate layer. It was concluded that phosphosilicate glass films, having negligible intrinsic polarizability, can be used to effectively stabilize IGFET threshold voltages against changes (0.1V in 10 yr at 80°C under a field of 2 x 10^6 V/cm) due to the presence of large amounts of sodium.

Phosphosilicate glass (PSG) films, formed on a thermally grown SiO_2 layer, can enhance markedly the surface stability of silicon planar junction devices and field-effect transistors (1). Without it, large shifts in the silicon surface potential can arise from field-induced drifting and accumulation of mobile sodium ions within the SiO_2 layer (2, 3). Mobile alkali ions, initially present in SiO_2 are gettered by the PSG during its formation, and those introduced subsequently tend to be trapped also in the glass (3-5).

Since the PSG itself is polarizable (6) it can by itself cause large Si surface potential instabilities, which can be minimized by decreasing the PSG-SiO_2 thickness ratio (6) and the P_2O_5 concentration (7). Since the effectiveness of the PSG as a sodium ion barrier depends on its thickness (5) and composition (8), an understanding of the extent of these dependencies is needed to optimize IGFET device performance.

In this study, both the PSG composition and the sodium ion concentrations were systematically varied in MOS structures and the sodium drift was measured as a function of applied field, temperature and time. The P_2O_5 concentrations in the PSG films were 8 m/o at most, in order to virtually eliminate their intrinsic polarizability effects. Projections were made of the lifetime stability of n-channel IGFET threshold voltages, containing various concentrations of sodium ions between the PSG and metal layers. A model for the phosphosilicate glass-sodium ion interaction will be suggested.

Experimental Procedure

Metal-PSG-SiO_2-Si capacitor structures were prepared on 2 ohm-cm, n-type, (100) oriented silicon substrates having chemically-mechanically polished surfaces. SiO_2 layers were grown in dry O_2 at 1100°C; thin phosphosilicate glass films were formed by adding P_2O_5 at 800°C in a furnace initially containing 0.14% $POCl_3$, 9% O_2, and 91% N_2 to form P_2O_5 by pyrolysis, followed by a heat treatment in N_2 at 975°C. The thicknesses and compositions of the glass films were controlled by appropriate selection of the deposition and heat treatment times, and were analyzed by plotting the total thicknesses (as measured ellipsometrically) against total elapsed etching time in a 2% solution of hydrofluoric acid at 25°C. The P_2O_5 concentrations (in mole per cent) were obtained, to within ±1%, from the etch rate-composition relationship found by Eldridge and Balk (9). By keeping the P_2O_5 concentration in the 0 to 8 m/o range with SiO_2-to-PSG thickness ratios of 7 to 1 or greater, sodium drifting could be followed without being obscured by any significant PSG polarization effects (6, 7). Sodium concentrations in the 10^{11} to 10^{15}/cm^2 range were then deposited on the oxide surfaces in a vacuum system by evaporating the residue of a drop of an aqueous solution of NaCl or NaI of appropriate normality. Kerr (10) has shown that the sodium concentration obtained in this way can be accurately calculated from the cosine distribution law when the source-substrate distance is known, and is proportional to the normality of the original solution over a wide range. An oxidized wafer without PSG was included in each salt deposition run to provide a second sodium measurement. Previous radiotracer experiments (5, 10) had shown that deposited sodium is entirely transported as Na^+ ions through SiO_2 by moderate electrothermal stressing (*e.g.* a few hundred seconds at 200°C under a field of 10^6 V/cm); during this time, the ions are detectable by current measurements. High-purity aluminum electrodes (area $\approx 5 \times 10^{-3}$ cm^2) were deposited from a source heated by an electron gun. Electrical measurements on additional control oxides that were not subjected to glassing and sodium contamination indicated a combined mobile ionic contamination level from the as-grown SiO_2 and the metallization to be less than 10^{11} ions/cm^2. After metallization, the wafers were annealed at 500°C in N_2 for 5 min to simulate the IGFET processing step used to lower contact resistance and eliminate interface states (11).

Sodium drifting through the PSG was determined in two ways. In the first, the small-signal capacitance of a given MOS structure was measured at room temperature, using a frequency of 10 kHz and a d-c ramp in order to obtain the initial silicon flatband potential (V_{FB}). Several capacitors (normally eight per wafer) were biased with the metal positive for a given time at an elevated temperature; then the wafer was quickly cooled under bias to room temperature and the C-V curves remeasured. The flux in ions/cm^2 Na^+ ions drifted through the composite PSG/SiO_2 is then: $N_I = -C_{ox}\,\Delta V_{FB}/q$ where C_{ox} is the oxide capacitance/cm^2;

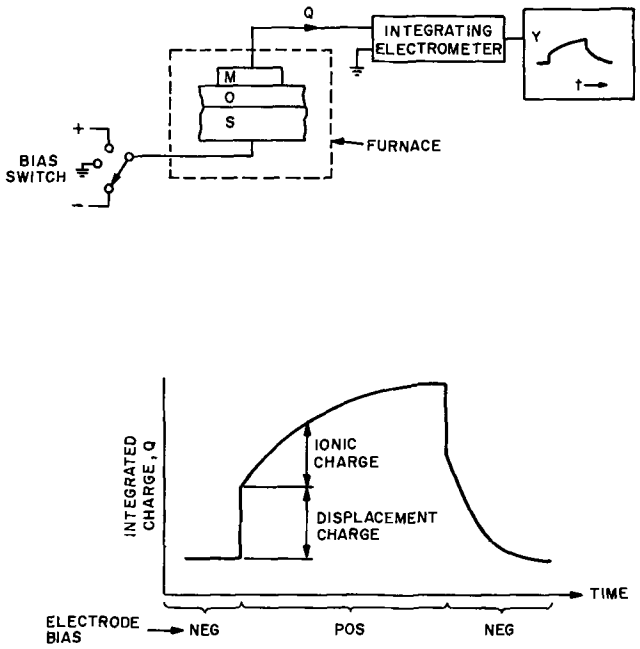

Fig. 1. Schematic diagram of electrical set-up used to measure charge transport in MOS structures, along with a typical charge vs. time trace. [After Kerr (5).]

ΔV_{FB} is the sodium-induced shift in flatband potential; q is the electronic charge. Repeated stressing and measuring cycles were used to determine the N_I *vs.* drifting time curves.

In the second method, schematically illustrated in Fig. 1, the wafer specimen is placed in a temperature cell with one capacitor that is contacted by a platinum probe from an external charge-meter (Keithley Model 610B electrometer). The silicon is initially biased positively, and is then switched stepwise to a predetermined negative value. A displacement charge step occurs instantly which is equal to the product of the oxide capacitance and the voltage change; this is followed by a much slower charge increase as the sodium ions move toward the Si. Since the electrode area is known, the density of transported ions can be directly calculated as a function of time. This technique is practical for the relatively short drift times (in the range of 1 to 1000 sec) observed at higher temperatures while the *C-V* shift method is generally useful for the much longer times encountered at ~200°C and lower. It will be shown later that the two methods yield results which are in good agreement. This agreement is expected since, to a good approximation, both techniques register only those ions which escape from the PSG to reach the SiO_2/Si interface. Later results will show that the time needed for the sodium to traverse the SiO_2 region is orders of magnitude less than that needed to pass through the PSG; hence, it follows that the Na^+ ions are either in the glass layer or the SiO_2/Si vicinity. Large SiO_2-to-PGS thickness ratios were employed so that the limited Na^+ displacements in the PSG make little impact on the *C-V* (2) and *Q-t* results. Thus, both techniques actually measure the transport-limited motion of sodium through the PSG.

Experimental Results

Even without an applied electric field, considerable amounts of sodium diffused into the phosphosilicate region during post-metallization annealing (12). The progressively larger, negative shift of the silicon flatband voltage with increasing NaCl surface contamination in Fig. 2 show this sodium ion penetration through a PSG (4% P_2O_5-125Å)/SiO_2 (900Å) composite layer during a 5 min, 500°C annealing treatment in N_2. Evidently Na^+ diffuses faster than Cl^- and I^- through the PSG, as well as through SiO_2 (3) so that the resultant uncompensated positive charge in the interior of the PSG can significantly alter the Si flatband potential.

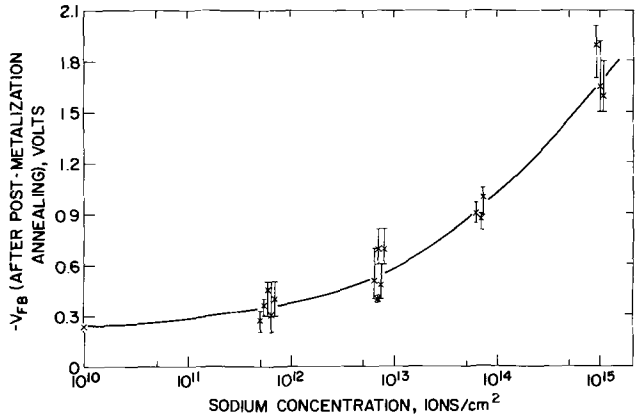

Fig. 2. Dependence of the flat band voltage on sodium contamination level in Al/NaCl/PSG (4% P_2O_5, 125Å)/SiO_2 (900Å)/Si structures after a typical post-metallization annealing treatment (5 min in N_2 at 500°C).

From the known dependence of V_{FB} on the uncompensated charge profile in the oxide (2), it was estimated that as many as 5 x 10^{12} ions-cm^{-2} penetrated approximately halfway into the glass for the 1 x 10^{15} Na^+/cm^2 specimens during the anneal. Although the effect of the PSG composition on this particular type of instability was not determined, it can still be concluded that the gate oxide region of IGFET's can withstand only moderate alkali ion contamination if the threshold values are to be held within a narrow, well-defined range of values, even when a PSG layer is present.

When typical IGFET operating fields (~10^6 V/cm) are applied at elevated temperatures, the Na^+ ions can be driven through them to the SiO_2-Si interface (5, 12, 13). The rate of displacement depends very strongly on various testing and materials parameters. Thus, from an initial surface contamination concentration of N_O (= 7 x 10^{12} NaCl/cm^2), Fig. 3 shows that the quantity (N_I) of Na^+ ions, transported

through a 4 m/o P_2O_5 x 125Å thick phosphosilicate glass[1] layer is closely proportional to the square root of the stressing or biasing time (t) for $N_I \lesssim 0.2\ N_o$. The transport process is strongly thermally activated while the results of other experiments indicated that the anion (either Cl^- or I^-) used for adding sodium did not affect the Na^+ drift rate.

The rate of Na^+ drifting, as characterized by the initially constant slopes, is roughly proportional to the initial sodium contamination level, as shown in Fig. 4. These data were obtained over a time interval of ten orders of magnitude by combining the results of the two measurement techniques. It is evident that the activation energy Φ, as calculated from the slopes in Fig. 4, decreases appreciably with increasing sodium ion contaminations. The factor of ½ is used here to facilitate a direct comparison between these activation energies and those obtained earlier (14) from the slopes of log τ *vs.* $1/T$ plots, where τ is taken as the time required for a given amount of Na^+ transport. The results from the two experimental approaches are in good agreement and apparently the same Na^+ transport process is operative throughout the temperature interval from 80° to 350°C. Thus, the Φ values are characteristic of a given glass composition, sodium concentration and field.

These data indicate that a limited amount of sodium contamination, introduced after the PSG is present, can still produce appreciable threshold shifts at approximately 100°C in field-effect devices. For sodium concentrations as high as 1 x 10^{15}/cm^2, threshold shifts of several tenths of a volt occur within an hour in room temperature stressing at 2 x 10^6 V/cm.

A constant stressing field and sodium level of 1 x 10^{13}/cm^2 was used to assess the effect of P_2O_5 concentration on sodium drift. It can be seen in Fig. 5 that the rate of charge transport decreases rapidly while Φ becomes larger with increasing phosphorus oxide concentration. Although the PSG thickness of the P_2O_5-richest structures were somewhat higher (by ~50%) than that (125Å) of the lowest, the relative effects of glass thickness and composition could not be accurately separated from these data. Inspection of the 6 and 8 m/o P_2O_5 results indicates, however, that the composition parameter is the more important one. Comparison of the room temperature Na^+ drift behavior for the 2150Å SiO_2 and the PSG (4% P_2O_5-125Å)/2025Å SiO_2 structures provides a quantitative demonstration of the strong retarding power of the glass for sodium. Thus, eight more magnitudes of time are required for a given amount of sodium to drift through the date dielectric region in PSG-stabilized films than in pure silica ones. Obviously, the drift of Na^+ ions is rate-limited in the PSG layer in composite PSG-SiO_2 systems.

Discussion

Snow *et al.* (2) reported a $N_I \propto t^{1/2}$ dependence for the early stage of Na^+ transport through thermally grown SiO_2 films, deliberately contaminated in aqueous NaCl solutions. Although they proposed another model, this time-dependence can be attributed also to the temperature- and field-induced emission of Na^+ ions from trapping centers located near the metal-SiO_2 interface. These traps presumably arise from the partial chemical reduction of SiO_2 by the metal electrode. As shown by Hofstein (14), who computed the effects of small Gaussian distributed spreads (σ) in the activation energy for ion emission (Φ) from such traps, the quantity of drifted sodium is closely proportional to $t^{1/2}$ for $\sigma \simeq 3kT$ for small amounts ($N_I < 0.5\ N_o$) of Na^+ transfer. Results from the present study, such as those shown in Fig. 3, yield a σ value of $\simeq 4kT$ when fitted to the charge-time waveform curves computed by Hofstein. A $N_I \propto t^{1/2}$ dependence results for this σ value provided that $N_I \lesssim 0.2\ N_o$, in agreement with our experimental findings. This time dependence was then employed in order to reduce the number of measurements needed to complete this study. Such σ values are reasonably consistent with a proposed structural model for the polarization of phosphosilicate glass

[1] Recall at this point that the bulk polarization contributions of the PSG films to the observed ΔV_{FB} values are quite negligible, in view of the limited P_2O_5 concentrations and the large SiO_2-to-PSG thickness ratios used (7).

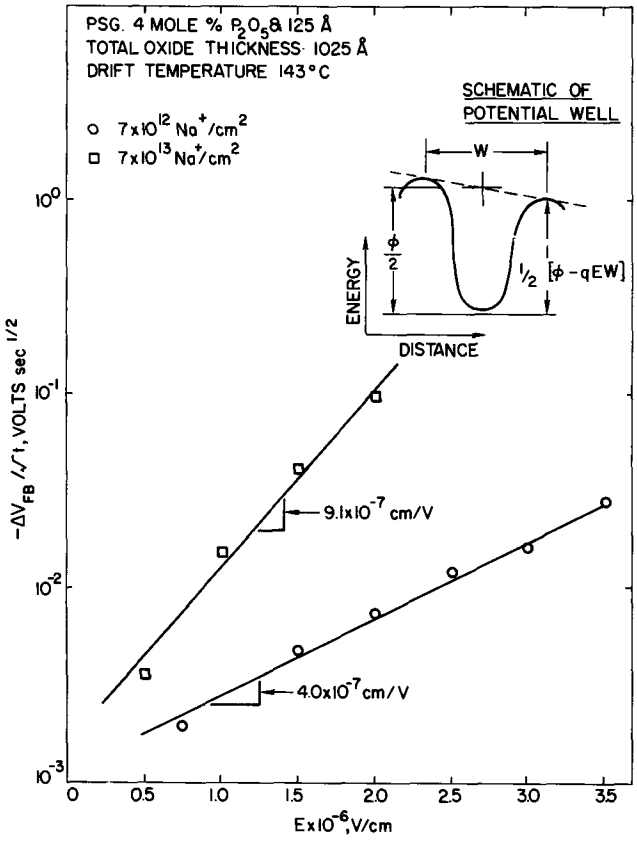

Fig. 6. Dependence of the sodium drift rate on biasing field and Na^+ concentration for a given PSG-SiO_2 barrier. A schematic diagram of a potential well has also been included to indicate how Φ is lowered by E.

where a limited spread ($\sim 2kT$) in the activation energy has been noted (6, 7).

The electric field dependence of the transport process is also consistent with a trapping model. As shown schematically in Fig. 6, the trapping center can be crudely represented by a potential energy well scheme having an average width W, and depth $\Phi/2$. To a first approximation, application of a field E lowers $\Phi/2$ by $q \cdot E \cdot W/2$. The results of this present investigation can be combined into a single, phenomenological expression

$$N_I = -C_{ox} \cdot \Delta V_{FB}/q = N_o \cdot K \cdot t^{1/2} \quad [1]$$

where N_o is the initial sodium concentration, and K is the rate constant

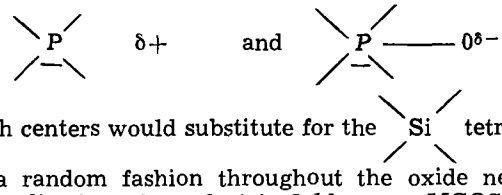
$$K = K_o \exp\left[(-\Phi + q \cdot E \cdot W)/2kT\right] \quad [2]$$

It follows that Φ and W may be estimated from experimental data by separating Eq. [2] into field- and temperature-dependent terms

$$\log\left[-\Delta V_{FB} \cdot t^{-1/2}\right] = \frac{1}{4.60kT} \cdot \{+ q \cdot E \cdot W - \Phi\} - \log K' \quad [3]$$

where various incidental constants have been included in K'. The data in Fig. 6 shows the expected field dependence. The simple potential energy well model is possibly too naive since the data seem to fit equally well to a log $(-\Delta V_{FB} \cdot t^{-1/2}) \propto E^{1/2}$ relationship, suggestive of a Poole-Frenkel mechanism. However, insufficient data were taken to differentiate between these two mechanisms. Based on the present model, an average trap width of ~6Å for Na^+ ions drifting through a 4 m/o P_2O_5 phosphosilicate layer from a surface source concentration of 7 x 10^{12} NaCl-cm^{-2} was calculated. An increase in the sodium level to 7 x 10^{13} cm^{-2} effectively raises W from ~6 to 13Å for this particular PSG film. Such an effect might have the following physical origin: at the higher sodium level the $Na^+ - Na^+$ distances are roughly comparable to the spacings between the trapping centers, *i.e.* ~12Å. Hence, the negatively charged, nonbridging oxygen ion can interact coulombically with more than one Na^+ ion at a time, on the average, and consequently, Φ will be lower (as found in Fig. 4). Since a range of well widths presumably exist in the glassy layer, those traps configurations having the largest W values will emit their ions first, owing to the direction proportionality between W and barrier lowering. In other words, since W values are being evaluated from data taken during a limited amount of charge transport (*i.e.* $N_I << N_o$), the field dependence reflects ion emission from the traps having the largest W values.

The results of this investigation lend support to the following structural model previously proposed to account for the intrinsic polarizability of the phosphosilicate glass (7, 12, 13). Thermally grown SiO_2 is thought to consist of a somewhat randomized, three-dimensional network of SiO_4 tetrahedra which are connected only at the oxygen sites. The addition of a P_2O_5 molecule should produce two different tetrahedral charge centers



Such centers would substitute for the tetrahedra in a random fashion throughout the oxide network.

Application of an electric field across MGOS structures produces a bulk PSG polarization (6) whose magnitude is proportional to the square of the P_2O_5 concentration (7). This dependency suggests that the polarization process is favored by having the two types of phosphorus centers close to each other, in which case the nonbridging oxygen ion can jump from one to the other group. Although the polarizabilities of the films used in the present investigation were deliberately made small by limiting the P_2O_5 concentrations to $\lesssim 8\%$, the negatively charged, nonbridging oxygen ions are still present in sufficient numbers ($>10^{15}/cm^2$ in a 4% P_2O_5 x 125Å PSG layer, for example) to trap coulombically the positive sodium ions. Thus, this model can also account for the so-called "stabilization effect" of PSG films on SiO_2, as shown in Fig. 7.

As noted above, Φ decreases as progressively larger amounts of sodium are added for a given PSG layer. Thus, traps having molecular configurations with higher energy levels will be emptied first. (See Fig. 8). Although these results, taken from Fig. 4 and 5, were obtained using one field value, they support the present arguments. Since calculated Φ values are actually somewhat dependent on the field, a better anal-

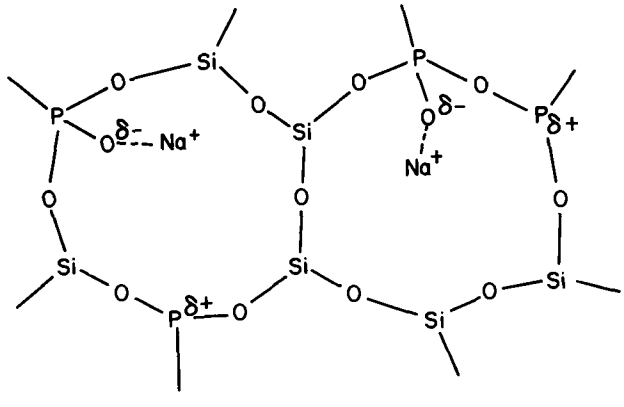


Fig. 7. Schematic two-dimensional model of the phosphosilicate glass structure, indicating the suggested mechanism of Na^+ ion trap *via* a coulombic interaction.

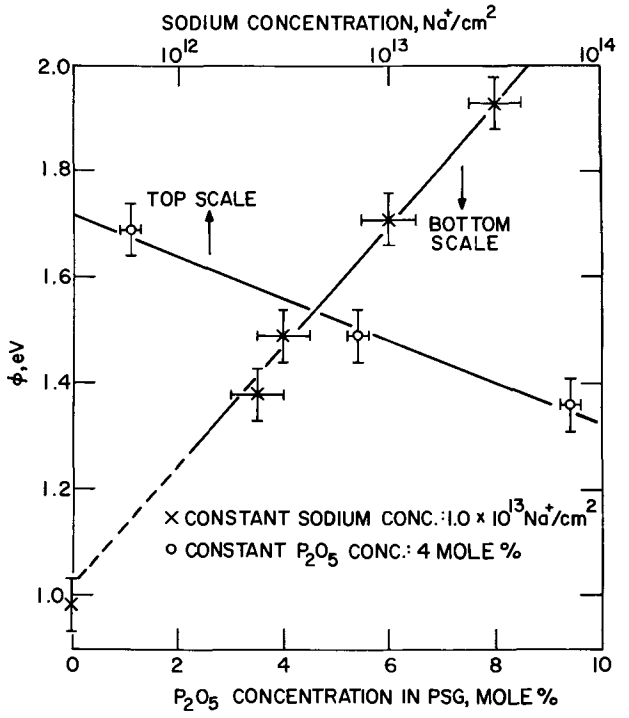

Fig. 8. Dependence of Φ on PSG composition for a constant sodium concentration and vice versa.

ysis should be developed on the field-free ion emission energies which can be obtained by extrapolation. Unfortunately, we failed to obtain enough data for such an evaluation.

In the present model, Φ increases with the P_2O_5 concentration of the PSG, when the sodium level is held constant. Thus, the approximate doubling of Φ, on going from pure SiO_2 to an 8 m/o P_2O_5 glass, results from the introduction of relatively large concentrations of nonbridging oxygen traps, some of which have lower energy configurations. This behavior also results from the simple, idealized density of states for the traps in the glasses shown in Fig. 9. In this approach, Φ is a measure of the energy difference between the released ion, that is, at the horizontal axis, and that near the top region of the filled traps. The effects of Na^+ and P_2O_5 concentrations on Φ follow directly and are consistent with the trends observed experimentally.

Based on the above experimental results, reasonably sound reliability projections can be made of the

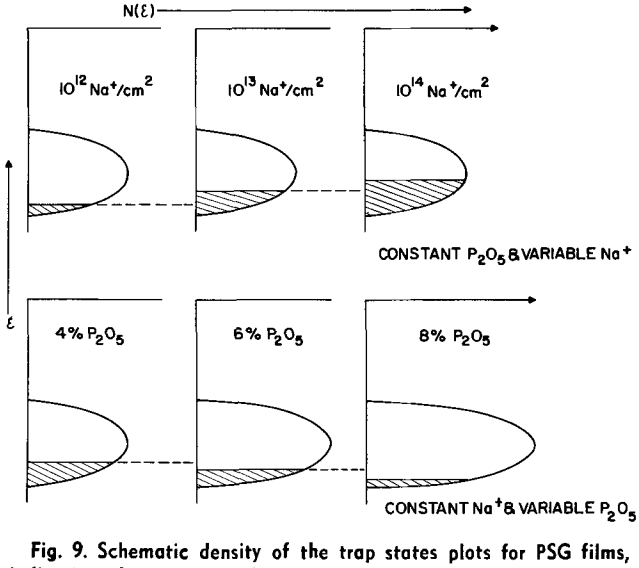

Fig. 9. Schematic density of the trap states plots for PSG films, indicating the origin of the dependence of Φ on glass composition and sodium concentration.

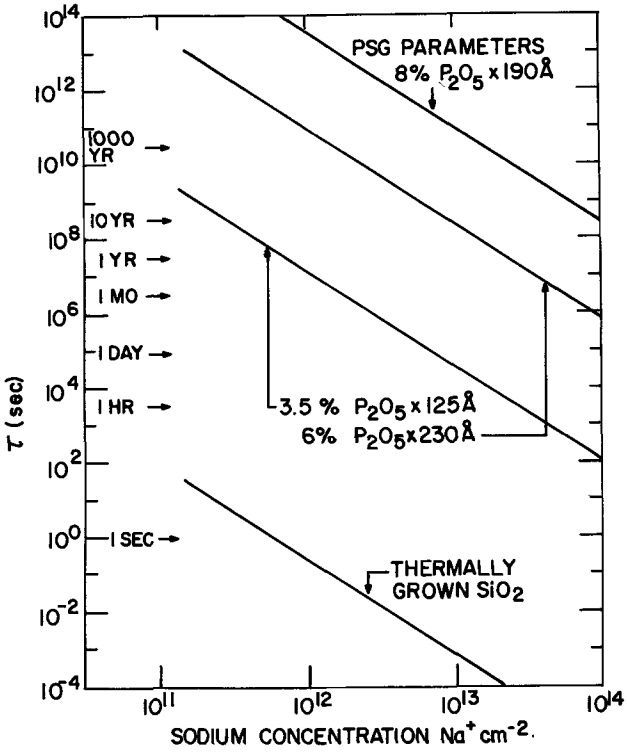

Fig. 10. Dependence of estimated time, τ (needed for a sodium-induced −0.1V threshold shift) for various PSG passivating layers. Calculated for a gate oxide thickness of 1000Å, at 80°C under a field of 2 x 10^6 V/cm with metal biased positively.

threshold voltage stability for IGFET structures, contaminated with sodium during device fabrication. A typical projection for a 1000Å thick oxide, showing the time (τ) required for sodium drift to cause a threshold shift of −0.1V at 80°C under a field of 2 x 10^6 V/cm, is presented in Fig. 10. The 3.5% P_2O_5 x 125Å thick PSG film forms an effective barrier for ion drift for sodium concentrations up to ~5 x 10^{11}/cm^2, if a device lifetime of approximately ten years at 80°C is needed. Although the use of P_2O_5 richer PSG films result in even more effective barriers, the limited but very significant Na^+ diffusion occurring during post-metallization annealing will produce an undesirably large spread in threshold values for higher ($\gtrsim 10^{13}$ cm^{-2}) contamination levels. (Recall Fig. 2.) Hence, considerable care must be taken during all IGFET fabrication steps to ensure that the PSG-stabilized gate oxide is never exposed to sodium-containing reagents, etc. By contrast, the pure SiO_2 is vulnerable to very large and fast threshold shifts, due to even a limited amount of Na^+ contamination. (See Fig. 5 and 10.) The advantages of the phosphosilicate glass stabilization, over that of the so-called "clean SiO_2" approach are evident.

Summary and Conclusions

A detailed investigation has been made of the field-induced drifting of intentionally deposited sodium ions through various phosphosilicate layers under a range of stressing conditions. It was found that the amount (N_I) of sodium initially transported through the PSG to the SiO_2-Si interface can be expressed by

$$N_I = N_o \cdot t^{1/2} \cdot K_o \exp\left[(-\Phi + q \cdot E \cdot W)/2kT\right] \quad [4]$$

where N_o is the initial Na^+ concentration; t is biasing time; K_o is a constant, dependent on the PSG thickness and composition; Φ is the activation energy for Na^+ ion emission from traps; q, the electronic charge; E is the field; and W is the average width of a trap well. These results are quite consistent with a transfer process limited by the emission of the Na^+ ions from

trapping centers in the PSG. The evidence suggests that these centers are the same as those responsible for the intrinsic polarizability of the phosphosilicate glass; namely, nonbridging oxygen ions attached to phosphorus ions in tetrahedral positions. Based on the present data, projections were made of the degree of protection against Na^+ induced threshold voltage shifts of IGFET's by various phosphosilicate films. These projections indicate that relatively thin (~4% P_2O_5) PSG layers will effectively stabilize the threshold voltage of IGFET's under typical operating conditions of temperature and field, even when significant levels of sodium ion contamination are present.

Partial and Total Vapor Pressures over Molten Bi_2Te_3

R. F. Brebrick*,[1] and F. T. J. Smith

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

The total vapor pressure, P_Σ, over $Bi_2Te_3(l)$ has been determined between 980° and 1169°K by using a new manometric technique. The lower end of an evacuated, inverted, fused silica U-tube was immersed in a large reservoir of melt inside a transparent furnace. The value of P_Σ and the density of $Bi_2Te_3(l)$ were obtained at each temperature by visually observing the height to which the melt rose in the U-tube as a function of the external argon pressure applied to the reservoir surface. In separate experiments a sealed, evacuated, fused silica optical cell was maintained at 1000°C while the temperature of a sidearm reservoir containing $Bi_2Te_3(l)$ was held at a lower temperature. By measuring the optical density as a function of wavelength between 1990 and 5500Å, it was possible to determine the partial pressure of $Te_2(g)$, p_{Te_2}, and the partial optical density of BiTe(g) as functions of the $Bi_2Te_3(l)$ temperature between 943° and 1200°K. If it is assumed, consistent with all the evidence, that Te_2 and BiTe are the principal vapor species, the results of both sets of experiments are represented by

$$\log_{10}P_\Sigma(\text{atm}) = -6.4691(10^3)/T + 4.3219$$
$$\log_{10}p_{Te_2}(\text{atm}) = -6.3048(10^3)/T + 4.1396$$
$$\log_{10}p_{BiTe}(\text{atm}) = -8.978(10^3)/T + 5.4432$$

According to these expressions $Bi_2Te_3(l)$ neither vaporizes nor effuses congruently since p_{BiTe} is never more than 15% of p_{Te_2}. The density of $Bi_2Te_3(l)$ is 7.4 g/cm³ at 973°K and 7.0 g/cm³ at 1170°K.

The total vapor pressure, P_Σ, over $Bi_2Te_3(l)$ between 952° and 1265°K has been measured by using a Bourdon gauge (1). Values of P_Σ over $Bi_2Te_3(c)$ between 700° and 806°K have been determined twice (2, 3) with excellent agreement from the weight loss of a Knudsen cell on the assumption that $Bi_2Te_3(c)$ effuses congruently according to the reaction

$$Bi_2Te_3(c) \rightarrow 2\,BiTe(g) + 1/2\,Te_2(g) \qquad [1]$$

Values of P_Σ over $Bi_2Te_3(c)$ between 714° and 833°K have been determined (4) from torsion effusion data. As evidence for congruent effusion, ref. (4) cites the observation that a sample which had been subjected to a 30% weight loss by effusion was found to be single phase by metallographic examination and gave the same x-ray diffraction pattern as an unheated sample.

The temperature dependence of P_Σ found in ref. (4) is close to that of ref. (2) and (3), but the values are only about half as large. Aside from this discrepancy, the experimental situation is unsatisfactory for two more serious reasons. First, when the data for P_Σ are extrapolated to the maximum melting point of $Bi_2Te_3(c)$, 860°K, the values at this temperature derived from the low-temperature effusion measure-

Key words: properties of molten salts, optical absorption, incongruent vaporization.

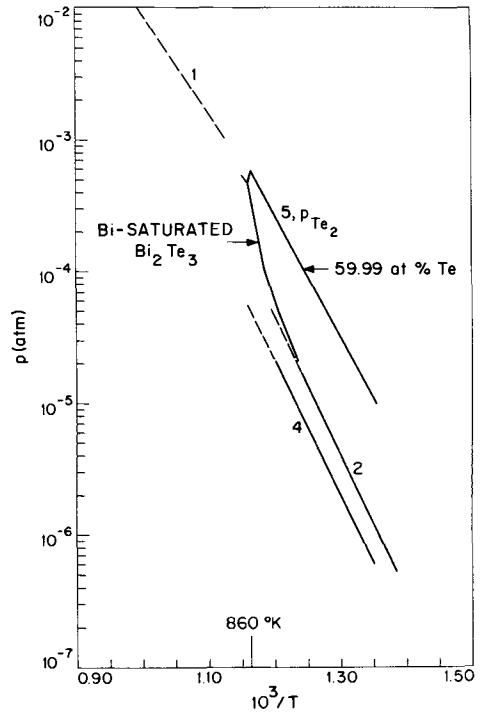

Fig. 1. Pressure in atm on a logarithmic scale plotted as a function of reciprocal absolute temperature. The numbers attached to the curves are the reference numbers. The solid portions of the lines cover the temperature range of the measurements. Lines 1, 2, and 4 give the total vapor pressure, P_Σ, for Bi_2Te_3(c, l). The loop for curve 5 gives the partial pressure of Te_2, p_{Te_2}, for the labeled compositions of Bi_2Te_3(c). The short segment attached to the high-temperature end of this loop gives p_{Te_2} for a 59.99 a/o Te melt.

ments are only 20% [ref. (2) and (3)] or 10% [ref. (4)] of the value obtained from the high-temperature Bourdon gauge measurements [ref. (1)]. Second, the results of the effusion measurements on Bi_2Te_3(c) are completely inconsistent with the values for the partial pressure of Te_2, p_{Te_2}, determined by optical density measurements (5). Thus the values of P_Σ are only 7-20% of the p_{Te_2} values measured for stoichiometric Bi_2Te_3(c) and are comparable to the p_{Te_2} values for Bi-saturated Bi_2Te_3(c). According to reaction [1], $p_{Te_2} = (1/5)(0.89)P_\Sigma$. Therefore the effusion measurements yield values of p_{Te_2} which are only 1-4% of those obtained by the optical density measurements for 59.99 a/o (atom per cent) Te Bi-Te and only 10-20% even of those for Bi-saturated Bi_2Te_3(c). The experimental results are summarized in Fig. 1. For simplicity only the values of p_{Te_2} for 59.99 a/o Te and for Bi-saturated Bi_2Te_3(c) are selected from the extensive data of ref. (5). It is seen that the extrapolated values of P_Σ obtained by the Bourdon gauge measurements are slightly higher than the values of p_{Te_2} over Bi_2Te_3(l) obtained by the optical density measurements.

The present study was undertaken in an attempt to resolve the above discrepancies. Values of P_Σ were measured for Bi_2Te_3(l) between 980° and 1169°K by using a new manometric technique involving visual observation through a transparent furnace. In separate experiments the previous optical density measurements on the vapor over Bi_2Te_3(l) were extended to higher temperatures so that the partial optical densities of Te_2(g) and BiTe(g) could be obtained at a number of wavelengths and values of p_{Te_2} could be determined from calibration experiments on Te(l). Straight lines can be drawn through the log P_Σ-$10^3/T$, log p_{Te_2}-$10^3/T$ and log (partial optical density of BiTe)-$10^3/T$ data such that the difference between P_Σ and p_{Te_2} is proportional to the partial optical density of BiTe(g). Thus on the assumption, given support later, that BiTe is the only other major vapor species, it appears that BiTe obeys Beer's law and p_{BiTe} can then be calculated.

Our results show that Bi_2Te_3(l) is not congruently vaporizing, since the vapor contains 95 a/o Te rather than 60 a/o Te. This is in agreement with an earlier (13) observation of incongruent effusion for Bi_2Te_3(l). Moreover, it appears that Bi_2Te_3(c) is not congruently subliming nor congruently effusing either, so that reaction [1] does not describe an equilibrium process. Since the vapor is Te-rich, a Bi_2Te_3(c) sample of any initial composition upon being subjected to indefinite sublimation becomes Bi-saturated and eventually enters the broad homogeneity range of the compound decomposing peritectically at 836°K and 57 a/o Te (5-7). The x-ray powder diffraction patterns for this peritectic phase and for Bi_2Te_3(c) have recently (8, 9) been shown to be remarkably similar. The patterns can easily be judged to be identical unless the low angle lines are accounted for. We therefore suggest that the workers using effusion cells were misled in concluding from x-ray diffraction patterns that Bi_2Te_3(c) effuses congruently under equilibrium cell conditions.

Experimental

Total pressure measurements.—To explain the principle of the method, we refer to the schematic of the high-temperature part of the apparatus shown in Fig. 2(a). The manometer cell, shown in detail in Fig. 2(b), consists essentially of an inverted, fused silica U-tube whose open ends are immersed in a reservoir of molten Bi_2Te_3 contained in a silica crucible. Argon pressure from an external source is applied to the surface of this reservoir via a long silica capillary. When this pressure is varied, the height of the melt in each leg of the U-tube changes until the pressure inside that leg at the level of the reservoir surface equals the pressure on the reservoir surface outside the U-tube. Provided that no residual foreign gas is trapped in the U-tube, the inside pressure is the sum of the total vapor pressure over Bi_2Te_3(P_Σ'), the hydrostatic pressure of the column of molten Bi_2Te_3 of height h above the reservoir surface, and a term due to capillary action. The outside pressure is equal to the argon pressure measured external to the cell, P_{ex}. Setting the outside and inside pressures equal gives

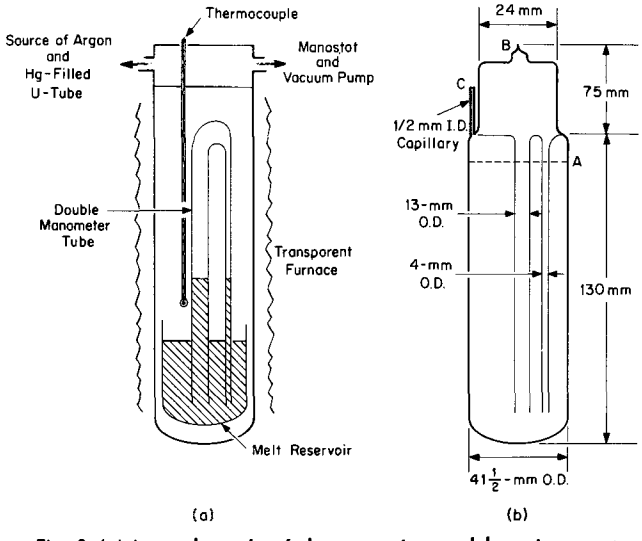

Fig. 2 *(a)* is a schematic of the apparatus used here to measure the total vapor pressure of Bi_2Te_3(l). *(b)* is a detailed drawing of the fused silica manometer cell. Access for the externally imposed argon pressure is through the capillary tube shown schematically as a straight section at the upper left hand portion of the cell ending at C. Actually this tube was about 30 cm long with 4 U-bends so that it was close to the main body of the cell and did not extend above the seal-off tip at the top of the cell, B. After loading with a pre-cast Bi_2Te_3 ingot, the bottom test-tube portion of the cell is sealed to the upper portion at A.

$$P_{ex} = P_\Sigma' + hd_M g + \frac{2\gamma_M}{r} \quad [2]$$

where P_{ex} and P_Σ' are expressed in dynes/square centimeter, and h is in centimeters. The quantities d_M (in grams/cubic centimeter) and γ_M (in dynes/centimeter) are, respectively, the density and surface tension of molten Bi_2Te_3, g is the acceleration due to gravity, and r is the radius of the U-tube leg in centimeters.

If the external measurement of argon pressure is made by means of a mercury-filled U-tube, $P_{ex} = Hd_{Hg}g$, where H is the difference in centimeters between the mercury levels in the two arms and d_{Hg} is the density of mercury. Then Eq. [2] can be rewritten as

$$H = P_\Sigma + h(d_M/d_{Hg}) + \frac{2\gamma_M}{rd_{Hg}g} \quad [3]$$

where $P_\Sigma \equiv P_\Sigma'/d_{Hg}g$ is the total vapor pressure of the melt expressed in centimeters of Hg. In principle, γ_M can be determined by comparing the values of h for different values of r when H and P_Σ are fixed. In our experiments, within the measurement accuracy of 0.005 cm the values of h were the same for the two legs of the U-tube, which had radii of 0.535 and 0.13 cm, respectively. This showed that the capillary force term can be neglected and that γ_M is less than 57 dynes/cm. Omitting this term from Eq. [3] and rewriting gives

$$h = (d_{Hg}/d_M)H - (d_{Hg}/d_M)P_\Sigma \quad [4]$$

Therefore, a plot of h as a function of H should give a straight line which yields the values of P_Σ (equal to H when $h = 0$) and d_M (equal to the reciprocal slope times d_{Hg}). If residual gas is trapped in the upper part of the U-tube, the pressure it exerts will cause deviations from linearity at sufficiently high values of H, with the slope decreasing as H increases. [In order to minimize the error due to any residual gas, the upper part of the U-tube shown in Fig. 2(b) was enlarged to a volume of about 21 cm^3.] Thus in this type of measurement, one not only gets a value of P_Σ, but also has some indication of its reliability when the experimentally observed relationship between h and H is linear and when the derived density agrees with independently measured values.

The following procedure was used to measure h as a function of H. The spectroscopically pure elements were each weighed to the nearest 0.1 mg to make a total of 361.36g of a Bi-Te mixture containing 60.00 a/o Te. The mixture was put into a previously cleaned and outgassed 40 mm OD, 25 cm long silica synthesis tube which was then evacuated to $2(10^{-6})$ Torr with a turbomolecular pump. The lower part of the tube was slowly heated to 793°K and $8(10^{-6})$ Torr. The valve to the vacuum system was closed, and N_2 at 110 Torr (passed through a liquid nitrogen-cooled trap) was admitted in order to minimize loss of material during the synthesis reaction. The sample was then heated at 893°K for 1/2 hr, at which point it was entirely molten. The temperature was lowered to 873°K, still above the melting point at 860°K, and the valve to the N_2-source closed and that to the vacuum opened in order to remove any dissolved N_2. Bubbling occurred in the melt and heavy sublimation took place to the upper parts of the tube. After about 2 min, when the pressure was about $2(10^{-6})$ Torr, the vacuum valve was closed and the melt cooled by immersing the bottom part of the tube in water. The tube was then sealed off at $5(10^{-7})$ Torr. No sublimate film was visible on the vacuum side of the seal-off point. The tube was placed in a box furnace at 773°K for 93 hr and quenched in water. (After the first 16 hr the heavy sublimate film on the upper part of the tube had entirely disappeared, having been driven into the Bi_2Te_3 ingot.)

The Bi_2Te_3 ingot was removed from the synthesis tube and slipped into the 41.5 mm OD tube forming the bottom section of the manometer cell, shown below A in Fig. 2(b). The upper part of the manometer cell, which included the two manometer legs and a 0.5 mm ID capillary 30 cm long, was then fused to the bottom part at A while the ingot was kept cool by a wet wrapping about the tube. The manometer legs fitted into holes in the BiTe ingot left by closed tubes which had been sealed to the bottom of the synthesis tube. This design of the synthesis tube decreased the dead space in the manometer cell and allowed the cell to be made shorter for a given weight of Bi_2Te_3. This in turn made it possible to establish more nearly isothermal conditions in the subsequent measurements. The capillary tube at C was closed by a close fitting silica cap held in place by a small piece of plastic tubing, and the assembled cell was then attached to a vacuum system through a seal-off constriction at B in Fig. 2(b). The lower part of the cell containing the Bi_2Te_3 ingot was outgassed by heating to 823°K for about ½ hr and the cell was then sealed off at B. The pressure reading on an ion gauge located 10 in. away on a connecting 1 in. ID glass tube was $3(10^{-6})$ Torr. There was no visible deposit of material on the vacuum side of the seal-off.

The sealed manometer cell was next placed in the apparatus shown schematically in Fig. 2(a). The cell rested on the bottom of a 76.2 cm long silica tube closed at the top with a brass cap and a Viton O-ring. The brass cap provided a central entry for a thermocouple tube and two side ports, one connecting to a mechanical fore pump through a Hg manostat, the other connecting to an argon cylinder through a silica tube packed with Ti-turnings, which during operation was heated to 973°K for gettering the argon. A side arm between this getter tube and the long tube led to a vertical Hg-filled U-tube, one arm of which was evacuated, and to a Dubrovin gauge which could be read to the nearest 0.01 cm Hg. The manometer cell, enclosed in the long silica tube, was centered in a resistance furnace consisting of three adjacent zones, each 25.4 cm long and heated by 8 equispaced, concentrically placed, vertical wires enclosed in insulators. This open-structured furnace was in turn surrounded by a 83 cm long, close fitting, open-ended Pyrex tube, the interior of which was covered by a vacuum-deposited gold film about 30-50 nm thick. The gold layer was sufficiently transparent in the visible to permit observation of the cell while simultaneously reflecting and containing most of the infrared radiation, thereby reducing the power requirements for the furnace and improving the uniformity of its temperature.

With the manometer cell in place, the containing silica tube was evacuated through the port in the brass cap and the three zones were heated to 773°K. The plastic tube holding the silica cap over the capillary tube at the top of the manometer cell decomposed and the silica cap dropped off the capillary. The manometer cell was heated to 913°K for about 2 hr to melt the ingot and seal the manometer legs while removing any residual gas and then an argon pressure of 10 cm Hg was admitted to start the measurements. At this point there was no visible deposit of material outside the manometer cell although here, as well as at previous points, a deposit of well under 200 mg should have been visible.

For each determination of the total vapor pressure the power to the three furnace zones was adjusted until the temperatures at points A and B in Fig. 2(b) and at the bottom of the manometer cell were within 3°K of each other, the uppermost point at B being the hottest. Temperatures were measured to the nearest 0.2°K using Pt, Pt, 13% Rh thermocouples, an ice reference junction, and a K-3 potentiometer. The temperature-measuring apparatus was checked using the melting points of Zn and Te. After setting the external argon pressure, the levels of the Bi_2Te_3-melt in the two legs of the manometer, the level of the melt in the crucible, and the levels in the two arms of the Hg-

manometer were read to the nearest 0.005 cm with a cathetometer to determine h and H. Below 2.0 cm Hg, H was read with the Dubrovin gauge to the nearest 0.01 cm Hg, as well as with the Hg-manometer, the two values usually agreeing within experimental precision. After a change in the argon pressure usually 30-40 min were required until the levels in the Bi_3Te_3 manometer legs became steady, the levels in the Hg manometer and the temperatures holding constant within the experimental accuracy cited above. The disadvantage of a long time constant for changes in h, caused by the restricted opening through the long capillary into the manometer cell, was accepted in order to minimize the loss of material from the cell by vaporization.

A 5W fluorescent lamp placed behind the manometer cell allowed the melt levels to be clearly seen up to 1170°K, the melt appearing black. At each temperature, readings were taken for four to seven values of the argon pressure, H, usually in order of decreasing H. When the apparatus was left overnight the temperature was lowered to 873°K and H held at 12-15 cm Hg. During the course of the measurements a black film slowly built up to opaqueness near the top of the long tube containing the manometer cell, where the temperature was about 673°K. A total of nine days was taken to complete the measurements, after which the apparatus was cooled to room temperature and the Bi_2Te_3 removed and weighed.

Optical density measurements.—The present measurements are an extension of earlier ones (5) which gave p_{Te_2} at lower temperatures for a number of compositions including some inside the $Bi_2Te_3(c)$ homogeneity range. The details of the method are given in ref (5). Essentially the experiment consists of measuring the optical density, $D = \log I_o/I$, of the vapor in a fused silica optical cell at a fixed temperature as a function of wavelength between 1990 and 7000Å and as a function of the temperature of a sidearm reservoir containing a Bi-Te melt of known composition. In the present study the composition was 59.99 a/o Te, and measurements were made with two cells having path lengths of 99.9 and 22.4 mm. The reservoir temperature was varied between about 943 and 1200°K, and consequently to prevent condensation on the windows the optical cell temperature was 1273°K rather than 1028°K as in the earlier study. The vapor over pure Te(c,l) consists essentially of $Te_2(g)$ in the range of temperatures and total Te-pressures encountered, and the spectrum at 1273°K is well characterized from an earlier study (10).

Results

Total pressure measurements.—At the completion of the experiment, after the manometer cell had been at 873°K or above for nine days, the surface of the Bi_2Te_3 appeared clean and no sign of white TeO_2 could be found anywhere in the system. The black Bi-Te sublimate of unanalyzed composition was found only on part of the apparatus where the temperature had been 873°K or below. The Bi_2Te_3 ingot had undergone a weight loss of 3.2g, putting an upper limit of ±0.5 a/o Te on the associated change in composition. Most likely the largest part of any composition change occurred during the measurements themselves.

A summary of the measurements and the results of a least squares fit to the linear relation between h and H embodied in Eq. [4] are given in Table I, in which the runs are listed in chronological order. Consistent with the observations in the preceding paragraph the temperature dependence of P_Σ does not change significantly with time. Comparison of runs 2 and 8 shows P_Σ was changed less than 3% by any change in sample composition. It is seen that a linear relationship between h and H is observed for h as large as 11.64 cm. At this value of h, the melt meniscus was in the enlarged, top-portion of the inverted U-tube.

Table I. Total vapor pressure and density of Bi_2Te_3 (l)

The total vapor pressure, P_Σ, of $Bi_2Te_3(l)$ is determined by a least squares fit of $h = \left(\frac{13.53}{d}\right)H - \left(\frac{13.53}{d}\right)P_\Sigma$ at various temperatures. H is the pressure of argon expressed in cm Hg; h is the height of $Bi_2Te_3(l)$ in the manometer tube; d is the density of $Bi_2Te_3(l)$ at the temperature in question. The runs are listed in the order in which they were taken. $\sigma(i)$ is the standard deviation in i.

Run	$10^3/T$	No. of data points	Range in h, cm	$\sigma(h)$, cm	$d \pm \sigma(d)$, g/cm³	$P_\Sigma \pm \sigma(P_\Sigma)$, atm
1	1.021	6	0.27-11.64	0.050	7.288 ± 0.068	(5.84 ± 0.34)10⁻⁶
2	0.9970	5	0.365-8.34	0.035	7.240 ± 0.081	(8.39 ± 0.31)10⁻⁶
3	0.9588	4	0.62-10.64	0.008	7.473 ± 0.013	(1.34 ± 0.009)10⁻²
4	0.9268	6	0.54-9.46	0.030	7.438 ± 0.054	(2.19 ± 0.02)10⁻²
5	0.9025	6	0.13-7.86	0.024	7.079 ± 0.054	(3.06 ± 0.01)10⁻²
6	0.8554	3	2.31-5.85	0.004	6.994 ± 0.027	(5.93 ± 0.00)10⁻²
7	0.9615	4	1.68-7.64	0.011	7.265 ± 0.027	(1.25 ± 0.02)10⁻²
8	1.000	7	0.95-9.5	0.030	7.406 ± 0.054	(8.28 ± 0.03)10⁻⁶

The densities of $Bi_2Te(l)$ obtained from the slopes of the h-H lines are plotted against temperature in Fig. 3. The error bars are placed at plus and minus one standard deviation in d. For comparison the density values obtained elsewhere using a pycnometer technique (11) are plotted as circles. Putting error bars on these data commensurate with their scatter would result in both sets of data overlapping above 700°C except for four of our points which appear to be high. The measurements giving the high densities do not show correspondingly high values of P_Σ.

Optical density measurements.—The spectrum of the vapor at 1273°K emanating from $Bi_2Te_3(l)$ at a lower temperature appears to be a superposition of the spectrum for $Te_2(g)$ and that of another species which shows vibronic bands between 2200 and 2450Å, where the $Te_2(g)$ spectrum has no structure. Runs using a pure Bi reservoir showed that the additional bands are not due to $Bi_2(g)$ or Bi(g). [These runs also showed that our detection limit for p_{Bi_2} is 10^{-5} atm. The value of p_{Bi_2} over $Bi_2Te_3(l)$ is below this limit even at the highest temperatures. The corresponding upper limit for p_{Bi}, calculated from the dissociation constant (12) of $Bi_2(g)$, is $2(10^{-4})$ atm.] We conclude that these additional bands are due to BiTe(g), which has been detected by mass spectrographic studies (13) as a major species over $Bi_2Te_3(l)$. The absorption band maxima are generally close to those obtained at higher resolution by Sharma (14), who also attributed them to BiTe(g). Between 2200 and 2345Å, Sharma reports 34 band heads with the strongest absorption at 2235Å. We observe 14 maxima in this region with the strongest absorption at 2231Å.

At the higher partial pressures of BiTe(g), p_{BiTe}, the relative optical densities of the strongest Te_2 peaks in the 1995-2056Å interval depart from the values ob-

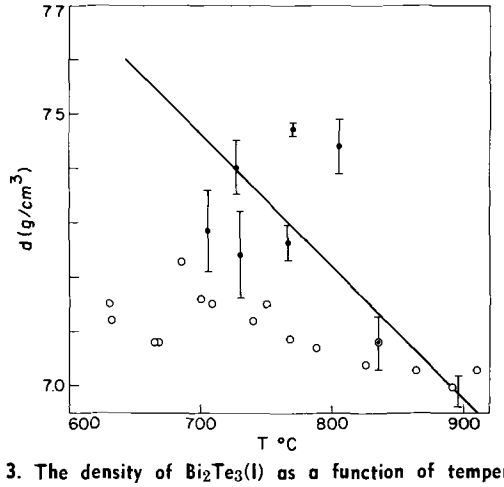

Fig. 3. The density of $Bi_2Te_3(l)$ as a function of temperature. Our points are shown with error bars at one plus and minus standard deviation. Circles are from ref. (11).

served with a pure Te reservoir (10), indicating that BiTe(g) absorbs to some extent in this interval. It does not absorb appreciably at 4357, 5000, or 5500Å, however, since the relative optical densities at these wavelengths are the same as those observed with pure Te. Therefore, the value of p_{Te_2} was obtained from the values of D at these three visible wavelengths by using the calibration curves obtained with a pure Te reservoir [Fig. 2 of ref (10)] and the vapor pressures of Te(l) given by Brooks (15) and by Ustygov (16), which are consistent with optical density measurements (17). The lowest straight line in Fig. 4 gives the values of p_{Te_2} for the 59.99 a/o Te melt plotted on a logarithmic scale against $10^3/T$. The corresponding equation is

$$\log_{10} p_{Te_2}\ (\text{atm}) = -(6.3048 \pm 0.032)\,(10^3/T) + (4.1396 \pm 0.030) \qquad 1.01 \geqq 10^3/T \geqq 0.85 \quad [5]$$

The values of p_{Te_2} calculated from Eq. [5] agree with the observed pressures to within ±2% for 17 of the 29 points obtained and to within ±3% for 22 points. The calculated and observed pressures differ by more than ±4% for only 3 points, where the differences are 4.3, 5.7, and 6.0%. Equation [5] is essentially a least squares fit of the data with the 3 high points omitted.

The partial optical densities of BiTe(g), r_λ, at four of its absorption maxima (2200, 2231, 2309, and 2319Å) were calculated by subtracting the contribution of Te_2-absorption at each wavelength from the total optical density observed. Taking the total optical density at 4357, 5000, and 5500Å as entirely due to Te_2(g), the contributions of Te_2(g) to the absorption at the wavelengths in the uv were read from a graph giving log D_λ as a function of the reciprocal temperature of a pure Te(l) reservoir [see Fig. 2 of ref. (10)]. The partial optical densities of BiTe(g) obtained in this way are shown as the upper four lines in Fig. 4, where r_λ is plotted on a logarithmic scale against $10^3/T$. Results are given for both the 99.9 mm path length cell and the 22.4 mm cell. The values of r_λ for the latter are normalized to 99.9 mm by multiplication by the factor 99.9/22.4. It is seen that the data for the four wavelengths are well represented by four parallel straight lines, consistent with the assumption that they represent absorption by a single vapor species that satisfies Beer's law. At 2231Å, 85-90% of the total absorption is due to BiTe(g). This percentage decreases with increasing wavelength to 62-68% at 2319Å. The partial optical densities of BiTe(g) satisfy the equations

$$r_{2231} : r_{2220} : r_{2309} : r_{2319} = 100 : 46.5 : 31.2 : 18.7 \quad [6]$$

$$\log_{10} r_{2231} = -(8.978 \pm 0.207)\,(10^3/T) + (8.8041 \pm 0.195) \quad [7]$$

where r_{2231} is the partial optical density at 2231Å for a 99.9 mm path length at 1273°K. The uncertainties quoted are the standard deviations of the slope and intercept obtained in a least squares fit of 65 points in which the data at the other three wavelengths were converted to the equivalent value at 2231Å using Eq. [6]. The standard deviation in log r_{2231} is 0.079.

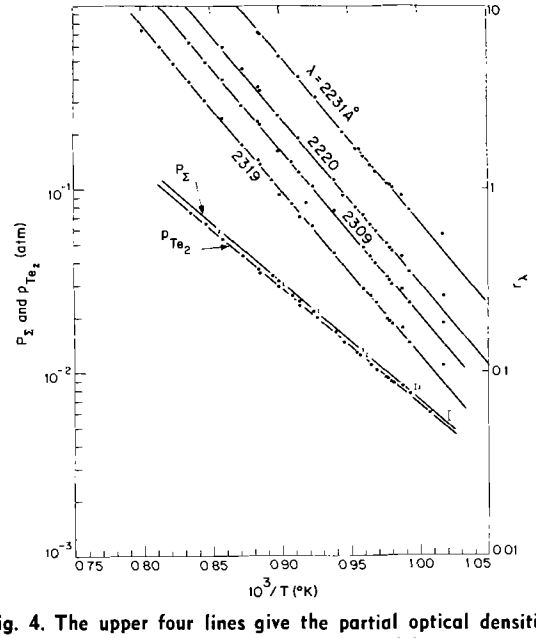

Fig. 4. The upper four lines give the partial optical densities of BiTe(g) at the indicated wavelengths for a 99.9 mm optical path length at 1273°K, plotted on a logarithmic scale (on the right side of the figure) as a function of the reciprocal temperature of Bi_2Te_3(l). The bottom two lines are semi-logarithmic plots on the same scale of the pressures over Bi_2Te_3(l) as a function of reciprocal temperature. The lower of these gives p_{Te_2} as determined by optical density measurements, and the upper gives P_Σ as determined by the manometric method.

Discussion

The values of total vapor pressure, P_Σ, for Bi_2Te_3(l) given in Table I are plotted on a logarithmic scale against $10^3/T$ in Fig. 4. The line representing the data, which for reasons discussed below was not obtained from a least squares fit, is given by

$$\log_{10} P_\Sigma\ (\text{atm}) = -6.4691(10^3)/T + 4.3219 \qquad 1.02 \geqq 10^3/T \geqq 0.85 \quad [8]$$

It is seen that this line fits five of the eight experimental points within the error bars shown (fixed at plus and minus one standard deviation in P_Σ), but the three points at the lowest temperatures lie somewhat above the line. The line is almost parallel to Ustygov's line for P_Σ, an extrapolation of which is shown in Fig. 1, but our P_Σ values are about 35% less than his. Our line for P_Σ lies just above the line for p_{Te_2} obtained by the optical density measurements and has a slope intermediate between that for p_{Te_2} and those giving the partial optical densities, r_λ, of BiTe(g).

From the discussion under Optical density measurements, the sum of the partial pressures of Bi_2 and Bi is below $2(10^{-4})$ atm and therefore is less than 3% of $P_\Sigma - p_{Te_2}$ at the highest temperatures. Consistent with this result and with extensive optical density measurements on Bi-Te melts to be published elsewhere, it appears that $p_{BiTe} + p_{Te_2}$ is within 3% of the total vapor pressure of Bi_2Te_3(l) over the entire temperature range. Therefore to a good approximation we can write

$$P_\Sigma = p_{Te_2} + p_{BiTe} \quad [9]$$

We also assume, consistent with experimental observations on a number of molecular species, that the optical absorption of BiTe(g) obeys Beer's law

$$p_{BiTe}(\text{atm}) = \alpha r_{2231} \quad [10]$$

where α is the Beer's law constant for a 99.9 mm path length at 1273°K. Using Eq. [7] for r_{2231} as a function of $10^3/T$ and obtaining p_{BiTe} by substituting Eq. [5] and [8] into Eq. [9], α as a function of temperature can be calculated from Eq. [10]. The values of α obtained in this way remain constant within about 8% over the interval 0.85-1.00 in $10^3/T$, ranging from $4.18(10^{-4})$ at the extremes of this range to $4.53(10^{-4})$ near the middle. We do not believe this variation to be excessive in view of the fact that p_{BiTe} is a small difference between the nearly equal quantities P_Σ and p_{Te_2}. Any adjustment in the P_Σ line to obtain a better fit to the experimental data at the three lowest temperatures, while still maintaining a close fit at high temperatures, leads to a significantly larger variation in α. Thus Eq. [8], rather than an equation obtained by a least squares fit, has been adopted as the best line through the P_Σ data in view of all the data. It leads to a temperature dependence for p_{BiTe} most nearly the same as that observed for the partial optical

densities for BiTe(g) given by Eq. [7]. The use of Ustygov's equation for P_Σ gives values for α that vary by more than a factor of 2 between $10^3/T = 0.85$ and 1.00.

The partial pressure of BiTe(g), p_{BiTe}, is obtained from Eq. [7] and [10] with an average value of $4.35(10^{-4})$ for α as

$$\log_{10} p_{BiTe}(\text{atm}) = -8.978(10^3)/T + 5.4432 \quad [11]$$

There are two points to be emphasized in connection with Eq. [11]. Although p_{Te_2} appears to be given to within about $\pm 3\%$ by Eq. [5] and P_Σ to within some less well-defined percentage, say $\pm 10\%$, by Eq. [8], p_{BiTe}, being the difference of these nearly equal quantities, is much more uncertain. Although the temperature dependence of p_{BiTe} is known to within 2% through Eq. [7] and [10], the absolute value could be in error by 50-100%. Second, although the total pressure must be constant throughout the optical cell and side-arm, because of the temperature difference between the optical cell and sidearm, p_{Te_2} and p_{BiTe} may vary due to the chemical dissociation of BiTe(g) and thermal diffusion. Thus p_{Te_2} given by Eq. [5] and p_{BiTe} given by Eq. [11] are the partial pressures in the 1273°K optical cell, but these may differ somewhat from the values prevailing over the Bi_2Te_3 melt in the sidearm reservoir. These differences are greatest at the lowest reservoir temperatures.

Some indication of the thermal effects can be gained by comparing the present results with our earlier measurements (5) using a 1028°K optical cell. For a 59.99 a/o Te melt at 1000°K the value of p_{Te_2} was $6.2(10^{-3})$ atm, the partial optical density of BiTe at 2231Å for a 99.9 mm path was 1.03, and the partial pressure of Bi_2 was below the experimentally detectable limit of about 10^{-5} atm. The reservoir and optical cell temperatures in this case were close enough to make thermal effects negligible, and the value of p_{Te_2} over $Bi_2Te_3(l)$ at 1000°K can be taken as the measured value of $6.2(10^{-3})$ atm. The 10% higher value of $6.83(10^{-3})$ atm obtained in the present study with a 1273°K cell is due to the increased degree of dissociation of BiTe(g) at this higher cell temperature. The values of p_{Te_2} obtained here with a 1273°K optical cell will differ even less from the actual value of p_{Te_2} over the $Bi_2Te_3(l)$ at higher melt temperatures. Therefore we can conclude that p_{Te_2} over $Bi_2Te_3(l)$ is given correctly to within 10% by Eq. [5]. Therefore $Bi_2Te_3(l)$ is not congruently vaporizing between 1000° and 1169°K. Taking the difference between P_Σ and p_{Te_2} as equal to p_{BiTe}, the vapor is more than 95 a/o Te, rather than 60 a/o Te. At 1000°K, even if the difference of $9.1(10^{-4})$ atm between P_Σ and p_{Te_2} were due to Bi_2 rather than BiTe, the vapor would be 87 a/o Te.

Extrapolation of Eq. [8] to 860°K, the maximum melting point of $Bi_2Te_3(c)$, gives $P_\Sigma = 6.4(10^{-4})$ atm. This is a factor of 4.2 higher than the extrapolated P_Σ value from ref. (2) and (3) and a factor of 11.6 higher than the extrapolated value from ref. (4), the first two obtained by effusion measurements on the assumption that effusion is congruent according to reaction [1]. It would appear from present results that serious doubt is cast on the validity of the sublimation reaction given by Eq. [1]. We suggest that this discrepancy results because reaction [1] is not valid for the Knudsen effusion nor for equilibrium sublimation of $Bi_2Te_3(c)$, and therefore the calculations of P_Σ from the effusion data are incorrect. Preliminary analysis of the earlier optical absorption results (5) and our present results supports the conclusion that $Bi_2Te_3(c)$ does not sublime congruently.

Preparation and Electrical Resistivity of Ultrahigh Purity Niobium[1]

R. W. Meyerhoff

Union Carbide Corporation, Linde Division, Tarrytown Technical Center, Tarrytown, New York 10591

ABSTRACT

Niobium samples with residual resistivity ratios greater than 20,000 were prepared *via* a two-step process. First, a fused salt electroplating process was used to prepare niobium having an exceptionally high purity with respect to the substitutional transition metal impurities tantalum and tungsten. Second, this electroplated niobium was vacuum degassed to remove the interstitial impurities, oxygen, nitrogen, and hydrogen. The major contributions to the residual resistivity after vacuum degassing were from the impurities nitrogen, tantalum, and tungsten. The electrical resistivity of these ultrahigh purity niobium samples can be calculated from the relation

$$\rho_T = \rho(T) + 10.0 \times 10^{-6} C_{N2} + 2.49 \times 10^{-7} C_{Ta} + 11.0 \times 10^{-7} C_W \text{ ohm-cm}$$

where $\rho(T)$ represents the thermal contribution to the resistivity at the temperature T and C_{N2}, C_{Ta}, and C_W represent respectively the concentrations in atomic per cent of nitrogen, tantalum, and tungsten. The value of C_{N2} for the vacuum degassed samples is given by

$$C_{N2} = 6.2 \times 10^{-4} (p_{N2})^{1/2} \exp (23{,}000/T)$$

where p_{N2} represents the partial pressure (Torr) of nitrogen in the vacuum system and T represents the temperature (K) of the sample during outgassing.

This study of the preparation and electrical resistivity of ultrahigh purity niobium was prompted by the observation that the a-c losses in superconducting niobium wire samples decreased as the residual resistivity of these samples decreased (1). Thus, it was hoped that if those factors most strongly affecting the residual resistivity were identified it might then be possible to prepare niobium samples with lower residual resistivities and hence lower a-c losses.

In 1962 Stromberg and Swenson (2) reported the preparation of niobium with a residual resistivity ratio ($\rho 293/\rho 4.2$) of ~2,000. This value, the highest obtained prior to this work, was attained by vacuum degassing a niobium wire at a temperature close to its melting point at a pressure of the order of 10^{-9} Torr. Attempts by others to achieve significantly higher residual resistivity ratios by either vacuum degassing and/or electron beam zone refining were unsuccessful. In some cases the highest residual resistivity ratios attained were as small as 100-500. Some of these low values can be explained by the low temperatures and/or poor vacuum used to degas the niobium. One significant difference between these studies, however, was the tantalum concentration in the starting material. Stromberg and Swenson had used niobium containing less than 200 ppm tantalum while many of the other studies were made with niobium containing as much as 1,000 ppm tantalum. No attempts to attain high residual resistivity ratios have been reported in which niobium containing less tantalum than that in the niobium used by Stromberg and Swenson was used as the starting material. Two conclusions were drawn from this early work. First, electron beam zone refining of niobium does not result in any significant reduction of the tantalum content. Second, in general the highest residual resistivity ratios were reported by those investigators using niobium with the lowest tantalum content.

With the exception of cases where the impurities were present in the form of precipitates rather than in solid solution most elements previously prepared with exceptionally high residual resistivity ratios contained considerably less than 100 ppm total impurities. Previous attempts to produce ultrahigh purity niobium started with niobium containing about 200 ppm tantalum in addition to the other impurities present. This new look at the preparation of ultrahigh purity niobium was prompted in part by the development of Mellors and Senderoff (3) of a fused salt electroplating process which provided a means of preparing niobium samples containing less than 10 ppm tantalum. The work described in the remainder of this paper demonstrated that tantalum was indeed the culprit and other factors such as thermal scattering, lattice defects, dislocations, grain boundaries, *etc.* cannot account for the resistivity at 4.2K previously observed by others in "high purity" niobium.

Experimental Procedure

The first step in the preparation of the ultrahigh purity niobium samples was the formation of sheets of niobium having a low tantalum content by means of a fused salt electroplating process. Only a brief description of this process is given below since it has been described in considerable detail by Mellors and Senderoff (3). The electrolyte was prepared by melting, in a graphite crucible under an argon atmosphere, a salt mixture containing 26.2 weight per cent (w/o) LiF, 10.5 w/o NaF, 47.1 w/o KF, and 16.2 w/o K_2NbF_7. During plating this electrolyte was maintained at 775°C. Commercial niobium sheet was used for the anode and OFHC copper sheet for the cathode. The niobium was electrodeposited at a current density of 25 mA/cm^2, corresponding to a deposition rate of ~25 μ/hr. The plated niobium metal was removed from the copper cathode by dissolving the copper in a 1:1 mixture of HNO_3:H_2O. These niobium sheets were typically 3x10x0.5 cm.

The first niobium plated from a new electrolyte will contain less than 2 ppm tantalum; however, since this is considerably less than the tantalum concentration in the niobium anodes the tantalum concentration in the electrolyte will increase as plating is continued with a concomitant small increase in the tantalum concentration in the electroplated niobium. Although the as-plated niobium has a low tantalum content the concentration of interstitial impurities, especially oxygen and nitrogen, are sufficiently high to limit the residual resistivity ratio to a value less than 70. Thus, in order

[1] This work was supported in part by the Air Force Materials Laboratory under contract number AF 33 (615)-5393.

Key words: ultrahigh vacuum degassing, residual resistivity, low tantalum niobium.

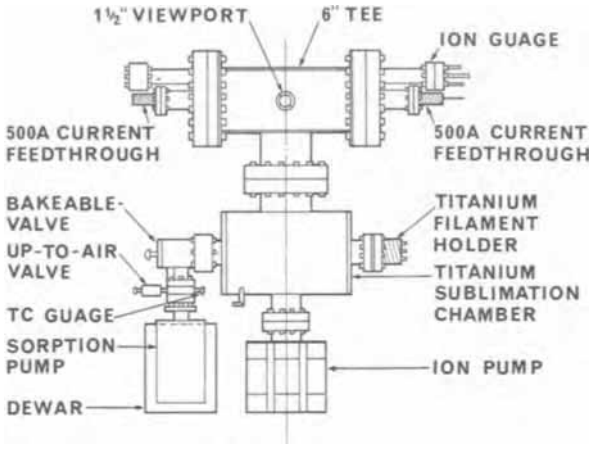

Fig. 1. Schematic of vacuum system used for degassing niobium samples.

to obtain very high residual resistivity ratios it is necessary to lower the concentration of the interstitial impurities by vacuum degassing the electroplated niobium.

The vacuum system used to degas the electroplated niobium samples is illustrated in Fig. 1. Liquid nitrogen cooled molecular sieve (Linde 5A) was used for rough pumping. The ultrahigh vacuum pumping system consisted of a 50 liter/sec ion pump and a 1,000 liter/sec titanium sublimation pump. At pressures below 10^{-4} Torr the pressure was determined from both the current *vs.* pressure calibration curve for the ion pump and a nude Bayard-Alpert gauge mounted adjacent to the sample as illustrated in Fig. 1. The sample temperature was measured with an optical pyrometer sighted on the samples through a 1.5 in. diameter view port. The samples were mounted between the ends of the two 500A electrical feed throughs by means of copper clamps such as that illustrated in Fig. 2. The only flange that had to be opened to change both the niobium samples and the titanium elements in the sublimator was that between the sample chamber and the titanium sublimator chamber.

Generally, samples in the form of ribbons 12.0 x 1.0 x 0.025 cm, cut from sheets produced by cold rolling the thicker electroplated sheets, were used. The samples were resistively heated by means of a d-c current. The samples were degassed for several days at temperatures up to 2700°K at pressures as low as 3×10^{-10} Torr. The ribbon-like shape of the samples and the use of a d-c current were chosen in the hope that some additional degree of purification could be obtained during the vacuum degassing by means of electrotransport refining. At 2700°K the d-c heating current used corresponded to a current density within the samples of $\sim 1 \times 10^4$ A cm^2 and an electric field of ~0.7 V/cm.

The following procedure was used to determine the residual resistivity ratio of the vacuum degassed niobium samples. The niobium ribbon was mounted in

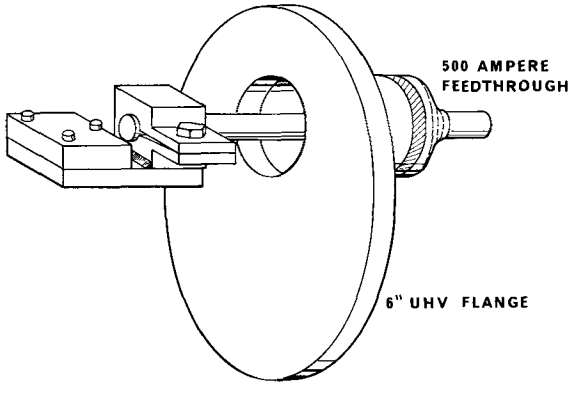

Fig. 2. A clamp used to hold samples during vacuum degassing

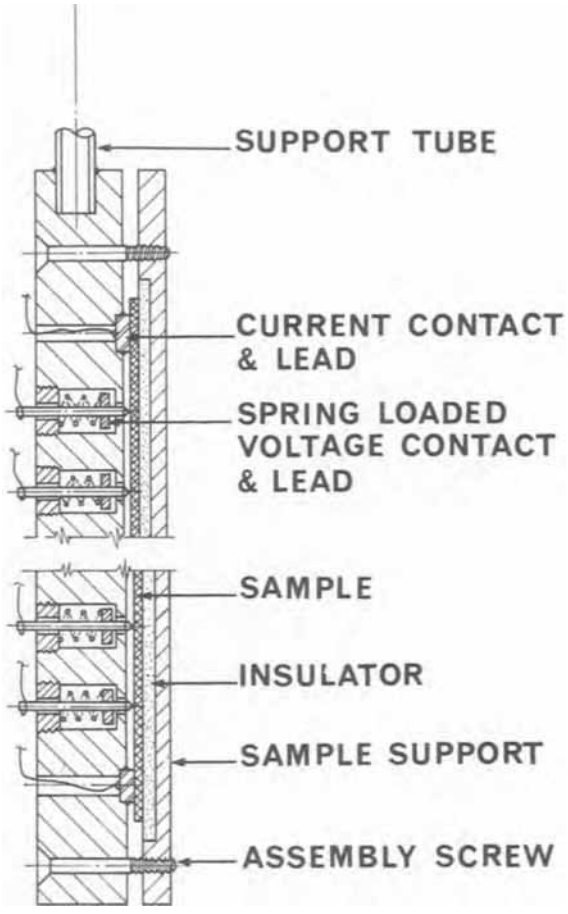

Fig. 3. Schematic of sample holder used in electrical resistivity measurements.

the sample holder illustrated schematically in Fig. 3. Current was supplied to the sample through the copper contacts at either end of the holder. The nine voltage probes are spring-loaded and were constructed from copper wire. Each of the probes was connected to two Leeds and Northrup rotary switches, the moving contacts of which were connected to one half of a Rubicon double six dial potentiometer. Thus, the voltage drop between any two of the nine voltage probes could be measured. In this way it was possible to look for any small variation in electrical resistivity along the length of a sample which might be attributable to electromigration of one or more impurities. The second half of the potentiometer was used to measure the voltage drop across a standard resistor in series with the sample. The sample current, usually $\sim 10^{-1}$A, was calculated from this voltage drop. A Keithley Model 147 Nanovolt Null Detector served as the null detector for the potentiometer.

Since niobium is a superconductor, a magnetic field large enough to destroy the superconducting state was used in all the measurements of the residual resistivity. Considerable care was taken, however, to ensure that the sample was as close as possible to being parallel to the applied magnetic field since the transverse field magnetoresistance of niobium is quite large and would lead to anomalously high values of the residual resistivity. Measurements made between 5 and 60 kg with the applied magnetic field parallel to the sample axis generally showed an increase of less than 10% in the residual resistivity over this field range.

Results and Discussion

The highest purity niobium sample prepared had a residual resistivity ratio, β, of ~22,500. This sample was prepared by vacuum degassing an electroplated niobium ribbon at ~2700°K at a pressure of $\sim 2 \times 10^{-10}$ Torr. However, while this sample had by far the

highest value of β ever reported for niobium, its residual resistivity ratio was still significantly below values which have been obtained for a few other elements. It is of interest, therefore, to examine the factors which limited the value of β for this sample.

If the electron mean free path is sufficiently short so that size effects, *i.e.* surface scattering, are negligible, Matthiessen's rule is applicable. The resistivity is then given by

$$\rho(T) = \rho_L(T) + \Sigma\, \rho_d + \Sigma\, \rho_i \qquad [1]$$

where $\rho_L(T)$ represents the temperature dependence of the electrical resistivity of the pure defect free metal. The terms $\Sigma\, \rho_d$ and $\Sigma\, \rho_i$ represent respectively the temperature independent contributions from defects and impurities. The assumption that size effects are negligible is questionable; however, the data required to calculate the electron mean free path are not known with sufficient accuracy to permit a precise calculation of the magnitude of the size effect. It is possible that the actual bulk residual resistivity ratio may be as much as five times greater than the 20,000 measured. However, measurements made on thicker samples than the 0.25 mm thick ribbons discussed in this paper invariably showed higher residual resistivities than the thin samples due to the difficulties associated with degassing these thicker samples. Thus, no direct evidence of a size effect limited resistivity was observed.

For most metals the term $\rho_L(T)$ in Eq. [1] can be calculated from the Grüneisen-Bloch relation (4)

$$\rho_L(T) = \frac{KT}{\theta_R^2}\, G(X) \qquad [2]$$

$$X = \theta_R/T$$

where K is a constant, θ_R is a characteristic temperature, and $G(X)$ is given by the relation

$$G(X) = 4\,\frac{T^4}{\theta_R} \int_0^X \frac{Z\ dZ}{(e^z - 1)(1 - e^{-z})} \qquad [3]$$

Assuming that $\theta_R = \theta_D = 240$ K and using tabulated values (4) of $G(X)$, one finds from Eq. [2], $\rho 295/\rho 4.2 = 10^6$. This relation, which predicts $\rho_L(T) \propto T^5$ at low temperatures, does not take into account the contributions at low temperature of either electron-electron scattering or Umklapp processes both of which tend to increase the value of the electrical resistivity at low temperatures. These would then lead to a smaller value of $\rho 295/\rho 4.2$ than that calculated from Eq. [2]. The results of White and Woods (5, 6), and of Webb (7) show that $\rho_L(T) \propto T^n$, where $n \approx 3$ at low temperatures. Thus, the electrical resistivity of niobium decreases less rapidly with temperature than would be expected from the Grüneisen-Bloch relation and one would not expect a value of $\rho 295/\rho 4.2 = 10^6$ even for an absolutely pure defect-free niobium sample.

Electrical resistivity measurements made on a number of samples degassed at different temperatures and pressures showed a difference in resistivity of $\sim 3.8 \times 10^{-10}$ ohm-cm between 4.2 and 1K. If one assumes that this difference is only due to the thermal contribution to the resistivity and is independent of the impurity concentrations and that the thermal contribution varied as T^3, then the first term in Eq. [1] at low temperature may be expressed as

$$\rho_L(T) = 5.14 \times 10^{-12}\, T^3 \text{ ohm-cm} \qquad [4]$$

Since $\rho 295 \approx 14 \times 10^{-6}$ ohm-cm this expression predicts values of $\rho 295/\rho 4.2$ and $\rho 295/\rho 1.0$ respectively of ~37,000 and ~5,100,000. While these values are significantly lower than those calculated from the Grüneisen-Bloch relation, they are much larger than the experimentally observed values. Thus, it is clear that thermal scattering is not limiting the value of the residual resistivity ratio measured at 1K in samples with values of $\rho 295/\rho 4.2 \approx 20{,}000$.

I will next consider the contribution of defects to the residual resistivity (the second term in Eq. [1]), in particular the contributions of dislocations, grain boundaries, and vacancies are estimated. Nordheim's concentration rule (8) states that the contribution of an impurity to the resistivity is proportional to $x(1 - x)$ where x represents the mole fraction of the impurity. In this discussion it will be assumed that the concentration of the individual impurities and defects are sufficiently low so that Nordheim's rule may be approximated by

$$\rho_i \propto x_i \qquad [5]$$

Although the effect of dislocations on the electrical resistivity of niobium has not been determined experimentally, studies of other metals (9) indicate that

$$\rho_{\text{dislocation}} \approx 5 \times 10^{-19}\, N \text{ ohm-cm} \qquad [6]$$

where N is the dislocation density in lines/cm^2. The exact value of the dislocation density in this material is not known. However, studies of the anomalous transmission of x-rays in this material by Weissman (10) showed that the dislocation density was less than 10^4 lines/cm^2. A dislocation density as high as 10^4 lines/cm^2, in the absence of other impurities or defects, would limit the residual resistivity ratio to $\sim 3 \times 10^9$. In the case of a sample with a residual resistivity ratio of 20,000 a dislocation density of 10^7 lines/cm^2 would contribute less than 1% of the measured residual resistivity. Thus it appears that the contribution of dislocations to the residual resistivity of these samples is negligible.

One approach to evaluating the contribution of grain boundaries to the electrical resistivity of metals is to treat the boundary as a region approximately 2 atomic distances wide (9) and having a resistivity equal to the resistivity of the metal at its melting point ρMP. In this way one can calculate, assuming $\rho_{MP} = 60$ μohm-cm, that each grain boundary the current must cross contributes a resistance of 3×10^{-12} ohm. In the high purity vacuum outgassed and annealed niobium samples there are approximately three grain boundaries per centimeter. Thus, the boundaries would contribute $\sim 1 \times 10^{-11}$ ohm-cm to the electrical resistivity at 4.2K, *i.e.* approximately 1% of the measured resistivity. Measurements by Andrews (11) of the effect of grain boundaries on the electrical resistivity of copper gave a value about six times greater than that obtained by assuming the grain boundary to be a layer 2 atomic distances thick with a resistivity $\sim\rho_{MP}$. In either case, the contribution of grain boundaries is still relatively small. In some of the high purity niobium samples prepared in this laboratory there were single grains large enough so that their electrical resistivity could be measured. The values measured on those single crystals were not significantly different from those measured at other positions in the sample where the resistance across one to five grain boundaries was included. Thus it appears that the contribution of grain boundaries to the residual resistivity of these samples is negligible.

Both theoretical and experimental investigations (9) of the effect of vacancies on the resistivity of metals give values of approximately 2×10^{-6} ohm-cm/atomic per cent (a/o) vacancies. The ratio of the number vacancies, n, to the number of lattice sites, N, at any temperature T is given by

$$\frac{n}{N} = \exp(-U/RT) \qquad [7]$$

where U is the energy of formation of one mole of vacancies and R is the gas constant. Although U is not known for niobium, Frenkel (12) has given a simple argument for estimating U, which shows that U should roughly be equal to the heat of vaporization.

The maximum number of vacancies one would expect to find in a well-annealed metal would be the number in thermal equilibrium at the melting point if the quench rate were high enough to retain that number. For niobium using 2733°K as the melting point and $H_{vap} = 170$ kcal/mole, one obtains

$$\frac{n}{N} = \exp(-31.1) = 10^{-13.5} \quad [8]$$

which corresponds to approximately 3×10^{-12} a/o vacancies. In order for the residual resistivity ratio to be limited by vacancies to a value of 20,000 a vacancy concentration of 3.5×10^{-4} would be required. If $U \approx 0.4\ H_{vap}$ the vacancy concentration would be this high at the melting point. It is highly unlikely however, since several seconds are required for the sample to cool below 1000°K, that an appreciable number of the vacancies in thermal equilibrium at the melting point would be quenched in by such slow cooling rates. Furthermore, as the degassing temperature was increased, and all other parameters being held constant, the residual resistivity decreased. If quenched in vacancies were a significant contributor to the residual resistivity one would see an increase rather than a decrease in this quantity as the degassing temperature was increased.

It appears, therefore, that in these niobium samples, having residual resistivity ratios as high as 20,000, the contributions to the resistivity of vacancies, dislocations and grain boundaries may be ignored. In the remainder of this section I will discuss the contribution to the residual resistivity of the last term in Eq. [1], namely the contributions to the residual resistivity by impurities.

The major substitutional impurities in these niobium samples were tantalum and tungsten. The concentrations of these two elements were respectively 7 and 1.8 ppm corresponding to 3.6×10^{-4} a/o tantalum and 9×10^{-5} a/o tungsten. Electrical resistivity measurements made on a vacuum annealed and degassed sample of niobium containing 0.08 a/o tantalum gave a value of $d\rho/dc$ of 2.49×10^{-7} ohm-cm/a/o tantalum. Similar measurements were made on a vacuum degassed sample of Cb 752, a commercial niobium alloy having a nominal composition of 5 a/o tungsten and 2.5 a/o zirconium. After vacuum degassing the sample was analyzed to determine the tungsten and zirconium concentration as a considerable fraction of the zirconium was removed during the vacuum degassing. A value of 11×10^{-7} ohm-cm/a/o tungsten was calculated from the measured residual resistivity after subtracting the contribution from the zirconium which was calculated from the measured zirconium concentration using the value of 12.0×10^{-7} ohm-cm/a/o zirconium found by Berlincourt and Hake (13). These results along with values of $d\rho/dc$ for other elements dissolved in niobium are given in Table I.

For these electroplated and vacuum degassed niobium samples the substitutional impurities tantalum and tungsten contribute 1.9×10^{-10} ohm-cm to the residual resistivity. For a sample having a residual resistivity ratio of 22,500 the residual resistivity is 6.2×10^{-10} ohm-cm. This leaves a residual resistivity of 4.3×10^{-10} ohm-cm to be accounted for by the interstitial impurities. Of the four interstitial impurities, carbon, hydrogen, nitrogen, and oxygen only the last two are of importance in this analysis since the carbon concentration is very low due to the nature of the electroplating process and hydrogen is reduced to negligible levels by the vacuum degassing. Cost and Wert (17) have found for nitrogen that

$$C_{N_2} = 6.2 \times 10^{-4} (P_{N_2})^{1/2} \exp(23{,}000/T) \quad [9]$$

where C_{N_2} is the atomic per cent nitrogen and P_{N_2} is the partial pressure of nitrogen (Torr). From Eq. [9] one finds, for a niobium sample vacuum degassed at 2×10^{-10} Torr and 2700°K, a nitrogen concentration of 4.6×10^{-5} a/o. Using this value and the value of $d\rho/dc$ for nitrogen given in Table I, one obtains a value of 4.6×10^{-10} ohm-cm for the contribution of nitrogen to the residual resistivity. This is indeed quite close to the value of 4.3×10^{-10} ohm-cm left to be accounted for in a sample degassed under these conditions. It has been often suggested that oxygen is a larger contributor than nitrogen to the residual resistivity of vacuum degassed niobium samples. However, in the present study I have found a good fit to the experimental results when I assumed the partial pressure of nitrogen was equal to the measured total pressure and used Eq. [9] to calculate the nitrogen concentration and hence nitrogen's contribution to the residual resistivity. Similar calculations based on the concentration of oxygen gave totally unsatisfactory results since at the temperatures and pressures used for the vacuum degassing the calculated oxygen concentration was considerably lower than the calculated nitrogen concentration and made a negligible contribution to the residual resistivity.

Table I. Values of $d\rho/dc_A$ for A dissolved in niobium

A	$d\rho/dc$, ohm-cm/a/o A	Ref.
Titanium	14.3×10^{-7}	Berlincourt and Hake (13)
Titanium	9.6×10^{-7}	Fietz (14)
Zirconium	12.0×10^{-7}	Berlincourt and Hake (13)
Hafnium	14.0×10^{-7}	Berlincourt and Hake (13)
Tantalum	2.49×10^{-7}	This work
Tungsten	11.0×10^{-7}	This work
Oxygen	69.0×10^{-7}	Tedmon, Rose, and Wulff (15)
Nitrogen	100.0×10^{-7}	Pasternak and Evans (16)

Summary

The analysis of the residual resistivity of niobium samples presented in the previous section showed that at low temperatures where the thermal contribution to the resistivity varies as T^3 the resistivity of electroplated and vacuum degassed samples is given by

$$\rho(T) = 5.14 \times 10^{-12} T^3 + 10.0 \times 10^{-6} C_{N_2} + 2.49 \times 10^{-7} C_{Ta} + 11.0 \times 10^{-7} C_W \quad [10]$$

where the value of C_{N_2}, which depends on the degassing temperature and pressure, is given by Eq. [9]. In Fig. 4 lines of constant nitrogen concentration calculated from Eq. [9] are shown as a function of vacuum degassing temperature and pressure. Values

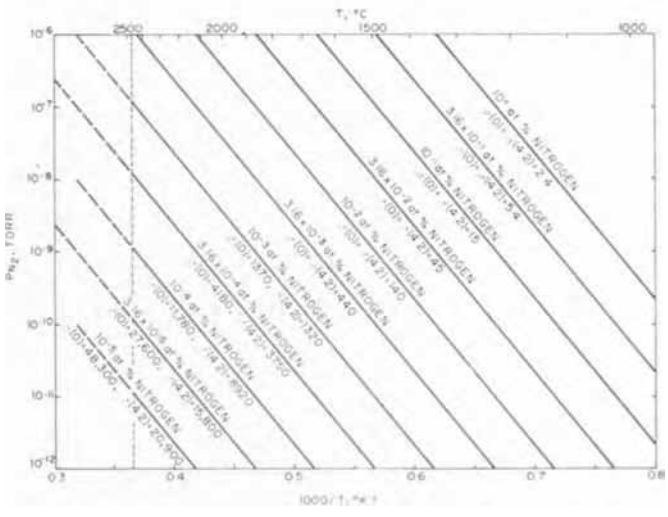

Fig. 4. Lines of constant nitrogen concentration calculated from Eq. [9] and values of resistivity ratios between room temperature and both 0 and 4.2K calculated from Eq. [10] for electroplated niobium containing 7 and 1.8 ppm respectively of tantalum and tungsten.

of the resistivity ratio, between room temperature and both 0 and 4.2K, calculated from Eq. [10] are also given in Fig. 4 for samples containing 7 and 1.8 ppm respectively of tantalum and tungsten. Although the analysis given above contains some assumptions, the agreement between calculated and measured resistivities was within 20% for the samples studied. This included samples vacuum degassed between 1400° and 2700°K at pressure in the range 10^{-7} -2 x 10^{-10} Torr.

Acknowledgments

The author wishes to express his appreciation to W. J. Runkle for his valuable assistance in the experimental part of this work and to Dr. D. C. Freeman, Jr. for his keen interest and helpful discussions.

Growth, Texture, and Surface Morphology of SiC Layers

Kenneth A. Jacobson[1]

Solid State Research and Development, Dow Corning Corporation, Hemlock, Michigan 48626

ABSTRACT

Highly oriented SiC layers were grown on (001) and (111) silicon substrates by the reduction of $(CH_3)_2SiCl_2$ in an excess of hydrogen at a temperature of 1365°C. Layers up to $\approx 100\mu$ thick were grown at a rate of 4.3 μ/min. The material was predominantly β-SiC with a resistivity range of 0.5-34.5 ohm-cm, n-type. Laue x-ray analysis indicated that the degree of preferred orientation varied with thickness and that multiple orientations exist on the (001) silicon substrates. A higher degree of preferred orientation was achieved on the (001) compared to the (111) substrates. At various thicknesses, faceted grains on the order of 1-2μ in diameter were visible using the scanning electron microscope. The fact that oriented growth was achieved at higher than typical CVD rates for epitaxy suggests that detrimental effects such as substrate evaporation or impurity deposition were overcome by the higher deposition rate.

SiC has been deposited on a variety of substrates for electronic and protective coating uses. For the latter application, attempts are made to achieve high density, small grained polycrystalline deposits (1). On the other hand, noninsulating electronic applications usually require single crystalline epitaxial layers. Device quality α-SiC layers deposited on α-SiC substrates have been achieved (2, 3) and various techniques for SiC deposition on substrates other than SiC have met with some success although not enough to warrant large scale device production (4).

Approaches to the formation of β-SiC films on silicon have included vapor deposition from organosilanes or separate silicon and carbon containing compounds (5, 6), the reaction of carbon or hydrocarbons with hot silicon (6-9), and the immersion of very hot silicon into organosilane liquids (10). The failure to achieve high quality β-SiC layers on silicon substrates using chemical vapor deposition has never been formally explained. It may involve the high thermal etch rate of the silicon substrates at growth temperatures which allow enough surface diffusion for epitaxy to occur (11). Even at the growth temperature limit, the surface mobility of deposited SiC may still be too low. In addition, the role of impurities in the reactants has not been assessed for this system.

In the course of investigating SiC deposition on silicon by the reduction of $(CH_3)_2SiCl_2$, we found that at normal epitaxial growth rates (0.05 to 1.0 μ/min), some preferred orientation was achieved in the SiC film, but increasing the growth rate by a factor of 5 to 100 increased the orientation at greater thicknesses. Consequently, the growth and structure of these thicker layers was studied. Bean and Gleim (12) also studied SiC growth on silicon at higher growth rates and observed some epitaxial material; however, their interest was in polycrystalline films which were hard, chemically stable, and of high resistivity.

Growth

Deposition system and process definition.—Layer growth was done in a horizontal quartz tube epitaxial reactor. The silicon substrates were heated on a SiC coated graphite susceptor coupled to an external rf coil. The liquid feed materials, $SiCl_4$ for silicon deposition and $(CH_3)_2SiCl_2$ for SiC deposition, were va-

[1] Present address: Department of Biophysical Sciences, State University of New York at Buffalo, Amherst, New York 14226.

Key words: semiconductors, ceramics, structural analysis, chemical vapor deposition, thin films.

porized and carried through the reactor by hydrogen. Depositions were done at a total pressure of 1 atm.

The substrates ranged in surface finish from as-cut to chemically polished (15:5:2, HNO_3:HF:HAc). In the reactor, the substrate was etched first in hydrogen and then by HCl vapor, both at 1250°C. Then a 10μ thick silicon epitaxial layer was deposited via the thermal reduction of $SiCl_4$ with H_2 at 1250°C. Next, SiC was deposited by the vapor reaction of $(CH_3)_2SiCl_2$ and hydrogen. Typical SiC deposition conditions were: (*a*) mole ratio ($[CH_3]_2 SiCl_2/H_2$) = 5 x 10^{-3}, (*b*) total flow rate of 2.5 liters/min, (*c*) growth temperature of 1365°C, and (*d*) growth times of <1-40 min.

The SiC deposition was extremely sensitive to input reactant purity: oriented growth would occur only using an ultra-pure grade of hydrogen in conjunction with triply distilled $(CH_3)_2SiCl_2$. The $(CH_3)_2SiCl_2$ feed, when decomposed to yield a SiC coating on thin tungsten filaments, typically gave material with less than 2 ppma total impurities (exclusive of N_2, O_2, and Au) as measured by solid-state mass spectroscopy (13).

Oriented SiC growth was found to occur over relatively narrow deposition condition ranges:

1. Mole ratio ($[CH_3]_2SiCl_2/H_2$) : <5 x 10^{-3} to 2 x 10^{-2}
2. Total flow rate: 1 to 2.5 liters/min
3. Growth temperature: 1315° to 1400°C.

Note that substrate temperatures within 100°C of the silicon melting point were required. We found that oriented growth on the (100) as-cut silicon surface was much easier to achieve than on the (111) silicon surface; it appeared to be less sensitive to impurity concentrations in the $(CH_3)_2SiCl_2$ feed material. Rai Choudhury and Formigoni (6) have reported that in thinner SiC depositions from $(CH_3)_2SiCl_2$, growth on the (100) silicon substrates shows a single preferred orientation while growth on (111) and (110) substrates is multiple oriented. In growth from separate silicon and carbon containing compounds, Jackson (14) found that depositions on the (100) silicon substrates had far fewer inclusions of apparently polycrystalline material than those grown on (111) substrates.

To try to improve the texture of the SiC layers, a preliminary post-deposition annealing study was done. Layers having their silicon substrates removed by HF-HNO_3 etching were heat treated for 2-10 hr in argon at 2000°C. Unfortunately, an excessive coverage of large (50-100μ) crystallites grew and these had no preferred orientation.

Layer composition.—The SiC coated silicon substrate had a dark gray appearance. After the silicon substrate was removed in an HF-HNO_3 etch, the remaining SiC layer was golden yellow and translucent. The strong 795 cm^{-1} (12.6μ) infrared lattice band, characteristic of SiC (15), was observed in the infrared reflection and transmission spectra of these layers. Measurement of pinhole x-ray diffraction patterns of predominantly polycrystalline layers (Fig. 2c) identified the material as β-SiC. However, patterns obtained with the more sensitive Guinier focusing camera using monochromatic CuK_α radiation showed a few faint anomalous lines (16). These could be interpreted as trace amounts of one or several α-SiC polytypes; however, considering the nonequilibrium nature of the deposition they may derive from multiple twins and associated faults. To a spatial resolution of 10μ, electron beam microprobe analysis (17) of the top surface layers (to a depth of about 1μ) indicated the silicon content to be stoichiometric to within the detection limits of the probe [± ½ w/o (weight per cent) Si]. Using a finer electron beam diameter of 0.5μ or spatial resolution of 0.7μ, slight inhomogeneities are detected, with maximum silicon excesses or deficiencies ranging from 1.0-1.4 w/o.

Table I. Kinetic data for the SiC deposition on (001) silicon

A. Growth rate *vs.* mole ratio $\left(\frac{\text{moles } Me_2SiCl_2}{\text{moles } H_2}\right)^a$

Crystal No.	Mole ratio	Growth rate, μ/min	Layer structure
1	1 × 10^{-3}	0.4	Random polycrystalline
2	5 × 10^{-3}	4.3	Oriented
3	1 × 10^{-2}	6.8	Oriented

B. Growth rate *vs.* growth temperature[b]

Crystal No.	Growth temp, °C	Growth rate, μ/min	Layer structure
4	1250	3.0	Random polycrystalline
5	1300	3.4	Random polycrystalline
6	1315	4.4	Oriented
7	1365	4.3	Oriented

[a] For these experiments: growth temperature = 1365°C, total flow rate = 2.5 liters/min.
[b] For these experiments: mole ratio = 5 × 10^{-3}, total flow rate = 2.5 liters/min.

Deposition kinetics.—Infrared interference thickness measurements (18) of the layers as a function of growth time revealed a constant growth rate of 4.3 μ/min for the typical growth conditions defined above, using (001) silicon substrates.

Table I summarizes some kinetic data for SiC deposition on (001) silicon substrates. In the parameter range (growth temperature, reactant concentration, and total flow rate) where oriented growth occurred, the growth rate was strongly dependent on reactant concentration but insensitive to temperature. This suggests some form of mass transport or total reactant input limitation rather than a thermal activation limitation.

Texture, Surface Morphology, and Electrical Properties

Preferred orientation analysis.—Transmission electron diffraction through films grown to a thickness of about 1000Å on (001) silicon substrates yielded patterns such as shown in Fig. 1. This pattern shows strong (001) β-SiC orientation indicating that partial epitaxy [(001) β-SiC || (001)Si] is occurring. Some polycrystalline rings appear showing that nonepitaxial deposition is also occurring. This is substantiated by reflection electron diffraction patterns of initial growth

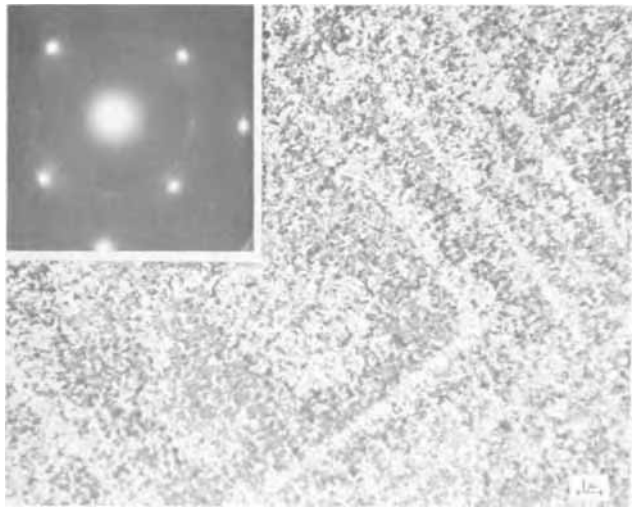

Fig. 1. Transmission electron micrograph (2950X) and corresponding transmission electron diffraction pattern (upper left) of initial SiC film (1000Å thick). The film was floated from the silicon substrate using an HF-HNO_3 etch.

which show polycrystalline β-SiC. Evidently, the early polycrystalline growth extends above the epitaxial growth and thus dominates the reflection electron diffraction pattern. The remainder of Fig. 1 is a transmission electron micrograph of the initial growth which yielded the diffraction pattern. It shows a grain structure which is considerably less than ½μ in the surface plane. Thus, a very fine grained mixture of random and epitaxial nucleation initiated the layer growth. At this thickness, these films have a greater degree of polycrystallinity than those grown from $SiCl_4$ and C_3H_8 by Jackson and Howard (5) as judged by transmission electron diffraction. Presumably, this is in part due to the 10-fold higher growth rate used in this study. However, the reactants used may also play a role as Rai-Choudhury and Formigoni (6) have noted that SiC films grown on silicon from a single organosilane, $(CH_3)_2SiCl_2$, grew faster but were less ordered than those grown from $SiCl_4$ and CH_4.

Information about the crystallography at greater layer thickness was obtained using the Laue transmission x-ray technique with molybdenum radiation and a flat plate camera. Before exposure, some of the silicon substrates were removed by $HF-HNO_3$ acid etching. Exposure times of 6 to 16 hr at tube voltages of 40 kV and currents of 18 mA were necessary to produce the patterns seen in Fig. 2. Figure 2 shows the Laue patterns from a series of films grown on (001) silicon substrates with the same mole ratio, total flow rate, and deposition temperature values but differing deposition times. Figure 2a is a pattern from a 13μ thick film (substrate removed), Fig. 2b from a 32μ thick films (substrate remaining), and Fig. 2c from an 86μ film (substrate removed). This series shows that through a thickness of 13μ, the layer is highly oriented giving rise to a Laue pattern; increasing the thickness results in more random polycrystalline β-SiC growth as evidenced by the filling in of the powder pattern rings at 32μ and the fading out of the Laue pattern. By 86μ, all the rings are nearly uniform indicating that random polycrystalline growth is the dominant contribution to the diffraction pattern.

Examination of the pattern in Fig. 2a shows that the Laue spots are elongated radially and many of the spots are close to arcs on the powder pattern rings. We think the spot enlargement is due to a small angular distribution of crystallite orientations about the preferred orientation. Some of the elongation and streaking may also be due to faults incorporated as the layer grows. These effects may be the result of the growth process itself or they may be caused by the differential thermal expansion stresses accompanying the cooling down of the layer and substrate.

To tentatively index the Laue pattern in Fig. 2a, we have made the following hypothesis: diffraction from the same set of crystallite planes generates both the enlarged Laue spots and powder pattern arcs adjacent to those spots because of an angular distribution of grain orientations about the preferred orientation. A given set of planes (hkl) within such an angular distribution of crystallites will diffract not one but a narrow spectrum of wavelengths from the continuous background resulting in a radially elongated Laue spot. When this spectrum includes the characteristic radiation, an arc will appear on an adjacent powder pattern ring (hkl) on the same radius as the spot.

We found that three orientations were required to index all the spot-arc pairs subject to the condition that the spot be formed by the same set of planes as the arc. The orientations were: (001) β-SiC || (001) Si and two (110) β-SiC || (001)Si orientations, one with [001] β-SiC || [$\bar{1}$10]Si, the other with [1$\bar{1}$0] β-SiC || [$\bar{1}$10]Si. The maximum angular range of grain orientations about the preferred orientation was found to be ±2.5°. Gnomonic projections on planes perpendicular to the [001] and [110] growth directions in the layer verified the tentative indexes given above and provided indexes for the spots not close to powder pattern rings. Figures 3a, 3b, and 3c show the identification of the Laue spots and their corresponding orientation. (For clarity, indexes of some of the weaker spots have been omitted.) Comparison of the (001) β-SiC pattern in Fig. 3a to the (001) silicon pattern underlaying Fig. 2b shows that the [100] β-SiC || [100] Si.

In summary, we conclude that the layer growth through about 50μ consists of sets of β-SiC grains having at least three orientations with the (001) orientation being epitaxially related to the (001) silicon substrate. Interspersed among the oriented grains is random polycrystalline material whose proportion increases with increasing thickness from about 12μ.

Laue patterns from SiC depositions on the (111) silicon substrates showed a similar course of growth: initial growth leading to a maximum in orientation and then a progressive decline in the amount of oriented *vs.* random growth. However, in spite of nearly equal growth rates under identical growth conditions, the strongest orientations appeared from 70 to 75μ from the substrate surface and was not as pronounced as that seen with the (001) substrates.

Surface morphology.—Information on the surface morphology was obtained using a Cambridge Stereoscan scanning electron microscope (SEM). The irreg-

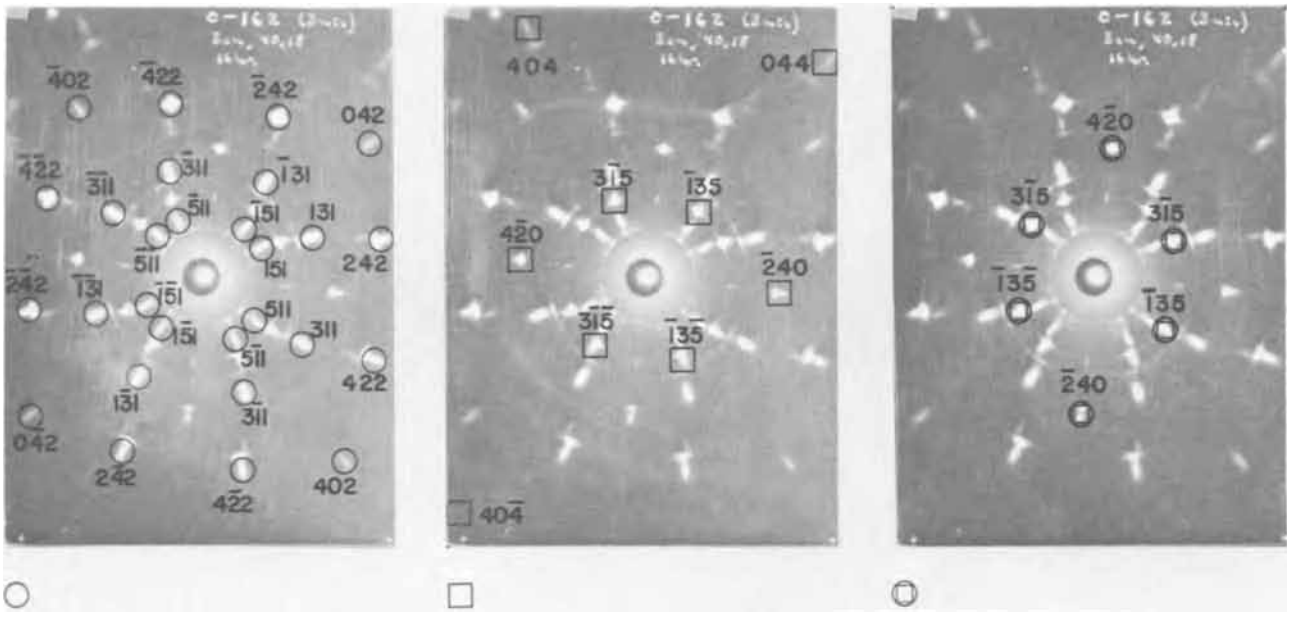

Fig. 3. Indexed components of Laue pattern in Fig. 2a. a (left): Spots, outlined by ○, arising from (001) β-SiC orientation. (001) β-SiC || (001)Si. b (center): Spots, outlined by □, arising from one (110) β-SiC orientation. (110) β-SiC || (001) Si with [001] β-SiC || [$\bar{1}$10] Si. c (right): Spots outlined by ◎, arising from second (110) orientation. (110) β-SiC || (001)Si with [1$\bar{1}$0]β-SiC || [$\bar{1}$10]Si.

ular topography and fine surface structure could be clearly observed using the SEM. Samples were conductive enough so that no metallic overcoating was required.

Figure 4 shows a series of scanning electron micrographs giving surface morphology as a function of layer thickness (growth time) for growth on (001) silicon substrates. Figure 4a (3395X) shows the surface of the 13μ thick film whose x-ray diffraction pattern is shown in Fig. 2a. Note the irregularly faceted surface and the absence of pronounced grain boundaries. In Fig. 4b, a micrograph of a 43μ thick layer at 715X, the rougher, more grainy surface that develops at larger thicknesses is shown. The grain size in the surface dimension is on the order of 5μ. Note the appearance of a few sharply faceted grains. Figure 4c is a micrograph at 720X of a layer 86μ thick whose x-ray diffraction pattern is given in Fig. 2c. By the time this layer has grown to the thickness where random, fine-grained growth strongly predominates, the deposited material has grown into larger morphological units on the order of 40μ in diameter (in the surface plane). This surface structure resembles the "growth cone" morphology seen in many polycrystalline chemical vapor depositions.

The occurrence of pips on the surfaces in Fig. 4 is of interest. These appeared in constant surface density on every grown surface examined except where strongly faceted growth had occurred. They did not appear on the fracture surfaces we examined. Thus, we do not think they are an artifact of the microscope technique. Rather, the pips represent either nucleation and early growth of additional material or are associated with the termination of the deposition.

If the growth was stopped at certain thicknesses, some of the deposited material displayed a precisely faceted grain structure. A dramatic example of this is seen in Fig. 5a which shows faceted growth of SiC polytype on (111) silicon substrates at 6080X; grain size in the surface dimension is about 1-2μ. This SiC layer is about 80μ thick. A top view at lower magnification (1200X) is shown in Fig. 5b. The surface morphology indicates that most of the polytype grains are in nearly the same orientation. The rough material

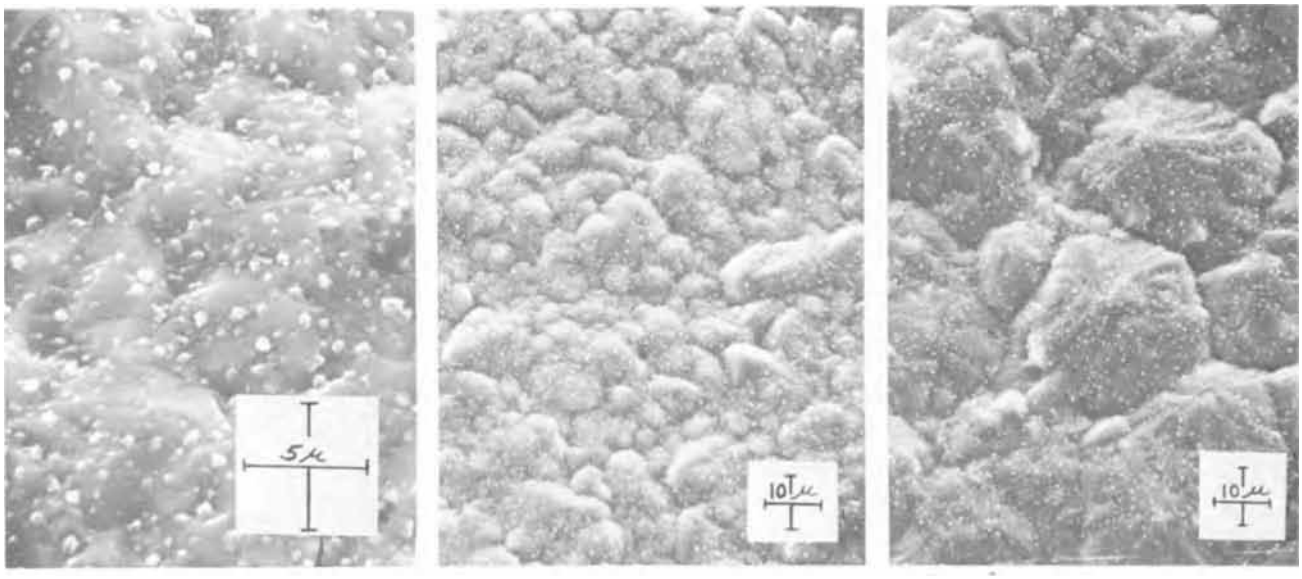

Fig. 4. Scanning electron micrographs of SiC layer surfaces at different thicknesses. a (left), 13μ thick, 3395X; b (center), 43μ thick, 715X; c (right), 86μ thick, 720X.

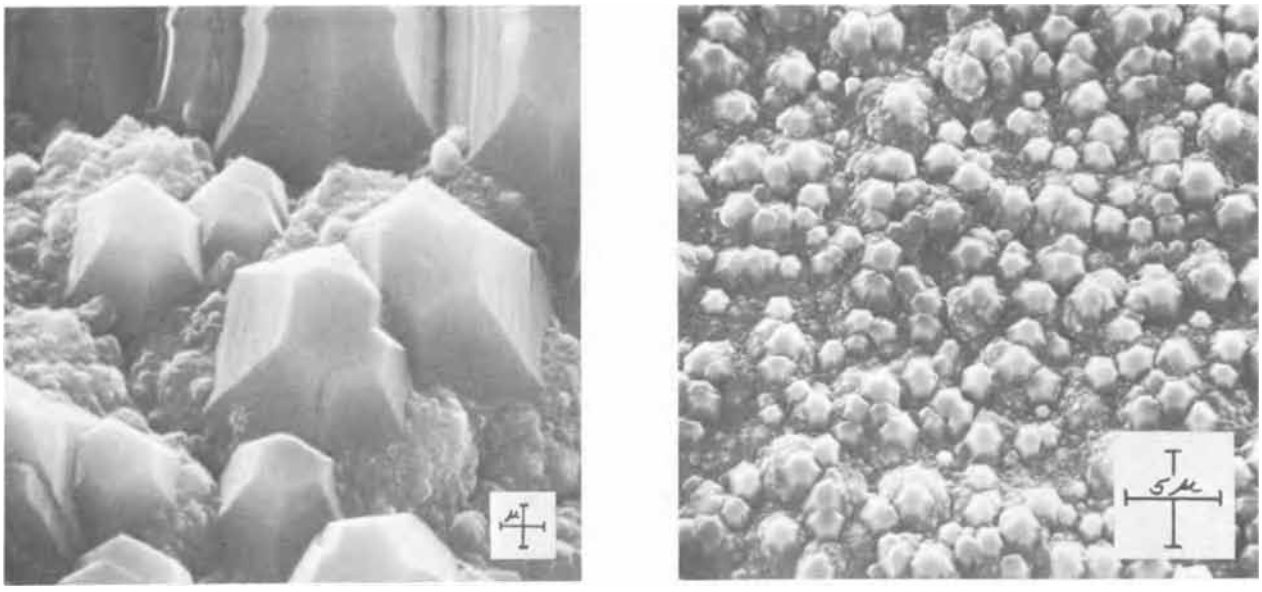

Fig. 5. Scanning electron micrographs of faceted grain structure appearing at the layer surface. a (left), 6080X; b (right), 1200X

between the faceted grains is probably much finer grained polycrystalline material.

Examination of the side facets of less perfect grains showed that they are not smooth planes but rather are composed of a series of steps; this is suggested by the striations in the side facets of the grains shown. The steps which exist are probably twin and/or polytype boundaries (lamellae). Isolated hexagonally faceted grains were also observed in growths on the (001) silicon substrates but never in such copious amounts as seen in Fig. 5.

We cannot be certain whether the hexagonal morphology indicates the presence of hexagonal or rhombohedral SiC polytypes or a multiple (111)-twinned β-SiC deposit.

Relation of layer perfection to processes occurring in growth.—The analysis of this material makes possible some speculation on the nature of SiC growth on silicon using CVD at atmospheric pressure. The faceted grain growth described above indicates that SiC single crystalline-like growth can proceed in a limited region of space and time between 1300° and 1400°C. The fact that orientation occurs at growth rates of 4 μ/min but not in the usual CVD range of 0.1-1 μ/min for epitaxy suggests that effects destroying orientation at lower growth rates are overcome at higher growth rates. These effects may include the evaporation of silicon from the substrate surface (thermal etch) or the codeposition of some impurity such as SiO_2 or carbon. At higher growth rates, partial epitaxial growth does occur and the rapidly growing epitaxial grains apparently predominate to give maximal coverage of oriented SiC at a certain thickness. However, disorienting effects such as lattice mismatch and thermal expansion and tensile strength differences (4) between substrate and film become more pronounced at greater film thicknesses perhaps accounting for the observed optimum in orientation as a function of thickness.

Preliminary electrical evaluation.—To evaluate this material electrically, the silicon substrates were removed from the SiC layers by etching in $HF-HNO_3$ mixture. Contacts were made by fusing a gold-tantalum alloy (19) into the material at 1200°-1300°C in a hydrogen ambient. All layers tested were n-type as measured by the hot probe technique. Resistivities, as measured by the van der Pauw method (20), ranged from 0.5 to 35.5 ohm-cm on layers about 25μ thick. Effective Hall mobilities for these layers fell in the range of 4-7 cm^2/V-sec. These numbers give information about the electron transport properties parallel to the layer surface. The low value of mobility probably indicates extensive grain boundary scattering due to interspersed random polycrystalline material and multiple grain orientations.

Summary

1. By increasing the CVD growth rate to 4.3 μ/min at temperatures close to the melting point of silicon (~1365°C) and by using the highest purity reagents available, SiC layers were deposited on (001) silicon which, at 12μ thick, had crystallites which were sufficiently oriented to produce a Laue x-ray pattern.

2. Such layers had both multiple orientations and inclusions of sharply faceted grains. The inclusions appeared to be more prevalent in growth on the (111) than on (001) silicon substrates.

3. The epitaxial texture changed with thickness. A mixture of random and epitaxial nucleation initiated the growth. After this, the balance between random and oriented growth varied such that the proportion of oriented growth reached a maximum and then degenerated to completely polycrystalline growth at large thicknesses (~100μ). Maximum orientation was more pronounced, reproducible, and more quickly reached in growth on the (001) silicon substrates as compared to the (111) silicon substrates.

Acknowledgments

The author thanks the late Uldis Plics of Dow Corning Corporation for the electron microscopy and diffraction analysis and Harry Baker of Dow Chemical Company for the scanning electron microscopy work. I also thank Lorenzo Sturkey of Dow and David Harker of the Center for Crystallographic Research, Buffalo, New York, for advice in interpreting the x-ray diffraction patterns. Finally, I thank Erhard Sirtl of Dow Corning and John Blocher of the Battelle Memorial Institute for their helpful comments.

Technical Notes

Effect of Nitrogen on the Linear Oxidation of Niobium

C. Catella and R. Streiff*,[1]

Laboratoire de Métallurgie et Chimie du Solide associé au C.N.R.S., Faculté des Sciences, Nancy, France

Above 400°C, the oxidation of niobium exhibits typical paralinear kinetics (1, 2). The linear oxidation rate has been found to be strongly dependent on oxygen pressure, the rate decreasing with decreasing pressure (1-3). The oxidation of niobium in air should therefore be slower than in pure oxygen. This behavior has been noted in some previous investigations (5, 6) and could be purely a result of the reduction in partial pressure. Now, it has been recently shown that one cannot always assume nitrogen to be inert, especially in the oxidation of reactive metals by air (7) or at high temperature in which cases formation of oxynitrides has been observed involving changes in kinetic laws and rate values. This reaction could be possible with niobium.

Consequently, in order to determine whether or not nitrogen affects the oxidation rate, the partial pressure of oxygen has to be kept constant, in experiments both with or without nitrogen. Similar investigations, limited to the effect of small percentages of nitrogen from 1 to 10%, have already been carried out by McLintock and Stringer (4). In the present study, the effect of high percentages of nitrogen (from 10 to 90%) has been investigated.

The reaction was followed by weight gain in a microbalance. The apparatus had a large volume and the change in gas pressure was negligible. Thus, the total pressure could be assumed to be constant. The linear rate constants were determined with several experiments at each temperature in order to reduce the uncertainty of each value. The present results are shown in the form of variations of the linear constants (in micrograms per square centimeter per minute) *vs.* the reciprocal absolute temperatures. For each partial pressure of oxygen, two sets of experiments were carried out, one with pure oxygen, the other in an oxygen-nitrogen mixture with equivalent oxygen partial pressure and total pressure equal to atmospheric.

The effect of oxygen on the linear rate over the range 0.1-1 atm and at temperatures in the range 450°-1000°C is shown in Fig. 1. We observed some well-known features of the niobium oxidation behavior. The two reversals in the temperature dependence (1-2) of the oxidation rate are perceptible around 600°C and between 800° and 900°C.

The effect of nitrogen on the linear oxidation of niobium at several oxygen partial pressures is shown in Fig. 2, 3, and 4. At all temperatures, a reduction in the reaction rate in the presence of nitrogen is observed. The retardation seems not to be strongly influenced by the percentage of nitrogen. Likewise, the reduction in the rate seems not dependent on temperature ranges on both sides of the minimum rate where a stronger effect is observed. These observations are in agreement with those of Stringer (4) who noted only a very small effect of nitrogen content or variations from 1 to 10%. The present study confirms these observations over a large range of temperature and nitrogen pressure.

Besides, the presence of nitrogen does not affect the morphology of the oxide scales formed during the oxidation. The only phases observed are Nb_2O_5 with various crystal structures depending on the oxidation temperature, and the suboxides NbO_2 and NbO. Neither Kjëldhal chemical analysis nor x-ray analysis revealed the formation of nitride or oxynitride.

Microanalysis of the amount of nitrogen in the formed oxide scales by use of nuclear reaction[2] led to the same conclusions. The ratio of nitrogen is always lower than 10^{-2} $\mu g/cm^2$. Analysis of the compact scale-porous scale interface revealed a higher content of nitrogen in the porous scale than in the compact scale. This could be due to adsorption of nitrogen in

the pores of the outer scale or at the compact scale-porous scale interface.

The decrease in the oxidation rate can therefore not be ascribed to the formation of a layer of nitride or oxynitride as formerly observed in the oxidation of calcium by air (7). It also cannot be due to the effect of a very small dissolution of nitrogen in the niobium oxide. Such a nitrogen solution in oxygen-deficient Nb_2O_5 should increase the concentration of vacancies and hence the diffusion rate in the inner compact scale, as it can be expressed in terms of the Wagner-Hauffe model, thereby increasing the over-all linear rate. That is in contradiction with Stringer's and our own observations. The nitrogen effect has to be examined with regard to an interface rate-controlled process (8). The rate of oxidation then is dependent on the oxygen concentration at some interface, this concentration being determined by an equilibrium adsorption process. The effect of nitrogen may be due to competition with oxygen on the adsorption sites at the interface compact-porous scale. The presence of nitrogen lowers the number of available adsorption sites and therefore decreases the linear oxidation rate.

Fluorescence of Alkaline-Earth Silicates Activated with Divalent Europium

T. J. Isaacs

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

The fluorescence of a number of silicates activated by divalent europium has been reported on by various authors (1-5). In this paper, a new family of silicate phosphors having the general composition $M^{2+}Al_2Si_2O_8:Eu^{2+}$, where M^{2+} can be Ca, Sr, Ba, is discussed. This family is the feldspars which are alumino-silicate framework structures with the divalent cations occupying hexagonal interstitial positions.

Experimental Procedures

Spectrographic grade starting materials from Johnson-Matthey of 5 nine's purity ($CaCO_3$, $BaCO_3$, $SrCO_3$, α-Al_2O_3, SiO_2, Eu_2O_3) were weighed in appropriate proportions, mixed in a SPEX mixer mill with approximately 10% by weight of an NH_4Cl flux for 15 min, and then fired in capped fused quartz capsules at a temperature range of 1150°-1410°C under an atmosphere of approximately 95% N_2, 5% H_2 for 2 hr. The product was ground and refired under the same conditions for the same duration of time. The run was brought rapidly to room temperature in this atmosphere. It was found that the addition of a small amount (approximately 1-2 g-atom %) of sodium (in the form of sodium carbonate) in place of strontium or calcium often brought about narrower emission peaks with greater luminous intensity. One of the three polymorphs made in this work of $BaAl_2Si_2O_8$ (celsian) was synthesized using the hydrothermal method. In this run $EuCO_3$ was used as the source of europium, and no flux was employed. The run was made at a temperature of 700°C under a pressure of approximately two kilobars; the duration was a week.

X-ray powder diffraction patterns using the Debye-Scherrer method were taken of all the compounds made to identify the materials and ascertain that they were of one phase. The exposure times varied from 8-10 hr. The x-ray diffraction pattern of the two "hexagonal" barium feldspars were very similar, and the patterns reported in the literature (6-10) were not definitive. We found that the emission spectrum gave a better indication of the number of phases present than did the diffraction patterns.

Key words: barium feldspar, strontium feldspar, calcium feldspar, emission and excitation spectra, x-ray diffraction patterns.

Emission and excitation spectra were determined at room temperature on a double-beam monochromator system designed and built by Riedel (11).

Measurements of phosphor performance of some of the materials were made at selected temperatures in the interval from room temperature to 500°C. The apparatus used was also designed and built by Riedel. An Osram HBO-100 w/2 short-arc high-pressure mercury-vapor lamp is the exciting source. The excitation wavelength is selected by using one of three interference filters with peak transmissions at 254, 313, and 365 nm respectively, and a passband of about 2 nm. The intensity of the excitation radiation, and the amount of radiation reflected from the sample are monitored by two separate photomultipliers equipped with identical interference filters. A third photomultiplier monitors the luminescence emission. A filter is used to select the desired wavelength region. The samples are kept in a stagnant nitrogen atmosphere during the runs.

Results and Discussion

The $CaAl_2Si_2O_8$ which we made corresponds to the mineral anorthite. Three polymorphs of $BaAl_2Si_2O_8$ were made, one corresponding to the mineral celsian, and the other two being similar to the so-called hexagonal celsians reported by numerous authors (6-10, 12-14). While there is some general agreement between the x-ray diffraction patterns given in the literature, and with our patterns, there are significant differences and only two of them [ref. (6, 9)] could be indexed according to hexagonal symmetry by our least squares refinement technique. One of the authors (9) reported an orthorhombic polymorph with a similar x-ray pattern to the "hexagonal" form, but using this data we were not able to index this pattern according to orthorhombic symmetry. The x-ray diffraction patterns reported in the literature and our two patterns are given in Table I for comparison purposes. The pattern given by Ito (7) has been omitted as it

completely disagrees with all the others. The product which one obtains seems to be in good part dependent on starting materials and method of synthesis as well as temperature and duration of the run. For the sake of simplicity, we shall refer to our barium alumino silicates as celsian, and low- and high-temperature α-$BaAl_2Si_2O_8$. $SrAl_2Si_2O_8$ is reported to have both a low- and a high-temperature form (8), the former of which is hexagonal (and supposedly metastable) and the latter triclinic. We were not able to synthesize the hexagonal form as a single-phase compound but always had some of the triclinic form present.

These materials show fluorescence from the near ultraviolet to blue under 254 nm excitation. The spectra were broad with peaks at approximately 423 nm for $CaAl_2Si_2O_8:Eu^{2+}$, 427 nm for celsian, 413 nm for low-temperature α-$BaAl_2Si_2O_8$, 371 nm for high-temperature α-$BaAl_2Si_2O_8:Eu^{2+}$, 407 nm for the high-temperature $SrAl_2Si_2O_8:Eu^{2+}$, and 411-414 nm for the mixed phases $SrAl_2Si_2O_8:Eu^{2+}$. The emission spectra are shown in Fig. 1. The intensities of the curves are not drawn relative to each other as the differences in intensity are too great.

Excitation spectra of these materials show a broad band extending from approximately 213 to 390 nm for $CaAl_2Si_2O_8:Eu^{2+}$, two broad bands, one peaking at 257 nm, the other at 310 nm for celsian, a broad band with a peak at 273 nm for low-temperature α-$BaAl_2Si_2O_8:Eu^{2+}$, three bands with peaks at 202, 232, and 300 nm for high-temperature α-$BaAl_2Si_2O_8:Eu^{2+}$, and two broad bands with peaks at 260 and 330 nm for the high-temperature form of $SrAl_2Si_2O_8:Eu^{2+}$. The spectra are shown in Fig. 2. The arbitrary units are individual for each curve.

Quantum efficiency for a sample of high-temperature $SrAl_2Si_2O_8:Eu^{2+}$ containing 1 m/o (mole per cent) Eu^{2+} was determined to be 85 ± 7% at 254 nm when compared with NBS Standard $MgWO_4$ No. 1027. The other materials were not measured as this was the most intense of the compounds made.

Studies of the effects of elevated temperatures on the intensity of emission were conducted on some of

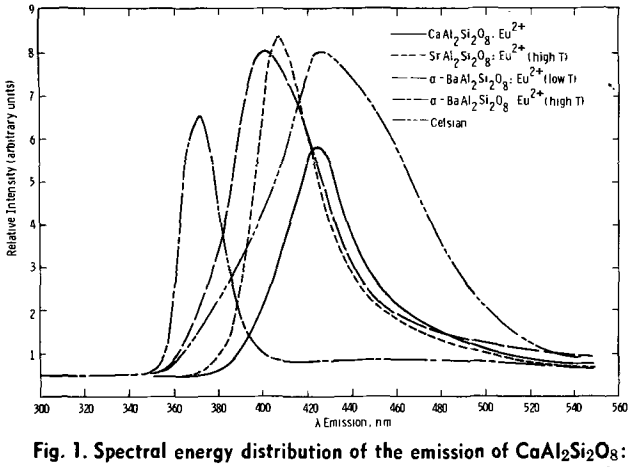

Fig. 1. Spectral energy distribution of the emission of $CaAl_2Si_2O_8$: Eu, $SrAl_2Si_2O_8$:Eu, and $BaAl_2Si_2O_8$:Eu at 254 nm excitation. The Eu^{2+} concentration is at 1%.

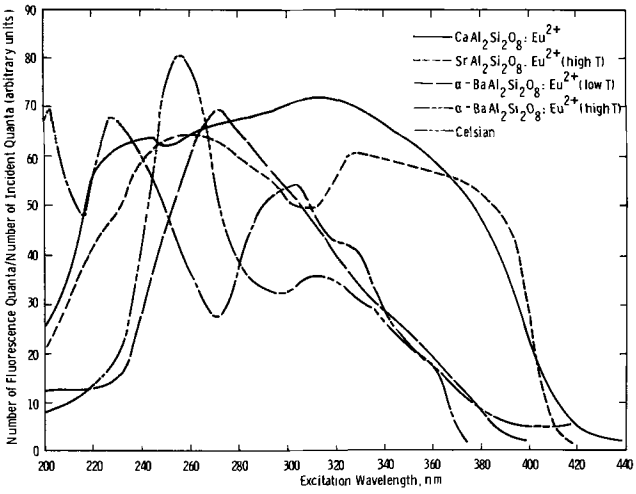

Fig. 2. Excitation spectra of Eu^{2+} fluorescence of the phosphors $CaAl_2Si_2O_8$:Eu, $SrAl_2Si_2O_8$:Eu, and $BaAl_2Si_2O_8$. The Eu^{2+} concentration is at 1%. The fluorescence wavelength was monitored at the peaks shown in Fig. 1.

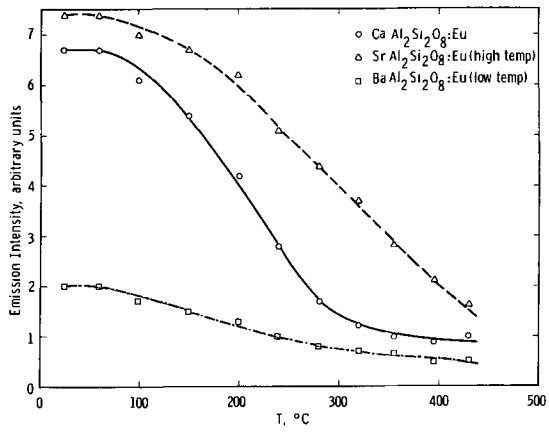

Fig. 3. Emission intensity as a function of temperature. λ_{exc} = 254 nm.

these materials, and the results are shown in Fig. 3. A Corning 3-75 filler was placed in front of the S-20 photomultiplier used to detect the fluorescence. Quenching temperatures (those temperatures at which emission intensity falls to 50% of room temperature) were approximately 225°C for $CaAl_2Si_2O_8:Eu^{2+}$, 240°C for the low-temperature α-$BaAl_2Si_2O_8:Eu^{2+}$, and 310°C for the high-temperature form of $SrAl_2Si_2O_8:Eu^{2+}$

The feldspars are complex materials and extensive work has been done on the more common members. There is confusion about the barium alumino silicates and certainly it would be desirable for us to know exactly the material we have been studying for fluorescence. Such a study would necessarily be quite extensive and therefore beyond the scope of this work.

Acknowledgments

The author wishes to thank Andrea Price for help in the preparation of the phosphors and Roy Williams for measuring the spectra and the temperature dependence. The computer program used for indexing the x-ray powder patterns was obtained from the U. S. Geological Survey.

Mobile Ion Transfer to SiO_2 Films from Ethanol

S. I. Raider* and R. Flitsch

International Business Machines Corporation, Components Division,

East Fishkill Facility, Hopewell Junction, New York 12533

The relationship between the contamination of SiO_2 surfaces with organic reagents and the subsequent ionic drift has been interpreted in different ways. Hofstein (1), using neutron activation, ^{22}Na radiotracer analyses, electrical measurements, and tritiated ethanols in his studies, concluded that mobile protons are transferred from ethanol to SiO_2 films. Oddly, it was the less chemically reactive protons on the α- and β-carbons of ethanol, and not the hydroxyl group proton, that were correlated with the mobile species. Sunshine (2) indicated that ethanol and other organic materials, independent of alkali ions, caused ionic drift in SiO_2 films. Gregor (3) correlated shifts in flat-band voltage with contamination of oxide surfaces using high-purity organic reagents, including ethanol, as contaminants. It was suggested that the aluminum electrode reacted with the treated oxide surface to release an active positive species, but no conclusion was reached as to whether the observed ionic drift was due to mobile protons or to sodium ions. Yurash and Deal (4) measured the ionic drift in metal-oxide-silicon (MOS) structures after immersing oxides in acetone and trichloroethylene and compared these results with the number of Na^+ ions present in these solvents. The ionic drift and the Na^+ ion concentration in these two organic solvents were found to be directly related. MOS structures were also contaminated with

*Q = net ionic charge; q = unit charge.

organic reagents after the aluminum electrodes had been deposited and annealed. From the latter experiment, Yurash and Deal suggested that the shifts observed in the C-V plots after the MOS structures were stressed were related to ionic contaminants diffusing in from the edges of the electrodes. Reactions between the aluminum electrodes and the organic molecules which might produce mobile species were therefore considered unlikely.

In the present work, the effect of contaminating an oxide surface with ethanol was re-examined with respect to the corresponding ionic drift and the Na^+ ions present in the ethanol. Using oxygen-steam-oxygen, oxide films 5700Å thick were thermally grown on p-type, 2 ohm-cm, <100>, silicon wafers. Aluminum dots (20 mils in diameter, 5000Å thick) were evaporated through metal masks onto the oxides after contaminating the surfaces with ethanol. Aluminum was also evaporated onto the backs of the wafers. The wafers were then annealed at 400°C for 20 min in N_2 gas. Table I shows the results of flame photometric analyses of trace amounts of Na^+ ions in 100% ethanol (U.S.I. Absolute Ethanol, Reagent Grade), and also lists the number of electrically mobile ions transferred to the oxide films as a result of immersing them in ethanol.

To reduce the Na^+ content of the ethanol contacting the oxide surface, the ethanol was evaporated from a heated beaker onto an oxide film held above the beaker. The effect of contaminating an SiO_2 surface in the absence of Na^+ ions with liquid ethanol was examined after first distilling the ethanol twice, using a quartz distillation column. Hofstein's experimental procedure was stimulated by heating the distilled ethanol between two oxide surfaces at 75°-80°C for 15 min. In addition, wafers were immersed in the distilled ethanol and heated both at room temperature and at 75°-80°C for 5 min. Ionic drift results from these experiments are listed in Table I, together with those from experiments by Hofstein and by Gregor.

When the experiments described in Table I were repeated without the 400°C postmetallization anneal, similar drift results were obtained. Finally, since it had been demonstrated (5) that Na^+ impurities are most concentrated near the air surface of thermally grown SiO_2, about 250Å of each of the oxides were removed by etching with dilute HF before contaminating these surfaces with ethanol. The results of contaminating these etched oxide surfaces with distilled and nondistilled ethanol are similar to those obtained with no etching.

The results in Table I indicate that the number of electrically mobile ions found in SiO_2 films after the surfaces of these films were contaminated with ethanol appears to be related to the number of Na^+ ions present in the ethanol. Heating the distilled ethanol at 75°-80°C between two oxide surfaces had little effect on the ionic drift. Since neither the evaporated nor the distilled ethanol affected the ionic drift, it must be concluded that, contrary to Hofstein's findings, there is no evidence of mobile protons in SiO_2 resulting from ethanol contamination. The distribution of tritium that Hofstein observed in SiO_2 after he contaminated silica surfaces with tritiated ethanols does not necessarily indicate that tritium is electrically mobile in SiO_2; rather, the distribution may be indicative of a secondary effect resulting from the movement of Na^+ ions.

Acknowledgments

The authors wish to thank Drs. L. V. Gregor and D. R. Kerr for their suggestion that the question of mobile species in SiO_2 resulting from ethanol contamination be re-examined.

Manuscript submitted Nov. 4, 1970; revised manuscript received ca. March 12, 1971. This was Recent News Paper 245 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Modulation of Dopant Segregation by Electric Currents in Czochralski-Type Crystal Growth

M. Lichtensteiger, A. F. Witt,* and H. C. Gatos*

Center for Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Extremely rapid modulation of dopant segregation was observed in tellurium-doped indium antimonide single crystals brought about by electric currents applied across the growth interface during Czochralski-type crystal growth. The time constant of the modulation was found to be in the millisecond range and thus orders of magnitude smaller than that encountered in diffusion-controlled processes. Abrupt changes in the microscopic growth rates associated with Peltier cooling were quantitatively determined. Concurrent changes in the facet growth were also observed.

A dual output function generator and high-speed programmable power supply were used to produce current pulses of controlled amplitude and duration. Positive current pulses were applied (from seed to melt) across the crystal-melt interface of a tellurium-doped (10^{17}/cm^3) indium antimonide system leading to Peltier cooling (see circuit diagram in Fig. 1). All results were obtained with crystals of about 1.4 cm in diameter pulled in the <111> direction without rotation [to achieve constant microscopic growth rates (1)] at a rate of 2.5 cm/hr; they were cut along the growth axis, polished, and etched. The etching rate is a sensitive function of dopant concentration (it decreases with increasing Te concentration) and the resulting surface topography reflects in detail the compositional changes in the crystal (2).

The effects of current pulses (see insert, Fig. 2), with a repetition rate of 4 sec, on dopant segregation are shown in Fig. 2. It is seen that every pulse results in an instantaneous increase in dopant concentration, the magnitude and duration of which are controlled by the pulse characteristics. It is most interesting to note that the increased dopant concentration remains at a constant level throughout the period of current flow. Similarly, upon termination of the pulse, the dopant concentration decreases instantaneously and again remains constant throughout the 3 sec interval between successive pulses (multiple beam interferograms showed that the etched regions grown with and without current flow were flat).

From the rise time of the pulses (20 msec) and the linear resolution of light microscopy ($\sim 0.2\mu$), the time constant associated with the current-induced dopant concentration change is found to be at most of the order of several milliseconds. A time constant of a similar magnitude is apparently operative during relaxation of the dopant segregation upon the termination of current pulses. From the width of the region grown during the application of pulses (800 msec), an average growth rate greater by a factor of 3.7 than the actual pulling rate was found. The regions between pulses grew at a rate which was within 5% of the pulling rate.

The effect of sloped current pulses (see insert, Fig. 3) on the dopant segregation are shown in Fig. 3; both an off-core region (right-hand side) and a core region (left-hand side) of the crystal are shown. A continuous elevation increase from top to bottom (confirmed by multiple beam interferometry) corresponding to the pulse shape is observed. It reflects the direct dependence of dopant segregation on cur-

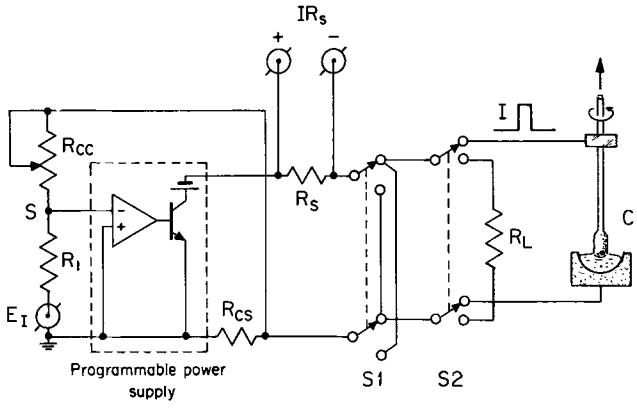

Fig. 1. Simplified diagram for programmed current pulse generator. The pulse generator signal, E_I, is fed through input resistance, R_I, to the summing point, S, of a high-speed programmable power supply (with 55V compliance) used as compensated summing amplifier. Its output, I, is controlled by a negative feedback current, IR_{CS}/R_{CC}, where R_{CS} and R_{CC} are sensing and control resistors. The voltage drop, IR_S, is used to monitor the waveform of the pulses on a differential plug-in oscilloscope. Switch S_1 permits polarity reversal of the pulses applied across the growth system, C, whose total resistance measured approximately 300 mohms for the experiments described, and switch S_2 allows current shunting across a "dummy-load," R_L, for adjusting the pulse characteristics before start of the experiment.

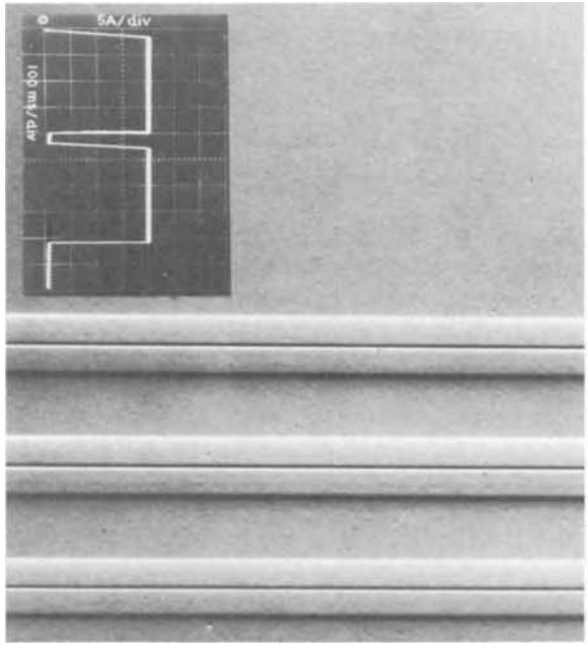

Fig. 2 (211) "Off-core" section of Te-doped InSb single crystal cut along the growth axis (grown without rotation). Composite current pulses with the characteristics shown in the figure were applied during growth. The instantaneous increase and decrease in dopant segregation associated with the onset and termination of current flow is clearly visible. Magnification 355X.

Key words: crystal growth, impurity distribution, indium antimonide.

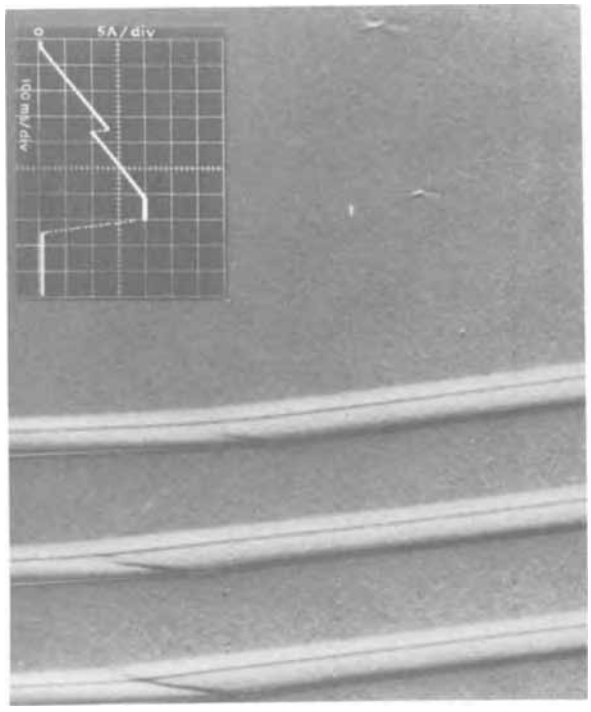

Fig. 3. (211) Section of a Te-doped InSb single crystal cut along the growth axis (grown without rotation). The long rise time of the current pulse, shown in the figure, causes a gradual increase in dopant segregation. The temporary decrease in current is reflected as a dark line (see text). Magnification 355X.

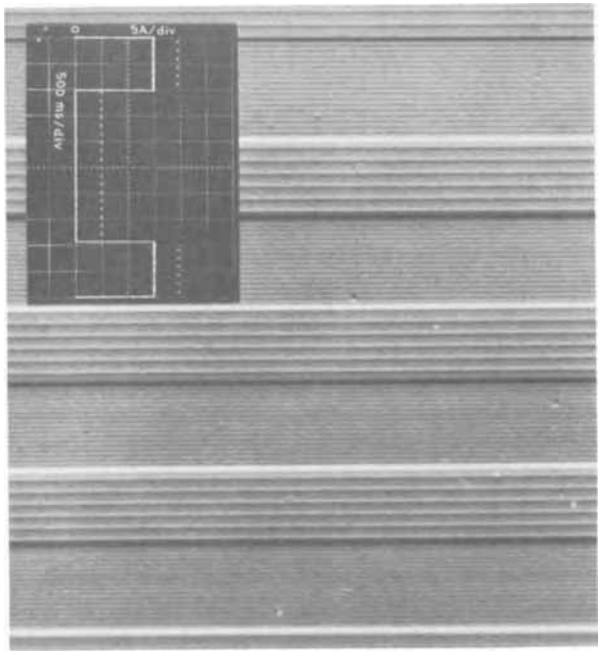

Fig. 4 (211) "Off-core" section of a Te-doped InSb single crystal cut along the growth axis (grown without rotation). The effects of superimposed 15 msec pulses (see insert) are clearly visible and are utilized as rate striations. The regions grown with current flow contain 6 and those grown between successive pulses 18 rate striations. Their relative separation shows that current flow increases the microscopic rate of growth (see text). Magnification 405X.

rent density. The asymmetric position of the dark line within the pulsed region (caused by the current reduction as shown in insert of Fig. 3) demonstrates a current-controlled growth rate. It is also seen that the current-induced increase in growth rate is greater in the off-core than in the on-core region, reflecting the differences in the prevailing growth mechanisms. Figure 3 shows further that the off-core to on-core delineation which corresponds to the transition from curved to flat growth interface is very pronounced in the regions of increased growth rate associated with current flow; it is barely visible in the parts of the crystal grown with no current flow. It is also observed that the increased growth rate associated with current flow results in a rapid facet (core) expansion into the off-core region which relaxes upon the decrease in growth rate caused by termination of the pulse. The extent of core expansion is a function of the curvature of the prevailing solidification isotherm and the magnitude and duration of the current pulse. This growth interface behavior is consistent with the spontaneous tendency of the facet to expand under unrestricted (accelerated) growth conditions. The microscopic dopant distribution in the core region adjacent to the off-core is complex and reflects the transition from one growth mechanism to another (3).

The effects of relatively long current pulses (as discussed above) on the microscopic growth rate were studied by superimposing 15 msec pulses of 5A amplitude and a frequency of 6/sec [serving as rate striations (4)]. The results are shown in Fig. 4. The regions grown with current flow (1 sec duration) can be readily differentiated from the regions grown during the 3 sec intervals between successive pulses; the former contain 6 and the latter 18 rate striations.

Measurements of the spacing of the "rate striations" show that the growth rate upon the application of the current pulses increases instantaneously by 340% and remains constant for the duration of the pulses; during the intervals between the successive pulses, the growth rate is also constant and about 8% higher than the actual pulling rate.

In the light of the instantaneous response of the growth system to the onset and termination of current flow, it is apparent that current pulses of short duration and low amplitude used for introducing "rate striations" do not interfere with the over-all growth characteristics of general concern.

The presently reported very rapid modulation of the dopant segregation cannot be explained by the prevailing theoretical treatments based on a constant interface segregation coefficient and diffusion-controlled mechanisms (5). According to these treatments, the dopant segregation readjustment to an abrupt change in growth rate should be roughly 90% completed within 1 sec, or about 0.1% completed in 10 msec. The present results show that compositional readjustment following the onset and termination of current flow takes place in less than 10 msec with no subsequent detectable composition changes for periods ranging up to 3 sec. It is evident that the presently observed dopant segregation phenomena are not diffusion controlled. We believe that they result from changes in the interface distribution coefficient which is generally assumed to be constant.

Well-defined current pulses constitute a powerful tool in fundamental crystal growth studies and in materials design, such as the formation of abrupt controlled changes in dopant concentration and the formation of dopant superlattices. Controlled crystal growth induced by Peltier cooling is currently being applied to liquid phase epitaxy.

Brief Communication

The Dependence of Emission Spectrum and Efficiency of GaAs:Si Diodes on the Silicon Concentration

B. H. Ahn, R. R. Shurtz, and C. W. Trussell

Night Vision Laboratory, USAECOM, Fort Belvoir, Virginia 22060

Amphoteric GaAs:Si electroluminescent diodes are quite efficient at room temperature, and domed configuration GaAs:Si diodes have power efficiency as high as 28% (1, 2). Many investigators have made electrical absorption and photoluminescent measurements on GaAs:Si epilayers (3-5), but these parameters were not correlated to the device performance.

We present the dependence of spectral emission and power efficiency on the substrate orientation and the Si concentration in the melt. GaAs:Si diodes were fabricated by liquid phase epitaxy (6). N-GaAs substrates were used which were oriented in (100), (111)-A, and (111)-B directions and doped with Si to 2-5 x 10^{18}/cm^3. The tilt temperature was 970°C and the cooling rate was logarithmic with the fastest segment cooling at 2.5°C/min and the slowest at less than 0.5°C/min. Silicon in the melt was varied from 0.8 a/o (atomic per cent) to 2.4 a/o. The tilt temperature was high enough to have resulted in the amphoteric p-n junction growth at all the Si concentrations and all orientations. Figures 1, 2, and 3 show the emission peak dependence on the Si concentration in the melt. The longest emission spectrum (10,160Å)

Key words: amphoteric, III-V compound, electroluminescence, orientation effect.

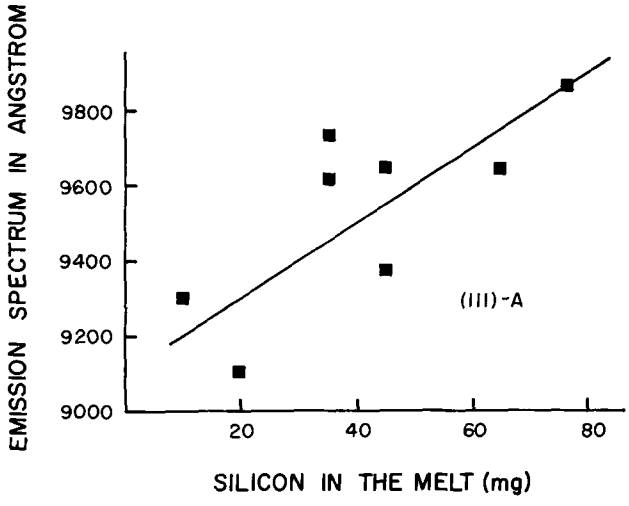

Fig. 2. Plot of emission spectrum peak *vs.* Si concentration in the melt. The GaAs substrate is oriented in (111)-A.

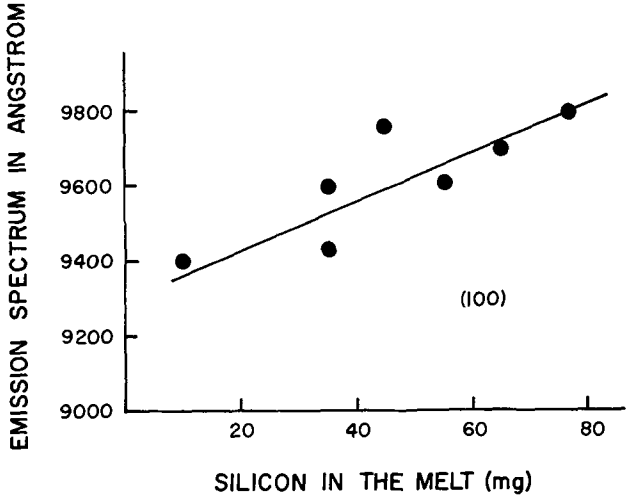

Fig. 1. Plot of emission spectrum peak *vs.* Si concentration in the melt. The GaAs substrate is oriented in (100).

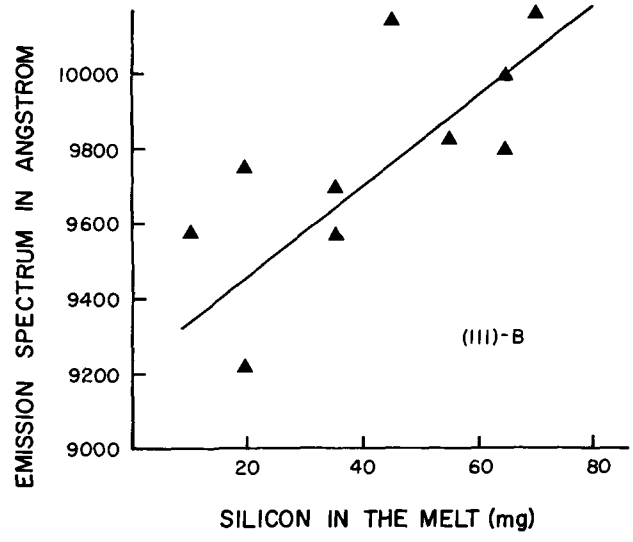

Fig. 3. Plot of emission spectrum peak *vs.* Si concentration in the melt. The GaAs substrate is oriented in (111)-B.

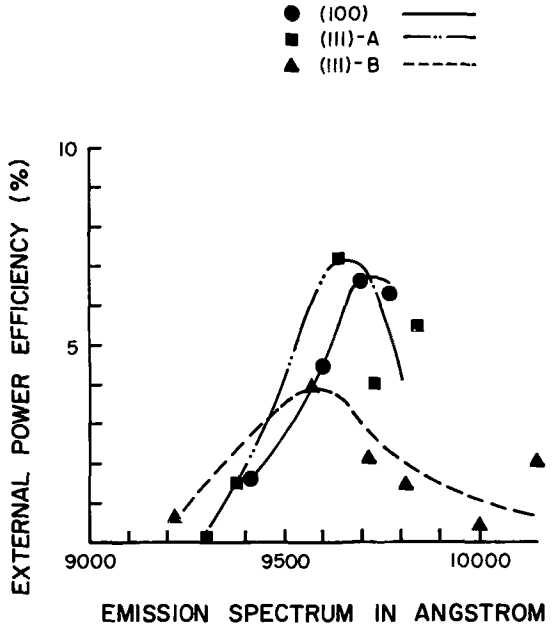

Fig. 4. Plot of the power efficiency of diodes grown at different Si concentrations on three orientations *vs.* their emission spectrum peak. Notice the (111)-B diodes are the least efficient.

was observed only in diodes grown on (111)-B oriented substrates. While there is only a small fluctuation from the straight line for (100) orientation, there exists quite a large fluctuation for the (111)-A and (111)-B. Our results indicate that Si_{As} and Si-complex atoms form a broad acceptor band, the peak of which varies as the Si in the melt is varied. The band is apparently formed by the acceptor levels seen previously by others at 0.03, 0.100, and 0.23 eV above the valence band. The Si concentration apparently changes the relative concentration of these levels.

Figure 4 shows the relationship between the spectral peak and the power efficiency. There is an optimum efficiency range between 9600 and 9700Å [these correspond to 144 and 157 meV deviation from the GaAs bandgap (7)]. We believe that lower power efficiency at shorter and longer spectral ranges is due to bulk absorption and nonradiative absorption by Si-complex atoms, respectively.

Contact Resistance in Diffused Resistors

I. F. Chang (pp. 368-372, Vol. 117, No. 3)

H. H. Berger:[1] In his paper, Chang introduces what he calls a "Modified Transmission Line (MTL) Model" to describe the contact of a diffused resistor. He does this for two basic reasons:

(*a*) The original Transmission Line Model (TLM)[2,3] cannot consider the influence of the gap between the contact and the resistor side edges, since it is a strictly one-dimensional model.

(*b*) There are contact fabrication processes, which might modify the conductivity of the semiconductor region beneath the contact metal.

To alleviate the first problem, Chang proposes to shunt the series resistance of the TLM by the resistance of the two stripes between contact and resistor side edges. This would result in smaller end corrections than predicted by the original TLM. However, when the contact becomes smaller at a fixed resistor width, an increasing constriction resistance in the contact vicinity adds to the contact end correction, suggesting rather that the original TLM would give too small values for the total end correction. Chang's modification would make it worse.

The main issue, however, is whether for practical contacts a correction is needed at all. The maximum influence of the constriction resistance can be estimated by considering the constriction for an ideal contact as has been done theoretically (conformal mapping) by Ting and Chen[4] and experimentally (resistance paper model) by D'Andrea and Murrmann.[5] Both results suggest that the original TLM is sufficiently accurate for most practical purposes. Chang himself provides direct experimental evidence that there is indeed no need for the proposed modification: Table I of his paper shows that his samples excellently followed the inverse proportionality between contact end correction term R_{cc} and the contact width (W-2a) as the original TLM would predict. The same applies to the term R_c.

To solve the second problem, no modification of the TLM is needed either, unless a second blocking junction is formed along with the conductivity change of the semiconductor region beneath the contact. Namely, since the TLM describes the contact region only, it is self-evident that the actual semiconductor series resistance of this region must be inserted in the model. The real problem is not an inadequacy of the TLM to describe contacts with semiconductor sheet resistances different from the resistor bulk; rather it is an inadequacy of the resistor test pattern, as applied by Chang (Fig. 1 of his paper) to directly determine the series resistance for the TLM of such contacts. This test pattern was originally devised[2] for cases where the sheet resistances of the resistor bulk and the contact region remained equal. Hence it is this structure which might need a modification, not the TLM.

[5] G. D'Andrea and H. Murrmann, *IEEE Trans. Electron Devices*, ED17, 484 (1970).

In the case of Mo-PtSi-Si-contacts, the blocking action of the second (PtSi-Si) junction seems to be negligible after Chang's results. This would justify the application of the TLM to these contacts. The series resistance of the TLM could then again be directly determined with a structure according to Fig. 1 (Chang's paper), if the PtSi were applied all over the entire resistor.

On aluminum-silicon contacts, I have not found any evidence for a strong modification of the semiconductor conductivity beneath the contact.[6] Theoretically, instead of the decrease observed by Chang, one would expect an increase of the series resistance beneath the contact, since the aluminum dissolves a small layer of silicon during the sintering process.

I. F. Chang: Berger's discussion questions the two significant features of the MTL model[7]:

(*a*) The influence of the gap, *a*, between the contact and the resistor side edge (see Fig. 1 published here) in predicting contact correction for diffused resistor.

(*b*) The need of a contact sheet resistance, ρ_s', in addition to the resistor diffusion sheet resistance, ρ_s, to obtain a correct contact correction term, R_{cc}.

The MTL model introduced[7] has demonstrated clearly why these considerations are necessary. Only by considering both the existence of a gap and a contact sheet resistance, ρ_s', different from the bulk diffusion resistance, ρ_s, can one obtain good agreement with experimental data on various sizes of aluminum and molybdenum contacts to silicon. Berger has quoted

other work,[8,9] and has made qualitative comparisons on their results to support his arguments. Therefore, it seems appropriate to present some detailed numerical results concerning various theoretical models to illustrate that care must be taken in making comparisons. Hopefully, these results, along with the MTL result, the TL result, and the experimental data all shown in Fig. 2 published here, will clear doubts on this subject.

I. Theoretical Modeling of Contact Correction in Diffused Resistor

Let us consider a realistic contact in a diffused resistor as shown in Fig. 1(a). The total resistance of the resistor is defined as the sum of the bulk diffusion resistance and two times the contact correction term, R_{cc} (Eq. [1] in footnote 7). R_{cc} consists of the crowding resistance of the contact (beneath the contact as well as at two sides of the contact) and the contribution from contact resistance. The latter is a fabrication process and contact geometry dependent. The former term (excluding the effect of diffusion profile on current crowding) depends mainly on contact and resistor geometry. These two types of contribution to R_{cc} cannot be separately determined by experimental measurements; thus, a correct analytical model must consider them simultaneously. However, most analytical treatments reported only deal with an ideal contact[8,10,11,12] (that is, neglecting contribution due to contact resistance) and/or a simplified contact-resistor

[11] Case 3 in Section I is a typical example.
[12] B. R. Chawla, *Proc. IEEE*, 59, 305 (1971).

geometry[13-15] (neglecting part of the current crowding effect due to geometry). Therefore, one should be aware of the assumptions made in each treatment and interpret their results with care. We briefly discuss a few cases below and present numerical results for each case to illustrate this point.

Case 1.—As shown in Fig. 1(b), this case assumes an ideal contact with a simple geometrical configuration (*i.e.*, the contact width, W_c, equals the resistor width, W_R). Therefore, mathematically, one can reduce this problem to a two-dimensional one. Using the Schwartz-Christoffel transformation and the definition of sheet resistance, one can solve the Laplace equation and obtain

$$R = \rho_s \frac{L}{W} + 2\left[\frac{2\rho_s X_j}{\pi W} \ln \frac{2}{(1 - e^{-\pi d/X_j})}\right] = \rho_s \frac{L}{W} + 2\,R_{cc,g1} \quad [1]$$

as given by Eq. [17] in footnote 7 and Eq. [2] in footnote 8. One notes that $R_{cc,g1}$ increases with decreasing W and increases very little with decreasing contact length, d, since $X_j << d$. The numerical result for Eq. [1] is plotted in Fig. 2 as curves 1 and 2. One notes that, because the assumption $W_R = W_c$ is made in deriving Eq. [1], it would predict ambiguous results for resistors with ideal contact of $W_c \neq W_R$. This is best illustrated in Fig. 2, curves 1 and 2, which, on LHS, presents contact correction term for a given contact (W_c = 0.3 mil) situated in resistors of various widths and, on RHS, presents R_{cc} for a given resistor (W_R = 2.3 mils) having contacts of various widths. Obviously, the constant value predicted by Eq. [1] on each side is an incorrect prediction. The varying portions of curves 1 and 2 are the approximate correction term for an ideal contact by neglecting the current distribution and crowding on the two sides of the contact.

Case 2.—Considering a thin sheet resistor (neglecting current crowding in the Z direction) shown in Fig. 1(c), Ting and Chen[8] worked out the correction term due to a current crowding in the X-Y plane alone under the assumption $d \geq 4a$ and $L/2 >> W_R$. The result is

$$R = \rho_s \frac{L}{W_R} + 2\left[\frac{\rho_s}{2\pi}\left(\frac{1}{K} \ln \frac{K+1}{K-1} + \ln \frac{K^2-1}{K^2+1}\right)\right] = \rho_s L/W_R + 2\,R_{cc,g22} \quad [2]$$

where $K = W_R/2a$. They consider that the sum of $R_{cc,g1}$ and $R_{cc,g22}$

$$R = \rho_s L/W_R + 2\,R_{cc,g1} + 2\,R_{cc,g22} = \rho_s L/W_R + 2\,R_{cc,g2} \quad [3]$$

to be a good approximation of contact correction due to current constriction. However, one notes that the assumption of $W_R = W_c$ in Case 1 is not consistent with that in Case 2, therefore, it is ambiguous whether W_R or W_c should be used for $R_{cc,g1}$ in the sum equation, or whether they can be added at all for representing the net crowding resistance. In some cases [small (a) falls within the assumption $d \geq 4a$], $R_{cc,g1}(W_c)$ and $R_{cc,g1}(W_R)$ have a difference much greater than the second correction term $R_{cc,g22}$ making it insignificant compared to the first correction term. Furthermore, $R_{cc,g2}$ or $R_{cc,g22}$ being independent of d is obviously a crude approximation. Numerical results for $R_{cc,g2}$ are also shown in Fig. 2 (curves 3 and 4). However, one should note that the valid region for $R_{cc,g2}$ (curves 3 and 4) is limited to $a < d/4$. It is worthwhile mentioning that Chawla,[12] using a numerical technique, has recently obtained analytical expression for an ideal contact in a "dog bone" resistor. The author claims that, when imposing the condition $W_R = W_c + 2a$, the expression

$$R_{cc} = \rho_s \left[0.325e^{-2.5W_c/W_R} + \left(0.834 - 0.247\frac{a}{W_R}\right)\frac{a}{W_R}\right] \quad [4]$$

should also be applicable to a straight resistor. However, one should be aware that the bulk path of the resistor considered in Chawla's case is L-$2a$ rather than L.

Case 3.—Another approach to the problem may be taken if one assumes that the actual resistor may be partitioned as shown by dotted lines in Fig. 1(a). This is a fair approximation at least in the resistor body up to the vicinity of the contact corner. Under this assumption, we can treat the resistor as two parallel conduction paths as shown in Fig. 1(d). R_1 is the main resistor whose contact correction term can be evaluated under equivalent condition of Case 1. R_2 is equivalent to two parallel resistors of two R_2 in series. The correction term for R_2 can be evaluated in a similar manner as for R_1 by recognizing the analogy $X_j \rightarrow a$, $W_c \rightarrow X_j$ and d remains unchanged (the current crowding in the Z direction in R_2 has been neglected). Thus, we have

$$R_1 = \rho_s L/W_c + 2\frac{2\rho_s X_j}{\pi W_c} \ln \frac{2}{(1 - e^{-\pi d/X_j})} = \rho_s L/W_c + 2\,R_{cc,g1}(W_c) \quad [5]$$

$$R_2 = \rho_s L/2a + 2\frac{\rho_s}{\pi} \ln \frac{2}{(1 - e^{-\pi d/a})} = \rho_s L/2a + 2\,R_{cc,g33} \quad [6]$$

$$R = R_1 // R_2$$

$$= \frac{\rho_s \frac{L}{W_R} + \frac{\rho_s \frac{L}{W_c} 2\,R_{cc,g33} + \rho_s \frac{L}{2a} 2\,R_{cc,g1}(W_c) + 2\,R_{cc,g1}(W_c) \cdot 2\,R_{cc,g33}}{\rho_s L(1/W_c + 1/2a)}}{1 + [(2\,R_{cc,g1}(W_c) + 2\,R_{cc,g33})/\rho_s L(1/W_c + 1/2a)]}$$

$$\cong \rho_s \frac{L}{W_R} + \left(\frac{W_c}{W_R}\right)^2 \cdot 2\,R_{cc,g1}(W_c) + \left(\frac{2a}{W_R}\right)^2 \cdot 2\,R_{cc,g33} = \rho_s L/W_R + 2\,R_{cc,g3} \quad [7]$$

One notes that as a approaches 0, Eq. [7] reduces to Eq. [1] indicating that Case 1 is a special case of Case 3. As W_c becomes smaller, the first correction term decreases and $R_{cc,g3}$ approaches $R_{cc,g33}$ which is a function of d/a. This may be a better representation for the contact correction term than Eq. [3] since it is independent of d/a. Numerical results of this case are plotted in Fig. 2 as curve 5. It decreases significantly as d increases.

Significance of MTL Model and Comments on H. Berger's Discussion

The above discussions are for an ideal contact. In the case of a real contact, the presence of contact resistance has the effect of spreading out the current distribution beneath the contact and along two sides of the contact. If the current distribution can be described in terms of a passive network, one may then approximate the real contact to be two parallel distributive resistance networks, one responsible for the current

[13] Case 1 in Section I is one example.
[14] H. Murrmann and D. Widmann, *IEEE Trans. Electron Devices*, ED16, 1022 (1969).
[15] H. H. Berger, IEEE-ISSCC Dig. Techn. Paper, pp. 160-161 (1969).

spreading beneath the contact and one for along the two sides of the contact (due to symmetry two sides can be combined). The MTL model is just based on this concept. The model parameters, the distributive resistance elements (ρ_s' and σ_c in addition to ρ_s) for any given fabrication process can be uniquely derived from experimental measurements using a test pattern such as shown in Fig. 1, footnote 7. The fact that the model calculation agrees very well with experimental data of various sizes of Al and Mo contacts (see Fig. 4-6, footnote 7) seems to support this concept.

To further discuss the significance of MTL model, we plot its numerical result (curve 6) in Fig. 2 for a typical resistor (width = 2.3 mil) on the RHS and for a typical contact (width = 0.3 mil) on the LHS. On the RHS curve 6 and other theoretical calculations (except curve 1) all predict the same tendency, *i.e.*, when the contact becomes smaller at a fixed resistor width, R_{cc} increases. One notes that although other calculations (curves 2, 3, 4, 5, and 7) do qualitatively indicate the trends of variation, only the MTL result agrees with the experimental data (circles in Fig. 2). This is what is expected. Now let us examine the TL model: If the contact sheet resistance, ρ_s', were not introduced, the model would predict much too high a correction (~30% too high compared with experimental data). If the proper sheet resistivity, ρ_s', under the contact were used in the TL model (Eq. [12], footnote 7), it would result in still higher end correction (curve 7) than the MTL result (curve 6) as Berger indicates in his discussion. However, the experimental data (from Fig. 4, footnote 7) seem to fit the MTL result better, particularly when a, the gap, is large (the experimental data is not inversely proportional to W-$2a$ in Fig. 4-6, footnote 7). The difference between the TL result (curve 7) and the MTL result or the experimental data is about 5 ohms for $a = 0.9$ or $W_c = 0.3$ mils.

Berger has quoted the theoretical result of Ting *et al.*[8] (curve 3 or 4 in Fig. 2) and experimental result of D'Andrea and Murrmann[9] to support the sufficiency of the TL model. However, the result of Ting and Chen does not necessarily predict the accurate maximum influence of the constriction resistance. This is due to the ambiguity in their sum equation as pointed out in Section I. Furthermore, their result plotted in Fig. 2 (curve 3 or 4) gives much lower end correction than the experimental data and the MTL prediction. The experimental result of D'Andrea and Murrmann[9] (Modelling by Resistance paper) also does not predict the maximum influence of current crowding effect since it neglects the crowding beneath the contact. Their result expresses only a partial constriction resistance and should be compared with Eq. [2] given above. Nevertheless, it is worthwhile mentioning that their calculated results using TL model (Table II, footnote 9) are much higher than their measured data for most cases except one where the calculation uncertainty is largest. This discrepancy seems to suggest that the proper contact sheet resistance and the influence on contact correction due to the existence of a gap, a, should have been considered.

Now let us turn to this question: For a fixed contact width, W_c, how does R_{cc} vary with varying resistor width, W_R, or gap, a? The answer lies in LHS of Fig. 2. The MTL model predicts that R_{cc} decreases with increasing a or W_R (curve 6) whereas the TL model predicts a constant R_{cc} regardless of the resistor size (curve 7). If one would use W_R instead of constant W_c in TL's expression (Eq. [12], footnote 7), one would obtain curve 8 on LHS and result in a constant value on RHS of Fig. 2. Note that curves 7 and 8 trace out a closed loop in Fig. 2. This closed loop is similar to that traced out by curves 1 and 2, which result from the fact that Eq. [1] was derived under the assumption $W_R = W_c$. When this assumption no longer holds, it is uncertain whether W_R or W_c should be used in the calculation. The MTL model does not have this ambiguity; it does predict correct contact correction term for various contacts in a given resistor (RHS, Fig. 2). However, it would be interesting to obtain experimental data for a given contact contained in resistors of various widths to confirm the LHS of curve 6.

It has been demonstrated in my original paper that, in order to correctly predict both R_{cc} and R_c of aluminum and molybdenum contacts, the parameter, ρ_s', has to have values much lower than the original diffusion sheet resistance, ρ_s. This may or may not have physical significance, since there is no other direct evidence verifying the physical significance of the model parameters ρ_s' and σ_c simultaneously. Therefore, it would be interesting to see Berger's unpublished data on these parameters. Nevertheless, the fact that ρ_s' and σ_c can be uniquely derived from experimental test structure (Eq. [7, 15] and Eq. [5, 16] in footnote 7—two equations with two unknowns), it warrants the necessity of introducing ρ_s' in addition to ρ_s (which is determined by another independent equation, Eq. [6], footnote 7). The fact that the model calculation does agree with experimental data (Fig. 4-6, footnote 7) suggests that MTL is at least a good phenomenological model which can give a realistic estimate of contact correction term for any given contact size and fabrication process provided the model parameters are determined experimentally. This is the purpose of MTL model.

The Ga-GaP-GaAs Ternary Phase Diagram

G. A. Antypas (pp. 700-703, Vol. 117, No. 5)

G. B. Stringfellow:[16] Concerning the paper by G. A. Antypas, the author uses the Darken quadratic formalism for calculating activity coefficients in the ternary liquid phase. For calculating activity coefficient ratios, *i.e.* γ_i/γ_i^{STC}, where i = A, B, or C, the Darken quadratic formalism is equivalent to the regular solution formalism. For example, in the Darken formalism

$$\ln(\gamma_B) - \ln(\gamma_B^{STC}) = \ln(\gamma_B/\gamma^\circ_B) - \ln(\gamma_B^{STC}/\gamma^\circ_B)$$
$$= -2\alpha_{AB}N_B + (\alpha_{BC} - \alpha_{AB} - \alpha_{AC})N_C + \alpha_{AB}N^2_B + \alpha_{AC}N^2_C + (\alpha_{AB} + \alpha_{AC} - \alpha_{BC})N_BN_C - (-\alpha_{AB} + \alpha_{AB}/4)$$

This can be reduced, using the relation

$$N_A + N_B + N_C = 1$$

to give

$$\ln(\gamma_B) - \ln(\gamma_B^{STC}) = \alpha_{BC}N^2_C + \alpha_{AB}N^2_A + (\alpha_{BC} - \alpha_{AC} + \alpha_{AB})N_AN_C - \alpha_{AB}/4$$

which is the expression calculated using the regular solution model (see Prigogine and Defay[17]).

The equilibrium equations used in the calculation of III-V binary and ternary phase diagrams, contain activity coefficients only in the ratios γ_i/γ_i^{STC}. Thus, the regular solution formalism is equivalent to the Darken quadratic formalism for all such calculations.

G. A. Antypas: Dr. Stringfellow observed that since the activity coefficients appear in the form of ln γ_i/γ_i^{STC}, the Darken formulation is equivalent to the regular solution in describing III-V ternary liquid solutions. An inherent assumption made in showing

spreading beneath the contact and one for along the two sides of the contact (due to symmetry two sides can be combined). The MTL model is just based on this concept. The model parameters, the distributive resistance elements (ρ_s' and σ_c in addition to ρ_s) for any given fabrication process can be uniquely derived from experimental measurements using a test pattern such as shown in Fig. 1, footnote 7. The fact that the model calculation agrees very well with experimental data of various sizes of Al and Mo contacts (see Fig. 4-6, footnote 7) seems to support this concept.

To further discuss the significance of MTL model, we plot its numerical result (curve 6) in Fig. 2 for a typical resistor (width = 2.3 mil) on the RHS and for a typical contact (width = 0.3 mil) on the LHS. On the RHS curve 6 and other theoretical calculations (except curve 1) all predict the same tendency, *i.e.*, when the contact becomes smaller at a fixed resistor width, R_{cc} increases. One notes that although other calculations (curves 2, 3, 4, 5, and 7) do qualitatively indicate the trends of variation, only the MTL result agrees with the experimental data (circles in Fig. 2). This is what is expected. Now let us examine the TL model: If the contact sheet resistance, ρ_s', were not introduced, the model would predict much too high a correction (~30% too high compared with experimental data). If the proper sheet resistivity, ρ_s', under the contact were used in the TL model (Eq. [12], footnote 7), it would result in still higher end correction (curve 7) than the MTL result (curve 6) as Berger indicates in his discussion. However, the experimental data (from Fig. 4, footnote 7) seem to fit the MTL result better, particularly when a, the gap, is large (the experimental data is not inversely proportional to W-$2a$ in Fig. 4-6, footnote 7). The difference between the TL result (curve 7) and the MTL result or the experimental data is about 5 ohms for $a = 0.9$ or $W_c = 0.3$ mils.

Berger has quoted the theoretical result of Ting *et al.*[8] (curve 3 or 4 in Fig. 2) and experimental result of D'Andrea and Murrmann[9] to support the sufficiency of the TL model. However, the result of Ting and Chen does not necessarily predict the accurate maximum influence of the constriction resistance. This is due to the ambiguity in their sum equation as pointed out in Section I. Furthermore, their result plotted in Fig. 2 (curve 3 or 4) gives much lower end correction than the experimental data and the MTL prediction. The experimental result of D'Andrea and Murrmann[9] (Modelling by Resistance paper) also does not predict the maximum influence of current crowding effect since it neglects the crowding beneath the contact. Their result expresses only a partial constriction resistance and should be compared with Eq. [2] given above. Nevertheless, it is worthwhile mentioning that their calculated results using TL model (Table II, footnote 9) are much higher than their measured data for most cases except one where the calculation uncertainty is largest. This discrepancy seems to suggest that the proper contact sheet resistance and the influence on contact correction due to the existence of a gap, a, should have been considered.

Now let us turn to this question: For a fixed contact width, W_c, how does R_{cc} vary with varying resistor width, W_R, or gap, a? The answer lies in LHS of Fig. 2. The MTL model predicts that R_{cc} decreases with increasing a or W_R (curve 6) whereas the TL model predicts a constant R_{cc} regardless of the resistor size (curve 7). If one would use W_R instead of constant W_c in TL's expression (Eq. [12], footnote 7), one would obtain curve 8 on LHS and result in a constant value on RHS of Fig. 2. Note that curves 7 and 8 trace out a closed loop in Fig. 2. This closed loop is similar to that traced out by curves 1 and 2, which result from the fact that Eq. [1] was derived under the assumption $W_R = W_c$. When this assumption no longer holds, it is uncertain whether W_R or W_c should be used in the calculation. The MTL model does not have this ambiguity; it does predict correct contact correction term for various contacts in a given resistor (RHS, Fig. 2). However, it would be interesting to obtain experimental data for a given contact contained in resistors of various widths to confirm the LHS of curve 6.

It has been demonstrated in my original paper that, in order to correctly predict both R_{cc} and R_c of aluminum and molybdenum contacts, the parameter, ρ_s', has to have values much lower than the original diffusion sheet resistance, ρ_s. This may or may not have physical significance, since there is no other direct evidence verifying the physical significance of the model parameters ρ_s' and σ_c simultaneously. Therefore, it would be interesting to see Berger's unpublished data on these parameters. Nevertheless, the fact that ρ_s' and σ_c can be uniquely derived from experimental test structure (Eq. [7, 15] and Eq. [5, 16] in footnote 7—two equations with two unknowns), it warrants the necessity of introducing ρ_s' in addition to ρ_s (which is determined by another independent equation, Eq. [6], footnote 7). The fact that the model calculation does agree with experimental data (Fig. 4-6, footnote 7) suggests that MTL is at least a good phenomenological model which can give a realistic estimate of contact correction term for any given contact size and fabrication process provided the model parameters are determined experimentally. This is the purpose of MTL model.

such equivalence, however, is that the interaction parameters (α_{ij}) are independent of composition. In calculating the interaction parameters of III-V compounds, Vieland's[18] regular solution approach has been used extensively which results in temperature-dependent parameters only. A recent analysis of available thermodynamic data of GaAs and GaP made by Rao and Tiller[19] showed that the interaction parameters of these compounds in addition to being temperature dependent are also strong functions of composition. Under this condition, the ratio of the activity coefficients based on Darken's formulation becomes

$$\ln \frac{\gamma_B}{\gamma_B^{STC}} = \alpha_{BC}N_C^2 + \alpha_{AB}N_B^2 + (\alpha_{BC} - \alpha_{AC} + \alpha_{AB})N_AN_C - \alpha_{AB} + \frac{3}{4}\alpha_{AB}^{STC}$$

[18] L. J. Vieland, *Acta Met.*, **11**, 137 (1963).
[19] M. V. Rao and W. A. Tiller, *J. Phys. Chem. Solids*, **31**, 191 (1970).

where α_{AB}^{STC} is the interaction parameter of AB at the stoichiometric composition.

A second assumption made in showing such equivalence is that the i^{th} component must be treated as a solute in both the ternary and stoichiometric binary solutions. This is the case in ternary systems having one column III and two column V elements (assuming of course that the column III element is always the solvent for both the ternary and the two stoichiometric binary solutions). However, for a ternary system, A-B-C, where A and B are column III elements and C is a column V element with B and C being the solutes, the activity coefficient ratio $\ln \gamma_B/\gamma_B^{STC}$ does not reduce to that described by the regular solution even when the interaction parameters are independent of composition. For such a system, γ°_C in A (the activity coefficient at infinite dilution of C in A), γ°_C in B and γ°_B in A are needed to describe the ternary system using Darken's formulation. None of these parameters, however, are required for the regular solution treatment.

The Microstructure of Sintered Silver Electrodes

IV. Formation of AgO during Charges

Charles P. Wales*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

Silver electrodes were cycled in 35% KOH solution and examined at various times during constant current charges. The initial formation of AgO took place on the surface of Ag_2O after charge potential rose to the Ag_2O/AgO plateau. Preferred locations for initial oxidation of Ag_2O were in the interior of the electrode, around the grid and near large Ag particles where the Ag_2O coating which formed earlier in the charge was comparatively thin. After initial AgO formation in an electrode, oxidation of nearby Ag and Ag_2O took place as the charge continued. Little or no additional Ag was oxidized in other areas of the electrode until AgO had formed there also.

The structure of silver electrodes of the type used in storage batteries is of interest, because knowledge of the structure helps in explaining the capacity changes observed when cells containing Ag electrodes are cycled. Earlier papers in this series have described changes in structure during discharges (1) and at the end of discharges (2), as well as formation of Ag_2O during charges (3). Electrodes in this work were cycled using the relatively fast 1 hr rate of discharge and the 20 hr rate of charge.

The size of Ag produced during a discharge as silver oxides are reduced depends on the rate of reduction. Fast discharges produce smaller Ag particles than slow discharges (1, 2). The electrolyte plays an important role in the formation of these particles. During a discharge, the electrolyte becomes supersaturated with dissolved Ag_2O (4). Although reduction can take place through a dissolved species, the reduction of dissolved Ag_2O is reported to be much slower than reduction of the oxide on the surface of an electrode (5). At a high discharge C.D., there are larger concentration gradients in the electrolyte and in the oxide than during slow discharges. These differing conditions promote formation of small dendritic Ag particles during a rapid discharge (2), while much larger Ag particles form during a slow discharge (6).

The size of particles produced during a discharge is very important, because in the subsequent charge small Ag particles are oxidized more readily and to a greater extent than large particles. This advantage of fast discharges in producing small particles is partially offset by fast discharges taking place at lower potentials. As a result, cells can reach the cutoff potential before all oxides have been reduced to Ag.

Experimental Procedure

Sintered Ag electrodes were cycled in 35% KOH solution at 25°C. All charges were done at the 20 hr rate of constant current, and all discharges at the 1 hr rate. Samples were cut from the electrode at various times during charges. Polished cross sections of the samples were examined using a light microscope. Details of the experimental procedure were presented earlier (1).

Results

Oxidation of Ag_2O to AgO.—All Ag particles in a porous Ag electrode had a definite Ag_2O coating by the time that potential reached the peak that ends the Ag/Ag_2O potential plateau and begins the Ag_2O/AgO plateau of a constant current charge (3). This was the condition of the active material in an electrode when AgO began to form.

The formation of AgO in a cycled electrode which had been partially charged at the Ag_2O/AgO potential is shown in Fig. 1. All photographs in this paper are cross sections through electrodes and, therefore, show cross sections through the individual crystals or particles in an electrode. After charge potential had reached the peak, the electrode in Fig. 1 was given an additional amount of charge equal to 8% of the total capacity usually accepted during a complete charge. This additional charge would have been sufficient to oxidize 21% of the Ag_2O that had formed earlier in this charge, if the reaction had consisted only of Ag_2O being oxidized to AgO. It was evident, however, that some Ag had also been oxidized after reaching the potential peak. The total charge given the electrode shown in Fig. 1 was 47% of the charge usually accepted before oxygen evolution began.

AgO had formed in many areas of this partly charged electrode, chiefly in the interior. An area where a large amount of AgO was present is in the center of Fig. 1. AgO was comparatively rare on the surface of the electrode. It had formed around all of the grid members and usually was found adjacent to the large Ag particles in an electrode. Almost all of the largest AgO particles had formed near large Ag particles. Most areas surrounding clumps of AgO crystals in the partly charged electrode were still largely Ag_2O and Ag. These areas of Ag_2O and Ag were identical in appearance to the Ag_2O and Ag present in an electrode charged to the potential peak (3), except that small AgO particles were often present in these areas. A few

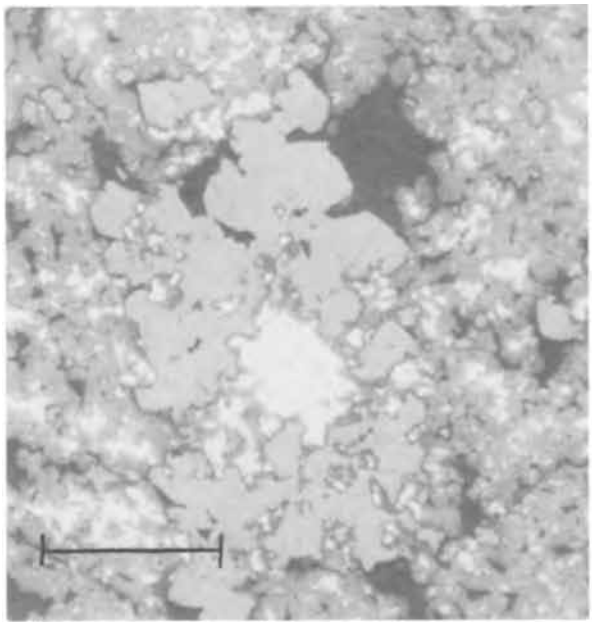

Fig. 1. Silver electrode partly charged at Ag_2O/AgO potential plateau at cycle 6, showing large AgO crystals that form after Ag_2O has formed in the electrode. Metallic Ag is white, AgO is light gray and predominates in the central areas of this photograph, Ag_2O is darker gray, and void areas are black. Marker indicates 15μ.

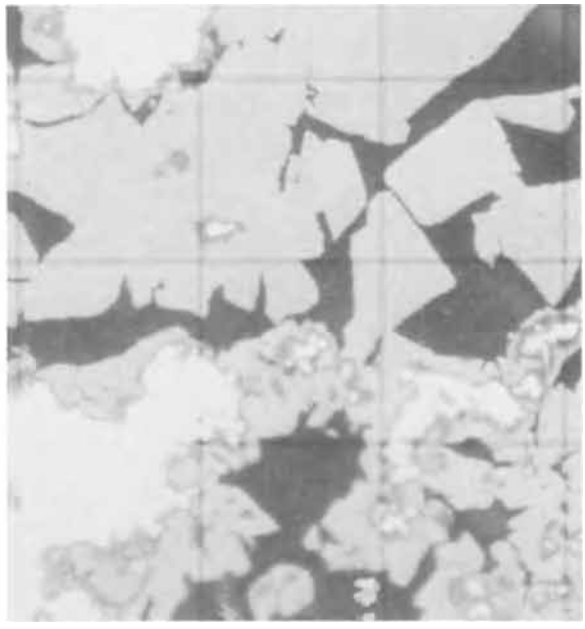

Fig. 2. Silver electrode charged to oxygen evolution at cycle 2. The majority of the active material was oxidized to AgO (light gray). Silver was the next most common form present (white). A thin layer of Ag_2O (darker gray) separated the Ag from the AgO. Small Ag_2O particles were also present at scattered sites in the AgO. Lines forming squares are 15μ apart.

small AgO particles can be seen among the Ag_2O and Ag in Fig. 1.

Charged electrode at cycle 2.—Conditions during the first charge were different from those during later charges. The average size of Ag particles in an unused sintered Ag electrode was larger than the size produced as silver oxides were reduced during a fast discharge. At cycle 2 and at later cycles, much of the oxidation was taking place on the small Ag particles which had been formed in the fast discharges. Thus the appearance of an electrode at cycle 2 is a better starting point than cycle 1 for describing the gradual changes that take place as an electrode is cycled using fast discharges.

Typical AgO formations in an electrode charged to oxygen evolution at cycle 2 are shown in Fig. 2. This electrode had accepted approximately 66% of theoretical capacity before oxygen evolution became strong. Some areas of the electrode contained large clumps of AgO crystals, such as the top of Fig. 2. The area at the bottom of Fig. 2 contained smaller AgO crystals and resembled the center of Fig. 1. In some parts of the electrode, the active material was more densely packed and contained less void space than is shown in Fig. 2. A few small areas contained several oblong AgO particles which were aligned approximately parallel to each other. Different groups of these oblong particles were aligned at random, although particles in any one group tended to be aligned in a single direction.

The Ag_2O coating that separated the remaining Ag from the AgO was thicker on small Ag particles than on large Ag particles. Although relatively little Ag_2O remained in some areas of the electrode (top of Fig. 2) Ag_2O was prominent in areas containing small Ag particles and where Ag_2O particles were present in small clumps.

Another area of the same electrode is shown in Fig. 3. This illustrates the sizes of AgO particles and voids early in the cycle life. The AgO crystals at the end of a charge were larger than the Ag_2O crystals that had formed earlier while charging at the Ag/Ag_2O potential. Many small pores had been present in the Ag_2O but, as the charge took place at the Ag_2O/AgO potential, the AgO which formed tended to fill these pores. The large voids between clumps of active material changed little in size during a charge.

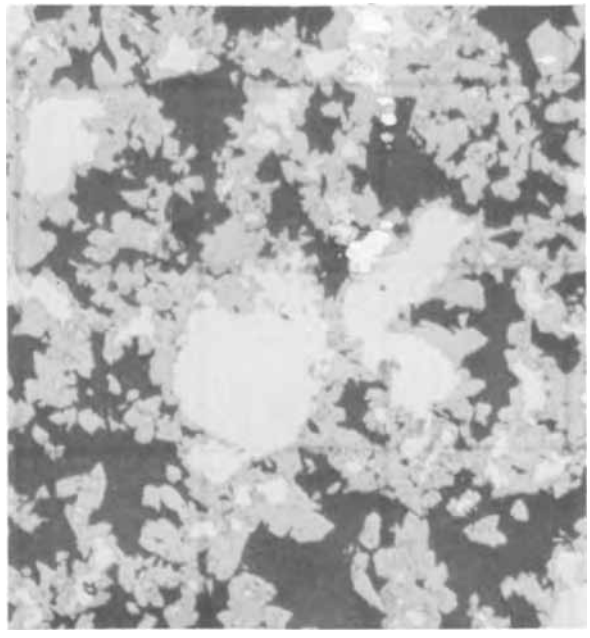

Fig. 3. Electrode charged to oxygen evolution at cycle 2. Same electrode as shown in Fig. 2, but at lower magnification. Lines forming squares are 60μ apart.

Effects of C.D. and cycling.—The capacity accepted during a charge gradually decreased as electrodes were cycled. The rate of decrease varied greatly, depending on conditions of the preceding discharges. The charges shown in Fig. 4 indicate typical potentials as electrodes were cycled. Capacity decreased slowly when all discharges were done at the 1 hr rate. Results from an electrode always discharged at the 20 hr rate are included in Fig. 4 for comparison. As can be seen by the charge curves at cycle 1, the two electrodes had accepted somewhat different amounts of capacity when the previously unused electrodes were charged for the first time. Then charge acceptance

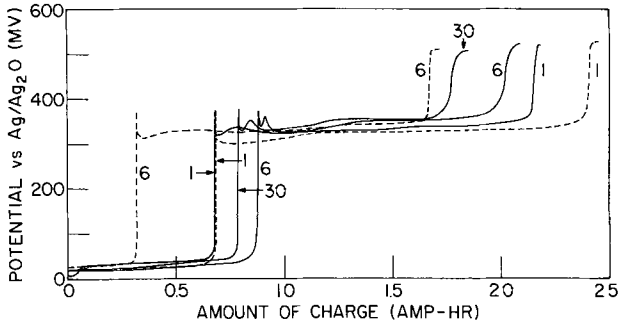

Fig. 4. Potentials at two Ag electrodes during charges at the 20 hr rate in 35% KOH at 25°C. Solid lines show charges at cycles 1, 6, and 30 of an electrode always discharged at the 1 hr rate. Dashed lines show charges at cycles 1 and 6 of an electrode always discharged at the 20 hr rate.

decreased rapidly during the first few cycles using slow discharges. As a result of this rapid decrease, the charge acceptance was less after 6 slow discharges than after 30 fast discharges.

Another change was in the shape of the potential curve at the end of a charge as potential rose to the oxygen evolution value. The final rise in charge potential was slow following rapid discharges. This can be seen in Fig 4 by comparing the gradual rise in potential shown by the solid lines at cycles 6 and 30 with the faster rise at cycle 1. Potential rise to oxygen evolution was much more rapid at the end of charges following slow discharges (dashed line at cycle 6).

The proportion of a charge that was accepted at the Ag_2O/AgO potential plateau varied, depending on discharge conditions (Fig. 4 and 5). During the first few charges that followed fast discharges, increasing amounts of Ag_2O were formed before potential reached the charge peak, while capacity accepted at the Ag_2O/AgO potential decreased proportionately. This resulted in a decrease in the per cent of a charge that took place at the Ag_2O/AgO plateau (circles, lower portion of Fig. 5).

In contrast, sharply decreasing amounts of Ag_2O formed during the first few charges that used slow discharges, while charge acceptance at the Ag_2O/AgO plateau also decreased, but more slowly. The per cent of a charge taking place at the Ag_2O/AgO potential plateau increased in this period for electrodes given slow discharges (Fig. 5). Charge acceptance became relatively constant beginning at cycle 3 when fast discharges were used, and at cycle 4 or 5 when using slow discharges.

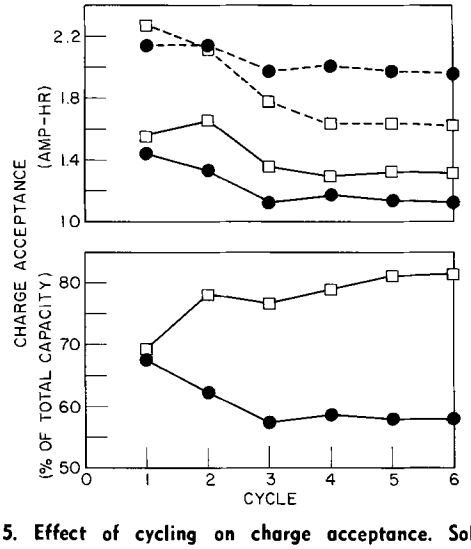

Fig. 5. Effect of cycling on charge acceptance. Solid lines, charge acceptance at the Ag_2O/AgO potential. Dashed lines, total charge acceptance. Circles are averages of 4 electrodes always charged at the 20 hr rate and discharged at the 1 hr rate. Squares are averages of 9 electrodes always charged and discharged at the 20 hr rate.

In calculating the arithmetic means shown in Fig. 5, the charge acceptance was assumed to equal the capacity given electrodes when charge potential reached 450 mV *vs.* the Ag/Ag_2O reference electrode. The computations did not include any electrodes from which samples had been removed, because of uncertainty as to the exact amount that capacity was lowered when each sample was cut. Small cracks often developed when a sample was cut and pieces of active material broke away from the electrode. A charged electrode was particularly brittle and subject to cracking when a sample was cut.

Some electrodes always accepted and delivered a greater or smaller capacity than other electrodes treated similarly. This variation in capacity resulted in the measured values being spread over a range. If a sufficiently large number of electrodes had been used, no doubt the difference in the calculated arithmetic means would have disappeared for the first charge of a previously unused electrode. The significance of the difference between the means for charge acceptance expressed as per cent was determined by the t-distribution test. These means (lower portion of Fig. 5) were not significantly different for the two sets of electrodes at cycle 1. The differences became highly significant (less than 0.1% probability that the differences were not significant) when the means for the two sets of electrodes were compared at cycles 2-6.

Charged electrode at cycle 15.—One of the most noticeable structural changes as an electrode was cycled was the gradual clumping of the active material. This change was evident in both discharged and charged electrodes (2, 3). The AgO in a charged electrode was in the form of small angular particles at cycle 2, with small voids in the AgO (Fig. 3). The active material agglomerated sufficiently rapidly that by cycle 5 large clumps of AgO were present at the end of a charge. The clumps continued to grow in size as an electrode was cycled. An example of the AgO in a charged electrode at cycle 15 is given in Fig. 6. The angular shapes typical of AgO in the early cycles (Fig. 2, 3) were less common at cycle 15. The number of small voids in the active material

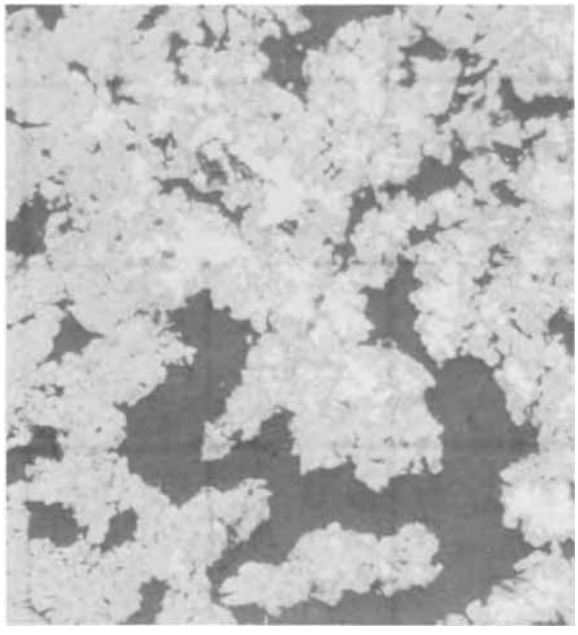

Fig. 6. Silver electrode charged to oxygen evolution at cycle 15. Lines forming squares are 60μ apart. Comparison with Fig. 3 indicates the way active material clumped as an electrode was cycled.

gradually decreased as an electrode was cycled, while the large voids were increasing in size.

Another change that took place with cycling was the increased amount of Ag_2O present at the end of a charge. Although AgO was the predominant form of oxide in an electrode charged to oxygen evolution, much Ag_2O was also present at cycle 15. The amount of Ag_2O present at the end of a charge had increased in the first few cycles which used discharges at the 1 hr rate. Little additional change in the Ag_2O was noted after cycle 5.

The oxide coating that formed on large Ag particles and on the grid gradually thickened with cycling. The grids were closer to one surface of the electrode than to the other. A charged electrode usually had a gray-colored surface but, in the sample taken at cycle 15, the grid was outlined in a shade of gray that was lighter than most of the remainder of the surface. When a cross section of this electrode was examined under the microscope, however, no difference was noted between the AgO on the surface next to a grid member and the AgO in other areas of the surface. The difference in shades of gray may have resulted from fewer voids on the parts of the surface next to grid members.

Charged electrode at cycle 28.—Many of the structural changes that had taken place between cycles 2 and 15 continued to take place as an electrode was given additional cycles. A portion of a charged electrode at cycle 28 is shown in Fig. 7. The surface of this electrode had a granular appearance and contained light and dark gray areas, with dark gray predominating slightly. The clumps of active material were larger than they had been at cycle 15 (compare Fig. 7 with 6). The size of large voids between the clumps had increased between cycles 15 and 28, but the change in size was less than the increase between cycles 2 and 15 (Fig. 3 and 6).

In a charged electrode that had been cycled many times, part of the AgO was present as large groups of crystals. An example of an area where many AgO crystals had grown together is shown in Fig. 8. Large areas that were mainly AgO were common in the early cycles (see top of Fig. 2). These areas gradually became less common as an electrode was cycled. The angular shapes typical of AgO crystals became less evident as an electrode was cycled and masses of AgO crystals tended to be more tightly packed. The oxide layer on the grid of a charged electrode gradually thickened and was much thicker at cycle 28 than at cycle 2.

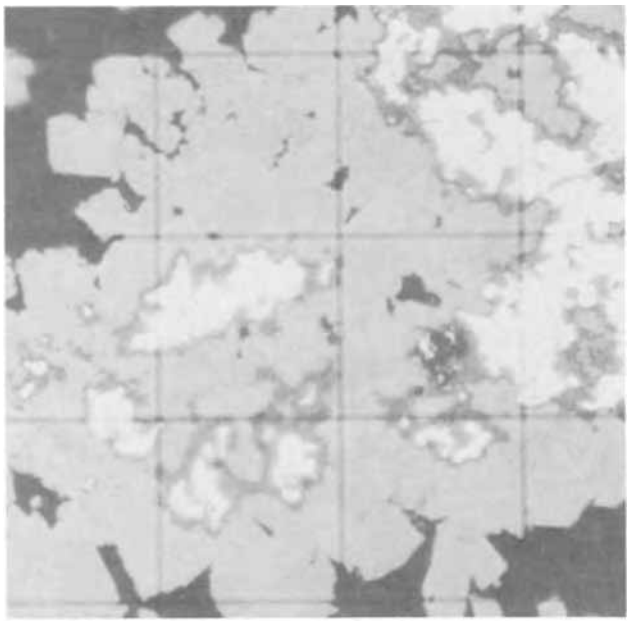

Fig. 8. Large clumps of AgO crystals present in an electrode charged to oxygen evolution at cycle 28. Same electrode as Fig. 7, but a different area and at higher magnification. Lines forming squares are 15μ apart.

Although unpolarized light was the most useful illumination for general viewing of polished cross sections of the electrodes, polarized light often gave additional information. All photographs from Fig. 1 to 8 were made using unpolarized light. The same area shown in Fig. 8 is shown in Fig. 9 using polarized light and a sensitive tint plate. Under both types of illumination, the light was at right angles to the polished surface of the electrode. The polycrystalline nature of the AgO clumps became evident when polarized light was used. This technique does not differentiate between individual Ag crystals or Ag_2O crystals. Ag_2O crystals must be smaller than AgO crys-

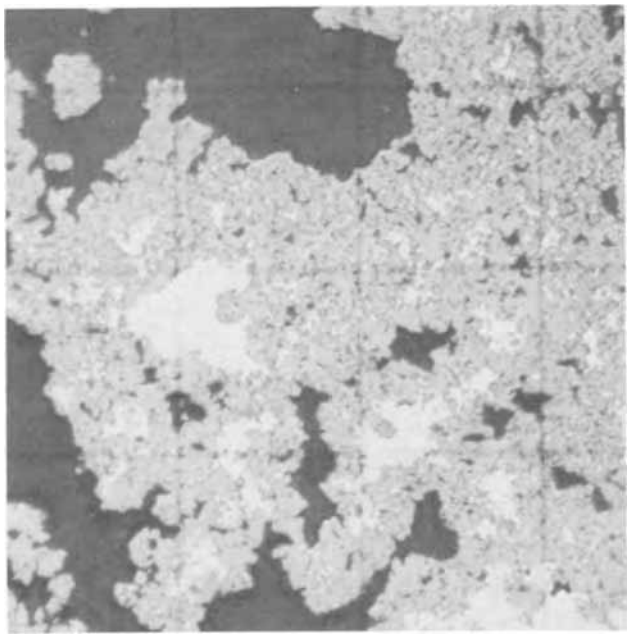

Fig. 7. Silver electrode charged to oxygen evolution at cycle 28. Lines forming squares are 60μ apart. Comparison with Fig. 3 and 6 shows that cycling resulted in a gradual increase in size of voids and clumps of active material.

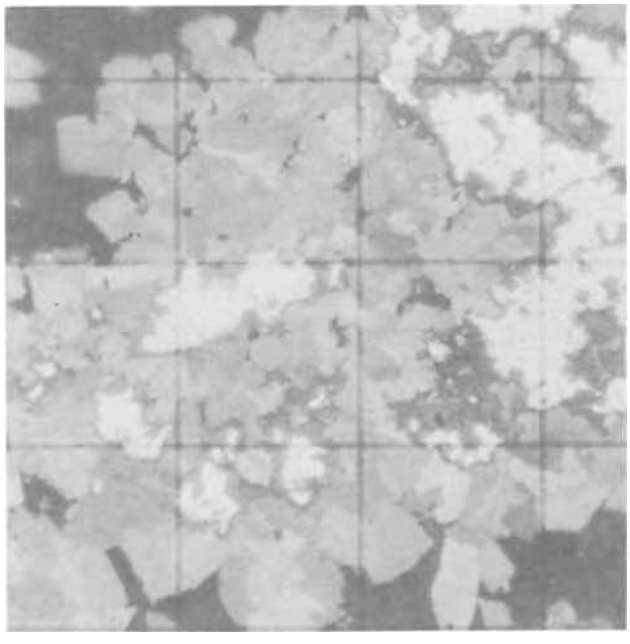

Fig. 9. Same area as Fig. 8, but using polarized light and a sensitive tint plate so that many of the individual AgO crystals can be differentiated from each other.

tals, however, because individual Ag_2O clumps were smaller than most AgO crystals.

At the end of a charge, most areas of well-cycled electrode contained more Ag_2O than the area shown in Fig. 8. A more typical area of the same electrode is given in Fig. 10. Many small Ag_2O clumps and Ag particles were present in this electrode. By the time that oxygen evolution began, all Ag was covered with Ag_2O and the Ag_2O covered with AgO. In a few areas, the Ag_2O layer that separated Ag from AgO was thicker than the layer shown in Fig. 8-10. The area shown in Fig. 10 should be compared with the bottom of Fig. 2 where a somewhat similar structure was present. Only small regions with a structure such as this were found at cycle 2.

Oxides having a particular clump size were randomly distributed in a charged electrode in the early cycles, but distribution became uneven as the cycling progressed. The surface areas of a charged electrode differed from the interior in several ways at cycle 28. AgO crystals near the electrode surface were smaller than the AgO in the interior. Ag_2O was more abundant in the surface areas than elsewhere. Clumps of particles oriented at right angles to the surface were sometimes found on the electrode surfaces at cycle 28, but were not common. None of these differences between the surface and interior were present in an electrode at cycle 2.

The particles of metallic Ag that remained at the end of a charge were not randomly distributed at cycle 28 but predominated in the interior of the electrode. Earlier work has shown that large particles of Ag gradually developed in the interior of an electrode under the cycling conditions used here (2). Many Ag particles remained in the large AgO clumps at the end of cycle 28 charge (Fig. 7 and 10). The number of intermediate-sized Ag particles had also increased.

Discussion

Anodic formation of AgO.—It is well known that Ag_2O is the first product when Ag is anodically oxidized in alkaline solution. Then, under constant current conditions, AgO begins to form after anodic potential makes a sharp rise of approximately 0.3V above the Ag/Ag_2O potential plateau. Small amounts of AgO can be detected after potential exceeds the Ag_2O/AgO equilibrium value but before potential reaches the peak (7). After reaching the peak, potential declines to the Ag_2O/AgO charging plateau and formation of AgO is the main reaction. A secondary reaction is the oxidation of additional Ag to Ag_2O. It has been established by x-ray diffraction that the initial formation of AgO takes place on the surface of Ag_2O crystals next to the electrolyte (7, 8). Observations using electron microscopy (9, 10) and light microscopy (6) have shown that AgO crystals grow to larger sizes than Ag_2O crystals when Ag electrodes are oxidized anodically in alkaline solutions. Kinetic work on the anodic oxidation of Ag_2O to AgO leaves some doubt as to the way the oxidation occurs, since the conclusions reached in different studies do not agree with each other (11, 12).

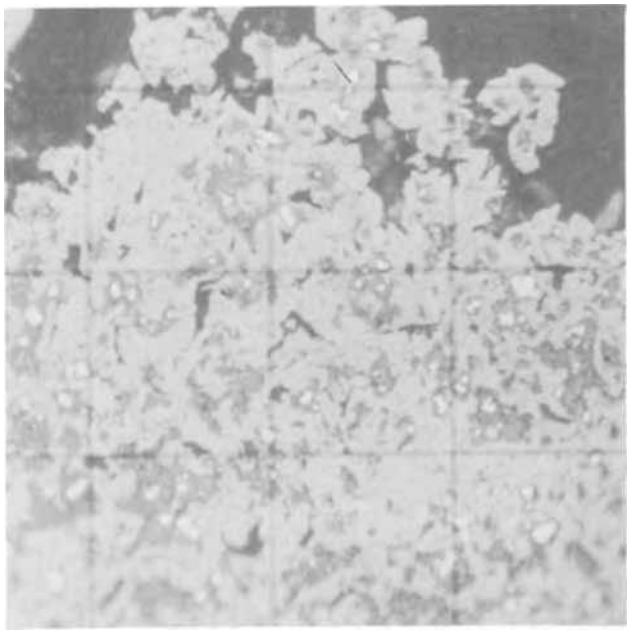

Fig. 10. Small Ag particles and clumps of Ag_2O that were present in the AgO near the surface of a charged electrode at cycle 28. Same electrode as Fig. 7-9. Lines forming squares are 15μ apart.

Microscopic examination of the electrodes indicated that the formation of AgO differed from formation of Ag_2O. Ag_2O had formed at scattered sites throughout the electrode, both at the surface and the interior (3). Ag_2O had formed preferentially and to a greater extent on the smallest Ag particles. When AgO began to form during a charge, however, AgO tended to form first near large Ag particles and around the grid members. These were places where the Ag_2O coating was thinnest.

The grid and most large Ag particles served as a conducting network in the electrode. Potential drop between the Ag_2O/solution interface and this conducting network should be smallest in places where the Ag_2O coating was thinnest. Therefore, when potential rose above the Ag_2O/AgO equilibrium value, the potential at the Ag_2O/solution interface was highest on the grid and on the large particles, and AgO nucleated here initially. The reason that AgO was comparatively rare on the surface of an electrode that was partly charged at the Ag_2O/AgO potential plateau was because most large Ag particles were in the interior of the electrode and not on the surface.

After the initial nucleation of AgO at various sites in the electrode, the AgO then spread to surrounding areas. It can be seen in Fig. 1 that metallic Ag was less common where AgO had formed than in adjacent areas where Ag_2O predominated. After AgO had formed, oxidation of neighboring Ag and Ag_2O took place simultaneously. Oxidation was concentrated near these AgO areas, with no additional oxidation of Ag to Ag_2O visible in other areas until AgO had formed there also.

Groups of AgO crystals grew together into relatively large bodies (Fig. 2, 8). Judging by the size of individual crystals in these large masses of AgO (Fig. 9), it is likely that the individual crystals formed from different clumps of Ag_2O. Many of the large masses of AgO crystals may begin forming in the way illustrated in Fig. 1, with AgO first forming a layer around Ag particles that is almost free from pores. There seems to be little additional oxidation of Ag particles after a complete coating of AgO has formed around the Ag. After a certain thickness is reached, the AgO does not thicken appreciably as a result of additional oxidation of the coated particles, but thickens as the surrounding Ag_2O and Ag are oxidized to AgO and the AgO clumps contact each other. The AgO needs only to have electronic conduction for large bodies of AgO to form in this way. Electrolyte diffusion should become increasingly hindered during a charge because AgO occupies a larger volume than Ag or Ag_2O and tends to fill the smallest voids in the electrode.

The amount of Ag_2O present at the end of a charge gradually built up as the cycling progressed (Fig. 3, 6, 7). Perhaps the reason for increased Ag_2O, and for it being more abundant near the surface of the electrode, was connected to changes in the current distribution as the active material clumped with cycling. Many of the Ag and Ag_2O particles in a charged electrode had only a thin AgO coating (less than 1μ) separating the particles from the electrolyte (Fig.

10). The fact that these particles had not been oxidized to AgO during the charge indicated that ion conduction did not take place through the solid AgO to a very great extent under these charging conditions.

Decline of capacity with cycling.—Capacity changes were the result of changes in the microstructure of these electrodes. It was mentioned earlier that larger Ag particles gradually developed as an electrode was cycled, particularly in the interior of the electrode. Since large Ag particles do not oxidize as completely or as readily as small particles, a greater amount of Ag remained in an electrode at the end of a charge at cycles 25-30 than at cycles 1-5. The increased amount of metallic Ag present at the end of a charge was reflected in a gradual decrease of the charge acceptance as an electrode was cycled. Charge acceptance usually fell in the range 60-65% of theoretical capacity at cycle 28. Earlier these electrodes had accepted 65-80% at cycle 2.

In contrast, electrodes discharged at the 20 hr rate gave a large capacity at cycle 1, since almost all oxide could be reduced during a slow discharge (Fig. 5). But, electrodes discharged at this slow rate formed Ag particles that were more than 10 times the size of the small particles which formed during a discharge at the 1 hr rate. Capacity dropped rapidly as a result of the large Ag particles not oxidizing completely in subsequent charges.

When potential fell to the cutoff value at the end of a discharge at the 1 hr rate, an electrode still contained approximately 1/10 of the oxide that had been present at the end of a charge. The proportion of oxide that was not reduced during a discharge remained approximately constant with cycling, when all cycles used the same rate of discharge. As a result of the same amount always remaining, and little oxygen evolving except at the end of a charge, beginning with cycle 2 the electrodes gave close to 100% efficiency. At cycle 1, however, efficiency averaged only 92% because part of the charge current was used in forming oxide which was not reduced during cycle 1 discharge. Judging only by charge acceptance, capacity seemed to decline 6% from cycle 1 to 6 (solid lines in Fig. 4), but the actual decrease in measured discharge capacity was only 2%. This difference between charge acceptance and discharge capacity resulted from the inefficiency of cycle 1, mentioned above.

Conclusions

1. The capacity decline with cycling was the result of changes in the microstructure. As larger Ag particles gradually developed in the electrode, mainly in the interior, a larger proportion of the active material remained in the metallic state at the end of a charge.

2. AgO formation showed a preference for sites where Ag_2O was thin, such as on the surface of large Ag particles and around the Ag grid in the electrode. This contrasted with Ag_2O forming at random sites earlier in a charge.

3. After AgO had formed, nearby Ag and Ag_2O were oxidized simultaneously, but further oxidation of Ag in other areas of an electrode did not take place until AgO had also formed in these areas.

4. AgO crystals were larger than Ag_2O crystals. Groups of AgO crystals grew together into large polycrystalline masses and tended to fill small pores in the active material.

5. As an electrode was cycled, it became less common to find large areas which were mainly AgO in a fully charged electrode. Instead, more small Ag particles and clumps of Ag_2O were present in a charged electrode.

6. At the end of a charge, the surface of a well-cycled electrode contained smaller AgO crystals and more Ag_2O than the interior.

General Equations for Gas Phase Compositions in Epitaxial Flow Systems

I. Amron*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Equations are derived for computing the concentration of each reagent entering an epitaxial reactor from a gas train. The two basic types of systems are: (*a*) a main diluent stream, part of which is diverted through a number of parallel saturators, each containing several mutually miscible components; and (*b*) an all-gaseous system with several dilution stages. In addition, the equations for a hybrid system, which combines the two types, are also derived. The equations have no limits on the number of components or dilution stages.

Since the rate of growth of an epitaxial layer is determined by a number of factors, among which is the composition of the gas phase entering the reactor, it is necessary that the gas phase composition be known and well controlled. In order to achieve desired growth rates, the gas phase content of the epitaxial matrix source reagent must be low, usually a mole fraction less than 0.001. If the film is to be doped in a con-

* Electrochemical Society Active Member.
Key words: vapor saturators, multicomponent flow systems.

trolled manner, then the amount of dopant reagent must be even lower; in some instances, the mole fraction of dopant must be as low as 10 parts per billion in the gas phase.

The techniques, developed for attaining the low gas phase concentrations, all involve the dilution of the source reagents in a controlled manner. Gaseous source compounds may be purchased prediluted with carrier gas and used directly down to about 5 ppm. For lower concentrations, additional controlled-dilution stages must be provided in the gas supply train. With liquid reagents, sufficient dilution may be obtained by diverting a fraction of the carrier gas stream through a flow meter, which monitors the carrier flow rate through a bubble saturator. By thermostatic control of the saturator temperature, the vapor pressure of the source reagent in the diverted carrier gas stream is maintained at a constant and controlled level. The saturated carrier gas stream is then mixed with the main carrier gas stream, which serves to dilute the source vapor concentration to a moderately low level. A highly desirable feature of this technique is the wide range of concentrations which may be obtained by changing the relative flow rates of the main and diverted streams and/or changing the temperature of the saturator. This technique is sufficiently accurate and simple for use down to concentrations of the order of 1 ppm. However, the extremely low concentrations required for the lowest epitaxial film dopant levels are frequently difficult to obtain with reasonable precision, because of the very low flow rates ($\leqq$ 1 cm^3 min^{-1}) and low saturator temperatures ($\leqq$ −30°C) which must be controlled and measured. To obtain the required low dopant reagent concentrations, the saturator technique can be modified by using a dilute solution of dopant reagent dissolved in the liquid matrix reagent, *e.g.* BBr_3 dissolved in $GeBr_4$.

Practical systems may be either of the above-mentioned types or a combination of the two. As a result, once a system has been designed, it becomes essential to develop the computational equations for obtaining the gas phase compositions. This chore may become a rather frustrating one because of the extensive algebraic manipulation associated with even a moderately complex system. With the objective of reducing the required effort, this paper describes the general equations for computing the concentration of each reagent entering the reactor from a gas train, which consists of: (*a*) a main diluent stream, part of which is diverted through a number of parallel saturators, each containing several mutually miscible components; (*b*) an all-gaseous system with several dilution stages; and, finally, (*c*) a hybrid system, which utilizes both dilution methods. Thus, by starting with the most general equation appropriate for a specific system, the user may easily reduce the equation to that which applies in his case.

A Multiple-Saturator System

The model for the multiple-saturator system is shown in Fig. 1. The following assumptions are made in the derivations:

1. The ideal gas laws and Raoult's law are valid for the components used in the system.
2. The liquids in the saturators are mutually miscible at the concentrations used, and the solubility of the carrier gas in the liquids is negligibly small.
3. The saturators are capable of saturating the carrier gas at the equilibrium partial pressures of each of the liquids contained in each of the saturators.
4. The pressure drop is negligible from the point of release of the bubbles from the liquid to the reactor.
5. All of the flow meter calibrations are corrected to the same standard conditions of pressure and temperature.

The exact general solution for the model in Fig. 1 is

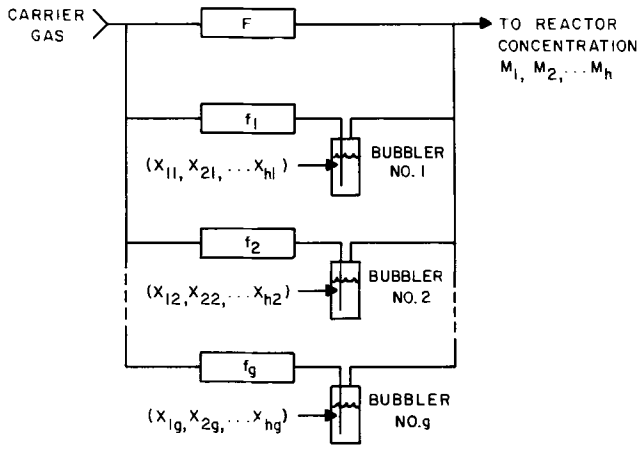

Fig. 1. Model for the multiple-saturator system

$$M_i = \frac{\sum_{j=1}^{g} \left\{ f_j (x_i P_i)_j \Big/ \left[P - \left[\sum_{i=1}^{h} x_i P_i \right]_j \right] \right\}}{F + P \sum_{j=1}^{g} \left\{ f_j \Big/ \left[P - \left[\sum_{i=1}^{h} x_i P_i \right]_j \right] \right\}} \quad [1]$$

where: M_i = the mole fraction of the i^{th} component in the gas stream entering the reactor
f_j = the volume rate of flow of carrier gas entering the j^{th} saturator
$(x_i P_i)_j$ = the partial pressure of the i^{th} component in the j^{th} saturator; x_i is the mole fraction of the i^{th} component in the liquid contained in the j^{th} saturator and P_i is the vapor pressure of pure i at the temperature of the j^{th} saturator
P = the ambient pressure downstream of the saturator
F = the volume rate of flow of diluent carrier gas being added to the vapor-saturated gas streams from the saturators

The derivation of Eq. [1] is given in the Appendix.

The following cases represent four particular applications of Eq. [1]:

A. One saturator, one pure reagent.—A by-pass carrier stream in parallel with one saturator, which contains a single pure liquid, m. The mole fraction of the vapor, M_m, entering the reactor is given by

$$M_m = \frac{P_m}{\frac{F}{f}(P - P_m) + P} \quad [2]$$

where: P_m = the vapor pressure of pure m at the saturator temperature.

B. One saturator, two reagents.—A bypass carrier stream in parallel with one saturator, which contains a solution of a dopant reagent, d, and a matrix reagent, m. The mole fractions are given by Eq. [3a] and [3b]

$$M_d = \frac{x_d P_d}{\frac{F}{f}(P - x_d P_d - x_m P_m) + P} \quad [3a]$$

$$M_m = \frac{x_m P_m}{\frac{F}{f}(P - x_d P_d - x_m P_m) + P} \quad [3b]$$

where: P_d, P_m = the vapor pressures of pure d and pure m, respectively, at the saturator temperature
x_d, x_m = the mole fractions of d and m, respectively, in the saturator

C. *Two saturators, each with one pure reagent.*—A by-pass carrier stream in parallel with two saturators, one containing pure m and the other pure d. The saturators need not be at the same temperature.

$$M_d = \frac{P_d\left[\frac{f_d}{f_m}\left(\frac{P-P_m}{P-P_d}\right)\right]}{\frac{F}{f_m}(P-P_m) + P\left[1+\frac{f_d}{f_m}\left(\frac{P-P_m}{P-P_d}\right)\right]} \quad [4a]$$

$$M_m = \frac{P_m}{\frac{F}{f_m}(P-P_m) + P\left[1+\frac{f_d}{f_m}\left(\frac{P-P_m}{P-P_d}\right)\right]} \quad [4b]$$

where: f_m, f_d = the volume flow rates of carrier gas through the pure m and d saturators, respectively

D. Two saturators, one with pure reagent and a second with two reagents.—A bypass carrier stream in parallel with two saturators, where saturator 1 contains pure m and saturator 2 contains a solution of d and m. The two saturators are at the same temperature.

$$M_d = \frac{x_d P_d}{\frac{F}{f_2}(P - x_d P_d - x_m P_m) + P\left[1+\frac{f_1}{f_2}\left(\frac{P-x_dP_d-x_mP_m}{P-P_m}\right)\right]} \quad [5a]$$

$$M_m = \frac{P_m\left[x_m+\frac{f_1}{f_2}\left(\frac{P-x_dP_d-x_mP_m}{P-P_m}\right)\right]}{\frac{F}{f_2}(P - x_d P_d - x_m P_m) + P\left[1+\frac{f_1}{f_2}\left(\frac{P-x_dP_d-x_mP_m}{P-P_m}\right)\right]} \quad [5b]$$

where: f_1, f_2 = the volume rates of flow of carrier gas through saturators 1 and 2, respectively

x_d, x_m = the mole fractions of d and m, respectively, in saturator 2. (Note: x_d and x_m for saturator 1 are zero and unity, respectively.)

A Multiple-Dilution System

The model for the multiple gas dilution system is shown schematically in Fig. 2. In this schematic, the first subscript, k, identifies the active component (*i.e.*, a particular matrix or dopant reagent) and the second subscript, n, identifies the dilution stage. The number of dilution stages, m_k, may be different for each reagent. M_{k0} is the concentration (mole fraction) of the k^{th} reagent in the supply tank, whereas M_{kn} is its concentration after the n^{th} dilution; f_{kn} represents the volume flow rate of the k^{th} reagent plus diluent from the previous dilution stage into the n^{th} dilution stage. The supply tanks may contain pure reagents ($M_{k0} = 1$), or they may be prediluted with carrier gas. F_{kn} is the volume flow rate of diluent into the n^{th} dilution stage of the k^{th} reagent.

The general equation for the concentration, M_{km_k}, of the k^{th} reagent in the gas stream entering the reactor is

$$M_{km_k} = \frac{M_{k0}\left[\prod_{n=1}^{m_k} f_{kn}\right] \Big/ \left[\prod_{n=1}^{m_k-1}(f_{kn}+F_{kn})\right]}{F + \sum_{k=1}^{p} f_{km_k}} \quad [6]$$

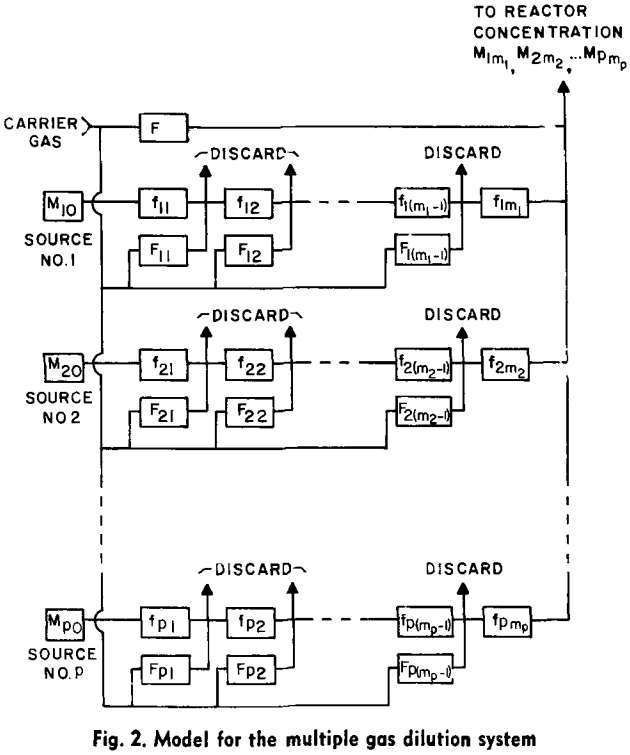

Fig. 2. Model for the multiple gas dilution system

with the detailed derivation of Eq. [6] in Appendix II.

For illustration, the reagent concentrations for a system, in which the matrix is diluted twice and the dopant reagent four times, are

$$M_{m2} = \frac{M_{m0} f_{m1} f_{m2}}{(F + f_{m2} + f_{d4})(f_{m1} + F_{m1})} \quad [7a]$$

$$M_{d4} = \frac{M_{d0} f_{d1} f_{d2} f_{d3} f_{d4}}{(F + f_{m2} + f_{d4})(f_{d1} + F_{d1})(f_{d2} + F_{d2})(f_{d3} + F_{d3})} \quad [7b]$$

Equations [7a] and [7b] may be used in a system in which, for example, SiH_4 is the source of epitaxial silicon and B_2H_6 the source of p-type dopant.

In Eq. [1] and [6], the numerator in each equation represents the partial volume rate of flow of the designated component, *i.e.* i in Eq. [1] and k in Eq. [6], and the denominator represents the total volume rate of flow of all the components into the reactor. Furthermore, each term in the denominators of Eq. [1] and [6] represents the contribution of each branch of the systems to the total flow in each system.

A Hybrid System

An example of such a system would be one in which the matrix reagent is pure liquid germanium tetrachloride, and the dopant reagents are prediluted gaseous B_2H_6 or PH_3.

The general equations for a hybrid system, consisting of h reagents supplied from g saturators, and p reagents, each supplied from a train of m_k dilution stages, are

$$M_i = \frac{\sum_{j=1}^{g}\left\{f_j(x_iP_i)_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\}}{F + P\sum_{j=1}^{g}\left\{f_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\} + \sum_{i=1}^{p} f_{kmk}} \quad [8a]$$

$$M_{kmk} = \frac{M_{k0}\left(\prod_{n=1}^{m_k} f_{kn}\right) \Big/ \left(\prod_{n=1}^{m_k-1} (f_{kn} + F_{kn})\right)}{F + P\left\{\sum_{j=1}^{g} f_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\} + \sum_{k=1}^{p} f_{kmk}} \quad [8b]$$

APPENDIX

Derivation of Composition Equations [1] and [6]

The volume rate of flow out of a single saturator, j, at ambient conditions is given by

$$f_j' = f_jKT \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right] \quad [A]$$

where:
- f_j = the volume rate of flow measured by the j^{th} flow meter at the standard calibration conditions, P_s and T_s
- $K = P_s/T_s$
- P_s, T_s = the standard pressure and absolute temperature, respectively, of the flow meter calibrations
- P, T = the ambient pressure and absolute temperature of the gas downstream from the saturators
- $(x_i)_j$ = the mole fraction of the i^{th} component in the j^{th} saturator
- $(P_i)_j$ = the vapor pressure of the pure i^{th} component at the temperature of the j^{th} saturator
- $\left(\sum_{i=1}^{h} x_iP_i\right)_j$ = the sum of the x_iP_i (partial pressure) terms for the j^{th} saturator only

The volume rate of flow of carrier gas at ambient conditions contributed by the bypass flow meter is given by

$$F' = FKT/P \quad [B]$$

where: F = the volume rate of flow measured on the bypass flow meter at the standard calibration conditions

The total volume rate of flow, F_t, into the reactor is the sum of the carrier gas bypass flow rate and of the sum of flow rates from all the saturators, *i.e.* Eq. [C]

$$F_t = F' + \sum_{1}^{g} f_j' \quad [C]$$

$$F_t = FKT/P + \sum_{j=1}^{g}\left\{f_jKT \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\} \quad [D]$$

$$F_t = \frac{KT}{P}\left[F + P\sum_{j=1}^{g}\left\{f_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\}\right] \quad [E]$$

The partial volume flow rate, f_i, of the i^{th} reagent from all the saturators into the reactor computed at ambient conditions is the sum of all the partial volume flow rates of the i^{th} reagent from g saturators, as given by Eq. [F]

$$f_i = \sum_{j=1}^{g} f'_{ij} = \frac{KT}{P}\sum_{j=1}^{g}\left\{f_j(x_iP_i)_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\} \quad [F]$$

where: f'_{ij} = the partial volume flow rate of the i^{th} reagent from the j^{th} saturator computed at ambient conditions.

Having determined the partial volume of the i^{th} reagent, Eq. [F], and the total volume of gas, Eq. [E], entering the reactor, the equation for the mole fraction of the i^{th} reagent, M_i, in the gas mixture in the reactor can now be written, since $M_i = f_i/F_t$.

$$M_i = \frac{\sum_{j=1}^{g}\left\{f_j(x_iP_i)_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\}}{F + P\sum_{j=1}^{g}\left\{f_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\}} \quad [G]$$

Equation [G] represents an exact general solution for a gas mixture prepared by combining a bypass carrier gas flow with the flows from g saturators, each of which contains different concentrations of each of h reagents and is maintained at a different temperature, which determines the contribution of the i^{th} component from the j^{th} saturator by the term $(x_iP_i)_j$.

A likely simplification to consider is that in which all of the saturators are maintained at the same temperature. In this case, P_i in the $(x_iP_i)_j$ term is the same for all the saturators; *i.e.*, it is the vapor pressure of the pure i^{th} reagent at the common saturator temperature. Then Eq. [G] may be rewritten as follows

$$M_i = \frac{P_i\sum_{j=1}^{g}\left\{f_jx_{ij} \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\}}{F + P\sum_{j=1}^{g}\left\{f_j \Big/ \left[P - \left(\sum_{i=1}^{h} x_iP_i\right)_j\right]\right\}} \quad [H]$$

The derivation of the composition equation for a multiple dilution system begins with the statement of the concentration of reagent in the output of each dilution stage, M_{kn}, as a function of the input concentration, M_{k0}, and the flows involved; *e.g.*, for the first dilution stage

$$M_{k1} = M_{k0}\left(\frac{f_{k1}}{f_{k1} + F_{k1}}\right)$$

where: f_{k1} = the input flow rate of gas to the first dilution stage from the source tank, which contains a mole fraction, M_{k0}, of reagent diluted with carrier gas
F_{k1} = the input flow rate of diluting carrier gas to the first dilution stage

Similarly,

$$M_{k2} = M_{k1}\left[\frac{f_{k2}}{f_{k2}+F_{k2}}\right] = M_{k0}\left[\frac{f_{k1}}{f_{k1}+F_{k1}}\right]\left[\frac{f_{k2}}{f_{k2}+F_{k2}}\right]$$

$$M_{k3} = M_{k2}\left[\frac{f_{k3}}{f_{k3}+F_{k3}}\right] = M_{k0}\left[\frac{f_{k1}}{f_{k1}+F_{k1}}\right]\left[\frac{f_{k2}}{f_{k2}+F_{k2}}\right]\left[\frac{f_{k3}}{f_{k3}+F_{k3}}\right]$$

$$\vdots$$

$$M_{k(m-1)} = M_{k0}\left[\prod_{n=1}^{m-1} f_{kn}\right] \Big/ \prod_{n=1}^{m-1}\left[f_{kn}+F_{kn}\right]$$

The equation for the last stage (the m^{th}) differs from the others, since the diluent flow in this stage contains the main carrier gas bypass flow as well as the output flows of all the other diluted reagents from their respective $(m_k - 1)$st stages (m_k is used here for clarity, since the value of m may vary from one reagent dilution train to another.) Thus, for the last stage

$$M_{km} = M_{k(m-1)}\left\{\frac{f_{kn}}{F+\sum_{k=1}^{p} f_{kn}}\right\}$$

$$= \frac{M_{k0}\left[\prod_{n=1}^{m} f_{kn}\right] \Big/ \left[\prod_{n=1}^{m-1}\left(f_{kn}+F_{kn}\right)\right]}{F+\sum_{k=1}^{p} f_{kn}} \quad [I]$$

Since the numerators of Eq. [G] and [I] represent the partial volume flow rate of the i^{th} or k^{th} reagent, respectively, and the denominators represent the total gas flow into the reactor, the derivation of the composition equations for a hybrid system, in which some of the reagents are supplied by saturators and others by multiple gas dilution trains, becomes very simple. For reagents supplied from saturators, the numerator for computing M_i is identical with that of Eq. [G], and the denominator of Eq. [G] is modified by the addition of $\sum_{k=1}^{p} f_{kn}$ to obtain the total gas flow. For reagents supplied by multiple gas dilution trains, the numerator for computing M_{kn} is the same as that in Eq. [I], and the same denominator is used as for the saturator-supplied reagents in the hybrid system.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 117, No. 8 and 10 (August and October 1970).

A Method for the Synthesis of BI_3 for Use as a Dopant Source

M. Berkenblit and A. Reisman (pp. 1100-1101, Vol. 117, No. 8)

F. E. Stafford:[1,2] Berkenblit and Reisman describe a method for reacting B_2H_6 with HI in the presence of hydrogen to generate BI_3. A fivefold excess of B_2H_6 is used. The reaction is observed to go to completion with the reactor at 250°C according to

$$6B_2H_6 + 6HI \rightleftarrows 2BI_3 + 5B_2H_6 + H_2 \quad [1]$$

They observe, however, that "At [450° and 800°C], there was no measurable trace of BI_3, indicating that K is much smaller (→ O) than the calculated value." They conclude that "these results do not appear to be due to kinetic limitations, and would indicate that the thermochemical data [given in the JANAF tabulation[3]] are in considerable error."

We disagree with this conclusion and offer the following interpretation. Diborane is unstable with respect to decomposition to boron and hydrogen, the equilibrium pressure at the temperatures in question and in the presence of 1 atm H_2 being 10^{-12} atm or less. Depending on the contact time and pressure, this decomposition is "slow" at room temperature and somewhat above, but becomes rapid with increasing temperature. (See *e.g.* Baylis *et al.*[4].) It is logical to assume, therefore, that the decomposition reaction is "slow" at 250°C under the particular conditions used by Berkenblit and Reisman and compared to the forward rate of Eq. [1].

At 450°C and above, the rate of decomposition to boron should be fast. (Whether boron containing species survive the reaction is not mentioned. Alternately, higher boranes could be formed and give a test for boron, but not react to form BI_3.) The principal net reaction then becomes

$$B + 3HI \rightleftharpoons BI_3 + 3/2\ H_2 \quad [2]$$

For 10^4 ppm HI (= 10^{-2} atm) at 700°K, and with 1 atm H_2 (or 10^{-2} atm), the equilibrium partial pressure of BI_3 is calculated to be $10^{-9.4}$ (or $10^{-6.4}$) atm, explaining the non-observation in the paper under discussion of BI_3.

In fact, the observation that Eq. [1] proceeds to the theoretical limit at 250°C, and that[5] BI_3 can be formed in appreciable yield by direct reaction of iodine with boron, indicates that the quoted[3] electron impact enthalpy of formation is essentially correct. It would be hard to change the enthalpy in a way to account for the present observations in the discussed paper.

Accordingly, control of the kinetic conditions—wall contact, contact time, B_2H_6 partial pressure—seems to be important for success of the synthesis.

M. Berkenblit and A. Reisman: Stafford begins his thesis with a misquote from our report, adds a second

[1] Department of Chemistry and the Materials Research Center, Northwestern University, Evanston, Illinois, 60201.

[2] Supported by the United States Atomic Energy Commission, Document COO-1147-39.

[5] R. M. Adams, Editor, "Boron, Metallo-Boron Compounds, and Boranes," p. 276, Interscience Publishers, New York, N. Y. (1964).

misquote, uses these misquotes to argue that his logic must be accepted, and then ends with a generality which, to us, also happens to be irrelevant.

Firstly, our experiments were conducted with equal partial pressures of B_2H_6 and HI, not with a five-fold excess of B_2H_6 (see Vol. 117, p. 1101, column 1, paragraph 1). Secondly, we are quoted as stating that BI_3 can be formed in appreciable quantities from the direct reaction of boron and iodine. We made no such statement nor do we profess any knowledge of the experimental conditions needed for such a synthesis.

Our interpretation may or may not be valid. Unfortunately Stafford has not provided any new information which would enable us to reconsider our conclusion. Restated, we found that based on trivial thermodynamic calculations, the reaction shown in Eq. [1] should have yielded some BI_3 at 450°C. None was observed. One explanation is that the thermochemical data is in error, and this is the one we suggested. It is also possible that the B_2H_6 decomposes, that B drops out, and that the HI fails to react with it. Another is that B_2H_6 polymerizes etc., the products of such reaction(s) being unreactive with HI. The latter we doubt, since B_2H_6 is an effective semiconductor dopant source at elevated temperatures. Perhaps there exist ten other explanations. In lieu of proof in support of any one of them, ours is as reasonable as any and does not require invoking other obvious but more complicated conjecture.

The Effect of Several Electrode and Electrolyte Additives on the Corrosion and Polarization Behavior of the Alkaline Zinc Electrode

F. Mansfeld and S. Gilman (pp. 1328-1333, Vol. 117, No. 10)

S. M. Davis:[6] In Table III of the paper by Mansfeld and Gilman, a comparison of theoretically calculated and experimentally determined values for the corrosion potential of a pure zinc electrode in 6N KOH, containing a variable addition of ZnO, is presented. The experimentally determined values are somewhat too negative for ZnO concentrations greater than zero. No explanation is offered for this phenomenon.

Since the ZnO used in these experiments is stated to be of AR grade purity, it is likely that small but significant quantities of certain heavy metals of high hydrogen overpotential were introduced into the electrolyte solution along with the zinc oxide; notably Pb which may be present in AR grade ZnO up to 0.005%, and possibly also Sn, Cd, In, or Tl. Such additions could deposit on the zinc, raising the hydrogen evolution overpotential, thereby shifting the cathodic Tafel curve in a more negative direction and lowering the experimentally measured corrosion potential.

A simple test of this hypothesis would consist of comparing the experimentally measured corrosion potentials obtained with AR grade ZnO to those obtained with spectrographic grade ZnO in which the total metallic impurity content is <10 ppm.

F. Mansfeld and S. Gilman: The authors welcome the comment of Dr. Davis. It is not true, however, that no explanation has been offered for the fact that experimental corrosion potentials in Table III were somewhat more negative than the theoretical values. In the Discussion Section, we point out that dissolved zincate might lower the water activity according to Eq. [9] which then increases the hydrogen overvoltage which in turn leads to a decrease of corrosion rates and a shift of the corrosion potential in the negative direction. It is, of course, possible that impurities in the zinc oxide of AR grade purity like Pb or Sn increase hydrogen overvoltage as suggested by Dr. Davis. This is the effect we wanted to show in our paper. On the other hand we have shown[7] that addition of 10^{-4} M Pb to a solution of KOH + ZnO completely changes the morphology of the deposit on a zinc single crystal. Since this amount of lead ions corresponds to about 0.002%, we have to conclude that the amount of active lead in the AR grade zincate must be much smaller and, therefore, probably cannot effect the results of Table III as suggested by Dr. Davis. The same argument applies to Sn as an impurity.[8]

Conduction Domains for Solid Electrolytes

J. W. Patterson*

Department of Metallurgy, Iowa State University, Ames, Iowa 50010

ABSTRACT

The use of solid oxide electrolytes for determining oxygen concentrations in liquid metals has motivated much research of solid electrolyte properties over wide ranges of chemical potential and temperature. A useful scheme for assessing the electrolytic properties of solid electrolytes is that of plotting electronic and electrolytic conduction domains simultaneously with proposed application domains on chemical potential *vs.* $1/T$ diagrams. Accordingly, the concept and theoretical origins of conduction domains for solid electrolyte materials are outlined briefly. The origin and usefulness of the concept is discussed with respect to proposed applications of these solid electrolyte materials. Conduction domains for a number of known solid electrolytes are deduced from various conductivity and galvanic cell measurements and the results are presented in the form of conduction domain maps in log P_{X_2} *vs.* $1/T$ space. These maps constitute a survey of present status of knowledge regarding the materials considered. The solid electrolyte materials AgBr, AgI, CuBr, CuI, CuCl, CaF_2, $Zr_{0.85}Ca_{0.15}O_{1.85}$, and $Th_{0.85}Y_{0.15}O_{1.925}$ are discussed. Controversial implications and interpretations of conflicting data are pointed out.

The usefulness of solid electrolytes in research and other applications is based on two salient features: I. The open-circuit emf E across a solid electrolyte is a measure of a chemical potential difference; hence a solid electrolyte can function as a chemical potential (P_{X_2}) gauge. II. The charge passed through a solid electrolyte is a measure of ion transport; hence a solid electrolyte can function as a solid state ion pump.

A number of works (1-7) have reviewed research applications and have emphasized the solid electrolyte galvanic cell technique as an important quantitative method for studying the thermodynamics and kinetics of selected reactions at elevated temperatures. For the most part the solid electrolytes have been either AgI, CaF_2 or one of the oxide solid electrolytes CSZ (calcia stabilized zirconia) or YDT (yttria doped thoria) and have been employed in chemical potential (P_{F_2} or P_{O_2}) gauges in open-circuit emf measurements.[1] To a much lesser extent copper and silver halides have also been employed as solid electrolytes. Also a limited number of the reported applications have made use of the ion-pumping ability of the solid electrolytes. The most important metallurgical applications of these coulometric titration techniques involve the study of selected metal (8) and metalloid (9, 10) diffusivities in liquid and solid metallic hosts.

In contrast with these research-oriented applications, proposed application of solid electrolytes to metals technology has been almost exclusively concentrated on open-circuit emf measurements over oxide solid electrolytes. In particular, these applications involve the sensing of oxygen chemical potentials in liquid metals (11-17) at elevated temperatures. The ability to continuously monitor this thermodynamic variable is of critical importance in liquid steel refining and also in controlling the corrosivity of liquid sodium coolants to be employed in modern fast breeder reactors.

Because electronic conduction prevails in most solids, electrolytes (defined here as compounds exhibiting ionic transference numbers $t_{ion} \geq 0.99$) comprise only a very small subclass of all known compounds. More importantly, however, even the known solid electrolytes retain their predominant ionic conductivity over only limited ranges of temperature and chemical potential, *i.e.*, only over their respective electrolytic domains (18). For quantitative results from emf measurements it is most desirable that the application conditions lie within the electrolytic domain. Otherwise, the electrolytic domain boundaries must be precisely known if a quantitative interpretation of the open-circuit emf's is to be made.

The purpose of this paper is to present estimates of the electrolytic domain boundaries for several known solid electrolytes. These domains are most conveniently presented in the form of a log P_{X2}, $1/T$ map according to a scheme given by Patterson (18). The scheme is essentially an extension of an analysis first given by Schmalzreid (19, 20). It combines various conductivity and/or emf measurements in order to estimate the location of the electrolytic domain boundaries in a manner consistent with Wagner's phenomenological theory of mixed conduction (7, 21) in virtually stoichiometric compounds. Because t_{ion} is the ratio of ionic conductivity to total (ionic plus electronic) conductivity, the present definition of a solid electrolyte (namely, $t_{ion} \geq 0.99$) implies virtually exclusive ionic conduction. This definition is motivated by the desirability of reducing Wagner's general relationships (21)

* Electrochemical Society Active Member.

Key words: solid electrolytes, electrolytic domain, mixed conduction.

[1] The compositions of these electrolytes may be given by the following chemical formulas: CSZ is $Zr_{0.85}Ca_{0.15}O_{1.85}$, and YDT is $Th_{0.85}Y_{0.15}O_{1.925}$.

$$E = \phi'' - \phi' = -\left(\int_{\mu'_{X_2}}^{\mu''_{X_2}} \left[\frac{t_{ion}}{Z_x}\right] d\mu_{X_2}\right) \Big/ (2\mathbf{F})$$

$$= -\left(\int_{\mu'_M}^{\mu''_M} \left[\frac{t_{ion}}{Z_M}\right] d\mu_M\right) \Big/ (\mathbf{F}) \quad [1]$$

to the simplified version

$$E = \phi'' - \phi' = -(\mu''_{X_2} - \mu''_{X_2})/(2Z_X\mathbf{F})$$

$$= -(\mu''_M - \mu'_M)/(Z_M\mathbf{F}) \quad [2]$$

The symbols X and M in Eq. [1] and [2] denote, respectively, the nonmetal and metal components of the M_aX_b mixed conductor; whereas the double and single primes refer to the electrodes contacting the opposite ends of the compound. Z is valence, ϕ is electrostatic potential, μ is chemical potential, and $\mathbf{F}$ is Faraday's constant. In general, t_{ion} is a cumbersome function of chemical potential as well as temperature; however, within the electrolytic domain the simplified forms [2] serve as an adequate approximation to the corresponding integrals of t_{ion} on chemical potential (18-20). The chemical potential μ_{X_2} of the gaseous X_2 dimer is related to its partial pressure P_{X_2} (atm) and absolute temperature T(°K) by

$$\mu_{X_2} = \mu^o_{X_2} + 2.303\,RT \log P_{X_2} \quad [3]$$

where R is the universal gas constant and $\mu^o_{X_2}$ is the chemical potential of X_2 gas in its standard state. Equation [3] allows the variable log P_{X_2} to be used in place of the chemical potential at any given temperature. Also, most experimental or application conditions conform to finite polygons in log P_{X_2}, $1/T$ space. For these and other reasons given below it is convenient to formulate restrictions on the applications of solid electrolytes in terms of these two variables.

Conduction Domains in Log P_{X_2} $1/T$ Space

At elevated temperatures solid electrolyte materials exhibit an ionic conductivity which is virtually P_{X_2} independent. In contrast, their excess electron and positive hole conductivities, $\sigma_\ominus$ and $\sigma_\oplus$, are found to be proportional to $P_{X_2}{}^{-1/n}$ and $P_{X_2}{}^{+1/n}$, respectively, at constant temperature. The value of n is determined by the predominant defect structure of the M_aX_b solid electrolyte, but is otherwise independent of P_{X_2} and T. On the other hand, at constant P_{X_2}, all three conductivity modes exhibit an Arrhenius-type temperature dependence with apparent activation energies Q_{ion}, $Q_\ominus$, and $Q_\oplus$ that are also P_{X_2}- and T-independent. Mechanistic interpretations of these (iso-P_{X_2}) Q values do not seem to be justified beyond the point of qualitative assertions.

In view of these considerations it is possible to characterize the total conductivity σ_T in solid electrolytes as follows

$$\sigma_T = \sigma_{ion} + \sigma_\oplus + \sigma_\ominus \quad [4]$$

where

$$\sigma_{ion} = \sigma^o{}_{ion} \exp\left(-\frac{Q_{ion}}{RT}\right) \quad [5]$$

$$\sigma_\oplus = \sigma^o{}_\oplus P_{X_2}{}^{1/n} \exp\left(-\frac{Q_\oplus}{RT}\right) \quad [6]$$

$$\sigma_\ominus = \sigma^o{}_\ominus P_{X_2}{}^{-1/n} \exp\left(-\frac{Q_\ominus}{RT}\right) \quad [7]$$

and where the quantities $\sigma^o{}_{ion}$, $\sigma^o{}_\oplus$, $\sigma^o{}_\ominus$, n, Q_{ion}, $Q_\oplus$, and $Q_\ominus$ are all P_{X_2}- and T-independent. In order to discuss the nature of particular conduction domains for a given solid electrolyte, consider the log σ_T surface plotted over log P_{X_2}, $1/T$ space as shown in Fig. 1. Also shown in Fig. 1 are the surfaces corresponding to log σ_{ion}, log $\sigma_\oplus$, and log $\sigma_\ominus$ which, because of their functional form, plot as planar sheets in log σ, log P_{X_2}, $1/T$ space. Figure 1 may be thought of as the conductivity analog to a three-dimensional Kroger and Vink diagram (22, 23). It is apparent that regions or domains exist wherein only one of the conduction modes (ion, electron, or the positive hole mode) individually dominates the total conductivity of the M_aX_b mixed conductor. When this occurs, the log σ_T surface approaches coincidence with the planar sheet of the dominant conduction mechanism.

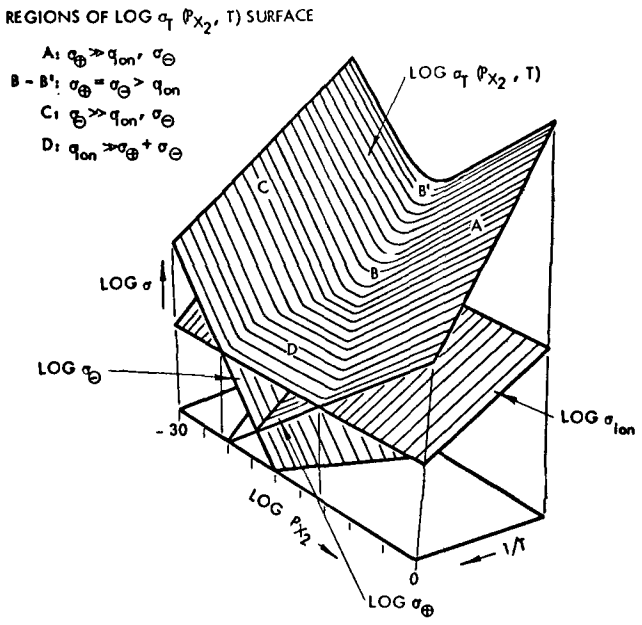

Fig. 1. Schematic representation of log σ surfaces over log P_{X_2}, $1/T$ space for $\sigma = \sigma_{ion}, \sigma_\oplus, \sigma_\ominus$, and σ_{total}.

Thus in region A of Fig. 1, $\sigma_\oplus$ is two or more orders of magnitude greater than either σ_{ion} or $\sigma_\ominus$ so that log σ_T and log $\sigma_\oplus$ are virtually identical. For the same reason, the log σ_T surface conforms to the log $\sigma_\ominus$ plane in region C whereas it conforms to the log σ_{ion} plane in region D. The projections of these regions onto the log P_{X_2}, $1/T$ plane may be called the positive hole, excess electron, and electrolytic conduction domains for the mixed conductor in question. Thus the electrolytic domain falls well within the ionic domain which is defined by the condition that σ_{ion} is simply greater than either $\sigma_\oplus$ or $\sigma_\ominus$, *i.e.*, $t_{ion} \geq 0.50$.

Various domain boundaries separate the regions where each mechanism of conduction dominates the others by at least two orders of magnitude. These boundaries represent transition conditions for the mixed conductor. Analytical expressions for them may be readily deduced by equating the appropriate conductivity expressions, taking the logarithm of the results, and then rearranging. Thus the $\sigma_\oplus$ to $\sigma_\ominus$ (p to n) transition boundary may be defined as the locus of log P_{X_2}, $1/T$ points where $\sigma_\oplus = \sigma_\ominus$. This leads to

$$\log P_{pn} = -\frac{n}{2}\left(\frac{Q_\ominus - Q_\oplus}{2.303R}\right)\frac{1}{T} + \frac{n}{2}\log\frac{\sigma^o{}_\oplus}{\sigma^o{}_\oplus} \quad [8]$$

This locus of log P_{X_2}, $1/T$ points plots as a straight line with slope $-n/2[Q_\ominus - Q_\oplus/2.303R]$ and intercept $n/2$ log $\sigma^o{}_\ominus/\sigma^o{}_\oplus$. Geometrically, it is the projected intersection of log $\sigma_\oplus$ and log $\sigma_\ominus$ planar sheets of Fig. 1. Similarly boundaries of the ionic domain may be deduced by equating $\sigma_\oplus$ and $\sigma_\ominus$ to σ_{ion} and taking the logarithm of the results; this gives

$$\log P_\oplus = -n\left(\frac{Q_{ion} - Q_\oplus}{2.303R}\right)\frac{1}{T} + n\log\frac{\sigma^o{}_{ion}}{\sigma^o{}_\oplus} \quad [9]$$

and

$$\log P_\ominus = +n\left(\frac{Q_{ion} - Q_\ominus}{2.303R}\right)\frac{1}{T} - n\log\frac{\sigma^o{}_{ion}}{\sigma^o{}_\ominus} \quad [10]$$

where the symbols $P_\oplus$ and $P_\ominus$ have been introduced in accordance with Schmalzried's usage (20).

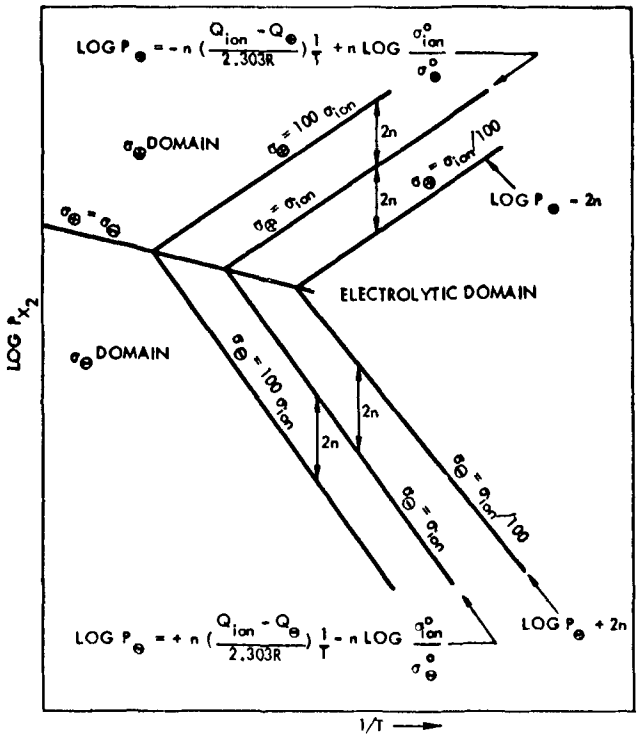

Fig. 2. Relationship between electrolytic and ionic domain boundaries in the log P_{X_2}, $1/T$ plane.

In this paper, we are mainly interested in the electrolytic domain boundaries. According to the electrolyte definition given above, these boundaries may be deduced by equating σ_{ion} to 100 $\sigma_\oplus$ and 100 $\sigma_\ominus$. In log P_{X_2}, $1/T$ space the equations for electrolytic domain boundaries are (18)

$$\log P_{X_2} = -n\left(\frac{Q_{ion}-Q_\oplus}{2.303R}\right)\frac{1}{T} + n\log\frac{\sigma^o{}_{ion}}{100\,\sigma^o{}_\oplus} = \log P_\oplus - 2n \quad [11]$$

and

$$\log P_{X_2} = +n\left(\frac{Q_{ion}-Q_\oplus}{2.303R}\right)\frac{1}{T} - n\log\frac{\sigma^o{}_{ion}}{100\,\sigma^o{}_\ominus} = \log P_\ominus + 2n \quad [12]$$

As mentioned previously, these boundaries are critical in the evaluation of a given mixed conductor for use as a solid electrolyte. Any application requiring electrolytic behavior must correspond to log P_{X_2}, $1/T$ conditions which lie between the lines corresponding to Eq. [11] and [12]. It is important to note that to a limited extent these lines may be extrapolated even if direct measurements have established their positions only over limited ranges of P_{X_2} and T. Such extrapolations are justified over ranges where the parameters Q_{ion}, $Q_\oplus$, $Q_\ominus$, $\sigma^o{}_{ion}$, $\sigma^o{}_\oplus$, $\sigma^o{}_\ominus$ remain constant. However, caution is required for polymorphic materials or materials in which more than one mechanism for σ_{ion}, $\sigma_\oplus$, or $\sigma_\ominus$ is possible. Figure 2 shows the relationships among the various domain boundaries discussed above.

It is apparent from this more or less geometrical viewpoint that experimental measurements made for a particular mode of conductivity can be used to uniquely establish its conductivity "sheet" in log σ, log P_{X_2}, $1/T$ space. Establishing the location and orientation of each of the conductivity sheets, then, serves to define their intersections and hence any of the desired domain boundaries as projected onto the log P_{X_2}, $1/T$ plane. In addition, emf measurements involving an electrode that establishes a log P_{X_2} value lying outside the electrolytic domain can be used (19, 20). The departure of the measured emf from the thermodynamic value may then be used to gain further information regarding the electrolytic domain boundaries. Permeability measurements may also be interpreted quantitatively in terms of domain boundary parameters. Patterson (18) has summarized methods for determining conduction domain boundaries from various experimental measurements.

Log P_{X_2}, $1/T$ Domain Maps for Some Known Halide Solid Electrolytes

Figure 3 is a master plot of log P_{X_2}, $1/T$ electrolytic domains of several known solid electrolytes. Only those materials are represented for which an electrolytic domain is known to exist and for which experimental data allow a quantitative estimation of the electrolytic domain boundaries. At low temperatures the chlorides, bromides, and iodides of silver and copper are represented. These compounds are characterized by an anion to cation site ratio of unity, and cations are the predominantly mobile ionic carriers in these electrolytes (1, 24). In contrast, the oxide solid electrolytes and calcium fluoride exhibit electrolytic behavior at more elevated temperatures. They have anion to cation site ratios equal to two, and anions dominate their ionic conduction modes.

Log P_{X_2}, $1/T$ diagrams for silver and cuprous halides. —The electrolytic domains of the known silver and cuprous halide electrolytes are bounded on the low P_{X_2} side by the stability limit of the electrolyte itself. Thus, in Fig. 3 the electrolytic domain of CuCl under reducing conditions is bounded by the log P_{Cl_2}, $1/T$ line corresponding to Cu, CuCl equilibrium coexistence. This boundary may be readily deduced from a tabulation (25) of the standard free energy of forma-

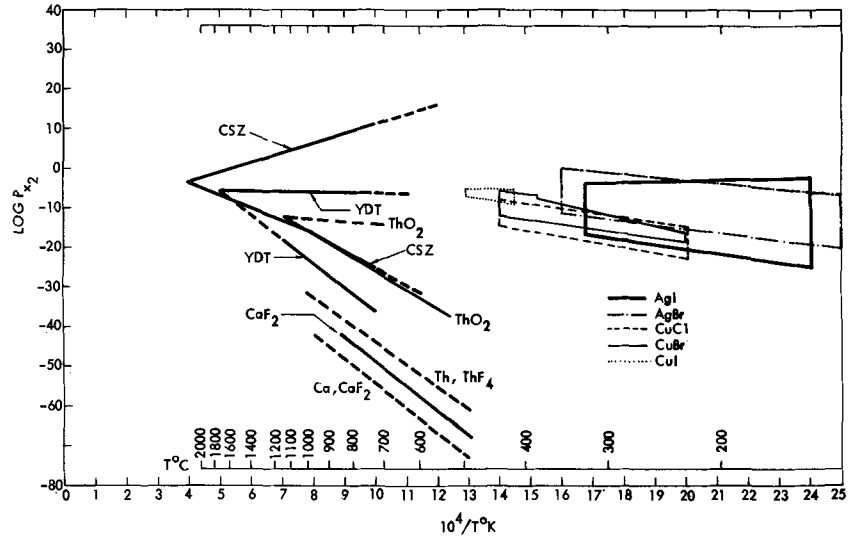

Fig. 3. Master plot of electrolytic domains in log P_{X_2}, $1/T$ space for selected halide and oxide solid electrolytes.

tion data for CuCl. The same is true for CuBr, CuI, AgCl, AgBr, and AgI. The electronic conduction in these silver and cuprous halides is dominated by positive hole (as opposed to excess electron) carriers (26-28). According to theory (7, 29, 30) and measurements (26-28), the positive hole conductivities, $\sigma_\oplus$, increase in proportion to $P^{1/2}{}_{X_2}$, where X_2 may be Cl_2, Br_2, or I_2, depending on which halide is involved. However, the ionic conductivities are found to be P_{X_2}-independent (7, 29) as suggested previously. Thus, at increased P_{X_2} values, the electrolytic domain is truncated by the onset of positive hole conduction. For the silver and cuprous halides this occurs at P_{X_2} values well below 1 atm as may be seen from Fig. 3. The following example briefly summarizes the details of determining these high P_{X_2} boundaries.

By employing d-c polarization measurements and C. Wagner's theoretical analysis (7, 29, 30), Wagner and Wagner (28) found the partial electronic conductivity of the cuprous halides to be dominated by hole conduction which in certain temperature ranges was orders of magnitude below the total (a-c) conductivity in these materials. Furthermore their observed current *vs.* d-c voltage data traverses confirmed the proportionality of $\sigma_\oplus$ to $P^{1/2}{}_{X_2}$ under conditions corresponding to Cu, CuX equilibrium coexistence. Thus from these quantitative measurements the functional dependence of log $\sigma_\oplus$ on log P_{X_2} and $1/T$ (*i.e.*, the location and orientation of the log $\sigma_\oplus$ sheet in log σ, log P_{X_2}, $1/T$ space) may be uniquely specified for each stable phase in the temperature range studied. In order to deduce the electrolytic domain boundaries at high P_{X_2} for the cuprous halides, it is only necessary to combine these results with the a-c conductivity measurements which at Cu, CuX, coexistence are an excellent approximation to only the ionic conductivity. This situation for CuCl is depicted schematically in Fig. 4. In this manner the high P_{X_2} electrolytic domain boundaries shown in Fig. 3 for CuCl, CuBr, and CuI were deduced solely from conductivity measurements. The high- and low-temperature boundaries of these same electrolytic domains are determined either by phase transformations which produce an electronic conducting phase or else by the temperature beyond which quantitative conductivity measurements have not yet been reported.

This same procedure was used in constructing the electrolytic domains for AgBr and AgI[2] shown in Fig.

[2] The electrolytic domain for AgCl is not shown primarily because of discrepancies in the d-c polarization results reported by Ilschner (27). Until further measurements resolve the presently unexplained current-voltage dependence exhibited by AgCl, quantitative determinations of the electrolytic domain boundary do not seem justified.

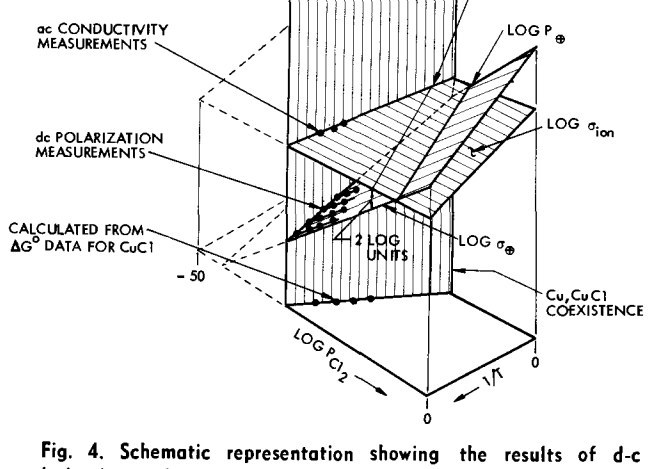

Fig. 4. Schematic representation showing the results of d-c polarization and a-c conductivity measurements in log σ, log P_{X_2}, $1/T$ space.

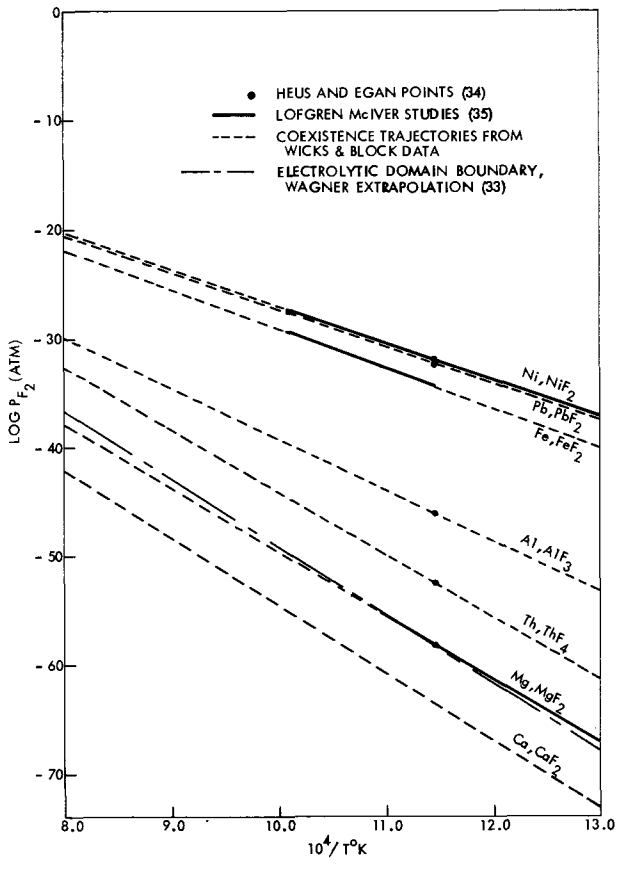

Fig. 5. Log P_{F_2}, $1/T$ diagram showing the estimated electrolytic domain boundary for CaF_2 together with selected metal, metal fluoride equilibrium coexistence loci.

3. The calculations employ the d-c polarization results of Raleigh (26) and Ilschner (27) and the a-c conductivities reported by Kurnick (31) and by Biermann and Jost (32).

Log P_{F_2}, $1/T$ diagram for CaF_2.—Figure 3 shows the proposed low P_{F_2} electrolytic domain boundary for CaF_2 to be about midway between the coexistence lines of Ca, CaF_2, and Th,ThF_4. This estimate is based on the recent analysis by Wagner (33). The practical difficulties associated with conductivity and/or emf measurements on CaF_2 in high P_{F_2} atmospheres at elevated temperatures seem to have thus far discouraged the experimental measurements required to determine the high P_{F_2} electrolytic domain boundary for this material. However, in view of the extreme electronegativity difference between $Ca^{\cdot\cdot}$ and F' ions and the correspondingly large forbidden bandgap for CaF_2 it would not be surprising if this boundary were found to be located far above 1 atm fluorine pressure. Figure 5 shows a number of selected metal, metal fluoride equilibrium coexistence trajectories superimposed on the proposed electrolytic domain for CaF_2. Only those trajectories are represented that have been studied as coexistence electrodes in conjunction with CaF_2 as the solid electrolyte at elevated temperatures (34, 35). Because of the limited number of such studies on fluoride systems, the trajectories shown can only be approximately located on such a plot at the present time.[3]

Log P_{X_2}, $1/T$ Domain Maps for Some Known Oxide Solid Electrolytes

A number of considerations serve to distinguish the known oxide solid electrolytes from the halide elec-

[3] A much more comprehensive emf study involving CaF_2 solid electrolytes is presently under way so that many more additional coexistence trajectories may be added soon. The results already indicate that CaF_2 has negligible electronic conductivity up to the Cu, CuF_2 coexistence trajectory.

trolytes treated above. Thus, the low P_{X_2} electrolytic domain boundaries of the oxide solid electrolytes CSZ and YDT are determined by the onset of excess electron (n-type) conduction rather than by the stability limit of the solid electrolyte material. Also the oxide electrolytes require comparatively large cation dopant additions before electrolytic behavior can be realized. This is in contrast with the previously discussed electrolytes that exhibit finite electrolytic domains even without the addition of selected dopant additions. Kiukkola and Wagner's solid electrolyte study (6) stimulated much of the current interest in the oxide solid electrolyte CSZ and in the application of solid electrolyte galvanic cell measurements in thermodynamic investigations. Partly on the basis of these thermodynamic studies and partly on the bases of various conductivity (36), permeability (37), and open-circuit emf studies (12, 13, 14, 19, 38, 39), Patterson (18) gave a conservative assessment of the electrolytic domain of CSZ. The results of Patterson's assessment are shown in Fig. 6. As shown in Fig. 7, the proposed electrolytic domain boundary at low P_{O_2} was placed conservatively. This was done as a safety measure to assure the validity of first-order approximations asserting the electrolytic behavior of CSZ under various experimental conditions. Thus, virtually all reported emf studies falling above that domain boundary choice had also been reported to be free from electronic conduction effects. It was apparent that other studies had suggested the true boundary might be significantly lower, but that certain investigators did not concur. In view of the uncertainties, the conservative domain boundary is retained, but it is understood that significant extension of the electrolytic domain to lower P_{O_2} values might well be possible if suitable precautions can be observed.

Evidence of electrolytic behavior for CSZ at much lower P_{O_2} values is now becoming more abundant (15, 40). On the basis of thermodynamic emf measurements in liquid iron alloys, Fruehan *et al.* (15) recently reported that the onset of electronic conduction in CSZ (*i.e.*, the electrolytic domain boundary) at

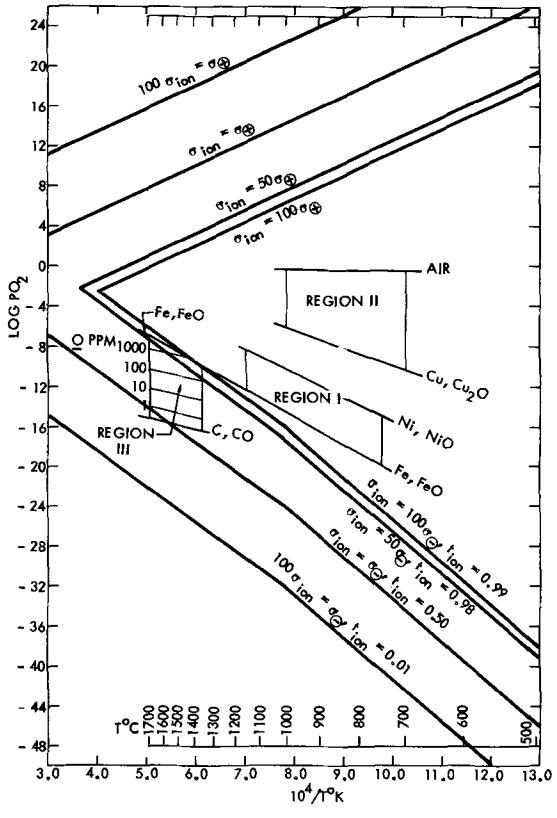

Fig. 6. Selected galvanic cell application regions with respect to the electrolytic domain of CSZ.

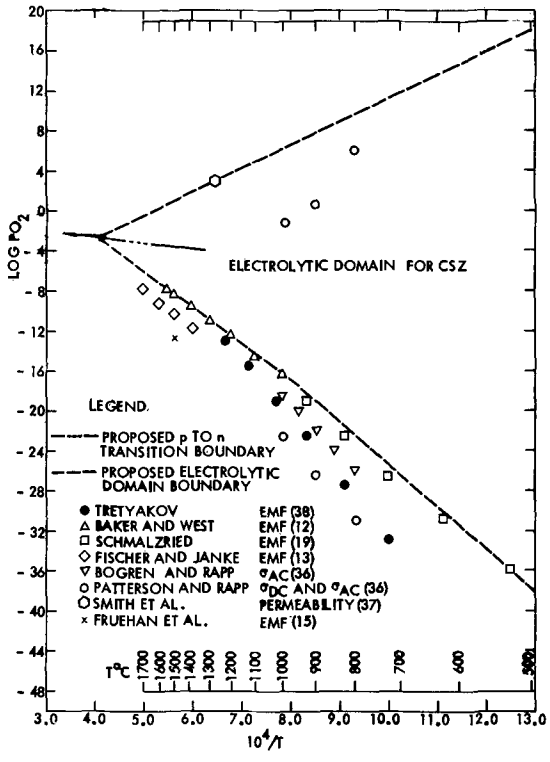

Fig. 7. Electrolytic domain boundaries and related data for CSZ

1600°C is at about 3-8 x 10^{-13} atm P_{O_2} or about down to Cr, Cr_2O_3 equilibrium coexistence. It is clear from Fig. 6 that this is well within the liquid steelmaking domain (Region III in Fig. 6). It is also well below the electrolytic domain boundary indicated by all previous assessments including Patterson's (18) and by all previous investigations including those conducted in the steelmaking domain (12-14). It is unfortunate that Fruehan *et al.* (15) did not report similar results over a range of temperatures, because then a finite boundary rather than an isolated point could be plotted in Fig. 7. Also shown on the log P_{O_2}, $1/T$ map of Fig. 6 are two additional application domains that have been investigated previously. However, these domains, (Region I) swept out by Kiukkola and Wagner (6) with the cell

Fe, FeO/CSZ/Ni, NiO (Cell I)

and that spanned by Rizzo *et al.* (39) (Region II) with the cell

Cu,Cu_2O/CSZ/Air (Cell II)

both fall entirely within the previous estimates (18) for the electrolytic domain boundaries of CSZ. Clearly much remains to be done before these estimates can be replaced with definitively established electrolytic domain boundaries.

Figure 8 shows the proposed electrolytic domain for YDT in log P_{O_2} $1/T$ space. The high P_{O_2} boundary shown in Fig. 8 was estimated by analyzing total conductivity data reported by Baurle (41) and Lasker and Rapp (42) in weighted combination with Schwerdtfeger's (40) assertion that incipient electronic (hole) conduction at 1500°C may be expected to occur at $P_{O_2} \approx 10^{-7}$ atm. The approximate temperature independence of this high P_{O_2} boundary implies that the iso-P_{O_2} activation energies $Q_{\oplus}$ and Q_{ion} for conduction in YDT are approximately equal. Because numerous open-circuit emf measurements confirm the onset of positive hole conduction as determined by conductivity studies, the electrolytic domain boundary for YDT at high P_{O_2} shown in Fig. 8 may be regarded as fairly well established.

However, as in the case of CSZ, the low P_{O_2} electrolytic domain boundary appears to be a much more controversial issue at the present time. Three recent emf

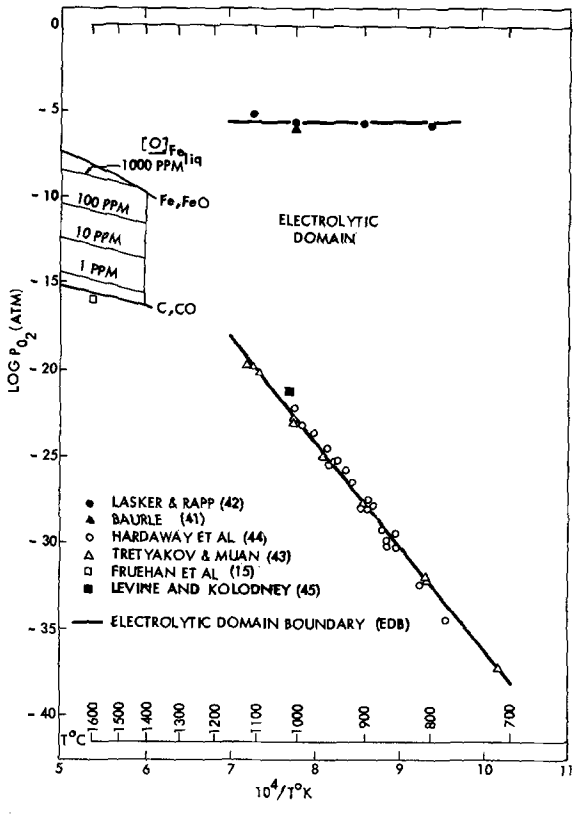

Fig. 8. Electrolytic domain boundaries and related data for YDT

studies (43-45) conducted at temperatures below the melting point of iron have been reported. These studies were performed quite independently and with significantly different means for controlling oxygen potentials. However, the electrolytic domain boundaries deduced from these studies are in substantial agreement as may be seen from Fig. 8. Extrapolating the results of these studies to the steelmaking temperature range suggests that only a small part of the steelmaking application domain lies within YDT's electrolytic domain. This is in accord with the results of Baker and West (12) who reported very substantial electronic conduction in YDT (as well as CSZ) exposed to liquid iron containing dissolved oxygen.

However, emf measurements by Schwerdtfeger (40) and by Fruehan *et al.* (15) involving YDT in liquid iron alloys indicate that a very significant portion of the steelmaking domain is within the electrolytic domain of YDT. The estimate of the onset of electronic conduction at 1600°C by Fruehan *et al.* is also shown on Fig. 8. Obviously there is much disagreement regarding the location of the low P_{O_2} electrolytic domain boundary especially at temperatures in the neighborhood of 1500° to 1600°C. For these reasons the proposed low P_{O_2} electrolytic domain boundary shown in Fig. 8 has not been extended above the 1100° point. Also, future measurements may reveal the need to modify the 700° to 1100°C low P_{O_2} boundary which is based on the works of Tretyakov and Muan (43) and Hardaway (44). However, insufficient quantitative results have been reported in the literature to justify such a modification at the present time.

Because it is beyond the intended scope of the present paper, no discussion is offered regarding the various explanations that have been given for the departures from thermodynamic emfs reported by different authors. However, the observations of Fruehan *et al.* (15) strongly suggest that at least some of the observed departures are probably not due to the onset of electronic conductivity as had been supposed. Assuming the electrolyte to be free from cracks and voids, the other major possibilities include (*a*) unreliable reference electrode behavior, (*b*) concentration polarization at the liquid metal electrode, and (c) reaction between the electrolyte and the liquid metal electrode. The present author leans to the view that explanation (c) would account for more of the discrepant emf results now in the literature than any of the other explanation possibilities.

Conclusion

In summary, the conduction domain scheme may be used to assess the useful application conditions for a given solid electrolyte. Construction of the electrolytic conduction domain on a log P_{X_2}, $1/T$ map from various conductivity data and/or emf data has been accomplished. Such domain maps are very useful for comparing observations from various investigators and for estimating the experimental conditions wherein selected solid electrolyte galvanic cell measurements may be expected to be free from deleterious electronic conduction effects. Accordingly, electrolytic domain estimates in the form of log P_{X_2}, $1/T$ maps have been given for several known electrolytes and in this context some of the more controversial domain boundaries have been pointed out and discussed.

SYMBOLS

M	Metal component of the solid
X_2	Nonmetal component dimer gas molecule; *e.g.*, F_2, I_2, Br_2, Cl_2, O_2
P_{X_2}	Partial pressure in atm of X_2 gas
t_{ion}	Ionic transference number
E	Cell emf
ϕ	Electrostatic potential at electrode
μ_{X_2}	Gibbs free energy per mole of X_2 (chemical potential) at electrode
μ_M	Gibbs free energy per mole of M
Z_M, Z_X	Valence of cations and anions of the solid electrolyte
", '	Double and single primes indicate different electrodes
$\mathbf{F}$	Faraday's constant
T	Absolute temperature, °K
μ^o	Standard state chemical potential
R	Gas constant
$1/n$	Exponent of P_{X_2} in the functional dependence of $\sigma_\oplus$ on P_{X_2}
σ	Partial electrical conductivity
$\oplus$	Positive hole carriers (subscript indicator)
$\ominus$	Excess electron carriers (subscript indicator)
ion	Any or all ionic carriers (subscript indicator)
Q	iso P_{X_2} activation energy for carrier indicated by subscript
σ^0	Partial electrical conductivity extrapolated to infinite temperature and 1 atm P_{X_2}
σ_T	Total electrical conductivity
P_{pn}	P_{X_2} at which $\sigma_\oplus = \sigma_\ominus$
$P_\oplus$	P_{X_2} at which $\sigma_\oplus = \sigma_{ion}$
$P_\ominus$	P_{X_2} at which $\sigma_\ominus = \sigma_{ion}$

Emf Measurements of Electrochemically Prepared Lithium-Aluminum Alloy

N. P. Yao,* L. A. Herédy, and R. C. Saunders

Atomics International, A Division of North American Rockwell Corporation, Canoga Park, California 91304

ABSTRACT

The open-circuit voltages of the cell Li(l)/LiI-KI-LiCl/Li_xAl(s) were measured over the composition range of 6.9-50 a/o (atom per cent) Li in Li_xAl alloy in the temperature range 282°-389°C. The composition of the Li_xAl alloy was varied by coulometrically charging and discharging the cell. The emf values of the cell are independent of the composition up to 47 a/o lithium in the alloy and their temperature dependence follows the relationship $E = 451.07 - 0.2202T$ ($\sigma = 0.3$), where E is in millivolts, T in °K, and σ is the standard deviation. The constant potential exhibited by the alloy is ascribed to the formation of β-LiAl phase on the alloy surface. The standard free energies of formation for β-LiAl are estimated to be −7.49, −7.24, and −7.09 kcal/mole at 300°, 350°, and 380°C, respectively. The standard enthalpy and entropy of formation are constant, −10.40 kcal/mole and −5.08 cal/mole · deg, respectively, in this temperature range. Since the electrochemically prepared lithium-aluminum alloy has a constant potential over a wide composition range and exhibits good electrochemical behavior, it can serve as a good reference electrode as well as a high energy density anode in molten salt systems containing lithium.

The use of lightweight and highly electropositive lithium metal electrodes is desirable for high energy density, high power density battery systems. Liquid lithium metal has been extensively utilized in some high power density molten salt batteries, e.g. Li/Cl_2 (1), Li/S (2, 3), Li/chalcogen (4). High self-discharge rates due to corrosion of cell components by liquid lithium coupled with some appreciable solubility (5) of liquid lithium in the molten salt electrolytes often cause difficulties in material selection and battery cell design. These difficulties, however, can be circumvented through the use of a solid alloy of lithium. One such alloy is the lithium-aluminum alloy (6) which has been utilized as the solid negative electrode in Sohio's Li/Cl_2 (7) battery. Excellent electrochemi-

cal performances of lithium-aluminum alloy [composition range 5-30 w/o (weight per cent) Li] in molten salt systems have been reported (8-10). The lithium-aluminum alloy was shown to have a stable electrode potential during discharge and charge (10, 11) and the alloy, if properly prepared, is capable of charging and discharging at current densities up to 2 A/cm^2 (7).

In this paper, equilibrium emf measurements of an electrochemically prepared lithium-aluminum alloy in the cell Li/LiI-LiCl-KI/Li_xAl are reported in the composition range 6.9-50 a/o lithium and in the temperature range 282°-389°C. The eutectic mixture of lithium iodide, lithium chloride, and potassium iodide (12, 13) (mp 264°C) serves as the electrolyte.[1] Thermodynamic free energy, enthalpy, and entropy for the formation of the LiAl compound are calculated from the emf data.

Experimental

In order to avoid air contamination of the salts and reaction of lithium metal with air, the entire salt preparation and cell experiments were performed in an argon gas filled dry box (Vacuum Atmosphere-Allen Jones Company).

Chemicals.—Anhydrous, polarographic-grade LiI and LiCl were supplied in 200g ampoules by Anderson Physics Laboratory, Champaign, Illinois. Baker reagent-grade KI and purified LiF powder (Matheson Coleman and Bell) were vacuum dried over a 2 week period at gradually increasing temperatures up to 250°C and at 13μ Hg pressure. The eutectic mixtures of LiI-LiCl-KI (12) (59 m/o-8.5 m/o-32.5 m/o) and LiI-LiCl-LiF (15) (59.2 m/o-29.1 m/o-11.7 m/o) were prepared. The melts were colorless and clear. The melting points of the eutectic mixtures from cooling curves were 264° and 341°C, respectively, in agreement with the literature values (12, 15). Lithium metal (99.97% purity) was obtained in 1 lb ingots from Foote Mineral Company. The metal was cut and melted in a tantalum cup. It was then wetted to a nickel screen welded to the base of an inverted nickel cup current collector at 600°C. Aluminum sheet metal (99.99% purity, 0.127 in. thick) was supplied by Wilkinson Company, Santa Monica, California. The sheet metal was machined to a 1.2 in. diameter circular disk.

Apparatus.—The cylindrical cell for the electrochemical preparation of Li-Al alloy and for the emf measurements is shown in Fig. 1. The cell consists of a stainless steel cell body, an aluminum disk (0.127 in. thick, 1.2 in. diameter) welded to the cell base, and floating lithium contained in an inverted nickel cup which was supported externally. A BeO spacer was placed between the lithium electrode and the stainless steel cell wall. The annulus between the cell wall and the BeO spacer was rendered electrolyte free by the Grafoil sealing which was under compressive force transmitted by the BeO spacer. A thermocouple well and a lithium reference electrode (lithium wetted on nickel screen) were also incorporated in the cell as shown in the figure. The cell was heated at the base with a heating plate regulated with a Variac. The cell was thermally insulated by a preshaped porous alumina insulation block (1 in. thick). In this manner, the cell temperature was controlled to ±1°C. No temperature variation was observed at various depths of the molten salt electrolyte and the electrolyte temperature was within 1°C of that measured at the thermocouple well. Constant current was maintained by a d-c power supply (Hewlett-Packard 6203B) and a variable resistance pot (25 ohms, 50W) connected in series to the cell. The current was read on a Milliamperes Meter (Weston Instruments). The cell voltage and individual electrode polarizations were monitored on two strip chart recorders (Hewlett-Packard, 7100B). Equilibrium emf values of the cell were read on a Volt Potentiometer (Leeds & Northrup Company, Catalog No. 8687) and the temperature was measured with a sheathed Chromel-Alumel thermocouple. The Chromel-Alumel thermocouple was calibrated in a temperature range of 195°-505°C by intercomparison with two platinum-platinum 10% rhodium standard thermocouples certified by the National Bureau of Standards. The uncertainty for the thermocouple readings was less than 0.3°C in the temperature range.

Procedure.—The Li-Al alloy was prepared in the cell by coulometrically charging lithium into the pure aluminum disk (2.88g). The current density was 14-70 mA/cm^2 and the temperature range was 300°-390°C. On charging cathodically, the aluminum potential fell quickly to the alloy potential (about 0.3V for alloy *vs.* lithium). The initial charging current density was 14 mA/cm^2 and the current density was gradually increased as the alloy was cathodically and anodically cycled. The cell voltage during cycling was always stable and the maximum alloy polarization was less than 40 mV at the highest current density. Coulombic efficiency was greater than 93% during the repeated cyclings. The open-circuit voltage (OCV) of the cell was established to within a few millivolts of the equilibrium emf values in a period of a few minutes. The alloy composition was varied from 6.9 a/o up to 50 a/o lithium by charging and discharging it *vs.* the lithium counterelectrode, and the equilibrium OCV was determined at different compositions in the temperature range 280°-390°C. Equilibrium OCV data were normally taken after 1 hr at a constant temperature and, in some cases, the data were taken after 15 hr (overnight) and 60 hr (over a week end). The values were reproducible to within 0.1 mV in all cases.

Results and Discussion

The equilibrium emf values of lithium-aluminum alloys (*vs.* Li/Li^+) in LiI-KI-LiCl eutectic mixture are given in Table I as a function of alloy composition (in a/o and w/o lithium) and temperature. The emf values up to 46.97 a/o lithium composition were found to be independent of lithium content in the alloy and are only dependent on temperature. This is shown in Fig. 2 where the emf values (alloy *vs.* Li/Li^+) up to 46.97 a/o lithium are plotted as a function of temperature. The data in the composition range of 7-47 a/o lithium can be represented by a least-squares equation with a standard deviation $\sigma = 0.3$ mV

$$E = 451.07 - 0.2202T \qquad [1]$$

where E is emf in millivolts and T is temperature in °K. With increasing lithium content in the alloy above 46.97 a/o lithium, the emf values of the alloy (*vs.* Li/Li^+) approach zero, *i.e.* the potential of pure lithium, as shown in Fig. 3, indicating some local lithium saturation of the alloy surface. The local lithium

[1] Potassium ions of this salt mixture were not expected to interfere with the electrode reactions of lithium, on the basis of thermodynamic considerations (14). This was confirmed in the present study where the emf values of lithium-aluminum alloy (*vs.* Li/Li^+ reference) in LiI-LiCl-KI eutectic were found to be identical to those in LiI-LiCl-LiF eutectic, a pure lithium salt mixture.

saturation appears to commence at approximately 46 a/o lithium composition from the extrapolation of the emf data (dotted line) as shown in Fig. 3.

The equilibrium lithium-aluminum phase diagram has been reported (6). Electrical resistivity and microhardness studies (16) of aluminum-rich alloys

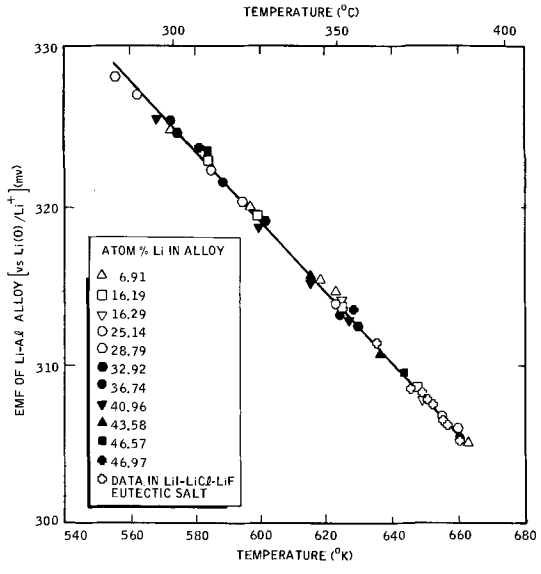

Fig. 2. Emf of lithium-aluminum alloy [vs. $Li(O)/Li^+$] as a function of composition and temperature in LiI-KI-LiCl eutectic salt.

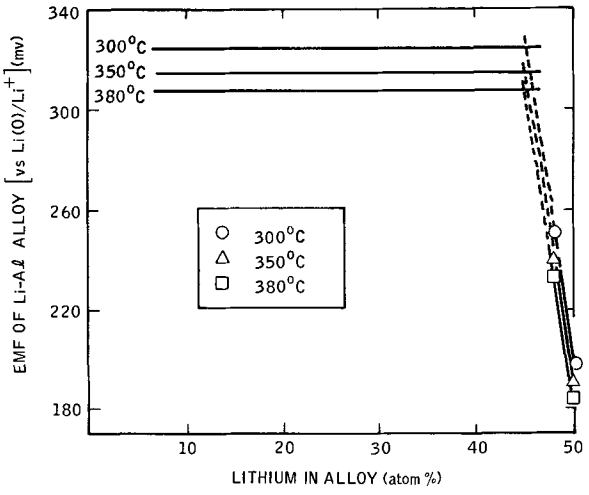

Fig. 3. Emf of lithium-aluminum alloy [vs. $Li(O)/Li^+$] as a function of temperature and composition.

showed that a solid solution of lithium in aluminum was formed up to 7.1 a/o lithium at 300°C and up to 8.5 a/o lithium at 400°C. This α phase was later confirmed by quantitative metallography and lattice-parameter measurements (17). With increasing lithium concentration at these temperatures, two phases are formed corresponding to α phase and β phase, respectively (17), where the β phase consists of the compound LiAl. The two-phase region extends to approximately 45.8 a/o lithium and has this boundary value constant over the temperature range 150°-550°C (17). In the present study, constant potential was indicated by the alloy up to 46.97 a/o lithium, which implies that a constant lithium activity exists on the alloy surface over the composition range from 6.91 to 46.97 a/o lithium in aluminum. This surface layer is likely to contain a stable compound corresponding to the β-LiAl in equilibrium with α-Al. The low emf values at 6.91 a/o lithium (in Table I) and at 8.11 a/o lithium (in Table II) seem to indicate that the surface layer of β-LiAl was formed even at these low lithium concentrations; *i.e.*, the surface concentration of lithium probably exceeded the true bulk concentration. On the other hand, further charging of lithium into the β-LiAl above 47 a/o up to 50 a/o yields a single phase, the lithium activity of which is a strong function of composition.

A duplicate run was made to prepare a lithium-aluminum alloy (up to 50 a/o lithium composition) in the LiI-LiCl-LiF eutectic mixture (mp 341°C) to assure the absence of potassium deposition. The equilibrium emf values of the alloy (*vs.* Li/Li^+) in the temperature range 362°-388°C are given in Table II, and the data up to 44.6 a/o lithium are plotted (open + points) in Fig. 2 for comparison with those obtained in the

LiI-KI-LiCl eutectic mixture. The two results were identical within the experimental accuracy. This shows that the potassium ion does not interfere with the lithium reaction in the temperature range studied, as was expected from thermodynamic considerations (14).

The cell reaction, in the alloy composition range 7-47 a/o lithium, is therefore the formation of solid β-LiAl compound on the surface corresponding to

$$\text{Li(l)} + \alpha\text{-Al(s)} = \beta\text{-LiAl(s)}$$

where α-Al(s) is the solid solution of lithium in aluminum (up to 7.1 a/o lithium at 300°C and up to 8.5 a/o lithium at 400°C). For practical purposes, however, the α-Al phase may be considered to be pure aluminum during the course of electrochemical alloy preparation. This is true since the reaction time of lithium and aluminum is much shorter than the solid diffusion time of lithium atoms in aluminum for α-phase formation. The diffusivity of lithium in aluminum is reported to be 1.2-1.7 x 10^{-10} cm^2/sec at 417°C (18). On this basis, the standard free energy of formation for β-LiAl saturated with α-Al from molten lithium and solid pure aluminum can be estimated from the emf data

$$\Delta G^\circ_f = -n\mathbf{F}E = -10.40 + 5.078 \times 10^{-3}\, T$$

where n is 1 equiv/mole, $\mathbf{F}$ is Faraday's constant, and T is temperature in °K. The standard enthalpy and entropy of formation are, respectively, −10.40 kcal/mole and −5.08 cal/mole · deg in the temperature range 282°-389°C. The standard free energy, enthalpy, and entropy of formation for β-LiAl at 300°, 350°, 380°C are summarized in Table III.

The lithium-aluminum alloy was prepared in the present work by constant-current cyclings in the gradually increasing current density range 14-70 mA/cm^2. As the result of expansion on charging and contraction on discharging, the alloy structure became increasingly porous. The fully charged alloy was subsequently discharged and charged at an apparent current density of as high as 150 mA/cm^2 without showing any significant polarization, presumably due to the high surface area of the alloy and an anomalous mechanism of lithium transport in the β-LiAl phase. The coulombic efficiency greater than 93% at the relatively high discharge current density would, otherwise, be impossible if the lithium atoms are transported from the alloy interior to the surface solely by solid diffusion.

The constant potential exhibited by the solid lithium-aluminum alloy over a considerable lithium concentration in LiI-LiCl-KI and LiI-LiCl-LiF eutectic salts, coupled with the good charge and discharge performance of the high surface area alloy, makes such an alloy an excellent high energy density anode material and also provides a stable reference electrode in high-temperature molten salt systems containing lithium.

Table III. Standard free energy, enthalpy, and entropy of formation for β-LiAl

T(°C)	ΔG°_f (kcal/mole)	ΔH°_f (kcal/mole)	ΔS°_f (cal/mole·deg)
300	−7.49	−10.40	−5.08
350	−7.24	−10.40	−5.08
380	−7.09	−10.40	−5.08

Thin-Film Electrolytic Cells

John H. Kennedy* and Fred Chen**

Department of Chemistry, University of California, Santa Barbara, Santa Barbara, California 93106

ABSTRACT

Thin-film electrolytic cells have been prepared using silver bromide as the electrolyte. Deposits of silver bromide were highly oriented, (111) and (222), when deposited on silver or gold substrates at high temperature. The more random deposits obtained at ambient temperature exhibited electrical conductivities three orders of magnitude higher than the intrinsic conductivity of silver bromide. Cells of the type Ag/AgBr/Au were found to be accurate coulometers under limited conditions. The cells had a long life and could be cycled several thousand times without failing.

In the wake of the extensive amount of research being conducted on solid electrolyte materials, it has become apparent that solid electrolyte cells in the form of thin films might offer potential utility and overcome the high electrical resistance problems inherent to many of these systems. During the last few years, several articles have described the development of thin-film batteries (1-3), while our work has been aimed at developing thin-film cell configurations which could be employed as electrolytic coulometers. Although coulometers do not require extremely high conductivity, film cells also offer the possibility of cell arrays where multiple timing or integrations are required. In addition, some electrochemical systems may be coulometrically accurate, but are too resistive in conventional pellet form. Information gained from studying a known solid electrolyte coulometric system in film form could then be applied to other solid electrolytes.

Briefly stated, an electrolytic coulometer simply tabulates coulombs of charge by plating a metal (or chemical compound) on an inert indicator electrode. The counterelectrode in the cell is usually the same metal which is to be plated on the indicator electrode. A typical example is a cell consisting of a gold indicator electrode and a silver counterelectrode separated by an electrolyte containing silver ions (either solid or liquid electrolyte). Several papers have described these coulometers in detail (4-6). A thin-film electrolytic coulometer can be envisaged then by depositing a film of gold, solid electrolyte, and then silver on a substrate. Although metal films such as silver and gold are easily prepared and have been well characterized, films of solid electrolytes have not been extensively investigated. Because of its importance to the coulometer system, a detailed study of the solid electrolyte's film characteristics must be made. For initial studies, we chose silver bromide because of its simple stoichiometry and, from our pressed pellet studies (4), we knew it had a reasonable electrical conductivity of about 10^{-5} $(\text{ohm-cm})^{-1}$.

Experimental

Film depositions.—Film depositions were carried out at Sloan Technology Corporation, Santa Barbara, California. The films were vacuum deposited at several rates from 20 to 1000 Å/sec, while substrate temperatures were maintained at values from 20° to 250°C. Crystallite structure and size were controlled by the substrate temperature, and precautions had to be taken to prevent substrate temperature from increasing during the deposition. Deposition rate had to be maintained slow enough to prevent heating of the substrate.

X-ray diffraction.—X-ray diffraction studies were made with a Philips x-ray diffraction unit with CuKα radiation. A Philips Type 52572 scintillation counter with chart recorder was used for the x-ray diffractometer measurements.

Scanning electron microscopy.—Scanning electron micrographs were taken at Sloan Research, Santa Barbara, California. The samples were mounted on a sample stage with conductive silver paint. Care was taken to assure that the gold electrodes were grounded to the stage to bleed off induced charges. Some charging was still encountered due to the poor conductivity of the silver bromide. This caused focusing problems at high magnification along with some raster deflection. Overcoating the samples with a thin-film conductor will be considered for future work.

The examinations were made using a JSM-2 scanning electron microscope. A 25 kV electron beam focused to approximately 100Å diameter was rastered over the samples. All photographs were taken using the secondary electron emission mode. The samples were tilted 30° with respect to the impinging beam in order to enhance surface relief.

Constant current readout.—A Bissett-Berman Corporation E-Cell Digital Coulometer was used for constant current charging of cells and for those experiments designated as constant current readout. This unit has a built-in trigger which cuts off the constant current supply when cell voltage reaches a predetermined value.

Pulse discharge readout.—A Bissett-Berman Corporation EDR-300 E-Cell Digital Readout was used for pulse charge and discharge of cells. The unit was modified to deliver pulses of 1 μcoulomb in place of the normal 100 μcoulombs.

Temperature control.—An Associated Testing Laboratory SW-5101 environmental chamber was used for temperatures other than ambient.

Results

Silver bromide film characteristics.—Sample silver bromide films were vacuum deposited on silver, gold, silicon monoxide, and directly on a glass substrate. X-ray diffraction patterns of these films were taken, and the results are shown in Table I. Depositions were carried out at both high and low temperatures, and the

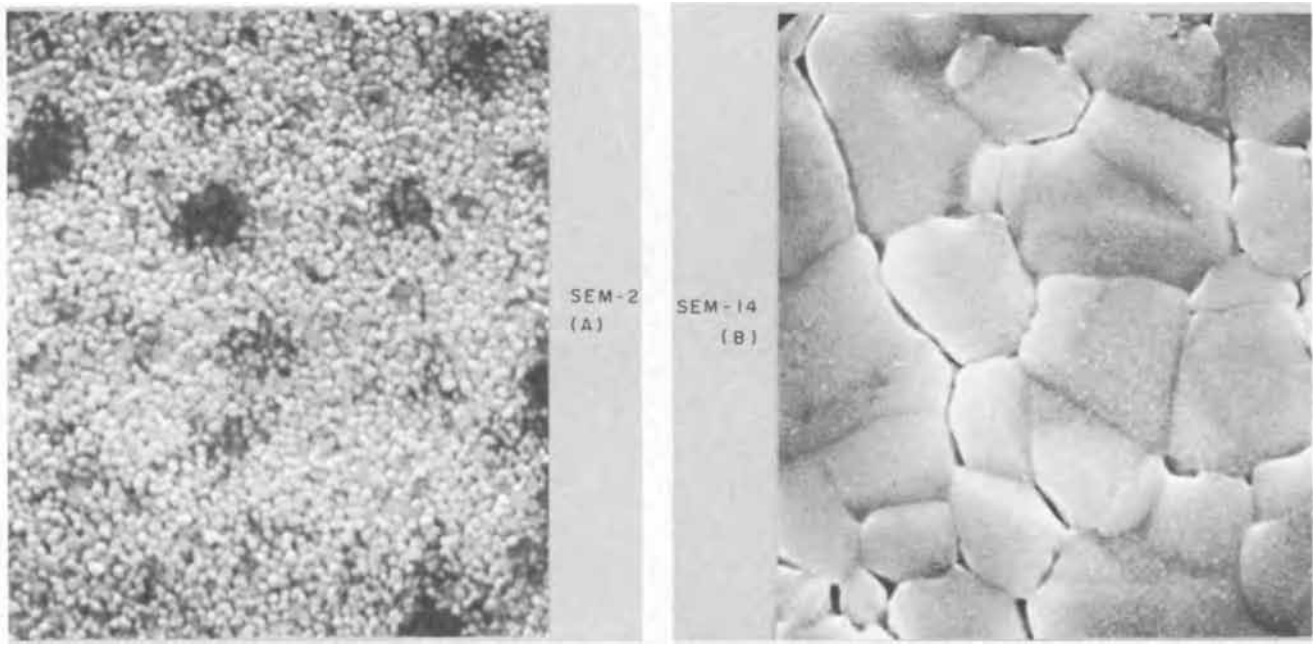

Fig. 1. Scanning electron micrographs of silver bromide films: (A)—AgBr deposited at 25°C (7600X), (B)—AgBr deposited at 250°C (7600X)

main finding was that silver bromide films were highly oriented along (111) and (222) planes when deposited at high temperature on gold or silver substrates. The primary line for powder AgBr is from the (200) reflection, and essentially the same pattern was observed for AgBr films deposited on SiO or glass. The orientation was also more random when deposited at low temperature on gold or silver and as the silver bromide film became thicker.

It appears from these results that growth along (111) and (222) planes is favored on gold and silver substrates, especially at high temperature where thermal energy allows recrystallization on the surface. Other investigators have also reported similar observations (8). This orientation is one in which a layer of bromide ions would cover the metal substrate as opposed to a surface containing both silver ions and bromide ions. This crystallite growth at high deposition temperature also meant, however, that crystallite size would be larger than films prepared at lower temperatures. This effect is readily seen in Fig. 1. Scanning electron micrograph (A) was taken of a AgBr film deposited at ambient temperature while (B) was taken of a film deposited at 250°C to gain information concerning crystallite size and shape. The crystallites formed at high temperature were 1-3μ in size, while at low temperature the crystallites were only 0.2μ.

Most of the electrolyte films for electrolytic coulometers were nominally 100,000Å thick (10μ) although several successful cells with only 20,000-30,000Å films of AgBr were prepared. Thinner layers, however, were extremely prone to electrical shorting.

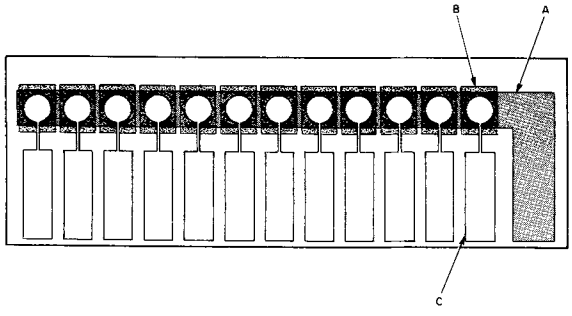

Fig. 2. Thin-film cell configuration: A—silver strip electrode (common), B—silver bromide electrolyte (12 squares), C—gold electrode (12 circles with rectangular tab for contact).

Electrolytic cell configuration and electrochemical characteristics.—The cell configuration is shown in Fig. 2. First, a set of 12 gold electrodes was deposited on the glass substrate or over a Nichrome base to obtain better adherence. Second, a set of 12 silver bromide square pads of electrolyte covered the gold electrodes. Finally, a common silver electrode strip was deposited over the entire 12 cells. The cell area was determined by the circular gold electrode which was 0.10 cm^2. The reverse deposition order was attempted, but it appeared that the silver electrode oxidized before the silver bromide deposition could be carried out. The experimental conditions were such that the films were exposed to air after each deposition.

The electrical conductivity of silver bromide films was extremely sensitive to the deposition temperature as can be seen in Table II. The conductivities of films are compared to the intrinsic conductivity of AgBr and that of pressed powder (4). In previous work, it has been shown that AgBr pressed powders gave conductivities 100 times greater than intrinsic values and that this effect appeared to be due to grain boundary conduction (4, 7). The small crystallites produced by low-temperature deposition have an extraordinary amount of grain boundaries leading to conductivities another order of magnitude higher than the pressed powder.

The conductivity was also measured as a function of temperature. The usual plot of log σ *vs.* $1/T$ was linear with an activation energy of 4.6 kcal/mole. This is considerably less than the activation energy for the intrinsic conductivity measured at high temperature which is about 20 kcal/mole. This result again emphasizes the point that the conductivity observed for AgBr films is extrinsic and probably due to a grain boundary conduction mechanism.

Although the cells made by depositing AgBr at high temperatures performed reasonably well as coulom-

Table II. Conductivity of AgBr films

Material	Deposition temp, °C	Conductivity (ohm-cm)$^{-1}$	Film resistance, ohms
Intrinsic conductivity	—	$<0.01 \times 10^{-5}$	—

Film	250	0.052×10^{-5}	19,300
Film	100	0.182×10^{-5}	5,500
Film	25	9.1×10^{-5}	130

eters, the small number of conduction paths made them highly resistive and frequently led to electrical shorting during operation. Shorting was observed with both silver plating on silver and silver plating on gold. Cells which operated several cycles usually shorted when plating silver on silver. This observation was reported earlier with pressed pellet coulometers (4). Coulometry results given below are only for cells containing AgBr deposited at ambient temperature.

After a measured amount of silver has been plated on the gold indicator electrode, the cell is a silver/silver system until all the silver is anodically stripped from the gold electrode. The open-circuit potential is essentially zero, and the applied voltage during stripping remains close to zero with just IR drop and electrode polarization contributions. After all the silver has been stripped from the gold electrode, the voltage rises steeply to the point where gold itself oxidizes or the decomposition voltage of the electrolyte is reached. A voltage/time curve during stripping for a thin-film cell is shown in Fig. 3. A charge of 150 μcoulombs of silver had been plated on the gold electrode and was then anodically stripped at 3 μA. The test equipment was set to cut off automatically when the cell reached 0.5V. Without the cutoff, the voltage rises to about 0.8V which is the decomposition voltage of AgBr. It is also in the range where gold can be oxidized to form gold bromide.

The sensitivity of a coulometer depends on how sharp this final rise curve is and can be characterized by an apparent capacitance value. The capacitance is calculated by

$$C = i \Big/ \frac{dv}{dt}$$

It must be emphasized that this is not the true capacitance since faradaic effects can also be taking place at the gold electrode as the potential changes. These faradaic effects may include oxidation of impurities at the gold surface from the silver bromide or gold and some oxidation of the gold itself at the higher voltages. After several charging and stripping cycles, apparent capacitances increased possibly due to silver residing in the gold grain boundaries being oxidized at high voltages. The thin-film cells exhibited apparent capacitances of 30-60 μf or 300-600 μf/cm². This range of values is similar to results for other AgBr studies (9). Roughness factors could also lead to high capacitance values, and no direct measurement was made on the gold films. High reflectivity and microscopic examination of the surface leads us to assume roughness factors comparable to gold foil of 1.5-4. The higher value then leads to corrected capacitance values of 75-150 μf/cm².

After silver has been completely stripped from the gold electrode, the gold indicator electrode can be held at a positive potential with respect to the silver electrode, and the current will decay to a small residual value. The gold acts as a "blocking" electrode toward ionic processes so that the residual current is a function of the electronic conductivity. Wagner (10) and Ilschner (11) have shown that silver bromide exhibits electron conductivity under these conditions, and that the following relation holds in the plateau region of residual current *vs.* applied voltage

$$i_o = \frac{RT}{LF}\sigma_o$$

where:

i_o = residual current density
L = electrode spacing
σ_o = electronic conductivity

Residual currents for most thin-film cells were <1 nanoA, and no appreciable change in residual current was observed between 0.2 and 0.5V. A plateau was difficult to demonstrate, however, since the readings were often near the low limit of our measuring equipment (0.1 nanoA). Previous work has shown that this voltage range is in the plateau region for AgBr (11). Electronic conductivity values calculated from these residual currents were $<4 \times 10^{-10}$ (ohm-cm)$^{-1}$. This would represent the maximum electronic conductivity contribution since there might still be an ionic contribution to the residual current under the experimental conditions used.

Coulometry results.—The principal function of an electrolytic coulometer is to store a charge in the form of silver atoms on the gold indicator electrode and, then, to determine this charge by anodic stripping. If a known charge is plated on the indicator electrode and stripping is carried out at constant current, the coulometer performs a timing function. Table III illustrates results for thin-film cells stripped at constant current at various temperatures. Results are within 1-2% of the true value on the average, particularly in the 200-1000 μcoulomb range. It should be noted that 2% of 200 μcoulombs is only 4 μcoulombs while a monolayer of silver atoms on the gold is about 25 μcoulombs (or greater, depending on surface roughness). The end-point or cutoff voltage was nominally picked at 500 mV. A change in cutoff voltage will only affect the first readout for the cell, provided all succeeding cycles use the same cutoff value. There was a tendency for high results at low currents and high temperatures noted (Table III: 20 sec at 1 μA at +50°C = +21.3% error) which is related to the increase in residual current as the temperature increases. Obviously, a cell can never reach 500 mV at a given current if the residual current is higher than the operating current. Under most operating conditions, the errors are usually negative. This is attributed to the migration of silver into the gold along grain boundaries to become essentially "lost." Another effect which may account for low results when large amounts of charge were used is the possibility of

silver losing contact with the gold electrode and becoming an island in the silver bromide electrolyte. These two effects will limit both the low and high charge capability for the coulometers.

Previous work with pressed powder cells showed that, by pulsing charge and observing the cell potential after the pulse, problems due to *IR* drop and polarization could be decreased (6). This technique was also applied to thin-film cells, and the results are given in Table IV. There was no marked improvement with errors of 1-2% observed in the range of 500-1000 μcoulombs. Somewhat greater errors were observed for charges of 100-200 μcoulombs. However, the pulsing technique could be used to apply charges of 3000-5000 μcoulombs without shorting the cells. Errors were −1 to −5% for these large charges.

The pulsing technique was also used to study charge storage capability. A charge of 1000 or 2000 μcoulombs was plated on the gold and allowed to stand for several days at ambient temperature before the stripping cycle. Figure 4 shows the results. There was a rapid loss of silver during the first day amounting to about 100 μcoulombs of charge and, then, little further loss was observed. Again, this can be explained by silver migrating into the gold along grain boundaries (bulk diffusion is much too slow to account for these results).

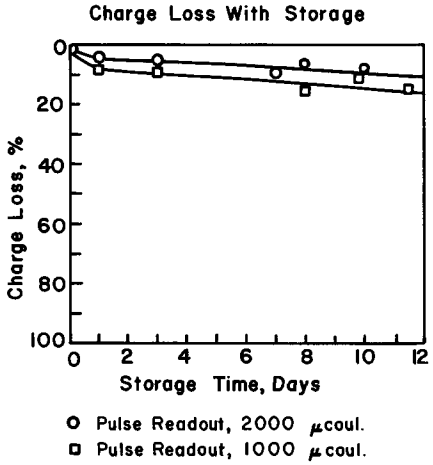

Fig. 4. Charge loss with storage

The gold surface becomes "saturated" quickly after the easily accessible sites are filled. A very slow diffusion deeper into the gold may still take place causing additional loss on long-term storage.

Memory applications.—For some applications, a coulometer must stay at the cutoff voltage after being brought to this point while the cell stands at open-circuit conditions. After a period of time, interrogation of such a cell must show it to be at a high potential, indicating that there is no silver on the gold. A slide of thin-film cells was tested for this type of application, and the results are given in Table V. Four of the cells were brought to 500 mV, while five other cells were plated with 200 μcoulombs of charge. After 16 hr, the cells were checked. Cleared cells still registered 400-464 mV, and the plated cells were read out at constant current. A loss of about 30-50 μcoulombs was noted. The coulometry cells were replated and, after 98 hr, a second check was made. Cleared cells were now 320-430 mV and, for comparison, the voltages of plated cells were 2-5 mV. Small potentials are observed for plated cells because low coverage of silver electroplated on gold has a slightly lower activity than the pure silver film. Again, the plated cells exhibited coulometric errors of 15-50 μcoulombs. As discussed above, charge loss with storage occurs within the first day and little additional loss would occur in the next 3 days.

Cell life.—The life of these cells has been surprisingly long considering the close electrode spacing. Some cells were cycled continuously with 200 μcoulombs of charge and underwent over 20,000 cycles with no apparent damage.

Resistance of pressed pellets tended to rise with time, but film cells had exactly the same resistance after 6 months. Crystallites whose boundaries have been physically pressed together appear to react slowly with time, forming fewer grain boundary conduction paths. Silver bromide films, on the other hand, exhibit no such reaction over the period of time studied. In fact, in some cases where cells were used extensively, the resistance decreased a few per cent. This was attributed to a better electrode/electrolyte contact being produced with usage.

Cell operation was not affected by light although the top of the silver electrode tarnished and some color change of the silver bromide extending beyond the electrodes was noted. It must be remembered that because of the cell dimensions only the silver bromide directly between the gold and silver electrodes will experience current flux. This part of the silver bromide is not exposed to light because of shielding by the gold and silver electrodes.

Cathodic Behavior of N-Type Cadmium Fluoride

M. M. Nicholson*

Atomics International, A Division of North American Rockwell Corporation, Canoga Park, California 91304

ABSTRACT

The cathodic reduction of n-type cadmium fluoride single crystals in a 1M lithium perchlorate-propylene carbonate electrolyte was investigated by discharge at constant current densities of 0.1 and 0.2 mA/cm^2. The semiconductive cadmium fluoride was reduced through an electronic mechanism which did not occur with an undoped crystal. Bulk resistivities of the crystals were determined, and contact resistances at the boundary between the semiconductor and the indium amalgam current collector were examined. A cathodic passivation effect which limited the utilization of active material to the equivalent of a 0.1-0.2μ layer on the crystal surface was observed. Implications of the results for battery cathode performance are discussed.

Studies of faradaic processes at semiconductor electrodes have been confined mainly to the anodic dissolution of germanium and silicon (1, 2) and the charge-transfer reactions of redox systems on semiconductor substrates (3). The cathodic reduction of semiconductors with known electronic properties has received much less attention, although semiconductivity is thought to play a significant role in the discharge of certain battery cathodes containing an oxide or sulfide as the active ingredient (4-6). In this investigation, the cathodic behavior of n-type cadmium fluoride single crystals was examined galvanostatically in a 1M lithium perchlorate-propylene carbonate electrolyte. Each crystal specimen was characterized by measurement of its bulk resistivity before it was placed in the electrochemical cell. The contact resistivity at the interface between the semiconductor and the indium amalgam current collector was also investigated.

Cadmium fluoride, with an energy gap of 6.0 eV (7), is normally an insulator. Prener and Kingsley discovered that this compound can be converted to an n-type semiconductor with a resistivity of the order of 1 ohm-cm by doping with Y(III) or certain trivalent rare-earth cations and subsequent exposure to cadmium vapor at 500°C (8). Because this conversion method was available, the cathodic response of electronically conductive and nonconductive forms of cadmium fluoride could be readily compared. Such a comparison for a metal halide system is of particular interest in current efforts to develop more active cathode materials for high-energy batteries using lithium anodes and electrolytes dissolved in aprotic organic solvents. Cadmium fluoride offers a theoretical energy density of 399 Whr/lb in combination with a lithium anode, which is high enough to merit its use as a practical battery cathode material (9, 10).

Experimental Procedures

Materials.—Undoped and yttrium-doped cadmium fluoride crystals weighing 20-30g were grown by the Bridgman closed-crucible method, starting with high-purity cadmium fluoride powder from the Chemical Products Plant of the General Electric Company in Cleveland, Ohio. Prior to crystal growth, the powder was dried for several hours at 400°-600°C in a stream of anhydrous hydrogen fluoride. The yttrium fluoride dopant was introduced by fusion at concentrations from 0.01 to 1 m/o (mole per cent).

One-millimeter sections of the doped crystals, cut perpendicular to the growth axis, were washed in benzene to remove the cutting oil, polished on an abrasive stone, etched in 1:1 hydrochloric acid, and sealed into evacuated quartz or Pyrex tubes containing small pieces of cadmium metal. Heating for several minutes at 500°C produced the blue coloration characteristic of semiconductive cadmium fluoride. The colored specimens were re-etched in hydrochloric acid to remove the undoped layer which was known to form on the surface during cadmium exposure (8).

Propylene carbonate of 99% purity, manufactured by Jefferson Chemical Company, was dried by percolation through a Linde 4A molecular sieve and distilled at ~3 mm under argon at a 5:1 reflux ratio, using a 50 x 230 mm column packed with ⅛ in. Pyrex helices. The center third of the distillate had a conductivity of 2.89×10^{-8} ohm^{-1} cm^{-1} at 25°C. Gas chromatographic analysis of this fraction by the method of Jasinski and Kirkland (11) indicated 10 ppm water, 3 ppm propylene glycol, and <0.5 ppm propylene oxide.

Reagent-grade lithium perchlorate from G. Frederick Smith Chemical Company was heated 16 hr at 160°C in a stream of argon to remove traces of water. A typical weight loss of 0.33% occurred at this temperature within the first 2 hr. No further loss was observed on fusion of the dried material. The lithium metal was 99.97% pure ribbon from Foote Mineral Company. The cell materials were handled by dry box and argon-blanketing techniques.

Resistivity measurements.—Bulk resistivities of the cadmium fluoride crystal specimens and area resistivities of the indium amalgam contacts were measured by means of the conventional four-terminal arrangement shown in Fig. 1. Details are given here to clarify the notations used in reporting the results. Constant current densities ranging from 0.05 to 35 mA/cm^2 were passed between the ends of the crystal through terminals F and G by means of a 45V battery and a dropping series resistor. Electrical connections to the amalgam contacts were made with the assistance of a four-element micromanipulator assembly. Potential differences between the various terminals were measured with a Leeds & Northrup K-3 potentiometer.

The bulk resistivity, ρ, was calculated from the equation

* Electrochemical Society Active Member.
Key words: cadmium fluoride, nonaqueous electrolyte.

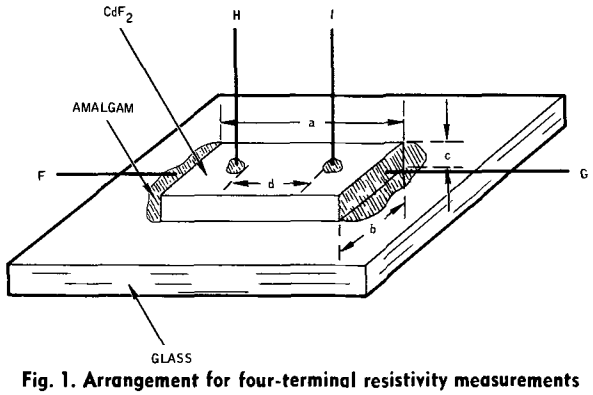

Fig. 1. Arrangement for four-terminal resistivity measurements

$$\rho = \frac{E_{H-I}}{E_s} \cdot R_s \cdot \frac{bc}{d} \qquad [1]$$

where E_{H-I} represents the potential difference between the probes at terminals H and I, E_s is the potential drop across a standard resistor, R_s, in a series with the crystal, and b, c, and d are the dimensions indicated in Fig. 1. With this technique, the bulk resistivity measurement is not ordinarily influenced by relatively large potential drops across the current-carrying boundaries. The area resistivity of the surface F was defined as

$$\rho_F = \frac{E_{F-H}}{bc} \cdot \frac{R_s}{E_s} \qquad [2]$$

and a corresponding definition was taken for the surface G.

A 50 w/o (weight per cent) indium amalgam proved more satisfactory than other contact materials that were investigated, including indium solder, several pressure-applied solid metals, and carbon paste. Acid-etched cadmium fluoride surfaces tended to produce poor contacts, even with the amalgam. Further washing in organic solvents failed to eliminate the resistive film. Amalgam contacts on freshly cleaved crystal surfaces were essentially ohmic, however.

Electrochemical measurements.—The electrochemical cell contained a single-crystal cadmium fluoride cathode mounted as shown in Fig. 2, a lithium anode, which was separated from the cathode by a glass frit, and a lithium reference electrode connected to the cathode compartment through a Luggin capillary. The crystal surface exposed to the solution was freshly cleaved and essentially parallel to the growth axis. The opposite surface was scraped to assure good contact through the amalgam to the external circuit. The exposed electrode area was typically 0.05 cm^2, and the crystal length, 0.5 cm. The cell was placed in a water bath at 25°C during the electrochemical measurements.

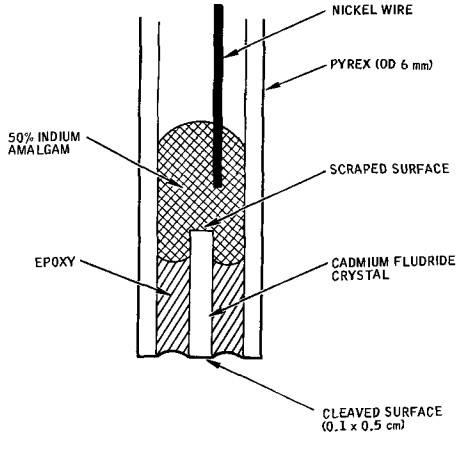

Fig. 2. Single-crystal electrode

Constant currents from an Electronic Measurements Model C633 power supply were applied between the crystal electrode and the lithium anode. The potential of the crystal was monitored with respect to the reference electrode on a General Radio Type 1230-A electrometer, with the output signal applied to a Sargent MR recorder. By means of current pulse measurements on a dummy copper electrode having the same geometry as the crystal, it was established that the solution ohmic drop between the crystal electrode and the reference was only a few millivolts.

Results and Discussion

The fluorides and chlorides of transition metals have been investigated over a period of several years as cathode materials for organic electrolyte batteries. These solids have low conductivities; their discharge apparently involves dissolution of the metal ion and its transport through the solution, followed by electron transfer at the surface of an inert current collector such as carbon. Ionic conduction in the solid state would lead, instead, to metal deposition at the boundary between the active solid material and the current collector, while electronic conduction would result in electrodeposition of the metal at the semiconductor-solution interface. In this work, it was of central importance to verify the existence of an electronic mechanism for the reduction of n-type cadmium fluoride and to determine the rate and depth of discharge obtainable by this reaction path on a known surface area. It also proved necessary to evaluate the potential drop at the interface between the semiconductor crystal and its metal contact to the external circuit.

Contact resistivities.—The contact resistivities of acid-washed and freshly cleaved surfaces on the 1.3 ohm-cm crystal are compared in Fig. 3. Notations F and G refer to the current-carrying contacts at appropriate ends of the crystal, as identified in Fig. 1. A negative current density corresponds to the passage of electrons from the amalgam into the crystal, as would occur in the cathodic reduction process. The rectification effect at this boundary, which is evident in Fig. 3, would oppose the electrochemical reaction. This problem was greatly reduced by cleaving the crystal. The area resistivity on the 1.3 ohm-cm specimen was then less than 10 ohm-cm^2 for current densities between −5 and +15 mA/cm^2. At higher Y(III) concentra-

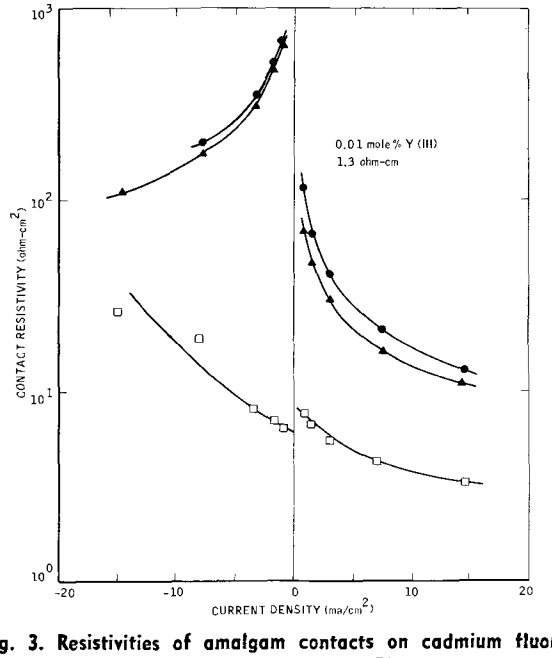

Fig. 3. Resistivities of amalgam contacts on cadmium fluoride crystal: —●—, contact F, washed in 1:1 HCl; —▲—, contact G, washed in 1:1 HCl; —□—, contact F, freshly cleaved.

tions, cleaved interfaces exhibited more ideally ohmic behavior, with a typical area resistivity of 0.3 ohm-cm^2, although the resistivities on acid-washed and benzene-washed surfaces still approached 10^3 ohm-cm^2. Since the electrochemical current density did not exceed 0.2 mA/cm^2, the potential drop at the amalgam contact on a freshly scraped surface should have been only a few millivolts. With a contaminated surface, however, this drop could easily have been of the order of 1V. These results emphasize the importance of a good electronic contact for a semiconductor electrode. The ohmic drop through the bulk of the crystal ranged from ~0.02 to 0.3 mV.

Cathodic discharge behavior.—The thermodynamic potential of a cell with the reaction

$$2Li(s) + CdF_2(s) \rightarrow Cd(s) + 2LiF(s)$$

is 2.70V. Initial open-circuit potentials determined experimentally on the doped crystals were 2.4-2.6V *vs.* Li/Li$^+$ (1M), while 1.7V were observed on an undoped crystal with a resistance >3 x 10^7 ohms.

Preliminary discharges of 1 min duration were made on each of the doped crystals at 0.1 and 0.2 mA/cm^2, to compare initial polarizations and to establish a suitable current density level for longer discharge experiments. The preliminary curves for a 0.68 ohm-cm crystal are shown in Fig. 4. Following rapid potential drops of 0.25 and 0.7V, respectively, the discharge proceeded smoothly under these conditions, and the cathode recovered within several minutes on open circuit to a new potential approaching the theoretical value. The initial drop apparently was localized at the semiconductor-solution interface, but the mechanism of its origin has not yet been determined. Corresponding curves for crystals with resistivities up to 3.2 ohm-cm differed very slightly from those of Fig. 4.

With continued discharge, a dark layer of cadmium metal became visible on the outside of the cadmium fluoride crystal, while no change was observed at the amalgam contact. A discharged electrode, when removed from the cell, washed in water, and dried, showed high surface conductance on a d-c ohmmeter. Thus, an electronic reduction mechanism was indicated for the semiconductive materials. As expected, an undoped crystal failed to pass a current of 0.1 mA/cm^2, even when 420V were applied between the anode and cathode.

Figure 5 illustrates the behavior of a doped crystal on prolonged discharge at 0.1 mA/cm^2. Data for several

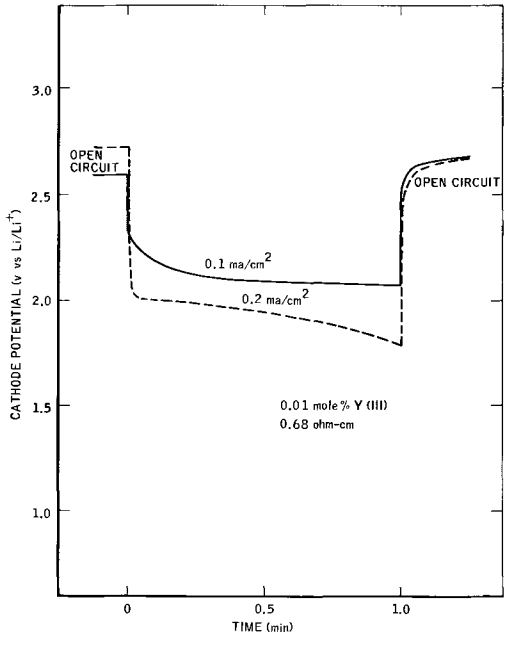

Fig. 4. Preliminary discharges of cadmium fluoride crystal

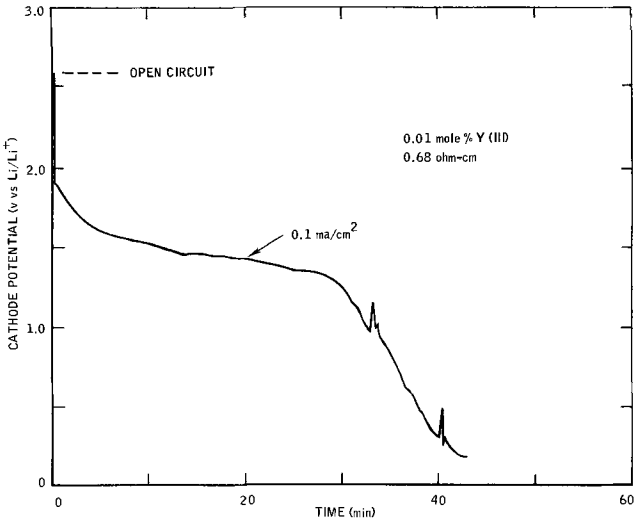

Fig. 5. First continuous discharge of cadmium fluoride crystal

crystal electrodes are given in Table I. A plateau in the potential-time curve generally occurred near 1.5V *vs.* Li/Li$^+$ (1M), followed by a transition region of the type shown in Fig. 5. A practical end of the discharge could be taken at 1.1V *vs.* Li/Li$^+$ (1M), although some minor inflections appeared at lower potentials. This cutoff corresponded to the utilization of a cadmium fluoride layer 0.1-0.2μ in thickness. Although the electrode recovered subsequently on open circuit to a potential above 2.0V, essentially no discharge capability remained, as is shown in Fig. 6. The potential dropped almost immediately when a second prolonged discharge was attempted. Cathodic activity was restored, however, by exposure of the discharged crystal to water. Two passivation mechanisms may be readily visualized—coating of the crystal by a nonporous layer of cadmium metal or by a layer of lithium fluoride. The sharp peaks in the transition region (Fig. 5) may be due to occasional fractures in the passivating film.

Implications for cadmium fluoride battery cathodes.—The preparation of secondary cathodes by anodizing cadmium metal in complex fluoride-organic solvent electrolytes has been reported by Shaw and others (9, 10). Doped crystals of the type used in the present study will not be reconstructed from the metal by anodic charging. It was of interest, nevertheless, to examine briefly the behavior of a discharged semiconductor electrode under anodic current. The results are shown in Fig. 7 and 8. At a charging current density of 0.2 mA/cm^2, the total cathode potential rose in 13 min to 8.7V *vs.* Li/Li$^+$ (1M). Of this final value, nearly 6V appeared to be a nonohmic component associated with the semiconductor/electrolyte interface. This is indicated in Fig. 7 by the immediate drop of

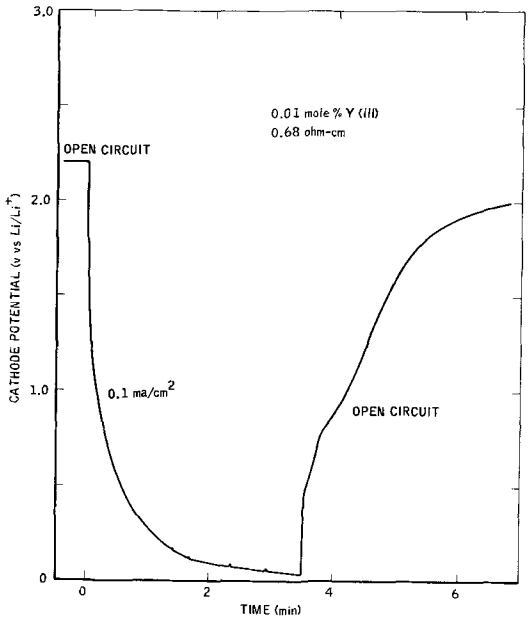

Fig. 6. Second continuous discharge of cadmium fluoride crystal and recovery on open circuit.

5.7V which occurred on interruption of the charging current. The initial voltage step in cathodic discharge at the same current immediately thereafter (Fig. 8) was only 0.25V. Such asymmetric behavior is expected for an n-type crystal, on which oxidations should be generally difficult because of the tendency to form an exhaustion layer at positive potentials (12). Although Fig. 8 indicates that some discharge capacity within the cadmium fluoride potential region resulted from charging, the anodic process occurred at low energy efficiency with the semiconductor crystal in the circuit.

In conclusion, the electronic reduction mechanism in n-type cadmium fluoride offers an alternative path for the discharge reaction, which is not available with the undoped material. In a porous electrode, this route may supplement or supplant that of another process, such as the reduction of dissolved cadmium ion. To utilize the electronic mechanism efficiently, one must provide a low-resistance contact at the semiconductor-current collector interface and control the cathodic passivation which was observed in a lithium perchlorate-propylene carbonate electrolyte. The latter problem, which may be caused by a film of cadmium or lithium fluoride, is under further investigation.

Solid-State Ionics—Coulometric Titrations and Measurements of the Ionic Conductivity of Beta Ag_2Se and Beta Ag_2Te and Use of These Compounds in an Electrochemical Analog Memory Element

Takehiko Takahashi* and Osamu Yamamoto

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

The ionic conductivities of β Ag_2Se and β Ag_2Te have been determined as a function of the metal-to-nonmetal ratio with the help of the cell Ag/$RbAg_4I_5$/β Ag_2X/$RbAg_4I_5$/Ag (X = Se or Te), and the concentrations of the ionic defects at the ideal stoichiometric composition of these compounds have been calculated to be $3.5 \times 10^{17}/cm^3$ for β Ag_2Se at 105°C and $9.7 \times 10^{18}/cm^3$ for β Ag_2Te at 97°C. The coulometric titrations have been studied with the help of the cell Ag/$RbAg_4I_5$/β Ag_2X/Pt to derive the theoretical equation in order to explain the relation between the cell voltage and the deviation from the ideal stoichiometric composition. Based on these studies, a new type of electrochemical cell, Ag/$RbAg_4I_5$/β Ag_2Te, $RbAg_4I_5$ and graphite, has been proposed. The emf of the cell is changed linearly in the range of 120 to 0 mV by the coulombs passed through the cell at room temperature. At open circuit, the emf of the cell decreases only by a few per cent in several hundred minutes.

In recent years, considerable interest has been taken in solid electrolyte galvanic cells (1-3). Electrochemical cells using solid electrolyte in place of the conventional liquid electrolyte have many advantages of achieving appreciable miniaturization and operation over a wide temperature range. However, only a little work has been reported on these devices, except for galvanic cells. One of these was a solid electrolyte coulometer reported by Yamamoto and Takahashi (4) and Kennedy and Chen (5) which consisted of the solid electrolyte held between the silver and gold electrodes. The other example was a memory with variable resistance which was proposed first by Widrow (6) and examined later by Takahashi, Yamamoto, and Kuwabara (7).

The most important problem in this field is the improvement of the low conductivity of solid electrolytes at ambient temperature. Recently, some solid electrolytes have been reported by Takahashi and Yamamoto (8), Bradley and Greene (9), and Owens and Argue (10) to have high ionic conductivity at room temperature. These were the double salts such as Ag_3SI and $RbAg_4I_5$ which show conductivities comparable to those of aqueous electrolyte solutions at room temperature. It may be possible, therefore, to develop many types of electrochemical cells with these solid electrolytes. The purpose of this paper is to examine a new type of electrochemical cell using $RbAg_4I_5$ which has a silver ion conductivity of 2.1×10^{-1} $(ohm\text{-}cm)^{-1}$ at 25°C (10).

The system investigated in this study consists of a silver electrode, electrolyte ($RbAg_4I_5$), and a silver chalcogenide such as β Ag_2Te or β Ag_2Se, the cell construction being

$$Ag|RbAg_4I_5|\text{Silver chalcogenide} \qquad \text{(I)}$$

Silver chalcogenides have been known to have nonstoichiometric composition and exhibit mixed conductivity partly ionic and partly electronic. Upon passing the current across cell (I) from right to left (charging process), a definite amount of silver is transferred from the silver chalcogenide phase to the silver electrode, decreasing the metal-to-nonmetal ratio, r, in silver chalcogenide. If the direction of current is reversed (discharging process), r increases. In silver chalcogenides, such as Ag_2Se and Ag_2Te, silver ions and electrons are both mobile so that the metal-to-nonmetal ratio becomes rapidly uniform, especially at high temperature.

$RbAg_4I_5$ is essentially an ionic conductor, and the chemical potential of silver μ_{Ag} in Ag_2Se or Ag_2Te is related to the electromotive force, E, of cell (I) by

$$\mu_{Ag} - \mu^{o}_{Ag} = -E\mathbf{F} \qquad [1]$$

where μ^{o}_{Ag} is the chemical potential of pure silver and $\mathbf{F}$ the Faraday constant. By denoting the chemical potential of excess electron, electron hole, and silver ion in β Ag_2Se or β Ag_2Te by μ_e, μ_h and μ_{Ag+}, respectively, one obtains the following expression

$$\mu_{Ag} = \mu_{Ag+} + \mu_e = \mu_{Ag+} - \mu_h \qquad [2]$$

From Eq. [1] and [2], at the ideal stoichiometric composition of β Ag_2Se or β Ag_2Te

$$\mu'_{Ag} - \mu^{o}_{Ag} = -E'\mathbf{F} \qquad [3]$$

and

$$\mu'_{Ag} = \mu'_{Ag+} + \mu'_e = \mu'_{Ag+} - \mu'_h \qquad [4]$$

are established where μ'_{Ag}, μ'_e, μ'_h, and μ'_{Ag+} are chemical potentials of each species at the ideal stoichiometric composition of β Ag_2Se or β Ag_2Te, respectively, and E' the emf of cell (I) with the ideal stoichiometric β Ag_2Se or β Ag_2Te. By combining Eq. [1], [2], [3], and [4], one obtains

$$(\mu_{Ag+} - \mu'_{Ag+}) + (\mu_e - \mu'_e) = (\mu_{Ag+} - \mu'_{Ag+}) - (\mu_h - \mu'_h) = -(E - E')\mathbf{F} = -\Delta E\mathbf{F} \qquad [5]$$

At low concentrations of interstitial silver ion and silver ion vacancy, it may be assumed that the change of chemical potential of silver ion is expressed by the following equation

$$\mu_{Ag+} - \mu'_{Ag+} = RT \ln n_o/\bar{n}_o = -RT \ln n_{\square}/\bar{n}_{\square} \qquad [6]$$

where n_o and $n_{\square}$ are the concentrations of interstitial silver ion (Ag^{+}_{o}) and silver ion vacancy ($Ag^{+}_{\square}$), and $\bar{n}_o$ and $\bar{n}_{\square}$ are those at the ideal stoichiometric com-

* Electrochemical Society Active Member.

Key words: solid electrolyte; coulometer; $RbAg_4I_5$, Ag_2Te, Ag_2Se; memory device; deviations from stoichiometry.

position. The concentrations of excess electron, n_e, and electron hole, n_h, are related to μ_e and μ_h by

$$n_e = \frac{\pi(8m_e^* \cdot kT)^{3/2}}{2h^3} \cdot \mathbf{F}(\eta_e) \quad [7]$$

and

$$n_h = \frac{\pi(8m_h^* \cdot kT)^{3/2}}{2h^3} \cdot \mathbf{F}(\eta_h) \quad [8]$$

where $\eta_e = \mu_e/RT$, $\eta_h = \mu_h/RT$, m^*_e and m^*_h are the effective mass of electron and electron hole, respectively, $\mathbf{F}(\eta)$ is the Fermi-Dirac function, and the other symbols have the usual meanings. According to the table of Fermi-Dirac function computed by McDougall and Stoner (11), the following approximation may be available for a narrow range of η values

$$\mathbf{F}(\eta) = ke^{\eta/C} = ke^{\mu/CRT} \quad [9]$$

By combining Eq. [7] and [9], or [8] and [9], one finds

$$\mu_e = CeRT \ln n_e/Ne \quad [10]$$

and

$$\mu_h = C_hRT \ln n_h/N_h \quad [11]$$

where, Ce, C_h, Ne, and N_h are constant parameters depending on the mean value of n_e or n_h within the range considered. Therefore

$$\mu_e - \mu'_e = CeRT \ln n_e/\bar{n}_e \quad [12]$$

and

$$\mu_h - \mu'_h = C_hRT \ln n_h/\bar{n}_h \quad [13]$$

are obtained where $\bar{n}_e$ and $\bar{n}_h$ are the concentrations of excess electrons and electron holes at the ideal stoichiometric composition. Substituting Eq. [6] and [12] into Eq. [5], we have

$$-\Delta E\mathbf{F} = RT \ln (n_o/\bar{n}_o)\ (n_e/\bar{n}_e)^{C_e} \quad [14]$$

If no silver atoms are present in β Ag_2Se or β Ag_2Te, the deviation from the ideal stoichiometric composition, Δr, is equal to the difference of the concentration of the two atomic imperfections or the two electronic imperfections

$$n_o - n_\square = n_e - n_h = \Delta r(No/Vm) \quad [15]$$

where Vm is the molar volume of β Ag_2Se or β Ag_2Te, and No the Avogadro number. In β Ag_2Se and β Ag_2Te, the atomic imperfection is present according to the Frenkel equilibrium

$$Ag^+ \rightleftharpoons Ag^+_o + Ag^+_\square$$

i.e.

$$n_o \cdot n_\square = \bar{n}^2_o \quad [16]$$

Further, the thermal equilibrium is established with the excess electron and electron hole

$$e + h \rightleftharpoons 0$$

i.e.

$$\mu_e + \mu_h = 0 \quad [17]$$

From Eq. [12], [13], and [17], we have

$$(n_e)^{C_e}\ (n_h)^{C_h} = (\bar{n}_e)^{C_e+C_h} \quad [18]$$

Substitution of Eq. [16] and [18] into Eq. [15] gives

$$\left(\frac{n_o}{\bar{n}_o}\right)^2 - \frac{\Delta r}{\bar{n}_o}\left(\frac{No}{Vm}\right)\left(\frac{n_o}{\bar{n}_o}\right) - 1 = 0 \quad [19]$$

and

$$\left(\frac{n_e}{\bar{n}_e}\right)^{(1+C_e/C_h)} - \frac{\Delta r}{\bar{n}_e}\left(\frac{N_o}{Vm}\right)\left(\frac{n_e}{\bar{n}_e}\right)^{C_e/C_h} - 1 = 0 \quad [20]$$

Finally, the relation between ΔE and Δr is given by

$$-\Delta E\mathbf{F} = RT \ln f(\Delta r) \cdot \{g(\Delta r)\}^{C_e} \quad [21]$$

where $f(\Delta r)$ and $g(\Delta r)$ are the solutions of Eq. [19] and [20], respectively.

The deviation from the ideal stoichiometric composition, Δr, is expressed by Faraday's law as

$$\Delta r = q/x\mathbf{F} = \frac{1}{x\mathbf{F}}\int_{E=E'}^{E} i\,dt \quad [22]$$

where q is the number of coulombs passed through cell (I), and x the number of moles of selenium or tellurium. According to Eq. [21] and [22], cell (I) must have a cell voltage depending on the deviation from the ideal stoichiometric composition of β Ag_2Se or β Ag_2Te. This means that the cell voltage is changed by the coulombs passed through the cell. This fact suggests that this cell will be able to be used as a coulometer. Further, if the cell voltage is kept constant for a certain period of time, the cell will be used as a memory device, for example as a memory with variable resistance.

It is clear from Eq. [19], [20], and [21] that the knowledge of the concentration of imperfections and the values of C_e and C_h allows the examination of the relation between Δr and ΔE. Studies on electronic imperfection have been done by Dalven and Gill (12) and Miyatani (13), and the concentration of interstitial silver ion in β Ag_2Se has been measured by Valverde (14). In this study, by measuring the ionic conductivities of β Ag_2Se and β Ag_2Te as a function of the metal-to-nonmetal ratio, the concentrations of atomic imperfection at the ideal stoichiometric composition of these compounds have been determined with the help of the theories of Koch and Wagner (15) and Stasiw and Teltow (16).

Experimental

Preparation of materials.—Silver telluride and silver selenide were prepared from the elements. A mixture of silver powder (99.999% purity) and tellurium powder (99.999% purity) or selenium powder (99.999% purity) was thoroughly ground before being sealed under vacuum in a Pyrex tube and heated at 420°C (for silver telluride) or 350°C (for silver selenide) for 48 hr. The solid electrolyte, $RbAg_4I_5$, was prepared according to the method described by Owens and Argue (10). Weighing of 0.8 mole fraction of silver iodide and 0.2 mole fraction of rubidium iodide was followed by mixing and grinding. The mixture was sealed in a glass tube under vacuum and heated at 500°C for 2 hr. Then, after being cooled abruptly, it was maintained at 160°C for 24 hr, thereby synthesizing $RbAg_4I_5$.

Ionic conductivity measurements.—The ionic conductivity measurements for β Ag_2Se or β Ag_2Te were carried out by the following cells which were similar to those used by Weiss (17)

$$Ag|RbAg_4I_5|\beta\ Ag_2Se|RbAg_4I_5|Ag \quad (II)$$
$$\uparrow$$
$$Pt$$

and

$$Ag|RbAg_4I_5|\beta\ Ag_2Te|RbAg_4I_5|Ag \quad (III)$$
$$\uparrow$$
$$Pt$$

Ag_2Se or Ag_2Te was pressed into the form of a cylindrical pellet 13 mm in diameter and 1-2 mm in thickness. In order to reduce the electrode polarization, a mixture of powdered silver and $RbAg_4I_5$ (2:5 weight ratio) was used for the silver electrode. When a d-c voltage below the decomposition voltage of $RbAg_4I_5$ and β Ag_2Se or β Ag_2Te is applied between two silver electrodes, the current is carried practically by silver ion because $RbAg_4I_5$ is a pure silver ion conductor. As the ohmic resistance of $RbAg_4I_5$ is known, the ionic resistance of β Ag_2Se or β Ag_2Te can be calculated from the total resistance. A current of 1-100 μA was used in this experiment. In order to change the cation-to anion ratio in β Ag_2Se or β Ag_2Te, the current was passed

between the silver electrode and the platinum electrode which was inserted into the pellet of β Ag_2Se or β Ag_2Te. The measurements were carried out at above 70°C, as it was necessary to wait a long period of time to obtain a steady voltage at lower temperatures.

The structure of the electrochemical cell.—A typical schematic diagram of the cell is shown in Fig. 1. A mixture of powdered silver and $RbAg_4I_5$ was used as the silver electrode. For the counterelectrode, a mixture of Ag_2Te (or Ag_2Se), $RbAg_4I_5$, and graphite was used to increase the electrode reaction area, the composition of which was selected to obtain a high performance. For example, a mixutre of 0.2g powdered silver and 0.7g $RbAg_4I_5$, 1.2g $RbAg_4I_5$, and a mixture of 0.2g powdered graphite, 1.5g $RbAg_4I_5$ and 0.4g β Ag_2Te, were pressed successively at 2 tons/cm^2 to form a pellet and it is pressed at 5 tons/cm^2 under vacuum for 10 min. The diameter of the pellet was 13 mm. A graphite block was placed on the β Ag_2Te electrode to give the electronic contact upon which a silver wire was put to make it serve as the lead wire and a silver plate was used as an electronic collector of the silver electrode. The following measurements were carried out under vacuum.

Experimental Results and Discussion

Ionic conductivity of β Ag_2Se and β Ag_2Te and the concentration of Frenkel defects at the ideal stoichiometric composition.—In 1970, the concentration of interstitial silver ion in β Ag_2Se at the ideal stoichiometric composition was measured with the help of coulometric titration (14). In this study, in order to know the concentration of ionic defects in β Ag_2Se or β Ag_2Te, the ionic conductivity was measured by a similar method proposed by Wagner (18) and examined for β Ag_2S by Weiss (17). In the study made by Weiss, AgI was used as the solid electrolyte and the measuring temperature was always above 147°C, which was the transition temperature of AgI. Below this temperature, however, the ionic conductivity of AgI was too low and in this study, therefore, $RbAg_4I_5$, which has high ionic conductivity even at room temperature, was used as the solid electrolyte to carry out the measurement at relatively low temperature.

In general, it is difficult to synthesize ideal stoichiometric β Ag_2Se or β Ag_2Te from the elements. The ideal stoichiometric compositions of these compounds were determined by coulometric titrations (19). Wagner and Schottky (20) have pointed out that in disordered crystals a point of inflection appears in chemical potential *vs.* composition curves at the ideal stoichiometric composition. The cell voltage between the platinum and the silver electrodes of cell (II) or (III) is drawn *vs.* coulombs passed through the cell and, from the maximum slope of this curve, the ideal stoichiometric composition of β Ag_2Se or β Ag_2Te was determined. For example, the maximum slope appeared at 53 mV in β Ag_2Te at 97°C and at 180 mV in β Ag_2Se at 105°C.

The current was passed between the silver and the platinum electrodes in order to change the cation-to-anion ratio in β Ag_2Se or β Ag_2Te and, at each Δr value, the ionic conductivity of these compounds was measured with the help of cell (II) or (III). The ionic

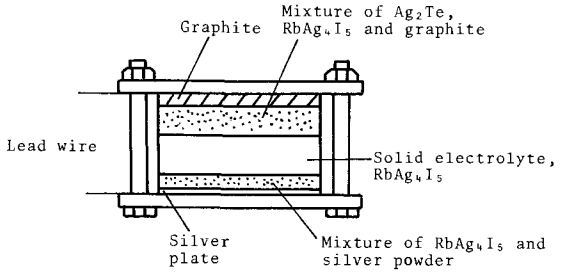

Fig. 1. Schematic diagram of the electrochemical cell

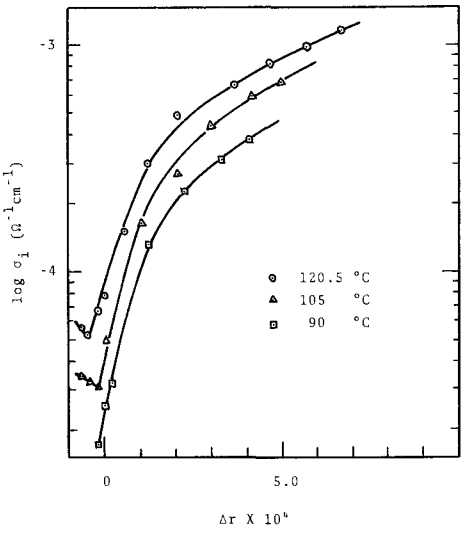

Fig. 2. The ionic conductivity of β Ag_2Se, σ_i, as a function of the deviation from the ideal stoichiometric composition, Δr.

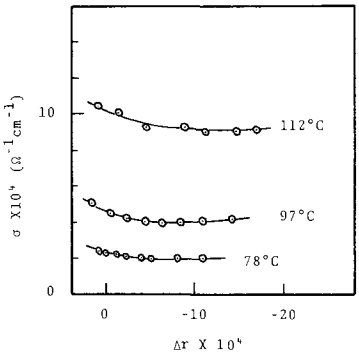

Fig. 3. The ionic conductivity of β Ag_2Te σ_i as a function of the deviation from the ideal stoichiometric composition, Δr.

conductivity of β Ag_2Se is shown in Fig. 2 as a function of the deviation from the ideal stoichiometric composition, Δr. The ionic conductivity increases rapidly with increasing Δr, indicating that the excess silver in β Ag_2Se dissociates to interstitial silver ion and excess electron. The dependence of ionic conductivity of β Ag_2Te on Δr is shown in Fig. 3. In this case, the change of ionic conductivity is not so remarkable.

The phenomenon of producing the interstitial silver ion or silver ion vacancy by removing or injecting silver from or into the lattice is considered to be similar to that of adding an impurity into a pure crystal, the theoretical approaches for which have been done by Koch and Wagner (15) and Stasiw and Teltow (16). The dependence of ionic conductivity on Δr is examined with the help of the theory of Teltow *et al.* as follows.

If the ionic carriers in β Ag_2Se or β Ag_2Te are interstitial silver ion ($Ag^+{}_o$) and silver ion vacancy ($Ag^+{}_\square$) and the other ionic defects are negligible, the ionic conductivity, σ_i is represented as

$$\sigma_i = en_o u_o + en_\square u_\square \qquad [23]$$

where u_o and $u_\square$ are the mobilities of $Ag^+{}_o$ and $Ag^+{}_\square$. The intrinsic ionic conductivity, $\bar{\sigma}_i$, at the ideal stoichiometric composition is expressd by

$$\bar{\sigma}_i = e\bar{n}_o u_o + e\bar{n}_\square u_\square \qquad [24]$$

Substituting Eq. [15] and [16] into Eq. [23] and using Eq. [24], we have

$$\frac{\sigma_i}{\bar{\sigma}_i} = \sqrt{\left(\frac{\Delta r N_o}{2\bar{n}_o V m}\right)^2 + 1} + \left(\frac{\Delta r N_o}{2\bar{n}_o V m}\right)\frac{\phi - 1}{\phi + 1} \qquad [25]$$

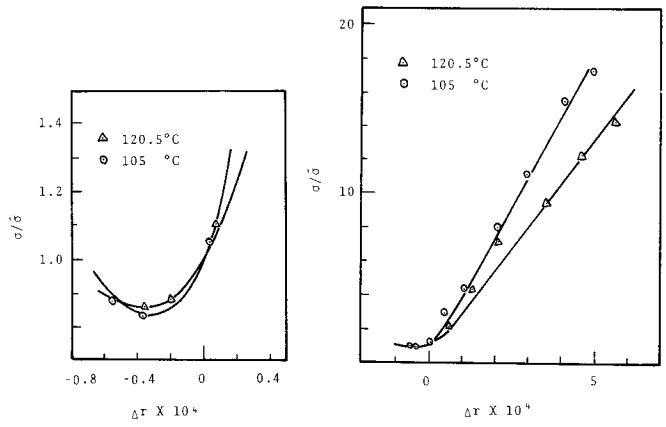

Fig. 4. The relative conductivity, $\sigma_i/\bar{\sigma}_i$ of β Ag_2Se as a function of the deviation from the ideal stoichiometric composition, Δr. The circles and triangles represent the experimental values and the lines are theoretical isotherms.

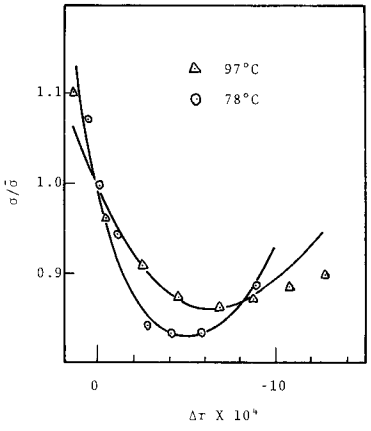

Fig. 5. The relative conductivity, $\sigma_i/\bar{\sigma}_i$ of β Ag_2Te as a function of the deviation from the ideal stoichiometric composition, Δr. The circles and triangles represent the experimental values and the lines are theoretical isotherms.

where $\phi = u_o/u_\square$. According to Eq. [25], a plot $\sigma_i/\bar{\sigma}_i$ *vs.* Δr shows a minimum at the ordinate value

$$\left(\frac{\sigma_i}{\bar{\sigma}_i}\right)_{\min} = \frac{2\sqrt{\phi}}{1+\phi} \qquad [26]$$

The relation between $\sigma_i/\bar{\sigma}_i$ and Δr is shown in Fig. 4 for β Ag_2Se and in Fig. 5 for β Ag_2Te. From these curves, ϕ can be calculated by solving Eq. [26] and $\bar{n}_o$ by substituting the numerical values of $\sigma_i/\bar{\sigma}_i$, Δr and, ϕ in Eq. [25]; ϕ and $\bar{n}_o$ obtained by this method are listed in Table I. In Fig. 4 and 5, the real lines are obtained from Eq. [25] using the numerical values of ϕ and $\bar{n}_o$. In these figures, the experimental values are found to coincide with the theoretical curves, showing that the association of interstitial silver ion or silver ion vacancy with the excess electron or electron hole is negligibly small.

Table I. Characteristic quantities of β Ag_2Se and β Ag_2Te

Substance	Temp, °C	ϕ	$\bar{n}_o$
β Ag_2Te	78	3.5	5.3×10^{18}
	97	3.1	9.7×10^{18}
β Ag_2Se	105	4.5	3.5×10^{17}
	120.5	3.1	4.8×10^{17}

ϕ is the ratio of the mobility of the Ag^+ interstitial to that of the Ag^+ vacancy; $\bar{n}_o$ is the concentration of Frenkel defects at the stoichiometric composition.

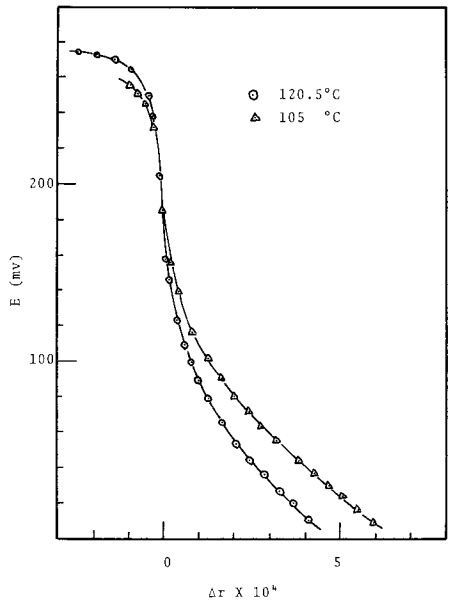

Fig. 6. The cell voltage, E, of the cell $Ag|RbAg_2I_5|\beta$ Ag_2Se *vs.* the deviation from the ideal stoichiometric composition, Δr.

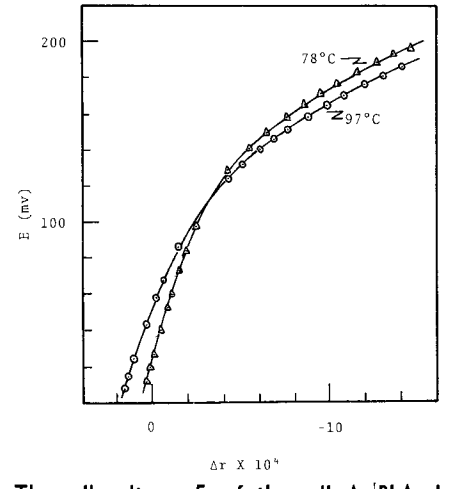

Fig. 7. The cell voltage, E, of the cell $Ag|RbAg_4I_5|\beta$ Ag_2Te *vs.* the deviation from the ideal stoichiometric composition, Δr.

The relation between the cell voltage of $Ag/RbAg_4I_5/\beta$ Ag_2Se or β Ag_2Te and the deviation from the ideal stoichiometric composition of β Ag_2Se or β Ag_2Te.—The cell voltage (E) of $Ag/RbAg_4I_5/\beta$ Ag_2Se or β Ag_2Te *vs.* the deviation (Δr) from the ideal stoichiometric composition is shown in Fig. 6 for β Ag_2Se and in Fig. 7 for β Ag_2Te. These curves were obtained passing a constant current of 10 μA between the silver and platinum electrodes in cell (II) or (III) to add or subtract silver in or from β Ag_2Se or β Ag_2Te, the cell voltage of which coincided with that kept at open circuit for 10 several minutes showing that the equilibrium was attainable immediately at as small a current as 10 μA. Δr was calculated from Eq. [22]. It is seen from Fig. 6 and 7 that E increases with decreasing Δr to reach a constant value of 270 mV for β Ag_2Se at 105°C or 190 mV for β Ag_2Te at 97°C. These values correspond to the open-circuit voltages of cell $Ag/RbAg_4I_5/Se$ and $Ag/RbAg_4I_5/Ag_{1.9}Te$ (21), respectively.

According to Eq. [21], it is necessary to know the concentration of imperfections and the values of C_e and C_h in order to examine the relation between Δr and ΔE. The numerical values of $\bar{n}_o$ and $\bar{n}_e$ are sum-

Table II. Concentrations of interstitial silver ion or silver ion vacancy ($\bar{n}_o = \bar{n}_{\square}$) and excess electron or electron hole in silver chalcogenides at ideal stoichiometric composition

Compound	Temp, °C	$\bar{n}_o = \bar{n}_{\square}$	Ref.	$\bar{n}_e = \bar{n}_h$	Ref.
β Ag_2Se	105	3.5×10^{17}	Table I	5×10^{18}	(12, 13)
	120	4.8×10^{17}	Table I	7×10^{18}	(12, 13)
	75	9.7×10^{16}	14		
	100	2.3×10^{17}	14		
β Ag_2Te	78	5.3×10^{18}	Table I	1.4×10^{18}	(12, 13)
	97	9.7×10^{18}	Table I	1.9×10^{18}	(12, 13)

marized in Table II, in which the values of $\bar{n}_e$ at the temperature considered were obtained by extrapolating the values measured at the other temperatures reported by Dalven and Gill (12) and Miyatani (13).

For β Ag_2Se, the concentration of excess electron at the ideal stoichiometric composition is distinctly larger than that of interstitial silver ions as shown in Table II, so that Eq. [21] may be reduced to a simple form of

$$\frac{\Delta r N_o}{\bar{n}_o V m} \cong \exp(-\Delta E\mathbf{F}/RT) - \exp(\Delta E\mathbf{F}/RT) \quad [27]$$

A plot of Δr *vs.* $\exp(-\Delta E\mathbf{F}/RT) - \exp(\Delta E\mathbf{F}/RT)$ should give a straight line with a slope of $\bar{n}_o V m/N_o$. This plot is shown in Fig. 8 giving a straight line from which $\bar{n}_o(\bar{n}_{\square})$ is determined to be 3.8×10^{17} at 120.5°C and 2.8×10^{17} at 105°C. These values are comparable to those estimated from the ionic conductivity measurements.

On the other hand, the difference between $\bar{n}_o$ and $\bar{n}_e$ in β Ag_2Te at the temperature investigated is not so large that Eq. [21] cannot be reduced to a simple form such as Eq. [27]. In Eq. [21], there are two unknown parameters of C_e and C_h, which may be calculated from the table of the Fermi-Dirac function if the effective masses of electron and electron hole are known. Substituting the values of $\bar{n}_e$ and m_e^*/m into Eq. [7], we have

$$\mathbf{F}(\eta_e) = 3.3 \text{ at } 97°C$$

and

$$\mathbf{F}(\eta_e) = 2.8 \text{ at } 78°C$$

where m_e^*/m was assumed to be 0.06 at both temperatures, which has been evaluated by Miyatani (13) at 100°C. According to the table of the Fermi-Dirac function, these values correspond to $\eta \cong 2.6$ and 2.2, respectively, and, substituting the values of $\mathbf{F}(\eta)$ at the vicinity of $\eta = 2.6$, and 2.2 into Eq. [9], we have $C_e \cong 2.2$ at 97°C, and $C_e \cong 2.0$ at 78°C.

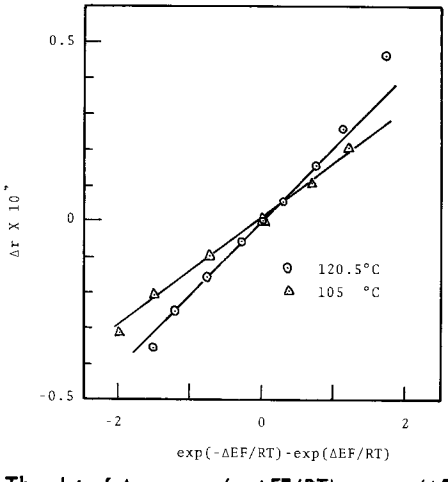

Fig. 8. The plot of Δr *vs.* $\exp(-\Delta E\mathbf{F}/RT) - \exp(\Delta E\mathbf{F}/RT)$ for β Ag_2Se.

Table III. Values of C_e and C_h

Temp, °C	$(d\Delta E/d\Delta r)_{\Delta r=0}$ (mV)	$\bar{n}_o$	$\bar{n}_e$	C_e	C_h
97	-2.6×10^2	9.7×10^{18}	1.9×10^{18}	2.2	1.6
78	-3.3×10^2	5.3×10^{18}	1.4×10^{18}	2.0	1.6

By differentiating Eq. [21] with respect to Δr, the slope of the ΔE *vs.* Δr curve at $\Delta r = 0$ is given by

$$\left(\frac{d\Delta E}{d\Delta r}\right)_{\Delta r=0} = -\frac{RT}{2\mathbf{F}} \cdot \frac{N_o}{Vm}\left(\frac{1}{\bar{n}_o} + \frac{2C_eC_h}{C_e + C_h} \cdot \frac{1}{\bar{n}_e}\right) \quad [28]$$

Substituting the values of $(d\Delta E/d\Delta r)_{r=0}$, $\bar{n}_o$, $\bar{n}_e$, and C_e into Eq. [28], C_h can be determined. The experimental values of $(d\Delta E/d\Delta r)_{r=0}$ and the values of C_h thus determined are listed in Table III. The relation between ΔE and Δr is shown in Fig. 9, where the lines are obtained by the theoretical calculation of Eq. [19], [20], and [21] using the numerical values listed in Table III. The experimental results agree with the theoretical lines in the range of Δr between 0.7×10^{-4} and -2×10^{-4} at 78°C, and 1.0×10^{-4} and -1.5×10^{-4} at 97°C. Above these ranges of Δr, remarkable differences are recognized between theoretical lines and experimental values as indicated in the figure. This discrepancy may be due to the fact that Eq. [9] is an approximate one and can be used only for certain limited ranges of η_e and η_h.

The characteristics of the electrochemical cell using β Ag_2Te electrode for a coulometer or memory device. —As described above, it has been found that the $Ag|RbAg_4I_5|\beta$ Ag_2Se or β Ag_2Te cell has a voltage depending on the deviation from the ideal stoichiometric composition of β Ag_2Se or β Ag_2Te, and the relation between the cell voltage and the deviation from the stoichiometry is expressed by Eq. [21].

For practical use, it is usually convenient to use the cell at ambient temperature. However, it has been found from preliminary experiments that β Ag_2Te could be used as the electrode material for this purpose and β Ag_2Se could not because the cell with the β Ag_2Se electrode showed high electrode polarization to give a hysteresis effect in charge and discharge processes at room temperature. A mixture of β Ag_2Te, $RbAg_4I_5$, and graphite was used for the electrode material in order to increase the electrode reaction area

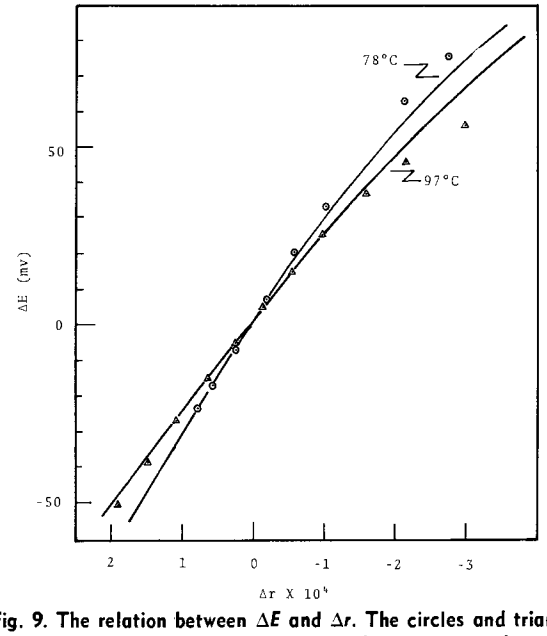

Fig. 9. The relation between ΔE and Δr. The circles and triangles represent the experimental values and the lines are theoretical curves.

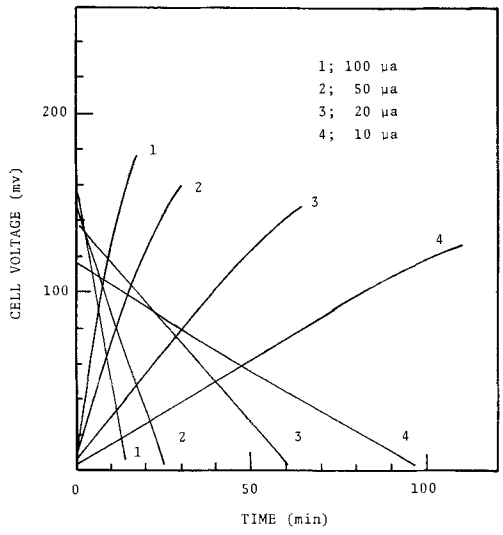

Fig. 10. The cell voltage vs. time curves of the cell Ag|$RbAg_4I_5$|β Ag_2Te (0.4g), $RbAg_4I_5$ (1.5g), graphite at 30°C.

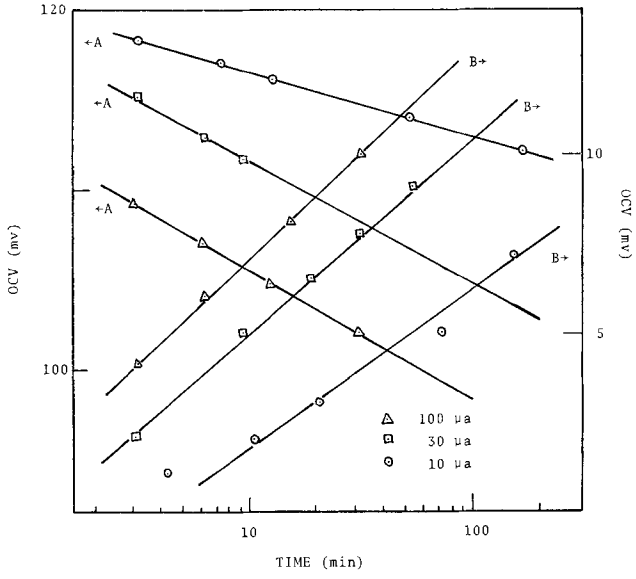

Fig. 11. The time dependence of OCV of the cell Ag|$RbAg_4I_5$|β Ag_2Te (0.4g), $RbAg_4I_5$ (1.5g), graphite (0.2g) at 22°C.

which would reduce the polarization when sufficiently high current density is used. The charge and discharge curves of the cell Ag|$RbAg_4I_5$|β Ag_2Te(0.4g), $RbAg_4I_5$ (1.5g), graphite (0.2g) were drawn at various current densities in Fig. 10. The silver telluride electrode was a mixture of 1.5g $RbAg_4I_5$, 0.4g β Ag_2Te, and 0.2g graphite. It is found in Fig. 10 that a linear relationship exists between the cell voltage (E) and time (t) in the voltage range of 0-120 mV, and the slope of the E-t curve increases with increasing current density. At higher current (>200 μA), however, the abrupt change of the cell voltage was observed immediately after a current was passed through the cell, and the slope of the E-t curve did not coincide for removing and adding silver from and to the silver telluride electrode. On the other hand, at lower current (<100 μA), the slope of the E-t curve for the charge process agreed with that for the discharge process.

The accuracy of this type of coulometer was checked with a current of 0-400 μA for a period of 0-30 min, using a triangular wave current. The relation between the cell voltage and coulombs passed through the cell was preliminarily examined by the constant current drain; and the initial and final cell voltages, after a triangular wave current was passed, were compared with the standard E vs. t curve. The error (ϵ) was calculated by the following equation

$$\epsilon = \frac{q - q_s}{q} \qquad [29]$$

where q_s is the coulombs calculated by the standard E vs. q curve. The error is less than 10% in all cases as shown in Table IV. The error decreased with decreasing current which may be due to decrease of the electrode polarization.

If the new type of electrochemical cell is charged to a certain cell voltage and the open-circuit voltage (OCV) is kept constant for a certain period of time, the cell may be used for analog memory devices. In practice, after the current was passed, OCV showed a slow change with time. The changes are shown in Fig. 11, where curves A were obtained after the cell was charged from 0 to 120 mV, and curves B after the cell was discharged from 120 to 0 mV. These results indicate that, for a limited interval of time between several minutes and several hundreds of minutes, the time dependence of OCV (E_{OCV}) will be expressed by Eq. [30]

$$E_{OCV} = A + B \log t \qquad [30]$$

where A and B are constants. The change of OCV with time is probably due to the concentration polarization and nonuniformity of the Ag-to-Te ratio through the β Ag_2Te electrode. In the case of curves A, the electronic conduction in the electrolyte $RbAg_4I_5$ is negligible for the OCV change in the short time period (<100 min) because the electronic conductivity of $RbAg_4I_5$ is less than 10^{-9} (ohm-cm)$^{-1}$ at room temperature (22). However, for the change in the long time period (>1000 min), OCV did not obey Eq. [30] but decreased linearly with time, suggesting that the electronic conductivity of the electrolyte might play a role. The change of OCV for the short time period (10-100 min) may be due mainly to the slow diffusion of silver in β Ag_2Te, and a relatively long period of time is necessary to obtain the homogeneous activity of silver in β Ag_2Te. Therefore, increase of the ionic conductivity of silver ion in β Ag_2Te is desirable to obtain a good performance cell. In general, the ionic conductivity of solids may sometimes be improved by incorporation of small amounts of various additives. In this experiment, it was found that the addition of CdTe to β Ag_2Te made the ionic conductivity of β Ag_2Te increase. For example, by the addition of 5 m/o (mole per cent) CdTe to β Ag_2Te, the ionic conductivity increased to 5×10^{-5} (ohm-cm)$^{-1}$ from that of pure β Ag_2Te which is 2×10^{-5} (ohm-cm)$^{-1}$ at 25°C. The cell using β Ag_2Te −5 m/o CdTe as the electrode material indicates the change of OCV with time as shown in Fig. 12. It is clear that the change can be greatly reduced by the addition of CdTe to β Ag_2Te. In this cell, the E vs. q curve gives a straight line in the range of 0 and 120 mV and dE/dt increases proportionally with current density. The cell using a β Ag_2Se electrode showed a larger change of OCV than that of β Ag_2Te. This may be due to the low ionic conductivity of β Ag_2Se shown in this paper.

Table IV. Accuracy of the electrochemical cell

Current, μA	Coulombs	Error, %
0—352	13.7	10.6
0—187	15.1	8.0
0—78	12.2	4.9
0—20	15.3	4.1

Conclusion

The ionic conductivities of β Ag_2Se and β Ag_2Te were measured as a function of the metal-to-nonmetal ratio. It was found from these results that the concentration of silver ion vacancy at the ideal stoichiometric composition of these compounds could be determined by the theory of Teltow *et al.* The dependence of silver

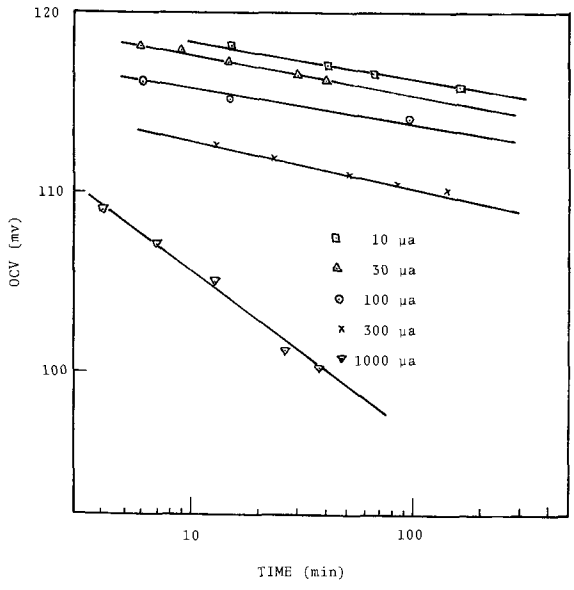

Fig. 12. The time dependence of OCV of the cell $Ag|RbAg_4I_5|\beta$ Ag_2Te-CdTe (0.4g), $RbAg_4I_5$ (1.5g), graphite (0.2g) at 25°C.

activity in β Ag_2Se or β Ag_2Se on the deviation from the ideal stoichiometric composition was determined by the concentrations of ionic and electronic imperfections. In β Ag_2Se, the activity of silver depended mainly on ionic imperfection and, in β Ag_2Te, on electronic imperfection.

Although the new type of electrochemical cell proposed in this paper may have not sufficiently high accuracy, it will have many advantages, such as attainment of appreciable miniaturization. This type of cell can be used in an electronic circuit as a coulometer or memory device.

The Relevance of Accelerated Electrochemical Pitting Tests to the Long-Term Pitting and Crevice Corrosion Behavior of Stainless Steels in Marine Environments

B. E. Wilde* and E. Williams

Applied Research Laboratory, U. S. Steel Corporation, Monroeville, Pennsylvania 15146

ABSTRACT

Values of the critical breakdown potential, E_c for a series of iron-chromium binary alloys and some commercial stainless steels in aerated 3.5% sodium chloride are presented. The results are correlated with previously published data on the same materials after prolonged exposure to a marine environment. Exact correlations were obtained between the pitting performance of the iron/chromium alloys and that predicted from electrochemical tests over an exposure period of eight years. The highly beneficial influence of chromium additions on the pitting resistance of the steels is shown by the pronounced increase in the nobility of E_c over the range 12-28% chromium. Analysis of corrosion data on commercial stainless steels after 4.25 years' exposure to sea water has shown that the degree of crevice corrosion attack is directly related to the nobility of the "protection or repassivation" potential, as determined from cyclic anodic-polarization curves.

Critical breakdown potentials, E_c, have been used extensively as an index of the pitting susceptibility of alloys in halide media (1-6). Over the last few years, however, various researchers have questioned the validity of the above use, claiming that there is no correlation between electrochemically induced pitting and that induced by chemical redox systems (7), and that pitting corrosion can occur at potentials more active than E_c (8). In an attempt to clarify the situation, we have demonstrated recently (9) that in

short-duration tests there is almost quantitative agreement between electrochemical and chemical accelerated pitting tests on stainless steels in halide media. Further, it has been shown that previous data (8), although correct, were obtained in an environment where the passive state was stabilized by the redox couple in a manner not relevant to the electrochemical tests used in comparison.

The main question of how valid are data obtained in short-term electrochemical tests, with regard to long-term exposures in a freely corroding situation, remains unanswered. Several authorities (4, 10, 11) have expressed the opinion that E_c is not a unique parameter, but varies with time and the experimental technique used in evaluating it. Little data are available on a long-term basis to either support or refute these opinions and to provide the design engineer with a satisfactory answer to the main question.

This study presents an analysis of long-term exposure data on a series of iron/chromium binary alloys and some commercial stainless steels exposed to marine environments for 8 and 4.25 years, respectively. Correlations are made between these data and parameters obtained from electrochemical polarization measurements conducted in 3.5 w/o (weight per cent) sodium chloride solutions at 25°C.

Materials and Experimental Work

The iron/chromium alloys used in this study were originally used to assess the influence of chromium on the corrosion resistance in marine atmospheres (12). Alloy compositions are shown in Table I. The ingots were hot-rolled to 0.635 cm (0.25-in) thick plate, and were heat-treated for 2.5 hr at 774°C (1425°F), followed by an air cool. Exposure samples (10.2 cm by 15.2 cm by 0.318 cm) were machined from the heat-treated plate to a number 4 finish, after being descaled in molten sodium hydroxide containing 2 w/o sodium hydride. Samples were exposed at Kure Beach, North Carolina, at the 80- and 800-ft lots in 1955. The exposure and mounting technique was the same as that recommended in the standard ASTM testing method. Samples were removed periodically to check for weight loss, and pit-density and pit-depth measurements were also made.

In another program aimed at determining the corrosion behavior of steels fully immersed in sea water, several commercial stainless steels were machined into test samples (10.2 cm by 30.5 cm by 0.635 cm) from mill-annealed plate stock. The compositions of the alloys are shown in Table II. Each sample was degreased in trichlorethylene and mounted on racks as shown in Fig. 1, with Nylon washers used to insulate the samples from the support rack. The panels were exposed to sea water at the Wrightsville Test Station so that they were totally immersed at all times. The samples were periodically inspected from 1964 to 1968 to check for weight loss.

Fig. 1. Photograph of holding assembly used for sea water immersion tests on stainless steels.

Samples for electrochemical polarization studies were machined from the same stock as the above exposure-test samples. Coupons (2.54 cm by 2.54 cm by 0.313 cm) were "potted" in an epoxy mount[1] containing a Teflon-sheathed copper conductor for electrical contact. Care was taken in the curing of the epoxy to avoid producing extraneous crevices (13). The potted samples were abraded through 600-grit silicon carbide paper, ultrasonically degreased in a detergent, washed with distilled water, and hot-air dried. The polarization equipment was the same as that described in detail elsewhere (15-17). Test samples were immersed for 60 min in the corrodent prior to polarization to allow the establishment of a steady-state corrosion potential (14). Polarization curves were constructed by running in the noble direction at a sweep rate of 0.600 V/hr.

The corrodent was prepared from reagent-grade sodium chloride diluted to 3.5 w/o with distilled water (7.4 megohm cm at 25°C). During each polarization run, the corrodent was saturated with air at a flow rate of 1.2 liters/min, resulting in a dissolved oxygen content of 7.9 ppm as measured on a Beckman Process Analyzer. It has been assumed in this work that the behavior of stainless alloys in sodium chloride solution is representative of their behavior in natural sea water. We have as yet no specific data to support this assumption. Long-term corrosion potential (E_{corr}) *vs.* time studies were conducted with samples prepared as above. The potential was measured with a saturated calomel reference electrode (SCE) connected to a L&N multipoint recorder via an electrometer switching system.

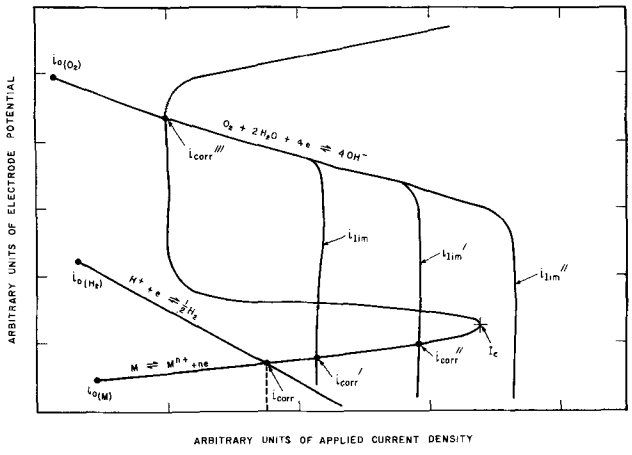

Fig. 4. Schematic representation of partial processes leading to spontaneous passivation.

Results and Discussion

In regard to our terminology used in describing the polarization curves, reference is made to Fig. 2, where a schematic of a typical "cyclic polarization curve" is shown. The point designated E_c, where a marked increase in the anodic dissolution rate occurs, will be termed the critical breakdown potential. The point E_p, where the dissolution rate again becomes equal to the passive current density, will be termed the protection potential (9, 18). We have analyzed our results on the basis that E_c uniquely relates to the process of pit initiation in the absence of crevice corrosion. Similarly, we believe that E_p relates specifically to the crevice or pit-propagation mechanism and not the initiation process.

Iron/chromium alloys.—Potentiodynamic anodic-polarization curves were obtained on each alloy shown in Table I, and typical curves are shown in Fig. 3, after submersion for 60 min in the corrodent. Very distinct breakdown potentials were observed, reproducible to ±10 mV in replicate experiments. A summary of the anodic-dissolution parameters is given in Table III. Two features in Fig. 3 are of immediate interest.

1. The changeover from active-passive behavior to one of stable passivity as the chromium content is increased over 12.2 w/o Cr. This behavior can be explained by reference to Fig. 4, where a typical anodic-dissolution curve is shown as $M \rightleftharpoons M^{n+} + ne$. Superimposed on this curve are two sets of cathodic reduction curves; one for the $H^+ + e \rightleftharpoons \frac{1}{2} H_2$ couple, the other for the $O_2 + 2H_2O + 4e \rightleftharpoons 4\ OH^-$ couple. In the latter case, the reduction rate is shown to be under various limiting diffusion conditions; for example, i_{lim}, i_{lim}'. It is known from previous work (19, 20) that a steel will spontaneously passivate when the total reduction rate exceeds the critical anodic current density I_c. The absence of an active-passive transition for alloys 2, 3, 4, and 5 (Fig. 3) indicates that they must have the condition $I_c < i_{lim} + i_{H_2}$. Similarly, alloy 1 must have an I_c greater than the limiting cathodic reduction rate.

2. The pronounced influence of chromium content on the nobility of E_c is shown in Fig. 5. Similar behavior has been noted previously (21) and also on the nickel/chromium binary alloys (22) in acidic halide media. It is apparent that chromium is very effective in stabilizing the passive state to breakdown by chloride ions.

The E_{corr} *vs.* time behavior of the alloys is shown in Fig. 6 and the final steady-state values are summarized in Table III. It is apparent that although random fluctuation in corrosion potential occurred during the first 100 hr of tests giving a quite active corrosion potential, all the alloys approached a relatively noble steady state within 300 hr. The redox potential of the corrodent, measured on bright platinum electrodes, was between +0.280 and +0.310 V_{SCE} over the 300-hr period. On the basis of the data presented in Table III, one would expect that alloys number 1, 2, and 3 would pit in an aerated sodium chloride environment because their long term corrosion potential was more noble than the value of E_c determined for these alloys. Similarly, one would not ex-

pect alloys 4 and 5 to initiate pits, since the corrosion potential never went more noble than the corresponding E_c values.

The pitting tests on the iron/chromium binary alloys, although not originally designed for the present study, were particularly useful in that the mode of testing in salt spray eliminated any interference by crevice corrosion. We have noted many times that alloys totally immersed in sea water suffer from crevice attack around the retaining washer to the exclusion of pitting corrosion. This effect is probably due to galvanic protection of the bulk surface once a crevice anode has initiated before the onset of pitting. This phenomena is discussed in the next section. The results of the exposure tests on alloys 1 through 5 are shown in Table IV and V for the 80- and 800-ft lot, respectively. Typical pitted samples from the 800-ft lot exposure are shown in Fig. 7, where it is important to note that no crevice corrosion took place. This fact is important since the rating of alloys based on E_c is restricted to the pit-initiation process only, and not the propagation mechanism, which we believe to be identical to that of crevice corrosion. Inspection of Table V for the 800-ft lot indicates that alloys 1, 2, and 3 all pitted, whereas alloys 4 and 5 did not. Thus, the results of 8-yr exposure tests are in exact agreement with the prediction of the short-term electrochemical studies.

Inspection of Table IV for the 80-ft lot reveals that pitting corrosion occurred on all the samples,

although the severity of attack decreased markedly in the order predicted from electrochemical studies. The fact that pitting occurred on all samples at the 80-ft lot should not be interpreted as a conflict with the predictions of the accelerated tests without consideration of the following factors:

1. Because of the method of exposure, alternate wetting and drying possibly occurred on all samples. If such a process did occur, a build-up of chloride ion concentration would occur to levels greater than those present in the original sea-spray; for example, 3.5 w/o NaCl. In view of the greater salt "fall-out" which undoubtedly occurred at the 80-ft lot, it is reasonable to suppose that the pitting environment on these samples was more aggressive than that at the 800-ft lot. This factor would have the effect of increasing the severity of pitting over that predicted from Table III, since it has been shown previously (4) that E_c tends to become more active as the chloride ion concentration is increased.

2. It is possible in the 80-ft location, that more fluctuation in temperature occurred than experienced further inland. This behavior could also have a pronounced effect on the pitting tendencies of the alloys, since it is well known that E_c for Type 316 stainless steel, for example, is temperature sensitive.

We believe that the above data lend strong support to the long-term applicability of E_c as an index to pitting susceptibility.

Commercial stainless steels.—Typical potentiodynamic anodic polarization parameters for alloys 6 through 12 are shown in Table VI. It is clear from these data that all the alloys except numbers 8 and 12 would be expected to pit, since their steady-state corrosion potentials were more noble than their respective values of E_c, determined after a 60-min immersion in the corrodent. However, when the samples were removed from sea water after 4.25 years' immersion, pronounced crevice corrosion had taken place at the washers with little or no pitting corrosion on the general surface away from the washers, as shown in Fig. 8. This behavior demonstrates the previously mentioned fact that the induction period for

*** Determined by reversing the potential sweep after an applied current of 10 mA/cm² was attained.

crevice corrosion is much shorter than that of pit initiation. Further, once crevices are activated they appear to protect the bulk of the surface against subsequent pit initiation. Inspection of Table VI indicates a very important fact with regard to the behavior of alloy 8. In this case, according to the E_{corr} and E_c data, no pitting corrosion should occur, whereas in practice pronounced crevice corrosion took place. This point admirably emphasizes the fact that the applicability of E_c data is limited to situations where no crevices are present (situations of little engineering significance), and if not so limited may result in crevice corrosion.

Weight loss data obtained from the immersion tests are summarized in Table VII. Inspection of Tables VI and VII indicated that the weight loss decreased with increasing nobility of E_p. For Hastelloy C, no crevice attack was observed, and no E_p was measurable since no hysteresis was observed on cyclic polarization. It would appear, therefore, that E_p could be used as an index of susceptibility to crevice corrosion and also as a screening parameter with which to rate the severity of attack of alloys in sea-water.

* Exposed for 14 months.

It has been shown previously (9) that once initiated, pit propagation can be maintained at potentials more active than E_c and noble to E_p (see Fig. 2). On this basis, and in accord with previous suggestions (23), we believe that the pit-propagation mechanism and that of crevice corrosion are the same; that is, accelerated attack in a confined space due to acid hydrolysis of corrosion products. To explore the relevance of E_p to crevice corrosion, we exposed a sample of AISI Type 430 stainless steel containing an artificial crevice to 3.5 w/o aerated sodium chloride at potentials both active and noble to E_p. The crevice was made by placing a tight-fitting neoprene O-ring circumferentially around a (0.625-diam by 2-cm) sample, fitted to a Stern-Makrides gasket (24). For the sample exposed noble to E_p, crevice corrosion initiated after 27 hr, with no evidence of pitting corrosion. The sample exposed to potentials active to E_p (determined by reversing the sweep when the applied current reached 10 mA/cm²) did not evidence crevice or pitting corrosion after 230 hr. These data were qualitatively reproducible in replicate experiments.

The use of E_p in the above context, however, should be made with caution. The results of recent experiments to be published (25) indicate that E_p is not a unique parameter, but is a strong function of the number of coulombs passed after exceeding E_c during polarization. Typically, E_p approaches quite active potentials if anodic dissolution is maintaned at rates equal to or greater than 150 mA/cm²; *e.g.*, −0.400 V_{SCE} for Type 430 stainless steel.

However, we believe that to a first approximation, alloys may be screened with regard to crevice-corrosion resistance by a comparison of E_p determined in an identical manner on all samples.

Conclusions

The following conclusions may be drawn from the data presented:

1. That predictions with regard to pitting susceptibility based on accelerated electrochemical tests are valid on stainless steels exposed to a marine atmosphere for at least eight years.
2. There appears to be a direct correlation between both the susceptibility and severity of crevice corrosion of stainless steels in sea water, and the value of the protection potential determined from electrochemical polarization tests.
3. Increasing the chromium content over the range of 12-28% markedly increases the resistance to pitting corrosion, as evidenced by the increase in nobility of the critical breakdown potential.

Stress Corrosion Cracking of Pure Copper

E. Escalante and J. Kruger*

Institute for Materials Research, National Bureau of Standards, Washington, D. C. 20234

ABSTRACT

It is known that the rate of tarnish film formation is an important factor in the stress corrosion cracking (SCC) of brass. Because copper immersed in cupric acetate and sulfate solutions has tarnish film growth rates comparable to those found for brasses susceptible to SCC, it should undergo cracking in such solutions if kinetics play a role. It was found that pure copper is susceptible to cracking in cupric acetate solution but not in cupric sulfate. Light, which retards film formation on copper, but not corrosion, prevents stress cracking in the cupric acetate solution. In the absence of stress, oxide forms all over the copper surface, while stress concentrates oxide formation at the grain boundaries. These experiments point to a brittle-film rupture mechanism of stress cracking.

A recent study by Green, Mengelberg, and Yolken (1) has shown that the rate for formation of a tarnish film on copper and copper-zinc alloys in tarnishing ammoniacal solutions increases with the percentage of zinc. It is also known that the rate of cracking of α-brass in these ammoniacal environments increases significantly with increasing zinc content (2). One theory of stress corrosion cracking (SCC), the "brittle-film" model of Forty and Humble (3), suggests that the rate of tarnish film formation determines the rate of cracking. The study by Green *et al.* showed that pure copper, which is nonsusceptible, does have a low rate of film formation in the tarnishing solution they used. If the predictions of the brittle-film model are valid, pure copper should crack in an environment that produces a similar film to that in the ammonia tarnishing solutions provided the rate is comparable to that observed for the susceptible α-brasses. Such environments are the cupric ion solutions (mostly cupric acetate and cupric sulfate) studied by Miller and coworkers (4-6). These solutions produce epitaxed Cu_2O films on copper that are similar to those that form in ammonia solutions on α-brass. They also grow on pure copper at a rate that is comparable to a susceptible brass (90 Cu-10 Zn). Thus the brittle-film model would predict that pure copper should crack in Miller's solutions. This study will determine if such cracking can be observed.

If cracking of pure copper does occur in Miller's solutions, however, it is still necessary to establish whether it is "true SCC." Recently there have been two directly contradictory papers, one by Pugh, Montague, and Westwood (7) indicating that pure copper can undergo intergranular stress corrosion cracking, the other by Uhlig and Duquette (8) indicating that what was observed by Pugh *et al.* was not SCC but instead a weakening by deep intergranular corrosion. Both of these studies used a 15*N* NH_4OH solution preconcentrated with a 2.5 g/l of copper powder. However, Pugh *et al.* indicate that this solution did not produce a tarnish film. Uhlig and Duquette did observe a "dark surface oxide film." This uncertainty about tarnishing makes it difficult to ascertain whether pure copper would indeed undergo stress corrosion cracking under conditions where a tarnish film exists.

In addition to determining whether pure copper fails under conditions of rapid tarnishing, this study seeks to resolve the question of whether this film formation is an integral part of the failure process or whether simple intergranular weakening is involved.

Experimental

All experiments were carried out either in 0.4*N* cupric sulfate or 0.05*N* cupric acetate using reagent grade chemicals and deionized, double distilled water. The specimens were stressed in a constant load lever system in all but one case. Since surface cleanliness has a strong influence on the rate of oxide growth on

* Electrochemical Society Active Member.

Key words: copper, cupric acetate, kinetics, oxidation, stress corrosion, tarnish film.

a single crystal (9), initial experiments were carried out using the careful surface preparation described by Miller *et al.* (10). It was found, however, that the results were not significantly affected as long as a surface was prepared that was free of any adsorbed organic contaminants.

The following surface preparation procedure was adopted: shortly before an experiment, the specimens were immersed in a 2:1 solution of nitric acid in water for 15 sec, then rinsed in flowing distilled water for 30 sec. The specimens were then dried in a stream of warm air and installed in the testing cell. At this point the oxide forming solution was introduced into the cell. After 1 min the load was applied to the specimen.

The following materials were studied:

99.9% copper wire.—The first experiments carried out in the copper system were done using electrolytic copper having a diameter of 0.254 mm. The tensile load applied was approximately 220 meganewtons/meter (32 ksi) or just slightly more than the yield strength of the material, thus, causing some plastic deformation to occur. The copper wire was tested in both solutions.

Large grain 99.999% copper.—Continuous cast copper rods of 99.999% purity were machined to make flat tensile specimens 10 mm wide at their reduced section, 0.71 mm thick, and 19 mm long. These specimens had relatively large grains ranging from an average of 1-7 mm in diameter. This material was tested only in the cupric acetate solution.

Small grain high purity copper.— Some 99.999% Cu with large grains was reduced 50% in cross section by rolling. Specimens 6.3 mm wide, 0.36 mm thick, and 25 mm long were cut out from the resulting sheet. These specimens were recrystallized in hydrogen by heating to 700°C for 5 min then quickly cooling to room temperature at 300°C/min. The resulting grain size was of the order of 0.1 mm diameter. Surface preparation of this material was more critical because it was to be examined by electron microscopy. It was, therefore, electropolished, then carefully rinsed in distilled water before testing in the cupric acetate. Two separate sets of experiments were done with this material. One set was the tarnishing of the material in an unstressed condition, and the other set was the tarnishing of the material under stress.

Results

Morphology of attack and susceptibility.—The lower purity copper described above and the 70-30 brass were exposed to the 0.05*N* cupric acetate and the 0.4*N* cupric sulfate solutions under tensile loads exceeding the yield strength of the material. No cracking was ever observed at these loads when the specimens were not immersed in the cupric ion solutions. Failure of the 99.9% copper was observed for times as short as 18 hr in the acetate solution. Figure 1a shows that the cracks formed were always found to occur in oxide film growing into the metal. This micrograph looks similar to those published by Forty and Humble (3) for α-brass in ammonium hydroxide-copper sulfate solutions.

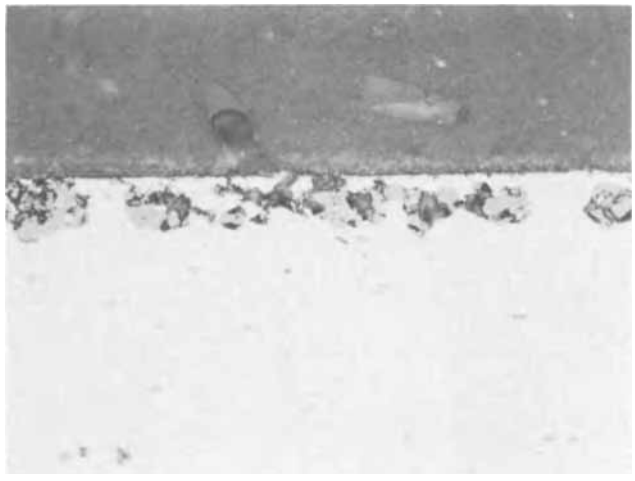

Fig. 1b. 99.9% copper specimen showing general corrosion and pitting. Stressed in 0.04*N* cupric sulfate. Magnification, 430X.

The 99.9% copper did not fail in the cupric sulfate solution. The micrographic examination indicated that oxidation was more general over the whole surface with pitting but no evidence of cracking as shown in Fig. 1b.

The large grain high-purity copper failed in as short a time as 88 hr in the acetate solution. Practically all cracks found were initiated at grain boundaries or at surface imperfections within the grain as shown in Fig. 2a and 2b. The longer time to failure may possibly be due to the fewer grain boundaries at the surface as a result of the large grain size. As Fig. 2a shows for a large-grained specimen, crack initiation would usually occur in a grain boundary normal to the stress direction, but, because the boundary did not continue in this direction, the crack would leave the boundary.

Because we were interested in locating the initiation site of the crack, the fine grain size material was made. This made it easier to locate a grain boundary at the high magnification used with the electron microscope. The grain boundaries of the unstressed and stressed material were examined. Figure 3a showing the unstressed boundaries, revealed no unusual features other

than the many oxide crystallites which formed on the grains, whereas the stressed material showed fissures at the boundary after 1 hr in the acetate solution and had less extensive oxidation in the grain interiors as seen in Fig. 3b. In general, the grain boundaries with fissures were perpendicular to the applied stress.

A few experiments were carried out on commercial 70-30 brass containing <0.8% Pb. This metal did not

fail for times as long as seven days in either solution, and as Fig. 4 shows, the morphology of attack was quite different. This attack appeared to be intergranular and involved an actual loosening of surface grains in the acetate solution. In the sulfate solution most of the attack occurred on the compression side while the tension side was relatively uncorroded.

Effect of illumination.—Because it is known that illumination retards oxide growth on copper (11), the effect of light on the failure of copper in 0.05*N* cupric acetate solution was examined. Two experiments were run in parallel. In one, the copper wire was exposed to the solution under load and illuminated on two sides by 150W high-intensity incandescent lamps. The other was carried out in an identical manner, but light was excluded. There was no measurable temperature difference between the illuminated and unilluminated tests. No failure was observed for illuminated specimens for periods as long as five days. The ones kept in the dark always failed in less than 24 hr.

Discussion

It was found that both 99.9 and 99.999% purity copper will crack in an environment where the rate of tarnish film formation is comparable or greater than the rate of tarnish for susceptible brasses. The results also indicate that cracking occurs in the oxide that forms by growth into the grain boundaries. Before considering the question of the mechanism of the failure and whether we are looking at intergranular weakening or SCC, it is useful to discuss the meanings of the phenomena observed in connection with the formation of the oxide film. In order to do this it is necessary to look at the electrochemical theory of copper corrosion as worked out by Ives and Rawson (12). They propose that the copper-cuprous oxide-solution system can be divided into three zones: zone 1 is made up of a compact, adherent film of Cu_2O and the copper substrate; zone 2 is a porous film of Cu_2O and; zone 3 is the aqueous solution containing oxygen. Each of these zones has associated with it half-cell reactions. The half-cell reaction for zone 1 is the film growth process

$$Cu^\circ + \tfrac{1}{2} H_2O \rightarrow \tfrac{1}{2} Cu_2O + H^+ + e^- \qquad [1]$$

where at 25°C $E_1 = 0.471 - 0.0592$ pH. Both film growth and film dissolution occur in zone 2 and are regarded by Ives and Rawson as constituting a hypothetical redox electrode. These reactions are

$$Cu^{2+} + \tfrac{1}{2} H_2O + e^- \rightarrow \tfrac{1}{2} Cu_2O + H^+ \text{ (film growth)} \qquad [2a]$$

$$\tfrac{1}{2} Cu_2O + H^+ \rightarrow Cu^{2+} + \tfrac{1}{2} H_2O + e^- \text{ (film dissolution)} \qquad [2b]$$

where at 25°C $E_2 = 0.203 + 0.0592\ pH + 0.0592 \log [Cu^{2+}]$. Finally, the half-cell reaction at zone 3 is

$$\tfrac{1}{4}\ O_2 + H^+ + e^- \rightarrow \tfrac{1}{2}\ H_2O \qquad [3]$$

The whole system of electrode reactions can be regarded as two cells coupled to each other, reactions [1] and [2a] are anodic and cathodic reactions, respectively, involving film growth and reactions [2b] and [3] are anodic and cathodic reactions, respectively, involving film dissolution.

We can now apply this set of half-cell reactions to four situations pertinent to the results obtained:

Film formation in the absence of light and stress.—Our results show film growth over the entire surface. The film growth observed is simply a combination of reactions [1] and [2a], as pointed out by Porterfield and Miller (6)

$$Cu^\circ + Cu^{2+} + H_2O \rightarrow Cu_2O + 2H^+ \qquad [4]$$

or if all four reactions of Ives and Rawson are used

$$Cu^\circ + \tfrac{1}{4}\ O_2 = \tfrac{1}{2}\ Cu_2O \qquad [5]$$

Both Porterfield and Miller, and Green *et al.* (1) require a porous film to provide access of Cu^{++} or O_2 to the copper substrate. If there is a compact film at the substrate (zone 1) and it is sufficiently thin, rapid solid-state diffusion through it may be a possibility.

Film formation with stress applied in the absence of light.—Our results show enhanced film growth at the grain boundaries normal to the direction of stress and diminished film growth elsewhere. To arrive at an explanation of these results it is necessary to determine which of the combinations of reactions [1], [2a], [2b], and [3] predominate in their contribution to the overall corrosion current. We can only suggest plausible ways in which the experimental results can be explained. When there is no stress and we observe growth of Cu_2O over the entire specimen, apparently the combination of reactions [1] and [2a] and/or [1] and [3] result in growth both in the grain interiors and in the boundaries. When stress is applied, very small areas of metallic copper are exposed by rupture of the Cu_2O film at the grain boundary, and reaction [1], because it involves metallic copper, predominates in the boundaries and is polarized to higher potentials than with no stress. This occurs because the current density at the bare sites must be high as a result of the small areas involved as compared to the large uncracked cathodic areas. Because stress probably makes reaction [1] the predominant growth reaction in the grain boundaries, and as our results show, causes oxide dissolution to occur in the interiors of the grains, it is reasonable to speculate that the current density for the growth reaction in the grain interiors decrease and the dissolution reaction ([2a] plus [3]) takes over. This is probably what happened in the experiments of Pugh *et al.* (7), with all the tarnishing occurring at the grain boundaries and none detectable elsewhere. Since they observed no tarnishing in the absence of stress, it must be guessed that in their solution reactions [2a] plus [3] were always predominant in the grain interiors.

Role of illumination.—Ives and Rawson (13) have shown that illumination results in enhanced corrosion of copper with greater concentrations of Cu^{2+} ions found in the corroding media. Duwell (14) also found an enhancement of corrosion rate in light. Kruger and Calvert (11) showed that the effect of the light was to cause a dissolution of a Cu_2O film present on the surface. This means that reaction [2b] predominates. Also, Duwell's work suggests the reverse of reaction [1], the production of metallic copper, can also occur. Thus, it appears that light retards or stops the growth of the Cu_2O that forms in the grain boundaries and, by doing so, retards or stops the cracking process.

Role of the anion.—Our results show that the cracking observed when cupric acetate is used is not found when sulfate is substituted. Miller and co-workers (10) found that they could separate two general types of oxide topographies, one relatively smooth, and the other composed of polyhedra. The smoother topographies are formed in acetate and formate solutions, the other in sulfate and perchlorate. They were able to show that these changes were probably due to the fact that in the sulfate and perchlorate solution, a decrease in pH occurred during the film formation process, whereas the acetate and formate ions acted as buffers and prevented any significant lowering of pH. When the pH is lowered, the dissolution reaction [2b] predominates, and oxide formation is retarded or stopped. This lowering of pH with its attendant oxide dissolution would be especially pronounced in restricted geometries such as cracks (15). Elsewhere on the surface, oxide film formation can, and does, take place. But as Miller has shown, there are sites (between polyhedra of Cu_2O) where very little film forms.

From chemical and electrochemical considerations we can conclude that failure results under those circumstances which promote oxide formation at grain boundaries. This oxide formation in a sense results in a dissolution of copper from the grain boundary but it is not the same as simple dissolution without formation of oxide. Such dissolution (probably enhanced) can occur when copper is illuminated or when sulfate ions are present. If intergranular weakening by dissolution at the grain boundaries were involved, sulfate which lowers the pH in cracks would enhance the opportunity for failure. It does not. However because oxide formation is retarded or stopped in the grain boundaries, no cracking results. Thus, intergranular weakening by simple metal dissolution is ruled out as an explanation for the cracking observed for copper in cupric acetate solutions. Because these experiments have shown that film formation is necessary, it would appear that the brittle film theory of Forty and Humble (3) fits the results better. It also seems reasonable that the complex relationships between the mechanical properties of the film, as affected by the metal and the environment, and the rate of film formation in the grain boundaries play a role. An explanation of the failure to crack brass in the cupric acetate solutions will depend on a better future understanding of these relationships.

The Influence of Chloride and Sulfate Ions on the Corrosion of Iron in Sulfuric Acid

S. E. Traubenberg[1] and R. T. Foley*

Department of Chemistry, The American University, Washington, D. C. 20016

ABSTRACT

The influence of chloride and sulfate ions on the corrosion of iron in H_2SO_4 media at pH near 3 was studied. It was shown that both ions could be either aggressive or not aggressive under definite conditions. Chloride ions accelerate corrosion considerably when the anodic reaction contributes significantly to the over-all kinetics. Sulfate ions accelerate corrosion when the reaction is under cathodic control. Chloride ions decreased the protective action of so-called anodic inhibitors ($K_2Cr_2O_7$ and NH_2-CH_2-CH_2-OH) whereas sulfate ions interfere with the action of thiourea, a cathodic inhibitor. The corrosion potential is independent of the chloride concentration but is shifted in the negative direction by sulfate, These observations are interpreted in terms of the properties of Fe-Cl^- and Fe-$SO_4^=$ complexes. The chloride complex serves simply to carry Fe^{++} away from the metal surface.

The corrosion of iron in various electrolytes is a very complex process making it difficult to separate out a single effect and demonstrating in an unequivocal way how it affects the over-all process. Bengough (1), for example, listed six metallic factors and eight environmental factors involved in the corrosion of metals in sea water. These factors do not operate independently; electrolyte concentration, oxygen concentration, temperature, and pH are all interrelated. Not withstanding the difficulty, from an experimental standpoint, of evaluating individual effects in the complex process, it is important to clarify environmental effects in iron corrosion, or, more specifically, the influence of anions. Such a clarification must come before any elucidation of the mechanism of iron corrosion which many consider to be the most important technological problem in the corrosion field.

From a review of the literature (2) it was concluded that there is no generally accepted viewpoint on the role that anions play in iron corrosion. Divergent views are held regarding the aggressive or non-aggressive nature of various anions and the manner in which the anions operate. Most discussion has been in terms of the adsorption of anions on the Fe surface or the penetration by anions of passive films. With the intent of unifying the divergent thinking on the subject, it was proposed that anions influence the corrosion rate by virtue of the type of metal-anion complex (compound) that is formed. Thus, a stable insoluble species would inhibit corrosion whereas a transitory, readily dissociable complex would accelerate corrosion. In neutral solutions or weakly acid solutions chloride ions would form a FeCl complex which under normal circumstances would dissociate and have the net effect of carrying Fe^{++} away from the surface. This would imply that Cl^- is involved in the anodic process. In most of the environments commonly encountered, Fe corrosion is controlled by the cathodic process and any influences on the anodic process are obscured in relation to the over-all corrosion kinetics. This makes it difficult to test any proposition related to the anodic process.

In the following, attempts have been made to develop the experimental conditions wherein the kinetics of the anodic process influence the over-all corrosion rate. The paper is restricted to the effect of chloride ions and sulfate ions in sulfuric acid medium at pH near 3. Both chloride ions and sulfate ions are considered "aggressive" anions.

The corrosion of Fe in its active region, at pH in the range of 2-4 has considerable technological interest. It has been shown by Rosenfel'd and Marshakov (3) that the pH within a pit or crevice in a chloride medium will stabilize at a value determined by the hydrolysis of ferrous chloride which is about 3. Herbsleb (4) also describes pitting in neutral solutions in terms of a build-up of Cl^- concentration in the pit due to transference and a decrease in pH due to hydrolysis. Recently it has been shown by direct measurements by Brown *et al.* (5) that the pH of the solution in the advancing crack of a 0.45C steel undergoing stress corrosion cracking in nearly neutral 3.5% NaCl solution is about 3.8. Thus, the behavior of iron in the pH range 2-4 is directly related to the behavior of Fe during such processes as pit propagation and stress cracking.

Several of the studies reported in the literature have dealt with chloride effects in low concentration. The present study deals with the effect of relatively high concentrations, in the range of technological interest, *e.g.*, marine environments.

Experimental

High-purity iron samples of approximately 20 cm^2 area and a thickness of 0.050 cm were used for the experiments. The preparation of the iron ingot was described by Huber (6). The reduced strip was vacuum annealed at 815°C, cut into coupons, and finally stress relieved at 500°C for 1 hr. The samples were chemically cleaned in a solution of HCl (1:1) for 1-2 min; rinsed with distilled water and immersed in a solution of concentrated H_2SO_4 and HNO_3 (1:1) for 15 sec. After rinsing with distilled water the strips were placed in a solution of NaCN (5 g/100 ml) for 5 min, rinsed with distilled water and acetone, and

stored under acetone. Solutions of H_2SO_4, H_2SO_4 + NaCl, and H_2SO_4 + Na_2SO_4 were used as the corrosive solutions; the pH of the solutions was about 3. The effect of chloride and sulfate ions on the corrosion of iron was studied in the concentration range from 0.1 to 3M NaCl and from 0.1 to 1M Na_2SO_4. The strips were immersed, in triplicate, in the solutions (100 ml) on glass hooks and were exposed to these solutions from 0.5 to 24 hr at 35°C. After exposure the samples were rinsed with distilled water and acetone and then dried. The weight loss was determined and the corrosion rate was expressed in terms of milligrams per square centimeter in a certain time interval or as grams per square meter per hour.

Strips of iron and copper fastened with plastic bolts were used to study the influence of chloride and sulfate ions on the galvanic process. $CuSO_4$ (0.1M) was added to the corrosive solution. The time of these experiments was from 0.5 to 6 hr.

Some experimentation was done with different inhibitors of iron corrosion. The duration of these experiments was 4-24 hr. As anodic inhibitors, potassium dichromate $K_2Cr_2O_7$ and monoethanolamine NH_2-CH_2-CH_2-OH (7) were used; as a typical cathodic inhibitor, thiourea NH_2-CS-NH_2 was used (7). The concentration of $K_2Cr_2O_7$ and NH_2-CH_2-CH_2-OH was 0.1M and the concentration of NH_2-CS-NH_2 was 0.5M. The concentration of inhibitors was chosen from the results of preliminary experiments with H_2SO_4 solutions in the absence of NaCl and Na_2SO_4. The protective action of the inhibitors was calculated according to the following accepted formula

$$H\% = \frac{\rho_0 - \rho}{\rho_0} \times 100$$

where H = protective action, ρ_0 corrosion rate in H_2SO_4 solution and ρ corrosion rate in solution with inhibitor.

A Wenking potentiostat, Fast Rise Model 61 RS, was used for the potentiostatic measurements. A conventional three electrode system was used, the working electrode a modified version of the type described by Myers *et al.* (8). The auxiliary electrode was a platinum screen and the reference a mercury-mercurous sulfate electrode. The solutions were deaerated with purified nitrogen and stirring was provided with a magnetic stirrer. The potential-current data were tabulated manually and transformed to a potential (*vs.* normal H_2 electrode)-current density plot by means of a Fortran IV E program with an IBM 1130 computer and an on-line incremental plotter. A Keithley 600A electrometer measured changes in the electrode potential of iron during corrosion (24 hr).

Results and Discussion

Effect of chloride ion and sulfate ion on corrosion kinetics.—The corrosion of iron as a function of chloride and sulfate ion concentration is given in Fig. 1.

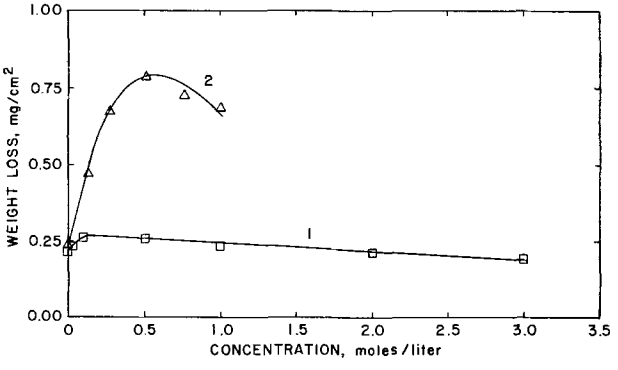

Fig. 1. Dependence of the corrosion of iron on the concentration of NaCl and Na_2SO_4 in H_2SO_4 medium. Curve 1, NaCl at pH 2.72, 35°C, for a 4 hr period. Curve 2, Na_2SO_4 at pH 2.90, 35°C, for a 6 hr period.

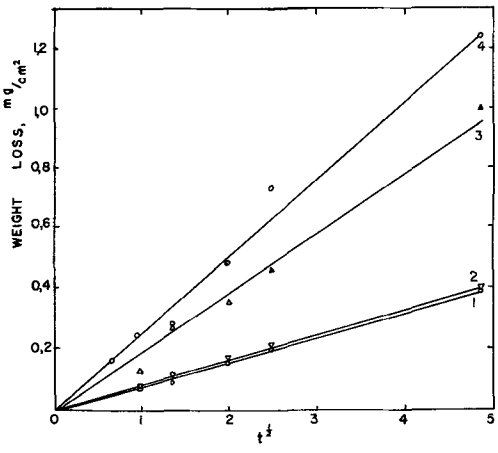

Fig. 2. Influence of Na_2SO_4 and NaCl on the kinetics of the dissolution of iron. Curve 1, $-H_2SO_4$ (pH = 2.78); curve 2, $-H_2SO_4$ + 0.5M NaCl; curve 3, $-H_2SO_4$ + 0.5M NaCl + 0.5M Na_2SO_4; curve 4, $-H_2SO_4$ + 0.5M Na_2SO_4.

These tests were conducted at 35°C at a pH of about 2.8. The weight loss as a function of concentration is similar to that previously reported in the literature for neutral salt solutions. The initial increase in corrosion which for the chloride ion is not great is usually ascribed to the increased conductivity of the solution. For concentrations greater than 0.5M the corrosion decreases and for neutral solutions this has been interpreted in terms of the decreased solubility of oxygen as discussed in detail by Evans and Hoar (9) and others. In these acid solutions it is likely that the cathodic process goes with mixed hydrogen and oxygen depolarization and a decrease in the concentration of oxygen would be expected to have a bearing on the rate. Further experimentation was done with 0.5M solutions of NaCl and Na_2SO_4 which approximated the solutions exhibiting maximum corrosion.

The effect of 0.5M additions of NaCl and Na_2SO_4 and a mixture of the two salts to H_2SO_4 solution at pH 2.78 is given in Fig. 2. The dissolution rate of Fe in these solutions follows a parabolic relationship of the type

$$W^2 = kt$$

where W is the weight loss in mg/cm², t is the time in hours, and k is a constant. The magnitude of k taken from the parabolic plot in Fig. 2 is 0.64×10^{-2} for both H_2SO_4 and H_2SO_4 + NaCl solutions (curves 1 and 2). Thus the presence of chloride ion has no great effect on corrosion over the 24 hr period investigated. This agrees with Kolotyrkin's observation (10) that addition (into acid solution) of chloride, bromide, and iodide ions has only a small influence on the dissolution of metals in the active state.

Sulfate ion on the contrary, has a very significant effect on the dissolution rate of iron in sulfuric acid solutions as shown in Fig. 2 (curve 4). The parabolic rate constant is greater, 6.5×10^{-2}, than that describing the kinetics in H_2SO_4 solution.

In the solution with 0.5M NaCl and 0.5M Na_2SO_4 the corrosion rate was higher than that in the solution with only NaCl but less than that with only Na_2SO_4. This rules out the possibility that the sulfate effect might be due only to an increase in ionic strength.

Polarization behavior.—The cathodic and anodic behavior of the iron electrode in H_2SO_4 solutions with various concentrations of NaCl is shown in Fig. 3. Curve 1, 0.001*N* H_2SO_4 without any chloride addition, reflects the low conductivity of the electrolyte requiring considerable departure from the equilibrium potential to achieve a significant current density (at 25°C). A customary procedure in an experiment of this type is to use a supporting electrolyte. However, this would introduce other anions which would interfere with the interpretation of chloride and sulfate

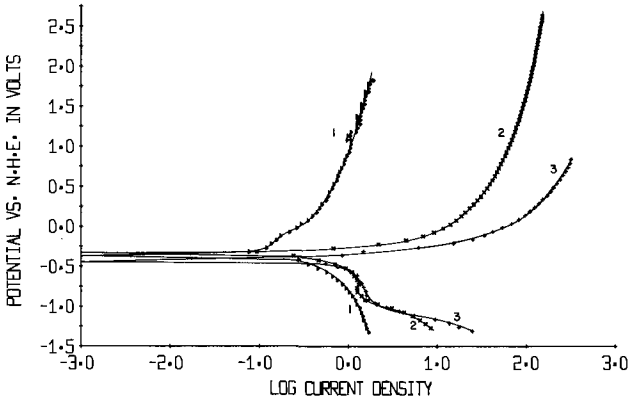

Fig. 3. Polarization behavior of the Fe electrode in H_2SO_4 solutions at pH 3 containing various concentrations of NaCl. Potential vs. normal H_2 electrode, current density mA/cm^2. Curve 1, —0.001*N* H_2SO_4; curve 2, —0.001*N* H_2SO_4 + 0.1*N* NaCl; curve 3, —0.001*N* H_2SO_4 + 0.5*N* NaCl.

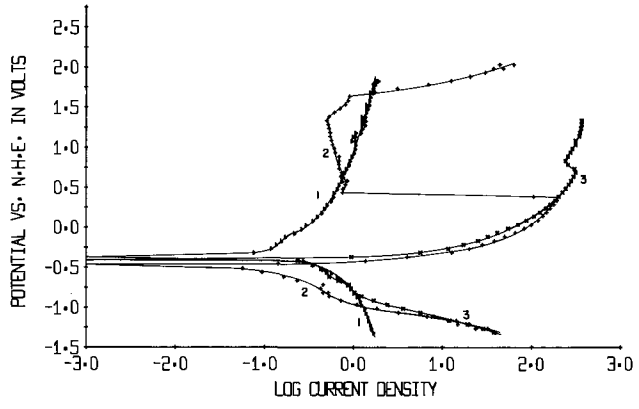

Fig. 4. Polarization behavior of the Fe electrode in H_2SO_4 solutions at pH 3 with Na_2SO_4. Potential vs. normal H_2 electrode, current density mA/cm^2. Curve 1, —0.001*N* H_2SO_4; curve 2, —0.001*N* H_2SO_4 + 1*N* Na_2SO_4; curve 3, —0.001*N* H_2SO_4 + 1.0*N* Na_2SO_4 + 0.1*N* NaCl.

effects. These curves were obtained by experiments run in deaerated solutions which means that corrosion rates, in terms of corrosion currents, cannot be obtained by extrapolation to the equilibrium potential. The distinguishing feature of the curves in Fig. 3 is the increase in the anodic current with increase in NaCl concentration. In the presence of 0.1*N* NaCl the Fe electrode is not passivated anodically, a result which has been observed previously at lower NaCl concentration (11).

Figure 4 illustrates the effect of sulfate additions to 0.001*N* H_2SO_4 solutions. In a solution containing 1.0*N* Na_2SO_4 there is a considerable increase in anodic current comparable to that realized with the chloride addition. However, in this solution anodic passivity is achieved at the appropriate potential. The potential and current density agrees well with that reported by Nobe and Tobias (11) whose pH 3 solution was prepared by neutralizing 1*N* H_2SO_4 and should agree with curve 2 in Fig. 4. The sulfate ion shifts the corrosion potential in the negative direction. The addition of 0.1*N* chloride ion to this solution essentially removes these two effects.

Bimetallic corrosion.—The corrosion rate of Fe in H_2SO_4 solution at pH 3 is controlled by a slow cathodic reaction process. Experiments wherein Cu was connected to Fe to form a bimetallic corrosion couple were performed to create the situation wherein the cathodic reaction proceeded rapidly. In a series of experiments copper and iron strips were fastened together with Nylon bolts and the couple was immersed in sulfuric

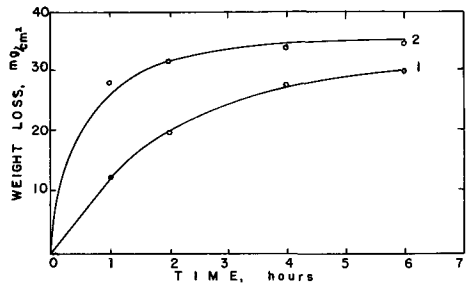

Fig. 5. Influence of NaCl on the kinetics of the dissolution of Fe in the presence of $CuSO_4$. Curve 1, —0.001*N* H_2SO_4 + 0.1M $CuSO_4$; curve 2, —0.001*N* H_2SO_4 + 0.1M $CuSO_4$ + 0.5M NaCl.

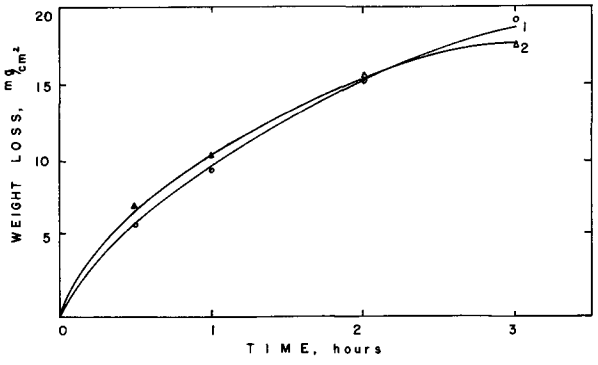

Fig. 6. Influence of Na_2SO_4 on the corrosion of Fe in the presence of $CuSO_4$. Curve 1, —0.001*N* H_2SO_4 + 0.1M $CuSO_4$; curve 2, —0.001*N* H_2SO_4 + 0.1M $CuSO_4$ + 0.5M Na_2SO_4.

acid solutions containing 0.1M $CuSO_4$ with and without NaCl. In these solutions the cathodic reaction, $Cu^{++} + 2e = Cu^\circ$ would be expected to go at a rapid rate, and in these solutions chloride ion accelerated corrosion in a significant way (Fig. 5). After 1 hr, the corrosion rate in a solution containing 0.5M NaCl was more than twice that in the control solution (283 and 124 g/m^{-2}/hr^{-1}, respectively). In a similar set of bimetallic couple experiments it was found that sulfate ion had very little influence on corrosion (Fig. 6). After 1 hr, the corrosion rate in the control solution (H_2SO_4 + $CuSO_4$) was 94 g/m^{-2}/hr^{-1} as compared with 104 g/m^{-2}/hr^{-1} in a solution containing 0.5M sodium sulfate; after 2 hr the rates were 76 g/m^{-2}/hr^{-1} and 76 g/m^{-2}/hr^{-1}, respectively. Because of the considerable amount of corrosion and deposited copper the precision of these experiments was not as good as those described above. However, it can be concluded that the chloride effect is definitely exerted when the rate of the cathodic reaction is increased to a point at which it is comparable to the anodic dissolution reaction, $Fe^\circ = Fe^{++} + 2e$.

Corrosion potentials.—The corrosion potential of Fe was measured in solutions of H_2SO_4 containing NaCl and Na_2SO_4 at several concentrations after corrosion for 24 hr. The results are given in Table I. The electrode potential was independent of chloride ion but was 25-40 mV more negative when $SO_4^=$ was present in

Table I. Potential of iron electrode in different solutions after 24 hr

the solution. The chloride effect agrees with results obtained by Nobe and Tobias (11). The more negative value in sulfate solutions suggests a Fe-$SO_4^=$ species which is sufficiently stable to lower the Fe^{++} concentration.

Inhibitor experiments.—Experiments were conducted with three inhibitors, $K_2Cr_2O_7$, NH_2-CH_2-CH_2-OH, and NH_2-CS-NH_2. Potassium dichromate and ethanolamine are considered to be "anodic" inhibitors and thiourea a "cathodic" inhibitor (7). The mechanism of inhibition by potassium dichromate appears to be generally accepted. However, there is evidence that ethanolamine and thiourea may be involved in both the anodic and cathodic reaction depending on the *p*H of the solution (12). Nevertheless, these compounds were taken to examine the effects of Cl^- and $SO_4^=$ on inhibited solutions.

The results of the gravimetric measurements are given in Table II. Potassium dichromate inhibits corrosion in H_2SO_4 solution at a *p*H of 3 for periods of 4 and 24 hr. The efficiency of inhibition, *H*%, is not affected by the presence of 0.5M Na_2SO_4. However, in the presence of 0.5M NaCl, corrosion exceeds that in the uninhibited solution yielding negative values for *H*%. This result is in keeping with prior observations on the behavior of "dangerous" oxidizing inhibitors. To previously stated conditions such as insufficient concentration must be added the requirement for the formation of an unstable anodic complex. The anodic and cathodic polarization behavior of iron in these solutions agree with the gravimetric results (Fig. 7). There is little change in the cathodic polarization but the anodic polarization behavior indicates that the chloride ion prevents passivation from being achieved at the appropriate potential.

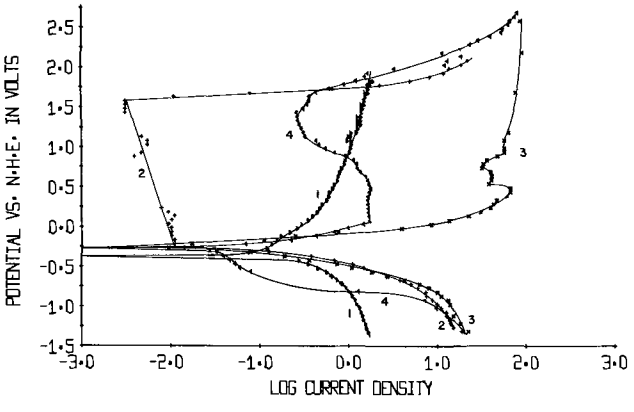

Fig. 7. Polarization behavior of the Fe electrode in inhibited solutions. Potential vs. normal H_2 electrode, current density mA/cm². Curve 1, −0.001*N* H_2SO_4; curve 2, −0.001*N* + 0.1M $K_2Cr_2O_7$; curve 3, −0.001*N* H_2SO_4 + 0.5*N* NaCl + 0.1M $K_2Cr_2O_7$; curve 4, −0.001*N* H_2SO_4 + 0.5M Na_2SO_4 + 0.1M $K_2Cr_2O_7$.

Ethanolamine, also classed as an anodic inhibitor has a high efficiency in this system at the 0.1M concentration. The efficiency in the presence of sulfate ion is also high but in the presence of chloride ion drops off. The polarization behavior of Fe in these solutions agrees with the gravimetric results. In the presence of the inhibitor anodic polarization brings Fe into the passive range. In the presence of sulfate the anodic current is reduced by two decades. In the presence of chloride there is no substantial change in the anodic behavior in the presence or absence of the inhibitor.

Thiourea, classed as a cathodic inhibitor, is much less effective than either potassium dichromate or ethanolamine with an efficiency of only 21%, under the conditions used here. Generally, cathodic inhibitors are less efficient than those of the anodic type (13). The efficiency of this compound is not substantially affected by the presence of chloride ion but the sulfate ion reduces the efficiency by about 25%. The polarization behavior of Fe in these solutions is altered by the presence of thiourea, mainly in the cathodic direction, but to a minor extent.

Conclusions

The salient observations from the experimental work comparing the effects of chloride and sulfate ions on the corrosion of iron may be summarized.

1. In the corrosion of Fe at 35°C and a *p*H of about 3 under conditions wherein the cathode reaction is rate controlling, chloride has virtually no effect, whereas sulfate increases corrosion.
2. In the presence of sulfate ion the Fe electrode is passivated by polarizing anodically (normal behavior). In the presence of chloride ion this passivation does not occur.
3. In a Cu-Fe bimetallic corrosion couple wherein a fast cathodic reaction is supplied by the reduction of copper ions, chloride greatly enhances corrosion, sulfate has little effect.
4. The corrosion potential (after 24 hr) is independent of chloride ion concentration. In the presence of sulfate ion the potential is shifted 25-40 mV in the negative direction.
5. Chloride ion will greatly reduce the efficiency of "anodic" inhibitors but does not affect the functioning of thiourea, classed as a cathodic type. Anodic inhibitors are effective in the presence of sulfate but the cathodic type drop in efficiency.

As was stated above an extended review of the literature (2) led to the conclusion that the best explanation for the effect of anions on the corrosion of iron was in terms of the formation of metal-anion complexes. Likewise these experimental results are best interpreted by assuming the formation of Fe-Cl or Fe($SO_4^=$) complexes at the reacting Fe surface.

What is postulated, and this is speculative, is that Cl ion forms a transitory Fe-Cl species of sufficient stability. In most of the usual corrosion situations investigated the anodic dissolution process is so rapid that the stability of the Fe-Cl is sufficient to enable it to remove the Fe^{++} away from the dissolving metal surface. From a mechanistic viewpoint the Fe-Cl complex can form in competition with Fe-O or Fe-OH species, thus the difficulty in achieving anodic passivity or passivity with inhibitors. Sulfate ion forms a relatively stable species as indicated by the negative shift in potential (Nernst law concentration effect). Further, it would appear that the sulfate complex in some manner assists the cathodic process (note Fig. 2.) It is postulated that this is related to the adsorption or desorption of oxygen species that would depolarize the cathode. It has been established that various anions are involved in "bridging" reactions of this type so it appears reasonable that $SO_4^=$ perhaps through the formation of HSO_4^- species can promote depolarization.

The concept of species such as Fe-Cl and $Fe(SO_4^=)$ participating directly in the corrosion of Fe must remain speculative until direct observation of these species is made. Whereas, instability constants for chloride and sulfate complexes with ferric ion are tabulated (14) there is no comparable data for ferrous complexes. These equilibrium constants would be a guide to the interpretation of kinetic data which are recognized as a measure of the rate the system attempts to attain the equilibrium condition.

These experiments, as well as many reported in the literature (2), demonstrate the specific effects of anions. Chloride and sulfate act in a manner that precludes any explanations based on ionic strength, conductivity, etc. They also argue against the significant role of such species as Fe-OH or $Fe-H_2O$ as these would be expected to be present in both chloride and sulfate solutions.

Free-Convection Mass Transfer with a Supporting Electrolyte

Jan Robert Selman* and John Newman*

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Free convection and ionic migration effects are reviewed. Electrolytic free convection is treated theoretically for $CuSO_4-H_2SO_4$ solutions and for $K_3Fe(CN)_6-K_4Fe(CN)_6$ solutions without added electrolyte and with additions of KOH or NaOH. The effect of ionic migration on limiting currents is investigated. The presence of supporting electrolyte lowers the electric field, as in stagnant or forced convective systems. In addition, the concentration distributions of added electrolytes affect the density distribution, hence, the velocity profile in free convection, and, indirectly, the value of the calculated limiting currents.

Mass transfer to a vertical surface in free convection and the effect of ionic migration on limiting currents have both been studied extensively. Here, electrolytic systems are treated where both factors enter simultaneously.

* Electrochemical Society Active Member.
Key words: ionic migration, limiting current, vertical electrode, current distribution.

Free convection.—Fluid flow along a vertical wall as a result of a density gradient shows a boundary-layer structure. The pressure in horizontal planes is uniform and constant and equal to the hydrostatic pressure. The convection is caused by the difference in density along horizontal planes. By means of a similarity transformation, the fluid-mechanical and mass-transfer equations can be reduced to ordinary differ-

ential equations (1, 2), which are relatively much easier to solve than partial differential equations. The quantities of practical interest following from the solution of these equations are the mass transfer to the wall and the shear stress at the wall. For a constant density difference $\Delta\rho$ between the vertical surface and the bulk solution, these results can be expressed in dimensionless form as

$$Nu = C_b\,(ScGr)^{1/4} \qquad [1]$$

and

$$\tau_o/Lg\Delta\rho = B_b\,(ScGr)^{-1/4} \qquad [2]$$

where Nu is the average Nusselt number (defined for our systems in Eq. [32]), τ_o is the shear stress at the wall averaged over the length L, and g is the magnitude of the gravitational acceleration. Sc is the Schmidt number, Gr is the Grashof number

$$Gr = g\Delta\rho L^3/\rho_\infty\nu^2 \qquad [3]$$

and C_b and B_b are dimensionless coefficients which depend on the Schmidt number. Values of C_b and B_b for free convection in a binary fluid at a vertical surface are given in Table I.

The problem of isothermal mass transfer in a binary fluid is identical, mathematically, to that of heat transfer in a pure fluid, in which case the Prandtl number replaces the Schmidt number as a parameter in the analysis.

For free convection to a vertical surface with a constant density difference $\Delta\rho$, the local rate of mass transfer is inversely proportional to $x^{1/4}$, and the local shear stress is proportional to $x^{1/4}$, where x is the vertical distance along the surface measured from the beginning of the boundary layer.

Morgan and Warner (4) have shown how to treat this free-convection problem in the limit of an infinite value of the Schmidt number. This limit is of interest in the present context since, for electrolytic solutions, the Schmidt number is on the order of 1000. For high Schmidt numbers, the velocity profile extends to much greater distances from the surface than the region of concentration variations; that is, the hydrodynamic boundary layer is much thicker than the diffusion layer, and a singular-perturbation treatment is appropriate. Within the diffusion layer it is permissible to neglect the inertial terms in the equation of motion, and outside the diffusion layer the concentration is uniform and equal to the bulk value. It turns out that it is possible to determine the velocity and concentration distributions within the diffusion layer without carrying out the treatment of the velocity profile outside the diffusion layer.

In this manner, Le Fevre (5) determined the limiting values of C_b and B_b as given in Table I. The singular-perturbation expansions were carried out by Kuiken (6) to obtain three terms in the expansions of C_b and B_b for large Schmidt numbers. A similar perturbation treatment was given by Roy (7). Acrivos (8) has shown that this treatment can be applied, in the limit of infinite Schmidt number, to other geometries besides the vertical surface. Then, for two-dimensional geometries, the average Nusselt number is expressed as

$$Nu = C_b\,(ScGr)^{1/4}\left[\frac{1}{L}\int_0^L (\sin\epsilon)^{1/3}dx\right]^{3/4} \qquad [4]$$

Table I. Coefficients expressing the rate of mass transfer and the shear stress for free convection at a vertical plate from a binary fluid with a uniform density difference $\Delta\rho$ between the vertical surface and the bulk solution [from Ref. (1, 3, 5)]

Sc	C_b	B_b	Sc	C_b	B_b

0.01	0.2421	0.3528	10	0.6200	0.8434
0.03	0.3049	0.4419	100	0.6532	0.9005
0.72	0.5165	0.7045	1000	0.6649	0.9225
0.733	0.5176	0.7057	∞	0.670327	0.932835

where ϵ is the angle between the normal to the surface and the vertical. For the axisymmetric case, see Ref. (8) or (23).

The limit of small Schmidt numbers was treated by Le Fevre (5), and the problem was carried to a higher-order term by Kuiken (9).

We confine ourselves to the analysis of laminar free convection. The transition to turbulence is discussed in connection with the present results for the ferricyanide-ferrocyanide system with supporting electrolyte.

The effect of ionic migration.—The flux of an ionic species contains a contribution due to migration in the electric field as well as those due to diffusion and convection. Frequently in mass-transfer studies, a supporting or inert electrolyte is added to the solution in order to reduce this contribution of migration. In this case, the concentration of the reactant obeys the equation of convective diffusion, applicable in nonelectrolytic mass transfer. This should make the results directly comparable to those of experiments in heat transfer and nonelectrolytic mass transfer. In the case of mass transfer from a solution containing a single electrolyte, the concentration again obeys the equation of convective diffusion (10), but with the diffusion coefficient of the electrolyte rather than the reactant.

With intermediate amounts of supporting electrolyte, it is necessary to solve a more complicated set of equations. Eucken (11) has carried this out for three univalent ions in the, somewhat artificial, Nernst stagnant diffusion layer. Heyrovský (12) rejected this analysis because it did not agree with polarographic experiments for the discharge of hydrogen ions from HCl-KCl solutions and introduced an approximate correction for migration involving the transference number of the reactant.

Newman (13) solved the relevant equations numerically for a variety of electrolytic systems in the following cases: steady mass transfer to a rotating disk at large Schmidt numbers; unsteady mass transfer to a growing drop (polarography); unsteady mass transfer into a stagnant, semi-infinite fluid; and steady mass transfer in a stagnant, Nernst diffusion layer of finite thickness. Okada *et al.* (14) also solved numerically the problem for a growing mercury drop. Newman (15) showed that the case of steady migration through laminar diffusion layers generally, at high Schmidt numbers, is mathematically identical to that of migration to the rotating disk, solved earlier (13).

Newman's results (13) showed good agreement with the polarographic experiments on HCl-KCl solutions [see also Ref. (16)], thereby removing Heyrovský's objections to the methods of analysis based on the equations of electrolytic mass transfer.

Attempts to obtain an approximate solution to the problem of migration are also necessarily more restricted. Gordon, Newman, and Tobias (17) treated the rotating disk electrode by assuming a constant potential gradient in the diffusion layer. The rigorous solution by analytic means is hardly tractable (18-20), even if the velocity corresponds to a simple hydrodynamic situation.

Hsueh and Newman (21) treated the $CuSO_4$-H_2SO_4 system with no dissociation of the bisulfate ion and with partial dissociation according to its dissociation constant. The earlier treatment (13) of this system had assumed complete dissociation of bisulfate ions. This source (21) also gives the effect of migration for a stagnant Nernst diffusion layer with ions of arbitrary valence.

The migration effect is most simply expressed as the ratio I_L/I_D of the limiting current to the limiting "diffusion current," corresponding to the absence of migration, that is, with an excess of supporting electrolyte. The ratio I_L/I_D can be expressed as a function of the composition, characterized by the ratio of supporting electrolyte to total electrolyte.

Free convection in electrolytic systems.—The addition of supporting electrolyte to a solution does not make the free-convection problem directly comparable to that of heat transfer and nonelectrolytic mass transfer in a binary fluid because, while it does reduce the effect of ionic migration, the concentration variation of the supporting electrolyte affects the density variation to roughly the same extent as the reactant and thus influences the velocity profile. Nevertheless, it has frequently been assumed that the mass-transfer rate is adequately expressed by Eq. [1]. Ibl (22) has reviewed the experimental work on this problem and the applicability of Eq. [1] [see also Ref. (23)].

The evaluation of $\Delta\rho$ in the Grashof number (see Eq. [3]) has focused attention on the estimation of the concentration of the supporting electrolyte at the electrode surface, a quantity which is of secondary interest in forced convection. The method traditionally used for this estimation was originally developed by Wilke, Eisenberg, and Tobias (24) for $CuSO_4$-H_2SO_4 solutions. The papers of Wagner (25), Ibl and Braun (26), and Asada *et al.* (27) are relevant in this regard. Recently, Ravoo (28) has challenged the method of Wilke, Eisenberg, and Tobias on the basis of a bisulfate model applied to the stagnant Nernst diffusion layer [see also Ref. (21)].

Brenner (29) succeeded in quickly freezing the solution surrounding a hollow cathode and cutting slices off the frozen mass in order to analyze them. By measuring the refractive index profile, Hsueh and Newman (21) have obtained values of the sulfuric acid concentration at the electrode for unsteady diffusion into a stagnant medium.

Not all experiments in free convection have involved a supporting electrolyte and a vertical electrode. Ibl and Müller (30) have used aqueous solutions of copper sulfate. Schütz (31) experimentally investigated free-convection mass transfer to spheres and horizontal cylinders [see also Ref. (23)].

Analysis

The set of equations which determine free convection as a result of concentration variations in electrolytic solutions near a vertical electrode are the following. The equation of continuity

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0 \qquad [5]$$

The equation of motion

$$\nu \frac{\partial^2 v_x}{\partial y^2} + \frac{\rho - \rho_\infty}{\rho_\infty} g_x = 0 \qquad [6]$$

The mass-transfer equation for each solute species

$$v_x \frac{\partial c_i}{\partial x} + v_y \frac{\partial c_i}{\partial y} = D_i \frac{\partial^2 c_i}{\partial y^2} + z_i u_i \mathbf{F} \frac{\partial}{\partial y}\left(c_i \frac{\partial \Phi}{\partial y} \right) \qquad [7]$$

The electroneutrality equation

$$\sum_i z_i c_i = 0 \qquad [8]$$

Equation [6] is the boundary-layer form of the x-component of the equation of motion, and Eq. [7] is the boundary-layer form of the mass-transfer equation. Here y is the normal distance from the electrode. The inertial terms have been omitted from Eq. [6]. This is a valid approximation within the diffusion layer at high Schmidt numbers, as discussed in the introduction. The boundary-layer equations break down in small elliptic regions near the ends of the electrode. A detailed analysis of these regions is not attempted here.

The density is supposed to be the only variable physical property of the system, and is represented here by a linear expression in terms of the solute concentrations

$$(\rho - \rho_\infty)/\rho_\infty = \sum_i \alpha_i (c_i - c_{i\infty}) \qquad [9]$$

where α_i is a (constant) "densification coefficient." The mobility is assumed to be related to the diffusion coefficient by the Nernst-Einstein relation [see Ref. (10)]

$$D_i = RTu_i \qquad [10]$$

The boundary conditions for the velocity are

$$v_x = v_y = 0 \text{ at } y = 0 \qquad [11]$$

$$\partial v_x/\partial y = 0 \text{ at } y = \infty \qquad [12]$$

$$v_x = 0 \text{ at } x = 0 \qquad [13]$$

The boundary condition at $y = \infty$ corresponds to the matching condition for the inner region (the diffusion layer) in the first term of the singular-perturbation expansion for large Schmidt numbers (4). The inner region can be solved without treating the outer region.

A general expression for the electrode reaction is

$$\sum_i s_i M_i^{z_i} \rightleftarrows n e^- \qquad [14]$$

where s_i is the stoichiometric coefficient of species i, and M_i is a symbol for the chemical formula of species i. The current density is thus proportional to the flux of a reacting species at the electrode

$$s_i i_y = -n\mathbf{F}N_{iy} \text{ at } y = 0 \qquad [15]$$

Since the current density is not known in advance, we express the boundary condition on the species fluxes as

$$D_i \frac{\partial c_i}{\partial y} + z_i u_i \mathbf{F} c_i \frac{\partial \Phi}{\partial y} = \frac{s_i}{s_R}\left(D_R \frac{\partial c_R}{\partial y} + z_R u_R \mathbf{F} c_R \frac{\partial \Phi}{\partial y} \right) \text{at } y = 0 \qquad [16]$$

the convective contribution to the fluxes being zero at the solid electrode. Species R is a reactant called the "limiting reactant," whose concentration is taken to be constant at the electrode surface

$$c_R = c_{RO} \text{ at } y = 0 \qquad [17]$$

At the limiting current, which is of interest here, the concentration of the limiting reactant is zero at the electrode, corresponding to the maximum possible rate of mass transfer. Far from the electrode and at the beginning of the boundary layer, the concentrations have their bulk values

$$c_i = c_{i\infty} \text{ at } y = \infty \qquad [18]$$

$$c_i = c_{i\infty} \text{ at } x = 0 \qquad [19]$$

We now introduce the similarity transformation

$$\xi = y \left[\frac{3g\alpha_R (c_{R\infty} - c_{RO})}{4\nu D_R x} \right]^{1/4} \qquad [20]$$

$$\psi = \frac{4}{3} D_R x \left[\frac{3g\alpha_R (c_{R\infty} - c_{RO})}{4\nu D_R x} \right]^{1/4} f(\xi) \qquad [21]$$

where ψ is the stream function defined so that the equation of continuity [5] is satisfied identically

$$v_x = \frac{\partial \psi}{\partial y}, \quad v_y = -\frac{\partial \psi}{\partial x} \qquad [22]$$

With the dimensionless variables

$$\phi = \frac{\mathbf{F}}{RT}[\Phi - \Phi_0(x)], \quad \theta_i = \frac{c_i}{c_{R\infty} - c_{RO}} \qquad [23]$$

Eq. [5] to [10] become

$$f''' = \pm \sum_i \frac{\alpha_i}{\alpha_R} (\theta_i - \theta_{i\infty}) \qquad [24]$$

$$(D_i/D_R)[\theta_i'' + z_i(\theta_i\phi')'] + f\theta_i' = 0 \qquad [25]$$

$$\sum_i z_i \theta_i = 0 \qquad [26]$$

where the primes denote differentiation with respect to ξ. In Eq. [24], the plus sign applies if ρ_0 is less than ρ_∞, and *vice versa*.

The boundary conditions [11] to [13] and [16] to [19] become

$$\left.\begin{aligned} \theta_i' + z_i\theta_i\phi' = (s_iD_R/s_RD_i)(\theta_R' + z_R\theta_R\phi') \\ f = f' = 0,\ \theta_R = \theta_{RO} \text{ at } \xi = 0 \end{aligned}\right\} \qquad [27]$$

and

$$f'' = 0,\ \theta_i = \theta_{i\infty} \text{ at } \xi = \infty \qquad [28]$$

The densification coefficients in Eq. [9] are not unique for ionic species since the solution must be electrically neutral. The value of α_i can arbitrarily be set equal to zero for one ionic species. As a consequence of this arbitrariness, numerical values of ξ and f are not physically significant, and any results should rather be expressed in terms of the dimensionless distance η and the dimensionless stream function $F(\eta)$ defined according to

$$\eta = y\left[\frac{3g\Delta\rho}{4\nu D_R\rho_\infty x}\right]^{1/4} \qquad [29]$$

and

$$\psi = \frac{4}{3}D_R x\left[\frac{3g\Delta\rho}{4\nu D_R\rho_\infty x}\right]^{1/4} F(\eta) \qquad [30]$$

The density difference $\Delta\rho$ is not known at the outset; consequently, the calculations must be carried out in terms of ξ and f.

The principal results of interest are the mass-transfer rate or limiting current density and the shear stress at the wall. These are expressed by Eq. [1] and [2] with the coefficients C_b and B_b replaced by C and B. Here, the Schmidt number is

$$Sc = \nu/D_R \qquad [31]$$

and the average Nusselt number is

$$Nu = \frac{N_{R,avg}L}{D_R(c_{RO} - c_{R_\infty})} = \frac{s_R L\, i_{avg}}{n\mathbf{F}D_R(c_{R_\infty} - c_{RO})} \qquad [32]$$

Of interest also are the concentrations of the nonreacting ions at the electrode, θ_{iO}. These are necessary to calculate the density difference $\Delta\rho$ used in the correlation of the current density and the shear stress.

Method of Calculation

Equations [24] to [26] form a set of coupled, nonlinear differential equations with boundary conditions at zero and infinity. These equations can be linearized about a trial solution producing a series of coupled, linear differential equations. In finite difference form, these give coupled, tridiagonal matrices which can be solved readily on a high-speed digital computer (32). The nonlinear problem is then solved by iteration. For the principal results, 150 mesh points were used. A mesh width on the ξ scale of 0.0611 was used for the $CuSO_4$-H_2SO_4 system and a mesh width of 0.08 was used in the ferricyanide-ferrocyanide systems.

Ionic diffusion coefficients are calculated from limiting ionic mobilities at infinite dilution (33, 34). The densification coefficients for the various systems are given in Table II. The basis for these values can be found in Ref. (35). The $CuSO_4$-H_2SO_4 system will be considered both with complete and with no dissociation of bisulfate ions. For the ferrocyanide-ferricyanide redox system, the OH^- ions or the Na^+ ions may be absent in certain cases treated here.

As a preliminary check on the accuracy of the numerical method, calculations were carried out for a binary fluid at Sc = 1, 10, 100, 1000, and ∞ and for metal deposition from a binary electrolytic solution in the limit of large Schmidt number. Comparison of these results with those in Table I leads to the conclusion that our method is generally accurate to four significant figures. For metal deposition from a binary electrolytic solution, one can show that

Table II. Values of the densification coefficients (35) used in the calculations

$$C = \frac{(D_s/D_R)^{3/4}}{1 - t_R}C_b(Sc_s) \qquad [33]$$

and

$$B = (D_s/D_R)^{1/4}B_b(Sc_s) \qquad [34]$$

where Sc_s is based on the diffusion coefficient of the salt

$$D_s = \frac{D_+D_-(z_+ - z_-)}{z_+D_+ - z_-D_-} \qquad [35]$$

and t_R is the transference number of the reacting cation.

Results

$CuSO_4$-H_2SO_4.—The effect of the supporting electrolyte, sulfuric acid, can be expressed in the ratios C/C_b and B/B_b, permitting a comparison with the behavior of a binary fluid. These ratios depend on the relative amount of sulfuric acid, expressed as

$$r = \frac{c^\infty_{H_2SO_4}}{c^\infty_{H_2SO_4} + c^\infty_{CuSO_4}} \qquad [36]$$

One is also interested in the concentration of supporting electrolyte at the electrode, in particular in order to calculate $\Delta\rho$, entering into the Grashof number. This is expressed on the graphs as

$$\frac{\Delta c_{H_2SO_4}}{c_{CuSO_4}} = \frac{c^0_{H_2SO_4} - c^\infty_{H_2SO_4}}{c^\infty_{CuSO_4}} \qquad [37]$$

In view of the low value of the dissociation constant of bisulfate ions, the calculations were carried out for no dissociation of bisulfate ions as well as for complete dissociation to sulfate and hydrogen ions. To obtain an idea of the behavior when partial dissociation is considered, one should consult Ref. (21).

Results are shown in Fig. 1 for B/B_b for complete dissociation of bisulfate ions and the ratio C/C_b for both no dissociation and complete dissociation of bisulfate ions. Dashed lines show the corresponding values of I_L/I_D for a rotating disk (21).

As r approaches unity, one would expect C/C_b and B/B_b to approach unity if the appearance of $\Delta\rho$ in the Grashof number were sufficient to correlate the effect of the supporting electrolyte. The contrary behavior emphasizes the fact that these ratios express not only the effect of ionic migration but also the effect of the density profile not being similar to that for a binary fluid. Where Wilke, Eisenberg, and Tobias's correlation (24) works with $C = C_b$, this may indicate that the errors in assuming $C = C_b$ and in estimating the diffusion coefficients compensate for the error in their method of estimating $\Delta\rho$.

To be specific, the diffusion layer thickness is greater for H_2SO_4 than for $CuSO_4$ on account of the larger value of the diffusion coefficient of hydrogen ions. Thus, the density difference in the outer part of the

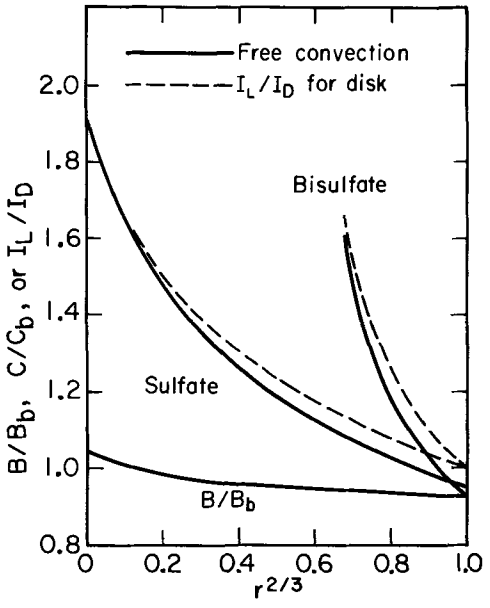

Fig. 1. Coefficients for shear stress (complete dissociation only) and mass transfer in the $CuSO_4$-H_2SO_4 system. Dashed curves show for comparison the values of I_L/I_D for the rotating disk.

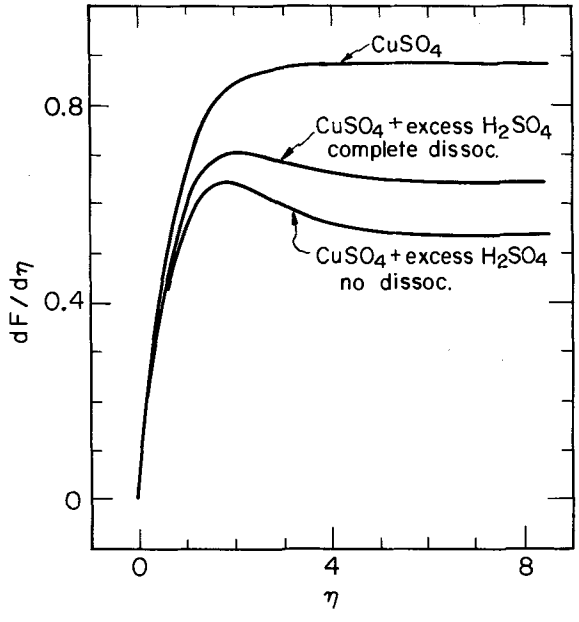

Fig. 2. Velocity profiles for binary salt solution ($CuSO_4$) and for $CuSO_4$ with excess H_2SO_4 ($r = 0.99998$) completely dissociated and undissociated.

diffusion layer is positive while it is negative near the electrode. Consequently, the value of $\Delta\rho$ does not, by itself, give sufficient information about the density profile. In fact, with added H_2SO_4, the velocity profile shows a maximum within the diffusion layer. This is shown for excess sulfuric acid in Fig. 2. The profile for a binary fluid is labeled $CuSO_4$.[1] Since these phenomena occur in a more drastic fashion in the redox systems, we shall postpone their further discussion.

The ratio B/B_b varies little since it does not involve the dominant effect of ionic migration found in the limiting currents expressed in C/C_b. Values of B/B_b for the bisulfate system are in the same range as those for complete dissociation. They extrapolate to 0.8342 at $r = 1$.

The refractive index profile is shown in Fig. 3 for complete dissociation of bisulfate ions. A slight maxi-

[1] Actually, the profile for a binary fluid would involve D_s instead of D_R in the definitions [29] and [30] of η and F.

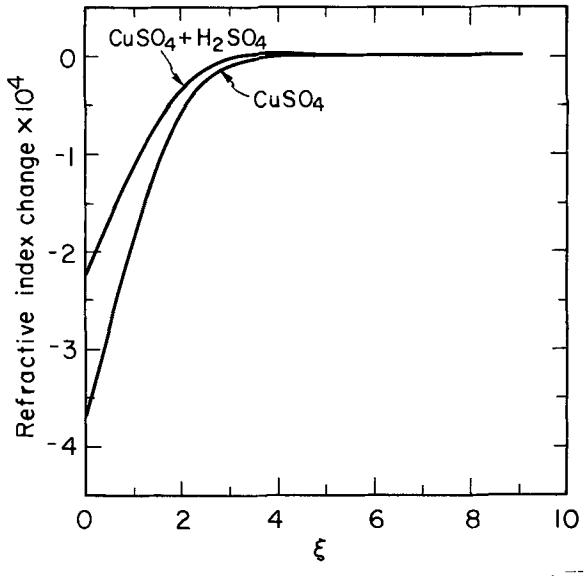

Fig. 3. Refractive index (relative to bulk) in $CuSO_4$-H_2O (0.02M bulk, 0.01M cathode) and in $CuSO_4$-H_2SO_4-H_2O (excess H_2SO_4, 0.01M $CuSO_4$ bulk).

mum occurs when sulfuric acid is present, due again to the larger diffusion-layer thickness of sulfuric acid. These can be compared with Fig. 7-12 and 7-14 in Hsueh's dissertation (36). The basis for the refractive index calculation can be found in Ref. (35).

After the actual velocity profiles have been calculated, one could separate the effect of ionic migration on C/C_b from that due to the dissimilar density profiles. Thus

$$\frac{I_L}{I_D} = (3/4)^{3/4}\, C \int_0^\infty \exp\left\{ -\int_0^\eta F d\eta \right\} d\eta \quad [38]$$

Here, the "diffusion current" I_D corresponds to the mass transfer by diffusion and convection with the actual velocity profile. Then I_L/I_D approaches unity at $r = 1$. For $r = 0$, I_L/I_D does not coincide with the value of C/C_b given by Eq. [33] unless $D_s = D_R$. However, this separation has little practical utility since the two effects cannot be separated experimentally. For a system where the diffusion coefficients of the solutes are roughly the same, one could estimate the value of I_L/I_D from calculations for other hydrodynamic situations (13) and then assume that this is equal to the value of C/C_b for free convection with little error. But if detailed calculations for free convection are carried out, one might as well report values of C/C_b, which account for both effects.

The wide range of predictions for the H_2SO_4 concentration at the electrode for the sulfate and bisulfate models and for various hydrodynamic situations is shown in Fig. 4. Also shown are some values obtained by the method of Wilke, Eisenberg, and Tobias (24). Ravoo's predictions (28) are based on the bisulfate model for a stagnant Nernst diffusion layer of finite thickness. The value 0.71 is deduced from the results of one of Brenner's experiments (29). Hsueh and Newman (21) obtained four values in the range from 0.50 to 0.57 and one value of 0.75.

$K_3Fe(CN)_6$-$K_4Fe(CN)_6$.—The redox reaction

$$Fe(CN)_6^{3-} + e^- \rightleftarrows Fe(CN)_6^{4-} \quad [39]$$

is popular in mass-transfer studies and has been used in free convection, although it is not common. The densification in this system is much weaker than in copper sulfate solutions since the excess of product ion largely compensates for the deficit of the reactant.

Results for the unsupported ferricyanide-ferrocyanide system are shown in Fig. 5. Values of I_L/I_D calculated for the rotating disk (13) are also shown. The

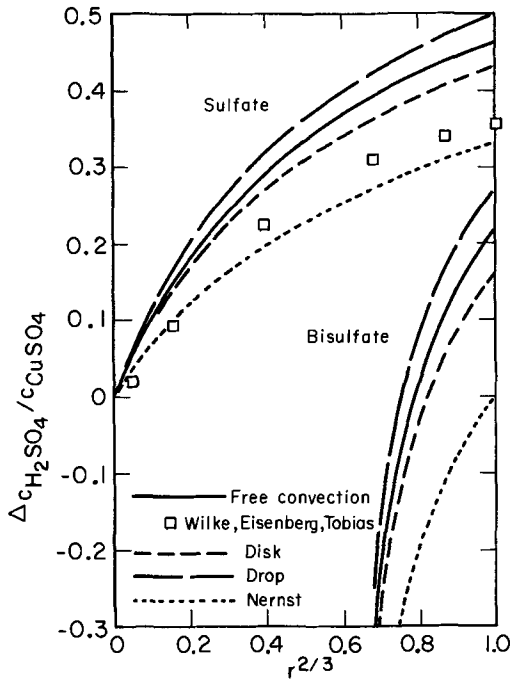

Fig. 4. Excess sulfuric acid at the electrode divided by the bulk copper concentration.

abscissa is the concentration ratio r_a for the anodic reaction and r_c for the cathodic reaction

$$r_c = 1 - r_a = \frac{c^{\infty}_{ferro}}{c^{\infty}_{ferro} + c^{\infty}_{ferri}} \qquad [40]$$

The product concentration at the electrode minus that in the bulk, divided by the bulk reactant concentration, is denoted $-\Delta c_P/\Delta c_R$. The effect of ionic migration on limiting currents is relatively small in this system, as observed earlier (13), since the product ion will always prevent the electric field from becoming infinite at the electrode.

By varying the densification coefficients and diffusion coefficients of the ions, we can study the importance of these factors. The relative unimportance of free convection interacting with migration is evidenced by the fact that it makes little difference for C/C_b or the product concentrations if we assign equal densification coefficients to the reacting and product ions, although the sign of the density difference $\rho_0 - \rho_\infty$ reverses and consequently the flow reverses from upward to downward, or *vice versa*. This emphasizes the fact that the density differences driving the convection in this system are very small. The consequences of this are seen below when we consider the effect of adding KOH or NaOH as a supporting electrolyte.

Supported ferricyanide-ferrocyanide.—We consider next solutions of $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ with KOH or NaOH added as a supporting electrolyte. The latter, although leading to a five-ion system with consequent complications in physical-property estimation, has been used as frequently as the former in reported investigations (37, 38).

In the results, the concentration of supporting electrolyte is expressed in the ratio

$$r = \frac{c^{\infty}_{OH^-}}{c^{\infty}_{K^+} + c^{\infty}_{Na^+}} \qquad [41]$$

Figures 6-8 give the results for these systems for equal bulk concentrations of ferricyanide and ferrocyanide ($r_a = r_c = 0.5$). Additional results for $r = 0.5$ and various values of r_a or r_c are given in Table III. In Fig. 6, values of I_L/I_D for the rotating disk with KOH supporting electrolyte (13) are plotted for comparison.

Figure 6 shows a conspicuous deviation of the values of C/C_b from the values of I_L/I_D for the rotating disk, and Fig. 7 shows a much greater variation of B/B_b than was observed for the $CuSO_4$-H_2SO_4 system. In contrast, the concentration ratios shown in Fig. 8 are essentially independent of the hydrodynamic situation, almost coinciding with results for the rotating disk (which are not shown).

Figures 6 and 7 reflect the strong dissimilarity of the density profile in the supported solutions compared to that in a binary solution. A dramatic consequence of this is shown in the velocity profiles in Fig. 9. There is a velocity maximum which becomes more pronounced as KOH is added, and the magnitude of the velocities becomes smaller. The profile for $r = 0.95$ yields a converged but physically unreasonable solution, since the velocity far from the electrode has reversed sign. Reasonable solutions were not obtained in the cathodic

case for r greater than 0.85 for KOH, and 0.75 for NaOH, supporting electrolyte. The situation is different only in degree from the one encountered in the case of supported $CuSO_4$. Normalized density profiles for the two cases are compared in Fig. 10. The ferricyanide-ferrocyanide system has a weaker densification than $CuSO_4$, and consequently the addition of supporting electrolyte can have relatively a much greater effect on the density profile, as we see in Fig. 10. The velocity far from the electrode (at the outer limit of the diffusion layer) can be expressed as

$$f'(\infty) = -\int_0^\infty \frac{\rho - \rho_\infty}{\rho_\infty \alpha_R C_{R^\infty}} \xi d\xi \qquad [42]$$

Consequently, in order for there to be a flow reversal,

the first moment of the normalized density profile in Fig. 10 must be negative.

The boundary-layer model clearly breaks down when reversed flow occurs. But even before this happens, the velocity profile may have become unstable. It is known from the theory of hydrodynamic stability (39, 40) that boundary layers with an inflection point in the velocity profile are inherently less stable with respect to low perturbation frequencies. It follows that if transition to turbulence takes place in supported solutions, where the supporting ion has a larger diffusion coefficient, it may take place at lower Grashof numbers than for free convection in heat

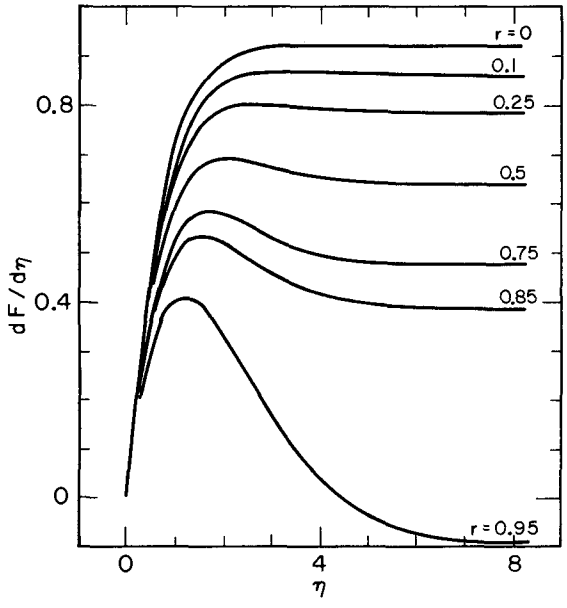

Fig. 9. Velocity profiles for various values of r for cathodic reduction of ferricyanide ions with KOH supporting electrolyte ($r_c = 0.5$).

transfer or in binary solutions. This conclusion should be open to experimental verification.

Unfortunately, the experimental evidence on transition in free convection is rather confusing. Only in heat-transfer experiments with air (with a Prandtl number of 0.7) has the transition region been defined by measuring velocity and temperature fluctuations. In air, the lower limit of transition is, by agreement of several experiments (41, 42), $Gr > 2 \times 10^9$. An upper limit of transition is $Gr < 10^{10}$, above which fully turbulent heat transfer occurs.

In heat-transfer experiments (45) with water and with liquids of Prandtl numbers on the order of 100, the transition criterion was put at $Pr\ Gr = 4 \times 10^{10}$. Wilke, Tobias, and Eisenberg (46) report experiments on dissolution of organic acids in water, where laminar mass-transfer relations still hold at $Sc\ Gr = 2 \times 10^{10}$. Wagner (43), in salt dissolution experiments, observed that the flow was still laminar at $Sc\ Gr = 5 \times 10^{11}$.

Fouad and Ibl (38) place the transition in acidified $CuSO_4$ solutions, observed optically, between $2 \times 10^{11} < Sc\ Gr < 4 \times 10^{13}$. They suggest that there is a separate dependence on Sc. Wilke, Eisenberg, and Tobias (24) correlate laminar free convection in acidified $CuSO_4$ solutions up to $Sc\ Gr = 5 \times 10^{11}$. Fouad and Gouda (44) report transition in ferricyanide reduction with excess NaOH at $Sc\ Gr = 4.6 \times 10^{11}$.

One can hardly infer that destabilization had taken place in the supported solutions. However, in such solutions the density has to be estimated [usually by the method of Wilke, Eisenberg, and Tobias (24)], which can lead to appreciable errors.

Since the inertial terms in the equation of motion were neglected in this analysis, it follows that a theoretical treatment of instability in electrolytic free convection could also simplify the unsteady equation of motion, retaining only viscous and buoyancy terms. The result would be analogous in form to the so-called viscous solutions in forced flow instability (40), except for the unknown effect of coupling to the diffusion equation. No solutions are available for high-Pr free-convection instability. Gebhart (47) reports the absence in low-Pr free-convection instability of a critical layer, corresponding in forced flow to the velocity profile inflection, where the disturbance velocity equals the steady velocity. One might conclude, therefore, that the velocity profile inflection obtained in this work does not necessarily indicate instability.

At any rate, the appearance of velocity profiles which exhibit maxima within the diffusion layer can lead to values of C/C_b and B/B_b considerably different from unity so that Eq. [1] and [2] do not adequately represent the predictions of these calculations for solutions with a supporting electrolyte having a high diffusion coefficient. This is because the density difference $\Delta\rho$ does not, by itself, give sufficient information about the density profile.

Discussion and Conclusions

This investigation concerns the contribution which migration in the electric field makes to the limiting current density in free convection. The effect of migration itself (Eq. [38] is referred to here) is very similar to that calculated for other hydrodynamic situations. However, the effect of migration also leads to a nonuniform concentration of the supporting electrolyte and, here, in contrast to forced convection, this can change considerably the velocity profile and also affect the limiting current. Because this effect can be partly correlated by using the over-all density difference $\Delta\rho$ in the Grashof number, we have reported here the concentration of supporting electrolyte at the electrode.

The method of using the results of this paper to predict the limiting current density at a vertical electrode would be as follows. From the composition of the bulk solution, one estimates the composition near the electrode from Fig. 4, 5, or 8. The concentration of the limiting reactant is zero at the electrode, and the electroneutrality condition determines the concentration of the remaining ion. The density difference $\Delta\rho$ is then determined from the values of α_i in Table II, and this allows the Grashof number to be calculated from Eq. [3]. Equation [1], with C_b replaced by C, gives the Nusselt number, C being obtained from Fig. 1, 5, or 6. The limiting current density is then related to the Nusselt number by Eq. [32]. Similarly, the shear stress τ_0 at the wall can be calculated from Eq. [2], with B_b replaced by B, where B is obtained from Fig. 1 or 7.

Frequently used supporting electrolytes, acids, and bases, have higher diffusion coefficients than the reacting species. This means that the diffusion layer for the supporting electrolyte extends farther from the electrode than that for the reactants. This leads to a velocity maximum within the diffusion layer if the density difference due to the supporting electrolyte opposes that due to the reacting species, as was the case here.

The analysis applies to large Schmidt numbers. In this limit, the present results can be applied to other geometries by using the transformation of Acrivos. This means that C_b in Eq. [4] is replaced by C.

SYMBOLS

B	Coefficient for shear stress
B_b	Coefficient for shear stress in a binary fluid
c_i	Concentration of species i (mole/cm^3)
C	Coefficient for mass transfer
C_b	Coefficient for mass transfer in a binary fluid
D_i	Diffusion coefficient of species i (cm^2/sec)
D_s	Diffusion coefficient for a binary electrolyte (cm^2/sec)
f	Dimensionless stream function
$\mathbf{F}$	Faraday's constant (96,487 C/equiv)
F	Dimensionless stream function
g	Magnitude of the gravitational acceleration (cm/sec^2)
Gr	Grashof number $= g\Delta\rho L^3/\rho_z\nu^2$
i_y	Normal component of the current density (A/cm^2)
I_D	Limiting diffusion current
I_L	Limiting current
L	Height of the vertical electrode (cm)
M_i	Symbol for the chemical formula of species i

n Number of electrons transferred in the electrode reaction
N_{iy} Normal component of the flux of species i
Nu Average Nusselt number $= s_R \mathrm{Li}_{avg}/n\mathbf{F}D_R (c_{R_\infty} - c_{Ro})$
r Ratio of supporting electrolyte to total electrolyte
r_a, r_c Ratios of ferricyanide and ferrocyanide concentrations
R Universal gas constant (joule/mole-°K)
s_i Stoichiometric coefficient of species i
Sc Schmidt number $= \nu/D_R$
t_i Transference number of species i
T Absolute temperature (°K)
u_i Mobility of species i (cm²-mole/joule-sec)
v_x Velocity component parallel to the electrode (cm/sec)
v_y Velocity component perpendicular to the electrode (cm/sec)
x Distance along the electrode measured from the beginning of the boundary layer (cm)
y Normal distance from the electrode (cm)
z_i Valence or charge number of species i
α_i Densification coefficient of species i (liters/mole)
ϵ Angle between the normal to the surface and the vertical
η Similarity variable representing dimensionless distance (see Eq. [29])
ξ Similarity variable representing dimensionless distance (see Eq. [20])
θ_i Dimensionless concentration
ν Kinematic viscosity (cm²/sec)
ρ Fluid density (g/cm³)
$\Delta\rho$ $|\rho_\infty - \rho_0|$
τ_0 Shear stress averaged over the electrode (dyne/cm²)
ϕ Dimensionless potential
Φ Electrostatic potential (volt)
ψ Stream function (cm²/sec)

Limiting Current on a Rotating Disk with Radial Diffusion

William H. Smyrl*

ABSTRACT

The edge effect on limiting currents due to radial diffusion is calculated by a singular-perturbation technique for large Schmidt numbers, and a correction to the Levich formula is thereby obtained.

Radial diffusion, which is usually ignored, is included here in an analysis of the limiting current distribution on a rotating disk electrode. This small edge effect has created a controversy over whether or not it can cancel the correction for a finite Schmidt number. The results of this analysis are also applicable to the trailing edge of other electrodes.

Steady transfer of a solute species obeys the equation of convective diffusion

$$\underline{v} \cdot \nabla c_i = D_i \nabla^2 c_i \qquad [1]$$

if, for one reason or another, electric migration of this species can be ignored. This condition applies to a neutral solute and to a minor ionic solute in a solution with an excess of inert, supporting electrolyte. The equation also applies to a solution of a single electrolyte where the migration terms can be eliminated by means of the electroneutrality condition (1-3). In this case, D_i is replaced by the diffusion coefficient of the electrolyte.

The appropriate form of this equation for the diffusion layer on a rotating disk, including radial diffusion, is

$$Ay\left(r\frac{\partial c_i}{\partial r} - y\frac{\partial c_i}{\partial y}\right) = D_i\left[\frac{\partial^2 c_i}{\partial y^2} + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial c_i}{\partial r}\right)\right] \qquad [2]$$

where $A = a\Omega\sqrt{\Omega/\nu}$. For large values of the Schmidt number $Sc = \nu/D_i$, as encountered in electrolytic solutions, the diffusion layer is much thinner than the hydrodynamic boundary layer, and it is appropriate to approximate the normal and radial components v_y and v_r of the velocity by the first terms of their power-series expansions in the normal distance y from the disk. This introduces the rotation speed Ω, the kinematic viscosity ν, and the dimensionless constant a from the solution of the hydrodynamic problem (4-6) where it is assumed that the mass-transfer process does not influence the hydrodynamics.

The radial diffusion term is usually neglected on the basis of the thinness of the diffusion layer compared with the radius of the electrode. At the limiting current, this "diffusion-layer solution" is

$$c_i = \frac{c_\infty}{\Gamma(4/3)}\int_0^\zeta e^{-x^3}dx \qquad [3]$$

where

$$\zeta = y(a\nu/3D_i)^{1/3}(\Omega/\nu)^{1/2} \qquad [4]$$

and gives a uniform current density on the disk electrode.

We wish to consider the effect of radial diffusion on the limiting current density distribution at the downstream end of a diffusion layer, still at high Schmidt numbers. The rotating disk electrode is assumed to be embedded in an insulating plane. The region where radial diffusion is important is very small, and the problem can be treated by a singular-perturbation method similar to that used to treat the breakdown of the diffusion-layer method at the rear of a bluff body (7, 8) and at the upstream end of an electrode embedded in an insulator (9).

In the region of radial diffusion near the edge of the disk, use stretched coordinates

$$X = (r - r_0)(Ar_0/2D_i)^{1/2} \text{ and } Y = y(Ar_0/2D_i)^{1/2} \qquad [5]$$

so that Eq. [2] becomes

$$\frac{2r}{r_0}Y\frac{\partial c_i}{\partial X} - 2Y^2\left(\frac{2D_i}{Ar_0^3}\right)^{1/2}\frac{\partial c_i}{\partial Y} = \frac{\partial^2 c_i}{\partial X^2} + \frac{\partial^2 c_i}{\partial Y^2} + \frac{r_0}{r}\left(\frac{2D_i}{Ar_0^3}\right)^{1/2}\frac{\partial c_i}{\partial X} \qquad [6]$$

Neglecting terms of order $(2D_i/Ar_0^3)^{1/2}$, we obtain

$$2Y\frac{\partial c_i}{\partial X} = \frac{\partial^2 c_i}{\partial X^2} + \frac{\partial^2 c_i}{\partial Y^2} \qquad [7]$$

Since $\zeta = Y(8D_i/9Ar_0^3)^{1/6}$, ζ is small in this region, and the concentration must match the diffusion-layer solution for small values of ζ. In other words, the region of radial diffusion is embedded in the diffusion layer and

$$c_i \to \frac{c_x\zeta}{\Gamma(4/3)} = \frac{c_\infty Y}{\Gamma(4/3)}\left(\frac{8D_i}{9Ar_0^3}\right)^{1/6} \quad \text{as } X \to -\infty \text{ or } Y \to \infty \qquad [8]$$

Consequently, let us define Θ as

$$\Theta = \Gamma(4/3)\frac{c_i}{c_\infty}\left(\frac{9Ar_0^3}{8D_i}\right)^{1/6} \qquad [9]$$

Then, Θ satisfies the differential equation

$$2Y\frac{\partial\Theta}{\partial X} = \frac{\partial^2\Theta}{\partial X^2} + \frac{\partial^2\Theta}{\partial Y^2} \qquad [10]$$

and the boundary conditions

1. $\Theta \to Y$ as $Y \to \infty$
2. $\Theta \to Y$ as $X \to -\infty$
3. $\Theta = 0$ at $Y = 0, X < 0$
4. $\partial\Theta/\partial Y = 0$ at $Y = 0, X > 0$
5. $\partial^2\Theta/\partial X^2$ becomes negligible as $X \to \infty$

[11]

The coordinate stretching makes the radial and normal diffusion terms appear to be of the same magnitude in Eq. [10]. At the same time, the normal convection term disappears, and the radial convection term assumes a simpler form. From the form of the problem for Θ one perceives that by appropriate stretching of distances and concentration the problem

* Electrochemical Society Active Member.
Key words: current distribution.

for the effect of streamwise diffusion at high Schmidt numbers at the downstream end of any diffusion layer, where the electrode is embedded in an insulating surface, can be reduced to the same problem, and the results obtained here will also apply to those cases.

The ratio of the size of the region where radial diffusion is important to the thickness of the diffusion layer is $(8D_i/9Ar_0^3)^{1/6}$ or of the order of the square root of the ratio of the diffusion layer thickness to the electrode radius. Thus, the size of the region where radial diffusion is important is much smaller than the diffusion-layer thickness, whereas one might at first have assumed them to be of the same order. For a rotation speed of 300 rpm (Ω = 31.416 radian/sec), r_0 = 0.25 cm, ν = 0.01 cm^2/sec, and $D_i = 10^{-5}$ cm^2/sec, the value of this ratio is $(8D_i/9Ar_0^3)^{1/6} = 0.093$.

The fifth boundary condition means that radial diffusion again becomes negligible far downstream in the diffusion layer on the insulator. This condition can be stated more explicitly by obtaining the asymptotic solution for large X. Seek a similarity solution of Eq. [10] with the term $\partial^2\Theta/\partial X^2$ neglected and subject to the boundary conditions 1 and 4.

$$\Theta \to (9X/2)^{1/3} f(\xi) \text{ as } X \to \infty \qquad [12]$$

where

$$\xi = Y(2/9X)^{1/3} \qquad [13]$$

The function f is found to satisfy the ordinary differential equation

$$f''' + 3\xi^2 f' - 3\xi f = 0 \qquad [14]$$

with the boundary conditions

$$f' = 0 \text{ at } \xi = 0,\ f \to \xi \text{ as } \xi \to \infty \qquad [15]$$

and the solution

$$f = \xi + \frac{e^{-\xi^3}}{\Gamma(2/3)} - \frac{3\xi}{\Gamma(2/3)}\int_\xi^\infty x e^{-x^3}\,dx \qquad [16]$$

To effect a numerical solution of the problem for θ, we used parabolic coordinates in order to avoid infinite derivatives at the origin. The mass-transfer rate near the edge of the disk is shown in Fig. 1. Here the normal derivative of Θ is multiplied by $\sqrt{-X}$ in order to give an accurate representation of the results; the limiting current density becomes infinite near the edge of the disk as $\partial\Theta/\partial Y = 0.601/\sqrt{-X}$ at $Y = 0$. The recovery of the concentration on the insulating surface downstream is shown in Fig. 2; the diffusion-layer solution is given by

$$\Theta_0 = \Theta(X,0) = (9X/2)^{1/3} f(0) = (9X/2)^{1/3}/\Gamma(2/3) \qquad [17]$$

The recovery of the surface concentration is hindered by the back diffusion to the disk and is not so rapid

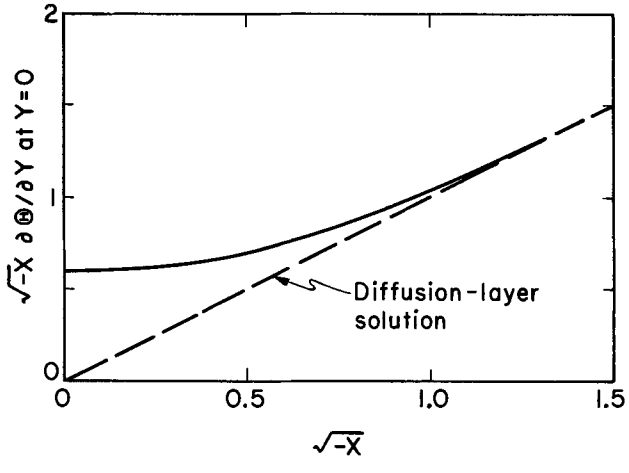

Fig. 1. Mass-transfer rate near the edge of the disk when radial diffusion is considered.

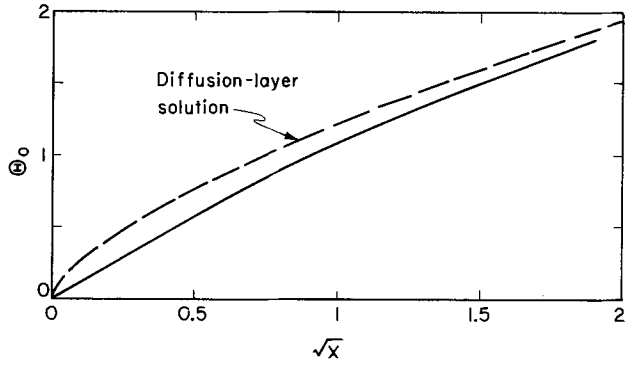

Fig. 2. Recovery of the surface concentration downstream of the disk.

as would be predicted by the diffusion-layer solution in the absence of radial diffusion. This back diffusion results in the infinite current density at the edge of the disk electrode. (This diffusion layer solution for the surface concentration beyond the disk electrode can also be obtained from Eq. [13] or [14] of Ref. (10) by letting r approach r_0.)

The mass-transfer rate shown in Fig. 1 approaches the diffusion-layer solution rather rapidly for large values of $\sqrt{-X}$ in contrast with the behavior depicted in Fig. 2 for the recovery of the surface concentration for large values of $\sqrt{X}$. The reason is that effects are propagated more easily downstream than upstream in a diffusion layer.

The correction to Levich's formula for the limiting current on a rotating disk electrode can now be obtained.

$$\frac{I_{\text{lim}}}{I_{\text{Levich}}} = \frac{1}{\pi r_0^2}\int_0^{r_0} \left.\frac{\partial\Theta}{\partial Y}\right|_{Y=0} 2\pi r\,dr$$
$$= 1 + B/Sc^{1/2}Re^{3/4} \qquad [18]$$

where $Re = r_0^2\,\Omega/\nu$ and

$$B = 4\sqrt{2/a}\int_0^\infty \sqrt{-X}\left[\left.\frac{\partial\Theta}{\partial Y}\right|_{Y=0} - 1\right] d\sqrt{-X} = 1.9193 \qquad [19]$$

The value of B is obtained from the results plotted in Fig. 1.

For the same values of the parameters as used in the last example, the correction to Levich's formula amounts to only 0.116%. For this system, the Schmidt number correction (11, 12) would be −3.1%, and the two effects cannot cancel. This comparison is of some interest since Levich (13) has discussed data which purport to support his formula rather than the Schmidt number correction. These data have since been repudiated (14).

Figure 3 indicates how a plot of limiting current *vs.* square root of rotation speed might be expected to look. Levich's solution plots as a straight line; Eq. [18] is represented by a solid curve. Levich's result is the asymptotic solution for large values of $ScRe^{3/2}$. Equation [18] gives the first correction, again valid for large values of $ScRe^{3/2}$. Additional correction terms would become necessary for smaller values of $ScRe^{3/2}$. The dotted curve represents a guess at the true solution; the intercept, $4/\pi$, is known for this curve but not its initial slope.

Conclusions

A singular-perturbation procedure allows treatment of the edge effect for the rotating disk for large values of $ScRe^{3/2}$. A large value of the Schmidt number was also assumed. The current density at the edge of the disk becomes infinite when radial diffusion is taken into account, and the recovery of the surface concentration is correspondingly less rapid than the diffusion-layer solution predicts. These results allow one to ob-

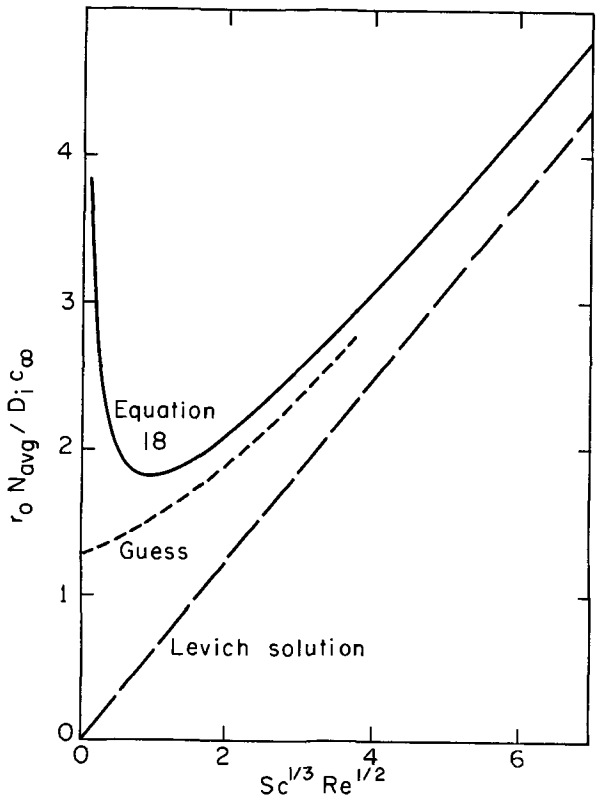

Fig. 3. Limiting current vs. the square root of rotation speed (in dimensionless form) in the absence of free convection.

tain a correction to the classical formula of Levich for the limiting current to a rotating disk electrode. The region near the edge of the disk where radial diffusion is important lies well within the diffusion layer for large values of $ScRe^{3/2}$.

Application of Isosurface Concentration Voltammetry at a Rotating Disk Electrode to Simple Electron Transfer Kinetics

Barry Miller,* Maria I. Bellavance, and Stanley Bruckenstein*,[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Isosurface concentration voltammetry (ISCVA) at a rotating disk electrode has been applied to the measurement of kinetic and thermodynamic quantities of simple electron transfer steps. The technique involves scanning, or modulating, current through an electrode and measuring its potential while holding the surface concentrations of electroactive species constant. Experimentally, this is accomplished by keeping the ratio $i/\omega^{1/2}$ fixed. The theoretical basis of the procedure is outlined for the advantageous condition of a linearized rate equation. The general application of the controlled concentration polarization method to kinetic experiments is discussed.

The rate of the simple electron transfer

$$\mathrm{Ox} + ne = \mathrm{Red} \qquad [1]$$

may be written as

$$i = -i_o\,[\exp(-\alpha n\phi\eta) - \exp(1-\alpha)\,n\phi\eta] \qquad [2]$$

where[2]

$$i_o = n\mathbf{F}v \qquad [3]$$

and

$$v = k_o C_O^{1-\alpha} C_R^{\alpha} \qquad [4]$$

Anodic currents and overpotentials are treated as positive. In the case

$$\mathrm{M}^{+n} + ne = \mathrm{M} \qquad [5]$$

$$v = k_o C^{1-\alpha}{}_{\mathrm{M}^{+n}} \qquad [6]$$

The interpretation of current-potential data is frequently complicated by concentration overpotentials. The usual technique in this situation is to calculate the magnitude of this overpotential, or to obtain a function which may be extrapolated in an appropriate manner to eliminate it. The rotating disk electrode, because of its well-defined mass transfer conditions, has been used to treat the concentration overpotential problem, and several approaches are given elsewhere (2-6).

Another problem, always present when current flows, is the determination (or elimination during the experiment) of any ohmic contributions to the electrode potentials. Potentiostatic experiments are particularly sensitive to such problems and usually require real-time (*e.g.*, positive feedback) correction, in contrast to controlled-current techiques which can be corrected for ohmic effects after data acquisition.

If i-η data are interpreted under conditions such that the surface concentrations, C_O and C_R, or C_{M+n}, are constant and known, the evaluation of k_o and α from [2] and [4] is greatly simplified. As was pointed out earlier by us (7), mass transfer at the rotating disk electrode can be automatically controlled to achieve these surface concentration conditions.

While it is, in principle, possible to obtain the data corresponding to these conditions manually without automatic programming of angular velocity, the numerous practical problems encountered with the use of solid electrodes dictate that data be acquired as rapidly as possible. Our experience indicates that automatic control is far superior to other techniques.

[1] Present address: Department of Chemistry, State University of New York at Buffalo, Buffalo, New York 14214.

Key words: rotating disk voltammetry, controlled concentration polarization, metal anodization.

[2] Symbols are tabulated at the end of this paper. Actually, this definition of i_o does not include the double-layer effect, activities, or stoichiometric numbers. These considerations may be incorporated in our expressions as summarized in Delahay's monograph (1).

It follows directly from the Levich equation

$$i = \pm\, 0.62\, n\mathbf{F}D^{2/3}\nu^{-1/6}\omega^{1/2}(C_j^b - C_j) \qquad [7]$$

that, in a given solution, a constant surface concentration, C, is produced for any value of $|i| \leq |i_L|$ by holding the ratio $i/\omega^{1/2}$ constant (+ sign in [7] when $j = R$, − sign when $j = O$). The latter condition is relatively easy to achieve and was used to evaluate the uncompensated ohmic potential drop in a situation where mass transfer, rather than electrode kinetics, determines the current-potential curve [method HP2 of (7)]. In this paper, we develop the theoretical basis for determining k^o, α, ohmic contributions, n, and the Nernst potential for systems described by [2], using i-E data obtained by scanning i at constant $i/\omega^{1/2}$. We now refer to the procedure of obtaining i-E curves while scanning i at constant $i/\omega^{1/2}$ as isosurface concentration voltammetry, ISCVA, since we feel this term is descriptive of the experiment.

Experimental verification of the theoretical results is given for Fe(III)/Fe(II) in 1.0M H_2SO_4 at platinum and in 0.1M HCl and 1.0M NaCl at gold. The extrapolation of the i-E curve to $i = 0$, for data obtained at constant $i/\omega^{1/2}$, yields the equilibrium potential for the system studied, free of kinetic and ohmic complications. Such data are presented for the anodic oxidation of Ag, Cu, and Hg, in addition to the Fe(III)/Fe(II) studies.

Theoretical

Separation of charge transfer overpotential from ohmic potential drops in the linear overpotential region.—As will soon become evident, the method described in this paper is particularly well suited to the study of fast electron transfer processes, *i.e.* to large values of k_o (and i_o). For the situation in which the convective-diffusion current density, i, of [2] and [7] is much smaller than i_o in [2], then

$$i = i_o\, n\phi\eta \qquad [8]$$

is a good approximation to [2] (1). In our experiment, the observed overpotential, η_{exp}, (and potential, E_{exp}) is given by

$$\eta_{exp} = \eta + iAR_u = E_{exp} - E_{eq} \qquad [9]$$

E_{eq} depends on the constant value of $i/\omega^{1/2}$ being used, and [10] gives E_{eq} for the Ox/Red system

$$E_{eq} = E_f + \frac{1}{n\phi}\ln\frac{C_O}{C_R} \qquad [10]$$

Combining [8] and [9] yields

$$E_{exp} = E_{eq} + \frac{i}{i_o n\phi} + iAR_u \qquad [11]$$

From [11], we see that the plot of E_{exp} *vs.* i gives a straight line that extrapolates to the equilibrium potential, E_{eq}. The charge transfer resistance, R_p, is defined as

$$R_p \equiv \left(\frac{\partial n}{\partial i} \right)_{i \to 0} = \frac{1}{n\phi i_o} \quad [12]$$

Hence, the slope of E_{exp} *vs.* i in [11], R_{exp}, is

$$R_{exp} = R_p + AR_u \quad [13]$$

When $R_p >> AR_u$, the experimental slope corresponds to the charge transfer resistance. If AR_u cannot be neglected, we substitute [3] and [12] into [13] to obtain

$$R_{exp} = \frac{1}{\phi n^2 \mathbf{F} v} + AR_u \quad [14]$$

We note that v is a function of k_o and surface concentrations (see [4] and [6]), so that plots of R_{exp} *vs.* the concentration-dependent part of v would yield straight lines of slope $(\phi n^2 \mathbf{F} k_o)^{-1} = 1/i_{o,s}$ and intercept AR_u. These surface concentration dependencies can be expressed explicitly in terms of the bulk concentrations, impressed current, limiting convective diffusion currents, and other parameters occurring in the Levich equation. These relations are given in Table I for a number of cases.

One simple situation, which we have experimentally investigated, occurs if only Ox is present in solution. From Table I, we write

$$v = \left[k_o \left(\frac{D_R}{D_O} \right)^{2\alpha/3} (1 - f)^{1-\alpha} f^{\alpha} \right] C_O{}^b = \frac{k_{app}}{2} C_O{}^b \quad [15]$$

where $f = i/i_c$. The factor ½ on the right side of [15] compensates for the value of $(1 - f)^{1-\alpha} f^{\alpha}$ being ½ at $i/i_c = ½$. Substituting [15] into [14] yields

$$R_{exp} = \frac{2}{\phi n^2 \mathbf{F} k_{app} C_O{}^b} + AR_u \quad [16]$$

k_{app} may be obtained from [16] by plotting R_{exp} *vs.* $(C_O{}^b)^{-1}$, while f is held constant throughout the experiment (constant f corresponds to constant $i/\omega^{1/2}$). One can then repeat the above experiment at different constant levels of f (or $i/\omega^{1/2}$) and obtain the corresponding values of k_{app}. The value of AR_u obtained in such a series of experiments will be constant, provided the Luggin capillary is reproducibly positioned with respect to the disk electrode and the solution resistance is determined solely by the supporting electrolyte.

Alternately, once AR_u has been determined for one f value, k_{app} may be directly calculated from [17]

$$k_{app} = \frac{2}{\phi n^2 \mathbf{F} C_O{}^b (R_{exp} - AR_u)} \quad [17]$$

using the experimental values of R_{exp} and $C_O{}^b$.

In the Ox/Red system, AR_u can be obtained from plots of [16] without *a priori* knowledge of α. In the M/M^{+n} system, linearization of the corresponding form of [17] requires curve-fitting to determine the value of the exponent, $(1 - \alpha)$, that appears in the current functions given in Table I.

Evaluation of k_o and α.—In the Ox/Red system when $C_R{}^b = 0$, k_o and α can be obtained from k_{app} and f by transforming equation [15] to [18]

$$\log \frac{k_{app}}{2f} = \log k_o \left(\frac{D_R}{D_O} \right)^{2\alpha/3} + (1 - \alpha) \log \left(\frac{1 - f}{f} \right) \quad [18]$$

and plotting $\log k_{app}/2f$ *vs.* $\log [(1 - f)/f]$. Provided α is not potential dependent, a straight line of slope $(1 - \alpha)$ will be obtained. At $f = ½$, $\log [(1 - f)/f] = 0$, and we obtain

$$k_o = \left(\frac{D_O}{D_R} \right)^{2\alpha/3} (k_{app})_{f=1/2} \quad [19]$$

As in all kinetic techniques involving concentration polarization, the evaluation of k_o requires the diffusion coefficients of Ox and Red. However, even for relatively large ratios of D_R/D_O, an accurately known α is not required to obtain a reliable value of k_o. For example, with $D_R/D_O = 1.25$, and $\alpha \sim 0.5$, choosing $\alpha = 0.4$ or 0.6 leads to a relative error in k_o of 1.5%, while twice as large an error in α is 3% in k_o. Hence, if only k_o is required, no serious error would be made where α is not ~0 or ~1 if k_{app} were determined at $f = ½$ and [19] were used assuming $\alpha = ½$.

Differentiating [18] with respect to f yields

$$\frac{d \ln k_{app}}{df} = \frac{\alpha}{f} - \left(\frac{1 - \alpha}{1 - f} \right) \quad [20]$$

From [20], we see that the maximum value of k_{app}, and thus i_o, occurs at $f = \alpha$. Hence, the maximum in the k_{app} *vs.* f plot might be used to determine α. Our experimental results indicate that determining the slope of [18] is preferable since i_o is relatively insensitive to f variation in the region of $f = \alpha$.

We do not explicitly state equations analogous to [15]-[20] for the other cases listed in Table I, since we do not make use of them in this paper.

Determination of E_{eq} and n.—Frequently, the thermodynamic, rather than the kinetic, parameters of a redox couple are of the most interest. In voltammetry, ohmic potential drops and η may interfere in obtaining E_{eq}. In such a case, in the linear overpotential region, E_{eq} at different points on the current potential curve can be obtained from the intercept of [11]. This extrapolation procedure will, in general, remove kinetic and uncompensated ohmic potential drop complications.

In the Ox/Red system whose kinetics were considered in detail above for $C_R{}^b = 0$, the reversible i-E curve is

$$E_{eq} = E_f + \frac{2}{3n\phi} \ln \frac{D_R}{D_O} + \frac{1}{n\phi} \ln \frac{i_c - i}{i} \quad [21]$$

Hence, using the values of E_{eq} (from extrapolation, as above) and the ordinary voltammetric plot of E_{eq} *vs.* $\ln [(i_c - i)/i]$, we obtain E_f and n. In essence, the extrapolation based on [11] allows the simple and rapid conversion of moderately irreversible, and/or IR-distorted current-potential curves to their reversible form.

The latter transformations should be valuable in a number of cases. These include measurements in nonaqueous media of moderate resistance, in Deford-Hume type (8) determinations of stability constants of slightly irreversible couples, and in situations where it

Table I. Surface concentration-current function

Reaction	Species present in bulk	Current function for v/k_o
$Ox + ne = Red$	Ox	$C_O{}^b \left(1 - \frac{i}{i_c}\right)^{1-\alpha} \left(\frac{i}{i_c}\right)^{\alpha} \left(\frac{D_R}{D_O}\right)^{\frac{2\alpha}{3}}$
	Red	$C_R{}^b \left(\frac{i}{i_a}\right)^{1-\alpha} \left(1 - \frac{i}{i_a}\right)^{\alpha} \left(\frac{D_O}{D_R}\right)^{\frac{2(1-\alpha)}{3}}$
	Ox and Red	$(C_R{}^b)^{\alpha} (C_O{}^b)^{1-\alpha} \left(1 - \frac{i}{i_c}\right)^{1-\alpha} \left(1 - \frac{i}{i_a}\right)^{\alpha}$
$M^{+n} + ne = M$	Nothing	$\left(\frac{i}{k_L \omega^{1/2}}\right)^{1-\alpha}$
	M^{+n}	$\left(C^b{}_{M^{+n}} + \frac{i}{k_L \omega^{1/2}}\right)^{1-\alpha}$

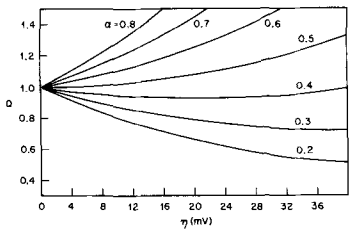

Fig. 1. Plot of $Q = \dfrac{\left(\dfrac{\partial i}{\partial \eta}\right)_{\eta}}{\left(\dfrac{\partial i}{\partial \eta}\right)_{\eta=0}}$ vs. η from Eq. [2]. Alpha values of 0.2-0.8 indicated on curves.

is convenient to electrogenerate a reactive or relatively unstable species, Ox or Red, and direct potentiometry is difficult.

Applicable range of linearized equations and their use outside these limits.—Considerable discussion of the range of validity of [8], the linearized form of the general rate equation [2] for charge transfer control, has appeared in the literature for particular experimental conditions. In Fig. 1 we have plotted

$$Q = \frac{\left(\dfrac{\partial i}{\partial \eta}\right)_{\eta}}{\left(\dfrac{\partial i}{\partial \eta}\right)_{\eta \to 0}}$$

vs. η according to [2] for α values of 0.2-0.8. The deviation of Q from unity is a measure of the departure of [8] from linearity at that particular value of η. In our method of recording E_{exp} *vs.* i at constant $i/\omega^{1/2}$, the slope of the $E_{exp} - i$ trace, R_{exp}, is the parameter of interest. The linearized form of the ISCVA method ultimately fails at large η. However, as is apparent from Fig. 1, the deviation of Q from the theoretical value becomes less the closer η approaches zero.

If an ISCVA plot shows curvature, the tangent to the *I-E* curve at the lowest value of i (and $\omega^{1/2}$) should be measured to minimize errors arising from linearization limitations. This tangent yields R_{exp}, and thus R_u and k_{exp} *via* [16], and thermodynamic quantities from the potential at which the tangent intersects $i = 0$.

Figure 1 may now be applied to obtain a practical limit for the ISCVA method by first choosing the maximum acceptable error, *i.e.* the Q value. We then determine the η level corresponding to this error (ignoring any further experimental error in drawing the tangent to the i-η curve) and express it in terms of the minimum value of k_o and other parameters occurring in the Levich equation.

For example, consider the case representing the experimental example reported in this paper, the reduction of Ox (Fe(III)) to Red (Fe(II)) at the disk. We eliminate i between [7] and [8] obtaining

$$-i_o \phi \eta = 0.62\, \mathbf{F}\, D_O^{2/3}\, \nu^{-1/6}\, \omega^{1/2}\, (C_O^b - C_O) \quad [22]$$

i_o is eliminated from [22] and k_o introduced by substituting [3], [4], and [15], yielding

$$k_o \geq \frac{0.62\, D_O^{2/3}\, \nu^{-1/6}\, \omega^{1/2}\, (C_O^b - C_O)}{2\phi |\eta_{max}| C_O^{1-\alpha}\, C_R^{\alpha}} \quad [23]$$

From [23], we see that the minimum value of k_o for which the linearization technique may be applied is determined by the value of η corresponding to the maximum acceptable error in the slope. The minimum k_o value depends on the surface and bulk concentrations, and [23] is conveniently written in terms of f. For simplicity, we assume that $D_O = D_R$; then

$$C_O = (1 - f)\, C_O^b \quad [24]$$

and

$$C_R = C_R^b + f\, C_O^b = (C_O^b - C_O) + C_R^b \quad [25]$$

The largest value of k_o (worst case) occurs if C_R^b in [25] is zero. Under these conditions, [23] becomes

$$k_o \geq \frac{0.62\, D_O^{2/3}\, \nu^{-1/6}}{2\, \phi |\eta_{max}|} \left(\frac{f}{1 - f}\right)^{1-\alpha} \quad [26]$$

At $f = 1/2$

$$k_o \geq \frac{0.62\, D_O^{2/3}\, \nu^{-1/6}\, \omega^{1/2}}{2\, \phi |\eta_{max}|} \quad [27]$$

Assuming $D_O = 8 \times 10^{-6}$ cm^2/sec, $\nu = 1/64$ cm^2/sec, and a conservative lower limit of rotation speed

$$\omega^{1/2} = 6.5 \left(\frac{\text{rad}}{\text{sec}}\right)^{1/2} \sim (400 \text{ rpm})^{1/2}$$

we obtain from [27]

$$k_o \geq \frac{41 \times 10^{-3}}{|\eta_{max}|} \text{ cm/sec} \quad [28]$$

For the solvent system we studied, Fe(III) in 1.0M H_2SO_4, $D = 4.5 \times 10^{-6}$ cm^2/sec, hence, instead of [28], $k_o \geq 31 \times 10^{-3}/|\eta_{max}|$ cm/sec. In this case, we found $k_o \sim 6 \times 10^{-3}$ cm/sec and $\alpha \sim 0.5$ using the theory based on linearization of the overpotential relation. Hence, our interpretation of the experimental data would be valid to within 1%, provided all slopes were obtained for ISCVA data at $\eta \leq 5$ mV. At 400 rpm, $\eta \cong 5$ mV when $f = 1/2$, and the use of slope data obtained under these conditions does not introduce any errors. Even at the maximum speed of our apparatus, 10,000 rpm, the error in the slope for the Fe(III)/Fe(II) system is only $\sim$ 10%, and it is difficult to detect the curvature in the ISCVA plot.

The form of [27] indicates that the optimum application of the ISCVA method requires careful choice of electrode mantle shape (11) and ω scan rate in order to maintain Levich behavior at the lowest possible $\omega^{1/2}(\eta)$.

Since the derivative $(\partial\eta/\partial i)_c$ in the limit $i \to 0$ is the value sought, other experimental approaches to improve the accuracy of its experimental estimate may be taken when k_o becomes too small (or α is very different from 0.5). For example, an angular velocity modulation procedure to be outlined below gives $(\Delta\eta/\Delta i)_c$ directly with higher precision. Plots of $(\Delta\eta/\Delta i)_c$ for different values of i can be extrapolated back to $i = 0$, rather than taking the tangent at the lowest i actually measured. If such a linear extrapolation to zero i is used, we find that there is a threefold or more reduction in the minimum error predicted by Fig. 1 for the estimate of $(\Delta\eta/\Delta i)_{i=0}$. Our present apparatus provides for superimposed angular velocity modulation (9) and has been applied to direct measurement of $(\Delta\eta/\Delta i)_c$ *vs.* i under ISCVA scanning conditions. However, in the Fe(III)/Fe(II) cases, it was not necessary to scan the current while modulating ω.

Considering [24], [25], and [26], we see that using lower f-values and having $C_R^b > 0$ will cause the linearization approximation to be valid at lower k_o-values. This approach becomes impractical as $C_R/C_R^b \to 1$, *i.e.* when the current is small enough that little or no concentration polarization occurs and the ISCVA procedure becomes superfluous.

If the values of k_o and α are such that the linear approximation is not valid, two additional cases remain. If the reaction is so slow that all the accessible Levich constants lie in the Tafel region, conventional logarithmic transformations can be used, without introducing any ambiguity arising from variations in surface concentrations. In the overpotential region lying between the Tafel and linear regimes, the data may be fitted graphically to an Allen-Hickling plot (1, 10), if an estimate of the equilibrium potential can

be made. Alternately, k_o, α, and E_f can be obtained solely from ISCVA data using a nonlinear least-squares technique.

The facile control of surface concentration *via* the ISCVA method is of substantial utility outside the linear i-η region. In contrast, most relaxation methods (12-14), whose theory is based on linearity assumptions, cannot be used when η becomes large. Thus, using the ISCVA method, steady-state data can be taken and used to calculate kinetic parameters over virtually the entire range of known reaction rates.

For extremely fast electron transfer processes, the limitations on the ISCVA method become experimental rather than theoretical. Overpotentials for high k_o-values are small, and the uncompensated ohmic potential may become greater than η. Our approach to extending the ISCVA method to very fast processes ($i_{o,s} \sim 40$ A/cm^2) involves additional refinements to the $\omega^{1/2}$-modulation method in a way that retains steady-state mathematics and will be treated elsewhere (15).

Experimental

Apparatus and materials.—The $i/\omega^{1/2}$ scanning scheme, electrode construction, cell, and electronics are similar to those described previously under method HP2 (7). A detailed description of the present motor control apparatus is given elsewhere (9), including the velocity modulation circuitry necessary to perform the step changes in $\Delta i(\Delta\omega^{1/2})$ at constant $i/\omega^{1/2}$. All data reported below refer to hydrodynamic conditions that allow the use of the Levich equation. Nonsteady-state aspects of the velocity programming are discussed in the previously cited reference (9).

Solutions were prepared from triply distilled water and reagent-grade chemicals (electronic-grade acids) without further purification. All Fe(III) solutions were analyzed volumetrically using Ce(IV). Concentration studies were made by adding increments of Fe(III) stock solutions prepared in the same electrolyte to known volumes of that electrolyte present in the cell.

Gold, platinum, silver, and copper electrodes were polished to a 0.3μ Linde A finish. A mercury disk was prepared from a gold disk of 0.317 cm^2 area by amalgamating with a drop of mercury and spinning the excess off at 10,000 rpm to provide a flat mercury surface. All other disk areas were measured to be within 1% of 0.178 cm^2. For the gold and platinum kinetic studies, the surface states of these electrodes were critical in determining the measured levels of k_o. In the 0.1M HCl-1.0M NaCl studies, the gold electrode was anodized before $\omega^{1/2}$ scans at current densities comparable to those being used in the next experiment. This pretreatment converted the electrode surface to a reproducible state, giving it a matte finish. On a surface that retained a polished appearance, the apparent rate constants were lower and less reproducible. Such surface effects are well known in the study of heterogeneous rate processes. These rate constant differences are thought to arise both from impurity adsorption and surface area changes. Similar phenomena were found for Pt in 1M H_2SO_4, but we were not able to obtain as reproducible surfaces solely by anodization. Instead, we employed a technique first used by Johnson (16) to counteract inhibition effects in oxygen reduction. If $10^{-5}M$ Pt(IV) is added to the solution, platinum deposits continually during the reduction of Fe(III) and produces a relatively reproducible surface. In the absence of Pt(IV), the rate constants we found varied over a twofold range. This variation was observed in several separate experiments over a period of time using different solutions. The largest k_o values approached that obtained with *in situ* platinizing. Johnson's technique typically increased the surface area by about 50%, as measured by comparing the coulombs used in platinum oxide reduction before and after platinization.

Procedure.—The following procedure was used to study the reduction of Fe(III) in 0.1M HCl-1.0M NaCl at gold and in 1.0M H_2SO_4 at platinum: (*a*) An increment of Fe(III) stock solution was added and the i-E curve at a constant ω (ordinarily 2500 rpm) was determined; (*b*) the limiting current, i_c, [or i_a for Fe(II)] was measured; (*c*) the apparatus was adjusted to produce the desired surface concentration of Fe(III)—*e.g.*, to obtain $f = 1/4 = C/C_b$, $i/\omega^{1/2}$ was adjusted to 3/4 ($i_c/\omega^{1/2}$); (*d*) i was scanned, holding $i/\omega^{1/2}$ constant, and E_{exp} recorded *vs.* i.

Equations [18] and [21] require the value of the ratio $(D_R/D_O)^{2/3} = i_c/i_a$. These mass transport parameters for Fe(III) and Fe(II) were determined from i_c and i_a data obtained by repeating steps (*a*) and (*b*) above at constant ω to cover the desired C_b range. Results from one typical set of such data for Fe(III) in 0.1M HCl-0.1M NaCl at 2500 rpm are given in Fig. 2.

The α determination procedures require precise estimation of R_{exp}. When it is established that $\Delta\eta/\Delta i$ accurately represents R_{exp} ([8] is valid), a significant improvement in the precision of R_{exp} is obtained by superimposing a square-wave modulation on a constant $i/\omega^{1/2}$ condition, again while holding the value of $(i + \Delta i)/(\omega + \Delta\omega)^{1/2}$ constant (9). Measurement of the modulated part of the potential and current produces $\Delta\eta$ values as a function of Δi.

This modulation technique is decidedly advantageous in solid electrode studies, where surfaces may be altered in a time-dependent manner when they are exposed to wide changes of current and potential. Modulation methods are particularly well adapted to repetitive measurements and signal averaging. The direct reading of the necessary Δi and $\Delta\eta$ values may be done numerous times within the period required for a steady-state scan determination. These factors all contribute to increased accuracy and reproducibility in the value of $\Delta\eta/\Delta i$.

Results and Discussion

Evaluation of k_o.—A set of ISCVA plots for Fe(III) in 1M H_2SO_4 for $f = 0.5$ at platinum is shown in Fig. 3. The data are linear, considering the experimental error, as predicted by [11], within the limitations suggested by [27]. They are plotted, according to [16], in the form of R_{exp} *vs.* $1/C_O^b$ in Fig. 4. The major source of deviation is the sensitivity of the surface to pretreatment. The data sets obtained with 10^{-5}M Pt (IV) present are similar except for a decrease in slope corresponding to a slightly higher $i_{o,s}$. The data in Fig. 4 represent the highest k_{exp} found when only anodic pretreatment of polished platinum electrode was used.

ISCVA kinetic data for Fe(III) in 0.1M HCl-1M NaCl for $f = 0.5$ at gold are shown in Fig. 5 and 6. The data of both Fig. 4 and 6 are linear as predicted by [16]. The least-squares values of AR_u from the intercepts of these figures are 2.5 ± 8.5 and 5.3 ± 3.6 ohms, respectively. Independent interrupter (16) estimates of AR_u (5 and 8 ohms, respectively) were within the error range of the intercepts. Values of AR_u calculated according to Newman (17) were 4 and 7 ohms, re-

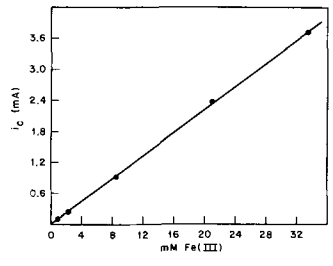

Fig. 2. Plot of i_c *vs.* Fe(III) concentration in 0.1M HCl-1.0M NaCl for 0.178 cm^2 gold disk rotated at 2500 rpm. Least-squares slope = 111 ± 3 μA/mM, $D_{Fe^{+3}} = (5.12 \pm 0.2)\ 10^{-6}$ cm^2/sec.

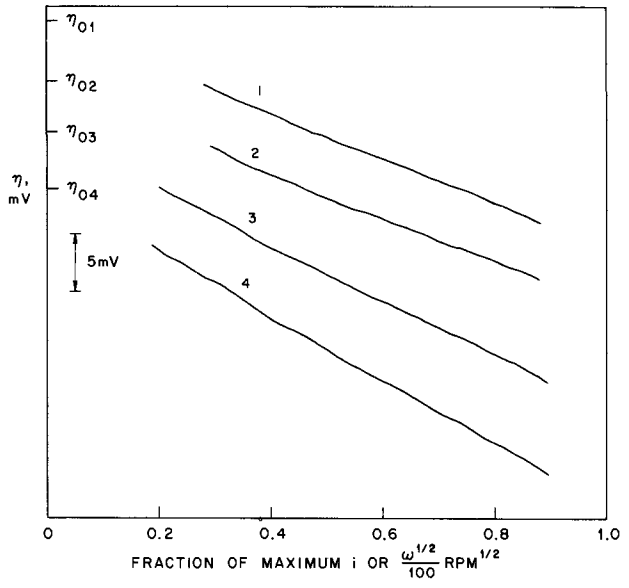

Fig. 3. Normalized ISCVA plots for the reduction of Fe(III) in 1M H_2SO_4 at Pt as a function of $C^b_{Fe(III)}$. $f = 0.5$. Tracings of actual data shown. The ordinate η is defined as $E_{exp} - (E_{exp})_{i\to 0}$. $\eta_{0,1}$ refers to η_0 for curve 1. The vertical sensitivity is 5 mV/ indicated division. Abscissa plotted as fraction of maximum current (at 10,000 rpm). Concentrations of Fe(III) are: 1—0.50, 2—0.99, 3—1.96, and 4—4.75 mM, respectively. The maximum currents are 51.2, 101.4, 232.0, and 559 μA, respectively.

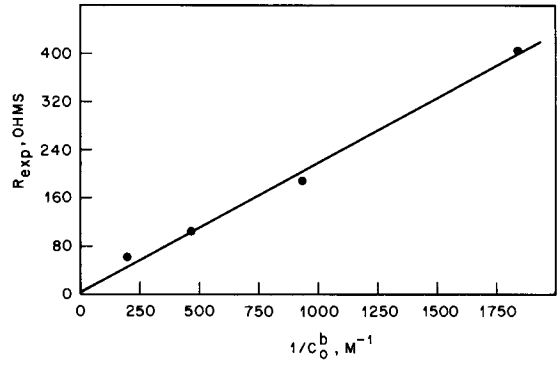

Fig. 4. Plot of R_{exp} vs. $1/C_O{}^b$ for data of Fig. 3. R_{exp} values taken from slopes of corresponding Fig. 3 traces. Least-squares intercept = 2.5 ± 8.5 ohms, slope = 0.216 ± 0.03 ohm-molar, $i_{o,s} = 0.66$ A/cm^2-molar, $k_o = 6.8 \times 10^{-3}$ cm/sec.

spectively. The uncertainties in the intercept of [16], AR_u, are not critical as long as the uncertainty in the slope, which yields k_{app}, is low. This is the case for the Fe(III) system at the 1-10 mM concentration level.

The range of k_o values obtained at polished platinum was 3-6.5 x 10^{-3} cm/sec in 1M H_2SO_4. For the platinized surface, $k_o = 7.5 \times 10^{-3}$ cm/sec. The latter value is consistent with the values we found for k_o on polished platinum after the ~50% increase in area is taken into account. Copa (17) has summarized the literature values of k_o for this system, and the range of previously reported values includes our results.

The values of k_o obtained at gold from Fig. 6 and from Fig. 8 below are 5.5 and 5.7 x 10^{-3} cm/sec, respectively. The supporting electrolyte of 0.1M HCl-1M NaCl is about the same as that of Barnartt (20) who reported the higher value of $k_o > 3 \times 10^{-2}$ cm/sec on the basis of a potential step method employing positive feedback to provide *IR* compensation. However, Bockris *et al.* (21), using a galvanostatic method, found k_o in 1M HCl at gold to be about the value found by the ISCVA technique.

Evaluation of α.—The determination of α for a 9.7 mM Fe(III) solution in 0.1M HCl-1M NaCl at a gold

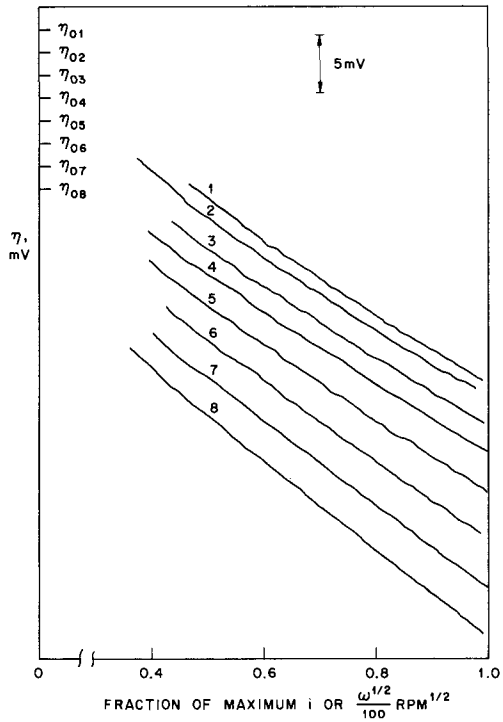

Fig. 5. Normalized ISCVA plots for reduction of Fe(III) in 0.1M HCl-1.0M NaCl at gold as a function of $C^b_{Fe(III)}$. $f = 0.50$. Concentrations of Fe(III) are (in mM): 1—1.28, 2—1.60, 3—2.22, 4—2.83, 5—4.63, 6—6.37, 7—8.03, 8—10.16. Maximum currents (in μA) are: 1—145, 2—181, 3—251, 4—320, 5—523, 6—720, 7—907, 8—1,148. Other data same as in Fig. 3.

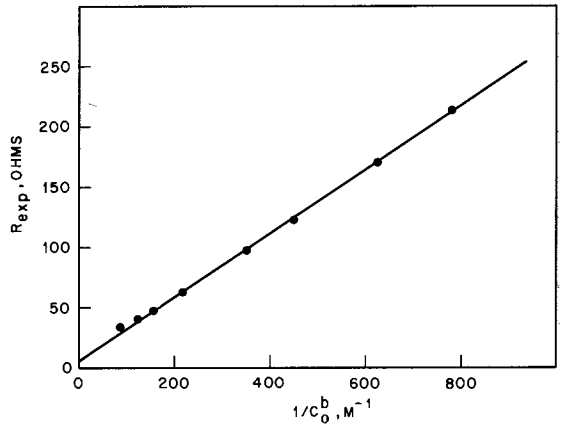

Fig. 6. Plot of R_{exp} vs. $1/C_O{}^b$ for data of Fig. 5. R_{exp} values taken from slopes of corresponding Fig. 5 traces. Least-squares intercept 5.3 ± 3.6 ohm, slope = 0.270 ± 0.024 ohm-molar. $i_{o,s} = 0.53$ A/cm^2-molar. $k_o = 5.5 \times 10^{-3}$ cm/sec.

electrode was performed in two ways: (*a*) by plotting k_{app} *vs.* f according to [20] to produce a curve with a maximum in k_{app} at $\alpha = f$, Fig. 7, and (*b*) according to [18] by plotting log $k_{app}/2f$ *vs.* log $[(1-f)/f]$ which gives α from the slope, Fig. 8. The R_{exp} data were obtained using the more precise modulation procedure as discussed earlier. All R_{exp} data were corrected to R_p values using the least-squares estimate of AR_u obtained from the intercept of Fig. 6, and k_{app} was then calculated from [17].

In Fig. 7, theoretical $i_o - f$ plots for $\alpha = 0.4$, 0.5, and 0.6 are given along with a plot of the experimental data. The maxima of the $i_o - f$ plots are broad and visual inspection of Fig. 7 leads to an estimate of $\alpha = 0.5 \pm 0.05$. The graphical procedure using [18] in Fig. 8 yields $\alpha = 0.48$ and is the preferable technique. The α-values collected by Copa (19) for 1M H_2SO_4, rather than Cl^-, range from 0.46 to 0.62. The plots in Fig. 8 deviate from linearity at values of $(1-f)/f$ re-

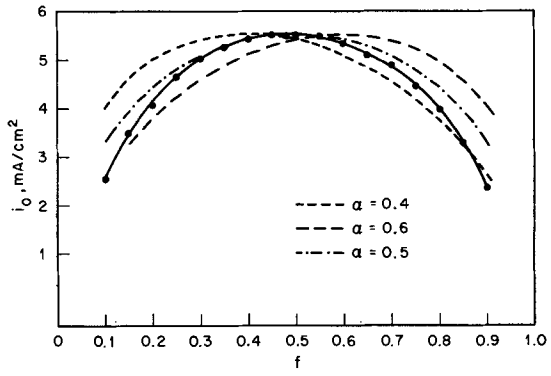

Fig. 7. Plot of i_o vs. f for 9.7 mM Fe(III) in 0.1M HCl-1.0M NaCl at gold. Data from modulation procedure, calculated as described in the text. Also shown are theoretical i_o-f plots for α = 0.4, 0.5, and 0.6 (dashed lines). The maximum of each α curve is made coincident with the experimental curve at $\alpha = f$.

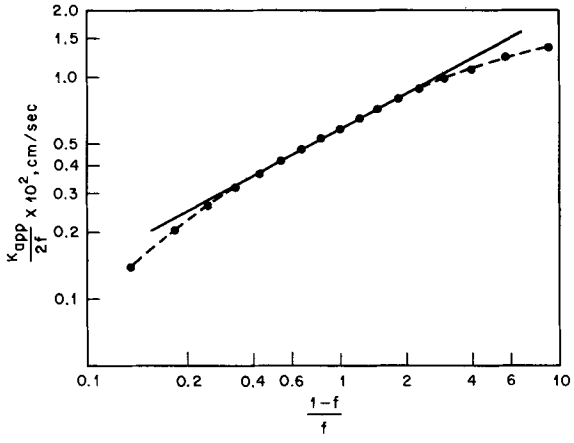

Fig. 8. Plot of log $k_{app}/2f$ vs. log $[(1 - f)/f]$ for data of Fig. 7. Slope, from linear portion, is $1 - \alpha = 0.52$. $(k_{app}/2f)_{f=1/2} = 5.85 \times 10^{-3}$ cm/sec.

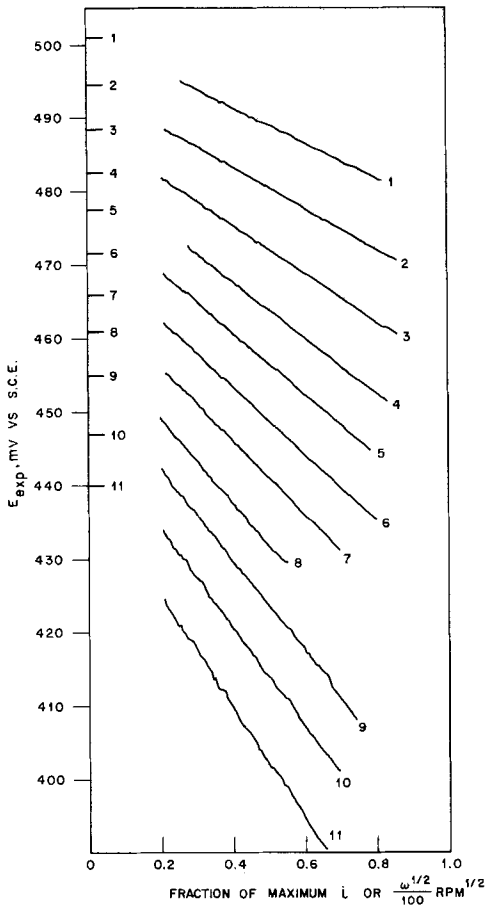

Fig. 9. ISCVA data for 9.7 mM Fe(III) in 0.1M HCl-1.0M NaCl solution at gold at different values of f. Actual data shown. E_{eq} obtained by the extrapolation to zero current of each tracing is indicated. f values for the experimental lines are 1—0.260, 2—0.312, 3—0.364, 4—0.416, 5—0.468, 6—0.520, 7—0.572, 8—0.624, 9—0.676, 10—0.728, 11—0.780.

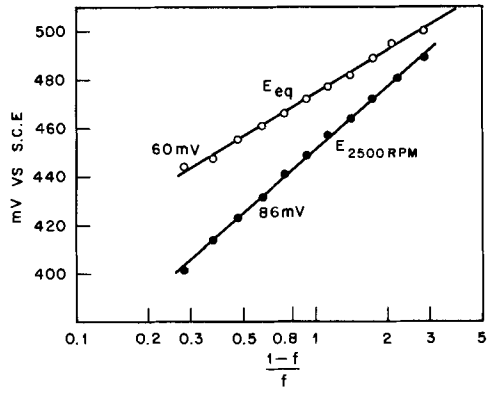

Fig. 10. Plot of E_{eq} vs. log $[(1 - f)/f]$ from zero i extrapolations of Fig. 9 traces. Experimental slope is 60 mV. A plot using E_{exp} from the 2500 rpm current points of Fig. 9 showing slope 86 mV is also included.

moved from unity. The curvature of high f is partly due to the deviation of $\Delta\eta/\Delta i$ from theoretical values, *i.e.* [26]. Changes of α over extended potential ranges, particularly when using our simplified form of the rate equation [2], may be responsible for the curvature at low f values [see Delahay (1)].

Evaluation of E_f and n.—E_{eq} was determined as a function of f using the above-mentioned 9.7 mM Fe(III) solution in the chloride electrolyte. ISCVA scan measurements were interpreted using [11], and the data used for the extrapolation of E_{exp} to zero current are shown in Fig. 9. The i-E plots in Fig. 9 are all linear, some over a relatively large E range. This is not inconsistent with the error conclusions based on Fig. 1 since (*a*) in 9.7 mM Fe(III) the IR drop represents about 25% of η_{app} and (*b*) the value of α (= 0.48) is almost optimum for minimized deviation from linearity.

The plot of E_{eq} *vs.* log $[(1 - f)/f]$ according to [21] (f is substituted for i/i_c) is given in Fig. 10. The slope of this plot yields $1/2.303\ n\phi = 60$ mV, in keeping with a one-electron redox process. Using the value of E_{eq} at $f = 1/2$, the diffusion coefficient ratio for Fe(III) and Fe(II) previously obtained from the i_c/i_a ratio, and [21], a formal potential, E_f, of 470 mV *vs.* SCE is found. The latter value is in satisfactory agreement with the values of Barnartt (20). He reported 465 and 464 mV, on the basis of potentiometric data for 40 and 200 millimolal total Fe(III) and Fe(II) solutions, respectively, in nearly the same electrolyte.

The original E_{exp} *vs.* f data were used to obtain a plot of E_{exp} at 2500 rpm *vs.* log $[(1 - f)/f]$. This conventional voltammetric plot is included in Fig. 10 and has a markedly irreversible slope of 86 mV/decade. It is apparent that a single conventional i-E curve obtained at constant ω is of little value in estimating n or E_f. *In lieu* of the ISCVA technique, the tedious manual procedure involving (*a*) the determination of i-E curves at different constant angular velocities, followed by (*b*) plotting E_{exp} *vs.* i at constant f to obtain E_{eq} at $i = 0$ could be used to obtain n and E_f by means of [21].

When the scan data in Fig. 10 were used in a plot equivalent to Fig. 7, they gave considerably more scatter and a much less precise estimate of α as com-

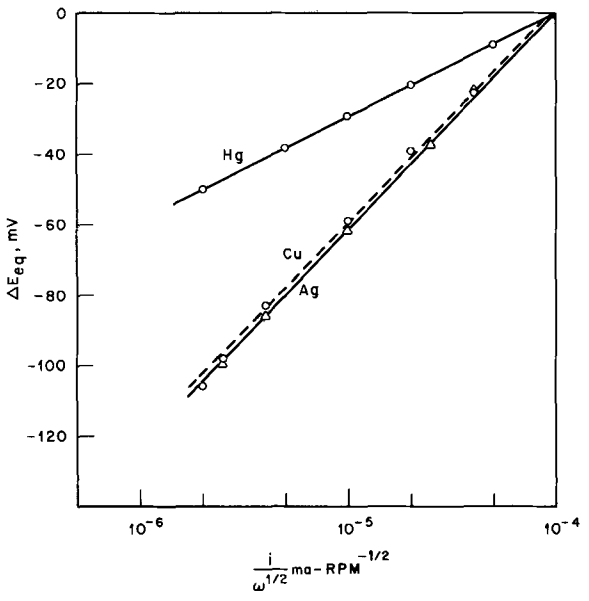

Fig. 11. Plot of ΔE_{eq} vs. log $\left(\frac{i}{\omega^{1/2}}\right)$ for oxidation in three metal/supporting electrolyte systems: Ag in 1M $HClO_4$, Cu in 1M HCl, and Hg in 1M $HClO_4$. $\Delta E_{eq} = (E_{eq})_{(i/\omega^{1/2})_{max}} - (E_{eq})_{i/\omega^{1/2}}$. Each point represents the zero current extrapolation of an E_{exp}-i plot at constant $i/\omega^{1/2}$. Slopes in mV are 62 (Ag), 62 (Cu), and 29 (Hg).

pared to the results obtained with the modulation data. The reproducibility of R_{exp} obtained by scanning was a few per cent, quite satisfactory for i_o, E_{eq}, or n determination, but distinctly less so for the α procedure.

The i-η characteristic of fast metal dissolution reactions may be curved if α is quite different from 0.5 and/or rate determining solid-state processes rather than simple electron transfer govern the kinetics. If this curvature is not extreme, extrapolation of a limiting tangent to the potential-axis ($i \rightarrow 0$) will produce relatively small errors in E_{eq}. In two cases, Ag/Ag(I) in 1.0M $HClO_4$ and Cu/Cu(I) in 1M HCl, complications produce curvature. The very fast electron transfer process for Hg/Hg_2^{+2} in 1M $HClO_4$ exhibits no curvature. Three examples of plots of ΔE_{eq} vs. log $(i/\omega^{1/2})$ are given in Fig. 11. The value of $i/\omega^{1/2}$ in each case is proportional to the metal ion concentration and the slope should be $1/2.303\ n\phi$. For $Ag \rightarrow Ag^+ + e$ and $Cu + 2\ Cl^- \rightarrow CuCl_2^- + e$, both slopes found from Fig. 11 are 62 mV, and for $2\ Hg \rightarrow Hg_2^{++} + 2e$, the slope is 29 mV, as expected.

The detailed treatment of the kinetics in these three cases involves certain refinements, either theoretical or experimental as the situation requires, beyond the scope of this discussion, and therefore will be considered elsewhere. The plots in Fig. 11 indicate that E_{eq}, n, and therefore related parameters such as stability constants for metal/electrolyte systems may be conveniently obtained by oxidation under ISCVA conditions in the appropriate supporting electrolyte. The determination of stability constants by this method requires a knowledge of the diffusion coefficients of the aquo and complexed ions. The latter data are obtainable from Levich constant determinations using a single known concentration of the ion (which can be coulometrically generated) in the two supporting electrolytes.

Summary and Conclusions

The advantages of isosurface concentration voltammetry at rotating disk electrodes have been exploited in the study of electrode kinetics. i-η data have been automatically obtained at fixed surface concentrations of all electroactive species by scanning i while holding $i/\omega^{1/2}$ constant. The variation of apparent resistance, $\Delta\eta/\Delta i$, with different constant surface concentrations (regulated by $i/\omega^{1/2}$ control) has been used to separate the charge transfer and uncompensated ohmic components of this resistance. Charge transfer rate constants and the symmetry factor, α, have been found. Equilibrium potentials and the number of electrons transferred in the electrode reaction have been established using the same data by extrapolation to zero current.

Although the kinetic systems treated were chosen to permit the ISCVA data to be interpreted on the basis of the linearized rate equation, this need not be the case. The use of the experimental scheme for automatic $i/\omega^{1/2}$ control should be of general kinetic use since the ISCVA data may be treated applying the generalized rate expression. Concentration polarization may be important even in the Tafel regime in many experimental situations, and any method depending on simultaneous electrogeneration of the potential determining species requires knowledge of the relevant surface concentrations.

The automatic scanning and modulation aspects of the ISCVA technique make available certain favorable characteristics of pulse and relaxation methods, while retaining the theoretical advantages of the steady-state regime. In ISCVA experiments, rapid changes of the equilibrium state are accomplished and measured without the necessity of considering non-steady state behavior.

Electrochemical Behavior of Substituted Oxadiazoles

G. L. Smith and J. W. Rogers

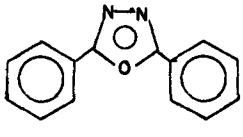
Department of Chemistry, Midwestern University, Witchita Falls, Texas 76308

ABSTRACT

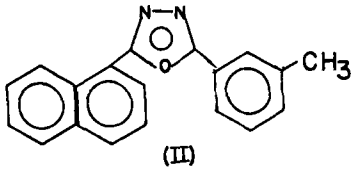
An electrode reduction mechanism is reported for two aromatic-2,5-substituted oxadiazoles in DMF solvent as part of a continuing study of the electrochemistry of five-membered nitrogen oxygen heterocyclics. Polarography, cyclic voltammetry, chronoamperometry, and uv spectroscopy were techniques employed in the study. The effects of a proton donor on the stability of reduction intermediates is discussed.

Reports of the application of electroanalytical techniques to problems dealing with oxidation-reduction properties of molecules are extensive (1-3). A number represent studies dealing with heteroaromatic compounds of general chemical or biochemical importance (4-6). We wish to report in this paper the work that has continued in this laboratory on the electrochemical reduction of various oxazoles and oxadiazoles in aprotic media.

It has previously been shown that both symmetrically and nonsymmetrically 2,5-aromatic-substituted oxazoles are reduced in two polarographic steps in N,N-dimethylformamide (DMF) via the same mechanism (7). In contrast, further investigations show that the mode of reduction of 2,5-aromatic-substituted oxadiazoles is quite sensitive to the nature of the aromatic substituents. The results of polarographic, potentiostatic, cyclic voltammetric, and spectrophotometric investigations of 2,5-diphenyl-(I) and 2-(m-tolyl)-5-(1-naphthyl)oxadiazole(II) in aprotic and protic media are presented.



(I)



(II)

An electrochemical reduction mechanism is postulated to explain the experimental results.

Experimental

Apparatus.—The instrumentation, cells, and electrodes have been described elsewhere (7). All uv-visible spectra were recorded with a Perkin-Elmer 202 uv-visible spectrophotometer.

The product resulting from mass electrolysis of II at the third plateau was recovered from the electrolysis solution by successive benzene extractions from a 50% water electrolysis-solution mixture. The benzene was removed under vacuum and the residual brown oil was eluted from a silica gel column with chloroform. One primary fraction was observed and collected.

Key words: electrochemical reduction oxadiazole.

Chemicals.—Compounds I and II were obtained commercially from Alfred Bader Chemicals. Purification by recrystallization from pure methanol did not change the melting ranges of 138°-140° for I and 122°-127° for II. Hydroquinone was obtained from J. T. Baker Chemical Company and was recrystallized from a 50% water-ether solution before use. Spectroquality N,N-dimethylformamide containing approximately 0.03% water was obtained from Eastman Organic Chemicals. It was vacuum distilled at 70°C from anhydrous $CuSO_4$ before use. The tetra-N-propylammonium perchlorate was produced and purified as previously described (7).

Results

Polarography at a DME.—The compound 2,5-diphenyloxadiazole (I) exhibits two well-defined polarographic waves in DMF solvent at −1.87 and −2.24V *vs.* saturated calomel electrode (SCE). Behavior and characteristics of the waves (Table I) suggest that material transfer is diffusion controlled at the potential of each plateau. The first wave appears to be the result of a reversible one-electron transfer, the second also a one-electron but complicated by a coupled chemical reaction.

The compound 2-(m-tolyl)-5-(1-naphthyl)-oxadiazole (II) is reduced at a DME in three diffusion-controlled steps at −1.72, −2.11, and −2.43V *vs.* SCE in DMF solvent, Table I. The first two waves appear to represent polarographic processes analogous to those of the two waves of (I). The structure and behavior of the third wave suggest that it is the result of a complex multielectron transfer.

Voltammetry at solid electrodes.—Typical cyclic voltammograms of I are shown in Fig. 1. Voltage excursion and reversal at potentials more negative than the first $E_{1/2}$ at a planar platinum disk electrode

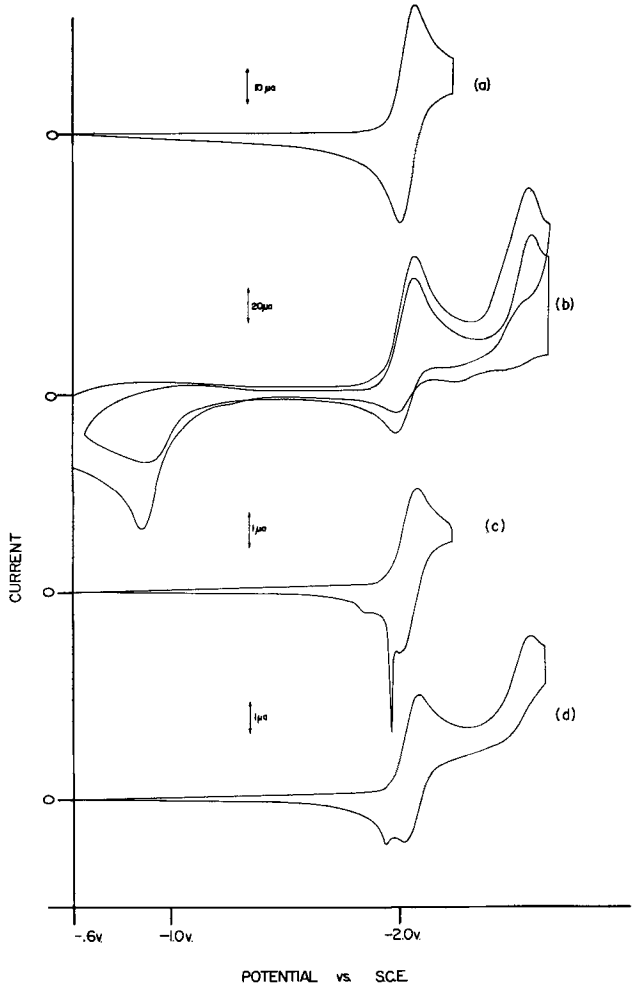

Fig. 1. Cyclic voltammograms of 2,5-diphenyloxadiazole (I) in DMF solvent at (a) a PPDE with sweep reversal 120 mV past first wave, (b) a PPDE with multicyclic sweep reversed 80 mV past second wave with 5-sec hold on second sweep, (c) a HMDE with sweep reversal 120 mV past first peak, (d) a HMDE with reversal and hold 60 mV past second wave. All solutions were 1 mM in compound (I) and 0.1M in TPAP supporting electrolyte. Spectroquality DMF was dried and distilled for experiments described in a and b only.

(PPDE) in DMF produces a voltage-current curve exhibiting properties indicative of a fast, one-electron transfer with no rapid following reactions, Table II (8). Cyclic experiments at a PPDE carried to potentials above the second $E_{1/2}$ produce a reduction current peak with no corresponding anodic current, Fig. 1. The current-peak potential, $(Ep)c$, shifts cathodic and the current function, $(ip)c/v^{1/2}$), decreases with increasing potential sweep rate (v). This behavior suggests that the electron transfer is followed by a rapid homogenous reaction (8). Cyclic experiments in which the potential is held briefly ($\sim$ 3 sec) above the second $E_{1/2}$, reveals a greatly reduced monoanion oxidation peak and an intense follow-up oxidation current at -0.75V on the anodic going segment, Fig. 1. Multicyclic experiments show that the follow-up peak has no corresponding reduction wave, Fig. 1. This behavior is analogous to that of substituted oxazoles and suggests that the product of the reaction following the second electron transfer is oxidized to the parent oxadiazole at the follow-up peak. Compound I exhibits similar behavior at a hanging mercury drop electrode (HMDE).

The influence of small amounts of water impurity on the first wave of I in voltammetric experiments conducted at solid electrodes is pronounced. The cathodic current half-peak height to full peak sepa-

ration, $(Ep)c/2 - (Ep)c$, is broadened slightly and the cathodic to anodic current ratio, $(ip)c/(ip)a$, becomes less than 1.0 at all potential sweep rates in experiments conducted in spectroquality DMF not treated with a drying agent and redistilled before use, Table II. The effect is most pronounced in experiments conducted at a HMDE, Table II. On mercury, a product adsorption peak is observed anodic of the diffusion peak representing oxidation of the anion radical, Fig. 1. The increased impurity level has no influence on the character or behavior of the second wave on platinum or mercury, Table II. The broadened cathodic wave and the enhanced anodic current at the PPDE cannot be explained totally in terms of adsorption of reactant or product or any other one electrochemical phenomenon. It does seem consistent, however, to postulate that the anion radical is protonated to a certain degree and the resulting neutral radical is adsorbed (9). This explanation for the platinum, as well as the mercury electrode, is substantiated by experiments in which the switching potential exceeds the second plateau. A diminished anion oxidation current and the absence of an adsorption peak, Fig. 1, suggest that the reaction occurring at potentials above the second $E_{1/2}$ removes any adsorbed species.

Typical voltammograms of compound II in DMF taken at a PPDE are shown in Fig. 2. The voltammetric data is summarized in Table III. The invariance of the current function, $(ip)c/v^{1/2}$, $(Ep)c/2 - (Ep)c$, and the ratio, $(ip)c/(ip)a$, of the first wave to the sweep rate is again indicative of a reversible one-electron process producing a radical species stable during the course of the experiment (8). The 30 mV cathodic shift and the 10% decrease of the current function of the second wave with a ten fold increase in sweep rate is indicative of a rapid chemical reaction following a reversible electron transfer (8). Identical to the behavior of I, the oxidation of the product of the reaction occurring at the second wave of II is noted to occur anodic of the anion radical oxidation peak, Fig. 2. These observations certainly suggest that the first two waves of II and the two waves of I represent identical electrochemical processes. Further evidence for this assertion is presented.

The cathodic peak of the third cyclic voltammetric wave of II shifts cathodic and the current function markedly decreases with an increase in potential sweep rate, Table III. The great sensitivity of the current function to the sweep rate can probably be attributed to a large n apparent.

[a] Solution was 1 mM in compound II and 0.1M in TPAP in dried spectroquality DMF.
[b] $(ip)a$ was measured by employing the potential hold method. Potential was reversed 120 mV past $(Ep)c$.
[c] $(ip)c$ for waves two and three was measured by extrapolating current from previous peak.

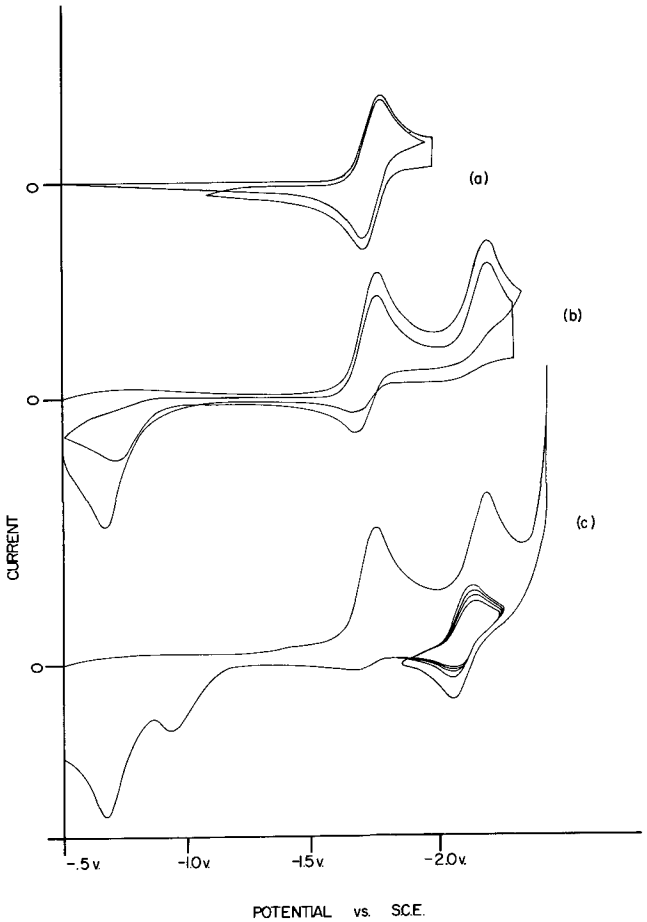

Fig. 2. Cyclic voltammograms of 2-(1-naphthyl)-5-(m-tolyl)-oxadiazole (II) in DMF solvent at a PPDE (a) with sweep reversal and reversal and hold 120 mV past first wave, (b) with sweep reversal and reversal and hold 100 mV past second wave, (c) with reversal and hold on rising portion of third wave followed by multicyclic sweep in potential region showing reversible reduction of third-wave product. All solutions were 1 mM in compound (II) and 0.1M in TPAP supporting electrolyte in dried spectroquality DMF.

Chronoamperometry.—The potential step-chronoamperometric experiment often may be simply and effectively employed in the determination of n apparent values. Plots of $it^{1/2}$ *vs.* t from diffusion current-time decay curves recorded at a constant potential corresponding to the first polarographic plateau of each compound yield straight lines of zero slope that may be employed as one-electron reference points. Similar plots from experiments carried out at potentials of the second wave of I and the second and third waves of II yield straight lines of approximately zero slope. This behavior is expected for very rapid following reactions (10). The potentiostatic data and n apparent values are summarized in Table III.

The n apparent values and the voltammetric and polarographic behavior show that the reduction of I, and the first two reduction steps of II, closely parallels that of 2,5-diphenyloxazole (7). The mechanism may be represented in the following manner:

First wave

$$R + e^- \rightleftarrows R^{\cdot -}$$

Second wave

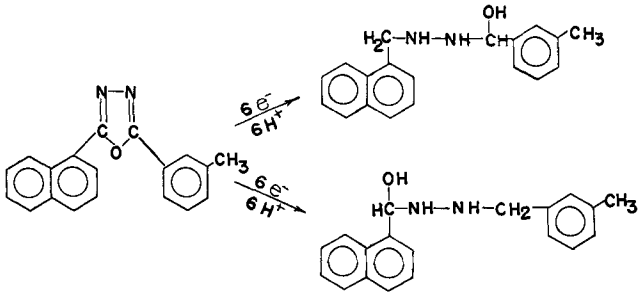
$$R^{\cdot -} + e^- \rightleftarrows R^=$$

$$R^= + SH \rightarrow RH^- + S^-$$

Production oxidation wave

$$RH^- \rightarrow R + H^+ + 2e^-$$

The n apparent of 6.0 for processes carried to potentials above the third wave of compound II strongly suggests very rapid, complete saturation and ring opening reactions of the type:



This reaction is also suggested by the work of Bezuglyi *et al.* (11) with oxadiazoles in protic solvents. The extent of the reduction process even in an aprotic solvent such as DMF reveals the great basicity of the transient intermediate reduction products of II.

Mass electrolysis.—Compounds I and II were mass electrolyzed at a mercury pool cathode in DMF solvent at predetermined potentials corresponding to various polarographic steps. The experiments were conducted to further study the stability of the postulated reduction products, $R^{-}\cdot$ and RH^{-}. The course of each electrolysis experiment was followed with uv spectroscopy and with an *in situ* three-electrode configuration employed to oxidize the mass electrolysis products (7).

Electrolysis of both compound I and II at potentials corresponding to the first polarographic plateau produces an intensely yellow solution sensitive to small quantities of O_2. The parent compound absorbance of uv spectra taken of aliquants of the electrolyzed solutions over a 2-hr period showed only a slight decrease. Oxidation of the yellow solution at a PPDE showed one intense current peak with a potential corresponding to the oxidation of the monoanion of the parent compound. This behavior exactly parallels that of oxazole compounds (7).

Electrolysis of both compounds at potentials corresponding to their second diffusion plateaus produces a purple solution that is stable in the presence of N_2 but unstable to small amounts of O_2. Oxidation of the purple solution at the *in situ* PPDE after about 1 hr of mass electrolysis shows two small current peaks, one appearing at the potential corresponding to the oxidation of the monoanion and the other at the potential corresponding to the oxidation of the EC process product, RH^{-}. The oxidation peak of RH^{-} does not increase significantly even after exhaustive electrolysis. The uv absorbance of the parent oxadiazole shows that the substance undergoes an irreversible reaction at the potential of the second wave at a rate not detectable on the time scale of the rapid cyclic or potentiostatic experiments but more rapid than similar reactions of oxazoles (7). The exact nature of the reaction product has not been determined.

Effect of proton donors.—The nature of the proposed electrochemical reactions suggests that the addition of proton donating substances should have a pronounced effect on the reduction process responsible for each voltammetric wave. Hydroquinone (HQ) has been shown to be useful in studies of this type (12).

Figures 3 and 4 illustrate the effect of added HQ on the polarographic behavior of compounds I and II. The first wave of I is only slightly perturbed by the addition of the proton source. The polarographic $E_{1/2}$ is not shifted significantly even with the addition of

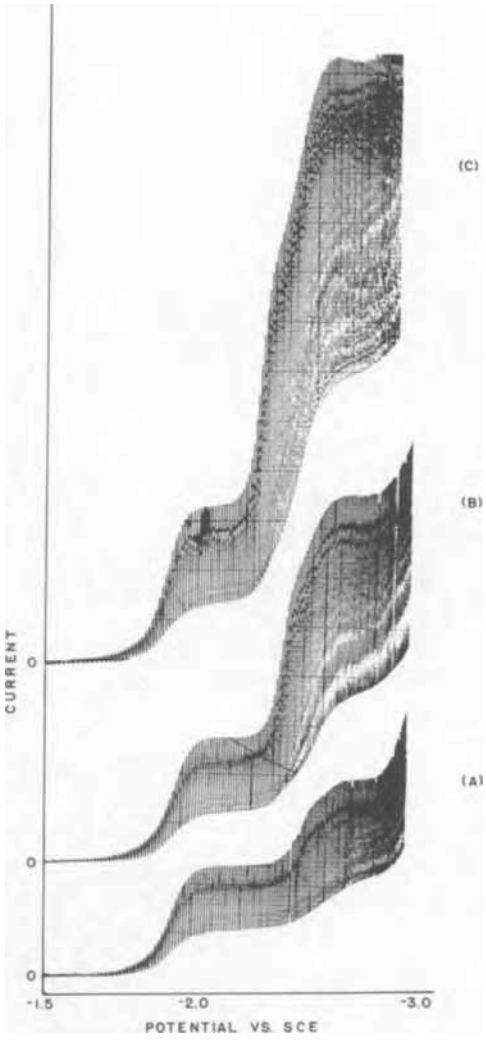


Fig. 3. Polarograms of 2,5-diphenyloxadiazole (I) in DMF showing effect of added hydroquinone (HQ). (a) No HQ, (b) 10 mM in HQ, (c) 60 mM in HQ. All solutions were 1 mM in compound (I) and 0.1M in TPAP supporting electrolyte.

enough HQ to produce a 0.06M DMF solution. However, the wave is broadened and the diffusion current is enhanced slightly by this addition of HQ, Fig. 3. The first wave of compound II is influenced in a similar manner, Fig. 4.

The second wave of compound I shifts anodically as HQ is added to the test solution, Fig. 4. There is a simultaneous, pronounced increase in the diffusion current approaching a limiting value at high concentrations of the proton donor, Fig. 3. The n apparent becomes approximately six at the higher HQ concentrations.

The great sensitivity of the diffusion current of the second polarographic wave of I to small quantities of solvent impurity is illustrated by a comparison of polarograms of I, 1 and 0.1 mM, in spectroquality DMF containing approximately 0.03% H_2O. This represents a ratio of electroactive compound to water impurity of 1/5 in the concentrated solution and 1/50 in the dilute mixture. The ratio of the first diffusion current to the second of the two plateaus is 1/1 in the more concentrated solution and 1/1.5 in the dilute. Decreasing the oxadiazole to proton source ratio in the concentrated solution to a value of 1/30 by adding HQ results in a first to second plateau diffusion current ratio of 1/1.9. This result suggests that water is almost as effective a proton donor in DMF as HQ, a result not noted in the study of aromatic hydrocarbons in aprotic media (13).

The second and third waves of compound II coalesce at low HQ concentrations (~7 mM) to one wave with

Table IV. Potential step chronoamperometric data for reduction of compounds I and II in DMF

Compound	Potential, V (V vs. SCE)	$it^{1/2}$ (μA sec$^{1/2}$)[b]	n apparent
2,5-Diphenyloxadiazole (I)	−1.96	38.86	1.0[c]
	−2.42	82.84	2.1[d]
2-(m-tolyl)-5-(1-naththyl)-oxadiazole (II)	−1.75	34.16	1.0[c]
	−2.18	71.63	2.1[d]
	−2.52	205.85	6.0[d]

[a] Solutions 1 mM in electroactive compound and 0.1M in TPAP. Experiments conducted at a PPDE having a cross sectional area of 0.78 cm^2.
[b] Values computed for times ranging from 0.75 to 4.0 sec.
[c] Assigned by various criteria discussed in text.
[d] Calculated by reference to $it^{1/2}$ value at first-wave potential.

an $E_{1/2}$ approximately the same as the second wave of II in dried DMF and with an n apparent of approximately six, Fig. 4. The diffusion current of the combination wave increases slightly with additional HQ but does not exhibit the great sensitivity noted of other waves.

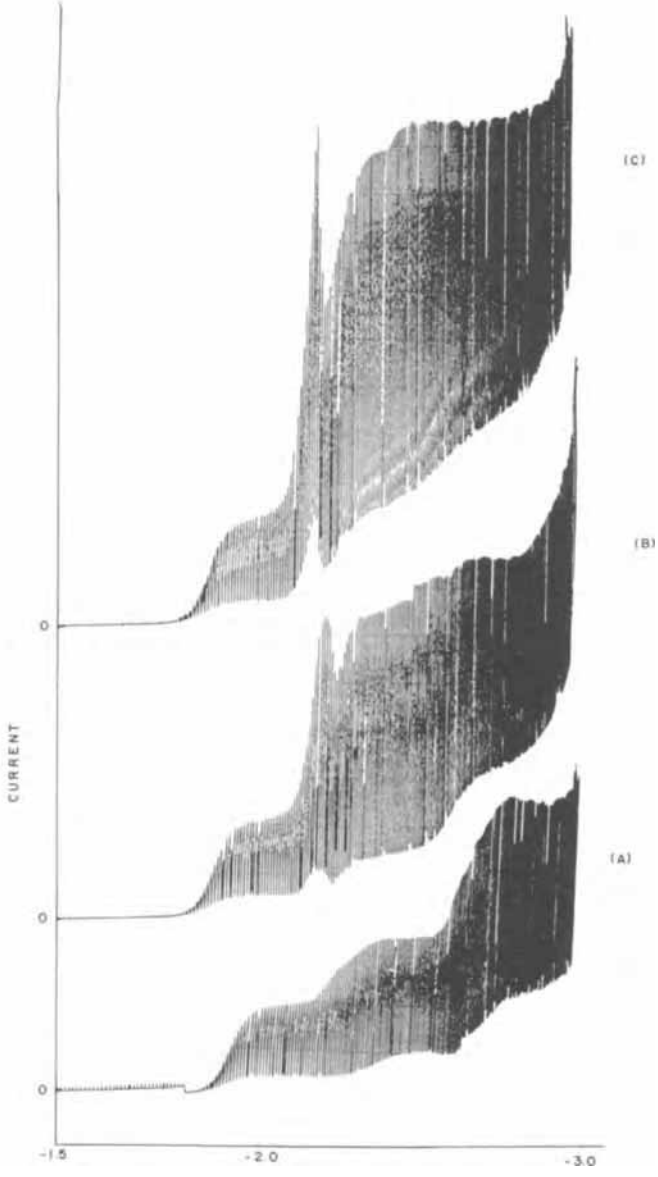

Fig. 4. Polarograms of 2-(1-naphthyl)-5-(m-tolyl)-oxadiazole (II) in DMF showing effect of added hydroquinone. (a) No HQ, (b) 6 mM in HQ, (c) 20 mM in HQ. All solutions were 1 mM in compound (II) and 0.1M in TPAP supporting electrolyte.

These results suggest the following mechanism for reduction of compounds I and II in the presence of HQ.

First wave

$$R + e^- \rightleftarrows R\cdot^-$$

$$R\cdot^- + HQ \rightarrow RH\cdot + Q^- \text{ (EC process)}$$

Second wave

$$RH\cdot + 5e^- + 5HQ \rightarrow \text{Ring opened products}$$

In contrast to oxazoles (7), other heteroaromatics and aromatic hydrocarbons (14), the protonated monoanion radical does not appear to undergo further significant reduction (an ECE process). The great dependency of the diffusion currents of the second polarographic waves of I and II is consistent with the noted instability of RH^- in the mass electrolysis experiments. This species is apparently a stronger base than the corresponding oxazole radical (7).

Summary and Discussion

Electrochemical information presented in his paper and that presented previously (7) show that aromatic-2,5-substituted oxazoles and oxadiazoles are reduced via similar mechanisms in DMF solvent. Differences in reactivity of the common reduction intermediates $R\cdot^-$ and RH^- are noted. The anion radicals of the oxadiazoles studied appear to be quite basic. These are protonated by small amounts of water. However, addition of proton donors show that the protonated radical is not significantly reduced at the potential of the first-electron addition step.

The protonated dianion of both oxadiazoles, produced by the EC process of the second polarographic step, appear to be significantly more reactive than the analogous species derived from oxazoles. The species reacts rapidly with small quantities of added hydroquinone forming saturated and ring opened products.

The nonsymmetrically substituted oxadiazole exhibits a third polarographic wave in dry DMF solvent. Addition of small quantities of HQ to the electrolysis solution shifts the $E_{1/2}$ of the wave to coincide with the second wave but does not greatly alter the n apparent of 6. This behavior is consistent with an exhaustive reductive process with a rate greatly dependent on the proton availability of the medium.

The oxidation going segment of cyclic experiments in dry DMF in which the electrolyzing potential is held at the third wave of compound II for several seconds reveals the existence of a reversible product couple with an $(Ep)c$ of −2.31V, Fig. 2C. The postulated neutral product of the third polarographic step may be thought of as a substituted naphthylene. This aromatic substance is expected to exhibit a one-electron reversible wave in DMF near the potential of the product wave, Fig. 2C (15). The existence of the reversibly reducible product may be construed as substantiation of the reduction process postulated as responsible for the polarographic wave.

More direct evidence for this postulated process is found in the IR spectrum of the product isolated from a DMF solution of II exhaustively electrolyzed at a potential controlled at the third plateau. The appearance of bands at 3200, 2900, and 3400 cm^{-1} when the product is dissolved in CCl_4 strongly suggests the electrolytic production of hydroxyl, alkyl, and secondary amine functions. The purified product melted in the range 90°-95°C.

Dissolution of Barrier Layer of Aluminum in Sulfuric Acid Electrolyte Containing Cs^+ Ion

Michiko Shimura

Faculty of Engineering, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo, Japan

ABSTRACT

Examination of the recovery phenomenon for the anodic oxidation of aluminum in sulfuric acid electrolytes containing Cs^+ ion confirmed the suppression of the dissolution of the barrier layer. Lengths of the induction period and the current-increasing period in the recovery region were recorded. Electron microscope studies were carried out on samples taken out at the recovery region to examine the pore structure. Since the recovery currents result from the dissolution of barrier layers at the bottom of primary pores, the dissolution rates were calculated from the length of the induction period in the recovery region for $CsHSO_4$ and H_2SO_4 electrolytes. The conclusions are: (*i*) the presence of Cs^+ ions decreases the frequency factor for the dissolution process, and (*ii*) Cs-alum seals the porous layer of the oxide film and makes the steady-state current smaller.

Porous oxide film is produced by local action of electrolytes when aluminum is anodized in acid solutions. The action is temperature dependent (1, 2) and is promoted chiefly by protons in the electrolyte (1, 3) and the electric field across the barrier layer (4). The presence of an alkali metal ion such as Cs^+ improves the hardness and the coating ratio of the films (5), since an alum is deposited tightly on the porous film shortly after the beginning of the anodic oxidation. The stability of the alum increases in the order of the ionic radii of the alkali metal ions (6). The effect of Cs^+ ions on the dissolution process of the barrier layer was elucidated by examining the porous structure of the anodic films taken out at the so-called recovery period (7) during anodization.

Experimental Procedures

Observations with the oscilloscope.—Aluminum foils of 99.99% purity, 1 x 2.5 cm, were carefully electropolished in H_3PO_4-CrO_3-H_2SO_4 electrolyte and stripped in H_3PO_4-CrO_3 solution just before anodic oxidation. A 1.8*M* $CsHSO_4$ (*p*H 0.6) solution was used for the oxidation, and H_2SO_4 of the same *p*H value for a reference run. The *p*H values were adjusted to be the same since the dissolution of the film was largely dependent on the concentration of protons in the electrolyte. Parallel circuits were constructed in order to perform the oxidation simultaneously in $CsHSO_4$ and H_2SO_4. Constant voltages E_1 and E_2 were applied from two d-c power supplies. Anodization was carried out for a certain time at the higher voltage (E_1). Afterward the voltage was switched down to the lower voltage (E_2). Throughout the whole period, the I-t curves were recorded by the oscilloscope. The results were obtained in the range of 10°-40°C, E_1 = 9-15V, E_2 = 8V, length of the initial oxidation at E_1 being 90 sec to 200 min.

Examination by electron microscope.—In case of fairly thin films, anodized samples were cut off with about the size of 3 x 3 mm and immersed in CH_3OH-I_2 solution to peel off the oxide film. After rinsing with CH_3OH, the oxide films were examined by direct transmission electron microscopy using JOEL electron microscope model JEM 100. For thick films, the two-step cellulose-carbon replica technique was used. The numbers of pores were counted at a magnification of 180,000 and averaged on three different 3 x 3 cm squares. The spots were selected at random. The porosities were obtained by summing up the pore areas in the squares.

Results

Recovery effect at E_1 = 10V (5 min) and E_2 = 8V.—When the samples were anodized at 10V (E_1) in the temperature range of 10°-40°C, the current rapidly decreased to a minimum and subsequently increased to a steady-state value which became larger with the electrolyte temperature. After anodizing for 5 min under this condition, the applied voltage was switched to 8V. The current decreased suddenly to almost zero, stayed there for a while, the induction period depending on the electrolyte temperature, *i.e.*, 70 sec at 10°C, 20 sec at 25°C, and 7 sec at 40°C, and then increased to retain new steady states (Fig. 1). The existence of Cs^+ ion extended the induction period to a small extent and slightly reduced the new steady current.

Effect of prolonged anodization at the initial voltage.—In connection with the amount of alums produced, the induction period was examined as a function of

* Key words: oxide dissolution, barrier layer, aluminum.

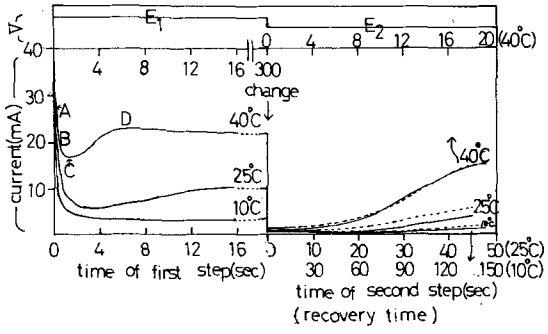

Fig. 1. I-t curves at two step oxidation, left, first step (E_1 = 10V) and right, second step (E_2 = 8V), ——— in $CsHSO_4$, – – – – in H_2SO_4.

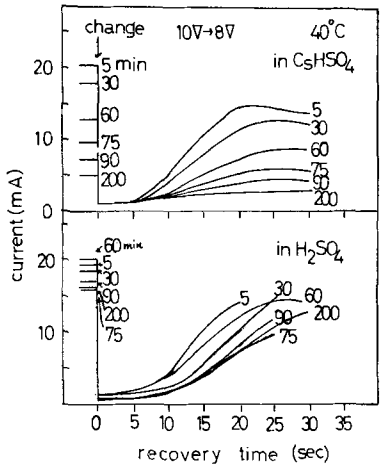

Fig. 2. Recovery behavior at various durations of E_1

the anodizing time at the initial voltage at 40°C. As is shown in Fig. 2, the induction periods did not change with the prolongation of the anodic oxidation either in $CsHSO_4$ or H_2SO_4 within 200 min. The steady-state currents at the end of the anodization both at 10V and 8V decreased with the prolongation of the oxidation in $CsHSO_4$, whereas they did not in H_2SO_4. As is discussed later with the results of the electron microscope study, the decrease of the current is explained by the sealing action of Cs-alum near the top of the pores.

Recovery effect at various voltage differences.—Figures 3 through 6 show the recovery effect at the voltage differences ΔE = 4V (12V → 8V) and ΔE = 6V (14V → 8V). The induction periods became larger with the increase of ΔE both in $CsHSO_4$ and H_2SO_4 electrolytes. The prolongation of the anodic oxidation at E_1 never changed the length of the induction period, not even at increased values of E_1. The ratio of steady-state currents, $I_{(E_2)}/I_{(E_1)}$ decreased with the anodizing time at E_1. The trend is more distinct for the increase

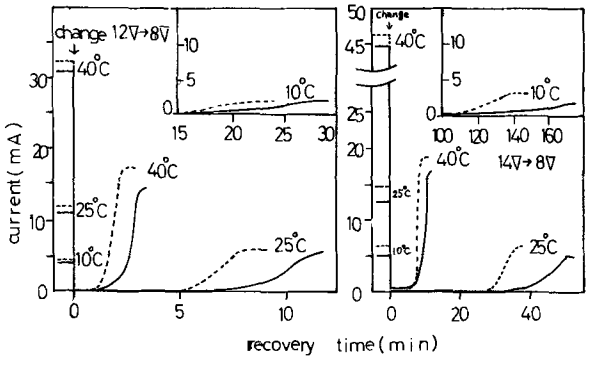

Fig. 3 (left) and Fig. 4 (right). Recovery behavior of two step oxidation; ——— in $CsHSO_4$, – – – – in H_2SO_4.

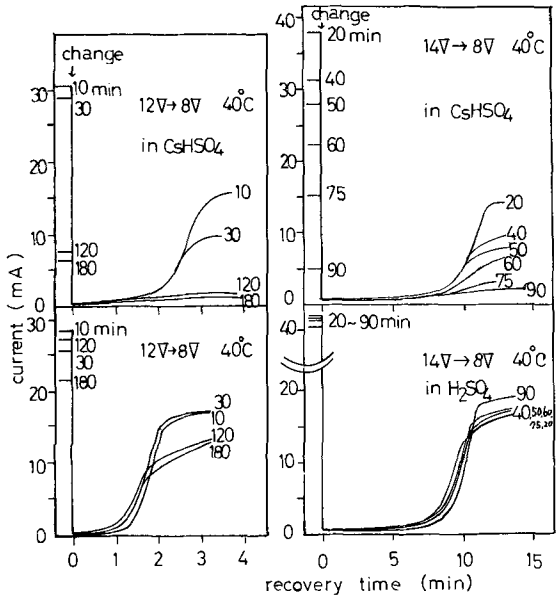

Fig. 5 (left) and Fig. 6 (right). Recovery behavior at various durations of E_1.

of ΔE at a fixed value of E_2. This suggests that the sealing of the pores with Cs-alum proceeds vigorously in the recovery region at a higher voltage E_1. The following results also confirm the sealing mechanism. The steady-state current increases exponentially with the applied voltage (8). The steady-state current is attained when the dissolution rate of the oxide at the bottom of pores is equal to the current density for the oxide formation. The rate of formation of Cs-alum is determined by the concentration of the dissolved Al^{3+} ions in the equation

$$v = k[Al^{3+}][Cs^+][SO_4^{2-}]^2$$

I-t curves plotted in a logarithmic scale are distinctly divided into an induction period and a region of increasing current. For the former region, the change of the current is too small to measure. For the latter region, the slope is nearly uniform in spite of changes of temperature, electrolytes, and voltage difference. Accordingly, the current increase should be caused by other types of dissolution than the conventional chemical dissolution. Diggle *et al.* (4) introduced field-assisted dissolution. As is shown in the next section, rapid dissolution of the film like the pore initiation at the early stage of anodic oxidation occurs at the current-increasing region.

Structure of the porous film taken out at recovery region.—Figure 7 shows the porous structure of the samples taken out at different times t in the recovery region when E_1 = 14V (90 sec) and E_2 = 8V. The structure of the anodic films formed in $CsHSO_4$ and H_2SO_4 is very similar. The size and the shape of the pores are somewhat irregular, and secondary pores are barely recognizable with the increase of magnification. The number of the primary pores in 3 x 3 cm squares on the pictures taken at 180,000X are roughly constant for all samples (Fig. 8). The tiny secondary pores, which have been observed dimly before the recovery region, become distinct with increasing time t. Therefore, the recovery effect is understood to thin the barrier layer by dissolution at the bottom of the primary pores (Fig. 9), allowing ionic current to flow again.

Porosities were examined at various times in the recovery region by summing the pore areas statistically (Fig. 8). The total pore area was almost constant in the recovery period but increased in the region of increasing current. Therefore, in the region of increasing current, the rate of the dissolution process is

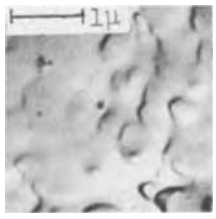

Fig. 10. Surface with Cs-alum deposits taken by replica method, 90 min, 40°C; 14V in $CsHSO_4$.

changed by some other cause than chemical dissolution.

The thickness of the oxide films differed in $CsHSO_4$ and H_2SO_4 when the initial oxidation at E_1 was longer than 5 min at 40°C. In $CsHSO_4$, the oxide film gradually thickened with time and made the direct transmission observation impossible (9). The Cs^+ ion is likely to suppress the dissolution process by decreasing the activity of the protons near the anode. After longer oxidation in $CsHSO_4$, Cs-alum was deposited and covered the surface of the oxide. It was difficult to scrape off or to dissolve by dipping in hot water (Fig. 10).

Discussion

Dissolution reaction in the recovery region.—The results of the electron microscope study clarified that the recovery effect is accompanied by the dissolution of the barrier layer at the bottom of the primary pores and that the dissolution proceeded slowly in the induction region. It was accelerated in the region where the current increased. The length of the induction period depends on the electrolyte temperature; *e.g.*, the duration at 10°C is about ten times that at 40°C in the case of $\Delta E = 2$V. Beside colorimetric analysis by Nagayama *et al.* (10) and capacitance measurements by Diggle *et al.* (4), the author's experiments (11) suggest that the dissolution is slow in the induction period, and that the concentrations of ions at the double layer of the interface oxide/electrolyte are approximately constant. Thus, the apparent reaction of the dissolution is assumed to be of zero order. Since there is an equation, $i = A \exp(B \cdot E/D)$ between current density i, applied voltage E, and the thickness D of the barrier layer, where A and B are constants, the layer thickness to be dissolved before the current begins to rise at $E_2 = 8$V is given by $D_s = (E_1 - E_2) \cdot K$, where K is a constant (*ca.* 14Å/V). The mean rate of dissolution is given by D_s/t, where t is the length of the induction period. The activation energies of dissolution were the same both for $CsHSO_4$ and H_2SO_4, Cs^+ ions having no influence on the activation energy. The frequency factor is found to decrease with the presence of Cs^+ ion. The dissolution process is governed solely by protons. Cs^+ ions are considered to decrease the local concentration of protons near the anode to some degree. Since the current tends toward a steady state some time after the pore initiation, the main role of dissolved Al^{3+} is to suppress the activity of protons.

Relation between voltage difference and activation energy of the dissolution process.—The activation energies of the dissolution process were examined as a function of the voltage difference ($\Delta E = E_1 - E_2$) when E_1 was applied for 5 min. The apparent activation energy was found higher with the decrease of the electric field across the barrier layer. The apparent activation energy W_a is the sum of the activation energy W_o and a term representing the electric field E/D

$$W_a = W_o - n \cdot F \cdot E/D \qquad [1]$$

As is shown in Fig. 11, the activation energy W_o decreases with the increase of the electric field. The electrochemically produced materials are assumed to be transformed into more soluble ones by the aid of the electric field.

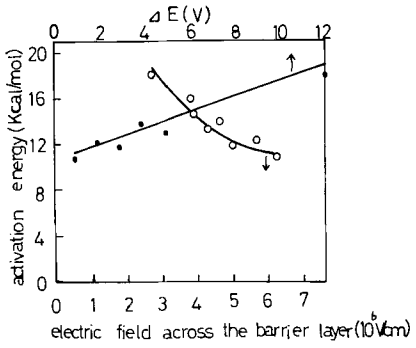

Fig. 11. Relation between apparent activation energies of dissolution process and electric field across barrier layers.

Conclusion

1. The recovery phenomenon in the induction region depends strongly on temperature while the one in the region of increasing current is independent of temperature. If the former phenomenon is regarded as zero-order dissolution, the activation energy is calculated 11-18 kcal/mole and decreases with the increase of the electric field across the barrier layer. It is in good agreement with the value obtained by Vermilyea (12) (17 kcal/mole) for the surface hydrolysis of amorphous Al_2O_3, a value close to the activation energy of diffusion for proton in many oxides. The dissolution of the barrier layer is considered to depend on the diffusion of protons through it.

2. The addition of Cs^+ in H_2SO_4 electrolyte contributes to the decrease of the frequency factor of the barrier layer dissolution.

3. Cs-alum is probably deposited at the upper part of the inner surface of pores and not at the bottom since the recovery time never changes with the prolongation of the initial oxidation when Cs-alum is deposited.

Transport Behavior in Dimethyl Sulfoxide

I. Conductance Studies

Neng-Ping Yao*,[1] and D. N. Bennion*

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Conductance of the salts $NaClO_4$, NaSCN, CF_3SO_3Na, CH_3SO_3Na, $NaB(Ph)_4$, and $(i\text{-amyl})_3BuNB(Ph)_4$ in dimethyl sulfoxide (DMSO) were determined over a concentration range 10^{-4} mole/liter to near saturation and a temperature range 25°-55°C. $NaClO_4$, NaSCN, and CF_3SO_3Na are completely dissociated while CH_3SO_3Na, $NaB(Ph)_4$, and $(i\text{-amyl})_3BuNB(Ph)_4$ appear to be slightly associated. Single-ion conductivities were determined using triisoamylbutylammonium tetraphenylboride as the reference electrolyte. The effective ionic radii for $(i\text{-amyl})_3BuN^+$, Na^+, $CF_3SO_3^-$, ClO_4^-, and SCN^- ions were determined to be 5.12, 4.32, 3.03, 2.82, and 2.37Å, respectively, at 25°C. Na^+ ion is solvated with three DMSO molecules while the $(i\text{-amyl})_3BuN^+$ ion and the anions are relatively unsolvated. The effective ionic radii in DMSO are insensitive to temperature over the temperature range studied. Activation energies for ionic conductance in dilute solutions of $(i\text{-amyl})_3BuNB(Ph)_4$, $NaB(Ph)_4$, $NaClO_4$, CF_3SO_3Na, and NaSCN are, respectively 3.50, 3.30, 3.23, 3.21, and 3.16 kcal/mole. Limiting ionic mobilities λ_o, for alkali-halide ions and other ions in DMSO at 25° are examined in the light of the Fuoss, Boyd, and Zwanzig theories of dielectric relaxation. The limiting ionic mobilities predicted by the Zwanzig theory are in qualitative agreement with the observed values, but the predicted magnitudes are low.

Dimethyl sulfoxide (DMSO) is an aprotic solvent which possesses many useful properties for applications in electrochemical systems (1) and in organic syntheses (2). Thermodynamic data which have been reported for electrolyte solutions in DMSO are some solubilities (3, 4), some acid-base equilibria (5), cryoscopic data (6), heat of solution (7, 8), and emf measurements (9-11). A few conductance studies have been reported (3, 6, 12-14). Ionic transport behavior in DMSO solutions is yet to be elucidated with systematic studies of transport parameters.

[1] Present address: Atomics International Division of North American Rockwell Corporation, Canoga Park, California 91304.
Key words: conductance, dimethyl sulfoxide, ion size, limiting ionic conductance.

This paper reports the results of conductance studies of some sodium salts in DMSO over a concentration range 10^{-4}M to near saturation and a temperature range 25°-55°C. Triisoamylbutylammonium tetraphenylboride, $(i\text{-amyl})_3BuNB(Ph)_4$, was included in the present study to provide the basis for evaluating single-ion conductivities. The effective ionic radii in DMSO were obtained and the limiting ionic mobilities for various ions in DMSO were examined in the light of the theory of dielectric relaxation (15-18).

Experimental

Solvent.—DMSO was supplied by Crown Zellerbach Corporation, Camas, Washington, in five gallon size polyethylene containers. DMSO as received was purified by fractional distillation at 3.3 mm Hg pressure and 40°C. Volume of the initial charge to the boiling flask was approximately 1500 ml. The middle portion of distilled DMSO, approximately 60% of the initial charge, was collected and was stored in a nitrogen-filled dry box for subsequent use. Kolthoff and Reddy (19) reported that refluxing over CaO or BaO caused extensive decomposition and that removal of all the decomposition products, not identified, was impossible. Since the effect of the drying agents on the degree of decomposition of DMSO is not known, no special dehydration procedure was undertaken prior to the vacuum distillation. Water content in DMSO was determined to be less than 30 ±5 ppm by electrometric titration with Karl Fischer Reagent (KFR). Repeated determinations of water concentration in distilled DMSO over several months of standing showed that water content was less than 100 ppm for all cases. NMR analysis of distilled DMSO showed no detectable organic impurities peak. However, the accuracy of the NMR analysis was limited to 0.1% based on carbon 13 calibration.

Triisoamylbutylammonium tetraphenylboride, $(i\text{-amyl})_3BuNB(Ph)_4$.—This salt was prepared following the method of Coplan and Fuoss (20). The $(i\text{-amyl})_3BuNB(Ph)_4$ was thoroughly washed and then recrystallized four times from 3:1 (v/v) acetone-water (approximately 1.5g salt/100 ml solution). The recrystallized $(i\text{-amyl})_3BuNB(Ph)_4$ formed fluffy, needle-like crystals. The salt was then dried *in vacuo* at 105°C for 21 hr. Its melting point was determined to be 275°C as reported (20). Infrared spectrum analysis showed absorption peaks at 16.5, 14.2, 13.7, 13.5, 6.77, and 3.38 μm. This spectrum does not appear to have been previously reported.

Sodium trifluoromethanesulfonate, CF_3SO_3Na.—This salt was prepared by first converting $(CF_3SO_3)_2Ba$, supplied by the 3M Company, Saint Paul, Minnesota, into an acid solution of CF_3SO_3H with dilute H_2SO_4 solution, and then the acid solution was neutralized to a neutral end point with dilute Na_2CO_3 solution. The resultant solution was evaporated to dryness under reduced pressure. The dried CF_3SO_3Na was recrystallized three times from acetone. The pure white salt was dried *in vacuo* at 140°C for 42 hr. The melting point of the salt was determined to be 248° ± 1°C which is in agreement with the value of 248°C for CF_3SO_3Na as reported by Gramstad and Haszeldine (21). Infrared spectrum of the salt showed absorption peaks at 7.9, 8.6, and 9.6 μm. Gramstad and Haszeldine (21) reported absorption peaks at 7.82 and 9.60 μm for CF_3SO_3Na corresponding respectively to asymmetric and symmetric stretching of $-SO_2-$group.

Sodium methanesulfonate, CH_3SO_3Na.—This salt was prepared by neutralizing CH_3SO_3H (Eastman Organic, Reagent Grade) acid solution with basic Na_2CO_3 (J. T. Baker, Analyzed Reagent Grade) solution. As the solution was evaporated to dryness, it was filtered several times prior to precipitation of the CH_3SO_3Na. The dry salt was pure white and was insoluble in acetone, but slightly soluble in CH_3OH. The salt was recrystallized twice from 1:1 (v/v) MeOH-H_2O mixture and once from 1:1 (v/v) acetone-water mixture. The salt was then dried in a vacuum oven at 140°C for 48 hr. Infrared spectrum of the salt showed two absorption peaks at 8.3-8.5 μm and 9.5 μm. These values are in agreement with 8.37 and 9.43 μm which are assigned to the asymmetric and symmetric stretching respectively of the $-SO_2-$group as reported by Gramstad and Haszeldine (21).

Sodium tetraphenylboride, $NaB(Ph)_4$.—"Baker Analyzed" Reagent Grade $NaB(Ph)_4$ powder (minimum purity of 99.5%) was purchased from J. T. Baker Chemical Company, Phillipsburg, New Jersey. Recrystallization of the salt from 1:1 (v/v) acetone-toluene mixture (22) was unsuccessful. The dissolution of $NaB(Ph)_4$ salt had a negative temperature coefficient and positive heat of solution in the acetone-toluene mixture. The salt was, however, recrystallized three times successfully from pure acetone. The salt was then dried *in vacuo* at 80°C for 48 hr. The salt was pure white and had no phenolic odor. Infrared spectrum of the $NaB(Ph)_4$ salt showed two large absorption peaks at 13.4 and 14 μm, and four small peaks at 6.7, 7.0, 8.4, 8.7 μm all of which were identical to that shown in Sadtler Standard Spectra (23).

Sodium perchlorate, $NaClO_4$.—Anhydrous purified grade $NaClO_4$ (City Chemical Corporation, New York City) was recrystallized three times from redistilled water as done by Ames and Sears (24). The salt was dried *in vacuo* at 100°C for 66 hr and was followed by additional heating at 120°C for 7½ hr *in vacuo*. Infrared spectrum of the salt showed two absorption peaks at 8.8-9.3 μm and 16 μm which is identical to that reported (25).

Sodium thiocyanate, NaSCN.—Reagent grade NaSCN (crystals, minimum purity 99.0%, J. T. Baker) was recrystallized three times from redistilled water (12) and was dried *in vacuo* at 60°C for 29 hr. The salt is extremely hygroscopic and no reliable infrared spectrum data are available.

Potassium chloride, KCl.— "Baker Analyzed" Reagent Grade KCl (crystal, minimum purity 99.5%, J. T. Baker) was recrystallized three times from redistilled water as recommended by Daggett, Blair, and Kraus (26). The salt was dried *in vacuo* at 140°C for 40 hr. Aqueous KCl solutions of various concentrations were prepared to calibrate cell constants of conductance cells.

All purified salts were stored in vacuum dessicators over molecular sieves until used.

Preparation of solutions.—All solutions except aqueous KCl solutions were prepared in a nitrogen-filled dry box. The solutions were prepared by weights corrected to vacuum values with density data. Volume concentration was obtained from the weight concentration and density. Solutions of different concentration were prepared by successive dilution of a stock solution of near saturation.

The lowest concentration prepared for each electrolyte in DMSO was normally in the order of 10^{-4} mole/kg solution, below which solvent conductance became significant and the conductance of electrolyte solutions had to be appropriately corrected.

All glassware used in the preparation of solutions was cleaned in 1:1 ratio concentrated HCl-HNO_3 acid mixtures, followed by extensive rinse with redistilled water and reagent grade acetone. The glassware was then dried *in vacuo* at 80°C for 20 hr prior to use in the dry box.

Conductance measurements.—Conductances of the electrolyte solutions were measured with an a-c bridge (27). Sinusoidal signals of frequencies ranging from 100 Hz to 80 kHz and amplitude of approximately 15V to very low values were generated by an oscillator (General Radio Company, Type 1302-A). The cell resistance and capacitance were balanced with variable decade resistors and variable capacitors. The variable decade resistors were General Radio precision decade

Table I. Density, viscosity, and dielectric constant of distilled DMSO

Temperature, °C	Density, g/ml	Viscosity, centipoise	Dielectric constant at 80 kHz
25	1.0961	1.998	46.4
35	1.0855	1.652	44.7
45	1.0745	1.394	43.3
55	1.0637	1.192	41.9

resistors (General Radio Company, Type 510-A through Type 510-F), 0.1 ohm/step to 10 k-ohm/step with accuracies of ±0.5 to ±0.025% and with no frequency dependence up to 200 kHz. The variable precision capacitance box was of 100 to 1150 pico farad range (General Radio Company, Type 1422-N) placed in parallel with the variable decade resistors. The null point was detected by a Hewlett-Packard Model 120B oscilloscope which had a sensitivity of 10 mV/cm. All electrical wires and connections were shielded from noise by using concentrically shielded cable and BNC connectors. Further description is given elsewhere (27).

Because of the wide concentration range of electrolyte solutions to be investigated, conductance cells of various geometry were designed to give cell constants appropriate to solution resistances. Five conductance cells were designed and fabricated from Pyrex glass. The details of the cell description are given elsewhere (27). Bright platinum electrodes were utilized in these cells. Resistance measurements were made between frequency 600 Hz and 20 kHz. True resistance was obtained by linear extrapolation of resistance *vs.* reciprocal of frequency to infinite frequency. Usually resistance readings became independent of frequency when frequency was above 4 kHz.

Cell constants of the conductance cells at 25°C were determined with standard 0.1, 0.01, 0.001, and 0.0005*N* KCl solutions (28). Conductance of KCl solutions below 0.01*N* was obtained using the smoothed equation of Lind, Zwolenik, and Fuoss (29) which has an accuracy of about 0.013% at 25°C. The cell constants for the five cells were respectively 13.20, 2.676, 4.747, 0.6644, and 0.008809 cm^{-1} at 25°C. Allowing for the thermal expansion of glass and the metal electrodes, the temperature coefficients of the cell constants were calculated. At the maximum temperature, 55°C, of the present studies, the change of cell constants was negligible compared to the experimental accuracy of ±0.1%.

Filling of all solutions into the conductance cells was performed in the nitrogen-filled dry box. The cells were subsequently sealed in the dry box before being immersed in oil baths in room air. Oil bath temperature was maintained to ±0.03°C. Thermal equilibration was assumed attained when the resistance value became invariant with time, normally about 30 min.

The conductance data were reproducible to within 0.1% as the temperature was raised and lowered between 25° and 55°C. Over-all accuracy of the conductance data is estimated to be better than 0.3% based on the uncertainty of individual readings and variations between readings.

Viscosity, density, and dielectric constant measurements.—Viscosity, density, and dielectric constant of the solutions were determined respectively by modified Cannon-Ubbelohde viscometers, a two capillary relative densitometer (30), and an a-c capacitance bridge. The detailed descriptions of the apparatus and the calibration procedure have been described elsewhere (27). The over-all estimated accuracies for the viscosity, density, and dielectric constant measurements are better than ±0.1, ±0.1, and ±2%, respectively.

Data and Results

Density, viscosity, and dielectric constant of distilled DMSO at 25°, 35°, 45°, and 55°C are given in Table I. The viscosity data given in Table I represent the average value of twelve measurements of distilled DMSO. The values of density, viscosity, and dielectric constant at 25°C are in good agreement with those reported by Sears *et al.* (12), Cowie and Toporowski (31), and Lindberg and Kenttämaa (32).

Equivalent conductance of $NaClO_4$, NaSCN, $NaB(Ph)_4$, $(i\text{-amyl})_3BuNB(Ph)_4$, CF_3SO_3Na, and CH_3SO_3Na in DMSO as a function of concentration and temperature are tabulated in Tables II through VII. Solvent viscosity, η_o, and specific conductance, κ^o_{sp}, are also given in these tables.

The conductance data in the dilute concentration range, *i.e.*, $\kappa_a^o \leqq 0.2$, where the highest concentration in the dilute range was marked by an asterisk in Tables II through VII, were analyzed by the Fuoss-Onsager theoretical equation for unassociated 1-1 electrolytes

$$\Lambda = \Lambda_o - SC^{1/2} + EC \log C + (J(\overset{o}{a}) - B\Lambda_o)C \quad [1]$$

for associated electrolytes

$$\Lambda = \Lambda_o - S(C\alpha')^{1/2} + E(C\alpha') \log (C\alpha') + (J(\overset{o}{a}) - B\Lambda_o)C\alpha' - K_A C\alpha'\gamma_{\pm}^2\Lambda \quad [2]$$

Kay's least-squares computer program (33) was used for the analyses. In the computer analyses, the viscosity *B* coefficients were obtained by analyzing the viscosity data with the Jones-Dole equation (34). The
