ABSTRACT

The total electrical conductivity and the electronic conductivity in silver beta alumina have been determined between 23° and 800°C over a wide range of oxygen partial pressure using a-c and d-c techniques. The ionic transference number was found to be very close to unity under all conditions. Comparison of these measurements with tracer diffusion studies shows that the diffusion of silver ions takes place by an interstitialcy mechanism.

Previously reported measurements (1-3) of the ionic conductivity and the diffusion coefficient of monovalent ions, M, in materials of the beta alumina structure, represented by the general formula $MAl_{11}O_{17}$, have indicated that this phase might prove to be very useful as a solid electrolyte or transducer element in electrochemical cells.

In order to evaluate materials for such purposes, however, knowledge must be obtained about the transference numbers of both ionic and electronic species as well as the total electrical conductivity over broad ranges of temperature and other thermodynamic variables. Widely useful materials should have low values of electronic conductivity and relatively rapid ionic transport under conditions whereby they might be applied. It is not enough to have this information for only a limited set of experimental circumstances.

Information concerning the electrical conductivity of single crystals of beta alumina containing silver as the monovalent cation is presented in this paper. In this case simple (silver) metallic electrodes could be used which are essentially reversible to both M ions and electronic species over wide ranges of both temperature and oxygen partial pressure. In addition to standard a-c and d-c measurements, the Wagner asymmetric polarization technique (4-8) was used to investigate the electron and hole conductivities. Experiments were conducted from 23° to 800°C, and over a range of oxygen partial pressures, from 0.2 to 10^{-24} atm.

Experimental and Results

Preparation and analysis of samples.—Batches of single crystals of sodium beta alumina were obtained from the Carborundum Company, and crystals which were optically free of a second phase were selected for study. Samples of silver beta alumina were prepared from the sodium beta alumina starting material by immersion in pure silver nitrate at a temperature slightly above its melting point (1). However, in this case, elemental silver was also present in the bath, so that the silver activity was maintained at unity. A process of solid-state ion exchange takes place by chemical diffusion among the monovalent cations in the beta alumina structure, with the sodium ions being replaced by silver ions. After equilibration (about 24 hr) the samples were removed, washed, and weighed to indicate the amount of exchange, and replaced in a fresh batch of silver nitrate so that the sodium activity was again reduced to a very low value. This process was repeated until no further detectable weight change occurred. Except in the case of large crystals, this normally involved only one exchange. Completeness of the exchange of the monovalent ions was checked by arc spectrographic techniques. In all cases, the residual sodium content was found to be less than 0.1% by weight; the other major impurities present were silicon (0.1%), calcium (0.03%), and iron (0.02%).

The assumption that only the identity of the monovalent cations was being changed by this process was investigated by similar reconversion of samples to sodium beta alumina. Weight measurements indicated that this assumption was justified, as complete reversibility was found.

In all cases, an excess of the monovalent cation concentration was found, relative to the stoichiometric formula $MAl_{11}O_{17}$. Expressing the composition as $Ag_{1+x}Al_{11}O_{17}$, the value of x was found to be 0.158 ± 0.004 for eight different samples.

X-ray diffraction experiments of the samples containing silver showed that they had the same structure as that reported (9-11) for sodium beta alumina, but with lattice parameters of $a_o = 5.596$Å and $c_o = 22.47$Å. These agree well with the results of Yao and Kummer (1), who found the values of 5.594 and 22.498Å, for a_o and c_o, respectively. Analysis of the intensities of the various diffraction lines indicated that they could be best explained by assuming the presence of 15-20% excess silver ions residing in the secondary (alternative) monovalent cation site in the loosely packed layer in this structure (10). The site geometry within this bridging layer, which is adjoined by blocks having the spinel structure of $MgAl_2O_4$, the Mg^{2+} sites also being occupied by Al^{3+} ions, is indicated in Fig. 1.

Measurements of the total electrical conductivity.—Crystals about 5 mm square and 1 mm thick were

mounted between silver electrodes in a quartz cell assembly in which the oxygen partial pressure could be controlled. The c-axis was perpendicular to the large faces, and the electrodes were placed so that conduction was measured parallel to the a-axis. The nature of the crystal structure is such that highly anisotropic behavior is expected, with very much slower transport in the c-direction. Contact to the solid silver electrodes was enhanced by coating the appropriate edges of the crystals with Engelhard silver resinate solution, which was baked at 500°C to give a coherent film of silver metal. Excess silver was removed by nitric acid, and the electrodes attached by the application of more resinate solution and baking the whole assembly. A small amount of mechanical force was applied by an external steel spring to press the electrodes and sample together. This procedure gave excellent mechanical and electrical contact.

In order to remove spurious effects due to the presence of residual silver ions from the resonate solution on the crystal surface, samples were annealed for 12 hr at 800°C prior to conductivity measurements. The measuring cell was contained in a furnace, whose temperature control and stability were better than 0.5°C.

The use of elemental silver electrodes fixed the chemical activity of the silver in the beta alumina at unity; however, in such a ternary system the activity of one of the other components must also be controlled in order to properly define the thermodynamic state of the sample. In this case the oxygen partial pressure was controlled by the use of a flowing gas system. Helium was used as the flowing gas and its oxygen content was controlled by passage over hot titanium or calcium chips; the gas was subsequently dried by passage through liquid nitrogen. The oxygen partial pressure in the helium was monitored continuously by the use of the solid-state electrochemical transducer technique (8, 12-14) with a stabilized zirconia tube and air at the reference electrode.

The total a-c conductivity was measured by use of a General Radio Type 1608A impedance bridge and an external oscillator. No frequency dependence was observed over the span 10^2-10^5 Hz at any combination of temperature and oxygen partial pressure within the range investigated. Measurements made under d-c conditions also gave the same values of conductivity if the value of total current was maintained less than about 5 mA/cm² (at high temperatures). At higher current fluxes the apparent conductivity was found to decrease gradually, possibly because of void formation at the interface between the crystal and the silver source electrode or polarization at this interface.

Measurements of both a-c and d-c conductivity were obtained for five crystals; results are shown in Fig. 2 for a typical sample. It is seen that the data produce a linear relation between the logarithm of conductivity-temperature product and the reciprocal of the absolute

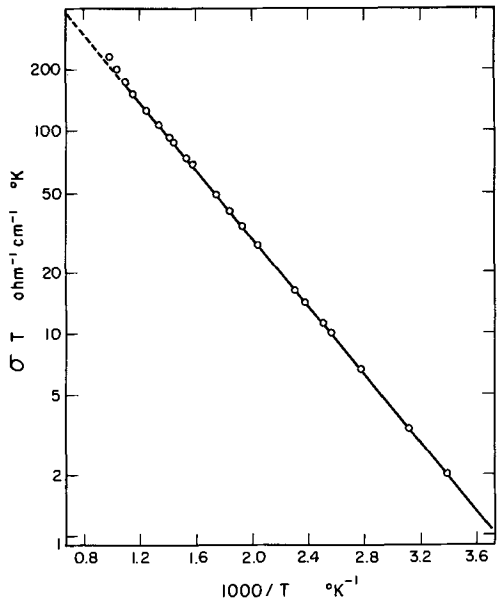

Fig. 2. Total conductivity of silver beta alumina

temperature from room temperature to above 650°C, as expected from the general relation

$$\sigma = (\sigma_0/T) \exp(-Q/RT) \quad [1]$$

The origin of the positive deviation from this relation at higher temperatures, which was observed for all samples, is not definitely known but may be due to a change in the diffusion mechanism.

The apparent activation energy Q for the linear range was found to have the value 3.98 ± 0.08 kcal/mole. The conductivity at 23°C was (6.41 ± 0.30) x 10^{-3} (ohm-cm)$^{-1}$.

Attempts to measure the oxygen partial pressure dependence of the total conductivity resulted in the conclusion that the dominant conduction process is essentially independent of oxygen partial pressure over the range from that of air to about 10^{-24} atmospheres. Experiments from 600° to 800°C showed an effect of less than 5%, which is deemed to be within experimental error.

Measurements of the electronic contribution to the conductivity.—Following the method of Wagner (4-7), the electronic conductivity of silver beta alumina has been deduced from current-potential curves for the cell

$$-\text{Ag/AgAl}_{11}\text{O}_{17}\text{/Pt} + \quad (\text{I})$$

On applying a potential below the decomposition voltage of silver beta alumina to the cell (I) with the negative pole on the left silver ions will tend to flow to the left and electrons to the right. However there is no source of silver ions at the right electrode, so the crystal will become depleted in silver at this electrode which will cause silver to flow toward this end under a chemical concentration gradient. At equilibrium the flow of silver ions due to the electrical gradient will equal the flow due to the chemical gradient, and the total current will be carried solely by electrons and positive holes.

This current in a cationic conductor is given by

$$I = (RT/LF)[\sigma_e(1 - \exp[-EF/RT]) + \sigma_h(\exp[EF/RT] - 1)] \quad [2]$$

where I is the current, L the cell constant which is determined by the crystal geometry, σ_e and σ_h the electron and hole conductivities, respectively, and E the applied potential difference. This may be rearranged (7) to give the more experimentally useful expression

$$I/[\exp(EF/RT) - 1] = RT/LF[\sigma_e \exp(-EF/RT) + \sigma_h] \quad [3]$$

Thus the value of σ_e may be obtained from the slope of a plot of $I/[\exp(EF/RT) - 1]$ against $\exp(-EF/RT)$ and σ_h from the intercept on the $I/[\exp(EF/RT) - 1]$ axis.

For this set of experiments a crystal was prepared as described above for the total conductivity measurement except that platinum resinate solution was used to form one of the electrodes. The sample was suspended in the furnace by means of wires attached to the electrodes so that there was no possibility of a sample holder short-circuiting the specimen. In all cases it was found necessary to keep the cell at about 800°C for several days, with an applied voltage across it to prevent the migration of silver across the surface. After this treatment the current attained a steady low value which was much less than originally observed. Subsequently when the applied potential was changed, polarization occurred fairly rapidly and the equilibrium current was usually attained within an hour. Measurements of the current using a Cary 401 electrometer were made on cell (I) between 555° and 790°C over a wide range of oxygen partial pressure. Figure 3 shows the results obtained at 790°C.

The intercept on the potential axis is influenced by two (extraneous) different effects. In cell (I) the oxygen activity at the platinum electrode is fixed by the surrounding oxygen partial pressure; however at the silver electrode the silver activity is fixed at such a high value that the oxygen activity will be very low, and so only at very low oxygen partial pressures will the activity of the oxygen at both electrodes be equal. Thus there will be an oxygen concentration gradient across the beta alumina causing a potential drop across the sample opposite in sign to the applied potential. In agreement with the experimental observations, this potential decreases with decrease of ambient oxygen partial pressure, however the curves still do not go through the origin at very low pressures.

The silver activity at the platinum interface is described by $a_{Ag} = \exp(-EF/RT)$, and as silver is soluble in platinum (15) there will be a flow of silver into the platinum which will create a silver ion current in the beta alumina. This current which may be large at low potentials will cause the measured current to fall to zero at some positive potential as observed. Figure 4 shows the effect of these different behaviors on the measured current-potential curve at 790°C where the oxygen partial pressure was 0.2 atm. Similar behavior has been reported for AgBr (16) and AgCl (17).

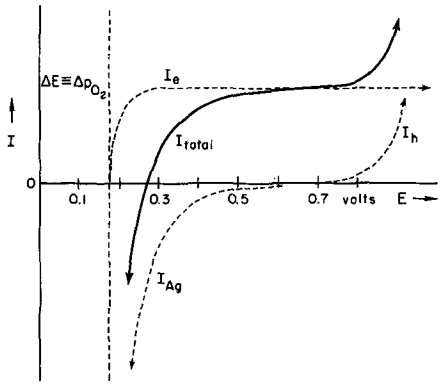

Fig. 4. Contributary and total current-potential curves at 790°C for $p_{O_2} = 0.2$ atm.

As Eq. [3] can clearly not be used when there is an appreciable silver ion current, which varies with the applied potential, the electron conductivity was calculated from the current plateau using the expression

$$\sigma_e = ILF/RT \qquad [4]$$

which is simply Eq. [2] with no positive hole conduction. These results are given as a function of temperature in Fig. 5. Satisfactory results could not be obtained at lower temperatures because of both long equilibration times and as no plateau was reached in the current-potential curve although one was obviously being approached. This latter behavior was undoubtedly due to the silver ion contribution to the total current. In no case was any positive deviation from the current plateau observed, indicating that the positive hole conductivity was at least three orders of magnitude less than the electron conductivity.

Replacement of the platinum in cell (I) by graphite, in which silver is not expected to be soluble, gave current-potential curves which appeared to go through the origin as expected from the above theory. However this cell could not be used for quantitative measurements as the results obtained were unreproducible and were accompanied by a large amount of "noise" of the kind described by Van der Meulen and Kröger (17). For platinum this noise was completely eliminated by the initial high-temperature anneal, but such a treatment had no effect on the graphite cell. This noise is most probably due to poor interface contact at the blocking electrode.

Discussion

Defect structure of beta alumina.—Silver beta alumina was shown above to contain a considerable excess of the monovalent ion, silver. It may thus be described as a highly defective nonstoichiometric compound. As none of the ions show any polyvalent character and the electronic conductivity is so low, it is highly probable that the excess silver ions are charge balanced by other lattice defects rather than by electronic defects. As mentioned earlier, the crystal structure of beta alumina is made up of cubic close-packed blocks, four layers thick, of oxygen ions in which the aluminum ions take up both the magnesium and the aluminum positions of the spinel $MgAl_2O_4$; these blocks are held together by a loosely packed layer containing Al-O-Al bridging groups and silver ions. The arrangement in this layer was shown in Fig. 1. It is clear that extra ions can be readily accommodated in this layer.

X-ray studies (10) on the silver and thallium beta aluminas indicate that the excess monovalent ions, M, are present as interstitials, M_i, on the interstitial site indicated in Fig. 1. These may be charge balanced either by addition of negative charge in the form of interstitial oxygen ions, O''_i, or by removal of positive charged aluminum ions giving aluminum vacancies, V'''_{Al}. A third possibility is the replacement of some of the aluminum ions by divalent cations. However there were not enough such impurity ions present to compensate the observed silver excess. Impurity effects will therefore be ignored. X-ray data have not yet been able to distinguish between the first two models as they involve low defect concentrations of poor x-ray scatterers, *e.g.*, in the second case, aluminum vacancies on less than 0.5% of the total aluminum sites would compensate a 15% excess of M. It is most probable that such aluminum vacancies or replacement ions will be in the region of the bridging layers so as to be close to the defects they are compensating. Excess oxygen ions could reside upon a number of positions, *e.g.*, some of the oxygen ions on the normal lattice sites might be displaced slightly to give small regions of the magnetoplumbite structure (18), or they might displace some of the M ions from their lattice sites. It is unlikely that oxygen ions would reside on the interstitial sites suggested for the excess silver ions as this would involve placing an oxygen ion between two other oxygen ions which would be energetically unfavorable.

The effect of the oxygen partial pressure on the concentrations of defects in the first two models, and hence on their electrical conductivity, will now be discussed. In both cases it is assumed that the concentrations of electrons and positive holes are small compared to those of the lattice defects of the same charge; this is consistent with the known ionic conductivity of these materials. At high oxygen pressures the predominant defects are likely to be cation interstitials, $M^{\bullet}_i$, and its compensating defect, either V'''_{Al} or O''_i, whereas at low oxygen pressures the compensating defect is more likely to be a cation vacancy, V'_M. The latter is simply Frenkel disorder in the M lattice. Figures 6 and 7 show the results of calculations based on these defect models, and using the experimental data at 550°C with the assumption that the electron and hole mobilities are unity.

Both these models suggest that at high oxygen pressures the concentrations of interstitial cations and electrons, $[M^{\bullet}_i]$ and [e'], should depend on the oxygen partial pressure. This was not found to be the case experimentally and suggests that either (*i*) all oxygen pressures investigated were within the lower range, (*ii*) the defect models considered are incorrect, or (*iii*) the silver beta alumina samples were not in equilibrium with the environment. As the models considered here seem to be the most feasible, and no

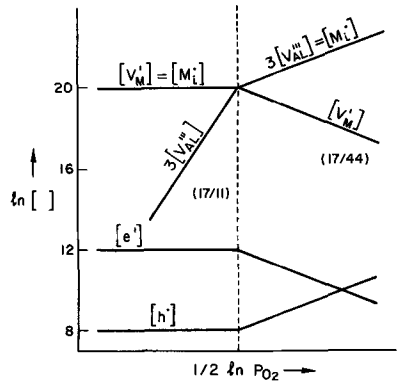

Fig. 6. Defect equilibrium diagram where V'''_{Al} is predominant at high p_{O_2}. |Slopes| are given in ( ).

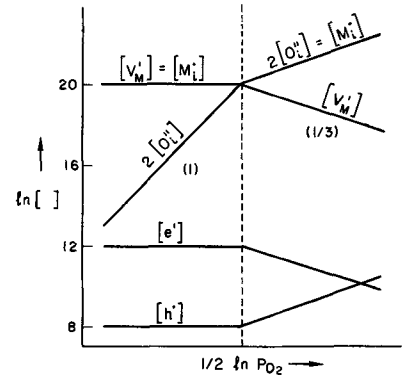

Fig. 7. Defect equilibrium where O''_i is predominant at high p_{O_2}. |Slopes| are given in ( ).

excess of M is expected in the lower oxygen pressure range, the possibility of nonequilibrium with the environment is the most likely. The sodium beta alumina from which these samples were obtained was crystallized from the melt at about 2000°C; at no subsequent time were the samples raised to such temperatures. It is thus possible that if one of the compensating defects were frozen in on cooling from this temperature the silver concentration would reflect the thermodynamic condition (and sodium content) expected at that high temperature rather than of the temperature at which it was prepared by the ion exchange technique or present during the subsequent measurements. This assumption leads to a differentiation between the two proposed compensation mechanisms. If compensation were by means of oxygen interstitials then there is no *a priori* reason why these defects should not show a reasonably high diffusion coefficient and be able to come to equilibrium with the environment at 800°C considering the open nature of the planes containing these ions. However, if the compensating defect were an aluminum vacancy, then it could be frozen into any part of the close-packed blocks or in the bridging groups; in either case it would be expected to have a much lower diffusivity than the oxygen interstitial. It is therefore suggested that the compensation mechanism for the excess M ions in the beta alumina structure involves aluminum vacancies and that for all practical purposes these vacancies should be considered frozen into the lattice at the temperatures of these experiments.

Mechanism of diffusion of silver in beta alumina.—The diffusion coefficients for silver diffusion in silver beta alumina, obtained from the conductivity data of Fig. 2 using the Nernst-Einstein relationship

$$D = \sigma RT/cq^2 \qquad [5]$$

and from the tracer diffusion studies of Yao and Kummer (1), are compared in Fig. 8. The concentra-

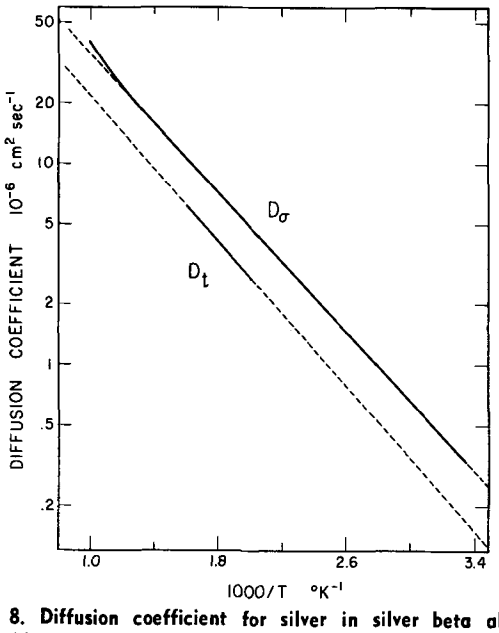

Fig. 8. Diffusion coefficient for silver in silver beta alumina. ——— Measured, - - - - - extrapolated.

tion of silver ions, c, was taken as equal to that of the stoichiometric compound, which is 5.453 x 10^{-3} moles/cc. The conductivity results show that in the equation

$$D = D_o \exp(-Q/RT) \quad [6]$$

D_o and Q have the values of 2.55 x 10^{-4} cm^2 sec^{-1} and 3.98 kcal/mole, as compared with tracer diffusion values (1) of 1.65 x 10^{-4} cm^2 sec^{-1} and 4.05 kcal/mole. The value of D_σ/D_t at 280°C, the center of the measured temperature range, is 1.64. This suggests that diffusion does not take place by an interstitial mechanism. Inspection of Fig. 9 shows that an interstitialcy mechanism is the most probable; it may also be noted that the structure precludes the possibility of a collinear interstitialcy mechanism. Theoretically (19) for the interstitialcy mechanism the correlation factor, f, is given by

$$D_\sigma/D_t = 1/f = (a_i/a_t)^2/2(1 + \overline{\cos\theta}) \quad [7]$$

where a_i is the effective jump distance of an interstitial ion, a_t is the jump distance of the tracer, and θ is the angle between a tracer jump from an interstitial site to a normal lattice site and the next jump from the normal site to an interstitial site. In this case, a_i is the distance between two interstitial sites and a_t the distance between an interstitial and a normal lattice site. For this structure $(a_i/a_t)^2 = 3$ and the value of $1 + \overline{\cos\theta}$ has been calculated, by direct summation of the jumps of an interstitial, to be 0.898 ± 0.002 assuming no interaction between interstitials and only completely free silver ions on normal and interstitial sites. This gives $D_\sigma/D_t = 1.67$ in excellent agreement with experiment. It should be remembered however that there is a 15% occupancy of the interstitial sites. This has been ignored in the above treatment, but is expected to reduce the value of D_σ slightly, thus decreasing the ratio D_σ/D_t, and raise the value of f.

The linear variation of log (σT) with $1/T$ in Fig. 2 is in accordance with a model in which there is a large number of charge carriers, which does not change appreciably with temperature. The small positive deviation at the higher temperatures may be associated with excitation of some of the silver ions from normal lattice sites to interstitial sites thus creating a larger number of charge carriers. It may also be due to an actual change in the diffusion mechanism, *e.g.*, to a multiple jump mechanism.

Comparison with other fast ionic conductors.—The ionic conductivities of several "good" electrolytes are compared in Fig. 10. Only two, AgI and $RbAg_4I_5$, have appreciably higher conductivities than $AgAl_{11}O_{17}$, and the difference between these two can be accounted for by the difference in silver concentration. It is interesting to consider why there is such a large difference in the conductivity [6.4 x 10^{-3} and 2.1 x 10^{-1} (ohm-cm)$^{-1}$, respectively, at 23°C] between $AgAl_{11}O_{17}$ and $RbAg_4I_5$, when the crystal structure of beta alumina is so open. In $RbAg_4I_5$ all the silver ions are on equivalent sites (25) so that they are all equally capable of diffusing in a potential field; however, in beta alumina the silver ions are on two different sites and because of the diffusion mechanism the "effective number" of mobile ions is equal to the concentration of occupied interstitial sites. Thus the number of charge carriers, n, is 1.13 x 10^{22} cm^{-3} for $RbAg_4I_5$ and about 15% of 3.28 x 10^{21} or 4.92 x 10^{20} cm^{-3} for $AgAl_{11}O_{17}$.

Using the common expression, $\sigma = nq\mu$, the mobility, μ, of the silver ion in beta alumina is found to be 70% of that in the rubidium iodide. It is clear that the main reason for the conductivity difference does not lie in the ionic mobility but in the number of ions available for conduction. The conductivity of beta alumina might thus be improved by increasing the number of interstitial ions, *e.g.*, by doping with a divalent metal such as magnesium which will reside on an aluminum site. There should be no difficulty in doing this as the block structure of beta alumina is that of the spinel $MgAl_2O_4$ and replacement of only 4.5% of the aluminums by magnesium will increase the silver content to

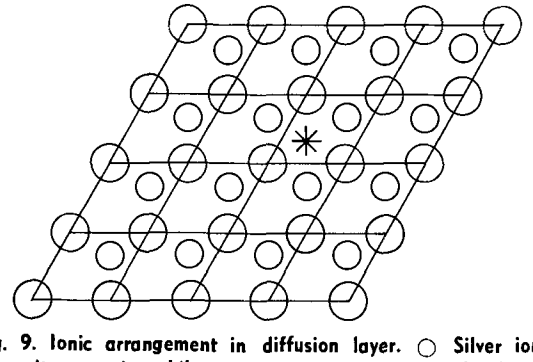

Fig. 9. Ionic arrangement in diffusion layer. ○ Silver ion on lattice site; ⊗ immobile oxygen ion; ✳ interstitial silver ion.

50% over stoichiometric and thus the present interstitial concentration by more than a factor of three. However, the diffusion mechanism will probably change at some value of the interstitial concentration when the assumption that the interstitial ions are independent of one another breaks down.

Inspection of the tracer diffusion data of Yao and Kummer (1) shows that the sodium ion in the beta alumina has a mobility about double that of the silver ion. Sodium beta alumina is thus expected to have the highest known mobility of any known solid electrolyte at ambient temperature, and suitable doping of the alumina matrix as discussed above should be capable of producing values of ionic conductivity comparable in magnitude with that of $RbAg_4I_5$.

The structure of sodium beta" alumina (10, 11, 26) is very similar to that of beta alumina, but it contains about twice the concentration of sodium ions, all of which are thought to be in identical sites. The diffusion mechanism may then be similar to that in the two highly conducting silver iodides so that all the sodium ions participate in the diffusion process.

To be useful as an electrolyte in batteries or solid-state cells a material must exhibit rapid ionic transport of one or more species, and at the same time have a very low electronic transference number over wide ranges of temperature and partial pressures of the components. Silver beta alumina clearly fulfills these criteria. From the data of Fig. 2 and 5 the electron transference number can be found as a function of temperature. Results are shown in Fig. 11. These values of the transference number for electronic carriers are lower than the measured values of any of the other solid electrolytes shown in Fig. 10, several of which are being used as electrolytes in batteries and other solid-state cells. It has the added advantage that it appears be be unaffected by light contrary to the behavior of some other silver compounds. Thus silver beta alumina appears to be a very interesting solid electrolyte for both technological and scientific uses.

The Microstructure of Sintered Silver Electrodes

III. Ag_2O Formation during Charges

Charles P. Wales*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

Ag electrodes were charged at the 20-hr rate of constant current and discharged at the 1-hr rate in 35% KOH solution at 25°C. Cross sections of samples cut from the electrodes during charges at cycles 1-30 were examined. Almost all Ag particles had a visible coating of Ag_2O when an electrode was charged for half the capacity accepted at the Ag/Ag_2O potential plateau. The electrode surface had the same structure as the interior. In a cycled electrode approximately 60% of the Ag had been oxidized to Ag_2O when the potential peak separating the Ag/Ag_2O and Ag_2O/AgO plateaus was reached.

The present paper describes structural changes in Ag electrodes as Ag_2O was formed in an alkaline solution. The Ag electrodes were of the type used in Ag-Zn and Ag-Cd storage batteries.

There have been two previous papers in this series concerning the microstructure of sintered Ag electrodes. The first paper described the structures present as charged electrodes were being reduced during discharges (1). The second described the structures present at the end of a series of complete discharges (2). The formation of AgO will be the subject of a later paper. The electrodes in this series of investigations were always discharged at the 1-hr rate and charged at the 20-hr rate of constant current in 35% KOH solution.

When Ag electrodes are discharged in a KOH solution at a high current density for a series of cycles the electrode capacity is maintained at a higher value than when a low discharge C.D. is used. This difference in capacity results from changes in the microstructure of the electrodes. The microstructure of a cycled electrode depends partly on the discharge C.D. that is used. A discharge at the relatively fast 1-hr rate results in formation of small Ag particles, many having a size on the order of 1μ. Particles of this size oxidize readily during the next charge. When the slow 20-hr discharge rate is used, however, most of the Ag particles that form are 10-25μ (3).

Particles of Ag larger than 4 or at most 5μ do not oxidize completely during a charge. Oxidation usually stops before an oxide layer reaches a thickness of 2μ. As a result, the central portion of large particles remains as metallic Ag at the end of a charge instead of being oxidized. Once large particles form in an electrode during a slow discharge, the original discharge capacity is not regained readily. When slow discharges are used, the capacity decreases so rapidly that by cycle 3 the electrodes always discharged at the 20-hr rate give less capacity than electrodes always discharged at the 1-hr rate. This occurs despite the fact that approximately 10% of the oxide remains at the end of a fast discharge, and almost all of the oxide is reduced during a slow discharge.

Experimental Procedure

Only a brief account of the experimental procedure will be given here, because it has already been described (1). Sintered Ag electrodes were cycled individually in an excess of 35% KOH solution at 25°C. The Ag electrodes were charged using constant current at the 20-hr rate until oxygen began to evolve. Electrodes were discharged using constant current at the 1-hr rate. These currents were not based on theoretical capacity of the electrodes but were the currents that actually resulted in a charge reaching oxygen evolution in 20 hr and a discharge reaching the cutoff potential in 1 hr. Discharges were ended at a potential of −500 mV *vs.* the Ag/Ag_2O reference electrode, the equivalent to approximately 1.0V for a typical Ag-Zn cell. Electrodes were given up to 30 charge-discharge cycles.

Samples for microscopic examination were cut from the Ag electrodes at various times during charges. After a sample had been washed and dried, it was impregnated with an epoxy resin while under a vacuum. Then a cross section of the sample was prepared by grinding and polishing. Finally a sample was examined with a metallurgical microscope and the appearance of significant areas recorded by photography.

Results

Oxidation of Ag to Ag_2O.—A small area of an electrode that had been partly charged at the Ag/Ag_2O potential plateau is shown in Fig. 1. All photographs in this paper are of cross sections through electrodes. The photographs, therefore, also show cross sections

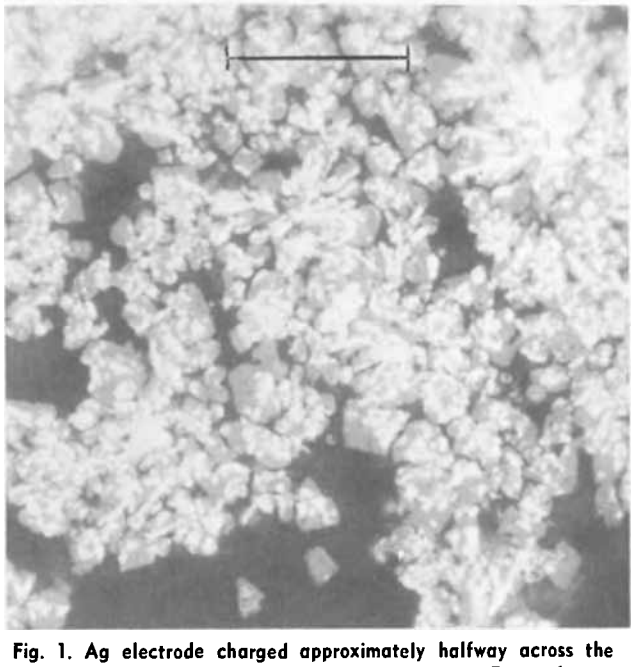

Fig. 1. Ag electrode charged approximately halfway across the Ag/Ag_2O potential plateau at cycle 6 in 35% KOH. Electrode was given 19% of average charge acceptance. Metallic Ag particles are the lightest shade in the photograph. Ag_2O that formed during the charge is medium gray. Void areas are the darkest shade. Marker indicates 15μ.

Key words: silver electrode, silver oxidation, silver oxide, electrode structure.

through the individual crystals in the active material of an electrode. This sample was taken from an electrode during cycle 6 charge. The electrode had always been charged at the 20-hr rate and discharged at the 1-hr rate.

The electrode shown in Fig. 1 had been given half the capacity this electrode would accept during a charge at the Ag/Ag_2O potential plateau. The partial charge amounted to approximately 19% of the capacity usually accepted before oxygen evolution began. The surface of this electrode had the black color of Ag_2O. Microscopic examination showed that the surface had the same structure as the interior. The reaction was uneven in the electrode, however, with a greater amount of Ag_2O having formed in some areas than in others.

The small Ag particles within the Ag_2O of Fig. 1 were the unoxidized remainder from Ag particles that formed during the previous discharge. Most of the Ag in a discharged electrode was present as small particles or needles. Some larger Ag particles were also present. These larger particles of Ag were residual from the particles present in the unused electrode. Small Ag particles and needles of Ag are visible in the partly charged electrode shown in Fig. 1. Only 5% of a typical unused electrode consisted of particles over 15μ in size. The area shown in Fig. 1 did not include any of these large Ag particles.

A definite Ag_2O coating had formed on most of the Ag particles during the partial charge given the electrode shown in Fig. 1. Based on the weight of Ag present in the unused electrode (excluding the grid of expanded sheet Ag) the partial charge at the Ag/Ag_2O potential had oxidized approximately 28% of the Ag to Ag_2O. If the charge had not been interrupted the amount of Ag_2O in the electrode would have doubled before charge potential rose sufficiently that AgO could begin to form. Only a very small proportion of the Ag had no visible Ag_2O coating.

Ag_2O and AgO appear as different shades of gray when unpolarized light is used and under most conditions can be distinguished from each other readily. Identification may be less certain when using unpolarized light if only one of the oxides is present, but under polarized light Ag_2O and AgO have quite different colors. Under polarized light the crystals in Fig. 1 were definitely identified as being Ag_2O and not AgO crystals.

Figure 2 shows an electrode charged until potential rose to the peak that ends the Ag/Ag_2O potential plateau. The area shown includes some of the larger Ag particles present in an electrode. Comparison with Fig. 1 shows changes that took place as Ag_2O was forming. Ag particles had decreased in size as the result of additional oxidation of their surfaces. Very few of the needlelike particles of Ag remained in electrodes charged to the end of the Ag/Ag_2O plateau.

The oxidation did not take place evenly throughout an electrode. Figure 3 shows another area of the same electrode already shown in Fig. 1 but after the electrode was charged twice as much. Based on the weight of Ag present in this electrode, the charge had oxidized approximately 60% of the Ag to Ag_2O. In the area shown in Fig. 3, an area of very small Ag particles, 80-90% of the Ag had been oxidized. In some other areas where larger Ag particles were present, less than 50% of the Ag had been oxidized to Ag_2O.

Small Ag particles were still present within almost all of the Ag_2O in an electrode charged to the end of the Ag/Ag_2O potential plateau. A few individual crystals or small clumps of Ag_2O crystals not containing metallic Ag were also found. Although Ag_2O from the surfaces of adjacent Ag particles tended to grow together, many small voids remained in the Ag_2O. The Ag_2O did not form into large solid masses in the way that AgO formed later in a charge. No AgO formed before the potential peak was reached.

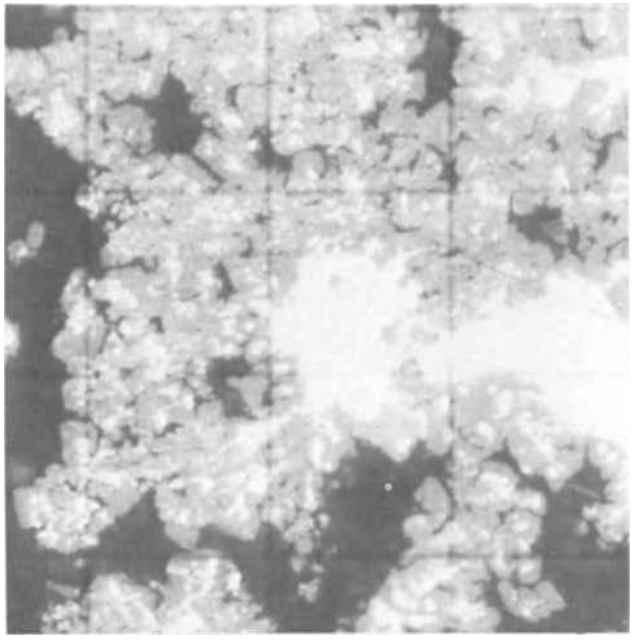

Fig. 2. Ag electrode charged at cycle 2 until potential reached the peak that ends the Ag/Ag_2O plateau. Lines forming squares are 15μ apart, same magnification as Fig. 1.

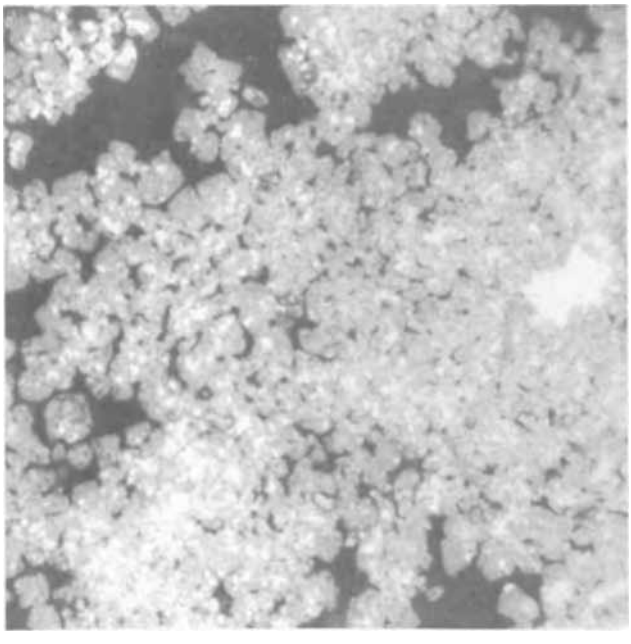

Fig. 3. Ag electrode charged at cycle 6 until potential rose at the end of the Ag/Ag_2O potential plateau. Electrode was given 39% of average charge acceptance. Small Ag particles in the area shown had largely oxidized to Ag_2O. Same magnification as Fig. 1 and 2.

A lower magnification view of Ag_2O formation is given in Fig. 4. This electrode, charged at cycle 2 until potential rose to the peak that ends the Ag/Ag_2O potential plateau, is the same electrode shown in Fig. 2. Magnification is one-fourth as much as was used in Fig. 1-3. The lower magnification emphasizes the fact that the active material was in clumps.

Part of the expanded metal grid and a few of the larger Ag particles are included in Fig. 4. The large particles were distributed randomly in an electrode at cycle 2. Ag_2O had formed on the surface of the Ag particles as well as on the grid. The surface of the grid in an unused electrode was comparatively smooth. Penetrating attack was already noticeable on the grid surface shown in Fig. 4. The large Ag particles had the same amount of surface attack as did the grid. Thicker

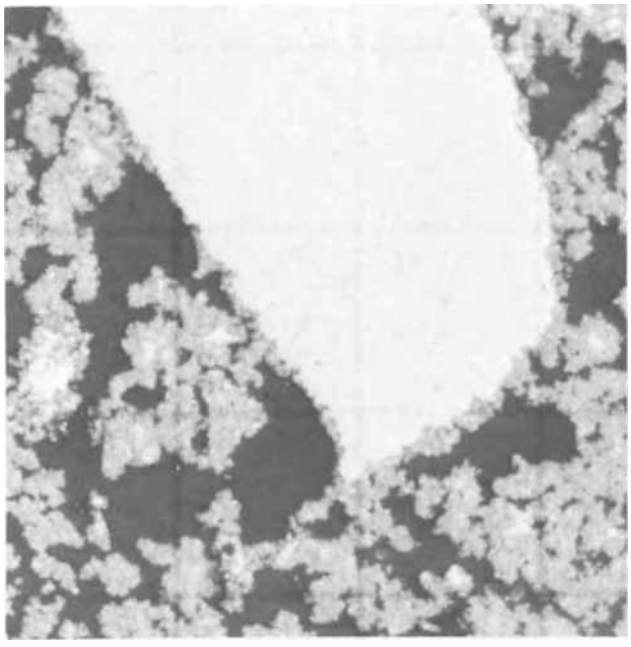

Fig. 4. Ag electrode charged at cycle 2 until potential rose at the end of the Ag/Ag_2O potential plateau, showing typical Ag_2O formation found in early cycles. Large white object is part of the Ag grid. Lines forming squares are 60μ apart.

Ag_2O layers had formed on the grid and on the large Ag particles of this partly charged electrode at cycle 2 than had formed during the first charge. The Ag_2O layer was thickest on the small Ag particles.

Effects of current density and cycling.—The amount of Ag_2O that formed during a charge was strongly influenced by the conditions used for the previous cycles. When electrodes were always discharged at the relatively fast 1-hr rate, the charge acceptance at the Ag/Ag_2O potential plateau increased during the first few charges. Consider cycle 2, for example. The electrode shown in Fig. 2 had been charged to approximately 22% of theoretical capacity. This means that an estimated 44% of the Ag had been oxidized to Ag_2O by the time that potential reached the peak that separates the Ag/Ag_2O and Ag_2O/AgO plateaus. Charge acceptance at the Ag/Ag_2O plateau had increased at cycle 6. Approximately 60% of the Ag had oxidized to Ag_2O in the electrode shown in Fig. 3. As charge acceptance at the Ag/Ag_2O plateau increased, charge acceptance at the Ag_2O/AgO plateau had decreased proportionately. Total capacity accepted before oxygen evolution began was relatively constant in this period. The electrodes shown at cycles 2 and 6 had accepted 33% and 39% of total capacity, respectively, when charge potential reached the peak.

Figure 5 gives the charge capacity that Ag electrodes accepted before their potential reached the peak ending the Ag/Ag_2O plateau. Each of the four electrodes whose capacity is shown had close to the same capacity acceptance during the first charge. All the electrodes were charged at the 20-hr rate. Two were discharged at the 1-hr rate and the other two at the 20-hr rate. The changes in discharge capacity when these four electrodes were cycled have been shown in Fig. 6 of reference (2).

All electrodes given the same cycle treatment tended to accept approximately the same amount of charge at the Ag/Ag_2O potential. After the first few cycles, electrodes always discharged at the relatively fast 1-hr rate formed approximately three times as much Ag_2O as did electrodes always discharged at the slow rate (Fig. 5). When the 1-hr discharge rate was used, the charge accepted at the Ag/Ag_2O level at cycle 1 was 33-39% of the capacity of the following discharge. From cycles 3 to 30 the charge was usually in the range of 37-46% of discharge capacity.

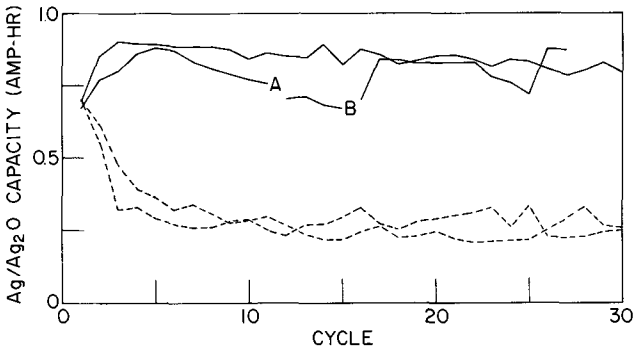

Fig. 5. Charge capacity accepted at Ag/Ag_2O level when electrodes were charged at the 20-hr rate in 35% KOH at 25°C. Solid lines are for two Ag electrodes always discharged at the 1-hr rate. Dashed lines are for two electrodes always discharged at the 20-hr rate. At point A one cell stood discharged 74 days and at point B the electrolyte in this one cell was replaced.

A larger discharge capacity was obtained at cycle 1 when the 20-hr discharge rate was used than when the 1-hr rate was used. The charge accepted at the Ag/Ag_2O level at cycle 1 was 27-32% of capacity of the following discharge when the discharge was done at the 20-hr rate. The charge at the Ag/Ag_2O level decreased for the next few cycles and then from cycle 5 to cycle 30 was usually in the range 15-22% of the capacity of the slow discharges.

Replacing the old electrolyte with fresh 35% KOH made a noticeable difference in charge acceptance. Electrolyte was replaced in one cell at point B of Fig. 5. The charge acceptance at the Ag/Ag_2O level was somewhat larger after the electrolyte was replaced, but the total discharge capacity had increased by a greater proportion.

Changes in structure after repeated cycling.—The average size of Ag particles in an electrode tended to increase as an electrode was cycled using fast discharges. Figure 6 illustrates an electrode charged at cycle 28 for half the capacity the electrode would accept at the Ag/Ag_2O potential plateau. Most of the Ag particles were covered with a layer of Ag_2O. Ag_2O coatings were the same on particles at the surface of

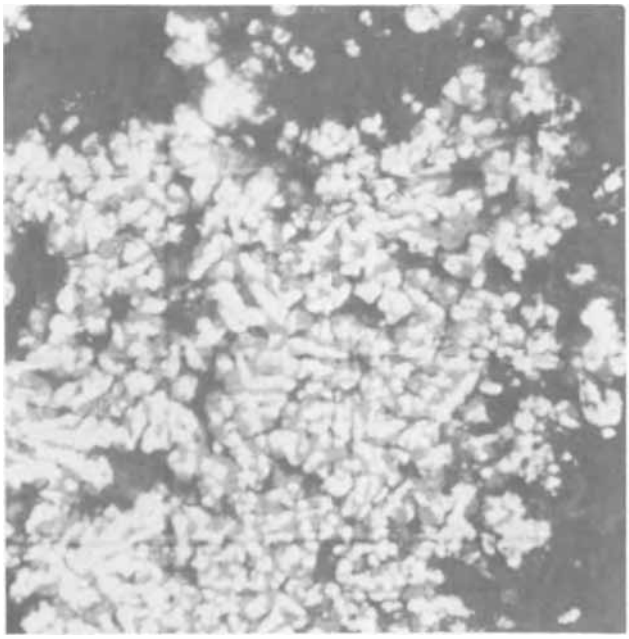

Fig. 6. Ag electrode charged approximately halfway across the Ag/Ag_2O potential plateau at cycle 28. The surface of the electrode is included at the right of this photograph. Compare with Fig. 1 to see changes in particle size that gradually took place as electrode was cycled. Lines forming squares are 15μ apart.

the electrode as in its interior. A small proportion of the particles had no Ag_2O coating visible at the magnifications used (up to 1600X). Many Ag particles larger than those shown here were present in other areas of the electrode.

When the charge of this electrode was continued until potential rose to the peak that ends the Ag/Ag_2O potential plateau, additional Ag_2O formed as shown in Fig. 7. The area shown in Fig. 7 included larger Ag particles than were shown in Fig. 6. The changes to be noted are the decrease in size of the small Ag particles and increase in Ag_2O thickness. Based on the weight of Ag in the unused electrode, 27% and 52% of the Ag had been oxidized to Ag_2O in the electrodes shown in Fig. 6 and 7, respectively. The size of typical Ag particles was larger at cycle 28 than at cycles 2 and 6. This can be seen by comparison of Fig. 6 with Fig. 1, and also by comparison of Fig. 7 with Fig. 2 and 3.

When an electrode was cycled repeatedly the distribution of the large Ag particles became uneven. The large Ag particles had a marked tendency to form in the interior of an electrode rather than in areas near a surface (2). The small Ag particles became less common as the large particles developed. Many of the smallest Ag particles present at the beginning of cycle 28 charge had already been oxidized to Ag_2O before the state of charge shown in Fig. 7 was reached, because the current oxidized small particles in preference to large particles. Figure 7 was typical of the structure at the end of the Ag/Ag_2O potential plateau at cycle 28, although a few areas similar to the one shown in Fig. 3 were still present. Individual isolated crystals of Ag_2O or groups of these crystals had been found in the early cycles but were rare at cycle 28. Almost all clumps of Ag_2O contained metallic Ag.

The active material gradually clumped as an electrode was cycled. Figure 8 gives a lower magnification view of another part of the electrode shown in Fig. 7. Comparison of Fig. 8 with Fig. 4 shows that the active material was in larger clumps at cycle 28 than in cycle 2. The Ag_2O still formed as a quite porous mass, much as in the early cycles. As the clumps of active material became larger, the distribution of void space worsened and large voids formed in the electrode.

A small number of clumps of particles had become oriented parallel to each other as an electrode was cycled. An example of particles in clumps parallel to other clumps is shown at the right side of Fig. 8. These oriented clumps were not common. They were found most often at the surfaces of the electrodes, with the clumps aligned at right angles to the electrode surface.

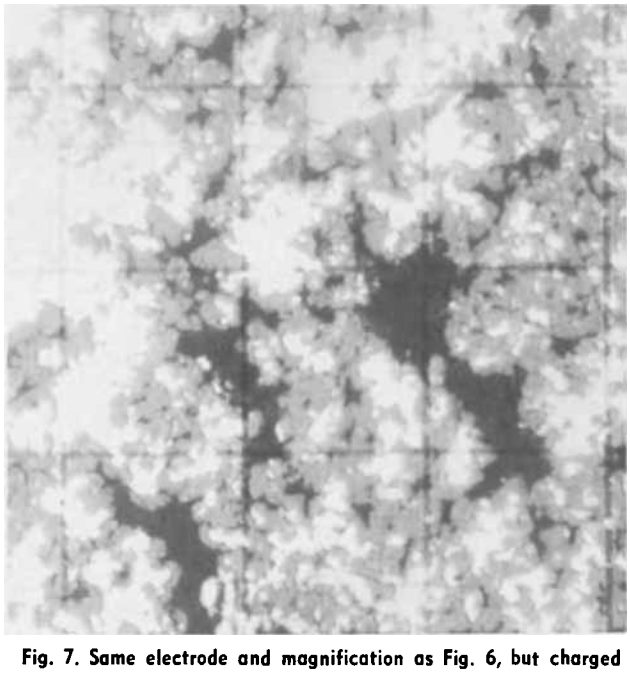

Fig. 7. Same electrode and magnification as Fig. 6, but charged until potential rose at the end of the Ag/Ag_2O potential plateau at cycle 28. Compare with Fig. 2 and 3 for changes with cycling.

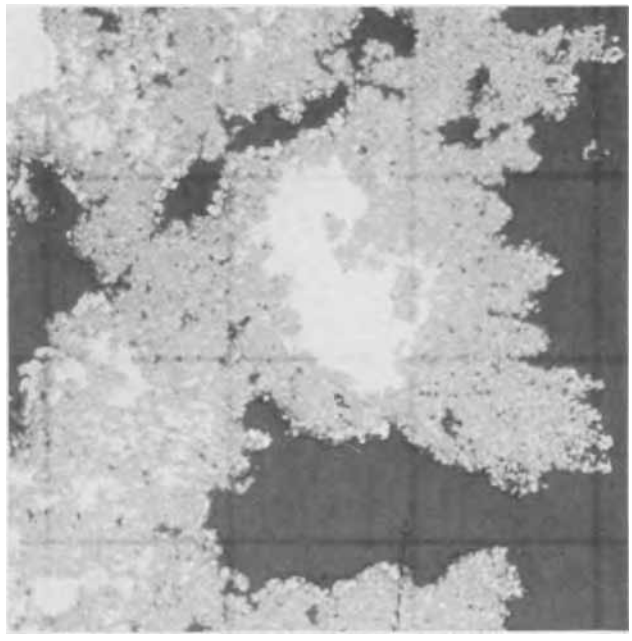

Fig. 8. Another area of the electrode shown in Fig. 7, but at lower magnification with lines forming squares being 60μ apart. Electrode surface is at the right. Comparison with Fig. 4 shows that active material had clumped as electrode was cycled.

Discussion

Anodic formation of Ag_2O.—It has been established that the anodic oxidation of Ag to Ag_2O in an alkaline solution takes place through two mechanisms (4-6). When a bare Ag surface is anodically oxidized, the initial reaction is Ag going into solution, probably as the ion $Ag(OH)_2^-$. The solution becomes supersaturated in the early part of a charge (7). Dissolved Ag precipitates on the Ag surface as Ag_2O. Through this process the amount of Ag in a particle can increase or decrease as the Ag is oxidized. In practice, little or no change in average particle size was observed during a charge. The oxidation mechanism changes after a layer of Ag_2O has deposited on Ag and then Ag_2O forms directly at crystallization centers. Obviously the number of crystallization centers present in the sintered electrode was very large. This was evident from the fact that almost all individual Ag particles had a coating of Ag_2O before the formation of Ag_2O was half completed. The formation and growth of Ag_2O crystals on smooth Ag has been studied by electron microscopy of surface replicas by Yoshizawa and Takehara (8) and in more detail by Briggs *et al.* (9). Although most of the present work was not directly comparable with this electron microscopy, the results agreed in general. The present work differed in using cross sections of porous electrodes and in viewing these at a much lower magnification. The fact that particles near the surface of porous electrodes differed from the interior after cycling indicated that conditions in sintered Ag particles can be significantly different from those on smooth Ag.

Measurements have shown no appreciable photochemical decomposition of Ag_2O under ordinary conditions (10). When anodic current is being passed, illumination can result in nonequilibrium conditions at the surface of the electrode, resulting in lowered resistance and AgO forming at potentials lower than usual (11-13). This process can take place only near the surface where light penetrates and probably had no effect on the present work using relatively thick electrodes which were never illuminated strongly. The experimental cell was exposed to some room light during daytime, but light reaching the electrode was

limited by the translucent polyethylene cell case and also by the opaque separator material which was wrapped around the electrode.

There are indications that Ag_2O and AgO are not the only oxides of silver. For example, Vol and Shishakov heated thin films of Ag at 100°-200°C in O_2 near atmospheric pressure and detected by electron diffraction what they considered to be a thin surface peroxide film of "AgO_2" having a cubic structure with a = 5.52 ± 0.02Å (14). Later Gossner and Polle used electron diffraction and detected a surface oxide which they call "AgO_x" when Ag reacted with H_2O_2 or when Ag was anodically oxidized in 0.1M NaOH (15). This oxide was reported to have a cubic structure with a = 5.55 ±0.01Å and is obviously the same material found earlier (14). No chemical analyses have been reported for this AgO_2 or AgO_x.

More recently Gossner *et al.* studied the anodic oxidation of Ag in 0.01M NaOH and claim that this AgO_x always forms as an intermediate between Ag_2O and AgO (16). They reported that after a coating of Ag_2O has formed on the surface of Ag under constant current conditions, then AgO_x forms in place of the Ag_2O as potential rises toward the peak at the end of the Ag/Ag_2O plateau, and no Ag_2O remains on Ag at the potential peak. AgO is then formed from the AgO_x. They find the same formation sequence under potentiostatic conditions.

If it is assumed that Ag_2O is entirely converted to some other oxide such as AgO_x before potential reaches the peak, then the photographs in the present work should show this other oxide and not Ag_2O. However, there actually is no valid reason for believing that any oxide except Ag_2O is shown in the photographs. When earlier work is considered, it becomes obvious that the statements of Gossner *et al.* (16) cannot be accepted as universally true. For example, the results of x-ray diffraction performed while Ag was being anodically oxidized in 8.4M KOH showed the presence of only Ag_2O and Ag as potential approached and reached the peak (17). The Ag_2O diffraction pattern did not broaden or shift as Ag_2O was then oxidized to AgO. Obviously all Ag_2O had not been converted to a material such as the proposed AgO_x before AgO formed. In fact, if any AgO_x was present under these conditions it must have been present in only such a small amount or such a thin layer that AgO_x was undetectable by x-ray diffraction.

Perhaps the difference between much of the literature concerning the anodic oxidation of Ag and the results of Gossner *et al.* comes from the weakly alkaline solution they used (16) in contrast to the strongly alkaline solutions more often used. However, even in 1*N* KOH Briggs *et al.* found only Ag_2O in samples oxidized anodically up to the potential peak (9). There is no reason to doubt that in the present work when an electrode was oxidized to the potential peak the oxide was mostly or entirely Ag_2O and not AgO_x.

Oxidation of Ag in porous electrodes.—Ag_2O occupies a greater volume than does metallic Ag, per atom of Ag. Void space between particles of Ag decreased, therefore, as Ag_2O was formed during a charge. This change can be seen by comparing Fig. 1 with Fig. 2 and 3. It can also be seen by comparing Fig. 6 with Fig. 7.

Although the oxidation of Ag did not take place simultaneously in all areas of the porous electrodes used in the present work, Ag_2O had formed on most of the Ag particles before an electrode was 20% charged. Approximately 40% of the active material in a cycled electrode still remained as metallic Ag when potential reached the peak between the Ag/Ag_2O and Ag_2O/AgO plateaus. Most of this Ag consisted of the larger Ag particles in the electrode, particles that did not oxidize completely during a charge. The smaller Ag particles had been oxidized to a greater extent, and only small remnants of these remained as Ag metal (Fig. 2, 3, 7).

Approximately one-tenth of the silver oxide in a charged electrode was not reduced during a discharge at the 1-hr rate, but still remained when potential reached the cutoff value and discharge ended. The amount of oxide remaining gradually increased as the electrolyte aged, apparently the result of carbonate concentration slowly becoming larger while KOH concentration decreased proportionately. An increase in capacity was obtained by replacing the electrolyte with fresh KOH solution. Part of this increase is indicated in Fig. 5 by the increased amount of Ag_2O which formed in cycles after point B.

Changes in structure after repeated cycling.—The charge capacity that an electrode accepted at the Ag/Ag_2O potential depended on whether large or small Ag particles had been formed during the preceding discharge. There was a large change in the structure of Ag electrodes during their first discharge, with the change depending on the discharge C.D. As mentioned, during a fast (1-hr) discharge Ag formed as particles having a size on the order of 1μ. These particles were smaller than those in the unused electrode. On the other hand, Ag particles ten times larger than those in the unused electrode had formed during the first slow (20-hr) discharge. Most Ag particles that form during a slow discharge are in the range of 10-25μ in size. During cycle 2 charge an increased amount of Ag_2O formed from electrodes containing small particles, while a decreased amount of Ag_2O formed from the large particles. An example of the large Ag particles that formed during slow discharges is given in Fig. 9. Since the large particles were only oxidized to a depth of 1-2μ at their surfaces, approximately 82% of the Ag remained in the metallic state in the electrode shown in Fig. 9. The effect of C.D. on particle size is reflected in Fig. 5 by the rise in the solid lines and fall in the dashed lines during the first few cycles.

After electrodes that always used fast discharges were given a number of cycles, the average size of Ag particles had increased. Despite this increased size the Ag particles were still much smaller after 27 cycles than after 5 cycles using slow discharges. This can be seen by comparing Fig. 6 and 7 with Fig. 9, all at the same magnification. Only a small proportion of par-

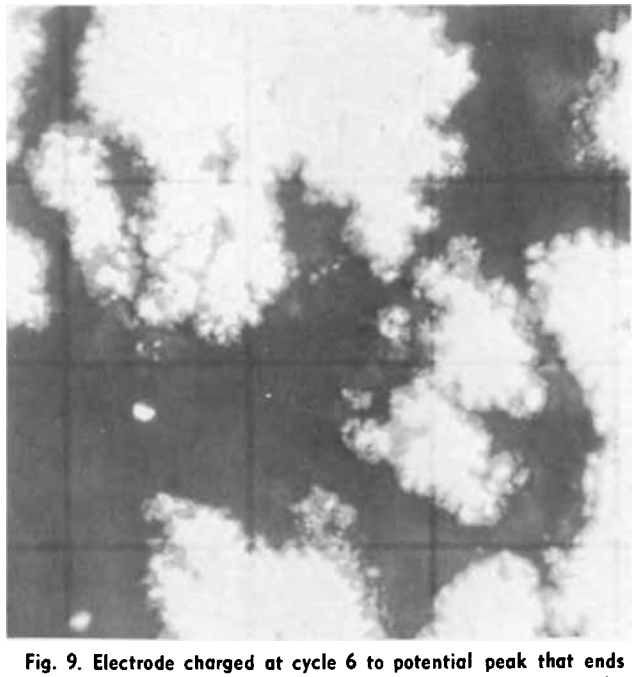

Fig. 9. Electrode charged at cycle 6 to potential peak that ends the Ag/Ag_2O plateau. This electrode was always discharged at the 20-hr rate, in contrast with other photographs where the 1-hr rate was always used. Comparison with Fig. 3 and 7 shows effect of discharge rate on subsequent formation of Ag_2O. Lines forming squares are 15μ apart.

ticles were larger than 5μ in an electrode never given slow discharges.

Although the proportion of particles having a particular size changed with cycling, the range of particle sizes and shapes did not change. When an electrode was viewed at high magnification (800X or higher), areas could be found in a well-cycled electrode that closely resembled areas in an electrode after only 1 or 2 cycles. The changes that took place during a particular charge as Ag particles were oxidized to Ag_2O were usually best observed at high magnifications.

Lower magnifications (100X to 400X) were useful for studying changes in structure that took place gradually over a series of cycles, such as changes in sizes of voids and of clumps of active material, as well as changes in the proportion of active material having a given structure. The clumping of active material during cycling can be seen by comparing Fig. 4 and 8 for electrodes at cycles 2 and 28. Clumping can also be seen, but less readily, by comparing Fig. 1 and 6. The clumping of active material resulted in large voids developing while small voids decreased in number. The active material tended to clump around large Ag particles and around the Ag grid. A study of the changes during cycles 1 and 2 indicated that probably all this deposition of active material on large Ag particles and on the grid took place during discharge and probably none during charge.

Conductivity must have been good because examination of these electrodes in various states of charge and discharge did not indicate that reactions took place at the grid (Fig. 4) in preference to the remainder of the electrode. Particles or groups of particles that appeared to be isolated reacted to the same extent as particles obviously touching each other. There must have been connections between the particles that were above or below the planes where the electrodes had been cut to reveal the cross sections. Many Ag particles that remained at the end of a charge, particularly the larger particles, served as parts of a conductive network together with the grid. During a fast discharge groups of small Ag particles formed on the Ag of the conductive network.

Even at the end of cycle 1 charge, before active material had clumped, adjacent crystals of AgO were often found touching each other. Since the oxides were slightly soluble in the KOH solution, oxides close to conducting particles could be reduced on these particles. In this way the deposit of small dendritic Ag particles gradually thickened on larger particles and on the grid as an electrode was cycled (compare Fig. 4 and 8). As a result the active material came to be present in increasingly large clumps of particles. At the same time voids between the clumps grew in size. The clumping and development of voids was the same whether the electrode was given fast or slow discharges.

The small Ag particles that deposited near the large Ag particles and near the grid during a fast discharge were of suitable size to be oxidized completely during the next charge. Thus the oxide layers in charged electrodes gradually became thicker with cycling. It was pointed out earlier that the small Ag particles oxidized before the grid surface and formed a coating protecting the grid from serious attack, in contrast with the large Ag particles which formed during slow discharges (2).

The fact that a few groups of particles developed an alignment at right angles to the electrode surface (right side of Fig. 8) suggests that formation of these groups was connected with either current paths or diffusion in the electrolyte. The aligned groups shown in Fig. 8 must have been present at the end of the previous discharge, because Ag particles were visible within the Ag_2O. A few similarly oriented groups of AgO were found at the end of a charge. It is not known whether the alignment of particles took place during charges or discharges.

Conclusions

1. Ag_2O formed on Ag particles at the surface and interior of electrodes without preference during a charge, but more Ag_2O formed in some areas than in others.
2. Most of the Ag particles had a definite Ag_2O coating before the Ag/Ag_2O potential plateau was half completed. Very few particles were completely oxidized to Ag_2O when the potential peak ending the Ag/Ag_2O plateau was reached.
3. Ag_2O did not form into large solid masses but contained many small voids. Void space within an electrode decreased during a charge, however, because Ag_2O occupied a greater volume than did Ag.
4. Electrode capacity was definitely related to the microstructure. Charge acceptance at the Ag/Ag_2O potential plateau increased during the first few charges following discharges at the 1-hr rate. In contrast, charge acceptance decreased following discharges at the 20-hr rate until only one-third as much Ag_2O formed. The difference resulted from small Ag particles forming during fast discharges while large particles formed during slow discharges
5. Conductivity was good within the electrode, apparently because many Ag particles served as parts of a conductive network together with the grid. Nearby oxides could be reduced on the conducting particles during discharges. As a result, during a series of cycles the active material gradually clumped around large Ag particles and around the grid.
6. Fast discharges repeated for many cycles resulted in changes within an electrode, but little change at the surfaces. It can, therefore, be misleading to draw conclusions about structure after examining only the surfaces of an electrode.

Electrodissolution Kinetics of Iron in Chloride Solutions

Part I. Neutral Solutions

S. Asakura* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

Anodic dissolution of iron in unbuffered neutral chloride solutions has been investigated by transient polarization techniques. A new method to correct for the ohmic potential drop has been proposed. It has been observed that the anodic Tafel slopes were 40 mV/decade for fast polarization and 80 mV/decade for slow or steady-state polarization. Steady-state anodic characteristics of iron have been studied by superimposing short cathodic potential and current pulses. At steady-state anodic polarization a Tafel relation was obtained between the cathodic potential (ϕ_c) and the cathodic current (i_c) with a Tafel slope of about 120 mV/decade for both potentiostatic and galvanostatic pulses. The difference in anodic Tafel slopes has been interpreted in terms of the formation of a hydroxochloro-iron complex, $[Fe(OH)_m(Cl)_n]^{2-m-n}$. The cathodic pulse polarization results indicate that $m = 1$.

Numerous studies of the anodic dissolution of iron in acidic chloride solutions have been carried out. There have not been as many studies of iron in neutral solutions in spite of their practical importance. Hoar and Farrer (1) studied the anodic polarization of mild steel in dilute neutral chloride solution and obtained Tafel slopes of about 60 mV. Stern (2) observed marked hysteresis for iron in 4% NaCl solutions of pH 1-4. Stern and Roth (3) indirectly deduced the anodic Tafel slope of iron in this solution as 78 or 68 mV. On the other hand, Hurlen (4) obtained reproducible Tafel lines with slopes of 30 mV for iron in acidic KCl solutions. He observed deviations from the Tafel line at high current densities and at high pH. Based on extensive experiments, Bockris, Drazic, and Despic (5) obtained anodic Tafel slopes of 40 mV for iron in acidic sulfate and chloride solutions.

Nobe and Tobias (6) observed that the anodic polarization of iron in H_2SO_4 in the active state was not appreciably affected by chloride ions. Podesta and Arvia (7) found that the steady-state anodic polarization of iron yielded Tafel slopes of 32-54 mV (2M NaCl) and 37-61 mV (0.2M NaCl) for solutions of various pH values.

Ross, Wood, and Mahmud (8) studied the anodic behavior of iron in flowing solutions of HCl and H_2SO_4. While no effect of flow was observed at low current densities, polarization decreased as the flow rate increased at high current density. They ascribed the latter to the formation of a porous surface compound formed at high current densities. Foroulis (9) observed considerable hysteresis in HCl solutions and surmised that this hysteresis was due to adsorption of Cl^- and subsequent complex formation. Complex formation of this kind had been previously proposed by Schottky (10). Morozumi and Posey (11) applied the pH-stat technique (12) to the detection of an iron complex. Florianovich, Sokolova, and Kolotyrkin (13) have suggested the formation of an iron-sulfate complex.

In this work, the anodic dissolution of iron in unbuffered neutral solutions has been investigated by transient techniques.

Experimental

The electrolyte used was 1*N* potassium chloride solution, deaerated with purified nitrogen. The test specimen was Ferrovac E iron with a purity of 99.91%. The 1 cm diameter rod was sealed in Teflon such that only one cross-sectional surface was exposed to the electrolyte. This surface was polished by 2/0 emery paper. The electrode was degreased with detergent and rinsed several times with distilled water and benzene. When surface roughing became pronounced during an experiment, the electrode was repolished, degreased, and rinsed again in the same manner. Electrical signals were generated by combining the potentiostat (response time, 1 μsec) with function generators and pulse generators. The responses were recorded on either an oscilloscope or an X-Y recorder. The electrochemical cell was constructed of Pyrex and was the common three-electrode type cell. The temperature was maintained at 25° ± 1°C.

Results

Steady-state anodic polarization.—The open triangle in Fig. 1 shows the apparent potential (E_a)-current (i_a) relation under steady-state anodic polarization. While the plot follows Tafel behavior at low current density, the deviation is considerable at high current density due to the ohmic potential drop. The potential after the subtraction of the ohmic drop from the apparent potential is plotted as closed circles. The solution resistance was determined by the pulse technique.

The electrode potential was also measured by the current-interrupting method. Current was interrupted for 120 μsec. The interruption was repeated at intervals of 10 Hz. The open circles represent the potential immediately after interrupting the current. The plots, after correction for the ohmic drop, show Tafel behavior with a slope of about 80 mV/decade up to 200 mA/cm^2.

Linear anodic potential sweep polarization.—The linear potential sweep method was used to obtain the anodic polarization behavior under transient conditions. The potential sweep in the anodic direction was started at the open-circuit potential (E_o). The open-

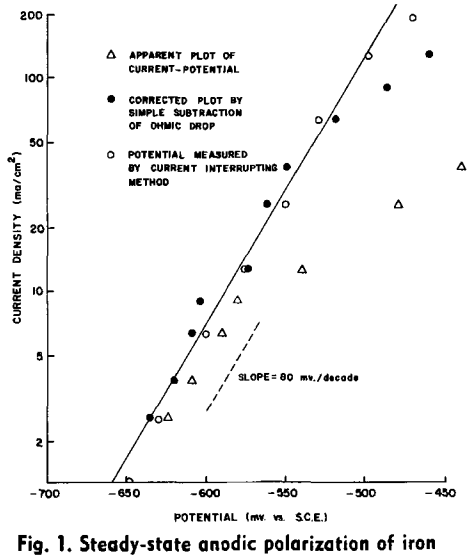

Fig. 1. Steady-state anodic polarization of iron

* Electrochemical Society Active Member.

Key words: corrosion, anodic behavior, transient behavior.

circuit potential was around −780 mV *vs.* SCE. At high sweep rates, the charging current for the double layer capacitance, *i.e.*, nonfaradaic current, was dominant in the low current density region. However, at high current densities the ohmic drop became considerable. Therefore, in order to obtain the faradaic current at fast potential sweeps the ohmic drop must be eliminated.

The tangent method has been developed to eliminate the ohmic drop. The procedure is as follows. As illustrated in Fig. 2, a line tangent to a point on the apparent potential-current curve is drawn and extrapolated to zero current. The intercept of the tangent line with the potential axis ($i_a = 0$) is an important parameter as shown below.

The apparent potential (E_a) is equal to the sum of the electrode potential (ϕ_a) and the ohmic drop $R_s i_a$

$$E_a = \phi_a + R_s i_a \qquad [1]$$

where R_s is the solution resistance. The line tangent to the curve at (i_{al},E_{al}) is expressed by

$$E_a = \left[\left(\frac{\partial \phi_a}{\partial i_a} \right)_{i_a = i_{al}} + R_s \right] (i_a - i_{al}) + E_{al} \qquad [2]$$

The potential of the intercept, E_{ax}, is obtained by putting $i_a = 0$

$$E_{ax} = \phi_a - i_{al} \left(\frac{\partial \phi_a}{\partial i_a} \right)_{i_a = i_{al}} \qquad [3]$$

Equation [3] does not include the term for the ohmic potential drop given in Eq. [1]. In other words, E_{ax} is only a function of ϕ_a. The solution of the differential Eq. [3] with respect to ϕ_a is shown in Eq. [4].

$$\phi_a = i_{al} \int_{i_{al}}^{\infty} (E_{ax}/i_a^2)\, di_a \qquad [4]$$

Thus, the electrode potential ϕ_a, which does not include the ohmic potential drop, can be deduced from the intercept E_{ax}. For the special case where ϕ_a obeys the Tafel equation

$$\phi_a = a + b \log i_a \qquad [5]$$

E_{ax} can be expressed by

$$E_{ax} = a - b/2.3 + b \log i_a \qquad [6]$$

Equation [6] indicates that a plot of E_{ax} *vs.* log i_a is a straight line with the slope b. Therefore, ϕ_a is determined from

$$\phi_a = E_{ax} + b/2.3 \qquad [7]$$

An example of a plot of ϕ_a *vs.* log i_a is shown in Fig. 3 and compared with the apparent Tafel plot. At low current densities, E_a and ϕ_a show good agreement because of the negligible ohmic potential drop. At high current densities, E_a deviates from the straight line, while ϕ_a still follows the linear relationship. The plots of ϕ_a *vs.* log i_a were determined for various sweep rates. At high sweep rates these plots were still linear in the high current density region. The Tafel slopes thus obtained are shown in Fig. 4. The Tafel slope was found to change from 80 to 40 mV/decade with increase in sweep rate. Limitations of the function generator precluded results at higher sweep rates.

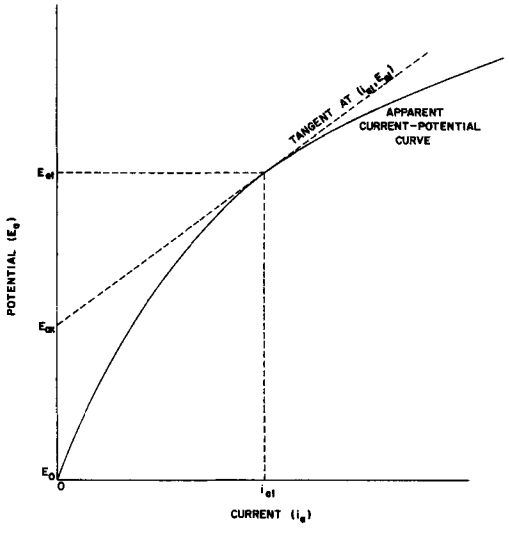

Fig. 2. Illustration of the tangent method

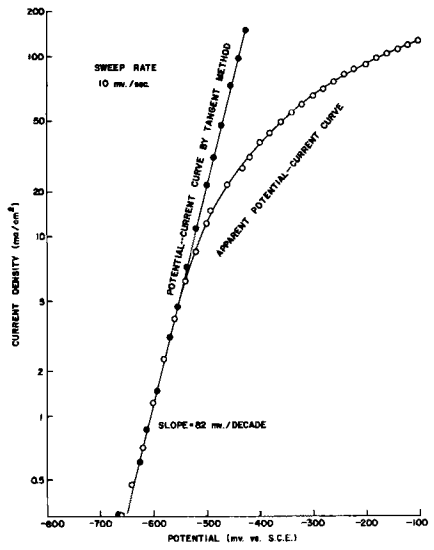

Fig. 3. Comparison of polarization curves obtained directly and by the tangent method.

Potentiostatic anodic pulse polarization.—A short single potential pulse was imposed on the electrode at the open-circuit potential, as shown in Fig. 5. An analysis of the responding current yields the polarization behavior corrected for the ohmic potential drop. The

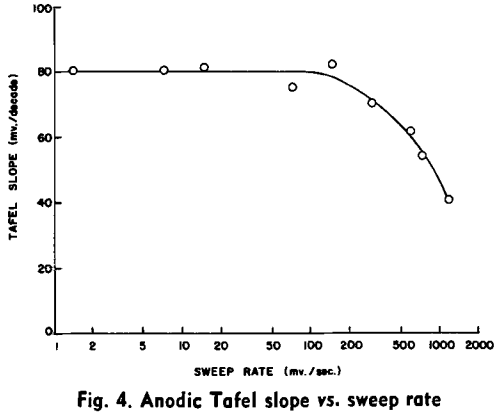

Fig. 4. Anodic Tafel slope *vs.* sweep rate

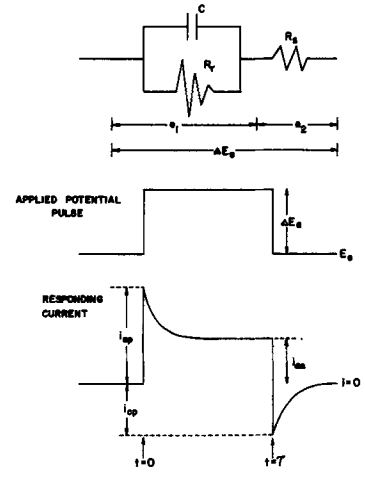

Fig. 5. Transient behavior during pulse polarization

principle is as follows. The equivalent circuit of the electrode is given by the top figure in Fig. 5. The applied potential pulse ΔE_a can be divided into the change in the electrode potential, e_1 and the ohmic potential drop, e_2, *i.e.*

$$\Delta E_a = e_1 + e_2 \qquad [8]$$

Immediately after ΔE_a is imposed, e_1 is zero due to the double layer capacitance C_{dl}. Therefore

$$e_2 = \Delta E_a \text{ at } t = 0 \qquad [9]$$

Then, the current i_{ap} at $t = 0$ is

$$i_{ap} = \Delta E_a / R_s \qquad [10]$$

After C_{dl} is charged, the current reaches a constant value, i_{as}. At this stage

$$e_1 = \phi_a - E_o \qquad [11]$$

$$e_2 = R_s i_{as} \qquad [12]$$

where ϕ_a is the electrode potential, exclusive of the ohmic potential drop.

When the pulse is shut off at $t = \tau$ ($\Delta E_a = 0$), e_1 still follows Eq. [11]. Then, i_{cp}, the current at $t = \tau$ is related to ϕ_a by

$$\phi_a = R_s \mid i_{cp} \mid + E_o \qquad [13]$$

Thus, ϕ_a can be determined because of the existence of the double layer capacitance. Experimentally, the double layer charging was completed within 1 msec. R_s was determined from the plot of i_{ap} *vs.* ΔE_a. By substituting R_s, thus obtained, into Eq. [13], ϕ_a can be determined. ϕ_a is plotted *vs.* log i_{as} in Fig. 6. The plots show straight lines up to high current densities in spite of the large ohmic drops. When ΔE_a is small, the points for short pulses deviated from these plots due to the nonfaradaic current. Tafel slopes were about 40 mV/decade for short pulses, while it was about 80 mV/decade for long pulses.

Potential pulse reduction of an anodized electrode.— An anodically polarized electrode at a steady state was periodically reduced by short constant cathodic potential pulses. The potential pulse width was 5 msec and the time interval between pulses was 0.5 sec. The duration of the potential pulse was so short that the anodic process can be considered to be maintained at steady-state conditions. Figure 7 shows an example of the current transient (i_c) due to a reducing cathodic potential pulse. The plot is shown as the logarithm of $|i_c|$ *vs.* time (t). A slow linear decrease in log current is observed after a sharp decrease which corresponds to the charging of the double layer capacitance. The plots of the current (i_{ci}) at $t = 0$ *vs.* the applied pulse potential give straight lines as shown in Fig. 8.

Since a double layer capacitance exists between the electrode and solution as shown in Fig. 5, the electrode

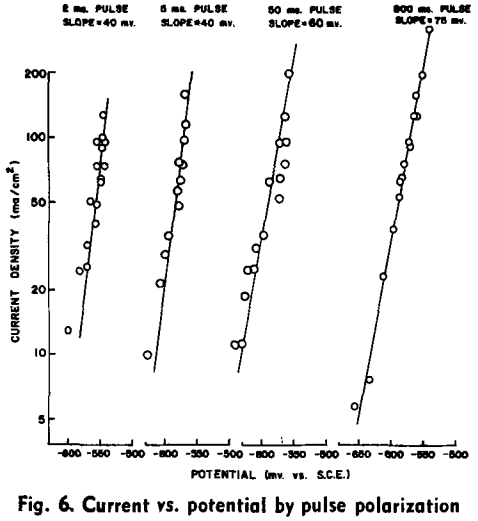

Fig. 6. Current *vs.* potential by pulse polarization

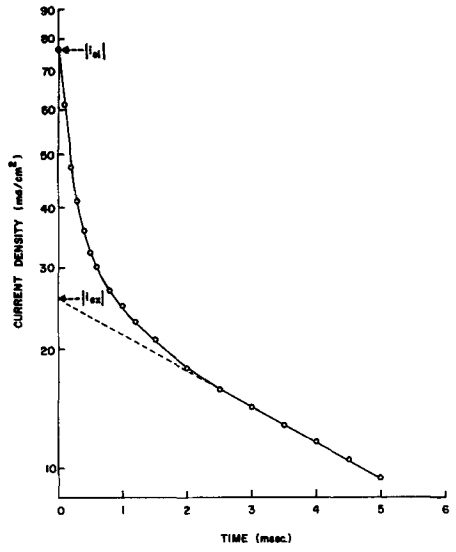

Fig. 7. Current transient of a cathodic potential pulse during anodic polarization of iron.

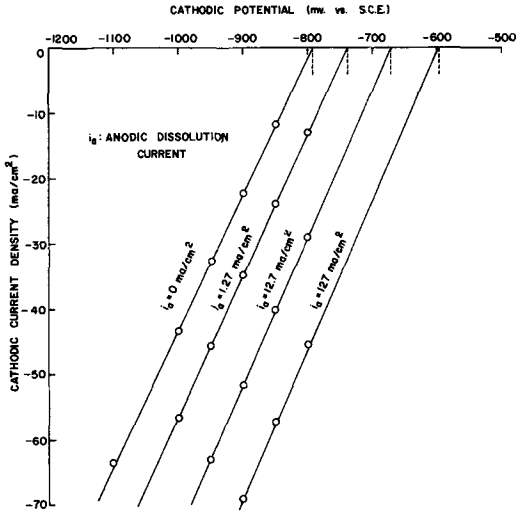

Fig. 8. Plots of i_{ci} *vs.* the cathodic potential pulse

potential at steady-state anodic polarization, ϕ_a, is still maintained at $t = 0$. Then, the relation

$$i_{ci} = (E_c - \phi_a)/R_s \qquad [14]$$

is obtained, where E_c is the applied cathodic pulse potential. Therefore, the slopes of the lines in Fig. 8 express the solution conductance $1/R_s$ and the extrapolation of these lines to zero current gives, ϕ_a, the steady-state anodic potential exclusive of the ohmic potential drop. The anodic electrode potential, ϕ_a, thus obtained, is plotted against the logarithm of the anodic current, i_a, in Fig. 9. The Tafel slope of this line is about 80 mV/decade.

$$\partial \phi_a / \partial \log i_a = 80 \text{ mV/decade} \qquad [15]$$

This value is in good agreement with that obtained from the direct steady-state anodic polarization data discussed above. Thus, the anodic Tafel slope of iron in neutral chloride solutions for steady-state polarization has been confirmed by another method. Morozumi (14) reported nearly the same value for iron in neutral sodium chloride solutions.

The slow decrease in the log $|i_c|$ probably results from a change in the surface state of iron. The extrapolation of the linear portion of the curve in Fig. 8 to zero time would give the cathodic current, i_{cx}, at conditions where the iron surface and its environment have not changed appreciably from that at steady-state anodic polarization. The charging current is only

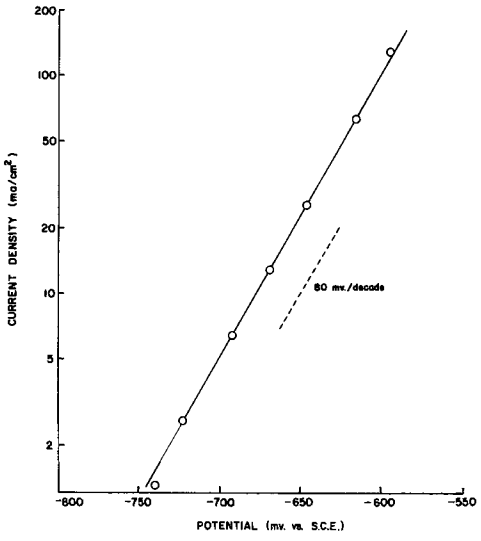

Fig. 9. Steady-state anodic Tafel plot obtained by the cathodic potential pulse method.

a negligible part of i_{cx}. The logarithm of $|i_{cx}|$ is plotted in Fig. 10 against ϕ_c which is the cathodic potential exclusive of the ohmic potential drop. The slope of the plots was about −120 mV/decade

$$\left(\frac{\partial \phi_c}{\partial \log |i_{cx}|}\right)_{i_a} \approx -120 \text{ mV/decade} \qquad [16]$$

Figure 11 shows the dependence of the cathodic current i_{cx} on the steady-state anodic current, i_a. It is found that log $|i_{cx}|$ is linearly related to log i_a with the slope of about 1

$$\left(\frac{\partial \log |i_{cx}|}{\partial \log i_a}\right)_{\phi_c} \approx 1 \qquad [17]$$

Galvanostatic pulse reduction of an anodized electrode.—A short cathodic current pulse, i_c, was superimposed on the constant anodic current. The cathodic current pulse width and time interval between pulses were 5 msec and 0.5 sec, respectively. The anodic process was maintained at steady state. The potential transient for a reducing cathodic current pulse is shown in Fig. 12. At $t = 0$, the potential abruptly drops to E_{ci} due to the ohmic potential drop followed by a gradual decrease. The linear part of the curve is extrapolated to $t = 0$ and the intercept is defined as E_{cx}. Both E_{ci} and E_{cx} include the ohmic potential drop, $R_s i_c$, *i.e.*

$$E_{ci} = \phi_a + R_s i_c \qquad [18a]$$

$$E_{cx} = \phi_{cx} + R_s i_c \qquad [18b]$$

where ϕ_{cx} is the cathodic potential, exclusive of the ohmic potential drop.

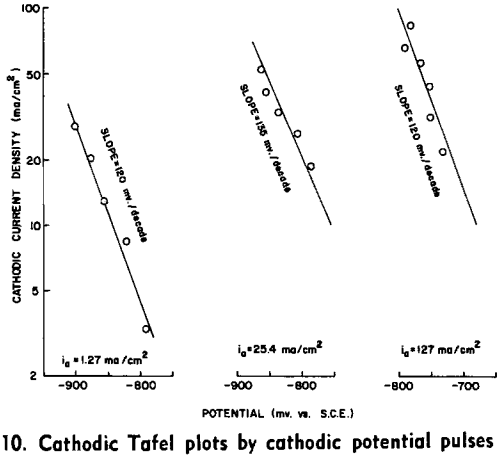

Fig. 10. Cathodic Tafel plots by cathodic potential pulses during anodic polarization.

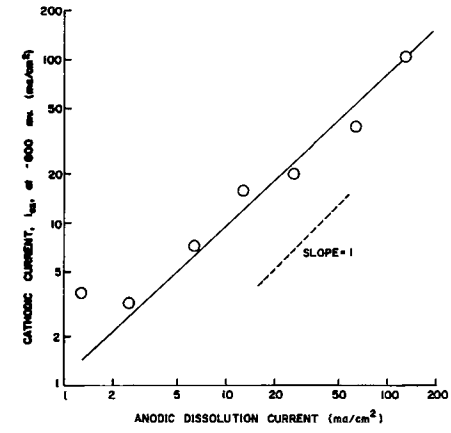

Fig. 11. Extrapolated cathodic current (i_{cx}) vs. the steady-state anodic current.

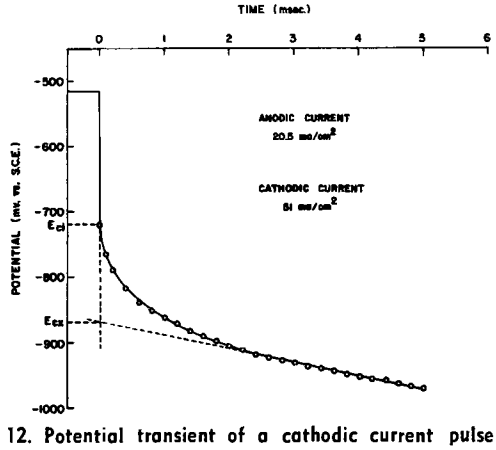

Fig. 12. Potential transient of a cathodic current pulse during anodic polarization of iron.

Therefore

$$E_{ci} - E_{cx} = \phi_a - \phi_{cx} \qquad [19]$$

and does not include the ohmic potential drop. Since ϕ_a is independent of i_c, the following relation holds

$$\left(\frac{\partial (E_{ci} - E_{cx})}{\partial \log |i_c|}\right)_{i_a} \approx -\left(\frac{\partial \phi_{cx}}{\partial \log |i_c|}\right)_{i_a} \qquad [20]$$

The plots of log $|i_c|$ *vs.* $(E_{ci} - E_{cx})$ are shown in Fig. 13. These plots exhibit straight lines with slopes of about 120 mV/decade. Therefore, the following relation is obtained

$$\left(\frac{\partial \phi_{cx}}{\partial \log |i_c|}\right)_{i_a} \approx -120 \text{ mV/decade} \qquad [21]$$

The plots of E_{cx} *vs.* log i_a at constant i_c are shown in Fig. 14. A linear relation is observed with slopes of

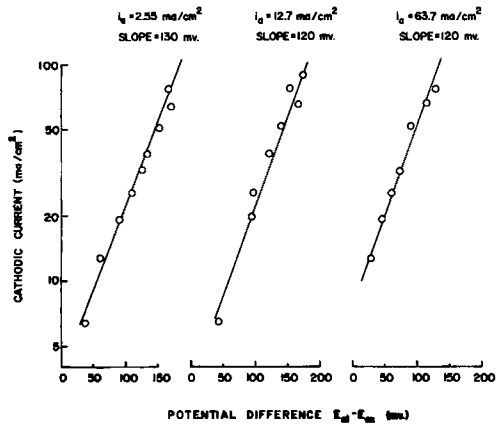

Fig. 13. Cathodic Tafel plots by cathodic current pulses during anodic polarization of iron.

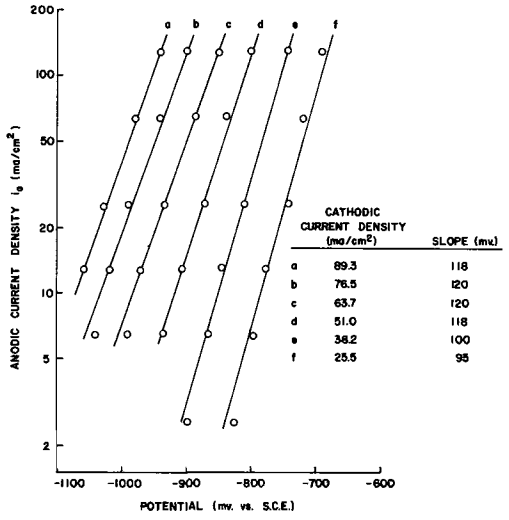

Fig. 14. Plots of the extrapolated cathodic potential (E_{cx}) vs. log i_a at constant cathodic current.

between 120 to 95 mV/decade, *i.e.*

$$\left(\frac{\partial E_{cx}}{\partial \log i_a}\right)_{ic} = 120 \text{ to } 95 \text{ mV/decade} \qquad [22]$$

By introducing Eq. [18b], Eq. [22] becomes

$$\left(\frac{\partial \phi_{cx}}{\partial \log i_a}\right)_{ic} = 120 \text{ to } 95 \text{ mV/decade} \qquad [23]$$

Discussion

As mentioned above, the anodic Tafel slopes were about 40 mV/decade for fast polarization and about 80 mV/decade for slow or steady-state polarization. The Tafel slope for fast polarization is consistent with that deduced from the Bockris mechanism. Akiyama *et al.* (15) reported the same value for iron in 1*N* H_2SO_4 under steady-state polarization. It is evident that the *p*H at the electrode is much different from that of the bulk solution in unbuffered neutral solutions. In this experiment, the anodic passivation was not observed even at a current density of 200 mA/cm². The critical current density for the neutral solutions in the absence of chloride ions has been reported to be less than 100 μA/cm² (16). In acidic solutions, *e.g.*, 1*N* H_2SO_4, the critical current is about 200 mA/cm² in the absence of chloride ions (17). The absence of passivation even at high current densities and Tafel behavior in the entire range indicate the probable formation of a soluble iron complex with chloride ions. The existence of an iron complex with chloride ions has been suggested previously by Schottky (10) and Foroulis (9). Therefore, it seems reasonable that the results of this work can be interpreted by assuming the formation of a hydroxochloro-iron complex and the consequent *p*H change at the electrode surface. In addition, the Bockris mechanism (5) with low coverage of reaction intermediate, Fe(OH), is assumed.

Reaction mechanism.—The Bockris mechanism (5) for iron dissolution is as follows

$$Fe + OH^- = (FeOH)_{ads} + e \qquad [24a]$$

$$(FeOH) \xrightarrow{RDS} FeOH^+ + e \qquad [24b]$$

$$FeOH^+ = Fe^{++} + OH^- \qquad [24c]$$

In addition, the reaction for the formation of the complex is assumed to be at equilibrium

$$Fe^{++} + mH_2O + nCl^- = [Fe(OH)_m(Cl)_n]^{2-n-m} + mH^+ \qquad [24d]$$

Therefore, the over-all reaction can be expressed by

$$Fe + mH_2O + nCl^- = FeX + mH^+ + 2e \qquad [24e]$$

where FeX represents the complex ion, $[Fe(OH)_m(Cl)_n]^{2-n-m}$. According to Eq. [24e] the solution at the electrode becomes more acidic as the reaction proceeds. When step [24b] is rate determining and the hydrogen ion concentration at the electrode surface is $(a_{H^+})_{x=0}$

$$i_a = k_a(a_{H^+})^{-1}_{x=0} \exp(1+\beta)\mathbf{F}\phi_a/RT \qquad (25)$$

where k_a and β are the rate constant and the transfer coefficient, respectively. It has been assumed that the surface coverage of FeOH is low and that the Langmuir isotherm is valid.

Fast anodic polarization.—The concentration of H^+ at the electrode can remain nearly constant during polarization because the amount of H^+ produced by reaction [24d] is not appreciable. Therefore

$$\frac{\partial \phi_a}{\partial \ln i_a} = RT/(1+\beta)\mathbf{F} \qquad [26]$$

The Tafel slope corresponding to this equation is 40 mV/decade for $\beta = \frac{1}{2}$ at 25°C. This value is consistent with that obtained experimentally.

Steady-state anodic polarization.—At steady state, the H^+ and FeX produced must diffuse away continuously. Also the current is proportional to the diffusion rates of H^+ and FeX. The relation can be expressed by

$$i_a = -2\mathbf{F}D_{FeX}\left(\frac{\partial a_{FeX}}{\partial x}\right)_{x=0} = \frac{-2\mathbf{F}D_{H^+}}{m}\left(\frac{\partial a_{H^+}}{\partial x}\right)_{x=0} \qquad [27]$$

Application of diffusion layer theory simplifies Eq. [27]. Also, $(a_{H^+})_{x=0}$ is assumed to be much larger than the activity of H^+ in the bulk solution. Then

$$i_a = 2\mathbf{F}D_{H^+}(a_{H^+})_{x=0}/m\,\delta = 2\mathbf{F}D_{FeX}(a_{FeX})_{x=0}/\delta \qquad [28]$$

where δ is the diffusion layer thickness. Insertion of $(a_{H^+})_{x=0}$, thus obtained, into Eq. [25] gives

$$i_a^2 = \frac{2\mathbf{F}k_aD_{H^+}}{m\delta}\exp[(1+\beta)\mathbf{F}\phi_a/RT] \qquad [29]$$

that is

$$i_a = \sqrt{2\mathbf{F}k_aD_{H^+}/m\delta}\exp(1+\beta)\mathbf{F}\phi_a/2RT \qquad [30]$$

Therefore

$$\partial\phi_a/\ln i_a = 2RT/(1+\beta)\mathbf{F} \qquad [31]$$

The Tafel slope corresponding to Eq. [31] is 80 mV/decade. Thus, the difference in the Tafel slopes can be interpreted on the basis of *p*H changes at the iron surface. As discussed above, a number of authors have reported irreproducibility and deviation from anodic Tafel behavior at relatively high *p*H. At least part of these complications are the result of the *p*H change at the electrode surface.

Potential pulse reduction of an anodized electrode.—Since the complexation reaction is assumed to be at equilibrium, the following equation holds for a large excess of chloride ions

$$\frac{a_{FeX}a^m_{H^+}}{a_{Fe^{++}}} = K \qquad [32]$$

where K is the equilibrium constant. Equations [28] and [32] give

$$(a_{Fe^{++}})_{x=0} = K^{-1}(a_{FeX})_{x=0}(a_{H^+})^m_{x=0} = K'i_a \cdot i_a^m = K'i_a^{m+1} \qquad [33]$$

where

$$K' = \frac{mK^{-1}}{D_{H^+}D_{FeX}}\left(\frac{\delta}{2\mathbf{F}}\right)^2$$

When Eq. [24b] is also rate determining for the cathodic deposition reaction, the faradaic cathodic current is expressed by

$$i_{cx} = -k_c(a_{Fe^{++}})_{x=0}(a_{OH^-})_{x=0}\exp -(\beta'\mathbf{F}\phi_c/RT) \qquad [34a]$$

or

$$i_{cx} = -k'_c(a_{Fe++})_{x=0}(a_{H+})^{-1}{}_{x=0}\exp -(\beta'\mathbf{F}\phi_c/RT) \quad [34b]$$

where k_c and k'_c are rate constants and β' is the transfer coefficient corresponding to the reverse reaction of Eq. [24b]. Combining Eq. [34b] with [28] and [33], the cathodic current for conditions where the electrode surface and its environment are at the steady-state anodic polarization is obtained

$$i_{cx} = -k''_c i_a{}^{m+1} i_a{}^{-1}\exp -(\beta'\mathbf{F}\phi_c/RT)$$
$$= -k''_c i_a{}^m \exp -(\beta'\mathbf{F}\phi_c/RT) \quad [35]$$

where k''_c is a constant.

From Eq. [35], the following relation can be deduced

$$\left(\frac{\partial \phi_c}{\partial \log |i_{cx}|}\right)_{i_a} = \frac{-2.3RT}{\beta'\mathbf{F}} \quad [36]$$

$$\left(\frac{\partial \log |i_{cx}|}{\partial \log i_a}\right)_{\phi_c} = m \quad [37]$$

From Eq. [36]

$$\left(\frac{\partial \phi_c}{\partial \log |i_{cx}|}\right)_{i_a} = -120 \text{ mV/decade}$$

for $\beta = \frac{1}{2}$ at 25°C.

This is consistent with the values obtained from Eq. [16] and [21]. A comparison of Eq. [37] with Eq. [17] gives $m = 1$. This result can also be determined from the galvanostatic reduction experiments. In this case, Eq. [35] is transformed to

$$i_c = -k''_c \exp\left[-\frac{\beta'\mathbf{F}}{RT}\left(\phi_{cx} - \frac{RT}{\beta'\mathbf{F}} m \ln i_a\right)\right] \quad [38]$$

Therefore, when i_c is constant, the following relation is obtained

$$\left(\frac{\partial \phi_{cx}}{\partial \log i_a}\right)_{i_c} = \frac{2.3RT}{\beta'\mathbf{F}} m \quad [39]$$

By inserting Eq. [23], m is obtained as

$$m = 0.8 \text{ to } 1$$

Thus, the pulse reduction studies of anodized electrode have been shown to be consistent with the Bockris mechanism of iron electrodissolution, the formation of a hydroxochloro-iron complex, $[Fe(OH)_m(Cl)_n]^{2-n-m}$, $m = 1$ and the related pH change at the electrode surface.

Electrodissolution Kinetics of Iron in Chloride Solutions

Part II. Alkaline Solutions

S. Asakura* and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The anodic behavior of pure iron in alkaline chloride solution was studied by potential sweep and galvanostatic methods. For active dissolution anodic Tafel slopes of 65 and 66 mV/decade were obtained from the galvanostatic and potential sweep experiments, respectively. These values can be interpreted in terms of the Bockris mechanism with Temkin adsorption. Passivation was also observed. The peak current or critical current which appeared in the potential-current curve obtained by potential sweeps was proportional to the square root of the sweep rate. The potential associated with the peak current varied linearly in the anodic direction as the log of the sweep rate with a slope of 33 mV/decade. The square root of the passivation time obtained from galvanostatic polarization was inversely proportional to the current. These results were interpreted by assuming that passivation occurred when the iron chloride complex attained its solubility limit.

Comparatively few studies have been reported previously of iron in alkaline chloride solutions. Kabanov, Burstein, and Frumkin (1) found that the rate of anodic dissolution was not affected by the concentration of chloride ions ranging from 0.01 to 4*N* in 0.01*N* NaOH. They concluded that Cl^- did not actually participate in the anodic process. Hurlen (2) carried out some galvanostatic experiments in alkaline potassium chloride solutions. His chronopotentiograms showed active dissolution and passivation behavior. Shepherd and Schuldiner (3) studied the potentiostatic behavior of iron in a closed, high-purity alkaline system. They showed that iron acted like an inert noble metal but with addition of chloride ions extensive iron corrosion occurred; however, passive behavior as shown in potential-current curves was observed.

The complexation of iron in alkaline chloride solutions could play an important role in the iron dissolution processes. The importance of the formation of iron chloride complexes has been pointed out previously by Schottky (4) and Foroulis (5). Recently, Ogura, Haruyama, and Nagasaki (1) studied the open-circuit potential decay of passivated iron in neutral solutions containing chloride ions. They interpreted their results by assuming the formation of the complex FeOCl, which had been suggested previously by Schottky (4).

In this paper the anodic behavior of iron in an alkaline chloride solution was investigated by potential sweep and galvanostatic methods. The results have been interpreted in terms of the formation of an iron chloride complex, as proposed in a previous paper (7), and its precipitation on the electrode.

Experimental

A 1*N* potassium chloride and 0.1*N* potassium hydroxide solution was used as the electrolyte. The solution was deaerated with prepurified nitrogen. The test specimen was Ferrovac E iron with a purity of 99.9%. The temperature was maintained at 25° ± 1 C°. The electrical signals were generated by a potentiostat and function generators. The electrical responses were recorded by an X-Y and ordinary pen recorders.

Results

The electrode was reduced at about −1.5V (*vs.* SCE) and then left at open-circuit conditions until the electrode potential reached a constant value. After this treatment, the electrical signals were imposed on the electrode.

Potential sweep experiments.—The potential sweeps in the anodic direction were started from the open-circuit potential. Examples of the potential-current curves are shown in Fig. 1. Passivation behavior was observed, and it is seen that the shape of the curves was affected by the sweep rate (λ). The logarithm of the peak current (i_p) is plotted against log λ in Fig. 2. The log i_p was found to be linearly related to log λ with the slope of 1/2. Hence, the following relation was obtained

$$i_p = k_1\sqrt{\lambda} \qquad [1]$$

where k_1 is a constant. The primary passivation potential (E_p), *i.e.*, the potential associated with the peak current is plotted *vs.* log λ in Fig. 3. The slope of the linear relationship was 33 mV/decade

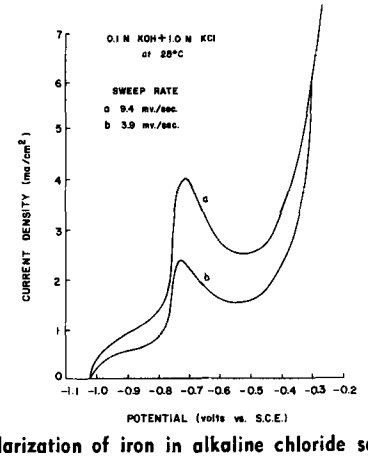

Fig. 1. Polarization of iron in alkaline chloride solutions by the potential sweep method.

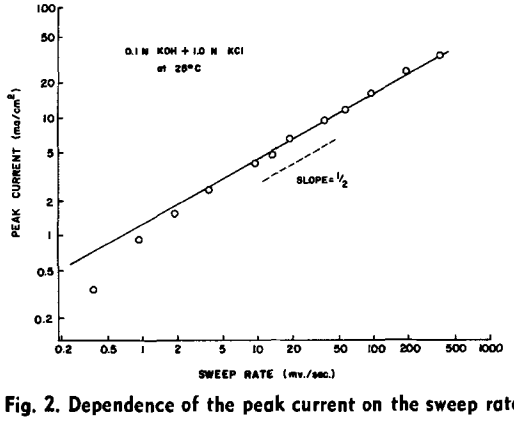

Fig. 2. Dependence of the peak current on the sweep rate

* Electrochemical Society Active Member.
Key words: corrosion, passivation, anodic behavior.

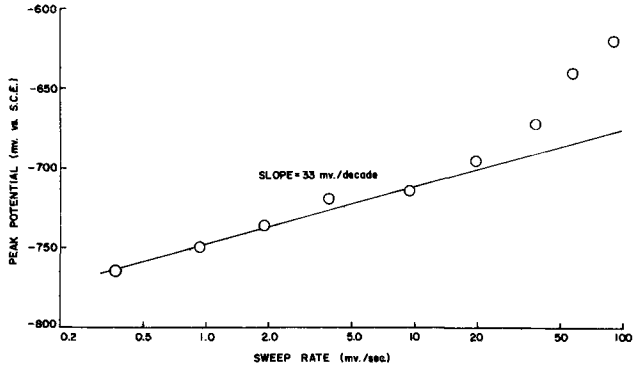

Fig. 3. Dependence of the peak potential on the sweep rate

$$\frac{\partial E_p}{\partial \log \lambda} = 33 \text{ mV/decade} \qquad [2]$$

The nonlinearity of the plot at high sweep rates was probably due to the ohmic potential drop.

Galvanostatic experiments.—A typical chronopotentiogram is shown in Fig. 4. There is a potential arrest at E_a and then a subsequent increase in potential. E_a can be regarded as the active potential corresponding to the applied current (i_a).

E_a is plotted against log i_a in Fig. 5. The Tafel slope was about 65 mV/decade

$$\frac{\partial E_a}{\partial \log i_a} = 65 \text{ mV/decade} \qquad [3]$$

The passivation time (t_p) was determined in the manner shown in Fig. 3. The plot of log t_p *vs.* log i_a is given in Fig. 6. A linear relation is obtained with the slope of −2 giving the following relation

$$i_a\sqrt{t_p} = k_2 \qquad [4]$$

where k_2 is a constant.

Discussion

In the previous paper (7) the dissolution kinetics of iron in neutral chloride solutions was interpreted in terms of the Bockris mechanism with the additional consideration of the formation of an iron chloride complex. The present results can also be interpreted on the same basis.

The Bockris mechanism (8) is as follows

$$\mathrm{Fe} + \mathrm{OH^-} = \mathrm{Fe(OH)} + e \qquad [5a]$$

$$\mathrm{FeOH} \xrightarrow{\text{RDS}} \mathrm{Fe(OH)^+} + e \qquad [5b]$$

$$\mathrm{Fe(OH)^+} = \mathrm{Fe^{++}} + \mathrm{OH^-} \qquad [5c]$$

The complexation reaction of iron in alkaline chloride solutions is

$$\mathrm{Fe^{++}} + m\mathrm{OH^-} + n\mathrm{Cl^-} = [\mathrm{Fe(OH)}_m\ (\mathrm{Cl})_n]^{2-m-n} \qquad [6]$$

Then, the over-all reaction is

$$\mathrm{Fe} + m\mathrm{OH^-} + n\mathrm{Cl^-} \rightarrow \mathrm{FeX} + 2e \qquad [7]$$

where FeX represents the complex ion

$$[\mathrm{Fe(OH)}_m\ (\mathrm{Cl})_n]^{2-m-n}$$

In alkaline solutions, the reaction mechanism would differ from that in neutral solutions as follows: (*A*) The surface coverage of the reaction intermediate Fe(OH) is considerably larger due to the high concentration of OH^-. (*B*) The change of *p*H at the electrode surface is not appreciable. (*C*) The nature of the complex FeX in alkaline solutions is different than in neutral solutions.

Anodic Tafel slope.—The Bockris mechanism (8) predicts the anodic Tafel slope of iron in acidic solutions as 40 mV/decade. In acidic solutions, the surface coverage of the reaction intermediate FeOH is assumed to be very low. Therefore, the Langmuir isotherm was applicable. This assumption was shown to be also valid for iron dissolution in neutral solutions (7). However, in alkaline solutions, the coverage of FeOH should be much greater. Therefore, the Temkin isotherm would be more appropriate than the Langmuir isotherm. The rate equations of reaction [5a] for Temkin adsorption can be written as (9)

$$r_a = k_a\,(1-\theta)\,[\mathrm{OH^-}]\exp(\beta E\mathbf{F}/RT)\exp(-\alpha f\theta) \qquad [8a]$$

$$r_{-a} = k_{-a}\,\theta\exp[-(1-\beta)E\mathbf{F}/RT]\exp[(1-\alpha)f\theta] \qquad [8b]$$

where, r_a and r_{-a} = the rate of the forward and backward reactions; k_a and k_{-a} = rate constants of the forward and backward reactions; β = symmetry factor;

E = potential; α = proportionality constant ($0 < \alpha \leqq 1$); f = Temkin free energy parameter; θ = coverage of FeOH.

Since θ is in the range $0.2 < \theta < 0.8$, in the case of Temkin adsorption, Eq. [8] can be approximated as follows

$$r_a = k_a [OH^-] \exp(\beta EF/RT) \exp(-\alpha f\theta) \quad [9a]$$

$$r_{-a} = k_{-a} \exp[-(1-\beta) EF/RT] \exp[(1-\alpha) f\theta] \quad [9b]$$

Since Eq. [5a] is at equilibrium

$$r_a = r_{-a} \quad [10]$$

Then, $f\theta$ can be obtained as

$$f\theta = \ln\left[\left(\frac{k_a}{k_{-a}}\right)[OH^-] \exp(FE/RT)\right] \quad [11]$$

Now, the rate equation for Eq. [5b] can be written as

$$r_b = k_b \theta \exp(\gamma FE/RT) \exp(\epsilon f\theta) \quad [12]$$

where k_b, γ, and ϵ are the rate constant, the symmetry factor, and the proportionality constant for reaction [5b], respectively. Equation [12] is simplified to

$$r_b = k'_b \exp(\gamma FE/RT) \exp(\epsilon f\theta) \quad [13]$$

Finally, the reaction rate can be obtained by inserting Eq. [11] into Eq. [13]

$$i_a = k''_b [OH^-]^\epsilon \exp[(\gamma + \epsilon) FE/RT] \quad [14]$$

where k''_b is a constant.

Usually, ϵ is equal to $(1 - \gamma)$ and γ is 1/2. Therefore, the actual rate equation can be given by

$$i_a = k''_b \sqrt{[OH^-]} \exp[FE/RT] \quad [15]$$

The Tafel slope is obtained as

$$\frac{\partial E}{\partial \log i_a} = \frac{2.3\,RT}{F} \quad [16]$$

This value is 60 mV/decade at 25°C, which is in good agreement with the result of active dissolution of iron given by Eq. [3].

Interpretation of passivation phenomena.—The passivation phenomena can be interpreted based on the following assumptions: (*I*) Active dissolution proceeds until passivation occurs. (*II*) When the concentration of FeX attains the solubility limit, passivation occurs. (*III*) The equilibrium constant of the complexation process, Eq. [6], is sufficiently large, *i.e.*, $[Fe^{++}] << [FeX]$.

The concentration, C, of FeX can be obtained by solving the diffusion equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \quad [17]$$

where, D = diffusion coefficient of FeX
t = time after the imposition of the electrical signals
x = the distance from the electrode surface.

Since the concentration of FeX in the bulk solution is negligible, the following conditions apply

$$C(\infty, t) = 0 \quad [18]$$

$$C(x, 0) = 0 \quad [19]$$

According to assumption (*III*), the current is related to the concentration of FeX in the following manner

$$-D\left(\frac{\partial C}{\partial x}\right)_{x=0} = i_a/2F = F(t) \quad [20]$$

Laplace transformation can be utilized to solve the above differential equations (10). Equations [17], [18], and [20] are transformed with respect to time

$$su(x,s) = D\frac{d^2u(x,s)}{dx^2} \quad [21]$$

$$u(\infty,s) = 0 \quad [22]$$

$$-D\left(\frac{du(x,s)}{dx}\right)_{x=0} = f(s) \quad [23]$$

where s is the Laplace parameter and $u(x,s)$ which satisfied Eq. [21], [22], and [23] is

$$u(x,s) = \sqrt{\frac{1}{Ds}} f(s) \exp\left(-\sqrt{\frac{s}{D}}x\right) \quad [24]$$

Applying the convolution theorem, the inverse transform of Eq. [24] can be obtained

$$\mathcal{L}^{-1}u(x,s) = \frac{1}{\sqrt{D}}\mathcal{L}^{-1}f(s) * \mathcal{L}^{-1}\left[\frac{1}{\sqrt{S}} \exp\left(-\sqrt{\frac{s}{D}}x\right)\right] \quad [25a]$$

Equation [25a] can be transformed to

$$C(x,t) = \frac{1}{\sqrt{\pi D}}\int_0^t F(t-\tau)\frac{1}{\sqrt{\tau}}\exp\left(\frac{-x^2}{4D\tau}\right)d\tau \quad [25b]$$

Finally, the concentration of FeX at the electrode surface is given by

$$C(0,t) = \frac{1}{\sqrt{\pi D}}\int_0^t F(t-\tau)\frac{1}{\sqrt{\tau}}d\tau \quad [26]$$

In accord with assumption (*II*) passivation occurs when $C(0,t)$ attains the solubility limit, C_s

$$C(0,t_p) = C_s \quad [27]$$

where t_p is the passivation time. In the case of galvanostatic polarization, $F(t)$ is constant

$$F(t) = F_o \quad [28]$$

Then, t_p is given by

$$C_s = \frac{2F_o}{\sqrt{\pi D}} \cdot \sqrt{t_p} \quad [29a]$$

Introducing Eq. [20], i_a is related to t_p

$$i_a\sqrt{t_p} = FC_s\sqrt{\pi D} = \text{constant} \quad [29b]$$

Thus, the empirical relation of Eq. [4] has been deduced theoretically.

In the case of the potential sweep experiments, $F(t)$ is given by the Tafel relation for active dissolution, according to assumption (*I*). When the potential sweep starts from the open-circuit potential, $F(t)$ is expressed by

$$F(t) = k \exp(E/K) \quad [30]$$
$$E = \lambda t + E_o$$
$$K = b/2.3$$

where, k = a rate constant
b = Tafel slope
λ = sweep rate
E_o = open circuit potential

The insertion of Eq. [30] into Eq. [27] gives

$$C_s = \frac{k}{\sqrt{\pi D}}\exp(Ep/K)\int_0^{t_p}\frac{\exp(-\lambda\tau)}{\sqrt{\tau}}d\tau \quad [31]$$

where $E_p = \lambda t_p + E_o$.
Putting $y = \lambda t/K$, Eq. [31] becomes

$$\sqrt{\frac{D\lambda}{K}}C_s = k\exp(E_p/K) \cdot \frac{1}{\sqrt{\pi}}\int_0^{(E_p-E_o)/K}\frac{\exp(-y)}{y}dy \quad [32]$$

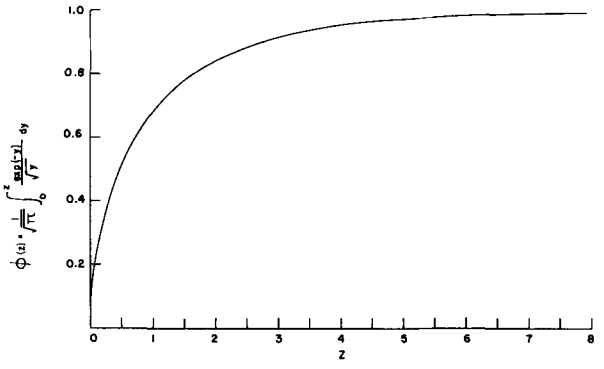

Fig. 7. ϕ (z) vs. z plot

The function

$$\phi(z) = \frac{1}{\sqrt{\pi}} \int_0^z \frac{\exp(-y)}{\sqrt{y}}\, dy \qquad [33]$$

is plotted in Fig. 7. For $z > 4$, $\phi(z)$ is almost unity

$$\phi(z) \approx 1, \quad z > 4 \qquad [34]$$

In the present experiments, $(E_p - E_o)$ is greater than 250 mV and b is about 60 mV/decade. Therefore, the approximation of Eq. [34] is valid for this experiment. Equation [32] is simplified to

$$C_s \sqrt{\frac{D\lambda}{K}} = k \exp(E_p/K) \qquad [35]$$

Since the peak current is expressed

$$i_p = 2\mathbf{F} \cdot \mathbf{F}(t_p)$$

the combination of Eq. [35] with Eq. [30] gives

$$i_p = 2\mathbf{F}k \exp[E_p/K] = 2\mathbf{F}C_s \sqrt{\frac{D\lambda}{K}} \qquad [36]$$

As C_s and D are constant, i_p is proportional to $\sqrt{\lambda}$. Thus, Eq. [1] can be derived theoretically. Also, E_p can be deduced from Eq. [35] as follows

$$E_p = \frac{K}{2} \ln \lambda + \ln 2\mathbf{F}C_s \sqrt{\frac{D}{K}} \qquad [37]$$

Therefore

$$\frac{\partial E_p}{\partial \log \lambda} = \frac{b}{2} \qquad [38]$$

The Tafel slope can be obtained by inserting the experimental value of Eq. [2]. The anodic Tafel slope, b, thus calculated is 66 mV/decade. This value is in approximate agreement with that obtained from the galvanostatic experiments, Eq. [3], and also with that derived theoretically, Eq. [16].

Anodic Polarization Behavior of 25% Chromium Ferritic Stainless Steels

E. A. Lizlovs* and A. P. Bond*

Research Laboratory, Climax Molybdenum Company of Michigan, Ann Arbor, Michigan 48106

ABSTRACT

Potentiodynamic polarization curves in 1*N* H_2SO_4 and in 1*N* HCl were obtained for 25% Cr ferritic stainless steels containing 0-5% Mo and 0-4% Ni. High-purity alloys and alloys containing the usual commercial levels of C, N, Si, and Mn were investigated. The critical current density was decreased by molybdenum and molybdenum-nickel additions in both acids. All the high-purity 25% Cr steels containing 3.5 or 5% Mo were immune to pitting corrosion and highly resistant to crevice corrosion at 25°C in 1*N* HCl and in 0.33M $FeCl_3$. Alloys containing commercial levels of impurities, on the other hand, were all subject to pitting attack in 1*N* NaCl solution under potentiodynamic conditions and in immersion testing in ferric chloride solution. The relative pitting resistance, however, was still improved by molybdenum additions.

The engineering applications of the austenitic stainless steels are sometimes limited by stress-corrosion cracking in chloride-containing media. The ferritic stainless steels, *e.g.* Types 430 and 434, are immune to stress-corrosion cracking (1), but their use is limited by their comparatively poor resistance to general corrosion. It is therefore of interest to investigate the possibility of improving the general corrosion resistance of ferritic stainless steels by increasing their alloy content, while preserving their good resistance to stress-corrosion cracking.

Molybdenum and nickel were the two additional alloying elements selected for this study on improving the general corrosion resistance of the iron-chromium

* Electrochemical Society Active Member.

Key words: corrosion, potentiodynamic polarization, molybdenum, pitting, sulfuric acid, hydrochloric acid.

[a] NA = not analyzed, but assumed to be similar to analyzed values for other materials of similar major alloy content.

alloy. The 25% Cr alloy was selected as the base composition since it, in combination with molybdenum, was expected to retain a ferritic structure with nickel contents, as high as 4%. The choice of the base ferritic alloy composition studied was supported by the work of Harada *et al.* (2). These authors conducted polarization experiments in 5% H_2SO_4 at 70°C and at the boiling point with an extensive series of 25% Cr stainless steels alloyed with nickel and molybdenum, and their experiments suggest that such alloys should possess good general corrosion resistance.

This study was conducted in two steps: first, high-purity, vacuum-melted alloys were investigated; then, alloys containing the usual commercial levels of C, Si, N, and Mn were studied. Since even high-purity nickel-containing alloys were shown to be susceptible to stress-corrosion cracking (3), no nickel alloys of commercial purity were investigated.

Experimental Procedures

Materials.—The chemical compositions of the high-purity and commercial-purity ferritic stainless steels studied are given in Table I. The high-purity heats were vacuum melted using Plastiron, low-carbon ferrochromium, nickel-shot, and molybdenum pellets. Commercial-purity alloys were melted from Armco iron, pure molybdenum chips, ferrochromium, ferromanganese, ferrosilicon, and graphite, and were prepared by melting in argon and casting in air. The split-heat technique (3) was used for both series of alloys. The ingots were hot forged and hot rolled to strips 0.76 cm (0.3 in.) thick and then cold rolled to a 0.38 cm (0.15 in.) thickness.

High-purity alloys were heated at 980°C (1800°F) for 1 hr and water quenched. Micrographic examination showed that 980°C was the minimum temperature that insured the absence of a second phase in the high-purity high-molybdenum alloys. The commercial-purity alloys were heated at 1095°C (2000°F) for 1 hr and water quenched, then heated at 705°C (1300°F) for 1 hr and water quenched. The 1095°C treatment was used to minimize the presence of the second phase in high-molybdenum alloys, and the lower temperature (705°C) treatment to minimize the sensitization to intergranular corrosion resulting from the high-temperature treatment. In contrast to high-purity alloys, the sensitization caused by high-temperature heat treatment is expected for the commercial-purity alloys because of the higher carbon and nitrogen levels (4).

Polarization experiments.—The electrodes for the potentiodynamic polarization studies were mounted in acrylic plastic, the exposed surface (0.5 by 0.6 cm) always being a longitudinal section parallel to the rolled surface. The exposed surface was polished using standard metallographic techniques, ending with a distilled water slurry of 0.3μ alumina. For the pitting potential measurements, the fine crevices between plastic and alloy were masked by Glyptal or the electrode surface was masked with electroplater's tape (Scotch 470), except for a circular area 0.36 cm in diameter. Masking of the electrodes was undertaken to prevent crevice corrosion of the electrode in chloride media.

The potentiodynamic polarization experiments were performed using standard equipment and techniques. Potentials were measured with respect to a saturated calomel electrode. The experiments were performed in 1*N* H_2SO_4, 1*N* HCl, and 1*N* NaCl saturated with prepurified nitrogen at 29.8°C. The potential scanning rate was 0.15 mV/sec.

Potentiostatic experiments were performed in 1*N* HCl with the materials that did not undergo pitting under potentiodynamic polarization conditions. For the potentiostatic experiments, the electrode was first activated and then the potential of the electrode was abruptly changed from the natural corrosion potential to the selected passive potential by switching the potentiostat on with a potential preset at the desired value. The polarization current and potential were recorded by a two-pen strip chart recorder. The electrode was usually kept overnight (over 16 hr) at the desired potential.

Potentiostatic holding experiments at −0.250V were also performed with all commercial-purity materials in 1*N* HCl. Since these experiments were designed to determine the mode of attack in hydrochloric acid in a near-passive range, the electrodes were not masked for these experiments.

Immersion tests.—Both the high-purity and commercial-purity materials were tested in acidified (*p*H 2) 0.33M $FeCl_3$. High-purity materials were also tested in oxygen-saturated 1*N* H_2SO_4 and nitrogen-saturated 1*N* HCl. Test coupons for the latter experiments were activated by touching with a magnesium rod immediately after immersion in acid. All immersion tests were performed at room temperature, 25° ± 1°C.

Results

Polarization behavior in the active-passive transition region.—Typical potentiodynamic polarization curves in the active-passive transition region in 1*N* H_2SO_4 for high-purity alloys are shown in Fig. 1 and 2. Molybdenum additions to both series of alloys caused a decrease in critical current density.[1] This decrease in critical current with increasing Mo content was more pronounced for high-purity alloys than for the commercial-purity steels. In addition, the critical current density for the commercial-purity 25% Cr steel

[1] Terms "critical current density" and "primary passivation potential" are defined in Ref. (5).

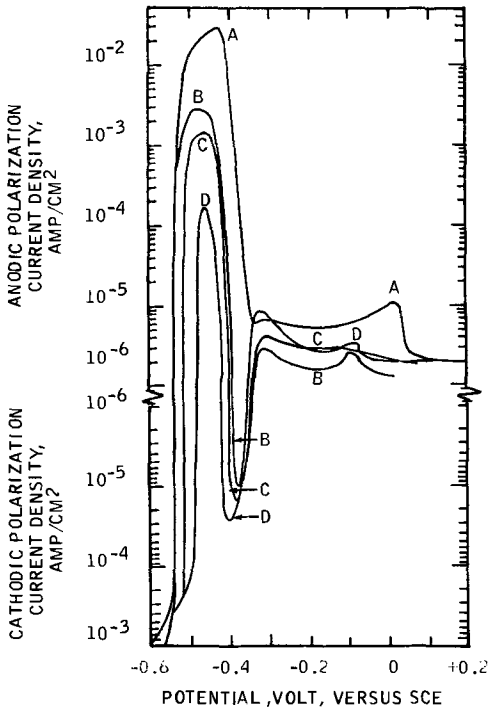

Fig. 1. Potentiodynamic polarization curves for the high-purity 25% Cr stainless steels in 1*N* H_2SO_4 at 29.8°C. Curve A, 25% Cr; curve B, 25% Cr-2% Mo; curve C, 25% Cr-3.5% Mo; curve D, 25% Cr-5% Mo.

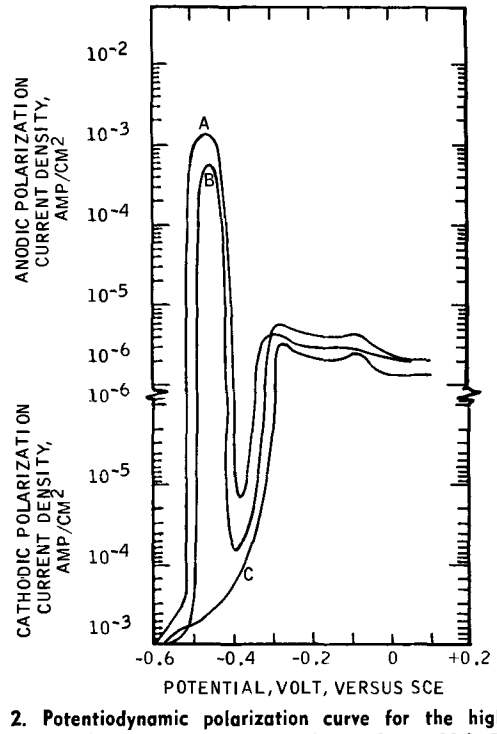

Fig. 2. Potentiodynamic polarization curve for the high-purity 25% Cr-3.5% Mo stainless steels in 1*N* H_2SO_4 at 29.8°C. Curve A, 25% Cr-3.5% Mo; curve B, 25% Cr-3.5% Mo-1% Ni; curve C, 25% Cr-3.5% Mo-2.5% Ni.

was considerably lower than for the high-purity 25% Cr alloy (Fig. 3). In the 25% Cr-3.5% Mo steels, nickel lowered the critical current density in 1*N* H_2SO_4. The increase in nickel content from 1 to 2.5% decreased the critical current density in 1*N* H_2SO_4 to such an extent that local action cathodic current was larger than the critical current and, as a result, the critical behavior could not be observed and was marked only as some deviation from the expected cathodic polarization curve (Fig. 2).

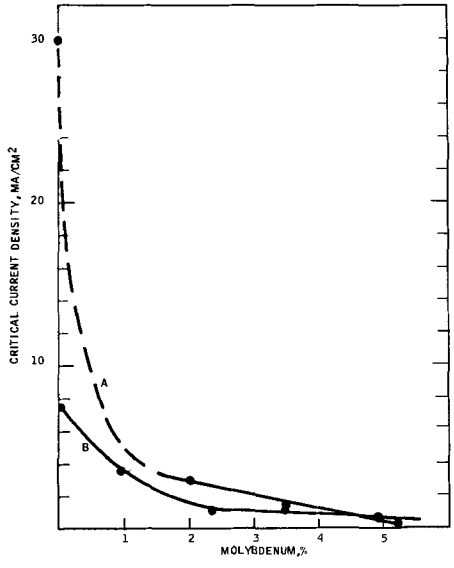

Fig. 3. Dependence of critical current density on molybdenum content for the 25% Cr stainless steels in 1*N* H_2SO_4 at 29.8°C. Curve A, high-purity alloys; curve B, commercial-purity alloys.

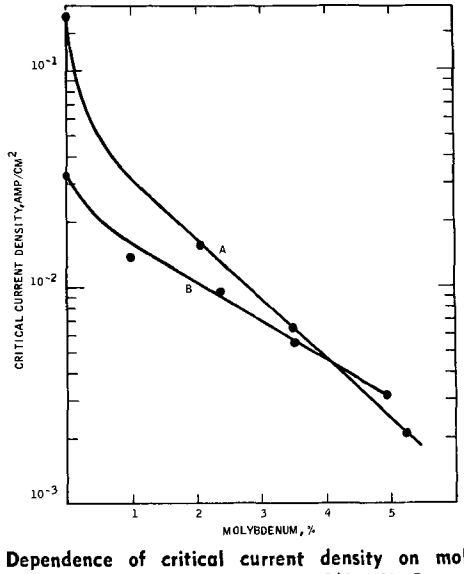

Fig. 4. Dependence of critical current density on molybdenum content for the 25% Cr stainless steels in 1*N* HCl. Curve A, high-purity alloys; curve B, commercial-purity alloys.

The decrease of critical current density with molybdenum content was also observed in 1*N* HCl. In general, the critical current densities were considerably higher in 1*N* HCl (Fig. 4) than in 1*N* H_2SO_4. Again, the decrease in critical current density was more pronounced for high-purity materials than for commercial-purity alloys, and the 25% Cr high-purity alloy had considerably higher critical current density than the 25% Cr commercial-purity alloy (Fig. 4). Nickel additions also decreased the critical current density in the high-purity 25% Cr-3.5% Mo alloys in 1*N* HCl (Fig. 5).

The effect of alloying elements on the primary passivation potential is shown in Fig. 6. Primary passivation potentials for the pure 25% Cr alloy were considerably more noble than corresponding primary passivation potentials for commercial-purity alloys in 1*N* H_2SO_4 and in 1*N* HCl. For the pure alloys, the addition of 2% Mo to the base composition resulted in significantly more active primary passivation potentials in 1*N* H_2SO_4 and in 1*N* HCl. Further increases in molybdenum content rendered primary passivation potentials slightly more noble in 1*N* H_2SO_4 for both series of alloys. Increasing amounts of molybdenum

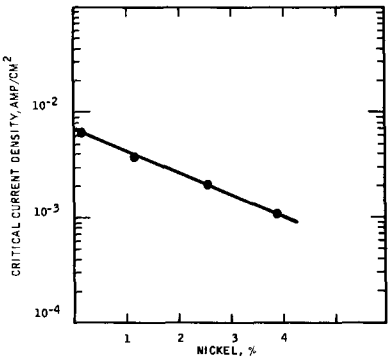

Fig. 5. Dependence of critical current density on nickel content for the high-purity 25% Cr-3.5% Mo stainless steels in 1*N* HCl at 29.8°C.

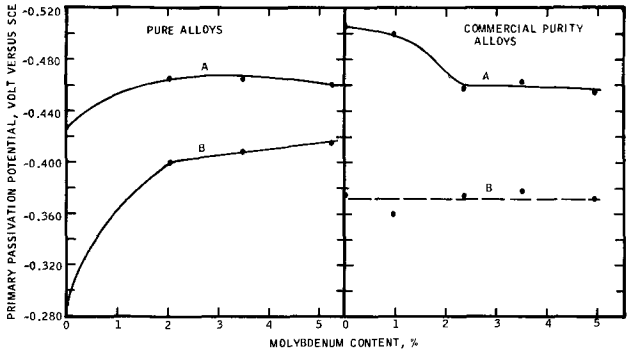

Fig. 6. Dependence of primary passivation potentials on molybdenum content for the 25% Cr stainless steels (A) in 1*N* H_2SO_4 and in (B) 1*N* HCl at 29.8°C.

in pure alloys rendered primary passivation potentials more active in 1*N* HCl, but no definite molybdenum effect was observed in commercial-purity materials. In general, primary passivation potentials for pure alloys in 1*N* HCl were more active than for commercial-type steels. In the pure 25% Cr-3.5% Mo series of steels, nickel rendered the primary passivation potentials more noble in both acids.

With the exception of the molybdenum-free alloy, all the pure alloys displayed a cathodic loop on polarization curves in 1*N* H_2SO_4, indicating that a stable passive state is possible in a given medium. Only the 25% Cr-3.5% Mo and 25% Cr-5% Mo steels of the commercial-purity series displayed a cathodic loop on the polarization curve in 1*N* H_2SO_4. The extent and the maximum value of the cathodic loops increased with alloying content (Fig. 1). Cathodic loops were never obtained in polarization experiments in 1*N* HCl.

Polarization behavior in sulfuric acid in the passive range.—The passive range for all materials in 1*N* H_2SO_4 terminated at the expected transpassive transition range, *i.e.* +0.85 to +0.95V. The passive potentiodynamic polarization curves above 0.1V were uneventful. The passive current densities under continuous potential scanning conditions were of the order of 1 x 10^{-6} A/cm² for all the high-purity materials. Under potentiostatic conditions, current densities even at the threshold of the transpassive transition range (0.80V) gradually decreased to the order of 1 x 10^{-7} A/cm², and possibly even lower, so that no true dependence of passive current density on the potential or alloy composition was observed for high-purity stainless steels. For the commercial-purity steels, the lowest passive current densities were observed with 25% Cr and 25% Cr-1% Mo alloys. Increases in molybdenum content resulted in increased passive currents with the 25% Cr-5% Mo steel having the highest current densities of all materials. This steel had a passive current density of the order of 10^{-5} A/cm² even under potentiostatic conditions at +0.60V.

Polarization behavior in hydrochloric acid in the passive range.—The current density for the 25% Cr, high-purity alloy in 1*N* HCl decreased very sharply after reaching the critical value. However, the current density beyond the primary passivation potential did not decrease below 2.7 mA/cm². Furthermore, the polarization current increased as the electrode potential was scanned toward more noble values. Similar behavior was also observed with the pure 25% Cr-2% Mo steel, except that the minimum polarization current was about two orders of magnitude lower than that of the 25% Cr steel. A potentiostatic-holding experiment with the high-purity 25% Cr alloy at −0.10V showed that it suffered general etching at this potential in 1*N* HCl. The masked 25% Cr-2% Mo electrode, on the other hand, could be passivated in 1*N* HCl when its potential was jumped from the active corrosion potential to +0.80V, and passivity could be maintained potentiostatically at this potential for more than 16 hr with the final polarization current of the order of 1 x 10^{-7} A/cm². Hence, the relatively high current densities in the passive range observed with unmasked electrodes of the above alloys would correspond to general corrosion for the 25% Cr steel and only to crevice corrosion for the 25% Cr-2% Mo steel.

The remaining high-purity alloys, *i.e.* all the 3.5 and 5% Mo alloys, exhibited complete passivity up to the normal transpassive transition potentials. Polarization current densities under potentiodynamic conditions were of the order of 1 x 10^{-6} A/cm² and were comparable to passive current densities in 1*N* H_2SO_4. Furthermore, all the high-purity 3.5 and 5% Mo steels completely passivated in 1*N* HCl when the potential of the unmasked electrode was jumped from the corrosion potential to +0.80V, and the passivity could be maintained at this potential for over 16 hr with no indication of any tendency of the passive polarization current to increase at the end of the experiment. The final polarization current density at +0.80V was of the order of 1 x 10^{-7} A/cm² and was the same as the current density in 1*N* H_2SO_4 under the same conditions.

For all the commercial-purity steels, current densities beyond the critical peak in 1*N* HCl first decreased to some minimum value, then increased again with an increase in potential. The lowest current densities in the passive state were observed for the 25% Cr-3.5% Mo and 25% Cr-5% Mo alloys. For the 25% Cr-5% Mo steels, current densities from 0 volt to transpassive transition potentials remained between 7 x 10^{-4} and 3.6 x 10^{-4} A/cm². The drastic differences in passive polarization behavior between high-purity and commercial-purity alloys in 1*N* HCl are illustrated in Fig. 7, which shows polarization curves for 25% Cr-5% Mo alloys. Potentiostatic-holding experiments showed that all commercial-purity materials suffered general etching at −0.250V. Hence, high current densities in the passive range in 1*N* HCl for commercial-purity alloys would correspond not only to crevice corrosion but to general corrosion as well. In no case was pitting observed for any of the materials in 1*N* HCl.

Experiments with a masked high-purity 25% Cr electrode showed that a complete passive range could be obtained in 0.1*N* HCl under potentiodynamic polarization conditions. However, passivity could not be potentiostatically maintained at +0.80V for a prolonged time. On the abrupt potential change from the corrosion potential to a selected potential in the passive range, the masked 25% Cr electrode would passivate in 0.1*N* HCl at +0.40V but would pit at +0.50V.

Polarization behavior in 1N NaCl.—Potentiodynamic polarization experiments in 1*N* NaCl solution were designed to obtain pitting potentials. Definite pitting potentials for commercial-purity alloys were only obtained for the two lowest alloyed materials, *i.e.* the

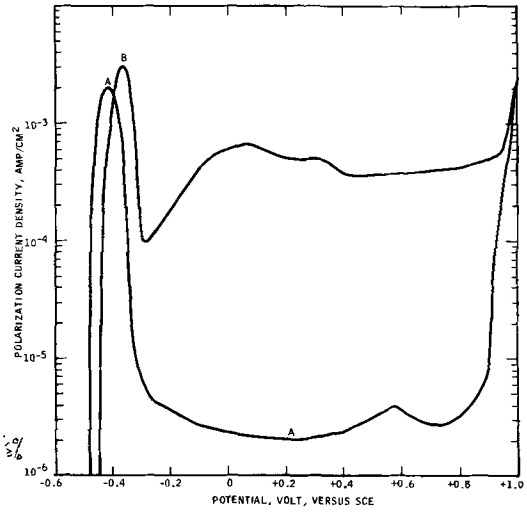

Fig. 7. Anodic potentiodynamic polarization curves in 1N HCl at 29.8°C for 25% Cr-5% Mo alloys. Curve A, high-purity alloy; curve B, commercial-purity alloy.

25% Cr and 25% Cr-1% Mo alloys. The 25% Cr alloy pitted at +0.15V and the 25% Cr-1% Mo alloy pitted at +0.16V. For the materials of the higher molybdenum content, current in the passive state was irregular and gradually increased. For the 25% Cr-3.5% Mo and 25% Cr-5% Mo steels, current remained at relatively low values (10^{-6} to 10^{-5}A) throughout the passive range up to the normal transpassive transition range. While no definite potential could be assigned to the onset of pitting, microscopic examination revealed some small pits and localized etching. The pure 25% Cr alloy pitted in 1N NaCl solution under potentiodynamic polarization conditions only at 0.79V.

Immersion tests in ferric chloride.—Corrosion rates in 0.33M $FeCl_3$ solution are given in Table II. The high-purity alloys, with the exception of the 25% Cr steel, did not pit. All the commercial-purity alloys were pitted. The most severe pitting was sustained by the 25% Cr and the 25% Cr-1% Mo steels. The 25% Cr-5% Mo alloy was the least pitted. Pitting occurred over all surfaces of the coupon.

Immersion tests in sulfuric acid and hydrochloric acid.—Corrosion rates in 1N H_2SO_4 and 1N HCl at room temperature (25°C) are given in Table III. Molybdenum additions decreased the corrosion rates in both media. An especially dramatic decrease in corrosion rate was observed between the 25% Cr and the 25% Cr-2% Mo alloys. The 25% Cr-3.5% Mo and 25% Cr-5% Mo alloys repassivated in 1N H_2SO_4 after activation with magnesium and they remained passive for the duration of the test (6 days). In no case was pitting observed and any corrosion was uniform.

Discussion

The materials that show a passive range up to normal transpassive transition potentials in 1N HCl with masked electrodes under potentiostatic conditions could be considered to be immune to pitting corrosion at the given chloride ion concentration and temperature. It follows that all molybdenum-bearing, high-purity 25% Cr steels are immune to pitting corrosion in 1N HCl at 29.8°C. The molybdenum-free 25% Cr steel could be pitted under potentiodynamic conditions in 1N NaCl at the potential close to the transpassive transition (+0.79V) and under the potential-jumping conditions in 0.1N HCl. These data indicate that molybdenum-free 25% Cr steel could pit under some circumstances when exposed to chloride media. The ferric chloride test verified this prediction. Only the 25% Cr steel of the high-purity series was pitted when immersed in 0.33M $FeCl_3$. The immersion in $FeCl_3$ solution would approximate the conditions of potential-jumping experiments in HCl.

Some qualitative conclusions concerning the susceptibility of stainless steels to crevice corrosion could be deduced from the passive polarization behavior of unmasked electrodes in hydrochloric acid. It has been found that susceptible alloys always display a rise in current within the normal passive region at potentials more active than the pitting potential, indicating that unmasked electrodes prepared by the techniques used always contain unintentional crevices (6, 7). Thus, since all the high-purity 25% Cr steels containing 3.5% or more molybdenum with or without nickel do not display any unusual current rise in the passive range up to transpassive transition in 1N HCl, these alloys should be highly resistant to crevice corrosion under experimental conditions. In another investigation employing a special crevice corrosion cell, it was shown that 25% Cr-3.5% Mo indeed is immune to crevice corrosion in 1N Cl^- concentration at room temperature (8).

The detrimental effects of impurities on the corrosion resistance of 25% Cr steels already manifested themselves in the passive state in 1N H_2SO_4. Passive polarization densities for 2.5-5% Mo steels were higher than for the corresponding pure alloys under comparable experimental conditions. In 1N HCl, the current densities in the passive state of commercial-purity alloys were several orders of magnitude higher than for the pure alloys and etching actually occurred at passive potentials. Furthermore, all the commercial-type steels were subject to pitting corrosion and, while crevice corrosion was not specifically studied, there is little doubt that all the commercial-purity 25% Cr steels would be subject to crevice attack in chloride media.

The deleterious effects of impurities on the resistance to pitting corrosion are probably due to the presence of carbide and nitride precipitates. Furthermore, metallographic examination showed that 2.5-5% Mo alloys of commercial purity contained an intermetallic phase, presumably chi-phase (9). While it was possible to bring this second phase into solution by a heat treatment at 1095°C, a desensitizing treatment at 705°C resulted in the reappearance of the second phase. Thus, there exists a dilemma with respect to heat treatment of commercial-purity alloys. Since, according to the previous experience in this Laboratory, ferritic stainless steels that have been

sensitized to intergranular corrosion have much poorer resistance to pitting corrosion than in the desensitized condition, all the alloys were tested in the desensitized state with an intermetallic phase present for the high-molybdenum steels. It is possible that the presence of a second phase was detrimental to the stability of the passive state, as indicated by relatively high passive current densities in sulfuric acid and general etching in the passive region in hydrochloric acid of 2.5-5% Mo alloys. No such effects were observable for comparable high-purity alloys.

A very strong effect of molybdenum was observed on active corrosion rates of pure alloys in 1*N* H_2SO_4 and 1*N* HCl at room temperature (Table III). With an increase in molybdenum content from 0 to 2%, corrosion rates were reduced approximately by a factor of 10 in 1*N* H_2SO_4 and by a factor of 30 in HCl. For 3.5 and 5% Mo alloys in oxygenated 1*N* H_2SO_4, repassivation occurred and corrosion rates were consequently nil. Apparently, the critical current density for these materials was sufficiently small so that the oxygen reduction current could polarize these alloys beyond the critical peak. Sharp reduction of active corrosion rates for pure 25% Cr alloys with additions of molybdenum in 1*N* H_2SO_4 was also reported by Chernova and Tomashov (10).

The observed decrease in critical current density with an increase in molybdenum content in 25% Cr stainless steel was in accord with the results from previous work with 17% Cr steels (7, 11) and the results of other investigators on a variety of stainless steels (10, 12-15). Of special interest, however, is the large difference in critical current density between the commercial-purity and high-purity 25% Cr steels, commercial-purity material having the lower critical current density. A similar difference in critical current density in 5% (1*N*) H_2SO_4 was observed earlier between the high-purity 17% Cr alloy and its commercial counterpart Type 430 steel (11, 16). In the present case, the elements that are present in considerably larger amounts in commercial-purity materials than in high-purity materials are C, N, Si, and Mn. Silicon already has been shown to have no significant effect on critical current density (11). The effect of manganese is not well known; however, it has been shown by other investigations to have an effect of increasing critical current density to some extent for Type 304 steel (17) and 200 series (Cr-Ni-Mn) stainless steels (18). Thus, the sharp lowering of the critical current density for commercial-type ferritic stainless steels as compared to high-purity counterparts most probably is the combined effect of residual carbon and nitrogen. Carbon has been shown by Wilde and Greene to lower the critical current density very considerably for Type 304 stainless steel (17). The effect of nitrogen on critical current density, however, is not known. Further work is needed to clarify the effect of nitrogen and also the effect of carbon on critical current density for ferritic stainless steels.

The analysis of the critical current density data showed some interesting correlations with the molybdenum or nickel content. The decrease in critical current density in sulfuric acid was linear with increase in molybdenum content from about 2% for pure alloys and from about 2.4% for commercial-purity alloys (Fig. 3). For the commercial-purity steels, the slope of the linear portion was quite small, so that the effect of molydenum additions on critical current density was less pronounced than for high-purity alloys. The linear relationship between molybdenum content and critical current density in 1*N* H_2SO_4 obtained in this investigation is in agreement with the results of Chernova and Tomashov (10). Their investigation showed that the addition of even 0.5% Mo to the 25% Cr, high-purity alloy results in a sharp reduction of the critical current density in 1*N* H_2SO_4 and that further reduction is linear up to a molybdenum content of 3%. The dashed portion in Fig. 3 refers to the estimated portion of the critical current density curve based on the similar curve given by Chernova and Tomashov. The decrease of critical current density in 1*N* HCl was logarithmic with an increase in the molybdenum content from about 1 to 5% for both series of alloys (Fig. 4). The logarithmic relationship was also observed for the decrease of critical current density in 1*N* HCl for 25% Cr-3.5% Mo alloys with an increase in the nickel content (Fig. 5).

It should be noted that, while commercial-type alloys had critical current densities either lower than or comparable to the pure alloys, their corrosion properties were inferior to those of pure alloys. Thus, the lowering of the critical current density by alloying additions cannot always be taken as a sole characteristic parameter for improving the corrosion resistance of stainless steel, especially for the alloys containing appreciable amounts of precipitates and second phase. There appears to be no simple connection between the magnitude of the critical current density and stability of the passive state. The lowering of the critical current density predicts only the ease of transition from an active to a passive state and only for the alloys of similar composition and structure.

The 25% Cr-3.5% Mo steels alloyed with nickel showed some desirable corrosion properties: the absence of an active region in 1*N* H_2SO_4 indicated that these materials should remain passive in dilute sulfuric acid, and the passive range up to normal transpassive transition in 1*N* HCl indicated that excellent pitting and crevice corrosion resistance of the 25% Cr-3.5% Mo alloy is not adversely affected by alloying with nickel. However, the usefulness of the nickel-containing ferritic stainless steels is very seriously limited by their susceptibility to stress-corrosion cracking (3).

Of all the effects of molybdenum on the corrosion properties of ferritic stainless steels discussed above, the most remarkable is the increase of the strength of the passive film with the increase of molybdenum content. Assuming that the strength of the passive film will be reflected in the density of the polarization current in the passive region in hydrochloric acid as well as in the pitting potential and relative resistance to breakdown of passivity within a crevice, the relative strength (or stability) of the passive film of various stainless steels can be inferred from the polarization diagrams in 1*N* HCl. Comparison of the polarization behavior of 17% Cr steels (7) and 18% Cr-16% Ni steels (6) in 1*N* HCl and the results of this investigation of 25% Cr steels indicate that the degree of the passive film stability achieved by a certain amount of molybdenum is dependent on the chromium content. Thus, it is the chromium-molybdenum combination that primarily determines the stability of the passive film toward the chloride ions in particular and, probably, toward aggressive ions in general.

Conclusions

Molybdenum and nickel additions lowered the critical current density of 25% Cr stainless steels in 1*N* H_2SO_4 as well as in 1*N* HCl. The critical current density for commercial-purity 25% Cr steel was considerably lower and the primary passivation potential more active than for the high-purity 25% Cr alloy in both 1*N* H_2SO_4 and 1*N* HCl. This phenomenon is most probably due to the combined effect of higher carbon and nitrogen levels in commercial-type alloys.

All the high-purity alloys containing molybdenum were immune to pitting in 1*N* HCl under potentiostatic conditions and in acidified 0.33M $FeCl_3$ solution at room temperature. The high-purity alloys containing 3.5% Mo or more were also highly resistant to crevice corrosion under potentiostatic conditions in 1*N* HCl.

The commercial levels of carbon and nitrogen were detrimental to the pitting corrosion resistance of 25% Cr steels; all the commercial-purity 25% Cr materials were pitted in 0.33M $FeCl_3$ solution.

Effects of Amides on the Passivation of Iron

Keh-Chi Tsai and Norman Hackerman[1,] *

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The passivation of iron in acidic mediums with and without added amides has been studied by the steady-state polarization method. An empirical equation for the dissolution of iron was obtained from the polarization curves. A mechanism, based on the competitive adsorption by amides and the inhibiting species, $Fe(OH)_2$, for the anodic process is proposed. Assuming that the Langmuir adsorption isotherm is followed for this mechanism, a series of equations were derived for the surface coverages by $Fe(OH)_2$, θ_1, and by amides, θ_2, as well as the formation constant of $Fe(OH)_2$, K_1, and the adsorption constants of amides, K_2. These equations have been verified by experiments. K_1 was calculated by varying pH in a given system and K_2 by varying the amide concentration at a given pH. Linear relationships between the critical overpotentials and pH, as well as the logarithm of critical current densities and pH, were all obtained from this derivation and confirmed by the experiments. The surface coverage by amide reveals that the adsorption and desorption processes depend on the applied potential, since a surface coverage maximum is always observed in the $E_{crit} \sim E_p$ region. In the active region, the adsorption of amide is predominant and reversible. However, beyond the critical potentials, the formation of inhibiting species is predominant and is irreversible in the passive region.

There is some agreement that the initiation of passivation is associated with the appearance of a monolayer or less of inhibiting species (1, 2). In the case of iron, these inhibiting species are believed to be FeO or its hydrated species, $Fe(OH)_2$ (3, 4). A recent study by Pigeaud and Kirkpatrick (5) strongly supported this point of view. If this is so in steady-state measurements, the most likely electrochemical reaction for this precursory process for the passivation of iron in acidic mediums can be regarded as (1, 6, 7)

$$Fe(H_2O)_2 \rightleftarrows Fe(OH)_2 + 2H^+ + 2e^- \qquad [1]$$

Smialowski (8) has studied the effect of acids on the passivation of steel and concluded that the fatty acid anions reduced the number of active sites on the surface of iron and hence facilitated its passivation. From the adsorption theory of passivity (9), it is expected that the adsorption of organic species and the inhibiting species [*i.e.*, $Fe(OH)_2$] on the metal surface are competing processes.

This paper presents an attempt to elucidate the kinetic cause for the passivation of iron in acidic mediums in the presence of organic materials. A series of amides were chosen for this study because of their chemical and electrochemical stabilities (10) which restricts these organic species to a simple adsorption process and avoids complications arising from the anodic oxidation of these organic species as can be the case (8).

Experimental

All chemicals used were analytical reagent grade. The solutions were all 0.10M in K_2SO_4, were made from triple-distilled water, and were deaerated by bubbling through He. The He gas was purified and deoxygenated with activated copper. The pH values were measured with a Beckman expandomatic pH meter and adjusted with 2M H_2SO_4 to the range 1.1-4.9. The reaction vessel was thermostated at 5°C. The working electrodes were made of zone-refined iron (99.995% of Fe by weight, supplied by Battelle Memorial Institute and said by them to have no more than 45 ppm impurities). They were about 4 mm diameter rods which were inserted into a cylindrical Teflon plug, leaving one flat edge exposed. The plug was mounted in a glass support with a brass center rod screwed into the Teflon plug and the iron rod to provide good electrical contact. Immediately before use, the exposed

Key words: surface coverage, inhibition, polarization.

face of the electrode was abraded with 0 and 4/0 emery papers, degreased with acetone and pentane, and finally electropolished in 4 volumes of 70% $HClO_4$ to 1 of glacial CH_3COOH. A $Hg-Hg_2SO_4$ half cell was used as the reference electrode. A large platinum mesh cylinder was built in the reaction vessel and used as the counterelectrode. Electrode potentials were measured using a Luggin capillary and were converted to the hydrogen scale by adding 0.64V to measured values.

A Model 610B Keithley Electrometer was used to measure the rest potential and a Model 61RS Wenking Potentiostat was used to obtain anodic polarization curves. An ultrasensitive d-c microammeter (RCA) was used for current measurements in the passive region. Each potential setting was controlled manually and the current readings were taken at 50 mV intervals, except near the critical potential where 10 mV intervals were used.

The amides (11) listed in Table I were obtained from Eastman Organic Chemicals. The DMF, DMA, and NMP were vacuum distilled at less than 1 mm Hg. The other liquid amides were used as received. The purity of these amides was checked by conductivity measurements (12) which showed a specific resistance of at least 5 x 10^6 ohm-cm at 24°C for all. The solid amides, A, NMA, and P, were recrystallized from 50:50 acetone:chloroform (13) and vacuum dried.

Results and Discussion

Mechanism of the anodic process.—Empirical equation for iron dissolution at high overvoltage.—It is observed from the anodic polarization curves shown in Fig. 1 that at high overpotentials (*e.g.*, $\eta > 300$ mV) the slope $d\eta/d \log i$ is greater than the usual reciprocal Tafel slope. These slopes extend over 300-500 mV, depending on pH, and their magnitude depends on pH but not on the presence or absence of amide. The corresponding values of these slopes at various pH's, together with some electrochemical data obtained from Fig. 1, are given in Table II, where E_R is the rest potential and E_P is the passivation potential.

From Table II, it is found that the anodic reciprocal slopes at high overpotentials (*i.e.*, concentration polarization region) are related to pH by

$$d\eta/d \log i = 2.54 - 0.45\,pH \qquad [2]$$

Integration of Eq. [2] with η from 0 to η and i from i_0 to i gives

$$i = i_0 \exp\left(\frac{2.303\,\eta}{2.54 - 0.45\,pH}\right) \qquad [3]$$

Equation [3] gives the dissolution rate of iron at high overpotentials in the active polarization region.[2]

From Table II it is seen that the current density at $\eta = 0$, i_0, is related to pH as

$$i_0 = k\,[H^+]^\gamma \qquad [4]$$

in which $k = 10^{2.48}$ (mA/cm²) is the dissolution rate constant for iron in the concentration polarization region at pH 0 and $\gamma = 0.456$. Substituting Eq. [4] into Eq. [3] gives the expression for dissolution of iron in the concentration polarization region, *i.e.*

$$i = k\,[H^+]^\gamma \exp\left(\frac{2.303\,\eta}{2.54 - 0.45\,pH}\right) \qquad [5]$$

Formation of inhibiting species, $Fe(OH)_2$, on metal surface.—When the applied potential reaches the Flade arrest, E_F, it is believed that kinetically it is possible for an oxygen-metal ion complex to be formed due to the adsorption of oxygen on the metal surface (1, 4). However, this is offset by the chemical dissolution of this species. The detailed mechanism for the $Fe(OH)_2$ formation reaction is still controversial but, under the steady-state condition in the active polarization region, this reaction is generally regarded as

$$Fe(H_2O)_2 \rightleftarrows Fe(OH)_2 + 2H^+ 2e^- \qquad [1]$$

Anodic processes for amide adsorption.—The addition of amides to the solutions would be expected to cause change in passivation mechanism in two ways: (*a*) The amide may form complex compounds with ferrous ions in the metal surface which would accelerate the anodic dissolution reaction and thus be detrimental to the formation of passive films. (*b*) A competitive adsorption between amides and H_2O (or $SO_4^=$) on the active sites of metal could result in the inhibition of iron corrosion and facilitate the passivation. There was no experimental evidence found for process (*a*) since

* Data from Ref. (10), (11), and (23).

Table II. Some electrochemical data from Fig. 1

pH	E_R (mV)	E_{crit} (mV)	i_o (mA/cm²)	i_{crit} (o) (mA/cm²)	$d\eta/d \log i$ (mV/decade)
1.1	−300	670	100	260	2100
2.3	−350	560	24	86	1500
3.5	−400	450	8.2	52	980
4.0	−420	400	5.2	42	750
4.9	−560	200	1.6	21	420

i_{crit}(o) is the critical current density with no amide in the solution; i_o is the extrapolated current density from the anodic reciprocal slopes at $\eta = 0$; E_{crit} is the critical potential (see Fig. 1 with pH 4.9 as example).

[2] In the polarization curve, the potentials between E_R and E_{crit} are defined as active polarization region.

all the corrosion rates decreased in the presence of amides. The decrease of the corrosion rates were proportional to the increase of the amide concentrations. The reciprocal anodic slopes at high overvoltage show no change with respect to the values listed in Table II. Therefore, a mechanism based on the competitive adsorption between amide and water (or $SO_4^=$) on the active iron surface was considered to be a proper mechanism in the anodic process for this system.

From the values of the acidity constant ($K_a \sim 10^{-16}$) and the basicity constant ($K_b \sim 10^{-15}$), it is believed that amides, unlike amines, will remain neutral or hydrated species in aqueous solution within a certain pH range (14).

Previous workers (1, 7, 15, 16) proposed that the active iron surface is $FeOH^o$ and not Fe by virtue,

$$Fe\ (H_2O) \rightleftarrows FeOH^o + H^+ + e^- \qquad [6]$$

and the adsorption mechanism of polar organic inhibitors of Hackerman and Makrides (17) suggest the most likely mechanism for the adsorption of amides on the iron surface to be

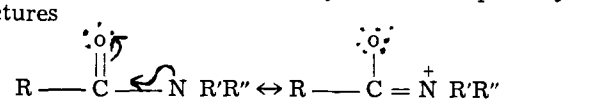
$$FeOH\cdot OH_2 + A \rightleftarrows FeOH\cdot A + H_2O \qquad [7]$$

In steady-state measurements, the over-all adsorption process for these organic species would include Eq. [6] and [7]. Therefore, the over-all adsorption reaction is

$$Fe(H_2O) + A \rightleftarrows FeOH\cdot A + H^+ + e^- \qquad [8]$$

where A represents amide.

It must be emphasized that in Eq. [8] the chemisorbed site of the amide molecule in the metal surface is considered to be by means of the oxygen atom and not the nitrogen atom, since the structures of amides are best described as resonance hybrids of the primary structures



where R, R', and R'' = H, CH_3, C_2H_5, and C_3H_8 for the different amides in this study. Thus, electrostatically, the electron-rich oxygen atom would be favored for adsorption on the metal surface. Furthermore, it has been proved from infrared spectra that all amide complexes are coordinated with the metal through the oxygen rather than the nitrogen atom (18).

Over-all mechanism of the anodic process.—Following the discussion of the sections under Results and Discussion, we may obtain the most probable mechanism for the electrochemical reactions of iron in the presence of amides in $K_2SO_4 + H_2SO_4$ solutions in the concentration polarization region as

$$\underset{(1-\theta)}{Fe(H_2O)} + A \overset{K_2}{\rightleftarrows} \underset{\theta_2}{FeOH\cdot A} + H^+ + e^- \qquad [8]$$

$$\Big\downarrow k \qquad + H_2O \overset{K_1}{\rightleftarrows} \underset{\theta_1}{Fe(OH)_2} + 2H^+ + 2e^- \qquad [1]$$

$$Fe^{++} + 2e^- \qquad [9]$$

in which Eq. [9] is the final expression for iron dissolution reaction. In the above mechanism, θ_1 and θ_2 are the surface coverages of the metal surface by $Fe(OH)_2$ and amides, respectively. K_1 is the formation constant of $Fe(OH)_2$ and K_2 the adsorption constant for amides; k is the dissolution rate constant defined by Eq. [4]; and $\theta = \theta_1 + \theta_2$ is the total surface coverage.

It is observed from all the polarization measurements that the total surface coverage, θ, on the electrode surface is always small ($\theta < 0.1$) in the active polarization region. Therefore, before a detailed discussion of the various surface coverages, θ, θ_1, and θ_2, is given, a Langmuir type isotherm (19) (*i.e.*, the free energy of the active site surface will not be affected by the surface coverage, *etc.*) is considered for this mechanism and the following derivation is deduced, based on this isotherm.

Both Eq. [1] and [8] comprise the transport of protons and electrons. Although the high transport number of protons and the high applied field in the anodic process will tend to remove protons from the electrode, the rate of these transports is still very small compared to the charge transfer reaction of Eq. [9] in the active polarization region. The choice between passivation and continuous dissolution therefore appears to depend on the comparative ease with which protons and ferrous ions (or Fe^{++} complexes) pass through the interface.

Below the oxygen reversible potential, reaction [1] cannot proceed continuously and a quasi-equilibrium will obtain in which θ_1 will be potential dependent according to the electrochemical isotherm.

$$\frac{\theta_1 [H^+]^2}{1-\theta} = K_1 \exp\left(2\,(E_H - E_R)\mathbf{F}/_{RT}\right) = K_1 \exp\left(2\,\eta\mathbf{F}/RT\right)$$

$$\frac{\theta_1}{1-\theta} = K_1 e^{2x} [H^+]^{-2} \qquad [10]$$

where $\eta = E_H - E_R$, $x = \eta\mathbf{F}/RT$.

Equation [8] is the adsorption reaction of amides on the iron surface comprising one charge only. A quasi-equilibrium is considered in which θ_2 is dependent on potential according to the relation

$$\frac{\theta_2 [H^+]}{(1-\theta)\,[A]} = K_2 e^x$$

$$\frac{\theta_2}{1-\theta} = K_2 e^x [A]\,[H^+]^{-1} \qquad [11]$$

From Eq. [10] and [11]

$$1 - \theta = \frac{[H^+]^2}{[H^+]^2 + K_1 e^{2x} + K_2 e^x [A]\,[H^+]} \qquad [12]$$

which corresponds to the active surface area for the anodic dissolution reaction of Eq. [9]. Equations [10] and [11] also suggest that the corresponding surface coverages for the chemisorbed species, $FeOH\cdot A$, and the inhibiting species $Fe(OH)_2$, are

$$\theta_2 = \frac{K_2 e^x [A]\,[H^+]}{[H^+]^2 + K_1 e^{2x} + K_2 e^x [A]\,[H^+]} \qquad [13]$$

$$\theta_1 = \frac{K_1 e^{2x}}{[H^+]^2 + K_1 e^{2x} + K_2 e^x [A]\,[H^+]} \qquad [14]$$

and the total surface coverage

$$\theta = \theta_1 + \theta_2 = \frac{K_1 e^{2x} + K_2 e^x [A]\,[H^+]}{[H^+]^2 + K_1 e^{2x} + K_2 e^x [A]\,[H^+]} \qquad [15]$$

Under Langmuir isotherm conditions and in terms of the absolute rate theory (19), the final expression for the dissolution rate of iron in the presence of adsorption species for this system at high overpotentials is

$$i = k\,[H^+]^\gamma\,(1-\theta)\exp\left(\frac{2.303\,\eta}{2.54 - 0.45\,pH}\right) \qquad [16]$$

From Eq. [12], Eq. [16] reads

$$i(A) = \frac{K[H^+]^{2+\gamma}}{[H^+]^2 + K_1 e^{2x} + K_2 e^x [A]\,[H^+]} \exp\left(\frac{2.303\,\eta}{2.54 - 0.45\,pH}\right) \qquad [17]$$

If the system does not contain amides, the active corrosion current density will be

$$i\,(o) = \frac{k[H^+]^{2+\gamma}}{[H^+]^2 + K_1 e^{2x}} \exp\left(\frac{2.303\,\eta}{2.54 - 0.45\,pH}\right) \qquad [18]$$

The formation constant and the coverage of $Fe(OH)_2$ in the active polarization region.—Should the active anodic polarization curves follow Eq. [17] and [18], then the following properties will be observed from the experiments:

$$\text{At } E_H = E_{crit}, \left.\frac{di}{d\eta}\right|_{pH} = 0,$$

$$\text{where } \eta = E_H - E_R \text{ and } \frac{dx}{d\eta} = \frac{F}{RT}$$

The result for Eq. [18] will be

$$K_1 e^{2x}{}_{crit} = \frac{[H^+]^2}{91.2 - 16.2\,pH} \qquad [19]$$

The coefficient $2F/2.303\,RT = 36.3\ V^{-1}$ has been included in the denominator of Eq. [19]. The critical current density can be expressed in the form

$$i_{crit}(o) = \frac{k[H^+]^\gamma\,(2.51 - 0.45\,pH)}{2.54 - 0.45\,pH} \exp\left(\frac{2.303\,\eta_{crit}}{2.54 - 0.45\,pH}\right) \qquad [20]$$

From Eq. [19] the formation constant of $Fe(OH)_2$, K_1, can be calculated for various pH values and is given in Table III. K_1 at pH 0 is calculated from the extrapolated η^o_{crit} in which $\eta^o_{crit} = E^o_{crit} - E^o_R$ and $x^o_{crit} = F/RT\ \eta^o_{crit}$. The average K_1 is 4.8×10^{-40}. The small formation constant reveals that the formation of the inhibiting species in the active corrosion region of the polarization curve is not important. This effect should become noticeable at higher overpotential, especially when $\eta \rightarrow \eta_{crit}$.

The location of the Flade arrest has not always been a matter of agreement between investigators (4, 20, 21). This disagreement becomes even greater at pH ~ 7.0 (21). The Flade arrest is related to pH for passivity decay by

$$E_F = E_F{}^o - \frac{2.303\,RT}{zF} \cdot pH$$

This relation was first observed by Franck (22) for iron in sulfuric acid solutions. According to the adsorption theory of passivity, E_F is the potential at which oxygen begins to adsorb on the metal surface. However, the adsorption of oxygen is restricted either by the dissolution of metal or by the chemical dissolution of the inhibiting species resulting from the oxygen adsorption. The kinetics of the chemical dissolution of the inhibiting species in the passivation process is still unknown. Therefore, a theoretical attempt to explain the linear relationship between E_F and pH or the slope, $2.303\,RT/\eta F = 59$ mV at 25°C for iron in the potentiostatic polarization curves is almost impossible. However, an attempt based on the previous derivation to correlate η_{crit} rather than E_F with pH is possible.

Based on Eq. [14], there is a tendency to form the inhibiting species even at the corrosion potential (E_R) in the anodic process. This tendency becomes significant only when the metal surface is highly saturated with metal ions. At the critical potential, E_{crit}, the acceleration of metal dissolution *via* Eq. [9], along with the chemical dissolution of $Fe(OH)_2$, becomes equal to the acceleration process of protective film formation according to Eq. [1]. Following Eq. [19], a linear relation between the critical overpotential, η_{crit}, and pH can be obtained for this system, *i.e.*

$$\eta_{crit} = \eta^o_{crit} - b\,pH \qquad [21]$$

where

$$\eta^o_{crit} = \frac{2.303\,RT}{2F} \log \frac{4}{91.2K_1} \text{ and } b = \frac{2.303\,RT}{2F}\ (1.92)$$

in which a simplification has been made such as

$$\ln(1 + x) \approx +x \text{ for } |x| << 1$$

and is only valid at low pH (acidic mediums). With $K_1 = 4.8 \times 10^{-40}$, the calculated $\eta^o_{crit} = 1.029$ (volts) and $b = 0.053$ (volts).

This behavior has been verified from experiments, and it is shown in Fig. 4 that

$$\eta_{crit} = 1.025 - 0.054\,pH \qquad [22]$$

which is very close to the calculated values.

From Eq. [20] and [21] it can be further shown that

$$i_{crit}(o) = K[H^+]^\lambda \qquad [23]$$

where $K \doteqdot 10^{2.80}$, $\lambda \doteqdot 0.284$. These calculated values are valid only at pH < 5.0.

The experimental pH dependence of $i_{crit}(o)$ is shown in Fig. 2. This gives the relation

$$i_{crit}(o) = 10^{2.72}\,[H^+]^{0.286}$$

in fair agreement with the calculated values.

Coverage by the $Fe(OH)_2$, θ_1, can be calculated from Eq. [10] in which

$$\theta_1 = \frac{K_1 e^{2x}}{[H^+]^2 + K_1 e^{2x}} \qquad [24]$$

Experimentally, coverage by $Fe(OH)_2$ can be obtained from the simple expression obtained from Eq. [5] and [16], namely

$$\theta_1 = \frac{i_a - i(o)}{i_a} \qquad [25]$$

Here $i(o)$ is the actual measured current density in the absence of amides and i_a is determined from Fig. 1 by extrapolation of the logarithmic active metal dissolution section up to the given potential. The active metal dissolution in the concentration polarization region is expressed by Eq. [5] and not by the usual Tafel relation. However, as seen from Fig. 1, the current difference between i_a and $i(o)$ is too insensitive to be detected from the experiment in the active polarization region. At the critical potentials, the calculated surface coverages by the inhibiting species, θ_1, for pH = 1.1, 2.3, 3.5, 4.0, and 4.9 are 0.027, 0.045, 0.075, 0.110, and 0.145, respectively.

Table III. Calculated formation constant of $Fe(OH)_2$, K_1, from different pH

pH	η_{crit} (mV)	$e^{-2x_{crit}}$	$K_1 \times 10^{-40}$
0	1025	$10^{-37.73}$	2.1

Adsorption constants of amides and the competitive surface coverages by $Fe(OH)_2$ and amides in the active polarization region.—The polarization curves in the presence of amides look very much like those without amides. Some important features which have been observed are: (*a*) the rest potentials and critical potentials show no change with respect to the previous study; (*b*) at potentials near the E_{crit}, iron dissolution rate decreases with increasing amide concentration. Therefore, a relation between η_{crit} and pH can also be described by Eq. [21].

Table IV shows the concentration effects of four amides on the critical current density at various pH's. It is seen from this table that i_{crit} (A) is related to pH by

$$i_{crit}(A) = K'[H^+]^{\lambda} \qquad [26]$$

which is similar to Eq. [23]. This equation is derived from Eq. [17] and [21] following the same argument given previously for the system without amides and is confirmed by experiments (shown in Fig. 2). The experimental values of K' for 0.50M DMA and NMP found in Fig. 2 are $10^{2.68}$ and $10^{2.64}$, respectively.

Table V lists the critical current densities, $i_{crit}(A)$, for 0.10M amides at various pH's. It is obvious that the addition of amides decreases the critical current density, thus decreasing the dissolution rate of iron at the critical potential. The adsorption of amides on the metal surface therefore decreases the active sites of the surface for metal dissolution which in turn decreases the dissolution of the metal in the active corrosion region.

Although the change of dissolution rate due to the adsorption of amide is small in all cases, a detailed study of the polarization curves provides evidence that amides with higher dielectric constants adsorb on the iron surface more effectively than do the lower ones. From Fig. 2 and Table IV, the relative adsorption effect for the four amides is NMP > F > DMA > DMF. This is also the order of decreasing dielectric constant for these compounds (10, 23, 24). In other words, the higher dielectric amides are better inhibitors than those amides with lower dielectric constants.

In general, the adsorption constant of the amide, K_2, can be obtained from polarization studies by varying the amide concentration in a given system.

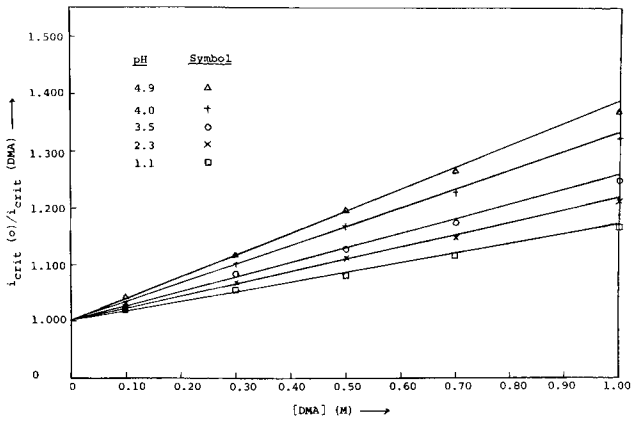

Fig. 3. A plot of $i_{crit}(o)/i_{crit}(DMA)$ vs. [DMA]

At η_{crit}, the ratio of the uninhibited and inhibited critical current densities from Eq. [17] and [18] is

$$\frac{i_{crit}(o)}{i_{crit}(A)} = 1 + \frac{K_2 e^{x_{crit}}[H^+]}{[H^+]^2 + K_1 e^{x_{crit}}} \cdot [A]$$

From Eq. [19], this ratio becomes

$$\frac{i_{crit}(o)}{i_{crit}(A)} = 1 + \rho[A] \qquad [27]$$

in which

$$\rho = K_2 \frac{2.51 - 0.45\,pH}{2.54 - 0.45\,pH} \cdot \frac{e^{x_{crit}}}{[H^+]}$$

Experimentally, ρ is obtained from a plot of $i_{crit}(o)/i_{crit}(A)$ *vs.* the concentration of amide, $[A]$. A typical plot based on Table IV is shown in Fig. 3 for dimethylacetamide. Fairly straight lines were obtained for each pH and it was observed that a relatively large slope was obtained at higher pH. According to the proposed mechanism, as shown in Eq. [8], the adsorption of amides is accompanied by proton transport from the metal surface into the solution. This proton transport will be smaller at lower pH due to the retardation of this process by hydronium ions in the solutions which, in turn, will result in a smaller adsorption of amides and therefore a smaller slope.

The adsorption constant, K_2, can be obtained directly from Eq. [27] in the form

$$K_2 = \left(\frac{2.51 - 0.45\,pH}{2.54 - 0.45\,pH} \cdot \frac{e^{x_{crit}}}{[H^+]} \right)^{-1} \cdot \rho \qquad [28]$$

Based on Table IV, different plots similar to Fig. 3 can be obtained for DMF, F, and NMP. These plots give different slopes, ρ, which enable us to calculate the adsorption constants of amides, K_2, by using Eq. [28]. Table VI gives the various slope values, ρ, and the calculated adsorption constants, K_2, for F, NMP, DMA, and DMF. It is seen that, for each amide, the adsorption constant is independent of pH. The average K_2 for F, NMP, DMA, and DMF is 5.5 x 10^{-20}, 7.8 x 10^{-20}, 4.7 x 10^{-20}, and 4.4 x 10^{-20}, respectively. A higher K_2 indicates a better inhibitor.

Relating Eq. [13], [17], and [18], we are able to find a simple expression for the surface coverage, θ_2, by amide at any given potential, *i.e.*

$$\theta_2 = \frac{i(o) - i(A)}{i(o)} \qquad [29]$$

Table V. Critical current densities, i_{crit} (A), for 0.10M amides at various pH's

pH \ Compound	F	NMF	DMF	A	NMA	DMA	P	NMP	DMP	DMB	—

A plot based on Eq. [29] and [13] for DMA at pH 4.0 with three different concentrations is given in Fig. 4 as an example of the adsorption of amides. The relative surface coverage by this amide changes drastically with respect to the potential change. It is important to note also that the critical overpotenial which corresponds to the maximum dissolution rate of iron in a given system is not synonymous with the maximum surface coverage by the organic species. This is also true for the coverage of $Fe(OH)_2$ (see Fig. 5). As can be seen in Fig. 4, θ_2 increases continuously beyond $\eta_{crit} = 820$ mV. Therefore, from the experimental observation, it is apparent that the quasi-equilibrium reactions of Eq. [1] and [8] will proceed at the potential beyond the critical potential, E_{crit}. A detailed discussion on the surface coverages in the potential region $E_{crit} - E_p$, where $E_p > E_{crit}$, is presented in the next section.

Figure 5 shows the competitive surface coverages by $Fe(OH)_2$, θ_1, and by DMA at 0.50M, θ_2. This figure shows that the surface coverage by amide is always greater than the coverage of inhibiting species in the active polarization region. It is obvious from this that the adsorption of amide plays a predominant role on the total surface coverage at any given potential in this region.

Adsorption process in the $E_{crit} \sim E_p$ region.—In the potential region immediately more noble than the critical potentials, the anodic currents flowing at a given potential decrease with time, eventually reaching a low steady value. With amides added in the solution, the time required to obtain the steady value is longer. This shows that the passivating film is gradually becoming more protective. However, the film is not completely protective against metal dissolution since a quasi-equilibrium reading of current (constant reading within a certain period of time) can still be obtained at a given potential until a certain potential (E_p), considerably more positive than the critical potential, is reached. In general, it is difficult to identify from the anodic polarization curves obtained in this investigation, a marked discontinuity which could be definitely associated with the iron surface becoming completely protective by the passive film. This is a phenomenon observed by many other investigators (25-28) also. The potential corresponding to the completely protected passive film is known as the passivation potential and is represented as E_p (Fig. 1).

Normally, as can be seen from Fig. 1, the potential range of $E_{crit} \sim E_p$ extends from about 50 mV (for pH 1.1) to 300 mV (for pH 4.9), depending on pH. At lower pH, the potential range is narrower and reveals the ease of onset of the complete protective film. At pH 4.9, this range extends approximately 300 mV, revealing the difficulty of onset of complete protection by the passive film.

The onset of complete passivity, E_p, represents the complete coverage of the electrode surface with the inhibiting species. This potential also corresponds to the reversible minimum for Eq. [1], the $Fe(OH)_2$ formation reaction. An approximate evaluation of this portion of the electrode surface covered by a surface film, θ, at any given potential between E_{crit} and E_p can be obtained from the relation

$$\theta = \frac{i_a - i(A)}{i_a}, \quad \theta = \theta_1 + \theta_2 \qquad [30]$$

which is equivalent to Eq. [25] except that the measured current density is $i(A)$ instead of $i(o)$. A more precise polarization measurement (a potential step of 10 mV instead of the 50 mV used in most of this investigation) in this portion, $E_{crit} \sim E_p$, reveals the possibility of calculating the coverage by $Fe(OH)_2$, θ_1,

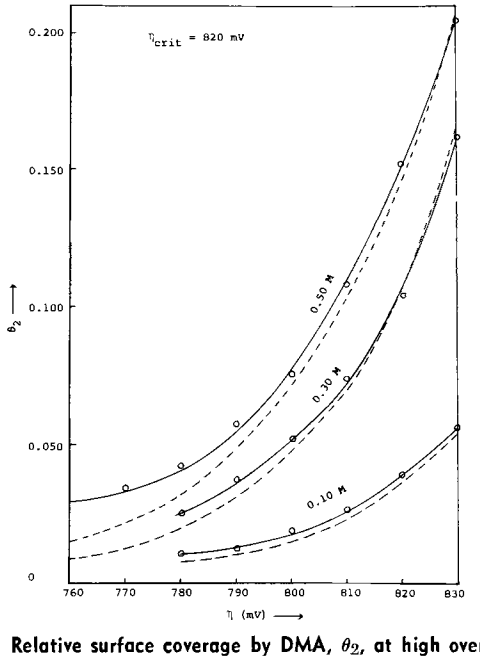

Fig. 4. Relative surface coverage by DMA, θ_2, at high overpotentials at pH 4.0 with concentrations of 0.10, 0.30, and 0.50M: ——— experimental (by Eq. [29]), - - - - - - - - - - calculated (by Eq. [13]).

as well as the surface coverage by amide, θ_2. Figure 6 shows the polarization curves with and without DMF at pH 3.5. The upper straight line is the extrapolation of the logarithmic active metal dissolution governed by concentration polarization. Figure 7 shows the comparison of the calculated coverage by $Fe(OH)_2$ using Eq. [24] with the experimental values using Eq. [25] based on Fig. 6. It is seen that the coverage of $Fe(OH)_2$ changes drastically with respect to a small change of applied potential. Figure 8 shows the total surface coverage, θ, using Eq. [30] and the coverage by DMF, θ_2, using Eq. [29]. The calculated curves using Eq. [15] for θ and Eq. [13] for θ_2 are also given in this figure for comparison.

These figures show that the coverage of $Fe(OH)_2$ is a continuous process before the onset of the complete protection at E_p. However, the surface coverage by amide reveals that the adsorption and desorption processes depend on the applied potential since an adsorption maximum exists in the $E_{crit} \sim E_p$ region. In

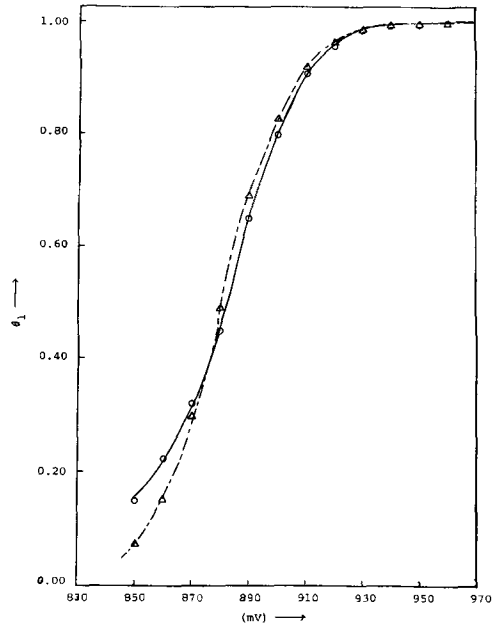

Fig. 7. The coverage of $Fe(OH)_2$, θ_1, in the E_{crit} — E_p region at pH 3.5: ——— experimental, - - - - - - - - - - calculated.

Fig. 8 it is seen that θ_2 at the potential near E_p is negligible compared to θ_1. This is to be expected if the proposed mechanism is correct since it can be assumed that, under quasi-equilibrium conditions, the adsorption of amide and the $Fe(OH)_2$ formation are competitive reactions. Beyond the critical potential, the $Fe(OH)_2$ formation is predominant and desorption of amide occurs. This desorption continues until the potential reaches E_p at which the active electrode surface is essentially completely covered by the inhibiting species. Beginning at E_p, the adsorption of amide must take place on the passive metal surface material rather than on the active surface. A detailed discussion on the amide adsorption in the passive region is given in the next section.

Effect of amide adsorption in the passive region.— Beginning at the onset of the complete passivity, E_p (Fig. 1), the rate of anodic process is independent of potential. The reason for this constant rate of anodic process is still controversial (1, 9). According to the adsorption theory, the anodic reaction on a passive metal, as on an active metal, consists of the transfer of lattice cations into the bulk solution. Passivation is due to an increase of the overvoltage of this transfer which is the result of some changes in the properties of the adsorbing oxygen on the metal surface. The mechanism of these changes is not clear. The oxide film theory explains that the constant current of the anodic process is due to the chemical dissolution of the passivating oxide, not to the formation of hydrated cations. The cations arrive in the solution as the result of the subsequent dissociation of this oxide and is considered to be an ordinary electrically neutral chemical reaction (29).

These two theories must work from the same conclusion that metal cations appear in the solution and their formation is governed by Faraday's laws. With an increase in the anodic potential and the electrical field in the film, the rate of the penetration of metal ions from the active metal surface through the protective film in the opposite direction increases, resulting in protective film thickening. Therefore, the oxide film thickness is directly dependent on the applied potential (30).

Although it is generally agreed that the initiation of passivation before E_p is associated with the appearance of a monolayer or less of an "adsorbed" inhibiting species (2, 3), the entity of this "species" has not been fully understood. In the case of iron, the adsorbed in-

Table VII. Passivation current densities, i_p (μA/cm^2), of 0.10M amides at different pH's

hibiting species is believed by some to be FeO or its hydrated species, $Fe(OH)_2$. The alternate oxide species, Fe_3O_4, is also possible since ferrous hydroxide may decompose to a mixture of magnetite and iron (21, 31).

$$4\,Fe(OH)_2 \rightarrow Fe_3O_4 + Fe + 4\,H_2O$$

Beginning at E_p, a more protective oxide film other than $Fe(OH)_2$ is formed on the metal surface (1, 4). From electron diffraction (32) and chemical analysis (27) of this oxide film, the passive film of iron is said to consist of γ-Fe_2O_3 and Fe_3O_4. The dissolution species in the passive state, no matter whether it is coming from the corrosion of the active metal surface or the dissolution of oxide film, is ferric ions instead of ferrous ions (21).

Table VII lists the passivation current densities, i_p, with and without 0.10M amides at various pH's. Each i_p is the average of three experiments.

Table VIII shows the concentration effect of four amides on the passivation current density. The current densities decrease with increase of concentration at a given pH. If we regard the passivation current density as the dissolution rate of the passive state, then it is clear that amides will behave as an inhibitor on the passive iron. Comparing Tables IV and VIII, the inhibiting effect of the organic material is seen to be much more effective in the passive than in the active region. Unless a fully detailed chemical analysis of the oxide film is carried out, it is very difficult at this stage to guess whether the amides will be incorporated in the oxide film growth. It seems likely that the effects of amides on the passivation current densities are associated with their strong adsorption on the passive metal surface. This adsorption should lead to decreased ionic conductivity in the passive film.

The marked inhibition effect of amides on the passive state as compared to that for the active state is probably due to the interference by metal dissolution in the latter. The large dissolution rate of iron in the active polarization region suggests a less competitive adsorption of these organic species on the active metal surface, while the small and constant dissolution rate of oxide film should permit a more competitive adsorption of amides on the passive metal surface.

Crystallographic Factors in High-Rate Anodic Dissolution of Copper

D. Landolt*,[1], R. H. Muller,* and C. W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Surface textures resulting from the anodic dissolution of polycrystalline and single crystal copper at 50 A/cm^2 in 2M KNO_3 have been studied. Electrolyte flow velocities of 2500 and 400 cm/sec have been used for dissolution in the active and transpassive mode. Results obtained by light and electron microscopy show that surface topography resulting from active dissolution depends on crystal orientation. Flow streaks appear in transpassive dissolution. Transpassive pitting was observed in polycrystalline samples only.

An important problem in the process of electrochemical machining is the control of the resulting surface finish. In previous studies of high-rate anodic metal dissolution (1-3), it has been shown that the surface finish resulting from the anodic dissolution of copper in a given electrolyte depends both on flow velocity and current density. The micrographs shown in Fig. 1 exhibit a transition from etching to polishing dissolution along a line running approximately from the upper left to the lower right of the array. Below this line, the surface appears etched and dull; above it, smooth and bright, with pits increasing in prominence with the separation from the transition region. The transition in surface finish coincides with the transition from a low voltage dissolution mode, which we have termed active, to a high voltage mode, which we call transpassive. It is to be expected that structural factors of the anode material also affect the resulting surface finish. In the present study, the surface topography resulting from the high-rate anodic dissolution of copper specimens has been investigated under active and transpassive dissolution conditions in 2 molar potassium nitrate solution. Polycrystalline samples of variable grain size and single crystals of different orientations have been used.

Experimental

The flow system and the electrical circuit employed have been described before (1). Two flow rates have been employed, 2500 cm/sec for dissolution in the active mode and 400 cm/sec for dissolution in the passive mode. Electrolysis was conducted at a constant current of 50 A/cm^2 with a stainless steel cathode of 3 mm diam positioned 0.5 mm from the anode. During each experiment, a charge of 25 coulombs/cm^2 was passed, which corresponds to an average dissolution depth of 10μ (based on the formation of Cu^{++}).

Disk anodes of 1.5 mm diam and 45 mm length, embedded in cylindrical polypropylene holders of 5 mm diam, were used. They were prepared from 99.999% copper rod (Cominco Co., Spokane, Washington). Polycrystalline specimens were used as received or were annealed (1750°F, 4 hr in argon, after 7.5% diam reduction). Single crystals were grown from the same material in induction-heated graphite molds, using spherical seed crystals. The surfaces of the embedded electrodes were gently polished over extended periods (6-30 hr) with 1 and 0.5μ chromium oxide abrasive. Structural damage due to this treatment was sufficiently shallow that it was not visible in the x-ray diffraction pattern of single crystals. In order to put a limit on the depth of lattice damage expected to be still present on the surface (without affecting the x-ray diffraction pattern), experiments were performed to determine the thickness of distorted copper necessary to obliterate the diffraction from an underlying single crystal. Cold-rolled copper foils of different thicknesses were attached to the surface of a (100) oriented crystal. No discernible diffraction pattern was obtained with a 10μ thick foil and a greatly attenuated one resulted from 5μ, independent of the closeness of contact of the copper foil. These results indicate that surface damage due to polishing extended to a depth of much less than 5μ, and the anodic dissolution indeed proceeded into the undisturbed crystal. The smoothness and flatness of the polished electrode surface was ascertained by interference microscopy. Deviation from flatness over the

entire surface was usually less than 2μ as illustrated in Fig. 2. Residual polishing marks were at most 0.05μ deep (Fig. 3).

Before use, the electrodes were cleaned with acetone and detergent and subjected to cathodic hydrogen evolution in 1M NaOH (100 mA/cm², 3 min). After the dissolution experiment, the electrodes were immediately removed from the flow channel cell, rinsed with distilled water, and dried with acetone. Without delay, they were examined by optical microscopy and interference microscopy. From some surfaces, plastic-carbon replicas were prepared for transmission electron microscopy; others were examined in the scanning electron microscope.

Active Dissolution

Figure 4 shows the surface of an annealed polycrystalline electrode after dissolution in the active mode. The exhibition of individual grains, similar to chemical etching, suggests that anodic attack depends on crystallographic orientation. The same surface viewed at higher magnification (Fig. 5) demonstrates that the different appearance of grains is due to the development of ridges and shallow etch pits, whose orientation and shape vary among adjacent grains. Still higher magnification reveals that ridges and etch

pits are composed of submicroscopic steps (Fig. 6). These observations are similar to those reported from electrocrystallization and vaporization studies. They can be related to the mechanism of removal of atoms from the crystal lattice which can be described by the movement of atomic ledges across close-packed lattice planes.

In order to investigate the effect of crystal orientation, experiments were also carried out with single crystal electrodes. Contrary to the polycrystals which exhibited a dull appearance after active dissolution, single crystal surfaces of low index orientation remained bright without visible etching. This difference is illustrated in Fig. 7 which may be compared with Fig. 5 taken at the same magnification. The (110) face employed in Fig. 7 shows surface texture at the limit of optical resolution. On the (100) face, only the electron microscope revealed shallow crystallographic etch patterns. The (111) face (even at that resolution) was almost featureless, as shown in Fig. 8. These results seem to support a dissolution mechanism involving the motion of monatomic ledges on tightly packed lattice planes (6). These observations are also consistent with those of Hulett and Young (7) who found the formation of etch pits on (111) copper faces in HCl at low current densities only after the addition of HBr

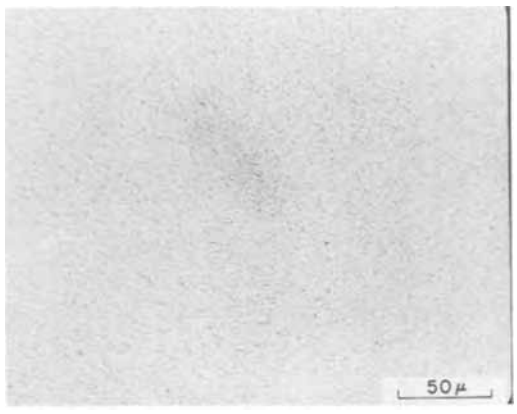

Fig. 7. (110) single crystal surface with barely visible texture after active dissolution. Optical micrograph.

Fig. 8. Smooth copper (111) surface after active dissolution. Latex sphere of 0.53μ diam provides scale for direction and length of shadows. Electron micrograph of two-stage carbon replica.

which acted as a poison for ledge motion. No such poisoning appears to have occurred under the present dissolution conditions. According to the ledge motion mechanism, dissolution starting with a high index crystal plane (comparable to the random orientation of grains in polycrystalline material) is expected to result in a faceted surface. Such facets have been observed on several randomly oriented crystals. A typical example is shown in Fig. 9. This surface texture is similar to the one reported for iron cathodically deposited at high (150-200 mV) overvoltage (8). The surface textures resulting from active dissolution indicate that dissolution at very high rates does not proceed by a basically different mechanism from that at low rates, provided that removal of reaction products from the surface by convective diffusion and migration is sufficiently fast.

Transpassive Dissolution

Figure 10 illustrates a polycrystalline surface after transpassive dissolution. In contrast to the appearance of the same specimen after active dissolution (Fig. 4), the surface now is bright and differences between individual grains are barely discernible at the optical level of resolution. A large number of round, deep pits, some arranged in rows, are distributed over the surface. Streaks in the flow direction, due to a waviness of the surface, extend from the leading edge over most of the specimen. Bright and pitted surfaces, resulting from dissolution in the presence of an anodic passivating layer, have also been reported for electropolishing at much lower current densities (9). Brightness is due

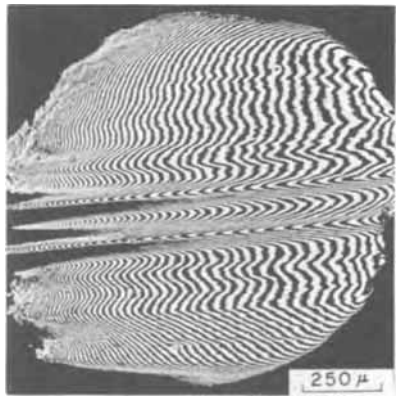

Fig. 13. Flow streaks resulting from transpassive dissolution of (100) single crystal face. Interference micrograph. Flow direction from left to right.

to a greatly reduced micro-roughness, and the even attack on differently oriented grains has been explained by the equalizing effect of an oxide layer (10). At much higher resolution, differences in surface texture between neighboring grains occasionally become visible. The electron micrograph, Fig. 11, illustrates one of the most pronounced microtextures observed after transpassive dissolution. Compared with the surface resulting from active dissolution shown in Fig. 6 at the same magnification, the roughness is an order of magnitude lower.

The difference in microtexture between active and transpassive dissolution is particularly pronounced with a randomly oriented single crystal. The electron micrographs in Fig. 12 illustrate this situation for a surface oriented 10° off the (110) plane. Interestingly enough, no pitting has been observed on any of the single crystals studied. Flow streaks appeared on single crystals in transpassive dissolution similar to the ones observed on polycrystalline specimens. The interferogram, Fig. 13, shows the associated macroscopic waviness of the surface. Typically these profiles are 0.1 mm wide and a few microns deep and they become shallower and wider downstream. Flow streaks observed under technical ECM conditions have been attributed to cavitation effects. In the present study, flow streaks have not been observed in active dissolution, where cavitation is more likely, due to the higher flow rates (2500 cm/sec active, 400 cm/sec transpassive).

Conclusions

1. The present study shows that crystallographic factors influence the surface texture resulting from high-rate anodic dissolution of copper in the active mode. Transpassive dissolution proceeds in the pres-

ence of anodic layers, which diminish the effect of crystal orientation and lead to brightening.

2. In the active mode, submicroscopic facets lead to the development of ridges, which give the surface an etched appearance. This appearance depends on crystallographic orientation and results in a differentiation between grains in polycrystalline material. Active dissolution of (100) and (111) faces has not resulted in the formation of facets. These observations are in agreement with a dissolution mechanism based on the motion of atomic ledges on tightly packed lattice planes.

3. Flow streaks are associated with transpassive dissolution, while the surface resulting from active dissolution is independent of flow direction.

4. Transpassive pitting is linked to metallurgical factors not present in the single crystals studied.

Acknowledgment

Anode Potentials in High-Rate Dissolution of Copper

D. Landolt,*,[1] R. H. Muller,* and C. W. Tobias*

Inorganic Materials Research Division, Lawrence Radiation Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A constant current interrupter technique was employed in the experimental determination of anode potentials during high-rate anodic dissolution of copper. The influence of ohmic voltage drops in the solution on measured overvoltage has been compensated by electronic means. For short electrolysis times, dissolution proceeds in the active mode; in sulfuric acid, Tafel behavior was observed up to the highest current densities employed (100 A/cm^2). Passivation effects may lead to significantly higher anodic potentials.

In electrochemical machining (ECM), metals are dissolved anodically at current densities of many amperes per square centimeter. In order to get a better understanding of electrochemical factors governing metal dissolution proceeding at such high rates, meaningful anode potential measurements are needed. Potential measurements performed at high current densities with rapidly dissolving anodes pose many problems (1), and anode potential data reported for technical ECM conditions appear to be of questionable value (2, 3). The anodic dissolution of copper has been chosen in this laboratory for the study of some fundamental aspects of ECM (1, 6-8). For high-rate anodic dissolution of copper, abrupt potential changes of many volts have been found, coinciding with a change from an active to a transpassive dissolution mode (1). However, the experimental techniques employed did not allow for the subtraction of ohmic voltage drops from the potential values measured. Electrode potential data obtained at low current densities have been extrapolated by Hoare *et al.* to predict high current density behavior of ECM electrolytes (4, 5). In view of many unknowns inherent in ECM it appeared desirable, however, to develop experimental procedures that allow direct potential measurements over a wide range of current densities. In the present paper, a galvanostatic interrupter technique is described which was applied to the determination of anode potentials prevailing under conditions of high-rate dissolution of copper in sulfate electrolytes. Experiments were performed under free as well as under forced convection conditions.

Experimental

Two cell types were employed, each assuring fast electrical response through low capacitance and careful exclusion of ground loops. Cell I (Fig. 1) was of cylindrical geometry, thus providing for even current distribution. No external convection was employed. A 10 mil diam, 6.3 mm long 99.999% copper wire served as anode, providing a surface area of 5 mm^2. Since, due to dissolution, considerable loss of diameter resulted during experiments, it was necessary to replace the anode frequently. This was accomplished by simply advancing the continuous wire (A) by approximately ½ in. During experiments, the anode was sealed by two Teflon compressible inserts (E) which were held tight by means of nylon screws (G). The anode was

ence of anodic layers, which diminish the effect of crystal orientation and lead to brightening.

2. In the active mode, submicroscopic facets lead to the development of ridges, which give the surface an etched appearance. This appearance depends on crystallographic orientation and results in a differentiation between grains in polycrystalline material. Active dissolution of (100) and (111) faces has not resulted in the formation of facets. These observations are in agreement with a dissolution mechanism based on the motion of atomic ledges on tightly packed lattice planes.

3. Flow streaks are associated with transpassive dissolution, while the surface resulting from active dissolution is independent of flow direction.

4. Transpassive pitting is linked to metallurgical factors not present in the single crystals studied.

Acknowledgment

The authors wish to thank Mr. W. T. Giba for the preparation of electron microscope replicas and for other valuable assistance in this investigation. This work was conducted under the auspices of the U.S. Atomic Energy Commission.

Manuscript received Sept. 30, 1970. This was Paper 219 presented at the Atlantic City Meeting of the Society, October 4-9, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

ABSTRACT

A constant current interrupter technique was employed in the experimental determination of anode potentials during high-rate anodic dissolution of copper. The influence of ohmic voltage drops in the solution on measured overvoltage has been compensated by electronic means. For short electrolysis times, dissolution proceeds in the active mode; in sulfuric acid, Tafel behavior was observed up to the highest current densities employed (100 A/cm^2). Passivation effects may lead to significantly higher anodic potentials.

In electrochemical machining (ECM), metals are dissolved anodically at current densities of many amperes per square centimeter. In order to get a better understanding of electrochemical factors governing metal dissolution proceeding at such high rates, meaningful anode potential measurements are needed. Potential measurements performed at high current densities with rapidly dissolving anodes pose many problems (1), and anode potential data reported for technical ECM conditions appear to be of questionable value (2, 3). The anodic dissolution of copper has been chosen in this laboratory for the study of some fundamental aspects of ECM (1, 6-8). For high-rate anodic dissolution of copper, abrupt potential changes of many volts have been found, coinciding with a change from an active to a transpassive dissolution mode (1). However, the experimental techniques employed did not allow for the subtraction of ohmic voltage drops from the potential values measured. Electrode potential data obtained at low current densities have been extrapolated by Hoare *et al.* to predict high current density behavior of ECM electrolytes (4, 5). In view of many unknowns inherent in ECM it appeared desirable, however, to develop experimental procedures that allow direct potential measurements over a wide range of current densities. In the present paper, a galvanostatic interrupter technique is described which was applied to the determination of anode potentials prevailing under conditions of high-rate dissolution of copper in sulfate electrolytes. Experiments were performed under free as well as under forced convection conditions.

Experimental

Two cell types were employed, each assuring fast electrical response through low capacitance and careful exclusion of ground loops. Cell I (Fig. 1) was of cylindrical geometry, thus providing for even current distribution. No external convection was employed. A 10 mil diam, 6.3 mm long 99.999% copper wire served as anode, providing a surface area of 5 mm^2. Since, due to dissolution, considerable loss of diameter resulted during experiments, it was necessary to replace the anode frequently. This was accomplished by simply advancing the continuous wire (A) by approximately ½ in. During experiments, the anode was sealed by two Teflon compressible inserts (E) which were held tight by means of nylon screws (G). The anode was

surrounded by a circular counterelectrode made of copper (B). The whole interelectrode space was filled with liquid. Holes drilled in the cell cover (H) near the cathode provided for escape of cathodically evolved gas. The reference electrode (C), made of copper, was connected to the cell compartment by capillary D, positioned at a distance of 24 mm from the center. The cylindrical geometry of the cell allowed one to calculate the ohmic voltage drop between capillary and anode. No provision for excluding oxygen was made, since at the high current densities employed here its effect on the dissolution kinetics was considered negligible. On the other hand, the presence of oxygen might influence the potential of the reference electrode by establishing a mixed potential. Numerical estimation showed, however, that this effect was always much smaller than 10 mV and, hence, could be neglected within the accuracy of the present study. Before insertion in the cell, the copper electrodes were cleaned in nitric acid and rinsed with distilled water. Several short anodic current pulses were applied before the start of measurements.

Cell II (Fig. 2) was a rectangular flow channel (E) through which the electrolyte was moved by means of a piston pump (C). A Teflon piston was advanced at constant, preset rate in a PVC cylinder, sweeping out a volume of 400 cm^3. At the end of each stroke, the motion of the piston was stopped by means of microswitches. The direction of rotation of the motor was then reversed to refill the cylinder with electrolyte. An electrolyte reservoir of 2 liters was employed. Except for the electrodes, no metal parts were in contact with the solution.

The 0.5 x 3 mm copper anode was cast into epoxy, and its short length was positioned parallel to the flow direction. A copper counterelectrode of the same surface area was used. The distance between anode and cathode was 0.5 mm, fixed by the thickness of a Teflon spacer into which a 3-mm wide slot—the flow channel—was cut. The cell was sealed by pressing the flat anode epoxy cast against the Teflon spacer by means of 4 knurled screws.

Linear flow velocities at the electrodes up to 10 m/sec were used, corresponding to a minimum discharge time of the pump of 25 sec. In order to reach such high velocities without requiring excessive inlet pressures, the distance between cell inlet and anode was kept short (1.5 cm). Thus, the hydrodynamic conditions in

the present cell were not as well defined as those in previous experiments (1, 6). In the present study, using transient techniques, it was considered more important, however, to achieve a compact design which allowed one to keep electrical connections to the cell short and which made it possible to avoid any metallic contact other than the electrodes with the electrolyte solution. In addition, the present design permitted the achievement of high flow velocities at the electrodes without requiring large electrolyte volumes. A copper reference electrode was located in the cell wall upstream from the cathode. All experiments were carried out at room temperature.

A galvanostatic pulse method was chosen for this study because it offers the most convenient technique for the elimination of large ohmic voltage drops inherent in high current density potential measurements. The electrical circuit is given schematically in Fig. 3. Current was drawn from a pulse generator[2] capable of providing square-pulses of up to 100V and 2A with rise time < 15 nsec. Pulse duration was varied between 10 μsec and 10 msec. Constant current through the cell was established by means of a series resistance (H). The current was measured in each experiment over a 5 ohm resistance (I) and displayed on a dual beam oscilloscope.[3]

[3] Model 555 Dual Beam Tektronix.

Two types of potential measurements were performed. On the one hand, the over-all behavior of potential transients was determined on a millisecond time scale. These experiments yielded information on relative potential changes associated with passivation phenomena. On the other hand, potential decay upon switching off the current was measured on a microsecond time scale. These experiments allowed for estimates of the nonohmic part of anode potentials in both the active and transpassive dissolution mode. Electronic compensation of ohmic voltage drops between capillary and anode surface was necessary in these experiments. This was achieved by means of variable gain preamplifier (E), the output signal of which was subtracted from the output signal of amplifier (F) connected to the reference electrode (G). A commercial amplifier unit[4] was used in this procedure. The difference signal was displayed on the dual beam oscilloscope together with the current signal and recorded on Polaroid film. Among several compensation procedures investigated, the following was found to give most satisfactory results. Low current density pulses, typically in the order of 20 mA/cm^2, were applied to the cell in order to determine the ohmic resistance between capillary and anode. Double layer charging was sufficiently slow under these conditions to allow for easy separation of the ohmic and the nonohmic part of the charging transient. The cell was then disconnected and replaced by an ohmic resistance of accurately known value, usually lower than the measured resistance between capillary and anode. The gain of amplifier (E) was adjusted to provide compensation equal to the value of the inserted resistance. The cell was then reconnected for the experiment while keeping the gain of (E) to the adjusted value. The use of a fixed compensating resistance of well-known value, together with variable amplifier gain, allowed for frequent and easy recheck of the accuracy of compensation. Partial, rather than full, compensation of the ohmic electrolyte resistance was used in order to avoid saturation of the differential amplifier. The uncompensated part of the ohmic electrolyte resistance was subtracted from the decay transient in a conventional way.

Active Dissolution

At high flow rates or very short experimental times, copper dissolves anodically in sulfate solutions in the active dissolution mode (1). Experiments were performed here to investigate the validity of extrapolating Tafel behavior found at low current densities (9) to high currents. For this purpose, anode potentials as a function of current density were determined from decay transients. The length of the applied current pulse was kept short enough to avoid any significant influence of concentration polarization effects on the anode potentials measured. On the other hand, pulse lengths were long enough to completely charge the electrical double layer. Depending on current density, pulse duration was between 10 μsec and several milliseconds.

Results obtained in cell I with a 1M sulfuric acid solution containing 0.1 mole per liter copper sulfate are given in Fig. 4. Within the accuracy of the measurements, Tafel behavior is observed up to the highest current density studied (39 A/cm^2). The accuracy of the data at high current densities is limited mainly by two factors: the *IR* drop in the solution and the rate of double layer discharge. The influence of the latter may be estimated by setting for the rate of change of overvoltage η after current switch-off

$$\frac{-d\eta}{dt} = \frac{|i_F|}{C} \qquad [1]$$

with i_F = Faradaic current density, C = double layer capacitance. For constant C and Tafel kinetics the solution of Eq. [1] becomes (10)

$$\eta_{t=0} - \eta = b \log \left(1 + \frac{2.3\,|i|\,t}{bC}\right) \qquad [2]$$

where i = applied current density.

Due to limitations in the frequency response of the amplifiers, η cannot be determined experimentally exactly at $t = 0$. One expects, therefore, that measured η values are lower than the true overvoltage prevailing at current switch-off. The possible magnitude of this error was estimated by inserting typical numerical values into Eq. [2]. From oscilloscope traces, it was estimated that in present experiments, potential readings were possible within at least 0.5 μsec after switch-off. Decay traces suggested that a reasonable value for C was 50 μF/cm^2. (Experimentally determined C values showed large scatter, and the value given has to be regarded as an order of magnitude estimate only.) The value of b was determined from Fig. 4 to be 40 mV. With these numerical values, one calculates $\eta_{t=0} - \eta_{t=0.5\,\mu sec}$ = 21 mV at 4 A/cm^2 or 55 mV at 40 A/cm^2. The resulting uncertainty in potential measurements is indicated in Fig. 4 by the dotted line.

Large ohmic voltage drops exist between capillary and anode as illustrated by Fig. 5 in which measured *IR* drops and anode potentials for the experiments of Fig. 4 are plotted on a linear scale. At the highest current density of 39 A/cm^2, the ohmic voltage drop is approximately 28 times larger than the actual anode potential. From the measured slope, one calculates a conductivity of 0.364 ohm^{-1} cm^{-1} at 24°C, in good agreement with the value one obtains at 25°C by using the estimation formula given by Hsueh (11), 0.379 ohm^{-1} cm^{-1}. By employing optimum compensation conditions as described above, it was estimated that the value of the nonohmic decay potential could be measured to ±1% of the *IR* drop corresponding to the current density of the measurements. The resulting uncertainty in measured anode potentials is indicated by the dashed line in Fig. 4. A least square fit of the measured points in Fig. 4 yielded a Tafel slope of 40 mV, coinciding with the value reported by Mattson and Bockris (9) for copper dissolution in highly purified sulfuric acid electrolytes at low current densities under exclusion of oxygen. Tafel parameters for anodic copper dissolution in sulfuric acid as well as values from the literature are summarized in Table I. Present

results extend the previously reported Tafel region to higher current densities by two orders of magnitude.

At high current densities, uncertainties associated with fast double layer discharge and ohmic compensation become increasingly more important. The indicated Tafel behavior up to 40 A/cm² has, therefore, to be considered as an approximation rather than an exact representation of real behavior. Indeed, a deviation from the given Tafel slope of 40 mV at high enough current density is to be expected if the two-step charge transfer mechanism suggested by Mattson and Bockris prevails

$$Cu \overset{\text{fast}}{\rightleftarrows} Cu^+ + e \qquad (I)$$

$$Cu^+ \overset{\text{slow}}{\rightleftarrows} Cu^{2+} + e \qquad (II)$$

The species Cu^+ is considered adsorbed on the surface, its surface concentration depending on potential. Assuming no loss of Cu^+ due to diffusion, the current for such a two-step charge transfer process can be expressed (12) by

$$i = 2\frac{\exp[-(\alpha_1+\alpha_2)f\eta] - \exp[(2-\alpha_1-\alpha_2)f\eta]}{\frac{1}{i_{01}}\exp[(1-\alpha_2)f\eta] + \frac{1}{i_{02}}\exp(-\alpha_1 f\eta)} \qquad [3]$$

where α_1 and α_2 are the charge transfer coefficients for steps I and II, i_{01} and i_{02} are the respective exchange current densities. Following the assumption usually made, one may set $\alpha_1 = \alpha_2 = \alpha = 0.5$. For the case of $i_{01} >> i_{02}$ and intermediate overvoltage η, the first terms in the numerator and denominator can be neglected and Eq. [3] reduces to

$$i = -2\,i_{02}\exp[(2-\alpha)f\eta]\left(1 << f\eta << \ln\frac{i_{01}}{i_{02}}\right) \qquad [4]$$

This equation predicts a Tafel slope of 39 mV. At high values of η, the limiting value of Eq. [3] is

$$i = -2\,i_{01}\exp[(1-\alpha)f\eta]\ (f\eta \to \infty) \qquad [5]$$

corresponding to a Tafel slope of 118 mV. Since we do not know the value of i_{01}, no quantitative test of the above relationships is possible. A slight deviation from the slope of 40 mV consistent with the prediction of Eq. [4] cannot be excluded at the highest current density, but the measured results seem to fit Eq. [4] much better than Eq. [5]. No further mechanistic interpretation of results is justifiable here.

Table I. Tafel parameters for anodic copper dissolution in sulfuric acid

H_2SO_4 (M)	Electrolyte $CuSO_4$ (M)	Current density (A/cm²)	Cell	Ref.	*a* (mV)	*b* (mV)
1	0.1	5×10^{-3} to 39	I	present	171 ± 16	40 ± 15
1	0.1	8×10^{-3} to 140	II	present	184 ± 21	51 ± 16
0.5	0.5	—		(9)	81,† 82	40 ± 6,† 36 ± 10
0.5	0.075	5×10^{-3} to 0.2*		(9)	93,† 113	44 ± 4,† 45 ± 4
0.5	0.011	—		(9)	100	41 ± 4

* The range of current density in which Tafel behavior was observed was estimated from two figures given in Ref. (9).

† First value for He annealed copper, second for electrodeposited copper. The standard deviation of the results given in Ref. (9) was multiplied by two to get a 95% confidence limit. The values of *a* were calculated from i_0 values given in Ref. (9).

Flow channel cells have been used previously for studying high-rate metal dissolution under forced convection conditions (1, 6-8). Their advantage lies in the control of mass transfer and temperature effects. On the other hand, current distribution is inhomogeneous in such cells. To investigate experimentally the error that might be introduced in potential measurements performed under nonideal current distribution conditions, the same experiments described above were performed with cell II, the geometry of which resembled that of previously used flow channel cells.[5] Results comparable to those given in Fig. 4 are indicated in Fig. 6. The least square fit yielded a slope of 50 mV which is somewhat higher than the 40 mV obtained with cell I having cylindrical geometry. The scattering of data did not allow a quantitative analysis of this difference. Some qualitative comments may be appropriate, however. Upon current switch-off, two discharge processes may proceed now. Aside from the Faradaic current, a current may flow in the solution between differently charged regions of the double layer. The second effect will be larger when the current distribution is more nonuniform. In the case of Tafel kinetics and in the absence of concentration polarization, the uniformity of current distribution is characterized by the magnitude of the parameter $K = \kappa b/li$,

[5] Since experimental times were kept short in the present experiments, convection did not influence these results.

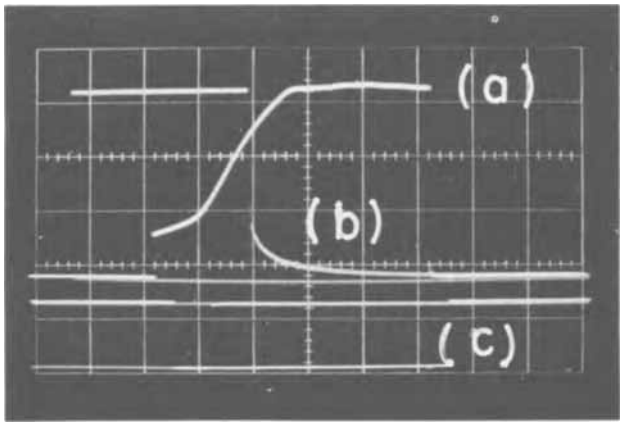

Fig. 7. Transpassive behavior of copper in 1M H_2SO_4 + 0.1M $CuSO_4$, Cell II. Current density, 77 A/cm^2; flow velocity, 140 cm/sec; no *IR* compensation. Trace a: over-all potential transient; anode potential, 10 V/div; time, 1 msec/div. Trace b: decay transient after current switch-off; anode potential, 10 V/div; time, 5 μsec/div. Trace c: current transients; 5 V/div.

where l is a characteristic length, i the current density, κ the electrolyte conductivity, and b the Tafel slope. Primary current distribution prevails for $K << 1$; secondary current distribution, for $K >> 1$. In our case $\kappa = 0.38$ ohm^{-1} cm^{-1}, $l = 0.5$ mm, $b = 40$ mV. One may, therefore, assume primary current distribution for $K \leq 0.1$ or $i \geq 3$ A/cm^2 and secondary current distribution for $K \geq 10$ or $i < 30$ mA/cm^2. In the intermediate region, a gradual change from secondary to primary current distribution occurs with increasing current, *i.e.* the current density at the edge of the electrode will increase more than the average current density. The ohmic part of the measured decay transient, on the other hand, is independent of current distribution (14). Therefore, in the intermediate region $0.1 < K < 10$, one would expect that the measured nonohmic part of the anode potential increases faster with current density than that corresponding to the true Tafel slope. This is qualitatively consistent with the observed behavior of Fig. 6. It appears that, in the case of active copper dissolution in acid sulfate solutions, the anodic behavior at high current densities can be described adequately by extrapolating Tafel kinetics valid for low current density. For many electrochemical machining purposes, possible inaccuracies in anodic overvoltage measurements resulting from a nonuniform current distribution can be neglected.

Transpassive Dissolution

At sufficiently high current densities and longer experimental times, solid anodic layers may be formed which lead to a sharp rise in measured anode potentials. The behavior is illustrated by Fig. 7, trace a. The measurement was performed in cell II at a flow velocity of 140 cm/sec and a current density of 77 A/cm^2. The electrolyte was 1M H_2SO_4 + 0.1M $CuSO_4$; no *IR* compensation was employed. An increase in over-all measured anode potential by 25V takes place 1 msec after start of the galvanostatic run.[6] It has been shown previously that dissolution in the high voltage mode proceeds with different stoichiometry (7) and leads to a different surface texture (1). The transition between the two dissolution mechanisms, active and transpassive, is mass transfer controlled (1). In the present study, experiments were performed aimed at further characterizing the current voltage behavior of copper anodes dissolving in the transpassive mode. This included the study of the influence of flow rate and of current density on the measured voltage rise and the measurement of decay potentials in the transpassive region.

Optical observation of anodically dissolving copper electrodes in acidic sulfate solutions suggested that relatively thick loosely adherent oxide layers are formed upon passivation (8). One would expect that their thickness and, hence, their effect on measured over-all anode potential would strongly depend on the prevailing hydrodynamic conditions; at high flow velocities, the loosely adherent deposits would be washed away from the anodes much more easily, and the extent of the voltage rise upon passivation ought to be reduced. Figure 8 gives five superimposed transients measured at 89 A/cm^2 with flow rates ranging from 65 to 1000 cm/sec. Qualitatively, the expected decrease in measured voltage with increasing flow rate is indeed observed, but the effect is small; for example, the difference between initial voltage (which represents mostly the *IR* drop in the solution) and maximum voltage is $\Delta E = 26$V at 65 cm/sec and $\Delta E = 23$V at 1000 cm/sec. This indicates that the observed voltage increase is caused by a tightly adherent layer rather than by the loosely adherent solids observed visually. The magnitude of the observed voltage increase cannot be explained by the formation of insulating solid dissolution products which block the anode surface and thereby increase the effective ohmic resistance. Figure 8 shows a 25-V potential increase taking place within a time interval of approximately 2 msec during which a charge of 154 mcoulomb/cm^2 is passed. The thickness of a compact cuprous oxide layer formed at 100% current efficiency during this time would be 3.8×10^{-5} cm. So as to explain the observed voltage drop across such an insulating layer by electrolytic conduction in pores, a porosity in the order of 10^{-4} would have to be postulated.

Other observations lead to a similar conclusion. A change in specific electrolyte conductivity by approximately a factor of two had no measurable effect on the voltage rise ΔE. Furthermore, a large fraction of ΔE was found to be nonohmic as indicated by trace b in Fig. 7, which represents the potential decay after current interruption (time resolution 5 μsec/div) for the same electrolysis conditions under which charging trace a was observed.

The above discussion suggests that during transpassive dissolution the anode potential is determined by the presence of a thin compact layer. It can be speculated that dissolution occurs through this layer by solid-state conduction, although no experimental proof for this view exists at present. An increase in ionic conductivity of an anodic layer with increasing current density due to heating effects is qualitatively

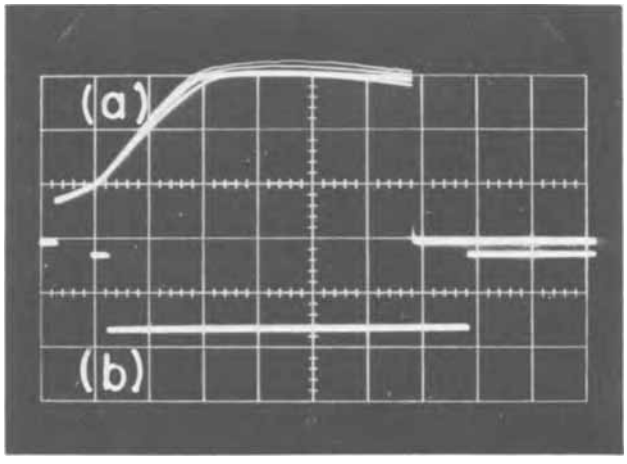

Fig. 8. Effect of flow rate on anodic transients in transpassive region. Current density (b), 89 A/cm^2; time, 1 msec/div; anode potential (a), 10 V/div. Flow rate for transients from top to bottom: 65 cm/sec, 140 cm/sec, 370 cm/sec, 610 cm/sec, and 1000 cm/sec.

[6] Potential time transients of the type given exhibit a maximum before steady state is reached. This does not show here because of the short pulse length employed. The indicated voltage increase upon layer formation is therefore larger than the steady-state voltage difference across the layer.

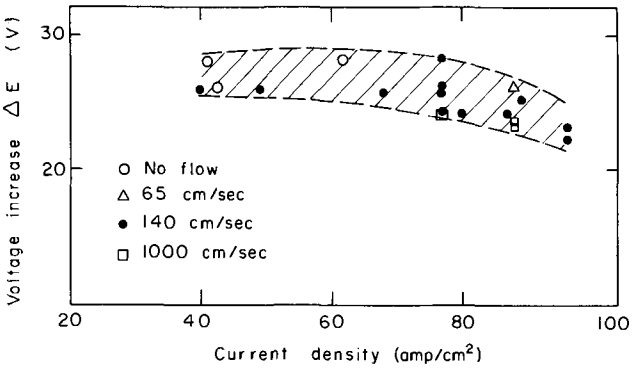

Fig. 9. Voltage increase upon anodic layer formation in function of current density. ΔE, peak voltage minus initial voltage.

consistent with the results shown in Fig. 9. The voltage rise is almost independent of current density, which indicates that the effective resistance of the layer decreases strongly with increasing current density (and hence increasing power dissipation). It is possible that, as a result of the heating effect, stresses are generated within the layer, which lead to its periodic rupture during the anodic dissolution process.

A more detailed understanding of the nature of the anodic layers present is necessary to determine the sequence of events in transpassive dissolution. Kinoshita *et al.* (7, 8) analyzed solid reaction products during copper dissolution in sulfate media by x-ray diffraction. The products were sampled continuously downstream from the anode. Cuprous oxide which may disproportionate into copper ion and metallic copper was found to be a major constituent. The direct analytical study of anodic layers is complicated, however, by the fact that upon current switch-off their nature may be changed within a matter of milliseconds. This is evidenced by the experiments illustrated in Fig. 10 and 11. Two identical current pulses were applied to the anode in time intervals ranging from a fraction of a millisecond to several milliseconds. The shape of the second pulse then depended strongly on the elapsed time between the two pulses (Fig. 10). The time interval necessary for the second pulse to become identical with the first pulse was considered equivalent to the time necessary for removal of the anodic layer after current switch-off. In Fig. 10, this corresponds to approximately 6 msec. The time for removal depended on the flow rate as well as on the current density at which the layer had been formed. This is evidenced by Fig. 11 in which the difference between the initial voltage of the second pulse and that of the first pulse, as determined from transients similar to those given in Fig. 10, is plotted as a function of the elapsed time

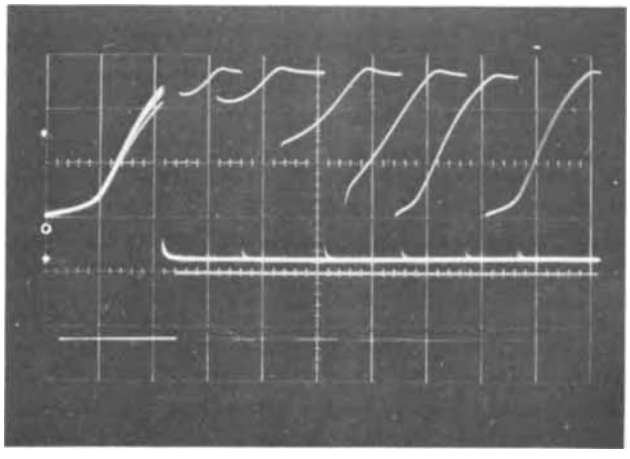

Fig. 10. Double pulses applied at different time intervals. Current density, 77 A/cm²; flow rate, 1000 cm/sec; anode potential traces, 10 V/div, time scale, 1 msec/div.

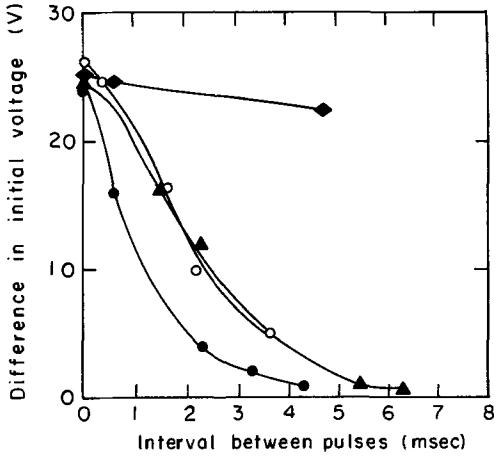

Fig. 11. Difference in initial voltage between first and second pulse as a function of time interval between pulses: ●, 93 A/cm² at 1000 cm/sec; ○, 46 A/cm² at 1000 cm/sec; ▲, 93 A/cm² at 140 cm/sec; ◆, 50 A/cm² at 140 cm/sec.

between two consecutive pulses. The layers formed at high current density appeared to be removed faster than those formed at lower current density. Increasing flow rate also accelerated removal. The latter effect is not unexpected; it may be related to an enhancement of either mechanical removal of solid products or to an increase in rate of mass transport of dissolved products. It is to be noted, however, that layer removal took somewhat longer than layer formation (Fig. 10). Since layer formation is initiated by a mass transport limited process (1), it appears that removal is not entirely governed by a simple mass transport process. Accelerated layer removal with higher formation current density may be due to higher local temperatures of the surface which speed up chemical dissolution, or to larger concentrations of hydrogen ions accumulated at the surface under conditions of high formation current density.

Summary and Conclusions

Galvanostatic transient techniques have been used for the study of current voltage relationships characterizing anodic copper dissolution at current densities of up to more than 100 A/cm². With the possible accuracy of high current density potential measurements, results for active dissolution obtained in the present study were consistent with the Mattson-Bockris mechanism. Presence of oxygen and preelectrolysis of the solution apparently have little influence on measured anodic Tafel slopes at high dissolution rates.

Potential current relationships for active dissolution obtained in a flow channel cell were little different from those measured in a cylindrical cell. This indicates that the error introduced into transient measurements by the nonideal geometry of the flow channel was small, and it appears that such cells are well suited for the study of active as well as transpassive metal dissolution under controlled flow conditions.

Dissolution in the transpassive mode proceeds by a different mechanism at much higher anode potential. Experimental results and numerical estimations show that the observed high values of the anode potential in the transpassive mode are due to a thin, well-adhering layer. Since earlier studies showed that loose solid reaction products are generated during transpassive dissolution, it has to be assumed that the anodic layer has a dual structure, consisting of a thin compact layer in contact with the metal and loose material (mostly cuprous oxide) sitting on top of it. The loose material has little influence on observed galvanostatic transient behavior which is governed by the properties of the adherent layer. The effective resistance of this layer was shown to decrease with increasing current density, an effect which is attributed to local heating. Quantitative models for the description of the dy-

namics of transpassive dissolution have not been developed so far.

The Anodic Oxidation of Platinum: Evidence for a High-Field Ionic Conduction Mechanism

J. L. Ord* and F. C. Ho†

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

ABSTRACT

The anodic oxidation of platinum in 1*N* H_2SO_4 is studied by using open-circuit transients to determine Tafel slopes and by following film growth optically with an ellipsometer. The Tafel slope values are found to be proportional to the film thicknesses measured with the ellipsometer. This result is interpreted in terms of an ionic conduction model in which the overpotential appears across the anodic oxide film, and the logarithm of the ionic current density is proportional to the field in the oxide. The results are compared with the results of similar measurements on iron and tantalum. Although platinum, iron, and tantalum have quite different chemical properties, and their oxides span a thickness range from a monolayer to several thousand angstroms, it is concluded that the same basic process is responsible for the anodic oxidation of the three metals.

The formation of anodic oxide films on metals is a process for which no particular model is usually applied to more than a small class of similar metals. For valve metals such as tantalum, it is agreed that the electric field in the layer limits the process, and, although no single model is universally accepted, all models used to describe the formation of anodic oxides on these metals consider ionic transport in a high electric field to be rate limiting. The passive metals such as iron form another class of similar metals for which models describing the formation of anodic oxide films have been proposed. There is no general agreement on the rate-limiting step in the case of the passive metals, and, as a result, the models proposed have virtually nothing in common.

The studies of anodic oxidation carried out in our laboratory have attempted to determine whether anodic oxidation is really a process which changes markedly from metal to metal and electrolyte to electrolyte, or whether one model can account for the basic features of the process on a variety of quite different metals. We found that remarkably similar results were obtained when the same measurements were made on iron and tantalum (1, 2), and we concluded that a high-field ionic conduction model could be used to account for the growth of anodic oxide films on both metals. To account for all the features of the anodic behavior of iron, a dissolution reaction competing with oxide film formation at low potentials, and an electronic tunneling current above the oxygen-evolution potential must be added to the basic model.

In this paper we present the results obtained when platinum is used as a substrate in the experiments whose results on iron and tantalum form the basis for the high-field model. Platinum is an ideal metal on which to study anodic oxidation because it is possible to study the process from its initiation on a bare surface, through partial surface coverage, to growth beyond monolayer thickness. It is a simpler metal to study than either iron or tantalum in that its anodic oxide is reducible and no dissolution reaction precedes oxide formation, but the narrow potential region over which oxide is formed before oxygen is evolved restricts the film thicknesses to very low values. The three metals have one feature common to their anodic behavior: under galvanostatic oxidation the potential increases linearly with time across the layer growth region. In the case of platinum this is one of the criteria used to test for cleanliness of the system (3). This behavior is required by a field-limited model, and without it such a model could be rejected for the anodic oxidation of platinum without further study.

Key words: anodic oxidation, platinum, ellipsometry.

In principle, it is a straightforward matter to determine whether the field or the potential drives an activation-controlled process. The Tafel slope expresses the change in overpotential required to produce a specified (usually tenfold) change in the current density. If the change in the current density is produced by a change in the field in the layer, then the measured Tafel slope must be directly proportional to the layer thickness ($V = D\,E$, hence $\Delta V = D\,\Delta E$); otherwise the Tafel slope should be independent of the layer thickness. Hence simultaneous Tafel slope and layer thickness measurements can provide direct evidence enabling field-limited processes to be distinguished from potential-limited processes.

In practice, values obtained for Tafel slopes on oxide-covered electrodes often depend on the experimental technique used in their determination (1, 2, 4, 5). This difficulty arises because the Tafel slope is defined as the partial derivative of the overpotential with respect to the logarithm of the current density, and it is difficult to select experimental conditions to measure this partial derivative without making a basic assumption about the nature of the process under study. We choose to measure Tafel slopes by analyzing open-circuit transients using a technique similar to that proposed by Grahame in his paper on the current-interrupter method (6). We feel that a measurement of this type disturbs the system only slightly, and as a result provides a value for the Tafel slope which comes close to being a true partial derivative.

Experimental

In situ optical measurements were made during anodic oxidation using a following ellipsometer. Two following ellipsometers have been built in our laboratory, and their construction, operation, and performance have been described in the literature (7, 8). They differ from conventional ellipsometers in that they can be nulled in less than 1 sec with 0.01° resolution, and hence can make null measurements on surfaces covered by films which are growing at slow to moderate rates. The data presented in this paper illustrate this performance and show how the accuracy of the measurements (as indicated by the scatter in the data) compares with the resolution of the instrument. A small helium-neon gas laser is used as a light source, and all our refractive index values were determined at its wavelength, 6328Å.

The cells used with the ellipsometer are constructed for a specified angle of incidence. Angles of incidence of both 60° and 75° were used in this study, but only data obtained at 60° are presented here. The 60° cells consist of hollow glass equilateral prisms with standard taper joints in the top for mounting the electrode, platinum counterelectrode, mercurous sulfate reference electrode (with 0.1*N* K_2SO_4 salt bridge), and gas dispersion tube. The cell used for 75° measurements has a separate compartment in which the electrode is mounted. An angle of incidence of 60° was chosen for sets of measurements where a reproducibility from run to run of ± 0.01° was required because the 60° cells have a better geometry for sweeping out the trace amounts of hydrogen and oxygen which are evolved even in experiments designed to minimize evolution of these gases. The cell is bubbled with argon for a day prior to an experiment, and the bubbling is continued throughout the experiment, keeping the cell at a slight excess pressure of argon and minimizing the leakage of oxygen into the cell through the Teflon-sleeved standard-taper joints. All experiments were performed at room temperature (23°C).

A major factor influencing reproducibility of the optical data from run to run is the roughness of the surface. A study of the smoothing and roughening of the single-crystal platinum surface was carried out using a variety of electrolytes, and conditions were determined under which a series of experiments could be carried out with no change in the roughness factor of the surface. The study of the effect of varying surface roughness on optical measurements was too extensive for a description of the experiments to be included here.

The platinum sample used in the experiments was a single crystal which was clamped between Teflon washers in a glass electrode holder exposing a cylindrical surface of 1.2 cm^2 area to the electrolyte. A flat on one side of the cylinder was used for the optical measurements, although the laser source and double-pinhole lens-free optics of the ellipsometer enable measurements to be made on cylindrical surfaces. The electrolyte used in all the experiments was 1*N* H_2SO_4 prepared from high-purity sulfuric acid purchased in 10*N* concentration. Measurements of the steady-state current density gave values comparable to those obtained by other workers using closed systems (9). A Tafel slope is often used to express the potential dependence of this steady-state current density, and we would like to emphasize that this Tafel slope is in no way related to the Tafel slope for anodic oxidation which we study in this paper. The steady-state current is the residual current which flows after the anodic oxidation process has slowed to an imperceptible rate, and as such it is very sensitive to trace impurities in the system. The current whose potential dependence we express using a Tafel slope is the current flowing when the anodic oxidation reaction is proceeding at an appreciable rate. We measure this Tafel slope over a range of current density during the open-circuit self-discharge transient, but all current densities in this range (typically 1-10 $\mu A/cm^2$) are well in excess of the steady-state current density at the same potential. Our measured Tafel slope values are not strongly affected by the cleanliness of the system, and we find that greater care is required to achieve reproducibility in the optical data than in the electrical data.

The electrical circuitry uses high-impedance operational amplifiers for a galvanostat, potentiostat, potential sweep circuit, and follower. The potential is monitored on a strip chart recorder in the laboratory, but the transients from which Tafel slopes are determined are recorded using the A/D converter of the IBM 1710 process control computer, The computer sets a latching contact to open a relay in the cell circuit, then samples the potential at fixed time intervals (every 4.8 msec) and stores data at specified potential intervals. The recording of data in this manner provides a set of results directly suited to a least squares analysis of potential *vs.* log *t*. The computer carries out this analysis and prints out the Tafel slope and an estimate of its standard deviation.

The capacitance can be determined from the open-circuit transient analysis, however the curve-fitting procedure is less sensitive to capacitance errors than it is to Tafel slope errors. We can monitor the capacitance continuously during an experiment by adding an a-c component to the current from the galvanostat. A lock-in amplifier detects the component of the a-c voltage 90° out of phase with the current, and the output of the lock-in amplifier is plotted *vs.* potential on an X-Y recorder.

Results and Discussion

A typical anodic oxidation transient is shown in Fig. 1. The platinum electrode is held initially at a potential of +0.27V (on the hydrogen scale). At point A the electrode is switched to the galvanostat set for a current density of 10 $\mu A/cm^2$. The potential rises rapidly at first, then increases linearly with time along BC. At point C (1.37V) the galvanostat is switched to −10 $\mu A/cm^2$, and the potential traces out the s-shaped reduction curve to point D at which the electrode is switched back to its initial potential, +0.27V. A series

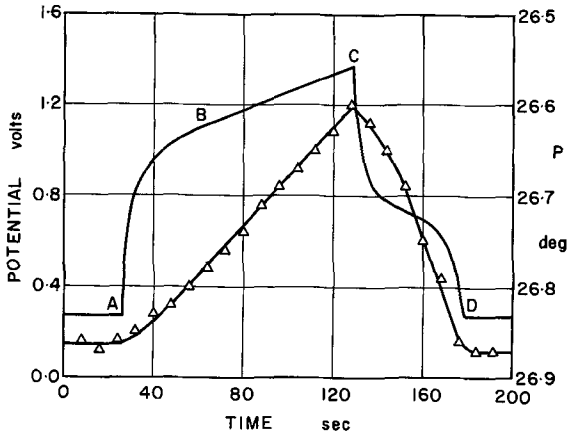

Fig. 1. Variation of potential (solid curve) and polarizer null reading (triangles) for galvanostatic oxidation (ABC) and reduction (CD) at 10 $\mu A/cm^2$ of a platinum electrode in 1*N* H_2SO_4.

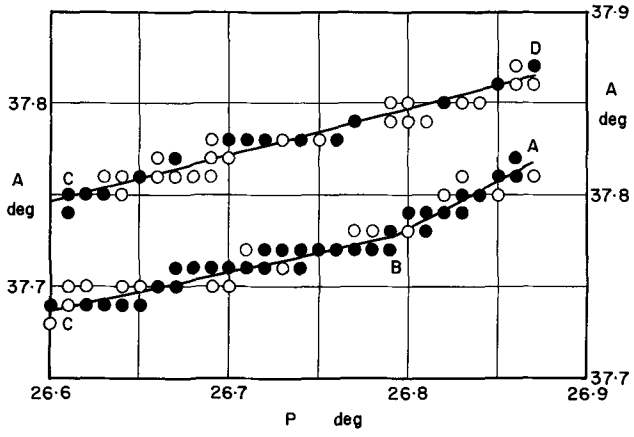

Fig. 3. *P-A* plot of the optical data recorded during the galvanostatic transient plotted in Fig. 1. To avoid overlap, different A scales are used for the oxidation data (ABC, right A scale) and the reduction data (CD, left A scale). Open circles show points which were recorded once only; solid circles show points recorded two or more times.

of polarizer and analyzer null readings are recorded by the following ellipsometer as the transient is swept out. The polarizer null readings (P) at 8 sec intervals are plotted *vs.* time along with the potential in Fig. 1. P changes linearly with time in the region BC in which the potential increases linearly with time, and returns to its initial value at point D after cathodic reduction. The over-all change in P is only 0.27°, and hence the accuracy and reproducibility of the data are very important. The narrowness of the range of variation of P made it necessary to carry out a study of the effect of variation in surface roughness on reversibility and reproducibility of the data. Under the experimental conditions used to obtain the data in Fig. 1, the optical data can be reproduced in a succeeding run to within ± 0.01°. The accuracy of the data is not apparent in Fig. 1 in which points at 8-sec intervals are plotted. In Fig. 2 the section of Fig. 1 from $t = 50$ to $t = 100$ sec is plotted on an expanded time axis. The data points show very little scatter; in fact, in the latter half of the time interval, no scatter is detectable, and the only deviation from linearity is produced by 0.01° resolution of the instrument. Fifty-nine data points were recorded in this 50-sec interval, but only 53 distinct points appear in the figure because only two of the 18 printer columns were used to record time, and the data have a limited 1-sec time resolution. As a result, in two instances two values of P appear as distinct simultaneous points, and 6 other points overlap the plotted points.

In Fig. 1 and 2, P is used to represent the optical data, but an actual optical measurement includes the analyzer null reading, A, also. The optical results can be displayed conveniently on an X-Y plot of P vs. A. This is the form in which the data are monitored during an experiment, and the same form is used when fitting the data using a graphic display computer terminal. Figure 3 is a *P-A* plot of the optical data

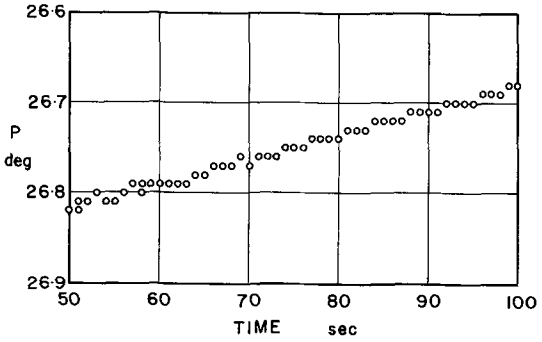

Fig. 2. Complete polarizer null data for a segment of the transient plotted in Fig. 1.

recorded during the transient plotted in Fig. 1. The points A, B, C, and D in the figure are the points so identified in Fig. 1. The optical data show a slight inflection at point B during anodic oxidation, but show no inflection along CD during cathodic reduction. The lines AB (47 points, slope 0.509 with standard deviation 0.026), BC (75 points, slope 0.215 with standard deviation 0.021), and CD (58 points, slope 0.254 with standard deviation 0.006) were fitted to the data using least squares. The inflection during anodic oxidation occurs at a potential of 1.1V, and the change in slope is statistically significant.

The changes in P and A produced by growth of a uniform film depend on both the complex refractive index of the film, $n - ik$, and its thickness, D. For thin films the locus traced out in the *P-A* plane as D increases with n and k constant is simply a straight line whose slope depends on n and k, and whose length is proportional to D. The data in Fig. 3 fall on three lines of significantly different slope and hence cannot be generated by a process in which only D is varying. The inflection at point B can be accounted for either by the growth of a second layer with different index on top of the initial layer grown from A to B, or by a progressive change in the refractive index as the layer continues to grow beyond the 1.1V potential. (A structure of this type would not be produced by the growth of a monolayer whose effective index varies with surface coverage, followed by growth beyond a monolayer at constant index; such behavior would require A, B, and C to be co-linear points, BC to be a straight line, and AB to deviate from linearity.) The fact that the data fall on one line of intermediate slope as the layer is removed by cathodic reduction suggests that only one layer is present on the surface at point C, and hence favors a model in which the film index changes progressively as the potential increases beyond 1.1V. A detailed analysis to determine the refractive index of the layer at point C is presented in the Appendix. A unique value cannot be determined for the layer index or the absolute thickness. A reasonable estimate of the calibration factor relating changes in P to changes in film thickness is found to be 10-20 Å/deg P with higher values possible. This gives a range of 0.8-1.6Å for the thickness at B, and 2.7-5.4Å at C.

A set of Tafel slopes can be determined at points along the transient plotted in Fig. 1 by opening the circuit briefly at selected points and recording potential-time data for Tafel slope analysis. The parameter we use to designate the point at which the Tafel slope is measured is the potential reached just prior to

opening the circuit. We refer to this potential as the formation potential, V_f. The Tafel slope expresses the dependence of current density on overpotential and is not itself a function of overpotential, but it may depend on the state of the electrode surface, and this state may be specified uniquely in these experiments by two parameters: the formation potential and the formation current density (the value set on the galvanostat).

The Tafel slopes obtained at a formation current density of 10 μA/cm^2 are plotted *vs.* formation potential in Fig. 4 along with the corresponding values of (P_o-P). For values of V_f above 1.1V, the Tafel slope increases linearly with formation potential, whereas below 1.1V the Tafel slope remains approximately constant at 19 mV. (P_o-P) also increases linearly with V_f above 1.1V. The linear portions of the (P_o-P) and Tafel slope plots both extrapolate to zero at 0.975V, and hence the Tafel slope is proportional to (P_o-P) over the region in which both increase linearly with V_f. We would prefer to plot film thickness rather than (P_o-P) in Fig. 4, but this is not possible. If we ignore the variation in refractive index above 1.1V, the curve ABC in Fig. 4 can be considered a plot of relative thickness *vs.* V_f, and we can conclude that the Tafel slope is proportional to the thickness of the film. If the slight variation in index above 1.1V is taken into account, the relative film thickness plot will still be a curve similar to ABC, but the section BC may be rotated slightly about B. A rotation about B will shift the intercept away from D, but, since BD is short compared with BC, a slight variation in index will not invalidate our conclusion that the Tafel slope for anodic oxidation is proportional to the thickness of the oxide film, and hence the process is limited by the field in the film.

The extrapolation of the Tafel slope plot to intersect the formation potential axis at 0.975V determines the zero of overpotential for the anodic oxidation process. In a series of potentiostatic measurements, Reddy, Genshaw, and Bockris (10) found that a film formed suddenly when the potential crossed 0.98 $\pm$ 0.01V. Our value for the zero of overpotential is consistent with their measurements.

The abrupt change in the slope of V_o curve in Fig. 4 at $V_f = 1.1$V, and the slight inflection in the *P-A* plot in Fig. 3 at the same potential, lead us to conclude that this is the point at which the surface is covered by a monolayer of oxide. Below this value of V_f the Tafel slope retains a value proportional to the thickness of the layer partially covering the surface, whereas the optical measurements involve an average over the bare and covered portions of the surface. The optical estimate of the monolayer thickness, 0.8-1.6Å or higher, is not unreasonable when compared with the ionic radii of platinum and oxygen, 0.5 and 1.4Å. The progressive change in layer index above 1.1V suggests that PtO can be formed as a monolayer, but, as the oxide grows beyond monolayer thickness, there is a tendency for its oxidation state to rise.

The value of the capacitance whose self-discharge is studied during an open-circuit transient is determined by the analysis used to obtain the Tafel slope. In addition, the a-c voltage at a phase angle of 90° to a superimposed a-c current can be plotted *vs.* formation potential. The a-c measurement is displayed directly in a convenient form, whereas the results from open-circuit transients are obtained only after a least squares analysis, but the interpretation of the a-c measurements is less direct. The reciprocal capacitance values from open-circuit transients are plotted in Fig. 5 along with a tracing of the a-c voltage for a 10 μA/cm^2 50 Hz a-c current density superimposed on a 40 μA/cm^2 formation current density. For this frequency and formation current density, the a-c impedance at 90° phase angle is not just $1/\omega C$, but the dependence of the a-c voltage on V_f will be due mainly to the dependence of $1/C$ on V_f.

The two sets of data plotted in Fig. 5 show a consistent dependence on V_f, but this dependence is not the simple linear dependence found in Fig. 4 for the Tafel slope, although in any simple high-field model both parameters should be proportional to film thickness. The failure of the $1/C$ values to increase with formation potential beyond 1.2V is probably related to the progressive change in the refractive index which we have attributed to the raising of the oxidation state of the layer. The same type of dependence of Tafel slope and reciprocal capacitance on formation potential was found by DeSmet (11) in his work on the anodic oxidation of nickel, another metal whose anodic oxide can be raised to a higher oxidation state. Although the capacitance measurements can be made consistent with a high-field model, they cannot be claimed to provide direct support for such a model.

The high-field model can be used to predict the dependence of layer thickness on formation potential at higher potentials where oxygen evolution becomes important. Even if other processes are going on, the ionic current is determined by the field in the film, and the growth rate of the film is proportional to the ionic current. The model considers oxygen evolution to be due to an electronic tunneling current which flows through the layer to the metal once its potential exceeds the oxygen evolution potential. The total current flowing through the layer therefore consists of an electronic component and a field-limited ionic component. In the layer growth region below oxygen evolution (region BC in Fig. 1) a linear potential

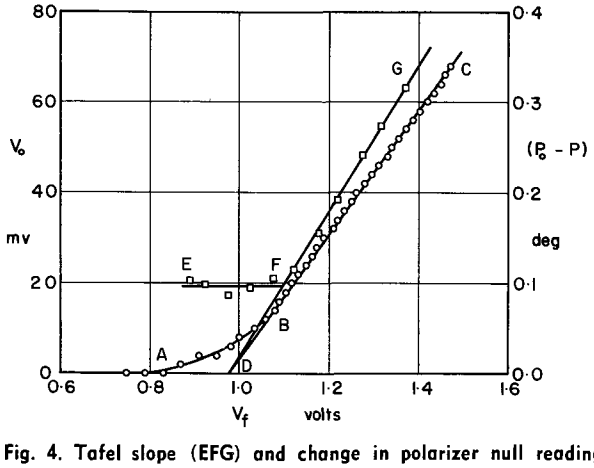

Fig. 4. Tafel slope (EFG) and change in polarizer null reading (ABC) plotted as a function of formation potential for a formation current density of 10 μA/cm^2.

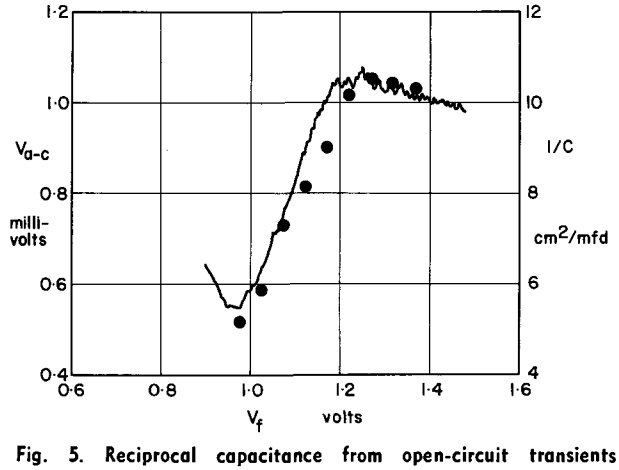

Fig. 5. Reciprocal capacitance from open-circuit transients (circles) and a-c voltage 90° out of phase with a 50 Hz a-c current of 10 μA/cm^2 superimposed on a d-c current of 40 μA/cm^2, both plotted as a function of formation potential.

sweep and a constant current are equivalent, but once oxygen evolution begins the two experimental conditions are quite different and result in different dependences of layer thickness on formation potential.

In a galvanostatic experiment the total current is fixed, and hence an increase in the electronic component can only result from a decrease in the ionic component caused by a decrease in the field in the layer. This drop in the field shows up in a plot of layer thickness *vs.* formation potential as an increase in the slope once the oxygen evolution potential is crossed. (Although layer thickness increases more slowly with time once oxygen evolution begins, it increases more rapidly with formation potential.) The (P_o-P) measurements from a galvanostatic experiment at a current density of 40 μA/cm^2 trace out the curve RST in Fig. 6 when plotted *vs.* V_f. The predicted increase in slope is found as the oxygen evolution potential is crossed.

In a linear potential sweep experiment, the ionic and electronic currents would seem to be independent, but actually they are coupled. The coupling arises because the currents are not driven by the same overpotential: the overpotential across the layer sets up the field which drives the ionic current, but the electronic current results from a reaction controlled by an overpotential across the double layer in electrolyte (*i.e.*, the tunneling process is not rate determining). These overpotentials are in series, and the constraint that their sum increase linearly with time couples the ionic and electronic processes. Once the formation potential includes an increasing series component across the double layer, the slope of the (P_o-P) *vs.* V_f graph decreases. The results from an experiment in which the potential is swept linearly at 10.8 mV/sec appear in Fig. 6 plotted along XYZ. The predicted decrease in slope is observed as the oxygen evolution potential is crossed.

The above discussion, although qualitatively correct, is not complete. The two effects which produce deviations in opposite directions from a linear (P_o-P) *vs.* V_f plot, the reduced ionic current and the reduced overpotential across the layer, are both present whenever the potential exceeds the oxygen evolution potential. A more detailed discussion could show that the reduced ionic current effect dominates in a galvanostatic transient, whereas the reduced overpotential effect dominates in a potential sweep transient. The results plotted in Fig. 6 are of some importance because they show that the high-field model can be used to predict the results of more than just the Tafel slope experiments from which the model was derived.

Conclusions

We have shown that the anodic oxidation of platinum meets the basic requirements for a process limited by the field in the oxide layer, and hence we conclude that the anodic oxidation of platinum and tantalum are governed by the same general laws. We do not expect this conclusion to be accepted universally by workers studying anodic processes on platinum, for the very good reason that the oxide film and the potential across it have virtually no effect on reactions for which the platinum electrode acts simply as a sink for electrons. The tunneling process will not itself be rate determining, and the potential of importance in tunneling will be the potential of the platinum electrode, not the potential of the oxide surface.

Our conclusion says considerably more about the anodic oxidation process than it does about the anodic behavior of platinum. If the same basic laws govern the anodic oxidation of metals as dissimilar as platinum, iron, and tantalum over a range of oxide film thicknesses from monolayer coverage on platinum to thousands of angstroms on tantalum, then any meaningful theory of anodic oxidation must not be overly sensitive to either the chemistry of the metal or the structure of the oxide.

APPENDIX

The bare surface measurement at 60° incidence, $P_o = 26.86°$, $A_o = 37.81°$, gives a value of 2.32-5.14*i* for the refractive index of platinum at 6328Å. As is usual with very thin films, a unique value cannot be determined for the refractive index of the oxide. The set of n-ik values which give layer growth curves with slopes $\Delta A/\Delta P$ equal to the slope of the experimental curve AC in Fig. 3 can be displayed as a curve in the n-k plane. This curve is plotted in Fig. 7 and has two segments, AB and CD. Any point on either segment

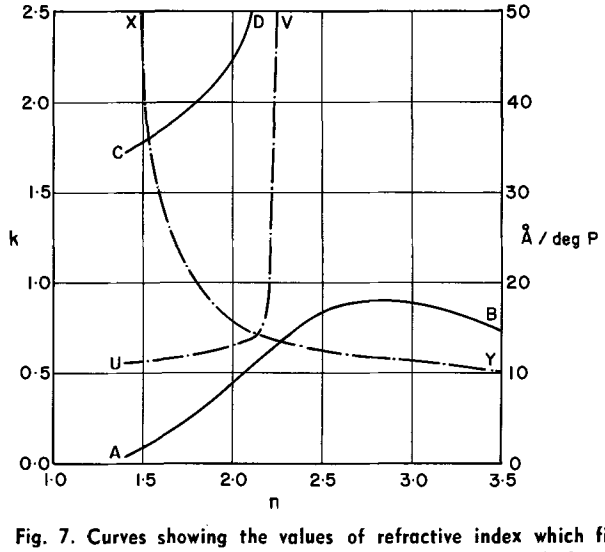

Fig. 7. Curves showing the values of refractive index which fit the experimental data (AC in Fig. 3), and the absolute thickness calibration factors. The index values are represented in the n-k plane by AB and CD, and the corresponding calibration factors are plotted *vs.* n along XY and UV.

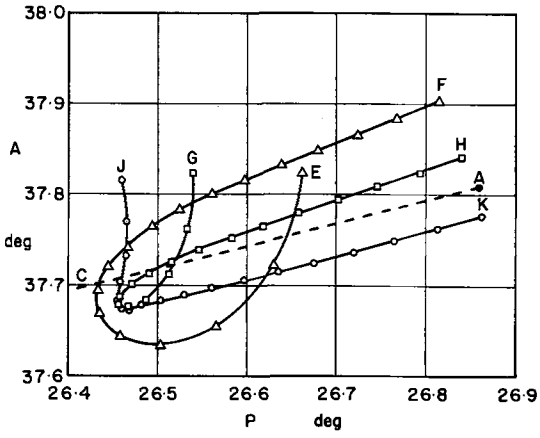

Fig. 8. Theoretical curves showing the loci traced out when k is incremented from 0.0 to 5.1 in 0.3 steps for a film with a thickness of 5Å and real index component of 1.7 (EF), 2.1 (GH), and 2.5 (JK). Point A is the bare substrate reading, and the dashed line AC shows the slope of the experimental curve generated as the layer is removed from the surface.

represents a possible value of the refractive index of the layer. The absolute thickness calibration factor, in Å/deg P, depends on the value chosen for the layer index, and is plotted *vs.* n in Fig. 7. This curve also has two segments, XY and UV, corresponding to the segments AB and CD of the refractive index curve.

Three theoretical curves are plotted in Fig. 8 to indicate how Fig. 7 is generated, and why it has two segments at low n. The bare surface measurement is plotted at point A, and the dashed line AC shows the slope of the experimental curve AC in Fig. 3. Curve EF is the locus traced out in the P-A plane as k is varied in 0.3 steps from 0.0 at E to 5.1 at F for a layer of fixed $n = 1.7$ and $D = 5$Å. The curve EF intersects AC at two points corresponding to $k = 0.2$ and $k = 1.9$. The $k = 0.2$ value lies on AB in Fig. 7, and the 1.9 value lies on CD. The thickness calibration factor depends on the distance from A to the intersection of AC with EF, and hence its two values at $n = 1.7$ differ by about a factor of two.

For values of n equal to 2.1 and 2.5, curves GH and JK are traced out as k goes from 0.0 to 5.1 for $D = 5$Å. AC intersects GH at two points giving two values for k and two nearly equal values for the thickness calibration factor. AC intersects JK at only one point, and hence only one value of k is possible for $n = 2.5$.

The shape of the curves in Fig. 7 is quite sensitive to the slope AC which in turn depends on V_f (due, we concluded, to the raising of the oxidation state as V_f increases). In particular, it is apparent from Fig. 8 that if the slope of AC is increased somewhat, it will no longer intersect GH, and hence 2.1 will not be a possible value of n for any value of k. Our index values are not inconsistent with the value quoted by other workers (10) for $\lambda = 5461$Å, but the sensitivity to the slope AC and the wavelength difference make a direct comparison impossible.

The Effect of Superimposed A.C. on D.C. in Electrodeposition of Ni-Fe Alloys

Zlata Kovac* [1]

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The effect of superimposing a sinusoidal alternating current on a direct current during electrodeposition of Ni-Fe alloys is discussed in terms of the following factors: (*a*) maintaining the *p*H at the electrode equal to that of the bulk electrolyte, (*b*) ionic diffusion processes, and (*c*) chemical processes in solution prior to electrochemical reduction. The effect of frequency, amplitude, and the ratio of a.c. to d.c. on the composition of electrodeposited alloy are given for acid solutions of different *p*H and for alkaline solutions of metallic complexes with a variable concentration of complexing agent. The behavior observed can be explained in terms of the factors listed above. In particular, it is shown that by proper choice of conditions, electrodeposited Fe-Ni alloys can be prepared with a uniform composition throughout their thickness.

Alternating current has a significant influence on many electrode processes and is widely used in such electrochemical investigations as the study of electrical double layers (1-3), the kinetics of the formation and dissolution of oxide films (4), fast electrode reactions (5, 6), and in the electrodeposition and dissolution of metals (7, 8).

Vagramyan and Sutyagina (9) reported that alternating current can effect the grain size, brightness, and porosity of electrodeposited metals. Marchese (10) showed that the superposition of a.c. on d.c. reduces internal stresses in electrodeposited nickel. The magnetic properties of electroplated Ni-Co films could also be improved by superimposing a.c. on d.c. during their codeposition (11).

Our interest was to find what effect a.c. (of variable frequency and amplitude) has on the composition and uniformity of electrodeposited Ni-Fe alloys.

First, let us examine ways in which superimposed alternating current can affect the electrodeposition process. We will consider the cases where:

[1] Present address: PPG Industries, Inc., Springdale, Pennsylvania.
* Electrochemical Society Active Member.
Key words: electrodeposition, alloys, permalloy, Ni-Fe films, a-c, d-c.

1. For some portion of each cycle, the a-c component converts the electrode from cathode to anode.
2. Current is controlled by ionic diffusion in the electrolyte.
3. Deposition at the electrode is preceded by a chemical reaction in the solution.

Case 1

During electrodeposition of most metals, discharge of H_3O^+ or H_2O occurs concurrently with pH changes in the vicinity of the electrode surface. For metals with small hydrolysis constants this alkalization will be reflected in the formation of metallic hydroxides, which subsequently can be incorporated into the deposit, thus causing nonuniformity. In the codeposition of two or more metals this phenomenon can cause preferential deposition of one metal, so-called anomalous codeposition (12), and a concentration gradient across the deposit thickness (13), which will be the most pronounced in the first 500Å.

If one superimposes a.c. on d.c. during electrodeposition of such metals, then during the time for which the electrode is the anode, oxidation of adsorbed hydrogen formed in the cathodic cycle will take place according to

$$H^+ + e^- \underset{\text{anod.}}{\overset{\text{cath.}}{\rightleftarrows}} H_{ads}$$

In the ideal case of balancing the rate of cathodic discharge of H^+ ions with its rates of oxidation and diffusion from solution, one can achieve control of pH on the surface such that pH (surface) → pH (bulk). Hence, the above-mentioned difficulties should be minimized if not completely eliminated. Mathematically, this presents a complex problem. However, experimentally one can easily find the condition where there is no preferential deposition of one of the metals and where there is no composition gradient in the deposit, *i.e.*, the condition of constant pH.

Case 2

Passage of either direct or alternating current through an electrolytic cell will produce concentration changes, which are susceptible to mathematical treatment. Sand (14) solved the diffusion equation for the case of electrolysis with a constant direct current and Warburg (15) and Kruger (16) for the case of sinusoidal alternating current. Both treatments start from Fick's second law

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \qquad [1]$$

where c is the concentration of one ionic species, D is its diffusion coefficient, and x is the distance from the electrode into the solution.

Both d-c and a-c currents have the same boundary conditions, namely

$$c_{x=0} = c_{x=\infty} \text{ for } t = 0$$

and

$$\frac{\partial c}{\partial x} = 0 \text{ for } x \to \infty \text{ and } t > 0$$

Here, $c_{x=0}$ is the concentration at the electrode surface and $c_{x=\infty}$ is the bulk concentration.

The solution of Eq. [1] for constant d.c. is

$$c_{(0,t)} = c_\infty - \frac{2i}{n\mathbf{F}}\sqrt{\frac{t}{\pi D}} \qquad [2]$$

where i is the current density, t is time, n is the number of electrons involved in the electrode reaction, and $\mathbf{F}$ is Faraday's constant. For steady-state conditions

$$c_0 - c_\infty = -\frac{i\delta}{n\mathbf{F}D} \qquad [3]$$

or

$$\Delta c = Ki\delta$$

where δ is the thickness of the diffuse layer, and K includes all constant terms.

For sinusoidal a.c. the solution of Eq. [1] is (15, 16)

$$c_{(0,t)} = c_\infty - \frac{I}{n\mathbf{F}\sqrt{D\omega}}\exp\left(-\sqrt{\frac{\omega}{2D}}\cdot x\right) \cdot \sin\left(\omega t - \sqrt{\frac{\omega}{2D}}x - \frac{\pi}{4}\right) \qquad [4]$$

where I is the amplitude of the current density, and $\omega = 2\pi f$ where f is the a-c frequency.

At the electrode surface where $x = 0$, Eq. [4] becomes

$$\Delta c = -\frac{I}{n\mathbf{F}\sqrt{D\omega}}\sin\left(\omega t - \frac{\pi}{4}\right) \qquad [5]$$

or

$$\Delta c = \frac{A}{\sqrt{\omega}}\sin\left(\omega t - \frac{\pi}{4}\right)$$

where $A/\sqrt{\omega}$ is the amplitude of concentration wave.

If both currents act simultaneously on the system, then the net concentration changes can be obtained by adding together the concentration change that would be produced by each current taken separately (17) (since the sum of a number of solutions of a linear differential equation is likewise a solution). Thus

$$\Delta c = -\left[i\delta + I\sqrt{\frac{D}{\omega}}\sin\left(\omega t - \frac{\pi}{4}\right)\right] \Big/ n\mathbf{F}D \qquad [6]$$

Suppose one electrodeposits a binary alloy, with one of the depositable metal ions under diffusion control and the other under charge transfer control. In such a case Eq. [6] is applicable to only one constituent of the alloy, and the other constituent will be deposited as if the a.c. were not present, since a.c. does not effect charge transfer reactions.

Now, let us examine the conditions under which a.c. and d.c. have comparable effect on concentration change of Fe, which is deposited under diffusion control (13). For a 10^{-3}M Fe solution and a total direct current density of 2 mA cm^{-2}, the partial current for discharge of Fe is found to be 0.32 mA cm^{-2}, which from Eq. [3] gives $\Delta c = 8.5 \times 10^{-6}$M cm^{-3}. Suppose we take I to be 15 mA cm^{-2}, then the amplitude of the concentration wave from [5] is 2.6×10^{-6} and 0.37×10^{-6}M cm^{-3} for a frequency of 20 and 1000 Hz, respectively. In other words, a.c. of low frequency produces 30% and of high frequency 4% of the total concentration change. If the d.c. is increased, then the effect of a.c. becomes even smaller (2% for 1000 Hz and $i_{d\text{-}c}$ of 4 mA cm^{-2}). Clearly the effect of diffusion becomes progressively smaller with increasing frequency. Theoretically (Eq. [5]), one can increase the effect of a.c. by increasing its amplitude. Practically, however, it is not desirable to go too high into the anodic region, where dissolution of the alloy and oxide formation can take place.

Case 3

If electrodeposition is carried out from a solution of complex ions, then a reduction to the metallic state can take place either directly from the complex ion or this electrochemical step can be preceded by a chemical step or several steps in series (18, 19).

If one assumes that electrochemical reduction is preceded by a homogeneous chemical reaction of a type

$$M_mC_n^{(z_1+z_2)} \underset{k_b}{\overset{k_f}{\rightleftarrows}} mM^{z_1} + nC^{z_2}$$

then the rate of formation of the metallic ions is

$$v = k_fC_{MC} - k_b\,(c_M)^m\,(c_C)^n \qquad [7]$$

where k_f is the rate constant for dissociation of the

complex and k_b that for the recombination, and c_{MC}, c_M, c_C are the concentrations of metallic complex, metal ion, and complexing agent, respectively. Equation [7] can be written as

$$v = v_o - kc_M^p \quad [8]$$

where v_o is the reaction exchange rate, $k = k_b c_C$ is the reaction rate constant, and p is the reaction order.

As a result of diffusion and chemical reaction the change of concentration with time and distance at the surface of electrode can be represented by Fick's second law in extended form

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} + v \quad [9]$$

Equation [9] applies to both direct and alternating currents. The direct current due to the deposition of metal with a slow chemical step and $p = 1$ is (20)

$$i = -n\mathbf{F}\sqrt{v_o c_M D}\sqrt{1 + \frac{1}{2}\left(\frac{c_s}{c_M}\right)^2 - 2\frac{c_s}{c_M}} \quad [10]$$

where c_M is equilibrium concentration of metal ions determined by $c_M = Kc_{MC}/c_C$, K being the stability constant for a given complex. When the concentration of metal ions at the surface, c_s, becomes zero, a limiting reaction current i_r is reached, given by

$$i_r = -n\mathbf{F}\sqrt{v_o c_M D} \quad [11]$$

and from its value one can calculate v_o and k (since at equilibrium $v = 0$ and v_o becomes equal to $k \cdot c_M$). The reaction exchange rate is also related to the thickness of the reaction layer, δ_i, by the following equation

$$\delta_i = \sqrt{\frac{Dc_M}{v_o}} \quad [12]$$

Passage of a.c. through a system where chemical reaction occurs prior to charge transfer will produce concentration changes which depend not only on $\omega^{-1/2}$ but also on k.

Vetter (21) [who simplified Gerischer's original derivation (22)] gave the concentration change as a difference of ohmic and capacitive components of the electrolyte, both of which are function of $\omega^{-1/2}$ and k/ω. The concentration wavelength as well as penetration depth are also dependent on the same parameters. This derivation is valid only for very small differences between c_M and c_s. Furthermore, the a-c and d-c solutions of the differential equation cannot be added in this case, since the differential equation is nonlinear. A quantitative treatment has therefore not been attempted. Qualitatively, however, one would expect that at a low frequency the concentration wave will be able to follow the slowly varying current, and that the penetration depth would be of the same length as d-c reaction layer thickness. At higher frequencies, the formation and decomposition of metal complexes will be increasingly less important, since they cannot follow fast changes of current. In addition the penetration depth of the concentration wave will become smaller. For both these reasons, it is to be expected that at high frequencies the d-c behavior will dominate.

When two or more metallic complexes are present in the system, a-c will effect them differently depending upon the value of k/ω for each complex. Hence by superimposing a.c. on d.c. one can affect the deposition kinetics of alloys in a very practical way.

Experimental Procedure

Experiments were performed in two compartment cells. The cathode was Cu-sheet or evaporated Ag on glass (2 x 2 cm), placed horizontally in one compartment of the cell. The back of the electrode was masked, so that electrodeposition was carried out on one side only. A Pt-mesh auxiliary electrode was placed ~2 cm above the working electrode. The reference electrode

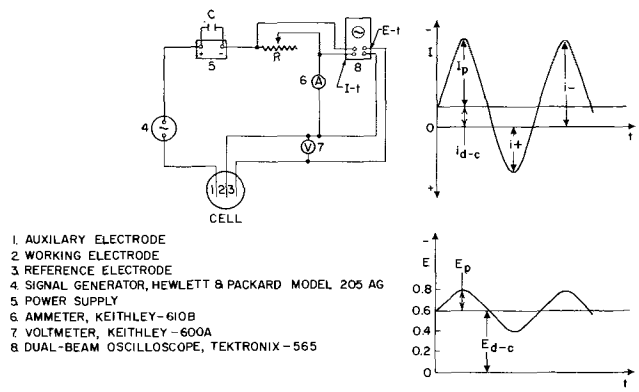

Fig. 1. Electrical arrangement for electrodeposition with combined d.c. and a.c. On the right-hand side are shown the net current and potential curves.

compartment (SCE) was connected with the main compartment through a Luggin capillary carefully bent to avoid any shielding effect.

The electrical circuit [similar to one used by Marchese (10)] is shown in Fig. 1. Current-time and potential-time curves were recorded simultaneously on a dual-beam oscilloscope (Tektronix Model 565). It is important that one records the potential, since this provides a means of determining the region in which the oxidation of hydrogen takes place by a method which minimizes dissolution of alloy and avoids its oxidation.

Experiments were carried out in acid and alkaline solutions. The acid solutions had the following compositions (23): "low Ni": 0.024M $NiSO_4$, 0.006M $FeSO_4$, 0.035M $NaKC_4O_4O_6$, pH = 3 or 4.6. The molar ratio of (Fe/Ni) in solution was 20/80. "High Ni": as above, but with 0.114M $NiSO_4$ and pH = 3, 3.8, or 4.6. Here, the (Fe/Ni) ratio in solution was 5/95. The alkaline solutions were ammoniacal-citrate solutions (24), the compositions of which were: "high citrate": 0.125M $NiCO_3$, 0.032M Fe dust, 0.301M $C_6H_8O_7$, 0.332M $(NH_4)_2HC_6H_5O_7$ and NH_4OH for pH = 9.25. The "low citrate" solution had the same pH and concentration of Ni and Fe, but it contained 0.127M $C_6H_8O_7$ and 0.137M $(NH_4)_2HC_6H_5O_7$. The molar ratio of (Fe/Ni) in solution was 20/80.

The solutions were made of ACS grade chemicals and deionized water. The citrate solutions were prepared according to Stephan's patent (25).

After electroplating, the samples were cut into 1.5 x 1.5 cm squares and analyzed by the x-ray fluorescence method for weight per cent Fe (accuracy ± 1 w/o) and thickness (accuracy ± 150 Å).

Results

In the first series of experiments we examined the effect of frequency on the rate of deposition and on the composition of the deposited alloy. In Fig. 2 and 3 are shown the rate and per cent Fe as a function of log frequency in low and high nickel solutions, respectively, for conditions of constant pH, i_{d-c} and I_{peak}. On the left-hand sides are given values for direct current plating only.

As was mentioned earlier, one expects a diminishing effect of a.c. with increasing d.c. in the system. This prediction is clearly seen from Fig. 4. With d_{d-c} of 2 mA cm^{-2} the Fe content varies from 9.5 to 30%, but changes only from 15.2 to 18% with i_{d-c} of 5 mA cm^{-2} at constant I_{peak} and pH (3.8).

Figure 5 shows a log i-E plot for the high citrate solution. It can be seen that for high values of total current, i_{Fe} reaches a limiting value, which is taken as the limiting reaction current according to Vetter's criteria (21). In Fig. 6 and 7 are given the deposition rates and per cent Fe as a function of log frequency for two values of direct current density.

The variation in composition with the density of direct current at constant frequency and amplitude of

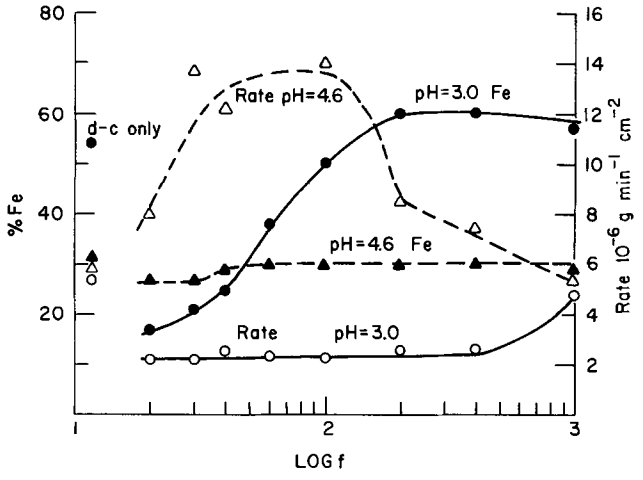

Fig. 2. Fe content and the rate of alloy deposition as a function of log f in low nickel solutions of pH = 3.0 and pH = 4.6. $(Fe/Ni)_{sol}$ = 20/80, with i_{d-c} = 2 mA cm^{-2} and i_p = 13.7 mA cm^{-2}.

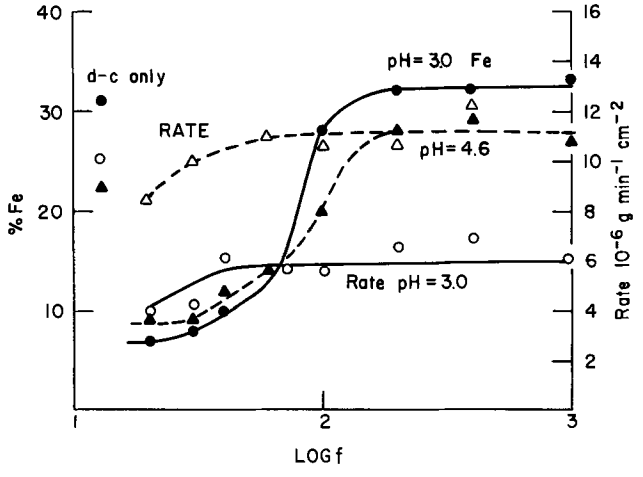

Fig. 3. Fe content and the rate of alloy deposition as a function of log f in high nickel solution of pH = 3.0 and 4.6, $(Fe/Ni)_{sol}$ = 5/95, i_{d-c} = 2 mA cm^{-2}, I_p = 13.75 mA cm^{-2}. Data in the left corner with d.c. alone.

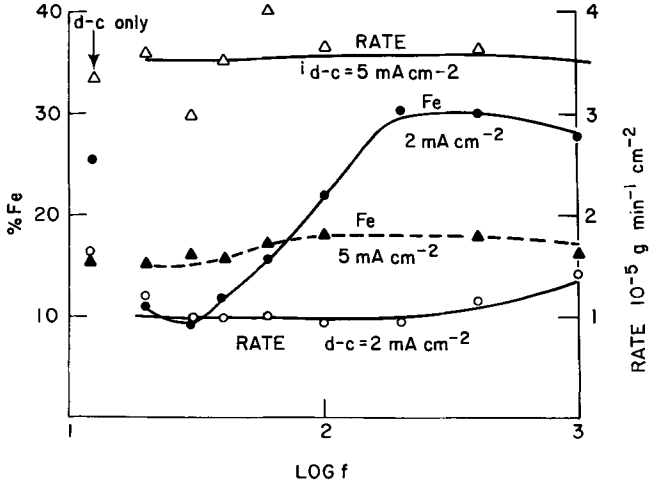

Fig. 4. Fe content and the rate of alloy deposition in high nickel solution of pH = 3.8 with i_{d-c} of 2 mA cm^{-2} and 5 mA cm^{-2} and I_p = 13.75 mA cm^{-2}.

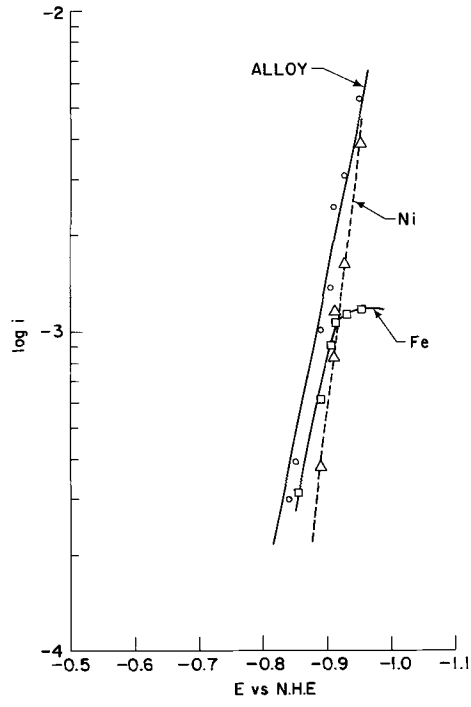

Fig. 5. Log direct current density vs. potential in high citrate solution of pH = 9.25.

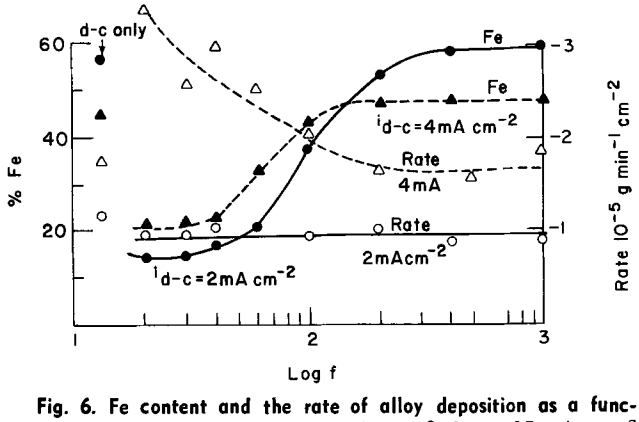

Fig. 6. Fe content and the rate of alloy deposition as a function of log f with i_{d-c} of 2 and 4 mA cm^{-2}, I_p = 15 mA cm^{-2} and $(Fe/Ni)_{sol}$ = 20/80. Data in left corner are the values of d.c. alone.

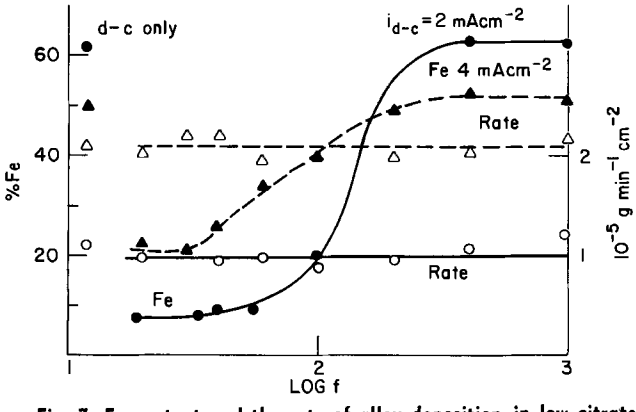

Fig. 7. Fe content and the rate of alloy deposition in low citrate solution of pH = 9.25, $(Fe/Ni)_{sol}$ = 20/80 with i_{d-c} of 2 and 4 mA cm^{-2} and I_p = 15 mA cm^{-2}.

alternating current is given in Fig. 8 and 9 for acid and alkaline solutions, respectively. For the purpose of comparison, data for d-c plating alone are also given and designated as f = 0.

From Eq. [5] one expects that the amplitude of the diffusion concentration wave to increase with increasing I_{peak}, and hence that the iron content of both the surface electrolyte and the deposit should decrease. This indeed can be seen from Fig. 10.

Since temperature affects the equilibrium constant for the dissociation of metallic complexes, it can be expected to exert an influence on the deposition rate.

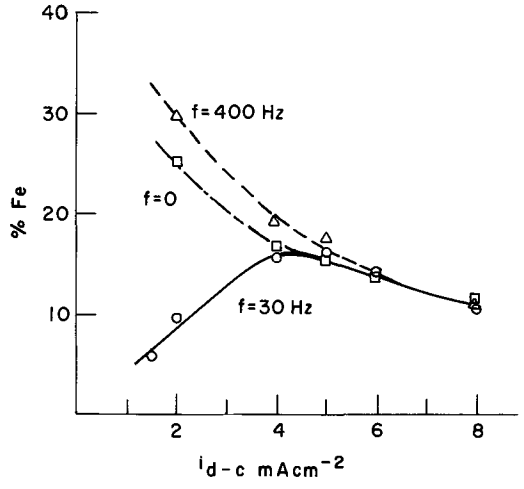

Fig. 8. Fe content as a function of direct current density for f = 0, 30, and 400 Hz with I_p = 13.75 mA cm^{-2}, (Fe/Ni)$_{sol}$ = 5/95 and pH = 3.8.

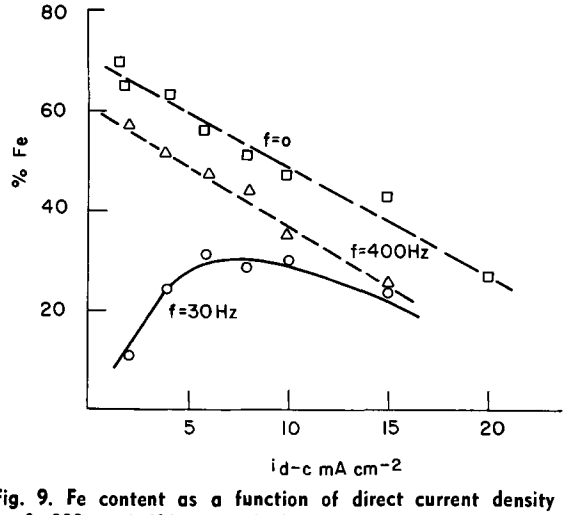

Fig. 9. Fe content as a function of direct current density for f = 0, 300, and 400 Hz in high citrate solution of pH = 9.25 and (Fe/Ni)$_{sol}$ = 20/80, I_p = 16.7 mA cm^{-2}.

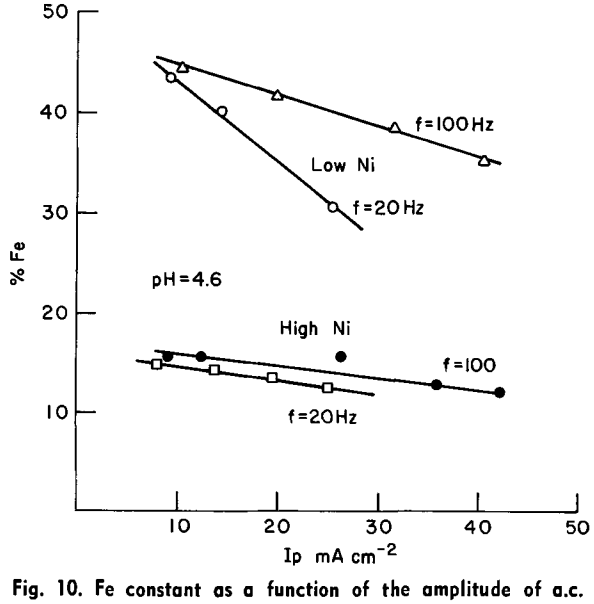

Fig. 10. Fe constant as a function of the amplitude of a.c. in low nickel, (Fe/Ni)$_{sol}$ = 20/80 and high nickel solution, (Fe/Ni)$_{sol}$ = 5/95 for f = 20 and 100 Hz and pH = 4.6.

In Fig. 11 are given rates and per cent Fe for the high citrate solution as a function of frequency for temperatures of 25° and 40°C. At higher temperatures the

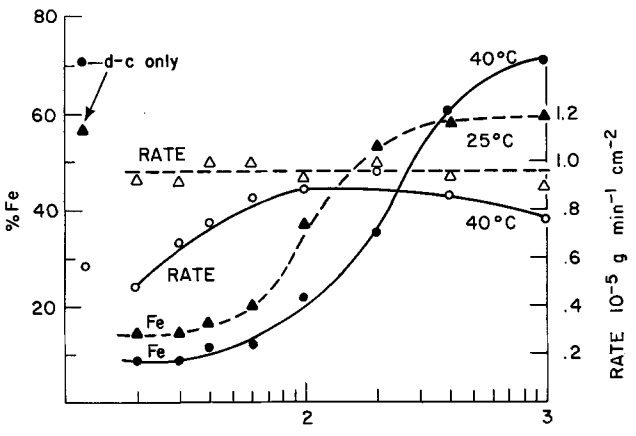

Fig. 11. Fe content the rate of alloy deposition as a function of log f in high citrate solution, with i_{d-c} = 2 mA cm^{-2}, I_p = 15 mA cm^{-2} for T = 25° and 40°C.

corrosion rate of the alloy becomes too large for meaningful study.

Discussion

From Fig. 2, 3, 4, 6, 7, and 11 one can clearly see to what a large extent the composition of the deposit is influenced by frequency. Since the percentage of one metal is a function both of its deposition rate and of the total rate of metal deposition, it is more meaningful to examine how the iron rate alone varies with frequency. The diffusion law predicts a linear dependence on $\omega^{-1/2}$, *c.f.*, Eq. [6]. From the plots given in Fig. 12-14 it can be seen that the rate of Fe deposition is indeed linearly dependent on $\omega^{-1/2}$, approaching its d-c value at high frequencies, where the contribution from the a-c component becomes negligible. However, there

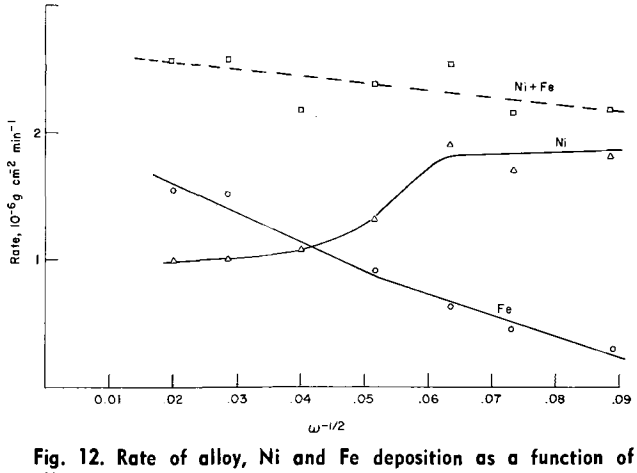

Fig. 12. Rate of alloy, Ni and Fe deposition as a function of $\omega^{-1/2}$ in low nickel solution, (Fe/Ni)$_{sol}$ = 20/80 and pH = 3.00, i_{d-c} = 2 mA cm^{-2}, I_p = 13.75 mA cm^{-2}.

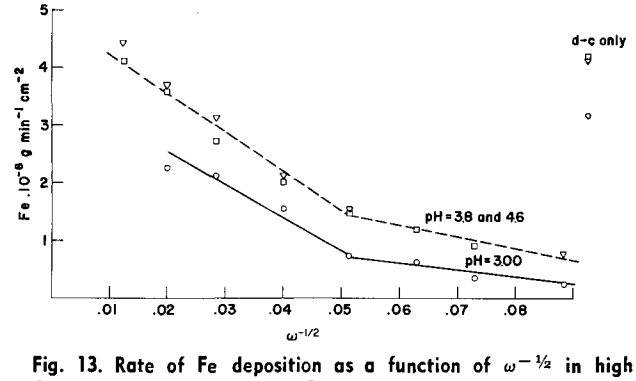

Fig. 13. Rate of Fe deposition as a function of $\omega^{-1/2}$ in high nickel solution, (Fe/Ni)$_{sol}$ = 5/95 at pH = 3, 3.8 and 4.6, i_{d-c} = 2 mA cm^{-2}, I_p 13.75 mA. Data in the right corner are the values for d.c. alone.

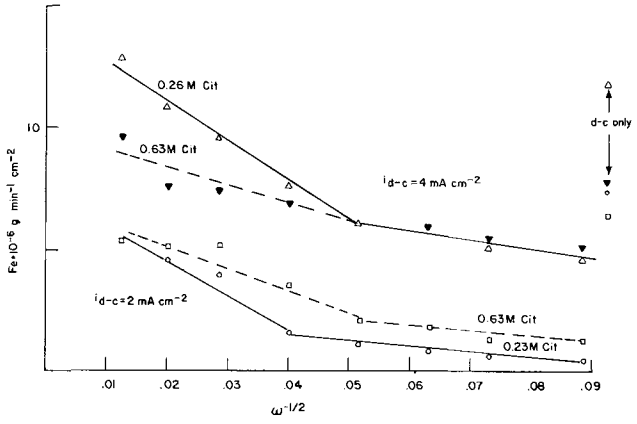

Fig. 14. Rate of Fe deposition as a function of $\omega^{-1/2}$ at i_{d-c} of 2 and 4 mC cm^{-2} in low and high citrate solution.

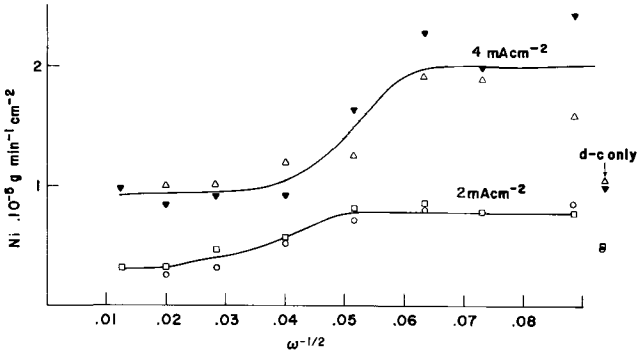

Fig. 15. Rate of Ni deposition as a function of $\omega^{-1/2}$ at 2 and 4 mA cm^{-2} in low (○, △) and high citrate solutions (□, ▼).

are two regions, one being that of low frequency, *i.e.*, 20-100 Hz, and the other from 100 to 1000 Hz for which the slope of the line has different values, being smaller at lower frequencies. The explanation of this behavior is discussed separately below for the two different types of solutions employed.

Deposition from acid solutions.—In the solution of pH = 3, the rate of alloy deposition is lower under a.c. plus d.c., than under d.c. alone. This indicates that some dissolution of alloy is taking place. One can argue that Fe dissolves faster than Ni, hence there is less Fe present in a deposit. However, there is no trend in the variation of alloy deposition rate with frequency. Furthermore, in the solutions of pH = 4.6, the total rate is not affected with a.c., but the Fe rate is lower and shows the same clearly defined two regions of different dependence on frequency. In the region of low frequency the contribution of a.c. is twofold. First, its effect on diffusion is the largest, and second, there is an effect on the surface pH. For, when the potential is varied slowly, the electrode remains in the anodic region sufficiently long to allow oxidation of adsorbed hydrogen on its surface (26). Hence, $pH_{surface}$ is brought back to its original value for the next cathodic cycle. If $pH_{surface}$ does not increase, the formation of hydroxides does not occur, hence there is no anomalous deposition of iron and the Ni deposition is not suppressed. This can be clearly seen from Fig. 12. With increasing frequency, the electrode spends less and less time in the anodic region, and the kinetic processes apparently cannot follow such rapid changes. As a result, $pH_{surface}$ increases sufficiently to cause the formation of iron hydroxide, which prevents the discharge of Ni. It is interesting to note that already at 100 Hz Ni and Fe deposit with the same rate, *c.f.*, Fig. 12, in spite of the fact that the bulk concentration of Ni is four times higher than that of Fe. Above 100 Hz Fe deposits with a higher rate than Ni. In Fig. 13 are shown the rates of Fe deposition for three values of bulk pH. Within the experimental error, Fe deposits from the solutions of pH = 3.8 and pH = 4.6 with the same rate, indicating that a.c. produced the same surface pH.

With increasing bulk pH, or by increasing the d-c level, the a-c component becomes less effective in controlling the pH of the surface (*c.f.*, Fig. 2, 3, and 4). It should be pointed out that according to Bockris *et al.* (25), the Fe rate, *i.e.*, partial current density for iron deposition, is closely connected with pH through the following relationship $(\partial \ln i_{Fe}/\partial \log c_{OH^-}) = 1$.

Examining Fig. 2, one can see that in the low Ni solution of pH = 4.6, the rate of alloy deposition is higher under a.c. plus d.c. then under d.c. alone. If adsorbed hydroxides block the surface, then a hydrogen evolution reaction from the rather dilute bath might be kinetically the most favorable reaction. With a.c. present adsorption of hydroxides does not occur, and hence the rate is higher.

Deposition from complex solutions.—As was mentioned earlier, deposition of the alloys from complex solutions with superimposed a.c. on d.c. presents a rather interesting problem on account of the dependence on the k/ω ratio. Furthermore, in such systems the two currents are more comparable since the reaction layer thickness for d.c. is approximately the same as the penetration depth for a.c. ($\sim 7.5 \cdot 10^{-5}$ cm). From Fig. 6 and 7 it can be seen that just by varying frequency one can vary the Fe content from 14-59%, or, by decreasing the concentration of complexing agent for Fe, from 8-63%.

In Fig. 14 are given the rates of Fe deposition as a function of $\omega^{-1/2}$ for two values of d.c. and two concentrations of citrate ions. At i_{d-c} = 2 mA cm^{-2} a quite surprising effect is found, namely, Fe deposits with a higher rate from the solution containing more of its complexing agent. When i_{d-c} is increased to 4 mA cm^{-2}, Fe deposits with the same rate from both citrate solutions in low-frequency region. However, at higher frequencies the situation becomes "normal," *i.e.*, with more complexing agent there are less Fe ions available for deposition. This "abnormality" can be explained if one compares the values of the rate constant for low and high citrate solution.

The reaction exchange rate, v_o, can be calculated from Eq. [11] if the limiting reaction current, i_r, is determined experimentally. For the high citrate solution i_r = 1.54 mA cm^{-2}, giving $v_o = 2.06 \cdot 10^{-4}$. For the low citrate solution i_r = 2.02 mA cm^{-2} and $v_o = 1.37 \cdot 10^{-4}$ mole cm^{-3} sec^{-1}. From these v_o values k was calculated to be $4.63 \cdot 10^3$ and $1.19 \cdot 10^3$ sec^{-1} for high and low citrate, respectively. It has been pointed out earlier that the rate depends not only on $\omega^{-1/2}$ but also on the ratio of k to ω. This ratio varies from 37 to 0.74 in the high citrate solution, but only from 9.5 to 0.19 in the low citrate, when f is varied from 20 to 1000 Hz. The rate constant is equal to ω at 740 and 190 Hz for high and low citrate, respectively. Since k is an order of magnitude larger than ω at low frequencies in the high citrate solution, Fe deposits with a higher rate than from low citrate solution where k and ω are of the same order of magnitude. At 1000 Hz the ratio of k/ω in both solutions are of same magnitude (0.74 and 0.19), hence there is very little difference in Fe rates (*c.f.*, left side of Fig. 14).

By increasing i_{d-c} more material is required according to Faraday's law, and therefore the effect of d.c. becomes more pronounced. When the frequency is increased the effect of a.c. is still further diminished, hence the transition to "normal" behavior is observed.

If the concentration of citrate ions is changed, one would not expect to see any changes in Ni rate, since Ni is present in solution as the $[Ni(NH_3)_n]^{++}$ complex. Experimental data given in Fig. 15 clearly bear out this expectation.

By superimposing a.c. on d.c. one expects that variation in Fe composition on the surface and consequently in the deposit will take place within the time of one cycle, *i.e.*, $\sim 10^{-2}$ sec. On a microscopic scale this means uniform composition, which is indeed observed experi-

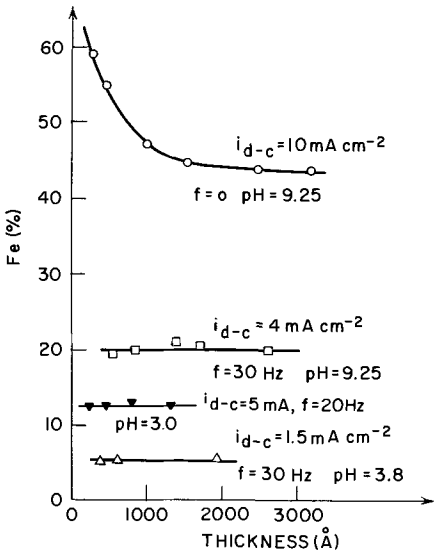

Fig. 16. Fe content as a function of film thickness in acid and alkaline solutions.

mentally, as shown in Fig. 16. The line at the bottom of the graph represents per cent Fe obtained from the solution with molar ratio of Fe/Ni = 5/95. Note that the composition of the solution is reflected exactly in the deposit throughout its thickness.

Conclusions

By superimposing a.c. on d.c. during the electrodeposition of alloys

1. One can diminish if not completely eliminate anomalous codeposition. Furthermore, inclusion of hydroxides into deposits can be excluded. This regulation can be used not only for iron group metals, but in all cases where one deals with metal ions which readily form hydroxides (Zn, In, Cd).
2. From the same solution the composition of an alloy can be varied in a rather wide region (8-60% Fe) merely by varying the frequency. This method could be usefully applied in studies of physicochemical properties (such as stress, morphology of a deposit, grain size, etc.) as a function of composition at constant d.c.
3. Deposits of uniform composition can be obtained.

Acknowledgments

Grateful acknowledgment is given to Mrs. Judith Olsen for her skillful, enthusiastic and patient experimental assistance. Thanks are due to Doctors B. Berry, I. M. Croll, J. F. Freedman, and L. T. Romankiw for helpful discussions.

Manuscript submitted April 20, 1970; revised manuscript received Aug. 28, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

The Effect of Molecular Structure on the Electrode Kinetics of Aminoquinones and Quinone Thioethers

Jeffrey L. Huntington and Donald G. Davis*

Department of Chemistry, Louisiana State University in New Orleans, New Orleans, Louisiana 70122

ABSTRACT

The electrochemistry of a number of aminoquinones and quinone thioethers has been investigated in aqueous-ethanol solutions. Half-wave potentials as a function of pH have been measured polarographically and heterogeneous rate constants for several of the compounds have been determined by cyclic voltammetry. The $E_{1/2}$'s and the $k_{s,h}$'s have been compared with hyperfine splitting constants determined by ESR spectrometry and conclusions arrived at as to the effect of spin density on electrochemical parameters.

A substantial number of naturally occurring quinones have been shown to be essential to life. Many of these are involved in the transport of electrons in biological systems (1). Also, it has been reported that menadione is an effective sensitizer in the radiotherapy of certain types of cancer (2). The effectiveness of menadione has been attributed to its ability to react with thiol groups such as cysteinyl residues in proteins

* Electrochemical Society Active Member.
Key words: ESR, cyclic voltammetry, heterogeneous rate constants, polarography.

(3). Because of these facts, we decided to investigate the reactions of quinones with thiol and amine groups and to study the electrochemistry and ESR spectra of the resultant products. In this way it was hoped that a better understanding of the biochemistry of quinones would result.

Simple quinones have been studied electrochemically by many workers but only recently has the biologically important ubiquinone-6 been studied comprehensively (4). The first report of an ESR spectrum of an aminoquinone appeared in 1960 (5). Russell *et al.* have published the spectrum of 2,5-bis (t-butylamino) benzoquinone in DMSO and some work with aminoquinones in acetonitrile has also been reported (6).

For this work we chose 50% ethanol in water because this solvent allows good solubility of quinones. The hyperfine splitting constants reported in nonaqueous solvents (6, 7) are roughly proportional to ours in aqueous ethanol but are only about two thirds as large.

The syntheses of the various aminoquinones and thioethers used in this study are reported elsewhere (8). Table I shows the structures of the various quinones studied. The same number is used to designate the quinone, semiquinone, or hydroquinone in any state of protonation. When a proton is spoken of as being α, β, or γ, the proton in question is attached to the α, β, or γ carbon, respectively, in the side chain or ring connected to the quinone moiety by the heteroatom.

Experimental

The measurement of the ESR spectra of the quinones listed in Table I and a number of others has been previously reported (8), as have the syntheses, analyses, and NMR spectra. The solvent chosen for the ESR and electrochemical studies was "50% ethanol" prepared by mixing equal volumes of 100% ethanol and distilled water. In a number of cases it was found necessary to add a few per cent of chloroform to the "50% ethanol" to increase the solubility of the quinone. This practice had little effect on the ESR spectra (see compounds 8 and 13 in Table II) or the electrochemistry.

Reagents and buffers were generally the best commercial grade available and were used without further purification. Solutions were deaerated as necessary with prepurified nitrogen.

No system of "pH" measurement for nonaqueous solvents is universally employed (9). The "pH" values reported here are operationally defined. The procedure was simply to measure the pH with a glass electrode after standardization with aqueous buffer, even though pH values in ethanolic solutions tend to be lower than found in an aqueous solution of the same buffer (9). The pH readings were generally quite reproducible.

Coulometry, polarography, cyclic voltammetry, electrogeneration of radicals, and chronopotentiometry, all with three electrodes, were carried out by means of an operational amplifier, multipurpose electrochemical instrument, and triangle wave generator described elsewhere (10). Complete plans for this instrument are also available (11). The readout devices were a Hickock Model DMS-3200 digital voltmeter, a Houston Instruments HR-95 X-Y recorder, or a Tektronix Model 564 and/or Model 561A oscilloscopes with appropriate plug-in amplifiers and time bases.

Electrochemical cells were of local design and were constructed completely of Pyrex. The hanging mercury drop electrode used in many of the studies was supplied by Brinkmann Instruments and consisted of a stainless steel micrometer which extruded mercury from a Lucite reservoir through a glass capillary.

A dropping mercury electrode was constructed in these laboratories, entirely of glass. The mercury in a 2 mm capillary standpipe was supported by compressed air in a chamber above the mercury reservoir. The mercury column was pumped to the desired height by squeezing a pipette bulb. After closing the stopcock the mercury head would remain constant to within a few millimeters for a matter of hours. A second stopcock led from the reservoir to a full-length Sargent capillary (2-5 sec.) A platinum wire sealed through the glass just above the capillary made electrical contact, obviating the long lead which could be a source of excess noise.

The various electrochemical techniques were applied in the usual ways. Cyclic voltammetry was used to measure heterogeneous rate constants as proposed by Nicholson (12). Some of the details of this application are discussed below.

Results and Discussion

Controlled potential coulometry.—In various solvents, quinones have been reported to undergo one- (13), two- (7), or four-electron reduction (14) so it was necessary to establish the number of electrons transferred for representative quinones upon reduction in 50% ethanol at moderate pH. The reduction of compound **21** at a mercury pool in a pH 5 buffer consumed 1.98 electrons per molecule at $E = 0.50$V *vs.* SCE. Reoxidation at $E = 0.20$V recovered 1.8 electrons. Reduction of **7** under the same conditions consumed 2.09 electrons of which 2.01 were recovered on reoxidation. Evidently, reduction of aminoquinones in acidic solution is an over-all two-electron process and is not accompanied by decomposition.

Polarography.—Aminoquinones and quinone thioethers gave reversible or quasi-reversible polarographic waves except that both classes of compounds often exhibited large maxima. In solutions of *p*H 5 or above, the maxima disappeared spontaneously over the period of an hour or less. Quinone thioethers decompose sufficiently rapidly at *p*H 8 or above to prevent the gathering of useful data except for approximate half-wave potentials. For this reason the following discussion is concerned primarily with aminoquinones.

For quinones and aminoquinones, polarographic limiting currents are proportional to the square root of the mercury head, and the half-wave potentials do not depend on the drop time, the state of oxidation, or the supporting electrolyte concentration. The temperature coefficients of the $E_{I/2}$'s (including the effects of temperature on *p*H and junction potentials) are small, about −1 mV/°C, so it may be concluded that the waves are under diffusion control. Whereas the theoretical value of $dE/d \log [i/i_d - i]$ is 30 mV for a reversible two-electron wave at 25°C, the experimental is 32 mV for **21** and 34 mV for **7**. By way of comparison, the slope is 34 mV for duroquinone, **19**. The plots of log $[i/i_d - i]$ *vs.* *E* are linear, and the $E_{1/2}$ does not depend on quinone concentration, which implies that the electrode process is essentially reversible and does not involve a dimerization.

The less soluble compounds, such as **12**, frequently gave abnormally steep or otherwise misshapen waves, particularly below room temperature. That the difficulty here is insolubility is corroborated by the normal appearance of the waves upon warming to 50°C. This encouraged us to attempt to improve the electrochemistry by adding chloroform to improve the quinone solubility. This approach achieved a measure of success at chloroform concentrations of around 2%. Above 5%, however, the aminoquinone waves became increasingly irreversible, the $E_{1/2}$'s shifted cathodically, and the drop time became erratic. This is presumably a surface effect, but why only 5% of so innocent a solvent as chloroform should have such an adverse influence remains unexplained. Adding as much as 10% chloroform did not noticeably mitigate the enormous maxima observed at *p*H 5 and below.

The equilibrium constants for the formation of aminosemiquinones by disproportionation are far too small in aqueous solution to influence the shape of the polarographic wave. Alkylthiosemiquinones are stable enough at high *p*H to be studied electrochemically, but the rapid decomposition of the parent quinones makes precise measurements nearly impossible.

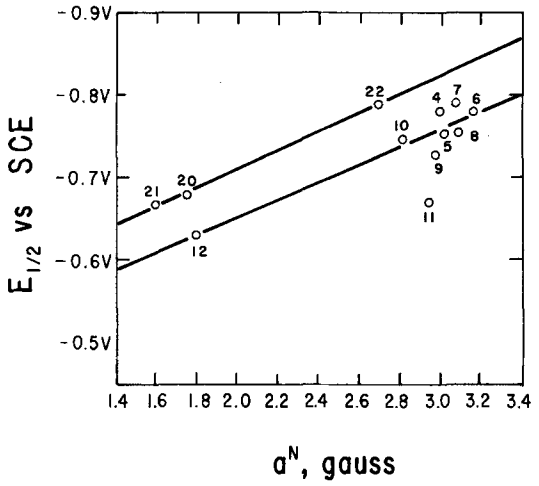

Fig. 1. Dependence of polarographic half-wave potential on aminosemiquinone nitrogen splitting constant: *p*H 11.0 glycinate buffer, 50% ethanol, 0.20*M* $NaClO_4$. Numbers beside experimental points refer to Table I.

Diffusion coefficients at 24°C in 50% ethanolic *p*H 11 glycine buffer containing 2.0 moles of $NaClO_4$ per liter were calculated from the Ilkovic equation to be 2.70 x 10^{-6} cm^2 sec^{-1} for **21**, and 2.82 x 10^{-6} cm^2 sec^{-1} for **8**. Duroquinone, **19**, gave a diffusion coefficient of 3.52 x 10^{-6} cm^2 sec^{-1} under the same conditions. These values are a little smaller than would be predicted for molecules of like size in aqueous solution, but the higher viscosity of 2.0*M* $NaClO_4$ in 50% ethanol makes them seem reasonable (11).

Table II is a compilation of the results of ESR studies on the compounds of interest to this work.

Despite the scatter in the data, it is obvious from Fig. 1 that half-wave potentials of bis(alkylamino) benzoquinones shift cathodically roughly in direct proportion to the hyperfine splitting constant of the semiquinone amine nitrogen. There are two principal trends: the compounds lacking substituents in the 3 and 6 positions fall on a line of slope −200 mV/G, and the ortho-disubstituted aminoquinones fall on a higher line with a somewhat shallower slope. It appears that the splitting constant of the semiquinone amine nitrogen is a measure of the ability of the nitrogen to donate electrons to the ring by resonance. Inductive and resonant effects of other groups must be considered, however, and those compounds with 3 and 6 position substituents must again be treated separately.

Table II. ^1H and ^{14}N hyperfine splitting constants of semiquinone, aminosemiquinone, and thioethersemiquinone radical anions

All spectra observed at approximately 3350 gauss, all splitting constants in gauss, listed without sign.

Allylamine would be expected to be a superior electron donor, and the $E_{1/2}$ of compound **10** does appear more cathodic than the main line. It may be seen in Table II that 2,5-bis(N-glycyl) benzoquinone, **11**, was anomalous in having no measurable α-proton splitting constant. Whether this lack of delocalization accounts for the position of **11** anodic of the trend is difficult to say. The inductive effect of a carboxylate anion ought in any case to be electron releasing rather than withdrawing. It also may be that compounds **12**, **20**, and **21** are set apart from the rest due to steric hindrance of their substituents which may force a nonplanar configuration of the radical and a lowering of a^N.

The ortho-substituted aminohydroquinones are stronger reductants than would be predicted from resonant electron release alone, as judged from a^N. This may be due in part to a decrease in steric repulsion when the rigidly planar hydroquinone is converted to the slightly more flexible cross-conjugated quinone. Probably more important is the increased ability of the nitrogens to donate electrons inductively when the net positive charge on the nitrogen due to conjugative electron release is lessened.

At the present level of precision, there is not a significant correlation between $E_{1/2}$ and a^{H}_{α} or a^{H}_{ring}. Because a^{H}_{NH} is approximately proportional to a^N, much the same correlation with $E_{1/2}$ is found with either.

Table III is a compilation of half-wave potentials as a function of substituents and pH. The cathodic shift upon thioether substitution is only 100-280 mV. The typical bis (alkylthio) quinone is then comparable in oxidizing strength to 2,5-dimethyl benzoquinone (compound **1**) and is actually stronger than 2,5-diethyoxy-benzoquinone (15). This indicates that electron release by the formation of π bonds involving sulfur is of less consequence than π bonding between an etheral oxygen and the quinone ring. This is supported by the facts that the ring proton hyperfine splitting constants of 2,5-dialkoxysemiquinones are smaller, and the α-proton splittings larger, than the corresponding 2,5-bis (alkylthio) benzoquinone (16).

It is apparent from Table III that the $E_{1/2}$ of a representative 2,5-bis(alkylamino)benzoquinone is 500 mV more cathodic at pH 11 than the $E_{1/2}$ of 2,5-dimethylbenzoquinone, **1**. Eleven or 12 kcal worth of electron release by the amino substituent (per mole) bespeaks very extensive conjugation of the nitrogen to the ring, as predicted from the substantial nitrogen hyperfine splitting constants.

Linear free-energy relationships in monoaminoquinones and monoamino-p-phenylenediamines have been developed with fair success (17). Those diamino- and dihydroxy-compounds which have been studied, however, generally show nonadditivity of Hammett or Taft parameters, which has been attributed to various ortho effects. Whereas nonadditivity of $E_{1/2}$ shifts upon multiple methyl- or chloro-substitution are manifested in a decreasing effect per substituent as the number of substituents increases, two nitrogen or oxygen substituents oriented para to each other may give more than twice the shift of a single substituent.

We observe such an instance in 2-isopropylamino-5-t-butylbenzoquinone, **26**, whose $E_{1/2}$ at pH 11 is 157 mV more cathodic than t-butylbenzoquinone, **24**, but 252 mV more anodic than 2,5-bis(isopropylamino)-benzoquinone. The comparison is not quite straightforward, because of the loss of inductive electron release by the t-butyl group, but the inference seems safe that two isopropylamino groups oriented para to one another are each more electron releasing than a single isopropylamino group para to a t-butyl. Rather than a peculiarity of the ortho relationship between carbonyl and amine, this would be better described as a "para effect," due to the increased resonant interaction between the two amine groups. The EPR spectrum of the monoaminoquinone, **26**, shows an a^N of 2.05G, very significantly smaller than the a^N of 3.08G found in the bis(amino)quinone, **7**. Rather than the second amine group pirating spin from the first, the two interact synergistically to increase their spin densities at the expense of the rest of the molecule. Such a large increase in a^N in the face of an increase from one nitrogen to two predicts a large cathodic shift in $E_{1/2}$ according to Fig. 1, which is exactly what is found.

The most serious impediment to comparison of quinone, aminoquinone, and quinone thioether half-wave potentials is the difference in pH dependence shown in Fig. 2. In the reduction $Q + ne^- + p(H^+) \rightarrow QH_p^{(p-n)+}$, the formal potential will shift cathodic by 59 p/n mV per pH unit at 25°C (18). Quinones and hydroquinones are very weak acids and bases

Table III. Polarographic half-wave potentials of quinones, aminoquinones, and quinone thioethers at pH 5, 8, and 11

pH buffer is 0.2*M* acetate, pH 8 buffer is 0.2*M* tris(hydroxymethyl)-aminomethane, pH 11 buffer is 0.2*M* glycinate. All buffers are 0.20*M* $NaClO_4$ in 50% ethanol. The reference electrode is a saturated calomel electrode.

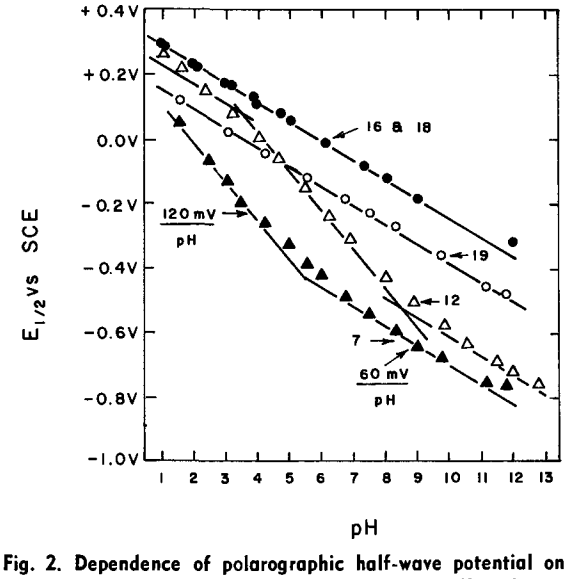

Fig. 2. Dependence of polarographic half-wave potential on pH for 2,5-bis(isopropylthio)benzoquinone (**16**), 2,4-bis(2-carboxyethylthio)benzoquinone (**18**), tetramethylbenzoquinone (**19**), 2,5-bis(1-piperidinyl)benzoquinone (**12**), and 2,4-bis(isopropylamino)benzoquinone (**7**). Glycine, citrate, imidazole, and tris(hydroxymethyl)-aminomethane buffers, 50% ethanol, 0.50M $NaClO_4$. 25° ± 2°C. The interpolated lines are of either 60 mV/pH or 120 mV/pH slope; the fit to the experimental points of compound **12** is arbitrary.

(although semiquinones are not) (19), and both species are generally neutral from pH 1 to about pH 10-13. Since both p and n equal 2, the plot of $E_{1/2}$ *vs.* pH is a straight line with slope 59 mV/pH. Duroquinone, bis(isopropylthio)-benzoquinone and bis(carboxyethylthio)benzoquinone live up to this expectation admirably. Bis(isopropylamino) benzoquinone, however, shows a region of 120 mV slope, a region of about 60 mV slope, and the curve shows signs of leveling off as the pH exceeds 11. A 120 mV slope means the consumption of four protons during the reduction, so the product must be the diprotonated hydroquinone. The intersection of the extrapolated 60 and 120 mV regions lies between pH 5.5 and 6, so the first two pK_a's of this diprotonated hydroquinone must lie near 5.5 or 6. Lack of protonation of the nitrogen of the quinone form at low pH's may be due to their amide character (8).

The $E_{1/2}$ of bis(1-piperidyl)benzoquinone, **12**, shifts with varying slopes as the pH is changed. There is a variety of excuses for such behavior in systems which are irreversible, proceed by complex mechanisms, or involve species highly charged and therefore liable to "double-layer effects," but that is not the case at hand. If the mechanism is single step, and n is 2, the implication that $p = 3$ or 4 is inescapable. It would come as quite a surprise that 2,5-bis(1-piperidyl)-hydroquinone would be a strong enough base to be protonated at pH 8 or above. Even at high pH's the semiquinones appear to be too unstable to effect these results.

It does not seem plausible to attribute the strange acid-base behavior of **12** to the effects of adsorption at the electrode surface; dialkyl- and tetra-alkylbenzoquinones apear to be even more strongly adsorbed (20), and the $E_{1/2}$ *vs.* pH diagram of duroquinone **19** is normal. To insure that the readings were not influenced by changes in junction potentials, duroquinone was present in solution with the aminoquinones as a "chaperon" and its $E_{1/2}$ was checked against previously determined values at each pH.

Measurement of heterogeneous electron transfer rates.—Substituent effects on electrochemical thermodynamics are well documented (13, 17) but the effects of substituents on electrochemical kinetics through stabilization of the transition state are much less understood. The suspicion that the electronic structures of free radicals should bear strong analogies to the electronic structures of excited states prompted us to search the semiquinone ESR spectra for clues to elucidating the dependence of aminoquinone electrode kinetics on structure.

There were several difficulties in obtaining kinetic data. Radical anions could be studied only in basic solution so it seemed fitting to study electrode kinetics in basic solution as well. However, most of the quinones decompose in basic solution and thus cause problems with kinetic studies. For this reason heterogeneous rate constants were measured at pH 8 where the quinones were found to be stable. The solutions contained 1% chloroform. Adsorption at the electrode surface also rendered attempts to measure $k_{s,h}$ invalid for a number of compounds so that electrode kinetics could be accurately measured only for seven different quinones.

Of the many techniques for measuring electrode kinetics, cyclic voltammetry was selected because it is applicable to a wide range of rate constants (12, 21), problems with adsorption are immediately apparent from the experimental data (22), and diagnostic criteria exist for multistep electrode mechanisms, with or without homogeneous complications (21, 22).

If the scan rate is sufficiently slow, the electron transfer process will be rapid compared to the time scale of the experiment and "reversible" behavior will be observed. As the scan rate increases, the assumption of reversibility fails and the peak separation increases beyond $57/n$ mV. Nicholson has published solutions to equations describing the dependence of peak potential on electrode kinetics, scan rate, *etc.* (12). Nicholson's derivation assumes that $\alpha = 0.50$. Fortunately, the calculation is very insensitive to α and the experimenter need satisfy himself only that α is between 0.3 and 0.7. For compounds **7** and **9** we obtained values of α between 0.4 and 0.6 which are sufficiently close to 0.5 to justify using Nicholson's Table (12). The α values were measured from a plot of the logarithm of the peak current *vs.* the peak separation (21).

It should be remembered that Nicholson's solution is for a single-step process and is not explicitly applicable to quinone systems since two electron transfers and two protonations are involved. If, however, the activation energies for the rate-controlling steps for the forward and reverse processes are the same, it ought to be possible to use the single-step model. This work rests on this assumption and thus the rate constants reported are to be considered apparent ones, recognizing that other factors beside electron transfer rates may influence the peak separation.

At the hanging mercury drop electrode, it was possible to obtain meaningful heterogeneous rate constants ($k_{s,h}$) at pH 8 (50% ethanol) for six bis(alkylamino)benzoquinones and for 2,5-bis(isopropylamino)-3,6-dimethylbenzoquinone. The measured rates at 25°C were:

21	0.0030

These values were for the first scan at a fresh drop. At high scan rates, the inability to compensate completely for ohmic potential drops causes the cyclic voltammogram to be distorted and the peak separation to become large regardless of the rate constant of the couple under study. The so-called "uncompensated resistance" was electronically corrected for by means of positive feedback (10). The feedback was adjusted by increasing it just to the point of oscillation and then reducing it by the equivalent of 1 ohm. Full compensation within an ohm or two was achieved up to scan rates of about 500 V/sec. No quantitative data were collected above this rate. On the other hand, rate constants can be calculated only when the scan rate is fast enough to cause a peak separation measurably larger than the reversible 30 mV, which required scan rates of about 50 V/sec for compound **4**. The larger rate constants could be measured only over a single decade of scan rates and the precision of the $k_{s,h}$ values above 0.1 cm sec^{-1} is about 20%. Smaller rate constants are precise to about 10%.

Some of the rate constants could also be measured at pH 11 (50% ethanol) and were not greatly different from those at pH 8. The $k_{s,h}$'s for **4** and **10** were about 0.3 cm sec^{-1} and the $k_{s,h}$ for **21** remained about 3×10^{-3} cm sec^{-1}.

Correlations between $k_{s,h}$ *and structure.*—Hyperfine splitting constants are a measure of spin densities at the nuclei in question, which are a function of the electronic energy levels of the radicals' diamagnetic precursers; hfs constants in radicals should therefore give some information about reactivity and kinetics of diamagnetic molecules. Latta and Taft (23) used hfs constants of N,N-dimethylaniline cation radicals to calculate Tafy σ-parameters for various substituents, which could then be applied to kinetic and thermodynamic linear free-energy relationships. Poole and Griffith (24) found a better correlation between re-

activity toward nitration at various sites in phenanthrene and hfs constants of protons at those positions in the phenanthrene radical than any reactive index calculated from molecular orbital considerations. The logarithm of the homogeneous rate constant for nitration at a particular position varied linearly with proton hfs constant at that position over nearly a decade of rate constants.

Peover and Powell (25) have published the only known direct correlation between hfs constants and electrode kinetics. The logarithms of the standard rate constants for the one-electron reduction of ten nitrated hydrocarbons in DMF varied linearly with the nitrogen hyperfine splitting constants in the same solvent. As the absolute value of $a^{N_{NO_2}}$ increased, log $k_{s,h}$ increased. On the assumption that charge distribution in radical anions parallels spin distribution, this behavior is explained in terms of the influence of excess charge at the nitro group on the solvation energy of the radical anion. The more the odd electron is localized on the nitro-group, the higher the energy of the transition state and the slower the reaction.

The linear dependence of log $k_{s,h}$ on the hyperfine splitting constant of the α-protons is shown in Fig. 3. Various other correlations were attempted but this proved to be the only fit. Compounds **4**, **5**, **6**, and **7** form an homologous series and are used to define the straight line. Compound **9** has no α-protons and thus cannot be plotted on Fig. 3 but its rate constant is somewhat larger than **7**. Compound **10** has two vinyl groups not present in any other compound, so any conjugative influence on kinetics should be emphasized. Compound **21**, unlike the others in Fig. 3, is substituted in the 3 and 6 position. This evidently indicates **21** must be considered as belonging to a different series (see also Fig. 1).

That the logarithm of the standard rate constant increases monotonically and linearly with $a^H\alpha$, implies that the spin distribution in the radical is a measure of the substituent influences on the energy of the electrochemical transition state. This might be due to stabilization of the paramagnetic species by delocalization of the unpaired electron onto the carbons. Release or withdrawal of charge can also accompany hyperconjugation, and the resulting charge delocalization might lower the solvation energy of the transition state enough to increase the rate of electron transfer appreciably.

The free energy of the electrode process can be estimated from absolute reaction rate theory according to

$$k_{s,h} = \frac{kt}{h} p \exp(-\Delta G^*/RT)$$

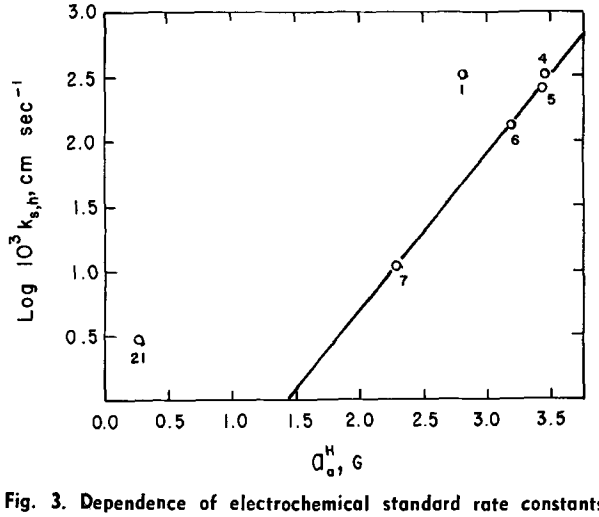

Fig. 3. Dependence of electrochemical standard rate constants for aminoquinones on aminosemiquinone α-proton hyperfine splitting constants. See text for definitions and explanation.

Where ΔG^* is the Gibbs free energy of activations of either the cathodic or anodic reaction at $E = E'_0$, and p is a parameter needed to correct the homogeneous collision number to heterogeneous units (26). In this equation, k is the Boltzmann constant, and h is Planck's constant. The magnitude of p is usually taken to be of the order of 10^{-8} cm, which implies a heterogeneous collision number of about 10^4 cm/sec (27). The ΔG^* for **21**, the slowest bis(alkylamino)-benzoquinone measured, is then around 8-9 kcal mole^{-1}. The semiquinone anions in solution are so unstable that it is hard to see how they could be of lower energy than the transition state and therefore be a candidate for a discrete intermediate. However, the energy of a paramagnetic species at the electrode surface could be substantially lowered by electron delocalization through overlap with the electrode (28). If the electrode mechanism were a simple two-electron transfer (and we have no evidence to the contrary for aminoquinones), acceptance of a single electron could occur at the high point on the reaction coordinate diagram. The transition state could thus have a structure analogous to that of the semiquinone anion without necessarily being at the same energy.

Polarographic Estimation of Ion-Solvent Interaction of the Alkali Metal Ions in Water and Other Solvents

John Broadhead and Philip J. Elving*

The University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

The half-wave potentials and diffusion current constants of all five of the alkali metal ions have been measured for the first time in wholly aqueous solution in a related series of experiments. A significant relationship has been shown to exist between the diffusion current constant and the Jones-Dole *B* value for each ion, where the *B* value is a measure of the solvent structure-making properties of the ion. The half-wave potential and diffusion current constant data for the alkali metal ions in water and thirteen other solvents are compared, together with other pertinent data where available, *e.g.*, heterogeneous rate constants and spectroscopic measurements; the relative half-wave potentials are best interpreted on the basis of ion-solvent interaction. Such comparison of the electrochemical data illuminates the nature of the electrode processes involved and allows postulation of the forms of the ion-solvent complex for the different solvents.

Despite the common occurrence of the alkali metal ions and their general analytical importance, the polarographic parameters in wholly aqueous media have never been measured for all of the ions in a single study. The scarcity of data for aqueous solutions has resulted in use being made, when comparing data in different solvent media, of "aqueous" data obtained in water-organic solvent mixtures. In connection with the present comparative study of the polarographic behavior of the alkali metal ions, all of them were examined in aqueous solution.

A recent comparison (1) on the rubidium scale (2, 3) of the half-wave potentials of the alkali metal ions in pyridine showed that the reduction of lithium(I) occurs at considerably more negative potential than that of other members of the series; further, the electrochemical data (polarography, cyclic voltammetry, coulometry) generally demonstrated the complicated nature of the Li(I) reduction. In the present study, analogous approaches, including consideration of kinetic and spectroscopic data, are used to analyze the voltammetric data for water and thirteen other solvents in order better to correlate the mechanistic reduction paths as reflected in the potential data. In particular, it is shown that the half-wave potentials of the alkali metal cations in different solvents are best compared on the basis of ion-solvent interactions. For example, a provocative linear relationship was found for the alkali metal cations in water between the diffusion current constant and the *B* term of the Jones-Dole equation (4), which is a measure of solvent structure making and breaking properties of the ion.

Experimental

Reagents.—Reagents were prepared as previously described (1).

Apparatus.—The instrumentation and cell have been described (1). The reference electrode was a calomel electrode with 0.1*M* tetraethylammonium chloride substituted for 0.1*M* KCl. A 0.1*M* tetraethylammonium perchlorate (TEAP)/agar plug and glass frit separated the reference and working compartments. The Sargent S-29417 mercury capillary used (mercury head = 54.1 cm) gave dropping mercury electrode (DME) capillary constants on open circuit in 0.1*M* TEAP of $t = 5.20$ sec and $m = 1.21$ mg sec^{-1}.

Procedure.—All test solutions were prepared by dissolving TEAP and electroactive species in the requisite quantity of water. The solution in the polarographic cell was deoxygenated with argon and a stream of argon was passed over the solution during experiments. Mean diffusion currents were determined by measuring the distance from the mid-point of the current oscillations on the plateau to the background current. Drop-times were measured at the same potential as that used for current measurement. Cyclic voltammograms were recorded on a hanging mercury drop electrode (HMDE) formed by collecting two mercury drops from the polarographic capillary.

Results.—The alkali metal ions gave well-defined polarograms in water, which did not exhibit maxima or abnormalities (*cf.* Fig. 1 and 2). Table I summarizes the polarographic results for aqueous solutions of the alkali metal ions.

All of the alkali metal ions exhibited redox couples on cyclic voltammetry. The peak potential separations for Na(I) through Cs(I) are essentially the same; for K(I), it is typically 0.37V (0.23V, when corrected for background current). However, Li(I) shows an anodic peak only when lithium is accumulated in the HMDE by holding the potential at −2.64V for 10 sec. These results are in accord with the work of Imai and Delahay (5) who found heterogeneous rate constants for the alkali metal ions in the range of (2 to 9) x 10^{-3} cm sec^{-1}, when corrected for double layer effects.

Comparative Polarographic Data

The excellent review by Takahashi (6) provides a useful starting point for the collation of the polarographic data on inorganic ions in nonaqueous solvents

available up to 1965. Several bases have been used in correlating the potential data. Thus, the half-wave potentials of the alkali metal ions in different solvents have been compared with the donor numbers of these solvents (7, 8); however, this type of comparison is arbitrary and severely limited by the lack of donor number values. Comparisons have also been based on the variation in dielectric constant of the solvents (9, 10). Since the dielectric constant is a macroscopic manifestation of a microscopic property, it is considered more meaningful to correlate half-wave potentials with the structural characteristics of the solvent, which affect the state of the ion in solution.

Table I. Polarographic data for the alkali metal ions in water (0.1M TEAP) at 25°

Ion[a]	$-E_{1/2}$,[b] V	I[c]	Wave slope[d]
Li(I)	2.41 ± 0.01	1.8 ± 0.1	47

K(I)	2.22 ± 0.01	2.6 ± 0.1	55
Rb(I)	2.22 ± 0.01	2.8 ± 0.1	50
Cs(I)	2.19 ± 0.01	3.3 ± 0.1	48

[a] The ionic concentration range is 0.1 to 2.0 mM.
[b] Data given represent the mean and average deviation of eight to twelve measurements at 25°C. The reference electrode is described in the text.
[c] Diffusion current constant, I = μA mM^{-1} $mg^{-2/3}$ $sec^{1/2}$.
[d] Calculated from relation, $E_{1/4} - E_{3/4}$ = slope.

Potential variation.—Table II summarizes the $E_{1/2}$ data for the alkali metal ions in fourteen solvents on the rubidium scale of potential (2, 3). The solvents are arranged in order of negativity of the lithium $E_{1/2}$ because this ion shows the greatest characteristic interaction with the solvent. [In the similar comparison by Gutmann *et al.* (7), the references to polarographic measurements in water, acetonitrile, and benzonitrile should include the work of Coetzee *et al.* (11).] In connection with Table II, it should be noted that some degree of irreversibility is shown by Li(I) in dimethylsulfoxide, dimethylacetamide, dimethylformamide [via ref. (20) but not according to ref. (10)], pyridine, water, isobutyronitrile, propylene carbonate, sulfolane, and acetonitrile. Cs(I) shows some indication of irreversibility in isobutyronitrile.

The polarographic reduction of lithium(I) in dimethylsulfoxide (DMSO) (12, 13) and dimethylacetamide (DMA) is difficult, *i.e.*, $\Delta E_{1/2}$ is large and negative [the data in ref. (13) only give values of $E_{1/2}$ for Li(I), Na(I), and K(I); the values of $\Delta E_{1/2}$ on the K(I) scale agree to within 30 mV with those in ref. (12)]. In truly anhydrous DMA, Li(I) is irreducible; reduction only occurs when 3% of water is present (14). In anhydrous DMSO, the Li(I) reduction is slow; the heterogeneous rate constant is of the order of 3 x 10^{-5} cm sec^{-1} (15).

In ethylenediamine (EDA) (16), dimethylformamide (DMF) (10, 13, 17), and pyridine (1), Li(I) is reduced at less negative potentials than in DMSO or DMA [the data on DMF in ref. (17) agree with those of ref. (10) to within 20 mV, but there is disagreement between ref. (10) and (13); data in Table II are taken from ref. (14)].

In water (no organic solvent present), the polarographic reduction of Li(I) appears reversible (18) with a $\Delta E_{1/2}$ of −0.19V, but cyclic voltammetry at the

[c] Data recorded at 30°C.
[d] $\Delta E_{1/2}$ calculated on the Na(I) scale.

HMDE does not show a cyclic couple. An anodic Li(0) oxidation wave is only observed when Li(0) is accumulated in the mercury drop before the reverse sweep to positive potential is started, *i.e.*, it is seen only by stripping voltammetry.

The Li(I) reduction in morpholine (19) occurs at a relatively small $\Delta E_{1/2}$ (*cf.* pyridine).

Before considering the nitrile solvents, the Rb(I) half-wave potentials in these solvents should be examined. Since the solubility of rubidium perchlorate in nitrile solvents is extremely low, Coetzee *et al.* (11) measured the $E_{1/2}$ of rubidium iodide in tetrabutylammonium iodide solutions of these solvents and attempted to correct the measured potentials to "hypothetical" $RbClO_4$ values in tetraethylammonium perchlorate solution. The latter calculation involved estimation of the change in ion association from a study of the anion effect on the "comparable" Na(I) system and estimation or neglect of the change in liquid junction potential. The correction often shifted the Rb(I) potentials by as much as 100 mV. Because of the assumptions and approximations involved in this approach, it is proposed that a secondary reference potential be used. McMasters *et al.* (20) have used the Na(I) as a pilot reference ion. Although this ion may not be quite as "ideal" as Rb(I), the data in Table II for DMSO through morpholine indicate that had a Na(I) $E_{1/2}$ reference been used, the Li(I) potentials would be shifted by 20 mV or less (with the notable exception of EDA). Upon this basis, another $\Delta E_{1/2}$, based on Na(I), has been calculated for Li(I); these values, enclosed in parentheses, are also shown in Table II.

On the basis of the Na(I) standard, isobutyronitrile (21) has a $\Delta E_{1/2}$ for Li(I) similar to that of morpholine. Propylene carbonate (PC) (22) and sulfolane (Sulf) (23-25), however, would be reordered to follow the nitriles in the potential series. Li(I) is polarographically reduced at the same potential in propionitrile (26) and acetonitrile (27) and at less negative potentials in benzonitrile (26) and phenylacetonitrile (26).

Current magnitudes.—Diffusion current constant (I) data for the alkali metal ions in several of the solvents are summarized in Table III; the values of $I\eta^{1/2}$ in the table compensate for the different solvent viscosities. Because the I values are proportional to $D^{1/2}$, the corrected I data are, therefore, diagnostic of the size of the diffusing species and, together with the $\Delta E_{1/2}$ values, can be used to examine the nature of the ion-solvent complex.

Discussion

Review of the relative half-wave potentials of the alkali metal ions shows, as already mentioned, that only in the case of Li(I) does $\Delta E_{1/2}$ vary significantly from one solvent to another; EDA is probably the only exception to this generalization. Consequently, the subsequent discussion is mainly concerned with the variation in nature of the Li(I) solvation. Where supplementary spectroscopic or thermodynamic data are not available, there is some speculation concerning the nature of the Li(I)-solvent bond.

Dimethylsulfoxide.—Although cyclic voltammetric data are not available for the reduction of Li(I) in DMSO, the $\Delta E_{1/2}$ of −0.39V suggests a strong association between solvent and Li(I), which strong interaction is confirmed by NMR and thermodynamic studies (28-30); the relatively small heterogeneous rate constant of 3×10^{-5} cm sec^{-1}, observed for Li(I) reduction in DMSO (15), also suggests a strong solvent-solute linkage. However, recent data on diffusion current constants (13) disagree with the preceding; the relatively large values of I reported would indicate the presence of a small (relatively unsolvated) diffusing species. Further consideration of these I values is included with the DMF discussion. If the solvation bonding is between Li(I) and the oxygen of DMSO, the methyl groups of the latter will be outermost in the solvation shell and reduction of either the complex or the Li(I) through an electron bridge formed by the solvent molecules would be difficult because of the nonpolar nature of the methyl groups.

Dimethylacetamide.—In anhydrous DMA, the solvation of Li(I) is such that the complex entity is irreducible. If complexation is due to bonding between the nitrogen and Li(I), an array of methyl groups will be present on the outside of the solvation species forming an even more complete sheath of methyl groups than with the DMSO-Li(I) complex. Furthermore, I for the reduction of Li(I) (unfortunately in a 3% water-DMA mixture) indicates a bulky diffusing species. In a 3% H_2O-DMA solution (1.6*M* H_2O), hydrolysis of an amide group in the lithium solvation sheath may occur via hydrolytic attack of the C-N bond, which is weakened by the close proximity of the Li(I) ion. This process would momentarily leave the Li(I) entity open to reductive attack and would explain the formation of the lithium amalgam claimed by Gutmann *et al.* (14).

Ethylenediamine.—EDA is the only solvent in which there is a significant variation in $\Delta E_{1/2}$ for all of the alkali metals. This separation in potential may be due to the selective chelating property of this solvent. Na(I) and K(I) are probably chelating by the normal mechanism, thus promoting reduction via a $-NH_2$ bridging group. Li(I), however, being a small ion, may not form a stable chelate and may only solvate with EDA in an end-on position, leaving a less favorable path for electron transfer via a N-C-C-N bridge. Such end-on or monodendate complexation has been observed in the complexes of Ag(I) with EDA (31, 32). Cs(I) and Rb(I) probably do not form either type of complex and are not solvated to any appreciable extent.

[a] Data in parentheses are for $I\eta^{1/2}$: product of the diffusion current constant and the square root of the viscosity. The diffusion current constant is in units of $\mu A\ mM^{-1}\ mg^{-2/3}\ sec^{1/2}$; the viscosity is in centipoise.
[b] Solvent abbreviations are given in Table I.
[c] $I\eta^{1/2}$ values are quoted to two significant figures because the viscosity of pyridine is given for 20°C. For the calculation, a "25°C" value of η was used by assuming a 2% per degree temperature coefficient.
[d] Data for 30°C; I values are calculated from current values at maximum drop size.
[e] Recently, the viscosity of propylene carbonate has been reported (41) to be 2.48 centipoise. Use of this value would change the $I\eta^{1/2}$ products for this solvent by 0.86.

Dimethylformamide.—The $\Delta E_{1/2}$ and I values for DMF given by Brown *et al.* (10) and Headridge *et al.* (17) and the $\Delta E_{1/2}$ values of Humar and Pantony (13) are consistent; there is solvation of Li(I). The latter (13), however, report very large I values which are in poor agreement with the other data; the discrepancy may lie in the method of measurement of the diffusion current. The solvation complex, which is probably formed between the nitrogen of DMF and Li(I), is not as resistant to reduction as the corresponding complex with DMA. This slightly enhanced activity may well be related to the presence of an H—C(=O)— group in the cluster of methyl groups. The diffusion current constant suggests that the complex is similar in bulk to the Li(I)-DMA entity.

Pyridine.—Li(I) forms a stable complex with pyridine (33) and there is strong evidence to suggest that electroreduction involves fission of a C-N bond in one of the pyridine molecules attached to the lithium ion (1). When small amounts of water are present, another process apparently is observed whereby a pyridine ring, which is hydrogen bonded through a water molecule to Li(I), also is opened by reductive fission, *e.g.*, two reduction peaks are observed when water is present.

Water.—Reduction of Li(I) in water proceeds to the amalgam, although cyclic voltammetry and stripping voltammetry indicate that the generation is not quantitative. However, the aquo solvation does not appear to hinder reduction to the degree observed with the previously discussed solvents. The faradaic rectification technique used by Imai and Delahay (5) shows a slightly lower corrected heterogeneous rate constant for the electroreduction of Li(I) than for the other alkali metal ions ($k^t_{Li(I)} = 0.002$; $k^t_{Na(I)} = 0.009$; $k^t_{K(I)} = 0.005$ cm sec^{-1}). Although there is little variation in $\Delta E_{1/2}$ for the other alkali metal ions in water, there is a marked trend in the corrected I values, which may well be linked to the abnormal structure of water. Because water is strongly hydrogen bonded with regions of crystalline regularity (ice-like and "quartz-like" structures), the solvation of an ion is much more long range in its effect, *i.e.*, the solvent structure well beyond the first solvation sheath has a measurable influence on the transport rate (34). Because of this long range influence, there is a much more pronounced degradation in solvation from Li(I) through Cs(I) in the case of water, as can be seen from the change in the B coefficient of the Jones-Dole equation (4), which describes the relative viscosity of an ionic solution in terms of the expansion

$$(\eta/\eta_0) = 1 + AC^{1/2} + BC \qquad [1]$$

where η is the viscosity of the salt solution of concentration C, η_0 is the viscosity of water, and A and B are coefficients. The B coefficient is a measure of the ion-solvent interaction and the solvent structure-making or structure-breaking properties of the ion; a large positive value [0.150 for Li(I)] indicates strong ion-solvent interaction and a negative value [−0.045 for Cs(I)] a weak interaction (structure-breaking).

The approximately linear relationship between diffusion current constant (related to diffusion coefficient), I, and B coefficient (Fig. 3) suggests that the variation in I is related to the characteristic change in viscosity of water and hence to the change in structural parameters of ionic aqueous solution. Indeed, it has been proposed that negative values of B indicate a negative solvation of the ionic species (35, 36). The individual I values for each metal ion in water are, however, all larger than the corresponding values in most other solvents. In addition to the structure-breaking properties of the large alkali metal cations, the abnormal proton jump and hydrogen bond exchange mechanisms in water effectively reduce the friction coefficient between ion and solvent below that for ion-nonaqueous systems.

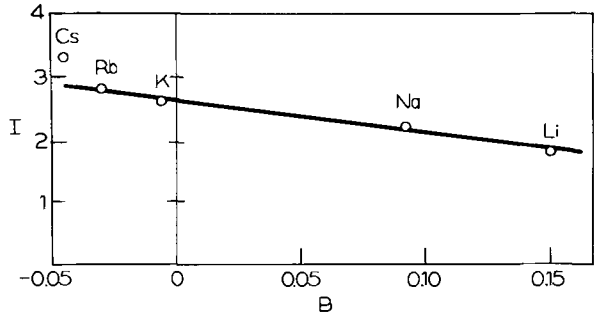

Fig. 3. Dependence of the diffusion current constant, *I*, for the alkali metal cations in aqueous solution on the Jones-Dole *B* coefficient (4). *I* is in μA mM^{-1} mg$^{-2/3}$ sec$^{1/2}$ and *B* is in l mole^{-1}.

The close agreement between Debye-Hückel theory and the solubilities of K(I), Rb(I), and Cs(I) perchlorates in aqueous solution over a range of ionic strength has been interpreted as indicating the virtual absence of ion-pairing (37).

Since factors other than ion solvation can influence the half-wave potential at mercury electrodes, *e.g.*, the free energies of amalgamation and of formation of the alkali metals, the values of such thermodynamic quantities are tabulated in Table IV for comparison with the polarographic data of Table I. The factors involved are discussed by Davies, Schwartz, Yeager, and Hovorka (38).

Morpholine.—In morpholine, the $\Delta E_{1/2}$ values are all very small or zero, except for Li(I), indicating that the lone pair of electrons on either the oxygen atom or the nitrogen atom of the molecule is sufficiently active for morpholine to solvate Li(I) strongly. The corrected I value for Li(I) confirms the bulkier nature of this species.

Nitriles.—The nitrile solvents are considered as a group because the —C≡N group appears to be the dominant influence in electrochemistry in these solvents. It is not clear whether donation from the solvent to the metal ion occurs from the π-bonds of the —C≡N linkage or from the lone pair on the nitrogen atom. However, the π-bonding electrons of the nitrile group form a relatively easy bridge for electroreduction of Li(I), especially in benzonitrile and phenylacetonitrile (least negative $\Delta E_{1/2}$ of the nitrile series), where the π-bonding of the benzene ring probably contributes to the electroreduction mechanism.

Propylene carbonate and sulfolane.—In PC and sulfolane, the small or zero $E_{1/2}$ for the reduction of Li(I) suggests that steric hinderance of solvent molecules prevents the strong solvation which is normally exhibited by this small ion. Of the data on sulfolane (23-25), only the work by Coetzee *et al.* (23) is quoted here since the other two investigations report measurements either at 40°C or at temperatures below the natural freezing point of the solvent. The large I values for Li(I) in both PC and sulfolane further support the

notion that only small or negligible solvation occurs in these two inert solvents.

The presence of water in PC gives rise to a peak on cyclic voltammetry; a plot of the limiting value of $i_p/v^{1/2}$ *vs.* concentration of water yields a straight line from 50 to 600 ppm of water (39). The same workers showed that water can be determined chronopotentiometrically and inferred that an insoluble porous film of LiOH was formed over part of the electrode as a result of proton reduction. A similar effect was also noted by Dey (40).

Mass Transfer to a Rotating Disk

B. T. Ellison[1] and I. Cornet*

Department of Mechanical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Experimental rates are reported for oxygen mass transfer to a disk rotating in 3½% (0.6M) aqueous NaCl. Average Sherwood numbers, $\overline{Sh}$, were obtained over a range of temperatures from 0.6°C (33°F) to 100°C (212°F), a range of Reynolds numbers, Re, from 10^4 to 1.18 x 10^7, and a range of Schmidt numbers, Sc, from 34 to 1400. The laminar flow results agree with generally accepted theories such as the Newman extension of the Levich theory, Sparrow and Gregg, and Gregory and Riddiford. Transition from laminar to turbulent flow was found to occur at $Re = 3.0 \times 10^5$. A least squares analysis indicates that the turbulent flow results for $8.9 \times 10^5 < Re < 1.18 \times 10^7$ and $34 < Sc < 1400$ can be correlated by

$$\overline{Sh} = 1.17 \times 10^{-2} Re^{0.896} Sc^{0.249} \quad \text{(I)}$$

with a standard error of the estimate of ±8.9%. For $3.0 \times 10^5 < Re < 8.9 \times 10^5$, Eq. (I) requires modification because there are significant contributions (over 10%) to the average Sherwood number due to laminar flow in the center. The experimental average Sherwood numbers agree well with friction analogy theories using either the Tien, Wasan, and Wilke or the Deissler eddy diffusivity profiles.

The present investigation is concerned primarily with mass transfer characteristics by induced flow about a disk rotating at very high Reynolds number in turbulent flow.

Heat, mass, and momentum transfer by flow about a rotating disk have been studied extensively in recent years not only because of their importance in practical applications but also because the disk is a convenient experimental tool for the study of three-dimensional boundary layers. Work on transport about a rotating disk is summarized by Kreith (1), Dorfman (2), Riddiford (3), and Levich (4). Laminar flow heat and mass transfer to a rotating disk has been studied extensively, and generally good agreement between theory and experiment has been recorded, *e.g.*, Cobb and Saunders (5), Riddiford (3), Tien and Campbell (6), Newman and Hsueh (7), Daguenet (8), Kreith *et al.* (9). Some semitheoretical and approximate theories have been developed for turbulent flow about a rotating disk by Kreith *et al.* (9), Davies (10), Dorfman (11), Levich (4), and Hartnett *et al.* (12). There have been several experimental investigations of heat or mass transfer to a rotating disk in induced turbulent flow by Kreith *et al.* (9), Tien and Campbell (6), Daguenet (8), Cornet and Kaloo (13), and Cobb and Saunders (5); however, these investigations have generally covered a limited range of Reynolds numbers.

Previous investigations have shown that when a rotating disk induces turbulent flow, the central portion of the fluid will be in laminar flow up to a local Reynolds number of about 2.5 x 10^5, depending on surface roughness, Cornet *et al.* (14). For a disk rotating at a Reynolds number below 10^6 and at Schmidt numbers below 1000, there are significant contributions to the average Sherwood number from the fluid in laminar flow. The maximum Reynolds numbers obtained in previous investigations were 7 x 10^5 (5, 6, 9), 10^6 (13), and 1.4 x 10^6 (8). It is difficult to ascertain from such data the behavior of the fully turbulent portion of the fluid, because the laminar portion accounts for more than 10% of the average Sherwood number. One objective of the present work was to obtain mass transfer data for Reynolds number $>10^6$, where the contributions to the average Sherwood numbers from the laminar portion of the fluid are negligible.

Key words: corrosion, turbulence, cathodic protection, oxygen reduction.

Preliminary Considerations

Typically mass transfer rates for flow about a rotating disk are presented in the form of local or average Sherwood number as a function of the local or over-all Reynolds number and the Schmidt number. The local Sherwood number is defined as

$$Sh = N\, r/(D\, \Delta C) \quad [1]$$

where, N = mass flux to the disk
r = local radius
D = diffusion coefficient
ΔC = concentration difference between bulk and surface

The average Sherwood number is defined as

$$\overline{Sh} = \overline{N}\, r_o/D\, \Delta C \quad [2]$$

where

$$\overline{N} = 2r_o^{-2} \int_0^{r_o} N\, r dr$$

The local mass transfer rate to a rotating disk in the laminar regime is given as

$$Sh_{lam} = C_1\, Re^{1/2}_{local}\, Sc^{1/3} \quad [3]$$

where C_1 is specified for high Schmidt numbers by Levich (15), for Schmidt numbers greater than 100 by Newman (16), and for Schmidt numbers lower than 100 by Sparrow and Gregg (17). The local Sherwood number in turbulent flow is given by

$$Sh_t = C_2\, Re^m_{local}\, Sc^n \quad [4]$$

where m has been given as 0.8 by various investigators (9-12), but as 0.9 by Levich (4). Values proposed for n have ranged between ¼ and 1. Equations [3] and [4] can be integrated to give

$$\overline{Sh}_{lam} = C_1\, Re^{1/2}\, Sc^{1/3} \quad [5]$$

or

$$\overline{Sh}_t = C_3\, Re^m\, Sc^n \quad [6]$$

The average Sherwood number for a disk with the outside flow turbulent and center in laminar flow can be expressed as

$$\overline{Sh} = r_c/r_o\,[\overline{Sh}_{lam,c} - \overline{Sh}_{t,c}] + \overline{Sh}_t \qquad [7]$$

where c denotes that the Sherwood number is evaluated at the radius at which transition from laminar flow begins. For Reynolds numbers $>10^6$ and Schmidt numbers >34, accepted correlations show

$$\overline{Sh} \simeq \overline{Sh}_t$$

within 10%. Equation [6] then is an asymptote which has been approached by previous investigators and reached for a short Reynolds number span by Cornet and Kaloo and by Daguenet.

Equipment and Procedure

Mass transfer rates were measured by determining the current required to reduce oxygen arriving at the surface of a rotating disk in 3½ weight per cent (w/o) aqueous sodium chloride solution.

The over-all electrochemical reaction may be considered to be

$$O_2 + 2H_2O + 4e^- \leftrightarrow 4\,OH^- \qquad [8]$$

Under limiting current conditions the oxygen concentration at the cathode solution-metal interface may be taken as zero.

Equipment is shown schematically in Fig. 1. The cathode was a 24.8 cm (9¾ in.) diameter monel 400 alloy (ASTM B16.4 Class A) disk insulated on the back and outer edges. The disk rotated in a 64.5 cm (24 in.) diameter, 78.6 cm (31 in.) long, steel pressure vessel coated with coal tar epoxy on the inside to prevent corrosion. The anode was a titanium disk 38.1 cm (15 in.) in diameter with strips of platinum foil 64.5 cm^2 (10 $in.^2$) in area attached to the titanium by spot-welding. The anode was bolted to the back head of the pressure vessel and insulated from it. The reference electrode was 99.99% silver, partially coated with silver chloride, immersed in the 3½% aqueous NaCl. This electrode was insulated by a glass tube, inserted through the back head and through an opening in the anode, so that about 0.63 cm (¼ in.) of the electrode extended beyond the glass tube, to within 2.54 cm (1 in.) of the cathodic disk.

The disk was driven by either a 3 or a 15 hp motor, at speeds ranging from 10 to 2500 rpm. Temperatures between 0.6°C (33°F) and 100°C (212°F) were obtained by circulating the fluid between experiments through an outside heat exchanger. Oxygen concentration in solution was determined by Winkler analysis (18). Additional details of equipment and procedure are available (19).

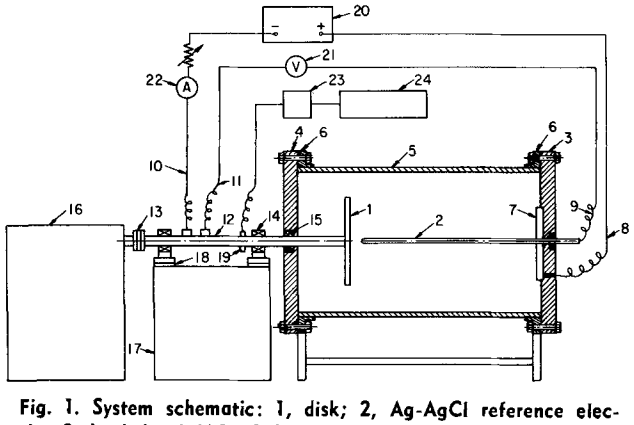

Fig. 1. System schematic: 1, disk; 2, Ag-AgCl reference electrode; 3, back head (ASA 250 lb standard blind flange); 4, front head (ASA 250 lb standard blind flange); 5, shell (24 in. dia. ½ in. wall SA-53); 6, 2—ASA 250 lb standard slip-on welding flanges; 7, platinum titanium anode; 8, anode lead wire (insulated from head); 9, probe lead wire; 10, current supply; 11, potential measuring contact; 12, shaft; 13, insulating coupling; 14, 2—bearings; 15, packing gland; 16, 15 hp motor Varidrive; 17, bearing support table; 18, insulating block; 19, 60-tooth gear and induction pickup; 20, regulated power supply; 21, high impedance voltmeter (Hewlett Packard 412A); 22, ammeter (Weston 430); 23, pulse amplifier; 24, counter.

Results and Discussion

A typical set of polarization curves is shown in Fig. 2. The mass transfer limiting current, *i.e.*, the mass flux of oxygen to the surface of the disk when the concentration of oxygen on the surface is zero, was chosen as the point of inflection on the polarization curves. From the limiting current data of Fig. 2, it is possible to evaluate Sherwood number, $Sh = qr/n\mathbf{F}D\Delta C$ at a given Reynolds number $Re = r^2\omega/\nu$. The diffusion coefficient for oxygen, D, was obtained by applying a temperature correction, after Wilke (20), to values from the International Critical Tables.

Typically the limiting current could be determined from the point of inflection to within ± 5%. In Fig. 2 some of the curves at similar rpm's represent differing oxygen concentrations, so the agreement in mass transfer is better than the curves might imply.

The experimental average Sherwood numbers for laminar flow are shown in Fig. 3 and 4 as a function of Reynolds number for Schmidt numbers of 53, 110, 400, and 1400, which correspond to electrolyte temperatures of 82°C (180°F), 54°C (130°F), 24°C (75°F), and 0.6°C (33°F). It is seen that the experimental data agree with well-known theoretical predictions within 5%, except for the lowest Reynolds numbers where free convection may be contributing substantially to the mass transfer. Agreement with conventional heat and mass transfer correlations is obtained by assuming four electrons are transferred per molecule of oxygen in the mass transfer limited cathodic reduction.

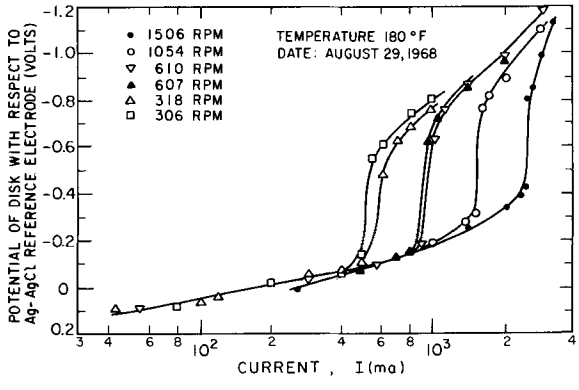

Fig. 2. Polarization curves

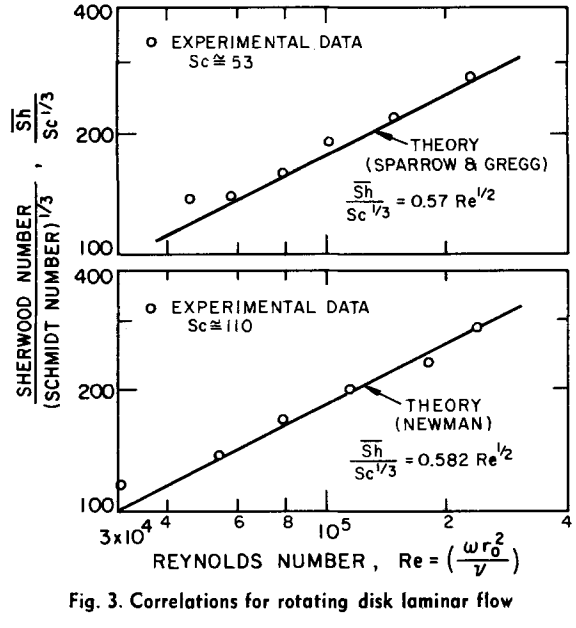

Fig. 3. Correlations for rotating disk laminar flow

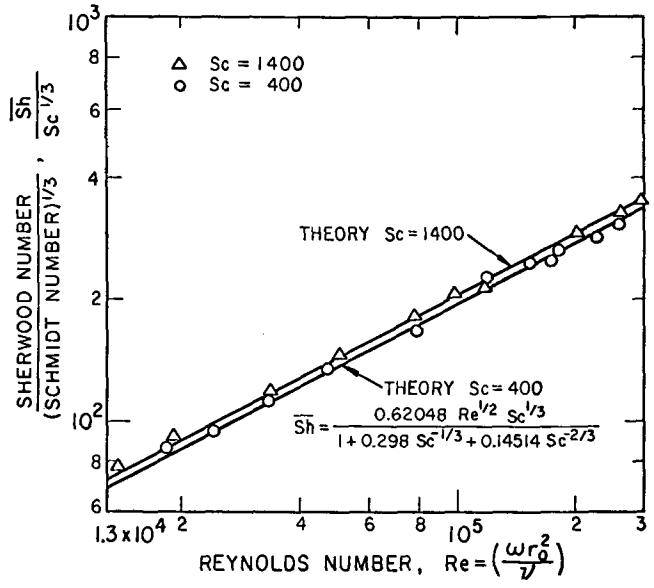

Fig. 4. Rotating disk laminar flow (theory after J. S. Newman)

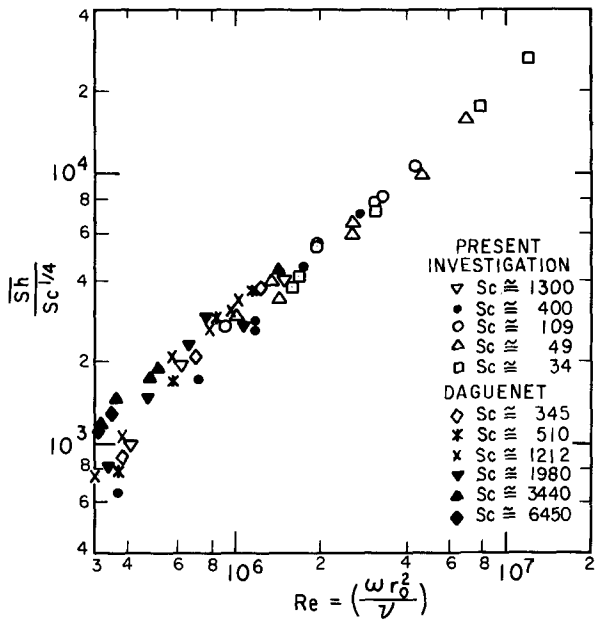

Fig. 6. Rotating disk turbulent flow

There was some variation of temperature between several experimental runs so that the actual value of the Schmidt number may differ by as much as 7% from the mean value reported; however, the actual value of the Schmidt number was used to calculate the ratio $\overline{Sh}/Sc^{1/3}$ for the plotted experimental points.

Transition from laminar to turbulent flow was found to occur at $Re = 3.0 \times 10^5$.

Figure 5 is a plot of $\overline{Sh}/Sc^{1/4}$ *vs.* Re for turbulent flow with Schmidt numbers of 34, 49, 109, 400, and 1300. Note that most of the data presented are for Reynolds numbers above 10^6 and that the highest Reynolds number attained was 1.18×10^7, which is almost an order of magnitude higher than previous published heat or mass transfer data.

Above a Reynolds number of 8.9×10^5 a straight line can be passed through the data. A least squares analysis indicates that the equation of the best straight line through the data is

$$\overline{Sh} = 1.17 \times 10^{-2}\ Re^{0.896}\ Sc^{0.249} \qquad [9]$$

with a standard error of the estimate of ± 8.9%.

Figure 6 is a plot of the present data and the high Schmidt number electrochemical mass transfer data of Daguenet. There is considerable scatter in the data at low Reynolds numbers. As the Schmidt number changes, the extent of the laminar contribution to the over-all Sherwood number changes. It is seen, however, that as the Reynolds number increases the scatter decreases, until at a Reynolds number above 8.0×10^5 Daguenet's and the present data are in reasonable agreement.

Figure 7 is a plot of the present data and representative points from Kreith, Taylor, and Chong (9), and Tien and Campbell (6) for the mass transfer of naphthalene ($Sc = 2.4$) as well as the heat transfer data of Cobb and Saunders (5) for $Pr = 0.72$. The ratio $\overline{Sh}/Sc^{1/4}$ is slightly lower for the naphthalene mass transfer than the present results and considerably lower for the heat transfer results. The reason for this is that as the Prandtl or Schmidt number decreases both the laminar and turbulent flow asymptotes decrease (17, 21).

Previous theories except for Levich's (4) do not agree with the data since their forms are

$$\overline{Sh_t} = C_3\ Re^{0.8}\ Sc^n \qquad [10]$$

The Levich theory with its unspecified constant fits the

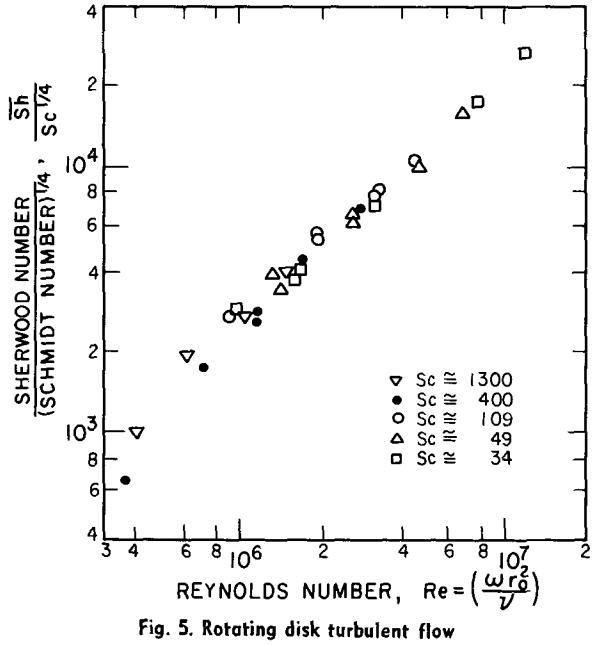

Fig. 5. Rotating disk turbulent flow

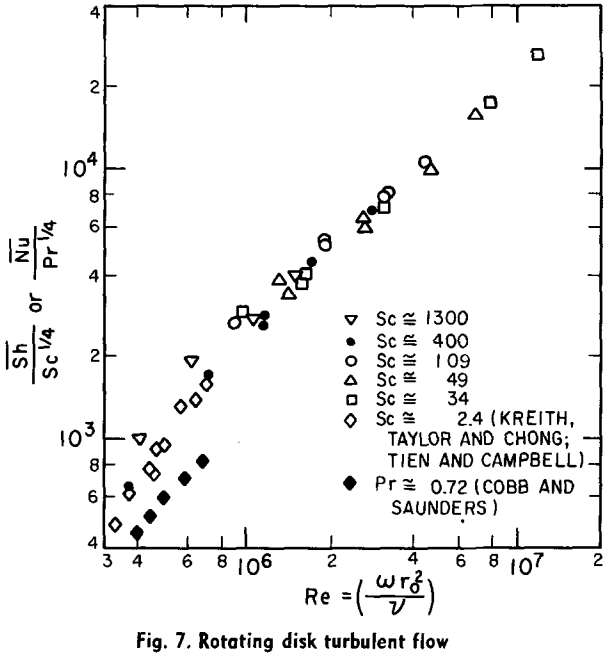

Fig. 7. Rotating disk turbulent flow

data since it predicts approximately the right power of the Schmidt and the Reynolds numbers.

$$\overline{Sh}_t = C_3\, Re^{0.9}\, Sc^{1/4} \qquad [11]$$

Previous theories except for Levich do not agree too closely with the present experimental data since they were developed for low Schmidt number flows. At low Schmidt numbers, the Sherwood number is proportional to the Reynolds number times the friction factor, whereas for high Schmidt numbers the Sherwood number is usually considered to be proportional to the Reynolds number times the square root of the friction factor (21-23).

Using Kreith's technique (9), but with a friction factor after Dorfman (2) and with eddy diffusivity profiles of either Deissler (21) or Tien, Wasan, and Wilke (22, 23) two equations have been derived which closely fit the present experimental results. Dorfman's friction factor (2) was chosen because it agrees more closely with the drag data than the previous theories of von Kármán (24) or Goldstein (25). The correlation based on the Deissler eddy diffusivity profile yields for the average Sherwood number

$$\overline{Sh}_t = 1.12 \times 10^{-2}\, Re^{0.91}\, Sc^{0.25} \qquad [12]$$

The Tien, Wasan, and Wilke correlation yields

$$\overline{Sh}_t = 5.93 \times 10^{-3}\, Re^{0.91}\, Sc^{0.34} \qquad [13]$$

Both of the above correlations are approximations valid for high Schmidt numbers. The Deissler high Schmidt number approximation predicts Sherwood numbers about 8% too high (when compared to Deissler's exact solution) at a Schmidt number of 34. The high Schmidt number approximation of the Tien, Wasan, and Wilke theory predicts values of the Sherwood number about 1% too high.

Both theories predict that the power of the Reynolds number is 0.91 as compared to the experimental value of 0.896. The Deissler theory more closely predicts the experimental value of the power of the Schmidt number, 0.249, than does the Tien, Wasan, and Wilke theory. Figure 8 shows a representative plot of average Sherwood number as a function of Reynolds number for constant Schmidt number, as well as the predictions of Eq. [12] and [13]. From Fig. 8 it is seen that the Eq. [12] based on a Deissler eddy diffusivity profile is almost an upper bound for the experimental data and that Eq. [13], based on a Tien, Wasan, Wilke eddy diffusivity profile is almost a lower bound on the data.

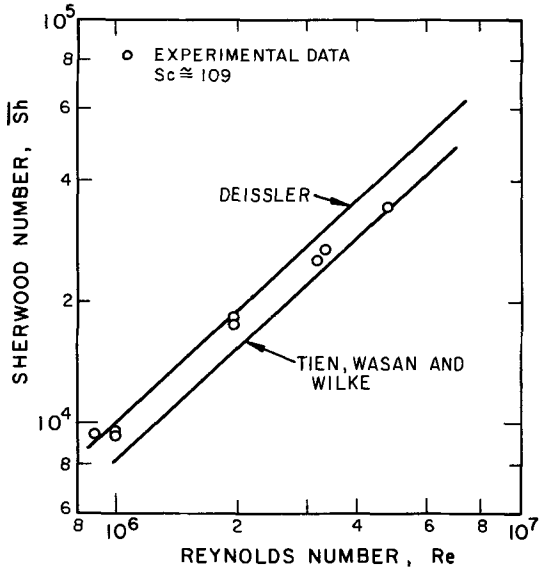

Fig. 8. Sherwood number vs. Reynolds number for Schmidt number ≃ 109.

It is remarkable that the above two equations fit the experimental results so closely. They are based on eddy diffusivity profiles which were developed for pipe flow data, where the only mean velocity component is along the axis of the pipe; in contrast, the rotating disk has a three-dimensional boundary layer with mean velocity components in the radial, circumferential, and axial directions.

Conclusions

It can be concluded from the experimental results that for Reynolds numbers between 8.9 x 10^5 and 1.18 x 10^7 and for Schmidt numbers between 34 and 1300 the mass transfer rate to a rotating disk can be represented by

$$\overline{Sh} = 1.17 \times 10^{-2}\, Re^{0.896} Sc^{0.249}$$

Furthermore, this correlation may be closely approximated from a friction analogy, using either the Deissler or Tien, Wasan, and Wilke diffusivity profiles.

LIST OF SYMBOLS

ΔC	difference in concentration of oxygen between bulk of solution and metal-fluid interface, g moles/cm³
C_1, C_2, C_3	constants
$C_3 = \frac{2}{1+2m} C_2$	an integration constant
D	diffusion coefficient, cm²/sec
$\mathbf{F}$	Faraday's constant, 96,500 coulomb/g equivalent
m, n	exponential constants
n	number of electrons transferred in electrochemical reaction, in $Sh = qr/n\mathbf{F}D\Delta C$
N	mass flux to the disk, g moles/(cm² sec)
$\overline{N}$	average mass flux to the disk
q	current density, A/cm²
r	local radius, cm

Subscripts

c	critical radius at which transition from laminar flow begins
lam	laminar
o	outside
t	turbulent

Greek Symbols

ω	angular velocity, radians/sec
ν	kinematic viscosity, cm²/sec

Dimensionless groups

Re	Reynolds number, $r^2\omega/\nu$
Sc	Schmidt number, ν/D
Sh	local Sherwood number, $Nr/(D\Delta C)$
$\overline{Sh}$	average Sherwood number

The Transient Behavior of Graphite-Silver Iodide and Platinum-Silver Iodide Interfaces in a Solid-State System

Michael N. Hull* and Arthur A. Pilla*

ESB Inc. Research Center, Yardley, Pennsylvania 19067

ABSTRACT

The electrochemical characteristics of the interface formed by solid silver iodide in contact with either platinum or graphite have been studied by linear sweep voltammetry, chronopotentiometry, and the potential and current step techniques. The results indicate that the graphite-silver iodide interface exhibits pure double-layer behavior over the potential range of -0.03 to $+0.46$V (*vs.* Ag/AgI), with no frequency dispersion effects observed up to approximately 1 MHz. In contrast, pure double-layer behavior could not be isolated for the platinum-silver iodide case under the same conditions. It is suggested that, for cathodic potentials, this is due to the rapid discharge of silver atoms onto the platinum surface at subunit activity, and at anodic potentials to liberation of iodine. Comparison of the two electrode systems in terms of recent ideas concerning molten salt double-layer behavior indicates that in both of these systems, the double layer is essentially determined by the structure of solid AgI. The graphite interface behaves very much in an ideally polarized manner while the platinum interface behaves very much as an ideally reversible system because of the rapid faradaic reactions prevalent throughout the entire accessible potential range.

In recent years there has been a growing reawakening of interest in the use of solid electrolytes in power sources. This has been primarily due to the discovery of a family of compounds of general formula M Ag_4I_5 (where M = K, Rb, or NH_4) which have an ionic conductivity of comparable magnitude to that normally associated with good liquid electrolytes (1-11). In these compounds, and also in the parent compound, silver iodide, conduction occurs solely by the movement of silver entities through the crystal lattice. It is therefore both of theoretical and practical interest to begin to obtain more basic information on the nature and kinetics of electrochemical processes which can occur in solid-state systems.

One of the major questions to be answered is that concerning the structure of the solid electrolyte-electrode interface. This is particularly so in view of the considerable theoretical and experimental work which has been reported (12-23) concerning space charge polarization in solid and liquid systems. These studies, which actually involve diffuse double-layer behavior, have attempted to explain the frequency dispersion noted when, *e.g.*, a solid electrolyte in contact with an ideally polarizable electrode is perturbed using a-c or transient techniques. The exact manner in which the diffuse double layer responds as a function of the frequency of a low level perturbation is still somewhat unclear (23). It is, however, certain that as charge is injected onto an ideally polarizable electrode, it is possible for a static concentration gradient of an ionic species of given sign to be established which extends to a significant extent into the bulk electrolyte. This phenomenon is, of course, well known in dilute aqueous electrolytes (24-26). However, it has also been observed in solid electrolytes (27) and suspected in molten salts (21). In a typical study of solid electrolytes (16), the a-c impedance of Ag/AgBr/Ag and Au/AgBr/Au arrays at temperatures of 200°-300°C was determined. Frequency dependent resistance and capacitance effects, with the latter having values of the order of 100 $\mu F \cdot cm^{-2}$, were observed. The interpretation of these and other similar studies is open to some doubt since, although no steady state faradaic current can flow through an array such as Au/AgBr/Au within the potential limits of stability

of the electrolyte, a transient faradaic current is possible as will be seen below. More recent work (28, 29) has pointed out that the study of such arrays can be placed on a more thermodynamically reasonable basis if one of the electrodes is reversible to one of the electrolyte components while the other electrode is inert. At the inert electrode, there again will exist a potential range over which no steady-state current will flow, but a transient faradaic current is possible which, according to the Nernst equation, will tend to readjust the activity of each of the electrolyte components at the inert electrode according to the applied d-c potential. For example, in the system Ag/AgI/M, where M is an electrode having no common ion with the electrolyte, the activity, a, of Ag and I_2 at the M/AgI interface is given by, for Ag

$$a_{Ag} = \exp - \frac{FE}{RT} \quad [1]$$

and for I_2

$$a_{I_2} = \exp - \frac{2F(E_D - E)}{RT} \quad [2]$$

where E_D is the decomposition potential of the electrolyte, E the potential of M with respect to Ag/AgI; the other terms have their usual significance. For a given change in the inert electrode potential, E, both a_{Ag} and a_{I_2} undergo a readjustment by faradaic processes, the rates of which are, of course, not predicted by Eq. [1] and [2]. It is expected, however, that the ease with which, *e.g.*, an M-Ag bond forms determines to a great extent these rates as has been shown in recent work concerning the Pt/Cu and Pt/Bi systems (30).

An interesting recent study (28) examined the double-layer behavior of the interface formed between a single crystal of silver bromide with single and polycrystalline graphite, platinum and gold electrodes at temperatures of 244°-292°C. This investigation showed that the response of such interfaces to potential step perturbations could not be represented by a simple RC series network as would be expected for pure double-layer behavior (17, 31), but that the cell response consisted of a mixture of several time constants. This behavior was suggested to be analogous to the frequency dependence of the a-c capacitance which is observed in aqueous systems at many solid electrodes (32, 33). Electrode capacitance values, calculated by dividing the total charge transferred during the repolarization of the interface by the magnitude of the potential step, gave values of several hundred $\mu F \cdot cm^{-2}$ for platinum electrodes and values approximately one order of magnitude smaller with graphite. However, the high temperature of these systems most probably resulted in relatively high rates for the faradaic processes, rendering the separation from double layer charging difficult.

The work described here examines the properties of the interface formed between a polycrystalline electrolyte and two polycrystalline electrodes at room temperature, thus keeping the faradaic reaction rate as low as possible. The system Ag/AgI/M where M is graphite or Pt was examined, silver iodide was chosen as the electrolyte in view of its relatively high ionic conductivity (0.0001 mho-cm^{-1}) at room temperature compared to other simple solid electrolytes. It may be noted that the intrinsic conductivity of AgI at room temperature is $\sim 10^{-8}$ ohm^{-1} cm^{-1}, but higher values are observed where grain boundary conduction predominates as is the case for the polycrystalline material utilized in this study.

Experimental

The experimental cell, which consisted of a silver counterelectrode, silver iodide electrolyte in which a small silver wire was imbedded to act as a reference electrode, and a platinum or graphite working electrode, was assembled by compressing the various constituents together in a steel die under a pressure of 40,000 psi to produce a pellet of 1.27 cm diameter and 0.2 cm thick. The procedure followed before pressing the pellet was as follows: 0.4g of powdered silver was placed in the die and pressed lightly to give a smooth, compacted surface. On top of this, 0.4g of powdered silver iodide was evenly spread and lightly compacted followed by a 2.0 cm length of 0.0122 cm diameter silver wire which was positioned for a portion of its length along the circumference of the die. Another 0.4g portion of the silver iodide was then added and again gently compacted to give a flat surface on top of which 0.05g of either powdered platinum black or powdered pyrolytic graphite was spread. The die contents were then compressed at the designated load. After removal of the pellet from the press, it was carefully sanded along the edge to reveal the wire reference electrode which was then pulled out at right angles to the cell as shown in Fig. 1. The cell was clamped between Teflon blocks, electrical contact being made to the counter and working electrodes by means of "plastic carbon" disks interposed between each of the Teflon blocks and the corresponding electrode. The complete experimental cell is shown in Fig. 1. Due to the fact that cumulative effects of repeated experimental runs on any one cell were not negligible, a fresh pellet was used for each run of each type of experiment. In this way, excellent reproducibility of the system response was obtained.

Anodic and cathodic potential and current perturbations were applied to the study electrode as shown in Fig. 2 and 3. For the potentiostatic experiments (see Fig. 2), a fast-rise Tacussel PIT 20-2X Potentiostat (A, Fig. 2) was programmed from a Tacussel GITP Pulse Generator (G, Fig. 2) for the step experiments or a Tacussel GSTP-2 Function Generator (G, Fig. 2) for linear sweep studies. For galvanostatic measurements, the potentiostat was employed in the mode shown in Fig. 3. In this, a resistor, R, (Fig. 3) two orders of magnitude greater than that of the ohmic resistance of the cell was placed in series with the latter. In addition, the feedback arrangement was such that a potential step could be applied across both R and the cell allowing the potentiostat (A, Fig. 3) to operate in its fastest mode (34).

Because of the large electrolyte resistance ($\approx$ 300 ohms) and the high electrode capacitances encountered

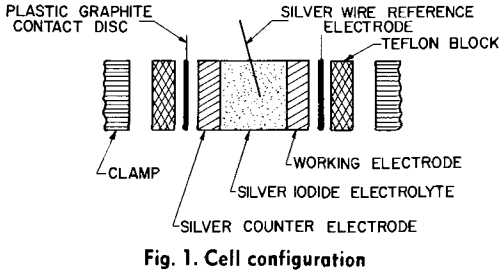

Fig. 1. Cell configuration

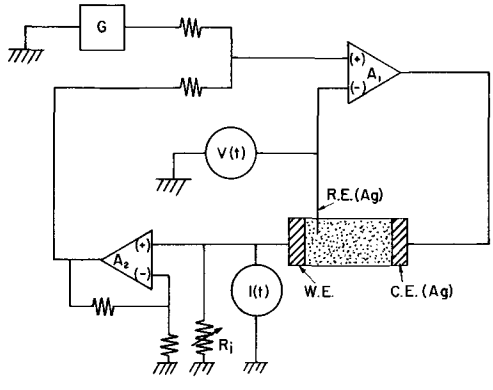

Fig. 2. Block diagram of the circuit employed for potentiostatic experiments with IR compensation.

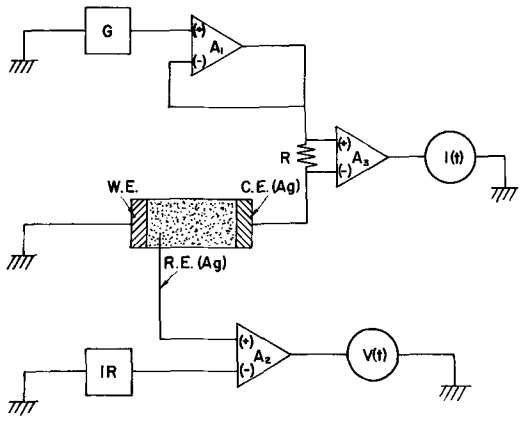

Fig. 3. Block diagram of the circuit employed for galvanostatic experiments with IR compensation.

(up to several thousand $\mu F/cm^2$), it was necessary in both potentiostatic and galvanostatic studies to introduce ohmic drop compensation. In the former case, (see Fig. 2), this was accomplished by reinjecting (via A_2, Fig. 2) a signal proportional to the magnitude of the current flowing through the cell back into the noninverting input of the potentiostat. Details of this circuitry have been published elsewhere (34). This mode of operation allows a critically damped current response having a minimum time constant (τ_{min}), beyond which the system exhibits damped oscillations (34), approximately two orders of magnitude lower than that of the uncompensated system to be readily achieved.

For galvanostatic studies, the ohmic component of the voltage response was removed by employing a high-speed differential probe (Tektronix P6046, A_2 Fig. 3) arranged as shown in Fig. 3. It can be seen that by applying a d-c voltage (IR, Fig. 3) to the inverting input of the differential probe of magnitude equal to that of the observed IR component appearing at the noninverting input, the ohmic-free voltage response of the electrode is obtained. All current and voltage functions were displayed on a Tektronix 565 dual beam, dual time base oscilloscope (V(t) and I(t), Fig. 2 and 3) utilizing type 3A7 differential input preamplifier plug-ins (A_3, Fig. 3).

Results

Linear sweep voltammetry and chronopotentiometry. —The over-all electrochemical behavior of each array was investigated by sweeping the potential of the study electrode in both the anodic and cathodic directions from an initial starting potential of +0.46V (*vs.* Ag/AgI). This value was chosen since platinum cells exhibited an open-circuit potential of +0.46V within several minutes of their construction. (Initially, the open-circuit potential of the array is zero since the cell is in a shorted state until it is removed from the steel die.) As Eq. [1] and [2] show, a potential of +0.46V corresponds (for $E_D = 0.68V$) to that at which the activity of silver and iodine at the platinum-silver iodide interface are equal (and, therefore, minimum). In contrast, graphite cells maintained an open-circuit voltage of zero after construction. However, this electrode could be polarized to any potential between approximately −0.03 and +0.5V, and the imposed voltage would be retained under open circuit conditions indefinitely. Thus the graphite-silver iodide interface appears to be an example of an ideally polarized interface (35) in a solid-state system.

As may be seen from Fig. 4, no appreciable faradaic current is observed to flow across a graphite-silver iodide interface as the potential is swept cathodically (region A-B) until an electrode potential of approximately −0.03V is attained, at which point silver deposition commences abruptly. This type of behavior indicates that Eq. [1] is not obeyed in the graphite case within the time scale of the experiments described here and that there is therefore no silver on the surface initially even at a potential of zero corresponding to an activity of unity. After the sweep direction is reversed at C, silver deposition occurs at potentials below the initial starting point, B. This shows that further deposition onto the electrode is occurring at those sites which are already covered with a layer of deposited silver and that this process can continue at a lower overvoltage than that required for deposition onto the silver-free sites. Between D and A, the deposited silver is removed from the surface and the current passes through a peak at about 0.1V.

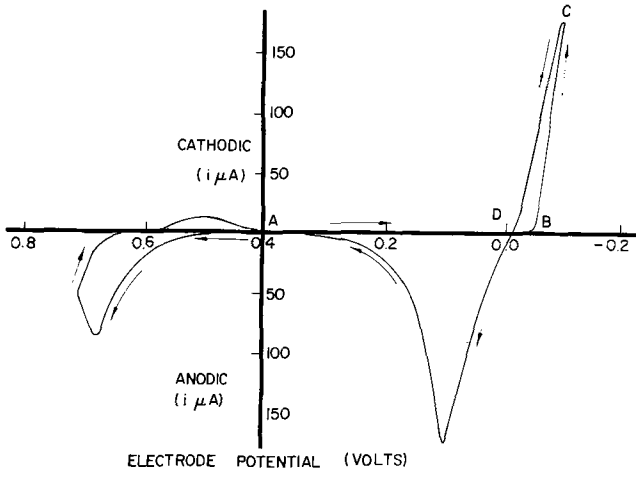

Fig. 4. Current-potential behavior of a graphite electrode recorded at a sweep rate of 5 mV-sec^{-1}.

The above behavior may be contrasted to that exhibited by platinum cells as shown in Fig. 5. One may see that, in this case, an increasingly larger amount of current flows through the system at all potentials cathodic to the cell open-circuit potential of +0.46V. This type of behavior suggests that silver deposition is taking place on the platinum electrode at subunit activity according to the dictates of Eq. [1]. After sweep reversal, an anodic peak due to the removal of silver from the surface is again observed similar to that in the graphite case. This is to be expected since silver is being removed from silver in both cases.

The liberation of free iodine occurs at approximately +0.5V for graphite and +0.46V for platinum electrodes during an anodic potential sweep as can be seen from Fig. 4 and 5. The liberated iodine, in each case, gives rise to a broad reduction peak on the return sweep.

Chronopotentiometric studies were conducted using various cathodic currents with the study electrodes at

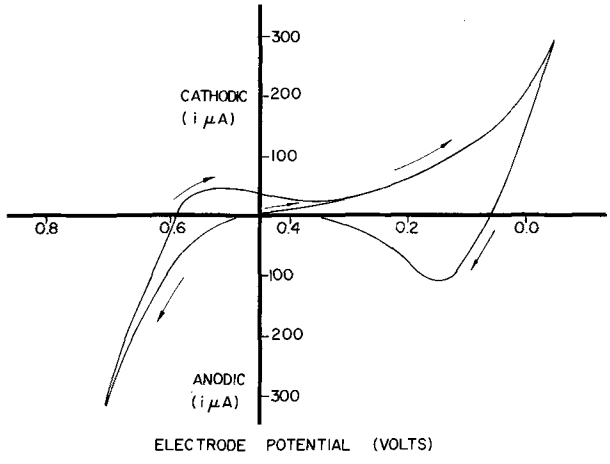

Fig. 5. Current-potential behavior of a platinum electrode recorded at a sweep rate of 5 mV-sec^{-1}.

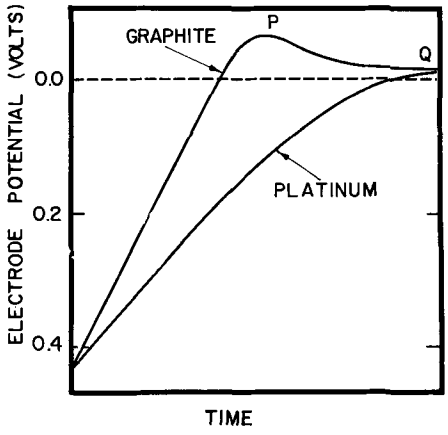

Fig. 6. Schematic illustration of the differences in chronopotentiometric behavior between graphite and platinum electrodes.

an initial potential of +0.46V similar to the linear voltage sweep studies. The general behavior exhibited by each electrode is shown schematically in Fig. 6. It can be seen that the potential of a graphite electrode underwent a linear increase with time until the abrupt onset of silver deposition at P. The potential then decreased to a steady-state value at Q. This potential overshoot which corresponds to the behavior exhibited using linear sweep conditions (see BCD Fig. 4) reflects the gradual transition from silver deposition on graphite to that of silver deposition on silver as a monolayer of silver is built up on the electrode surface. On the other hand, the corresponding response of a platinum electrode did not exhibit linearity, and the approach of the final steady-state value required an order of magnitude longer time than graphite and was not preceded by any "overshoot" region. The above patterns of behavior closely parallel those of the graphite-silver bromide and the platinum-silver bromide interfaces whose behavior at somewhat higher temperatures (244°-292°C) was reported earlier (28).

Both the linear voltage sweep and the chronopotentiometric studies show that there exists a range of potentials from approximately +0.5 to −0.03V for graphite arrays within which no appreciable faradaic reaction occurs and within which one should be able to observe solely the charging of the double layer on application of an appropriate low level perturbation. At potentials more negative than −0.03V and more positive than +0.5V, faradaic processes due to the deposition of silver and the liberation of free iodine, respectively, occur. In contrast, it appears that there is no potential range within which the platinum-silver iodide interface behaves as ideally polarized. The measurement of the double-layer capacitance of this interface could thus be expected to be complicated in all potential regions by faradaic processes associated with either the discharge of silver onto the electrode surface at subunit activity or the liberation of iodine by electrolyte decomposition.

Potential and current step studies.—Potential steps of low amplitude (<5 mV) were applied to each interface with various degrees of ohmic drop compensation. This was achieved by setting the degree of positive feedback, as determined by the value of R_i (Fig. 2), such that either the fastest stable response (τ_{min}) or some fraction of τ_{min}, *e.g.*, 90%, was obtained. In practice, the degree of compensation was adjusted using a "sacrificial" cell which was then replaced by a freshly prepared array for the experimental measurement. All of the results reported here were obtained from the first pulse applied to a new cell.

In Fig. 7, two representative response curves for the graphite-silver iodide interface are presented in semilogarithmic form. These were recorded at + 0.41V (*i.e.*, within the potential range for which no transient

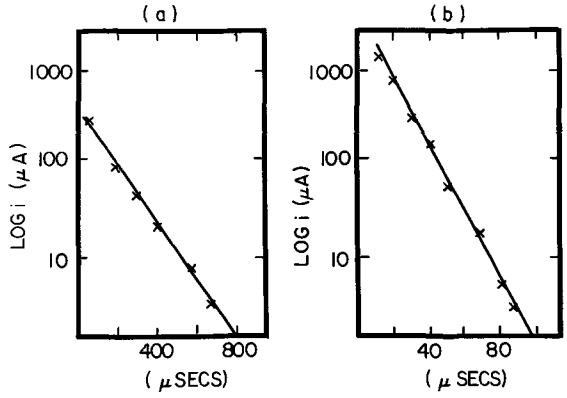

Fig. 7. Semilogarithmic plots of the response of a graphite electrode to a 5 mV potential step for differing degrees of IR compensation: (a) 90% τ_{min}; (b) τ_{min}.

faradaic reaction can occur) and with different degrees of positive feedback. As a first point, it may be noticed that both plots of log *i* *vs.* *t* are completely linear over the whole of the time scale of the charging process as one would expect for a system behaving as a simple RC series circuit. Thus for the cell configuration employed in this investigation, the capacitative properties of these interfaces may be studied without complications of the cell response by frequency dispersion effects. This single time constant behavior exhibited by the graphite-silver iodide interface was observed for times extending to seconds if the degree of IR compensation was sufficiently reduced and may be contrasted to that of the platinum-silver iodide interface for a similar potential step perturbation within the potential region for which no steady-state current can flow but which is active under transient conditions (see Fig. 5). Figure 8 shows the semilogarithmic current-time response curves for a platinum electrode at two different electrode potentials and with 90% τ_{min}. It may be seen that in this case there is no region of the response curve within which linearity of the functions plotted is observed even for times as long as several seconds after application of the potential step, although more recent studies (36) indicate that compensation in the presence of rapid faradaic reactions may be relatively difficult to interpret. Further, the amount of charge required to repolarize the interface is several orders of magnitude larger than that required for repolarization of the graphite-silver iodide interface under identical conditions indicating again that processes in addition to those associated with charging of the double layer are taking place.

In view of the above behavior, galvanostatic studies of the platinum electrode were conducted since IR

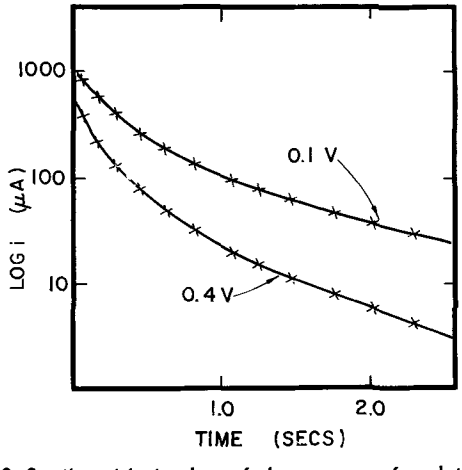

Fig. 8. Semilogarithmic plots of the response of a platinum electrode to a 5 mV potential step at 90% τ_{min}.

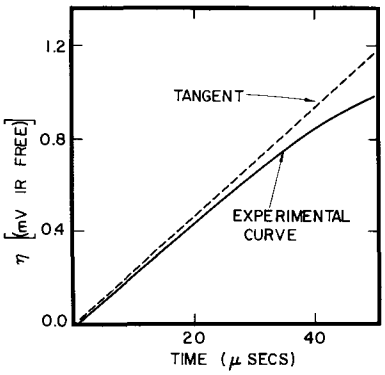

Fig. 9. IR free overvoltage response of a platinum electrode potentiostatted at an initial potential of +0.41V during a cathodic galvanostatic pulse of 780 μA.

free measurements could be made at shorter times than those employing compensated potential steps. It was believed that this procedure would increase the possibility of isolating the double layer parameters in this case. The response of this electrode to a 780 μA cathodic galvanostatic pulse applied at an initial starting potential of +0.41V is shown in Fig. 9. It is evident that even for times of the order of a few microseconds, the potential-time relationship is not linear as would be expected if the system were exhibiting simple RC behavior. A similar form of response curve is observed at all potentials within the studied range. These results indicate that the process giving rise to deviations from simple RC series behavior is still playing a predominant role at these short times. Galvanostatic studies of the graphite-silver iodide interface gave results identical to those observed in potentiostatic studies.

Discussion

One of the advantages of studying the double-layer behavior of a solid electrolyte is the absence of any effects associated with the presence of a solvent. However, although a one-component system should be inherently simple in its behavior, one suffers from the disadvantage that each ion in the double layer is a potentially electroactive species. Thus the problem of achieving an experimental separation between nonfaradaic and faradaic processes might be expected to be greater than for the case in aqueous layer studies where the majority of the ions in the double layer are inert in many cases (37).

The criterion that ideal double-layer charging is being observed has been shown to be the presence of a single time constant over a sufficiently large time range (at least one order of magnitude) from the shortest experimentally accessible times (31). Thus for a potential step experiment in which the rise-time of the step is much shorter than the electrode time constant(s), the double layer capacitance may be calculated from the equation

$$i(t) = \frac{V_o}{R_e} \exp - \frac{t}{R_e C_D} \qquad [3]$$

where V_o is the magnitude of the potential step, R_e the electrolyte resistance, and C_D the total double-layer capacitance. For the galvanostatic case, the equation

$$V(t) = i_o R_e + \frac{i_o t}{C_D} \qquad [4]$$

may be employed where i_o is the magnitude of the current step.

In the graphite case, these equations were found to be obeyed over the whole time range of the electrode response at each potential within the range +0.50 to −0.03V (see Fig. 7). This indicates that in this case, all of the charge accepted by the interface in the above potential range is utilized in solely a nonfaradaic process. In addition, it is evident that for the cell configuration utilized in these studies, as has been pointed out earlier, there is no frequency dispersion of the measured capacitance. This is in contrast to the behavior reported for the graphite-silver bromide interface at temperatures close to the melting point of the electrolyte (28).

Note that in view of the fact that graphite acts as an ideally polarized electrode over the potential range +0.46 to −0.03V, it might be expected that a diffuse double-layer effect would be observed as the potential becomes more cathodic than +0.46V due to the necessary accumulation of positive charge from Ag^+ ions at the interface. The effect of the presence of a diffuse double layer is generally considered to be simply a capacitance one. In other words, it is presumed to be a capacitance, C_d, in series with the inner layer capacitance, C_i, such that $1/C_D = 1/C_i + 1/C_d$, indicating that C_d is a lumped parameter showing no spatial dependence (25). It might therefore be assumed that the series RC model for which Eq. [3] and [4] hold is valid whether or not the diffuse layer capacitance contributes significantly to the measured C_D. This model, however, must inherently be wrong since the very existence of a diffuse double layer presupposes a concentration (and potential) gradient extending into the bulk electrolyte (25). It is thus surprising that the majority of studies concerning the a-c behavior of the diffuse double layer result in an equivalent electric circuit with lumped parameters (23). Exceptions to this are the work of Ferry (12), Anson (20), and Barker (19) who implicitly assume a distributed parameter system for the equilibrium diffuse double-layer structure. Presently work is being conducted in this laboratory to confirm the expected spatial dependence of both the diffuse double layer and the electrolyte resistance (39).

The above discussion indicates that the presence of a diffuse double layer would be expected to result in frequency dispersion with respect to a simple RC series circuit model. However, in order to observe this effect at presently available frequencies, it is necessary that both the total C_d (which can be evaluated from classical diffuse layer theory) be of the same order of magnitude or smaller than C_i, and that the extent to which the concentration (potential) gradient extends into the bulk electrolyte be significant. The second condition results from the conclusion that, in most cases, a simple finite RC transmission line is adequate to describe the spatial dependence of the diffuse double layer (12, 19, 20, 39). Since the line is finite, its behavior, under the boundary conditions present in this problem, will reduce to that of a simple RC series circuit at a frequency depending on the length of the line for a given system. If, in addition, the total impedance of the line is much less than that of C_i, which would tend to be the case if the total C_d, as obtained from the line, is much larger than C_i, it is then virtually impossible to isolate the frequency dependence of the transmission line from that of C_i. Classical diffuse layer theory (24) predicts that, except possibly for potentials very close to the point of zero charge, C_d is much greater than C_i, thus allowing only C_i to be observed.

In the case of solid AgI electrolyte in contact with graphite, the following will show that the spatial dependence of C_d is not likely to be observed. The total charge injected into the graphite/AgI system to move the potential 0.5V cathodic with respect to a potential of +0.46V is 4 μC cm^{-2}. Since solid AgI is a close-packed structure of I^- with highly mobile Ag^+ ions, it appears reasonable to assume that, in order to satisfy this charge requirement, more Ag^+ ions move into the double layer area. A simple calculation based upon the fact that 10^5 coulombs represent 6.23 x 10^{23}

Ag^+ ions shows, however, that there are more than enough Ag^+ ions (by one order of magnitude) in the first layer (of 1 cm^2) adjacent to the electrode to satisfy the 4 μC charge requirement assuming that there is one Ag^+ in each 10 $Å^2$ of a plane parallel to the electrode surface. Based on the above, it appears reasonable to assume that a concentration (potential) gradient of Ag^+ extending into the bulk is virtually nonexistent and, therefore, the diffuse double layer should act as a lumped parameter in the over-all series RC equivalent circuit.

The capacitance values for the graphite electrode which can now be considered as those of the true inner layer capacitance, in view of the above observations, are plotted in Fig. 10 as a function of potential. It can be seen that, within the potential range mentioned above, C_i is invariant and has a value of 8.0 $\mu F\ cm^{-2}$. Beyond these potential limits, the onset of the relatively rapid faradaic reaction corresponding to the discharge of either silver or iodine gives rise to additional time constants which mask the measurement of the double-layer capacitance in this region. The capacitance values plotted in these latter regions were those calculated from the tangent of the initial portion of the response curves to a galvanostatic step at the shortest accessible times. The values obtained, therefore, contain a contribution to the true value of C_i from the impedance associated with the particular faradaic process occurring.

It is interesting to speculate on the origin of the relatively low and invariant value of C_i observed in this case. To do this, reference may be made to recent work (40) concerning the double-layer structure of molten salts which indicates that to a very good approximation, this quantity is in large part determined by the structure of the particular molten salt. These studies have shown that the inner layer is present as a simple parallel plate capacitor and that it is essentially in series with another capacitor whose value is determined by the degree of long range order in the molten electrolyte which tends to prevent the formation of a very compact inner layer. In the case of solid AgI, the I^- ions are hexagonal close packed (41) at room temperature, and the bulk electrical properties are ohmic in nature. Similar to molten salts, it is to be expected (even more so in the case of a solid since it is difficult to visualize how the structure can become more compact) that this structure will predominate up to the inner layer region. This region, however, is far from ohmic and exhibits, as shown earlier, simple capacitive behavior. As a first approximation, the parallel plate capacitor model might then predict the observed value of C_i. This is given by

$$C_i = \frac{K_D \epsilon_0 A}{d} \qquad [5]$$

where K_D is the dielectric constant, ϵ_0 the permittivity of free space, d the distance between the capacitor plates, and A is the surface area. Since Ag^+ ions are relatively mobile with respect to I^- ions in the solid structure, it is to be expected that the Ag^+ ion population in a plane parallel to the graphite surface acts as the electrolyte side of the parallel plate capacitor model. The microscopic structure of the inner layer is thus most probably a plane of free electrons in the graphite extending to its surface, which is parallel to and opposite a plane of positive charges consisting of Ag^+ ions. For this model, d would then be expected to be given by the ionic radius of Ag^+ (1.2Å). The proposed inner layer structure also supposes that, in contrast to aqueous solution and molten salts (although the value of K_D for the inner layer may be a wrong assumption in this case) free space exists between the two capacitor plates in which case, $K_D = 1$. Substitution of the above values of d and K_D in [5] results in an inner layer capacitance of 7.4 $\mu F\ cm^{-2}$ in good agreement with the observed value of 8.0 $\mu F\ cm^{-2}$.

Application of Eq. [3] and [4] in the determination of the double-layer capacitance of the platinum electrode was not possible at even the shortest time ranges experimentally accessible at any electrode potential. This is well illustrated in Fig. 9 for the galvanostatic case where it is obvious that at short times, a deviation from the expected linearity (Eq. [4]) occurs. It may therefore be seen from a comparison of the behavior of both electrode systems that, although for each change of the electrode potential, Eq. [1] and [2] require that the activity of the silver and iodine at the interface should readjust to new equilibrium values by charge transfer, no such process appears to occur in the graphite case in the region of ideal polarizability within the time range of the above experiments. On the other hand, in the platinum case a rapid readjustment does occur involving, for example, the discharge of a finite quantity of silver onto the platinum surface for a cathodic potential step. That this readjustment does involve the formation of submonolayer quantities of deposited silver atoms and not adsorbed silver ions as has been suggested previously for the platinum-silver bromide case (28) has been proven by examining platinum electrodes with an electron microprobe after they had been potentiostatted at various positive electrode potentials. Clear proof of the presence of deposited silver on the platinum surface at such potentials was obtained (42). In view of the very rapid faradaic process occurring at the platinum-silver iodide interface, it is useful to consider the potential dependence of the total capacitance as determined by integration of the total charge passed during a 5 mV potential step. This dependence is shown in Fig. 11 where in the potential region for

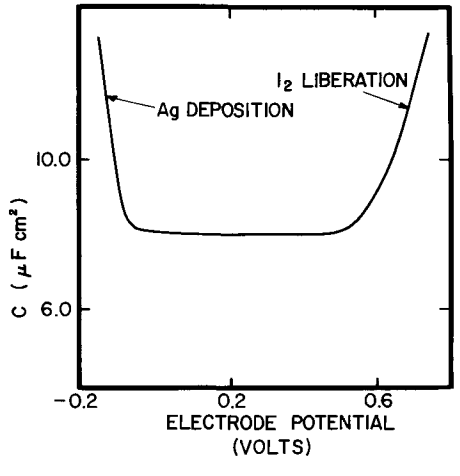

Fig. 10. Potential dependence of the capacitance of a graphite electrode determined from galvanostatic measurements recorded at microsecond times.

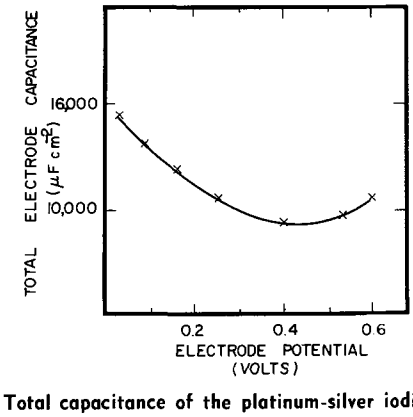

Fig. 11. Total capacitance of the platinum-silver iodide interface as a function of the electrode potential.

which no steady-state faradaic current flows (~0.0 to 0.5V), the form of the capacity-potential curve increases monotonically in either direction from the minimum at ~0.46V.

It is interesting to note that the form of the capacitance-potential curve shown in Fig. 11 is similar to that exhibited by liquid metal-molten alkali systems (40), where it has already been suggested that the high values of capacitance and its rapid increase as the potential becomes anodic or cathodic to the point of zero charge is due to contributions from the reversible faradaic reactions occurring at the interface (43). As stated earlier, faradaic complications are not present in the graphite case. It might thus be expected that the true double-layer capacitance of the platinum-silver iodide interface should exhibit a functional relationship with potential similar to that of graphite. This is particularly so since, as shown earlier, the capacitance of the double layer is predominantly determined by the ionic structure of the solid electrolyte and to a much lesser degree, by the nature of the particular electrode employed. Approximate evaluations of electrode capacitance at microsecond times obtained from results such as those shown in Fig. 9 yield substantially lower capacitance values (40-400 μF cm^{-2}). These measurements indicate that the true value of C_D might be obtainable if data could be gathered at times as short as several nanoseconds. This is possible through the use of the recently developed Transient Impedance Technique (31) which will be employed in future work on these systems.

In view of the difficulty in achieving an experimental separation of faradaic and nonfaradaic processes in the platinum system at room temperature and of the recently published (40) ideas concerning regions of ideal polarizability and ideal reversibility in molten salt systems, it appears important to exercise extreme caution in the interpretation of such experimentally measured capacitance values in terms of the structure of the interface and its eventual influence on electrode kinetics.

Electrochemical Studies in Liquid and Solid AgBr

D. O. Raleigh and H. R. Crowe

Science Center, North American Rockwell Corporation, Thousand Oaks, California 91360

ABSTRACT

The comparative electrochemical properties of Pt electrodes have been studied in liquid AgBr at 429°C and solid AgBr at 300°-417°. At all temperatures, a significant time range of ideal polarization kinetics was observed. The intrinsic AgBr|Pt double-layer capacitance is the same for liquid and solid AgBr and is constant over the solid-state temperature range investigated. In addition, the principal characteristics of Ag submonolayer deposition are the same above and below the AgBr melting point. The results indicate the electrochemical properties are determined by an interfacial ion layer whose characteristics are independent of the state of the electrolyte. Decreasing double-layer charging rates were observed with decreasing solid-state temperature and are attributed to interface strain due to differential thermal contraction.

In a brief communication (1), the authors previously reported the achievement of ideal polarization kinetics at the AgBr|Pt solid-solid interface. While these findings were felt to be of special interest with regard to a previous body of literature on polarization capacitance in ionic solids (2), they were partial results of a more broadly based study to determine intrinsic electrode properties in a typical solid-electrolyte system. The purpose of the present publication is to present the full results of the study and give a better account of the experimental techniques involved.

Several previous studies (3) in our laboratory with the solid electrolyte AgBr were directed primarily toward determining the magnitude of its differential double-layer capacitance against various electrode materials at temperatures (>250°C) where it possesses good ionic conductivity. With polarizing d-c biases (Ag side negative) on solid-state cells of the type Ag|AgBr|(Pt or C), voltage steps were applied and the capacitances obtained by current integration. Static capacitance of order 25-45 $\mu f/cm^2$ were found against graphite, which could be attributed to a diffuse space charge layer in the AgBr. With platinum electrodes, minimal capacitances an order of magnitude larger were attributed to charge storage by an Ag^+ ion layer on the Pt surface. In addition, as the electrode voltage approached the silver potential, a large pseudocapacitance was observed, which could be attributed to the gradual buildup of an Ag monolayer on the Pt by Ag^+ ion discharge.

An additional item of interest in this previous work was the kinetics of interface charging. In contrast to the behavior expected for ideal polarized electrodes, plots of log i *vs.* t in response to the voltage steps were not linear. Their course suggested charging with a mixture of time constants, but the exact curve shapes showed some run-to-run variability, so effects involving the electrode contact were suspected. These cells consisted of cylindrical AgBr pellets spring-loaded between smoothed electrode faces, with contact made either by 1-hr annealing just below the AgBr melting point, or by briefly heating the cell above the melting point to flash-melt the electrode regions.

A principal objective of the present study was to reinvestigate the charging kinetics of the AgBr|Pt interface with a cell arrangement that permitted a more controlled method of forming the solid-solid interface. The cell employed consisted of a cylindrical Ag metal cup filled with fused AgBr, into which was lowered a centered Pt wire. The solid-solid interface was formed by slow cooling through the melting point. Because of the relatively large area of the Ag electrode, its impedance could be ignored. Since the arrangement also permitted electrochemical studies in the liquid state, a second objective of the experiments was to compare electrode characteristics in liquid and solid AgBr. Initial experiments were carried out at 429° and 417°, corresponding to several degrees on each side of the melting point (423°C), and later experiments explored the effect of cooling to 350° and 300° in the solid state.

Key words: solid electrolyte, AgBr electrochemistry, AgBr double layer.

Experimental

Cylindrical crucibles of 1 in. height, ½ in. ID, and ⅛ in. walls were machined from high-purity ¾ in. silver rod stock and cleaned in KCN and HBr solutions. For the melt loads, ½ in. cylinders of 99.95% AgBr single crystal rod stock, obtained from Semi Elements Inc., were used. Heating was carried out in a temperature-controlled Marshall furnace, using a vertical quartz furnace tube and a purified flowing argon atmosphere. Rubber tubing was avoided because of possible sulfur contamination. A stainless-steel-sheathed chromel-alumel thermocouple in the silver crucible wall served as an electrode lead and temperature indicator. The platinum electrode was attached to a coaxially mounted support rod which could be raised and lowered via a Pyrex sleeve seal.

Thermocouple-grade 20-mil Pt wire was generally employed for the working electrode. In one run, a 20-mil single-crystal Pt wire obtained from the Aremco Corporation was used. No observable difference in electrochemical properties was seen. Prior to their use, these wires were electropolished in fused NaCl-KCl as described previously (3b). In later runs, this operation was followed by an overnight anneal at 1550°C in air. Before immersion of the working electrode, a sacrificial Pt electrode was placed in the melt for several days at 0.2V (positive) to oxidize photolytic silver and help remove any melt impurities. In most runs, the AgBr was kept in the molten state for less than a week in all, in order to avoid extensive dendritic recrystallization of the Ag crucible walls.

On completion of electrochemical operations in the melt, the cell was cooled through the freezing point at about 2°C/hr. On freezing, the Pt electrode immersion remained the same, with a small contraction "pipe" forming at one side of the solidified melt. Electrochemical properties showed good reproducibility on cycling through the melting point and on cooling to room temperature and reheating. In the absence of other electrochemical operations, an 0.2V polarizing d-c bias was maintained on the cell.

The electrochemical operations carried out on the cell were cyclic voltammetry, a-c impedance measurements, galvanostatic chronopotentiometry, and potentiostatic chronocoulometry. The potentiostatic and galvanostatic operations were carried out essentially as described previously (3b). Series a-c resistance and capacitance were measured with a standard Wheatstone bridge arrangement (4) employing Gen-

eral Radio Company decade resistance and capacitance boxes, oscillographic nulling, and a 10-20 mV a-c signal amplitude. The frequency range was limited to 0.1 to 10 kHz because of the small resistance and large capacitances generally involved. Cyclic voltammetry was carried out with a standard arrangement.

Results

Steady-state cell current.—Solid-state cells of the type Ag|AgBr|Pt, which consist of a reversible and a more noble "inert" electrode, have been termed "polarization cells" (5) because of their ability to completely block steady-state ionic current over a wide range of applied d-c bias. In the appropriate bias range, the inert electrode functions as a capacitor toward ionic current and the only d-c cell current observed (in the absence of accidental depolarization effects) is a small electronic current. This current flows under field-free conditions, being due to an electron concentration difference at the two electrodes. In the present case, the current is given by (5, 6)

$$i_e = \frac{RT}{GF}\sigma_e^0 (1 - e^{-\epsilon F/RT})$$

where ϵ is the d-c bias, σ_e^0 is the local electronic conductivity at the interface with the reversible electrode, and G is the cell constant. Such cells have, in fact, been used to measure low-level electronic conductivity in predominantly ionic-conducting solids (6). Analogous experiments, however, have not been carried out with the same electrolyte in the liquid state.

At solid-state temperatures, steady-state cell currents <10 μA were obtained which showed the expected bias dependence and agreed well with previous data (7). In the liquid state at 429°, the current was 6-8 times as large as at 417°. The same bias dependence was observed, but the current level showed day-to-day drifts and agreed only approximately among various cells. It appears that an electronic current is still involved. Where the solid-state current, however, is strictly a diffusional current, it seems likely that at least some of the enhancement in the liquid state is due to convection. Thus, liquid-state cells, at least in the present configuration, do not seem especially suited to electronic conductivity measurements. Since such currents are in any event small and reasonably constant in the short term, their effects can be ignored in electrochemical measurements by instrumentally compensating for them in potentiostatic measurements and by using relatively large currents in galvanostatic ones. At 350° and 300°C these currents were small enough to neglect completely. In a-c impedance measurements, they represent a high-resistance parallel circuit path that can be ignored.

Cyclic voltammetry.—To obtain an over-all picture of the electrode behavior throughout the polarizing range, cyclic voltammagrams were carried out at all four temperatures. Figure 1 shows comparative sweep curves at 429° and 417°, corrected for steady-state cell current. The solid-state curve shows a broad range of purely capacitative charging. As the Ag potential is approached, a current attributed to gradual Ag monolayer deposition (3) is observed, with the start of the reverse sweep corresponding to monolayer stripping. Above 0.6V, effects attributable to a mixture of electronic hole current and Br_2 discharge are observed.

In the liquid state, the low-bias behavior is similar, but an apparent redox process appears above 0.4V and limits the range of liquid-state polarizability. Pt bromides at these temperatures are not stable in their standard states (8), but one expects bromination in the melt to be favored by halogen complex formation and melt dilution. In solid AgBr, it is unlikely that Pt halogen complexes could form in the crystal lattice and equally unlikely for Pt ions to have appreciable mobility. This seems the most likely explanation for the significant difference in electrochemical behavior observed here with the liquid and solid electrolytes.

Cyclic voltammagrams at 300° and 350°C were similar to one another and differed mainly from the 417° curves in the low-bias region. Figure 2 shows comparative curves at 417° and 350° in this region. The main difference is an apparent delayed monolayer stripping peak at 417°. When sweeps at 417° were made at successively more rapid rates, the delay shortened and eventually became negligible. It appears that the diffusion coefficient of Ag in Pt is large enough at the two highest temperatures to permit some in-diffusion of the monolayer during slow sweep cycles, resulting in a stripping delay. This and related effects will be discussed more extensively in subsequent sections.

A-C cell impedance.—The first a-c impedance measurements taken were series resistance and capacitance as a function of frequency at several fixed cell biases. The biases chiefly used were 0.05 and 0.25V to correspond to regions of the faradaic monolayer process and double-layer charging, respectively. In the molten state, impedances at 0.05V showed reasonable stability and run-to-run reproducibility, but early measurements at 0.25V gave considerable problems in this respect. Figure 3 shows a collection of capacitance-frequency results in the double-layer charging region at 429° from various runs. In addition to considerable day-to-day drift and irreproducibility in capacitance values, large low-frequency series resistances (up to 80 ohms at 0.1 kHz) were observed. These were electrode resistances, since the bulk (high-frequency limit) cell resistance at 429° was ~1 ohm.

A number of attempts were made to achieve more ideal capacitative charging behavior. These involved melt pretreatment, Pt electrode preparation, and cycling through the electrolyte melting point. In Fig. 3, a single data set (run 5, 4th cycle) gave a virtually frequency-independent capacitance associated with a

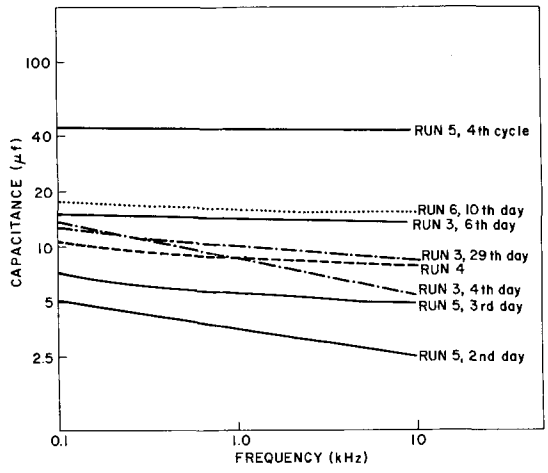

Fig. 3. A-C capacitance of Pt electrode in AgBr(l) at 429° and 0.25V as function of frequency (various runs).

very low (0.5 ohm) electrode resistance. This behavior was finally reproduced and stable, reproducible impedances obtained by the use of melt pretreatment with one or more sacrificial Pt electrodes, and the previously described Pt electropolishing and annealing procedures. With these precautions, the capacitance at 0.25V varied as little as 1% per decade of frequency and agreed to within 5% among various runs. It is felt that adsorbable melt impurities and electrode surface irregularities were chiefly responsible for the previous nonideal behavior.

When ideal capacitative charging (frequency-independent capacitance, low series electrode resistance) was achieved, the first operation was to monitor the a-c capacitance at 0.25V and 1 kHz during a slow cooling through the electrolyte melting point. On freezing, no change whatever was observed. Figure 4 shows the capacitance at 1 kHz as a function of cell voltage (potential with respect to the Ag electrode) at 429° and 417°. Above 0.4V, the curves diverge, presumably because of the Pt oxidation indicated in the cyclic voltammetric studies. At lower potentials, however, the curves are virtually congruent. It would appear, then, that the kinetics and magnitude not only of double layer charging but of the faradaic monolayer process are essentially identical in liquid and solid AgBr. We may anticipate somewhat our discussion of this result by recalling that we had previously (3) attributed the large double layer capacitance of AgBr on Pt to charge storage by a layer of adsorbed electrolyte ions. Our results would then indicate that the nature of this layer is independent of the state of the electrolyte.

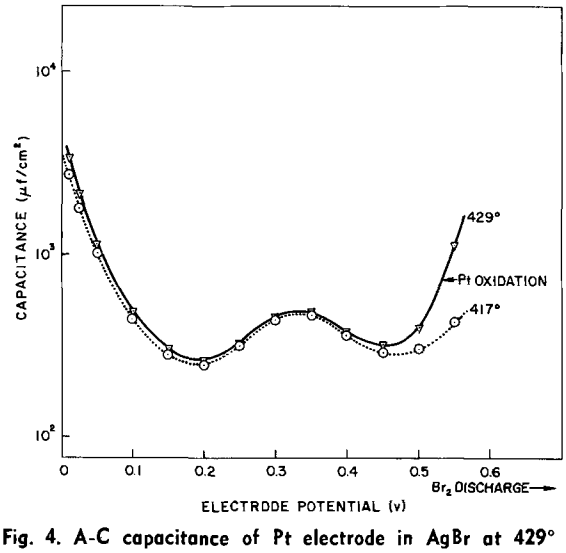

Fig. 4. A-C capacitance of Pt electrode in AgBr at 429° and 417° at 1 kHz as function of cell voltage.

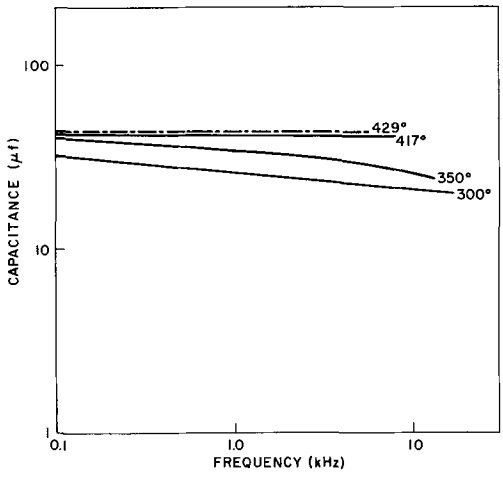

Fig. 5. A-C capacitance of Pt electrode in AgBr at 0.25V as function of frequency and temperature.

At 350° and 300°, capacitance values were smaller and more frequency-dependent. Figure 5 shows the frequency dependence in the double-layer region at the four temperatures. Capacitance-voltage curves at 1 kHz showed the same shape as the 417° curve of Fig. 4, being displaced downward by a more or less constant fraction. This and the appearance of Fig. 5 suggested the onset of finite charging kinetics with decreasing temperature, rather than a change in the intrinsic interface capacitance. Subsequent data confirmed this picture.

In the faradaic region, a-c capacitances were higher and generally more frequency dependent. Figure 6 shows the relative frequency dependences of the electrode capacitance in the double layer and faradaic regions at 429° and 300°C. In the 0.05V case, the "capacitance" is properly a pseudocapacitance. Its frequency dependence appears to reflect a finite rate for the monolayer faradaic process. With decreasing temperature, the magnitude of the pseudocapacitance decreased, but its frequency slope remained relatively unchanged. The result is that the frequency dependences at 0.05V and 0.25V were roughly the same at 300°. No attempt was made to fit the faradaic pseudocapacitance to a reaction model. As we shall see, more direct evidence on the nature of the faradaic process was provided by potentiostatic coulometry measurements.

Potentiostatic coulometry (capacitative region).—We noted above that Fig. 5 and the shapes of a-c capacitance-bias curves at 350° and 300° suggested the onset of finite double-layer charging kinetics at these temperatures rather than a change in the intrinsic capacitance. This was verified by preliminary potentiostatic coulometry measurements with an X-Y

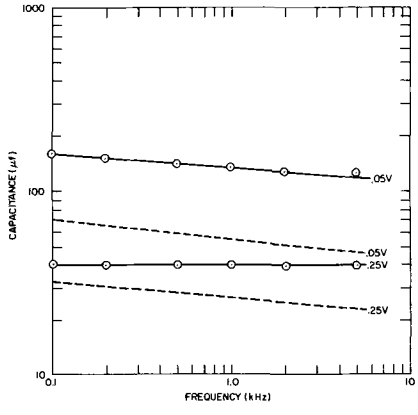

Fig. 6. A-C capacitance of Pt electrode in AgBr at 429° (solid) and 300° (dotted) in faradaic (0.05V) and capacitative (0.25V) voltage regions as a function of frequency.

recorder, which showed that the total (static) differential capacitance at these temperatures was the same as the a-c capacitance at 417° and 429°. The same measurements, however, showed the total capacitance at 417° and 429° to be significantly greater than the a-c capacitance. To clarify the situation, d-c voltage steps were applied in the capacitance charging region at all four temperatures and $Q(t)$ monitored continuously over the time range 0.1 msec to several hundred seconds by a combination of oscillographic and recorder displays.

Figure 7 shows a $Q(t)$ curve at 417° for the voltage step 0.20-0.25V. Qualitatively similar curves were seen elsewhere in the capacitative region at 417° and 429°. Two distinct charge transfer processes, well separated in time scale, appear to be involved. The capacitance corresponding to the first plateau was the same at all four temperatures, was well reproduced from run to run, and matched the a-c capacitance data at 417° and 429°. This was taken to be the intrinsic interface capacitance.

The capacitance corresponding to the slow second charge transfer process was significant only at 417° and 429°, was generally different at these temperatures, and varied by up to a factor of two among various runs. It was first thought to correspond to slow double-layer relaxation involving ion redistribution about irregularities on the electrode surface. Its magnitude, however, was too large for this. Its most likely source was indicated from the results of $Q(t)$ *vs.* $t^{1/2}$ plots. Figure 8 shows such a plot for the Fig. 7 data in the time range 10 msec to 225 sec. A linear variation is seen for times up to 90 sec, corresponding to a time range of almost four orders of magnitude. It appears that a diffusion-limited impurity current is involved; the $t = 0$ intercept gives the intrinsic capacitance. The fact that the charge transfer terminates indicates simply that the impurity "reservoir" is of finite extent. Since the total amount of impurity charge involved throughout the capacitative voltage range is only of order one monolayer, it seems pointless to guess as to the nature of the specific impurity or mixture of impurities.

Figure 9 shows the effective capacitance from $Q(t)$ curves at all four temperatures. The voltage step in question is 0.225 → 0.275V, so corresponds to the capacitance at or near 0.25V. At 429° and 417°, the effective capacitance was augmented at long times by the above-described impurity diffusion, which effect was essentially absent at 350° and 300°. At the short-time end, the intrinsic charging kinetics at 429° are apparently too fast to be observed as a finite charging rate. Supplemental oscillographic

sweeps showing charge and voltage rise times indicated no charging lag down to 20 μsec. At 417°, evidence of finite charging kinetics appears. The effect is more pronounced at 350° and still more pronounced at 300°. Since coulometrically determined capacitances are only valid for times at least several times as large as the intrinsic RC charging time of the cell, the curves shown here are for t such that $(1 - e^{-t/RC})$ is at least 0.98. Here, R is the cell resistance and C is the plateau-level capacitance. The start of the curve shifts to successively longer times at lower temperatures because of increasing electrolyte resistance (~40 ohm at 300°). The curves, then, show the relative interface charging kinetics at the four temperatures.

The principal result of the Fig. 9 curves is to define a single temperature-independent intrinsic interface capacitance. Similar sets of curves were obtained at other voltages in the capacitative charging region, the range of which is estimated to be about 0.15V to 0.55V. In this range, plateau-level capacitances from $Q(t)$ curves with various cells, voltages, and temperatures agreed with the Fig. 4 values to an average of 5%. Thus, the 417° curve of Fig. 4 in this region gives the intrinsic interface capacitance of AgBr against Pt to solid-state temperatures at least as low as 300°. In the temperature range investigated, corresponding to a factor of 40 change in electrolyte conductivity, the capacitance appears to depend solely on the electrode potential.

A further matter of interest in this voltage region was that $Q(t)$ curves in the neighborhood of the capacitance maximum (~ 0.33V) showed several distinct differences from $Q(t)$ curves at the minima on

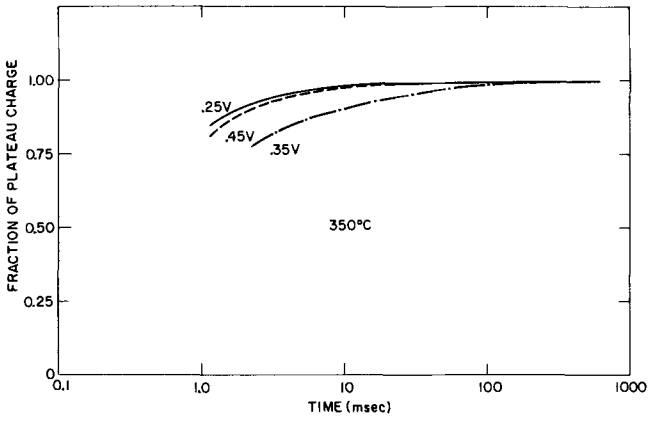

Fig. 10. Initial portions of chronocoulometric curves from 0.225-0.275V, 0.325-0.375V, and 0.425-0.475V voltage steps at 350°C, expressed as fraction of plateau-level charge.

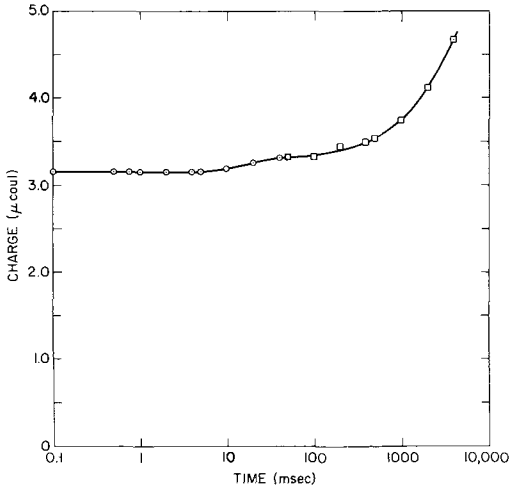

Fig. 11. Coulometric curve at 429° for voltage step (0.30-0.35V) in neighborhood of capacitance maximum. Open circles indicate oscillographic data; squares are X-Y recorder data.

either side. First, at temperatures where finite interface charging kinetics were observed, charging was several times slower at the capacitance maximum. This is shown in Fig. 10 for 350°C data, which indicates a factor of three slower charging time at the maximum. In addition, the full charging curves for voltage steps in the maximum region showed an unusual sigmoidal feature. This feature, seen in the time range 5-50 msec in Fig. 11, was most readily visible at 429° and 417°C, was partially observed at 350°, and was not seen at 300° because of masking due to decreasing interface charging rates at the lower temperatures. Both this and the decreased charging kinetics in the maximum region suggest structural characteristics of the interface double layer which will be discussed.

Potentiostatic coulometry (monolayer faradaic region).—We have already mentioned that a-c impedance measurements showed generally slower kinetics for the monolayer faradaic process than for capacitative charging. It was of interest to see what further information on the faradaic process could be obtained coulometrically. Earlier work (3) showed that submonolayer electrodeposition in response to an appropriate voltage step occurred more slowly than the stripping process due to the reverse step. Since this effect presumably involves steric factors in the process of depositing a uniform monolayer, it was felt that more basic information could be obtained from studying the stripping process.

A cell was equilibrated at 0.002V to achieve nearly complete monolayer coverage at a polarizing bias and the voltage then stepped to 0.200V to achieve

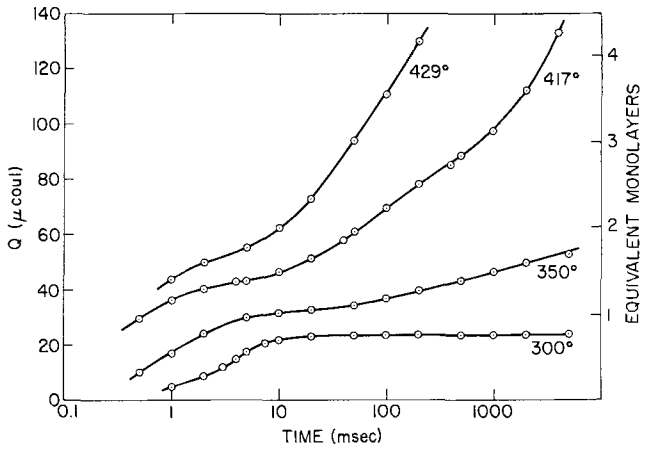

Fig. 12. Coulometric stripping curves corresponding to voltage step 0.002-0.200V. Right-side ordinate gives equivalent number of monolayers corresponding to charge values on left side.

nearly complete stripping. Figure 12 shows the $Q(t)$ curves at all four temperatures. Although not shown here, and although often obscured by slow drifts in the steady-state cell current, the curves were generally observed to level out to show completed charge transfer in the time range of several hundreds of seconds.

Only at 300°C was a clean coulometric stripping curve obtained in the subsecond region. The higher temperatures appear to show a rapid primary stripping process mixed with an increasing contribution from one or more slower faradaic processes. We noted earlier (Fig. 2) that cyclic voltammagrams indicated Ag diffusion into Pt at the two highest temperatures during a cyclic sweep. Accordingly, it was expected that the primary stripping process in Fig. 12 was being augmented by outdiffusion of Ag that had entered the Pt during the previous equilibration at 0.002V.

Figure 13 shows the data for the three highest temperatures in Fig. 12 replotted as $Q(t)$ *vs.* $t^{1/2}$ in the time range 0.5 msec to 4.0 sec. At each temperature, a curve with two linear regions is obtained, possibly indicating outdiffusion by a mixture of mechanisms. In any event, the curves permit a clean separation of kinetics presumably associated with diffusion and with the primary stripping process, allowing extrap-

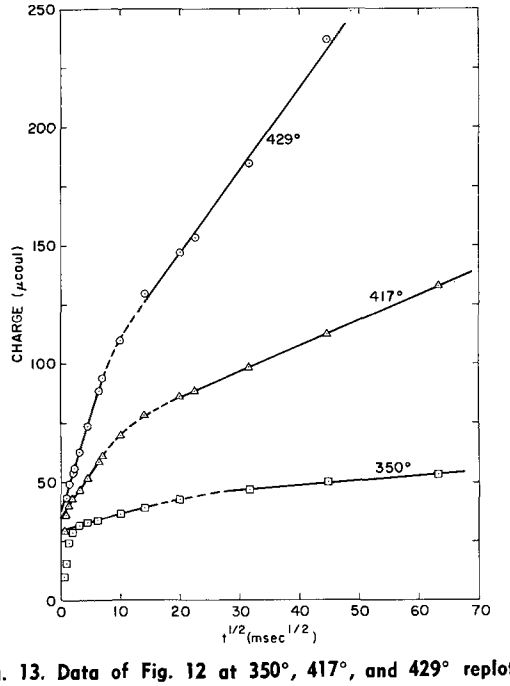

Fig. 13. Data of Fig. 12 at 350°, 417°, and 429° replotted as Q *vs.* $t^{1/2}$.

olation to $t = 0$ to obtain the charge associated with the latter process.

To obtain the monolayer coverage from the $t = 0$ intercepts, it was necessary to correct for double layer charging and incomplete monolayer stripping. An admittedly arbitrary double layer correction was made by assuming that the minimum capacitance of 0.19V from the 417° curve of Fig. 4 applied across the monolayer voltage region. Galvanostatic monolayer coverage curves from the present and previous (3) work indicate that the coverage at the 0.002V initial voltage for the stripping step is close to 94% complete and that, at 0.200V, stripping is essentially complete. The double-layer corrected $Q(t = 0)$ values were thus divided by 0.94 in calculating the number of monolayers coverage. Table I gives the coverage data for a particular run, along with galvanostatically derived coverage values.

At 417° and 429°C, the total charge transfer, obtained with charge integration times of several hundreds of seconds, was considerably greater than the "fast" monolayer charge. At these temperatures, charge values varied a good deal from run to run, showing a range of 5 to 20 equivalent Ag monolayers. Integrations carried out step wise over the voltage range 0-0.2V showed the same general voltage dependence pattern as the a-c capacitance in this range. Thus, it was felt that Ag metal, rather than an impurity, was involved. With sufficiently long waits, the slower charge transfers corresponding to (reverse polarity) monolayer buildup voltage steps approached those obtained with stripping steps. From this and the fact that completed charge transfer was generally observed in the long-time limit, it appeared that the presumed Ag diffusion processes involved a porous surface layer on the Pt, backed up by relatively impermeable bulk Pt.

Galvanostatic chronopotentiometry.—Previous chronopotentiometric studies (3) on the AgBr(s)|Pt(s) system had been carried out at 250° and 300°C to determine the nature of Ag electrodeposition on bare Pt and obtain data on the fractional monolayer coverage as a function of Ag activity. The present galvanostatic work was carried out in much the same way, with the objectives of extending the previous studies to higher solid-state temperatures and to the liquid state.

In these measurements, the cell is abruptly (~4 msec) switched from a polarizing bias well outside the monolayer range (*e.g.*, 0.3V) to a constant-current mode which passes Ag^+ ions toward the Pt, and the voltage is monitored oscillographically. The voltage trace is initially approximately linear, corresponding to double-layer charging. As the theoretical Ag(s)|AgBr(s) potential (zero volts) is approached, the trace rounds off and approaches it asymptotically, indicating gradual submonolayer deposition and the absence of any appreciable overpotential. By extrapolating the initial linear part, one can correct the total charge ($Q = it$) at any time t for the double-layer charging contribution, to obtain the faradaic charge as a function of voltage. If matching data are obtained at various current levels, the iR-corrected voltage may be assumed to be the equilibrium electrode voltage and, accordingly, data on fractional ideal monolayer coverage obtained as a function of Ag activity.

The present sweeps were carried out at at least 7.5 mA/cm² so that the electronic cell current at 429° would be relatively negligible, *i.e.*, ionic current would predominate. At these current levels, coverage is completed in at least 50 msec, so that contributions from Ag diffusion into the Pt should be minor. Comparisons of 7.5 and 15 mA/cm² sweeps on the basis of total charge passed as abscissa showed excellent congruence. Figure 14 shows an activity-coverage plot at 429° and 7.5 mA/cm² current level. As before, linear log-log plots were obtained through most of the submonolayer region. Deviations at low activities probably represent a systematic extrapolation error in the double layer charge at the low charge levels involved. The slight superunit Ag activity in the postmonolayer region was independent of the current level and is again (3b) attributed to some variety of relaxable stress in the monolayer. Extrapolation of the sub- and postmonolayer trace portions permits determination of an effective monolayer coverage.

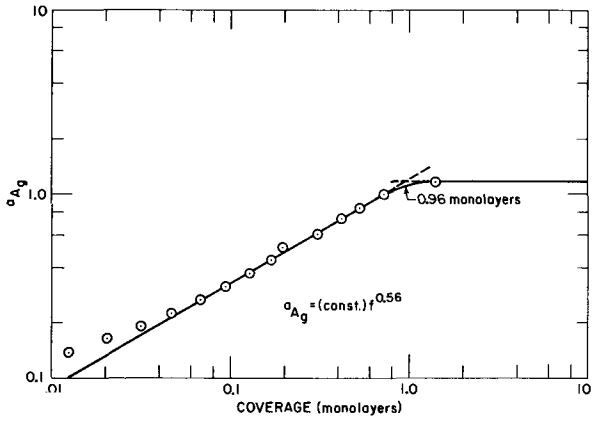

Fig. 14. Silver metal activity at AgBr|Pt interface vs. fraction of ideal monolayer coverage, from galvanostatic data at 429°C and 7.5 mA/cm².

Activity-coverage slopes, representing n in the empirical relationship $a_{Ag} = (\text{const})\ f^n$, averaged 0.60. These ranged 0.55 to 0.65 more or less randomly, showing no temperature dependence. The average value is in good agreement with that from the previous work (0.57). Thus, the activity-coverage power-relationship is not a function of the temperature or state of the electrolyte. The monolayer coverage values for a given run are shown in Table I, along with those from the potentiostatic data. The range of coverages is about the same by the two methods. The galvanostatic determinations, however, involve more random error, as seen by the scatter of n values and the smoother temperature dependence of the potentiostatic coverages. Because of this, as well as unknown contributions from Ag diffusion and monolayer buildup steric effects in the galvanostatic process, the potentiostatic coverages are felt to be more reliable.

Table I. Fractional Ag monolayer coverage at unit activity from coulometric and galvanostatic data

	429°C	417°C	350°C	300°C
Coulometric	1.09	0.97	0.82	0.58
Galvanostatic	0.96	0.80	0.60	0.65

Discussion

Two results are of special interest. First, of course, is success in preparing a solid-solid interface with a time range of electrochemically ideal polarization behavior. This behavior is manifested as a range of frequency-independent a-c capacitance and as an appreciable time range of completed charge transfer in $Q(t)$ plots. Solid-solid interfaces are, needless to say, a relatively unexplored area. The present results indicate it is indeed possible to prepare such interfaces in a sufficiently reproducible manner to obtain properties characterizable as "intrinsic." In the case of the interface between an ionic and an electronic conductor, electrochemical techniques provide a sensitive, sophisticated means of interface characterization.

In the present system, however, it is perhaps equally interesting that, with the exception of Pt oxidation in the melt above 0.45V, there was little if any basic difference in interface behavior with the electrolyte in liquid and solid forms. We already noted from the impedance data that, in the neighborhood of the electrolyte melting point, the kinetics and magnitude

of both double-layer charging and the monolayer faradaic process are essentially the same. Such variations in electrochemical properties as were observed were more a matter of the temperature than the state of the electrolyte.

One might expect that the electrochemical processes most influenced by whether the electrolyte is liquid or solid would be those whose rate was at least partially determined by transport in the electrolyte. In the present case, AgBr is a good ionic conductor on both sides of its melting point; the conductivity rises only severalfold on melting. Since no supporting electrolyte is involved, polarization in the electrolyte can only be ohmic and, in the present case, ohmic effects were small. Also, as we have stated, the size of the double-layer capacitance of AgBr against Pt requires it to involve charge storage in a compact ion layer. Thus, the electrolyte in the present case enters the picture only as one member of a phase boundary at which the natures of the electrochemical processes of interest are determined. The present results indicate that the nature of the first ion layer on the Pt and of a partially deposited Ag monolayer are independent of whether the electrolyte is liquid or solid. It is perhaps reasonable, then, to think of the electrolyte as no more than a mobile transport medium for supplying ions to an interface layer which has its own structural characteristics.

For the source of the large double-layer capacitances, we postulate a considerable variability in the composition of the interface ion layer with changing voltage. For the maximum charge storage capability, we visualize the extremes of a close-packed layer of purely cations and purely anions at the ends of the electrode potential range corresponding to Ag and Br_2 deposition. Such a layer would presumably involve chemisorptive bonding to the platinum and be thought of as distinct from the AgBr crystal lattice behind it. Because of the virtually, identical structures and lattice parameters of Ag and Pt, a layer of close-packed Ag^+ ions on Pt should represent the same charge as a single lattice layer of Ag metal; about 240 μcoul/cm^2. If we assume the Br^- ion coverage to be reduced by the square of the Ag^+:Br^- ionic radius ratio (0.42), the maximal Br^- coverage contributes 100 μcoul/cm^2 for a total of 340 μcoul/cm^2.

It is of interest to compare this figure with an estimate from Fig. 4 of the total double-layer charge over the full electrode potential range for AgBr. From galvanic cell measurements of Yushina *et al.* (9), the full electrode potential range, *i.e.*, the AgBr decomposition potential, is about 0.81V near the AgBr melting point. Earlier, we estimated the double-layer capacitance in the faradaic region of Fig. 4 to be given by the capacitance minimum at 0.19V. In fact, it would be more realistic to assume that the capacitance from the above type of ion-layer charge storage model would drop to zero at the two ends of the voltage range (corresponding to complete anion or cation coverage) and rise to a maximum at an intermediate potential. With this assumption, we estimate crudely from Fig. 4 that the total double-layer charge in the voltage range zero to 0.81V is about 175 μcoul/cm^2, or roughly half the maximal theoretical value. Thus, the ion layer model provides sufficient charge storage capability without the necessity of assuming full ionic coverage at the ends of the potential range. We feel this model best accounts for the large, reproducible capacitances of AgBr on Pt observed with both single-crystal and polycrystalline electrodes and with a number of different interface preparation techniques.

In this respect, two points seem significant. First, there is a considerable literature on double-layer capacitance in fused salts (10). Several double-layer models have been proposed, but these were developed to account for parabolic-shaped experimental capacitance-voltage curves with relatively small (20-40 μf/cm^2) and sharp capacitance minima. Moreover, these models dealt rather specifically with the liquid state. The totally different qualitative and quantitative aspects of the present results required a substantially different model, equally applicable to the liquid and solid states. The model proposed, however, is in line with the general observation in a recent review (10) that the double-layer capacitance in fused salts is most likely a special property of the melt structure at the interface.

Second, although the results reported in the present and previous (3) work allow one to characterize distinct voltage regions in terms of a predominant faradaic process and predominant double-layer charging, it is reasonable to inquire whether a faradaic component might nonetheless be partially responsible for the large apparent double-layer capacitances. Galvanostatic data, such as shown in Fig. 14, indicate negligible Ag monolayer coverage above 0.15V. Capacitances are frequency-dependent below 0.15V and frequency-independent above this voltage. The monolayer coverage, as well as apparent long-time impurity and diffusion effects (Fig. 8, 13) were temperature-dependent, while the presumed intrinsic capacitance is not. A possibility worth considering is that of a residual "tail" of low-activity metallic Ag in the double-layer region, rather more tightly bonded to the Pt than the bulk of the Ag monolayer. Such a faradaic component, however, should monotonically diminish with increasing potential, where, in fact, we see a capacitance maximum at 0.33V. Moreover, a frequency-independent faradaic capacitance above 0.15V would require faster reaction kinetics for the "residual" Ag than for the bulk monolayer. This seems unlikely for more tightly bonded Ag. The good run-to-run reproducibility of the presumed intrinsic capacitance tends to rule out fast faradaic impurity reactions. In sum, significant faradaic contributions seem unlikely.

The ion layer capacitance model provides a basis for interpreting the observed decrease in the capacitative charging rate with decreasing temperature, as well as the unique kinetics effects associated with the capacitance maximum. Regarding the former, it seems likely that interface strain induced by different thermal expansion rates of the solids in question is an inevitable property of solid-solid interfaces. At the melting point, the interface is presumably formed in a strain-free condition. On cooling to 300°C, the linear contraction in AgBr is about 1.3% (11); in Pt, it is about one-tenth this value. Thus, significant strain can be expected. The result may be that work is required to exchange Ag^+ ions between the interface region and the bulk electrolyte, resulting in decreased charging kinetics. In the present cell configuration, the interface region would be compressively strained. Other strain and resultant kinetic effects might be expected with other configurations.

The ion layer model implies that the capacitative charging in Fig. 4 involves cations at low biases, anions at high biases, and possibly a mixture of them in the neighborhood of the maximum. (It should be remarked here that anion layer formation with a cation-conducting electrolyte can be readily imagined in terms of removal of cations from a normal lattice layer.) In fact, the decreased charging kinetics and development of charge relaxation behavior (Fig. 10 and 11) in the neighborhood of the capacitance maximum suggests some manner of ordering or layer structure in this voltage range. This might be expected with a mixture of anions and cations in the layer, though its structure and composition might be quite different from a normal lattice layer of AgBr. In any event, an ordered structure might well involve decreased charging kinetics for steric reasons and might involve rearrangement from a "fast" initial configuration. It is perhaps appropriate at this time to note that the capacitance maximum was well reproduced with a number of different cells and that no peak lags were observed in cyclic voltammetric sweeps. Thus, it seems likely

to be a double-layer effect rather than to have resulted from an impurity redox reaction.

A number of characteristics of the monolayer faradaic reaction were ascertained. From the relative frequency slope of a-c capacitances at 0.05V and 0.25V (Fig. 6), it appears that the double-layer charging process is considerably faster at 429°, but that the rates of the two processes are about the same at 300°. Much the same picture is indicated by the potentiostatic coulometry data. Since both processes involve ion migration, to or from the electrode surface, the comparison at 429° would indicate a finite rate for the electron transfer step. With decreasing temperature, the decreasing rate for the charging process indicates both processes become rate determined by ion transport into or out of the interface region.

We have previously discussed galvanostatic monolayer coverage results for Ag on Pt in some detail (3b). In the present work, it was possible to extend the data to higher solid-state temperatures and to the liquid state. In addition, the potentiostatic coulometry measurements provided independent coverage data and supplied information as to the role of Ag diffusion into the Pt. The observed effect of increasing temperature was to increase the total coverage without changing the power dependence of the activity-coverage relationship, *i.e.*, to shift the Fig. 14 type curve to the right. The total coverage is envisioned here as the "surface solubility" or absorptivity of metallic Ag on Pt, which is about one full monolayer at the upper temperatures and decreases with decreasing temperature. The constancy of the activity-coverage slope indicates that it essentially involves the thermodynamics of the Ag-Pt system, irrespective of the temperature and state of the electrolyte.

Finally, we consider some aspects of Ag diffusion in the Pt. We have already noted that the leveling out of faradaic $Q(t)$ curves in the long time limit of several hundred seconds, as well as approximate agreement of indiffusion and outdiffusion charge values, indicates the Pt consists of a relatively porous surface layer backed up by relatively impermeable bulk Pt. Possible sources of the surface porosity are microcracks, dislocations, and a high concentration of point defects (*e.g.*, vacancies) near the surface.

The existence of two linear regions in the Q *vs.* $t^{1/2}$ plots of Fig. 13 suggests a combination of porosity types, but another explanation is also possible. Since defects such as microcracks and dislocations are scattered about in specific locations on the electrode surface, diffusion in them should also involve lateral diffusion in the interface. In this case, the over-all diffusion rate should be limited by interface diffusion at short times and diffusion in the electrode at long times. We have already indicated that interface strain in the solid state reduces ion mobility in the interface, as suggested by the decrease of capacitative charging kinetics with decreasing temperature. This may help explain the considerable reduction in the extent of diffusion at the lowest temperatures. A similar explanation may, in fact, apply to the previously observed impurity currents (Fig. 8) in the capacitative charging region.

Manuscript submitted July 28, 1970; revised manuscript received *ca.* Sept. 16, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Technical Notes

Electrochemical Properties of $RbAg_4I_5$ Solid Electrolyte

I. Conductivity Studies

Bruno Scrosati,* Giovanni Germano, and Gianfranco Pistoia

Universita' di Roma, Rome, Italy

The recent discovery of highly conductive electrolytes of the MAg_4I_5 type (1-5) has stimulated renewed interest in solid electrolytes, particularly in view of the development of solid-state batteries with high current capabilities.

The most stable of these electrolytes is the rubidium salt on which, consequently, the attention has been mainly focused. Nevertheless relatively few studies on the chemical and electrochemical properties of $RbAg_4I_5$ as well as on the electrochemical characteristics of cells containing this electrolyte have been so far reported.

The crystal structure of $RbAg_4I_5$ has been studied by Bradley and Greene (4) and by Geller (6). The distribution of 16 Ag^+ ions over 56 available interstitial sites per unit cell explains the high mobility of the Ag^+ ions and the high entropy of the compound. The physical properties of $RbAg_4I_5$ are summarized in Table I.

From the data of Table I a particular disagreement in the reported $RbAg_4I_5$ a-c specific ionic conductivity data is obvious. Bradley and Greene found a value of

Table I. Physical properties of $RbAg_4I_5$ at 25°C

Free energy of formation	-142.3 ± 0.1 kcal/mole	(8)
Entropy	~20 cal/deg. mole	(4)
Density	5.38 g/cm³	(5)
Transport number of Ag^+	1.00 ± 0.01	(7, this work)
Silver diffusion coefficient	2.10^{-6} cm²/sec	(9)
Electronic specific conductivity	$<10^{-11}$ ohm^{-1} cm^{-1}	(7)
Decomposition potential	0.67 ± 0.01V	(10)
Ionic specific conductivity (Flat silver electrodes)	0.124 ohm^{-1} cm^{-1}	(2)
Mixtures of electrolyte and powder silver electrodes)	0.210 ohm^{-1} cm^{-1}	(5)
Mixtures of electrolyte and powder silver electrodes)	0.170 ohm^{-1} cm^{-1}	(11)
(Amalgamated silver electrodes)	0.250 ohm^{-1} cm^{-1}	(10)
(Electrodes not reported)	0.260 ohm^{-1} cm^{-1}	(7, 13)

0.124 ohm^{-1} cm^{-1} at 20°C, using flat silver electrodes (2), Argue and Owens a value of 0.210 ohm^{-1} cm^{-1} at 20°C, using a mixture of powdered silver and $RbAg_4I_5$ as electrodes (5), Takahashi and Yamamoto, using the same kind of electrodes, a value of 0.170 ohm^{-1} cm^{-1} at 25°C (11), and De Rossi, Scrosati, and Pistoia a value of 0.250 ohm^{-1} cm^{-1} at 25°C, using amalgamated silver electrodes (10). Finally Oxley and Humphrey reported a $RbAg_4I_5$ conductivity value of 0.260 ohm^{-1} cm^{-1} at room temperature but without describing the type of electrodes used in their studies (7).

In this paper a detailed study of the $RbAg_4I_5$ ionic conductivity is reported, particularly regarding contact resistance problems and reproducibility, in order to clarify the reason for the scattering in the reported values of the solid electrolyte ionic conductivity.

Experimental Section

The preparation of $RbAg_4I_5$ has been described already (10). The final product was compressed under vacuum into pellets for the experiments using a press of the Beckman RIIC type. The average density of the pellets, determined by weighing a known volume, was 5.40 g/cm³ at 25°C. Conductivity measurements have been performed by the use of a cell made of two amalgamated silver disks in contact with the electrolyte pellet. A-c conductivity was determined at 800 Hz by a Yokogawa Kohlrausch bridge K-IA type using a 545 B Tektronix oscilloscope as null detector.

The Ag^+ transport number in $RbAg_4I_5$ at 25°C has been determined by passing a known amount of charge through a cell made of two silver electrodes in contact with a solid electrolyte pellet and comparing the corresponding coulombs with those obtained by measuring the loss in weight of the anode. The transport number of Ag^+, as an average of 10 determinations, was 1.00 ± 0.01 in agreement with the value reported by Oxley and Humphrey (7).

Results and Discussion

As shown in Table I, there is a certain scattering among the ionic conductivity values. The relatively low value found by Bradley and Greene (2) may be explained in terms of contact resistance. In fact Mrgudich has shown that the use of flat silver electrodes in measuring the conductivity of solid electrolytes results in severe contact polarization effects which can be overcome using amalgamated silver electrodes (12).

With this type of electrode the conductivity of $RbAg_4I_5$ has been found in our laboratory to be of the order of 0.250 ohm^{-1} cm^{-1} at room temperature. Contact polarizations have also been overcome using a mixture of powdered silver and $RbAg_4I_5$ as electrodes, as shown by Owens and Argue (5). No discussion of the 0.260 ohm^{-1} cm^{-1} found by Oxley and Humphrey at room temperature (7) is possible since the technique used for the conductivity measurements is not described in their report.

Undoubtedly contact polarizations and, consequently, the type of electrodes used in the measurements, play an important role in the conductivity determination of $RbAg_4I_5$ solid electrolyte, as shown in Table II: amalgamated electrodes definitely behave better than the flat silver ones and than those formed by compressing powdered silver directly on the surfaces of the electrolyte pellets. An attempt to vapor deposit silver on the pellet has also been made but without success. The electrolyte assumed a green-brownish color, the silver layer a yellowish color, and the conductivity of the assembly was very poor and not reproducible. This effect, which has been previously noticed by Bentle (9), is not very easily explained, and it is still under study.

Table II. Ionic a-c specific conductivity of $RbAg_4I_5$ measured at 25°C with several types of electrodes. (Compression pressure of the electrolyte pellet 1200 kg/cm²)

Type of electrodes	Conductivity (ohm^{-1} cm^{-1})
Amalgamated silver	0.243 ± 0.007
Mixture of $RbAg_4I_5$-Ag (1:1 in weight)	0.200 ± 0.007
Flat silver	0.090 ± 0.007
Compressed silver	0.096 ± 0.008
Evaporated silver	Not successful

It is also possible that the discrepancies in the reported values of the conductivity may be explained not only in terms of physical contact problems but also in terms of differences in the compression of the electrolyte pellet. To check this effect, a-c conductivity of different pellets prepared by different compression pressures, has been measured. The results, reported in Table III and Fig. 1, show that the $RbAg_4I_5$ ionic conductivity indeed depends to a certain extent on the pressure at which the pellet is compressed. Measurements were made after the source of pressure was removed. The conductivity, measured with amalgamated silver electrodes, reaches maximum values for compression pressures of the order of 1200 kg/cm². The decrease in conductivity at higher compression pressure could be associated with a certain decomposition

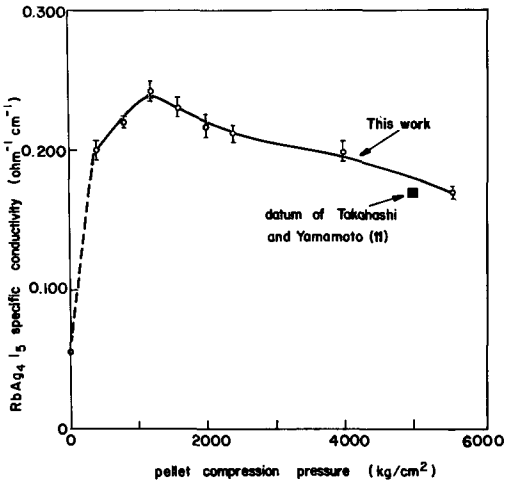

Fig. 1. Specific conductivity of $RbAg_4I_5$ pellets as a function of the compression pressure at 25°C (amalgamated silver electrodes).

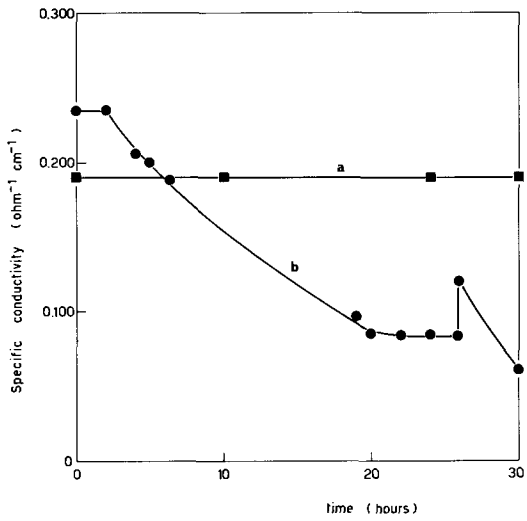

Fig. 2. Specific conductivity of $RbAg_4I_5$ as a function of time at 25°C (pellet compression pressure 1600 kg/cm²) where curve b refers to amalgamated silver electrodes and curve a to $RbAg_4I_5$-Ag mixture (1:1 ratio in weight) electrode determinations.

of the electrolyte or to possible phase changes. An x-ray study of $RbAg_4I_5$ pellets, compressed at pressures higher than 1200 kg/cm², could give a definite explanation of this effect. Such a study, however, is beyond the scope of this work which has been mainly intended as limited to a detailed conductivity study in order to try to find an explanation of the discrepancies existing in the literature on the $RbAg_4I_5$ ionic conductivity determinations.

The relatively lower conductivity observed for the pellets at low compression could be explained by the fact that at low pressures a complete uniformity of the pellet itself could not be achieved. Grain boundary and other similar effects, which should increase in extent when the compression pressure decreases, should accordingly hinder the silver ion mobility through the electrolyte and, therefore, lower its ionic conductivity. This explanation is supported by the fact that the ionic conductivity of powdered $RbAg_4I_5$, just slightly compressed between two amalgamated silver electrodes, is of the order of 0.055 ohm^{-1} cm^{-1}, as reported in Fig. 1.

On the basis of differences in compression pressure the relatively low (0.170 ohm^{-1} cm^{-1}) conductivity value found by Takahashi and Yamamoto (11) may find its explanation. These authors have reported that the pellets utilized in their solid state cells were pressed at 5 tons/cm², and it seems reasonable to believe that also the pellets for the conductivity measurements were compressed at the same pressure. With this assumption, the Takahashi and Yamamoto value is reported in Fig. 1. The agreement with the data found in this work at the same pressure is quite satisfactory.[1]

The conductivity measurements, reported in Table II, have been obtained with pellets of different dimensions and the results show that, for a given pellet-compression pressure, the $RbAg_4I_5$ specific conductivity is independent of pellet thickness and surface, *i.e.*, that it obeys Ohm's law in the dimension range examined.

From all the evidence so far discussed the beneficial effect of the amalgamation on the minimization of contact polarization effect and, consequently, on the $RbAg_4I_5$ ionic conductivity is clear. Nevertheless some disadvantages are associated with the use of this kind of electrode with the solid electrolyte. The most serious among them is the fact that mercury seems to slowly react with the electrolyte to form a definite compound which is less conductive than $RbAg_4I_5$. In Fig. 2 is shown the trend of the $RbAg_4I_5$ conductivity, measured with amalgamated silver electrodes, as a function of time. Conductivity remains constant for about 2 hr and then slowly decreases with time to reach a constant value which depends on the amount of mercury used for the amalgamation of the electrodes. The break in the curve corresponds to a time at which the cell was disconnected. The mercury was clearly transferred from the electrodes to the electrolyte whose color changed from white to yellow. When the electrodes were reamalgamated and the cell assembled again, the decrease in conductivity was sharper due to the new amount of mercury supplied.

The phenomenon is general and takes place any time mercury comes in contact with the electrolyte. An $RbAg_4I_5$ sample was left for a week in contact with an excess of mercury. The color of the electrolyte turned from white to yellow, and its specific conductivity, using a pellet compressed at 1200 kg/cm², was 0.006 ohm^{-1} cm^{-1} at room temperature.

Since the conductivity, measured with amalgamated silver electrodes, remains constant for about 2 hr and then decreases due to the presence of the unknown $RbAg_4I_5$ decomposition product, and the periods of time for the measurements reported in Fig. 1 are far smaller than 2 hr, the behavior reported in this figure is undoubtedly related simply to $RbAg_4I_5$ and not to the decomposition product.

Conclusion

The dependence of the a-c conductivity of $RbAg_4I_5$ pellets on the compression pressure and resistance effects at the boundary between electrodes and electrolyte may well explain the scattering in the solid electrolyte ionic conductivity values reported in literature.

Amalgamated silver electrodes behave quite well for a-c conductivity measurements of $RbAg_4I_5$. On the other hand these determinations are not reproducible with time since mercury slowly reacts with the electrolyte.

During the revision of the manuscript the authors became aware of work by Raleigh on ionic conductivity of single-crystal and polycrystalline $RbAg_4I_5$ (14), in which it is stated that variations in pressing conditions do not affect the $RbAg_4I_5$ polycrystalline conductivity, reported as 0.28 $(ohm\ cm)^{-1}$ at 25°C. On the other hand it is not clearly reported in the paper which was the pressure range in which the conductivity was tested and the precision of the polycrystalline conductivity data. Apparently, the measurements were done over a range of 1500 to 3000 kg/cm² and, since it is stated that the results compare both with a 0.26 and a 0.22 $(ohm\ cm)^{-1}$ previously reported values, one

[1] Note added in proof: Recently Takahashi reported that his conductivity data were indeed obtained with pellets compressed at 5000 kg/cm² (15).

could assume a precision of ± 0.06 (ohm cm)$^{-1}$. If this is the case then Raleigh's data also agree with those reported in the present work, according to which the conductivity varies from 0.24 to 0.21 (ohm cm)$^{-1}$ in the pellet compression range of 1500 to 3000 kg/cm^2.

Furthermore, in Raleigh's paper it is reported that a contact of 1 hr with mercury gives $RbAg_4I_5$ a yellowish coloration but not resistance changes. These findings are in perfect agreement with the observations reported in this work where resistance changes were observed at times exceeding two hours.

Ellipsometry of Anodic Oxide Films on GaAs

C. J. Dell'Oca,[1,*] G. Yan, and L. Young[**]

Department of Electrical Engineering, The University of British Columbia, Vancouver, British Columbia, Canada

The growth of anodic oxide films on GaAs is of current interest in connection with several potential device applications. The oxide may be used as a dopant diffusion mask or as a dielectric (1).[2] Anodization could be used for the controlled thinning (*e.g.*, profiling) of GaAs. Oxide films of appropriate optical thickness could be used to increase the external efficiency of GaAs light-emitting diodes. Little published information is as yet available on the anodization of GaAs. In a patent application (1), GaAs was anodized in an aqueous solution of boric acid and sodium tetraborate. Revesz and Zaininger (2) anodized GaAs wafers in acetic anhydride saturated with potassium nitrate. They reported that the anodic oxide seemed uniform but its refractive index could not be determined due to severe pitting of the substrate during anodization because of dissolution of GaAs. In another paper, Zaininger and Revesz (3) determined the refractive index of GaAs to be 3.923-j0.304 by obtaining the asymptotic values of Δ and ψ of the GaAs surface which has been successively etched. Weinreich (4) reported a refractive index of 1.78 ± 0.02 for GaAs oxides grown in an oxygen plasma. Navratil (5) obtained a refractive index of 1.55 for thermally oxidized GaAs. In the present work we report an ellipsometric investigation of the properties of anodic oxides made in dilute aqueous ammonium pentaborate solution. This gave uniform oxides, provided the anodization period was short.

Experimental Procedure

The GaAs specimens, about 1 x 1 x 0.2 cm^3, were abraded, mechanically polished with 0.3 μm alumina powder, cleaned in boiling trichlorethylene, boiling acetone, and propanol, and then treated for 1-2 min in $7H_2SO_4(98\%):H_2O_2(30\%):H_2O$ at 80°C. A eutectic composition of gold-germanium was evaporated onto the reverse side of each GaAs mirror and later alloyed in a hydrogen atmosphere (6). This procedure has been found to produce ohmic contacts. In some experiments it was found convenient to use tantalum wire point-contacts as used for silicon anodization (7) (the tantalum is anodized and no stop-off is required). Specimens were normally mounted (using Silastic and Koldmount) in a recess in a Teflon plate (Fig. 1) such that only the polished surface was exposed to the electrolyte during anodization. A groove on the Teflon plate allowed the Teflon-coated wire to be brought out above the electrolyte. The Teflon plate was mounted on a holder which can be set at a fixed position with respect to the ellipsometer. Ellipsometry measurements were made on the unanodized GaAs and at intervals during anodization. Alignment was maintained in repeated anodization steps and ellipsometry measurements by transferring the entire unit (Teflon plate and holder) between the ellipsometer and the anodization bath. After each anodization the specimen was immediately rinsed in distilled water and carefully dried with lint-free paper. Anodization was carried out in subdued light in a solution of 2 g/liter ammonium pentaborate in water kept at 25°C. The anodization circuit was closed as soon as the specimen was immersed in the solution, a switch operated by the weight of the specimen assembly being used to facilitate this. A thin tantalum wire served as the cathode. The voltage between the cathode and the anode was measured using a Fluke Model 881AB differential voltmeter. The ellipsometer and the method used in taking

ellipsometry measurements have already been described (8).

Results

Figures 2 and 3 show ellipsometry data for anodized polycrystalline and single-crystal n-type GaAs, respectively. The respective room-temperature resistivities of the GaAs specimens were 3.8 x 10^{-3} and 0.07 ohm-cm. They were anodized at a constant current density of 1 mA/cm^2. The ellipsometric readings were taken with 5461Å light at a 70° angle of incidence. The

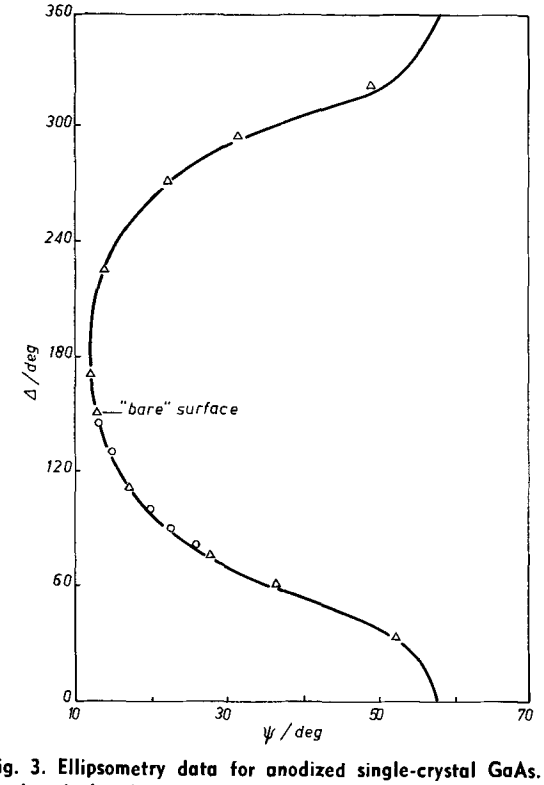

Fig. 3. Ellipsometry data for anodized single-crystal GaAs. The curve is calculated with $n_1 = 1.82$, $n_2 = 4.00 - j0.300$. △, First cycle; ○, second cycle.

Table I

GaAs substrates	n_1	n_2	$\langle\sigma_\psi\rangle$	$\langle\sigma_\Delta\rangle$	Total No. of points	Final oxide thickness
Polycrystal	1.82	4.00-j0.307	0.22	0.95	19	2395Å
Single crystal	1.82	4.00-j0.300	0.25	2.00	15	2150Å

refractive indexes of the oxide films and the GaAs substrates were obtained by curve fitting the experimental points using a computer program (8, 9). A best fit was obtained by varying the refractive indexes of the film and substrate such that mean square deviation between computed and experimental points was a minimum. The ellipsometry data shown in Fig. 2 and 3 are in good agreement with the computed curves for uniform, nonabsorbing films. Table I contains the fitted values of the refractive indexes of the oxide and the substrate (n_1 and n_2, respectively) and the mean standard deviation $\langle\sigma_\psi\rangle$ and $\langle\sigma_\Delta\rangle$ between computed and experimental results for ψ and Δ, respectively. The index of refraction of the film and the real and imaginary part of n_2 were varied in sequence and the fit to the experimental results was detectably worse for variations of ±0.02 in n_1 and ±0.03 $\pm j0.005$ in n_2 from the values in the table.

The oxide is amorphous. Electron reflection diffraction at 50 and 100 kV produced patterns which showed only very diffuse halos. The oxide was slowly dissolved by the forming solution and by distilled water. The interference colors, on a sample that was anodized at constant current to 50V and then left immersed in the solution for about 5 hr with no voltage applied, disappeared indicating that the oxide was being dissolved. Ellipsometry indicated that a 2000Å thick oxide was dissolved away from a sample after it had been in water for 2 days. Because the dissolution tends to be nonuniform, formation at constant voltage will in general lead to films of nonuniform thickness. For example, if an oxide is grown to 90V at 1 mA/cm^2 and then held at this voltage, the current then decays with time and a uniform increase in oxide thickness takes place at first. However, a time is reached when the current becomes almost constant (at 90V this is about 0.3 mA/cm^2) which probably corresponds to a rough equivalence between film growth and dissolution and the oxide becomes nonuniform. The film uniformity can be restored by increasing the voltage to produce an increase in current or growth rate. No changes in the ellipsometric readings were measured in an oxide held in air for about 15 hr, indicating a stable oxide. Growth at constant current gives results typical of anodic oxide growth on valve metals. That is the voltage and thickness increase linearly with time corresponding to a linear dependence of voltage on thickness with a zero film thickness intercept typically of about −2V. A typical dependence of voltage on thickness is shown in Fig. 4. The electric field in the oxide as esti-

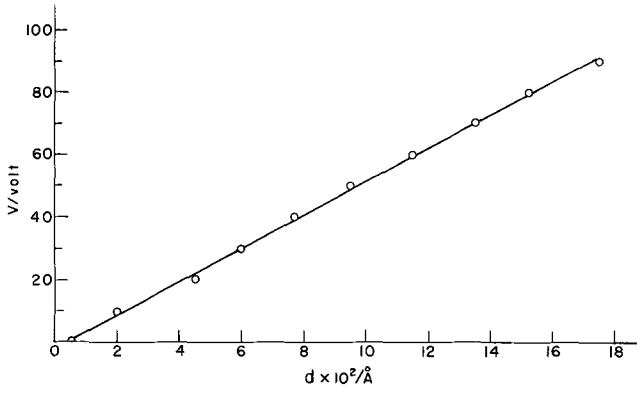

Fig. 4. Typical dependence of voltage on oxide thickness under anodization at constant current of 1 mA/cm^2.

mated from dV/dd was 5 x 10^6 V/cm both for polycrystalline and single-crystal material under growth at 1 mA/cm^2 (not corrected for leakage or dissolution) at 25°C. This field value is somewhat lower than for the same total current density applied to tantalum in dilute electrolytes at 25°C.

Relaxation of Internal Stresses in Electrodeposits during Stress Measurement by Null-Deflection Methods

J. M. Sykes and G. P. Rothwell

University of Cambridge, Department of Metallurgy, Cambridge, England

In most of the methods used to measure stress in electrodeposits, a thin metal strip is plated on one side only and the deflection produced, or the force required to prevent that deflection is measured (1-7). From these measurements the stress in the deposit may be calculated. The principal criticism of methods in which a deflection is measured is that in the tests relaxation of the internal stresses in the deposit will occur as the strip bends, whereas in practice the substrate is usually too thick to be deformed by stresses in the deposit. Although one can often calculate what the original stress must have been, relaxation can affect the behavior of subsequent layers of deposit. For instance, relaxation can prevent cracking of a brittle deposit. To prevent this kind of effect, null-deflection methods have been developed, such as the Hoar-Arrowsmith balance (7), in which the restoring force needed to prevent deflection is measured.

We show below, however, that if the restoring force is applied to the end of the strip, even if the whole length of the strip is plated, the resultant bending moment will not be zero along the whole length of the strip. The bending moment caused by the deposit will be the same at any point along the strip, but that due to the restoring force will be proportional to the distance from the point of application of the force, so that curvature of the strip will result. This leads to a new formula relating the restoring force to the stress in the deposit and allows the curvature of the strip to be compared with that of an unrestrained strip.

Another effect that has not been thoroughly investigated is relaxation of stress in the direction perpendicular to that in which the strip is restrained. This causes a decrease in elastic strain across the strip and will lead to a similar reduction in the elastic strain along the length of the strip, with a consequent reduction in the measured stress, determined by Poisson's ratio for the deposited metal. It will be shown that this is comparable with the relaxation which would occur in unconstrained bending and that it cannot be eliminated by suitable choice of dimensions for the test strip.

Calculation

In the simplest case, where the substrate and deposit have the same Young's modulus, E, and the thickness of the deposit, d, is small compared with that of the substrate, t, the bending moment, M_S, at any point in the strip due to a mean stress S in the deposit is given by (8)

$$M_S = \frac{Sb\,td}{2} \qquad [1]$$

where b is the width of the strip.

If this couple causes the beam to bend to a radius of curvature r, the elastic resistance of the combined beam will generate a bending moment M_e given by (8)

$$M_e = \frac{E(t+d)^3 b}{12r} \qquad [2]$$

If the strip, of length l, is fixed at one end and a restoring force, F, is applied at the other, a bending moment, M_F, will be generated at any point in the strip, which will be dependent on x, the distance from the fixed end. This moment is given by (9)

$$M_F = (l-x)F \qquad [3]$$

If the strip is in equilibrium the resultant of these three bending moments must be zero at all points in the strip.

$$M_S + M_e + M_F = 0,$$

$$\frac{Sbtd}{2} + \frac{E(t+d)^3 b}{12r} + (l-x)F = 0 \qquad [4]$$

Thus, the curvature

$$\frac{1}{r} = -\frac{12}{E(t+d)^3 b}\left[\frac{Sbtd}{2} + (l-x)F\right] \qquad [5]$$

But

$$\frac{1}{r} = -\frac{d^2y}{dx^2}$$

where y is the deflection of the strip at a distance x from the fixed end (9). Therefore

$$\frac{d^2y}{dx^2} = \frac{12}{Eb(t+d)^3}\left[\frac{Sbtd}{2} + F(l-x)\right] \qquad [6]$$

and by integration

$$\frac{dy}{dx} = \frac{12}{Eb(t+d)^3}\left[\frac{Sbtdx}{2} + F\left(lx - \frac{x^2}{2}\right)\right] + A \qquad [7]$$

Key words: mechanical properties, electroplating, Stresometer.

Because $dy/dx = 0$ for $x = 0$, the integrating constant $A = 0$. Further integration yields

$$y = \frac{12}{Eb(t+d)^3}\left[\frac{Sbtdx^2}{4} + F\left(\frac{lx^2}{2} - \frac{x^3}{6}\right)\right] + B \quad [8]$$

Because $y = 0$ for $x = 0$, the integrating constant B is also zero.

Now in null-deflection methods the value of F is fixed so that $y = 0$ for $x = l$.

Therefore

$$\frac{12}{Eb(t+d)^3}\left[\frac{Sbtdl^2}{4} + \frac{Fl^3}{3}\right] = 0$$

and

$$F = -\frac{3}{4}\frac{Sbtd}{l} \quad [9]$$

[The formula normally used (7) gives

$$F = -\frac{1}{2}\cdot\frac{Sbtd}{l}. \ ]$$

Substituting the value of F (Eq. [9]) into Eq. [5]

$$\frac{1}{r} = \frac{3\,Std(3x - l)}{El(t+d)^3} \quad [10]$$

From this equation we may obtain the curvature at particular points. Thus, for $x = l/3$, $1/r = 0$ (no curvature). Elsewhere, the strip will be curved, and maximum curvature occurs for $x = l$, when

$$\frac{1}{r} = \frac{6\,Std}{E(t+d)^3} \quad [11]$$

At this point the applied force has no bending moment (Eq. [3]) and the curvature will be approximately the same as that for an unrestrained strip (8). Maximum negative curvature occurs for $x = 0$, when

$$\frac{1}{r} = -\frac{3\,Std}{E(t+d)^3} \quad [12]$$

half the value for an unrestrained strip.

In summary, at the point at which the force is applied the relaxation of the internal stress will be the same as that for an unrestrained strip but will decrease toward the point of zero curvature, where there will be no relaxation. Along the final third of the length the stress in the deposit will become increasingly higher than its true (zero curvature) value as the support is approached.

By substitution from Eq. [9], Eq. [8] becomes

$$y = \frac{3}{2}\cdot\frac{Stdx^2(x - l)}{El(t+d)^3} \quad [13]$$

from which it may be shown that the maximum deflection of the strip occurs at $x = 2l/3$.

Let us now consider bending across the width of the strip. Where the strip is fixed to its support there can be no bending, but this constraint will be reduced further along the strip. For a long, thin strip at a sufficient distance from the support there will be virtually no constraint. Brenner and Senderoff (8) show that for an unconstrained strip the radius of curvature is given by

$$r = \frac{Et(t+d)}{6Sd} \quad [14]$$

The strip will describe an arc of a circle subtending a small angle θ at the center, such that $w = r\theta$ where w is the width of the strip. The mean radius of curvature for the deposit, r', will be given by

$$r' = r - \frac{t}{2}$$

Therefore the width of the deposit after contraction, $w' = r'\theta = (r - t/2)w/r$.

The contraction due to bending, $\Delta w = w - (r - t/2)w/r$. Thus

$$\Delta w = wt/2r \quad [15]$$

Strain in deposit

$$\Delta w/w = t/2r$$

But

$$r = \frac{Et(t+d)}{6Sd}$$

so that

$$\frac{\Delta w}{w} = \frac{3Sd}{E(t+d)} \quad [16]$$

If Poisson's ratio for the deposit is ν

$$\frac{\Delta l}{l} = \nu\cdot\frac{\Delta w}{w} = \frac{3\nu Sd}{E(t+d)} \quad [17]$$

Therefore the relaxation in the measured stress ΔS is given by

$$\Delta S = E\frac{\Delta l}{l} = \frac{3\nu Sd}{(t+d)},$$

$$\frac{\Delta S}{S} = \frac{3\nu d}{(t+d)} \quad [18]$$

This relaxation depends only on Poisson's ratio and the ratio of deposit thickness to total thickness, and not as has been suggested (7, 11) on the length/width ratio of the specimen. This is in agreement with Arrowsmith's observation (10) that the measured stress is independent of the length/width ratio over a wide range of values. If we put values into Eq. [18] above, for example: $\nu = 0.4$ for nickel, $d = 10^{-3}$ mm, $t = 10^{-1}$ mm

$$\frac{\Delta S}{S} = \frac{0.4\cdot 3\cdot 10^{-3}}{10^{-1}} \approx 1.2\times 10^{-2}$$

$$= 1.2\%$$

Thus for small thicknesses this effect may be disregarded, but we may note that this relaxation is of the same order of magnitude as the relaxation in an unrestrained strip and will increase as the deposit thickness increases.

Conclusions

We have shown that even in null-deflection methods there will be some stress relaxation due to bending of the test strip and that because of this bending the stress should be calculated using the formula

$$S = \frac{4}{3}\cdot\frac{Fl}{btd}$$

Similarly there will be some relaxation because constraint is not applied across the strip, but for thin deposits this will only lead to a small decrease in measured stress. The only method that rigorously simulates true plating conditions is clamping the specimen completely flat during plating and measuring curvature upon subsequent release (3). For continuous measurements some stress relaxation in the deposit has to be tolerated.

Electroless Deposition of Certain Metal Oxides

II. Tl_2O_3, MnO_2

W. Mindt*[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

The object of this study is the deposition of metal oxides through surface catalyzed oxidation of metal ions from aqueous solutions by an oxidizing agent. In part I (1) deposition of α-PbO_2 was described. The electrochemical mechanism of this process was found to be analogous to electroless metal plating, being a mixed electrolytic reaction with superposition of anodic and cathodic partial currents according to the classical concept of Wagner and Traud (2). In general, the process can be described by the two partial reactions.

$$mMe^{z+} + nH_2O \rightarrow Me_mO_n + 2nH^+ + (2n - mz)e^- \quad [1a]$$

$$(2n - mz)(Ox + e^- \rightarrow Red^-) \quad [1b]$$

where Me^{z+} is a metal ion which can be oxidized to a higher oxide, and Ox and Red^- the oxidized and reduced species of a redox system.

The conditions under which electroless deposition of a metal oxide is possible have been outlined previously (1). In the present paper, deposition of two other oxides is reported under experimental conditions similar to those used for PbO_2.

Reactions of the type studied here may be valuable in cases in which an easy, room temperature deposition method of an electrically conductive metal oxide film is desired. An important feature of the method is that deposition on rough surfaces or in the pores of porous material may be possible. Two of the oxides (MnO_2 and PbO_2) are of interest for use as counterelectrodes in solid valve metal oxide capacitors (3-5). Other applications in thin-film devices may be limited by the chemical instability that is exhibited by most of the higher metal oxides for which this deposition technique would be applicable.

Experimental

As oxidizing agent, ammonium persulfate was used as described in part I. All experiments were carried out in a supporting electrolyte of M ammonium acetate. Tl_2O_3 and MnO_2 electrodes were prepared in two different ways: (*i*) by electrodeposition on platinum anodes—deposition of a 0.5μ thick layer was carried out in the same electrolyte used for the current potential measurements described below by applying an anodic current density of 0.5 mA/cm^2, and (*ii*) by chemical precipitation on glass substrates (1 × 3 in. slides)—the substrates, without special pretreatment, were immersed in a solution containing ammonium acetate, thallous or manganous acetate, ammonium persulfate, and silver nitrate as a catalyst for the persulfate oxidation. Precipitation of the metal oxide in the solution started after an induction time of several minutes. The substrates were left in the solution until a several hundred Angstrom thick layer of the oxide was formed. In the case of Tl_2O_3 a pH of 8.0 and for MnO_2 a pH of 5.0 proved to be optimal for this purpose. The platinum substrate electrodes were used for the current potential measurements; the weight gain measurements were carried out with electrodes prepared in both ways.

It should be noted that precipitation of the metal oxide in the solution did not occur during the experiments described below in which $AgNO_3$ was not added; the thallium baths remained clear for several days. In the manganese baths, precipitation of MnO_2 usually started after 10 to 30 min; the solution was then exchanged for a freshly prepared one.

The current potential measurements were carried out potentiostatically, using a platinum counterelectrode and an normal calomel reference electrode. Stationary conditions were achieved after several seconds at higher current densities and after a few minutes at current densities below 10 μA/cm^2.

The reagents used were analytical reagent grades of $TlC_2H_3O_2$, $Mn(C_2H_3O_2)_2$, $AgNO_3$, $(NH_4)_2S_2O_8$, and $NH_4C_2H_3O_2$ (prepared from glacial acetic acid and 30% NH_4OH). The pH of the solutions was adjusted by addition of NH_4OH. The electrolyte was agitated. All experiments were carried out at 25°C.

Results and Discussion

In Fig. 1, stationary current voltage curves of Tl_2O_3 electrodes are shown which were obtained in a solution of 50 mM thallous acetate in M ammonium

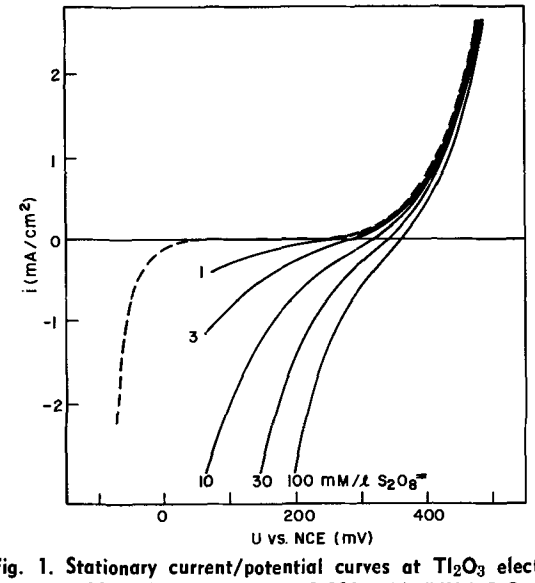

Fig. 1. Stationary current/potential curves at Tl_2O_3 electrodes. Electrolyte: 50 mM $TlC_2H_3O_2$ + 1-100 mM $(NH_4)_2S_2O_8$ in M $NH_4C_2H_3O_2$ at pH 10. Dashed line: without $(NH_4)_2S_2O_8$.

Key words: electroless deposition, oxide films, manganese dioxide, thallic oxide.

acetate at different concentrations of ammonium persulfate. In this solution the anodic reaction is

$$2Tl^+ + 3H_2O \rightarrow Tl_2O_3 + 6H^+ + 4e^- \quad [2]$$

In the presence of persulfate, the net current results from superposition of reaction [2] and reduction of $S_2O_8^=$

$$S_2O_8^= + 2e^- \rightarrow 2SO_4^= \quad [3]$$

At zero current, *i.e.*, under open-circuit conditions, deposition of Tl_2O_3 occurs at a rate given by the current density of the anodic partial reaction (dotted line) at the open-circuit potential. This was confirmed by weight gain measurements under open-circuit conditions at different $S_2O_8^=$ concentrations.

The situation in the case of MnO_2 (Fig. 2) is somewhat different because the zero current plateaus in the absence of persulfate (dotted lines) corresponding to the reaction

$$Mn^{++} + 2H_2O \rightarrow MnO_2 + 4H^+ + 2e^- \quad [4]$$

are not as well defined as for Tl_2O_3. One can recognize, however, the effect of the addition of persulfate. The curves were not as reproducible as those of Tl_2O_3; however, weight gain measurements at open circuit gave the expected growth rate within errors of ± 30%.

Properties of the films.—The deposits obtained on glass substrates were continuous and of uniform thickness. No pores could be seen by light microscopy. Good adherence was achieved up to a thickness of about 10μ with Tl_2O_3 and up to about 0.5μ with MnO_2. X-ray studies showed sharp lines of the cubic Tl_2O_3. No patterns were observed in MnO_2. The electrical resistivity of Tl_2O_3, determined by the four-point method, was 5×10^{-4} ohm-cm. The resistivity of MnO_2 depended on the pH of the electrolyte, *e.g.*, values of 4×10^2 ohm-cm and 2×10^4 ohm-cm were obtained at pH values of 8 and 6.3, respectively. These lie within the range of resistivities found for pyrolytic material.

Thermodynamic remarks.—The equilibrium potentials of both reactions [2] and [4] depend on the pH of the electrolyte. Thus, the current potential curves shift with pH as was seen in Fig. 2 with MnO_2. This results in a pH dependence of the growth rate. In addition, there exist some other pH dependent thermodynamic equilibria which may interfere with the deposition process. These are summarized in Fig. 3 and 4. The potentials are calculated from free energy data (6-8) for concentrations of 50 mM in Tl^+ and Mn^{++}.

Since only one lower oxide of thallium (Tl_2O) exists, the conditions are easy to survey in this case.

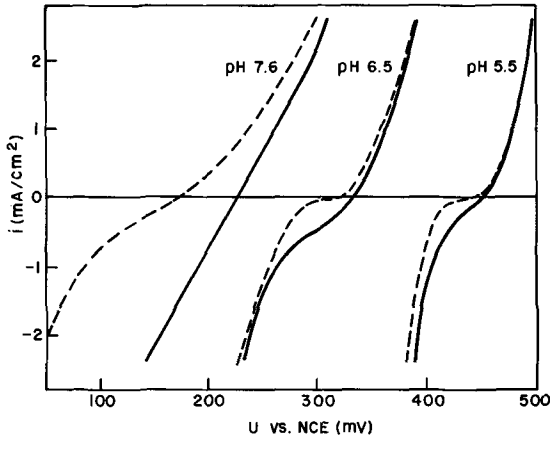

Fig. 2. Stationary current/potential curves at MnO_2 electrodes. Electrolyte: 50 mM $Mn(C_2H_3O_2)_2$ + 0.5M $(NH_4)_2S_2O_8$ in M $NH_4C_2H_3O_2$ at pH 5.5, 6.5, and 7.6. Dashed lines: without $(NH_4)_2S_2O_8$.

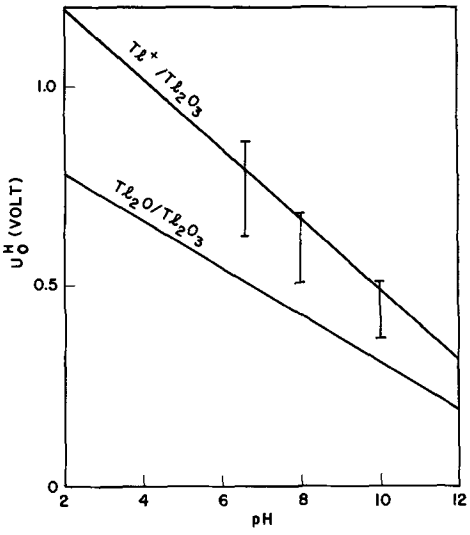

Fig. 3. Equilibrium potentials of reactions [2] and [5], calculated from thermodynamic data (6, 8), vs. pH. Bars show zero current plateaus at Tl_2O_3 electrodes measured in a solution of 50 mM $TlC_2H_3O_2$ in M $NH_4C_2H_3O_2$.

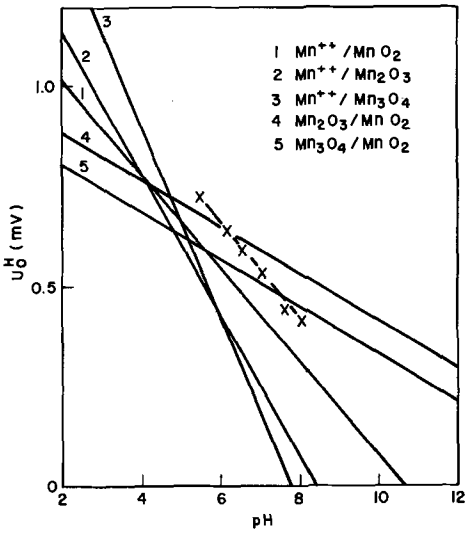

Fig. 4. Equilibrium potentials of reactions [4], [6]-[9], calculated from thermodynamic data (6,7), vs. pH. Crosses show open-circuit potentials of MnO_2 electrodes measured in a solution of 50 mM $Mn(C_2H_3O_2)_2$ in M $NH_4C_2H_3O_2$.

The equilibrium potentials of the reaction

$$Tl_2O_3 + 4H^+ + 4e^- \rightleftarrows Tl_2O + 2H_2O \quad [5]$$

are well below those of reaction [2] in the studied pH range. An influence due to this equilibrium at anodic currents is unlikely to occur. With cathodic currents, reduction of Tl_2O_3 to Tl_2O becomes possible. The potential range in which a zero current plateau is observed is shown in Fig. 3. However, since no activity coefficients and liquid junction potentials have been taken into account, this comparison gives only a rough confirmation that Tl_2O is not involved.

The situation in the case of MnO_2 is more complex, since equilibria of Mn^{++} and MnO_2 with lower oxides of manganese are thermodynamically possible. The equilibrium potentials of the following reactions (together with [4]) are plotted in Fig. 4

$$2Mn^{++} + 3H_2O \rightleftarrows Mn_2O_3 + 6H^+ + 2e^- \quad [6]$$

$$3Mn^{++} + 4H_2O \rightleftarrows Mn_3O_4 + 8H^+ + 2e^- \quad [7]$$

$$Mn_2O_3 + H_2O \rightleftarrows 2MnO_2 + 2H^+ + 2e^- \quad [8]$$

$$Mn_3O_4 + 2H_2O \rightleftarrows 3MnO_2 + 4H^+ + 4e^- \quad [9]$$

The experimentally observed open-circuit potentials are also shown. The equilibrium potentials of reactions [6] and [7] cross that of reaction [4] between pH 4 and 5. It is interesting to note that at pH values lower than 5 the electrical resistivity of the electrodeposited films becomes very high, so that finally deposition is no longer possible. This may indicate the beginning of co-deposition of an insulating lower oxide. The question of how much the equilibria [8] and [9] interfere with reaction [4] cannot be answered here. It appears, however, that at higher pH the cathodic parts of the current potential curves in Fig. 2 are determined by these reactions, since cathodic passivation occurs.

Acknowledgments

The author wishes to thank P. C. Milner for helpful discussions and interest in this work. He is also indebted to G. W. Kammlott for carrying out the x-ray studies.

Anodic Oxidation of Carbohydrates and Related Compounds in Neutral Saline Solution

A. J. Appleby* and C. Van Drunen

Institute of Gas Technology, Chicago, Illinois 60616

In a previous communication (1) the oxidation of glucose and derivatives at platinum black electrodes in pH 7.4 saline solution isotonic with human plasma was discussed with the objective of determining the feasibility of consuming such materials in an implantable energy conversion device. Small versions of a fuel cell of this type (power ~100 μW) are capable of supplying electrical energy to a heart pacemaker, urinary stimulator, or physiological monitor device. Larger versions (power 4.5W or more) are potentially capable of supplying sufficient power for a prosthetic heart device. In each case the anodic process would be oxidation of carbohydrates at an electrode with an associated diffusion membrane to prevent contact with blood or intercellular fluid, and the cathodic process would be reduction of oxygen derived either from intercellular fluid (for the smaller devices) (2) or from the air via a percutaneous lead (for the prosthetic heart power source) (3).

In the present communication the catalytic effects of different electrode materials on the anodic oxidation process are discussed along with the order of reaction and probable kinetic rates that may be obtained with currently available catalytic materials at workable overpotentials.

Apparatus

The apparatus used was a conventional glass and Teflon 3-compartment cell with platinum counterelectrode and saturated calomel reference electrode. The electrolyte was Ringer's phosphate buffer solution of physiological strength and pH. A supply of electrolyte (about 500 ml) containing the required concentration of carbohydrate was deaerated using nitrogen in a spiral deoxygenator (4), where it could be stored under nitrogen until required. Electrolyte could be transferred directly under nitrogen from the deoxygenator to the cell. The whole apparatus was maintained at 37°C in a water bath.

A potentiostatic pulsing technique was used to prepare reproducible electrode surfaces. Polarization results, however, were obtained using a conventional galvanostatic circuit.

Electrocatalysis Experiments

Electrodes consisted of Pt and Au foils, and Ir, Ru, Rh, and Pt/Rh alloy plates cut from small rods or castings using a diamond saw. Areas varied from 0.51 to 2.0 cm^2. All were ground and polished, welded to gold wires, degreased, and washed in concentrated HCl and conductivity water. Preliminary experiments established that gold is a very poor catalytic surface for carbohydrate oxidation (see below); hence the presence of gold suspension wires will not be expected to affect data. In addition, a number of experiments were conducted on 1-cm^2 gold foils electroplated with Pt and Rh blacks. Areas were measured using the chronocoulometric hydrogen stripping method in dilute sulfuric acid.

Experiments were conducted in physiological strength (0.005N) glucose solution. Each bright electrode was first given an anodic and cathodic pulse treatment to ensure a reproducible clean surface. The electrode was first pulsed to 700 mV *vs.* calomel (1390 mV *vs.* hydrogen at the same pH), then given a reductive pulse to −900 mV *vs.* calomel, after which it was left on open circuit for 2 min to allow any hydrogen formed during the cathodic pulse to dissipate and to give sufficient time to allow glucose adsorption. A small anodic current was then applied, and the polarization measured after 2 min.

Initial open-circuit potentials on all electrodes were in the range from −610 to −626 mV *vs.* calomel (from +80 to +64 mV *vs.* hydrogen in the same solution). Decay on open circuit was very small (1 mV or less) during the initial period of rest. After this period a small anodic current was applied to the electrode, and the polarization measured after 2 min. The pulsing procedure was repeated before each current density was applied.

Current densities quoted for each electrode in Table I represent values where the onset of poisoning phenomena was considered to occur. Poisoning in this context is defined as rapid positive movement of potential (on the order of 5 mV or more in 2 min) that is irreversible so that the electrode does not return to the initial open-circuit value when the polarizing current is removed.

Table I. Current densities at which poisoning occurred on smooth electrodes

Electrode	Current density, $\mu A/cm^2$
Pt	0.5-1.0
Rh	5.0-7.0
Ir	2.0-3.0
Ru	0.5
Au	0.5
Pt-8 a/o Ru	2.0-3.0
Pt-18 a/o Ru	4.0
Pt-40 a/o Ru	3.0-5.0
Pt-60 a/o Ru	5.0

In all cases the potential at which poisoning became apparent was in the range from −605 to −610 mV *vs.* calomel (from +85 to +80 mV *vs.* hydrogen in the same solution).

It is evident that rhodium, closely followed by platinum-ruthenium alloys, gives the best catalytic performance of the materials studied. Platinum-ruthenium alloys have been shown in other contexts to be effective oxidation catalysts for organic fuels in energy-conversion devices and are known to be resistant to poisoning effects in the oxidation of carbonaceous compounds (5).

In view of the above conclusion, further work was conducted on rhodium black electrodes. Platinum black electrodes were simultaneously used as a standard of comparison.

Oxidation on Black Electrodes

Experiments were conducted on glucose oxidation using 1-cm^2 gold foil electrodes plated with rhodium (area roughness factors 167 and 26.7) and with platinum (area roughness factor 2.9). Black electrodes were given a pulsing treatment for initial surface activation similar to that for bright electrodes but were then left on open circuit for 10 min, followed by polarization at a given current density for 10 min.

Results were obtained in 0.005, 0.001, and 0.0002 M glucose solutions. Open-circuit potentials are given in Table II.

Overnight open-circuit values refer to electrodes left 16 hr in the solution after pulsing. Although there is a slight tendency for the initial open-circuit value on Pt to fall with decreasing glucose concentration, the opposite is the case for electrodes left overnight in the solution. Open-circuit values on Rh electrodes are essentially concentration independent. Smooth Rh and Pt electrodes had overnight open-circuit voltages ~300 mV NHE, and showed more rapid decay.

Initial polarization behavior on the 167-cm^2 Rh black electrode is illustrated in Fig. 1. On this electrode, poisoning was not apparent below 20 $\mu A/cm^2$, which on a real area basis is 0.12 $\mu A/cm^2$. Polarization curves for the three glucose concentrations studied as shown. In addition, a polarization plot for the 0.001M solution after the electrode had been allowed to stand for 1 hr after activation is shown (dashed line). The other group of polarization plots refers to the three solutions for electrodes that had been allowed to stand 16 hr after pulsing. It can be seen that the effect of glucose concentration is small, except at high current density where mass transport effects may start to predominate. In general the slow change in potential at constant current density (on a geometric-area basis) was much less on electrodes of high specific area, but

Table II. Open-circuit potentials on black electrodes

	Rhodium open circuit		Platinum open circuit	
	Initial	Overnight	Initial	Overnight
Glucose M	mV *vs.* calomel			
0.005	626-630	572	639-641	510
0.001	641-640	575-578	633-637	
0.0002	629-634	572	617-629	523

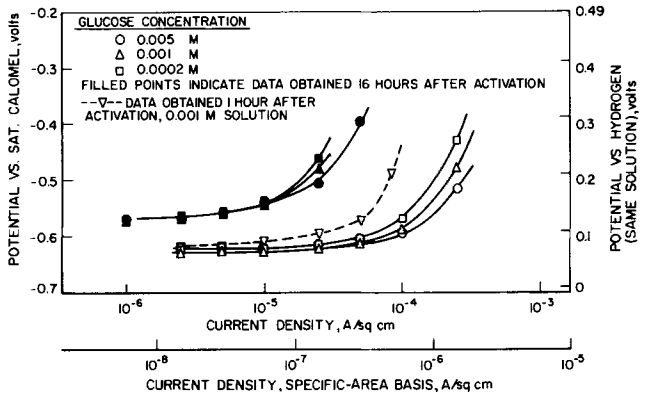

Fig. 1. Oxidation of glucose on rhodium black in Ringer's phosphate buffer (roughness factor 167) at 37°C.

these were not as good as smooth electrodes on a specific-area basis from the initial polarization point of view. This can be attributed to difficulty of diffusion of poisoning products within the porous structure, and perhaps to pH changes in the pore structure if local production of $[H^+]$ exceeds the buffering capacity of the electrolyte.

A series of tests similar to the above was carried out in 0.005, 0.001, and 0.0002M gluconic acid and glucosamine solutions. On the low-specific-area Rh black electrode (26.7 cm^2), polarizations of 23, 13, and 18 mV, respectively, were noted in the three glucose solutions at a geometric-area current density of 5 $\mu A/cm^2$ 10 min after activation. Open-circuit voltages were 628-632 mV *vs.* calomel. In glucosamine solutions, open-circuit potentials were 10-15 mV more negative, and corresponding polarizations were ~1, 4, and 4 mV only at 5 $\mu A/cm^2$ under the same conditions. Gluconic acid solutions gave open-circuit potentials ~15 mV more positive than glucose, and very large polarizations were recorded at 5 $\mu A/cm^2$ after 10 min (99 mV at 0.005M, 58 mV at 0.001M, and 23 mV at 0.0002M). The latter results are interesting in that they show a negative reaction order. Results on Pt black electrodes were similar with low apparent reaction orders for glucose and glucosamine. Again glucosamine showed the lowest and gluconic acid the highest polarizations, although the differences were not so marked as in the case of rhodium (~40 and 27 mV polarization for 0.005M and 0.0002M glucose; ~20 and ~30 mV, respectively, for similar glucosamine solutions; and ~40 and 50 mV for similar gluconic acid solutions at a geometric-area current density of 5 $\mu A/cm^2$).

Oxidation of a typical polysaccharide was studied using a 0.02% chondroitin sulfate solution. Preliminary results established initial polarization behavior to be midway between that for glucose and gluconic acid on both platinum and rhodium black electrodes. After allowing steady state to be reached (after about 16 hr in the solution) a Tafel plot on a platinum black electrode shows a slope of about 100 mV/decade (Fig. 2).

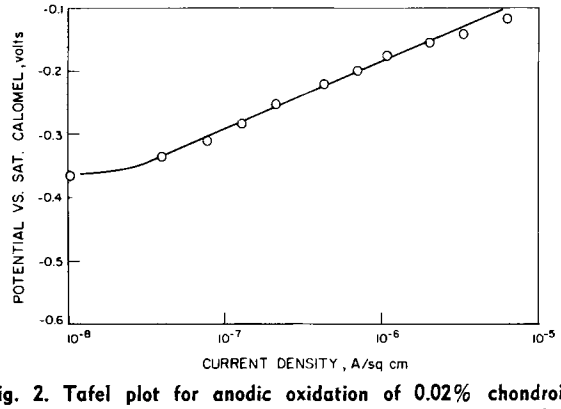

Fig. 2. Tafel plot for anodic oxidation of 0.02% chondroitin sulfate solution in Ringer's phosphate buffer on rhodium black (roughness factor 26.7) at 37°C.

Tafel plots of slope approaching $2RT/F$ are also given by glucose and gluconic acid solutions on poisoned electrodes (1).

Conclusions

Results obtained indicate that rhodium and Pt-Ru alloy electrodes are more effective than platinum for glucose oxidation, although gluconic acid is more effectively oxidized on platinum. Rate constants for gluconic acid oxidation appear to be lower than those for glucose in the +50 to +250 mV range *vs.* hydrogen in the same solution, in agreement with Rao and Drake's conclusions (6). Electrodes show a time-dependent rate constant due to poisoning effects. Reaction orders for glucose, gluconic acid, and glucosamine oxidation are low, and Tafel slopes approach $2RT/F$ for all the carbohydrate compounds studied when measurements are taken after a sufficiently long time. This suggests that the mechanism of carbohydrate oxidation is similar to that reported for ethylene and other organic compounds (5, 7) with the production or reaction of adsorbed OH as the rate-determining step, depending on the substrate.

The polarization data obtained in this work will be used in a mathematical model of a glucose diffusion anode for use in a proposed fuel cell for prosthetic heart propulsion.

Nomographs for the Diffusivities of Salts, Acids, and Bases in Very Dilute Water Solutions

Adam Zanker

Kiriat-Jam "G," Haifa, Israel

Two nomographs were constructed in order to predict and calculate the diffusivity of electrolyte molecules in very diluted water solutions. As a basis for these nomographs, the following equations were chosen: (*i*) the Nernst equation, which allows calculation of the diffusivity at a certain temperature when the required conductivities are known (1); and (*ii*) the Reid and Sherwood equation, which allows prediction and calculation of the diffusivity at various temperatures when only a diffusivity at 25°C is known (2). These equations were chosen for two reasons: first, they give relatively good results, in many cases very close to the measured values; and second, they are in nomographable form.

The maximum discrepancies between calculated and measured values are as follows (in per cent) (3)

Molecule type \ Concentration of electrolyte in water	up to 0.001M, %	up to 0.01M, %
Molecules of 1:1 type (such as NaCl, KNO_3)	3	8
Other types of molecules	10	15

In the majority of cases the calculated results are much closer to the measured values so that the use of these nomographs gives quick and relatively reliable results. The equations used are:

1. *The Nernst Equation*

$$D_{25} = 8.931 \times 10^{-10} \times T \cdot \frac{(L_+^\circ \times L_-^\circ)}{(L_+^\circ + L_-^\circ)} \cdot \frac{(Z_+ + Z_-)}{(Z_+ \times Z_-)}$$

where: D_{25} = diffusivity of the molecule, cm²/sec (at 25°C)

Key words: graphical calculations (in chemistry), ionic conductance (at infinite dilutions), electrolyte solutions, temperature-diffusivity relationships, mobility of ions.

I_+° = cationic conductance at infinite dilution cm² · ohm⁻¹/equiv (at 25°C)
I_-° = anionic conductance at infinite dilution cm² · ohm⁻¹/equiv (at 25°C)
T = absolute temperature, in °K (taken as constant, T = 298°K = 25°C)
Z_+ = absolute valency of cation (without sign)
Z_- = absolute valency of anion (without sign)

2. *The Reid and Sherwood Equation*

$$D_T = D_{25} \cdot \frac{T}{334 \cdot \mu_T}$$

where: D_T = diffusivity of molecule, cm²/sec, at temp. T °K
D_{25} = diffusivity of molecule, cm²/sec, at 25°C (298°K)
T = required temperature, in °K
μ_T = viscosity of water, at temp. T °K, in cP.

In order to facilitate use of the nomographs, several values of anionic and cationic conductances at 25°C were plotted on suitable scales (4, 5). Both nomographs are based on the above equations, but it was found more useful to construct two separate nomographs, one for salts only and the other for acids and bases.

Due to the large difference between the conductance of H^+ and OH^- ions, and other cations and anions, a nomograph covering the full range of ionic conductances turned out to be very inaccurate in the conductance of salts. The possiblity of plotting a number of values of cationic and anionic conductances was also limited.

Use of the nomographs is as follows:

(*a*) The known values of anionic and cationic conductances, plotted on a suitable scale, have to be con-

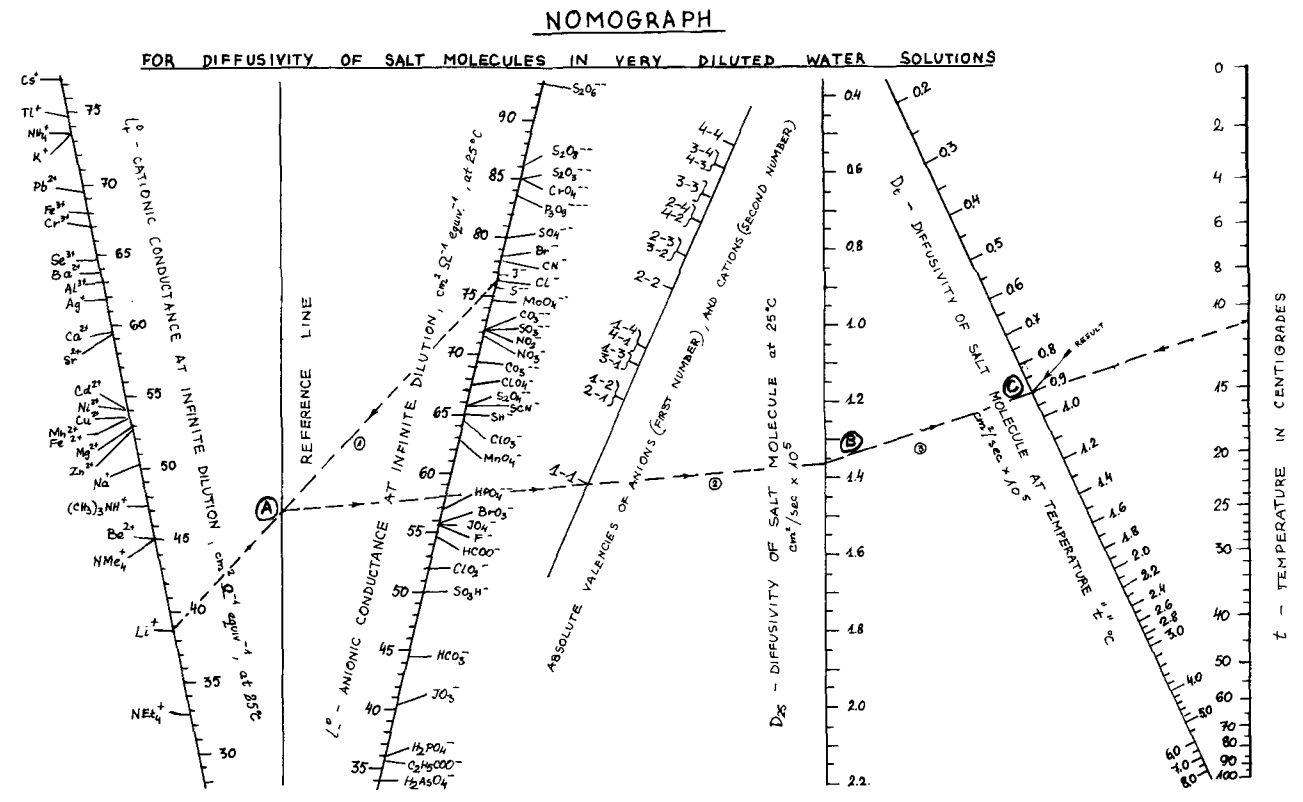

Fig. 1. Nomograph for diffusivity of salt molecules in very diluted water solutions

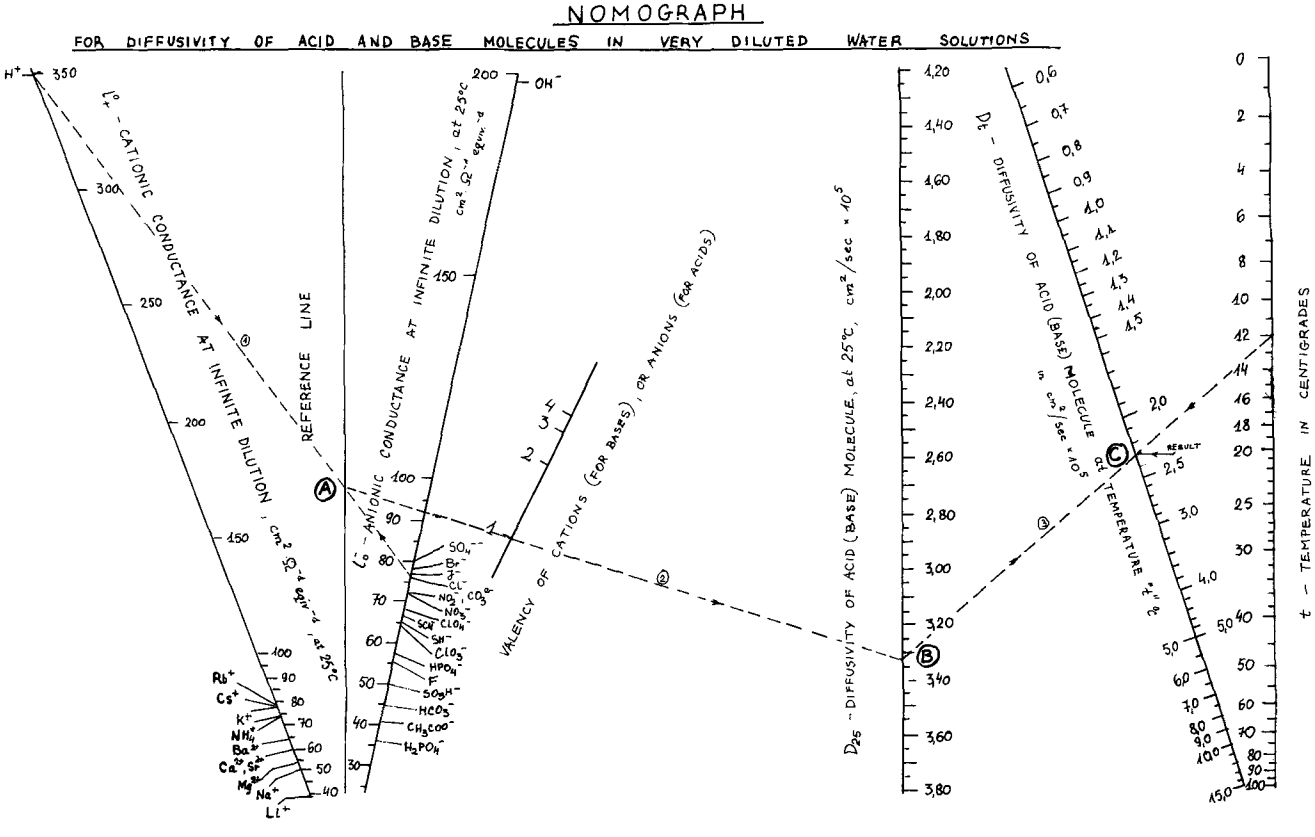

Fig. 2. Nomograph for diffusivity of acid and base molecules in very diluted water solutions

nected with a ruler. The intersection point of the ruler with the "reference line" gives the first auxiliary point, A.

(b) Point A has to be connected with a ruler with a suitable point on the scale which gives "valencies of the cations and the anions." This line has to be extended to the intersection point with the scale marked "diffusivity of molecule at 25°C," point B. This point gives the intermediate result, D_{25}.

(c) If it is desired to learn the diffusivity at a temperature other than 25°C, the value of D_{25} is to be connected with a ruler with the required temperature (t = °C) on the t scale. The intersection of the ruler with the D_t (oblique) scale gives the final result. In

order to illustrate use of the nomograph, an example is drawn, with a dotted line, on each of the nomographs shown.

Example 1. Nomograph for Diffusivity of Salts

What will be the diffusivity of diluted (0.01*N*) LiCl solution at 11°C? The conductance of Li^+ is 38.6 $cm^2 \cdot ohm^{-1}$/equiv at 25°C, and the conductance of Cl^- is 76.35 $cm^2 \cdot ohm^{-1}$/equiv at 25°C. Both values are plotted on suitable scales, and both values have to be connected with a ruler and the intersection point A with the reference line has to be found (dotted line 1).

The valencies of both cation and anion are 1 and 1. The point marked 1-1 on the valency scale is to be connected with the previously found point A, and the line extended up to the D_{25} scale (the dotted line 2 and point B). The value found is $D_{25} = 1.37\ 10^{-5}$ cm^2/sec. [The measured value is $1.313 \cdot 10^{-5}$ cm^2/sec (6).]

Point B should then be connected to a temperature of 11°C on the temperature t scale (dotted line 3 on the nomograph). The final result is found on the D_t scale (point C). The result is $D_t = 0.90 \cdot 10^{-5}$ cm^2/sec at 11°C. [The measured value is $0.93 \cdot 10^{-5}$ cm^2/sec (7).]

Example 2. Nomograph for Diffusivity of Acids and Bases

What will be the diffusivity of diluted (0.01*N*) HCl solution at 12°C? The conductance of H^+ is 349.8 $cm^2 \cdot ohm^{-1}$/equiv at 25°C and the conductance of Cl^- is 75.35 $cm^2 \cdot ohm^{-1}$/equiv at 25°C. Both values are plotted on suitable scales. Connect both values and find the intersection point A on the reference line (dotted line 1).

The valency of the cation is 1. The previously found point A has to be connected with the value 1 on the valency scale, and this line has to be extended up to the intersection with the D_{25} scale, pointed B (dotted line 2). The intermediate result is $D_{25} = 3.33 \cdot 10^{-5}$ cm^2/sec. [The measured value, graphically interpolated is $3.18 \cdot 10^{-5}$ cm^2/sec (8).]

The intermediate result, point B, has to be connected with the temperature 12°C on the temperature t scale (dotted line 3). The final result is then found on point C of the D_t scale and is $D_t = 2.3 \cdot 10^{-5}$ cm^2/sec at 12°C. [The measured value is $2.38\ 10^{-5}$ cm^2/sec (9).]

Brief Communication

Note on the Electrodeposition of Magnesium from an Organic Solution of a Magnesium-Boron Complex

Abner Brenner*

National Bureau of Standards, Washington, D. C., 20234

Thus far no successful method of electrodepositing magnesium from a solution operated at room temperature has been published. Magnesium is too active a metal to be electrodeposited from aqueous solutions and electrolysis of various Grignard solutions has not yielded sound, coherent deposits of magnesium. The cathode deposits are mossy, dark in color, and obviously contaminated. I have reviewed the unsatisfactory situation pertaining to the electrodeposition of magnesium (1).

I have developed an organic plating bath, which deposited smooth, white, somewhat ductile coatings of magnesium. It was obtained by reactions involving decaborane, $B_{10}H_{14}$.

The first step in the preparation of the bath is the preparation of a lithium derivative of decaborane with a solution of lithium methyl in ether.[1] Lithium methyl in diethyl ether (25 ml of a commercial 1.7M solution) was introduced into an oxygen-free vessel through which pure argon flowed. Decaborane, 1g, dissolved in 10 ml of terahydrofuran (THF) was slowly added. The THF needs to be anhydrous.[2] With each addition of the decaborane solution a vigorous effervescence occurred, which probably represented the evolution of methane. A heavy, yellow layer separated out which contained most of the lithium.[3] On electrolysis of this two-phase solution at 0.1 to 1.0 A/dm^2, lithium deposited on the cathode but in much greater quantity from the lower layer which obviously had much greater conductivity.[4] At high current density, the lithium deposited as dendrites from the lower layer instead of as a smooth deposit.[5]

To the two-layer system of lithium-decaboron complex, 25 ml of a saturated solution of anhydrous magnesium chloride in THF was added. The system

* Electrochemical Society Active Member.

Key words: magnesium—electrodeposition of, decaborane, organometallic compound, nonaqueous electroplating, lithium deposition.

[1] Both materials are commercially available. Decaborane at the moment costs about $3 a gram, and, therefore, a research chemist might prefer to spend his money on platinum. However, with boric acid priced at about five cents a pound, there is no inherent reason why decaborane should not be produced more cheaply.

[2] The distillation with lithium aluminum hydride, so frequently described in the literature, is quite unnecessary. It is sufficient to add a sodium hydride suspension, a commercial 50% suspension of NaH in mineral oil, in small quantities to several hundred milliliters of THF until the gassing ceases, let stand until the excess NaH settles out, and then decant off the THF as needed.

[3] This lower layer had much higher conductivity than the supernatant liquid.

[4] This electrolysis contrasts with the initial solution of lithium methyl which scarcely conducts at all and from which lithium does not deposit.

[5] In some cases needles so fine as to be scarcely visible grew with great rapidity, for example, 1 cm in a minute, and shorted out the cell.

became homogeneous forming the plating bath.[6] The conductivity of the resulting solution was much higher than that of the lithium-decaboron solution from which it was formed. The magnesium complex in the solution appeared to be soluble at least to the extent of 1 mole per liter. The resulting solution on electrolysis yielded smooth, white, sound deposits of magnesium. The bath may be operated at current densities between 0.1 and 1.0 A/dm^2. The cathode and anode efficiencies were approximately 100%. With further development the process should be on a par with the hydride-ether aluminum plating process.

The bath can be prepared directly from a Grignard reagent and decaborane, for example, by mixing 60 ml of a THF solution of magnesium ethyl chloride (commercially obtainable) with a gram of decaborane and adding some magnesium chloride-THF solution. This bath was not as satisfactory as the one derived from the lithium complex, but with further investigation it might be improved.

The magnesium bath was prepared with rigid exclusion of oxygen, but after preparation it was stable on exposure to dry air. Moisture would undoubtedly decompose the magnesium complex. The bath is stable. A bath, which had evaporated to about half-volume during a six-month storage period, again became operative after THF was added to bring the bath up to volume together with some additional magnesium chloride in THF.

[6] Magnesium chloride dissolves slowly in THF and may at first give the appearance of low solubility, but the saturated solution has a concentration of about 0.75 molar. The salt and the THF may need to stand for several days or be stirred a number of hours. On long standing (some weeks or months) the saturated solution fills with a mass of colorless crystals of the THF etherate.

The deposit has not been quantitatively analyzed, but the indications are that it may contain a small amount of boron, perhaps below 1%. Tubes of magnesium were electroformed by depositing the metal on thin-walled aluminum tubing, serving as a master, which was subsequently dissolved out with caustic soda.

A beryllium analog of the magnesium bath is under investigation, but it does not yield as yet satisfactory deposits.

The compound present in the decaborane magnesium bath is probably not $Mg \cdot B_{10}H_{12} \cdot 2Et_2O$, which was prepared by N. N. Greenwood and N. F. Travers (2) by the reaction of diethyl magnesium with decaborane in a solution of diethyl ether. Their compound was prepared at $-78°$ and was described as being rapidly decomposed in air and insoluble in all common organic solvents, a behavior quite at variance with the stability and solubility of the magnesium complex in the plating bath.

Kinetics of the High-Temperature Phosphidation of Nickel

Yoshinori Sasaki, Akemi Kato, and Shiro Ueda

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba, Japan

ABSTRACT

A study has been carried out on the kinetics of phosphidation of nickel sheets exposed to phosphorus vapor of 1 Torr to 2 atm at temperatures from 400° to 600°C by means of a sealed-tube method. The phosphidations were revealed to follow parabolic behavior. The values of the rate constant K_p at 2 atm have fallen into the category of order of 10^{-6} to 10^{-8} g^2/cm^4-min, whose Arrhenius plot yielded the activation energies of 15 ± 2.5 and 33 ± 3.5 kcal/mole for 400°-500° and 500°-600°C, respectively. The pressure dependence of K_p resulted experimentally in the expression $K_p \propto P^{0.055\sim0.109}$ at 500°C, which could be interpreted in terms of the mass action law. X-ray powder diffraction patterns indicated the phosphides to be composed mainly of Ni_2P, and an electron microprobe analysis showed that the phosphide layer in contact with nickel phase is Ni_2P. Metallographic observations showed the phosphidation to progress generally with formation of phosphide mounds, and sometimes with growth of whiskers and platelets.

The phosphides of nickel have extensively been studied by many groups of workers. Konstantinow (1) determined the phase diagram of the nickel-phosphorus system up to 36 atomic per cent (a/o) phosphorus, showing the existence of the phases Ni_3P, Ni_5P_2, and Ni_2P. X-ray investigations by Nowotny and Henglein (2) showed that in the same range of phosphorus concentration a compound Ni_7P_3 exists in addition to the above. Thermal decompositions and x-ray investigations of nickel-phosphorus compounds by Biltz and Heimbrecht (3) indicated the existence of NiP_3, NiP_2, and Ni_6P_5 as higher phosphides.

The heats of formation (4) and magnetic properties (5-7) of nickel phosphides have also been investigated. Recently the phase diagram (8) and the crystal structures of Ni_3P (9), Ni_5P_2 (10), $Ni_{12}P_5$ (11), Ni_2P (5, 12), Ni_5P_4 (13), NiP_2 (6, 14), and NiP_3 (7) have been studied in detail.

However, the investigation on the reactivity of nickel with phosphorus has not been extended beyond that on the reactivity which was estimated by measuring the variation in electric resistance of a technical nickel wire specimen exposed to phosphorus vapor (15). Especially, no reports dealing quantitatively with the rate of reaction of nickel with phosphorus have appeared up to the present.

In a previous paper (16), the rate of reaction of copper with phosphorus vapor was determined using a quartz helix method. The present study was undertaken to determine the rate of reaction between a nickel sheet and phosphorus vapor by means of an evacuated- and sealed-tube method, described below, in the temperature region 400°-600°C at phosphorus pressures ranging from 1 Torr to 2 atm. The phosphides obtained were identified by comparing their x-ray diffraction patterns with those of known phosphides. In addition, observations were metallographically made of surfaces and cross sections of the phosphidized specimens, and the distributions of phosphorus in the phosphide layers were also surveyed.

Key words: nickel phosphides—formation of Ni_2P, nickel phosphides—formation of NiP_2.

Experimental

Materials.—Nickel sheet 0.25 mm thick was cut into coupons of approximately 7 by 25 mm. According to an analysis supplied by the manufacturer, the amounts of main impurities in the nickel sheet are as follows: Co < 0.25; Mn, 0.03; Fe, 0.03; and Cu, 0.01 weight per cent (w/o). The coupons were abraded through 0/5-0/9 emery papers, degreased in trichloroethylene, and vacuum-annealed for 1 hr at 650°C. After these treatments the specimens to be phosphidized were chemically polished for 40 sec at about 90°C in a solution composed of 10 parts by volume 95% H_2SO_4, 10 parts 85% H_3PO_4, 30 parts 60% HNO_3, and 50 parts glacial acetic acid. The polished specimens then were rinsed in distilled water and subsequently in acetone.

Purification of red phosphorus is similar to that described in the previous paper (16).

Preparation of the sealed tube containing the sample nickel sheet and white phosphorus.—After an appropriate amount of the refined red phosphorus was introduced into a one-side-closed Pyrex or silica tube (inside diameter: 7 mm) and some clean glass wool was packed, the nickel specimen was put in this tube. This tube, including the specimen and the red phosphorus, was evacuated to 10^{-2} Torr at room temperature, then was filled to 1 atm with argon gas purified by passing through phosphorus pentoxide and heated active copper, and finally was reevacuated. The evacuating and the filling were repeated five times at 200°C in order to remove moisture, oxygen, and other gaseous impurities adsorbed on the red phosphorus, the glass wool, and the inner wall of the tube. In this case, only the nickel specimen placed near the entrance end of the tube was not heated. After these operations this tube was sealed under vacuum.

It seems reasonable for red phosphorus with a variety of structures not to give constant phosphorus

vapor pressures. Therefore, a conversion from red to white phosphorus is necessary to secure the more stable pressures of phosphorus vapor in the closed system. In this study, prior to the run, the phosphorus vapor that evolved by heating the red phosphorus in the sealed tube was condensed into white phosphorus by water cooling in the neighborhood of the packed glass wool.

Apparatus and procedure.—A schematic drawing of a phosphidation apparatus employed is represented in Fig. 1. It consists simply of two furnaces, in which each temperature was regulated individually by two automatic regulators within temperature variations of less than 3°C. A phosphorus vapor pressure is governed by the minimum temperature in the closed system. The phosphidation temperatures were given by one furnace, whereas the minimum temperature in the neighborhood of the contact part of the two furnaces was controlled by adjustment of the temperature of the other furnace.

The white phosphorus vapor pressure, P_{Torr}, is given as a function of the absolute temperature, T, as follows (17): $\log P_{Torr} = 7.808 - 2.729 \times 10^3/T$, 349.6° (1 Torr) $\leq T \leq$ 553°K (760 Torr). A temperature of 320°C gives 2 atm for the phosphorus vapor pressure (18). The above equations were used to obtain the desired phosphorus pressures.

Since the gaseous phosphorus molecule in the form of symmetrical p_4 tetrahedra scarcely dissociates into P_2 molecules at temperatures below 800°C, the phosphorus vapor can be regarded as consisting of P_4 molecules over the temperature region of 400°-600°C employed in this work.

After the desired period of time of phosphidation, the tube was taken out of the furnace and immediately the end of the tube opposite the specimen was quenched to avoid the condensation of the phosphorus vapor on the phosphidized specimen. No appreciable attack on the Pyrex and silica tubes was detected. After the phosphidized specimen was removed from the sealed tube and weighed, its surfaces were observed using a microscope. Distributions of phosphorus in the phosphide films were also surveyed with an electron microprobe (AKASHI Tronalyser TRA-25). The compositions of the obtainable phosphides were confirmed with x-ray diffraction patterns.

Experimental Results

Kinetics.—It is impossible to measure continuously the weight change, being caused by phosphidation, of a sample sheet *vs.* time by means of the sealed-tube method employed in this study.

Kinetic results are shown in Fig. 2 on phosphidation of the nickel sheets exposed to phosphorus vapor of 2 atm at temperatures from 400°-600°C. It should be noted that each data point represented here was obtained by phosphidizing a distinct specimen. The rate of the nickel phosphidation increases obviously with

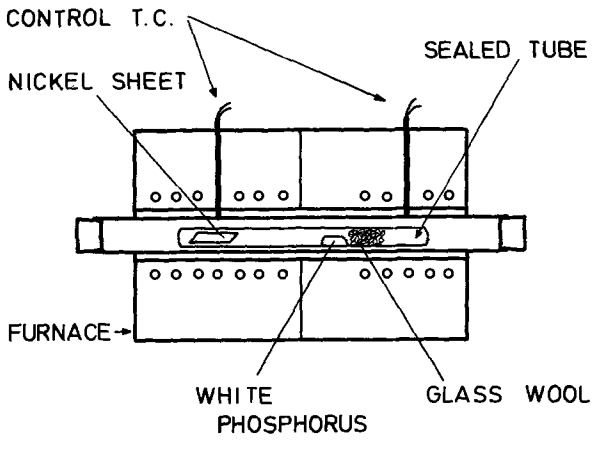

Fig. 1. Schematic drawing of apparatus

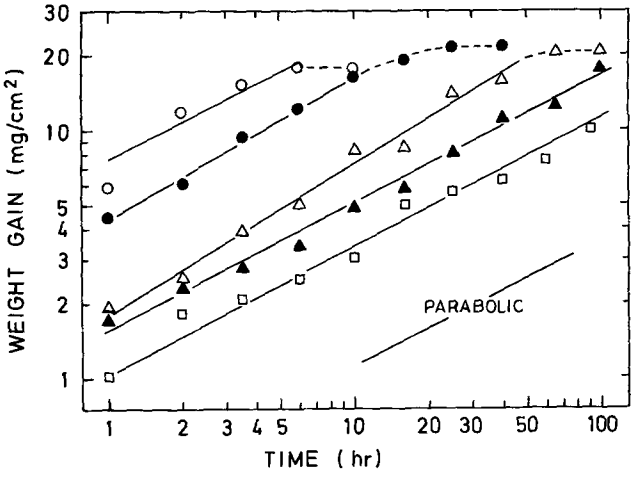

Fig. 2. Phosphidation of nickel at a phosphorus pressure of 2 atm: ○ 600°; ● 550°; △ 500°; ▲ 450°; □ 400°C.

an increase of temperature at a phosphorus vapor pressure of 2 atm.

Although these log-log plots are somewhat scattered, they yield straight lines with a slope equal to one-half. Therefore, the phosphidation may be regarded to follow a parabolic rate law based on a diffusion process.

After extended periods, the appearance of saturation curves in the phosphidations at 500°, 550°, and 600°C means the nickel sheets to have completely become the phosphides. This was determined from microscopic observations of the cross sections of these phosphidized specimens, and in this case their average compositions were estimated to be $NiP_{0.6}$, obtained by weight calculations.

Figure 3 gives results of phosphidation of nickel at 500°C under phosphorus pressures of 1, 4, and 20 Torr, and shows that each phosphidation obeys parabolic behavior. Consequently, it is concluded that the parabolic rate law governs the nickel phosphidation in the pressure range 1 Torr to 2 atm at 500°C.

From the above we conclude that an interface or adsorption reaction is distinctly faster than a diffusion process; hence, diffusion control predominates throughout the reaction time.

Values of the parabolic rate constants, K_p, obtained from the weight gain-time relationships are summarized in Table I.

X-ray diffraction.—Figure 4 illustrates the results of x-ray diffraction patterns taken at room temperature, employing nickel-filtered copper radiation. A broad division can be made between results of pulverized phosphides and those of the surface of the phosphide films. The diffraction pattern of powder reflects the bulk of phosphide scaling layers.

The resulting powder diffraction patterns (Fig. 4A) reveal the products to consist mainly of Ni_2P. For comparison, known patterns of nickel phosphides are illustrated in the same figure. Any peaks of NiP_3, NiP_2, and Ni_6P_5 have seldom been observed.

In diffraction patterns of the surface, however, the inherent peaks of NiP_2 appear for the specimens which were phosphidized in 2 atm phosphorus at 400°, 1 hr; 500°, 100 hr; and 550°C, 25 hr. Consequently, it may be emphasized that NiP_2 as higher phosphide is formed

Table I. Parabolic rate constants for the phosphidation of nickel

Temp, °C	Pressure	$K_p \times 10^8$ g²/cm⁴-min
400	2 atm	1.8 ± 0.2
450	2	4.0 ± 0.2
500	2	8.5 ± 2
550	2	38.0 ± 2
600	2	97.0 ± 15
500	20 Torr	5.3 ± 0.3
500	4	4.8 ± 0.2
500	1	4.2 ± 0.2

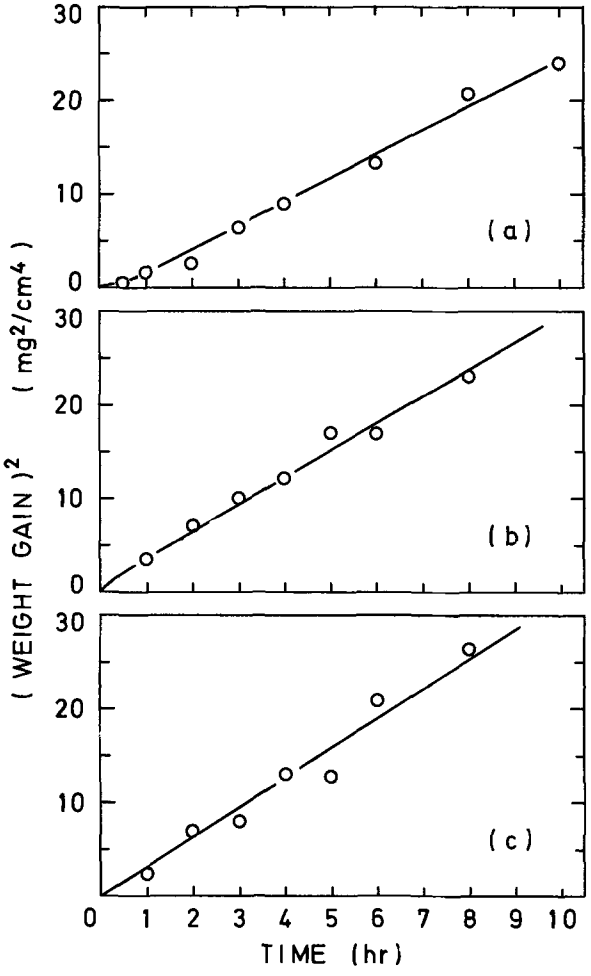

Fig. 3. Phosphidation of nickel at 500°C under various phosphorus pressures: (a)-1, (b)-4, (c)-20 Torr.

at relatively low temperatures and at early periods of phosphidation. It is also noteworthy to see that the weight increases obtained under the experimental conditions of "500°C 2 atm 100 hr" and "550°C 2 atm 25 hr" are just on the saturation curves shown in Fig. 2. Diffraction patterns at 400°C and 450°C in 2 atm of phosphorus for long periods of time were similar to their patterns for 6 hr, and the patterns at 500°, 550°, and 600°C have hardly varied with phosphidation time.

The diffraction patterns of the reverse sides of phosphide scaling films are in close agreement with that of Ni_2P (Fig. 4B). This fact is very important from the viewpoint that the formation of Ni_2P is found to take place at the phosphide/nickel interface. A large number of faceted crystals have grown on the surfaces at 500°C at 1 Torr for 4 and 8 hr. The x-ray diffraction pattern showed distinctly these faceted crystals to be Ni_2P (Fig. 4C). Under the experimental conditions employed, the existence of Ni_7P_3 and Ni_5P_2 as lower phosphides could be seldom detected from the x-ray diffractions. These results are important, suggesting one side of a characteristic feature of the nickel phosphidation mechanism.

Distribution of phosphorus.—Distribution of phosphorus in the phosphide scaling films, obtained by an electron microprobe, is shown in Fig. 5. This figure shows that the content of phosphorus in the phosphide films decreases toward inner scaling layers.

The nickel diphosphide already has been indicated to be present in the outer layer. It must be noted that plateaus having a certain constant content of phosphorus appeared in the bulk phosphide. The compositions of these plateaus have been assured to consist of Ni_2P from the x-ray diffraction patterns. It is worth giving special attention to the fact that no phosphides which are more rich in nickel than Ni_2P have been

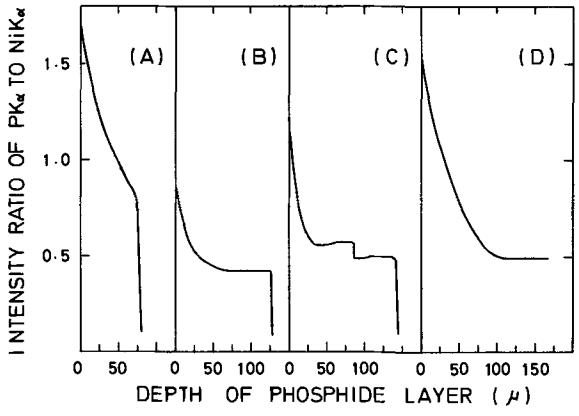

Fig. 5. Distributions of phosphorus in the phosphide scaling layers: (A)-400°, 60 hr; (B)-450°, 65 hr; (C)-500°, 40 hr; (D)-600°C, 10 hr.

formed. The upper step in the plateau in Fig. 5C suggests the presence of a phase other than Ni_2P, and corresponds reasonably to higher phosphide than Ni_2P.

Figure 5 suggests that the phosphorus dissolution and the phosphide formation occur simultaneously. Consequently the rate of phosphidation under the experimental conditions employed is expected to be controlled by the transport properties of the well-defined layer of phosphide in contact with the metal phases, that is, the rate is determined by a lattice-diffusion process at the Ni_2P/Ni interface.

Microscopic observation.—The phosphidation has generally progressed with growth of mounds of nickel phosphides, which seem to be related to the reaction velocity. For example, a micrograph of the surface of the specimen phosphidized for 16 hr at 450°C under 2 atm of phosphorus is shown in Fig. 6. This surface is covered all over with phosphide mounds of various sizes. Under the experimental conditions employed, in general, phosphide surfaces slowly became relatively flat with the lapse of time, and phosphide scales were generally very adherent to the metallic nickel even at room temperature.

An interesting phenomenon is the dapple aspect, shown in Fig. 7, of the phosphide surface which formed in comparatively early stages. Figure 8 is also a micrograph of the nickel substrate surface after removal of the phosphide film which formed for 3 hr at 500°C and 20 Torr. An aspect similar to that in Fig. 7 appears. These features suggest that phosphides have been formed with dependence on each crystal grain of the metallic nickel.

Growth of phosphide needles or whiskers were found in 2 atm of phosphorus over the entire temperature range employed and sometimes in the lower phosphorus pressures. An example is shown in Fig. 9, which is a micrograph of the phosphide needles or whiskers

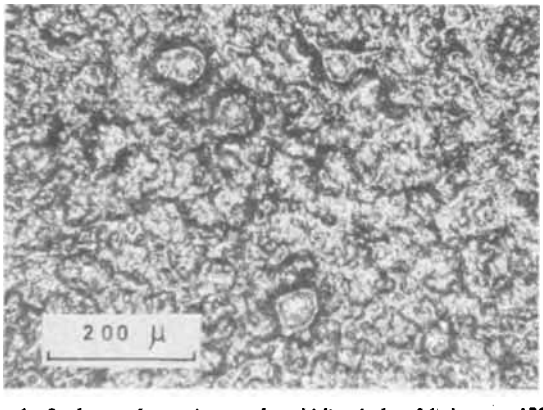

Fig. 6. Surface of specimen phosphidized for 16 hr at 450°C and 2 atm phosphorus.

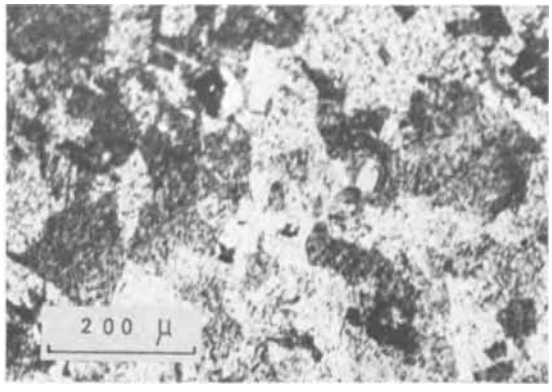

Fig. 7. Surface of specimen phosphidized in 2 atm of phosphorus at 500°C for 2 hr.

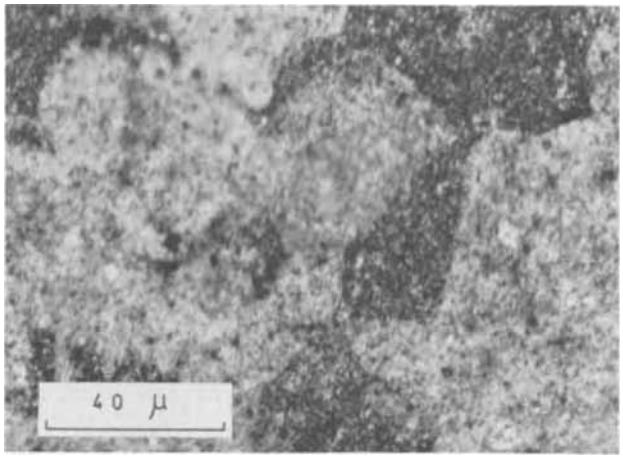

Fig. 8. Surface of nickel substrate after removal of the phosphide scale. Sample phosphidized at 500°C and 20 Torr phosphorus for 3 hr.

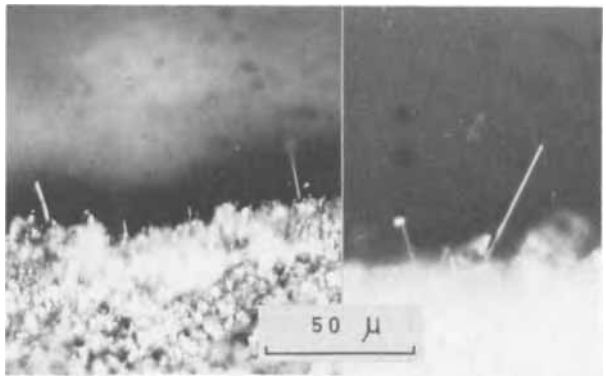

Fig. 9. Phosphide whiskers grown on the surface. Sample phosphidized at 500°C for 25 hr in 2 atm of phosphorus.

grown in spots and local areas on the surface of the specimen phosphidized at 500°C and 2 atm for 25 hr.

The phosphide appeared in the form of a large number of platelets lying more or less normally to the phosphide/metal interface at 500°C under the lower pressures such as 20, 4, and 1 Torr phosphorus. A view of numerous platelets grown on the surface is illustrated in Fig. 10, which refers to the specimen phosphidized for 3 hr at 550°C and 4 Torr phosphorus. In Fig. 10, platelets with corner of angle of 120° are also seen. Platelets were found alone or in combination with whiskers of phosphide.

Wrinkle-like phosphide surfaces were partly found at 500°C at 1 Torr for 0.5 and 1 hr. Faceted crystals also were sometimes observed at 500°C and 1 Torr, and the explanation on its x-ray patterns was discussed previously.

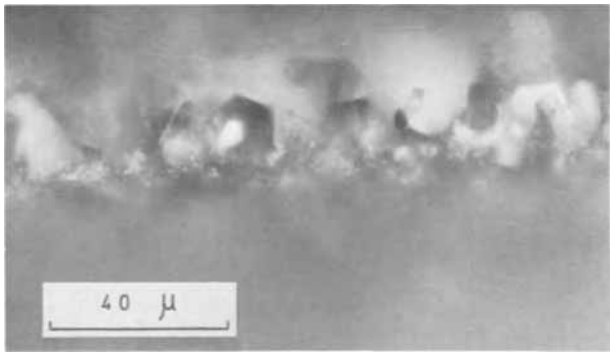

Fig. 10. Phosphide platelets grown on the surface of specimen phosphidized at 500°C for 3 hr in 4 Torr of phosphorus.

At low temperatures and low pressures the diffusion rate is so slow that the growth of various phosphide crystals seems to have become the predominant feature of the phosphidation.

There were voids in the bulk of almost all the scales produced.

Discussion

The temperature dependence of K_p at 2 atm is plotted in Fig. 11. The relationship gives two straight lines. Activation energies were evaluated to be 15 ± 2.5 kcal/mole for the temperature range 400°-500°C and 33 ± 3.5 kcal/mole for 500°-600°C. The discrepancy in activation energy between the higher and the lower temperature regions results presumably from differences in phosphidation products and in nucleation and growth of nickel phosphides.

A log-log plot of K_p at 500°C against the phosphorus vapor pressure is shown in Fig. 12, giving a straight line, whose slope coresponds to 0.082 ± 0.027.

It was ascertained from the x-ray diffraction patterns that the Ni_2P formation takes place in the interface between metallic nickel and the resulting phosphide layer. It is assumed that the lattice defect equation for high temperature is written as follows

$$1/4\,P_4(g) \rightleftarrows Ni_2P + 2(Ni\square''\cdot n\oplus) + 2(2-n)\oplus$$

where n has values of 0-2, and $Ni\square''$ and $(Ni\square''\cdot n\oplus)$ stand for a cation vacancy and a cation vacancy with n trapped electron holes $\oplus$, respectively. The $n = 0$ means the electron holes to be completely dissociated from the cation vacancies.

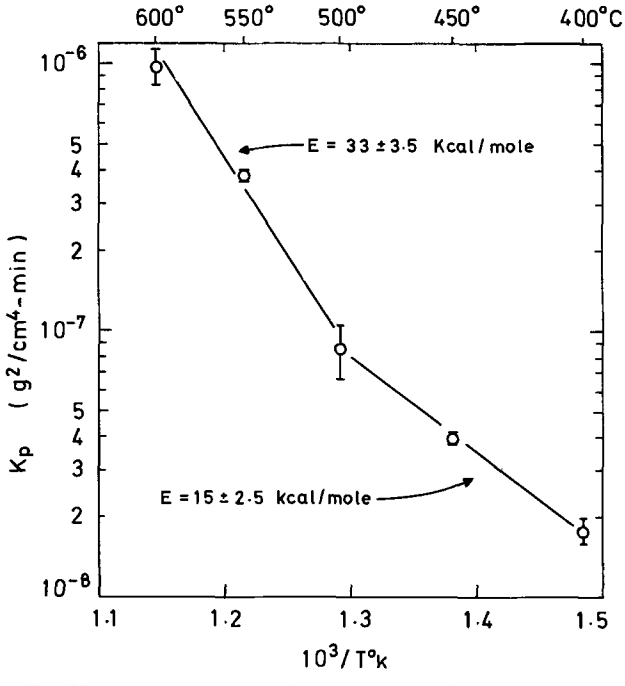

Fig. 11. Temperature dependence of the parabolic rate constant for the nickel phosphidation between 400° and 600°C.

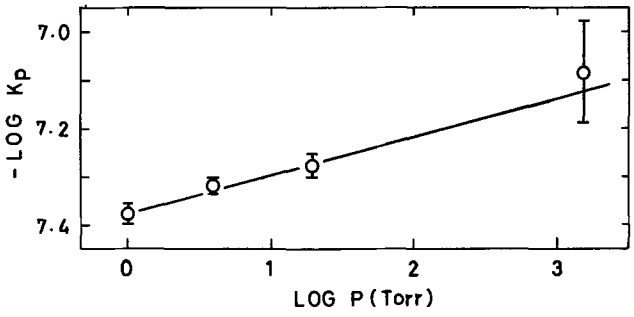

Fig. 12. Phosphorus-vapor-pressure dependence for the parabolic rate constant of phosphidation of nickel at 500°C.

The mass action law under ideal conditions similar to the ideal state in very dilute electrolytes is expressed as

$$X_{\oplus}^{2(2-n)}\cdot X^2_{(Ni\square''\cdot n\oplus)} = KP^{1/4}$$

where X denotes the respective concentrations and P is the pressure of the phosphorus vapor consisting of P_4 molecule. The phosphorus pressure dependence of the lattice defect concentration—with the electrical neutrality condition $X_{\oplus} = (2-n)X_{(Ni\square''\cdot n\oplus)}$—may be found

$$X_{\oplus} = (2-n)X_{(Ni\square''\cdot n\oplus)} = \text{const}\,P^{\frac{1}{8(3-n)}}$$

When $n = 0$, $X_{\oplus} = 2X_{Ni\square''} = \text{const}\,P^{0.0417}$, and when $n = 1$, $X_{\oplus} = X_{Ni\square'} = \text{const}\,P^{0.0625}$.

A parabolic rate constant seems to be proportional to $X_{\oplus}$ or $X_{Ni\square''}$. The above consideration in the case of $n = 1$ is in agreement with the experimental result $K_p \propto P^{0.055\sim0.109}$ obtained in this study.

In the nickel-phosphorus system a series of stepwise decompositions have been found as shown below (3).

$$4NiP_3 \rightleftarrows 4NiP_2 + P_4;\qquad \log P_{Torr} = -9340/T + 12.865$$

$$24/7NiP_2 \rightleftarrows 4/7Ni_6P_5 + P_4;\qquad \log P_{Torr} = -12430/T + 14.315$$

$$2Ni_6P_5 \rightleftarrows 6Ni_2P + P_4;\qquad \log P_{Torr} = -13740/T + 14.951$$

where P_{Torr} and T stand for the partial pressures of P_4 vapor and the absolute temperature, respectively.

Figure 13 shows the chemical potential diagram of the nickel-phosphorus system obtained from these

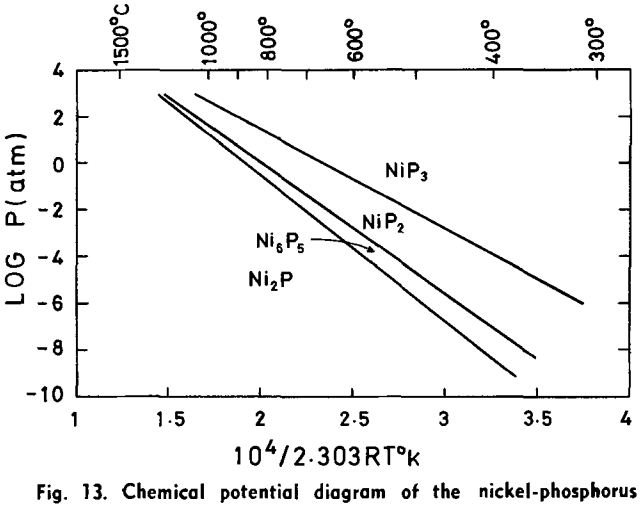

Fig. 13. Chemical potential diagram of the nickel-phosphorus system.

relations. If the reaction is controlled by a diffusion in the scaling film, the phosphorus potential in the film decreases toward the metallic nickel substrate. The stable phosphide phases corresponding to the phosphorus potential can be obtained from Fig. 13 so that the phosphide layer structure becomes $NiP_3/NiP_2/Ni_6P_5/Ni_2P$.

The formation of NiP_2 for short periods of time at relatively lower temperatures and that of NiP_2 on the saturation curves of weight gain *vs.* time at higher temperatures can be explained in terms of this thermodynamic consideration.

The interpretation of the phosphidation mechanism is complicated by many difficult factors such as the competition between phosphide film formation and phosphorus dissolution in the metal, and the correlation between the morphology of the reaction products and the associated rate curves, and other factors.

Conclusions

Experimentally it has been found that:

1. Phosphidations of nickel by phosphorus vapor follows parabolic behavior under the experimental conditions employed, *viz.* in 2 atm phosphorus at temperatures from 400°-600°C, and under the phosphorus pressures of 1 Torr to 2 atm at 500°C.

2. All of the parabolic rate constants, K_p, obtained have fallen into a category of order of 10^{-6} to 10^{-8} g^2/cm^4-min, as listed in Table I. The K_p increased with an increase of temperature between 400° and 600°C at 2 atm.

3. The activation energies were estimated to be 15 ± 2.5 and 33 ± 3.5 kcal/mole for the temperature regions 400°-500° and 500°-600°C, respectively.

4. The correlation between K_p and phosphorus pressure P was experimentally expressed as $K_p \propto P^{0.055 \sim 0.109}$ at 500°C, which could be explained in terms of the mass action law.

5. The x-ray diffraction patterns of the powdered phosphides showed the products to consist mainly of Ni_2P generally, and those of surfaces of specimens phosphidized at relatively lower temperatures showed the presence of NiP_2 as well as Ni_2P.

6. An electron microprobe analysis of the cross sections of specimens phosphidized has shown the content of phosphorus to decrease from the outer to inner scaling layers over the entire temperature range employed. It was also evident in combination with the x-ray diffraction work that Ni_2P forms at the phosphide/nickel interface, and that no phosphides richer in nickel than Ni_2P were formed.

7. Morphological observations showed the phosphidation to proceed with dependence on each crystal grain of nickel, generally with growth of phosphide mounds, and sometimes with growth of platelets and needles or whiskers, especially in comparatively lower pressures.

Acknowledgments

The authors wish to thank Mr. T. Hase for the use of electron microprobe facilities of the Tokyo Institute of Technology and for this measurement, and Mr. J. Mochinaga for helpful advice on this analysis.

Selective Growth of Epitaxial Silicon and Gallium Arsenide

P. Rai-Choudhury* and D. K. Schroder

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Homoepitaxial layers of silicon and gallium arsenide are grown selectively from a number of processes, namely, silane-hydrogen, silane-argon, silicon tetrachloride-hydrogen chloride-hydrogen, and trimethyl gallium-arsine-hydrogen systems. Silicon dioxide is used as the primary masking material. The thermodynamic considerations of the processes are in general agreement with the experimental results. The general conclusion is that in order to achieve selective growth it is either necessary for the masking material to react with the depositing or arriving atoms to form volatile products such as SiO, Ga_2O, etc., or to introduce into the system additional species, such as HCl gas, which will prevent adsorption of reactants preferentially on the mask. Preferential epitaxial growth using a SiO_2 mask is carried out most effectively in the presence of controlled amounts of HCl gas.

Preferential or selective growth of epitaxial layers, such as those of silicon and gallium arsenide, has many applications in integrated circuits. For example, it allows the use of SiO_2 masked regions as isolation walls between components of a circuit. It can also serve to produce elevated electrodes for the silicon photodiode array (1).

Generally, the method consists of the deposition of an epitaxial layer on selected areas of the substrate which are exposed via windows etched through a protective insulating film, *e.g.*, SiO_2, Si_3N_4, Al_2O_3, etc. In the H_2-$SiCl_4$ system (2-4), the selective growth is effected by injecting a stream of HCl gas which prevents growth on the masking film. When pyrolysis of SiH_4 is used for the epitaxial growth, it is necessary to establish a balance between the SiH_4 partial pressure and deposition temperature (5). In the growth of GaAs epitaxial layers from elemental sources using H_2 and HCl carrier gases, preferential growth through a SiO_2 mask can also be achieved (6).

The major problem in the preferential epitaxial growth, however, has been effectively and reproducibly to prevent nucleation and growth on the surface of the masking material. Since, under normal circumstances, hardly any surface exists in the real world which does not have heterogeneous nucleation sites, it is not likely to be rewarding to seek a clean and defect-free surface of the masked region. Also, a highly passive masking material may not be effective in preventing growth over the mask, because any arriving atom may remain on the surface unconsumed or unreacted. In such a case it is necessary to use additives, such as HCl gas, which prevent growth on the insulating layer, *e.g.*, Si_3N_4, by some unknown mechanism. If the insulator, *e.g.*, SiO_2, reacts with the deposits, *e.g.*, Si, forming a volatile compound, *e.g.*, SiO, then a delicate balance of reaction temperature and reactant partial pressures is necessary to prevent growth there. Another possibility which may exist with SiO_2 masks is the formation of an oxygen deficient surface (7) when heated in H_2 carrier gas. An arriving Si atom could then attach itself to a surface Si atom without significant steric hindrance from neighboring oxygen atoms. If this model is valid, then it may be possible to grow epitaxial Si selectively in the unmasked areas from pyrolysis of SiH_4 in an inert carrier gas.

In this investigation selective growth of Si on Si and GaAs on GaAs are studied under different conditions with the aim of improving the technology and better understanding of the various processes.

Key words: epitaxial, silicon, gallium arsenide, thermodynamics, silane, chlorides, hydrogen, argon.

Thermodynamic Considerations

In a relatively simple system, such as the pyrolysis of SiH_4 in a H_2 carrier gas, the possible interaction with the SiO_2 layer may be represented by the following reactions

$$SiO_2(s) + Si(s) = 2SiO(g) \quad [1]$$

$$SiO_2(s) + H_2(g) = SiO(g) + H_2O(g) \quad [2]$$

Reaction [1] takes place between the depositing Si atoms and the surface layers of the SiO_2 as well as between the substrate Si atoms and the SiO_2 surface in contact with the substrate. Hence, if it proceeds too rapidly, it might result in blistering or lifting of the entire SiO_2 mask. Reaction [2] is likely to proceed only in H_2 carrier gas. Figure 1 represents the equilibrium partial pressure of SiO as a function of temperature for these two reactions. It is apparent that reaction [1] is much more likely than reaction [2] and, by selecting proper growth conditions, could be utilized to prevent growth on the SiO_2 film.

In the $SiCl_4$-H_2 system the process is considerably more complicated. Since preferential epitaxy using this system has been successful only through the in-

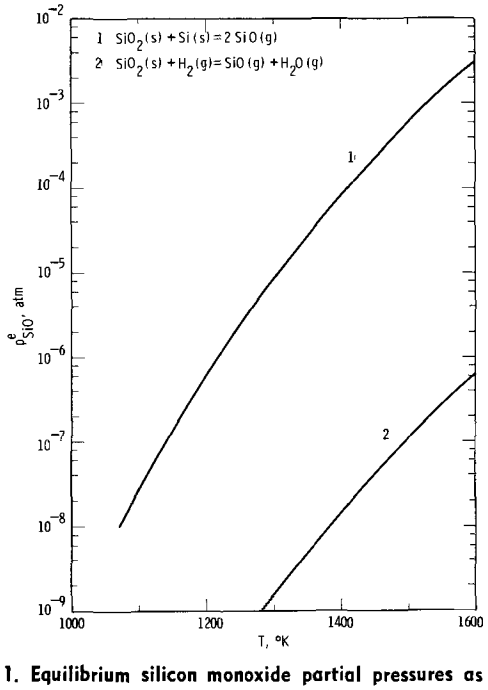

Fig. 1. Equilibrium silicon monoxide partial pressures as a function of temperature from reactions of silicon dioxide with silicon and hydrogen.

jection of appropriate amounts of HCl gas, the reactions involving HCl are considered now

$$SiO_2(s) + 4HCl(g) = SiCl_4(g) + 2H_2O(g) \quad [3]$$

$$SiO_2(s) + 2HCl(g) + H_2(g) = SiCl_2(g) + 2H_2O(g) \quad [4]$$

Reaction [3] is not favorable since the equilibrium $SiCl_4$ partial pressure is about 7×10^{-7} atm at 1500°K while the inlet $SiCl_4$ partial pressure is usually of the order of 10^{-2} atm. Figure 2 shows the equilibrium partial pressure of $SiCl_2$ as a function of temperature for reaction [4] at three levels of HCl partial pressures. This is also not a likely reaction under normal growth conditions, since the equilibrium $SiCl_2$ partial pressure from this reaction is orders of magnitude less than that from the $SiCl_4$-Si interactions. Further, HCl is known to prevent growth on Si_3N_4 masks (4) which is considerably more inert toward HCl. One likely explanation is that HCl prevents adsorption of reactant species on only the masked area while the unmasked areas remain active. The bond energies of adsorbed reactants to the surface atoms are likely to be weaker on an oxide or nitride surface than on a bare silicon surface. Possibly HCl may have an etching action which is sufficient to remove any adsorbed reactant species from the masked area.

During the growth of GaAs through windows etched in SiO_2 in the absence of HCl, any GaAs deposited on the mask could react as follows

$$SiO_2(s) + GaAs(s) = SiO(g) + \tfrac{1}{2}Ga_2O(g) + \tfrac{1}{2}As_2(g) \quad [5]$$

If this reaction proceeds at a suitable rate, growth on the masked area can be prevented. In the presence of HCl gas a mechanism similar to that operating in the selective growth of Si with HCl is probably effective.

Experimental Procedure

Chemical-mechanical polished silicon substrates, oriented in the (100) and 2° off from the (111) plane, were thermally oxidized in wet oxygen at 1100°C to produce an oxide layer of about 10,000Å thickness. On some of the wafers, 1700-2500Å films of silicon nitride were deposited from a SiH_4-NH_3-Ar system at about 850°C. GaAs used was of (100) orientation, semi-insulating and chem-mechanically polished. A 4000Å film of SiO_2 was deposited on these GaAs substrates from a SiH_4-O_2-Ar system at about 600°C. Windows, 9-20μ in diameter, were then etched through these masks using photolithographic techniques and appropriate etchants. Epitaxial layers were grown in a conventional horizontal quartz reactor, having a SiC-coated graphite susceptor, heated externally by an rf coil. Epitaxial layers of Si were grown in the exposed areas by a number of processes, namely, pyrolysis of SiH_4 in H_2, pyrolysis of SiH_4 in Ar, and from the $SiCl_4$-H_2 system with HCl injection. Provisions for doping with B_2H_6 and/or AsH_3 were also made. Epitaxial layers of GaAs were deposited from the trimethyl gallium (TMG)-AsH_3-H_2 system as well as from the $AsCl_3$-Ga-H_2 system.

The layers were evaluated by light microscopy and scanning electron microscopy (SEM) for growth morphology, and by electron microscopy for the quality of the deposited layer. A high resolution spreading resistance technique (8) was used to measure the impurity profile of the epitaxial silicon layers. Resistivity, net carrier concentration, and mobility of the gallium arsenide films were measured by the van der Pauw technique (9), using test slices where the epitaxial layers were deposited on a substrate without an insulating film.

Results

Selective growth of Si.—As mentioned earlier, selective growth of Si was carried out by three methods, namely, pyrolysis of SiH_4 in H_2, pyrolysis of SiH_4 in Ar, and from the $SiCl_4$-H_2 system with HCl injection. In the SiH_4-H_2 system, it was necessary to use a relatively high deposition temperature (>1200°C) in order to prevent growth on the SiO_2 mask. Figure 3 shows a scanning electron micrograph of a 5μ thick layer grown at 1220°C using a SiH_4 partial pressure of 1.0×10^{-3} atm. As can be seen from the micrograph, the masked regions are free from Si deposits. Reflection electron diffraction patterns from these layers were indicative of good quality epitaxial Si. Considerably more growth islands were observed on accompanying Si_3N_4-coated wafers. Also, frequent appearance of microcracks in the nitride film during epitaxial growth was noted whenever the nitride film was 2000Å or thicker. Thus prevention of growth on SiO_2 masks, when a SiH_4-H_2 system is used, is probably the result of reaction [1]. When higher deposition temperatures

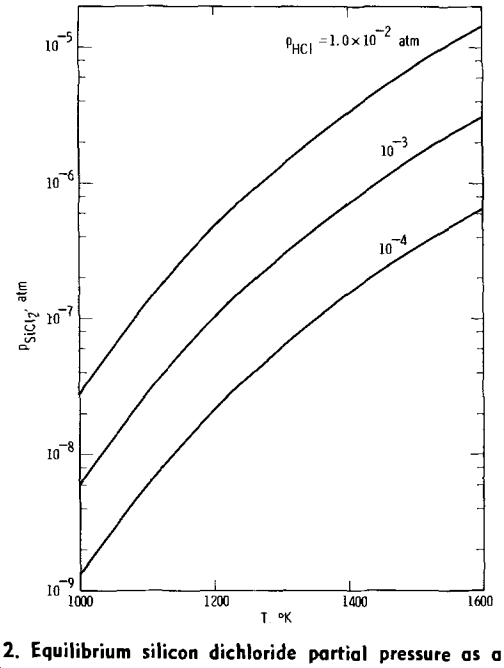

Fig. 2. Equilibrium silicon dichloride partial pressure as a function of temperature at various hydrogen chloride partial pressures from the reaction $SiO_2(s) + 2HCl(g) + H_2(g) = SiCl_2(g) + 2H_2O(g)$.

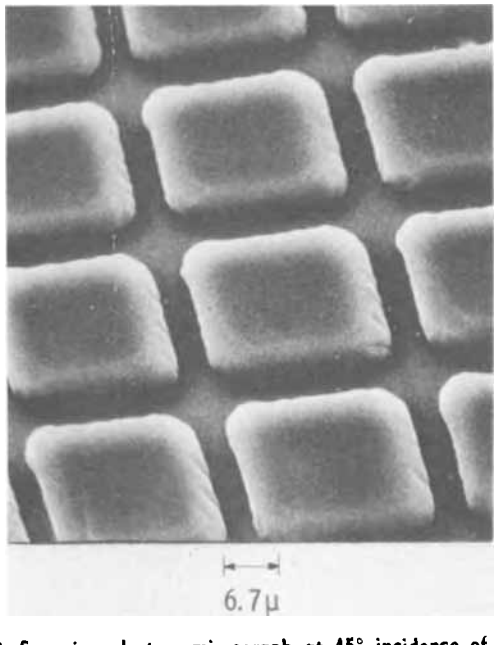

Fig. 3. Scanning electron micrograph at 45° incidence of selectively grown silicon in square windows etched through thermally grown SiO_2 using the silane-hydrogen system at 1220°C for 5 min; growth rate 1 μ/min.

(>1270°C) were used, the SiO_2 mask frequently lifted, probably due to the increased rate of reaction [1] at the substrate-oxide interface. It seems, therefore, that preferential growth from the SiH_4-H_2 system is rather sensitive to the growth conditions.

The possibility of Si nucleation or growth on an oxygen deficient surface of SiO_2 was tested by making runs in argon carrier gas, which should prevent the reduction of the oxide. Scattered deposits of Si on the oxides were generally observed and the results were considerably inferior to those shown in Fig. 3. This was not surprising since thermodynamic considerations indicate reaction [2] to be unlikely anyway. Use of ultrahigh-purity Ar instead of the usual palladium-purified H_2 possibly introduced a few impurities which may have caused the deposits to be less preferential relatively.

Experiments with the $SiCl_4$-H_2 system gave good results when a controlled amount of HCl was injected during the growth of the layers. Interaction of HCl gas with the SiO_2 was first tested to determine the extent of reactions [3] and [4]. In all cases no measurable change in the oxide thickness was noticeable as a result of HCl treatment at 1270°C. However, frequently the oxide lifted because of the HCl attack of the Si substrate surface through pinholes in the insulator. Thus it was confirmed that reactions [3] and [4] are not significant. Figure 4 shows a scanning electron micrograph of a 5μ layer grown at 1120°C in the $SiCl_4$-H_2 system at $SiCl_4$, HCl, and B_2H_6 partial pressures of 7.4×10^{-3}, 5.5×10^{-3}, and 9.7×10^{-8} atm, respectively. The doping level of the grown layer was 2×10^{17} at./cm^3, and the concentration profile as measured by the spreading resistance technique indicated normal, good quality epitaxial silicon having a very sharp substrate-epitaxial interface.

The growth rate of the silicon islands shown in Fig. 4 was about 1 μ/min whereas on the accompanying unmasked silicon wafer it was only 0.4 μ/min. Such increase in growth rate in the presence of a mask was also observed by Dumin (5) using a SiH_4-H_2 system and is confirmed in the present studies. It is interesting to note this common feature of two epitaxial systems of considerably different chemistry. The atomistics of this enhanced growth process is rather complex, and any model to explain the results could, at best, be a speculation. An explanation from a macroscopic point of view might be that, given the conditions which prevent reaction on the SiO_2 surface, the effective concentrations of the reactants are increased with a decrease in the reactive surface, namely, the unmasked region. Another noteworthy feature of the $SiCl_4$-H_2-HCl process of selective growth is that, unlike the SiH_4-H_2 system, it is considerably less sensitive to variations in reactant concentrations and growth temperature. For example, results comparable to those shown in Fig. 4 were obtained at 1220°C without the need to adjust any of the reactant partial pressures.

Selective growth of GaAs.—In previous investigations (6) on selective epitaxial growth of gallium arsenide, HCl was introduced either as a reactant or as a reaction product from the H_2 reduction of $AsCl_3$. To test the importance of HCl in the selective growth of gallium arsenide it was necessary to use a system free from any HCl gas. Epitaxial layers were deposited from the TMG-AsH_3-H_2 system on GaAs substrates of (100) orientation through a 4000Å SiO_2 mask. The quality of the grown layer from this system has been described elsewhere (10). Figure 5 shows a scanning electron micrograph of a 6μ layer grown through masked GaAs substrates where the exposed regions were squares 20 x 20μ with 2.5μ of SiO_2 separating the squares. The layer was grown at 700°C and partial pressures of TMG and AsH_3 of 6.5×10^{-4} atm and 1.2×10^{-2} atm, respectively. The high ridges on the micrograph represent growth on the SiO_2 mask whereas the pits or craters represent growth on unmasked regions. It appears that when growth occurs on the insulator the amount of deposit on the oxide exceeds that on the unmasked regions. This is also what is observed in the case of Si growth from the SiH_4-H_2 system. The rate of growth of the polycrystalline silicon on the masked regions is found to be greater than that of single crystal silicon through the windows. The reflection electron diffraction pattern from GaAs grown through the SiO_2 mask gave only a single crystal pattern with some twins. However, the transmission electron microscopic examination of the sample indicated the growth on top of the oxide to be highly disturbed, polycrystalline material which etched considerably more rapidly than the GaAs grown in the windows. In order to eliminate growth on the SiO_2 mask, an attempt is being made in which controlled

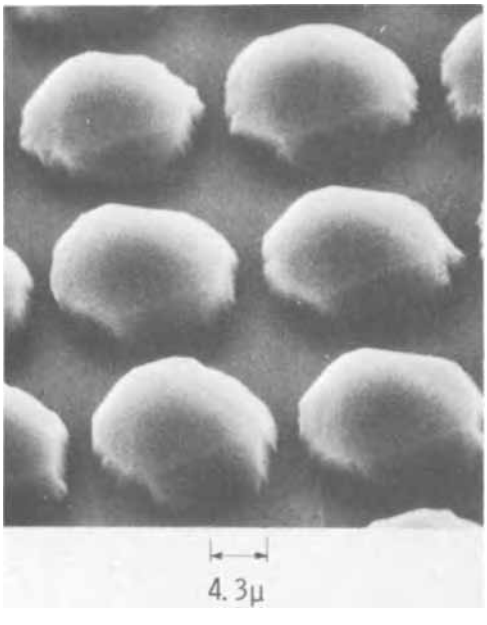

Fig. 4. Scanning electron micrograph at 45° incidence of selectively grown silicon in circular windows etched in thermally grown silicon dioxide using the $SiCl_4$-HCl-H_2 system at 1120°C for 5 min; growth rate 1 μ/min.

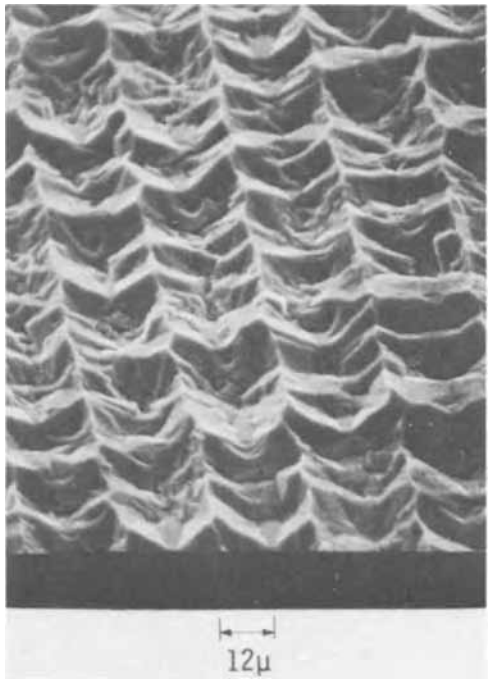

Fig. 5. Scanning electron micrograph at 40° incidence showing growth morphology of GaAs deposited from TMG-AsH_3-H_2 system onto GaAs substrate with SiO_2 mask.

amounts of HCl gas are injected into the main stream. The results of using an HCl-free system, namely, TMG-AsH_3-H_2, to grow GaAs selectively indicate that reaction [5] is not very effective in preventing growth on the SiO_2 mask under present experimental conditions. From these results, together with those from systems containing HCl gas (6), it is apparent that HCl is playing a significant role in preventing growth on the SiO_2 mask. Results identical to those shown in Fig. 4 were obtained using the $AsCl_3$-Ga-H_2 system.

Summary

Epitaxial silicon was grown selectively at about 1200°C using the SiH_4-H_2 system. The process was found to be relatively sensitive to growth temperature and reactant concentrations. For the $SiCl_4$-H_2 system, the epitaxial silicon growth through windows etched in a masking SiO_2 layer proceeds more effectively and also at lower temperatures than in the SiH_4-H_2 system. Growth on the masked regions is prevented by injecting appropriate amounts of HCl gas. The growth rate in the windows was approximately 1 μ/min. HCl is also important in preventing growth of GaAs on SiO_2 masks. Whenever conditions are such that GaAs growth does take place on the SiO_2 mask, the resulting deposition rate of polycrystalline material on the mask is higher than the rate of single crystal growth rate through windows etched into the SiO_2 mask.

Facets Formed by Hydrogen Chloride Vapor Etching on Silicon Surfaces through Windows in SiO_2 and Si_3N_4 Masks

Katsuro Sugawara

Semiconductor and Integrated Circuits Division, Hitachi, Ltd., Kodaira, Tokyo, Japan

ABSTRACT

Selective etching of silicon by HCl gas through windows in SiO_2 and Si_3N_4 masks was investigated on silicon surfaces with nine different orientations on the [110] zone, including (001), (111), and (110). In the etched holes {111}, {311}, and {110} facets were observed, depending on the specimen orientation. For specimens with Si_3N_4 films, facets were developed directly below the film as well as on the periphery of the bottom of the etched area. For specimens with SiO_2 films, however, few facets could be found directly below the film. This difference might be explained by assuming that, in the case of SiO_2 film, the reaction of Si-SiO_2, which is dominant at higher temperature as indicated by thermodynamic calculations, occurs at the periphery of the etched hole, giving rise to faces without facets.

Selective epitaxial growth of desired dimensions, conductivity, and impurity concentration in desired locations is demanded both from a clarification of the crystal growth mechanism and from the formation of special integrated circuits for practical use. In fact, several papers on Si (1-9) and GaAs (10-13) already have been published. The author and his collaborators (14) have examined vapor etching by HCl as a first step toward this epitaxial growth and observed in the etched hole facets characteristic of the surface orientations of the silicon substrates. They also found a difference in the appearance of the facets between SiO_2 and Si_3N_4 films used as a mask for vapor etching. In this paper crystals of additional orientations were selected and details of the facet appearance were further investigated. Also, since examinations of the cause of differences in the facet appearance between SiO_2 and Si_3N_4 films have been conducted, the results are reported herein.

Key words: selective vapor etching, Si-SiO_2 reaction, SiO_2-coated Si surface, Si_3N_4-coated Si surface.

Experimental

As stated in a previous paper (14), a normal horizontal epitaxial reactor was used, and vapor etching was performed on an R.F. heated SiC-coated graphite susceptor.

Boron-doped (110) single crystals with resistivity of about 5 ohm-cm were grown by the Czochralski method. Crystals of nine orientations, (001), (711), (511), (311), (211), (111), (331), (551), and (110) on the [1$\bar{1}$0] zone were cut. The specimen orientations, (001), (511), (311), (211), (111), (311), and (110) were confirmed to agree with an accuracy of one degree or less by x-ray diffraction. Since the diffraction of other surfaces was weak, the (110) surface taken out on the

side was used as the standard, and seeking the angle formed with each surface, slicing was done. Even the crystal surface sliced in this manner is considered to be within 2°.

SiO_2 and Si_3N_4 films were formed on the mirror-polished wafers. An oxidized SiO_2 film of about 7000Å in thickness was formed in a wet oxygen atmosphere. Using the SiH_4-NH_3 system, a Si_3N_4 film of about 3000Å was deposited at 880°C. Ten holes, the diameters of which were arranged between 50 and 500μ at an interval of 50μ, were made on these wafers at a regular spacing of 1 mm by the usual photolithographic technique. Standard conditions for vapor etching consist of a temperature of 1250°C (corrected for emissivity), a mole fraction of HCl to H_2 of 0.025, and an etching time of 60 sec. The orientation of facets were determined by a goniomicroscope and/or 60° angle lapping.

Results

Facet appearance on (001) surface.—Figure 1 represents photographs of the facets as seen through the window opened in an SiO_2 film. The upper half of Fig. 1(a) is focused on the facets, while the lower half is a cross-sectional view of 60° angle lapping. The figure represents a synthesis of these two photos. As visible from the cross-sectional photo, the characteristic of the slope in the hole is a comparatively mild incline directly below the film. No facet is observed on this part, but at the bottom of the hole, a mildly inclined facet of (311) can be observed. Figure 1(b) is a synthesis of photographs of the facets (upper half) and of directly below the SiO_2 film (lower half). From the lower half of the photograph, it can be seen that by utilizing the above-mentioned etching conditions, the initial hole in the SiO_2 film expands but

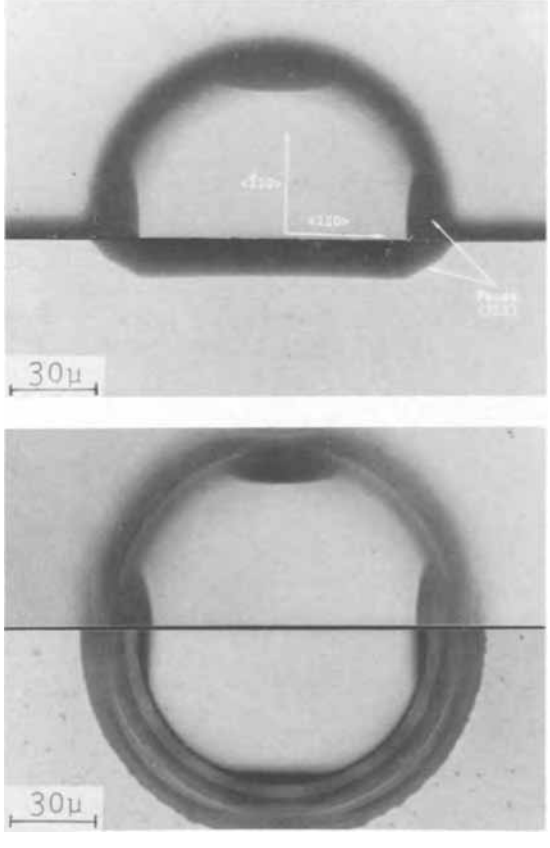

Fig. 1. Facets revealed on (100) surface when etched through a window of 100μ diameter in SiO_2 mask. Fig. 1 (a) (top) Upper half is the facets and the lower half is the cross section after 60° angle lapping; Fig. 1 (b) (bottom) Lower half shows directly below the SiO_2 film.

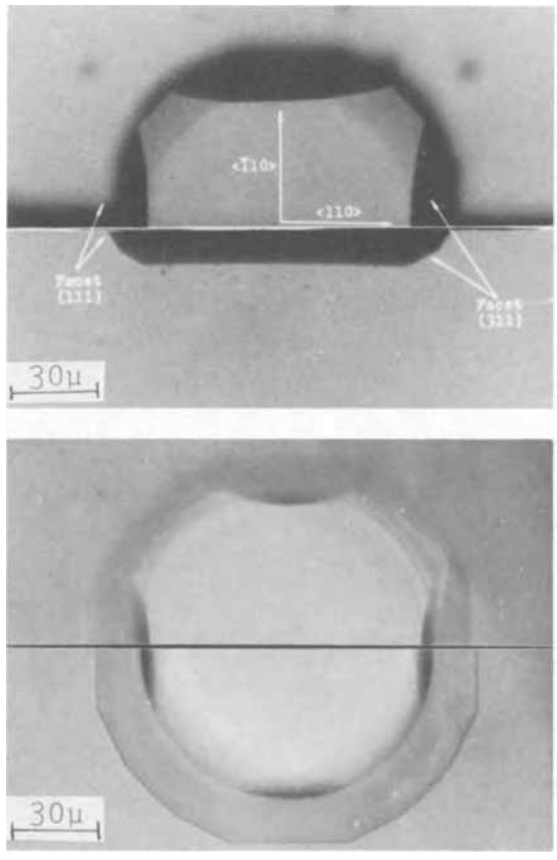

Fig. 2. Facets revealed when etched through Si_3N_4 mask: Fig. 2(a) (top) and 2(b) (bottom) correspond to Fig. 1(a) and 1(b) for SiO_2 film, respectively.

maintains its initial contour of a round shape during vapor etching. Figure 2(a) and 2(b) for Si_3N_4 film correspond to Fig. 1(a) and 1(b) for SiO_2 films. In Fig. 2(a), as steep (111) facets appear in the window, observation of the facets from directly above is rather difficult. The facets develop from under the film [Fig. 2(a)], and the etched shape is exhibited in a polygonized form [Fig. 2(b)]. At the bottom of the etched hole, mildly inclined (311) facets can be seen as in the case of the SiO_2 mask.

SiO_2 films of 5000, 8000, and 13,000Å and Si_3N_4 films of 400, 950, and 2000Å in thickness were made, and similar experiments were carried out, but no difference in the facet appearance due to film thickness was observable. In addition to thermally oxidized SiO_2 films, tetraethyl orthosilicate pyrolytic decomposition films at 760°C and SiH_4-O_2 vapor-grown films at 350°C were made and similar experiments were performed, but no difference in the facet appearance could be observed.

Crystal orientation and facet appearance.—Schematic illustrations of the facet appearance on the surface of various crystal orientations are given in Table I for SiO_2 film and Table II for Si_3N_4 film. The tables are arranged according to crystal orientations along the $(\bar{1}10)$ zone from (001) to (110). The asterisks in the tables indicate those facets that have appeared in common for both SiO_2 and Si_3N_4 films. The fourfold symmetry of (001) changes as the orientation changes to (117), showing the threefold symmetry of (111), and finally becomes the twofold symmetry of (110). Outstanding features evident from the two tables are as follows:

1. With SiO_2 films, few facets generally develop directly under the film; facets existing at a comparatively deeper bottom are observable.

2. With Si_3N_4 films, facets appear directly under the film. For this reason, polygons are formed mostly.

Table I. Facet appearance through windows in SiO_2 masks The asterisks (*) indicate facets that appeared common for both SiO_2 and Si_3N_4 masks

Crystal orientation	Appearance of facets	Angle between facets and specimen surface
(001)		(1)(311)* 25.2° (2)(110)* 45.0°
(117)		(1)(311)* 13.8° (2)(311)* 27.6° (3)(311)* 36.7° (4)(110)* 37.6° (5)(110)* 53.6°
(115)		(1)(110)* 38.9° (2)(311)* 9.5° (3)(311)* 29.5° (4)(311)* 41.1° (5)(110)* 35.3°
(113)		(1)(111)* 29.5° (2)(311)* 35.1° (3)(311)* 50.5° (4)(311)* 50.5° (5)(110)* 31.5°
(112)		(1)(111)* 19.5° (2)(311)* 10.0° (3)(311)* 42.4° (4)(311)* 42.4° (5)(110) 30.0°
(111)		(1)(311)* 29.5° (2)(110) 35.3°
(331)		(1)(111)* 22.0° (2)(311)* 26.0° (3)(311)* 40.5° (4)(110) 13.3°
(551)		(1)(111)* 27.2° (2)(111)* 43.3° (3)(311)* 27.6° (4)(311)* 36.7°
(110)		(1)(111)* 35.3° (2)(311)* 31.5°

3. Facets that appear near the periphery of the hole are common both for SiO_2 and Si_3N_4 masks.

4. Only {111}, {311}, and {110} planes appear as facets.

5. When any specific facet becomes anomalously large, facets that should appear may be hidden from view, as in the case of the (110) facets near the (111) facet of (331) orientation in SiO_2 mask.

Discussion

Difference in the facet appearance between SiO_2 *and* Si_3N_4 *coated specimens.*—As can be seen from Tables I and II, there is a marked difference in the appearance of facets directly under the film surfaces. Under the circumstances, the difference was considered to be due to a difference in chemical reaction between Si-SiO_2 and Si-Si_3N_4 films during vapor etching, and the following investigations were made:

Reaction between Si *and films.*—According to Alexander (4), the following are conceivable as the reactions between Si and SiO_2.

$$Si + SiO_2 = 2SiO \qquad [1]$$

$$K_1 = (P_{SiO})^2 \qquad [1a]$$

$$Si + H_2O = SiO + H_2 \qquad [2]$$

$$K_2 = \frac{P_{SiO} \cdot P_{H_2}}{P_{H_2O}} \qquad [2a]$$

$$SiO_2 + 2H_2 = Si + 2H_2O \qquad [3]$$

$$K_3 = \frac{(P_{H_2O})^2}{(P_{H_2})^2} \qquad [3a]$$

$$SiO_2 + H_2 = SiO + H_2O \qquad [4]$$

Table II. Facet appearance through windows in Si_3N_4 masks

$$K_4 = \frac{P_{SiO} \cdot P_{H_2O}}{P_{H_2}} \qquad [4a]$$

P_i and K_i are a partial pressure of each substance and an equilibrium constant of each reaction, respectively. With Si_3N_4 films, on the other hand, there are no data available for nitrides of a composition other than this chemical formula, and consequently, no reaction with silicon is conceivable.

Etching reaction of silicon.—The following reactions were considered, taking into account the thermodynamic analysis of the Si-HCl system reported by Lever (15), Shepherd (16), and Seki *et al.* (17).

$$Si + 4HCl = SiCl_4 + 2H_2 \qquad [5]$$

$$K_5 = \frac{P_{SiCl_4} \cdot (P_{H_2})^2}{(P_{HCl})^4} \qquad [5a]$$

$$Si + SiCl_4 = 2SiCl_2 \qquad [6]$$

$$K_6 = \frac{(P_{SiCl_2})^2}{P_{SiCl_4}} \qquad [6a]$$

$$Si + 3HCl = SiHCl_3 + H_2 \qquad [7]$$

$$K_7 = \frac{P_{SiHCl_3} \cdot P_{H_2}}{(P_{HCl})^3} \qquad [7a]$$

The equilibrium constant of each reaction was calculated from Janaf's thermochemical tables (18).

The total pressure P_{tot} in connection with vapor etching can be expressed as

$$P_{tot} = P_{H_2} + P_{HCl} + P_{SiCl_4} + P_{SiCl_2} + P_{SiHCl_3} = 1 \text{ (atm)} \qquad [8]$$

The mole fractions 0.025 (standard experimental condition), 0.05 and 0.1 of the initial HCl are included,

and the partial pressure of each gas component is calculated by a computer with Eq. [6a], [7a], [8a]. Then, when the partial pressure $(P_{Si})_I$ of the hypothetical Si to be vapor etched is calculated, the equations obtained are

$$(P_{Si})_I = P_{SiCl_4} + P_{SiCl_2} + P_{SiHCl_3} \quad [9]$$

Using the HCl/H_2 mole fraction as a parameter, Fig. 3 shows the temperature dependence of hypothetical partial pressure (P_{Si}).

Meanwhile, it can be seen from the equilibrium constants that between Si and SiO_2, reactions [1] and [2] are liable to occur at around 1250°C. However, as the dew point of H_2 carrier gas is limited to below −70°C, the H_2O gas contained in H_2 gas from the beginning need not be considered in the reaction of Eq. [2]. Oldham (7) claims that Eq. [3] and [4] need not be considered since the reactions are slow, but if it is assumed that the total H_2O arising in Eq. [3] and [4] causes the reaction of Eq. [2], the hypothetical Si partial pressure $(P_{Si})_{II}$ due to such reactions can be expressed as

$$(P_{Si})_{II} = (P_{Si})_1 + (P_{Si})_2 = \frac{\sqrt{K_1}}{2} + K_2 \frac{P_{H_2O}}{P_{H_2}} \quad [10]$$

Figure 3 shows $(P_{Si})_{II}$ also. According to the above hypothesis, the contribution of $(P_{Si})_2$ from Eq. [2] is small compared with $(P_{Si})_1$ from [1]. As these partial pressures of hypothetical Si are considered proportional to the etching rate, Fig. 3 shows the relative extent of reaction between vapor etching and Si-SiO_2 film.

What can be seen from Fig. 3 is that $(P_{Si})_I$ undergoes practically no change due to reaction temperature and is close to the trends of Shepherd's calculations and experiment in value (16). However, the Si-SiO_2 reaction rate is highly dependent on the reaction temperature. The fact that the vapor etching rate is dependent on orientation can be seen from the formation of facets. With Si_3N_4 films, vapor etching alone occurs, and the facets appear from directly under the film surface, thus forming an angular shape such as shown in Fig. 2(b). On the other hand, since the Si-SiO_2 reaction is not dependent on orientation the facets directly under the film do not appear so easily with SiO_2 films. Items that support this reasoning are:

1. This trend was recognized by examining the etching rate of Si through windows in SiO_2 and Si_3N_4 films etched simultaneously. The etching rate parallel to the specimen surfaces was obtained from the distance between the initial film surface and the part where no facet appeared with Si_3N_4 films. The etching rate normal to the surfaces was obtained from the distance between the film surface and the spot where the etching was deepest. The etching rate parallel to the specimen surfaces is clearly greater with SiO_2 films, as can be seen in Fig. 4.

2. If the mole fraction of HCl/H_2 is increased, the facet appearance even with SiO_2 films approaches that of Si_3N_4 films, as seen in Fig. 5. The same phenomenon was observable with ribbon oxide (19), the effective mole fraction of which changes within a single wafer.

3. Similarly, when the reaction temperature is lowered, the appearance with SiO_2 film approaches that with Si_3N_4 film. While Fig. 6 shows the facets etched at 1150°C, a part of them displays an angular shape, unlike the shape shown in Fig. 1(b).

4. The result of heating without vapor etching in H_2 is shown in Fig. 7(a) for SiO_2 film and shown in Fig. 7(b) for Si_3N_4 film. It is clearly observable that with SiO_2 film, reaction is taking place below the film and the initial round part is enlarged. On the other hand, no reaction is observable with Si_3N_4 film.

Facet appearance by other etchant.—Hays (20) has reported that vapor etching on the silicon surface by SF_6 was nonpreferential and did not reveal the facets. Besides HCl, vapor etching by HBr was tried. In the case of SiO_2 mask, sizes of facets were larger and the facets were easily observed. There was no large difference in the case of Si_3N_4 film. Dependence of the

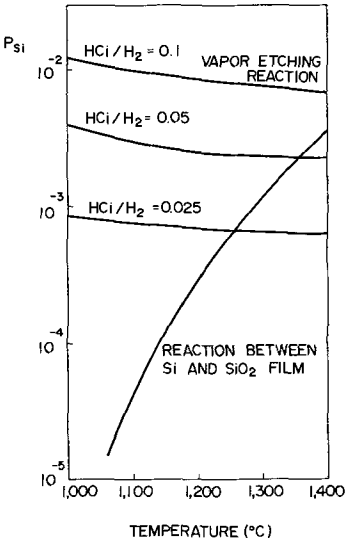

Fig. 3. Temperature dependence of hypothetical partial pressure of silicon P_{Si} to be etched off in the vapor etching reaction and in the reaction between Si and SiO_2 film.

etching rate on orientation seemed to differ little from that of HCl.

Conclusions

Silicon wafers with nine different orientations on the [110] zone, including (001), (111), and (110) were vapor etched by HCl through the windows made in SiO_2 and Si_3N_4 films. The results are summarized as follows:

1. Facets were identified to be {111}, {311}, and {110}. The mode at which the facets appeared, depended on the surface orientations.
2. When etching was carried out through a window made in SiO_2 film, the facets appeared only at the periphery of the bottom of the etched area, but when Si_3N_4 film was used, facets appeared directly under the film as well as at the periphery of the bottom. The shape of the holes directly under the film was almost circular for SiO_2 film but become angular for Si_3N_4 film.
3. Differences in the facet appearance between SiO_2 and Si_3N_4 films consisted of an occurrence of Si-SiO_2 reaction at the periphery of the etched hole besides HCl etching in the case of SiO_2 film, and should this reaction have no dependence on orientation, a qualitative explanation for the differences is possible.

Acknowledgments

The Effect of Growth Orientation on the Crystal Perfection of Horizontal Bridgman Grown GaAs

T. S. Plaskett,* J. M. Woodall,* and A. Segmüller

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The crystalline perfection of Sn-doped GaAs crystals grown by the horizontal Bridgman technique was found to be dependent on the crystal growth direction. The highest perfection occurred for crystals grown near the <013> direction. Portions of both seeded and unseeded doped crystals grown in this direction were found to be dislocation-free. Also, undoped crystals seeded in the <013> direction were dislocation-free.

Steinemann and Zimmerli (1) have grown dislocation-free undoped crystals of GaAs by the Czochralski technique by maintaining careful control of the stoichiometry of the melt composition and of the temperature gradients in the solid. In this paper we report the growth of dislocation-free undoped and heavily Sn-doped GaAs crystals by the sealed horizontal Bridgman technique. The advantage of the horizontal Bridgman technique is that heavily doped crystals grown by this method are more homogeneous than doped crystals grown by the Czochralski technique. For device applications, crystals of high perfection and chemical homogeneity are required.

Experimental Technique

The crystals were grown in a sealed quartz system in quartz boats. Synthesis was performed from the elements *in situ* prior to growth. A schematic diagram of the apparatus and temperature profile used for the experiments is shown in Fig. 1. Two important features of the apparatus are (*a*) the zirconia tube located in the core of the melt control furnace which tends to reduce local radial and axial thermal variations and also retards the rate of devitrification of the sealed quartz system and (*b*) the use of Fiber-Fax insulating board between the two furnaces to produce a sharp temperature gradient. For the growth of the Sn-doped crystals, the Sn/Ga weight ratio in the melt was 3.3×10^{-2}. This amount gives between 2 to 5 x 10^{18} atoms/cm^3 in the first half of the crystal. The effective distribution coefficient for Sn, which was determined by fitting the dopant profile to a normal freeze curve, was found to be about 3.5×10^{-3} for this growth system. The dopant profile was determined from radiochemical analysis and electrical measurements. The growth was performed at a constant As pressure by controlling the coldest portion of the ampoule at 614° ± 0.2°C. This As pressure is nominally about 1 atm. At this pressure the melt is essentially at the stoichiometric composition.

It was found that unseeded crystals did not grow along any of the major axes. Therefore, in order to study crystalline perfection for growth along these axes, it was necessary to grow seeded crystals. Seeding of the melt was performed in specially designed quartz crucibles as shown in Fig. 2. The inside of the crucible was sand blasted to prevent wetting. The seed was placed in the end of the crucible with the small rectangular cross section. To ensure that seeding occurred, about one-half of the seed was allowed to melt back before growth commenced. A typical crystal grown by this technique is shown in Fig. 3. The sealed ampoule was moved through the furnace with a precisely controlled furnace gradient at a rate of about 0.85 cm/hr. Except for differences in growth direction, all crystals were grown under the same conditions.

* Electrochemical Society Active Member.
Key words: crystal growth, GaAs, crystal perfection.

The degree of perfection of a crystal was determined on chemically polished (111) or (100) wafers cut from the positions shown in Fig. 3. Metallographic examination for dislocation etch pits and other structures was performed on the (111) wafers. X-ray transmission topographs, using the scanning oscillatory technique of Schwuttke (2), were taken on either (111) or (100) wafers that were first chemically

thinned to about 0.05 mm using the technique of Reisman and Rohr (3).

Results

The various growth orientations that were investigated for the Sn-doped crystals are shown in Fig. 4. (This is a double stereographic triangle which is required because of the polar nature of GaAs.) The crystalline perfection level observed for each orientation is indicated by the symbols. Around the major axes the crystals were grossly imperfect, with dislocation densities greater than 10^4 lines/cm^2 and with some dislocations aligned to form low-angle boundaries; *i.e.*, lineage structure as shown in Fig. 5b. In the central area of the double triangle the only defect structures that were observed were dislocations with densities less than 10^4 lines/cm^2 (Fig. 5a). The highest crystalline perfection occurred around the <013> direction and the dislocation densities were less than 10^3 lines/cm^2. Some portions were essentially free of dislocations. An x-ray transmission topograph taken from a Sn-doped crystal grown in this direction is

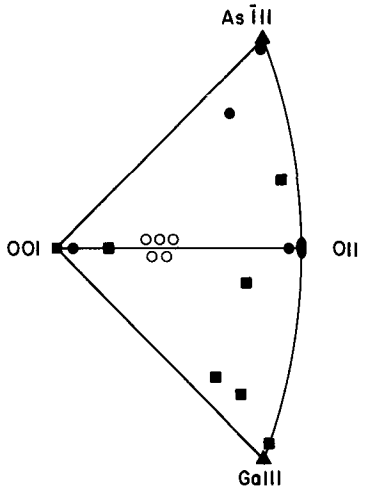

Fig. 4. Crystalline perfection for the various growth orientations investigated. ● grossly imperfect, ■ dislocated with densities between 10^3 and 10^4 lines/cm^2. ○ dislocated with densities less than 10^3 lines/cm^2 and with some positions dislocation-free.

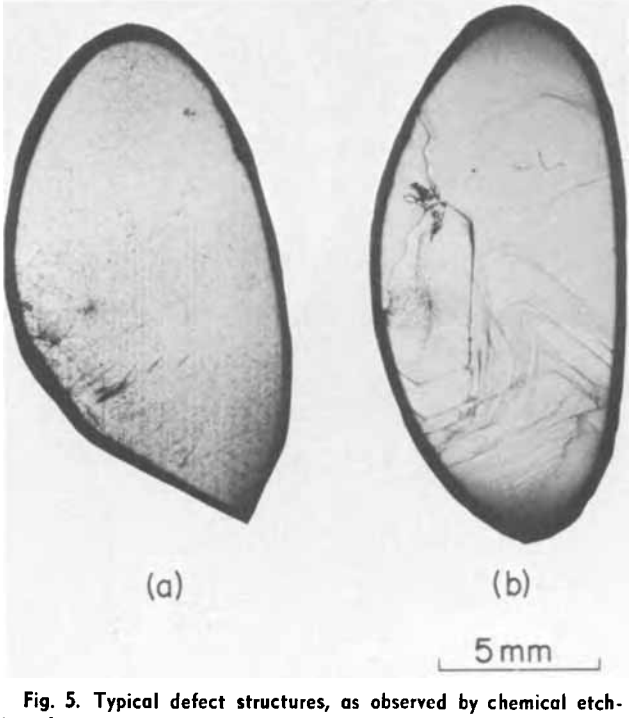

Fig. 5. Typical defect structures, as observed by chemical etching, for a crystal with the growth axis (a) away from the major axes and (b) near the major axes.

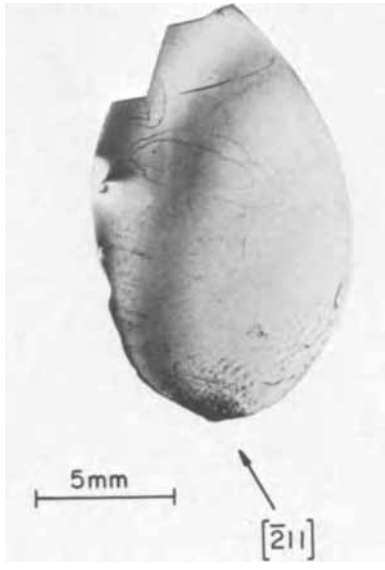

Fig. 6. X-ray topograph of a wafer from a crystal grown in <013> direction. A few dislocation loops are evident in the plane of the wafer. The broad dark band is a "Pendellösung" fringe due to the wedge shape of the wafer. The arrow denotes the diffraction vector. The Burgers vector of the two large loops is parallel to their long axis, a [1̄10] direction.

shown in Fig. 6. A few dislocations are evident as slip lines on the top free surface. At the edges of the wafer the dislocation density is higher. Two or three dislocation loops are evident in the plane of the wafer and are clearly resolved. This perfection level is typical for position A, B, and sometimes position C (see Fig. 3) for crystals grown in the <013> direction. At the lower edge of the wafer shown in Fig. 6 some cellular structure is evident. This is the only indication of chemical inhomogeneity present in this region of this doped crystal. More typically at position C the amount of cellular structure increased slightly from that shown in Fig. 6. Beyond position C the cross section shows both the cellular structure and two-phase growth. No striae were detected by etching or by infrared transmission microscopy in the first half of the crystal.

For Sn-doped crystals it was found that for all the orientations studied the highest crystal perfection occurred in crystals grown along the <013>. This is true for nonseeded Sn-doped crystals and for Sn-doped crystals seeded in the specially designed boat. However, when Sn-doped crystals were seeded with seeds having the same cross section as the bulk of the crystal and grown along the <013>, the resulting crystals exhibited dislocation densities $>10^4$ lines/cm^2. In addition several undoped crystals were seeded and grown in the <013> in the specially designed boat and were found to be nearly dislocation-free.

Except for the grossly imperfect crystals, the dislocations were generated by plastic deformation resulting from thermal stresses as evident from the slip line pattern shown in the etched sample in Fig. 5b and in the x-ray topograph in Fig. 7. The deformation undoubtedly occurred at elevated temperatures where GaAs is ductile. From the analysis of the slip line patterns of the sample, which showed only one set of slip lines, it was determined that the thermal stresses were uniaxial.

Discussion

Since the dislocations were generated by plastic deformation, the dependence of the dislocation density on growth orientation must be related to the high temperature strength of the crystal. The higher the strength, the less mobile are the dislocations, and therefore the greater are the stresses required to generate them. A mechanism whereby the crystal is

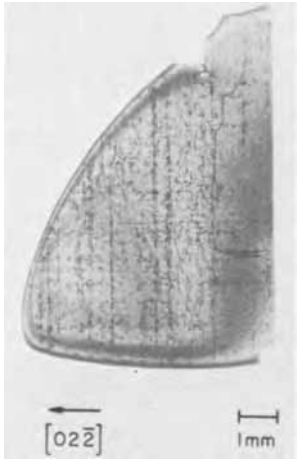

Fig. 7. X-ray topograph of a dislocated wafer. Most of the dislocations lie in slip planes which indicates that they were generated by plastic deformation. The arrow denotes the diffraction vector.

strengthened by the alloying action of the Sn dopant seems unlikely since the Sn concentration profile did not vary with orientation and <013> seeded undoped crystals could also be produced nearly dislocation-free. Also, the differences in the resolved shear stress to which the crystal was subjected during growth for the various growth directions cannot account for the orientation dependence; calculation of the resolved shear stresses of the <110> {111} type dislocation showed that the <013> growth direction had the highest relative value, although the differences in values for the various low-index growth directions were small.

The Dash (4) model may in part explain the growth of the dislocation-free seeded crystals. In the Dash technique initial growth conditions are provided which cause the dislocations to form in simple lines. These dislocations will then eventually grow out to a surface and be eliminated if the line of the dislocations is at some angle to the growth axis. In GaAs the axis of the most common dislocation is the <110> direction. The <013> growth direction makes an angle of about 27° to the axis of the line dislocations. This Dash type of dislocation behavior occurs when there are no radial or transverse thermal gradients. For the Czochralski technique this condition is met by necking the crystal down to a small diameter after seeding. In the present study it was found that the seed must have a smaller cross-sectional dimension than the crystal to be grown, which is equivalent to the necking down of the Czochralski crystals.

If conditions for the Dash model were the only criteria then the <111> and <100> would also be preferred directions. However, this was not found to be the case and this would indicate that other parameters are important.[1] Moreover, the Dash model does not explain why nonseeded doped crystals which grew in the <013> direction were dislocation-free right from the start. It is apparent, therefore, that further studies must be performed in order to completely understand the orientation effect observed.

Conclusions

From this investigation it was shown that it is possible to grow homogeneously doped and undoped GaAs crystals with a high crystalline perfection by the horizontal Bridgman technique. Crystals properly seeded in the <013> or unseeded Sn doped crystals which grew in this direction were of the highest perfection with portions of the crystal being dislocation-free.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

[1] One of the reviewers of this paper suggested that the reason the <111> and <100> are not preferred directions may be explained by the considerations of Sangster, who proposed that <311> to <511> should be preferred growth directions since none of the major axes offer an ideal combination of nucleation ease, surface stoichiometry, surface packing, and surface planarity. Growth directions such as the <311> (or <013>) which combine the favorable properties of the {100}, {110}, and {111} surfaces are, therefore, expected to produce crystals of higher perfection. [R. C. Sangster, "Model Studies of Crystal Growth Phenomena in the III-V Semiconducting Compounds," in "Compound Semiconductors," Vol. 1, R. K. Willardson and H. L. Goering, Editors, Reinhold Publishing Corp., New York (1963).]

Preferential Etching and Etched Profile of GaAs

Yasuo Tarui, Yoshio Komiya, and Yasoo Harada[1]

Electrotechnical Laboratory, Tanashi, Tokyo, Japan

ABSTRACT

The Br_2-CH_3OH system has been found to give good results for preferential etching of GaAs. The etch rates for the low-index planes of GaAs in this system have been investigated as a function of Br_2 concentrations in CH_3OH. The order of the etch rate at 1% Br_2 by weight has been found to be {110} $\gtrsim$ B{111} $\gtrsim$ {100} > A{111} where the A{111} planes have been only slightly etched. The A{111} planes have played an important role for the etched profiles produced by this etching system. A V-shaped groove, a reverse mesa-shaped structure, and a triangular prism-shaped "bridge" have been formed by channels being etched on the {100} planes. The sizes of the V-shaped groove and the "bridge" have been controlled by the width of the opening in the oxide mask. A channel etched groove in the B{111} planes has also exhibited crystal habit. Interesting etched profiles which are applicable for the design and fabrication of device structures are described.

The III-V intermetallic compounds with the zinc blende structure exhibit polarity along the <111> directions. Consequently, this structure has two types of the {111} planes designated as the A{111} planes or A planes and the B{111} planes or B planes. Regarding the difference in the etching behavior between the A{111} and B{111} planes, it has been proposed that the B{111} planes are chemically very reactive because of having an unshared pair of electrons, but the A{111} planes have not (1, 2). Br_2-CH_3OH (3) or H_2SO_4-H_2O_2 systems have usually been employed as the etchants which are capable of producing highly polished surfaces on GaAs. For silicon, the design and fabrication of device structures by means of preferential etching have been reported (4-6). However, for GaAs there has been no report on device shaping by using preferential etching.

In the present paper, we show preferential etching characteristics of GaAs in the Br_2-CH_3OH system and then demonstrate geometrically etched profiles produced in the B{111} and {100} planes by employing this system. Special emphasis has been placed on the unique device structures which are produced by the difference in the etch rate between the A{111} planes and the other low-index planes of the intermetallic compounds.

Experimental Procedure

Sample.—The wafers employed were slices of the low-index planes cut from GaAs single crystals (Te doped, carrier concentrations ranging from 5.3 to 15 x 10^{17} cm^{-3}), *i.e.* the A{111}, B{111}, {110}, and {100} planes, with an uncertainty of 1° or less. The surfaces of these wafers were lapped and polished with fine abrasive alumina (0.05-0.1μ particle size). After being degreased and rinsed with deionized water (ρ > 5 meg ohms), they were chemically polished in a slowly stirred solution of 5 H_2SO_4-1 H_2O_2-1 H_2O for 4 min at 50°-55°C.

Masking pattern.—The method selected for preparing the mask and determining the directions of the masking pattern was as follows.

1. The surfaces of the wafers, except for a portion near the corner, were coated with black wax.
2. The uncoated surfaces were etched in a solution of one volume of 33 w/o (weight per cent) CrO_3 aqueous solution–two volumes of 46 w/o HF (Sirtl etch) for 4 min at room temperature. The etched figures produced by this process are employed in the following photoetching process for the purpose of orientation alignment.
3. The wafers were degreased and rinsed with deionized water after removing the black wax. Then, their surfaces were masked with a 0.3-0.5μ thick Al_2O_3 layer by electron beam evaporation. The source was Al_2O_3 (99.999%).
4. The photoengraving process was carried out.
5. Heated phosphoric acid was employed to etch the Al_2O_3 film.

Etch solution.—The preferential etchant employed was Br_2-CH_3OH and etching experiments were carried out at room temperature. The Br_2 concentrations in CH_3OH were varied up to 5.0% Br_2 by weight. A large quantity of solution (~300 ml) was prepared to prevent the etching temperature from elevating and the etch composition from varying during the experiments (Br_2 purity ≥99.0%, CH_3OH purity ≥99.5%).

Etch rate determination.—The step heights etched were measured using a microscope after obtaining the etched cross sections of the samples by appropriate cleavage. The smallest step heights measured were about 0.5μ, where the accuracy of the microscope measurement was about 0.2μ.

Results and Discussion

Etch figures.—Schematic diagrams and photographs of the etch figures produced on the B{111} and {100} planes of GaAs in the CrO_3-HF system are shown in Fig. 1. The etch figures on the B{111} planes revealed an equilateral triangle as well known for silicon. However, the figures on the {100} planes of GaAs did not show a square as produced on silicon but indicated a rectangle because of the polarity along the <111> directions.

Br_2 *concentration dependence of the etch rate.*—Figure 2 shows the average Br_2 concentration dependence of the etch rate for 10 min on the A{111}, B{111} and {100} planes of GaAs, and the etch ratio B{111}/A{111}. The etch rates on these planes increased with Br_2 concentrations up to at least 5.0% Br_2 by weight. The ratio gives a minimum near 3.0% Br_2 by weight. This result indicates that, at the lower Br_2 concentrations, etching is more preferential; the B{111} planes of GaAs are very chemically reactive compared with the A{111} planes. Consequently, when a suitable etchant such as this system is employed, the etch rate on the A{111} planes is slower than on the B{111} planes (1, 2).

Orientation dependence of the etched depth.—Figure 3 shows the linearity between the etch depth and etch time with 5 min intervals for the low-index planes of GaAs at 1.0% Br_2 by weight. The order of magnitude of the etch rate was {110} $\gtrsim$ B{111} $\gtrsim$ {100} > A{111}, and the etch rate on the A{111} planes was very slow.

Key words: polarity of zinc blende structure, etching rate, Br_2-CH_3OH system, Gunn effect device.

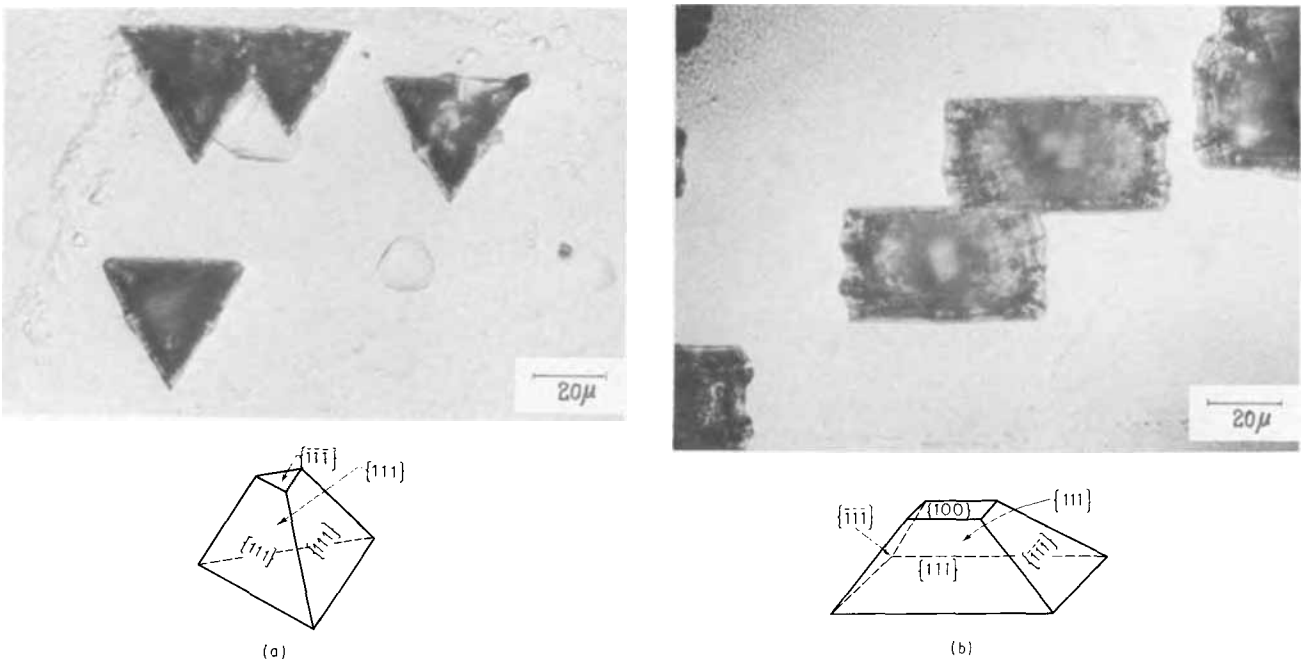

Fig. 1. Etch figures produced on B{111} and {100} planes of GaAs in CrO_3-HF system (room temp, 4 min) and schematic diagram of individual etch figures: (a) and (b) = etch figure on B{111}, {100}, respectively, and schematic diagram of individual etch figure (approx 300X).

When the B{111}, {110}, or {100} planes of GaAs which intercept the A{111} planes are employed as preferential etching surfaces, the etched grooves exhibiting crystal habit are formed because the etching stops at the A{111} planes, where the etch rate is slowest. These results suggest that the orientation effects produced by this system could be utilized in the design and fabrication of certain device structures.

Cross section of etched channels.—The cross sections of channels etched in the {100} and B{111} planes of GaAs are demonstrated in Fig. 4 and 5, respectively. Figure 4(a) shows the cross section of channels etched parallel to the short sides of the etch figures revealed in Fig. 1(b). The etched profile was a reverse mesa-shaped structure which exhibited crystal habit, while cross sections of channels etched parallel to the long sides of the rectangular figures in Fig. 1(b) were V-shaped as demonstrated in Fig. 4(b). This etched profile also exhibited crystal habit. Figures 5(a) and (b) show, respectively, cross sections of channels

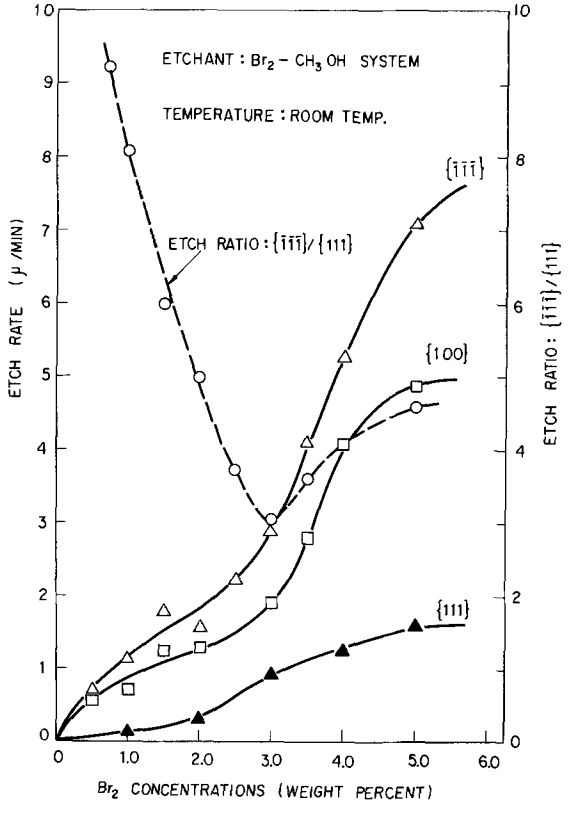

Fig. 2. Br_2 concentration dependence of the etch rate and etch ratio B{111}/A{111}: △, □, ▲ = etch rate on B{111}, {100}, A{111}, respectively; ○ = etch ratio B{111}/A{111}.

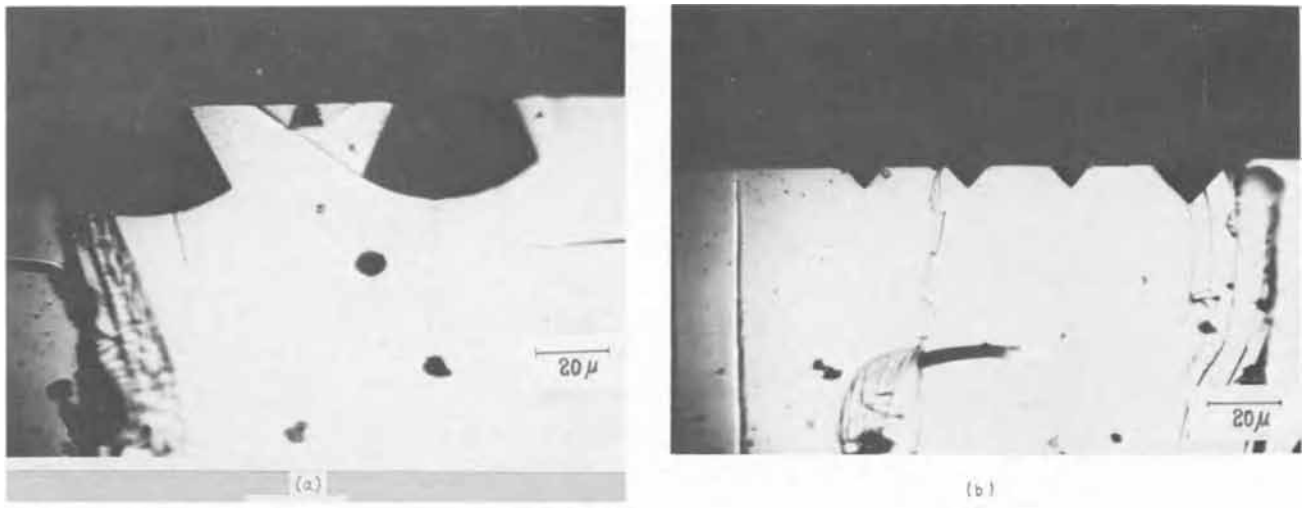

Fig. 4. Cross section of channels etched in {100} planes of GaAs and relation between a rectangular etch figure shown in Fig. 1(b) and the directions of a channel etching on {100} planes: (a) = cross section of channels etched parallel to the short side of etch figure at 1% Br_2 by weight for 10 min; (b) = cross section of channels etched parallel to the long side of etch figure at 4.8% Br_2 by weight for 10 min; (c) = relation between etch figure and the directions of channels being etched (approx 300X).

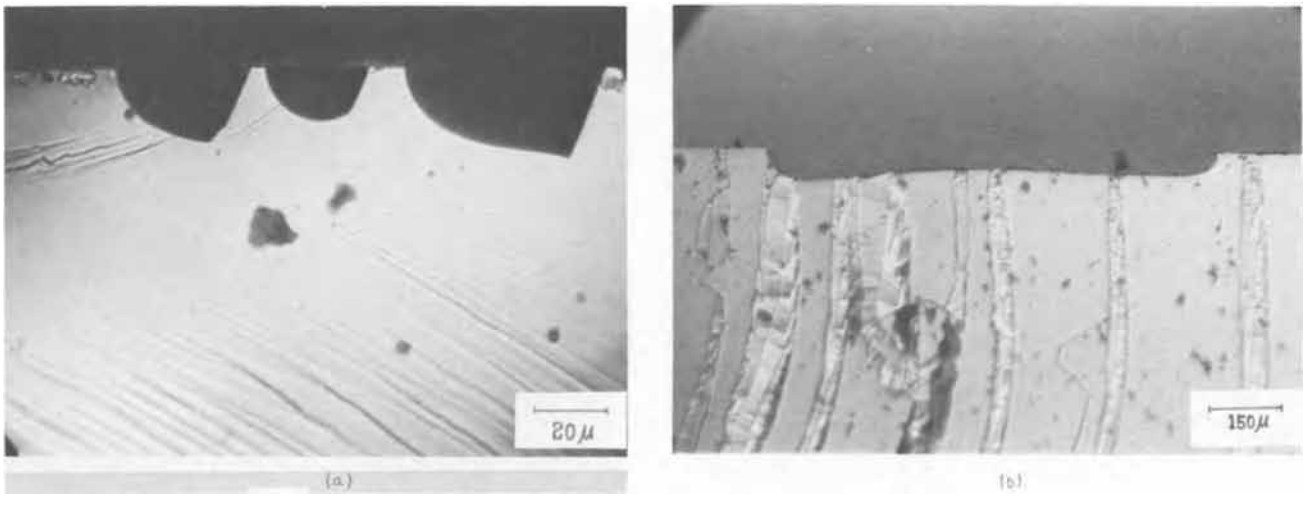

Fig. 5. Cross section of channels etched in B{111} planes of GaAs and relation between a triangular etch figure revealed in Fig. 1(a) and the direction of channels being etched on B{111} planes: (a) = cross section of channels etched parallel to one side of etch figure at 1% Br_2 by weight for 30 min (approx 300X); (b) = cross section of channel etched perpendicular to the one side of etch figure at 4.8% Br_2 by weight for 10 min (approx 90X); (c) = relation between etch figure and the direction of channel being etched.

etched parallel and perpendicular to the one side of the triangular figures shown in Fig. 1(a).

An etched groove demonstrated in Fig. 5(a) exhibited crystal habit but an etched one in Fig. 5(b) did not. The etched profile obtained in Fig. 4(a) is associated only with the intermetallic compounds, but the profile demonstrated in Fig. 4(b) is the same as for silicon (5, 6). This unique profile is formed because of the difference in the etch rate between the A{111} planes and the other low-index planes. Furthermore, we obtained a triangular prism-shaped "bridge," demonstrated in Fig. 6, by continuing the etching further in the case of Fig. 4(a). As shown by these results, when the direction of channels being etched on the {100} planes of GaAs is adjusted to the proper orientation, a V-shaped groove, a reverse mesa-shaped structure, and a triangular prism-shaped "bridge" as illustrated in Fig. 7 can be formed with Br_2-CH_3OH system.

Schematic diagrams of the etched cross section for the zinc blende structure are shown in Fig. 8 and 9 by perspective drawing through the {110} planes. Figures 8(b) and (c), respectively, show cross sections of a channel etched parallel to the $[0\bar{1}\bar{1}]$ and $[01\bar{1}]$ orientation in the (100) plane.

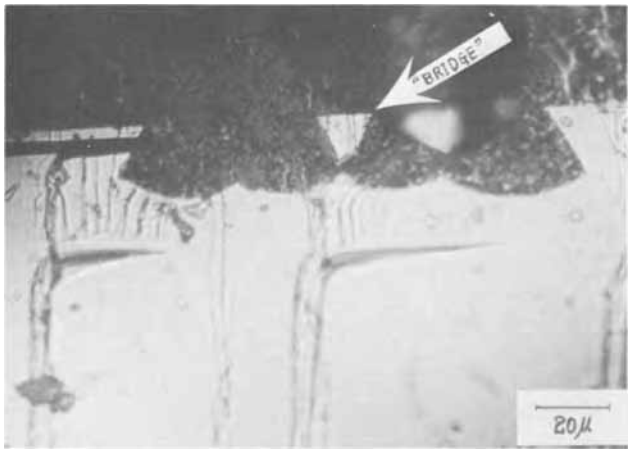

Fig. 6. Cross section of a triangular prism-shaped "bridge" obtained in {100} planes of GaAs by the Br_2-CH_3OH system (4.8% Br_2 by weight, 10 min) (approx 300X).

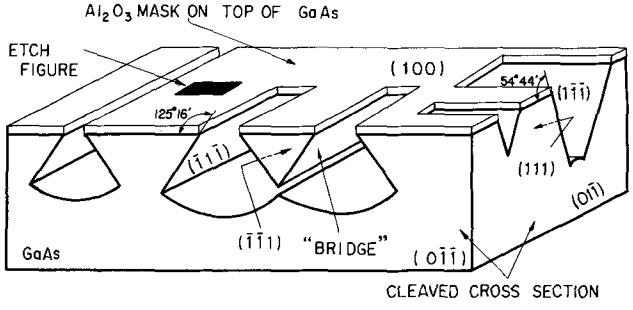

Fig. 7. Etched profile produced in {100} planes of GaAs by the Br_2-CH_3OH system.

There is twofold symmetry of the A{111} or B{111} planes intersecting the {100} planes as illustrated in Fig. 8(a). In Fig. 8(b), the $[\bar{1}1\bar{1}]$ and $[\bar{1}11]$ orientations intersect the [100] orientation at 125°16′, respectively, and, on the other hand, in Fig. 8(c), the $[1\bar{1}1]$ and [111] orientations intersect the [100] orientation at 54°44′, respectively. The $(\bar{1}1\bar{1})$ and $(\bar{1}11)$ planes are perpendicular to the $(0\bar{1}\bar{1})$ plane [Fig. 8 (b)] and also the $(1\bar{1}\bar{1})$ and (111) plane intersect the $(01\bar{1})$ plane at right angles [Fig. 8 (c)].

In the case of preferential etching in the [100] direction, the side etching proceeds up to the A{111} planes, *i.e.* the $(\bar{1}1\bar{1})$, $(\bar{1}11)$, $(1\bar{1}\bar{1})$, and (111) plane, while the etch rates on the B{111}, {110}, and {100} planes are much faster than the A{111} planes. Consequently a V-shaped and a reverse mesa-shaped profile are obtained whose sides form, respectively, an angle of 54°44′ and 125°16′ with respect to the (100) surface. The "bridge" can also be obtained whose sides form an angle of 125°16′ with respect to the (100) surface.

As schematically shown in Fig. 9(a), both the A{111} and B{111} planes form tetrahedrons having as all four sides either only the A{111} or only the B{111} planes. In one case, the insides of tetrahedrons are composed of only the A{111} planes and the outsides are surrounded by only the B{111} planes [Fig. 9 (a)]. In the other case, the insides are the B{111} planes and the outsides are the A{111} planes. Consequently, the $[\bar{1}\bar{1}\bar{1}]$ orientation intersects the $[1\bar{1}\bar{1}]$ orientation at 70°32′ and the $(1\bar{1}\bar{1})$ plane is perpendicular to the $(1\bar{1}0)$ plane as shown in Fig. 9 (b), which shows the cross section of a channel etched parallel to the $[1\bar{1}0]$ orientation in the $(\bar{1}1\bar{1})$ plane alone. When the channel of the mask pattern is aligned perpendicular to one side of the triangular etch figures, the etched cross section does not reveal crystal habit as shown in Fig. 5(b).

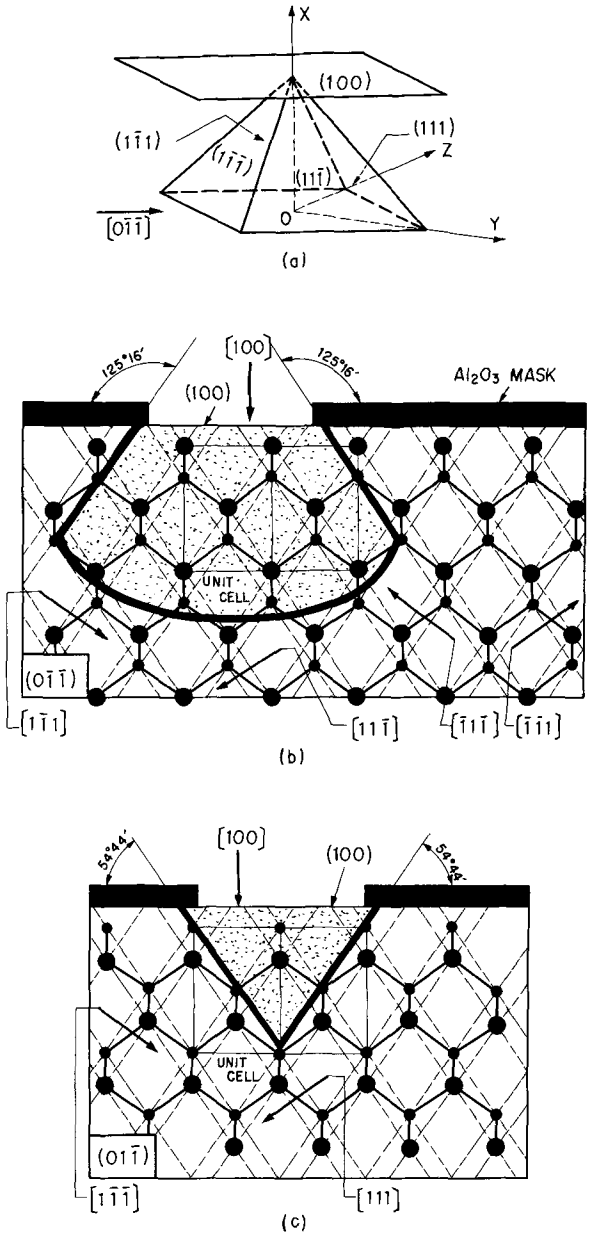

Fig. 8. Schematic diagrams of cross sections etched in {100} planes for zinc blende structure by perspective drawing through {110} planes and of relation between {100} and A{111} or B{111} planes: ○ = group III; ● = group V atoms; (a) = relation between {100} and A{111} or B{111}; (b) = cross section of a channel etched parallel to $[01\bar{1}]$ in (100); (c) = cross section of a channel etched parallel to $[0\bar{1}\bar{1}]$.

These results indicate that a triangular cone-shaped groove will be formed in the B{111} planes when a triangular mask pattern is aligned parallel to each side of the etch figures shown in Fig. 1(a).

Mask size and etched profile.—The sizes of a V-shaped groove, a triangular prism-shaped "bridge," and a triangular cone-shaped groove all can be controlled by the width of the opening in the oxide mask, since these geometric shapes are found to be surrounded by the A{111} planes. The similar, but unsymmetrical, etched profiles can be also formed by employing the higher index planes, *i.e.* {211}---, as the etching surfaces.

Proposed device structures.—We can widely apply the etched profiles described to the design and fabrication of device structures. Especially, the unique "bridge" structure shown in Fig. 6 and 7 has the advantage that the "bridge" is isolated by air and its size can be controlled by the window width of the

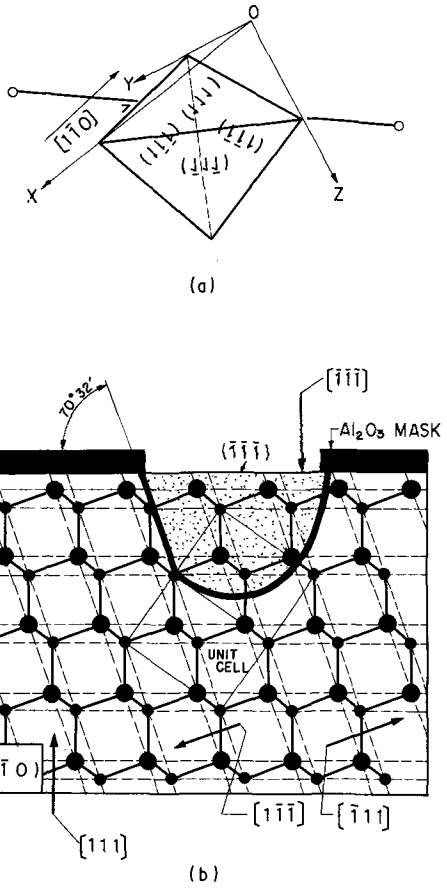

Fig. 9. Schematic diagrams of cross sections etched in B{111} planes for zinc blende structure by perspective drawing through {110} planes and of geometric tetrahedrons composed of only A{111} planes, *i.e.* (111), ($\bar{1}\bar{1}1$), ($1\bar{1}\bar{1}$), ($\bar{1}1\bar{1}$), or of only B{111} planes, *i.e.* ($\bar{1}\bar{1}\bar{1}$), ($11\bar{1}$), ($1\bar{1}1$), ($\bar{1}11$): • = group III; ● = group V atoms; (a) = insides of tetrahedrons are composed of (111), ($\bar{1}\bar{1}1$), ($\bar{1}11$), and ($1\bar{1}\bar{1}$); (b) = cross section of a channel etched parallel to [$1\bar{1}0$] in ($\bar{1}\bar{1}\bar{1}$).

oxide mask. By using the technology of semiconductor integrated circuits, we can monolithically fabricate the device structures composed of lots of the elements which are isolated by air and have small, geometric cross sections.

In the case of operating Gunn effect devices (7, 8) by utilizing the "bridge" structure, we can suppress the Gunn oscillation because the "bridge" section is small (9). Moreover, the problem of heat emission due to the power consumption of Gunn effect devices or luminescent devices will be much improved when the grooves around the "bridge" are refilled with a material of efficient heat conduction. These structures make the devices work at higher power. When we fill the grooves around the "bridge" with material which has a dielectric constant different from that of the semiconductor substrates used, we can control the state of the Gunn oscillation (10).

Field effect devices can be designed such that the structures with P-N junctions or Schottky contacts are fabricated on the upper surface of the "bridge." Gunn effect devices or luminescent devices with such a field effect structure can be modulated by the gate signal.

Conclusion

The Br_2-CH_3OH system gives good results for preferential etching of GaAs. Below 3% Br_2 by weight, the lower the Br_2 concentrations, the more preferential the etching behavior. The slowest etching planes are the A{111} planes, which play an important role for the etched profiles produced by this system. When the mask pattern is aligned in the proper orientation, an etched groove having crystal habit can be formed with this system. V-shaped grooves and triangular prism-shaped "bridge" structures can be fabricated, with sizes controlled by the width of the opening in the mask. These shaping methods give much flexibility to device fabricators.

Studies of the Defect Structure of Nonstoichiometric Cerium Dioxide[1]

R. N. Blumenthal, P. W. Lee,[2] and R. J. Panlener

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The electrical conductivity of sintered specimens of $Ce_{1+y}O_2$ was measured over the temperature range 800°-1500°C and from 1 to 10^{-21} atm of oxygen. Based on the agreement between these experimental data and theoretically derived relations obtained using the law of mass action, the nonstoichiometric defect structure of $Ce_{1+y}O_2$ was interpreted in terms of a defect structure consisting of triply and quadruply ionized cerium interstitials and localized electrons. The standard enthalpies of formation for the following defect reactions in $Ce_{1+y}O_2$ were determined

(a) $V_i + 5Ce_{Ce} + 2\,O_o = Ce_i^{\cdots\cdot} + 4Ce'_{Ce} + O_2(g)$; $\Delta H_a^o = 10.4\text{ eV} \pm 0.3$

(b) $V_i + 4Ce_{Ce} + 2\,O_o = Ce_i^{\cdots} + 3Ce'_{Ce} + O_2(g)$; $\Delta H_b^o = 8.5\text{ eV}$[3]

(c) $Ce_{Ce} + Ce_i^{\cdots} = Ce_i^{\cdots\cdot} + Ce'_{Ce}$; $\Delta H_c^o = 1.9\text{ eV}$[3]

Nonstoichiometric cerium dioxide, $Ce_{1+y}O_2$, has been the subject of several x-ray (1-3), thermodynamic (4-6), and electrical conductivity investigations (7-12). Based on these experimental observations, $Ce_{1+y}O_2$ may be classified as a metal-excess, n-type semiconductor. Such a metal excess may arise from the presence of a defect structure involving anion vacancies or cation interstitials in the crystal. However, in spite of all this scientific interest in $Ce_{1+y}O_2$, there has been no conclusive experimental evidence to indicate which of the above defect models predominates.

Brauer and Gingerich (3, 4) studied the influence of temperature on the cerium oxide system by measuring the oxygen dissociation pressure in the region CeO_2-$Ce_{1.33}O_2$, from 600° to 1000°C, and by high-temperature x-ray powder-diffraction analysis in the region CeO_2-$Ce_{1.11}O_2$ over the temperature range 20°-1050°C. From the results of their investigation, it can be concluded that, above 800°C, a homogeneous cubic solid solution extends from CeO_2 to about $Ce_{1.20}O_2$ and, from $Ce_{1.20}O_2$-$Ce_{1.33}O_2$, a two-phase region exists.

Kuznetsov *et al.* (5) utilized both a galvanic cell technique and a gas equilibrium method to obtain the thermodynamic properties of cerium oxide over the composition range $Ce_{1.26}O_2$ to $Ce_{1.02}O_2$. The results of their investigation indicate the existence of a single-phase region between $Ce_{1.20}O_2$ and $Ce_{1.02}O_2$ above 700°C. Bevan and Kordis (6) measured the oxygen dissociation pressure of $Ce_{1+y}O_2$ and found that a single-phase region exists between CeO_2 and $Ce_{1.16}O_2$ at all temperatures above 685°C. Thus the phase field limits of $Ce_{1+y}O_2$ determined by high-temperature x-ray and thermodynamic measurements appear to be in good agreement.

More recently, Kofstad and Hed (13) have interpreted the thermodynamic data obtained by Bevan and Kordis in terms of a defect model involving singly and doubly charged interstitial cations and electrons localized at cerium ions on normal lattice sites. Atlas (14) has proposed a statistical model to account for partial ordering of anion vacancies and reduced cations in a hypostoichiometric fluorite type metal oxide. Although $Ce_{1+y}O_2$ is thermodynamically stable (4-6) over a wide range of P_{O_2} and temperature (*e.g.*, $Ce_{1+y}O_2$ is thermodynamically stable to values of P_{O_2} as low as 10^{-20} atm at 1023°C) most of the electrical conductivity (7-10) investigations on $Ce_{1+y}O_2$ have been limited to the oxygen pressure region 1 to 10^{-4} atm.

Rudolph (7) measured the electrical conductivity of $Ce_{1+y}O_2$ as a function of P_{O_2} at only one temperature, 987°C, and found

$$\sigma \sim P_{O_2}{}^{-1/5.7}$$

Greener *et al.* (8), using a two-probe method, measured the electrical conductivity of $Ce_{1+y}O_2$ in the temperature range 650°-1400°C and from 0.006 to 1 atm of oxygen. They found that their experimental data could be represented by the following relation

$$\sigma_T = \sigma_{Od} \exp\frac{(-2.2)}{kT} P_{O_2}{}^{-1/5} + \sigma_{Oi} \exp\frac{(-1.45)}{kT}$$

They interpreted their results in terms of a defect structure involving either quadruply ionized cerium interstitials or completely ionized oxygen vacancy pairs.

Kevane (9) analyzed the conductivity data of Greener *et al.* (8) and the gravimetric data of Bevan and Kordis (6) and concludes that it is possible to interpret these results for $Ce_{1+y}O_2$ on the basis of an oxygen vacancy model.

The results of these conductivity measurements over a very limited range of P_{O_2} have not provided an unambiguous determination of the defect structure in $Ce_{1+y}O_2$. Thus, in order to help elucidate the defect structure in $Ce_{1+y}O_2$, work was initiated in this laboratory on the electrical conductivity of $Ce_{1+y}O_2$ as a function of temperature and oxygen partial pressure from 800° to 1500°C and from 10^{-17} to 1 atm of oxygen.

The initial results of this investigation were reported recently by Blumenthal and Laubach (12). Based on the observed curve fit between the theoretically derived relation

$$\sigma^3 = (A\sigma + B) P_{O_2}{}^{-1/2}$$

and the experimental conductivity data from 1000° to 1500°C, in the "high" and "intermediate" oxygen pressure region, they interpreted the nonstoichiometric defect structure of $Ce_{1+y}O_2$ in terms of a defect model involving quasi-free electrons and both singly and doubly ionized oxygen vacancies. At the lower oxygen pressure regions in the range 1200°-1500°C, the electrical conductivity of $Ce_{1+y}O_2$ appeared to be relatively insensitive to oxygen pressure. This region was qualitatively interpreted as possibly due to degenerate semiconducting behavior because of a large departure from stoichiometry.

There appear to be at least two major difficulties with the above defect model:

[1] Supported by the U.S. Atomic Energy Commission. This is AEC report COO-1441-6.

[2] This paper is based in part on a thesis submitted by P. W. Lee in partial fulfillment of the requirements for the M.S. degree, Marquette University, August 1968.

[3] Approximate values.

Key words: electrical conductivity, defect structure, electron mobility.

1. The expression relating σ and P_{O_2} was derived assuming that $Ce_{1+y}O_2$ was in a region close to stoichiometry (*i.e.*, assuming unit activity for the cerium and oxygen atoms on the normal occupied lattice sites).

2. The assumed defect model could not quantitatively account for the relative insensitivity of σ to P_{O_2} in the low oxygen pressure region.

The purpose of this investigation was to eliminate these difficulties by obtaining additional conductivity data over a larger oxygen pressure region and by attempting a more comprehensive analysis of the conductivity data particularly in regions which show a significant departure from stoichiometry.

Theory

The metal excess nature of nonstoichiometric $Ce_{1+y}O_2$ may arise from the presence of a defect structure involving either anion vacancies or cation interstitials. For electronic conduction, the electrical conductivity is proportional to the concentration of electrons and the electron mobility. If the mobility is assumed to be temperature dependent only, then using the law of mass action in combination with the assumed defect reaction and the appropriate simplified electroneutrality equations, theoretical expressions can be derived relating the electrical conductivity to the partial pressure of oxygen.

Thus, if the metal excess behavior arises from a defect reaction involving cerium interstitials in a single state of ionization, the theoretical pressure dependence of the electronic conductivity may be expressed as (8, 12)

$$\sigma \sim P_{O_2}^{-1/m} \qquad [1]$$

where m represents the extent of ionization (m = 2,3,4, or 5 for a singly, doubly, triply, and quadruply ionized cerium interstitial, respectively). Similarly, for a defect reaction involving oxygen vacancies in a single state of ionization, the theoretical pressure dependence of the electronic conductivity may be expressed by the same relationship with m = 4 or 6 for singly and doubly ionized oxygen vacancies, respectively.

Blumenthal and Laubach (12) have extended the above mass action approach by considering an electroneutrality condition involving two states of ionization. For example, the electroneutrality condition for triply and quadruply ionized cerium interstitials is

$$[e'] = 3[Ce_i^{\cdots}] + 4[Ce_i^{\cdots\cdot}]$$

where $[e']$, $[Ce_i^{\cdots}]$, and $[Ce_i^{\cdots\cdot}]$ are the concentrations of electrons, triply ionized interstitials, and quadruply ionized interstitials, respectively. Using the above relation the electronic conductivity may be expressed as

$$\sigma^5 = (D\sigma + E)P_{O_2}^{-1} \qquad [2]$$

where D and E are constants related to the mass action constants, the electronic charge, and the electronic mobility.

Similarly, for a defect structure involving singly and doubly ionized oxygen vacancies, the electroneutrality condition is

$$[e'] = [V_o^{\cdot}] + 2[V_o^{\cdot\cdot}]$$

where $[V_o^{\cdot}]$ and $[V_o^{\cdot\cdot}]$ are the concentrations of singly and doubly ionized oxygen vacancies, respectively. The electronic conductivity may be expressed as

$$\sigma^3 = (A\sigma + B)P_{O_2}^{-1/2} \qquad [3]$$

where A and B are constants similar to D and E.

The above expressions relating the electronic conductivity to the partial pressure of oxygen were derived using the following assumptions:

(*a*) Only defects arising from nonstoichiometric defect reactions were considered. The concentration of defects created by thermal disorder and foreign impurities were assumed to be small compared to the concentration of nonstoichiometric defects.

(*b*) The possibility of associated defects was excluded because only atomic defects with like charges were considered. It was assumed, on the basis of coulombic interaction, that these defects would tend to repel one another.

(*c*) Henry's law was valid for the defects (*i.e.*, the activity coefficients are independent of defect concentration).

(*d*) An activity of one was assumed for the normal cerium and oxygen atoms, and also for the vacant interstitial sites (*i.e.*, Raoult's law was assumed to be valid for these species and $Ce_{1+y}O_2$ was assumed to be in a composition region close to stoichiometry).

In this paper, the same assumptions were made with the exception of (*d*). Instead of unit activities, the cerium, oxygen, and vacant interstitial site activities were equated to the fraction of the available sites occupied. These fractions may differ significantly from one because cerium dioxide is stable over a wide range of nonstoichiometry (*e.g.*, CeO_2-$Ce_{1.20}O_2$). Also in this analysis a first-order attempt, similar to that used by Kofstad and Hed (13), is employed to account for interaction between defects on near neighbor sites. Thus, for a defect structure involving quadruply ionized cerium interstitials and localized electrons (13, 15), the following reaction may be written

$$V_i + 5Ce_{Ce} + 2\,O_o = Ce_i^{\cdots\cdot} + 4Ce'_{Ce} + O_2(g) \qquad [4]$$

where V_i is a vacant interstitial site, Ce_{Ce} and O_O are cerium and oxygen ions, respectively, on their normal lattice sites, $Ce_i^{\cdots\cdot}$ is a quadruply ionized cerium interstitial, and Ce'_{Ce} is an electron localized at a cerium ion on a normal cerium site. Applying the law of mass action yields

$$K_1 = \frac{[Ce_i^{\cdots\cdot}][Ce'_{Ce}]^4 P_{O_2}}{[V_i][Ce_{Ce}]^5[O_o]^2} \qquad [5]$$

where K_1 is the mass action constant and the square bracketed terms represent the number of a given species divided by the number of sites available for that species.

Since the oxygen sublattice is unaffected by the interstitial defect, $[O_o] = 1$. The concentration of normal cerium sites, however, should be corrected for the occupancy of some sites by localized electrons. Kofstad and Hed (13) have also proposed that an ionized interstitial may block the six neighboring normal cerium ions from electron occupation. The number of interstitial sites in $Ce_{1+y}O_2$ is equal to the number of normal cation sites. Thus

$$[Ce_{Ce}] = 1 - [Ce'_{Ce}] - 6(1-\alpha)[Ce_i^{\cdots\cdot}] \qquad [6]$$

where α is the relative probability of a neighboring Ce_{Ce} site being occupied by an electron.

In addition, each ionized cerium interstitial may block the 12 nearest neighboring interstitial sites from occupation because of coulombic repulsion. Thus

$$[V_i] = 1 - [Ce_i^{\cdots\cdot}] - 12(1-\beta)[Ce_i^{\cdots\cdot}] \qquad [7]$$

where β is the relative probability of occupation of interstitials in neighboring interstitial sites.

Assuming the predominant atomic defect is $Ce_i^{\cdots\cdot}$, then $y = [Ce_i^{\cdots\cdot}]$ and the electroneutrality relation is $[Ce'_{Ce}] = 4[Ce_i^{\cdots\cdot}]$. Combining these relations with Eq. [6] and [7], Eq. [5] can be written as

$$K_1 = \frac{4^4 y^5 P_{O_2}}{[1 - y(13 - 12\beta)][1 - y(10 - 6\alpha)]^5} \qquad [8]$$

or

$$K_1' = \frac{\sigma^5 P_{O_2}}{\mu^5[1 - (c\sigma/\mu)(13 - 12\beta)][1 - (c\sigma/\mu)(10 - 6\alpha)]^5} \qquad [9]$$

since

$$y = \frac{c\sigma}{\mu} \qquad [10]$$

where c is assumed to be a constant and μ is the electron mobility.

A quantitative analysis of the conductivity data using Eq. [9] would require knowledge of the temperature and composition dependence of the electron mobility. Since only the temperature dependence of the electron mobility (15) in the range 800°-1200°C is currently available, Eq. [9] has been closely approximated by

$$\sigma^5 = (E - E_1\sigma)P_{O_2}^{-1} \quad [11]$$

to facilitate quantitative analysis. Equation [11] was derived as described below. The denominator of Eq. [8] was calculated as a function of y from $y = 0.0$ to $y = 0.14$, which is approximately the maximum value of y according to existing thermodynamic data (6). These results are shown in Fig. 1 for the four combinations corresponding to the limiting values (*i.e.*, 0 and 1) of α and β. Three of the four curves go to zero and become negative before the maximum value of y is attained. This behavior is inconsistent with the above defect model. It appears that, in the region where the quadruply ionized cerium interstitial predominates, α and β are both closer to one than to zero. Thus, as a first approximation, only the fourth curve was considered, where $\alpha \simeq \beta \simeq 1$. In addition, it was found that this curve could be approximated by a linear function in y from $y = 0.0$ to $y = 0.05$ with less than 7% error for all points where $y < 0.04$ and less than 15% error for $y < 0.05$.

With this motivation, Eq. [8] is written as

$$K_1 = \frac{y^5 P_{O_2}}{a - by} \quad [12]$$

where a and b are constants. The justification for Eq. [12] lies in that only a few of the data points to be analyzed here fall beyond the limiting value of y (*i.e.*, $y \simeq 0.05$) and therefore the error introduced due to these points in using Eq. [12] will be small. Equation [11] can then be obtained by combining Eq. [10] and [12]

$$\sigma^5 = (E - E_1\sigma)P_{O_2}^{-1} \quad [11]$$

where

$$E = K_1 a \mu^5 / c^5 \quad [11a]$$

$$E_1 = K_1 b \mu^4 / c^4 \quad [11b]$$

For a defect structure involving a predominance of triply ionized cerium interstitials, the following expression can be derived (16)

$$\sigma^4 = (D - D_1\sigma)P_{O_2}^{-1} \quad [13]$$

where D and D_1 are parameters similar to E and E_1.

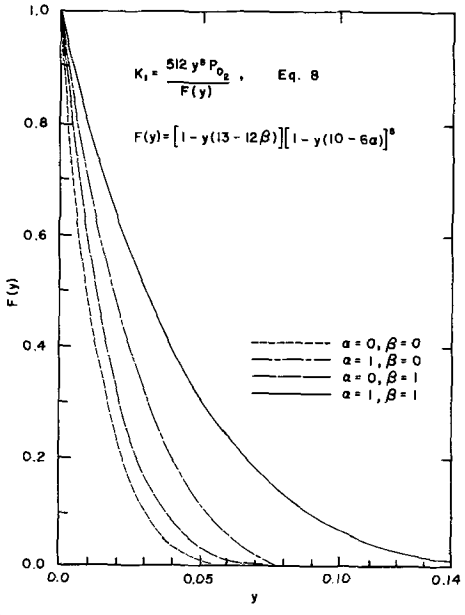

Fig. 1. The relation between $F(y)$ and y for $Ce_{1+y}O_2$

Similarly, for a defect structure involving singly ionized oxygen vacancies the following expression can be obtained (16)

$$\sigma^2 = (A - A_1\sigma)P_{O_2}^{-1/2} \quad [14]$$

For a defect structure involving doubly ionized oxygen vacancies, the following expression can be derived (16)

$$\sigma^3 = (B - B_1\sigma)P_{O_2}^{-1/2} \quad [15]$$

Since the electronic conduction mechanism is a "hopping type" process (15), the temperature dependence of the mobility may be expressed by the well-known relation

$$\mu = \mu_0 \exp(-\Delta E/kT) \quad [16]$$

If the defect model employed in obtaining Eq. [11] is valid, then the activation energy, ΔE, can be determined from the temperature dependence of the parameters E and E_1 as follows

$$E/E_1 \propto \mu \quad [17]$$

From Eq. [16]

$$E/E_1 \propto \exp(-\Delta E/kT) \quad [18]$$

Therefore

$$\Delta E = -k\frac{d[\ln(E/E_1)]}{d(1/T)} \quad [19]$$

The standard enthalpy of formation for a nonstoichiometric defect reaction is related to the mass action constant, K, by the well-known expression

$$K \propto \exp(\Delta S^\circ/k) \exp(-\Delta H^\circ/kT) \quad [20]$$

All of the above electrical conductivity models contain parameters that are proportional to the electronic mobility and to the mass action constants corresponding to particular defect reactions. Thus, since the temperature dependence of the electronic mobility has been determined (15), the standard enthalpy of formation of the defect reaction can be determined from the temperature dependence of the corresponding parameter.

Experimental

Specimen preparation.—The conductivity specimens were prepared by cold pressing and sintering CeO_2 powder obtained from the American Potash and Chemical Company (12, 16). Specimens 1 and 2 were made from 99.999%[4] and specimen 3 from 99.9999%[4] minimum purity CeO_2 powder. The results of a mass spectrographic analysis of a sintered specimen prepared from 99.999% type CeO_2 powder is shown in Table I.

The electrical conductivity measurements of $Ce_{1+y}O_2$ as a function of P_{O_2} in the temperature range 800°-1500°C were made in a molybdenum wound resistance furnace. A standard four-probe d-c technique was employed for the electrical conductivity measurements. The experimental apparatus employed was essentially the same as that described in an earlier publication (18).

Oxygen partial pressures were achieved by means of two methods. For pressures from 1 to 10^{-4} atm, premixed and analyzed O_2-Ar mixtures at 1 atm total pressure were used in the study. Controlled oxygen partial pressures in the low-pressure region were obtained by introducing known mixtures of CO and CO_2 at 1 atm total pressure. The well-known free energy values for the CO/CO_2 reaction were then used to calculate the oxygen partial pressure. A linear flow rate of 0.9 cm/sec was maintained for all gas mixtures used in this investigation to avoid errors arising from thermal diffusion (19). Isothermal electrical conductivity measurements at 100° intervals between 800° and 1500°C were made for both increasing and decreasing partial pressures of oxygen. Since the composition of $Ce_{1+y}O_2$ has a unique equilibrium value for each oxygen partial pressure and temperature, the above

procedure insures the measurement of equilibrium values of the conductivity, because the equilibrium state was approached from both higher and lower compositions of oxygen.

Results and Discussion

The electrical conductivity of sintered specimens of $Ce_{1+y}O_2$ was measured isothermally at 100° intervals between 800°-1500°C and from 1 to 10^{-21} atm of oxygen. The results of the conductivity measurements for specimen 1 (83% theoretical density) from 800° to 1100°C and specimen 2 (85% theoretical density) from 1200° to 1500°C are shown in Fig. 2. A check of the absolute magnitude of the conductivity of each specimen was performed at 1100°C and good agreement was observed over the entire oxygen pressure region investigated. The results of the conductivity measurements on specimen 3 (70% theoretical density) are shown in Fig. 3.

The values of m calculated from Eq. [1] depend on both the temperature and the partial pressure of oxygen. Thus, for the purpose of convenience of discussion, the conductivity data are divided into four regions as shown in Fig. 2 and 3.

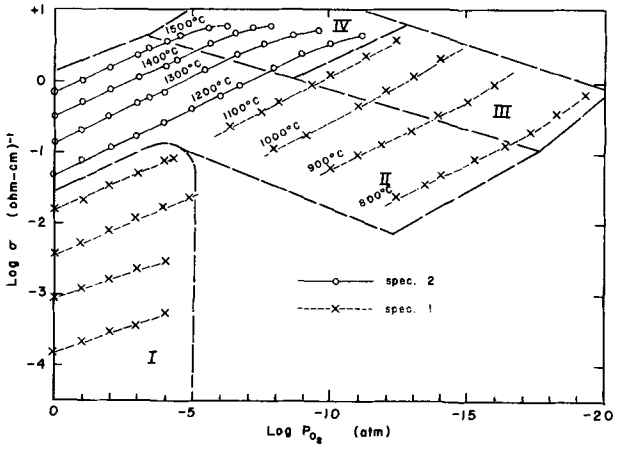

Fig. 2. Isothermal relation between the electrical conductivity of $Ce_{1+y}O_2$ and oxygen partial pressure for sintered specimens 1 and 2.

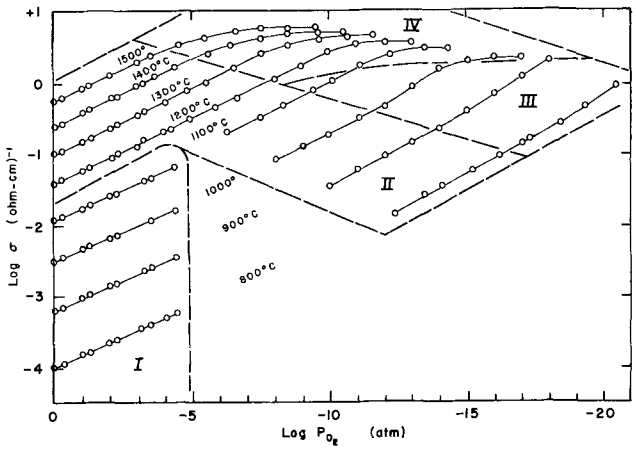

Fig. 3. Isothermal relation between the electrical conductivity of sintered $Ce_{1+y}O_2$ and oxygen partial pressure for specimen 3.

A qualitative explanation of the observed electrical conductivity data in terms of the four regions of m is described as follows:

1. The values of m in region I decrease from about 7.5 to 5.4 with increasing temperature as shown in Fig. 2. This can be interpreted in terms of the decreasing influence of impurities on the conduction process with increasing temperature. In Fig. 3, the values of m vary differently from Fig. 2, probably because the type and concentration of impurities were different.

2. In region II between 800° and 1100°C, m was approximately equal to 5. Above 1100°C, m increases to 5.3 at 1500°C. This region may be characterized by a predominance of quadruply ionized cerium interstitials or a combination of singly and doubly ionized oxygen vacancies.

3. In region III, m is approaching a value of 4. This can be interpreted as a defect model involving primarily either triply ionized cerium interstitials or singly ionized oxygen vacancies (18).

4. In region IV, the conductivity appears to be relatively insensitive to oxygen pressure. Blumenthal and Laubach (12) have qualitatively interpreted this insensitivity as due to degenerate behavior of the electron because of the large concentration of electronic defects. Another possible explanation for this behavior is that $Ce_{1+y}O_2$ exhibits a large departure from stoichiometry (6, 20). Thus, the assumption of unit activity for the cerium and oxygen atoms on normal lattice sites and the unoccupied interstitial sites may no longer be valid.

In order to obtain a quantitative explanation of the oxygen partial pressure dependence of the conductivity, the various equations corresponding to the aforementioned defect models were tested with a nonlinear curve fitting technique using a digital computer. Since region I was interpreted as an impurity controlled region, no attempt was made to analyze this region in terms of nonstoichiometric defect models.

A defect model involving quadruply ionized cerium interstitials

$$\sigma = EP_{O_2}{}^{-1/5} \qquad [1]$$

was tested using the conductivity data in region II. Below 1000°C, the result was in good agreement with the experimental data. Above 1100°C, this model did not provide a good fit of the data because the value of m in Eq. [1] is 5, whereas the value of m calculated from the data was greater than 5.

A curve fit of the conductivity data in regions II and III ($4 \leq m \leq 5$) was then attempted using each of the following equations which represent nonstoichiometric defect models involving defects with two states of ionization

$$\sigma^5 = (D\sigma + E)P_{O_2}{}^{-1} \qquad [2]$$

for triply and quadruply ionized cerium interstitials

and

$$\sigma^3 = (A\sigma + B)P_{O_2}^{-1/2} \quad [3]$$

for singly and doubly ionized oxygen vacancies. A good fit of the conductivity data was obtained for Eq. [2] or [3] at low temperatures (below 1100°C for specimen 1 and below 1000°C for specimen 3).

It is interesting to note that region III decreases in size with increasing temperature and does not appear to exist above 1200°C. Equation [2] does not provide a good fit of the conductivity data for region II above 1200°C because the maximum value of m is 5, whereas the value of m calculated from the experimental data was greater than 5. Equation 3, however, does provide a good fit of the conductivity data in this region because the value of m may vary between 4 and 6.

Although the singly and doubly ionized oxygen vacancy model provides a good curve fit of the conductivity data in regions II and III, it does not fit the data in region IV. The values of m calculated from the experimental data in region IV are greater than the maximum value of 6 allowed by Eq. [3] and increase with decreasing P_{O_2}.

On the basis of the thermogravimetric studies of $Ce_{1+y}O_2$ by Bevan and Kordis (6) and Balser (20), region IV corresponds to a region where the departure from stoichiometry is large (*i.e.*, $y > 0.02$). An attempt was made to analyze the conductivity data in regions II and IV between 1200° and 1500°C using Eq. [11], [13], [14], and [15]. These equations represent nonstoichiometric defect reactions where the departure from stoichiometry is large and account for the dependence of the activity for the cerium and oxygen atoms on the normal occupied lattice sites and vacant interstitial sites on defect concentration. All of the conductivity data in regions II and IV between 1200° and 1500°C, except the data points where the conductivity was independent of oxygen pressure, were analyzed for specimens 2 and 3. Only Eq. [11], which is based on a defect model involving a predominance of quadruply ionized cerium interstitials, provided a good fit of the conductivity data. The curve fit of Eq. [11] is shown in Fig. 4 where log σ is plotted as a function of log P_{O_2} for specimen 3.

The question arises whether a defect model with a predominance of triply ionized cerium interstitials and with values of the parameter α and β less than one would also fit the conductivity data in these regions. This possibility may be eliminated for the following reason. In region II below 1200°C the departure from stoichiometry is small. Thus the curve fit of any of the aforementioned defect models is independent of the values used for α and β. The only interstitial defect model which fits these data is one involving a predominance of quadruply ionized cerium interstitials. The same argument applies for most of the data in region II above 1200°C

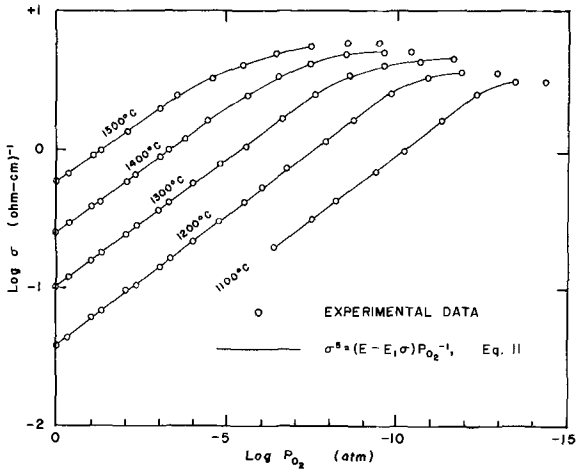

Fig. 4. A comparison of the curve fit of the quadruply ionized cerium interstitial model (Eq. [11]) with the experimental conductivity data as a function of oxygen partial pressure for specimen 3.

It should be noted, however, that in region IV where large departures from stoichiometry are encountered the possibility may exist that the concentration of triply ionized cerium interstitials is significant. The presence of triply ionized cerium interstitials should have the effect of increasing the dependence of the conductivity on the oxygen pressure (*i.e.*, a steeper slope should be observed such as shown in region III). This effect, however, may be masked in region IV for the following reasons:

(*a*) For large departures from stoichiometry, the decrease of available sites coupled with interactions described by α and β has the effect of decreasing the dependence of the conductivity on oxygen pressure.

(*b*) The electronic mobility which is a hopping type conduction process (15) should decrease with increasing defect concentration; *i.e.*, the concentration of normal cerium sites available for electron occupation, $[Ce_{Ce}]$, decreases with increasing departure from stoichiometry. To a first-order approximation, the compositional dependence of the mobility may be written as

$$\mu \propto \{1 - 4y - 6(1 - \alpha)y\} \quad [21]$$

Thus, in order to obtain a more comprehensive analysis of the conductivity than the analysis presented here, the following would be required:

(*a*) Eliminate the linear approximation used for the denominator in Eq. [11].

(*b*) Allow the parameters α and β to vary between 0 and 1.

(*c*) Allow the atomic defect to exist in more than one state of ionization when the departure from stoichiometry is large.

(*d*) Consider the compositional dependence of the electronic mobility. However, the results of such an analysis would be questionable until more information is obtained concerning both the nature of the nonstoichiometric defects and the compositional dependence of the electron mobility at large departures from stoichiometry.

In summation, based on the analysis of the conductivity presented here, the only defect model which is consistent with the experimental data over a wide range of temperature oxygen partial pressures is a nonstoichiometric defect structure involving triply and quadruply ionized cerium interstitials and localized electrons.

The standard enthalpy of formation for the nonstoichiometric defect reaction corresponding to the defect reactions can be calculated as discussed under Theory. For the defect reaction

$$V_i + 5Ce_{Ce} + 2\,O_o = Ce_i^{\cdots\cdot} + 4Ce'_{Ce} + O_2(g) \quad [4]$$

$\Delta H_a^\circ = 10.3 \pm 0.3$ eV was calculated using Eq. [2], [11], and [20] and the temperature dependence of E, which is shown in Fig. 5 for specimens 1 and 2 as log E *vs.* $1/T$. A correction has been made for the experimental activation energy of the mobility (15). The tolerance quoted is based on a 95% confidence limit corresponding to the over-all temperature dependence of E. Good agreement was obtained for the value of $\Delta H_a^\circ = 10.5 \pm 0.3$ eV calculated for specimen 3.

The values of E shown in Fig. 5 correspond to two different equations. Equation [2] was used to analyze the conductivity data in regions II and III between 800° and 1100°C. Between 1200° and 1500°C, Eq. [11] was used where only regions II and IV were observed. Since the values of E in Fig. 5 lie on essentially the same straight line, it appears that Eq. [2] and [11] are consistent with the assumed defect model.

In a similar manner, the standard enthalpy of formation, ΔH_b°, for the defect reaction

$$V_i + 4Ce_{Ce} + 2\,O_o = Ce_i^{\cdots\cdot} + 3Ce'_{Ce} + O_2(g) \quad [22]$$

was found to be equal to 8.4 and 8.6 eV for specimens

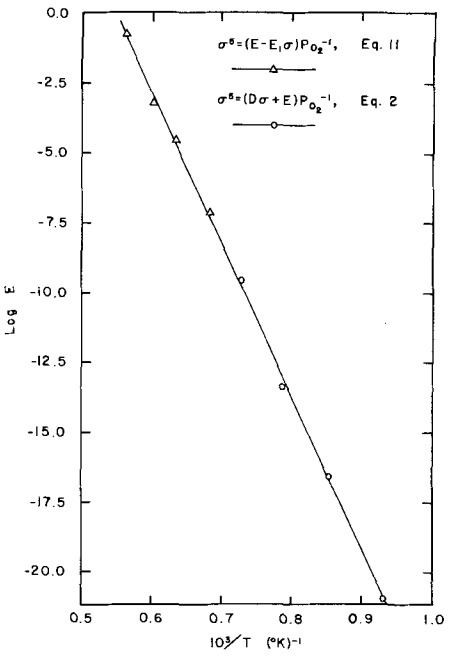

Fig. 5. A plot of the logarithm of E vs. $1/T$ for specimens 1 and 2 in the temperature range 800°-1500°C.

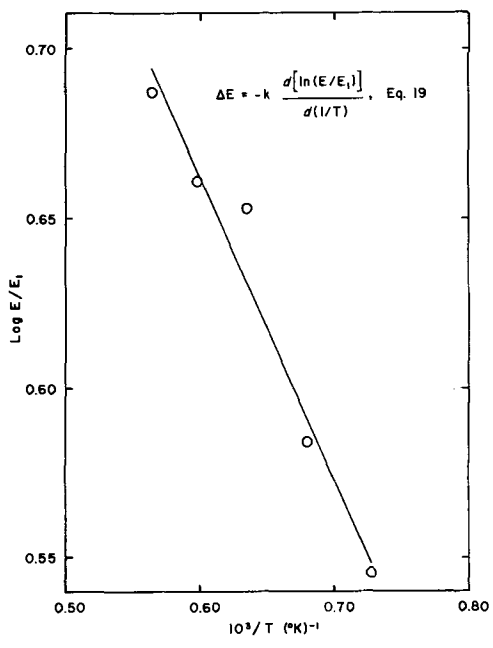

Fig. 7. A plot of the logarithm of E/E_1 vs. $1/T$ for specimen 3 in the temperature range 1100°-1500°C.

1 and 3, respectively. This result was obtained from the temperature dependence of D which is shown in Fig. 6 as log D vs. $1/T$ and correcting for the temperature dependence of the mobility. A calculation of tolerance is not meaningful in this case because of the relatively small number of data points.

Therefore, the standard enthalpy for the defect reaction

$$Ce_{Ce} + Ce_i^{\cdots} = Ce_i^{\cdots\cdot} + Ce'_{Ce}; \quad \Delta H_c^o = 1.9\ eV \quad [23]$$

calculated from the relation

$$\Delta H_c^o = \Delta H_a^o - \Delta H_b^o \quad [24]$$

should be regarded as an approximate value.

It is interesting to note that the differences in standard enthalpy of formation of the defect reactions for specimens 2 and 3 were in agreement within 4% even though the densities of these specimens differed by more than 20%. Thus it appears that, although the measured value of the conductivity depends on the density, the calculated values of the enthalpy of formation of the defect reaction are relatively insensitive to density.

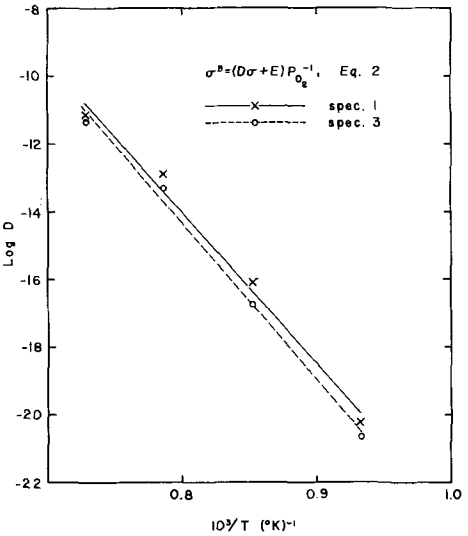

Fig. 6. A plot of the logarithm of D vs. $1/T$ in the temperature range 800°-1100°C for specimens 1 and 3.

Kofstad and Hed (13) have interpreted the thermodynamic data of Bevan and Kordis (6) in terms of a defect structure involving singly and doubly ionized cerium interstitials. Most of the data obtained by Bevan and Kordis were at temperatures and oxygen pressures lower than the conductivity data in this investigation. However, in the region that does overlap (*i.e.*, region III below 1100°C), we have interpreted the predominant defect reaction as involving triply ionized cerium interstitials rather than doubly ionized cerium interstitials as Kofstad and Hed have.

It is interesting to note, however, that ΔH_b^o is approximately equal to the value of $\Delta H_1 = 7.9$ eV calculated by Kofstad and Hed for the defect reaction corresponding to the formation of doubly ionized cerium interstitials.

A thermodynamic study of the composition of cerium dioxide over larger oxygen pressure and temperature regions is currently in progress in this laboratory to independently test the validity of the defect model proposed in this investigation.

Since the conductivity data were obtained using sintered specimens and accurate thermodynamic data over the entire oxygen pressure region were not available, an accurate determination of the absolute magnitude of the mobility could not be obtained. However, since the electronic conduction mechanism is a "hopping type" mechanism (15), the experimental activation, ΔE, may be obtained from the temperature dependence of the ratio, E/E_1, if Eq. [11] is valid. $\Delta E = 0.18$ eV was calculated from Eq. [19] and the slope of the line shown in Fig. 7 where log E/E_1 is plotted as a function of $1/T$. Although this result is in good agreement with the recently reported value, $\Delta E = 0.14$ eV (15), it nevertheless may be fortuitous. The exact interpretation of the parameter E_1 depends on the validity of Eq. [11] at relatively large departures from stoichiometry. And, as previously mentioned, this would be difficult to ascertain from this type of analysis.

Manuscript submitted May 16, 1969; revised manuscript received Aug. 25, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

The Effects of Epoxy Encapsulant Composition on Semiconductor Device Stability

R. C. Olberg*

Research and Development Laboratory,
Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

This paper describes the effects of various ingredients in an epoxy resin formulation on the electrical stability of encapsulated transistors with only thermal oxide passivation. The type and level of ionic impurities and/or polar contaminants in a completely formulated epoxy resin, which affect the electrical characteristics of transistors, are discussed with specific reference to the nature of the epoxy, hardener, promoter, filler, and other ingredients used. Although the study was directed toward the development of improved epoxy resins for semiconductor applications, the principles involved are applicable to other organic or inorganic dielectric materials.

A plastic material suitable for encapsulation of semiconductors must perform many functions: It must provide protection against the ambient to which the device is likely to be exposed (*e.g.*, high humidity and various chemical agents), as well as wide temperature fluctuations and mechanical shock. It must provide such protection with a minimum of effect on device parameters over an extended period of time, and be relatively inexpensive and easy to process.

Although many thermosetting resins have been evaluated for this application, only epoxies, silicones, and phenolics have been used extensively. Initially, the resins chosen were formulated to meet the requirements of other end uses. Hence, proper care in the selection of raw ingredients by the formulator was not considered. As a consequence, semiconductor devices encapsulated in these resins exhibited poor reliability, and producers and consumers of semiconductor devices alike concluded that plastic packaging was synonymous with poor reliability. However, over the past few years, the resin suppliers have improved the electrical properties of their resins to the point where plastic packaged integrated circuits and discrete devices are presently exhibiting a reliability approaching that of the so-called hermetically packaged devices under most ambient conditions.

Little has been published concerning the effect of the composition of encapsulating resins on the electrical parameters of the devices. Lee, Licari, and Valles (1) reported the adverse effects of ammonia in phenolic molding powders. The ammonia originates from the decomposition of hexamethylene tetramine used as the cross-linking agent. They further disclosed a correlation between the elevated temperature resistivities of various coating materials with the performance of these materials as encapsulants. Licari and Browning (2) disclosed the dependence of stoichiometry and purity of the ingredients in an epoxy resin on the reverse current leakage of microdiodes at elevated temperatures, but did not identify the ingredients most responsible for the observed results.

In the present work we have attempted to identify those ingredients and/or impurities in a formulated epoxy resin that are most responsible for the degradation of the electrical stability of thermal oxide passivated semiconductor devices.

Factors Influencing Reliability of an Epoxy Resin

The reliability of an epoxy resin for semiconductor use is dependent upon its composition which, in turn, is directly related to the bulk electrical and physical properties of the cured resin. Therefore, in formulating an epoxy for semiconductor use, our main concern is the nature and purity of the epoxy resin, hardener, promoter, and other ingredients in the formulation, the ratio of reactants employed, the polarity of the ingredients, the concentration and type of ionic contaminants, and the completeness of the cure. All these affect the electrical and physical properties. Although many of these properties are interrelated, the specific properties of interest are listed separately, as follows.

Electrical properties:

Stability of transistor under high-temperature reverse bias due to electrical characteristics of the epoxy[1]
Volume resistivity at elevated temperature
Dielectric constant and dissipation factor
Conductance of aqueous extract of cured epoxy

* Electrochemical Society Active Member.
Key words: epoxy ingredient effect on semiconductors.

[1] Used principally in this paper for evaluation of various epoxy formulations.

Physical properties:

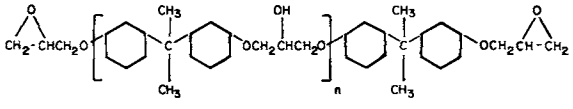
Moisture absorption and permeation
Adhesion
Thermal expansion
Thermal conductivity
Heat distortion temperature: second-order transition temperature
Tensile-elongation
Viscosity-flow
Cure shrinkage
Thermal stability
Cosmetic appearance

Epoxy resins.—Although there are literally dozens of epoxy resins available commercially, those in widest use in casting and molding formulations are diglycidyl ethers of bisphenol-A (BPA resins), epoxy novolacs, and aliphatic or cycloaliphatic epoxy resins. Examples of these are shown in Fig. 1. The BPA resins are most common and least expensive. The value of n is low, approaching zero for the low viscosity grades, and one for the more viscous grades. When n is greater than one, the resins are brittle solids. The epoxy novolac resins also vary from highly viscous liquids to brittle solids, but have a functionality greater than two. Because of this, they are used frequently where high-temperature properties are required. The aliphatics or cycloaliphatics made by the peracetic acid oxidation of the corresponding olefins are usually low in viscosity; for this reason they are frequently used as reactive diluents and have outstanding electrical properties and tracking resistance. Their bulk physical properties normally are not as outstanding as the BPA or epoxy novolac resins.

Hardeners.—Polyfunctional aliphatic amines, di- or polyfunctional anhydrides, and Lewis acids or bases are among the most common hardeners used for curing epoxy resins. However, the anhydrides are preferred for semiconductor application since they give better high-temperature and electrical properties than amine cured systems.

A large number of anhydrides are available, ranging from low viscosity liquids to high melting solids. Frequently, mixtures are used to tailor properties for a specific end use. Examples of some typical anhydride hardeners include dodecenylsuccinic anhydride, which is a liquid; hexahydrophthalic anhydride, which is a low melting solid; and phthalic anhydride and benzoylphenone tetracarboxylic dianhydride, which are high melting solids. Structures are shown in Fig. 2.

Promoters.—Although the more highly functional anhydrides produce cured resins without the use of promoters, most require tertiary amines or metal-



Diglycidyl ether from epichlorohydrin and bisphenol A (BPA Resins)

organic salts to promote the cure. The stoichiometry of the reactants is greatly affected by the nature of the promoter, and the effectiveness of various promoters is likewise associated with the type of epoxy and hardener employed.

Fillers.—Since fillers frequently comprise a high proportion of the total epoxy resin formulation, they exert a major influence on the final properties. Those most commonly used in epoxies for semiconductor application include silica, alumina, barium sulfate, and antimony oxide. The latter, when used in conjunction with a bromine substituted epoxy, confers flame-proofing properties to the epoxy. Fillers are used to modify the physical properties of the epoxy. They lower the cure shrinkage, the exotherm, and the thermal expansion coefficient of an epoxy formulation; they raise the thermal conductivity and the viscosity; and they act as reinforcing agents, particularly those in fiber form. The hydrated silicas are frequently employed to confer thixotropic properties to the formulation. Fillers also affect the electrical properties of the formulated epoxy. Ionic contamination and polar or polarizable groups in the filler contribute to a lowering of the electrical stability of the resin, particularly under high humidity and/or under electrical bias.

Other ingredients.—Other ingredients that may be present in a formulated epoxy resin included reactive diluents, plasticizers or flexibilizers, pigments, flow control agents, and mold release agents. A single formulation will seldom contain all of the above secondary ingredients. The end use determines the number needed in addition to those discussed above. Although a mold release agent is necessary in a molding powder formulation to aid in the release of the device from the mold, normally it is not used in a casting formulation.

Although the present investigation does not include an evaluation of the other ingredients, the conclusions regarding their nature and purity are applicable.

Experimental Procedures

npn Transistors (Fairchild TXB-1250 HB) packaged in standard TO-18 metal cans were used for evaluating the various casting resins. After removal of the metal tops from the cans, the resins were cast into the cavity and cured. The low heat distortion temperature formulations were cured for 2 hr at 90°C and 22 hr at

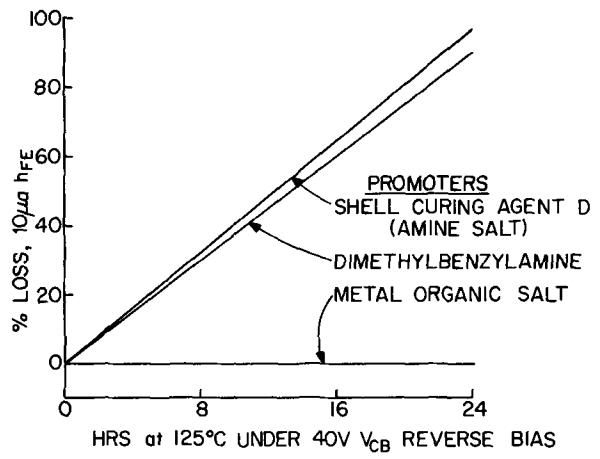

Fig. 3. Influence of the chemical nature of the promoter in an epoxy resin on the electrical stability of the encapsulated device.

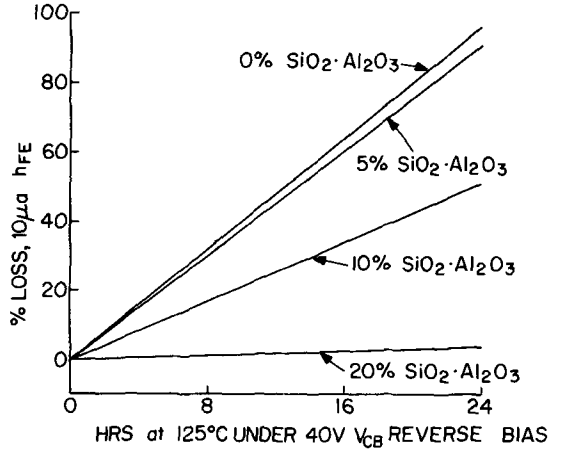

Fig. 4. Use of an acidic filler to neutralize the deleterious effect of an amine promoter.

150°C; the high heat distortion temperature formulations were cured at 175°C for 16 hr, and in some cases, followed by 200°C for up to 4 hr.

A Fairchild tester, Model 500, was used to determine the following electrical parameters of the encapsulated devices: I_{CBO} at 25V; I_{EBO} at 4V; I_{CEO} at 10V; BV_{CBO} at 10 μA; BV_{EBO} at 10 μA; BV_{CES} at 500 μA and 2 mA; $V_{CE,SAT}$ 1/0.1; and h_{FE} at 10V and 10 μA, 500 μA, and 10 mA. After the initial readout the units were subjected to 40V reverse bias at 125°C or 150°C with periodic readouts for up to 1000 hr. In each case, the units were cooled to room temperature under bias before the readout. Normally, 10 to 30 units were employed with each casting resin.

Of the above electrical parameters, the 10 μA beta was found to be the most sensitive to compositional variations in the encapsulant. Therefore, in this investigation the average loss in beta under reverse bias was used for comparing the stability of various epoxy formulations. However, increases in leakage currents could have been used and would have led to similar conclusions. Catastrophic failures due to shorts and opens under stressing were also noted.

The flatband voltage shift, at various current densities under reverse bias and at elevated temperatures, on a gate-controlled npn test device was also used in one instance for screening epoxies.

Results and Discussion

Effect of promoters.—As mentioned previously, when an anhydride is used to cure an epoxy resin, the reaction usually requires a promoter. Anhydride-cured epoxies are preferred for semiconductor application because of their superior electrical properties. Tertiary amines, tertiary amine salts, or metal-organic salts are commonly used to promote the reaction. Figure 3 compares the low current beta stability of transistors encapsulated in epoxy formulations utilizing the various promoters when subjected to 40V V_{CB} reverse bias at 125°C. The epoxy resin (DER 332)[2] and anhydride hardener (hexahydrophtalic anhydride, *HHPA*)[3] used were common to each formulation. Both the amine (dimethylbenzylamine) and amine salt (Shell curing agent D)[4] promoted epoxies caused over 90% loss in the 10 μA h_{FE} in 24 hr, while the metal-organic salt (DB VIII)[5] caused essentially no change in beta under the same conditions. No fillers were incorporated in these formulations.

Further evidence for the effect on device stability of the nature of the promoter used in an epoxy composition was obtained by the following flatband voltage shift of encapsulated gate-controlled npn test devices under high-temperature reverse bias (HTRB) at 125°C for 200 hr. The amine promoted epoxy formulation gave ΔV_{FB} of 25V compared to 9V for the metal-organic salt promoted formulation. The latter was similar to that of the metal can control device.

Effect of fillers.—The mechanism by which amines and other polar organic ingredients cause loss in beta under high temperature reverse bias is not fully understood. It appears to be a surface effect (3, 4). The extent of the degradation increases with time under bias. This suggests migration of polar groups to the surface of the device and alignment of polarizable groups in an electric field. When the field is removed at elevated temperatures, a random thermal scattering of the polar groups leads to partial recovery of beta, but the recovery is not complete. If the polar groups are alkali metal ions that can diffuse through the oxide, the effect is not reversible. Furthermore, the alkali content of the tertiary amine promoters is as low or lower than that in the epoxy resins (~1 ppm), and represents a minor portion of the over-all formulation. In order to gain further insight into the degradative mechanism, 5-20% filler containing Lewis acid sites (silica-alumina cracking catalyst) was added to the above formulation promoted with N, N-dimethylbenzylamine. The results, illustrated in Fig. 4, support the view that when the amine promoter is immobilized by the acidic filler, the stability of the epoxy on the surface of the transistor is indeed improved. Further, it was observed that the presence of the acidic filler had no effect on the rate and extent of the cure of the epoxy resin; the amine promoter was just as effective in the presence of the acidic filler.

Although fillers can improve stability by adsorption of polar impurities from the resin, they can also degrade the stability of the resin. An example is Minusil 10,[6] a 10μ precipitated silica. Formulated resins containing 50% by weight of untreated Minusil 10 silica cause rapid loss in low current beta under HTRB at 125°C. However, if the silica is first washed thoroughly with hot deionized water, the stability of the formulated resin is equivalent to that of resins containing naturally occurring sand filler (Clemcosil 325 mesh silica).[7] This is illustrated in Fig. 5.

The conductivity of the water extract is indicative of the soluble salts removed from the filler during washing; that from Minusil 10 was 1.7×10^{-3} *vs.* 6.4×10^{-4} mhos/cc from Clemcosil. The residue recovered during evaporation of the water extract from Minusil 10 was double that obtained from the Clemcosil silica, in agreement with the higher conductivity observed. However, the compositions of the two residues were quite similar; they consisted mainly of alkali and alkaline earth metals. Whether or not this similarity extends to the nature of the original soluble salts extracted from each silica is unknown. Qualitatively, we

observed that a heavy precipitate of silver halide resulted from the addition of silver nitrate to the aqueous extract from Minusil 10, while only a trace of precipitate was observed with the Clemcosil extract, which suggests a higher concentration of halide anion in the Minusil 10 silica.

Effect of epoxy resin purity.—The low hydrolyzable chloride, DER 332LC epoxy resin, is more stable than the less pure DER 332 resin, although the difference in the stability is not marked; a higher temperature is required to distinguish between them. The improvement in the stability is not traceable to lower sodium content, since the flame spectral analysis indicated 1 ppm sodium in the DER 332LC resin *vs.* 0.8 ppm in the DER 332 resin. This is illustrated in Fig. 6

Effect of anhydride purity.—The purity of the anhydride hardener likewise affects the electrical stability of the resin as shown in Fig. 7. Tetrafunctional benzophenone tetracarboxylic dianhydride (BTDA)[8] was employed in this study because the reactivity associated with high functionality precluded the use of promoters, thereby making the results less ambiguous. It was further demonstrated that the very high-temperature properties attainable in these highly cross-linked epoxy systems correlate with electrical stability on the surface of a transistor.

Effect of added impurities.—In order to determine the specific impurities that can lead to high failure rates, we undertook a study whereby certain polar organic compounds and inorganic salts were added to a stable, high-purity epoxy formulation (75 parts HHPA in 100 parts DER 332). The loss of 10 μA beta under HTRB at 125°C was followed as a function of time. The impurities selected were mainly ones that can arise either from the method of preparation or the initial purity of the ingredients from which the epoxy or anhydride is synthesized, or the source and purity of the filler and the nature of the promoter. Thus, the bisphenol A and epichlorohydrin impurities can arise from their incomplete reaction in the synthesis of the BPA epoxy resin. Glycidyl chlorohydrin can result from incomplete dehydrochlorination and sodium chloride from incomplete removal of the salt formed during the dehydrochlorination process. Certain alcoholic groups are formed during the curing reaction; glycols are sometimes used to accelerate cure. The results of this study are shown in Fig. 8 and 9.

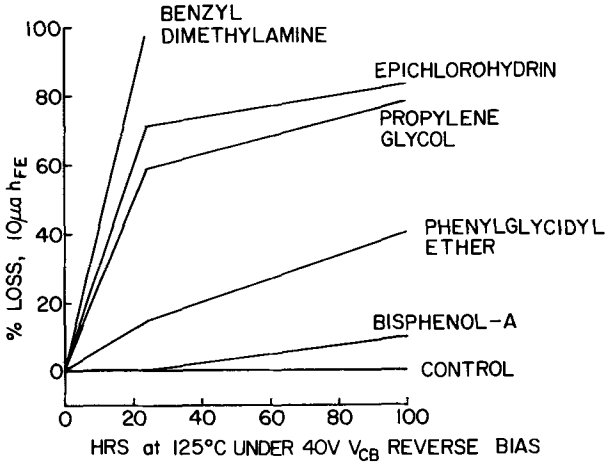

Fig. 8. The effect of various added organic impurities in an epoxy resin on the electrical stability of the encapsulated device.

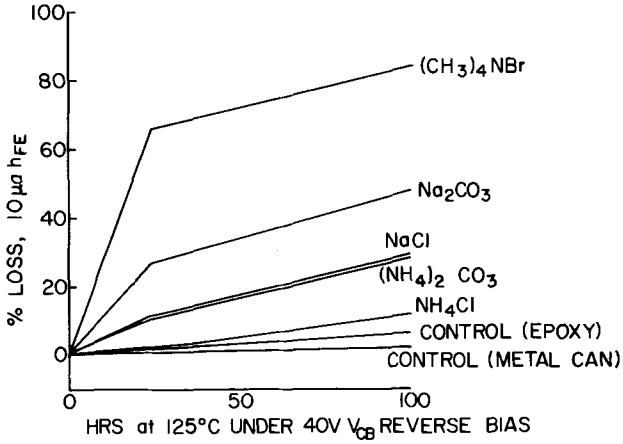

Fig. 9. The effect of various added inorganic impurities in an epoxy resin on the electrical stability of the encapsulated device.

An unfilled resin system was used for the organic contaminant study, since the compounds are completely soluble and therefore uniformly incorporated. They were added at a ratio of 1 part per 100 parts resin. However, because the volatility of epichlorohydrin required a lower gelation temperature to prevent excessive loss, it was run separately along with a control containing no contaminant. In spite of this, extensive volatilization occurred during the cure cycle. Following are the conclusions of this study:

1. The polar glycols and epichlorohydrin, which are capable of polarizing in an electric field, lead to extensive loss in low current beta.
2. The phenolic hydroxyls in bisphenol-A are more reactive and presumably are consumed during the cure; therefore, they cause very little loss in beta.
3. Phenylglycidylether is likewise consumed, but leads to partial loss in beta due to the excess epoxy groups which upset the stoichiometry and lower the heat distortion temperature.
4. The basic dimethylbenzylamine is the most deleterious ingredient added.
5. Volatile impurities such as epichlorohydrin can lead to degradation of uncontaminated units occupying the same cure oven. This was indicated by the excessive loss exhibited by control units compared to the epoxy control units run with the less volatile organic and inorganic contaminated devices. Apparently, epichlorohydrin vapor diffuses rapidly into the uncontaminated epoxy control units. This indicates a potential problem and the need for maintaining uncontaminated ovens.

With respect to the added inorganic contaminants, the following conclusions can be drawn:

1. The relative degradation effect exhibited may be more a reflection of the solubility than the nature of the impurity, since saturated solutions of the various salts in the epoxy resin were employed.
2. Although it is not shown in Fig. 9, sodium-containing impurities result in lower initial beta than the ammonium salts even though in some cases the loss in beta under HTRB is lower. This suggests that whenever the sodium ion contacts the surface of the device, rapid diffusion into the oxide occurs. On the other hand, the ammonium ion at the surface does not diffuse into the oxide; since the initial concentration is low, the effect is not seen until migration occurs under bias.

Conclusions

Both the polar organic groups and inorganic salts cause rapid degradation of the electrical parameters of devices in contact with them. The extent of degradation increases with time and temperature under bias. This suggests migration of the polar groups to the surface of the device and alignment of polarizable groups in an electric field. This is supported by the fact that the rate of degradation is increased by lowering the heat distortion temperature of the epoxy (lowering the cross-link density). Also, when the surface of the device is covered with a pure silicone, degradation will still occur with increased time, and the rate is still dependent on the level of contaminants in the epoxy external coating. Furthermore, as indicated previously, partial recovery of beta occurs on heating the devices in the absence of an electric field, presumably due to the random thermal scattering of polar groups.

The mechanism by which amines and other polar ingredients cause loss in beta is still undefined. The application of an image charge through the thermal oxide is one possibility. However, a thin film of silicon nitride over the oxide appears to give adequate protection. Another possibility is electron transfer. Experiments are under way to assess these hypotheses.

Acknowledgments

I wish to take this opportunity to express my deepest appreciation to Edward Martich who carried out most of the experimental work, to Eugene Held and Jose Rios who assisted with the electrical testing, and to Drs. Harry Sello and Bruce Deal whose encouragement and counsel have been invaluable.

Phase Relationships in the In-S System

H. G. Ansell and R. S. Boorman

Materials Section, Research and Productivity Council, Fredericton, New Brunswick, Canada

ABSTRACT

Three binary compounds, In_2S_3, In_6S_7, and InS are stable in the In-S system. Solid solution was found only in In_2S_3, which contains up to 1.0 m/o (mole per cent) more indium than does stoichiometric In_2S_3. A rapid decrease in indium solubility, probably due to the inversion of tetragonal $In_{2+x}S_3$ to isometric symmetry, occurs at 837°C. A high-temperature form of InS may be present in the temperature range 657°-679°C. The compounds In_3S_4 and In_3S_5, noted in previous studies, were not found. The electrical properties of In_2S_3 are probably strongly affected by the deviation from stoichiometry as outlined in this study.

Although several studies have been made in the In-S system (1-3), parts of the phase diagram are ambiguous. The compound In_3S_4 is still considered a stable phase despite having been discredited (2), and several phase boundaries have not been closely investigated. As a result, during our work on ternary sulfide systems containing indium, we considered it necessary to re-examine portions of the In-S binary. These data were required both for our work on

Key words: indium sulfides, sulfides In system.

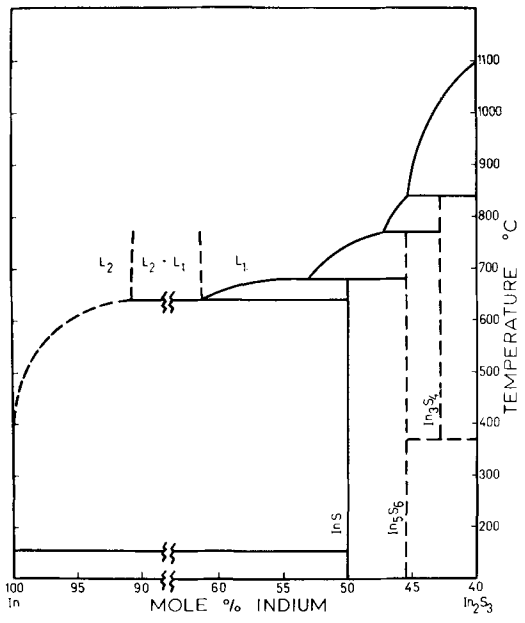

Fig. 1. Phase diagram of the In-In_2S_3 join, after Stubbs *et al.* (3).

natural systems containing indium and for materials application studies on indium sulfides.

Previous Work

Stubbs *et al.* (3) reported four indium sulfides, InS, In_5S_6, In_3S_4, and In_2S_3, to be stable between 150° and 1100°C (Fig. 1). The composition of In_5S_6 has since been shown to be In_6S_7 (5). Miller and Searcy (2) reported that the $InS_{1.12}$ (In_6S_7) phase had a solid solution field of 3.3 ± 0.4 a/o (atomic per cent) at 600°C which decreased to 0.8 ± 0.1 a/o at 664°C. Stubbs *et al.* (3) and Duffin and Hogg (1) were unable to synthesize In_3S_4. The possibility of it being present as an unquenchable phase has been discounted by Miller and Searcy (2). Zargarova and Gamidov (4) recently claimed to have synthesized In_3S_4 and a phase, In_3S_5, which is more sulfur-rich than In_2S_3 (Table I). Rooymans (6) has shown that the low-temperature In_2S_3 identified by Hahn and Klingler (7) is a poorly crystallized form of their high-temperature phase, rather than a distinct In_2S_3 polytype.

Experimental Procedure

Approximate phase boundaries were established from a series of furnace runs, the products of which were analyzed by x-ray diffraction. Starting mixtures were prepared from weighed amounts of indium metal (99.999+ %, ASARCO) and precipitated In_2S_3. Preparation of the In_2S_3 has been described previously (9).

All furnace charges were sealed in evacuated Vycor glass tubes and placed in electrically heated horizontal tube furnaces controlled to ±5°C. Runs were allowed to equilibrate over periods of 1-5 days. All charges were quenched to room temperature either in air or in cold water, and the products were examined under binocular and reflected light microscopes. An electron microprobe was used to determine the limits of solid solution fields.

Accurate delineation of phase boundaries was accomplished by differential thermal analysis. The work was carried out on a R. L. Stone Model 202 DTA system, using a platinum sample holder with post-type thermocouples. Two operative methods were used to ensure that no oxidation took place. In one series of runs, the sample was placed in platinum cups, the sample chamber was evacuated and then flooded with argon or nitrogen. With the second method, the sample was sealed under vacuum in specially prepared Vycor tubes. In each case, the sample was ground to −100 mesh and heated at a rate of 5°C/min.

Table I. Phases in the In-S system

Phase	Composition m/o In	Crystallography			Ref.
In_2S_3	40.0	Tetragonal,	$I4_1/amd$	$a = 7.623$Å $c = 32.36$	(6, 8)
In_6S_7	46.2	Monoclinic,	$P2_1/m$	$a = 9.090$Å $b = 3.887$ $c = 17.705$ $\beta = 108.20°$	(1, 5)
InS	50.0	Orthorhombic,	Pmnn	$a = 3.994$Å $b = 4.447$ $c = 10.648$	(1)
In_3S_4*	42.9	Hexagonal		$a = 9.86$Å $c = 20.5$	(4)
In_3S_5*	37.5	Hexagonal		$a = 7.59$Å $c = 20.3$	(4)

* Not confirmed by present study.

Results

No compounds other than In_2S_3, In_6S_7, and InS were synthesized (Fig. 2, Table II). In furnace runs containing more than 60 m/o sulfur, the only phases present in the charge tubes were In_2S_3, sulfur vapor, and condensed sulfur. The phase In_3S_5 described by Zargarova and Gamidov (4) was not found. No optical or x-ray evidence was found for the existence of In_3S_4 in the compositional range between In_6S_7 and In_2S_3.

All charge products were crystalline, fine-grained, and generally less than 0.1 mm in size, although a few large crystals of each indium sulfide were synthesized. The InS occurred as elongated red prisms up to 1 mm long, or as granular masses of smaller reddish-brown crystals. Crystals of In_6S_7 were black and acicular, up to several millimeters long. When coarsely crystalline, In_2S_3 occurs as dark red crystals with pyramidal faces and distinctive twinning, as described in detail by Goodyear and Steigmann (10). In polished section,

52.7	572	90	InS + In
52.7	627	75	InS + In
56.0	595	95	InS + In
60.0	595	95	InS + In

InS is strongly anisotropic from deep blue to pale yellow, with vivid red internal reflections. In contrast, In_6S_7 has weaker anisotropism and lower reflectivity, while In_2S_3 appears isotropic with faint red internal reflections. Indium metal polishes poorly and appears as grainy light orange patches under reflected light.

The unit cell of In_2S_3, when in equilibrium with In_6S_7, decreases with increasing temperature. A minimum is reached at the In_6S_7 breakdown temperature at 768°C (Fig. 2). At 752° and 782°C the lattice parameters are $a = 7.585 \pm 0.005$Å and $c = 32.20 \pm 0.03$Å. Above 768°C, where In_2S_3 coexists with an indium-rich melt, the cell size increases slightly at first, then sharply at 837°C to a value approximating that of the stoichiometric In_2S_3 cell ($a = 7.623$Å, $c = 32.36$Å) (8). The decrease in the In_2S_3 cell size is related to an increase in indium solubility, shown by microprobe analyses to reach an approximate maximum of 41.0 ± 0.4 m/o indium. Stoichiometric In_2S_3 has a composition of 40.0 m/o In. Electron microprobe analyses of co-existing phases showed no measurable solid solution (±0.4 m/o indium) for either In_6S_7 or InS.

Six different endothermic reactions were obtained by differential thermal analysis (Table III). The reaction at 893°C was obtained only sporadically and with runs in which the sample was flooded with argon gas. When the sample was heated in evacuated Vycor tubes, no reaction was recorded at that temperature. For the peaks at 633°, 657°, 679°, and 768°C (peaks 1-4, Fig. 2), maximum heat absorbed (ΔH max in Table III) was found to be at >60, 50, 50, and 47 m/o indium, respectively. No definite maxima were obtained for the reactions at 837° and 893°.

X-ray diffraction analyses of samples after DTA confirmed that InS and In_6S_7 break down at 679° and 768°C, respectively. The 657° endotherm appears to be closely related to the compound InS, since the maximum heat transfer occurs consistently at 50 m/o indium. At least three lines (d = 5.85, 5.13, 3.79Å) that are not present in the x-ray diffraction pattern for InS below 657° appear in the pattern for the material quenched from between 657° and 679°C. Rapid quenching of runs above 837° revealed, in some cases, that the moderately strong diffraction peak, d = 5.11Å, for tetragonal In_2S_3 was absent.

Discussion

Although the thermal reaction at 837°C (peak 5, Fig. 2) corresponds to the breakdown temperature of In_3S_4 proposed by Stubbs *et al.* (3), their lower stability limit at 370° was not recorded in this study. Also, the event at 768° marking the breakdown of In_6S_7 was noted in runs of bulk composition 41.8 m/o indium (Table III). This is well within the mutual stability field of In_3S_4 and In_2S_3 on the Stubbs *et al.* phase diagram (Fig. 1). Runs above the In_6S_7 decomposition temperature with bulk compositions between 40 and 48 m/o indium produced only In_2S_3 and a melt, even with very rapid quenching. Thus we suggest that In_3S_4 is not a stable phase in this system.

The reaction at 837°C could mark a structural inversion in In_2S_3. This "inversion" probably results from excess indium in the tetragonal lattice, because the thermal reaction at 837°C is not found in the stoichiometric compound. Inversions from tetragonal to isometric symmetry are common and often unquenchable. For example, the stable form of chalcopyrite ($CuFeS_2$) at 700°C is isometric. Inversion to the low-temperature tetragonal form occurs when chalcopyrite of maximum sulfur content with a Cu/Fe atomic ratio of approximately 1 is cooled, even rapidly, from 700° (11). The possibility of a similar inversion occurring in In_2S_3 is supported by x-ray diffraction evidence. The absence of the 5.11Å line in some high-temperature In_2S_3 makes it possible to index the remaining reflections as isometric, with a cell edge of approximately 10.78Å.

The erratic occurrence and magnitude of the thermal reaction at 893°C suggests that it may not be significant in terms of In-S phase relationships and that it may be related to the presence of argon in the sample chamber, or caused by reaction of the sample with the platinum cup.

Miller and Searcy (2) note that two crystallographic modifications of InS may exist and our differential thermal analysis tends to support this. An endothermic reaction was obtained at 657°C, below the breakdown of InS at 679°. Also, x-ray diffraction patterns for InS above and below 657° differed slightly. The few additional reflections noted may belong to a high-temperature modification of InS.

Rehwald and Harbeke (13) demonstrated that single crystals of In_2S_3 have n-type conductivity with a range of more than six decades in resistivity and Hall coefficient at room temperature. They attributed this wide range to a deviation from In_2S_3 stoichiometry. The main effect on concentration and sign of charge is due to a sulfur deficiency. Therefore indium substitution may be the factor controlling the inherent semiconductor properties of In_2S_3. Increased amounts of indium in the indium sulfide lattice will produce a surplus of interstitial cations which should strengthen the n-type conductivity. The thermal reaction at 837°C (Fig. 2) may be of special importance is this respect. The sharp drop in indium solubility above the In_2S_3 inversion could result in a marked increase in resistivity approaching p-type conductivity.

Conclusions

In_2S_3 is the only indium sulfide with measurable solid solution (approximate maxium 1.0 m/o indium). The thermal reaction at 837°C, previously attributed

to the breakdown of In_3S_4 by Stubbs *et al.* (3), could mark an inversion of tetragonal $In_{2+x}S_3$ to a higher symmetry form, possibly isometric. In order to establish the effect of the inversion on the electrical properties of In_2S_3, conductivity measurements are needed on crystals synthesized above and below 837°C. A high-temperature modification of InS may exist in the temperature range 657°-679°C. No evidence was found to support the existence of either In_3S_4 or In_3S_5.

Energy Levels of Divalent Manganese in ZnS

Anjani Mehra

College of Environmental Sciences, University of Wisconsin, Green Bay, Wisconsin 54305

Manganese doped ZnS is well known for its interesting luminescence properties. A clear understanding of the mechanism of these phosphors requires a knowledge of energy levels of ions in the crystal. In spite of extensive optical studies (1-6) of Mn^{2+} doped ZnS, the assignments of various bands to intercombination transitions within the d^5 configuration of Mn^{2+} are still not well understood. Present study of the energy levels of Mn^{2+} ion in T_d symmetry of ZnS was undertaken to resolve this uncertainty.

The theory of d^5 configuration in octahedral (O_h) symmetry is well established (7-9). The crystal field energy matrices and energy level diagrams have been calculated by Tanabe and Sugano (7) and Orgel (8). Goode (9) has discussed the relative intensities of transitions to various quartet and doublet levels. Orgel (8) has discussed the bandwidths. Since the d^5 configuration is its own hole equivalent, the energy matrices and energy level diagram for it remain unaffected by the change of sign of Dq between O_h and T_d coordinations, and, therefore, one expects the general features of the spectra in the two cases to be quite similar. However, the magnitude of Dq in T_d complexes is found to be much smaller than that in O_h complexes, and it is found that this can result in different order for the levels and the corresponding bands in the spectra of two types of complexes.

Experimental energies of the observed band maxima and the assignments of the bands are listed in Table I. The band positions are taken from McClure's (1) data. The absorption spectrum consists of five main absorption bands. We shall first discuss the spectrum qualitatively with the help of the energy level diagram shown in Fig. 1. The spectra of transition metal ions could be discussed in both strong field or weak field schemes but for small Dq values as those of T_d complexes, it is more convenient to employ the weak field terminology which is adopted in the present work.

Key words: manganese, crystal field, optical absorption, zinc sulfide.

The two lowest energy bands at 18,850 and 20,100 cm^{-1} should be assigned to the two lowest levels $^4T_1$ (G) and $^4T_2$ (G) arising from the ^4G level of the free ion. The remaining two levels arising from ^4G level are $^4A_1$ and ^4E which should be degenerate in a simple cubic approximation, but in practice the degeneracy is removed due to several perturbations although the levels still lie quite close to within 300 cm^{-1} (10). These two states should be contained in the 21,555 cm^{-1} band and its associated structure.

The main problem is the assignment of next two bands at 23,000 and 25,700 cm^{-1}. Three quartet levels $^4T_2$ (D), ^4E(D), and $^4T_1$(P) are expected to lie in this region. In O_h complexes ^4E band is found to be sharper than the $^4T_2$ and $^4T_1$ bands which lie on its lower and higher energy sides, respectively. On examining the 23,000 and 25,700 cm^{-1} bands, it is found that the 25,700 cm^{-1} band has sharper structure and hence is more likely to involve the ^4E(D) state. Moreover, the assignment of 23,000 cm^{-1} band to ^4E(D) level was found to lead to unrealistic values for the crystal field parameters B and C. $^4T_2$ and ^4E levels arise from the ^4D level of the free ion, and the separation between them increases with increase in Dq value, but the $^4T_2$

Table I. Experimental and calculated band energies of Mn^{2+} in ZnS. Calculated energies are for $B = 780$, $C = 2400$, $Dq = 320$, and $\alpha = 76$ cm^{-1}.

Transition $^6A_1(^6S)$	Observed[a] energy in cm^{-1}	Calculated energy in cm^{-1}
$^4T_1$(G)	18,850	18,875
$^4T_2$(G)	20,100	20,973
$^4A_1$(G), ^4E(G)	21,270	21,320
	21,555	
$^4T_1$(P)	23,300	24,699
$^4T_2$(D)	25,374	25,176
^4E(D)	25,700	25,716

[a] Taken from ref. (1).

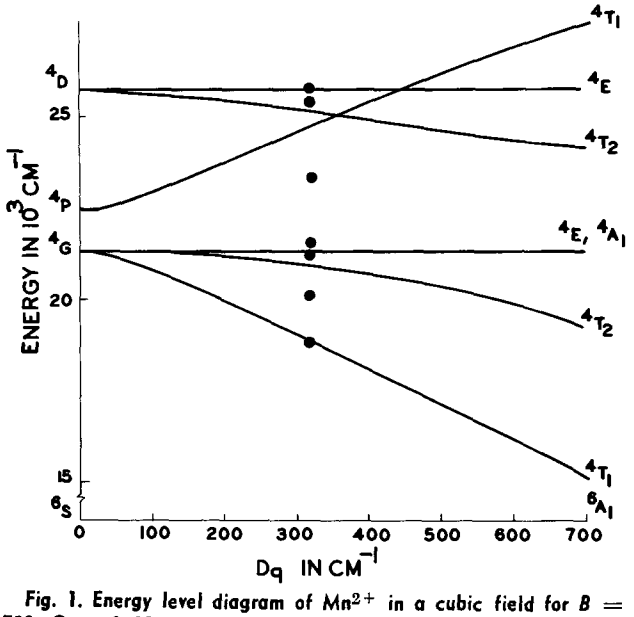

Fig. 1. Energy level diagram of Mn^{2+} in a cubic field for B = 780, C = 2400, α = 76 cm^{-1}. The observed band energies of Mn^{2+} in ZnS are marked ●. Crystal field levels arising from the ^4F level of the free ion are not shown.

level always lies lower to ^4E in energy. If one assigns the 23,300 cm^{-1} band to $^4T_2$ level (3), it is found that the separation of 2400 cm^{-1} between the so assigned $^4T_2$ and ^4E levels is larger than the corresponding separation of 1900 cm^{-1} observed in MnF_2 (10) which has near O_h symmetry. Because of the expected lower Dq in the present case, this separation should also be less, and hence it is unlikely that 23,300 cm^{-1} may correspond to $^4T_2$ level. In our view, this level should be contained in the structure of 25,700 cm^{-1} band, and the 23,300 cm^{-1} band should involve the other electronic state $^4T_1(P)$.

The only other possibility is the assignment of 23,300 cm^{-1} band to $^2T_2$ (^2I) level (2). This doublet level lies lowest among the doublet levels and ultimately becomes the ground state of the ion in the high field, low spin case. Its position is markedly dependent on the Dq value and goes down in energy for increase in Dq value. Theoretically calculated position (11) of this level in MnF_2 is around 29,000 cm^{-1}, and it is unlikely that it may come down to 23,300 cm^{-1} in the present case. Moreover, the intensity of 23,300 cm^{-1} band is of the same order as the intensities of the other bands which are transitions to the quartet levels, whereas the intensity of transition to a doublet level should have been much less than the intensities of transitions to the quartet levels (9). Thus we feel justified in assigning the 23,300 cm^{-1} band to $^4T_1(P)$ level on the basis of only the qualitative arguments. It is interesting to note that according to present assignment this level lies lower than ^4E level as against the reversed order of the levels found in O_h complexes.

In the calculation of energy levels, we employed a set of four parameters B, C, Dq and α in the weak field scheme. This set of parameters has been found quite suitable for Mn^{2+} spectra (11-13). The Trees correction parameter α was as usual fixed at the free ion value of 76 cm^{-1}. Parameters B and C were determined from the Dq independent [$^4A_1(G)$, $^4E(G)$] and $^4E(D)$ states and the values obtained are 780 and 2400 cm^{-1}, respectively. A Dq value of 820 cm^{-1} was chosen to fit the $^4T_1(G)$ level which is most sensitive to changes in Dq value. The calculated levels are given in Table I. The calculated energy of the other well assigned transition to $^4T_2(G)$ state is found to be in excellent agreement with the observed energy which justifies the choice of parameters. As expected, the calculated separation of about 550 cm^{-1} between $^4T_2(D)$ and $^4E(D)$ states is quite small and makes the assignment of 23,300 cm^{-1} band to $^4T_2(D)$ state very unlikely. The structure of 25,700 cm^{-1} band extends over 1000 cm^{-1}, and it is possible that it may contain both the electronic states. We have chosen a prominent line at 25,374 cm^{-1} as belonging to $^4T_2(D)$ state whose energy is quite close to the calculated one, but this assignment is by no means very certain. However, while analyzing the structure of this band, the presence of both the electronic states should be taken into account.

Although the agreement for $^4T_1(P)$ level is not very good, it at least supports the argument in this paper that this level could lie below $^4E(D)$ level. An inspection of the energy level diagram shows clearly that $^4T_1(P)$ level lies lower than the ^4E level on the low Dq side, but because of its large dependence on Dq it goes above ^4E on the high Dq side. In the free ion (10) too the parent level ^4P of this level lies lower than the parent level ^4D of the ^4E level. In octahedral complexes the Dq value is large and $^4T_1(P)$ level lies higher than the $^4E(D)$ level while in T_d complexes where the Dq value is small $^4T_1(P)$ can be expected to lie lower than the $^4E(D)$ level, as in the present case.

The degeneracy of $^4A_1(G)$ and $^4E(G)$ is not removed within the present calculations, and hence no separate assignment for the two is tried although two prominent lines at 21,270 and 21,555 cm^{-1} are mentioned and approximately the mid position is taken as the degenerate position. It may be mentioned that we have used the band maxima in our calculations to avoid the uncertainty associated with the location of zero phonon lines and also to keep the present parameters in line with the literature where the parameters have been mostly evaluated from the band maxima. Considering the appreciable amount of covalent bonding (14) in ZnS the usefulness of simple crystal field approach is quite satisfactory.

The Dq value obtained here is of the same order as obtained in other transition metal doped ZnS crystals. The reported Dq values (15) in Co^{2+} and Ni^{2+} doped ZnS are 375 and 475 cm^{-1}. Slack, Ham, and Chrenko (16) have obtained a value of 340 cm^{-1} for Fe^{2+} in ZnS. Koda *et al.* (5) find a value of 410 cm^{-1} for Dq for Mn^{2+} in ZnS from their pressure studies on the luminescence. Ikeda, Itoh, and Sato (17) have studied Mn^{2+} in CdS and have estimated $Dq \sim 490$ cm^{-1}. It is interesting to note that in spite of the low Dq value for the crystal, a comparatively large ground state splitting of about 23 x 10^{-4} cm^{-1} is observed in the paramagnetic resonance (18) of Mn^{2+} in ZnS. The calculated splitting in the ionic model using the parameters obtained from the optical spectrum should be less than 10^{-4} cm^{-1}, which is more than an order of magnitude smaller than the observed splitting. The presence of appreciable amounts of covalent bonding in the crystal is perhaps responsible for this discrepancy. However, a quantitative estimate of the effect of covalent bonding on the ground state splitting is not possible at present. In the optical studies the presence of covalent bonding is evident from the large reduction in the values of B and C from the free ion values of 910 and 3270 cm^{-1}, respectively (11).

Silicon Impurity Distribution as Revealed by Pulsed MOS C-V Measurements

W. van Gelder* and E. H. Nicollian*

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania 18103 and Murray Hill, New Jersey 07974

The purpose of this work is to discuss the application of the pulsed MOS C-V method (11) and its limitations in measuring doping profiles in silicon.

Several methods of measurement have been reported. Grove *et al.* (1) measured the redistribution of acceptor and donor impurities during thermal oxidation of silicon using an incremental capacitance-voltage technique on shallow (0.2μ) diffused p-n junctions. Theory and practice of the p-n junction dC/dV technique can be found in refs. (2) through (5). A variation of the junction dC/dV technique is described by Meyer and Gulbrandsen (6) who apply a sine wave to the junction and then measure the ratio k_2 of the second harmonic voltage to the first harmonic voltage generated by the diode. They showed that doping concentration as a function of depth is proportional to C^2V_1/k_2 where C is measured capacitance and V_1 is applied alternating voltage. Another elegant variation of the junction technique which makes direct plotting of the inverse doping profile possible was recently published by Copeland (7). Deal *et al.* (8) measured the redistribution of impurities due to thermal oxidation using the MOS structure. They measured maximum and minimum high-frequency capacitance and calculated doping concentration at the surface by applying a depletion approximation. Other workers have reported the same MOS C_{max}/C_{min} technique using essentially the same depletion approximation (9, 10).

Both the junction dC/dV and the MOS C_{max}/C_{min} method have their disadvantages. The diffusion of the p-n junction may alter the doping profile to be measured and the depth of the junction inherently prevents measurement close to the surface. Schottky barrier diodes would help in measuring closer to the surface, but fabrication of either a p-n junction or a Schottky barrier is destructive when these devices are not desired in later processing. The MOS C_{max}/C_{min} method can be considered nondestructive because the metal field plate can be easily removed from the oxide layer. The MOS C_{max}/C_{min} method cannot, however, measure a profile because it measures an undefined average over a maximun depletion width which in itself is a function of the doping concentration. As mentioned by Deal *et al.*, the method is based on a theory which assumes doping uniformity whereas that very method is used in the determination of a deviation from this condition (8).

The pulsed MOS C-V method is of interest because it not only is nondestructive but it also can be used to measure a true point-to-point doping profile over a greater distance into the silicon than the MOS C_{max}/C_{min} method. Its theory is remarkably similar to the one used for the step junction dC/dV method.

* Electrochemical Society Active Member.

Key words: pulsed MOS measurements, silicon impurity distribution, pulsed C-V measurements, impurity profile.

Theory

Consider a MOS capacitor which can be driven into deep depletion by the application of pulse bias (11). Only the depletion region of the capacitor characteristics will be treated here, and it will be assumed that interface states have a negligible influence.

A small increase in applied voltage dV is equal to

$$dV = dV_o + d\phi = dQ_{sc}/C_o + d\phi \quad [1]$$

where V_o = voltage drop across the oxide
ϕ = silicon surface potential
C_o = oxide capacitance/unit area
Q_{sc} = space charge density/unit area.

The increase of charge in the depletion layer causes an increase in the electric field

$$dE = dQ_{sc}/\epsilon_s \quad [2]$$

in which ϵ_s is the dielectric permittivity of silicon. The corresponding increase in surface potential is approximately

$$d\phi = W dE \quad [3]$$

Substituting [2] and [3] into [1]

$$dV = dQ_{sc}\,(1/C_o + 1/C_s) = dQ_{sc}/C_m \quad [4]$$

where C_m is total measured capacitance, $C_s = \epsilon_s/W$, and W is space charge width. Using the relation $dQ_{sc} = q\,N(W)dW$ in [4], where $N(W)$ is the doping concentration as a function of W, we get

$$dV = q\,N(W)\,dW/C_m \quad [5]$$

But,

$$dW = \epsilon_s\,d(1/C_s) = \epsilon_s\,d(1/C_m) \quad [6]$$

as $1/C_s = 1/C_m - 1/C_o$. Substituting [6] into [5] and solving for $N(W)$, we get

$$N(W) = 2(q\epsilon_s\,d(1/C_m^2)/dV)^{-1} \quad [7]$$

This equation shows that the doping concentration $N(W)$ can be calculated from the slope of the $1/C^2$ *vs.* V curve.

Other authors have mentioned that the impurity concentration can be measured from the slope of the $1/C^2$ *vs.* V curve (11, 12). However, these authors dealt exclusively with an integrated version of [7] which can be written as

$$C_o/C_m = (1 + 2C_o^2(V_G - V_{FB})/(q\epsilon_s N))^{1/2} \quad [8]$$

where V_{FB} = flatband voltage. Equation [8] cannot be simply differentiated to give [7] because [8] is normally derived with the assumption that N is not a function of W. Note that [7] is the same equation as used in the step junction dC/dV method given by Grove (13). The only difference is that C_m in [7] includes C_s and C_o in series while in the junction dC/dV method C_s is measured directly.

Limitations

Equation [7] is valid even when interface states are present provided they do not follow either the a-c measuring signal or the pulse. In practice, for typical pulse widths of several milliseconds and a-c signal frequencies of about 1 MHz, interface states follow neither the a-c signal nor the pulse over most of the deep depletion range because interface state time constants are too large. In this range [7] is valid. The time constants become smaller when the depletion depth is decreased. This happens when the applied bias is changed towards the flatband voltage. Interface states begin following first the pulse and then the a-c signal. When this happens, the slope of the $1/C^2$ *vs.* V curve is modified giving erroneous values of $N(W)$ from [7].

The space charge width at which interface state influence becomes important will depend on doping density as well as a-c frequency and pulse width. The value of W at which interface state influence becomes a factor can be roughly estimated by measuring an admittance *vs.* d-c bias curve at a frequency corresponding to a reciprocal pulse width. This value of W will occur when the equivalent parallel conductance becomes appreciable. Experience has shown that this occurs at a surface potential of around 0.4V or so, which corresponds to $W = 0.7$ μm for $N = 10^{15}$ cm^{-3} and $W = 0.2$ μm for $N = 10^{16}$ cm^{-3}.

The range of W over which interface state influence is negligible can be extended, of course, by using higher a-c frequencies ($>$ 500 kHz) and smaller pulse widths ($<$ 6 msec) than the ones used in this work.

Even if interface states are completely absent, [7] is not valid at the flat band condition where majority carrier density becomes comparable to space charge density. The limiting surface potential is in this case a few kT/q which at room temperature amounts to ~0.05V. In practice, this limitation is of no interest because the interface state effect is dominant.

The largest distance into the silicon at which [7] can be used is at the onset of breakdown either by avalanche for low doping density or by tunneling for high doping density. A basic limitation, characteristic for all C-V profile measurements, is the fact that higher doping levels require higher voltage to measure at a certain desired depth while the breakdown voltage decreases with increasing doping level.

Limitations pointed out by Kennedy *et al.* (15) concerning the fact that the junction dC/dV measurement establishes the distribution of majority carriers rather than the distribution of impurity atoms are of equal validity for the pulsed MOS case and should be taken into account when an attempt is made to measure the impurity distribution with either technique.

Apparatus and Measurement Technique

Apparatus and measurement technique used were identical to those outlined by Goetzberger and Nicollian (11). Signal frequency was 500 kHz, pulse width 6 msec, and duty cycle 6%.

Sample Preparation

MOS capacitors were made on <100> oriented silicon slices cut from Sb doped pulled crystals with $N_D \approx 10^{15}$ cm^{-3}. The slices were ~ 8 mil thick, lapped on both sides, and polished on one side. The metal field plate was filament evaporated aluminum. Contact was made to the back of a slice by evaporated aluminum and a vacuum chuck. A total of three slices were oxidized, each one in a different manner to produce a different "redistribution" of impurities at the surface. Before oxidation the four point probe resistivity was measured. Prior to each application of the aluminum field plate the slices were baked in N_2 at 1100°C for 25 min to assure a moderate interface state density.

The first oxidation of the three slices took place in separate runs in a tube furnace at 1100°C in wet O_2 (oxygen bubbled through 80°C water.) Oxide thickness was ~ 1200Å.

Table I shows the four-point probe N_D before oxidation and the N_D at the surface as measured from MOS C_{max}/C_{min} after oxidation. Note that slice 3 was oxidized together (in one run) with six N^+ phosphorous diffused bulk silicon slices. The N^+ diffused slices were prepared from slices similar to the 3 samples by subjecting them to a one-step phosphorous prediffusion deposition at 900°C for 20 min and then removing the phosphorous glass. The N_D from MOS C_{max}/C_{min} was measured according to the method of Deal *et al.* (8). Apparently, the presence of the N^+ slices during oxidation caused a large increase in N_D. [Evidence of this kind of phosphorous N-skin formation on silicon by vapor transport was recently reported by Edwards (14).] Apart from slice 3 the difference in N_D in row 1 and row 3 could be explained by the "pile-up" effect or "redistribution" during oxidation (8).

Table I. Sequence of process steps and measurements

		Slice No. 1	Slice No. 2	Slice No. 3
1	Initial four-point probe N_D, cm^{-3} × 10^{15}	0.75	0.50	0.89

4	Process	Strip oxide Steam oxidize 1100°C, 6000A	—	—
5	Process	Strip oxide Wet O_2 oxidize 1100°C, 1200A	—	—
6	MOS C_{max}/C_{min} N_D, cm^{-3} × 10^{15}	3.45	—	—
7	Process	Si etch left half Strip oxide Wet O_2 oxidize 1100°C, 1200A	—	—
8	MOS C_{max}/C_{min} N_D, cm^{-3} × 10^{15}	Left 2.17 Right 4.32	—	—
9	Pulsed MOS measurements	See Table II and Fig. 1	See Table II and Fig. 1	See Table II and Fig. 1
10	Final four-point probe N_D, cm^{-3} × 10^{15}	Left 0.80 Right 0.80	0.51	1.01

Slice No. 1 was further treated as follows (see Table I). (Read this table from top to bottom to get the proper sequence of operations.) The Al dots and the SiO_2 were stripped in boiling HCl and HF, respectively, and the slice was oxidized in 100% steam at 1100°C to an SiO_2 thickness of 6000Å (~ 60 min). This oxide layer was stripped again in HF and the slice was oxidized again in wet O_2 at 1100°C to a thickness of ~ 1200Å SiO_2. Al dots were reapplied and the N_D from MOS C_{max}/C_{min} was 3.45 x 10^{15} cm^{-3}. This amounted to a large increase in N_D compared to the previous MOS measurement of 1.05 x 10^{15} cm^{-3} or the initial four-point probe value of 0.75 x 10^{15} cm^{-3}. The increase was too large to be explained by the "redistribution" effect. To investigate further the depth of this increase the aluminum and the oxide were stripped again but only from the left half of the slice. The slice was then etched in a silicon etch (5 HNO_3:4.4 acetic acid: 1 HF saturated with iodine) for 12 sec, and 1.1 μm of silicon was removed from the left half. The oxide on the right half was only slightly attacked by the etch. This oxide was removed and the whole slice was oxidized again in wet O_2 at 1100°C to form 1200Å of oxide. Aluminum dots were again evaporated over the whole slice. At this point the 3 slices were subjected to the pulsed MOS C-V measurements. After these measurements the slices were stripped and four-point probe measured. Row 10 shows the final four-point probe N_D. It is clear from these values, especially in the case of slice 3, that the MOS-measured increase in N_D was confined to a thin layer at the surface. The purpose of the pulsed MOS measurements was thus twofold: first, to determine if such measurements are practical and, second, to confirm the evidence from the four-point probe measurements that the large build-up of N_D at the surface as measured by MOS C_{max}/C_{min} is indeed confined to a thin layer at the surface.

Results of Pulsed MOS C-V Measurements

Measurements are summarized in Fig. 1 where $(1/C_m)^2$ is plotted against $V_A - V_{FB}$. A least square straight line was fitted as indicated. The slope of the straight line gave calculated values of N_D using [7]. Depth of measurement can be read from the right-hand ordinate. This ordinate is strictly valid for only one value of C_o = 2.5 x 10^{-8} F/cm² which was the oxide capacitance of slices 1 and 3. The C_o for slice 2 was 2.08 x 10^{-8} F/cm² and the W scale in Fig. 1 is therefore not strictly valid for slice 2, although it is a good approximation.

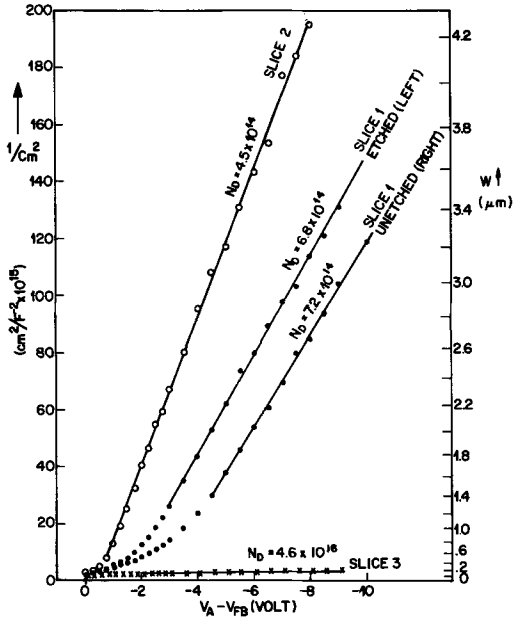

Fig. 1. Plots of $1/C_m^2$ vs. the applied voltage minus flatband voltage ($V_A - V_{FB}$). The right-hand ordinate indicates the depth (W) of the measurement below the Si surface (see Table II).

* From these points on a straight line was fitted as shown in Fig. 1.

Table II gives the correct relation between W and N_D for all slices. Values of W in this table were calculated by taking the average of each two neighboring $(1/C_m)^2$ values and then correcting for C_o. Each corresponding N_D value was calculated from the slope of the straight line between the points in Fig. 1.

Discussion of Results

The straight line portions of the curves in Fig. 1 yield N_D values that correspond well with the initial and final four-point probe values in Table I except for slice 3. Apparently the depth of measurement was large enough for slices 1 and 2 to reach into the undisturbed region of bulk doping. The largest value of W was ~ 3 μm for slice 1 and ~ 4 μm for slice 2. Slice 3 however did not go deeper than 0.24 μm although the applied maximum voltage was the same. This points out a basic limitation in all C-V profile measurements as discussed in the section on limitations. The higher doping levels require higher voltage to measure at the same depth, but the breakdown voltage, which limits the maximum applicable voltage, is lower for higher N_D. In the case of slice 3 the N_D value from Fig. 1 corresponds more to the MOS C_{max}/C_{min} value of Table I than to the initial or final four-point probe. The measurement apparently did not reach deep enough to reveal the bulk N_D.

The N_D value for slice 2 (Table II) becomes equal to the bulk N_D at $W \geqq 0.5\mu$. It is interesting to note how high N_D is for $W = 0.15\mu$. (see section on limitations.)

As expected, slice 1 unetched differs in profile from slice 1 etched. The difference is shown in Fig. 2.

It appeared that the repeated process sequence of oxidation-oxide strip caused an increase in N_D at the surface after each oxidation and that this "build-up" can be removed by etching the silicon. The exact reason for and mechanism of this phenomenon is unknown.

Remarks and Conclusion

The amount of experimental data in this communication is limited to three silicon slices because the measurements are meant merely to illustrate the cor-

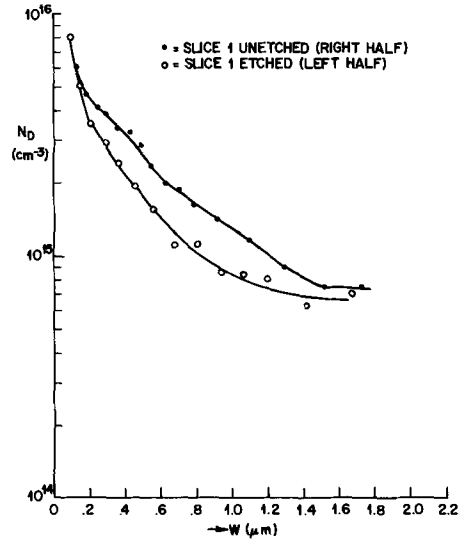

Fig. 2. Difference in N_D vs. W of slice 1 unetched and slice 1 etched.

rectness of theory and practicality of method. The measurements in addition dealt with an actual problem in device fabrication whereby an anomalously high increase in doping occurs at the surface of an n-type silicon slice. With these remarks in mind it is concluded that the pulsed MOS C-V technique can be a useful tool in revealing impurity profiles in silicon. The pulsed MOS technique has been used successfully to confirm 4-point probe evidence that an impurity increase due to repeated oxidation and stripping of the oxide is confined to a thin layer of ~ 1 μm at the surface.

Use of HCl Gettering in Silicon Device Processing

P. H. Robinson* and F. P. Heiman[1]

RCA Laboratories, Princeton, New Jersey 08540

It is well known that metals such as gold, copper, and iron severely degrade the minority carrier lifetime in silicon by forming recombination centers in the forbidden gap (1-4). These contaminants are generally present in most diffusion and oxidation furnaces, and it is common practice to getter them from the silicon after device processing (5-7). One gettering technique involves a long bake at 800°-1000°C with a phosphorus glass in contact with the silicon surface.

Transmission electron microscopy and infrared microscopy have been used to verify this gettering action by observing the disappearance of copper precipitates on dislocations after treatment (3, 8).

Another troublesome metallic impurity is sodium, which introduces unstable positive charge into the silicon dioxide layer (9). This has generally been avoided in silicon processing by ultraclean techniques, but most devices which are sensitive to sodium contamination (*e.g.*, MOS transistors) incorporate a phosphorus glass layer or silicon nitride layer to prevent contamination during metallization and subsequent handling.

The idea for using HCl as the gettering agent for sodium and other contaminants was first demonstrated by using a mixture of hydrochloric acid and distilled wafer as the source of steam for oxidation (14). Oxides were produced with essentially zero oxide charge using this technique even though the starting wafers were contaminated with sodium.

We reproduced this experiment but found no improvement in minority carrier lifetime. We reasoned that dry oxidation containing gaseous HCl would be more suitable for forming volatile metallic chlorides; the water vapor might favor the formation of involatile metal oxides. Indeed, most metals oxidize more rapidly in water vapor than in dry O_2.

Measurements of minority carrier lifetime using silicon films grown on both spinel and sapphire have yielded values of the order of 10^{-10}-10^{-9} sec. Bipolar transistors fabricated in these low lifetime films required very narrow base regions which in turn lead to many emitter-to-collector shorts, as well as low current gains (10). An improvement in minority carrier lifetime through use of the gettering technique described herein facilitated device processing and resulted in significantly higher performance. The procedure developed is described below.

Experimental Procedure

Systems for HCl processing in dry oxygen with either rf heating or resistance furnace heating were used for these studies and the procedure often included HCl etching of the silicon surface prior to high temperature HCl oxidation. This technique has yielded excellent results for preserving as well as recovering minority carrier lifetime in bulk and thin-film silicon. The procedure is only a minor modification of standard device processing; *i.e.* the inclusion of 0.5-1.0% HCl by volume into the oxygen gas stream. HCl cannot be used with other gases because the silicon will be etched in a nonoxidizing ambient. The furnace

Key words: gettering, minority carrier lifetime, thin film silicon, transient response MOS.

exhausts into a hood and plastic or glass tubing is used throughout. Termination of oxidation in an oxygen ambient will result in positive oxide charge (11). A 5 min anneal in an inert atmosphere at oxidation temperature will remove this charge.

Results on Bulk Silicon

Using the above technique, zero oxide charge has been reproducibly obtained in thermally grown oxide as determined by the capacitance-voltage curves and very high lifetime has been observed from the transient response of the MOS capacitor (12). Sodium, copper, and gold, *etc.* form highly volatile metal chlorides at elevated temperature and are presumably removed from the chamber as a gas. In addition, any of the metal impurities present in the silicon can be gettered during this oxidation step.

Typical results obtained with 8 ohm-cm N-type and P-type silicon wafers are as follows: (a) a steam-oxidized wafer exhibited an effective lifetime of 0.3 μsec. After 16 hr at 1200°C in 1% HCl/O_2 mixture, the minority carrier lifetime increased to 100-300 μsec, (b) one hour oxidation at 1100°C in 1% HCl/O_2 was found to preserve the minority carrier lifetime of 10-40 μsec which was measured before heat treatment, (c) increasing the HCl content to 10% by volume resulted in the formation of water (hydrochloric acid) in the cold parts of the furnace tube. The silicon wafer was badly pitted. HCl concentration below 1% does not affect the oxidation rate and it is presumed that very little water is formed.

A word is in order concerning the measurement technique. Lifetime is measured by observing the rate at which the inversion layer forms under an MOS capacitor after the application of a large depleting voltage (12). The generation rate in the depletion region, g, is related to minority carrier lifetime, τ, by

$$g = \frac{n_i}{2\tau} \qquad [1]$$

where n_i is the intrinsic carrier density. This expression is accurate if electron hole capture cross sections are equal, and all traps are locked at the center of the forbidden energy gap. It can be shown (13), however, that the generation out of traps located a distance ΔE from the center of the gap is reduced by exp $(\Delta E/kT)$. Thus, only those traps near the center are important in this process. This means that determination of lifetime by measuring the generation rate always results in a value $\geq$ the photoconductive lifetime. However, values taken before and after gettering are indicative of a change in impurity concentration and relate directly to the change in leakage current of diodes fabricated in the material.

Typical results are shown in Fig. 1 and 2. In Fig. 1, we see the transient response of an MOS capacitor whose oxide was grown in steam at 1100°C. Anneal in H_2 at 500°C for 30 min assures a low density of

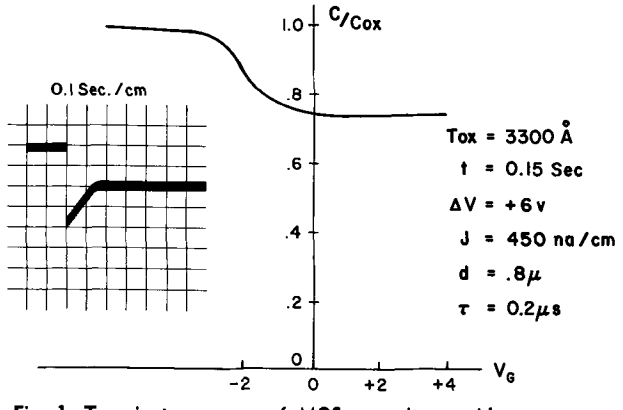

Fig. 1. Transient response of MOS capacitor; oxide was grown in steam at 1100°C.

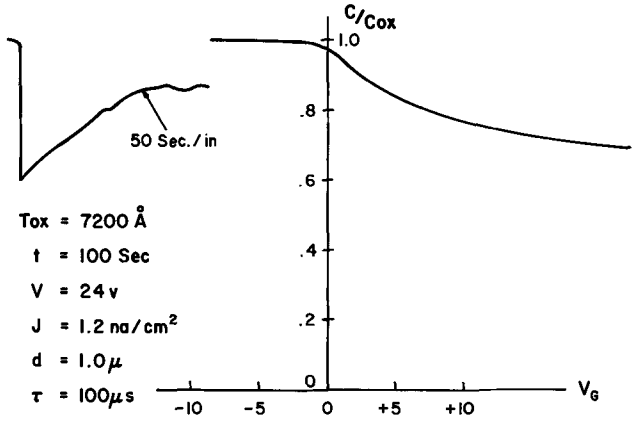

Fig. 2. Transient response of MOS capacitor; steam oxide was gettered in HCl/O_2 atmosphere at 1200°C for 16 hr.

interface states.[2] The total transient time is about 0.15 sec which corresponds to an average of 450 nA/cm^2. The capacitance measurement indicates an average depletion region depth of 0.8μ which yields a lifetime of 0.2 μsec. The transient response shown in Fig. 2 depicts the situation after gettering in 1% HCl/O_2 at 1200°C for 16 hr. A similar analysis yields a value for lifetime of 100 μsec.

Results with Thin-Film Silicon Grown on Insulators

Several experiments were performed using 2μ thick silicon-on-sapphire films. Measurement of lifetime in films before gettering resulted in values of 0.5 to 1 nsec. However, a 1 hr oxidation at 1100°C in HCl as described previously resulted in a lifetime of 3 nsec. Gettering for 16 hr increased this lifetime to over 13 nsec.

Lifetime measurements were also made on 2μ silicon films grown on aluminum-rich spinel obtained from Germany, having an Al_2O_3:MgO ratio of 3.3 to 1. The measured lifetimes were determined to be quite poor ($\approx$ 0.1 nsec) even though the films had essentially bulk mobilities. HCl gettering at 1100°C for 15 min did not improve the lifetime. Higher temperatures were not used due to the exsolution problem associated with Al rich spinel. Either this spinel is an infinite source for lifetime-killing impurities or the impurities which are affecting the lifetime are not being gettered. Additional experiments are being planned to determine why lifetime in silicon grown on this kind of spinel is so poor.

Some preliminary experiments on the growth of silicon-on-sapphire by the pyrolysis of silane in helium (15) at temperatures ranging from 800° to 1000°C have begun. Single crystal silicon films as determined by electron diffraction patterns were obtained at growth temperatures of 880°C and above. Films obtained at 925°C at a growth rate of ¼ μ/min were N-type with a resistivity of 2 ohm-cm. Hall measurements made at room temperature gave an electron mobility in the range of 450-500 cm^2/V-sec. Hall mobility *vs.* temperature was measured and results indicate that a negligible amount of aluminum is present in the silicon films.

Lifetime measurements were made on the helium grown silicon films without gettering. Values of 14 nsec were obtained on several films. These were then oxidized at 1200°C in the presence of HCl and lifetime increased to 43 nsec.

Several other silicon-on-sapphire films were grown by the pyrolysis of silane in helium at 1050°C. These films were 2μ thick, P-type with a resistivity of 0.5 ohm-cm. Mobility *vs.* temperature measurements indicated that these films were Al-doped presumably due to the higher growth temperature and a hole mobility of 125 cm^2/V-sec was determined.

[2] The authors have analyzed the effect of surface generation on the results. This can be separated out by careful waveform analysis and does not affect the values given in this report.

Lifetime measurements, however, resulted in very low minority carrier lifetimes of 0.5 nsec, and no significant improvement was found after HCl oxidation-gettering. This result suggests that Al present in the silicon films or aluminum-oxygen conglomerates after oxidation could be affecting the thin-film silicon lifetime.

Conclusions

We have observed that a small amount of dry gaseous HCl introduced into the gas during oxidation can significantly reduce the generation rate in silicon. This is presumed due to the gettering of metallic impurities from the silicon through the formation of volatile metal chlorides. HCl gettering processes are being used in the fabrication of silicon-on-sapphire bipolar transistors and complementary MOS transistor circuits.

Further work is underway to investigate, in detail, the time-temperature dependence of the process.

Acknowledgments

The authors would like to thank J. Jaklik and R. O. Wance for processing the devices and R. Ronen and E. Moonan for results obtained with silicon-on-sapphire bipolar transistors.

Influence of Silicon Slice Curvature on Thermally Induced Stresses

H. R. Huff,* R. C. Bracken,* and S. N. Rea

Texas Instruments Incorporated, Dallas, Texas 75222

The generation of thermally induced dislocations in silicon slices has been investigated recently for both diffusion furnace and epitaxial reactor geometries (1-3). It has further been shown that the detailed method of slice preparation can exert a considerable influence on the dislocation generation (4-8). For example, conventionally prepared 2-in. diameter silicon slices are observed by Talysurf measurements to exhibit curvatures up to several mils (5). This curvature arises from both the sawing operation and subsequent mechanical processing. The contribution of each to the slice curvature is a function of the particular processing technique utilized. Although curve-free slices can be prepared utilizing extreme care in performing each processing step, conventionally prepared slices do exhibit curvature.

In the present note, we will illustrate the influence of slice curvature as a mechanism for generating thermal stresses in slices placed on a uniformly heated susceptor. It is shown that these stresses may be of sufficient magnitude to activate residual surface dislocation sources and cause their propagation throughout the initially dislocation-free slice volume[1] (see Fig. 1). The dislocations thereby generated should be especially detrimental in that subsequent high-temperature processing may lead to their multiplication as well as their interaction with various types of point and higher-order defects (9).

A bowed slice sitting on a uniformly heated susceptor exhibits a temperature variation across its radius because of the variation in thermal coupling between slice and susceptor. The slice is heated by the susceptor through both conduction and radiation while it loses heat primarily by radiation. At points of maximum separation between slice and susceptor, the heat transport by conduction across the gaseous interface is substantially lower than at contact points. Therefore, that portion of the slice in intimate contact with the susceptor attains a temperature near that of the susceptor while the slice portion bowed away from the susceptor attains some lower temperature. The presence of thermal radiation introduces a strong nonlinearity in the differential equation governing slice

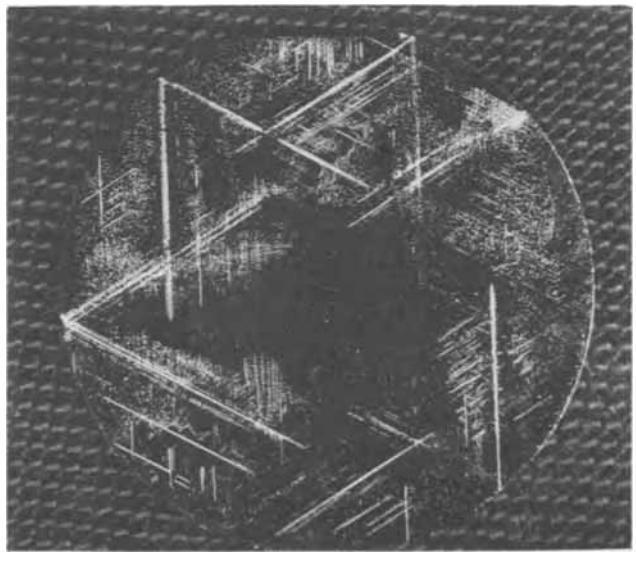

Fig. 1. Epitaxially processed slice after subsequent Sirtl etching

Key words: epitaxy, dislocations, computer simulation.

[1] Determined by Sirtl etching.

temperature and necessitates computer solution. A finite-element computer model was used following standard procedures (10). This involved dividing the slice into many small elements (nodes), performing an energy balance on each node, and, through a relaxation scheme, determining the temperature distribution across the slice. The slice was assumed to be in a hydrogen atmosphere.

Calculated temperature distributions for such curved slices, as shown in Fig. 2, indicate that radial temperature variations on the order of 20°C are possible in 8-mil thick, 2-in. diameter slices, depending on the amount and sign of curvature. A perfectly flat slice exhibits a negligible temperature variation. The radial temperature distribution is fairly insensitive to slice thickness. Calculated temperature distributions for 4, 8, and 16-mil thick, 2-in. diameter slices were virtually identical.

The silicon slice is represented as a thin, circular disk of radius R with a radially symmetric temperature distribution about the center. By neglecting the stress component normal to the surface,[2] the stress tensor may be written in cylindrical coordinates as

$$\sigma = \begin{pmatrix} \sigma_r & 0 & 0 \\ 0 & \sigma_\theta & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad [1]$$

with (11)

$$\frac{\sigma_r}{\alpha E} = \frac{1}{R^2}\int_0^R T(r)\,r\,dr - \frac{1}{r^2}\int_0^r T(r)\,r\,dr$$

$$\frac{\sigma_\theta}{\alpha E} = -T(r) + \frac{1}{R^2}\int_0^R T(r)\,r\,dr + \frac{1}{r^2}\int_0^r T(r)\,r\,dr \quad [2]$$

where, for an isotropic solid, α is the linear thermal expansion coefficient, E is Young's modulus, and $T(r)$ is the radial temperature distribution.

Once the radial (σ_r) and tangential (σ_θ) stresses are determined from Eq. [2], the maximum shear stress ($\tau_{s,max}$) may be determined through the Mohr circle procedure as

$$\tau_{s,max} = \tfrac{1}{2}\,|\,\sigma_r - \sigma_\theta\,| \quad [3]$$

We have estimated whether the resulting shear stress is sufficient to produce yielding by employing the maximum shear-stress criterion (12). That is, yielding occurs when the maximum shear stress equals the value it has when yielding occurs in the tensile test (taken as one-half the upper yield point, σ_{uyp})

$$\tau_{s,max} = \tfrac{1}{2}\,\sigma_{uyp} \quad [4]$$

[2] Calculated results indicate that temperature variations across the slice thickness are negligible.

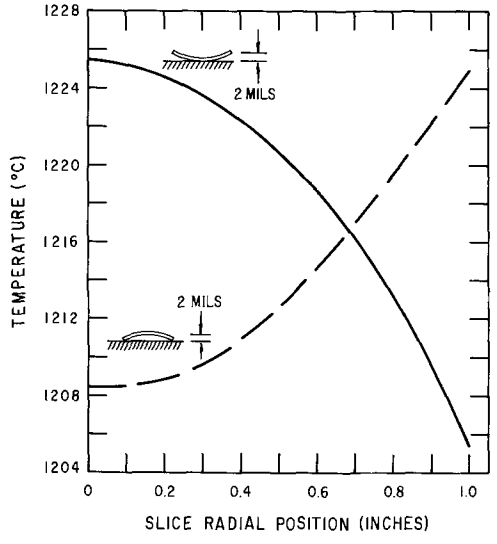

Fig. 2. Theoretical radial temperature distributions in a 2-in. diameter, 8-mil thick slice, susceptor temperature 1230°C.

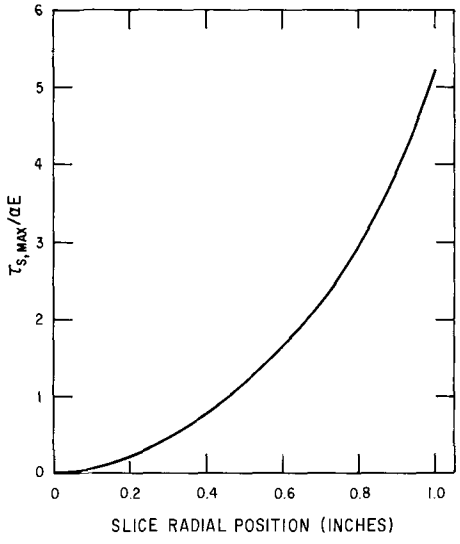

Fig. 3. Theoretical maximum shear stress variation in a 2-in. diameter, 8-mil thick concave slice (2-mil curvature).

The variation of $\tau_{s,max}/\alpha E$ as a function of radius was obtained by numerical integration of Eq. [2] and application of Eq. [3]. Figure 3 presents results based on the concave slice of Fig. 2 (solid line). The maximum shear stress at the slice periphery is estimated to be 21% of the upper yield point at 1200°C by taking $\sigma_{uyp} = 2 \times 10^8$ dynes/cm^2 (13), $\alpha = 4 \times 10^{-6}$ (°C)$^{-1}$ (14), and $E = 1.9 \times 10^{12}$ dynes/cm^2 (14). Since dislocations are observed in germanium at approximately 25-30% of the upper yield point (15) at 515°C (788°K or 64% of the melting point), the development of dislocations in silicon at 1200°C (1473°K or 87% of the melting point) is not unexpected. Thus, it appears that the thermal stress developed from typical slice curvatures may be sufficient to cause the activation of residual surface dislocation sources.

It should be noted, however, that the upper yield point is an extremely structure-sensitive property and is strongly dependent on whether surface or bulk sources are dominant (16-18). Furthermore, Young's modulus data at epitaxial temperatures are not available, although there are indications that it may be as much as 50% lower than the room temperature value.

A uniformly heated susceptor was assumed in the foregoing calculations. In practice, the susceptor itself can exhibit a substantial temperature variation which, coupled with the slice curvature effects, might more readily activate residual surface dislocation sources.

Acknowledgments

The authors wish to express their appreciation to Mrs. Betty Purkey for her assistance with the computer programming, and to Dr. L. D. Dyer for his constructive comments.

Silicon Optical Constants in the Infrared

P. A. Schumann, Jr.,* W. A. Keenan,* A. H. Tong,* H. H. Gegenwarth, and C. P. Schneider

IBM Components Division, East Fishkill Laboratory, Hopewell Junction, New York 12533

The optical constants of semiconductors, primarily silicon, are becoming increasingly important because of the emphasis on optical measurement techniques. These techniques are very promising, being in general nondestructive and contactless (1). At present they all require some knowledge of the optical constants primarily due to free carriers. The most important of the optical measurement techniques now used in the semiconductor industry are infrared interference for the measurement of epitaxial layer thickness (2-7), substrate carrier concentration (8, 9) and part of the outdiffused profile (10, 11), plasma resonance for measurement of high carrier concentration (12-14) and diffusion surface concentration (15-18), total internal reflection techniques for the measurement of the carrier concentration of the epitaxial layer (19, 20), pseudo-Brewster angle for the measurement of carrier concentration and diffusion surface concentration (21), and direct measurement of the absorption coefficient to determine carrier concentration. In addition, there are many infrared absorption techniques for impurities such as carbon and oxygen in silicon (22) and cryogenic absorption for other impurities.

All the measurements were made at room temperature with a Perkin-Elmer Model 621 spectrophotometer utilizing their Micro Specular Reflectance Accessory for reflectance. Reflectance and transmittance were measured and reduced to the optical constants using the technique previously reported (23, 24). For normal incidence, the reflectivity R of a semi-infinitely thick sample is (24)

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \qquad [1]$$

where n is the index of refraction, and k is the extinction coefficient.

The extinction coefficient k is related to the absorption coefficient α by the equation

$$k = \frac{\alpha\lambda}{4\pi} \qquad [2]$$

where λ is the wavelength in vacuum.

The transmission through a sample of finite thickness d is

$$T = \frac{(1-R)^2 e^{-\alpha d}}{1 - R^2 e^{-2\alpha d}} \qquad [3]$$

The measured reflectivity r for a sample of finite thickness d is (25)

$$r = R(1 + T e^{-\alpha d}) \qquad [4]$$

The simultaneous solution of Eq. [3] and [4] yields α and R; n and k can then be calculated from Eq. [1] and [2].

Carrier concentration was measured by determination of resistivity and utilization of Irvin's curves (26). These results were checked where possible by use of the plasma resonance minimum, in which the published calibration curves (14) were used. The average difference in the two techniques was 12% for n-type and 34% for p-type silicon. Thirty-five samples were measured with carrier concentrations between 8.6×10^{14} and 6.2×10^{19} cm^{-3} in the wavelength range from 2.5 to 40 μm. An intrinsic sample was also measured to study the lattice absorption bands; these absorption data were then compared with the previous data of Collins and Fan (27), as shown in Fig. 1. As can be

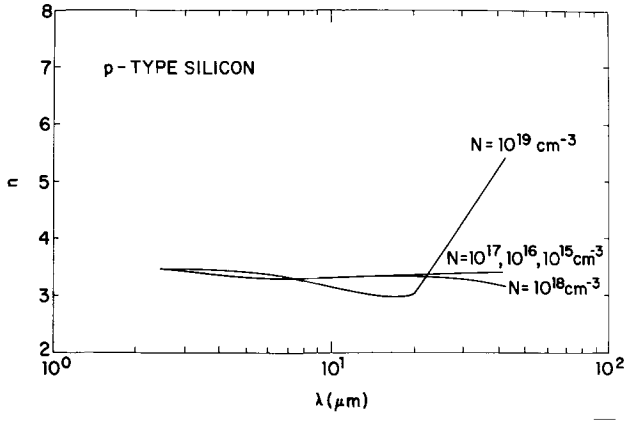

Fig. 3. Index of refraction n as a function of wavelength λ in micrometers for p-type silicon with various carrier concentrations.

seen, the agreement between the two sources of data is excellent.

Direct determination of the optical constants from the reflectance and transmittance is very sensitive to experimental variation in these quantities. A smoothing procedure was adopted to reduce the effects of this variation. After lattice absorption was subtracted from the reflection and transmission data, the optical constants were calculated by the technique above. The optical constants were first plotted as a function of concentration for the various wavelengths.[1] Smooth curves were hand-drawn through these data points. Values were then taken from these smooth curves and used to construct the optical constant *vs.* wavelength curves for various concentrations shown in Fig. 2-5.

Most of the published work on the optical constants reports only the absorption coefficient. The absorption coefficient has thus been chosen to compare previously published experimental data, this work, and theoretical calculations from a semiclassical free carrier absorption model (13). Representative curves are shown for n- and p-type silicon. Figures 6-9 are plots of the absorption coefficient as a function of carrier concentration, indicating both experimental and theoretical data. The dotted line is a hand-drawn estimate of the experimental data.

Figure 6 shows the data of Spitzer and Fan (23), Vavilov (28), Ukhanov (29), Spitzer, Gobeli, and Trumbore (30), and the authors for n-type silicon at a wavelength of 5 μm. The agreement between the experiment and theory is good. Figure 7, however, which shows the data of Vavilov (28), Hara and Nishi (31), and the authors for p-type silicon at the same wavelength, indicates even better agreement between theory and experiment.

At a wavelength of 40 μm the agreement is not good, as shown in Fig. 8 and 9. The data of Walles (32), and Walles and Boija (33) are given in Fig. 9. For n-type silicon the theory misses the experimental data completely. For p-type silicon, the theory crosses the experimental data and thus represents a better fit, pos-

sibly. In all cases, the authors' experimental data agree very well with the previously published data, thus offering for the first time a wide range of optical constants as a function of carrier concentration and wavelength.

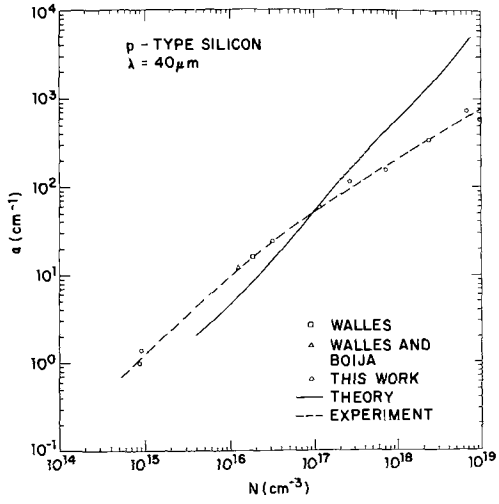

Fig. 9. Absorption coefficient α as a function of carrier concentration for p-type silicon at a wavelength of 40 μm.

The theoretical model used to calculate the optical constants appears to fit the experimental data well at short wavelengths, but the longer wavelength fit is not successful. It would appear necessary therefore to alter the theoretical model or improve it to better fit the long wavelength optical constants.

Manuscript submitted June 1, 1970; revised manuscript received ca. Sept. 10, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Brief Communications

Luminescence of Bi^{+3}-Activated LaOCl under X-Ray Excitation

P. Y. Simons

E. I. du Pont de Nemours & Co., Inc., Photo Products Department, Parlin, N. J. 08859

The luminescence of Bi^{+3}-activated LaOCl over a narrow bismuth composition range under ultraviolet, cathode ray, and x-ray excitation has been reported by Swindells (1). Blasse and Bril (2) in their investigation of Bi^{+3}-activated phosphors report on LaOCl activated with 1 a/o (atomic per cent) bismuth.

This present work concerns a study of the luminescence properties of Bi^{+3}-activated LaOCl over a wide composition range under x-ray excitation.

Experimental

A series of Bi^{+3}-activated phosphors were prepared by dissolving the appropriate amounts of La_2O_3 (99.99%) and reagent grade Bi_2O_3 in distilled water and HCl, evaporating to dryness, and firing the residue ($LaCl_3$ nH_2O) in air overnight at 600°C in porcelain crucibles. An additional firing in air at 1000°C for 3 hr was performed to increase phosphor crystallinity. All samples were checked by powder x-ray diffractometry and only single-phase LaOCl was found.

The emission spectra were recorded on a spectroradiometer system[1] with the x-ray excitation from a Faxitron[2] x-ray unit. The apparatus consists of a quartz prism monochromator[3] coupled to a photomultiplier microphotometer employing a 1P28 photomultiplier which in turn was coupled to a strip chart recorder. Automatic scanning was obtained by connecting a reversible motor to the micrometer which drove the monochromator. Since the output is a nonlinear wavelength *vs.* light intensity peak, all spectra were replotted in a linear scale and the intensity corrected for the detector system response.

The x-ray beam was collimated to reduce stray radiation in the x-ray chamber, and the powdered sample was completely immersed in x-rays during excitation. All spectra were taken at room temperature with the unfiltered tungsten target operating at 80 kVp and 3 mA. The dose rate at the sample position was about 1.7 roentgen/sec as measured with an ionization roentgen meter.[4]

Results and Discussion

Under x-ray excitation Bi^{+3}-activated LaOCl is characterized by broad-band emission at 365 nm and 450 nm (measured at peak half height). At all bismuth compositions below 25% the 365 nm is the more intense. Blasse and Bril (2) also observed these emissions in LaOCl:Bi(0.01) under ultraviolet excitation. The dependency of the emission on increasing bismuth content is given in Fig. 1, and the emission spectra of LaOCL doped with 10 and 25 m/o (mole per cent) bismuth are given in Fig. 2.

The 365 nm emission intensity reaches a maximum at a bismuth concentration of 10 m/o, and with

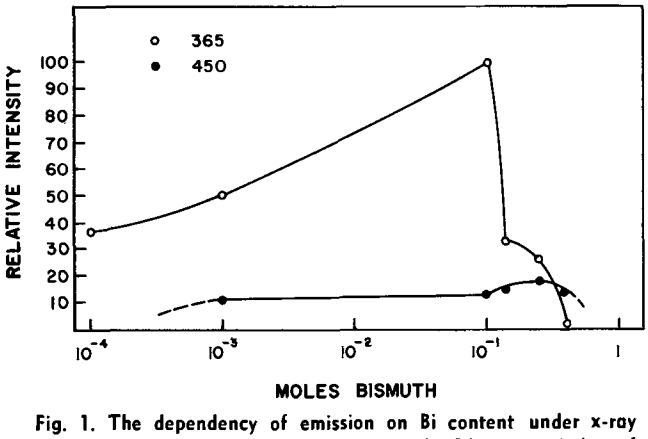

Fig. 1. The dependency of emission on Bi content under x-ray excitation. The intensity is normalized for the 365 nm emission of LaOCl:Bi(0.10) equal to 100.

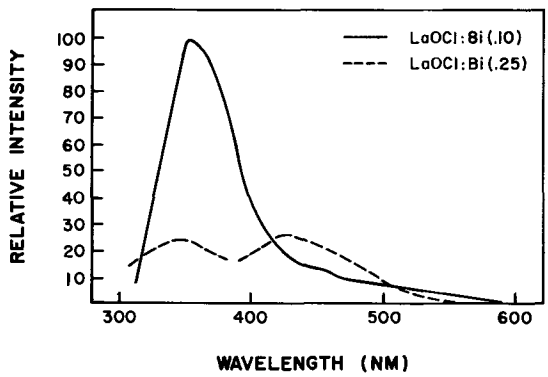

Fig. 2. Emission spectra of LaOCl:Bi(0.10) and LaOCl:Bi(0.25) under x-ray excitation.

increasing bismuth this emission is severely quenched. On the other hand, the 450 nm emission intensity appears to reach a maximum at 25% bismuth. Note that while the 365 nm emission is being quenched the 450 nm band intensity increases. A weak emission at 500 nm is also observed in the LaOCl:Bi spectrum. This band is due to impurities in the starting material. Undoped samples of LaOCl prepared from La_2O_3 gave this weak emission, whereas undoped LaOCl prepared from $La(NO_3) \cdot 5H_2O$ did not emit at 500 nm although it had weak bands at other wavelengths. BiOCl was also prepared but it did not luminesce under x-ray excitation.

The nature of the emission centers in Bi^{+3}-activated phosphors is not completely understood. Emissions have been assigned to electronic transitions between s^2-sp states or activator-matrix states (2). Emission in Y_2O_3:Bi has been attributed to bismuth occupying two centers in the host (3). Without excitation spectra the assignments of the transitions responsible for emissions in this system cannot be determined. However, based on the assignment of the $1P_1 \rightarrow 1S_0$ transition for the Bi^{+3} emission in YOCl:Bi^{+3} by Blasse and Bril (2) it appears reasonable to assign this transition to the 365 nm emission in LaOCl:Bi. It may also be reasonable to assume that the 450 nm emission is due to the $3P_1 \rightarrow 1S_0$ transition because this is the only other allowed transition of an ion with a s^2-sp excited configuration. However, this assignment cannot be made unequivocally without a detailed study of the absorption and excitation spectra of LaOCl:Bi emissions.

Inhibition of Silicon Growth Rate During the Deposition of Arsenic-Doped Epitaxial Silicon Layers on Silicon by Pyrolysis of Silane

R. F. C. Farrow and J. D. Filby

Ministry of Technology, Royal Radar Establishment, Malvern, Worcestershire, England

The production of epitaxial layers of silicon by the pyrolysis of silane (SiH_4) on silicon substrates is well known (1, 2) to offer several advantages over present methods which involve hydrogen reduction of trichlorosilane ($SiHCl_3$) or silicon tetrachloride ($SiCl_4$). In the course of investigations into the effect of group III and V dopants on the epitaxial growth of silicon on silicon by pyrolysis of a molecular beam of silane, we have observed that silane pyrolysis on a (111) silicon substrate is inhibited by the presence of arsine at the surface. Since this inhibition implies a reduction in the growth rate of arsenic-doped epitaxial silicon layers using pyrolysis of silane we have examined the effect in some detail and report here our preliminary findings.

The system used in our investigations is shown schematically in Fig. 1. A molecular beam of silane is formed in a triple aperture, ultra-high vacuum system and impinges on the (111) face of a heated silicon specimen in a target chamber. The target and collimation chambers are each pumped by oil diffusion pumps fitted with molecular sieve traps and thermoelectrically cooled chevron baffles to prevent back diffusion of silicone oil. Gas species scattered from the silicon specimen are detected by a quadrupole residual gas analyzer. The entire system is baked at 350°C prior to each run, and base pressures in the region of 10^{-10} Torr in all parts of the system are achieved. Residual carbon and oxygen contamination of the surface is removed by heating the specimen to 1250°C for 5 min (3) before exposing it to the molecular beam. Group III or V dopants are introduced by adding the appropriate helium diluted dopant gases, *e.g.*, diborane, phosphine, arsine, to the silane beam.

The kinetics of pyrolysis of silane and arsine were studied by monitoring gas species desorbed from the (111) silicon surface as a function both of beam intensity and substrate temperature. It was found that the onset of pyrolysis of both silane and arsine was marked by a rapid increase in the flux of H_2 desorbed from the surface as a function of temperature. From a plot of the logarithm of the fractional increase in the H_2 signal as a function of reciprocal of absolute temperature (Arrhenius plot) activation energies of 10 ± 1 kcal/mole and 12 ± 1 kcal/mole were derived for pyrolysis of silane and arsine, respectively, on a clean (111) silicon surface. Furthermore, it was found that the fractional increase in the H_2 signal was linearly proportional to the beam intensity for both silane and arsine pyrolysis, *i.e.*, the production of H_2 by pyrolysis of silane and arsine is a first order reaction.

In addition to studying the kinetics of pyrolysis of arsine and silane separately, the effect on silane pyrolysis of the introduction of arsine to the silane beam was also investigated. It was found that the introduction of arsine led to an inhibition of the silane pyrolysis. This effect is shown in Fig. 2 in which the ratio of the H_2 signal for a given incident flux of silane molecules with arsine present to the H_2 signal for the same incident flux of silane molecules without arsine is plotted as a function of time for three different

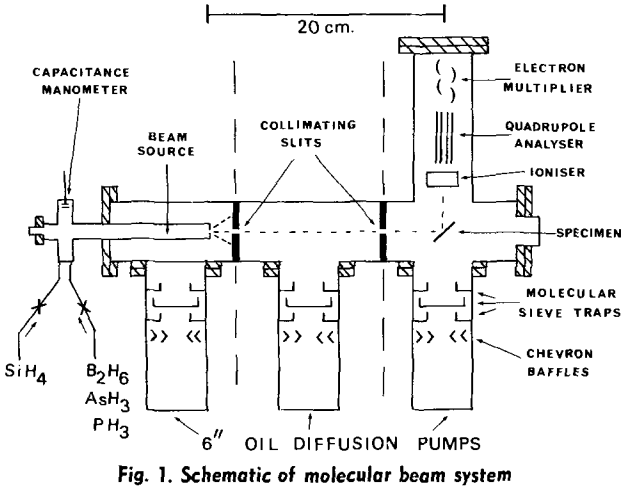

Fig. 1. Schematic of molecular beam system

Key words: surface reaction kinetics, pyrolysis.

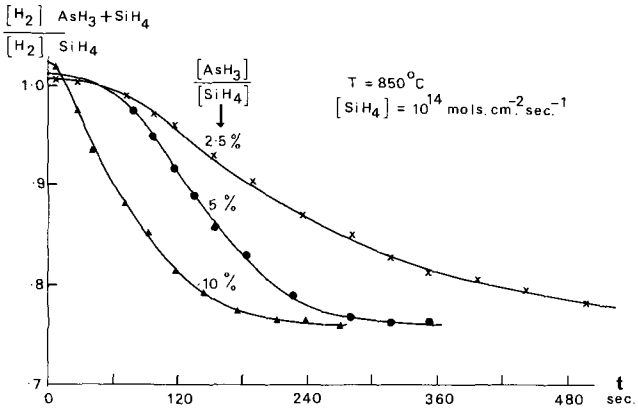

Fig. 2. Inhibition of hydrogen production during pyrolysis of a molecular beam of arsine + silane.

concentrations of arsine in the beam. The time zero represents the instant at which the arsine is added to the silane beam. It is seen that initially the H_2 signal with arsine present is greater than with only silane present due to the contribution of arsine pyrolysis to the H_2 signal. However, with increasing time the H_2 production is progressively inhibited and approaches a lower limit at which the H_2 signal is only 7% greater than the H_2 signal at ambient temperature. (The H_2 signal at ambient temperature is due to cracking of silane in the quadrupole residual gas analyzer.) This corresponds to an 80% reduction in the rate of silane pyrolysis. It can also be seen that increasing the concentration of arsine in the beam leads to a more rapid approach to the lower limit of the pyrolysis rate but does not affect this limiting rate. Moreover, by recording corresponding data to that shown in Fig. 2 for various specimen temperatures it was found that the activation energy for silane pyrolysis was increased to 14 ± 1 kcal/mole in the presence of arsine.

On the basis of these experimental facts, the most likely explanation for the inhibition of silane pyrolysis is that as arsenic is produced at the silicon surface it becomes strongly bound to certain surface sites which are active in inducing silane pyrolysis, thus preventing access of impinging silane molecules to these sites. At the present time the nature of these active sites is not clear although one possibility is that they are sites at the edge of atomic steps which are known to exist on thermally cleaned (111) silicon surfaces (4) and on the surface of silicon layers deposited on (111) silicon substrates under ultra-high vacuum conditions (5).

The preceding suggestion that arsenic "poisons" active sites on the silicon surface is supported by the fact that arsenic is well known as a catalyst poison in other chemical reactions, notably in the case of SO_3 production from SO_2 and O_2 in which traces of arsenic are sufficient to poison a platinum catalyst. Additional support for the observation of inhibition of silane pyrolysis by arsine is provided by the work of Eastwood *et al.* (6) who found that the deposition rate of arsenic doped SiO_2 layers (on silicon substrates) formed by pyrolysis of a gaseous mixture of silane, oxygen, and arsine decreased with increasing arsine concentration.

Table I. Thickness and resistivity of silicon layers

$\frac{[AsH_3]}{[SiH_4]}$ %	Thickness, μ	Resistivity, ohm-cm	Carrier concentration, cm^{-3}
0	12	20	$3 \cdot 10^{14}$
1	6	0.010	$5 \cdot 10^{18}$
2.5	2.4	0.007	$9 \cdot 10^{18}$
5	1.8	0.006	$1.1 \cdot 10^{19}$
10	1.2	0.005	$1.5 \cdot 10^{19}$

We have confirmed by measurement of the thickness of epitaxial silicon layers deposited using a conventional ultra-high vacuum system that the presence of arsine does indeed inhibit the silicon growth rate. This can be seen from Table I which summarizes the thickness and resistivity of layers grown in 60 min at 850°C with a silane pressure of 0.1 Torr.

It should be pointed out that inhibition of silane pyrolysis by arsine may prove a practical limitation only at high arsine concentrations where inhibition takes place in a time shorter than the time required for deposition of the epitaxial layer. At arsine concentrations below 0.1% we have found that the inhibition takes several hours to reach its maximum effect. This would explain why no inhibition of growth rate was reported either by Swanson and Tucker (7) or Richman and Arlett (2) who investigated the arsenic doping of epitaxial (111) silicon layers grown by pyrolysis of silane. The ratio of arsine to silane used in their work did not exceed 0.04%, and their layers were deposited in less than 1 hr.

Isothermal Solution Mixing Growth of Thin $Ga_{1-x}Al_xAs$ Layers

J. M. Woodall*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Since the development of the liquid phase epitaxial growth of $Ga_{1-x}Al_xAs$ electroluminescent devices (1, 2), this method has been used to realize considerable improvements in threshold current densities for injection lasers. These improvements are due to the use of GaAs and $Ga_{1-x}Al_xAs$ heterojunction structures (3-5). The most recent optimization (6) employs a 1μ thick Si doped p-type GaAs layer sandwiched between an n-type and a p-type $Ga_{1-x}Al_xAs$ layer with $0.2 \leq x \leq 0.5$. Further improvement could be expected

* Electrochemical Society Active Member.
Key words: crystal growth, thin layers, $Ga_{1-x}Al_xAs$.

if the thickness of the p-type GaAs layer could be reduced even more. Previously, layers 1μ thick were grown using a specially designed apparatus (6) in which melts of different composition were brought into contact with the surface of a layer which was mechanically wiped clean of the previous melt. In order to avoid the possibility of mechanically damaging the surface of a thin layer during wiping, a new technique for heterojunction growth has been developed which is reported in the present communication. This method promises to have the capability for growing multilayered structures with thicknesses $<<$ 1μ. The purpose of this report is to describe the method, the apparatus, and some preliminary results.

A photograph of the apparatus used for isothermal solution mixing (ISM) is shown in Fig. 1. The main features of this apparatus are a cylindrical substrate holder and a partitioned crucible which can contain two melts. All parts are made of high-purity, high-density graphite. The substrate can be brought into contact with either melt by a rotation of the holder such that the substrate is aligned with one of the windows on the inner wall of the crucible. This apparatus can be used in either the normal liquid phase epitaxial growth mode or the ISM growth mode or both. For the ISM mode of growth a certain amount of one melt is trapped in the holder as it is rotated into the other melt. This trapped melt becomes supersaturated as it mixes with the other melt, causing crystal growth.

Melt preparation procedures are similar to those reported previously (7, 8). However, a notable difference in procedure for this method is the vacuum baking at 200°C of the system and substrate and the subsequent back filling by hydrogen which is purified by means of a palladium diffuser. This process step has notably improved the wetting of the substrate by the melt during the initial stages of growth. A Ga-Al melt is saturated with As using a rectangular bar of undoped GaAs with a mass in excess of that required for saturation. Using this procedure it is important to allow sufficient time for complete saturation to occur before rotating the substrate into the melt. This time is usually 1 hr and 15 min at 830°C. Bringing the substrate into contact with the melt before this time can result in complete dissolution of the substrate.

The composition profiles along the growth axis for two types of growth procedure are shown in Fig. 2 and 3. Figure 2 shows the profile of a layer which was grown from two different melts at a growth rate of 0.1°C/min. The layer was grown on the (100) face of an undoped GaAs substrate. The first part of the layer was grown from an As saturated melt containing 30g Ga with an Al/Ga weight ratio of 3 x 10^{-3}, and cooled from 862° to 852°C. The substrate was then rotated into a melt containing 30g Ga with an Al/Ga weight ratio of 5 x 10^{-3}, and cooled between 852° and 842°C. It should be noted that the composition profile is very flat for that part of the growth occurring in each melt. The decrease in Al concentration occurring near the end of the profile is due to fast freezing of the melt

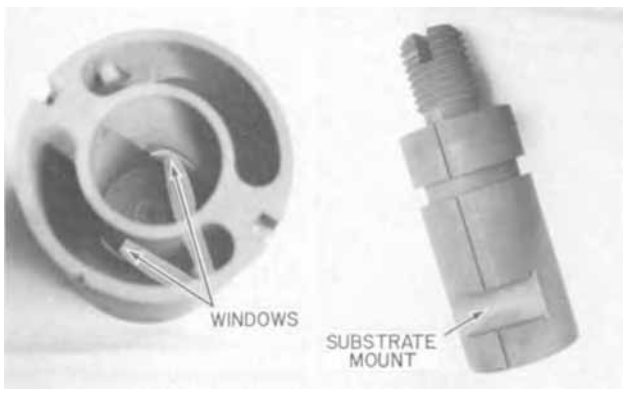

Fig. 1. Apparatus for isothermal solution mixing growth

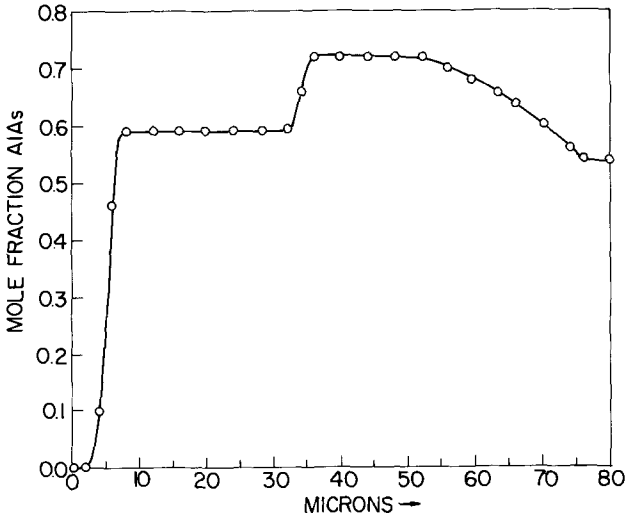

Fig. 2. Composition profile for layer growth by 0.1°C/min cooling and single rotation between two melts.

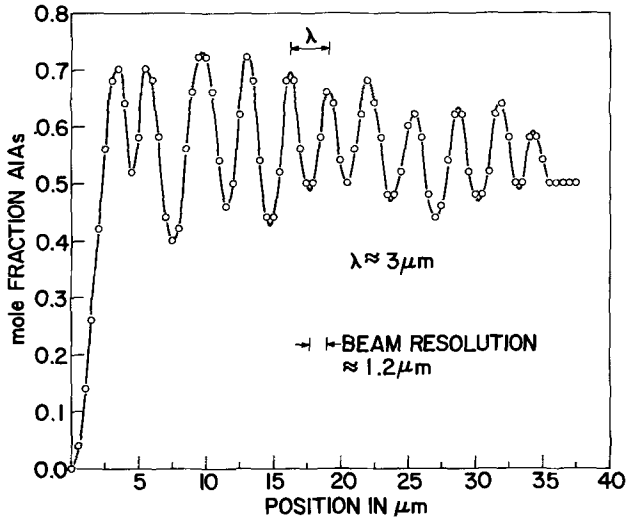

Fig. 3. Composition profile for layer growth by 0.1°C/min cooling and 23 melt changes.

which is trapped in the holder when the furnace is turned off.

Figure 3 shows the composition profile of a layer grown in the ISM mode by many rotations between two melts. It is seen that the layers show a periodic variation in Al concentration along the growth axis and that there is an over-all decrease in amplitude along the growth axis. The period is about 3μ, and hence each sublayer is about 1.5μ thick. One melt had an Al/Ga ratio of 10^{-3} and the other had a ratio of 5 x 10^{-3}. Rotation was done by rotating within a 2-sec time period from one melt to another and holding for 3 min. It was found that the thickness and spacing of the sublayer structure was independent of cooling rates between 0.03° and 0.1°C/min and rotation cycle time of 3 min/melt and 30 sec/melt. This appears to be good evidence that the growth of the substructure is due to the supersaturation which occurs during the mixing of the trapped melt which is brought over by the holder with the other melt.

The ISM epitaxial growth can be explained by the isothermal phase boundary-composition relations in the $Ga_{1-x}Al_x$ system (7, 9). A close examination of the Ga rich portion of this system shows that a solid-liquid phase boundary exists over a large composition range, and that the isothermal liquidus curve is such that when two melts having different composition on the liquidus line are mixed, the mixed melt will be supersaturated and hence crystallization can occur. This effect is shown in Fig. 4 which schematically rep-

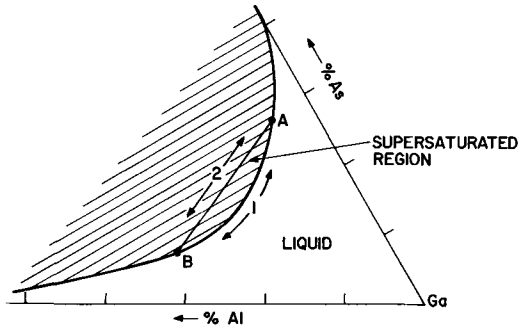

Fig. 4. Schematic Ga-Al-As-phase diagram at Ga rich corner

resents the Ga-Al-As liquidus line at constant temperature T at the Ga rich corner of the phase diagram. Points A and B represent two melts of different composition at solid-liquid equilibrium. Under equilibrium conditions the composition of the liquid melt can change along path 1 between A and B. When the melts are mixed the final composition of the mixed melt will lie at some point along path 2, the actual point depending on the volume ratio of the two melts. However, any point along path 2 at T except for points A and B lies in a region of supersaturation. This supersaturation is relieved by the growth of $Ga_{1-x}Al_xAs$ crystal.

The volume ratio of the melt compartment to the melt trapped in the holder of the apparatus in Fig. 1 is 25. It should be possible by the proper selection of this volume ratio, as well as the growth temperature and melt volume, to grow any desired thickness of such a sublayered structure. We have successfully employed this apparatus to grow a heterojunction layer structure (6) in which the $Ga_{1-x}Al_xAs$ layers are 1μ thick and the GaAs p-type layer is 1μ. This structure has produced lasing thresholds as low as 3600 A/cm^2 for a 75μ x 300μ Fabry-Perot cavity at room temperature.

Acknowledgments

The author wishes to thank R. M. Potemski and J. Grandia for technical assistance in the crystal growth experiments and contributions to the apparatus design; J. D. Kuptsis for electron beam probe measurements; and A. Benoric for preparing the laser devices.

Nonaqueous Batteries with $LiClO_4$-Ethylene Carbonate as Electrolyte

Gianfranco Pistoia

Istituto Chimico, Università di Roma, Rome, Italy

ABSTRACT

An evaluation of the use of ethylene carbonate as a solvent for high-energy nonaqueous batteries has been performed. The results are compared with those obtained for propylene carbonate. A 1.0M $LiClO_4$-EC solution has higher conductivity, lower viscosity, and lower influence on the polarization of Li, CuF_2, and NiS electrodes than an analogous $LiClO_4$-PC solution. Discharge curves at 1.0 and 2.4 mA/cm^2, obtained under the same conditions in 1.0M $LiClO_4$-EC and PC solutions for Li-CuF_2 and Li-NiS cells, gave better results when EC was used. A test cell Li/1.0M $LiClO_4$-EC/CuF_2, capable of providing about 200 Whr/kg (outside casing excluded) when discharged at 1.0 mA/cm^2 at 30°C, has been fabricated.

Research on the development of high-energy nonaqueous batteries has been focused mostly on propylene carbonate (PC) electrolytic solutions.

In 1964, Elliott *et al.* (1) pointed out that addition of ethylene carbonate (EC) to such solutions improved the system by increasing the dielectric constant, decreasing the viscosity, and increasing the conductivity of the solutions. No further investigation on the use of this solvent in nonaqueous batteries has been reported since, however.

Pistoia, De Rossi, and Scrosati (2) have recently shown in a preliminary note some of the advantages of using EC solutions in electrochemical cells, for instance the higher specific conductivity with respect to the PC solutions. EC is solid at room temperature (mp 36.2°C) but the high molal lowering of the freezing point (5.5°C) can give liquid solutions at room temperature. Furthermore, the addition of only 9% PC is sufficient to obtain another 5°C decrease in the freezing point.

On the other hand, the use of EC solutions of low salt concentration, which are solid at room temperature, would significantly reduce the solubility shown by many substances used as cathodes (*e.g.*, CuCl, CuF_2, NiF_2, and others) and the resulting self-discharge processes. Batteries containing the above-mentioned solid EC solutions could be thermally activated and should need a very low activation energy because of the small temperature increase necessary to melt the solutions.

Electrolytic solutions in aprotic solvents must possess certain basic properties in order to be used in a battery; they must:

(*a*) be inactive toward the electrodes and, particularly, have low solubility effects toward the cathodic materials
(*b*) have sufficiently high conductivity to minimize the *IR* losses in voltage
(*c*) not appreciably influence the electrode polarization and allow high utilization coefficients, especially of the positive electrode

Key words: lithium, ethylene carbonate, nonaqueous batteries.

This work was carried out to see if these conditions are fulfilled for EC electrolytic solutions and if such solutions are more practical than those of PC.

To this end, viscosity and conductivity measurements of KCNS, KPF_6, and $LiClO_4$ in EC solutions, and solubility measurements of CuF_2 in solutions of $LiClO_4$ in EC at various concentrations, have been performed. Furthermore, polarization curves of Li, CuF_2, and NiS electrodes in $LiClO_4$-EC solutions and constant current discharge curves for cells having lithium anodes and CuF_2 or NiS as cathodes, respectively, have been determined. All results have been compared with those obtained under the same conditions for equivalent PC solutions.

As mentioned above, in addition to CuF_2, which is one of the most frequently used cathode materials (3) in primary organic batteries (the theoretical specific energy for the Li-CuF_2 couple is about 1660 Whr/kg), the NiS cathode was examined (the theoretical specific energy of the Li-NiS couple is 1100 Whr/kg).

The feasibility of using some sulfides such as CuS (4) and NiS (5) in organic batteries has been demonstrated recently. In particular, the nickel sulfide electrodes have been shown to be electrochemically active, capable of high-energy density values, and relatively insoluble in $LiClO_4$-PC. Also, for the sulfides it is possible to develop primary cells only, since Li_2S is apparently insoluble both in $LiClO_4$-PC and $LiClO_4$-EC solutions.

Experimental Section

Materials.—EC (Merck LAB product) was purified by the following vacuum (*ca.* 1 mm Hg) distillation procedures:

(*a*) without additives
(*b*) on Li ribbon
(*c*) on CaO
(*d*) on a molecular sieve (4A) after 2 days' storage.

Usually, 180 cm^3 of solvent were distilled, of which only the middle 60 cm^3 cut was employed. The distillation temperature was about 75°C, that of the pot about 110°C. The commercial product and the four

samples distilled as above were analyzed by gas chromatography. The conductivity measurements were obtained on the same samples (see below). For the preparation of all other solutions and of the cells to be discharged, the middle fractions of EC distilled on CaO were used.

PC (anhydrous Fluka product) was distilled under vacuum without additives.

$LiClO_4$ (anhydrous Fluka product), as received, contained 1.2% of water determined by the Karl Fischer method. Drying under vacuum for 3 days at 150°C reduced the water content to 0.5%. Fusion under vacuum at 260°C was more effective since, after this treatment, the water content was further reduced to 0.1%. Still, this is greater than the amount contained in the solvent after purification (see below).

KCNS (Erba product), KPF_6 (Alfa Inorganics product), and CuF_2 (anhydrous Ozark Mahoning product) were dried by heating under vacuum (10^{-3} mm Hg). NiS was prepared according to the method described by Jasinski (5), by reacting $NiCl_2 \cdot 6\ H_2O$ with $(NH_4)_2S$. The final product was washed with water and dried under vacuum. This salt also contained about 0.1% water.

Graphite (Southwestern 1651) and polyethylene powder were used as received (after drying) for the preparation of the electrodes. The lithium anodes and the molecular sieve (Type 4A, BDH product) for the purification of EC were also used as received.

Apparatus and technique.—Gas chromatography.—Gas chromatograms were obtained on a Perkin Elmer Model 880 instrument with a flame ionization detector, using a 2m stainless steel column, packed with 60-80 mesh chromosorb W coated with 20% Carbowax 1500. Helium was used as the carrier gas (flow rate, 50 cm^3/min). The column, injection block, and detector temperatures were held at 130°, 140°, and 130°C, respectively.

Water content determination.—The water content in the distilled EC samples and in $LiClO_4$ was determined by the Karl Fischer method using a Type TTA1/KF Radiometer apparatus connected to a Type TTT1 Radiometer titrator.

Specific conductivity.—For these measurements, a Type 4896 Tinsley bridge with a Heathkit oscilloscope as null detector and conductivity cells of the type described by Kraus (6) were used. For EC and PC solutions, a cell having a constant of 3.371 cm^{-1} has been employed. For the pure solvent samples, due to their high resistance, a cell having a lower constant, *i.e.* 0.2686 cm^{-1}, was used.

The specific conductivity (χ) *vs.* concentration (c) curves were obtained for the KCNS, KPF_6, and $LiClO_4$-EC solutions at 25.00° ± 0.02°C by the dilution technique. Concentrated solutions for each salt were prepared and the χ of these solutions was determined. Subsequently, weighed amounts of molten EC were progressively added and the resultant χ values were measured after thermal equilibration.

Solubilities.—The CuF_2 solubility at 30.00° ± 0.05°C in $LiClO_4$-EC solutions at various concentrations and in a 0.92M $LiClO_4$-PC solution was determined by adding CuF_2 to about 20 cm^3 of each solution and allowing these to equilibrate for 7 days in a stirred, thermostatted bath. Aliquots of the supernatants from saturated solutions were collected and the Cu^{+2} content determined polarographically with a differential cathode ray polarograph (Southern Davis Analytical, Type A 1660).

Polarization studies.—The lithium anodic polarization and the CuF_2 and NiS cathodic polarization, respectively, in $LiClO_4$-PC and EC solutions were obtained at 30°C by a Type 551 AMEL potentiostat with a Type 494 AMEL cell. A high impedance electrometer (610 C Keithley) was used to measure voltages between working and reference electrodes. In all polarization runs, a lithium sheet counterelectrode and a lithium rod reference electrode, placed near the working electrode, were used. The electrode dimensions were: lithium (working and counter), sheet of 1.8 x 1.0 cm; lithium (reference), rod of 0.8 cm diameter and 1.8 cm height; CuF_2 and NiS (prepared as described below), sheet of 1.5 x 0.7 cm.

The counter and working electrodes were separated about 0.8 cm by a frittered glass plate. The resistance between the working and reference electrodes was about 20 ohms at 30°C. It was found that the *IR* loss between them was not significant for this type of polarization study. In fact, on moving the reference electrode appreciably from the initial position (almost in contact with the working electrode), a maximum voltage change of only 0.05V was detected. This value is of the same dimension as the reproducibility of the polarization measurements. Therefore, no correction was made for this in the voltage data.

Current-voltage curve.—Two platinum electrodes (1.3 cm^2 sheet), separated by 0.1 cm, rigidly mounted in a Plexiglas holder, were dipped in a 1.0M $LiClO_4$-EC solution at 30°C, gently stirred by a water-free nitrogen flux. Variable voltages were supplied to the electrodes by a conventional battery connected to a potentiometer. Keithley electrometers were used to determine both voltages and currents.

Viscosities and densities.—Viscosities at 30.00° ± 0.02°C were determined by a Haake Falling Ball viscosimeter having a precision of about 0.3%. The densities of the solutions at the same temperature were measured with a conventional pycnometer.

Preparation of the solutions.—The handling of the solvents and of the salts for the preparation of the solutions was all done in a dry box under an argon atmosphere. KPF_6 and KCNS in EC and PC solutions showed a certain turbidity, perhaps due to some impurities in the salts. These solutions were filtered before use.

CuF_2 electrodes.—This type of electrode was initially prepared by spreading a paste obtained by dissolving in hot toluene a powder of CuF_2 (85%), graphite (10%), and polyethylene (5%) on a copper net (225 mesh). Before being pressed, the electrode was heated in an oven for 10 min at 90°C. Using this treatment, the adherence of the paste on the metallic support was very satisfactory. However, such electrodes, made with 200 kg/cm^2 pressure, do not have utilization coefficients higher than 15% at 0.5 mA/cm^2. Furthermore, on standing overnight, the performance of these electrodes was adversely affected.

CuF_2 electrodes, obtained by heating the powder in the same proportions under N_2 for 1 hr and pressing at 1000 kg/cm^2 (7), behave much better. Lower compacting pressures resulted in a poor adherence of the powder on the metallic support; higher compacting pressures lowered the utilization coefficient (7).

NiS electrodes.—This type of electrode was prepared according to the method of Jasinski (5). A powder made of NiS (90%) and graphite (10%) was pressed on a copper net electrolytically coated with nickel. This powder shows better adherence properties than that used for the CuF_2 electrode. Therefore, a pressure of 400 kg/cm^2 was sufficient to obtain a good adherence on the support. No attempts to further improve this type of electrode and the CuF_2 electrode were made for this work.

Cell assembly and discharge curves.—The cells were prepared by sandwiching a CuF_2 or NiS cathode (4.3 cm^2 surface each side), surrounded by a glass fiber separator (0.28 mm), between two lithium anodes of the same dimensions as the cathode. This assembly was dipped in an excess of electrolyte (about 15 cm^3 of EC or PC-$LiClO_4$ 1M solutions). External contact to the lithium anodes was made with alligator clips; the cathodes were spot-welded to silver wires.

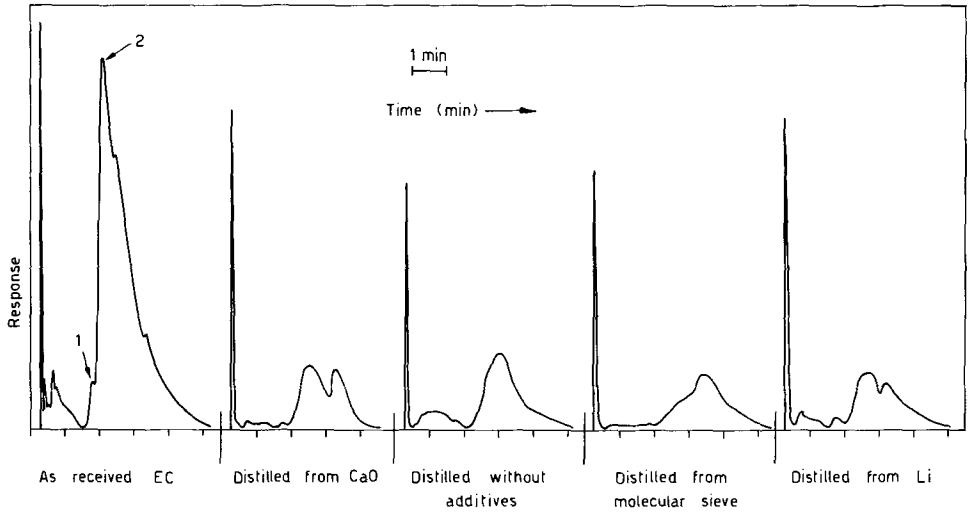

Fig. 1. Gas chromatograms of commercial EC and EC distilled under various conditions.

Approximately 0.6g of cathodic paste was used which corresponded to a nominal capacity of 0.27 A-hr for the CuF_2 electrodes (0.53 A-hr/g) and 0.32 A-hr for the NiS electrodes (0.59 A-hr/g).

The constant current discharges (1.0 or 2.4 mA/cm^2) at 30°C were usually run without interruption. Still, no appreciable changes in performance were detected even when the discharge was interrupted overnight. A Model 370 Keithley recorder connected to a Keithley electrometer was used to record the discharge curves.

Results and Discussion

Purification of the solvent.—In Fig. 1 are shown EC gas chromatograms before and after purification. The results obtained do not differ from each other significantly. Among the organic impurities, propylene glycol (PG, peak 1, 1.8 min retention time) and ethylene glycol (EG, peak 2, 2.2 min retention time) have been identified.

Using gas chromatograms of distilled EC containing 1% each of EG and PG for calibration, the commercial product was found to contain 2500 and 125 ppm, respectively, of these contaminants. In the several distilled materials which were prepared, the EG content is not appreciable and the PG content is 15-20 ppm. Jasinski (8) reports an increase in PG from 30 to 200-500 ppm on distilling PC over CaO. In our preparation of EC from CaO, however, all impurity levels decreased.

The experimental procedure under which the gas chromatograms were obtained is such that it was not possible to determine the water content of the samples. This quantity was measured instead by the Karl Fischer method and varied from 15 to 50 ppm for the several samples examined. Also, the results for a single sample, measured during multiple distillations, fell in this range, indicating the necessity to carefully avoid contamination by moisture.

In Table I are shown the specific conductivity values of various EC samples distilled under vacuum. The conductive impurity level seems to decrease from the sample distilled on a molecular sieve to the one distilled on CaO.

Current-voltage curve.—For a 1M $LiClO_4$-EC solution, the curve at 30°C has the shape shown in Fig. 2. The "decomposition potential" is about 5.7V. Clearly, this value has little significance because of its dependence on the electrode materials used.

Table I. Specific conductivities at 40°C of EC and PC ($ohm^{-1}cm^{-1}$ .10^7)

EC as received	51.7
EC distilled from molecular sieve	5.91
EC distilled without additives	4.19
EC distilled from Li	3.47
PC distilled without additives	2.07
EC distilled from CaO	1.51

Specific conductivity of the solutions.—The conductivity at 25°C of $LiClO_4$, KCNS, and KPF_6, respectively, in EC solutions, is shown in Table II. Solutions close to saturation were progressively diluted to observe the maximum in the χ *vs.* c curves. In the case of the KPF_6-EC solution, only one datum is reported since a decrease in concentration immediately caused the solution to solidify. For the KCNS and particularly the $LiClO_4$ solutions, on the contrary, overcooling experiments across a wide range verified that the solutions, even at low concentration, remain liquid at 25°C. For all salts, the maximum χ values are greater than those of PC solutions (2). In particular, the specific conductivity of a 1.0M $LiClO_4$-EC solution (7.8 x 10^{-3} ohm^{-1} cm^{-1}) is 1.4 times greater than that of a 1.0M $LiClO_4$-PC solution (5.6 x 10^{-3} ohm^{-1} cm^{-1}) (9).

Figure 3 shows the behavior of the conductivity *vs.* temperature for those solutions in which the maximum conductivity is seen. The behavior is linear and the $d\chi/dt$ values for KCNS, KPF_6, and $LiClO_4$ are 0.000307, 0.000263, and 0.000172 ohm^{-1} cm^{-1} $°C^{-1}$, respectively.

Viscosity of the solutions.—The viscosities at 30°C of 1*M* (molal) solutions of KPF_6, KCNS, and $LiClO_4$ in EC and PC were determined. The values obtained are reported in Table III where η_d is the dynamic viscosity and η_c the kinematic viscosity. The ratio η_d $LiClO_4$-PC/η_d $LiClO_4$-EC is 1.05, whereas the ratio of the specific conductivity of 1*M* solutions χ $LiClO_4$-EC/χ $LiClO_4$-PC is 1.5, and that of the equivalent conductances is 1.3 at the same concentration. Therefore, the higher conductivity, observed in $LiClO_4$-EC cannot be related to the lower viscosity only, but it is also due to a lesser amount of associated nonconducting forms

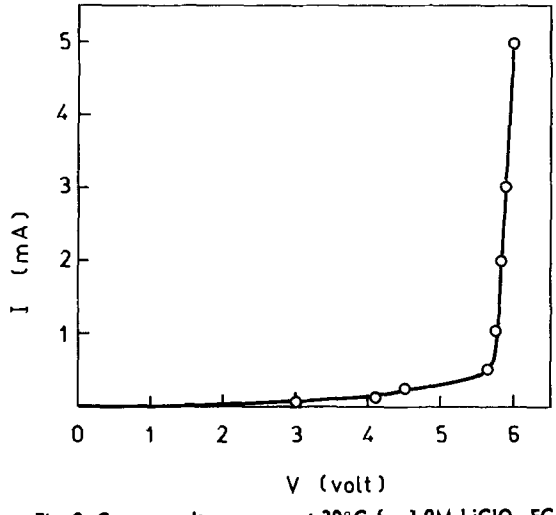

Fig. 2. Current-voltage curve at 30°C for 1.0M $LiClO_4$-EC

Table II. Specific conductivities at 25°C of EC solutions

Salt	c (g/100g solvent)	$\chi \cdot 10^3$ ($ohm^{-1} \cdot cm^{-1}$)
KPF_6	19.0	11.32
KCNS	9.0	11.40
	13.1	11.84
	16.1	11.62
	22.5	10.68
	25.3	10.07
	29.0	9.27
	32.0	8.50

KPF_6	4.82	3.36	4.87	3.78

Table IV. Solubility of CuF_2 in $LiClO_4$-EC and $LiClO_4$-PC solutions

$LiClO_4$ concentration (M)	Solubility, (moles/kg solution)
0.92 (in PC)	0.0085
0.84 (in EC)	0.0098
1.07 (in EC)	0.0079
1.47 (in EC)	0.0063
1.84 (in EC)	0.0062

(ion pairs and higher associated species), due to the higher dielectric constant of EC.

Solubility of CuF_2 in $LiClO_4$-EC and PC solutions.—The trend of the solubility of CuF_2 as a function of $LiClO_4$ concentration in EC is reported in Table IV. As observed in $LiClO_4$-PC solutions (3), the solubility decreases as the $LiClO_4$ concentration increases. This pattern could be related to an increase in the activity coefficients of the CuF_2 ions with the increase of the ionic strength of the solutions. The solubility of a 0.92M $LiClO_4$-PC solution shows that there is no appreciable difference between the two solvents. It is possible that the solubility of CuF_2 in $LiClO_4$-EC and $LiClO_4$-PC solutions is influenced by the occurrence of the reaction

$$CuF_{2(s)} + 2LiClO_4 \rightleftharpoons 2LiF_{(s)} + Cu(ClO_4)_2$$

One cannot exclude the possibility that the results obtained are affected to a certain extent by the incomplete drying of $LiClO_4$ (0.1% of water).

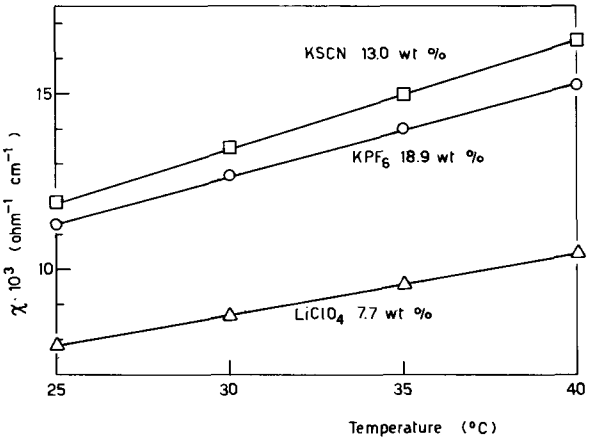

Fig. 3. Specific conductivity as a function of temperature for KPF_6, KCNS, and $LiClO_4$ in EC at the indicated concentrations.

With these values of solubility, it is obviously impossible to maintain Li-CuF_2 cells in activated storage. A test made on a cell Li/1.0M $LiClO_4$-PC/CuF_2, kept 8 days after preparation in a dry box at about 18°C, showed a decrease in the percentage of utilization of the cathode (from 53 to 14%) and in the average potential of discharge to a very low value (*ca.* 1.4V).

Polarization studies.—The behavior of Li, CuF_2, and NiS electrodes was investigated under forced discharge at various current densities (Fig. 4 and 5), using Li rod as a reference electrode; this is considered to be a satisfactory reference electrode in 1.0M $LiClO_4$-PC (10).

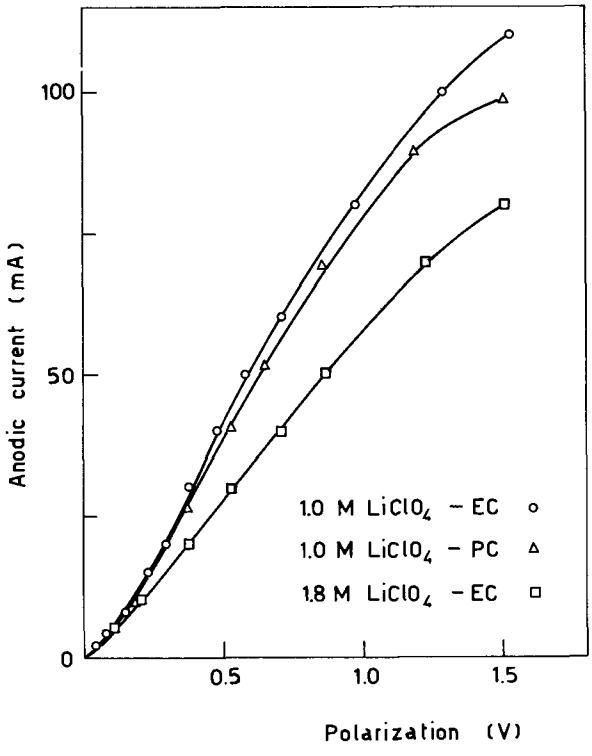

Fig. 4. Lithium anode polarization at 30°C in $LiClO_4$-EC and $LiClO_4$-PC solutions. Electrode surface 1.8 x 1.0 cm.

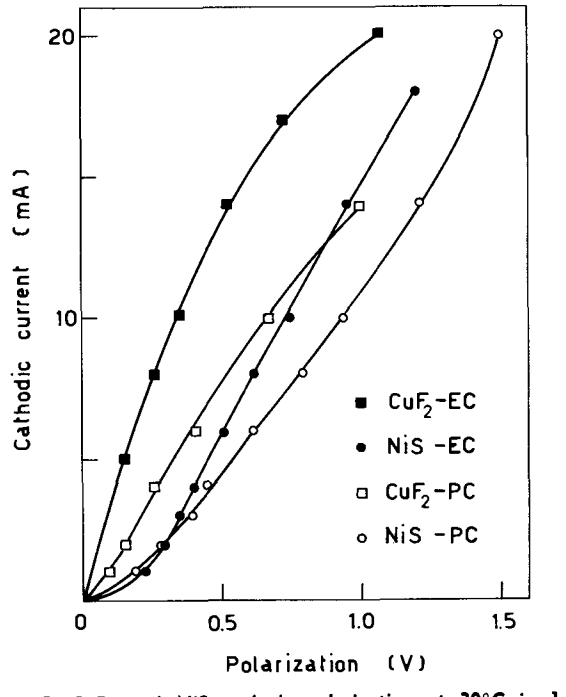

Fig. 5. CuF_2 and NiS cathode polarization at 30°C in 1.0M $LiClO_4$-EC and PC solutions. Electrode surfaces 1.5 x 0.7 cm, OCV 3.45V for CuF_2 and 3.25V for NiS vs. Li/Li^+.

Li seems to show a somewhat better anodic behavior in $LiClO_4$-EC than in the corresponding PC solution. A lower viscosity and a higher conductivity could explain this behavior. A 1.8M $LiClO_4$-EC solution, in fact, shows a more pronounced tendency toward polarization, for the same values of anodic current, with respect to a 1.0M solution having higher χ and lower η.

CuF_2 and NiS electrodes clearly seem to behave better in EC than in PC, probably because they are more sensitive than Li anodes to the effect of viscosity, and conductivity of the solutions. In fact, their reduction reaction involves Li ions

$$CuF_2 + 2\,Li^+ + 2e \rightarrow Cu + 2\,LiF$$

so that the transport of these ions from the bulk of the solution to the cathode could be the rate-determining step.

The polarization seems to be more severe for NiS than for CuF_2, particularly at low current densities. As suggested by Jasinski (5), it is possible that a certain amount of S is present in NiS, this making the OCV *vs.* Li/Li^+ (3.25V) quite high and accounting for the initial rapid decay in voltage. No difference in the polarization behavior was observed between two NiS electrodes prepared at different compacting pressures (400 and 1000 kg/cm^2, respectively).

Cell discharge.—Discharge curves at 1.0 and 2.4 mA/cm^2 for Li-CuF_2 cells are reported in Fig. 6 and those for Li-NiS cells in Fig. 7. The utilization coefficient of CuF_2 in the two solvents at 1 mA/cm^2 (53%) is in agreement with the work of Boden for 1.0M $LiClO_4$-PC (7). At the same discharge current density, the utilization coefficients are practically the same in EC and PC, but the curves in EC have substantially higher V values. The curves for Li-NiS cells show not only higher V values, but also higher utilization coefficients in EC. These results were to a certain extent expected on the basis of the polarization behavior of the positive electrode and of the viscosimetric and conductometric data obtained for $LiClO_4$ solutions in EC and PC. At 30°C the conductivity of 1.0M $LiClO_4$ in EC is 8.68 x 10^{-3} ohm^{-1} cm^{-1}, whereas that of 1.0M $LiClO_4$ in PC is 5.81 x 10^{-3} ohm^{-1} cm^{-1}, the latter value being in agreement with that found by Keller at 25°C (9). This higher specific conductivity in $LiClO_4$-EC is especially beneficial in reducing the concentration polarization resulting from the low electrolyte transport rate. This is also the main cause of the decrease observed in the utilization coefficient of the cathode when discharge current density varies from 1.0 to 2.4 mA/cm^2.

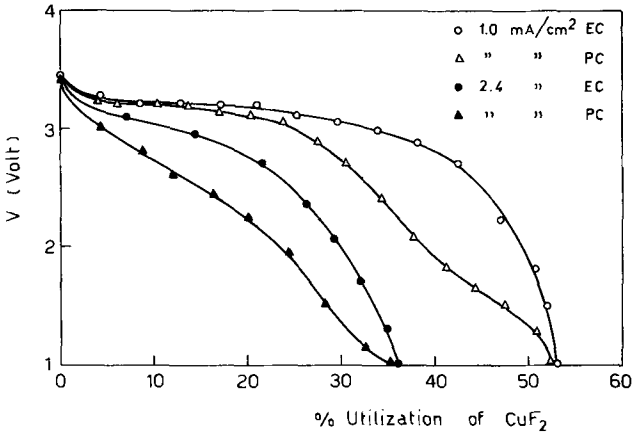

Fig. 6. Discharge curves at 1.0 and 2.4 mA/cm^2 at 30°C for Li-CuF_2 cells in 1.0M $LiClO_4$-EC and PC.

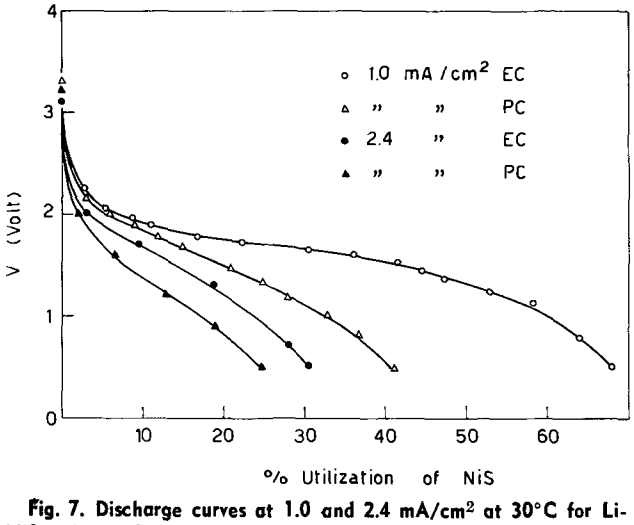

Fig. 7. Discharge curves at 1.0 and 2.4 mA/cm^2 at 30°C for Li-NiS cells in 1.0M $LiClO_4$-EC and PC.

The difference shown by the curves of the Li-NiS cells at 1.0 mA/cm^2 in the two solvents is exaggerated; some unknown factor might have increased the difference in favor of the cell containing $LiClO_4$-EC.

A calculation of the watthours obtained per weight of CuF_2 or NiS in the discharges at 1.0 mA/cm^2 gave the following results: 0.80 Whr/g(CuF_2) and 0.62 Whr/g(NiS). Therefore, the higher average potential of discharge shown by CuF_2 counterbalances the lower utilization coefficient.

Discharge at 1.0 mA/cm^2 was repeated in a cell Li/1.0M $LiClO_4$-EC/CuF_2 in which the weights of the various components (electrodes, electrolyte, and separator) were minimized, except for the outside casing. In particular, a lightweight steel net (4.3 cm^2, 0.16g) was used in place of the copper net as a positive electrode support (0.6g of a cathodic paste); the electrolyte was reduced to the minimum amount (0.8g) required to avoid decrease of the utilization coefficient of CuF_2 (7). Under these conditions, a specific energy of 195 Whr/kg was measured (outside casing excluded). This value could be increased, for example, by increasing the ratio between the weight of the cathodic paste and that of the metallic support or by using a lighter separator. The increase in the total weight due to a lightweight polyethylene case is about 12% (7).

Conclusion

Electrolytes in EC (in particular, $LiClO_4$) and Li, CuF_2, and NiS electrodes in $LiClO_4$-EC solutions seem to behave better than in PC solutions. Discharge curves obtained under the same conditions in the two solvents confirm that EC can be advantageously used in high-energy nonaqueous batteries. At the moment, cells containing an EC solvent obviously have a minimum temperature range limit. This limit can be lowered either by adding PC or by using another salt capable of lowering the EC freezing point still further. On the other hand, solid solutions of electrolytes in EC could solve shelf-life problems in the activated storage of these cells, providing that the cathodes are mechanically stable, *i.e.* not deformable during the solidification. Due to the low temperature gradient necessary for a completely liquid solution, a low activation energy would be required for such thermal batteries.

The Mechanism of Adhesion Failure of Plated Plastics in Corrosive Environments

R. R. Wiggle,* V. Hospadaruk,* and D. R. Fitchmun

Ford Motor Company, Dearborn, Michigan 48121

ABSTRACT

The mechanism of adhesion failure of plated ABS and polypropylene (PP) plastics exposed to service conditions was determined. Adhesion failure, through the formation of blisters, proceeds by a corrosion mechanism which involves (*a*) the rapid lateral anodic dissolution of the thin electroless nickel layer at the plastic-metal interface or (*b*) the relatively slower preferential dissolution of an electroless copper layer and the equally reactive adjacent electrodeposited copper layer. The rate of lateral development of blisters is related to the surface topography of the etched plastic substrate. The high-density crack patterns and surface roughness of etched PP provide a greater path length for the anodic dissolution of the thin electroless nickel layer—thereby retarding the lateral undercutting more than with a plastic which has a relatively smooth etched surface (ABS). When the less reactive electroless copper is present in a copper-nickel-chromium system, the plastic substrate surface topography has no effect on the lateral rate of blister development. The weaker tendency toward blister formation is due to preferential corrosion of the relatively thick, two-layered copper deposit.

The use of electroplated plastics has increased dramatically since the commercialization of electroplated ABS plastic. The commercialization was due in large part to the development of molding and process conditions which gave measurable adhesion between the electrodeposit and plastic.

When electroplated plastics became a reality, it was erroneously felt that, since the plastic is a noncorrodible substrate, highly corrosion-resistant electroplating systems were not needed. However, it was soon apparent that the outdoor service performance of plated ABS was frequently not satisfactory and even with good corrosion-resistant systems had a tendency to develop excessive blistering and premature failure. Saubestre and co-workers (1) studied the nature of corrosion of electrodeposits on ABS and found that blistering failure was common. They used the CASS and Corrodkote accelerated corrosion tests in the study and the results showed that sacrificial corrosion in the electrolytic copper layer was the main cause of blistering failure; of secondary importance was the electroless metal. All-nickel decorative coatings tended to blister at or near the plastic-metal interface for reasons not established.

After the advent of electroplated crystalline polypropylene (PP), early service exposure data for some of the specimens showed that it was superior to plated ABS. Adhesion of the electroplate to the plastic was also substantially greater. Innes (2), in comparative study of plated ABS and PP, verified the superior performance of PP. The results were derived from environmental and accelerated tests. Innes did not determine the underlying mechanism of blister failure, but for ABS suggested that moisture absorption, sensitivity to molded-in stresses, and adhesion fluctuations were important factors.

Service exposure results of electroplated plastics showed that a large portion of the blister failures occurred in corrosive environments and seemed to involve the plastic-metal interface. The first consideration was to determine if one of the primary factors was the preferential corrosion of the electroless metal deposits. In agreement with others, it was found that the performance of plated PP was also markedly better than ABS. It was important to understand the reasons for the substantially better service performance and plastic-to-metal adhesion of the PP and the mechanism of failure of both plated ABS and PP. This paper describes the mechanism of blister failure which occurs during exposure of plated ABS and PP to corrosive *service* environments.

Experimental Methods

Service corrosion specimens.—The plated plastic corrosion specimens used in the determination of the failure mechanism were from the Ford Exposure Program. The specimens were exposed to chloride road deicing salts on trucks fitted with special racks. The specimens were flat, 3 x 4 in. panels of ABS and PP, supplied by Marbon Division, Borg-Warner Corporation, and Avisun Corporation, respectively. They were chemically plated with the MacDermid Inc. MACuplex RT process, an alkaline hypophosphite electroless nickel. The electrolytic deposits used were nickel strike (Watts), copper (Udylite UBAC), semibright nickel (Harshaw Perflow), bright nickel (Udylite 66), and chromium (conventional).

* Electrochemical Society Active Member.

Key words: adhesion failure, plated plastics, corrosion.

Reactivity studies.—The relative reactivities of the various deposits were determined by anodic polarization using potentiodynamic techniques. The electrolyte consisted of 1.0 normal sodium chloride (reagent grade in distilled water) at pH 6.0-6.5 which approximates outdoor service electrolytes. The electrolyte was carefully deaerated with prepurified nitrogen for at least 2 hr before the test specimens were immersed. The specimens were immersed at open circuit for a minimum of 1 hr before polarization at a rate of 10 mV/min where the electrode potential was measured relative to a saturated calomel electrode (SCE).

Thermal cycle testing.—Panels were thermal cycled in order to determine if adhesion failure due to thermally induced stresses was significant. All panels used in thermal cycle testing were plated on one side only. This was designed to yield high stresses at the plastic-metal interface resulting from the high differential in the coefficients of expansion for the metal and plastic. The test procedure consisted of the exposure of the panels to the following sequence of temperatures: (*a*) 180°F for 2 hr; (*b*) ambient temperature for 1 hr; (c) −20°F for 2 hr; and (*d*) ambient temperature for 1 hr. This constitutes one cycle.

Results and Discussion

Service performance.—Examination of service exposed panels indicated that good adhesion of decorative plated systems to a plastic substrate does not guarantee good over-all service and corrosion performance. An examination of failed service parts showed the presence of blisters with gradations from fine blisters barely visible to the naked eye to massive detachment of the electrodeposit. The number and size of the blisters were greater on the service parts exposed to the more severe corrosive environments indicating that blistering is related to corrosion attack. Indeed, examination of the exterior of the blisters revealed the presence of a corrosion pit in the center of each blister.

The association of corrosion pits with all of the blisters examined indicates that blister failures solely due to thermally induced stresses normally encountered in service are not significant. This observation was verified by thermal cycle studies of both plated ABS and PP panels. PP panels plated with various composite coatings withstood as many as 20 thermal cycles with no evidence of adhesion loss. Similar results were obtained with plated ABS subjected to 3 thermal cycles. However, the possibility that blister failure, in some instances, may be accelerated by extreme thermal environments is not disregarded.

Some of the metal films on failed service parts were mechanically stripped from the plastic substrate in order to examine the underside or interior of the blisters as shown in Fig. 1. Region A is the underside of the electrodeposit stripped from the surface of an ABS panel and folded back. Region B is the surface of the ABS panel. The periphery of the blisters is indicated by C, and in the centers of the blisters are corrosion pits, D, which extend through the electrodeposit. When the pits are close together, the blisters that develop often coalesce to form larger blisters. The darker rings or bands, E, of corrosion products are probably due to a variable corrosion rate in service. The electron microprobe scanned across these rings or bands, both on the underside of the electrodeposit and the surface of the plastic, revealed the presence of phosphorus-rich residues.

As-plated electroless nickel from hypophosphite baths is not pure nickel but is a nickel-phosphorus alloy (3). Phosphorus is incorporated in the deposit as a result of complicated side reactions which occur during the oxidation of the hypophosphite reducing agent.

Again referring to Fig. 1, a thin layer of plastic, F, adhering to the underside of the electrodeposit is present when deposits with intact plastic-metal interfaces are mechanically stripped. The fracture presumably occurs in a weakened polymer surface layer formed during the etch step. The undersides of the blisters are free of plastic—indicating an essentially electrochemical "detachment" of the metal coating at the plastic-metal interface through anodic dissolution of the electroless deposit.

These results indicate that blister formation is associated primarily with the preferential corrosion of the electroless nickel layer.

To further characterize the exact location of the failures, cross sections of the service blisters were analyzed by optical microscopy and the electron microprobe. Figure 2 is a cross section of a representative service blister showing the center of the corrosion pit, A. The center portion of the blister is shown on the right, and the edge showing the intact plastic-metal interface on the left. The composite system includes ABS plastic, electroless nickel (not

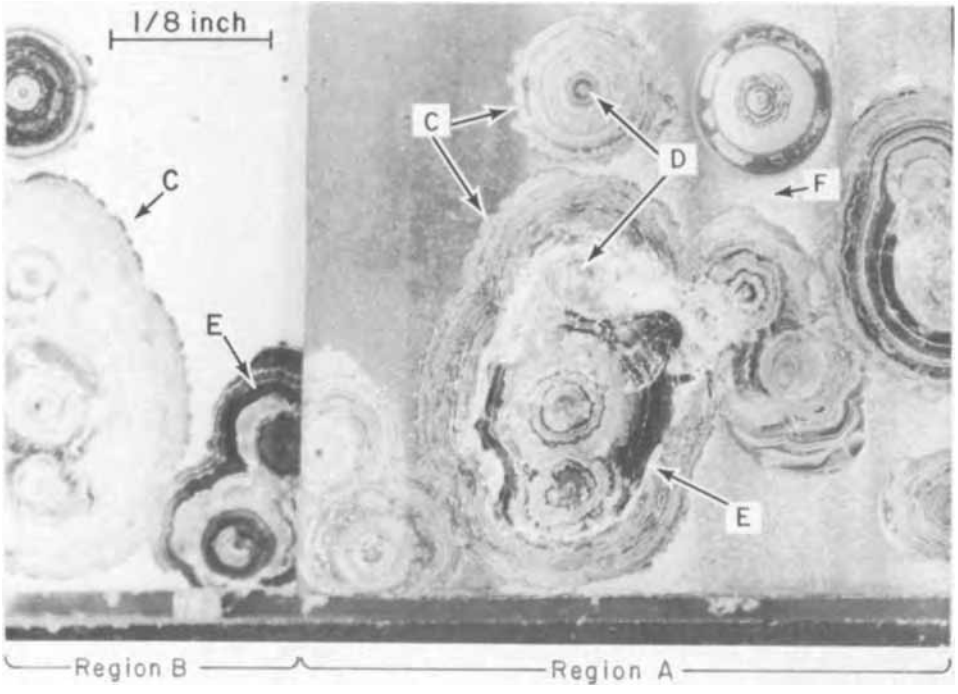

Fig. 1. Underside of blistered electrodeposit mechanically stripped from plastic substrate on failed service part.

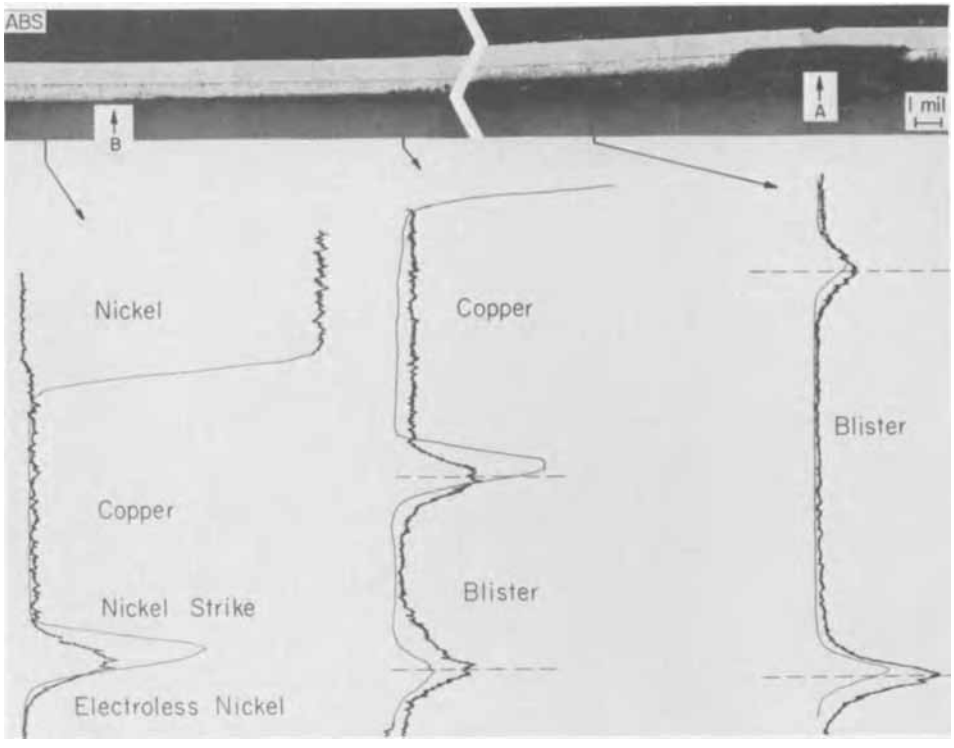

Fig. 2. Cross section of service blister showing location of failure with the aid of electron microprobe traces for phosphorus and nickel.

visible), nickel strike, copper, duplex nickel, and finally chromium. Corrosion has proceeded from the corrosion pit, A, to point B, beyond which the interface is intact. Optical photomicrographs indicated that the corrosion followed a path on the underside of the electrodeposit at or near the plastic-metal interface. The electron microprobe was scanned across the interface and blister void at the points indicated to determine the presence and relative concentrations of two elements, phosphorus and nickel. The phosphorus trace is the complex dark line and the nickel trace is the finer line, with increasing concentration of the elements from left to right along the horizontal axis. The microprobe scanned across the intact interface showed the presence of phosphorus and nickel in the electroless nickel layer, pure nickel in the nickel strike layer, and, of course, no nickel in the copper region and only pure nickel in the duplex nickel region. The middle microprobe traces across a portion of the blister (the separation distance indicated by the region labeled "Blister") showed the presence of phosphorus and nickel residues on the surface of the plastic, and phosphorus and nickel residues plus pure nickel (from the nickel strike) on the underside of the electrodeposit. At another portion of the blister with a wider separation, the microprobe showed the presence of phosphorus and nickel residues both on the plastic surface and underside of the electrodeposit.

Microprobe results of other systems gave similar results and it is concluded that apparent adhesion failure and blisters are related to corrosion in the thin electroless nickel layer. Whether the electrodeposit adjacent to the electroless nickel layer is nickel or copper appears to have little effect on the mode of corrosion after the corrosion pit reaches the electroless nickel deposit. Furthermore, the preferential lateral corrosion of the electroless nickel layer indicates that it is more reactive than the other metals of the composite.

Reactivity studies.—In order to investigate the unusually high anodic reactivity of the electroless nickel, polarization studies were conducted of the various metals deposited. Figure 3 shows the results of anodic polarizations in neutral 1.0M (molar) sodium chloride.

Semibright nickel is the least reactive of the electrodeposited metals followed in order by bright acid copper and the highly reactive bright nickel. The anodic reactivity of electroless copper is identical to that of electrodeposited copper. The polarization curve for electroless nickel shows a definite increase in anodic reactivity, even greater than that of the highly reactive bright nickel. This shows that sacrificial corrosion of the electroless nickel layer can readily occur. After a corrosion pit has penetrated to that layer, it is preferentially dissolved producing blisters by lateral undercutting.

From the data presented so far, it would seem to indicate that the use of a less reactive electroless nickel would be advantageous for service performance. The relative reactivities of other commercial electroless nickel deposits in sodium chloride solution have been determined, two of which are shown in Fig. 4.

Curve A is the reactivity of an electroless nickel deposit containing 4.5 w/o (weight per cent) phosphorus, obtained from the MacDermid 9340 alkaline hypophosphite bath used in most of these corrosion studies. Electroless nickels deposited from commercial acid hypophosphite baths (curves B and C) incorporated a higher weight per cent of phosphorus. Unexpectedly, the relative reactivities are less and the anodic polarization curves approach that for the highly reactive bright nickel shown by the dashed line. Nevertheless, the polarization study has shown that all of the commercial electroless nickels investigated are more reactive than the other metals in neutral and acid chloride media.

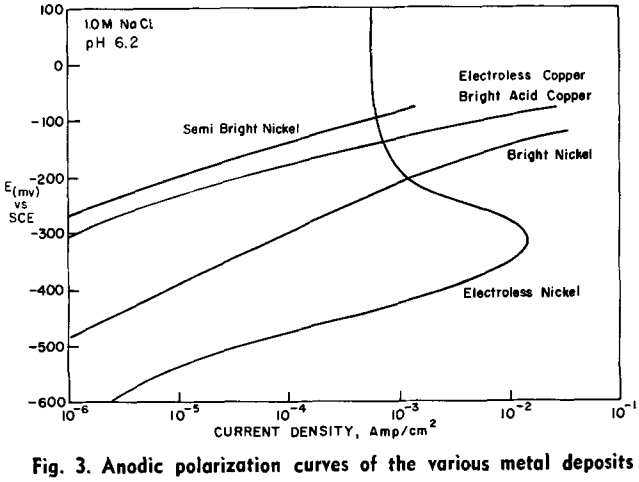

Fig. 3. Anodic polarization curves of the various metal deposits used on the plastics.

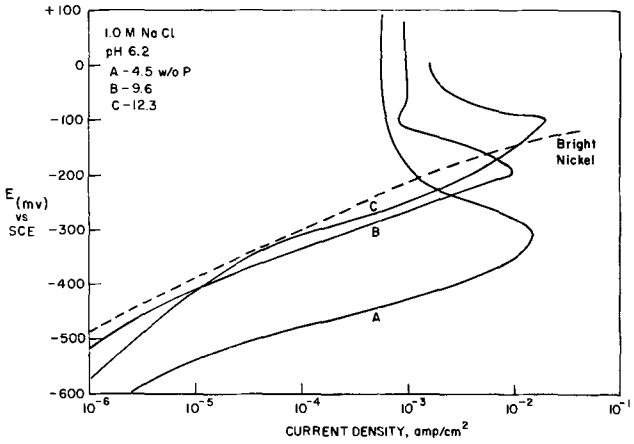

Fig. 4. Anodic polarization curves of some commercial electroless nickel deposits, A, B, and C, containing different amounts of phosphorus. Curve for bright nickel included.

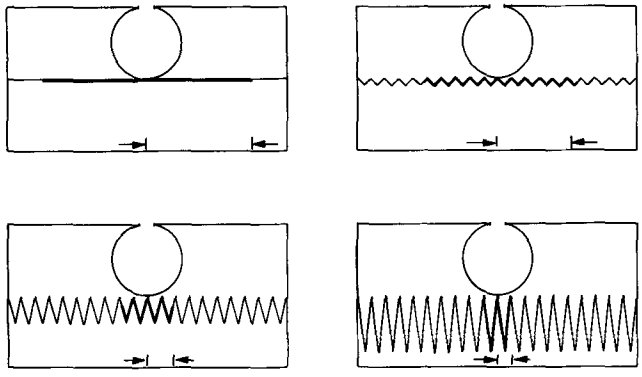

Fig. 6. Schematic showing relationship between surface roughness and degree of lateral undercutting.

It is known that an increase in nickel reactivity can be effected by addition of certain elements to the metal. The effect of the additives on the anodic reactivity of *electrodeposited* nickel was studied by DiBari and Petrocelli (5). Small amounts of the elements sulfur, selenium, tellurium, and phosphorus increased the reactivity of nickel, where the relative reactivities were related to the element electronegativities.

Growth rate of blisters.—Although the investigation had shown that the undercutting and blistering phenomenon is due to the rapid preferential corrosion of the electroless nickel (4.5 w/o P) layer, it was not readily apparent why the blistering tendency for ABS was much greater than for PP with systems using this electroless nickel. To understand the difference, cross sections of plated ABS and PP were studied with a high magnification microscope and electron microprobe.

Figure 5 shows service blisters on ABS and PP substrates polished to the center of the corrosion pit. The electrodeposited systems are the same in both cases and composed of electroless nickel, nickel strike, bright acid copper, duplex nickel, and finally chromium. Blisters on the ABS were 10-100 times larger in diameter than those on the PP. The lower photographs are enlargements of the blister edge and intact plastic-metal interface. Metal filled cracks are clearly visible which extend into the surface of the PP. These characteristic cracks are produced in the surface of the PP, a semicrystalline polymer, by the pretreatment steps (swellant and etchant) of the chemical plating process. The amorphous regions of the PP which are swollen in the hot organic conditioner are oxidized at a greater rate than the crystalline regions in the hot chromic acid producing a cracked surface.

The electron microprobe showed that most of the metal in the cracks is nickel strike. Microprobe studies of both systems showed that the corrosion path is confined essentially to the very thin electroless nickel layer present on the polymer surfaces. For ABS with its relatively smooth interface, corrosion follows a relatively straight lateral path, while, for PP, corrosion has to follow a tortuous path around each of the cracks. Even if the same amount of electroless nickel were anodically dissolved in both cases, the lateral distance of undercutting is less for the PP. This is schematically illustrated in Fig. 6.

Assuming the same amount of electroless nickel anodically dissolved in all cases (darker line), a reasonable conclusion would be that the rougher the surface topography of the plastic substrate, the less would be the distance of lateral undercutting and hence the tendency for blister formation to occur.

This was verified by corroding specially prepared samples of PP in a 1.0M sodium chloride, 0.02M ferric chloride solution. The samples were electroplated with 0.5 mil of bright nickel and 10 μin. of regular

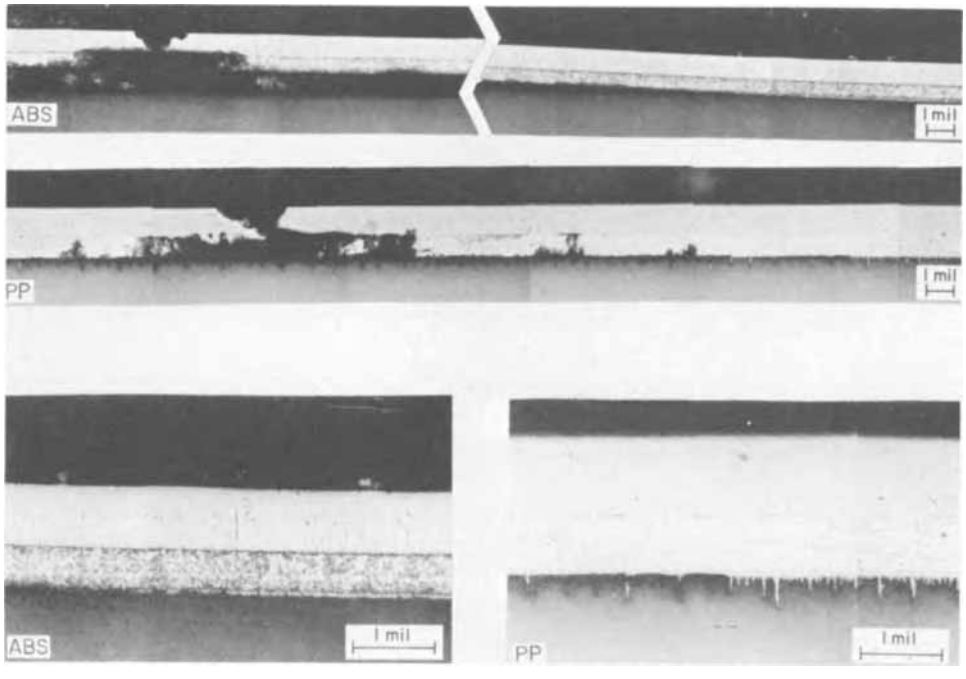

Fig. 5. Cross sections of service blisters on ABS and PP showing relative blistering tendencies.

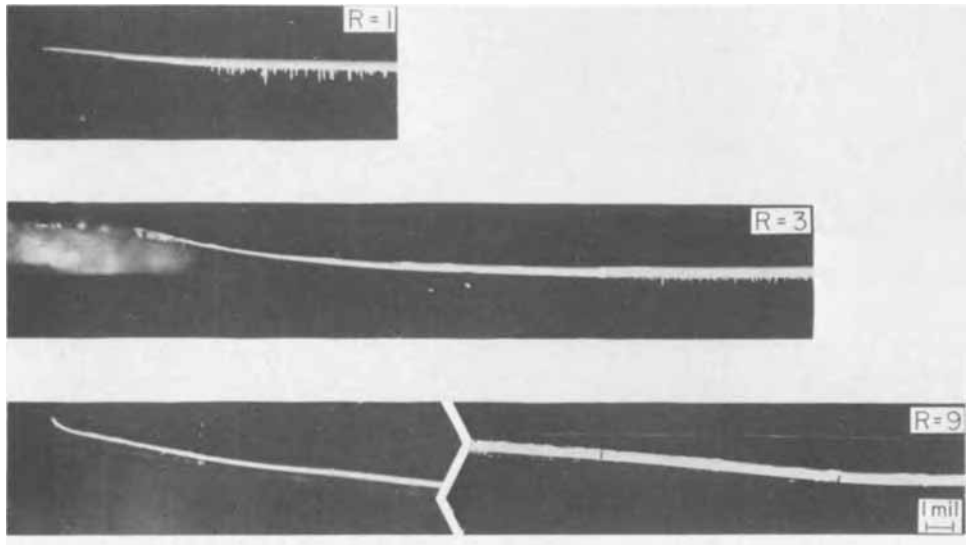

Fig. 7. Cross sections of specially prepared PP samples showing relation of crack pattern and surface roughness to rate of lateral development of blisters. R is the relative blister radius.

chromium. The PP panels were injection molded using conditions determined to produce a surface morphology amenable to uniform crack pattern development (4). The crack depth and density were deliberately varied, by using several combinations of swell and etch times, from 10 to 15μ (top photograph) to essentially a smooth interface (bottom photograph).

Photomicrographs of cross sections of blisters formed on these specimens are shown in Fig. 7. Only half of each blister is shown, the left edge of the photograph corresponding to the center of the corrosion blister. Using the relative radius (R) of the blister in the top photograph as 1, it can be seen that the radius of the blisters increases with decreasing crack depth. In the bottom photograph, with a relatively smooth substrate, the blisters were about 10 times wider than those in the first case.

As with service performance, these results show that there is a direct relation between the surface topography or roughness and service performance. The rate of lateral blister development is related to the crack pattern and type of surface roughness of the etched plastic substrate. Complex crack patterns provide a greater path length for the anodic dissolution of the thin electroless layer—thereby retarding the lateral undercutting more than with an etched plastic which has a relatively smooth surface.

It should be noted that adhesion values for plated plastics as determined by the Jacquet Peel Adhesion Test (6) do not necessarily reflect the blister formation tendency in corrosive environments. As shown above, any increase in crack density and depth yields a corresponding increase in resistance to blister formation. However, adhesion values represent a balance between crack depth and diminished surface strength incurred in the etch step (4). Although adhesion usually increases with crack depth, overetching may actually decrease adhesion even though the crack depth has been increased. For maximum resistance to blister formation, care must be exercised in the control of the molding operation and the pretreatment steps of the plating process to produce plastic surfaces yielding optimum adhesion values without excessive degradation of the plastic substrate.

To complete the picture of the failure mode, it was essential to determine the effect of surface roughness with a less reactive electroless metal. One particular combination of interest involved the use of electroless copper, whose anodic reactivity is identical to the adjacent electrodeposited copper. Unfortunately, no plated PP systems containing electroless copper had been exposed to service for comparison to ABS. However, plated polysulfone (PS) exhibits surface cracking similar in nature to PP, and was used for comparison, shown in Fig. 8.

The metal deposit is composed of electroless copper, bright acid copper, duplex nickel, and chromium. Examination of the blisters of this plating system shows a corrosion mechanism different from that obtained with systems containing electroless nickel. Corrosion is not confined to the electroless metal layer and the blisters are due to preferential corrosion in *both* the electrodeposited and electroless copper layers. No further undercutting has occurred past the points visible in the photograph. The blisters on the plated ABS and PS panels are very small and equal in size.

The data indicate that, as the reactivity of the electroless metal decreases and approaches that of the adjacent electrodeposited layer, the effect of the plastic surface topography on the lateral rate of blister development diminishes. Retardation of the blistering tendency should be evident if less reactive electroless nickels are used and studies with such nickel deposits are in progress.

Conclusions

The adhesion failure mechanism for ABS and PP plated plastic parts involves the formation of blisters by the preferential corrosion of the thin, highly reactive electroless nickel layer. The rate of lateral development of blisters for electroless-nickel-containing systems is related to the surface topography of the etched plastic substrate. Plastic substrates with rougher surface topography (etched PP) retard lateral

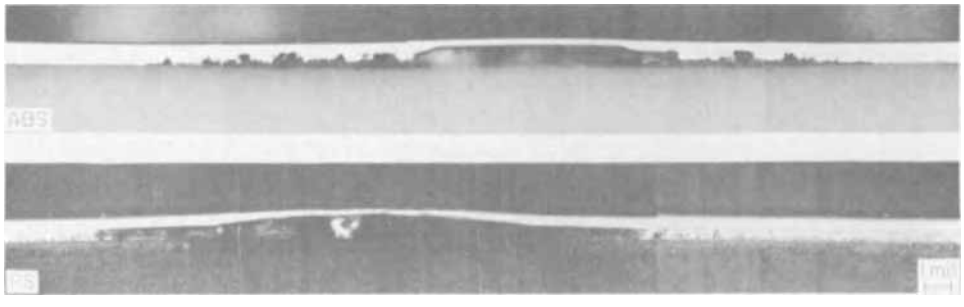

Fig. 8. Cross sections of service blisters showing the combined effects of surface roughness and electroless metal reactivity on the rate of lateral development of blisters.

undercutting more than those with relatively smooth surfaces such as etched ABS.

The lower blister forming tendency for coatings containing electroless copper is due to the essentially equal reactivities of the electroless and adjacent electrodeposited copper layer. The plastic surface topography has no effect on the lateral rate of blister development for coatings which have electrodeposited copper on electroless copper.

Premature failure of plated plastics may be avoided by the use of: (*a*) less reactive metals on the plastic substrate such as electroless copper or less reactive electroless nickel deposited from an acid hypophosphite bath; (*b*) plastics with uniformly cracked surfaces such as properly prepared PP; and (c) suitable composite coatings designed to retard corrosion pit penetration to the electroless metal layer.

Chromium Deposition from Dicumene-Chromium to Form Metal-Semiconductor Devices

N. G. Anantha, V. Y. Doo,* and D. K. Seto*

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Thin chromium films were deposited on silicon openings of oxidized silicon wafers by thermal decomposition of dicumene chromium (DCC) in an argon atmosphere at temperatures between 350°-520°C. The metal-silicon interface thus obtained was characterized by current-voltage and capacitance-voltage measurements. The interface exhibited a rectifying effect and functioned as a Schottky barrier junction. A barrier height of 0.59 ± 0.02 eV with respect to Fermi energy was obtained. The switching speed of the Schottky barrier diodes was found to be less than 0.1 nsec. The electrical properties of the chromium films obtained under various conditions are discussed. This chemical deposition technique, where chromium containing a small amount of carbon can be deposited, gives high quality Schottky barrier diodes.

Fisher and Hafner (1) found that in dicumene chromium (DCC) the chromium atom is attached to two cyclic hydrocarbons by electrons shared with the organic rings. They pointed out that in this unusual type of bonding, the chromium atom is in a metallic or zero-valent state. Consequently, pyrolytic decomposition of DCC occurs readily in the absence of any reducing agent such as hydrogen. Also, because of loose bonding between the chromium atom and the organic rings, the chromium films thus deposited are less contaminated with carbon and oxygen than those from chromium carbonyl (2, 3). Consequently, it appears that the deposition of chromium films by the pyrolytic decomposition of dicumene chromium would be a highly desirable method for making Schottky barrier devices. The purpose of this paper is to demonstrate the feasibility of using just this approach to make excellent Schottky diodes.

Experimental Procedures and Results

The apparatus used for the deposition of chromium by the chemical vapor decomposition of DCC is similar to those horizontal reactors used in depositing epitaxial silicon (4). Briefly, it consisted of a feed system and a quartz reactor (Fig. 1). The feed system consisted of pressure regulators, flow meter, valves, and a DCC vapor generator. To have a realistic deposition rate, the DCC vapor generator was heated to 195°C to obtain a vapor pressure near 12 mm of Hg. The argon carrier gas passed through the vapor generator at a rate of 100 ml/min. The gas lines from the vapor generator to the reactor were heated to minimize the condensation of DCC. The main gas line argon had a flow rate of 2.4 liters/min. The DCC was transferred and kept under argon at all times; this prevents exposure to air and the formation of DCC-hydroxide which does not decompose thermally. A vitreous carbon susceptor was placed in the 50 mm diameter quartz reactor. The susceptor was used as the substrate holder and was inductively heated to deposition temperatures with a megacycle rf generator.

The deposition temperature covered in this work was 350°-520°C, a range desirable for Schottky barrier work. Within the temperature range and gas flow conditions stated above, the deposition rate varied from 45 to 65 Å/min as shown in Fig. 2; note that the peak deposition rate appeared at about 450°C. A deposition rate peak is often observed in chemical vapor deposition systems (4, 5). The deposition rate can be raised to much greater than 60 Å/min by increasing the DCC partial pressure in the reactor. However, our primary objective was to find the most desirable way to

fabricate the high-quality Schottky barrier diode's abrupt metal-silicon interface, rather than to investigate the wide range of the chromium deposition kinetics. Because the resistivity of the deposited chromium films was indicative of impurity contamination, the film resistivity was carefully determined. The measured resistivity of the deposited Cr films was plotted as a function of deposition temperature as shown in Fig. 3. The resistivity decreased rapidly with increasing deposition temperature in the 320°-380°C range. The decrease in resistivity due to the increase in deposition temperature above 380°C was at a much slower rate. This latter result is indicative of different contaminating influences; it is surmised that the reaction products within the desired chromium film

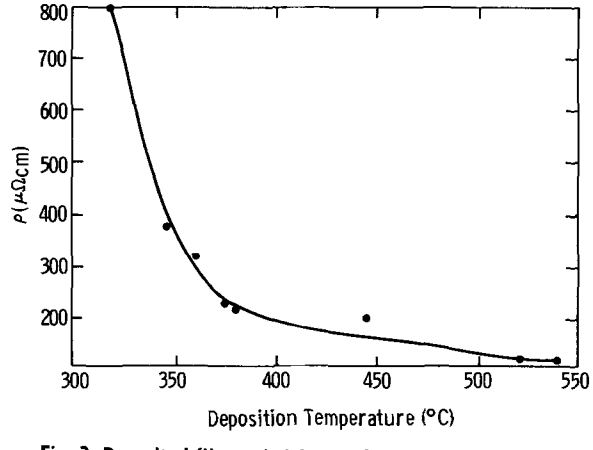

Fig. 3. Deposited film resistivity vs. deposition temperature

below 380°C contain organic contaminants. Above 380°C, the contamination is believed to be only carbon since Knap *et al.* (6) reported only moderate variations of carbon content for large deposition temperature changes. The low change rate of resistivity above 380°C deposition temperature leads to the desired operating temperatures to form Schottky barrier diodes utilizing chromium contaminated with carbon.

For the fabrication of Schottky barrier diodes, epitaxial silicon on heavily doped silicon substrate wafers was used. The substrate wafers had (100) orientation and were "chem-mech" polished using the cupric ion process (7). The epitaxial layer was 4μ thick with a resistivity of 0.25 ohm-cm. The substrate resistivity was 0.002 ohm-cm. After epitaxial deposition, the wafers were oxidized at 970°C using a dry-wet-dry process. Oxide windows were opened using regular photolithographic techniques. The wafers were then placed on the carbon susceptor and a 1200Å layer of chromium was deposited using the above method at 405°C. A high-conductivity metal layer was built on top of the deposited chromium. The oxide windows were 1 mil in diameter; metal patterns 3 mils in diameter were etched using regular photolithographic techniques. The diodes thus formed were diced using an ultrasonic cutter; the chips were mounted on TO-18 headers.

A typical current-voltage measurement of a silicon-chromium diode is shown in Fig. 4. The current-voltage relationship of a Schottky barrier diode can be expressed as

$$J = J_S \{e^{qV/nkT} - 1\} \quad [1]$$

where J is the current density
J_S is the saturation current density, and is given by

$$J_S = A^* T^2 \exp(-q\phi_b/kT) \quad [2]$$

ϕ_b is the barrier height in volts
V is the applied voltage
A^* is the modified Richardson constant
T is the absolute temperature
k is the Boltzmann constant
n is the diode ideality factor. For an ideal Schottky diode, n is numerically equal to one.

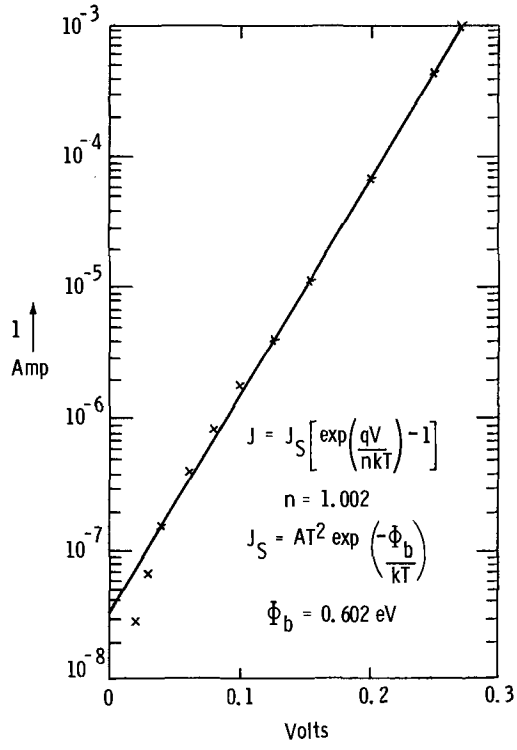

Fig. 4. Current-voltage characteristics of Si-Cr diode

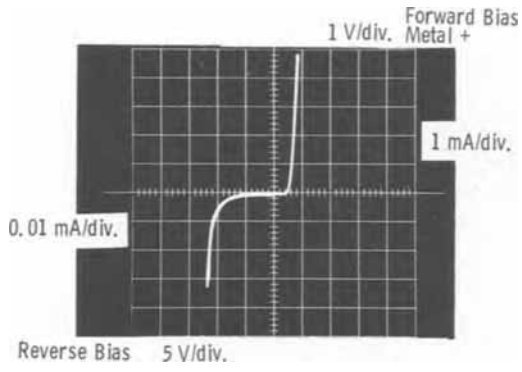

Fig. 5. Typical current-voltage relationships with forward and reverse bias.

Using Eq. [2] and a value of $A^* = 2.05 \times 120$ A/cm²/°K² for the (100) silicon surface (8), we obtain a value of $\phi_b = 0.6$ eV for the silicon-chromium barrier.

The diodes had breakdown voltages of 10-12V at 10 μA and a forward drop of 0.4V at 1 mA. A typical current-voltage relation is shown in Fig. 5. The reverse bias capacitance of the diodes was measured using a Boonton capacitance bridge at a fixed frequency of 1 MHz/sec. Figure 6 shows a plot of $1/c^2$ *vs.* reverse bias voltage, V. From this figure the intercept on voltage axis, V_i, is -0.44V. The barrier height, ϕ_b, is calculated using the relation (8)

$$\phi_b = V_i + \phi_f + \frac{kT}{q} - \Delta\phi \qquad [3]$$

where V_D is the diffusion potential equal to $V_i + kT/q$, ϕ_f is the Fermi potential (Fig. 6) which is calculated using the doping concentration (9), and $\Delta\phi$ is the image force lowering of the barrier height (10). The term kT/q is due to the electric field. Using Eq.

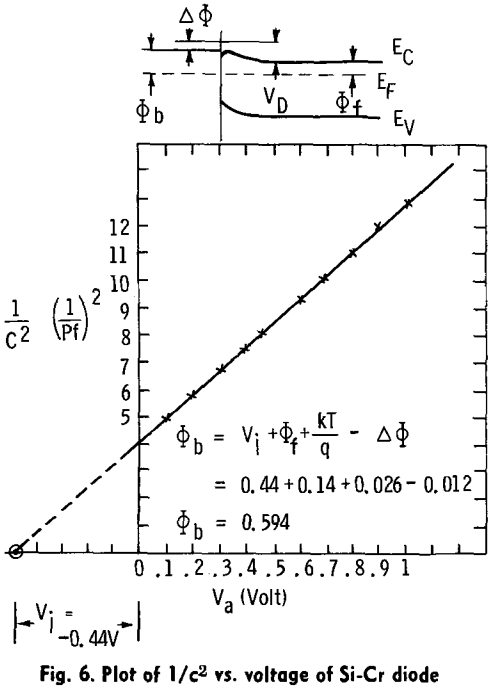

Fig. 6. Plot of $1/c^2$ vs. voltage of Si-Cr diode

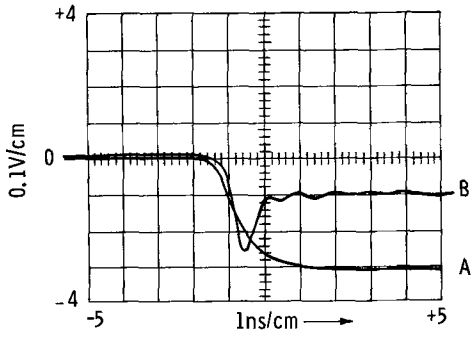

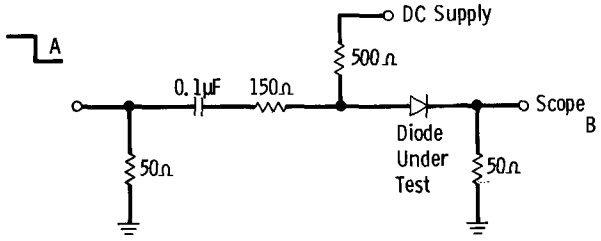

MEASURING CIRCUIT

Fig. 7. Stored-charge measurement of Si-Cr diode

[3] and the values of V_D, ϕ_f, and $\Delta\phi$ shown in Fig. 6, we obtain a value of 0.59 eV for ϕ_b.

The switching speed of the diodes was measured by turning off the forward-biased diode with a fast negative-going pulse as shown in Fig. 7. The total area of the curve below the zero level gives the total stored charge. From this value of stored charge and the forward current, the switching speed was estimated to be about 100 ps.

Conclusion

Chromium-silicon Schottky barrier diodes can be fabricated using chromium deposited by thermal decomposition of dicumene-chromium. This provides an alternative to regular evaporation or sputtering techniques.

Studies on the Deposited Asbestos Diaphragm with a Miniature Diaphragm-Type Chlorine Cell[1]

Fumio Hine* and Masaki Yasuda

Nagoya Institute of Technology, Gokiso-cho, Nagoya 466, Japan

ABSTRACT

Mass transfer and voltage drop in the deposited asbestos diaphragm were studied with a miniature chlorine cell. The diaphragm was formed on the steel-mesh cathode with a vacuum, and the voltage drop in the compressed asbestos layer was large. The streaming potential through the diaphragm was very small because of the highly conductive electrolytic solution.

The rate of development of the amalgam-type chlorine cell in the 20 years after World War II is surprising, and many articles have been and are being published on this subject. On the other hand, although the diaphragm-type chlorine cell accounts for a major share of the chlorine produced in the United States, comparatively few papers have been published on the diaphragm cell (1-4).

In the diaphragm cell, the principal anode reaction involves a charge transfer from Cl^- ion to Cl_2 gas, which takes place at the surface of a graphite anode in contact with concentrated NaCl solution.

Other anodic reactions also take place as a consequence of the back migration of OH^- ion through the diaphragm from the catholyte.

The principal cathode reaction involves the formation of hydrogen gas from water in the mixed solution of NaOH and NaCl in contact with a steel cathode. Secondary reactions take place as a consequence of dissolved chlorine in the anolyte which percolates through the diaphragm into the catholyte. The possibility of cathodic reduction of ClO_3^- ion, which also comes from the anode compartment to the cathode, is discussed in a separate paper (5).

Mass transfer and voltage balance in the deposited asbestos diaphragm on the steel-mesh cathode are discussed in this paper.

Mass Transfer and Voltage Drop in the Diaphragm

Since MacMullin (6) was concerned about the possible effects of the zeta potential on the mass transfer through the porous diaphragm, the streaming potential has been determined.

Asbestos fiber for the Hooker Cell, Grade 5D, was deposited on steel-mesh in a glass cylinder cell of 3.6 cm inner diameter at about 70 mm Hg vacuum as shown in Fig. 1. The thickness was 2.5 to 3.0 mm. Calomel electrodes were placed in front of and in the rear of the deposited asbestos diaphragm. The concentration of NaCl was varied from 26 x 10^{-4} to 26 w/o (weight per cent) and the pressure difference was varied between 10 and 60 mm Hg. Temperature was 24°C. The results obtained are shown in Fig. 2.

The streaming potential was proportional to the pressure drop and the slope increased with decreasing NaCl concentration as shown in Fig. 2. Using the Helmholtz-Smoluchowski equation (7), the zeta potential was calculated (Eq. [1]). The results are listed in Table I.

$$\zeta = 4\pi\eta\kappa E_s/DP \qquad [1]$$

where E_s = streaming potential, volt
D = dielectric constant (*ca.* 80), e.s.u.
P = pressure drop, dyne/cm^2
κ = conductivity, mho/cm
η = viscosity, poise
ζ = zeta potential, volt

[1] This study was conducted at Kyoto University at Uji, 1967-1968.

Key words: streaming potential, mass transfer, current efficiency.

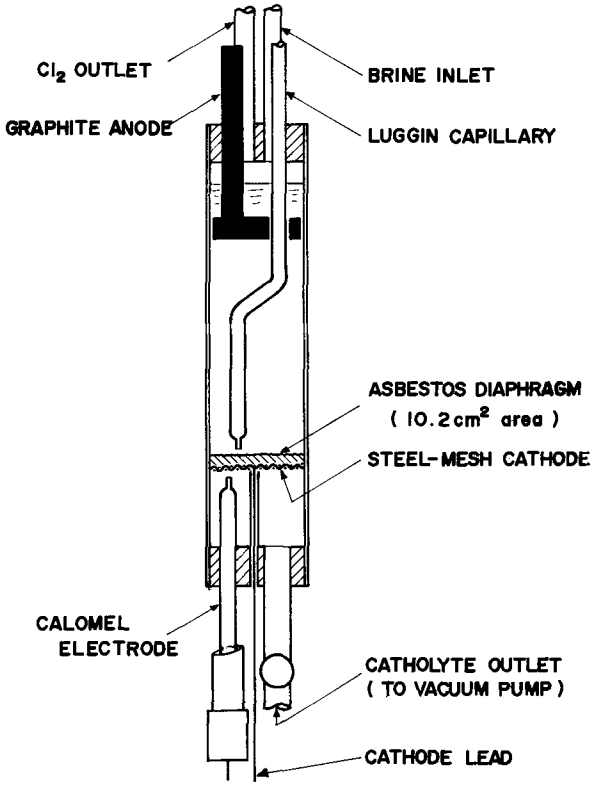

Fig. 1. The miniature diaphragm cell

Because the streaming potential in concentrated solution is very small, no significant effect of the electrokinetic phenomena on a practical diaphragm cell is assured.

The *IR* drop in porous media has been studied by MacMullin *et al.* (8). It was proposed that the resistivity in a diaphragm is uniform, while the porosity may vary in the direction of thickness. Matsuno considered similar assumptions and he estimated a characteristic factor for diaphragms (9). Mukaibo studied the mass transfer phenomena through the diaphragm in a chlorine cell with the assumption of uniform porosity (10).

A graphite anode was placed at the top of the cell shown in Fig. 1. A movable Luggin capillary connecting with a calomel electrode was set in front of the diaphragm and cathode mesh. An example of the *IR*

26 × 10^{-2}	2.74_2 × 10^{-3}	−31.9

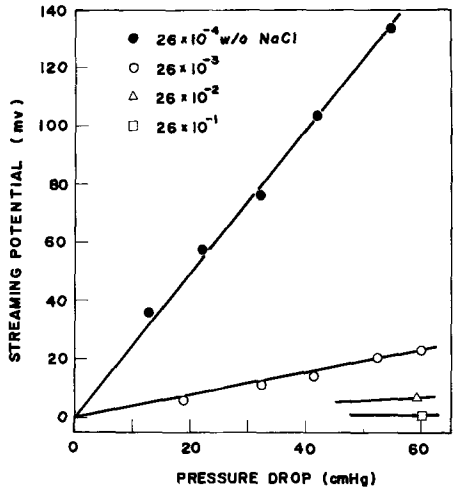

Fig. 2. The streaming potential vs. pressure drop curves in NaCl solutions at 24°C.

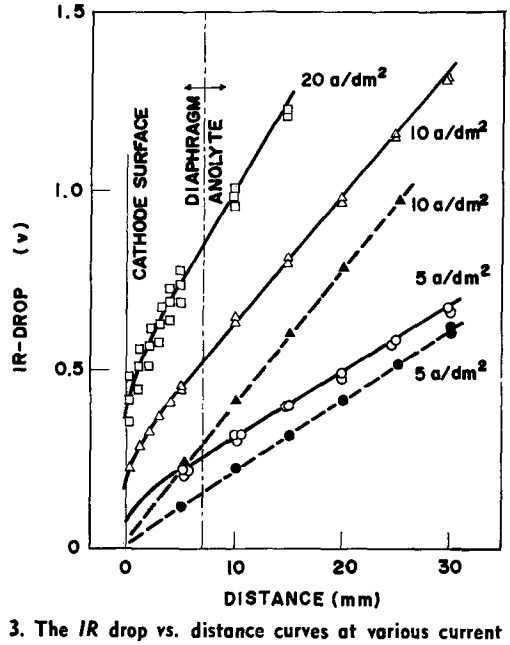

Fig. 3. The IR drop vs. distance curves at various current densities. Pressure drop, 50 cm Hg. Solid line, IR drops with diaphragm; broken line, IR drops without diaphragm.

drop *vs.* distance curve is shown in Fig. 3. As shown in Fig. 1, the tip of the lower calomel electrode is pressed to the back of the steel-cathode screen. The tip of the upper Luggin capillary can be inserted in the deposited asbestos diaphragm until it touches the upper surface of the cathode wire. The potential difference between the two probes would involve the cathode overvoltage and the *IR* drop between them. Our reference point $x = 0$ in Fig. 3 and 4 is the upper surface of the steel cathode and, hence, there is some space between two probes even at $x = 0$. The *IR* drops at $x = 0$ in Fig. 3 are exactly proportional to the current density as shown in Fig. 5, which means a simple *IR* drop between two probes. The relatively low slope of the *IR* drop *vs.* distance curve (Fig. 3) at high current density is probably due to the temperature rise in the vicinity of the cathode caused by electrolysis. The solid lines with open points have curvature in the vicinity of the cathode, but further away they are almost parallel with the corresponding broken lines which show the *IR* drop of the solution at the same current density labeled. The *IR* drop in the diaphragm varies with pressure as shown in Fig. 4.

The compressed layer of the deposited asbestos diaphragm exists near the surface of the steel-mesh cathode, and its thickness is expected to be 2 to 3 mm.

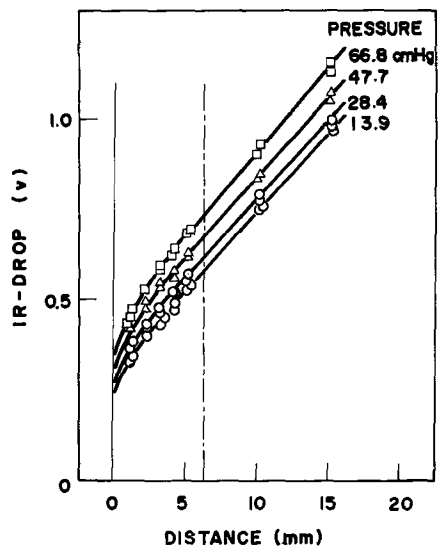

Fig. 4. The *IR* drop vs. distance curves at various pressure drops. Current density, 20 A/dm²; temperature, 55°C.

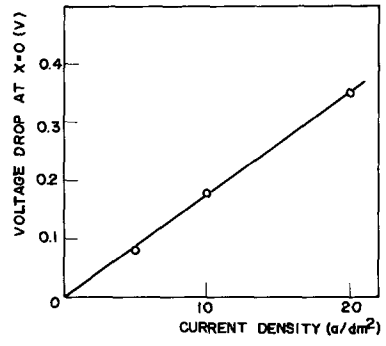

Fig. 5. The voltage drop vs. current density at $x = 0$ calcu from Fig. 3.

Assuming that the resistivity of this compressed layer is linear with distance, the *IR* drop is formulated as follows

$$\rho - \rho_0 = -K(x - L)$$

and

$$V = i\int_0^L \rho\, dx = i\left(\rho_0 L + \frac{K}{2}L^2\right) \qquad [2]$$

where ρ = resistivity at x, ohm-cm
ρ_0 = resistivity beyond L, ohm-cm
K = coefficient, ohm
V = *IR* drop, volt
i = current density, A/dm²
x = distance from the cathode, cm
L = thickness of the compressed layer, cm

The value, K, calculated by this equation with the data in Fig. 3 and 4 is an approximately linear function of the pressure drop as shown in Fig. 6.

MacMullin (11) has offered an alternate explanation from the data plotted in Fig. 3. The slopes of the volt-

age gradient outside the diaphragm in the anolyte and inside the diaphragm are related to the respective resistivities by the following equation

$$\rho = \frac{dV}{dx}\frac{1}{i} \qquad [3]$$

where x = cm, i = A/cm², and ρ = ohm-cm. The results are given in Table II. Applying this same procedure to Fig. 4, the effect of pressure drop is obtained as shown in Table III. The last two columns are added in order to read the fractional space $f = 1 - \epsilon$ occupied by the fibers from the conductivity ratio $Km = \rho_o/\rho$, using the Meredith plot, Fig. 1 in Ref. (4).

Thus, high flow rates correspond to high pressure drop across the diaphragm, and this compresses the fibers, reduces the voids, and increases the resistivity of the diaphragm, all in the expected way.

The above is not the complete answer. Stender *et al.* have published an excellent article (3) in which the mathematics is correct except for one simplifying assumption—that the conductivity of the electrolyte in the diaphragm is constant. This assumption is inconsistent with his demonstration that the OH^- concentration varies with x, the distance from the cathode inside the diaphragm. That is, when $x = 0$, C_{OH^-} is the same as for the catholyte itself and, when $x = \delta$ (the thickness), C_{OH^-} is practically zero. Realizing that OH^- ion conducts better than Cl^- ion, if OH^- varies, the conductivity must vary. Qualitatively, this appears to be so as shown in Fig. 7. Therefore, the *IR* drop in the diaphragm should be concave upward as shown in Fig. 8. As Stender says, there are no data on the conductivity of mixtures of NaCl and NaOH, as functions of C_{Cl^-}, C_{OH^-}, and temperature.

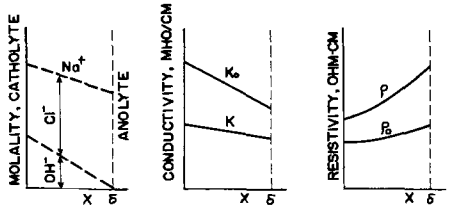

Fig. 7. Model in the diaphragm [by R. B. MacMullin (11)]

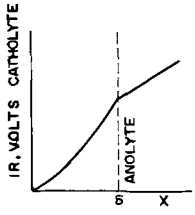

Fig. 8. The *IR* drop in the vicinity of the cathode screen [by R. B. MacMullin (11)].

MacMullin's comments are reasonable if the porosity distribution across the deposited asbestos diaphragm is uniform. But it is obvious that the porosity varies with the normal direction through the cake deposited (12). The curvature of the *IR* drop *vs.* distance diagram in Fig. 3 and 4, then, differs from the estimation shown in Fig. 8. The asbestos in contact with the cathode screen is greatly compressed, while that facing toward the anolyte is rough. Therefore, the voltage gradient at the surface of the diaphragm does not vary significantly.

Operation of a Miniature Cell

A miniature cell shown in Fig. 1 was operated for a few hours, and the flow rate, concentration of NaOH, and cathode potential were measured with time. The temperature stabilized about 60 min after start-up, and other factors reached steady state as shown in Fig. 9. The logarithm of flow rate *vs.* logarithm of pressure drop in Fig. 10 is linear with the slope of about 45°. According to Perry (13), the permeable medium seems to be rigid when the slope of this curve is exactly equal to 45°. However, the diaphragm in this study was somewhat compressible since the *IR* drop between the cathode screen and the upper Luggin capillary, placed 3 mm above the top of the cathode, increases slightly with pressure drop. The concentration of NaOH in the catholyte decreases with increasing pressure drop because of increase in the percolation rate of the brine.

Current efficiency for the formation of NaOH can be calculated with the data of flow rate and concentration. For the particular experimental cell used, it appeared to depend on the current density as shown in Fig. 11 and as independent of other factors such as pressure and temperature. It might be affected by diaphragm material. MacMullin has analyzed the data differently as follows (11).

The current efficiency was calculated from the caustic yield at six different current densities as shown in Fig. 11. However, this does not indicate the current efficiency is dependent solely on current density. The relationship between the current efficiency and the current density has been described by Kircher (14) and Stender (3). Quite simply put, current efficiency depends chiefly on the ratio of current density to percolation rate through the diaphragm. A Hooker cell can achieve a current efficiency of 94-96% over a current density range of 5-15 A/dm² if the conversion

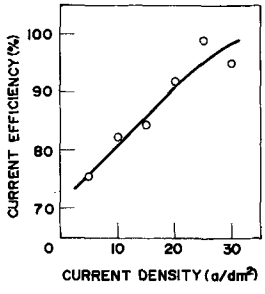

Fig. 11. The current efficiency vs. current density curve

per pass of around 45-55% and a temperature above 95°C are maintained. From Fig. 9, at i = 15 A/dm^2, after 2 hr the current efficiency can be calculated to be 87.5%, which is acceptable for a temperature of 38°C. From Fig. 10, at i = 30 A/dm^2, the average current efficiency for the six runs is 92.8%. The catholyte flow rate varies from 0.085 cm/min up to as high as 0.65 cm/min. The catholyte rate in a typical Hooker cell, at 15 A/dm^2, is about 0.025 cm/min and for the same conversion, at 30 A/dm^2, which is not yet achievable commercially, would be about 0.05 cm/min. The current efficiency is generally about 96%.

Figure 12 shows the current efficiency as a function of the ratio of current density to catholyte flow rate. As shown, the larger the current density and the larger the flow rate at a given current density, the larger is

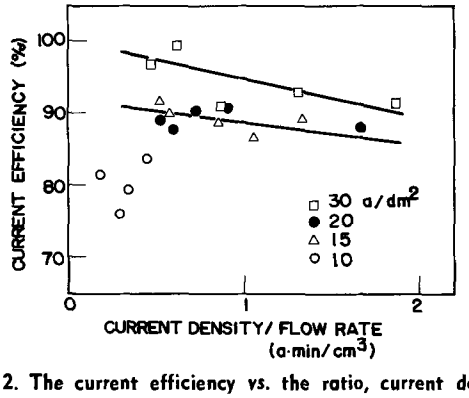

Fig. 12. The current efficiency vs. the ratio, current density to the flow rate of anolyte.

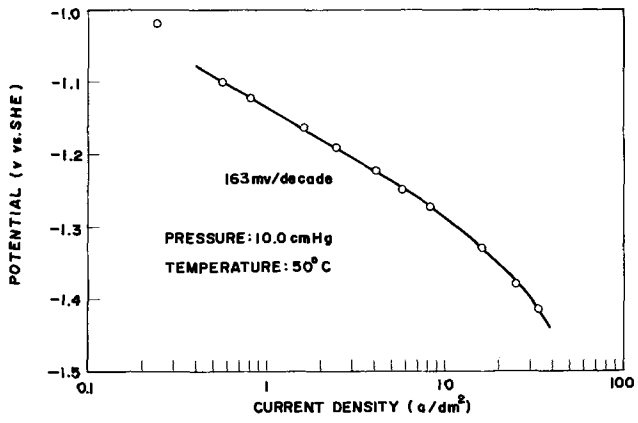

Fig. 13. The potential vs. current density curve of the steel cathode.

the current efficiency. Why the current efficiency decreases with decrease of the flow rate of the catholyte is not clear, but it probably would be due to the back-migration of OH^- through the diaphragm because the concentration of OH^- increases with decreasing flow rate.

Figure 13 shows an example of the polarization curve of the steel-mesh cathode in the same cell. The potential is linear with the logarithm of current density in a range 1-10 A/dm^2 with a slope of 160 mV/decade. The curve deviates from the Tafel line at high current densities. The potential became more noble by a few millivolts with increasing pressure drop at constant current density, the reason for which was not clear. Measurement of the hydrogen overvoltage in concentrated NaOH at elevated temperature is somewhat difficult. The hydrogen overvoltage decreases with increasing temperature. Relative data on the hydrogen overvoltage on the graphite cathode in concentrated NaOH at high temperature ranges have been published by Hine (15).

Complications arise, in that the catholyte of the diaphragm-type chlorine cell is a mixed solution of concentrated NaOH and NaCl, and it contains some amounts of ClO^- and ClO_3^-; thus, the cathode reaction is affected by these contaminations. Details of the cathode reaction are discussed in other papers (5, 16).

Acknowledgments

The authors express many thanks for the useful suggestions of Mr. Robert B. MacMullin, Niagara Falls, New York, and for his financial support of a part of this work. Samples of asbestos were supplied from Nissan Chemical Company, who operate the Hooker S-type chlorine cells at their Oji plant, Tokyo.

Manuscript submitted Aug. 13, 1968; revised manuscript received ca. Sept. 25, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Studies on the Cathodic Reaction in the Diaphragm-Type Chlorine Cell[1]

Fumio Hine* and Masaki Yasuda

Nagoya Institute of Technology, Gokiso-cho, Nagoya 466, Japan

ABSTRACT

Polarization of a rotating platinum cathode in mixed solutions of NaCl and NaOH containing dissolved chlorine was measured. At relatively low current densities, cathodic reduction of ClO^- took place as the main reaction. The diffusion-limiting current density was a function of the concentration of ClO^- in solution and the reaction was first order with respect to ClO^-. Therefore, it was concluded that the mechanism

$$ClO^- + H_2O + e = Cl_{ad} + 2\,OH^-$$

$$Cl_{ad} + e = Cl^-$$

was operative at low current densities. At high current densities, hydrogen formation is, of course, the main reaction.

There is no doubt that the hydrogen electrode process is a high light of theoretical electrochemistry. Thus, many papers have been published.

The main reaction on steel-cathode screens in the diaphragm-type chlorine cell under operating conditions—that is, relatively high current densities such as 10-15 A/dm^2—is, of course, hydrogen evolution from H_2O in concentrated caustic soda solution. However, the catholyte of the diaphragm-type chlorine cell is a mixed solution of concentrated NaOH and NaCl and it contains some amounts of ClO^-. Hypochlorite ion, ClO^-, is reduced easily at the cathode and it is one of the factors in the decrease of current efficiency in chlorate cells (1, 2) because of the relatively low current density as compared with chlor-caustic cells.

Frumkin and his co-workers (3) studied the cathodic reaction of chlorine on the rotating platinum cathode in acidic solution and they stated that the over-all reaction was controlled by two consecutive processes, [*A*] and [*B*]

$$Cl_2 + e = Cl_{ad} + Cl^- \qquad [A]$$

$$Cl_{ad} + e = Cl^- \qquad [B]$$

Since the cathodic reduction of chlorine in alkaline solution has not yet been described in detail, mechanisms for the reduction of dissolved chlorine at the rotating platinum cathode in concentrated alkali solution are now discussed.

The rotating steel cathode was examined several times for consideration as a practical chlorine cell, but complicated results were obtained at relatively low current densities due to the anodic dissolution of steel by local cell action. At high current densities, on the other hand, a similar mechanism can be assumed on both platinum and steel cathodes; that is, the hydrogen formation reaction.

Because the equilibrium constant for reaction [C]

$$Cl_2 + 2OH^- = Cl^- + ClO^- + H_2O \qquad [C]$$

is large, 1.33 x 10^{16} at 25°C (4), chlorine passing through the diaphragm toward the cathode compartment may exist as ClO^- on the cathode surface. Hydrogen formation is, of course, taking place at the cathode at high current densities and hence two reactions, [*D*] and [*E*], are proceeding:

$$2H_2O + 2e = 2OH^- + H_2 \qquad [D]$$

$$E_1^\circ = -\,0.828\text{V } vs.\text{ SHE at } 25^\circ\text{C}$$

and

$$ClO^- + H_2O + 2e = Cl^- + 2OH^- \qquad [E]$$

$$E_2^\circ = +\,0.88\text{V } vs.\text{ SHE at } 25^\circ\text{C}$$

where E_1° and E_2° are the standard reversible potentials for [*D*] and [*E*], respectively.

Experimental Procedure

A rotating disk platinum cathode of 5.03 cm^2 area was inserted in a plastic holder and located at the center of the glass electrolytic cell of about 1 liter capacity as shown in Fig. 1. The graphite anode was set in its compartment and was separated from the cathode with a sintered glass diaphragm. Electrolyte was prepared from extra-pure NaOH and NaCl and with deionized water. Chlorine from a cylinder was passed through 2*N* NaOH to prepare NaClO and this solution was added into the cell. The concentration of ClO^- was titrated by iodometry. The solution was deaerated with purified hydrogen for at least 2 hr. Temperature of the cell was controlled at 50° ± 0.5°C.

The mercuric oxide electrode consisting of Hg/HgO/2*N* NaOH was used as the reference elec-

[1] This work was conducted at Kyoto University at Uji, 1967-1968.
* Electrochemical Society Active Member.

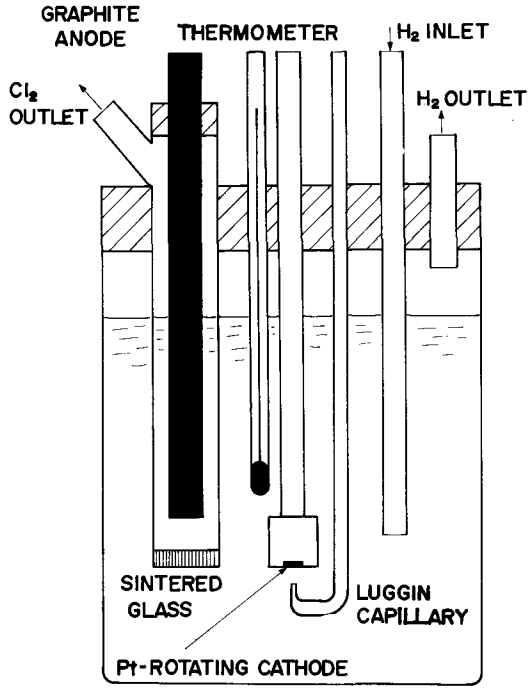

Fig. 1. The cell for polarization measurement

trode and its potential was referred to the hydrogen electrode.

The *IR* drop between the working electrode and the Luggin capillary was calibrated by means of extrapolation of the potential *vs.* distance curve to zero distance.

The working cathode was pre-electrolyzed to stabilize the surface several times before measurement.

Results and Discussion

Because of the large value of the equilibrium constant for reaction [*C*], no change of the concentration of dissolved chlorine due to hydrogen purge can be expected. Contamination of chlorine generated at the anode was also not significant.

Figure 2 shows the potential *vs.* current density curves in 2*N* NaOH + 3*N* NaCl containing various amounts of ClO^- at a constant rotating speed of 1660 rpm. The dotted line is the polarization curve of the rotating platinum cathode in the mixed solution without chlorine. Therefore, hydrogen formation reaction [*D*] may take place in this case. The limiting current density depends on the concentration of ClO^-, but is independent of the concentrations of NaCl and NaOH as shown in Fig. 3 and 4, respectievly. The limiting current density, i_L, at −0.5V *vs.* SHE is proportional to the concentration of ClO^- as shown in Fig. 5.

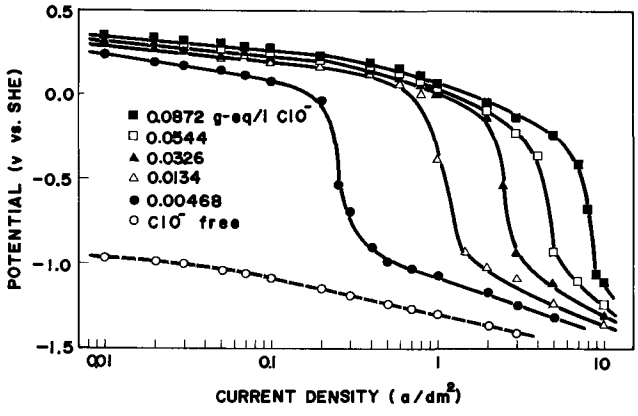

Fig. 2. The potential *vs.* current density curves in 2*N* NaOH + 3*N* NaCl containing various amounts of ClO^-. Rotating speed, 1660 rpm.

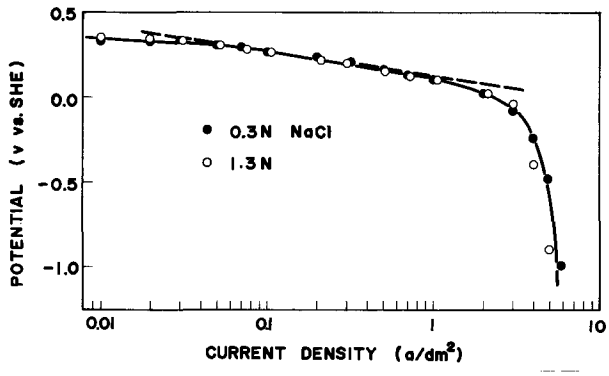

Fig. 3. The potential *vs.* current density curves in 1.45*N* NaOH containing 0.05 g-equiv/liter ClO^-. Rotating speed, 1660 rpm.

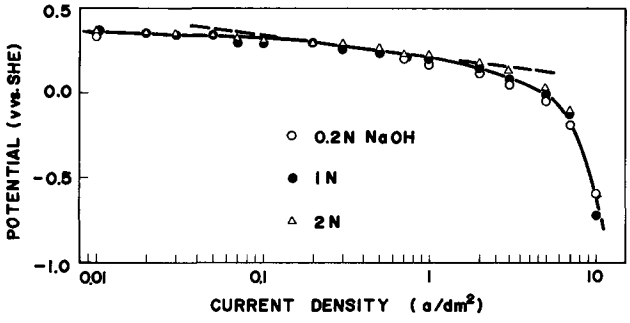

Fig. 4. The potential *vs.* current density curves in 0.2*N* NaCl containing 0.09 g-equiv/liter ClO^-. Rotating speed, 1800 rpm.

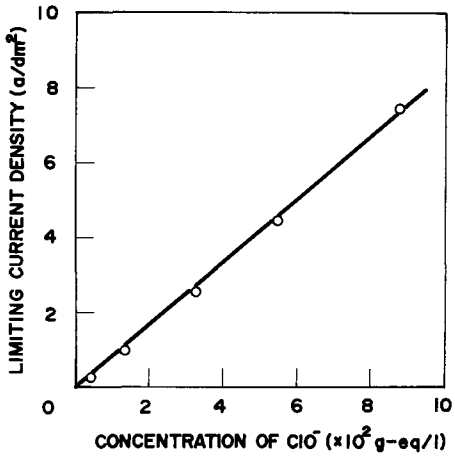

Fig. 5. The diffusion current *vs.* concentration of ClO^- curve at −0.5V. Rotating speed, 1660 rpm.

Lewich described the relationship between the current density, *i*, and the rotating speed, ω, as follows (5)

$$i = A(C - C_0)\omega^{1/2} \qquad [1]$$

where A = constant
C = concentration in the bulk of solution
C_0 = concentration at the electrode surface

At the diffusion-limiting current density

$$i_L = AC\omega^{1/2} \qquad [2]$$

Therefore, the limiting current density is linear to the square root of the rotating speed as shown in Fig. 6.

The current density due to electrochemical reaction is a function of concentration of reactant, *C*, as follows

$$i = kC_0^p \qquad [3]$$

where k is the rate constant and p is the order of reaction. The concentration, C_0, becomes C as the rotating speed approaches infinity, that is

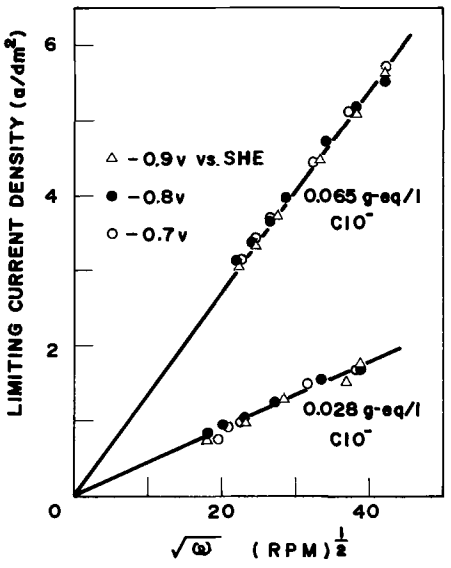

Fig. 6. The limiting current density vs. rotating speed curves in solutions containing various amounts of ClO^-.

$$i = i_r = kC^p \text{ at } \omega = \text{infinity} \quad [4]$$

Because the charge transfer reaction is first order with respect to ClO^- as described below, the next equation is obtained from Eq. [1], [3], and [4]

$$\frac{1}{i} = \frac{1}{i_r} + \frac{1}{AC\omega^{1/2}} \quad [5]$$

The $(1/i)$ *vs.* $(1/\omega^{1/2})$ is shown in Fig. 7. The straight lines project into the origin; therefore, the reaction limiting current density, i_r, is not present in this range.

According to Vetter (6), the reaction rate or the current density for two successive charge transfer reactions, [*F*] and [*G*]

$$S_r = S_m + e \quad [F]$$

$$S_m = S_o + e \quad [G]$$

is represented by Eq. [6]

$$i = -2k'a(1-\theta)\exp\left[-\frac{(1-\alpha)\mathbf{F}}{RT}E\right] \quad [6]$$

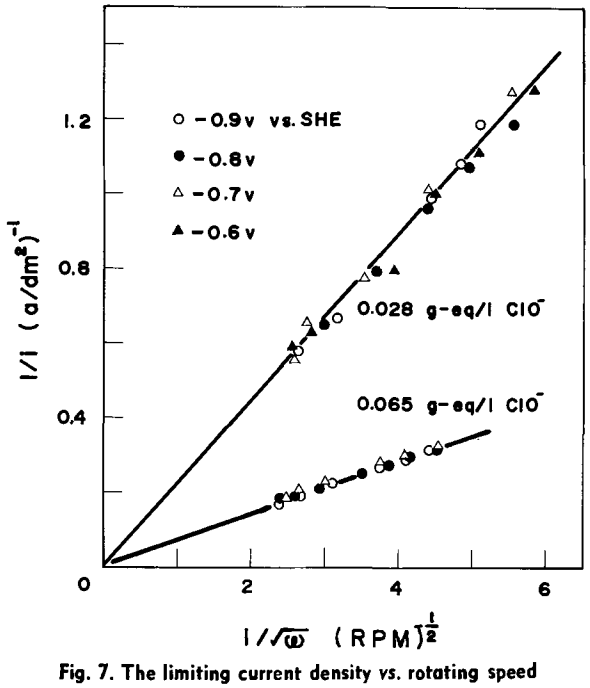

Fig. 7. The limiting current density vs. rotating speed

where k' = rate constant
a = activity of S_o
θ = coverage
α = transfer coefficient

if the overvoltage is much greater than $(RT/\mathbf{F})\ln(i_o'/i_o)$, where i_o and i_o' are the exchange current densities for [*F*] and [*G*], respectively.

Assuming the following relation between the current density and the activity of reactant, a, due to lack of diffusion in the vicinity of the working electrode

$$\frac{a_o}{a} = 1 - \frac{i}{i_L} \quad [7]$$

for reactions [*H*] and [*I*]

$$ClO^- + H_2O + e = Cl_{ad} + 2OH^- \quad [H]$$

$$Cl_{ad} + e = Cl^- \quad [I]$$

$$ClO^- + H_2O + 2e = Cl^- + 2OH^- \text{ (over-all reaction)} \quad [J]$$

we have the next equation from Eq. [6] and [7]

$$\frac{i}{1 - \frac{i}{i_L}} = -2k'a(1-\theta)\exp\left[-\frac{(1-\alpha)\mathbf{F}}{RT}E\right] \quad [8]$$

The dotted lines in Fig. 3 and 4 show the corrected Tafel line by Eq. [8] in a range of diffusion control. The slope of the Tafel line is 120-140 mV/decade and, hence, the transfer coefficient is 0.47-0.54. Here the activity coefficient of the ClO^- ion was assumed to be unity because of the dilute solution.

The current density at a given potential, 250 mV *vs.* SHE, was plotted *vs.* the concentration of ClO^- as shown in Fig. 8. The slope of the curve, $(d \log i/d \log C)$, is unity; therefore, the reaction is first order with respect to ClO^-. Thus, it is concluded that the elementary reaction in this case is reaction [*H*] instead of reaction [*J*], because the latter process is the two-charge transfer reaction for ClO^-. Reaction [*I*] follows reaction [*H*].

MacMullin offers the following comments on the cathodic reduction of ClO^- and ClO_3^- (7):

"The loss of current efficiency due to dissolved Cl_2 in the anolyte seeping into the diaphragm is quite small in a Hooker cell. However, the loss due to ClO^- and ClO_3^- formation in the anolyte is more serious. This loss results from the OH^- back migration through the diaphragm. Most of the chlorate thus formed is reduced to chloride at the cathode, so that only minor amounts of chlorate are left in the cell liquor under normal conditions.

"It would be worthwhile to consider a similar approach to the more important problem of reduction of chlorate at the cathode.

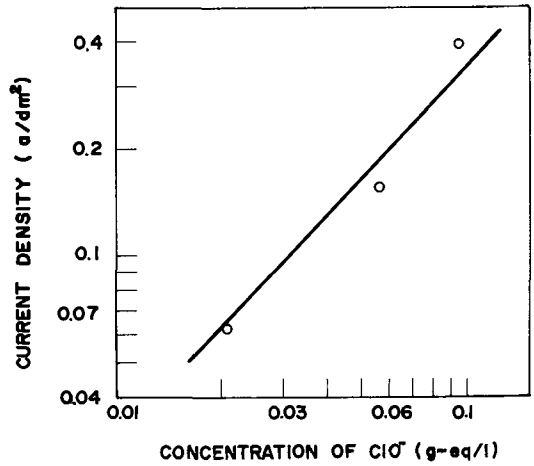

Fig. 8. The current density vs. concentration of ClO^- curve at 250 mV vs. SHE.

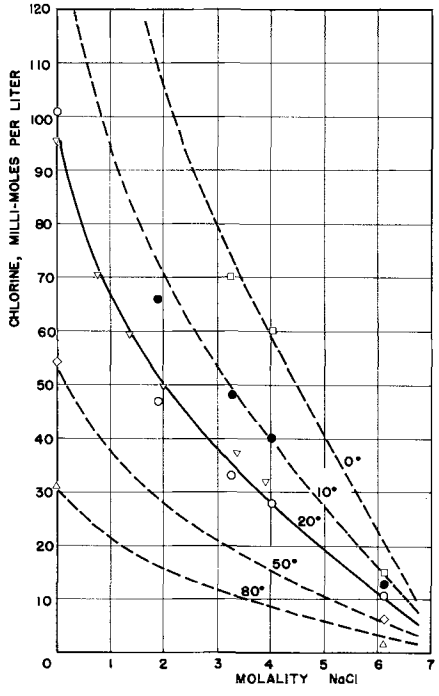

Fig. 9. Effect of NaCl molality on solubility of chlorine in brine (7). Total pressure, 760 mm Hg. 20°C Solid line: ▽, Oliveri-Mandala; ○, Kumpf, Kohn, and O'Brien. 0°, 10°, 50°, 80° Dashed lines: assumes salt effect at 20°C is constant over entire temperature range. Reduced experimental data of Kumpf, Kohn, and O'Brien: □, 0°C; ●, 10°C; ○, 20°C; ◇, 50°C; △, 80°C.

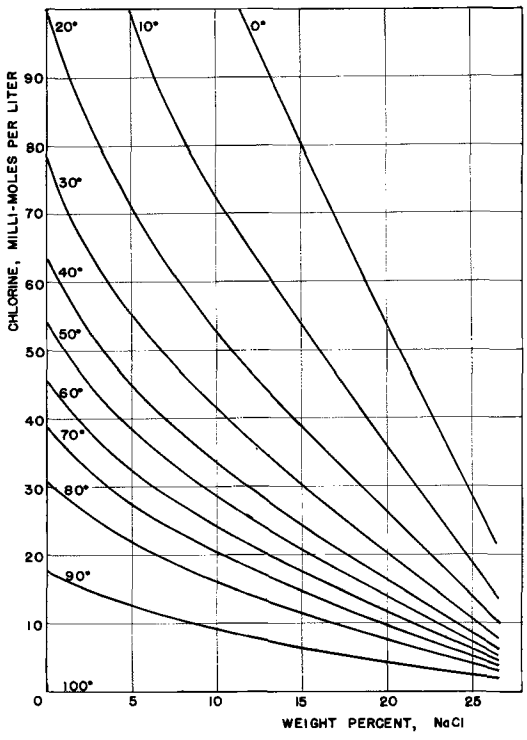

Fig. 10. Estimated solubility of chlorine in NaCl brine, not acidified (7).

"On Fig. 2, assuming the anolyte was 5*N*, or 24.4% NaCl, and the temperature 50°C, the solubility of Cl_2 in the anolyte is about 8 mmoles/L, or the concentration of ClO^- = 8 mmoles/L = 16 mequiv/L, or 0.016 equiv/L. This is in the range of ClO^- concentrations tested in this report. However, in a Hooker cell, where the anolyte is about 22% NaCl, temperature 95°-97°C, the chlorine solubility is only 0.15 mmole/L, corresponding to an ClO^- concentration of 0.0003 equiv/L." [Estimates of Cl_2 solubility made by MacMullin (7) are given in Fig. 9 and 10.]

"On the other hand, the $NaClO_3$ content of the cell liquor leaving the cell is about 0.07 gpl or 0.004 equiv/L of ClO_3^-. The $NaClO_3$ formed at the anode represents a current inefficiency of about 0.5%, if the pH is 4. Assuming 50% decomposition of the salt, this corresponds to a concentration of about

$$(0.005 \times 5N)/2 = 0.0125 \text{ equiv } ClO_3^-$$

or 0.0021 g-mole $NaClO_3$ in the anolyte which seeps through the diaphragm. So, most of the chlorate is reduced to chloride by the cathode, leaving very little ClO_3^- in the cell liquor. There is, of course, no ClO^- left in the cell liquor."

Since receiving MacMullin's comments, the authors have carried out experiments on the cathodic reduction of ClO_3^-. The results obtained with the same procedure as described for ClO^- have been reported in a separate paper (8).

Information on the anodic process would be very useful for discussion of the mechanism of the cathodic reduction of ClO^- and ClO_3^-, but experimental work is difficult because of passivation of platinum electrodes in alkaline solution containing chlorine.

Anodic Mechanism of Electrochemical Machining: Study of Current Transient on a Rotating Electrode

Der Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Using potentiostatic transients and employing rotating steel anodes, a study has been made of the anodic mechanism occurring during electrochemical machining in sodium chloride and sodium chlorate solutions. For chloride, transient behavior reveals the formation, on the anode surface, of a porous, nonprotective film resulting from the precipitation of the anode product. For chlorate, a less porous film, about 1000Å thick, is formed. Transient behavior reveals that the film is formed by anodic oxidation and that the rate of film growth increases with the increase in the rate of iron dissolution.

During the last decade, electrochemical machining (ECM) has had an impact in machining hard metal alloys. Although the process is still in a state of art, increasing efforts have been devoted to the search of reaction mechanisms. By understanding its electrochemical fundamentals, it is possible to broaden its application as an industrial metal removal method.

ECM generally takes place in a flow cell composed of closely spaced workpiece (anode) and cathode. Metal is removed anodically from the workpiece at a rate on the order of 0.05 in./min, and the dissolution products are removed by flushing electrolyte through the electrode gap space. The most commonly used electrolyte for ECM of steel is the concentrated water solution of sodium chloride. However, sodium chlorate has been found to be a more favorable electrolyte because of its good dimensional control and better surface finish (1, 2). In a series of steady-state polarization (3, 4) and cathodic stripping (5) studies, Hoare and his co-workers relate this excellent property of sodium chlorate to the formation of a protective film on the surface of the workpiece.

Knowledge regarding the formation and property of this film would, therefore, be useful in the development of the ECM process. For this purpose the potentiostatic transient of a steel anode in NaCl and $NaClO_3$ solutions has been investigated. Since the ECM process requires a high flow rate of electrolyte, the study was carried out under hydrodynamic conditions of a rotating disk electrode. Polarization studies of ECM using rotating electrodes have been reported by Hoare, LaBoda, McMillan, and Wallace (3) and by Davydov, Kashcheev, and Kabanov (6). This paper describes transient behavior of a rotating steel anode in the ECM electrolyte. The results are presented in terms of the nature of passivation and the mechanism of film growth on the anode surface.

Experimental

The cell arrangement (Fig. 1) was the same as reported in Ref. (3). The anode was an epoxy rotating disk, 1 in. OD, with an active central portion, 1/8 in. diameter, made of SAE 5160H steel. The cathode was a 1/2 in. copper disk cemented on a Lucite rod, which was inserted through a hole of a Lucite block on the bottom of the cell container, and was fixed in position with a nylon set screw. An electrode spacing of 1 in. was used throughout the study. Aqueous solutions of sodium chloride or sodium chlorate were used as electrolytes. The electrolyte temperature was maintained at 23° ± 1°C, and the concentration varied from 0.1 to 4 moles/liter. A saturated calomel electrode placed in a capillary tube was used to measure the anode potential. The tube was immersed in the electrolyte, and its tip was brought up to the downstream side of the steel anode. Unless otherwise noted, all the anode potentials given in the report are with respect to this reference.

The anode potential was controlled by a GMR-built potentiostat. A Weston d-c milliammeter (Model 911) was used to measure the steady-state current. The current transient was determined by passing the current through a standard resistor and subsequently recording the voltage drop across the resistor on a Sanborn recorder (Model 296).

For each series of runs the surface of the rotating anode was first ground until the steel center and the electrically inert epoxy surface became flush. The surface was then rubbed with a Carbimet 320-grit wet grinding paper, and treated with 6*N* HCl for 1 min followed by rinsing in water. The clean anode was then quickly transferred to the electrolyte, and installed on the spindle of the rotating assembly. To insure reproducibility, the anode was cathodically

Key words: passivity of steel electrode, passive films, anodic dissolution of steel in chloride and chlorate.

treated in the electrolyte for 1 min. A separate electrical circuit having a steel counterelectrode and powered with three Burgess 1.5V batteries was used for the cathodic treatment. After the cathodic treatment, several minutes were required for the anode potential to return to its equilibrium position. The cell circuit was then switched on for a preset anode potential, and the current was recorded on the recorder.

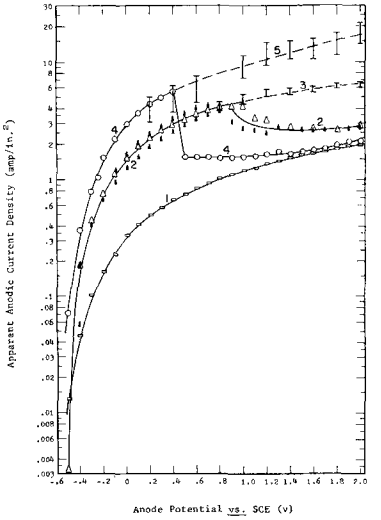
Results

Steady-state measurement.—Before the transient measurement, a run was made for determining the steady-state polarization curves at various electrolyte concentrations and rotational speeds of the disk electrode. Typical results from the NaCl electrolyte are given in Fig. 2 as data points connected by solid lines (curves 1, 2, and 4). The dashed lines (curves 3 and 5) are the plateau current density; its meaning will be explained in the next section. The steady-state current density in 1.0M NaCl is given for two different anode revolution rates. It is seen that the speed of rotation does not have a significant effect on the rate of iron dissolution. The sudden drop on curves 2 and 4 demonstrates that the anode becomes passive beyond the active potential, which increases with decreasing electrolyte concentration. For 0.2M NaCl no passivation occurred with the potential range investigated.

Polarization curves of $NaClO_3$ are given in Fig. 3. The curves were obtained at an electrode speed of 1000 rpm; repeated measurements at different speeds of rotation gave essentially the same results. It is seen that the passive region is approximately from 0.5 to 1.4V *vs.* SCE, beyond which the transpassive region begins and the anodic gas evolution was observed. The active potential also increases with decreasing concentration; at 0.1M, no active-passive transition took place within the potential range investigated.

Current transient in NaCl electrolytes.—Typical transient curves in NaCl electrolytes are given in Fig. 4, where the curves drawn in wide striped bands represent oscillation of the current. The width of the band is the peak-to-peak amplitude of the oscillation.

Curves 4a and 4b were obtained in 1M NaCl at the potentials corresponding to the active region of steady-state polarization curves. These two curves are characterized by an initial current, a rapid drop to a minimum and recovery to a steady-state value having the same order of magnitude as the initial



NaCl Conc. (M)	Curve No. and Symbol	Disk Speed (rpm)	Type of Current
0.2	1 □	1000	Steady state

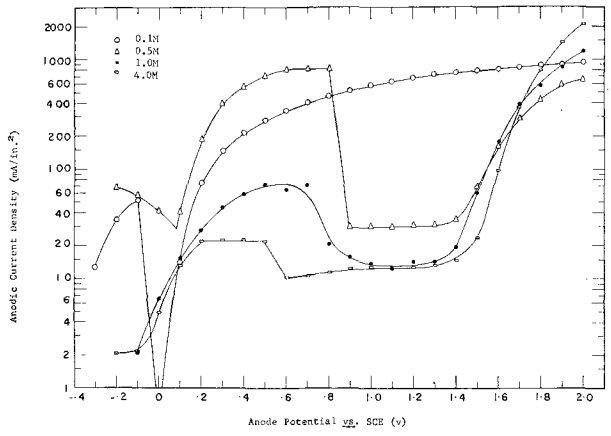

Fig. 3. Steady-state polarization curves in the sodium chlorate electrolyte.

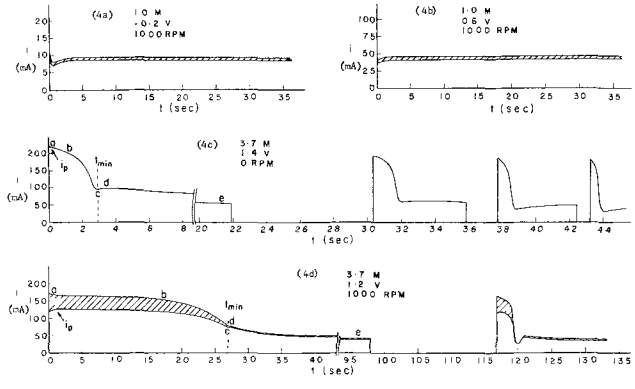

Fig. 4. Recorder traces of current transients in NaCl electrolytes

current. Repeated measurements at higher concentrations showed the same characteristics; the phenomenon of initial current and overshoot to the minimum, however, diminished with increasing electrolyte concentration. In a 3.7M NaCl electrolyte, for instance, a steady-state current was recorded immediately after switching on the cell circuit. If an overshoot did occur, its time constant was too short to be seen on the recorder used presently.

Curves 4c and 4d are typical current transients at the passive potentials for 3.7M NaCl electrolyte. Similar results were also obtained at lower concentrations. These two curves differ from those obtained at lower potentials by having a flat initial current and showing longer recovery time to the steady state. Besides, their steady-state current is considerably smaller than their initial current. The main features of these curves are:

(*a*) An initial plateau, a-b, where the current is large and oscillates about the average value with a frequency equal to the rotational speed of the anode. Curve 4c was obtained at zero revolutions per minute; thus no oscillation occurred in that particular run.

(*b*) A decrease to a minimum, b-c, while the oscillation is also decreasing as the current drops.

(*c*) A fast rise to a second maximum, c-d, and then decreasing asymptotically to a second steady-state value, d-e. In this stage the current oscillates again; its peak-to-peak amplitude, however, is much smaller than stage a.

In these two particular runs, the cell was switched off for varying lengths of time and then switched on again. It is seen that, for every switch-on, the current jumps to the initial value and repeats steps *a* to c as described above. The initial period, however, is much shorter, and the overshoot to the minimum becomes more prominent. The time required to attain the minimum of the subsequent on-period depends on the length of the previous off-period: the longer the off-

period, the longer will be the initial period and the slower the drop to the minimum value. This phenomenon is the same as the anodic transient of iron in sulfuric acid, for which evidence has shown that anodic products precipitate on the anode surface as an adsorbed layer, which in turn hinders the dissolution of iron into the electrolyte (7-9).

In the present study, a layer of dark blue film was observed on the anode surface. The film was so porous that it could be washed away easily with a jet of water. On several occasions, the film fell from the anode as a dark blue platelet at high rotational speeds, and the current jumped up immediately from the steady-state value to that of the higher initial current.

Figure 4 indicates that the current oscillated about its average when the electrode was rotating. For curves 4a and 4b, the peak-to-peak amplitude (for convenience this will be referred to as amplitude henceforth) was about 10% of the average current; for curve 4d, the amplitude was about 30% in the plateau period, a-b, and diminished to 5% in the third period, d-e. The frequency of the oscillation was equal to the frequency of the rotating anode. When the anode was stationary, no oscillation was observed as shown in curve 4c. At this point one might think that this oscillation was an artifact caused by the experimental device, such as the slip-ring contact of the rotating anode. However, with the same experimental setup there was virtually no current oscillation when sodium chlorate was used as electrolyte.

With regard to the film, the time required to reach the minimum current may be designated as a measure of the period of film formation. This time is denoted at t_{min} as shown in curves 4c and 4d. The amount of electricity per unit anode surface area required to pass through the cell before such a film has been formed can be approximated as

$$Q = \frac{1}{S}\int_0^{t_{min}} i\,dt \qquad [1]$$

where i is the total current, and S the apparent surface area of the anode. Figure 5 is a plot of Q and t_{min} at 1000 rpm as a function of anode potential for two different concentrations of NaCl. It is seen that both Q and t_{min} decrease substantially with increasing potential and electrolyte concentrations. The quantity, Q, was calculated graphically from the recorder trace. Since the current was oscillating, the integration was carried out separately according to the upper and the lower limits of the curve. Thus, for each transient measurement, two integrals were obtained; the difference of these two values was then represented by the length of I bars and rectangles as shown in Fig. 5a.

Figure 4 indicates that t_{min} of curve 4c is an order smaller than that of curve 4d. In Fig. 6, Q and the plateau current, i_p, measured at an anode potential of 1.4V are plotted against the rotational speed of the anode (the plateau current is the current of the initial flat portion of the transient as shown in curves 4c and 4d). Again, I bars are used to indicate the upper and the lower limits of the current output, if the current was fluctuating. The data for the plateau current are fairly scattered, and no dependence of the current on the anode speed could be drawn from the data points. The flat line in Fig. 6a is the average of these points. The quantity, Q, and thus the time required to reach the current minimum t_{min}, on the other hand, increases substantially with increasing speed beyond 300 rpm (Fig. 6b). It seems that the rotational speed has a great effect on the current transient in the NaCl electrolyte.

In Fig. 2 variations of the plateau current density with changes in anode potentials are shown as I bars connected by dashed lines (curves 3 and 5). It is seen that the logarithm of the plateau current density increases in direct proportion to the anode potential. In addition, curves 3 and 5 appear to be a smooth extension on the prepassivation, steady-state anodic current density. It seems evident that if no passivity occurred, the plateau current should represent the dissolution rate of iron beyond the activation potentials.

Current transient in $NaClO_3$ electrolytes.—For a given potential setting, the current transient in $NaClO_3$ electrolytes was independent of the speed of electrode rotation. The reproducibility, however, became better at higher speeds. For this reason, all the transients in $NaClO_3$ are reported at 1000 rpm.

Figure 7 represents typical transient curves at various passive and transpassive potentials. The current jumps to a large value as soon as an anode potential is applied; it then drops rapidly to a steady-state value. It has been found that the current can be described by an empirical relation

$$i = \alpha e^{-t/\tau} + i_s \qquad [2]$$

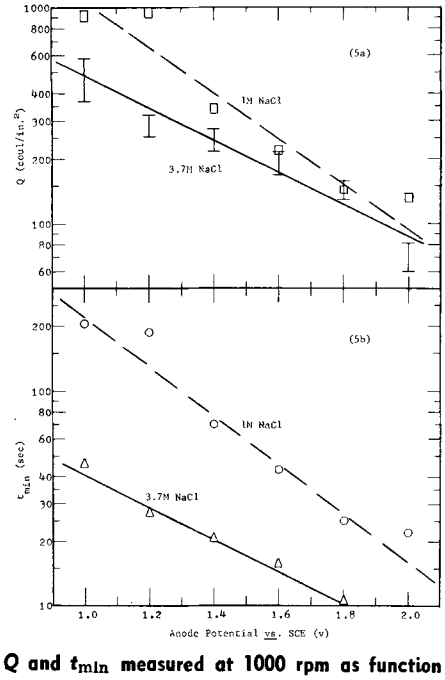

Fig. 5. Q and t_{min} measured at 1000 rpm as function of anode potentials.

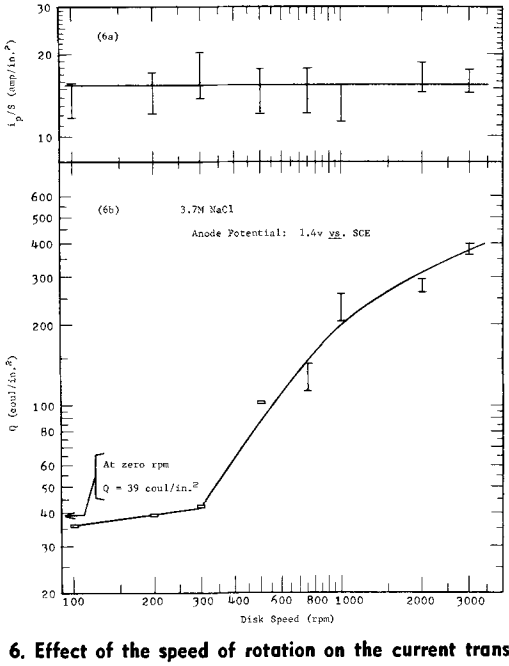

Fig. 6. Effect of the speed of rotation on the current transient

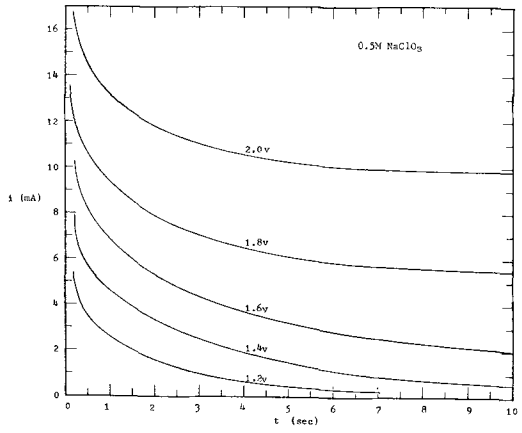

Fig. 7. Current transient in the $NaClO_3$ electrolyte

where α and τ are constants, and i_s is the steady-state current. Figures 8 and 9 are the plots of log $(i-i_s)$ *vs.* t for 0.5M and 4M $NaClO_3$ electrolytes. For $t > 1$ sec, Eq. [2] fits perfectly the experimental data obtained at different passivity potentials. In the transpassive region, the data points plotted this way are slightly curved (see Fig. 8), indicating that the equation is not valid in this region. The cell current measured with 4.0M electrolyte at different passivity potentials falls closely about a straight line. It seems that the potential dependence of the current transient decreases with increasing electrolyte concentration.

Discussion

Nature of passivation in NaCl electrolytes.—Both the transient behavior and the steady-state polarization curves have clearly shown that the steel anode becomes passive in NaCl electrolytes when the anode potential is beyond the active potential. Experimental observation has revealed that the dark blue film formed on the anode surface is quite thick and porous. Parallel examples of this kind are the passivity of iron in sulfuric acid (7-9) and of copper in hydrochloric acid (10). At the passivity potentials, these two systems have the same transient behavior as shown in curves 4c and 4d. Their passivity has been attributed to the formation of an adsorbed layer of anodic product; in the copper-hydrochloric acid system, this layer was identified by Cooper (10) as CuCl.

Apparently, the passivity of steel in the NaCl solution can also be attributed to the formation of an adsorbed layer of anodic products on the electrode surface. The exact composition of this layer is not known. It has been found that during ECM of steel in NaCl, iron dissolves into the electrolyte to form a final product of $Fe(OH)_2$ (11). At sufficiently high potentials, the anodic current density is very large, and the electrolyte in the neighborhood of the anode becomes supersaturated with ferrous compounds. Some of the ferrous compounds, such as $Fe(OH)_2$, thus precipitate on the anode surface as a porous layer of ferrous salts.

This hypothesis may be confirmed by comparing the transient data with Muller's theory of the film formation due to precipitation of reaction products on the electrode surface. The behavior of curves 4c and 4d indicates that the current at the initial period is not affected by the precipitation of the anode product. Only when the electrode becomes nearly covered with the precipitates does the resistance of the film control the flow of current. The current flowing through the cell, therefore, remains constant until the anode is nearly covered with the film, and then drops rapidly. For the film growth of this kind, Muller (12) has derived an equation for the behavior of current when the film nuclei are spreading from random sites to form a platelet over the electrode surface. The current-time relation during this stage of film growth is given as

$$t = C_1 + C_2\left(-\frac{1}{i_p - i} + \frac{1}{i_p}\ln\frac{i_p - i}{i}\right) = C_1 + C_2 f(i) \qquad [3]$$

where i_p is the plateau current, and C_1 and C_2 are constants for a given transient. The constant, C_1, is a measure of the duration of the current plateau, and C_2 is inversely related to the rate of current decrease. To test the validity of the Muller theory to this particular problem, the function, $f(i)$, (calculated for the transient curve, Fig. 4c, obtained at zero revolutions per minute) is plotted against the time, t, in Fig. 10. It is

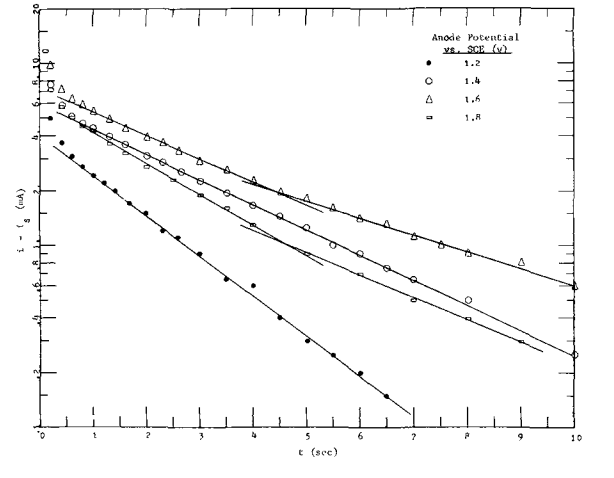

Fig. 8. Semilogarithmic plot of anode transients for 0.5M $NaClO_3$.

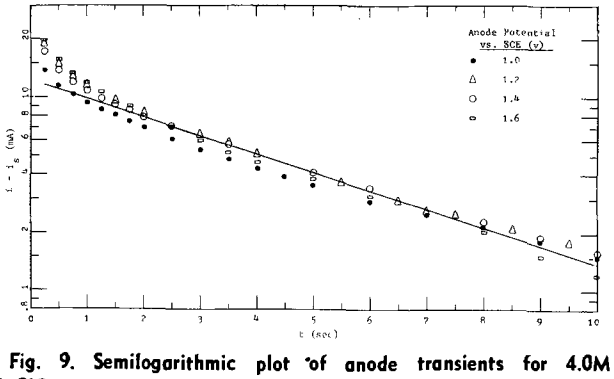

Fig. 9. Semilogarithmic plot of anode transients for 4.0M $NaClO_3$.

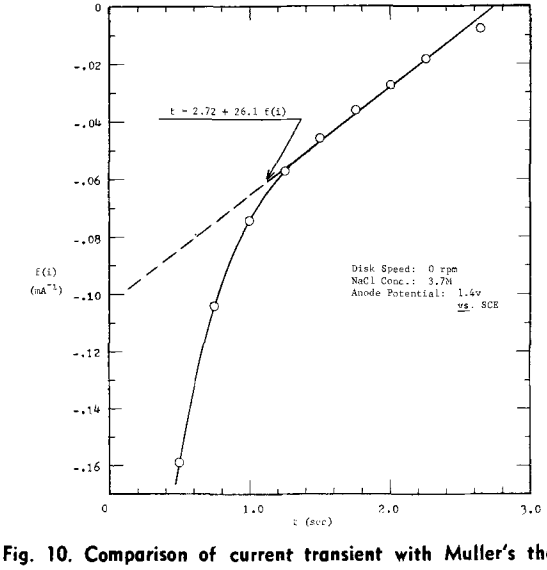

Fig. 10. Comparison of current transient with Muller's theory

seen that for t larger than 1.2 sec, the decrease of current is indeed described by the Muller equation. The time constant C_1 calculated this way is 2.72 sec; interestingly, this value is very close to t_{min} = 2.8 sec as shown in curve 4c.

Since the Muller theory only describes the behavior of current drop, one may assume that the initial period of the current transient represents the period of film nucleation and growth of film nuclei to the critical sizes before spreading over the anode as platelets. Two factors could influence the duration of this period. The first factor is the rate of iron dissolution: the higher the dissolution rate, the higher will be the supersaturation of the anodic product near the anode surface, and consequently the faster will be the rate of nucleation and growth of the nuclei. Figure 2 indicates that the plateau current density represents the dissolution rate before the anode is covered by the film. Therefore, the higher the plateau current, the shorter will be the initial period. This tendency is clearly seen in Fig. 5, where t_{min} and Q are plotted against the anode potential. Recall that t_{min} is the length of time required for the current to reach the minimum; it is nevertheless also a good measure of the duration of the nucleation period because the period of current drop is very small. Since the plateau current, as shown in Fig. 2, increases with potential and electrolyte concentration, it is not surprising that t_{min} decreases considerably with increasing potential and concentration. Furthermore, the amount of charge, Q, required to pass through the cell before a complete layer of film has formed, also decreases with the dissolution rate. This can be seen with a closer look at Fig. 2 and 6a: Take 3.7M NaCl, for instance. The value of Q decreases from 500 coulombs/in.^{2} to about 90 coulombs/in.^{2} when the anode potential increases from 1.0 to 2.0V *vs.* SCE, whereas the corresponding plateau current densities at these two potentials are 9 and 17 A/in.^{2}.

The second factor that affects the period of film nucleation is the convection of the electrolyte in the neighborhood of the anode. In a flowing NaCl electrolyte, apparently only a fraction of the anodic product formed precipitates on the anode surface as a solid film; the rest is washed away by the electrolyte. Figure 6 demonstrates the effect of convection to the length of the nucleation period. In that particular run the plateau current is nearly the same for all the speeds investigated; the duration of nucleation as denoted by Q, however, increases sharply with increasing speeds of rotation beyond 300 rpm. Assuming that there is a boundary layer over the electrode surface within which the electrolyte is saturated with the anode product, the increase in the rate of electrolyte flow would reduce the thickness of this layer and, consequently, more anode product is carried away by the electrolyte before it precipitates on the surface. Therefore, the length of the nucleation period increases with increasing flow rate.

The phenomena of current oscillation and the overshoot to the minimum as shown in Fig. 2 are rather puzzling. At present there are no satisfactory explanations; further investigations are necessary before a definite conclusion can be reached.

Anodic film in $NaClO_3$ electrolytes.—Figure 3 indicates that a protective film is formed on the anode surface when the applied potential is between 0.5 and 1.4V *vs.* SCE. Hoare and his co-workers (3-5) have attributed the property of good shape control of sodium chlorate to the formation of this film on the surface of workpieces. They point out that the extent of shape control increases with increasing slope of transition from the passive to the transpassive region on the steady-state polarization curve. It seems that, among the curves shown in Fig. 3, the best shape control will be obtained at 4.0M. This result agrees with the experience that good cutting can be achieved only in highly concentrated $NaClO_3$.

The composition of the film, according to x-ray diffraction studies (3), is a layer of γ-Fe_2O_3. Nagayama and Cohen (13), who have studied the passivity of iron in borate-boric acid, suggest that the inner layer of the oxide film is composed of Fe_3O_4. In a later paper, Sato and Cohen (14) give an empirical equation

$$i = A \exp\left(-\frac{Q_t}{B}\right) \qquad [4]$$

to describe the growth of an oxide film on iron in the borate-boric acid electrolyte. Here A and B are constant for a given potential and electrode surface area; the quantity, Q_t, is the amount of charge accumulated in the film at the time, t. Accordingly, if the current transient curve is replotted in the form of log i *vs.* Q_t, one should obtain a straight line. The transient data of 4.0M $NaClO_3$ plotted this way are shown in Fig. 11, where Q_t is calculated graphically from the data as $\int_0^t (i - i_s)dt$, for the steady-state current does not contribute to the formation of the film. It is seen that the data are not described by Eq. [4]. Therefore, the mechanism of the film growth in $NaClO_3$ is different from that in the borate-boric acid electrolyte.

At the passivity potentials, Fig. 3 indicates that the anodic current density is on the order of 60 mA/cm^2, while the corresponding current density of an iron anode in borate-boric acid is at least 1000 times smaller. This suggests that the oxide film formed in the chlorate electrolyte is porous in nature, although it serves as a protective layer to prevent the wild cutting in ECM operations. The porosity may be confirmed by comparing Eq. [2] with Vermilyea's theory of film growth. For the situation where the growth is controlled by the rate of metal dissolution, he has derived the following relation describing the decay of current due to spreading of a nonconductive film from random nuclei (15)

$$i = \alpha e^{-t/\tau} \qquad [5]$$

and

$$\tau = \frac{SnF\rho\delta}{\alpha M}$$

Here α is the initial current, and M, ρ, and δ are the molecular weight, density, and thickness of the film. The constant, n, is the number of electrons transferred in the film-formation reaction, and S is the surface area of the electrode. Since there are numerous nuclei spreading laterally during the growth process, the anode surface is soon covered with a film having a great number of pores. One of the major assumptions in Eq. [5] is that the pores are closed entirely; thus, no current will be permitted to flow through the cell after the anode has been covered with the film. Comparing Eq. [2] and [5], it is seen that the two equations have exactly the same form, except that Eq. [2] has an

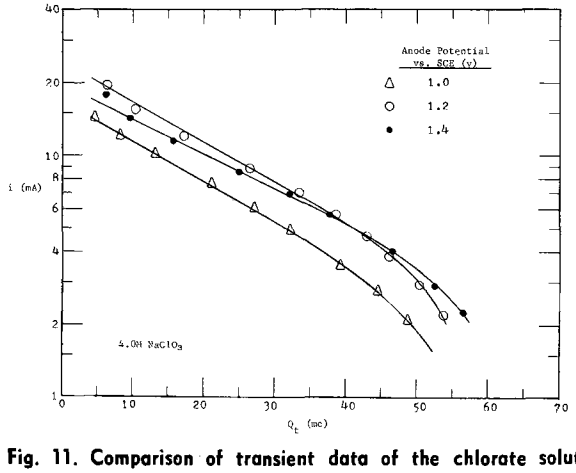

Fig. 11. Comparison of transient data of the chlorate solution with Sato and Cohen's empirical equation.

additional term, i_s. It appears that, after reaching an equilibrium condition, the pore area of the film in the chlorate electrolyte will not diminish to zero. Apparently, there are two processes taking place simultaneously during the anodic treatment of steel in $NaClO_3$. The first one is the dissolution of iron into the electrolyte, and the second one is the formation of an anodic film. The dissolution is inhibited by the film formation process, for the spreading of the film would reduce the area of active sites where the dissolution is taking place. After the steady state has been reached, the normal dissolution reaction can occur only within the pores of the film, and the steady-state current, i_s, may be regarded as the rate of dissolution within the pores. With the assumption that the pores are not closed entirely, Eq. [2] could be derived in a manner similar to that for Eq. [5]. In this case, the time constant, τ, should be modified to

$$\tau = \frac{SnF\rho\delta}{(\alpha - i_s)M} \qquad [6]$$

Figures 8 and 9 show that Eq. [2] fits perfectly with the transient data obtained at the passivity potentials. Probably a surface reaction that controls the rate of iron dissolution is the slowest step in the film-formation process. The rate of film formation would increase with increasing the dissolution rate.

Assuming that the film is γ-Fe_2O_3, one may estimate the film thickness from Eq. [6] with values of α and t evaluated graphically from Fig. 8 and 9. For approximation, the density of the film is assumed to be 5 g/cm^3 (16), and the apparent surface area of the anode is used for all the calculations. The results are listed in Table I. Also given in the table is the thickness calculated from coulometry. The two sets of computation agree with each other very well. The estimated film thickness is on the order of 1000Å. This result agrees with the fact observed from the ECM operation that a visible coating is always obtained on the workpiece after machining, for a film with a thickness of 1000Å is visible to the naked eye.

Table I. Estimated thickness* of oxide film in the chlorate electrolyte

Concentration $NaClO_3$ (M)	Anode potential *vs.* SCE (V)	Coulometry Q_∞,*** mc/cm^2	Coulometry $\delta \times 10^5$** (cm)	Equations 2 and 6 τ, sec	Equations 2 and 6 α, mA	Equations 2 and 6 $\delta \times 10^5$** (cm)
0.5	1.2	144	0.79	1.97	4.0	0.55
	1.4	250	1.40	3.14	6.0	1.32
4.0	1.0	700	3.8			
	1.2	710	3.9	4.79	12.2	4.1
	1.4	780	4.3	4.79	12.2	4.1

* The film is assumed to be γ-Fe_2O_3 having density of 5 g/cm^3 (16).
** Apparent surface area of the anode is used for the calculations.
*** Q_∞ is the amount of charge density required to produce a complete layer of the oxide film on the anode surface.

In summary, the transient measurement reveals formation of an anode film during the ECM of steel in sodium chloride and sodium chlorate solutions. For chloride, the film is very porous and nonprotective; its formation results from precipitation of the anodic product. For chlorate, the film is formed by anodic oxidation; electrode transient reveals that the film is about 1000Å thick and the rate of film growth increases with the increase in the rate of iron dissolution.

Manuscript submitted June 1, 1970; revised manuscript received *ca.* Oct. 1, 1970. This was Paper 218 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Technical Notes

Chemical Polish for Rare Earth Orthoferrites

L. K. Shick

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Proposed magnetic domain devices require large numbers of strain-free slices of suitable magnetic materials. Presently, after slicing, bulk grown single crystals of rare earth orthoferrites are polished to approximate required thickness using conventional diamond abrasives. The required final finish is obtained by an additional polish utilizing Syton. Syton, a trade name of Monsanto, consists largely of SiO_2 abrasive in

Key words: ferrites, phosphoric acid, polishing, rare earth ferrites, chemical polishing.

a basic colloidal suspension (1). Such polishing produces a smooth surface but has a tendency to round the edges of slices and produce taper in the material. The chemical mechanical action of this process is not understood.

The Syton process produces excellent, usable specimens, but the removal rate is very slow. Estimates of this rate range from 0.125 mil/hr to 0.25 mil/hr and it depends upon a variety of conditions including pad age and wear, total area of slices to a lap, applied pressure, and lap speeds.

A search has been conducted for a suitable chemical polish that would effect a more rapid removal rate and also produce strain-free surfaces. A review of the literature revealed a wide variety of etchants based on common laboratory chemicals. Many have been used successfully on refractory oxide materials (2-4). A survey was made to determine the effect of a number of these etchants on several of the general class $RFeO_3$ (R = rare earth) compounds. The conditions and results are presented in Table I. Ratios are in parts by volume.

As can be seen from the table, few of these etches have any effect. The HF containing formulations seemingly react, but do not polish. The rare earth fluorides are generally only slightly soluble and it is likely that an insoluble fluoride is produced at the surface precluding further reaction.

Phosphoric acid has been used to chemically polish several garnets including YIG (4). The phosphoric acid containing etches all produce pits in orthoferrites at lower temperatures. At temperatures above 160°-180°C only H_3PO_4 remains (commercial H_3PO_4 is 85% acid and evolves H_2O as steam at 160°-180°C and thereby concentrates). Other common diluents will evaporate at elevated temperatures. Above 300°C, H_3PO_4 polishes rare earth orthoferrites. The results reported here have been obtained at 380°-425°C. At 500°C, rapid attack of the crystal is evident and results in a poor surface.

Procedure

Phosphoric acid is heated in a platinum crucible to about 170°C and held there until the vigorous evolution of steam ceases. The temperature is then raised to the polishing range. There are no experimental difficulties encountered in using phosphoric acid at 500°C when only a slight white vapor evolves. However continued heating results in polymerization and increased viscosity necessitating frequent changes of the acid.

The sample to be polished is mounted in a suitable holder at the end of a fused silica rod. Some samples have been tied to the rod with 0.010 in. Pt wire but due to the fragility of the samples a holder similar to that shown in Fig. 1 is preferred. Boron nitride does not react with H_3PO_4 during the short polishing times required and has been used successfully to fabricate the holder. Such a holder could easily be built to accommodate a large number of slices of uniform dimensions. This assembly is rotated at about 40 rpm and immersed in the acid for the desired polishing time. After removal the chips are allowed to cool and then washed in distilled water to remove any remaining acid.

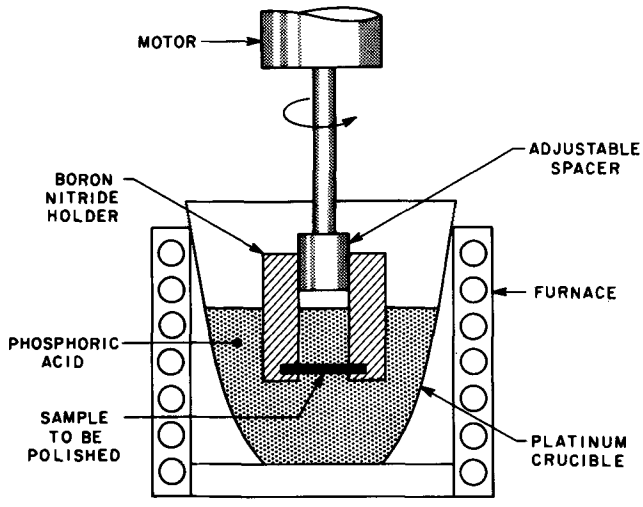

Fig. 1. Apparatus for chemically polishing rare earth orthoferrites

Results and Discussion

The material removal rate at 400°C has been determined by observing the weight loss of a sample during polishing. This rate for polishing times of 1-5 min is about 0.4 mil/min/side.

The surface of slices polished is smoothed to the extent that few features remain upon which an optical microscope can be focused. The Tally Surf trace shown in Fig. 2(a) is of a randomly selected slice of $Sm_{0.55}$ $Tb_{0.45}$ FeO_3 after Syton polishing. The trace in Fig. 2(b) is of a similar slice after a one minute chemical polish. The surface variation is of the order of $\pm 0.25\mu$ for the chemically polished piece while the single peak on the Syton slice is $>0.5\mu$ above the average surface.

Smoothing action of the polish is enhanced by slow rotation of the sample. Static polishing produces surfaces with greater ripple than that evident in Fig. 2. Very fast rotations, *i.e.*, >1000 rpm, result in spiral patterns of ripple on the surface due to vortex effects in the liquid. Results reported here are from samples rotated at about 40 rpm.

Residual surface strain induced in diamond polished rare earth orthoferrites renders them useless for device utilization unless the strain is relieved by annealing (5) or Syton polishing. The domain pattern may be observed by the Faraday rotation of polarized light. A white edge on a normally black domain indicates that the wall passes through the slice at some

Table I. The effects of various etchants on rare earth orthoferrites

Etchant	Temp, °C	Time	Results
1 Cr_2O_3 (Sat H_2O): 3H_3PO_4	80-100	30 min	pits
1 Sat $K_2Cr_2O_7$: 0.1 H_2SO_4: 0.02 Sat NaCl	*room temp*	*several hours*	no effect
1 Sat $K_2Cr_2O_7$, 0.1 H_2SO_4: 0.02 Sat NaCl	180	4 hr	no effect
Sat $K_2Cr_2O_7$ in H_2O	80-100	1.25 hr	no effect
Sodium Potassium Tartrate	molten	1 min	no effect
1 H_3PO_4: 1 HCl: 1 MeOH	80-100	25 min-1.5 hr	pits
1 NaOH: 1 30% H_2O_2	90	15 min	no effect
1 NH_4OH: 1 30% H_2O_2	90	15 min	no effect
1 HF: 2HNO_3: 3H_2O	80-100	5-30 min	attacks surface slowly—leaves it rough
1 HF: 1 H_2SO_4: 1 H_2O	boiling	10 min	opaque film on surface
1 HF: 1 H_2O_2: 1 MeOH	75	5 min	no effect
1 H_3PO_4:1H_2O	rapid "boiling"	5-6 min	smooths damage but tends to pit
1 H_3PO_4: 3 H_2O	rapid "boiling"	5 min	no effect
H_3PO_4	300	1 min	pits
H_3PO_4	400-425	1 min	polishes
H_3PO_4	500	1 min	rapid attack of crystal

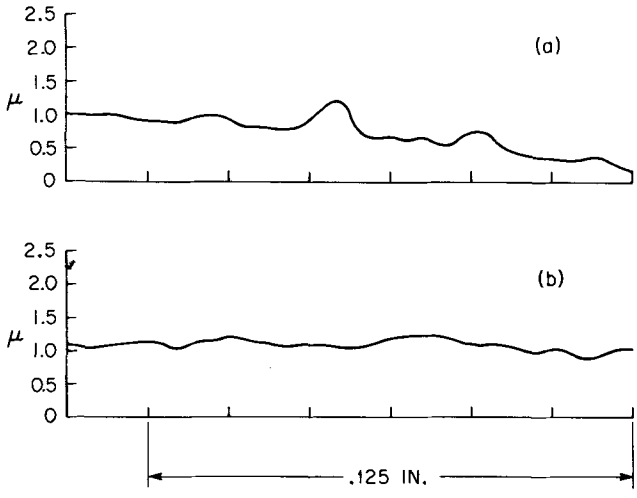

Fig. 2. (a) Tally Surf trace of Syton polished $Sm_{0.55}Tb_{0.45}FeO_3$. (b) Tally Surf trace of chemically polished $Sm_{0.55}Tb_{0.45}FeO_3$.

angle other than 90° thereby changing the Faraday rotation angle. The effect of surface strain on the domains is illustrated in Fig. 3(a) which is a portion of the domain pattern of a 0.004 in. thick slice of $Sm_{0.55}$ $Tb_{0.45}$ FeO_3 that had been polished with 0.1μ diamond abrasive paste. The irregular domain widths and ragged walls are indicative of locally high coercivity induced by surface strain. That the surface is highly strained is further evidenced by the alternate white and black edges of the domain pattern.

Low surface strain is characterized by domains of uniform width and parallel walls. The domains tend to stretch into smooth walled strips with only large radius curves to minimize wall energy. The effect of the chemical polish in removing surface strain is shown in Fig. 3(b) which is a portion of the domain pattern of the same slice shown in Fig. 3(a) after chemically polishing for 10 sec. Much of the strain evident in Fig. 3(a) has been removed. The smooth domain walls, the near uniformity of the domain widths, and absence of the changing Faraday rotation suggest that the strain has been significantly reduced resulting in lowered coercivity. Figure. 3(c) illustrates the domain pattern in a portion of a Syton polished slice of $Sm_{0.55}$ $Tb_{0.45}$ FeO_3. The patterns in Syton polished and chemically polished slices are comparable in that surface strain effects such as seen in Fig. 3(a) are eliminated in each. However the Syton operation required several hours to achieve this degree of strain removal whereas the chemical polish effected a similar result in only 10 sec.

In order to determine sample perfection and suitability for device use, Shumate (6) has developed a device that enables a single cylindrical domain to be systematically scanned through the chip. When the

domain encounters a defective area in the crystal, it is indicated by a deflection in a chart trace. At the completion of scanning, a map of the defects in the crystal results. A map of a slice of $TmFeO_3$ that had been Syton polished is shown in Fig. 4(a). The deflections have been joined to emphasize linear defects such as cracks, twins, or scratches. Several scratches are evident through the center of the slice as well as other unidentified domain pinning points. The line formation in lower left is a crack and the nearly vertical line at left is due to a difference in thickness of the slice. The device is sensitive to distortions of the domain and since the domain diameter is a function of chip thickness (7), variations in thickness will appear on the map. A serious defect appears at lower right.

The slice was chemically polished for 10 sec and remapped. The resulting trace is shown in Fig. 4(b). The slice broke along the crack at the left during handling so the shape is different from Fig. 4(a). The central scratches and most of the pinning points in that region have been eliminated. The thickness effect at left remains and two smaller line defects have developed in the upper left. The serious defect at right has been reduced to a single large pinning point. The long line at right is associated with the point of contact of the slice with the holder.

Due to the high sensitivity of the mapping technique and the severe surface strain in crystals that have been diamond polished, it is not possible to obtain a meaningful map of an orthoferrite slice prepared in this manner for direct comparison.

Conclusions

Phosphoric acid at 380°-425°C has been shown to polish thin slices of rare earth orthoferrites rapidly and to remove residual surface strain induced by conventional mechanical polishing. Certain types of defects remaining after Syton polishing are also removed while maintaining comparable smoothness.

It is evident the chemical polish removes many of the defects left behind by mechanical or chemical mechanical polishing methods. Crystallographic defects of course can be eliminated by neither method, but may be exposed by chemical polishing.

Acknowledgments

My sincere thanks are due to P. W. Shumate for mapping the $TmFeO_3$ sample and to R. F. Fischer and S. L. Blank for valuable discussions during the course of this work.

On the Cathode Reaction in Solutions Containing ClO_3^-

Fumio Hine[*,1] **and Masaki Yasuda**[1]

Kyoto University at Uji, Uji, Japan

The cathodic reduction of ClO^- in the diaphragm-type chlorine cell has been described in a previous paper (1). Since the effects of ClO_3^-, which may form at the graphite anode, on the cathode reaction should be considered (2), some experiments have been carried out.

Hydrogen evolution from H_2O

$$2H_2O + 2e = H_2 + 2\,OH^- \qquad [A]$$

is well known to be the main reaction at the steel cathode of the diaphragm cell, but two processes

$$ClO^- + H_2O + 2e = Cl^- + 2\,OH^- \qquad [B]$$

and

$$ClO_3^- + 3H_2O + 6e = Cl^- + 6\,OH^- \qquad [C]$$

are also considered to be the side reaction according to Kircher *et al.* (3). Of these, reaction [*B*] is fast, but is limited by diffusion of ClO^- to the electrode surface at high current densities.

The anodic formation of ClO_3^- has been studied by many authors and the mechanism is summarized according to Ibl *et al.* (4) as follows

$$6ClO^- + 3H_2O = 2ClO_3^- + 4Cl^- + 6H^+ + \frac{3}{2}O_2 + 6e$$

(by anodic oxidation) [*D*]

$$Cl_2 + H_2O = HClO + Cl^- + H^+ \qquad [E]$$

$$HClO = ClO^- + H^+ \qquad [F]$$

and

$$2HClO + ClO^- = ClO_3^- + 2Cl^- + 2H^+ \qquad [G]$$

(by chemical reaction)

On the other hand, papers on the cathodic reduction of ClO_3^- have not yet been published. Whether reactions [C] and [*D*] take place at the cathode in alkaline solution of NaCl is discussed here.

Experimental Procedure

The electrolytic cell used for polarization measurements was the same as that of previous work (1). A platinum rotating disk of 0.95 cm^2 area was used as the working electrode. The cathode of the diaphragm cell consists of a steel screen. Thus, a steel disk electrode was first examined. Unfortunately, satisfactory results were not obtained due to the disturbance caused by the local anodic dissolution of iron at low current densities. The mechanism of the cathode reaction on both steel and platinum electrodes is the same, while the exchange current density is, of course, related to the cathode material. Therefore, the data obtained with the noble metal cathode are considered feasible for discussion, particularly at high current densities.

The solution was prepared with analytical grade NaCl, NaOH, and $NaClO_3$ with deionized and distilled water. The concentration of ClO_3^- was varied from 0 to 0.4 g-equiv/liter. Chlorate ions were titrated with standard solutions of Mohr salt and cerium sulfate (5).

The electrolytic solution was deaerated with purified hydrogen for 2-3 hr, and pre-electrolyzed with a platinum cathode of about 5 cm^2 area at 10-20 mA for about 12 hr before use.

The potential of the working electrode was measured against the reference electrode consisting of Hg/HgO/2*N* NaOH, then it was converted into the normal hydrogen electrode scale.

Since the *IR* drop between the working electrode and the Luggin probe was considerable at high current densities, it was corrected by extrapolation of the potential *vs.* distance curve to zero distance at a given current (6).

The current efficiency of the hydrogen evolution from the cathode having 1.26 cm^2 area was determined by means of gas analysis.

Results and Discussion

An example of the potential *vs.* current density curve is shown in Fig. 1. The potentials observed in

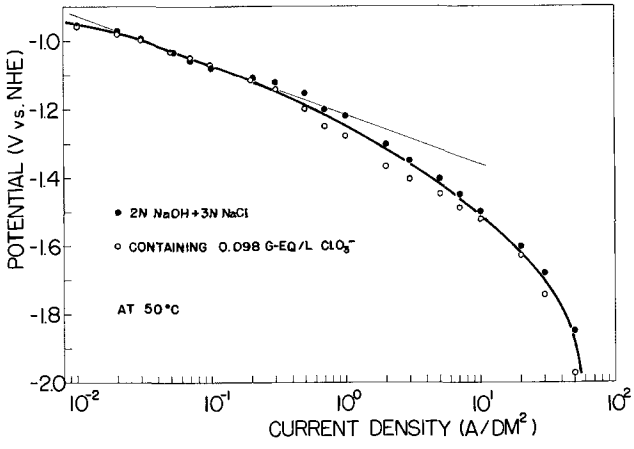

Fig. 1. The potential *vs.* current density curves of a Pt cathode in alkaline solutions of NaCl with and without ClO_3^-.

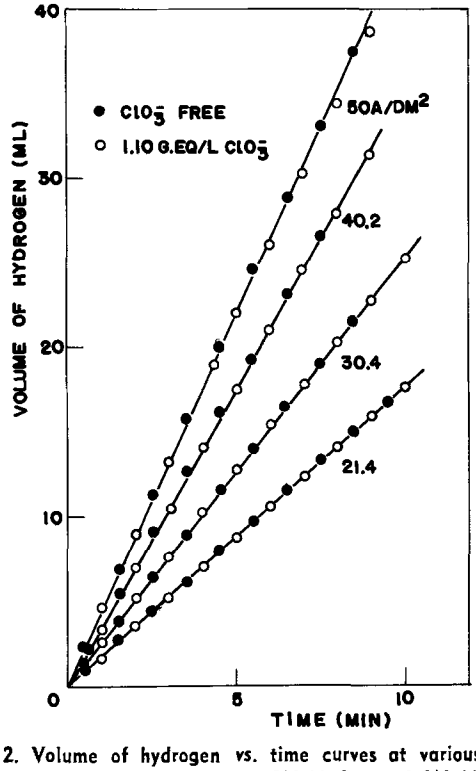

Fig. 2. Volume of hydrogen *vs.* time curves at various current densities in solutions consisting of 2*N* NaOH and 3*N* NaCl with and without ClO_3^- at 20°C (cathode area: 1.26 cm^2).

a solution consisting of 2*N* NaOH and 3*N* NaCl free from ClO_3^- are shown by the closed points and the open points illustrate the data in a solution containing 0.098 g-equiv/liter ClO_3^-. At low current densities, less than 1 A/dm^2, the slope of the potential *vs.* logarithm of current density curve is about 140 mV/decade, if α in the Tafel coefficient, $RT/\alpha\mathbf{F}$, is assumed to be 0.5, as shown by the straight line in Fig. 1. The potential deviates from the Tafel plot at high current densities and the potential tends to be extremely less noble at current densities more than 50 A/dm^2, probably due to the lack of the active sites on the electrode surface. Because the potential *vs.* current density curve is not affected by ClO_3^-, it was assumed that the cathode reaction in a solution containing ClO_3^- is similar to one in a solution free from chlorate ions.

An example of the volume of hydrogen evolved *vs.* time curve is shown in Fig. 2. The closed points show the data obtained in a solution consisting of 2*N* NaOH and 3*N* NaCl without ClO_3^- at 20°C. The current efficiency was almost 100% for various current densities. The open points are the data in a solution containing 1.10 g-equiv/liter ClO_3^- under the same conditions. It also shows that the current efficiency of the hydrogen evolution reaction is independent of ClO_3^-. The same results were found with a variety of solutions as shown by the solid line in Fig. 3. It is interesting that the broken line, which shows the data obtained in a solution containing ClO^-, is lower than and parallel to the solid line. The cathodic reduction of ClO^-, at a limited rate due to the slow step of diffusion, takes place in advance of the charge transfer of H_2O to convert into H_2 and OH^- as described elsewhere in detail (1).

In conclusion, the charge transfer of ClO^- at the cathode is fast, but the cathodic reduction of ClO_3^- may not take place under operating conditions of the diaphragm-type chlorine cell in practice.

Acknowledgment

Platinum Electrodes and Calcia-Stabilized Zirconia

The Relation between Electrode Processes and Electrode Structure

R. J. Brook,[1] W. L. Pelzmann,[2] and F. A. Kröger*

University of Southern California, Los Angeles, California 90007

ABSTRACT

Measurements of the direct current-voltage characteristics of calcia-stabilized zirconia using platinum electrodes of various types have been made to investigate possible electrode processes. Depending on the form of the electrode, the rate-limiting step in the electrical conduction sequence can be (*a*) ionic conduction by $O^=$ in the zirconia, (*b*) electronic conduction in the zirconia, (*c*) oxygen atom diffusion through the platinum cathode, (*d*) the transfer of oxygen from the gas phase into the zirconia at the zirconia-gas interface on the cathode side. The conditions, under which each of these situations exists, are explained in terms of the structure of the electrode.

Earlier studies on cells Pt, $O_2|0.85\ ZrO_2 \cdot 0.15\ CaO|Pt$, O_2 with platinum point electrodes (1), or porous platinum electrodes (2), showed the I-V characteristic to be markedly nonohmic. The rate-controlling step responsible for this behavior was found to be confined to the cathode. Two mechanisms of electrode operation appeared to be important (2). At low voltages (*e.g.*, <2.5V), the voltage dependence and oxygen pressure dependence of the I-V characteristic can be explained by a model in which diffusion of oxygen atoms through the platinum grains from the gas phase to the platinum-zirconia interface is the rate-limiting step in the over-all conduction process. However, as discussed in greater detail further on, other processes involving the diffusion of atomic oxygen cannot be excluded. At higher voltages, extreme polarization occurs within the zirconia in the neighborhood of the platinum cathode, and as a result the surface of the zirconia becomes sufficiently nonstoichiometric that it supports electronic conduction. Then, again from consideration of the form of the I-V characteristics and its independence of oxygen pressure at high voltages, it was found that oxygen can move directly from the gas phase into the zirconia and that the rate-controlling step consists of the reaction

$$O\ (\text{adsorbed}) + V_O^x \rightarrow O_O^x \qquad [1]$$

Here O_O^x represents a normal oxygen ion in the zirconia, and V_O^x represents an oxygen ion vacancy with two trapped electrons. Another high voltage mechanism, electronic conduction, requires comparatively long times to build up and was almost completely eliminated by using short observation times. It might be questioned whether the use of this technique does not forbid the application of stationary state considerations as used to arrive at the mechanism characterized by Eq. [1]. We believe, however, that the slow process setting up electronic conduction represents only a small perturbation and that, therefore, the results arrived at are essentially correct. We shall use the same approach in the present paper.

The aim of the present study has been to consider two questions arising from the earlier work, namely: (*i*) if diffusion of oxygen through platinum is rate controlling, then the value of the conductance should be inversely proportional to the diffusion path length. Examination of foil electrodes should reveal this relation specifically; also, the conductance of the paste electrode should depend on the temperature at which it was sintered, *i.e.*, on the grain size of the resulting electrode. (*ii*) If the second mechanism depends on the existence of free zirconia-oxygen interface, then it should be possible to suppress it by examining configurations where such an interface is absent, *i.e.*, cells having large area foil electrodes. Under these conditions, and by allowing sufficient time for a stationary state to be reached, the electronic conduction which is relatively unimportant with the porous electrodes should become the dominant mechanism.

Possible Electrode Mechanisms

The discussion given here is valid in principle for any system in which current flow through an essentially ionic conductor requires reaction at a metal electrode of one of the components of the conductor in gas form. For convenience, the discussion is concentrated on the system ZrO_2*-Pt-O_2. Here and further on, ZrO_2* indicates stabilized zirconia of the composition $0.85\ ZrO_2 \cdot 0.15\ CaO$.

The parameter of interest in the study of electrode mechanisms in this type of system is the extent to which the electrode is blocking for the species present in the gas phase, *i.e.*, is effective in preventing access of ionic carriers to the electrolyte. Where the electrode is partially blocking, it is possible to investigate the path taken by those ionic carriers that are allowed through to the electrolyte by observing the d-c current-voltage characteristics. The presence of electrode effects is then revealed by the nonohmic response of

Key words: electrode structure, platinum electrodes, stabilized zirconia, electrode processes.

the system as a whole, and the nature of these effects can be determined by a study of the partial pressure dependence of the current.

A major division among electrodes can be made on the basis of their porosity. If the electrode is nonporous, for instance a dense foil pressed onto the electrolyte surface, then, as discussed by Tedmon *et al.* (3), ionic carriers are prevented from direct access to the electrolyte surface and must diffuse through the electrode material itself. Under these conditions the rate-limiting step in the ionic conductance may be diffusion of an atomic species from the gas to the conductor through the metal foil or of molecules of the conducting species through a boundary layer in the gas phase to the surface of the electrode. With $ZrO_2^*|O_2$ the diffusing species in the former process should be atomic oxygen, O, and it would have a rate dependent on the root of the gas phase oxygen pressure, $pO_2^{1/2}(g)$. For the case of rate limitation by gas diffusion, the diffusion species would be molecular oxygen, O_2, and would have a rate linearly dependent on $pO_2(g)$. The relative importance of these mechanisms will depend on such factors as foil thickness, gas phase composition, gas phase boundary layer thickness, and magnitude of the attainable ionic current.

When the electrode, by one or other of the mechanisms, is partially effective in blocking the passage of the ionic species, polarization of the electrolyte occurs, and a gradient in the chemical potential of oxygen is established across the electrolyte, which gives rise to electronic conduction. For systems such as stabilized zirconia in which the ionic conduction is practically independent of pO_2, the electronic conductivity of the electrolyte at any point x in the stationary state is given by (4, 5)

$$(\sigma_e)_x = \sigma_e^{\circ} \exp \frac{-[\mu O_{2,x} - \mu O_{2,a}]}{4kT} \qquad [2]$$

Here $\mu O_{2,x}$ and $\mu O_{2,a}$ are the chemical potentials of O_2 inside the zirconia at x, and at the anode, respectively, and σ_e° is the electronic conductivity under zero polarization as it is determined at the anode by the prevalent oxygen pressure. This formula is valid only if σ_e° is independent of the current, *i.e.*, if no overvoltage effects for oxygen discharge and evolution occur. Formula [2] indicates that under extreme polarization large values of σ_e can be attained.

To determine the interaction between the ionic and electronic conductances, the electrode reaction may be written as

$$\tfrac{1}{2}O_2 \rightarrow O_O^x - V_O^{\cdot\cdot} - 2e';$$
$$\tfrac{1}{2}\mu O_2 = \mu(O_O^x) - \eta(V_O^{\cdot\cdot}) - 2\eta(e') \qquad [3]$$

where $V_O^{\cdot\cdot}$ represents a vacant oxygen ion site in the zirconia and e' an electron; the η's are electrochemical potentials. Assuming local equilibrium, and neglecting $d\mu(O_O^x)/dx$ which is practically zero, the gradients should satisfy

$$\frac{1}{4}\frac{d\mu(O_2)}{dx} = \frac{d\eta(e)}{dx} + \frac{1}{2}\frac{d\eta(V_O^{\cdot\cdot})}{dx} \qquad [4]$$

If the electrode is fully transmitting (nonblocking) to ions and electrons

$$\frac{1}{4}\frac{d\mu(O_2)}{dx} = q\frac{J_e}{\sigma_e} - q\frac{J_i}{\sigma_i} = q\frac{dE}{dx} - q\frac{dE}{dx} = 0 \qquad [5]$$

and from [2]

$$\sigma_e = \sigma_e^{\circ} \qquad [6]$$

Here J_e and J_i are current densities of electrons and ions, σ_e and σ_i are the respective conductivities, q is the magnitude of the electronic charge, and E is the electrical potential.

For an electrode totally blocking to ionic carriers, $J_i = O$, and

$$\frac{1}{4}\frac{d\mu(O_2)}{dx} = q\frac{J_e}{\sigma_e} = q\frac{dE}{dx} \qquad [7]$$

Integrating [7] from the anode to the cathode, using [2], assuming the area and J_e to be independent of x, gives

$$\sigma_e = \sigma_e^{\circ}\left[\exp\left\{\frac{qE}{kT}\right\} - 1\right] \qquad [8]$$

This is under the assumption that hole conduction is negligible under all circumstances. If not, then an appropriate hole term has to be added (6, 7). For the intermediate case of a partially blocking electrode, the actual ionic current density, J_a, will be less than the ionic current that would occur in the absence of polarization, J_i, but will be more than zero. Then

$$\frac{1}{4}\frac{d\mu(O_2)}{dx} = q\frac{J_e}{\sigma_e} - q\frac{J_a}{\sigma_i} = q\frac{J_e}{\sigma_e} - q\frac{J_i}{\sigma_i}\frac{J_a}{J_i}$$
$$= q\frac{dE}{dx} - q\frac{dE}{dx}\frac{J_a}{J_i} \qquad [9]$$

Under conditions where blocking is incomplete but nevertheless large, $(1 - J_a/J_i)$ is a slowly varying function of E and the electronic current density is given by

$$J_e = \frac{kT}{ql}\sigma_e^{\circ}\left[\exp\left\{\frac{qE}{kT}\left(1 - \frac{J_a}{J_i}\right)\right\} - 1\right]$$
$$\approx \frac{kT}{ql}\sigma_e^{\circ}\exp\left\{\frac{qE}{kT}\left(1 - \frac{J_a}{J_i}\right)\right\} \qquad [10]$$

with l the specimen thickness. The approximation holds for large E.

In summary, nonohmic behavior in the conductance of a system with a dense, nonporous electrode may arise from the control of ion motion by diffusion through the gas phase or the electrode, or from electron motion, the extent of electronic conductivity being determined by the blocking efficiency of the electrode. A convenient measure of the blocking efficiency is the parameter J_a/J_i which is zero for a totally blocking electrode and unity for a totally transmitting electrode. A schematic picture of the relation between J_a/J_i and σ_e is shown in Fig. 1, where the two contributions to the electron flux, *i.e.*, from the electron concentration gradient (diffusive) and from the electric potential gradient (electrical field) are distinguished. The considerations given so far are limited to the relatively mobile charged species. In the actual system, nonmobile or less mobile species $V_O^{\cdot}$ and V_O^x are formed by the trapping at $V_O^{\cdot\cdot}$ of electrons formed by the polarization process. The centers are visible as color centers (8, 9). The trapping tends to reduce the electronic current until a stationary state has been reached in which just as many electrons are trapped at $V_O^{\cdot\cdot}$ as

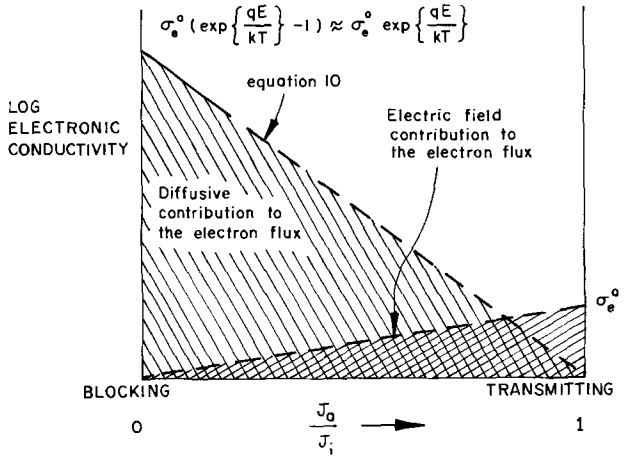

Fig. 1. Effect of the electrode blocking efficiency on the nature of the driving force for electronic conduction. The blocking electrode is the cathode and the anode is the reversible electrode.

are released from $V_O^{\cdot}$ and V_O^x. The time involved in reaching this stationary state was found to be considerable, *i.e.*, $\approx$ 4 hr at 600°C.

For porous electrodes, the situation is more complicated. Tedmon *et al.* (3) have again discussed some of the possibilities. If, for example, the porous electrode consists of a partially sintered platinum paste, then there are so-called triple points where the gas phase (O_2), the platinum (supplying electrons) and the electrolyte all come together. Ionic access then occurs over a limited area in the region of this triple junction which has led to the concept of a "constriction" resistance, where ionic flux through the triple junction is seen as the rate-limiting step.

Convincing evidence for the importance of the triple point has been provided by Karapachev (10), who found that the current provided by a platinum coating is increased at a given voltage by scratching lines in the coating and thus increasing the length of the triple junction. However, the importance of the junction does not in itself explain the detailed mechanism of oxygen access to the electrolyte. An effective junction must have some finite area at which O atoms are transformed into $O^=$ ions, and across which these ions enter the electrolyte.

If this area is at the platinum-zirconia interface, diffusion of oxygen through either the Pt or the zirconia (or along the $Pt|ZrO_2$ interface) must be involved and may be rate controlling. The rates of all three are proportional to $pO_2^{1/2}$ if the diffusion occurs in neutral atomic form as O_i^x. Diffusion of oxygen through Pt was proposed as the rate-limiting step in the low-voltage mechanism for ZrO_2* cells with porous Pt electrodes by Yanagida *et al.* (2). Solution of oxygen in the zirconia at the gas-zirconia interface, followed by diffusion of oxygen through the zirconia to the Pt-zirconia interface was proposed as the main low-voltage mechanism by Tannenberger *et al.* (11). The latter type of mechanism is believed to be the dominant one for gas electrodes in liquid electrolytes (12). Since bulk diffusion in neutral form does not, as a rule, take place to an appreciable extent in inorganic solid compounds (*vide* the Wagner theory of oxidation) we do not consider this a likely mechanism. However, diffusion along the $Pt|ZrO_2$ interface may presumably occur in neutral form, so this possibility remains open.

In principle, transport of O_2 by diffusion through the gas phase may also be rate controlling: mass transport polarization in the terms of Tedmon (3). This would lead to a rate $\propto pO_2$, but this type of limitation is to be expected only at large current densities.

If the transfer area lies at the gas-zirconia interface, electrons from the Pt have to reach the oxygen atoms by diffusion over the surface or through the subsurface of the zirconia. This requires that the zirconia surface be electronic conductive. This is normally not the case for ZrO_2* in contact with an oxidizing atmosphere, but it may become so as a result of polarization. Actually, Kleitz (1) observed that polarization of a Pt point on zirconia made the area of the zirconia around the point electronic conductive. Yanagida proposed this mechanism as the high voltage mechanism for diodes with porous Pt electrodes (2). The limiting step now is either the diffusion of O_2 in the gas phase, or one of the reactions involved in the take-up of oxygen in the zirconia. The latter was found to be the case.

Kleitz (1) suggested that surface diffusion of oxygen toward the triple junction and electrons from this junction along the ZrO_2*-gas interface limited the reaction rate at low voltages. However, as we saw above, electronic surface conduction is not to be expected for zirconia in contact with oxygen in the absence of considerable polarization. Therefore this mechanism may be rejected.

Summarizing the possible mechanisms for a porous electrode or for an electrode with an adjoining free zirconia oxygen interface, ionic conduction may be limited by gas phase diffusion, by diffusion through either the platinum or the zirconia or over the zirconia surface to the platinum-zirconia surface, or (at higher voltages and lower oxygen pressures) by one of the reactions involved in direct incorporation of oxygen into the zirconia at the free zirconia-oxygen interface. In addition, at sufficiently high voltages and after sufficiently long times, bulk polarization and therewith electronic conduction may occur. As noted earlier, it has been shown (2) that for partially sintered platinum pastes the steps limiting the ionic current are diffusion of oxygen through the platinum at low voltages and reaction [1] at high voltages.

Tests on other forms of electrode are the subject of the present work.

Experimental

The electrolyte in all the experiments consisted of specimens of 7.5% by weight calcia stabilized zirconia (0.85 ZrO_2·0.15 CaO), cut from disks, 2.5 cm in diameter and 0.75 mm thick obtained from the Zirconium Corporation of America. The samples, square plates with an area of 20 mm^2 were polished with 1μ diamond powder to a final thickness of $\approx$0.7 mm before application of the electrodes. The grain size of the zirconia was about 30μ in diameter.

The electrodes were prepared in a number of ways. Early in the study it was found that thinly sputtered platinum electrodes gave an ohmic I-V characteristic with a resistance equal to the bulk ionic resistance of the zirconia, a feature already noted by Heyne (13). Accordingly, in all subsequent tests, the electrode to be studied as a cathode was placed on one side of the specimen, and a standard thinly sputtered electrode (1500V, 5 x 10^{-2} Torr argon, 2 min, 2½ cm anode-cathode distance) entirely covered the other side. In this way, it was certain that deviations from an ohmic I-V characteristic could be attributed to the test electrode, and it also guarantees that the value of μO_2 at the anode remains at the equilibrium value; overvoltage of oxygen discharge and O_2 evolution would reveal itself by nonohmic behavior of the $Pt|ZrO_2|Pt$ cell with both electrodes consisting of sputtered Pt.

The test electrodes comprised

(*a*) Nonporous foil platinum electrodes prepared by attaching layers of 30μ thick foil to the zirconia. The foil was attached by pressing it against the zirconia under a 600g load (with powdered Al_2O_3 between the load and the foil to prevent adhesion) and heating to 1350°C for 1 hr.

(*b*) Nonporous foil platinum alloy (40% by weight rhodium) electrodes, attached in a similar way. These electrodes, referred to below as platinum 40-rhodium, behaved as did platinum except for their smaller oxygen diffusion coefficient.

(*c*) Nonporous sputtered electrodes prepared as for the standard electrode but with sputtering times up to 20 min.

(*d*) Porous paste electrodes prepared from nonfluxed platinum "inks" consisting of submicron platinum powder suspended in an organic vehicle. These were painted on the zirconia and fired to different temperatures to vary the degree of porosity and the value of the grain size.

(*e*) A nonporous paste electrode prepared as for (*d*) except that 10 w/o of lead borosilicate glass was added to the ink. This provides a nonporous "fluxed" electrode.

Measurements of the I-V characteristics were made in the circuit shown in Fig. 2. For the studies of ionic processes in all the electrodes, the I-V plot was made by applying an increasing voltage in 1-min steps of 0.6V and measuring the current at the end of the minute. This technique, by limiting the formation and diffusion of F-centers (2), gave the clearest information about the ionic conduction mechanisms. For electrodes (*a*) and (*b*), when in particular the electronic processes were being studied, values were taken after 1 hr when the system had come close to equilibrium;

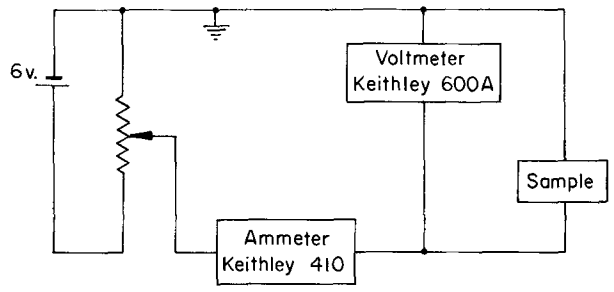

Fig. 2. Scheme of the test circuit

deviations from the true equilibrium value were negligible to two figures.

Measurements were made at temperatures between 500° and 700°C, and in oxygen pressures between 1 and 10^{-4} atm, established by mixing oxygen and technical nitrogen (containing 10^{-5} atm O_2). Buffer systems (H_2O/H_2) were used to achieve lower pressures (10^{-20} atm) but are not satisfactory for the observation of low pO_2 effects due to the decomposition of H_2O at the electrode, as will be discussed.

All the measurements were carried out for $E < 3V$. At this voltage, electrolysis sets in, as indicated by currents increasing continuously with time; the same was reported earlier by Yuan *et al.* (14).

Results

Nonporous foil electrodes.—Low voltage mechanism: the effect of foil thickness.—Thickness effects were tested by using foil electrodes composed of several sheets of the 30μ thick Pt foil. The electrodes were 4 mm^2 in area covering 1/5 of zirconia plates 20 mm^2 in area. The data are shown in Fig. 3.

When the foils were connected as the anode, the I-V curves were ohmic and similar to the I-V curves for cells with thin sputtered electrodes on both sides represented by the dotted line in Fig. 3. The solid lines are all for the foils as cathodes, *i.e.*, where they act as barriers to oxygen access to the electrolyte.

Yanagida *et al.* (2) analyzed the I-V characteristic for the situation where diffusion through a platinum layer is rate controlling in terms of the equation

$$V = IR_b + \frac{RT}{4F}\left[\ln pO_2(g) - 2\ln\left\{pO_2^{1/2}(g) - \frac{I}{B}\right\}\right] \qquad [11]$$

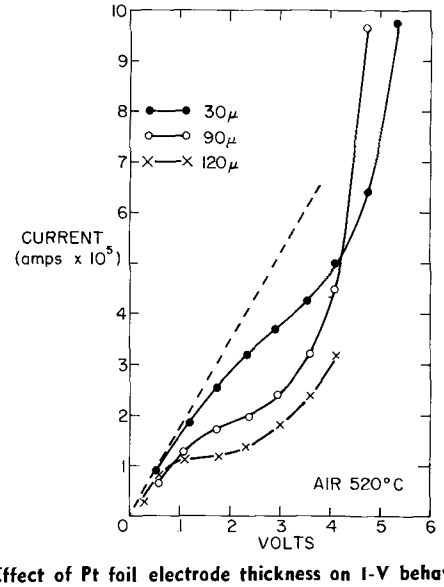

Fig. 3. Effect of Pt foil electrode thickness on I-V behavior. The dotted line is for a thin sputtered electrode. All electrodes are Pt and are observed as cathodes. S (cathode area) = 4 mm^2. The electrode thickness is indicated on the figure.

where R_b is the bulk ionic resistance (in the absence of polarization) and B is a term descriptive of the electrode. For justification of the use of this stationary state equation to describe an essentially nonstationary state, see the introductory paragraphs.

$$B = 2FS\frac{D}{\delta}K_1 \qquad [12]$$

Here S is the area of the electrode, D the diffusion coefficient of oxygen atoms in the Pt electrode, δ the electrode thickness, and K_1 the equilibrium constant for the reaction

$$\tfrac{1}{2}O_2 \rightarrow O(Pt) \qquad [13]$$

$R_b = 6 \times 10^4$ ohms and $pO_2(g) = 0.2$ atm (air). From [11], it may be seen that the current saturates ($V \rightarrow \infty$) when $I = pO_2^{1/2}(g)B$. From Fig. 3 it is seen that a saturation plateau for the thickest foil electrode (120μ) exists at 1.15×10^{-5}A; this means that B has the value 2.57×10^{-5}.

In Fig. 4, the data for the thickest electrode are compared with Eq. [11] plotted with the above values for R_b, $pO_2(g)$, and B. The data match the equation below and at saturation; above saturation another mechanism of conduction appears which is discussed in the next section.

Since B for the 120μ electrode is known, use of Eq. [12] allows calculation of B for the other electrodes since δ is the only variable. Then, from [11], the saturation currents for the other electrodes may be found; these are 1.5×10^{-5}A and 4.6×10^{-5}A for the 90 and 30μ electrodes, respectively. Figure 3 shows substantial agreement with these values, although the saturation levels are less clearly defined than for the 120μ electrode. The evidence is strong, however, that diffusion through the foil is the rate-controlling process at low voltage. This rules out the process in which neutral oxygen diffusion through the zirconia to the Pt-ZrO_2* interface is rate limiting, which is not surprising since a well-made foil electrode does not leave a free ZrO_2*-gas interface. This process, although unlikely for reasons mentioned earlier, still remains a possibility for porous electrodes. However, in view of the similarity in the low voltage behavior of porous and nonporous electrodes, it seems likely that both are limited by the same process, O-diffusion through Pt. Use of the experimental values of Fig. 4 in Eq. [12] indicates that at 520°C DK_1 is 4×10^{-11} g at. cm^{-2} sec^{-1} atm$^{-1/2}$ (D in cm^2/sec. and K_1 in g at. cm^{-3} atm$^{-1/2}$).

High voltage mechanism: electronic conduction.—In the data of Fig. 3, the I-V characteristic was plotted in the 0.6 V-min mode as described earlier. If, however, the sample is allowed to equilibrate under the applied voltage and if measurements are made at lower oxygen pressures, the rapid increase in current at voltages >2V becomes very pronounced as shown in Fig. 5. From the discussion earlier, it is anticipated that this is

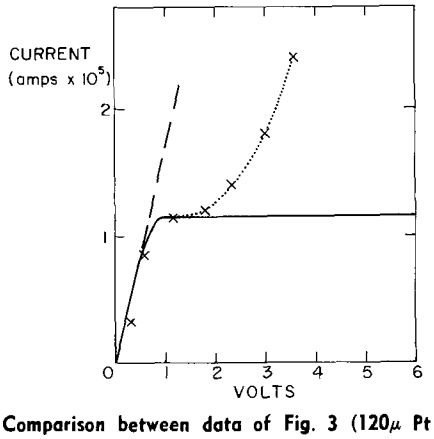

Fig. 4. Comparison between data of Fig. 3 (120μ Pt electrode) and Eq. [11] (ionic current limited by oxygen diffusion through the electrode). T = 520°C; pO_2 = 0.2 atm.; S = 4 mm^2.

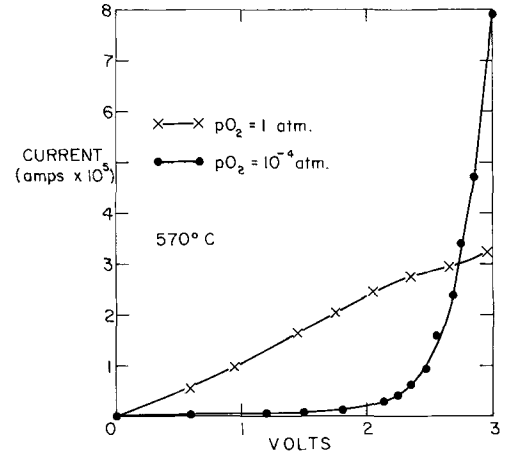

Fig. 5. Equilibrated I-V curves for 30μ foil electrodes under different oxygen pressures; T = 570°C; S = 4 mm^2; δ = 120μ.

caused by electronic conduction and that Eq. [10] should apply when $J_e > J_i$. Taking logarithms (4)

$$\log I = \log \frac{kT}{ql}\sigma_e^0 + \frac{qE}{2.3\,kT}\left(1 - \frac{J_a}{J_i}\right) \quad [14]$$

and

$$\frac{d\log I}{dE} \approx \frac{q}{2.3\,kT} \quad [15]$$

Comparison of the data with the theoretical gradient is shown in Fig. 6 where it can be seen that when the electrode area is smaller than the zirconia area, but, with a completely covering anode, agreement is unsatisfactory. The assumption that $J_a << J_i$ is indicated to be invalid. However, if the electrode area is made equal to the zirconia area, *i.e.* the interface zirconia-oxygen is removed, then agreement between the theoretical line and the data is excellent at high voltages.

The explanation for this effect is analogous to that for the behavior of porous electrodes at high voltages. Under strong polarization the zirconia in the vicinity of the electrode becomes electronically conducting, and direct access of oxygen to the zirconia can occur by [1]. An electronically conducting ring then forms around the foil electrode across which oxygen can move directly into the zirconia; the ionic current, J_a, remains high and so the behavior of [15] is not found. When the foil covers the whole surface, the growth of an electronically conducting region out into the free zirconia surface is restricted to the edges of the sample, J_a remains small, and the high voltage data match Eq. [15].

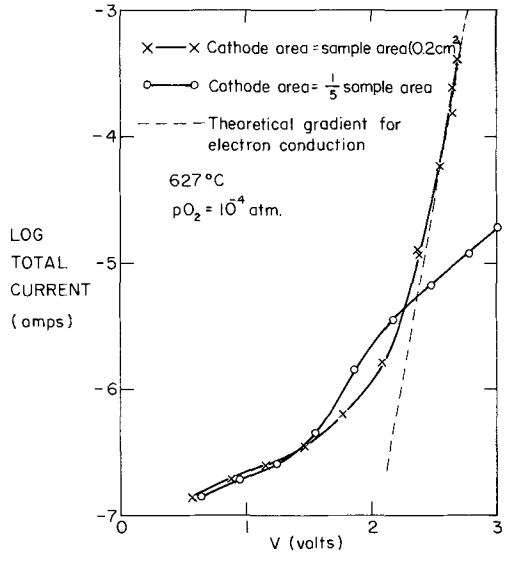

Fig. 6. Comparison between the I-V curves for foil electrodes and the theoretical expression for electronic conductivity in polarized electrolytes for cells in which the electrode area is equal to or 1/5 of the sample area. The large electrodes (S = 0.2 cm^2) are Pt:40 Rh and 200μ thick; the small electrodes (S = 4 mm^2) are Pt and 120μ thick.

Data for several temperatures, taken with the large area Pt:40 Rh electrodes, are compared with the theoretical gradients in Fig. 7. By extrapolating back to zero voltage the data in the region where Eq. [15] is obeyed, the value of σ_e^0 can be calculated from Eq. [14]. This is the electronic conductivity of ZrO_2* under conditions of zero polarization; as seen in Fig. 8, it has an activation energy of 4.62 eV, larger than the value ≈4.15 eV that may be deduced from data reported by Patterson *et al.* (5) (*see*, however, Fig. 10).

The electronic conductivity σ_e^0 should be $\propto pO_2^{-1/4}$ (5, 15). Although Fig. 9 indicates a decrease of σ_e^0 with increasing pO_2, it has not been possible to demonstrate this dependence quantitatively. If we assume a $pO_2^{-1/4}$ dependence, then the σ_e^0 data of Fig. 7 and 8 can be represented by

$$\sigma_e^0 = 1.5 \times 10^7\, pO_2^{-1/4} \exp(-4.62\ \text{eV}/kT) \quad [16]$$

Combination with $\sigma_i = 1.5 \times 10^3 \exp(-1.26\ \text{eV}/kT)$

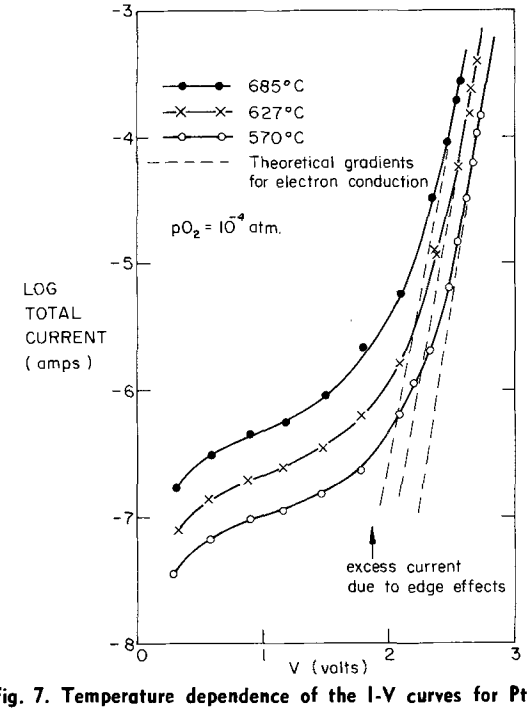

Fig. 7. Temperature dependence of the I-V curves for Pt:40 Rh foil electrodes where the cathode area equals the sample area. S = 0.2 cm^2; δ = 200μ.

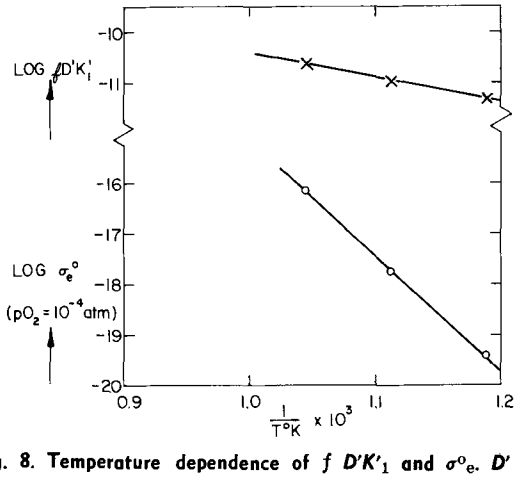

Fig. 8. Temperature dependence of f $D'K'_1$ and σ^0_e. D' is the diffusion coefficient for oxygen atoms in the Pt:40 Rh electrode, and K'_1 the equilibrium constant for the reaction $\frac{1}{2}O_2(g) \rightarrow O$(Pt/40 Rh).

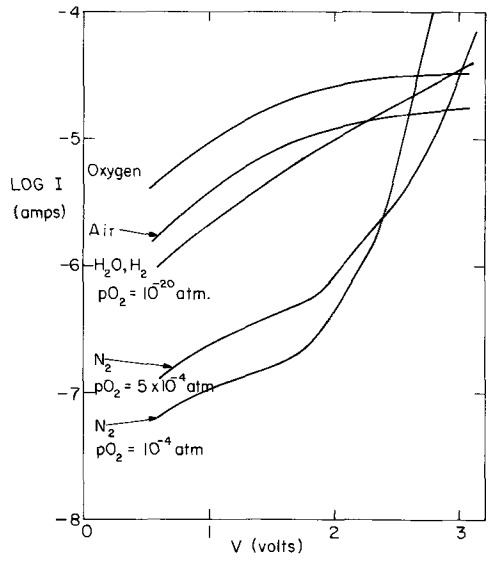

Fig. 9. Oxygen pressure dependence of I-V curves for (Pt:40 Rh) foil electrodes. Cathode area = sample area. T = 570°C; S = 0.2 cm²; δ = 200μ.

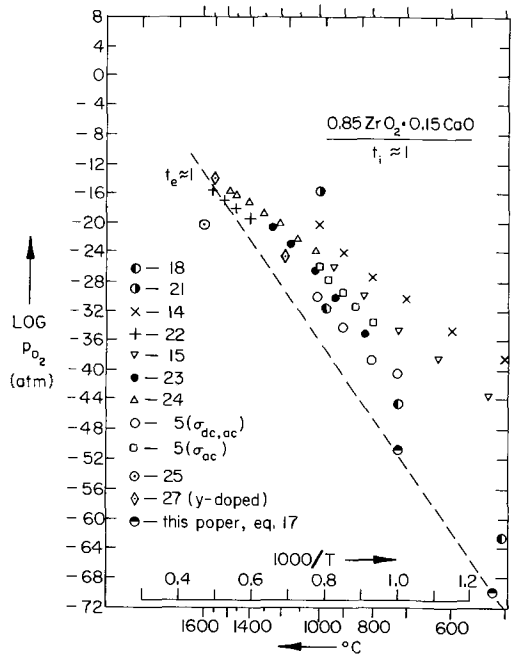

Fig. 10. Values of $p_{\ominus}$, the low-pressure boundary of the ionic conductivity range in ZrO_2* where $\sigma_i = \sigma_e$, according to various authors.

as given by Kingery *et al.* (16) leads to the following expression for $p_{\ominus}$, the oxygen pressure at which

$\sigma_e = \sigma_i$ and where $t_e = t_i = \frac{1}{2}$ (17)

$$p_{\ominus} = 10^{16} \exp(-13.44 \text{ eV}/kT) \qquad [17]$$

As shown in Fig. 10 the values represented by this expression are considerably lower than those found in most other investigations. Only Tretyakov (18) reports data close to ours.[3] Tretyakov's results have been shown to be obtained on the basis of fallacious argument (20).

In the conductivity at low voltages where the oxygen diffusion mechanism applies, the rate $\propto pO_2^{1/2}$, as observed by Kleitz (1) and Yanagida *et al.* (2) is again seen for oxygen pressure $\geq 10^{-4}$ established by gas mixing. The use of buffer systems is not satisfactory since, as shown, the electrode is capable of taking up oxygen from the water vapor by decomposition of the H_2O, and this results in an appreciable current. This also was noted earlier (2, 14), and a similar behavior was found for CO_2 (1). The curves for $N_2 + 10^{-4}$ and 5×10^{-4} O_2 shown in Fig. 9 demonstrate the opposite direction of the oxygen pressure dependencies in the high and low voltage regions by the presence of the cross-over of curves for different oxygen pressures at medium voltages, but J_a in the less pure nitrogen experiment is sufficiently large that correspondence to Eq. [15] and a reliable value for σ_e are not demonstrated.

Figure 7 can be used to find the activation energy for oxygen diffusion in Pt:40 Rh. Subtraction of the electronic currents from the total currents should give the ionic current. Yet the curves obtained do not show clear saturation as required by [11]. An excess of current in the range 1.5-2V, although ionic in nature, is probably due to edge effects by the free surface mechanism. Qualitative examination suggests saturation of the current due to the low voltage mechanism at ≈1V. Both the similarity in the form of the three different curves and the theoretical expression for the low voltage mechanism [11] indicate that a reliable activation energy can be found from current values below saturation.

Using primes to distinguish parameters for Pt:40 Rh from those for Pt, Fig. 8 shows the values of $fD'K'_1$ at 0.9V, f being the ratio of the ionic current to its saturation value; the "activation" energy is 0.94 eV. Assuming the points to represent 80% saturation, *i.e.*, $f = 0.8$, $D'K'_1$ may be represented by

$$D'K'_1 = 2.2 \times 10^{-6} \exp(-0.94 \text{ eV}/kT) \qquad [18]$$

This leads to $(D'K'_1)_{520°C} = 2.2 \times 10^{-12}$ and $(D'K'_1)_{25°C} = 3 \times 10^{-22}$ g at. cm^{-1} sec^{-1} atm$^{-1/2}$. Comparison of the 520°C value of $D'K'_1$ for Pt:40 Rh with the corresponding value for Pt as found earlier, $DK_1 = 4 \times 10^{-11}$, it is seen that the permeability for oxygen is slightly less for Pt:40 Rh than for pure Pt. The room temperature value may be compared with results on pure Pt by Hoare (21), who reports $D = (1.8 - 4.4) \times 10^{-11}$ cm² sec^{-1}. He assumes an oxygen solubility of 1 at. O per atom Pt, *i.e.*, for $pO_2 = 1$ atm, K_1 = density of Pt/atomic weight Pt ≈ 0.1 g at. cm^{-3} atm$^{-1/2}$; therefore $(DK_1)_{25°C} \approx 3 \times 10^{-12}$ g at. (cm sec atm$^{1/2}$)$^{-1}$, much larger than the extrapolated value for $D'K'_1$ found above. Although we found a small difference between the oxygen permeability for Pt:40 Rh and Pt at 520°C, it is unlikely that this will result in a 10^{10} discrepancy at 25°C. This large discrepancy must probably be explained by the predominance of grain boundary diffusion at low temperatures.

Nonporous sputtered electrodes.—All the sputtered electrodes tested were found to have an ohmic I-V characteristic with $R = R_b$. Since even the thickest sputtered film has a thickness <1μ, the value of B is >120 x 2.57 x $10^{-5} \approx 3 \times 10^{-3}$ at 520°C. In air, with $pO_2^{1/2}(g) = 0.447$, this implies a saturation current $I_s \approx 1$ mA, and some 60V would have to be applied before nonohmic effects would appear. Since electrolysis limits the voltage to 3V, such effects cannot be observed.

Porous paste electrodes: the effect of firing temperature.—In the case of paste electrodes, the parameter δ is less clearly defined than in the case of foil electrodes, but it is expected to bear some relation to the grain size of the platinum in the electrode, *i.e.*, the maximum diffusion path length from the gas phase to the electrolyte should be through a single grain of the platinum for a porous electrode. If the paste is fired at 800°C, the organic suspending medium is removed, but the platinum grain size is not markedly increased above that in the original ink (<1μ). Ac-

[3] Tretyakov (18) and Patterson (19) give an expression for pO_2 at the point where $t_e = 0.01$; for $\sigma_e \propto pO_2^{-1/4}$, $p_{\ominus}$ is 10^8 × smaller.

cordingly, in such a sample, δ is itself $<1\mu$ and, as described in the preceding section, nonohmic behavior from diffusion limited currents is not expected below 60V. Results for such a paste are shown in Fig. 11, and they are indeed seen to be ohmic with $R = R_b$.

An additional point is that the over-all thickness of the electrode does not affect this result (Fig. 11). This indicates that gas phase polarization is unimportant in the paste electrodes even at a thickness of 40μ. Actually considerations given in ref. (3) indicate that gas phase polarization is to be expected at ionic current densities of $\approx$10 A/cm^2, *i.e.*, approximately four orders of magnitude higher than the currents of 2 x 10^{-3} A/cm^2 at which the nonlinear effects observed by us occurred.

In pastes fired at 1350°C, sintering and grain growth occur in the platinum until the final structure resembles a slightly porous foil. As seen in Fig. 11, these samples have non-ohmic I-V characteristics and show a thickness dependence similar to that of the foils. The initial current values are less than for the foils since the area of the platinum contact regions is less than the total foil area. The high voltage mechanism in these pastes is as identified by Yanagida *et al.* (2) (Eq. [1]); it occurs because areas of free zirconia surface are directly accessible to the gas phase.

Nonporous paste electrode; the effect of a fluxing agent.—The I-V characteristic with the fluxed paste as cathode is shown in Fig. 12. If the value of I_{sat} is taken from the graph as 5 x 10^{-5}A, B is then 1.1 x 10^{-5} and δ is 280μ, assuming the same value for DK_I as in the case of the foil (Fig. 3). This is close to the total thickness of the electrode which was found by metallographic examination to be around 300μ. Apparently the glass acts to seal the pore phase in the electrode, δ takes on the value of the total electrode thickness, and, as seen in Fig. 12, the high voltage mechanism appears to be electronic. The latter is expected, since the zirconia is protected from the gas phase by the glass and no free, accessible surface is available.

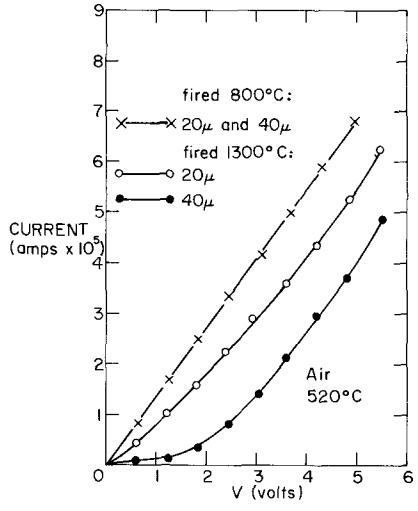

Fig. 11. I-V curves for porous, nonfluxed, paste electrodes fired at different temperatures: $S \approx 4$ mm^2.

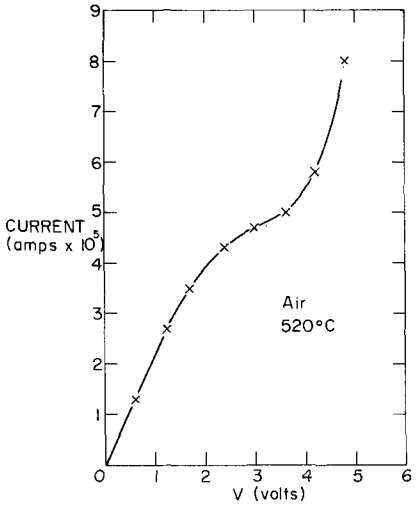

Fig. 12. I-V curve for fluxed (nonporous) platinum paste electrode. $S \approx 4$ mm^2; total electrode thickness $\approx 300\mu$.

Discussion and Summary

The combination of the data in the present paper with those obtained in the earlier work (2) allows a complete description of the electrode effects found in the Pt-ZrO_2* system. These are summarized in Table I. The equations describing the I-V characteristics for the various processes are

$$(\sigma_i)_{ZrO_2}^*: \quad V = IR_b \qquad [18]$$

$$(\sigma_e)_{ZrO_2}^*: \quad I = \frac{kTA}{ql}\sigma_e^{\circ}\exp\left\{\frac{qE}{kT}\left(1-\frac{J_a}{J_i}\right)\right\} \qquad [19]$$

$$D_{O,Pt}: \quad V = IR_b + \frac{RT}{4F}\left[\ln pO_2(g) - 2\ln\left\{pO_2^{1/2}(g) - \frac{I}{B}\right\}\right] \qquad [20]$$

$$(1): \quad V = IR_b + \frac{RT}{2F}\ln\frac{I}{C} \qquad [21]$$

where A is the electrode area and C a constant. Equations [19] and [21] only apply at relatively high voltage (>2V) where substantial polarization has already occurred. The common combinations (v. Table I) are [20] followed by [19], an example of which is shown in Fig. 4, and [20] followed by [21], an example of which is shown in Fig. 11 for the high fired pastes.

There are a number of features in this scheme that may be mentioned. In the first place, for tests designed to measure the bulk ionic conductivity of the electrolyte, the thinnest possible electrodes should be used; from the data here, sputtered electrodes are well suited for this purpose. Low fired pastes also appear to be satisfactory.

Second, in tests designed to observe polarization effects, it is important to use electrodes covering the entire faces of the specimen as emphasized in Fig. 6. Also, unless very thick foils are used (or equally thick fluxed pastes), the value of $I_{sat.}$ provided by oxygen diffusion through the foil can be considerable. Thus, for instance, in the experiments of Danforth and Bodine (22), where the dynamic resistance of ThO_2 was measured as a function of the polarization voltage, it is probable that the dynamic resistance was ionic in nature, and their finding that the two parameters were independent is expected.

Vest *et al.* (23), who carried out polarization experiments with fluxed Pt paste electrodes, cited the above experiment to justify assuming that the electronic resistance is independent of polarization. From the present measurements (Fig. 7) and from Eq. [19], this seems to be invalid.

A final feature in polarization measurements is that the applied voltage should remain below the decom-

Intergranular Corrosion of Austenitic Stainless Steel

C. S. Tedmon, Jr.,* D. A. Vermilyea,* and J. H. Rosolowski

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The well-known susceptibility of austenitic stainless steels to intergranular corrosion after heat-treatment in the temperature range of 550°-800°C (*i.e.*, "sensitization") has long been attributed to depletion of Cr from regions of the alloy matrix adjacent to grain boundaries in which $Cr_{23}C_6$ had precipitated. Those regions of the steel in which the local Cr composition falls below about 12% have a diminished ability to form a passive film and hence corrode preferentially.

We have made thermodynamic calculations of the Cr-C-$Cr_{23}C_6$ equilibria in and near grain boundaries in order to determine the chromium content in the vicinity of carbide particles. The calculations show that the equilibrium chromium content is a strong function of the temperature and of the carbon and alloy content of the steel. It is inferred from the analysis that variations in the susceptibility to intergranular attack are determined primarily by changes in the equilibrium chromium content near the carbides and not by changes in the number and distribution of particles. For instance, above 800°C the chromium content near the carbides is high enough to produce passivity, and the alloy is immune not because of the absence of carbides but because chromium depletion is not severe. Experimental studies of rates of grain boundary attack as functions of temperature and composition have confirmed the predictions of the analysis.

A further factor of less importance is the distribution of carbides in the grain boundary. Calculations were made to determine the Cr concentration gradient within the boundary between carbide particles as a function of temperature and composition as well as the Cr gradient normal to the boundary. These calculations predict a strong interdependence between susceptibility to intergranular corrosion, carbide particle spacing, and sensitizing temperature. Experimental results on thinned samples of sensitized material corroded in a Strauss solution and examined by electron microscopy are in good agreement with predicted effects.

In their classic paper (1), Bain, Aborn, and Rutherford developed a model for the intergranular corrosion of sensitized stainless steel which has had general and widespread acceptance for nearly forty years. Their model attributes sensitization to the precipitation of chromium carbide at grain boundaries with concomitant depletion of chromium in regions adjacent to the boundary to levels below that required for passivity. Although other models have been proposed

Intergranular Corrosion of Austenitic Stainless Steel

C. S. Tedmon, Jr.,* D. A. Vermilyea,* and J. H. Rosolowski

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The well-known susceptibility of austenitic stainless steels to intergranular corrosion after heat-treatment in the temperature range of 550°-800°C (*i.e.*, "sensitization") has long been attributed to depletion of Cr from regions of the alloy matrix adjacent to grain boundaries in which $Cr_{23}C_6$ had precipitated. Those regions of the steel in which the local Cr composition falls below about 12% have a diminished ability to form a passive film and hence corrode preferentially.

We have made thermodynamic calculations of the Cr-C-$Cr_{23}C_6$ equilibria in and near grain boundaries in order to determine the chromium content in the vicinity of carbide particles. The calculations show that the equilibrium chromium content is a strong function of the temperature and of the carbon and alloy content of the steel. It is inferred from the analysis that variations in the susceptibility to intergranular attack are determined primarily by changes in the equilibrium chromium content near the carbides and not by changes in the number and distribution of particles. For instance, above 800°C the chromium content near the carbides is high enough to produce passivity, and the alloy is immune not because of the absence of carbides but because chromium depletion is not severe. Experimental studies of rates of grain boundary attack as functions of temperature and composition have confirmed the predictions of the analysis.

A further factor of less importance is the distribution of carbides in the grain boundary. Calculations were made to determine the Cr concentration gradient within the boundary between carbide particles as a function of temperature and composition as well as the Cr gradient normal to the boundary. These calculations predict a strong interdependence between susceptibility to intergranular corrosion, carbide particle spacing, and sensitizing temperature. Experimental results on thinned samples of sensitized material corroded in a Strauss solution and examined by electron microscopy are in good agreement with predicted effects.

In their classic paper (1), Bain, Aborn, and Rutherford developed a model for the intergranular corrosion of sensitized stainless steel which has had general and widespread acceptance for nearly forty years. Their model attributes sensitization to the precipitation of chromium carbide at grain boundaries with concomitant depletion of chromium in regions adjacent to the boundary to levels below that required for passivity. Although other models have been proposed

Key words: intergranular corrosion, stainless steels, carbide precipitation, sensitization, thermodynamics, localized attacks.

(2-5), it seems clear that the model of Bain *et al.*, is qualitatively valid in most instances. One of the very few cases for which their model is inadequate is that of intergranular corrosion of solution-treated austenitic stainless steels in highly oxidizing environments such as HNO_3-Cr^{+6} solutions (5-6). This rather special case will be considered in a subsequent section of this paper. A critical summary of the various theories of intergranular corrosion of stainless steel has recently been presented by Gellings and deJongh (7).

The theory of Bain *et al.* is based on the fact that a certain minimum chromium content of about 13-15% (8-9) (all compositions are expressed in weight per cent), is required in the steel to render it corrosion resistant. The alloy matrix immediately adjacent to a carbide particle will have a chromium content X_{Cr} which for the case of sensitized steel will be less than the value of 13-15%. Attempts to measure this value, or the gradient adjacent to sensitized grain boundaries have generally been unsuccessful (10-11), probably because of the very limited width of the depleted zone.

It is obviously important to know quantitatively the variation of X_{Cr} with temperature, heat-treatment, and steel chemistry. Further, it has been shown (3, 12) that the carbides which form at grain boundaries may not necessarily be present as a continuous film, but rather, as discrete particles. Therefore, if values of X_{Cr} were known, it would be possible to calculate the chromium gradient within the boundary between carbide particles and determine whether or not the chromium content in and near the boundary between carbide particles exceeds the critical level of 13-15%. If it does not, then the entire boundary would be effectively sensitized even though the carbide was not continuous in the boundary. Alternatively, if the chromium level in the boundary at some point between carbide particles exceeded the critical concentration, then a "patchy" type of intergranular corrosion would be expected.

Values of X_{Cr} and of the chromium concentration gradient in a boundary between carbide particles are usually not experimentally accessible, so it is necessary to resort to analytical techniques for their evaluation. In a recent paper (13), Stawström and Hillert have presented a theory for intergranular corrosion of 18-8 austenitic stainless steel which describes a method for calculating the chromium concentration in the steel adjacent to a grain boundary carbide. An important feature of their model is the assumption that this chromium content is thermodynamically determined by the alloy-carbon-$M_{23}C_6$ local equilibrium. This is in contrast to the more usual assumption that the chromium content in the vicinity of the carbide particles is negligible, and that variation in the degree of sensitivity results from changes in the morphology or distribution of particles along the boundary and not from variation in chromium composition. Stawström and Hillert evaluated the equilibrium using some unpublished thermodynamic expressions which had been developed by Nishizawa for the iron-chromium-carbon system (14). They assumed throughout their analysis that grain boundary diffusion was sufficiently fast at typical sensitizing temperatures that there would be no variation in chromium composition within the boundary between carbide particles. In addition they considered in detail the kinetics of the desensitizing process.

In this paper we present a model for the intergranular corrosion of stainless steel that is conceptually similar to that of Stawström and Hillert, but differs considerably in detail and result. Like Stawström and Hillert, we also make the basic assumption that the grain boundary chromium concentration determines the degree of sensitization, and that this quantity is thermodynamically fixed. However, our method of calculating the grain boundary chromium concentration is much different from theirs, and we believe it to be a more general approach, which can be applied to a variety of alloy compositions. Further, instead of assuming a uniform chromium composition throughout the grain boundary, we will describe a theoretical method for calculating the chromium concentration profile both within the grain boundary between carbide particles, and also normal to the boundary. Both analytical and experimental evidence will be presented to show that for many cases the chromium concentration in a grain boundary is by no means uniform, but in fact, very large gradients exist between carbide particles, which have a significant effect on the corrosion behavior. We do not consider the desensitizing process.

Thermodynamic Analysis

The basic problem is to calculate the minimum chromium content at the grain boundary. For the reaction

$$23Cr + 6C \leftrightharpoons Cr_{23}C_6 \qquad [1]$$

The equilibrium constant is given by

$$K = \frac{1}{(\gamma_{Cr}X_{Cr})^{23}(\gamma_C X_C)^6} \qquad [2]$$

where unit activity has been assumed for the carbide, and compositions are expressed as mole fractions. Iron solubility in the carbide is neglected. Data for the free energy of formation of $Cr_{23}C_6$ are available in the literature (15), and hence K may be determined. In order to calculate X_{Cr} it is then only necessary to determine the activity coefficients for carbon and chromium. Values for these quantities are not available in the literature, but there are several methods by which they may be estimated. It was decided to use the Wagner analysis (16) for calculation of the carbon activity coefficient. Advantages of this approach are that it incorporates available experimental data and permits a physical interpretation to be made of the effect of various alloying elements. Details on the calculation are presented in the Appendix. Figure 1 shows the dependence of γ_C on chromium composition for several temperatures for a nickel composition of 10%. Chromium strongly lowers the carbon activity coefficient, which is expected in view of the pronounced tendency of chromium and carbon to form compounds. The influence of temperature is relatively small. It is noted that the thermodynamic factors

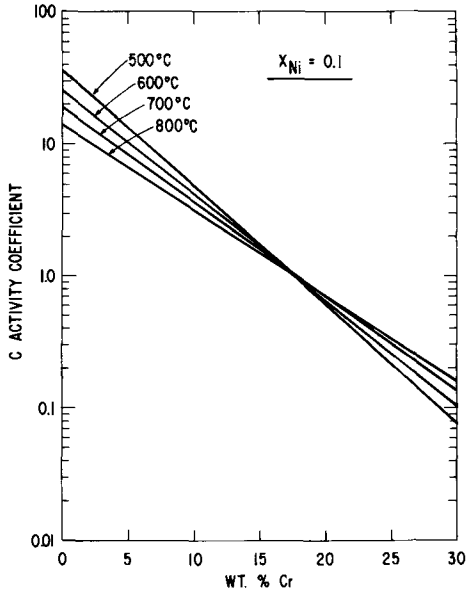

Fig. 1. Carbon activity coefficient vs. chromium content for an austenitic alloy containing 10% Ni, for various temperatures.

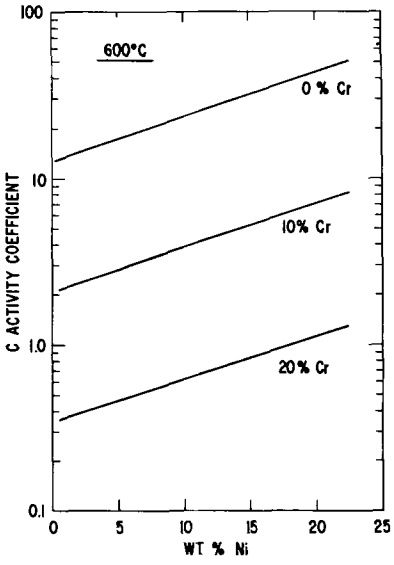

Fig. 2. Carbon activity coefficient in austenitic steel vs. nickel content at 600°C for various chromium levels.

balance in such a way as to result in an ideal solution at about 17.5% chromium. At that point, the activity coefficient is unity and temperature independent.

Nickel acts to increase γ_C as shown in Fig. 2 at 600°C for three chromium levels. This effect is not unexpected in view of the low solubility of carbon in nickel and the absence of stable carbides of nickel.

The dependence of γ_C on carbon content is small, because X_C is small, usually less than 5 x 10^{-3} mole fraction, and for all practical purposes one can assume $\gamma_C \neq f(X_C)$.

The activity coefficient for chromium dissolved in stainless steel can, in principle, be calculated using the Wagner analysis. However, examination of available thermodynamic data for the iron-chromium binary system shows that the higher order terms pertaining to these two elements cannot be neglected (17). The influence of nickel additions on γ_{Cr} in stainless steel is not known. Also, data are lacking for the influence of carbon on γ_{Cr}, although the term $X_C \cdot (\partial \ln \gamma_{Cr}/\partial X_C)$ will probably be small because X_C is usually small. In the absence of these data one approach would be to use the data for the Fe-Cr binary system (17) for γ_{Cr} in stainless steel. However, values of X_{Cr} calculated using this data are somewhat in disagreement with the corrosion results. Treating γ_{Cr} as a semi-adjustable parameter and forcing a fit to corrosion data (see Experimental section for detail) for Type 304 stainless steel that was sensitized at 600°C gives the results shown in Fig. 3. The temperature dependence was estimated by assuming a regular solution, as described in the Appendix for carbon. One means of checking the

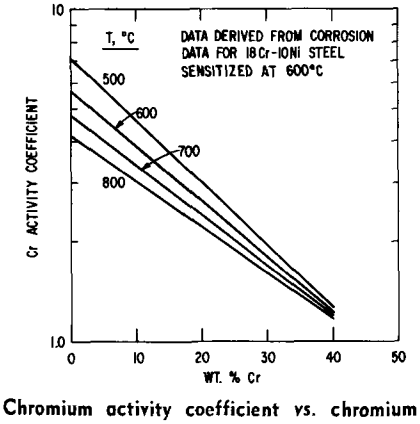

Fig. 3. Chromium activity coefficient vs. chromium content in austenitic stainless steel at various temperatures.

validity of this method is to compare corrosion data for steels sensitized at temperatures other than 600°C with predictions based on values of γ_{Cr} taken from Fig. 3. This point will be discussed subsequently.

Having obtained values for γ_C and γ_{Cr}, the chromium composition at the grain boundary in equilibrium with the carbide may be calculated from Eq. [2], if the assumption is made that the carbon activity is fixed by the bulk chromium composition. This assumption seems reasonable, and at typical sensitizing conditions carbon atoms are much more mobile than chromium atoms.

Grain Boundary Diffusion and Chromium Concentration Profiles

Brailsford and Aaron (18) determined the concentration of diffusant in a grain boundary during the growth of a grain boundary particle using the method described by Shewmon (19) in his solution of the mathematically analogous problem of surface diffusion from an infinite circular source. Leakage of diffusant out of the grain boundaries into the adjacent material was taken into account. This closed form solution gives the concentration of diffusant in the grain boundary after a long diffusion time and is a good approximation to that for the usual times of interest. Shewmon's solution, however, does not give accurate values for the concentration of diffusant in the material adjacent to the grain boundary, especially at large distances from the source. This is because the calculated grain boundary concentration, which is the source of the leakage flux, is much higher than actually is the case during the early stage of the diffusion. This results in overestimating the amount of diffusant that will be found adjacent to a grain boundary.

In calculating the chromium concentration around a carbide particle in a grain boundary we have made many of the same assumptions as Brailsford and Aaron, but have used a different analytical approach to the problem. The method has been described in detail elsewhere (20) so only a few comments on some of the assumptions are made here. Specifically, we have assumed that direct volume diffusion of chromium to the carbide particle can be ignored compared to that which diffuses to it along the grain boundary. Also, we have ignored the complication introduced by the fact that the boundary of the carbide particle is moving. Both of these assumptions have been discussed by Brailsford and Aaron who concluded that no significant error is introduced by invoking them provided the precipitate particles are greater than a few hundred angstroms in size and that reasonable values of the bulk and boundary diffusion coefficients were used.

Figure 4 presents calculated values for the chromium concentration in a grain boundary as a function of distance in the boundary from the carbide particle after 24 hr at 600°C. In the calculation, the following quantities were used: grain boundary width = 10Å; bulk diffusion coefficient, $D_V = 10^{-16}$ cm²/sec (21); D_{GB}/D_V (ratio of grain boundary to bulk diffusion coefficient) = 10^6; carbide radius = 1000Å; bulk Cr content = 18%; Cr content in equilibrium with carbide = 10%. The last value is derived from the thermodynamic analysis of the preceding section and is typical for these conditions. If it is assumed that in order to form a passive film a minimum of 14% chromium is required, then this calculation predicts that the grain boundary will be depleted below this level to a distance of nearly 1μ. This calculation also predicts that it is not necessary to have continuous carbide in the grain boundary for the boundary to be sensitized everywhere. For example, as a first approximation, this calculation indicates that discrete particles separated from each other in the boundary by about 2μ or so ought to lead to a continuously depleted boundary. Data supporting this prediction are presented in the next section.

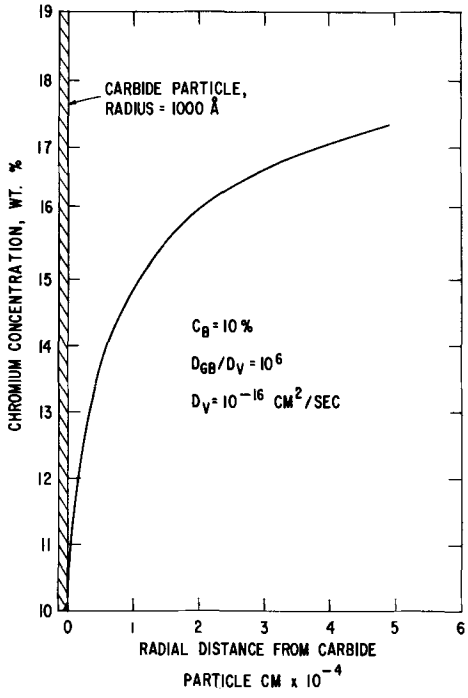

Fig. 4. Chromium concentration in grain boundary vs. radial distance from carbide particle having a radius of 1000Å. Data appropriate to 600°C were used (see text).

In addition to the chromium concentration in the grain boundary between carbide particles, it is also of interest to consider the chromium concentration gradients normal to a grain containing a carbide particle as a function of distance from the carbide. Figure 5 presents results of this calculation for the previous conditions. Note the very rapid change of concentration with distance from the grain boundary compared with the much more gradual change within the boundary (Fig. 4). These calculations indicate that, at least for these particular conditions, direct experimental determination of the chromium concentration gradient normal to a grain boundary, as with a microprobe for example, would be impossible with available instrumentation.

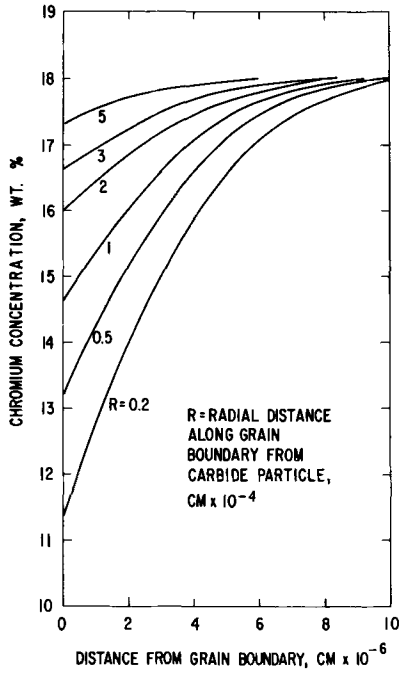

Fig. 5. Chromium concentration as a function of distance perpendicular to the grain boundary for varying distances from the carbide particle. Data appropriate to 600°C were used.

The volume of a chromium carbide particle growing in grain boundary must be consistent with the depletion of chromium and carbon integrated over the volume around the nucleation site. The shape of the particle is determined by the relative rates at which material is brought to it by diffusion along the grain boundary and that at which it is redistributed over the surface of the particle by interfacial diffusion. In the calculations referred to above, a thickness for the carbide particle was not specified, but the volume has been implicitly fixed although its shape has not.

It is evident, by reference to Fig. 4 and 5 that conditions may arise in which the grain boundary is not uniformly sensitized. This will happen when the carbide is present as discrete particles, separated by distances large enough to allow the chromium concentration in the boundary between the particles to exceed 13-15%. Experimental evidence of such nonuniform sensitization will be presented subsequently, and it will be seen that this behavior occurs in samples heat-treated in the upper end of the sensitizing range, because of the lower ratio of grain boundary to bulk diffusion coefficient.

Experimental

Two types of experiments were conducted in order to verify predictions of the theoretical considerations. The first was designed to determine the uniformity of the chromium depletion and consisted of scanning electron microscopy, transmission electron metallography, and surface replica electron metallography of thin specimens which had been sensitized and exposed to corrosive solutions. Specimens of Type 304 annealed stainless steel sheet containing 0.045% carbon were sensitized by heating in a vacuum for 24 hr at 600°C, 1 hr at 650°C, 1 hr at 700°C, 1 hr at 750°C, or 10 min at 800°C. The sensitized specimens were electropolished in an ethanol-perchloric acid-butyl cellosolve solution, exposed to a suitable corrosive solution, and examined. The two solutions used were boiling Strauss solution (10% H_2SO_4 plus 10% $CuSO_4 \cdot 5H_2O$ by weight) and 65% HNO_3 at 25°C.

The second type of experiment was designed to obtain an estimate of the grain boundary chromium content as a function of both heat-treatment and steel composition. Several commercial and experimental alloys were used in these experiments; compositions are given in Table I. The general plan was to obtain data for the rate of corrosion in boiling Strauss solution of Fe + 10 Ni + Cr alloys as a function of chromium content and then to compare the rates of grain boundary penetration in sensitized alloys with the rate *vs.* chromium content data to estimate the grain boundary chromium content. Corrosion rates of induction-melted, rolled, and annealed Fe + 10 Ni + Cr alloys were determined by measurements of weight change. Grain boundary penetration rates of sensitized specimens were determined by breaking corroded specimens in tension and measuring both the fracture stress and the depth of penetration as observed with a microscope. The specimens were in the form of wires or small rods sheared from sheet; dimensions were about 0.030 to 0.060 in. Plots of penetration *vs.* time and strength *vs.* time permitted a determination of penetration rate. Disagreement between these two rates was taken as evidence of patchy behavior, and in such cases the greater rate (always the optically determined rate) was taken.

Prior to corrosion the specimens were abraded to remove shear marks or drawing marks, and were solutionized by heating to 1100°C for 15 min, followed by water quenching. The specimens were again abraded to remove the scale, then sensitized by heating followed by water quenching or cooling at a variety of rates. After a final abrasion they were exposed to the boiling Strauss solution.

Experimental Results

Electron microscopy.—Figures 6, 7, and 8 show micrographs made from direct carbon surface replicas of the surfaces of samples sensitized at 600°, 700°, and 800°C, respectively, which were subsequently exposed to boiling Strauss solution for 10 min. Figure 6 shows that, at 600°C, the grain boundary is uniformly and severely attacked by the Strauss solution, even though the carbide is present as discrete particles and not as a continuous film. This is in agreement with the thermodynamic prediction and supports the diffusion calculation. At 700°C (Fig. 7) the boundary is still susceptible to corrosion, whereas a sensitization treatment at 800°C (Fig. 8) caused carbides to form, but no grain boundary attack occurred. According to the thermodynamic analysis, this is because the chromium content in equilibrium with the carbide exceeds the critical quantity required for passivation. It should be noted that samples sensitized at 600°C and then electropolished as described above showed the grain boundary carbides, but were otherwise generally featureless, thus demonstrating that it was the Strauss solution that produced the grain boundary attack.

Electron transmission micrographs of sensitized and corroded foil reinforce the observations made with surface replicas. Figure 9 is from a sample of this

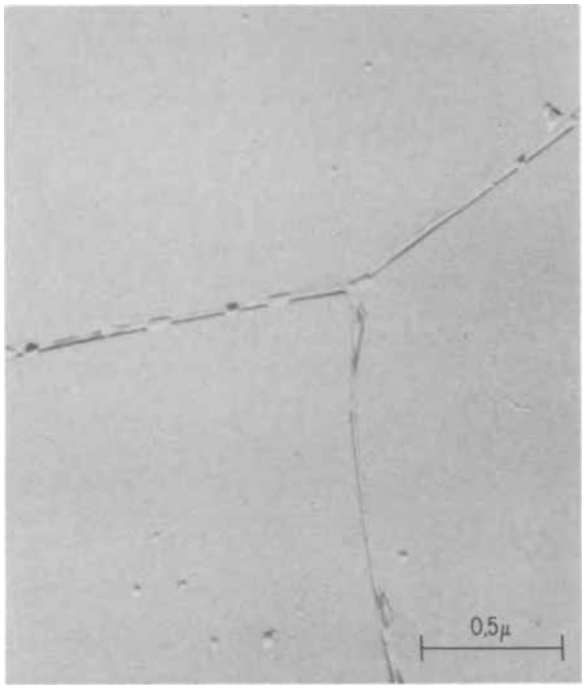

Fig. 6. Electron micrograph of surface replica from sample of Type 304 stainless steel that was sensitized at 600°C for 24 hr, then polished and exposed to a boiling Strauss solution. Note that the grain boundary attack is relatively uniform although the carbide particles do not form a continuous film. Magnification approximately 36,500X.

Fig. 7. Electron micrograph of surface replica from sample of Type 304 stainless steel that was sensitized at 700°C for 1 hr, then polished and exposed to a boiling Strauss solution. Magnification approximately 36,500X.

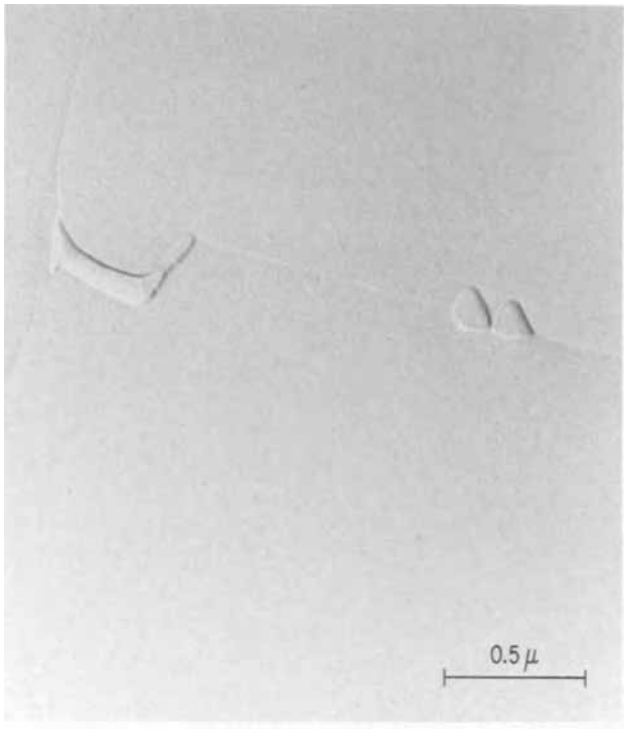

Fig. 8. Electron micrograph of surface replica from sample of Type 304 stainless steel sensitized at 800°C for 1 hr, polished, and exposed to a boiling Strauss solution. Essentially no grain boundary attack has taken place although carbides are present. Magnification approximately 37,500X.

Fig. 9. Transmission electron micrograph of Type 304 stainless steel sensitized at 700°C for 1 hr, then corroded for 10 min in boiling Strauss solution, showing "patchy" type of attack, which arises because grain boundary is not uniformly depleted in chromium. Magnification approximately 6360X.

steel that had been rolled to foil, thinned, sensitized at 700°C for 1 hr, and then exposed to a Strauss solution. In this case, the sample is too thick for significant transmission through the grains, but the corroded

Fig. 10. Transmission electron micrograph of Type 304 stainless steel sensitized at 700°C for 1 hr and then corroded for 10 min in boiling Strauss solution. Note patchy attack in boundary, and lack of attack on carbide particles. Magnification approximately 13,000X.

Fig. 11. Transmission electron micrograph of Type 304 stainless steel sensitized at 800°C for 1 hr and then corroded for 10 min in boiling Strauss solution. Note absence of attack at grain boundaries although grain boundary carbides are clearly present. Magnification approximately 7150X.

grain boundaries are evident, and it is clear that the attack is nonuniform, or "patchy." Figure 10 taken from a thinner region of the same sample provides further evidence of the "patchy" behavior, and further shows that the carbides themselves are inert. Figure 11 is from a sample sensitized at 800°C. Very little if any attack has occurred at or near the carbide particles. An attempt to make such photographs with a specimen sensitized at 600°C resulted in complete uni-

form penetration of the boundaries, and the detached grains fell off the specimen so that no thin section was left for transmission microscopy.

Summarizing the electron microscopic observations, it is evident that sensitization at 600°C produces a depleted zone which is very susceptible to attack and continuous or nearly so. A 700°C treatment produces a less susceptible, patchy boundary, while after heating at 800°C the boundary is fairly resistant.

Further evidence that the 700°C boundaries are patchy was obtained using the scanning electron microscope. A Type 304 stainless steel specimen having a carbon content of 0.076% and dimensions about 0.034 x 0.068 x 3 in. was sensitized at 700°C, corroded is boiling Strauss solution for 4238 min and pulled in tension. Although the fracture surface clearly showed that grain boundaries had been corroded even in the center of the section the specimen still had 35% of the strength of an uncorroded specimen. Figure 12 shows a photograph taken of the fracture surface with the scanning electron microscope. The fracture surface comprises flat areas of intergranular fracture and rough areas of ductile rupture. The fact that some boundaries have been attacked in the center of the specimen while some areas near the periphery were still uncorroded is convincing evidence for the patchy character of sensitization at 700°C.

Grain boundary penetration rates.—Figure 13 shows the corrosion rates of experimental alloys having a composition typical of Type 304 stainless steel, but with varying amounts of chromium. The corrosion rate increases very rapidly when the chromium content is less than 12%. Data from Osozawa and Engell (9), who measured currents in the passive region for 1M H_2SO_4 at 90°C are shown for comparison. It is probable that steels with less than 12% Cr are not fully passive in the Strauss solution.

Table II lists grain boundary corrosion rates for various steels and heat-treatments; from the experimental scatter we believe that the rates are only reproducible to about a factor or two. Several characteristics of sensitization are apparent from these data.

1. For a particular heat-treatment the corrosion rate increases rapidly with carbon content, as predicted by the theory.
2. For a given carbon content the corrosion rate decreases greatly with increasing sensitizing temperature, in agreement with the theory.
3. Slow cooling following heating at 600°-800°C results in far more severe sensitization than water quenching. The effect is very pronounced at higher sensitizing temperatures. We interpret this result to mean that carbides nucleate at the high temperatures, and that on cooling the chromium content adjacent to the carbides approaches a value characteristic of equilibrium at some lower temperature.
4. Reheating to 800°C a specimen sensitized at 600°C and water quenching renders it nonsusceptible to attack. We believe this means that the chromium content near the carbides is that appropriate to the equilibrium at 800°C.
5. Of the duplex (austenite plus ferrite) alloys (308, 308L, 309S, 3734, 3735, IN 744), only Types 308, 308L, and 309S became slightly sensitized. The interpretation for the resistance of this group of alloys is that the carbon activity is low because of the relatively high chromium to nickel ratio, and hence the equilibrium chromium content is high. The high chromium and low nickel contents also result in the duplex structure, and hence there is a correlation between the presence of ferrite and resistance to sensitization.

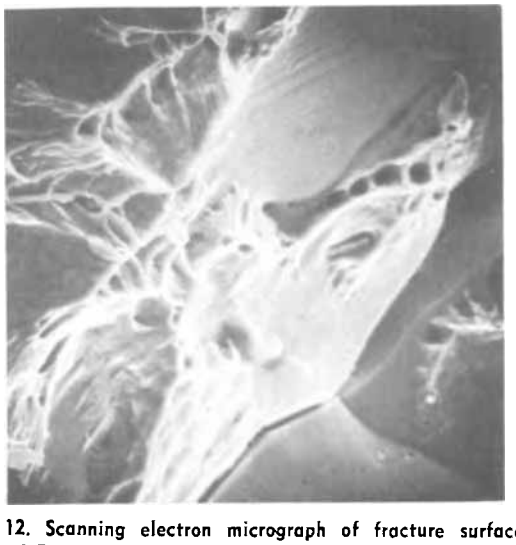

Fig. 12. Scanning electron micrograph of fracture surface of sample of Type 304 stainless steel that was sensitized at 700°C for 1 hr, exposed to boiling Strauss solution, then pulled in tension. Intergranular attack occurred throughout sample, but was "patchy" because the grain boundaries were not uniformly depleted in chromium. Flat facets show areas of intergranular attack; characteristic regions of ductile rupture indicate areas where chromium depletion did not occur. Magnification approximately 1000X.

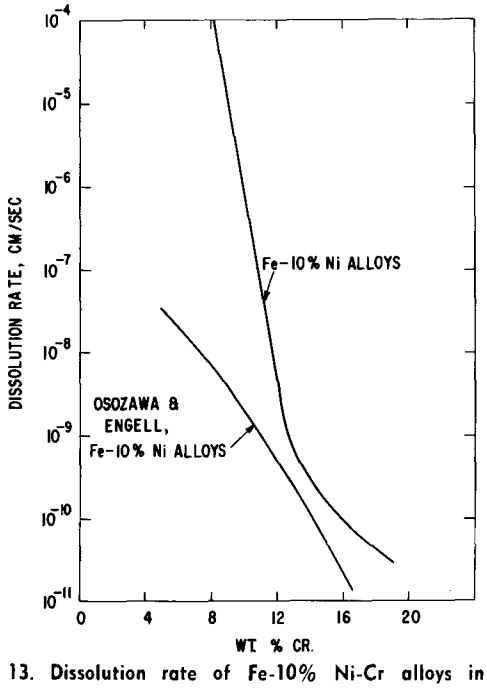

Fig. 13. Dissolution rate of Fe-10% Ni-Cr alloys in boiling Strauss solution as a function of Cr content.

From the data in Table II it is possible to make a quantitative comparison of the experimental results with the thermodynamic theory. The grain boundary penetration rates from Table II are first compared with the data in Fig. 13 to estimate the chromium content in the depleted zone along the boundary. Figure 14 compares data so obtained with the predictions of the thermodynamic theory. While the experimental points for a given temperature suggest a less pronounced variation of equilibrium chromium concentration with carbon content than predicted by the theory the general agreement is very satisfactory. The method is limited to chromium contents between about 9 and 12% because at higher chromium contents the rate is too slow to measure conveniently while at lower chromium contents the rate is limited by diffusion through the grain boundary crevice. Also included in this plot for comparison are results from Stawström and Hillert (adapted from Fig. 9 of their paper). Their curves are derived for a steel containing 8% nickel, so minor variation might be expected from this composition difference. It is evident that at 600°C, both calculated curves are in good agreement with the experimental

Table II. Grain boundary corrosion rates in Strauss solution

[1] "Slow" means cooled in a furnace. Cooling rate about 0.05°C/sec to 0.2°/sec.
[2] "W.Q." means water-quenched.

data. At 700°C, the agreement is fair. At 800°C, there is considerable difference between the two calculated curves; the experimental data appears to be more in agreement with our result. At 500°C, there is again a significant difference between our result and that of Stawström and Hillert; however, we have no experimental data to support either calculation.

It should be noted that our method of experimentally estimating grain boundary compositions may overestimate the chromium content of the boundaries for two reasons. First, if the grain boundary depletion is patchy the measured penetration rate may be slower than that corresponding to the average depletion. Second, the coupling of the grain boundary region to the matrix may result in passivation of a lower chromium alloy than can be passivated when not coupled, so that the observed corrosion rate would again be too low. It is difficult to estimate the magnitude of the possible errors.

In an effort to obtain more information about the effect of cooling rate from the sensitizing temperature, several solutionized specimens of 3025 alloy were annealed at 700°C and water-quenched, followed by reheating at 500°, 550°, and 600°C. The rates of grain

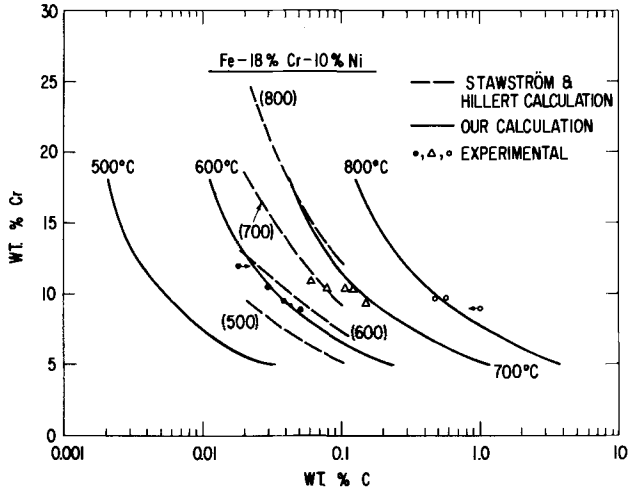

Fig. 14. Comparison of Cr-C-$Cr_{23}C_6$ equilibrium data for Type 304 stainless steel with experimentally obtained corrosion data, for several temperatures.

boundary penetration for these specimens were 4×10^{7}, 1.1×10^{-6}, and 1.1×10^{-6} cm/sec, respectively. A control specimen annealed for only 1 hr at 600°C did not corrode noticeably in 360 min, so the rate was $<10^{-7}$ cm/sec.

It is known from Fig. 6, 8, and 9 that carbides are formed at 700°C. These experiments show that it is possible to form carbides at 700°C, but that the chromium depletion is not severe enough even in an alloy with 0.075% to result in sensitization. Reheating to 500°-600°C allows the attainment of a lower chromium content in the grain boundary and susceptibility to attack.

Discussion

With the thermodynamic analysis presented earlier, it is possible to make quantitative chromium-carbon equilibria predictions for other alloys in addition to Type 304 steels. Figure 15 presents calculated carbon-chromium equilibrium values for various sensitizing temperatures for a nominal Fe-25% Cr-20% Ni alloy. This composition is characteristic of Type 310 austenitic stainless steel. In alloys of this type, the chromium level is increased to provide increased oxidation resistance, and the nickel is also increased in order to keep the alloy austenitic. From the point of view of increased resistance to intergranular attack, however, there is relatively little improvement over Type 304 because the effect of the increased chromium content on lowering the activity coefficient of carbon is largely offset by the effect of nickel on raising γ_C.

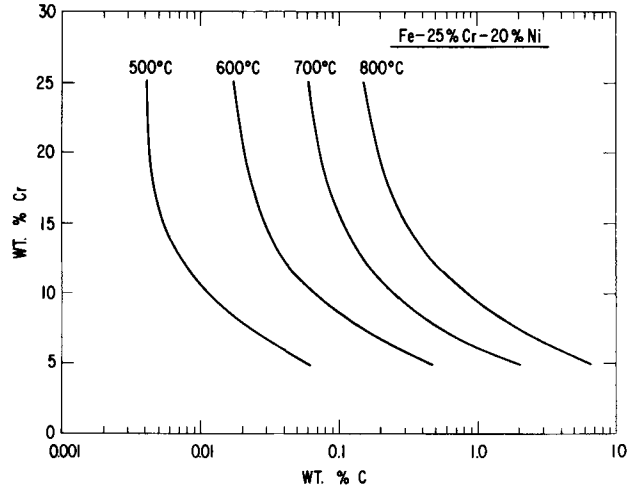

Fig. 15. Calculated Cr-C-$Cr_{23}C_6$ equilibria for Type 310 stainless steels (Fe-25% Cr-20% Ni) for several temperatures.

The data presented in Table II showed that duplex stainless steels were very resistant to intergranular attack. There are also data from the literature (22, 23) that agree with this. We interpret this as follows. In order to make the steel duplex, that is, have both austenitic and ferritic phases present, either the nickel content (austenite stabilizer) is decreased or the chromium content (ferrite stabilizer) is increased, or both. The effect of either is to lower γ_C and for a given carbon content, the carbon activity is therefore lowered. From Eq. [2] it is therefore expected that the equilibrium chromium content X_{Cr} will be higher.

A quantitative discussion is difficult because the compositions of the two phases are generally not known, especially with respect to the carbon distribution. One approach is to ignore the fact of two phases and simply to calculate the chromium content as if the alloy were homogeneous. Results from this calculation are presented in Fig. 16. It may be seen by comparison with austenitic steels (Fig. 14 and 15) that the duplex steels can tolerate much more carbon without becoming susceptible to sensitization.

The effect of the existence of two phases on the behavior of duplex alloys can be rationalized as follows. It is known that the ferrite phase of such alloys is enriched in chromium and depleted in nickel (24). Because of the dependences of γ_C on nickel and chromium contents we therefore expect the ferrite phase to be enriched in carbon. We may therefore expect that during annealing at 500°-850°C carbides will precipitate at the ferrite grain boundaries, but because of the generally low carbon activity X_{Cr} will still be high enough to prevent sensitization. In the austenite grains the chromium will be relatively low and the nickel high, but again the carbon activity will be low in the entire alloy, and hence the austenite grain boundaries will not be susceptible to sensitization either. We expect that the austenite grains of a 26% Cr-6% Ni steel with 0.08% C might have a composition approximating Type 304L (18% Cr-10% Ni-0.02% C).

Another fact made clear by these considerations is the mechanism of weld sensitization of Type 304 stainless. Our isothermal studies show that for 304 with about 0.05% carbon a temperature of 600°C is required to cause sensitization, and that at least several hours at 600°C are needed. The area near the weld is not heated long enough at 600°C to allow carbide precipitation. However, nearer to the weld the steel is heated to the range 700°-750°C, where carbide nucleates within minutes. Then on cooling through the range 500°-650°C the chromium content near the carbide is decreased toward values appropriate for the lower temperature and the steel becomes susceptible.

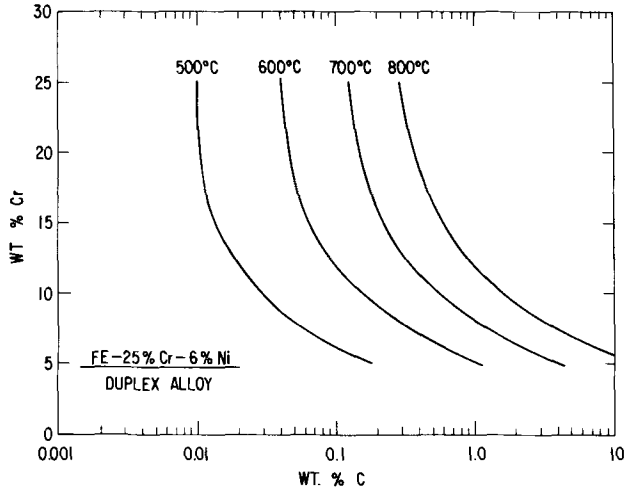

Fig. 16. Calculated Cr-C-$Cr_{23}C_6$ equilibria for Fe-25% Cr-6% Ni duplex stainless steel, for several temperatures.

Reheating to 700°-800°C and water quenching would restore immunity.

Although the thermodynamic analysis has been concerned primarily with the effects of carbon, chromium, and nickel on γ_C, it is of interest to consider the effect of other elements commonly found in stainless steels. Impurities such as phosphorous, sulfur, and nitrogen will probably have relatively little effect on γ_C, because although the derivative terms $\partial \ln \gamma_C/\partial X_i$ may be large, the mole fractions X_i will be small and consequently the product $X_i \cdot (\partial \ln \gamma_C/\partial X_i)$ will be small. An interesting case to consider, however, is that of manganese, which has been used as an austenite stabilizer when nickel was in short supply. It is generally recognized that these steels are less susceptible to intergranular corrosion than their nickel-containing counterparts. The interpretation in terms of thermodynamic behavior of these elements is that whereas nickel acts to increase γ_C the effect of manganese is just the opposite (25), so that in manganese-stabilized steels the carbon activity is lower and the chromium content in equilibrium with the carbide is higher than in the corresponding nickel-stabilized steels.

It is known that solutionized and quenched austenitic stainless steels can be made to corrode intergranularly in highly oxidizing solutions such as HNO_3-Cr^{+6}(5,6), or by potentiostatic corrosion at very high potentials in H_2SO_4 (26). It must be emphasized that corrosion in these environments is fundamentally different for several reasons from that which occurs when sensitized steel is exposed to less oxidizing solutions such as in a Strauss or Huey test. Both uniform surface corrosion as well as intergranular attack take place in these highly oxidizing environments, presumably because they can oxidize Cr^{+3} in the passive film to Cr^{+6} which is soluble. Such oxidation may require the transport of electrons through the oxide film to the metal. Impurities segregated at grain boundaries (5) could locally increase the electronic conductivity of the passive film, thereby facilitating the oxidation and corrosion at grain boundaries (27).

Comment should be made concerning some of the assumptions used in the thermodynamic analysis. First, the principal justification for the basic assumption that these stainless steels are "dilute" alloys (see Appendix) is the success of the model in quantitatively predicting the compositional and temperature dependence of intergranular corrosion of sensitized steel, of weld sensitization, and of the immunity of duplex alloys for intergranular corrosion. It was pointed out earlier that the activity coefficient of chromium was treated as a semiadjustable parameter; that is, using calculated data for γ_C and experimental corrosion data, γ_{Cr} at 600°C was derived. Although it must be admitted that obtaining activity coefficients from corrosion data is not a standard method, we feel it provides reasonable values. Further, the values thus obtained are in very good agreement with Goodell, who from chromium-nitrogen-nitride solubility data for austenitic stainless steel obtained $\gamma_{Cr} \approx 3.1 - 3.5$ at 650°C (28).

Although the approach used here is similar in principle to that of Stawström and Hillert, it differs considerably in detail and yields somewhat different results and predictions. First, it was demonstrated experimentally that their assumption of uniform grain boundary composition is inadequate in certain cases, and, in fact, patchy grain boundary corrosion may result as a consequence of large variations in the chromium content in the boundary. Second, the Wagner analysis permits predictions to be made of the effect of various alloying elements for which interaction coefficient ($\partial \ln \gamma_C/\partial X_i$) data are available. The Stawström-Hillert method leads to the prediction that the carbon solubility in stainless steels increases beyond about 20% chromium. To account for this, they suggest

that the chromium-carbon interaction parameter may be composition dependent, but there are no experimental data to support their prediction, and it seems more likely that it is a result of the method of calculation.

In summary, the theoretical predictions are well supported by the experimental study, and we believe that they are plausible. It is therefore our contention that the chromium content in equilibrium with the carbide particles is a strong function of the steel composition and of the sensitizing temperature and can be predicted by the thermodynamic theory. Furthermore, because of rapid grain boundary diffusion, the chromium depletion may be reasonably uniform despite a considerable separation of carbide particles. When "patchy" behavior is encountered it will generally be more pronounced at higher heat-treatment temperatures, because of the lower ratio of grain boundary to bulk diffusion coefficient. Our results demonstrate that the degree of sensitivity is controlled primarily by the thermodynamically controlled minimum chromium content, with morphological features of carbide particles playing a secondary role.

Acknowledgments

The authors are greatly indebted to D. E. Broecker and Mrs. C. F. Kirk who carried out much of the experimental work, to E. F. Koch for the electron microscopy, and to Dr. E. Lifshin and R. Bolon for the scanning electron microscopy. The Metals Processing Unit provided many of our test alloys, and their assistance is appreciated. The kindness of the International Nickel Company for providing samples of their experimental alloy IN 744 is gratefully acknowledged. We are also indebted to the United States Steel Company for samples of Type 304 steel with varying carbon contents. Stimulating discussions with Dr. H. S. Spacil and Professor J. F. Elliott of the Massachusetts Institute of Technology were very helpful in developing the thermodynamic analysis.

APPENDIX

Calculation of Carbon Activity Coefficients by the Wagner Analysis

Wagner derived an expression for the logarithm of the activity coefficient of a particular alloying component by a Taylor series expansion of the excess partial molar free energy. Thus, for carbon in iron with mole fractions X_i of the various other solute element, one obtains

$$\ln \gamma_C = \ln \gamma^\circ_C + \left[x_c \frac{\partial \ln \gamma_C}{\partial x_C} + x_{Ni} \frac{\partial \ln \gamma_C}{\partial x_{Ni}} + x_{Cr} \frac{\partial \ln \gamma_C}{\partial x_{Cr}} \right] + \left[\tfrac{1}{2} x^2_c \frac{\partial^2 \ln \gamma_C}{\partial x_C^2} + x_C x_{Ni} \frac{\partial^2 \ln \gamma_C}{\partial x_C \, \partial x_{Ni}} + \dots \right] \quad [1A]$$

The higher order terms which appear within the second set of brackets can usually be neglected; they are generally small because the product $x_i x_j$ is small. Also, values for the cross-term derivatives are usually lacking. In principle, the expansion may be made around any composition of interest, but data for evaluation of the derivative terms $\partial \ln \gamma_C / \partial x_i$ are available only for the constituent binary systems. Consequently in practice the expansion is really made around the compositional origin, *i.e.*, at $x_{Fe} \rightarrow 1$, and the derivatives are evaluated for the limiting case of zero concentration of all solutes. Hence, calculations based on this procedure are implicity applicable to dilute solutions only and extension to evaluation of γ_C for stainless steels is based on the assumption that the alloy is a "dilute" solution. With these assumptions, and considering stainless steel to be a solution only of carbon, nickel, and chromium in iron, Eq. [1A] is simplified to

$$\ln \gamma_C = \ln \gamma^\circ_C + x_C \frac{\partial \ln \gamma_C}{\partial x_C} + x_{Ni} \frac{\partial \ln \gamma_C}{x_{Ni}} + x_{Cr} \frac{\partial \ln \gamma_C}{\partial x_{Cr}} \quad [2A]$$

Data for the derivative terms in Eq. [2A] can be obtained from the literature (25, 29). In general the data are not available for the temperature range of interest (500°-800°C). Therefore, the activity coefficient is calculated for the temperature at which the data are available, and the temperature dependence is then estimated by assuming a regular (Hildebrand-type) solution, yielding the following expression

$$\ln \gamma_C = \frac{H^m}{RT} \quad [3A]$$

It is reasonable to assume that the enthalpy of mixing, H^m, is not significantly a function of temperature at least over a relatively small range of temperature. Therefore, if γ_C is known at one temperature, it can be estimated at other temperatures using Eq. [3A].

Equation [2A] was evaluated using the data of Heckler and Winchell (29) and Chipman and Brush (25). Conversion was made to a graphite standard state. It is readily apparent that an advantage of this approach is that the effects of the various alloying elements on the carbon activity coefficient are made explicit in Eq. [2A].

The Kinetics of Hydrogen Absorption into Iron during Cathodic Hydrogen Evolution

C. D. Kim and B. E. Wilde*

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania 15146

ABSTRACT

An electrochemical technique has been developed with which the steady-state concentration of adsorbed hydrogen on an iron surface, θ, can be determined. By using values of θ determined by electrochemical techniques, a method of evaluating the specific rate constant for hydrogen absorption into iron, k_{abs}, has been developed. Values of θ determined on a cathodically polarized iron surface in 0.0001*N* sodium hydroxide + 0.1*M* sodium sulfate were between 5 and 12% of the total monolayer coverage, over the current-density range 10-300 μA/cm^2. This current-density range represents a hydrogen generation rate equivalent to a corrosion rate of 5-150 mils penetration per year. The variation of θ with cathodic overpotential was in close agreement with theory; values of $\delta\eta/\delta \log_{10} \theta$ were 3.5 V/decade measured experimentally and 4.2 V/decade theoretically. Experimental values of θ permit, for the first time, determination of the specific rate constant for the absorption reaction.

The application of high-strength steels in aqueous corrosive environments is often limited by their susceptibility to hydrogen embrittlement. In general, the higher the yield strength of the alloy, the more susceptible to cracking it becomes. Many workers have studied this problem in attempts to correlate cracking propensity with chemical composition and microstructure (1-5). Most of the approaches to date, however, have been empirical and have not led to a successful solution to the problem. Consequently, steels with yield strengths in excess of 80 ksi are susceptible to hydrogen embrittlement in environments capable of promoting hydrogen entry into the steel.

Because the source of the problem is the absorption of hydrogen into the steel as a result of either (*a*) corrosion, (*b*) electroplating, or (*c*) cathodic protection, we have chosen a new approach in which the kinetics of the hydrogen absorption process are determined. This approach is new in that it studies the aqueous side of the steel/environment interface as opposed to metallurgical studies which are concerned with the solid solution side of the interface. Such a study may indicate some way to hinder the absorption process and thereby preserve or extend the life of the steel without loss of mechanical properties.

Theoretical Background

Almost all the hydrogen embrittlement encountered in practice results from one or more of the above-mentioned processes occurring in aqueous environments. During such reaction, hydrogen is generated on the steel surface by the mechanisms described elsewhere (8). From the viewpoint of the present investigation, the rate of the reaction in Eq. [1] is the critical factor, and depends simply on the specific rate constant k_{abs} and the steady-state concentration of hydrogen atoms on the surface, θ. The present work is concerned with the evaluation of θ and the effect of environmental and metallurgical variables on k_{abs}.

$$H_{adsorbed} \underset{k_{des}}{\overset{k_{abs}}{\rightleftharpoons}} H_{absorbed} \qquad [1]$$

To date no successful evaluation of k_{abs} for hydrogen absorption in steel from aqueous solutions has been made. The reason for this is the extreme difficulty in measuring θ on iron and steel surfaces. The work of the Bockris school is noteworthy in pioneering the development of techniques for measuring θ, but has largely been confined to face-centered-cubic materials such as nickel, silver, etc. (6-11). There have, however, been a few attempts (12, 13) to apply these techniques to body-centered-cubic materials, but problems have been encountered because of the enhanced hydrogen diffusivity in bcc metal and increased metal dissolution rates.

As a starting point, we selected the galvanostatic pulse technique (10) and applied an analysis to correct for both the above problems and make this technique applicable to ferrous materials. Briefly, the principle of this technique is the rapid electrochemical oxidation of adsorbed hydrogen on the metal surface by an anodic pulse. For simplicity, a steady-state θ was maintained by the use of a constant cathodic current applied to the iron in dilute alkaline solution, rather than by direct corrosion of the iron in more acidic environments. Upon application of a relatively large anodic current, i_a, the potential transient varies in shape depending on the steady-state value of θ. Under these conditions, the change in electrode potential with time can be described as

$$\left(\frac{dV}{dt}\right)_i = \frac{1}{C_V}\left[i_a - i_H - i_{ox}(1-\theta)\right] \qquad [2]$$

where i_H is the partial current used to oxidize the adsorbed hydrogen on the surface, $i_{ox}(1-\theta)$ is the partial current used to oxidize the iron, and C_V is the capacity of the electrical double layer at potential V. If the iron surface is oxidized as above, without the presence of adsorbed hydrogen, the transient (dV/dt)

* Electrochemical Society Active Member.

Key words: hydrogen absorption, surface coverage, hydrogen diffusion, electrochemical oxidation, electrode kinetics.

becomes

$$\left(\frac{dV}{dt}\right)_2 = \frac{1}{C_v}[i_a - i_{ox}] \quad [3]$$

From Eq. [2] and [3], it can be seen that the term $(i_H - i_{ox}\theta)$ is given by

$$(i_H - i_{ox}\theta) = C_v\left[\left(\frac{dV}{dt}\right)_2 - \left(\frac{dV}{dt}\right)_1\right] \quad [4]$$

To evaluate Eq. [4], we must determine C_v from Eq. [3] at potentials close to the reversible H_2 potential and assume that i_{ox} is negligibly small. This latter assumption is made on the basis of data to be presented in the discussion and is at present being verified by experiments designed to determine C_v by methods independent of those used in Eq. [3] (14). The area under the curve obtained by plotting $(i_H - i_{ox}\theta)$ against time is equivalent to the amount of adsorbed hydrogen on the iron surface.

Values of θ determined in the above manner can be used in conjunction with hydrogen permeation measurements to evaluate k_{abs}. The principles of the permeation techniques used are as follows. Consider the permeation of hydrogen through an iron membrane, where one side of the membrane is maintained at a constant cathodic overpotential to produce a steady-state value of θ. Let hydrogen be oxidized electrochemically at the opposite side at a rate fast enough to maintain a zero concentration at all times. Under these conditions, the transfer of hydrogen through the membrane may be considered in the following stages.

(*i*) Transference of the adsorbed hydrogen from the surface into the metal matrix. At steady state, the net input flux J_∞ is given by

$$J_\infty = k_{abs}\theta - k_{des}C_o \quad [5]$$

where k_{des} is the rate constant for the desorption process at the entry surface, and C_o is the concentration of metallic hydrogen at the entry surface.

(*ii*) Diffusion of hydrogen within the membrane. At steady state

$$J_\infty = \frac{D}{L}(C_o - C_e) \quad [6]$$

where C_e is the concentration of hydrogen at the exit side (*i.e.*, zero) and L is the thickness of the membrane.

(*iii*) Oxidation of the diffusing hydrogen at the exit surface, which is palladium-plated (13), to avoid problems associated with metal dissolution and hydrogen bubble formation. From Eq. [5] and [6], it can be seen that

$$\frac{1}{J_\infty} = \frac{L}{D\theta}\cdot\frac{k_{des}}{k_{abs}} + \frac{1}{k_{abs}\theta} \quad [7]$$

This equation is similar to that derived previously (13) but had been modified to eliminate an error arising from an incorrect assessment of the boundary conditions prevalent at the input and exit surfaces. By plotting $1/J_\infty$ against L for various membrane thicknesses, $1/(k_{abs}\theta)$ can be evaluated, and because θ is known from previous experiments, k_{abs} can be determined.

Materials and Experimental Work

The apparatus used for the determination of θ is shown schematically in Fig. 1. One compartment contained a platinized platinum electrode which served as a reference. Another compartment contained a bright platinum auxiliary electrode and the central compartment contained the working electrode (iron). The iron electrode, of the composition shown in Table I, was machined to 5 mm diameter by 10 mm long and was prepared by abrasion with silicon carbide paper down to a 600 grit finish. The electrode was mounted on a Stern-Makrides (15) holder and placed in the cell. All three compartments were continuously washed

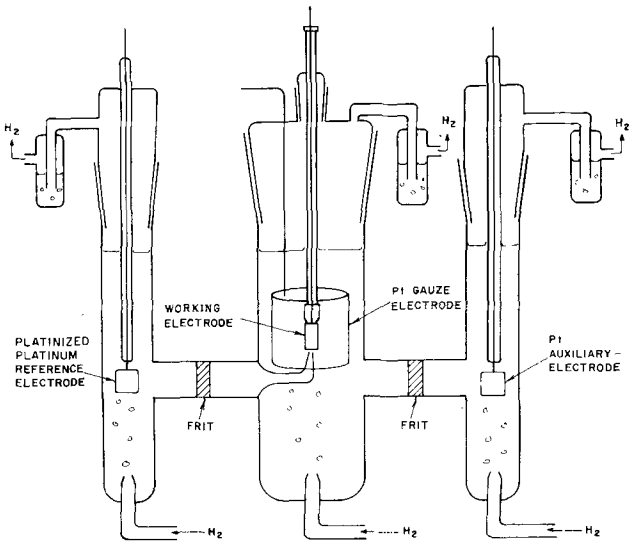

Fig. 1. Schematic representation of polarization assembly

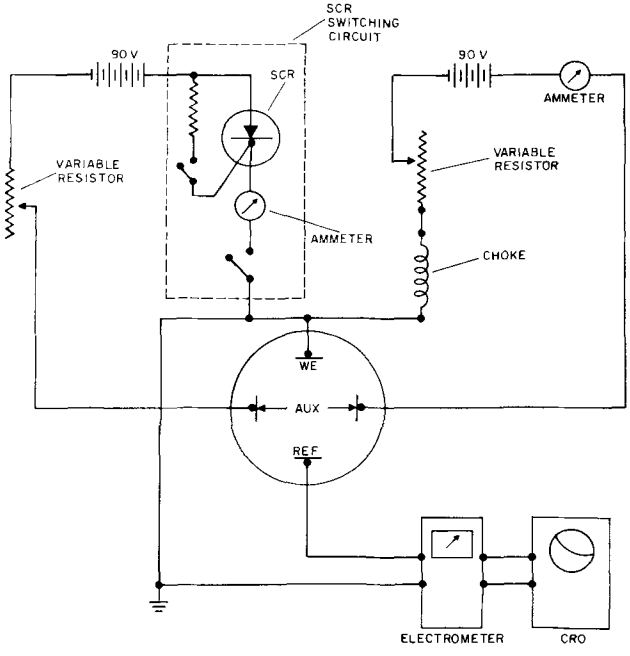

Fig. 2. Schematic representation of electrical circuit

with palladium-purified electrolytic hydrogen.[1] An additional platinum gauze electrode was placed circumferentially around the iron electrode to serve as a cathode during the anode pulsing.

The electrolyte was 0.0001*N* NaOH + 0.1*M* Na_2SO_4 made from reagent-grade chemicals and distilled water (7.6 megohm cm) to give a final *p*H of 9.5 at 25°C. To enhance experimental reproducibility, the electrolyte was pre-electrolyzed on a bright platinum cathode at 30 mA for 12 hr prior to experimental use.

The electrical circuit used is shown in Fig. 2. Two separate polarization circuits were superimposed on the test electrode as previously described (10): one to maintain a constant value of θ on the iron surface by a constant cathodic current, and the other to apply the anodic pulse used to oxidize the adsorbed hydrogen. A high-capacity choke was used to isolate the two

circuits. Electrode potentials were measured with a Keithley electrometer (Model 610 B), which was also used as an amplifier to drive the Y axis of an oscilloscope (Tektronix Model 564). To achieve almost instantaneous turn-on of the anodic pulse, a silicon rectified switching system (SRC) was employed, as shown in Fig. 2. Two 90V dry cells were used as current sources.

To establish the potential transient for $i_H = 0$, the iron electrode was immersed in the electrolyte and was polarized to 20 mV more positive than the reversible hydrogen potential. When a steady-state overpotential was established, an anodic galvanostatic pulse was applied to the iron (35 mA/cm^2), and the potential transient was recorded on the oscilloscope with a Polaroid camera attachment. A fresh iron electrode was then cathodized at a constant current for several hours to establish a steady-state θ and a uniform absorbed hydrogen concentration in the electrode. This electrode was then subjected to a 35 mA/cm^2 anodic pulse, and the transient recorded. Data at various values of θ were determined as above by using different cathodic polarizing currents. We have chosen in this study to express θ in coulomb/cm^2 or grams hydrogen/cm^2 as in Fig. 6. However, previous workers have expressed θ in terms of the fraction of the surface covered with a monolayer of hydrogen. This latter method assumes a 1:1 iron to hydrogen ratio on a (100) plane of the body-centered-cubic cell, having a total of 192 μcoulomb/cm^2 for full coverage. Our data is also presented this way in Fig. 7, although the rate constant k_{abs} is calculated on θ in grams H/cm^2.

Permeation studies were conducted in the manner previously described (16), except that the oxidation side of the membrane was maintained at +100 mV_{SCE} in 1*N* NaOH solution at 25°C and was palladium-plated to prevent loss of sensitivity due to other reactions taking place in preference to hydrogen oxidation.

Results and Discussion

Anodic and cathodic polarization curves were determined potentiostatically (Wenking Model 66 TS-3), from which Tafel constants of +0.041 and −0.127V were obtained. It is important to note that the above constants were not influenced over two decades of applied current by the saturation of the iron electrode with hydrogen in solid solution.

Potential transients were determined over various values of θ; typical results are shown in Fig. 3 for a cathodic current density of 100 μA/cm^2. Values of $(dV/dt)_1$ and $(dV/dt)_2$ were evaluated at various potentials for Fig. 3 and were used to determine $(i_H - i_{ox}\theta)$ from application of Eq. [4]. Values of $(i_H - i_{ox}\theta)$ plotted against pulse time are shown in Fig. 4 and represent the amount of hydrogen adsorbed on the iron surface at a given cathodic current, along with an error term resulting from the oxidation of hydrogen dissolved in solid solution over the time period of the pulse.

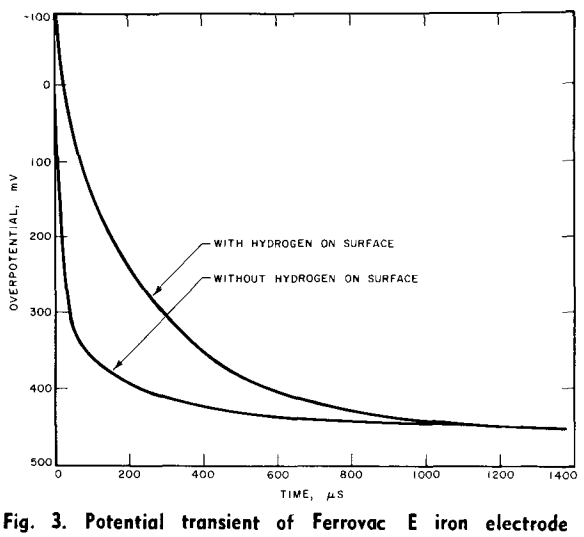

Fig. 3. Potential transient of Ferrovac E iron electrode in 0.0001*N* NaOH + 0.1*M* Na_2SO_4 solution (i_{ca} = 100 μA/cm^2; i_a = 35 mA/cm^2).

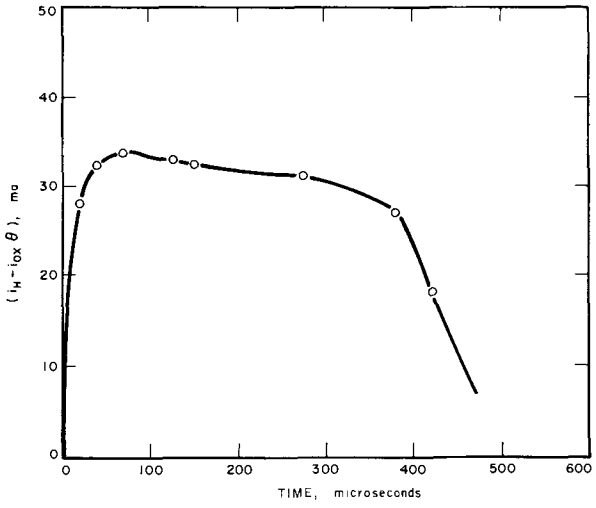

Fig. 4. (i_H-i_{ox}) calculation at various times

To correct θ for this error term, the following analysis was applied. Assume that the dissolved hydrogen was uniformly distributed in the iron and that the concentration at the electrode surface remains zero at all times during the anodic pulse. Under these conditions, a solution to the diffusion equation can be derived for a cylindrical specimen geometry, in terms of Q, the quantity of hydrogen remaining in the iron at time, t

$$Q = \frac{32\, C_0 \rho^2 L}{\pi} \left[\sum_{n=0}^{\infty} \frac{\exp\left[-(2n+1)^2 \pi D t/L^2\right]}{(2n+1)^2} \right] \times \left[\sum_{n=1}^{\infty} \frac{\exp\left[-D \cdot \beta_n^2 \cdot t/L^2\right]}{\beta_n^2} \right] \quad [8]$$

where D is the diffusivity of hydrogen, L and ρ are the length and diameter of the iron electrode, β_n is the root of the zero order Bessel function of the first kind, and C_0 is the initial concentration of metallic hydrogen in the iron. This latter term was obtained by permeation techniques (16) on an iron membrane cathodized in the same manner as that used in the pulse studies.

Values of Q were determined at various times by using a computer. The rate of removal of dissolved hydrogen, R, is simply $-dQ/dt$, and the results are shown in Fig. 5 for the general case of C_0 = 10 mc/cm^3. The portion of the curve relevant to the data in Fig. 4 is shown in the inset, where the hatched area represents the error fraction in θ resulting from the oxidation of dissolved hydrogen. In several experiments R was found to be independent of D over the range 10^{-4} to 10^{-6} cm^2/sec for the first second. The corrected value of θ (determined by subtracting the data in Fig. 5 from that in Fig. 4) varied slightly with applied cathodic current (or input fugacity), as shown in Fig. 6. Previous theoretical studies (17) have shown that θ should vary with overpotential according to

$$\theta = k_{exp}\left(-\frac{\eta F}{4RT}\right) \quad [9]$$

where K is a constant, η is the overpotential, and **F** R, and T have their usual meaning. The data shown in Fig. 6, when plotted in terms of log θ *vs.* η, did produce the straight line required by Eq. [9], as shown in Fig.

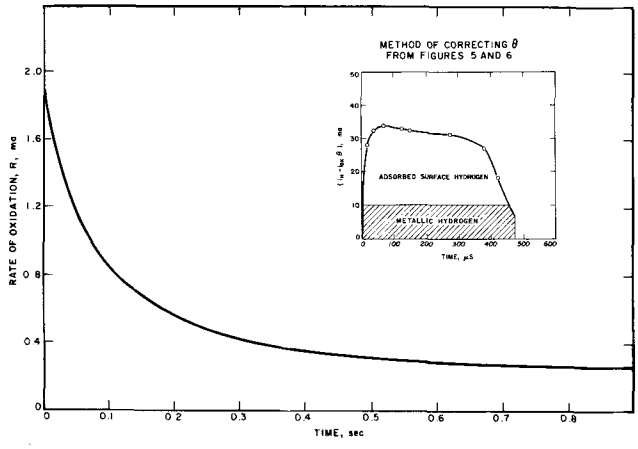

Fig. 5. Computed rate of oxidation of metallic hydrogen during the anodic pulse for an initial hydrogen concentration of 10 mcoulomb/cm³.

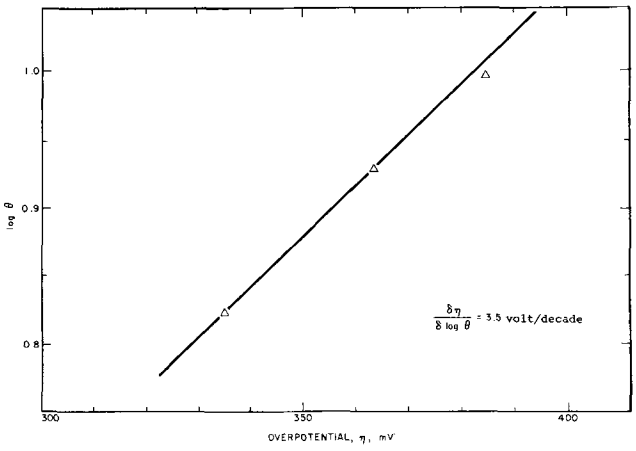

Fig. 7. Relationship between degree of coverage, θ, and the applied cathodic overpotential on iron in 0.0001N NaOH + 0.1M Na_2SO_4 at 25°C.

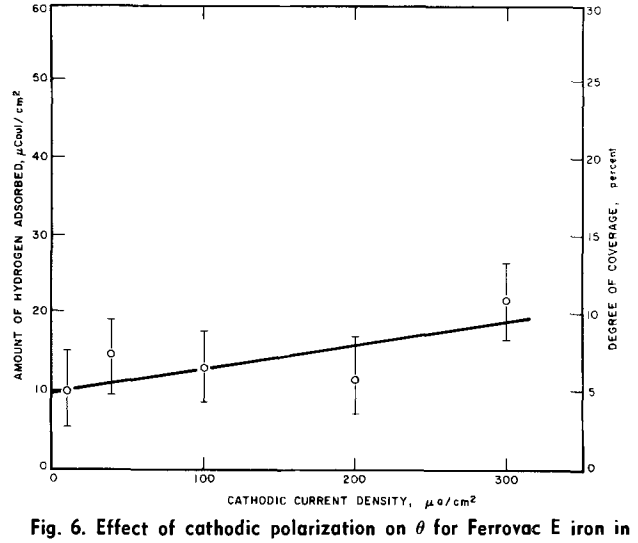

Fig. 6. Effect of cathodic polarization on θ for Ferrovac E iron in pH 9.5 solution.

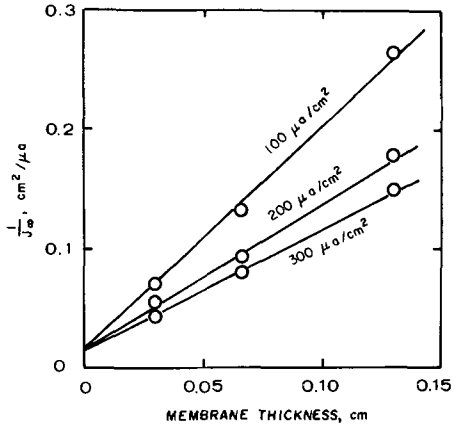

Fig. 8. Variation in the reciprocal of the permeation flux with membrane thickness for several cathodic current densities.

7. According to theory, the slope in Fig. 7 should be equal to $-\mathbf{F}/4RT$ at a maximum, or 4.2 V/decade. The actual slope obtained from Fig. 7 was 3.5 V/decade indicating quite close agreement with theory. On the basis of this close agreement, we feel that the term $i_{ox}\theta$ in Eq. [4] must of necessity be small with respect to i_H, as assumed in the analysis presented earlier.

The permeation flux, J_∞, was determined at three cathodic current densities on iron membranes over the thickness range 0.025-0.13 cm. The data obtained are shown in Fig. 8. It is clear that the relationships for each cathodic current converge to distinct points on the ordinate at $L = 0$, which when analyzed with θ give a value of k_{abs} which is independent of θ, as required by kinetic theory for a first order reaction. The intercept $1/(k_{abs} \cdot \theta)$ was evaluated and solved for k_{abs} by using the corrected values of θ obtained from the pulse measurements. These data are summarized in Table II, where θ has been expressed as grams hydrogen/cm² and k_{abs} has the dimensions of sec^{-1}. The measured values of k_{abs} appeared not to change significantly over the potential range investigated.

Summary

The galvanostatic pulse technique for measuring θ, the adsorbed hydrogen concentration on metal surfaces during cathodic hydrogen evolution, has been successfully applied to ferrous base materials. With this technique, the concentration of adsorbed hydrogen on a cathodically polarized iron surface in 0.0001N NaOH + 0.1M Na_2SO_4 solution has been shown to vary with overpotential in the manner predicted by theory.

Values of θ at three cathodic current densities have been used, along with permeation studies, to evaluate the fundamental adsorption rate constant for hydrogen into iron.

An Ellipsometric Study of the Anodic Deposition of Iron Oxide Films

J. L. Ord*

Department of Physics, University of Waterloo, Waterloo, Ontario, Canada

and D. J. De Smet*

Department of Physics, University of Alabama, University, Alabama 35486

ABSTRACT

Films of iron oxide were deposited on iron, platinum, and gold substrates by the anodic oxidation of ferrous ions contained in neutral electrolytes. The film growth was followed optically to thicknesses of several thousand angstroms with a following ellipsometer. The films deposited from borate electrolyte onto iron and platinum substrates were found to have a real refractive index equal to 1.7 at a wavelength of 6328Å. The films deposited onto a gold substrate from borate electrolyte were found to have a refractive index with a real component of 1.7 and a small but nonzero absorption coefficient. The films deposited onto a platinum substrate from perchlorate electrolyte were found to have a real refractive index equal to 1.93. We conclude that films with index 1.7 have an amorphous structure, films with index 1.93 are crystalline, and films deposited on gold substrates have trace amounts of gold incorporated in the film.

In an earlier paper (1) we presented ellipsometric measurements on the anodic oxidation of an iron substrate in a neutral borate electrolyte. In the course of these measurements, we found that ferrous ions, resulting from the anodic dissolution of iron in the active state, were oxidized in the passive state to a ferric oxide which deposited on the electrode. In that study we excluded ferrous ions from the electrolyte in order to study films formed by direct anodic oxidation of the iron substrate. In this paper we present ellipsometric measurements on the oxide film formed by the anodic oxidation of ferrous ions contained in neutral electrolytes. Iron, platinum, and gold are used as substrates for the deposition. This process has been studied extensively by Cohen and co-workers (2-5) who concluded that the films could be deposited onto any reasonably inert substrate, but that amorphous films were deposited from borate electrolyte whereas crystalline films were deposited from sulfate and perchlorate electrolytes. In the work we present here, we have used *in situ* optical measurements during the deposition of films from borate, sulfate, and perchlorate electrolytes onto iron, platinum, and gold substrates to test these conclusions.

Experimental

The electrodes used as substrates for the deposition were prepared from single crystals of iron, platinum, and gold. In each case the sample was prepared in the form of a cylinder 0.3 in. long by 0.2 in. in diameter. A small hole was drilled down the axis of the cylinder for the mounting assembly (1, 6) and a flat surface for the optical measurements was ground on one side of the cylinder. The samples were then given electrolytic surface treatments. For iron, a mixture of water, oxalic acid (100 g/liter), and hydrogen peroxide in a ratio of 20:7:1 at a temperature of 35°C was used as a chemical polish (7). The film left on the surface after the polishing was removed by cathodic reduction. The platinum sample was cleaned by immersion in concentrated nitric acid then in concentrated hydrochloric acid. The gold was anodized in sulfuric acid (8), then immersed in concentrated hydrochloric acid. The softness of the gold sample made it necessary to remove considerable material in this manner before a clean single-crystal surface was produced.

The cell used was an equilateral hollow prism of 75 ml capacity in which were mounted a platinum cathode, a mercurous sulfate reference electrode, a gas dispersion tube, and the electrode assembly. The surface of the sample under study was vertical. All experiments were performed at room temperature. The electrical equipment and circuitry are similar to those used in earlier work (9).

The electrolytes used were similar to those used by Cohen and co-workers (2-5). The borate electrolyte was the pH 8.4 buffered electrolyte used in our earlier work (1). The sulfate and perchlorate electrolytes were of the same approximate pH but were not buf-

* Electrochemical Society Active Member.
Key words: ellipsometry, anodic deposition, iron oxide.

fered. All electrolytes were bubbled with argon for at least 12 hr prior to the beginning of an experiment in order to remove any traces of dissolved oxygen. The bubbling was continued throughout the course of an experiment, stirring the electrolyte mildly. Ferrous ions were introduced into the electrolyte either by anodic dissolution of iron or by addition of a small amount of ferrous ammonium sulfate. The anodic dissolution introduced only ferrous ions, but low current densities (and hence long dissolution times) were required to avoid passivation of the iron. The experimental results were not sensitive to the method used to introduce the ferrous ions. The ferrous ions can only be maintained in the electrolyte provided it is free of dissolved oxygen.

The following ellipsometer used in this study is described in detail elsewhere (10). It is capable of making a measurement in one second with a resolution of 0.01°. This following speed was more than adequate for the deposition rates used in this work. A helium-neon gas laser (wavelength 6328Å) was used as a light source, and the angle of incidence was 60° for all of the data reported here. Several digital computer programs, including the original program by McCrackin and Colson (11), were used to generate theoretical curves in both tabular and graphical form for fitting the optical data.

Results and Discussion

The first deposition experiment was carried out using an iron electrode as a substrate in neutral borate buffer. The ellipsometer was nulled initially on a cathodically reduced iron surface, then it was set for automatic nulling to follow the film growth. The electrode was passivated at a constant current density of 100 μA/cm^2 to a potential of 0.3V (with respect to the mercurous sulfate reference electrode) and then was held at this potential. The current density was allowed to decrease to 1 μA/cm^2 before ferrous ions were added to the electrolyte. The growth of the deposited film was then followed through several thousand angstroms.

The results of this experiment are shown in Fig. 1 and Fig. 2. In these figures an optical measurement at a particular thickness appears as a point, and as a film grows, the points generally trace out a smooth curve. The actual experimental data consist of over 2000 points, and only representative points are plotted in the figures. The solid lines in the figures are theoretical calculations of the polarizer and analyzer null positions which would result from the growth of layers of constant refractive index. In Fig. 1 the bare surface measurement is plotted at point A, and data obtained during the anodic oxidation of the iron substrate are plotted

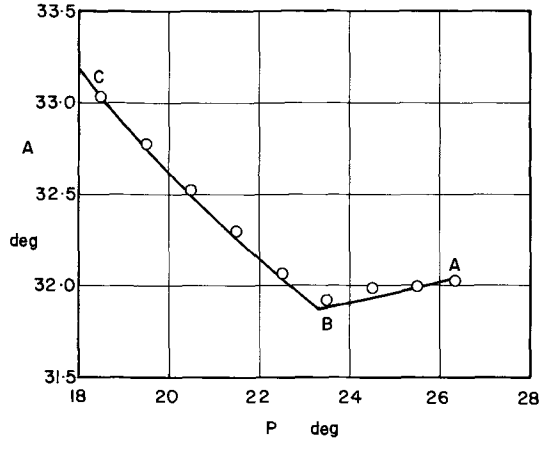

Fig. 1. Optical data on the anodic oxidation of iron in a neutral borate electrolyte (A to B) followed by deposition of an iron oxide (B to C) by anodic oxidation of ferrous ions added to the electrolyte. The curve from A to B is calculated for the growth of a layer of index 2.4-0.3*i* to a thickness of 40Å, and from B to C for an additional layer of index 1.7 to 150Å.

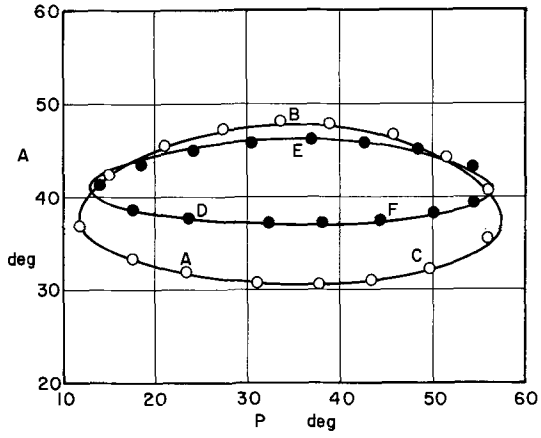

Fig. 2. Optical data on an anodic deposition of iron oxide layers from neutral borate electrolyte containing ferrous ions onto iron (ABC) and platinum (DEF) substrates. The curves in the figure are calculated for the growth of layers with a real refractive index equal to 1.7.

from A to B. The line between A and B is a theoretical curve for the growth of a layer of index 2.4-0.3*i* to a thickness of 40Å on a substrate of index 3.16-3.72*i*. (Other values for the index of the anodic oxide layer are possible, but the choice of an index for this thin layer has virtually no effect on the calculation of the index of the deposited layer.) The data plotted from B to C were obtained after ferrous ions were added to the electrolyte. The curve from B to C represents the growth of a layer of real index 1.7 to a thickness of 150Å. The curve traced out during deposition is plotted in Fig. 2 on a less expanded scale. (The figure also shows the results of the deposition experiment on platinum described below.) The experimental data trace out the loop ABC in the figure as the deposited layer grows. The closure of the loop at A is characteristic of the growth of a layer with a real refractive index. The curve fitted to the data in the figure represents the growth of a film of index 1.7 to a thickness of 2500Å when the curve closes on itself. The fit to the experimental data is good for a layer whose thickness is expected to be somewhat nonuniform due to the diffusion-limited nature of the deposition process. The considerable difference between the index of the layer formed by oxidation of the iron substrate and the index of the deposited layer shows that the layers must differ in composition and structure.

The second deposition experiment was carried out using a platinum single-crystal substrate in borate electrolyte. The ellipsometer was nulled initially on the platinum surface which was under cathodic reduction in an electrolyte containing ferrous ions. The ellipsometer was then switched to the following mode, and the electrode was driven galvanostatically at 20 μA/cm^2 to a potential of 0.4V with respect to the reference electrode, where it was held for the balance of the experiment. The current density was about 10 μA/cm^2 during the deposition. The results of this experiment are plotted in Fig. 2 also. The experimental data trace out the clockwise loop DEF as the layer grows, and the loop closes at D. The theoretical curve through these data represents the growth of a layer of the same index, 1.7, as was used in fitting the iron substrate data. The fit to the data is reasonable, but there is more evidence of layer nonuniformity than previously. From the two sets of data in Fig. 2 we conclude that layers with the same composition and structure are deposited on platinum and iron in borate buffer. The difference between the two sets of data is due solely to the difference between the refractive indices of the iron and platinum substrates.

In an attempt to determine if this film could be deposited on any reasonably inert substrate we next tried a similar experiment using a gold single crystal.

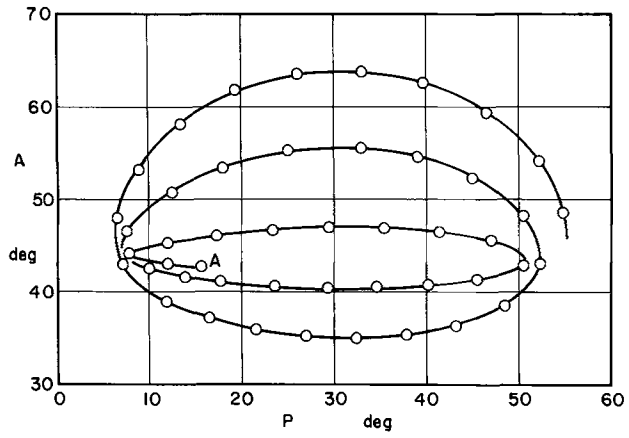

Fig. 3. Optical data on the anodic deposition of an iron oxide layer onto a gold substrate in borate buffer. The data points start at A and trace out an outward clockwise spiral as the layer grows.

The results of this experiment are plotted in Fig. 3. The data points start at A and trace out a clockwise outward spiral as the layer increases in thickness. The first few hundred angstroms of layer growth can be fitted to the growth of a layer of real index 1.7, but an index of $1.7-0.01i$ is required to fit the first complete loop. The final loop of the spiral can only be fitted by assuming that the imaginary part of the index has increased by a factor of three by the time the final thickness is reached. (The layer definitely has a small absorption coefficient, but the apparent increase in the absorption coefficient with thickness actually may be due to nonuniformity of the layer.)

We did not expect that the layer deposited on gold would differ from the layer deposited on the other two metals, but in retrospect the result cannot be considered surprising. Of the three metals, only gold can be anodized, and hence it is not as inert a substrate for oxygen evolution as is either iron or platinum. If gold is not an inert substrate for oxygen evolution, there is no reason to expect it to be inert for oxidation of ferrous ions. Data on the galvanostatic anodic oxidation of gold in a borate electrolyte free of ferrous ions are presented in Fig. 4. The data obtained on the growth of an anodic oxide film below the oxygen evolution potential are plotted from A to B, and the data on continued film growth at low current efficiency during oxygen evolution are plotted from B to C. The inflection in the data at point B shows that the anodized film differs in index from the anodic oxide film formed at lower potentials. Neither iron nor platinum grow a secondary oxide film during oxygen evolution, presumably because the anodic oxide acts as a barrier between the metal and the electrolyte. Once the oxygen evolution potential is reached with these metals, electrons can tunnel through the film, but ions require a field across the film to assist their motion. The film will thicken somewhat after oxygen evolution begins, but since the potential no longer rises, the increase in thickness lowers the field in the film, and a point is soon reached at which ionic conduction and hence further growth effectively ceases. Gold appears to behave quite differently. Conduction of electrons from either the oxygen evolution or ferrous ion oxidation reactions appears to enable ionic transport to continue. The film formed in this manner has a different structure from the anodic oxide film as is indicated by the difference in its refractive index. The results plotted in Fig. 3 cannot be accounted for by assuming that, as the deposited film grows, an anodized film grows under it. The symmetric outward spiral can only be accounted for by the growth of a single layer, and hence we conclude that a trace of gold is incorporated in the deposited film and causes it to be slightly absorbing.

We next devoted considerable effort to studying films deposited onto platinum in neutral sulfate electrolyte. We could not obtain reproducible optical data for this process, and our single positive result was obtained from an x-ray powder pattern of material from a thick deposited film. We identified the material as γ-$Fe_2O_3 \cdot H_2O$ (lepidocrocite) with the aid of the ASTM index of powder patterns. Leibenguth and Cohen (4) made the same identification using electron diffraction techniques.

Hashimoto and Cohen, in reporting their measurements on deposition from perchlorate electrolytes (5), stated that they obtained better electron diffraction patterns than were obtained in sulfate electrolyte. This comment led us to suspect that the films we had been depositing from sulfate electrolyte were not single-phase crystalline films, and hence our optical data on their growth could not be expected to fit theoretical curves for the growth of uniform films. We then tried depositing onto platinum in neutral perchlorate electrolyte, and obtained the data plotted in Fig. 5. Two theoretical curves are plotted in the figure, ABC for a layer of real index 1.7, and ADC for a layer of real index 1.93. The data clearly fall on the latter curve, and we conclude that the iron oxide layer has an index of 1.93 when it is deposited in the crystalline phase as opposed to 1.7 when it is deposited as an amorphous film.

Conclusions

Our measurements confirm the conclusions of Cohen and co-workers that iron oxide films can be deposited anodically onto both iron and platinum, and that the films deposited from perchlorate electrolyte differ in

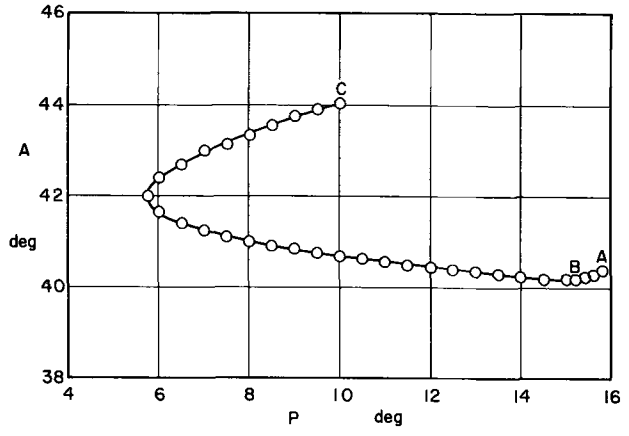

Fig. 4. Optical data on the anodic oxidation of gold in a neutral borate electrolyte. The data from A to B were obtained during the growth of an anodic oxide below the oxygen evolution potential; the data from B to C were obtained as an oxide film grew during oxygen evolution.

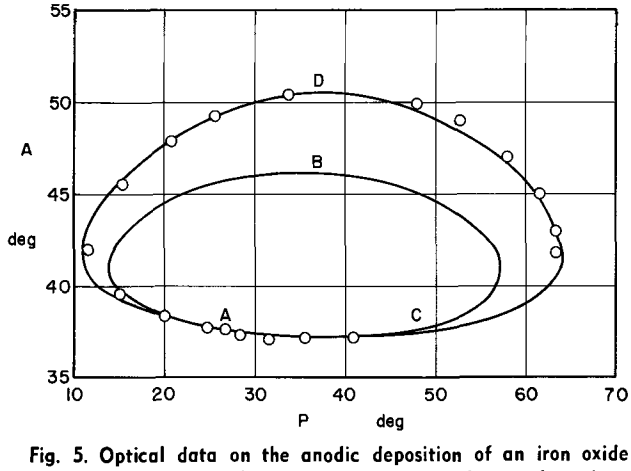

Fig. 5. Optical data on the anodic deposition of an iron oxide layer onto a platinum substrate in neutral perchlorate electrolyte. The curve ABC is calculated for the growth of a layer of real index 1.7; the curve ADC for a real index 1.93.

structure from those deposited from borate electrolyte. We conclude in addition that trace amounts of gold are incorporated in films deposited on gold substrates, rendering the films slightly absorbing. We were unable to deposit uniform single-phase films in sulfate electrolyte.

On Preferential Anodic Dissolution of Alloys in the Low-Current Region and the Nature of the Critical Potential

H. W. Pickering* and P. J. Byrne

Edgar C. Bain Laboratory For Fundamental Research, United States Steel Corporation, Research Center, Monroeville, Pennsylvania 15146

ABSTRACT

Previous investigations on Cu-Au and Cu-Zn alloys have shown that the polarization curves for anodic dissolution of the less noble metal are complex, that the mechanism of preferential anodic dissolution involves the interdiffusion of the components in an alloy layer next to the surface, and that appreciable surface roughening occurs. In the present paper the mechanism of preferential anodic dissolution at lower overpotentials and the nature of the transition (current increases sharply) which occurs at a certain (more noble or oxidizing) potential, E_c, are examined. Results of electrochemical investigations on polycrystalline Cu-Au alloys at $E < E_c$ indicate that Cu atoms in direct contact with the electrolyte readily dissolve, and that a Cu-depleted layer forms both above and below E_c. At potentials more noble than E_c appreciable transport of Cu through the Cu-depleted layer occurs as a result of the onset at E_c of gross surface roughening which provides for a relatively short and time-independent, interdiffusion distance. The change in diffusion conditions which leads to a surface instability at E_c is reasoned to be related to a potential-dependent concentration of excess (di)vacancies in the interdiffusion layer.

Gerischer and Rickert (1) have observed that a stationary current is reached only after a rather long time during anodic dissolution of Cu from Cu-Au alloy at constant potential. It is, however, by no means obvious that a stationary current should be reached since with increasing time an increasing amount of the more noble component is accumulated at the alloy surface and, therefore, anodic dissolution of the less noble component, Cu, is impeded. Pickering and Wagner (2) have shown that the current is maintained by the interdiffusion of the components in the alloy; x-ray and electron diffraction data indicate that Cu diffuses to the surface and Au diffuses backward into the alloy. As a limiting case suppose that only one-dimensional diffusion (normal) to a plane surface occurs. Then the current density would be inversely proportional to the square root of time (2). Actually, however, the situation is far more involved since roughening of the surface also occurs (3-5). Although surface roughening makes the observance of a quasi-stationary current qualitatively understandable, it is difficult to analyze such observations since the increase in the length of effective diffusion path in the alloy with time, and surface roughening both affect (in opposite directions) the current.

Further insight may be obtained from the observation of certain transient phenomena. One may conduct experiments in which the alloy initially is kept at a fairly low potential E'. Subsequently, one may jump the potential to a hgher value E'' at which normally (in the absence of a pretreatment at E') a rather high current (1) and roughening of the surface (4, 5) are observed immediately. During the initial stage (E') Cu atoms are presumably removed from the uppermost lattice plane of the alloy, and subsequently copper depletion may extend to a depth of several lattice planes via counterdiffusion of Cu and Au. Accordingly, the current falls off as the supply of Cu atoms in direct contact with the electrolyte decreases with time (2). When after this pretreatment a higher potential E'' is applied, one may expect first a high current in view of the charging of the double layer of

the electrode; subsequently a rather low current is expected as transport conditions within the Cu-depleted layer adjust in order to attain the higher current characteristic of a sample held solely at E''. This is shown schematically in Fig. 1.

Appropriate potentials for potential-jump investigations may be chosen with the aid of current density-potential curves for dissolution of Cu from Cu-Au alloys. According to data of this kind already available [Gerischer and Rickert (1)], a typical polarization curve contains a region where Cu dissolves at a low, potential-independent rate and another region at higher potentials where the rate of Cu dissolution increases sharply with potential. It is for the increasing current region that Pickering and Wagner found that preferential dissolution of Cu from Cu-Au alloys occurs via interdiffusion of the components in the alloys. Potential-jump investigations then may be made most advantageously, for a range of E' potentials corresponding to the potential-independent, low-current region of the polarization curve, with potentials in the increasing-current region usually chosen for E''. Accordingly, information is obtained on the mechanism of dissolution in the low-current region, and on the nature of the potential E_c (referred to as the critical potential) at which transition to potential-dependent and high currents occurs.

Experimental Procedure

Investigations at 23°C were carried out mainly on Cu-13 a/o (atomic per cent) Au alloy (Cu13Au) in 1N Na_2SO_4-0.01N H_2SO_4 or in 1N Na_2SO_4-0.1N $CuSO_4$-0.01N H_2SO_4. Data are also reported for Cu-18 a/o Au (Cu18Au) and Cu-25 a/o Au (Cu25Au) alloys. High-purity alloys were made from 99.999% Cu and 99.99% Au. After homogenization at 700°C for 48 hr in evacuated silica capsules, cylindrical specimens were prepared by swaging, drawing to final diameter (0.216 cm), machining to length = 1.42 cm (area = 1 cm^2), and mechanical polishing, except with Cu25Au where sheet specimens were prepared by cold rolling. Unless otherwise stated the electrodes were annealed in evacuated silica capsules for 2 hr at 700°C and air cooled, and just prior to a run were polished on fine emery and rinsed in distilled water and methanol.

The cell of Pyrex and Teflon construction is shown in Fig. 2. A stream of prepurified He was passed through the cell prior to and during the run in order to remove oxygen. The reference cell was a mercury-mercurous sulfate electrode in contact with 1N H_2SO_4. The potentials are all reported relative to the standard hydrogen electrode (SHE). Switching of the potential was accomplished with a mechanical switch and two independent power supplies connected to a Wenking potentiostat. Doubly distilled water and reagent-grade chemicals were used to prepare the electrolyte.

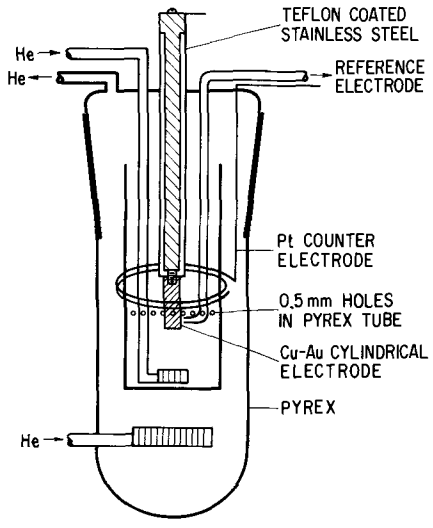

Fig. 2. Cell used for current-time transient experiments

As a check that the directly measured (meter) current was due mainly to Cu dissolution, quantitative chemical analysis of the electrolyte was made after several runs with 1N Na_2SO_4-0.01N H_2SO_4. A cell similar to that in Fig. 2 was used, but which provided for quick draining of the electrolyte (generally 60 ml) from the inner compartment. The minimum Cu content which could be detected was $\sim$ 0.15 μg/ml, whereas the actual amounts in solution after anodic dissolution were more than an order of magnitude higher. Chemical analysis data for a specimen were obtained in two or more dissolution periods. After a 1-hr initial dissolution period the electrolyte was drained for analysis. This was followed by the introduction of fresh electrolyte for further dissolution of the specimen at the same potential, and this procedure was repeated in successive dissolution periods. An average current density for each period was calculated from the amount of Cu in the electrolyte on the basis of the projected area of the specimen. Currents obtained by chemical analysis are specifically indicated in the text or in figure captions; otherwise currents given are the directly measured (meter) values.

Results

Log i_{Cu}-E curve.—In order to arrive at a polarization curve for Cu dissolution from Cu13Au the current-time behavior was determined at various constant potentials. For all potentials of Cu dissolution the current initially is high but falls at a rapid, although ever-decreasing rate; after 1 hr there is little further decrease (quasi-stationary current). Typical current-time transients are shown in Fig. 3 and 4. The curve in Fig. 4 was constructed from data obtained by chemical analysis of the electrolyte as well as from the directly measured current. Excellent agreement was obtained between the current on the microammeter and the current calculated from the amount of copper in the electrolyte.[1] No gold was found in the electrolyte, in agreement with thermodynamic considerations and the results of others (6).

It is clear from the current-time behavior at constant potential shown in Fig. 3 and 4 that in order to arrive at an easily interpretable log i_{Cu}-E curve the time of dissolution must be held constant, although this condition may be relaxed at longer times. Accordingly, the (meter) currents at 2 hr were used to construct the log i_{Cu}-E curves for dissolution of Cu from Cu13Au and Cu18Au (Fig. 5). The curves exhibit

[1] The average current density calculated for the first period, however, is not very meaningful since the current changes by several orders of magnitude; roughly half the charge for this period was estimated to pass in the first few minutes, and accordingly the first period point was plotted at 4 min.

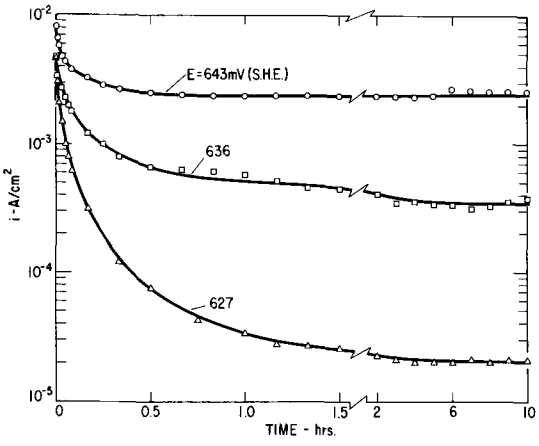

Fig. 3. Log i_{Cu}-t curves based on the projected area for Cu13Au in 1*N* Na_2SO_4-0.1*N* $CuSO_4$-0.01*N* H_2SO_4 with $E_c \cong 630$ mV. Surface roughening occurs at $E \gtrsim E_c$.

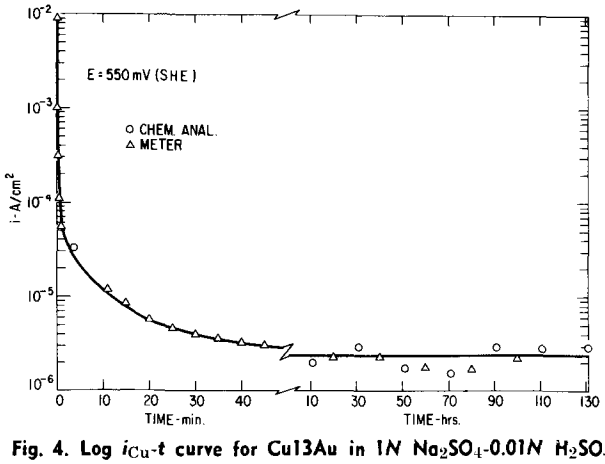

Fig. 4. Log i_{Cu}-t curve for Cu13Au in 1*N* Na_2SO_4-0.01*N* H_2SO_4 at $E = 550$ mV (SHE) with $E_c \cong 630$ mV.

a potential-independent, low-current region, a strongly potential-dependent, increasing-current region, and a critical potential, E_c, which increases with increasing Au content of the alloy. The solid curves in Fig. 5 were obtained with 1*N* Na_2SO_4-0.01*N* H_2SO_4 and the dashed curve with 1*N* Na_2SO_4-0.1*N* $CuSO_4$-0.01*N* H_2SO_4. With the former electrolyte containing no $CuSO_4$, the directly measured current was determined to be entirely due to dissolution of Cu by quantitative chemical analysis of the electrolyte from a 20-hr dissolution period following an initial 1-hr period. With the latter electrolyte containing $CuSO_4$, a higher current of $\sim 10^{-5}$ A/cm² was recorded (meter) at $E < E_c$ (dashed line); at $E > E_c$ the currents were the same for both electrolytes. IR voltages between the specimen and Luggin capillary were negligible, except possibly at the higher current densities and surface roughnesses, and may account in part or total for the "bending over" of the polarization curves at $i \gtrsim 1$ mA/cm².

The critical potentials for Cu13Au and Cu18Au in Fig. 5, defined as the intersection of the tangents drawn to the plateau and the inflection point of the increasing-current regions of the log i-E curve, are $E_c \cong 590$ mV (SHE) and $E_c \cong 810$ mV, respectively. E_c for Cu25Au is ~ 1000 mV, and the current at $E < E_c$ for Cu25Au decreases to less than 0.5 μA/cm² in 1 hr. The critical potentials were quite reproducible for specimens given the prescribed thermal and mechanical treatment as a group; but E_c varied for different groups of specimens. E_c for three groups of Cu13Au specimens was 590, 630, and 660 mV.

The log i_{Cu}-E curve was also obtained for Cu13Au specimens in the "as swaged and drawn" condition (cold worked). The results were qualitatively the same as for annealed alloy (Fig. 5), with E_c generally somewhat lower and varying even among specimens of the same group.

These data may be compared to similar current-time and current-potential data recently obtained for preferential dissolution of Zn from Cu-Zn alloys (dezincification) (7). Sole dissolution of Cu from Cu-Au alloy over the potential range investigated is analogous to the sole dissolution of Zn from Cu-Zn alloys below about +50 mV (SHE). E_C shifts to higher potentials with increasing content of the more noble metal in both systems. The increase of E_c with content of the more noble metal is such in both systems that E_c may be expected to be in the range of dissolution of the more noble metal for alloys rich in the more noble metal, as has actually been observed with α-brass (7). Also preferential dissolution of Zn from Cu-Zn alloys has been found to occur at $E > E_c$ via interdiffusion of the components in the alloy (8), just as was found for preferential dissolution of Cu from Cu-Au alloys (2).

Potential-jump investigations.—When the potential is jumped to $E'' > E_c$ after a pretreatment at $E' < E_c$, there is a period of up to 10^2 sec at E'' when the rate of Cu dissolution is considerably lower than in the absence of the pretreatment. One observes, on jumping the potential to E'', a decreasing current and then a minimum followed by a gradual increase and eventual joining with the current characteristic of a specimen without pretreatment. Thereafter, the curves superimpose and a normal decay of the current occurs in the approach to a quasi-stationary value. A typical current transient for Cu13Au is shown in Fig. 6 where $E' = 627$ mV and $E'' = 640$ mV with $E_c = 630$ mV. In-

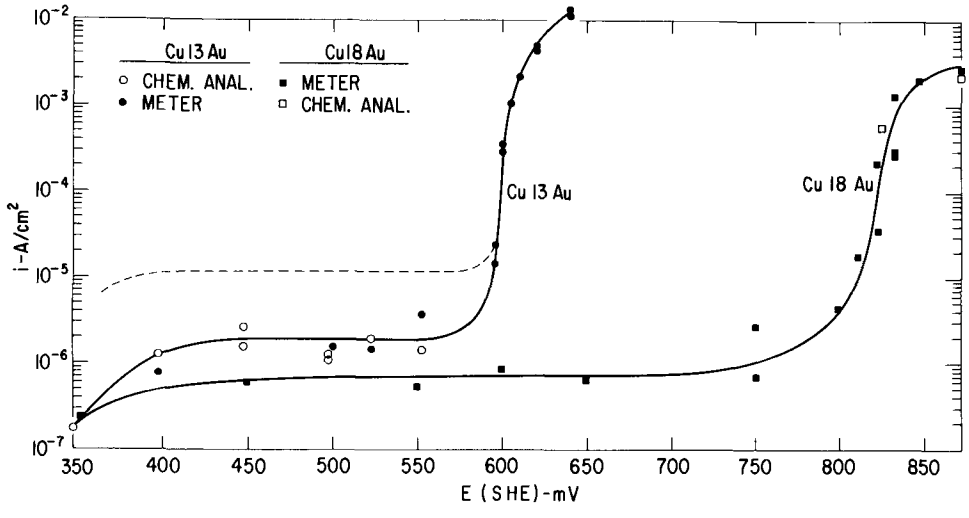

Fig. 5. Quasi-stationary log i_{Cu}-E curves based on the projected area for anodic dissolution of Cu from Cu13Au and Cu18Au in 1*N* Na_2SO_4-0.01*N* H_2SO_4. Higher currents in the plateau region for dissolution in 1*N* Na_2SO_4-0.1*N* $CuSO_4$-0.01N H_2SO_4 are indicated by the dashed line. Fig. 6. Current-time transients for dissolution of Cu from two Cu13Au specimens held at E'' = 640 mV ($E_c \cong$ 630 mV) in 1N Na_2SO_4-0.01N H_2SO_4, of which one had been pretreated for 1 hr at E' = 627 mV.

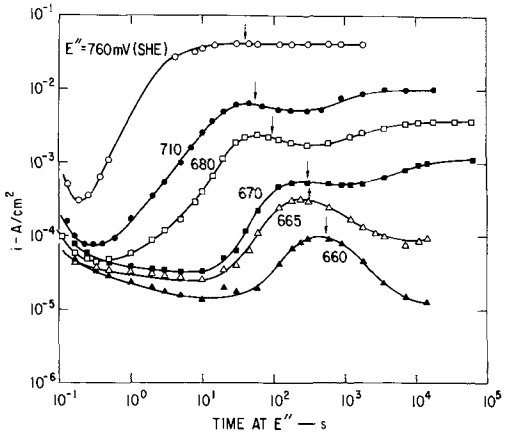

Fig. 7. Current-time transients at various E'' potentials for Cu dissolution from Cu13Au specimens which had received identical pretreatments of 1 hr at 635 mV. 1N Na_2SO_4-0.1N $CuSO_4$-0.01N H_2SO_4. $E_c \cong$ 660 mV. Arrows indicate the approximate time that the current-time behavior becomes identical to that for a nonpretreated specimen held at the same E''.

tegrating the current over the time of pretreatment at E' in Fig. 6 gives 0.8 C/cm², equivalent to 4 x 10^{-6} mole/cm² or ~ 1900 atom layers of dissolved Cu. The reduction in Cu current from the time the E'' potential is impressed until normal dissolution behavior characteristic of E'' is attained, amounts to the equivalent of roughly 800 atom layers of Cu as given by the difference in areas under the E'' curves.

In Fig. 7 current-time data at E'' are shown for 6 Cu13Au specimens jumped to different E'' values after identical pretreatments of 1 hr at E' = 635 mV which provided for the dissolution of ~ 500 atom layers of Cu. At each of the E'' potentials, the rate of Cu dissolution is much lower than that which is obtained for a nonpretreated specimen; the current-time curves for the nonpretreated specimens are not shown but are qualitatively the same as in Fig. 6.

The amount of Cu dissolution during the transient period at E' depends strongly on the E' potential. Table I gives the amounts of dissolved Cu for Cu13Au specimens held 1 hr at different E' potentials ranging from 400 to 635 mV. Also given are the corresponding amounts of Au excess. The response of these specimens when jumped to the same E'' varied greatly as seen in Fig. 8. The specimen held at the highest pretreatment potential, E' = 635 mV, shows the most severe depression in the rate of Cu dissolution when the potential is jumped to E'' (bottom curve). As E' is decreased, the current recovery at E'' is faster. For E' = 400 mV corresponding to the dissolution of less than 10^2 atom layers of Cu, the current at E'' is only slightly depressed compared to a specimen with no pretreatment (top curve).

Table I. Amounts of dissolved Cu from Cu13Au and Au excess on the basis of the projected area in 1 hr at various E' potentials. E_c = 660 mV

	Cu dissolved			Au excess
E', mV	C/cm²	Mole/cm²	Atom layers	Atom layers
400	0.025	1 x 10^{-7}	64	10
500	0.077	4 x 10^{-7}	200	30
600	0.106	6 x 10^{-7}	280	42
635	0.224	11 x 10^{-7}	580	87

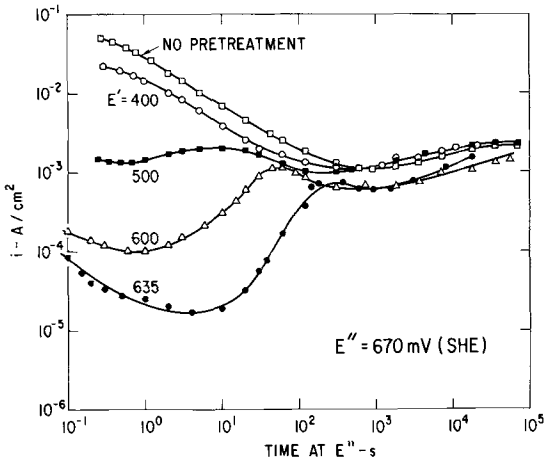

Fig. 8. Current-time transients for Cu dissolution from Cu13Au specimens which were held at different E' potentials for 1 hr prior to jumping the potential to E'' = 670 mV. 1N Na_2SO_4-0.01N H_2SO_4. $E_c \cong$ 660 mV. The curve at E'' for a specimen without pretreatment is also shown.

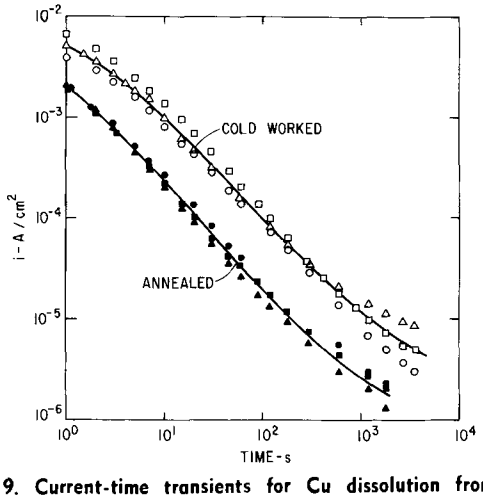

Fig. 9. Current-time transients for Cu dissolution from three cold-worked (open symbols) and from three annealed Cu13Au specimens at 500 mV. 1N Na_2SO_4-0.01N H_2SO_4.

Results of potential-jump investigations with the "as swaged and drawn" (cold worked) Cu13Au specimens, although qualitatively the same as for annealed specimens, always showed higher currents. The amount of dissolved Cu during the transient period at $E < E_c$ is much greater for cold-worked than for annealed specimens. This is illustrated in Fig. 9 where i_{Cu}-time data are shown for cold-worked (open symbols) and annealed Cu13Au specimens held at 500 mV. Approximately five times as much Cu (0.85 *vs.* 0.18 C/cm²) is dissolved in the approach to the quasi-stationary current (~ 10^{-6} A/cm²) from the cold-worked than from the annealed specimens. The cold-worked specimens were prepared as previously described. Other cold-worked specimens from this group were given an

anneal at 500°C in vacuum prior to dissolution.[2] When these specimens were jumped to a higher potential (E''), the currents were higher than for annealed specimens treated similarly. The fact that E_c differs from the cold-worked and annealed conditions, however, precludes the possibility of a detailed comparison at E'' for the two conditions.

A comparison of the amounts of charge passed in the approach to a quasi-stationary current was also made for ordered and disordered Cu25Au specimens. Disordered specimens were obtained by quenching from 700°C. Highly ordered specimens were prepared by cooling from 700° to 400°C in a few hours and from 400° to 100°C at 2.3°C/hr (9). The kinetics of Cu dissolution is different for the two conditions as noted by two rather large deviations from linear behavior (in opposite directions) in a log i_{Cu}-log t plot for the ordered specimens compared to approximately linear behavior for the disordered specimens, although averaged over the total time the charges passed were the same within the experimental error, 0.015 and 0.017 C/cm² for ordered and disordered specimens, respectively.

Metallographic examination.—Metallographic examination of the cross sections of specimens held at $E > E_c$ shows a dark layer next to the surface. In prior investigations this layer was shown to be porous by a-c impedance measurements (4, 5) in agreement with other investigations by Graf (10) and others (1, 6, 11) and was found to be Au-rich by x-ray and electron diffraction (2). The low currents which flow at $E < E_c$ preclude the recognition of Cu dissolution by metallographic examination. Specimens held at E'' after a pretreatment at E' appear much the same as specimens held at E'' without a pretreatment; the thickness of the porous layer varies greatly over the surface, and usually at least one area of the surface is essentially free of attack as seen in Fig. 10a. A much more uniform layer has been observed with specimens made from cold-rolled and annealed stock (2). Some grain boundary penetration is occasionally observed as in Fig. 10b.

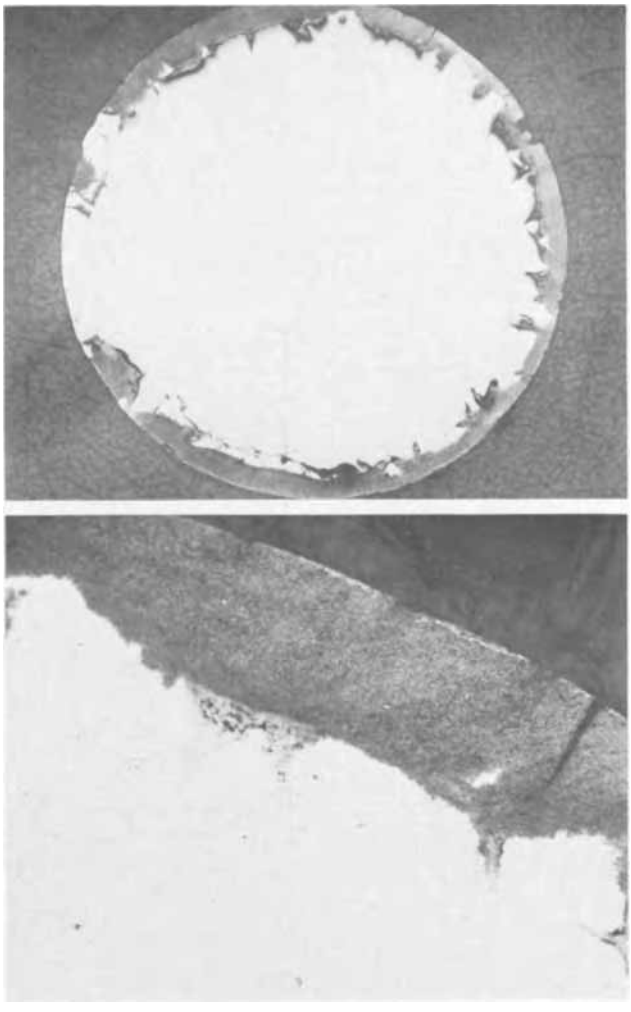

Fig. 10. Cross-section of a Cu13Au specimen which was maintained at $E' = 627$ mV for 1 hr and then jumped to $E'' = 636$ mV for 72 hr. $E_c \cong 630$ mV. a (top) Magnification X30; b (bottom) Magnification X195.

Discussion

The reported current-time and current-potential data for dissolution of Cu from Cu-Au alloy are essentially in agreement with earlier results of this kind obtained by Gerischer and Rickert (1). For the $CuSO_4$-free electrolyte there is at $E < E_c$ a quasi-stationary Cu current of $\sim 10^{-6}$ A/cm² (solid line in Fig. 5) according to quantitative chemical analysis data. The higher quasi-stationary current of $\sim 10^{-5}$ A/cm², which is obtained at $E < E_c$ when 0.1N $CuSO_4$ is added to the electrolyte (dashed line) and which was obtained also by Gerischer and Rickert who used only the $CuSO_4$-containing electrolyte, is probably mainly due to the electrode reaction $Cu^+ = Cu^{2+} + e^-$. The source of the cuprous ion may be impurity in the salt or that formed by equilibration of cupric ion with Cu in particles which have become detached from the electrode. A rough calculation shows that at high overpotentials a current of this magnitude may be expected for the oxidation of cuprous to cupric ion in 0.1N $CuSO_4$ equilibrated with metallic copper. Also, it was found that the current increased by a factor of 2 or 3 with increased stirring, in agreement with this hypothesis.

The high Cu currents recorded at all potentials ($400 < E < 900$ mV) on first contact of the specimen with the electrolyte indicate that Cu atoms in direct contact with the electrolyte are readily ionized, in accord with the existing large overpotential for Cu dissolution ($E°_{Cu/Cu2+} = 337$ mV). At $E < E_c$ the current falls quickly to a very low value as access of Cu atoms to the electrolyte is (effectively) stifled. The possible sources of this stifling process are considered next, followed by a discussion of the nature of E_c.

On the basis of earlier data obtained at $E > E_c$ preferential anodic dissolution is currently best understood as follows (2, 7): Initially, dissolution occurs by the usual (as with a pure metal) lateral motion of steps (12) [kink-step-terrace model of a surface (13, 14)]. Gradual blocking of steps soon begins as a result of the accumulation of the more noble metal (Au in the case of Cu-Au alloy) on the surface eventually causing cessation of step motion. Dissolution of the less noble metal (Cu) continues, however, from sites (2, 8) which result in the formation of surface vacancies, in the interdiffusion of the components in an alloy layer next to the surface and in surface roughening.

When appreciable surface roughening occurs, as is known to be the case at $E > E_c$, (4, 5) a rather high diffusion-controlled, quasi-stationary current is possible (2, 3); but in the absence of surface roughening the interdiffusion distance must on theoretical grounds increase and the current decrease indefinitely (2). The data in the present paper give support to the idea that at $E < E_c$ dissolution occurs by the aforementioned mechanism but that the process is effectively stifled because of an insufficient amount of surface roughening (per unit amount of dissolved copper),

[2] A fine emery treatment was given to some of these specimens to make the surface condition more comparable to that of the cold-worked specimens which also received a (final) fine emery treatment. The amount of dissolved Cu (0.040 C/cm²) for the annealed and emeried specimens was about twice that of the annealed specimens without the emery treatment and probably reflects the cold work introduced by the emery treatment.

i.e., a Cu-depleted layer forms but the average interdiffusion distance, δ, increases with time. Yet the current does not decrease indefinitely but approaches a low value of $\sim 10^{-6}$ A/cm^2, indicating that other factors enter, which may include deformation and cracking of the Cu-depleted layer, diffusion along special paths (*e.g.*, subboundaries and dislocations) or incipient surface roughening. Deformation and cracking of the Cu-depleted layer may occur because of stress arising out of the difference in atom sizes and inhomogeneous accumulation and annihilation of vacancies. Both of these processes tend to decrease the interdiffusion distance and increase the rate of dissolution (15). The greater amount of Cu dissolution and, hence, greater depth of Cu depletion, prior to the attainment of the quasi-stationary value with the cold-worked specimens is in agreement with a defect-enhanced diffusion process.

By the formation of such a Cu-depleted layer at $E < E_c$, one understands the appreciable lag time ($\sim$ 200 sec) at E'' after pretreatment at E' (see Fig. 6) as a period of readjustment of parameters, such as the excess vacancy concentration and the surface roughness, associated with diffusion of Cu through the layer to the surface. Since the number of geometrically different sites (itself a high value for random surfaces) from which Cu atoms may be dissolved may be expected to increase with increasing overvoltage for Cu dissolution (12, 16), it is reasonable to assume that the excess vacancy concentration in the Cu-depleted layer increases with potential through the operation of many of these sites (2, 8). It follows then (*a*) that Cu diffusion to the surface occurs more rapidly as E'' is made more noble (Fig. 7), and (*b*) that the depth of the Cu-depleted layer at $E < E_c$ increases with increasing potential as indicated in Table I and Fig. 8.

Incipient surface roughening is indicated at $E \lesssim E_c$ by the relatively large amounts of Cu dissolution at potentials approaching E_c, *e.g.*, $\sim$ 540 atom layers of dissolved Cu in 1 hr at $E' = 635$ mV with $E_c = 660$ mV (Table I) and $\sim$ 1900 atom layers of dissolved Cu for E' virtually equal to E_c (Fig. 6). In the absence of surface roughening, a diffusion length, δ, of 10^3 Å is required to explain these data on a diffusion basis and this is an order of magnitude longer than that calculated assuming a large excess concentration of vacancies (2). That dissolution of Cu does not occur at $E < E_c$ solely via diffusion of Cu to a planar surface is also indicated by the fact that the current is inversely proportional to the square root of time only for an initial period of a few tens of seconds; thereafter higher currents are observed. Finally, there is a relatively large initial surge of current on jumping the specimens from E' to E'', which in addition to charging the double layer may be the dissolution of Cu atoms in certain "near-surface" sites which are not active dissolution sites at E' but are active at the higher driving force, E''.

The aforementioned data suggest that the change in kinetics at E_c involves the establishment of certain diffusion-surface roughening conditions rather than a change in the basic nature or mechanism of the preferential dissolution process. E_c may coincide with the attainment of a certain diffusion-controlled rate of surface roughening such that the rate of recession of the alloy surface at the base of a penetration becomes equal to the rate of migration of the diffusion front, *i.e.*, the average interdiffusion length, δ, becomes constant as illustrated in Fig. 11, thereby providing the necessary condition to maintain a quasi-stationary, diffusion-controlled current. The increase in the quasi-stationary current with potential at $E > E_c$ follows if the (excess) (di)vacancy concentration increases with potential as has already been assumed.

Data in Fig. 5 show that E_c is a strong function of the Au content of the alloy. This may be explained in

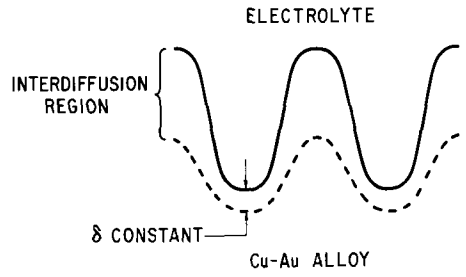

Fig. 11. Schematic diagram illustrating possible situation during preferential anodic dissolution of Cu at $E > E_c$.

the following way. As the Au content of the alloy increases the amount of excess Au per unit amount of dissolved Cu increases. This means, as shown in calculations for diffusion to a plane surface (2), that at a given potential and time the rate of dissolution of Cu will be less and the interdiffusion distance greater for alloys of increasing Au content; also the rate of vacancy production may be expected to be lower with increasing Au content as a result of a correspondingly lower number (at any given time) of Cu-occupied surface sites. This expectation is supported by the data, *e.g.*, 0.017 C/cm^2 of Cu dissolve in the attainment of the quasi-stationary value at 750 mV for annealed Cu25Au compared to roughly the same amount at only 500 mV for annealed Cu13Au. Hence, if a certain diffusion condition, *e.g.*, the concentration of excess vacancies, is important for the establishment of the continuing diffusion-surface roughening process (constant δ), a higher potential must be applied the higher the Au content.

This hypothesis of the nature of E_c clearly is tentative since no formulation can be given which relates quantitatively the value of E_c to the composition of the alloy and other parameters which can at least in principle be determined by independent measurement. Nevertheless, it seems worthwhile to follow the consequences which result from the model indicated in Fig. 11. The model contains the important assumption that the concentration of vacancies in the Cu-depleted layer is much greater than the equilibrium value and that this excess concentration increases with increase in the single-electrode potential. To the extent that there is indirect evidence that excess vacancies are present in Cu-depleted layers, in the demonstration of the occurrence of appreciable volume diffusion during preferential dissolution at $E > E_c$ (2, 8), this assumption is justified; clearly, however, additional experimental support is needed particularly with regard to the potential dependency aspect of the vacancy concentration. Also, coalescence of vacancies will occur to form voids and may contribute to surface roughening, as will deformation and cracking of the Cu-depleted layer. The rates of these processes may increase with potential and content of the less noble metal in the alloy. Finally, the proposed mechanism implies that surface energy (and other forces tending to reduce surface roughness) does not play a dominant role in establishing conditions for a continuing diffusion-surface roughening dissolution process. Surface energy may be expected to be relatively unimportant when the free energy decrease per unit volume accompanying dissolution is large compared to the surface energy; *i.e.*, at high overpotentials for Cu dissolution. That surface energy is of only secondary importance in determining E_c is indicated in the fact that although E_c is a strong function of alloy composition, the surface energy at a given potential may be expected to vary little with (bulk) alloy composition, since the surface composition during dissolution must be roughly the same (nearly pure Au) for all of the alloys.

It is interesting that the factors which are important for preferential anodic dissolution at 23°C are basically

the same as those that are important in preferential dissolution and oxidation at elevated temperatures, as outlined by Wagner (3, 17). Although these processes must differ in detail in view of the different conditions, there are marked similiarities which can go even beyond the main factors of diffusion in the alloy as the rate-determining step and the occurrence of gross surface roughening. Lichter and Wagner (18) found that during sulfidization of Cu-Au alloys at 500°C the Cu-rich alloys form an outer homogeneous sulfide layer and an inner two-phase layer consisting of sulfide and metal. The metal was found to be a sponge-like network of (nearly) pure Au in accord with preferential sulfidization of Cu with interdiffusion of the components in the alloy as rate determining. It was further noted that the tendency for surface roughening and the extent of sulfidization decreased with increasing Au content of the alloy. The decrease in sulfidization rate was more drastic with the Au-rich alloys in agreement with the virtual absence of surface roughening. Similarly as mentioned already, the tendency for surface roughening during preferential anodic dissolution of Cu from Cu-Au alloys decreases with increasing Au content, and preferential anodic dissolution is essentially restricted to the Cu-rich Cu-Au alloys (E_c for the Au-rich alloys appears to be more noble than the potential of Au dissolution).

Conclusions

Log i_{Cu}-t and log i_{Cu}-E relations are presented for the preferential electrolytic dissolution at 23°C of Cu from Cu-rich, Cu-Au alloys. The log i_{Cu}-t data show that at all potentials the current is initially high but falls rapidly at an ever decreasing rate. The log i_{Cu}-E curve (for a given time of dissolution) exhibits a potential-independent current region and a composition-dependent critical potential, E_c, at which potential the rate of Cu dissolution becomes strongly potential dependent, in agreement with the data of Gerischer and Rickert (1).

The results of potential-jump investigations indicate that at $E < E_c$ a Cu-depleted layer forms over the surface which limits the rate of Cu dissolution to that of Cu diffusion through the layer; the latter process becomes very slow since the interdiffusion distance necessarily increases with time in the absence of appreciable surface roughening. The amount of Cu dissolution and hence, the depth of the Cu-depleted layer, required to effectively stifle dissolution at $E < E_c$ is found (*a*) to increase in the direction of more positive potentials, in agreement with an expected increase in the kinetics of vacancy generation with increasing driving force for dissolution of the less noble component, and (*b*) to be larger for cold-worked specimens with their higher defect density than for annealed specimens, also in agreement with a defect enhanced bulk diffusion process at $E < E_c$, and not unlike that found previously by x-ray and electron diffraction investigations at $E > E_c$.

The factor which accounts for the drastic change in kinetics at E_c appears to be the extent of surface roughening. At $E < E_c$ only incipient surface roughening occurs, whereas at $E > E_c$ the surface area continuously and very rapidly increases with time, *i.e.*, a surface instability occurs at E_c and provides for a constant (average) interdiffusion distance in the alloy at the advancing alloy-electrolyte interface, as illustrated in Fig. 11. It is proposed that the change in diffusion conditions which leads to a surface instability is related to a potential-dependent concentration of excess (di) vacancies in the interdiffusion layer.

Acknowledgments

The authors are especially grateful to Professor Dr. Carl Wagner of the Max Planck Institut für Physikalische Chemie for suggesting the potential-jump studies and to him and Drs. R. A. Oriani and R. P. Frankenthal for helpful comments on reading of the manuscript, and to Dr. C. A. Johnson for helpful discussions. The skillful assistance of Mr. H. A. Hughes with the metallographic examination and of Messrs. G. W. Momeyer, W. L. Doyle, and C. C. Sharp with the chemical analysis is gratefully acknowledged. All except Professor Wagner are (or were) members of the E. C. Bain Laboratory for Fundamental Research of the United States Steel Corporation.

Cathode Overpotential and Electrosorption Effects of Normal Monocarboxylic Acids during Electrodeposition of Copper

R. O. Loutfy and A. J. Sukava*

Department of Chemistry, University of Western Ontario, London, Ontario, Canada

ABSTRACT

The cathode overpotential and electrosorption effects of some normal monocarboxylic acids during electrodeposition of copper were studied galvanostatically at current densities up to 20 mA-cm^{-2}. Equations were derived by means of which overpotential increments caused by the blocking action of adsorbed additive can be used to calculate the separate adsorption free-energy contributions of the carboxyl and methylene groups in the additive molecule, and also a coverage-dependent lateral interaction free energy arising primarily from dipole-dipole interaction between adjacent carboxyl groups in the adsorbed phase. The carboxyl group contribution was found to be −1570 cal mole^{-1} at zero coverage, while the methylene group contribution was −704 cal mole^{-1} and independent of coverage.

A previous paper from this laboratory (1) dealt with the cathode overpotential and electrosorption effects of normal monocarboxylic acids in the electrodeposition of copper from acid sulfate electrolyte. The overpotential data, interpreted in terms of the simple blocking theory, indicated that the adsorption of such compounds on a copper cathode can be represented at low surface coverages by a Langmuir-type isotherm from which the net free energy of adsorption can be calculated. By application of Traube's rule, the adsorption free energy could then be interpreted in terms of the separate contributions of the functional and methylene groups in the additive molecule.

Further work with monocarboxylic acids has shown that a more careful and detailed study is needed, particularly in view of the emerging doubt about the general applicability of the basic Langmuir isotherm to these systems due to the importance of lateral interaction in the adsorbed phase. More complete data are presented and analyzed in this report.

Experimental

Cathode overpotentials were measured with a Luggin probe in a simple glass cell shown in Fig. 1. A cylindrical copper-wire cathode, about 2 mm in diameter, was immersed in about 100 ml of solution. The cathode was fitted with a tight Teflon sleeve so placed that a geometrical 1 cm^2 of its surface was in contact with the solution.

The tip of the Luggin capillary was placed about 1 mm from the cathode, a distance greater than its outside diameter, to avoid possible shielding of the cathode surface from access of polarizing current (2, 3). This causes an error in total overpotential values due to *IR* drop between Luggin tip and cathode surface, but such error cancels out because only the increments in overpotential caused by organic additives were of interest and because such additives can be assumed to have no significant effect on the solution resistance since only highly conducting solutions were employed (1.0M H_2SO_4). Measurement of the *IR* drop from transient overpotential build-up, using a cathode-ray oscilloscope, gave a value of 3 ± 1 mV for all solutions at an apparent current density of 20 mA-cm^{-2}, whether or not additives were present.

It was found that this cell design, with the cathode-to-anode distance much greater than the cathode radius, resulted in a cylindrically symmetrical field in the vicinity of the cathode at all experimental current densities. Overpotential values were the same for a given current density and solution composition, within experimental error, regardless of the location of the Luggin probe in any horizontal plane around the cathode and regardless of vertical displacement along the cathode length, provided only that the distance between cathode surface and probe tip was the same.

Steady-state overpotentials were measured at constant temperature, 25° ± 0.1°C, and at constant apparent current densities controlled and maintained by means of a Harrison Laboratories Type 6201 d-c power supply. Measurements were made with a Sargent SR recorder and in some cases with a L&N Type K potentiometer. Current adjustment was made to give the desired apparent current density for overpotential measurement, taking into account the cathode radius at steady state. The wire cathodes were etched with nitric acid and then thoroughly washed prior to use to ensure removal of possible surface contaminants.

Key words: homologous, additives, interaction, free energy, theory.

The preparation of the standard solution (0.5M $CuSO_4$ and 1.0M H_2SO_4) was in all respects the same as described previously (1). High-purity monocarboxylic acids were used as additives and only the normal straight-chain isomers were chosen for study.

Results

The overpotential data in this report are the increments in total steady-state cathode overpotential caused by the additives employed. In these experiments, the overpotential attributable to the standard electrolyte alone with no additive present was 105 ± 5 mV at an apparent current density of 20 mA-cm^{-2}. The overpotential increments were obtained by subtracting this value from the total overpotential in the presence of additive. The total values were reproducible to within ±5%. Steady states were usually obtained after about 45 min of electrolysis.

Data for different concentrations of normal monocarboxylic acids from propanoic to octanoic inclusive are given in Table I. The cathode overpotential increases in each case with increased concentration of additive.

When the overpotential increment is plotted against the concentration of a given additive, it is found that the curve approaches linearity as the concentration approaches zero. Typical behavior is shown in Fig. 2. The initial slopes for all the additives, given in Table II, show that the logarithm of the initial slope increases linearly with the number of methylene groups in the additive molecule, counting the terminal methyl, as shown in Fig. 3. Advantage was taken of this linearity to obtain graphically smoothed overpotential data for the low concentrations of the additives used. For this purpose, smoothed values of the initial slopes as obtained from Fig. 3 are given in the last column in Table II.

Table I. Concentration of additive and cathode overpotential increment

Current density = 20 mA-cm^{-2}; temperature = 25° ± 0.1°C

Overpotentials obtained in this study differ to a degree from those obtained previously with the Haring cell (1). However, just as before (1), and within the accuracy of the measurements, it was found that the Δη *vs.* log C relations for all the homologous monocarboxylic acids can be represented by a family of parallel curves equally spaced along the log C axis as shown in Fig. 4. Advantage was taken of this behavior to obtain graphically smoothed overpotential values for the higher additive concentrations, thus minimizing the effect of error in individual overpotental measurement. The curves in Fig. 4 are the smoothed results

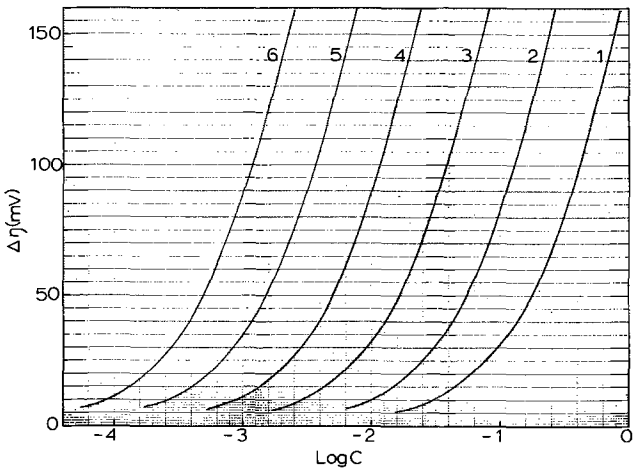

Fig. 4. Overpotential increment vs. logarithm of concentration, monocarboxylic acids: 1, propanoic; 2, butanoic; 3, pentanoic; 4, hexanoic; 5, heptanoic; 6, octanoic.

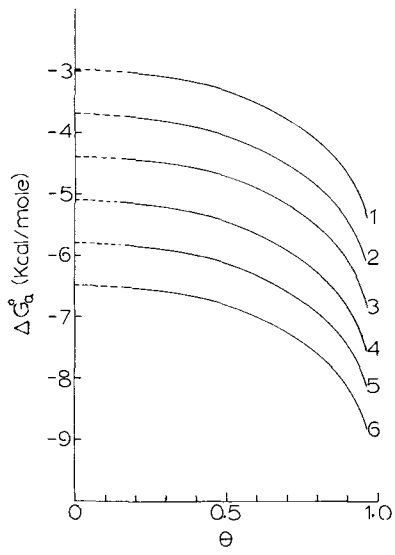

Fig. 5. Free energy of adsorption vs. coverage, monocarboxylic acids: 1, propanoic; 2, butanoic; 3, pentanoic; 4, hexanoic; 5, heptanoic; 6, octanoic.

arising from the data in Table I and the smoothed initial slopes in Table II.

Measurement of steady-state overpotentials at different apparent current densities ranging from about 2 to 20 mA-cm^{-2} gave the same Tafel slope, 52 ± 1 mV, with all the monocarboxylic acids. This indicates that these compounds do not affect the charge-transfer kinetics of copper deposition, their only effect being to increase the true current density in accordance with the simple blocking theory (1, 4, 5).

Discussion

The cathode overpotential effects of normal monocarboxylic acids shown in Fig. 4 can be interpreted and understood in terms of the blocking theory as expressed in the equation (1, 6)

$$\theta = 1 - \exp(-\Delta\eta/b) \qquad [1]$$

where θ is the fraction of the surface covered by adsorbed additive and b is the Tafel slope. Appropriate adsorption theory can be used to derive quantitative relations between the overpotential increment $\Delta\eta$ and additive concentration C.

Calculation of θ from Eq. [1] for the overpotential increments in Fig. 4, with the Tafel slope taken as the experimental 52 mV, and calculation of the standard free energy of adsorption from the Langmuir-type isotherm (1, 7)

$$\frac{\theta}{(1-\theta)^n}\,\frac{\{\theta + n(1-\theta)\}^{n-1}}{n^n} = \frac{C}{55.5}\exp(-\Delta G^\circ_a/RT) \qquad [2]$$

where n, the number of water molecules displaced by a molecule of adsorbed additive, is taken as 2 (1, 8), results in the family of parallel ΔG°_a *vs.* θ curves shown in Fig. 5. It is immediately obvious that the free energy of adsorption of monocarboxylic acids on a copper cathode is markedly dependent on the coverage, becoming increasingly negative with increasing θ. This coverage dependence, which is much the same as that observed by Bockris and Swinkels (7) for the adsorption of n-decylamine on copper, can presumably be attributed to spontaneous lateral interaction in the adsorbed phase (7, 9).

Lateral interaction free energy.—Equation [2], which is a general modification of the Langmuir isotherm for adsorption from solution involving solvent displacement, depends for its basic derivation on the assumption that no lateral interaction occurs in the adsorbed phase (7, 10, 11). In this equation, the adsorption free energy ΔG°_a should therefore be regarded, strictly, as independent of coverage. However, the use of Eq. [2] in calculating ΔG°_a for Fig. 5 assumes the applicability of a modified isotherm similar to that discussed by Conway and Barradas (10) in which ΔG°_a is recognized as coverage dependent.

The curves in Fig. 5 show that the addition of each methylene group to a monocarboxylic acid molecule results in the same increase in the adsorption free energy regardless of coverage. Accordingly, assuming the validity of all procedures leading to Fig. 5, the hydrocarbon part of a monocarboxylic acid makes no significant net contribution to the lateral interaction in the adsorbed phase. This behavior, which is consistent with the applicability of Traube's rule to the adsorption of compounds belonging to a homologous series (1, 12), means that the standard free energy of adsorption of a given monocarboxylic acid on copper can be written as

$$\Delta G^\circ_a = x\,\Delta G^\circ_{CH_2} + \Delta G^\circ_p + g(\theta) \qquad [3]$$

where x is the number of methylene groups present, $\Delta G^\circ_{CH_2}$ is the free energy contribution of each methylene group, ΔG°_p is the contribution of the polar carboxyl group at coverages approaching zero, obviously the same for all the monocarboxylic acids, and $g(\theta)$ is the coverage-dependent lateral interaction free energy, also the same for all the monocarboxylic acids at the same coverage.

An appropriate isotherm for the adsorption from solution of a normal monocarboxylic acid on copper can be written by substituting Eq. [3] for ΔG°_a in [2] and rearranging to give

$$f(\theta)\exp(g(\theta)/RT) = \frac{C}{55.5}\exp\left(\frac{-x\Delta G^\circ_{CH_2} - \Delta G^\circ_P}{RT}\right) \qquad [4]$$

where $f(\theta)$ is the left-hand side of [2]. It will be noted that the θ-dependent exponential factor on the left of [4] is a Frumkin-like correction for lateral interaction (13) except that $g(\theta)$ does not vary linearly with θ at other than very low coverages.

While values of $\Delta G^\circ_{CH_2}$ and ΔG°_P can be estimated by extrapolating the curves in Fig. 5 to zero coverage, it will be useful to consider methods by which these quantities can be obtained more accurately by calculation from the cathode overpotential and additive concentration data.

Calculation of the components of adsorption free energy.—The ΔG°_a *vs.* θ curves in Fig. 5, which are in fact the same $g(\theta)$ *vs.* θ curve, can be shown to correspond very closely to the power series

$$g(\theta) = A\theta + B\theta^2 + C\theta^3 + D\theta^4 + E\theta^5$$

where the coefficients A, B, C, D, and E are −0.56, 2.25,

−12.65, 20.48, and −12.04 kcal, respectively. A more useful quantitative relation is easily derived, however, by rearranging Eq. [4] to give the straight-line equation

$$g(\theta) = RT \ln C - RT \ln f(\theta) - x\Delta G^{\circ}_{CH_2} - (\Delta G^{\circ}_{p} + RT \ln 55.5)$$

where the combination of terms

$$RT \ln C - RT \ln f(\theta) - x\Delta G^{\circ}_{CH_2} = f(C,\theta,x) \quad [5]$$

is the same for all the monocarboxylic acids since the same $g(\theta)$ *vs.* θ relation applies to all. $\Delta G^{\circ}_{CH_2}$ can be calculated directly from the concentration data in Fig. 4 by subtracting Eq. [5] for any two of the additives at a given overpotential increment, since the term $RT \ln f(\theta)$ cancels out in the subtraction. The value found is −704 cal/mole.

To calculate ΔG°_{p}, the free energy contribution of the carboxyl group at zero coverage, it will be necessary to consider the overpotential *vs.* concentration behavior shown in Fig. 3.

Electrosorption effects of monocarboxylic acids at concentrations approaching zero.—The linearity observed in Fig. 3, where the logarithm of the initial slope $(\Delta\eta/C)_{C\to 0}$ is plotted against the number of methylene groups in the monocarboxylic acid molecule, follows as a consequence of the applicability of Traube's rule to this homologous system, and corresponds in essence to the known behavior of these compounds in affecting the surface tension of aqueous solutions as described by Ward (12). A useful equation directly pertinent and applicable to Fig. 3 can be derived from Eq. [4].

According to Fig. 5, $g(\theta)$ becomes zero as θ approaches zero. Application of Eq. [4] to the zero-coverage condition then gives for the homologous monocarboxylic acids

$$f(\theta) = C\left[\frac{e^{-\Delta G^{\circ}_{p}/RT}}{55.5}\right][e^{-\Delta G^{\circ}_{CH_2}/RT}]^{x} = C\alpha\beta^{x} \quad [6]$$

where α and β are constants at constant temperature as shown. On substituting for θ from Eq. [1], and taking n as 2 (1, 8), it is easily shown that $f(\theta)$, the left-hand side of [2], can be written as

$$\tfrac{1}{4}(e^{2\Delta\eta/b} - 1)$$

With these substitutions Eq. [4] becomes

$$e^{2\Delta\eta/b} - 1 = 4C\alpha\beta^{x}$$

which, on substituting the series expansion for $e^{2\Delta\eta/b}$ and dividing through by C, gives

$$\frac{2}{b}\frac{\Delta\eta}{C} + \left(\frac{2}{b}\cdot\frac{\Delta\eta}{C}\right)^{2}\cdot\frac{C}{2!} + \left(\frac{2}{b}\cdot\frac{\Delta\eta}{C}\right)^{3}\cdot\frac{C^{2}}{3!} + \cdots = 4\alpha\beta^{x}$$

In the limit, as C approaches zero for zero coverage, this becomes

$$(\Delta\eta/C)_{C\to 0} = 2b\alpha\beta^{x}$$

The logarithmic form gives the straight-line equation for Fig. 3 as

$$\log (\Delta\eta/C)_{C\to 0} = \log (2b\alpha) + x \log \beta \quad [7]$$

Clearly, according to Eq. [6] and [7], $\Delta G^{\circ}_{CH_2}$ and ΔG°_{p} might be calculated from the experimental slope and intercept, respectively, in Fig. 3. In the present study, because of some uncertainty in the values of $(\Delta\eta/C)_{C\to 0}$ in Table II, the slope for Fig. 3 was first calculated from the value of $\Delta G^{\circ}_{CH_2}$ (−704 cal mole^{-1}) found from Fig. 4 and Eq. [5], and this was then used with the experimental points as shown to find the intercept, as 1.42. Using the experimental 52 mV for the Tafel slope, we then find $\Delta G^{\circ}_{p} = -1570$ cal mole^{-1}.

Certain relevant observations can be made. Since the −704 cal mole^{-1} found for $\Delta G^{\circ}_{CH_2}$ in this study is not very different from the −760 cal mole^{-1} obtained by Ward (12) for the methylene-group contribution to the free energy of adsorption of monocarboxylic acids at the air-solution interface, then, apparently, there is no strong specific interaction between the hydrocarbon chain and the copper surface. In contrast, the −1570 cal mole^{-1} found for ΔG°_{p}, the free energy of adsorption of the bare carboxyl group at zero coverage, is appreciably greater than the adsorption energy at the air-solution interface of methanoic acid, with which the carboxyl group may be theoretically compared. This value for methanoic acid can be estimated roughly as −900 cal mole^{-1} by extrapolating from the results of surface tension measurements made by Ward and Tordai (14) on solutions of the normal monocarboxylic acids, butanoic to decanoic inclusive. The indication here is that significant specific interaction probably does occur between the carboxyl group and the copper surface, and, although the interaction energy appears to be less than 700 cal mole^{-1}, it might be speculatively taken to indicate possible orientation of the carboxyl group toward the metal. This would be contrary to expectation for the adsorption of aliphatic compounds on metals (15), and further study and clarification are required. In any case, if perpendicular orientation actually occurs, then the same value of n in Eq. [2] must apply to the adsorption of all normal monocarboxylic acids regardless of length of the hydrocarbon chain, as appears to be the case.

The quantity β in the above equations is the Traube coefficient for the homologous monocarboxylic acids (12). It is the factor by which the initial slope in Fig. 2 and Table II is multiplied on the addition of each successive methylene group to the additive molecule. Its value as obtained from our data is 3.28.

Theoretical Calculation of $g(\theta)$.—Since $g(\theta)$, the lateral interaction free energy, is not significantly affected by the hydrocarbon part of a monocarboxylic acid molecule (Fig. 5), then it seems reasonable that this free-energy component should be calculable to a first approximation for any coverage θ from only the dipole-dipole interaction expected between adjacent carboxyl groups in the adsorbed phase. Dispersion interaction can be ignored as negligibly small since this effect would in any event arise mainly from the hydrocarbon chain (7).

The interaction between two like dipoles is given by (7)

$$U_{dip.} = -(\mu^{2}_{D}/\epsilon r^{3})$$

where μ_D is the dipole moment, ϵ the dielectric constant of the medium, and r the distance between the dipoles. None of these quantities is accurately known for an adsorbed additive in the primary cathode layer, but reasonable values can be assumed for monocarboxylic acids on the basis of which a calculation of $g(\theta)$ gives approximate agreement with experiment.

The dipole moments of monocarboxylic acids vary with the state and with the solvent, but for a given state the values are nearly the same for all the additives used in this study (16). The pure-liquid value of about 1.3 Debye units will be taken as appropriate in the present calculation since the adsorbed state can be assumed to approximate the liquid state of a particular adsorbate, especially at full coverage. The dielectric constant of the primary layer has been considered to vary linearly with coverage (7, 17). It is assumed to vary in our system from the zero-coverage value of 6 suggested by Bockris, Devanathan, and Müller (15) to the pure-liquid monocarboxylic-acid value of about 2.5 (18) at full coverage, giving $\epsilon = 6 - 3.5\theta$. Finally, an average distance of closest approach between adsorbed dipoles can be estimated from the dimensions of the carboxyl group as about 4Å.

With these values of μ_D, ϵ, and r, and with the added assumption that monocarboxylic acids adsorb on copper in hexagonal array and in parallel orientation (7), it is then possible, using equations given by Bockris and Swinkels (7), to calculate the lateral interaction free energy as the chemical potential due to dipole-dipole interaction, either for localized adsorption from

$$g(\theta) = 9.24\,\theta U_{\text{dip.}}$$

or for nonlocalized adsorption, using

$$g(\theta) = 11.55\,\theta^{3/2} U_{\text{dip.}}$$

The results, converted to kcal mole^{-1}, are shown and compared with the experimental data in Fig. 6.

While it seems that the nonlocalized-adsorption model gives the better agreement with experimental results, no clear distinction can be made between the two models, especially at low coverage, because of the rough approximations used in the calculations. Accordingly, no definite conclusion can be drawn except that dipole-dipole interaction is the most likely cause of the lateral interaction free energy. Adjustment of the parameters can be made to improve agreement with experiment, but the data are not sufficiently reliable to justify this procedure. It should be noted, in addition, that the dipole moment has been treated in this calculation as a constant, while it might in all probability vary with coverage.

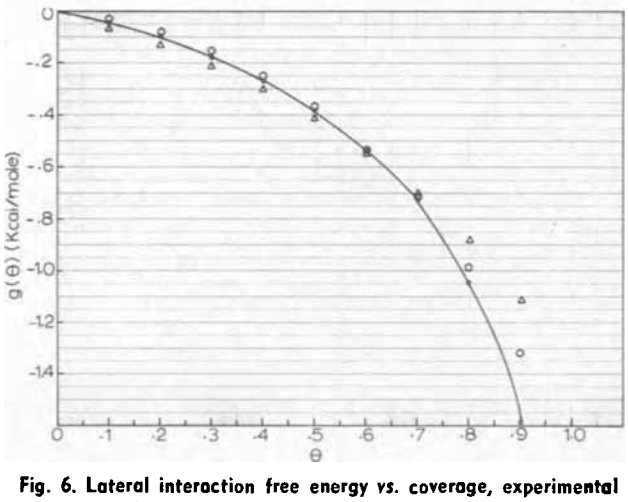

Fig. 6. Lateral interaction free energy vs. coverage, experimental curve compared with calculated values for localized, △, and nonlocalized, ○, adsorption.

Electrodeposition of Coherent Coatings of Refractory Metals

VII. Zirconium Diboride

G. W. Mellors and S. Senderoff*

Union Carbide Corporation, Parma Research Laboratory, Parma, Ohio 44101

ABSTRACT

The electrodeposition of coherent coatings of zirconium diboride from a solution of ZrF_4 and B_2O_3 in the molten eutectic mixture of NaF-KF-LiF is described. A constant composition is maintained by using a ZrB_2 anode and composition such that no volatile BF_3 is formed. The function of B_2O_3 as an oxide ion getter in the solution is demonstrated.

Zirconium diboride is a hard intermetallic compound, with a melting point in excess of 3000°C, that has, according to recent reports, excellent oxidation resistance at high temperatures, and good stability in contact with many molten metals, *e.g.*, Al and liquid steel. It has been stated (1) that methods for producing ZrB_2 crucibles, boats, tubing, heaters, etc., by pressing in molds are unsatisfactory. A slip casting technique was described as superior, but shrinkage on sintering was excessive, and the final porosity of the articles exceeded 12%. Such articles could probably ideally be made by electroforming with excellent conformation to the dimensions of the substrate and without any porosity.

* Electrochemical Society Active Member.

Key words: zirconium diboride, electrodeposition, refractory metal coatings, fused salts.

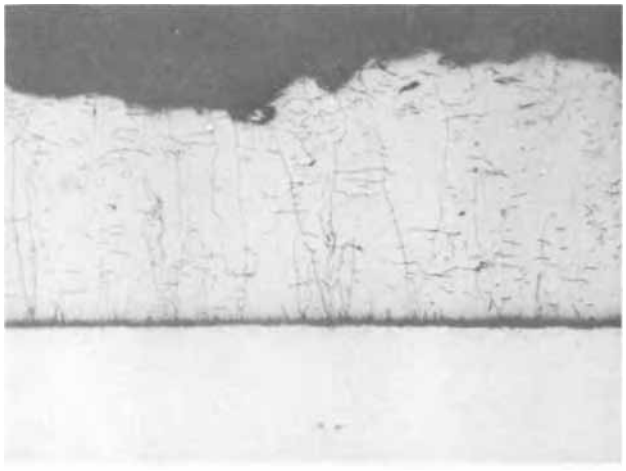

Fig. 1. Cross section of ZrB_2 deposited from pure fluoride melt at 800°C (approximately 150X).

Although there are a number of reports of the electrodeposition of ZrB_2 in particulate form from molten mixed oxide-fluoride systems (2-4) from a mixed fluoride-chloride system (5), and of coherent coatings of TiB_2 from a borate-titanate system (6), the only previous description of the electrodeposition of coherent coatings of ZrB_2 is in a paper (7) and patent (8) by the present authors in which a pure fluoride electrolyte, LiF-KF-K_2ZrF_6-KBF_4, was used for this purpose. Deposits were obtained on stainless steel cathodes by electrolysis of the molten system Flinak[1] containing 9 w/o (weight per cent) ZrF_4 and 10 w/o KBF_4 at 800°C and 250 mA/cm^2 cathode current density. A photomicrograph of this deposit is shown in Fig. 1 and demonstrates the soundness and coherence of this material. The optimum conditions for deposition of ZrB_2 coatings were similar to those for zirconium, but the allowable ranges of current density and temperature were greater and the concentration of boron uncritical above a minimum amount.

Anthony and Welch (3) in discussing this process comment that "this method (7, 8) can be controlled for only a limited period due to the continuous change in melt compositions." The present authors recognized at that time that the use of zirconium metal as anode and the excessive volatility of BF_3 led to composition changes in the bath. In order to obtain a more satisfactory process the following problems had to be overcome: (*a*) at the anode, 4**F** dissolve 1 mole of zirconium while 10**F** are required to deposit 1 mole of ZrB_2 at the cathode and there is thus a net increase of zirconium in the bath; (*b*) while only a relatively low boron content (approx. 1 ~ 3 w/o) is required, the addition has been made as KBF_4 which increases the quantity of KF in the solution; and (c) from this solution boron trifluoride will volatilize, and therefore on prolonged standing the concentration will be reduced to essentially zero. If a ZrB_2 anode could be used in this system, and if BF_3 could be added continuously to the melt to replace the volatilized BF_3, these problems could be solved. Alternatively, a source of boron other than KBF_4 may be sought. Experiments carried out with Flinak-ZrF_4 melts through which BF_3 was bubbled with an argon carrier showed that ZrB_2 could be deposited using a Zr anode. However, the agitation caused by the passage of these gases produced deposits rougher than normal. It became obvious that the bubbler system must be baffled in some manner since the high vapor pressure and low solubility of BF_3 in this bath suggest that to obtain a workable boron concentration the additions of BF_3 must be continuous and not batch-wise. Literature figures (9)

[1] "Flinak" is the acronym for the eutectic composition of KF-LiF-NaF which melts at 454°C. Its composition in mole per cent is 46.5 LiF, 11.5 NaF, 42.0 KF.

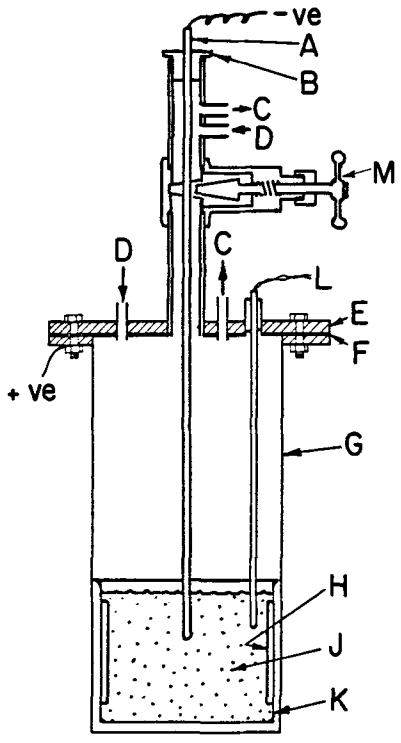

Fig. 2. Apparatus used in electrolysis of fluoride and fluoride-oxide melts: A, stainless steel cathode; B, "Teflon" stopper; C, argon outlets; D, argon inlets; E, stainless steel lid; F, "Teflon" or Sauereisen gasket; G, "Hastelloy, alloy X" can; H, zirconium or ZrB_2 anode; J, fluoride melt; K, nickel or stainless steel crucible; L, thermocouple and well; M, gate valve (1 in.).

indicate that, at 700°C at the saturating pressure of 1.90 atm, the solubility of BF_3 is 6.30 x 10^{-5} moles/cc of melt in the LiF-BeF_2-ZrF_4-ThF_4-UF_4 (65-28-5-1-1) melt. Assuming these figures apply to the Flinak-ZrF_4 melts under discussion here, then at 700°C under about 2 atm pressure a concentration of 0.43 w/o BF_3 could be maintained. This would probably be sufficient for continuous ZrB_2 plating.

The present paper describes further work using pure fluoride melts and some extensions using B_2O_3 additions rather than KBF_4 or BF_3 to overcome this problem.

Experimental

ZrF_4 and K_2ZrF_6 were obtained from General Chemical Division, Allied Chemical and Dye Corporation.

Zirconium in sheet form was obtained from Reactive Metals Inc.

Alkali fluorides (ACS specifications) were obtained from Fisher Scientific Company.

Boron trioxide was obtained from either Matheson, Coleman and Bell or from American Potash and Chemical Corporation.

Zirconium diboride was obtained from the Carborundum Company.

Boron trifluoride was obtained from Harshaw Chemical Company.

Electrolytic cells.—The melts were contained in either a nickel or ATJ graphite[2] crucible. The electrolytic operations were carried out in the apparatus of Fig. 2 which has been described in an earlier publication (10).

Results

Experiments were carried out in the low melting system KF (32.4 w/o)-ZrF_4 (67.6 w/o), mp 390°C. This system will not yield coherent zirconium metal on electrolysis and on the addition of KBF_4 produces mixtures of Zr and ZrB_2 powders. Thus the advantage

[2] Carbon Products Division, Union Carbide Corporation.

of lower BF_3 volatility at 400°-425°C is completely negated by the failure to yield coherent ZrB_2.

The problems of volatility made it necessary to seek other sources of boron for these melts. During work on the electrodeposition of zirconium (11) 0.6 w/o B_2O_3 was added to a working bath in an effort to make ZrB_2 or perhaps to observe an "addition agent" effect. However, the cathodic product obtained between 625° and 750°C was a compacted powder, and little was done further in that direction at that time.

Present work indicates that additions of about 10 w/o B_2O_3 to systems of the type Flinak-(or KF-LiF) ZrF_4 yield far more interesting results. Electrolysis of the melt containing Flinak (80 w/o)-ZrF_4 (8 w/o)-B_2O_3 (12 w/o) in a graphite crucible at 750°C produces a smooth, dark colored deposit at 100% cathode current efficiency, based on the assumption of 10 F/mole of ZrB_2. The anode was zirconium and the cathode a nickel strip. X-ray investigation of the deposit shows it to be ZrB_2, but a photomicrograph (Fig. 3) reveals a poor structure having many voids and inclusions of salts. On raising the temperature to 800°C, a bright, coherent plate was obtained (at 100% cathode current efficiency) that again was identified as ZrB_2. However, the photomicrograph now showed a sound, void free, columnar structure (Fig. 4a). It will be noticed that there exists a considerable diffusion layer between the ZrB_2 and the nickel substrate. This layer is a nickel boride, from which zirconium is absent. By the same token nickel is absent from the ZrB_2 deposit. This indicates that some boron diffuses into the nickel from the initially deposited ZrB_2, resulting in a deposit at the interface having a B:Zr ratio slightly less than two. Electron probe analysis indicates that the intermediate layer is, in all probability, Ni_3B, and it is thought that the presence of this material contributes to the adherence of ZrB_2 to the substrate.

Fig. 3. Plate and cross section of ZrB_2 deposited from fluoride-B_2O_3 melt on nickel at 750°C (approximately 200X).

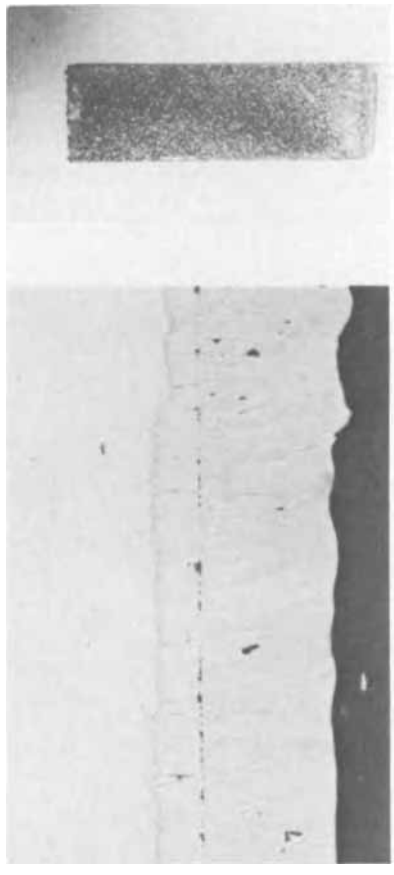

Fig. 4a. Plate and cross section of ZrB_2 deposited from fluoride-B_2O_3 melt on nickel at 800°C (approximately 200X).

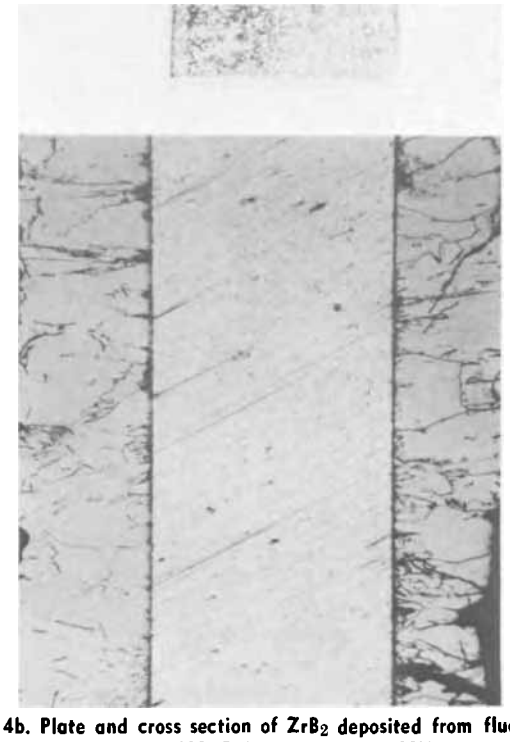

Fig. 4b. Plate and cross section of ZrB_2 deposited from fluoride-B_2O_3 melt on copper at 800°C (approximately 200X).

On copper substrates, adhesion is again excellent, but a photomicrograph (Fig. 4b) shows the almost complete absence of a diffusion layer. Figure 4c is a cross section of a deposit on an ATJ graphite substrate.

Fig. 4c. Plate and cross section of ZrB_2 deposited from fluoride-B_2O_3 melt on ATJ graphite at 800°C (approximately 500X).

Analysis of the bath after the run producing the deposit of Fig. 4a showed 5.81 w/o Zr, 1.77 w/o B, and 6.11 w/o oxygen.

The effect of temperature was shown to be completely reproducible and reversible. If the temperature were lowered from 800°C to 750°C, a poor plate of the type shown in Fig. 3 was obtained. On raising the temperature again to the region of 800°-810°C, the good quality, bright coherent material having the microstructure of Fig. 4a was again deposited. Although excellent plates may be obtained at temperatures in excess of 900°C, it is preferable to operate at 800°C in view of the increased durability of apparatus at the lower temperature.

The cathode current density may range from 5 to 100 mA/cm², but the plates become significantly rougher with increasing current density.

Continued running of Zr anodes through melts of the Flinak-ZrF_4-B_2O_3 type and extraction of ZrB_2 ultimately leads, as previously mentioned, to significant composition changes. However, considerably before the boron content was exhausted, the apparent cathode efficiency increased suddenly to 250-300% (based on the assumption of 10 F/mole of ZrB_2 deposited). The deposits, although superficially satisfactory, were proved to be compacted powders on closer examination. These powders were analyzed and found to be mixtures of ZrB_2 and a glassy phase consisting of ZrO_2 and alkali zirconates. It was this occluded material which caused the apparently high values of current efficiency.

It was found that if B_2O_3 were added to the system, then good deposits of ZrB_2 might again be obtained for a limited time. After the passage of 28 A-hr, through the approximately 1300g of melt, compacted powder deposits of ZrB_2/ZrO_2/zirconate were again produced. Four separate additions each of 100g B_2O_3 were made, but when this procedure was attempted a fifth time the bath could not be resuscitated. Analyses indicated that the bath now contained approximately 32 w/o B_2O_3 and 30 w/o K_2ZrF_6. This, of course, does not imply that boron, oxygen, and zirconium are present as these entities, but serves to indicate the large changes in the concentrations of these materials from the initial values. Experiments were performed with baths containing 35 w/o B_2O_3 initially and between 10 and 30 w/o K_2ZrF_6. These compositions would not plate coherent ZrB_2 under any set of conditions. Also, when melts consisting initially of Flinak-K_2ZrF_6 (or ZrF_4) and $Na_2B_4O_7$ were electrolyzed, nothing but compacted ZrB_2/ZrO_2/zirconate powders were obtained. The implications of these results will be considered later in the Discussion section.

It was thought that possibly a reaction of B_2O_3 with molten alkali fluorides might be involved in this process, especially as compounds with B-O-F linkages are known. For example, in the preparation of BF_3, the following reaction occurs

$$KBF_4 + 2B_2O_3 \rightarrow K[B_4O_6F] + BF_3\uparrow$$

B_2O_3 (119g) was reacted with KF (95.2g) at 800°C. A little gas was evolved that turned out to be dissolved water vapor from the B_2O_3, not BF_3 as might be expected from the above equation. Analysis of the product after holding overnight at temperature gave the following results:

%	Nominal Initial Composition	Analyzed Final Composition
B	17.46	17.42
O	38.10	31.00
K	29.91	29.70
F	14.53	13.70
Totals	100.00	91.82

It may be concluded that BF_3 is not formed from these components and, in view of the near constancy of three of the four elements, it is likely that the difficulties of oxygen analysis may account for the discrepancy in the fourth. The very small loss of fluoride, if real, may have been as HF resulting from hydrolysis with the water vapor impurity.

It was now evident that the mixed oxide-fluoride system had overcome one of the major difficulties experienced with the pure fluoride melt, *i.e.*, that of volatility of BF_3. However, owing to the use of zirconium anodes, the zirconium concentration in the melt was increasing while on the other hand, that of the boron was decreasing. To determine whether ZrB_2 could be used as an anode, a new bath containing Flinak (80 w/o)-ZrF_4 (10 w/o)-B_2O_3 (10 w/o) was electrolyzed with a centrally mounted zirconium anode in a graphite crucible which also acted as a cathode. A layer of ZrB_2 was thus built up on the walls of the crucible. On making the ZrB_2-plated crucible the anode and inserting a centrally located nickel cathode, good quality ZrB_2 was deposited on the cathode. This experiment demonstrated that electroformed ZrB_2 is a satisfactory anode.

To prove the point beyond all reasonable doubt, it would be more desirable to electroform a ZrB_2 anode in one cell followed by the electrorefining of this material through a second cell.

A deposit of ZrB_2 about 0.2 in. total thickness on a copper cathode was prepared by electrolysis of a Flinak-ZrF_4-B_2O_3 melt in a nickel crucible using a zirconium anode. This cathode was then made the anode in an identical second cell. An excellent deposit was obtained and is shown together with a photomicrograph in Fig. 5.

A commercially obtained compacted slug of ZrB_2 [3] (1 in. diameter, 4 in. long) proved to be a very satisfactory anode, dissolving smoothly at 100% anode current efficiency and depositing clean coherent ZrB_2

[3] Carborundum Company.

Fig. 6. Plate and cross section of ZrB_2 plated from fluoride-B_2O_3 melt on copper at 800°C (approximately 200X). Anode: pressed ZrB_2 (Carborundum Company).

at 100% cathode current efficiency. A typical sample prepared at 810°C is shown together with a photomicrograph of the same material in Fig. 6. The substrate material is copper.

A life test was performed on the above bath and continued until 90.35 A-hr had been passed through the cell which would correspond to the dissolution and deposition of 38.4g ZrB_2 (1 A-hr deposits 0.425g ZrB_2). The initial composition of the cell contained 32.18g Zr and 22.0g B, so it may be seen that while almost complete turnover of the zirconium has been achieved (38.4g ZrB_2 contains 31.03g Zr and 7.37g B) some time remains before the same can be said for the boron. The reason for the relatively slow rate of turnover is that it is necessary that the anode current density be of the order of 5 mA/cm^2 to obtain satisfactory dissolution. Given the present anode together with the geometry of the small laboratory cells, it has been necessary to operate at a slower rate than would be possible with larger equipment. In the latter case one would arrange for a large anode area and obtain consequent low anode current density while a reasonable plating rate would be obtained with a cathode current density of 50 mA/cm^2, *i.e.*, anode:cathode area ratio of 10:1.

Chemical analysis of a typical ZrB_2 deposit showed 79.85% Zr and 19.80% boron compared with the theoretical values of 80.82 and 19.18%, respectively. X-rays of many samples showed excellent matches for both "d" spacings and intensities with the ASTM card. There were no extraneous lines in the patterns.

Discussion

The uniqueness of the present method is that under the experimental conditions and compositions described, it produces only coherent ZrB_2 deposits. The authors have confirmed that the mixed chloride-powders and the oxide-chloride or oxide-chloride-fluoride mixtures are no better. Fullam (5) noted the fluoride bath of Fullam (5) produces only compacted adverse effect of oxide on the purity and yield of ZrB_2. The deposits of Anthony and Welch (3) were also compacted powders containing considerable amounts of occluded electrolyte as can be seen in Fig. 3 of ref. (3).

Although in practice the fluoride-oxide baths described in this paper would be operated using ZrB_2 anodes, the experiments described above in which zirconium anodes were used are valuable in throwing light on the mechanism of the process.

When zirconium anodes are used the zirconium content increases while that of boron decreases. It was found that additions of B_2O_3 would restore the bath to operating condition, but that this process could not be continued *ad infinitum*. At a certain level of B_2O_3 ($\approx$ 32 w/o), the bath failed, and baths made up initially containing this amount of B_2O_3 would not yield coherent deposits under any circumstances.

Analyses showed that, although in all cases sufficient boron and zirconium were present in the bath, when the O/B mole ratio exceed 1.75, the bath failed, *i.e.*, it produced compacted powder deposits of ZrB_2 and ZrO_2. Therefore it is believed that the mechanism of bath revival may be as follows: as the system is electrolyzed boron is extracted, the O/B mole ratio increases above 1.5 (that of B_2O_3) and the reaction occurs.

$$2B_2O_3 + O^{2-} \rightarrow B_4O_7^{2-}$$

When the O/B ratio exceeds that in $B_4O_7^{2-}$, *i.e.*, 1.75, compounds containing oxygen-zirconium bonds are formed, perhaps of the zirconyl type $[ZrO]^{2+}$, and these may not be reducible at a cathode to form coherent ZrB_2. When fresh B_2O_3 is added to the system the reaction

$$[ZrO]^{2+} + 2B_2O_3 \rightarrow B_4O_7^{2-} + Zr^{4+}$$

then takes place. As evidence for this hypothesis the fact is offered that if melts of Flinak-K_2ZrF_6 and $Na_2B_4O_7$ are electrolyzed only compacted powders are obtained. However, on adding B_2O_3 to the melt, despite the presence of $Na_2B_4O_7$, coherent ZrB_2 is then deposited at 100% cathode current efficiency.

It is not implied firmly that $B_4O_7^{2-}$ is the limiting composition; since boron-oxygen structures are numerous, it could well be that a more complex entity is involved. What is fairly certain is that B_2O_3 acts as a getter for excess O^{2-} ions, thus preserving the Zr^{4+} in fluoride complexes for reduction at a cathode.

A perusal of Andrieux's (2) work shows that the O/B ratio of his melts was always well in excess of 7.75 and, if the above hypothesis has validity, not unsurprisingly, powder deposits were always obtained by this author.

Applying this postulate to the work of Anthony and Welch the oxygen:boron ratio of the added oxide components was 2.5:1 whereas the total oxygen:boron ratio was 0.455, including the boron originally associated with KBF_4. It may be that the former ratio is more important, and this would imply that there was insufficient B_2O_3 at the outset to getter all the oxide ions present. Thus, coherent deposits were not obtained.

It is perhaps valuable to contrast and compare the bulk compositions used in the present work, ref. (2) by the same authors and Anthony and Welch (3), as shown in Table I.

Reference has already been made in the preceding text to the deleterious effects of small amounts of B_2O_3 to working fluoride-zirconium baths (11), and it may be that the failure to produce coherent deposits from the solution of ref. (3) may be in part explained by the low B_2O_3 concentration.

Summary

Zirconium boride has been anodically dissolved and cathodically deposited as a coherent coating in both Flinak-ZrF_4-KBF_4 and Flinak-ZrF_4-B_2O_3 solutions. The latter solution has been found to be a superior medium for this purpose mainly because of the negligible volatility of the boron compounds in this solution. Coherent deposits of ZrB_2 have been obtained at 100% cathode current efficiency. Ranges of composition, current density, and temperature for satisfactory operation have been established. The preferred composition is shown in the first column of Table I. The preferred cathode current density and temperature are approximately 50 mA/cm^2 and 800°C, and ZrB_2, operated at 5 mA/cm^2, is the preferred anode material. Consideration of the composition changes when using Zr anodes and when resuscitating the bath with B_2O_3 additions has led to useful concepts regarding the nature of the interaction between zirconium fluoride complexes and B_2O_3. The use of ZrB_2 anodes has been shown to be feasible, and that when such anodes are used, the bath composition remains constant indefinitely, with no replenishment of salts required.

Photomicrographs of deposits show sound columnar material and the adherence to thin sheets and tubes of copper, nickel, graphite, and other substrates is excellent. A thicker than usual diffusion layer, shown in all probability to be Ni_3B, is present when ZrB_2 is deposited on nickel.

Metal/Metal Ion Electrodes with Two Charge-Transfer Steps: Me_x-Alloy/Me^{z+} and $Me^{z+}/Me^{(z+1)+}$ Potentiostatic Transients under Charge-Transfer and Diffusion Control

K. J. Bachmann

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

A theoretical treatment of the transients obtained in potentiostatic single pulse experiments on metal alloy/metal ion electrodes coupled to a redox reaction is presented. Formulas have been derived for the concentration of the electrochemically active component in the alloy and of the corresponding metal ions of different valent state which form the redox couple in the electrolyte, respectively, as a function of the distance from the interface and the duration of the voltage pulse. Expressions for the partial current densities carried by the two consecutive charge-transfer reactions, $Me = Me^{z+} + ze^-$ and $Me^{z+} = Me^{(z+1)+} + e^-$, and for the total current density flowing through the cell have been worked out. Analysis of the current density transients on the basis of these expressions allows interpretation of experimental curves in terms of the characteristic kinetic parameters of the electrochemical system.

In electrochemical systems containing polyvalent ions, the over-all electrode reaction frequently involves a series of consecutive charge-transfer steps. Although the theory for interpreting experiments under steady-state conditions is well established (1, 2), very little is known on the behavior of such systems under nonsteady-state conditions.

In a preceding paper (3) potentiostatic transients on a pure metal/metal ion electrode with two charge-transfer steps were considered assuming that the surface of the metal remains in equilibrium with the bulk of the metal. It is the aim of this paper to extend the treatment to alloy electrodes where changes in the concentration of the electrochemically active component (Me) at the interface, *i.e.*, diffusion of Me in the alloy, has to be taken into account. Examples of this would be the well-known amalgam electrodes and other types of liquid metal alloy electrodes. At the elevated temperatures of molten salt systems also a sizable mass flow occurs in solid alloy electrodes which are included in this treatment. It should be pointed out, however, that surface alloying ("metalliding") of a pure metal which inherently starts from nonequilibrium conditions requires an independent consideration.

The first charge-transfer step which is considered here is the metal/metal ion charge-transfer reaction

$$Me = Me^{z+} + ze^- \qquad [1]$$

in which the electrochemically active component of the alloy is anodically removed or cathodically deposited on the interface. This charge transfer reaction is coupled to a redox reaction

$$Me^{z+} = Me^{(z+1)+} + e^- \qquad [2]$$

in which the metal ion changes its valency by 1.

Derivation of Concentration of Me in the Alloy and of Me^{z+} and $Me^{(z+1)+}$ in the Electrolyte, Respectively, as a Function of Distance from Interface and of Duration of Voltage Pulse

In the formulation of the diffusion problem, the following assumptions are made:

1. The only irreversible processes are charge-transfer and diffusion in the alloy and in the electrolyte, respectively. In molten salt systems certain metals are soluble in the electrolyte melt as uncharged particles. It is assumed that this does not apply to the metal electrodes treated here.

2. A perfectly rectangular voltage pulse is applied to the electrode.

3. Prior to the voltage pulse the electrode is in equilibrium in respect to both reaction [1] and [2].

4. Changes in the activity coefficients of Me, Me^{z+} and $Me^{(z+1)+}$ can be neglected, *i.e.*, only small signals are considered.

5. The electrode surface is an infinite plane, so that diffusion takes place in a direction x perpendicular to the interface. Although the metal diffuses in a different half volume than the ions Me^{z+} and $Me^{(z+1)+}$, x will be always taken ≥ 0, *i.e.*, x will be defined as distance from the interface. This convention considerably facilitates economical formulation of the diffusion equations and their solutions.

6. Neither stirring nor convection limits the diffusion layer thickness.

7. The disproportionation reaction

$$(z + 1)\ Me^{z+} = zMe^{(z+1)+} + Me$$

does not occur.

If these conditions are fulfilled, the diffusion of Me, Me^{z+} and $Me^{(z+1)+}$ is described by

$$\frac{\partial c_r}{\partial t} = D_r \frac{\partial^2 c_r}{\partial x^2} \qquad [3]$$

$$\frac{\partial c_m}{\partial t} = D_m \frac{\partial^2 c_m}{\partial x^2} \qquad [4]$$

$$\frac{\partial c_o}{\partial t} = D_o \frac{\partial^2 c_o}{\partial x^2} \qquad [5]$$

where $c_r = c_r(x,t)$ is the concentration of Me (most reduced substance of the electrochemical system) in the alloy, $c_m = c_m(x,t)$ is the concentration of Me^{z+} (intermediate substance) and $c_o = c_o(x,t)$ is the concentration of $Me^{(z+1)+}$ (most oxidized substance) in the electrolyte. D_r, D_m, and D_o are the diffusion constants of Me, Me^{z+}, and $Me^{(z+1)+}$, respectively.

The initial conditions are

$$c_r = c_{r,0};\ c_m = c_{m,0};\ c_o = c_{o,0} \text{ for } 0 \leq x \leq \infty \text{ and } t = 0 \qquad [6]$$

The boundary conditions are

$$c_r = c_{r,0};\ c_m = c_{m,0};\ c_o = c_{o,0} \text{ for } x = \infty \text{ and } t \geq 0 \qquad [7]$$

• Key words: potentiostatic single pulse method, electrochemical kinetics.

$$\frac{\partial c_r}{\partial x} = \frac{i_r}{zFD_r} \text{ for } x = 0 \text{ and } t \geqq 0 \quad [8]$$

$$\frac{\partial c_m}{\partial x} = \frac{zi_o - i_r}{zFD_m} \text{ for } x = 0 \text{ and } t \geqq 0 \quad [9]$$

$$\frac{\partial c_o}{\partial x} = -\frac{i_o}{FD_o} \text{ for } x = 0 \text{ and } t \geqq 0 \quad [10]$$

$i_r = i_r(t)$ and $i_o = i_o(t)$ are the current densities carried by reaction [1] and reaction [2], respectively. The total current density is

$$i(t) = i_r(t) + i_o(t) \quad [11]$$

Since the partial current densities $i_r(t)$ and $i_o(t)$ are related to the concentrations $c_r(0,t)$, $c_m(0,t)$ and $c_o(0,t)$ by the equations

$$i_r(t) = i_{r,0} \cdot \frac{c_r(0,t)}{c_{r,0}} \cdot \exp\left(\frac{\alpha_r zF}{RT}\eta\right) - i_{r,0} \cdot \frac{c_m(0,t)}{c_{m,0}} \cdot \exp\left(-\frac{[1-\alpha_r]zF}{RT}\eta\right) = \frac{c_r(0,t)}{c_{r,0}} \cdot i_{r,+} - \frac{c_m(0,t)}{c_{m,0}} \cdot i_{r,-} \quad [12]$$

and

$$i_o(t) = i_{o,0} \cdot \frac{c_m(0,t)}{c_{m,0}} \exp\left(\frac{\alpha_o F}{RT}\eta\right) - i_{o,0} \cdot \frac{c_o(0,t)}{c_{o,0}} \exp\left(-\frac{[1-\alpha_o]F}{RT}\eta\right) = \frac{c_m(0,t)}{c_{m,0}} \cdot i_{o,+} - \frac{c_o(0,t)}{c_{o,0}} \cdot i_{o,-} \quad [13]$$

the differential Eq. [3], [4], and [5] are coupled by the boundary conditions [8], [9], and [10]. Both anodic currents and overvoltages (η) are taken positive. The terms $i_{r,0}$ and $i_{o,0}$ represent the exchange current densities for the two charge transfer reactions [1] and [2], respectively. The terms α_r and α_o are the corresponding charge transfer coefficients. $i_{r,+}$; $i_{o,+}$ and $i_{r,-}$; $i_{o,-}$ are the partial anodic and cathodic current densities (all taken positive), as determined by charge-transfer only. The differences

$$i_{r,D} = i_{r,+} - i_{r,-} \text{ and } i_{o,D} = i_{o,+} - i_{o,-} \quad [14]$$

represent the current densities carried by reaction [1] and [2] under pure charge-transfer control, *i.e.*, when no changes in the concentrations c_r, c_m, and c_o have yet occurred at the interface. Since under potentiostatic conditions the exponentials in Eq. [12] and [13] are constants, boundary conditions [8], [9], and [10] can be rewritten as

$$\left(\frac{\partial c_r}{\partial x}\right)_{x=0} = K_1 c_r(0,t) - K_2 c_m(0,t) \quad [15]$$

$$\left(\frac{\partial c_m}{\partial x}\right)_{x=0} = -K_3 c_r(0,t) + K_4 c_m(0,t) - K_5 c_o(0,t) \quad [16]$$

$$\left(\frac{\partial c_o}{\partial x}\right)_{x=0} = -K_6 \cdot c_m(0,t) + K_7 c_o(0,t) \quad [17]$$

where K_1, K_2 - - -, K_7 are constants. With the initial conditions [6] and the boundary conditions [7], [15], [16], and [17] the differential Eq. [3], [4], and [5] have the following solutions

$$\frac{c_r(x,t)}{c_{r,0}} = 1 - \frac{i_{r,D}}{zF\sqrt{D_r}c_{r,0}} \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1}-\sqrt{\tau_2}} \cdot F_r(x,t) - \frac{i_{r,D}i_{o,-}\sqrt{D_m}c_{m,0} + (i_{r,D}i_{o,+} + i_{o,D}i_{r,-})\sqrt{D_o}c_{o,0}}{i_{r,-}i_{o,-}\sqrt{D_r}c_{r,0} + i_{r,+}i_{o,-}\sqrt{D_m}c_{m,0} + i_{r,+}i_{o,+}\sqrt{D_o}c_{o,0}} \cdot G_r(x,t) \quad [18]$$

$$\frac{c_m(x,t)}{c_{m,0}} = 1 + \frac{i_{r,D} - zi_{o,D}}{zF\sqrt{D_m}c_{m,0}} \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1}-\sqrt{\tau_2}} \cdot F_m(x,t) + \frac{i_{r,D}i_{o,-}\sqrt{D_r}c_{r,0} - i_{o,D}i_{r,+}\sqrt{D_o}c_{o,0}}{i_{r,-}i_{o,-}\sqrt{D_r}c_{r,0} + i_{r,+}i_{o,-}\sqrt{D_m}c_{m,0} + i_{r,+}i_{o,+}\sqrt{D_o}c_{o,0}} \cdot G_m(x,t) \quad [19]$$

$$\frac{c_o(x,t)}{c_{o,0}} = 1 + \frac{i_{o,D}}{F\sqrt{D_o}c_{o,0}} \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1}-\sqrt{\tau_2}} \cdot F_o(x,t) + \frac{(i_{r,+}i_{o,+} - i_{r,-}i_{o,-})\sqrt{D_r}c_{r,0} + i_{o,D}i_{r,+}\sqrt{D_m}c_{m,0}}{i_{r,-}i_{o,-}\sqrt{D_r}c_{r,0} + i_{r,+}i_{o,-}\sqrt{D_m}c_{m,0} + i_{r,+}i_{o,+}\sqrt{D_o}c_{o,0}} \cdot G_o(x,t) \quad [20]$$

The functions $F_j(x,t)$ and $G_j(x,t)$ are defined by

$$F_j(x,t) \equiv \exp\left(\frac{x}{\sqrt{D_j\tau_1}} + \frac{t}{\tau_1}\right)\operatorname{erfc}\left(\frac{x}{2\sqrt{D_jt}} + \sqrt{\frac{t}{\tau_j}}\right) - \exp\left(\frac{x}{\sqrt{D_j\tau_2}} + \frac{t}{\tau_2}\right)\operatorname{erfc}\left(\frac{x}{2\sqrt{D_jt}} + \sqrt{\frac{t}{\tau_2}}\right) \quad [21]$$

and

$$G_j(x,t) \equiv \operatorname{erfc}\left(\frac{x}{2\sqrt{D_jt}}\right) - \frac{\sqrt{\tau_1}}{\sqrt{\tau_1}-\sqrt{\tau_2}} \cdot \exp\left(\frac{x}{\sqrt{D_j\tau_1}} + \frac{t}{\tau_1}\right)\operatorname{erfc}\left(\frac{x}{2\sqrt{D_jt}} + \sqrt{\frac{t}{\tau_1}}\right) + \frac{\sqrt{\tau_2}}{\sqrt{\tau_1}-\sqrt{\tau_2}} \cdot \exp\left(\frac{x}{\sqrt{D_j\tau_2}} + \frac{t}{\tau_2}\right) \operatorname{erfc}\left(\frac{x}{2\sqrt{D_jt}} + \sqrt{\frac{t}{\tau_2}}\right) \quad [22]$$

(j = r, m, o).

The time constants τ_1 and τ_2 are given by

$$\tau_{1,2} = \left(\frac{\alpha}{2\beta}\left[1 \pm \sqrt{1 - \frac{4\beta}{\alpha^2}}\right]\right)^2 \quad [23]$$

where

$$\alpha = \left(\frac{i_{r,+}}{zF\sqrt{D_r}c_{r,0}} + \frac{i_{r,-}}{zF\sqrt{D_m}c_{m,0}} + \frac{i_{o,+}}{F\sqrt{D_m}c_{m,0}} + \frac{i_{o,-}}{F\sqrt{D_o}c_{o,0}}\right) \quad [24]$$

and

$$\beta = \frac{i_{r,-}i_{o,-}\sqrt{D_r}c_{r,0} + i_{r,+}i_{o,-}\sqrt{D_m}c_{m,0} + i_{r,+}i_{o,+}\sqrt{D_o}c_{o,0}}{zF^2\sqrt{D_rD_mD_o}c_{r,0}c_{m,0}c_{o,0}} \quad [25]$$

It can be shown that without exception $\alpha^2 > 4\beta$, *i.e.*, the time constants are always real and positive, τ_1 being greater than τ_2.

By setting $x = 0$ and defining

$$\theta_k(t) \equiv \exp\left(\frac{t}{\tau_k}\right) \cdot \operatorname{erfc}\left(\sqrt{\frac{t}{\tau_k}}\right), \ (k = 1,2) \quad [26]$$

the following expressions for the concentrations of Me, Me^{z+}, and $Me^{(z+1)+}$ at the interface are obtained from Eq. [18], [19], and [20]

$$\frac{c_r(0,t)}{c_{r,0}} = 1 - \frac{i_{r,D}}{zF\sqrt{D_r}c_{r,0}} \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1}-\sqrt{\tau_2}} \cdot (\theta_1 - \theta_2) - \frac{i_{r,D}i_{o,-}\sqrt{D_m}c_{m,0} + (i_{r,D}i_{o,+} + i_{o,D}i_{r,-})\sqrt{D_o}c_{o,0}}{i_{r,-}i_{o,-}\sqrt{D_r}c_{r,0} + i_{r,+}i_{o,-}\sqrt{D_m}c_{m,0} + i_{r,+}i_{o,+}\sqrt{D_o}c_{o,0}} \cdot \left[1 - \frac{\sqrt{\tau_1}}{\sqrt{\tau_1}-\sqrt{\tau_2}}\theta_1 + \frac{\sqrt{\tau_2}}{\sqrt{\tau_1}-\sqrt{\tau_2}}\theta_2\right] \quad [27]$$

$$\frac{c_m(0,t)}{c_{m,0}} = 1 + \frac{i_{r,D} - zi_{o,D}}{zF\sqrt{D_m c_{m,0}}} \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} \cdot (\theta_1 - \theta_2)$$
$$+ \frac{i_{r,D}i_{o,-}\sqrt{D_r c_{r,0}} - i_{o,D} \cdot i_{r,+}\sqrt{D_o c_{o,0}}}{i_{r,-}i_{o,-}\sqrt{D_r c_{r,0}} + i_{r,+}i_{o,-}\sqrt{D_m c_{m,0}} + i_{r,+}i_{o,+}\sqrt{D_o c_{o,0}}}$$
$$\cdot \left[1 - \frac{\sqrt{\tau_1}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_1 + \frac{\sqrt{\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_2\right] \quad [28]$$

$$\frac{c_o(0,t)}{c_{o,0}} = 1 + \frac{i_{o,D}}{F\sqrt{D_o c_{o,0}}} \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} (\theta_1 - \theta_2)$$
$$+ \frac{(i_{r,+}i_{o,+} - i_{r,-}i_{o,-})\sqrt{D_r c_{r,0}} + i_{o,D}i_{r,+}\sqrt{D_m c_{m,0}}}{i_{r,-}i_{o,-}\sqrt{D_r c_{r,0}} + i_{r,+}i_{o,-}\sqrt{D_m c_{m,0}} + i_{r,+}i_{o,+}\sqrt{D_o c_{o,0}}}$$
$$\cdot \left[1 - \frac{\sqrt{\tau_1}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_1 + \frac{\sqrt{\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_2\right] \quad [29]$$

Current Density as a Function of Time

The current densities $i_r(t)$ and $i_o(t)$ carried by charge-transfer reaction [1] and [2], respectively, can be calculated by introducing [27], [28], and [29], in [12] and [13].

$$i_r(t) = i_{r,D} \cdot \left[\frac{\sqrt{\tau_1}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_1 - \frac{\sqrt{\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_2\right]$$
$$- \left[\frac{i_{r,D} \cdot i_{r,+}}{zF\sqrt{D_r c_{r,0}}} + \frac{i_{r,D}i_{r,-}}{zF\sqrt{D_m c_{m,0}}} - \frac{i_{o,D}i_{r,-}}{F\sqrt{D_m c_{m,0}}}\right]$$
$$\frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} (\theta_1 - \theta_2) \quad [30]$$

$$i_o(t) = i_{o,D} \cdot \left[\frac{\sqrt{\tau_1}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_1 - \frac{\sqrt{\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_2\right]$$
$$- \left[\frac{i_{o,D}i_{o,+}}{F\sqrt{D_m c_{m,0}}} + \frac{i_{o,D}i_{o,-}}{F\sqrt{D_o c_{o,0}}} - \frac{i_{r,D}i_{o,+}}{zF\sqrt{D_m c_{m,0}}}\right]$$
$$\frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} (\theta_1 - \theta_2) \quad [31]$$

An expression for the variation of the total current density flowing through the working electrode with time is obtained by summing [30] and [31]

$$i(t) = (i_{r,D} + i_{o,D}) \cdot \left[\frac{\sqrt{\tau_1}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_1 - \frac{\sqrt{\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}}\theta_2\right]$$
$$- \left[\frac{i_{r,D}i_{r,+}}{zF\sqrt{D_r c_{r,0}}} + \frac{(i_{r,D} - zi_{o,D})(i_{r,-} - i_{o,+})}{zF\sqrt{D_m c_{m,0}}}\right.$$
$$\left. + \frac{i_{o,D}i_{o,-}}{F\sqrt{D_o c_{o,0}}}\right] \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} \cdot (\theta_1 - \theta_2)$$
$$= A \cdot f(t) + B \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} \cdot g(t) \quad [32]$$

where A and B are time independent parameters.

Discussion

The measured quantity in potentiostatic single pulse experiments $i(t)$ depends according to Eq. [32] in a rather complicated form on the kinetic parameters of the electrochemical system. Therefore, in the following discussion some characteristic features of the $i(t)$ curves will be worked out which may be used as a guide in the interpretation of experimental current density transients.

As long as a change in electrode potential starting from equilibrium is considered the initial current density is always

$$i(t = 0) = \sum_{m=1}^{n} i_{m,D} \quad [33]$$

where $i_{m,D}$ is the current density carried by the mth charge-transfer step under pure charge-transfer control. This applies for any electrode reaction with an arbitrary number of n consecutive charge-transfer steps, since at the begining of the pulse no changes in the concentrations c_j have yet occurred (initial conditions) and the applied overvoltage in this moment is pure charge-transfer overvoltage. If unlimited diffusion layer thickness is assumed, the $i(t)$ curve approaches zero at infinite time also independently from the special system under consideration, since the concentration gradient becomes zero (boundary conditions).

In practice, however, the overvoltage pulse has a finite rise time and after some time ($t \gtrsim 1$ sec) convection limits the diffusion layer thickness. Therefore, in previous papers (3, 6) on the potentiostatic single pulse method, extrapolation techniques have been proposed for the determination of $i(0)$ and for the consideration of $i(t)$ at large t where the reaction is diffusion controlled. In these treatments, approximations were used for $t << \tau$ and $t >> \tau$, respectively, which facilitate interpretation of the $i(t)$ transients. For small arguments $t/\tau_k << 1$ the approximation

$$\exp\left(\frac{t}{\tau_k}\right) \cdot \operatorname{erfc}\left(\sqrt{t/\tau_k}\right) \approx 1 - 2\sqrt{t/\pi\tau_k} \quad [34]$$

may be applied. Introducing Eq. [34] in Eq. [32] one obtains

$$i(t) = A + B \cdot \frac{2}{\sqrt{\pi}} \cdot \sqrt{t} \quad \text{for } t << \tau_2 \quad [35]$$

On the basis of Eq. [35] the value of A can be derived by an extrapolation to $t = 0$ of the linear part of a plot $i(t)$ *vs.* $\sqrt{t}$. However, such a linearization requires a judgment on the range of useful data points which may be misleading, and the determination of A from an $i(t)$ *vs.* $\sqrt{t}$ plot can only be considered as a first orienting step in the analysis of the $i(t)$ curves. For $t/\tau >> 1$ where

$$\exp(t/\tau_k) \cdot \operatorname{erfc}\left(\sqrt{t/\tau_k}\right) \approx \frac{1}{\sqrt{\pi}} \cdot \sqrt{\tau_k/t} \quad [36]$$

Eq. [32] can be written in the approximate form

$$i(t) \approx \text{const.} \frac{1}{\sqrt{t}} \quad \text{for } t >> \tau_1 \quad [37]$$

Since at large t the current density *vs.* time curves are very likely to be influenced by convective limitation of the diffusion layer thickness, this approximation may not always be applicable and an analysis of the $i(t)$ curve at intermediate time, where both diffusion and charge-transfer determine its shape, appears to be preferable.

The general properties of the $i(t)$ curves in this intermediate time range can be worked out by a consideration of the functions $f(t)$ and $g(t)$. Since

$$\lim_{t \to 0} \theta_k = 1 \text{ and } \lim_{t \to \infty} \theta_k = 0 \quad [38]$$

$f(t)$ monotonically decreases from $f(0) = 1$ to $f(\infty) = 0$ whereas $g(t)$ is 0 at the beginning of the pulse and 0 at infinite time but positive in between. Consistent with the above mentioned conclusions from the initial and boundary conditions, this leads to $i(0) = A = i_{r,D} + i_{o,D}$ and $i(\infty) = 0$. In a previous paper (3) on pure metal/metal ion electrodes with two consecutive charge-transfer steps it was shown that a delayed extreme value $|i_{max}| > |i_{r,D} + i_{o,D}|$ in the c.d. curve may occur. This appearance, which is characteristic for a system with consecutive charge-transfer steps can be

expected for alloy electrodes, too, although additional terms containing $i_{r,+}/\sqrt{D_r}c_{r,0}$ show up in both B and the time constants, thus making the discussion of the alloy case more complex.

The conditions for delayed extreme value in the c.d. curves may be understood best by a consideration of the derivatives

$$f'(t) = \frac{1}{\sqrt{\tau_1} - \sqrt{\tau_2}} \left(\frac{\theta_1}{\sqrt{\tau_1}} - \frac{\theta_2}{\sqrt{\tau_2}} \right) \quad [39]$$

and

$$g'(t) = \frac{\theta_1}{\tau_1} - \frac{\theta_2}{\tau_2} + \frac{\sqrt{\tau_1} - \sqrt{\tau_2}}{\sqrt{\tau_1 \cdot \tau_2}} \cdot \frac{1}{\sqrt{\pi t}} \quad [40]$$

Since $f(t)$ is a monotonically decreasing function, $f'(t)$ is always negative starting from $f'(0) = -1/\sqrt{\tau_1\tau_2}$ and approaching 0 at infinite time. The derivative of $g(t)$ starts with an infinitely large positive value and becomes 0 both at $t = t_{gm}$, where $g(t)$ has its maximum, and at $t \to \infty$ being negative for $t_{gm} < t < \infty$. The slope of the c.d. curve is given by

$$i'(t) = A \cdot f'(t) + B \cdot \frac{\sqrt{\tau_1\tau_2}}{\sqrt{\tau_1} - \sqrt{\tau_2}} \cdot g'(t) = a'(t) + b'(t) \quad [41]$$

Figures 1 and 2 show curves $i'(t)$ *vs.* t and the scaled functions $a'(t)$ and $b'(t)$ corresponding to $f'(t)$ and $g'(t)$, respectively, for same η but slightly different parameter combinations. The conditions for Fig. 1 are such that A and B have same sign. Since $f'(t)$ and $g'(t)$ are opposite in sign for $t < t_{gm}$ there exists always a $t_{im} < t_{gm}$ where $i'(t_{im}) = 0$, *i.e.*, in case sign(A) = sign(B) the function $|i(t)|$ has always a maximum. In Fig. 2 the kinetic parameters were chosen that A and B are opposite in sign. Under these circumstances $i'(t)$ could become 0 only for $t > t_{gm}$. However, in this time range $|a'(t)| > |b'(t)|$ and no minimum appears in the corresponding $i(t)$ curve (compare Fig. 2 and 4).

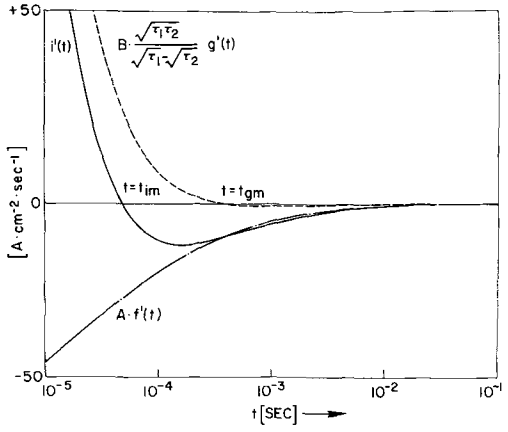

Fig. 1. Slope $i'(t)$ of the c.d. curve as a function of time t. $\eta = +80$ mV, $i_{r,0} = 10$ mA/cm², $i_{o,0} = 1$ mA/cm², $\alpha = 0.5$, $z = 1$, $D_r = D_m = D_o = 1.5 \times 10^{-5}$ cm²/sec, $c_{r,0} = 10^{-2}$M, $c_{m,0} = 10^{-4}$M, $c_{o,0} = 10^{-1}$M.

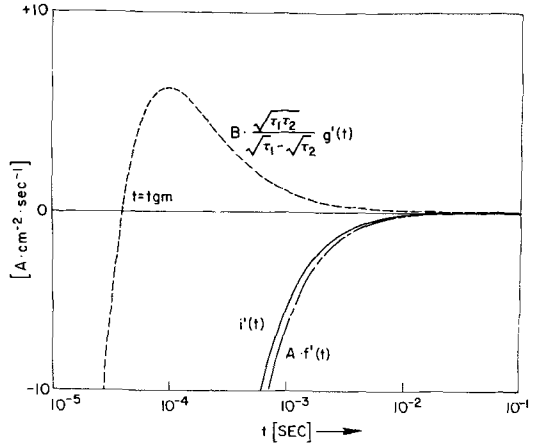

Fig. 2. Slope $i'(t)$ of the c.d. curve as a function of time t. All parameters as Fig. 1 except $c_{r,0} = 10^{-3}$M.

From Eq. [32] it follows that B is the sum of 3 terms $B = -(T_1 + T_2 + T_3)$. Since A and $T_1 + T_3$ have same sign, sign(B) = sign(A) requires sign$(T_2) \neq$ sign$(T_1 + T_3)$. If $\eta > 0$ this condition can only be satisfied for $i_{r,0} > i_{o,0}$ and $i_{r,-} < i_{o,+}$, *i.e.*, $\eta > \eta_{min}$. If $\eta < 0$, sign(B) = sign(A) requires $i_{r,0} < i_{o,0}$ and $i_{r,-} > i_{o,+}$, *i.e.*, $|\eta| > |\eta_{min}|$. Since the relative values of T_1, T_2, T_3 depend on the relative values of the terms $\sqrt{D_j} \cdot c_{j,0}$ in the denominators, the conditions given above are necessary but not sufficient. The behavior of B as a function of overvoltage is demonstrated in Fig. 3a and 3b which show families of curves B *vs.* η with $i_{o,0}$ as parameter and $i_{r,0}$ fixed. In Fig. 3a the intermediate substance is assumed to exist in a much lower concentration than both the reduced and the oxidized substance. In Fig. 3b the initial concentrations of S_r and S_m were assumed both equal and small compared with $c_{o,0}$. Note that in the cathodic branch large variations in $c_{r,0}$ (or D_r) have very little effect on the limit of $|\eta_{min}|$, where sign(B) becomes equal to sign(A), whereas a drastic change occurs in the anodic branch. Varying the initial composition of the electrochemical system and observing the effect on the occurrence of delayed maxima in the $|i(t)|$ curve, provides, therefore, a valuable means for confirming a proposed model of the electrode reaction under investigation.

Figures 4, 5, and 6 show families of digitally simulated $i(t)$ *vs.* t curves (t-axis logarithmic) with $c_{r,0}$ as parameter and $c_{m,0}$ and $c_{o,0}$ fixed. Figure 4 represents an anodic case with $i_{r,0} > i_{o,0}$ and $i_{r,-} < i_{o,+}$. For $c_{r,0} \geq 10^{-5}$ mole/cm³, delayed maxima occur in the $i(t)$ curve (compare the dashed curve in Fig. 3a and the full curve in Fig. 1). However, if $c_{r,0} \leq 10^{-6}$ mole/cm³ the term T_1 in B overrides the influence of T_2, *i.e.*, B has opposite sign of A and the delayed maximum in $i(t)$ disappears (compare Fig. 2 and 3b). Figure 6 represents a cathodic case with $i_{r,0} < i_{o,0}$ and $i_{r,-} > i_{o,+}$. Since at large cathodic overvoltage the term T_1 in B is of minor influence, all curves have maxima. However, with decreasing $c_{r,0}$ the values $i(t_{im})/i(0)$ become smaller and t_{im} is shifted to shorter times. Therefore, the delayed maximum is not observable in curves with $c_{r,0} \leq 10^{-8}$ mole/cm³ assuming that the best attainable rise time of a potentiostatic system at present is of the order of 10^{-6} sec. In Fig. 5 the parameters are chosen in such a way that $i_{r,0} > i_{o,0}$ but $i_{r,-} > i_{o,+}$, *i.e.*,

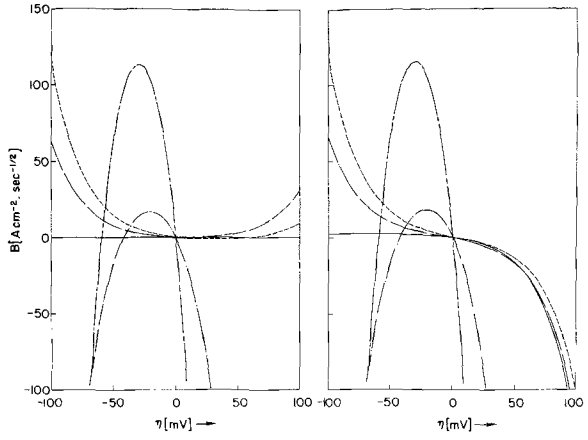

Fig. 3. Coefficient B *vs.* overvoltage η for various $i_{o,0}$. $i_{r,0} = 10$ mA/cm², $\alpha = 0.5$, $z = 1$; $i_{o,0} = 1$ mA/cm² — — — —; $i_{o,0} = 5$ mA/cm² — · — · —; $i_{o,0} = 10$ mA/cm² ————; $i_{o,0} = 50$ mA/cm² — ·· — ·· —; $i_{o,0} = 100$ mA/cm² — — — —; $D_r = D_m = D_o = 1.5 \times 10^{-5}$ cm²/sec. sign$(B) \neq$ sign(A) for all $i(t)$ curves which exhibit no delayed maxima.

Conclusions

From a consideration of the general properties of $i(t)$ *vs.* t curves in potentiostatic single pulse experiments on systems involving two consecutive charge-transfer reactions, the following steps are suggested to be taken in the analysis of experimentally obtained $i(t)$ transients:

1. Approximate values for A are determined for a set of overvoltages from plots $i(t)$ *vs.* $\sqrt{t}$ and an approximate value for $1/i_{r,0} + 1/i_{o,0}$ is evaluated by a conventional analysis of the charge-transfer resistance.
2. By varying η and, if necessary, by changing initial composition the system is checked for the conditions under which delayed maxima are established in the $i(t)$ curve. If such maxima exist at anodic overvoltages, $i_{r,0} > z \cdot i_{o,0}$; if they exist at cathodic overvoltages, $i_{r,0} < z i_{o,0}$.
3. The limit $|\eta_{min}|$ for which maxima are observable and the way the maxima are affected by changes in composition are investigated. A model of the electrode kinetics is made up on the basis of these observations, *i.e.*, a reasonable range of values is coordinated to the different kinetic parameters.
4. The model has to be confirmed by fitting these parameters to experimental $i(t)$ curves covering the full time range where both diffusion and charge-transfer control the electrochemical reaction. Final adjustments are made in the parameters to obtain best fit for a variety of η and $c_{j,0}$.

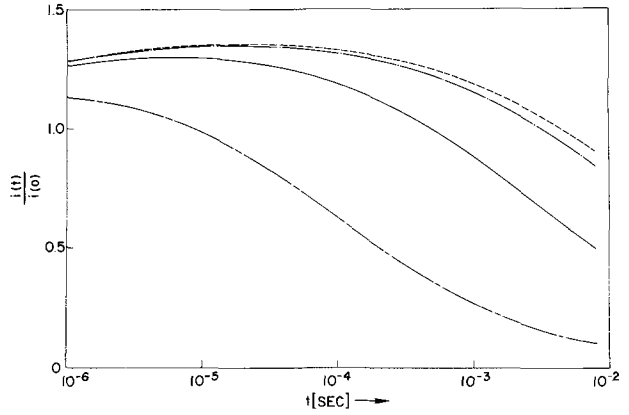

Fig. 6. Current densities $i(t)$, expressed as fractions of the initial current density $i(0) = i_{r,D} + i_{o,D}$, as a function of time t; varied parameter $c_{r,0}$. $\eta = -80$ mV, $i_{r,0} = 10$ mA/cm², $i_{o,0} = 50$ mA/cm², $\alpha = 0.5$, $z = 1$, $D_r = D_m = D_o = 1.5 \times 10^{-5}$ cm²/sec, $c_{m,0} = 10^{-4}$M, $c_{o,0} = 10^{-1}$M; $c_{r,0} = 10^{-1}$M — — — —; $c_{r,0} = 10^{-3}$M — · — · —; $c_{r,0} = 10^{-4}$M ———; $c_{r,0} = 10^{-5}$M — — — —.

Considering the relatively poor accuracy in recording of $i(t)$ data at high speed and the possible systematic errors in potentiostatic single pulse experiments, a quantitative analysis of $i(t)$ curves for electrochemical systems, which do not allow the observation of delayed maxima, appears to be unrealistic at the present state of experimental technique.

Summary

A theoretical treatment of the transients obtained in potentiostatic single pulse experiments on metal alloy/metal ion electrodes coupled to a redox reaction is presented. Formulas have been derived for the concentration of the electrochemically active component in the alloy and of the corresponding metal ions of different valent state which form the redox couple in the electrolyte, respectively, as a function of the distance from the interface and the duration of the voltage pulse. Expressions for the partial current densities carried by the two consecutive charge-transfer reactions, $Me = Me^{z+} + ze^-$ and $Me^{z+} = Me^{(z+1)+} + e^-$, and for the total current density flowing through the cell have been worked out. Analysis of the current density transients on the basis of these expressions allows interpretation of experimental curves in terms of the characteristic kinetic parameters of the electrochemical system.

Free Energies of Formation of Hydrous Oxides of Technetium in Its Lower Valencies[1]

G. H. Cartledge

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

It has been found possible to measure reversible electrode potentials for couples containing technetium and one or more of its hydrous oxides. The procedure disclosed the existence, in films, of technetium in 1+, 2+, and 3+ valence states, besides oxides Tc_3O_4 and Tc_4O_7, and provided direct means for evaluating their free energies of formation from the metal. The previous calorimetrically based free energy of formation of $Tc(OH)_4$ was confirmed to within 1%. It was found that the radioactivity of technetium is involved in certain processes on the electrode.

The oxides of technetium previously known were TcO_2, TcO_3, and Tc_2O_7. Electroanalytical procedures have been used to study the reduction of the pertechnetate ion, and Tc(III), Tc(V), and Tc(VI) were shown to be formed as intermediate products under certain conditions, besides Tc(IV) (1, 2). The 3+ state was found also as a chlorocomplex by Busey (3), and both the 2+ and 3+ states were isolated as ditert-arsine complex compounds by Fergusson and Nyholm (4). There is no known report, however, of oxides or hydroxides from a valence state lower than 4+.

The initiation of a study of the electrochemical behavior of iron alloyed with a small amount of technetium immediately showed the necessity for determining the anodic behavior of elemental technetium. These experiments led to the result that several lower oxides (hydrous or "precipitated") could be identified and their free energies of formation determined electrochemically. Confidence in the validity of the observation of several reproducible couple potentials was immediately established by the fact that the potential of a technetium electrode coated cathodically with $Tc(OH)_4$ gave a free energy of formation for this hydroxide which closely matched a value previously derived. This earlier value was calculated by combining the measured heat of combustion of technetium to pertechnic acid (5) with the author's determination of the reversible potential of the Tc(IV-VII) electrode (6).

The present study consisted of the measurement of the potential of metallic technetium in sulfate or other electrolytes after various polarizations, with or without prior coating of the electrode with a film formed cathodically from TcO_4^-. Other measurements were made on gold or platinum electrodes after they were coated with a film and subjected to various polarization procedures. It was somewhat surprising to discover that all these types of electrodes gave characteristic halts, or plateaus, in potential-time charts, and that, so far as was investigated, the potentials had the 59 mV/*p*H dependence that would be expected. Although certain of the couples were metastable in that the electromotively active components of the film slowly changed chemically and produced a different couple, even these were found to be sufficiently stable for identification and use in calculating free energies of formation. The results furnish a direct and independent means of referring the free energies of technetium compounds to the metal. In addition, couples were identified which indicate the existence, on the electrode, of new compounds derived from technetium in the 1+, 2+, and 3+ valence states, besides the hybrid oxides, Tc_3O_4 and Tc_4O_7. The results are particularly striking in that hard metals coated with oxides do not usually give reversible potentials.

Key words: technetium, technetium oxides, electrode potential, free energy, ionic potential, polarization.

Experimental

For preparation of certain electrodes, the chosen substrate was coated with a film of black, hydrous oxide by cathodic deposition from alkaline TcO_4^-. If the current density is in the range of 0.5 mA/cm^2, electrolysis for a few minutes at room temperature produces a brownish-black film which, after being dried at 110°C in air, has the same electron diffraction pattern as the product from hydrolysis of $K_2Tc(IV)Cl_6$. This product is $TcO_2 \cdot 2H_2O$ or $Tc(OH)_4$. [The author is indebted to Dr. R. H. Busey for the hydrolytic product and to Mr. T. E. Wilmarth, of the Analytical Chemistry Division, for comparison of the diffraction patterns. As is seen subsequently, vigorous cathodic deposition may give a film containing lower oxides in addition to, or rather than, $Tc(OH)_4$.] Elementary technetium, gold, platinum, and gold-plated platinum were used as substrates for the preparation of coated electrodes. The use of gold facilitated observation of colors.

Other electrodes consisted initially of technetium from which any oxide film had been removed either by treatment with ammoniacal hydrogen peroxide, by fusion just above the melting point in KOH containing a little KNO_3, or by reduction in hydrogen at around 425°C, with cooling in helium. In numerous experiments, a 0.72g pellet of rf-melted technetium was used. (The pellet was prepared by Mr. W. J. Martin from powder produced in the Isotopes Division by reduction of fission-product NH_4TcO_4 by hydrogen.) The results obtained with the pellet were confirmed and extended by use of an electrode consisting of a gold coil sealed into soft glass and plated with metallic technetium from 2*N* H_2SO_4 containing $7 \times 10^{-3}f$ $KTcO_4$ (7). The plating covered the golden color completely and gave a bright deposit resembling platinum after reduction in hydrogen. As a variant, a gold coil was first coated with $Tc(OH)_4$, and the black film was then rinsed, dried, and reduced in hydrogen. Two such treatments gave a bright platinum-like surface. For work in the more noble regions of potential, platinum or gold electrodes were coated with technetium tetrahydroxide and subjected to cathodic polarization to produce couples having oxides which correspond to valence states below 4+. The different kinds of electrodes may be identified in the subsequent paragraphs by reference to Table I. Electrolytes were 1*N* and 0.01*N* H_2SO_4, 0.05*f* phthalate buffers, or a mixture 0.9*N* in sulfate and 0.1*f* in phthalate. The acidities for certain couples covered the range of *p*H from 0.35 (1*N*

Table I. Types of electrodes

F.	Platinum or gold carrying cathodically formed film

H_2SO_4) to 6.76. Solutions were prepared from triply distilled water, and concentrated C.P. H_2SO_4 was heated to fuming to remove SO_2 before dilution.

Polarization of electrodes was accomplished by both galvanostatic and potentiostatic procedures (FairPort Instruments, Inc., Model 610). Potentials or currents were measured through a vibrating reed electrometer (APL Model 30) and a Hewlett-Packard Recorder (Model 7100B), stable potentials being checked directly with a Rubicon Potentiometer. Measurements were made at thermostatically controlled room temperature, 24°C, and air was displaced from a large H-cell by helium which had passed over copper turnings at 425°C. Potentials are expressed in accordance with the Gibbs-Stockholm convention (8). Measurements in terms of SCE are converted to SHE by addition of +245 mV. Energies are expressed in thermochemical calories, 1 cal = 4.184J.

Most of the study of the Tc-$Tc(OH)_4$ couple was done with the pellet of technetium, Type B, the result of many such measurements being completely confirmed by use of electrodes of Type E. The pellet was suspended in the electrolyte by a platinum stirrup. When it was found that stable or metastable potentials other than that of the Tc-$Tc(OH)_4$ couple were being observed, electrodes of elementary technetium were used to explore the less noble range of potentials. For this purpose, electrodes of Type A, C, or D were anodically polarized, chiefly in 1*N* H_2SO_4, to form films possibly capable of existence in lower valence states. Alternate anodic and cathodic polarizations (sometimes by chance!) led to recognition of several well-defined potentials in the lower range.

When it developed that the Tc-$Tc(OH)_4$ couple is electrochemically metastable with respect to couples of more noble potential, other measurements were made with electrodes of Type F. These were subjected to a variety of polarizations, from which results were obtained which confirmed certain of the couple potentials observed when electrodes of Type A, B, or E were merely allowed to "age" in the cell. Other details for locating and identifying specific potentials are given under "Results."

Results

The Tc-$Tc(OH)_4$ couple.—The potential of this couple was obtained many times when freshly filmed and rinsed electrodes were inserted into the electrolyte with a rapid stream of helium passing. The potential initially observed depended somewhat on the method of forming the film. Thus it could be varied by changing the current density, by brief reversal of the coating current, or by allowing the electrode to remain in the coating cell briefly after shutting off the current. In any event, the potential soon shifted to a more or less steady value before beginning to drift to a more noble potential. This shift required a few hours or, sometimes, overnight before a second stable potential was attained. Measurements at several *p*H values served to show that both potentials had approximately the 59 mV/*p*H dependency required for couples of the types possibly existing between the metal and one of its insoluble hydroxides, or between two such hydroxides as discrete phases on a conducting, electrochemically inert substrate. The results of 19 determinations of the lower potential and 10 of the more noble one are shown in Fig. 1. When the results are corrected to *p*H = 0 and SHE, one finds V^o_H = 0.296 ± 0.006 and 0.516 ± 0.007V, respectively.

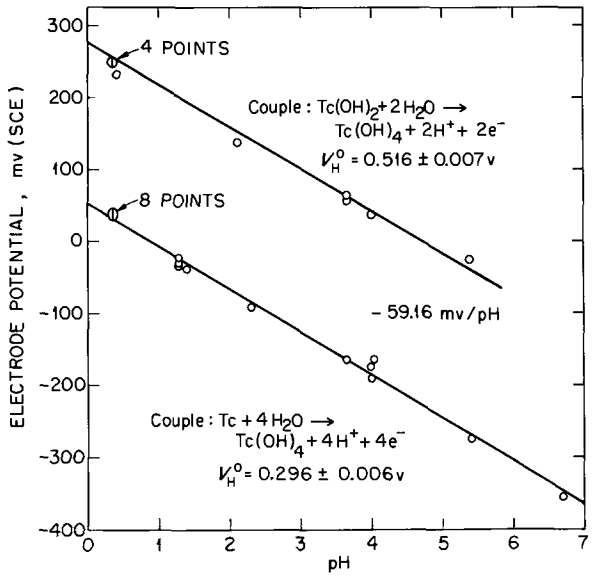

Fig. 1. Electrode potentials (ref. to SCE) as a function of *p*H. The lines are drawn with the theoretical slope.

If V^o_H = 0.296V is taken to be the reversible potential of the couple, $Tc + 4H_2O \rightleftarrows Tc(OH)_4 + 4H^+ + 4e^-$, ΔF^o = +27.3 kcal, from which ΔF^o_f for formation of $Tc(OH)_{4(pptd)}$ is −199.5 ± 0.7 kcal. This is seen to be very close to the value −202 kcal derived from the earlier calorimetric and electrochemical data. The agreement not only approximately confirms the indirectly obtained free-energy value, but shows the surprising speed with which technetium establishes electrochemical equilibrium with this film. (The value −199.5 kcal is adjusted to −199.7 kcal subsequently, for better internal consistency of the several stationary potentials discovered.)

Other couple potentials.—The noble potential V^o_H = 0.516V cannot be ascribed to effects associated with a mere "aging" of the film, such as a change in crystal form or degree of hydration, since the observed potentials show that such processes would have a positive free-energy change. It is therefore necessary to assume that the potential shifts because of slow formation of a couple having at least one new component. Calculations which are explained subsequently show that either $Tc(OH)_2$ or $Tc(OH)_3$ in association with $Tc(OH)_4$ would result in a reasonable free energy for the lower hydroxide, but the data obtained in later experiments are necessary for discrimination between the two possibilities. The existence of such a stable potential, however, is clear evidence of the formation of a couple containing a lower oxide and having an exchange current sufficiently great to escape serious polarization by reaction of metallic technetium. Should there actually be such a polarization, the true couple potential would be even more noble. The fact that the potential of 0.516V was repeatedly observed and had a proper *p*H dependence indicates also that chemically discrete phases are present in the mixed film, rather than a composite phase of continuously variable composition, which may sometimes be formed.

Further measurements were therefore made with both coated and initially uncoated electrodes in order to detect other characteristic potentials. In certain cases, the procedure was to build films by anodic polarization of technetium electrodes (Types A, C, and D). This procedure was used to explore the less noble region of potentials. For the more noble region, Type F electrodes were used. In all these cases, various mild anodic and cathodic polarizations were applied, as necessary, to insure the integrity of observed stationary potentials. By these devices a total of 15

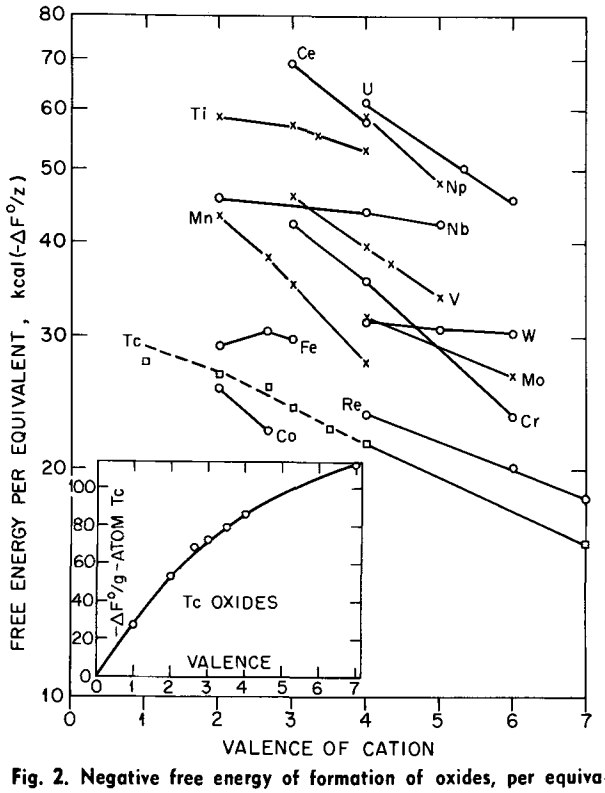

Fig. 2. Negative free energy of formation of oxides, per equivalent, as a function of the valence of the cation. Insert: Negative free energy per gram-atom of Tc, vs. valence of cation.

significant potentials was established, including the two shown in Fig. 1. The values are given in Table III, following a description of the procedure by which the couples responsible for the different potentials were identified.

Identification of the couples.—In earlier publications (9), it was shown that many properties of inorganic compounds may be interpreted or correlated in terms of the ratio of the charge to the radius of their ions. This function, z/r, was designated the ionic potential. Thus, it was shown (10) that, in a series of compounds with a common anion, such as oxides, there is a quite general semilogarithmic relation between the heats or free energies of formation per equivalent and the ionic potentials of the cations based on their univalent crystal radii. The present problem involves the hydroxides or oxides of a single element in various valence states, however, and here the regularities are less obvious. Nevertheless, certain fair approximations become apparent from an inspection of a graph of the free energies of oxides, per equivalent, plotted logarithmically against the valence of the cation. Figure 2 is such a graph. The data were taken chiefly from Brewer (11) and the revisions of Circular 500 of the Bureau of Standards (12). A few are from Latimer (13), and recent redeterminations for rhenium are from King, Richardson, and Mrazek (14). The value for Tc_2O_7 is from Ref. (5). It is to be noted that, in the absence of specific information on the structure of hydrous oxides, Latimer considers them preferably as hydroxides. For the present approximations, the free energies of the oxides and the hydrous, or "precipitated," oxides may be considered to differ by half the free energy of liquid water for each equivalent. Thus, from $\Delta F°_f$ for $Tc(OH)_4$ = −199.5 kcal/mole, we find $\Delta F°_f$ for ¼ TcO_2 to be (¼) [−199.5−(−2 x 56.7)] = −21.5 kcal/equiv.

Table II. Estimated and experimental free energies of formation*

	$\Delta F°_f$(est)	$\Delta F°_f$(exp)

$Tc(OH)_4$	(−199.5)	−199.7

* kcal/mole; $\Delta F°_f$(est), estimated from Fig. 2; $\Delta F°_f$(exp), adjusted for maximum consistency of observed potentials.

Figure 2 shows that, for a given metal, the negative free energy decreases numerically as the valence increases, and the slight deviations from straight lines follow similar patterns. It may be assumed, therefore, that the free energies of perhaps hypothetical lower oxides of technetium will not differ greatly from those indicated by the dashed curve in Fig. 2, which was based on a comparison of the experimental values for Re_2O_7, ReO_3, and ReO_2 with the established values for Tc_2O_7 and TcO_2. From this curve, free energies of formation were calculated for TcOH, $Tc(OH)_2$, and $Tc(OH)_3$, with the results shown in Table II in the column $\Delta F°$(est). These estimated free energies were then used for calculation of reversible electrode potentials for the ten couples conceivably obtainable by combining the metal with one of its hydroxides, or two hydroxides as discrete phases on an electrochemically inert substrate. So long as only insoluble components are involved, the potentials of all such couples will have a −59 mV/pH dependence. The initially approximated potentials are shown in Table III under $V°_H$(est). The column headed $V°_H$(obs) gives the potentials of the observed halts in potential-time

curves, corrected to pH = 0 and SHE, the number of observations of each couple being shown in parentheses. The last column shows the pH values at which the couple was found. Although most of the work was done in 1*N* H_2SO_4, the table shows that each valence state was confirmed in at least one other electrolyte.

It is seen that most of the estimated potentials are within a few millivolts of one of the observed halts. For couples containing TcOH as one component, there was a significant discrepancy between an estimated potential and one of the experimental potentials. All these discrepancies were removed by taking ΔF°_f for TcOH to be −56.0 kcal/mole, rather than the postulated −57.35. A smaller correction in the free energy for $Tc(OH)_2$ was also indicated. From couples *b*, *f*, and *l*, we may infer the presence of $Tc(OH)_2$ and $Tc(OH)_3$ in the films, with free energies essentially equal to those based on Fig. 2. A completely self-consistent set of values for the ten estimated potentials was found to be achieved by use of the slightly adjusted values of the molar free energies given in Table II under ΔF°(exp). The corresponding standard electrode potentials are shown in Table III under V°_H(normalized) and, without exception, are within the limits of error of the measurements.

In Fig. 2, the points denoted by □ are the free energies of the respective oxides (per equivalent) derived from the ΔF°_f(exp) values of the hydroxides in Table II. In a discussion of the method used to identify the couples, Dr. R. H. Busey suggested that a check on the semilogarithmic curves of Fig. 2 may be obtained from a linear graph so as to include the metal as origin. The insert in Fig. 2 shows the free energy per gram-atom of metal plotted against the valence state. The points represent the experimentally derived values, and the curve is seen to extrapolate neatly to zero.

In certain experiments, definitely stationary potentials were repeatedly observed which did not correspond to any of the ten previously postulated couples. By considering the possible formation of a discrete phase analogous to Fe_3O_4, it was found that certain of these potentials could, indeed, be accounted for by assuming a technetium oxide with a free energy corresponding to the point at an average valence 2.67 in Fig. 2. Figure 3, curve B, which is discussed later, shows one example of the formation of a couple containing this compound. In like manner, other potentials occasionally obtained corresponded almost certainly to formation of a component of average valency 3.5, which might be $Tc_2O_3 \cdot 2TcO_2$, or Tc_4O_7. Curve A in Fig. 3 illustrates this case. The uncertainty in the identification of the lower hydroxide in this couple arises from the fact that almost the same agreement

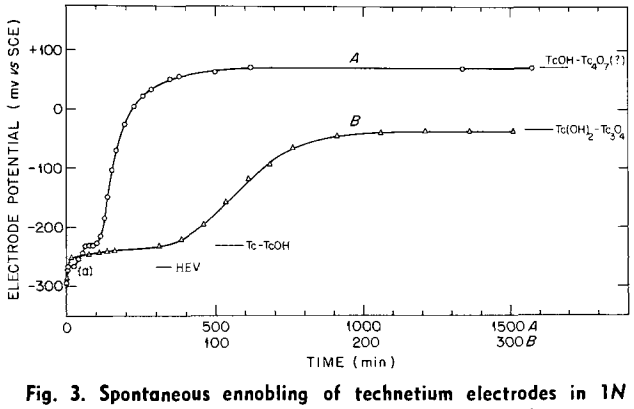

Fig. 3. Spontaneous ennobling of technetium electrodes in 1*N* H_2SO_4 in absence of air (continuous recordings). Curve A, in large H cell, with H_2 passing 25 min (to point *a*), followed by He. Curve B, in miniature cell with He passing. HEV is the reversible potential of the hydrogen electrode at pH = 0.35. The line for Tc-TcOH represents the potential of this couple in 1*N* H_2SO_4, and similarly for the other potentials indicated.

with the observed potential would result if the lower hydroxide were $Tc(OH)_3$, instead of TcOH. The latter seems more probable, however, in view of the demonstrated stability of the TcOH component when the experiment is begun at a low potential and, also, the closer agreement with Fig. 2.

To illustrate the consistency of the observed potentials among themselves, it may be noted that Tc_3O_4 appeared in couples with TcOH, $Tc(OH)_2$, $Tc(OH)_3$, and $Tc(OH)_4$, respectively, in 12 independent observations. By using the ΔF°_f(exp) values for these hydroxides as shown in Table II, one calculates ΔF°_f for Tc_3O_4 to be −206.1 ± 0.4 kcal/mole. [The hybrid compounds, Tc_3O_4 and Tc_4O_7, are written in the anhydrous form, partly for simplicity and also because Feitknecht showed clearly that Fe_3O_4 is formed as magnetite in the incomplete oxidation of $Fe(OH)_2$ in aqueous media (15).]

The metastability of the Tc-$Tc(OH)_4$ couple accords with the potentials of the other couples given, in that several spontaneous reactions are possible. Experiments in which elementary technetium was polarized anodically in H_2SO_4 showed that it first forms a film of TcOH and becomes essentially passive when this film is complete. It is this low reactivity of the passivated metal which permits couples containing two hydroxides to be established reversibly. The potential V°_H = 0.516V spontaneously reached slowly in numerous experiments is seen to be very close to the value calculated for the Tc(II-IV) couple, but 100 mV lower than that for the Tc(III-IV) couple. The assignment of this value to the Tc(II-IV) couple is therefore unambiguous and entirely consistent with the free energy of $Tc(OH)_2$ derived from the Tc(0-II) couple. The free energies of $Tc(OH)_2$, $Tc(OH)_3$, and Tc_3O_4 are such that the hybrid oxide is stable, but apears to be formed only slowly.

The standard potentials of Table III indicate the possible disproportionation only of $Tc(OH)_3$, under the conditions of the experiments. Values for couples (n) and (p) show that its conversion to Tc_3O_4 and $Tc(OH)_4$ would have a free-energy change of only −0.9 kcal/mole, however, and the fact that electrode potentials involving this component were obtained in 29 instances suggests that such a kinetically complex reaction does not occur readily. For TcOH, the situation is just the reverse. Disproportionation to Tc and $Tc(OH)_2$ is disfavored by the small free-energy change of +0.9 kcal/mole. It is to be emphasized, however, that all the measured potentials for TcOH relate to the surface film. It is entirely conceivable that loss of stabilization by surface forces could result in a change in the sign of the free-energy change and instability for material in bulk. The data show that $Tc(OH)_2$ is moderately stable with respect to disproportionation. $Tc(OH)_4$, of course, is a very stable compound (5).

The sluggishness of the solid-state reactions in the film accounts for the observation of a potential for the $Tc(OH)_3$-$Tc(OH)_4$ couple, although it is indicated that Tc_4O_7 may result as a stable phase. The Tc(III-IV) couple was definitely established in several experiments in which the stable potential was approached from both higher and lower potentials.

Spontaneous ennobling of electrodes.—The spontaneous ennobling of the potential of a technetium electrode coated with $Tc(OH)_4$ turned out to be a special case of a quite general behavior. This was further investigated by starting with technetium electrodes which were so treated as to be free of oxide film or else reduced below the potential of the Tc-TcOH couple and then left in the cell with helium passing. In 1*N* H_2SO_4 with H_2 passing initially, such an electrode indicated the reversible hydrogen couple potential (HEV) identically with a platinum electrode. This is shown at point *a* in curve A Fig. 3,

where hydrogen was passed for 25 min before being replaced by helium. Completion of the TcOH film in helium was indicated by a 30 min halt at the potential of the Tc-TcOH couple at *p*H 0.35, after which the potential rose slowly until it stabilized at the value provisionally assigned to the TcOH-Tc_4O_7 couple.

Results of this kind necessitate some oxidation process. Although the H cell in which the experiments were conducted was believed to be adequately protected from access of air, further experiments were carried out to eliminate this possibility more certainly. For this purpose, a miniature cell (25 ml) was constructed to contain the experimental electrode, a platinized platinum electrode, a silver-silver chloride reference electrode, and inlet and outlet tubes for gas. This cell was then mounted in a jar through which helium passed. In starting an experiment, the electrolyte (1*N* H_2SO_4 containing 10^{-3} *N* HCl) was boiled and cooled in helium to expel air just prior to its introduction into the cell. Hydrogen was passed briefly to insure that the electrode was at an active potential. In numerous experiments with this cell, the spontaneous ennobling still proceeded, an example being given by curve B in Fig. 3. In this case, the electrode came quickly to the corrosion potential in 1*N* H_2SO_4 in helium (average value −246 mV SCE) and ennobled slowly as the film of TcOH formed. It is seen that much more rapid ennobling followed passage through the potential of the Tc(0-I) couple, until a stable potential corresponding to the $Tc(OH)_2$—Tc_3O_4 couple was reached. It can only be concluded that the behavior does not depend on access of air into the cell.

Discussion

The number and reproducibility of the more or less stable potentials observed and the close agreement of one of these with the value derived from the calorimetric result for the Tc-$Tc(OH)_4$ couple are sufficient evidence of the reliability of the electrochemical measurements. It is also clear that the approximations from Fig. 2 are a valid basis for identification of the various couples in terms of components of a film in which technetium has valencies less than 4+. The possibility of changing the components in the film by both cathodic and anodic polarization was repeatedly demonstrated, and in only a few instances did the potential fail to come ultimately to one of the numerous calculated couple potentials.

The fact that the potential of the Tc-$Tc(OH)_4$ couple is measurable does not imply a four-electron process. Depending on the conditions under which a film is formed cathodically from a pertechnetate, the film may contain the lower hydroxides as well as $Tc(OH)_4$. Since potentials were observed for couples containing each valence state coupled by a one-electron change with another, these kinetically preferred couples may be regarded as forming cells in series, so that the measured potential will be that of the strongest reducing agent (Tc) coupled with the strongest oxidizing agent (Tc-IV).

Furthermore, the spontaneous shifts of the potential in the noble direction may be accounted for by reactions among the different hydroxides, in view of the demonstrated low reactivity of the metal. The unknown and undoubtedly very complex kinetics of these processes precludes any detailed analysis, but one example may be chosen as a possible illustration. Thus, a technetium electrode (plated on platinum) was subjected to a variety of polarizations in the noble region, after which it was reduced cathodically until it established the Tc-$Tc(OH)_2$ potential. Ennobling set in up to the potential of the $Tc(OH)_2$—$Tc(OH)_3$ potential. This halt was confirmed by brief cathodic and anodic displacements of the potential. Following this halt, a further slow drift to more noble potentials set in. The standard potentials in Table III show that an electrode containing $Tc(OH)_2$ together with either $Tc(OH)_3$ or $Tc(OH)_4$ is only metastable. Thus, if the free energies are expressed as volt-Faradays

$$3Tc(OH)_2 \rightarrow Tc_3O_4 + 2H_2O + 2H^+ + 2e^-; \quad \Delta F^\circ = 0.468 \text{ VF}$$

$$2Tc_3O_4 + 10H_2O \rightarrow 6Tc(OH)_3 + 2H^+ + 2e^-; \quad \Delta F^\circ = 1.536 \text{ VF}$$

$$Tc(OH)_2 + 2Tc(OH)_3 \rightarrow Tc_3O_4 + 4H_2O; \quad \Delta F^\circ = -0.356 \text{ VF} = -8.2 \text{ kcal}$$

If $Tc(OH)_3$ were in excess, the potential could rise from that of the $Tc(OH)_2$—$Tc(OH)_3$ couple (V°_H = 0.412V) to that of the Tc_3O_4—$Tc(OH)_3$ couple (V°_H = 0.768V).

Such solid-state reactions cannot be the sole reason for the spontaneous ennobling, however, for the initial presence of a film containing technetium in a valence higher than 1+ is requisite. Similar ennobling was demonstrated in experiments like that illustrated in curve B of Fig. 3. Here the electrode was drastically reduced prior to the experiment, and yet the rise of potential ensued. It seems necessary to consider the possible effects of the radioactivity of technetium. This is a beta activity of 0.3 MeV maximum energy with a specific activity of 16 μC/mg. It is reasonable to assume a radiolytic *g* factor of 2 for production of hydrogen and hydroxyl radicals in 1*N* H_2SO_4. The reaction is reversible, but the formation of OH at the surface of the metal or one of the hydroxides, while the accumulation of hydrogen is minimized by the gas stream, creates conditions favorable for consumption of hydroxyl by oxidation of the surface. From the data given above, it may be calculated that a single layer of close-packed technetium atoms ($\sim$1.4 x 10^{15}/cm^2) will produce 8 x 10^5 OH radicals per sec per cm^2. The range of the beta particles in the metal is of the order of 10^6Å, or something like 4 x 10^5 atomic layers. Self-absorption, back scattering, recombination of radicals, *etc.*, make a close calculation impossible, but if even a small fraction of the total disintegrations within range of the surface is radiolytically active it follows that self-oxidation of the interface is definitely possible as a slow process.

Possible confirmation of this interpretation may be seen in the observation that the platinum electrode responded fully to replacement of helium by hydrogen in some experiments like those of Fig. 3 only after renewal of the electrolyte in the cell. The oxidant, presumably H_2O_2, would be expected to polarize the technetium potentials also, but this was avoided by replacing the electrolyte in case a long exposure had been necessary to establish the potential.

It is possible that the somewhat surprising formation of discrete solid phases in the film is also a consequence of the radioactivity, which may act to aid the nucleation of stoichiometric components from a film of mixed composition.

Summary

It has been shown that elementary technetium gives reversible electrode potentials when it is electrolytically coated with a film of hydrous oxide. By utilizing an empirical correlation between the valence of the cation and the free energy of formation of the oxides of a given metal in different valence states, it was possible to assign the numerous stationary or metastable potentials observed to definite couples containing technetium in valence states less than 4+. In this way, free energies of formation of TcOH, $Tc(OH)_2$, $Tc(OH)_3$, $Tc(OH)_4$, Tc_3O_4, and Tc_4O_7 in films were established directly. It is suggested that the radioactivity of technetium plays a role in the observations.

Electrochemical Hydrogenation of Ethylene, Acetylene, and Ethylene-Acetylene Mixtures

H. James Davitt[1] and Lyle F. Albright

School of Chemical Engineering, Purdue University, Lafayette, Indiana 47906

ABSTRACT

The electrochemical hydrogenations of ethylene, acetylene, and ethylene-acetylene mixtures were investigated on a platinum cathode as a function of applied potential (0.23V to −0.05V NHE), temperature (25°, 40°, and 55°C), and reactant partial pressures (0.01 to 1 atm) using 2*N* H_2SO_4 as the electrolyte. The principal products of the reactions were ethane and ethylene (from acetylene). Methane formation sometimes occurred at 40° and 55°C. The selective production of ethylene from acetylene or from an ethylene-acetylene mixture generally increased with temperature, acetylene partial pressure, and potential. The hydrogenation of acetylene or ethylene-acetylene is often controlled by the amount of electrically discharged hydrogen atoms at the cathode surface. The rate determining step in the hydrogenation of ethylene may be either mass transport of ethylene or surface kinetics.

Electrochemical hydrogenation of ethylene or acetylene has been investigated to only a limited extent (1-5), and the mechanisms of the reaction are not well understood. Catalytic hydrogenations of these compounds although investigated more thoroughly also involve a complicated mechanism which is not completely understood (6-15).

Langer and Landi (1, 2) reduced electrochemically several unsaturated hydrocarbons in a continuous flow reactor. Reactants in their system were minimally soluble in the electrolyte to avoid diffusion between the anode and the cathode chambers. This restriction resulted in a slow rate of reduction, which is undesirable for a commercial reactor that needs a high rate of mass transport of reactants to the electrodes.

Burke *et al.* (3, 4) report that the rate of ethylene hydrogenation in HCl and NaOH solutions at 25° and 50°C on platinum or palladium electrodes is limited by the supply of electrically discharged hydrogen ions at potentials which are more positive than about 0.08V (NHE) and by the diffusion of ethylene at potentials less than about 0.08V. Their results for the hydrogenation of acetylene were rather preliminary however. Ethylene and acetylene were reduced in a batch system by Beloslyudova and Sokol'skii (5) using platinum electrodes immersed in sulfuric acid. Possible accumulation of reaction products affected their kinetic data.

[1] Present address: Sun Oil Company, Marcus Hook, Pennsylvania 19061.

Key words: fuel cells, platinum, kinetics, catalyst poisoning.

Hydrogenations of ethylene, acetylene, and ethylene-acetylene mixtures were examined in the present investigation as a function of applied potential, temperature, and reactant partial pressure. The rate data indicate the most likely reaction mechanism and the probable reactive surface species.

Equipment and Operating Procedure

The electrochemical reactor used is shown in Fig. 1. The Plexiglas cell consisted of three parts sealed by silicone rubber gaskets: an electrolyte reservoir, a support for the electrodes and filter paper, and a gas cap. The bottom section (H_2SO_4 reservoir) consisted of three subsections which were connected hydrodynamically. A liquid bridge connected the reactor to a reference saturated calomel electrode in a separate constant temperature bath at 30°C. The electrodes employed were American Cyanamid Type AA-1 matrix fuel cell electrodes which were Teflon-bonded tantalum screens impregnated with platinum (16). The electrodes were supported by a Plexiglas sheet and were wetted from the bottom by filter paper dipped into the electrolyte of each subsection. The top of each electrode was exposed to the flowing gas stream. A platinum wire was spot welded to each electrode and extended outside the reactor. The gas cap contained three compartments each of which covered an electrode and corresponded to a subsection in the electrolyte reservoir. The middle electrode (1 x 2 in.)

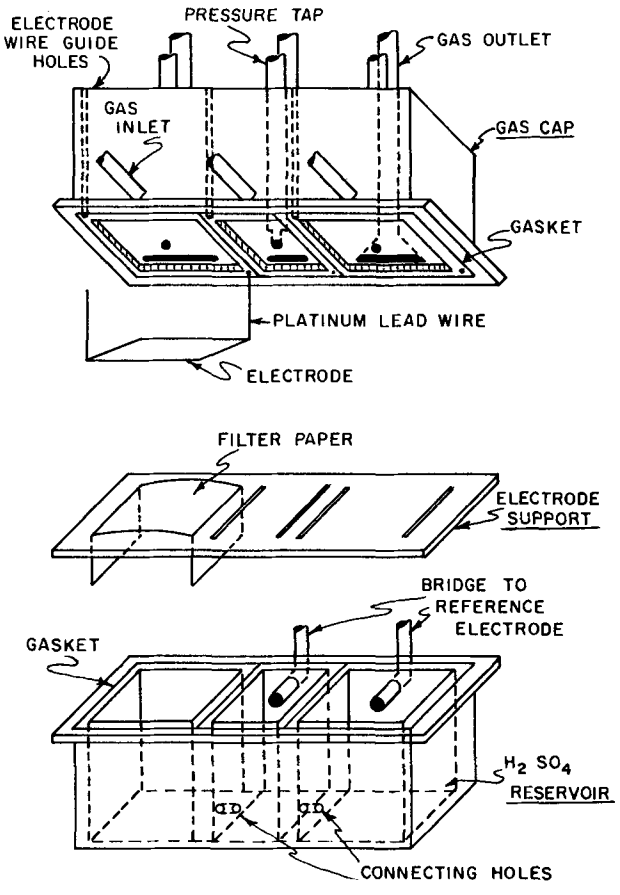

Fig. 1. Reactor design

was used as the anode and the two outside electrodes (each 2 x 2 in.) as the cathodes. The reactor was positioned in a constant temperature bath which was maintained at ±0.01°C of the desired temperature.

The electrolyte was 2*N* H_2SO_4 prepared from reagent grade sulfuric acid. The reactant gases obtained from Matheson Company were electrolytic grade hydrogen, c.p. grade ethylene, and purified acetylene. The hydrogen was purified with a catalytic converter to remove traces of oxygen. The acetylene was contacted with activated alumina and silica gel to remove traces of acetone. Ethylene, acetylene, and helium were each bubbled through pyrogallol solution to remove traces of oxygen, dried in a Drierite column, and then passed through a H_2SO_4 solution at reactor temperature.

Gas flow rates to the reactor were maintained at approximately 20 cc/min. Purified helium was used as a diluent in the feed gas stream for many runs, and the total gas pressure in most runs was about 760 mm Hg.

The potential of the cathode was controlled using a potentiostat to within 0.002V, and the current was continuously recorded. A saturated calomel electrode was used as reference electrode and all potentials were measured with respect to this electrode and were then adjusted to the open-circuit potential of the hydrogen electrode at the operating temperature. Potentials reported here are referenced to this normal hydrogen electrode at the operating temperature. A Perkin-Elmer Gas Fractometer with a silica-gel and activated alumina column was used to analyze the organic streams.

The following procedure was found necessary to obtain reproducible current results in each run. After approximately 4 hr of helium purging at electrical open circuit, the potential of the cathode was adjusted to 1.5V for 10 min followed by 5 min of 0.0V. This cycle of potential adjustments was repeated two additional times for runs with ethylene, and three times for runs with acetylene (since the acetylene was more strongly adsorbed on the cathode). The potential was then adjusted to 0.4V and maintained there for approximately 10 hr. The potential was once again cycled to 1.5V for 5 min and returned to 0.4V (twice in the case of acetylene) until the start of the next run (75 min).

At the start of each run after the reactant gas flows had been established, the polarization of the cathode at 0.4V was stopped, and the change in open-circuit potential with time was recorded for 1 hr. At the end of 1 hr, a potential was applied to the cathode (usually 0.23V) and the change in current with time was recorded for 1 hr. The potential was then adjusted in steps each hour to 0.20, 0.15, 0.00, 0.05, 0.00, and −0.05V. Gas chromatographic samples of the exit organic stream were taken during the 1 hr period at open circuit and at the end of each succeeding hour just before the potential change. After 1 hr at the last potential studied (−0.05V), the circuit was again opened and the change in open-circuit potential with time was recorded for 1 hr.

Open-Circuit Potential Behavior

Rest potentials at start-up.—Upon contact of the cathode with the unsaturated hydrocarbon, the open-circuit potential decreased rapidly during the first 5 min from 0.4V (where it had been maintained potentiostatically), sometimes passed through a minimum, and generally rose after several additional minutes to within 0.010V of the rest potential which was obtained after 1 hr, as reported in Table I. The rate of change of the open-circuit potential was usually less than 0.005 V/hr at the end of the 1-hr period. Exceptions were runs either with low partial pressures of ethylene (the remainder helium) at 25°C or with low partial pressures of acetylene (the remainder helium) at 25° and 40°C. In these cases, the open-circuit potential was changing as much as 0.070 V/hr after 1 hr.

Gas chromatographic analyses of the exit organic gas stream showed that dehydrogenation-hydrogenation reactions and cracking of the reactants were occurring during the open-circuit runs as indicated below:

1. Ethylene equilibrations. Ethane and methane were produced at rates which decreased with time in the 1-hr runs. Higher concentrations of methane and ethane were generally found in runs at low ethylene partial pressure (P_E) than at high pressures, at 55°C than at 40° or 25°C, and with a new cathode than an old one.

2. Acetylene equilibrations. Generally, ethylene concentrations increased with decreased acetylene partial pressures (P_A) and with increased temperature. Ethylene concentrations decreased during the 1-hr period. Only trace quantities of ethane were found at 40° or 55°C; whereas, at 25°C the concentra-

tion of ethane increased with decreased acetylene partial pressure. Methane was never detected.

3. Equilibrations for ethylene-acetylene mixtures. No significant production of ethane or methane was detected under any conditions.

Open-circuit potential after obtaining rate data.— After the rate data were obtained, generally ending at —0.05V, the circuit was opened. The potential usually increased asymptotically to within about 0.04V of the rest potential after 15 min, as indicated by curve 1 of Fig. 2.

An inflection point sometimes occurred in the curve of potential *vs.* time at a potential near 0.0V and less than 12 sec after cessation of polarization (curves 2 and 3, Fig. 2). Immediately after the inflection point, the potential increased asymptotically toward its rest potential. The phenomena occurred in the following runs:

1. All ethylene runs at 55°C except those in which an unusual rapid current increase occurred prior to the cessation of polarization (to be discussed later), and for the first few runs at 40°C immediately following a run at 55°C.

2. Acetylene runs at 55°C for low acetylene partial pressures and the second consecutive run at 40°C for low acetylene partial pressures. Exceptions to the above also occurred when an unusual rapid increase in current occurred prior to the cessation of polarization.

3. Runs at 55°C using ethylene-acetylene mixtures having an acetylene partial pressure of approximately 17 mm Hg (ethylene partial pressure of 761 mm Hg).

Discussion of Open-Circuit Results

The ethylene and acetylene rest potentials reported in Table I are generally consistent with comparable results reported by Wroblowa *et al.* (17) and Johnson *et al.* (18). The suggestion has been made (19-22) that the rest potentials obtained by organic compounds in contact with platinum electrodes are caused by dissociative adsorption (dehydrogenation) followed by equilibration of the adsorbed hydrogen with the solution. The slow increase of the open-circuit potential with time ($\sim$ 0.005 V/hr) probably indicates a decrease of the surface concentration of hydrogen. Dissociative adsorption likely occurred only at sites with a high energy for adsorption or at sites which had adjacent empty sites. As these sites became covered or poisoned with residual hydrocarbon or carbon species, dissociative adsorption was slowly displaced by associative adsorption. The decreasing rates of dehydrogenation and cracking with time during these equilibrations tends to support this postulate.

As discussed above the establishment of the organic rest potential is a dynamic equilibrium between hydrogenation and dehydrogenation. The rate of obtaining this equilibrium is retarded by low temperatures and low organic partial pressure because in these cases stable rest potentials were not established even after 1 hr.

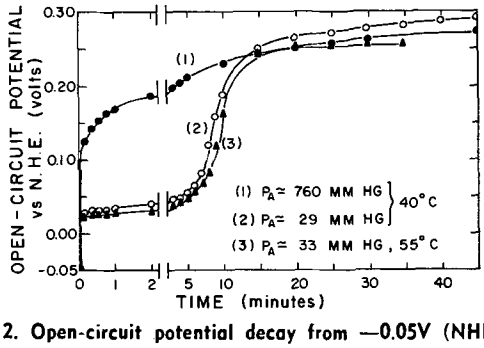

Fig. 2. Open-circuit potential decay from —0.05V (NHE), after obtaining acetylene rate data, *vs.* time.

It is reasonable to expect as a rule more ethylene dehydrogenation than acetylene dehydrogenation; consequently the ethylene rest potential should be the less positive one because of higher hydrogen concentrations. The ethylene rest potential changed little with temperature, indicating that the activation energies for dehydrogenation and hydrogenation were approximately the same. For acetylene, however, the activation energy for dehydrogenation may be higher than hydrogenation since its rest potential decreased with increased temperature.

Current-Time Behavior

The current-time behavior was extensively investigated for the hydrogenations of ethylene, acetylene, and mixtures of them. Immediately after the potential was decreased, a current surge occurred and then the current began to drop. Generally the rate of decay was small after 1 hr, and higher currents occurred at lower potentials. Such results which were noted in most runs are shown in the following figures for the indicated reactants:

1. Ethylene: Fig. 3; curves 1 and 2.
2. Acetylene and ethylene-acetylene mixtures: Fig. 4; curves 1, 2, and 3.

Different types of current-time behavior were found at these conditions:

1. Ethylene (see Fig. 3): At 55°C and at potentials between 0.10 and —0.05V. The very rapid initial current decrease, such as shown by curve 4, always followed a behavior as shown by either curves 3 or 5. The inflection point in the decay of open-circuit potential (see Fig. 2) only followed a series of runs in which curve 3 appeared but not curve 5.

2. Acetylene (see Fig. 4): At 55°C or the second consecutive run at 40°C all at low partial pressures and at potentials between 0.10 and —0.05V. Two maximums were observed in the decay curve at 0.10V (curve 4) for the second consecutive run at 40°C instead of only one maximum for the first such run (curve 2). Subsequent potential changes produced curve 5 which shows a very rapid current decrease from the initial current peak.

3. Ethylene-acetylene mixtures: similar to acetylene runs.

Methane was noted at the end of the hour period in which the unusual current decay phenomena described above occurred (curve 5 of Fig. 3 and curve 4 of Fig. 4). Subsequent gas samples usually also contained some methane. Figure 5 illustrates the changing exit gas composition with potential during Run No. 3-6 shown in Fig. 4. No methane was detected during this run, but in the next run, Run No. 3-7 which was made at duplicate operating conditions and which was made immediately after Run No. 3-6, methane first appeared at a potential of 0.10V, increased by fivefold at 0.05V

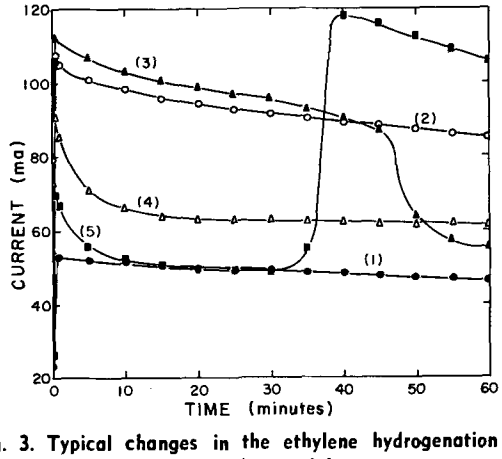

Fig. 3. Typical changes in the ethylene hydrogenation current *vs.* time as a function of applied potential.

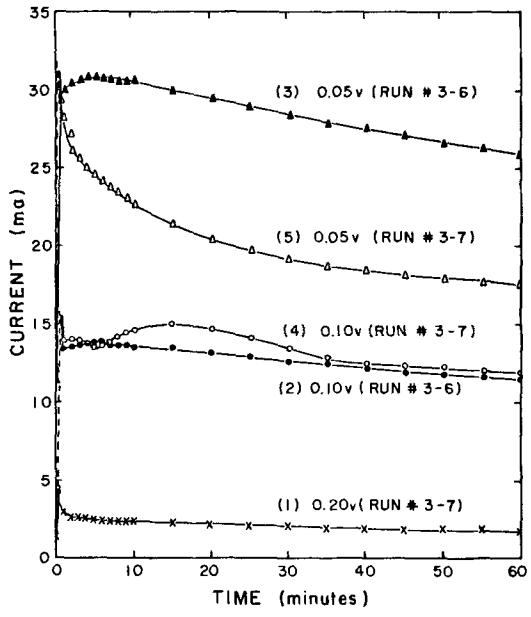

Fig. 4. Typical changes in the current produced during acetylene hydrogenation vs. time as a function of applied potential.

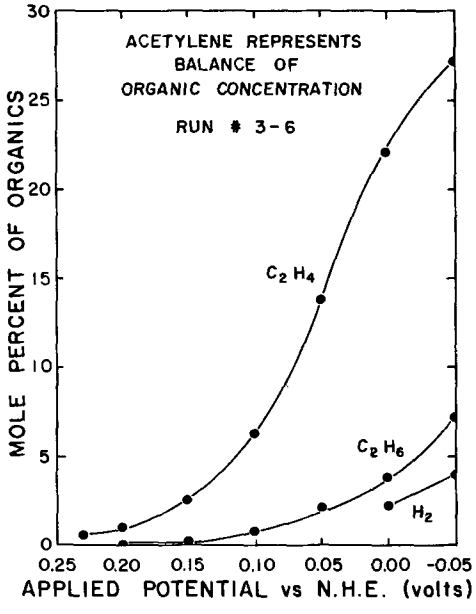

Fig. 5. Exit organic gas composition of acetylene hydrogenation vs. applied potential at 40°C and an acetylene partial pressure of 29 mm Hg.

to about 0.2% concentration, and then decreased to about the same level at 0.00V as at 0.10V. Only a trace of methane was found at −0.05V. Somewhat greater amounts of ethane were produced in the range from 0.05 to 0.10V in Run No. 3-6 as compared to Run No. 3-7, and considerably more hydrogen was obtained in Run No. 3-7. Hydrogen concentrations varied from 5 to 14% as the voltage varied from 0.00 to −0.05V for the latter run. Ethylene concentrations in Run No. 3-7 were in general significantly lower, reaching only 14% at −0.05V. Hydrogen was generally produced at 0.00V and/or −0.05V during runs in which acetylene was a reactant but never in runs in which ethylene alone was a reactant.

Rates of Hydrogenation

Ethylene runs.—Average rate data (currents) for the hydrogenation of ethylene at two partial pressures and 25°, 40°, and 55°C are shown in Fig. 6 as curves 4 through 7. These data, obtained at the end of 1 hr at a given potential, were generally reproducible

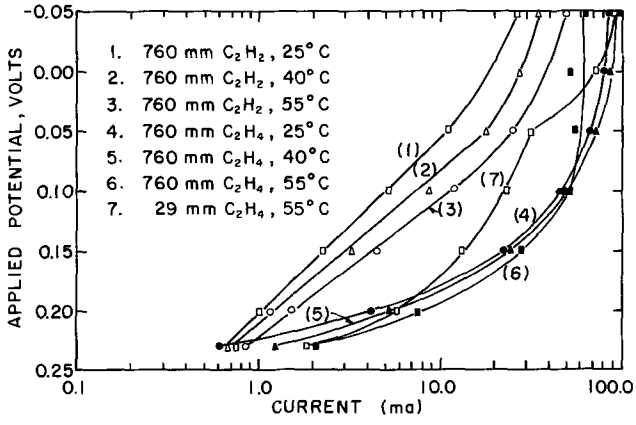

Fig. 6. Current produced during acetylene and ethylene hydrogenation vs. applied potential as a function of reactant partial pressure and temperature.

to within 10% of the average value of 3 to 5 replicate runs. Calculations indicated that the current noted was caused by the simple reduction of ethylene to ethane. The results of these runs are summarized as follows:

1. The logarithm of the current increased for all runs at 25° and 40°C at a decreasing rate with respect to the applied potential. At 55°C and P_E of about 29 mm Hg, however, the current passed through an inflection point as a result of the wide variance in currents as discussed earlier; no significant portions of these curves were found to be linear.

2. Ethylene partial pressure was found to have no significant effect on the rate of hydrogenation at either 25° or 40°C. Currents did increase with increased ethylene partial pressure at 55°C between 0.23V and 0.05V. At 0.00V and −0.05V, the results were inconclusive because of the wide variation in currents as previously noted.

3. At high ethylene partial pressures, the rate of reaction increased with increased temperatures between 0.23V and 0.10V, but between 0.05V and −0.05V, the order of increasing rates was 55°, 25°, and 40°C. At low ethylene partial pressures, the order of increasing rates was also 55°, 25°, and 40°C except at 0.23V and 0.20V. The apparent activation energy for the high partial pressure runs at 0.23V was approximately 8 kcal/mole, but it decreased to about 0.6 kcal/mole at 0.10V.

Acetylene runs.—The results of acetylene hydrogenations at potentials between 0.23V and −0.05V, temperatures of 25°, 40°, and 55°C, and high acetylene partial pressures are shown in Fig. 6 as curves 1 through 3. Reproducibility of these data was generally within 10% of the average value at each experimental condition. Calculations indicated that the current generated was accounted for within 10% by the reduction of acetylene to ethylene and ethane and by the evolution of hydrogen.

A linear relationship existed between the potential and the logarithm of the current between 0.23V and 0.05V for most acetylene runs. Exceptions were the second consecutive run at 40°C and all 55°C runs at low acetylene partial pressures where the linear region was between 0.23V and 0.10V. The data (100 data points) in the linear region were correlated using regression analysis. Only variables with a probability level greater than 97% were retained, and the following equation correlates the data with a correlation coefficient of 0.995 corrected for the mean

$$\ln i = 89.7 + 0.78\,(\ln P_A) - 48.4(E) - 1408.8/(T) - 276.5(\ln P_A)/(T) + 9609.7\,(E)/(T) \quad [1]$$

or

$$i = (\text{antiln } 89.7)\,(P_A)^{(0.78\,-\,276.5/T)} \exp\,[\,-48.4(E) - 1408.8/(T) + 9609.7(E)/(T)\,] \quad [2]$$

Table II. Acetylene hydrogenation kinetic constants

Temperature, °C	b′	γ	βn
25	142 mV ± 4*	−0.15 ± 0.03*	0.42 ± 0.02*
40	130 ± 4	−0.10 ± 0.03	0.48 ± 0.02
55	120 ± 4	−0.06 ± 0.03	0.54 ± 0.02

* 2σ limits.

where P_A = average partial pressure of acetylene (mm Hg), E = potential *vs.* NHE (volts), and T = temperature, °K.

"Tafel" slopes (b′), listed in Table II, were calculated at each temperature from

$$\frac{1}{b'} = \frac{\partial \log i \times 10^{-3}}{\partial E} = \frac{1}{2.3}\left[-48.4 + \frac{9609.7}{T}\right] \times 10^{-3} \quad [3]$$

Acetylene partial pressure had no significant effect on the value of b′.

The current increased with decreased acetylene partial pressures at potentials between 0.23V and 0.05V (or 0.10V) at all temperatures. Equation [4] was used to calculate the effect of acetylene partial pressure on the reaction rate

$$\frac{\partial \ln i}{\partial \ln P_A} = \gamma = 0.78 - 276.5/T \quad [4]$$

Values of γ (see Table II) indicate that the acetylene partial pressure had less effect on the rate at higher temperatures. An extrapolation of Eq. [4] indicates that γ is zero at about 80°C.

Apparent activation energies were calculated for the hydrogenation of acetylene using all the terms involving temperature in Eq. [1]. The standard Arrhenius form for calculating activation energies is as follows

$$i = K\,[\exp(\Delta H^*/RT)] \text{ or } \ln i = \ln K + \Delta H^*/RT \quad [5]$$

Therefore, equating terms with $(T)^{-1}$

$$\Delta H^*/R = -1408.8 - 276.5(\ln P_A) + 9609.7(E) \quad [6]$$

The resulting ΔH^* are listed in Table III as a function of potential and at P_A = 760 mm Hg. Equation [6] shows that at a constant potential ΔH^* decreases with a decreased partial pressure of acetylene.

The first attempt at correlating the acetylene data of the linear regions of curves 1 through 3 of Fig. 6 using a model more consistent with traditional "Tafel" models was unsuccessful. The model tested was the following

$$i = B_1 \times (P_A)^{B_2} \times \exp(B_3 E/T) \quad [7]$$

where $B_3 = \beta n\mathbf{F}/R$ and β is the transfer coefficient, $\mathbf{F}$ is the Faraday constant, and R is the gas constant. This model was unsuccessful because the "constant" βn, was not constant but varied linearly from 0.42 to 0.54 with increased temperature as shown in Table II.

Selectivity (S) for acetylene reductions is defined as the ratio of ethylene production to the total ethylene plus ethane production. The change in S with acetylene partial pressure, temperature, and applied potential is illustrated in Fig. 7. Calculated values of S were within ± 0.04 and often within ± 0.01 of the average value for a constant potential. In general, S increased with increased acetylene partial pressure and temperature; a similar finding for normal catalytic hydrogenations of acetylene has been previously reported (8). S also increased with increased potential. The pronounced minimums shown in curves 5 and 7 are related to the unusual current phenomenon discussed in connection with Fig. 4 and 5, *i.e.*, the history effect of the second consecutive run at 40°C and 55°C runs at low acetylene partial pressures.

Table III. Apparent activation energies (ΔH^*) for acetylene reduction at P_A = 760 mm Hg

Potential *vs.* NHE, V	ΔH^*, kcal/mole
0.05	5.5
0.10	4.5
0.15	3.6
0.20	2.6

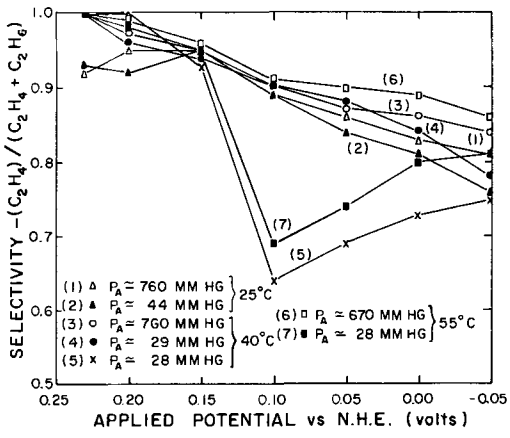

Fig. 7. Selectivity of acetylene hydrogenation to ethylene *vs.* applied potential as a function of temperature and acetylene partial pressure (P_A).

Essentially no ethane was formed during any run at either 40° or 55°C and a potential of 0.23V. Some ethane was formed at 25°C but its concentration varied widely; therefore, the very small increase in S between 0.23V and 0.15V may not be significant.

Runs with ethylene-acetylene mixtures.—The effects of potential and temperature on the rate of hydrogenation of ethylene-acetylene mixtures of high and low partial pressures respectively are shown in Fig. 8. The reproducibility of these data (three runs at each condition) was generally within 10%. One preliminary run was also made at very low acetylene partial pressures ($P_A \simeq$ 5-17 mm Hg) at each temperature to determine the general effect of very low acetylene partial pressures on the rate of hydrogenation.

Plots of the potential *vs.* the logarithm of current had a linear region between 0.23V and 0.10V at all temperatures. The logarithm of the current below 0.10V increased at an increasing rate.

The following empirical equation correlated the data of the linear region (48 data points) with a correlation coefficient of 0.996 corrected for the mean

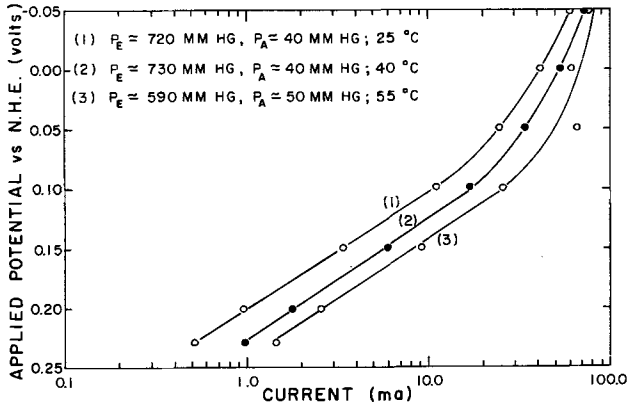

Fig. 8. Current produced during ethylene-acetylene hydrogenation *vs.* applied potential as a function of temperature.

$$\ln i = 15.85 - 0.06\ (\ln P_A) - 23.05(E) - 3261.8/(T) \quad [8]$$

or

$$i = \text{antiln}(15.85) \times (P_A)^{-0.06} \times \exp[-23.05(E) - 3261.8/(T)] \quad [9]$$

Interactions between these variables and also ethylene partial pressure were eliminated with probability levels less than 97%.

The "Tafel" slope (b') calculated from Eq. [8] was independent of temperature and organic partial pressure and was equal to 100 mV ± 3 (2σ limits).

Increased acetylene partial pressure decreased the reaction rate as shown by Eq. [9]. The exponent of P_A varied with 2σ limits of ± 0.03. A single apparent activation energy of 6.5 kcal/mole ± 0.5 (2σ limits) was calculated by equating the temperature term of Eq. [8] to the temperature term in the Arrhenius equation (Eq. [5]).

The actual conversion of acetylene to ethylene and ethylene to ethane could not be calculated because of the large error involved in subtracting two numbers of essentially equal size (acetylene or ethylene concentrations). Therefore, the actual selectivity (S) could not be calculated. The maximum S, S_{max}, and the minimum S, S_{min}, could be calculated however. S_{max} was calculated by assuming that all the ethane produced was from the ethylene feed. S_{min} was calculated by assuming that all the ethane was produced from the acetylene feed. S_{max} values were usually reproducible to within 0.05 of the average for three repeat runs, and decreased from about 0.97 to 0.71 as the potential decreased from 0.25 to −0.05V. S_{min} values decreased over the same potential range from about 0.93 to 0.43. In general selectivity increased slightly from 25° to 40°C. The selectivity at 55°C was lower than that at 40°C and at potentials less than 0.15V.

Discussion of Mechanisms and Rates of Hydrogenation

Ethylene hydrogenation was not apparently limited solely by either kinetics or mass transport of reactants. Kinetics controlled at low reaction rates because the rate increased more than two orders of magnitude and was generally unaffected by ethylene partial pressure. The reaction rate approached a constant value at high rates indicating a mass transport limit.

The results of this study support the following electrolytic reduction mechanism for acetylene between 0.23V and −0.05V

$$C_2H_{2soln} + (*) \rightleftharpoons \underset{*}{C_2H_2}$$

$$(*) + H^+ + e^- \rightleftharpoons \underset{*}{H}$$

$$\underset{*}{C_2H_2} + \underset{*}{H} \rightleftharpoons \underset{*}{C_2H_3} + (*)$$

$$\underset{*}{C_2H_3} + \underset{*}{H} \rightleftharpoons \underset{*}{C_2H_4} + (*)$$

The symbol (*) represents an active site and the second of the above reactions is the rate determining step (R.D.S.). This conclusion is drawn from the following data:

1. The negative effect of acetylene partial pressure on the rate and the zero pressure effect for ethylene hydrogenation indicate that neither acetylene nor any intermediate derived from it could be involved in the rate determining step.
2. Adsorbed hydrogen atoms are known to exist on platinum surfaces in contact with sulfuric acid electrolyte at potentials less than 0.4V which is within the potential range studied (23).
3. The predicted and observed "Tafel" slopes are in the same general range (100-140 mV).
4. The same reaction products resulted from open-circuit studies as from rate studies indicating that although the source of the hydrogen was different, the reactions were probably the same.

At potentials less positive than about 0.05V (high rates of reaction), the rate controlling step appears to be changing from kinetic control to mass transport control (see Fig. 6 and 8).

Associative adsorption of acetylene (and ethylene) is assumed to be the predominate mode of adsorption for the following reasons:

1. Associative adsorption is more energetically favorable than dissociative adsorption (17).
2. The correspondence (usually within 5% for ethylene hydrogenations and 10% for acetylene hydrogenations) between the rates of reaction calculated from gas chromatography and recorded currents which account for all the hydrogen used.
3. The decreasing rates of dehydrogenation and cracking during ethylene or acetylene equilibrations discussed earlier indicated a shift from dissociative to associative adsorption prior to each rate study run.

Apparent activation energies for the hydrogenation of acetylene of 5.5 to 2.6 kcal/mole at 0.05V and 0.20V respectively, although low, are similar to the values reported by Beloslyudova and Sokol'skii (5) of 6.6 kcal/mole in an electrochemical system and by Bond (8) of 9 kcal/mole for the usual gas phase chemical hydrogenation of acetylene on alumina-supported platinum between 40° and 96°C.

The driving force (ethylene partial pressure) for maintaining ethylene on the electrode surface was much greater in the hydrogenations of the mixtures than in pure acetylene alone. The rate of reaction, therefore, should change more, for a given potential change, in the hydrogenation of ethylene-acetylene mixtures than in the hydrogenation of acetylene alone: this was found experimentally [the acetylene "Tafel" slopes were larger than those of ethylene-acetylene (120-140 mV *vs.* 100 mV)].

Figure 9 emphasizes that acetylene in ethylene-acetylene mixtures, even in as low a concentration as 1.0% dominates the surface and controls the rate of reaction. The dominating effect of acetylene on the rate diminishes however as the potential decreases. Increased amounts of adsorbed hydrogen available at lower potentials and the slower rate of acetylene hydrogenation enables ethylene to compete more favorably with acetylene for the available hydrogen as indicated by lower selectivity for ethylene produc-

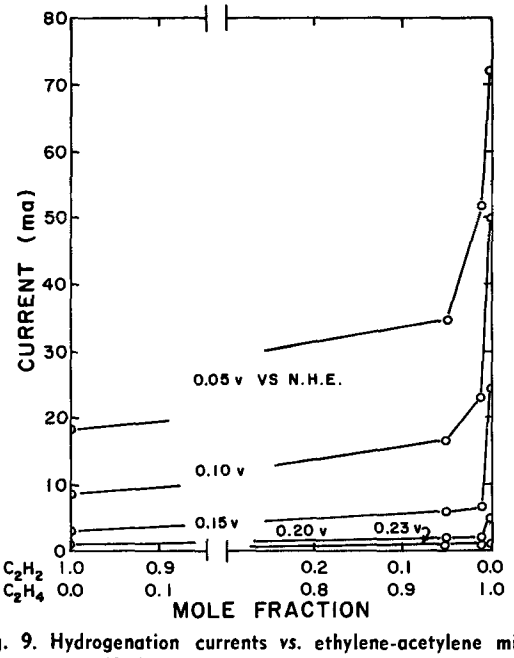

Fig. 9. Hydrogenation currents *vs.* ethylene-acetylene mixtures composition at 40°C and a total organic partial pressure of 760 mm Hg.

tion with decreasing potential (see Fig. 7 as one example).

Increased selectivity with increased temperature may be due to a higher activation energy for the desorption of ethylene relative to its hydrogenation (9) or to decreased hydrogen atom coverage because of increased acetylene coverage. Increased acetylene coverage with temperature is inferred from the findings of Gilman (24), which indicate that ethylene coverage increased with temperature. Since acetylene is more strongly adsorbed than ethylene, its coverage may also increase with temperature. Bond and Wells (8) reported similar selectivity findings for the chemical heterogeneous hydrogenation of acetylene.

Surface Species

The dominate reactive surface species during electrolytic hydrogenation, as mentioned earlier, are believed to be associatively adsorbed ethylene and acetylene and monatomic hydrogen. The "unusual" current-time behavior (Fig. 3 and 4) and open-circuit potential-time behavior (Fig. 2) are complex functions of potential, temperature, organic partial pressure and electrode previous history. These "unusual" behaviors are probably related to changes in the normal distribution of reactive surface species. For example, this redistribution of reactive surface species was in some way connected to the methane production observed during the rate studies. In addition the inflection point in the open-circuit potential curve (Fig. 2), which may be associated with the transient presence of hydrogen, occurred in runs similar to that of curve 7 of Fig. 6. Interestingly, the inflection point was not observed in at least one case each when it was expected for runs with ethylene, acetylene, or mixtures of the two. In each instance, however, a sudden current increase had occurred (curve 5, Fig. 3) at 0.00V or −0.05V prior to the end of the run. Apparently the reactive specie or species, which were responsible for the inflection point, were eliminated from the surface.

Redistributions of surface species at low acetylene partial pressures at 40° and 55° for acetylene-helium mixtures and ethylene-acetylene mixtures aided the rate of ethylene hydrogenation at the expense of acetylene hydrogenation. Sharp decreases in selectivity, therefore resulted at a potential of 0.10V where methane production first started.

Conclusions

The rates of hydrogenation of acetylene and ethylene-acetylene mixtures on platinum in sulfuric acid are limited by the supply of electrically discharged hydrogen ions between 0.23V and about 0.05V. At lower potentials the rate is limited by diffusion of reactants.

The controlling step in the reduction of ethylene in this investigation cannot be unambiguously defined as either mass transport of ethylene or an electrochemical kinetic step.

Ethylene and acetylene first adsorb dissociately on platinum in contact with an acid solution, but later adsorb associatively as the surface becomes "poisoned" with residual hydrocarbon species from the dehydrogenation and cracking reactions.

Selectivity for the production of ethylene from acetylene or ethylene-acetylene mixtures in general increases with increased temperature, increased acetylene partial pressure, and increased potential. Major redistributions of reactive surface species sometimes occurred under conditions of high temperatures and low acetylene partial pressures and potentials, which produced methane as a product and caused a sharp decrease in selectivity.

Anodic Dissolution of Beryllium in Anhydrous Media

H. Aida, I. Epelboin,* and M. Garreau

Physique des Liquides et Electrochimie, Groupe de Recherches du C.N.R.S. associé à la Faculté des Sciences de Paris, Faculté des Sciences, Paris V, France

ABSTRACT

When the residual water content of currently used ClO_4^- electropolishing solution is reduced to less than 0.1 g/l, the anodic dissolution of beryllium follows Faraday's law with a valence of one over an extended range of anodic potentials. This result is interpreted in terms of a dissolution mechanism occurring in a succession of two individual steps, each involving a simple electron, thus

$Be \rightarrow Be^+ + e^-$ (electrochemical step)
$Be^+ +$ oxidant $\rightarrow Be^{++}$ (chemical step occurring away from the electrode)

Support for the transitory existence of the monovalent ions is derived from thermodynamic considerations allied with the structure of the anodic layer. Microscopic examination of the state of the anode surface during and after the dissolution shows clearly that a mechanical disintegration of the metal lattice by the action of the current cannot be the origin of the anomalous valence observed. On the contrary, it is shown that disintegration of this type contributes only at low anodic potentials. This phenomenon, known as the "chunk effect," is clearly observable by scanning electron microscopy and accounts for faradaic "efficiencies" of greater than 200% in certain electrolytic conditions.

Since 1955 it has been known that the application of Faraday's law to the anodic dissolution of beryllium could lead to calculated anode weight losses which were lower than measured values (1-7).

Although, for more than a century now, a number of investigations has been devoted to the study of analogous effects on other metals, the origin of these anomalous dissolution valences remains very controversial. For some investigators, it consists of nothing more than a more or less incidental intervention of a side effect (difference effect, chunk effect[1]) (7-12). On the other hand, there are those who consider these discrepancies to be evidence, on a macroscopic scale, of a fundamental reaction process. This process, potentially applicable to all dissolution processes leading to multivalent ions, concerns the mechanism of the charge transfer at the metal/electrolyte interface and is proposed as a series of individual single electron steps (13-21). With this latter view, the systematic study of these "deviations" from Faraday's law provides an approach to a better understanding of the electrolytic dissolution of a metal, and thus, as pointed out specifically by Uhlig (22), also to the essential processes in metallic corrosion.

A metal such as beryllium has favorable characteristics for studying anodic dissolution in terms of these two different concepts of the anomalous valences. First, one can use it in the form of the usual industrial polycrystalline material, a form in which it ought to be more sensitive to the occurrence of difference, or chunk, effects, than a single crystal, since these effects are initiated by structure defects. Second, there are conditions, well known, in which Faraday's law will be rigorously followed if one uses a valence of one, a result conforming to that which would be expected, in the limit, if transitory Be^+ ions only are formed in the first step of the dissolution process.

The primary purpose of this paper is to establish the fundamental role played by solvation in the solution of a metal, which we propose should be an essential part of the theoretical study of this phenomenon. In particular, we shall show how these anomalous valences of dissolution may perhaps be due to an insufficiency of solvation molecules in the anodic layer, and to an insufficiency which leads to a local inversion of the relative thermodynamic stability of the ions Be^+ and Be^{++}. Following this we shall show, using results from studies of anodic dissolution in an anhydrous environment, and the complete range of faradaic efficiencies as established by observation of the anodic surface by the scanning electron microscope, that the two concepts of anomalous dissolution (intervention or not of transitory species of unusual valence) are in fact not irreconcilable, but may simply be alternately applicable in different experimental domains.

Theoretical

The concept that anomalous anodic dissolution valences must be a manifestation on a macroscopic scale of a reaction mechanism which must include the formation of monovalent ions as a first step has grown in acceptance at a rate proportional to the increase in examples of "abnormal" dissolutions. There has as yet, however, been no theoretical basis from quantum mechanical considerations to support this hypothesis. Since a quantum treatment of electron transfer at the metal/electrolyte interface in the presence of adsorption is not possible at the present time, we have looked toward using thermodynamic considerations, linked to the structure of the anodic layer, as a means of placing the participation of these transitory ions in the dissolution process on a sounder theoretical basis (19-23).

* Electrochemical Society Active Member.

Key words: dissolution anomalous valences, cation solvation, anodic dissolution efficiency, electrolytic polishing, microscope scanning electron.

[1] The "chunk effect" consists of the disintegration of the metallic lattice under the action of the electrolysis current; a heterogeneous dissolution on an atomic scale provokes a sort of "detachment" of little crystalline unities which are then carried into the solution. The particles thus detached from the metal are sometimes observed in the appearance of a dark coloration in the region of the anode. X-ray studies of these anode layers have shown the presence of particles of significant dimensions, i.e., several microns.

By "difference effect" is meant a modification, under the influence of the current, of the rate of self-dissolution of a metal in an electrolyte. This phenomenon originally was studied only for metals which were attacked by the solution at open-circuit potentials. However, the term "difference effect" has been used recently even in cases where the rate of chemical attack is zero in the absence of an external current. This effect is attributed to a loss of cohesion of the protective layer which isolates the metal from the environment, and which originates at certain defects in the structure of the metal (heterogeneous dissolution).

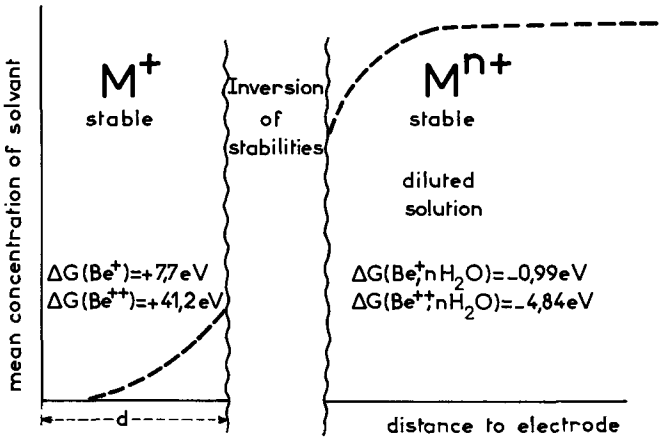

Fig. 1. Pictorial description of the relative stabilities of ions M^+ and M^{n+} in relation to distance to electrode.

These considerations may be summarized briefly using the pictorial description of the anodic layer as given by Fig. 1.

Starting from a concept first given by Epelboin and Darmois (14) in 1953, there exists at the anode a zone of low concentration of solvent molecules, created by the joint action of the electric field and the specific adsorption of anions from the solution. The solvent content then increases regularly with distance from the surface (dashed curve).

A calculation based on the Born-Haber cycle shows that, in the absence of solvation, it is the monovalent ion M^+ which, among all the possible ions which the metal can form, forms with the least energy. It is thus this ion which exhibits maximum stability in the immediate vicinity of the anode where the normal solvation is sharply restricted.

Figure 1 gives the values, for beryllium, of the free energies of formation,[2] ΔG, of the ions Be^{++} and Be^+ in the metal, in dilute aqueous solution [ΔG ($Be^{z+} \cdot n\ H_2O$)] and in absence of solvent [ΔG (Be^{z+})] (limiting case).

The monovalent ion is not stable thermodynamically except in the immediate vicinity of the electrode. As it migrates from the electrode it very rapidly reaches a zone sufficiently rich in solvent molecules that the electrochemical oxidation

$$Be^+ \cdot n\ H_2O \rightarrow Be^{++} \cdot n'\ H_2O + (n' - n)\ H_2O + e^- \quad \text{(from the metal)} \quad [1]$$

will proceed with a decrease in free energy.

There is thus an inversion of the thermodynamic stability in favor of the divalent ion. The distance d between the electrode surface and the zone of stability inversion depends on the electrolyte conditions. The electron involved in the electrochemical oxidation [1] must traverse the distance d to reach the electrode. Now, as the distance across which the charge transfer must take place increases, the rate of the transfer reaction will decrease very rapidly (24). In practice beyond a certain distance the ion M^+ can no longer be oxidized electrochemically. Thus, on arriving in the solvent rich zone, it will be oxidized chemically by reaction with some solution component

$$Be^+ \cdot x\ H_2O + \text{oxidant} \rightarrow Be^{++} \cdot x'\ H_2O + (x' - x)\ H_2O + \text{reduction products} \quad [2]$$

In the presence of perchlorate, for example, analyses have shown that a part of the ClO_4^- has been reduced to Cl^-.

The total number of electrons Ne (initial valence of dissolution) released into the exterior circuit per atom of metal leaving the anode thus depends on the relative magnitudes of reactions [1] and [2]. When the distance at which reaction [2] can proceed easily is clearly greater than the distance at which the rate of reaction [1] goes to zero, Ne attains the limiting value of one.

In some respects one can predict the way in which the profile of the curve of Fig. 1 will be altered as a result of a modification of experimental conditions, and consequently the way in which the faradaic efficiency ρ (or Ne) of the dissolution will be affected. In particular it is noted that lower values of Ne are favored by increasing temperature (23) and by a reduction in residual water content of the (anhydrous) electrolyte. Finally, there should exist an optimum region of anodic potential for values $Ne \rightarrow 1$.

These theoretical predictions have been found to be in good agreement with our results obtained for the anodic dissolution of aluminum in the ternary mixture: ethanol-water-$LiClO_4$ (23). In the case of beryllium, as we have mentioned, the limiting value $Ne = 1$ can be obtained without unusual experimental precautions. Nevertheless, this value $Ne = 1$ does not occur except in a narrow potential range. It is these results which have led us to undertake a study of this anodic dissolution at elevated temperatures and in solutions of very low water content in an attempt to extend the potential range where Ne is rigorously equal to 1, while still maintaining conditions such that any "chunk" or "difference effect" may be excluded.

Before describing the experimental work, it should be noted that several attempts have been made by other workers to detect directly the existence of ions M^+ of unusual valence at some distance from the electrode [ring disk electrodes (6), detection of reducing products in an indicated anode compartment (27-29)].

For ions like Be^+ and Al^+ which are very unstable in dilute aqueous solutions, these tests have resulted either in failures to detect the species or have given evidence which is not particularly convincing. For the same conditions, more stable ions like Cu^+, In^+, . . . , have been detected in a manner which is hardly disputable (30, 31). These results tend to indicate a very narrow depth to the zone near the electrode in which the ions Be^+ and Al^+ are stable.

On the other hand we have verified that in the case of aluminum the rotation of the anode did not lead to a change in the mechanism of dissolution. For rotation speeds up to 1500 rpm, we observed no measurable change in Ne, a result one would expect if the anodic layer consists of a zone of low water content, the thickness of which is small in relation to the total thickness of the diffusion layer. In these conditions it appears unlikely that, as proposed by Kabanov (15), the value of Ne is related to the velocity of diffusion into the solution of the unstable M^+ ions formed at the anode.

Experimental

Electrolyte.—The electrolyte is a ternary mixture of ethanol, water, and lithium perchlorate (reagent grade from G. Frederick Smith Chemical Company, Columbus, Ohio).

In order to reduce the residual water content to very low values, we have used molecular sieves with their selective properties of fixation (27). Possible con-

[2] The Born-Haber relation, for the case of the solution of a metal in water to form an ion M^{n+}, is given as

$$\Delta G = S + I - \Delta G_h - n\psi$$

where S, I, ΔG_h represent, respectively, the energies of sublimation, ionization, and hydration, and $n\psi$ the work to return to the metal the n electrons formed by the ionization. For the case of ions which are not stable in dilute aqueous solutions (Be^+, Al^+, Mg^+, etc.) ΔG_h must be evaluated by an indirect method. To obtain the value in Fig. 1 we have used the Born-Webb relation which is based on the mutual potential energy of ions and solvent molecules

$$\Delta G_h = \frac{Ne^2 z^2}{2}\left(1 - \frac{1}{\epsilon} - \frac{1}{r}\right)$$

where z = charge on the ion, ϵ = dielectric constant of the solvent, and r the effective radius of the ion (23, 25, 26).

tamination of the electrolyte by the sieves is avoided by operating in the gaseous phase, and heating effects are minimized by distilling under reduced pressure. The alcohol (with water) vapor from the boiling solution traverses a sieve column where it is dehydrated, then is returned by reflux condenser to the boiling solution. For safety purposes, one thus avoids the heating of these concentrated perchlorate solutions. This method makes it possible to prepare solutions which, by titration, contain less than 0.1g water per liter.

Electrolysis cell.—In order to work with solutions as anhydrous as possible, the anodic dissolutions have been carried out directly in the boiling flask of the dehydration apparatus.

The counterelectrode is a platinum plate (16 cm^2) and the anode a beryllium plate (1 cm^2).

The principal impurity in the beryllium is the oxide (0.2%); the total impurities are of the order of 0.3%. Dissolutions were carried out in an argon atmosphere. Water contents were determined by Karl Fischer titration.

Measurement of dissolution efficiency.—For the quantitative characterization of the dissolution anomaly, one normally uses either the value of faradaic efficiency of dissolution (rates of weight loss predicted by Faraday's law with valence equal to that of the ion actually found in solution to weight loss actually measured) or the initial valence of dissolution Ne (the average number of electrons flowing in the external circuit per atom of metal dissolved).

Thus

$$\rho = \frac{W_{exp}}{W_{th}};\quad Ne = \frac{AQ}{\mathbf{F}W_{exp}};\quad \rho = \frac{n}{Ne}$$

W_{exp} = weight loss measured
W_{th} = weight loss predicted by Faraday's law
A = atomic weight of metal
Q = quantity of electricity through the cell
$\mathbf{F}$ = Faraday's constant
n = valence of ion found in solution.

The quantity of electricity passing the cell was measured with an electronic integrator, with an accuracy of less than 0.5%. The precision in the determinations of weight losses depends primarily on the treatment of the anode before and after electrolysis. Before dissolution, the anodes are electrolytically polished. During both the electropolishing and the dissolution, there is formed on the metal a viscous layer which can be removed by the vigorous action of an ultrasonic ethanol bath. After repeated cleaning and drying, the weight of the electrode can be obtained within an absolute uncertainty of less than 0.05 mg. Since the quantities of metal dissolved anodically are at least 20 mg, the relative uncertainty in the value of ρ does not exceed 0.5%. It follows that the relative uncertainty in Ne is

$$\frac{\Delta Ne}{Ne} = \frac{\Delta Q}{Q} + \frac{\Delta W}{W} \cong 1\%$$

Observation of the surface state of the metal.—An examination of the anodic layer alone is not sufficient to make definitive conclusions as to the existence of the "chunk" effect in the anodic dissolution. Even the appearance of a gray coloration or the actual identification of the presence of metallic particles in the anode region, although they constitute a strong presumption in favor of this effect, cannot be taken as indisputable proof, since the formation of these metallic particles may always be attributed to the dismutation reaction

$$2Be^{+} \rightarrow Be^{++} + Be\downarrow$$

Only the direct observation of the microprofile of the dissolving metal surface can furnish the necessary complementary information to make a definitive statement as to the existence of the chunk effect.

For beryllium, these very interesting observations, *i.e.*, the anode in microrelief, were made with a scanning electron microscope (Cambridge Stereoscan) in collaboration with Mr. Froment.

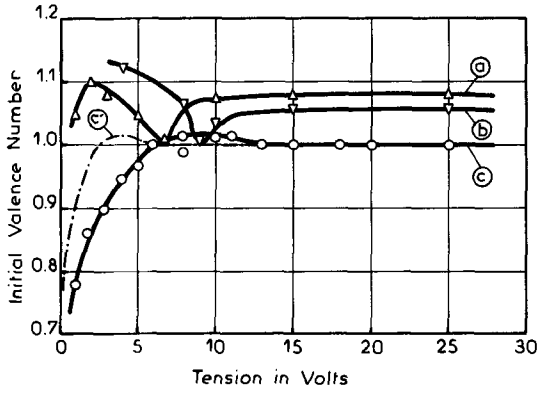

Fig. 2. Anodic dissolution of beryllium in a ternary mixture of ethanol, water, and lithium perchlorate (50g). a, $[H_2O]$ = 25 g/l, t = 25°C; b, $[H_2O]$ = 25 g/l, t = 50°C; c, $[H_2O]$ = 0.1 g/l, t = 60°C; c', curve c after correction of the potential V for the ohmic potential drop.

Results

Measurement of Ne.—Curves a and b of Fig. 2 show Ne as a function of applied potential for anodic dissolutions carried out in solutions containing 25g H_2O and 50g $LiClO_4$ per liter, maintained, respectively, at 25° and 50°C. These curves show, as previously discussed, the critical value $Ne = 1$ at the minima in a very narrow potential range ($\Delta V \simeq 0.5$V). The higher temperature shifts this minimum to higher potentials, but no decrease in the value of Ne at the minimum is observed. This furnishes a first evidence of the limiting nature of the value $Ne = 1$. Curve c of Fig. 2 was taken under conditions most favorable to the observance of low values of initial dissolution valence (high temperature, 60°C, and low water content, < 0.1 g/l).

With these solutions of very low water content, we have attempted to evaluate the magnitude of the potential drop, of ohmic origin, which exists in the anodic layer.

For this evaluation we have studied the response of the cell to the action of an exterior perturbation, using a method developed for another purpose (32). The behavior of the anodic layer is found to be very complex. We first evaluated the impedance of the cell over the frequency range 10^3 to 10^5 Hz.[3] From the values obtained we have obtained curve c' of Fig. 2 from curve c by correcting the potential V for the ohmic potential drop $\Delta V_\Omega = I R$. The curve c' is only a fair approximation, since the system is not sufficiently stable to allow a precise determination of ΔV_Ω. On the other hand the current interruption method (23, 32) does not yield, on returning to the equilibrium potential, a curve $V = f(t)$ with the expected two relaxation time constants. Only the simple exponential trace is observed, with a time constant of the order of 10 μsec, a value which is both too large for an ohmic decay and too small for the analogous anode potential decays observed in aqueous solutions.

Thus important facts are obtained from a comparison of the curves a and b with c': (*i*) the elimination of water leads to the formation of an extended potential range for the value $Ne = 1$, replacing the sharp minima previously observed; (*ii*) at potentials less than 2.5V (curve c'), values of Ne less than 1 are observed, to our knowledge for the first time, in noncorrosive solutions on open circuit.

[3] A perturbation ΔV is imposed on the potentiostatically applied working potential, and the current response ΔI of the cell is followed. On the region of linear response, the ratio $\Delta V/\Delta I$ is the impedance Z of the electrode.

Observation of the state of the surface.—Anhydrous solution.—Samples dissolved at high applied potentials with values of $Ne = 1$ present very smooth surfaces. No appreciable step forming effects can be noticed between the grains of the sample. This aspect of the surface confirms the remarkably homogeneous character (electrolytic polishing) of the dissolution which had been foreseen from previous *in situ* observations by optical interference microscopy, with an objective immersed in the electrolyte (4).

The beginning of the increase in *Ne*, near 5V, is accompanied by the appearance of some relatively rare zones of a granular aspect, separated from a surface still very smooth, Fig. 3.

As soon as *Ne* takes on values less than 1, the grain surfaces lose their parallelism. Near 2V, where *Ne* begins to decrease rapidly, the surface (in relief) becomes very rugged. On the other hand, it no longer presents any of the granular aspect which is observed in the potential range where *Ne* is greater than 1.

For potentials leading to values of *Ne* less than 0.9, clifflike structures can be clearly seen on the surface, overhanging the rest of the surface at their edges, Fig. 4.

For the lowest potential studied, the surface presents an aspect of deep ravines cut through the original surface left intact (summits, plateaus, at the same level), Fig. 5. The dissolution does not take place except along certain valleys with very steep walls. At the interior of the ravines can be seen zones of some several microns in diameter, retained by attachment bridges ready to be broken, thus liberating into the solution bulk metal particles, Fig. 6. It is also easy to distinguish regions in which particles of somewhat larger size (tens of microns) seem to be displaced a small distance from the zone from which they were detached, leaving a corresponding cavity which can itself be clearly distinguished, Fig. 7.

Water containing solutions.—The regular dissolution extending over the entire surface, as obtained with the anhydrous solutions, is not observed in water-containing solutions even at high anodic potentials. Zones appear in which the dissolution occurs in a very heterogeneous fashion. At low potentials, this heterogeneous dissolution extends over the entire surface. There is yet another essential difference between the aspects observed with and without residual water in the electrolyte: in the presence of water the dissolution remains sensitive to crystalline orientation of the grains at all potentials (formation of needles of different orientations following the grains, Fig. 8), an aspect similar to that described by Straumanis for dissolution carried out in aqueous HCl (7), while in the absence of water the orientation effect is no longer visible at potentials for which *Ne* is significantly less than 1.

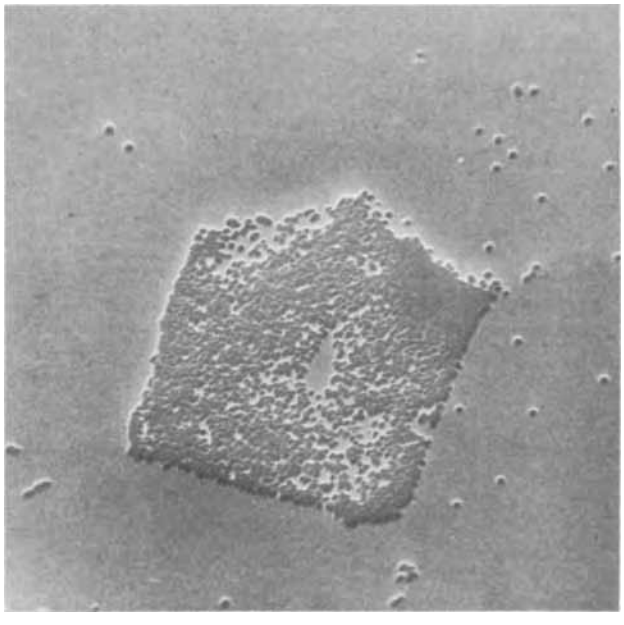

Fig. 3. Scanning electron micrograph (Fig. 3 through 8). Anodic dissolution of beryllium. $[H_2O] < 0.1$ g/l, $V = 5V$, $Ne = 1.02$. Magnification 1400X.

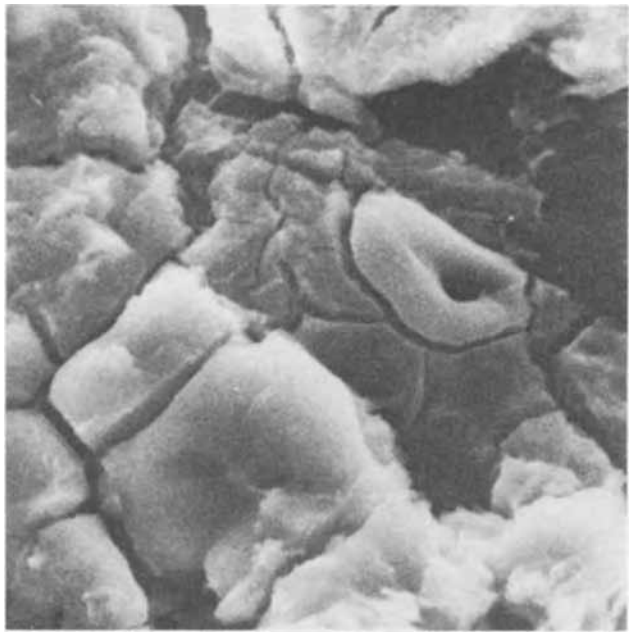

Fig. 4. $[H_2O] < 0.1$ g/l, $V = 1V$, $Ne = 0.86$. Magnification 2000X.

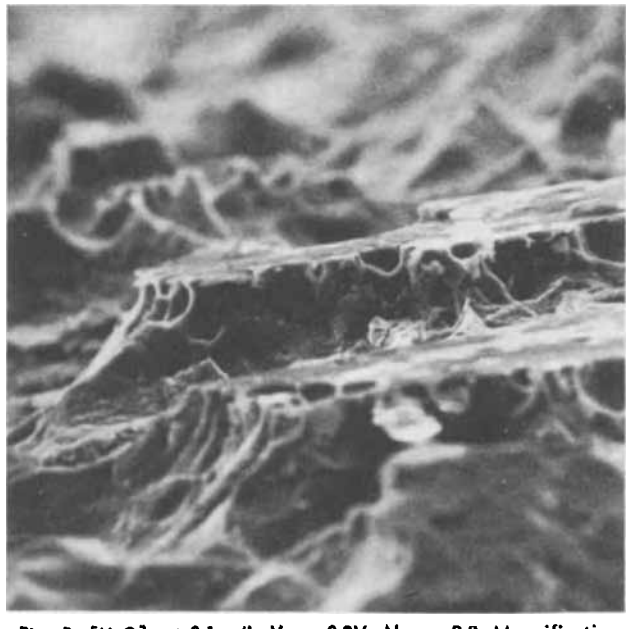

Fig. 5. $[H_2O] < 0.1$ g/l, $V = 0.2V$, $Ne = 0.8$. Magnification 255X.

Discussion

The observation, in practically anhydrous solutions, of the value $Ne = 1$ over an extended anodic potential range constitutes a decisive argument in favor of the number of mechanisms which postulate the exclusive formation of the ion Be^+ as the initial step of the dissolution, whatever the ultimate reactions envisaged for these ions by the different mechanisms. The particular experimental conditions for which this critical

Fig. 6. [H_2O] < 0.1 g/l, V = 0.2V, Ne = 0.8. Magnification 1300X.

Fig. 8. [H_2O] = 25 g/l, V = 1V, Ne = 1.04. Magnification 1200X.

Fig. 7. [H_2O] < 0.1 g/l, V = 0.2V, Ne = 0.8. Magnification 1200X.

limiting value is observed (high anodic potentials and temperature, practically anhydrous solutions) support the previously advanced ideas according to which an obligatory formation of the monovalent ion species as the first step in the dissolution does not lead to a modification of the remainder of the over-all reaction except when conditions give rise to a locally restricted supply of solvent molecules in the anodic layer.

Moreover, under experimental conditions which lead to values Ne = 1, the dissolution occurs in a remarkably uniform and homogeneous fashion over the entire surface. The microprofile observed is absolutely incompatible with any appearance of a chunk effect or with a chemical attack which is concentrated at the grain boundaries. The anodic layer which constrains the metal to dissolve in the form of Be^+ ions constitutes also a protective film which imposes a uniform dissolution on the surface (condition of electrolytic polishing), and excludes the secondary phenomena (parasitic processes) which might lead to values of Ne less than 1.

At potentials less than 2V (curve c', Fig. 2) or in the presence of water, deviations from unity of the value of Ne indicate a more complex mechanism. The dissolution does not occur according to the simple: $Be \rightarrow Be^+ + e^-$ (electrochemical step I) followed by: Be^+ + oxidant $\rightarrow Be^{++}$ + reduced species (chemical step II), but calls into play other steps which are clearly indicated by the different aspects of microrelief revealed in the photomicrographs, (Fig. 2-8).

Thus, the increase of Ne to values greater than 1 (curve c') is accompanied by the appearance (2) of the zones of granular appearance allied with the formation of an oxide (33). The observed modification might be attributed to a diminution of the solvent-poor layer covering the surface, due to a decrease in the strength of the electric field at the metal/electrolyte interface. The previously mentioned difficulties encountered in the application of perturbation methods have, however, prevented us from obtaining the precise character of this layer at low potentials.

For experimental conditions which lead to values of Ne less than 1, it appears to be well established from the observed structural features of the anode surface that the metallic particles which color the solution are due to the "chunk" effect. This physical disintegration of the surface will not appear except when the anodic potential becomes too small to insure the maintenance of the solvent-poor layer which protects the metal.

Determination of the Diffusion Layer Thickness at a Cathode in $CuSO_4$ Solutions

Aladar Tvarusko* and Laurence S. Watkins[1]

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

ABSTRACT

The diffusion layer thickness, δ, was measured as a function of time by a Mach-Zehnder interferometer on a vertical cathode in $CuSO_4$ solution with and without an excess of H_2SO_4 at current densities, i, up to 100 mA/cm^2. The thickness δ increased linearly with $t^{1/2}$ up to the start of hydrogen gas evolution in $CuSO_4$ solutions with and without H_2SO_4; in the presence of tenfold excess of H_2SO_4, δ rapidly increased just before the gas evolution. At a constant cathodic charge, log δ decreased linearly with increasing log i in both solutions and δ is larger in pure $CuSO_4$ solution than in the presence of excess of H_2SO_4.

A new beam deflecting technique, based on the Lloyd mirror interferometer, has been described for the determination of the refractive index gradient and the concentration change in the cathodic diffusion layer normal to the electrode (1). Either this refractive index gradient, d_n, or the thickness of the diffusion layer, δ, can be calculated from the measurement of the path length change of the deflected beam in the diffusion layer (1,2). Since δ, the subject of this paper, can be independently obtained by the Mach-Zehnder interferometer, d_n was calculated from the path length change (1-3).

The knowledge of the diffusion layer thickness is important from both theoretical and practical viewpoints independently of the aforementioned need. This thickness can be measured directly [see, *e.g.*, ref. (4)] or calculated [see, *e.g.*, ref. (5)]. In this investigation the diffusion layer thickness was measured by a Mach-Zehnder interferometer as a function of time at high current densities up to 100 mA/cm^2 during the electrodeposition of copper.

Experimental

The entire experimental setup based on the Mach-Zehnder interferometer was described earlier in detail (4). The camera was focused onto the end of the vertical cathode nearest the camera. All the sides of the cathode (11.5 mm wide, 0.47 mm thick, 17 mm immersion length) were plastic coated, except the working side. The electrodes were placed in a Plexiglas cell of 23 x 66 x 31 mm dimension and the anode-cathode distance was 6 cm. The cathode was aligned by observing its image and rotating the cell for a minimum cathode image; this could be done to an accuracy of 0.05 mm or better. The diffusion layer thickness values were taken only at one height, about 8 mm below the solution surface (4). $CuSO_4$ solutions were used with and without H_2SO_4 for the galvanostatic experiments.

The interferograms were evaluated on a microphotometer (Jarrel-Ash, Model 23-100). The film was placed between two clear spectrographic plates which were separated by two feeler gauge strips of proper thickness on both sides of the film and held together by pressure sensitive tape. This arrangement ensured the flatness of the film and the movement of the film during the evaluation of an interferogram was prevented by immobilizing the film on both sides of the spectrographic plate. The hair-line on the projection screen was superimposed on the very distinct edge of the horizontal fringe and the position of the reference scale was read to μm. The carriage was moved until the hair-line was superimposed on the edge of the horizontal fringe on the other side of the electrode. The edge of the diffusion layer was taken where the fringes turned down from the horizontal indicating the reduction in refractive index gradient. For the high current density, only the very beginning of this could be seen. The thickness of the diffusion layer was obtained from the difference of these readings from which the electrode

width, measured from the same film before the addition of the current, was deducted.

Results and Discussion

Figure 1 shows two typical interferograms in 0.24M $CuSO_4$ solution taken before and 4.6 sec after the beginning of electrolysis at a current density of 62.5 mA/cm². The primary horizontal interference fringes are perpendicular to the vertical cathode the right side of which is the working surface. It can be clearly seen that (*a*) the cathode/solution interface is seemingly displaced in the presence of the large refractive index gradient and (*b*) the interference fringes are absent in this extended region, *i.e.*, diffusion layer [compare with Fig. 2 of ref. (4)].

It is well known that a beam of light (r_1,r_2) passing through a layer of varying index of refraction and thickness δ, is deflected into the region of high refractive index as shown in Fig. 2 [for references see ref. (1)]. Because of this beam deflection, the interference fringes and thus the concentration change cannot be determined accurately or at all in the presence of large refractive gradients, *i.e.*, at high current densities on cathodes of a few millimeter widths. This has been described in several studies (4, 6-9). The primary horizontal interference fringes do show the diffusion layer/bulk solution interface (Fig. 1) because the rays outside of the diffusion layer (r_3) travel without deflection (Fig 2), but the position of the working surface of the cathode is not visible. Thus, δ must be

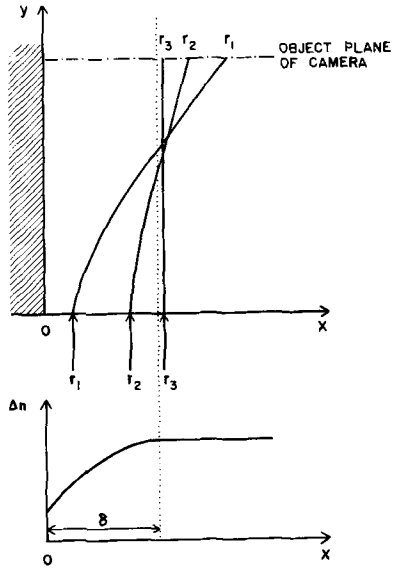

Fig. 2. Deflection of light rays (r_1, r_2) in the diffusion layer caused by the refractive index gradient. Ray r_3 travels without deflection outside of the diffusion layer of thickness δ.

determined indirectly from a nonworking surface (4, 7, 10, 11) or properly placed marking outside the diffusion layer.

Let us return to Fig. 1 and discuss the interferograms in detail in view of the multiplicity of fringes present therein (an inherent problem when using a laser). The slightly diagonal fringes (sloping down to the right) extend over the whole picture and are due to reflections from the beam splitter back surface. These are of no significance to the experiment; nor are the vertical fringes extending from the left, coated side of the cathode since they do not change throughout the experiment. These vertical fringes were a function of cathode alignment and are presumably diffraction effects from the front edge of the cathode or its plastic coating. Since they rarely occurred on the working side of the cathode, the latter explanation seems more likely.

The horizontal fringes are the ones of interest and indicate the constant refractive index outside the diffusion layer. In Fig. 1a they are horizontal right up to the cathode edge. In Fig. 1b they terminate before the cathode edge and begin to turn down indicating the decrease of refractive index at the edge of the diffusion layer. They do not continue toward the cathode, however, because of the deflection produced by the large refractive index gradient. This results in the fringes occurring outside the diffusion layer. The large number of fringes is an indication (not accurate for a Mach-Zehnder interpretation) of the large refractive index change. It is interesting to note that the distance between these fringes decreases with increasing distance from the cathode. This is because the ray undergoes a large optical path length change near the cathode due to the larger refractive index gradient and is deflected more than the ray near the diffusion layer/bulk solution interface. The fringes of minimum separation come from nearest the cathode where the refractive index gradient is largest.

The small circular fringes are caused by pits or depressions in the cell surface which was not specially finished. Finally, there is a small change in the interference fringes of the nonworking side of the cathode (Fig. 1b). This is quite small, amounting to about ½ fringe, and may be due to refractive index gradient changes extending round the front and back edges of the cathode.

Figure 3 shows two interferograms taken just before and after the start of hydrogen gas evolution in 0.24M $CuSO_4$-2.36M H_2SO_4 solution. It can be clearly seen that the gas evolution disrupts the interferogram.

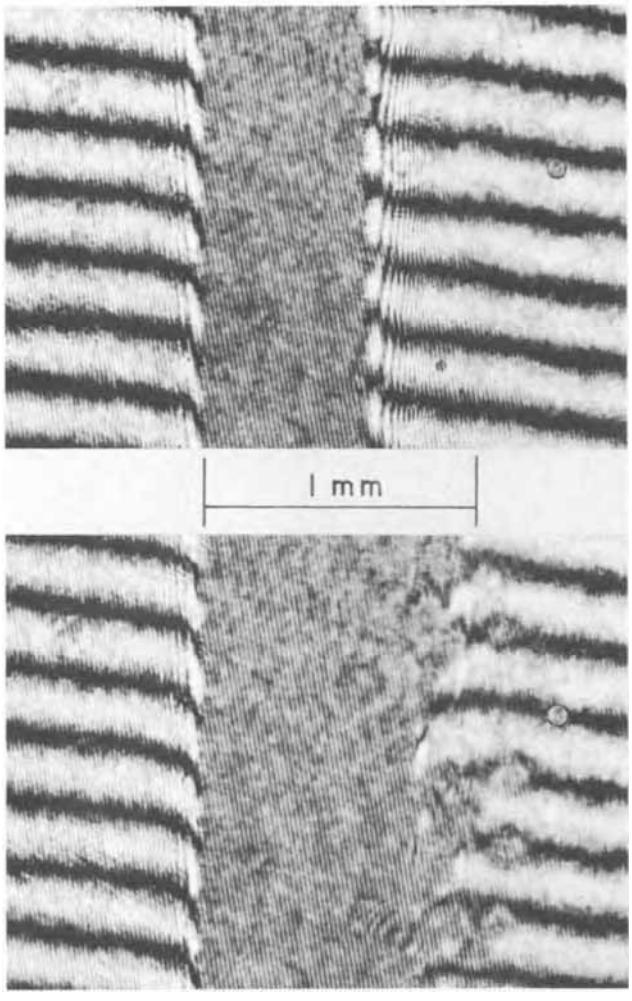

Fig. 3. Mach-Zehnder interferogram of a cathode in 0.24M $CuSO_4$-2.36M H_2SO_4 solution before and after the start of H_2 evolution at 69.1 mA/cm^2. a (top), 2.75 sec; b (bottom), 3.38 sec.

Therefore, meaningful diffusion layer thickness values can be obtained only below and at the limiting current density for metal deposition, i_L. Since the gas evolution does not start instantaneously after the application of current densities higher than i_L, the initial stages of the increase of the diffusion layer can be also investigated. The thickness of the diffusion layer at a gas evolving electrode is nonuniform in time and space. The secondary interference fringes are superimposed on the primary fringes also in the presence of H_2SO_4 but their extent is smaller than in the pure $CuSO_4$ solution. The circular interference fringes are caused by individual gas bubbles.

Figure 4 shows the diffusion layer thickness determined from the nonworking side of the cathode as a function of square root of time in 0.24M $CuSO_4$. The thickness δ increases linearly at all current densities up to the start of the transition to steady state or start of hydrogen gas evolution, respectively. The difference at the three highest current densities investigated is small and the current density seems to have little influence above the limiting current density. This indicates that the conditions in the diffusion layer remain nearly the same above the limiting current density before the start of the hydrogen gas evolution. All the regression lines were fitted by the least squares method and the regression line constants are shown in Fig. 4 (A-intercept, B-slope, R-coefficient of correlation). The linear regression analysis of all data reported here is statistically significant at greater than 95%.

It is to be noted that the displacement of the cathode/solution interface due to the electrodeposited copper

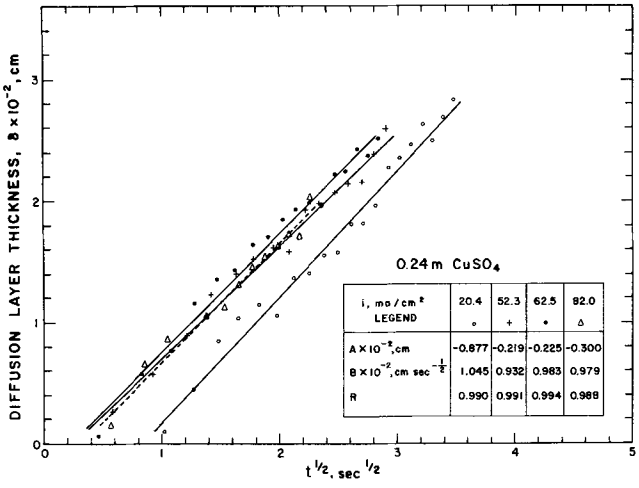

Fig. 4. Diffusion layer thickness as a function of $t^{1/2}$ in 0.24M $CuSO_4$ at various current densities. The regression line constants are given in the inserted table.

layer is negligible in comparison to the diffusion layer thickness because the electrodeposited copper layer is at least three orders of magnitude smaller than δ.

A comparison of Fig. 4 and 5 reveals that the behavior of δ is different in these two solutions. In the presence of tenfold excess of H_2SO_4 it was found that: (*a*) the $\delta - t^{1/2}$ relation is linear only below the limiting current density and in the very beginning of the galvanostatic experiments above i_L; (*b*) the rate of increase of δ with $t^{1/2}$ (slope B) is approximately one third smaller than in pure $CuSO_4$; (c) δ rapidly increases just before the start of the hydrogen gas evolution; the position and to a certain degree, the rate of this increase depends on the current density; and (*d*) the linear $\delta - t^{1/2}$ relation is practically independent of the current density over a larger range than in pure $CuSO_4$ or in the presence of small amount of H_2SO_4 (3). In the presence of 0.11M H_2SO_4 the slope of the $\delta - t^{1/2}$ linear relation (4) falls between the two extreme values (Fig. 4 and 5).

The influence of H_2SO_4 is obvious from these results. In the presence of a large excess of H_2SO_4 the increase of δ is slower than in pure $CuSO_4$ solution. The hydrogen evolution, however, starts at shorter times in the presence of H_2SO_4 than in its absence. The decrease of the elapsed time before H_2 evolution in the presence of H_2SO_4 is supported by the reported results during powder formation at the limiting current density (12). The addition of indifferent electrolytes shortens the time to powder formation (12), *i.e.*, the time required for the metal ion concentration to decrease very closely to zero at the cathode/solution interface. In view of

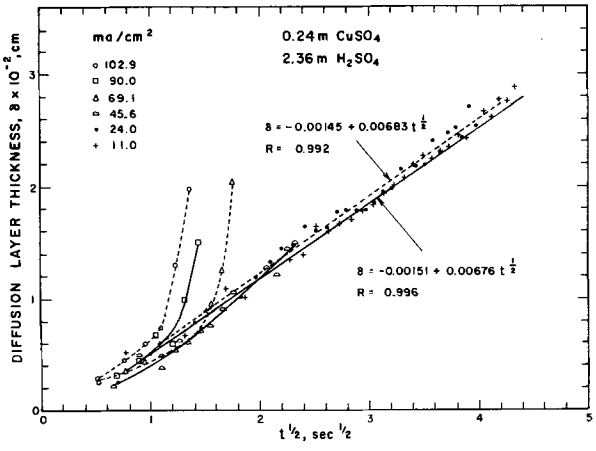

Fig. 5. Diffusion layer thickness as a function of $t^{1/2}$ in 0.24M $CuSO_4$-2.36M H_2SO_4 solution at various current densities.

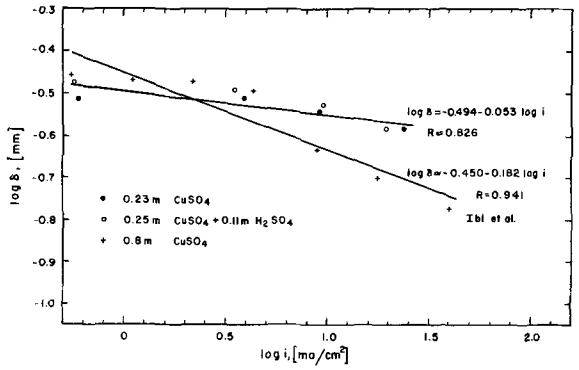

Fig. 6. Steady-state diffusion layer thickness as a function of current density in various $CuSO_4$ solutions.

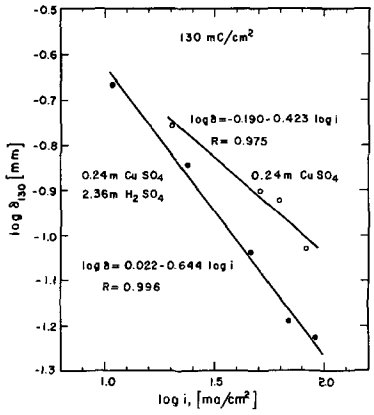

Fig. 7. Diffusion layer thickness as a function of current density at a constant quantity of electricity of 130 mC/cm² in $CuSO_4$ solutions with and without an excess of H_2SO_4.

these facts, the rapid increase of δ before the hydrogen evolution seems to be inevitable.

Figure 6 shows the logarithm of steady-state diffusion layer thickness as a function of the logarithm of current density in three $CuSO_4$ solutions. The steady-state δ decreases with increasing current density. The slope of the linear regression line is −0.053 for our data and the coefficient of correlation, R, is very low. The experimental slope is markedly lower than the theoretically predicted value of −0.20 (10). The δ values of Ibl *et al.* [Table 3, ref. (10)] in 0.8M $CuSO_4$ yield −0.18 for the slope (Fig. 6) which is in closer agreement with the theoretical value. The other data of Ibl *et al.* (10) show smaller slopes and larger scatter of data. Ibl *et al.* (13) found that the experimental determination of $\delta_{0.1}$, *i.e.*, the distance at which the concentration decreased to 10% of the total change, is more reliable than that of δ (the true thickness of the diffusion layer). However, the slope of the experimental line in 0.6M $CuSO_4$ is only −0.16. Our δ values at low current densities (<5 mA/cm²) are comparable to those of Ibl *et al.* (10) but deviate considerably at the higher current densities. In view of our interest in the nonsteady-state behavior of δ at high current densities, the reason for this deviation has not been pursued further.

The steady-state δ values are meaningless at very high current densities ($i > i_L$) because δ varies in time and space due to the evolving H_2. Figure 7 shows the diffusion layer thickness for a constant quantity of electricity of 130 mC/cm², δ_{130} as a function of current density. This value was chosen because it is just below the quantity of electricity at which δ rapidly increased before the H_2 evolution in the 0.24M $CuSO_4$ −2.36M H_2SO_4 solution. Log δ_{130} decreases linearly with increasing log i in both solutions. The slope of the regression line in the $CuSO_4$ solution is approximately a third lower than in the presence of tenfold excess of H_2SO_4. The magnitude of δ_{130} is affected also by the nature of solution and δ_{130} is larger in $CuSO_4$ solution than in the presence of tenfold excess of H_2SO_4. The aforementioned results seem to be caused by the concomitant change of mainly the cation transference number, and to a lesser degree of diffusion coefficient, viscosity and density of the solution near the cathode surface.

Manuscript submitted April 9, 1970; revised manuscript received *ca.* Sept. 16, 1970. This was Paper 288 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Modification of the Cottrell Equation to Account for Electrode Growth; Application to Diffusion Data in the Ag-Au System

K. B. Oldham[1,*] and D. O. Raleigh[**]

Science Center, North American Rockwell Corporation, Thousand Oaks, California 91360

ABSTRACT

The Cottrell equation is invalid if the electrode reaction causes motion of the electrolyte/electrode boundary. The equation has been modified to take account of this effect and the modification applied to previously published data on the interdiffusion of silver and gold. The recalculated interdiffusion coefficients show excellent agreement with values obtained from literature sources. The applicability of the modified equation is discussed and a new method for the measurement of diffusion coefficients is advanced.

A previous publication from this laboratory (1) described a solid-state electrochemical method for determining diffusion coefficients in selected binary metal systems at elevated temperatures. Data were reported for the chemical diffusion coefficient of silver in silver-gold alloys at 394°C. In the composition range 10-50 atomic per cent (a/o) Ag, reasonable agreement was obtained with extrapolation of diffusion data (2) measured conventionally at 650°-1000°C. At higher concentrations, increasing discrepancies were observed, which were attributed to extrapolation errors. It was noted (3), however, that the diffusion treatment should properly include a correction factor to take account of electrode boundary movement during diffusion, but that the complexity of the treatment required its postponement to a future publication. We here report the development of this correction factor, note that it brings the electrochemical data into good agreement with the previous work throughout the composition range, and discuss its range of general applicability.

The diffusion measurement technique which was employed (1) was to measure the faradaic current $i(t)$ which flows following the application of a constant potential E across the cell

$$(-)\,\mathrm{Ag}|\mathrm{AgBr}|(\mathrm{Au\text{-}Ag})\,(+) \qquad [1]$$

The current, crossing the AgBr|(Au-Ag) interface by virtue of the reaction

$$\mathrm{Ag}^+ + e^- = \mathrm{Ag(Au\text{-}Ag)} \qquad [2]$$

flows to maintain the silver activity in the surface layer of the alloy electrode at a value

$$a_s = \exp\{-\mathbf{F}E/RT\} \qquad [3]$$

demanded by the thermodynamic Nernst equation, despite the diffusion of silver into or out of the bulk of the alloy. Equation [3], in which **F**, R, and T have their usual significance, is valid if activation, crystallization, and ohmic polarizations may be ignored, which was the case in these experiments.

The chemical diffusion coefficient of silver was calculated from the current-time dependence by use of the Cottrell equation (6)

$$i(t) = A\mathbf{F}(C_s - C_o)\sqrt{\frac{D_{Ag}}{\pi t}} \qquad [4]$$

where A is the electrode area, C_s is the concentration of silver in the surface layer of the electrode, and C_o is the initial concentration of silver in the electrode, *i.e.* the bulk concentration. Well-established thermodynamic data (4, 5) were used to calculate C_s from the silver activity a_s which was in turn calculated using Eq. [3].

The derivation of the Cottrell equation treats the electrode surface as fixed in space. In the above experiments, however, the electrode surface moves because of the continuous electrodeposition of silver. Indeed, this is the case for any electrolytic metal deposition, although, as we shall see, the effect in most electrodepositions, such as from aqueous solution, is negligible. In what follows, we examine the moving-boundary diffusion problem with a fixed surface concentration and reassess the previous experimental results in the light of the new theoretical result.

Mathematical Analysis

Perpendicular to the planar electrode we erect a distance coordinate, y, choosing $y = 0$ to correspond to the initial position of the silver bromide/electrode interface, and positive y toward the metallic phase. We let $Y(t)$ denote the thickness of the electrodeposit, so that $y = -Y(t)$ is the position of the electrolyte/electrode interface. At $t = 0$, when the previously open-circuited cell is subjected to the constant potential E, $Y(0) = 0$. For $t > 0$, $Y(t)$ is an increasingly positive quantity corresponding to the advance of the interface into the electrolyte phase. By $C(y,t)$ we denote the local concentration of silver in the alloy phase at time $t \geqq 0$ and at positions $y \geqq -Y(t)$.

In the previous study (1), conventionally and electrochemically obtained diffusion data were compared on the basis of the chemical diffusion coefficient of Ag in Ag-Au alloys, as assumed to be given by Eq. [4]. It is more convenient, however, to carry out the present derivation and subsequent literature comparison in terms of the interdiffusion coefficient $\tilde{D}$ (7), which characterizes diffusion in a binary system in terms of a single quantity. We seek a solution to Fick's second law of diffusion

$$\tilde{D}\frac{\partial^2}{\partial y^2}C(y,t) = \frac{\partial}{\partial t}C(y,t) \qquad [5]$$

The initial condition is

$$C(y,0) = C_o,\ y > 0 \qquad [6]$$

and the two boundary conditions are

$$C(L,t) = C(\infty,t) = C_o \qquad [7]$$

and

$$C(-Y(t),t) = C_s,\ t > 0 \qquad [8]$$

The first boundary condition is appropriate because, as

[1] Present address: Trent University, Peterborough, Ontario, Canada.

is generally the case in electrochemical experiments, the thickness, L, of the electrode used by Raleigh and Crowe (1) was very large compared with diffusant penetration depth. The second boundary condition reflects the potentiostatic constraint (Eq. [3]).

The total number of moles of silver present at any time, t, in the electrode is equal to the number present initially plus those added by electrodeposition, *i.e.*

$$A\int_{-Y(t)}^{L} C(y,t)\,dy = ALC_o + \int_o^t \frac{i(t)}{\mathbf{F}}\,dt \qquad [9]$$

On differentiation of this equation wtih respect to time, we obtain

$$\int_{-Y(t)}^{L} \frac{\partial}{\partial t} C(y,t)\,dy + \frac{dY(t)}{dt} C(-Y(t),t) = \frac{i(t)}{A\mathbf{F}} \qquad [10]$$

an equation we will eventually use to formulate $i(t)$.

An equation similar to [9] expressing the conservation of gold throughout the experiment

$$A\int_{-Y(t)}^{L} C'(y,t)\,dy = ALC'_o \qquad [11]$$

where $C'(y,t)$ is the concentration of gold in plane y at time t and C'_o is the bulk gold concentration, serves to completely specify the system. The concentrations of the two components of the binary alloy obey the relationship

$$C(y,t)V_m = x(y,t) = 1 - C'(y,t)V_m \qquad [12]$$

where x denotes the atomic fraction of the silver in the alloy and V_m is the molar volume of the alloy. V_m might be expected to be itself a function of x. Fortunately, however, the lattice dimensions of silver-gold alloys are virtually independent of composition (8), so we may treat V_m as a constant in the present application. With this simplification, Eq. [11] can be recast as

$$\int_{-Y(t)}^{L} \left[\frac{1}{V_m} - C(y,t)\right] dy = L\left[\frac{1}{V_m} - C_o\right] \qquad [13]$$

and time-differentiated to give

$$\int_{-Y(t)}^{\infty} \frac{\partial}{\partial t} C(y,t)\,dy = \frac{dY(t)}{dt}\left[\frac{1}{V_m} - C(-Y(t),t)\right] \qquad [14]$$

wherein we have substituted ∞ for the upper limit, L.

The moving-boundary problem represented by Eq. [5], [6], [7], [8], and [14] was solved by use of a dimensional analysis approach. The solution is

$$C(y,t) = C_o + \frac{(C_s - C_o)\ \mathrm{erfc}\left((y/2\sqrt{\tilde{D}t}\right)}{\mathrm{erfc}\ (-\sigma)} \qquad [15]$$

where erfc ( ) denotes the error function complement operator and σ is a constant for a given experiment. This constant satisfies the functional equation

$$\sqrt{\pi}\,\sigma \exp(\sigma^2)\ \mathrm{erfc}\ (-\sigma) = \frac{C_sV_m - C_oV_m}{1 - C_sV_m} = \frac{x_s - x_o}{1 - x_s} \qquad [16]$$

where x_s and x_o are, respectively, the atomic fractions of silver in the surface layer and bulk of the electrode. Figure 1 shows the values acquired by σ for various values of the $(x_s - x_o)/(1 - x_s)$ ratio.

Comparison of Eq. [8] and [15] shows that

$$Y(t) = 2\sigma\sqrt{\tilde{D}t} \qquad [17]$$

and if this expression is substituted into [10], together with result [15], we find

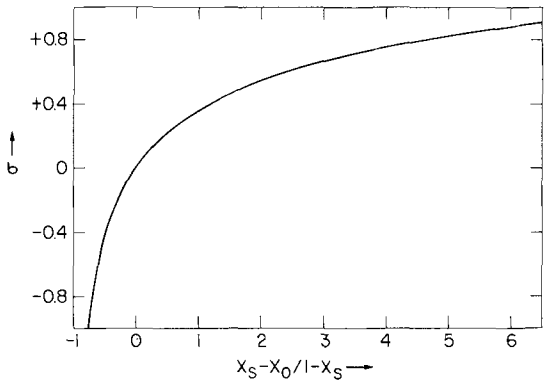

Fig. 1. Graph of σ as a function of $\sqrt{\pi}\,\sigma \exp(\sigma^2)$ erfc $(-\sigma)$

$$i(t) = \frac{\sigma A\mathbf{F}}{V_m}\sqrt{\frac{\tilde{D}}{t}} \qquad [18]$$

This is the result which replaces the Cottrell equation.

Notice that if $x_s < x_o$, σ is negative according to Fig. 1 and that $i(t)$ is negative (anodic) as expected. An experiment under these conditions was termed "out-diffusion" by Raleigh and Crowe (1).

It is pertinent to investigate the limiting form of Eq. [18] when $(x_s - x_o)$ is small. Then, as Fig. 1 shows, σ is also small. In this circumstance, a power expansion of the left hand side of Eq. [16] gives

$$\frac{x_s - x_o}{1 - x_s} = \sqrt{\pi}\,\sigma + 2\sigma^2 + \sqrt{\pi}\,\sigma^3 + \ldots \qquad [19]$$

which results in

$$\sigma = \frac{x_s - x_o}{\sqrt{\pi}(1 - x_s)}\left[1 - \frac{2}{\pi}\left(\frac{x_s - x_o}{1 - x_s}\right) + \frac{8 - \pi}{\pi^2}\left(\frac{x_s - x_o}{1 - x_s}\right)^2 - \ldots\right] \qquad [20]$$

on reversion. Insertion into Eq. [18] leads to

$$i(t) = \frac{A\mathbf{F}(C_s - C_o)}{(1 - x_s)}\sqrt{\frac{\tilde{D}}{\pi t}}\left[1 - \frac{2}{\pi}\left(\frac{x_s - x_o}{1 - x_s}\right) + \ldots\right] \qquad [21]$$

which should be compared with the Cottrell Eq. [4], where we note $\tilde{D} \to D_{Ag}$ in the limit of dilute Ag concentration. We see that the classical result is valid only if both x_o and x_s are small, not only when their difference is small. If D_{cot} is the apparent diffusion coefficient according to the Cottrell equation, then this value is seen to differ from the true interdiffusion coefficient by the factor

$$\frac{\tilde{D}}{D_{cot}} = \frac{(x_s - x_o)^2}{\pi\sigma^2} \qquad [22]$$

Comparison with Previous Work

The previous experimental work (1) reported D_{cot} values for eight $(x_s - x_o)$ compositional jumps of 10 a/o Ag in the range 10-90 a/o Ag, for both "in-diffusion" $(x_s > x_o)$ and "out-diffusion" $(x_s < x_o)$. In this work, the measured diffusion coefficients, which varied with composition, were assigned to the mean compositional values $\frac{1}{2}(x_s + x_o)$. In Table I, we show D_{cot}, the calculated conversion factor (Eq. [22]), and $\tilde{D}$ for those experimental results that were compared with the previous work of Slifkin *et al.* (2). The latter work reported values for D^*_{Ag} and D^*_{Au}, the radiochemical diffusion coefficients of Ag and Au in Ag-Au. These were reported in terms of best values for D^*_o

and Q, the parameters of the conventional temperature depedence expression $D^* = D^*_o \exp(-Q/RT)$ for the various compositions investigated.

In the previous article (1), comparison was made between D_{cot} and the chemical diffusion coefficient D_{Ag}. The relationship

$$D_{Ag} = D^*_{Ag}\left(1 + \frac{d \ln \gamma_{Ag}}{d \ln x_{Ag}}\right) \quad [23]$$

applies (7), where γ_{Ag} is the activity coefficient of silver in the alloy. Values of D^*_{Ag} were taken from the best smooth curve through values of $D^*_o \exp(-Q/RT)$ calculated from Slifkin's data (2) at 394° and $d \ln \gamma_{Ag}/d \ln x_{Ag}$ was evaluated from existing thermodynamic data (4, 5). For comparison with present results, we now calculate $\tilde{D}$ from the Slifkin data by use of the expression (7)

$$\tilde{D} = (x_{Au}D^*_{Ag} + x_{Ag}D^*_{Au})\left(1 + \frac{d \ln \gamma_{Ag}}{d \ln x_{Ag}}\right) \quad [24]$$

where D^*_{Ag} and D^*_{Au} are calculated directly for the specific compositions used in these data and $d \ln \gamma_{Ag}/d \ln x_{Ag}$ is evaluated as before.[2] In addition, a further value of $\tilde{D}$ is available from the work of Cook and Hilliard (9), who employed a novel evaporated-film technique to obtain values for the 50 a/o composition in the range 200°-245°C. These authors presented a graph combining their values with those of Johnson (10) at higher temperatures, from which an intermediate value at 394° may be extracted.

In Fig. 2, the values of $\tilde{D}$ calculated from experimental in-diffusion data in Table I are shown together with the Slifkin and Cook-Hilliard values. Agreement is seen to be respectable throughout the entire composition range. The in-diffusion values were used for this comparison, since they correspond to the phenomenological situation obtaining in conventional diffusion coefficient determinations.

The values of the ratio $\tilde{D}_{out}/\tilde{D}_{in}$ are of special interest because of the possibility of nonunity ratios being due to effects such as boundary motion. Actually, we see from Table I that values of $\tilde{D}/D_{cot}$ for in-diffusion and out-diffusion at a given mean composition differ by less than 10% for all but the two most silver-rich compositions. Figure 3 shows the $\tilde{D}_{out}/\tilde{D}_{in}$ ratio as a function of composition. For this plot, the original D_{cot} values were taken from smoothed curves [Ref. (1), Fig. 5] rather than individual data points, in order to avoid the large scatter previously obtained in out-diffusion data and attributed to the basic nature of the out-diffusion process. We see that significantly nonunity out:in ratios are still obtained. A best smooth curve through the individual ratio points indicates a fairly constant ratio in gold-rich compositions and a possible fall off to unity at the limit of pure silver. The enhancement of out-diffusion was previously attributed to a vacancy injection process resulting from creation of a large expected surface vacancy concentration on selective anodization of the alloy. Such a process might indeed be expected to be most effective when the nonanodized alloy component is present in substantial amount.

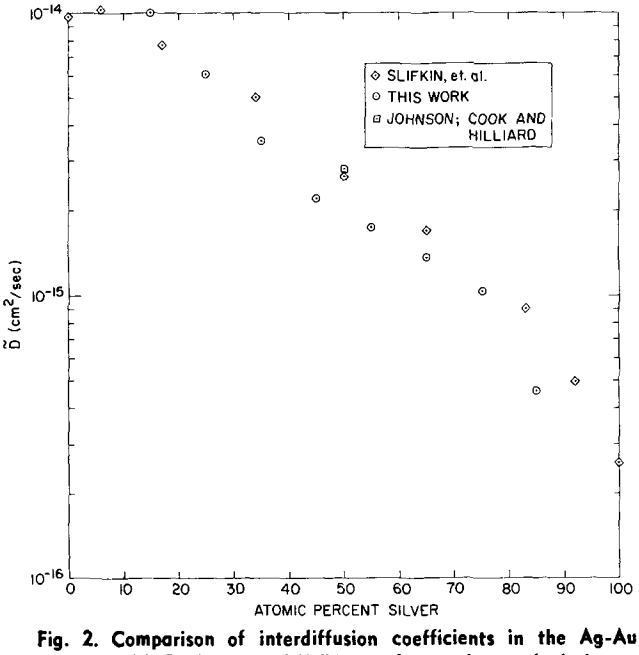

Fig. 2. Comparison of interdiffusion coefficients in the Ag-Au system at 394°C: ◇, data of Slifkin et al.; ⊙, these calculations; □, datum from the work of Johnson, Cook, and Hilliard (see text).

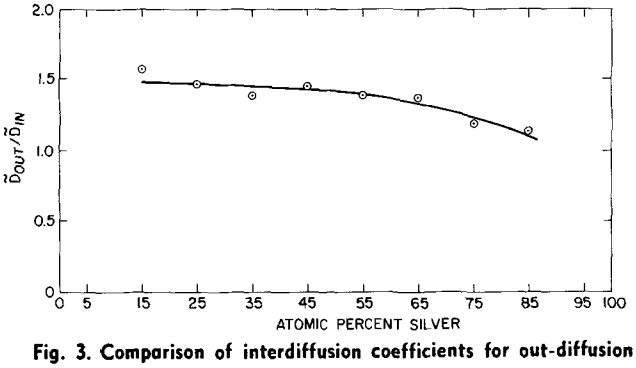

Fig. 3. Comparison of interdiffusion coefficients for out-diffusion and in-diffusion.

[2] Evaluation of $d \ln \gamma_{Ag}/d \ln x_{Ag}$ was aided by use of the fact that it equals unity at both extremes of the phase diagram because of Raoult's law and the Gibbs-Duhem relationship.

Generality of the Modification

In principle, modification to the Cottrell equation is required whenever the electrode reaction leads to the incorporation of material into the electrode or removal of material from the electrode. Many reactions used in electroanalytical chemistry, for example

$$Cd^{2+} + 2e^- \rightarrow Cd(Hg) \qquad [25]$$

fall into this category. A corresponding modification is required for other voltammetric relationships (the Sand equation, Ilkovic equation, *etc.*).

In practice, however, the vast majority of electrochemical experiments employ electroactive species in mole fractions which are very small. In such circumstances the Cottrell equation is always an excellent approximation as Eq. [21] demonstrates.

One circumstance in which the Cottrell equation is not an acceptable approximation is the electrodissolution of a metal from an electrode containing a small amount of an electroinactive impurity in solid solution. Then x_o is close to unity, but, on account of the accumulation of the impurity at the electrode surface, x_s becomes significantly smaller than x_o. The ratio $(x_s - x_o)/(1 - x_s)$ approaches -1, σ has a large negative value as Fig. 1 illustrates, and the asymptotic expansion

$$\sqrt{\pi}\,\sigma \exp(\sigma^2)\,\mathrm{erfc}(-\sigma) = -1 + \frac{1}{2\sigma^2} - \frac{3}{4\sigma^4} + \ldots \qquad [26]$$

may be curtailed after two terms. This permits a simplified definition of σ, namely

$$\sigma = -\sqrt{\frac{1 - x_s}{2(1 - x_o)}} \qquad [27]$$

and leads to a replacement for the Cottrell equation in the form

$$i(t) = \frac{-A\mathbf{F}}{V_m}\sqrt{\frac{\tilde{D}(1 - x_s)}{2(1 - x_o)t}} \qquad [28]$$

In the circumstances of almost pure metal initially, Raoult's law may be used to relate x_o directly to the open-circuit potential, E_o, prior to the experiment; thus

$$1 - x_o \approx 1 - a_o = 1 - \exp\left(\frac{-\mathbf{F}E_o}{RT}\right) \approx \frac{\mathbf{F}E_o}{RT} \qquad [29]$$

If the applied potential E is not too different from E_o, the approximation

$$1 - x_s \approx \frac{\mathbf{F}E}{RT} \qquad [30]$$

similarly holds. The Cottrell replacement then assumes the very simple form

$$i(t) = \frac{-A\mathbf{F}}{V_m}\sqrt{\frac{\tilde{D}E}{2E_o t}} \qquad [31]$$

where we recall from our discussion of Eq. [21] that $\tilde{D}$ becomes the chemical diffusion coefficient of the impurity species in the dilute limit. Thus, a new and simple method is suggested for measuring the diffusion coefficient of a dilute solute in a more electroactive solvent metal. The method has the advantage of requiring no knowledge of the activity-composition relationship. Such determinations, however, are necessarily limited to temperatures high enough for $\tilde{D}$ to be characterizable as an intrinsic property. Thus, for instance, anodization of Fe from carbon steel in aqueous solutions would give highly sample-specific results reflecting extrinsic diffusion processes (11).

Technical Notes

Investigation of the Direct Reduction of Zinc Oxide in Alkaline Electrolytes

D. Drazic[1] and Z. Nagy*

Electrochemistry Laboratory, University of Pennsylvania, Philadelphia, Pennsylvania 19104

In a Zn/ZnO alkaline battery electrode, the reaction, in principle, can proceed by two considerably different mechanisms: through a soluble intermediate by a dissolution-precipitation mechanism, or through a direct, solid-state, reaction. The solution route has been generally favored (1, 2), but no direct proof has appeared in the literature for the exclusion of the solid-state process. On the contrary, recently the solid-state reaction was proposed as the predominant mechanism (3). The direct electrochemical reduction of zinc oxide, in aqueous electrolytes, to zinc and water has been reported (4, 5) but no kinetic data

* Electrochemical Society Student Associate.
[1] On leave of absence from the Faculty of Technology, University of Belgrade, Belgrade, Yugoslavia.
Key words: alkaline batteries, Zn/ZnO electrode, solid state reduction, dissolution-precipitation.

were given. The possibility of direct reduction in absolute alcohol has also been suggested (6). The aim of this paper is to present some direct evidence which allows the proper selection of the mechanism.

Experimental

Two experimental methods were used. In the first one a ZnO single crystal was polarized cathodically in zincate containing potassium hydroxide solutions at constant current, and the potential-time behavior was recorded. In the second one, the ZnO was cathodically polarized at constant current in either potassium hydroxide or potassium sulfate solutions, and the resulting zinc deposit was determined by anodic stripping in the same solutions. The test electrode was a ZnO single crystal needle (about 3 mm wide and 20 mm long) mounted in epoxy resin and mechanically polished approximately perpendicular to the "c" axis; ohmic contact to the crystal was made through indium amalgam. The crystal was obtained from Semielements, Inc. (Saxonburg, Pennsylvania). Purity was 99.995%; no doping agent was added. Specific resistance of the crystal was approximately 1 ohm-cm. The source of donors causing this high conductivity is not known. Undoped ZnO is usually considered to have interstitial zinc (7) causing the n-type conductivity, although it also has been suggested that the conductivity is due to oxygen vacancies or chemical impurities (8). The cell (9), and the galvanostat (10) are described elsewhere. During the chronopotentiometric experiments, a still solution and a zinc wire reference electrode were used. For the second set of experiments a saturated calomel reference was used and the solution was streamed over the surface of the ZnO electrode at an estimated velocity of 10 cm/sec. All tests were carried out at room temperature.

In the first tests the electrolyte was 0.3M KOH, supersaturated with zincate. The chronopotentiograms exhibited two plateaus; hydrogen gas evolution was observed during the second plateau. One example is shown in Fig. 1. The transition times of the first plateau for different current densities and zincate concentrations are given in Table I. [A diffusion coefficient of 0.7 x 10^{-5} cm^2/sec was used in the calculations (11).]

During the second set of experiments, the ZnO was cathodically polarized at different current densities, for different time durations, in flowing 1M KOH or 0.1M K_2SO_4 solutions. The galvanostat was connected to the electrodes before the solution entered the cell to avoid chemical dissolution of the crystal prior to the application of the cathodic current. After the cathodic treatment, the cell was totally flushed, to remove hydrogen bubbles, and the crystal anodically polarized at 4.5 mA/cm^2 current density. The change of electrode potential with time was recorded, and the sudden shift in positive direction was taken as the indication of the end of zinc removal. The electrode was repolished with 400 and 600 grit silicon carbide papers before each experiment. The amount of charge needed to dissolve the zinc from the surface is plotted against cathodic current density, and length of cathodic treatment in Fig. 2 and 3.

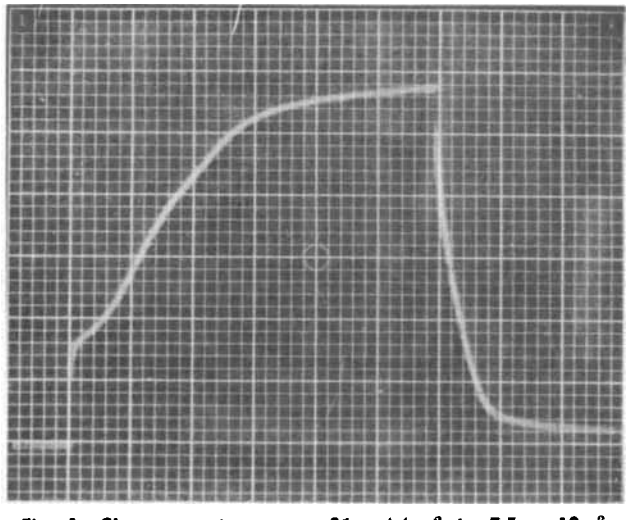

Fig. 1. Chronopotentiogram at 86 mA/cm^2 in 7.5 x 10^{-3}m zincate solution. 100 mV/div, 5 msec/div.

7.5	86	2	1.7
3	8.6	20	27
3	3.2	200	195

Discussion

In the chronopotentiometric experiments three cathodic processes are possible: reduction of zincate, reduction of zinc oxide, and hydrogen evolution. Be-

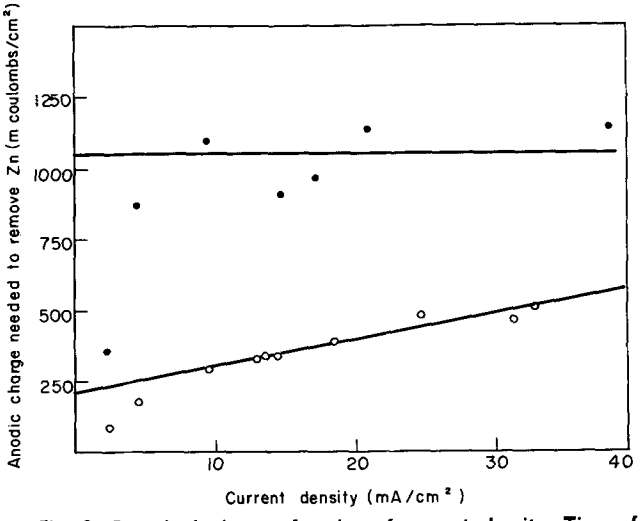

Fig. 2. Deposited zinc as function of current density. Time of cathodic treatment: 360 sec; ●, 1M KOH; ○, 0.1M K_2SO_4.

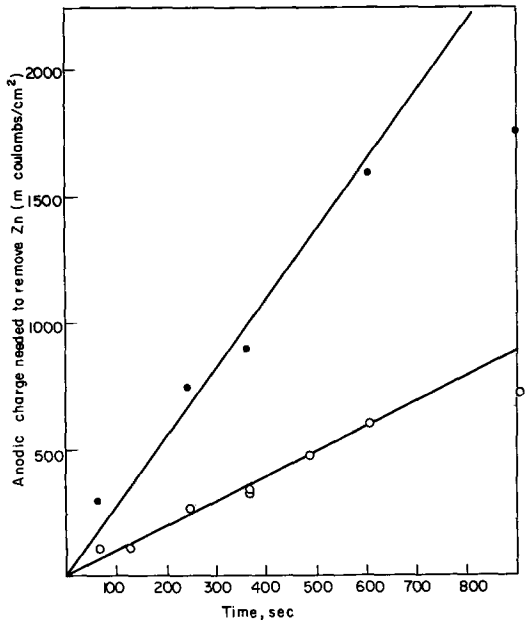

Fig. 3. Deposited zinc as function of time. Cathodic current density: 14 mA/cm^2. ●, 1M KOH; ○: 0.1M K_2SO_4.

cause of the low zincate concentration its reduction should deplete the solution fast; transition times were calculated for this process, using the Sand equation, and are compared to the measured ones in Table I. The agreement is satisfactory. It was concluded therefore that the first plateau represents zincate reduction from the solution and the second plateau represents hydrogen evolution. These data alone indicate that direct reduction in the battery cannot have an important role. At the low overvoltage plateau the current efficiency for direct reduction must be small, if not zero, in view of the good agreement of the measured and calculated transition times for zincate reduction. At the higher overvoltage the current efficiency of direct ZnO reduction cannot be determined from these experiments, but the fact that it proceeds with vigorous hydrogen evolution at 300-400 mV more cathodic overvoltage than that of the zincate reduction, excludes it as a battery process, since these overvoltages are usually not reached in practice.

The second set of experiments gives a possibility to estimate the current efficiency of the direct reduction of zinc oxide, during the hydrogen evolution. For this evaluation, the following simple model is suggested as a first approximation. The zinc coating formed on the surface results from two mechanisms, the crystal can chemically dissolve in the electrolyte and the resulting ions are cathodically deposited, or the crystal can be reduced directly in a solid state reaction. It is further assumed that the resulting coating is porous in nature and does not hinder the further dissolution of the crystal, and the "active area" of the crystal is constant during the experiments except at long times. The current efficiency of direct reduction is assumed to be independent of the current density, within the explored range. Then

$$Q = at + ibt$$

where Q(mcoulomb/cm^2), is the charge needed to remove anodically the zinc coating.
a (mA/cm^2), the chemical dissolution rate of the crystal expressed in equivalent current density.
t(sec), time of cathodic treatment
b, current efficiency of direct ZnO reduction
i (mA/cm^2), applied cathodic current density.

From a Q *vs.* i plot, at constant time, both a and b can be determined; the slope of the Q *vs.* t plot, at constant current density, can then be calculated as $(a + bi)$ and compared to the measured value. These are shown in Table II.

These data indicate that the current efficiency of direct zinc oxide reduction is practically zero even during the hydrogen evolution period in potassium hydroxide solution. Indication of direct reduction in potassium sulfate solution was found with an efficiency of 2.7%. It should be noted that because of the much higher chemical dissolution rate in KOH, and because of the scatter of the points, a small (1-2%) direct reduction efficiency in KOH would be undetectable.

Table II. Chemical dissolution rates and current efficiencies of direct reduction

	1M KOH	0.1M K_2SO_4
a (mA/cm^2)		
Chemical dissolution rate	2.9	0.57
b		
Current efficiency of direct reduction	0	0.027
$(a + bi)$	2.9	0.95
Slope of the Q *vs.* t plot	2.8	1.0

The chemical dissolution rate of ZnO in 1M KOH has been measured before and is reported to be equivalent to 4 mA/cm^2 (12) for sintered ZnO pellet, and 8 mA/cm^2 (13) for a passive layer on a zinc electrode. Considering that the roughness factor in these two cases could be higher than that for the present single crystal, and realizing that the "active area" of the crystal was smaller than the geometric area, the agreement is satisfactory. The deviation from linearity in the plots at low cathodic current densities is probably due to the loss of zincate in the effluent, and that at long times to the change of the active area.

It can be concluded therefore that while the direct reduction of the zinc oxide to zinc in a solid-state process is possible, the contribution of this reaction to the battery electrode process is not likely to be more than a few per cent, if any. The battery electrolyte is more concentrated than the one used in this work, but the conclusions are expected to hold also under actual battery conditions. The chemical dissolution process will be much faster at the higher *p*H (12), and there is no reason to suspect that the direct, solid-state process would be *p*H dependent.

The results of Hladik and Schwabe (3), who suggest the solid-state reaction as the predominant one, could also be explained by the solution mechanism. Their strongest argument in favor of the solid-state reaction is that in 1M and 11M KOH solutions the behavior of their electrode is similar. However, with their "paste electrode" it is quite possible that a large part of the overvoltage is resistance polarization, controlled by the conductivity of the electrolyte. The conductivity goes through a maximum with increased KOH concentration (14), which could explain their data.

A Study of HCl in the LiCl-KCl Eutectic

John D. Van Norman*,[1] and Richard J. Tivers

Brookhaven National Laboratory, Upton, New York 11973

Many investigations have been made in recent years into the behavior of gases dissolved in molten salts. With the increased interest in high-temperature batteries, fuel cells, and metallurgical processes, the need for knowledge of chemical, electrochemical, and transport properties of gases in solution in molten salts is great.

Since the LiCl-KCl eutectic has become a fairly standard chloride solvent and the generally accepted manner of drying the mixture involves prolonged treatment of the eutectic, both in the solid and liquid state, with HCl gas, it was decided that a study of the behavior of HCl dissolved in the eutectic would be valuable. This paper is a report on the solubility of HCl in the LiCl-KCl eutectic as a function of temperature and on its electrochemical behavior; apparent diffusion coefficients are also presented.

Experimental Section

All chemicals used were of reagent grade. The lithium chloride-potassium chloride eutectic was prepared in a manner described by Laitinen, Ferguson, and Osteryoung (1). The apparatus for the measurement of the solubility of gases in molten salts has been described earlier (2). The method simply stated is to isolate a known volume of eutectic saturated with HCl, then to sparge the HCl from the eutectic with argon and to collect the HCl in water. The HCl is then titrated with standard NaOH solution.

The chronopotentiometric measurements were made in a cell previously described (2). The indicator electrode was a vitreous carbon electrode sealed into Pyrex glass. The vitreous carbon (made by the Beckwith Carbon Corporation) is impermeable to gases and has a coefficient of thermal expansion matched by some Pyrex glass so that the glass to carbon seal was leak tight. A silver foil immersed in an AgCl solution in a separate fritted compartment served as the reference electrode; a porous graphite rod was the counterelectrode. Chronopotentiograms were obtained by passing a constant current between the carbon and graphite electrodes while recording the potential between the carbon and the silver electrodes as a function of time. The constant current regulator was built by the Instrumentation Division of Brookhaven National Laboratory and the chronopotentiograms were recorded on an L&N High Speed Speedomax 6 recorder that had a pen speed of 0.25 sec full scale and a chart speed of 2.0 or 4.0 ips.

The eutectic was saturated with HCl at atmospheric pressure by bubbling HCl through the melt for at least 4 hr, a time found to be more than sufficient to saturate the melt, and an atmosphere of HCl was maintained above the melt at all times for both the solubility and chronopotentiometric studies.

Results

The solubility of HCl was measured at three temperatures, 490°, 570°, and 675°C. Each value reported is an average of eight or more determinations with the average deviation being quoted. The solubility of HCl in the LiCl-KCl eutectic at 490°C is 1.20 ± 0.14 x 10^{-6} moles/cc which corresponds to a mole fraction of 4.11 x 10^{-5}; at 570°C the solubility is 1.44 ± 0.10 x 10^{-6} moles/cc or a mole fraction of 5.05 x 10^{-5} while at 675°C the solubility is 1.74 ± 0.11 x 10^{-6} moles/cc or a mole fraction of 6.31 x 10^{-5}.

The solubility of HCl increases somewhat with temperature. A plot of log X_{HCl} *vs.* $1/T$ should be linear with a slope equal to $\Delta H°/2.303R$, where $\Delta H°$ is the heat of solution of HCl in the LiCl-KCl eutectic. Figure 1 shows this plot. The $\Delta H°_{HCl}$ so calculated is +3.5 kcal/mole with an estimated error of ±10%.

The solubilities found in this investigation are of the same order of magnitude as those found by Ukshe and Devyatkin (3, 4) at higher temperatures for single salts and NaCl-KCl mixtures. They also found that with the exception of the 1:1 mixture of NaCl and KCl the solubility of HCl increases with temperature.

Cathodic chronopotentiograms were obtained for the reduction of HCl in the LiCl-KCl eutectic at various temperatures. As mentioned, the cathode was a vitreous carbon surface and, as was found previously for chlorine systems (2), extreme care had to be taken to make sure there was no bubble formation on the electrode surface. Electrodes were inspected visually for any bubbles which might interfere with proper diffusion conditions at the electrode surface.

Figure 2 shows a typical cathodic chronopotentiogram of hydrogen chloride dissolved in LiCl-KCl eutectic. The transition time, τ, is taken at that point at which the potential rise becomes linear. The basic equation of chronopotentiometry is

$$i_0\tau^{1/2} = \frac{nF\pi^{1/2}D^{1/2}C}{2} \qquad [1]$$

The product $i_0\tau^{1/2}$ should be a constant at any given concentration and temperature, a fact which was verified experimentally for each run, within ±5%, the experimental error.

Many chronopotentiograms were obtained at 490° and 570°C, but attempts to secure meaningful results above 570°C failed because of softening of the Pyrex glass seal around the vitreous carbon electrode. Chronopotentiograms obtained in the absence of HCl showed no holdup of potential indicating no residual H^+ or any diffusion of Cl_2 generated at the anode to the

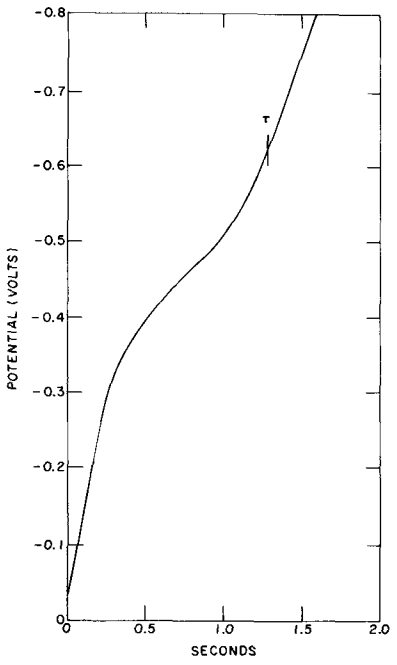

Fig. 2. Cathodic chronopotentiogram of HCl dissolved in molten LiCl-KCl eutectic at 570°C, current density 3.25 mA/cm^2.

cathode. Diffusion coefficients were calculated for the diffusion of HCl in molten LiCl-KCl eutectic. Each diffusion coefficient obtained is the average of ten or more determinations in each of two or more separate batches of salt. The experimental error can only be estimated but, because of variations between batches of salt, the difficulty of getting exact electrode areas and the possibility of undetected bubbles the error is placed at ±20%. The diffusion coefficient of the HCl species in the eutectic, D_{HCl}, is 2.4 ± 0.5 x 10^{-4} cm^2/sec at 490°C and 2.3 ± 0.5 x 10^{-4} cm^2/sec at 570°C.

This value is an order of magnitude greater than usually found for metal ions in the eutectic, 10^{-5} cm^2/sec. A similarly large value was found previously for the diffusion coefficient of Cl_2 in molten chlorides (2, 5). It is also interesting to note that the diffusion coefficient remains constant within experimental error as a function of temperature, again similar to that for Cl_2 in the eutectic (2). However, whereas the high diffusion coefficient results for Cl_2 were rationalized in terms of the trichloride ion Cl_3^- and a chain conduction mechanism, it is difficult to visualize a similar explanation for the D_{HCl} results. It is more likely that the small size of the H^+ ion formed from the dissociation of HCl permits more rapid diffusion through the ionic liquid.

It was impossible to determine from the chronopotentiometric measurements whether the reduction of HCl, or H^+, proceeds in a reversible manner in the eutectic. Further work is needed to ascertain this fact.

Electrocapillary Measurements in the Presence and Absence of Superimposed A-C Potential

John Lawrence and David M. Mohilner*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80521

During the last five years there has been some controversy (1-4), in studies of the mercury-solution interface, concerning the origin of the discrepancies between thermodynamic data derived from measurements of differential capacitance by the a-c bridge method and corresponding data derived from measurements of interfacial tension with a Lippmann capillary electrometer. The thermodynamic relationship (5) between interfacial tension and differential capacitance is

$$\left(\frac{\partial^2\gamma}{\partial E^2}\right)_{T,p,\mu} = -C \qquad [1]$$

Here γ is the interfacial tension, C the differential capacitance, E the electrode potential, and the subscripts T, p, and μ imply that measurements are made at constant temperature, pressure, and composition. It follows that double integration of a differential capacitance-potential (C-E) curve should yield the electrocapillary curve if the relevant integration constants are available. Numerous comparisons of this type have been made (1-4, 6) and it has been noted that, for dilute solutions of weakly adsorbed electrolytes, the Lippmann capillary electrometer gives results which are consistently lower on the anodic branch than those calculated from differential capacitance.

Three explanations have been suggested for these discrepancies: (i) inaccuracies in the methods of calculation before a comparison can be made (4), *i.e.*, during double integration of the capacitance data or, as has occasionally been attempted, during double differentiation of electrocapillary data; (ii) a potential-dependent finite contact angle at the three phase boundary mercury-solution-glass inside the electrometer capillary (4, 7); or (iii) the presence of the small a.c. across the interphase giving rise to a nonequilibrium double layer during differential capacitance measurements (1).

Recent evidence (4, 6, 8) indicates that (ii) is the most likely explanation since electrocapillary curves obtained by other methods which do not rely on contact

* Electrochemical Society Active Member.
Key words: double layer, differential capacitance, birth detector, maximum bubble pressure.

angle, *e.g.* drop time measurements and the "maximum bubble pressure" method, agree well with data derived from capacitance measurements. With modern computational procedures (i) has been shown to be incorrect (4, 9-11) but (iii) has never been subjected to a rigorous experimental test. The present investigation of (iii) was undertaken primarily in order to assess the feasibility of constructing a digital-computer-controlled capillary electrometer based on the "maximum bubble pressure" method described recently by Schiffrin (6). In addition, in view of the fundamental importance of the thermodynamic relationship between differential capacitance and interfacial tension (Eq. [1]) to the interpretation of double layer properties, it seemed worthwhile to attempt to settle experimentally the question whether the superimposition of a small a-c potential on the d-c potential of an ideal polarized electrode in dilute solution seriously disturbs the double layer equilibrium and thereby invalidates the conclusions drawn from analysis of *C-E* curves as was suggested previously (1).

Experimental

Following the basic principles described recently by Schiffrin (6), the classical method of "maximum bubble pressure" (MBP) has been successfully applied to the determination of electrocapillary curves. The gas pressure system had a nitrogen inlet and outlet bleed arrangement for coarse adjustment of the pressure and a screw copper bellows for fine adjustment. A 2 liter ballast volume facilitated fine pressure changes. The pressure was measured on a U-tube mercury manometer. The capillary was drawn from regular 1 mm Pyrex tubing to an internal radius of 15μ and then bent into a U-shape so that the tip was inverted. It was then "dewetted" by drawing the vapor of dichlorodimethyl silane (12) through the capillary for a few minutes, and the tip was then recut. The potential of the working electrode was controlled with an operational amplifier potentiostat circuit employing a Philbrick P85AU as control amplifier and a P25AU as voltage follower. The solutions were deaerated with prepurified nitrogen.

The gas pressure above the mercury reservoir was slowly increased during a measurement until the first droplet or "bubble" began to form at the tip of the capillary. This maximum pressure, which is directly proportional to the mercury-solution interfacial tension, was obtained by reading the manometer with a cathetometer and adding to this measurement the height of mercury in the reservoir above the capillary tip. The latter quantity did not change appreciably during the several hours that were required to obtain a complete electrocapillary curve. At the end of each measurement it was necessary to reduce the pressure to near atmospheric in order to stop the flow of mercury through the capillary. The proportionality constant used to convert the maximum "bubble" pressures to interfacial tensions was easily determined by a series of measurements with a solution for which the interfacial tension was known, as is done in the case of the conventional Lippmann electrometer. The absolute precision of the method, using a microscope to determine the instant of droplet formation at the tip, was usually better than ± 0.1 dyne cm^{-1}.

With the eventual aim of running the entire experiment on-line with a PDP-8/I digital computer, an electronic detector was designed which would give an output pulse of several volts at the instant when the first droplet of mercury begins to grow at the tip of the capillary. A controlled 5 mV, 10 KHz a-c potential was superimposed on the d-c potential of the working electrode using the control amplifier in a standard adder configuration (13).

Figure 1 shows the complete "birth" detector circuit which was constructed from Philbrick operational amplifiers. The a-c current flowing across the interphase was monitored by passing it through a current-to-voltage converter, the output of which is shown in Fig. 2(a). This trace shows a very small current until the mercury surface begins to expand at the tip, at which time it increases with a finite slope until the first droplet falls off. Half-wave rectification and smoothing of this a-c signal result in a d-c potential trace of similar shape, shown in Fig. 2(b). Differentiation of this signal then leads to a sharp voltage pulse (of about 40 msec rise time and 3-5V amplitude) at the instant when the mercury surface first begins to expand. This is illustrated in Fig. 2(c) where a dual beam oscilloscope was used to record simultaneously the smoothed d-c signal and the pulse output from the differentiator. The final operational amplifier shown in Fig. 1 is a simple 1/1 inverter to give a positive pulse suitable as an input to a voltage level converter[1] on the interface of the computer. Even in the absence of a computer for on-line experiments, it is much less tedious to determine the "birth" of the droplet by displaying the pulse on an oscilloscope than to observe the capillary tip visually through a microscope.

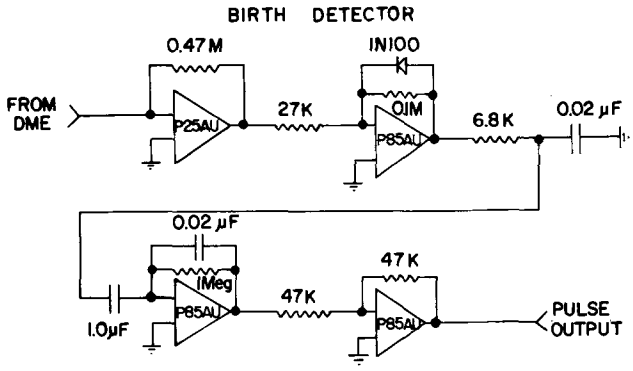

Fig. 1. Birth detector circuit

Results and Discussion

Figure 3 shows a comparison of an electrocapillary curve obtained by the MBP method with the second integral of the corresponding capacitance data for 0.01M NaF. The latter was derived from Grahame's charge density-potential data (17) which he obtained by integrating his own differential capacitance measurements from a potential of zero charge determined from the streaming electrode. We then integrated Grahame's charge density-potential data from five different potentials on the cathodic branch of the electrocapillary curve, taking as the integration constant the value of the interfacial tension determined by the MBP method. The smooth curve in Fig. 3 is the average of these five double integrations. Unlike Fig. 4 of Ref. (4) where an electrocapillary curve obtained with a Lippmann electrometer is compared with capacitance data, it can be seen that there is no systematic deviation between the two curves. It should also be noted in Fig. 4 of Ref. (4) that the size of the deviations (as large as 20 dynes cm^{1-}) depends strongly on the potential, and the deviations disappear on the cathodic branch of the curve.

The necessary requirement for the Lippmann electrometer is that the contact angle at the three phase boundary, mercury-solution-glass inside the capillary must be the same both for the solution used to calibrate the apparatus and for any test solution. Otherwise the radius of mean curvature (15) of the meniscus electrode calculated from the calibration data will not be the same as the radius of mean curvature prevailing in the case of the test solution. {It is usually assumed that the contact angle is not only equal in the presence of calibration and test solutions, but is actually zero. This is equivalent to assuming that the apparatus will behave satisfactorily only when the wall

[1] A DEC W-510 positive level converter and an R-302 one shot delay produce a pulse which can be used to trigger the A/D converter of the computer (14).

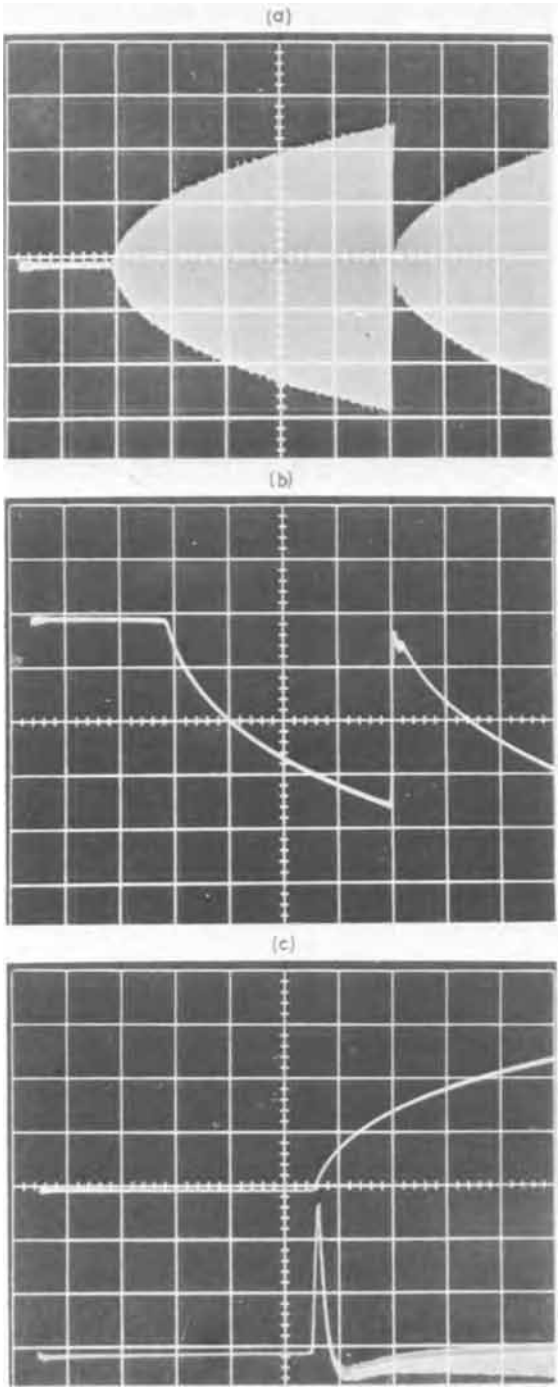

Fig. 2. The three stages of birth detection: (a) a-c current trace (0.5 sec/division, 0.2 V/division); (b) d-c potential trace (0.5 sec/division); (c) d-c potential trace and pulse output (0.5 sec/division, 1.0 V/division).

of the glass capillary is perfectly wet by the solution [*cf.* Gouy (16)].} The condition for mechanical equilibrium of the meniscus electrode is given by the Laplace equation which relates the pressure difference, Δp, across the curved interface to the interfacial tension, γ, and the radius, r, of mean curvature

$$\Delta p = 2\gamma/r \qquad [2]$$

In the calibration procedure, one measures Δp and then, knowing γ from independent (*eg.*, sessile drop) measurements, calculates the radius of mean curvature, r. When one uses a test solution one measures Δp and calculates γ using the same value of r determined in the calibration. If the contact angle is zero in the calibration experiment but finite in the presence of the test solution, the actual radius of mean curvature

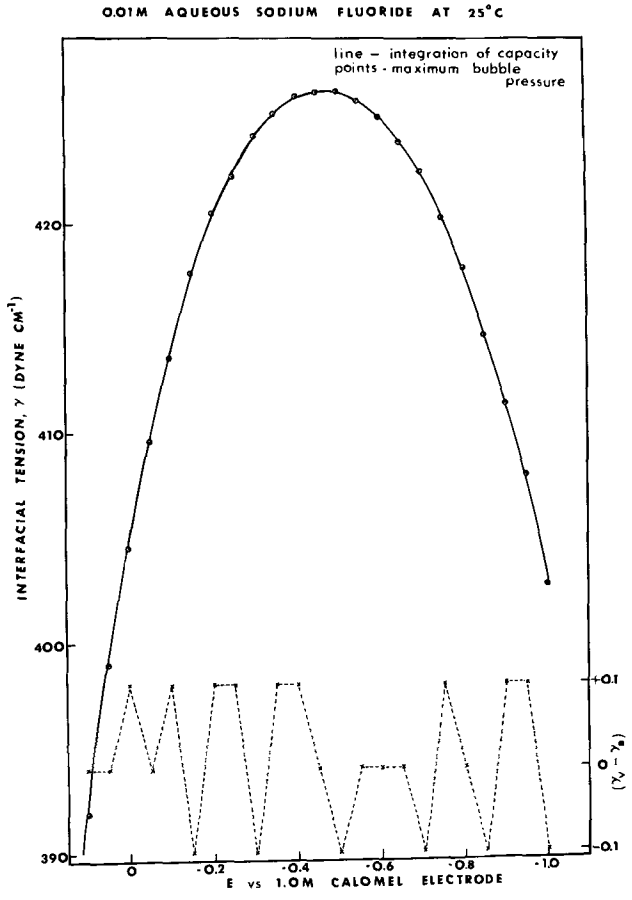

Fig. 3. Electrocapillary curve for 0.01M aqueous NaF at 25°C. Solid curve is doubly integrated differential capacitance. Points are determined by MBP method both visually and by electronic birth detection. Lower points connected by dotted lines indicate difference (γ_V-γ_E) between visual and electronic detection. Scale for these differences is on lower right of figure.

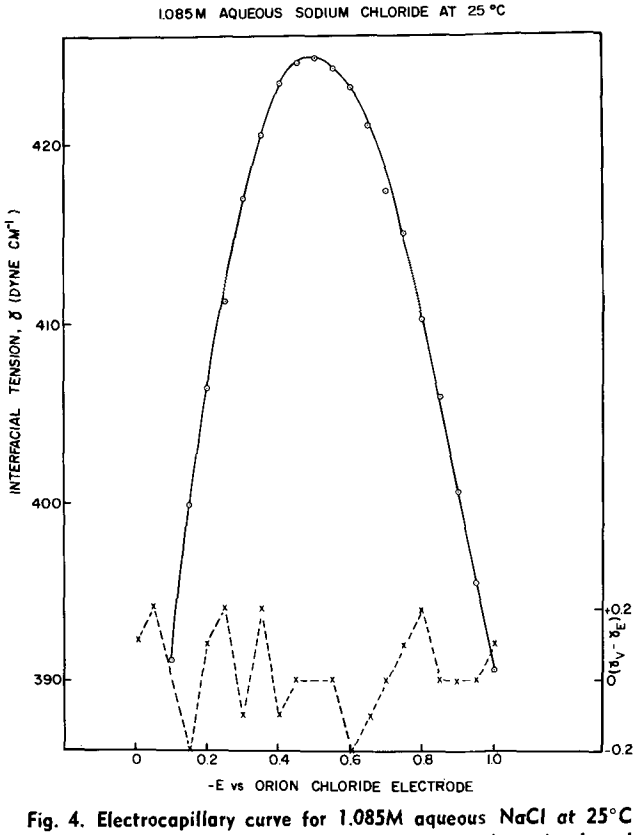

Fig. 4. Electrocapillary curve for 1.085M aqueous NaCl at 25°C and difference (γ_V-γ_E) between measurements using visual and electronic detection.

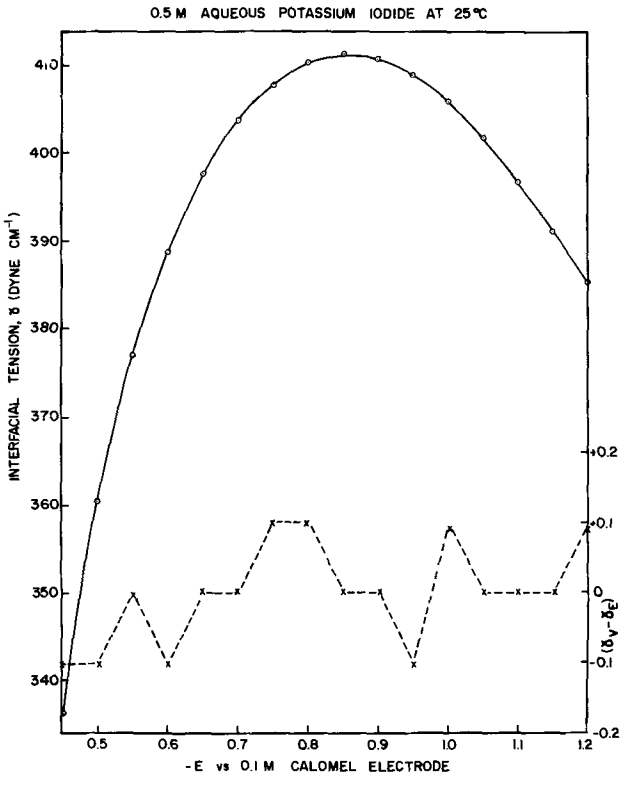

Fig. 5. Electrocapillary curve for 0.5 aqueous KI at 25°C and difference (γ_V-γ_E) between measurements using visual and electronic detection.

of the meniscus electrode in the presence of the test solution will have a different value $r' > r$. Therefore, the value of γ calculated from a Δp measurement with the test solution will be too small because one will necessarily substitute the value r determined by calibration rather than the (unknown) value r' into the Laplace equation. The negative deviations of γ measured with a Lippmann electrometer from those calculated by double integration of differential capacitance curves which were reported in Ref. (4) for the case of NaF solutions can therefore be explained by a finite contact angle at the three phase boundary inside the capillary in the presence of the NaF. Evidently [*cf.* Fig. 4, Ref. (4)] this contact angle becomes larger as the potential becomes more positive and as the solution becomes more dilute. In contrast, measurements of interfacial tension made by the maximum bubble pressure method are not subject to this source of error (6).

The data in Fig. 3-5 were obtained using both visual and electronic methods of "birth" detection in order to investigate precisely the effect of the a.c. on the equilibrium properties of the double layer. During measurements employing visual detection, the detector circuit and the a-c source were disconnected from the cell. The dotted lines show that the measurements obtained by the two methods agreed, within experimental error, for both dilute solutions of weakly adsorbed electrolytes (0.01M NaF in Fig. 3) and concentrated solutions of moderately or strongly adsorbed electrolytes (1.085M NaCl in Fig. 4 and 0.500M KI in Fig. 5). It must be concluded, therefore, that the effect of a low-amplitude a-c potential applied across the interphase is too small to be detected with present experimental techniques. Certainly the large discrepancies observed previously (1-4) cannot be attributed to the presence of the a-c potential.

The above discussion suggests that the controversial differences between electrocapillary measurements and differential capacitance measurements are due to systematic errors in the capillary electrometer and not to the effect of the a-c potential applied during capacitance measurements. Consequently it is suggested that, in all future studies of the electrical double layer involving dilute solutions of weakly adsorbed electrolytes, the conventional Lippmann capillary electrometer should not be used. If electrocapillary curves are required, it is recommended that they be obtained by MBP measurements.

Crystal Structures of the Elements of the Periodic Table and the Mechanisms of Electrolytic Hydrogen Evolution

Ashok K. Vijh*[,1]

Hydro-Quebec Institute de Recherche, Varennes, Quebec, Canada

In previous discussions (1-3) of the mechanisms of hydrogen evolution reaction (h.e.r.) on various metals, exchange current densities (i_o) for h.e.r. have been related to various fundamental properties of the metal, *e.g.*, work function, atomic number, compressibility, heat of sublimation, etc. It was shown (3) that these correlations arise primarily because of the relationship of i_o to the M-H bond strengths which in turn are partly determined by M-M bond energies through the Pauling's well-known equation (4). The M-M energies are usually (1-3) estimated from heats of sublimation by assuming a coordination number of 12 so that

$$D_{(M\text{-}M)} = \frac{1}{6}\Delta H_{Sub}$$

In this type of calculation, it is implicitly assumed that the crystal structure, and hence the coordination number, of the metal has little relationship to the mechanisms of h.e.r. As far as arguments involving M-H bond strength are concerned, this assumption is quite correct since small corrections to the estimated values of M-H bond strength would arise if the crystal structure and the coordination number of every metal were taken separately into account. This has been discussed by Conway and Bockris (1). However, such an implicit assumption of lack of influence of crystal structure of the metal on the mechanisms of h.e.r. contradicts some empirical observations which have been outlined in the following paragraphs.

As regards mechanisms of h.e.r., all metals of the Periodic Table may be divided into two main classes:

Class I: h.e.r. proceeds without significant steady-state chemisorption of hydrogen. The metals are: Zn, Cd, Hg, Al, In, Tl, Pb, Ga, Sn, Sb, As, Bi, Te, Se, Mn, etc.

Class II: h.e.r. proceeds with significant steady-state adsorption of hydrogen. All metals not mentioned in class I belong to this class: *e.g.*, Cu, Ag, Au, Ni, Fe, Pt, Rd, Ir, Mo, Ta, Nb, Ti, Re, etc.

It has been observed that all the metals of class II (*i.e.*, involving chemisorbed hydrogen and hence proceeding with radical-ion or atomic recombination as the r.d.s.), are typical metals in the strictest sense because:

(*A*) They crystallize into one of the three metallic structures, namely, face-centered cubic (fcc), body-centered cubic (bcc) or close packed hexagonal (cph).

(*B*) Their crystals may be regarded to be composed of approximately spherical units packed as closely together as possible.

(C) The crystallographic coordination numbers for these metals are obviously high, *i.e.*, 8 or 12.

However, metals of class I (*i.e.*, which proceed with initial discharge as the r.d.s.) are atypical in the sense that they do not meet one or more of the above three characteristics of typical metals. Even though some of the elements in class I have one of the three (fcc, bcc, cph) metallic structures they are noticeably modified. For example, even though cadmium and zinc are cph, the distance between atoms along one axis is greater than that obtained by packing spheres as closely as possible. Despite the fact that aluminum and lead are cubic, the distance between their atoms is greater than expected on the basis of closely packed spheres. The crystal arrangement in arsenic, antimony, and bismuth is rhombohedral hexagonal type with the atoms arranged as double layers so that each atom has three close neighbors in three directions; the neighbors are farthest away in this structure. This arrangement gives rise to a lattice structure in which the coordination number within a single layer is three. In Se and Te, the atoms are arranged in long spiral chains, with each atom having two close neighbors (5).

According to Slater (6) crystal structures of Mn, Hg, Ga, In, Sn, As, Sb, Bi, Se, and Te are not typically metallic (fcc, bcc, cph), which is consistent with their position in the class I elements here. Again in the classification of Slater (6) based on crystal structures of elements, many of the elements contained in class I here (*e.g.*, Ga, As, Se, In, Sn, Sb, Te, Tl, Bi) are not ordinary metals, but are peculiar in the sense that these elements verge on the nonmetals. One evidence of this approach to nonmetallic behavior in these elements is the fact that their bonds are very similar to nonpolar bonds. Ordinary metals (*viz.* class II here) do not, of course, form homopolar bonds in the accepted sense; this has profound consequences which distinguish them from the typical metals of class I here. Lack of homopolar bonding and the related directional property of the bonds gives rise in ordinary metals (*viz.* class II) to a behavior in which atoms act like spheres without preferred direction, thence the crystal structures with characteristic close packed spheres. From the foregoing the following conclusions may be made:

1. On the basis of crystal structure and related consideration, it has been shown that typically metallic elements (class II) are associated with mechanisms (*i.e.*, radical-ion and atomic recombination) in which h.e.r. proceeds with appreciable amounts of chemisorbed hydrogen in the steady-state. Conversely, on atypical metals (class I), h.e.r. proceeds through a mechanism (initial discharge) involving negligible steady-state concentration of chemisorbed hydrogen on the electrode surface.

2. Previous discussions of the mechanisms of h.e.r. on various metals which were based on the implicit assumption of the same crystal structure and same coordination number for all metals even though resulting in essentially correct arguments, are inaccurate in detail.

Why h.e.r. Involves Chemisorbed Hydrogen Only on Typical Metals?

Any attempt to provide a satisfactory and quantitative answer to this question would be somewhat presumptuous. However, a few lines of speculative thinking may be mentioned. It may be easily shown that, on the whole, the metals in class II here have high heats of sublimation and consequently high M-H (metal-hydrogen) interaction energies. This would tend to favor mechanisms involving strongly chemisorbed hydrogen. This approach has been successfully

Key words: hydrogen evolution reaction on metals, dondenergies, crystal structures of metals.

quantified by Conway and Bockris (1) and recently reviewed by Matthews (3). This type of analysis does not, however, yield satisfactory explanation of the qualitative relationship between crystal structure and the mechanisms of h.e.r. on various metals, as outlined here.

It is known that mechanical properties of the metals are closely related to their crystal structures. The close packing arrangement of typical metals (class II) provides the largest number of "planes of flow" when the crystal is stressed. A typical metal, under stress, would not cleave or fracture, but instead form a glide plane in which layers of atom slip over each other with insignificant loss of energy and with the re-establishment of the original structure. In the case of an ideal typical metal (class II) of an absolute purity, it is possible that, it would glide without loss of energy at all, under application of infinitely small stress. In other words, activation energy for the formation of dislocations would aproach zero for an ideal metal (5). In a real typical metal, one may assume that the activation energy for the formation of dislocations, even though not zero, would tend to be small. Since dislocations and other crystal defects are usually regarded as the sites favoring facile chemisorption, it follows that typical metals (class II) would tend to involve reaction mechanisms involving chemisorbed hydrogen as contrasted to atypical metals of class I.

It may be emphasized that the foregoing speculation does not provide a satisfactory causative explanation for the fact that typical (class II) metals sustain h.e.r. with significant steady-state coverage by chemisorbed hydrogen whereas on atypical (class I) metals, h.e.r. proceeds through initial discharge as the rate-determining step.

A generally held view (1-3) that facile chemisorption of hydrogen on class II metals, most of which are transition metals, arises because of presence of unfilled d-bands merits some comment here. These conclusions regarding the high chemisorption activity of transition metals in relation to unfilled d-bands have been derived on the basis of gas-phase adsorption of molecular gases, including hydrogen. Even though the hypothesis of relationship between unfilled d-bands and pronounced tendency to undergo chemisorption appears an attractive one, it does not stand up under closer examination, for the present case where the chemisorption does not involve dissociation of gaseous hydrogen molecules. According to analysis of Ehrlich (7), on chemisorption from gas-phase, the gases lose their molecular constitution and are bound as atoms. The chemisorption, therefore, is dictated by the considerations of thermodynamics: the chemical potential of hydrogen atoms bound together in the hydrogen molecule must exceed that of hydrogen atoms held by the solid in order for chemisorption to take place. Ignoring the entropic factor as a first approximation, the chemisorption would occur if the M-H bond strength of the hydrogen atom to the metal M exceeds half the dissociation energy of the hydrogen molecule in the gas phase. The experimental evidence only shows that among the transition metals this requirement is met, undoubtedly owing to their high heats of sublimation. For the present case of electrolytic hydrogen evolution, the chemisorption results from an initial discharge step which, for acidic solution, is

$$M + H_3O^+ + e^- \rightarrow M - H + H_2O$$

In this case, in order to demonstrate a unique dependence of chemisorption on the electronic structure of the metal, it is necessary to consider the gas-phase adsorption of atomic hydrogen and not molecular hydrogen. It has been found that there is no correlation between d-band configuration of the solid and its chemisorption behavior toward gas-phase atomic hydrogen (7). In fact, it has been observed that chemisorption of hydrogen atoms from gas-phase can occur on such nontransition metals as mercury, aluminum and potassium. It may hence be concluded that the mechanisms for h.e.r. involving significant chemisorption, on class II metal, probably do not arise because of the presence of unfilled d-bands in the transition metals. Other factors, the origin of which is not clear at present, must be involved. The ultimate explanation of the matters outlined in this note must lie in the satisfactory resolution of the rather fundamental questions such as: why do different metals have different crystal structures? In what causative manner are the magnitudes of heats of sublimation and coordination numbers, and thence the M-M bond energies, related to the crystal structure of metals? What are the basic factors which determine the magnitude of M-H bond strength for the chemisorption of electrolytically produced atomic hydrogen? And, finally, how can these and other factors be interrelated to yield a coherent picture which would predict high steady-state chemisorption of hydrogen, and thence the radical-ion and atomic recombination mechanisms, on metals of class II? Lack of significant steady-state chemisorption by atomic hydrogen during h.e.r. on metals of class I will also have to be explained in the foregoing terms. A detailed quantitative study of some of the foregoing matters is in preparation (8).

Brief Communication

The Exchange of Zn^{65} Between ZnO(s) and Potassium Zincate

L. A. Vander Lugt* and T. P. Dirkse**

Calvin College, Grand Rapids, Michigan 49506

Studies of the system Zn/Zn(II), KOH, especially in concentrations ordinarily used in battery systems, have revealed certain anomalies. Among these may be mentioned the ease of production and stability of supersaturated zincate solutions (1), and the appearance of maximums and minimums in correlations of certain kinetic constants with KOH concentration [exchange currents (2), conductance (3), and passivation time constants (4)]. These anomalies appear to be connected with the electrolyte phase. A fuller understanding of the chemical characteristics of the electrolyte is needed in order to more fully understand the electrochemical behavior of the system.

We have attempted to get more information by investigating the rate of attainment of equilibrium between the electrolyte and the various solid phases using radioactive zinc isotopes. In this note we present some results of our study of the equilibrium between solid ZnO and the potassium zincate electrolyte.

The exchange of Zn^{65} between the complex zincate ion and solid ZnO was studied by following the decrease in activity of the solution phase due to the uptake of Zn^{65} by the ZnO. The results are shown in Fig. 1. Curves 1 and 2 record exchange between powdered ZnO (0.3μ) and the zincate ion. For curve 1 the isotope was added after the solution was saturated with ZnO, while for curve 2 the isotope was added before the solution was saturated with ZnO. Curve 3 shows the exchange between solid crystalline zinc acetate and a saturated solution of zinc acetate at pH = 4.8. Curve 4 shows the same exchange at pH = 5.5.

These results show that exchange of Zn between ZnO and the zincate ion is extremely slow. In fact, no significant exchange occurs over a period of 500 hr. The solid ZnO showed no radioactivity after the exchange study was terminated. Curve 2 suggests that during the saturation period, a small amount of exchange may occur. However, once saturation is achieved (~24 hr) no further exchange is evident.

For zinc acetate the exchange process is normal (curves 3 and 4). The effect of decreasing pH is as predicted, increasing the exchange rate by suppressing hydrolysis. It is interesting to note that the extent of this is somewhat larger than expected.

It has been shown by Gerischer (5) that the following reaction is fast

$$Zn(OH)_4^{=} \rightarrow Zn(OH)_2 + 2\,OH^- \qquad [1]$$

Consequently, it may be concluded from our results that the reaction

$$ZnO + H_2O \rightarrow Zn(OH)_2 \qquad [2]$$

is slow. The apparent low rate of reaction [2] may be of fundamental significance in interpreting the processes occurring in zinc-alkaline batteries where supersaturated zincate electrolytes and solid ZnO are common products of discharge.

This exchange of Zn between ZnO and zincate ion is being studied in a range of electrolyte compositions in an effort to achieve a better understanding of the chemistry of this system. At present we can suggest no mechanism to explain this low rate of exchange.

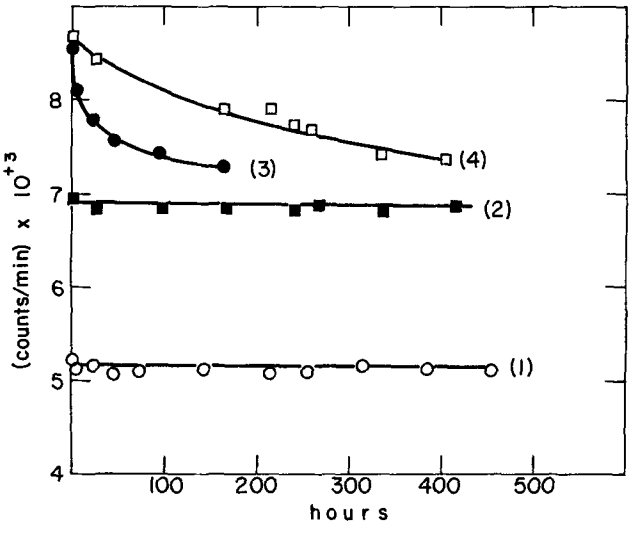

Fig. 1. Radioactivity of solution vs. time curves at 25° for the following systems: (1) solid ZnO, 35% KOH saturated with ZnO; (2) solid ZnO, 30% KOH saturated with ZnO; (3) solid zinc acetate, water saturated with zinc acetate, pH = 4.8; (4) solid zinc acetate, water saturated with zinc acetate, pH = 5.5. Each system had approximately the same amount of dissolved and undissolved zinc compound.

Sulfur Hexafluoride as an Etchant for Silicon

P. Rai-Choudhury*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Sulfur hexafluoride (SF_6) gas in hydrogen ambient is used to *in-situ* etch silicon wafers producing very smooth surfaces. The subsequently grown epitaxial silicon layers are of high quality (stacking fault density ≤ 4 per cm^2), and the impurity profiles as measured by the spreading resistance technique are indicative of layers not doped with sulfur. The entire process of etching and epitaxial growth are carried out at temperatures ($\leq 1100°C$) sufficiently low so that no dislocations are generated due to high thermal stresses. Some of the basic limitations introduced by such a highly reactive etchant are discussed.

The importance of substrate surface preparation and cleanliness in the epitaxial growth of silicon is well known to investigators of electronics materials. The defects in the epitaxial films could be caused by several factors; the primary causes are: (*a*) surface impurities derived from the substrate material, (*b*) surface impurities derived from chemical or mechanical polishing treatments, and (*c*) thermal stresses set up due to excessive temperature gradients from rf heating.

In-situ etching in the epitaxial reactors may be effective in removing certain surface oxides and films, mechanical damage, and other impurities which do not homogenize during the initial heating-up period because of their slow diffusion rates. Unfortunately, most of the harmful impurities, such as heavy metals, are fast diffusants and must be removed either at room temperature by some chemical treatment or at higher temperatures by gettering (1). Thermally induced dislocations (2) also suggest the use of low-temperature etchants. Even if one succeeds in developing a low-temperature etch, then the problems of subsequently growing an epitaxial silicon at low temperature still remain. The quality of the epitaxial material may be expected to be poor with decreasing deposition temperature when compared with the currently available good-quality Czochralski or float zone bulk crystals. This is a rather complicated subject under current investigation and therefore only a passing mention is made here. However, many desirable features, such as etching through oxide masks and in the presence of buried layers, make a search for a low-temperature etch worthwhile.

In a recent communication (3), etching characteristics of hydrogen sulfide were examined and compared with those of water vapor and hydrogen chloride. H_2S was found to etch Si at a lower temperature and at a very rapid rate, leaving a smooth surface. However, some of the undesirable features of this etch are high toxicity, extreme poisonousness in small quantities, and low purity. H_2S etching occasionally leaves deposits of sulfur compounds in the downstream of the reaction chamber, although no detrimental effect of sulfur could be detected on the subsequently grown layers. Sulfur hexafluoride (SF_6), on the other hand, is a nontoxic, noncorrosive, less poisonous, and odorless gas available in fairly high purity. Among the major reaction products from SF_6 etching are fluorides and sulfides of Si. If the fraction of SiS_2 formed increases significantly, then the system becomes very similar to the H_2S system, and the etching should be accompanied by some deposits of sulfur compounds near the exhaust of the reaction tubes along with the characteristic odor of sulfur. If the fluorides of silicon are the primary reaction products, then, of course, the reaction tube should be essentially free of deposits and odor of sulfur. The importance of hydrogen carrier gas may also be tested by carrying the reaction in an inert ambient which makes the formation of certain products, such as HF, impossible.

The purpose of this study is to explore the feasibility of SF_6 as a low-temperature etchant for Si so that the *in-situ* etching, as well as the subsequent epitaxial growth, of Si may be carried out below the "critical temperature" without introducing too many dislocations (2). The possibility of low-temperature vapor etching of substrates with mechanical damage resulting from lapping and sawing operations is also examined such that the rate of propagation of the damage-induced dislocations may be less than the rate of etching. Etching of holes in Si through oxide masking is also briefly examined.

Experimental Procedure

The apparatus used was a horizontal quartz reaction chamber in which substrates were placed on a graphite susceptor and heated by an external rf coil. The graphite susceptor was coated with silicon (at about 1500°C) in runs where *in-situ* etching was followed by epitaxial growth. SF_6 used was 10% by volume in ultrapure hydrogen. Desired concentrations of SF_6 were obtained by mixing controlled amounts with palladium-purified hydrogen. The initial surfaces of the silicon (111) wafers used for SF_6 etching were chemically polished, chem-mechanically polished, as well as lapped. In order to explore the possibility of etching holes in the silicon through an SiO_2 mask, oxidized wafers with etched widows were also used. An extensive cleaning and degreasing procedure was

* Electrochemical Society Active Member.
Key words: epitaxial, dislocation, hydrogen, ambient, impurities.

followed to minimize any wafer surface contaminants. Temperatures were measured by a disappearing filament pyrometer corrected for emissivity and absorption errors (4). The etch rates were determined from weight loss and wafer thickness measurements. Scanning electron microscopy (SEM) was used to characterize these surfaces.

Epitaxial layers were grown on etched substrates from the $SiCl_4$-H_2 process, and provisions for doping with B_2H_6 and AsH_3 were made. These layers were subjected to optical examination for stacking faults and other defects. The concentration profiles and any resistivity inhomogeneities were measured by the spreading resistance technique (5).

Results

In order to gain some understanding of the reactions taking place, experiments were carried out in H_2 carrier gas as well as in Ar carrier gas at 1100°C. In both cases comparable etch rates were obtained (~2.0 μ/min). Based on these results, assuming that HF is not formed in any significant amounts, the overall reaction may be tentatively written as

$$4Si(s) + 2SF_6(g) = SiS_2(s \text{ or } l) + 3SiF_4(g)$$

The standard free energy of this reaction is −706.81 kcal at 1400°K, and the equilibrium constant is a very large number indicating that the reaction is spontaneous and irreversible under most experimental conditions. A similar conclusion is reached if SiS instead of SiS_2 is considered as a reaction product. The choice of SiS_2 rather than SiS as one of the reaction products was justified elsewhere (3). Among the reaction products only SiS_2 will condense near the outlet of the tube and emit the characteristic sulfur odor during unloading of the tube. The etched surface in H_2 carrier gas was mirrorlike, whereas in Ar ambient the etching was relatively nonuniform. It is quite possible that the trace amounts of HF that may be formed in H_2 ambient are effective in removing any surface oxides during etching. Unlike H_2S etching, in all these runs the deposits on the tube walls were negligible (provided an uncoated susceptor was used), and only a faint odor of sulfur was detectable during unloading of the reactor tube.

Figure 1 shows the temperature dependence of the etch rate at an SF_6 partial pressure of 1 x 10^{-3} atm and a total H_2 flow rate of 100 liters/min (linear velocity ~25 cm/sec). Although the etch rates are based on the change in total thickness, the back of the wafers remained practically unetched. The shape and the slope of the curve are indicative of the increasing importance of the mass transfer rates, through a boundary layer, to or from the wafer surface, with increasing temperature. The dependence of the etch rate on SF_6 partial pressure at a temperature of 1050°C is shown in Fig. 2. The slope of the curve is only

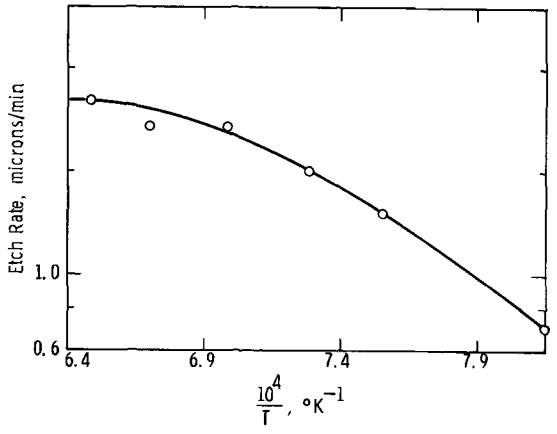

Fig. 1. Effect of temperature on etch rate of silicon: p_{SF_6} = 1 x 10^{-3} atm; total flow rate 100 liters/min.

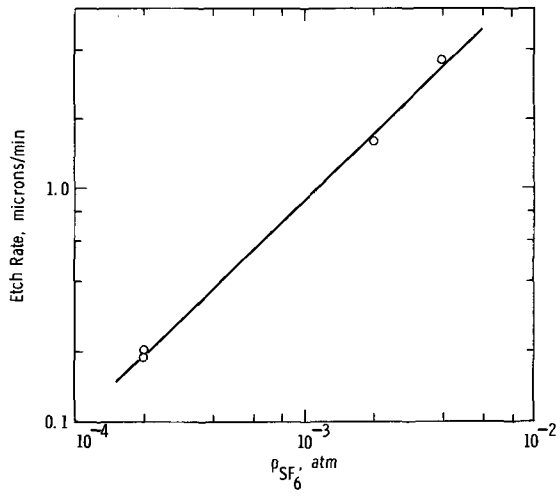

Fig. 2. Effect of sulfur hexafluoride partial pressure on etch rate of silicon at a temperature of 1050°C.

slightly less than unity and indicates that the etch rate is approximately directly proportional to the SF_6 partial pressure. Thus, the rate of diffusion or transport of SF_6 to the Si surface is playing a significant role in the etching process.

The quality of the surface resulting from etching an initially (chemically as well as chem-mechanically) polished surface is described first. The results of SF_6 etching of lapped surfaces are described subsequently. At low temperatures (~850°C), etching is preferential and dislocation etch pits become visible. Smooth nonpreferential etching results from about 1050°C and above. Figure 3 shows scanning electron micrographs of etched surfaces at 1100°C and SF_6 partial pressure of 2 x 10^{-4} atm. The results in general indicate that the temperature is much more critical than the SF_6 partial pressure in determining the surface quality.

Direct etching of a lapped surface is, of course, not desirable, because during heating the mechanical damages from sawing and lapping will anneal out into dislocations which may then propagate into the bulk of the wafer. However, this provides a reasonable indication of the nonpreferential nature of the SF_6 etch. Figure 4 shows how an initially lapped surface changes with the etching temperature. The initial lapped surface (Fig. 4a) has abrasion-induced triangular as well as some hexagonal pits and is relatively free from deep craters or pits. At 950°C the triangular pits almost disappear, and the surface is characterized by deep hexagonal craters as well as some remnants of thin silicon flakes protruding out of the surface. These flakes appear bright in the micrograph because they are thin enough for the primary electron beam to penetrate and produce secondary electrons on both sides of the flakes. It appears that at 950°C the hexagonal pits are etched faster than the rest of the surface, probably because of deeper mechanical damage. At 1050°C relatively larger and shallow etched morphology begins to appear (Fig. 4c) and becomes smoother with increasing temperature (Fig. 4d). X-ray topographs of an initially lapped wafer from which about 136μ were removed at 1100°C (etch rate ~1.7 μ/min) indicate the absence of significant propagation of damage-induced dislocations. It seems surprising that the etching time (~80 min) was not sufficient to propagate damage-induced dislocations through the entire thickness of the wafer (~300μ). The results indicate that, although it may be possible to thin a lapped wafer by vapor etching without inducing dislocations, the etched surface is not suitable for epitaxial growth and subsequent device fabrication.

In the absence of any pinholes, SiO_2 films grown thermally on silicon substrates can be effectively used as a mask against SF_6 etch. However, in the presence of pinholes or etched windows (by standard photo-

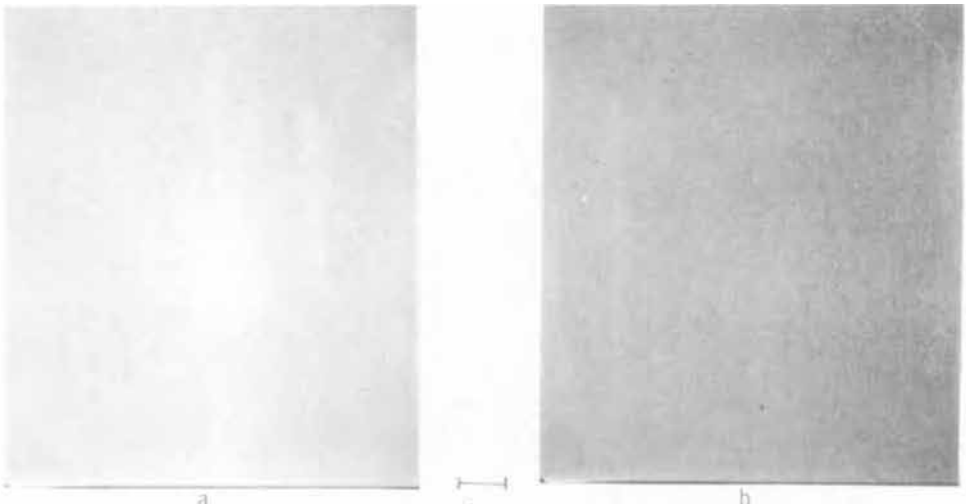

Fig. 3. Scanning electron micrographs at 45° incidence showing smooth surface of silicon etched with SF_6 at 1100°C: (a) surface initially chem-mechanically polished, (b) surface initially chemically etched in $HF\text{-}HNO_3$ mixture.

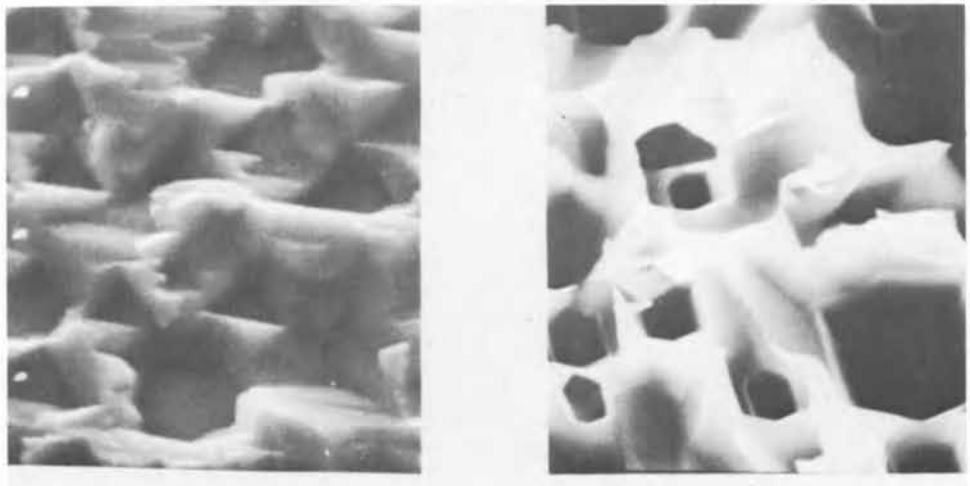

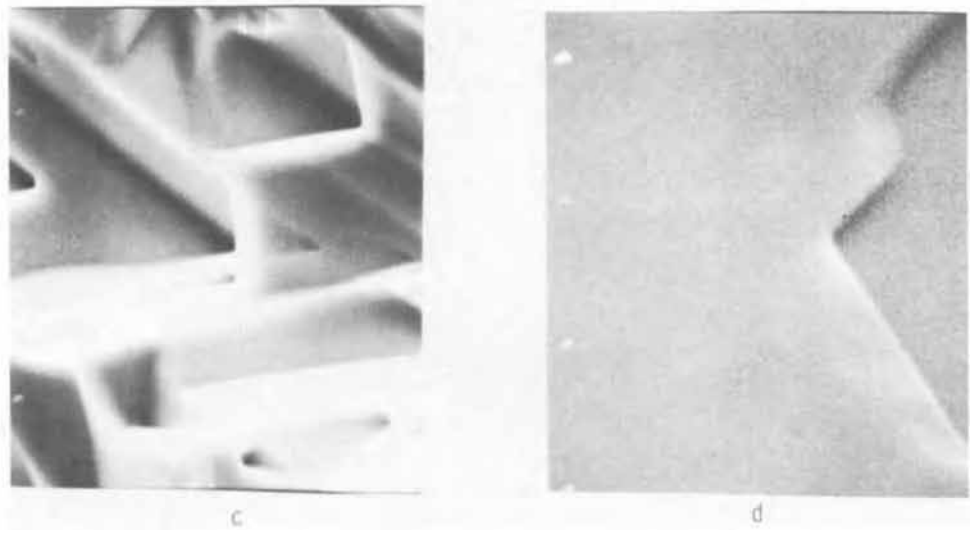

Fig. 4. Scanning electron micrographs at 45°C incidence of surfaces etched at different temperatures starting with a lapped initial surface: (a) initial lapped surface, (b) etched at 950°C, (c) etched at 1050°C, and (d) etched at 1160°C.

lithographic techniques), considerable undercutting of the mask was observed. The SF_6 etching was performed on circular patterns, 9μ in diameter, with center to center separation of 18μ, and about 4μ of Si were removed. Figure 5 is a scanning electron micrograph of an etched silicon surface through an SiO_2 mask showing considerable undercutting.

One of the problems with the SF_6 etch is its extremely high reactivity which imposes severe limitations on selection of materials such as susceptor, reactor tube, *etc.* Although a bare graphite or a SiC-coated susceptor apparently produces good results in the etching cycle of the operation, they are undesirable susceptor materials for the subsequent epitaxial growth operation. Graphite or SiC or any particle that etches relatively slowly in SF_6 gets embedded in the epitaxial layer and often causes stacking faults. A silicon-coated susceptor is preferred only in the sense

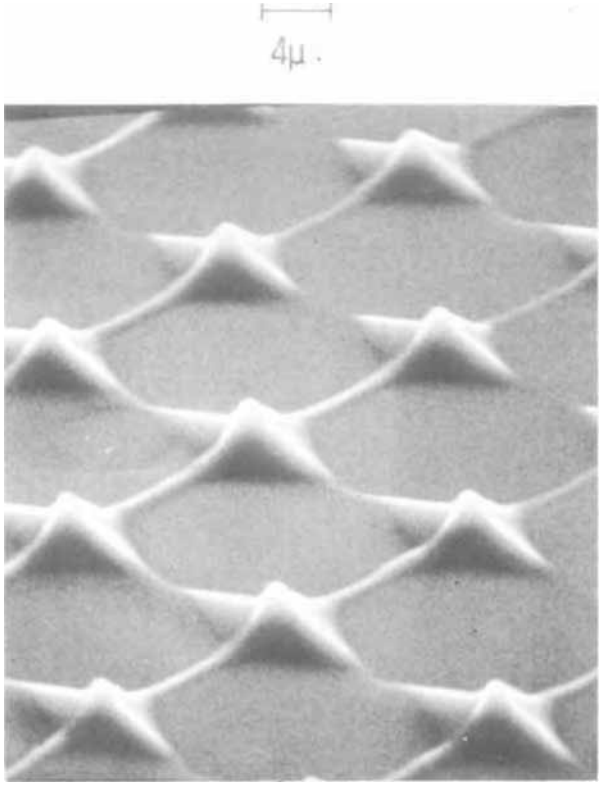

Fig. 5. Scanning electron micrograph at 60° incidence showing the results of etching silicon through an SiO_2 mask.

that the reaction products from such a susceptor are volatile. The undesirable feature of a silicon-coated susceptor is that the susceptor is stripped of silicon during etching, exposing bare graphite surfaces. This problem may be avoided by restricting the etching time. Another limitation of this etch is that it adsorbs strongly on the gas lines and becomes a potential source of contamination and defect nucleation during epitaxial growth. Using the best available susceptor, namely a silicon-coated (at about 1500°C) graphite susceptor, the stacking fault densities in the grown layers were minimized by restricting the *in-situ* etching to about 5μ and introducing SF_6 gas through a separate line. Following these precautions epitaxial layers were consistently grown having a stacking fault density of 2-4 faults/cm^2. The SF_6 etching as well as the epitaxial growth were carried out at 1050°-1100°C, a temperature range at which a significant number of dislocations are not introduced (2).

Several runs were made following SF_6 etching, and the layers were doped with AsH_3 giving net impurity concentrations in the range of 10^{14} to 10^{16} atm/cm^3. The impurity profiles as a function of depth measured by a high-resolution spreading resistance technique (5) indicate normal good-quality epitaxial silicon with *no* detectable effects of sulfur contamination. The substrates used for these runs were 20 ohm-cm, p-type. The doping level of the substrates did not change from the possible introduction of donor levels due to sulfur contamination. However, due to its high diffusivity in silicon, the effects of sulfur at low levels in reducing the carrier lifetime in silicon cannot be ruled out.

In conclusion it should be emphasized that the limitations of the SF_6 gas mentioned should be common among most low-temperature etchants. Besides formation of volatile reaction products a prerequisite for a low-temperature etchant is its high reactivity, and the consequences of its high reactivity are the problems of selection of susceptor material and purging out and/or desorption of the residual etchant from the system.

Summary

Sulfur hexafluoride, unlike hydrogen chloride, etches silicon irreversibly and spontaneously, producing volatile sulfides and fluorides of silicon. The etching results in a very smooth surface on chemically as well as chem-mechanically polished starting substrates, and the process is suitable for wafer thinning. Although lapped wafers may be etched at low temperatures and rapid rates so that significant numbers of damage-induced dislocations are not generated, the resultant surface is relatively rough and is therefore unsuitable for device quality epitaxial growth. SiO_2 does not provide effective masking for etching holes in selective areas of the substrate because of severe undercutting. The entire process of etching and growth on chemically and chem-mechanically polished substrates is carried out at low enough temperatures ($\leq$1100°C) so that no significant dislocations are generated from the thermal stresses induced in the epitaxial reactor. However, because of the high reactivity of SF_6 the silicon coating of the susceptor is attacked rapidly, and the subsequent epitaxial layers are not entirely free from stacking faults.

Factors Affecting the Growth Rate of Plasma Anodized Al_2O_3

John F. O'Hanlon*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

This paper discusses the affects of anodization parameters on the growth rate of plasma anodized Al_2O_3. Variations in growth rate were inferred by observing the variations in the anodic current decay while anodizing at a constant bias potential. The following effects have been observed: (*a*) Sputtered cathode oxide was found to contribute significantly to the total film thickness unless adequate shielding was employed. (*b*) Heating the substrate from 30°C to 100°C caused the current to decay tenfold faster. (*c*) A maximum growth rate (quickest current decay) was observed at an O_2 pressure of approx. 50m Torr. Probe measurements taken at the location of the sample showed a maximum electron density at this pressure. The maximum electron density and quickest decay rate shifted to higher pressures (approx. 100m Torr) as the discharge current was increased. (*d*) The presence of small amounts of water vapor in the discharge slightly increased the anodic current decay rate.

The kinetics of oxide growth in a plasma anodizing system are affected by several system parameters. The most important of these are the cathode sputtering rate, oxide temperature, oxygen partial pressure, and water vapor partial pressure. Different investigators (1-3) have studied the effects of a different one or two of these variables while exercising little or no control over the remaining parameters. In addition no two investigators have pursued these studies with identical experimental systems, thus making comparisons of plasma characteristics, sputtering rates, and water vapor content impossible. The purpose of this paper is to systematically study the effects of each of the above parameters on the growth rate of thin (200Å) Al_2O_3 films in a low pressure oxygen d-c glow discharge.

Oxide growth is accomplished by positively biasing an aluminum sample which is immersed in the negative glow of a d-c oxygen glow discharge. The growth of an aluminum oxide film is shown schematically in Fig. 1. It is seen that the oxide growth rate and sample current become diminishingly small with time until the film assumes a limiting thickness. For the purposes of this investigation, the time required for the current to decay to 10% of its initial value shall arbitrarily be taken as a measure of the time required to grow the film.

Experimental System

The vacuum system in which the data were taken is shown schematically in Fig. 2(A). The aluminum cathode ring is mounted between two stainless steel plates which are the anodes; the sample is mounted on a support below the level of the cathode ring to avoid direct exposure to reactively sputtered cathode oxide. Figure 2(B) shows a detailed view of the sample holder. This design, used by Jennings and McNeill (4), was suitably modified so that it could be heated or cooled by N_2 gas. Care was taken to thermally isolate the sample face and the Pyrex walls of the sample holder tube; this was necessary when it was desired to cool the sample to near liquid nitrogen temperature without the complication of the walls acting as a source or sink of water vapor. An independent liquid nitrogen trap was provided for that purpose.

The system pressure was held in dynamic equilibrium by controlling the rate of oxygen input and sorption pump exhaust. Mass analysis of the gas discharge was accomplished by sampling a small amount of the gas in the discharge through a controlled leak.

Prior to anodizing, the sample was rf sputter cleaned in 10m Torr of argon for 25 min to remove any oxide present. Ten minutes after initiating the oxygen glow discharge, a fixed bias voltage ($V_b \simeq 5V$) was applied

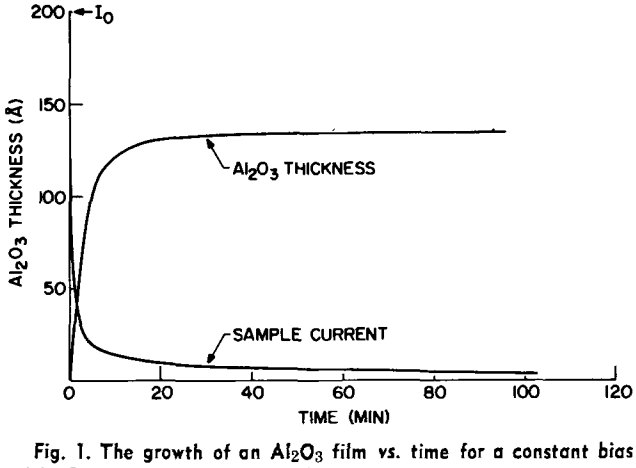

Fig. 1. The growth of an Al_2O_3 film vs. time for a constant bias of 6V [after Miles and Smith (1)].

Key words: Al_2O_3 growth rate, plasma anodization, oxygen glow discharge.

and the time dependence of the current decay was recorded. The thickness, T, of the Al_2O_3 film grown should be no greater than

$$T \leq (V_b - V_w)K$$

where V_w is the floating potential (−4.5V) and K is the anodization constant (22 Å/V) obtained by Miles and Smith (1) and Tibol and Hull (5) while anodizing to completion at constant voltage in a similar discharge. Thus, these films should be approximately 200Å thick. By successively sputter cleaning and anodizing, all of the data were taken on one sample without breaking the vacuum seal. RF sputter cleaning continually left a mirror smooth surface; however, d-c sputter cleaning was found to leave a rough surface with macroscopic patches of oxide. This is in agreement with Jona (6), who found that rf sputtering was necessary to obtain good LEED patterns on single crystal aluminum surfaces.

The electron density measurements were made with a spherical gold Langmuir probe (r_p = 2 mm). For each probe measurement the electron temperature and saturation electron current at the "knee" of the curve were obtained (see inset, Fig. 6); from these data the electron density of the plasma was obtained. For a weakly electronegative O_2 plasma of this density, the error in estimating the electron density is unlikely to be greater than 40% (7).

Results

Cathode sputtering.—Contamination of the growing oxide by reactively sputtered cathode material (Al_2O_3 in this instance) previously has been shown to increase the thickness of the oxide (8). Two of those observations bear repeating here: First, with the sample a few cm from, and facing the cathode, sputter deposition rates of 2.5 Å/min and higher were recorded. Second, with a sample shielded from the cathode, as in Fig. 1, considerably lower sputter deposition rates were recorded. For the electrode spacings used in this study, the rates were 0.45 to 0.55 Å/min (Al_2O_3) respectively for the 50 mA and 80 mA discharges. Were the sample to be mounted 20 cm below the cathode plane, these deposition rates could be reduced to approx. 0.02 Å/min.

Temperature effects.—In Fig. 3 the effect of substrate temperature at constant pressure on the rate of current decay is illustrated for the range 32°C to 105°C; one observes that the 105°C film formed in one-tenth the time of the 32°C film. The current decay data can be approximately fitted to the sum of two exponentials; an unexplained rapid decay lasting less than 25 sec, followed by a slower temperature dependent decay. An activation energy of 1.8 ± 0.1 eV was obtained for the slower decay which agrees with Charlesby's work on solution anodized aluminum (9), but is higher than the value of 1.3 ± 0.15 eV obtained by Harkness and Young (10) by solution anodization. Since the film thicknesses were not measured, and the anodization constant is temperature dependent, the temperature dependence of the current efficiency could not be obtained.

Some elementary characteristics of the constant current d-c oxygen discharge operating in the range 10m Torr $< P \lesssim$ 150m Torr will be described here. At a suitably low pressure, say 10m Torr, the negative glow is weak and diffuses out from the cathode to fill the volume; good thermal contact exists between the glow and the sample, and the sample temperature, T_s, is high (100°C for the 50 mA discharge). As the pressure is increased toward 150m Torr, less power is required to maintain the discharge current and the negative glow contracts around the cathode, isolating the sample from the source of heat. For these reasons the uncontrolled substrate temperature was found to decrease to 60°C at a pressure of 50m Torr, and 30°C at 150m Torr The strong observed temperature dependence of the growth rate points out the necessity of adequate substrate temperature control while studying the effects of pressure variations on the growth rate.

Pressure effects.—Miles and Smith (1) and Fopiano (3) have observed a pressure dependence in the time required for film growth; both observed a minimum in the time required to form the oxide at pressures of 50 to 60m Torr. These data were taken in systems with a geometry rather like the one used here, that is, a geometry with a large anode to cathode area ratio. These measurements were repeated in this study with similar results. In Fig. 4, the time dependence of the current decay is plotted for three pressures with all other variables held constant. The initial current was maximum, and the current decay time was minimum at a pressure of approx. 110m Torr. From data of this type, one can obtain the relation between the formation time and pressure shown in Fig. 5; the data from this study taken at two discharge currents are shown along with the data of Fopiano (3). For each discharge current studied, a minimum formation time was observed. The minimum for the 50 mA discharge occurred at approximately 50 to 60m Torr, while the minimum for the 80 mA discharge occurred at about 110m Torr.

The effective bias across the oxide is the potential difference between the applied bias voltage and the surface potential of the oxide-plasma interface. In all

cases the bias voltage was held at +5V, and probe measurements showed the plasma floating potential to be −4.5 ± 0.5V for 10m Torr < $P \lesssim$ 150m Torr. For pressures greater than 150m Torr, the floating potential became very large (−15V at P = 220m Torr) as the negative glow concentrated around the cathode. In this high pressure range the effective bias across the sample is larger and the film is growing to a greater limiting thickness than at pressures less than 150m Torr where the effective bias remained nearly constant; analysis is therefore limited to the pressure range 10 to 150m Torr.

To aid in interpreting the data in Fig. 5, the electron density was measured at the location of the sample with a spherical gold Langmuir probe for the same values of oxygen pressure and discharge current shown is Fig. 5. In Fig. 6 the electron density is seen to have a maximum roughly corresponding to the minimum in anodization time. The variation in electron density may be explained by recalling the discharge characteristics. For low pressures the electron density increases with pressure, but for high pressures where the range of the negative glow becomes less than the cathode-sample distance, the electron density decreases, and the electron temperature increases at the location of the probe. In the abnormal glow, increasing the discharge current causes the negative glow to expand, slightly shifting the peak density to a higher pressure.

The explanation for the minimum anodization time is not obvious. Although the minimum anodization time corresponds to the maximum electron density, the variation in anodization rate with pressure is much greater than the corresponding change in electron density. It was also found that the pressure dependence of the initial value of anodizing current (see Fig. 4) was exactly like the pressure dependence of the saturation electron current (not electron density) of the gold probe, while the total charge passed in forming the film (the area under the I-t curve in Fig. 4) was less for the pressure of most rapid growth, indicating that the current efficiency was greatest for this

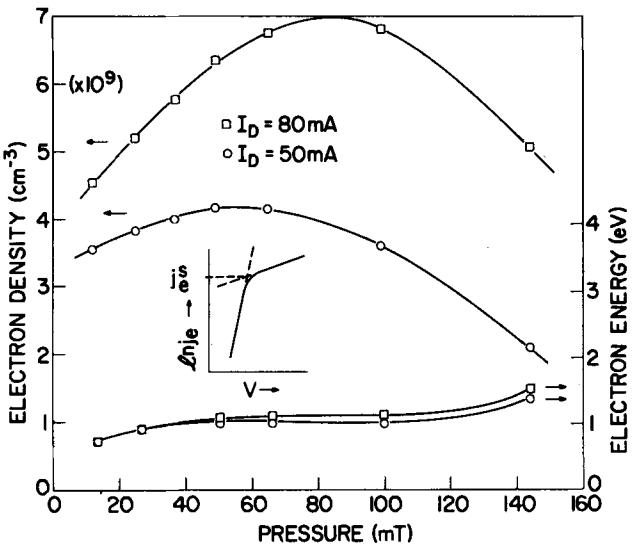

Fig. 6. Electron density vs. pressure and discharge current as measured by a spherical gold Langmuir probe (r_p = 2 mm). The electron density was calculated from the saturation electron current density at the "knee" of the log J_e vs. V curve shown in the inset.

case. These observations imply a large pressure dependence of the negative ion density.

From a practical viewpoint, it is important to know that there exists an optimum pressure for each system of this type which is dependent on the ratio of the negative glow length to the cathode-sample distance; this observation is not valid for cylindrical-confined discharges of equal cathode-anode area.

Water vapor effects.—The effect of water vapor in the glow on the rate of anodization has been observed. In Fig. 7 the current decay for two oxide formation runs at 54°C is illustrated. In one run a liquid nitrogen trap was used, in the second run no liquid nitrogen trap was used, but all other parameters were

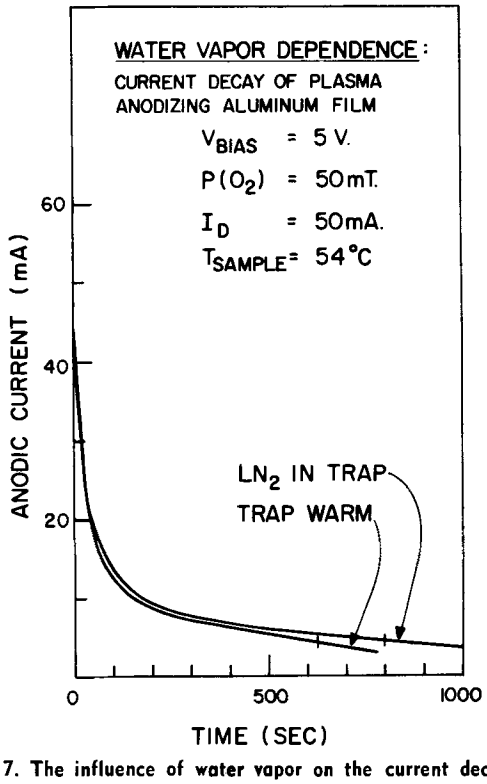

Fig. 7. The influence of water vapor on the current decay of a plasma anodizing aluminum film. V_B = 5V, P = 50 mTorr, I_D = 50 mA, T_s = 54°C.

identical. This second sample anodized about 20% faster.

Mass analysis of the discharge revealed the water vapor pressure to be 10^{-6} Torr, when the auxiliary trap was warm. With the trap cooled to 77°K and locally pumping water vapor, mass analysis in a differentially pumped system is no longer valid. The following experiment demonstrates the effectiveness of the trap in removing water vapor near the sample. When an aluminum sample was cooled to 140°K, the presence of water vapor caused anomalous film growth. To observe this effect, the aluminum sample was anodized at a constant current density of 0.2 mA/cm^2, and a temperature of 140°K; the voltage increased linearly to 5V in 3000 sec. Upon repeating the experiment without use of the auxiliary cold trap, the voltage was observed to rapidly increase to 25V in 2000 sec, implying formation of a very thick film; temperature cycling this second sample to 300°K caused the voltage to drop sharply to 5V, showing that this film was most likely ice. This demonstrates that the cold trap is capable of reducing the water vapor pressure to a lower, unknown value.

Miles and Smith (1) observed that the resistance of tunnel junctions was increased by the presence of water vapor in the discharge and suggested that the aluminum was reacting directly with the water vapor. Such a reaction for very low water vapor concentrations would be in agreement with the more rapid current decay observed here in the formation of thin Al_2O_3 films.

Conclusion

For a given electrode geometry, discharge intensity and sample location, it has been determined that there is an optimum pressure for most rapid anodization. For the parameters used in this study, the optimum pressure occurred between 50 and 100m Torr. It should be emphasized that the particular values of optimum pressure obtained are valid only for this geometry; each similar system will have its own characteristic optimum pressure dependence. Increasing the substrate temperature was also found to increase the current decay rate and probably the oxide thickness for the pressure range studied. Unless the substrate temperature is independently controlled, the substrate will obtain a higher temperature at low pressures where the sample is immersed in the glow. A small increase in the H_2O content of the discharge was found to slightly increase the anodization rate for samples with normal anodization temperatures.

Energy Loss and Energy Storage from the Eu^{+3} Charge-Transfer States in Y and La Oxysulfides

W. H. Fonger and C. W. Struck

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

In Y_2O_2S:Eu and La_2O_2S:Eu, concentration- and temperature-dependent loss and storage effects are observed for excitation into the Eu^{+3} charge-transfer states (CTS) and into certain Eu^{+3} ^5D states. It is shown that the losses and storage both occur from the CTS. They occur for ^5D excitations only as a consequence of the ^5D excitation having reached the CTS through thermally promoted $^5D \rightarrow$ CTS crossovers. The losses and storage are both attributed to the Eu^{+3} CTS dissociating thermally into Eu^{+2} plus a free hole. The freed holes are stored in hole traps. If the holes are thermally or IR stimulated back to the Eu^{+2} centers and re-form the Eu^{+3} CTS, the stored energy is retrieved as Eu^{+3} line emissions. If the extra electrons at the Eu^{+2} centers migrate through the Eu activators and recombine nonradiatively at the hole centers, the stored energy is lost.

We have recently described transitions that take place between the ^5D and charge-transfer states (CTS) of Eu^{+3} in oxysulfide and oxychloride hosts (1, 2). A configurational-coordinate diagram accounting for these transitions through crossovers was also provided. We now report on energy-loss and energy-storage events that occur from the CTS in oxysulfides. The interplay between these events and $^5D \leftrightarrow$CTS crossovers leads to some interesting luminescence phenomena.

Key words: luminescence, phosphors, rare-earth spectra, concentration quenching, energy transfer.

Configurational-coordinate models with crossover losses to the ground state have been proposed for broad-band luminescence centers by several authors (3). See, for example, their recounting in Blasse and Bril's recent discussion of niobate phosphors (4). However, oxysulfide CTS crossovers to the ground ^7F

multiplet appear to be too high (1, 2) to be significant for losses. Moreover, the oxysulfide losses increase with Eu concentration, whereas the models cited are single-center models and predict losses insensitive to the activator concentration.

For concentration-dependent losses, Dexter and Schulman (5) proposed an ion-ion energy-transfer model. The excitation migrates undegraded through the activator ions until lost at special quenching centers. Many workers in the rare-earth field have emphasized a second energy-transfer model with no special quenching centers. The excitation is degraded in a single transfer of part of the energy to a second activator ion. For example, Van Uitert and Johnson (6) have so interpreted concentration quenching observed from the Sm^{+3} $^4G_{5/2}$, Eu^{+3} $^5D_0$, Tb^{+3} $^5D_3$, Er^{+3} $^4S_{3/2}$, and Nd^{+3} $^4F_{3/2}$ levels.

Van Uitert and Johnson's explanations were directed toward rare-earth losses that occur from emitting 4f levels because they used excitations that efficiently populated these levels. However, if very energetic excitation is used, losses can occur from higher levels. For example, Bril, Blasse, and Bertens (7) have found that most Eu^{+3} phosphors with losses under Hg 254 mμ excitation are very efficient for excitation into the emitting ^5D levels. Riedel (8) similarly found that the dominant losses in Y_2O_3:Eu occur above the ^5D levels.

The work here will show that the oxysulfide losses[1] are of the "higher" variety and, in particular, occur from the short-lived CTS. Although the losses do occur for excitation into certain ^5D states, the work here will show that such losses occur only as a consequence of the ^5D excitation having reached the CTS through thermally promoted $^5D \rightarrow$ CTS crossovers.

With the losses tied to the CTS, the challenge is then to understand their concentration dependence from the short-lived CTS. Insight for this understanding is provided by the more readily interpreted energy-storage effect.

The novel aspect of the oxysulfide storage effect, first discovered by Forest, Cocco, and Hersh (9) in La_2O_2S:Eu, is that it can be induced by excitation into certain ^5D states. One can, under proper conditions, excite into ^5D states with lifetimes less than a millisecond and still induce energy storage for days or weeks. The stored energy is released by thermal or IR stimulation and reappears as normal Eu^{+3} $^5D \rightarrow {}^7F$ line emissions.

The $^5D_2$ state played a special role in the work of Forest *et al.* because they induced storage for $^5D_2$ and higher excitations but not for $^5D_1$ or $^5D_0$ excitation. However, the $^5D_2$ state is incidental to the effect. The work here will show that the storage, like the losses, occurs from the CTS and occurs for ^5D excitations only as a consequence of the ^5D excitation having reached the CTS through thermally promoted $^5D \rightarrow$ CTS crossovers.

The long storage times argue for some spatial separation of electrons and holes. With the losses and storage both tied to the CTS which can be regarded as a hole bound to Eu^{+2}, we believe that both effects commence with thermal dissociation of the CTS into Eu^{+2} plus a free hole. The freed holes become stored in hole traps. The question as to whether the stored energy can be retrieved or is lost then becomes the question as to whether or not the trapped holes can be returned to the Eu^{+2} centers.

Measurements that tie the losses and the storage to the CTS are described in the sections Energy Losses and Energy Storage, and our interpretation of both effects is given in the Discussion section.

[1] In oxysulfides, the Eu^{+3} emissions shift from mixed ^5D emissions at low Eu concentration to mainly $^5D_0$ emissions at high Eu concentration. See J. W. Haynes and J. J. Brown, *J. Electrochem. Soc.*, 115, 1060 (1968). Such shifts are due to excitations in upper ^5D states concentration quenching to $^5D_0$ via Eu-Eu energy transfers of the Van Uitert-Johnson variety. However, since these transfers only redistribute the populations within the ^5D states and do not decrease the total number of $^5D \rightarrow {}^7F$ emissions, they will not be counted as losses here.

Summary of Oxysulfide $^5D \leftrightarrow$ CTS Crossovers

Direct CTS $\rightarrow$ ^5D feeding transitions and inverse $^5D \rightarrow$ CTS quenching transitions were established in ref. (1) and (2). The main results of these references will now be summarized.

Figure 1 of either reference gives the configurational-coordinate diagram showing the ^5D-CTS crossovers. In the feeding direction, the CTS feed all the emitting ^5D states but especially $^5D_2$ and $^5D_1$.

In the quenching direction, excitation in ^5D_j is promoted thermally to the CTS according to the rate constant $A \exp(-E_j/kT)$, where A is $\sim 10^{11}$ sec^{-1} and E_j is the activation energy to the crossover. These upward $^5D_j \rightarrow$ CTS transitions compete with all downward processes from ^5D_j, namely, emission to lower ^5D and ^7F states and relaxation to lower ^5D states via multiphonon emissions and Eu-Eu energy transfers. The rate constant summed over all downward processes is $\sim 10^4$ sec^{-1}. This rate and the rate of upward $^5D_j \rightarrow$ CTS transitions become equal at a temperature T_j approximated by $E_j/kT_j = 17$. Above T_j, $^5D_j \rightarrow$ CTS transitions dominate, and all downward processes fall off sharply. The rate of fall off, determined by the variation of $\exp(E_j/kT)$ near T_j, is about one order per 15% increase in T. Below T_j, downward processes dominate, and $^5D_j \rightarrow$ CTS transitions fall off sharply (about one order per 15% decrease in T).

Table I summarizes, for Y_2O_2S and La_2O_2S, observed and estimated $^5D \rightarrow$ CTS activation energies and the corresponding T_j's. The systematic differences between the two hosts arise because the CTS lie at somewhat higher energy in Y_2O_2S ($\approx$1100 cm^{-1} higher).

Temperature dependences of ^5D emissions described in ref. (2) and temperature dependences of ^5D excitations of storage described in the present paper have mirror-image relationships about the T_j's. Emission from ^5D_j is relatively constant below T_j but falls off sharply above T_j where all downward processes fall off sharply. On the other hand, ^5D_j excitation of storage is relatively constant above T_j but falls off sharply below T_j where $^5D_j \rightarrow$ CTS transitions fall off sharply. These mirror-image relationships will be demonstrated in four figures below.

Experimental

The oxysulfide phosphors were powdered materials prepared under the direction of Dr. P. N. Yocom by the sulfur-carbonate flux method (10). The train for the optical measurements has been described previously (2). ^5D temperature dependences were monitored through prominent lines of each ^5D series. In Fig. 3-6, these dependences were normalized to give the percentages of emitted photons in each ^5D series at 295°K. All slow buildups and decays of luminescence were measured on a recorder with a response time of a few seconds.

The energy stored in a phosphor depends on sample history. For the excitations of storage described in Fig. 8 through 12, traps were emptied prior to each excitation either thermally or optically.[2]

[2] Light from a tungsten lamp through a Corning 3-70 filter, that is, tungsten light above 500 mμ.

Table I. Activation energies E_j from the Eu^{+3} ^5D states to the CTS in oxysulfides. Temperatures T_j at which E_j/kT_j is 17 are also given

State	E_j, cm^{-1}		T_j, °K	
	Y_2O_2S	La_2O_2S	Y_2O_2S	La_2O_2S
$^5D_3$	2100	1100	180	90
$^5D_2$	4400	3000	370	250
$^5D_1$	$\approx$6600	5100	$\approx$560	430
$^5D_0$	>8000	$\approx$6500	>640[a]	$\approx$520[a]

[a] Used $E_0/kT_0 = 18$ because of the longer $^5D_0$ lifetime for downward processes.

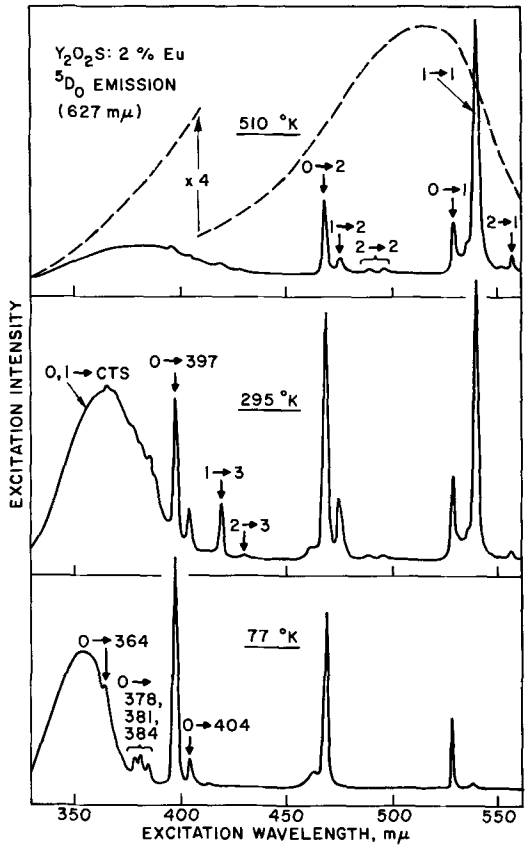

Fig. 1. Excitation spectra (uncorrected) of the $^5D_0$ emissions of Y_2O_2S:2% Eu. The dotted curve gives the distribution of the excitation source (tungsten lamp plus $CuSO_4$ solution plus monochromator) as determined with the quantum counter liumogen. Excitation $^7F_i \rightarrow {}^5D_j$ is labeled i → j. The 4f states above $^5D_3$ are indexed by their absorption wavelengths (mμ) from $^7F_0$. The broad excitation band is $^7F_{0,1}$ → CTS excitation. The shift of the long-wavelength end of this excitation band from 380 mμ at 77°K to 430 mμ at 510°K is temperature broadening due to the large Franck-Condon shift between the CTS and ^7F states. See Appendix of ref. (1).

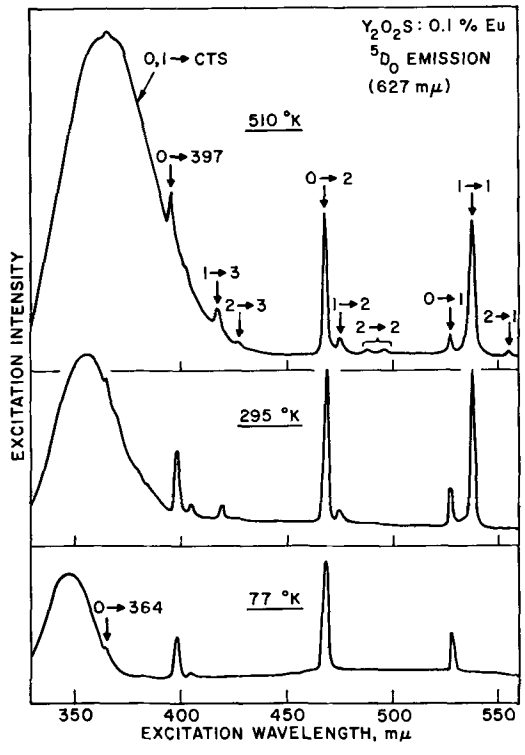

Fig. 2. Excitation spectra of Y_2O_2S:0.1% Eu. See caption of Fig. 1 for conditions and notation. Detector gain was higher than in Fig. 1 but was fixed for all three spectra in each figure.

Energy Losses

It was shown in ref. (2) that Y_2O_2S:0.1% Eu was efficient up to 520°K but that Y_2O_2S:2% Eu developed losses under CTS excitation above ~350°K. The main differences between 0.1 and 2% materials are shown by the excitation spectra in Fig. 1 and 2. The 0.1% material is efficient at all temperatures shown.[3] However, the 2% material shows, at 510°K, inefficient excitation into the CTS [4] and into all 4f states above $^5D_1$.

Figure 3 shows, for the 2% material, detailed temperature dependences of the $^5D_1$ and $^5D_0$ emissions for both CTS and $^5D_1$ excitation. The losses shown above ~350°K for CTS excitation do not occur for $^5D_1$ excitation up to at least 520°K. Thus, the losses do not occur from $^5D_1$ or $^5D_0$. Their absence for $^5D_1$ excitation is consistent with the losses occurring from the CTS because $^5D_1$ excitation is not thermally promoted to the CTS below the 560°K T_1 temperature cited for Y_2O_2S in Table I.

The intermediate case of $^5D_2$ excitation is shown in Fig. 4. The strong decrease in the $^5D_2$ emission above 370°K is due not to losses but to $^5D_2$ emptying thermally to the CTS; see the Y_2O_2S T_2 temperature cited in Table I. [The thermal quenching of these $^5D_2$ emissions and of the La_2O_2S $^5D_0$ and $^5D_1$ emissions shown in Fig. 5 and 6, respectively, complement the ^5D thermal quenching data shown in ref. (2) and (11). These quenchings have been analyzed in the manner of ref. (2). The three dotted projections in Fig. 4-6 show these three ^5D emissions as estimated for no ^5D emptying to the CTS, and the corresponding crosses (×) show, as in ref. (2), the good fit of thermal quenching theory to the observed quenchings. The empirical ^5D-to-CTS activation energies used to fit

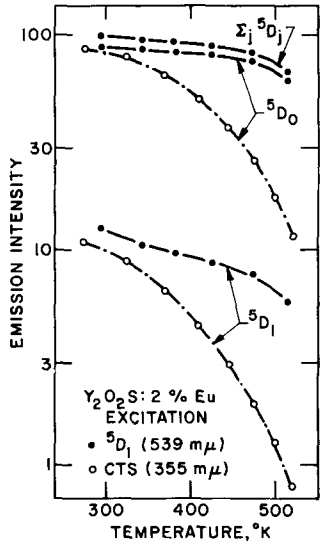

Fig. 3. Temperature dependences of the $^5D_1$ and $^5D_0$ emissions of Y_2O_2S:2% Eu for $^5D_1$ and CTS excitation. These dependences are given for constant excitation intensity. For $^5D_1$ excitation, the excitation was assumed proportional to the temperature-dependent population of $^7F_1$, the initial state for 539 mμ excitation. For CTS excitation, no correction was necessary: the excitation wavelength was selected such that $^7F_{0,1}$ → CTS excitation was insensitive to temperature, as was evidenced by the temperature-insensitive total $^5D \rightarrow {}^7F$ emission observed for low Eu concentrations where losses were small.

[3] In the 0.1% material, excitations to 4f states above $^5D_2$ appear to be weak at 77°K. This is due not to losses but to the monitored $^5D_0$ emissions being smaller relative to total ^5D emissions for these 77°K excitations. See ref. (1).

[4] The broad F → CTS excitation bands in Fig. 1 and 2 were distorted by the excitation source used (spectral distribution given by dotted curve in Fig. 1). This distortion plus temperature broadening of the CTS absorption caused the observed CTS bands to shift progressively with temperature to greater wavelength and amplitude. The corrected CTS excitations peak near 330 mμ.

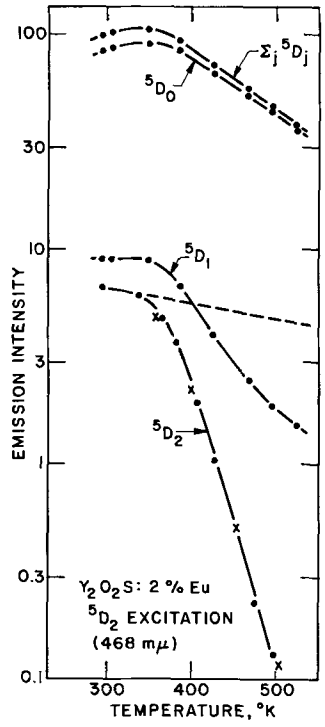

Fig. 4. Temperature dependences of the ^5D emissions of Y_2O_2S: 2% Eu for $^7F_0 \rightarrow {}^5D_2$ excitation. Correction was made for the thermal population of $^7F_0$.

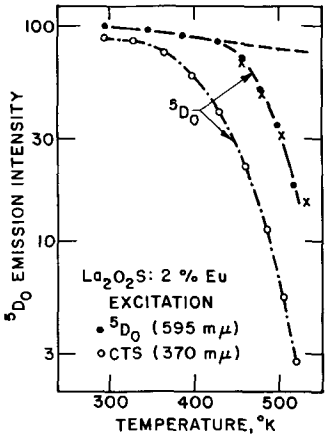

Fig. 5. Temperature dependences of the $^5D_0$ emissions of La_2O_2S: 2% Eu for $^5D_0$ and CTS excitation. For $^5D_0$ excitation, correction was made for the thermal population of the initial $^7F_1$ state.

these data were 4400 cm^{-1} for Y_2O_2S $^5D_2$ and 6300 and 5000 cm^{-1} for La_2O_2S $^5D_0$ and $^5D_1$, respectively. These values have already been quoted in Table II of ref. (2).] The decreases in the $^5D_1$ and $^5D_0$ emissions above 370°K are due to losses. When $^5D_2$ empties to the CTS, feeding of $^5D_1$ and $^5D_0$ is revised from $^5D_2 \rightarrow {}^5D_1$, $^5D_0$ to the chain $^5D_2 \rightarrow$ CTS $\rightarrow {}^5D_1$, $^5D_0$. Since the losses are known not to occur from $^5D_1$ or $^5D_0$, they occur from either $^5D_2$ or the CTS. However, since their 370°K onset coincides with $^5D_2$ emptying to the CTS, it is reasonable to conclude that they occur from the CTS.

With respect to excitation into 4f states above $^5D_2$, it was noted in connection with Fig. 1 and 2 that such excitations, while efficient at 295°K, are, in 2% material, inefficient at 510°K. Above 180°K, all of these excitations reach the CTS via thermally promoted $^5D_2 \rightarrow$ CTS crossovers. Thus, these observations too are consistent with losses developing from the CTS in 2% material above 350°K.

For Eu in La_2O_2S host, Wickersheim, Buchanan, and Yates (11) showed that 0.1% material was efficient

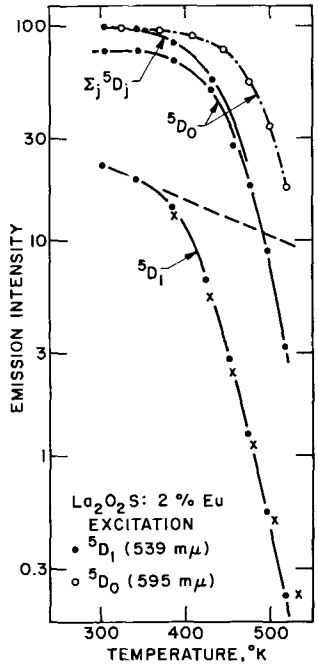

Fig. 6. Temperature dependences of the ^5D emissions of La_2O_2S: 2% Eu for $^7F_1 \rightarrow {}^5D_1$ and $^7F_1 \rightarrow {}^5D_0$ excitation. Correction was made for the thermal population of $^7F_1$.

under CTS excitation up to 530°K, but we (2) showed that 2% material developed losses above ~350°K. Temperature dependences of the dominant $^5D_0$ emissions of the 2% material are shown in Fig. 5 for both CTS and $^5D_0$ excitation. The losses shown above ~350°K for CTS excitation are deferred to ~500°K for $^5D_0$ excitation. Thus, these losses do not occur from $^5D_0$. As cited in Table I, La_2O_2S $^5D_0$ excitation tries to empty thermally to the CTS near 520°K. If the CTS is free of losses (0.1% material), the excitation is returned to $^5D_0$ by reverse CTS $\rightarrow {}^5D_0$ crossovers, and the $^5D_0$ emissions do not decrease. If losses do occur from the CTS (2% material), the excitation is not returned to $^5D_0$, and the $^5D_0$ emissions do decrease.

The intermediate case of $^5D_1$ excitation is shown in Fig. 6 together with a repeat of $^5D_0$ excitation. The strong decrease of the $^5D_1$ emissions above 430°K is due to $^5D_1$ emptying thermally to the CTS; note the La_2O_2S T_1 temperature cited in Table I. The decrease in the $^5D_0$ emissions above 430°K is due to losses. When $^5D_1$ empties to the CTS, $^5D_1 \rightarrow {}^5D_0$ feeding is revised to the chain $^5D_1 \rightarrow$ CTS $\rightarrow {}^5D_0$. Since for $^5D_1$ excitation the onset of the losses is advanced to 430°K and there coincides with the onset of $^5D_1$ emptying to the CTS, one again infers that the losses occur from the CTS.

For $^5D_2$ excitation of 2% material (not shown), the onset of losses is further advanced to ~350°K and there coincides with the onset of losses for CTS excitation. This is to be expected if the losses occur from the CTS since, as noted in Table I, La_2O_2S $^5D_2$ empties thermally to the CTS below the ~350°K temperature at which losses develop.

In summary, losses are small at low Eu concentration in both Y_2O_2S and La_2O_2S. However, at 2% Eu concentration, losses develop above ~350°K for CTS excitation and also for ^5D excitations that empty thermally to the CTS by 350°K. For Y_2O_2S, the onset of losses is deferred to 370°K for $^5D_2$ excitation and to above 520°K for $^5D_1$ or $^5D_0$ excitation. For La_2O_2S, the onset is deferred to 430°K for $^5D_1$ excitation and to 520°K for $^5D_0$ excitation. These deferred onsets are just those required for the excitations in question to empty thermally to the CTS. We conclude that the losses occur from the CTS and occur for ^5D excitations only as a consequence of the excitation having reached the CTS through thermally promoted $^5D \rightarrow$ CTS crossovers.

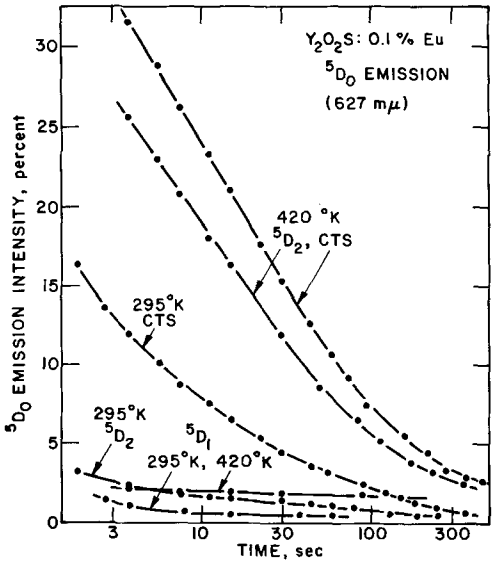

Fig. 7. $^5D_0$ phosphorescence of Y_2O_2S:0.1% Eu after CTS (355 mμ), $^5D_2$ (468 mμ), and $^5D_1$ (539 mμ) excitations at 295° and 420°K. The phosphorescence is given as a per cent of the steady-state $^5D_0$ emission during excitation.

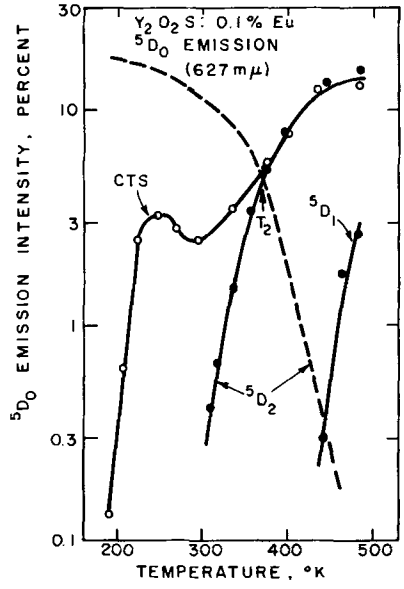

Fig. 8. $^5D_0$ phosphorescence (as per cent of steady-state emission) of Y_2O_2S:0.1% Eu 15 sec after CTS, $^5D_2$, and $^5D_1$ excitations. The dotted curve shows the mirror-image steady-state $^5D_2$ emissions as traced from Fig. 3 of ref. (2). Corresponding phosphorescence per cents are smaller here than in Fig. 7 for two reasons: first, higher excitation intensity was used in Fig. 8, and the ratio of phosphorescence to steady-state emission decreased slightly with increasing excitation intensity; second, the phosphor was annealed at 500°K before each excitation in Fig. 8 but was not annealed in Fig. 7.

Energy Storage

The oxysulfide energy-storage effect was first discovered by Forest, Cocco, and Hersh (9) in La_2O_2S. They excited into $^5D_2$ at a low-temperature T_E and, on heating the phosphor, found that stored energy was released as a glow peak near 270°K. The glow was normal Eu^{+3} $^5D \rightarrow {}^7F$ line emissions. Although small for T_E below 200°K, the glow increased strongly as T_E was raised from 200° to 250°K. At 250°K, excitation into any state above $^5D_2$ (*e.g.*, $^5D_3$, the 4f state at 397 mμ, the CTS) also induced the storage, but excitation into $^5D_1$ below $^5D_2$ did not.

We describe experiments here which show that the storage is induced from the CTS and occurs for ^5D excitations only as a consequence of thermally promoted $^5D \rightarrow$ CTS crossovers. The experiments of Forest *et al.* can be explained this way. As noted in Table I, T_2 for La_2O_2S is 250°K. Below 250°K, $^5D_2 \rightarrow$ CTS crossovers fall off sharply, and $^5D_2$ excitation cannot reach the CTS. Moreover, at 250°K, excitation into any 4f state above $^5D_2$ empties thermally to the CTS, but excitation into $^5D_1$ below $^5D_2$ does not.

The energy-storage effect manifests itself through the slow buildup and decay of luminescence and through thermally or IR stimulated glow peaks. We discovered the effect independently in the course of establishing oxysulfide $^5D \leftrightarrow$ CTS transitions (1, 2). It was found that the resolution of the Y_2O_2S:0.1% Eu $^7F_0 \rightarrow {}^5D_2$ excitation line (468 mμ) was lost above 370°K. This was determined to be due to the slow buildup and decay of Eu^{+3} luminescence during the excitation sweep through this line.[5] Since we knew that Y_2O_2S $^5D_2$ empties to the CTS above 370°K, we suspected from the start that the storage occurs from the CTS.

Slow decays of Y_2O_2S:Eu luminescence at 295° and 420°K are shown in Fig. 7. For CTS excitation, the phosphorescence is strong at both temperatures. However, for $^5D_2$ excitation, it is strong only at the higher temperature, and, for $^5D_1$ excitation, it is weak at both temperatures.

Detailed temperature dependences of the 15-sec phosphorescence (emission 15 sec after termination of the excitation) are shown in Fig. 8. For CTS excitation, the phosphorescence is strong at every temperature above 220°K. However, for $^5D_2$ excitation, strong phosphorescence is deferred to above 370°K, and, for $^5D_1$ excitation, it is further deferred to the highest temperatures studied. The dotted curve shows the temperature dependence of the steady-state $^5D_2$ emissions as traced from Fig. 3 of ref. (2). This curve was normalized to intersect the $^5D_2$-excitation-of-phosphorescence curve at 370°K, the Y_2O_2S T_2 temperature cited in Table I. These two intersecting curves are, for $^5D_2$, the mirror-image emission and excitation-of-storage curves discussed in the section on Summary of Oxysulfide $^5D \leftrightarrow$ CTS Crossovers. The corresponding intersection of mirror-image $^5D_1$ curves is estimated to lie beyond the temperature range studied near $T_1 = 560$°K.

Analogous temperature dependences of La_2O_2S:Eu 30-sec phosphorescence are shown in Fig. 9. Again, for CTS excitation, the phosphorescence is strong at every temperature above 220°K. However, in agreement with the lower T_j temperatures for La_2O_2S, the onset of strong phosphorescence is deferred to only 250°K for $^5D_2$ excitation and to only 430°K for $^5D_1$ excitation. The two dotted curves show the temperature dependences of the steady-state $^5D_2$ and $^5D_1$ emissions. These curves were traced from Fig. 8 of ref. (2) and were independently normalized to intersect their corresponding excitation-of-phosphorescence curves at the La_2O_2S T_2 and T_1 temperatures cited in Table I. These two pairs of intersecting curves are, for $^5D_2$ and $^5D_1$, the mirror-image emission and excitation-of-storage curves discussed in the section on Summary of Oxysulfide $^5D \leftrightarrow$ CTS Crossovers.

In summary, in both Y_2O_2S and La_2O_2S, ^5D excitations of phosphorescence are consistently deferred to the T_j temperatures at which the ^5D excitations empty strongly to the CTS. We conclude that the phosphorescence is induced from the CTS and occurs for ^5D excitations only as a consequence of thermally promoted $^5D \rightarrow$ CTS crossovers.

Our Y_2O_2S:0.1% Eu material had strong glow peaks near 240° and 470°K. Indeed, the existence of these strong peaks was already indicated by the 240° and 470°K maxima in the CTS-excitation-of-phosphores-

[5] Indeed, the 510°K excitation spectrum shown in Fig. 2 was taken at the slow scan rate of 100 mμ/hr so that the excitation would approximate steady-state intensity.

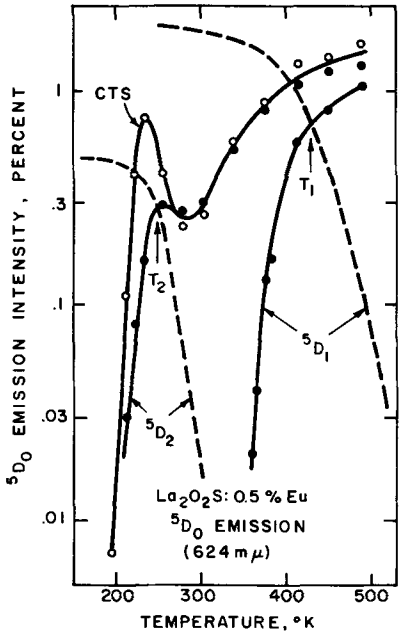

Fig. 9. $^5D_0$ phosphorescence of La_2O_2S:0.5% Eu 30 sec after CTS, $^5D_2$, and $^5D_1$ excitations. The dotted curves show mirror-image steady-state $^5D_2$ and $^5D_1$ emissions as traced from Fig. 8 of ref. (2).

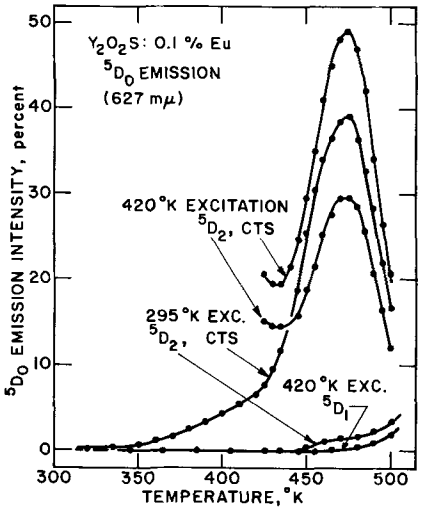

Fig. 10. Thermally stimulated $^5D_0$ glow of Y_2O_2S:0.1% Eu following 10-min CTS, $^5D_2$, and $^5D_1$ excitations at 295° and 420°K. The glow is given as a per cent of the steady-state $^5D_0$ emission during excitation. The heating rate was 6°C/min.

cence curve in Fig. 8. The 470°K glow peak is shown in Fig. 10 for excitations at 295° and 420°K. For CTS excitation, the glow peak is strong for both excitation temperatures. However, for $^5D_2$ excitation, it is strong only for the higher temperature excitation, and, for $^5D_1$ excitation, it is weak for both excitation temperatures.

Detailed temperature dependences of excitations of both glow peaks are shown in Fig. 11. The curves below 300°K give the area under the 240°K glow peak as a function of excitation temperature. This area was integrated from the excitation temperature to 315°K. The integration included whatever phosphorescence followed excitation but did not include phosphorescence during excitation. The curves above 300°K give the analogous area under the 470°K glow peak integrated to 495°K.

For CTS excitation, the glow areas are large for every excitation temperature above ~150°K. However, $^5D_2$ excitation of the 240°K glow peak is always weak, and strong $^5D_2$ excitation of the 470°K glow peak is deferred to above 370°K. The dotted curve shows the

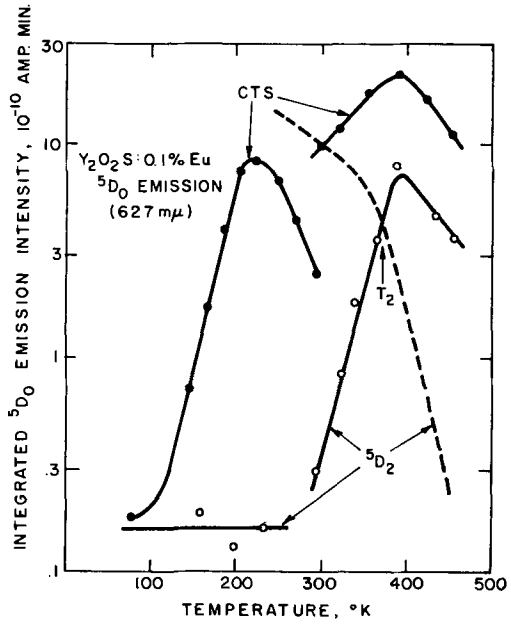

Fig. 11. $^5D_0$ glow areas for the Y_2O_2S:0.1% Eu glow peaks near 250°K (curves below 300°K) and near 470°K (curves above 300°K). The glows followed 5-min CTS and $^5D_2$ excitations at abscissa temperature. The areas are given in arbitrary units (photomultiplier output current × time). The dotted curve shows the mirror-image steady-state $^5D_2$ emissions as in Fig. 8.

mirror-image steady-state $^5D_2$ emissions as traced from Fig. 3 of ref. (2) and normalized to intersect the $^5D_2$-excitation-of-glow curve at Y_2O_2S T_2.

Detailed temperature dependences of $^5D_1$ excitations of glow were not measured. However, it was shown in Fig. 10 that $^5D_1$ does not excite the 470°K glow peak up to at least 420°K. This is consistent with the high Y_2O_2S T_1 temperature.

Our La_2O_2S:0.5% Eu material had strong glow peaks near 250° and 380°K. Excitations of the 250°K glow peak are shown in Fig. 12. In this case, the stored energy was retrieved by IR stimulation rather than heating.

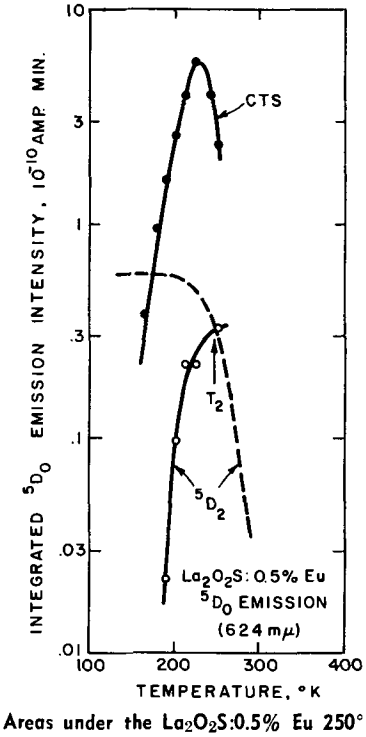

Fig. 12. Areas under the La_2O_2S:0.5% Eu 250°K glow peak following 10-min CTS and $^5D_2$ excitations at abscissa temperature. The dotted curve shows the mirror-image steady-state $^5D_2$ emissions as in Fig. 9.

Following excitation and a brief period of phosphorescence, the IR intensity[6] was increased slowly to give an IR-stimulated glow peak of convenient shape. The curves give the area under the IR-stimulated glow plus the phosphorescence as a function of the excitation temperature.

For CTS excitation, the glow area is, as for Y_2O_2S host, large for every excitation temperature above ~150°K. However, in agreement with the lower La_2O_2S T_2 temperature, the onset of strong $^5D_2$ excitation of the glow is deferred only slightly to ~200°K. The rapid increase of glow for $^5D_2$ excitations above 200°K is analogous to that reported by Forest *et al.* (9) for their La_2O_2S 270°K glow peak. The dotted curve shows the mirror-image steady-state $^5D_2$ emissions as traced from Fig. 8 of ref. (2) and normalized to intersect the $^5D_2$-excitation-of-glow curve at La_2O_2S T_2.

The 380°K glow peak of our La_2O_2S:0.5% Eu material was, at 295°K, strongly excited by CTS and $^5D_2$ excitation but not by $^5D_1$ excitation.

In summary, in both Y_2O_2S and La_2O_2S, ^5D excitations of glow peaks are consistently deferred to the T_j temperatures at which the ^5D excitations empty strongly to the CTS. We conclude that the glow peaks are induced from the CTS and occur for ^5D excitations only as a consequence of thermally promoted $^5D \rightarrow$ CTS crossovers.

Discussion

^5D excitations of energy loss and storage have been successfully explained as consequences of the excitation having reached the CTS through thermally promoted $^5D \rightarrow$ CTS crossovers. This simple explanation of complex loss and storage data gives additional support to oxysulfide $^5D \leftrightarrow$ CTS crossovers. However, we regard these crossovers as already well established (1, 2). Moreover, this particular support was already cited (2) in the work establishing $^5D \leftrightarrow$ CTS crossovers. We turn now to a newer topic, namely, explanation of the losses and storage from the CTS.

The long storage times of the storage effect argue for some spatial separation of electrons and holes. Now the CTS can be regarded as a hole bound to Eu^{+2}. We believe that storage commences with thermal dissociation of the CTS into Eu^{+2} plus a free hole. This CTS dissociation competes with CTS feeding of the ^5D states (CTS $\rightarrow$ ^5D crossovers) which would lead to $^5D \rightarrow {}^7F$ line emissions. The freed holes are trapped in hole traps. After a storage time, thermal or IR stimulation refrees the holes and enables them to return to Eu^{+2} sites. The CTS is re-formed, and CTS $\rightarrow$ ^5D feeding can ensue.

Once the holes are trapped, the effect has analogies to a CaF_2 storage effect studied by Merz and Pershan (12). Their storage was induced by irradiating CaF_2:Re^{+3} with x-rays. The stored energy was released by heating and appeared as glow peaks of Re^{+3} line emissions. The temperatures of the glow peaks were independent of the particular Re activator. The x-ray irradiation induced optical absorption bands that were attributed to Re^{+2}, and these bands disappeared as the glow peaks were annealed out. The following interpretation was given: the x-rays generate free electrons and holes; the electrons are trapped at Re^{+3} centers and reduce them to Re^{+2}; the holes are trapped at hole centers characteristic of the host; heating makes the hole centers mobile; Re^{+2} and a mobile hole center combine to form an excited Re^{+3} center; and relaxation of the excited Re^{+3} leads to the observed Re^{+3} glow. The effect was also observed for SrF_2 and BaF_2 host, and details of the hole centers were elucidated through EPR (13).

In our oxysulfide case, the Re is Eu, and the excited Re^{+3} center is, initially, the Eu^{+3} CTS and, after a crossover, a Eu^{+3} ^5D state. The identities of the hole traps are not known. The multiple glow peaks show that more than one type of hole trap is present.

Forest, Cocco, and Hersh (9) have also considered explanations of the storage effect in La_2O_2S. Although their experiments did not show that the storage occurred from the CTS, one of their explanations is equivalent to the model just given. The first written descriptions of this model, both by Forest and by ourselves, may be found in the discussions at the end of ref. (1).

We turn now to the concentration-dependent losses from the CTS. It is known from studies of ^5D thermal quenching that the lifetime of the CTS against crossovers to the ^5D states is about 10^{-11} sec (2). Thus, it is hard to suggest a Eu-Eu effect that would be fast enough to account for concentration-dependent losses from the CTS. However, this difficulty is overcome if the separation of charges argued in the storage effect also occurs for the loss effect. We believe that the losses similarly commence with thermal dissociation of the CTS into Eu^{+2} plus a free hole. The extra electron bound at the Eu^{+2} center has, at room temperature, a lifetime against thermal detrapping of weeks or greater. More time is thus available for concentration-dependent Eu-Eu effects.

The freed holes are again stored in hole traps as in the storage effect. At low Eu concentrations, the extra electrons remain immobilized at the originating Eu^{+2} centers, and the stored energy can be retrieved by stimulating the holes back to these Eu^{+2} centers (storage effect). At high Eu concentrations and temperatures, the extra electrons can migrate through the Eu ions to the hole centers and recombine there nonradiatively (loss effect). This explanation is offered with no definite picture of the terminating loss process. However, it must differ chemically from free-hole capture at Eu^{+2} which leads to Eu^{+3} line emission.

Thus, storage and loss are viewed as complementary effects which are emphasized at low and high Eu concentrations, respectively. This picture for concentration-dependent losses differs from conventional energy-transfer models in that charges as well as energy are transported.

According to the model given, dissociations of the CTS, in themselves, reduce the Eu emissions. On the other hand, re-formations of the CTS (driven by Eu^{+2} and free-hole concentrations) increase the Eu emissions. Thus, when excitation is applied, steady-state Eu emission can be realized only after these opposing CTS dissociations and re-formations come to equilibrium. Emission transients observed prior to steady state and their interpretation will be described elsewhere (14). However, the emissions described in the section on Energy Losses are steady-state emissions, and any reductions in these emissions must be ascribed to losses, not storage.

The activation energy for dissociation of the CTS is near 1100 cm^{-1} in both Y_2O_2S and La_2O_2S. Detailed measurements showing this value will be reported elsewhere (14). This activation energy prevents dissociation of the CTS at 77°K and leads to the temperature onset for CTS excitation of glow near 150°K cited for both Y_2O_2S (Fig. 11) and La_2O_2S (Fig. 12). CTS excitation of phosphorescence was deferred to $\approx$ 200°K for both hosts (Fig. 8 and 9). These deferred onsets for phosphorescence are attributed to low concentrations of hole traps that empty between 150° and 200°K.

Our La_2O_2S:0.5% Eu had a weak background absorption that also induced storage retrievable as Eu^{+3} line emissions. This absorption extended from 300 to 500 mμ (that is, overlapped the CTS absorption band) and induced storage across a broad temperature range down to at least 77°K. Effects due to this background absorption were subtracted out of the La_2O_2S excitation-of-glow data shown in Fig. 12. With this subtraction, there was no CTS excitation of storage at 77°K. In all other figures, effects due to such background

[6] The IR stimulation was light from a tungsten lamp through a Wratten 87C filter, that is, tungsten light above 850 mμ.

absorptions were negligible compared to the larger effects due to CTS and ^5D excitations.

Although the Forest, Cocco, and Hersh paper (9) is somewhat unclear on this point, they agree (15) that there is no CTS excitation of storage in La_2O_2S at 77°K.

Conclusions

Energy losses and energy storage occur from the Eu^{+3} CTS in Y_2O_2S and La_2O_2S. Both effects also occur for excitation into certain ^5D states but only as a consequence of the excitation having reached the CTS through thermally promoted $^5D \rightarrow$ CTS crossovers. Both effects begin with thermal dissociation of the Eu^{+3} CTS into Eu^{+2} plus a free hole. The holes are stored in hole traps. The stored energy is retrieved as Eu^{+3} $^5D \rightarrow {}^7F$ glow peaks if the holes are stimulated back to the Eu^{+2} centers by thermal or IR stimulation. At high Eu concentrations and temperatures, the extra electrons at the Eu^{+2} centers can migrate through the Eu ions and recombine nonradiatively at the hole centers.

Acknowledgments

We thank Dr. P. N. Yocom for synthesis of the phosphors and Dr. H. Forest for a preprint of the Forest, Cocco, and Hersh paper (9) on storage in La_2O_2S:Eu.

Low-Temperature Reduction of Fast Surface States Associated with Thermally Oxidized Silicon

P. L. Castro* and B. E. Deal*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The effects on fast surface states associated with SiO_2-Si structures due to anneals in nitrogen and hydrogen-nitrogen ambients in the temperature range 300°-550°C are compared with similar anneals of Al-SiO_2-Si structures. Results are reported in terms of capacitance-voltage characteristics and surface recombination velocity values. Although the hydrogen-nitrogen ambients are found effective in the 400°-450°C range for reduction of states in the nonmetallized structures ($s_o \approx 5$ cm/sec for (111) p-type silicon), the final densities are not as low as those found for the structures involving aluminum field plates ($s_o \approx 2$ cm/sec). The role of hydrogen in the reduction of fast surface states is discussed.

During the past two decades much work has been directed toward understanding the behavior of the various surface charges associated with the silicon-silicon dioxide interface (1-3). The use of silicon dioxide for passivation and also as part of circuit components in the bipolar and MOS technologies has resulted in the necessity of understanding the relationship between these surface charges and the processing of the units. Only with this knowledge can the processing be designed to result in optimum device and integrated circuit performance.

The effects of oxidation and high-temperature anneals on the fixed surface state charge, Q_{ss}, have been well documented (4-6). In addition, the effects due to mobile charge, Q_o (positive ion contamination), in the oxide (7-10) and the effects of radiation-induced surface charge, N_{ot}, (11-14), have been thoroughly investigated and are reasonably well understood. It is the fast surface states, N_{st}, that have been investigated most extensively, however, and it is these states which remain the least understood of all the charges associated with the Si-SiO_2 interface (1, 2, 6, 15). Because the fast surface states are located in the silicon band gap near the Si-SiO_2 interface, the total charge in the surface states depends on their distribution in energy through the band gap, the surface potential and their resulting position relative to the Fermi level, and their electrical character, *i.e.*, whether they are acceptor or

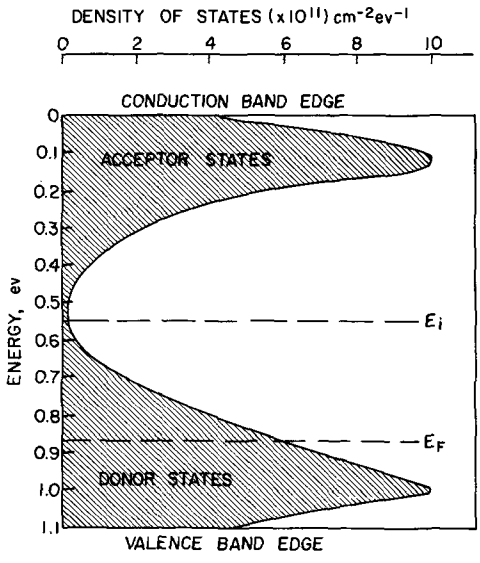

Fig. 1. Approximate distribution of fast states associated with the silicon-silicon dioxide interface following a rapid quench into the room ambient from a 1200°C dry O_2 oxidation.

donor states. These states respond rapidly to fluctuations in the surface potential by charging and discharging according to their position relative to the Fermi level. The data of Nicollian and Goetzberger (15) and Gray and Brown (16, 17), as well as work at this laboratory (18), indicate the distribution of the fast surface states through the silicon band gap has peaks near both band edges with a fairly continuous distribution through the center of the band gap. This is shown in Fig. 1 for a typical 1200°C dry O_2 oxide structure.

Suggestions as to the nature or origin of the fast states generally involve some uncompensated bond defect usually near the Si-SiO_2 interface, which is attributed to the disruption of the periodicity of the silicon lattice (19). Whatever their origin, it has been shown that the density of the fast states can be reduced to a relatively low level by annealing in an inert ambient, such as nitrogen, at low temperatures if an active metal, *e.g.*, aluminum, is present over the thermal oxide (20). Speculating that some hydrogen species is produced by the reaction of water adsorbed on the oxide and the aluminum during this treatment, and is therefore responsible for the reduction of the states, a number of investigators have examined the effects of hydrogen anneals on fast surface states (21-27). The conclusions that can be drawn from these experiments are almost as numerous as the number of investigations. This is probably because very few, if any, systematic studies have been made of the low-temperature reduction of fast states. In addition, other effects such as the presence of competing charges and nonreproducible processing have tended to confuse the results that have been obtained. Therefore a program was carried out to study the reduction of fast surface states in which the processing conditions were closely controlled and the contamination and other competing reactions minimized. The results of these experiments, in which the ability of hydrogen gas to reduce fast states is compared to the effectiveness of the aluminum-water reaction in the temperature range 300°-550°C, are summarized in this paper.

Experimental

Materials.—Single-crystal, Czochralski-grown silicon was obtained in the form of sawed, circular slices approximately 575μ thick. Dislocation densities ranged from 5 x 10^3 to 5 x 10^4 cm^{-2}. All silicon used as starting material for this work was p-type (boron-doped) with concentration in the range 0.5-1.0 x 10^{16} cm^{-3}. Crystal orientation was (111).

The aluminum used for contacts and field plates was specified as 99.999% pure.[1] Filament evaporation of the aluminum was employed to avoid radiation-induced traps in the oxide, which are characteristic of electron beam evaporation. Contamination charge density resulting from the evaporation averaged 3 x 10^{11} cm^{-2}. Gases used for oxidation and annealing (O_2, N_2, and H_2) were obtained in a liquid form.[2] Molecular traps were used in all gas lines to remove any excess water or hydrocarbons. Analyses of these gases had previously shown H_2O content to be less than 1 ppm.

Processing.—For this study, silicon n^+-p gate-controlled diodes were processed which had circular geometry with a junction area of 2.5 x 10^{-4} cm^2. An aluminum field plate (gate), with an area of 1.3 x 10^{-3} cm^2, extended over the metallurgical junction. In addition, an outer gate was used to accumulate the surface adjacent to the gate area and therefore prevent channels from being formed due to Q_{ss}, the fixed positive surface charge associated with the Si-SiO_2 interface.

To ensure that the silicon surface was free of mechanical damage, a careful surface preparation procedure was devised. Initially, the slices were cleaned in both organic and inorganic solvents, and then etched in an iodine-containing HF-HNO_3-acetic acid etchant to remove 125μ from each slice. One side, to be used for device fabrication, was further finished by mechanically lapping to remove 100μ. The slices were cleaned once more and then chemically etched to remove 200μ. The final thickness of each slice was approximately 150μ. A standard processing schedule was followed for the formation of n^+-p diodes in which phosphorus was diffused into oxide cutouts formed by photoresist techniques. The devices were subsequently gettered for low leakage currents. At this stage of processing, the slices were stripped of all oxide in hydrofluoric acid and reoxidized[3] in 1200°C dry O_2 to an oxide thickness of 2000Å in a contaminant-free oxidation furnace. Following reoxidation, the slices were immediately removed from the furnace and allowed to cool quickly in the room ambient. Oxide cutouts for contacts to the diodes were made using photoresist techniques. Throughout the processing history of the diodes, great care was taken to ensure contaminant-free structures. This included the use of organic and inorganic solvent cleaning procedures whenever possible between processing steps. In addition, care was taken to ensure that all slices processed for this study received identical processing, except for the final low-temperature annealing treatment. A control slice was included with each run of diodes to characterize the initial fast surface-state densities of the various runs.

The final low-temperature treatments were carried out in a resistance-heated furnace at temperatures ranging from 300° to 550°C, in 50°C intervals. Ambients employed at each temperature included 100% N_2, 10% H_2-90% N_2, and 50% H_2-50% N_2. Anneal times were 5 or 25 min, with each anneal including an additional 5 min pre-purge of the system prior to introduction of hydrogen, and a 5 min post-purge after the hydrogen was turned off. To ensure that the purging time did not influence the results, 10 min were added to the 100% N_2 anneals. A 7-min total time control anneal in 100% N_2 was also included at each temperature to approximate the effects of the N_2 purging. Slices of diodes in each of three states of processing were included for each anneal: (*a*) slices following oxide cuts, after reoxidation but before aluminum evaporation, referred to as bare oxide anneals for purposes of this paper; (*b*) slices following the aluminum evaporation, but before aluminum gate and contact etch, referred to as pre-alneals (*aluminum anneals* prior to pattern definition); and (*c*) slices following

[1] Cominco Products, Inc., Spokane, Washington.
[2] Air Reduction Company, Richmond, California.
[3] Reoxidation to a lesser oxide thickness was necessary for the type of measurement used. Special tests, however, indicated very little differences in the device characteristics between the original and the reoxidized samples.

the aluminum gate and contact etch, referred to as post-alneals (*al*uminum an*neals* after pattern definition). Following the anneals, processing was continued for the bare oxide annealed and pre-alnealed slices.

Evaluation.—Fast surface states have been investigated using a number of different measurement techniques. Among these, the MOS capacitor is probably the most widely used because of the relative ease in processing the device. Measurements with the MOS capacitor include capacitance-voltage characteristics in which the shift in the flatband voltage, V_{FB}, at liquid nitrogen temperature from the room-temperature curve can be related to the density of fast surface states near the edge of the band gap (16, 19). Other distortions in the C-V curve have been noted with particular processing of the capacitors and have been related to fast surface states elsewhere in the silicon band gap, as well as to effects on device operation. The distortion characteristics of the C-V curves related to fast surface states have been labeled by Deal *et al.* as the Ⓐ-, Ⓑ-, and Ⓒ-state voltages (18, 28), as shown in Fig. 2. A discussion of these states as to their probable location in the silicon band gap and their effects on device operation has been given in ref. (18). The same terminology for the various characteristics will be used in this paper. Instead of MOS capacitors, however, the MOS structure employed in this work was the large gate area of the gate-controlled diode. For the C-V measurements the diode junction and outer gate were grounded to the substrate while the inner gate voltage, V_G, was varied. Although the C-V curves were made at a frequency of 100 kHz, the diffused n^+ region, thus connected, supplied enough minority carriers during the surface inversion to provide the low frequency-type C-V curve. This permitted measurement of all the labeled states, if present. Specifically, the Ⓐ- and Ⓒ-state voltages, related to the peaks of states near the band edges, were obtained.[4]

The gate-controlled diode is also ideally suited for examination of the density of the states in the center of the band gap through the measurement of the surface recombination velocity, s_o. This measurement technique is illustrated in Fig. 2b. It is seen that when the gate is biased to accumulate the surface, the reverse bias current, I_R, of the diode is restricted to the metallurgical junction current, $I_{gen,MJ}$. When the surface is inverted, the current is increased by the field-induced junction current, $I_{gen,FIJ}$. As the gate voltage varies from accumulation to inversion, the surface becomes depleted, but not inverted, at some particular voltage. For the MOS structure employed in this work the depletion voltage is near $V_G = 0$V. During surface depletion, the fast surface states, which are generation-recombination centers, are in the space-charge region of the reverse-biased diode, and will contribute to the reverse current until the surface becomes inverted. This additional current, $I_{gen,s}$, is directly proportional to s_o through the relationship (30)

$$I_{gen,s} = qn_i s_o A_s \quad [1]$$

where q is the electronic charge, n_i is the intrinsic carrier concentration of silicon, and A_s is the area of the depleted surface under the aluminum gate. Using the definition of s_o

$$s_o = \sigma_s v_{th} N_{st} \quad [2]$$

[4] The Ⓒ-state voltages obtained from the C-V curves, as shown in Fig. 2, were subsequently corrected by subtracting the theoretical Ⓒ-state voltage (2.0V for the structure used) from the measured values. It has been pointed out by Nicollian (29) that the channel cutoff effect at higher frequencies can cause an increase in the Ⓒ-state voltage as defined in this paper. Experiments performed by Nicollian on alnealed control devices from this work indicate that the cutoff effect is appreciable above approximately 10 kHz. The Ⓒ-state voltage reported for these devices at 100 kHz, 0.5V, is found to be due entirely to the channel cutoff effect. When measured at 100 Hz, the Ⓒ-state voltage is approximately 0V, or theoretical. Although this effect is present to some extent in all Ⓒ-state voltage values reported in this paper, the relative values of Ⓒ-state voltages for the various anneal conditions are still an indication of the relative density of fast surface states. The authors are grateful to Nicollian for his help in demonstrating and explaining the effect.

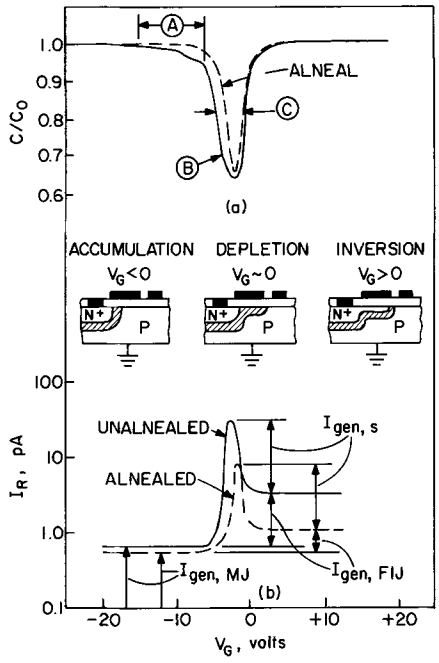

Fig. 2. Typical C-V and I_R-V_G experimental data obtained with the gate-controlled diodes. Both initial (solid lines) and alnealed (dashed lines) data are shown.

where σ_s is the effective capture cross section, v_{th} is the thermal velocity, and N_{st} is the density of fast surface states contributing to surface recombination, we can relate $I_{gen,s}$ to a density of fast states if values are assumed for capture cross section and thermal velocity. The theory of this device, both for C-V and s_o measurements, has been explored extensively by Grove and Fitzgerald (30).

Another technique for investigation of fast surface states is the conductance method of Nicollian and Goetzberger, which employs the frequency dependence of the equivalent parallel conductance of MOS capacitors in determining the distribution and density of fast surface states through the center portion of the silicon band gap (15). Comparison of s_o values obtained on the same devices by the two different techniques has indicated that both methods give the same results. Because the measurement techniques and data analysis are less complicated using the gate-controlled diode, this method was selected for the present work.

The gate-controlled diodes were measured both as MOS capacitors and as reverse-biased diodes. The C-V curves were taken using procedures described earlier (4) which allowed continuous X-Y recorder plots to be made. The gate-controlled diodes were examined for I_R-V_G characteristics at a reverse bias, V_R, of 300 mV. Metallurgical junction currents ranged from 0.5 to 1.0 pA and were measured with a Hewlett-Packard 425AR picoammeter with a sensitivity of 0.1 pA. A Moseley 60B log converter was used to provide a logarithmic current scale for the X-Y recorder. These plots were stepped manually rather than continuously plotted to prevent charging currents which were present with the continuous plots. In both types of measurements, V_G was varied from −20 to +20V. All measurements on the slice were taken at room temperature, using tungsten probes for contacts to the devices. During the measurements, the devices were shielded from exposure to light to prevent spurious generation of carriers. Measurements were taken in a shielded room to eliminate noise interference with the low currents being examined.

The Ⓐ- and Ⓒ-state voltage distortions are the results of the peaks in the distribution of fast states near the silicon band edges. Attempts have been made to convert the Ⓐ-state voltage to a density of fast surface states, N_{st}, (19), but the relationship is only

approximate because the states are not completely at discrete levels. Results of measurements on numerous gate-controlled diodes, following various processing procedures, indicate that the Ⓐ-state voltage is approximately twice the Ⓒ-state voltage for the particular structure, measurement frequency, and techniques employed in this work (18). Although the Ⓒ-state voltage can be measured with reasonable accuracy at room temperature, the Ⓐ-state voltage can only be measured accurately if it is about 5V or greater. The Ⓐ-state voltage values involved in this work are on the order of 5V. Therefore, the results of this experiment will be discussed in terms of the Ⓒ-state voltage, with the understanding that the same discussion applies for the Ⓐ-state voltage. Because the *C-V* curve has a theoretical width of 2.0V, characteristic of the MOS structure involved (31), the experimental Ⓒ-state voltages were corrected by subtracting this amount from the measured data. The variation in the corrected Ⓒ-state voltage and s_o with anneal conditions gives a relative indication of the variation in the density of fast states, and no attempt was made to convert these data to actual N_{st} values.

Results—Effects of Low-Temperature Anneals on Fast Surface States

Initial values of fast surface states.—All of the diodes processed for this experiment had the same history prior to the final low-temperature anneal. Control slices, from each run of ten slices processed together, were examined for fast surface-state densities prior to any low-temperature anneal. These initial values were therefore characteristic of the last high-temperature treatment, the 1200°C, dry O_2 reoxidation with a rapid quench into the room ambient. Initial experimental Ⓒ-state voltage values for these control devices of the ten runs processed ranged from 2 to 3V, after correction for the theoretical Ⓒ-state voltage for this particular MOS structure (2.0V). The initial s_o values ranged from 8 to 12 cm/sec. Based on the reproducibility in values of the initial Ⓒ-state voltage and s_o among the control devices, it was assumed that the initial values of all the devices processed were approximately the same.[5]

Additionally, half of each control slice was given a standard low-temperature post-alneal treatment at 550°C for 2 min in N_2, for comparison of the response of the control devices to an alneal treatment. Following this alneal, the corrected Ⓒ-state voltage values ranged from 0.6 to 1.0V and s_o ranged from 2 to 4 cm/sec. Low-temperature (liquid nitrogen) Ⓐ-state voltages were found to be approximately 0.5V for these units. Again, the reproducibility of the control data indicated that all devices initially were equivalent.

Temperature effects.—Representative data illustrating the variation of s_o and the Ⓒ-state voltage with anneal temperature are given in Fig. 3-5. Each data point represents at least five values with a standard deviation of 10% or less. Minimum values of fast surface-state densities are found in the 400°-450°C range in general. The density of fast states in some cases tends to increase with higher temperatures. In particular, the bare oxide anneals show this increase with temperature, with 550°C anneals resulting in densities actually greater than the initial values. When aluminum is present over the oxide during the alneals, a reduction in the densities of fast states is observed at temperatures as low as 350°C. Additionally, the increase with increasing temperatures does not occur. In most instances, the Ⓒ-state voltage is found to vary with temperature in a manner similar to the s_o data.

Time effects.—The variation with time of the Ⓒ-state voltage and s_o for bare oxide anneals and pre-alneals in ambients of 100% N_2 and of 50% H_2-50% N_2 are shown in Fig. 6 and 7. Results for post-alneals were very similar to the pre-alneal results. The time selected for the anneals included 5 and 25 min anneals. The additional pre- and post-purge times of 5 min each were accounted for by a 7-min total time anneal in N_2 for each set of anneal conditions. The purging time had little or no effect on the bare oxide conditions except at above 500°C, where it significantly increased both the Ⓒ-state voltage and s_o. For the pre- and post-alneals, the purging time was sufficient to reduce, appreciably, the fast surface states at 350°C and above.

The effects of the 5 and 25 min nitrogen anneals in addition to the effects of the purging time in nitrogen were mainly to increase the fast surface states with increasing time for bare oxide anneals. The presence of hydrogen in the ambient tended to suppress this increase somewhat. The increase was more evident in s_o measurements than in Ⓒ-state voltage data. For

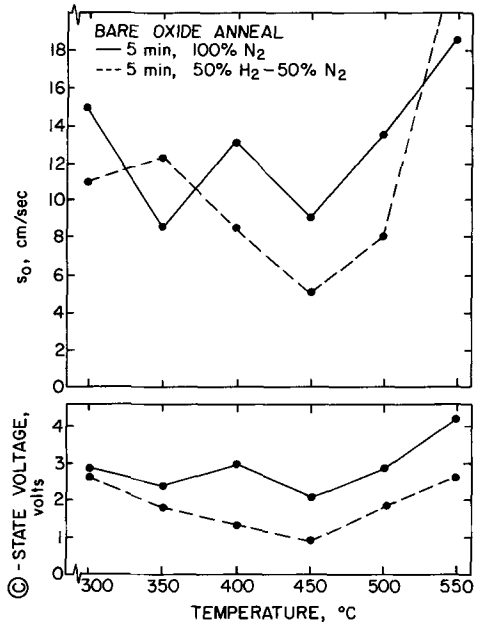

Fig. 3. Temperature dependence of surface recombination velocity and Ⓒ-state voltage for bare oxide anneals in 100% N_2 and in 50% H_2-50% N_2 ambients.

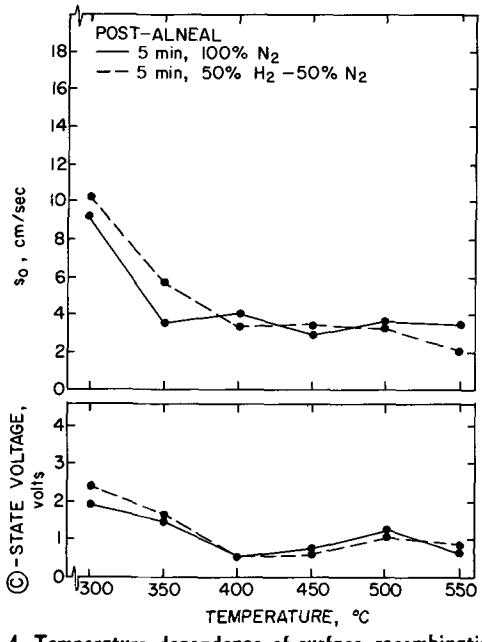

Fig. 4. Temperature dependence of surface recombination velocity and Ⓒ-state voltage for post alneals in 100% N_2 and in 50% H_2-50% N_2 ambients.

[5] It had previously been found that the relatively low value of fast states was due to the moisture content of the room ambient. On the other hand, cooling in a dry ambient (N_2 or O_2) results in a very high fast state density.

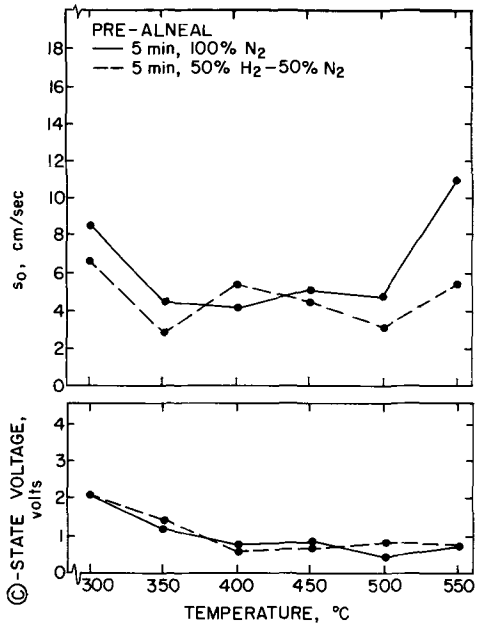

Fig. 5. Temperature dependence of surface recombination velocity and Ⓒ-state voltage for pre-alneals in 100% N_2 and in 50% H_2-50% N_2 ambients.

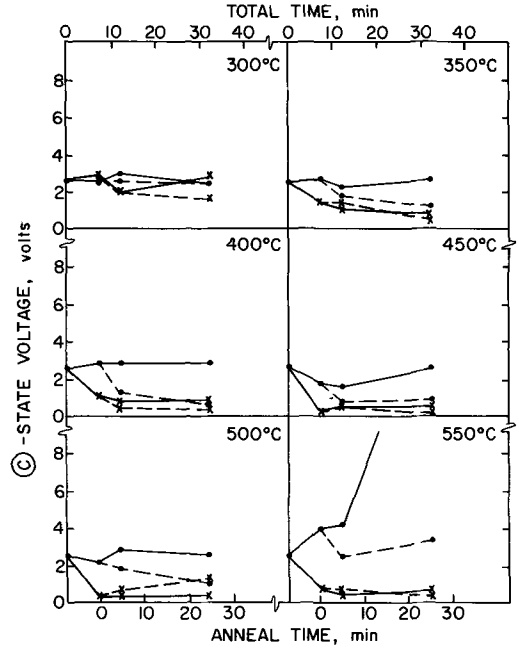

Fig. 6. Dependence of Ⓒ-state voltage on time of anneal treatment at various temperatures for 100% N_2 and 50% H_2-50% N_2 ambients. Anneal time has been offset by 7 min to account for the purging time of the system in 100% N_2. (● Bare oxide, × pre-alneal, — 100% N_2 -- 50% H_2-50% N_2.)

the alneal conditions, the increase with time was not as pronounced. In a few cases the tendency was to decrease with time. In particular, the pre-alneals at 550°C showed an increase in s_0 at shorter times, which then decreased for the longer alneals.

Ambient effects.—The effect of the presence of hydrogen in the annealing ambient was most pronounced for the bare oxide conditions investigated. Generally the greater concentration of hydrogen, 50% H_2, resulted in the lowest values of s_0 and the Ⓒ-state voltage for the bare oxide anneals. However, 10% H_2 was found to be effective in reducing the states to below the values attained with 100% N_2. The optimum temperature for the effectiveness of hydrogen for the bare oxide anneals was found to be in the 400°-450°C range. In general, the shorter anneal times gave lower

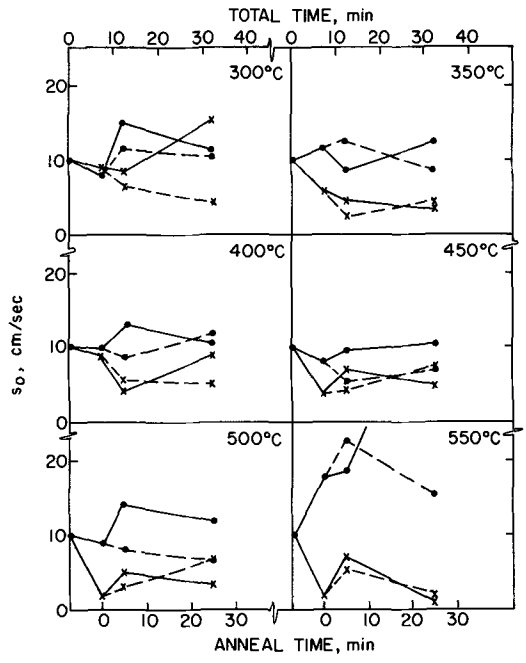

Fig. 7. Dependence of surface recombination velocity on time of anneal treatment at various temperatures for 100% N_2 and 50% H_2-50% N_2 ambients. Anneal time has been offset by 7 min to account for the purging time of the system in 100% N_2. (● Bare oxide, × pre-alneal, — 100% N_2 -- 50% H_2-50% N_2.)

values than the longer times. Under the optimum conditions, the values of s_0 and the Ⓒ-state voltage approached the low values obtained with aluminum present over the oxide-passivated junction.

For the post- and pre-alneals, the presence of hydrogen in the annealing ambient did not appreciably influence the values of s_0 or the Ⓒ-state voltage, as compared with results of similar alneals in 100% N_2.

Because the 7 min N_2 control of purging conditions indicated a large increase in fast surface states at 550°C for bare oxide anneals, it was desirable to separate the effects of the hydrogen anneal and the post-purge in N_2 at this temperature. With the resistance-heated furnace, the only feasible experiment was to process a bare oxide anneal in 50% H_2-50% N_2 at 550°C for 5 min and then to turn the furnace power off, allowing the furnace to cool to room temperature with the hydrogen in the ambient. The cooling time was approximately 3 hr. The values of s_0 and the corrected Ⓒ-state voltage resulting from this treatment were 3.2 cm/sec and 0.6V, respectively. In contrast, the bare oxide hydrogen anneal at 550°C with the standard post-purge in N_2 for 5 min and rapid cool to room temperatures resulted in an s_0 value of about 20 cm/sec and a corrected Ⓒ-state voltage of 3V. A further post-alneal of the specially treated devices did not appreciably change the fast surface-state densities from their low values. It would appear that at least at the higher temperatures, the N_2 post-purge required of the resistance-heated furnace operation was possibly responsible for the introduction of new fast surface states. However, the furnace did cool through the 400° 450°C temperature range, found optimum for reduction of the states of the bare oxide, and this may have been responsible for the extremely low density of the fast surface states resulting from this treatment.

Structure effects.—For any given anneal condition in this work (time, temperature, and ambient), the presence of aluminum over the oxide-passivated junction resulted in lower values of s_0 and the Ⓒ-state voltage than for the same bare oxide anneal conditions. A comparison between the effectiveness of the post- and pre-alneals indicates that the pre-alneal was more effective at the lower and higher temperatures, but that the post-alneals gave the lower values in the

400°-450°C range. The most effective alneals found in this experiment were for the 5 min post-alneals at 400°C and the 5 and 25 min pre-alneals at 550°C, all in a 10% H_2-90% N_2 ambient.

For bipolar devices, the aluminum pattern is usually limited to contact areas within the diffused regions. Therefore no aluminum is present over the oxide-passivated metallurgical junction. For these units, the results of post-alneals will be similar to the bare oxide anneals reported in this paper. If a reduction of the fast surface states is desired and a post-alneal is required, hydrogen anneals in the 400°-450°C range would give the best results.

Discussion

It has been proposed by Balk (20) that when aluminum is present over the SiO_2-Si interface, the annealing of fast surface states is due to the action of a hydrogen species produced by the reaction of the aluminum with water on the oxide surface. The purpose of this study was to attempt to simulate this annealing effect using molecular hydrogen in place of the aluminum-water reaction. To some extent this was successful in that the fast surface states of the bare oxide were reduced from their initial values when hydrogen was present in the annealing ambient in the temperature range 400°-450°C. The reduction, however, was not as complete as in the aluminum-water reaction. This would indicate that either (*i*) the post-anneal purge for 5 min in N_2 is introducing new fast surface states, or (*ii*) the hydrogen species produced by the aluminum-water reaction is some active form of hydrogen and not entirely molecular hydrogen, H_2.

Actually, both situations probably exist to some extent. The first, however, is largely discounted for temperatures below 500°C. This reasoning is based on the effects of the 7 min N_2 purge control anneals of the bare oxides, which showed little or no effects compared to initial values of the devices at the lower temperatures. At 550°C the 7 min N_2 anneal greatly increased the density of these states. It was also found that if the devices were cooled from 550°C to room temperature in a hydrogen ambient, the fast surface-state density was low. This again suggests that at 550°C the N_2 anneal of bare oxides introduces large densities of fast surface states. In addition, the longer anneal times in N_2 at 550°C resulted in greatly increased densities of states.

It would seem reasonable, therefore, to assume that the aluminum-water reaction does produce some active species of hydrogen which is the primary agent in the reduction of fast surface states. Hydrogen is known to exist naturally in three states: molecular hydrogen (H_2), atomic hydrogen ($H\cdot$), and ionic hydrogen (H^+). In chemical equilibrium, any volume of hydrogen contains a very small percentage of both atomic and ionic hydrogen. This percentage depends on temperature, increasing with increasing temperature. This correlates with the greater reduction of the fast states at higher temperatures for the bare oxide anneals in hydrogen. At even higher temperatures, the reduction due to active hydrogen is probably obscured by the effect of the post-anneal in N_2. Therefore, the reduction of the fast states which did occur during the hydrogen anneals of the bare oxides could be attributed to the small amount of the active hydrogen species present in the hydrogen gas.

Another factor that points to active hydrogen being the actual species responsible for the reduction of the states is the absence of any additional reduction of the states due to the presence of molecular hydrogen during the post- and pre-alneals. In these cases, the amount of active hydrogen present in the ambient hydrogen is probably insignificant compared to the amount being produced at the Al-SiO_2 interface. It is also significant to note that the rapid increase in fast states seen at 550°C for the bare oxide anneals, particularly in 100% N_2, is suppressed when aluminum is present. This suggests a close relationship between the two processes.

Earlier work which employed palladium field plates to dissociate molecular hydrogen into atomic hydrogen at 800°C showed that, while molecular hydrogen was unable to diffuse through a silicon nitride layer of an MNOS structure, the active hydrogen species not only diffused through the silicon nitride layer, it also reduced the large density of states at the SiO_2-Si interface (18). Additionally these MNOS devices exhibited positive ion polarization following the palladium-hydrogen dissociation reaction. These experimental data, combined with the present work, strongly support the theory that the aluminum-water product which is responsible for the reduction of fast surface states is some active hydrogen species and not molecular hydrogen.

For all the anneal and alneal conditions examined, the relationship between the s_0 values and the Ⓒ-state voltage values tends to be approximately constant, *i.e.*, any significant increase or decrease in one is seen in the other to some extent. This leads to the assumption that the fast surface-state distribution, as initially produced during the reoxidation and rapid quench to room ambient, has some fixed relationship between the states in the peaks near the band-gap edges and the generation-recombination centers near the middle of the band gap. The reduction of these states by the anneals reported in this work is such that the relationship is maintained. The density of fast states in the peaks at the band edges appears to be about two orders of magnitude greater than in the center of the gap. Because of the similarities between the states contributing to the Ⓐ-state voltage distortion and those contributing to the Ⓒ-state voltage distortion in the *C-V* curve, it might be proposed that the defects which are responsible for these states have an amphoteric nature and can contribute donor and acceptor levels in pairs. The donor levels are found below the intrinsic Fermi level, E_i, and the acceptor levels are found above E_i. If this is the case, the peak distributions would be similar to discrete levels, the difference being that their distribution with energy through the band gap tends to have a tail both toward the center of the gap and toward the band edges.

Because the initial density and distribution of the fast states are consistently reproducible for a given process treatment, the nature of the fast states is most likely related to the fabrication of the structure. This suggests that the states are related to uncompensated bonds at the interface, as has been suggested in the literature (19). Active hydrogen appears to complex with these bonds and to eliminate their active electrical character.

Summary

In an effort to test Balk's earlier proposal (20) that hydrogen is responsible for the reduction of fast surface states associated with the Al-SiO_2-Si structure during low-temperature treatments in dry nitrogen, a comparison was made of the effects of this reaction and of hydrogen-nitrogen anneals of SiO_2-Si structures. In general, the hydrogen ambient was found to be effective in reducing the density of fast states of the SiO_2-Si structure, with the reduction approaching, but not equaling, that of the Al-SiO_2-Si structure in the 400°-450°C range. At higher temperatures an increase in fast surface states was found for the SiO_2-Si structures which was attributed to the post-purge in nitrogen following the hydrogen-nitrogen anneal.

Summarizing, the results indicate that:

1. Hydrogen anneals of SiO_2-Si structures are most effective in the 400°-450°C range for reducing or annihilating fast surface states.

2. Heat treatments in dry nitrogen of Al-SiO_2-Si structures are effective at temperatures as low as 350°C for reduction of the fast surface states.

3. Shorter anneal times at a given temperature tend to give lower densities of fast states.

4. Hydrogen anneals of SiO_2-Si structures do not result in as low a density of fast states as nitrogen anneals of the Al-SiO_2-Si structures.

5. The hydrogen which is the more effective in the reduction of fast surface states is some active species of hydrogen and is not believed to be primarily molecular hydrogen. This agrees with earlier results of an experiment involving the palladium dissociation of hydrogen in which active or atomic hydrogen was found to diffuse through silicon nitride and annihilate fast surface states (18).

Acknowledgments

The authors wish to thank L. Pazdel, P. Fleming, M. Sklar, and P. Kodama for assistance in device processing and electrical measurements during this investigation. They also appreciate the helpful discussions and suggestions concerning this work which were provided by T. Klein, M. Barry, M. Lenzlinger, and E. MacKenna.

Properties of Gold Films Formed from Organometallic Solution

A. A. Milgram[1]

E. I. Du Pont de Nemours & Company, Electrochemicals Department, Experimental Station, Wilmington, Delaware 19800

ABSTRACT

An experimental study was made of the properties of gold films, nominally 1000Å thick, formed by the thermal decomposition of an organometallic solution. The influence of the firing temperature and of the gaseous atmosphere on the structural, optical, and electrical properties was determined. A model for the film growth during the firing temperature cycle was developed which is consistent with the experimental observations. Film properties were affected by minor additions of soluble compounds of rhodium and chromium to the basic solution. The chromium addition dealkalized the substrate surface. This was accompanied by a significant effect upon the nature of the gold colloids at the substrate-gold interface. Specifically, the fractional volume occupied by the gold colloids at the substrate surface is directly related to the alkali content of the surface. The rhodium addition inhibited grain growth of the gold particles during the film-forming process and produced films which were specularly reflecting and electrically continuous. Gold films not containing the rhodium additive were diffuse reflectors of light and were electrically discontinuous. The residual electrical resistivity was less than 0.2×10^{-6} ohm-cm for gold films containing the Rh addition. This magnitude for the residual resistivity compares with the values obtained for thin gold films formed by vacuum deposition.

Extensive research has been done on gold films prepared by vacuum deposition and by sputtering (1-8). With these methods, great care has been taken to minimize contaminants. However, the optical and electrical properties of sputtered and vacuum-deposited gold films usually differ from those of the bulk material. It has been shown by most of these investigators that the discrepancies are related to the film structure. Deposition parameters such as deposition rate, substrate temperature, and gas environment, have a profound effect on the grain size, orientation, and agglomeration of the deposited film.

The ceramic industry has been using thin gold films to decorate china and glassware for more than a century. In their case, they coat a substrate by the method of thermal decomposition of organometallic compounds applied in solution. Chemical solutions of this nature are described by Langley (9) and by Boetcher (10). A gold film is easily formed simply by firing the solution in air. A proprietary art has developed whereby additives are put into the solution to achieve specific physical (nonelectrical) properties. Although these additives are a relatively small part of the solution, they have a profound effect on the electrical properties of the fired gold film. For example, it was demonstrated from the work to be described that the residual resistivity of a gold film can be as low as 0.2×10^{-6} ohm-cm when the gold film is prepared using rhodium as an impurity additive.

It is the purpose of this paper to discuss the structural and electrical properties of gold films formed from an organometallic compound. The influence of the gaseous atmosphere, the firing temperature, and of additives such as Rh and Cr used in the organometallic solution have been determined. These studies have produced a model of film growth starting from the organometallic solution coated on a substrate and ending in a film of metallic gold.

Experimental

Gold metal decorating solutions (9-13) were used in this work. The organometallic solution (referred to as "liquid gold solution") consisted of pinene mercaptan gold (gold chloride reacted with pinene mercaptan to produce monovalent gold bonded to an organic complex) mixed with B-terpineol and organic resins. Soluble organometallic derivatives of chromium and rhodium were added to the solution. There was approximately 15 w/o gold in the solution, with 0.05 w/o Cr and 0.02 w/o Rh. A du Pont differential thermal analyzer/thermogravimetric analyzer (DTA-TGA) was used to examine the thermal properties of the ingredients of the organometallic solution. The solution was applied to 96% alumina (American Lava Alsimag No. 614) and to glass substrates (New York Laboratory Supply No. 63000 Microscope slides) by brushing on and by screen printing. The substrates were first cleaned in an ultrasonic cleaner using soap and water. After coating, the films were dried in air at 150°C for 15 min and then heated to a higher temperature. The maximum firing temperature was 625°C for the microscope glass slides and 1000°C for the Al_2O_3 substrate.

An investigation was made of the nature of the gold film at the glass-gold interface using optical and electron microscopy. A piece of cellophane tape was placed on top of the gold film and then stripped from the glass surface. In many cases a portion of the gold film would be removed with the tape, and a faint purple color would be observed on the glass slide. The material causing this color at the interface between the glass slide and the solid gold film was examined using optical microscopy. A two-stage carbon replication technique was used to make replicas of this material on the glass surface for study using electron microscopy.

An experiment was performed which demonstrated the effect of the chromium additive. Three glass slides were cleaned and an oxygen-gas torch was played over the surfaces in such a manner that a figure "X" was formed on each surface by fire polishing. One of the glass slides was rinsed with distilled water, dried, then coated with a liquid gold solution containing chromium resinate. This slide was fired in air at 625°C and the gold-glass interface was examined optically. The surface of the second glass slide was examined for sodium using an electron microprobe analyzer. The third glass slide was partially coated with a chromium resinate solution. This last slide was dried and heated in air at 500°C for 30 min. After the glass cooled, it was cleaned,

Key words: thin films, gold, electrical properties.

coated with a thin coat of liquid gold solution (not containing chromium resinate), dried, and fired in air at 625°C. The gold-glass interface was examined optically.

The effect of rhodium additive on the gold film was determined both optically and by x-ray diffraction. Two identical liquid gold solutions were prepared except that one contained the Rh additive while the other did not. The slides, after being coated and dried, were heated to progressively higher temperatures. A representative slide was removed from the furnace at 20°C intervals. An x-ray diffraction pattern was also taken of the partially formed gold film using Cu $K\alpha$ radiation.

Rhodium powder (100.00% Rh, J. Bishop and Company) was examined by x-ray diffraction using Cu $K\alpha$ radiation. This powder was then heated to 600°C in air and re-examined by x-ray diffraction. This same powder was then heated to 600°C in a 90% N_2-10% H_2 reducing atmosphere for 1 hr. Other samples of rhodium powder which had been similarly heat treated were examined in a du Pont DTA-TGA analyzer by heating from 20° to 1000°C. These samples were heated in both air and in dry nitrogen.

The electrical resistance of the fired gold films was measured at temperatures between 20° and 100°C by a digital ohmmeter. The lead resistance was measured and subtracted from the total resistance. The electrical resistance at temperatures less than 20°C was measured using a four-point probe method with a Keithley Model 503 milliohmmeter. To effect this type of measurement, an indium solder[2] with a melting point of 138°C was used to make solder connections of 0.003 in. copper strip to the gold film. Two copper strips were used as current electrodes. Another two narrow copper strips were soldered at the edge of the gold film between the current electrodes to act as voltage probes. Measurements were made at 293°, 195° (by immersion in powdered dry ice), and 78°K (by immersion in liquid nitrogen).

The effect of reducing gas atmosphere on the structure of the fired Au films was studied. Gold films were formed by firing glass pieces coated with liquid gold solution containing a rhodium resinate in air at 620°C for 10 min. Opaque gold films were produced. The glass pieces were put in a tube furnace containing a mixture of 90% nitrogen with 10% hydrogen gas. The films were heat-soaked for 15 min at 400°C, and then examined optically for structural changes. This heat-soaking procedure was repeated at 425°C and at higher temperatures in 25°C temperature steps. The optical transmission of a film heated at 600°C in this reducing atmosphere was measured with a Cary spectrophotometer using a dual beam technique. The optical transmission was compared to that of an air-fired gold film.

Results and Discussion

Effect of temperature on the liquid gold composition.—Pinene mercaptan gold compound.—As shown by the TGA in Fig. 1, the pinene mercaptan gold was observed to dissociate rapidly, beginning at approximately 185°C. By 240°C the reaction was essentially complete. The behavior was the same in both air and nitrogen. An endothermic reaction beginning at approximately 185°C can be seen on a typical sample DTA run in Fig. 1B. This agrees with the TGA result. A well-defined exothermic peak believed to be due to the formation of crystalline gold colloids is observed at 230°C.

Rhodium resinate.—Self-heating of the samples was observed by TGA in the vicinity of 300°-335°C due to oxidation of the rhodium. Between the temperatures of 325° and 375°C, the decomposition and oxidation of the rhodium was complete.

Chromium resinate.—A TGA performed on a sample indicated decomposition of the resinate and oxidation of the Cr. The Cr begins to oxidize at 300°C and continues until the resinate completely decomposes at 400°C.

[2] 25 In, 37.5 Sn, 37.5 Pb in weight per cent.

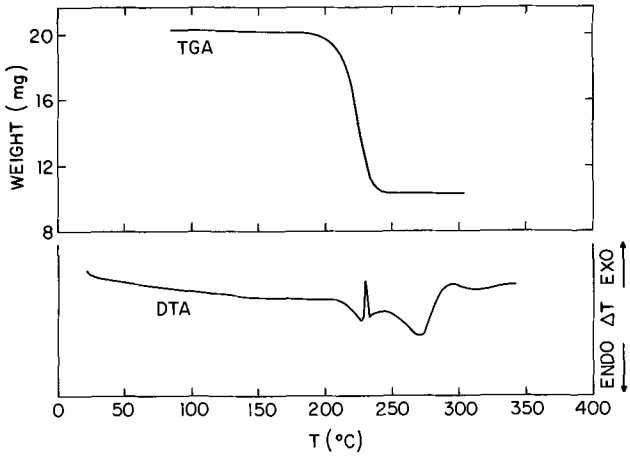

Fig. 1. DTA and TGA of pinene mercaptan gold using a heating rate of 10°C/min. The behavior was the same in both air and nitrogen atmosphere.

Glass-gold interface.—Nature of Gold Structure.—Representative electron micrographs of the surface are shown in Fig. 2A and 2B. Well-formed submicron-size gold crystals showing an octahedral configuration were found. Clusters of larger gold particles surrounded by spaces devoid of gold are seen in both Fig. 2A and 2B. This suggests that particles of 100Å size migrated over the surface to form larger gold particles.

Effect of chromium additive.—The region of the first glass slide (coated with a gold film) that had been fire polished with the X shape had no pronounced color at the gold-glass interface. However, in the vicinity surrounding this fire-polished area, there was a pronounced reddish color. Electron microprobe measurements on slide No. 2 determined that the surface area immediately adjacent to the fire-polished region had excess sodium. The third glass slide, which had been pretreated with chromium resinate solution before firing on the gold film, was examined for coloration at the glass-gold interface. For those areas adjacent to the fire-polished region which had received the pretreatment, there was no pronounced coloration.

The action of the flame, according to Weyl and Marboe (14), is to cause the alkali to migrate over the surface of the glass to a cooler region. Evidently, the presence of excess alkali on the surface influences the nucleation mechanism. The excess alkali causes the gold to form highly dense colloidal deposits on the surface during the firing process. The surface is believed to be dealkalized through the formation of Cr_2O_3, which reacts with the alkali to form Na_2CrO_4 (14).

Effect of firing temperature.—On gold particle size.—The x-ray diffraction patterns all exhibited line-broadening due to particle size effects. In Fig. 3, the gold particle size (computed using the Scherrer formula and the measured width of the diffraction curve) is given as a function of the maximum firing temperature to which the film has been exposed. The particle size for the gold film made from a solution containing the rhodium additive remains constant at approximately 350Å for firing temperatures of greater than 400°C. However, without rhodium, the gold particle size increases with firing temperature. The absence of line broadening indicated a particle size greater than 1000Å for a 400°C firing temperature. For this latter case, the gold particle size increases continuously due to agglomeration at the higher firing temperature. The optical micrograph in Fig. 4 of a gold film (with no Rh additive) fired at 600°C indicated a particle diameter of approximately 6μ.

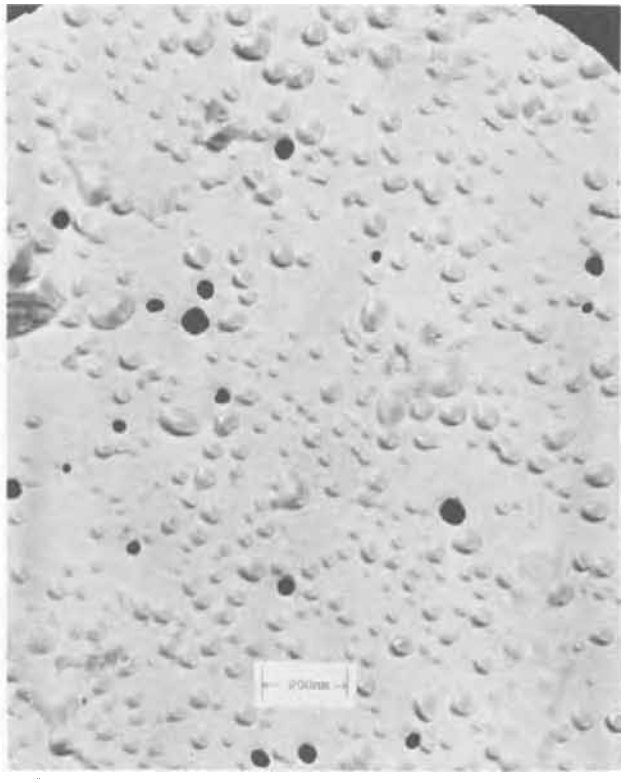

Fig. 2A (left) Fig. 2B (right). Electron micrographs of the glass-gold interface. The light colored particles represent gold. The black particles are due to actual gold particles removed from the glass surface with the carbon replica during the stripping operation. (The black particles were found to be gold by direct electron diffraction of the material on the carbon replica.)

Optical micrographs were made of gold films formed on Al_2O_3 to demonstrate the effect of high firing temperature on the film structure. The gold films containing Rh which were formed at temperatures below 800°C were continuous. Figures 5A and 5B show gold films fired at 900° and 1000°C, respectively. The black portions are the gold. At higher temperatures the gold breaks up into chains and isolated particles, and the agglomeration increases. For a gold film fired at 1000°C, less than 50% of the surface is covered with gold particles.

For firing temperatures of less than 350°C the gold film is a colloidal structure with completely random orientation. As the firing temperature is increased, the degree of (111) orientation increases.

On rhodium powder.—The x-ray diffraction results are tabulated in Table I.

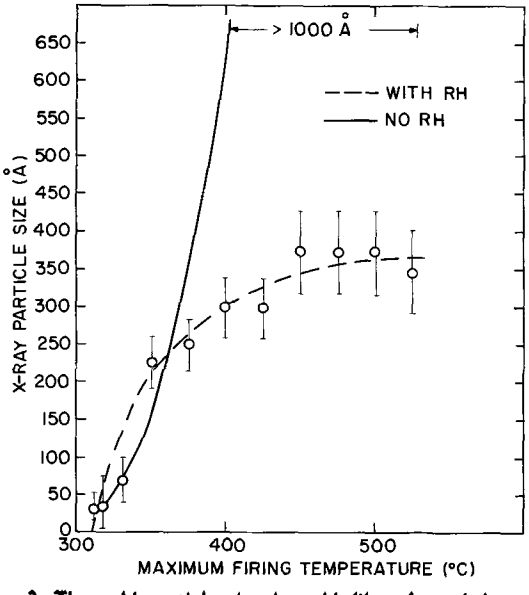

Fig. 3. The gold particle size in gold films formed from liquid gold solution with Rh and without Rh. The gold particle size was calculated using the Scherrer formula and the measured width of the x-ray diffraction curve. The particle size is plotted vs. the maximum firing temperature to which the film has been exposed.

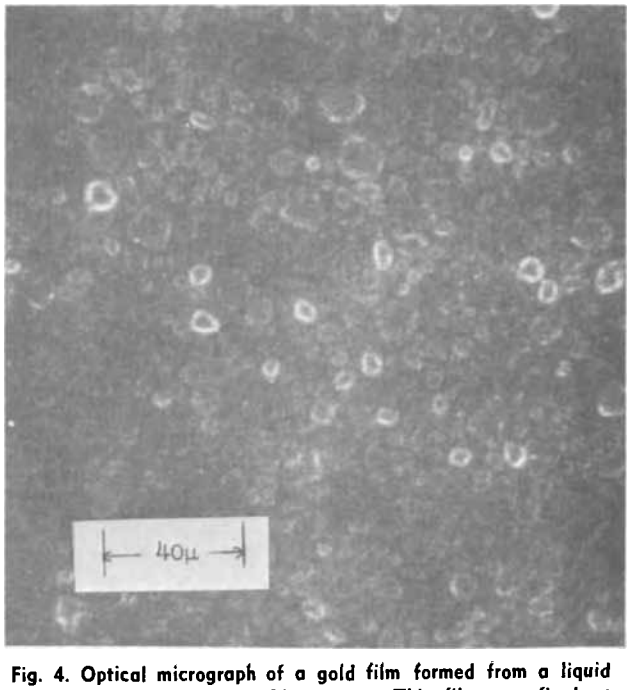

Fig. 4. Optical micrograph of a gold film formed from a liquid gold solution not containing Rh resinate. This film was fired at 600°C.

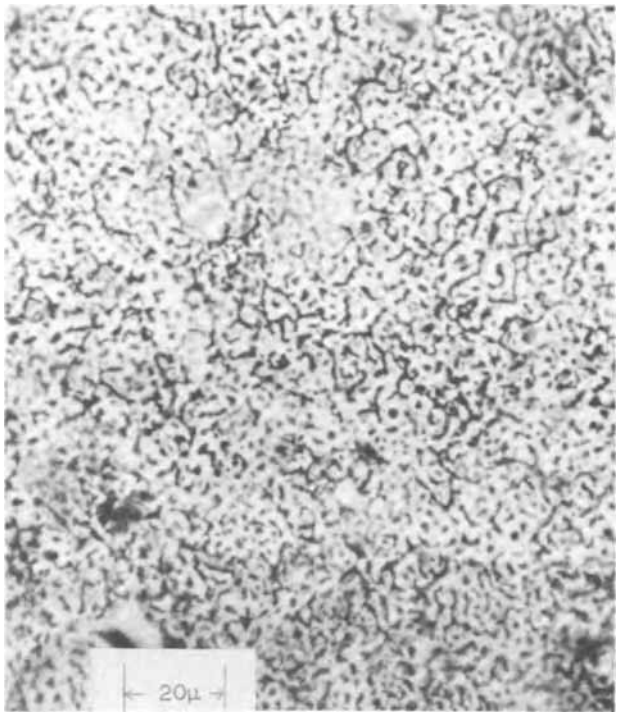

Fig. 5A. Optical micrograph of a gold film formed from a liquid gold solution containing Rh resinate. The gold film was fired in air onto 96% Al_2O_3 at a maximum firing temperature of 900°C. The micrograph was taken using transmitted light through the Al_2O_3 substrate, so that the gold appears as black regions.

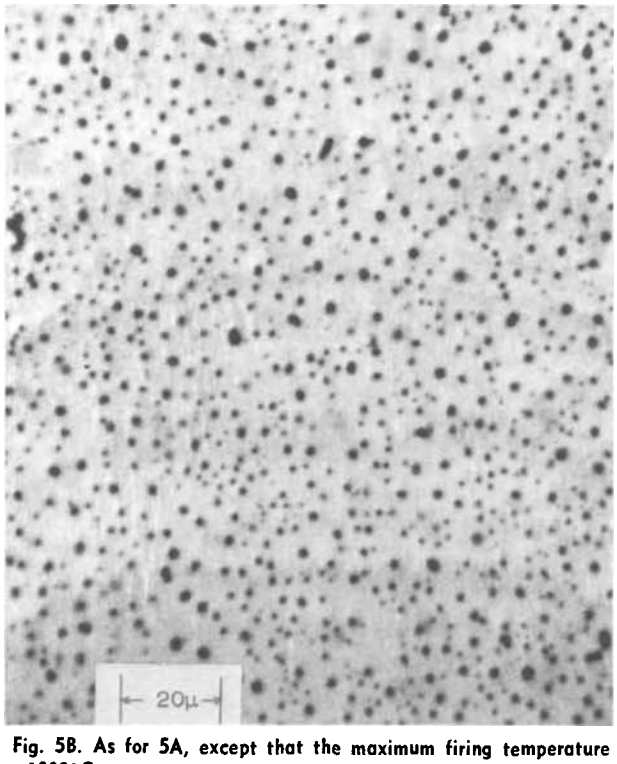

Fig. 5B. As for 5A, except that the maximum firing temperature was 1000°C.

From Table I, it is known that Rh powder heated at 600°C for 1 hr will have been transformed to Rh_2O_3. The TGA results on the oxide sample are shown in Fig. 6. The Rh_2O_3 rapidly decomposes in nitrogen at temperatures greater than 750°C. The decomposition is complete at 900°C. The calculated weight loss (19%) agreed with the observed weight loss (19 ± 1%). No decomposition is observable in air at temperatures up to 1000°C.

Table I. X-ray determination of phases present after heating Rh powder

Sample No.	Sample condition	Phases present
1	Normal	Rh
2	Sample No. 1 heated at 600°C in air	Rh_2O_3
3	Sample No. 2 heated at 600°C in a reducing atmosphere	Rh

Table II. Electrical properties of gold films containing rhodium

Max. firing temp, °C	R(22°C),[a] ohms	Temp. coeff. resistance, α,[b] ppm/°C
300	500×10^6	−10,800
310	600×10^6	−11,000
325	2×10^6	−7,000
335	7.0	+500
350	3.0	+900
375	2.6	+1,000
400	2.2	+1,100
450	1.0	+1,300
500	0.85	+2,000
550	0.42	+2,800
600	0.40	+3,200
625	0.40	+3,300

[a] R(22°C) is the sheet resistance of the film at 22°C. In this case, the distance between measuring electrodes is the same as the width of the film.
[b] The temperature coefficient of resistance at 22°C was calculated from the measured resistance *vs.* temperature relationship over the temperature interval 20°-100°C.

Thus far, results have shown that addition of rhodium resinate to the basic solution produces a gold film that is continuous and fine-grained. The Rh is known to oxidize at 300°-325°C and thus exists as an oxide before the gold particles make physical contact. (It will be shown in the section below on Electrical properties that gold particle contact begins for firing temperatures in excess of 325°C.) The gold film readily decomposes to an agglomerated structure for firing temperatures of greater than 800°C. Rh_2O_3 was also observed to rapidly decompose at temperatures greater than 750°C. These results suggest that Rh_2O_3 precipitates on the grain boundaries of the gold particles during the firing process. The Rh_2O_3 would then prevent the ready diffusion of gold from one gold particle to the next when the particles make physical contact. The results displayed in Fig. 3 show that the gold particle size is constant for firing temperatures beyond that at which the gold particles make physical contact. This result agrees with the concept that the Rh_2O_3 inhibits grain growth of the gold.

Electrical properties.—Gold films not containing Rh additive were electrically discontinuous. Measurements of electrical properties were made on gold films containing the Rh additive. Results for the resistance and temperature coefficient of resistance as a function of the firing temperature are given in Table II. The film resistance was greater than 10^9 ohm/square for firing temperatures less than 300°C. (These gold films had

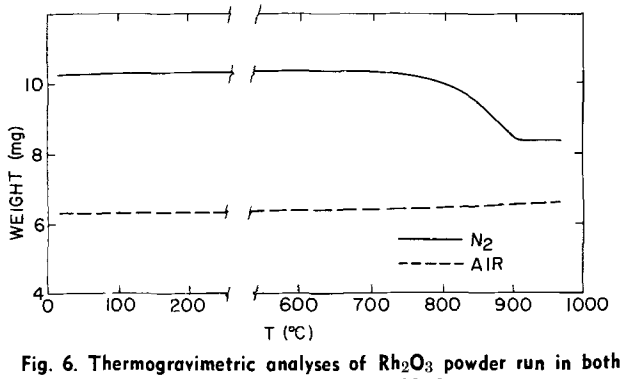

Fig. 6. Thermogravimetric analyses of Rh_2O_3 powder run in both nitrogen and in air. The heating rate was 10°C/min.

dimensions of one resistance square.) The film thickness was measured by a Clevite Brush Surfanalyzer Model No. 150 recording profilometer. The thickness varied between 700 and 1000Å over the surface; thus, no attempt was made to measure the resistivity of the film.

It is noted from Table II that the sheet resistance of the films at 22°C decreased with increase of firing temperature. This type of behavior would not be characteristic of gold films produced by vacuum evaporation. In this latter case, gold is deposited onto a heated substrate in a high vacuum chamber. The ratio of experimentally determined resistivity of vacuum-deposited films to the bulk resistivity reaches a minimum for a substrate temperature during deposition of 360°C (5, 7). When this substrate temperature is employed, the residual resistivity is approximately 0.2×10^{-6} ohm-cm (5, 7). For depositions on substrates at temperatures less than 360°C the resistance ratio is large, presumably due to defects; above 360°C, the resistivity increases with temperature, presumably due to agglomeration. Increasing agglomeration was shown to be characteristic of gold films formed from liquid gold solutions not containing rhodium.

The gold films were electrically discontinuous when fired at temperatures below 300°C. At a slightly higher firing temperature, the films became conducting ($\rho \sim 10^{-4}$ ohm-cm) with a negative temperature coefficient of resistance, as evident in Table II. This behavior is typical of electron tunneling between noncontacting colloids of gold (15). At approximately 340°C the gold colloids form partially continuous chains throughout the film. The resistance decreased by a factor of 10^6 and the temperature coefficient of resistance increased from −10,000 ppm/°C to nearly +0 ppm/°C. At a higher firing temperature, the film resistance continuously decreased, presumably due to annealing of defects. Similarly, the temperature coefficient of resistance (at 20°C) increased from +0 ppm/°C for a 340°C firing temperature to +3300 ppm/°C at a 625°C firing temperature.

The gold films which provided the results in Table II were used in the calculation of the residual resistivity associated with the gold films. The residual resistivity was calculated as follows using data from sheet resistance measurements made at 293°, 195°, and 78°K.

$$\rho(T) = \rho_o(T) + \rho_i \qquad [1]$$

Assuming Matthiesson's rule, and assuming that the resistivity of these films is independent of film thickness,

where $\rho_o(T)$ = resistivity behavior of pure, well-annealed gold at temperature, T
$\rho(T)$ = observed resistivity (sheet resistance) behavior of gold film at temperature, T, °K
ρ_i = residual resistivity.

Using algebra

$$\rho_i = \left\{ \frac{\dfrac{\rho_o(T)}{\rho_o(78)} - \dfrac{\rho(T)}{\rho(78)}}{\left[\dfrac{\rho(T)}{\rho(78)} - 1\right]} \right\} \rho_o(78) \qquad [2]$$

For pure, well-annealed gold (16)

$$\frac{\rho_o(195)}{\rho_o(78)} = 2.50 \qquad [3a]$$

$$\frac{\rho_o(293)}{\rho_o(78)} = 3.87 \qquad [3b]$$

and $\rho_o(293) = 2.4 \times 10^{-6}$ ohm-cm.

There exists another independent method of calculating ρ_i using the temperature coefficient of resistance. Empirically, this method yields more accurate results than does the first method. Equation [1] can be restated as follows

$$\rho_o\alpha_o = \rho\alpha \qquad [4]$$

where α = the experimentally determined temperature coefficient of resistance and α_o refers to the temperature coefficient for the ideal metal. Using the appropriate values for ρ_o and α_o and the empirical value for α at $T = 293$°K, the value of ρ and the residual resistivity can be calculated. Results are tabulated in Table III. The residual resistivity for a gold film containing rhodium formed at 625°C was calculated from Eq. [4] to be 0.2×10^{-6} ohm-cm.

Table III. Residual resistivity of gold films containing rhodium

Max firing temp, °C	Calculated from Eq. 2: T = 293°K, ×10⁻⁶ ohm-cm	Calculated from Eq. 2: T = 195°K, ×10⁻⁶ ohm-cm	Calculated from Eq. [4], ×10⁻⁶ ohm-cm
625	0.4	0.4	0.2
600	0.4	0.4	0.2
550	1.0	1.0	0.5
475	4.2	—	2.1
460	4.5	—	2.1

For gold films containing rhodium, the oxide coating at the interface between the gold particles produces an additional resistance. It was shown by Milgram and Lu (17) that an oxide as thin as 20Å can produce a resistance of 10^{10} ohms/ square for the gold films used in this work. The additional resistance decreases rapidly as the oxide thickness decreases. Experimentally, it was shown that the additional resistance was less than 10^{-1} ohms. Thus, the oxide must be of monolayer thickness to avoid the additional oxide resistance. It is shown in the Appendix that the oxide of rhodium would just coat the surface of a gold particle if it were to exist as a monolayer coating.

Effect of reducing atmosphere.—Film structure.—The first evidence of partial transformation of the continuous film to a discontinuous film was found at a firing temperature of 475°C when the film was soaked for 15 min in a 90% N_2-10% H_2 atmosphere (1 bar). The transformed region consisted of 1μ diameter particles in the form of flat platelets of irregular size. At progressively higher firing temperatures in the reducing atmosphere, the film completely converted to a discontinuous film consisting of irregularly shaped gold platelets of 1-5μ diameter. At approximately 600°C, there was complete conversion to a discontinuous film when the film was exposed for 15 min. In this last case, the gold was in the form of regularly shaped, 1μ diameter gold hemispheres. The film has the particle distribution as shown in Fig. 5B; however, the particles are more uniform than those shown in Fig. 5B.

The effect of heating a fired gold film in a reducing atmosphere was irreversible. A glass piece coated with gold, which had been treated in a reducing atmosphere to bring out an agglomerated structure, was subsequently heated in air again to 600°C. The gold film was found to maintain an agglomerated structure.

The above results are in accordance with the hypothesis that the Rh_2O_3 inhibits the growth of the gold particles. When the Rh_2O_3 is reduced to Rh by heating in a reducing atmosphere, the gold particles can agglomerate. The agglomeration proceeds rapidly with higher temperature due to the increased mobility of the gold. Once the gold particles agglomerate into a discontinuous structure, a postfiring treatment in air will be ineffectual.

Optical transmission.—Gold films were formed from solutions not containing the Rh additive. All of the films were diffuse reflectors of light. However, the addition of Rh to the basic solution yielded fired films with specular reflectivity. The transmission color of gold films containing a rhodium additive was found to be related to the maximum firing temperature.

The observed colors of transmitted light as a function of firing temperature are tabulated in Table IV.

Table IV. Weight per cent of gold in the film and the film transmission color as a function of firing temperature

Maximum firing temperature, °C	Weight per cent gold,[a] %	Transmission color
300	43	Ruby-red
325	46	Dark blue
350	53	Dark blue
375	77	Dark blue
388	94	Light blue
400	96	Light blue-green
425	97	Light blue-green
450	98	Light blue-green
475	99 +	Light green-blue
625	100	Light green

[a] The weight per cent gold in the film was determined by performing a TGA on a liquid gold solution. Between 500° and 650°C there was no observable change of weight. It was assumed that no organic remained in the film at 625°C firing temperature. The weight per cent gold in the film was then calculated directly from the TGA curve.

The ruby red color observed at 300°C is due to the highly dense noncontacting gold colloids embedded in the organic matrix. At a higher firing temperature, the gold particles made contact and produced a green transmission color characteristic of bulk gold. At intermediate temperatures, the transmission color had a blue component due to the influence of the organic remaining in the film.

The optical density of a gold film containing Rh was measured; it had been fired in air at 625°C. The gold film reflected light specularly. It was then heated at 600°C in a reducing atmosphere and the optical density remeasured. Results are given in Fig. 7. The gold film fired in air had a minimum in optical density at 495 nm, which is similar to the behavior of vacuum deposited gold films (6). However, the gold film after being exposed to the reducing atmosphere underwent a major structural change which affected the optical transmission. The optical transmission was flat *vs.* wavelength except between 480 and 700 nm where there was a broad absorption band centered at 540 nm. This transmission minimum is due to the optical properties of submicron size colloidal gold, as shown by the work on vacuum evaporated and sputtered gold films (6, 10). (The reflectivity also peaked in the neighborhood of 540 nm, because the gold film appeared green by reflection from a white light source.)

Summary and Conclusions

The observed electrical and optical behavior can be explained by assuming that film growth proceeds by the following steps during the firing temperature cycle:

1. Dissociation of the organometallic compound and formation of gold colloids. Nucleation is observed throughout the volume of the liquid solution as the organic burns out. Nucleation also takes place at the glass-gold interface.

2. Increase in size of the gold colloids. The particulate size and density at the glass-gold interface will be determined by the same nucleation mechanisms as for vacuum deposited thin films. Gold films formed by vacuum deposition are known to form an agglomerated structure similar to that shown in Fig. 2A and 2B (1, 2). Due to this unique structure at the glass-gold interface, the optical constants vary significantly as a function of the wavelength and will give rise to selective reflectivity (3). The observed color from the back-side of a glass substrate containing a gold film formed from the liquid gold solution will be dependent on the colloidal nature of the gold at the interface. Various colors can be produced depending upon the fractional volume occupied by the colloidal layer (3).

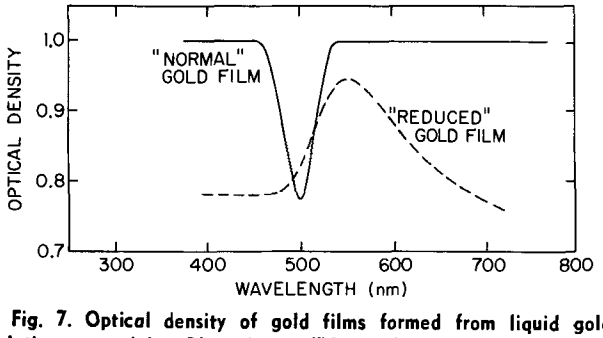

Fig. 7. Optical density of gold films formed from liquid gold solutions containing Rh resinate. "Normal" represents the optical density for an air-fired film. "Reduced" represents the optical density for an air-fired film which has undergone a postfiring in a reducing atmosphere.

It has been determined from this work that the alkali content of the glass surface will affect the particle size and density at the interface during the growth process. The presence of Cr_2O_3 in the gold solution will change the alkali content on the glass surface during firing; thus, the size and density of gold particles at the glass-gold interface will be affected. Because the nucleation mechanisms are the same as for vacuum deposited films, it is suggested that the alkali content of the glass surface affects the nucleation of vacuum deposited gold films.

3. Inhibition of diffusion of gold by the presence of rhodium oxide. Without the rhodium oxide, the gold particles continually increase in size with increase of firing temperature.

4. Loss of the organic material until the gold colloids make contact and form partially continuous networks. If rhodium oxide is present in the film, the gold particle size will not increase after the gold particles make contact. The rhodium oxide is believed to be present at the grain boundaries between gold particles and prevents grain boundary diffusion of the gold. Reducing the oxide by either heating to the decomposition temperature or by heating in a reducing atmosphere causes the gold particle size to increase as if the rhodium were not present.

5. Loss of the rest of the volatile matter from the gold film in addition to annealing of the gold particles in the film. With respect to the specific property of residual resistivity, the gold film containing rhodium compares to that of well-annealed vacuum deposited or sputtered gold films prepared using ultraclean procedures (5, 7). The optical absorption of the former film also compares to that of the latter (6).

The gold films not containing rhodium were electrically discontinuous. Gold films containing rhodium became electrically discontinuous after being exposed to reducing conditions. In this latter case, the film consisted of gold particles of one micron diameter, uniformly spaced on the substrate.

The encouragement and thoughtful comments of D. G. Kelemen of the Du Pont Company are appreciated.

APPENDIX

Thickness of Rh_2O_3 Layer on a Gold Particle

If the rhodium were to be present only at the surface of the gold particle, then for a gold particle diameter (considered to be spherical) of 350Å, and a rhodium content of 0.2%

$$\frac{V_{Rh}}{V_{Au}} = \frac{M_{Rh}}{M_{Au}} \times \frac{\rho_{Au}}{\rho_{Rh}} \qquad [1A]$$

where V = volume, M = mass, ρ = density, Rh = rhodium, and Au = gold.

$$\frac{V_{Rh}}{V_{Au}} = 0.2\% \times \frac{19}{12} = 3 \times 10^{-3} \qquad [2A]$$

$$V_{Au} = \frac{4}{3}\pi R^3 \qquad [3A]$$

where R = radius of gold particle.

$$V_{Rh} = 3 \times 10^{-3} \times \frac{4}{3}\pi R^3 \qquad [4A]$$

$$\frac{\text{Rh atoms}}{\text{cm}^3} = \frac{N_o \rho_{Rh}}{N_{Rh}} \qquad [5A]$$

where N_o = Avogadro's number = 6×10^{23} molecules per gram-molecular weight, N_{Rh} = molecular weight of Rh = 103, and ρ_{Rh} = 12.4.

Define $\gamma \equiv$ Number of Rh atoms (in gold particle volume)

$$\gamma \equiv \frac{N_o \times 12}{100} \times 10^{-3} \times 4\pi R^3 \qquad [6A]$$

The surface area per gold particle, S, is given by

$$S = 4\pi R^2 \qquad [7A]$$

$$\frac{\gamma}{S} = 1.3 \times 10^{14} \frac{\text{Rh atoms}}{\text{cm}^2 \text{ Au surface}} \qquad [8A]$$

Using Eq. [5A] with the appropriate values for Au, $N_{Au} = 197$ and $\rho_{Au} = 19.3$

$$\frac{\text{Au atoms}}{\text{cm}^2 \text{ Au surface}} = 2 \times 10^{15} \qquad [9A]$$

Thus, there is approximately one Rh atom for every lattice cell of 5 gold atoms at the surface of the gold particle. After oxidation, the oxide of rhodium (presumably Rh_2O_3) occupies an area less than or equal to the complete surface area of the gold particle. This assumes uniform distribution of the rhodium, uniformly spherical gold particles, and monolayer coverage of the gold.

Glass Source B Diffusion in Si and SiO_2

D. M. Brown* and P. R. Kennicott

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The general characteristics of B_2O_3-SiO_2 film diffusion sources formed by the oxidation of SiH_4 and B_2H_6 by O_2 were examined, and the diffusion of B from these glass sources into Si and through SiO_2 films was studied at 1000°-1100°C. B diffusion in (100) Si in the solid solubility region exhibits strong concentration variations as junction depths are observed first to increase and then suddenly to decrease with increasing concentrations. B diffusion through SiO_2 films was examined in two distinct regions (*i*) the "solid" state region and (*ii*) the "melt through" region where the doped glass layer dissolves the SiO_2 barrier layer at the diffusion temperatures. Understanding of these glass film diffusion sources as "glasses" aids in the interpretation of these phenomena.

It has been previously ascertained that the use of glass film diffusion sources for the formation of Si planar junctions has several advantages (1). Some of the advantages offered by these glass film diffusion sources formed by the oxidation of gaseous silanes and hydrides are: (*i*) diffused Si surface concentrations can be controlled over a wide range by variation of the dopant concentration in the glass; (*ii*) for shallow diffusions the oxide acts as a source of constant dopant concentration which helps in the reproducibility and predictability of surface concentrations and junction depths; (*iii*) surface concentrations can be held just below solid solubility which results in a minimum number of dislocations being introduced during diffusion. For instance, Fisher *et al.* have eliminated the "emitter dip" phenomenon in diffused planar n·p·n transistors (1). In addition, the dielectric qualities of these glass diffusion sources offer special advantages for the formation of self-registered MOSFET integrated circuits since the glass layer not only acts as a "well-defined" diffusion source, but in addition can also be utilized to isolate dielectrically the first and second level metallization patterns (2).

The use of doped oxide diffusion sources formed by reactive sputtering of doped Si cathodes in O_2 has been reported by Shortes and Wurst[1]; and Benjamini *et al.* have mentioned the formation of doped oxide diffusion sources by the anionic oxidation of Si[2]. Olmstead and Scott (3) have described doped oxides deposited by the pyrolysis of organosilanes. In their method, solutions of organosilanes and trimethyl borate or trimethyl phosphate were utilized as the glass forming sources. A variation of this method was utilized to form the glass sources over thin films of

patterned refractory metal diffusion masks for the formation of self-aligned refractory metal gate MOSFETs (4).

Borosilicate Glass from SiH_4, B_2H_6, and O_2

The use of glass diffusion sources made from the low-temperature oxidation of hydrides has been reported by Mecs (5), Barry and Olofsen (6), and Fisher *et al.* (1, 7). The diffusion data in these previous works are almost exclusively those obtained from Si samples with (111) surfaces coated with the doped glass. Our interest, however, was primarily directed to the investigation of the diffusion of the boron dopant from the glass through undoped barrier oxides. A motivation for this was that, in the fabrication of self-registered MOSFETs, the diffusion of the dopant from the glass through the gate oxide is more direct since it eliminates an etching process. This in turn avoids a possible gate to substrate shorting problem which could occur if any undercutting of the gate oxide beneath the gate electrode is produced during gate oxide removal in the source and drain apertures. The (100) Si surface orientation was used because it is the preferred surface for low threshold p-channel MOSFETs.

Within this context, a number of goals are definable: (*i*) to understand these B_2O_3-SiO_2 glass film diffusion sources as glasses; (*ii*) to obtain high B concentrations within the Si after diffusion in order to minimize contact resistance; (*iii*) to diffuse for reasonable times at temperatures low enough to obtain good control of junction depth; and (*iv*) to fabricate glasses with etch rates suitable for standard photoresist patterning. As a result, these investigations using diffusion temperatures of 1000°-1100°C have (*i*) been limited primarily to the attainment of surface concentrations at or near the solid solubility limit of B in Si, and (*ii*) examined the diffusion of the boron dopant from the glass films through underlying undoped thermal oxides in two distinct regions (*a*) the region of solid-state diffusion in which the glass remains solid, and (*b*) the "melt through region" where the glass layer rapidly converts the undoped oxide into a doped glass.

Chemistry.—The primary reactions taking place in the formation of SiO_2-B_2O_3 glass from the oxidation of SiH_4 and B_2H_6 are shown in Fig. 1. Oxygen was used as the oxidant in this case (reactions A and B); however, other oxidants such as NO also appear to be favorable (A' + B').[3] The reaction kinetics taking place during the deposition of the doped glass are quite complicated, and one must guard against premature reactions in the gas stream before the gases reach the heated substrate. Other factors to consider are the relative instability of B_2H_6 and SiH_4 (C and D) and the oxidation of refractory metal films whenever one wishes to cover a refractory metal FET pattern with these glass diffusion sources (4). These problems were minimized by dilution of the O_2 and the SiH_4/B_2H_6 mixture with an argon buffer gas before introducing these mixtures into the reactor and by using a low deposition temperature (300°C). In addition, the wafers were heated to the deposition temperature in argon before introducing the reactants into the argon gas streams.

The reduction of B_2O_3 by Si (reaction E) at the glass-Si interface is usually assumed to be the mechanism that releases free B from the glass, whereupon it diffuses as an atomic impurity into the Si. The attainment of solid solubility implies the existence of a silicon-boron phase which is produced at the interface whenever the diffusion conditions are such that more B is supplied to the interface than can be dissolved in the Si. The observable existence of this phase, which may be SiB_6 (8), has been utilized by many workers to insure maximum B surface concentrations during Si diffusion processing.[4] However, this phase, usually indicated by a slight brownish stain on the wafer, is not soluble in HF acid, and its presence at the Si surface will probably be reflected in an increase in contact resistance when the diffused region is provided with a metallic electrical contact. In addition, Busen *et al.* (9) have pointed out that complete removal of this phase is required for optimal diffusion results; this requires additional processing steps. No additional steps are required when glasses of proper composition are utilized as the dopant sources during diffusion, because the formation of the B-rich Si phase can be prevented.

[3] The oxidation of SiH_4 and B_2H_6 could form H_2O rather than H_2; both reactions are favorable [see ref. (1), p. 534].

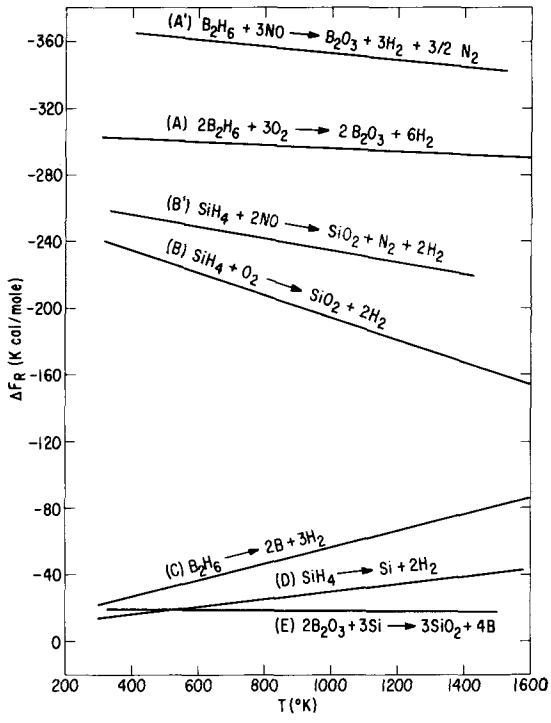

Fig. 1. Free energy of reaction vs. temperature plot for the possible reactions taking place during the pyrolysis of mixtures of SiH_4, B_2H_6, and O_2 or NO. Reaction E is generally assumed to be the reaction at the Si-glass interface which releases B from the B_2O_3 glass during diffusion. From JANAF thermochemical tables (Dow Corning).

Experimental—Sample Preparation

1 ohm-cm n-type (100) Si wafers, 2.5 cm in diameter, obtained from pulled crystal ingots, were purchased with lapped surfaces. These samples were heavily etched in $3HNO_3$:1HF and rinsed in distilled water. Thermal oxidations were carried out in dry oxygen in an apparatus previously described (10). Oxide thickness on adjacent batch control wafers was measured using both ellipsometry and MOS capacitance-voltage curves. In most instances, the thermal oxide was removed from half of the wafer's surface by photoresist and etching techniques before glass deposition. This was done in order to compare accurately the junction depths and surface concentrations for bare Si and for Si covered by undoped thermal oxides whose thickness ranged from 100 to 1500Å.

The glass depositions were done in a quartz vertical reactor 6 cm in diameter. A resistance heated platform 3 cm in diameter provided the heat required for the formation of the glass from SiH_4 diluted to 1% in A, B_2H_6 diluted to 1% in A, and pure O_2. Argon was used as the buffer gas at a total flow rate of 3800 cc/min; the flow rate of the 1% SiH_4 was fixed at 140

[4] The existence of this phase has also been indicated by studies of the ternary system Si-B-O by P. J. Gielisse, T. J. Rockett, and W. R. Foster, "Fundamentals of Silicon Integrated Device Technology," Vol. 1, p. 15, R. M. Burger and R. P. Donovan, Editors, Prentice-Hall, Inc., Englewood Cliffs, N. J.

cc/min and the O_2 at 20 cc/min.[5] The 1% B_2H_6 gas flow was varied from 1 to 100 cc/min which results in a $B_2H_6/(B_2H_6 + SiH_4)$ ratio of from 0.7% to 42%.[6] The SiH_4 and B_2H_6 flows were mixed and added simultaneously to half of the A buffer gas, the other half being added to the O_2 flow. These two flow mixtures were brought together at the reactor. During deposition, the substrate's heater platform was held at 300°C.[7] Diffusions were carried out in a very dry A atmosphere at temperatures of 1000°, 1050°, and 1100°C.

Experimental—Glass Properties

Glass composition.—The glass compositions were determined by a flame emission technique before diffusion. After etching in $3HNO_3$:1HF, wafers were rinsed, dried, and weighed on a microbalance.[8] Oxides were deposited using various flow rates of 1% B_2H_6, as described above. After deposition, the wafers were again weighed and etched in 10% HF to remove the glass. The resultant solution was diluted and measured on a flame emission spectrometer[9] to determine the concentration of boron. After etching, wafers were given a final weighing. Film weights obtained by difference between weights before and after deposition agreed with those obtained by weights after deposition and after glass removal to within ±4%. Typical film weights were of the order of 1 mg.

The flame emission spectrometer was calibrated with a series of standards prepared from a stock primary standard solution of boric acid by diluting with 10% HF.

By means of the wafers used for composition studies, a working relationship could be established between gas flow rates used to prepare the glasses and their compositions. This relationship is shown in Table I. Also included in Table I are the ratios of the 7μ B-O and 9μ Si-O infrared absorbance peaks that can be used for nondestructive quantitative control. Another means of determining glass composition is to correlate B surface concentrations in the Si after diffusion with the data of Barry and Olofsen. This comparison is described later.

Glass whose composition exceeded about 40% B_2O_3 were not intensively investigated because of their increasing tendency to absorb water.

Glass growth and etch rates.—The growth rates of the films were found to increase whenever additional amounts of the hydride reactants were added to the gas stream. This effect is shown in Fig. 2 where the growth rate is plotted *vs.* the mole per cent in the reactants and in glass. What is remarkable about this is that the growth rate increase is more than that which can be accounted for by a simple linear combination of SiO_2 and B_2O_3 deposition rates. Index of refraction and preliminary density measurements indicate that the density of these films is not abnormally

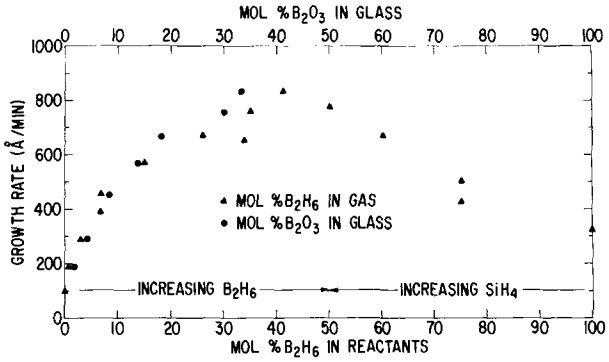

Fig. 2. Doped glass growth rates at 300°C *vs.* molar per cent B_2H_6 in gaseous reactants and molar per cent B_2O_3 in glass. From 0-50 molar per cent, SiH_4 flow kept constant at 140 cc/min; from 100-50 molar per cent, B_2H_6 flow kept constant at 140 cc/min.

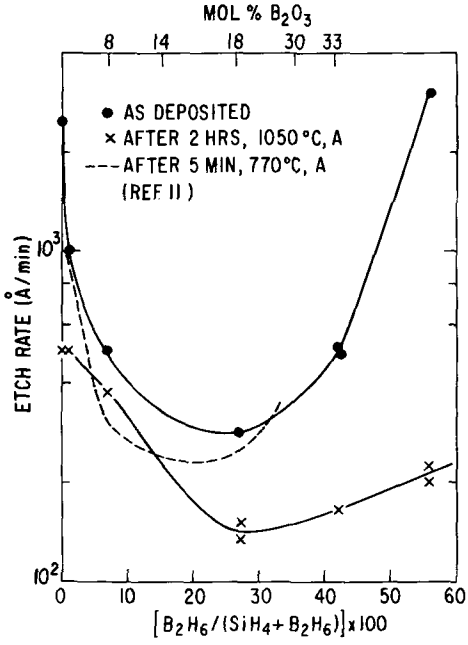

Fig. 3. Buffered HF etch rates of B_2O_3-SiO_2 glass *vs.* $B_2H_6/(SiH_4 + B_2H_6)$ flow rate ratio and glass composition. Rates given are for films after deposition and after 1050°C heating in A. The samples at highest flow ratio were made by reducing the SiH_4 flow to 80 cc/min, and using a B_2H_6 flow of 100 cm/min. Rates from ref. (11) for films heated to 770°C are included.

low. This implies that the presence of another glass forming reactant increases the over-all reaction efficiency and enhances the deposition rate.

The etch rates[10] of these glasses in buffered HF are shown in Fig. 3. The etch rates of the B_2O_3-SiO_2 glasses before being subjected to high temperatures vary between 3000 and 300 Å/min depending on composition. The lightly doped glasses etch much faster than the 750 Å/min rate obtained for dry thermal oxides. This is also true for the heavily doped glasses before heating. As shown in Fig. 3, there is a distinct minimum in the etch rate curve at a $B_2H_6/(SiH_4 + B_2H_6)$ flow rate ratio of about 0.3 (~20% B_2O_3).

A qualitative explanation for this minimum etch rate might be as follows. SiO_2 is dissolved rapidly by HF acid. As B_2O_3 is added to the glass, the etching effectiveness of the buffered HF is initially reduced. B_2O_3, on the other hand, is hygroscopic and very soluble in water, whereas SiO_2 is not, and with increasing amounts of B_2O_3, the glass begins to get hygroscopic and the dissolution rate increases rapidly again.[11] Heat-

[5] Using flowmeters calibrated for air. Flow of A = setting × 0.86.
[6] An exception to this is found in Fig. 2 where in order to investigate the growth rate *vs.* gas ratios above 40% the B_2H_6 flow was fixed at 140 cc/min and the SiH_4 flow increased.
[7] W. Kern and R. C. Heim, [*This Journal*, 117, 562 (1970)] have carried out extensive investigations on deposition techniques.
[8] Cahn Electrobalance.
[9] Instrumentation Laboratory Inc. Model 153.

[10] 10NH_4F (40%):1HF. In a 6:1 solution the etch rates are about 2X faster than those shown in Fig. 2 (J. Sprague, Private communications).
[11] Kern and Heim (11) have shown that dilute HF [1HF (49%): $2H_2O$] produces rapid dissolution of B_2O_3-SiO_2 glass and that the dissolution rate increases markedly with increases in B_2O_3 content. Their observations are consistent with this model.

ing these B_2O_3-SiO_2 glasses to 1050°C causes the etch rates to decrease markedly. Presumably this is because these films originally formed at 300°C are not formed at full density and heating to elevated temperatures causes them to densify. For instance, for B_2H_6 flows <1 cc/min, the etch rate drops from about 2000 to 500 Å/min. This etch rate is lower than the 750 Å/min rate for thermal oxides. This is presumably caused by the presence of small amounts of B_2O_3 produced by reactor or reactor gas B contamination. The buffered HF etch rate data obtained by Kern and Heim (11) on films heated for only 5 min at 770°C are also included in Fig. 3. Comparisons of the data indicate that higher temperature heating results in a more marked decrease in buffered HF etch rates the higher the B_2O_3 concentration.

Experimental—Diffusion Studies

A large number of preliminary runs were made at 1050°C with different combinations of glasses, barrier oxide thicknesses, and diffusion times. Raw data obtained after each diffusion experiment consists of sheet conductivity in ohms per square from 4-point probe measurements and junction depth, x_j, obtained from angle lapping and staining. A conservative estimate of the accuracy of the junction depth determination is ±1000Å. Some of these data which generally summarize the findings are presented in Table II. Surface concentrations, C_s, can be obtained from these data by assuming a complementary error function distribution of electrically active diffused dopant within the Si and the use of Irvin's curves (12).[12]

Diffusion of B in Si

The surface concentration at the Si-glass interface depended on the glass composition. Within the limits of the experimental conditions, however, it was found that the surface concentration was essentially independent of doped glass thickness, diffusion time, or whether or not the B-doped glass is covered with a thin undoped capping oxide. These qualitative findings are in agreement with those reported by Fisher and Amick for diffusions at 1200°C (7).

A plot of C_s *vs.* molar per cent B_2O_3 in the glass is given in Fig. 4. Note that C_s increases with B_2O_3 concentration up to about 20%. Above 20%, C_s saturates indicating that the solid solubility of B in Si at 1050°C is about 3.8×10^{20}/cc. This number is in good agreement with the predictions of Trumbore (13) yet higher than the 2×10^{20}/cc recently given by Vick and Whittle (14).[13]

[12] This is an operational point of view. Barry and Olofsen (6) examined this point and found a satisfactory fit to the complementary-error-function distribution; however, most of their data were taken for high diffusion temperatures and lower concentrations where variations in diffusion constant with concentration are smaller.

[13] In ref. (14), Vick and Whittle assume that solid solubility is maintained by the B rich phase described in the text. These authors have apparently been very careful about taking into consideration the variations in the diffusion coefficient with concentration; however, the diffusion constants for low concentrations, where D_2 is independent of concentration, are considerably larger than any of those previously reported, *e.g.*, compare Fig. 5 and 8 of ref. (14) and (6).

After diffusion, the doping glasses were removed using buffered HF. The brownish stain and hydrophilic nature of the Si surface characteristic of the B rich Si phase (SiB_6) was observed for cases when the doping glasses contained >20% B_2O_3. As is indicated by Fig. 4 and the experimental observations described above, B concentrations approaching solid solubility in the Si can be attained by using glasses containing ≈18% B_2O_3 while at the same time eliminating the undesirable features associated with the formation of SiB_6.

Glass compositions can also be checked using the diffusion data in Fig. 4. Barry and Olofsen using flame photometric analysis showed that the B concentration in their glasses ranged from 2×10^{20} to 4×10^{21}/cc for Si surface concentrations after diffusion of from 4×10^{18} to 10^{20}/cc (6). This implies that our glasses contain about 10^{22} B/cc or about 20 molar weight per cent B_2O_3 when solid solubility in the Si is attained. Using Fig. 7 of ref. (6) with Fig. 4 enables us to check glass compositions for the range of concentrations covered by Barry and Olofsen; this correlation gives good agreement if it is assumed that all the B and Si in the films is in the form of B_2O_3 and SiO_2.

The 1050°C data and the 1000° and 1100°C data given in Table III show that for any particular diffusion time, the junction depth increases with increases in B surface concentration until solid solubility is reached whereupon there is a sudden decrease in junction depth. The raw data is summarized in Fig. 5 where

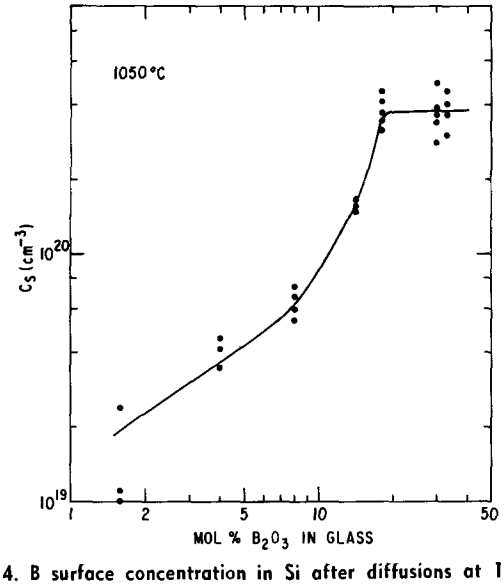

Fig. 4. B surface concentration in Si after diffusions at 1050°C *vs.* molar per cent B_2O_3 in glass sources. Assumes complementary error-function-distribution (see *e.g.*, W. R. Runyan, "Silicon Semiconductor Technology," p. 118, McGraw-Hill Book Co., New York (1965).

Table III. B/Si diffusion 1000° and 1100°C, 1 ohm-cm (100)

	Flow (1%) B_2H_6 (cc/min)	1	5	10	25	50	75	100
	Molar per cent B_2O_3 in glass	1.6	4	8	14	18	30	33

1100°C	X_j, μ	1.6	1.9	2.2	2.6	4.0	3.5	3.5
2 hr	ρ_s, ohm/□	180	52	33	10	3.6	3.7	3.7
	$C_s/10^{20}$ cc	0.14	0.48	0.7	2.3	4.2	4.7	4.7
	$D_2/10^{-14}$ cm²/sec	14	17	21	26	58	45	45

$(x_j/t^{1/2})$ *vs.* $(\rho_s x_j/t^{1/2})^{-1}$ is plotted,[14] x_j being the junction depth and t being the diffusion time.

The increasing part of the plot indicates that the diffusion constant of B in Si is increasing with B concentrations. This increase could be attributed to field aided diffusion (15) and/or by diffusion induced lattice defects. These variations in the diffusion constant with B concentration belie a strict adherence to the complementary error function distribution; however, in order to compare these data easily with others an error function distribution has been assumed

$$1 - \text{erf}\frac{X_j}{2\sqrt{D_2 t}} = \frac{C_B}{C_s} \qquad [1]$$

where C_B and C_s are the bulk concentration of n-type dopant and B surface concentration, respectively. This reduction of the data shown in Fig. 5 is given in Table III and Fig. 6 where the diffusion constant of B in Si, D_2, is plotted *vs.* the surface concentration obtained from Irvin's curves. These data agree well with the data of Barry and Olofsen for surface concentrations between 10^{19} and 10^{20}/cc. However, the data of Barry and Olofsen do not go beyond surface concentrations of 10^{20}/cc.

As pointed out previously, observed junction depths drop just as the solid solubility limit is reached.[15] This phenomenon is observed in the data presented in Tables II and III and Fig. 5. This in turn can be translated into a noticeable decrease in the diffusion constant as shown in Fig. 6. This decrease has not been observed previously by other workers. However, the data presented here extended to higher surface concentrations, and the experiments were done with the (100) Si surface orientation, in most cases on Si surfaces that had been stressed by thermal oxide growth previous to the deposition of the doped glass.[16]

It is not clear what this sudden decrease in the apparent diffusivity of B in Si at these very high concentrations indicates. It would be instructive to study the variation in the B diffusion profile on both sides of the peak to see if there is any noticeable change in the diffusion mechanism. For instance, the attainment of solid solubility might inhibit the substitutional/interstitial double-stream mechanism suggested by Rupprecht and Schwuttke (16). Another related speculation has to do with the character of these glass diffusion sources. During diffusion the deposited glasses could place considerable stress on the Si due to differences in thermal expansion. This stress could produce dislocations within the Si. In this regard, it is interesting to note that these glass sources begin to soften and show signs of liquification just as the solid solubility limit is reached. This point will be examined further when we examine B diffusion through SiO_2 films.

B Penetration of SiO_2 Layers

Covering undoped oxides with layers of B glass of known composition enables one to study carefully the B diffusion mechanisms through SiO_2 films. The diffusion data on the right side of Table II for these situations indicate that thin layers of SiO_2 mask the diffusion of B for the diffusion conditions stated if the glass composition does not exceed 18% B_2O_3. At higher B_2O_3 concentrations the masking ability of the SiO_2 is suddenly destroyed, and for these conditions it makes very little difference whether or not the oxide layer is there, since the junction depths and surface concentrations are nearly identical for diffusions with and without this layer. The reason for this is very likely that

[14] $\rho_s x_j$ is the parameter normally used to get surface concentrations, i.e., from Irvin's curves (12).

[15] The accuracy of the junction depth determinations at the 1-4μ level are $\leq \pm$ 10% using the $\pm$ 1000Å estimated accuracy of the angle lapping and staining technique. It is more difficult to estimate the over-all accuracy of the whole diffusion system. However, some estimate of this is found in the reproducibility of the phenomenon shown in Fig. 5 which summarizes all the data taken for different runs for various lengths of times.

[16] G. N. Willis, (*Solid State Electronics*, 12, 133), has reported a strong increase in the diffusivity of B for (100) oriented Si when diffusing in oxidizing conditions. Furthermore, dislocation generation occurs when Si wafers are thermally oxidized; see *e.g.* G. Onodera and P. Walker, *Physics of Failure in Electronics*, 5, 444 (1967).

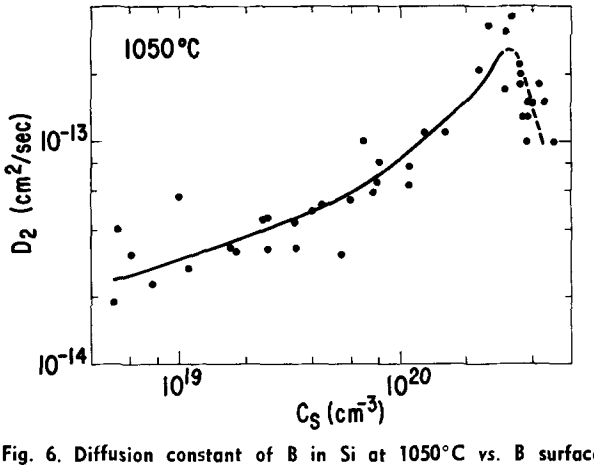

Fig. 6. Diffusion constant of B in Si at 1050°C *vs.* B surface concentration assuming complementary error function distributions.

at the higher concentrations of boron the doped glass rapidly dissolves or "melts through" the underlying oxide at high temperatures and brings B through to the Si surface with very little time delay. Similar observations were made by Horiuchi and Yamaguchi (17) who used a B_2O_3 vapor diffusion source, and found that for low B_2O_3 vapor pressures the migration of the B carrying species through the oxide can be characterized as a solid-state diffusion process but at higher pressures the underlying barrier oxide was transformed into a glassy compound by "glassy liquification."

It should be emphasized that the phase diagram for this system (18) shown in Fig. 7 is a phase equilibrium diagram in which the liquidus phase boundary divides the stable glass region (liquid) from the crystalline forms of quartz plus glasses. However, in our experiments, the substances are formed in the glassy amorphous state at low temperatures from gases, heated to diffusion temperatures and cooled. The samples, therefore, never experience the extended heating (days, weeks, months) required to attain the equilibrium state dictated by the phase diagram below the liquidus (18, 19). Above the liquidus these glasses are of course in full equilibrium. The viscosity of the glasses should have a curve similar to that exhibited by the phase equilibrium liquidus since additions of B_2O_3 lower the melting point as well as lowering the viscosity. Riebling's data at 1300°C show a very rapid decrease is viscosity with increasing B_2O_3 content for glasses containing between 0 and 55% SiO_2 (23). Decreases in viscosity reflect an increase in glass dissolution rates. A meaningful parameter for the description of interdiffusion of glasses would therefore be the viscosity; however, since the viscosity to our knowledge has not been explored for glasses containing 0-30% B_2O_3 and for lack of better words, we distinguish the two distinct regions of slow and rapid diffusion as "solid-state" or "high viscosity" diffusions and as "melt through" diffusions respectively.

In order to delineate these two distinct regions (solid-state diffusion and glassy liquification) two distinct sets of experiments were carried out: (*i*)

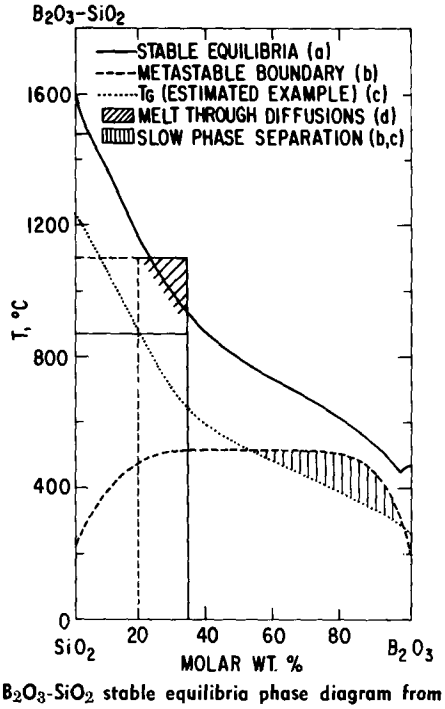

Fig. 7. B_2O_3-SiO_2 stable equilibria phase diagram from ref. (18), (a). Superimposed on this is the subliquidus miscibility gap discussed in ref. (19), (b). Included is an estimated example of the glass transition temperature curve, (c), using the information from ref. (20-22). The "melt through oxide" diffusions examined in this work (d), and the predicted region for phase separation as dictated by (b) and (c) are also shown.

Table IV. B_2O_3/SiO_2 diffusion at 1050° and 1100°C using 18% mol. % B_2O_3 glass

T, °C	t, hr	$D_2/10^{-13}$ cm²/sec	x_{of}, Å	$r^2/10^{-4}$	$D_1/10^{-17}$, cm²/sec
1050	15	1.4 ± 0.6	770	0.76	1.1
1100	8	4.0 ± 1	950	0.8	3.4

solid-state diffusions with glass sources made using a 50 cc/min B_2H_6 flow rate (~18% B_2O_3) and "melt through" diffusions using a glass source formed by using a 75 cc/min B_2H_6 flow rate (~30% B_2O_3).

Solid or high viscosity state diffusion through SiO_2 *films.*—The two boundary diffusion mode of Sah *et al.* (24) which results in a series expansion of erf terms, gives for the concentration of dopant in the Si, C_2

$$C_2(x,t) = m(1-\alpha)\, C_0 \sum_{n=0}^{\infty} \alpha^n \operatorname{erfc} \frac{(2n+1)x_o + rx}{2\sqrt{D_1 t}} \quad [2]$$

where C_0 is the concentration of dopant in the diffusion source layer; m is the segregation constant of diffusant at the Si-SiO_2 interface; $r = \sqrt{D_1/D_2}$ in which D_1 and D_2 are the diffusion constants of the dopant within the oxide and Si, respectively, and $\alpha = (m-r)/(m+r)$. This equation can be approximated by the first term of the series in the nearly masking condition for which x_o, the oxide thickness, is greater than rx_j and $x_o/2\sqrt{D_1 t} > 0.7$. The relation between the oxide thickness and the junction depth x_j then becomes

$$\frac{x_o + rx_j}{2\sqrt{D_1 t}} = \arg\left[\operatorname{erfc} \frac{C_3}{m(1-\alpha)C_0}\right] \quad [3]$$

where $C_3 = C_2(x_j,t)$. Since for a given diffusion condition the right-hand side of Eq. [3] is constant, one can plot x_j for a range of x_o for a constant diffusion time and temperature to obtain r. The extrapolation of this plot to $x_j = 0$ gives the mask failure condition, $x_o(x_j = 0) = x_{of}$ and by Eq. [3], $x_o + rx_j = x_{of}$.

The results of these experiments, Fig. 8, and the determination of D_1 at 1050° and 1100°C using the D_2 values of Fig. 6 and Table III are presented in Fig. 9 and Table IV. Figure 9 compares these points with the higher temperature extension of the D_1 *vs.* (T^{-1}) line of Horiuchi and Yamaguchi (17).

Melt through B *permeation of* SiO_2 *films.*—As pointed out previously there is a sudden appearance of B in the Si covered with thermal oxides if the doped glass layer contains about 30% B_2O_3. This implies a liquification and dissolution of the oxide layer by the doped glass. This phenomena was studied in more detail by covering a series of oxide layers with 3000Å of 30%

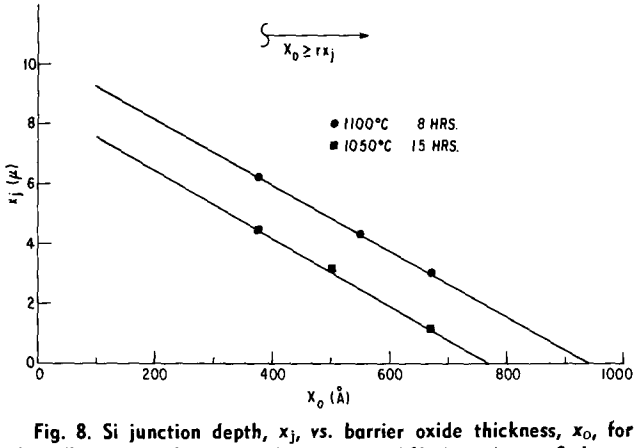

Fig. 8. Si junction depth, x_j, *vs.* barrier oxide thickness, x_o, for "solid" state diffusions with constant diffusion times; 8 hr at 1100°C and 15 hr at 1050°C. Doped glass source is 18% B_2O_3.

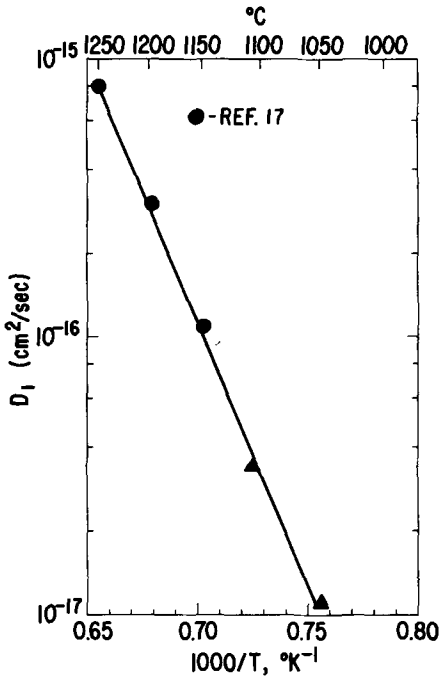

Fig. 9. "Solid" state diffusion coefficient of the B carrying species in amorphous thermal SiO_2 vs. 1000/T, °K^{-1}.

B_2O_3 glass and diffusing these series at 1000°, 1050°, and 1100°C. The junction depth and surface concentration data are summarized in Fig. 10. It can be contrasted to the data of Fig. 8. Several aspects of Fig. 10 are worth noting. For instance, this method greatly decreases the times required to obtain any given junction depth. In fact, for thin oxides this method of diffusion results in very little diminution of the junction depths and surface concentrations obtained for these same temperatures and times compared to those cases when the doped glass is placed directly on Si. The surface concentration obtained after heating is maintained close to the solubility limits by the glass source for a considerable range of underlying oxide thicknesses. For example, at 1100°C, the surface concentration is 3 x 10^{20}/cc for x_o = 1250Å even though the junction depth has been diminished to 1.8μ as compared to 4μ for the very thin oxide layers. This is because the 3000Å 30% B_2O_3 glass dopant source contains enough B_2O_3 to convert the underlying oxide as well as provide enough B to heavily dope the Si. The surface concentrations decrease rapidly by many orders of magnitude as the masking condition is approached. Masking oxides are indicated by the intercept of the curves with the abscissa for the conditions stated.

The mode in which the masking condition is approached is interesting to consider. The "liquid glass" as it "melts through" the underlying SiO_2 is being diluted by additions of SiO_2 and becomes more viscous.

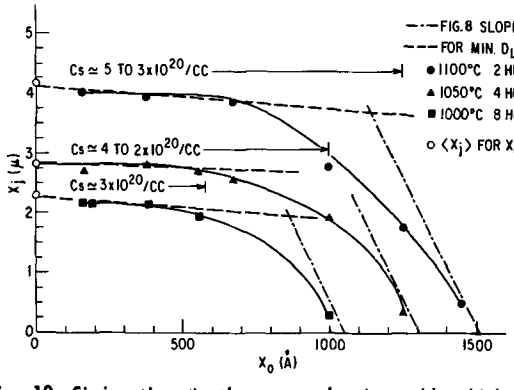

Fig. 10. Si junction depth, x_j, vs. barrier oxide thickness, x_o, for "melt through" diffusions. Doped glass is 3000Å of 30% B_2O_3.

When the concentration drops below that required to maintain a liquid or low viscosity condition, the front comes to a stop, and the diffusion of B impurities is governed by the "solid" state diffusivities of Fig 9. Thus the curves in Fig. 10 are seen to approach asymptotically the slopes given by Fig. 8, as shown. This self-limiting feature can be used to advantage. For instance, lateral diffusion of the dopant in the SiO_2 under the edges of a self-registered MOSFET gate electrode will be automatically inhibited by these glass characteristics.

A lower limit for the liquid or low viscosity diffusion constants of B_2O_3 in SiO_2 can be estimated using the dashed lines in Fig. 10 and Eq. [3]. These estimates for temperatures of 1000°C $\leq T \leq$ 1100°C give diffusion constants of 2 x 10^{-15} cm²/sec $\leq D_1(L) \geq$ 2 x 10^{-14} cm²/sec which are many orders of magnitude higher than the corresponding solid state diffusion constants of Fig. 9 ($\leq$4 x 10^{-17} cm²/sec).

Figure 10 shows that for temperatures $\geq$1050°C, rapid "melt through" diffusion of thin oxides ($\leq$1000Å) can be attained with a 30% B_2O_3 doped glass diffusion source. In turn the resultant glass at the glass-Si interface can supply enough B atoms to the Si to approach B solid solubility. Yet it is interesting to note that the resultant dilution of the 30% glass appears to prevent any noticeable formation of the B-rich Si phase. Visual observations on surfaces of samples with high surface concentrations showed that the side of the wafer that was covered by the thermal oxide was characteristically hydrophobic while the other side was hydrophillic and showed a brownish stain characteristic of the B-rich silicon phase. However, both sides of the wafer had nearly identical sheet conductivities characteristic of surface concentrations close to B solid solubility.

Summary

Glass film diffusion sources were examined from a broad perspective. Their properties as glasses were found to conform with observed diffusion phenomena in Si and SiO_2. An operational point of view was also maintained, because these films are thought to offer methods of fabricating self-registered MOSFETs and integrated circuits in general.

The growth and etch rates and diffusion properties of B_2O_3-SiO_2 glass films formed by the low-temperature oxidation of SiH_4 and B_2H_6, with O_2 were determined. The growth rates, for the conditions stated, ranged between 200 and 800 Å/min and yielded diffusion source glass films which made it possible to obtain B concentrations up to and including solid solubility in the Si surface at diffusion temperatures between 1000° and 1100°C. These films have good physical characteristics in this "solid solubility region." They show no evidence of being hygroscopic and measurement of the glass composition indicates that solid solubility is attained when the glass contains about 20 molar weight per cent B_2O_3. In addition, the B_2O_3-SiO_2 phase diagram indicates that no phase separation should occur for glasses containing less than 40% B_2O_3. "Melt through SiO_2 diffusions" were observed to occur at 30% B_2O_3, and this agrees at least qualitatively with expected decreases in glass viscosity. Unfortunately, the etch rates of the glasses in this region are rather low when buffered HF is used and this will limit the film thicknesses to about 3000Å for ordinary photoresist patterning. However, etches which etch B_2O_3-SiO_2 glasses at rates which increase with the molar per cent B_2O_3 have been developed by others (11, 25, 26) and might be used to advantage.

The diffusivity of B in Si and thermal SiO_2 films was carefully examined. The diffusion of high concentrations of B in Si at 1000°-1100°C exhibits a diffusivity that increases with concentration until the solid solubility limit is reached, whereupon it drops to a smaller level. This sudden decrease was found to correspond with the glass melt through condition, and possible mechanisms for this were discussed.

The diffusion of the boron carrying species in SiO_2 was examined in the region of "solid" state diffusion at 1050° and 1100°C and the diffusion constants, 1.1 and 3.4 x 10^{-17} cm^2/sec, respectively, were found to agree well with the previous higher temperature data of Horinchi and Yamaguchi (17).

The melt through condition for the dissolution of the underlying undoped SiO_2 film was established and examined for a range of temperatures and SiO_2 thicknesses.

The importance of using the melt through condition for diffusions appears to be that: (*i*) the time required to diffuse through thin undoped oxides is greatly reduced, which in turn makes the diffusion properties of B in Si the controlling factor in determining junction depth; and (*ii*) it is expected that the strain on the underlying Si and diffusion barrier films is greatly reduced. For instance, borosilicate glasses containing about 30 molar per cent B_2O_3 have linear thermal expansion coefficients close to that of Si and Mo (27).

The general applicability of these glass film diffusion sources for the fabrication of self-registered refractory metal MOSFETs will be examined in a subsequent article.

Acknowledgments

All the experimental work including the construction of the reactor, glass depositions, diffusions and experimental work was done by G. J. Charney. Oxide thicknesses were measured ellipsometrically by J. R. M. Viertl and by MOS capacitance methods by G. R. Zempel. The flame spectrometer was operated by R. F. Reihl. The authors gratefully acknowledge the discussions with R. J. Charles and J. Wong on B_2O_3-SiO_2 glass phase diagrams. The infrared absorbance information is due to E. A. Taft. Comments by W. E. Engeler, E. A. Taft, and R. N. Hall were extremely helpful.

Liquid Encapsulated Czochralski Growth of GaAs

M. E. Weiner,* D. T. Lassota, and B. Schwartz*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Melt growth of gallium arsenide single crystals by the Czochralski technique has required rather complex equipment because of the high vapor pressure of arsenic. A recently developed technique known as liquid encapsulated growth overcomes a number of the problems involved and allows gallium arsenide to be grown in a commercial silicon crystal puller. Crystals about 1 in. in diameter weighing 80g have been grown nearly routinely. One crystal with a maximum diameter of 2¼ in. weighing 370g was grown, but it appears to be highly strained. Undoped crystals grown in quartz or alumina crucibles have as-grown resistivities greater than 10^5 ohm-cm. On heat treatment at 800°C for 24 hr, the crystals grown in quartz convert to n-type with carrier concentrations in the range 10^{15} cm^{-3} to 10^{16} cm^{-3} and room temperature mobilities from 5400 cm^2/V-sec to 6300 cm^2/V-sec. The crystals grown in alumina retain high resistivity after heat treatment. The heat treatment behavior is explained by a model based on the incorporation of SiO molecules in the crystals grown in quartz and the breakup of these molecules into silicon atoms and SiO_2 molecules on heat-treatment.

The major problems in the melt growth of the III-V compounds GaP, GaAs, InP, and InAs are associated with the high vapor pressures of phosphorus and arsenic at their respective melting points. In order to keep the melt near stoichiometry, one must either control the vapor pressure of the volatile element or somehow prevent it from leaving the melt. In order to control the vapor pressure, one must have an excess of elemental phosphorus or arsenic at the coldest point in the system. For these compounds, this temperature is in the range 550°-700°C. Clearly, Czochralski growth of these compounds, with its requirement for high temperature gas-tight seals, presents severe technological problems if one must control the vapor pressure of the volatile element. A variety of techniques has been developed for Czochralski growth with vapor pressure control (1). These have been used successfully for GaAs and InAs, where the arsenic vapor pressures are 0.9 and 0.3 atm, respectively (1). However, the vapor pressures of phosphorus over GaP and InP are much higher, making melt growth by these techniques nearly impossible. In order to avoid the problems related to vapor pressure control, the liquid encapsulation technique was developed (2-4). This technique involves covering the melt with a suitable liquid and filling the remaining volume of the system with an inert gas above the vapor pressure of the volatile element. The volatile element is then trapped below the liquid (except for diffusion through it). The term "liquid encapsulation" arises from the idea that the ideal liquid would tend to "encapsulate" both the melt and the growing crystal, thus protecting both from loss of the volatile element and from reaction with the crucible. Since an inert gas is used to balance the vapor pressure of the volatile element, the walls of the crystal puller can be at room temperature. This clearly makes the problem of the gas-tight seals much simpler to overcome. In the case of InAs and GaAs, the pressures are low enough to allow the use of the same type of crystal puller designed for nonvolatile materials. Because the melting point of GaAs is not too far from the melting point of silicon [1238° *vs.* 1415°C (5)], it was decided to try to grow GaAs in a commercial silicon crystal puller. Although this article deals specifically with the problems of liquid encapsulated growths of GaAs, much of it is relevant to the growth of the other compounds mentioned above.

The Encapsulating Liquid

The ideal encapsulating liquid should have the following properties:

1. It should be less dense than the melt.
2. It should not react with the melt.
3. It should wet but not react with both the crucible and the growing crystal.
4. It should be immiscible with the melt.
5. It should be transparent.
6. It should melt well below and have a low vapor pressure at the melting point of gallium arsenide.
7. It should be available in a high-purity grade.

The encapsulant that has been most widely used in the liquid encapsulated growth of gallium arsenide is boric oxide (2-4); it is the only encapsulant used in the experiments described in this article. Boric oxide meets condition 1 very well ($\rho_{B_2O_3}$ = 1.8 g/cm^3 *vs.* ρ_{GaAs} = 5.3 g/cm^3). Condition 2 is met for undoped melts in that there is no reaction severe enough to prevent growth of a single crystal. However, the presence of a significant amount of gallium in the boric oxide after growth (see Table I) does indicate that a reaction of some kind has taken place. Because boric oxide is known to be very hygroscopic, and also because there is a very low concentration of boron in the gallium arsenide after growth (see Table II), it is believed that the presence of the gallium in the boric oxide is related to the presence of water of hydration rather than to a direct reaction with the boric oxide itself (see section on Analysis of Data). However, one

would expect the boric oxide to react with melts doped with strong reducing agents, such as silicon (4). Condition 3 is only partly met for quartz or alumina crucibles in that silicon or aluminum is detected in the boric oxide in significant amounts after growth (see Table III). This presents no obvious problems during the actual growth operation, but clearly the electrical properties of the grown crystals are affected (see section on Electrical Properties of Undoped Crystals). The quartz crucibles are wetted very well by the liquid boric oxide, whereas the alumina crucibles are wetted only slightly. There appears to be no reaction between the boric oxide and the growing crystal, and the crystal will be wetted by the boric oxide if the surface is cool enough. Condition 4 is met very well in that the interface between the boric oxide and the gallium arsenide melt is sharply defined. Condition 5 is met well for undoped melts unless the top surface of the boric oxide becomes too cool; then some very fine particles may appear. This visibility problem is eliminated as soon as the surface temperature is raised. Other visibility problems are associated with the high index of refraction (about 1.5) of the boric oxide and the inherent difficulty in seeing an interface between two radiating materials at the same temperature. Condition 6 is met well, since boric oxide melts at about 450°C (nearly 800°C below the melting point of gallium arsenide) and has a vapor pressure of about 0.1 mm at the melting point of gallium arsenide [calculated from thermochemical data (6)]. Actually, boric oxide should not be used below 800°C (2) because it becomes too viscous, but this presents no problems in the growth of gallium arsenide. There is some evidence of evaporation of boric oxide during growth, but not nearly enough to cause a problem. Condition 7 appears to be met satisfactorily, although it is very difficult to determine the source of trace impurities. The boric oxide used in all these experiments was Optran Grade Fused Lumps of 99.995+% purity supplied by the Atomergic Chemetals Corporation. Boric oxide of a lower grade has been used successfully by others (3). The major undesirable component in boric oxide is water (the level of water is not included in the quoted total impurity content). Large amounts of water will lead to severe bubbling when the boric oxide is heated and can cause a loss of up to 50% of the boric oxide by bubbling over the side of the crucible. The effect of a small amount of water seems to be similar to the effect of a small amount of oxygen or Ga_2O on Bridgman crystals (7) (see section on Analysis of Data). Approximately 50g of boric oxide were used for each run.

In order to remove most of the water from the boric oxide, a high temperature bakeout under vacuum conditions was used. The platinum crucibles used for this operation showed no evidence of reaction with the boric oxide and were used repeatedly. Because a determination of the absolute amount of water in the boric oxide is difficult, it was decided to use a standard bakeout procedure to minimize differences caused by variations in the amount of water. The bakeout was done at 1000°C (see Fig. 1) under a starting pressure

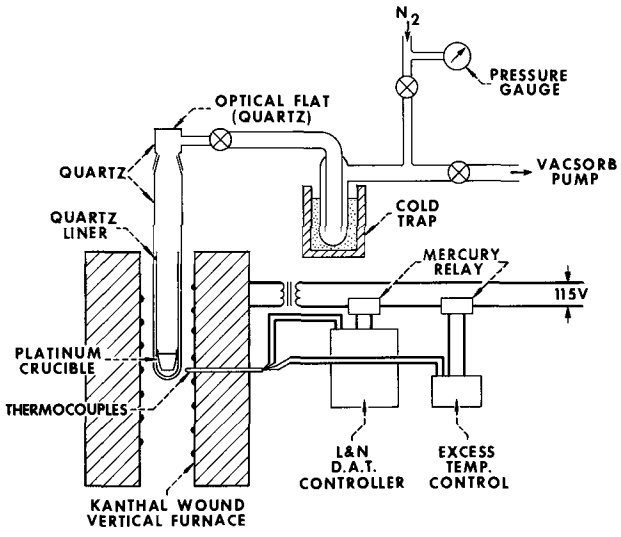

Fig. 1. System for vacuum drying of B_2O_3

of about 200 Torr of nitrogen, with a liquid nitrogen cold trap in the system. The pressure was gradually lowered while the degree of bubbling was observed through the optical flat. When the bakeout proceeded overnight, a dry ice-isopropyl alcohol trap was substituted for the liquid nitrogen trap in order to maintain the equilibrium vapor pressure of water at about 0.5μ. The entire procedure took approximately 24 hr, including 1-2 hr under a vacuum of about 10μ.

No simple way was found to remove the solid boric oxide from the platinum crucible after the bakeout procedure in order to transfer it to the crystal puller. It was decided, therefore, to position the platinum crucible containing the B_2O_3 upside down in the crystal puller and use the heat from the crystal puller to melt the boric oxide (see Fig. 2). Once the boric oxide melts, it pours over the gallium arsenide charge. This melting and pouring takes place with the gallium arsenide at about 700°C and the pressure in the crystal puller at 3-5 psig.

The Crystal Puller

The crystal puller used for all liquid encapsulated growths of gallium arsenide has been the NRC Equipment Corporation Model 2805 Czochralski furnace shown in Fig. 3. The glass rod passing through the viewing port on the right is used to manipulate the boric oxide container (see Fig. 2). The heater assembly used is that designed for NRC's smaller Model 2804 furnace. The only modifications necessary for growing

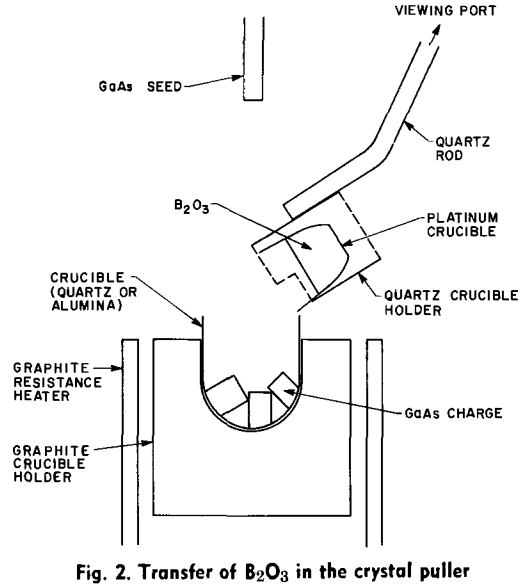

Fig. 2. Transfer of B_2O_3 in the crystal puller

Fig. 3. NRC Model 2805 crystal puller used for liquid encapsulated growth of GaAs.

gallium arsenide were the fabrication of a holder for the platinum crucible containing the boric oxide, and the use of a specially designed seed chuck. The furnace is heated by a graphite resistance heater which is powered by a saturable core reactor. The temperature sensing element is a L & N Rayotube, which is aimed at the bottom of the graphite crucible holder. The temperature may be controlled and programmed automatically via a L & N CAT controller, and the crucible and seed shaft may be rotated and translated at variable rates.

The graphite crucible holder was fabricated by the Ultra Carbon Corporation from grade UF-4S high purity graphite. It has close-fitting spacers available so that the crucible may be positioned at various heights in the holder. The quartz crucibles used in these experiments were fabricated by the Thermal American Fused Quartz Company from Vitreosil fused quartz. The alumina crucibles were supplied by the Coors Porcelain Company. They were grade AD-999 with a nominal purity of 99.98%. The holder for the platinum crucible containing the boric oxide (see Fig. 2) consists of a 9 mm quartz rod attached to a holder so designed that it supports the platinum crucible in an inverted position without itself coming into contact with the boric oxide during the pouring process. A coupling allows the rod to be moved so that the platinum crucible may be properly positioned for pouring the boric oxide and may be pulled out of the way during growth. The seed chuck consists of a molybdenum rod with a ⅛ in. hole drilled in it at its lower end. There is a stainless steel set screw positioned in the side of the rod about ½ in. above the bottom. The seed is supported by several strands of molybdenum wire which are wrapped around the seed and twisted above it. The twisted wire is inserted into a partly split molybdenum rod and held in place by the set screw. This method of supporting the seed is believed to have two main advantages over a more rigid technique. First, less vibration is transferred from the seed chuck to the seed, making it possible to take full advantage of damping by the highly viscous layer of boric oxide. Second, the seed is protected from breaking in case the melt suddenly freezes out to the crucible.

The Crystal Growth Operation

The crucible (quartz or alumina) is degreased, cleaned with aqua regia, rinsed with methanol and a 10% KCN solution, and positioned in the graphite crucible holder. Approximately 100g of polycrystalline gallium arsenide are degreased, etched with aqua regia, rinsed with methanol, and placed in the crucible. The graphite crucible holder is positioned with its top about ½ in. below the top of the heater. The seed is oriented in the <111> direction with the (111)A(Ga) face toward the melt. This arrangement has been shown to give a lower twinning probability than the (111)B(As) face (8). The platinum crucible containing the baked-out boric oxide is removed from the quartz vacuum chamber and positioned in the quartz holder just above the gallium arsenide source material (see Fig. 2). The crystal puller is then evacuated overnight. Before the heater is turned on, the crystal puller is flushed with argon or helium and pressurized to about 1 psig. Heating is started manually at a power level of about 3 kW. At this power level, the boric oxide starts to flow in 30-45 min. The gallium arsenide charge is at about 700°C by this time. After the boric oxide has finished flowing, the quartz holder is moved out of the way, the puller is pressurized to about 5½ psig, and the gallium arsenide is heated to its melting point. When the gallium arsenide starts to melt, one must proceed slowly and carefully, for once all the gallium arsenide is melted the temperature may rise rapidly, causing severe loss of arsenic as the arsenic vapor pressure rises above the inert gas pressure. Some arsenic is always lost during melting, as indicated by a coating on the viewing port. After the melt is stabilized at the growth temperature, very little arsenic is lost. Just prior to seeding, the graphite crucible holder is raised so that its top is level with the top of the heater. This allows a temperature gradient across the 1-1½ cm thick layer of boric oxide sufficient to minimize loss of arsenic from the grown crystal. Some difficulty is encountered in determining the point of contact between the seed and the melt and knowing when growth begins. With experience, however, these problems have gradually been solved. During growth, the seed is rotated at 23 rpm, the crucible is rotated at 7 rpm in the same direction, and the seed is pulled at 0.007 in./min. (Actually, pulling is started at a lower value and increased to this value after about ½ in. of growth.) The surface of the melt is always very clean during growth.

Control of the shape of the crystal is accomplished by varying either the crucible temperature or the rate of temperature change. The crucible is approximately 2 in. in diameter and 2 in. high, and the usual charge of gallium arsenide is 100g. The crystals grown are

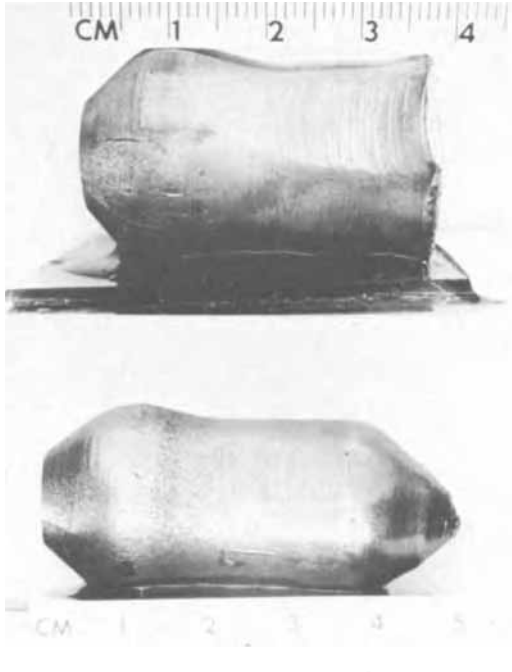

Fig. 4. Two typical liquid encapsulated GaAs crystals

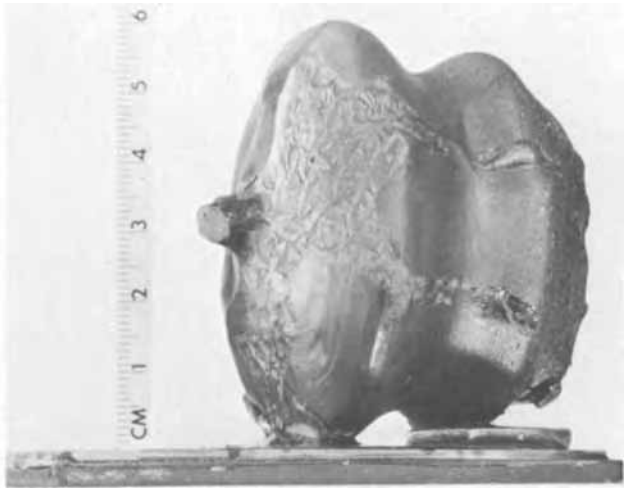

Fig. 5. Photograph of 2¼ in. diameter liquid encapsulated GaAs crystal.

generally ¾-1 in. in diameter and weigh about 80g. Photographs of two crystals of this size are shown in Fig. 4. One attempt was made to grow a crystal of larger diameter by using a larger crucible (3 in. in diameter) and a larger charge (460g). This crystal is shown in Fig. 5; it has a maximum diameter of 2¼ in. and weighs 370g. It is single, as indicated by symmetrical facets except near the end, where the charge was depleted and the crystal touched the crucible. From Fig. 5 it may be seen that the main problem in growing this crystal was temperature control. It appears that as the crystal diameter increased, diameter control became much more sensitive to temperature variations. The main growth problem was in "shouldering" the crystal. The problem of controlling the diameter of a crystal of this size can probably be solved by accumulating experience on temperature control and crucible configuration. A crack may be noticed in Fig. 6. Presumably it is due to strain resulting from too rapid cooling during growth; this problem could be overcome by the use of afterheaters. The "chipped" appearance of the surface was caused by B_2O_3 sticking to the crystal. This problem could be eliminated by varying thermal conditions to lower the viscosity of the B_2O_3. The surfaces of the crystals are usually shiny near the top and slightly etched near the bottom. This indicates that protection against loss of arsenic from the surface decreases as the level of the boric oxide drops. After the crystal is pulled out of the boric oxide and the furnace is cooled, the quartz crucibles generally shatter while the alumina crucibles either remain intact or show only one or two cracks. When a quartz crucible is used, the boric oxide is gray and opaque in appearance after growth, when an alumina crucible is used, the boric oxide is brownish and translucent. In either case, the boric oxide is full of bubbles generated during cooling. The platinum crucible which held the boric oxide is also slightly discolored, presumably because of the reaction of arsenic with the exposed platinum (9). The discoloration of the platinum disappears rapidly when the crucible is heated in air.

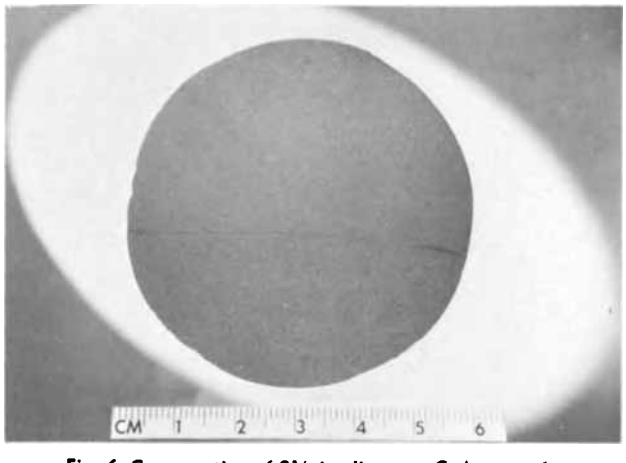

Fig. 6. Cross-section of 2¼ in. diameter GaAs crystal

Electrical Properties of Undoped Crystals

The properties of seven undoped crsytals are described in this article; four of these were grown in quartz and three in alumina. The source material for the four growths in quartz and for one of the growths in alumina was obtained from Bell and Howell Research Laboratories, and the source material for the other growths in alumina was obtained from the Monsanto Company. All seven crystals had resistivities greater than 10^5 ohm-cm as grown. A good value for the resistivities of the samples grown in quartz could not be obtained, apparently because of inhomogeneities in the material. Resistivity measurements on the samples grown in alumina were quite straightforward, with values from 2 x 10^7 to 6 x 10^7 ohm-cm. Slices cut from each of the seven crystals were heat treated in vacuum at 800°C for 24 hr. In order to avoid contamination of the gallium arsenide during heat treatment, Spectrosil fused quartz ampoules rinsed in a 10% KCN solution were used. The ampoules were evacuated with an ion pump to 10^{-6} Torr prior to sealing. After heat treatment, the slices from the crystals grown in quartz converted to n-type. The electron concentrations of the slices from the four crystals grown in quartz are shown in Fig. 7 and their Hall mobilities, in Fig. 8. The slices from the crystals grown in alumina showed no apparent change on heat treatment.

Analysis of Data

The conversion of semi-insulating gallium arsenide to n-type on heat treatment has been seen before by Woodall in Bridgman crystals grown in quartz with a small amount of Ga_2O_3 added to the melt (7). (He assumed that the Ga_2O_3 converts completely to Ga_2O by reacting with the melt.) It has been shown thermodynamically (10) that SiO vapor may be expected to form from the reaction of GaAs with quartz. Therefore, the major constituents of the environment above such Bridgman crystals are, in addition to arsenic vapor, Ga_2O and SiO. Since the effect of heat treatment on liquid encapsulated crystals of gallium arsenide grown in quartz is similar to that on these Bridgman crystals, some experiments and analyses were carried out to determine whether these same molecular species were present in the boric oxide. The boric oxide is assumed to be inert except for its role in determining the activities of the various molecular species. Comparisons between liquid encapsulated growth in quartz and the Bridgman growth described above will be qualitative in nature, since the heats of solution and the activities of the various molecular species in the boric oxide are not known.

The first analysis carried out was a quantitative analysis for gallium and silicon in the boric oxide. The results are shown in Table I. Note that there is a significant amount of gallium present in every case and a significant amount of silicon in every case except when an alumina crucible is used. Gallium and silicon are presumably dissolved in the boric oxide as oxides,[1] since one would not expect elemental gallium and silicon to be highly soluble. Although the temperature profile of the boric oxide during growth is not known, clearly the amounts of silicon observed must come from the gradual dissolution of the quartz crucible by the boric oxide. The lack of a large amount of boron in the gallium arsenide (Table II) and the fact that the amount of gallium in the boric oxide is independent of the crucible used (Table I) imply that residual water is responsible for the presence of gallium in the boric oxide. It has been shown by infrared measurements that it is difficult to reduce the water content of boric oxide below 0.05 w/o (weight per cent) by vacuum baking above 1000°C (12). Assuming the presence of 0.05 w/o water before growth and the complete conversion to an oxide after growth, the following possible amounts of gallium in the boric oxide are obtained

$$2Ga + H_2O \rightarrow Ga_2O + H_2 - 0.4 \text{ w/o Ga in } B_2O_3$$

$$2Ga + 3H_2O \rightarrow Ga_2O_3 + 3H_2 - 0.13 \text{ w/o Ga in } B_2O_3$$

The amounts observed (Table I) range from 0.12 to 0.22 w/o. Quantitative calculations of the amounts of each oxide cannot be made without determining the exact amount of H_2O before growth and the amount of any Ga_2O lost during growth. However, the values observed strongly imply that the gallium results from oxidation of the melt by water in the boric oxide.

In order to determine which oxides of silicon and gallium are present during growth, some further observations and experiments were necessary. First, as mentioned in the section on Crystal Growth Operation, the boric oxide is gray and opaque after growth in quartz and brown and translucent after growth in alumina. The gray, opaque color seems to be caused by a very fine metallic powder which forms in the boric oxide after growth during cooling. In either case, the boric oxide is full of bubbles which were generated on cooling. In order to explain both the gray color and the bubbling, the simple experiments shown in Table IV were performed. All the experiments were carried out in porcelain crucibles. The heat cycle consisted of 30 min at about 900°C in addition to the heating and cooling time. It should be noted that the presence of bubbles is correlated with the presence of gallium.

[1] It has been shown (11) that 70 w/o SiO_2 is soluble in B_2O_3 at 1000°C.

Table IV. Experiments to explain gray color and bubbling of boric oxide

	Sample	B_2O_3 after heat cycle
1.	5g Ga + 10g B_2O_3	Clear, full of bubbles generated on cooling.
2.	5g Ga + 10g B_2O_3 + 0.05g SiO_2	Gray, opaque near Ga, full of bubbles generated on cooling.
3.	5g Ga + 10g B_2O_3 + 0.5g SiO_2	Slight gray tint, full of bubbles generated on cooling.
4.	0.5g SiO_2 + 10g B_2O_3	Clear, no bubbles.

Since Ga_2O is the only vapor species associated with gallium, the bubbles must result from Ga_2O coming out of solution on cooling. The gray color is correlated with SiO_2. Furthermore, it is not proportional to the amount of SiO_2 and therefore it cannot be due to a complex silicate. The only other possibilities are

$$Ga_2O + SiO \rightarrow 2Ga + SiO_2$$

$$2SiO \rightarrow Si + SiO_2$$

with the gray color resulting from a very fine precipitate of gallium or silicon. In either case, the presence of SiO is indicated. Therefore, the boric oxide contains both Ga_2O and SiO, just as in the atmosphere over the melt in the Bridgman growth described above. A survey emission spectrographic analysis for all metallic impurities (Table III) shows (in addition to gallium and silicon) only the presence of several parts per million of calcium, magnesium, and aluminum except for the growth in alumina, in which case several tenths of a weight per cent of aluminum are present.

Since Ga_2O is always present in the boric oxide, it is expected that there will be oxygen incorporated in the grown gallium arsenide. Oxygen is known to cause deep level compensation and, therefore, high resistivity in gallium arsenide (7, 13, 14). In order to convert such compensated material to n-type with carrier concentrations in the range observed (see Fig. 7), one must either remove acceptors (shallow or deep) or add shallow donors such that the number of shallow donors exceeds the sum of all acceptors. Woodall (7) interpreted his results on the heat treatment of Bridgman crystals on the basis of a reduction in the number of acceptors as a result of the precipitation of an unidentified acceptor species. Since liquid encapsulated crystals grown in alumina do not show any conversion on heat treatment, the heat treatment behavior appears to be correlated with some form of silicon. Therefore, a model is proposed whereby N_D may be increased on heat treatment by means of a change in the oxygen coordination of silicon atoms. It should be noted that similar donor creation on heat treatment has been seen in silicon crystals containing oxygen (15).

The presence of SiO in the boric oxide must lead to the incorporation of some SiO in the grown crystal of gallium arsenide. Since melt-grown, silicon-doped gallium arsenide is always n-type, it is assumed that an SiO molecule is incorporated with the silicon atom on a gallium site and the oxygen atom on either an interstitial site or an arsenic site. It is known that SiO molecules in the vapor phase become less stable with respect to SiO_2 molecules as the temperature is lowered. Unfortunately, quantitative calculations of the concentrations of SiO and SiO_2 in gallium arsenide cannot be made without knowledge of their heats of solution. However, if one assumes that SiO molecules are quenched in during the rapid cooling of Czochralski crystals and broken up into SiO_2 molecules and silicon atoms on heat treatment by means of a short-range diffusion of oxygen atoms, then shallow donors are created. The gallium arsenide will be n-type if sufficient shallow donors are created such that the number of shallow donors exceeds the sum of all acceptors. The donor level observed (see Fig. 7) is about 0.003 eV or approximately the level expected for a shallow donor in gallium arsenide. This model may also explain the inhomogeneities in the electrical prop-

erties of the gallium arsenide grown in quartz (see section on Electrical Properties of Undoped Crystals). Since there is a strong radial variation in the thermal history of Czochralski crystals, one may expect partial heat-treatment effects in various regions of the crystal. The crystals grown in alumina remain semi-insulating on heat treatment because no shallow donors are created and the deep level compensation is not overcome. Since the crystals are not affected by heat treatment, no inhomogeneities in electrical properties result because of variations in thermal history. Resistivities can therefore be measured more accurately.

Conclusions

The liquid encapsulation process is capable of producing undoped gallium arsenide with electrical properties comparable to those of gallium arsenide prepared by other bulk-growth methods. Equipment problems are thereby greatly reduced and commercially available silicon crystal pullers can now be used. With more study of thermal conditions, growth of crystals over 2 in. in diameter is apparently possible. As suggested by Woodall (7) for his Bridgman crystals, heat treatment of undoped liquid encapsulated crystals grown in quartz may be a good way to obtain bulk gallium arsenide with electron concentrations in the 10^{15} cm^{-3} to 10^{16} cm^{-3} range, should such a need arise. In addition, oxygen-doped semi-insulating gallium arsenide may be grown routinely by using alumina crucibles.

It is evident that the liquid encapsulation process does not isolate gallium arsenide from quartz crucibles. The latter should not be used if silicon contamination is undesirable.

The residual water in the boric oxide after ordinary vacuum baking clearly affects the electrical properties of liquid encapsulated gallium arsenide because it leads to the incorporation of oxygen. In order to reduce the amount of water in the boric oxide, a drying technique more effective than vacuum baking must be developed.

Acknowledgments

The authors would like to thank F. Ermanis for measurements on high resistivity material and helpful discussions, C. J. Hwang for help in the heat treatments, D. Malm for the spark source mass spectrographic analysis of GaAs, D. Nash for the analysis of the B_2O_3 after growth, and A. S. Jordan for helpful discussions.

Properties of GaP Single Crystals Grown by Liquid Encapsulated Pulling

S. F. Nygren, C. M. Ringel, and H. W. Verleur

Bell Telephone Laboratories, Inc., Reading, Pennsylvania 19604

ABSTRACT

Because it allows the production of substantial quantities of large area, uniformly shaped substrates of GaP, the Liquid Encapsulated Czochralski technique is a major advance in GaP technology. Successful growth of single-crystal ingots requires maintenance of visibility of the growth interface. This is accomplished by baking out the B_2O_3 encapsulant before use, tightly packing the polycrystalline GaP charge into the bottom of the crucible before growth, locating the center of heat at the bottom of the crucible, and keeping the B_2O_3 relatively hot during growth. The resulting ingots have uniformly high Hall mobilities, generally being at least as high as those reported for GaP grown by other techniques. The central regions of the ingots have dislocation densities $\leq 1 \times 10^5$ cm^{-2}. Effective distribution coefficients for S, Se, Te, and Zn have been found to be 0.23 ± 0.08, 0.16 ± 0.05, 0.012 ± 0.003, and 0.096 ± 0.05, respectively.

The liquid encapsulation of a volatile melt to allow Czochralski-type crystal growth was first introduced by Metz *et al.* (1). This method was applied to the growth of GaAs and InAs single crystals by Mullin *et al.* (2); and Bass and Oliver (3) were the first to grow GaP by this technique. Gallium phosphide has a dissociation pressure of approximately 32 atm of phosphorus at its melting point, 1470°C. Without the presence of a liquid encapsulant, a phosphorus pressure in excess of 32 atm would have to be maintained

Key words: gallium phosphide, crystal growth, crystal defects, distribution coefficients.

over the melt to prevent the GaP from boiling. This would require that the walls of the crystal growth chamber be held at approximately 700°C. With a liquid encapsulant that has little interaction with the GaP, an inert gas may be used to maintain a pressure over the encapsulant which is high enough to prevent formation of phosphorus bubbles in the GaP melt. The chamber walls then no longer need to be held at a high temperature, and equipment design is considerably simplified.

Since 1969, crystal pullers suitable for high-pressure Liquid Encapsulated Czochralski (LEC) crystal growth have become commercially available. Their advent allowed, for the first time, the convenient preparation of single-crystal ingots of GaP. From such ingots many large area, uniformly shaped substrates could be prepared, all in a time short compared to the preparation of equivalent substrates by solution growth or vapor transport. As a result, the production of GaP electroluminescent devices has become economically attractive. Gallium phosphide red-emitting diodes have been fabricated on n-type LEC crystal substrates both by single liquid phase epitaxial growth of a p-type layer and by double epitaxial growth of an n-type layer and then a p-type layer. Quantum efficiencies of 1 and 4.5%, respectively, for these two types of structures have been obtained (4, 5). While these efficiencies are below those obtainable using solution-grown substrates (6 and 7%) (4), they establish the potential utility of LEC crystals in the fabrication of efficient electroluminescent diodes.

In the following section of this paper are discussed some of the growth conditions which have been found helpful in establishing a routine, high yield program of growing LEC GaP ingots. The techniques described were evolved during the growth of approximately 100 single-crystal ingots in a high-pressure puller similar to the one described by Mullin *et al.* (2).

The lower efficiencies of GaP electroluminescent diodes thus far obtained by using LEC crystal substrates instead of solution-grown substrates suggests the possibility of basic differences between LEC and solution-grown GaP crystals. The remaining portions of this paper discuss various properties of LEC GaP ingots, relating them to crystal growth parameters and comparing them to the properties of GaP grown by other techniques. In the section on Defect Structure of LEC GaP Ingots, the strain and the dislocation densities which are found in LEC GaP ingots are examined. The section on Controlled Incorporation of Impurities discusses the controlled incorporation of impurities into LEC crystals and presents the distribution coefficients of S, Se, Te, and Zn in GaP at its melting point. Some electrical properties of LEC GaP ingots are the subject of the section on Electrical Properties.

Crystal Growth

A schematic diagram of the LEC crystal growing apparatus is shown in Fig. 1. The GaP charge is totally encapsulated by a layer of B_2O_3,[1] and the encapsulated charge is supported by a vitreous silica crucible. The crucible, in turn, is supported by a carbon susceptor which is surrounded by a silica convection shroud. Heating is by rf coupling into the carbon susceptor. An overpressure of an inert gas (N_2) is contained by a stainless steel jacket.

The primary problem encountered during the growth of a single-crystal ingot from a liquid encapsulated volatile melt arises when some of the melt material mixes with or interacts with the encapsulant. This, in the case of GaP and B_2O_3, results in clouding of the encapsulant, causing loss of visibility of the growth interface and resulting in loss of control over the shape of the ingot. In addition, melt particles

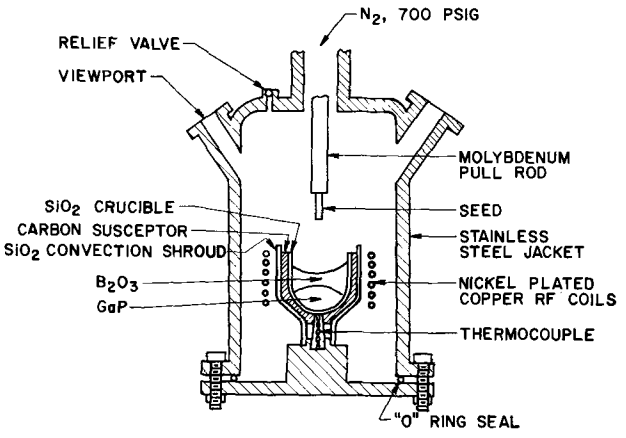

Fig. 1. Schematic diagram of the high pressure crystal puller

suspended in the encapsulant can affect the crystal perfection and even cause polycrystalline growth. To minimize these problems, the gas pressure above the encapsulant and the temperature gradient across the melt and encapsulant must be properly maintained. Also, the GaP charge and B_2O_3 encapsulant must be properly prepared.

Pressure.—The inert gas pressure which is maintained over the encapsulant must exceed the dissociation pressure of GaP at its melting point. An upper limit to this pressure may be obtained by lowering the ambient pressure inside the crystal puller during crystal growth until the melt begins to bubble. Such bubbling was observed at 32.3 atm. This pressure is not necessarily the true phosphorus pressure of GaP at its melting point since the temperature at the crucible walls may be higher than the temperature at the center of the crucible where growth is taking place. In order to protect against accidental overheating and subsequent volatilization during the melt-down period, crystal growth is routinely carried out at a pressure of about 48 atm.

Temperature gradient.—The temperature drop across the B_2O_3 must be chosen carefully. On one hand, a sharp temperature drop is desirable to insure at least initial visibility by minimizing decomposition of the seed when it enters the encapsulant. Since B_2O_3 is an insulator, a steep temperature gradient can easily be created by spacing the rf coils so that the center of heat is near the bottom of the crucible. Nielson and Von Neida (6) have measured the temperature drop across a 1 cm thick layer of B_2O_3 above a GaP melt to be about 240°C under growth conditions.

On the other hand, during the course of crystal growth, gallium and phosphorus from the melt and from the growing ingot contaminate the B_2O_3 and cause an eventual decrease in transparency. This problem can be reduced if the B_2O_3 is kept warm enough so that at least some contaminants can diffuse through the B_2O_3 and vaporize from it. The temperature gradient finally chosen is a compromise between these two desired conditions.

GaP *charge.*—The most desirable form for the starting material would be a solid chunk of polycrystalline GaP which is shaped to fit the lower portion of the crucible. However, this is not essential. In this study the starting material was polycrystalline GaP which had been prepared by dissolving phosphorus obtained from PH_3 into gallium which is held at an elevated temperature.[2] This material has very high purity, but it is porous and irregularly shaped. It is dried and crushed before use. The resulting small chunks and powder can be tightly packed into the crucible, leaving a minimum of voids and presenting a flat in-

[1] Johnson Matthey, High Purity.

[2] Monsanto, Polycrystalline Porous Chunk GaP.

terface to the B_2O_3. This will minimize penetration of the B_2O_3 into voids in the unmelted charge, preventing the GaP particles from being brought up into the encapsulant during melt down.

When the melt is to be doped, the particles of dopant are embedded in the GaP charge. The heating schedule is begun after the system is pressurized; and by the time the temperature reaches 800° or 900°C, the B_2O_3 has melted and has encapsulated the charge. It is hoped that this procedure prevents the loss of significant quantities of dopant from the charge by evaporation.

Encapsulant.—The presence of water in the B_2O_3 will cause bubbling when it is heated. These bubbles bring up particles from the GaP charge, clouding the B_2O_3 and causing loss of visibility. However, all that is necessary to remove most of the water from the B_2O_3 and thus prevent initial clouding of the encapsulant is to bake it out for 24 hr at about 900°C under partial vacuum (<0.1 atm).

To establish the proper temperature drop across the B_2O_3 layer, its thickness should be at least 1 cm when the rf coil geometry described above is used with a crucible that is 4.6 cm in diameter. If the layer is thinner, the B_2O_3 will be too hot to prevent decomposition of the seed and ingot during growth, and the decomposition products will cloud the B_2O_3 layer. A layer thicker than 2 cm inhibits crystal growth. This is probably due to the insulating property of B_2O_3 which prevents adequate heat dissipation to sustain crystal growth. When the proper B_2O_3 thickness is used, care must still be taken during crystal growth. As the large diameter portion of the ingot emerges from the B_2O_3, additional convection and radiation from the ingot will occur. At this time either the pull rate or the rf power must be increased in order to prevent a sudden increase in ingot diameter.

While the precautions discussed in this section will prevent initial and drastic clouding of the encapsulant, a gradual decrease in transparency of the B_2O_3 will take place during a run. This appears to be due to transport into the B_2O_3 of material produced by decomposition of the melt and by reaction of the GaP with H_2O, SiO_2, and B_2O_3. At the end of a run, the B_2O_3 has become colored. There is a greenish layer near the bottom and walls of the crucible, and a yellow layer near the top surface of the B_2O_3. The greenish region contains more gallium and phosphorus than the yellow region. The total amount of phosphorus in the B_2O_3 is considerably less than the total amount of gallium, indicating the loss of phosphorus from the B_2O_3. Weiner (7) has suggested a water vapor and SiO_2 reaction to account for the clouding of B_2O_3 in LEC growth of GaAs. For the growth of GaP, the dissociation process must also be considered.

Defect Structure of LEC GaP Ingots

Defects in grown crystals may arise in two ways. They may be propagated into the crystal from the seed, or they may be generated by forces exerted on the crystal as it solidifies and cools. Conventional techniques for minimizing defect densities in Czochralski-grown crystals include starting with a clean, dislocation-free seed (or, equivalently, growing a long, thin neck which becomes dislocation free before the main part of the ingot is begun), keeping the melt scrupulously clean in order to minimize spurious nucleation, and using a thermal geometry which minimizes the radial temperature gradient in the grown portion of the ingot. In Liquid Encapsulated Czochralski growth of GaP the same techniques are used, but problems in two areas are more severe than with conventional Czochralski growth. First, as has been mentioned, the encapsulant becomes increasingly cloudy as growth progresses, so that the probability of spurious nucleation by suspended matter becomes increasingly greater. This seems unavoidable. Second, the high pressure inside the crystal puller greatly increases the removal of heat from the periphery of the grown ingot by convection, thereby increasing the difficulty of reducing the radial temperature gradient in the growing crystal above the encapsulant.

To study the effects of various growth parameters on crystal perfection, approximately 50 <111> oriented single crystal LEC GaP ingots were chosen for examination. All of these ingots were grown from 60g charges of GaP, and generally all of each melt was used. The median value for the length of these ingots was 6.9 cm, with two-thirds of the ingots being between 5.4 and 8.7 cm. Visual examination of these crystals revealed them to be free from inclusions or polycrystallinity, with the following exception. Due to the accumulation of free gallium at the bottom of the crucible at the end of a run, the few millimeters closest to the tail end of an ingot often contained gross defects. These defects did not alter the quality of the rest of the ingot. Thus, ingots will henceforth be referred to as if they were completely free of gross defects, and it will be understood that such statements are meant to exclude the extreme tail ends of the ingots.

Each ingot was characterized by examining three polished slices which were taken from locations roughly 1.5, 3.0, and 5.0 cm from the seed end of the ingot. The slices were cut normal to the growth axis of the ingot and were about 425 μm thick.

Gallium phosphide crystallizes in the zinc-blende structure, and thus perfect GaP is expected to be optically homogeneous. This means that the principles of photoelasticity can be used to analyze the strain patterns in GaP (8). Figure 2 shows slices from two ingots which are viewed between crossed polarizers using parallel light. The sample on the left is a typical example, showing isoclinic fringes in the shape of a dark cross. It is found that the cross remains fixed with respect to the polarizers when the sample is rotated. Since an isoclinic fringe shows the locations where the directions of principle strain are parallel to the polarizers, it is concluded that the strain is predominantly radial. This is confirmed by the fringes on a slice cut out of the center of an ingot parallel to the growth axis.

The slice on the right in Fig. 2 shows another commonly observed pattern. In this case the slice is triangular with the apexes of the triangle pointing in <211> directions. Two arms of the isoclinic fringe are swept back slightly. These arms move slightly as the slice is rotated, always indicating that the directions of principle strain are parallel to and perpendicular to the surface of the ingot at the periphery of the slice. This is the strain pattern which is expected in a Czochralski ingot where the surface is cooled at a different rate from the core.

Defect densities were measured on the slices described above. They were etched at room temperature for 10 min in a rotating beaker in the ferricyanide etch (8g $K_3Fe(CN)_6$: 12g KOH : 100g H_2O). This etchant

reveals dislocation etch pits on the (111)Ga faces of GaP (9). It will also reveal the traces of twins and stacking faults.

In these ingots only dislocation pits were found; all ingots were free of twins and stacking faults. The data concerning dislocation density are summarized in Fig. 3. Each point represents the median value of a set of measurements, and the error bars show the range which includes two thirds of the samples for each measurement. The value for the dislocation density in the central portion of a slice is determined by measuring the average value over the area contained within one half of a slice radius. The value for the edge of a slice is the average value found 0.5 mm from the edge of the slice.

The distribution of dislocation densities on typical slices is shown in Fig. 4. The dislocation density is highest at the edge of a slice and then decreases until the center of the slice is reached. Occasionally, there is a slight increase at the very center of a slice.

As expected, the dislocation density is highest near the outside of an ingot, both because new dislocations are nucleated there and because that is the region which receives the greatest amount of stress. Slip traces are occasionally seen near the periphery of ingots. It is also no surprise that the dislocation density increases with the distance from the seed since the dislocations are expected to propagate downward and toward the center of the ingot as the ingot grows.

The influence of crystal growth parameters on crystal perfection follows the expected pattern. Among the parameters having no noticeable effect are the nature of the doping species, the doping level (1×10^{14}-1×10^{19} cm^{-3}), the pull rate (0.7-2.5 cm/hr), the rotation rate (3-60 rpm), the encapsulant thickness (0.7-2 cm), and the growth polarity [(111)Ga or (111)P]. On the other

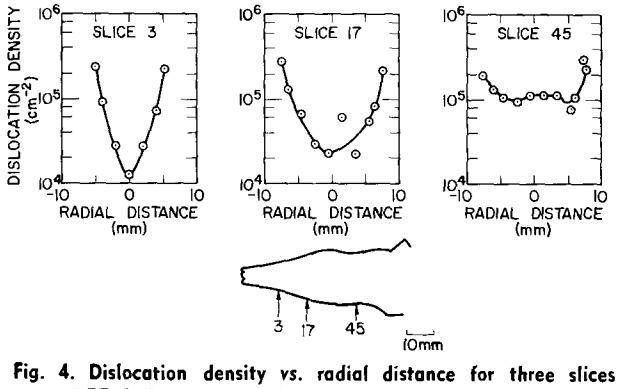

Fig. 4. Dislocation density vs. radial distance for three slices from an LEC GaP ingot. Slice No. 3 is closest to the seed end of the ingot.

hand, the condition of the seed and the geometry of the ingot neck were found to be important. Figure 5 shows the relationship between the neck dimensions (length/diameter) and the dislocation density in the central region of each ingot about 1.5 cm from the seed. Many ingot necks were not grown continuously; that is, some neck was grown, contact between the neck and the melt was broken, and then more neck was grown. Even so, it would be expected that either a long neck or a thin neck would allow dislocations to grow out, leading to ingots which have low defect densities when the neck dimensions are optimal. It is seen from Fig. 5 that this is indeed the case. However, good neck quality is not absolutely necessary for low dislocation density. In particular, one ingot is identified in Fig. 5 as having a low dislocation density but almost no neck; it did, however, have a low dislocation seed. Hence, low dislocation ingots may be prepared if the effective seed (either the seed itself or the region at the end of the neck) has a low dislocation density.

The use of afterheaters and radiation reflectors has been explored, but their effectiveness is severely limited by the relatively high dislocation density of a typical ingot. Afterheaters are most effective when they are used to reduce the radial temperature gradient in a perfect ingot. This reduces the strain in the ingot and minimizes the possibility of creating dislocations by slip. For ingots which have dislocation densities in the mid 10^4 cm^{-2} region, however, the use of afterheaters and reflectors offers no advantage since afterheaters will not remove existing dislocations nor will they prevent dislocations from propagating and interacting.

Growing low dislocation density LEC GaP ingots, then, is an evolutionary process. Using the principles above, a low dislocation density ingot can be used to make seeds with which ingots with still lower dislocation densities can be grown. Using this process, the best ingot obtained to date has a dislocation-free core which is 3 mm in diameter at a point 1.5 cm from the seed (total ingot diameter was 8 mm at this point).

The LEC GaP ingots described here generally compare favorably to GaP which is grown by vapor transport onto GaAs seeds. Such crystals are typically strained and have dislocation densities of 2×10^5-2×10^6 cm^{-2}. On the other hand, solution-grown GaP platelets have substantial areas which are strain and dislocation free (10). This difference between LEC and solution-grown GaP may be part of the explanation for the earlier mentioned difference in electroluminescent efficiencies of diodes grown on these two types of substrates.

Controlled Incorporation of Impurities

Control of the doping level of a semiconductor by the purposeful introduction of impurities requires that

Table I. Residual impurities in GaP

[b] ^{3}He activation analysis.

the undoped semiconductor have residual impurity concentrations which are far below the intended doping level. Thus it is an important result that LEC GaP ingots are quite pure by contemporary standards for GaP. A summary of the chemical analyses which have been performed is given in Table I, where each value is the average of several samples. The samples taken from LEC crystals were representative of the middles of the ingots. The bulk of the data is from mass spectroscopy. In addition, ^{3}He activation analysis (11) was used to provide a supplementary measurement of the oxygen concentration. Also, optical absorption was used to detect substitutional nitrogen and give a lower limit to total nitrogen concentration. In all cases, except for arsenic, the typical impurity concentrations in the LEC ingots are seen to be the same order of magnitude as those in the polycrystalline starting material.

Few electrically or optically active impurities are found in undoped ingots. Such crystals are typically n-type, with electron concentrations below 1×10^{15} cm^{-3}, mobilities above 175 cm^2/V · sec, and optical absorption coefficients less than 0.2 cm^{-1} in the range from 1.2-1.95 eV.

Since undoped ingots have carrier concentrations less than 1×10^{15} cm^{-3}, ingots can be purposely doped in a controllable fashion at concentrations greater than about 1×10^{16} cm^{-3}. The donors S, Se, Te, and the acceptor Zn have been studied in <111> oriented ingots to determine the relationship between the amount of dopant added to the melt and the carrier concentration in the resulting ingot. This is not quite the same as determining the distribution coefficients of these impurities in GaP for several reasons. First, there is no convenient way to measure the concentration of the impurity in the melt at the growth interface, and there is always the suspicion that part of the dopant evaporated from the melt before the melt was encapsulated. Second, since crystal growth is not done under equilibrium conditions, a true distribution coefficient cannot be obtained. Third, the impurity concentration in the ingot is not measured directly. Still, the measurement that is performed provides data which is quite useful in a practical sense, and it will be shown that the values obtained are expected to be very close to the values of the distribution coefficients.

Doping with sulfur was accomplished by adding Ga_2S_2 [3] to the melt. It has been shown that in solution-grown GaP, the concentration of sulfur is equal to the concentration of electrons as determined by surface barrier capacitance measurements up to an electron concentration of about 4×10^{18} cm^{-3}, after which the electron concentration saturates (13). In the present work it was assumed that this relationship also holds for LEC GaP, and sulfur concentrations were determined by measuring electron concentrations as given by surface barrier capacitance. In this fashion the sulfur concentration was measured at several locations along an ingot and then was extrapolated back to the seed end of the ingot using the normal freezing equation

$$C(g) = A(1 - g)^B$$

where g is the weight fraction of the ingot that was grown before the point which is being measured, C is the impurity concentration, and A and B are constants (14). The ratio of the impurity concentration at the seed end of the ingot, C_i, to the initial impurity concentration in the melt, C_o, is the effective distribution coefficient, k. Ideally, the constants A and B in the normal freezing equation should be $A = kC_o$, $B = k - 1$, and hence these two constants may be used to check the experiment for self-consistency.

The scatter in the carrier concentration data and the doping nonuniformity (which will be discussed in the next section) occasionally preclude the use of the constants A and B to determine k and C_o. When such a determination can be made, however, the value of k thus obtained corresponds within ±5% to the value of k determined from $k = C_i/C_o$. Moreover, the value of C_o obtained from the constants A and B corresponds within ±10% to the amount of dopant that was added to the melt, suggesting that very little of it volatilized. The sulfur-doped ingots that were measured had seed-end electron concentrations in the range 5×10^{16} to 5×10^{18} cm^{-3}, pull rates of 0.8-2.5 cm/hr, and rotation rates of 3-30 rpm. Over this range the effective distribution coefficient appears to be constant. The mean value of the distribution coefficient measured is $k = 0.23$, with a standard deviation of 0.08. The value is essentially independent of growth polarity. Since it is also independent of growth and rotation rates, it is likely to be near the equilibrium value of the distribution coefficient.

Selenium doping was investigated by adding Ga_2Se_3[4] to the melt. The doping experiments were interpreted by using the same analysis as for sulfur, assuming that the selenium concentration is equal to the electron concentration up to an electron concentration of 4×10^{18} cm^{-3} (13). Again the normal freezing equation provided self-consistent values for k and C_o. Over the range of doping from 6×10^{16} to 1×10^{18} cm^{-3}, of pull rates from 1.2 to 2.5 cm/hr, and of rotation rates from 6 to 60 rpm, the effective distribution coefficient appears constant at $k = 0.16 \pm 0.05$, suggesting that k is near its equilibrium value. It also appears independent of growth polarity.

The most data have been accumulated for the donor tellurium, for which the doping source was Ga_2Te_3.[5] In this case the electron concentration is expected to equal the donor concentration for $n < 2 \times 10^{18}$ cm^{-3} (13). The effective distribution coefficient appears to be quite independent of growth polarity and is found to be $k = 0.012 \pm 0.003$ over a range of doping from 8×10^{16} to 2×10^{18} cm^{-3}, of pull rate from 1.2 to 2.5 cm/hr, and of rotation rate from 3 to 16 rpm. In this case the normal freezing equation generally cannot be used to verify k and C_o since B usually cannot be found to an accuracy of better than ±5%. However, there was one case where k and C_o were verified, and the agreement for both k and C_o was within 30%.

The acceptor zinc has also been studied by the same technique, using pure Zn[6] as a dopant. Some severe difficulties arise, however. First, zinc is expected to be the most volatile of the four doping sources studied. Second, there is considerable difficulty relating the carrier concentration to the zinc concentration. It has been shown that surface barrier capacitance measurements on zinc-doped solution-grown GaP generally give hole concentrations which are smaller than the zinc concentrations, even at concentrations as low as 5×10^{17} cm^{-3} (13). On the other hand, room temperature Hall effect measurements give hole concentrations which may be greater or less than the zinc concentration, depending on the concentration level (15). In the present work, hole concentrations were ob-

[3] Alusuisse, 6 9's+ pure.

[5] Atomergic, 5 9's+ pure.
[6] Cominco, 5 9's pure.

tained by room temperature Hall effect measurements and were related to zinc concentrations by using the data presented in ref. (15). The interpretation then proceeds as for the donors. Although the scatter in the data is worse than for the donors, the effective zinc distribution coefficient is assigned the value $k = 0.096 \pm 0.05$ for zinc concentrations from 1×10^{17} to 2×10^{19} cm^{-3}, growth rates from 1.2 to 2.5 cm/hr, and rotation rates from 6 to 16 rpm. The constants A and B can be used to provide values of k and C_o which are self-consistent to ± 20%, suggesting that the volatilization of the zinc was not serious.

Electrical Properties

In addition to the defect structure of LEC GaP ingots, the electrical properties of this material ultimately determine its usefulness. Room temperature electrical properties of the GaP ingots were measured using conventional d.c. Hall effect techniques employing the Van der Pauw method. Following common practice, n-type samples were characterized by the relationships $n = (R_H e)^{-1}$, $\mu_H = R_H/\rho$, where n is the electron concentration, R_H is the Hall coefficient, e is the electronic charge, μ_H is the Hall mobility, and ρ is the resistivity. Equivalent relationships are used for p-type samples. Figures 6 through 8 show how electron and hole mobilities vary with carrier concentration.

Two things are apparent from Fig. 6 and 7. First, electron mobilities are consistently high. Very little scatter is seen, and the mobilities are generally at least as high as those reported for good quality GaP grown by other techniques (16, 17). Only GaP grown by vapor transport onto GaP seeds has higher mobilities; *e.g.*, $n = 3.0 \times 10^{16}$ cm^{-3}, $\mu_H = 187$ $cm^2/V \cdot sec$; $n = 1.3 \times 10^{17}$ cm^{-3}, $\mu_H = 170$ $cm^2/V \cdot sec$. Second, it is seen from Fig. 7 that the mobilities of Te-doped samples are somewhat lower than those of other n-type samples in the range of 5×10^{16}-5×10^{17} cm^{-3}. The difference is small, reaching a maximum of 4% at $n = 1 \times 10^{17}$ cm^{-3}, but it is consistent. A similar dependence of mobility on the specific dopant used has been seen in Ge and Si, the differences being as much as 30% at carrier concentrations near 1×10^{19} cm^{-3} (18, 19). These differences in Ge and Si have been attributed to differences in ionized impurity scattering among different ions (20).

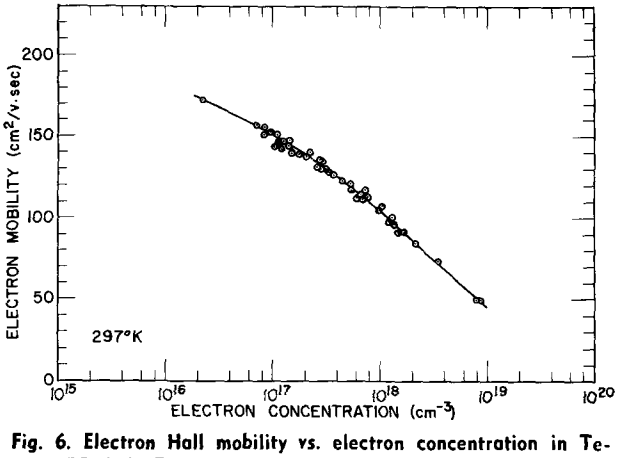

Fig. 6. Electron Hall mobility vs. electron concentration in Te-doped LEC GaP. The solid line has no theoretical significance.

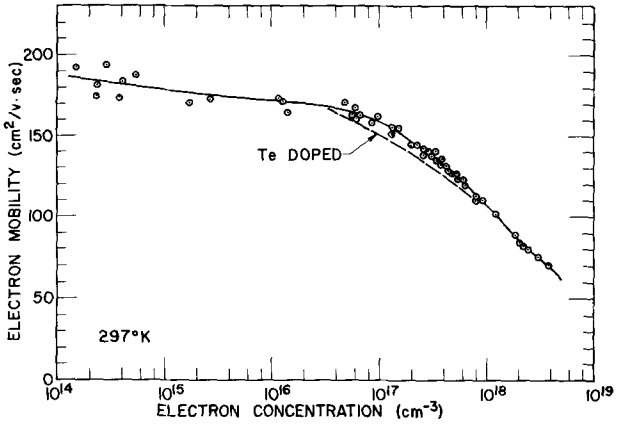

Fig. 7. Electron Hall mobility vs. electron concentration in n-type LEC GaP that is not doped with tellurium. The solid line has no theoretical significance. The broken line shows the mobilities of Te-doped ingots for comparison.

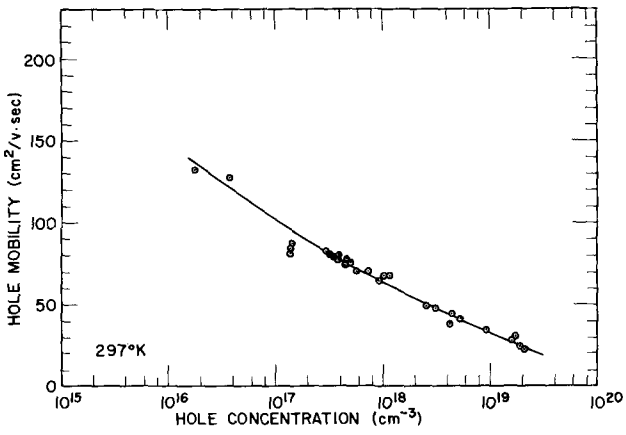

Fig. 8. Hole Hall mobility vs. hole concentration in p-type LEC GaP. The solid line has no theoretical significance.

In Fig. 8, all of the points correspond to zinc-doped samples except for the two at the lowest hole concentrations which correspond to carbon-doped samples. Again the mobilities shown are generally as high as those reported elsewhere, with only GaP grown by vapor transport on GaP seeds showing slightly higher mobilities (21, 22). In contrast, it is found that ingots doped with Zn and large amounts of Ga_2O_3 (1-2g) have mobilities as much as 25% higher than those shown in Fig. 8 at hole concentrations of 1×10^{17}-1×10^{18} cm^{-3}. This is not well understood.

The doping homogeneity of slices cut from <111> oriented LEC GaP ingots has been examined by using Schottky barrier diodes. Gold dots, 0.010 in. in diameter on 0.020 in. centers, were evaporated onto polished GaP surfaces. Doping levels at various points were then evaluated by surface barrier capacitance measurements. The results indicate that the doping level in a typical slice is constant to within ± 20%. The deviation from constancy shows a weak dependence on rotation rate (Fig. 9), but appears indepen-

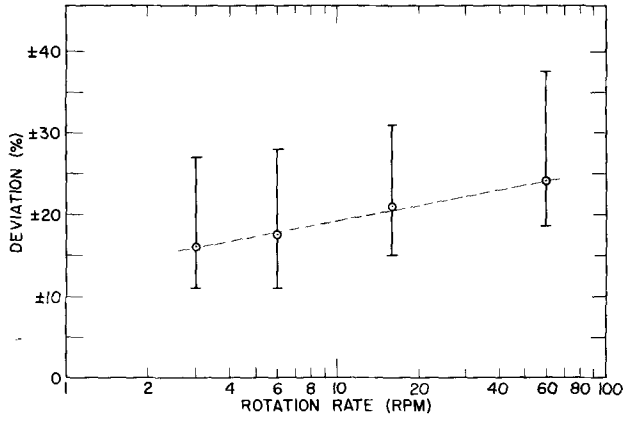

Fig. 9. Deviation in doping level along the diameter of an LEC GaP ingot vs. the rotation rate of the ingot. The points are median values, and the error bars show the ranges that include 2/3 of the samples.

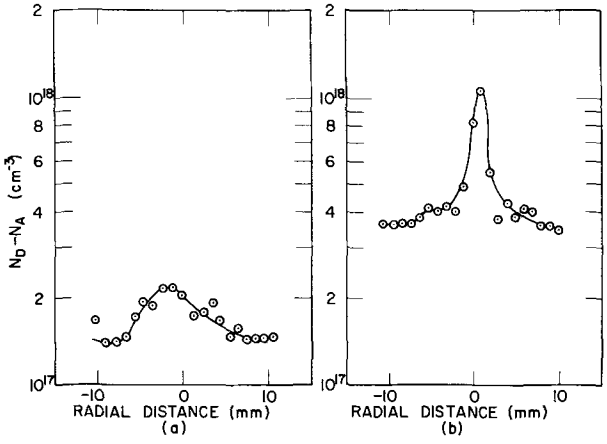

Fig. 10. Electron concentration (N_D-N_A) vs. radial distance in slices of LEC GaP. (a) Typical slice, (b) slice with preferential incorporation of impurities at core of ingot.

dent of slice diameter (0.75-2.5 cm), carrier concentration (6 x 10^{16}-5 x 10^{18} cm^{-3}), and fraction of the melt solidified.

It is found that a majority of <111> ingots have a broad maximum in doping level at their centers, an example being in Fig. 10a. In most cases, there is no evidence for preferential incorporation of impurities at facets; that is, no region of an ingot is found where the doping level is abruptly higher than in the surrounding regions. Occasionally, however, the core of an ingot does have a sharply higher doping level than the rest of the ingot. An example of such an effect is shown in Fig. 10b. If the carrier concentration at such a peak is on the order of 2 x 10^{18} cm^{-3} or higher, the region of increased carrier concentration is obvious under visual inspection as a dark spot in a polished slice.

Conclusion

It is thus seen that the growth of single-crystal gallium phosphide by the Liquid Encapsulated Czochralski technique is a major advance in GaP technology. The LEC process allows, for the first time, the convenient and relatively economical production of substantial quantities of large area, uniformly shaped GaP substrates of good crystal quality.

The main feature of the LEC growth process is the encapsulation of the GaP melt by a layer of B_2O_3. The presence of this layer eliminates the need for a high overpressure of phosphorus to keep the melt from volatilizing and allows the use of an inert gas instead. The major portion of the growth effort is then directed toward maintaining the transparency of the B_2O_3 so that the growth interface remains visible. It was found that the clouding could be made negligible by baking out the B_2O_3 to remove water, by locating the center of heat at the bottom of the crucible, by keeping the B_2O_3 relatively hot during growth, and by packing the GaP charge tightly into the crucible so that the B_2O_3 would not mix with it on melting.

Undoped ingots grown by this process are n-type. They are quite pure, having carrier concentrations less than 1 x 10^{15} cm^{-3} and Hall mobilities greater than 175 cm^2/V·sec. Doping experiments were carried out with S, Se, Te, and Zn, and effective distribution coefficients were obtained for carrier concentrations from 5 x 10^{16} to 5 x 10^{18} cm^{-3}. The values are, respectively, 0.23 ± 0.08, 0.16 ± 0.05, 0.012 ± 0.003, and 0.096 ± 0.05. Slices from ingots generally have carrier concentrations which are constant to ± 20%, independent of rotation rate.

Metallurgically, GaP ingots are superior to vapor-grown GaP. However, they are inferior to solution-grown GaP, and this may be one of the reasons why electroluminescent diodes fabricated on LEC GaP substrates are less efficient than those fabricated on solution-grown substrates. The LEC GaP crystals are strained in the radial direction and have dislocation densities which are typically 1 x 10^5 cm^{-2} in the greater portion of the ingot. However, one ingot was obtained which had a 9 mm^2 core near the seed end which was dislocation free. The GaP ingots have uniformly high mobilities, with the mobilities for both n-and p-type samples being generally as high as those from the best GaP produced by other methods. It is found that Te-doped samples have slightly lower mobilities than other n-type samples.

Acknowledgments

The authors express their thanks to D. L. Malm for providing mass spectroscopy data, C. K. Kim for the ^{3}He activation analysis, P. J. Dean for the measurement of nitrogen concentrations by optical absorption, and M. DiDomenico, Jr., for other optical absorption measurements. The technical assistance of Miss S. L. Davis is also gratefully acknowledged.

Etch Rate Characterization of Borosilicate Glasses as Diffusion Sources

R. O. Schwenker

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

For diffusion of boron into silicon from a doped oxide diffusion source, the surface concentration of boron in silicon and B_2O_3 in the glass at the glass-silicon interface are independent of diffusion time. In the temperature range studied, the surface concentrations are also independent of temperature and depend only on the dopant concentration in the deposited glass. This dependence is observed as long as the glass thickness is large enough so that the impurity source approximates a semi-infinite source. The concentration dependence of the diffusion coefficients of the B_2O_3 in the glass and the boron in silicon are determined, the diffusion coefficient for boron in silicon being about 100 times that of the diffusion in the oxide. Heating under an oxidizing ambient oxidizes the silicon at the silicon-glass interface with the thickness growth rate of the undoped SiO_2 layer being nearly independent of the original glass thickness. No such interface barrier to the boron diffusion process occurs when argon is used as an ambient.

Although a number of authors have studied doped oxides as diffusion sources for device fabrication (1-7), not all of the basic assumptions concerning the diffusion processes involved in such systems have been checked. In this report, boron diffusion into silicon from doped oxide has been studied as a function of glass composition, glass thickness, diffusion time and temperature, and type of ambient used.

In order to determine if there is equilibrium at the doped oxide-silicon interface during diffusion, it is necessary to know the concentration of B_2O_3 in the glass as well as the boron in the silicon near the silicon-glass interface. By knowing both concentrations, one can then determine the dependence of the segregation coefficient on the concentration of the B_2O_3 in the deposited glass.

The diffusion coefficient of the boron in the silicon has been shown to be concentration dependent (7). The concentration dependence of the diffusion coefficient for the dopant in the oxide is not so well known. Even the inaccurate radiochemical profiling techniques which have been used for phosphorus-doped oxides (8) cannot be used with borosilicates. However, this question and the others can be studied by the use of etch rate characterization of the oxide and electrical measurements of the diffused silicon. Another problem which can be studied by the technique of etch rate profiling is the different effects of oxidizing ambients on the diffusion processes.

Experimental Procedure

The system which was used for deposition of the doped oxide was the low-temperature oxidation of organosilicon and organoboron compounds (4). Silicon wafers were placed on a silicon carbide susceptor coated with silicon in a small round horizontal glass reactor. RF heating was used while an infrascope was used to monitor the 475°C temperature of the wafers during the deposition. Oxygen was bubbled through tetraethyl orthosilicate (TEOS) at room temperature while argon was used as the carrier gas for tri-n-propyl borate (TPB). Additional oxygen and argon were used as dilution gases during the deposition.

During the predeposition heat up cycle of the wafer, only argon was used as an ambient in order to avoid the formation of any silicon dioxide on the substrate. All work was done using 1.0 ohm-cm(100) n-type wafers. Prior to use, all wafers were oxidized under steam, then cleaned with concentrated HF, and finally rinsed with de-ionized water. The diffusions were done in furnaces with argon ambients.

Etch rate techniques (9) for determining characteristics such as densifications and impurity concentration profiles have been commonly used in the past for glasses or doped oxides. For a study of this type, it is necessary to have an etchant which has an etch rate with a strong dependence on the variable which is of interest in the study. We used an etchant of 500 ml nitric acid, 1 ml hydrofluoric acid, and 7 mg $Hg(NO_3)_2$. This etchant was found to etch the glass at a rate with a strong dependence on impurity concentration in the range of 5-15 m/o (mole per cent) B_2O_3 on the glass, as is shown in Fig. 1. This range was the principal range of interest for this study.

The B_2O_3 concentrations in the deposited glasses were determined by measuring the band intensity of the infrared absorption band at 1390 cm^{-1} for the B-O bond relative to the band intensity at 1090 cm^{-1} for the Si-O bond (10). These intensities are best determined by integrating the optical density, O. D., over the band width. The optical density is given by O.D. $= \log_{10} (To_\nu/T_\nu)$ where T_ν is the transmittance at frequency ν and To_ν is the background level at the same frequency. The background level is determined by the

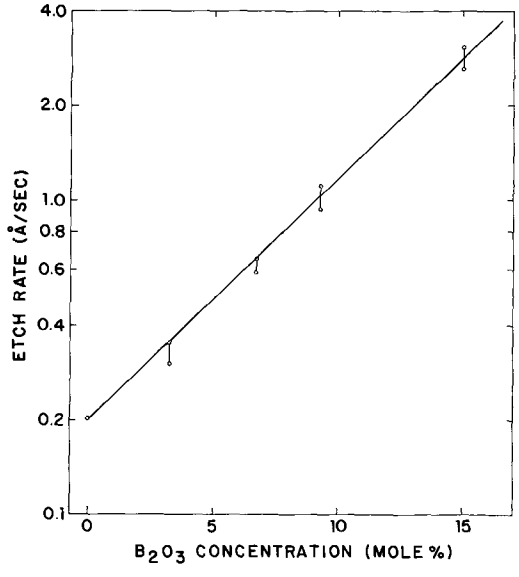

Fig. 1. Etch rate of densified doped oxide as a function of composition of B_2O_3 in the glass.

Key words: deposition, oxide, tetraethyl orthosilicate, tri-n-propyl borate.

line drawn tangent to the edges of the absorption band. Although the integrated intensity is a more accurate quantitative representation, a reasonably good approximation is obtained by using the optical density at the band maximum as was shown for SiO_2 (11). We have assumed that Beer's law is accurate for our range of concentrations so that the absorbance is proportional to the concentration of bonds. The relationship which we used to relate the optical densities to the concentration of the components is

$$\frac{1\text{-}Co}{Co} = 1.5\,\frac{\text{O.D. Si-O}}{\text{O.D. B-O}} \qquad [1]$$

where Co is the weight fraction of B_2O_3 in the glass. The proportionality constant is that determined by Pliskin for GE GSC-1 glass and several other borosilicate glasses (12). It has been shown that the addition of metal oxides in borosilicate glass causes a decrease in the specific intensity of the B-O band (10). However, the 4.5 w/o (weight per cent) Al_2O_3 in the GE GSC-1 glass should cause a reduction of less than 20% in the specific absorption intensity of the B-O bands (12). Ignoring the effect of the Al_2O_3 in the calibrating glass and using Eq. [1] for our two-component glass can result in the calculation of B_2O_3 concentrations which could be greater than the actual values by no more than 20%. Regardless of the absolute error involved, the relative error remains the same for all concentration levels and can be ignored for comparison purposes. The absorption due to oxygen dissolved in the silicon substrate was eliminated by using Lopex material for the infrared measurements instead of the pulled crystals used for diffusion studies.

The same wafers were then used to determine the etch rates for each dopant concentration. Both infrared and etch rate measurements were made after densification of the wafers at 800°C for two or more hours. Other heat treatments for longer times at 800°C and also at higher temperatures were found to produce densified glasses with insignificantly different etch rates from those of Fig. 1. The etchant etched densified glass slowly enough so that etching times of the order of minutes could be used to remove layers of oxide which were a few hundred angstroms thick. Agitation of the etchant was used in order to insure uniformity of the etching.

The thicknesses of the doped oxides on the silicon substrates were measured in all cases with an ellipsometer. This method permitted an accuracy to within a few angstroms in the thickness measurement of the layer removed by etching. In addition to the glass thickness measurement, the index of refraction of the boron-doped oxides in our range of investigation was determined to be $n = 1.460$. The closeness of this value to the index of refraction of SiO_2, $n = 1.463$ (13), allowed thickness measurements of composite layers of SiO_2 and boron-doped oxide to be readily made with the ellipsometric techniques.

Preliminary Studies

Measurements were first made in order to determine the uniformity of the doping of the deposited borosilicate glass. The etch rate profile on as-deposited glass showed a lower etch rate near the silicon-glass interface than the etch rate further from the interface. Since this could result from partial densification of the glass as it was being deposited, and not from an actual change in dopant concentration, a profile was made on deposited borosilicate glass after a 2-hr densification at 800°C in an argon atmosphere. This etch rate profile showed a uniform doping of 14.6 ± 0.3 m/o throughout the glass layer. Comparable uniformity was measured on glasses with lower B_2O_3 content.

The concentration profiles as determined by etch rates were observed to depend significantly on the type of ambient which was used during the densification heat treatment. Four silicon wafers with approximately 5000Å of 9.2 m/o borosilicate glass deposited on them were densified at 800°C for 3 hr under ambients of argon, nitrogen, oxygen, and steam, respectively. From the etch rate profiles of these densified oxides, it was obvious that both steam and oxygen formed SiO_2 at the glass-silicon interface with the steam-grown oxide having a thickness (~1000Å) about ten times thicker than that grown from the oxygen. A 25Å thick layer was present at the interface in the case where nitrogen was used as an ambient. Although temperatures higher than 800°C are generally thought to be necessary in order to produce silicon nitride by direct reaction (14), this layer, which could not be removed with our oxide etchant, was thought to be a nitride. The layer was not thick enough for characterization by a measurement of its index of refraction with the ellipsometer.

Various glass thicknesses were used to determine the growth rates for steam-grown silicon dioxide under the doped oxide layers. Silicon wafers with glass thicknesses of 0, 1100, 2100, 3000, and 4200Å of approximately 15 m/o B_2O_3 in SiO_2 were densified in a steam ambient at 800°C for 3 hr. The wafer with no glass originally present grew 1800Å of SiO_2 under these conditions while the wafers with doped oxide deposited on them grew 760-880Å of SiO_2. We conclude that the presence of the glass layer appreciably affects the growth of SiO_2 at the interface, but that the thickness of SiO_2 which is grown under a layer of borosilicate glass has almost no dependence on the thickness of the glass originally deposited on the wafer.

When we repeated this work with glass which was first densified at 800°C in argon, we got SiO_2 layers grown with thicknesses as given in Fig. 2. The oxide thicknesses were measured on the various wafers after 15 min, 30 min, and 1 hr at 800°C with a steam ambient. These results show that even densified borosilicate glass does not stop the diffusion of oxidizing ambients to the silicon substrate. This attribute could, of course, be used to remove the diffusion source from the silicon wafer without physically removing the wafer from the oven. By switching from an inert ambient to steam, the diffusion would be blocked by a rapidly formed layer of thermally grown SiO_2.

SiO_2 can also be used as a barrier to stop out-diffusion of the dopant from the doped oxide into the ambient. A layer of undoped SiO_2 1000Å thick deposited over the doped oxide layer will eliminate depletion of the dopant by this out-diffusion. An etch rate profile of a wafer with such a composite deposition of undoped SiO_2 over a layer of borosilicate glass is shown in Fig. 3. The wafer had been held at a temperature of 1050°C

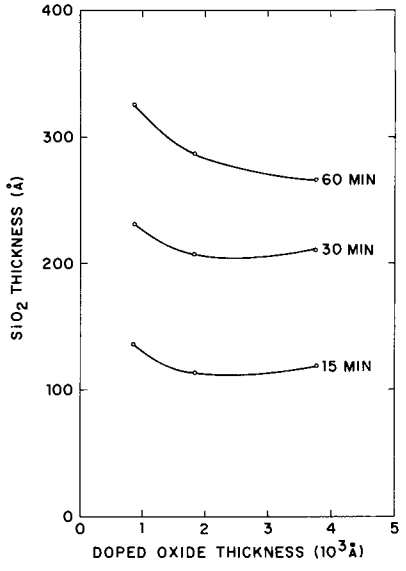

Fig. 2. Thickness of thermal SiO_2 grown from a steam ambient under a borosilicate layer as a function of the deposited glass thickness.

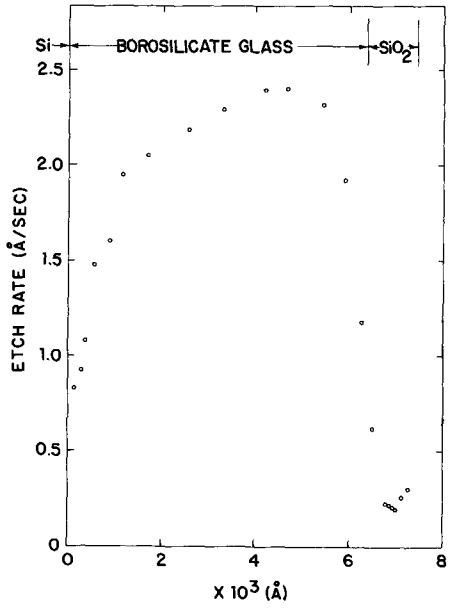

Fig. 3. Etch rate profile of ~15 (m/o) borosilicate glass with an SiO_2 cover after 17-hr-1050°C diffusion.

for 17 hr with an argon ambient. It is seen in the figure that diffusion of the B_2O_3 from the doped oxide into the SiO_2 is negligible since the etch rate drops sharply from a maximum value to the etch rate for undoped SiO_2, 0.2Å/sec. At the same time, appreciable diffusion of dopant into the silicon had occurred as evidenced by the etch rate profile of the doped oxide near the silicon-glass interface.

Diffusion Process

In order to be able to answer the remaining questions about the diffusion process, it was necessary to obtain profiles of the dopant concentrations in borosilicate glasses of various B_2O_3 deposition concentrations after diffusions at different temperatures and with various diffusion times.

According to calculations presented by Crank (15) and recently extended by Hu (16), the surface concentrations of an impurity at the interface between a semi-infinite source (here, the doped oxide) and a semi-infinite sink (the silicon) are time invariant. Crank considers only the simple case where the region $X < 0$ is of one substance with a constant diffusion coefficient D_1, and, in the region $X > 0$, the constant diffusion coefficient is D_2 for the other substance. As in our case, the initial conditions are that the region $X < 0$ is at uniform impurity concentration, Co, and in $X > 0$, the concentration is zero. By taking as his boundary conditions at the interface, a segregation coefficient and constant flux

$$C_2/C_1 = k, \; X = 0 \qquad [2]$$

$$D_1 \frac{\partial C_1}{\partial x} = D_2 \frac{\partial C_2}{\partial x}, \; X = 0 \qquad [3]$$

and by assuming error function solutions in the two regions, he shows that the concentrations at the interface, $X = 0$, are constant in time with the relationships

$$\frac{C_o}{kC_1} = \frac{C_o}{C_2} = \frac{1}{k} + \sqrt{\frac{D_2}{D_1}} \qquad [4]$$

The assumptions which were used to derive Eq. [4] are not completely consistent with our experimental conditions since it is known that the diffusion coefficient in the silicon, D_2, is not independent of the boron concentration (7). The erfc solutions assumed by Crank for his problem cannot be correct in our case. However Hu's work shows that even if the diffusivities in the two regions are concentration dependent and if the more general relationship, $C_2 = f(C_1)$, replaces the segregation coefficient of Eq. [2] at the interface where $f(C_1)$ is any arbitrary function, the impurity concentrations at the interface are still time invariant. Except for the special case of Eq. [2] and constant diffusivities, the simple form of Eq. [4] is not correct, and the interface concentrations would have to be calculated by a complex iteration calculation as given by Hu.

Etch rate profiles of the borosilicate glass on wafers which were diffused under various conditions of diffusion time and temperature were made for approximate Co values of 15, 9.2, and 6.8 m/o of B_2O_3 as the dopant in the glass. Although the concentration dependence of the etch rate method of profiling was not sensitive enough for use with the lowest concentration (see Fig. 1), the profiles of the 15 and 9.2 m/o glasses showed, for each dopant level, that the B_2O_3 concentration at the interface, $C_1(0)$, was independent of the length of time of the diffusion. This is seen for the 15 m/o glass in Fig. 4, where the concentration profiles are given as a function of the distance from the silicon-glass interface. Using complementary error function curves, the extrapolations of the etch rate profiles for all three diffusions give roughly the same intercept at the interface. This shows that the B_2O_3 concentration at the interfaces remained constant at about 8.8 m/o during the time of the diffusion and also are the same for the 1000° and 1100°C diffusions to within the limits of accuracy of the etch rate profiling technique. The time invariance is consistent with the theoretical calculations while the temperature invariance indicates that the reaction at the interface

$$2B_2O_3 + 3Si \rightarrow 4B + 3SiO_2 \qquad [5]$$

is not strongly dependent on the temperature.

A similar result was obtained for the 9.2 m/o glass with the extrapolated interface B_2O_3 concentration being approximately 5.5%. These results are listed in Table I.

We have shown that the constant concentration of B_2O_3 in the glass at the silicon-glass interface, $C_1(0)$, is a function only of the B_2O_3 concentration in the deposited glass, Co. This result can only be expected so long as the oxide can be regarded as a semi-infinite source layer. Since we are working with finite glass thicknesses, we made diffusion profiles on glasses of several thicknesses in order to determine the minimum thickness allowable for maintaining a constant surface concentration. In Fig. 5, diffusion profiles for four different thicknesses of glasses are given. The deposited

B_2O_3 concentration was 15 m/o and a 1-hr, 1050°C diffusion was used. Obviously, the combined effects of boron diffusion into the wafer and out-diffusion of the dopant into the ambient caused no appreciable reduction in the maximum B_2O_3 concentration for the three thickest layers in this case. There was a considerable reduction in the maximum B_2O_3 concentration for the 880Å layer, however. From this, it can be concluded that 2000Å of doped oxide is sufficient to assure that the interface B_2O_3 concentration, $C_1(0)$, would remain constant for a 1050°C-1-hr diffusion. For all of the other diffusions in this study, doped oxide thicknesses of at least 4000Å were used to assure no reduction in interface concentrations of B_2O_3.

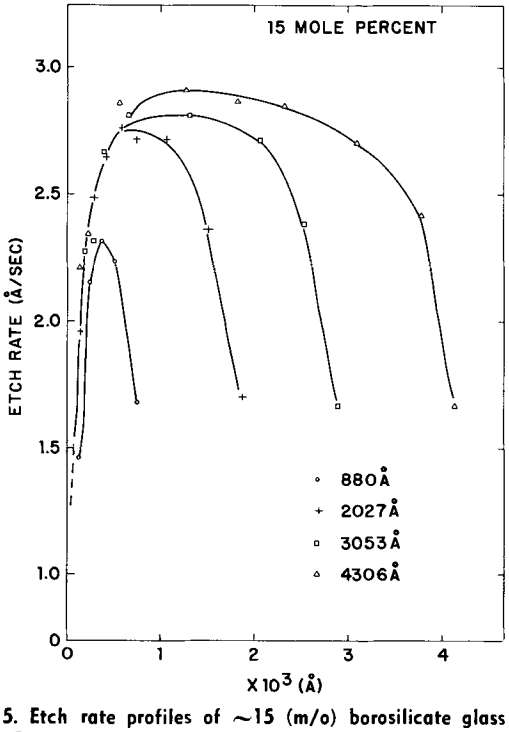

Fig. 5. Etch rate profiles of ~15 (m/o) borosilicate glass after a 1050°C-1-hr diffusion for different glass thicknesses.

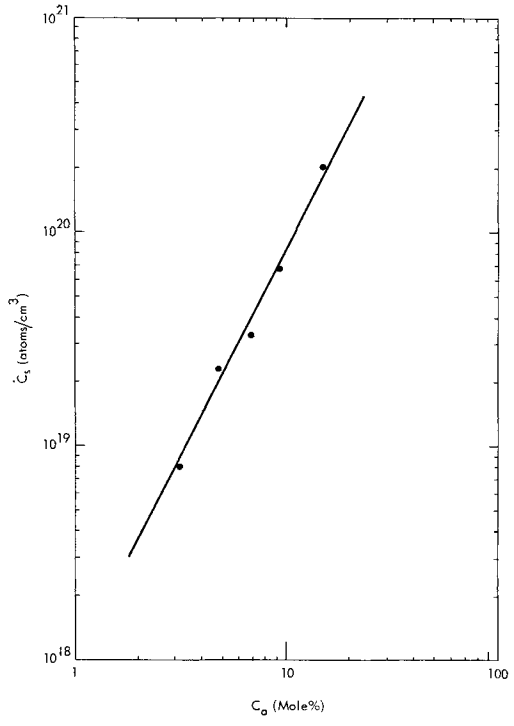

Fig. 6. Surface concentration of boron diffused into silicon as a function of B_2O_3 content in source glass.

The surface concentrations of boron in the diffused silicon wafers, Cs, were calculated from four-point probe sheet resistance and bevel and stain junction depth measurements of many diffused wafers. By assuming a complementary error function distribution and using Irvin's curves (17) these surface concentrations on the silicon side of the interface were also found to be independent of diffusion time and temperature. The values for Cs which were calculated in this way are plotted in Fig. 6 against the dopant concentrations of the B_2O_3 in the oxide. The segregation coefficients, k, as calculated according to Eq. [2], with $C_2(0) = Cs$, are given in Table I for the two highest B_2O_3 concentration sources.

If a complementary error function distribution is assumed for the boron in the silicon

$$C_2(X) = Cs \operatorname{erfc} (X/2\sqrt{D_2 t}) \qquad [6]$$

then, by substituting the junction depth, Xj, for X, and solving for $\sqrt{D_2}$ in the above equation, the diffusion into silicon can be calculated. $C_2(Xj)$ is the background dopant concentration in the silicon. Our values for $\sqrt{D_2}$, calculated in this way, are given in Tables I and II. It should be noted that, since the diffusion coefficient of boron in silicon is concentration dependent, the actual profiles should be flatter near the interface than the complementary error functions. The use of the error function could result in an over estimation of the surface concentration at the high doping levels in this study. In order to check this point, profiles of the electrically active boron were made on the silicon wafers which had been boron diffused at 1100°C for 2 hr. The sectioning was done by anodic oxidation while the sheet resistance measurements were made with a four point probe, as before. The surface concentrations which were obtained by using this measurement technique and Irvin's curves (17) were one half the surface concentration values which had been calculated by assuming a complementary error function distribution. Obviously, the values for k, as obtained from the erfc calculations of Cs and given in Table I, are also higher by a factor of two than the values obtained from the electrically active boron profiles.

Another possible source of error is that the sheet resistance measurement measures only the boron that

Table II. Diffusion coefficient for boron into silicon

$\sqrt{D_2}$(μ/hr½)	Surface concentration 20	6.8	3.3	Cs(10^{19} at./cm³) 2.3	0.8
Temp (°C)					
1000	0.11	0.060	—	—	—
1050	0.18	0.12	0.091	—	—
1100	0.32	0.20	0.18	0.23	0.22
1150	—	—	0.33	0.31	0.33

is in solid solution which is not equivalent to measuring the total boron in the silicon if precipitation or clustering of boron is present. Error due to this effect would cause the measured concentration of boron in the silicon to be lower than the actual concentration. These errors would be opposite in effect to the previously mentioned problem of calculating too large a concentration by means of the assumed complementary error function. Unfortunately, no sufficiently sensitive chemical or radiological method for directly determining the total boron concentration profile is available.

Although we expected the diffusivity of the dopant in the oxide also to be concentration dependent, we considered the profiles of the B_2O_3 concentrations after diffusion to fit a complementary error function of the form

$$Co - C_1(X) = (Co - C_1(0))\ \text{erfc}\ (X/2\sqrt{D_1 t}),\ X > 0 \quad [7]$$

If we rewrite Eq. [7] as

$$\sqrt{D_1} = X/2\sqrt{t}\ \text{arg erfc}\left(\frac{Co - C_1(X)}{Co - C_1(0)}\right) \quad [8]$$

it is easy to see that an average diffusion coefficient, D_1, can be calculated from the concentration profiles which were derived from the etch rate profiles. The diffusion coefficients which were calculated in this way are given in Table I along with the values of $\sqrt{D_2}$ for the boron in the silicon for corresponding temperatures. The large difference between the diffusion coefficients for the two dopant concentrations is inconsistent with the use of a complementary error function profile. This function was used only as a means for estimating an average diffusion coefficient in the oxide. From the table, it is easily seen that the ratio, $\sqrt{D_2}/\sqrt{D_1}$, is approximately 10. One can then roughly estimate that the partially depleted region of the doped oxide should extend a distance from the silicon-glass interface which is roughly equal to one-tenth of the junction depth in the silicon. This is consistent with the earlier result on diffusions from various thicknesses of glass since the 1050°-1-hr 15 m/o diffusion gave a junction depth in the silicon of 1.65μ and a depletion layer of thickness between 880 and 2000Å. Additional thickness over the $Xj/10$ amount should be allowed for the deposited glass layer unless a protective SiO_2 layer is deposited over the source layer to prevent out-diffusion.

Conclusions

The surface concentrations of boron in silicon and B_2O_3 in the glass at the glass-silicon interface have been shown to be independent of diffusion time. This agrees with theoretical calculations for a diffusion system where a doped oxide layer is the impurity source for diffusion into silicon. It was also seen that these surface concentrations are the same for 1000° and 1100°C diffusion temperatures and depend only on the dopant concentration in the deposited glass so long as the glass thickness is larger than the depleted layer thickness. From the ratio of the diffusion coefficients for boron in silicon to the diffusion coefficient for B_2O_3 in the oxide, $D_2/D_1 \sim 100$, it was determined that an interface oxide layer with a thickness equal to one-tenth of the junction depth in the silicon would be partially depleted during a diffusion. It would be possible to also compensate for out-diffusion from the oxide either by depositing a thicker oxide layer, say $Xj/5$ in thickness, or by depositing a diffusion barrier layer of SiO_2 over the doped oxide.

The segregation coefficient at the interface is apparently concentration dependent but the lack of an accurate measurement technique for boron limits the accuracy of our determination of this dependence. The diffusion coefficient of the B_2O_3 in the glass is concentration dependent at least in the 5-15 m/o range of doping, while the diffusion coefficient for boron in silicon is concentration dependent for the highest concentrations of this study.

The study has also shown that an oxidizing ambient will produce an SiO_2 barrier for diffusion at the silicon-glass interface with the oxide growth rate being nearly independent of the glass thickness. A similar, but always very thin, nitride layer might form when a nitrogen atmosphere is used during the diffusion heat treatment. No barrier was observed when argon was used as the ambient.

Acknowledgments

The author is indebted to Dr. J. Basi and Mr. C. Stalowski for providing the deposited oxide wafers and for assistance in making the electrical measurements. He would also like to thank Dr. J. Sandhu for his help and Mr. R. F. Lever for his valuable contributions during the evaluation of the data.

The Growth of Epitaxial Gallium Phosphide from the Vapor Phase by Halogen Transport

A. Mottram, A. R. Peaker, and P. D. Sudlow

Ferranti Ltd., Chadderton, Oldham, England

ABSTRACT

Gallium phosphide has been grown epitaxially by open tube vapor transport using the $H_2/PCl_3/Ga$ system. Although GaAs substrates have been used for the majority of the work, the more recent use of Czochralski grown GaP has enabled a reduction in both strain and stacking fault density of the epitaxial layer to be achieved. Sulfur, tellurium, and zinc have been used as dopants in the preparation of both n- and p-type layers, and relationships have been established between the dopant level in the vapor stream and the carrier concentration in the grown crystal. A Schottky diode technique has been used to detect variations in doping level throughout the depth of a slice and, after modifications to the growth process, uniform doping levels have been established. Measurements of the dependence of mobility on carrier concentration over the range 10^{14}-10^{19} cm^{-3} have been made on this substantially homogeneous material and consistent results obtained. The levels of compensation in n-type material have been shown to be between 1 and 2% over the range of carrier concentration 8 x 10^{16}-2 x 10^{18} cm^{-3}. The previously reported dependence of doping level on substrate orientation has been confirmed for (111) surfaces and extended to the (100) and (110) surfaces for homoepitaxy.

The growth of GaP from the vapor phase by halogen transport is a convenient method for the preparation of single-crystal slices, the $Ga/PCl_3/H_2$ system being used to deposit GaP epitaxially on single-crystal substrates of GaAs and GaP.

Previously published work describing this growth technique (1-3) has used various methods to incorporate dopants into the GaP but investigations into the homogeneity of the resultant GaP have not been made in any great detail, although some tentative conclusions have been reached by Taylor *et al.* (2). It is shown in this paper that unless adequate precautions are taken, very significant doping gradients are present in the grown gallium phosphide and it is thought that the use of modified growth techniques to avoid these gradients has enabled a considerable reduction in the scatter of the data relating to the GaP to be achieved.

In addition, a thorough examination of both the growth parameters and the doping processes involved has enabled a consistency of result to be established with the growth system. The material obtained, after removal of the GaAs substrate, has been in the form of self-supporting single-crystal slices and these have been used subsequently both as substrates in liquid epitaxy experiments and for planar array technology development.

Experimental Procedure

The apparatus, which is similar to that used by other workers for open tube vapor transport systems (4, 5), is shown schematically in Fig. 1. Close attention was paid to the elimination of all gas leaks and the complete apparatus was tested to be leak free at 10^{-2} Torr. As oxygen contamination of the gas stream during the growth process caused rapid nucleation and whisker growth of the GaP both on the substrate and in the surrounding deposition zone, a further precaution taken was to maintain the complete system at a pressure of 2-3 mm of mercury above atmospheric, thus keeping oxygen ingress to an absolute minimum. A three zone furnace was used in which the low-temperature region was only utilized for certain doping procedures, the center flat zone being used for the gallium source and the temperature gradient region for deposition purposes on the appropriate substrates. A liner tube was used to collect all dump products, thus enabling the same reaction tube to be used for a number of consecutive runs. Adhesion between the heavy deposit of GaP and the silica substrate holder in the deposition region, besides making removal of the slice from the silica plate difficult, often led to cracking of the grown slice before its removal from the apparatus. A hard carbon film, produced by the thermal cracking of acetone, deposited on the silica plate before insertion in the apparatus, overcame these problems by preventing adhesion, and a film similarly deposited on the liner tube prevented the severe cracking and erosion that normally takes place when the quartz apparatus cools down after deposition. As the presence of carbon in the reaction tube did not have any influence on the electrical properties of the grown material, carbon coating of the liner tube and substrate holder was used as normal procedure in the vapor epitaxy system. The liner tube was restricted to a maximum inner diameter of 19 mm; when larger tubes than this were used, streaming of the vapor resulted in incomplete reaction at the gallium source and inconsistent deposits of gallium phosphide in the growth zone.

A supply of 99.99% pure H_2, further purified by diffusion through a Pd/Ag tube, is passed through 99.999+% PCl_3 at 23°C and diluted using a by-pass supply of the purified hydrogen, thus enabling a wide range of PCl_3 partial pressures to be obtained in the system. The vapor stream is passed over the heated

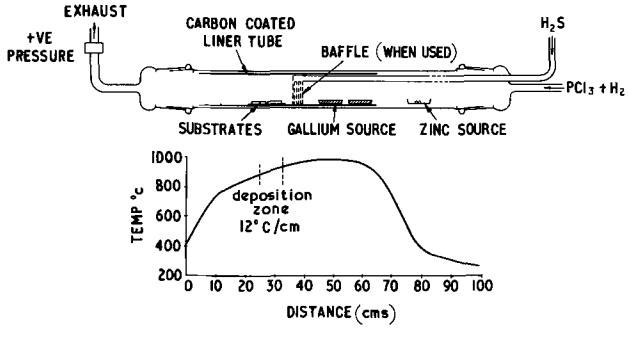

Fig. 1. Schematic diagram of the growth system and temperature conditions for the deposition of epitaxial gallium phosphide.

Key words: gallium phosphide, epitaxial, vapor phase, halogen transport, doping gradients.

gallium source and then down the temperature gradient in which a GaAs or GaP seed is situated. Epitaxial deposition of the GaP takes place on the substrate. For the normal growth system the following conditions have been established for a typical process: 35-40 ml min^{-1} of H_2 is passed through the PCl_3 and diluted to 100 ml min^{-1} with H_2, passed over the gallium source held at 970°C and then down a temperature gradient of 12°C cm^{-1} in which the substrate is situated at a temperature between 850°-910°C. A growth rate of 50-80 μm hr^{-1} has been obtained on (111)A orientated GaAs seeds with these conditions, which together with a growth period of 3-5 hr gave reproducible single-crystal GaP layers up to 400 μm thick. Both 25 and 50g gallium sources have been used, the PCl_3 figure quoted being that for the 50g source, while a correspondingly lower flow rate has been used for the 25g source. It was found that the optimum deposition temperature and the growth rate of the GaP layer were both dependent on the flow rate of the PCl_3, this single item being the principal factor governing the reproducibility of the growth. Complete quantitative examination of a small number of runs and a more comprehensive analysis of the relative Ga and PCl_3 consumption rates over a large number of runs have given experimental evidence for the proposed over-all reactions involved.

Examination of furnace profiles throughout the investigation has shown that the growth rate of the epitaxial layer is partly dependent on the temperature gradient of the growth zone. Under identical flow conditions a gradient of 6°C cm^{-1} gave smooth layers at growth rates up to 40 μm hr^{-1}, 12°C cm^{-1} increased the growth rate to 80 μm hr^{-1} while still maintaining smooth layers, but any further increase in the gradient resulted in hillocky growth.

The conditions outlined above were established for growth on the (111)A face of substrates of undoped n-type GaAs orientated within $\pm\frac{1}{2}°$, with dislocation densities $< 5 \times 10^3$ cm^{-2}. This orientation was chosen for the majority of our experiments because it was the fastest growing face and our prime concern, when growing on GaAs substrates, was for the preparation of self-supporting single-crystal slices. Prior to growth, the substrates were lapped, polished with diamond paste of particle size no greater than 1 μm, etched for 2 min in 3 : 1 : 1 $H_2SO_4/H_2O_2/H_2O$ at 60°C to remove any work damage, and finally etched in 1 : 9 : 10 $HF/HNO_3/H_2O$ at 50°C for 1 min immediately prior to insertion in the apparatus. The substrate was positioned (111)A face uppermost on the flat, carbon-coated, quartz spade. The furnace was heated with the substrate situated in the growth position and the reaction started without any deliberate back-etching procedure. Measurements taken on six consecutive runs have shown automatic back etching to take place, between 100-120 μm being removed in each instance. During the growth process, the GaP would normally be deposited on all faces of the substrate. A SiO_2 mask deposited on the (111)B face of the GaAs substrate, by pyrolytic decomposition of tetraethoxysilane, prevented deposition of GaP on this face and simplified removal of the GaAs after growth. This was done by first etching away the SiO_2 layer with HF and then dissolving the GaAs in hot 50% HNO_3. The (111)B face of the grown GaP layer was then lapped and polished to remove any $GaAs_xP_{(1-x)}$ deposit formed at the interface. The majority of slices of GaP obtained by this technique were self-supporting and single crystal. Growths have also been made on the (111)B, (100), and (110) faces of similar GaAs substrates as well as on all four principal orientations of GaP substrates grown by a liquid encapsulated Czochralski technique (6).

Undoped, sulfur, tellurium- and zinc-doped material have been grown using the standard procedure. Sulfur was introduced into the growth system as hydrogen sulfide, either directly from a bottled supply of 99.5% H_2S or by hydrogenation of 99.999% sulfur vapor in a small tube furnace held in excess of 800°C. Tellurium doping was obtained by adding Te metal to the gallium and continuing the growth technique in the usual manner. Zinc vapor was introduced into the growth ambient by passing the H_2/PCl_3 gas stream over a pellet of zinc situated in the low-temperature zone of the furnace prior to the gallium source.

Hall and resistivity measurements have been used to determine the carrier concentration and mobility of all the vapor epitaxial layers after removal of the GaAs substrate. The van der Pauw technique (7) with either clover leaf or trapezoidal samples has been employed and the measurements taken in a field of 1 kGs at a temperature of 20°C. A number of samples were also measured over a range of temperatures. Alloyed contacts were made in all cases in an atmosphere of 90% N_2/10% H_2, using either pure Sn or Au/2% Sn alloy for n-type material and Au/2% Zn alloy for p-type material. All undoped material grown on GaAs substrates proved to be high-resistivity n-type and the Au/2% Sn alloy was successfully used for contacting.

Doping gradients were investigated by evaporating a square mesh pattern of circular gold Schottky barriers over an angle lapped region of the grown slice and measuring the differential capacitance-voltage characteristics of the individual barriers. This type of construction provided discrete measurements of impurity concentration at equal intervals below the semiconductor surface, the impurity concentration being derived by the use of well-known theoretical relations from the *C-V* data obtained. This technique is described in detail elsewhere (8).

Results and Discussion

Over-all reaction.—A study of the amounts of gallium and phosphorous trichloride used in over two hundred standard runs showed the Ga/PCl_3 consumption ratio to be independent of the PCl_3 flow rate for the range of flow rates investigated, and a plot of the results (Fig. 2) gave an average mole ratio of 2.56. The amount of Ga used during each run and the weight of PCl_3 consumed over a number of consecutive runs were measured for each separate batch of PCl_3. This means that each point on the curve is in effect an average of not less than seven consecutive growths. The results were obtained from runs in which slow PCl_3 flow rates used a 25g Ga source and faster rates a 50g source. The mole ratio of 2.56 $\pm$ 0.1 is in agreement with the value of 2.64 predicted from thermodynamic data and supports the result of 2.5 $\pm$ 0.2 obtained with the halide transport system by Luther and Roccasecca (3). The weight of the GaP skin formed on the unused part of the 25g gallium source during

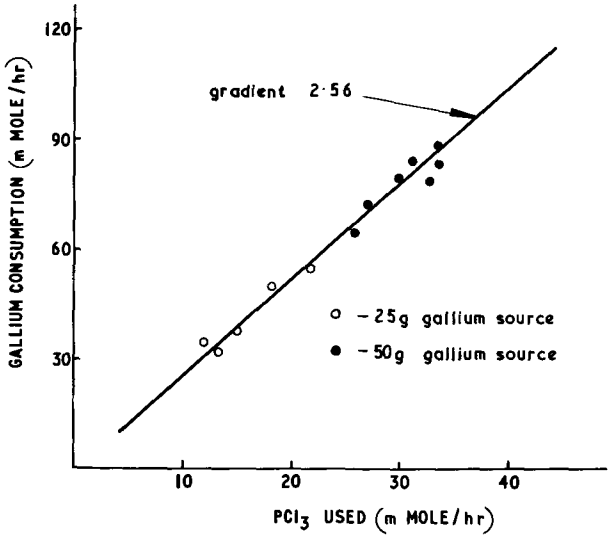

Fig. 2. Gallium:phosphorous trichloride consumption ratio

cooling was approximately 0.25g in each instance. This corresponds to the complete saturation of the gallium with phosphorus at 970°C (9) and indicates that the phosphorus-saturated gallium is very close to being in equilibrium with solid GaP during the growth process.

Observation of the early stages of the growth process showed that during the initial saturation of the source, gallium metal was transported to the dump end of the reaction tube and the GaAs substrate was back-etched to the extent of 100-120 μm by the excess halides present. If the PCl_3 was in excess at this stage, then the formation of white, needle crystals of $GaCl_3$ was apparent at the cold end of the tube, whereas the formation of the grayish $GaCl_2$ deposit indicated that the correct flow rates were being used. It has been assumed in previous publications that both the di- and trichloride are only present in negligible amounts at 970°C, and indeed the agreement between the practical Ga/PCl_3 consumption ratio and the theoretical value, in which $GaCl_2$ has been neglected, indicates that only GaCl and HCl are present in the reaction zone at 970°C. A further reaction must, therefore, take place in the deposition zone in which the incoming fraction of HCl which does not react with the gallium converts the monohalide to the dihalide. The $GaCl_2$ invariably shows some dissociation into Ga and $GaCl_3$, but this process is not included in the over-all scheme of the reaction. The above points indicate that the reaction may be described as follows

$$4PCl_3 + 6H_2 \rightarrow 12HCl + P_4 \quad \text{— } H_2 \text{ through the } PCl_3 \quad [I]$$

$$P_4 \rightarrow 2P_2 \quad \text{— Dissociation} \quad [II]$$

$$2Ga + 2HCl \rightarrow 2GaCl + H_2 \quad \text{— At 970°C} \quad [III]$$

$$4GaCl + 2HCl \rightarrow 3GaCl_2 + H_2 + Ga \quad [IV]$$

$$2Ga + P_2 \rightarrow 2GaP \quad \text{— At the deposition zone} \quad [V]$$

If at any stage the gallium source is reduced to a low level, then the excess HCl present in the growth zone can act as a transporting medium for the GaP previously deposited and a situation can arise whereby not only the GaP but also the GaAs seed can be completely removed by the HCl.

A quantitative examination of a number of experiments was made by measuring the weights of pure Ga and PCl_3 used during the run, weighing the total products obtained from the reaction, dissolving away the dump products, and finally reweighing the pure GaP formed. The results showed that the over-all equation most acceptable for the reaction was

$$5Ga + 2PCl_3 \rightarrow 2GaP + 3GaCl_2$$

This agrees with the above scheme of reaction and also supports the result observed by Kamath and Bowman (5).

Physical properties of the grown GaP.—Although layers were grown on the (111)A, (111)B, (100), and (110) orientations of both GaAs and GaP, very smooth surfaces were obtained only on the (111)A face, and as this was also the fastest growing surface it was used for the majority of growths where removal of the GaAs substrates was required. After removal of the GaAs substrate the GaP layers were shown to be self-supporting, and x-ray diffraction studies confirmed that they were single-crystal growths.

A comparison of the layers grown on both substrate materials showed those grown on GaAs to have much higher stacking fault and dislocation densities, as well as a great deal of residual strain in the crystal. Stacking faults and dislocations were revealed as line and point defects, respectively, by etching the (111)A face in boiling $K_3Fe(CN)_6/KOH/H_2O$ 2/3/25 for 60 sec (10).

Layers grown on GaAs always had densities $> 2 \times 10^5$, this being the case even when the GaAs was dislocation free. On the other hand the dislocation densities of those layers grown on GaP were more dependent on the substrate and were never greater than 2×10^5 even on substrates with a dislocation density (D) $> 10^6$. On good quality substrates ($D \leq 10^4$) the epitaxial layer was uniformly dislocated in the low 10^4 region.

It can be seen from Fig. 3a and b, which show representative areas of epitaxial layers grown under similar conditions on GaAs and GaP, respectively, that an order of magnitude increase in dislocation density caused by the use of GaAs substrates is represented by the predominance of dislocations aligned along slip planes; this is compared to a fairly uniform distribution of dislocations when GaP substrates were used. It is fairly obvious that the aligned dislocations are a result of the heteroepitaxy nature of the GaAs/GaP system in which the 4% lattice and 15% thermal mismatch between GaAs and GaP (11) causes severe strain in the epitaxial layer during cooling. The uniform distribution of dislocations observed when GaP substrates were used ($\sim 2 \times 10^4$ cm^{-2}) can be attributed to the growth conditions (deposition rate, thermal gradient, etc.). Progressive polishing and etching of layers throughout their total thickness (up to 500 μm) showed this level of dislocation to remain constant throughout the layer. A number of layers exhibited severe pitting which occurred during the latter part of the growth process, an example is shown in Fig. 4a. These appear to occur under conditions when excess HCl would be expected to be present in the vapor stream and are probably at the sites of impurity segregation caused by the dislocations formed at the growth temperature. The only other major surface

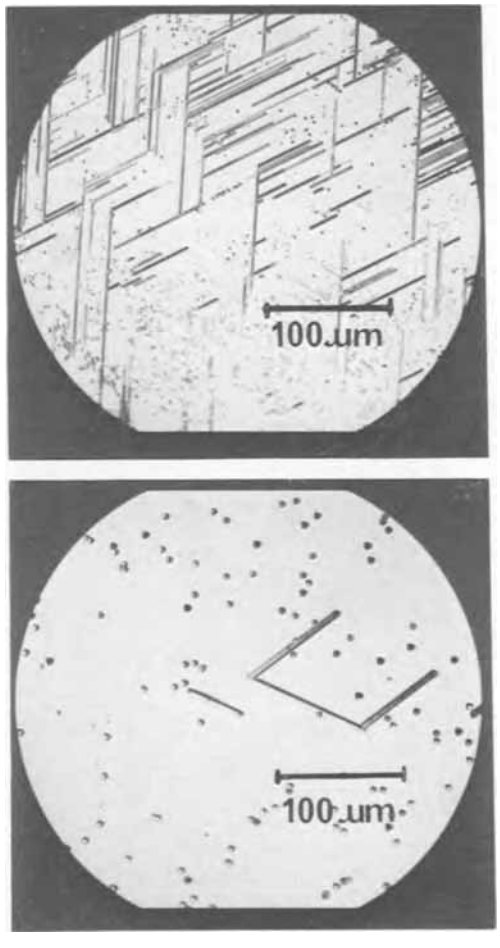

Fig. 3. Comparison between GaP layers grown on GaAs and GaP substrates, (a, top) shows the case in which a GaAs substrate was used and (b, bottom) the improvement obtained by using a GaP substrate.

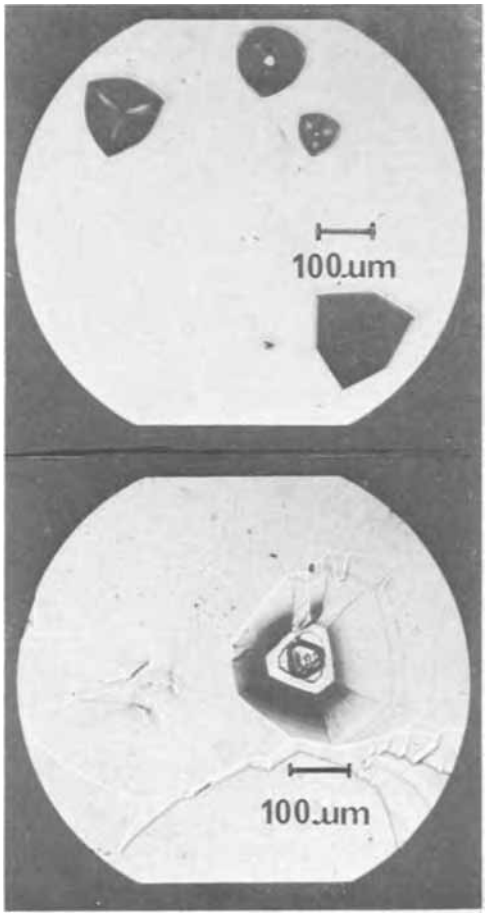

Fig. 4. Major surface defects on the GaP formed during growth, (a, top) pitting, (b, bottom) hillocks.

defect has been the formation of growth hillocks as shown in Fig. 4b. These are similar to those reported in GaAs epitaxy and have been attributed to dust particles or gallium droplet formation on the surface of the substrate immediately prior to GaP nucleation (12).

The difference in thermal expansion coefficients between the GaAs substrate and the GaP causes a pronounced curvature in the structure after cooling, and during the last stages of removal of the GaAs, microcracking at the interface is often observed. This extends a small distance into the GaP and together with the obvious inhomogeneity at the interface means that the (111)B face of the grown slice had to be lapped and polished before any further use could be made of it. Small inclusions, darker in color, found on the (111)B face, were determined by electron microprobe analysis as being regions of $GaAs_xP_{(1-x)}$ and mass spectrometric analysis of the GaP showed arsenic to be present in most layers between 0.01 and 0.1%. These results were obtained from layers where the GaAs substrates had no SiO_2 film on the (111)B face and it can be assumed that in all cases where the protective film has been used the arsenic contamination will have been somewhat reduced.

Doping gradients.—The gaseous doping technique initially used for sulfur, which involved passing a diluted supply of bottled H_2S into the vapor stream prior to the gallium source, was found to produce severe doping gradients throughout the entire thickness of the grown layer. Variations in doping level were found by angle lapping the crystal and using Schottky barrier measurements at fixed points throughout its thickness as described previously. The large variations of impurity with depth in earlier layers as seen in Fig. 5 are caused by the absorption of the sulfur by the gallium during the early stages of

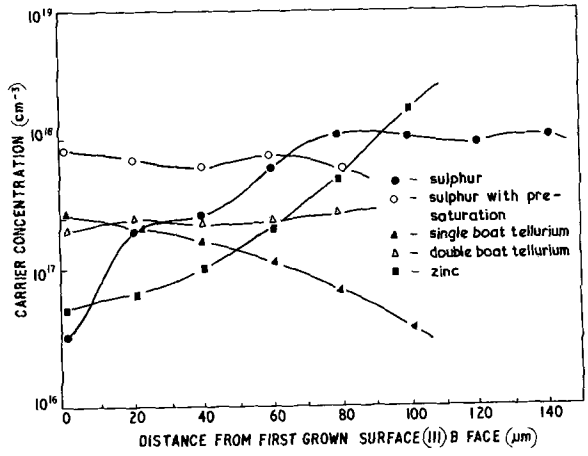

Fig. 5. Variation of carrier concentration with depth in epitaxial layers of GaP.

growth, followed by random fluctuations in the flow rate of the H_2S vapor during the remainder of growth. Elimination of the absorption effect was effected by either pre-quasi-saturation of the source or by the use of a baffle so that the dopant stream bypassed the gallium, this latter system caused nucleation prior to the deposition zone and was therefore later dispensed with. As minor fluctuations in flow conditions were found difficult to eliminate, very fine valve control being required over periods of 3-4 hr, the alternative means of sulfur doping by hydrogenation of sulfur vapor was used. This proved to be a much simpler system to control, as the doping level could be regulated by adjusting the temperature of the solid sulfur source and keeping the hydrogen flow over the dopant constant at 10 ml/min. A similar system of presaturation was again used and a typical doping profile through a grown layer (Fig. 5) indicated that a stable carrier concentration was established and maintained from the onset of growth.

Doping gradients were also present in tellurium- and zinc-doped layers, although in neither case were they as severe as sulfur. The tellurium-doped layers have since been grown free from severe doping gradients by using a double-boat gallium source. Both boats of gallium are identically doped with pure Te metal and held in the flat temperature zone in the reaction tube. One of the sources remains virtually unchanged throughout the entire growth period and thus provides a constant Te vapor pressure. A similar single-boat system yielded layers which were Te depleted toward the last grown surface, and Fig. 5 shows a comparison in doping profile of two layers grown by the separate systems.

Profiles of the zinc-doped layers indicated that although a constant doping level was maintained over their surface, a rapid rise in carrier concentration occurred toward the last grown face (Fig. 5). Although the absorption of zinc by the gallium source has been previously calculated by Luther and Roccasecca as being 3% of the total amount of dopant transported during the run (3), the evidence presented here suggests a much greater loss to the source and an effect similar to that seen in the sulfur-doped layers occurs in which zinc is absorbed into the gallium source during the earlier stages of growth.

Investigations of doping gradients in material with a mean carrier concentration of approximately 10^{18} cm^{-3} grown on gallium phosphide substrates and on orientations other than (111) have shown that the gradients observed in the material other than at the actual GaAs/GaP interface are functions of the growth conditions and not of the orientation or nature of the substrate. This is in contrast to the results of Taylor *et al.* (2) for selenium-doped material which indicated from Hall measurements and progressive lapping that the carrier concentration increased in the growth di-

rection on samples grown on GaAs but not on GaP substrates.

Electrical measurements made on early samples which were shown to have doping gradients or striations of varying carrier concentration throughout their depth indicated that the Hall value as measured by the van der Pauw technique gave a value weighted toward the more highly doped strata. For the almost uniform profiles now observed in slices grown by the modified techniques, the Hall measured values are in agreement with the free carrier concentration calculated from the Schottky diode measurements, and it is layers of this type that have been used in the investigations described in the remainder of this paper.

Although the variation in carrier concentration along the length of any individual crystal was found to be minimal, a check was made on the variation along the entire deposition zone. A factor of two change was observed over the temperature range 910°-850°C, the higher values being obtained at the higher temperature. Layers grown at lower temperatures as well as having low carrier concentration were also of poor surface nature. The growth zone, covering a range of 60°C, had a length of 5 cm and was therefore suitable for multiple crystal growths.

Added impurity and carrier concentration.—All carrier concentration values in this section were determined from GaP layers grown on (111)A orientated GaAs substrates. Undoped layers were always n-type with resistivities of the order 10^3 ohm-cm and carrier concentrations in the 10^{14} cm^{-3} range. Reproducible values for sulfur, tellurium, and zinc doping were obtained over the range of doping levels investigated.

For each of the dopants used a relationship was established between the impurity present in the vapor stream and its incorporation into the grown crystal in an electrically active form. In Fig. 6 a plot of the room temperature carrier concentration against the sulfur vapor pressure shows an almost linear relationship to about 2 x 10^{18} cm^{-3}. Above this value the carrier concentration tends to level off with further increases in the sulfur vapor and the crystal takes on a metallic appearance as the carrier concentration approaches 5 x 10^{18} cm^{-3}. At this point the solid solubility of sulfur in gallium phosphide is limiting the electrically active impurity concentration and an increasing proportion of the sulfur is present in the form of precipitates or neutral complexes at room temperature. A similar situation can be seen to occur in the case of tellurium, although the relationship is sublinear at a somewhat lower level. It is thought that complexes such as $GaTe_3$ are present in an electrically inactive form at the higher concentrations. A similar effect has been noted by Taylor in selenium-doped GaP, saturation occurring at a carrier concentration of 2 x 10^{18} (13).

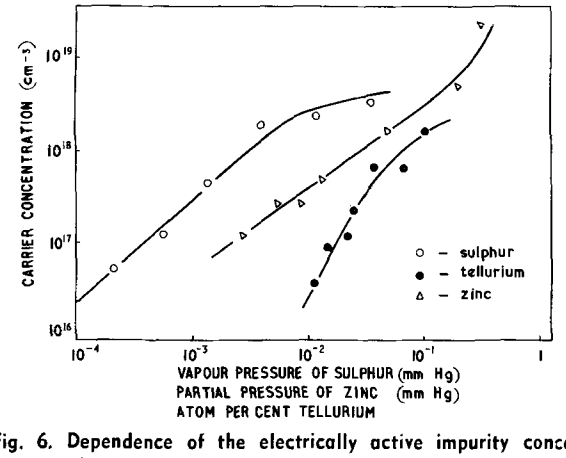

Fig. 6. Dependence of the electrically active impurity concentration in the grown crystal on the impurity level present in the vapor stream.

The case of zinc-doped material is somewhat different as the solid solubility of Zn in GaP at the growth temperature is known to be considerably higher than the impurity levels used (14) and there is no evidence for the formation of precipitates on cooling over the range of carrier concentrations investigated. In the region 10^{17}-10^{19} cm^{-3} the carrier concentration-partial pressure relationship is slightly sublinear, above this region the carrier concentration increases considerably faster than the partial pressure. This could be explained by the observations of Foster *et al.* (15) and Casey *et al.* (16) who measured hole densities greater than the zinc concentration in solution-grown and diffused gallium phosphide, respectively.

For the three separate dopants, over a limited range, a linear dependence of impurity concentration on the partial pressure of the dopant has been established when growth takes place on the (111)A face. For an extrinsic semiconductor, grown under equilibrium conditions, a square root dependence is normally expected and has in fact been observed both in solution (17) and vapor growth (18). The deviation observed here has been reported elsewhere (3) and can be attributed to the incorporation of the impurity being a nonequilibrium process in the halogen transport system. At the comparatively low temperatures used for deposition the diffusion of the dopants is slow, and fast growth rates have been used for the growth of all crystals measured. This means that a nonequilibrium situation is established between the absorption of the dopant atom on the growth face and their incorporation into the bulk crystal and creates the linear dependence observed.

Effect of substrate.—Unlike GaAs epitaxy in which the smoothest surfaces have always been obtained using substrates misorientated from the low index planes by a few degrees (19), misorientation of (111)A GaAs substrates by 1°, 2°, 3°, and 6°, produced increasingly severe pitting in the grown layer and a requisite of reproducibly smooth growths on this face was for the orientation to be within ±1° after polishing. The effect of misorientation on the other planes was not investigated and therefore a strict comparison with GaAs is not possible at this stage.

Although a high percentage of the runs carried out have used (111)A orientated GaAs substrates and consequently the information on doping levels, *etc.*, is particularly relevant to this orientation, a number of runs have been made on the other three principal orientations (111)B, (110), (100) of both GaAs and GaP.

Under similar flow conditions the growth rates could be placed in the order (111)A > (110) > (111)B > (100). This order appeared to be independent of the substrate material (GaAs or GaP) and under the flow conditions previously stated the growth rates were approximately 80 μm hr^{-1}, 50 μm hr^{-1}, 40 μm hr^{-1}, and 10 μm hr^{-1}, respectively. Layers grown on the (111)A orientation of either GaAs or GaP had mirror-like surfaces and were of uniform thickness, while the other orientations were generally faceted and of uneven thickness. Figure 7 shows a polished (111)A orientated GaAs substrate, an epitaxial GaP layer with the GaAs still intact and an unsupported single-crystal wafer of GaP.

The dependence of carrier concentration on growth orientation as observed on the (111)A and (111)B faces for both n- and p-type dopants as previously reported by Taylor *et al.* (2) is supported by the results obtained here for both GaAs and GaP substrates (Table I). Undoped layers grown on the (111)B face of both GaAs and GaP are strongly n-type with carrier concentration of the order 10^{17} cm^{-3}, whereas similar layers grown on the (111)A face prove to be high resistivity (10^3 ohm-cm), n-type for cases in which GaAs substrates were used and high resistivity p-type for GaP substrates. Previously reported values for undoped layers grown in the (111)A face have been p-type, and the result observed here can probably be accounted

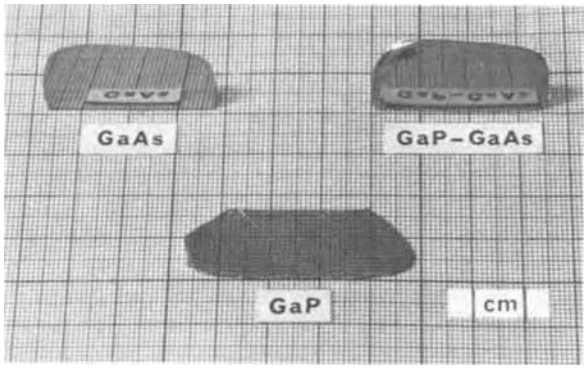

Fig. 7. Example of a GaAs slice; an epitaxial layer of GaP with the GaAs substrate still intact; and a polished self-supporting slice of epitaxial GaP.

for by autodoping from an n-type impurity present in the GaAs substrate.

A number of layers grown simultaneously on both the (111) faces of GaAs substrates showed that donor impurities (S, Te) were incorporated more readily into the (111)B face by a factor of between 10 and 30, while the acceptor zinc showed a similar marked preference for the (111)A face.

The use of GaP substrates, which removed the necessity of producing thick growths, meant that the orientations dependence could be investigated on all four principal orientations. A combination of the reduced layer thickness and the use of n-type (high 10^{17} cm^{-3}) substrates meant that the Schottky diode technique previously described was more suitable for carrier concentration determinations for growths on GaP substrates, and this method was used for all such values reported in Table I. It can be seen, that although the donor atom preference for the (111)B face is similar to that previously observed, the doping levels for both the (100) and (110) orientation are approximately midway between the two extremes and differ from the values observed by Taylor (13), where the doping levels tended to be biased toward the preferred orientation (111)B in each instance. The undoped values are similar to those reported and show both the (110) and (100) to be n-type at a level of 6×10^{16} and 8×10^{15}, respectively.

The orientation effect can be explained by the difference in bonding behavior of the orientated surfaces. A Group VI donor atom will substitute for a P atom in the lattice, this means that on the (111)A (Ga) face the donor atom will be loosely held by only one bond while on the (111)B (P) face three Ga atoms are available for bonding. The more loosely held donor atoms on the (111)A face will have a greater tendency to be lost to the vapor stream and thus establish a lower doping level in the crystal for similar growth conditions. A similar argument can be put forward for both the (100) and (110) values obtained. In the former case each P atom is bonded downward into the crystal to two Ga atoms, and normally would bond upward to another two Ga atoms. The donor atom, replacing the P atom and subsequently having two surface bonds, would therefore have a bonding force somewhere between the values obtained for the (111) faces. For the (110) surface, where each P atom makes two bonds to Ga atoms on the surface and only one bond to a Ga atom in the underlying layer, an arrangement similar to the (111)A face can be seen. The donor atom is only loosely held by one bond in the underlying layer, but this is immediately supported by two surface bonds, which again would lead to a bonding force somewhere between the opposite face (111) values.

Table II. Donor and acceptor concentrations

Sample	Dopant	N_D, cm^{-3}	N_A, cm^{-3}	E_D, meV
319	S	$(2.05 \pm 0.1) \times 10^{18}$	$(5.3 \pm 0.1) \times 10^{16}$	80 ± 5
371	S	$(8.0 \pm 0.3) \times 10^{16}$	$(1.2 \pm 0.3) \times 10^{15}$	107 ± 10
383	S	$(8.8 \pm 0.2) \times 10^{17}$	$(8.6 \pm 0.2) \times 10^{15}$	97 ± 10
2/213	Te	$(7.5 \pm 0.2) \times 10^{17}$	$(1.1 \pm 0.2) \times 10^{16}$	81 ± 10

Donor and acceptor concentrations.—The donor and acceptor concentrations and the donor binding energy of sulfur and tellurium-doped material have been determined by Hall measurements. The analysis (20, 21) assumes that only one donor level is present and that $N_D > 10\ N_A$, it also equates Hall and drift mobility. The experimental results obtained over the temperature range 80°-350°K were fitted to the relationship

$$\frac{n(n + N_A)}{N_D - n - N_A} = N_c \left\{ \frac{m^*}{m_o} \right\}^{3/2} g^{-1} \exp - \frac{E_D}{kT}$$

putting

$$N_c = 2(2\pi m_o\, kT/h^2)^{3/2}$$

Where n is the concentration of conduction electrons per cubic centimeter, N_D and N_A the donor and acceptor concentrations, N_c the effective density of states in the conduction band at temperature T, g the degeneracy factor associated with the donors, m^* the effective mass of the electrons, and E_D the donor binding energy. The results obtained on four typical samples are shown in Table II. It can be seen that the acceptor concentration increases with the donor concentration representing between 1 and 2% of total impurity content. It seems unlikely that this could be attributed to impurities in the hydrogen sulfide used for doping as the level is so high and is probably due to autocompensation effects associated with vacancies.

The values deduced for donor binding energy are in agreement with the results of Montgomery and Feldman (22) obtained on crystals produced by the floating zone technique. They show a linear relationship between E_D and $N_D^{1/3}$ which implies that the variation is due to interaction between donors.

Hall mobility.—The highest mobilities, measured at 20°C, were those of undoped samples with background carrier concentrations of 10^{14} cm^{-3}, the values obtained being in the range 140-150 $cm^2\ V^{-1}\ sec^{-1}$. As

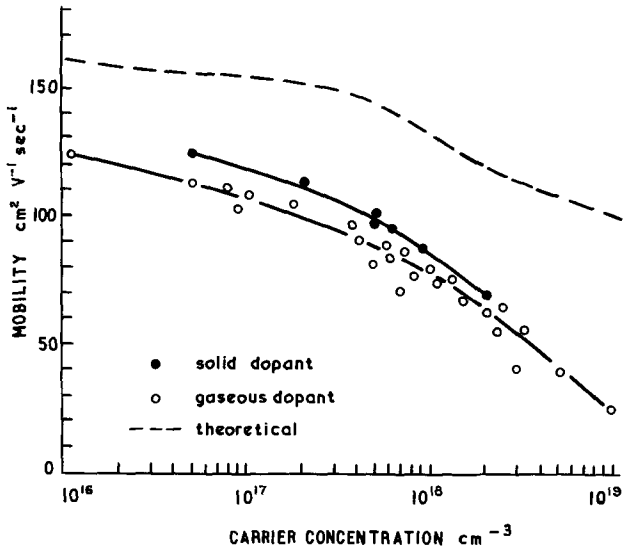

Fig. 8. Relationship between mobility and carrier concentration for sulfur-doped gallium phosphide at 20°C.

dopants are added the mobility falls, the values for sulfur-doped material being shown in Fig. 8. The mobility of layers doped using the solid sulfur source are approximately 10% higher than those prepared with the gaseous doping source. It is unlikely that this can be accounted for by the reduction in compensation due to the improved purity of the system and can almost certainly be attributed to the somewhat larger doping gradients in those layers doped via the bottled H_2S source and the improved homogeneity of the material prepared in the solid sulfur system as discussed previously.

The theoretical mobility relationship is derived from the work of Hara and Akasaki (23) and considers only the contribution of polar mode and ionized impurity scattering and assumes that the energy dependence of these relaxation times to be equal. The values calculated are much higher than those observed and as such discrepancies (30%) cannot be accounted for on the basis of the measured levels of compensation, it can only be assumed that other scattering mechanisms play a significant part.

The mobility of the tellurium-doped material (Fig. 9) is comparable with that of the sulfur-doped although the mobility decreases slightly more rapidly at the higher carrier concentrations. The results shown in Fig. 8 and 9 indicate that the hole mobility in zinc-doped GaP is considerably lower than the electron mobility in sulfur- and tellurium-doped material over the range 10^{16}-10^{18} cm^{-3}. At very high doping levels however, the hole mobility does not appear to fall rapidly as is the case with the electron mobility. This is probably a result of the much higher solid solubility of zinc and the consequent freedom from the additional contributions to scattering which will occur in the presence of sulfur and tellurium microprecipitates.

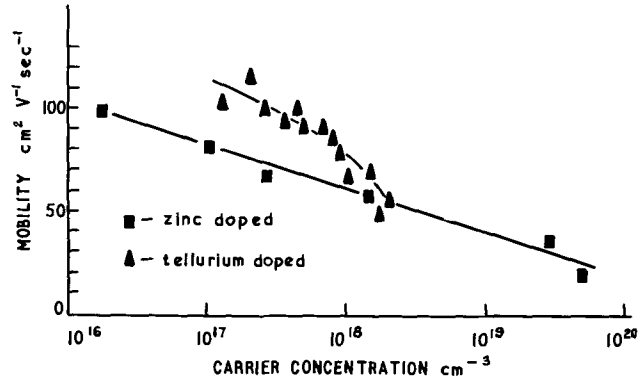

Fig. 9. Relationship between mobility and carrier concentration for zinc- and tellurium-doped gallium phosphide at 20°C.

Acknowledgments

We would like to thank Mr. M. Rowland of S.E.R.L. and Mr. R. Nicklin of the Plessey Company for helpful discussions, Dr. B. Smith and Mr. R. Grover of U.M.I.S.T. for their help with the electrical measurements and our colleagues at Ferranti for their assistance and advice. This work was done under a C.V.D. contract and is published by permission of the U.K. Ministry of Defence (Navy Department).

Manuscript submitted May 4, 1970; revised manuscript received *ca.* Sept. 16, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Tracer Investigation of Hydroxyls in SiO_2 Films on Silicon

P. F. Schmidt* and J. D. Ashner

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania 18103

ABSTRACT

The introduction of hydroxyls into steam-grown SiO_2 films on Si by application of an anodic bias about 20% below the forming voltage in a tritiated electrolyte has been measured; the concentration profile of the injected hydroxyls is exponential with distance. On contact with the electrolyte, there is an induction period during which the oxide surface is hydrated by reaction with the electrolyte; the electric field is able to aid the injection of hydroxyls only after hydration has taken place. At high field strengths the growth of anodic oxide films on Si occurs almost exclusively by cation drift; at low field strengths hydroxyls, if present in ample supply, are the mobile species and cause hydration of the growing or pre-existing SiO_2 film. Large concentrations of hydroxyls in the SiO_2 film enable penetration of protons from the electrolyte into a hydrogen-bonded network at low cathodic field strengths, whereas relatively "dry" SiO_2 films block the current also under cathodic bias.

It has been observed that lack of wettability by dilute HF solution is not necessarily an indication of a bare Si surface. Oxide-films 140-150Å were repeatedly seen to become hydrophobic. Beginning crystallinity of the SiO_2 film at the Si/SiO_2 interface has been observed rather regularly, both on (111) and (100) oriented surfaces. The detection efficiency when counting tritium from a thin solid film (about 88.4% for betas actually emerging from the front surface of the samples) in the Beckmann Low Beta II is excellent. We estimate that 2×10^{10} atoms H/cm^2 of a thin surface film can be conveniently detected by *in situ* counting.

This research was undertaken to gain a better understanding of the behavior of hydroxyl groups in thermal SiO_2 films, and also in order to clarify some questions left open by earlier work by one of the authors (1).

The tool chosen for this investigation was tritium tagging of the hydroxyl group of tetrahydrofurfuryl alcohol (THFA). It is not certain that incorporation of hydroxyl groups into growing SiO_2 films can proceed directly from the hydroxyl group of the alcohol; more likely the hydroxyl group is oxidized to water in a first step, and it is this water which then enters into the anodization reaction with the silicon (2). But regardless of the detailed mechanism, the method enables the incorporation and subsequent determination of the hydroxyl groups in the SiO_2 films. Aqueous solutions, as is well known, are not suitable anodization media for silicon because of the relatively high solubility of SiO_2 in water, which leads to the formation of porous films.

It is known that heavily tritiated organic compounds undergo autoradiolysis, with water being one of the reaction products, and that the rate of this radiolysis is accelerated by the presence of oxidizing species. Since water is detrimental for anodization of Si, it was not expected that the anodizing solution chosen for this work, 0.078M KNO_2 in THFA of a specific activity of 90 ± 10% curies/mole, would remain useful for anodization very long; the rate, however, at which deterioration would occur was unknown. This rate turned out to be too fast for many of the finer details which we had hoped to examine. But after the tracer solution had deteriorated to the extent that good quality anodic oxide films could no longer be grown in it, it still remained useful for the injection of hydroxyls into thermally grown SiO_2 films by subjecting these to an anodic bias. It was this latter type of investigation which yielded the more interesting results.

* Electrochemical Society Active Member.

Key words: anodization, growth mechanism, tritium counting, electrolytic rectification, mechanical stress.

We were specifically interested in the following questions: (*i*) role of hydroxyls in the anodic oxidation mechanism; (*ii*) concentration profile of anodically injected hydroxyls in thermal SiO_2 films; (*iii*) suitability of the Beckmann Low Beta II for determination of tritium in thin solid films; and (*iv*) effect of hydroxyl concentration in the SiO_2 film on electrolytic rectification by the film.

A comment is in order on the third of these points. Some of the literature on determination of tritium refers to *in situ* counting as the least attractive choice, because of low detection efficiencies and contamination of the counting chamber by volatile tritium compounds (3). These comments apply only to organic compounds. Thin inorganic films, composed of low atomic weight atoms, and with a thickness not much in excess of about 1000Å, should be ideal for *in situ* counting; at this thickness self-absorption of the low energy tritium betas is still negligible, and any tritium lost to the ambient as hydrogen gas or water vapor does not constitute a serious contamination problem; water absorbed on the walls of the counting chamber will readily exchange with moisture from the air.

The volatility of hydroxyls in (anodic) films was not known beforehand, but turned out to be sufficiently low not to interfere with the measurements. As expected, the counting efficiency for tritium in thin SiO_2 films turned out to be very high.

Experimental

The THFA was obtained from the Amersham (England) Radiochemical Centre through Nuclear Chicago Corporation. The activity upon receipt was 117 ± 10% curies/mole, but was reduced to 90 curies/mole by the addition of a solution of KNO_2 in normal THFA to arrive at a final concentration of 0.078 mole/liter of KNO_2. The water content of the tagged THFA, prior to the addition of KNO_2, was 0.7%, as established by infrared measurements. One week after addition of the KNO_2 the formation of anodic oxide films on bare Si surfaces became unsatisfactory, indicating that the water content had risen above 2%,

the highest water concentration tolerable for anodization of bare silicon; the solution, however, still was useful for anodization of thermally oxidized Si wafers. At the end of the investigation, about two months later, the water content seems to have risen above 5%.

Anodizations were carried out in a special anodization cell in which the cathode consisted of a mercury pool, and the reference electrode of an abraded tantalum wire. No hydrogen evolution could be detected at a Hg cathode in THFA, even at 100 mA/cm^2; thus the Hg cathode suppressed evolution of volatile tritium gas. Tantalum instead of platinum was used for the reference electrode in order not to catalytically accelerate the exchange of tritium in the hydroxyl group for hydrogen from the carbons atoms of the THFA molecule, thus reducing the effective activity during anodization. The anodization cell was cooled to 0°C before opening the vessel to further depress the vapor pressure of the THFA, already quite low at room temperature.

After anodization, wafers were carefully rinsed and swabbed to eliminate adhering solution, blown dry, and then counted *in situ* underneath the windowless detector of the Beckmann Low Beta II counting system. Highly active wafers had to be reduced in activity for the counting, in order not to jam the detector, by placing a metal mask over them, a small hole in the mask constituting a measured fraction of the total active wafer area.

Oxide thicknesses were determined by ellipsometry, and by means of a monochromatic light reflection technique (4), which enables film thickness measurements with good accuracy down to about 25Å. For determination of the concentration profile, the oxides were etched in 100-200Å steps in very dilute HF, the etching solutions saved, and later counted by means of liquid scintillation technique, while the wafers after each etching step were counted *in situ* with the Low Beta II.

In order to convert the counting rates to hydrogen concentrations, a standard is needed. Tritium standards are commercially available, however, only for liquid scintillation or for gas phase counting. The Low Beta II counts were therefore evaluated in two different ways.

1. A measured quantity of the tracer solution was diluted in a ratio 1:10^7, and the resulting solution counted by means of the liquid scintillation system,[1] for which the counting efficiency was known. Differences in counting rate between two etching steps obtained on the Low Beta II were then compared to the counting rates obtained by liquid scintillation on the etching solution stemming from the etching step in question.

2. A polymethylmethacrylate disk, supplied as a standard for gas phase[2] counting by New England Nuclear Corporation was counted in the Low Beta II, and the counting rate evaluated according to an approximation method indicated by Libby (5).

Comparison of the Low Beta II results with those from liquid scintillation lead to a detection efficiency of 88% for the Low Beta II (assuming that 50% of the betas were emitted in a direction which enables their detection); evaluation of the polymethylmethacrylate standard by Libby's approximation formula leads to a detection efficiency of the Low Beta II for tritium betas of 60%. We believe that the higher of the two figures (88%) is more nearly correct, but in any case it is obvious that the detection efficiency for tritium betas is indeed very high.

These counting efficiencies make sense when comparing various radioactive sources as to the average energy of the emitted beta particles, the number of ions formed per centimeter of path in air at atmospheric pressure (6), and the detection efficiency of the Low Beta II counting system as measured by us or stated by Beckmann Instruments (Table I).

[1] ANS—Picker Nuclear.
[2] After complete combustion of the plastic.

Table I. Comparison of radioactive sources

	Average energy of β's	Ion pairs/cm/particle	Detection efficiency, %
Tritium	0.0057 MeV	1520	88.4 (our determination, windowless)
Carbon^{14}	0.052 MeV	250	35 (Beckmann, ultra-thin window)
Phosphorus^{32}	0.675 MeV	46	15.25 (our determination, windowless)

The geometrical distances of the detection chamber are such that it appears reasonable that a large fraction of the ion pairs produced by the tritium primary beta will be able to reach the collector under the applied bias (1825V in the beta proportional region), whereas the primary beta from P-32 will be absorbed by the chamber housing after having traversed a distance of less than 1 cm, *i.e.*, before having had an opportunity to generate many ion pairs.

When comparing the advantages or disadvantages of using liquid scintillation or *in situ* counting in the Low Beta II for determination of tritium, it should be borne in mind that the efficiency of liquid scintillation detection is lower, and that the background of liquid scintillation is typically 15 counts/min, whereas the background of the Low Beta II is as low as 0.5 counts/min.

Results and Discussion

Anodic oxide films.—Mechanism of anodic oxide growth.—It has been shown by implantation of radioactive inert gas ions that both cations and anions move during anodization to higher voltages of anodic films on Al, Ta and W, whereas only oxygen ion movement was observed in ZrO_2 and HfO_2 (7). Silicon seemed to occupy a position by itself, in that experiments using P-32 as the marker indicated the motion of cations only; for instance, it is possible to encapsulate a phosphorous-doped anodic SiO_2 film in a layer of pure SiO_2 by anodization to a higher voltage (8) without loss of phosphorus to the solution or to the new-grown oxide layer, even at quite low phosphorous concentrations in the P-tagged film. It was, however, noticed that the constant current anodization of silicon must be done at a current density of not less than 3 mA/cm^{-2}, otherwise oxide films of inferior quality were obtained. The deterioration shows up as a slightly larger thickness/voltage increment, a slower decay of the current at constant voltage, and a larger final leakage current. The amount of water in the anodizing solution controls the current density at which deterioration of the anodic SiO_2 film becomes noticeable. The current density of 3 mA/cm^2 refers to a reasonably "dry" solution of KNO_2/THFA. This observation indicated that the mechanism of oxide growth on Si may be changing at lower field strengths. This expectation was fully confirmed by the tritium tracer experiment.

Anodization of silicon in dry electrolytes requires a field strength of about 2 x 10^7 V/cm; oxide growth rate falls to essentially zero if the field strength is lowered by 10% from the above value. Steam grown oxide films 1200-1500Å thick biased anodically in a dry electrolyte at a field strength of 1.5 x 10^7 V/cm do not increase in thickness beyond about 10-15Å, but the electronic leakage current through the film decreases with time to very small values (9). Initially the anodic leakage current of such a thermal SiO_2 film is much higher than that of an anodic SiO_2 film of the same thickness, but eventually decreases to values many orders of magnitude lower than characteristic of the anodic SiO_2 film.

This behavior changes with increasing water content of the anodizing solution. Substantial additional film growth occurred in the tracer solution on steam grown SiO_2 films at an initial field strength of 1.5 x 10^7 V/cm, but the leakage current, while decreasing with time, never reached the low levels characteristic of keeping the same films under anodic bias in a dry electrolyte. It also seemed that oxide growth did not stop at constant voltage (F = 1.5 x 10^7 V/cm, initially) at least not within reasonable lengths of time.

In the section on the concentration profile of injected hydroxyls it will be seen that the hydroxyls indeed penetrate all the way through the steam-grown oxide film. In other words, oxide growth at low field strength occurs by the inward motion of hydroxyl ions, thus leading to the formation of a hydrated, poor quality oxide film. Since even the driest electrolytes used for the anodization of silicon always contain some water during the actual anodization—it even appears possible that oxide growth may not occur in the complete absence of water—it can now be understood why anodization at current densities below 3 mA/cm^2 leads to oxide films of inferior quality. Silicon thus follows the pattern of aluminum with respect to the current density dependence of the cationic transport fraction during anodization, except that on silicon significant anionic transport commences at a rather sharply defined current density, whereas on aluminum the transition is rather gradual (7). It should, however, be noted that the current efficiency on Si is quite low, about 2.5% in the KNO_2/THFA solution, whereas on aluminum the current efficiency, while dependent on the particular anodizing solution, rarely drops below 60%. Thus when comparing total current densities, it must be remembered that the ionic current on Si constitutes only 2-3% of that on Al at the same total current density (*i.e.*, ionic + electronic current).

It is also worth noting that the theory of anodic oxidation is usually presented in a form which suggests that oxygen ions are the moving anionic species. We believe that hydroxyl ions may be carrying most of the anionic current during the anodization of some other metals as well, and that the oxide ions themselves are much less mobile than the hydroxyl ions. This is essentially the picture used by Hoar and Mott (10) to explain the formation of porous Al_2O_3 films, but it applies in all probability also to nonporous films.

In subjecting steam-grown SiO_2 films to an anodic bias in the tracer solution, an induction period, ranging from between 5 to 15 min could be clearly observed, during which time the leakage current of the film did not decrease. This incubation period is apparently related to a hydration of the oxide surface by reaction with water in the electrolyte. Dreiner (11) has observed a similar incubation period when following the increase of capacitance of anodic SiO_2 films in contact with electrolytes of different water content. The rate of capacitance change was independent of the *pH* of the solution, but depended on the water content of the solution. It could be accelerated, except for the incubation period, by application of a low anodic bias (insufficient to cause additional oxide growth). This result was interpreted to mean that the primary step involves reaction of the oxide surface with water in the electrolyte to produce OH groups: Si-O-Si + $H_2O \rightarrow$ 2 Si — (OH). The OH groups can then be acted upon by the electric field. An interesting aspect of Dreiner's work is the observation that the rate of change in capacitance with and without applied bias obeys a square-root-of-time law, though of different slope. This would tend to indicate that the field does not dominate the drift, but rather enhances the diffusion of the hydroxyl groups.

Hofstein (12), in a study of thermal SiO_2 films contaminated with ethanol, tritium tagged in the hydroxyl group, has shown that application of an anodic bias enhances tritium injection into the oxide film. In these experiments the SiO_2 surface was first contaminated by heating in ethanol for 15 min at 75°C, followed by evaporation of Al contacts and BT-stress at 250°C and 1 x 10^6 V/cm for 10 min. After removal of the bias, it was found, however, that the surface potential has not changed, indicating that the injected tritiated species is electrically neutral. Application of a cathodic instead of an anodic bias in the above experiment still permits injection of a tritiated hydroxyl, but at a reduced concentration compared to the anodic bias case. Hofstein suggested that the injected species is charged negatively only during some transition state at the metal/oxide interface at which point its injection into the oxide can be field aided. From Dreiner's work, and from the incubation period observed in this work, it appears, however, that the species is already inside the oxide at the time when its diffusion into the oxide can be accelerated by an electric field.

Two mechanisms appear plausible by which a strong electric field (about 4 x 10^6 V/cm at room temperature, as in Dreiner's experiments, or 1.0 x 10^6 V/cm at 250°C, as in Hofstein's work) might enhance the diffusivity of hydroxyls in SiO_2 films without dominating the drift: (*i*) distortion of the partially ionic SiO_2 lattice to facilitate the passage of the hydroxyl through constrictions along its path, and (*ii*) hydroxyl groups are known to be deep electron traps in SiO_2 (13). Since the anodic injection of hydroxyls is accompanied by a (relatively very large) electronic leakage current, many of the hydroxyls will become negatively charged by trapping of electrons. This should weaken the strength of the Si-OH bond, so that this bond will be broken more frequently than it would be in the absence of the field. The hydroxyl breaking away from a Si atom will probably not remain charged very long. It may become a free radical and re-attach itself at another lattice defect.

At the much larger fields used in our work (1.5 x 10^7 V/cm at room temperature) it might well be that drift will dominate over diffusion. Since we have made no rate studies, this question remains open.

Injection of tagged hydroxyl groups into steam-grown SiO_2 films also produced the answer to another question: Is it the degree of hydration or the change in structure, or both, which is responsible for the faster etch rate of anodic as compared to steam-grown SiO_2 films? Even though only the very slightest shift in the IR Si-O stretch frequency was noticeable after hydration of the steam-grown oxides in the tracer solution at 1.5 x 10^7 V/cm, the dissolution velocity of the hydroxyl-rich part of the film corresponded to that of anodic oxide films; the rate dropped back to that typical of thermal oxide when the hydroxyl concentration in the film dropped to low values. Thus it is mostly, or possibly exclusively, the degree of hydration which determines the etch rate.

It was pointed out before that the anodic resistance of the thermal oxide film increased as hydroxyls were being injected into it; this increase in resistance occurred without a significant change in structure of the film, since the IR spectrum showed almost no change. It would thus appear that the different structure of the anodic oxide film has relatively little to do with its electrical properties or its rate of etching. However, the oxide films hydrated in these experiments did not develop the very high electrical resistance typical of steam-grown oxide films anodized in a dry electrolyte, and it is quite possible that the very highest insulation resistance requires not only hydration of the oxide, but also a change in structure to that of the purely anodic film, this change in struc-

ture affecting the number and energy distribution of trapping sites. Elimination of crystalline nuclei by anodization (14) will, of course, also improve the resistivity of the film.

Mechanical stresses in anodic oxide films on Si.—In a separate study (15) it had been noticed that the mechanical stress in anodic oxide films is compressive at low forming voltages; goes through zero at about 1200Å, and becomes tensive at high forming voltages. Details depend on the forming solution. Prolonged exposure of a high-voltage film to moist air leads to a decrease in the tensive stress and can eventually reverse the sign of the stress. It was, therefore, thought that the transition from compressive to tensive stress with increasing film thickness is indicative of progressive dehydration of the growing film. This hypothesis can be checked by monitoring the tritium content of an anodic SiO_2 at successive anodization voltages, and by etchback from a given thickness.

The experiment was performed in a solution of 0.55g KNO_2 in 100 cc THFA with the addition of 0.5 v/o (volume per cent) H_2O, the water being tritium tagged to an activity of 50 mcuries cm^{-3}. This solution gave reproducible results.[3] It is still sufficiently dry that growth of anodic SiO_2 occurs only or almost only by cation migration, and keeping the film under constant voltage in this solution for 10 min (see below) does not falsify the hydroxyl profile of the as-grown film due to additional injection from the solution. The highest forming voltage that could be reached in this solution without deterioration of the silicon surface (a hazy appearance in reflected light) was only 210V. The maximum forming voltage in THFA for good quality SiO_2 films is apparently a sensitive function of the water content of the THFA (22).

A low resistivity P-type Si wafer was anodized at 10 mA/cm² in three 70V steps to 70, 140, and 210V. At each voltage the current was permitted to decay for 10 min at full forming voltage; the wafer was rinsed and swabbed to remove adhering radioactive liquid, and then counted in the Low Beta II system. The activity at the three different film thicknesses was little different, indicating that most of the activity in each case must be confined to the surface layer of the oxide. Actually, the activity of the film decreased in the ratio 1.00:0.93:0.90 with increasing film thickness. In the next experiment another wafer was anodized in one step to only 185V (10 min current decay) in order to avoid any possible surface deterioration, its activity measured, and the oxide then removed in small steps. The remaining activity was determined after each etch-back step. The result is shown in Fig. 1, where it can be seen that the activity, and therefore the hydroxyl content of the anodic oxide, does indeed decrease quite rapidly with increasing distance into the oxide.[4]

Only the general shape of the profile is important; not too much significance should be attributed to the individual points shown. Because of the required low activity of the tracer solution, long counting times were required to obtain sufficient number of counts. These long times in turn led to a loss of activity to the ambient, evident from a slight drop in counting rate during the course of an individual measurement. The error bars shown in Fig. 1 refer only to the counting statistics, they do not reflect the losses in activity to the ambient during counting. Also, the profile may differ from that obtained in a drier electrolyte.

Rectification behavior.—The tagged THFA solution, as received, did not permit the formation of cathodically blocking films, and the hydroxyl content of anodic SiO_2 films formed in this solution was very high already in the first anodizations tried (approximately 1×10^{20} cm^{-3}). The nonblocking property of the oxide was uniform across the whole surface of the (epitaxial) silicon disk. It was thus not possible to observe the gradual reduction of cathodic breakdown voltage with increasing hydroxyl content. The result, however, is what would be expected on the basis of the model postulated in (1), namely the easy penetration of protons into a hydrogen bonded network of hydroxyls.

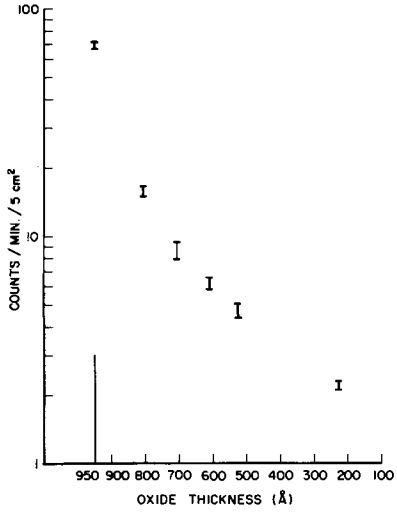

Fig. 1. Tritium activity profile in anodic oxide film grown to a thickness of 950Å in weakly radioactive KNO_2/THFA solution at a current density of 10 mA/cm². Current was permitted to decay to 1 mA/cm² during 10.0 min at the forming voltage of 185V.

Steam-grown oxide films.—Concentration profile of hydroxyl ions injected into steam-grown, SiO_2 *film.*—Figure 2 shows a typical concentration profile in a steam-grown SiO_2 film as obtained from *in situ* counting and from liquid scintillation counting. There is a small systematic shift between the two sets of data, which may stem from the assumption that 50% of the betas generated by radioactive decay are emitted under an angle leading to their detection. This assumption neglects the possibility of back-reflection, probably not a good assumption at the film

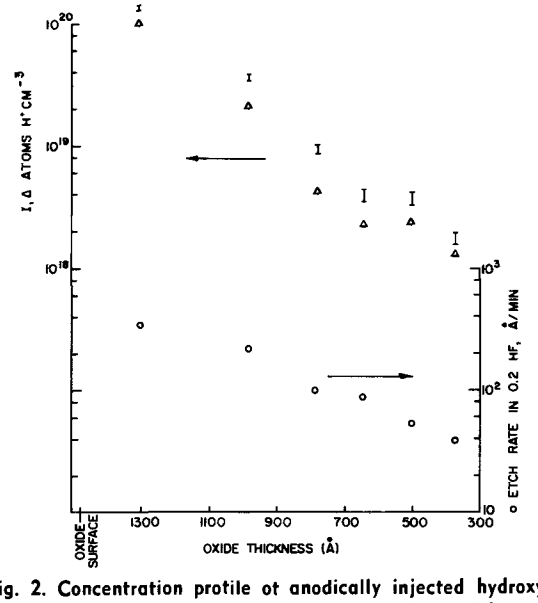

Fig. 2. Concentration profile of anodically injected hydroxyls in steam-grown SiO_2. Data from *in situ* counting (I) and from liquid scintillation counting (Δ), taken on the same sample. Bottom curve (O) shows etch rate of film *vs.* oxide thickness. The etch rate of a steam-grown (1050°C) SiO_2 film in 0.2*N* HF is approximately 20Å/min.

[3] Whereas the high activity THFA solution was not suitable for this experiment because of its high and rapidly varying water content.

[4] Dehydration of the oxide probably occurs by reaction of hydroxyls in the oxide with Si ions in transit through the oxide.

thickness employed. Also shown is the etch rate of the film in 0.2*N* HF.

It can be seen that the two sets of counting data are in good agreement with each other, and that the profile is exponential except for a deviation at about 800Å. A deviation in the etch rate is observed at the same film thickness. While the cause for these deviations is not known, it is believed that they are real and related to each other, as they were observed on a number of films. Error bars are shown for the Low Beta II data. The accuracy of the oxide thickness determination is about ±10Å in the oxide thickness range shown.

The fact that the diffusion profile shown in Fig. 2 is exponential rather than Gaussian suggests that initial penetration of the hydroxyls occurred along narrow channels rather than uniformly through the bulk. Lateral diffusion from the channel then results in an over-all diffusion profile that is exponential with distance, provided that the diffusion coefficient in the channel or grain boundary is much higher than in the bulk, as shown by Fisher (16) and by Smoluchovski (17). Channels of diameters "near atomic dimensions" have been postulated to exist in thermally grown SiO_2 films by Ing *et al.* (18) on the basis of permeation of gases through SiO_2 films. The channel area was found to occupy about a fraction of 10^{-8} of the total area. At first glance this degree of porosity looks too low to result in the uniform hydration of the anodized thermal SiO_2 films, as must be postulated on the basis of the very strong increase in electrical resistivity (9). In the gas permeation tests, however, a channel must be essentially open along the entire thickness of the film in order to enable fast diffusion of gases through the film. In the case of field-aided diffusion of hydroxyls this requirement may be relaxed considerably. This concept is also not in contradiction to the sodium drift results by Hofstein (12) since it is found there that only a small fraction of the total sodium is a fast diffusant. The same model of fast diffusion along "an inter-connected network of small disturbed regions" has also been used by Holmberg *et al.* in a very recent publication (23).

We are thus led to speculate on the existence of channel or grain boundaries in so-called amorphous films. It has been shown by Drobek (19) that steam-grown SiO_2 films crystallize quite readily even at room temperature. The eventual crystallization product is tridymite, with the open channels along the C-axis preferentially oriented perpendicular to the Si surface. Formation of tridymite, however, occurs via formation of beta-cristobalite, the latter having a close-packed, face-centered-cubic structure without any open canals in which enhanced diffusion could occur. Thus the grain boundary picture (rather than diffusion in open canals of a beta tridymite structure) appears more applicable. It was shown by Snow and Gibbs (20) that the open canals in natural quartz extend for an average length of 1000Å before being blocked by crystal defects. In the very poorly crystallized SiO_2 films (so poorly indeed that they have been regarded as amorphous until very recently) it is probably reasonable to assume that the length of grain boundaries will on the average be much less than 1000Å before the grain boundary terminates in a way that suppresses easy diffusion.

The extrapolated surface concentration of hydroxyls in the thermally grown SiO_2 film did not change from run to run, but the slope of the profile became progressively more shallow as the age of the anodizing solution; *i.e.*, its water content, increased. This change in slope is probably an indication that the diffusivity of hydroxyls in SiO_2 is concentration dependent, as indeed one would expect it to be.

Figure 3 shows the tagged, *i.e.*, newly introduced, hydroxyl concentration in a steam-grown SiO_2 film which was left in contact with the anodizing solution at room temperature for 28 hr without any bias applied. The profile shows the swing-up at the Si/SiO_2 interface also noted by Hofstein (12) for oxidized wafers heated in tritiated water at 100°C. The tritium is definitely present as hydroxyl groups and not as absorbed water. Even when the oxide films were etched down to thicknesses as small as 50Å, the remaining counting rate was quite stable during repeated measurements, indicating that the species present did not exchange rapidly with moisture from the air. It may also be noted in Fig. 3 that the hydroxyl content of the oxide after 28 hr in contact with the solution but without bias is considerably lower than after application of an anodic bias for 3-4 hr (Fig. 2). These two runs were taken a few days apart toward the end of the investigation, when the water content of the solution was no longer a rapidly varying function of time. The larger hydroxyl content in Fig. 2 shows directly the effect of the electric field on hydroxyl penetration. It should be pointed out that the applied field in Fig. 2 was considerably larger than in the corresponding experiments of Dreiner (11).

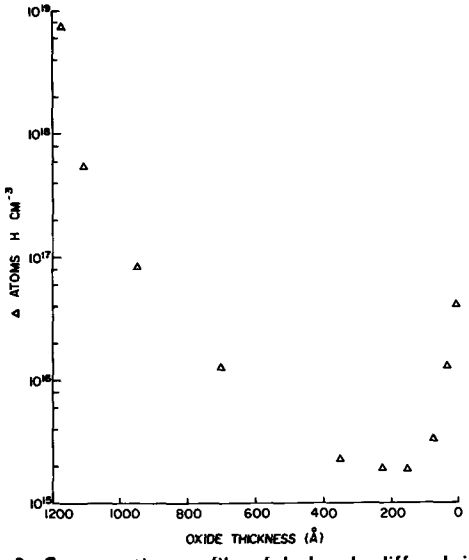

Fig. 3. Concentration profile of hydroxyls diffused into steam-grown SiO_2 at room temperature without application of a bias.

Wettability of oxide films.—A very interesting phenomenon was observed when etching down to very small oxide thicknesses. It was noted that the 0.2*N* HF ceased to adhere to the oxide surface at an oxide thickness of approximately 140Å, and water ceased adhering when the oxide thickness was approximately 25Å. There was still activity on the surface which could not be removed by further etching in 0.2*N* HF, and electron diffraction showed presence of a very thin film. Etching in buffered HF then would remove the last traces of activity.

Crystallographic effects on the adsorbtivity of HF and, consequently, on the dissolution rate of different crystal faces (and modifications) of quartz have been discussed by Ernsberger (21). The etching and wettability behavior appears reasonable if the oxide in the vicinity of the Si/SiO_2 interface is crystalline. Crystallinity of the nonwetted very thin oxide films was indeed detected rather regularly on our samples by means of electron diffraction. On <111> oriented wafers the crystallinity occurred in uniform fashion, whereas it was patchy on <100> oriented wafers.

Conclusions

The induction period observed in the decay of the anodic leakage current when first applying an anodic bias to thermally grown SiO_2 films strongly suggests that the primary step for injection of hydroxyls (and therefore probably also for protons) is the hydration of the oxide surface. In practice this means that SiO_2 films should not be exposed for any length of time to liquid water before metallization for MOS purposes.

The beginning crystallinity observed at the Si/SiO_2 interface raises the question whether the electrical sur-

face properties for the amorphous and for the crystalline SiO_2 in contact with the Si interface may be different. If this should be the case, then the interface will not be stable if nucleation and/or growth of the crystalline phase may proceed at room temperature. That crystallization of the steam-grown SiO_2 film does indeed happen quite regularly at room temperature was shown some time ago by Drobek by means of electron diffraction (19).

The cause for the hydrophobicity of oxide-covered Si surfaces at small oxide film thicknesses has not been established, but since it is at these oxide thicknesses that beginning crystallization of the SiO_2 was noted, there exists at least a suspicion that the structure of the oxide may be a contributing factor.

The excellent detection efficiency of counting tritium from a thin solid film by means of the Beckmann Low Beta II may well make this method attractive for determination of hydrogen content of thin solid films on conductive substrates. If one extra count per minute is accepted as a reasonable detection limit in view of the low background count of the Low Beta II, then at the specific activity employed in our experiments, ~100 curies/mole, a hydrogen concentration of 2×10^{10} atoms/cm^2 in a thin (10^{-5} cm) surface film is conveniently detectable. Since tritium is a very low energy pure beta emitter, a specific activity of 100 curies/mole does not constitute much of a health hazard and can be handled with ease.

Acknowledgments

We wish to acknowledge the extensive help by M. J. Rand in measuring the thickness of very thin SiO_2 films, the assistance of F. H. Doleiden with the liquid scintillation measurements, and of D. R. Wonsidler with examining surfaces by electron diffraction. As yet unpublished studies by J. Drobek on crystallization at the Si/SiO_2 interface were helpful in interpreting our results. Helpful discussions with A. L. Tyler, J. W. Colby, and C. Y. Bartholomew are gratefully acknowledged. Measurements of the water content of THFA solutions by infrared spectroscopy were carried out in the WE analytical laboratory under the supervision of T. H. Briggs. We are also indebted to E. H. Nicollian for bringing ref. (15) to our attention.

Notes Added in Proof

Limitation of breakdown strength of the oxide by the percentage of water in the anodizing solution has also been noted by C. R. Fritsche (21).

Movement of zirconium ions during anodization of Zr has now been shown to occur at very large field intensities, see P. A. Brook *et al.* Abstract 94, Corrosion Division, Electrochem. Soc. Extended Abstracts, Fall Meeting, Atlantic City, N. J., Oct. 4-8, 1970.

In a very recent publication (23), Holmberg, Kuper, and Miraldi use the same concept of fast diffusion in an "interconnected network of small disturbed regions" as proposed in this paper.

Manuscript submitted March 30, 1970; revised manuscript received *ca.* Sept. 11, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Properties of Polycrystalline Silicon Deposited on Silicon Nitride Layers

C. C. Mai,*[1] T. S. Whitehouse,[2] R. C. Thomas,*[3] and D. R. Goldstein[4]

Sylvania Electric Products Inc., Woburn, Massachusetts 01801

ABSTRACT

The properties of polycrystalline silicon deposited on silicon nitride by the thermal decomposition of silane were investigated. It was found that the deposition temperature of the silicon and the thickness of the layer had a marked effect on the diffusion characteristics. The diffusion profile of boron in the silicon layer was determined and the diffusion constant of boron into silicon at 1050°C was found to be 1.85-2.5 x 10^{-13} cm^2/sec. This compares with 3.3 x 10^{-14} cm^2/sec for (111) oriented single-crystal silicon under the same conditions. The ratio of Hall mobility of holes in polycrystalline silicon to the mobility in single-crystal silicon was found to be 0.57. No significant difference was found between the oxidation rate of polycrystalline-single and (111) oriented single-crystal silicon.

Recently there has been increased interest in the properties of silicon deposited on dielectrics because of the use of these layers in making silicon-gate field effect transistors (1, 2). Several processes are available for depositing silicon. These include sputtering, evaporation, and the vapor-phase reaction between hydrogen and silicon tetrachloride, or other silicon halides such as $SiHCl_3$, $SiBr_4$, or SiI_4.

It has been reported by Bhola and Mayer (3) that, at the relatively high concentrations required for the deposition reaction, halide ions can transport and deposit unwanted impurities at the growth face; they also report that silicon layers of excellent electrical properties can be deposited on silicon by the thermal decomposition of silane (SiH_4). Polycrystalline silicon has also been deposited by the decomposition of silane in a glow discharge at substrate temperature between 25° and 650°C (4).

Usually when silicon is deposited on a dielectric such as silicon dioxide or silicon nitride a polycrystalline silicon layer is formed. DeLuca reported the effect of deposition parameters on the structure of silicon film deposited by low-pressure silane pyrolysis (5). Very little has been reported on the diffusion and oxidation of polycrystalline silicon deposited on dielectrics. We have investigated layers deposited on silicon nitride by the thermal decomposition of silane. Reported here are:

1. The effect of deposition temperature on the properties of the deposited layers.
2. The characteristics of boron diffusion into the silicon layer.
3. The Hall mobility of holes in polycrystalline silicon.
4. The oxidation of polycrystalline silicon.

Deposition Apparatus

A schematic of the apparatus used is shown on Fig. 1. A 50 kW rf generator was employed. The source used was 10% silane in N_2. The carrier gases were N_2 and H_2. The susceptor was silicon carbide coated graphite ⅝ in. x 5 in. x 22 in. The tube had a rectangular cross section, 2 in. x 6 in. The susceptor was tilted to improve uniformity of deposition. The flow rates of gases were N_2, 43 liters/min; H_2, 15 liters/min: and SiH_4 mixture, 270 cc/min The gases were mixed before entering the reaction chamber.

Samples and Preparation

Silicon slices of (111) orientation, polished on one side, were used as substrates. Approximately 500Å of silicon nitride were deposited on each slice at 900°C, by the reaction of ammonia and silane. Polycrystalline silicon was then deposited on top of this nitride layer. Different thicknesses of silicon were deposited at various temperatures. All of the silicon layers obtained this way were intrinsic as determined by no deflection when using a thermal probe.

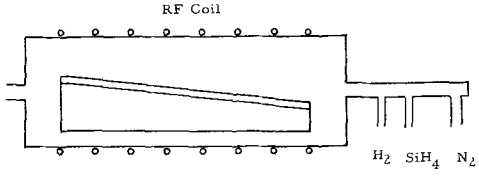

Fig. 1. Schematic of deposition apparatus

Effect of Deposition Temperature

It was found that the deposition temperature played a very important role in the characteristics of the polycrystalline silicon. The temperature range in this study was from 800° to 1000°C. The deposition was very slow for temperatures below 750°C.

Typical deposition rates for the standard condition used are shown in Table I. The samples of silicon deposited on silicon nitride at 800°, 900°, and 1000°C were examined by replica electron microscopy and reflection electron diffraction.

The 800°C sample shown in Fig. 2a, had a smooth, highly reflecting surface. The electron micrograph revealed a finely grained texture with an approximate grain size of 0.3μ. Both the 900°C (Fig. 2b) and the 1000°C (Fig. 2c) samples had extremely rough surfaces with a high density of small, deep pits, the latter being the worse of the two. The grain sizes on the 900°C and the 1000°C samples were very nonuniform. At growth rates up to approximately 2000Å/min at 800°C and in excess of 1μ in thickness, the 800°C sample still had a smooth, highly reflecting surface of silicon.

Reflection diffraction patterns revealed random orientation in the 800°C sample. Both the 900° and the 1000°C samples displayed some degree of preferred orientation as evidenced by the variation in the intensity of the (111) and (220) rings. At higher temperatures the silicon molecules possess higher energy al-

lowing them to attempt to rearrange themselves according to preferred growth directions. The lack of orientation below 800°C agreed with DeLuca's finding (5). To compare the effects of deposition temperature on the diffusion characteristics of polycrystalline silicon, layers of approximately 0.8μ were deposited at 800°, 900°, and 1000°C. These slices were then inserted into a boron diffusion furnace for a half hour at 1050°C with a BBr_3 source held at 20°C. The sheet resistance of the initial polycrystalline silicon layer was above 4500 ohms/square which is the upper limit of the available equipment.

The average sheet resistances obtained from a four-point probe are listed in Table II. A single crystal silicon slice of 6 ohm-cm N type has a sheet resistance of 21 ohms/square after the same treatment. As can be seen from the table, the sheet resistance goes up rapidly with deposition temperature.

The uniformity of four-point probe readings was much better in the layer deposited at 800°C than at higher temperatures. The variation on 800°C polycrystalline silicon was less than 20% from slice to slice and within different areas of the slices, while the 900°C deposited layer shows a variation of more than 40% and the 1000°C sample had a 100% variation. It was concluded that polycrystalline silicon deposited at 800°C has the most reproducible boron diffusion. Also a lower sheet resistance can be obtained.

The comparatively good uniformity of boron diffusion into the 800°C samples can be explained by the fact that this layer has a very fine and uniform grain size and is free of pits in the surface. As mentioned previously, the roughness of the surface and the preferred orientation of the polycrystalline silicon increases with deposition temperature, such that the 1000°C samples had a much higher density of pits than the 900°C samples. The uniformity of boron diffusion in the 1000°C sample was much worse than the 900°C samples.

The 800°C deposited polycrystalline silicon layer was used to study diffusion in further detail since diffusion uniformity is better and lower sheet resistance can be achieved.

Diffusion of Boron Polycrystalline Silicon

Effect of polycrystalline silicon layer thickness on sheet resistance after diffusion.—Different thicknesses of silicon were deposited on the top of silicon nitride. The range of thickness was from 2250 to 13,500Å. These slices were inserted into a boron deposition furnace for 30 min at 1050°C and then driven in steam for 40 min at 950°C. The sheet resistances of these slices were measured before and after drive. Another set of samples was driven for 45 min in argon at 1000°C after the same boron deposition. The data are shown in Fig. 3. It was found that the thickness of the polycrystalline layer did affect the sheet resistance. As the thickness went down, the sheet resistance went up. However, when the layer was thicker than 7000Å, the curve approached a saturation point and the sheet resistance changed very little with increasing layer thickness.

This change in resistance is due to the presence of silicon nitride. The flux of boron across the silicon surface is the same for thick or thin polycrystalline layers. In thin layers terminated by silicon nitride which acts as a diffusion barrier, the concentration of boron at the barrier builds up. This slows down the in-diffusion of boron due to the reduced gradient and results in a greater percentage of the boron being beyond the electrical solid solubility. This, combined with the

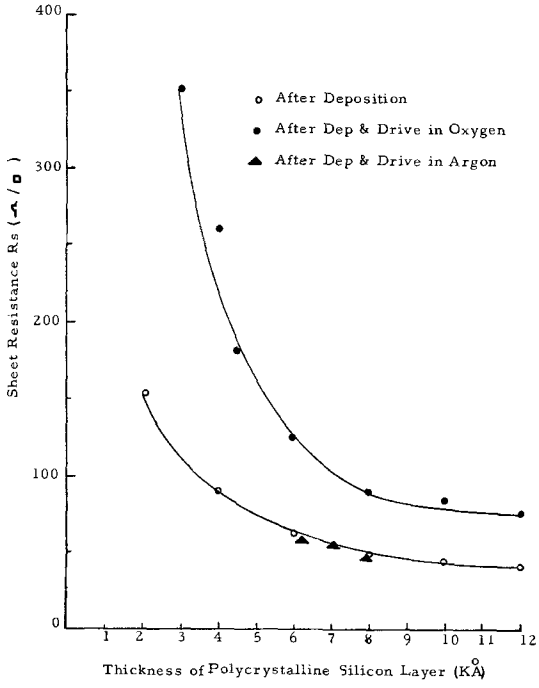

Fig. 3. Sheet resistance as a function of thickness of polycrystalline silicon layer after boron deposition and drive.

lower mobility of active carriers at high concentrations, results in higher sheet resistivities. The sheet resistance of the layer went up after a drive in an oxygen ambient primarily due to the redistribution of boron in the oxide formed during this drive. During this oxidation approximately 1200Å of silicon was consumed in forming the oxide. Thus in the thinner layers there is an additional increase in sheet resistivity beyond that due to the mechanism mentioned previously. The sheet resistance did not change significantly from the original value of boron deposition after 45 min drive in argon. This was due to the fact that no oxide was formed in the drive, so that no boron out-diffusion occurred.

It was concluded that a 7000Å layer of polycrystalline silicon is sufficient to produce either a low or a high sheet resistance after diffusion as desired.

Diffusion profile by anodic oxidation method.—A polycrystalline silicon layer 1.5μ thick was deposited on a nitride layer at 800°C. Then 15 min of boron diffusion was performed on these crystals at 1050°C with a BBr_3 source held at 20°C. Single-crystal silicon slices of 6 ohm-cm n-type were used as controls. Sheet resistance was measured after diffusion. They were 104-135 ohms/square for polycrystalline silicon and 22.6-31.6 ohms/square for the n-type control slices.

After boron diffusion, thin layers of the polycrystalline silicon were removed by the anodic oxidation and etch method (6). A sheet resistance was measured after each subsequent step. The sheet conductance was derived from the above data and plotted against the distance from the surface in Fig. 4. It was found that the slope of the curve dropped sharply after a distance of about 0.6μ from the surface.

The concentration profile of the diffusion was calculated from

$$Nx = \frac{1}{\mu q}\frac{d\sigma s}{dx}$$

Where σs is the sheet conductance, x the distance from the surface, $d\sigma s/dx$ the slope at point x in Fig. 4, μ the mobility, q the electron charge, and Nx the concentration of the active carrier at point x.

The profile calculated by the above equation is plotted in Fig. 5. The effective mobilities used in the calculation were 0.57 times the value for single-crystal silicon mobilities obtained from published data (7). This was done because the Hall mobility of the polycrystalline silicon was found to be 0.57 of the mobility for single-crystal silicon as will be discussed in a later section of this report.

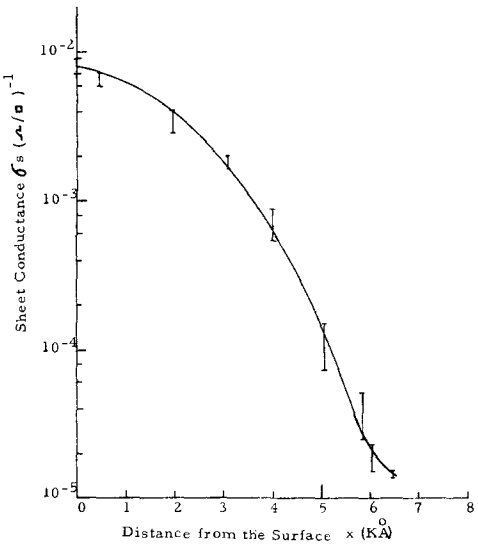

Fig. 4. Sheet conductance of the polycrystalline silicon layer as a function of depth after boron diffusion.

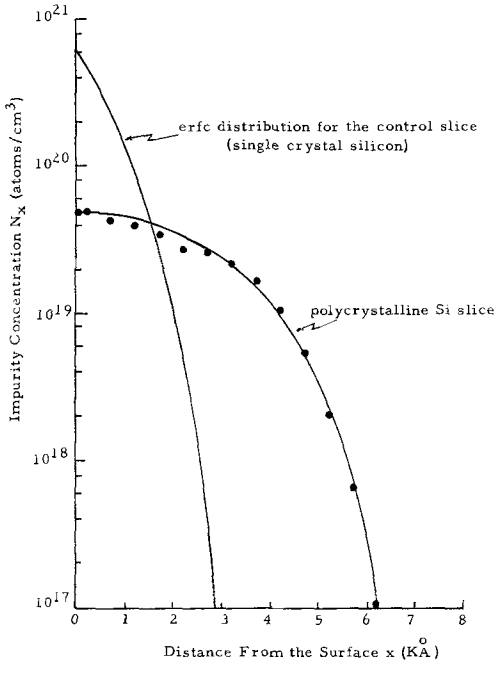

Fig. 5. Impurity concentration profile of the boron diffused layers

The concentration profile was neither a complementary error function nor a Gaussian distribution.

The profile of the control single crystal is also plotted in Fig. 5 for comparison purposes by assuming an erfc distribution. It is interesting to note that for the same diffusion condition, the junction depth was larger and the surface concentration was smaller for the polycrystalline silicon than the single-crystal silicon. It can be explained that the diffusion constant for polycrystalline silicon is higher as explained in the next section, hence a deeper junction. The lower surface concentration is probably due to more precipitation of species in the polycrystalline silicon so that these species were electrically inactive, and the four-point probe only measures the electrically active species.

The diffusion constant.—The diffusion constant was calculated by the equation (6, 8)

$$D\ (N = Nx) = \frac{1}{2t}\left(\frac{dx}{dN}\right) Nx \int_0^{Nx} x\, d\, N$$

where D is the diffusion constant, t is the time of diffusion, x is the distance from surface, and Nx is the boron concentration at point x. The integral was solved by graphical integration. The diffusion constant calculated from this method for polycrystalline silicon is 1.85-2.5 x 10^{-13} cm²/sec. The diffusion constant for the control single-crystal silicon was found to be 3.3 x 10^{-14} cm²/sec by assuming an erfc distribution and using Irvin's curves (9). This value is in agreement with published data (10). It is found that the diffusion constant for boron in a polycrystalline silicon layer is several times higher than in single crystalline silicon under identical diffusion conditions.

The higher diffusion constant in polycrystalline silicon is in agreement with the finding of other investigators (11). The reason for the higher diffusion constant can be explained as due to the presence of grain boundaries. The grain boundary diffusion is favored over bulk diffusion.

Hall Mobility of Holes in Polycrystalline Silicon

The Hall mobility of holes was measured by the method outlined by Van der Pauw (12). The samples were prepared in the same way as in the experiment on concentration profile. Namely, 1.5μ of polycrystalline silicon was deposited on a nitride layer at 800°C followed by a 15 min boron diffusion at 1050°C. The control single-crystal silicon slices went through the same diffusion. The Hall mobility of the polycrystalline silicon was 137 cm²/V-sec and for the single-crystal silicon it was 240 cm²/V-sec. It is well known that the Hall mobility is a function of impurity concentration. Most of the reported Hall mobility was measured on homogeneous silicon layers. But the above polycrystalline silicon and control slices both had a diffused graded profile. Therefore, the mobility we obtained was only an average mobility of the layers, not a value for any particular concentration. Hence the absolute value of this measurement has less significance than the ratio of the two values, namely

$$\frac{\text{Hall mobility of polycrystalline silicon}}{\text{Hall mobility of single crystal silicon}} = 0.57$$

The Hall mobility of holes in polycrystalline silicon was found to be about half of that in single-crystal silicon. This phenomenon is one of the reasons that the sheet conductance in polycrystalline silicon is lower than the single-crystal silicon under identical diffusion condition.

Oxidation of the Polycrystalline Silicon

Slices with polycrystalline silicon layers deposited on silicon nitride layers were oxidized in steam at 950°C for 1, 2, 3, 4, and 16 hr. Single-crystal silicon slices of (111) orientation were used as controls. The oxidation thickness *vs.* time is plotted in Fig. 6. It was found that no significant difference existed between the oxidation rate of polycrystalline silicon layers and single-crystal silicon of (111) orientation. The etch rate of the above two kinds of oxides was investigated. It was found that both have approximately the same etch rate in a buffered HF solution.

Conclusion

The properties of polycrystalline silicon deposited on a silicon nitride layer are very much process dependent, and significantly depart from single-crystal silicon. The grain boundaries have the effects of enhancing the diffusion of boron atoms, reducing active carrier concentration, and lowering hole mobility. Layers formed at lower temperatures have a more uniformly small grain size contributing to more reproducible diffusion characteristics as evidenced by sheet resistivity measurements.

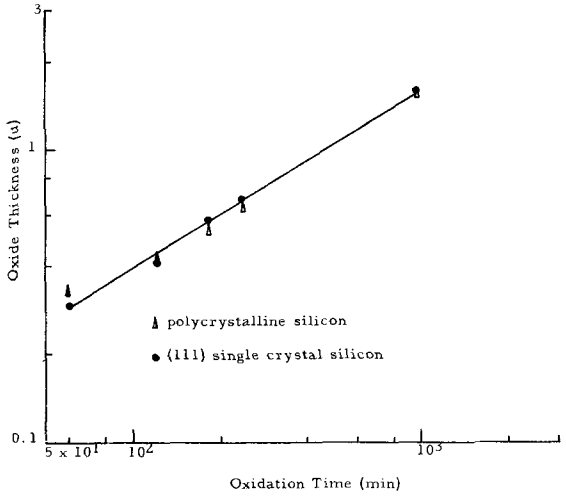

Fig. 6. Oxide thickness as a function of oxidation time at 950°C in steam.

It was found from this study that polycrystalline silicon layers thicker than 7000Å and deposited at 800°C can be made to approach the conductivity of diffused single-crystal silicon especially when non-oxidizing drives are used.

No significant differences between the oxidation properties of polycrystalline and single-crystal silicon were found.

Acknowledgment

The authors wish to acknowledge Mr. V. Lyn for his work on making the electron micrographs and reflection diffraction analysis on the samples, and also thanks to Mr. W. Heath who accomplished the experimental work on depositing the polycrystalline silicon layer.

ABSTRACT

Single-crystal layers of α-(hexagonal) silicon carbide (SiC) were successfully deposited on the [0001] and [000$\bar{1}$] surfaces of α-SiC substrates from silane and propane in a hydrogen atmosphere and in the 1500°-1650°C temperature range. Above 1650°C the amount of SiC deposited was found to be significantly decreased because of increased hydrogen etch rates and diffusion-limited reactant transfer to the substrate. The growth characteristics are best described by a model in which the surface of the sample is in equilibrium with the reactants diffusing through a boundary layer. Undoped n-type deposits (grown on p-type substrates) exhibited a resistivity of 0.40 ohm-cm and a Hall mobility of approximately 200 cm^2/V-sec at 77°C.

The use of SiC in electronic devices continues to be limited by problems of purity control and crystalline perfection; these problems are strongly related to the high temperatures (about 2500°C) at which α-SiC is grown by the standard Acheson and Lely techniques. Growing α-SiC from the vapor phase has the distinct advantage (regarding purity control) that it takes place at appreciably lower temperatures (about 1600°C). Growth of SiC from the vapor phase using SiH_4 and C_3H_8 (and other reagents) has been reported (1). This and subsequent studies (2) have considered the dependence of growth rate on temperature and the effects of varying the Si/C ratio. In all instances SiC was grown on SiC. It has been found, here and previously (1), that changes in temperature and in gas composition may lead to either α- or β- (cubic) SiC layers.

An important aspect of growing SiC from the vapor phase is that, at the temperature of growth, thermal etching of SiC takes place concurrently. Thus, it has been reported (1) that above 1775°C the growth was much reduced; by 1900°C the substrate was etched. The authors have found (3) that above 1550°C the etching rate of α-SiC in hydrogen varies with the susceptor material on which the inductively heated SiC rests. The highest etching rate was observed when molybdenum was used. The present study attempts to elucidate the growth by vapor deposition on the basis of the processes (chemical and physical) taking place between the vapor phase reactants and the substrate.

Experimental Procedure

The vapor growth experiments were performed in a 1.5 in. ID, horizontal, water-cooled, quartz reaction tube using a silane-propane mixture and hydrogen as carrier gas. Details of the experimental arrangement and procedure have been described elsewhere (3). The substrates, (0001) platelets of α-SiC, were polished with 3μ diamond paste, chemically etched in an alkaline ferricyanide solution (4), and thermally etched in hydrogen at 1650°C. This procedure yielded the extremely smooth surfaces desired for chemical vapor deposition. In all experiments a tantalum susceptor measuring ¼ x ⅞ x 2 in. was employed. All temperatures reported here are those of the susceptor, determined with an optical pyrometer (uncorrected readings).

The "thickness" of the grown layers was determined from the weight change of the samples; the substrate surface areas were measured from enlarged photomicrographs of the platelets or were computed from thickness and weight measurements. Since epitaxial deposition and "thermal etching" took place concurrently over the whole temperature range investigated, the growth rates are reported here not in microns per minute but in microns per Standard Time Interval (μ/STI). The STI was 22 min: a 2 min heat-up period in argon, a 2 min hold at deposition temperature in argon, a 2 min hold in pure hydrogen, a 10 min deposition period, and a 6 min hold in argon at deposition temperature.

Results and Discussion

Figure 1 shows the dependence of the growth rate on reactant input concentration (with a fixed Si/C ratio of 0.88) and temperature (a constant hydrogen flow of 6.0 liters/min was employed). Over the temperature range investigated, the growth characteristics of SiC varied markedly with increasing reactant input concentration. Up to about 1.5 x 10^{-4} moles/min of Si input, the system exhibited an "effective" negative growth rate. Since polycrystalline SiC deposits were observed occasionally under these conditions, it appears that the weight loss due to hydrogen etching on the bottom face of the substrate exceeded the weight increase due to SiC deposition on the upper face. Thus, in this range of reactant concentration the deposition rate is greater than the etching rate of the

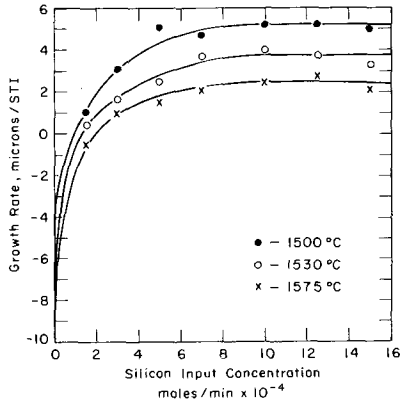

Fig. 1. Growth rate vs. Si concentration for α-SiC on α-SiC substrate.

Key words: silicon carbide, vapor deposition.

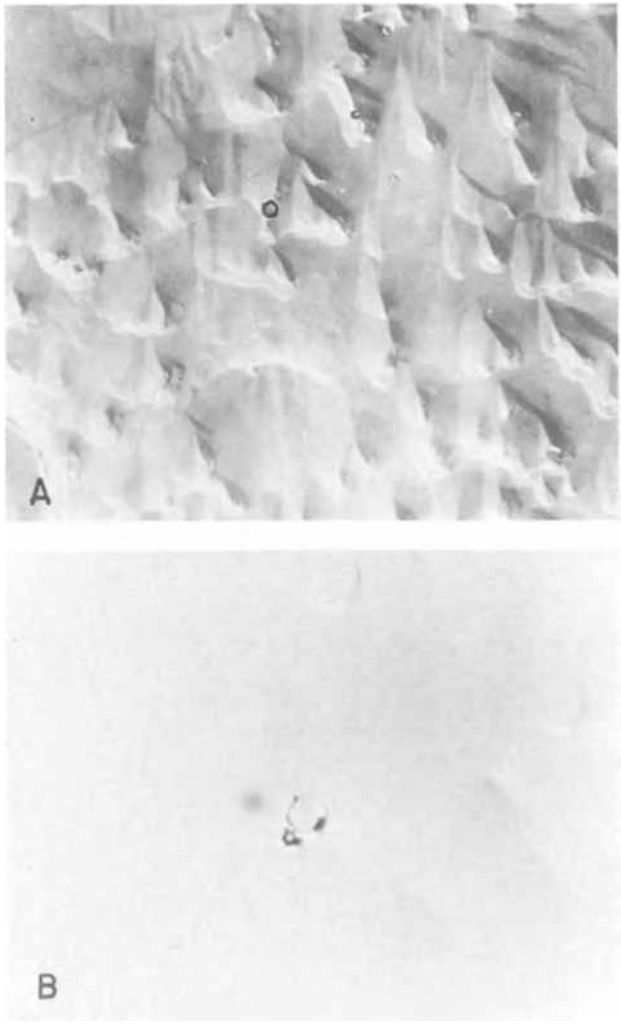

Fig. 2. Single-crystal SiC overgrowth on [0001] substrate: (A) 30X, (B) 150X.

surface available for deposition but less than the overall etching rate of the sample. Upon increasing the Si input concentration beyond 1.5×10^{-4} moles (to about 3.5×10^{-4} moles/min), the SiC deposit was single crystalline and the samples exhibited a net weight increase. Figure 2 shows typical epitaxial growth under these conditions. The hexagonal stacking faults on the deposit constitute a convenient identification of α-SiC. At Si input concentrations above 3.5×10^{-4} moles/min, the epitaxial deposits were invariably polycrystalline. The effective growth rate under such conditions is virtually independent of reactant input concentration and is apparently controlled by mass transport. The observed temperature dependence of the growth rate in this region, however, is not in good agreement with that expected for a process under diffusion control.

This result is not surprising because the etching rate of SiC increases as does the rate of homogeneous nucleation and heterogeneous nucleation of silicon on the reactor wall (5) with increasing temperature; furthermore, the efficiency of SiH_4 and C_3H_8 in forming SiC decreases with increasing temperature (2). It should be pointed out that the values of reactant concentrations at which either single crystal or polycrystalline growth takes place (Fig. 1) must not be considered absolute or specific to the silane-propane-hydrogen system. These values do depend, for example, on the geometry of the system and the interaction of the reactants with the susceptor material.

The growth experiments were primarily carried out on the Si (0001) surfaces of the SiC substrate platelets. However, deposits of the same nature were also obtained on the carbon (0001) surfaces except that the growth rate was about half of that for the silicon surfaces. This difference in growth rates has been observed in many other crystallographically polar materials (6), but the details of the growth mechanisms involved are still not clear.

Fig. 3. Polycrystalline β-SiC deposit in a stacking fault on α-SiC substrate (33X).

As in previous studies, hexagonal as well as cubic SiC was obtained, depending on the experimental conditions. The β-SiC form shown in Fig. 3 was obtained above 1640°C, and in relatively high reactant concentrations (Si $> 5 \times 10^{-4}$ moles, Si/C = 0.88, and H_2 = 0.27 moles). The polycrystalline cubic modification apparently nucleated on substrate irregularities and could be readily identified from its bright yellow color and its cubic morphology (not apparent in the photomicrographs).

Resistivity and Hall coefficient measurements [employing the van der Pauw (7) technique] were carried out at room temperature and 77°K on undoped n-type SiC layers deposited on p-type substrates. A few deposits became p-type at 77°K. Electron Hall mobility at 77°K was about 200 cm²/V-sec; resistivity was approximately 0.40 ohm-cm. No differences in electrical properties were observed between deposits grown on (0001) and on $(000\bar{1})$ substrates. The van der Pauw resistivity ratio, R_1/R_2, varied only 5% from room temperature to 77°K, whereas a variation of about 20% was measured for the substrate. It is believed that the less the variation of R_1/R_2 with temperature, the more homogeneous the sample (8).

There have been extensive theoretical treatments of epitaxial growth in open-tube systems. The results of the present study summarized in Table I are quite consistent with the model developed by Bradshaw (9) which is based on "boundary layer" considerations. Bradshaw's relationship is

$$G(Y) = 100S \left[\frac{VP}{\overline{M}Y} \right]^{1/2} \qquad [1]$$

where G is the growth rate in microns per minute, Y is the distance in centimeters from the leading edge of the boundary layer, V is the mainstream gas velocity in centimeters per second, P is the pressure in atmospheres, $\overline{M}$ is the average molecular weight of the boundary layer, and S is a term related to thermodynamic efficiency. The growth rate of α-SiC plotted in Fig. 4 and 5 as a function of $1/\sqrt{Y}$ is in reasonable agreement with Bradshaw's model. In the experiment the leading edge of the boundary layer was taken to be the front edge of the susceptor. The slope of the curves is indicative of the thermodynamic efficiency, S.

Based on "boundary layer" considerations but assuming somewhat different boundary conditions, Rundle (10) has arrived at the following relationship

$$G(Y) = \frac{120\,\overline{m}DC_{(o)}}{\overline{M}\,\rho\,b} \exp\left[-\frac{D\pi^2 Y}{4Vb^2} \right] \qquad [2]$$

where $\overline{M}$ is the average molecular weight of the boundary layer, $\overline{m}$ is the average molecular weight of the deposit, D is the diffusion coefficient of the reactant species in square centimeters per second at the mean temperature of the boundary layer (all reactants are assumed to have the same D), $C_{(o)}$ is the input concentration of reactants in grams per cubic centimeter, and b is the vertical distance from the substrate surface to the wall of the tube ($b = 1$ cm).

The difference between the two models is that Rundle assumes a concentration gradient in the vertical direction (perpendicular to the flow direction), whereas Bradshaw neglects it. Furthermore, Rundle assumes that the reaction at the substrate-gas interface goes to completion, *i.e.*, the reactant concentration is zero, whereas Bradshaw calculates a concentration for the reactant species at the interface. In Fig. 6, ln G of two runs at approximately 1550°C is plotted against Y. The diffusion coefficient for the transport process is obtained directly from the slope of the curves. The average of the two curves in Fig. 6 gives a value for $D = 2.41$ cm²/sec. This value is in good agreement with the value of 2.27 cm²/sec reported (3) for the diffusion coefficient of silicon in hydrogen at 1600°C. This present result implies a minimum value of about 2.41 cm²/sec for the diffusion of carbon in hydrogen at 1550°C.

Summary

Epitaxial single-crystal layers of α-SiC were successfully deposited from SiH_4 and C_3H_8 on [0001] and [000$\bar{1}$] surfaces of α-SiC. The growth characteristics were found to be consistent with a model in which the growth is controlled by the diffusion of the reactants through a "boundary layer" adjacent to the substrate surface. Above 1600°C, growth was significantly inhibited by thermal etching in the presence of hydrogen. The epitaxial layers exhibited higher crystalline perfection and better electrical characteristics than the α-SiC obtained by the standard direct crystal growth methods.

ABSTRACT

The equilibrium partial pressures of various vapor species in the system silicon-carbon-hydrogen were computed for conditions under which epitaxial SiC deposition has been achieved. It was found that in the temperature range 1300°-1700°C the tendency to form solid silicon carbide decreases with increasing temperature and with increasing silicon to carbon atom ratio. The limiting conditions under which single crystalline deposits of α-SiC could be experimentally obtained were those within which SiC was computed to be the only thermodynamically stable solid phase. At 1650°C single-phase silicon carbide condenses at Si/C ratios ranging from 0.2 to 0.89. The computed results were in good agreement with experiments.

The experimental conditions for single crystalline deposition of epitaxial α-SiC were examined in an earlier study (1). At present, the results of theoretical computations of equilibrium vapor pressures in the system silicon-carbon-hydrogen are reported and correlated with experimental findings. Under the conditions investigated it was found that up to 27 different vapor species can coexist with the three possible condensed phase species, *i.e.*, carbon, silicon and silicon carbide. Obviously this type of computation gives no information as to how the condensed phases physically coexist, which polytypes are formed, and whether or not α-SiC appears in single-crystal or polycrystalline form.

Results and Discussion

The computation of the equilibrium concentrations of the thermodynamically stable species (gaseous and solid) in the present system was carried out with a program (2) based on minimizing the total Gibbs free energy with the constraint of conservation of mass (3). The accuracy of the program was tested by applying it to similar systems for which experimental results were available (4). The agreement was found to be excellent. The thermochemical data in the temperature range from 1300° to 2000°C were computed for varying silicon and carbon input concentrations at a fixed pressure of 1 atm and a constant hydrogen concentration of 0.27 moles. The partial pressures of thermodynamically stable species for input concentrations of 3.0 x 10^{-3} moles silicon and 3.2 x 10^{-3} moles carbon in the temperature range from 1573° to 2173°K are listed in Table I, together with the concentration of stable condensed phases.

The computed compositions of the condensed phases as a function of silicon and carbon input concentrations at 1650°C are presented in Fig. 1. The solid lines delineate three regions of varying input concentrations (silicon and carbon) in which the vapor phase coexists

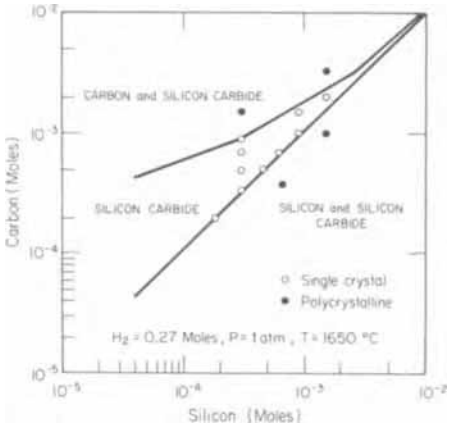

Fig. 1. Formation of silicon carbide as a function of carbon and silicon input concentration. Solid lines were theoretically computed; the circles represent individual experiments (see text). (Units for experimental points are moles per min.)

in equilibrium with one of the following condensed phases: SiC + C, SiC, or SiC + Si. The circles in the figure represent actual deposition experiments. The experimental procedure has been outlined elsewhere (1). It is of interest to note that single-crystalline deposits of α-SiC were consistently obtained over the whole input concentration range for which SiC is the only thermodynamically stable condensed phase. Polycrystalline layers of varying morphology were invariably obtained under conditions corresponding to the two-phase regions. Figures 2 and 3 are typical examples of deposits corresponding to the regions with excess carbon and silicon, respectively. These findings are in agreement with the observations by Lely (5) according to which monocrystalline SiC can exist only stoichiometrically [with a maximum deviation of 10^{-5} atomic per cent (a/o) from stoichiometry]. Figure 4 shows the upper and lower limits of partial pressures of two critical vapor species within which single-phase silicon carbide condensation can occur. If the concentration limits of either species are exceeded, two-phase condensation is observed. This figure reflects further the temperature dependence of the width of the single-phase silicon carbide region shown in Fig. 1 (for 1650°C).

Figure 5 presents the computed variation of the equilibrium partial pressure of acetylene as a function of reactant concentration and Si/C atom ratio. It is seen that $P_{C_2H_2}$ decreases with increasing Si/C ratio and increases with increasing input concentration. Furthermore, as shown in Fig. 6, the vapor pressure of C_2H_2 is directly related to the excess input carbon concentration; carbon excess is defined as input carbon

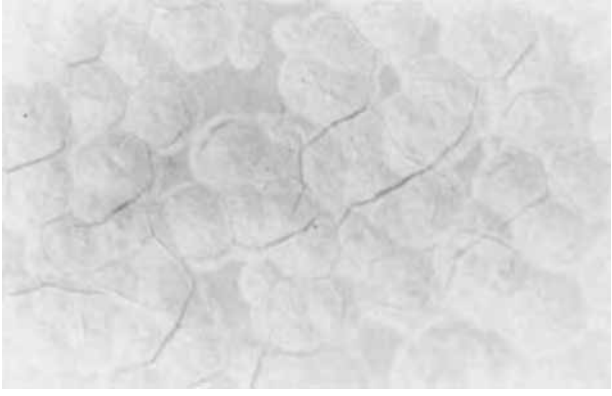

Fig. 2. SiC deposit on (0001) surface of SiC under conditions corresponding to the carbon and silicon carbide region of Fig. 1 (50X).

concentration (X_c) minus input silicon concentration (X_{si}).

The data presented in Fig. 5 and 6 explain why single-phase (stoichiometric) silicon carbide can be

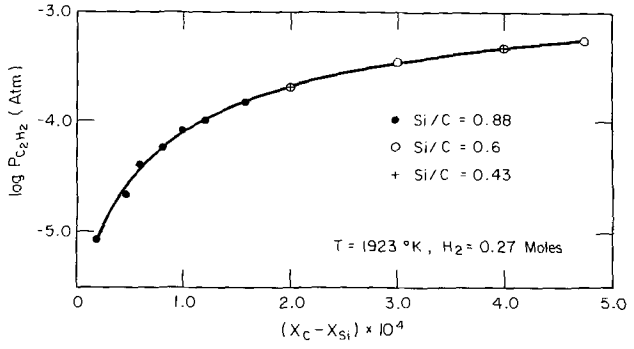

Fig. 6. Variation of partial pressure of C_2H_2 as a function of excess carbon concentration.

obtained over a considerable range of silicon to carbon input concentration ratios; when thermodynamically stable vapor-phase species of the constituent in excess (Si or C) are present and if these species can increase in concentration and, thus, "take up" the excess of that constituent, then stoichiometric condensation of SiC will take place. The finding that the boundary between the SiC single-phase region and the SiC + Si region has a slope of approximately one and an intercept of virtually zero (Fig. 1) is consistent with the fact that there are only five stable silicon vapor species of which four can achieve but negligible concentrations. On the other hand, there are more than 20 carbon vapor species of which at least five exhibit significant stability (see Table I); thus, significant amounts of carbon can be retained in the vapor phase, whereas very little excess silicon can be accommodated if single-phase SiC is to be achieved. The presence of carbon species such as C_2H_2 have essentially a "buffering" effect on the concentration of the carbon constituent. Thus, the position and shape of the boundaries of the single-phase SiC region in Fig. 1 obviously reflect the ability of the carbon and silicon vapor-phase species to accommodate any excess of either constituent.

The relative efficiency of silicon carbide formation as computed for equilibrium conditions at varying temperatures and Si/C atom ratios is summarized in Fig. 7 and 8. It can be seen that the efficiency decreases with increasing temperature and with increasing Si/C

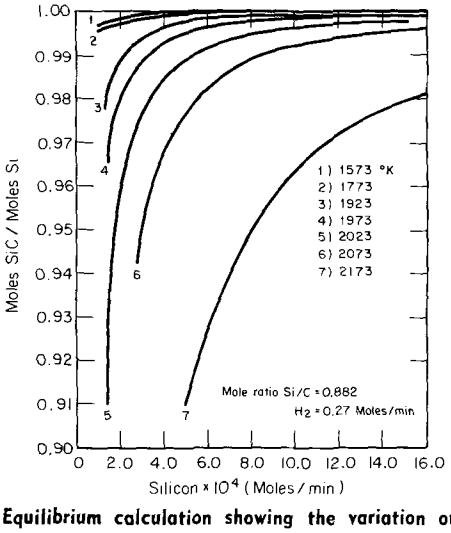

Fig. 7. Equilibrium calculation showing the variation of silicon carbide formation as a function of temperature and reactant concentration.

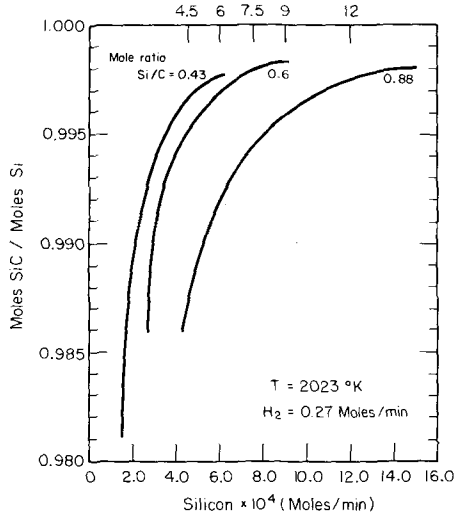

Fig. 8. Equilibrium calculation showing the variation of silicon carbide formation as a function of silicon to carbon atom ratio.

ratios. Since these results are computed for equilibrium conditions they are not expected to apply quantitatively (or in an absolute way) to the open-tube growth system. They are generally consistent, however, with the results reported in an earlier paper (1) and with the variation of the thermodynamic parameter, S [Table I, Ref. (1)], introduced by Bradshaw (4) in his boundary-layer model of epitaxial growth in an open-tube system.

Summary

The general variation of the growth characteristics of SiC from the vapor phase with temperature, reactant concentration, and Si/C atom ratios was computed through equilibrium calculations on the hydrogen-carbon-silicon system. The computed results were found to be in reasonable agreement with experimental data. It was theoretically explained why there is no unique Si/C atom ratio at which single-phase stoichiometric SiC deposition can be achieved: under actual SiC growth conditions, there are many more carbon-containing vapor species with significant vapor pressure than silicon-containing species allowing for stoichiometric SiC formation at Si/C input concentration ratios varying from 0.21 to 0.89.

Materials for Use in a Durable Selectively Semitransparent Photomask

W. Robert Sinclair,* Miles V. Sullivan, and R. A. Fastnacht

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The object of this study was to screen a group of metal oxides as possible candidates for use as semitransparent mask materials. For this study, all masks were prepared by d-c reactive sputtering onto glass. The uv-visible spectra for the entire group of oxide films were recorded. The spectral characteristics desired for a photomask are (*i*) transmission of less than 1% in the region below 404 nm (for masking), and (*ii*) transmission of greater than 30% at 589 nm (for the see-through characteristic). Because of inferior spectral absorption properties, the following systems were eliminated from further consideration: lead oxide-silicon oxide, lead oxide-germanium oxide, copper oxide, copper oxide-vanadium oxide, molybdenum oxide, chromium oxide, uranium oxide, mercury oxide, and zinc oxide. Those systems which satisfied the spectral requirements were: iron oxide, vanadium oxide, nickel oxide, iron oxide-nickel oxide, and iron oxide-vanadium oxide. These materials were then further evaluated to assure etchability in solvents compatible with photoresist processsing and resistance to abrasion. These latter two properties will be discussed in greater detail in a forthcoming article. Considering only sputtered films, the 10 m/o (mole per cent) iron oxide-90 m/o vanadium oxide is the most promising material based on these additional requirements.

Two main types of masks are used at present for defining images on photoresist materials in the manufacture of semiconductor devices and integrated circuits. One is the photographic emulsion-on-glass mask; the other is the chromium film-on-glass (1) mask. The silver emulsion mask acts by absorbing most of the incident light in desired areas and transmitting it in other areas to interact with the photoresist material thus making the photoresist either more soluble (positive resist) or less soluble (negative resist) (2) in these exposed areas. The chrome-on-glass mask performs the same function by a combination of reflection and absorption.

Both types of masks have liabilities. The emulsion mask is easily scratched and is difficult to clean. Its dimensions are affected by moisture absorption. The chrome-on-glass mask eliminates these difficulties, but unfortunately other problems arise. Registration of a chrome mask with prior patterns may be difficult when the substrate is also mirror-bright. The high reflectivity of the metal mask tends to increase the probability of halation effects and may result in loss of resolution in the exposed resists. Also, preparation of films free of pinholes is difficult.

The work to be described here was aimed at the fabrication of a durable, selectively semitransparent ("see through") mask which would be strongly absorbent to the light used in the exposure process but reasonably transparent to yellow or red light to allow observation for alignment purposes. At present, the radiation used in exposing photoresist is usually a mercury lamp with a strong line at 365 nm and a weak line at 404.6 nm. Microscope observation for alignment purposes usually employs the sodium D line at 589 nm. Our problem then was to prepare a hard film, etchable in solvents appropriate to the steps involved in processing photoresist, strongly absorbing in the spectral region of 360-404 nm, and reasonably (at least 30%) transparent near 589 nm.

For our study, oxide films, which are often hard, were chosen and the technique of reactive sputtering used because such a wide variety of materials can be deposited in this manner and because the equipment was available. Since use of this technique can easily lead to glassy films or films of very small crystal size, it was appropriate to consider the compositions of colored oxide glasses as a starting point for our investigation. From the literature of colored glasses, certain ions can be chosen as having absorption spectra in the region of interest (cf. Table I) (3). In addition, other ions which can give yellowish oxide compounds are Hg^{+2} and Mo^{+6}.

In this paper we present results of studies of oxide films of the various ions in Table I and of those mentioned above. In the text we discuss oxide films of the iron-vanadium system and of the iron-nickel system. In our studies these films came closest to meeting the properties desired in the proposed mask. Results obtained on other systems are presented in the Appendix.

Experiment and Discussion

The apparatus used is diagrammed in Fig. 1. Sputtering was upwards to minimize pinholes caused by dust. The clamped sample could be heated if desired. At a later date a water-cooled holder was used which led to valuable results. Typical and often optimal sputtering conditions were 100 mA at 2500V, and a total pressure of 60 mTorr. It will be noted that most of the ions in Table I are in their highest valence state and, therefore, usually a highly oxidizing atmosphere was used (10-100% O_2). Commercial grade oxygen and argon-oxygen were used without further purification. The sputtering electrodes were 6 ½ in. disks. The films were deposited onto 2 x 2 in. glass slides (Kodak HRP plates with emulsion stripped off).

Table I. Approximate wavelength of maximum absorption for various metal ions in oxide glasses, according to Weyl (3)

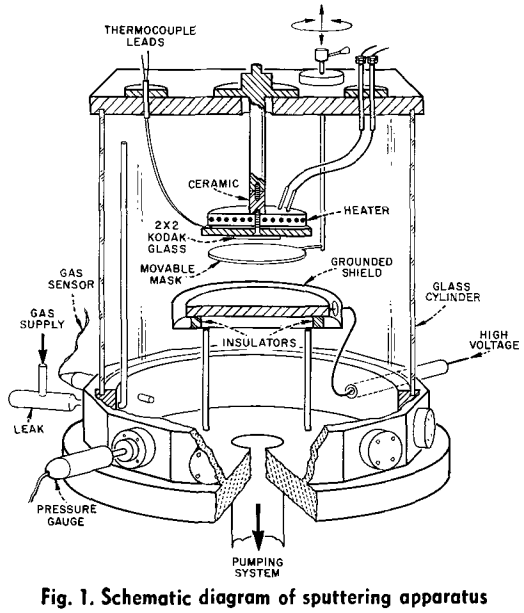

Fig. 1. Schematic diagram of sputtering apparatus

Exploratory work with iron electrodes (cold-rolled steel), vanadium foil electrodes (99.9% pure) and nickel (99% pure) showed some promising spectra as indicated in Fig. 2. Most of the systems studied deviated from Beer's law somewhat when prepared in different thicknesses, possibly because of temperature changes during a run, so that nonnormalized spectra are presented in the figures. The temperature of the substrate was not controlled, and the thermocouple attached to the metallic substrate holder indicated a temperature of about 160°C at the end of the run. The spectrum of the nickel oxide film showed too much absorption at 589 nm to be useful. Unfortunately, the iron oxide film, which exhibits a promising spectrum, is extremely insoluble in even concentrated HCl. The vanadium oxide film also possesses an encouraging spectrum and is etchable. Well-defined patterns could be produced as shown in Fig. 3, wherein windows 1.25 μm wide separated by 1.25 μm lines have been etched using standard photoresist procedures and a 1% HCl etch. However, the etch rate was so fast, even in water, that this film would not be practical for common use.

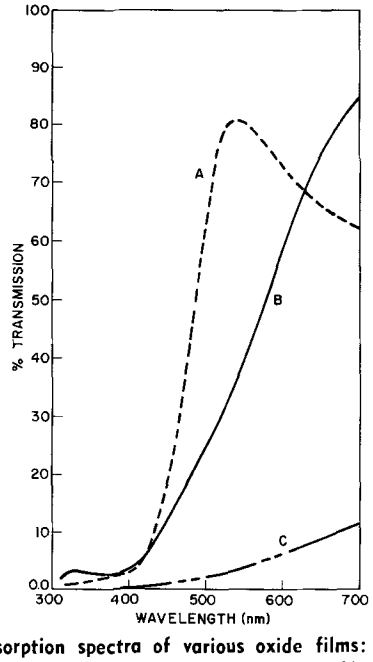

Fig. 2. Absorption spectra of various oxide films: A, vanadium oxide (800 nm thick); B, iron oxide (1800 nm thick); C, nickel oxide (4700 nm thick).

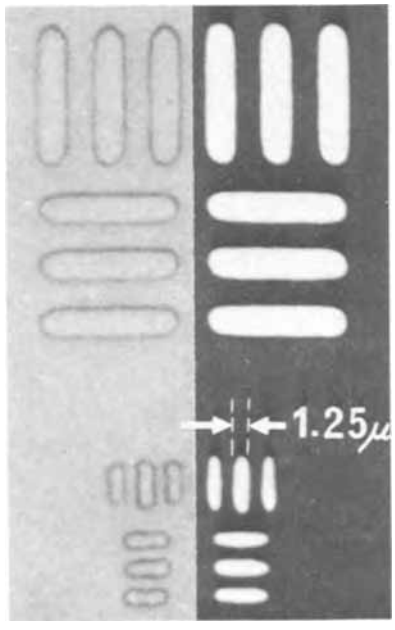

Fig. 3. Semitransparent vanadium oxide mask (left) compared with silver-gelatin master mask used in its preparation illustrating the fidelity and definition achievable using an inorganic oxide semitransparent photomask.

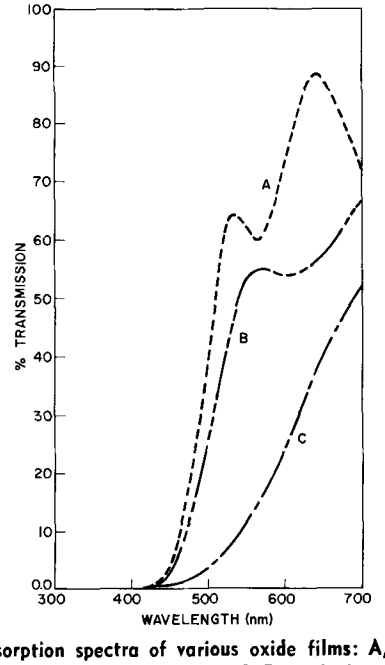

Fig. 4. Absorption spectra of various oxide films: A, iron oxide-vanadium oxide (3860 nm thick) from 25Fe-75V electrode; B, iron oxide-vanadium oxide (3150 nm thick) from 10Fe-90V electrode; C, iron oxide-nickel oxide (3700 nm thick) from 65Fe-35Ni electrode.

In addition, these films are too soft and thus easily scratched. It was felt that mixed films of vanadium oxide and iron oxide would have acceptable spectra and probably be intermediate in solubility and hardness between the two end members.

For exploratory measurements in the system iron oxide-vanadium oxide, varying numbers of ¼ x ¼ x 0.1 in. parallelepipeds of cold-rolled steel were spot-welded to a vanadium sputtering disk. From spectral transmission and etching results on films of several compositions, two, 10Fe-90V and 25Fe-75V,[1] were chosen for further study. Typical spectra are shown in Fig. 4 which also includes the spectrum for an oxide

[1] All materials compositions are expressed as mole fractions in per cent.

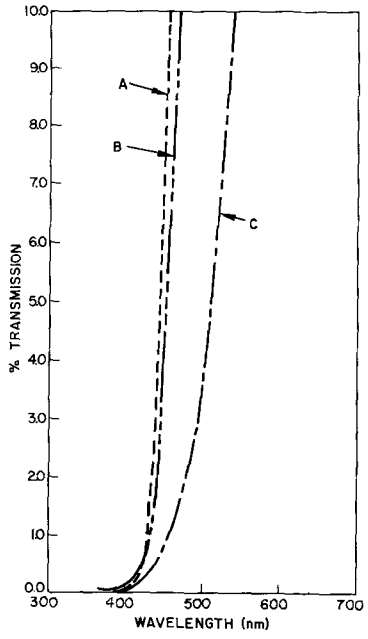

Fig. 5. Absorption spectra on an expanded scale near 400 nm for the same films as in Fig. 4.

film prepared from Nilvar (4), a 65Fe-35Ni alloy. Figure 5 shows on an expanded scale the spectra (near 400 nm, where strong absorption is required) for these same films.

These spectra (Fig. 4 and 5) are in general agreement with predictions from Table I. Thus, one notes that, as the Fe/V ratio increases, the absorption at wavelengths above 400 nm decreases presumably because the vanadium ion, which is being decreased in concentration, has an absorption maximum at about 425 nm. Such reasoning is highly suspect in general, however, because of the complex situation with respect to valence states possible in the system and the possibilities for charge transfer effects on the absorption spectrum.

The films in the iron-vanadium oxide system with a high vanadium oxide concentration show a strong tendency to become mottled when prepared on uncooled substrates. This has been shown to be due to plasma heating. In this regard, we note that the Fe_2O_3-V_2O_5 phase diagram (5) has a 635°C eutectic at about 12% Fe_2O_3 so that films with the highest percentage of vanadium oxide have a tendency to become fluid under our sputtering conditions. As the V_2O_5 concentration decreases, the fluidity should decrease with consequent decrease in mottling, as is observed.

Etching studies on these various film systems show that both the iron oxide and the iron oxide-nickel oxide films are extremely insoluble in both acids and bases when prepared either on uncooled substrates, where plasma heating raised the temperature of the substrate holder to about 160°C, or on substrates raised to 250°C with supplementary heaters. Etching studies on films prepared from the iron-vanadium alloy electrodes and deposited on either uncooled or heated substrates show a wide variety of solubilities from preparation to preparation even under ostensibly identical conditions. The tendencies were for the films with higher iron oxide concentration and those deposited at higher substrate temperatures (250°C was the highest studied) to be less soluble.

Concurrent with this investigation, MacChesney *et al.* (6) have been studying the preparation of iron oxide films by chemical vapor deposition. They noted a startling increase in solubility on lowering the substrate temperature from 185° to 160°C. It was found that the solubility of sputtered films containing iron oxide increased markedly if the temperature of the substrate holder was lowered to between 25° to 50°C by water cooling. Both the iron oxide and iron-nickel oxide lose patches of material during etching and the curvature of these patches suggests that there is strain in the films. These films are, therefore, not considered acceptable. The oxide film derived from the 10Fe-90V electrode could be heat treated at 300°C to decrease its solubility to values appropriate for use in preparing masks. Undoubtedly, this crystallite growth process would proceed considerably faster at 350°C but this has not been studied. The film dissolves nicely without the detached patches mentioned above for the iron oxide and iron-nickel oxide films. Long term heating of the film from the 25 Fe-75V electrode at 350°C apparently did not lead to sufficient crystal growth to decrease the solubility enough to be useful. It is possible that higher temperature heat treatment would be efficacious here but deformation of the glass substrate becomes increasingly a factor to consider. The etching rates of these and other films will be considered in greater detail in a forthcoming article.

In general, with these systems there is greater transmission above 500 nm if the films are prepared in 100% O_2 rather than 90% Ar-10% O_2. Somewhat surprisingly, the sputtering rates of the Fe-V alloys are higher in the pure oxygen than in argon-oxygen mixtures. This is perhaps due to the formation of a conducting ferric vanadate glass on the surface of the cathode (7). In general, d-c reactive sputtering deposition rates, of the order of 5-10 A/min, are undesirably low for practical use. However, Sosniak (8) has shown that deposition rates of about 100 A/min can be obtained by rf reactive sputtering. There is also the possibility of rf sputtering from an oxide cathode in argon.

Summary

Films of iron oxide, vanadium oxide, nickel oxide, iron oxide-vanadium oxide, and iron oxide-nickel oxide have been prepared by d-c reactive sputtering. All of these compositions show strong absorption of light near 400 nm and sufficient transmission at the sodium D line to be considered for use in a durable, selectively semitransparent mask. Of the various compositions studied, the films from the 10Fe-90V electrode show the most promising etching properties in acids and alkalis.

Acknowledgments

The authors are pleased to acknowledge help from a variety of sources. J. Sosniak performed some rf reactive sputtering studies which verified that practicable deposition rates can be obtained in the iron-vanadium oxide system. C. R. Kurkjian furnished advice on the selection of systems for study. Miss S. M. Vincent and J. E. Kessler performed the necessary chemical analyses.

Manuscript submitted March 13, 1970; revised manuscript received *ca.* Sept. 10, 1970. This was Paper 125 presented at the Los Angeles Meeting, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

APPENDIX

In addition to the systems discussed in the body of this paper, some other systems suggested by the list in Table I were investigated which proved to be less encouraging. These are grouped here for reference purposes with some remarks.

Lead silicate systems.—Lead silicate glasses are known (9) to absorb strongly in the spectral region near 400 nm. The electrodes used in preparing lead silicate films were made by wrapping lead foil around a silicon disk allowing both lead and silicon to be exposed. The ratio of lead to silicon was varied by varying the ratio of exposed areas. The composition of the gas phase (*i.e.*, the Ar/O_2 ratio) was quite important and may indicate that both valence states of

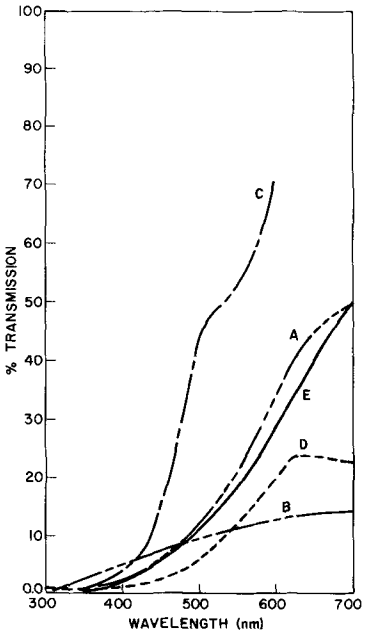

Fig. 6. Absorption spectra of various oxide films: A, lead silicate (2800 nm thick), Pb/Si ≈ 3 in. film; B, lead germanate (700 nm thick), Pb/Ge ≈ 3 in. film; C, molybdenum oxide (2800 nm thick); D, copper oxide (900 nm thick); E, vanadium oxide-copper oxide (2900 nm thick) from 50V-50Cu electrode.

lead should be present in approximately equal concentrations as suggested by Weyl (10). An example of one of the more encouraging spectra is shown in Fig. 6. Comparison with spectra in Fig. 4 for the films containing iron oxide indicates that the lead silicate films do not absorb as strongly at 400 nm as the iron oxide containing films. Etching of the lead oxide from the film was accomplished with hot (just below boiling) 30% H_2O_2. The resulting silica skeleton was removed by gently rubbing with a cotton swab. Fairly good test patterns were delineated as shown in Fig. 7.

Copper oxide.—This oxide film was formed by sputtering copper in 100% O_2. No etching studies were made (*cf.* Fig. 6).

Copper oxide-vanadium oxide.—This mixture was prepared from a 6½ in. disk electrode of copper on which ½ x ½ in. squares of vanadium foil were laid. The exposed areas were about 50Cu-50V. The etching properties of this combination were not studied because the Fe-V combination has a superior spectrum for our purposes. The Cu-V combination sputtered in O_2 about 4 times faster than Fe-V (*cf.* Fig. 6).

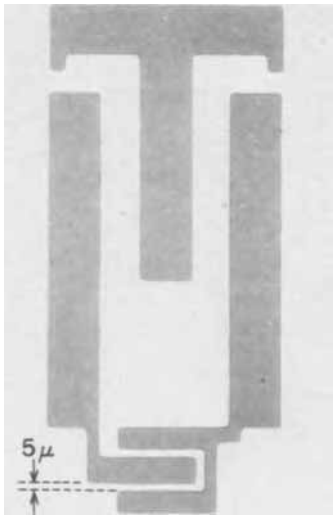

Fig. 7. A lead silicate photomask used to make an experimental transistor.

Molybdenum oxide.—Molybdenum oxide films were prepared by sputtering in 100% O_2. No etching studies were performed (*cf.* Fig. 6).

Other systems.—We have attempted to prepare CrO_3 and a high oxide of uranium with no success. Probably rf sputtering techniques should be used here. Also mercury oxide and zinc oxide films were prepared but proved uninteresting.

ABSTRACT

Electrical conductivity measurements were made on high purity ThO_2 at temperatures between 1000° and 1600°C and oxygen partial pressures of 10^{-1} to 10^{-22} atm. These measurements showed the presence of an oxygen pressure independent region of ionic conductivity at intermediate oxygen pressures and temperatures below about 1400°C, as well as a transition to predominant electron hole conductivity at high oxygen pressures. The Seebeck coefficient was measured over a wide range of oxygen partial pressures in several different gas mixtures at 1000° and 1200°C. The Seebeck coefficient in the region of pure ionic conduction is shown to be a function of the entropy of oxygen in the gas phase, rather than the oxygen partial pressure, as expected for the ionic Seebeck coefficient in the case of a constant ionic defect concentration. The behavior of the Seebeck coefficient in the mixed conduction region is also discussed.

It has been shown by Howard and Lidiard (1, 2) that valuable thermodynamic data for the enthalpies of formation of point defects and their heats of transport can be obtained by studies of the Seebeck coefficient in pure and doped ionic conductors. A number of such studies in the alkali and silver halides have appeared (3-6). Although some metal oxides are known to be ionic conductors over extensive temperature and oxygen partial pressure ranges, their ionic Seebeck coefficients have, until recently, received little attention. Recently, Ruka *et al.* (7), Fischer (8), and Goto *et al.* (9) have studied the ionic Seebeck coefficient of heavily doped metal oxide electrolytes containing very large charge carrier concentrations.

Previously reported studies (10-13) of nominally pure ThO_2 have shown that it is a mixed ionic-electronic conductor, the extent of the region of predominant ionic conduction being a function of temperature, oxygen partial pressure, and probably impurity content. The present study reports results of conductivity and thermal emf measurements on high purity ThO_2. The form of the Seebeck coefficient of a metal oxide mixed conductor in equilibrium with an oxygen electrode will be developed, and the experimental thermal emf results will be shown to be in accord with this analysis. Several of the contributions to the magnitude and temperature dependence of the ionic Seebeck coefficient will be discussed.

Experimental Techniques

Electrical Space Products (ESPI) 99.999% pure ThO_2 powder was pressed in a nylon die into bar-shaped, 3 x 3 x 15 mm specimens. The pressed samples, contained in ThO_2 crucibles and covered with loose pure ThO_2 powder, were sintered in air at 1800°C for about 4 hr. The resultant samples were typically about 96% of theoretical density. Mass spectroscopic analysis of the sintered specimens, given in Table I, showed less than 75 ppm of total metallic impurities and less than 15 ppm of nonmetallic impurities.

Thermoelectric power and total electrical conductivity measurements were made simultaneously on two specimens at temperatures between 1000° and 1600°C in oxygen partial pressures of 1 to 10^{-22} atm. These oxygen pressures were established by mixtures of oxygen-argon, CO_2-CO, or H_2O-H_2. The construction of the sample holder is shown in Fig. 1.

whose junctions were either embedded in small conical holes drilled through the ends of the bar-shaped sample or simply wrapped around the specimen ends. A cold finger immediately below the sample was used to impose various temperature gradients on the specimen. The gradients used did not exceed 10°C. Using a Fluke differential voltmeter and the platinum leads of the thermocouples, the thermal emfs at constant oxygen pressure and furnace temperature were measured as a function of the temperature gradient imposed. The Seebeck coefficient, $\alpha = |dE/dT|$, was calculated by a least squares analysis of about fifteen measured values of the thermal emf at various temperature gradients. The sign of the Seebeck coefficient was determined from the polarity of the cold end of the specimen, *i.e.*, from the relation $\alpha = (V_c - V_h)/(T_h - T_c)$ where the subscripts h and c denote the hot and cold ends respectively. Using this definition, the sign of α is consistent with the sign of the charge carrier.[3] The absolute Seebeck coefficient of ThO_2 was obtained by correcting the measured coefficient relative to platinum for the platinum contribution (14).

Platinum contacts were applied to the ends of the electrical conductivity sample with Engelhard platinum paste (No. 6082). At low oxygen pressures (in CO_2-CO and H_2O-H_2 mixtures) and high temperatures, particularly above 1400°C, the platinum wires supporting the relatively heavy ThO_2 specimens failed rapidly, apparently because of grain growth and boundary sliding. Two-terminal electrical conductivity measurements were made with a Wayne Kerr Type B601 radio frequency bridge. All of these measurements were made at 100 kHz after initial measurements showed no frequency dependence from 0.1 to 100 kHz and good agreement between a-c and d-c values.

Results

The results of the measurements of total electrical conductivity as a function of oxygen partial pressure at several fixed temperatures between 1000° and 1600°C are shown in Fig. 2. Three regions, characteristic of three different conduction mechanisms or charge carriers, are observed.

A region of pressure independent electrical conductivity is found at intermediate oxygen partial pressures at temperatures below about 1200°C. The galvanic cell measurements of Lasker and Rapp (10) showed that the ionic transference number in this region is essentially unity. It is clear in Fig. 2 that the decrease in width of this ionic conduction region with increasing temperature is caused by the rapid increase in n-type electronic conduction with increasing temperature

At high oxygen partial pressures, above about 10^{-3} atm, the conductivity appears to have a simple pressure dependence, of the form $\sigma \propto P(O_2)^{1/5}$. Simultaneous thermoelectric power measurements in this high oxygen partial pressure region showed that the electronic charge carriers involved are electron holes.

At high temperatures and low oxygen partial pressures ($T \geq 1400$°C and $P(O_2) \leq 10^{-10}$ atm), an n-type electronic conduction region was observed with $\sigma \propto P(O_2)^{-1/x}$ where x appears, from the very limited data available, to be about 6. The rapid increase in n-type electronic conduction with temperature would correspond to an activation energy of at least 3 eV for the defect formation process giving rise to the electrons.

The results of the measurements of the Seebeck coefficient of thoria in argon-oxygen, CO_2-CO, and H_2O-H_2 mixtures at 1000° and 1200°C are shown as a function of oxygen pressure in Fig. 3 and 4 respectively.

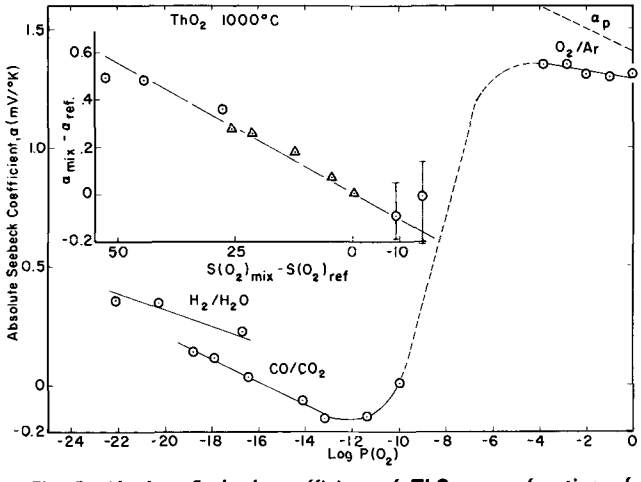

Fig. 3. Absolute Seebeck coefficient of ThO_2 as a function of oxygen partial pressure in several different gas mixtures at 1000°C. The inset is a plot of change in Seebeck coefficient with change in partial molar entropy of oxygen in the gas phase, relative to an arbitrary reference value. The dashed line, α_p, is the calculated electron hole Seebeck coefficient.

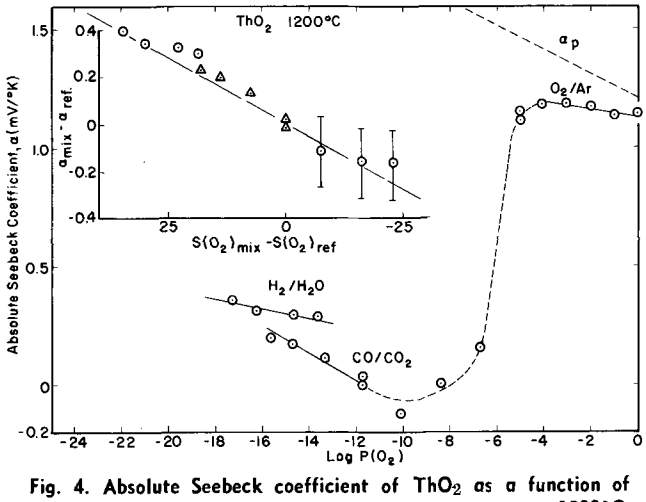

Fig. 4. Absolute Seebeck coefficient of ThO_2 as a function of oxygen partial pressure in several different gas mixtures at 1200°C. The inset is a plot of change in Seebeck coefficient with change in partial molar entropy of oxygen in the gas phase, relative to an arbitrary reference value. The dashed line, α_p, is the calculated electron hole Seebeck coefficient.

[3] This is always true for a pure electronic conductor. For a pure ionic conductor, only the homogeneous part of the Seebeck coefficient has a sign characteristic of the sign of the charge carrier. The homogenous and heterogeneous parts of the ionic Seebeck coefficient will be developed in a later section of the paper.

Discussion

The increased conduction at high oxygen partial pressures, shown in Fig. 2, is due to a transition from the purely ionic conduction observed at intermediate pressures to a predominance of p-type electronic conduction at 1 atm[10]. The apparent 1/5 dependence of the total conductivity on oxygen pressure is within the expected transition between the pressure independence of the purely ionic conduction region and a 1/4 dependence which would be expected for purely electronic conduction if the electron holes arise by either

$$O_2 \rightleftharpoons V_M'''' + 4h^\bullet \quad [1]$$

or

$$\tfrac{1}{2}O_2 \rightleftharpoons O_i'' + 2h^\bullet \quad [2]$$

with the ionic defect concentrations fixed (either intrinsically or by the presence of an impurity). The notation used and the development of the pressure dependence through the use of mass action and electroneutrality equations are described by Kröger and Vink (15). The symbol describes the defect, the subscript gives its position, the superscript gives its effective charge state (a prime representing a negative charge and a dot a positive one), and $h^\bullet$ represents an electron hole. This defect model involving a transition from ion to electron hole conduction within a region of constant ionic defect concentration was proposed by Lasker and Rapp (10). A detailed quantitative treatment of the conductivity behavior expected for this defect model and a fit of their experimental data to it has been given by Bransky and Tallan (16).

The 1/5 and 1/6 pressure dependences characteristic of Reactions [1] and [2], when the ionic defect concentrations involved are not constant, would be observed only at oxygen pressures much higher than those experimentally accessible. The nature of the predominant ionic defect in the ionic conduction region cannot, therefore, be stated with any certainty. However, based on geometrical considerations, it has frequently been suggested (10) that oxygen interstitials are the predominant ionic defect. For convenience, this assumption will be used throughout the remainder of this paper, since the essential features to be discussed do not depend on the nature of the ionic charge carrier assumed to be present.

The total Seebeck coefficient of a mixed ionic-electric conductor is given by the expression

$$\alpha_T = t_p \alpha_p + t_i \alpha_i \quad [3]$$

where α_T is the measured total Seebeck coefficient, α_p and α_i are the electron hole and ionic Seebeck coefficients, t_p is the electron hole transference number given by $\sigma(\text{hole})/\sigma(\text{total})$, and t_i is the ionic transference number given by $\sigma(\text{ionic})/\sigma(\text{total})$. Equation [3] and the specific forms of α_p and α_i for a given defect model can be derived for the cell

$$O_2(\text{gas}), \text{Pt} \;\overset{T}{||}\; ThO_2 \;\overset{T+\Delta T}{||}\; \text{Pt}, O_2(\text{gas}) \quad [4]$$

in a number of ways. The procedure that will be followed here is that used by Kröger (17) for a number of other materials and defect models. Three individual thermal potentials contribute to the over-all thermal potential measured; a homogeneous potential difference $\Delta\phi_{hom}$ due to the temperature gradient across the specimen, a heterogeneous potential $\Delta\phi_{het}$ due to the difference in contact potentials at the two electrode-specimen interfaces (which are at different temperatures because of the imposed temperature gradient), and the homogeneous potential differences $\Delta\phi_M$ due to the temperature gradients in the metal lead wires. When platinum is used for the leads, the potentials $\Delta\phi_M$ are very small (14) and will be neglected in the following discussion (the measured Seebeck coefficients reported here, however, have been corrected for the contribution of α_{Pt}). The over-all Seebeck coefficient of the cell is, therefore

$$\alpha_T = -\frac{\Delta\phi}{\Delta T} = -\frac{\Delta\phi_{hom}}{\Delta T} - \frac{\Delta\phi_{het}}{\Delta T} = \alpha_{hom} + \alpha_{het} \quad [5]$$

The specific case which will be treated here is that of an oxide with composition MO_2 having a defect structure dominated by a constant concentration of ionized defects introduced by impurities. Since as discussed earlier we do not know the true identity of the ionic charge carriers, we will assume here that they are fully ionized oxygen interstitials. The effect of alternate selections of the defect on the expression to be derived will be discussed later. We derive first the short-time homogeneous part of the ionic Seebeck coefficient, which is obtained from the potential across the oxide at times such that there is still no impurity concentration gradient, but the steady-state condition

$$2j(O_i'') = j(h^\bullet) \quad [6]$$

is fulfilled. The oxygen interstitial current, $j(O_i'')$, and the hole current, $j(h^\bullet)$, are given by

$$j(O_i'') = D(O_i'')\left\{ -\frac{\partial[O_i'']}{\partial x} + \frac{2q}{kT}[O_i'']\frac{\partial\phi}{\partial x} - \frac{Q(O_i'')}{kT^2}[O_i'']\frac{\partial T}{\partial x}\right\} \quad [7]$$

and

$$j(h^\bullet) = D(h^\bullet)\left\{ -\frac{\partial p}{\partial x} - \frac{q}{kT}p\frac{\partial\phi}{\partial x} - \frac{Q(h^\bullet)}{kT^2}p\frac{\partial T}{\partial x}\right\} \quad [8]$$

where $D(i)$ and $Q(i)$ are the diffusion coefficient and heat of transport of the *i'th* species. Since, in the present case, the total concentration of oxygen interstitials is assumed to be constant, fixed by the impurities, the concentration gradient of free oxygen interstitials appearing in the first term of Eq. [7] is obtained from the temperature dependence of the degree of association of interstitials and impurities given by

$$[(F_MO_i')] = \text{const}\,[O_i'']^2 \exp\left(\frac{\Delta H_p}{kT}\right) = [F_M]_T - 2[O_i''] \quad [9]$$

where $[F_M]_T$ is the total impurity content and ΔH_p is the enthalpy change for the association reaction

$$F_M^\bullet + O_i'' \rightleftharpoons (F_MO_i') \quad [10]$$

Accordingly

$$\frac{\partial[O_i'']}{\partial x} = \frac{\beta}{1+\beta}[O_i'']\frac{\Delta H_p}{kT^2}\frac{\partial T}{\partial x} \quad [11]$$

where β, the degree of association, is defined by

$$\beta \equiv \frac{[(F_MO_i')]}{[F_M]_T} \quad [12]$$

The hole gradient, appearing in the first term of Eq. [8], is obtained by applying the law of mass action to the defect formation reaction

$$\tfrac{1}{2}O_2 \rightleftharpoons O_i'' + 2h^\bullet \quad [13]$$

so that

$$p = \text{const}\,[O_i'']^{-1/2} P(O_2)^{1/4} \exp\left(-\frac{\Delta H_{ox}}{2kT}\right) \quad [14]$$

and

$$\frac{\partial p}{\partial x} = \frac{p}{2kT^2}\left\{\Delta H_{ox} - \frac{\beta}{1+\beta}\Delta H_p\right\}\frac{\partial T}{\partial x} \quad [15]$$

where $P(O_2)$ is the oxygen partial pressure and ΔH_{ox} is the enthalpy change for Reaction [13]. Combining Eq. [6-8], [11] and [15] and solving for $\partial\phi/\partial T$, we obtain for the homogeneous part of the Seebeck coefficient of the impurity controlled mixed conductor

$$\alpha_{hom} = -\frac{\partial\phi}{\partial T} = \frac{1}{qT}\left[t_p \left\{ \frac{\Delta H_{ox}}{2} + Q(h^{\cdot}) - \tfrac{1}{2}\frac{\beta}{1+\beta}\Delta H_p \right\} - t_i \left\{ \tfrac{1}{2}Q(O_i'') + \tfrac{1}{2}\frac{\beta}{1+\beta}\Delta H_p \right\} \right] \quad [16]$$

To obtain the heterogeneous part of the Seebeck coefficient applicable to this case, we consider the transfer reactions for oxygen between the gaseous oxygen electrode and the ThO_2

$$\tfrac{1}{2}O_2(g) + 2e^- \text{ (Pt)} \rightleftharpoons O^=\text{(elect)}$$
$$O^=\text{(elect)} \rightleftharpoons O_i'' \text{ (ThO}_2\text{)} \quad [17]$$

Equating the electrochemical potentials of the species involved in the over-all transfer reaction, the contact potential can be written

$$2q\,\Delta\phi_{Pt,\,ThO_2} = \tfrac{1}{2}\mu(O_2)_g + 2\mu(e^-)_{Pt} - \mu(O_i'')_{ThO_2} \quad [18]$$

where $\mu(i)$ is the chemical potential of the *i'th* species. The heterogeneous part of the Seebeck coefficient is given by

$$\alpha_{het} = -\frac{\Delta\phi_{het}}{\Delta T} = -\frac{1}{q}\left[\tfrac{1}{2}S(O_i'')_{ThO_2} - \tfrac{1}{4}S(O_2)_g - S(e^-)_{Pt}\right] \quad [19]$$

Since $Q(i)/T = S^*(i) - S(i)$, where $S^*(i)$ and $S(i)$ represent the transport and partial molar entropies respectively of the *i'th* species, Eq. [16] and [19] can be combined to obtain the total Seebeck coefficient. In the region of pure ionic conduction, where $t_i = 1$, the Seebeck coefficient for this defect model would be given by

$$\alpha_i = -\frac{1}{q}\left[\tfrac{1}{2}S^*(O_i'') - \tfrac{1}{4}S(O_2)_g - S(e^-)_{Pt} + \tfrac{1}{2}\frac{\beta}{1+\beta}\frac{\Delta H_p}{T}\right] \quad [20]$$

If α_i had been derived on the basis of a fully ionized metal vacancy model, it would have essentially the same form as Eq. [20], but would be given by

$$\alpha_i = -\frac{1}{q}\left[\tfrac{1}{4}S^*(V_M'''') - \tfrac{1}{4}S(O_2)_g - S(e^-)_{Pt} + S(O_o^x) + \tfrac{1}{4}\frac{\beta}{1+\beta}\frac{\Delta H_p}{T}\right] \quad [21]$$

where the partial molar entropy of oxygen on oxygen lattice sites is introduced because of the over-all transfer reaction

$$\tfrac{1}{2}O_2(g) + 2e^- \text{ (Pt)} \rightleftharpoons O_o^x + \tfrac{1}{2}V_M'''' \quad [22]$$

The form of α_p can be obtained easily by expressing the heterogeneous part of the Seebeck coefficient in somewhat different terms. If we consider the transfer of electrons between the electrode and the ThO_2 and make use of Eq. [15] for $\partial p/\partial T$, it can be shown that

$$\alpha_{het} \simeq \frac{1}{qT}\left[kT\ln\frac{N_v}{p} - \frac{\Delta H_{ox}}{2} + \tfrac{1}{2}\frac{\beta}{1+\beta}\Delta H_p\right] \quad [23]$$

where N_v is the density of states for electron holes. In the region of pure electronic conduction, where $t_p = 1$, the Seebeck coefficient for this defect model would be found by combining Eq. [16] and [23], to obtain

$$\alpha_p = \frac{k}{q}\left[\ln\frac{N_v}{p} + \frac{Q(h^{\cdot})}{kT}\right] \quad [24]$$

Although thermodynamic data are available for the calculation of $S(O_2)$ in the gas phase, the absolute Seebeck coefficient in the ionic region cannot be calculated from Eq. [20] or [21] without calculated or experimental values of the transport and partial molar entropies of the defects in the metal oxide and ΔH_p. However, as indicated by Ruka *et al.* (7), the Seebeck coefficient difference for two different gas mixtures can be calculated for a range of oxygen pressures over which all terms on the right of Eq. [20] or [21], except $S(O_2)$ in the gas phase, are either essentially constant or negligible. Under these conditions, Eq. [20] and [21] simplify to

$$(\alpha_i)_{gas\ 1} - (\alpha_i)_{gas\ 2} = \frac{1}{4\mathbf{F}}\left[S(O_2)_{gas\ 1} - S(O_2)_{gas\ 2}\right] \quad [25]$$

where **F** is the Faraday constant. Experimentally, it is convenient to choose the Seebeck coefficient at some gas mixture within the purely ionic conduction region as a reference value so that

$$(\alpha_i)_{gas\ 1} - (\alpha_i)_{ref} = \frac{1}{4\mathbf{F}}\left[S(O_2)_{gas\ 1} - S(O_2)_{ref}\right] \quad [26]$$

The calculation of molar entropies of oxygen in the gas phase is reviewed in the Appendix.

It may be noted from Eq. [26] that the change in ionic Seebeck coefficient is a unique function of the change in entropy of oxygen in the gas phase, not the change in oxygen partial pressure. Precisely this behavior was observed for ThO_2 in oxygen-argon, CO_2-CO, and H_2O-H_2 mixtures at 1000° and 1200°C, as shown in Fig. 3 and 4. The discontinuities in magnitude and slope between segments of the α_i *vs.* $P(O_2)$ plots obtained in different gas mixtures are absent in the α_i *vs.* $\Delta S(O_2)$ plots, which are linear with the anticipated $1/(4\mathbf{F})$ slope

Calculated values of α_i in the mixed conduction region, where $0 < t_p < 1$, are also included in the $\Delta\alpha$ *vs.* $\Delta S(O_2)$ plots of Fig. 3 and 4, along with their probable error limits. These values were satisfactorily calculated from Eq. [3] using values of the transference numbers calculated from Fig. 2, the measured values of α_T, and extrapolated values of α_p. The agreement of the $\Delta\alpha_i$ *vs.* $\Delta S(O_2)$ plot with Eq. [26] over a wide range of oxygen partial pressures indicates the validity of the assumptions made in the derivation of that equation for this case of nominally pure ThO_2.

Using the measured values for the magnitude of α_i, shown in Fig. 3, reported values of $S(O_2)_g$ (19) and $S(e^-)_{Pt}$ (14), and assuming $\beta\Delta H_p/T$ very small in Eq. [20], values for the transport entropy of oxygen interstitials can be calculated. The value found, $S^*(O_i'') = 14.5 \pm 0.5$ eu, at 1000°C over the whole range of oxygen pressures from 10^{-13} to 10^{-23} atm may be compared to the value of 10.3 to 10.9 eu found for $S^*(V_o'')$ in stabilized zirconia by Ruka *et al.* (7). Because of the small magnitude of α_i, evident in Fig. 3 and 4, it was not possible to obtain a good measured value for its temperature dependence and, therefore, it was not possible to obtain the temperature dependence of $S^*(O_i'')$ from the derivative of Eq. [20].

Thus, the Seebeck coefficient of the ThO_2 used in this study displays the behavior anticipated for a mixed ionic-electronic conductor with a fixed concentration of ionic defects. However, to extract thermodynamic values for the enthalpies of formation and heats of motion of the defects, one would have to have a ThO_2 specimen of sufficient purity that the intrinsic defect behavior can be observed.

APPENDIX

The molar entropy of oxygen in the gas mixture, $S(O_2)_g$, is calculated thermodynamically. Assuming the reaction

$$X + \tfrac{1}{2}O_2 \rightleftharpoons XO$$

where X can be CO or H_2 and XO would then be CO_2 or H_2O, then summing chemical potentials at equilibrium

$$\mu(XO) - \mu(X) - \tfrac{1}{2}\mu(O_2) = O$$

Over a range of gas mixtures where

$$\mu(a) - \mu^\circ(a) - RT \ln P(a)$$

where $P(a)$ is the partial pressure of gas "a" in the mixture

$$S(O_2)_g = -\frac{\partial \mu(O_2)}{\partial T}$$

$$= 2\left[S^\circ(XO) - S^\circ(X) - R \ln \frac{P(XO)}{P(X)}\right]$$

For a mechanical mixture of oxygen in an inert gas, one has simply

$$S(O_2)_g = S^\circ(O_2) - R \ln P(O_2)$$

Acknowledgment

The authors are indebted to Mr. William Leisler for his assistance in the experimental measurements involved in this study.

Technical Notes

The Effect of Water on the Dielectric Constant of Vapor Deposited Silica Films

T. O. Sedgwick* and S. Krongelb

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

While making capacitance *vs.* voltage measurements below room temperature on MOS structures fabricated with chemically vapor deposited SiO_2 on Ge, we found a marked decrease in the capacitance with decreasing temperature for some of the SiO_2 films. The temperature sensitivity of the dielectric constant was found to be dependent on the oxide deposition conditions and subsequent annealing treatments, and was shown to be related to the water content of the film. The temperature dependence of the capacitance proved to be a conveniently measured, nondestructive indicator of the water content in SiO_2 films on completed devices, and was used to demonstrate the reaction between water in the film and Al metallization.

Experimental

The oxide films were vapor deposited by the pyrolysis of tetraethylorthosilicate in oxygen at 432°C (1) (designated LT SiO_2) or in forming gas at 735°C (2) (designated HT SiO_2). Films 1500-2000Å thick were deposited on Ge wafers for electrical measurements or on doubly polished Si wafers for IR measurements. Where densification (DENS) is indicated, the samples were subjected to 800°C in forming gas for 17 min;[1] where temperature-humidity stressing (T&H) is cited, the films were exposed to 85% relative humidity at 85°C for 4 days. The MOS structures were completed by the evaporation of approximately 30 mils diam, 5000Å thick Au or Al dots through metal masks. Samples were stored in dessicators with "Drierite" between fabrication steps and measurements.

The capacitance of the devices was measured at 150 kHz under a d-c bias sufficient to accumulate strongly the Ge surface (4). Where it was desired to know the actual dielectric constant, the oxide thickness was measured by interferometry, and the dot size was measured with a Nikon shadowgraph. The IR optical density of the films was measured at 3400 cm^{-1} for H_2O and 3650 cm^{-1} for the SiOH absorptions (3).

Results and Discussion

Figure 1 shows the temperature dependence of the capacitance by plotting the ratio $C_{T°K}/C_{300°K}$ *vs.* tem-

* Electrochemical Society Active Member.

Key words: temperature dependence, anneal, MOS devices.

[1] Pliskin (3) has shown that densification in steam is more effective than treatment in a dry atmosphere; however, the high reactivity of Ge with water at elevated temperatures precluded the use of a wet densification process.

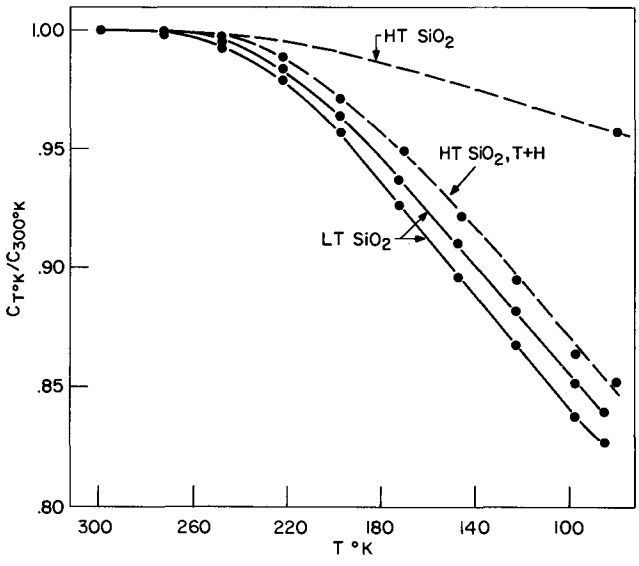

Fig. 1. Capacitance ratio, $C_{T°K}/C_{300°K}$ as a function of temperature for several SiO_2 films.

perature. We note that the capacitance of HT SiO_2 which was subject to T&H and the capacitance of LT SiO_2 exhibit a similar dependence on temperature, and that both of these films are much more sensitive to temperature than HT SiO_2 which was not subject to T&H. This behavior suggests that water or some polar reaction product of H_2O and SiO_2 whose dielectric relaxation motion is frozen out at low temperatures accounts for the low value of $C_{T°K}/C_{300°K}$. It would appear that H_2O is not present in the free state in the oxide films, since the capacitance did not exhibit a discontinuity at 0°C which could be associated with the freezing of an aqueous phase.

The above picture is supported by the data in Fig. 2 which show that the decrease in $C_{77°K}/C_{300°K}$ for various films correlates with an increase in the H_2O and OH content of corresponding films as measured by IR absorption. (The ratio of the capacitance at 77°K to that at 300°K is a convenient over-all indication of the temperature sensitivity of the dielectric constant and is the parameter used in subsequent discussion). The optical density per micron measured at 3400 cm^{-1} is used as an indicator of the H_2O content; a similar measurement at 3650 cm^{-1} represents the OH content.

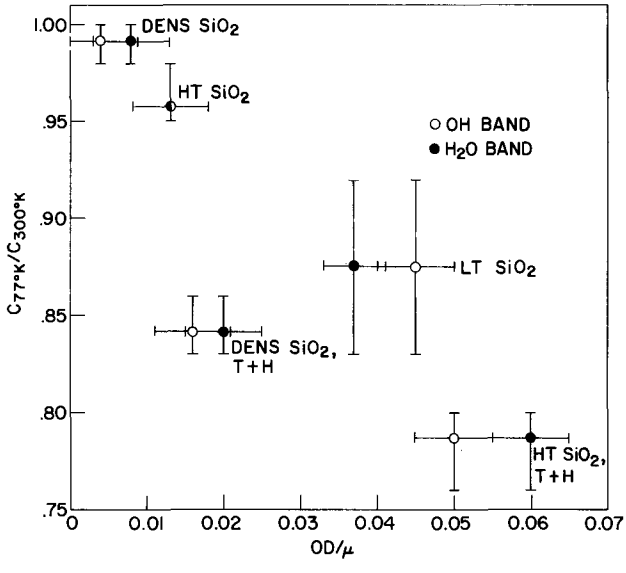

Fig. 2. Capacitance ratio, $C_{77°K}/C_{300°K}$, as a function of optical density per micron, O.D./μ, of H_2O (●) and SiOH (○) absorption maxima for various SiO_2 films.

Actually, there is some overlap of these bands, especially at the higher H_2O and OH levels, so there is considerable uncertainty in these measurements. Nevertheless, the general correlation between $C_{77°K}/C_{300°K}$ and the IR measurements is visually apparent for all but the DENS SiO_2, T&H samples. We can suggest no explanation for this one exception.

Figure 3 shows that the measured dielectric constant at room temperature for films, prepared in a variety of ways, approaches the value of 3.8-3.9 expected for pure SiO_2 as $C_{77°K}/C_{300°K}$ approaches 1.00. This finding is consistent with the hypothesis that water in the film is responsible for the decrease of $C_{77°K}/C_{300°K}$ from unity, since the addition of water to SiO_2 can increase the dielectric constant (5).

Several interesting features become apparent when we observe how the temperature sensitivity of the dielectric constant is affected by various annealing treatments as shown in Fig. 4. If we densify either LT SiO_2 or HT SiO_2, the capacitance ratio is increased to about 0.99 for both films. Previous work (3, 6) has shown that a densified film contains less water and is generally superior to ordinary HT SiO_2 which in turn is drier and superior to LT SiO_2. This grading of films is reflected in the ratio of $C_{77°K}/C_{300°K}$. Exposure of either the densified or undensified films to T&H (dotted lines) causes a marked decrease in $C_{77°K}/C_{300°K}$ indicating the pickup of water as discussed above.

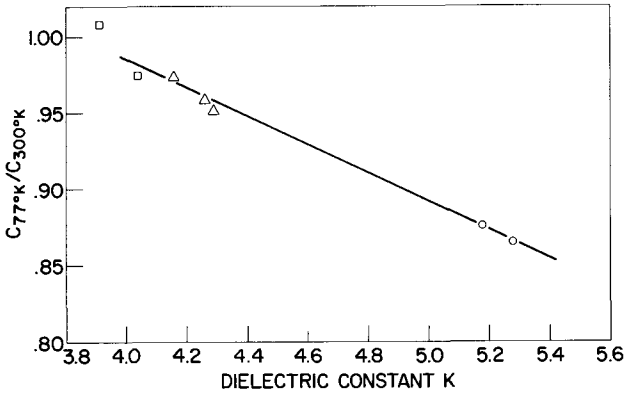

Fig. 3. Capacitance ratio, $C_{77°K}/C_{300°K}$ vs. dielectric constant for various SiO_2 films; □ DENS, △ HT, ○ LT SiO_2.

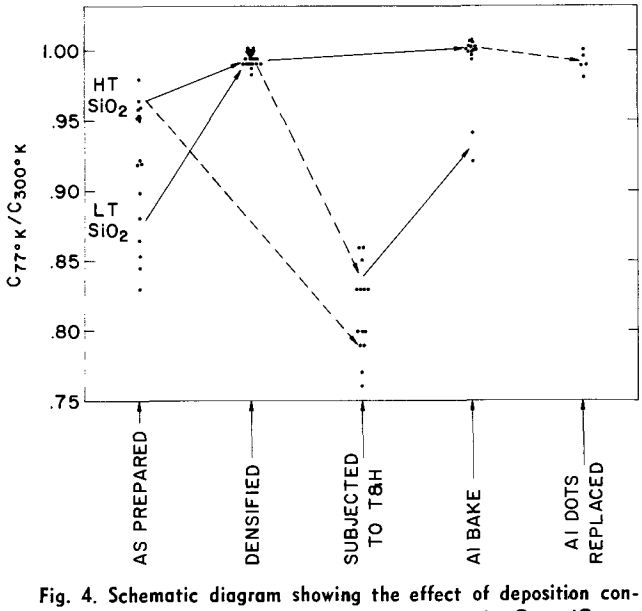

Fig. 4. Schematic diagram showing the effect of deposition conditions and annealing processes on capacitance ratio, $C_{77°K}/C_{300°K}$ for SiO_2 films (the terms LT SiO_2, T&H, Al BAKE, etc., are defined in text).

A particularly interesting point is the effect of annealing the completed devices, *i.e.*, with Al metallization in place, at 230°C in air for from 2 to 60 hr (referred to as Al BAKE). This treatment brings the $C_{77°K}/C_{300°K}$ ratio to 1.000 ± 0.003, which is as close to unity as we can measure. The reduction of the temperature sensitivity is attributed to the removal of water or of the water-SiO_2 reaction product and is demonstrated even more clearly in the case where the oxide has previously been exposed to T&H. The Al presumably reacts with the water or water-SiO_2 reaction product to form Al_2O_3 and some form of hydrogen. This picture is supported by the fact that in a similar experiment (not shown in Fig. 4) on HT SiO_2 in which gold, a nonreactive metal, was used in place of Al, there was no change in $C_{77°K}/C_{300°K}$. Since previously Hu and Young (7) and Burkhardt (8) have found no reaction between Al and thermal SiO_2 below 400°C we believe that the present results associated with Al BAKE are totally attributable to an Al-H_2O reaction.

If the Al is removed by wet chemical etching after the Al bake and a fresh Al metallization is applied, the $C_{77°K}/C_{300°K}$ ratio reverts to the pre-Al BAKE value of 0.99 (see Al REMOVE in Fig. 4). It is, therefore, thought that the last 1% difference is due directly or indirectly to H_2O retained in just the surface layers of the SiO_2.

It is interesting to note that Balk (9), Deal *et al.* (10), and Sedgwick and Krongelb (11) have all postulated that Al reacts with residual H_2O in SiO_2 to produce atomic hydrogen. The atomic hydrogen is thought to be responsible for the removal of surface states on Si surfaces or for the induced effective negative charge on Ge surfaces. The present work supports this hypothesis by showing that under certain conditions Al does interact with SiO_2 films resulting in a decrease in temperature sensitivity of the capacitance. This fact is most readily accounted for postulating that the Al reacts to remove some form of H_2O in the SiO_2 films.

The capacitance change with temperature effect reported on above would seem to be a relatively easy nondestructive technique for the determination of H_2O or water produced reaction products in SiO_2 films on completed devices.

Magnesium Germanate and Fluorogermanate

E. Kostiner* and P. W. Bless

Baker Laboratory of Chemistry, Cornell University, Ithaca, New York 14850

Manganese-activated magnesium germanate and magnesium fluorogermanate have found wide use as red-emitting phosphors. Since their original discovery (1) and further development (2-5), the activator center has been identified as quadrivalent manganese in an approximately octahedral crystal field (6, 7). Little or no mention has been made in the literature as to the effect of the addition of magnesium fluoride (to form the fluorogermanate) on the fluorescence properties of the manganese activator except for the increase in fluorescence efficiency (5).

The compound "Mg_4GeO_6" (magnesium germanate) has been reported to occur in the magnesium oxide-germanium oxide system as a stable phase up to a temperature of 1495° ± 10°C where it dissociates to form Mg_2GeO_4 (forsterite form) and MgO (8). The powder pattern of magnesium germanate has previously been indexed on the basis of an hexagonal unit cell (a_o = 11.773, c_o = 14.445Å) with several unassignable peaks (9).

We have been successful in growing small single crystals of both the germanate and the fluorogermanate by standard flux growth techniques. This note reports the crystal growth and powder x-ray crystallographic data for these two compounds.

Experimental

The phosphors were prepared using conventional ceramic techniques. Magnesium oxide (Mallinckrodt Analytical Reagent) and germanium oxide (Electronic Grade, Kawecki Chemical Company) in a 4:1 mole ratio with one mole per cent (m/o) manganese carbonate (Fisher Certified Reagent) added as an activator were mixed and ground under acetone to form the germanate. The formulation of the fluorogermanate involves the substitution of one-eighth of the MgO by magnesium fluoride (Crystal Grade, Sylvania Electric Products Company). After removal of the acetone at 110°C the mixtures were fired in platinum crucibles at 1000°C in air for one hour, reground and fired for 16 hr at 1200°C.

A suitable high temperature flux for the growth of the fluoride-free germanate was lead oxide (Fume Litharge, Evans Lead Company). Lead fluoride (Extra Pure Grade, BDH Chemicals Company, Ltd.) was used for the fluorogermanate. Typical crystal growth runs were : 67.5g PbF_2, 6.75g fluorogermanate; 75g PbO, 27g germanate; each in a 50 cc platinum crucible. The charges were held at 1300°C for 4 hr in a silicon car-

* Electrochemical Society Active Member.

Key words: crystal growth, magnesium germanate, magnesium fluorogermanate.

bide resistance-heated furnace, cooled at ~4°/hr to 900°C and then removed from the furnace. To protect the platinum crucibles dry oxygen was passed through the furnace.

The germanate crystals were removed from the flux by leaching with hot dilute hydrochloric acid. Since the fluorogermanate crystals are soluble in acid they had to be separated mechanically or by repeated extraction with water. In all cases, crystals of magnesium oxide were found as a secondary product.

Results

Crystals of both the germanate and the fluorogermanate are lathe-shaped with typical dimensions 1 x 2 x 0.2 mm. Occasionally, needle crystals grew out of the flux. Macroscopic twinning was quite common with a twin angle of 59-60°. The experimental densities (pycnometric) are both 3.98(4) g/cc.

The compounds are isostructural. Single crystal precession and Weissenberg photographs indicate *mmm* (orthorhombic) symmetry. The complete three-dimensional crystal structure of the unsubstituted germanate has been completed (10). This x-ray diffraction study, along with careful analytical results, establish the true stoichiometry to be $Mg_{3.5}Ge_{1.25}O_6$ rather than Mg_4GeO_6. Indeed, careful powder x-ray diffraction photographs (focusing Guinier camera) of a fully sintered ceramic mixture of composition $4MgO \cdot GeO_2$ show additional lines assignable to MgO.

The indexed powder patterns of ground single crystals (x-ray diffractometry and Guinier photographs, Cu Kα radiation) are given in Table I. Indexing was only carried out to a d-spacing of 1.56 since by that point an orthorhombic cell of this size gives a continuum of possible index assignments. Powder line assignments were made with the aid of the single crystal photographs.

A least squares refinement of the powder data gave the orthorhombic lattice parameters listed in the table. The relationship between the orthorhombic cell and the previously reported pseudo-hexagonal cell can be seen as follows: Each of the 100 planes of the orthorhombic cell describes a network of C face-centered hexagonal cells. Inspection of these networks indicates the presence of the orthorhombic b and c axes whose vector sum makes a 60° angle with the orthorhombic c axis and represents the pseudo-hexagonal a axis. This c axis in turn becomes one-half of the pseudo-hexagonal a axis. The a axis of the orthorhombic cell and the c axis of the pseudo-hexagonal cell are identical.

We are proceeding with the structure refinement of magnesium fluorogermanate. Analytical data indicates that approximately 8 w/o (weight per cent) fluorine is substituted into the structure and that charge compensation is attained by a deficiency of germanium. A detailed discussion of the stoichiometry will appear with the publication of the complete structure.

In summary, we have prepared single crystals of magnesium germanate and fluorogermanate and reported their indexed powder patterns. Analytical results indicate that fluorine is incorporated into magnesium fluorogermanate. Since crystal x-ray diffraction shows the two compounds to be isostructural and that the compound magnesium germanate does not have the stoichiometry Mg_4GeO_6 but $Mg_{3.5}Ge_{1.25}O_6$.

Work is in progress on the complete three-dimensional structure of the fluorogermanate and will be published shortly.

Reaction of Water Vapor with Anodic Aluminum Oxide

Studied by Wide-Line NMR Spectroscopy

Bernard R. Baker and Robert M. Pearson

Kaiser Aluminum and Chemical Corporation, Center for Technology, Pleasanton, California 94566

Porous anodic oxide films on aluminum are conventionally sealed by immersion in boiling water. Current theories state that conversion of essentially anhydrous oxide occurs, predominantly at the pore mouth, to form a less dense hydrated oxide which partially plugs the pores. The literature on sealing and on anodizing in general was reviewed by Diggle, Downie, and Goulding (1).

A different view of sealing, presented by Murphy, regards sealing as an ion exchange replacement of surface anions by hydroxyl ions (2). Murphy considers the coating produced in sulfuric acid electrolyte to consist of an array of alumina crystallites similar to a rock pile in which the pores are regions of lesser density packing of crystallites.

We have begun a study of the sealing process using wide-line proton NMR spectroscopy and present here the results of the first phase of our work, namely, the interaction of porous anodic oxides with water vapor.

A typical NMR spectrum of an anodic coating is shown in Fig. 1. This spectrum consists of a narrow line due to physically adsorbed water, $\Delta H \sim 0.2G$, superimposed on a broad line, $\Delta H \sim 7G$, due to hydroxyl groups, *i.e.*, chemisorbed water. The narrow line in Fig. 1 is artificially broadened here by instrument conditions.

The broad hydroxyl band can be suppressed by using a narrow modulation. Under these conditions a single narrow line is obtained which can be used as a quantitative measure of the adsorbed water present. The physically adsorbed water, and therefore the narrow band of the spectrum, can be removed under vacuum at room temperature allowing study of the broad band.

Experimental

Eight 6 x 4.05 in. pieces of 0.003 in. thick 1199 foil were partially slit into nine 0.45 in. strips leaving the ends intact. The eight pieces were bolt racked to a 2024 alloy frame as one rack load and were anodized for 1 hr at 15V in 15% sulfuric acid at 25°C. The work was thoroughly rinsed in deionized water and blown dry in a stream of nitrogen. The strips were hung as banks of nine from a glass frame in a covered battery jar containing a small amount of water. No direct contact of the work with liquid water was permitted. The jar was kept at ambient laboratory temperature (21° ± 2°C). At intervals a bank of nine strips was withdrawn. One strip was used for a coating weight determination; the remaining eight strips were cut into 1 in. pieces and placed in a 15 mm sample tube fitted with a ground glass joint and stopcock, allowing attachment to a vacuum line.

The NMR measurements were made at 16 MHz using a Varian spectrometer Model DA-100-15 equipped with a 4210 variable frequency oscillator. We found that the orientation of the sample strips relative to the receiver coil was critical, care being necessary to achieve a minimum reading on the detector level meter before introduction of the leakage to obtain an absorption mode spectrum. The magnetic field was modulated at 40 Hz with an amplitude depending on the width of the line. The amplitude varied between 0.125 and 2.0G, the wider modulation being used to study the broad hydroxyl band.

The area under the absorption curve can be obtained by double integration of a derivative curve such as shown in Fig. 1.

The concentration of physically adsorbed water on the anodic coating was measured by comparing the double integral of the NMR spectrum obtained using a modulation of 0.125G with the double integral of a

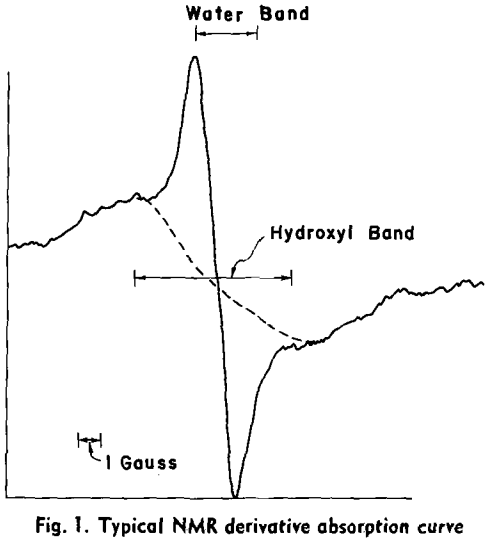

Fig. 1. Typical NMR derivative absorption curve

Key words: anodizing, sealing, adsorption.

spectrum from a transition alumina containing a known concentration of adsorbed water.

The anodic coating was then placed on a vacuum rack and the physically adsorbed water pumped off. The NMR spectrum was measured using a modulation of 2G. Double integration and comparison to a gibbsite spectrum gave the concentration of hydroxyl groups in the anodic coating.

Nitrogen adsorption and desorption isotherms were measured on an Aminco Adsorptomat using portions of each anodized sample reserved for that purpose. Pore radius distribution curves were calculated from these data along with surface area calculations by the BET procedure and cumulative area procedure assuming cylindrical pores.

Discussion

The rate of uptake of hydroxyl and physically adsorbed water is shown in Fig. 2 along with the weight gain expressed as a percentage of total oxide weight. The weight gain was about 14% after a two-week exposure to 100% relative humidity. The increase in hydroxyl content was something less than twice this value. This is consistent with the following mechanism for water adsorption. We assume the initial surface to be largely anhydrous. It must consist of oxide ions and a considerable concentration of aluminum ions having an incomplete coordination sphere similar to the picture developed by Peri for an active alumina surface (3). This is shown in Fig. 3. Every water molecule chemisorbed to fill an aluminum ion coordination site creates 2 hydroxyl groups on the surface. A concentration of 19% hydroxyl observed in Fig. 2 must therefore represent a 9.5% weight gain. The additional 4.5% weight gain shown in Fig. 2 is accounted for by the physically adsorbed water, presumably bound to the surface hydroxyls by hydrogen bonding.

The BET surface area of the sample before exposure to water vapor was 62 m^2/g. The mean pore diameter was 120Å. This is consistent with the known pore densities and diameters obtained by electron microscopy (4). After two weeks exposure to water vapor the specific surface area dropped to 5 m^2/g and the pore diameter fell to 40Å. Surface areas can also be estimated from the line width of the broad hydroxyl NMR band (5). This estimate is based on a linear relationship observed between line width and BET surface areas of a series of transition aluminas. The relationship was rationalized by the assumption that a surface hydroxyl proton is more mobile than that of an interior hydroxyl. Surface hydroxyls therefore give rise to a narrower band than do interior hydroxyls. Using this relationship we estimated the NMR surface area to be 329 m^2/g. The apparent discrepancy is resolved, however, if we consider the oxide structure to be a "rock-pile" of crystallites similar to the picture suggested by Murphy (2) and Michelson (6). We suggest that nitrogen adsorption occurs only on pore walls but that the internal surface in the crystallite interstices is accessible to hydrogen ions and oxide or hydroxyl ions by surface migration on the crystallite faces.

GaAs-GaAsP Heterostructure Injection Lasers

M. G. Craford, W. O. Groves,* and M. J. Fox*

Monsanto Company, St. Louis, Missouri 63166

GaAs-GaAlAs heterostructure injection lasers with performance far superior to previous GaAs lasers have been reported (1-5). These devices consist of a layer of p-type GaAs with a thickness, W, sandwiched between n-type GaAs and p-type GaAlAs. In this paper we report results obtained using a GaAs-GaAsP heterostructure.

The GaAs-GaAsP structure which can be grown using vapor phase epitaxy allows better control of the impurity profile and degree of compensation than can be obtained using the GaAlAs structure which must be grown by means of liquid phase epitaxy. On the negative side the lattice mismatch in the GaAsP system is much greater than in the GaAlAs system, the lattice parameters of GaP, GaAs, and AlAs being 5.4506, 5.6533, and 5.6606, respectively (2). The resulting lattice mismatch gives rise to dislocations at the GaAs-GaAsP interface (6) which can act as nonradiative recombination centers for the injected electrons.

In the laser heterostructure the high band gap alloy layer provides a barrier which serves both to confine the injected electrons in the narrow p-type GaAs region and as a waveguide to confine the modes of electromagnetic radiation. If the dominant effect of the barrier is to confine injected electrons, and if the misfit dislocations at the GaAsP-GaAs interface lead to a high surface recombination velocity, then no improvement in laser performance would be expected with this system. However, if the minority carrier diffusion length is short compared to the width of the confinement region and if the barrier is effective with regard to confining electromagnetic radiation, then improved laser performance should be possible because the dislocations would not be expected to provide effective photon scattering centers. As will be seen below, improved laser performance was not observed, and there was no evidence that electromagnetic mode confinement contributed to the performance of these devices. The reason that electromagnetic mode confinement apparently has a major effect in GaAlAs heterostructures and not in the GaAsP structures studied here is not understood.

Crystal Growth and Fabrication

The device structures which are shown schematically in Fig. 1 were grown using standard vapor epitaxial techniques on GaAs substrates. Initially a 100-200μ thick n-type layer of GaAs was grown with a Te impurity concentration of $n \sim 3 \times 10^{18}/cm^3$. This was followed by the growth of a compensated p-type GaAs layer of the desired thickness, W, which formed the recombination region of the device. In this layer the n-type carrier concentration remained unchanged, but Zn was added to give a net carrier concentration of $p \sim 1 \times 10^{19}$. Finally an uncompensated GaAsP alloy layer ($p \sim 1 \times 10^{19}$) was grown. For one series of runs the alloy layer was grown so that an abrupt alloy composition step from $x = 0.0$ to $x \sim 0.1$ m/o (mole per cent) GaP occurred at the GaAs-GaAsP interface, see Fig. 1(a). This composition change corresponds to change in band gap energy or barrier height of $\Delta E \sim 0.1$ eV. Previous work indicated that a barrier of this height would confine the majority of injected electrons (7) as well as provide an effective waveguide for electromagnetic mode confinement (4). It was hoped that interfacial dislocations could be reduced to a satisfactory extent by keeping Δx as small as possible.

In a second series of runs the alloy composition was graded to a final composition of $x \sim 0.10$ at the rate of $\sim 4\%/\mu$, Fig. 1(b). In all cases the total thickness of the alloy layer was $15 \pm 5\mu$.

In the case of the abrupt heterostructures the thickness of the recombination region was measured on the finished devices to within $\pm 0.2\mu$ using a scanning electron microscope. There was no clear boundary in the case of the graded structures so W was calculated from the growth rate with an estimated accuracy of $\pm 1\mu$.

After growth the heterostructure received a 10-min 875°C $ZnAs_2$ diffusion which lowered the diode resistance and eliminated contacting difficulties. Diode fabrication was standard and consisted of lapping the structure to a thickness of $\sim 100\mu$, metallizing the p- and n-type surfaces, and sawing and cleaving the wafer into 100 x 250μ chips. The Fabry-Perot surfaces were not metallized, and generally the structures were not heat-treated after growth. In a few cases the structures were heat-treated, but no significant improvement in performance was observed.

Experimental Results

The threshold current densities *vs.* W are shown in Fig. 2. Each data point in Fig. 2 as well as Fig. 3, 4, and 5 represents the average of a batch of ≥ 10 diodes. Diodes which exhibited markedly inferior performance were considered unrepresentative and were not included in the average. Values of W investigated range from $W = 0$, in which case the $GaAs_{0.9}P_{0.1}$ layer was grown immediately on the n-type epitaxial layer, to $W > 10\mu$ where the devices were simply grown junction GaAs lasers with no alloy layer.

It can be seen that at 300°K the threshold current density, J_{th} increases monotonically with decreasing W and for $W = 0$ lasing was not observed. The performance of devices with graded alloy layers was generally similar to that obtained with abrupt structures with the exception of the devices with $W = 5.6\mu$ which were somewhat better. The improved performance

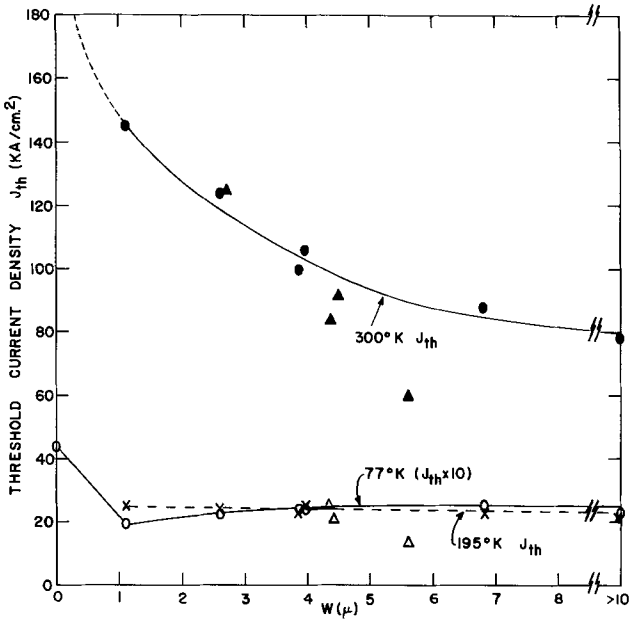

Fig. 2. Threshold current density vs. the p-type GaAs thickness. The abrupt heterostructure data are represented by closed (open) circles at 300°K (77°K) and crosses at 195°K. The graded heterostructure data is represented by closed (open) triangles at 300°K (77°K).

of this batch of devices is not understood but, due to the comparably large W and the fact that the alloy layer was graded, it appears unlikely that the heterojunction had an appreciable effect.

At 77° and 195°K the threshold current density is independent of W for $W \geq 1\mu$. For $W = 0$ the performance is degraded, but lasing was observed at 77°K. The threshold current densities are approximately ten times as high at 195° as at 77°K.

The data suggest that at 77° and 195°K the radiative lifetime is reduced and for $W > 1\mu$ few electrons penetrate to the GaAs-GaAsP interface. It is surprising that at these temperatures electromagnetic mode confinement, which apparently has a strong effect in GaAs-GaAlAs devices, has no observable effect in the GaAs-GaAsP devices studied here.

The external differential quantum efficiency of the abrupt laser structures is shown in Fig. 3. This efficiency was measured from one end of an uncoated de-

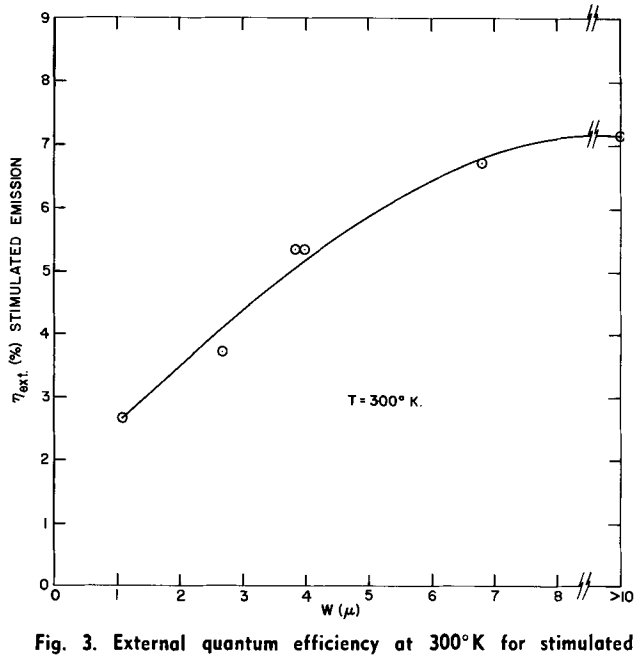

Fig. 3. External quantum efficiency at 300°K for stimulated emission vs. the p-type GaAs thickness for the abrupt heterostructure.

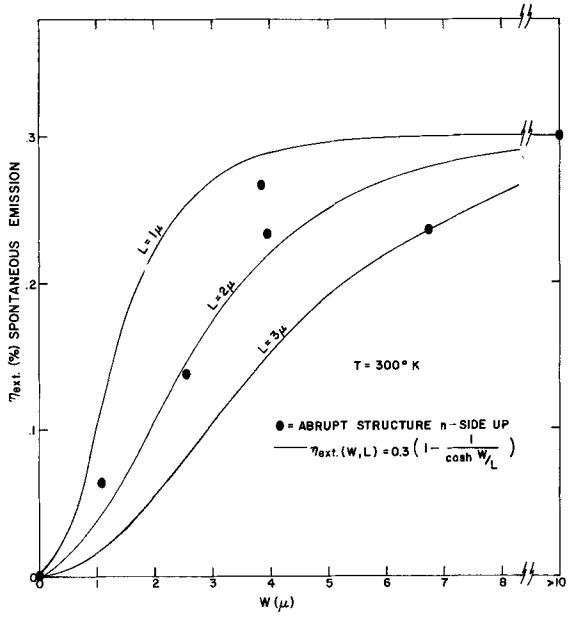

Fig. 4. External quantum efficiency at 300°K for spontaneous emission vs. the p-type GaAs thickness for the abrupt heterostructure. Also shown is the calculated efficiency for several different diffusion lengths.

vice so the total efficiencies are approximately twice the values shown. The spontaneous external quantum efficiencies for the abrupt heterostructures are shown in Fig. 4. The devices used to obtain the spontaneous data were square 375 x 375μ chips. The chips were planar and uncoated and were mounted n side up with the radiation being emitted through a 100μ thick GaAs layer. A 10 mA drive current was used.

Both the spontaneous and stimulated external efficiency increase with increasing W, correlating well with the decrease in threshold current density shown in Fig. 2. It is apparent from the data that interfacial dislocations are highly effective nonradiative dislocation centers and that a GaAs-GaAsP heterostructure cannot be used within the active region of a high performance light emitting device. The spontaneous efficiencies obtained with a graded alloy "window" are somewhat higher than that obtained with the abrupt structures. This may be due to the fact that by grading the alloy composition the window can be closer to the peak recombination region without introducing strain and dislocations which degrade the internal efficiency of the device. Efficiencies of ~0.5% have been obtained by reducing the thickness of the n-type GaAs layer. These spontaneous results are similar to those obtained earlier by Neuse *et al.* (8).

Also shown in Fig. 4 are calculated curves for the efficiency as a function of confinement distance for minority carrier diffusion lengths of 1, 2, and 3μ. These curves were calculated following the work of Burnham *et al.* (7) using the low-level injection formulation for a p/n junction. It can be shown that, as the surface recombination velocity at the GaAs-GaAsP interface approaches infinity, the ratio of the radiative current density, J_R, to the total injected current density, J_O, can be written as

$$J_R/J_O = K\left(1 - \frac{1}{\cosh W/L}\right)$$

where L is the injected minority carrier diffusion length and K is a constant of proportionality. This equation assumes that the radiative recombination current density is proportional to the total bulk recombination current density, J_B, and the total injected current density $J_O = J_B + J_I$ where J_I is the interfacial recombination current density and is assumed to be entirely nonradiative. Since the external efficiency is proportional to J_R/J_O the external quantum effi-

ciency as a function of W can be written as

$$\eta_{ext(W/L)} = 0.3\left[1 - \left(\frac{1}{\cosh W/L}\right)\right]$$

where the constant of proportionality was determined from the structure where $W > 10\mu$ ($W >> L$).

The data shown in Fig. 4 are scattered, but they do suggest an injected minority carrier diffusion length of $\sim 2\mu$ at 300°K.

If we assume $L \sim 2\mu$ at 300°K and that the electron mobility $\mu \simeq 2000$ cm^2/V sec, which is typical for GaAs with 3 x 10^{18} carriers/cm^3, we can approximate the lifetime for the injected electrons

$$\tau = \frac{eL^2}{kT\mu} \sim 10^{-9} \text{ sec}$$

At 77°K and 195°K the data indicate that $L < 1\mu$. It follows that $\tau \leq 3 \times 10^{-10}$ sec below 195°K assuming τ decreases monotonically with temperature. Both the lifetimes and diffusion lengths determined here are in reasonable agreement with those found by Vilms and Spicer (9).

Since at 300°K a significant number of the injected electrons penetrate $\geq 4\mu$ into the p-type region of the GaAs lasers studied here it is probable that they penetrate a similar distance in other types of GaAs lasers. In the case of GaAlAs heterojunction devices the optimum recombination region width W has been found to be $\sim 2\mu$ so many of the electrons would be expected to reach the GaAs-GaAlAs heterojunction. This implies that there is a very low dislocation density at the interface in the GaAs-GaAlAs system.

The change in diffusion length from $\leq 1\mu$ at 195°K to $\sim 2\mu$ at 300°K may also be related to the performance of GaAs lasers which do not have a confining GaAlAs barrier. Stripe geometry lasers with 2.5μ thick p-type regions have been operated continuously at temperatures up to ~200°K (10). The narrow p region was used to facilitate heat sinking of the devices. The ~200°K limit may be due predominantly to the increasing diffusion length in this temperature range which allows many of the electrons to traverse the p-type region and be lost at the metal contact thereby increasing the threshold of the device. The Q-switching which is observed in these devices between 100° and 300°K may also be related to electrons reaching the defects which undoubtedly are present at the GaAs metal interface.

The delay time at 300°K between the beginning of the current pulse and the onset of stimulated emission is shown in Fig. 5. The delay time has generally been measured immediately above threshold for stimulated emission, $I \simeq I_{th}$, but some workers have considered the delay at 50% above threshold, $I = 1.5\, I_{th}$ (11), to be a more reliable parameter because it is not so dependent on the exact shape of the current pulse. In Fig. 5 the delay time *vs.* W is plotted at both current levels as well as the delay at a constant current of 45A. As in Fig. 2 and 3 the data points represent average values for a batch of devices. For the delay time measurements there was approximately 20% scatter within a batch of diodes. The delay was measured from the time at which the rectangular (20 nsec rise time) current pulse reached its maximum value to the time at which the light output pulse reached 50% of its peak height. It can be seen that at both $I = I_{th}$ and $I = 1.5\, I_{th}$ the delay time decreases with decreasing W, and at a constant current the delay is nearly independent of W. For a given W the delay time decreased with current as has been previously observed. At 77°K no measurable delay time was observed in any of the devices.

The data indicate that the 300°K delay time in these devices is a function of the current density. This behavior is consistent with the idea that a certain density of traps, where the density is independent of W, must be filled before stimulated emission can occur (12). The presence of the misfit dislocations which strongly affects I_{th} and η_{ext} affect the delay time only through the dependence of I_{th} on W.

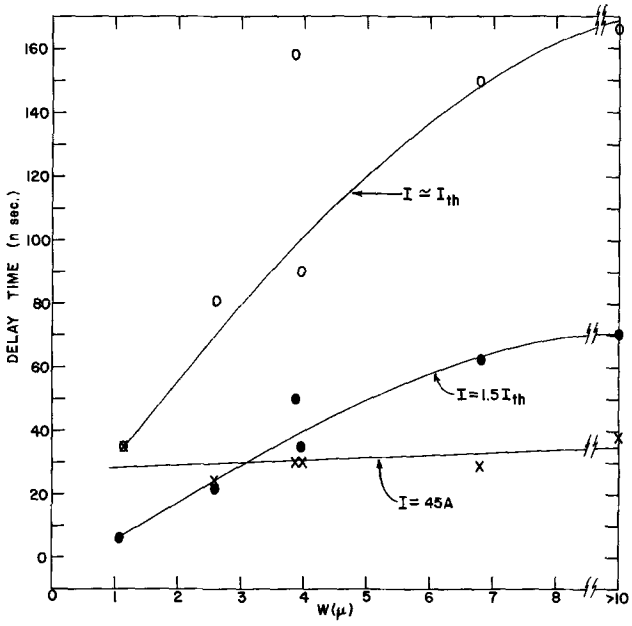

Fig. 5. Delay time at 300°K *vs.* the p-type GaAs thickness. The open and closed circles represent data taken at $I \simeq I_{th}$ and 1.5 I_{th}, respectively. The crosses represent data taken at a constant current of 45A.

The peak intensity of the emitted radiation of 77° and 300°K was investigated for stimulated emission at $I \sim I_{th}$ and for spontaneous emission at $I << I_{th}$. The spectral distribution of the emitted radiation is characteristic of heavily doped GaAs [λp(300°K) $\simeq$ 1.37 eV, λp(77°K) $\simeq$ 1.46 eV] and is relatively independent of W although there is a slight tendency for the energy to decrease with decreasing W. No detectable recombination takes place in the alloy layer. The fact that no radiation characteristic of the alloy layers is emitted indicates once again how effective the misfit dislocations are as nonradiative recombination centers. For $W = 0$ at 77°K the peak emission energy was somewhat higher [λp(77°K) $\simeq$ 1.47 eV] which may be due to hole injection and recombination in the n-type region of the device. The stimulated emission generally occurs at a slightly higher energy than the spontaneous peak due to band filling.

The emission spectra of the devices were also investigated in the region from 1.0 to 1.8μ using a PbS detector. Although some devices exhibited a broad band of radiation centered at ~1.2μ, the peak intensity of the band was 2-3 orders of magnitude lower than the band edge radiation and did not depend on W. This indicates that the misfit dislocations act as true nonradiative centers or, at least, very long wavelength centers and not as "normal" deep levels producing long wavelength radiation in the 1.0-1.5μ range.

Acknowledgments

A New Manganese-Activated Phosphor: $Li_2ZnGe_3O_8$

David A. Grisafe[1]

Chemical and Metallurgical Division, Sylvania Electric Products, Towanda, Pennsylvania 18848

In certain host lattices, it is well known that divalent manganese in tetrahedral coordination gives rise to a green luminescence. Well-known examples include the phenacite structure such as Zn_2SiO_4:Mn in which all the cations are in tetrahedral coordination or the spinel structure such as $ZnAl_2O_4$:Mn in which one-third of the cations—zinc in this example—possess tetrahedral coordination.

During the search for new manganese-activated green phosphors containing zinc as one of the host ions, the compound $Li_2ZnGe_3O_8$, discovered by Durif (1), was found to be activated by manganese. The present work contains the results of the investigation of this compound.

The desired amounts of reagent grade Li_2CO_3, $ZnCO_3$ or ZnO, $MnCO_3$ and GeO_2 were weighed to the nearest 0.0001g, mixed dry or mortared in an acetone slurry and fired in crucibles from 700° to 1000°C, usually for several hours. To insure complete reaction the materials were remixed and refired in the same temperature range. After pulverizing, the samples were heated in a mildly reducing atmosphere from 15 min to several hours, and the resulting powder was passed through a 325 mesh sieve.

Accurate x-ray diffraction data for the host lattice was obtained by back-packing powder into a sample holder and scanning at one-quarter degree 2θ per min using a curved crystal monochromator and CuKα radiation. Silicon was used as an internal standard. After indexing, the lattice parameter and standard deviation were obtained from a least squares computer program.

Using −325 mesh material, emission spectra under cathode ray excitation were obtained with a Jarrell Ash Spectrometer (Model No. 78-496) while spectra under ultraviolet radiation were obtained from a Perkin Elmer Spectrophotofluorimeter (Model No. 195).

X-ray powder data for $Li_2ZnGe_3O_8$ prepared in our laboratory are presented in Table I. The compound possesses a primitive cubic cell with a lattice parameter of $a_0 = 8.191 \pm 0.001$Å. The $00l$ reflections are only present when $l = 4n$ which indicates the space group is $P4_332$ or $P4_132$. In general, the strongest reflections are those whose Miller indices are all odd or all even thus suggesting a relation to the spinel structure. The data show strong similarity to those reported by Datta (2) for the low temperature form of $LiAl_5O_8$.

Unactivated $Li_2ZnGe_3O_8$ is a white material with a melting point of 1000°C ± 10°C. Assuming a spinel structure ($Z = 4$) the material possesses an x-ray density of 5.13 g/cm^3 compared with a picnometric density of 5.0 g/cm^3. These values compare relatively well with those of Durif (1) who reported $a_0 = 8.190 \pm 0.002$Å, a melting point of 995° ± 5°C, and a density of 5.11 g/cm^3.

When fired in air, $Li_2ZnGe_3O_8$:Mn samples showed a dull green luminescence and a tan body color typical of incompletely reduced manganese (to the divalent state). A variety of reducing conditions were explored

[1] Present address: State Geological Survey, University of Kansas, Lawrence, Kans. 66044.

Key words: green photoluminescence, green cathodoluminescence, pseudospinel phosphor.

in an attempt to eliminate the body color of the phosphor and improve its brightness. The phosphor is extremely sensitive to reducing conditions and turns a grayish color when exposed to only 1 or 2% hydrogen in nitrogen, the atmosphere often used for divalent manganese-activated spinel phosphors. The same discoloration was observed when the phosphor was fired in NH_3, CO and some NH_3-N_2 and CO-N_2 mixtures. An analysis of residue collected at the exhaust end of a tube furnace during one of these "over-reductions" showed a high germanium content. Firing in atmospheres such as CO_2, N_2, or N_2-H_2O did not sufficiently reduce the manganese.

The brightest phosphors were prepared by a stepwise reduction consisting of firing in short periods of nitrogen containing traces of hydrogen alternating with longer periods of nitrogen. Phosphors prepared in this manner possessed brightnesses of up to 60% of Zn_2SiO_4:Mn under cathode ray excitation and an $x = 0.245$ and $y = 0.718$.

Reflectance spectra in the ultraviolet region for the unactivated and manganese-activated $Li_2ZnGe_3O_8$ are shown in Fig. 1. Although the host lattice absorbs under 2537Å excitation, its emission is a very dull blue at best. The large increase in absorption due to the addition of manganese indicates the phosphor is largely activator-sensitized.

Typical emission spectra for $Li_2ZnGe_3O_8$:Mn and Zn_2SiO_4:Mn under 2537Å excitation are shown in Fig. 2. The germanate phosphor is brighter under 2537Å compared with cathode-ray excitation. The presence of only a green emission band and the similarity of the emission curve to such phosphors as β-$LiAl_5O_8$:Mn reported by Jaffe (3), Zn_2SiO_4:Mn, and $ZnAl_2O_4$:Mn are strong evidence that $Li_2ZnGe_3O_8$:Mn is activated by divalent manganese in tetrahedral coordination.

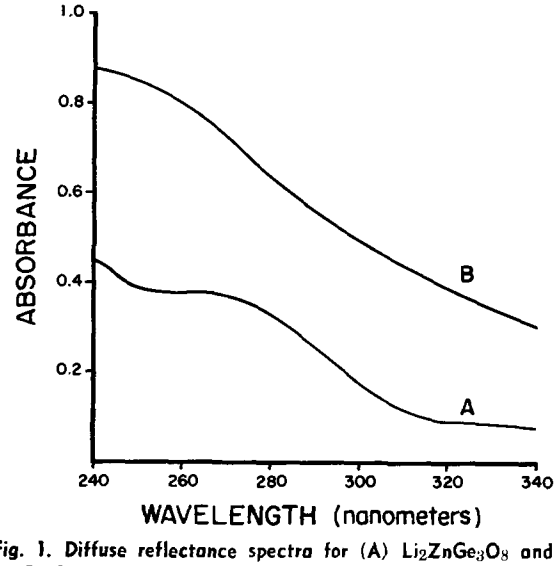

Fig. 1. Diffuse reflectance spectra for (A) $Li_2ZnGe_3O_8$ and (B) $Li_2ZnGe_3O_8$:Mn.

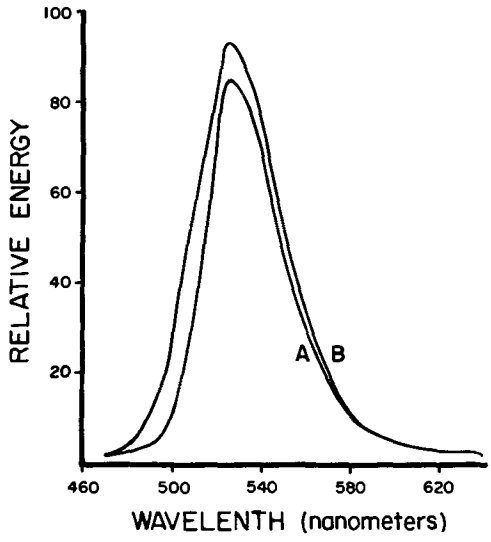

Fig. 2. Emission spectra for (A) $Li_2ZnGe_3O_8$:Mn and (B) Zn_2SiO_4:Mn under 2537Å excitation.

In summary, $Li_2ZnGe_3O_8$ possesses a primitive cubic lattice related to the spinel crystal structure and represents a new host lattice for manganese-activated green phosphors. The phosphor is extremely sensitive to reducing conditions, but when properly prepared, it yields an emission curve similar to green-luminescing spinels and phenacites.

Acknowledgments

The author is indebted to Olney Bullock for some of the sample preparation and to D. T. Palumbo for the corrected ulfraviolet spectra.

Depolarization Current Characteristics of Naphthalene Photoelectrets

P. K. C. Pillai and Malti Goel

Department of Physics, Indian Institute of Technology, New Delhi-29, India

Electret science is becoming an important branch of pure and applied physics. An electret is simply a dielectric material with remanent polarization. Thermoelectrets and photoelectrets are formed by simultaneous application of electric field and heat or light, respectively. Properties of naphthalene thermoelectrets were first discussed by Baldus (1) and then by Mascarenhas (2). Later Belyaev, Belikova, Fridkin, and Zheludev (3) reported on the thermo- and photoelectret effects in naphthalene and showed that these states are inseparable. Campos *et al.* (4) used the thermal depolarization technique to investigate trapped polarization in naphthalene thermoelectrets. The higher values of charge storage in naphthalene (3) led to further investigation. Depolarization current characteristics and contact electrification processes of naph-
