If the complexing ratio changed to a value of 2:1 (complexant: Ge) then one would expect the rate curves to level out at a higher concentration of the complexant in the solution. The curves for citric, oxalic, hydrochloric, hydrofluoric, and acetic acids all exhibit this behavior as can be seen in Fig. 2, 4, and 6. Citric acid was reported by Clark and Waddams (19) to complex germanium in a ratio of 2 citrates: 1 germanium. Their conclusions were based on conductivity, polarimetric, and pH measurements. The chemistry of germanium in oxalic acid solutions has been studied by several investigators (20-24). The results of these studies show that the complex that is present in the solution is highly dependent on the pH of the solution and the oxalate concentration. Douville *et al.* (23) concluded, from comparison of *IR* spectra of solutions containing germanium and oxalic acid with known oxalate complexes, that in acidic media the complexes are composed of tetravalent Ge. Other authors (20-22) have suggested that when germanium is in solutions containing compounds with two adjacent hydroxyl or carbonyl groups, the complexes take one of the following forms: $H_2Ge(C_2O_4)_3$; $Ge(C_2O_4)_2$ or $GeO(C_2O_4) \cdot xH_2O$. More recent investigations by Everest (24) have indicated that in solutions of oxalate concentrations below a pH of 3, a complex of the type $[GeO(C_2O_4)_2]^{2-}$ forms; whereas in high oxalate concentrations, the complexes were of the type $[Ge(C_2O_2)_4]^{2-}$. Johnson (25) has reported the existence of $GeOCl_2$. The observed rate data shown in Fig. 2, 4, and 6, indicate that this complexing ratio is reasonable for hydrochloric acid when compared to that observed in the 1:1 and 2:1 complexing ratios discussed above. Although it has not been possible to identify the fluoride complex of germanium in aqueous solutions, the etch rate data exhibit the same behavior as the hydrochloric acid curves, suggesting that the fluorine is complexed with the Ge in a ratio of 2:1. If it is completely analogous to the chloride case, one might expect it to be in the form $GeOF_2$.

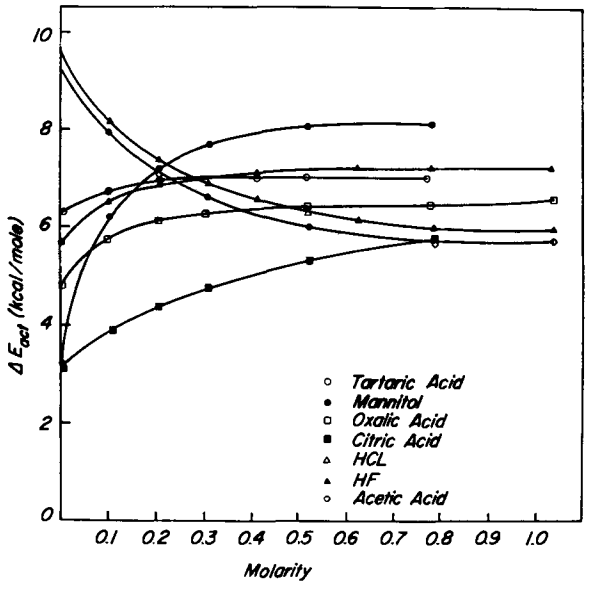

Fig. 7. Plot of the activation energy vs. molarity of the complexing agents in the etchant.

The curves for acetic acid, Fig. 2, 4, and 6, leveled off between 0.7 and 0.8M, suggesting a complex with a ratio of 2:1, although germanium-acetate complexes have not been reported in the literature. Some difficulty was noted in this system in obtaining consistent rate data when using solutions that were not fresh (*i.e.* older than 48 hr).

The etch rates presented in the data above are slightly lower than those presented by other investigators working in similar systems. This variation is normal in etch rate studies due to the numerous factors that can affect the rates such as surface area determination, resistivity, dislocation density, degree of agitation, temperature control and measurement, etc. The germanium crystals used in this study had an impurity content of less than 1 ppm and the dislocation density was less than 50 per cm^2. Both of these are very low and may possibly be a major factor to the lower rates.

The activation energies determined from the etch rates are plotted as a function of concentration in Fig. 7 for the systems discussed above. In each case the plots of the activation energy as a function of the concentration leveled off at approximately the same concentration as the rates did. Laidler (26) has separated the reaction mechanisms on solid surfaces for heterogeneous reactions into five consecutive steps:

1. Volume diffusions of the reacting species to the surface.
2. Adsorption of the species on the surface.
3. Reaction on the surface.
4. Desorption of the reaction products.
5. Volume diffusion of the products from the surface.

The activation energy calculated from comparison of the etch rates at two different temperatures using the Arrhenius equation is that for the slowest step in the reaction sequence above. Abramson and King (27) have suggested that the general limit for the diffusion controlled reactions is 10 kcal/mole or less, between 10 and 20 kcal/mole for the adsorption or desorption steps, and surface reactivity controlled reactions greater than 25 kcal/mole. All of the activation energies calculated in this study are well within the range of diffusion controlled reactions. The sensitivity of the etch rate to the degree of agitation of the solution, along with the observed dependence of the etch rate on concentration support the diffusion-controlled reaction mechanisms.

It would be tempting to relate the variation in activation energy at the lower concentrations of the complexing agents to the nature of the activated complexes; however, the present knowledge about the reacting species and over-all chemistry of the solutions does not permit this. Once the interface is "saturated," *i.e.* for every germanium that is dissolved there is one or more (depending on the complexing ratio) complexing species present at the interface, then the activation energies observed can be used for purposes of comparison between systems and reaction mechanisms determined. It must be remembered, however, that the measured activation energies are "apparent" (*i.e.* they are undoubtedly a sum of several steps rather than the actual activation energy for a single step.)

It is interesting to note that in the system Ge:HF:H_2O_2:H_2O (Fig. 2, 4, and 6), there was no variation in activation energy within temperature ranges as had been noted by Camp (6). Camp found that the activation energy for the (100) surface in this system (using concentrated reagents) was approximately 13.6 kcal/mole below room temperature, whereas above room temperature it was approximately 8.6 kcal/mole. This observation was verified in this study when using 48% HF and 30% H_2O_2; however, when using dilute HF solutions the effect was not present. The activation energies reported by Camp for the upper temperature region are in the same range as those determined in this study, therefore corroborating his suggestion that the reactions are diffusion controlled above 20°C.

Summary and Conclusions

It has been found that under carefully controlled conditions, the etch rate of germanium in etchants composed of *X*:30% H_2O_2:H_2O (1:1:4) (where *X* is HCl, HF, acetic, citric, oxalic, and tartaric acids, and mannitol) is a function of the complexing agent.

The dependence of the etch rate on the stirring rate of the solution, the parabolic behavior of the etch rate as a function of concentration, and the range in values of activation energies for the reactions strongly indicate that the etching processes are diffusion controlled.

Based on the results reported here and those by others, the following sequence for germanium etched in peroxide based solutions is suggested

$$2H_2O_2 \rightarrow H_3O_2^+ + O_2H^- \qquad [3]$$

which provides the peroxide ion for the oxidation step with the holes coming from the valence band of the germanium.

$$Ge + O_2H^- + H_2O + 2e^+ \rightarrow \underset{\text{surface}}{Ge(OH)_2^{++}} + OH^- \qquad [4]$$

The hydroxyl complex formed above then is desorbed from the surface and reacts with water

$$\underset{\text{solution}}{Ge(OH)_2^{++}} + H_2O \rightarrow H_2GeO_3(aq) + 2H^+ \qquad [5]$$

to form metagermanic acid. The metagermanic acid then reacts with the complexant. In the case of hydrochloric acid the reaction would be

$$H_2GeO_3 + 2HCl \rightarrow GeOCl_{2(aq)} + 2H_2O \qquad [6]$$

to form the germanium oxychloride species as the final reaction products.

A model is proposed for the crystal-solution interface whereby the etch rate of the material is a function of the concentration (specifically the number of complexing ions at the interface) of the complexing agent in the solution. The increase in rate of dissolution as the concentration of the complexant is increased is probably due to the increased availability of reactants. The rate continues to increase parabolically until, as in the case of a 1:1 complexing ratio, there is a complexing ion present at the crystal-solution interface for every germanium ion formed at the surface. In the case of a 2:1 complexing ratio, the concentration at which the rate becomes constant is just

twice that observed for a 1:1 complex. This model predicts then that once this constant, or the "saturated" zone is reached, the rate will remain constant no matter how much additional complexant is present in the solution. This behavior was observed in the systems studied.

It is further suggested from the rate data that the rate controlling step is the diffusion of the final reaction products from the interface.

Ionic Conduction in Calcium Doped Polycrystalline Lithium Iodide

Carl R. Schlaikjer* and Charles C. Liang*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

The ionic conductivity of polycrystalline lithium iodide containing 0 to 3% (mole) calcium iodide was studied at temperatures between −30° and 130°C. The conductivity increased linearly with the concentration of calcium iodide, and it was concluded that the introduction of calcium ions to the lithium iodide crystals induced Schottky defects. The activation energy for the ionic conduction process of 9.96 kcal/mole agreed well with the value obtained by other investigators. The electronic conductivity of the calcium doped lithium iodide polycrystals was negligible compared to the ionic conductivity.

In view of the recent developments in high voltage solid-state battery systems (1, 2), lithium iodide has received a great deal of attention as a solid electrolyte material. Its compatibility with the intrinsically high voltage anode material lithium, and the extremely low electronic conductivity of lithium iodide made it possible to develop high voltage solid state battery systems such as Li/LiI/AgI (1, 2). The relatively low ionic conductivity of lithium iodide electrolyte (10^{-7} ohm^{-1} cm^{-1} at 25°C) made necessary the fabrication of thin film, low capacity Li/LiI/AgI cells in order to obtain useful current densities. However, if the conductivity of lithium iodide could be increased substantially, cells with higher capacity and thicker electrolyte layers could be produced by the conventional fabrication techniques rather than the vacuum deposition techniques as reported previously (1, 2).

The formation of crystal defects in lithium halides by the addition of minute quantities of higher valent cations has been shown to increase the ionic conductivity (3). Magnesium doped lithium iodide was examined recently by Jackson and Young (4) who studied the Schottky disorder in lithium iodide single crystals and observed an increase in the ionic conductivity. The present work was undertaken to study the conductivity of polycrystalline lithium iodide with the inclusion of various quantities of calcium iodide in the crystal structure.

Experimental Techniques

The preparation of anhydrous lithium iodide.—Fisher reagent grade chemicals were used in the preparation of lithium iodide. Lithium carbonate was prepared by adding a 20 mole per cent (m/o) excess of ammonium bicarbonate solution to a lithium hydroxide solution. It was filtered and dried at 200° C for several hours.

Hydriodic acid was distilled under an argon atmosphere. After the distillation, the acid was treated with an excess of lithium carbonate through a long tube located at the top of the distillate flask. The carbon dioxide generated from the reaction and the argon gas

* Electrochemical Society Active Member.

Key words: Schottky defects, ionic conductivity, solid electrolytes, lithium iodide, calcium iodide.

present in the flask protected the acid from the atmosphere until an excess of carbonate was added.

Immediately after the excess of lithium carbonate had been filtered, the lithium iodide solution was placed in a vacuum oven and heated to 85°C until solid. The remaining water in the crystals was removed by heating in a vacuum oven at 120°C overnight. The lithium iodide was then transferred under dry carbon dioxide to a Vacuum Atmospheres dry box (less than 15 ppm H_2O). Analyses of the lithium iodide showed that the iodide content was as expected for anhydrous lithium iodide, and no excess of alkali was found in the sample. The lithium iodide so prepared could be fused in the dry box without decomposition or discoloration.

The preparation of calcium doped lithium iodide.—Mallinckrodt $CaI_2 \cdot 2H_2O$ was dehydrated by heating under vacuum in an evacuated flask first at 100°C for several hours then at 300°C for about 3 hr. The calcium iodide was transferred to the dry box in the flask. Analysis of the iodide present showed that it was anhydrous.

A powder mixture of the anhydrous lithium iodide and the anhydrous calcium iodide in a mole ratio of 10 to 1 was blended, fused at 600°C, quenched to ambient temperature, and pulverized. This powder was used to prepare further dilutions with lithium iodide. Samples of lithium iodide containing 0.2 m/o to 3 m/o of calcium iodide were prepared from the 10 to 1 stock by similar fusion and quenching processes.

The conductivity measurements.—The calcium doped lithium iodide samples were pulverized in a Fisher mechanical grinding apparatus for 30 min and annealed at 150°C for 30 min.

Pellet samples were prepared by pressing the powder in a 7/16" diameter steel die under a pressure of 66,500 psi with lithium electrodes incorporated on both sides of the pellet. Samples for the conductivity measurements at different temperatures were hermetically sealed in metal-ceramic cell cases and equilibrated in a Tenney constant temperature chamber until readings changed by no more than 2% over a half-hour period.

Conductivity measurements were made with square wave excitation from 1 to 10 kHz of a bridge constructed from Helipot precision potentiometers. A Tektronix Type E differential preamplifier made possible the application of only 3 mV peak to peak to the sample. The reproducibility of measurements was within ±2.5%.

The determination of the lattice parameter.—Debye-Scherrer powder patterns of lithium iodide containing various amounts of calcium iodide were obtained at room temperature immediately after annealing using conventional techniques with CuK_α radiation.

The lattice parameter of each sample was obtained by the Nelson-Riley extrapolation. The uncertainty in the results was about ±0.003Å. A precision camera was not used to reduce this uncertainty because of the extreme air sensitivity of the samples.

The characteristics of the electrochemical cell.—Mallinckrodt silver iodide was used as the cathode material. It was dried at 160°C for about 16 hr before use. Metz fine silver powder was used to form the cathode current collector. Lithium iodide containing calcium iodide was the electrolyte material and Foote lithium ribbon was used as the anode.

The $Li/LiI(CaI_2)/AgI$ solid electrolyte cells were fabricated by pressing the cathode current collector, the cathode, the electrolyte, and the anode in a 7/16 in. die under a pressure of 66,500 psi.

The cell voltages under open circuit and various discharge current densities were measured by means of a Keithley 610B electrometer and recorded by a Varian 14A strip chart recorder.

Results

The inclusion of calcium iodide caused a substantial increase in the conductivity of the polycrystalline lithium iodide. Figure 1a shows that the conductivity of lithium iodide increased linearly with the concentration of calcium iodide up to 1 m/o. An amount of 0.2 m/o of calcium iodide increased the conductivity at 28° ± 0.5°C from 4.5×10^{-7} ohm^{-1} cm^{-1} to 2.3×10^{-6} ohm^{-1} cm^{-1}. As the concentration of calcium iodide reached 1 m/o, the conductivity of the polycrystalline matrix was as high as 1.2×10^{-5} ohm^{-1} cm^{-1}.

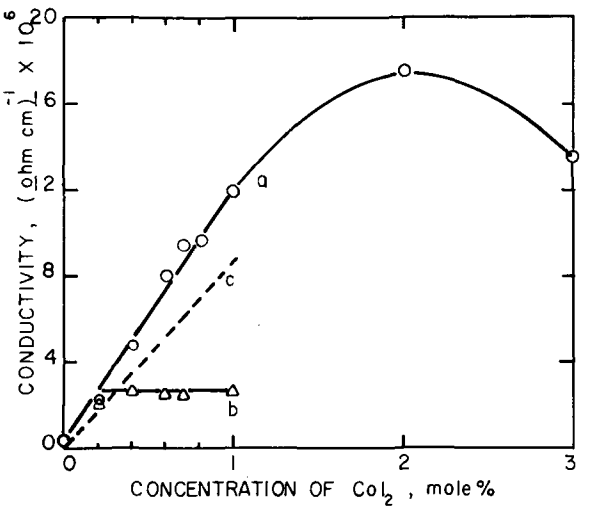

Fig. 1. The conductivity of lithium iodide as a function of the concentration of calcium iodide at 28° ± 0.5°C. (a) Freshly annealed at 150°C for 30 min, (b) 500 hr after annealing, and (c) based on the calculated mobility of the cation vacancy.

It was found that the conductivity of lithium iodide containing 0.4 m/o or more calcium iodide decreased substantially as a function of time after annealing at 150°C for 30 min. It reached a constant value of about 2.6×10^{-6} ohm^{-1} cm^{-1} at 28° ± 0.5°C after about 500 hr regardless of the initial calcium iodide concentration. The data of Fig. 1a represent the conductivity of the samples at 28° ± 0.5°C, measured as soon as possible after quenching from 150°C while those of Fig. 1b represent the conductivity of the samples at 28° ± 0.5°C measured long after quenching (at least 500 hr), when no change in conductivity with time was noted. In each case, the reproducibility of the measurement was ±2.5%. The change in ionic conductivity with doping level was calculated theoretically and the results are shown in Fig. 1c.

The above observation shows that the samples containing 0.4 m/o or more calcium iodide were metastable immediately after the 150°C annealing process. This was also evident from the fact that the conductivity measurements at various temperatures of the metastable sample were not reproducible over the time period required for the measurements over a temperature range of −30° to 130°C after one 30 min annealing treatment. However, the conductivity measurements at various temperatures for samples containing 0.2 m/o or less calcium iodide were reproducible (±2.5%) and independent of time. Nevertheless, it was found that reasonably reproducible conductivity measurements for lithium iodide containing 0.4 m/o or more calcium iodide could be obtained when the sample was annealed at 150°C for 30 min then quenched to the predetermined temperature before each measurement at each temperature. The results of these measurements were used to construct the log σ *vs.* $1/T$ plot shown by Fig. 2c.

The activation energy of the conduction process for the polycrystalline lithium iodide and the calcium doped lithium iodide was determined over the temperature range of −30° to 130°C. Previous investigators (3, 4) have shown that the extrinsic conduction region for lithium iodide occurs at temperatures below 250°C. Therefore, the activation energy of 9.96 kcal/mole, de-

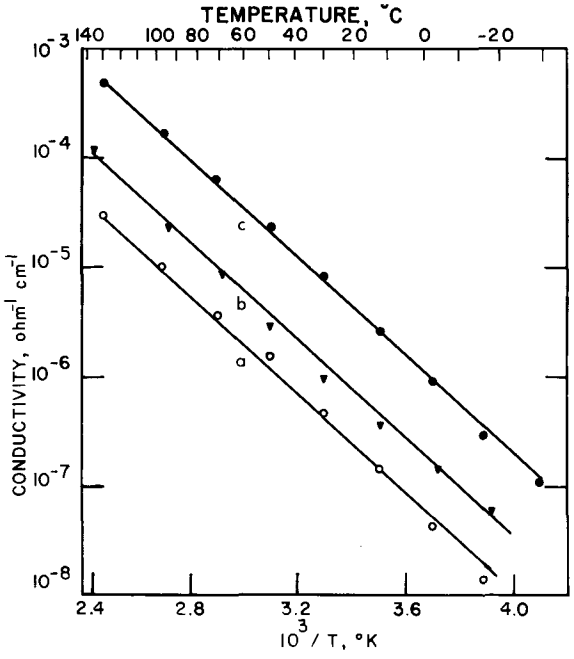

Fig. 2. The conductivity of lithium iodide containing calcium iodide as a function of temperature. Concentration of calcium iodide: (a) 0, (b) 0.2 m/o, (c) 1.0 m/o (the sample was annealed at 150°C for 30 min before each measurement).

termined from the slopes of the log σ *vs.* $1/T$ plots shown in Fig. 2, applied to the extrinsic conduction region. This result is in excellent agreement with the value of 0.43 eV or 9.93 kcal/mole obtained by Jackson and Young (4) for the magnesium doped lithium iodide single crystals.

The lattice parameters of the samples are given in Fig. 3. It was noted that the uncertainty of the measurements made the exact determination of the lattice parameter rather difficult. Nevertheless, the results suggested strongly that within the solubility limits of the calcium iodide in the polycrystalline lithium iodide, the lattice parameter increased with the concentration of calcium iodide.

The conductivity of lithium iodide containing 0.4 m/o or more calcium iodide decreased substantially as a function of time after annealing. It reached a constant value of about 2.6 x 10^{-6} ohm^{-1} cm^{-1} at 28° ± 0.5°C after about 500 hr regardless of the initial calcium iodide concentration. It was found also that the rate of the decrease in conductivity was higher for the sample containing higher concentration of calcium iodide as shown by Fig. 4.

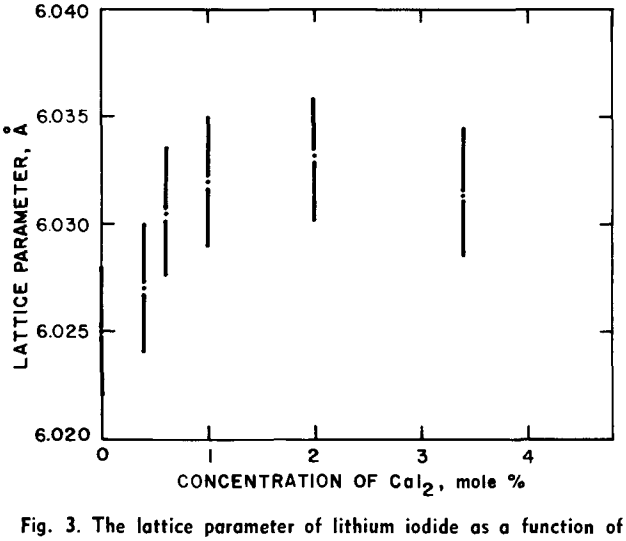

Fig. 3. The lattice parameter of lithium iodide as a function of the calcium iodide concentration (annealed samples).

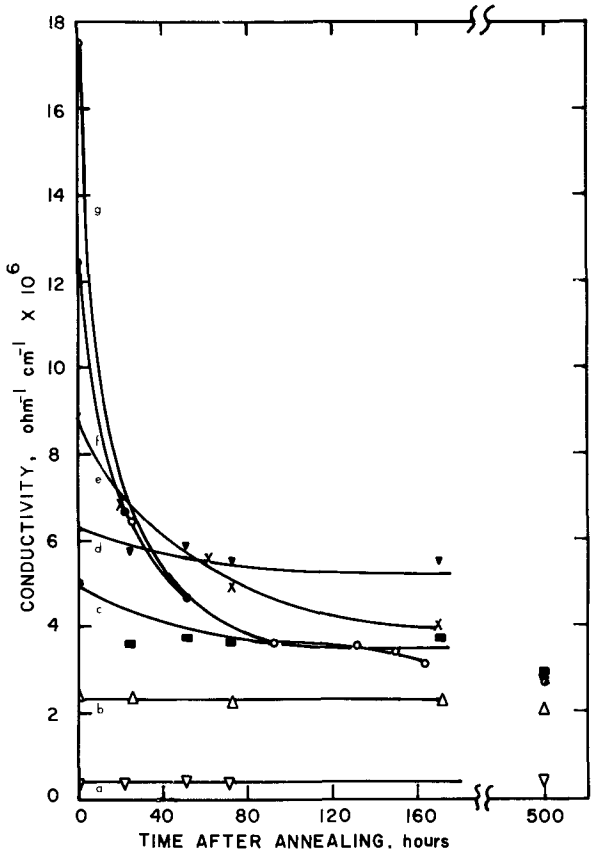

Fig. 4. The conductivity of lithium iodide containing calcium iodide as a function of time after annealing. Temperature: 28° ± 0.5°C. Concentration of calcium iodide: (a) 0, (b) 0.2 m/o, (c) 0.4 m/o, (d) 0.6 m/o, (e) 0.7 m/o, (f) 1.0 m/o, (g) 2.0 m/o.

Lithium-silver iodide solid electrolyte cells with calcium doped lithium iodide electrolytes exhibited an open circuit voltage of 2.1V which was expected from the Gibbs free energy change of the cell reaction (1, 5).

$$Li + AgI \rightarrow LiI + Ag$$

Figure 5 shows the polarization curve of a Li/LiI(0.2%

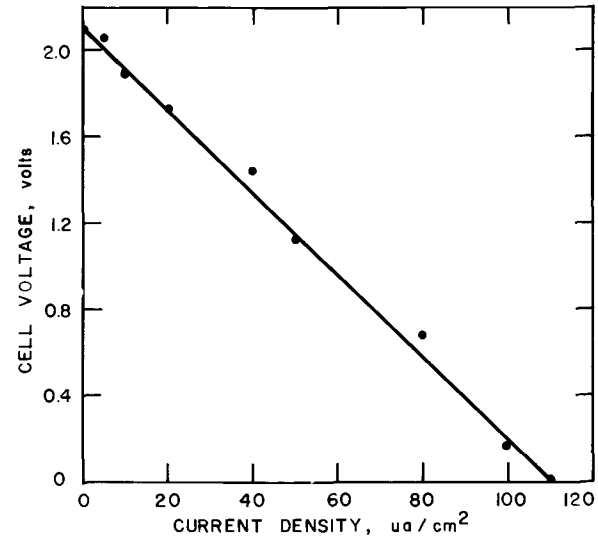

Fig. 5. The polarization curve of a typical Li/LiI (0.2 m/o CaI_2) AgI solid electrolyte cell. Temperature: 28° ± 0.5°C, thickness of the electrolyte: 0.04 cm, geometric surface area of the electrolyte: 0.7 cm^2.

CaI_2)/AgI solid electrolyte cell. The linearity of the polarization curve indicated that the voltage loss was of an ohmic nature and the observed short circuit current of 110 $\mu A/cm^2$ was expected from the resistance of the electrolyte layer with a measured thickness of 0.04 cm.

Discussion

As expected from the fact that the inclusion of divalent calcium ions in the lithium iodide matrix will induce defects (6), the ionic conductivity of lithium iodide increased linearly with the concentration of calcium iodide as shown by Fig. 1a. The fact that the linearity of the conductivity *vs.* concentration plot extended only to 1 m/o of calcium iodide can be explained by the saturation of calcium iodide in the polycrystalline lithium iodide under the experimental conditions.

The uncertainty in the determination of the lattice parameter was ± 0.003Å which makes the exact value uncertain by this amount. Nevertheless, Fig. 3 gives an indication that within the solubility limits of the calcium iodide in the polycrystalline lithium iodide, the lattice parameter increased nearly linearly with the concentration of calcium iodide as predicted by Vegard's law (7).

The formation of a solid solution between calcium iodide and lithium iodide is evident from the above experimental results. However, whether the dissolution of calcium iodide in lithium iodide formed a substitutional solution inducing Schottky defects or an interstitial solution inducing Frenkel defects needs to be discussed. It is known that lithium iodide forms a close packed, face centered cubic structure. Two types of voids exist in the lattice: tetrahedral voids and voids surrouding the lithium ions (8). The radii of the two types of voids are about 0.49Å (*i.e.* 0.225 x 2.2Å) and 0.29Å (*i.e.* 0.13 x 2.2Å), respectively. The empirical ionic radius of a calcium ion is 1.06Å (9) which is too large to squeeze in these voids without seriously distorting the crystal lattice. On the other hand, the space occupied by the lithium ion has a radius of about 0.91Å (8) which may be large enough for a calcium ion to replace the lithium ion resulting in a slight increase in the lattice parameter. Therefore, we believe that the inclusion of calcium ions in lithium iodide induces primarily Schottky defects and accordingly, the ionic conduction is due to the mobility of cation vacancies. This conclusion is in agreement with that of Jackson and Young (4) who observed that the inclusions of the divalent magnesium ions in the lithium iodide single crystals did not alter the ionic conduction behavior in the intrinsic region and concluded that Schottky defects were induced by the incorporated magnesium ions. Furthermore, the agreement between the activation energy of 9.96 kcal/mole with that determined by Jackson and Young (4) leads us to the conclusion that the extrinsic conduction mechanism in the polycrystalline matrix is similar to that in the single crystals, namely, that the conduction is due to the mobility of cation vacancies.

The theoretical mobility of the cation vacancy μ in the lithium iodide crystals can be calculated from the following equation (6)

$$\mu = \frac{4ea^2\nu}{kT} \exp\left(-\frac{E}{kT}\right)$$

where a represents the distance between the nearest neighbor cation and anion, E the activation energy (which is equal to the activation energy of the conduction process in the extrinsic region), ν the lattice frequency while e and kT have the usual significance. The vibrational frequencies for lithium iodide have been calculated by Karo (11) and a single value of 3.32×10^{13} sec^{-1} was selected to represent the vibrational spectra. We have adopted Karo's value of ν for the calculation of μ. The mobility of the cation vacancy in lithium iodide at 28°C calculated according to the above equation was 3×10^{-7} $cm^2/sec\text{-}volt$. Whereas the experimental value of μ at 28°C obtained from the slope of the conductivity *vs.* the concentration of calcium iodide in the lithium iodide plot (Fig. 1a) was 4×10^{-7} $cm^2/sec \cdot volt$. The agreement between the calculated value and the experimental value was quite satisfactory.

The decrease in the conductivity with time, of lithium iodide containing 0.4 m/o or more calcium iodide, shows that the equilibrium solubility of calcium iodide in lithium iodide is probably less than 0.4 m/o at 28° ± 0.5°C. During the 150°C annealing process, as much as 1 m/o of calcium iodide can dissolve in lithium iodide. As the temperature decreases to 28° ± 0.5°C, the excessive amount precipitates to form a separate phase. However, the rate of precipitation is rather slow as may be seen from Fig. 4. Since the conductivity of polycrystalline lithium iodide is directly proportional to the concentration of the calcium iodide in the lattice, we could determine the equilibrium solubility of calcium iodide in lithium iodide from Fig. 1b and a value of 0.23 ± 0.03 m/o at 28° ± 0.5°C was found.

All the Li-AgI test cells with the various lithium iodide-calcium iodide electrolytes exhibited an open circuit voltage of 2.1V, which is expected from relevant thermodynamic data (1, 5), and this leads to the conclusion that the electronic conductivity of the calcium doped lithium iodide is negligible compared to its ionic conductivity (10). The current capability of test cells with 0.04 cm thick electrolyte layers shown in Fig. 5 indicated that the cells had a purely ohmic impedence and that they were capable of delivering short circuit currents of 110 $\mu A/cm^2$ at room temperature.

Diffusion and Solubility of Yb^{3+} in CdS

W. W. Anderson and H. J. Chang

Department of Electrical Engineering, Ohio State University, Columbus, Ohio 43210

ABSTRACT

Diffusion studies were performed to determine the temperature and sulfur partial pressure dependence of Yb diffusion and solubility in CdS. Over the temperature range of 930° to 990°C and pressure range of 3.3-33 atm, the diffusion appears to consist of a saturated surface component and a slow deep diffusing component. The slow diffusing component can be described by the approximate relation

$$D \simeq 4 \times 10^{-4} P_{S_2}^{1/2} e^{-1.85/kT} \text{ cm}^2/\text{sec}$$

where the sulfur partial pressure, P_{S_2}, is measured in atmosphere and the activation energy for the process is $\Delta E = 1.85$ eV. The surface concentration (and hence solid solubility) of Yb^{3+} obeyed the relation

$$[Yb^{3+}]_{sat} \sim P_{S_2}^{1/2}$$

These results suggest that the diffusion and solubility of Yb^{3+} is determined by the cadmium ion vacancy concentration in CdS.

Diffusion studies were performed to determine the temperature and sulfur partial pressure dependence of Yb diffusion and solubility in CdS. From these studies we hoped to obtain information on the incorporation and diffusion mechanisms of the trivalent rare earth ions in the CdS lattice. Sample preparation and measurement techniques were identical to those used in a previous study (1) and are very briefly reviewed here.

Diffusion was from a saturated vapor phase source of Yb metal or Yb_2S_3. Since the crystal surface is a one-phase, three-component system, it is necessary to specify four intensive thermodynamic variables. In these experiments, the variables were partial pressure of Yb(g) or Yb_2S_3(g), partial pressure of S_2, total pressure, and temperature. The pressure, P_{S_2}, was determined by the quantity of sulfur included in the evacuated diffusion ampoule. The total pressure, P_T, is essentially identical to P_{S_2} for our range of sulfur pressures, $3.3 \leq P_{S_2} \leq 33$ atm. The diffusant partial pressure, P_{Yb} or $P_{Yb_2S_3}$ is the saturated vapor pressure of the gas phase over a liquid Yb(l) or solid Yb_2S_3(s) source. From observations of a luminescent flash when a diffusion ampoule containing metallic Yb and S is heated and examination of the solid yellowish residue after a diffusion run, it appears that metallic Yb is completely converted to Yb_2S_3 before significant diffusion begins and the equilibrium vapor over a Yb_2S_3(s) is the source of Yb diffusing into CdS.

The Yb concentration as a function of depth was measured by the intensity of Yb^{3+} photoluminescence as a function of depth from the surface. Hence, only the active Yb^{3+} concentration was measured which may differ from the total Yb^{3+} concentration and certainly differs from the total Yb concentration, especially in regions of high concentration.

The CdS crystals were obtained from Eagle-Picher Industries, Inc. They were undoped, ultrahigh purity grade, dark insulating, and photosensitive. The room temperature free electron concentration was not measurable by standard Hall effect techniques so that $n < 10^{11}$ cm^{-3}. The crystals used in the previous study by Girton and Anderson were characterized by a room temperature free electron concentration of $n = 3.5 \times 10^{15}$ cm^{-3} before diffusion (1). In both this and the previous study, the crystals were diffused without any equilibration process such as firing in Cd or S vapor, *i.e.* the diffusion was carried out on the as received material.

Key words: luminescence, rare earths, compound semiconductors.

Results

In Fig. 1, we show a typical plot of Yb^{3+} emission intensity as a function of depth from the diffused surface. The results of three different diffusion times are normalized and plotted on the one figure. The Yb^{3+} concentration (assumed to be proportional to Yb^{3+} emission intensity) follows neither a complementary error function nor Gaussian distribution. (The departure from ideal behavior near the surface is more evident on a plot of intensity *vs.* $d/\sqrt{t}$ than the intensity *vs.* d^2/t plot shown in Fig. 1. However, the surface saturation is easily seen from the first two plotted points of the 6 hr and 9 hr diffusions.) From the experimental conditions, a complementary error func-

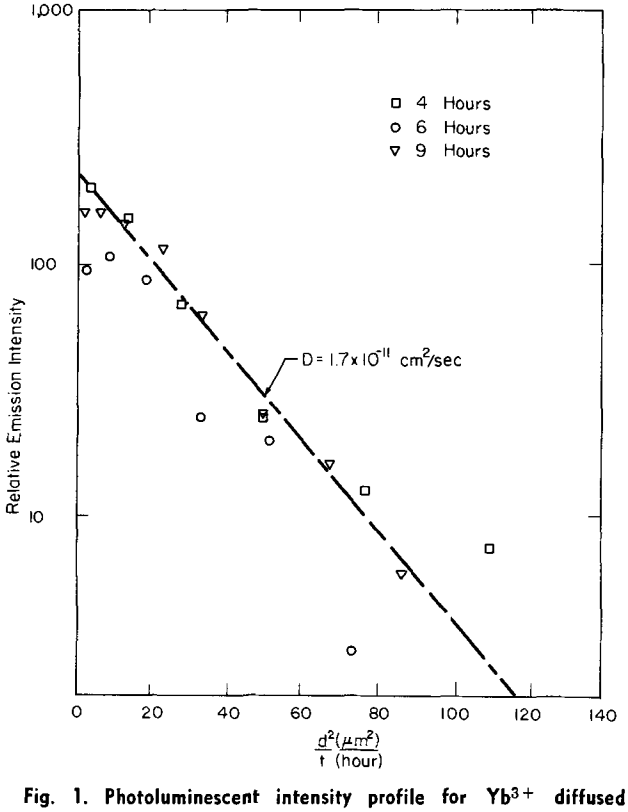

Fig. 1. Photoluminescent intensity profile for Yb^{3+} diffused into CdS at 930°C and 8 atm S_2 pressure.

tion distribution was expected. There are several possible reasons for the apparent saturation of the concentration near the surface including (*a*) concentration quenching of Yb^{3+} fluorescence (2), (*b*) out diffusion of Yb during quenching, (*c*) field-aided diffusion (3), (*d*) formation of diffusion barrier on surface, and (*e*) concentration dependent diffusion (4). The relative merit of some of these possibilities are discussed later.

Diffusion coefficients were obtained from the slope of the deep penetrating part of the log intensity *vs.* d^2/t curves as shown in Fig. 1. For

$$\frac{d^2}{t} > 4D \qquad [1]$$

this gives the correct value of D within 10% for the erfc distribution and is exact for the Gaussian. The straight line drawn in Fig. 1 gives some preferential weight to data points in the central portion of the measured intensity range. The lowest emission intensity points were subject to considerable (±50%) measured error. The highest emission intensity points were in the "non-normal" surface saturation region. However, diffusion coefficients determined from the slopes of lines drawn with maximum and minimum slopes as allowed by the given data points do not vary by more than 40%, *i.e.* the worst case uncertainty in diffusion coefficient is $D = (1.7 \pm 0.7)\ 10^{-11}$ cm²/sec. From our treatment of the data we believe the actual uncertainty of measured values of diffusion coefficient is better than the worst case value by at least a factor of two, *i.e.* $D = D_m \pm 0.2\ D_m$ where D_m is the reported value of diffusion coefficient at a particular temperature and sulfur pressure. Although a limited range of temperatures and pressures were investigated, the dependence of D and $[Yb^{3+}]_{sat}$ on T and P_{S_2} was readily evident as described in the following analysis.

An Arrhenius plot of the measured diffusion coefficients is shown in Fig. 2. The results at each of three different sulfur vapor pressures can be described fairly well by an activation energy of 1.85 eV.

The diffusion coefficient as a function of S_2 vapor pressure is shown in Fig. 3. At the two lower temperatures, 960° and 930°C, a very strong pressure dependence is indicated,

$$D \sim P_{S_2}^{0.67} \qquad [2]$$

The higher temperature data used to determine the two points at 990°C was not too reliable and so it is not possible to say with certainty that there is significant change in S_2 pressure dependence at this higher temperature. A change in the dominant mechanism determining charge neutrality in the crystal at the higher temperature would produce a change in slope (5, 6). However, on the basis of the limited data obtained and experimental uncertainties involved, it is reasonable to approximate all of the data points by

$$D \sim P_{S_2}^{1/2} \qquad [3]$$

and, for the crystals used in these experiments we find that

$$D \simeq 4 \times 10^{-4}\ P_{S_2}^{1/2}\ e^{-1.85/kT}\ \text{cm}^2/\text{sec} \qquad [4]$$

fits all of the data points obtained within 40%. The theoretical origin of proportional relation [3] will be given in the next section.

When the emission intensity is plotted as a linear function of distance from the surface rather than as the distance squared in Fig. 1, the apparent saturation of concentration extends for an appreciable distance. If we take this saturated intensity (concentration) as proportional to the maximum solubility of Yb^{3+} in CdS, we find the results shown in Fig. 4. The solubility is a strong function of sulfur pressure but does not vary significantly with temperature. Again, considering the experimental accuracy involved, the functional dependence of solubility is approximately

$$[Yb^{3+}]_{sat} \sim P_{S_2}^{1/2} \qquad [5]$$

Discussion

The strong P_{S_2} dependence of Yb^{3+} diffusion and solubility indicates a native crystal defect dominated incorporation and diffusion mechanism. Of the four simplest native crystal defects, Cd and S vacancies and interstitials, vacancies in the Cd sublattice seem the most likely defect to enhance the solubility and motion of a metal ion with size and electronegativity comparable to the Cd^{2+} ion (7). In addition, there is good evidence for vacancy controlled self-diffusion of Cd in CdS under excess sulfur vapor pressure (8, 9).

It has been suggested that the dominant native defects in CdS are Cd interstitials and vacancies (10). The density of neutral Cd vacancies at the diffusion temperature is completely determined by the S_2 pressure through the relation

$$[V_{Cd}] = \frac{K_F}{K_I K_{CdS}} P_{S_2}^{1/2} \quad [6]$$

where the equilibrium constants involved in Eq. [6] are defined by:

$K_F = [V_{Cd}][Cd_i]$, equilibrium constant for formation of neutral Frenkel pair

$K_I = [Cd_i]/P_{Cd}$, equilibrium constant for introduction of neutral Cd interstitial

$K_{CdS} = P_{Cd}P_{S_2}^{1/2}$, equilibrium constant for sublimation of CdS.

The equilibrium constant for sublimation of CdS is quite well-established by theory and experiment (11) to be

$$K_{CdS} = 2 \times 10^{10}\, e^{-3.38/kT}\ \text{atm}^{3/2} \quad [7]$$

There is one reported determination for K_I (5)

$$K_I \simeq 1.32 \times 10^{19}\, e^{-0.95/kT}\ \text{cm}^{-3}\ \text{atm}^{-1} \quad [8]$$

and an estimate of K_F (5)

$$K_F \simeq 4 \times 10^{44}\, e^{-5.38/kT}\ \text{cm}^{-6} \quad [9]$$

In this estimate, the enthalpy of Frenkel pair formation is only bracketed within a 0.5 eV range and the pre-exponential factor may be in error by a factor of $10^{\pm 8}$ due to neglect of vibrational entropy associated with a vacancy and interstitial (12).

If diffusion is *via* neutral Cd vacancies, V_{Cd}, the functional form of Eq. [6] is adequate to explain the present results. However, this will not account for the order of magnitude difference in the present values of D and those previously obtained on different samples of CdS (1). Normally, the density of singly and doubly charged vacancies exceed the density of neutral vacancies

$$[V'_{Cd}],\ [V''_{Cd}] > [V_{Cd}]$$

and diffusion may proceed *via* these charged vacancies. In fact, diffusion of Cd in CdS has been found to be *via* the doubly charged vacancy, V''_{Cd} (9). If the charge neutrality condition at the temperature of diffusion is determined by a donor impurity through the relation

$$n \simeq N_D >> \text{(other charged species)} \quad [10]$$

then both charged vacancy concentrations will also be proportional to $P_{S_2}^{1/2}$ through the relations

$$[V'_{Cd}] = \frac{2N_D}{N_c} e^{E_g - E_{A1}/kT}\,[V_{Cd}] \quad [11]$$

and

$$[V''_{Cd}] = \left(\frac{N_D}{N_c}\right)^2 e^{2E_g - E_{A1} - E_{A2}/kT}\,[V_{Cd}] \quad [12]$$

where E_g is the semiconductor band gap, E_{A1} and E_{A2} are the first and second ionization energies of the Cd vacancy double acceptor defect and N_c is the conduction band effective density of states (13). Calculations show that for Eq. [10] to be valid under our experimental conditions, $N_D \simeq 10^{18}\ \text{cm}^{-3}$ and K_F must be at least a factor of 10^{-3} smaller than given by Eq. [9]. This is not too surprising since the corresponding pre-exponential factor in CdTe is a factor of 10^{-8} smaller than the simple estimate (12, 13)

$$K_F \simeq N^2\, e^{-E_F/kT} \quad [13]$$

where N is the density of lattice points on the Cd ion sublattice.

A Cd ion vacancy density determined by Eq. [11] or [12] will be quite sensitive to donor impurity concentration. A series of experiments reported by Woodbury (8) on the self-diffusion of Cd in CdS suggest a simple vacancy diffusion process with

$$D_{Cd} \sim [V'_{Cd}] \sim N_D \quad [14]$$

However, the experimental conditions were such that, during diffusion

$$[V'_{Cd}] < [V''_{Cd}] \sim N_D^2 \quad [15]$$

and a functional dependence of the diffusion coefficient of the form

$$D_{Cd} \sim N_D^2 \quad [16]$$

might have been expected.

The important point of the above discussion is that metal ion diffusion, if it proceeds by a simple charged vacancy process, is experimentally and theoretically dependent on chalcogen partial pressure and pre-existing impurity concentration in the crystal. As memtioned in the beginning of the paper, crystals from different sources were characterized by different free electron concentrations at room temperature. Although the impurities and/or defects responsible for the observed electron concentration are unknown, different donor concentrations are to be expected. Thus, the difference in results of the two investigations, carried out under identical laboratory conditions but with crystals from different sources, are readily understandable.

If charge neutrality at the diffusion temperature is determined by some condition other than Eq. [10], charged native defect concentrations will generally be less pressure dependent than indicated by Eq. [11] and [12], *i.e.*

$$[V'_{Cd}] \sim P_{S_2}^{1/4} \quad [17]$$

if

$$[V''_{Cd}] \simeq [Cd_i^{\cdot\cdot}] >> \text{(other charged species)} \quad [18]$$

or alternatively

$$[V'_{Cd}] \sim P_{S_2}^{1/3} \quad [19]$$

and

$$[V''_{Cd}] \sim P_{S_2}^{1/6} \quad [20]$$

if

$$n \simeq 2[Cd_i^{\cdot\cdot}] >> \text{(other charged species)} \quad [21]$$

Numerical calculations indicate that if Eq. [10] describes the charge neutrality condition over a certain temperature and pressure range, then Eq. [21] will describe the charge neutrality condition over the same pressure range but at higher temperatures. Although the limited accuracy of the data from which Fig. 3 is constructed does not warrant firm conclusions, the indicated change in pressure dependence from the 930° and 960°C curves to the 990°C curve is not unexpected.

We now return to the problem of nonideal diffused concentration profiles mentioned in the Results. Since the maximum Yb^{3+} emission intensity at the surface saturates at different levels depending on the sulfur pressure at which the samples were prepared, we do not believe this saturation is a Yb^{3+} ion fluorescence concentration quenching phenomena. Furthermore, a number of experiments on different rare earth ions in a variety of crystals has shown an onset of concentration quenching at the relatively large value of 2×10^{20} rare earths/cm^3 (2). Such a concentration is two orders of magnitude greater than the maximum rare earth concentration it has been possible to introduce into a CdS crystal (14). We therefore eliminate possibility (*a*) of the Results as a cause of the nonideal concentration profiles.

The small values of Yb^{3+} diffusion constants measured eliminate the possibility of significant out diffusion of Yb^{3+} during the rapid quenching of the samples to room temperature from the diffusion temperature. Quench cooling time was typically 90 sec. We thus eliminate possibility (*b*) of the Results as a cause of the nonideal concentration profiles.

Field aided diffusion, (*c*), is significant only when charge neutrality is determined by the diffusing species and electrons or holes. However, the pressure dependence of solubility and diffusivity indicate a dominant concentration of other charged crystal defects. Formation of a diffusion barrier on the crystal surface, (*d*), such as an impermeable oxide can not be ruled out although microscopic examination of the surface showed no indication of a film. A concentration dependent diffusivity, (*e*), such as observed for Zn in GaAs (4) remains an open possibility.

Conclusion

The diffusion and solubility of Yb^{3+} in CdS has been shown to depend on the defect structure of the crystal. This defect structure is determined by impurities in the as grown crystals and vapor pressure of crystal constituents during diffusion annealing. The pressure dependence of diffusion constant and solubility suggest that vacancies in the Cd sublattice are the controlling factor. For a crystal with a fixed (but unknown) impurity concentration, it was possible to write a simple relationship, Eq. [4] for the pressure and temperature dependence of the deep diffusing component of the diffused impurity concentration.

Time-Dependence of Zinc Diffusion in Gallium Arsenide under a Concentration Gradient

C. H. Ting

and G. L. Pearson

Stanford University, Stanford, California 94305

ABSTRACT

The diffusion profiles of Zn in GaAs under a concentration gradient have been determined as a function of diffusion time for diffusions at 600° and 750°C. Pure radioactive Zn^{65} is used as the diffusion source. It is found that local equilibrium is not reached for these diffusions since the diffusion profiles can not be expressed in terms of a single variable $x/\sqrt{t}$. When the diffusion depth is plotted against the square root of diffusion time, a linear relationship is not obtained. The deviation from linear relationship is found to be quite pronounced at lower diffusion temperatures, and less so at higher diffusion temperatures. These observations indicated that the diffusion process can not be described by Fick's second law (with a concentration-dependent effective diffusion coefficient, $\overline{D}$). Under this condition, the Boltzmann-Matano analysis which has been used quite extensively to obtain values of the effective diffusion coefficient of $\overline{D}$ from the diffusion profiles of Zn in GaAs is not valid. Results are discussed in terms of nonequilibrium in the interstitial-substitutional diffusion. Complications due to the presence of diffusion-induced defects are also described.

Zinc diffusion in GaAs is anomalous in that the zinc concentration profiles obtained under concentration gradient diffusions from a constant vapor source do not obey a complementary error function, but exhibit a rather steep front (1, 2). The steep diffusion front indicates that the effective diffusion coefficient is strongly concentration-dependent. The concentration-dependent diffusion coefficient is generally interpreted

Key words: Boltzmann-Matano analysis, nonequilibrium interstitial-substitutional diffusion, diffusion induced defects.

in terms of the interstitial substitutional diffusion model (3-5) and can be obtained from the diffusion profiles through the Boltzmann-Matano analysis (1, 2, 5) if equilibrium is reached.

In spite of the wide application of the Boltzmann-Matano analysis for zinc diffusions in GaAs, no effort was made to check whether equilibrium is reached for diffusions under a concentration gradient. The possibility of nonequilibrium was discussed by Kendall (7), and also by Shaw and Showan (8). In this work, we demonstrated by measuring zinc profiles over a wide range of annealing time that equilibrium is not reached at lower diffusing temperatures.

Experimental Procedures

High purity (99.9999%) radioactive Zn^{65} was used as a diffusion source. The starting material was single-crystal GaAs wafers oriented in the <111> direction (obtained from Monsanto Company). The diffusions were carried out in evacuated quartz ampoules at 600°, 650°, and 750°C for various lengths of diffusion period. The quartz ampoules were cleaned in aqua regia, pumped down to a 10^{-6} Torr before being sealed off. A quartz plug was used in the ampoule to reduce the total volume to less than 1 cm^3. After diffusion, the samples were washed in dilute HCl for 30 min to remove any excess zinc on the surface, and were then cut into circular disks of 0.5 cm diameter. Diffusion profiles were obtained by measuring the radioactivity of the removed layer, using the standard lapping, weighing, and counting procedure.

For the diffusion temperatures in this study, the Zn_3As_2 phase is present in the Ga-As-Zn ternary system (8). Under this condition, the ternary liquid compositions are not on the pseudobinary line of Zn and GaAs, but lie on the gallium-rich side of the ternary phase diagram (2, 8). The experimental parameters for the 600°, 650°, and 750°C diffusions are summarized in Tables I, II, and III respectively.

Experimental Results

The zinc concentration profiles for the 600°, 650°, and 750°C diffusions are shown in Fig. 1, 2, and 3, respectively. For sample No. 1, the penetration depth is rather small; therefore, two sets of data points obtained from opposite sides of the sample were used to increase the accuracy in constructing the concentration profile.

The effective diffusion coefficient D of Zn in GaAs can be obtained from the concentration profiles through

the Boltzmann-Matano method. If $\overline{D}$ is only a function of zinc concentration, the diffusion equation in one-dimensional form is given by Fick's second law

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(\overline{D}\frac{\partial c}{\partial x}\right) \quad [1]$$

For diffusion in a semi-infinite media, this equation can be simplified by the Boltzmann transformation $\lambda = x/\sqrt{t}$. In terms of the new variable (λ) Eq. [1] becomes

$$-\frac{\lambda}{2}\frac{dc}{d\lambda} = \frac{d}{d\lambda}\left(\overline{D}\frac{dc}{d\lambda}\right) \quad [2]$$

Equation [2] can be integrated to give

$$\overline{D} = -\frac{1}{2t}\frac{\int_0^{c_x} x\,dc}{\left(\frac{dc}{dx}\right)_{c_x}} \quad [3]$$

Using Eq. [3], the value of D can be obtained from the concentration profiles by evaluating the area under the profile and the concentration gradient at the point of interest. In evaluating $\overline{D}$, large errors are involved in determining the slopes of the profiles, especially near the diffusion front where a large change in concentration occurs in a rather small distance. A method of improving the accuracy of the calculations near the extremes of the concentration range has been developed by Hall (10).

The value of $\overline{D}$ as a function of zinc concentration for the 600°C diffusions is obtained from the profiles shown in Fig. 1, using the technique developed by Hall. The results are shown in Fig. 4. Figure 4 shows that different values of $\overline{D}$, are obtained from profiles with different diffusion time. The values of $\overline{D}$ obtained by this method change not only with zinc concentration but also with diffusion time. Therefore, the Boltzmann-Matano analysis does not give valid values of the effective diffusion coefficient.

As indicated by Eq. [2], the diffusion equation can be expressed in terms of a single variable, $\lambda = x/\sqrt{t}$. The concentration of the diffusant C, therefore, will change only with $x/\sqrt{t}$, but not with respect to x and t separately. This would yield a fixed value of $x/\sqrt{t}$ for a given concentration level, regardless of the length of diffusion time. When the concentration profiles obtained for various diffusion time are plotted against the normalized distance $x/\sqrt{t}$, all profiles should coincide. Another way to express the same condition is to plot the diffusion depth (where concentration is equal to a fixed level C_d) against the square root of diffusion time ($\sqrt{t}$), then a straight line through the origin should be obtained.

The concentration profiles for the 600°C diffusions shown in Fig. 1 are replotted as a function of normalized distance $x/\sqrt{t}$ in Fig. 5. One can see clearly that the profiles do not coincide.This indicates that the diffusion process discussed here cannot be described by Fick's second law, as given by Eq. [1]. The diffusion depth, obtained from the concentration profile shown in Fig. 1 and 2, where zinc concentration is 10^{18} cm^{-3}, is plotted against the square root of diffusion time in Fig. 6. It can be clearly seen that a linear relationship is not obtained.

The X_d *vs.* $\sqrt{t}$ curves in Fig. 6 can roughly be separated into two regions. In the first region (where diffusion time is relatively short), the data points seem to fit a straight line through the origin. For the second region (where diffusion time is relatively long), the data points seem to fit another straight line which does not pass through the origin, *i.e.*

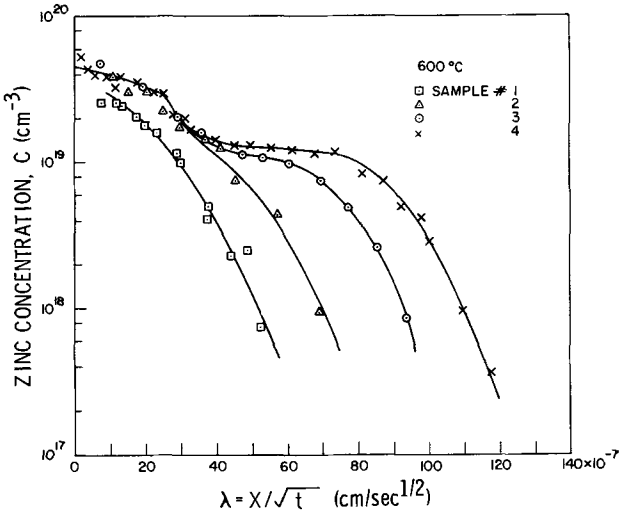

Fig. 5. Diffusion profiles of Zn in GaAs at 600°C as a function of $\frac{X}{\sqrt{t}}$.

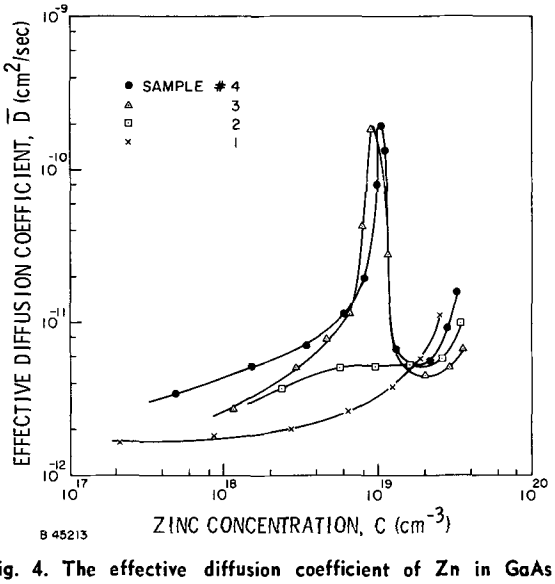

Fig. 4. The effective diffusion coefficient of Zn in GaAs vs. Zn concentration at 600°C as obtained from Boltzmann-Matano analysis.

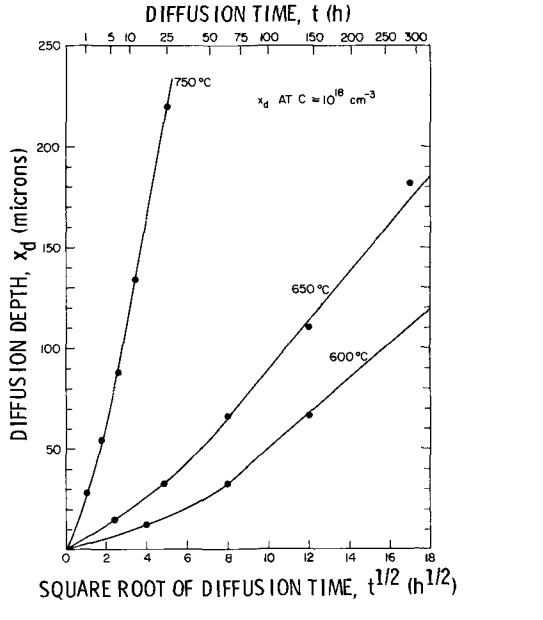

Fig. 6. Diffusion depth vs. square root of diffusion time for Zn in GaAs for diffusions at 600°, 650°, and 750°C.

$$X_d = S_2 (\sqrt{t} - \sqrt{t_o}) \quad [4]$$

where S_2 is the slope of the straight line, and t_o is the intercept of this straight line with the time axis. Figure 6 indicates that the intercept t_o decreases rapidly as the diffusion temperature is raised. At sufficiently high temperature, t_o will be so small that it will be comparable to or less than the necessary warm-up time of the diffusion sample. At this point, t_o can no longer be determined easily from the diffusion experiment and therefore can be ignored. Thus, the linear relationship between x_d and $\sqrt{t}$ will be a limiting case for high-temperature diffusions.

Nonequilibrium in Interstitial-Substitutional Diffusion

The nonlinear relationship in the x_d *vs.* $\sqrt{t}$ diagram, as shown in Fig. 6, cannot be explained by manipulating the concentration-dependent effective diffusion coefficient, $\overline{D}$. It is reasonable, therefore, that some nonequilibrium phenomena are responsible for this nonlinear behavior. The qualitative features of the nonequilibrium diffusion can be understood in terms of the interstitial-substitutional model.

In the literature, the interstitial-substitutional diffusion model has been used extensively to explain various experimental results of zinc diffusion in GaAs. However, local equilibrium between the interstitial and substitutional species is always assumed to be valid whenever this model is used (2, 4, 5, 10, 11). When an equilibrium condition is not reached, one must take the transitions between interstitial and substitutional zinc into consideration. Then Fick's law is no longer adequate to describe the diffusion process. The transitions between interstitial and substitutional zinc can be described by the reaction

$$Zn_i^{+r} + V_{ga} \underset{k_2}{\overset{k_1}{\leftrightarrows}} Zn_s^{-} + (r+1)e^{+} \quad [5]$$

where k_1 and k_2 are rate constant for the reversible reactions. Under this condition, the concentrations of interstitial and substitutional zinc C_i and C_s can be described by the following equations

$$\frac{\partial C_i}{\partial t} = D_i \frac{\partial^2 C_i}{\partial X^2} - k_1 C_v C_i + k_2 p^{(r+1)} C_s \quad [6a]$$

$$\frac{\partial C_s}{\partial t} = D_s \frac{\partial^2 C_s}{\partial X^2} + k_1 C_v C_i - k_2 p^{(r+1)} C_s \quad [6b]$$

where D_i and D_s are the interstitial and substitutional zinc diffusion coefficients, respectively, C_v is the gallium vacancy concentration, and p is the hole concentration. Equation [6a] simply states that the rate of change in interstitial zinc concentration is equal to the diffusion flux minus the amount that changed from interstitial into substitutional positions, plus the amount that changed from substitional into interstitial positions. The constants k_1 and k_2 are the transitional probabilities from interstitial into substitutional positions, and *vice versa*. Equation [6b] gives a similar expression for the rate of change in substitutional zinc.

If the equilibrium between interstitial and substitutional zinc is reached during the diffusion process, then the two transitional terms in Eq. [6] will just cancel each other, *i.e.* $k_1 C_v C_i = k_2 p^{(r+1)} C_s$. Under this condition the two transitional terms would disappear and Eq. [6] can be reduced to the form of Fick's second law, and the concentration will be a function of only $x/\sqrt{t}$. This corresponds to the extreme case that the transitions between interstitial and substitutional zinc can be considered as an instantaneous reaction. The other extreme case is that where the reaction by which the immobilized substitutional zinc is formed proceeds very fast compared with the diffusion process. In this case, local equilibrium can be assumed to exist between the interstitial and substitutional zinc. Here also Eq. [6] can be reduced to the form of Fick's second law. Except for the two extreme cases outlined above, the coupled diffusion Eq. [6] must be used to describe the diffusion process of zinc in GaAs. The diffusion Eq. [6] cannot be reduced to a single variable by using a new variable $\lambda = x/\sqrt{t}$; therefore, a linear relationship between x_d and $\sqrt{t}$ is not expected in this case.

Two time constants, T_i and T_s, can be obtained from Eq. [6]. They are

$$T_i = \frac{1}{k_1 C_v} = \text{the lifetime of interstitial zinc before conversion into substitutional zinc}$$

$$T_s = \frac{1}{k_2 p^{r+1}} = \text{the lifetime of substitutional zinc before conversion into interstitial zinc.}$$

At equilibrium $k_1 C_v C_i = k_2 p^{r+1} C_s$, therefore, the ratio of the interstitial and substitutional lifetime is equal to the ratio of equilibrium concentration of these two species, *i.e.* $T_i/T_s = C_i/C_s$. It has been estimated that the ratio C_i/C_s is very small, usually 10^{-5} or less (12); therefore, T_s is greater than T_i by a factor of 10^{+5} or more. The time constants T_i and T_s, generally, change exponentially with temperature. Since the time constant increases rapidly as temperature is lowered, the assumption that equilibrium between interstitial and substitutional zinc is probably good for a high diffusion temperature, but poor for a relatively low diffusion temperature. The above discussion agrees well with the qualitative feature of the X_d *vs.* $\sqrt{t}$ diagram, in that the deviation from the linear relationship is quite pronounced at lower diffusion temperatures and less so at higher diffusion temperatures.

Figure 6 shows that the diffusion is slower for shallow diffusions and more rapid for deeper diffusions. Two limiting cases can be used to illustrate this point. The first extreme case is for very short diffusion times. If the diffusion time is so short that it is less than the time constant T_2, then the transitions from interstitial to substitutional sites will not be completed. Under this condition, zinc diffuses as two separate streams, *i.e.* the interstitial and substitutional, with negligible interaction between them. The measured concentration profile is essentially the profile of substitutional zinc, since the interstitial concentration is so small. Therefore, this limiting case gives essentially a substitutional diffusion characterized by its low diffusion constant. The other extreme case is for very long diffusion time. If the diffusion time is so long that it is longer than the time constant T_s, then local equilibrium between the interstitial and substitutional is maintained. Under this condition, the diffusion is dominated by the transitions between the two species, which gives an effective diffusion coefficient. The value of $\overline{D}$ in this case is given by $\overline{D} = D_i \dfrac{\partial C_i}{\partial C_s}$ which is rather large. From the above discussion, it is reasonable to expect the effective diffusion coefficient to increase with the diffusion time as the interstitial-substitutional equilibrium is approached.

The discussion presented so far gives the correct qualitative features observed in the X_d *vs.* $\sqrt{t}$ plot; however, no quantitative agreement is available at present. This is because the parameters D_i, D_s, k_1, and k_2 used in Eq. [6] have not been determined by any measurements, and the vacancy concentration C_v may not be a constant. Therefore, without any detailed knowledge on the atomic interaction for zinc in GaAs, quantitative agreement between the nonequilibrium interstitial-substitutional model and the experimental results cannot be obtained at present.

Discussion

The interstitial-substitutional nonequilibrium is not the only possible nonequilibrium mechanism in the diffusion process. Other possible sources should not be

overlooked. The most important complication is the presence of diffusion-induced defects. It has been shown beyond doubt that zinc diffusion under a concentration gradient generates induced defects (12-14) when pure zinc is used as a diffusion source and when the diffusion time is sufficiently long. For a very short diffusion time, usually no induced defects can be detected. It seems possible that the appearance of the induced dislocations is the cause for the nonlinear behavior in the X_d *vs* $\sqrt{t}$ plot.

The induced dislocation represents a rapid diffusion path or a "diffusion pipe" for substitutional zinc; thus, the enhanced diffusion in the diffusion pipes may dominate the diffusion process (14). However, the assumption that zinc diffusion in GaAs is dominated by enhanced substitutional diffusion in the induced defects has many difficulties. A few of these difficulties are:

(*A*) For diffusion runs with relatively short diffusion time (where the diffusion depth is in the first region of the X_d *vs.* $\sqrt{t}$ plot) the effect of enhanced diffusion in the induced dislocations is supposed to be negligible and normal diffusion should result. However, the effective diffusion coefficient obtained from shallow diffusion still shows concentration dependence.

(*B*) The value of the effective diffusion coefficient obtained from shallow diffusions is too large for substitutional diffusions.

(*C*) The effective diffusion coefficient decreases with external arsenic vapor pressure (5). This observation can be explained only in terms of the interstitial-substitutional model.

(*D*) Isoconcentration diffusion for the melt-doped sample generates little or no induced dislocations; yet the value of the effective coefficient is very large (12).

In view of the above-mentioned difficulties and the excellent agreement between the interstitial-substitutional model and various experimental data of zinc diffusion in GaAs, it is reasonable to say that zinc diffusion in GaAs is not dominated by the enhanced substitutional diffusion in the induced dislocations. If the contribution of interstitial diffusion is reduced significantly, such as for diffusion under very high external arsenic pressure, then the contribution due to the enhanced diffusion in dislocations may be important.

Although it is unlikely that the diffusion process is dominated by the enhanced substitutional diffusion in the induced defects, it is possible that the induced defects may produce a significant change in the interstitial diffusion. For instance, the induced defects may increase the values of the interstitial diffusion coefficient or the ratio of interstitial to substitutional zinc. Under this condition, the effective diffusion coefficient, D, given by $\overline{D} = D_i \frac{\partial C_i}{\partial C_s}$, would be increased significantly in the region with induced defects so that the appearance of induced defects is responsible for the nonlinear behavior in the X_d *vs.* $\sqrt{t}$ relationship. This model also has its difficulties:

(*A*) The value of $\overline{D}$ obtained from the samples with fully developed induced defects is not larger than the value of $\overline{D}$ obtained from isoconcentration diffusions in melt-doped samples where no induced defects were observed (12).

(B) The value of $\overline{D}$ obtained from relatively shallow diffusions has a weak concentration dependence, as illustrated in Fig. 4, and also by Chang and Pearson (4). This is quite different from the C^2 dependence of $\overline{D}$ predicted from the equilibrium interstitial-substitutional diffusion model.

Even though it is difficult to explain the nonlinearity between X_d and $\sqrt{t}$ in terms of the induced defects alone, the fact that zinc diffusion does induce defects in GaAs should not be ignored. It is possible that the influence of the induced defects could be combined with the effects on nonequilibrium in interstitial-substitutional diffusion. However, we cannot conjecture about such a complicated diffusion model without additional experimental data.

Conclusions

From the series of diffusions at 600°, 650°, and 750°C, it is found that equilibrium is not reached for zinc in GaAs at these temperatures. This is demonstrated by the fact that the diffusion profiles for various diffusion time at a fixed temperature do not coincide when plotted against $X/\sqrt{t}$ and also by the fact that the diffusion depth X_d does not vary linearly with the square root of diffusion time. Under this condition, the well known Boltzmann-Matano analysis cannot be used to yield meaningful values of effective diffusion coefficient $\overline{D}$. This is illustrated by the fact that different values of $\overline{D}$ are obtained when the Boltzmann-Matano analysis is applied to the diffusion profiles with different diffusion times.

Quantitative verification of nonequilibrium in the interstitial-substitutional diffusion model is impossible since no experimental data are available regarding the time constants involved in the interstitial-substitutional transitions. The fact that the diffusion-induced defects are always observed in the long diffusion runs greatly increases the complications.

Vapor Growth of a Semiconductor Superlattice

A. E. Blakeslee*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

It has been predicted that under certain conditions a multilayer sandwich structure consisting of alternating close-spaced layers of two semiconductors of different energy gap will exhibit intriguing transport and optical properties, including a negative resistance. This type of structure has been created with a specially designed vapor growth system, wherein the composition is made to alternate many times between $GaAs_{1-x}P_x$ and $GaAs_{1-y}P_y$ ($0 \leq x < y$) with a period as small as 110Å. The presence of the repetitive structure has been confirmed by electron microscopy on cleaved and etched cross sections and by x-ray diffraction. The uniformity of spacing, as well as the period, is of prime importance. The effects of crystal orientation and reactant gas composition on this property are described.

Esaki and Tsu (1) have proposed the concept of the superlattice negative conductance amplifier. Essential to this concept is a semiconductor structure into which is built a periodic variation of potential. That is, if it is possible to create a structure in a monocrystalline semiconductor where the potential varies a few tenths of an electron volt in a periodic fashion and such that the period of the variation is less than the mean free path of the carriers, novel electrical and optical effects are predicted, the most striking of which is that a negative resistance can be observed at relatively low electric fields. The theoretical basis for this proposal is illustrated in Fig. 1, which is a plot of energy *vs.* electron momentum in *k*-space. The discontinuity in the curve occurs at the edge of the first Brillouin zone, corresponding to the normal lattice periodicity. In the superlattice device the additional periodicity of the superimposed potential subdivides the Brillouin zone into so-called mini-zones with boundaries inversely proportional to the superlattice spacing. The mini-zone boundaries occur at much lower momentum values and the associated forbidden energy gaps occur at lower energies. Just as in the normal Brillouin zone, there is an inflection point in E *vs.* k in the mini-zone, and an electron should decelerate upon increasing the applied potential past this point, resulting in a negative differential conductance.

Figure 2 shows two methods by which the proposed periodic structure might be achieved. In the top diagram the same semiconductor is changed back and forth from n-type to p-type, accompanied by the resultant movement of the band edges, by rapidly changing from an n-type to a p-type dopant. A maximum potential change in each band of close to the bandgap energy, E_g, is possible with this method. In the second method, with which this paper is concerned, the doping is constant or nearly so, but the basic semiconductor material is changed. It alternates between two different semiconductors with different energy gaps, E_{g1} and E_{g2}. The illustration shows the difference in forbidden gap energy, ΔE_g, to be divided equally between the conduction and valence bands, but such does not have to be the case and in general is not. Of the two methods, the second would be more stable against interdiffusion, since impurities have larger diffusion coefficients in general than do alloy constituents.

The structure produced by the alloy method is equivalent metallurgically to a long-period one-dimensional superlattice (Fig. 3). Natural superlattices (2) are thermodynamically stable at some temperature, whereas the artificial ones are not, but this distinction has no bearing on the present problem. Instead of an alternation of lattice planes containing different atoms A B A B A . . . , as in the simplest type of one-dimensional superlattice, in the present case there are n planes of A, m planes of B, n of A etc., where $n + m$ is the number of normal unit cells with spacing a within

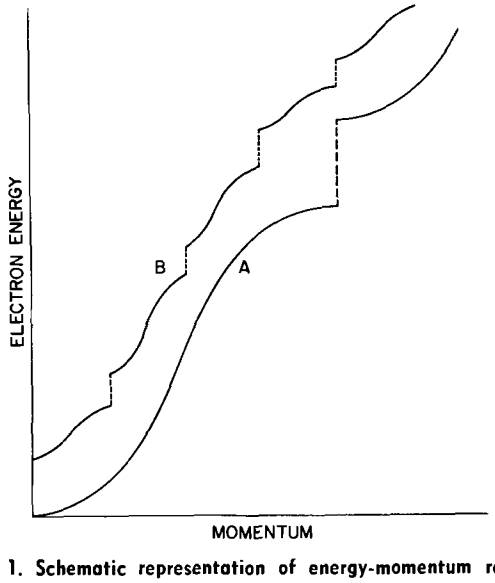

Fig. 1. Schematic representation of energy-momentum relationship in (A) normal crystal; (B) superlattice.

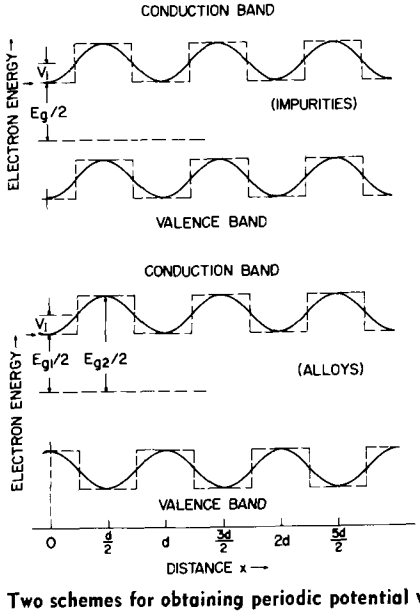

Fig. 2. Two schemes for obtaining periodic potential variation

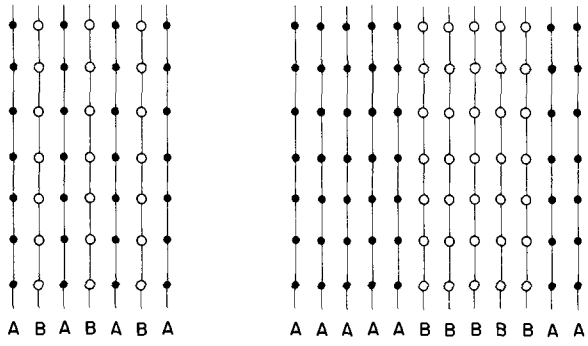

Fig. 3. Schematic illustration of one-dimensional superlattices

a superlattice having period d. This is an idealized description, of course. In any real case the transition from A to B would occur across more than one atom layer, and varying degrees of admixture might exist across the whole period. Calculations (1) show that for most suitable pairs of semiconductors A and B, $n + m$ should be of the order of 30; that is, the superlattice spacing should be about 100-300Å. The amplitude of potential variation within the pertinent band, *e.g.*, the conduction band for n-type material, should be a few tenths of an electron volt. Constancy of the lattice spacing across the superlattice is vital to the exhibiting of the predicted properties. The superlattice period must therefore be uniform to better than 5%, possibly even 1%.

Experimental

We have chosen to attempt to produce such a semiconductor superlattice by the technique of epitaxial vapor growth, using the ternary compound $GaAs_{1-x}P_x$. The value of x, which is the mole fraction of phosphorus on group V sites and is therefore nearly proportional to the potentials of the band edges, is made to oscillate between two values by varying the PH_3 concentration in the epitaxial reactor. The period of alternation is a few hundred angstroms. Thus in the idealized drawing of Fig. 3, material A would be GaAs, where $x = 0$, and B would be $GaAs_{1-x}P_x$ with some maximum value of x, say $x = 0.5$. This could produce a maximum change in bandgap of approximately 0.6 eV at room temperature. The difference between the maximum and minimum values of x that can be realized is directly a measure of the amplitude of the potential variation. The magnitude of this difference, Δx, is of more significance to the electrical behavior than is the steepness of the gradient. Whether a significant Δx can be built into and maintained in the crystal at such close tolerances obviously depends critically on the extent of interdiffusion of the P and As components both in the gas phase and in the solid. Results thus far indicate that neither of these phenomena has occurred to any serious degree.

Figure 4 is a schematic of the epitaxial structure in a form suitable for electrical testing. The substrate is (100)-oriented GaAs which is doped n-type to about 10^{18} carriers/cc. A layer of GaAs doped with sulfur is grown first, followed by the band of thin alternating layers and then by another uniform GaAs layer. The top and bottom GaAs layers provide ohmic contacts to

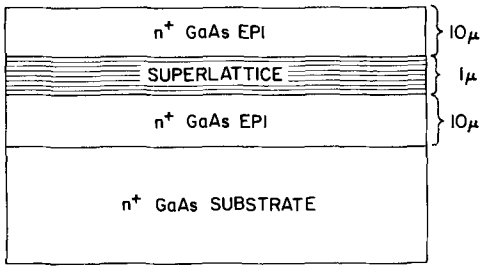

Fig. 4. $GaAs/GaAs_{1-x}P_x$ superlattice sandwich structure

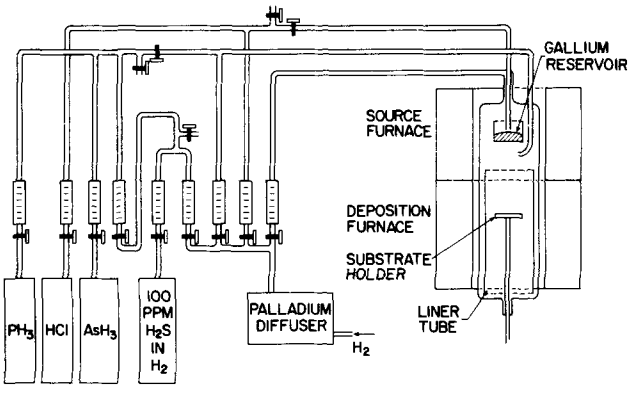

Fig. 5. Vapor deposition system for $GaAs_{1-x}P_x$

the superlattice. The superlattice portion is not intentionally doped. It turns out to be n-type, with between 10^{16} and 10^{17} carriers/cc.

The vapor growth system is illustrated in Fig. 5. It is essentially a modification of the process described by Tietjen and Amick (3). GaAs is obtained by reacting AsH_3 gas with GaCl vapor produced by chlorination of Ga with HCl gas at 900°C. The substrate temperature is usually about 760°C. The system shown is unsatisfactory for producing the thin-layered structures because of the relatively large reaction zone volume in which AsH_3 and PH_3 will mix by interdiffusion, preventing sharp separation in the crystal. To make the superlattice structure possible, a modification shown in Fig. 6 was introduced wherein an electromechanical valve served to send the PH_3 stream alternately into the reaction mixture or to vent it from the system. Also, the diameter of the reactor was constricted. By using narrow ID quartz tubing and relatively high flows of carrier H_2, it has been possible to achieve rapid injection of PH_3 into the growth region. The rate of injection can be as fast as once a second, and gas velocities as high as 5 m/sec are reached in some parts of the system. Typical values of gas flow rates are: HCl, 10 cc/min; AsH_3, 10 cc/min; PH_3, 5 cc/min. The sum total of all carrier H_2 flow rates was originally 1000 cc/min. In a second modification to the system the total carrier gas flow was increased to 2000 cc/min, but more importantly the diameter of the substrate zone was decreased from 45 to 15 mm, the result of the

τ	—	1.7 sec	0.055 sec

$$C_{mid} = C_0 \operatorname{erfc} \frac{x_{mid}}{2\sqrt{Dt}}$$

$$\tau = \left\langle \frac{4\sqrt{Dt}}{V} \right\rangle$$

two changes being to increase gas velocity in the vicinity of the substrate by a factor of 18.

A rough estimate of the expected effect of the modifications on the flow properties of the system is shown in Table I. The first parameter, C_{mid}, is the result of a simple complementary error function diffusion calculation, assuming two successive PH_3-bearing and PH_3-free pulses of gas are effectively semi-infinite in extent. C_{mid} is the concentration of PH_3 at the point x_{mid}, which is midway between two successive pulses of PH_3. C_0 is the initial maximum PH_3 concentration in the center of a PH_3 pulse. Since complete interdiffusion would result only in increasing C_{mid} from 0 to $1/2C_0$, the value of 0.85 C_0 given in the first column is physically impossible, showing that diffusion would be far too great in the wide tube. T is the residence time of PH_3 in the system between the solenoid valve and the substrate. The third parameter, τ, defined as $4\sqrt{Dt/V}$, is a time constant reflecting the two factors which primarily determine the sharpness of the gaseous interface, namely the diffusion length and the streaming velocity of the gas. From these three criteria it is seen that a large improvement is effected by constricting the upper part of the reaction tube and a somewhat further one by continuing the constriction past the substrate position.

Results

Observation by electron microscopy is the most usual evaluative procedure applied to the grown layers. The wafer is first cleaved across the epitaxial layers on a (110) cleavage face and etched for 15 sec in a 10:1:1 $H_2O:H_2O_2:HF$ solution. This brings out what appears under visual microscopy as a thin line parallel to the substrate. A platinum-shaded carbon replica is then made of the cleaved and etched surface, and this is examined by transmission electron microscopy.

Figure 7 shows the first attempted superlattice. A corrugated band of nearly parallel lines is clearly visible between the uniform GaAs layers at top and bottom. In some places where the edges are not in shadow it is possible to count the exact number of alternations which were attempted, namely 30. The wide layer just above the superlattice is not a part of it but rather an artifact of the growth procedure. The diagonal lines crossing the superlattice represent the intersection of (111) stacking faults with the cleavage plane. It can be seen that the spacing is variable in this picture, and a more detailed study at several points along this band would reveal a slight decrease of the average spacing in the direction of growth. The average spacing here is about 300Å and was produced by injecting the PH_3 for 3 sec and then turning it off for 3 sec, repeating this procedure 30 times. The corrugations themselves are produced by preferential etching, the GaAs layers etching faster than the $GaAs_{1-x}P_x$.

Scanning electron microscopy (SEM) is faster than the replica transmission method and offers the advantage that it is possible to observe the specimen directly while maneuvering it into different positions, but it lacks the high resolution of the replica method. A special adaptation of this type of examination is shown in Fig. 8. This is the double cleave technique, where after cleaving and etching the specimen it is cleaved again perpendicular to the original cleaved surface, and the intersection is then observed by SEM. Figure 8a illustrates clearly that the whole superlattice area is raised above that of the GaAs sandwiching it on both sides because the GaAs etched at a faster rate. The resolution of this microscope was not good enough to bring out the individual striations within this band. However, they are visible in the second photograph, Fig. 8b, which depicts a superlattice with a much larger spacing, in this case about 2000Å. It is not clear whether the deep gouge at the right of the photograph represents a defect in the original growth or whether it is simply a cleavage phenomenon.

Electron microscopic techniques are very useful to demonstrate when a superlattice has been successfully grown and to measure its period. However, they reveal very little about the amplitude of the concentration variation. It is known that relatively small concentration inhomogeneities and other effects such as temperature fluctuations can produce strong etching effects (4). Furthermore, a substantial lattice strain must be present due to the approximately 2% difference in lattice constants, and mismatch dislocations have been reported for this system (5). Strain and distortion of the lattice could be responsible for some of

Fig. 7. Replica transmission electron micrograph of 300Å superlattice structure.

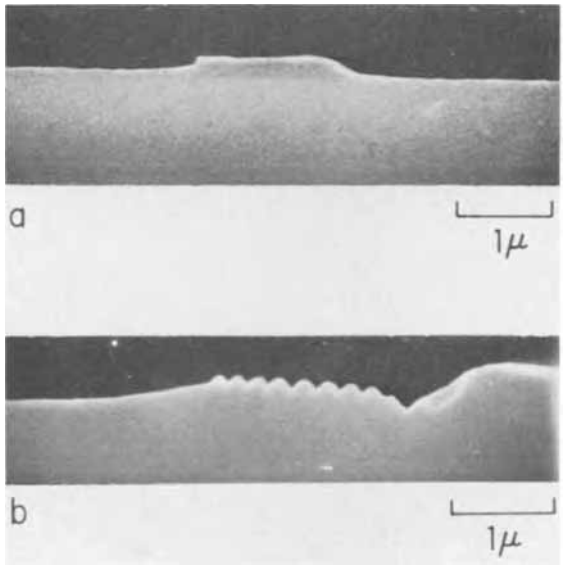

Fig. 8. Scanning electron micrographs of doubly cleaved superlattice structures.

the enhanced etching. Thus it was difficult to know whether the observed variation in etch rate corresponded to a change in phosphorus concentration sufficient to produce the desired effects. Some attempts at measuring the concentration profiles directly by counting neutron-activated layers removed by RF sputter etching and by the ion microprobe resulted in failure, presumably because removal of parallel layers only a few angstroms thick could not be accomplished.

The most conclusive proof that a nontrivial change in the phosphorus mole fraction actually exists within the superlattice has been obtained by an x-ray technique. The x-ray measurements were made by recording the intensity of (400) diffraction peaks from a type of sample that differed from those previously described in that the top layer of GaAs was not grown. This form of specimen, which is more suitable also for certain electrical measurements, allows the x-rays to penetrate directly into the superlattice. When very thin layers of two different crystalline substances are interleaved together and when the successive layers are thin enough that many of them can exhibit simultaneous and coherent x-ray diffraction, the separate peaks characterizing the two individual materials will disappear and be replaced by an average reflection with which are associated satellite peaks, or side bands. Previous work involving detection of satellites has always entailed naturally occurring superlattice crystals (2).

Satellite x-ray peaks have been observed for several of our specimens. Figure 9 shows the sharpest x-ray spectrum that has been seen, indicating that this specimen has the most perfect superlattice that has been grown to date. The peak at 66.2° is the (400) reflection from the GaAs substrate. The peak at 67.5° is the same reflection from the interleaved $GaAs_{1-x}P_x$ layers. The satellite peaks are seen 0.5° above and below this parent peak. Each of the peaks shows a splitting due to the α_1 and α_2 components of the CuKα radiation. Both the presence of the satellites and the α_1-α_2 resolution are indicative of the high degree of coherence of the superlattice. An analysis of this spectrum (6) has predicted that for this degree of sharpness to result, the period within the superlattice must be constant to better than 1% in this case. The high intensity (48% of that of the central peak) of the right hand side peak is strong evidence for the existence of a significant amplitude in the periodic phosphorus profile. The asymmetry in the height of the two side bands and the fact that the central peak position corresponds to a lattice constant smaller than expected for an unstrained combination of 0 and 50% GaP layers are attributed to an anisotropic stress distribution in the superlattice.

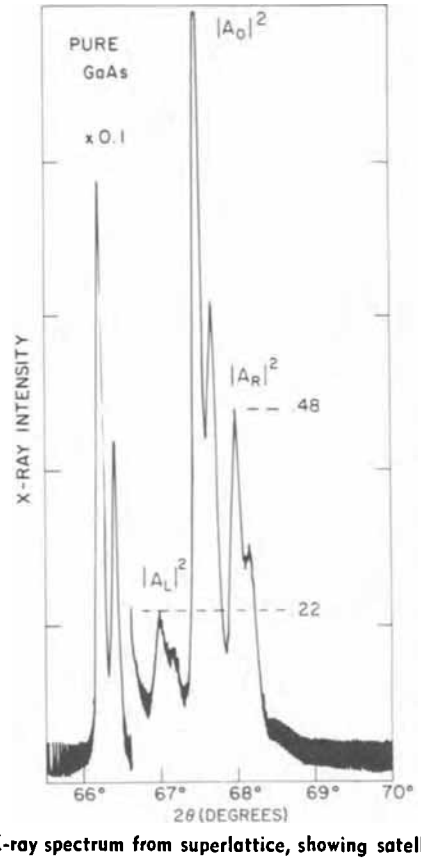

Fig. 9. X-ray spectrum from superlattice, showing satellite peaks

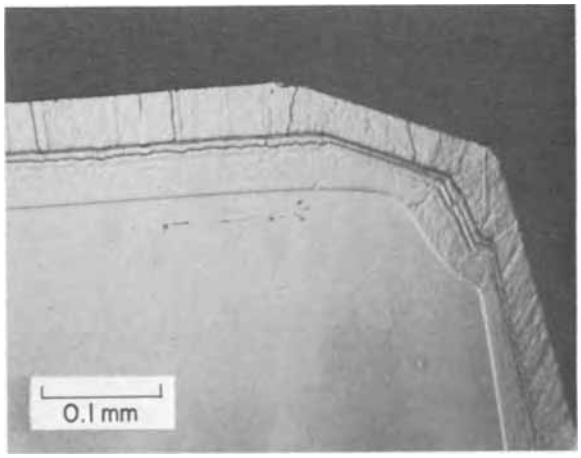
Various alternative hypotheses to account for the x-ray diffraction effects have been considered. One such model is that several discrete layers of material, each of which is homogeneous within itself but distinct in composition from the others, give rise to separate diffraction peaks; another is that the satellite peaks are due to slightly misoriented segments. The experimental observation that the angular spacings between satellite and parent peaks vary regularly and inversely with the layer spacings, in accordance with simple Bragg diffraction theory, supports the assumption of a superlattice as opposed to the fortuitous situations mentioned above as alternative hypotheses.

Having demonstrated the feasibility of making a superlattice, there remains the difficult task of perfecting it to the point where it can meet the stringent requirements imposed by the device theory. This reduces essentially to controlling the growth rate so that the layers are flat, parallel, and equally spaced. Many cases have been seen that are far from the ideal, for example the defective growth shown in Fig. 10, which shows a sample with four successive superlattice bands. Note that these bands are neither straight nor parallel. Since the growing interface obviously became rough before growth of the superlattice was begun, solution of this problem was equivalent to that of avoiding growth pits in epitaxial layers. Effects of temperature and orientation on the phenomenon of surface pitting have been reported (7), but neither of these effects was found to be responsible for the nonplanar epitaxy. The key to the problem turned out to be an unsuspected variable, the flow rate of HCl. A minimum HCl flow rate, and hence a minimum GaCl pressure in the reactor, was found necessary in order to ensure surface planarity. For (100) substrates and 750°-760°C, the minimum HCl flow is 10 cc/min; for higher temperatures and for (111A) substrates the rate must be higher.

Another way to improve the flatness is by suitable choice of the orientation. In looking at the epitaxial growth at the edge of the wafer shown in Fig. 10 it was noted that, although many kinks and jogs existed in the part growing in the <100> direction, there was



Fip. 10. Nonplanar growth on sample containing four superlattice bands.

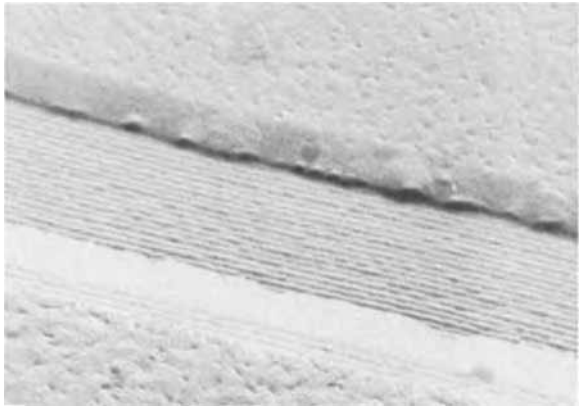


Fig. 11. 200Å superlattice with constant periodicity

another direction in which facets formed and the superlattice layers were flat and parallel. It was determined that this was the <311> direction. Subsequent superlattice growth on a (311A)-oriented substrate verified that the resulting layers were indeed very flat.

By applying some of this knowledge it was possible to greatly improve the morphology of the growth. An example of one of the best layers is given in Fig. 11. The spacing here is about 200Å. The layers are actually more parallel than they look because the corrugated surface is slightly mottled by the etching. The smallest spacing that has been resolved so far is 110Å, but this was not constant across the whole superlattice.

Electrical properties of these layers have been reported elsewhere (6). Very briefly they are the following. Foremost is the fact that the negative resistance has not yet been observed. However, existence of an electrical as well as a metallurgical superlattice, has been tentatively concluded from measurements of cathodoluminescence, capacitance *vs.* voltage at 4°K, and conductance *vs.* temperature. Since a barrier height of only 60 meV, which is only 10% of the maximum possible bandgap change, was detected, it is concluded that most of the potential oscillation exists in the valence band. Thus in order to realize the negative resistance properties it may be necessary to exploit the capability of the system described here with p-type $GaAs_{1-x}P_x$ or with another semiconductor system.

High-Temperature Annealing of Oxidized Silicon Surfaces

F. Montillo[1] and P. Balk

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The densities of fixed charge (Q_{ox}) and trapping centers (N_{ss}) on thermally oxidized silicon surfaces have been measured by the MOS capacitance technique upon annealing in O_2, N_2, He, and vacuum at various temperatures from 600° to 1100°C. These surface characteristics are always determined by the conditions of the final high-temperature process, except for Q_{ox}, which will never increase in neutral ambients. In all atmospheres, higher annealing temperatures yield lower Q_{ox} values. It was also found that the N_{ss} values are very sensitive toward trace amounts of water in the high-temperature ambient. They decrease for increasing water vapor pressure. Effects of other impurities were not observed in this study. Based on saturation values and kinetic data a discussion is given of some models for both types of centers.

The properties of oxidized silicon surfaces have been studied extensively during the past decade. The interest in this topic was strongly stimulated by the advent of the field effect transistor. Two characteristics are of particular significance for their effects on the performance of this device: the tendency of both n- and p-type silicon substrates to form n-type surfaces upon oxidation, and the presence of trapping states near the semiconductor-oxide interface (1). Accordingly, several workers in this field have investigated the conditions that determine the amount of positive surface or oxide charge (invoked to explain the excess of electrons occurring in n-type space charge layers at silicon surfaces) and the density of surface trapping states.

Notwithstanding the fact that these phenomena are well known, there is no generally accepted physical model to account for the above characteristics. In fact, three different models may be invoked to describe the observations: The first one distinguishes between fixed surface charge centers, located in the oxide, and inter-

[1] Present address: IBM Components Division, East Fishkill, New York 12524.

Key words: surface charge, interface states, CV-measurements.

facial trapping states (2). One must also consider the possibility that both surface charge and trapping states may be related to centers directly at the oxide-silicon interface (3). A third model allows only for centers in the oxide near the interface, and considers trapping states as induced by point charges in the oxide (4). Although many workers assume that the centers are related to vacancies in the oxide or at the interface, it has also been suggested that they are caused (2, 5) or stabilized by (6) impurities, notably Na.

With respect to the phenomenological behavior of the centers there is no complete clarity either. It has been reported that upon oxidation in O_2 to a given thickness, a larger oxide charge results for lower temperatures (7), and that at a given temperature the amount of charge is larger when the rate of oxidation before terminating the process was larger (3, 6). Annealing in neutral ambients, like N_2, will under certain conditions eliminate the charge, but it is not certain whether this will happen for a wide range of temperatures (7) or only for the very highest (6, 8).

The density of trapping states obtained upon oxidation in O_2 is strongly dependent on the partial pressure of water vapor in this ambient (9, 10). For dryer O_2 larger numbers of states have been observed. The situation with regard to nonoxidizing atmospheres is less clear. It has been reported that annealing of clean samples at very high temperatures (*e.g.* 1100°C) in neutral ambients will eliminate interface states (8). On the other hand, vacuum annealing surprisingly results in an increase in the trap density particularly at higher temperatures (10). Low temperature annealing (*e.g.* at 400°C) in H_2 (9, 11) or wet N_2 (11) will completely eliminate these centers.

Both the amount of oxide charge and the density of interface states obtained for O_2 or N_2 and He ambient annealing are dependent on sample orientation (2, 6, 7, 10, 12, 13).

In view of the uncertainties cited above, the present authors have attempted to explore the different annealing processes in a systematic fashion. In addition to a consistent set of data, some interesting similarities and differences in behavior between the centers responsible for oxide charge and those giving rise to interface trapping will be reported. Finally, we will attempt to explain some apparently contradictory observations described in the literature. The convenient MOS capacitance technique made it possible to include a wide variety of conditions in the experimental investigation. However, for establishing detailed models for the studied effects more sophisticated approaches may be necessary.

Experimental

The samples used in this study were 2 ohm-cm (100) and (111) orientated, chemically-mechanically polished Monsanto and Dow-Corning silicon wafers of both conductivity types. They were cleaned by rinsing with organic solvents, HF, and distilled water, and oxidized at 1000° or 1100°C, generally to 1000Å, in a rf heated silica tube (Fig. 1a) or in a silica tube in a resistance heated furnace. The oxidation ambient was either dry O_2 (water content $< 1 \times 10^{-2}$ Torr, as measured at the outlet of the tube) or O_2 into which a predetermined higher amount of water vapor (generally 6×10^{-2} Torr) had been injected. Water vapor pressures were determined using a Panametrics Al_2O_3 conduction cell. Very clean oxide films were obtained by vapor etching in H_2-HCl, followed by *in situ* oxidation in the rf heated tube (Fig. 1a). Some of the films were stabilized by forming a phosphosilicate glass layer approximately 100Å thick, containing 4 mole per cent (m/o) P_2O_5, on their surface (14).

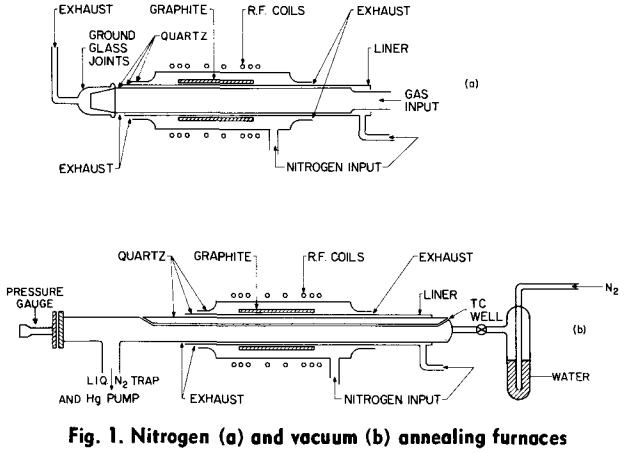

Fig. 1. Nitrogen (a) and vacuum (b) annealing furnaces

Neutral ambient annealing was done in helium or nitrogen in the temperature range of 500° to 1100°C. The helium was dried through a trap filled with Linde 13X molecular sieve at liquid nitrogen temperature, the nitrogen through a molecular sieve trap at room temperature. These treatments and also vacuum annealing (at 10^{-6} Torr and 500° to 1000°C) were carried out in very similar rf heated quartz tubes (Fig. 1b). The vacuum annealing tube was also used for annealing in N_2 ambients below atmospheric pressure. These N_2 ambients, containing various water vapor pressures, were obtained by bleeding dry N_2 or N_2, saturated at room temperature with water vapor, into the tube while pumping, and by adjusting the gas flow such that the desired total pressure was obtained. The samples were allowed to cool rapidly in the annealing ambient.

The samples were evaluated using the MOS capacitance or C-V technique (15) at room temperature and at liquid nitrogen temperature, for a measurement frequency of 1.5 Mc. To this end, aluminum dots were evaporated from a rf heated boron nitride crucible onto the unheated substrates. As a measure of the interface state density their number N_{ss} between the room temperature and liquid nitrogen temperature Fermi levels was used (10)

$$N_{ss} = \frac{C_{ox}}{q} [V_{FB} \text{ (room temp)} - V_{FB} \text{ (liq } N_2 \text{ temp)}] \quad [1]$$

where V_{FB} is the flatband voltage and C_{ox} the oxide capacitance, both obtained from the C-V plots. There is some uncertainty in the room temperature V_{FB} values, and consequently in N_{ss}, since even at 1.5 Mc the interface state capacity may not be completely eliminated. The surface or oxide charge was obtained from the shift of the room temperature C-V curves with respect to the theoretical curve for the proper resistivity and oxide thickness

$$Q_{ox} = C_{ox} [V_{FB} - V_{FB} \text{ (theor.)}] \quad [2]$$

These C-V measurements were made after a 5 min anneal at 500°C, which removes all interface states observable by field effect measurements (16) or by capacitance measurements according to Eq. [1]. It should be noted that the use of these operational definitions (1) and (2) for interface state density and oxide charge allows a direct comparison with results obtained by other workers only for the latter quantity. For interface state densities such comparisons are necessarily qualitative, except for comparisons with the work of Brown and Gray (10), who first introduced the technique adopted in this study.

Results

The experimental results obtained upon annealing of silicon substrates covered with "very clean," "regular" or P_2O_5 stabilized oxide films were always quite similar. It was found from electrothermal stressing tests that the "regular" oxides contained generally not more than 5×10^{10} mobile species (presumably Na ions) per cm^2 whereas the mobile charge level for "very clean" films was typically half this number or less. The mobile Na content in the stabilized films was below 1×10^{10} per cm^2. These numbers were not af-

fected by the different annealing treatments, nor did the outcome of such treatments show any correlation with variations in the low Na content of the samples. For P_2O_5 doped oxides the possibility of phosphorus penetration through the film strongly limited the maximum feasible annealing times at the highest temperatures. The only difference between "regular" and "very clean" films was in an area unrelated to the subject of interest for this paper. The incidence of defect breakdown (17) was considerably lower in the latter type of oxide film.

Although the results obtained on n and p-type substrates always showed the same trends, the N_{ss} values measured on n-type samples tended to be somewhat larger than those for the other resistivity type. A simple explanation for this observation may be that the part of the gap scanned, namely that between the room and liquid nitrogen temperature Fermi levels, is somewhat larger for n-type material because of its lower carrier density at a given resistivity.

The results did depend on the sample orientation: both Q_{ox} and N_{ss} values are generally larger for (111) than for (100) surfaces. Our data here are in agreement with those found in the literature.

When a sample was subjected to a sequence of annealing treatments in different ambients, the final values of Q_{ox} and N_{ss} were those characteristic of the last high temperature process. The behavior of Q_{ox} in neutral ambients forms an exception, which will be discussed later.

Oxygen annealing.—When the annealing is carried out below the oxidation temperature, both Q_{ox} and N_{ss} increase. The kinetics of the process is orientation dependent. It may be seen in Fig. 2 that for (111) oriented samples Q_{ox} passes through a maximum before obtaining its final value, whereas for (100) samples Q_{ox} increases monotonically until it reaches its maximum. Here and in the following figures and tables each set of N_{ss} and Q_{ox} values after a given treatment was obtained on a different sample. N_{ss} exhibits a similar behavior as Q_{ox}, and approximately the same amount of time is required for the change to take place. The rate of these processes depends not only on the annealing temperature, as expected, but also on the thickness of the oxide film. For example, the time required to reach the maximum in the Q_{ox} curve for (111) oriented samples is proportional to the oxide thickness (18). This suggests that the diffusion of oxygen through the layer is the rate-determining step in the process. In the times involved approximately one mono-molecular layer of oxide, and thus a completely new interface, is formed.

The temperature dependence of the saturation or equilibrium values of Q_{ox} and N_{ss} for (100) oriented samples is shown in Fig. 3. These curves can be traversed reversibly. Larger values were obtained for the (111) orientation.

It was reported by Brown and Gray (10) that the interface state density increases for decreasing water

content of the oxygen during the oxidation process down to 80 ppm of water (60 x 10^{-3} Torr). A similar relationship was found for most of the cases studied in the present investigation (Table I) between oxidation at 5 x 10^{-3} and 60 x 10^{-3} Torr. The effect of water vapor on Q_{ox} was very small in the cases investigated, which were all in the low pressure range.

N_2 and He annealing.—Annealing in N_2 and in He leads to the same results. However, in contrast to the results obtained for O_2, it may be seen (Fig. 4) that in neutral ambients N_{ss} and Q_{ox} do not always change in the same direction. Specifically, Q_{ox} will never increase but only remain constant or decrease upon annealing in neutral ambients, whereas N_{ss} may change in both directions. Figure 5 shows the dependence of the decrease of Q_{ox} on time for different temperatures upon annealing of (111) oriented samples in He. A high concentration of oxide charge had first been induced in the surfaces by exposure to O_2 at 600°C. Though the number of data points is rather limited, an exponential decay of the excess charge (towards the new saturation value) with time appears to give a good description of the kinetics. However, the oxide charge approaches a different final value for each temperature. The activation energy for the rate constant is rather low (approximately 0.5 eV). The in-

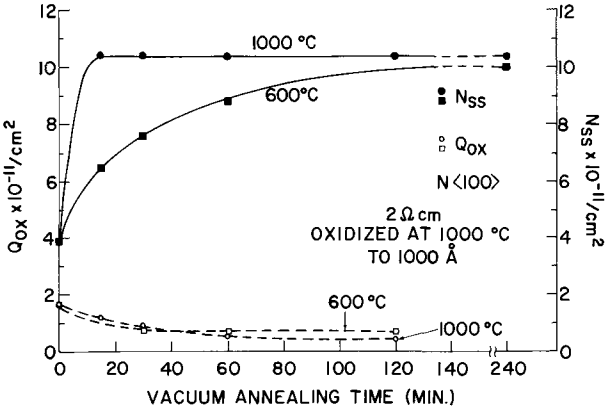

Fig. 8. Dependence of N_{ss} and Q_{ox} on annealing time in vacuum at 600° and 1000°C.

crease in N_{ss} at 600°C in Fig. 4 follows a similar rate law. The Q_{ox} values finally attained in this process are given in Fig. 6 as a function of temperature. They do not depend on the value before annealing, as long as that value was larger than or equal to the quasi-equilibrium value for the annealing temperature (as given by the declining curve in Fig. 6). The time required for the reduction in Q_{ox} is dependent on oxide thickness. An increase in Q_{ox} is never obtained during annealing in neutral ambients.

The N_{ss} data plotted in Fig. 7 demonstrate that the saturation value for this parameter tends to be independent of the value before annealing in the temperature range for which sufficient information is available (700° to 1100°C). The process thus appears to be reversible. At the lowest temperature investigated (500°C) no change at all was observed from the initial value even after many hours.

Vacuum annealing.—Vacuum annealing experiments were carried out only at or below 1000°C. At this temperature oxide shorts would gradually develop, which made electrical measurements more difficult. Our data (Fig. 8) indicate that vacuum annealing in the 600° to 1000°C temperature range always results in an increase in N_{ss} for samples prepared by oxidation in O_2 at 1000°C. On the other hand, such an increase was for N_2 annealing obtained only in the lower part of this temperature range (Fig. 4). The 1000°C vacuum annealing saturation values are in agreement with Brown and Gray's data (10). As in N_2, the approach of the saturation value for N_{ss} during vacuum annealing at 600°C can be satisfactorily described as a first order reaction. However, the process appears to be somewhat slower in vacuum.

These effects are again demonstrated in Table II, which also offers a comparison between the (111) and (100) surfaces. The trends are the same for both orientations, although the Q_{ox} and N_{ss} values are larger for the (111) surface. The data also indicate that the Q_{ox} values for N_2 and vacuum annealing at a given temperature are very similar, and become very small for the (100) orientation at 1000°C.

Water vapor in neutral ambient annealing.—The difference between the N_2 and vacuum annealing results at 1000°C is rather unexpected, since both ambients may be considered as nonreactive towards the SiO_2-Si system. The qualitative reversibility of the N_2 and vacuum annealing effects, shown in Table III, indicates that in each case the system moved toward an equilibrium condition, characteristic for the final ambient to which the sample was exposed. This observation led to the suspicion that some gaseous impurity might be responsible for the "N_2 results."

Measurement of the water content of the N_2 showed that this quantity is temperature dependent (Table

900	5 × 10^{-3} Torr	36 × 10^{-3} Torr
1000	7 × 10^{-3} Torr	60 × 10^{-3} Torr

IV). At room temperature it is very low. The increase at high temperatures must be caused by diffusion of water through the wall of the quartz tube, since the water content of the N_2 is inversely proportional to the flow rate of the gas. The non-negligible oxidation rates of silicon in "dry Ar" at 850° and 1000°C, observed by Nakayama and Collins (19), were probably also caused by water permeation through their quartz furnace tube. A quantitative comparison of the water vapor pressures estimated from their data (they are in the range from 0.1 to 1 Torr) with those following from the data of Table IV is difficult because of the different geometries of the systems.

Table V shows that indeed the N_{ss} values correlate directly with the water vapor pressure in the ambient, whereas any obvious relationship with the N_2 pressure is lacking. Even at low water content of the ambient the surface characteristics are still very sensitive to the actual value of the vapor pressure. These observations explain at the same time the difference between the N_2 and vacuum annealing results, discussed before. This difference is most pronounced at the highest temperature (1000°C) at which data are available for both cases. At 900°C the dependence of N_{ss} on the water vapor pressure is considerably weaker (Table VI).

Discussion

The implications of the foregoing results for the construction of models for oxide charge and interface state centers is discussed next. All such models are necessarily tentative, but they are useful in stimulating discussion and further experimentation.

Oxide charge centers.—The important findings are: At a given temperature and oxide thickness a distinct value of Q_{ox} is obtained in O_2. This value is generally lowered upon annealing in neutral ambients at the same temperature. At higher temperatures lower values are obtained. In the pressure range investigated (*i.e.* below 10^{-1} Torr) the water content of the ambient is relatively unimportant. The rate at which the new Q_{ox} value is reached decreases with increasing oxide thickness.

These observations are compatible with a model in which the oxide charge centers are defects in the oxide structure near or at the oxide-silicon interface. Such a model has first been proposed by Revesz *et al.* (6). The concentration of these centers would be determined by a dynamic equilibrium between the oxidation reaction, which disturbs the interfacial region and leads to formation of oxide charge centers, and an annealing process, which tends to eliminate them. The orientation dependence of Q_{ox} indicates that the charge must be located at or near the interface, since one does not expect that the entire SiO_2 glass film would exhibit substrate orientation dependent properties. The experimental results do not allow very specific conclusions with regard to the nature of the defects. However, it is possible that they involve hydroxyl groups (2). In this case their formation would require the presence of water or hydroxyl groups, whereas their removal would be determined by the outdiffusion of such species. Such a model would be compatible with the observed thickness dependent rate of decay of Q_{ox} in neutral ambient annealing.

Recently Fowkes and Burgess (5, 20) have proposed that oxide charge may be caused by Na^+ ions, located in positively charged Si-O-Na centers introduced near the interface upon oxidation at intermediate temperatures. During oxidation at very high temperatures, and particularly during neutral ambient annealing, oxygen vacancies would form throughout the oxide. These centers would readily trap electrons and immobilize Na^+ ions. However, from our finding that the mobile

Na content of the samples was not affected by annealing, and that it was also low on surfaces with high Q_{ox}, it appears unlikely that Na impurities were responsible for the charge in our experiments.

Interface states.—The observation that new equilibrium concentrations of oxide charge centers and interface states form in comparable times during O_2 annealing suggests a similarity in nature between the two types of centers. In addition, their orientation dependence is the same.

Nonetheless, there are also some striking differences in the annealing behavior of the centers. During vacuum annealing Q_{ox} and N_{ss} may change in opposite directions, such that Q_{ox} is virtually eliminated, whereas N_{ss} becomes very large. An outstanding feature of the interface states is their pronounced sensitivity towards water vapor in the annealing ambient, even at very low concentrations.

These observations are satisfactorily described by a simple model (9, 11) of the interface states as caused by chemically unsaturated silicon atoms at the interface. Such centers would be able to react with water at elevated temperatures under formation of silanol groups

$$\begin{array}{c} | \\ -\mathrm{Si}\cdot \\ | \end{array} + \mathrm{H_2O} \rightarrow \begin{array}{c} | \\ -\mathrm{Si}- \\ | \end{array} \mathrm{OH} + \mathrm{H}$$

A somewhat comparable reaction of water with intrinsic defects in SiO_2 was invoked by Weeks and Lell to explain their optical absorption and electron spin resonance data on bulk silica (21). At high temperatures in vacuum one has to assume a breaking of the Si-OH bond, and release of water vapor. The observed first order rate behavior of the vacuum and N_2 annealing processes at 600°C is compatible with this model. On the basis of the assumptions made in the foregoing section, the oxide defects related to Q_{ox} would tend to disappear due to removal of hydroxyl or water vapor under these experimental conditions, which would explain the opposite behavior of the two types of centers.

The model suggests that a set of two states of different energies may be observed for each center as is indeed the case (10). It also explains the high reactivity of interface state centers towards H_2 at low temperatures (200° to 500°C). They are completely eliminated in this ambient in 1 hr at temperatures as low as 300°C, most likely under formation of silane groups (9)

$$\begin{array}{c} | \\ -\mathrm{Si}\cdot \\ | \end{array} + \mathrm{H_2} \rightarrow \begin{array}{c} | \\ -\mathrm{Si}- \\ | \end{array} \mathrm{H} + \mathrm{H}$$

The observed linear pressure dependence of the rate of this reaction, which is not diffusion-limited, and its enhancement in atomic hydrogen (22) would indeed be expected for the above model. Above 500°C H_2 was found less and less effective with increasing temperature in removing interface states. This may reflect a decrease in stability of the Si-H bond at these higher temperatures which has also been suggested by Kooi (2).

As shown earlier, the N_{ss} values upon O_2 annealing are also sensitive toward the water content of this ambient. It is not clear if the decrease in saturation value with temperature requires a similar explanation as the parallel decrease in Q_{ox}. This decrease may also be caused by the increase in the water content of the O_2 with temperature due to the increased permeability of the quartz walls.

Finally, it may be interesting to note that very high interface state densities were observed on oxidized surfaces of germanium-doped silicon samples (23). A substantial fraction of these states could not be eliminated by low temperature reaction with hydrogen. This behavior suggests that in this case interfacial germanium atoms of valency less than four may be responsible for the centers. Such oxygen deficiency is known to occur readily in bulk GeO_2 (24).

Conclusions

The following conclusions may be drawn from the material obtained in the present investigation:

Q_{ox} and N_{ss} are in most cases a unique function of time, temperature and ambient in the last high-temperature annealing step to which the specimen was exposed. A notable exception to this rule is that Q_{ox} never increases during neutral ambient annealing.

N_{ss} is very sensitive towards the water content of O_2 and neutral annealing ambients even at partial pressures well below 10^{-1} Torr.

The amount of mobile Na in samples with a low concentration of this impurity is not affected by heating in clean O_2 or neutral ambients.

Explanation of the present data does not require the assumption that the occurrence of oxide charge and surface states are caused by Na.

The centers correlating with N_{ss} and Q_{ox} are distinctly different.

Growth of $In_{(1-x)}Ga_xP$ p-n Junctions by Liquid Phase Epitaxy

B. W. Hakki

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Liquid phase epitaxy (LPE) has been used to grow layers of $In_{(1-x)}Ga_xP$, in the range $0.4 < x < 0.8$, on the Ga (111) surface of GaAs. After an n-layer is grown, p-n junctions are made either by Zn diffusion or by LPE growth of a p-layer from a Zn-doped liquid. The rate of deposition and the dependence of layer composition on charge composition are found to be consistent with liquidus and solidus isotherms for the In-Ga-P system obtained by a first-order calculation.

$In_{(1-x)}Ga_xP$ is a material in which a maximum direct bandgap of 2.17 ± 0.02 eV, at 300°K, is obtained when the molar percentage of GaP is 63 ± 2% (1). This makes the material attractive as a potentially efficient electroluminescent source of visible light at wavelengths as short as 5900Å. The ternary material can be grown in bulk form (2), from solution (3), or by liquid phase epitaxy (4, 5). The principal objective of this paper is to relate experimental and theoretical results pertaining to the LPE growth of $In_{(1-x)}Ga_xP$. It also describes fabrication of p-n junctions by initial LPE deposition of an n-layer and subsequent formation of a p-region either by Zn diffusion or by a second LPE deposition from a Zn-doped liquid.

Growth Procedure

The ternary alloy was prepared by liquid phase epitaxial growth from an In-Ga-P solution on a suitable substrate. The growth apparatus is shown schematically in Fig. 1. The pyrolytic graphite growth vessel is contained in an open silica tube under a flow of hydrogen. Weighed amounts of polycrystalline InP and GaP were placed at the bottom of the well containing the indium. The combined weights of InP and GaP were held constant at 0.14 times the weight of indium.

After a preliminary heating of the charge at 900°C for 15 min, a substrate was tipped on the melt at 875°C and the temperature lowered at 2°-3°C/min. The temperature interval over which deposition took place was varied from 25°-75°C, depending on the desired thickness of the LPE layer. At the end of the cooling cycle the substrate was tipped off. Deposition was carried out on <100>, <311>, and <111> oriented crystals of Si, InP, GaP, and GaAs. The crystalline quality of $In_{(1-x)}Ga_xP$ was poor for all substrates except <111> oriented GaAs. For the latter, better results were obtained with the Ga face than with the As face. The lattice constant of GaAs is 5.65Å, which matches that of $In_{0.5}Ga_{0.5}P$ if Végard's law is valid for the ternary lattice constants.

The growth on the GaAs substrate was usually Te-doped. The ionized impurity concentration, as determined by Schottky barrier diode measurements, was typically 5×10^{17} cm^{-3} at 300°K. After growth of the n-layer, p-n junctions were produced either by Zn diffusion or by LPE growth of a p-layer. Zn diffusion was done by enclosing the n-layer, along with about 50 mg of Zn_3P_2, in a sealed quartz ampoule whose volume was 25 cc. The residual atmosphere was hydrogen at 10^{-2} Torr. The ampoule was then heated to 700°C for periods of time ranging from 0.2 to 1.5 hr, depending on the junction depth required.

LPE growth of p-layers was obtained by adding Zn to a charge and tipping on an n-type $In_{1-x}Ga_xP$ layer. The amount of Zn added to the charge varied from 0.03 to 0.3 a/o (atomic per cent). Because of the high partial pressure of Zn and the use of an open-tube system, it was not possible to get an accurate measure of the segregation coefficient of Zn in the quaternary melt. There were, in adddition, several complicating aspects about the double LPE growth of p-n junctions. First, it was necessary to match the ternary composition of the p-layer with that of the n-layer. Failure to accomplish this could lead to a lattice mismatch at the p-n interface. This lattice mismatch can be a potential source of a high concentration of nonradiative recombination centers for the minority carriers. Second, the cooling time during p-growth had to be short, in order to minimize indiffusion of Zn into the n-layer. Finally, the thickness of the p-layer had to be equal to or slightly larger than a minority carrier diffusion length.

Based on these considerations, double LPE p-n junctions were grown as follows: The n-layer was grown by cooling from 875° to 800°C. The p-charge was matched in liquidus composition to the n-charge. The p-charge was tipped at 805°-810°C, *i.e.*, 5°-10°C higher than the minimum growth temperature of the n-layer. This was done to produce some melt back into the n-layer, and thereby improve the composition match between the n- and p-regions. The p-layer was grown by cooling over a certain temperature interval ΔT, which determined the thickness of this layer.

Experimental Results

Liquidus data at 850°C.—To determine experimental liquidus data for In-rich compositions in the In-Ga-P system, mixtures containing known amounts of InP, GaP, and In were equilibrated in a separate apparatus at 850°C for one-half hour, after which the undissolved compound was retracted from the melt and weighed in order to measure by difference the amount

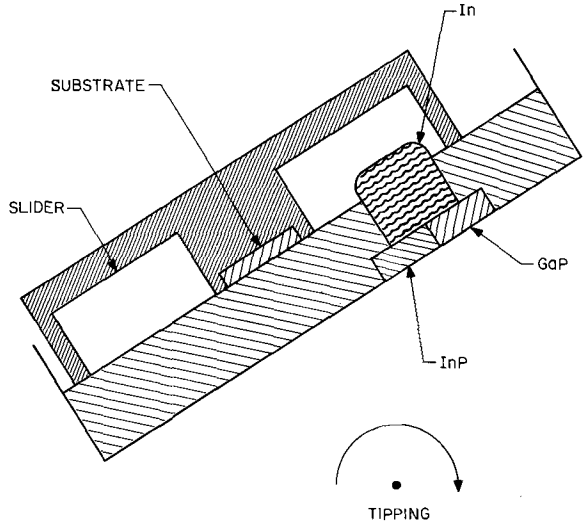

Fig. 1. Liquid phase epitaxial growth vessel

Key words: diffusion, doping, efficiency-electroluminescent, electroluminescence, indium-gallium-phosphide, liquid phase epitaxy, liquidus isotherms, p-n junctions, solidus isotherms, ternary.

that had gone into solution. The liquidus point for the In-P binary system was obtained by using an InP-In mixture containing more than enough InP to saturate the liquid with P. From the weight loss of InP, the atom fraction of P in the binary liquid at 850°C was found to be $X_P = 0.085$.

In determining ternary liquidus points, the amount of InP used was small enough to dissolve completely into the solution, regardless of the initial amount of GaP. (This indicates that the dissolution rate of InP in molten In is so much greater than the rate for GaP that all the InP dissolves before any appreciable amount of GaP does. This kinetic difference, which makes it convenient to use the present method for the liquidus determination, may be due to the lower melting point of InP compared to that of GaP). When the initial amount of GaP exceeded the quantity required to saturate the melt formed by dissolution of the InP, the difference in weight of the GaP before and after equilibration could be used, together with the initial weights of InP and In, to calculate the values of X_{Ga} and X_P for the liquidus composition.

Figure 2 gives the experimental liquidus data at 850°C. For low X_{Ga} and high X_P the error involved in estimating X_{Ga} was large. This was due to the fact that an $In_{(1-x)}Ga_xP$ layer formed on the surface of the GaP source during equilibration. The thickness of such a layer became quite large for high X_P. Since this layer had to be removed in order to obtain the net weight loss of the GaP source, error was introduced by the etching process.

Composition and thickness of the LPE layers.—For the solid ternary deposition it was found that when the total weight of GaP and InP in the source was held constant at 0.14 times the weight of the indium, the mole fraction of InP in the source determined the composition of the epitaxial deposit. An electron beam microprobe was used to measure the K_α and L_α line intensities and thereby deduce the $In_{(1-x)}Ga_xP$ composition in the epitaxial layer (1). Such measurements indicated that the mole fraction x in the deposit was equal, to within 10%, to x_c, the mole fraction of GaP used in the source, for the first and second runs on each charge. This was valid for the range of solid compositions $0.4 < x < 0.8$ investigated. For example, a source with $x = 0.6$ gave rise to a ternary deposit that varied in composition from $x = 0.66$ at 875°C to $x = 0.58$ at 800°C. Figure 3 gives a plot of composition in this deposit as a function of distance away from the substrate. The shift of composition toward InP as the growth temperature decreases is evident. The use of the slider in the growth process allowed the deposition to be terminated at a specific temperature, typically 800°C. This procedure was followed for the example given in Fig. 3. However, if during the tipping-off process a residue of the melt remained on the surface of the substrate, this residue continued to deposit material, of diminishing thickness, down to room temperature. The composition of the ternary that deposited out of the residue varied more rapidly as a function of distance than indicated in Fig. 3 and approached 100% InP.

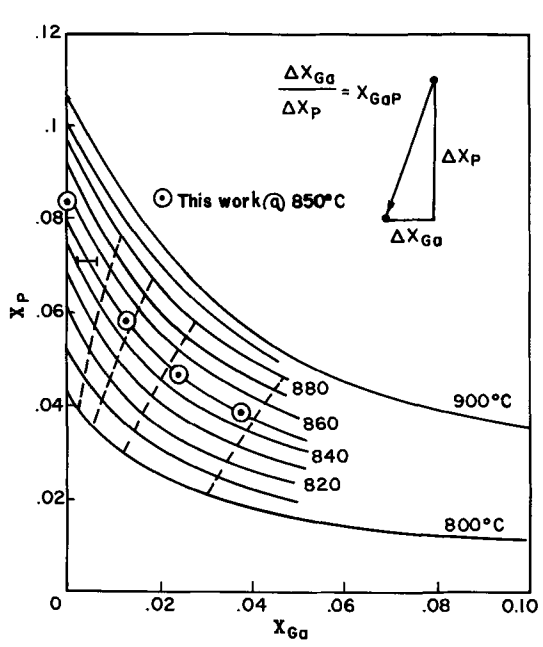

Fig. 2. Liquidus isotherms for the In-Ga-P system, wherein $X_{In} + X_{Ga} + X_P = 1$. The dashed lines give the change in composition of a melt as it is cooled. The experimental error is almost equal to the extent of the circle around each point.

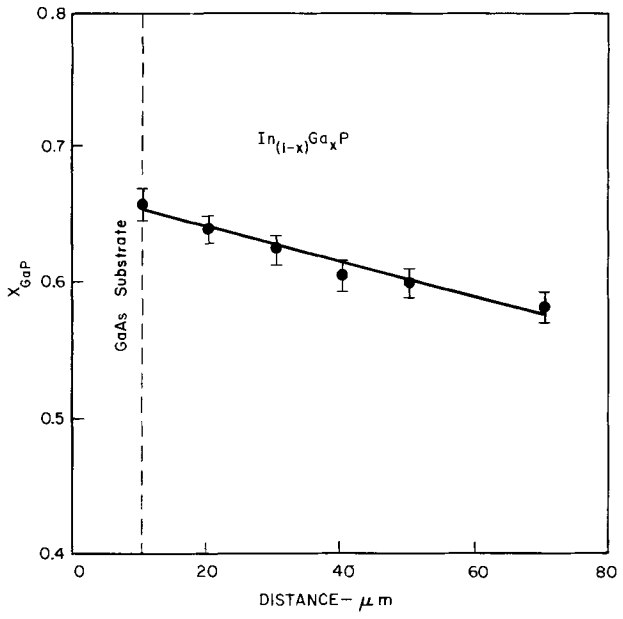

Fig. 3. Composition of LPE deposit as a function of distance away from the substrate.

Subsequent runs on the same charge led to a shift in composition of the LPE layer toward GaP (4). For example, a particular charge resulted in the deposition of $In_{0.47}Ga_{0.53}P$, $In_{0.42}Ga_{0.58}P$, and $In_{0.22}Ga_{0.78}P$ at the completion of the first, second, and third runs, respectively. The final temperature of deposition in each run of the sequence was 850°C.

In the direct bandgap $In_{(1-x)}Ga_xP$, as in any other direct bandgap semiconductor, in order to obtain efficient electroluminescence it is necessary to control accurately the depth of the p-n junction. This involves a compromise between the distance allowed the minority carriers to recombine radiatively, which is of the order of a diffusion length, and the resulting strong optical absorption suffered by the near band-edge emission. In the case of double epitaxial growth of the p-n junction the thickness of the LPE p-layer and thus the junction depth was controlled by adjusting the temperature interval ΔT over which growth took place. Figure 4 shows the thickness of the p-layer, grown in the neighborhood of 800°C, as a function of ΔT. Inspection revealed that deposition took place not only on the substrate but also on all of the external surface of the In-Ga-P melt, thus forming a right circular cylinder whose height and diameter were 0.5 and 0.64 cm, respectively. The weight of the indium charge, resulting in the deposition shown in Fig. 4, was 1.1g. Therefore, if the average thickness of the deposit on the external surface of the melt had the values shown in Fig. 4, then the rate of deposition at 800°C would be 5-7.5 x 10^{-5} cm^3, per gram of charge, per °C. Although a separate study was not made for n-type layers, it was found that in general the rate of deposition of n-doped material was similar to that described above for p-material.

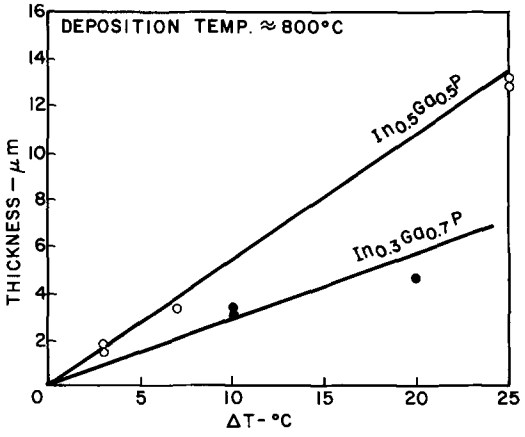

Fig. 4. Thickness of LPE deposit at 800°C as a function of cooling interval for two compositions of $In_{(1-x)}Ga_xP$.

Impurity segregation and diffusion.—For diffused structures, the depth of junction could be controlled by adjusting the diffusion coefficient and the diffusion time. The doping concentration in the host n-LPE layer is $\approx 5 \times 10^{17}$ cm^{-3}. Hence, the p-n junction occurs at a point where $N_{Zn} \approx 5 \times 10^{17}$ cm^{-3}. The junction depth (d) in a number of slices diffused at 700°C for different lengths of time (t) was measured by angle lapping a portion of each slice and etching in a 1:1 mixture of HF and H_2O_2, in the presence of strong light, to reveal the junction. Values of the diffusion coefficient (D) for Zn were then calculated from the relationship $D = d^2/4t$. This expression assumes that D is independent of concentration, so that the diffusing species exhibits an error function distribution. Although the diffusion of Zn in such compounds as GaAs and InSb is known to be strongly concentration dependent, in the absence of more detailed data for the ternary alloys the values of D obtained by using the simple relationship should be useful. These values, measured at 700°C, are shown in Fig. 5 as a function of the ternary composition. As the composition changes from $In_{0.5}Ga_{0.5}P$ to $In_{0.3}Ga_{0.7}P$, the diffusion coefficient of Zn decreases from $\approx 10^{-10}$ cm^2/sec to $\approx 4 \times 10^{-11}$ cm^2/sec. The decrease in diffusion constant as the composition shifts toward GaP is qualitatively consistent with the lower diffusion coefficient of Zn in GaP,

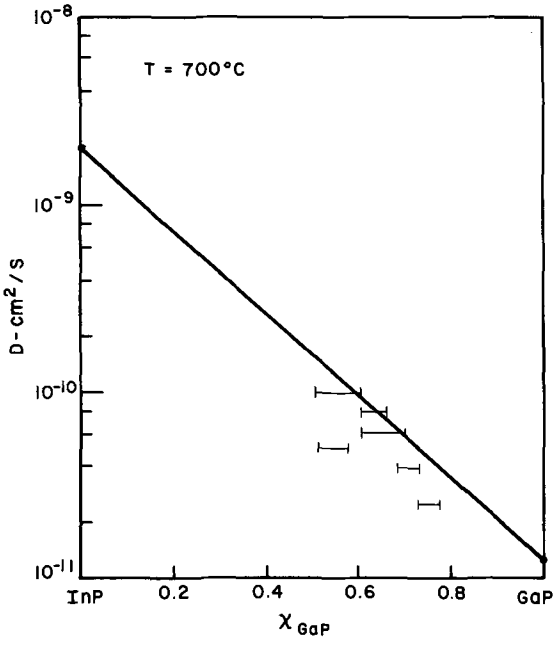

Fig. 5. Diffusion coefficient of Zn into various compositions of $In_{(1-x)}Ga_xP$. The diffusion temperature is 700°C, and the Zn concentration at the p-n junction is $\approx 5 \times 10^{17}$ cm^{-3}.

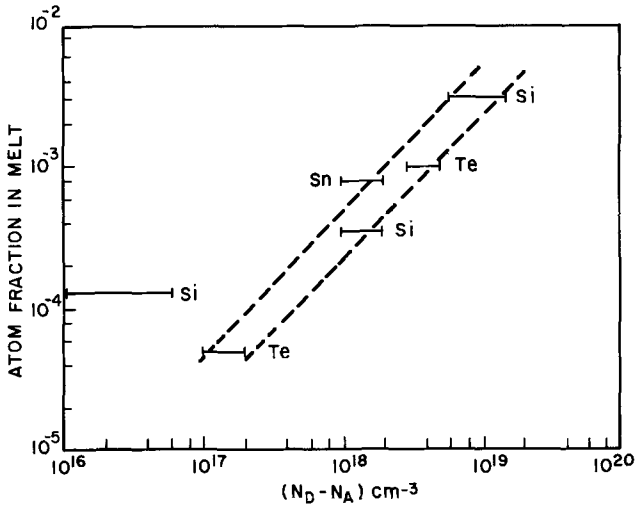

Fig. 6. Net ionized donor concentration ($N_D - N_A$) as a function of doping level in the melt.

$\approx 1.3 \times 10^{-11}$ cm^2/sec, as compared to that in InP, $\approx 2 \times 10^{-9}$ cm^2/sec at 700°C for similar Zn concentrations (6, 7).

Among the n-type dopants investigated, namely Sn, Si, Pb, Se, and Te, the best luminescent efficiencies were obtained by using Se and Te. The net ionized impurity concentration ($N_D - N_A$) in the LPE n-layer is given in Fig. 6 as a function of the atom fraction of dopant, Δ, in the melt. This impurity concentration can be represented by the approximate relation $(N_D - N_A) \approx 3 \times 10^{21}\Delta$ cm^{-3}. However, as seen in Fig. 6, for atom fractions of Si in the melt of about 2×10^{-4}, ($N_D - N_A$) was much smaller than the value indicated by this relation, and varied by over an order of magnitude along the surface of the deposit. This could be explained by a model whereby Si behaves as an amphoteric dopant, introducing a background of $\approx 5 \times 10^{17}$ acceptors per cm^3, for the doping level used. Therefore, for $\Delta < 2 \times 10^{-4}$, critical compensation would result (4). The lowest ionized net impurity concentration of undoped material was in the 5×10^{15} cm^{-3} range.

First-order Calculations

Liquidus and solidus isotherms in the In-Ga-P system.—The equations governing the equilibrium between the liquid and solid in the In-Ga-P system can be written in the simplified and approximate form (3)

$$K_{InP}X_{InP} = \gamma_P X_{In} X_P \quad [1]$$

$$K_{GaP}X_{GaP} = \gamma_P X_{Ga} X_P \quad [2]$$

for the liquid

$$X_{In} + X_{Ga} + X_P = 1 \quad [3]$$

and for the solid

$$X_{InP} + X_{GaP} = 1 \quad [4]$$

where K_{InP} and K_{GaP} are the proportionality constants governing the equilibrium between solid and liquid, γ_P is the activity coefficient for P, X_i is the atom fraction of species i in the liquid, and X_{ij} is the mole fraction of species ij in the solid. The activity coefficients of the various components in [1] and [2] were all set equal to unity, except γ_P.[1]

Equations [1]-[4] can be solved to obtain an equation for the liquidus composition

[1] The assumption that $\gamma_{In} = \gamma_{Ga} = 1$ is not strictly correct. Since $X_{In} \approx 1$, it is probably safe to assume $\gamma_{In} \approx 1$. However, the In-Ga binary data of Macur *et al.* (8) indicate that $\gamma_{Ga} \approx 1.2$, when $X_{Ga} << 1$. The fact that in the present work good agreement between experiment and calculation can be obtained by assuming all activity coefficients to be unity, except γ_P, is somewhat surprising. It is possible that a cancellation process takes place in Eq. [1] and [2] which reduces the error involved in making this assumption.

$$X_{In}^2 + X_{In}\left[-1 + X_{Ga}\left(1 + \frac{K_{InP}}{K_{GaP}}\right)\right] + \frac{K_{InP}}{\gamma_P} - X_{Ga}\frac{K_{InP}}{K_{GaP}}(1 - X_{Ga}) = 0 \quad [5]$$

The activity coefficient of P in the In-Ga-P system at 900°C has been measured by Panish (3) and is given by the empirical relations

$$\gamma_P = \exp(-2.15X_{Ga}^{1/2}) \quad [6]$$

for $0 < X_{Ga} < 0.1$ and

$$\gamma_P = 0.61 \exp(-0.645X_{Ga}^{1/2}) \quad [7]$$

for $0.1 < X_{Ga} < 1.0$.

From the binary data of Panish and Arthur (9), the values of K_{InP} at 900°, 850°, and 800°C are 0.095, 0.07, and 0.04, respectively. From the binary results of Thurmond (10, 7), the values of K_{GaP} at 900°, 850°, and 800°C are 2.16×10^{-3}, 1.25×10^{-3}, and 6.2×10^{-4}, respectively. From these values and (5), liquidus isotherms can be calculated. The calculated isotherms are shown in Fig. 2 for the temperature range 900°-800°C, along with the experimental liquidus points for 850°C. The agreement between the calculated curve at 850°C and the experimental results is adequate.

Once the liquidus composition has been calculated, the corresponding solid composition can be obtained through the use of either [1] or [2], in conjunction with [4]. For the purpose of the present work, the relevant curves are those of X_{GaP} as a function of X_P. These calculated curves are shown in Fig. 7 for 800°-900°C.

Change in composition.—It was observed experimentally (Fig. 3) that there was a shift in composition toward InP as the temperature of deposition decreased (1). This shift in composition can be explained on the basis of the liquidus and solidus isotherms of Fig. 2 and 7. To deduce the shift a graphical method of analysis is used. For example, let the starting temperature be 880°C, with $X_P = 0.067$. From Fig. 2 and 7, respectively, one obtains $X_{Ga} = 0.0185$ and $X_{GaP} = 0.5$. As the temperature is reduced to 870°C, the point in the liquidus curve of Fig. 2 has to move in a direction determined by the relation $X_{GaP} = (\Delta X_{Ga}/\Delta X_P)$. The new liquidus equilibrium point at 870°C is established at $X_P = 0.0635$ and $X_{Ga} = 0.0168$. The new solidus composition in equilibrium with this solution is $X_{GaP} = 0.498$, obtained from Fig. 7. This new GaP concentration establishes the slope in the liquidus diagram when the temperature is lowered from 870° to 860°C. It is seen from Fig. 2 and 7 that as the temperature is progressively lowered, the solidus fraction X_{GaP} gradually decreases. This is due to the depletion of the relatively small Ga content initially found in the solution.

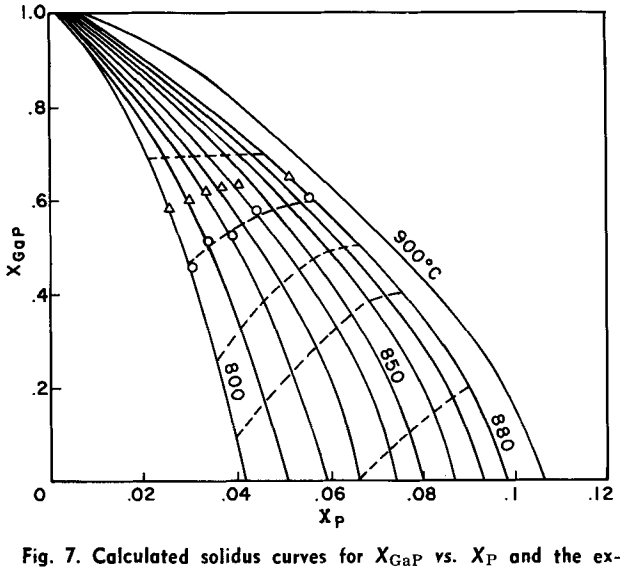

Fig. 7. Calculated solidus curves for X_{GaP} vs. X_P and the experimental curve obtained by cooling at 875°C; the dashed lines give the change in composition of the deposit as the temperature is lowered.

A series of calculated deposition loci are shown on the liquidus and solidus curves of Fig. 2 and 7. It is seen that the compositional variation with temperature is severe at low temperatures and InP-rich compositions. As long as $X_{GaP} > 0.4$, and the minimum deposition temperature is above 820°C, the change in composition with temperature is not very large. To compare the theoretically deduced deposition loci with experiments the liquidus isotherms of Fig. 2 are used in conjunction with Eq. [8] to replot the data of Fig. 3 in terms of X_{GaP} and temperature. These data points are given in Fig. 7 and are in agreement with the graphically deduced curves. For a different charge that gave a slightly higher initial GaP concentration of $x = 0.65$ at 880°C, the experimentally observed variation of x is depicted in Fig. 7 as a function of temperature. Although no theoretically deduced deposition curve is given for this initial composition, it is evident from Fig. 7 that the experimental data are in general qualitative agreement with other deposition loci.

Rate of deposition.—The rate of deposition of $In_{(1-x)}Ga_xP$ as a function of temperature can be determined from the results of Fig. 2 and 7. When the molecular weights are taken into account, the rates of deposition by weight of GaP and InP, as functions of temperature T, can be evaluated in terms of $\partial X_P/\partial T$, the temperature rate of change of the phosphorus fraction in the melt for a particular temperature and composition. For a density of ternary that interpolates linearly between those of InP and GaP, the volume rate of deposition is

$$\frac{\partial V/\partial T}{W_{In}} = 0.266\frac{(1 - 0.31X_{GaP})}{(1 - 0.14X_{GaP})}\frac{\partial X_P}{\partial T}\frac{cm^3}{g°C} \quad [8]$$

From [8] the rate of deposition of $In_{0.3}Ga_{0.7}P$ at 800°C is 6.5×10^{-5} cm³/g-°C and increases to 9×10^{-5} cm³/g-°C for $In_{0.6}Ga_{0.4}P$ at the same temperature. These rates are in fair agreement with the experimentally observed rates of 5-7.5 x 10^{-5} cm³/g-°C at these compositions and temperatures. Similarly, [8] gives rates of deposition of 1.2×10^{-5} and 2.5×10^{-4} cm³/g-°C for GaP and InP, respectively, at 800°C. Obviously, all rates of deposition decrease below 800°C because of the depletion of phosphorus in the melt.

Discussion

The mechanics of the growth process can be understood on the following basis: If the source were all InP, then at 900°C an amount of InP equal to 0.14 times the In weight would be required to saturate the solution with P, corresponding to $X_P = 0.106$ given by the liquidus curve of Fig. 2. The deposit obtained would be InP. As the amount of InP in the source is reduced and GaP is added to keep the total weight constant, the X_P derived from InP is not enough to saturate the liquid. In this case all the InP first dissolves and then enough GaP dissolves to produce a saturated solution of In + Ga + P. Equilibrium is achieved between this solution and a thin layer of $In_{(1-x)}Ga_xP$ which is observed to form on the GaP source. Upon cooling the solution, a ternary is deposited whose composition is predetermined by X_P, and therefore by the mole fraction of InP in the source. Thus, the atom fraction of phosphorus, X_P, acts as the controlling parameter in the growth process. Therefore the layer composition is actually fixed by the ratio of initial weights of InP in the source and the In. The weight of GaP in the source does not affect the layer composition as long as the

GaP available exceeds the amount required to saturate the In-Ga-P liquid.

Additional experimental observations concerning the growth process can now be explained. For instance, the shift in composition toward GaP during successive runs on the same charge is due to a reduction of X_P in the melt, which as seen from Fig. 7 increases X_{GaP} for a fixed temperature of depositions. The X_P reduction is due to two factors: (*i*) the depletion of the phosphorus during the growth process, and (*ii*) loss of phosphorus to the gas stream in the open-tube system.

Conclusion

$In_{(1-x)}Ga_xP$ was grown in the range $0.4 < x < 0.8$ by LPE on the Ga face of <111> oriented GaAs. The p-n junctions were made either by Zn diffusion or by LPE growth of a p-layer on top of the n-layer. The results of first-order calculations of the solidus and liquidus curves are in general agreement with experimental observations. It is also possible to predict the shift in composition of the grown layer as the temperature of deposition is lowered. Finally, the calculated rate of deposition of $In_{(1-x)}Ga_xP$ is in fair agreement with the experimentally observed values.

Mass Spectrometric Studies of Vapor Phase Crystal Growth

I. $GaAs_xP_{1-x}$ System ($0 \leq x \leq 1$)

Vladimir S. Ban

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

A mass spectrometer has been coupled to an open tube vapor phase crystal growth apparatus in order to study vapor phase processes leading to the deposition of $GaAs_xP_{1-x}$ crystals. Examination of the HCl transport of gallium showed that $GaCl_{(g)}$ was the main transporting species. It was found that vapor resulting from the thermal decomposition of AsH_3, PH_3, and PH_3-AsH_3 mixtures is very complex; dimers and tetramers of As and P, as well as various mixed species of the type As_xP_y ($x + y = 2$ or 4), were present in the vapor phase. The reaction governing the deposition of $GaAs_xP_{1-x}$ crystals was found to be

$$GaCl_{(g)} + \frac{1}{z}M_{z(g)} + \frac{1}{2}H_{2(g)} \rightarrow GaM_{(s)} + HCl_{(g)}$$

where M = As or P. It was established that the mixed As_xP_y species also readily participate in the deposition reaction. Significant deviations from thermochemical equilibrium were detected in the deposition system. The causes of these deviations and their influence on the deposition process are discussed.

Open-tube vapor transport is now a widely used method for the preparation of epitaxial layers of various III-V compounds and alloys. However, despite the significant practical success of this method, understanding of the fundamental chemistry of the growth process is still incomplete. In order to gain such understanding, it is necessary to specifiy the species present in the vapor phase qualitatively and quantitatively (*i.e.* to find the composition of the vapor phase); to determine the dependence of the vapor composition on variables such as temperature, flow rates, and input concentrations of reacting gases; and thereby to identify the chemical reactions occurring in the vapor phase.

Key words: mass spectrometry, vapor phase deposition, $GaAs_xP_{1-x}$ alloys, epitaxial growth, chemical kinetics, thermodynamics.

In recent years several studies have discussed vapor phase processes leading to the deposition of GaAs (1-5). In these articles the vapor phase was treated as a multicomponent system for which the conditions of thermodynamic equilibrium were calculated. Such treatment should, in principle, provide the required information about vapor composition and reactions involving the vapor phase. However, the thermodynamic calculations thus carried out necessarily required several basic assumptions. One had to assume that chemical equilibrium is established throughout the system (*i.e.* various kinetic effects are considered negligible); that all thermochemical data used in the calculations are correct; and that the assumed reactions indeed occur in the system.

The validity of these assumptions can be contested for several reasons. The open-tube growth apparatus is a dynamic system in which steady-state conditions possibly deviating from equilibrium conditions are to be expected. Further, high-temperature thermochemical data are frequently unreliable and contradictory. Finally, reactions have been assumed knowing only the input substances and the final product of the growth process. The experimental evidence which has been offered so far is based on the weight gain or the weight loss of the product and input substances, respectively. Such evidence can yield only indirect information about vapor phase reactions.

In view of the above, we decided to undertake a study which would give more direct information about the processes occurring in the vapor phase. For this purpose we coupled a mass spectrometer to a vapor phase crystal growth apparatus and studied the vapor phase under various experimental conditions. With this experimental setup it was possible to determine the composition of the vapor phase and its dependence on temperature and flow rates in the system, and also to identify reactions occurring in the vapor phase.

The purpose of this paper is to present and discuss the results of these mass spectrometric studies of the vapor phase processes leading to the deposition of $GaAs_xP_{1-x}$ ($0 \leq x \leq 1$) crystals in growth systems using AsH_3 and PH_3 as sources of pnictide elements. In particular, we shall discuss the following topics:

(*a*) HCl transport of gallium;
(*b*) Thermal decomposition of arsine, phosphine, and arsine-phosphine mixtures;
(c) Reactions responsible for the deposition of the $GaAs_xP_{1-x}$ crystals; and
(*d*) Deviations from chemical equilibrium occurring in the system and reasons for these deviations.

Experimental

The essential parts of our experimental set-up, schematically shown in Fig. 1, were a Bendix MA-1 time-of-flight mass spectrometer and an open-tube vapor growth system similar to the one first described by Tietjen and Amick (6).

Sampling of the vapor phase was done by means of a quartz capillary, which was connected to the mass spectrometer by a 20 mm ID quartz tube. In this manner a pressure reduction from 1 atm (the pressure in the growth tube) to 10^{-5} Torr or less (the pressure in the mass spectrometer) was accomplished. The diameter of the capillary was adjusted to give a maximum conductance compatible with the pumping speed of the mass spectrometer pumps.

This adjustment was made by reducing the conductance of a 1 cm long, 0.02 mm ID capillary by the insertion of a quartz fiber of a proper diameter into the capillary. The intake of the capillary was positioned directly in the growth tube. The distance between this intake and the mass spectrometer ion source was about 12 cm. The capillary was maintained at the temperature of the sampled gas.

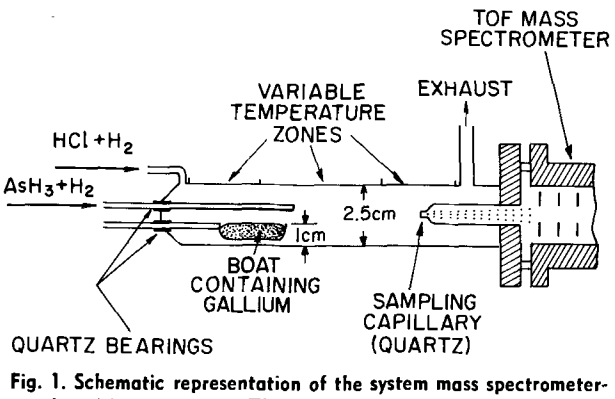

Fig. 1. Schematic representation of the system mass spectrometer-vapor deposition apparatus. The position of the boat and the AsH_3 inlet is variable.

In general, a capillary inlet system can introduce several sampling problems. The conductance of a capillary for a given gas is a function of the molecular weight and temperature of the gas. This can lead to a mass discrimination effect, *i.e.* the ratio of partial pressures of gases with different molecular weights is not the same on both sides of the capillary. The magnitude of this effect differs from system to system. We have calibrated our system by analyzing several gaseous mixtures of known composition (*e.g.* 1:1 AsH_3-PH_3 mixture, air). We found that this effect was generally small (<10%). Nevertheless, the correction factors were determined and applied in the determination of abundances of various gaseous species in the AsH_3-PH_3 mixtures.

Another potential source of trouble is the interaction of a sampled gas with the capillary walls. However, in our case these walls were made of the same material as the growth tube and maintained at the same temperature. Therefore no reaction different from those occurring in the growth tube would occur in the capillary.

The molecular beam, collimated by passing through the capillary, entered the ion source of the mass spectrometer. Since a mean free path at the pressure of 10^{-5} Torr is much longer than the distance between the capillary and the ion source, most molecules arrived at the source region without undergoing any interactions after leaving the capillary. We therefore believe that the sample introduced into the mass spectrometer is representative of the vapor phase in the growth tube.

There are three different zones in the vapor growth system. In the first zone ($T \approx 750$°C) HCl reacts with liquid gallium to form gaseous gallium chloride. In the second zone ($T \approx 850$°C) thermal decomposition of arsine and phosphine takes place. In the third zone ($T \approx 725$°C), gallium chloride reacts with the vapor species containing group V elements, and the deposition of $GaAs_xP_{1-x}$ crystals occurs. The whole process has been described in more detail in Ref. (6).

By varying the temperature profile and by moving the gallium-containing quartz boat or the arsine (or phosphine) inlet tube along the growth tube, we could simulate, in the vicinity of the sampling capillary, conditions characteristic of any of the three zones. This permitted us to study processes occurring in all three zones.

Temperature measurements were made with a thermocouple placed directly into the gas stream. It was found that at flow rates used in our experiments, the gas reached thermal equilibrium in 2 to 3 sec. Also, when varying the temperature profile, the temperature situation was always checked with an internal thermocouple before the mass spectrometric experiments.

By means of flow meters associated with the growth system we could vary the concentrations and flow rates of the input gases and consequently study the vapor phase processes under a variety of conditions. The mass spectrometer reacted almost instantaneously to changes in the growth tube.

We also grew several GaAs crystals in order to demonstrate that the conditions in our growth system were similar to the conditions normally present in open-tube growth systems. The crystallinity and the electrical properties of these crystals were similar to those of crystals prepared in standard systems, thus providing strong evidence that the conditions were also similar.

Results

HCl transport of gallium.—In our vapor growth system 1 liter/min of H_2 mixed with 3 to 5 cm^3/min of HCl is passed over the quartz boat containing liquid gallium at a temperature of about 750°C. The mass spectrometric results show that the following reaction

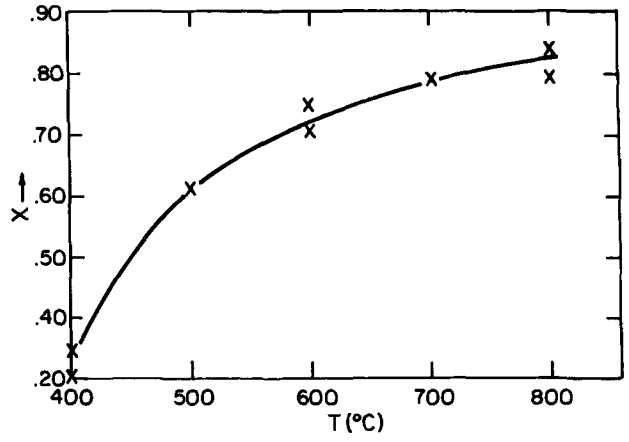

Fig. 2. Mole fraction (x) of HCl converted into GaCl at various temperatures (Reaction [1]). Pertinent parameters: flow rate = 1 liter/min, gas velocity = 5 cm/sec, Ga surface area = 20 cm^2, initial $P_{HCl} = 5.0 \times 10^{-3}$ atm.

occurs under these conditions

$$x\mathrm{Ga}_{(l)} + \mathrm{HCl}_{(g)} \rightarrow x\mathrm{GaCl}_{(g)} + (1 - x)\,\mathrm{HCl}_{(g)} + \frac{x}{2}\mathrm{H}_{2(g)} \quad [1]$$

where x = mole fraction of HCl reacting.

In all experiments, gallium monochloride was the only gallium species observed. The value of x was found by determining the ratio of the HCl signals with and without gallium in the system. Under typical growth conditions the value of x is about 0.80. The temperature dependence of x in the range of 400° to 800°C is shown in Fig. 2. In these experiments the initial partial pressure of HCl, P_{HCl}, was 5.0 x 10^{-3} atm. The flow rate was 1 liter/min, the gas velocity was 5 cm/sec, and about 20 cm^2 of Ga surface was exposed to the gas.

The dependence of x on flow rate of the H_2-HCl mixture over the gallium is shown in Fig. 3. In these experiments, the initial P_{HCl} was kept constant (*i.e.* 5.0 x 10^{-3} atm). A slightly larger gallium boat was used, so that 25 cm^2 of Ga surface was exposed. Gas velocities corresponding to flows of 1, 2, and 3 liters/min are 5, 10, and 15 cm/sec, respectively.

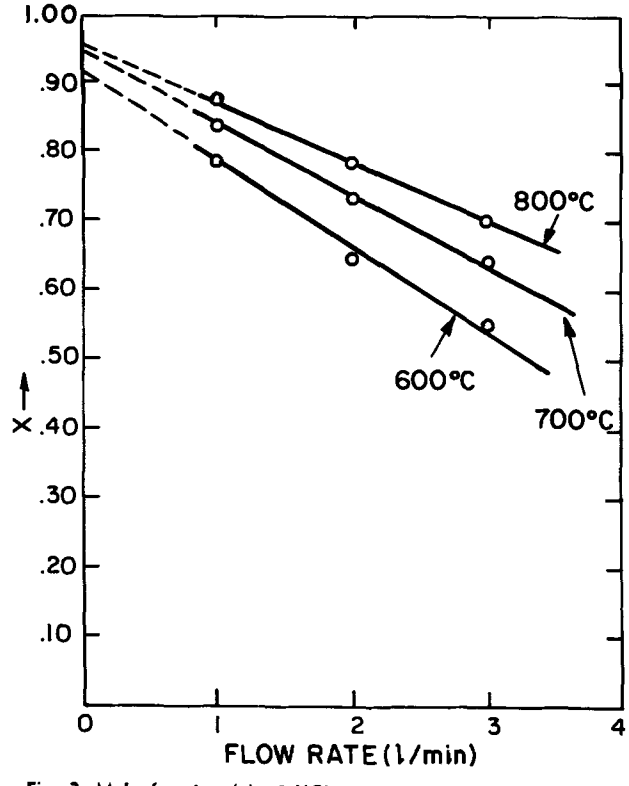

Fig. 3. Mole fraction (x) of HCl converted into GaCl (Reaction [1]) as a function of flow rate. Pertinent parameters: Ga surface area = 25 cm^2, initial $P_{HCl} = 5.0 \times 10^{-3}$ ohm.

Thermal decomposition of AsH_3,PH_3, and AsH_3-PH_3 mixtures.—The second zone in the growth apparatus is normally maintained at 850°C. In this zone 1.2 liter/min of H_2 mixed with 20 cm^3/min of AsH_3 (or PH_3) is introduced ($P_{AsH_3} = 1.6 \times 10^{-2}$ atm), and thermal decomposition of these gases takes place. The thermal decomposition can be described by the following equation

$$\mathrm{MH}_{3(g)} \rightarrow (1 - x)\,\mathrm{MH}_{3(g)} + (1 - \alpha)\frac{x}{4}\mathrm{M}_{4(g)} + \alpha\frac{x}{2}\mathrm{M}_{2(g)} + \frac{3}{2}x\mathrm{H}_{2(g)} \quad [2]$$

where $MH_3 = AsH_3$ or PH_3, $M_4 = As_4$ or P_4, $M_2 = As_2$ or P_2, x = mole fraction of MH_3 decomposing, and α = degree of dissociation of M_4 molecules. At T = 850°C the values of $x = 0.9$ and $\alpha = 0.50$ were obtained for the case of PH_3; in the case of AsH_3 the corresponding numbers were 0.99 and 0.45.

The mole fraction $(1 - x)$ of AsH_3 and PH_3 remaining undecomposed in the temperature interval from 400° to 850°C is graphically shown in Fig. 4.

We also studied the thermal decomposition of various AsH_3-PH_3 mixtures, ranging in composition from 10 to 80 volume per cent AsH_3. The initial total partial pressure of MH_3 gases was kept constant at 1.6 x 10^{-2} atm. A very complex vapor resulted from the decomposition of these mixtures. Besides the normally present As_4, As_2, P_4, and P_2 molecules, various mixed species of the type As_xP_y, where $x + y = 4$ or 2, were also present in amounts comparable to the amounts of nonmixed species. Relative abundances of various nonmixed and mixed species across the whole range of AsH_3-PH_3 mixtures are given in Fig. 5a and 5b, respectively. The trimeric molecules ($x + y = 3$) were also detected but only in relatively small amounts.

Deposition reactions.—Perhaps the most important part of our study was to properly identify the reactions governing the deposition of $GaAs_xP_{1-x}$ crystals. In order to collect the necessary data the temperature profile was adjusted in such a manner that the deposition took place several centimeters upstream from the sampling capillary. Several GaAs substrates normally used in the epitaxial growth process were positioned in the deposition zone, which was maintained at 680° to 720°C. The temperature of the capillary region was

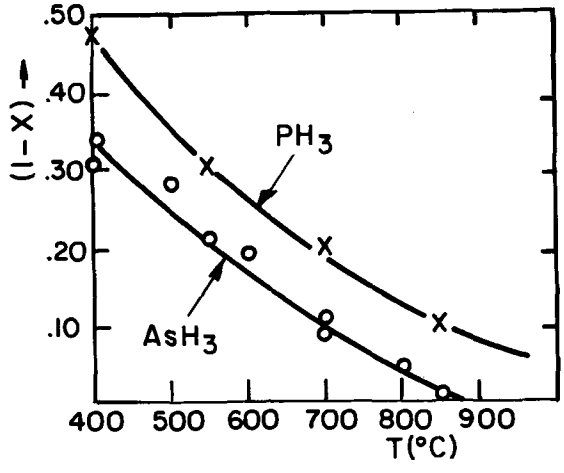

Fig. 4. Mole fraction (1 — x) of AsH_3 and PH_3 remaining undecomposed at various temperatures (Reaction [2]). Initial P_{AsH_3} or $P_{PH_3} = 1.6 \times 10^{-2}$ atm, flow rate = 1.2 liter/min.

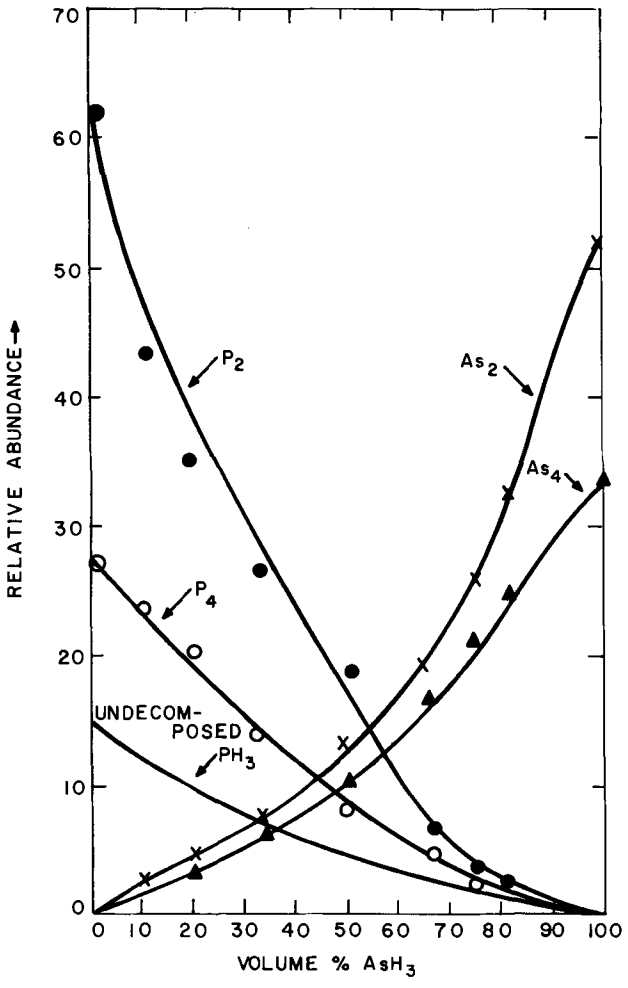
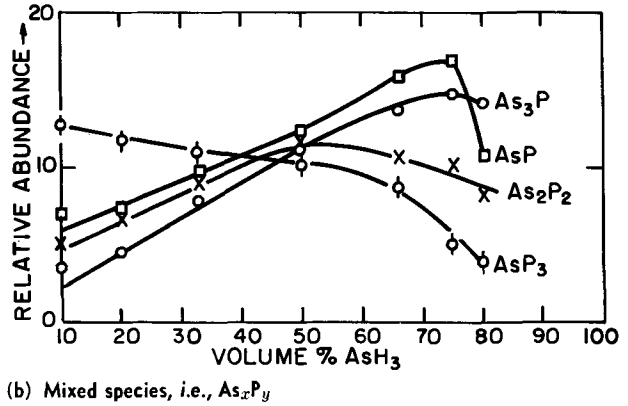


(a) Nonmixed species, *i.e.*, As_x and P_y



(b) Mixed species, *i.e.*, As_xP_y

Fig. 5. Relative abundances of vapor species resulting from the thermal decomposition of various PH_3-AsH_3 mixtures (initial $P_{AsH_3} + P_{PH_3} = 1.6 \times 10^{-2}$ atm, flow rate = 1.2 liter /min, $T = 850°C$).

somewhat higher in order to prevent clogging of the capillary.

With this arrangement we could identify the gaseous products of the reaction. Since the incoming gaseous reactants were known from our studies of the Ga transport and the thermal decomposition of MH_3 gases, and the solid products were also known, we were able to specify the deposition reaction completely. In the case of GaAs or GaP, the reaction was found to be

$$GaCl_{(g)} + \frac{1}{z}M_{z(g)} + \frac{1}{2}H_{2(g)} \rightleftarrows GaM_{(s)} + HCl_{(g)} \quad [3]$$

where M = As or P, and z = number of M atoms in the reacting molecule. This reaction is different from the one most frequently assumed to regulate the deposition of GaAs, *i.e.*

$$3GaCl_{(g)} + \frac{1}{2}As_{4(g)} \rightleftarrows 2GaAs_{(s)} + GaCl_{3(g)} \quad [4]$$

Gaseous $GaCl_3$ has not been detected in any of our experiments.

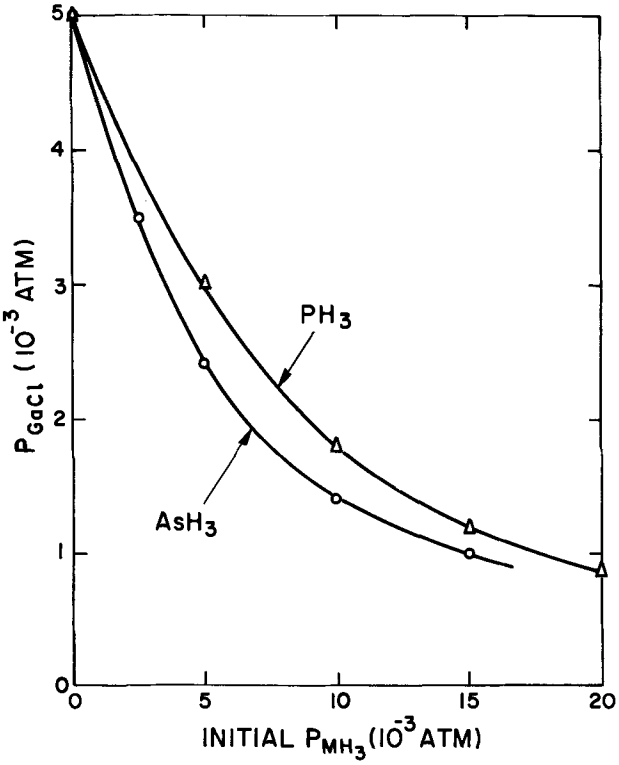


Fig. 6. Reduction of P_{GaCl} in the deposition reaction as a function of the initial P_{MH_3}. Temperature of reacting zone was 680° to 720°C, flow rate = 2.2 liter/min.

The consumption of $GaCl_{(g)}$ in reaction [3] increases as the initial partial pressure of MH_3 gases increases; this is graphically represented in Fig. 6, which shows the value of P_{GaCl} after the deposition at 680° to 720°C, for an initial $P_{GaCl} = 5 \times 10^{-3}$ atm and flow rate of 2.2 liters/min. Table I shows the decrease in percentages of various As_x, P_y, and As_xP_y species remaining after the deposition as a function of initial P_{GaCl}. It is important to note that all M-containing species, including the undecomposed fractions of AsH_3 and PH_3, react with $GaCl_{(g)}$ and thus contribute to the deposition of $GaAs_xP_{1-x}$. (Reaction of the AsP species could not be followed due to the interference of GaCl and AsP mass peaks.) In these experiments the initial values of partial pressures P_{AsH_3} and P_{PH_3} were 0.8×10^{-2} atm. Again, the deposition region was at 680° to 720°C, and the flow rate was 2.2 liters/min.

Table I. Percentages of various As- and P-containing vapor species remaining after $GaAs_xP_{1-x}$ deposition as a function of the initial P_{GaCl} (T = 680°-720°C, initial $P_{AsH_3} = P_{PH_3} = 0.8 \times 10^{-2}$ atm, flow rate = 2.2 liter/min)

Vapor species	Initial P_{GaCl} 10^{-3} atm			
	3.0	5.0	8.0	10.0
PAs_3	68	39	6	2
P_3As	73	44	12	8
As_4	73	44	8	6
P_2As_2	76	48	14	8
As_2	82	51	14	8
AsH_3	83	52	15	8
P_4	86	53	16	9
P_2	82	60	22	11
PH_3	90	70	31	16

Table II. Comparison of the observed partial pressures with the equilibrium partial pressures in the following systems (T = 850°C; P_{H_2} = 1 atm):
(A) Ga-HCl-H_2, (B) AsH_3-H_2, (C) PH_3-H_2, (D) AsH_3-PH_3-H_2

	Vapor species	$P_{(observed)}$ atm	$P_{(equilibrium)}$ atm	Initial pressure, atm
(A)	HCl	1.0×10^{-3}	5.0×10^{-5}	$P_{HCl} = 5.0 \times 10^{-3}$
	GaCl	4.0×10^{-3}	5.0×10^{-3}	
(B)	As_4	2.2×10^{-3}	3.9×10^{-3}	$P_{AsH_3} = 1.6 \times 10^{-2}$
	As_2	3.5×10^{-3}	7.0×10^{-4}	
	AsH_3	1.5×10^{-4}	1.0×10^{-8}	
(C)	P_4	1.8×10^{-3}	3.1×10^{-3}	$P_{PH_3} = 1.6 \times 10^{-2}$
	P_2	3.9×10^{-3}	1.7×10^{-3}	
	PH_3	1.1×10^{-3}	1.0×10^{-7}	
(D)	As_4, As_2	$\Sigma P_{As_x} = 0.7 \times 10^{-3}$	$\Sigma P_{As_x} = 2.0 \times 10^{-3}$	$P_{PH_3} = P_{AsH_3} = 0.8 \times 10^{-2}$
	PH_3, P_4, P_2	$\Sigma P_{P_x} = 0.7 \times 10^{-3}$	$\Sigma P_{P_x} = 2.5 \times 10^{-3}$	
	AsP, As_3P, As_2P_3, AsP_3	$\Sigma P_{As_xP_y} = 2.4 \times 10^{-3}$	Not considered in equilibrium calculations	

Discussion

Studies of Ga transport showed that the GaCl is practically the only gallium chloride present in the vapor phase. Furthermore, it was observed that the conversion of HCl is incomplete. The conversion efficiency drops with increase in flow rate and decrease in temperature. Extrapolating to zero flow rate, one finds that 96% of HCl would be converted at T = 800°C. Using these data one can calculate the equilibrium constant, and therefore the free energy of formation of GaCl at T = 1000°K: $\Delta F_f^\circ{}_{1000} = -30.8$ kcal/mole. This value is in good agreement with the value calculated from Kirwan's data (7): $\Delta F_f^\circ{}_{1000} = -31.7$ kcal/mole. These results suggest that $GaCl_{(g)}$ is the only stable chloride in the presence of liquid Ga at the temperatures maintained in the growth system. $GaCl_3$ could be present in negligible amounts only, since at partial pressures of reactants which exist in our system the following reactions would be shifted strongly to the product side (7)

$$GaCl_{3(g)} + 2Ga_{(l)} \rightarrow 3GaCl_{(g)} \quad [5]$$

$$GaCl_{3(g)} + H_{2(g)} \rightarrow GaCl_{(g)} + 2HCl_{(g)} \quad [6]$$

Reaction [6], however, could not be responsible for the HCl present in our system; the replacement of H_2 by He as the carrier gas did not appreciably change the conversion efficiency of HCl.

In Table II we compare partial pressures of species obtained from our mass spectrometric studies with partial pressures calculated by assuming that chemical equilibrium has been established in the systems considered. The equilibrium partial pressures have been calculated using thermochemical data collected in Ref. (7). The most obvious differences are the significantly higher partial pressures observed for HCl, AsH_3, and PH_3 as compared to values predicted by calculations. Also, the existence of the mixed As_xP_y species could not have been predicted by calculations because no thermochemical data for these species are available. The above results amply illustrate that the actual situation in the vapor phase can be significantly more complex than the models designed on assumptions mentioned in the beginning of this paper.

Our studies have found that the Reaction [3] governs the deposition of $GaAs_xP_{1-x}$ crystals. This is in agreement with the recently published results of Boucher and Hollan (5), who propose a similar reaction for the deposition of GaAs

$$2GaCl_{(g)} + \frac{1}{2}As_{4(g)} + H_{2(g)} \rightleftarrows 2GaAs_{(s)} + 2HCl_{(g)} \quad [7]$$

Our studies have further shown that the dimer molecules (As_2 and P_2), as well as the undecomposed MH_3 gases, react readily with $GaCl_{(g)}$. Thus they also contribute to the deposition of solid phases.

Using data given in Table I and Table II, one can assign the following individual contributions of various arsenic vapor species to GaAs deposition

$$GaCl_{(g)} + \frac{1}{4}As_{4(g)} + \frac{1}{2}H_{2(g)} \rightarrow GaAs_{(s)} + HCl_{(g)}$$

~55% of total GaAs deposited [8]

$$GaCl_{(g)} + \frac{1}{2}As_{2(g)} + \frac{1}{2}H_{2(g)} \rightarrow GaAs_{(s)} + HCl_{(g)}$$

~45% of total GaAs deposited [9]

$$GaCl_{(g)} + AsH_{3(g)} \rightarrow GaAs_{(s)} + H_{2(g)} + HCl_{(g)}$$

<1% of total GaAs deposited [10]

In the case of GaP, reactions equivalent to [9] and [10] play somewhat larger roles.

Table I indicates that all vapor species containing group V elements react readily with $GaCl_{(g)}$. There are, however, some differences in reactivity of these species. The reactivity is here defined as the percentage drop in concentration of any particular species with a given increase in initial P_{GaCl}. According to this definition, the reactivity of the various species follows this order

$$PAs_3 > P_3As \approx As_4 > P_2As_2 > As_2$$
$$\approx AsH_3 \approx P_4 > P_2 > PH_3$$

The difference in reactivity depends on P_{GaCl} and it diminishes at sufficiently high GaCl oversaturation. Under normal growth conditions when $P_{GaCl} = 3\text{-}5 \times 10^{-3}$ atm, the range of differences in reactivity of various species is quite significant (see Table I).

It has been observed previously in preparation of III-V alloys that the P/As ratio in the vapor phase is larger than the P/As ratio in the deposited solid phase (8); the lower reactivity of pure phosphorus species discovered in our experiments is in agreement with these observations.

Deviations from thermodynamic equilibrium in open-tube systems are the next topic of discussion. There are two main reasons for these deviations:

(*a*) Deviations can be caused by the relatively high flow rates which lead to flow patterns where some portion of the reactive gases does not come into contact with the desired surface; the dependence of HCl conversion efficiency on flow rates illustrates this point.

(*b*) Deviations can be caused by various kinetic effects, such as surface reactions and different reactivities of various vapor species; a discusison of these effects follows.

Several recent studies (5, 9, 10, 14) have shown that the growth rate of GaAs does not increase mono-

tonically with the decrease in temperature of the deposition zone, as one might expect from thermodynamic arguments. It was found experimentally that the growth rate peaks at a certain temperature which is dependent on the concentration of input substances, and then the growth rate decreases with the further decrease in temperature. The authors explain the observed effect by postulating the existence of a surface reaction on the substrate with an activation energy of about 40 kcal/mole. Thus the rate of this reaction decreases as the temperature is reduced.

Our data on the reactivity of various vapor species also indicate the importance of kinetics. If thermodynamics were the only factor governing the deposition process, the phosphorus species should have exhibited larger reactivity, since at 700°C GaP should be more readily deposited than GaAs. This follows from the fact that $\Delta F_f°_{900\text{-}1100}$ of GaP is more negative than $\Delta F_f°_{900\text{-}1100}$ of GaAs (7, 11, 12), and consequently, in this temperature range, the free energy change of Reaction [3] is more negative when GaP is deposited.

Our experimental data on reactivity of various vapor species contradict this thermodynamic reasoning, *i.e.* the pure arsenic and the mixed species react more readily than the pure phosphorus species. Following the analogy with the reduction of deposition rate of GaAs discussed elsewhere (5, 9, 10, 14), one might conclude that kinetic effects associated with the surface reaction play a dominant role at the temperature of our experiments (700°C). The consequence is a reduction in the rate of deposition of the phosphide component.

Another possible consequence of different reactivities of various As_xP_y vapor species is the preferential formation of certain solid phases in vapor grown $GaAs_xP_{1-x}$ alloys. It was reported (13) that during the preparation of graded $GaAs_xP_{1-x}$ layers ($x = 0.7\text{-}1.0$) compositions having As/P ratios of 7/1 and 6/2 were more readily formed than others, although the As/P ratio in the vapor phase was varied at a uniform rate. The authors proposed anion ordering as a cause of this phenomenon. Our data suggest that differences in reactivity of vapor species could also influence the composition of deposited layers. In the As-rich vapor the very reactive As_4 and As_3P species are highly abundant. The preferential reaction of $As_4 + As_3P$ (*i.e.* 7 As:1 P) and $As_3P + As_3P$ (*i.e.* 6 As:2 P) combinations would lead to the preferred As/P ratios of 7/1 and 6/2 observed in deposited layers.

The importance of some other kinetic effects in the deposition of III-V compounds has been demonstrated elsewhere, *e.g.* in Shaw's work regarding the influence of the substrate crystallographic orientation on the growth rate of epitaxially deposited GaAs layers (14).

The above discussion indicates that factors other than thermodynamic considerations significantly influence the deposition process, as well as the composition of the vapors in the analyzed systems.

Thermodynamic feasibility of a deposition process is a necessary but not a sufficient condition for successful crystal growth from the vapor phase. A neglect of kinetic factors leads to an oversimplified analysis of growth processes which does not properly describe the actual situation in an open tube crystal growth apparatus.

Conclusions

The main conclusions from this work are:

1. Gallium is transported only as GaCl, but the conversion of HCl into GaCl is incomplete in these growth systems.

2. The vapor resulting from the decomposition of AsH_3, PH_3, and PH_3-AsH_3 mixtures is very complex. Dimers and tetramers as well as various mixed species of the type As_xP_y ($x + y = 4$ or 2) are present in the vapor phase.

3. The reaction governing the deposition of GaAs, GaP, or $GaAs_xP_{1-x}$ crystals is of the type

$$GaCl_{(g)} + \frac{1}{z} M_{z(g)} + \frac{1}{2} H_{2(g)} \rightarrow GaM_{(s)} + HCl_{(g)}$$

4. All vapor species containing the group V elements contribute to the deposition of solid phases, although their reactivities differ somewhat.

5. Significant deviations from thermochemical equilibrium occur in vapor growth systems due to the high flow rates employed in these systems and due to the kinetic effects influencing the rate of deposition. These effects as well as the thermodynamics of the given system should be jointly considered when examining the feasibility of crystal growth from the vapor phase.

Acknowledgments

The author would like to thank A. E. White for excellent technical assistance in the construction and maintenance of the experimental apparatus. Frequent and useful discussions with J. J. Tietjen, D. Richman, R. E. Enstrom, and W. M. Yim are gratefully acknowledged.

Thermodynamic Analysis of the Open-Tube Chemical Vapor Transport of ZnO Using the Zn-H_2O Reaction

A. Reisman* and J. E. Landstein

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A thermodynamic analysis of the open-tube chemical vapor transport of ZnO using the reaction of Zn and H_2O has been attempted, assuming a simple reaction model for Zn and H_2O vapor phase species. Based on this analysis, computer data have been derived to show variation in ZnO vapor phase content as a function of temperature, and reactor Zn and H_2O concentrations. The range of Zn reactor pressures examined was from 0.00260-0.00013 atm with H_2O pressures varying from 10^{-3}-10^{3} of these values over a temperature interval of 723°-1473°K. For the range of Zn pressures examined, H_2O pressures of 10-100X these values lead to vapor phase concentration curves most amenable to precise experimental control. At H_2O pressures 10X those of Zn pressures particularly, high-temperature plateaus develop where vapor phase Zn content is relatively temperature insensitive and which look promising as transient ZnO source sites. Similar plateaus do not exist at lower temperatures where they might have value as temperature insensitive deposition sites.

A variety of methods for the chemical vapor deposition of ZnO have been reported in the recent literature (1-7). A number of these were studied in the present work but were found deficient for a variety of reasons. In some instances deposition rates were too low. When O_2 was admixed with Zn vapor phase species deposition was too abrupt. For some reactions sources of high purity reactants were not available. In others failure to obtain epitaxy was observed. One reaction subsequently abandoned because of an inability on our part to understand and control severe attack of the quartz containers showed some promise, and is worth mentioning, namely the transport of ZnO by H_2, Eq. [1].

$$ZnO(s) + H_2(v) \leftrightarrows Zn(v) + H_2O(v) \qquad [1]$$

This reaction proceeds via a hot to cold process, and in theory can be modulated by transport with H_2-He mixtures and further modulated by injection of H_2O into the reaction zone where deposition is desired. Thus, via use of this injection technique, the normal hot to cold mode can be changed so that deposition may be effected at temperatures greater than that of the ZnO source. Unfortunately, severe attack of the quartz reaction tube and sample holder always occurred in the 600°-700°C region, with or without the use of water injection, necessitating constant equipment replacement. Further, the unavailability of ultra-high purity ZnO and the explosion hazard inherent in H_2 systems coupled with the "corrosion" phenomenon led us to seek another method, despite some limited success in obtaining epitaxy on sapphire basal plane substrates.

The technique to be described below employs a Zn source, He as a carrier gas, and water vapor as a reaction medium. In effect then, the reaction involved is the reverse of the reaction shown in Eq. [1]. Unexplainably, using this approach, Eq. [2], there is no evidence of attack

$$Zn(v) + H_2O(v) \xrightleftharpoons{\text{He carrier}} ZnO(s) + H_2(v) \qquad [2]$$

of the quartz reactor at any temperature or concentration studied, including the range of compositions studied in the H_2 transport experiments. In addition, considerable success (to be discussed in a different publication) in obtaining epitaxial layers of ZnO on insulating substrates has been obtained thus far. The present paper is concerned only with a thermodynamic analysis of the system being studied.

The reaction while basically hot to cold in nature can, if desired, be conducted in the fashion of a pyrolytic reduction with the deposition zone being hundreds of degrees higher than the temperatures of the Zn and H_2O sources.

Experimentally, He is transpired over a Zn bed at a defined temperature at which the vapor pressure of Zn is p'_{Zn}. Simultaneously, He is transpired over a water source where the vapor pressure of H_2O is p'_{H_2O}. The reactants are mixed at a temperature T at which point the reaction depicted in Eq. [2] ensues. Either of two options may then be exercised. The point of mixing may be employed as a transitory ZnO(s) source for a ZnO hot to cold transport down stream, or the substrates may be placed directly in the mixing region for deposition there.

Theoretical Analysis

The symbols to be used in the following discussion are defined in the List of Symbols.

The system contains the four components, Zn, H_2, O, and He coexisting isobarically (at 1 atm nominally) in two phases. Consequently, it possesses three degrees of freedom, *i.e.*, the temperature and two composition variables. Once three such quantities are specified, the system is uniquely defined. We can choose for the concentration variables the component mole ratios of Zn, X, and O, Y, introduced into the reactor portion of the system as defined by Eq. [3] and [4].[1]

$$X = \frac{P_{Zn}}{P_{He^t} + P_{Zn} + P_O} = \frac{p_{Zn} + p_{H_2}}{p_{He} + p_{Zn} + p_{H_2} + p_{H_2O} + p_{H_2}} \qquad [3]$$

$$Y = \frac{P_O}{P_{He^t} + P_{Zn} + P_O} = \frac{p_{H_2O} + p_{H_2}}{p_{He} + p_{Zn} + p_{H_2} + p_{H_2O} + p_{H_2}} \qquad [4]$$

The component partial pressures are of course conserved via the actual species partial pressures, p_x (for each mole of Zn or H_2O reacted, a mole of H_2 species is formed).

Since four vapor phase species are assumed present, solution of their partial pressures requires simul-

Key words: ZnO vapor transport, thermodynamics, vapor transport.

[1] Appendix A presents the rationale for Eq. [3] and [4].

taneous solution of four independent equations. In addition to Eq. [3] and [4] those chosen are

$$K = \frac{p_{Zn}\, p_{H_2O}}{p_{H_2}} \quad [5]$$

and

$$1 = p_{H_2} + p_{He} + p_{Zn} + p_{H_2O} \quad [6]$$

Equation [5] is the equilibrium constant for Eq. [1] (the inverse of that for Eq. [2]), and Eq. [6] represents the nominal constant total pressure constraint in the open-tube system.

As a measure of the equilibrium state in the reactor as a function of T, X, and Y, we may use the quantity Z defined by

$$Z = \left(\frac{p_{Zn}}{p_{He}}\right)_{X,Y,T} \quad [7]$$

Z represents the vapor phase concentration of the component Zn present as the species Zn(v), referenced to the carrier gas and shows as a function of T the variation of Zn vapor phase content, since the He is always confined to the vapor phase. Z can be determined as a function of T for specified constant values of X and Y. For example, if we specify X and plot a family of curves, each curve being at this one value of X and a different value of Y, this family will comprise a set of univariant curves. By knowing the input value of Z, namely Z', we can for each curve determine the ZnO precipitation as a function of temperature by inspection. This matter is pursued further below.

Solutions for Species Partial Pressures

Employing Eq. [3], [4], [5], and [6], values for p_{Zn}, p_{H_2O}, p_{He}, and p_{H_2} at equilibrium can be obtained at specified values of X, Y, and T.[2] The temperature dependency of K referenced to a standard state of 1 atm is given by

$$\log K = \frac{-12{,}300}{T} + 9.179 \quad [8]$$

Specific data for calculating Eq. [8] were obtained from ref. (8) and (9). These are listed in Table I.

Equations [3] and [4] may be rewritten as Eq. [9] and [10] using Eq. [6]

$$X = \frac{p_{Zn} + p_{H_2}}{1 + p_{H_2}} \quad [9]$$

$$Y = \frac{p_{H_2O} + p_{H_2}}{1 + p_{H_2}} \quad [10]$$

Solving Eq. [9] and [10] for p_{H_2}, we obtain

$$p_{H_2} = \frac{p_{Zn} - X}{X - 1} \quad [11]$$

and

$$P_{H_2} = \frac{p_{H_2O} - Y}{Y - 1} \quad [12]$$

Therefore

$$\frac{p_{Zn} - X}{X - 1} = \frac{p_{H_2O} - Y}{Y - 1} \quad [13]$$

and

$$p_{H_2O} = \frac{(p_{Zn} - X)(Y - 1)}{(X - 1)} + Y \quad [14]$$

and

$$p_{Zn} = \frac{(p_{H_2O} - Y)(X - 1)}{(Y - 1)} + X \quad [15]$$

We can substitute Eq. [14] and [11] into Eq. [5] to obtain p_{Zn} as a function of X, Y, and K, Eq. [16]

$$p^2_{Zn}(Y - 1) + p_{Zn}(X - Y - K) + KX = 0 \quad [16]$$

From Eq. [15], [12], and [5], because of symmetry, we can write directly

$$p^2_{H_2O}(X - 1) + p_{H_2O}(Y - X - K) + KY = 0 \quad [17]$$

from which p_{H_2O} may be calculated. Once p_{Zn} and p_{H_2O} are known Eq. [5] may be used to define p_{H_2}, Eq. [18]

$$p_{H_2} = \frac{(\text{solution to Eq. [16]})(\text{solution to Eq. [17]})}{K} \quad [18]$$

Finally, p_{He} may be obtained from Eq. [6].

Species partial pressures were computer calculated as described below using the following values of X, Y, and T: $X = 2.60 \times 10^{-3}$ to $X = 0.13 \times 10^{-3}$ in steps of 0.13×10^{-3} (this coincides to $P_{Zn} = 2$ Torr down to $P_{Zn} = 0.1$ Torr in 0.1 Torr increments); $Y = 10^3X$ to $Y = 10^{-3}X$ in steps of $10X$ (the value $Y = 10^3X$ only provides physically meaningful results for certain values of X to be discussed below; $T = 723$°K to $T = 1473$°K in 50° steps.

Having calculated species partial pressures for all values of the variables, the data were used to machine plot two types of graphs. In the first of these the quantity Z, $(p_{Zn}/p_{He})_R$, which depicts the vapor phase concentration of the component Zn present as Zn species was plotted as a function of T. Thus, for each value of X, the value of Y at a fixed ratio to X was determined. This leads to seven families of curves, each family at constant R, *i.e.*, $R = 0.001$, 0.01, 0.1, 1, 10, 100, 1000. In the second type of graph, Z was calculated as a $f(T)$ for values of X which were kept constant while the seven values of Y relative to X were varied. This data was normalized to the value of Z for each curve at 1473°K, *i.e.*, $Z_T/Z_{1473°}$ was plotted as a $f(T)$ for each of the seven curves (where physically meaningful) in each family.

To obtain computer solutions to Eq. [16], [17], [18], and [6], given the several values of X, Y, and T (the latter being used to define the values of K), and to acquire the data for plotting described above, the program was written in Fortran IV. In the solutions of the quadratic equations for p_{Zn} and p_{H_2O}, one of the roots of each was found to be physically meaningless and was discarded. The values p_{H_2} and p_{He} were then calculated as were the ratios Z and $Z_T/Z_{1473°}$ used for plotting.

Plotting was accomplished using an IBM 1627 Plotter Compatible Software package which was called from the Fortran program. Through the use of the software package, plotter output was obtained concurrently on an IBM 1627 Plotter and on a Stromberg Carlson 4020 Computer Recorder.

The program was run on a System/360 Model 91 under OS taking 47 sec of CPU time which included not only all the calculations, but also the generation of all plots.

[2] Appendix B describes how a useful range of X and Y values can be defined from known experimental parameters.

Table I. Thermodynamic data used for calculating K

Species	Property	Ref. and Page No.	
ZnO(s)	$\Delta H_f°_{(298°K)} = -83.2$ kcal/mole	(8)	280
ZnO(s)	$S°_{298°K} = 10.4$ cal/deg mole	(8)	280
Zn(s)	$\Delta H°_{Sub\,1(298°K)} = 30.9$ kcal/mole	(8)	309
Zn(s)	$S°_{298°K} = 9.9$ cal/deg mole	(8)	280
Zn(v)	$S°_{298°K} = 38.45$ cal/deg mole	(9)	117
H_2O(v)	$\Delta H_f°_{(298°K)} = -57.8$ kcal/mole	(8)	248
H_2O(v)	$S°_{298°K} = 45.1$ cal/deg mole	(8)	248
H_2(v)	$S°_{298°K} = 31.2$ cal/deg mole	(8)	246

Discussion of Results

Figures 1-5 inclusive show the variation in Zn/He vapor phase concentration as a function of T(°K) under conditions of constant R. Because of the manner in which X and Y have been defined (see Appendix), they individually represent atmospheres of the components Zn and H_2O present in the reactor prior to reaction. While 20 curves are possible in each of the families shown in Fig. 1-5, not all of these have physical significance. Thus, in Fig. 1 (where $R = 0.001$)

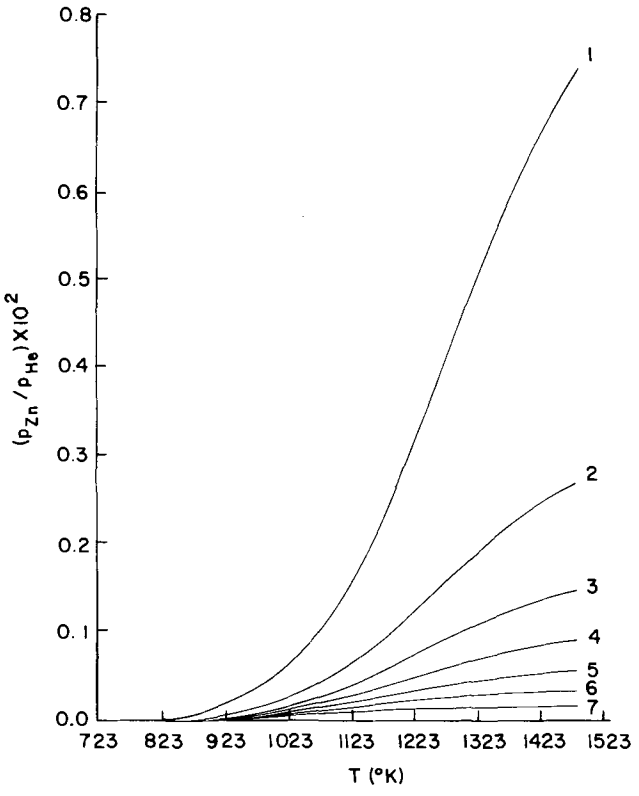

Fig. 1. Vapor phase variation in Zn concentration as a function of T at constant R. $R = 0.001$, $X = 1$, 0.00091; 2, 0.00078; 3, 0.00065; 4, 0.00052; 5, 0.00039; 6, 0.00026; 7, 0.00013.

Vapor phase variation in Zn concentration as a function of T at constant R. $R = 1.0$, $X = 1$, 0.00260; 2, 0.00247; 3, 0.00234; 4, 0.00221; 5, 0.00208; 6, 0.00195; 7, 0.00182; 8, 0.00169; 9, 0.00156; 10, 0.00143; 11, 0.00130; 12, 0.00117; 13, 0.00104; 14, 0.00091; 15, 0.00078; 16, 0.00065; 17, 0.00052; 18, 0.00039; 19, 0.00026; 20, 0.00013.

when the value of X achieves a value of 0.00091, the required value of Y would be 0.91. Since the total pressure cannot exceed 1 atm, the required value of Y for the next higher value of X ($X = 0.00104$) would violate the total pressure constraint. Consequently, only 7 curves appear in Fig. 1. In the remaining families, 20 curves are present in each. Figure 5 representing an R

value of 10 does not provide experimentally usable information, since as might have been anticipated, the miniscule concentration of water vapor employed, *i.e.*, 0.1 that of Zn introduced leads to only minor variations of Zn vapor phase content as a function of T above the Zn dewpoint at each Zn concentration. At R values of 100 and 1000 no change in Zn vapor phase concentration occurs in the temperature interval surveyed. Figures 1-4 show essentially monotonic variation of Zn/He ratio with T. It might be noted that the greatest variation in Z occurs at the lowest value of R, a not unexpected result. At $R = 0.1$ and 1, the curves exhibit plateaus which are potentially useful for maintaining sources in a nontemperature sensitive environment. Unfortunately, these plateaus, particularly at the lower Zn concentrations, extend to relatively low temperatures and would restrict the range of temperatures over which epitaxial deposition conditions could be sought. Several of the curves for $R = 0.001$ and 0.01, Fig. 1 and 2, respectively, appear to represent a reasonable experimental compromise for utilizing plateau regions for source control, while not sacrificing the temperature range for studying epitaxial phenomena.

Figures 6-10 show normalized data relative to Z at 1473°K for several selected starting Zn component partial presures. From these curves, the fraction of Zn precipitated at each temperature is evident by inspection. These curves enable estimation of the quantity of material deposited, starting with specified concentrations and total flow rates into the reactor.

The predicted occurrence of plateau regions in Fig. 1-10 provides an excellent qualitative tool for testing the validity of the equilibrium transport model in appropriate concentration-temperature regimes. After establishing source bed designs which result in the development of equilibrium partial pressures in the effluents, the reactants can be mixed at elevated temperatures. The drop out of ZnO along a temperature gradient can then be monitored in a liner tube in the reactor to determine the temperature at which deposition first occurs. Qualitatively, the results of such preliminary experiments have shown the analysis to be valid to first order. In addition, utilizing the curves shown in Fig. 6-10, the relative amounts of deposition expected at different temperatures have been monitored in epitaxial growth studies on sapphire and magnesium spinel. These experiments have also lent credence to the validity of the calculated data.

It is evident that Eq. [1] and [2] represent the identical equilibrium. The fused quartz corrosion problem experienced in attempting transport of ZnO powder in an H_2 or H_2-He carrier gas has not been en-

countered in implementing the experiment via Eq. [2]. Initially it was thought that this might be due to the high hydrogen content of the carrier gas stream employed in transporting the ZnO from a powder source via Eq. [1]. However, in H_2-He mixtures containing equivalent H_2/He ratios to those generated when Zn and H_2O react in a He stream, similar corrosion behavior was observed. The only conclusion that appears to provide a reasonable explanation for the difference in behavior of the two systems is that the "high purity" ZnO sources employed were contaminated by some unknown agent not detected by emission spectroscopic techniques.

APPENDIX A

It is most convenient to consider our analysis via the use of pressure values for components, *i.e.*, P_{Zn}, P_O, P_{He}, P_{H_2} and species p_{Zn}, p_{H_2O}, p_{He}, p_{H_2}. We know that for each mole of Zn introduced and subsequently consumed a mole of H_2 is formed. Similarly, for each mole of O introduced (as H_2O) and then consumed, a mole of H_2 is formed. Thus, we can conserve the component moles of Zn and O, m_{Zn} and m_O, respectively, in terms of the species moles present n_{Zn}, n_{H_2O}, n_{H_2}, via

$$m_{Zn} = n_{Zn} + n_{H_2} \qquad [A\text{-}1]$$

$$m_O = n_{H_2O} + n_{H_2} \qquad [A\text{-}2]$$

To convert these terms into pressures, we assume the applicability of the ideal gas equation

$$\text{moles} = \frac{PV}{RT} \qquad [A\text{-}3]$$

Therefore,

$$\frac{P_{Zn}V_{IN}}{RT} = \frac{(p_{Zn} + p_{H_2})V_{OUT}}{RT} \qquad [A\text{-}4]$$

or

$$P_{Zn}V_{IN} = (p_{Zn} + p_{H_2})V_{OUT} \qquad [A\text{-}5]$$

where V_{IN} can be thought of as the total volume prior to reaction which contains the component moles of Zn, m_{Zn} introduced, and in which its component pressure is P_{Zn}, and where V_{OUT} is the total volume after reaction occurs in which the unreacted Zn and its product are contained. Unless we know the term V_{OUT} we cannot rewrite Eq. [A-1] and [A-2] in terms of pressures alone. Suppose, however, we had chosen to define the ratio X where X is given by

$$X = \frac{m_{Zn}}{m_{Zn} + m_O + m_{He^t}} \qquad [A\text{-}6]$$

where m_{He^t} represents the total number of moles of He introduced into the reactor. Conserving the component moles specified, we see that

$$X = \frac{m_{Zn}}{m_{Zn} + m_O + m_{He^t}} = \frac{n_{Zn} + n_{H_2}}{(n_{Zn} + n_{H_2}) + (n_{H_2O} + n_{H_2}) + n_{He^t}} \qquad [A\text{-}7]$$

substituting for the m's and n's the result, Eq. [A-4], we obtain

$$X = \frac{P_{Zn}\, V_{IN}/RT}{(P_{Zn} + P_O + P_{He^t})\, V_{IN}/RT} = \frac{(p_{Zn} + p_{H_2})\, V_{OUT}/RT}{(p_{Zn} + 2p_{H_2} + p_{H_2O} + p_{He})\, V_{OUT}/RT} \quad [A\text{-}8]$$

cancelling terms leads to

$$X = \frac{P_{Zn}}{P_{Zn} + P_O + P_{He^t}} = \frac{p_{Zn} + p_{H_2}}{p_{Zn} + 2p_{H_2} + p_{H_2O} + p_{He}} \quad [A\text{-}9]$$

Note that if the P's are specified in atmospheres, the denominator $P_{Zn} + P_O + P_{He^t} = 1$ in our experiment, since the P_O term is derived exclusively from the H_2O introduced, and the three component pressures, $P_{Zn} + P_O$ (from H_2O) and P_{He^t} account initially for the total pressure.

Therefore,

$$X = P_{Zn}(\text{dimensionless}) = \frac{(p_{Zn} + p_{H_2})\,\text{atm}}{(p_{Zn} + 2p_{H_2} + p_{H_2O} + p_{He})\,\text{atm}} \quad [A\text{-}10]$$

Consequently, from an experimental point of view, both X and an analogous expression for an O ratio, Y, where Y is given by

$$Y = \frac{P_O}{P_{He^t} + P_{Zn} + P_O} = \frac{p_{H_2O} + p_{H_2}}{p_{Zn} + 2p_{H_2} + p_{He} + p_{H_2O}} \quad [A\text{-}11]$$

are simply the partial pressures of Zn and water (in atmospheres) introduced into the reactor prior to reaction, but after dilution has occurred.

APPENDIX B

Selection of X and Y Values

Experimentally, the values of X and Y depend on the vapor pressures of Zn and H_2O at their source sites, and on flow rates of the carrier gas through each source site. We can approach the problem in either of two ways for convenience:

1. We can choose the Zn and H_2O source bed pressures by fixing the source bed temperatures, translate these pressures into a desired ratio of effective Zn/H_2O flow rates, R, and then determine the required carrier gas flows through each source bed (where equilibrium is always assumed to obtain) required to satisfy these boundaries.
2. We can choose the flow rates of carrier gas through each source bed, and determine the vapor pressures of Zn and H_2O required to give specific values of X and Y (therefore of R).

Method 1 (Solving for the required He flow through the Zn source, F_{He}, and through the water source, F'_{He}, given p'_{Zn}, p'_{H_2O}, and R).—At the Zn source, since the total pressure is 1 atm, the partial presures of Zn, p'_{Zn}, and He, p^*_{He} must account for this total pressure. Since the He enters the Zn source at 1 atm and some defined flow rate monitored at a meter located prior to the source, the Zn vaporization must be accompanied by an over-all volume increase proportional to the Zn vapor pressure. The net effect then imposed by the constant pressure constraint is to increase the flow rate (referenced to room temperature, for example), so that the effluent flow out of the Zn source, F_1, is the sum of the input He flow rate, F_{He}, plus an effective Zn flow rate, F_{Zn}, Eq. [B-1]

$$F_1 = F_{Zn} + F_{He} \quad [B\text{-}1]$$

since

$$F_{Zn} = \frac{p'_{Zn}\,(\text{Torr}) \cdot F_1}{760\ \text{Torr/atm}} \quad [B\text{-}2]$$

We see that the relationship between the effluent flow from the Zn bed, F_1, and the He flow measured at a flow meter is

$$F_1 = \frac{F_{He}\, 760}{760 - p'_{Zn}\,(\text{Torr})} \quad [B\text{-}3]$$

Substituting for F_1 in Eq. [B-2], the value shown in Eq. [B-3] yields

$$F_{Zn} = \frac{p'_{Zn}\,(\text{Torr})\, F_{He}}{760 - p'_{Zn}\,(\text{Torr})} \quad [B\text{-}4]$$

At the H_2O source by an exactly analogous argument, we find that

$$F_2 = \frac{F'_{He}\, 760}{760 - p'_{H_2O}\,(\text{Torr})} \quad [B\text{-}5]$$

$$F_O = \frac{p'_{H_2O}\,(\text{Torr})\, F'_{He}}{760 - p'_{H_2O}\,(\text{Torr})} \quad [B\text{-}6]$$

Since effective component flow rates are directly related to the partial pressures of the unreacted components present, we may rewrite Eq. [3] and [4] according to

$$X = \frac{F_{Zn}}{F_{Zn} + F_{He} + F'_{He} + F_O} = \frac{F_{Zn}}{F_3} \quad [B\text{-}7]$$

and

$$Y = \frac{F_O}{F_{Zn} + F_{He} + F'_{He} + F_O} = \frac{F_O}{F_3} \quad [B\text{-}8]$$

where the various flow contributions refer to the unreacted components referenced to effective room temperature flow rates.

Let us now define a new quantity R given by

$$R = \frac{X}{Y} = \frac{F_{Zn}}{F_O} = \frac{p'_{Zn}\, F_{He}\,[760 - p'_{H_2O}\,(\text{Torr})]}{p'_{H_2O}\, F'_{He}\,[760 - p'_{Zn}\,(\text{Torr})]} \quad [B\text{-}9]$$

If we fix values of p'_{Zn} and p'_{H_2O} as well as F_3, the ratio R becomes unique. Since.

$$F_3 = F_1 + F_2 \quad [B\text{-}10]$$

we can write from Eq. [B-3] and its analog for the water bed effluent flow rate Eq. [B-5]

$$F_3 = \frac{F_{He}\, 760}{760 - p'_{Zn}\,(\text{Torr})} + \frac{F'_{He}\, 760}{760 - p'_{H_2O}\,(\text{Torr})} \quad [B\text{-}11]$$

Equations [B-11] and [B-9] may be solved simultaneously for F_{He} and F'_{He} to give Eq [B-12] and [B-13]

$$F_{He} = \frac{F_3 R\,[760 - p'_{Zn}\,(\text{Torr})]}{760\,[R + p'_{Zn}\,(\text{Torr})/p'_{H_2O}\,(\text{Torr})]} \quad [B\text{-}12]$$

$$F'_{He} = \frac{F_3[760 - p'_{H_2O}(\text{Torr})]p'_{Zn}(\text{Torr})/p'_{H_2O}(\text{Torr})}{760[R + p'_{Zn}(\text{Torr})/p'_{H_2O}(\text{Torr})]} \quad [B\text{-}13]$$

Method 2 (Solving for p'_{Zn} and p'_{H_2O} given values for X, R, F_{He}, and F'_{He}.—The output of a computer analysis may be easily specified in terms of fixed values of X at different values of the ratio R. Since the values of p'_{Zn} and p'_{H_2O} needed to give these X and R values depend on what flow rates of carrier gas are employed, the second method more nearly approximates the way an experiment might be performed. It is to be noted that if X and R are both specified along with F_{He} and F'_{He}, the value of Y is uniquely determined, therefore, p'_{Zn} and p'_{H_2O} are also both uniquely determined.

Substituting into Eq. [B-7] the values for F_{Zn} and F_O given by Eq. [B-4] and [B-6] respectively, X may be expressed in terms of p'_{Zn} (Torr), p'_{H_2O} (Torr), F_{He}, and F'_{He}.

Equation [B-9] gives R as a function of these same parameters. Consequently, the expressions for X and R may be solved simultaneously for p'_{Zn} and p'_{H_2O} to give Eq. [B-14] and [B-15], respectively

$$p'_{Zn}\,(\text{Torr}) = \frac{760\, F_{He^t}\, C_O R}{F_{He^t}\, C_O R + F_{He}\,(R - C_O)} \quad [B\text{-}14]$$

$$p'_{H_2O}\ (\text{Torr}) = \frac{760\ F_{He^t}\ C_o}{F_{He^t}\ C_o + F'_{He}\ (R - C_o)} \quad [B\text{-}15]$$

where $C_o = X/(1 - X)$.

Acknowledgments

The authors wish to acknowledge T. O. Sedgwick and M. Berkenblit for their many helpful discussions, and Y. van der Meulen and P. Balk for critically reviewing the manuscript.

Manuscript submitted Dec. 2, 1970; revised manuscript received April 22, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

LIST OF SYMBOLS

- p'_{Zn} partial pressure of Zn at a Zn source external to the reactor
- p_{Zn} equilibrium partial pressure of the species Zn after reaction
- P_{Zn} partial pressure of the component Zn in the reactor, prior to reaction having occurred, referenced to room temperature and 1 atm total pressure in the reactor
- F_{Zn} effective flow rate of the component Zn assumed present as the species Zn at the output of the Zn source
- X the ratio of F_{Zn}, as defined above, to the total flow rate in the reactor prior to reaction, referenced to room temperature
- p'_{H_2O}, p_{H_2O}, P_O, F_O: analogs of the Zn terms defined above for the water introduced into the system
- Y analog of the term X for the component O which is derived from the water introduced
- p_{H_2} equilibrium partial pressure of H_2 after reaction has occurred
- R the ratio X/Y ∴ the ratio F_{Zn}/F_O
- F_{He} the flow of He into the Zn source referenced to room temperature
- F'_{He} the flow of He into the water source referenced to room temperature
- F_{He^t} $F_{He} + F'_{He}$
- p_{He} equilbrium partial pressure of He after reaction has occurred
- p_{He^t} total component partial pressure of He introduced into the reactor prior to reaction, referenced to room temperature
- F_1 the flow $F_{Zn} + F_{He}$ emanating from the Zn source
- F_2 the flow $F_O + F'_{He}$ emanating from H_2O source
- F_3 the total flow in the reactor ($F_1 + F_2$) prior to reaction, referenced to room temperature
- Z equilibrium ratio p_{Zn}/p_{He} at specified X, Y, and T following reaction
- Z' the value P_{Zn}/P_{He^t} prior to reaction

Phase Relations and Liquid Structure in the System As-Sb_2Se_3-Se

John S. Berkes and Mark B. Myers

Xerox Corporation, Xerox Square-114, Rochester, New York 14644

ABSTRACT

The phase equilibria for the As-Sb_2Se_3-Se ternary system were determined by sealed system DTA and quench methods. The As_2Se_3-Sb_2Se_3 and As-Sb_2Se_3 ternary sections are true binary systems exhibiting simple eutectic behavior. The general phase relationships are discussed and the liquidus behavior and liquid structure of the selenium rich part of the ternary are treated in detail. A nonregular thermodynamic solution model is used to describe the solution behavior and calculate the size of structural units present in the ternary liquid. A physical interpretation, in terms of these structural units, is given for the observed incipient liquid immiscibility.

The nonoxide glass forming chalcogenides are of great interest because of their photoconductive and semiconductive properties. The preparation of these multicomponent materials in well-controlled and characterized states requires the availability of accurate data concerning their liquidus and subliquidus relationships.

Knowledge of the liquidus relationships can be as important for dealing with noncrystalline solids or glasses as for crystalline solids. A great amount of information concerning the nature of a multicomponent glassy material is available through the knowledge of the phase equilibria of the system. The liquidus temperature is the initial point where supercooling of the melt begins in order to realize the glassy state. Indeed it is the temperature interval between the liquidus and the region initiating glass behavior, conveniently demarked by the glass transition, which must be traversed by supercooling to realize the glassy state. The subliquidus and solidus relationships tell of the metastable and equilibrium states to which a supercooled liquid or glass will try to relax with time. Finally, significant insights concerning variations in the atomic arrangements or molecular associations of the melt and the related glassy state can be realized by a detailed investigation of the behavior of the liquidus as a function of composition. The liquidus often reflects variations in molecular associations or clustering in the liquid or glassy state which are not readily revealed by optical spectroscopy or x-ray radial distribution techniques.

The experimental determination and interpretation of the liquidus behavior in the As-Sb-Se ternary system is the object of this study. A thermodynamic method is employed to estimate the size of liquid species or associations in the melt. The thermodynamic approach is the inverse from the usual method of interpreting discrepancies between experimental

Key words: As-Sb-Se system, phase diagram As-Sb-Se, liquid structure, chalcogenide glasses.

and theoretical liquidus behavior by nonideal solution corrections. Instead, liquid species or groupings of the limiting end member structures are identified which can mix and form ideal solutions. These model mixtures are then considered to reflect the molecular constitution of the real multicomponent liquid.

The As-Sb-Se ternary is a very interesting system for these considerations. A great deal of information exists concerning the crystal and liquid structures of the important element and compounds in the system, namely, Se, As_2Se_3, and Sb_2Se_3. The liquid structure of Se exhibits a well-known temperature dependent ring-linear polymer chain equilibria (1-3), liquid As_2Se_3 is considered (4-6) to consist of aggregates of two dimensional $AsSe_{3/2}$ linked groupings, and liquid Sb_2Se_3 appears to be a loosely associated molecular liquid of low viscosity. The Se-Sb_2Se_3 system as indicated by the liquidus reported in the literature (7) shows a tendency for liquid immiscibility, reflecting marked differences in the liquid structures of Se and Sb_2Se_3. Thus, an investigation of the As-Sb-Se ternary system assures the consideration of the mixing of liquid species which in their pure state exhibit markedly different behavior. A number of different sections through this ternary involves the analyses of solutions of widely different molecular constitution.

Experimental

The mixtures necessary for the phase equilibria investigation were prepared by reaction of Gallard Schlesinger 99.9999% pure elemental components in vacuum sealed silica glass ampoules at 650°C for 16 hr in a rocking furnace. The reacted 50 gram samples were quenched in cold water to assure homogeneity. The quenched products were glasses for compositions with less than 20 atomic per cent (a/o) Sb and more than 35 a/o Se. All other compositions resulted in quenched material which was either partially or completely crystalline.

These prereacted mixtures served as standard starting materials in all subsequent DTA and quench runs. To check for possible inhomogeneities and weighing errors in these reacted mixtures, they were all analyzed by x-ray fluorescence. Calibration standards for these analyses were made by two different techniques. The first method for standards preparation was identical to that used in reacting the original mixtures. This was useful for compositions which quenched to a homogenous glass. The second method involved the mixing of As, Sb, and Se powders and subsequent pressing to theoretical density. These powders had to be sieved to a size smaller than 300 mesh to eliminate errors due to particle size. A check of all the mixtures indicated that they deviated no more than the accuracy of the measuring technique (±1 a/o) from their nominal compositions.

The phase equilibria were determined by DTA and quench methods. Due to the volatility of these materials all the work had to be carried out by sealed system techniques. This required the prereacted mixtures to be crushed and packed into specially designed fused silica ampoules which were subsequently used in DTA and quench experiments. The thermal analyses were carried out using a du Pont Model 900 DTA. This data was checked by static equilibration-quench methods to assure its accuracy and identify the phase fields. In the Sb_2Se_3 poor portion of the As-Sb_2Se_3-Se ternary, it was necessary to rely on quench data exclusively due to the high viscosities and slow reaction rates of these materials. The phase assemblages present in the quench runs were analyzed by x-ray powder diffraction methods. The added sensitivity of the Debye-Scherrer method was employed to aid in the accurate locating of phase boundaries.

Experimental Results

The compilation by Hansen (7) gives three different versions of the phase diagram for the Se-Sb system.

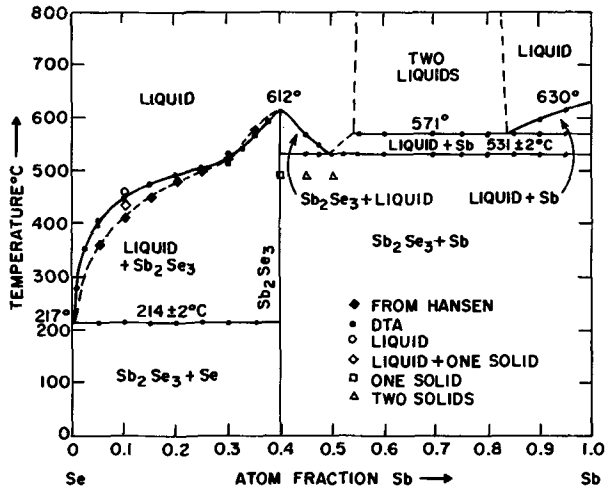

Fig. 1. Phase diagram for the system Se-Sb

In order to determine which of these versions most reliably represents the system, a redetermination has been carried out. Figure 1 contains the results of the present investigation. They are in good agreement with the work of Parravano (8) [from Hansen (7)] except for the detailed shape of the liquidus defining the Sb_2Se_3 + liquid phase field. The present investigation shows a more pronounced flattening of the liquidus indicating a stronger tendency towards liquid immiscibility.

Figures 2 and 3 represent sections in the ternary system which are true binary systems. The information contained in Fig. 1-3 combined with phase equilibria data at compositions distributed on a 5 a/o grid (As-Sb-Se basis) and the phase diagram for the Se-As binary system (5) were used to draw the liquidus for the As-Sb_2Se_3-Se ternary system shown in Fig. 4. A number of additional quench runs were made in the region close to the Se-As binary in order to accurately locate the phase boundaries most of which were located in this region of the ternary system.

Analysis of Ternary Solution Behavior

The experimental liquidus curves will be fitted to thermodynamic model solutions in order to estimate the average size of the liquid species or associations in the As-Sb_2Se_3-Se section of the ternary system. The Se-Sb_2Se_3, As_2Se_3-Sb_2Se_3, and As_4Se_4-Sb_2Se_3 sections are analyzed in detail. All sections have Sb_2Se_3 as one end member, and the liquidus to be analyzed defines the phase field of Sb_2Se_3 + liquid which covers most of this part of the ternary system.

Thermodynamic considerations.—The basic thermodynamic expressions used in this analysis are discussed in detail in most thermodynamic texts (9, 10). In order to convey the argument employed to analyze the liquidus behavior, the appropriate thermodynamic relationships will be outlined.

The basis for all analyses of multicomponent solution behavior is the Gibbs free energy expression

$$G_l = E_o + \int_o^T Cp\, dT - T\int_o^T \frac{Cp}{T} dT - kT \ln \frac{N!}{\prod_i n_i!} \quad [1]$$

The relationship describes the free energy of a solution, G_l, in terms of the internal energy of the solution at absolute zero, E_o, the temperature integrals of the specific heat, Cp, and the statistical complexions of a system of N particles of i distinct species each present in n_i numbers. In this expression the assumption is made that the pressure volume product is negligible making the enthalpy, H, equal to the internal energy, E_o. In addition it is assumed that a set of ideally interacting liquid species can always be defined.

The Gibbs function expressed in this manner is completely capable of representing the free energy of any solution. However in practice, its application is not possible because of the lack of Cp and E_o data. This difficulty is generally circumvented by making a number of approximations to account for the unknown variables. Indeed, the terminology used to describe the thermodynamic nature of solutions has resulted from the type of approximations applied.

The approximations are made in the following manner. The internal energy of the solution, E_o, can be represented as the sum of two quantities.

$$\mathbf{E}_o = U(X) + \sum_i X_i G^o_{li} \quad [2]$$

The first term is generally a nonlinear function of composition and the second term is the weighted sum of the internal energy of the end members in their liquid states, G^o_{li}. The relative concentration of the ith species is defined by $X_i = n_i/N$.

The same type of approximation is made for the two specific heat integrals the only difference being that the nonlinear term is a function of composition and temperature.

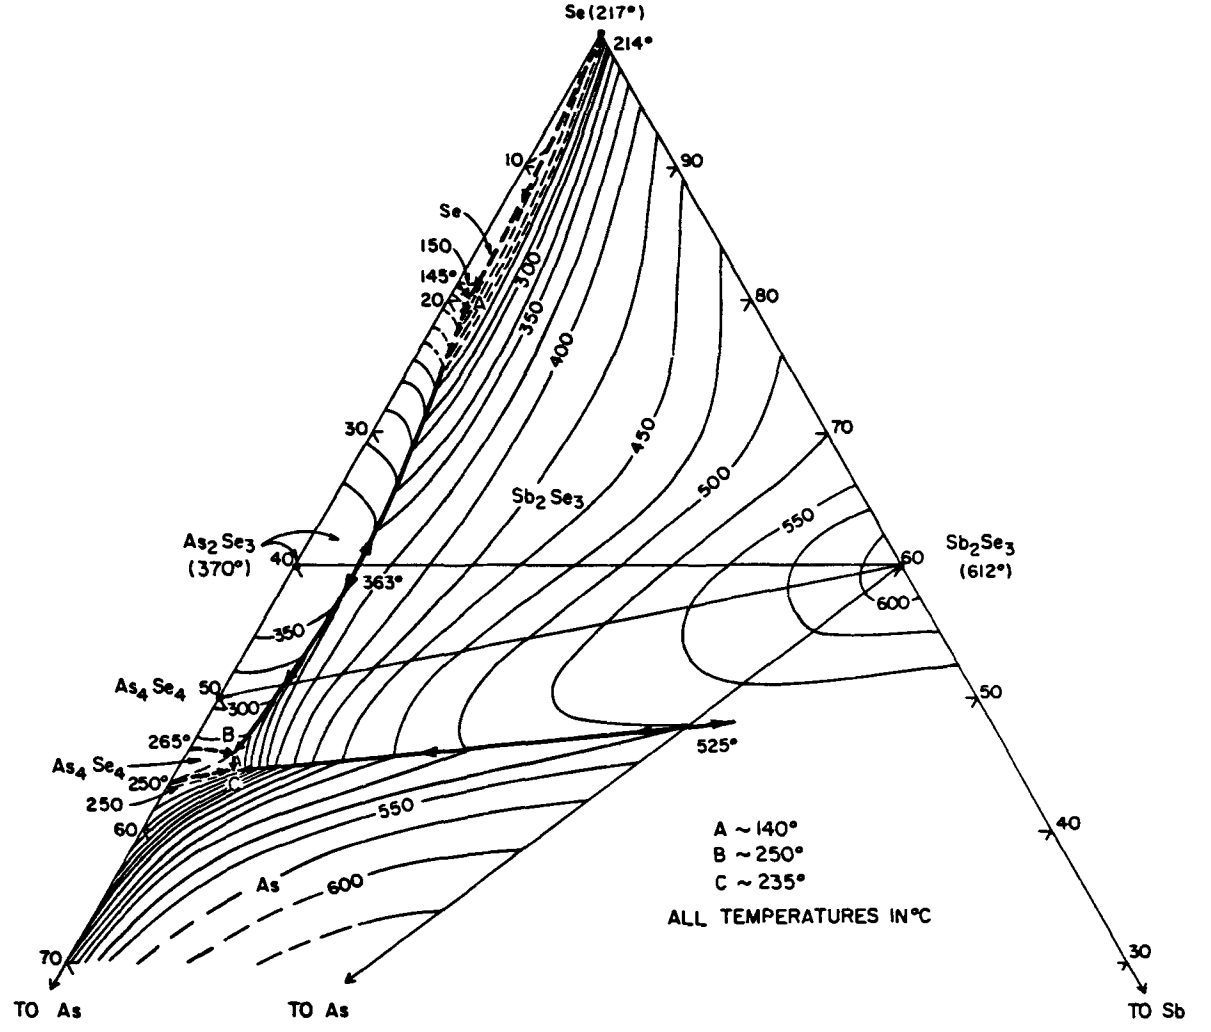

Fig. 4. Phase diagram for the system As-Sb_2Se_3-Se

$$\int_o^T Cp\,dT - T\int_o^T \frac{Cp}{T}\,dT = f(X,T) + \sum_i X_i\,G^T{}_{li} \quad [3]$$

The quantity $G^T{}_{li}$ is the energy of the ith end member obtained from the evaluation of the specific heat integrals. The second terms in Eq. [2] and [3] can be combined so that

$$\sum_i X_i\,G_{li} = \sum_i X_i\,G^o{}_{li} + \sum_i X_i\,G^T{}_{li} \quad [4]$$

Consequently, Eq. [1] can be written as

$$G_l = U(X) + f(X,T) + \sum_i X_i\,G_{li} + RT\sum_{i=1}^{j} X_i \ln X_i \quad [5]$$

The last term in Eq. [1] was transformed to the form in Eq. [5] by making the usual application of Sterling's approximation.

The free energy function expressed by Eq. [5] is the most general form for a solution made up of j distinct components. The equations employed for the various solution types are obtained by making the following approximations:

Ideal solution: $U(X) = 0, f(X,T) = 0$
Regular solution: $U(X) \neq 0, f(X,T) = 0$
Subregular or
nonregular solution: $U(X) \neq 0, f(X,T) \neq 0$

Consequently, for the ideal solution case Eq. [5] reduces to a simple linear combination of the end member parameters. In the regular solution case, this simple form is no longer applicable because the internal energy, $U(X)$, is a nonlinear function of composition. In binary systems, this compositional dependence is approximated (10) by

$$U(X) = \Omega X_1 X_2$$

For $\Omega < 0$, the solution shows a tendency for compound formation and for $\Omega > 0$ there will be a tendency for liquid immiscibility.

The third and most general solution type is the subregular (11) or nonregular (12) solution. In this case both the solution internal energy and specific heat components contribute energies which cannot be represented by a combination of end member quantities. For simplicity the compositional and temperature dependent contributions in Eq. [5] can be combined in the following manner

$$F(X,T) = U(X) + f(X,T)$$

It is noted that except for the $F(X,T)$ term Eq. [5] represents an ideal solution. The question to be asked is, what is the physical significance of $F(X,T)$? The answer has already been given in the name of the term, nonideal. The quantity $F(X,T)$ accounts for the nonideal behavior of the atoms in solution where they exhibit a tendency for the formation of cluster or "molecular" aggregates among like or unlike atoms.

An equally valid way to consider the source of the nonideal term, $F(X,T)$, is that the convenient concentration units employed to describe a solution often do not represent the nature of the molecular constitution of the liquid. In principal, it should be possible to redefine the concentration units of end members in such a way that the actual species present in the liquid are represented as end members and consequently, the property-composition relationships would be that for an ideal solution. For such a solution, composed of complex species, the $F(X,T)$ term will be zero and Eq. [5] will be reduced from the subregular to the ideal case. In choosing these "ideally" interacting species the assumption is made that such a set of species can be defined for any system.

These thermodynamic considerations are applied to the interpretation of the liquidus temperatures by relating free energy ($G_l{}^{X_i}$) of a liquid of composition $X_i{}^l$ to the free energy ($G_s{}^i$) of a coexisting solid end member (i) which has precipitated from the liquid. The condition defining equilibrium for this liquidus composition is

$$G_l{}^{X_i} - G_s{}^i = \left(\frac{\partial G_l}{\partial X_i}\right)_{T_l}(X_i - 1) \quad [6]$$

When Eq. [5] with $F(X,T)$ set to zero is substituted into Eq. [6], the following is obtained (9, 13)

$$(G_l{}^i - G_s{}^i)_{T_l} = -RT\ln X_l \quad [7]$$

where $G_l{}^i$ is the free energy of the end member liquid i. The difference $(G_l{}^i - G_s{}^i)$ is simply the free energy of fusion, ΔG_f, for the pure precipitating end member i at any temperature. The free energy of fusion is given by

$$\Delta G_f = \Delta H_f\left(1 - \frac{T}{T_f}\right) + \int_{T_f}^T \Delta Cp\,dT - T\int_{T_f}^T \frac{\Delta Cp}{T}\,dT \quad [8]$$

where

$$\Delta Cp = Cp\ (\text{liquid}) - Cp\ (\text{solid}) = a + bT + \ldots \quad [9]$$

and ΔH_f is the heat of fusion and T_f is the melting temperature.

The combination of Eq. [7], [8], and [9] provides a general equation for the liquidus of a precipitating end member in a multicomponent solution. The restrictions on its application require the precipitating end member to melt to a liquid specie whose stoichiometry is identical to that of the end member and concentration units are employed so that the liquid displays ideal behavior.

Analyses.—The application of this method to analyze the constitution of the liquid solution is straight forward. An ideal liquidus is calculated for a particular system with Eq. [7], [8], and [9]. Then the experimental liquidus is transformed to a coordinate system whose end members represent the molecular species which may be present in the liquid. If the ideal liquidus and the transformed experimental liquidus coincide, a possible solution has been obtained. It is noted that the ideal liquidus will always be numerically (X *vs.* T) the same independent of the section analyzed in the multicomponent system as long as the precipitating end member is not changed (*i.e.* as long as ΔH_f and ΔCp remain constant and the end member liquid specie does not vary with composition or temperature).

The coordinate or concentration transformation is carried out by a two-step process for the particular ternary system under consideration. The first transformation changes the experimental As-Sb-Se ternary coordinate data into a convenient As_uSe_v-Sb_2Se_3 binary coordinate system employing Eq. [10].

$$y = \frac{u - (u+v)y'}{u + (5 - u - v)y'} \quad [10]$$

The variable y' designates the antimony concentration, y represents the Sb_2Se_3 concentration, and u and v can assume any positive or zero value to define the section of interest. The second transformation involves going from this convenient As_uSe_v-Sb_2Se_3 binary section to a complex coordinate system representing the liquid species. The equation for this transformation will be developed for each specific case.

Three binary sections of the As-Sb-Se ternary will now be analyzed in detail. All of the sections have Sb_2Se_3 as a common end member. Consequently all of the analyses will use a common ideal liquidus for the comparison. The fusion temperature (T_f), the enthalpy of fusion (ΔH_f) and the ΔCp for Sb_2Se_3 used in the calculations are 612°C, 12,970 cal/mole and 18.9 cal/deg mole, respectively (14). The specific heat difference for Sb_2Se_3 was estimated from enthalpy data in the temperature region of the fusion temperature.

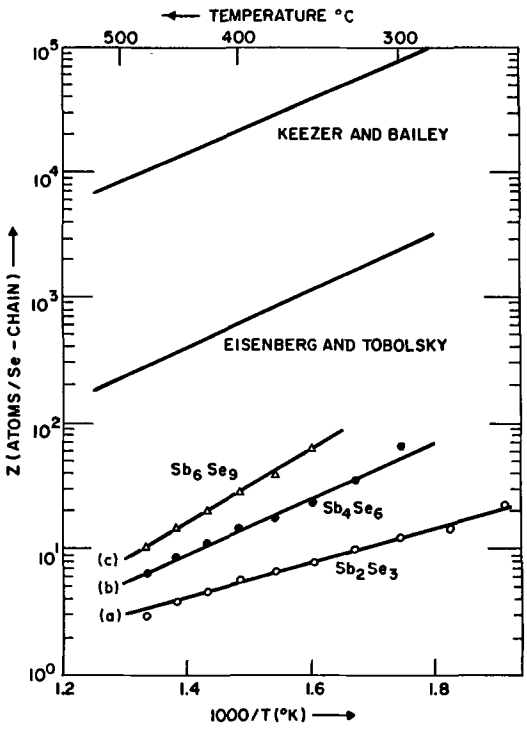

Fig. 5. Temperature dependence of the number average selenium chain length.

The Se-Sb_2Se_3 system.—In order to ascertain possible end member species for the experimental liquidus transformation, evidence for the limiting molecular configurations in this system will be examined. Consideration of the temperature dependence of the viscosity and the specific heat and the solubility or lack of solubility of various forms of Se in CS_2 has lead to the view that liquid selenium consists of a dynamic equilibrium between long polymer chains and eight-membered rings. The results of two different chain length calculations (2, 3) are shown in Fig. 5. The absolute magnitudes for the average chain lengths vary considerably between the two references but the temperature dependences are in good agreement.

The crystal structure for Sb_2Se_3 (15) indicates the presence of well-defined layer like chains with no obvious evidence for distinct $w Sb_2Se_3$ molecules. The melting of these crystals may be envisioned as disordering of the layers and a fragmentation of the chains into smaller $w Sb_2Se_3$ units. Observation of the Sb_2Se_3 melt indicates that it is a highly fluid liquid which cannot be readily quenched into a glass. Based on this observation (w) will probably be small assuming values such as 1, 2, 3, or perhaps 4.

As a first approximation the liquid species present in the Se rich part of the Se-Sb_2Se_3 system will be assumed to consist of Se_8 rings, Se_z chains, and a specie having the Sb_2Se_3 stoichiometry which will be designated by $w Sb_2Se_3$. Figure 6 contains the results of two sets of calculations which transformed the experimental liquidus data for the binary system

$$Se - Sb_2Se_3 \rightarrow (R)Se_8 - (1-R)Se_z - (w)Sb_2Se_3 \quad [11]$$

This transformation was carried out using Eq. [12]

$$X = \frac{y/w}{(1-y)\left[\frac{R}{8} + \left(\frac{1-R}{z}\right)\right] + \frac{y}{w}} \quad [12]$$

In this equation, the variable y designates the Sb_2Se_3 concentration in the Se-Sb_2Se_3 coordinate system and X represents the concentration of $w Sb_2Se_3$ in the ternary system. The quantity designated by X is identical to the ideal liquidus which was calculated using

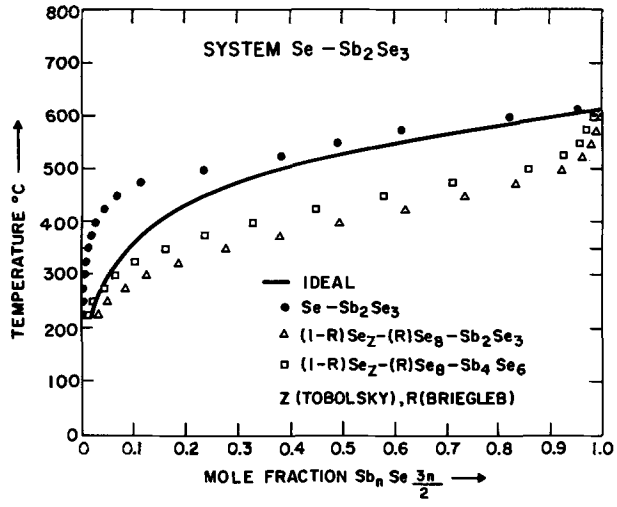

Fig. 6. Liquid structure calculation results for the system Se-Sb_2Se_3.

Eq. [7]-[9]. The variable R represents the fraction of Se in the Se_8 form, and Z is the chain length of the linear polymer molecules. In these transformations the magnitude of R and Z are those of Briegleb (1) and Eisenberg and Tobolsky (2) respectively.

The results of the two transforms designated by open triangles and squares in Fig. 6 were computed for $w = 1$ (Sb_2Se_3) and $w = 2$ (Sb_4Se_6) respectively. These calculations indicate that additional transforms using the same R and Z with other values of w would never result in a resonable fit between the transformed experimental and the ideal liquidus.

A more realistic approach to this problem requires the differentiation between a solution which is concentrated in Sb_2Se_3 and one which is dilute in Sb_2Se_3 (Se rich). If in the dilute solution case it is assumed that the ratio of the rings to chains is the same as for pure selenium but that the chain length as specified by Eisenberg and Tobolsky (2) or Keezer (3) is no longer valid, a magnitude for Z can be calculated using Eq. [12] and the experimental liquidus data. In Fig. 5 the results of these calculations carried out for various values of w are plotted. It is noted that the magnitude of Z for $w = 2$ (Sb_4Se_6) produces a curve whose temperature dependence is the same as the results of the previous workers (2, 3). On the basis of these chain-length temperature dependencies, Sb_4Se_6 is considered to be the best choice for the antimony triselenide specie. These observations suggest that Sb additions are not directly involved in the selenium polymerization reaction; however, they are effective selenium consumers decreasing the amount of selenium available for chain formation and their presence will change the configurational entropy of the solution. A similar but not completely analogous behavior was found for arsenic in arsenic-sulfur solutions (16).

The liquidus curves calculated based on these considerations is shown in Fig. 7. The open triangles show the fit obtained if the transform by Eq. [12] is carried out using the Briegleb (1) ring-chain concentrations (R), the calculated chain length denoted by (b) in Fig. 6, and the molecular unit for $w = 2$ (*i.e.* Sb_4Se_6).

The fit of the transformed data to the ideal liquidus is good, as it should be because the calculations were circular in nature. The experimental liquidus data was used to determine the chain lengths and "Sb_4Se_6" molecule for the transformation. At first it appears that no new information has been obtained, however this is not the case since these calculations have established that Sb_4Se_6 is a reasonable choice for the average molecular unit to which Sb_2Se_3 melts. This specie will be employed for all of the computations involving Sb_2Se_3 in other sections of the ternary system.

The concentrated solution case, near the Sb_2Se_3 end member, is not nearly as complicated as the dilute

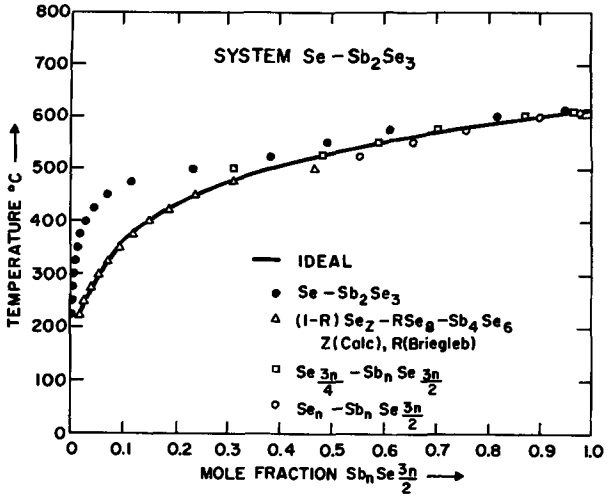

Fig. 7. Liquid structure calculation results for the system Se-Sb_2Se_3.

solution case. As indicated by the solid circles of Fig. 7, the Se-Sb_2Se_3 experimental liquidus almost coincides with the ideal liquidus in the Sb_2Se_3 rich portion. From this starting point, it was assumed that no Se_8 rings remained in these concentrated solutions, and that the liquid was composed of only two species Se_z chains and $w Sb_2Se_3$ aggregates. The open squares and circles of Fig. 7 show that the best fit results in liquid species where the Se chain is either three or four atoms long and the second species is Sb_4Se_6.

The As_2Se_3-Sb_2Se_3 system.—It has been concluded from viscosity (4), glass transition (5), infrared (6), and x-ray (17) studies that As_2Se_3 glasses are composed of $AsSe_{3/2}$ linkages forming $As_mSe_{3m/2}$ aggregates or networks. This conclusion will be applied to the interpretation of this binary system by carrying out the following transformation

$$As_2Se_3 - Sb_2Se_3 \rightarrow As_mSe_{3m/2} - (w)Sb_2Se_3 \quad [13]$$

by

$$X = \frac{y/w}{(1-y)\left(\frac{2}{m}\right) + y/w} \quad [14]$$

The variables X and y were identified in transformation 12 and m is an integer which specifies the size of the arsenic triselenide aggregate.

The transformation specified in Fig. 8 indicates that the best fit is for a liquid solution where the w/m ratio in Eq. [13] is one. Assuming the value of 2 for w the molecular constitution of the As_2Se_3-Sb_2Se_3 system in the 30 to 100 mole per cent (m/o) Sb_2Se_3 range would be a mixture of "average" species, of As_2Se_3 and Sb_4Se_6.

The As_4Se_4-Sb_2Se_3 section.—It is expected that no As_4Se_4 species should exist in the liquid because As_4Se_4 is an incongruently melting compound (5). That is to say, a liquid with an $As_{0.50}Se_{0.50}$ composition will probably be composed of liquid species other than those representative of the crystalline compound. This deduction is supported by x-ray analysis (17) of As_4Se_4 glasses where it appears that $AsSe_{3/2}$ dominates the short range order. Based on this knowledge, the following transformation will be employed

$$As_4Se_4 - Sb_2Se_3 \rightarrow As_\phi Se_p - (w)Sb_2Se_3 - As_{z'} \quad [15]$$

and carried out with Eq. [16]

$$X = \frac{y/w}{(1-y)\left[\frac{4}{p} + \left(4 - \frac{4\phi}{p}\right)\left(\frac{1}{z'}\right)\right] + \frac{y}{w}} \quad [16]$$

A large number of trial solutions determined the best fit to be a coordinate system having $As_3Se_{9/2}$, Sb_4Se_6 and As_4 or As_6 as end members. These results are shown in Fig. 9. Of the three alternate sets of solutions given in Fig. 9, the last one ($As_3Se_{9/2}$-Sb_2Se_3-As) is discarded because the Sb_2Se_3 is not consistent with previous considerations. The other two sets are nearly identical except for a slight difference in the size of the As molecules. In comparison with these results, it is noted that As_4 is the predominant molecular species found in As vapor (18). Particularly for molecular substances, there are often strong similarities between liquid and vapor species hence the above species appear reasonable.

Discussion and Conclusion

The results of the three sets of analyses of the experimental liquidus curves are summarized in Table I. It becomes apparent that the incipient liquid immiscibility in the Se-Sb_2Se_3 system is due to two types of liquid solutions composed of different molecular species. In the selenium rich part of the system, there is the temperature dependent equilibrium mixture of rings and chains in solution with a specie of antimony triselenide. In the selenium poor part of the system, the Se_8 rings are absent, and the liquid solution consists of very short selenium chains (Se_3 or Se_4) and an antimony triselenide liquid species. Within the assumptions made in the calculations, it is concluded that Sb_4Se_6 is the most probable average molecular specie for the antimony triselenide melt for all concentrations analyzed.

The results of the calculations on *in situ* liquids in the As_2Se_3-Sb_2Se_3 system indicate that the average

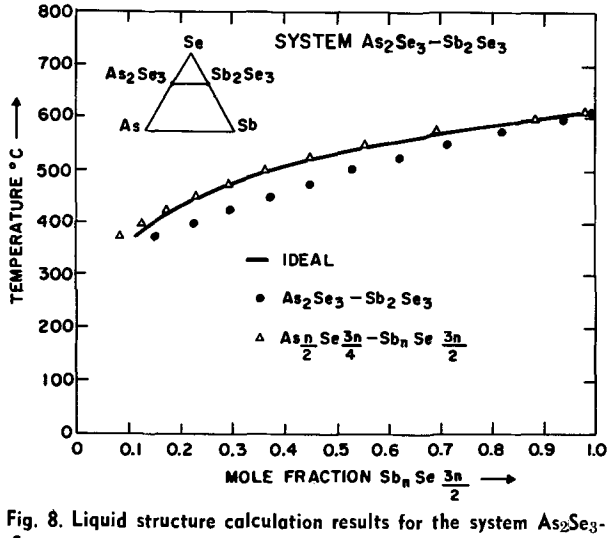

Fig. 8. Liquid structure calculation results for the system As_2Se_3-Sb_2Se_3.

Table I. Possible liquid species from the thermodynamic analyses of the specified systems

System	Liquid species	
	Dilute (Sb_2Se_3 poor)	Concentrated (Sb_2Se_3 rich)
$Se - Sb_2Se_3$	$(1-R)Se_8 - (R)Se_3 - Sb_4Se_6$ $z = 70(280°C) \longleftrightarrow 5(500°C)$	$Se_{3n/4} - Sb_nSe_{3n/2}$ $Se_n - Sb_nSe_{3n/2}$ } $n = 4$
$As_2Se_3 - Sb_2Se_3$		$As_{n/2}Se_{3n/4} - Sb_nSe_{3n/2}$ $n = 4$
$As_4Se_4 - Sb_2Se_3$		$As_8Se_{9/2} - Sb_2Se_3 - As$ $As_8Se_{9/2} - Sb_4Se_6 - As_4$ $As_8Se_{9/2} - Sb_4Se_6 - As_6$

liquid species are As_2Se_3 and Sb_4Se_6. The high viscosity and easy quenchability of the As_2Se_3 liquid has been previously related to a structure consisting of aggregates of $AsSe_{3/2}$ linked networks. It would appear that the As_2Se_3 species found in the As_2Se_3-Sb_2Se_3 system are not consistent with such properties. However, it should be noted that the present analysis is only valid for solutions with appreciable amounts of Sb_2Se_3 present. The phase equilibria work carried out in this investigation has found that the addition of Sb_2Se_3 to As_2Se_3 has a radical effect on the viscosity of the melt and the crystallization kinetics of As_2Se_3 crystals. Pure As_2Se_3 is extremely viscous and crystals grow very slowly, whereas at a composition of 20 m/o Sb_2Se_3, a glass will devitrify quite readily with the relatively rapid formation of As_2Se_3 crystals. These observations support the presence of smaller or less associated As_2Se_3 species calculated for the binary system.

The liquid in the As_2Se_3-Se-Sb_2Se_3 ternary also has a tendency towards immiscibility as can be seen in the flattening of the liquidus in Fig. 4. From the information obtained from the Se-Sb_2Se_3 and the As_2Se_3-Sb_2Se_3 systems, it is possible to estimate the type of liquid species present in the ternary solutions. The properties of the selenium rich liquid are still dominated by the temperature dependent ring-chain equilibrium. This part of the system is made up of Se_z chains, Se_8 rings, Sb_4Se_6 molecules, and $AsSe_{3/2}$ network elements. As the selenium content of the liquid decreases the dominance of the ring-chain equilibrium decreases and finally disappears resulting in a liquid made up of As_2Se_3, Sb_4Se_6, and possibly Se_z (z is small) depending on the composition of the liquid.

The analysis of the As_4Se_4-Sb_2Se_3 section (Table I) indicates that with the exception of compositions near As_4Se_4 the system is composed of $As_8Se_{9/2}$, Sb_4Se_6, and As_4 species. The presence of As_4 is not expected to have a strong influence on the properties of the liquid because it is present as a minor constituent in this particular section. The molecular constitution of this section is quite similar to the As_2Se_3-Sb_2Se_3 system, as indicated by similarities in viscosity and crystallization behavior.

ABSTRACT

A high-temperature hoop stress measurement apparatus has been developed for ring specimens of CVD tungsten or other refractory metal alloys. This apparatus has the advantage of being adaptable for high-temperature tensile testing. Force is applied to a tapered cone which transmits force to eight equal segments which press uniformly on the inner surface of the ring specimen. The specimen is heated by induction in either vacuum or a protective atmosphere. Equations are developed for stress and strain from hoop stress parameters. Room temperature hoop and tensile tests on aluminum, copper, and brass specimens were compared to ascertain the role of friction in the hoop stress tests. For temperatures up to 1400°C, the effective friction coefficient, μ, of the hoop testing apparatus was determined using CVD tungsten in a similar manner. Design details and the results of the elevated temperature tests on CVD tungsten are discussed.

In recent years there has been wide use of chemical vapor deposition (CVD) techniques to produce refractory metals and alloys. The most common CVD product has been thin-walled tubing. Standard tensile specimens are very difficult to prepare from such tubing.

Holman, Stiles, and Fung (1) have developed an apparatus for room temperature tensile tests of CVD rings. However, the mechanical behavior of tubular CVD materials at elevated temperatures had not been evaluated heretofore. A high temperature hoop stress measurement apparatus was developed for this purpose and is described in this paper. This new apparatus has the additional advantage of being adaptable to high temperature tensile testing.

Apparatus

Figure 1a shows a schematic of the high-temperature hoop stress apparatus. A downward force is applied to a tapered graphite cone which transmits force to eight equal segments that press out uniformly on the inner surface of the ring specimen putting the ring into tension. These components are shown in Fig. 1b. A helium gas atmosphere was used. Figure 2 shows a schematic of the high temperature tensile test apparatus. The transformation from hoop testing to tensile testing requires that only the support block and graphite cone be replaced by pull rods and specimen grips.

For descriptive purposes the apparatus is divided into the following parts: furnace chamber and heating system, load train, and temperature measurement.

Furnace chamber and heating system.—The furnace chamber is basically a 10 in. diameter stainless steel pipe, 13 in. high with ⅜ in. thick stainless steel flanges. A stainless steel plate is sealed with an O-ring to the top flange on the chamber. Motion of the upper pull (or compression) rod is achieved through a stainless steel bellows. The pull rod is a 15/16 in. diameter stainless steel rod, 7 in. long. The bottom flange of the chamber is O-ring sealed to a large stainless steel plate. A 2 in. long, 15/16 diameter stainless steel pull rod is welded to the bottom plate as shown in Fig. 2. Two flanged openings are provided on opposite sides of the heating chamber. A Pyrex window facilitates observation (for temperature measurement with an optical pyrometer) as well as vacuum and/or gas atmosphere introduction. The other flanged opening admits the induction coil. Water cooled copper tubing is wound around the outside and on the top of the furnace chamber.

A tantalum susceptor, heated by induction, radiates heat to the specimen. The power supply is a 20 kW Lepel Induction generator with a frequency of approximately 360,000 Hz. A 12:3 lead coil transformer is placed between the output of the generator and the vacuum seal coaxial lead into the furnace chamber. A 4-turn copper tubing coil with an inner diameter of 3 in. and a length of 1 in. was used for ring specimens. An inner diameter of 1¼ in. and a length of 1 in. was used for tensile specimens. The seamless tantalum susceptor had a ⅛ in. sighting hole to permit temperature measurement by an optical pyrometer.

Load train.—Hoop stress test apparatus.—The entire load train assembly is shown in Fig. 1a. The top of the stainless steel compression rod is threaded to the main compression rod. A ZrO_2 post, 2 in. in diameter and 1 in. high, is placed between the end of the compression rod and the top of the graphite cone to provide thermal insulation. Eight equal split ring graphite segments are set around the tapered cone; the angle of taper is 5°. Eight equal segments of a split ZrO_2 ring are placed between the graphite segments and the CVD ring specimen in order to prevent any possible carburization reaction between the graphite and the CVD tungsten. A ZrO_2 tube serves as a support for the two split rings, the specimen, and the cone. A typical CVD ring specimen is illustrated in Fig. 3b.

Tensile test apparatus.—The entire load train assembly is illustrated in Fig. 2. The top and bottom stainless steel pull rods are threaded into molybdenum alloy couplings. The latter are linked to molybdenum alloy pin grips. A typical flat CVD tungsten tensile specimen is illustrated in Fig. 3a.

Key words: deposition, hoop stress, high-temperature mechanical tests, chemical vapor deposition.

Fig. 1. High-temperature hoop stress measurement apparatus.

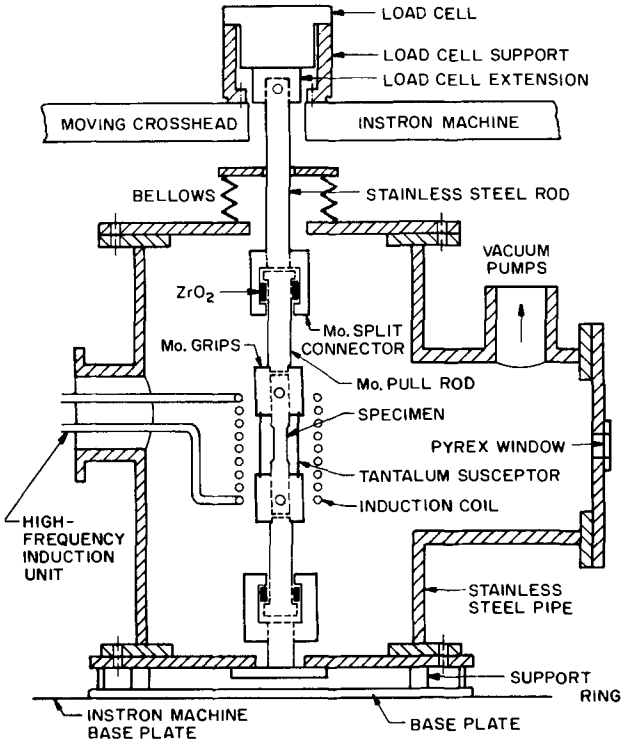

Fig. 2. High-temperature tensile testing apparatus

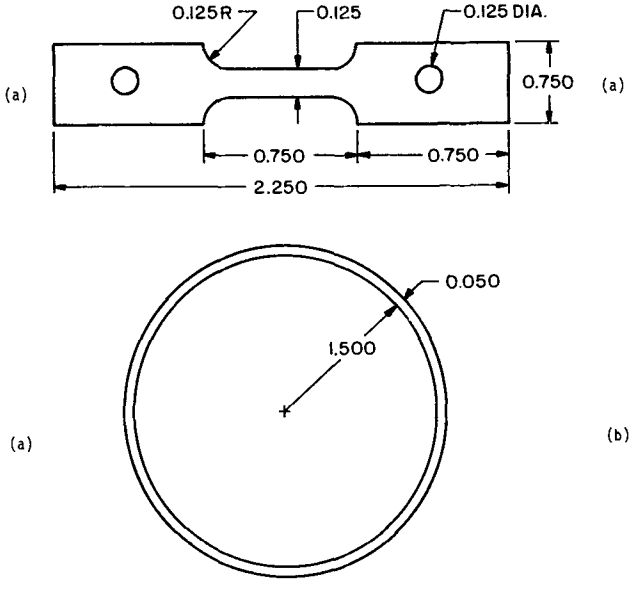

Fig. 3. Diagram of flat tensile (a) and thin-walled (b) specimens.

Temperature measurements.—Temperature measurements were made with an optical pyrometer calibrated by the National Bureau of Standards. An experiment was performed to estimate the temperature difference between an optical pyrometer focused on the specimen and a tungsten 5% rhenium-tungsten 26% rhenium thermocouple placed near the specimen. At 1400°C in a vacuum of 10^{-5} Torr, a temperature difference of 25°C was detected. In all subsequent tensile and hoop tests, the temperature was measured by the optical pyrometer.

Experimental

Sample preparation.—CVD tungsten tubes of 1.5 in. inside diameter and 0.050 in. wall thickness and flat 0.040 in. thick strips of CVD tungsten were purchased from the San Fernando Laboratories of Fansteel Metallurgical Company. The deposition conditions and chemical composition are presented in Tables I and II.

Ring specimens, ¼ in. long, were cut using a lathe tool post grinder with a 0.020 in. thick silicon carbide cutoff wheel operating at approximately 7000 rpm. The CVD tungsten tube was held in a soft collet. Gage

length and pin holes for flat tensile specimens were spark cut. Any slight damage to the specimen caused by spark cutting (and tool post cutting) was removed by electro-polishing (20g NaOH + 980 cc distilled water). The electropolishing produced a reduction of thickness of approximately 0.002 in.

Determination of texture.—Textures of flat and thin-wall tube CVD tungsten specimens were evaluated by the inverse pole figure x-ray technique (2, 3). A series of composite x-ray specimens were prepared from each of longitudinal, circumferential, outside and inside sections of the tubes, as illustrated in Fig. 4. The specimens were cut in a Servomet Spark Machine and electropolished. A GE X-RD5 diffractometer was used to measure the diffracted intensities. Texture results are expressed in terms of texture coefficients $TC_{(hkl)}$.

Testing procedure.—With the load train and specimen installed, the furnace chamber was evacuated, helium gas was admitted to the chamber, the specimen was slowly heated to the test temperature and left at this temperature for a period of 5 min to establish thermal equilibrium. Hoop stress and tensile tests were performed with an Instron Tensile Machine at a cross-head speed of 0.01 in./min.

Derivation of the Hoop Stress Equation

If a downward force F is applied to the graphite cone, see Fig. 1b, the conditions for equilibrium require

$$F = A_1N_1 (\sin \alpha + \mu_1 \cos \alpha) \quad [1]$$

where A_1 is the area of the tapered surface in contact with the split graphite ring, N_1 is the normal pressure on the tapered surface of the cone, α is the angle of taper, and μ_1 is the friction coefficient between the graphite cone and the graphite split ring.

Considering the split ring, the conditions for equilibrium require

$$A_2N_2 = A_1N_1 (\sin \alpha + \mu_1 \cos \alpha) \quad [2]$$

where A_2 is the total area of the bottom of the split ring and N_2 is the normal pressure on that area. Similarly, equilibrium requires that for the split ring, in the radial direction

$$A_rP + A_2N_2\mu_2 = A_1N_1 \cos \alpha - A_1N_1\mu_1 \sin \alpha \quad [3]$$

where A_r is the inner area of the ring specimen, P is the pressure on the inner surface of the ring, and μ_2 is the friction coefficient between the split ring and the support block.

Dividing Eq. [1] by Eq. [3], using the fact that from Eq. [1] and [2] $F = A_2N_2$, and assuming that μ_1 equals μ_2[1], then P is expressed by

$$P = \frac{F}{A_r}\left[\frac{(1-\mu^2)\cos\alpha - 2\mu\sin\alpha}{\sin\alpha + \mu\cos\alpha}\right] \quad [4]$$

If Eq. [4] is substituted into the hoop stress equation

[1] This assumption will be unnecessary in future work where the support block will also be graphite and the ZrO_2 split ring will not be in contact with the latter.

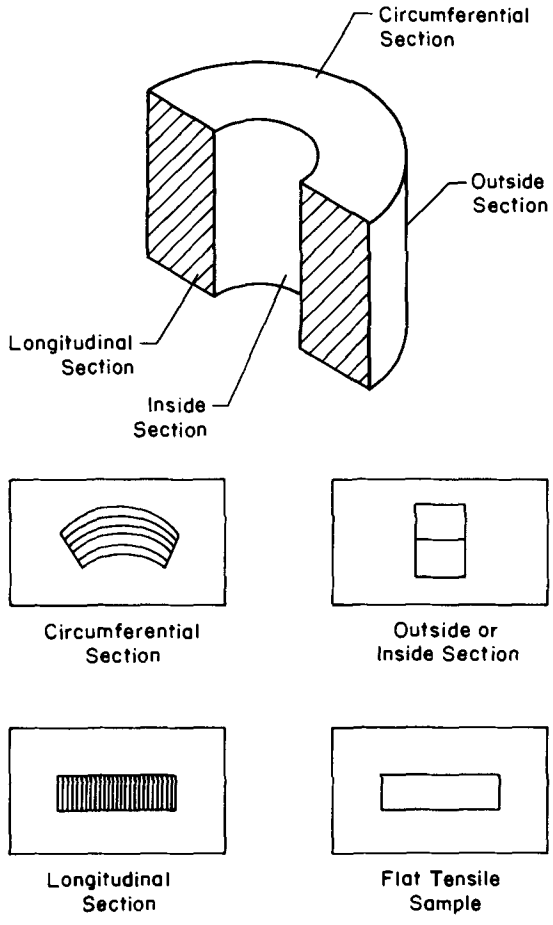

Fig. 4. Section designations for thin-walled CVD tungsten tubes and typical composite samples.

$$\tau_{hoop} = \frac{Pr}{t} \quad [5]$$

where τ is the circumferential stress, r is the internal radius of the ring specimen, and t is the ring thickness, then the hoop stress is expressed by

$$\tau_{hoop} = \frac{F[(1-\mu^2)\cos\alpha - 2\mu\sin\alpha]}{2\pi ht\,[\sin\alpha + \mu\cos\alpha]} \quad [6]$$

h being the height of the ring. Equation [6] has two unknowns, τ_{hoop} and μ the friction coefficient. The friction coefficient can be obtained from the following relation, assuming the tensile yield stress to equal the value of the hoop stress at yielding (See Appendix A).

$$\mu = \frac{-(\sigma/k\cos\alpha + 2\sin\alpha) + [(2\sin\alpha + \sigma/k\cos\alpha)^2 - 4\cos\alpha(\sigma/k\sin\alpha - \cos\alpha)]^{1/2}}{2\cos\alpha} \quad [7]$$

16	Brass	1/16	1/16	8968	48,000	5.35	0.115
17	Brass	1/16	1/16	8560	48,000	5.607	0.104
18	Brass	1/16	1/16	9375	48,000	5.12	0.120
19	Brass	1/16	1/8	9273	48,000	5.1763	0.117

Here k is $F/2\pi ht$ and σ is the yield stress, separately obtained from a tensile test. It can be shown that the strain is expressed by

$$\epsilon = \frac{C_f - C_i}{C_i} = \Delta r/r_i$$

$$\epsilon = \frac{(\text{vertical distance moved by cone}) \tan \alpha}{r_i} \quad [8]$$

where C_i is the initial circumference, C_f is the final circumference, and r_i is the initial radius of the ring specimen.

Experimental Results and Discussion

Mechanical behavior at room temperature.—The relation between hoop stress and tensile stress has been studied with respect to the influence of friction at room temperature for the metals aluminum, copper,

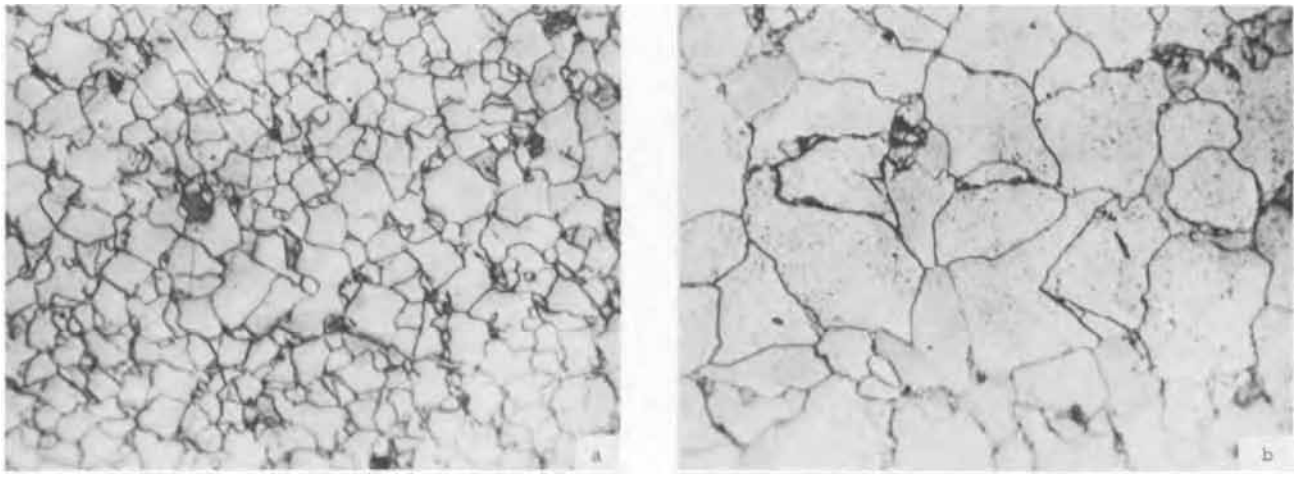

Fig. 5. Typical grain structure of flat specimens (300X). (a) Grain diameter of first deposited surface: 6.8 x 10^{-4} in. (b) Grain diameter 0.040 in. from first deposited surface: 1.1 x 10^{-3} in.

and brass. The tensile and hoop stress specimens were produced from the same plate for each metal.

The cone, split ring, and support block were of stainless steel. The results of tensile tests for these metals are summarized in Table III. The 0.2% yield stress values for each metal are self-consistent and reproducible. From tensile tests enumerated in Table III, the average value of 0.2% offset yield stress for brass is 48,000 psi, for aluminum 38,000 psi, for copper 17,000 psi. These values were substituted into Eq. [7] to obtain the effective friction coefficients for hoop stress measurements at room temperature. The effective friction coefficients for these metals are summarized in Table IV. For copper it varies from 0.17 to 0.19, for aluminum from 0.12 to 0.14, and for brass from 0.11 to 0.12. Thus, each metal has a very consistent and reproducible effective friction coefficient value. Since these results indicated the feasibility of hoop stress measurement at room temperature, the technique was extended to temperatures up to 1400°C for CVD tungsten.

Mechanical behavior at elevated temperatures.— Grain size and texture differences between the flat and thin-wall tube CVD tungsten were carefully noted since these could give mechanical property differences. Figure 5 shows typical flat specimen grain structures. The grain size of the first deposited surface was approximately 6.8 x 10^{-4} in. and 0.040 in. away from the first deposited surface the grain diameter became approximately 1.1 x 10^{-3} in. Figure 6 shows the grain structure of an as deposited CVD ring specimen. The first deposited surface grain diameter is approximately 3.1 x 10^{-4} in. and 0.050 in. away from the first deposited surface, the grain diameter was approximately 1.1 x 10^{-3} in. The tube outside surface grain diameter was almost the same as the last deposited surface of the flat specimens. Texture coefficients, $TC_{(hkl)}$, values for the various diffracting planes are plotted in standard stereographic triangles in Fig. 7. Contour lines include regions of similar TC values.

Circumferential, longitudinal, outside and inside tube sections have {100} as the highest intensity and a <100> fiber axis exists along the length of the tube. These results are similar to earlier findings of others (4, 5).

Figure 8 shows the temperature dependence of the 0.2% offset yield stress and the ultimate tensile stress of flat specimens. The temperature dependence of the elongation is shown in Fig. 9. The yield stress of 6,600 psi at 1400°C and the elongation of 30% at 1400°C are in good agreement with Taylor's (6) results.

The 0.2% yield stress values were substituted into Eq. [7] to obtain the friction coefficient μ for hoop stress tests at each temperature. The results are summarized in Table V. Figure 10 shows that μ decreases linearly with increasing temperature. Table VI shows that the strains calculated by Eq. [8] give very good agreement with the actual measurements. Appendix A presents some background equations and discussion of friction between specimen and segments.

Table V. Hoop stress data

Temperature (°C)	σ(Y.S. psi) from a tensile test	F (lb)	$k = F/2\pi ht$	σ/k	μ
800	6,900	315	4013	2.39	0.28
1000	8,500	240	3058	2.78	0.24
1200	7,300	170	2166	3.37	0.19
1400	6,600	120	1529	4.32	0.14

Table VI. Comparison of measured and calculated values of hoop strain

Temperature (°C)	Total measured strain (%)	Cross-head travel of instron (inches)	Strain calculated from Eq. [8] (%)
800	3.7	0.31	3.6
1000	2.4	0.19	2.2
1200	4.4	0.38	4.4
1400	4.4	0.38	4.4

Conclusions

The mechanical behavior at elevated temperatures of thin-walled CVD refractory metal tubing now can be evaluated directly from hoop stress tests. To do so, the friction coefficient, μ, of the apparatus must first be calibrated *via* tensile tests through the desired temperature range uisng the equation developed in this paper. The yield stress and elongation can then be readily calculated for hoop stress tests. Due to the segmented nature of the pressure on the specimen ring interior, one finds at larger plastic strains that straight chords develop between these segments. This makes the plastic behavior different from that of an ordinary tensile test. We therefore mainly advocate use of this method to determine high temperature yield stress values, although on a relative basis, the ring test is extremely useful in the plastic range as well.

The hoop stress method described here may be well suited to future application in the determination of friction coefficients of high-temperature materials. These would be used in the cone, base, and split ring components during such evaluation.

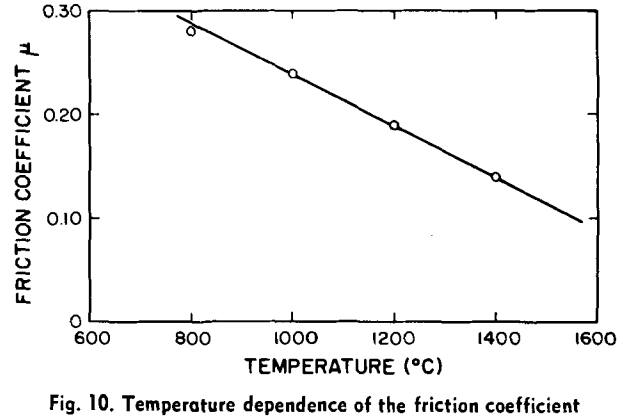

Fig. 10. Temperature dependence of the friction coefficient

APPENDIX A

Clearly the hoop stress test described produces seven straight unsupported chords in a ring specimen, between the eight ZrO_2 segments. This raises several questions: (*A*) Can a 0.2% offset yield stress value from a tensile test be put into Eq. [7] to evaluate μ? (*B*) What influence does friction between the segments and the specimen have? (*C*) How valid is Eq. [8]?

(*A*) If one calculates the change in circumference of a ring of radius 0.75 in. necessary to produce a 0.2% strain, the result is 0.00094 in. If this is distributed over the seven chords the individual chord length or segment separation distance would be 0.000135 in. If some of the 0.2% strain is distributed over supported specimen lengths as well, then clearly the segment separation is even less significant. In either case the tensile stress and strain should be essentially the same at all locations around the circumference of a ring.

(*B*) Frictional stress between the segments and the specimen should act on the inner surface of the specimen in a sense opposite to the tensile stress. Timoshenko (7) showed that the circumferential stress, σ_θ, in a cylinder of inner radius a and outer radius b, subject to internal pressure p_i is

$$\sigma_\theta = \frac{a^2 p_i}{b^2 - a^2}\left(1 - \frac{b^2}{r^2}\right) \qquad [9]$$

This stress is a maximum on the inner surface; however, if $b \leq 1.1a$, then σ_θ max, exceeds σ_θ min by only 10.5%. Thus one can assume a uniform stress equal to $p_i a/(b-a)$ through the wall thickness when $b \leq 1.1a$. This formula is the same as our Eq. [5]. In our case a and t are approximately 0.75 in. and 0.050 in., respectively; so that we are well within this limit. However, if there is some unbalance such that the applied tensile stress is higher at the inner surface, then the direction of any segment-specimen friction should help remove the unbalance. At plastic strains beyond the yield point seven straight chords should develop in the specimen. In the specimen parts in contact with the segments, the circumferential frictional force should be $A_r P \mu_3/16$, in which A_r and P are as defined in the text and μ_3 is the appropriate friction coefficient. The 16 comes from considering each half of each of the eight segments. On the outer specimen surface the friction force is zero, so on the average the stress contribution on the ring cross-section from friction would be $A_r P \mu_3/32$. Thus in the unsupported regions the stress would be the ordinary hoop stress Pr/t, but in the supported sections the stress would be $Pr/t - A_r P \mu_3/32ht$ or

$$\sigma_s = \frac{Pr}{t}\left(1 - \frac{2\pi\mu_3}{32}\right) \qquad [10]$$

where the subscript s on σ represents "supported." Thus beyond the yield point one may expect stress fluctuations from supported to unsupported regions of approximately 6% if $\mu_3 \simeq 0.3$. This consideration need not be considered with regard to Eq. [7] for the reason given in item 1 above but should be considered in the plastic range.

(*C*) Despite the problem raised in item (*B*) above, Eq. [8] does seem to predict the values of elongation at fracture fairly well. Equation [8] should, however, only be regarded as a first approximation to the actual situation.

Thermodynamic Properties of Ternary Refractory Carbides

I. Zirconium-Niobium-Carbon

C. K. Jun and M. Hoch

Department of Materials Science and Metallurgical Engineering, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

The nonstoichiometry of zirconium-niobium-carbide with the sodium-chloride type structure, $Zr_xNb_{1-x}C_y$, was studied by measuring the activities of the components as a function of composition. Equations for the activities of the components as a function of composition were derived from statistical considerations, based on the pairwise interaction energies between various components, E_{ij}.

$$RT \ln a_1 \cdot \frac{1}{x(1-y)} = E_1 + \frac{E_{11}}{2} + (1-x)^2 \left(E_{12} - \frac{E_{11}+E_{22}}{2} \right) + (1-x)y\,(E_{13} - E_{23}) - \frac{1}{2} y^2 E_{33} - RT \ln K_1(T)$$

$$RT \ln a_2 \cdot \frac{1}{(1-x)(1-y)} = E_2 + \frac{E_{22}}{2} + x^2 \left(E_{12} - \frac{E_{11}+E_{22}}{2} \right) + xy\,(E_{23} - E_{13}) - \frac{1}{2} y^2 E_{33} - RT \ln K_2(T)$$

$$RT \ln a_3 \cdot \frac{(1-y)}{y} = E_3 + xE_{13} + (1-x)\,E_{23} + yE_{33} - RT \ln K_3(T)$$

Subscript 1 refers to Zr, 2 to Nb, and 3 to C. The energy terms, $(E_{12} - (E_{11} + E_{22})/2)$, $(E_{13} - E_{23})$, and E_{33} were determined by measuring the variation with composition of the ratio of the activities of the various components. The ratio of activities of the various components at one composition was determined in one experiment; thus, the usual errors in temperature measurement were eliminated. For this study a Bendix Time-of-Flight Mass Spectrometer was used. The samples were prepared by heating the required amounts of oxides and graphite in a high-vacuum induction furnace. The metal-metal interaction energy

$$\left[E_{12} - \left(\frac{E_{11}}{2} + \frac{E_{22}}{2} \right) \right] = 6.54 \pm 0.27 \text{ kcal/mole}$$

is not much different from that in the bcc metallic zirconium-niobium system. The difference between the zirconium-carbon and the niobium-carbon interaction energies $(E_{13} - E_{23})$ is linearly dependent on composition

$$(E_{13} - E_{23}) = (1.08 \pm 0.11) - (6.15 \pm 0.44)\,x \text{ kcal/mole}$$

whereas E_{33}, the carbon-carbon interaction energy, can be expressed as

$$E_{33} = 15.62 + 9.37x - 29.50x(1-x) \text{ kcal/mole.}$$

Space-age requirements for high-temperature materials have created considerable interest in metal-carbon systems primarily because of their high melting temperatures and hardnesses. A number of the resulting investigations have been concerned with the high-temperature phase relationships in binary and ternary systems of refractory transition metals and carbon.

Since the transition metal carbides exist over a wide range of homogeneity, it is necessary to know the activities (or partial molar free energies) of the metal and carbon atoms as a function of composition in order to predict thermodynamic relations and investigate engineering applications.

Key words: carbides, zirconium, niobium, carbon, thermodynamics.

Hoch *et al* (1-5) studied those carbides, nitrides, and oxides of the refractory metals which have a sodium-chloride type structure, and deduced from statistical considerations equations to determine the activities of the components in compounds which deviate from stoichiometry.

The main purpose of the present investigation is to determine the relative activities of the components as a function of composition in the single-phase region of the ternary carbide system, $Zr_xNb_{1-x}C_y$.

Theory

In the single-phase region of the Zr-Nb-C system having a sodium-chloride type structure, the metal sites are randomly filled with zirconium and niobium

atoms, whereas some of the nonmetal sites are empty. Depending on the ratio of zirconium atoms to niobium atoms and the fraction of the nonmetal sites which are empty, the composition of the material can vary. The general formula of this material can be written: $Zr_xNb_{1-x}C_y$ where $0 < x < 1, 0 < y < 1$.

From statistical considerations, the grand partition function for this type of structure is

$$\text{GPF} = \sum \frac{N!}{N_1!(N-N_1)!} \cdot \frac{N!}{N_3!(N-N_3)!} [a_1K_1(T)]^{N_1} [a_2K_2(T)]^{N-N_1} [a_3K_3(T)]^{N_3} \exp\left[-\frac{1}{kT}\left(N_1E_1 + N_2E_2 + N_3E_3 + \frac{N_1^2}{2N}E_{11} + \frac{N_2^2}{2N}E_{22} + \frac{N_3^2}{2N}E_{33} + \frac{N_1N_2}{N}E_{12} + \frac{N_1N_3}{N}E_{13} + \frac{N_2N_3}{N}E_{23}\right)\right] \quad [1]$$

where N is the number of available metal (and carbon) sites and N_i is the number of atoms of element i (subscript 1 refers to Zr, 2 to Nb, 3 to C); a_i is the absolute activity of each component in the crystal phase; $K_i(T)$ is the contribution of an added atom to the partition function for the normal vibrational modes of the crystal; E_i is the energy required to bring an atom from its standard state into the sodium-chloride type lattice; and E_{ij} is the pairwise interaction energy. The small number of Schottky defects and Frenkel disorders present in the metal and nonmetal sublattice can be neglected.

By well-known treatment (6), the following equations are obtained.

$$RT \ln a_1 = RT \ln \frac{(N-N_2)(N-N_3)}{N^2} - RT \ln K_1(T) + \left[E_1 + \frac{N^2-N_2^2}{2N^2}E_{11} - \frac{N_2^2}{2N^2}E_{22} - \frac{N_3^2}{2N^2}E_{33} + \frac{N_2^2}{N^2}E_{12} + \frac{N_2N_3}{N^2}E_{13} - \frac{N_2N_3}{N^2}E_{23}\right] \quad [2]$$

$$RT \ln a_2 = RT \ln \frac{(N-N_1)(N-N_3)}{N^2} - RT \ln K_2(T) + \left[E_2 + \frac{N^2-N_1^2}{2N^2}E_{22} - \frac{N_1^2}{2N^2}E_{11} - \frac{N_3^2}{2N^2}E_{33} + \frac{N_1^2}{N^2}E_{12} + \frac{N_1N_3}{N^2}E_{23} - \frac{N_1N_3}{N^2}E_{13}\right] \quad [3]$$

$$RT \ln a_3 = RT \ln \frac{N_3}{N-N_3} - RT \ln K_3(T) + \left[E_3 + \frac{N_3}{N}E_{33} + \frac{N_1}{N}E_{13} + \frac{N_2}{N}E_{23}\right] \quad [4]$$

Introducing the equations

$$N_1 + N_2 = N$$

$$\frac{N_1}{N} = x$$

$$\frac{N_2}{N} = 1 - x$$

$$\frac{N_3}{N} = y$$

gives

$$RT \ln a_1 \cdot \frac{1}{x(1-y)} = E_1 + (1-x)^2\left[E_{12} - \frac{E_{11}}{2} - \frac{E_{22}}{2}\right] + \frac{E_{11}}{2} + (1-x)yE_{13} - (1-x)yE_{23} - \frac{1}{2}y^2E_{33} - RT \ln K_1(T) \quad [5]$$

$$RT \ln a_2 \cdot \frac{1}{(1-x)(1-y)} = E_2 + x^2\left[E_{12} - \frac{E_{11}}{2} - \frac{E_{22}}{2}\right] + \frac{E_{22}}{2} + xyE_{23} - xyE_{13} - \frac{1}{2}y^2E_{33} - RT \ln K_2(T) \quad [6]$$

$$RT \ln a_3 \cdot \frac{(1-y)}{y} = E_3 + yE_{33} + xE_{13} + (1-x)E_{23} - RT \ln K_3(T) \quad [7]$$

Equations [5], [6], and [7] reduce to the binary equations (1, 7) if either x or y are taken to be 0. By combining Eq. [5], [6], and [7], the following equations are obtained

$$RT \ln \frac{a_1}{a_2} \cdot \frac{(1-x)}{x} = E_1 - E_2 + (1-2x)\left[E_{12} - \frac{E_{11}}{2} - \frac{E_{22}}{2}\right] + \frac{1}{2}[E_{11} - E_{22}] + y[E_{13} - E_{23}] - RT \ln \frac{K_1(T)}{K_2(T)} \quad [8]$$

$$RT \ln \frac{a_1}{a_3} \cdot \frac{y}{x(1-y)^2} = E_1 - E_3 + \frac{E_{11}}{2} - E_{13} + (1-x)(1+y)[E_{13} - E_{23}] + (1-x)^2\left[E_{12} - \frac{E_{11}}{2} - \frac{E_{22}}{2}\right] - \left(y + \frac{y^2}{2}\right)E_{33} - RT \ln \frac{K_1(T)}{K_3(T)} \quad [9]$$

$$RT \ln \frac{a_2}{a_3} \cdot \frac{y}{(1-x)(1-y)^2} = E_2 - E_3 + \frac{E_{22}}{2} - E_{23} + x(1+y)[E_{23} - E_{13}] + x^2\left[E_{12} - \frac{E_{11}}{2} - \frac{E_{22}}{2}\right] - \left(y + \frac{y^2}{2}\right)E_{33} - RT \ln \frac{K_2(T)}{K_3(T)} \quad [10]$$

When a Knudsen cell at temperature T°K is placed in a mass spectrometer, the fundamental equation relating the partial pressure P_i of species i to the measured ion current I_i is

$$K_iP_i = I_iT \quad [11]$$

where K_i is a constant reflecting the physical and electromagnetic dimensions of the apparatus, the probability of formation of ions by electron bombardment, and the sensitivity of the detector to these ions.

A ratio of vapor pressures can thus be related to current intensities as follows

$$\frac{P_i}{P_j} = \frac{K_j}{K_i}\frac{I_i}{I_j} = C\frac{I_i}{I_j} \quad [12]$$

where $C = K_j/K_i$. Since

$$\frac{a_i}{a_j} = \frac{P_i}{P_j} \cdot \frac{P^o_j}{P^o_i} \quad [13]$$

the ratio of activities a_i can be related to the ratio of current intensities I_i

$$RT \ln \frac{a_i}{a_j} = \left(RT \ln \frac{I_i}{I_j} + RT \ln C \right) + RT \ln \frac{P^{o}_{j}}{P^{o}_{i}} \quad [14]$$

or

$$RT \ln \frac{a_i}{a_j} = RT \ln \frac{I_i}{I_j} + Q \quad [15]$$

where

$$Q = RT \ln C + RT \ln \frac{P^{o}_{i}}{P^{o}_{j}} \quad [16]$$

From Eq. [8], [9], [10], and [15], the energy terms in Eq. [5], [6], and [7] can be evaluated by measurements of the intensity ratios I_i/I_j as a function of composition.

In a mass spectrometer, ion intensities of various species can be measured at the same time; thus, the ratio of two activities can be obtained in one experiment. This is the great advantage of the present treatment. In all previous methods of measurement, the activity of a component has been obtained by measuring the pressure (or ion intensity) of the alloy in one experiment and that of the pure element in another. At high temperatures, though, it is difficult to obtain the same temperature in two different experiments because even the temperature determination with an optical pyrometer cannot be done better than ±5°K. As the pressure varies exponentially with temperature, an uncertainty of ±5°K in the temperature measurements can make the value of the derived activity very uncertain.

In the present experimental setup, the two activities are compared at the same temperature, the value of which may be uncertain to ±5°K. However, since the activity of the components does not vary much with temperature, this uncertainty is of no great importance. Moreover, because only the variation of the intensity ratios with composition is required, equilibrium is no longer necessary in the Knudsen cell. If Langmuir conditions are present and the components have vaporization coefficients α_i and α_j, the derived energy terms will be correct even when $\alpha_i \neq \alpha_j$. The only requirement is that α_i/α_j is independent of composition. This makes things much simpler than when equilibrium had to be established in the cell before meaningful activities could be obtained.

In addition, the use of the grand partition function and pairwise interaction energies provides a more detailed description of the activities of the component and the behavior of a solution than the quasichemical model or the more conventional polynomial expression for activities. Equations [5], [6], and [7] can be multiplied out to show that the present representation is equivalent to expressing the activity coefficient as a second order function of composition. The present interpretation also has the advantage that the coefficient can be related to mechanical properties (15).

Previous Investigations

Phase relationships.—The phase relationship in the binary zirconium-carbon system has been reviewed by Storms (8). The ZrC/Zr + ZrC boundary is located at $ZrC_{0.63}$ and is invariant in the temperature region 1900°-3300°C, and the ZrC/ZrC + C boundary is located at $ZrC_{0.96}$.

The phase relationships in the Nb-C system have also been reviewed by Storms (8). The homogeneity limits of the monocarbide are at $NbC_{0.70}$ and $NbC_{0.99}$.

The phase relationship of the Zr-Nb-C system was investigated by Stecher, Benesovsky, Neckel, and Nowotny (9). They found that the monocarbides formed a continuous series of solid solutions. At 1700°C, the lower limit of monocarbide region on the zirconium side was at $ZrC_{0.59}$ and at $NbC_{0.72}$ on the niobium side. The lattice parameter showed a very slight deviation from Vegard's law at the Nb-rich side when the carbon content was $y = 0.67$.

The phase relationship in the binary Zr-Nb metallic system is given by Elliott (10).

Thermodynamic investigations.—Hoch (7) has evaluated the activities of Zr and C and Nb and C in the binary carbides with the NaCl type structure and obtained the following results

For ZrC_y

$$RT \ln a_{Zr} \cdot \frac{1}{1-y} = (1 \pm 1) - (y^2)(14 \pm 1.5) \text{ kcal/mole} \quad [17]$$

$$RT \ln a_C \cdot \frac{1-y}{y} = -(35.2 \pm 4) - (28 \pm 3)(1-y) + 2.7 \times 10^{-3} T \text{ kcal/mole} \quad [18]$$

For NbC_y

$$RT \ln a_{Nb} \cdot \frac{1}{1-y} = -(0.05 \pm 1.0) - (y)^2 (7.6 \pm 1.3) \text{ kcal/mole} \quad [19]$$

$$RT \ln a_C \cdot \frac{1-y}{y} = -(28.6 \pm 2.5) - (15.2 \pm 2.5)(1-y) + 0.4 \times 10^{-3} T \text{ kcal/mole} \quad [20]$$

Though the data were deduced from experimental results obtained at very high temperatures (2500°-2700°K) they give heats of formation comparable to calorimetric measurements which are obtained at room temperature (11).

In the zirconium-niobium binary metallic solution, which is bcc, Hoch (12) has derived from the phase diagram the metal interaction energy in the solid $E_{12} - (E_{11}/2 + E_{22}/2) = 4.9 \pm 0.3$ kcal/mole.

Equipment and Materials

High-temperature, induction-heated, vacuum furnace.—A cylindrical, water-cooled, vacuum chamber, 6¼ in. ID and 12 in. high, was made out of copper. The power leads, copper tubing of ¼ in. diameter, enter the chamber through the rubber glass compression seals and are connected to a copper work coil. The work coil is 12 turns of ¼ in. diameter copper tubing, 3½ in. in length, 1½ in. ID, concentric with the heating chamber.

The vacuum system, connected to the chamber by a 2 in. ID copper pipe, consists of a 2 in. Veeco CT-200 brass cold trap, an N.R.C. H-4-P oil diffusion pump (Type 137), and a Welch Duo-Seal mechanical pump. The pressure is measured by a Veeco DG-2 cold cathode discharge gauge.

A tungsten crucible was placed on a tripod of tungsten rods in the center of the work coil. The power source used to heat material in the crucible is a 20 KW-Thermionic generator (Induction Heating Corporation, Model 1070) with an iron core, R.F. transformer (Taylor-Winfield Corporation, TD-74).

X-ray diffraction unit and mass spectrometer.—A Norelco x-ray diffraction unit and a Debye-Scherrer camera, with effective diameter of 114.6 mm and nickel-filtered copper Kα radiation, was used for taking x-ray diffraction patterns of the samples.

A Bendix Time-of-Flight Mass Spectrometer Model 12-101 was used to analyze the vapors effusing from the Knudsen cell.

Materials.—Carbon powder of 99.9999% purity, zirconium dioxide powder of 99.9% purity, and niobium pentoxide powder of 99.95% purity were obtained from Atomergic Chemetals Company, Division of Gallard Schlesinger Chemical Manufacturing Corporation, Carle Place, New York.

Experimental Procedure

Preparation of samples.—*NbC_y.*—Niobium pentoxide powder and carbon powder of desired compositions for $NbC_{0.95}$, $NbC_{0.9}$, and $NbC_{0.8}$ were mixed well and pressed into cylindrical pellets. Each pellet was then heated in the tungsten crucible at high vacuum for 24

hr at 2260°K. Afterwards Debye-Scherrer x-ray powder diffraction patterns were taken which confirmed the sodium-chloride type structure.

ZrC_y.—Zirconium dioxide powder and carbon powder of desired compositions for $ZrC_{0.95}$, $ZrC_{0.9}$, and $ZrC_{0.8}$ were mixed well and pressed into cylindrical pellets. Each pellet was then heated in the tungsten crucible at high vacuum for 24 hr at 1940°K. As for NbC_y, the fcc structure was subsequently confirmed by x-ray diffraction patterns.

$Zr_xNb_{1-x}C_y$.—ZrC_y powder and NbC_y powder of desired compositions for $Zr_xNb_{1-x}C_y$ were mixed well, pressed into cylindrical pellets, and heated in the tungsten crucible of the high vacuum furnace for 50 hr at a temperature of 2280°K. As with the two binary carbides, ZrC and NbC, the single phase of fcc structure was later confirmed by x-ray diffraction patterns.

One specimen of $Zr_{0.8}Nb_{0.2}C_{0.8}$ was submitted to Ledoux and Company for analysis and 20 ppm of oxygen was reported indicating very little oxygen contamination.

Mass spectrometer operation.—In order to maintain stable temperatures, tungsten Knudsen cells with 0.629 in. OD, 0.441 in. ID, and 0.562 in. height were used. The lids each had a 3/16 in. diam hole drilled into them. The samples were placed in a thin-walled tungsten cup which fitted into the Knudsen cell. Thus, the samples could not contaminate the Knudsen cell body. The relatively large hole in the lid allowed a large fraction of the vapor to escape from the Knudsen cell, and thus made experiments possible at the relatively low temperature of 2340°K.

The Knudsen cell power supply was operated at a constant filament current of 13.6A, and the bombardment voltage was adjusted to get the required temperature. A 15/1000 in. diam tungsten wire was used for the heating filament because it was found to have a much longer life than the 10/1000 in. diam recommended by the manufacturer.

When a new specimen is introduced into the Knudsen cell, it takes about 60-90 min to reach 2340°K. The temperature was measured with an L&N disappearing filament, optical pyrometer through a prism and a glass window, and then corrected for glass absorption and prism absorption.

The intensity of Zr^{90} (natural abundance 51.46%) was measured for zirconium. The intensity of Nb^{93} (natural abundance 100%) and the intensity of C^{12} (98.89%) were measured for niobium and carbon. The measured intensity was corrected for the deviation from electrometer linearity by calibrating with Cu^{63} and Cu^{65}.

Results and Discussion

The nominal composition of the samples is given in Table I, along with the lattice parameter. The lattice parameters were determined using the Nelson-Riley extrapolation method (13) to an accuracy of ±0.001Å.

Table I. Nominal composition and lattice parameter of samples

$Zr_xNb_{1-x}C_y$ x	y	Lattice parameter in Å Before exp.	After exp.	Literature

0	1			4.470 (14)

Table I also contains several lattice parameters which were determined from data obtained after the vapor pressure measurements had been carried out in the Knudsen cell. Within experimental error, these lattice parameters agreed with those measured prior to the vapor pressure runs indicating very small composition change.

The experimental temperature of 2340°K was chosen as the lowest temperature which would give accurately reproducible intensities for the Zr, Nb, and C peaks. At lower temperatures the danger of surface depletion is much less because the activation energy for vaporization is larger than the activation energy for diffusion. As a result of this precaution, the vaporization rate was very low. At 2340°K Sample No. 3 lost only 3.5 mg during 8 hr heating in the Knudsen cell. Less than 2 hr were required to complete the mass spectrometric measurements on each sample.

Intensity rations of Zr^{90} to Nb^{93}, Zr^{90} to C^{12}, and Nb^{93} to C^{12} were measured for all specimens and are given in Table II. For each intensity ratio in Table II, both were measured 10 to 12 times, and the average of the readings was used to calculate the ratio.

Using

$$\frac{I_{Zr}}{I_{Nb}} = \frac{I_{Zr90}}{I_{Nb93}} \cdot C_1 \qquad [21]$$

where C_1 is constant, Eq. [8] and [15] give

$$RT \ln \frac{I_{Zr90}}{I_{Nb93}} \cdot \frac{(1-x)}{x} = (1-2x)\left[E_{12} - \frac{E_{11}+E_{22}}{2}\right] + \frac{1}{2}[E_{11} - E_{22}] + [E_1 - E_2] + y[E_{13} - E_{23}] - RT \ln \frac{K_1(T)}{K_2(T)} - Q - RT \ln C_1 \qquad [22]$$

Plotting $RT \ln I_{Zr90}/I_{Nb93} \cdot (1-x)/x$ *vs.* $(1-2x)$, with y constant, (Fig. 1) shows a straight line relationship. Least squares analysis gives $\left(E_{12} - \frac{E_{11}+E_{22}}{2}\right) = 6.54 \pm 0.27$ kcal/mole, which is included in Table III. $\left(E_{12} - \frac{E_{11}+E_{22}}{2}\right)$ is the interaction parameter between the metal atoms in the fcc metal sublattice, and is of the same order of magnitude as the 4.9 ± 3 kcal/mole reported for the bcc metallic system (12).

By reorganizing Eq. [22] and plotting $\left[RT \ln \frac{I_{Zr90}}{I_{Nb93}} \frac{(1-x)}{x}\right] - \left(E_{12} - \frac{E_{11}+E_{22}}{2}\right)(1-2x)$ *vs.* y with x constant, $(E_{13} - E_{23})$ was calculated at various values of x. The results are presented in Table III, and Fig. 2 shows the linear variation of $E_{13} - E_{23}$

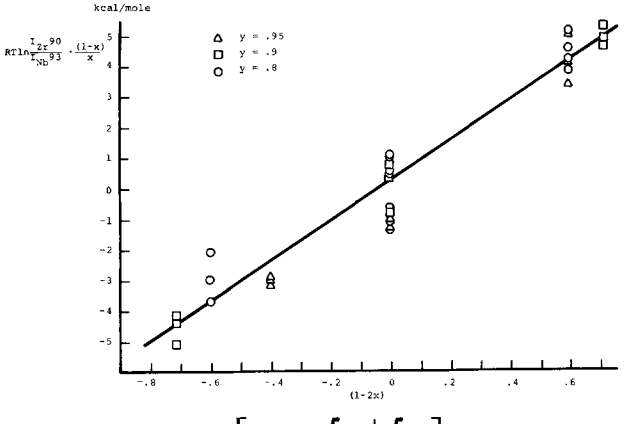

Fig. 1. Evaluation of $\left[E_{12} - \frac{E_{11}+E_{22}}{2}\right]$ in $Zr_xNb_{1-x}C_y$

with composition. Least squares analysis gives $E_{13} - E_{23} = (1.08 \pm 0.11) - (16.15 \pm 0.44)$ x kcal/mole.

From Eq. [9], [10], [15], [16], Eq. [23] and [24] are derived

$$RT \ln \frac{I_{Zr90}}{I_{C12}} \cdot \frac{y}{x(1-y)^2} = \left[E_1 - E_3 - E_{13} + \frac{E_{11}}{2} \right] + (1-x)(1+y)[E_{13} - E_{23}] + (1-x)^2 \left[E_{12} - \frac{E_{11}+E_{22}}{2} \right] - \left(y + \frac{y^2}{2} \right) E_{33} - RT \ln \frac{K_1(T)}{K_3(T)} - RT \ln C_2 - Q \quad [23]$$

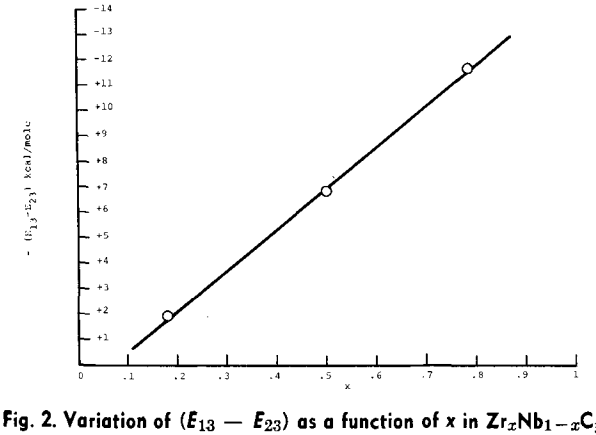

Fig. 2. Variation of $(E_{13} - E_{23})$ as a function of x in $Zr_xNb_{1-x}C_y$

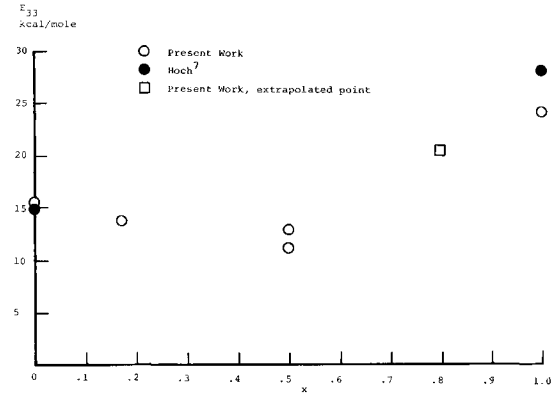

Fig. 3. Variation of E_{33} as a function of component in $Zr_xNb_{1-x}C_y$

$$RT \ln \frac{I_{Nb93}}{I_{C12}} \cdot \frac{y}{(1-x)(1-y)^2} = \left[E_2 - E_3 - E_{23} + \frac{E_{22}}{2} \right] + x(1+y)[E_{23} - E_{13}] + x^2 \left[E_{12} - \frac{E_{11}+E_{22}}{2} \right] - \left[y + \frac{y^2}{2} \right] E_{33} - RT \ln \frac{K_2(T)}{K_3(T)} - RT \ln C_3 - Q \quad [24]$$

Plotting

$$RT \ln \frac{I_{Zr90}}{I_{C12}} \cdot \frac{y}{x(1-y)^2} - (1-x)(1+y)[E_{13} - E_{23}] - (1-x)^2 \left[E_{12} - \frac{E_{11}+E_{22}}{2} \right]$$

vs. $[y + y^2/2]$ gives the carbon-carbon interaction energy, E_{33} varies as the composition of the sample changes. Its measured values are given in Table III. In addition, a value at $x = 0.8$ was obtained by using Sample No. 33 and an interpolated value between Samples No. 4 and 1. This value is therefore less accurate than the others.

In Fig. 3, E_{33} is plotted *vs.* composition. This shows the values for the binary systems, ZrC_y ($x = 1$, $E_{33} = 24.1 \pm 2.1$ kcal/mole) and NbC_y ($x = 0$, $E_{33} = 15.5 \pm 3.6$ kcal/mole), to be in very good agreement with values deduced by Hoch (7) (28 ± 3 kcal/mole and 15.2 ± 2.5 kcal/mole). Starting from niobium carbide on the left, E_{33} remains almost constant until $Zr_{0.5}Nb_{0.5}C_y$ and then rapidly increases to its value for zirconium carbide. This data can be well represented as a function of composition by $E_{33} = 15.62 + 9.37x - 29.50x(1-x)$ kcal/mole.

The carbon interaction energy in the ternary system can be looked upon as the interaction energy of two types of carbon atoms: a carbon atom belonging to niobium carbide and a carbon atom belonging to zirconium carbide. Therefore, there are in the system three

Table III. Calculated pairwise interaction energies in $Zr_xNb_{1-x}C_y$

Thermodynamic Properties of Ternary Refractory Carbides

II. Zirconium-Uranium-Carbon and Zirconium-Hafnium-Carbon

M. Hoch, M. G. Hapase, S. Yamauchi

Department of Materials Science and Metallurgical Engineering, University of Cincinnati, Cincinnati, Ohio 45221

ABSTRACT

The thermodynamic properties of [ternary] zirconium-uranium-carbide $Zr_xU_{1-x}C_y$ and zirconium-hafnium-carbide $Zr_xHf_{1-x}C_y$ both with a sodium-chloride type structure were studied using the time-of-flight mass spectrometer. The ratio of the activities of the components was measured as a function of composition at 2440°K, and from the variation of the ratio of activities with composition, the pairwise interaction energies were obtained. In the Zr-U-C system, the metal-metal interaction energy, $\left[E_{12} - \frac{E_{11} + E_{22}}{2}\right]$, was found to be 6.7 ± 0.6 kcal/mole, a value close to that obtained in the body-centered cubic, zirconium-uranium [metallic] system. The difference between the zirconium-carbon and uranium-carbon interaction energies, $E_{13} - E_{23}$ can be expressed as a function of composition by the equation

$$E_{13} - E_{23} = 8.5 \pm 0.05 - [23.6 \pm 0.2]x \text{ in kcal/mole}$$

In the Zr-Hf-C system, the metal-metal interaction energy, $\left[E_{12} - \frac{E_{11} + E_{22}}{2}\right]$ was found to be 1.9 ± 0.3 kcal/mole, again a value close to that obtained in the body-centered cubic, zirconium-hafnium [metallic] system. The difference between the zirconium-carbon and hafnium-carbon interaction energies, $E_{13} - E_{23}$, can be expressed as a function of composition by the equation

$$E_{13} - E_{23} = 9.8 \pm 0.05 - [7.5 \pm 0.2]x \text{ in kcal/mole}$$

In earlier papers, Hoch *et al.* (1-7) reported on studies of carbides, nitrides, and oxides of the refractory metals with sodium-chloride type structures. From statistical considerations they deduced equations to determine the activities of the components in these binary compounds which deviate from stoichiometry. This work was later extended to the ternary Zr-Nb-C system (8). The purpose of the present study is to add the single phase regions of Zr-U-C and Zr-Hf-C to the systems investigated. The theory has been described by Jun and Hoch (8).

Key words: carbides, zirconium, uranium, hafnium, carbon, thermodynamics.

Previous Investigations

The phase relationships in the Zr-C and Hf-C systems have been reviewed by Storms (9), and the thermodynamic data by Hoch (1). The phase diagram of the U-C system has also been summarized by Storms (9), and the thermodynamic data by Hoch, Sjodahl, and Juenke (10). A phase diagram for the Zr-U system was developed by Elliott (11), and lattice parameters for $Zr_{0.25}U_{0.75}C$ were given by Adam, Harrison, Riviere, and Thorpe (12).

Following Hoch, the activities of the components as a function of composition can be represented as
In ZrC (1)

$$RT \ln a_{Zr} \cdot \frac{1}{1-y} = (1 \pm 1) - (14 \pm 1.5)y^2 \text{ kcal/mole} \quad [1]$$

$$RT \ln a_C \cdot \frac{1-y}{y} = -(35.2 \pm 4) - (28 \pm 3)(1-y) + 2.7 \times 10^{-3}T \text{ kcal/mole} \quad [2]$$

In UC (10)

$$RT \ln a_C \cdot \frac{1-y}{y} = -28.1 \pm 1.6 \text{ kcal/mole}, \quad 0 < y < 1 \quad [3]$$

In HfC (1)

$$RT \ln a_{Hf} \cdot \frac{1}{1-y} = (1 \pm 1) - (7.5 \pm 4)y^2 \text{ kcal/mole} \quad [4]$$

$$RT \ln a_C \cdot \frac{1-y}{y} = -(47 \pm 10) + (15 \pm 8)(1-y) + 2 \times 10^{-3}T \text{ kcal/mole} \quad [5]$$

While in Zr-C and Nb-C, the high temperature thermodynamic data give heats of formation comparable to calorimetric data (2), this is not the case in Hf-C

Assuming $\Delta H_f = \Delta E_f$, ΔH_f, the heat of formation of HfC_y can be expressed as

$$\Delta H_f = (1 \pm 1) - (62 \pm 18)y + (7.5 \pm 4)y^2 \text{ kcal/mole} \quad [6]$$

This value is compared in Fig. 1 ($\Delta H_f/y$ *vs.* composition) with the values obtained by Mah (13), and Zhelankin and Kutsev (14) using combustion calorimetry. At higher carbon content, the values are in good agreement. At lower carbon content, however, the difference between the values calculated by Hoch (1), and measured by Zhelankin and Kutsev (14) increases. One reason is that Zhelankin and Kutsev's data show a large composition dependence indicating a very large pairwise interaction energy. In fact a straight line through Zhelankin and Kutsev's data in Fig. 1 gives for ΔH_f

$$\Delta H_f \simeq -118y + 64y^2 \text{ kcal/mole}$$

This yield carbon pairwise interaction energy, $E_{33}/2$, of 64 kcal/mole, which seems too high in relationship to the results in the other carbides as does a value of -118 kcal/mole for $(E_3 + E_{23})$.

Equipment and Materials

The same equipment used by Jun and Hoch (8) was employed. Carbon powder of 99.9999%, zirconium oxide of 99.95%, uranium dioxide 99.9% and hafnium oxide of 98.95% purity were obtained from Atomergic Chemetals Company, a division of Gallard-Schlesinger Chemical Manufacturing Corporation, Carle Place, Long Island, New York.

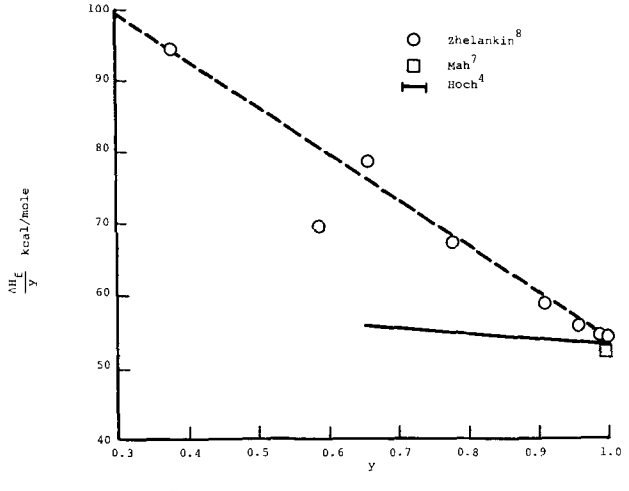

Fig. 1. Heat of formation of HfC_y

Experimental Procedure

Preparation of samples.—ZrC_y, HfC_y, and UC_y were prepared from the dioxide and carbon as described by Jun and Hoch (8). The oxygen to metal ratio in UO_2 was determined gravimetrically by oxidizing the material to U_3O_8, as described by Hoch and Momin (15). The ternary carbides were also prepared as described by Jun and Hoch (8). To avoid any reaction with the atmosphere, the uranium carbides were handled under argon.

Mass spectrometer operation.—Jun and Hoch (8) have described the use of the mass spectrometer. For carbon, the intensity of C^{12} (natural abundance 98.89%) was measured as the carbon peak. For uranium, the intensity of U^{238} (natural abundance, 99.274%) was measured. For zirconium, the intensity of Zr^{90} (natural abundance, 51.46%) was measured.

There are four stable isotopes of hafnium; Hf^{177} (18.5%), Hf^{178} (27.1%), Hf^{179} (13.8%), and Hf^{180} (35.2%). Since none is significantly larger than the others, the intensity of all four isotopes was measured and converted into the values of Hf^{180} using relative abundances. The average of these values was used in the calculations.

Results and Discussion

The nominal compositions of the samples, along with lattice parameters are given in Tables I and II. The lattice parameters were determined using the Nelson-Riley extrapolation method (16), and have an accuracy of ±0.001Å. In UC_y and ZrC_y, these values agree well with the data given by Storms (9).

The intensity ratios of Zr^{90}/U^{238} were measured for all Zr-U-C samples, and are given in Table III. For each intensity ratio reported both peaks were measured four times and the average of the readings used to calculate the ratio. It should also be noted that at

the experimental temperature of 2440°K, the evaporation rate is low in relation to the time needed for measurements so the results were not influenced by any change in composition. The intensity ratios of Zr^{90}/Hf^{180} were likewise measured for all Zr-Hf-C samples, and are given in Table IV. For this system the experiments were carried out at 2570°K.

To obtain the pairwise interaction energies, $RT \ln I_{Zr90}/I_{U238} \cdot (1-x)/x$ and $RT \ln I_{Zr90}/I_{Hf180} \cdot (1-x)/x$ was plotted *vs.* $(1-2x)$ with y constant as shown in Fig. 2 and 3.

Straight lines drawn on the basis of a least squares analysis give $\left[E_{12} - \frac{E_{11}+E_{22}}{2}\right] = 6.7 \pm 0.64$ kcal/mole in the Zr-U-C system, and $\left[E_{12} - \frac{E_{11}+E_{22}}{2}\right] = 1.86$ kcal/mole in the Zr-Hf-C system. These terms represent the interaction energies between the metal atoms in the fcc metal sublattice. They are of the same order of magnitude as those for the bcc metallic systems in U-Zr 4.4 ± 0.2 kcal/mole calculated from

the binary phase diagram using a method described elsewhere (17).

Kubaschewski (18, 19), assuming an ideal solution in Zr-Hf binary alloys, calculated the solidus and the liquidus curves for the Zr-Hf phase diagram, and his results showed fairly good agreement with experimentally determined phase relationships. This shows that the Zr-Hf binary alloy is an ideal solution, and therefore, $[E_{12} - \frac{1}{2}(E_{11} + E_{22})] \simeq 0$ for the Zr-Hf bcc metallic solution.

Using the method described earlier, the values of $[E_{13} - E_{23}]$ in both systems were calculated for different values of x, and the results are given in Table III as well as Fig. 4 and 5. Straight lines drawn on the basis of a least squares analysis give $[E_{13} - E_{23}] = 8.5 \pm 0.05 - [23.6 \pm 0.2]\ x$ kcal/mole in the system Zr-U-C, and $[E_{13} - E_{23}] = (9.6 \pm 0.8) - (7.8 \pm 0.2)x$ kcal/mole in Zr-Hf-C. The variation of $[E_{13} - E_{23}]$ with composition, which is the difference between the Zr-C and U-C bonds and the Zr-C and Hf-C bonds, will be discussed in a later paper (20).

Thus, the ternary $Zr_xU_{1-x}C_y$ and $Zr_xHf_{1-x}C_y$ systems behave quite similarly to the $Zr_xNb_{1-x}C_y$ system (8).

Etch Rate Characterization of Silane Silicon Dioxide Films

Lou Hall*

Texas Instruments, Inc., Dallas, Texas 75222

In semiconductor manufacturing, it is necessary to process a variety of silicon dioxide films containing different impurities and different impurity concentrations. The etch rate of oxide films is affected by the addition of impurities. If their distribution is such that reverse or vertical slopes are obtained, serious problems such as open metal can result. Impurities can change both chemical and/or the physical nature of the film.

The recent use of chemical vapor deposition has provided a technology which makes it possible to obtain favorable oxide profiles. Studies have been made of the effect of both boron and phosphorus doping on the etch rate of silane silicon dioxide films.

The system used for the deposition of the doped oxide films was the low temperature oxidation of di-

borane and silane, and phosphine and silane. The system was an RF heated production type unit. The chemical reactions involved have been discussed by a number of workers (1-3). The oxide films were deposited on 1½ in. <111> silicon wafers that were cleaned prior to use with H_2O-HNO_3-H_2O.

The etch used consisted of 91.2 weight per cent (w/o) of 40 w/o ammonium fluoride and 8.8 w/o of 49 w/o hydrogen fluoride. The etch temperature was 28°C (room temperature). The etch times were at fixed time increments and the thicknesses of the oxide steps were measured by use of a Talystep I. Photoresist was used as an etch mask. The amount of dopant in the oxide film was not measured but rather the dopant was introduced into the reaction chamber as a percentage of silane flow. The total flow was about 6 liters/min with the O_2 and silane being 1% and 0.25% of the total flow respectively.

The results of the etch studies are given in Table I. Etch rates from 4 positions on each wafer were averaged to obtain the rate given in the table. The use of photoresist masking permitted 4 etchings on the same wafer (Fig. 1). The spread in values was $\leq \pm 2\%$. After E_1 was obtained, oxide remained only in the center portion of the wafer (approximately ¼ of the total oxide area remained). E_2 was obtained by masking the wafer with photoresist so that only the center portion of the remaining oxide could be etched (Fig. 2). The difference in etch rate E_1 and etch rate E_2 is ascribed to an increase in stress in the remaining oxide film.

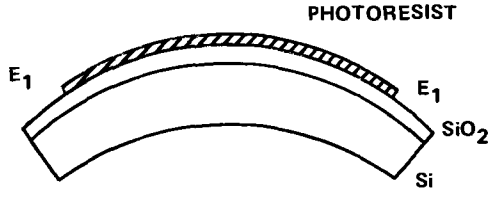

Fig. 1a. Compression

Fig. 1b. Tension

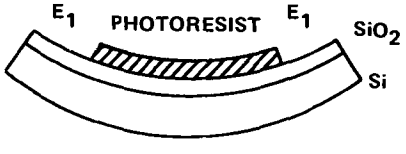

Fig. 2a. Compression

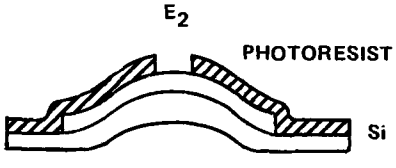

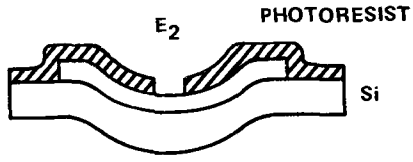

Fig. 2b. Tension

The etch rate of both boron and phosphorous doped silane oxide films are dependent on dopant concentration. The etch rate of the boron doped material decreases with increasing boron concentration while the etch rate of the phosphorous doped material increases with increasing phosphorous content (4). However, the boron doped silane oxides are more sensitive to changes in doping than are the phosphorous-containing films. The decrease in etch rate with increasing boron over the range studied is in agreement with that reported for other boron doped silicon dioxide films (5).

Figure 1 shows the portion of the film etched to obtain E_1. The oxide film and the silicon substrate have different coefficients of thermal expansion. Therefore, the wafer can be in either compression or tension as shown in Fig. 1a and 1b.

Once the outer portion of the oxide film is removed, the stress will be redistributed and the stress in the remaining oxide will increase. Experiments are in progress to determine the effect of stress on the etch rate independent of other parameters.

Figure 2 illustrates the portion of the film etched to obtain E_2. When the oxide films were masked so E_1 and E_2 were obtained simultaneously, E_1 and E_2 were equal. This is the expected result when the chemical composition and stress remains homogeneous across the oxide film.

In Table I the ratio E_1/E_2 is of interest. The boron-doped silane oxide is in compression while the phosphorous doped and undoped silane oxide films are in tension (6). Thus, the increase in etch rate due to stress appears to be independent of the type of stress. Also, the fact that the ratio E_1/E_2 remains constant over the range studied may indicate the stress in the oxide film is influenced more by redistribution of stress in the silicon than by addition of impurities to the oxide.

Two things obtained from Table I are that the etch rate of oxide films are affected both by addition of impurities and/or by stress. Thus, it is possible to have composite oxide films which will provide a controlled etching profile. An important area of application is multilevel fabrication.

Effect of Thorium on Ce^{+3} Phosphors

Mary V. Hoffman*

Lighting Research Laboratory, General Electric Company, Cleveland, Ohio 44112

The luminescent properties of Ce^{+3} and Tb^{+3} activation in the monazite structures $LaPO_4$ and $CePO_4$ have been described and the energy transfer from Ce^{+3} to Ce^{+3} and Ce^{+3} to Tb^{+3} in these and other structures have been established (1-3). Energy transfer also has been reported in which Ce^{+3} emission in YPO_4 was sensitized by Th^{+4} (4). The work reported here shows the enhancement of both Ce^{+3} and Tb^{+3} emission in the presence of Th^{+4} in the monazite structure, in which the Th^{+4} does not have a direct role in the energy transfer in the ultraviolet region.

Experimental

Two methods of preparation were used in these tests. Phosphors were prepared from cerium and lanthanum sources of 99.9% purity by co-precipitation of the composition from nitrate solutions with $NaH_2PO_4 \cdot H_2O$. When prepared from oxides of 99.999% purity, the oxides were mixed with $(NH_4)_2HPO_4$ and fired initially at 300°C. Final firing for both methods was 1000°C for several hours.

Spectral distribution curves, excitation data, and decay measurements were obtained by methods which have been described previously (5). Reflectance measurements were made on a Cary 14, using $BaSO_4$ as a reference standard.

Results

The Ce^{+3} emission in $CePO_4$ and $LaPO_4$ matrices is a double band, peaking at 320 and 340 nm, resulting from the splitting of the group state, $^2F_{5/2}$ and $^2F_{7/2}$ (Fig. 1). Green emisison is present when Tb^{+3} is incorporated in $CePO_4$, but is very weak in the $LaPO_4$ matrix unless Ce^{+3} is also present.

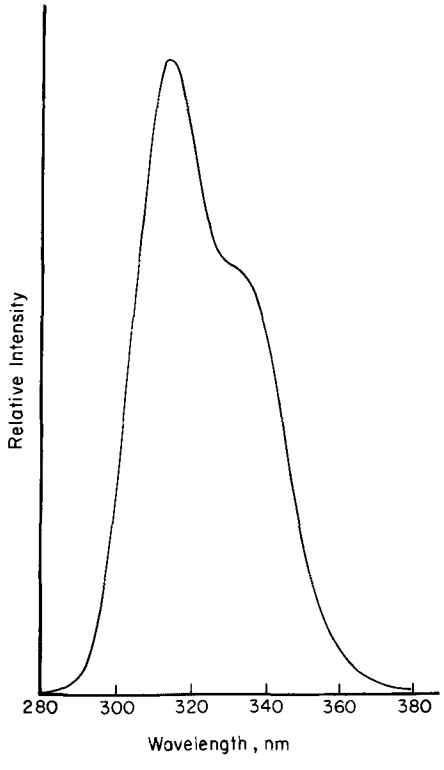

Fig. 1. Emission spectra, $LaPO_4$:Ce, 2537Å excitation

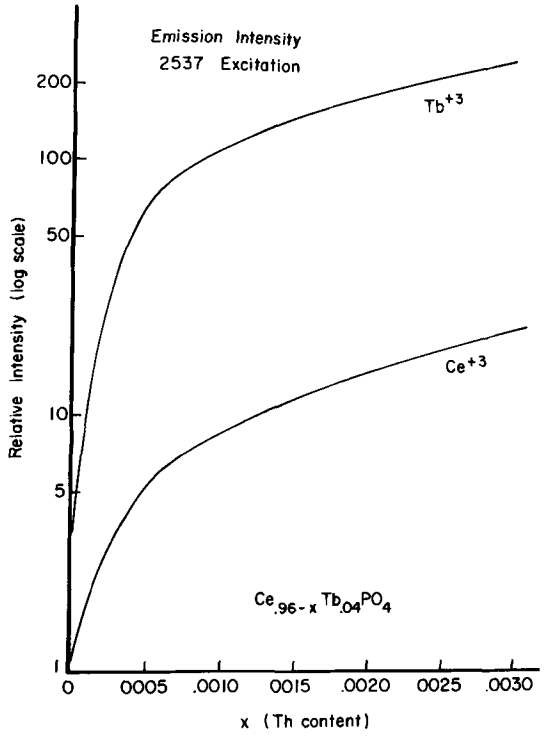

Fig. 2. Intensity of peak height of Tb^{+3} and Ce^{+3} emission in $Ce_{0.96-x}Th_xTb_{0.04}PO_4$ with increasing Th incorporation. 2537Å excitation.

In $CePO_4$ and $CePO_4$:Tb, the incorporation of Th in amounts as low as 0.0005 moles per formula resulted in enhancement of both Ce^{+3} and Tb^{+3} emission, with the maximum enhancement reached at about 0.003 moles of Th. Figure 2 shows the increased intensity of the Ce^{+3} and the Tb^{+3} emission with Th^{+4} incorporation in $Ce_{0.96-x}Th_xTb_{0.04}PO_4$. Figure 3 shows the effect of energy transfer from $Ce^{+3} \rightarrow Tb^{+3}$ in $Ce_{1-x}Tb_xTh_{0.008}PO_4$. Figure 4 shows the effect of Th^{+4} on the intensity of Ce^{+3} emission in $La_{1-x}Ce_xPO_4$, in which a similar enhancement is found.

In order to determine the effect of very low concentrations of Ce and Th, these matrices were prepared from oxides listed as 99.999% purity, but even in these, trace amounts of Ce^{+3} and Tb^{+3} were detected in the unactivated sample. The emission intensities are shown in Table I and are compared to a sodium salicylate standard with a peak height of 50.

Excitation curves were run on the $CePO_4$ and $LaPO_4$ matrices for Ce^{+3} and Tb^{+3} emission, both with and

without Th^{+4}. In $CePO_4$:Tb, the excitation is identical for both Ce^{+3} and Tb^{+3} emission, with no change found due to the presence of Th^{+4}. The excitation is that of absorption into the 5d levels of Ce^{+3}.

In the $LaPO_4$ matrix, the lower concentration of Ce permits better resolution of the excitation bands. The excitation of Ce^{+3} (Fig. 5) shows the same transitions, absorbing in the 5d levels. The excitation of Tb^{+3} in $LaPO_4$ (Fig. 6) is into the 5d level of Tb^{+3}, below 215 nm, with very little excitation occurring through the 4f levels. The combination of Ce^{+3} and Tb^{+3} shows an enhancement of the Tb^{+3} emission as a result of the Ce^{+3} absorption and transfer, with the excitation curve showing an additive effect over the range of Ce^{+3} absorption (Fig. 6). The excitation of the Ce^{+3} emission is diminished in the 200-220 nm range due to transfer into the 5d levels of Tb^{+3} (Fig. 5). Excitation curves for both Ce^{+3} and Tb^{+3} emission showed no change with incorporation of Th^{+4} into the lattice. At 205 nm, the incorporation of Ce^{+3} resulted in a two-fold enhancement of the Tb^{+3} emission, and the presence of Th^{+4} increased this to three-fold. The response under cathode-ray excitation showed no visual enhancement of Tb^{+3} emission by the presence of Ce^{+3} or Th^{+4}, but the afterglow of the Tb^{+3} emission was greatly increased with Th^{+4}, indicating that in the very high energy region, Th^{+4} enters into the energy transfer.

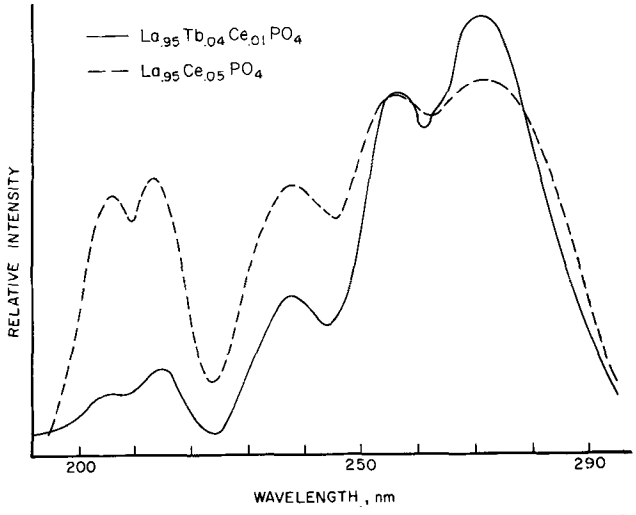

Fig. 5. Excitation spectra of Ce^{+3} emission in $LaPO_4$ matrix with and without Tb^{+3} present.

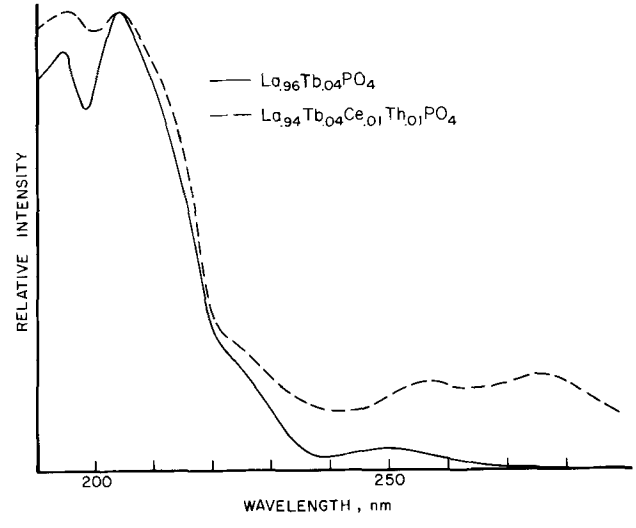

Fig. 6. Excitation spectra of Tb^{+3} emission in $LaPO_4$ matrix with and without presence of Ce^{+3}.

The function of Th^{+4} in the enhancement of both Ce^{+3} and Tb^{+3} emission in the monazite lattice is not one of energy transfer in the wavelength range above 200 nm, but of valence control of the cerium ion. Diffuse reflectance curves run on $CePO_4$ show that in Th^{+4}-free materials, such as those prepared from 5-9's oxides, an absorption edge is present in the region of 450 nm. When fired in a mildly reducing atmosphere (Table I) or when Th^{+4} is incorporated, the absorption edge is shifted to about 370 nm and the emission is increased. Absorption data supplied by the American Potash Company show that ceric ammonium nitrate has an edge at about 440 nm, and that cerous chloride has an edge at 370 nm. In $LaPO_4$, the addition of cerium gives an absorption at 475 nm, which is shifted to 370 nm with Th^{+4} present (Fig. 7). The presence of Tb^{+3} does not result in a change in absorption edge in this region.

The enhancement of emission intensity with the presence of Th^{+4} occurs because of the removal of Ce^{+4} ions in the lattice which provided an absorbing site for energy transferred from Ce^{+3}. Decay measurements on both Ce^{+3} and Tb^{+3} emission show a decrease in the decay time of Tb in the samples which

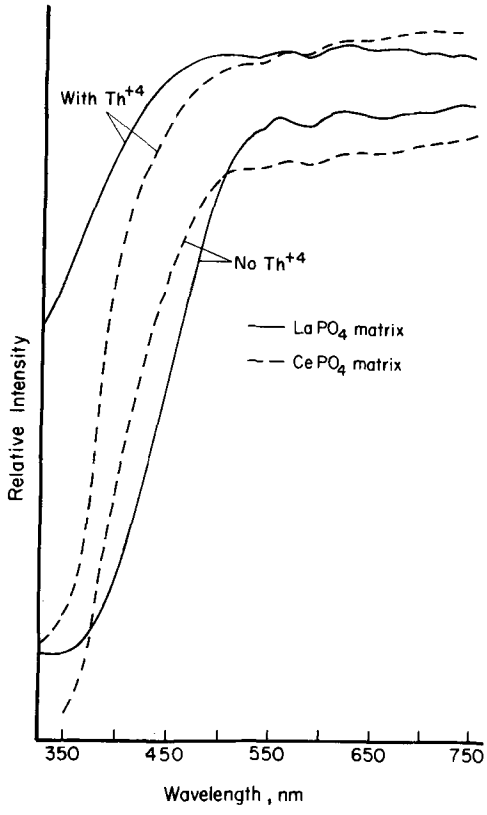

Fig. 7. Diffuse reflectance curves for $LaPO_4$ and $CePO_4$ matrices showing shift in absorption edge with Th^{+4} addition.

contain Ce^{+4} (Table II). The Ce decay times are all less than the 10^{-9}-sec limitation of the instrument, except for $CePO_4$:0.008 Th. This is the only material which does not have a second center accepting energy from the lattice Ce^{+3}, *i.e.*, $Ce^{+3} \rightarrow Ce^{+4}$ or $Ce^{+3} \rightarrow Tb^{+3}$.

These decay measurements show that an absorbing center exists in $CePO_4$ prepared without Th^{+4}, and this center correlates with the diffuse reflectance data indicating the presence of Ce^{+4}. No evidence was found to correlate with the emission and excitation reported by Awazu and Muto for Th^{+4} enhancement of Ce^{+3} in YPO_4. Incorporation of only Th into $LaPO_4$ showed no

Table II. Decay measurements

Composition	Decay time of emission	
	Ce^{+3}, sec	Tb^{+3}, μsec
$CePO_4$	$<10^{-9}$	—

$CePO_4$: 0.008 Th	10^{-9}	—

emission, nor was any other reference to Th absorption or emission levels in the ultraviolet region found in the literature.

The incorporation of Th^{+4} in $CePO_4$ (or $LaPO_4$) implies that a defect structure such as $Ce(M^{+4}\square^{-1})PO_4$ exists, with M^{+4} being Ce, Th, or Zr. The absorption data shows that when M is Th and above about 0.001 Th/Ce, all of the cerium is trivalent. There does not appear to be a distribution of Ce^{+4} and Th^{+4} cations. This can possibly be attributed to the size of the ions involved. The ionic radius of Th^{+4} is 1.02Å, closer to Ce^{+3} (1.07Å) than is Ce^{+4} (0.94Å). The effect of Th^{+4} occurs with a very low concentration; incorporation of 0.0005 moles Th per Ce shows a significant change in both the absorption edge and the emission intensity and 0.0030 is sufficient to optimize the intensity effect. This indicates a very limited solid solution of M^{+4} in the structure.

The Emission Colors of the Strontium Apatite Phosphor System

R. C. Ropp*,[1]

Westinghouse Electric Corporation, Bloomfield, New Jersey 07003

Although published studies of alkaline earth apatite phosphors have been quite numerous in the past, very little has been presented concerning the strontium apatites activated by Sb^{+3} and Mn^{+2}. This situation has perhaps arisen because of the great similarity of the strontium to the calcium system, despite the fact that both have been used commercially for some time, the former for color correction in blends and the latter as the major component in fluorescent lamps. Nevertheless, with the exception of the data given by Rimbach (1), no other information is to be found. Quirk (2) presented data on the color range spanned in the calcium system. The color range spanned by the strontium system is the subject of the present contribution.

* Electrochemical Society Active Member.
[1] Present address: Rutgers, the State University, Chemistry Dept., Newark, N. J. 07102.
Key words: apatites, strontium, colors, emission, phosphors.

Experimental

Phosphors were prepared by firing a mixture of luminescence grade materials, $SrHPO_4$, $SrCO_3$, SrF_2, $SrCl_2$, Sb_2O_3, and $MnCO_3$, for 6 hr at 1150°C. The formulation employed was: $Sr_{4.80}X_{0.96}(PO_4)_{3.00}:Sb_x:Mn_y$. This gives an apatite composition with a minimum of $Sr_2P_2O_7$ and antimonates, the latter not detectable by x-ray powder diffraction analysis. Spectral measurements were made on an energy-corrected instrument; x-y trichromatic color coordinates of the phosphors were calculated employing a suitable program *via* a 360 IBM computer, while those of the lamps were

determined experimentally. The emission monochromator of the instrument was calibrated in microwatts, for a given excitation density, using a standard lamp. A self-contained integrator then gave the integrated band intensity directly in microwatts.

Results

The emission band of Sb^{+3} in $Sr_5F(PO_4)_3$ consists of a blue-green band peaking at 498 nm, whereas that of Sb^{+3} in $Ca_5F(PO_4)_3$ is a blue band peaking at 480 nm (2). The addition of Mn^{+2} introduces a second band at 565 nm in $Sr_5F(PO_4)_3$ (see Fig. 1) whereas the introduction of chloride to form mixed apatites rapidly shifts the color greener. Most of this information is well known to the trade but perhaps less well known is the effect due to optimum activator concentration.

The emission color of the strontium apatites is not antimony dependent above about 3.0 mole per cent (m/o) Sb^{+3} per mole of apatite. Whereas upwards of 16 m/o of Mn^{+2} is required to saturate the emission color in $Sr_5F(PO_4)_3$, *i.e.* to the point where most of the emission lies in the Mn^{+2} emission band, the emission color becomes saturated in $Sr_5Cl(PO_4)_3$ as low as 4 m/o Mn^{+2}. This is illustrated in Fig. 1 and 2 for $Sr_5F(PO_4)_3$ and Fig. 3 for $Sr_5Cl(PO_4)_3$. In Fig. 2, the Sb^{+3} band intensity (integrated as microwatts) decreases almost linearly as the Mn^{+2} band intensity increases. These phenomena place a limitation on the usable formulations available since high chloroapatite compositions can only be employed at low Mn^{+2} concentrations or concentration quenching will be encountered. The upper, practical limit is about 0.75 Cl/0.25 F, although compositions at 0.875 Cl/0.125 F were investigated to fill out the data, despite the very low brightnesses usually encountered.

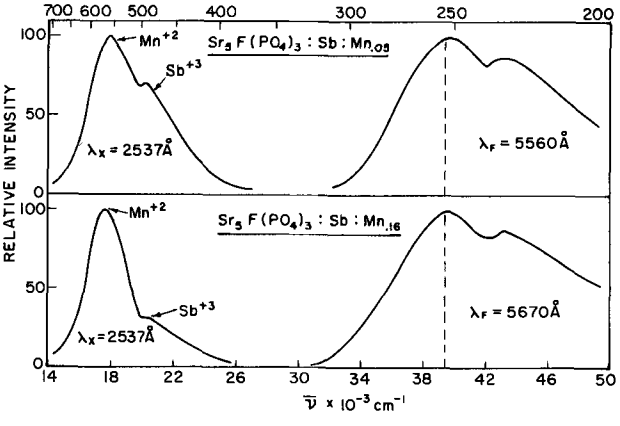

Fig. 1. Spectra of Sb^{+3} activated fluoroapatite phosphors

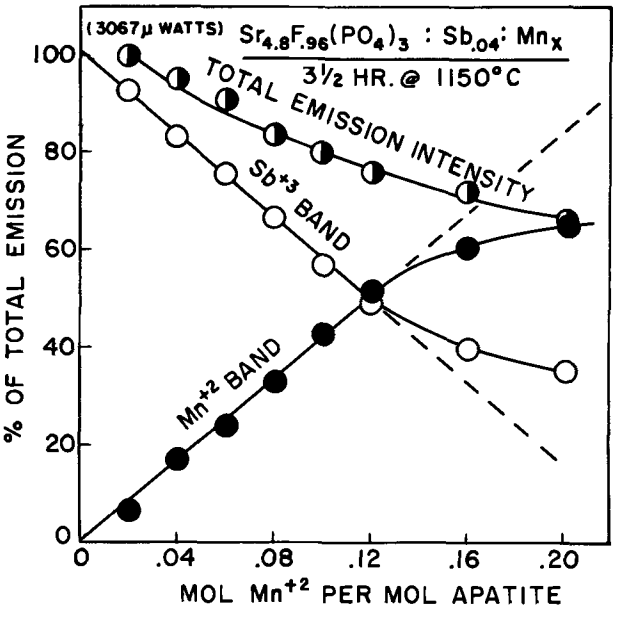

Fig. 2. Comparison of total energy emitted by Sb^{+3} and Mn^{+2} in strontium fluoroapatite.

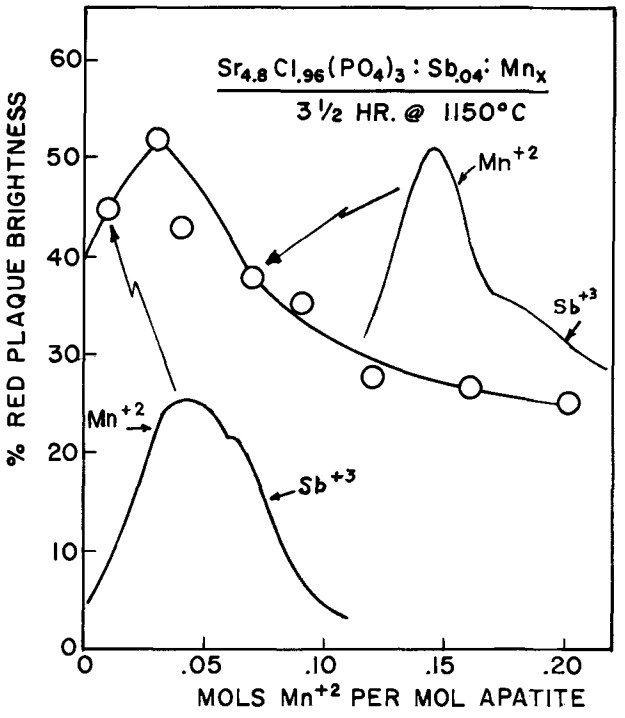

Fig. 3. Output and spectra for Mn^{+2} activation in strontium chloroapatite phosphors.

Figure 4 shows the trichromatic color coordinates calculated for the compositions indicated and were obtained from the emission spectra of the phosphors. In Fig. 5, the actual colors of 40W fluorescent lamps, as determined experimentally, are shown. These colors span the complete range of commercial lamp colors but are, in general, greener than the corresponding calcium halophosphate compositions. The displacement of the phosphor colors (Fig. 4) as compared to the lamp color (Fig. 5) is most certainly due to the mercury arc color contribution, as is well known. For comparison, Table I presents lamp brightnesses observed for 40T12 lamps, for the pure fluoroapatite and a 50/50 F-Cl: $Mn_{0.12}$ composition. Also given are lamp brightnesses for cool-white deluxe (CWX) and warm-white deluxe lamps made from these components. By comparison with known values for lamps made from components in the calcium halophosphate system having equivalent compositions, it may be concluded that the strontium halophosphates are very close in efficien-

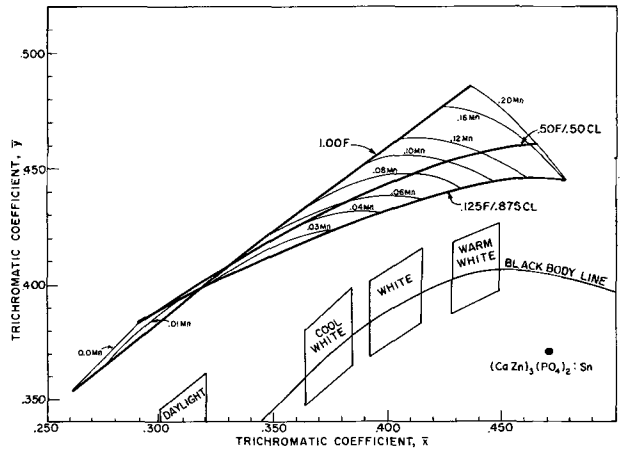

Fig. 4. Effect of composition on phosphor emission color (Sb^{+3} content — 6.0 m/o).

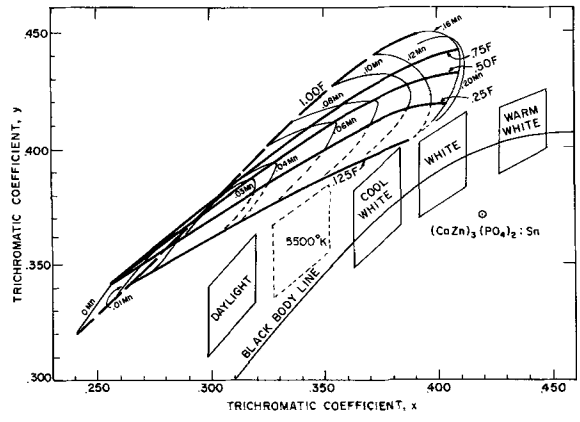

Fig. 5. Strontium halophosphate compositions and lamp color data (Sb^{+3} content — 6.0 m/o).

cy to their calcium counterparts, albeit somewhat greener in emission color.

Conclusions

There are a number of interesting facts which can be deduced from the data presented in the color measurements. First of all, the bluest phosphor is the pure fluorapatite. The addition of even a small amount of chloride serves to shift the color to a point much greener. Thus, it is essential to prevent any contamination by chloride in order to produce the bluest phosphor. It can also be noted that the color of the mixed apatites at zero manganese content is invariant at all F/Cl ratios (see Fig. 4). (Note also that the minimum amount of chloride necessary to cause this shift has not been determined in this work).

A second deduction indicates that the mixed apatites form a different set of loci than the pure fluoroapatite. Although the pure fluoroapatite is bluer than any of the mixed apatites, the addition of Mn^{+2} to the fluoroapatite produces phosphors which are greener than any of the mixed phases.

Table I. Lamp results for strontium halophosphate phosphors (containing 6 m/o Sb^{+3})

Color	Lamp lumens 0 hr	Lamp lumens 100 hr
Blue-green	2651	2558
Yellow	3549	3322
CWX	2471	2395
WWX	2735	2691

The third deduction which can be made shows that the greatest shift in color coordinates occurs at the lowest Mn^{+2} concentrations. Thus, if one should plot the shift in color *vs.* the Mn^{+2} content, *i.e.* $d\bar{x}/d(Mn)$ *vs.* Mn^{+2}, one would obtain a curve peaking at the very low Mn^{+2} contents and tailing out at the higher concentrations.

Perhaps the real value of the data presented in Fig. 4 and 5, lies in being able to choose a composition having suitable emission characteristics for a given application. For example, if one wished to choose phosphors to obtain a lamp close to 5500°K using a $(Ca,Zn)_3(PO_4)_2$:Sn phosphor as one of the components, compositions such as $Sr_5F_{0.75}Cl_{0.25}(PO_4)_3$:Sb:$Mn_{0.01}$ or $Sr_5F_{1.00}(PO_4)_3$:Sb:$Mn_{0.02}$ might be chosen.

Phosphorescence Decay of Calcium Oxide Activated by Yttrium

L. M. Schwartz, J. M. Voutay-Poncet, and J. Janin

Laboratoire de Spectroscopie et de Luminescence, Université Claude Bernard, Lyon I, 69-Villeurbanne, France

Long Duration Decay Theory

This theory assumes the existence of a continuous trap depth distribution between two limits E_1 and E_2 (1-8). First-order kinetics are involved with negligible retrapping. Under these conditions, with the frequency factor assumed to be constant, the luminescence intensity, at time t, is

$$L = C \int_{E_1}^{E_2} m_E(O)\, P_E \exp(-P_E t)\, dt$$

where P_E is the probability for an electron to escape from a trap

$$P_E = s \exp(-E/kT)$$

$m_E(O)$ is the trap distribution function when the powder is excited until saturation occurs and C is a constant. It is assumed that

$$m_E(O) = A \exp(-\delta E) \quad (8, 9) \qquad (\delta = \text{constant})$$

Key words: phosphorescence, CaO:Y, traps, decay curves, thermoluminescence.

The expression of L then becomes

$$L = AsC \int_{E_1}^{E_2} \exp\left[\left(-\delta - \frac{1}{kT}\right) E\right] \exp[-st \exp(-E/kT)]\, dE$$

Let us set $\epsilon = \delta kT$ and $u = st \exp(-E/kT) = \alpha t$. It follows

$$L = \frac{-ACkT}{s^\epsilon t^{1+\epsilon}} \int_{u_1}^{u_2} u^\epsilon \exp(-u)\, du$$

At fixed temperature, we may write: $ACkT/s^\epsilon = L_O$, then

$$L = -\frac{L_O}{t^{1+\epsilon}} \int_{u_1}^{u_2} u^\epsilon \exp(-u)\, du$$

The integral may be expressed by using the incomplete gamma function

$$\gamma(1 + \epsilon, x) = \int_0^x u^\epsilon \exp(-u)\, du$$

Thus

$$L = \frac{L_0}{t^{1+\epsilon}} [\gamma(1 + \epsilon, u_1) - \gamma(1 + \epsilon, u_2)]$$

That is the intensity expression *vs.* time since $u_i = \alpha_i t$ $(i = 1, 2)$

For such a formula to be verified, four parameters must be evaluated L_0, ϵ, α_1, and α_2. When α_1 and α_2 just as s are known, it is possible to compute the E_1 and E_2 level energies.

Yet, the upper expression generally does not overlap the whole decay interval between 2 and 10^4 sec. It is often necessary to consider the sum of two analogous expressions (9, 10), each of them would correspond to two different groups of traps responsible for the decay. Then it may be written

$$L = (L_0'/t^{1+\epsilon'})\{\gamma(1 + \epsilon'; \alpha_1' t) - \gamma(1 + \epsilon'; \alpha_2' t)\}$$
$$+ (L_0''/t^{1+\epsilon''})\{\gamma(1 + \epsilon''; \alpha_1'' t) - \gamma(1 + \epsilon''; \alpha_2'' t)\}$$

A table of gamma functions was computed for the values

$$-0.99 \leq \epsilon \leq 2 \text{ and } 0.001 \leq x \leq 5$$

Experimental Results

The upper representation was extended to powder samples of yttrium-activated calcium oxide at various temperatures.

For each group of traps, approximative values for the parameters are determined by studying the variations of the product $L \cdot t^{1+\epsilon'}$. That is, a certain value of ϵ' is chosen so that the obtained curve gives the best representation of a gamma function difference (convex curve with a very flat maximum). After an approximative value for ϵ' has been determined, the curves of the functions $L \cdot t^{1+\epsilon'}$ and $\gamma(1 + \epsilon'; \alpha_1' t) - \gamma(1 + \epsilon'; \alpha_2' t)$ are plotted on the same graph for different values of α_1' and α_2' and with a suitable scale so that they superpose each other. The trap distribution is characterized by the values of α_1' and α_2' giving the best superposition, possibly after retouching the precedently determined ϵ' value. The constant L_0' is easily deduced from the curves. Figure 1 shows a logarithmic plot of the decay of CaO(Y) at −78°C. The decay part between 80 and 4800 sec is approximately a straight line; this gives immediately the values ϵ' and L_0': $L_0' = 3.59 \times 10^5$ and $\epsilon' = 0.25$.

As a result of α_2' equals zero whatever t may be and $\gamma(1 + \epsilon', \alpha_1' t)$ must tend to its limit $\Gamma(1 + \epsilon')$ as soon as $t = 80$ sec and this imposes $\alpha_1' t \simeq 0.5$ and $\alpha_1' \simeq 0.06$. The values calculated from the formula

$$L' = (3.59/t^{1.25})\, \gamma(1.25; 0.06t)$$

coincide, with a good precision, with the experimental values until $t = 40$ sec. For $2 < t < 40$ sec, it is necessary that another trap distribution occurs, which is determined by computing for each value of t, the intensity $L'' = L - L'$ and studying the deformations of the curves $L'' \cdot t^{1+\epsilon''}$ for different values of ϵ''. The best coincidence with the experimental results takes place for $\epsilon'' = -0.2$. For this value of ϵ'', the curve system is plotted on Fig. 2 and, last, we carry $\alpha_1'' = 0.5$, $\alpha_2'' = 0.1$. Then it is easy to determine L'' and the formula

$$L = \frac{1.085 \times 10^5}{t^{0.8}} [\gamma(0.8; 0.5t) - \gamma(0.08; 0.1t)]$$
$$+ \frac{3.59 \times 10^5}{t^{1.25}} \gamma(1.25; 0.06t) \quad [1]$$

shows the decay of CaO(Y) at −78°C between 2 and 4800 sec, with an error of less than 8%. On Fig. 1, the points represent the calculated values from this relation.

The value of the frequency factor s is obtained from thermoluminescence curves of CaO(Y) samples irradiated by uv light at −196°C. The curves show several peaks, about −90°C, −50°C, and room temperature. The trap depths and s are determined either by

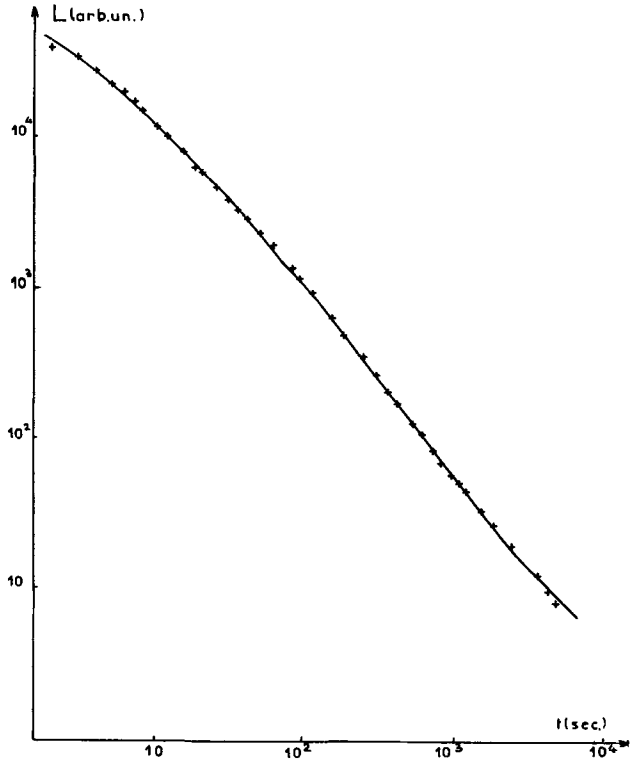

Fig. 1. Phosphorescence decay of CaO(Y) at −78.5°C. ——, Experimental curve; +, calculated values from Eq. [1].

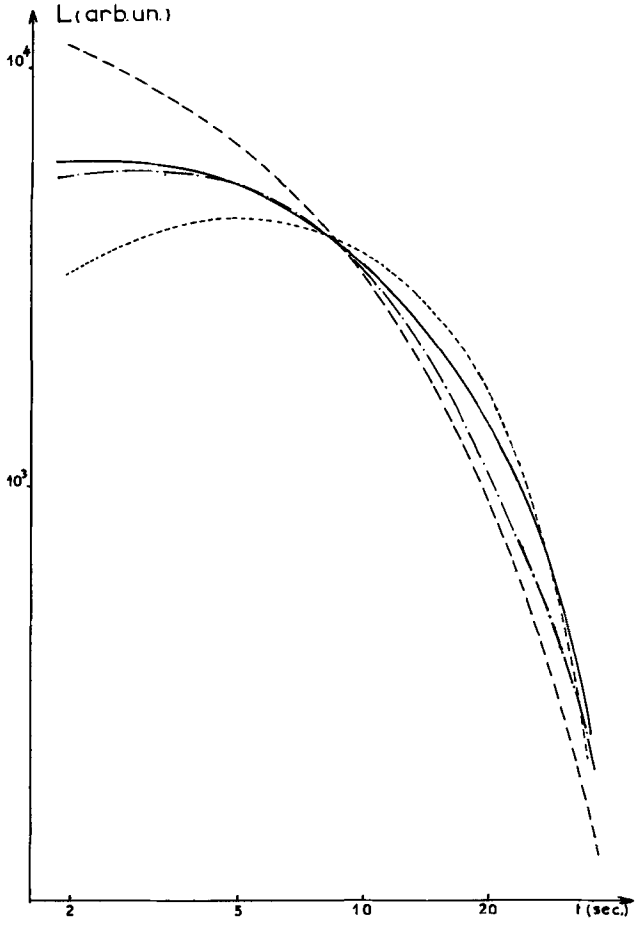

Fig. 2. Curve system for CaO(Y) at −78.5°C. ——, Experimental curve $L'' \cdot t^{0.8}$; — —, curve γ (0.8, $\alpha_1'' t$) − γ (0.8, $\alpha_2'' t$) for $\alpha_1'' = 0.5$, $\alpha_2'' = 0.2$; · — ·, curve γ (0.8, $\alpha_1'' t$) − γ (0.8, $\alpha_2'' t$) for $\alpha_1'' = 0.5$, $\alpha_2'' = 0.1$; - - - -, curve γ (0.8, $\alpha_1'' t$) − γ (0.8, $\alpha_2'' t$) for $\alpha_1'' = 0.2$, $\alpha_2'' = 0.1$.

varying the heating rate (12) or by Grossweiner's or Halperin and Braner's methods (13, 14). The mean value of s is 10^9. Thus we deduce the trap depths corresponding to the α coefficients obtained before. The values found are 0.36 eV for α_1'', 0.386 eV for α_2'', and 0.394 eV for α_1'. These results are consistent with those given by thermoluminescence: 0.32 eV for the peak at −90°C and 0.37 eV for the one at −50°C.

Other experiments were performed at −196°C and 25°C. Thus, at 25°C, an expression similar to the previous one has been found which is valid between 10 and 90,000 sec with an error less than 10% and leads to trap depths falling between 0.55 and 0.64 eV when thermoluminescence gives 0.57 eV

$$L = \frac{2.50 \times 10^5}{t^{1.10}} [\gamma(1.10; 0.5t) - \gamma(1.10; 0.06t)] + \frac{2.32 \times 10^5}{t^{0.835}} \gamma(0.835; 0.0157t)$$

The coefficients at 25°C are not deducible from those of −78°C because the decays correspond to two different thermoluminescence peaks between which there is no correlation.

Likewise, experiments performed with gallium-activated calcium oxide have shown that the above method once again gave results consistent with those set up by the usual thermoluminescence processes (10, 11).

Conclusion

The analysis method of phosphorescence decay curves with the help of the incomplete gamma functions does make it possible, by using one or two (three in certain cases) trap distributions to find an expression of the intensity valid from the early seconds after the excitation until the end of the decay.

Photometallic Etching of Holograms

P. J. Magill and C. A. Speicher

IBM Systems Development Division, Endicott, New York 13760

In recent years, various techniques have been employed in the construction and replication of holograms. For example, photoresists, bleached emulsions, and thermoplastics (1) have been used for phase-type holograms, whereas thin metallic films (2, 3) have been used for amplitude-type holograms. More recently, the photoanodic engraving of silicon (4) has been demonstrated as a useful technique for producing thin, phase-type holograms. The present note describes another novel method for the fabrication of holograms. This method permits the direct fabrication of holograms on metallic films by use of the photometallic process (5). Conceptually, this process could be used for the fabrication of either phase- or amplitude-type holograms. This would depend on the original film thickness. For example, a 200Å film would be used for an amplitude hologram whereas a film of approximately 5000Å or greater would provide sufficient path differences for a reflective, phase-type hologram. This, of course, assumes that proper control of the photometallic process is possible.

The photometallic process is a method for producing patterns by the preferential etching of surfaces. This process works by the photogeneration of material which subsequently reacts with the surface. The work of Burgess and Schaefer (5) demonstrated etch rates of approximately 100Å/min or greater and resolution capability of about 75 lines/mm. Although this process might be useful for microcircuitry, its application to holography is not readily apparent due to this limited resolution. However, some recent approaches to image formation (6), which use phase-type optical filters, do not require the high carrier frequency that is normally associated with holography. The present work was directed with this in mind and, consequently, only metallic films thick enough for phase-type reflective holograms were utilized.

Key words: holography, photochemistry, thin films, etching.

Two metals (copper and Nichrome) known to have been etched by Burgess and Schaefer, were selected for this study. The Ni-Cr films (≅1000Å thick) were prepared by vacuum deposition and the Cu films (≅3000Å thick) by r-f sputtering. Standard microscope slides were used as substrates which were subjected to a routine cleaning procedure prior to placement in either vacuum chamber. In the case of the r-f sputtered films, the substrates were also cleaned by a sputter-etch bombardment. This was followed by deposition in an argon atmosphere at 10^{-2} Torr at a rate of about 600Å/min. Films prepared in this fashion generally exhibit better adhesion than do similar films prepared by evaporation and, consequently, should permit a better evaluation of the etching process.

The procedure outlined by Burgess and Schaefer for etching was followed; the metal film was coated with a polymer system and subsequently exposed to the desired pattern. Since our primary interest was in producing a phase-type hologram, we were naturally interested in the gray scale patterns that could be obtained, since this would indicate a relationship between light intensity and etch rates.

In the case of Nichrome, the solvent used was methylethylketone (MEK). As previously shown by Burgess and Schaefer, no etching occurred during exposure. Etching did occur during post-irradiation treatment. Some gray scale capability was observed.

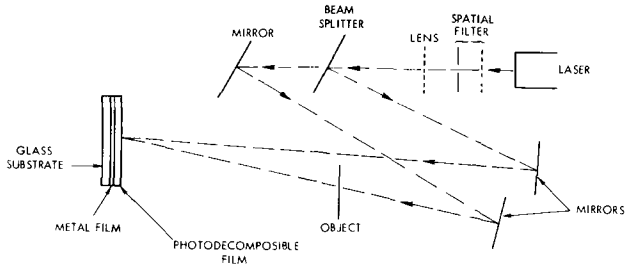

Fig. 1. Arrangement of holographic experiment

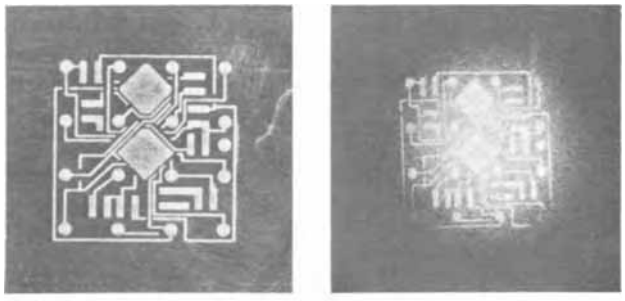

Fig. 2. Construction of a hologram by using the photometallic process. (a) Object, (b) reconstructed image.

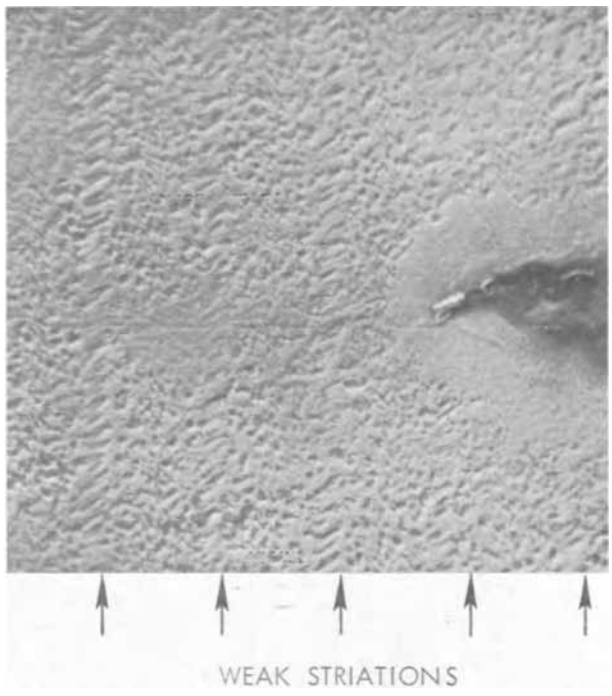

Fig. 3. Scanning electron micrograph (approx. 1700X) of a diffraction pattern etched in copper.

However, the results did not seem to indicate any direct relationship between etch rates and the light intensity. All further work was done using copper films.

For copper films, a 0.1M solution of iodoform in methanol was used as the photoetchant. In addition, 2.5g of alcohol-soluble butyrate (A.S.B.)[1] were dissolved in 50 ml of the 0.1M etchant. The copper films were dipped in the etchant and allowed to dry, leaving a polymer and iodoform film about 0.25 mm thick. Slight etching of the copper occurred during application of this etchant. The multilayer structure of copper and iodoform plus A.S.B. was then exposed to an ultraviolet light source for activation of the photodecomposible iodoform.

The experimental arrangement used to etch and therefore construct holograms in the copper film is shown in Fig. 1. Standard holographic techniques were used for the construction and reconstruction of the hologram. The collimated output of about 30 mW/cm^2 from an argon laser operating at the 3511Å wavelength was used for constructing the holograms. Interference between the reference beam and object beam resulted in intensity variations of the ultraviolet light on the photodecomposable material. The angle between the beams, about one degree, resulted in a spatial frequency of approximately 60 lines/mm. The exposure times were about 60 min.

Figures 2a and 2b show the mask used as the object and the reconstructed image, respectively, from the etched copper film. The reconstruction was obtained by reflecting a collimated beam from a He-Ne (6238Å wavelength) laser from the etched copper surface. The diffraction efficiency of this hologram was approximately 1%. There was also a relatively high level of background noise in the vicinity of the reconstructed image.

Subsequently, a simple hologram (*i.e.*, a diffraction grating) was made. This was done so the etching process could be evaluated. Talysurf[2] measurements of this grating indicated that the etch depth was not greater than 100Å (the resolution of the Talysurf instrument). This seems contrary to the work of Burgess and Schaefer, who demonstrated gray scale capability and relief-height variations that were proportional to the density variations. Holograms observed in reflected light depend on the surface topology. Under normal circumstances, the surface should have relief-height variations that produce the proper phase variations. Since no such surface variations were measured, it is possible that an alternative mechanism would explain the ability to reconstruct an image.

The diffraction grating was examined by a scanning electron microscope (SEM). The results (Fig. 3) show etched lines (evidenced by the faint striations indicated by arrows) resulting from constructive interference at a spatial frequency of about 50 liters/mm. This surface modulation (*i.e.*, the etched lines) produced by the etching process appears to be further modified by noise. This is probably due to a nonuniform etching which results in a relatively nonspecular surface.

The depth of modulation determines the diffraction efficiency. In the case of the present grating, low modulation depth seems apparent when considering the work presented by Jenny (7). He showed an SEM scan of a photopolymer diffracting grating (hologram). The striations that are weak in Fig. 3 are clearly observed in his work. Although his gratings were not metallized surfaces, the similarity of SEM pictures indicates preferential etching of the copper film.

A copper film also was etched using a photographic step tablet as a mask. Evaluation by the SEM appeared to reveal a difference in etch depths from step to step. However, the etching again is nonuniform and, in essence, leads to a different surface roughness for each step rather than to discretely different and uniform steps. Microscopic examination of this etched step tablet did not clarify this point. For the most part, it seemed to indicate localized etching (discrete rather than a continuum), which might be expected from the polymer system. The size of the microscopic etched sites depended on the light intensity; therefore, a variation in surface roughness does exist from step to step.

As a consequence of this variation in surface roughness (dependent on light exposure), light reflected from an etched grating (or hologram) is partially phase retarded and partially scattered. It would seem that the former provides for a reconstructed image as in a phase hologram. The depth of modulation (less than 100Å) would indicate an expected effi-

ciency of less than 1%. The scattered light arising from the nonspecular surface would seem to produce a noisy and, consequently, an inefficient hologram. It is possible, however, that this scattering, if it were preferential, could contribute to a reconstructed image as in an amplitude hologram. It is therefore conceivable that a compound effect is contributing to the reconstructed image.

The present work has shown that the photometallic process could be used for the fabrication of holograms. It has not, however, demonstrated that a phase hologram may be made distinct from an amplitude hologram. It should be realized that a multitude of materials and, presumably, a multitude of photoetchants are at one's disposal. With the proper combination, it is reasonable to expect that the attainment of either form of hologram is possible.

Acknowledgment

The authors are grateful to R. Lasky for obtaining the SEM information.

Orientation Effects on the Electrical Properties of High Purity Epitaxial GaAs

J. V. DiLorenzo* and A. E. Machala

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Electrical properties, growth rate, and surface morphology of III-V compound semiconductors grown from the vapor phase have a marked dependence on the crystallographic orientation of the substrate (1-8). The effects of substrate orientation on the electrical properties of GaP have been studied most extensively (1-5). These studies are concerned with the incorporation of deliberately added impurities at high concentrations, although some work has been done on the incorporation of background impurities into vapor grown GaP (4, 5). Moest (6) and Williams (7) have reported orientation effects on epitaxial GaAs grown from the vapor phase by transport of bulk GaAs with hydrogen chloride gas. Blakeslee (9) has reported variations in the electrical properties and growth rate of GaAs films grown on substrates misoriented off the {100} and {111} by as much as five degrees.

We have observed that the purity of GaAs epitaxial layers grown from the vapor using the $AsCl_3|Ga$ (saturated with GaAs) $|H_2$ technique (10) depends primarily on three parameters; substrate orientation, substrate temperature (11), and $AsCl_3$ mole fraction (12, 13). It is the purpose of this communication to report substrate orientation effects on the incorporation of low-level background impurities. The remaining growth conditions, $AsCl_3$ mole fraction and substrate temperature, were optimized to yield high purity epitaxial layers. Electron mobilities up to 9820 cm^2/V-sec and 199,000 cm^2/V-sec at 300°K and 77°K, respectively, have been obtained.

The films were grown on {100},[1] {111}A, {211}A and B, and {311}A and B faces of semi-insulating, Cr doped GaAs substrates. For the {211} and {111} orientations, the arsenic (B) or gallium (A) face was revealed by chemical etching with either a 2% Br_2 in CH_3OH solution or a $5H_2SO_4|H_2O|H_2O_2$ solution.

Chemical etching of substrates on the {311} orientation displayed only minor differences in etching behavior. A definite identification of the A and B faces of {311} orientations was achieved from anomalous x-ray scattering measurements at an absorption edge as outlined by Barns *et al.* (14).

Layers were deposited on as many as 4 substrates of different orientations in a single run. Typical growth conditions were as follows: Ga source temperature, 820°C; $AsCl_3$ mole fraction, 0.012-0.016; substrate temperature 702°-707°C.

Hall measurements were made at room temperature and at 77°K on "clover-leaf" samples as described by van der Pauw (15). Carrier concentrations were calculated from the Hall data based on layer thicknesses obtained from measurements of stained angle laps.

In Table I, the thickness and growth rate of epitaxial films are listed along with substrate orientations. For this table as well as the data presented in Tables II and III, all the orientations listed under a given sample number were grown in the same run. These results show that the order of decreasing growth rate is

6	{100}	1.0×10^{13}	≈30.0
	{311}B	1.3×10^{15}	2.4
7	{100}	3.0×10^{13}	6.5
	{111}A	1.7×10^{15}	5.0
	{211}B	2.2×10^{15}	3.2
	{311}B	2.6×10^{15}	2.2
8	{100}	4.7×10^{13}	3.5
	{211}B	1.5×10^{15}	3.0

{111}A > {211}A > {211}B > {311}B ≃ {311}A > {100}. The growth rates obtained in this work at 705°C are in fair agreement with those of Shaw (8) which were obtained at 750°C.

Table II lists the electrical properties of films grown on various orientations. Table III lists the compensation ratio, that is, the total number of ionized impurities, $N^+ + N^-$, divided by the free-carrier concentration, n, determined from the transport calculations of Rode and Knight (16).

The following is a summary of the major points evident from inspection of Tables II and III:

(*A*) Carrier concentrations as low as 3 x 10^{13} cm^{-3} and mobilities as high as 199,000 cm^2/V-sec at 77°K [Sample 8, {100}] can be achieved. Room temperature mobilities as high as 9820 cm^2/V-sec have been obtained.

(*B*) Carrier concentrations and total ionized-impurities can vary more than two orders of magnitude between samples grown on different orientations [Samples 6 and 7 for example].

(*C*) Growth on a plane 2° off {100} toward {110} produces, in general, more highly compensated films than growth on {211} or {311} planes.

(*D*) The growth rate of films on {311}A and B faces differ very little, even though the free carrier concentrations vary by two orders of magnitude.

(*E*) The arsenic faces of {211} and {311} orientations incorporate more impurities than the gallium faces.

Wolfe *et al.* (17) have recently pointed out that conducting inhomogeneities can cause anomalously high apparent mobilities. To substantiate the present data, the dependence of mobility on magnetic field was investigated for Sample 4 on {311}A, Sample 7 on {100}, and Sample 8 on {100}. The mobility varied from 9820-9400 cm^2/V-sec with a field change from 500-5000 gauss for Sample 4; from 182,200-181,000 cm^2/V-sec with a change of 410-820 gauss for Sample 7; and from 199,000-189,000 cm^2/V-sec with a change from 205-820 gauss for Sample 8. The decrease in mobility with increasing field demonstrates that these mobilities are real and not anomalous.

The influence of substrate orientation on the incorporation of impurities is undergoing detailed study. Further results will be the subject of a forthcoming publication.

Acknowledgments

The authors wish to thank F. Ermanis for performing Hall measurements and R. L. Barns for his x-ray determination of the polarity of the {311} face.

Thermal Conductivity Measurements of Nickel-Cadmium Aerospace Cells

Part I: Cell Conductivities

E. W. Brooman* and J. McCallum*

Battelle Memorial Institute, Columbus Laboratories, Columbus, Ohio 43201

ABSTRACT

Thermal conductivities of four types of sealed, 20 A-hr nickel-cadmium cells have been measured perpendicular to (x-direction) and parallel with (y-direction) the plane of the electrodes. The average conductivities for the discharged cells described are about 0.0030 and 0.0065 (cal/cm^2/sec)/(C/cm) for these x- and y-directions, respectively. Thermal resistance network models give reasonable quantitative agreement with the k_x measurements using conductivity values of 0.0019, 0.0016, and 0.0011 (cal/cm^2/sec)/(C/cm), determined in some preliminary experiments, for the wetted negative and positive electrodes and the separator, respectively. The thermal conductivity of the cells is found to change very little with state of charge.

A paucity of data exists in the published literature concerning experimentally determined values for the thermal conductivity of primary and/or secondary cells (1). Because of the thermal anisotropy of prismatic aerospace cells, reliable data are needed to calculate heat balances and heat dissipation efficiencies for various power system configurations for earth-orbiting and space vehicles. Thermal resistance, capacitance, and conductivity values are also important in evaluating the thermal design of batteries for other than space applications.

A research program to improve sealed, nickel-cadmium cells for the U. S. Air Force included the following thermal conductivity measurements. Because of terminal connections at the top and recessed case bottoms on some cells, measurements were made only in two directions. These two directions are perpendicular to (x-direction) and parallel with (y-direction) the plane of the electrodes, as shown in Fig. 1. The conductivities measured in these directions are referred to as k_x and k_y, respectively. Subsequently, thermal resistance networks were constructed, representative of an external heat source and heat flow through the cells in these directions, in order that the observed conductivities could be correlated with the arrangement and type of components comprising the cells.

Experimental

Sealed nickel-cadmium aerospace cells, having a nominal capacity of 20 A-hr, from four manufacturers were studied.These cells were given the identification of Types I through IV, depending on the manufacturer. All the cells were prismatic in shape, Types I and II cells being taller and thinner than Types III and IV cells. Types I and II cells and Types III and IV cells had similar over-all dimensions. No cell had a third electrode. Types I and II cells had the positive terminal electrically insulated from the cell case; Types III and IV cells had both terminals insulated from the cell case. The Type III cell had the adhesive tape, with which it was supplied, removed for the thermal-conductivity measurements. Typical physical characteristics of the four types of cell are given in Table I.

All the cells had previously been subjected to capacity and voltage matching procedures as part of another investigation (2, 3). Subsequently, the thermal conductivity of the sealed cells was determined after they had been discharged and shorted.

Thermal conductivities of the discharged cells were measured using the comparison technique, whereby, if

IV	8.02 × 10.04	3.75 × 10.04	No	2	18	19

the heat flow through the cell in question and a reference material is maintained constant, then the temperature drop across each is inversely proportional to the thermal conductivity of each and directly proportional to the distance the heat flux traverses in each (4). Thus, if k_2 is the thermal conductivity of the cell of cross-sectional area A and thickness d_2, if k_1 is the thermal conductivity of the reference material, also having a cross-sectional area A, but of a thickness d_1, and if the measured temperature drop across the cell is ΔT_2 and that across the reference material is ΔT_1

$$\frac{k_2}{k_1} = \frac{\Delta T_1}{\Delta T_2} \cdot \frac{d_2}{d_1} \quad [1]$$

or

$$k_2 = k_1 \cdot \frac{\Delta T_1}{\Delta T_2} \cdot \frac{d_2}{d_1} \quad [2]$$

The reference material chosen was Plexiglas acrylic sheet about 1.2 cm thick because this gave a reasonable temperature differential, similar to that across the cells. The thermal conductivity of this reference material was taken to be 0.492 x 10^{-3} (cal/cm²/sec)/(C/cm) according to Specification ASTM D702.

The experimental arrangement is shown schematically in Fig. 2. Strip heaters encased in silicone-rubber electrical insulation were held firmly against a copper block, 2.5 cm thick, used to provide a uniformly distributed heat flux. The cell under investigation was placed next to the reference block, and the whole apparatus was clamped between two retaining plates using 2 ft-lb of torque. Plate A was fabricated from Plexiglas and Plate E was fabricated from aluminum to promote a more unidirectional heat flux through the components. The copper block, reference block, and retaining Plate E, all had grooves key-slotted into them which were the exact depth and width of a 30-gauge copper-Constantan thermocouple. When inserted into the slots, the thermocouple's leads and junctions were flush with the surface. The temperature gradients could thus be calculated with precision, and good contact with both surfaces was assured. The junctions were located at the centers of B, C, and E, where the heat flux was assumed most uniform.

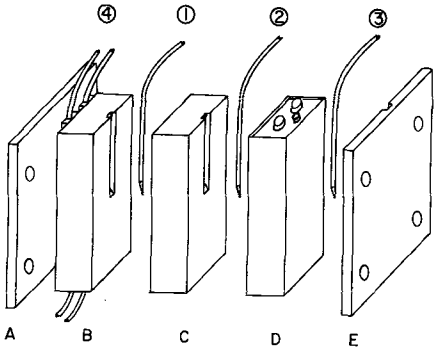

Fig. 2. Major components of the experimental apparatus used to measure thermal conductivities of cells. A, Plexiglas retaining plate; B, copper heating block; C, Plexiglas reference block; D, cell under investigation; E, aluminum heat sink/retaining plate; ① → ③, copper/Constantan thermocouples; ④, silicone-rubber-encased strip heaters.

Because the cells did not have flat faces, good thermal contact with the various components of the apparatus (low contact resistance) could not be assumed. Therefore, silicone vacuum grease, filled with pure aluminum powder to increase the thermal conductivity, was used between components B, C, D, and E before they were bolted together. It should be noted that a separate set of components was fabricated for each cell so that the cross-sectional area of B, C, and D was the same for each particular measurement. Because measurements were taken in directions parallel with and perpendicular to the plane of the electrodes for each of the four types of cells, eight sets of apparatus components were necessary.

The experimental procedure was as follows. The cell was removed from any retaining plates and wrappings and lightly cleaned with a metal polish. Thorough degreasing followed. The copper reference block and the aluminum retaining plate were also polished and degreased, while the Plexiglas components A and C and the thermocouples were just cleaned and degreased. The apparatus was then assembled and bolted together to a 2 ft-lb torque loading, as described previously. Excess, exuded grease was then removed, and the whole apparatus encapsulated with two layers of matted insulation and another of rigid Styrofoam 2.5 cm thick. The heat sink/retaining plate outside surface was left exposed to the laboratory atmosphere but shielded by the projecting Styrofoam to minimize the effects of draughts.

The strip heater(s) used power from the main supply by employing a Variac Autotransformer to reduce the voltage to 10 to 20V. The thermocouples were shielded and the outputs fed to a Sargent M-R recorder. At the beginning of each experiment the thermocouples were calibrated against each other using an ice bath as cold junction. The heater was then switched on and the apparatus allowed to come to the steady state. In the steady state the cell temperatures were about 32° ± 2°C (average of the thermocouple ② and ③ readings).

Steady state was achieved in about 18 hr and was determined from invariant thermal gradients across the cell and reference block. Accuracy of temperature measurement was about ±0.015°C. The error in measuring the lengths of the heat-transfer path was estimated to be ±0.05 cm because of the rounded edges of the cell cases and the small uncertainty of the distribution of the vacuum grease between components. These length measurements therefore probably determine the over-all accuracy of measurement. The reproducibility of the experiments, which were repeated, was about ±5%.

Results and Discussion

The k_x and k_y values obtained for the four types of 20 A-hr cells are summarized in Table II. The ratio k_y/k_x is also given as a measure of the thermal anisotropy of each cell.

In the x-direction, the average conductivity value measured is 0.0044 (cal/cm²/sec)/(C/cm)—hereafter referred to as cgs units. The values for the Types I, II, and III cells are similar and average 0.0030 cgs units, while the k_x value for the Type IV cell is 2 to 3 times higher. The y-direction conductivities for the Types I, II, and III cells are similar to each other, with an average value of 0.0065 cgs units.

Table II. Measured thermal conductivities of four types of nominal 20 A-hr nickel-cadmium cells

Cell type	Direction of heat flow[a]	Thermal conductivity (k), (cal/cm²/sec)/(C/cm)	Ratio k_y/k_x
I	y-direction	$k_y = 0.0070$	2.59
	x-direction	$k_x = 0.0027$	
II	y-direction	$k_y = 0.0067$	1.76
	x-direction	$k_x = 0.0038$	
III	y-direction	$k_y = 0.0056$	2.16
	x-direction	$k_x = 0.0026$	
IV	y-direction	$k_y = —$	—
	x-direction	$k_x = 0.0086$	

[a] See Fig. 1.

Conductivities in the y-direction.—The reported values for k_y for nickel-cadmium cells range from 0.0035 to 0.052 cgs units (5-9, 17), there seemingly being no correlation between the A-hr capacity of the cell and the conductivity value measured. Values obtained in this investigation range from 0.0056 to 0.0070 cgs units, and are higher by a factor of two than the range of values reported with one exception—the value for the Type III cell. Although the value given in Table II for the Type III cell is smaller than the other values obtained, this is the average of measurements on three different cells, the individual results differing by less than ±2%.

Thermal-resistance network models were constructed for the four types of cell (14), and evaluated to predict the k_y values using the relationship

$$R_i = d_i/k_i A_i \qquad [3]$$

where R_i is the thermal resistance of the ith network component. Figure 3 shows a typical network, in this instance for a Type II cell. Table III lists conductivity data used in calculating the R_i's for the various cell components. These individual component resistances were summed in parallel and series to obtain the overall, apparent thermal resistance and conductivity of each cell type. As shown in Fig. 3, the networks consist of the cell case and lining(s), where applicable, in series with the parallel combination of the positive and negative electrodes and separator. This network in turn is in parallel with the cell-case sides and top and bottom. It was difficult to determine the size of the gas gap between the case and the separators/electrodes, so that this network element was neglected. Consequently, only semiquantitative estimates were made (14) for the

[a] Included because it is useful in determining heat capacities in thermal resistance-capacitance models.

thermal networks, and these gave the following order of k_y values: I > II > III, which is in agreement with the measured values given in Table II.

The Type III cell exhibited the lowest measured conductivity, and is the only cell type with trapezoidally shaped electrodes. This electrode configuration leads to the highest thermal resistance value for the electrode pack (network elements ④, ⑤, and ⑥ in Fig. 2) of any cell type. In fact the calculated thermal resistances of the electrode packs were in the order III, IV > I, II. Thus, using Eq. [3], the estimated apparent conductivities of the electrode packs vary in the order I, II > III, IV, which is a similar order to that for the measured conductivities of the complete cells. The average k_y value calculated for the four types of electrode pack is about 0.0234 cgs units, if an average k_y value of 0.030 cgs units is assumed for both electrodes (based upon an 80% porous nickel plaque material). The k_y value calculated for the Type I, 20 A-hr cell electrode pack is about 0.0217 cgs units, which may be compared with a calculated value of 0.0233 cgs units for the electrode pack of an 100 A-hr cell from the same manufacturer (16).

Conductivities in the x-direction.—The reported values for k_x for nickel-cadmium cells range from 0.0016 to 0.0067 cgs units (5-9, 17), with an average value of about 0.0042 cgs units. The measured values for the four types of 20 A-hr cells range from 0.0026 to 0.0086, with an average value of 0.0044 cgs units. Thus, for the direction perpendicular to the plane of the electrodes, there is good quantitative agreement between the values reported here and the values from the literature. A contributing factor to this better correlation could be the fact that it is easier to measure the conductivity of the cell in this direction, because the compression on the cells exerted by the retaining plates in the apparatus forces the cell case and electrode pack together, giving better thermal contact. For the parallel measurements, with compression the thermal contact could have been worsened or improved, depending on whether the cell-case sides are convex or concave, respectively.

Because of differences in cell-case thickness, surface treatment, and possibly composition, it was thought that if measurements were made on the electrode packs alone (cells with the cell cases removed, but not the

Table IV. Measured thermal conductivities, k_x', of four types of 20 A-hr nickel-cadmium cells, with their cell cases removed

Cell type	Thermal conductivity, (cal/cm²/sec)/(C/cm)	Ratio k_x/k_x'
I	$k_x' = 0.0020$	1.38
II	$k_x' = 0.0016$	2.37
III	$k_x' = 0.0021$	1.20
IV	$k_x' = 0.0032$	2.69

Table V. Calculated values for the thermal conductivity of four types of 20 A-hr nickel-cadmium cells

Cell type	Thermal conductivity, (cal/cm²/sec)/(C/cm) k_x (with case)	k_x' (without case)	Ratio k_x/k_x'
I	0.0032	0.0021	1.52
II	0.0025	0.0018	1.39
III	0.0029	0.0019	1.53
IV	0.0028	0.0024	1.17

top containing the terminal fittings, etc.), then less spread in the experimental results for the four types of cells might be observed. The results of these k_x' measurements, made in the same way as for complete cells, are summarized in Table IV.

The spread in thermal conductivity values, k_x', is much smaller, as anticipated, and the average value is 0.0022 cgs units, compared with 0.0044 cgs units for the complete cells. Thus the parallel heat transfer paths afforded by the cell cases effectively double the apparent conductivity of the complete cells.

Thermal resistance network models were also set up to predict the k_x values for the four types of cells. Preliminary measurements made, using a Pyroceram 9606 heat-flow meter apparatus in an evacuable chamber (4), gave values of approximately 0.0019, 0.0016, and 0.0011 cgs units for the discharged, wetted negative and positive electrodes, and wetted separator, respectively, from a Type II cell. Other thermophysical-property data used to evaluate the networks are included in Table III which was compiled from handbooks and manufacturers' literature (13). The resistance networks set up were similar to that shown in Fig. 4 for a Type II cell. For the Type I cell, no element corresponding to the cell lining was interposed between the elements (1) and (3), and (5) and (7) in Fig. 4. Evaluating the networks for the four types of cells gave the calculated values shown in Table V. Both k_x (with cell case) and k_x' (without case) values were calculated, and the ratios k_x/k_x' are given for comparison with the ratios in Table IV. Quantitatively, reasonable agreement exists between the values for k_x' in Table V and in Table IV. The Type IV cell was predicted to have the highest conductivity, and the Type II cell the lowest. This is substantiated by the measurements. Reasonable quantitative agreement also exists between the predicted values for k_x in Table V and the measured values for k_x in Table II, with the exception of the k_x value for the Type IV cell. This Type IV cell conductivity anomaly has not been explained.

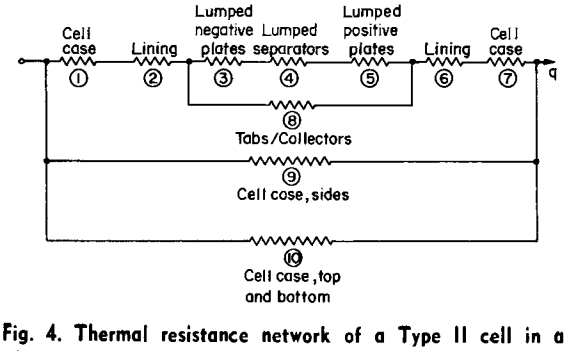

Fig. 4. Thermal resistance network of a Type II cell in a direction perpendicular to the electrodes (x-direction).

General.—When necessary, heat is normally removed from a cell in the x-direction, because the thermal anisotropy of the cell is normally assumed to be small, and the cross-sectional area, A_x, available for heat dissipation is the largest. However, the above results suggest that for some cell types the thermal anisotropy (a large k_y/k_x value) can be significant (see Table II). If the ratio of k_y/k_x far exceeds the ratio of cross-sectional areas A_x/A_y from which the heat is to be extracted, then consideration should be given to extracting heat in the y-direction, and not the x-direction.

In this present study, measurements were not made in the z-direction. Intuitively, if k_y is greater than k_x, then, because of the way in which the cells are constructed, k_z should also exceed k_x. Baker *et al.* (5) also make such an assumption, whereas Shair *et al.* (7) cite earlier experimental work which gave a ratio of about 1:3:6 for $k_x:k_y:k_z$, and Coggi (17) gives a ratio of about 4:9:11 for the $k_x:k_y:k_z$ conductivities. Thus, as discussed above, heat extraction in the z-direction can be more efficient than in the x-direction. However, because of the terminals and other fittings on the top of the cells, and the presence of recessed case bottoms on some cells, the extraction of heat in the z-direction is usually not practical.

In the calculations described above to compute k_y and k_x values for the 20 A-hr cells from thermal resistance networks, values of 0.0019, 0.0016, and 0.0011 cgs units were used for the conductivities of wetted, discharged negative electrodes, positive electrodes, and separator, respectively. These values are derived from some preliminary measurements reported in Ref. (4). If the measured value of the separator, 0.0011 cgs units, is taken in order to calculate the average conductivity of the electrodes from a Type II cell, then a value of 0.0017 cgs units is obtained. This calculated value is close to the average of the measured values of 0.0019 and 0.0016 cgs units for the Type II negative and positive electrodes, respectively. Conversely, if the measured conductivity values of the two types of electrode are substituted into the network shown in Fig. 4, a value of 0.0012 cgs units is obtained for the separator material. Consistency between the thermal resistance network models for the x-direction, and the subsequent conductivity measurements is thus evident.

Effect of state of charge.—The effect of state of charge on the thermal conductivity, k_x, of a Type I and a Type III cell was investigated. The cells were charged at a C/3 rate for 1.5 hr, and the conductivity was then measured, as previously described, while a trickle charge of 0.5A was flowing to maintain that state of charge. The cells were then charged at the C/3 rate for a further 1.5 hr, and put on the same trickle charge, while the conductivity was again measured. These conductivities are referred to as 50% and 100% state of charge conductivities, respectively. After charging, the cells were discharged at a C/2 rate, and the conductivity was measured with the cells shorted. The values obtained were taken as the 0% state of charge conductivities. The cells were taken through two of these charge-discharge cycles and the average increases in conductivity are given in Table VI. The conductivities are seen to increase in approximately a linear manner with increasing state of charge. To a

[a] Taken with reference to the discharged conductivities (0% state of charge).

first approximation, the values given for the discharged state (0% charge) may be used in performing thermal analyses, as these values are experimentally easier to determine and, therefore, are probably more accurate.

For an increase in thermal conductivity for a given cell (constant d and A in Eq. [3]) the thermal resistance must decrease. Intuitively, in a state of full charge, the negative electrode will contain a higher proportion of metallic cadmium than it will in the discharged state; thus, this may effectively lower the thermal resistance of the negative electrodes, and hence the whole cell. Experiments on charged and discharged electrodes are necessary to verify this expectation.

Thermal design.—Based upon the results of this investigation the following observations concerning thermal design of cells and batteries may be made. It is important to strive for the lowest thermal resistance of all cell components. Because the separators and electrodes are primarily chosen for their chemical and electrochemical properties the thermal conductivities of these components in the x-direction are essentially fixed. However, the thermal conductivity of the separator materials may be increased by using the maximum permissible amount of electrolyte consistent with the constraints imposed by the desired oxygen recombination rate within the cells (14).

The variable which may be adjusted to lower the thermal resistance of complete cells is the ratio of thickness to area, d/A. As Eq. [3] shows, R will be minimized when d/A is made as small as possible in the direction of maximum k. This criterion implies that for large k_y/k_x ratios the cells should have as small a y-dimension as possible, and have a maximum cross-sectional area through which the heat flow may traverse.

For complete cells the two thermal resistance network elements which may be influenced directly are the cell liners (electrically insulating the case from the electrodes) and the gas gaps between the edges of the electrodes and the cell case. These two network elements should have the lowest possible thermal resistance in order to lower the over-all cell thermal resistance. This may be achieved by using thin liners of high thermal conductivity, and by minimizing all gas gaps. The other important network element which can be manipulated to reduce the over-all thermal resistance of a cell is the cell case which is the only continuous metallic conduction path in any direction. For other than thermal design considerations (strength, corrosion resistance, and so on) the case is normally made of stainless steel, which is not a high conductivity metal. However, the apparent conductivity of the cell case material can be increased by plating the case with a high conductivity metal such as silver (15), or by using heat extraction fins in conjunction with the case material (4, 15, 17).

If the thermal resistances of all the cell components, hence the over-all cell, are kept to a minimum then temperature gradients within a cell will be minimized. Such small temperature gradients should help to control the diffusion of active materials, and to prolong cell life. Also, lower thermal resistances would result in lower cell operating temperatures, which in most applications would also lead to prolonged life, because of a lower rate of physicochemical degradation of the cell components.

In the design and fabrication of a battery a uniform cell-to-cell temperature is important. Such uniformity enables a more efficient control and balanced operation to be achieved. If all cells do not reach end of charge or discharge at about the same time, excessive heat generation, thermal runaway or cell reversal may occur in the nonuniform cells. In this respect, the efficient stacking of the cells, the choice of heat-dissipating aids (intercell plates, heat pipes, etc.), and the proper choice and control of the heat-sink temperature are important (16). The cell sides (x-direction) are usually the most efficient external surfaces for the extraction of internally generated heat (10), but the present study has shown that the cell end faces (y-direction) should also be considered, when the cell internal configuration is such that no large gas gaps exist in this y-direction, there is a high k_y value, and the cross-sectional area for heat extraction in this y-direction is large compared with the corresponding area for the x-direction.

Conclusions

The thermal conductivities have been measured for four types of 20 A-hr nickel-cadmium cells in the discharged condition, with and without their cell cases intact, and for two representative types of cell as a function of state of charge.

The average conductivity of a complete, discharged 20 A-hr cell in the x-direction (k_x, perpendicular to plane of electrodes) is 0.0030 (cal/cm^2/sec)/(C/cm) which may be compared with previously reported values of 0.0042, 0.0067, and 0.0020 (cal/cm^2/sec)/(C/cm) for 6, 6, and 12 A-hr cells, respectively (5-8). On this basis, thermal conductivity is approximately independent of A-hr capacity of the cells, as indeed, it should be. Through the use of thermal resistance networks, differences in materials and methods of fabrication are used to explain the variations among the measurements reported here. Different materials and details of fabrication should also account for the reported differences for various size cells.

The average conductivity of a complete cell in the y-direction (k_y, parallel with plane of electrodes) is 0.0065 (cal/cm^2/sec)/(C/cm), which may be compared with previously reported values of 0.052, 0.019, and 0.041 (cal/cm^2/sec)/(C/cm) for the 6, 6, and 12 A-hr cells referred to in the preceding paragraph. Once again, on the basis of the present data and the scant data published, the thermal conductivity in this direction appears to be essentially independent of cell size.

The ratios of the two conductivities, (k_y/k_x), taken as a measure of the thermal anisotropy of the cells, are always greater than unity, and are similar to values reported previously for smaller capacity cells. Heat extraction in the y-direction may therefore be more efficient than in the x-direction for certain cell configurations.

Thermal-resistance network models are able to quantitatively predict the k_x values, if the values obtained in some preliminary measurements for the discharged negative and positive electrodes and the separators are used. The values obtained are 0.0019, 0.0016, and 0.0011 (cal/cm^2/sec)/(C/cm), respectively.

Fuel Control in Methanol-Air and Formaldehyde-Air Fuel Cell Systems

K. J. Cathro

CSIRO, Division of Mineral Chemistry, P. O. Box 124, Port Melbourne, Victoria, 3207, Australia

ABSTRACT

Two types of fuel control units have been assembled and tested in conjunction with formaldehyde-air and methanol-air fuel cells. One type was based on a continuous fuel analyzer, while the other employed a load sensing technique. Both types gave satisfactory performance, and the advantages and disadvantages of each are discussed.

Fuel cell systems which employ a circulated aqueous electrolyte as a vehicle for bringing fuel to the anodes normally require some form of fuel control. This is necessary because there is usually a lower limit of fuel concentration below which anode performance falls off rapidly, while high concentrations lead to excessive loss of fuel by diffusion to the cathode with a consequent decrease in efficiency. If the cathode catalyst is also effective in promoting fuel oxidation, the oxidation of this diffused fuel could lead to overheating.

The present work describes the development of a fuel control subsystem suitable for low-power (approximately 50W) battery systems using either formaldehyde or methanol as fuel, and a dilute sulfuric acid electrolyte. Since the battery may be used in an application requiring long-term unattended operation (*e.g.* for 1000-3000 hr) reliability and adequate long term stability of the fuel control is essential. A further complication arises when using formaldehyde. Commercial formaldehyde is stabilized against polymerization by the addition of methanol and since formaldehyde is oxidized preferentially, the methanol builds up in the electrolyte, usually to an equilibrium level of about 0.5M. Further, formic acid builds up in solution since it is less rapidly oxidized than formaldehyde and is a partial oxidation product. Therefore, any method used for formaldehyde concentration control must function in the presence of these other constituents. Since the battery output is small, no more than a few watts can be allowed for controller operation.

Several possible methods of fuel control were studied. The first method considered employed a fuel addition rate proportional to battery current plus a constant allowance to cover nonfaradaic losses. This approach was initially dismissed as impractical, since a small error in the addition rate would lead to a cumulative error in fuel concentration. It was later reconsidered and shown to be practical in those cases where there is a concentration-dependent loss of fuel as is described later.

A second possibility was to use cell voltage as a measure of fuel concentration. Unfortunately, cell volt-

Key words: fuel cell, fuel control, formaldehyde, methanol.

age is also affected by such factors as load current, temperature, and the age of the cell. Although most of these other factors could be compensated, the aging effect is unpredictable. Moreover, in the concentration ranges of interest the rate of change of cell voltage with fuel concentration is small. Therefore, this method was discarded as unsatisfactory.

If fuel concentration could be monitored directly by a suitable analyzer, the output of this device could be used to control fuel addition. Since errors are not cumulative, and since the range of fuel concentration over which satisfactory operation of the fuel cell is obtained is relatively wide, the sensing device need not be very precise. It was decided to develop a fuel concentration sensing device. The output of this would be compared to a suitable reference, and fuel added as required to maintain the desired concentration.

Salathe *et al.* (1) in their study of fuel control systems for a hydrazine battery, also describe systems depending on fuel concentration monitoring or load sensing. They point out that a load sensing system (described in their paper as electrolysis pumping) is incapable of allowing for changes in nonelectrolytic consumption of fuel. Thus, the fuel concentration must be biased towards the high side of the usable range to prevent system failure due to low fuel concentration. This causes a high fuel consumption compared to that obtained using the direct concentration monitoring technique. Evans (2), in a paper describing the fuel feed control system for a hydrazine battery, came to similar conclusions.

The only methanol control system described to date (3) used a concentration sensing device. This consisted of a small electrolytic cell, the anode of which was of platinized platinum covered with a membrane. The membrane ensured that the anodic current through the electrode was controlled by the rate of diffusion of methanol through the membrane, thus avoiding errors due to change in activity of the platinum catalyst. A later publication (4) stated that this approach has been changed, with programmed addition of methanol fuel being used, and the detector being used only as an override safety device.

Control by Cyclic Voltammetry

A review of the physical properties of water-fuel-sulfuric acid solutions (*i.e.* such factors as viscosity, density, and surface tension) showed that these would not have sufficient discrimination for use in fuel concentration analysis, even if some suitable low-power method of instrumenting them could be devised. An electrochemical method was then sought. Estimation of the rate of diffusion of fuel through a membrane, measured by the anodic current sustained by an enclosed anode, has been described (3). We were not able to attain any degree of success with this method. In general, it was not possible to get reliable adhesion of available membrane types to the indicator electrode, and response time would have been poor. The simple method of monitoring potential at constant current, as used in hydrazine batteries (1, 2), is not suitable because of the change in the sensing electrode catalytic activity with time.

It was thought that electrode performance would be more stable if its potential were periodically taken to a highly oxidizing value in order to destroy any partially oxidized adsorbed species. This led to the use of cyclic voltammetry. Since the anodic oxidation of both methanol and formaldehyde on platinum is not diffusion controlled (5), there will be little effect of circulation rate on the current peaks observed, and it will be possible to choose the voltage span such that the electrode will be driven to a highly positive potential —and hence cleaned—during each cycle. Although such a system promised to be fairly complex electronically it was decided to test it as described below.

Preliminary experiments.—Preliminary tests were made using a conventional three-electrode cell, the potential of the sensing electrode (the anode) being

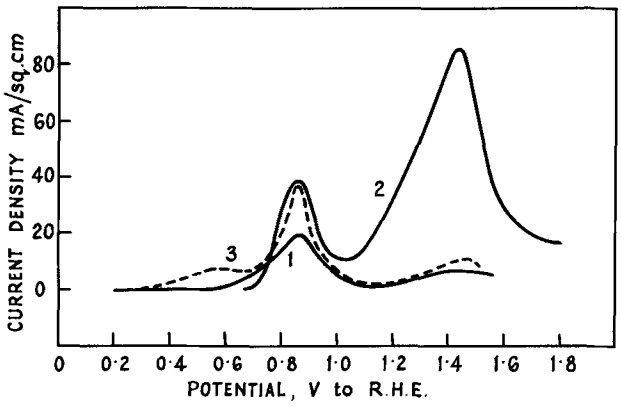

Fig. 1. Current-voltage curves. Curve (1) 0.86M methanol, (2) 0.90M formaldehyde, (3) 1.2M formic acid in 0.5M H_2SO_4 at 60°C on a 1 cm^2 platinum foil electrode. Voltage sweep is positive going at 50 mV/sec.

Electrolyte: (A) 0.5M formaldehyde, 0.5M H_2SO_4, 60°C; (B) As for (A), with 0.5 methanol and 0.5M formic acid; (C) As for (A) with 1M methanol and 1M formic acid. Electrode: 0.04 cm^2 platinum bead. Sweep: 50 mV/sec, positive going.

controlled by a potentiostat which was in turn programmed by a waveform generator. Current-voltage curves were recorded using either an *X-Y* recorder or an oscilloscope in the *X-Y* mode. The *X* (potential) axis was driven by a voltage follower, and the *Y* (current) axis measured the potential drop across a suitable resistor. Typical current-voltage curves are shown for the anodic oxidation of methanol, formaldehyde, and formic acid in Fig. 1. The electrolyte in all cases was 0.5M sulfuric acid.

The figure shows oxidation peaks which might be useful for control purposes. The current peak at 0.9V with methanol (which is the only oxidizable component in an operating methanol battery) is sufficiently well-defined for control. For a formaldehyde battery it is necessary to find if the presence of the expected concentrations of methanol and formic acid affect the peak current. Curves 1 and 2 also show that although the peaks would overlap, the peak at +1.5V to R.H.E.[1] in formaldehyde gives a much greater oxidation current than either methanol or formic acid. Thus it might be possible to get an approximate measure of the formaldehyde concentration from the peak current observed at this potential.

To check the possibility of determining formaldehyde in the presence of the other two components current-voltage curves were made on formaldehyde-methanol-formic acid solutions. A typical result is shown in Fig. 2. This shows clearly that the presence of the other components depresses the formaldehyde

[1] All potentials are reported with reference to a hydrogen electrode in the same solution (R.H.E.) unless otherwise stated.

peak at +1.5V. However, there is still a simple peak current-formaldehyde concentration relationship, as shown in Table I. The effect of change in methanol and formic acid concentrations on the magnitude of the formaldehyde peak current is shown in Table II. Although increasing the concentration of these components depresses the formaldehyde peak current by 20-35%, it seemed likely that their concentration in battery electrolytes would not vary widely, so that their presence would simply require appropriate calibration of the controller setting. It was thought then, that the peak current at +1.5V could be used for formaldehyde concentration control, while for methanol the peak current at +0.9V would be suitable.

The effects of sweep waveform, frequency and electrolyte temperature on the peak currents were examined. Figure 3 shows the effect of temperature, and Fig. 4 that of sweep rate on peak current. Two waveforms were tried also—sawtooth and isosceles triangle. There was little effect of the rate of sweep flyback on peak current in the forward sweep direction, but a triangular sweep was adopted in case the rapid rate of

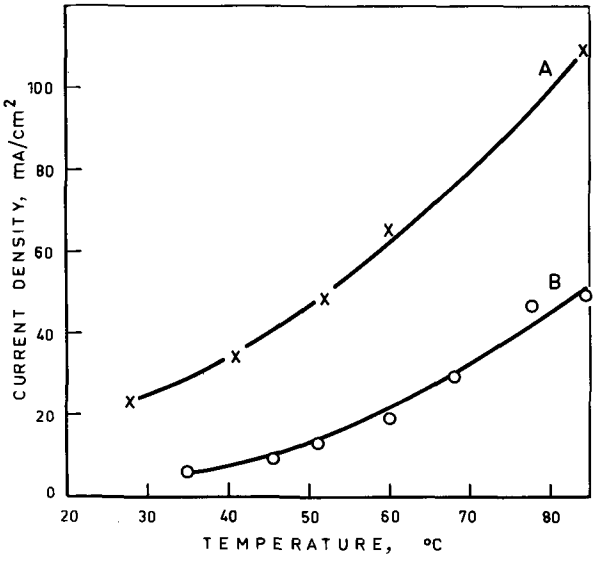

Fig. 3. Curve (A) effect of temperature on peak current for formaldehyde. Electrolyte: 0.50M formaldehyde, 0.5M H_2SO_4; electrode: 1 cm² platinum foil; sweep: 50 mV/sec, 2V triangle; peak measured: at 1.5V. Curve (B) effect of temperature on peak current for methanol. Electrolyte: 0.86M methanol, 0.5M H_2SO_4; electrode: 1 cm² platinum foil; sweep: 50 mV/sec, 2V triangle; peak measured: at 0.9V.

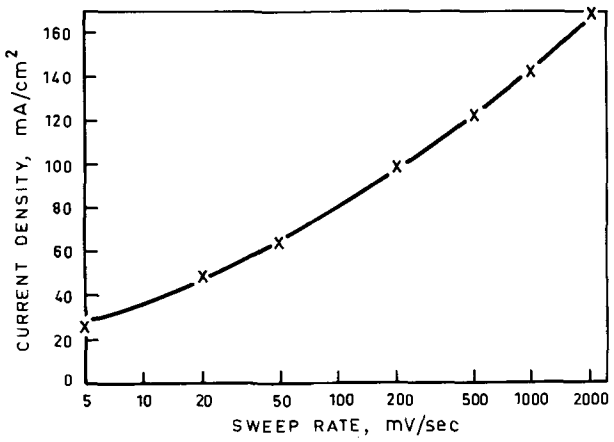

Fig. 4. Effect of sweep rate on peak current for formaldehyde. Electrolyte: 0.50M formaldehyde, 0.5M H_2SO_4; electrode: 1 cm² platinum foil; sweep: variable, 2V triangle; peak measured: at 1.5V.

oxide reduction occurring during a sawtooth flyback led to excessive electrode erosion (6). In fact, such erosion did not prove to be a problem, but the triangular sweep was used throughout the bulk of the work.

In selecting an appropriate sweep rate, it is necessary to note that increase in sweep rate increases peak current and hence sensitivity, and speed of response. Very high rates tend to give a broad peak so a compromise rate of 1 V/sec was chosen. Thus, the operating frequency was 0.25 Hz for triangular and 0.5 Hz for sawtooth waveforms. It is also clear that there is a great variation in peak current with electrolyte temperature. Thus, if the fuel concentration were correct at 70°C, it would be increased 5.3 times at 35°C. While some increase in fuel concentration at low temperature is desirable, this factor is much too high, so some form of temperature compensation is necessary.

For long-term operation the peak currents must be stable with time. During an extended run using methanol the peak current increased for the first few sweeps reaching a fairly steady value after about 20 cycles. Thereafter the value remained constant (±15%) for a further 1200 cycles, or 20 hr at the sweep rate used. A run of similar duration using formaldehyde with formic acid and methanol present showed a steady peak current (±16%) after the first 0.25 hr of operation.

The above tests were made using a 1 cm² platinum foil electrode or a small bead fused onto the end of a short length of platinum wire (area 0.04 cm²) in a conventional three-electrode potentiostatic system. In order to simplify the cell design for use in an actual battery system the reference electrode was omitted and the counterelectrode was made large (3 cm²), and of platinum black-P.T.F.E. hot pressed onto tantalum mesh. This was the cathode and acted as a hydrogen evolution electrode. Because of its large active area, the overpotential was small and did not vary greatly with current density in the range of interest. Thus it took up a potential of approximately 0.08V to R.H.E. when in use. This was further stabilized by passing a small (3 mA) cathodic current through the counterelectrode and a third auxiliary electrode. This reduced the current range to about 5:1 with the result that the potential of the counterelectrode did not vary by more than approximately 30 mV. The sensing electrode consisted of a small platinum sphere fused onto the end of a short platinum wire, as described earlier. This arrangement of a small working electrode and a large depolarized counterelectrode acting as a reference is similar to ordinary polarographic practice, and works well if the ohmic potential drop is small. This will be the case here as the solution resistance is low and the inter-electrode distance short. The wire from the

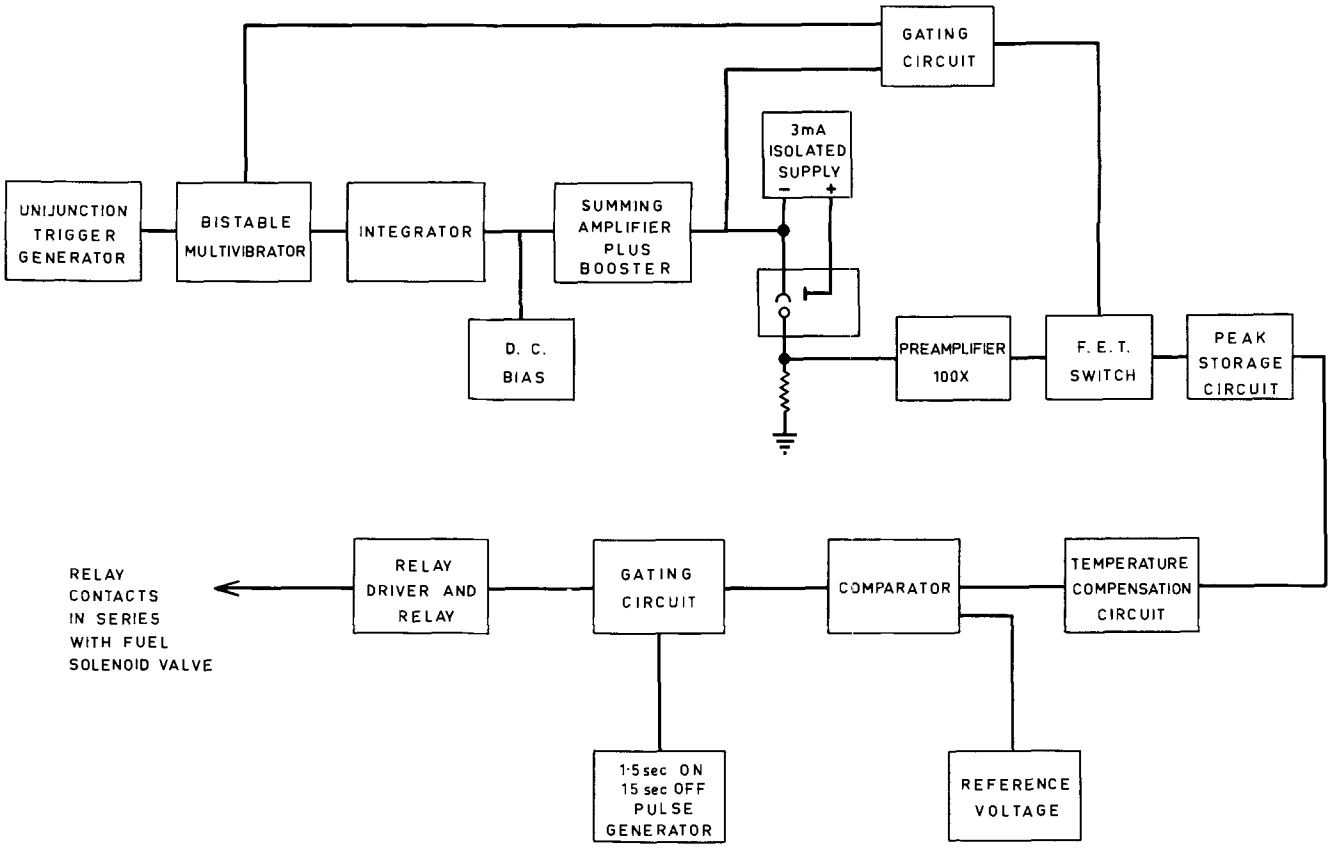

Fig. 5. Block diagram of control circuit for sensing electrode controller

platinum bead electrode was sealed into a glass tube, after a suitable lead-wire had been welded to the platinum wire. The other electrodes were supported by zirconium or niobium rods.

A zero to 2V negative going voltage was impressed on the counterelectrode, and the resulting current through the cell read off as the potential drop across a low value resistor in series with the sensing electrode. This potential drop was amplified, and the peak value in a selected potential range (0.7-1.2V for methanol, 1.3-1.7V for formaldehyde) stored in a reservoir capacitor via a simple field effect transistor switch and gating system. The voltage across the capacitor was read off by a source follower, fed to an electrolyte temperature compensation circuit, and the output of this was compared to a reference voltage. If it fell below the reference level the comparator changed state, turning on the relay which controlled the fuel addition solenoid valve. Fuel was added until the current at the indicator electrode rose above the desired value, when the solenoid would shut off within one cycle. Overshoot was minimized by placing the fuel addition pipe close to the sensing electrode so that the high local concentration of fuel would cause the fuel valve to close earlier than it otherwise would. In an alternative design, it was also arranged, as suggested by Evans (2), for the fuel valve to open on a 1.5 sec on —15 sec off cycle, rather than remaining on continuously. A block diagram of the circuit is shown in Fig. 5.[2] It was energized by a regulated ±6V and unregulated +12V d-c supplies obtained from a d-c/d-c converter. Total power input to the converter was 2.1W, inclusive of power for level and temperature control circuits. Use of a d-c/d-c converter effectively isolated the control circuit from the battery, and prevented difficulties with stray currents in the electrolyte which might have occurred had the system been operated directly from the battery output.

The control system.—Control in a formaldehyde battery.—A sensing electrode was tested for stability by operating it for 2167 hr in a 0.3M formaldehyde, 2M sulfuric acid electrolyte, containing 0.3M formic acid and 0.5M methanol, these concentrations being taken as typical of the steady-state levels achieved in a formaldehyde-air battery. The electrodes were as described above, the sensing electrode had a geometric area of 0.086 cm^2 and a hydrogen adsorption area of 0.11 cm^2 at the beginning of the test.

Using a circuit similar to that shown in Fig. 5, but modified to allow generation of a sawtooth rather than a triangular waveform, a 2V negative-going sweep was applied to the counterelectrode at a rate of 1 V/sec. The output of the peak reading circuit was recorded. From time to time the sensing electrode was withdrawn, the diameter measured, and the surface area determined by hydrogen adsorption. After 1008 hr the electrolyte was made 50 mg/liter in chloride (added as sodium chloride) and at 1296 hr a fresh electrolyte was made 50 mg/liter in ferrous iron (as ferrous sulfate), these being the most likely impurities that would be encountered in an actual system. The sphere diameter and surface area results are shown in Table III, the initial and final outputs of the peak reading circuit are shown as a function of formaldehyde concentration in Fig. 6, while the peak reader output as a function of time is presented in Fig. 7. It is clear that there is some deterioration in performance, particularly after 1000 hr, when the impurities were added. However, bearing in mind that fuel concentration is

not critical, the stability attained might well be adequate.

The electrode was not seriously attacked during the run. Reference to Table III shows a decrease in diameter of only about 6%, although there was considerable early surface roughening, as shown by the increased hydrogen adsorption area. This roughening was confirmed by microscopic examination.

The most important test of any fuel control unit is its performance as part of a total battery system. Three formaldehyde-air systems have been tested, the longest run being for 2260 hr. This used a circuit of the type shown in Fig. 5, and electrodes similar to those used in the long-term pot test described above. It is clear from Fig. 8 that fuel concentration was held within acceptable limits for 2200 hr, only failing towards the end of the run, probably due to the electrolyte solution becoming heavily contaminated with corrosion products due to attack on some stainless steel fittings. Figure 9 shows the short-term stability using pulsed addition in one case and continuous addition (until the required concentration is reached) in the other. There

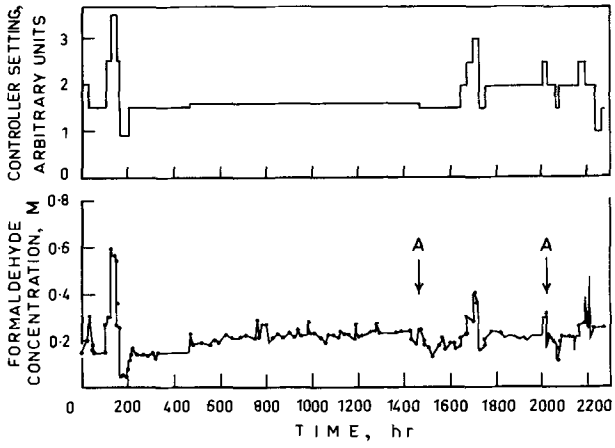

Fig. 8. Variation of formaldehyde concentration with time. Record of fuel concentration in a 40-cell battery system for various control settings. During this test the electrolyte temperature ranged from 45° to 71°C, the total battery load from 42 to 162W, the sulfuric acid concentration from 1 to 2M, the formic acid from 0.3 to 1.2M, and methanol from 0.2 to 0.5M. Electrolyte replaced with fresh at points (A).

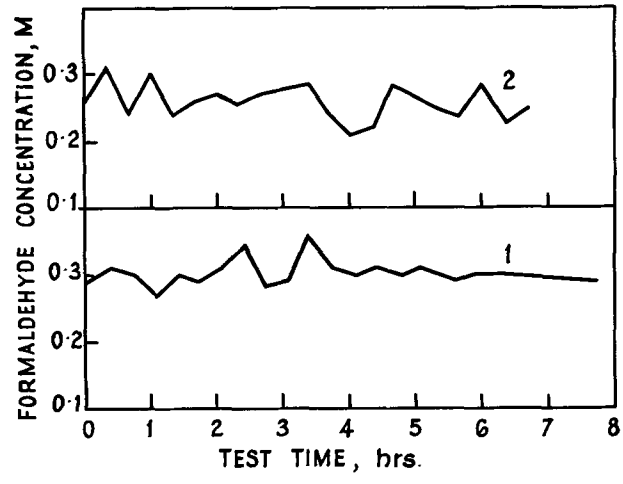

Fig. 9. Short-term stability of fuel controller. Same battery system as for Fig. 8, with controller setting of 2.5 (arbitrary scale). Curve 1: Test begun after 114 hr operation. "Pulsed" (*i.e.* 1.5 sec on, 15 sec off) addition of fuel. Mean concentration 0.30M, relative standard deviation 6.7%. Formic acid 1.04M, H_2SO_4 1.76M. Curve 2: Test begun after 161 hr operation. "Continuous" addition of fuel during addition period. Mean concentration 0.26M, relative standard deviation 10%. Formic acid 0.61M H_2SO_4 1.63M.

is no clear advantage in using pulsed addition. In general the reliability of the control system was good. The formaldehyde concentrations shown in Fig. 8 and 9 were determined volumetrically on a small aliquot of electrolyte.

There were no failures in the electronic section of the system during the whole of the run described, nor were any adjustments of such factors as sweep rate or d-c level required. The fuel addition solenoid valve required adjustment on several occasions, but this may have been due to using a low-powered solenoid.

Methanol battery.—The method described above was used to control methanol concentration in a sulfuric acid electrolyte. The peak current at approximately 0.9V was measured, but there were no other circuit changes from the conditions described for formaldehyde control. Since the absolute value of the peak current density was less than for formaldehyde the sensing electrode was changed to a small strip of platinum of approximately 0.25 cm^2, to give a similar total current. There was no detectable build-up of

partial oxidation products, and since the commercial methanol used contained only a little water as impurity, there was no complication from the presence of other oxidizable substances. Although this system therefore appeared simpler to deal with than that using formaldehyde, in practice control was not always satisfactory. Two long runs were made, one on a small six-cell battery, and the other on a twenty-cell system, auxiliaries being mains-powered in both cases. With both units the methanol concentration would be kept within the desired limits for long periods of time (hundreds of hours), then for no ascertainable reason the sensitivity of the sensing electrode would alter, and the methanol concentration would change rapidly to a new level often causing either fuel starvation or overheating.

The cause of this erratic behavior of the sensing electrode could not be determined. It seemed consistent with an electrode poisoning, as heating the electrode to red heat restored its performance. However, the sudden changes in sensitivity occurred both with reagent-grade and commercial methanol, and even during a test in an all glass pot cell. Since it was not possible to remedy this behavior in the time available an alternative method of fuel control was tested.

Faradaic Control

In principle, if the rate of fuel addition is exactly proportional to the current, then the initial fuel concentration will remain constant. Unfortunately, any errors in the control will be cumulative, so that in practice the fuel concentration would tend to either fall to zero or rise to an excessively high value. In the methanol battery with which the unit was to be used, there were two additional processes utilizing methanol apart from the generation of useful external current. These were the internal shunt current due to electrical leakage between cells via a common electrolyte and the direct oxidation of methanol at the air electrode. Leakage current losses are small and relatively constant, but the loss of methanol by diffusion to the cathode accounts for 25-50% of the fuel fed to the battery. While this is undesirable from the efficiency point of view it does provide a stabilizing influence on the fuel concentration since the diffusion of methanol is proportional to concentration in the electrolyte. Thus, if the control unit overadds slightly, the methanol concentration will rise, but this will be counteracted by an increased diffusion loss to the cathode. Providing that the rate of addition is not too greatly in error, the fuel concentration will equilibrate at some value above the optimum but still within the working range of the battery. To test this possibility a load sensing type of controller (called faradaic hereafter) was assembled and tested as part of a methanol-air system.

Since methanol is completely oxidized to carbon dioxide on the fuel catalyst used (7), the corresponding rate of addition may be calculated using Faraday's laws. The fuel lost to the cathode may be estimated from tests on small single cells. It may be represented by the equation $D = 0.013C\ (1+0.0007I)\ 10^{0.0127T}$, where D is the diffusion rate in mM/cm^2, hr, C is the fuel concentration in moles/liter, I the current density in mA/cm^2, and T the electrolyte temperature in °C. Shunt current losses are difficult to determine, but the presence of carbon dioxide bubbles in the liquid ducts minimizes such losses. In practice they are small and can be assumed constant. Thus the fuel consumption rate, f, can be expressed by Eq. [1]

$$f = a + b + ki \qquad [1]$$

where a and k are true constants, while b is independent of the current i, but is a function of methanol concentration and temperature. For a definite concentration and temperature Eq. [1] can be simulated by a simple analog circuit. The output/voltage of this summing unit is fed to an integrator which in turn causes a comparator to change state when the integrator output voltage exceeds a reference value. The comparator resets the integrator and also operates a three-way solenoid valve via a relay driving circuit. During its "on" time (4 sec) the valve discharges a fixed volume of methanol to the electrolyte reservoir: the metering volume is refilled during the "off" period, which varies with current but is about 10 min at normal load. A block diagram of the circuit is shown in Fig. 10. One point worthy of further discussion relates to the compensation necessary to maintain constant fuel concentration with change in electrolyte temperature. This can be achieved by variation of the voltage which represents the term $(a + b)$ of Eq. [1], and a passive thermistor-controlled circuit is adequate for this purpose. An uncompensated circuit has some advantages however, for as the temperature increases, the fuel concentration will tend to fall because of greater diffusion to the cathode through the separator. This reduction will minimize the possibility of overheating. There will be no significant loss in battery performance as there is a marked increase in fuel electrode activity with temperature. In the opposite case of a decrease in electrolyte temperature the fuel concentration will rise, counteracting the temperature fall, and minimizing loss in fuel electrode performance due to lower temperature.

A faradaic type controller of the type outlined above was constructed and used for fuel control on a 66-cell, 50W methanol system. Since the simpler design, with-

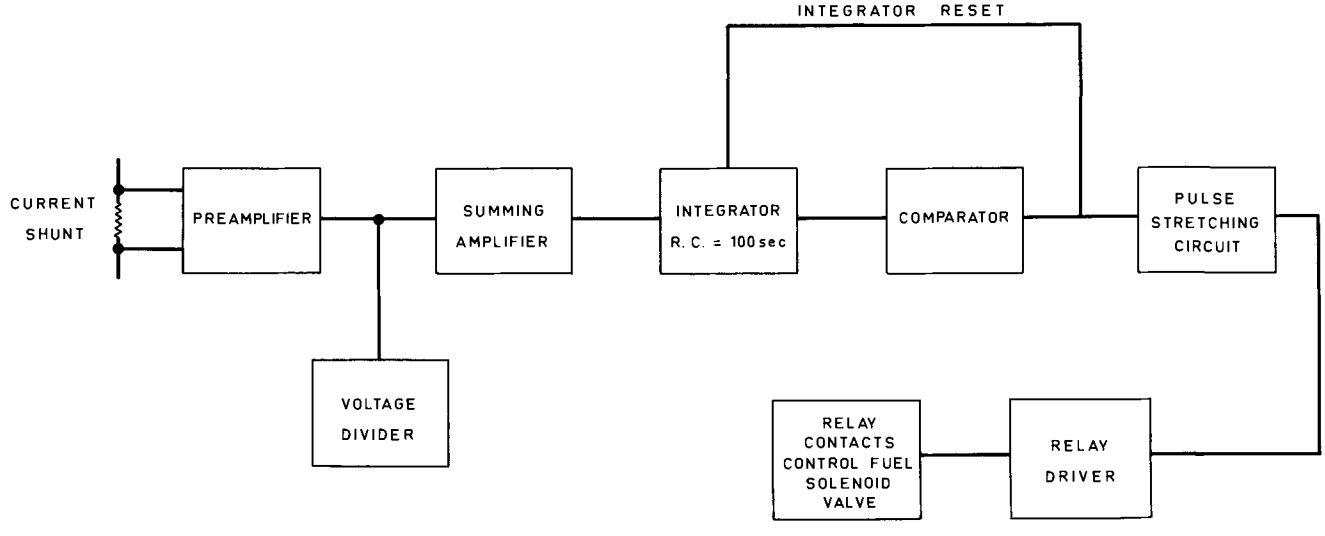

Fig. 10. Block diagram of control circuit for faradaic controller

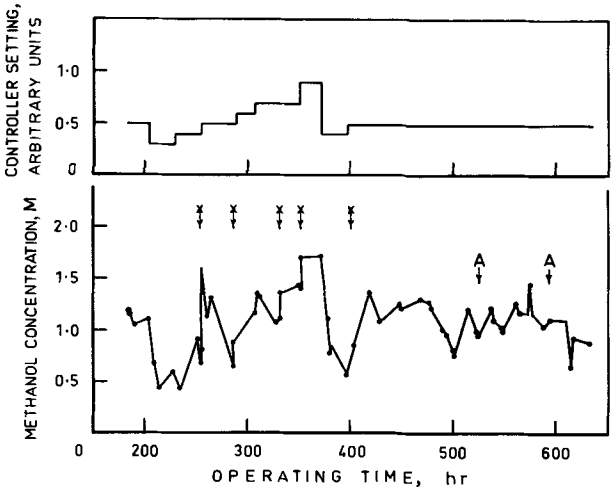

Fig. 11. Variation of methanol concentration with time. Record of fuel concentration in a 66-cell methanol system, for various controller settings, using a faradaic controller. During the period plotted the total battery load was varied from 19 to 110W, causing the temperature to vary between 42° and 76°C. No temperature compensation was used except between the points marked A-A. Points X show times at which fuel was added manually to the reservoir in order to adjust concentration rapidly. H_2SO_4 concentration was between 1.5 and 2M.

out temperature compensation, was likely to be more satisfactory than the temperature-compensated unit, the system assembled could be operated either with or without compensation. This unit was powered via a d-c/d-c converter in order to obtain electrical isolation. The power input to the converter was 1W. The solenoid valve took 10W, but its duty cycle was very low (typically 0.7%), and the over-all drain on the battery was negligible. A plot of fuel concentration (determined by gas chromatography) against time is shown in Fig. 11 for various control settings. It can be seen that the performance of the unit is adequate.

Comparison of the Two Controllers

Both types of controller have worked successfully over sufficient periods of time to prove their usefulness. However, there are some differences in characteristics which are worthy of comment.

Power consumption.—The faradaic type uses far less power which is important for a small battery system. However, the power taken by both types is sufficiently low to be acceptable.

Reliability.—The faradaic type has far fewer components and does not depend on sensing electrode stability. Therefore, in the electronic/electromechanical sense it should be appreciably more reliable. However, when considered in the context of the total system its continued good performance depends on there being no change in the over-all pattern of fuel usage (due for example to electrolyte leakage or a degradation in the cell separators). The direct sensing type is not affected by changes in fuel usage pattern. The tendency is for fuel consumption to increase with the age of a battery system so that a faradaic type controller is normally set to give a higher than optimum concentration early in the battery life. This improves the over-all system reliability, at the cost of reduced fuel efficiency.

Response to load changes.—The response of the sensing electrode system to load changes was dependent mainly upon the time taken by depleted electrolyte to reach the sensor. In the battery system tested this time was approximately 1 min. The faradaic controller is inherently rapid in that the time cycle of fuel addition is adjusted from the instant the load is changed. Due to the considerable amount of reserve fuel present in the electrolyte (at least 30 min at normal load) these response times were quite adequate.

Response to control setting changes.—The sensing electrode type responded rapidly to changes in the concentration control adjustment taking approximately 1 min to complete a concentration increase and 15 min for a concentration decrease. The faradaic type gave a slow approach to the new concentration; typically it took several hours for the new fuel level to stabilize.

Cost.—Absolute cost figures are difficult to prepare, but it is probably worth observing that the faradaic system contains only about 60% of the number of components of the sensing electrode type, and is easier to set up and check. It should therefore be significantly less expensive.

Kinetics of the Thermal Decomposition of Aqueous Manganese(II) Nitrate Solutions on Porous Tantalum

P. K. Gallagher and D. W. Johnson, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Porous tantalum electrodes were immersed in aqueous solutions of manganese(II) nitrate and the kinetics of the thermal decomposition of the adhering solution were determined, *in situ*. The rate laws for each of the stages in the decomposition were found to be different from those which best described the decomposition of the bulk solution. However, the activation energies were essentially the same as those for the bulk. The last stage of the decomposition, i.e., the decomposition of the intermediate manganese(III) oxynitrate, exhibited the same dependence on atmospheric moisture content as previously observed for the bulk material. The activation energy was reduced about 12 kcal/mole by the presence of moisture and the pre-exponential term of the Arrhenius equation was lowered by about 10^6 sec^{-1}. Surface area measurements gave smaller values for samples decomposed in moist atmospheres, and scanning electron micrographs indicated such surfaces were also more continuous and homogeneous. The decomposition occurred at lower temperatures for subsequent immersions.

In the manufacture of metal oxide capacitors a layer of semiconducting manganese(IV) oxide is frequently used as the counterelectrode. Such a layer is generally achieved by dipping the anodized metal into an aqueous solution of manganese(II) nitrate and subsequently heating this to decompose the adhering solution to the desired layer of manganese(IV) oxide.

Previous work has determined both the stoichiometry of the various stages (1) and the kinetics of the decomposition of bulk solution (2). The solution initially loses water to form a glassy phase having the approximate composition $Mn(NO_3)_2 \cdot 2H_2O$. This process follows the first-order rate law, $kt = -\ln(1 - \alpha)$, as would be expected. The quantity, α, is the fraction reacted.

At somewhat higher temperatures anhydrous manganese(II) nitrate is formed which decomposes to give the very transient intermediate manganese(III) oxynitrate. The rate law which best described this step for the bulk sample is the Eroffev equation with $n = 4$, $kt = [-\ln(1 - \alpha)]^{1/4}$. The intermediate oxynitrate decomposes to form the desired manganese(IV) oxide according to a contracting area formula, $kt = 1 - (1 - \alpha)^{1/2}$. A number of rate laws fit this portion of the decomposition reasonably well. The contracting area equation given above gave the best general fit to the data.

In this study the kinetics of these decomposition reactions are reinvestigated, *in situ*, rather than using a drop of bulk solution. Isothermal weight loss was followed in both moist and dry air. It was anticipated that the changes in geometry imposed on the solution by its adherence to and occlusion in the porous metal body would certainly change the rates and possibly change the mechanisms of the various steps in the thermal decomposition. In the actual manufacture of these devices it is generally necessary to repeat the process a number of times in order to build up a suitable electrode. Therefore, the possible effects of this change in substrate are also evaluated.

Experimental Procedures and Results

Materials.—Aqueous manganese(II) nitrate manufactured by the Lehigh Valley Chemical Company (capacitor grade, density 1.65) was used. Results of emission spectrographic analysis of the oxide resulting from heating a portion of this solution to 250°C overnight indicated magnesium was present at the tenth of a weight per cent level and calcium, copper, and iron were present in 10-100 ppm amounts. Three different concentrations of this solution were employed in the study. Dilutions were made with triply distilled water. Densities of these solutions were 1.645, 1.528, 1.449 g/cm^3 at 25°C.

Type 601B tantalum electrodes were obtained from the Western Electric Company in both an anodized and unanodized condition. The anodized electrodes were anodized at a constant current of 2A to 30V then held at 30V for 3 hr. The electrolyte was 0.061M HNO_3. The anodized electrodes were stored under deionized water. These particular anodes are cylinders about 4.6 mm in height and 3.3 mm in diameter having about 50% porosity. Attached to each is a tantalum lead wire 0.1 mm in diameter protruding about 13 mm.

Isothermal weight change.—A Perkin-Elmer thermobalance was modified to give weight and temperature as a function of time (2, 3). For these isothermal studies, only the weight portion was operated. The weight was averaged over predetermined constant intervals of time and automatically punched on paper tape. Time intervals ranged from 3-30 sec depending on the rate of weight loss. The temperature of each experiment was determined by measuring the control voltage of the Perkin-Elmer UU-1 controller and comparing it with the calibration equation. This equation was based on the use of magnetic standards as previously described (3). The heating rate for the calibration experiment was 1.25°C/min.

The lead wire was bent to form a convenient hook with which to suspend the sample. The balance was tared to approximately 2 mg less than the basic weight of the anode. Fortunately the control in manufacturing is sufficiently precise that it was not necessary to readjust the tare. Anodized samples were stored under water and consequently they contained about 20 mg of excess water in the porous structure. In the commercial processing they are heated to 135°C for 15 min to dry them. This weight loss represented the first kinetic phase. Both wet and dry air were passed over the sample at about 25 cc/min. The input gas was passed through a column of silica gel, and, if a wet atmosphere was desired, through a bubbler which saturated the gas with water vapor at room temperature.

An initial sample weight was obtained as quickly as possible and then the temperature was raised at a rate of approximately 320°C/min to a temperature in the range of 110°-130°C. The data acquisition unit was

Key words: capacitor technology, moisture catalysis.

started as soon as the UU-1 controller reached the control point. Data was collected at this temperature until essentially constant weight was reached at which time data taking was stopped and the sample cooled to room temperature.

The dried anode was then dipped into the manganese(II) nitrate solution and kept below the surface for 1 min. Care was taken to avoid collection of the solution on the hang down wire from the balance. The temperature was raised rapidly to 150°-200°C. Data collection was again resumed to constant weight. The temperature was then raised to 250°C to obtain a final weight.

The procedure was repeated starting with the dip in the aqueous solution of manganese(II) nitrate. A total of three dips was generally done with each sample, however, this was occasionally repeated as many as six times. On subsequent dips it was usually found that the reaction went nearly to completion in the 110°-130°C range and did not require an intermediate temperature between this and the final 250°C. In this manner there were three types of weight *vs.* time data determined for each anode. These corresponded to the loss of occluded storage water in the anode, 110°-130°C, the initial dehydration step, 110°-130°C, and the decomposition to manganese(IV) oxide, 110°-200°C. A few experiments were performed using unanodized electrodes which had not been stored under water and consequently there was no initial water loss for these samples.

Computer analysis.—The weight data on the tape was transferred to cards using a GE-635 computer. These data cards served as the input for three stages of computer processing. The first stage was to obtain a graphical output of the weight as a function time. Figure 1 is an example of such an output for a sample run in dry air. Figure 1(a) shows the isothermal weight loss at 109°C associated with original drying of the anodized sample; (b) at 110°C corresponds to the dehydration of the manganese(II) nitrate solution from the first dip; (c) gives the weight loss data associated with the decomposition of manganese(II) nitrate to manganese(IV) oxide at 153°C; and (d) shows this combined dehydration and decomposition step for the second dip. Plots of this type gave an over-all view or check on the experiment and served too as the basis for the determination of the initial and final weights for each step.

The second stage of data handling consisted of utilizing the initial and final weights for each step to determine values of α, the fraction reacted. The computer having calculated the values of α for each point then plotted these to conform to the eighteen kinetic equations given in Table I. These equations were selected because of their frequent application to the decomposition of solids. Appropriate equations were determined by visual inspection of the computer output plots for their linearity. As examples, the family of lines resulting from each of the over-all reactions for the initial dip using the solution of density 1.449 g/cm^3 are shown in Fig. 2-5. These data were taken using anodized electrodes in dry air.

It was frequently disconcerting to find that no single equation was obviously best at this point. The choice of equation was then based on the exact degree of fit

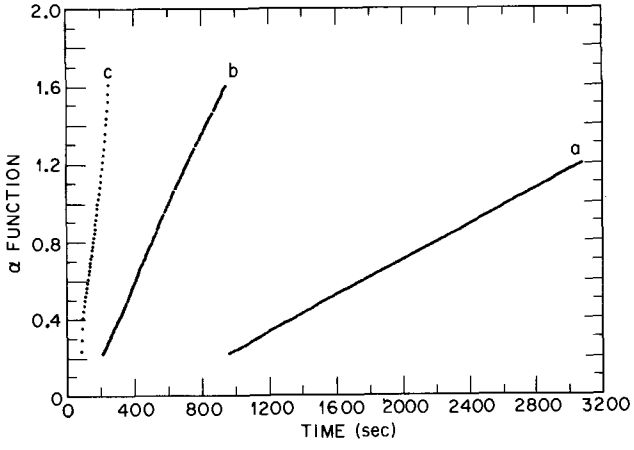

Fig. 5. — Ln $(1 - \alpha)$ vs. time for the second decomposition stage of aqueous manganese(II) nitrate ($d^{25°}$ = 1.449 g/cm^3) in dry air, 1st dip: a, 154°C; b, 174°C; c, 193°C.

better fit than did the contracting area form, however, it appears that the optimum value of n may be between 2 and 3. Similar behavior had been observed in previous work on iron(II) sulfate and the data was processed using a program which plotted the standard deviation as a function of nonintegral values of n in the contracting geometry equation (4). The optimum value in the current study was generally 3.0 but the observed trend was toward 2.0 with increasing temperature, decreasing density of solution, and the use of moist atmospheres.

After the most likely kinetic equation or equations had been selected for each reaction the appropriate experimental data were reprocessed using a third program to fit the best straight lines using a least squares technique. The printed output gave the best value of k and a standard deviation in terms of both $F_{(\alpha)}$ and α. The standard deviation in α is used to determine which equation is most suitable for those cases where several equations were considered.

A final program was devised to plot the values of log k vs. the reciprocal of the absolute temperatures (Arrhenius plot) and a least squares fit was made to determine the best straight line. The resulting activation energies and pre-exponential terms were printed along with the plot. The values are listed in Table II for the solution having a density of 1.449. Figure 6 shows the family of Arrhenius plots for the decomposition series in dry air for this same solution.

As previously mentioned the data can frequently be fitted moderately well by several equations. In all cases the activation energies show very little variation with choice of rate equation. The differences are reflected in the pre-exponential term and the activation energy is virtually independent of the equation in accordance with the results of previous work (2).

Surface area and scanning electron micrographs.— The BET technique of nitrogen absorption was used to determine the surface areas and a Perkin-Elmer Sorptometer was employed. The unanodized and anodized tantalum had a surface area of 0.3 and 0.6 m^2/g, respectively, prior to any further treatment. After immersion in the manganese(II) nitrate solution and the completion of kinetic studies, a number of anodes were randomly selected. Their surface areas were found to be 0.8-1.6 and 0.5-0.8 m^2/g for those which had been studied in dry and wet air, respectively.

Figure 7 presents representative scanning electron micrographs showing both unanodized and anodized surfaces before the manganese treatment. The surfaces after three dips and firings show that much of the original void space has been filled. When fired in dry air the surfaces showed cracks and debris and a generally more heterogeneous appearance than those fired in moist air.

Discussion

The evaporation of the water, entrapped in the anode during storage under water, took place in a simple linear fashion. This could be determined directly from the weight loss curves in Fig. 1 (a) and 2. The implication of this behavior is that the area of water exposed to the atmosphere remained constant during the evaporation process. The average amount of water initially held in the porous anode is about 20 mg. This indicates that the pores are essentially filled to capacity. It seems very unlikely that the total surface area, *i.e.*, internal as well as external, would remain constant during the entire weight loss period, therefore, it is concluded that the water escapes only from the external surface of the tantalum mass. The pores are constantly filled with either liquid water or steam but do not significantly effect the rate of weight loss. It is uncertain whether the actual process is simple vapor loss from the pore and thus the pore area at the surface is the critical factor or whether some form of capillary action is active and water evaporates from the entire external anodized surface. The observed activation energy in Fig. 6 is 6.1 kcal/mole and the pre-exponential constant is 8.2 sec^{-1}.

The overlap of the three reactions complicates the treatment of the data and introduces considerable uncertainty to the exact values. The separation of a progression of reactions, by redefining initial and final weights into a series of individual decompositions, has been done in similar studies (2, 4). It, nevertheless, is a highly idealized treatment which assumes that all of the intermediate is formed before any of it begins to react. For this reason, the beginning of the first reaction and the end of the second were stressed in making a determination of the rate law and constant.

Beside the problem of overlapping reactions, there are several other difficulties associated with the interpretation of the kinetics. One of the major ones concerns the nonideal or uncontrolled nature of the sample. There were no nicely sized fractions or pelletized samples to simplify the geometrical considerations. This is an attempt to deal with a real situation and consequently the starting particle size and morphology was restricted to that produced by the preceding evaporation or decomposition. Since several kinetic experiments were performed on the same sample, it meant that there were some variations in the thermal history among the samples, The fact that the data were frequently fitted reasonably well by several kinetic equations also urges caution in the interpretation of the kinetics in terms of a specific geometric mechanism. The individual reaction steps will be discussed with these basic considerations in mind.

Calculations based on the weight gained during the initial dip into the manganese(II) nitrate solution indicate that the pore structure is essentially filled for those samples which have been anodized and dried. The samples which were not anodized gained only 10-30% as much during the initial dip as the anodized samples. Subsequent dips were essentially the same. The anodized surface is apparently wet more readily.

The dehydration of the adhering solution proved very complex. Although the first-order equation was very markedy superior for the description of the weight loss of the bulk material (2) the contracting volume best described the data for the initial dip in this work. The dehydration of subsequent dips reverted to the first-order equation as shown in Table III. This along with the observations regarding the trends in the optimum value of n in the contracting geometry formula and the greatly reduced pickup of solution by the unanodized tantalum, suggest that the wettability of the tantalum by the manganese(II) nitrate solution is a critical factor. The increasing temperature, decreasing concentration of moisture in the

atmosphere, and presence of an oxide layer would intuitively all lead to enhanced spreading of the solution. If the solution remains compacted in a droplet during the process, the volume would be more important leading to a three dimensional dependence of the rate while if it spread over the surface a one dimensional or linear dependence of the rate is reasonable. Finally, if the exposed surface area remained constant as in the studies on the bulk solution (2), then the rate should follow a first-order law. This appears to be true for subsequent dips. For the initial dip, however, geometrical conditions seem to prevail. Actually the dependence should be combined with the first-order dependence which must also be acting, but, in a less significant capacity (6).

Fortunately the activation energy is relatively insensitive to the choice of kinetic equation (2) and the values given in Table II hold well for other concentrations. The values are not significantly different from those obtained for the bulk solution although the optimum kinetic equation is different.

Evaluation of the Arrhenius parameters for other than the first dip is deemed too tenuous to be of value. The surface area and thermal history would vary significantly among the samples and it would be fortuitous if a straight line resulted. The actual rates, in general, went through a maximum as a function of the number of dips for all three stages of the decomposition.

The second stage of the decomposition, *i.e.*, that which forms the very transient oxynitrate species, is best characterized by a simple linear rate law $kt = \alpha$ but the Erofeev equation with values of n from 1-2 fitted almost as well. Again this is different from that observed for the bulk solution which was best described by the Erofeev equation with $n = 4$ (2). The simple power law, however, fitted nearly as well. There does not appear to be any great dependence of the activation energy on moisture content of the atmosphere.

In contrast, the decomposition of manganese(III) oxynitrate shows the same marked and complex dependence on moisture as observed for the bulk solution (2). The effects on the activation energy and pre-exponential are opposed so that there is actually a crossover in the relative rates dependent on temperature. The pre-exponential term is much smaller presumably due to a reduction in surface area arising from improved crystallinity and increased sintering in the presence of moisture. The reduced surface area and smoother surface, see Fig. 7, of the samples decomposed in moist atmospheres are also consistent with this view. This reduces the reaction rate in the presence of moisture. The improved crystallinity means that there is less energy stored in the product phase and consequently the activation energy is lower and approaches the actual thermodynamic enthalpy of the reaction (5). This reduced energy of activation tends to increase the value of the rate constant and thus opposes the effect of the change in surface area.

The selection of the appropriate rate law was least well defined for this reaction. The first-order equation was slightly better than either the contracting volume or area equation although an intermediate value of n might have given the best fit.

Conclusions

There appear to be at least two deductions based on the observed rate which may be of value in the production of tantalum capacitors. First, the moisture content of the atmosphere has a decided effect on the rate and nature of the decomposition, particularly the last stage. Moisture apparently catalyses the decomposition and subsequent ordering of the amorphous oxide. It yields a surface which has a smoother, more homogeneous texture and a better sealed or healed appearance.

Second, the decomposition proceeds more rapidly for subsequent dips than it does for the initial dip. This is presumably the result of the increased surface area available for decomposition rather than an autocatalytic effect. Significant if not total weight loss can occur during what was previously thought to be just a dehydration step. This could allow for substantially reduced firing schedules.

Acknowledgments

The authors would like to thank Mr. F. Schrey for the measurements of the surface areas and Miss B. Cetlin for programming assistance. We are particularly grateful to Messrs. H. M. McKnight and W. M. Baldwin, of the Western Electric Company in Winston-Salem, for providing the tantalum samples, manganese(II) nitrate solution, and processing information.

Epitaxial Growth of Doped Silicon Using an Iodine Cycle

E. A. Taft*

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

A process for the epitaxial growth of doped silicon using an iodine cycle is described. Advantages in simplicity of equipment and in reproducibility of the deposited silicon layer are attained in a low-pressure closed system with the silicon substrate positioned close to a silicon source. Doping concentrations from 10^{15} to 10^{20} cm^{-3} are readily attained and growth rates exceeding 10 μ/min can be used. The effects of temperature, temperature gradient, and iodine pressure are discussed. The transport efficiency of some dopants is presented.

The reaction of iodine with silicon and works describing the thermal equilibrium conditions have been summarized by Rolsten (1). Chemical transport reactions involving silicon and its volatile iodides has been well referenced to 1966 by Nitsche (2). There appears to be less interest in most of the transport systems today with the ready availability of high-purity silane and of appropriate dopant hydrides which can be decomposed at relatively low temperatures. Decomposition of silane involves the handling of large volumes of hydrogen in the deposition area of a system. Doping of the growing silicon involves other gaseous compounds, and as decomposition proceeds gas ratios change. Thus the regulation and mixing of flowing gases becomes a primary consideration.

In a closed system transport rates were initially quite low (3) but soon rose to quite acceptable values through the use of close-spaced geometries (4). Enhanced deposition rates at low total gas pressures in the system have been recognized by Kurbatov *et al.* (5). Advantages in simplicity of equipment and in fixing of the doping of the deposited silicon layer may be attained in a low-pressure closed system with the silicon substrate positioned close to a silicon source. This paper describes such a system. The effects of temperature, temperature gradient, and iodine pressure on the growth of silicon are discussed. The transport efficiency of some dopants is presented.

Experimental

A typical apparatus, an all-glass demountable vacuum system, is illustrated in Fig. 1. The silicon source and substrate are separated by a quartz spacer, supported on a quartz pedestal, and enclosed by a quartz tube through which optical pyrometer readings can be made. The Viton "O" ring seal requires no grease when used on polished glass surfaces. The iodine reservoir with its thermostated temperature bath is sealed off by a magnetically manipulated polished glass valve. A second glass valve allows the apparatus to be closed to the vacuum system.

Transport studies were first made using ¼ in. thick silicon pieces 1 in. in diameter for both sources and substrates. (Later studies used thin wafers for substrates, this variation is described under Dopant Transfer Ratios.) These pieces allowed uniform temperatures across the diameter to be obtained with induction heating and permitted direct optical pyrometer readings on the sides of the silicon. The use of various quartz spacers and of positions of the rf coil gave all needed adjustments in temperatures and temperature differences. The iodine pressure was controlled by regulating the temperature over the solid or liquid iodine. All other parts of the system were held at a temperature slightly higher than that of the iodine.

In a typical deposition run, the system is evacuated to $<10^{-5}$ Torr with the walls heated. The silicon pieces are then raised to selected temperatures by inductive coupling with the rf coil, and the iodine temperature is adjusted. The valve to the pump is closed, and the one to the iodine is opened. The silicon temperatures are checked as the iodine vapor now in the system changes the heating slightly. After 10 min the valve to the iodine is closed, the one to the pump is opened, and the rf power is turned off. When the silicon pieces are removed, it is found that silicon has been transported from the colder crystal and epitaxially deposited on the hotter crystal.

Results

Growth Rates

The range of silicon temperatures and iodine pressures studied is shown in Fig. 2. The data is presented as observed crystal growth rate as a function of iodine ambient pressure for a series of source and substrate temperatures. The initial studies were made in the low-iodine pressure range of the 1150°-1230°P source-substrate curve. [°P is uncorrected optical pyrometer reading in degrees centigrade measured on the Si surface through a quartz wall. Emissivity corrections for silicon can be made with the aid of Allen (6)]. The transport rate is seen to increase with iodine pressure in this range and is also found to depend strongly on the temperature differences between source and substrate. The rate was found to decrease as the source-substrate spacing increased, up to at least 8 mm spacing.

The effect of spacing was also investigated with silicon temperatures and iodine pressures fixed. Steps were cut on the silicon as shown in Fig. 3, making it possible to determine the rate of deposition at three separation distances in a single run. This procedure tends to cancel effects that are due to adjustments or changes during the run in temperature of the silicon pieces or in iodine pressure. The results are shown in

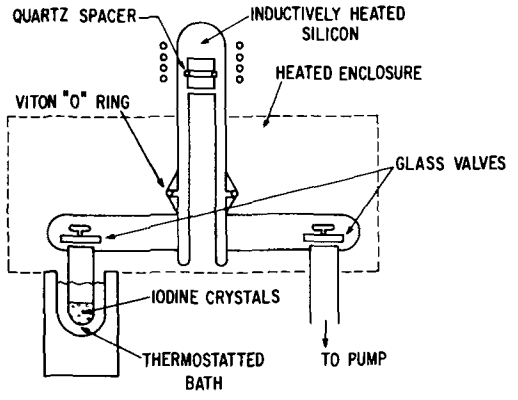

Fig. 1. System for transport of silicon in low-pressure iodine ambient.

* Electrochemical Society Active Member.

Key words: gas transport, thin films, single crystal, closed system, temperature gradient system.

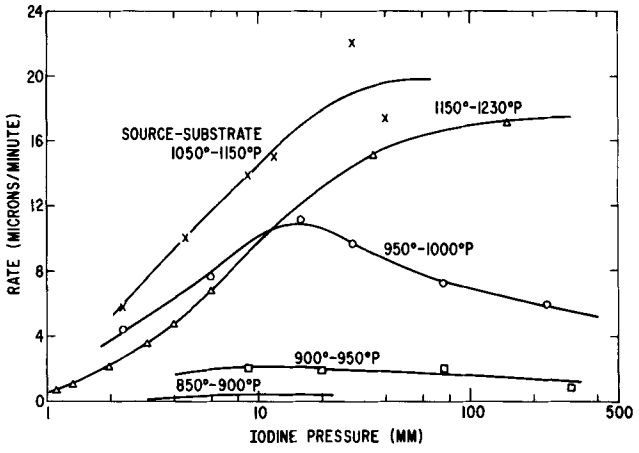

Fig. 2. Transport rates of silicon with 1 mm source-substrate spacing. The temperatures on each curve are for the source silicon and the substrate silicon, respectively, and are the uncorrected pyrometer readings on the centigrade scale.

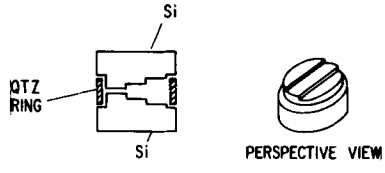

Fig. 3. Silicon configuration for simultaneous transport at several source-substrate spacings.

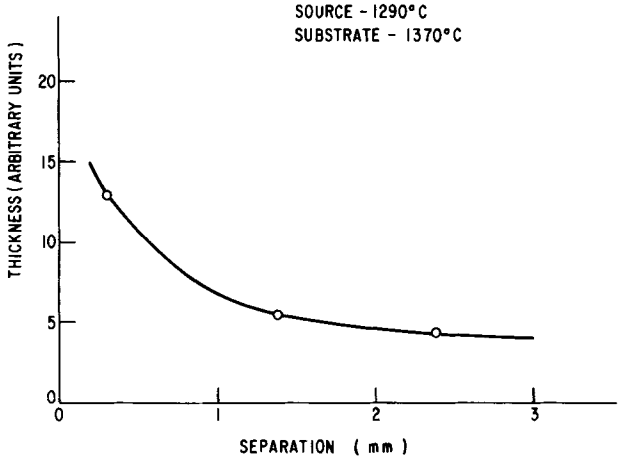

Fig. 4. Thickness of the grown epitaxial silicon layer with changes in source-substrate separation. Similar curves were obtained at iodine pressures of 0.4, 1.0, 2.3, and 5.5 mm.

Fig. 4 as a plot of relative thickness of epitaxial growth, as determined by stacking fault lengths (7), in arbitrary units *vs.* separation of source and substrate. Similar curves were obtained for iodine pressures of 0.4, 1.0, 2.3, or 5.5 mm. If plotted on an inverse spacing abscissa these curves were linear but did not all intersect at zero. The transport is, therefore, substantially diffusion limited at these temperatures with the maximum deposition occurring where the temperature gradient is largest.

These high-temperature, low-iodine pressure conditions readily produced silicon with no polycrystalline growth sites and stacking faults numbering less than 100 cm^{-2}. The good crystal growth was probably aided by the rather obvious thermal cleaning of the silicon if the temperatures were held for a few minutes in vacuum. Evaporated silicon films became visible on the quartz wall adjacent to the substrate within these few minutes at the higher temperatures (>1225°*P*) employed. For the runs at these temperatures, the iodine was introduced before the rf power was raised to the final setting. These runs were then made for times of greater than 10 min so that the initial changes in temperatures over the first minute were not of much consequence. When the growth rates were greater than 10 μ/min, the crystal perfection suffered if the substrate-source temperature differential was not carefully chosen in conjunction with the iodine pressure.

Going to the other curves of Fig. 2, the silicon layer growth rate for iodine pressures below 10 mm shows a definite peak at intermediate temperatures. The deposition rate increases rapidly as the temperature rises above 900°*P* and is greatest in the 1000°-1050°*P* range. At the higher temperatures the transport rate decreases for the same source-substrate temperature difference, as the iodide formation rate decreases with higher source temperatures. At higher iodine pressures the temperatures for maximum transport rates are increased.

Dopant Transfer Ratios

In the initial study of epitaxial growth, using large silicon pieces for temperature measurements, the resistivity of the grown layer appeared to correlate directly with the resistivity of the source silicon: the usual boron dopant was transported in the same ratio as the silicon host material. An extended test of dopant transport in the all-glass system was undertaken with several series of doped crystals used as source silicon. Single-crystal sources were used in these tests to allow accurate dopant evaluations. Substrate heating was accomplished through radiation from silicon susceptors heated by rf induction currents. The substrates could not be observed for pyrometry. Substrates were usually 1 in. diameter etched silicon wafers separated from the susceptor by a polished quartz plate. A 40 mil thick quartz spacer ring supported the source silicon. The susceptor and source diameters were selected to be larger than 1 in. so that the substrate was essentially enclosed by the heated areas. The system initial vacuum was less than 10^{-5} Torr. Total background pressure build-up from outgassing during a reaction period of 15 min with no iodine admitted was less than 10^{-3} Torr. From a given source crystal, a number of films were grown at selected temperatures of the substrate susceptor and of the source; several iodine pressures were utilized; film thicknesses were varied. The resistivities of the grown films were obtained with a four point probe. Normally a "p"-type film would be deposited on an "n"-type substrate and vice versa. The thickness of the epitaxial layers was determined from the observed length of stacking faulits on the (111) wafers (7).

The data has been collected in Fig. 5 where the dopant concentration of the epitaxial deposit is plotted against the source dopant concentration. The concentration was obtained from the room temperature resistivity (8). A large number of the data points are seen to fall on the forty-five degree line which represents a one to one transport of impurity with silicon. Each point is the average of more than three films formed from a given source. In the initial stages of the experiment, each source was run until the deposited film resistivities were shown to be reproducible to at least 10%. Film growth rates of 0.3-5 μ/min were observed as iodine pressures were varied from 0.3 to 10 Torr and source temperatures were varied from 900° to 1100°*P*. Single-crystal layers could be obtained for all growth rates and iodine pressures used. Later in the work fewer substrate wafers for each source were processed as the trend in the impurity transport became apparent. Six dopant elements were tried: B, P, and As appeared to transport reproducibly; Sb was quite variable in transport effectiveness, while Ga and Al seemed to transport very little if at all.

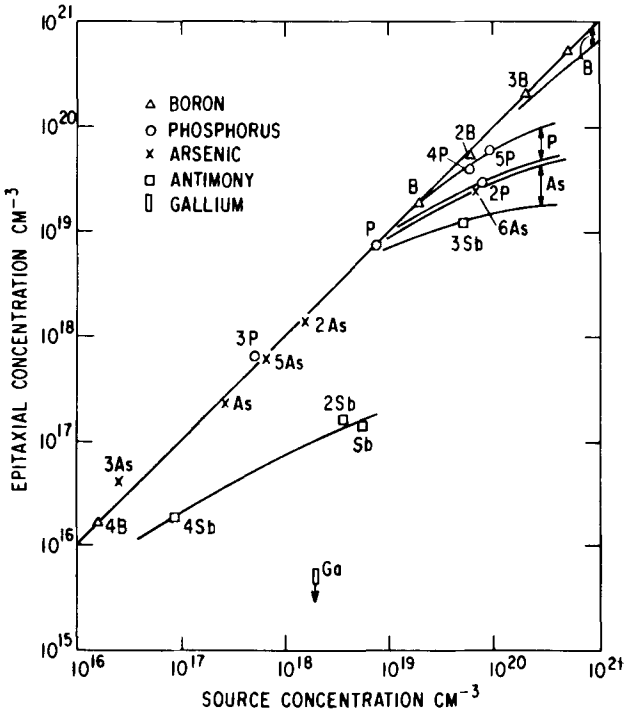

Fig. 5. Concentration of dopant in the epitaxial film vs. the concentration in the source. The upper curves for B, P, and As are for film growth at 3 μ/min; the lower curves obtain for film growth at 1 μ/min.

The data for boron in silicon was obtained for concentrations from 10^{16} to 5 x 10^{20} atoms/cm^3. The indication is for a one to one transport over this full range. However, near the 2 x 10^{20} doping level, a separate study gave a transport efficiency of only 60%. (This data was obtained by A. J. Yerman who used the same experimental system.) Several sources in this high-concentration range, including the one used by Yerman, showed transport efficiencies of 75-100%. The deposition rate of less than 0.2 μ/min selected by Yerman becomes significant and is the end point in a plot of the decrease in transport efficiency with a decrease in silicon film growth rate. This effect is clearly demonstrated in phosphorus or arsenic transport.

Phosphorus shows good transport for source concentrations below 10^{19} atoms/cm^3. At greater concentrations not all of the phosphorus transfers with the silicon from the source to the film. Variation of source or substrate temperature or a change in iodine pressure did not seem to affect the transport efficiency directly. The controlling factor appears to be the growth rate. The upper curve for phosphorus was obtained for growth rates of about 3 μ/min, while the lower curve was obtained for growth at about 1 μ/min.

The data for arsenic at lower concentration levels show the same 100% transport efficiency as do those for phosphorus and boron, but the transport efficiency begins to fall off sooner with increased concentrations. Again, the upper and lower curves were obtained for growth rates of about 3 and 1 μ/min, respectively.

Transport of antimony in doped silicon occurs with low efficiencies. Using the same source under essentially the same test conditions, variations of over 50% in resistivity from film to film, and even across the same film, were observed. With concentrations in the source of 10^{19}/cm^3 only a few per cent of this much antimony could be found in a silicon epitaxial layer. Of interest is the point 3Sb at 5 x 10^{19} cm^{-3} source concentration representing the third source used in the antimony tests. Clearly this silicon crystal was initially mislabeled, and it is arsenic doped, not antimony doped. Of course, this became clear only after the completion of substantiating work with antimony and with arsenic.

Several attempts to form gallium-doped epitaxial layers were unsuccessful. Sources containing greater than 10^{18} cm^{-3} of gallium rendered epitaxial films which generally probed "n" type with resistivities of several ohms-cm. The transport efficiency is thus very small. Considering the lack of control in antimony-doped films where the efficiency of dopant transport is not so small, no effort was expended in determining the actual value of the efficiency. In the case of aluminum, only one lightly doped source at 2 x 10^{16} cm^{-1} was available. But here again, as with gallium, the resulting epitaxial films of silicon were several ohm-cm "n" type. The transport efficiency of aluminum therefore is also small.

Discussion

The transport data for boron, phosphorus, and arsenic in silicon appears to be quite reproducible, although a factor in the transport efficiency for all of these elements at a given source concentration is the growth rate. Points 3As and 3P which are above the line of Fig. 5 by 80 and 30%, respectively, were caused by system contamination. The experiments immediately preceding these runs used sources which were very heavily doped. Acid cleaning of only the quartz parts in the high-temperature zone of the system was effective in removing the residual dopant pickup by the growing layer. While the transport efficiency falls eventually below 100% for all dopants studied, the concentration of dopant at which the decrease begins depends on the particular dopant. It appears that this decrease in antimony, gallium, and aluminum occurs before useful concentrations are obtained.

(It has been assumed that all of the transported dopant is electrically active in the deposited crystal. An actual analysis of the impurity content of the deposits was not made. However the deposits were single crystal and as the source material was also single crystal, the resistivity comparisons seem justified.)

The condition of the initial surface had a large effect on the uniformity and perfection of the deposited layer. The usual surface treatment was a 3:1 HNO_3:HF chemical etch followed by a water rinse. At 600X magnification the surface thus obtained appeared essentially featureless. Square centimeter areas could then be covered by silicon layers 20μ thick with the formation of only very small ripple marks on the surface. Some silicon deposits had large concentrations ($\sim 10^6$ cm^2) of stacking faults and nucleation sites of $\sim 10^4$ cm^2. These nucleation sites were associated with multiple stacking faults but otherwise were similar to widely described tripyramidal faults (9). This type of deposit tended to occur at lower substrate temperatures when combined with higher growth rates. The iodine pressure and the temperature gradient can be adjusted to minimize these crystal defects.

Contamination of the substrate was occasionally troublesome. Carbide film formation especially inhibited silicon growth. At the higher temperatures (>1200°P) used, silicon carbide then becomes, in fact, a useful mask material against epitaxial deposition. At these higher temperatures the residual surface oxide is reduced by the substrate to SiO which vaporizes leaving clean silicon to initiate the epitaxial growth. Added hydrogen gas at these temperatures apeared to be no more effective than the thermal etching in obtaining smooth growth layers. If small amounts of hydrogen were left in the system during the deposition run, the transport rate would decrease. The hydrogen did not appear to enter into the reaction, but only verified the fact that the process rate in this part of the operating range is diffusion limited. Small amounts of argon also reduced the silicon growth rate.

The uniformity in thickness of the deposits was very good as observed stacking fault lengths over the crystal area tended to be constant. The resistivity, in gen-

eral, also was uniform over the wafer. A clean system using reagent grade iodine would regularly produce epitaxial layers with resistivities greater than 50 ohm-cm. Deposits on crystalline surfaces near (111), (100), or (110) orientations did not show any marked variations in growth rate or in the perfection of the epitaxial layer.

A possible advantage of the closed system reaction in forming good crystal at low temperatures occurs with the kinetic exchange of silicon between source and substrate. The deposition or removal of silicon is the net result of partially balanced reactions at the opposed silicon surfaces. Particularly at low temperatures the rate of deposition is limited in part by the rate of decomposition of the iodide. The rate of formation of the volatile iodide remains high as observed through weight losses from both source and substrate silicon. With high chemical reactivity at the substrate surface in addition to the thermal energy, there is greater probability that silicon atoms deposited in positions for poor epitaxial growth will be removed and redeposited in more favorable crystalline positions before they are pinned by subsequently deposited atoms.

May (10) has used equilbrium assumptions to describe the transport for a small region near 1200°C silicon temperatures and 1 mm iodine pressures. For temperatures of 850°-900°C and total pressures near 10 mm the expected action of an equilibrium is toward a reversal in transport direction; that is, from the hotter to the colder silicon. The data of Fig. 2 do not fulfill this expectation, indicating that the iodine ambient atmosphere has modified the reactions to always favor the transport of silicon to the higher temperature substrate. This modifying effect then gives the process a more readily controlled growth parameter in the iodine pressure. The other primary growth parameters are substrate and source temperature. Again these are easily controlled for optimum deposition conditions. With the dopant concentration selected by the choice of source material, the system remains simple in concept, and epitaxial silicon growth factors can be easily adjusted.

Acknowledgments

The initial portions of this study were undertaken in collaboration with the late W. C. Dash. L. J. Keifer assembled the vacuum system and did much of the crystal growth at the higher iodine pressures.

Detection of Metallic Impurities in Acid Zinc Plating Baths

M. Maja and P. Spinelli

Istituto di Elettrochimica e di Chimica Fisica, Politecnico di Torino, Torino, Italy

The electrodeposition of zinc from sulfuric solutions containing impurities has in the past been the object of several investigations (1-8) carried out to determine the best working conditions of industrial cells. In our Institute the general behavior of impurities has been studied for a long time, and researches were developed particularly for nickel, cobalt, and germanium impurities in electrolytic solutions for zinc and manganese electrodeposition.

We found (9) that such impurities have an induction period before causing a reduction in current efficiency. In the case of zinc electrodeposition, for example, we observed that, at the beginning of electrolysis when nickel, cobalt, and germanium impurities are present, current efficiency has a value slightly lower than that found with pure solutions; after a period of induction, this value rapidly decreases to zero while the deposit dissolves into the electrolyte. The dissolution is so complete that the aluminum cathode is brought back to its initial state and a new deposit can start.

The formation and dissolution cycles of the deposit cause oscillations of the cathodic voltage if the electrolysis current is constant, while at constant voltage they cause oscillations of the current.

From analysis of the zinc and impurity deposition and hydrogen evolution characteristic curves, we found that the phenomenon does not depend on the amount of impurity deposited together with zinc, but on extension of the surface-contaminated zones of the cathode, because hydrogen evolution occurs at those zones with a lower overvoltage.

We also observed that zinc dissolution starts in the pores of the deposit which are already present at the beginning of electrolysis. The electrolyte in the pores is renewed with difficulty and the zinc ion concentration decreases so that the impurities are no longer covered with zinc as they are at the exposed surface of the cathode.

During the last few years, the zinc electrodeposition industry has felt the need for a device that could signal with reasonable rapidity when the impurity concentration in the baths exceeded fixed limits in order to effect proper depuration in a short time. Many devices, generally based on the corrosion rate of zinc deposited from impure solutions, have been proposed (11-13).

Key words: electroplating, zinc plating, impurities in zinc plating.

The study of the above-described phenomena suggested (10) a method of controlling the purity grade of the electrolyte, which is based on the determination of the induction time preceding dissolution of the deposit. Since the induction time not only depends on the impurity concentration but also on the temperature and acidity of the electrolyte, it is possible to reduce the time to a few minutes by increasing the temperature and decreasing the pH of the solution.

For example, in the case of an industrial zinc electrodeposition bath, increasing the sulfuric acid concentration up to 350 g/liter and electrolyzing at a current density of 5 A/dm^2, at a temperature of 50°C, by measuring the cathodic voltage it was possible in less than 20 min to detect as little as 2 mg/liter of nickel and cobalt and 20 μg/liter of germanium.

Since the phenomena occurring in the hollows of the deposit greatly affect current efficiency, we thought of improving the bath control method by making electrolysis tests with hollow-shaped cathodes.

Research has been developed for tin, arsenic, bismuth, antimony, cobalt, nickel, iron, copper, germanium, and cadmium in sulfuric solutions containing zinc at various pH's.

Experimental Results

Experiments were carried out depositing zinc at constant current on the internal surface of a hollow drilled into an aluminum electrode and measuring the cathodic voltage variations with time. The hollow, 3 mm wide and 22 mm deep, was drilled into an aluminum disk whose remaining parts were covered with PVC paint 0.25 mm thick.

The electrolytic cell, containing the hollowed cathode, a platinum counterelectrode, and a reference electrode, was fed by a galvanostat.

To define the behavior of the hollowed cathode, some initial electrolysis tests with pure solutions were made. Figure 1 shows how the cathodic voltage varies with time, electrolyzing a sulfuric acid solution (curve a) and a zinc sulfate solution (curve b).

Figure 2 shows the cathodic voltage variations *vs.* time for a zinc sulfate solution containing nickel impurity.

The voltage oscillations are caused by the hydrogen bubbles that are formed in the hollow and periodically released. The frequency of the oscillations depends on the hydrogen partial current, and their amplitude depends on the total characteristic curve for the reactions occurring at the electrode; in fact, the amplitudes are very different according to the electrolyte composition (curves a and b in Fig. 1).

When impurities are present, Fig. 2, there are also oscillations caused by the formation and dissolution cycles of the zinc deposit. These oscillations have a frequency greater than that found for smooth cathodes under the same experimental conditions.

The phenomenon, as shown in Fig. 2, can be divided into three stages:

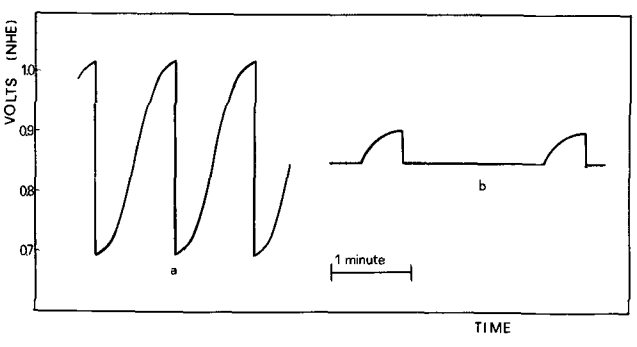

Fig. 1. Cathodic voltage *vs.* time of electrolysis for a hollowed aluminum electrode: (a) H_2SO_4 2*N*, T = 30°C, i = 5 A/dm^2; (b) H_2SO_4 2*N*, Zn^{++} 50 g/liter, T = 30°C, i = 5 A/dm^2.

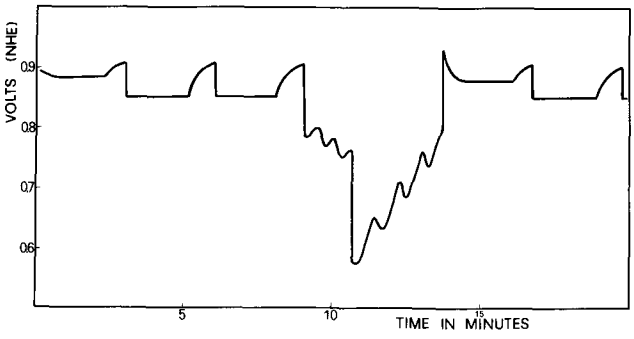

Fig. 2. Cathodic voltage vs. time of electrolysis for a hollowed aluminum electrode: H_2SO_4 2*N*, Zn^{++} 50 g/liter, Ni^{++} 1 mg/liter, T = 50°C, i = 2 A/dm^2.

(*a*) Regular electrolysis with a cathodic voltage greater (in absolute value) than the reversible zinc potential

(*b*) Dissolution of the deposit with a cathodic voltage a little lower (in absolute value) than the reversible zinc potential

(c) Hydrogen evolution on aluminum with a less negative potential and a new polarization of the cathode with respect to zinc.

In the course of the electrolysis (stage *a*), the impurity-contaminated area on the cathodic deposit enlarges and the ion zinc concentration in the hollow decreases. The modifications of the cathodic surface and of the solution composition yield a change in the hydrogen evolution and zinc deposition partial characteristic curves; as the total current is constant, the partial zinc current density decreases and the cathodic voltage becomes less negative until the reversible zinc potential is reached.

Under these conditions, the entire electrolysis current is due to hydrogen evolution and the zinc efficiency is zero. At this point, the corrosion of the deposit begins and continues with an autostimulating mechanism because the impurities previously incorporated into the deposit gradually come to the surface, further increasing the contaminated area on which hydrogen evolves (stage *b*).

When the zinc deposit dissolution has been completed, hydrogen evolves on aluminum and a new polarization of the cathode with respect to zinc begins (stage *c*).

After many formation and dissolution cycles of the zinc deposit, the frequency of the cycles increases, showing that the aluminum cathode is gradually contaminated by the impurities until zinc deposition can no longer occur.

For analytical purposes, it is convenient to consider the first cycle induction period, which is generally well reproducible. Such a period, as indicated before, depends on temperature, electrolyte acidity, and impurity concentration. For a solution containing 50 g/liter of zinc, 10*N* sulfuric acid, it was possible to reproduce the deposit formation and dissolution cycles down to a concentration of 10 μg/liter for germanium, 100 μg/liter for nickel, cobalt, and antimony, 10 mg/liter for bismuth, copper, and arsenic, and 20 mg/liter for iron and tin, Fig. 3.

These results, in agreement with industrial electrolytic cell practice, show the possibility of an impurity classification according to the following dangerous effect decreasing order: Ge, Sb, Ni, Co, Bi, Cu, As, Sn, Fe.

In a semilogarithmic diagram, Fig. 4, plotting the induction time determined for an impurity concentration of 40 mg/liter *vs.* hydrogen overvoltage corresponding to a current density of 10 A/dm^2 (15-16), it can be seen that for many impurities the induction time is a decreasing function of hydrogen overvoltage.

This result does not agree completely with other authors' conclusions (14), but confirms our previous

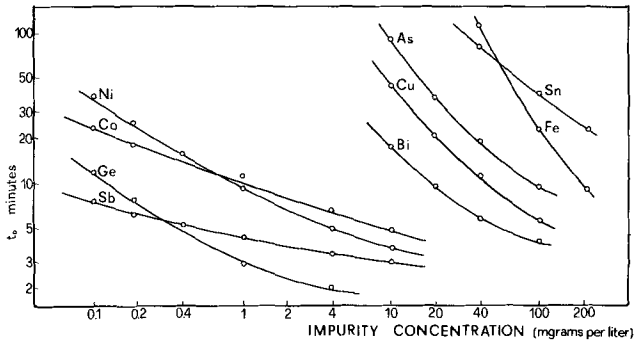

Fig. 3. Effect of impurity concentration on the induction time: H_2SO_4 10N, Zn^{++} 50 g/liter, $T = 50°C$, $i = 2$ A/dm^2.

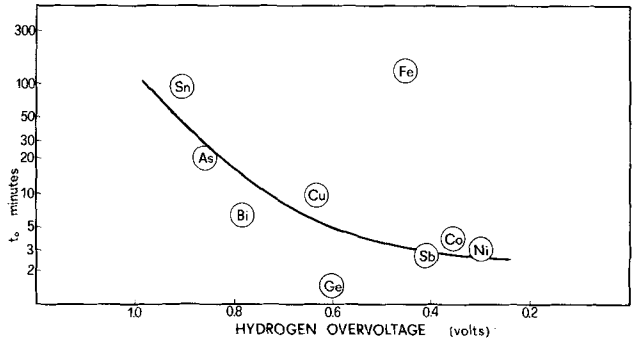

Fig. 4. Relationship between the induction time and hydrogen overvoltage on various impurities: impurity concentration 40 mg/liter, $T = 50°C$, $i = 1$ A/dm^2.

findings (10): the influence of the impurities on the current efficiency is scarcely due to the impurity deposition current and depends almost exclusively on hydrogen overvoltage on the contaminated areas. Anomalies were observed in the case of germanium and iron; such anomalies are probably related to the structure of the impurity in the deposit, because hydrogen overvoltage may have, correspondingly, very different values.

Experiments carried out when more than one impurity (Ge, Co, Ni) contaminates the zinc solution at the same time have shown independent behavior of such impurities, confirming our previous findings (10).

Chemical Vapor Deposition of Arsenosilicate Glass: A One-Liquid-Source System

J. Wong and M. Ghezzo*

General Electric Corporate Research and Development, Schenectady, New York 12301

In this note the chemical vapor deposition of binary arsenosilicate glasses in the range 0-20% As_2O_3 from a one-liquid-source system is described. High deposition rates (500-900 Å/min) at relatively lower substrate temperatures (300°-500°C) are the main advantages of the present system over the so-far reported two-liquid-source systems such as: (*a*) TEOS[1]-$AsCl_3$-O_2-N_2 (1-4); (*b*) TEOS-$AsCl_3$-O_2-Ar (2); (*c*) TEOS-$AsCl_3$-CO_2-H_2 (2); (*d*) $SiCl_4$-$AsCl_3$-CO_2-H_2 (2); and (*e*) TEOS-$AsCl_3$-N_2 (3). Preliminary results indicate definitely that the heat treatment characteristics of these binary glasses on silicon substrates at elevated temperatures are strongly dependent on the As_2O_3 content in the glass.

The system consists of an argon-diluted mixture of silane, oxygen, and arsenic trichloride vapor flowing over a heated silicon substrate supported by a molybdenum pedestal in a quartz vertical reactor similar to the one employed by Brown and Kennicott (5) for depositing binary borosilicate glasses. A schematic representation of the flow system is shown in Fig. 1. The reactant gases and vapor were allowed to premix and/or bypass the reactor while the substrate was being heated to the desired temperature in a pure argon atmosphere or at the end of a deposition run. This procedure assures uniformity of gas composition throughout the deposition and avoids predeposition of pure pyrolytic silica.

The silane tank (from the Matheson Company) contains a calibrated mixture of 1% silane in argon. The use of this diluted silane source eliminates dangers of explosion when mixed with oxygen (6) and measurement of very low flow rates (which is the case if an undiluted silane source is used). The substrates for glass deposition were 1 ohm-cm p-type (100)

* Electrochemical Society Active Member.

Key words: infrared spectrum, composition calibration, n-diffusion source.

[1] TEOS stands for tetraethoxysilane $(C_2H_5O)_4Si$.

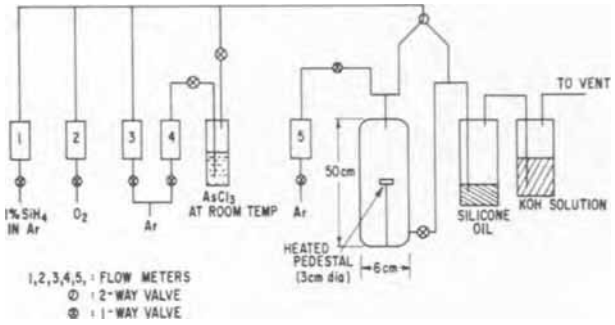

Fig. 1. Schematic representation of the flow system for depositing arsenosilicate glasses.

oriented silicon wafers, 2.5 cm in diameter obtained commercially. Prior to deposition the wafers were treated with an etching solution[2] and rinsed in distilled water. The total argon flow rate was set at 3500 cc/min and the 1% silane mixture flow rate at 230 cc/min, which corresponds to 2.3 cc/min of pure silane. Experiments were performed with oxygen flow rates of 20 cc/min and 95 cc/min. Argon was bubbled through arsenic trichloride at room temperature [24°C, at which $AsCl_3$ has a vapor pressure of 10 mm Hg (7)] with a flow ranging from 5 cc/min to 500 cc/min. With these flow rates, oxygen was always in excess and $AsCl_3$:SiH_4 ratios bracketed the stoichiometric ratio of 1.33 according to the following over-all reaction

$$3SiH_4 + 4AsCl_3 + 6\,O_2 \rightarrow 2As_2O_3 + 3SiO_2 + 12HCl$$

The temperature of deposition varied from 300° to 500°C. The glass deposition rate was found to depend on both the oxygen flow rate and the temperature of the silicon substrate. With an oxygen flow rate of 20 cc/min, the deposition rate varied between 100 and 600 Å/min in the temperature range 300° to 500°C (Fig. 2, curve a). With the oxygen flow rate of 95 cc/min, the deposition rate increased to 550-900 Å/min in the same temperature range (Fig. 2, curve b). Using the TEOS-$AsCl_3$ systems, however, the highest reported (1, 3) deposition rate for binary arsenosilicate glasses was of the order of 1.2 μ/hr, which corresponds to 200 Å/min, even at substrate temperatures up to 700°C.

The infrared spectrum of a film of binary arsenosilicate glass shows a relatively intense absorption band at 930 cm^{-1} which is absent in the corresponding spectrum in vitreous silica (bulk, pyrolytically or thermally grown). This band has been identified as a

[2] Conc. HNO_3:Conc. HF = 3:1 by volume.

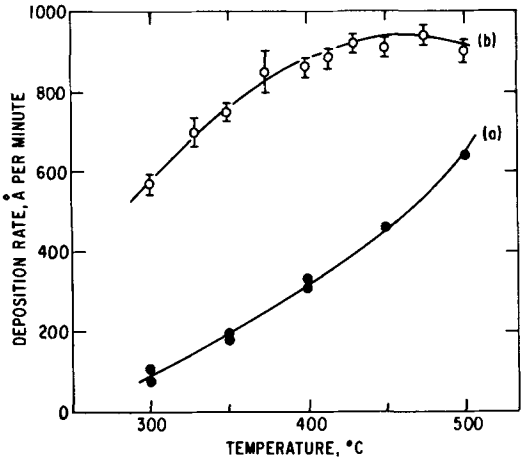

Fig. 2. Deposition rate vs. temperature of silicon substrate at constant flow rates of 1% SiH_4, Ar into $AsCl_3$, and Ar (230, 473, and 3500 respectively), and oxygen flow rate of 20 (curve a) and 95 (curve b). All flow rates in cc/min.

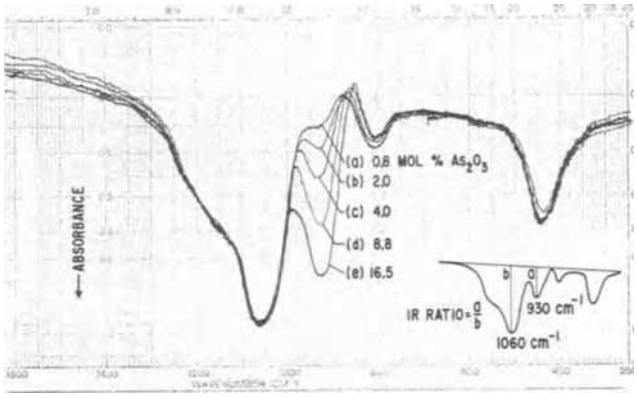

Fig. 3. Infrared spectra of binary arsenosilicate glass deposited at 450°C at constant flow rates of 1% SiH_4, O_2, and Ar (230, 95, and 3500 respectively), and at varying flow rates of Ar into $AsCl_3$: (a) 5; (b) 10; (c) 20; (d) 40; and (e) 100. All flow rates in cc/min. Inset illustrates the base-line method of calculating IR ratios.

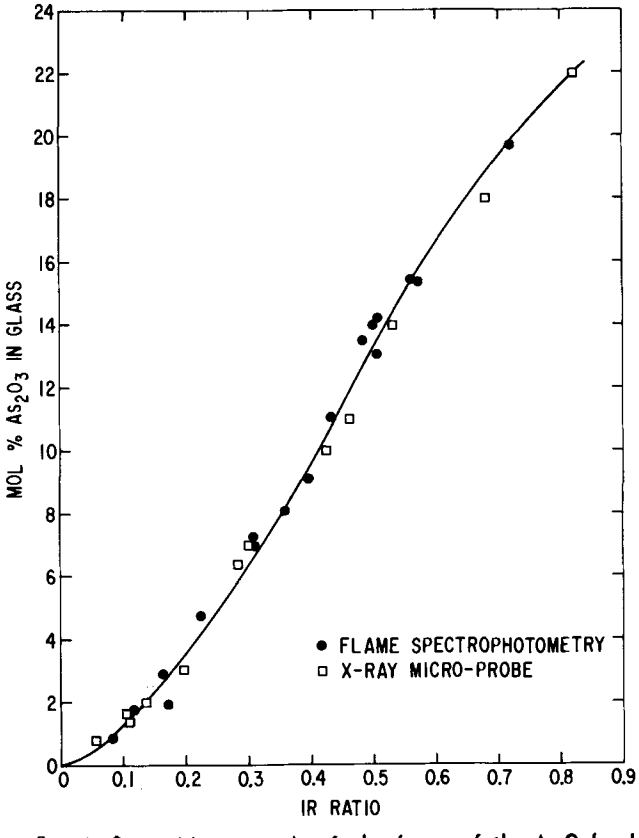

Fig. 4. Composition vs. ratio of absorbance of the As-O band at 930 cm^{-1} to that of Si-O band at 1060 cm^{-1} of as-deposited arsenosilicate glasses.

stretching vibration of arsenic-oxygen quasi-lattices in the binary glass (4). Furthermore, the absorbance of this band increases monotonically with increase in mole per cent (m/o) of arsenic oxide in the glass, as seen from Fig. 3.

A calibration curve has been constructed by measuring the optical density ratio of the As-O absorption peak at 930 cm^{-1} to that of the Si-O peak at 1060 cm^{-1} and plotting against the m/o As_2O_3[3] in the glass calculated from the weight of the film and flame spectrophotometric analysis of silicon in the glass dissolved in a HF solution. The results are shown in Fig. 4. In

[3] Trivalence of the arsenic in all deposited glass was established by the bright yellow precipitate it formed with $AgNO_3$ dissolved in a HF solution (8). Control experiments showed that pure As_2O_3 and pure As_2O_5 gave a similar bright yellow and dirty brown precipitate respectively with $AgNO_3$ in HF solutions.

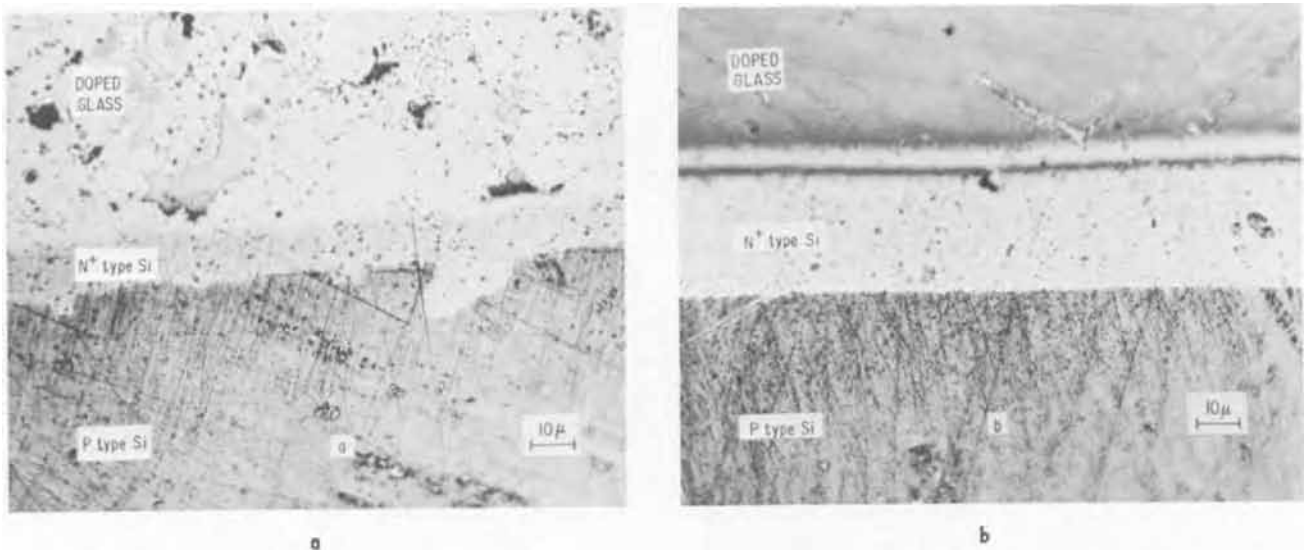

Fig. 5. Angle lapped sections of p-type (100) oriented 1 ohm-cm Si slice after arsenosilicate glass deposition and diffusion in argon at 1100°C. Beveling ratio is 20:1. Mole per cent As_2O_3 in the as-deposited glasses are: (a) 13.5 (IR ratio = 0.50) and (b) 0.5 (IR ratio = 0.05).

addition, composition data obtained for the atomic ratio of As and Si in the glasses by x-ray microprobe analysis using elemental silicon and high purity GaAs as standards, having been converted to m/o As_2O_3 and are plotted in Fig. 4. It can be seen that good agreement is obtained for the two independent sets of chemical analyses within 1 m/o As_2O_3 or better. The infrared spectrum together with the above calibration curve can thus be used as a nondestructive means determining the composition of as-deposited binary arsenosilicate glass films. The IR ratio method of determining composition has been discussed by Kern and Heim (9) for borosilicate glasses (but no calibration curve was given). Such a calibration curve has recently been reported from this laboratory (10) for as-deposited binary borosilicate glass films in the whole composition range obtained by chemical vapor deposition.

After film deposition, the wafers were heated in an argon atmosphere (flow rate: 1 ft^3/hr) at 1100°C for 5 hr. Glass damage was observed in glasses containing more than 1 m/o As_2O_3 (IR ratio = 0.08). Damage to the glass occurs soon after introduction of the wafers into the furnace, as shown by heating small portions of the wafers having various amounts of As_2O_3 in the glass under the above conditions for only 15 min. When the glass is damaged, the diffusion front appears irregular and contains deep spikes, which seem to reflect glass damage on the surface (Fig. 5a). Glasses containing less than 1 m/o As_2O_3 showed no damage during heat treatment; the diffusion front appears uniformly deep under the entire wafer, as determined by angle lapping and staining methods (Fig. 5b).

From the junction depth and the sheet resistivity of the semiconductor surface, measured with the four point probe method, calculations based on Irvin's curves (11) assuming a complementary error function distribution show that surface concentrations of carriers as high as 4×10^{20} per cm^3 can be achieved with undamaged glass samples.

A detailed study on the deposition characteristics of these arsenosilicate glasses, the nature of glass damage at elevated heat treatment temperatures, and the diffusion characteristics of As from the glass into silicon will be published in a subsequent article.

Summary

A one-liquid-source chemical system for depositing binary arsenosilicate glasses is described. Silane, oxygen, and arsenic trichloride are the reagents used. Low deposition temperature (300°-500°C) and high deposition rates (500-900 Å/min) are the main advantages of this system over the corresponding two-liquid-source system based on TEOS so-far reported. Glasses containing 0-20 m/o As_2O_3 and higher have been prepared. After diffusion at high temperature (1100°C) in an argon atmosphere, surface concentrations of carriers as high as 4×10^{20} per cm^3 were obtained.

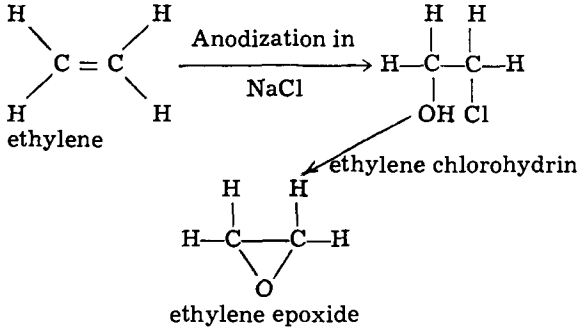
Polarization Behavior of Graphite in Sodium Chloride Solutions in the Presence and Absence of Ethylene

A. Belanger, G. Belanger,* and A. K. Vijh*

Hydro-Quebec Institute of Research, Varennes, P.Q., Canada

With the generally projected availability of inexpensive electric power in the near future, electrosynthesis of new organic compounds becomes increasingly more attractive commercially. It has recently been suggested that (1), partial electro-oxidation of low molecular weight hydrocarbons, with an aim to introduce desired functional groups, could provide an interesting avenue for exploitation of the commercial potentialities of the electrosynthetic procedures. In this connection, it has been claimed in the patent literature (2), that ethylene can be partially oxidized to ethylene epoxide by means of a graphite anode in aqueous NaCl solutions (*p*H adjusted to 10.6) through the following over-all reaction



The scope of the work reported here was to examine potentiostatically and potentiodynamically the polarization behavior of graphite in NaCl solutions in the presence and absence of ethylene. The object was to delineate the general electrode kinetic features (3) of the above electrosynthesis. In particular, it was sought to establish whether ethylene is oxidized chemically and homogeneously by the ClO^- produced anodically, as claimed (2), or by a heterogeneous path involving the oxidation of ethylene on the electrode surface. The studies were also extended to explore the cathodic behavior of graphite in the NaCl solution in the presence and absence of ethylene.

Experimental Section

The following instruments were employed in this investigation: Tacussel potentiostat, PRT 20-2B; Tacussel milliammer Type MAL 284; Tacussel digital voltmeter with high input impedance; Honeywell X-Y recorder, Type 550M; Tacussel function generator, Type GSTP 2; General Radio decade resistor box; constant-current d-c power supply (Kepco). Conventional potentiostatic, galvanostatic, and potentiodynamic circuitries were used (3).

Measurements were carried out in 3M sodium chloride solutions ("Baker analyzed") with *p*H adjusted to 10.6 by the addition of sodium hydroxide ("Electrolytic Pellets"—Fisher) solution. Solutions were made in deionized and doubly distilled water, both distillations being over alkaline potassium permanganate. Working electrodes were spectroscopic grade rods (Union Carbide) and were mounted into heat-shrinkable Teflon material as described previously (4). Graphite rod counterelectrodes and hydrogen reference electrodes were employed. The working and the counterelectrodes were thoroughly cleaned and degreased in boiling trichloro-ethylene. The platinized-platinum electrodes for the reference compartment were cleaned before platinization and were rinsed several times in doubly distilled water subsequent to platinization. A three-compartment Pyrex glass cell provided with solution-sealed stopcocks and various gas inlets and outlets (with water bubblers) was used. The working electrodes were carried on the ground-glass sliding tubes generally called "tru-bore" tubing.

Hydrogen gas for the reference electrode was "Electrolytic, Grade A" (Liquid Carbonic) and was deoxygenated by passing over a palladium catalyst ("Deoxo") and further purified by passage through activated charcoal and activated alumina, both at liquid nitrogen temperature. Helium gas for the working and counter compartments was the purest available grade (Grade A provided by Liquid Carbonic) and was deoxygenated over copper at 500°C. Any residual impurities in He were presumably removed by subsequent passage over active charcoal at liquid nitrogen temperature. The ethylene used was obtained from "Liquid Air of Canada" and was 98.5% pure. Ethylene was used without further purification. All connections between the gas lines and the electrolytic cell were made by means of glass-to-glass joints.

Optimum anodic pre-electrolysis, under helium atmosphere, was conducted in solutions in which anodic polarization behavior was subsequently examined; similarly cathodic pre-electrolysis of the solutions was carried out for the investigation of the cathodic polarization behavior. Both anodic and cathodic pre-electrolyses were carried out in solutions in which potentiodynamic scanning over wide ranges of potentials was done.

In the steady-state current-potential relationships, values of the current were read by stopping 1 min at every potential. Generally, quite steady readings of the current were obtained after about 20 sec. All electrode potentials refer to the hydrogen electrode in the same solution.

All experiments were carried out at room temperature in solutions thoroughly stirred by bubbling either helium or ethylene, depending on the type of experiment. Although the previous claims (2) to successful partial oxidation of ethylene refer to the work at 38°C, our experiments carried out at *ca.* 26°C would be expected to yield qualitatively similar results. This is because such moderate difference of temperature (~12°C) would, in general, affect only the rate of the reaction and not the identity of the reaction products themselves.

It may be added that the galvanostatic arrangement was used only during pre-electrolyses in order to pass the high currents (> 50 mA cm^{-2}) needed, with the stopcock between the working and the counter compartments being closed

The electrode kinetic measurements were supplemented by appropriate product analyses. The presence of ClO^- in the anodized solutions in which ethylene was not bubbled was established by means of iodine titration (5) and colorimetric methods (6). The detection of ethylene glycol, formed by hydrolysis of ethylene epoxide, was carried out by V.P. chromatography using a column made of Porapak Q.

Results and Discussion

The sodium chloride solution was first anodized on the graphite electrode by completely isolating the working compartment from the atmosphere and other

* Electrochemical Society Active Member.

Key words: graphite electrode, electrochemical behavior of graphite, electrosynthesis on graphite, anodic and cathodic polarization of graphite.

parts of the cell and in the absence of ethylene for 48 hr at 5 mA. It was observed that the solution became quite yellowish presumably owing to the dissolution of the anodically evolved chlorine gas. The dissolved chlorine gas gives rise to the ClO^- ions by means of the reaction (7)

$$Cl_2 + 2\,OH^- \rightleftharpoons Cl^- + OCl^- + H_2O \qquad [1]$$

The presence of OCl^- was confirmed titrimetrically (5) and colorimetrically (6) as mentioned earlier. When the ethylene was bubbled subsequently through this solution containing ClO^-, without the concomitant passage of current, ethylene glycol was formed thus confirming the previous results (2), namely, chemical homogeneous reaction between ClO^- and C_2H_4 to form epoxide. Essentially the same result, *i.e.* formation of ethylene glycol, was obtained on the anodic polarization of graphite in the NaCl solution in the presence of ethylene bubbling through the working compartment. In order to examine further the possibility of heterogeneous oxidation of ethylene in the latter case, potentiostatic and potentiodynamic studies were carried out. Briefly, it was observed that presence of ethylene does not alter the current potential relations, either potentiostatic or potentiodynamic, corresponding to the anodic polarization of graphite in NaCl solutions. The details on these results follow.

In the anodic polarization studies in the potential range between 1.1V and 2.0V approximately, it was observed that substitution of helium by ethylene in the working compartment did not bring about a significant change in the rate of the electrode reaction at a given steady-state potential. The plots of potentiostatically controlled steady-state potentials against the current density, both in the presence and absence of ethylene, are presented in Fig. 1. Introduction of ethylene does not result in substantial increase or decrease of current at a given potential, keeping in mind the poor reproducibility of the steady-state current-potential relationships probably arising from slow diffusion of chlorine into and out of the graphite electrode (8). The qualitative conclusion drawn from Fig. 1, is confirmed by Fig. 2, in which it is observed that the potentiodynamic profiles are exactly the same in the presence and absence of ethylene. In Fig. 2, the electrode was scanned between −1.2V and +1.9V respectively, and it was observed that ethylene has absolutely no effect on either the anodic or the cathodic portion of the potentiodynamic profile. Thus Fig. 2 would then be consistent with Fig. 1 in which no detectable heterogeneous oxidation of ethylene is indicated. The cathodic, on the potential scale, portion of Fig. 2, is

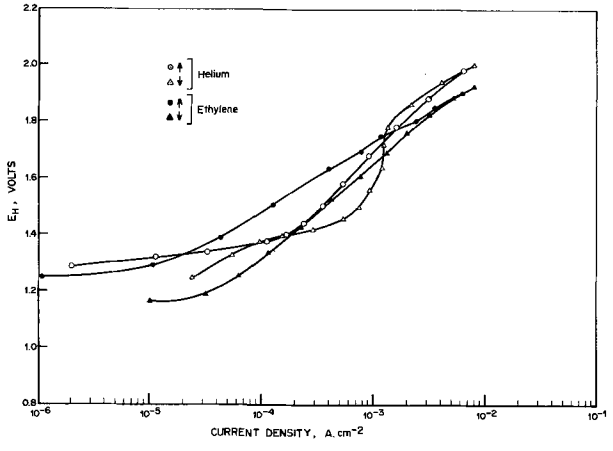


Fig. 1. Steady-state (point-by-point) anodic polarization curves on graphite in 3M NaCl solutions in presence and absence of ethylene. Electrode potentials, E_H, expressed against the hydrogen electrode in the same solution. Within the range of experimental reproducibility, oxidation of ethylene is not indicated (also see Fig. 2).

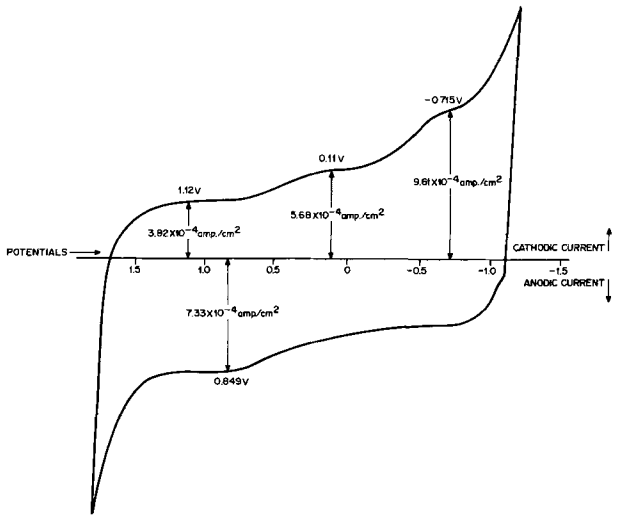

Fig. 2. Repetitive potentiodynamic profiles (sweep rate, dV/dt = 0.3 V sec^{-1}) on graphite in 3M NaCl solutions in presence and absence of ethylene. Essentially same result is obtained in single sweep profiles triggered from a prior steady-state potential. Even though pseudo-faradaic peaks are not observed over a wide range of sweep speeds, high value of (adsorption?) pseudocapacitance, $i \times \frac{dt}{dV}$, ranging between ca. 1000-3000 μF cm^{-2} are observed. There is no evidence of oxidation or reduction of ethylene.

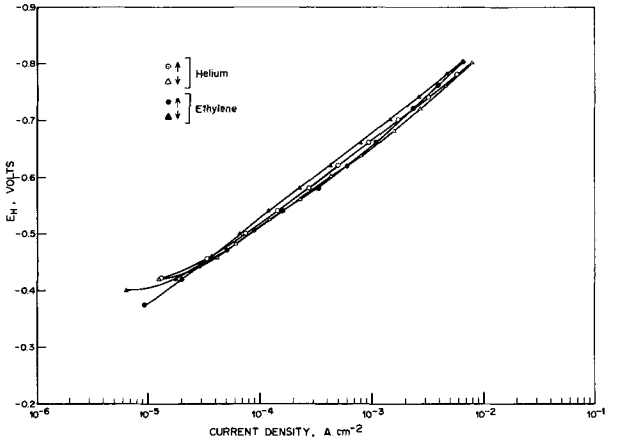

Fig. 3. Steady-state cathodic polarization of graphite in 3M NaCl solutions in presence and absence of ethylene. No reduction of ethylene is observed.

confirmed by Fig. 3, in which steady-state current-potential relationship in the potential range −0.4 and −0.8 are almost identical in the presence and absence of ethylene. It may thus be concluded that the hydrogen evolution reaction on the graphite in NaCl solutions is unaffected by the presence of ethylene, which presumably is neither adsorbed nor reduced (to C_2H_6) of these potentials. It may be added that cathodic reduction of ethylene has been accomplished, however, on platinum (9).

In addition to the negative conclusions, namely, ethylene is neither oxidized nor reduced on the graphite surface in NaCl solutions at room temperature, some positive aspects of Fig. 1-3 may also be discussed here.

In Fig. 2 even though clear-cut peaks indicative of the adsorption and desorption of reaction intermediates are not observed, the pseudocapacitance values estimated from the various portions of the hysteresis range between 1000-3000 μF cm^{-2} approximately with respect to the geometric area of the electrode. Although the real area of the electrode is not known, these capacitance values appear to be higher than the

double layer capacitance even when an appreciable value of the roughness factor is assumed. This would be consistent with the previous evidence on the substantial chemisorption of atomic chlorine on graphite during anodic polarization in solutions containing chloride ions. This information when combined with the generally high (>> 30 mV) Tafel slopes in Fig. 1 would suggest that the evolution Cl_2 on graphite proceeds by the steps

$$Cl^- + C \xrightarrow{\text{"fast"}} C - Cl + e \quad [2]$$

$$C - Cl + Cl^- \xrightarrow{\text{"slow"}} C + Cl_2 + e \quad [3]$$

where C represents a site on the graphite electrode and $C - Cl$ denotes a chlorine atom adsorbed on this site. It is assumed that the electrode coverage by Cl atoms is high, *i.e.* $\theta \to 1$.

Similarly, if it is assumed that the high capacitance values in Fig. 2 at cathodic potentials also indicate some adsorption pseudocapacitance (10) and thence significant steady-state coverage by adsorbed hydrogen, a radical-ion or atomic recombination mechanism for the cathodic hydrogen evolution on graphite would be indicated. The Tafel slope observed (Fig. 3) is near $2.3 \times 2RT/F$ which would tend to eliminate atomic recombination as the possible mechanism. One may thus conclude the following steps for the evolution of hydrogen

$$H_2O + C + e \xrightarrow{\text{"fast"}} C - H + OH^- \quad [4]$$

$$C - H + H_2O + e \xrightarrow{\text{"slow"}} C + H_2 + OH^- \quad [5]$$

The radical-ion step suggested here would be qualitatively consistent with the observed apparent exchange current density (Fig. 3), high heat of sublimation and melting point of graphite, and, good chemisorptive properties of graphite.

It may be added that in the potential range 1.1V to 0V, virtually no current was observed except around 0.95V at which a few microamperes were consistently noticed despite extended pre-electrolysis. This current must be attributed to an impurity redox reaction probably associated with the reduction of traces of oxygen which might have been irreversibly taken up by the graphite electrode before introduction into the solution (11). In any case the origin of this background current (< 8 μA), which did not appear to affect the results in rest of potential regions, could not be established.

Although direct oxidation of ethylene on the electrode surface has not been observed to occur on graphite in this study or previously (2), there has been a report (12) that such a heterogeneous oxidation can proceed on some special catalytic surface prepared by incorporating Ag into a graphite anode.

Acknowledgments

The authors are grateful to Mr. R. Jacques for contributions to the experimental aspects of this work. Thanks are also due to Dr. P. Lenfant for his interest and encouragement. Grateful acknowledgment is also made to the referees of this paper for their suggestions.

Electrochemical Alloying of Lithium in Organic Electrolytes

A. N. Dey*

P. R. Mallory & Company, Inc., Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

Lithium metal was found to alloy with the other metals including noble metals in an organic electrolyte electrochemical cell: Li/1M $LiClO_4$ in propylene carbonate/metal at ambient temperature with the evolution of electrical energy. The alloying occurred in many organic electrolytes containing lithium ions. Both the coulombic efficiency and the rate of alloying were found to be high. The alloys were gray to dark gray and brittle. Chemical and x-ray analysis indicated that they were intermetallic compounds.

It was observed (1, 2) earlier in our laboratory that a cathodic chronopotentiogram in the organic electrolyte consisting of 1M $LiClO_4$ in propylene carbonate consisted of several voltage plateaus prior to the lithium deposition. It was postulated that one of these plateaus might be due to the alloying of lithium with the substrate. In this paper, I wish to present some experimental evidence to show that lithium undergoes spontaneous electrochemical alloying (SEA) at ambient temperature with various metals including noble metals at appreciable rates in the organic electrolytes containing lithium salts. The phenomenon results in the dissolution of the lithium anode and the simultaneous deposition and alloying of lithium on the metal cathode, and the evolution of energy in a manner similar to a primary cell.

Experimental

Materials.—Propylene carbonate (PC) (Eastman Kodak) was vacuum distilled at 120°C, 1.2 mm Hg. Anhydrous $LiClO_4$ was used as received from G. Fredrick Smith Company. The water content of the electrolyte consisting of 1M $LiClO_4$ in PC was found to be 0.01% (volume). The other organic solvents such as γ-butyrolacetone, dimethyl sulfoxide, N, N-dimethyl formamide, methyl formate, tetrahydrofuran, and acetonitrile were used as received.

Electrodes.—The lithium anodes were made by pressing a rectangular piece of lithium ribbon (0.02 in. thick, Foote Mineral Company Inc.) on the expanded stainless steel current collector. The cathodes of the various metals such as Sn, Pb, Al, Au, Pt, Zn, Cd, Ag, Mg, Ti, Cu, and Ni were made by cutting out rectangular pieces (2 x 2 cm) of metal foil. The thicknesses of the available metal foils varied from 0.005 to 0.01 in.

Cell.—The cells were constructed by placing two lithium anodes on each side of the metal foil cathode with filter paper separators interposed between the electrodes. Two rectangular Teflon blocks were placed on each side of the anodes and were tied with string to provide stack pressure. The assembly was then placed in a sealed glass jar containing electrolyte (1M $LiClO_4$ in PC). The electrical connections were made either by spot welding stainless steel tabs to the anode current collectors and the cathode metal or by means of alligator clips. Care was taken to ensure that the points of contact were not wetted by the electrolyte. All the above operations were carried out in the dry box filled with dry argon with a moisture content of less than 2 ppm.

The cells were either directly shorted or were discharged through a known resistor. In the latter case, the cell potential was recorded as a function of time.

Spontaneous electrochemical alloying (SEA) and the determination of the alloy composition.—The cathodic alloying of the metal cathodes with lithium started as soon as the external circuit of cell [1] was completed

Li/1M $LiClO_4$-PC/metal [1]

The composition of the lithium metal alloy was determined by dissolving the alloy in water whereby the lithium reacted with water to form LiOH and the metal particles precipitated. The aqueous extract was then titrated with standard acid to determine the amount of lithium present in the metal. The titrations were repeated after various periods of equilibration of the alloy in water to ensure that most of the lithium reacted with water.

X-ray diffraction of the SEA alloys.—The metal foil cathodes (*e.g.*, Al, Sn, Pb, etc.) turned into a gray powder after shorting with the lithium anode in cell [1] for 8-10 hr. These powders (metal lithium alloy) were filtered and thoroughly washed with the PC and then with tetrahydrofuran and dried in the dry box. A portion of the powders which appeared free from any unalloyed metal particles was then packed in a quartz capillary in the dry box and the opening of the capillary was closed with silicone grease. The capillaries were then removed from the dry box and were sealed with a flame. The x-ray diffraction of the alloys were carried out with these capillaries using Debye Scherrer Powder Camera (116.4 mm diameter) with Norelco x-ray system (Cu Kα radiation, Ni filter).

Results and Discussions

The metals such as Sn, Pb, Al, Au, Pt, Zn, Cd, Ag, and Mg form gray or dark gray powder after shorting

* Electrochemical Society Active Member.

Key words: propylene carbonate, cathodic embrittlement, noble metals, lithium-metal alloys, intermetallic compounds.

with the lithium anode in cell [1] within periods of hours to days (at room temperature) depending on the metal. This alloying does not occur in electrolytes containing tetralkyl ammonium salts or salts which do not contain any lithium ions. The phenomenon occurs in many organic solvents such as propylene carbonate, γ-butyrolacetone, dimethyl sulfoxide, N, N-dimethyl formamide, methyl formate, tetrahydrofuran, acetonitrile. The short-circuit (through the ammeter) current densities obtained with several metal cathodes (*e.g.*, Al, Sn, Pb) were of the order of several milliamperes per square centimeter at room temperature. The phenomenon occurs at lower temperatures as long as the electrolyte remains liquid.

The phenomenon is strictly electrochemical. No alloying or any other change on the electrodes were observed as long as the external circuit of cell [1] was open. On closing the circuit, the anodic reaction was determined (weight loss) to be the dissolution of lithium

$$\mathrm{Li} \rightarrow \mathrm{Li}^+ + e \qquad [2]$$

and the cathodic reaction was determined to be the deposition of lithium (weight gain, and chemical analysis), and alloying

$$x\mathrm{Li}^+ + \mathrm{M} + xe \rightarrow \mathrm{Li}_x\mathrm{M} \qquad [3]$$

The initial open-circuit voltages of all the cells were greater than a volt (Table I). The high voltages are due to the presence of metal oxides on the metal cathodes. The shorting of the cells could cause initial electrochemical reduction of the surface oxide of the metals. The open-circuit voltage of the cells after the initial short circuiting varied a great deal from metal to metal. The open-circuit voltages of the cells also decreased as the duration of short circuiting increased.

According to the Nernst equation [4]

$$E = E_0 - 2.303\frac{RT}{\mathbf{F}}\log\frac{a_{\mathrm{Li}+}}{a_{\mathrm{Li}}} \qquad [4]$$

cell [1] is expected to exhibit zero voltage under the following conditions: (*a*) the absence of spurious reactions such as solvent decomposition, and (*b*) the activity of the freshly deposited lithium on the cathode is unity. It was shown earlier (3) that the solvent decomposition reactions did not occur on metal substrates to any measurable extent although it was a dominant reaction on a graphite substrate in a cell similar to [1]. However, the alloying of lithium with the metal caused the activity of Li (a_{Li}) to be less than unity on the metal substrate and hence, the metal electrode assumed a positive potential compared to the lithium anode. The lithium deposition continued as long as the alloying continued. It was found that the alloying continued with the metals such as Sn, Pb, Al, Au, Pt, Cd, Ag, and Mg until the brittle, powdery, dark alloy fell off and lost electronic contact.

Degree of alloying.—The metals examined for the spontaneous electrochemical alloying fell in the following two classes based on the degree of alloying as determined by the drastic change in appearance and the charge transferred through the cell of type [1] due to electrochemical alloying:

Class I: Metals which underwent changes in appearance on alloying: Sn, Pb, Al, Au, Pt, Zn, Cd, Ag, and Mg.

Class II: Metals which did not undergo any significant change in appearance: Ti, steel, stainles steel, Cu, and Ni.

It is apparent that the class I metals will be unsuitable as current collector materials for the lithium anode of the primary and secondary organic electrolyte cells.

Coulombic efficiency.—The apparent coulombic efficiency of the spontaneous electrochemical alloying was investigated by discharging the cells [1] through a 1 kohm resistor and by monitoring the voltage as a function of time. The voltage-time curves of the various cells with the class I metals are shown in Fig. 1. The amount of charge transferred through the external circuit was calculated by integrating the areas under the curves. The theoretical amount of lithium deposited on the cathode was calculated according to reaction [3]. The actual amount of lithium deposited in the metal cathodes was determined by chemical analysis. The coulombic efficiency of alloying of the class I and class II metals is given in the Table I. The open-circuit voltages of the cells and the initial voltages on constant load discharge, which are not obvious from Fig. 1, are also given in Table I.

The coulombic efficiency of the class I metals varied from 70 to 100%. The reasons for low electrochemical alloying efficiency for the metals like Au, Pt, Zn may be: (*a*) the inefficient extraction of Li by water treatment and (*b*) the oxide reduction. Normally, the fraction of the charge required for the oxide reduction is very small compared to the total charge passed for alloying and, therefore, it cannot account for such low efficiency. The efficiency of extraction of lithium by water treatment depends predominantly on the nature of the metal. For example, with soft, low-melting metals like Sn, the exothermic reaction of Li with water disintegrated the alloy into LiOH and finely powdered Sn within a few minutes. With Pb, the exo-

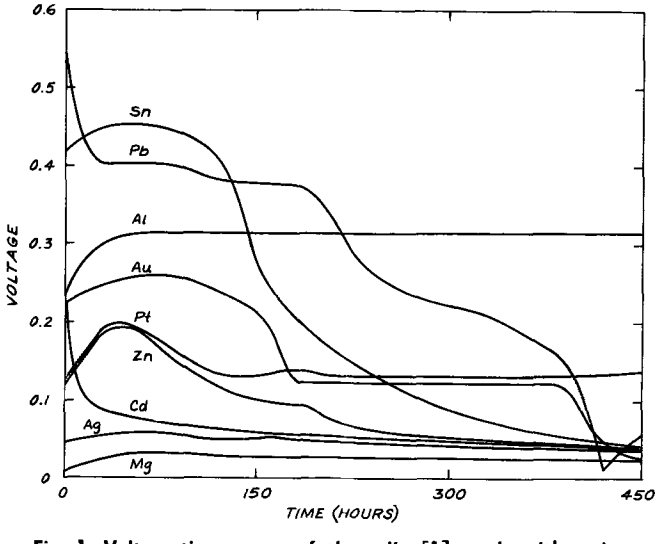

Fig. 1. Voltage-time curves of the cells [1] made with various metal cathodes and discharged with 1 kohm external load.

thermic reaction caused the Pb particles to sinter into porous Pb spheres. Whereas, with high melting metals like Pt and Au, although the initial reaction with water was quite vigorous, the diffusion of Li from the metal matrix to the solution was quite slow and the extraction might be incomplete. The low efficiency for the class II metals may be due to both (*a*) and (*b*), as the extent of alloying is so small that the experimental errors for the extraction and titrations can be very large.

Rate of alloying.—The relative rate of alloying of the various class I metals is directly proportional to the steady-state current flow through the 1 kohm resistor from the cells [1]. These currents are obtainable directly from the discharge curves shown in Fig. 1 by replacing the cell voltage units to milliampere current unit. The apparent voltage plateaus of the discharge curves of Sn, Pb, and Au might not have any significance as the electrodes in the specific cells were very thin and the alloying caused complete disintegration of the electrodes and the consequent loss of electronic contact. The voltage plateaus may be due to a change in the effective surface area of the metal cathodes. Based on the voltage maxima of Fig. 1 (after 60 hr of discharge) the relative alloying rates of the various metals approximately follow their relative hardnesses, *viz.*, the softer the metal, the higher the rate.

It is interesting to note that all the class I metals except Pb and Cd exhibit the initial voltage drop on discharge and the subsequent voltage recovery (Fig. 1). This may be due to the presence of oxide film which acts as a passive film, so to speak, to the electrochemical alloying process.

Lithium-metal alloy composition.—All the class I metals are known (4) to form one or more intermetallic compounds with lithium, whereas the class II metals do not. It appears highly probable that the observed alloying represents simply the electrochemical formation of the metal-lithium intermetallic compounds. Normally, these are formed by heating the metal and lithium at high temperatures, whereas here it is formed at room temperature spontaneously with the evolution of electrical energy.

The composition of the lithium-metal alloys formed electrochemically was determined by chemical analysis and is given in Table II. The known thermally prepared intermetallic compounds with similar compositions are also given in the same table for comparison. It appears that the electrochemically formed alloys are very similar in composition to that of the thermally formed known intermetallic compounds. The available x-ray diffraction data (5) on a specific intermetallic compound LiAl are compared with that of the SEA lithium-aluminum alloy in Table III. It is apparent that the thermally formed LiAl is identical to that of the alloy made by the electrochemical method described in this paper. The x-ray data indicate also the presence of small quantities of Li (dÅ, 2.48) and Al (dÅ, 2.33, 2.03, 0.978) in addition to LiAl in the SEA alloy.

Table II. Composition of the SEA alloys and the thermally prepared known intermetallic compounds

Conclusions

1. Lithium metal alloys with various metals such as Sn, Pb, Al, Au, Pt, Zn, Cd, Hg, and Mg electrochemically at ambient temperature in organic electrolytes containing lithium salt producing electrical energy in a cell of the following type

Li/1M $LiClO_4$-PC/metal

2. The coulombic efficiency of the spontaneous electrochemical alloying (SEA) is generally high (80-100%).

3. The alloy compositions are similar to the composition of known thermally prepared intermetallic compounds.

4. The x-ray diffraction data of the Li-Al SEA alloy show this to be identical to the thermally prepared intermetallic compound LiAl.

5. The phenomenon appears to be quite general in nature and can be termed as cathodic embrittlement of metals in contrast to the normally expected cathodic protection of metals.

Electrochemical Reduction of Oxygen in Carbonate and Carbonate-Halide Melts

P. K. Lorenz*,[1] and G. J. Janz*

Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

The electrochemical reduction of O_2 in molten carbonates occurs through two reactions:

$$\tfrac{1}{2}O_2 + CO_2 + 2e \rightleftarrows CO_3^{-2} \quad [1]$$

and

$$\tfrac{1}{2}O_2 + 2e \rightleftarrows O^{-2} \quad [2]$$

The onset of these two processes has been investigated in molten Li_2CO_3, the ternary eutectic (Li,Na,K)/CO_3, and the two binary eutectics, (LiCl,Li_2CO_3) and (LiF,Li_2CO_3). Reaction [1] is found to start at slightly negative potentials relative to the Au/O_2,CO_2 reference electrode and depends on the supply of CO_2 from the melt. The onset of reaction [2] occurs at more negative polarizations; both are affected by the solubility of O_2 in the melt. The results for reaction [1] correlate well with the thermal dissociation of carbonates as a function of temperature and melt composition. Reaction [2] appears inhibited at lower temperatures but can be obtained reproducibly if the electrode is potentiodynamically cycled several times through the voltage sweep range; at elevated temperatures it occurs readily. The results are examined relative to the differing viewpoints advanced relative to the electrochemical reduction of oxygen in such molten electrolytes.

The electrochemical reduction of molten carbonates has received attention previously, largely by the Russian workers, and differing viewpoints exist as to the over-all reactions and the electrode polarization potentials. The present communication reports the results of potentiodynamic studies on the electrochemical reduction of oxygen and carbon-dioxide-oxygen mixtures in molten Li_2CO_3 (m 618°C) and in the (Li, Na, K/CO_3) ternary eutectic (m 397°C). An extension of these studies to two binary carbonate-halide eutectics, LiCl-Li_2CO_3 (m 500°C) and LiF-Li_2CO_3 (m 608°C), was also undertaken and these results are also reported.

Experimental Results

The electrolysis cell and ancillary apparatus were those used in our studies on the CO and (CO, CO_2) electrodes and have been described elsewhere (1). Potentiodynamic data were gained with the automatic assembly, consisting of a voltage programmer, a potentiostat, and a dual power supply (Duffers Model 600 and 620, respectively). The reference electrode was also described previously (1) [Pt/(CO_2, O_2 in 2:1 ratio)], whereas the working electrode was a gold wire encased in two concentric Pythagoras porcelain tubes. By means of the latter it was possible to suppress the CO_3^{-2} ion dissociation reaction by maintaining an atmosphere of CO_2 (except during the current-voltage scans) above the melt in contact with the working electrode. When the tip of the working electrode contacted the molten electrolyte, measurements were initiated.

Li_2CO_3.—The electrochemical reduction was investigated in the temperature range of 750°-840°C with current-voltage scans and various atmospheres. Illustrative results at 840°C with O_2, CO_2, CO, and Ar atmospheres over the working electrode are in Fig. 1. The shape of the current-potential curve in the presence of O_2 suggests two reduction mechanisms. The initial reduction current under 1 atm of O_2 may be attributed to the reduction of both CO_2 and O_2 to carbonate, as proposed by Stepanov and Trunov (2)

$$CO_2 + \tfrac{1}{2}O_2 + 2e \rightleftarrows CO_3^{-2} \quad [1]$$

whereas, at higher polarization potentials (0.5-0.6V) the reduction of oxygen to oxide sets in (2), *viz.*

$$\tfrac{1}{2}O_2 + 2e \rightleftarrows O^{-2} \quad [2]$$

If there is no O_2 (or little O_2), this O_2 reduction cannot occur. The strong current undoubtedly indicates a high solubility of oxygen in molten Li_2CO_3. In the absence of CO_2 in the mixture, CO_3^{-2} ion formation process disappears. Due to the differences in diffusivities of O_2 and CO_2 in the electrolyte the optimum ratio of the partial pressures of CO_2 to O_2 is about 2.35 for reaction [1] to occur.

(Li, Na, K/CO_3) ternary eutectic.—In Fig. 2 the current-voltage scans in this electrolyte are shown. The increase of O_2 solubility in the melt with increasing temperature is clearly apparent, *i.e.* the currents cor-

responding to oxygen-oxide reduction reaction, Eq. [2]. The results in Fig. 2 are under conditions where the current-voltage scans are reproducible. It was found that above 680°C repeated cycling was not necessary for reproducible results, but at lower temperatures, *e.g.* 560°C, the oxygen reduction process attained reproducible potentials (*e.g.*, −0.6V) only after recycling about three times. At 440°C, it was not possible to induce the oxygen-oxide electroreduction, Eq. [2], even with repeated cycling. When a 2:1 mol ratio of (CO_2, O_2) was used rather than "O_2 only" over the working electrode, the current attributed to the oxygen-oxide electroreduction, Eq. [2], was smaller, while the initial current (attributed to CO_2, O_2, carbonate reduction reaction, *e.g.*, Eq. [1]) was larger.

(Li/Cl, CO_3) eutectic.—The value of the reference electrode potential was found to shift to more positive values (approx. 0.05V, at 800°C) in this electrolyte, compared with its use in molten carbonates. The current-voltage scans at 670°, 770°, and 820°C, in Fig. 3, show that the currents are relatively higher in the 0.0 to −0.6V region, and this correlates directly with a more pronounced thermal dissociation of CO_3^{-2} in this molten mixture, which increases the concentration of CO_2 in reaction [1]. Increased O_2 solubility with increasing temperatures is manifested by the increasing current in the region corresponding to reaction [2].

(Li/F, CO_3) eutectic.—Measurements were attempted at 800°C, but the corrosion of the Pythagoras tubing and baffles was too severe for meaningful results; measurements were limited to 720°C, and the current-voltage scans are illustrated in Fig. 4. The relatively greater thermal dissociation of the carbonate in this molten mixture is evidenced through the higher currents in the 0.0-0.4V region (cf. Eq. [1]). The large currents in the −0.5- −1.0V region indicate that solubility of O_2 is relatively great in such mixtures. Relative to the potential of the reference electrode, a small shift to more positive values was noted (*i.e.*, approx. 0.03V at 720°C).

Discussion

The electrochemical reduction of oxygen in molten carbonates has been investigated primarily by Stepanov and Trunov (2); Klevtsov, Arkhyov, and Stepanov (3); Paskov and Tyurikov (4); and Silakov, Tyurikov, and Vasilistov (5). Some aspects of these are summarized in Table I, and it is seen that there are differing viewpoints on electrochemical reduction of oxygen in carbonate electrolyses, namely Stepanov *et. al.* favoring two processes, the reduction of CO_2 and O_2 at low polarizations, Eq. [1], and the direct reduction of O_2 at higher anodic polarizations Eq. [2], whereas Silakov *et al.* propose peroxide at low anodic polarizations and the onset of a CO_2 reduction at higher polarizations.

Thermodynamically, from the data for Li_2CO_3, one may calculate the reduction potentials; it is thus found that the reduction of O_2 and CO_2 Eq. [1] is predicted

Table I. Electrolysis of molten carbonates

Investigation	Experimental aspects	Comments
Stepanov and Trunov (2)	(Li,Na,K)/CO_3 eutectic, porous Ag electrode	Support the onset of reaction [1] in the low cathodic polarization regions; maximum current when CO_2/O_2 ratio about 2/1.
Klevtsov, Arkhyov, and Stepanov (3)	(Li,Na,K)/CO_3 eutectic, cylindrical Pt electrode	There is a marked increase in i when the top of the electrode cylinder is raised to protrude about 5 mm above the melt; the rate of reaction [1] is thus limited by gaseous diffusion through the melt/electrode meniscus interface.
Paskov and Tyurikov (4)	(Li,Na)/CO_3, (Li,K)/CO_3, Ag wire electrode	Support the work of Klevtsov *et al.* (3), *i.e.*, a sharp increase in i when the meniscus interface is increased.
Silakov, Tyurikov, and Vasilistov (5)	(Li,Na,K)/CO_3, (Li,Na)/CO_3, Li_2CO_3, Pt and Pd electrodes to various degrees of air oxidation prior to electrolysis	The reaction at low potentials could be eliminated by extensive heating of electrode as pretreatment; proposed that anodic polarization of the electrode (without prior heat treatment) produces a metal peroxide ($MO_2 + 2e^- \rightarrow M + O_2^{-2}$), and at polarizations more negative than −0.5, the reduction of CO_2 to C or CO and carbonate was suggested.

feasible at potentials slightly negative to the reference electrode, whereas the reduction of O_2 to oxide Eq. [2] is not feasible until potentials more negative than −0.3V at 840°C are reached. Although the thermodynamic data for the mixtures are insufficient for such exact predictions, one may assume that the predictions for Li_2CO_3 hold in first approximation for the ternary carbonate eutectic, and more qualitatively provide guidelines for the carbonate/halide mixtures. The experimental results for Li_2CO_3 and the ternary eutectic (in Fig. 1 and 2) are in accord with the theoretically predicted potentials and support the viewpoint advanced by Stepanov *et al.*, namely that reaction [1] is the process occurring in the low cathodic polarization region. The current-voltage curves for CO_2 and Ar atm over the working electrode (Fig. 1) indicate that the CO_2 and carbonate reductions occur well outside the polarization range for the oxygen reduction reactions, and that these appear well separated. No changes in these current-voltage traces were observed if the electrode was heated in O_2 prior to the electrolyses; this contrasts with the observations of Silakov *et al.*, namely, that the reaction at low polarizations could be thus eliminated. The test electrodes in the work of Silakov *et al.* (5) were Pt and Pd, and it follows from the present results that Au does not show the same behavior.

It is also apparent at higher temperatures and in an O_2 atm that the CO_2, O_2 reduction Eq. [1] proceeds more readily as evidenced by the higher currents. This is not unexpected since the thermal dissociation of carbonates to CO_2 is enhanced with increasing temperatures; the increased rate is in accord with CO_2 being a limiting reactant. The current-voltage traces for the LiCl, Li_2CO_3 and LiF, Li_2CO_3 electrolysis in Fig. 3 and 4, respectively, provide additional support for this observation. The halide ion is known to influence the thermal dissociation of carbonates, the greatest effect being noted in LiF-Li_2CO_3 mixtures (6), and the observed currents are in relative agreement with the thermal dissociation to CO_2 of the carbonate, in the order LiF,Li_2CO_3 > LiCl,Li_2CO_3 > (Li,NaK)CO_3. Further, during the electrolysis of the ternary eutectic, if a 2/1 mixture of CO_2/O_2 was used over the working electrode, the current at lower polarization potentials was greater, and at higher polarizations, less, than with only oxygen as the atmosphere. The preceding observations, although qualitative, are firm support for the CO_2, O_2 reaction, *i.e.*, Eq. [1]

$$CO_2 + \tfrac{1}{2}O_2 + 2e \rightleftarrows CO_3^{-2} \qquad [1]$$

as the process in the low cathodic polarization region in the electrolysis of molten carbonates, and carbonate halide mixtures.

At the more negative polarizations, the process appears to be the direct reduction to the oxide ion, *i.e.*, Eq. [2]

$$\tfrac{1}{2}O_2 + 2e \rightleftarrows O^{-2} \qquad [2]$$

and at lower temperatures this proceeds reproducibly after the electrode is potentiodynamically cycled several times. As illustrated in Fig. 5, five successive cycles were required to obtain reproducibility at 560°C. The current increase accompanying reaction [2] moves from a potential of −1.3V to the reproducible values of −0.55V (Fig. 5, curves I, IV, and V, respectively). The potentials of about −1.0V (curves II and III, Fig. 5), correspond to the reduction of CO_2 (supplied from the thermal dissociation of the carbonate) to C and CO_3^{-2}, *i.e.*

$$3CO_2 + 4e \rightleftarrows C + 2CO_3^{-2} \qquad [3]$$

and after the onset of this reaction, the reduction of O_2 proceeded readily. If the inhibition of the oxide reduction reaction, Eq. [2], is due to an oxide layer on the Au electrode, the onset of the carbon deposition reaction, Eq. [3], followed by oxide layer attack

$$C + 3O^{-2} - 4e \rightleftarrows CO_3^{-2} \qquad [4]$$

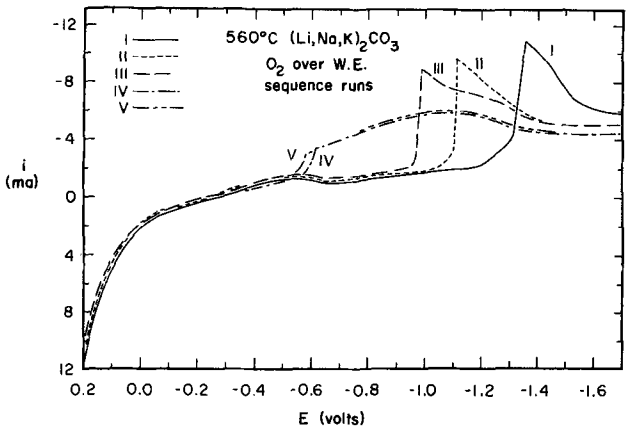

Fig. 5. Voltage-current scans of the working electrode (Au) vs. the Pt (CO_2/O_2) reference electrode during the electrolysis of the (Li,Na,K)/CO_3 ternary eutectic at 560°C, with O_2 over the working electrode. The electrode was cycled five times, and the traces are illustrated as I-V, respectively.

would account for the reproducibility attained in the O_2 reduction reaction (Eq. [2] and Fig. 5, curves IV and V), since the latter proceeds electrochemically apparently uninhibited, on the clean Au surface but not on a gold oxide surface. At 700°C, repetitive potentiodynamic cycling is no longer necessary to obtain reproducibility for the oxygen reduction reaction.

The cathodic deposition of carbon in fused carbonate electrolyses and the role of Li salts in such electrolytes have been discussed elsewhere (7-10). In the present work it is sufficient to note that while the current-voltage curves show clearly that CO_2 is reduced in electrolyses of the various carbonates, visual inspection (9) of the electrode showed C on the electrode at the lower temperatures only. Thermodynamic free energy considerations predict that the stability of C exceeds that of CO below 700°C, and that above this the CO_2 reduction to CO is favored

$$2CO_2 + 2e \rightleftarrows CO + CO_3^{-2} \qquad [5]$$

The difference in the thermodynamically predicted reduction potentials for reactions (Eq.) [3] and [5], respectively, is <0.1V, and separation in this temperature range was not attempted. Although the reduction products were not investigated in detail, it appears that reactions (Eq.) [3] and [5] are possibly the dominant processes contributing to the CO_2 reduction and that thermodynamic control (relative to C or CO end products) was undoubtedly operative for the temperature range investigated (440°-810°C).

Inspection of the results for the LiCl-Li_2CO_3 system shows the suggestion of two limiting currents (Fig. 3, 670° and 770°C, respectively). In light of the preceding considerations, it is significant to note that these two are observed as expected when reaction (Eq.) [1] occurs at slightly less negative potentials than reaction (Eq.) [2], and when reaction (Eq.) [2] is followed by, say, reaction (Eq.) [3]. A further result, namely that for electrolyses under CO_2 or Ar the second limiting current was not found, is additional support for the viewpoints advanced above.

Relative to the two oxygen reductions (reactions [1] and [2], respectively) it was of interest to examine the temperature-dependence of the electrolysis, and the derived enthalpies of activation, summarized in Table II, are from analyses of the log i *vs.* $1/T$ graphs at −0.4 and −0.7V, respectively. The enthalpy of activation for the CO_2, O_2 reduction process (16 kcal) is somewhat less than direct reduction of O_2 (20 kcal). The enthalpies of activation for the direct reduction of O_2 show only minor fluctuations for the different solvents. The hindrance of the O_2 reduction, thus, may be attributed to an electrode property, such as the postulated oxide

Table II. Heats of activation for O_2 reduction reactions

Electrolysis solvent	Slope × 10^{-3}	$\Delta H_{act.}$ kcal/mole
$CO_2 + \frac{1}{2}O_2 + 2e \rightleftarrows CO_3^=$		
$(Li,Na,K)_2CO_3$	4.0	18 ± 1
Li_2CO_3	3.2	15 ± 1
$LiCl\text{-}Li_2CO_3$	3.5	16 ± 1
$\frac{1}{2}O_2 + 2e \rightleftarrows O^=$		
$(Li,Na,K)_2CO_3$	4.6	21 ± 1
Li_2CO_3	4.1	19 ± 1
$LiCl\text{-}Li_2CO_3$	4.4	20 ± 1

layer, rather than a solvent property. By comparison, the enthalpies of activation, corresponding to CO_2 and O_2 reduction to carbonate show variations with the different solvents; the precision of the values probably does not justify conclusions other than that this process is dependent on the supply of CO_2 to the reaction zone.

Corrosion Inhibition Effects of Small-Sized Polymethyleneimine

Kunitsugu Aramaki*

Department of Engineering, Keio University at Hiyoshi, Yokohama, Japan

ABSTRACT

It has been reported that the inhibition effect of medium-sized polymethyleneimines on the corrosion of iron in HCl solution is notably good, and that this effect is closely related to strain in their rings. Inhibition mechanism of small-sized polymethyleneimines containing 2 to 5 methylene groups was studied. Corrosion rates of pure iron in HCl solution were determined by polarization measurement. Inhibition efficiency of these imines decreases with increase in number of methylene groups. Because of decreasing with increase in the methylene number, the strain in the imine ring seems to be related to the inhibition effectiveness of these imines. From discussions of the corrosion inhibition data together with basic strength, relative molecular area, and molecular structure of these imines, and with infrared spectra of reaction products derived from these imines, it is concluded that the inhibition efficiency of these imines does not depend on the π-electron bonding between metal and nitrogen atom, as shown for medium-sized ones. The high inhibition effect of C_2 and C_3 imine is caused by that of polymer molecules formed by the ring-opening reaction of these imines.

Structural effects of polymethyleneimines,[1] $\overbrace{(CH_2)_n NH}$, containing four to fourteen methylene groups on their corrosion inhibition have been studied by Hackerman and his co-workers (1-3). The inhibition efficiency of medium-sized polymethyleneimines with 9 to 12 methylene groups is markedly high, especially with 10, for iron corrosion in 6.1M HCl solution. This high efficiency is closely related to large strain in ring of these cyclic imines. Because of the large strain in the ring, angle of C-N-C bond in the imine ring is near 120°, which means sp^2 hybrid orbital geometry in nitrogen atom. This geometry provides an unshared π-electron pair on nitrogen atom. It has been concluded that the enhanced inhibition effectiveness of medium-sized polymethyleneimines is caused by donation of the π-electron pair on nitrogen atom to metal (3).

There also is a strain in ring of small-sized polymethyleneimines containing 2 to 4 methylene groups, and the strain of C_2 and C_3 imine is undoubtedly stronger than of C_{10} imine (4). The angle of C-N-C bond in the small-sized ring is, however, smaller than in C_5 imine ring which is free from the strain, while that in the medium-sized one is larger.

If this strong strain in C_2 and C_3 imine ring improves corrosion inhibitor performance of polymethyleneimine, the enhanced efficiency of these cyclic imines would be expected as shown in the case of C_{10} imine. In order to confirm effects of the ring strain on the corrosion inhibition, comparative study on the effi-

[1] The term "cyclic imine" and "secondary amine" are used for polymethyleneimine and symmetric dialkylamine in this paper as are C_n imine and C_n amine; for example, C_3 imine for trimethyleneimine and C_4 amine for diethylamine.

ciency of polymethyleneimines with 2 to 5 methylene groups and of symmetric secondary amines, $(C_{n/2}H_{n+1})_2NH$, with 2 to 6 carbon atoms was carried out. These differ in structure only in the presence of ring closing bond and of two hydrogen atoms. Ammonia was also tested as both cyclic imine and secondary amine without the methylene group. Some compounds which are to be formed by reactions of these cyclic imines in the corrosion environment were used as inhibitors for investigating details of the inhibition mechanism.

Corrosion rates were determined on pure iron wire in 6.1M HCl solution with and without inhibitors at 30°C by polarization measurement, by volumetric measurement of evolved hydrogen, and by weight loss measurement. Approximate area of metal surface covered by each inhibitor molecule in the adsorbed position was determined with arranged molecular models. Basic strength was also measured to compare the adsorption activities of these inhibitors with each others.

Experimental

Corrosion inhibitors.—Trimethyleneimine (C_3 imine) was synthesized by hydrogenolysis of N,N-trimethylene-*p*-toluenesulfonamide(5) which was prepared by the reaction of *p*-toluenesulfonamide with 1,3-dibromopropane(6). Hydrochloride of 2-chloroethylamine and 3-chloropropylamine, triethylenetetramine, heptaethyleneoctamine, and tripropylenetetramine were also synthesized by the usual procedures. These products were repeatedly purified by distillation or by recrystallization. Absence of impurities was confirmed by infrared spectrometry and by gas chromatography.

Ethyleneimine (C_2 imine), pyrrolidine (C_4 imine), piperidine (C_5 imine), ammonium chloride, dimethylamine hydrochloride, diethylamine hydrochloride, and dipropylamine were obtained as high grade commercial reagents and also purified by distillation or by recrystallization before use.

These inhibitors were dissolved in constant boiling (107°C) 6.1M HCl solution which was prepared by diluting analytical reagent grade solution.

Corrosion rate measurements.—Corrosion rates of pure iron wire (99.89%,[2] Mallinckrodt analytical reagent grade, 0.36 mm diameter) were determined in 6.1M HCl solution with and without inhibitor at 30°C by the three kinds of measurements in the same manner as previously given in detail (2).

The galvanostatic polarization was made by supplying current with a coiled platinum wire, a 90V battery and a variable resistor. Potential of iron electrode in the solution deaerated with nitrogen gas was measured by using a saturated calomel electrode and an electrometer.

The hydrogen evolution measurement was carried out with a gas burette for 4 hr together with the weight loss determination.

Effectively covered area was determined by arranging framework molecular models on a plane in an assumed conformation of the inhibitor molecule adsorbed on the metal by the formation of a metal-nitrogen coordinate bond. Chair type conformation was applied to C_5 imine, and half-chair type to C_4 imine. To keep alkyl groups of secondary amine apart from the plane, the models were arranged in gauche conformation for C-N bonds and in a staggered one for C-C bonds. Details of this measurement have also been shown (2).

The *p*Ka value was determined by titration with $HClO_4$ in 50% diethyleneglycol-water solution at 30°C. The pH of the solution was followed with a glass electrode and a pH meter.

Infrared absorption spectrometric analysis of products by the reaction of C_2 or C_3 imine in 6.1M HCl solution was carried out. The solutions of these imines at 0.1M concentration were dried up at 30°C in a vacuum desiccator containing concentrated sulfuric acid and sodium hydroxide pellets separately. Residual white powder was analyzed on an infrared absorption spectrometer with KBr disk.

Results

Corrosion current, i_{corr}, was determined by intersection of extrapolated anodic and cathodic Tafel lines. The data were obtained in the several runs at each of the inhibitor concentrations. They were reproducible within less than ±4% except the values of C_3 imine with deviation of about ±30%.

Corrosion currents for the cyclic imines are shown in Fig. 1 as a function of the inhibitor concentration. For small-sized imines, i_{corr} increases with increase in the number of methylene groups. The polarization curves for these cyclic imines showed that they inhibit both cathodic and anodic reaction of pure iron in the

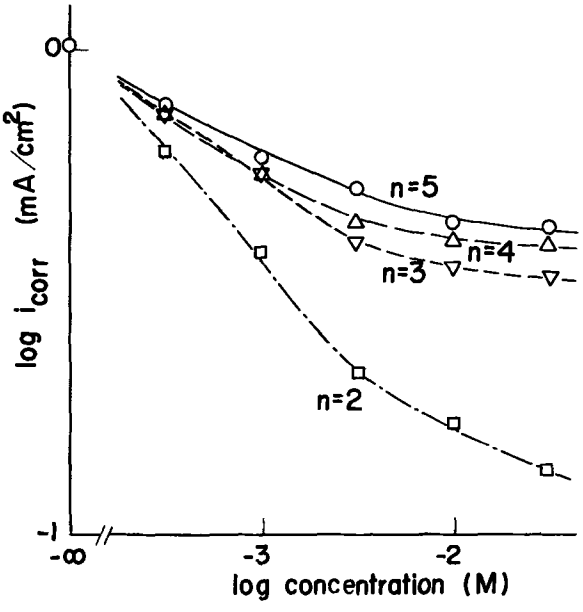

Fig. 1. Effect of cyclic imines on corrosion current; n = number of methylene groups.

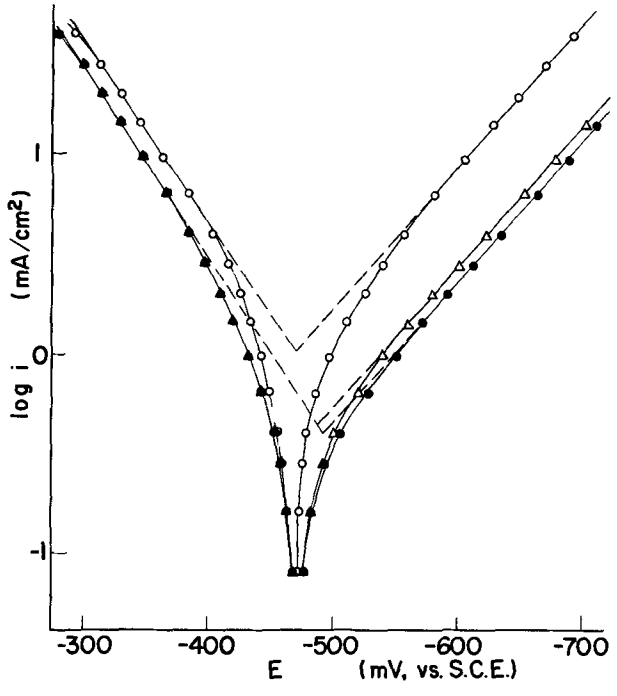

Fig. 2. Polarization curves of pure iron in 6.1M HCl without inhibitors (○), with C_4 imine (●), and with C_5 imine (△) at 0.01M.

acid solution and are more effective on the cathodic reaction than on the anodic one. Some typical curves with and without inhibitors are shown in Fig. 2. Corrosion potential was observed to shift toward less noble potential within 30 mV by the addition of these imines at the concentration given in the experiment.

Corrosion rates of iron wire in 6.1M HCl solution with and without inhibitors at 30°C were also measured by the hydrogen evolution and weight loss technique. Reproducibility of these rates was within ±4% with the exception for C_3 imine. The hydrogen evolution and weight loss data for these inhibitors are not shown here but correspond well to the corrosion rates calculated from the i_{corr} values, as for instance corrosion rates measured by polarization, by hydrogen evolution, and by weight loss are 26,200, 22,800, and 22,000 mdd without inhibitors, and 11,600, 10,700, and 9960 mdd with C_5 imine, respectively.

Corrosion currents for secondary amines are shown in Fig. 3 together with that for ammonia. The data indicate a decrease of i_{corr} with increase of the carbon number.

The i_{corr} values for 2-chloroethylamine, 3-chloropropylamine, triethylenetetramine, heptaethyleneoctamine, and tripropylenetetramine are collectively shown in Fig. 4. The data are plotted *vs.* the concentration of ethyleneimine unit, CH_2CH_2NH for triethylenetetramine and heptaethyleneoctamine, and of propyleneimine unit, $CH_2CH_2CH_2NH$ for tripropylenetetramine. Triethylenetetramine and heptaethyleneoctamine are good inhibitors, being better than 2-chloroethylamine. A high inhibition effectiveness of tripropylenetetramine is also shown in the figure.

The approximate area of metal surface effectively covered per an inhibitor molecule was measured by using molecular models. The ratio of the area of each inhibitor to the C_5 imine area is defined here as the relative molecular area and is shown in Table I. The larger area for C_4 imine than the value for C_5 imine was determined because the ring of C_5 imine in the adsorbed position is perpendicular to metal surface while that of C_4 imine seems to be kept almost parallel to the surface. The values of the relative molecular area for all the other cyclic imines and secondary amines show linear increases with the number of methylene groups.

The basic strengths of these imines and amines are also tabulated in Table I. These values correspond well

to those given previously (7). The pK_a value for the series of cyclic imines decreases with increase in the number of methylene groups with the exception for a notably lower value of C_2 imine. There are little differences in the values for the series of secondary amines.

The infrared absorption spectra of the products derived from C_2 and C_3 imine in the HCl solution are respectively shown in Fig. 5 and Fig. 6. Many frequencies of absorption bands in these spectra were observed to be inconsistent with those of C_2 and C_3 imine.

Discussion

For the series of cyclic imines, the order of inhibition effectiveness is $C_2 > C_3 > C_4 > C_5$, while $C_0 < C_2 < C_4 < C_6$ for the secondary amine series including ammonia as C_0. Because the strain in the small sized imine ring increases with decrease in the carbon number, the inhibition of cyclic imines seems to be related to the

Table I. pK_a value and relative molecular area of cyclic imines and secondary amines

Inhibitor	pKa	Relative molecular area
C_2 imine	8.00	0.74
C_3 imine	11.18	0.94
C_4 imine	11.15	1.06
C_5 imine	10.71	1.00
C_0 amine	9.14	0.37
C_2 amine	10.47	0.68
C_4 amine	10.51	1.01

strain in their rings. The inhibitor efficiency increases with the ring strain for the series of medium-sized cyclic imines. This relation of the ring strain or the C-N-C bond angle of medium-sized cyclic imines to the inhibition effectiveness has been concluded by discussing i_{corr} data *via* the relative molecular area, the basic strength value, and the molecular structure (2). To elucidate the relation between the inhibitor efficiency and the ring strain of small-sized cyclic imines, discussions in the same manner as reported for medium-sized ones were also tried in this paper.

Figure 7 shows log i_{corr} *vs.* relative molecular area plots for cyclic imines and for secondary amines at 0.01M of the inhibitor concentration. A linear relation is seen in this figure for secondary amines, decreasing log i_{corr} with the increase of relative molecular area. Ammonia is here assumed to be the smallest cyclic imine and to have no strain in the ring. All of secondary amines are also free from the ring strain as well as C_5 imine. A line which is drawn through the points of C_0 imine (ammonia) and C_5 imine is taken to be that for the series of small-sized cyclic imines without the strain in their rings because of the linear relation for secondary amines. Corrosion current deviations of each point for cyclic imines from this line were measured on the figure and plotted against the pK_a value in Fig. 8. The deviation, Δ log i_{corr}, means the decrease of log i_{corr} due to the ring strain. Because of a linear relation of Δ log i_{corr} to the basic strength for medium-sized cyclic imines, as shown in Fig. 8, it has been concluded that the ring strain plays an important role in the imine inhibition (2). As can be seen in the figure, however, this relation for small-

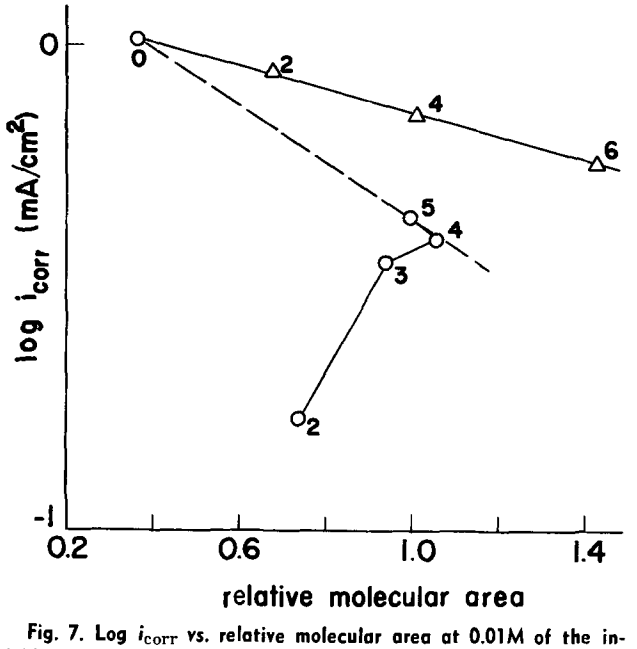

Fig. 7. Log i_{corr} vs. relative molecular area at 0.01M of the inhibitor concentration; cyclic imine ○, secondary amine △. Number indicates the carbon number.

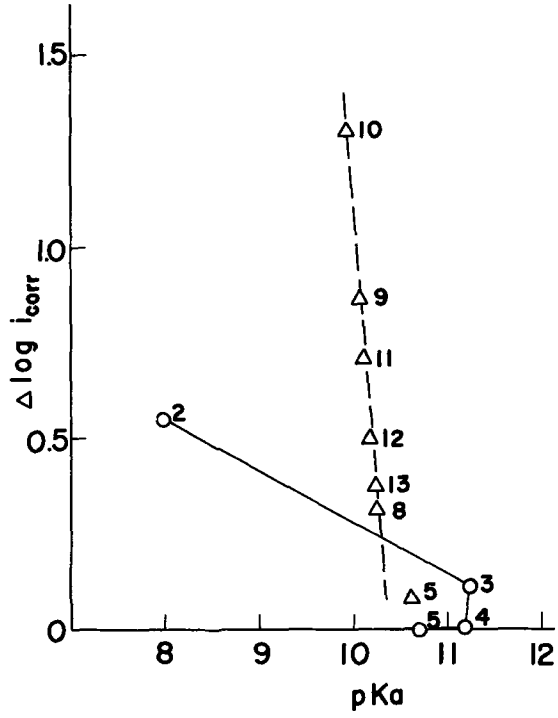

Fig. 8. Relation of pK_a to Δ log i_{corr} for the series of medium-sized cyclic imines △ and of small-sized cyclic imines ○. Number indicates the carbon number.

sized cyclic imines disagrees with that for medium-sized ones. This result suggests that effect of the ring strain or the C-N-C bond angle of small-sized imine on its corrosion inhibition is different from that of medium-sized one.

In consideration of rate constants and equilibrium constants for reactions of cyclic compounds, it is presumed that there is no possibility of unshared π-electrons on nitrogen atom of cyclic imines with less than five methylene groups except C_4 imine (8). In the small rings of C_2 and C_3 imine, bond angle strain is large and has a predominant effect. Since the C-N-C bond angles in C_2 and C_3 imine ring are of orders of 60° and 90°, sp^3 hybrid orbital geometry of nitrogen atom (C-N-C angle 109°28′) is favored over sp^2 geometry (C-N-C angle 120°), which provides unshared π-electrons on the nitrogen atom. Therefore, there can be no π-electron pair on the nitrogen atom in C_2 and C_3 imine ring.

In common rings of C_4 and C_5 imine, bond opposition strain caused by repulsion between hydrogen atoms seems to be of importance. The C_5 imine ring in which hydrogen atoms are of staggered conformation remains sp^3 hybridization of nitrogen atom. However, there seems to be the bond opposition strain in the ring of C_4 imine, because of eclipsed conformation of hydrogen atoms. To release this strain, the sp^3 geometry of nitrogen atom in C_4 imine may change to the sp^2 hybridization, since hydrogen atoms around the nitrogen atom are the stable staggered conformation in the latter hybridization. The effect of unshared π-electrons on the inhibitor performance might thus be observed only for C_4 imine.

According to the above discussion of the bond opposition strain in the imine ring, the sp^3 geometry of the nitrogen atom in pyrrolidinium cation is believed to be less stable than that in piperidinium cation. The presence of the sp^2 nitrogen geometry should, therefore, result in a weaker basic strength of C_4 imine than of C_5 imine. The pK_a value of C_4 imine, however, is larger as shown in Table I. A similar evidence has been indicated in dissociation constant data of C_4 and C_5 imine-trimethylborane complex (9). From these

facts the effect of sp^2 geometry on the C_4 imine inhibition is not taken to be predominant over that of the sp^3 geometry.

The anodic polarization current of iron electrode in HCl solution is not notably decreased by the addition of medium-sized cyclic imines, as has been shown for C_9 imine (1). This can be explained by means of chemical adsorption of these imines through formation of coordinate bond with their π-electrons to the anodic metal surface. If C_4 imine is adsorbed on iron surface via π-electron bonding as well as medium-sized imines, greater effect on anodic reaction than on cathodic reaction should be observed. The experimental results in Fig. 2 show that difference in i_{corr} values between C_4 and C_5 imine rather depends on that in cathodic polarization curves. This difference in cathodic polarization is probably caused by the enhanced basic strength of C_4 imine. Since the inhibition effect of C_4 imine on the anodic reaction is not significant, it is concluded that the π-electron bonding between metal and nitrogen atom of C_4 imine is not important to its inhibition effectiveness.

It cannot be explained in terms of the relative molecular area and pK_a values that C_2 and C_3 imine are better inhibitors than C_4 and C_5 imine. As mentioned above, the C_2 and C_3 imine rings are highly strained but have nothing to do with the π-electron bonding adsorption on metal. Ring-opening reactions of these imines due to the high ring strain are possible in the presence of proton (10). For example, C_3 imine may be decomposed in the presence of hydrochloric acid, forming 3-chloropropylamine

$$\overbrace{(CH_2)_3\,NH}^{\text{C}_3\text{ imine}} + HCl \rightarrow ClCH_2CH_2CH_2NH_2$$

or polypropylenepolyamine

$$m\ \overbrace{(CH_2)_3\,NH}^{\text{C}_3\text{ imine}} \rightarrow (CH_2CH_2CH_2NH)_m$$

The infrared absorption spectrum of the product by the reaction of C_3 imine in 6.1M HCl solution suggested the ring-opening reaction, because C-H bending band of C_3 imine at 1340 cm^{-1} disappeared in the spectrum. As C-Cl stretching band was observed at about 780 cm^{-1}, the formation of 3-chloropropylamine is presumable. Agreement of absorption bands for C_3 imine product with those for hydrochloride of polypropylenepolyamine such as tripropylenetetramine was also found in this spectrum. It can be concluded from these data that C_3 imine is reacted with hydrochloric acid, resulting in forming mixtures of 3-chloropropylamine and polypropylenepolyamine. Although the presence of corroding iron in the acid solution is not taken into account in this experiment, these ring-opened products of C_3 imine are believed to act as inhibitors of iron corrosion.

On the basis of this result, the corrosion inhibition effects of some compounds which are possibly derived from C_3 imine were determined. The i_{corr} value of tripropylenetetramine, one of polypropylenepolyamine is lower than of C_3 imine, while that of 3-chloropropylamine is higher as shown in Fig. 1 and Fig. 4. These data indicate that the inhibition effect of chlorinated amine is not important to the inhibitor performance of C_3 imine. Again, C_3 imine is not adsorbed on iron surface *via* π-electron bonding. In fact, this imine rather decreases the cathodic polarization current, the result being analogous to that of tripropylenetetramine. The inhibition efficiency of C_3 imine is thus concluded to depend on the action of polymer molecules. The large deviation of i_{corr} values for C_3 imine may be related to the selective formation of polymerized or chlorinated product by the reaction of C_3 imine in the HCl solution. The formation of polymer inhibitor gives rise to a good inhibition effectiveness, whereas that of chlorinated amine decreases the effect. No adsorption mechanism of polymer inhibitor together with chlorinated one on iron surface was further amplified.

The C_2 imine ring is also easily opened in the HCl solution, because of the high strain in the ring, resulting in the formation of chloroethylamine or polyethylenepolyamine. For this imine, however, the polymerization reaction may be predominant over the addition reaction of hydrochloride. The infrared spectrum of the product prepared by the reaction of C_2 imine in the HCl solution, shown in Fig. 5, is rather similar to that of polyethylenepolyamine hydrochloride, and no strong absorption band of C-Cl stretching frequency appears at 650-800 cm^{-1} region.

The inhibition efficiency of 2-chloroethylamine is too low to keep the sufficient inhibitor performance of C_2 imine. The polymer molecules are effective inhibitors for iron corrosion in the HCl solution. It is reasonable, therefore, that the high inhibition effectiveness of C_2 imine is caused by the inhibitor action of the polymer molecules formed by the reaction of C_2 imine in the solution.

Many molecular structures of the reaction products can be supposed in such the polymerization of C_2 imine. Two straight-chained polymers were chosen as typical ones in this study. Ring-closing polymerization is possible to result in forming rings containing more than 6 members, as

$$m\ \overbrace{(CH_2)_2\,NH}^{\text{C}_2\text{ imine}} \rightarrow \overbrace{(CH_2CH_2NH)}^{\text{polyethylenepolyamine}}_m$$

The formation of medium sized ring by means of the polymerization of C_2 imine cannot be expected, because large strain in this ring may interfere with the ring-closing reaction. Six-membered polymer is not such a good inhibitor as C_2 imine because i_{corr} obtained in an additional experiment for piperazine (six-membered polymer) at 0.01M is 0.412 mA/cm^2.

Conclusion

From these discussions, it is concluded that the inhibition effectiveness of C_2 and C_3 imine for the iron corrosion in the HCl solution depend on the formation of polymer molecules by the ring-opening reactions due to the high strain in their rings. These polymers probably including straight-chain and large ring compounds act as good corrosion inhibitors. This high effectiveness may arise from a markedly enhanced stability of net total adsorption bonding in the polymer molecules, as interpreted by Annand, Hurd, and Hackerman (11).

C_4 and C_5 imine with little strain in their rings are less effective on the inhibition of iron corrosion. These common-sized cyclic imines seem to be mainly adsorbed on cathodic area of metal surface because of the high stability of their ammonium cations. There seems to be no strong adsorption of these imines on metal by virtue of the π-electron bonding. Further studies on the common-sized cyclic imines including precise discussion of polarization curves, nitrogen conformation, and steric hindrance will be needed for elucidating the inhibitor mechanism.

Acknowledgments

The author wishes to express an appreciation to Dr. N. Hackerman of Rice University for his advice on the discussion of this paper.

An Ellipsometric Study of Chromium Passivation

M. A. Genshaw*,[1] and R. S. Sirohi[2]

The Electrochemistry Laboratory, The University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

In situ ellipsometry has been combined with electrochemical measurements to gain insight into the mechanism of passivation of chromium in pH 1.7 K_2SO_4 solution. At −410 mV *vs.* NHE a region of active dissolution at an apparently oxide-free surface was observed. With an anodic potential step to −360 mV, passivation occurs with growth of less than 1Å of oxide film. This film is thicker at more anodic potentials and probably consists of Cr_2O_3. The mechanism of passivation most consistent with the experimental observations is that of simultaneous oxide formation and metal dissolution, with passivation resulting from formation of a monolayer of film.

Chromium exhibits a very low dissolution current when passive and transmits this property to its alloys. Accordingly, numerous investigations into the cause of passivation of chromium have been undertaken. An excellent survey of this work is given by Gmelin (1) where the differing views are well summarized. A number of recent studies concerned with passivation of chromium as well as chromium alloys have been reported (2-20).

In this work, ellipsometry has been applied in conjunction with electrochemical measurements to give further insight into the nature and thickness of the film formed during the passivation process. In a very early application of ellipsometry, Micheli (21) could not detect any difference between active and passive chromium surfaces and concluded that no film was present. More recently, Andreeva (15) using *in situ* ellipsometry has observed increased thicknesses of the film at chromium with application of either cathodic or anodic polarization.

Experimental

Ellipsometer.—An L119 Gaertner ellipsometer with a horizontal plane of incidence was used in this study. The angle of incidence was 71.7° (65.2° outside the cell). The quarter wave plate was kept fixed at 45° orientation and was positioned between polarizer and electrochemical cell. A 2W tungsten arc lamp (Sylvania TC 2) operated from a well-filtered 90 mA d-c power supply was used as a source of light. The collimation was effected by a projection lens, the deviation from true collimation is expected to be less than 0.003 radian. A 3 mm aperture at the test surface was used. A photo transistor (Motorola MRD 300) with a current to voltage transducer was used as a light detector. The voltage output could either be read on a Keithley electrometer or be fed directly to a recorder. The highly stable (0.1% fluctuation) tungsten lamp along with the phototransistor makes an ideal combination for the study of transients. However, the phototransistor suffers from a disadvantage as its dark current is strongly affected by the variation in the temperature of the surrounding, and thus should not be used for long transients if the temperature is not controlled. An interference filter (50Å band width around 5500Å) was used just before the detector. The ellipsometer rested on a 1 in. thick aluminum plate which was supported by a shock absorber, to minimize the effects of outside vibration.

Cell.—The air-tight cell was made of Teflon. For the passage of light, ⅛ in. thick windows of synthetic quartz ($n = 1.460$ at $\lambda = 5500$Å) were held tightly against Viton o-rings, facing each other and perpendicular to the reflecting surface. Thus, the path of light through the windows was oblique. Connections to the cell were made through Beckman fittings. Solution could be transported to the cell from a reservoir of circulating, pre-electrolyzed nitrogen-saturated solution under nitrogen atmosphere. Electrolyte could be drained and the cell washed with conductivity water or electrolyte without distributing the optical alignment.

Electrodes.—A zone-refined polycrystalline chromium loaf (purchased from Material Research Corporation) was machined to a rod of cross-section 1.63 cm^2. One end of it was ground and polished flat with different grades of emery and γ-alumina. At the other end, a stainless steel screw was used to make connection with the external circuit. The rod was fitted in a tapered threaded Teflon piece with a Viton o-ring seal. This rod could be screwed into the cell so that the reflecting face was in the vertical plane.

A smooth platinum foil electrode sealed in a glass tube and separated from the solution by a fine frit was used as a counterelectrode. A saturated calomel electrode was used as a reference electrode, and all potentials are reported with respect to normal hydrogen electrode. The calomel electrode was positioned several millimeters diagonally above the test electrode. The experimentally determined *IR* drop at the highest current used was less than 10 mV.

Electrolyte.—All the solutions were made from conductivity water. The pH 1.7 H_2SO_4 + 0.5M K_2SO_4 solution was pre-electrolyzed at 1.35V between platinized platinum gauze in an atmosphere of nitrogen for at least 24 hr before using it.

Method of measurement.—Optical measurements were made by the method of equal intensity settings as described by Archer (22) The Δ and ψ values are

* Electrochemical Society Active Member.

corrected for the oblique traversal of rays through the quartz windows (23). Details of the ellipsometric technique and method of interpretation are given in the literature (22, 24-28). Transient measurements were made by measurements of intensity using an improved version (29) of the technique described earlier (28, 30) either applying potential steps or switching from a constant potential to constant current. Measurements were also made using linear potential sweep (31). Also measurements were made by potentiostating the electrode at various potentials and measuring Δ and ψ values. The current is also measured simultaneously by a Keithley electrometer.

In steady-state measurements Δ is measurable to 0.02° and ψ to 0.01°. In the transient measurements the changes in Δ and ψ are measurable to better than ±0.05°. The reproducibility of the reference values of Δ and ψ are within a range of 5° in Δ and 7° in ψ observed which are probably due to variations in surface roughness and orientation.

Results and Discussion

Current-potential relation.—Measurements are conducted potentiostatically with a freshly polished surface, which is initially passive as no dissolution occurs if it is potentiostated at −400 mV, by varying the potential in steps toward anodic values beginning at −760 mV. The variation of current with potential is shown in Fig. 1. As the potential is made more anodic, the rate of hydrogen evolution decreases and a region of active dissolution commences at −500 mV. The anodic current decreases sharply at ~ −385 mV, and a cathodic region is then observed. Over the range −160 to +840 mV the current density is less than 1 μA/cm^2.

The cathodic region between −360 and −60 mV is probably due to hydrogen evolution at the passive surface, as has been suggested by other workers (2, 9).

The bare surface parameters.—Since the hydrogen evolution in the experiment described above produced bubbles which prevented ellipsometric measurements, a special procedure was adapted to produce an active, bubble-free surface. The electrode was potentiostated for about 1 sec at −760 mV (19) and then held at −410 mV. Ellipsometric intensity measurements showed an increase in Δ while the electrode was at −760 mV, but no steady value is obtained before bubbles appear (after several seconds). At −410 mV after the brief reduction the dissolution current increased slowly to a constant value while ellipsometrically a large decrease in Δ occurred followed by an increase with a final value which is 3 to 4 degrees higher than that of the freshly polished electrode. During the same treatment ψ decreases 0.1 to 0.2 degrees.

An increase in Δ is characteristic either of the formation of a film with a refractive index less than that of the medium (solution) or the removal of a film of refractive index higher than that of the medium. Since the formation of a thin stable film of low refractive index, *e.g.* a gas, is unlikely, the increase in Δ was attributed to the removal of the passive film by reduction at −760 mV (19) and dissolution at −410 mV. The surface remained bright during the active dissolution. It should be noted that the increase in Δ (equivalent to 9-12Å as calculated for Cr_2O_3 with $n = 2.55$) corresponds well to the dissolution of the 10-15Å film reported to form on chromium in air (15, 32) and that the experimental value of Δ is higher, indicative of a cleaner surface, than that calculated for our conditions from data reported by other workers (Table I).

A calculation of the effect of the concentration gradient of Cr^{+++} in the solution shows that the change in refractive index near the surface would be about 0.0002 units, which should be insignificant (a gradient of 0.2°C would produce an equal change). In addition, stirring, which would affect the concentration gradient, has no effect on the measured Δ.

The surface state attained at −410 mV was used as an optical and electrochemical reference state for the transient measurements and all optical calculations are based on the assumption that no film is present at −410 mV. It is not possible to prove that the surface is indeed bare at this potential although the relatively free dissolution makes the presence of a film approaching a monolayer coverage unlikely.

The film present.—The transient (potential step, galvanostatic, and potential sweep) measurements give similar linear Δ-ψ plots which have an average slope $d\psi/d\Delta$ of −0.100 ± 0.002. Using the exact ellipsometry calculations for transparent film (*e.g.* imaginary part of refractive index is zero), a value of 2.54 ± 0.04 is obtained for the refractive index. This value is very close to 2.55 reported for Cr_2O_3 (36). Thus, it appears probable that the film is Cr_2O_3, as has been suggested by other workers (8, 9, 15, 37-39). From calculations using the exact ellipsometry equations for nontransparent films, the film must have the real part of its refractive index equal to or lower than 2.54. For refractive indices lower than 2.54 to fit the experimental data, the films must be light-absorbing.

As an approach toward limiting the number of fits to the optical data for nontransparent films, coulometric data is considered (Fig. 2). This data was taken from the anodic transients in the potential region in which, in the steady state, the metal is passive and, in the transients at constant current, a linear change in delta with time was observed. No correction for possible dissolution has been made with the presumption that the species produced does not dissolve at a significant rate. From these measurements, a change of 1.44 degrees in delta was found to correspond to a charge passed of one millicoulomb. By assuming a roughness factor (R) and a bulk density (assumed to be that of the bulk material with no correction for surface effects) one can calculate a relation between thickness and delta and from this, using the ellipsom-

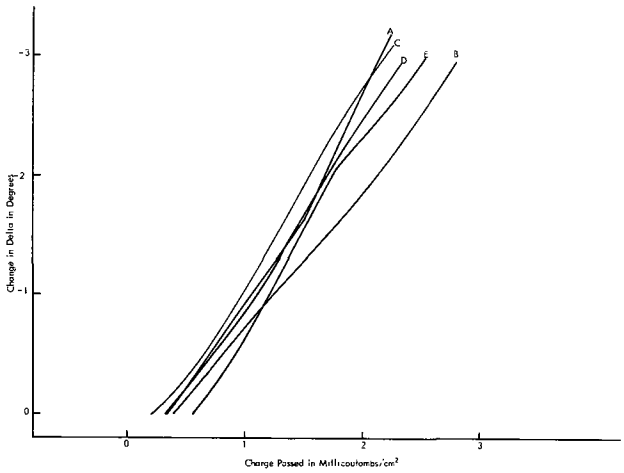

Fig. 2. The change of Δ from tre initial value (δΔ) as a function of change in galvanostatic oxidation transients. Curve A:2; B:4; C:6; D:8; and E:10 mA/cm².

etry equations, the film optical constants. As the roughness factor is an adjustable parameter, fits can be obtained for almost any desired value of the real part of the refractive index (n).

With roughness factor R, $R = 1.7$, and the bulk density of 5.21 g/cc [Ref. (36)] for Cr_2O_3, a refractive index of ~4.2 is required to fit the coulometric thickness and optical thickness (Δ). However, the $d\psi/d\Delta$ slope for this value of n is more positive than −0.01 which is incompatible with the observed −0.10. Thus, a fit is not possible.

A calculation for CrOOH using $R = 1.7$, $d = 4.11$ g/cc [Ref. (40)] requires n to be 2.90 which is again incompatible with the optical measurements [$n = 2.0 \pm 0.1$, Ref. (35)].

A fit for either Cr_2O_3 or CrOOH may be produced by varying the roughness factor taken. For Cr_2O_3 a fit at $n = 2.55$ exists if a roughness factor of 1.1 is taken; for CrOOH fits exist at $n = 2.55$ with $R = 1.5$, and at $n = 2.0 - 0.005\ i$ with $R = 1.15$. Thus, it is apparent that coulometry does not lead to a unique identification of the passive film. However, it is not possible to obtain fits for $Cr(OH)_3$ [$n = 1.620$, Ref. (40)] [$d = 3.12$ g/cc, Ref. (40)] and CrO_2 [$d = 4.88$ g/cc, Ref. (40)] with any value of roughness factor greater than 1.0, so that they cannot be the passive film, a conclusion which is supported by the high solubility of $Cr(OH)_3$, [Ref. (40)] and the reversible potential for formation of CrO_2 being very anodic to the potential of passivation (9, 41).

We conclude that the passive film at chromium is most probably Cr_2O_3, as supported by numerous other workers on passivity and a consistency with the ellipsometric measurements.

The film thickness required for passivation.—To determine the minimum film thickness required for passivation, potential step measurements, starting from −410 mV, were undertaken. The initial current at −410 mV was 1.0×10^{-3} A/cm². With a step to −385 mV the current initially increased, then during a period of 2 min decreased to 2×10^{-4} A/cm². The change in Δ at 2 min was 0.1°. At longer times the current remained constant while the film thickness increased substantially. Similarly, with a step from −410 to −360 mV, the current after 2 min reached a cathodic value of 4×10^{-5} A/cm² with a change in Δ of 0.25°. The onset of the cathodic current requires the virtual cessation of the anodic reaction and that passivation has occurred. The film thickness change (for $n = 2.54$) for a 0.25° change in Δ is 0.8Å. (For n of 2.0 the thickness would be 0.7Å, for $n = 3.0$ 1.0Å). In terms of charge this is equivalent to 170 microcoulomb/cm² (using $R = 1$). Thus, it is apparent that a film of the order of a monolayer is sufficient to cause passivation of chromium.

A very similar result has been obtained by Frankenthal (20) using Fe-24% Cr in 2N H_2SO_4. He reports a film thickness of 360 microcoulomb/cm² determined by coulometry at the potential of maximum cathodic current.

The role of dissolution in passivation.—A mechanism which has been proposed for film formation at several metals is the dissolution-precipitation mechanism (27, 42). This mechanism suggests that dissolution proceeds freely until a saturation concentration of ions is reached at the surface whereupon film formation proceeds. Since the film formed has been shown to probably contain Cr^{+++}, the saturation concentration of Cr^{3+} may readily be calculated from the solubility product data (41, 43) and is 0.3-0.9 moles/liter for the least soluble form of Cr_2O_3. A plot of $i\tau^{1/2}$ *vs.* i, where τ is the time of initial film formation as determined from the time at which the first measurable change in Δ occurred is linear as predicted from theory (44) (Fig. 3). It should be noted that the starting condition with chromium actively dissolving is not that required for the theoretical derivations (no dissolution before the current is applied). Applying the theory and using the slope and intercept of the $i\tau^{1/2}$ *vs.* i plot to calculate the saturation solubility of the precipitating species, a value of $\sim 7 \times 10^{-4}$ moles/liter is obtained. This is substantially lower than the saturation solubility of Cr^{3+} with respect to Cr_2O_3 (41). The presence of the initial concentration gradient of 0.01 M/liter would, as a first approximation, make the precipitation due to a change in concentration of 7×10^{-4} M/liter or about 10%. It seems unlikely that such a small change would be sufficiently reproducible to permit measurements or the attainment of a stable measurement of active dissolution. Thus, we conclude that a dissolution precipitation mechanism is not followed in chromium passivation.

The experimental data is also consistent with a constant value of $i\tau$ of 340 ± 80 microcoulomb/cm² for the amount of chromium dissolved during galvanostatic passivation transients over a current range 1-25 mA/cm² as obtained from the extrapolation of the linear Δ-time region of the transient to Δ equals zero (Fig. 2). This extrapolation presumes that the charge not utilized in film formation corresponds to chromium dissolved in the solution.

A second mechanism of film formation which has been proposed (45-47) is the occurrence of dissolution and film formation in parallel paths. In this type mechanism, the dissolution takes place at the surface not covered by the film. Although numerical relations between dissolution currents and film coverage have

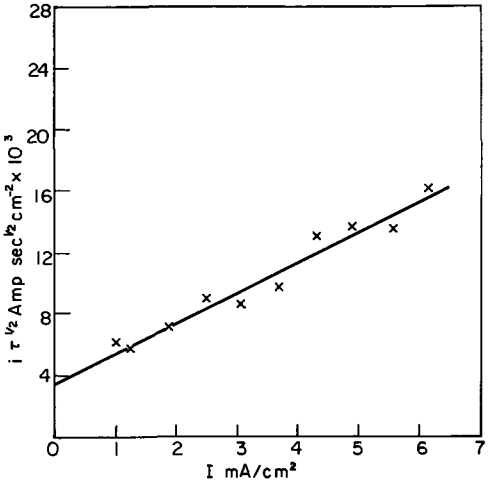

Fig. 3. Plot of $i\tau^{1/2}$ *vs.* i for initial film formation during galvanostatic passivation of chromium.

been proposed for the case of potentiostatic measurements (46), in the case of chromium a quantitative correlation is difficult because the fairly rapid dissolution process can lead to undercutting of the film and consequent exposure of fresh surface.

Qualitatively, this mechanism would predict that a significant amount of dissolution would occur during the passivation. For the case of equal rates of dissolution and oxide formation, somewhat less than a monolayer of chromium would dissolve during the formation of a monolayer of oxide. Since the rate of dissolution is experimentally much faster than the rate of oxide formation, even though less than a monolayer of oxide is sufficient for passivation, it is not unreasonable that the amount of dissolution experimentally observed (340 microcoulomb/cm^2) could take place.

The mechanism suggested by Frankenthal (20) for the passivation of iron-chromium alloys by the blockage of kink sites does not seem plausible as passivation should occur at coverages of the order of 0.01% when all kink sites are blocked. As passivation is observed at about 30% coverage, this mechanism does not seem likely.

Other mechanisms involving film transformation apparently do not occur as no evidence for the formation of more than one film was found.

Thus, we conclude that the most probable mechanism for chromium passivation is that of oxide formation and metal dissolution reactions occurring simultaneously, with passivation resulting when a monolayer (or possibly less) of oxide covers the surface.

The mechanism of film growth.—As apparent from the kinetic plots (Fig. 4 and 5), the kinetics of film growth do not obey either the direct or the inverse logarithmic law at all potentials. Similarly, any power ($t^{1/2}$, *etc.*) law is also not obeyed. This is not surprising when one considers that the film thickness varies from zero to a few layers and most mechanisms proposed apply to continuous films of sufficient thickness so that the interfaces and bulk processes may be differentiated.

When insufficient film is present to cause passivation ($-410 < V < -360$), the film growth continues

for a relatively long time (at least 15 min) and a thick film is formed which from Fig. 6 may be estimated to be ~100-120Å. Since simultaneous dissolution is occurring, the film present must not be a protective passive film. It would appear likely that it must be a porous film or incomplete monolayer which permits active dissolution of the metal below. At more anodic potentials, passivation occurs with the thick film remaining.

The thicker films present at more anodic potentials show growth kinetics which occur over decades of time but fit neither the direct nor inverse logarithmic laws.

The Difference between Potential Step, Linear Potential Sweep, Galvanostatic and Potential Staircase Results

A comparison between galvanostatic, potential step, and potential sweep measurements of Δ *vs.* potential is made in Fig. 7 and 8. It is apparent that the results are quite similar in trend when the sweep rate, current, or time are chosen to give approximately equivalent conditions.

With slow potential sweep measurements, Fig. 9, the changes in Δ become substantially greater with the major change occurring in the region −400 to −200 mV and nearly parallel curves at more anodic potentials.

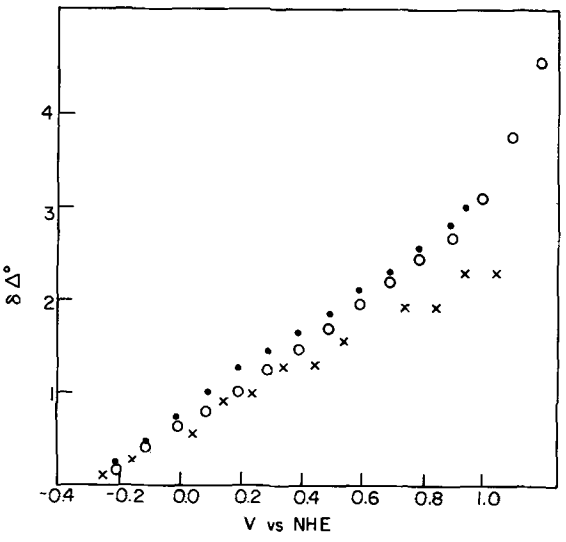

Fig. 7. Dependence of $\delta\Delta$ on potential. ● potential sweep at 2 V/sec, ○ galvanostatic at 2.5 mA/cm^2, X potential step at 0.1 sec.

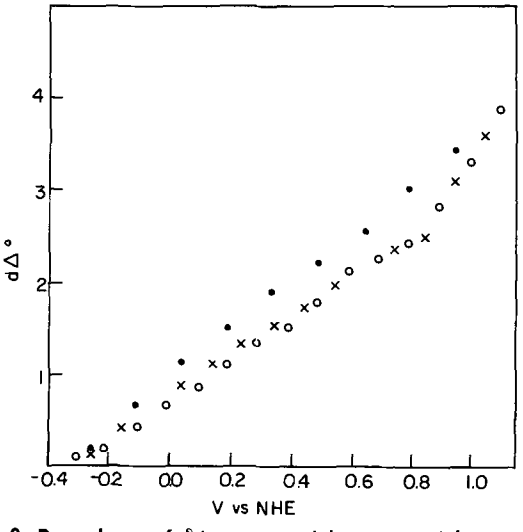

Fig. 8. Dependence of $\delta\Delta$ on potential. ● potential sweep 0.75 V/sec, ○ galvanostatic at 1 mA/cm^2, X potential step at 0.3 sec.

In the potential staircase measurements which are equivalent to a very slow potential sweep, this trend is even more pronounced, Fig. 6, with nearly all the change in Δ occurring in the potential region -410 to -380 mV. The changes in Δ in the potential staircase measurements are quite reproducible. The changes in ψ, Fig. 10, are much less reproducible in magnitude although similar in trend. Such a large variation in ψ would indicate that the film forms vary in their optical properties. Indeed, these films are distinctly different from those formed in the transient measurements in that they are visually apparent as a white appearance of the electrode. As the films should not be visually resolvable since the change in Δ indicates that they are 100-120Å thick, they must manifest themselves through scattering of light. This can occur if the simultaneous dissolution and film formation processes lead to the formation of inclusions of metal in the film as has been suggested for nickel (48). Such heterogenous films have been treated theoretically by Maxwell Garnett (49) and the calculations lead to values of optical constants which are not incompatible with those required to fit the experimental values of Δ and ψ.

Electrodeposition of Chromium and Nickel-Chromium from Amide Solvents

D. J. Levy* and W. R. Momyer*

Lockheed Palo Alto Research Laboratory, Lockheed Missiles & Space Company, Palo Alto, California 94304

ABSTRACT

Chromium was deposited from hexaamminechromium(III) formate in 30 mole per cent acetamide/formamide at cathode current efficiencies up to 50%. The current density range for optimum plating efficiency varied from 25 to 150 mA/cm^2 depending on the chromic ion concentration in the bath. Aquation of this chromic complex during electrolysis takes place at an appreciable rate when the water content exceeds 400 ppm and results in decreased plating efficiency. There was no correlation between the effectiveness of bridging groups for electron transfer between chromous and chromic ion and the electrodeposition of chromium in the amide solvent system. The observed effectiveness of ligands for promoting chromium deposition was: $SCN^- > NH_3 > Cl^-$ and $N_3^- > H_2O$. Sulfamic acid, boric acid, and sodium thiocyanate were effective in increasing plating efficiency at low concentrations; it was also observed that thiocyanate lowered the chromium deposition potential. Chromium-nickel alloys were produced over the entire concentration range of 0-100% chromium by the addition of hexaamminenickel(II) formate to the bath. Alloy composition was influenced more by electrolyte composition and bath temperature than by current density.

Chromic acid baths catalyzed with sulfate ion are generally utilized for electrodepositing chromium. However, these baths deposit chromium only at low plating efficiency, are unsuitable for alloy deposition, and possess many well-known undesirable operating characteristics. In addition, a more stable solvent system than water is desirable in the bath in order to increase chromium plating efficiency.

Deposition of chromium from aqueous trivalent solutions was known as early as 1853. Much of the earlier

* Electrochemical Society Active Member.

Key words: chromium electrodeposition, nonaqueous solvents, amides, nickel-chromium alloys.

work (1) and some later studies with chromic sulfate solutions (2-4) have been reviewed. Chromium deposition has also been reported from chromic chloride dissolved in formamide (5), acetone (6, 7), and a mixed dimethylformamide-water electrolyte (8). It has often been difficult to confirm results reported in the literature because insufficient details were given for preparing the specific chromic complex used.

The present authors recently reported (9) that chromium can be electrodeposited from ammonium reineckate, a $NH_4[Cr(NH_3)_2(SCN)_4]\cdot H_2O$, or thiocyanatopentamminechromium(III) thiocyanate to yield satisfactory chromium deposits at current efficiencies from 25 to 65%. However, the baths are unstable during prolonged electrolysis. The purpose of this investigation was to study the role of water and sulfur-containing ligands in the deposition reaction, to determine the effect on chromium deposition of bridging ligands known to facilitate electron transfer between chromic and chromous ions, to seek a suitable organic solvent with greater electrochemical stability than formamide, and to investigate the feasibility of electrodepositing chromium alloys.

Experimental

Apparatus and procedures.—The apparatus and procedures described previously (9) were used in the present investigation. Plating efficiency (cathode current efficiency) was again obtained from weight determinations and expressed as per cent of theoretical calculated on a trivalent basis. Experiments were performed with 60 ml of 0.2M hexaamminechromium(III) formate in an open electrolysis cell at 23°C and 25 mA/cm^2 unless stated otherwise. Plating experiments at low water levels were performed in a dry box and the water content of the bath monitored by titrating aliquots from the bath with Karl Fischer reagent (10). Alloy plating studies were performed in a sealed, two-compartment electrolysis cell using 100 ml of electrolyte. The electrolyte was transferred from the plating compartment to a storage compartment by means of vacuum and dry nitrogen before the cathodes were removed for weight determinations. This restricted water absorption from the ambient air and improved alloy bath stability. The composition of the alloy films was determined by electron microprobe analysis and, therefore, the per cent chromium and nickel reported are surface values rather than the average content of the bulk film.

Materials—All of the solvents used in the plating baths were either reagent grade or the highest purity available commercially. The solvents were predried for several of the experiments by passing them through a glass column packed with activated molecular sieves. The water content of the standard 30 m/o (mole per cent) acetamide/formamide solvent was easily reduced to less than 100 ppm by this technique.

Hexaamminechromium(III) and hexaammine nickel (II) complexes were prepared by the methods presented in ref. (11). The anhydrous chromic chloride for preparing the chromic complex was purchased from Research Inorganic Chemical Company (Sun Valley, California). Hexaamminechromium(III) chloride was converted to the formate salt by first adding the stoichiometric amount of freshly prepared silver carbonate to an aqueous solution of the complex. An excess of formic acid was added to destroy the carbonate and the mixture was filtered through a medium glass frit to remove the silver chloride precipitate. The filtrate was then added to a large volume of acetone to precipitate the desired complex. This complex was purified by redissolving the material in methyl alcohol, reprecipitating with acetone, and washing with ethyl alcohol and then acetone. The anhydrous hexaamminechromium(III) formate complex was obtained by equilibrating the complex with phosphorous pentoxide in a sealed glass container for several weeks. Chloropentaamminechromium(III) chloride was obtained as a byproduct from the hexaamminechromium(III) synthesis. This compound was used as the starting material for preparation of thiocyanatopentaamminechromium(III) and azidopentaamminechromium(III) complexes by the procedures outlined in Gmelin (12).

Discussion of Plating Studies

Chromium plating from acidopentaamminechromium (III) complexes.—Plating studies with ammonium reineckate and thiocyanatopentaamminechromium(III) thiocyanate indicate that thiocyanate catalyzes reduction of chromic ion in amide solvents (9), but the role of thiocyanate in the plating mechanism was not established. Skala (13) found that the purpeo complex, $[Cr(NH_3)_5Cl]\ Cl_2$, is suitable for electrodeposition of chromium in aqueous media while the luteo complex, $[Cr(NH_3)_6]\ Cl_3$, is not. The data suggest that the more efficient electroreduction of chromic ion to the metal in the presence of thiocyanate may be due to this ligand functioning as a bridging group for electron transfer.

The effectiveness of various bridging groups to facilitate electron transfer between chromous and chromic ions (14) is

$$Br^- \simeq N_3^- > Cl^- > OH^- > F^- > NCS^- > H_2O$$

The effectiveness of halides as bridging groups for electron transfer between chromous ion and pentaamminechromium(III) ion has also been established (15) and is in the order

$$I^- >> Br^- > Cl^- >> F^-$$

Several acidopentaamminechromium(III) complexes were compared to the hexaamminechromium(III) complex in order to determine the influence of the electron bridging group on chromium plating efficiency in the organic solvent system. The hexamminechromium (III) complex provides a good comparison because the coordinated ammonia is a relatively poor bridging group for electron transfer.

The halide salts of the pentaamminechromium(III) and hexaamminechromium(III) complexes are only slightly soluble in 30 m/o acetamide/formamide and it is necessary to convert these complexes to other salts for plating studies. The anion markedly influences the solubility of metallic salts in organic solvents and those salts which are highly solvated and most difficult to prepare in the anhydrous state exhibit the highest solubilities (16). Nitrate and thiocyanate salts are normally quite soluble in organic solvents but nitrate is more easily electroreduced than chromic ion and thiocyanate is of marginal electrochemical stability (17). Perchlorates also yield high solubilities and are desirable because they will not interact with the ammine chromic complexes (18). However, the oxidizing ability of this anion can create a safety hazard, particularly with nitrogen-coordinated complexes (12). Formamide is similar in solvent properties to water (16) and carboxylate salts offer the best possibility for improved solubility without interfering side effects. Acetate and formate yield the required degree of solubility for electroplating studies, but formate is the preferred salt because better quality deposits are obtained at slightly higher plating efficiencies.

The results of the bridging group experiments are presented in Table I. It is apparent that there is no direct correlation between chromium plating efficiency

Table I. Effect of bridging group on chromium plating efficiency

Chromic complex	Bridging group	Initial plating efficiency, %
$[Cr(NH_3)_5\ SCN](SCN)_2$	SCN-	62
$[Cr(NH_3)_5\ SCN](HCO_2)_2$	SCN-	56
$[Cr(NH_3)_6](HCO_2)_3$	NH_3	35
$[Cr(NH_3)_5Cl](C_2H_3O_2)_2$	Cl-	11
$[Cr(NH_3)_5\ N_3](HCO_2)_2$	N_3-	14
$[Cr(NH_3)_5\ N_3](C_2H_3O_2)_2$	N_3-	10

and the effectiveness of the bridging group for electron transfer between chromous and chromic ions. The thermodynamic stability of the chromic complex appears to be a more important consideration in electroplating chromium than kinetic effects introduced by the bridging groups.

The thiocyanatopentaamminechromium(III) complex yields the highest chromium plating efficiency of the four complexes. The formate salt produces better quality deposits than the thiocyanate salt although at slightly lower efficiency. The chloropentaamminechromium(III) complex is too unstable for plating studies. Rapid release of the coordinated chloride during electrolysis produces an insoluble pentaamminechromium(III) chloride. The azidopentaamminechromium(III) complex deposits chromium at the lowest efficiency in spite of the fact that azide is the best electron bridging group. The formate salt of this complex produces better quality deposits at slightly higher efficiency than the acetate salt. The hexaamminechromium(III) complex deposits the best quality chromium films at reasonable (30-35%) plating efficiencies.

Chromium plating from hexaamminechromium(III) formate.—Hexaamminechromium(III) formate (HAF chromium) possesses the following desirable properties as a potential source of chromium in the amide plating bath:

1. Excellent solubility in the organic solvent.
2. The complex is stable to oxygen and moderately stable to water (12).
3. Low thermodynamic stability of the complex permits efficient metal deposition at reasonable potentials.
4. Reaction kinetics for metal deposition appear favorable.
5. Chromous catalyzed decomposition of the complex is low because ammonia is a poor electron bridging group.
6. The ammonia ligand is volatile under the plating conditions which eliminates accumulation of ammonium salts in the electrolyte.
7. The formate anion can be electrolytically oxidized to volatile products which reduce salt accumulation and provide a more desirable anode reaction than solvent oxidation.

The optimum plating parameters and bath composition were established for the HAF chromium bath in order to evaluate more fully the stability and properties of this complex during electrolysis.

The effect of HAF chromium concentration on plating efficiency is illustrated in Fig. 1. A linear dependence is observed up to a concentration of 0.25M (molar) and doubling the concentration in this range roughly doubles the plating efficiency. Chromium plating efficiency does not increase substantially at concentrations above 0.4M and the maximum plating efficiency with this complex is near 50%.

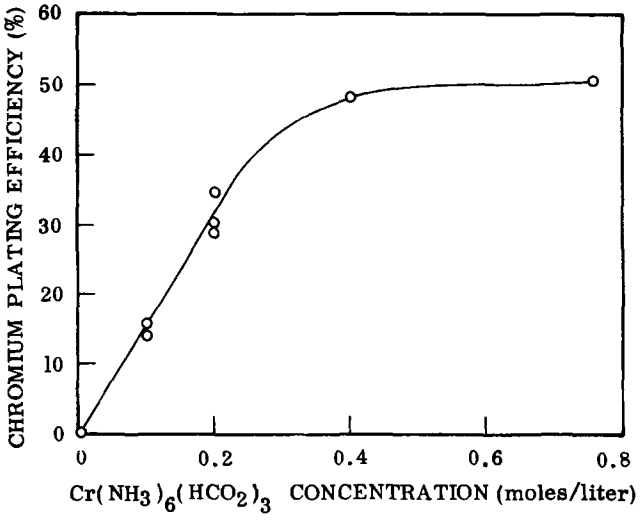

Fig. 1. Chromium plating efficiency as a function of hexaamminechromium(III) formate concentration.

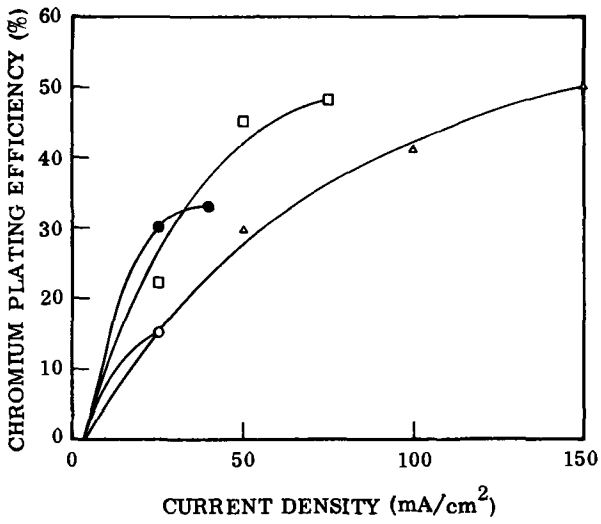

Fig. 2. Effect of current density and Cr(III) concentration on plating efficiency, 0.1M, ○; 0.2M, ●; 0.4M, □; 0.78M, △.

The current density for maximum plating efficiency increases as the HAF chromium concentration is increased (Fig. 2). A broader range of current density for plating is observed at the higher concentrations and the bath exhibits better covering and throwing power. The deposits are also somewhat brighter and smoother under these conditions. The more concentrated baths provide improved performance but the 0.2M HAF chromium bath was primarily investigated in the present study in order to minimize the effort of synthesizing the HAF complex.

The pH of the bath also affects the chromium plating efficiency. The bath normally buffers at a pH between 9 and 10 due to the release of large quantities of ammonia by the plating reaction, *i.e.*, $Cr(NH_3)_6^{+3} + 3e^- \rightarrow Cr^\circ + 6NH_3$. Maximum plating efficiency is obtained in this pH range. Adjusting the pH to 7 or less will drastically reduce plating efficiency because solvent reduction occurs at a lower potential and ammonium salts increase rapidly in the bath. Increasing the bath pH above 10 produces only a slight decrease in plating efficiency.

The chromium plating efficiency decreases as the temperature of the HAF chromium bath is increased. This parameter was not investigated quantitatively for this system, but a temperature dependence similar to the thiocyanatopentaamminechromium(III) bath (9) is expected. Formamide reduction proceeds more readily at higher temperatures and this is the principal reaction occurring at temperatures greater than 50°C. It is estimated from the data presented in Fig. 9 (plating performed at 32°C) that the plating efficiency decreases by 0.7%/°C temperature rise above 23°C.

Plating studies with thiocyanatopentaamminechromium(III) and hexaamminechromium(III) show that thiocyanate catalyzes chromium deposition. However, the increase in plating efficiency is probably not due to an electron bridging effect and coordination of thiocyanate to the chromic ion is not required. Sodium thiocyanate, sulfamic acid, and boric acid additives to the HAF chromium bath all result in a substantial increase in chromium plating efficiency at low concentrations (Fig. 3). The sharp concentration dependence with the sulfamic and boric acid additives is caused by a change in pH and can be eliminated by addition as the alkali metal salts. The lower initial plating efficiency with these two additives reflects a lower purity of HAF chromium. The complex used in these tests was prepared by a methathesis reaction between ammonium formate and hexamminechromium(III) nitrate in liquid ammonia and it is difficult to eliminate ni-

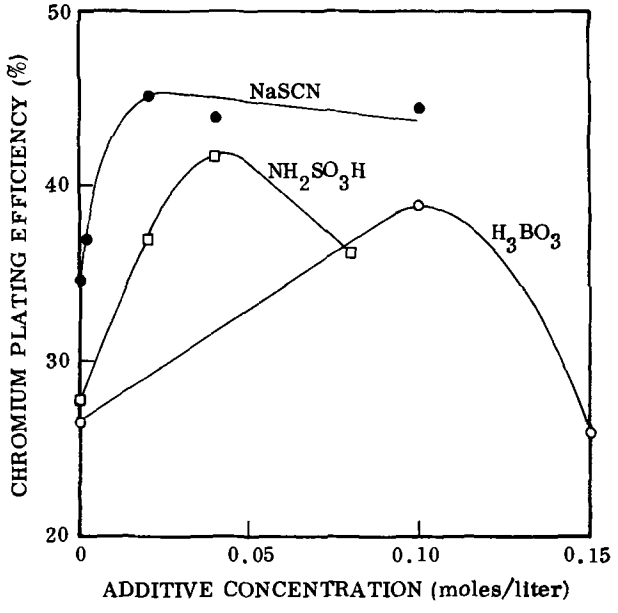

Fig. 3. Influence of various additives on chromium plating efficiency.

trate contamination by this method. The additives are not as effective in increasing plating efficiency when added to more concentrated HAF chromium baths (compare Fig. 1 with Fig. 7).

Current-potential curves were obtained on HAF chromium baths in an effort to establish the role of the thiocyanate additive in the plating mechanism. Figure 4 illustrates that lower potentials are required for chromium plating in the presence of thiocyanate. Chromium deposition first occurs at a potential of −1.16V (*vs.* Ag/AgCl) with thiocyanate while a potential of −1.36V is required to initiate plating without thiocyanate. Thiocyanate also reduces the plating potential by 80 mV at 25 mA/cm² (the current density for maximum plating efficiency).

The data indicate that thiocyanate also may be increasing the overpotential for the solvent reduction reaction. An attempt was made to measure the reduction potential of 30 m/o acetamide/formamide with and without sodium thiocyanate. The reduction potential listed in the literature (19) for pure formamide is −1.6V ($E_{1/2}$ *vs.* saturated calomel electrode). The reduction potential measured in the present study is −1.69V (*vs.* Ag/AgCl) for the solvent and −1.78V for the solvent with sodium thiocyanate (Fig. 5). Considerable error may have been introduced in obtaining the reduction potential from the graphical intercept of the slopes of the two curves because sharp limiting currents for solvent reduction were not obtained. However, the data suggest that thiocyanate does increase the overpotential for the solvent reduction reaction.

The performance of the HAF chromium bath was investigated during prolonged electrolysis in order to evaluate bath stability. Tests with the pentaamminechromium(III) complex indicate that bath deterioration occurs as a result of aquation of the chromic complex. The aquation rate of the hexaammine complex is of the same order of magnitude as the thiocyanatopentaammine complex (12) and, therefore, deterioration in the HAF chromium bath was also expected. Figure 6 illustrates the deterioration observed when less than 12% of the available chromium is plated from the bath. Poorer performance is obtained with the more concentrated bath because additional water is added with the HAF chromium complex. The hexamminechromium(III) formate, as synthesized, was not anhydrous but contained from ½ to 1 mole of water, *i.e.*, $Cr(NH_3)_6(HCO_2)_3 \cdot ½\text{-}1\ H_2O$. Spectral analysis of the baths after electrolysis indicated the presence of aquated chromic complexes.

An improvement in performance is observed when thiocyanate is added to the electrolyte (Fig. 7). Bath deterioration is not nearly as rapid, particularly in the case of the more concentrated bath, but the decrease in plating efficiency during electrolysis is still greater than can be accounted for by depletion of the chromic complex due to the plating reaction. The improved bath stability with thiocyanate is largely a

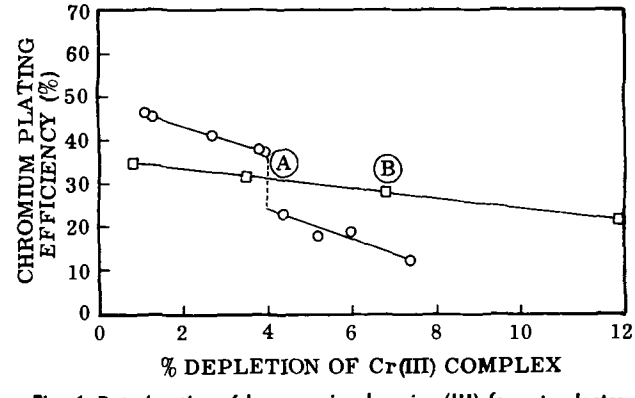

Fig. 6. Deterioration of hexaamminechromium(III) formate electrolyte during electrolysis. A. 24-hr interruption of test. Electrolyte color change from amber to purple. B. 24-hr interruption of test. Initial concentration: 0.4M HAF chromium, ○; 0.2M HAF chromium, □.

result of a decrease in the rate of the side reactions during electrolysis.

Thiocyanate reduces the rate of solvent reduction as a result of the increased chromium plating efficiency. However, the reduction products of formamide are probably not too detrimental to the bath because only hydrogen and volatile basic components are produced (19). The anode reactions appear to have more effect on chromium plating efficiency than the cathode reactions. The most desirable anode reaction for the HAF chromium bath is oxidation of formate, *i.e.*, $HCO_2^- \rightarrow CO_2 \uparrow + H^+ + 2e^-$. Sparging carbon dioxide into the bath reduces the plating efficiency slightly and produces a milky cast to the chromium deposit, but insoluble products do not form in the presence of carbon dioxide and the plating characteristics of the bath are not drastically affected unless the sparging rate is sufficient to reduce the pH of the bath. The basic by-products liberated at the cathode also neutralize the acid generated by formate oxidation at the anode. The result is that a pH of 9 to 10 is still maintained during electrolysis with the formate salt of hexaamminechromium(III) ion.

Formate oxidation is not the only anode reaction that occurs in the HAF chromium bath. Plating tests with ammonium reineckate in 30 m/o acetamide/formamide indicate improved bath stability with chromium rather than platinum anodes. Formamide oxidation to cyanuric acid proceeds in good yield on platinum anodes (20) and therefore the poorer performance with platinum anodes probably results from the generation of cyanuric acid. Better HAF chromium bath stability is also observed with chromium rather than platinum anodes, but chromium anodes are not completely inert in the bath. Small quantities of hexavalent (and lesser amounts of trivalent) chromium ions are produced during prolonged electrolysis. Completely insoluble anodes which catalyze formate, but not formamide, oxidation should improve bath stability.

The addition of thiocyanate to the HAF chromium bath provides other possible anode reactions. Oxidation of thiocyanate to sulfate occurs in the thiocyanatopentaamminechromium(III) thiocyanate bath and produces the insoluble, pale orange, chromic sulfate salt (9). An insoluble yellow material forms on the anode during prolonged electrolysis of the HAF chromium bath with the thiocyanate additive. The material is primarily an insoluble sulfate salt of the hexaamminechromium(III) complex but some thiocyanogen may also be produced. The oxidation of thiocyanate is not particularly deleterious to the bath and the net result is that thiocyanate and hexaamminechromium (III) ions are consumed and must be added to the bath periodically.

Thiocyanate addition to the HAF chromium bath is also desirable because anation[1] of the aquochromic

[1] Substitution of an anion for water in the coordination sphere.

complexes is possible. Anation of aquopentaamminechromium(III) ion with thiocyanate occurs readily in acidic aqueous solutions (11). Thus, it is possible to convert the aquochromic complexes, which are not suitable for efficient electroreduction, to the thiocyanato derivatives, which are easily reduced.

The HAF chromium bath with thiocyanate addition is relatively stable during prolonged electrolysis when the concentrations of thiocyanate and hexaamminechromium(III) ion are maintained within rather narrow limits (Fig. 8). However, some deterioration is evident after 15% of the available chromium is plated from the bath. The blue color characteristic of hexaaquochromic ion is observed in the bath at this point.

The primary cause of HAF chromium bath deterioration is aquation of the hexaamminechromium(III) complex. Figure 9 illustrates the effect of water content on chromium plating efficiency. The initial plating efficiencies are lower in these tests because the bath temperature in the dry box is slightly higher than ambient. Operating the bath at 32°C does not noticeably affect bath stability. Test I illustrates the decay in chromium plating efficiency during electrolysis without drying the bath. The initial plating efficiency is near 22% at a water content of 2640 ppm. The decay in plating efficiency during electrolysis is slightly greater than the baths with lower water contents. Reducing the water content to 200 ppm increases the initial plating efficiency to 26% (tests II and III). The decay in plating efficiency during electrolysis is a result of a decrease in the concentration of the chromic complex by the plating reaction (see Fig. 1). The bath is stable when the water content of the bath is less

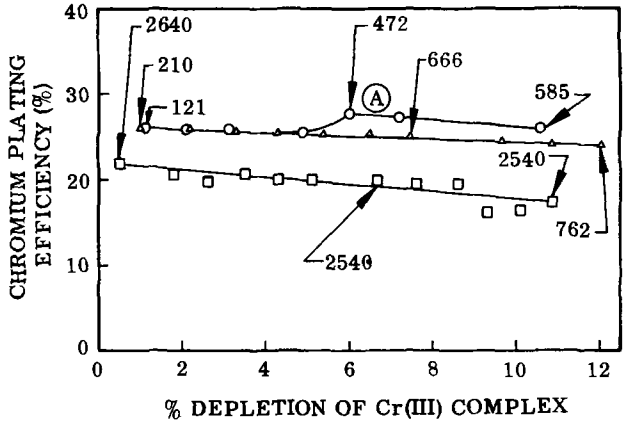

Fig. 9. Chromium plating efficiency at low water concentrations. Test I, □; test II, △; test III, ○. Numbers denote ppm water. 32°C. A=100-hr interruption of test.

than 400 ppm. Water concentrations above 1000 ppm substantially reduce the initial chromium plating efficiency and result in bath deterioration.

An interesting effect is illustrated in test III. The chromium plating efficiency begins to increase after electrolysis of the bath for several hours and the bath color changes from orange to red. Spectral analysis of the bath indicates the presence of the disolvotetraamminechromium(III) ion (21). Replacement of ammonia by the solvent (formamide or acetamide) in the chromic complex is therefore desirable because the weaker complex formed is more easily electroreduced in this solvent system. A hexasolvochromium(III) complex should yield substantially higher chromium plating efficiency than the hexaamminechromium(III) complex and provide a bath with fewer side reactions. Additional solvent would be the only material released into the bath by the plating reaction. However, the hexasolvochromium(III) complex is expected to be even more susceptible to aquation than the hexaamminechromium(III) complex.

Aquation of the chromic complex and deterioration of the HAF chromium bath can be eliminated by operation at low water levels, but it is difficult to maintain concentrations less than 400 ppm. Aquation of chromic complexes proceeds at measurable rates even in the very stable ethylenediamine complexes (12). Therefore, the only practical way to eliminate bath deterioration is by electroreduction of the aquated chromic complexes formed and higher reduction potentials are required to accomplish this efficiently. It is not feasible to investigate potentials much greater than −1.69V (*vs.* Ag/AgCl) in the present solvent system because formamide reduction occurs at potentials greater than this value and decreases the chromium plating efficiency. A solvent system with greater electrochemical stability is required in order to eliminate the aquation problem.

Chromium plating in other organic solvents.—Formate salts are generally of limited solubility in organic solvents and hexaamminechromium(III) formate is insoluble in most of the organic solvents which are more stable than formamide (Table II). Thiocyanatopentaamminechromium(III) thiocyanate is only slightly more soluble in these solvents which indicates that the anion is not the primary factor influencing solubility. Amminechromium(III) complexes are practically insoluble in the electrochemically stable organic solvents.

A hexaformamidochromium(III) complex might yield considerably better solubility in these solvents. Formamide is similar in solvent properties to water and hexaaquochromium(III) chloride and perchlorate are quite soluble in many of the stable solvents (9). The formamide complex would, however, be difficult to prepare because it is not very stable. A mixed formamidoamminechromium(III) complex is easier to synthesize and might provide the required solubility.

Dimethyl sulfoxide and an acetamide melt are the only relatively stable solvents other than formamide in which the HAF chromium complex is sufficiently soluble for electroplating studies (Table III). The dimethyl sulfoxide bath deposits bright chromium at low plating efficiency. Dimethyl sulfoxide is not sufficiently stable during prolonged electrolysis and the odor of sulfur-containing decomposition products is evident. An acetamide melt provides better performance than the dimethyl sulfoxide solvent but the chromium plating efficiency is low as a result of the higher operating temperatures.

Acetamide is quite soluble in DMF at room temperature and the HAF chromium complex readily dissolves in this mixture to yield stable solutions at chromic ion concentrations near 0.2M. Plating studies in this solvent yield metallic deposits at plating efficiencies near 65%. The initial chromium plating efficiency in the DMF mixture is roughly twice as great as that obtained with the standard formamide/acetamide solvent. However, the bath is unstable during prolonged electrolysis and insoluble products form. None of the other solvent systems tested are as satisfactory as the acetamide/formamide structure.

Alloy plating.—One of the principal advantages of a chromium plating bath utilizing trivalent chromium rather than chromic acid is that alloy deposition is possible. A brief experimental program was undertaken in order to demonstrate the feasibility of electrodepositing chromium alloys from the organic solvent system. Nickel-chromium alloy plating was investigated in the present study primarily because it was reported that nickel can be electrodeposited from hexaamminenickel(II) bromide dissolved in both formamide and acetamide (22). Hexaamminenickel(II) formate (HAF nickel) is therefore a convenient source of nickel which can be added to the standard HAF chromium bath without interfering with the chromium plating process. It should be relatively simple to deposit other chromium-metal alloys as long as the alloying metal is more easily electroreduced than hexaamminechromium(III) ion.

A suitable bath composition for plating nickel-chromium films is 0.2M HAF chromium and 0.04M HAF nickel dissolved in 30 m/o acetamide/formamide. The alloy films in the present tests were electrodeposited at a current density of 25 mA/cm^2 and at 23°C unless otherwise indicated. Semibright, metallic deposits are obtained under these conditions with a chromium content near 85%.

The chromium content in the alloy film can be controlled by adjustment of the bath temperature, HAF chromium and nickel concentrations, and cathode current density. Alloy films were plated with the chromium content varying from less than 1 to greater than 99% by adjustment of these three variables. Temperature is the most sensitive and convenient parameter for controlling the composition of the alloy film, but more rapid bath deterioration occurs at higher temperatures unless the water content is low (less than 400 ppm). Operation of the bath at temperatures greater than 100°C would simplify water control but the chromium content of alloy films plated under these conditions is quite low (Table IV). Evidently, there is no synergistic effect on chromium plating efficiency induced by the nickel in the alloy plating bath.

The effect of current density on the composition of the alloy film is illustrated in Fig. 10. The alloy composition does not change substantially in the current

22	25	4.5	94.6	5.4
100	25	4.5	0.25	99.75
100	12.5	2.4	0.04	99.96

density range from 12 to 37 mA/cm² (80-85% chromium and 15-20% nickel), but the deposit is practically all nickel at current densities less than 6 mA/cm². The relationship between the weight determinations and film thickness is as follows: 1 mg/cm² is equivalent to 1.4μ of chromium or 1.1μ of nickel. It is apparent from Fig. 10 that alloy films are deposited at reasonable plating rates in the current density range yielding nearly constant alloy composition.

The plating rate and chromium content of the alloy film continuously decreases during electrolysis if no attempt is made to control the water content of the bath (see Fig. 11). The bath is no longer effective for alloy plating after removal of approximately 22% of the available metal by plating. Aquation of the metal-ammine complexes is responsible for the bath deterioration.

Better performance is observed if the water intake of the bath is restricted (Fig. 12). The plating rate increases during the initial stages of plating as the metal-ammine complexes are converted to the solvo-ammine complexes. However, the plating rate begins to decrease after approximately 5% of the available metal is removed from the bath by plating. The high initial water content of the bath (near 2500 ppm) results in substantial aquation of the metal complexes even when additional water absorption is restricted.

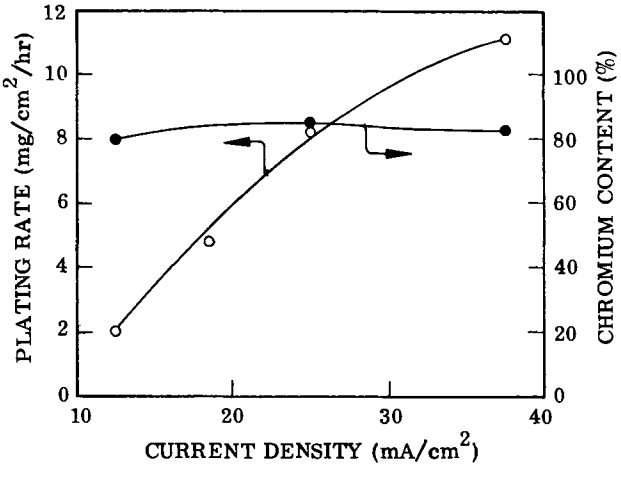

Fig. 10. Influence of current density on nickel-chromium alloy composition and deposition rate.

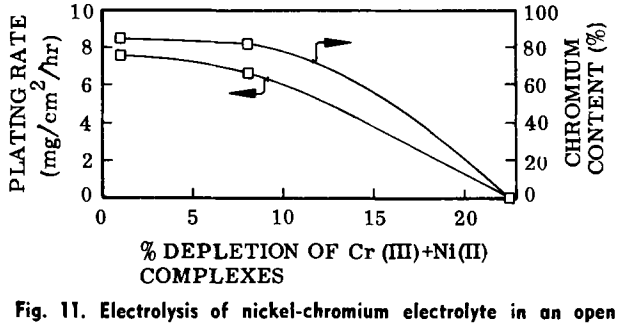

Fig. 11. Electrolysis of nickel-chromium electrolyte in an open cell. Initial water content ca. 2500 ppm.

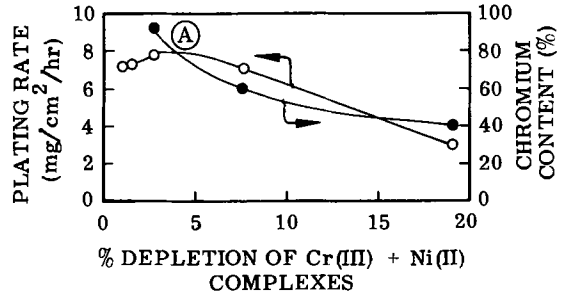

Fig. 12. Electrolysis of nickel-chromium electrolyte in a closed cell. Initial water content ca. 2500 ppm. A. 3-day interruption of test.

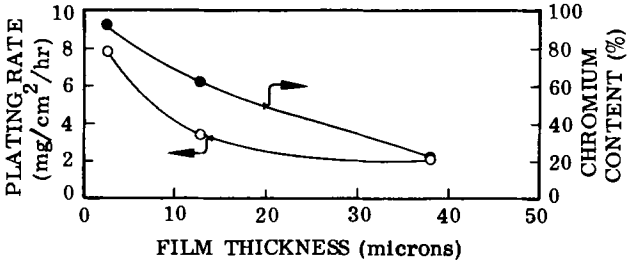

Fig. 13. Thickness effects of the nickel-chromium deposit

The bath is still effective for alloy plating after 19% of the available metal has been plated although the plating rate is considerably lower. The chromium content of the alloy film is stabilizing near 40% under these conditions. The plating rate and chromium content of the alloy films will level off at higher values if the bath is dried before sealing it in the cell.

The average plating rate and chromium content of the alloy film declines as thickness increases (Fig. 13). This effect is not entirely a result of bath deterioration due to aquation of the metal-ammine complexes. For example, a 2μ alloy film was electroplated immediately after plating a 13μ film. The 13μ film plated at a rate of only 3.5 mg/cm²/hr and the surface layer contained 62% chromium while the 2μ film plated at a rate of 7.1 mg/cm²/hr and the surface layer contained 85% chromium. This effect may be due to a decrease in the effective current density as a result of an increase in the surface roughness of the substrate during plating. Alloy plating under potentiostatic conditions rather than at a constant current should eliminate this effect.

The appearance of the alloy films is similar to the chromium films deposited from the thiocyanatopentaamminechromium(III) thiocyanate bath. Thin films have a metallic luster and are semibright. Thicker films, *i.e.*, greater than 10μ, have a matte appearance and some nodule formation is evident. An electron microprobe analysis indicates that nickel and chromium are the only constituents present. However, the analysis was not sufficiently accurate to determine low concentrations of the light elements and there may be small amounts of hydrogen, nitrogen, and oxygen in the electrodeposits (9). Films thicker than 10μ afforded good protection for copper substrates in accelerated corrosion tests (immersion in ammonium polysulfide). This indicates that defects are not continuous through the entire coating thickness and is an indication of good coating integrity. The adherence of the coating to copper is good in that the coating will survive bend tests through angles greater than 90 degrees.

Summary

Chromium can be electrodeposited from organic electrolytes at high cathode current efficiencies (near 50%). The plating baths consist of anhydrous chromic

complexes dissolved in amide solvents. An electrolyte of hexaamminechromium(III) formate in 30 m/o acetamide/formamide yields the most consistent plating results. The optimum hexaamminechromium(III) formate concentration in the bath is 0.2-0.4M and maximum plating efficiency is obtained by operating the bath at ambient temperature (23°C) in the current density range from 25 to 50 mA/cm^2.

The bath is stable only at water concentrations less than 400 ppm although satisfactory plating performance is obtained over a period of several days with water concentrations as high as 2500 ppm (steady-state value under ambient conditions). In the presence of water, aquation occurs and chromium is deposited at lower cathode current efficiency from the resulting complexes. Cathode current efficiency is increased by the addition of small concentrations of sulfur-containing compounds (thiocyanate or sulfamic acid) or boric acid. It was observed that thiocyanate reduces the potential for chromium deposition and may also increase the overpotential for amide solvent reduction.

Ligands known to be effective electron bridging groups for the chromous/chromic redox reaction are

$$N_3^- > Cl^- > SCN^- > H_2O$$

Substitution of these ligands for an ammonia group in the hexaamminechromium(III) complex showed that their effectiveness for promoting chromium deposition was

$$SCN^- > NH_3 > Cl^- \text{ and } N_3^- > H_2O$$

It was concluded that electron bridging groups have very little effect on the electroreduction of chromic ion and that low thermodynamic stability of the chromic complex is of greater importance than kinetic considerations.

It was demonstrated that chromium alloys can be efficiently electrodeposited from organic electrolytes. It is possible to electrodeposit nickel-chromium alloys by addition of hexaamminenickel(II) formate to the standard chromium bath. The composition of the alloy can be varied over the entire range of 0-100% chromium by proper selection of the HAF chromium and nickel concentrations, the bath temperature, and the plating current density. The alloy deposits exhibit good adherence to copper and accelerated corrosion tests indicate good film integrity. Electron microprobe analysis of the film indicates that nickel and chromium are the only metallic elements present.

Hexaamminechromium(III) formate was found to exhibit little or no solubility in a number of organic solvents which have good electrochemical stability. A thiocyanate counterion induced only slightly greater solubility than formate ion and it was concluded that the anion was not the primary factor affecting solubility. The former compound was soluble in dimethyl sulfoxide and in acetamide/dimethylformamide but these electrolytes exhibited low plating efficiency and insoluble reaction products, respectively.

The Structure of the Complexed Copper Species in Electroless Copper Plating Solutions

L. N. Schoenberg*
Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The bonding mode of the copper ion in various formulations of a well-known electroless copper bath consisting of copper sulfate, sodium hydroxide, potassium sodium tartrate, and formaldehyde has been determined by electron paramagnetic resonance spectroscopy. Other ligands related to tartrate in structure, but with fewer potential bonding sites, were also studied. It was discovered that 2,3-butane diol, α-hydroxy butyric acid, malic acid, glycolic acid, and mandelic acid could be substituted for tartrate in an electroless copper bath, but that succinic acid, β-hydroxy butyric acid, and salicylic acid could not. The plating rate of copper-tartrate solutions as a function of *p*H was studied, and it was found that the maximum plating rate occurs at about *p*H 12.8. The structure of the copper complex is *p*H dependent and is one factor affecting the deposition rate.

Procedures for the electroless deposition of copper have been known for some time. Solutions suitable for this purpose generally consist of a copper-containing salt, a complexing agent, a reducing agent, and a source of hydroxide ions. Various additional substances, such as brightening agents and stabilizing agents, may also be incorporated. The role of the complexing agent in determining important bath parameters such as stability and plating rate has not yet been well investigated.

The deposition of electroless copper can be considered to consist of two half reactions, namely, the reduction of copper ions to copper metal (cathodic reaction) and the oxidation of the reducing agent, generally formaldehyde to formic acid (anodic reaction). The catalytic surface mainly affects the rate of the anodic half reaction (1). In principle, it is possible to envision an alkaline electroless copper bath, consisting of a copper complex and a reducing agent, that is indefinitely stable in the absence of a catalytic surface and yet that in the presence of a catalytic surface plates very rapidly. To formulate a bath of this type, an understanding of the bonding mode of the copper ion in such solutions is clearly of importance.

Tartrate is the most commonly used complexing agent in electroless copper baths (2) and was chosen for study because of its suitability for investigation using the technique of electron paramagnetic resonance. It further provided the opportunity for gaining information about the nature of copper-tartrate complexes, a field long investigated but in a state of much confusion. The nature of the copper complex both before and after the addition of reducing agent was of concern, as is made clear below.

Copper Tartrate Complexes

A study of the mode of bonding between copper and the tartrate anion is complicated by the many conceivable bonding types that can be envisioned. The several ionizable hydrogen atoms make complex formation very *p*H dependent. Figure 1 indicates several of the copper-tartrate complexes that have been proposed at one time or another, mostly in the early literature (3). Other structures can readily be envisioned. Only two or three of the four positions in the first coordination sphere of copper have been indicated as filled. The other positions may be considered to be occupied by another molecule of tartrate or by hydroxide ions. While the structures in which copper is bonded to two carbonyl oxygens can be rejected tentatively because of the unstable seven-membered ring which would be required, the other structures are sterically possible (4). In addition, dimeric structures containing two copper atoms per molecule have been proposed and spectrophotometric evidence of their existence in 1 to 1 copper-tartrate solutions has been exposited (5).

To determine which of the oxygens might be bonding, it was decided to attempt to form electroless copper baths using as chelating agents various model compounds related to tartaric acid. The structures of these model compounds are depicted in Fig. 2.

The fact that the alcoholic oxygens can indeed participate in bonding if the *p*H is sufficiently high is evidenced by the successful use of 2,3 butane-diol in which coordination can take place only through alcoholic oxygens. Moreover the failure of succinic acid to coordinate indicates that where coordination through carbonyl oxygens would involve a seven-membered ring, the alcoholic oxygens are essential.

The fact that α-hydroxy butyric acid could be used as a chelating agent while β-hydroxy butyric acid under the same conditions could not is in accord with the tendency of copper to prefer a five-membered ring. As a result, certain structures in which an alcoholic oxygen and nonadjacent carbonyl oxygen are bonded to the copper atom may be considered as more remote possibilities.

In accord with the above facts, malic, mandelic, and glycolic acid, all of which have a carbonyl group and an adjacent hydroxide group, can successfully chelate copper. Salicylic acid is unable to form a copper complex under the same conditions. The reason for this is apparent from bond angle considerations. The relevant oxygen atoms are forced to remain too far apart to bond due to the rigidity of the benzene ring.

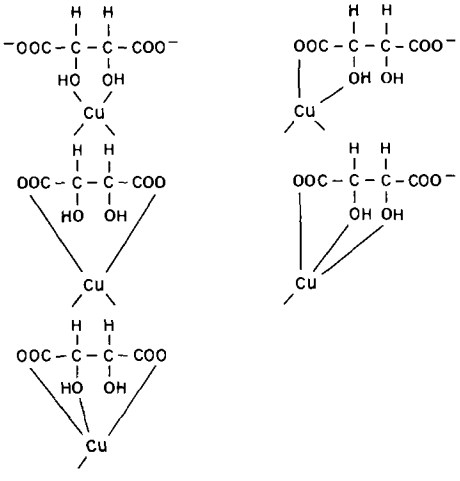

Fig. 1. Several of the possible structures of the copper-tartrate anion. Only two or three of the four positions in the first coordination sphere of copper have been indicated as filled.

Electron Paramagnetic Resonance

All of the electron paramagnetic resonance (EPR) spectra discussed below were obtained from frozen solutions. Therefore, a brief description of EPR as applied to frozen solutions is desirable. McGarvey (6) provides an understandable and rigorous treatment of the firm quantum mechanical base underlying the interpretation of EPR spectra. He also discusses the interpretation of frozen solution spectra.

Figure 3 depicts the splitting of the spin energy states of an electron, first by a magnetic field and second by interaction with the nuclear magnetic moment of the copper nucleus ($I = 3/2$). Also given is an approximate equation for the energy value of each level. The relevant selection rules are that $\Delta M_I = 0$ and $\Delta M_S = \pm 1$. Thus the four allowed transitions are those indicated by arrows and the energy of the four transitions can be approximated by

$$E = h\nu = g\beta H_0 + Am_I$$

where g = gyromagnetic ratio, β = Bohr magneton, h = Planck's constant, ν = frequency, A = hyperfine coupling constant, and $m_I = \pm 1/2, \pm 3/2$.

The parameters which are characteristic of the species being measured are g and A. In a nonsymmetrical molecule g and A are anisotropic, and in the case of a tetragonal molecule, g and A can be resolved into components parallel and perpendicular to the magnetic field. If θ is the angle between the magnetic field and the Z axis, then (7)

$$g = (g_{||}^2 \cos^2\theta + g_{\perp}^2 \sin^2\theta)^{1/2}$$

and

$$A = g^{-1} (A_{||}^2 g_{||}^2 \cos^2\theta + A_{\perp}^2 g_{\perp}^2 \sin^2\theta)^{1/2}$$

The spectra are obtained by varying the magnetic field strength at a fixed frequency. The spectra are presented as the first derivative of the absorption curves *vs.* the magnetic field, a method which enables greater sensitivity to be obtained. The parameters $g_{||}$, $g_{\perp}$, and $A_{||}$ can readily be extracted from such spectra. A representative spectrum is depicted in Fig. 4 and the procedure for calculating the parameters is indicated. D_1 is the distance in millimeters from the start of the scan to the point midway between the second and third peaks. D_2 is the distance from the start of the scan to the midheight point of the indicated line. Since all of the parameters in the first equation are known except $g_{||}$ and $g_{\perp}$, they can be calculated. $A_{||}$ in gauss is dependent on the distance between the second and third peaks (178 mm = 1000 gauss). The values of the parameters obtained from a frozen solution are average values for all of the bonds in the molecule under study.

The parameter g is affected primarily by the extent of splitting of the 3d energy levels by the ligand field and by the magnitude of spin-orbit coupling. The parameter A is affected primarily by the ratio of the nuclear magnetic moment to the nuclear spin and by the electron spin density in the immediate vicinity of the nucleus, *i.e.*, the closeness of the electron to the nucleus (8). In the present study, possible structures were assigned on the basis of trends in the values of these parameters.

EPR Results and Discussion

Until recently, no information on the EPR spectra of alkaline aqueous solutions of copper-tartrate complexes

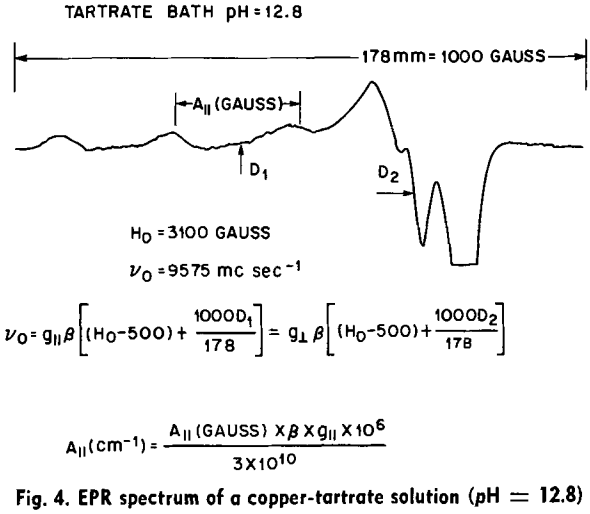

Fig. 4. EPR spectrum of a copper-tartrate solution (pH = 12.8)

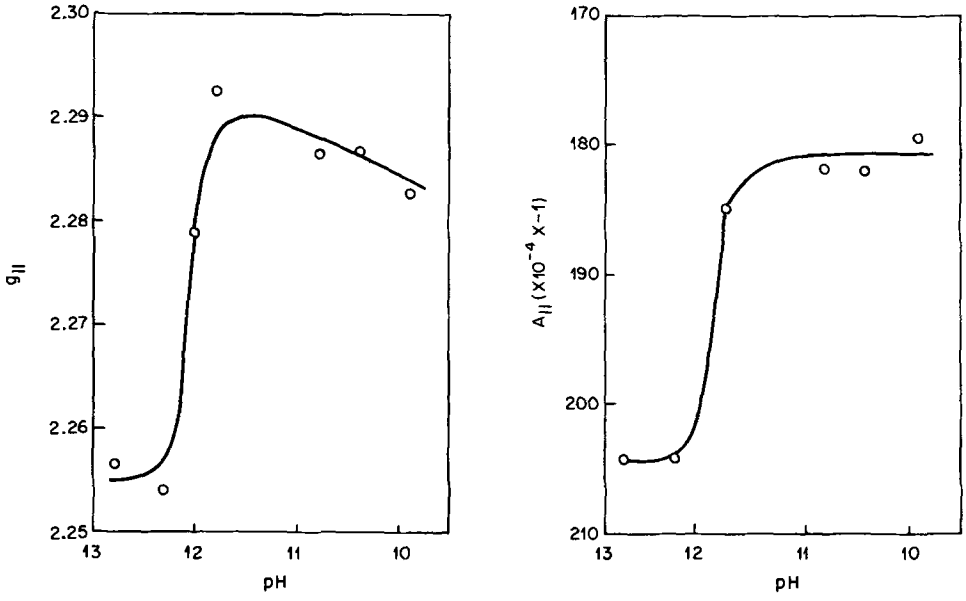

Fig. 5. Values of $g_{||}$ and $A_{||}$ of copper-tartrate solutions as a function of pH.

was available, although single-crystal measurements of the EPR parameters of Cu^{2+} in Rochelle salt had been reported (9). A recent paper, however, presented EPR parameters for 1 to 1 copper-tartaric acid solutions at two pH levels (4.3 and 11.3) (10). The present work has considered the entire range of pH from 5.2 to 13.7 in order to elucidate more fully this complicated system.

The parameters obtained from copper-tartrate solutions as a function of pH are shown in Table I along with the results obtained from a very highly basic solution of copper sulfate in which the complexed copper must be present as the tetrahydroxocuprate anion. The values of $g_{||}$ and $A_{||}$ as a function of pH are plotted in Fig. 5. It can be seen that as the pH decreases, $g_{||}$ increases and $A_{||}$ decreases. There is a jump at pH 12.0 which can be attributed to a change in bonding mode which will be subsequently discussed.

At pH 7.7 a spectrum characteristic of a dimer was obtained (Fig. 6). Its general outline is in accord with the shape that would be theoretically expected. Other examples of dimer spectra may be found in ref. (11). In the acidic pH range, the alcoholic hydrogen atoms are not ionized and different types of species are present which were not considered further due to their inapplicability to electroless copper plating.

No evidence of dimer formation was noted at high values of pH either in the solutions considered in Table I or in a solution ten times as concentrated (the concentration of practical electroless baths). This does not prove conclusively the nonexistence of dimers, but only that if a dimer is present, the copper atoms are far enough apart so as not to interact with each other. It can be shown, however, that for no effect to be noticed the copper atoms must be about six or more Angstroms apart. Molecular models indicate that such a large separation between two copper atoms connected by a tartrate molecule is unlikely, but barely possible.

† $cm^{-1} \times 10^4 \times -1$. $g_{||}$, $g_{\perp}$ ± 0.004. $A_{||}$ ± 6, α^2 ± 0.02.

At a pH of 13.7 two species were detected. Possible structural assignments will be discussed later.

The value of the parameter α^2 is a measure of the covalency of the copper-oxygen bond. Its value varies from 0.5 to 1.0. The tabulated values were calculated from the approximation (12)

$$\alpha^2 = \frac{-A}{P} + (g_{||} - 2.0023) + \frac{3}{7}(g_{\perp} - 2.0023) + 0.04$$

where P defines the principal value of A due to interaction between the copper ion nucleus and the unpaired electron. The value of P for $Cu^{2+} = 0.036$ cm^{-1}. The closer α^2 is to unity, the more ionic is the corresponding bond (13). The trend of the tabulated values is in accord with the expected trend, namely that the most ionic bonds are those in which hydroxide ions are bonded to the copper.

The postulated structures for the copper-tartrate complexes as a function of pH are depicted in Fig. 7. It is reasonable to assume increased hydroxide coordination with increasing pH. As mentioned above, the decreasing value of α^2 with decreasing number of coordinated hydroxides is in accord with the expected trend. As indicated in Fig. 7, the discontinuity in the parameters $g_{||}$ and $A_{||}$ is attributed to the coordination of a second tartrate anion.

Support for the theory that the change in bonding mode between pH 13.7 and 12.8 is between all hydroxide coordination at the higher pH and some car-

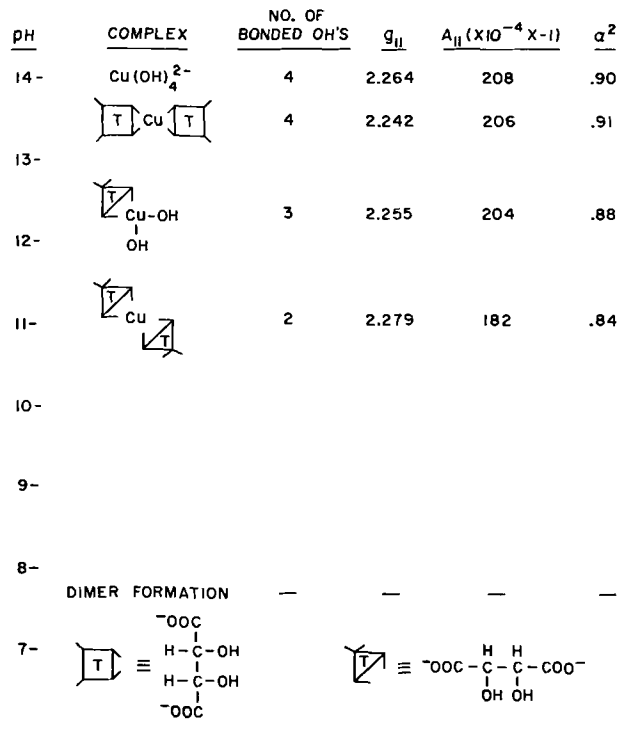

Fig. 7. EPR parameters and the proposed structures of copper-tartrate complexes as a function of pH.

bonyl coordination at the lower pH is found in the change in appearance of the $g_{\perp}$ region of the spectra (Fig. 8). Included for comparison is the spectrum of Cu-2,3 butane-diol in which coordination must be occurring through hydroxide groups. The spectral envelopes of the $g_{\perp}$ regions in all of the species in which four hydroxides are coordinated are similar. All of the Cu-tartrate spectra between pH 9.9 and 12.8 have $g_{\perp}$ regions similar to the right spectrum of Fig. 8 which is attributed to the coordination of three hydroxide groups.

Table II presents the EPR parameters obtained for various solutions using α-hydroxy butyric acid and 2,3 butane-diol as the complexing agents in place of tartrate. In every instance two species were noted in the solutions containing α-hydroxy butyric acid. The species with the lower $g_{||}$ value is the major component. A representative spectrum is shown in Fig. 9.

It has not been possible to assign a structure to these two species with certainty. The $g_{||}$ and $A_{||}$ parameters of the minority species are in agreement with those of the copper-tartrate species in which two molecules of tartrate are bonded through the hydroxyl and carbonyl oxygens. The $g_{||}$ value of the majority species is in accord with the value of the copper-tartrate species with one molecule of tartrate and two hydroxide ions. However, the $A_{||}$ and α^2 values of the α-hydroxy butyric acid species are somewhat low. Also there is no apparent change in the relative concentrations of the two α-hydroxy butyric acid species with pH.

With the thought that one of the species might be due to an impurity, α-hydroxy butyric acid was obtained from another manufacturer. Two species with similar EPR parameters to those mentioned above were formed. In the absence of other evidence, then, the above-discussed assignments are the best that can presently be made.

There is no difficulty with the assignment of structure of the butane-diol solution. Bonding can only occur through hydroxyl oxygens and the EPR parameters and the appearance of the $g_{\perp}$ region of the spectrum are in agreement with this bonding mode. Experiments in varying the pH of the butane-diol bath were not carried out, so the measured species may contain either one or two molecules of 2,3 butane-diol.

In Table III are depicted the parameters obtained before and after the addition of formaldehyde to a pH 12.8 Cu-tartrate solution (Cu^{2+} = 0.014M, tartrate = 0.06M). The formaldehyde was adjusted to pH 12.4 before the addition and one part by volume of formaldehyde to three parts by volume of Cu-tartrate were used. The final pH was approximately 12.7. Three measurements were made at varying elapsed times before freezing of the sample. In all cases there resulted a significant increase in $g_{||}$ and a corresponding decrease in $A_{||}$. This indicates very strongly that the formaldehyde, which in basic solution exists mostly as

the methylene glycol anion  has entered the first coordination sphere of the copper ion.

Moreover the new values of the parameters are very close to those of the species (Fig. 7 and Table I) in which it is proposed that two hydroxyl and two carbonyl oxygens are coordinated. It can be shown that formaldehyde cannot directly compete with hydroxide ions for copper ion since the addition of formaldehyde to a tetrahydroxocuprate solution resulted in no significant change in $g_{\parallel}$ and $A_{\parallel}$ (Table III). Therefore, it is highly likely that the methylene glycol anion is displacing the tartrate anion as one step in the electroless deposition process.

The fact that formaldehyde is indeed bonded to the copper can be substantiated by a consideration of the wavelengths of the maxima of the broad bands in the visible region of the absorption spectra. Upon the addition of 0.4M formaldehyde (pH 12.9) to a solution containing 0.02M copper sulfate and 0.4M potassium sodium tartrate (pH also 12.9), the maximum is shifted from 670 to 660 mμ.

The position of this maximum in complexes of transition metals is commonly related to the stability of the complex; a shift to lower wavelength (higher energy) indicating a more stable complex (14). Since the stability of the tartrate-formaldehyde-hydroxide-copper complex is apparently greater than that of the tartrate-hydroxide-copper complex, it would appear that a solution of the former complex would be indefinitely stable were it not for the tendency of the oxidation of formaldehyde to occur catalyzed by random variables such as dust particles and scratches in the container.

Plating Rate as a Function of pH

It has previously been reported that the pH of an electroless copper plating solution is the variable having the greatest effect on the deposition rate (15). Figures 10 and 11 are plots of the plating rate *vs.* pH obtained in the present work using solutions containing 0.02M $CuSO_4 \cdot 5H_2O$, 0.4M HCHO, and sufficient NaOH to obtain the desired pH. Plating was carried out on platinum substrates. Solutions containing 0.4M (Fig. 10) and 0.1M (Fig. 11) potassium sodium tartrate were studied. In both cases maxima at about pH 12.8 were obtained.

Maxima in plating rate *vs.* pH curves were not observed by Saito (15) but were observed by Okinaka at a somewhat higher pH (16). The electrochemical experiments of Saito indicated that both the anodic and cathodic half reactions are significantly affected by pH.

Methylene glycol is a weak acid with a dissociation constant of 1.62×10^{-13} at 23°C (17). The calculated per cent dissociation as a function of pH is given in Table IV.

When considered alone, the increase in concentration of methylene glycolate with pH would result in an ever-increasing plating rate. However, the concentration of hydroxide ions also increases with pH. At high pH's we have observed (Table III) that copper ion has a greater affinity for hydroxide than for methylene glycolate. Hence the maximum in the plating rate may be due to a competition between the two coordinating species.

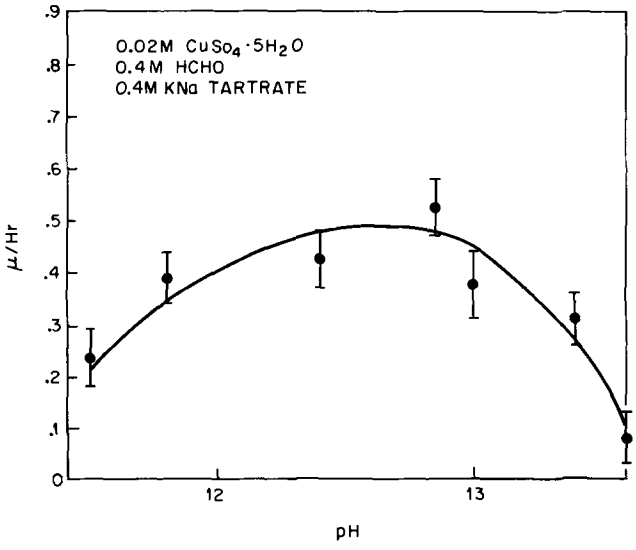

Fig. 10. Plating rate vs. pH in a solution containing 0.02M $CuSO_4 \cdot 5H_2O$, 0.4M HCHO, and 0.4M KNa tartrate.

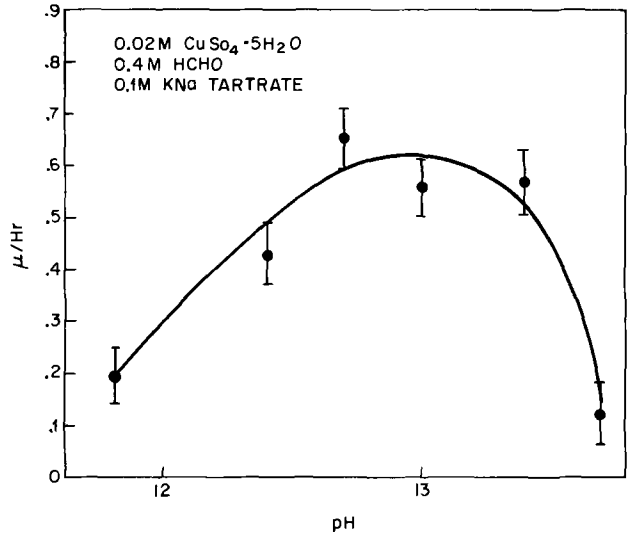

Fig. 11. Plating rate vs. pH in a solution containing 0.02M $CuSO_4 \cdot 5H_2O$, 0.4M HCHO, and 0.1M KNa tartrate.

The calculated concentration of methylene glycolate (from 0.4 moles of formaldehyde) and hydroxide are plotted as a function of pH in Fig. 12. A maximum in the plating rate in the vicinity of pH 12.8 could be predicted since the curves begin to converge rapidly at this point. The effect of this is that the concentration of hydroxide becomes comparable to and finally greater than the concentration of methylene glycolate. Therefore hydroxide bonding to the copper ions becomes predominant.

Table IV. Calculated per cent dissociation as function of pH

pH	% Dissociated
11	1.6
12	13.9
13	61.8
14	94.2

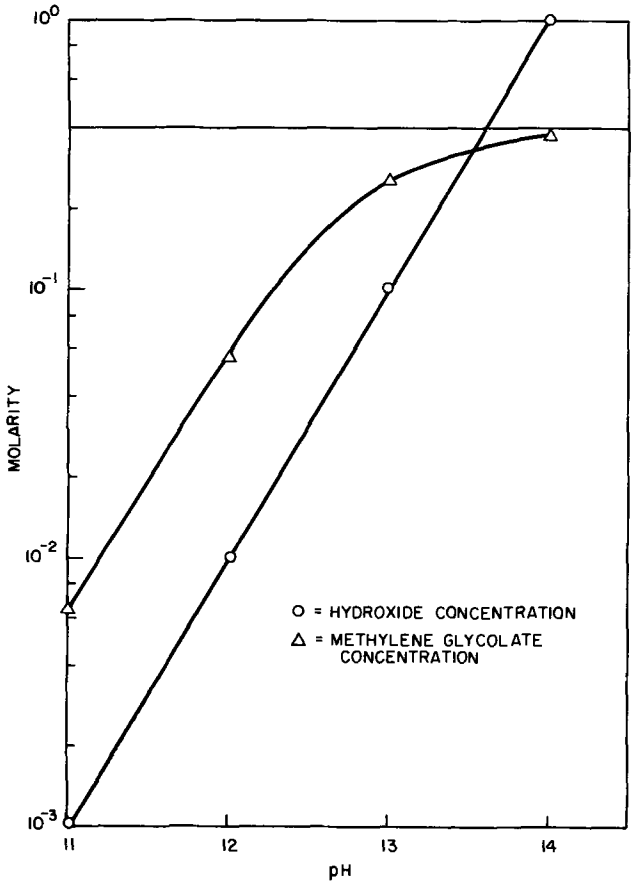

Fig. 12. Calculated concentration of methylene glycolate (from 0.4 moles of formaldehyde) and hydroxide as a function of pH.

A second factor which may cause the maximum is the variation in structure of the copper species. As the structure changes from one containing one tartrate ion and two hydroxide ions per copper ion to one containing two tartrate ions per copper ion (Fig. 7) steric hindrance may make it more difficult for methylene glycolate to enter the primary coordination sphere of the copper ion.

Since the nature of the copper complex and therefore the plating rate of an electroless bath changes with pH and since the pH of the bath changes with storage and during use, it is not surprising that problems in the reproducible use of electroless copper baths are often encountered. We have also found that the appearance of the deposits is pH dependent due to a change in the morphology of the copper deposit. Details of this and of the effect of certain additives are to be reported in a future publication.

Acknowledgment

The author is indebted to W. E. Blumberg for running the EPR spectra and for helpful discussions during the course of this work. D. R. Turner and P. J. Boddy reviewed the manuscript and made helpful comments.

Manuscript received Feb. 10, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Mechanism of the Electrocrystallization of Nickel and Cobalt in Acidic Solution

I. Epelboin* and R. Wiart

Groupe de Recherche du C.N.R.S., "Physique des Liquides et Electrochimie," Universite de Paris, Paris 5e, France

ABSTRACT

This mechanism is studied by means of the analysis of the polarization characteristic and of the cathodic impedance. The results, obtained from an acidic solution of the Watts type, strongly support the hypothesis that the cathodic reaction occurs in several steps probably involving an adion $(MeOH)_{ads}$. In the case of nickel, the results can be accounted for by a mechanism implying two successive transfer reactions in which $(NiOH)_{ads}$ acts as an intermediate compound and not as a catalyst. The presence in the electrolyte of either sodium benzenesulfonate or 2-butyne 1,4-diol (two inhibitors commonly used for the electrocrystallization of nickel) specifically modifies the kinetic parameters of transfer reactions and diminishes the capacity of the electrochemical double-layer. This capacity is defined thanks to a least-squares analysis of the cathodic impedance.

It is accepted in recent years that the electrocrystallization of a polyvalent metal Me^{z+} occurs in several steps. More particularly, authors agree (1-6) that an intermediate MeOH adsorbed at the electrode is formed during the cathodic reaction of the electrolytic deposition of nickel and cobalt in acidic medium. However, the electrochemical reactions leading to the metal are still a matter for discussion, and the intermediate $(MeOH)_{ads}$ is considered to be either a catalyst or a compound which is consumed at the electrode (7). In order to settle this problem, we have analyzed the cathodic polarization and the cathodic impedance during the electrocrystallization of nickel and cobalt from an electrolytic solution of the Watts type.

Furthermore, using the two above-mentioned methods, we have been able to study the influence on the reaction mechanism of two compounds commonly employed to inhibit the electrocrystallization of nickel (sodium benzenesulfonate and 2-butyne 1,4-diol). It is well known that the presence, in the electrolyte of one of these organic compounds (which are representative of two types of inhibitors: alkaline sulfonates and acetylenic alcohols) modifies, in a specific way, the state of the surface and the structure of the deposit (8). Moreover, organic compounds are adsorbed at the electrode, and this adsorption gives rise to a decrease of the electrochemical double-layer capacity (9-11). The definition of this capacity is difficult when electrochemical reactions occur at the electrode (12). We tried to define it more accurately by calculating (by a least-squares computer calculation) the elements of the equivalent circuit of the cathodic impedance.

Theoretical

In the present state of knowledge, authors accept the formation of an intermediate species, MeOH adsorbed at the electrode during the electrocrystallization of nickel and cobalt (1-6). The discharge arises from the ion $(MeOH)^+$ formed by the following chemical reaction

$$Me^{2+} + H_2O \rightarrow (MeOH)^+ + H^+$$

This ion adsorbs according to the Transfer Reaction [I]

$$(MeOH)^+ + e^- \underset{K_1'}{\overset{K_1}{\rightleftarrows}} (MeOH)_{ads} \qquad [I]$$

However, interpretations on what occurs after this latter step are divergent. Different reactions leading to the electrocrystallization of the metal are considered (2-5).

$(MeOH)_{ads}$ is a catalyst.—Heusler (2, 3) proposed a mechanism for the cathodic deposition of the iron group metals which is analogous to the catalytic mechanism he put forward for the anodic dissolution. Here, Reaction [I] is reversible, and the compound $(MeOH)_{ads}$ catalyzes the Transfer Reaction [II]

$$(MeOH)_{ads} + (MeOH)^+ + 2e^- \xrightarrow{K_2} (MeOH)_{ads} + Me + OH^- \qquad [II]$$

If MeOH is assumed to adsorb according to the Langmuir isotherm and if the electrolysis current I is not limited by the convective diffusion transport of the metal ions toward the cathode, then current I obeys Expression 1, established in the Appendix

$$I = \frac{2\mathbf{F}K_1K_2\beta[MeOH^+]^2}{K_1[MeOH^+] + K_1'\beta} \qquad [1]$$

where $\mathbf{F}$ is the Faraday and β the maximum number of $(MeOH)_{ads}$ species per surface unit, *i.e.* the maximum superficial density of $(MeOH)_{ads}$ expressed in mole·cm^{-2}. The electrochemical rate constants K_1, K_1', and K_2 are assumed to follow Tafel's law

$$K_i = k_i \exp(-b_iV) \qquad [2]$$

where $b_i = \alpha_i z_i \mathbf{F}/RT$, according to the previously used nomenclature (12); k_i, α_i, and $z_i\mathbf{F}$ denote the pre-exponential rate-constant, the cathodic transfer coefficient, and the number of coulombs per mole involved in the cathodic reaction, respectively.

According to Relation [1], the apparent order of the over-all deposition reaction, with respect to the metal ions, must be 2 near the equilibrium potential ($K_1[MeOH^+] << K_1'\beta$), whereas it must tend toward 1 at high cathodic polarizations ($K_1[MeOH^+] >> K_1'\beta$).

$(MeOH)_{ads}$ is an intermediate consumed at the electrode.—As in the case of the anodic dissolution of iron (12) during which $(FeOH)_{ads}$ desorbs according to the following process

$$(FeOH)_{ads} \rightarrow (FeOH)^+ + e^-$$

it can be considered that the $(MeOH)_{ads}$ species is consumed at the electrode during electrocrystallization. In the case of cobalt, Simonova and Rotinyan (4) proposed a mechanism in which $(MeOH)_{ads}$ is consumed during the Transfer Reaction [III]

$$(MeOH)_{ads} + (MeOH)^+ + 3e^- \xrightarrow{K_3} 2Me + 2\,OH^- \qquad [III]$$

* Electrochemical Society Active Member.

Key words: polarization curve, faradaic impedance, rotating-disk electrode, double-layer capacity, multistep mechanism, coverage relaxation, inhibition.

This reaction, which entails the transfer of 3 electrons, probably is an over-all reaction occurring in several steps which cannot be distinguished. We therefore shall take into account only Reactions [I] and [III] related by MeOH adsorbed according to the Langmuir isotherm.

If θ is the fraction of the cathodic surface covered by $(MeOH)_{ads}$ Reaction [I] will take place on the fraction $(1 - \theta)$, and Reaction [III] on the fraction θ. If Reaction [I] is supposedly irreversible ($K_1 >> K_1'$), and if convective diffusion transport is not the rate-determining step, the current-potential relation can be written (see Appendix)

$$I = \frac{4\mathbf{F}[MeOH^+]K_1K_3\beta}{K_1 + K_3\beta} \quad [3]$$

In this case, the apparent order of the over-all reaction with respect to the metal ions is 1, independent of the overpotential.

If the partial currents I_1 and I_3, which correspond to Reactions [I] and [III]

$$I_1 = 4\mathbf{F}K_1[MeOH^+] \quad [4]$$

$$I_3 = 4\mathbf{F}K_3\beta[MeOH^+] \quad [5]$$

are introduced into Eq. [3], we obtain

$$I = \frac{I_1 I_3}{I_1 + I_3} \quad [6]$$

Analysis of the faradaic impedance.—If we superimpose a sinusoidal variation of low amplitude and frequency f on the continuous polarization of the electrode, we can calculate the faradaic impedance Z_f. According to Heusler's mechanism, Z_f is inductive whatever the potential is, and becomes a mere transfer resistance when the overpotential tends toward an infinite value (13). On the other hand, if $(MeOH)_{ads}$ is an intermediate consumed at the electrode, this impedance can be either inductive or capacitive according to the potential (5).

A detailed calculation of the faradaic impedance of the electrode on which Reactions [I] and [III] evolve is given in the Appendix. This calculation leads to Eq. [7]

$$\frac{1}{Z_f} = \frac{I}{4}\left[b_1 + 3b_3 + \frac{(3I_3 - I_1)(b_1 - b_3)}{4\mathbf{F}j\omega\beta + I_1 + I_3}\right] \quad [7]$$

where $\omega = 2\pi f$

According to this equation, if $b_1 > b_3$, the reactive element is an inductance for $3I_3 > I_1$, and a capacity for $3I_3 < I_1$. It is well known that many faradaic impedances present such an inductance [(12) and references therein]. Equation [7] can be written as

$$\frac{1}{Z_f} = \frac{1}{R_t} + \frac{1}{\rho + jL\omega} = \frac{1}{R_t} + \frac{1}{\rho(1 + j\omega\tau)} \quad [8]$$

with the transfer resistance

$$R_t = \frac{4}{I(b_1 + 3b_3)} \quad [9]$$

the faradaic resistance

$$\rho = \frac{4(I_1 + I_3)}{I(3I_3 - I_1)(b_1 - b_3)} \quad [10]$$

and the faradaic time-constant

$$\tau = \frac{L}{\rho} = \frac{4\beta\mathbf{F}}{I_1 + I_3} \quad [11]$$

Equation [8] shows that the faradaic impedance consists of the transfer resistance R_t, set in parallel with the series connection of a resistance and a reactance.

The representative schema of the electrode over-all impedance, in the case of an inductive faradaic impedance, is given in Fig. 1. The resistance R_e is that of the electrolyte; the capacity C, set in parallel with the faradaic impedance, is that of the electrochemical double-layer. If this capacity is independent of frequency, this schema (Fig. 1) is an equivalent circuit, and the electrode over-all impedance can be written as

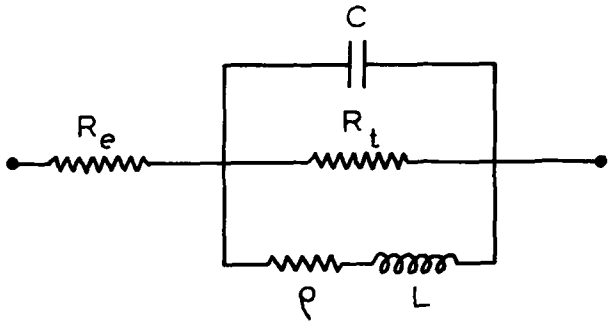

Fig. 1. Representative schema of the electrode impedance. R_e = Resistance of the electrolyte. C = Capacity of the electrochemical double-layer. R_t = Transfer resistance. ρ = Faradaic resistance. L = Self-inductance.

$$Z = R_e + \left[\frac{1}{R_t}(1 + j\omega\tau_{HF}) + \frac{1}{\rho(1 + j\omega\tau)}\right]^{-1} \quad [12]$$

where $\tau_{HF} = R_tC$ = high frequency time-constant.

This theoretical investigation reveals that it is possible to distinguish between the two considered mechanisms by studying the influence of the metal ion concentration and the cathodic potential on the electrolysis current I and the electrode impedance Z.

Experimental

Electrolytic solution and electrolysis cell.—In order to perform such a study, we chose an electrolyte of the Watts type, whose pH was constant. This solution is particularly suitable for it can (*i*) bear high current densities, (*ii*) maintain a cathodic efficiency close to unity for a large range of current densities, and (*iii*) allow the addition of organic compounds at relatively high concentrations. A liter of this solution contained 300g of $MeSO_4$, 7 H_2O, 35g of $MeCl_2$, 6 H_2O, and 40g of H_3BO_3, all these compounds being ultrapure.

The organic compounds added to the electrolyte were two inhibitors of electrocrystallization: sodium benzenesulfonate (C_6H_5-SO_3Na) and 2-butyne 1,4-diol (CH_2OH-$C{\equiv}C$-CH_2OH).[1] It is well known that these two types of compounds have a specific effect on the state of the surface of the nickel deposit, depending on the texture of this deposit (8, 14).

During the electrolysis, the solution was maintained at 50° ± 0.5°C by water circulation. The soluble anode was a nickel (or cobalt) cylinder whose area was close to 1 dm^2. The reference electrode was immersed in the electrolyte, and consisted of two compartments separated by fritted-glass. The compartment where the calomel electrode was immersed was filled with a KCl saturated solution; the other one contained the electrolyte of the cell.

Rotating disk electrode.—The metal deposition occurred on the cross section of a copper cylinder; this section, whose area (0.2 cm^2) was much smaller than that of the counterelectrode, was previously polished by emery paper (600 grade). The disk electrode was driven either by an asynchronous motor or by a compressed air turbine. Its rotation speed was sufficiently high so that the current was independent of the rotation speed, *i.e.* of the convective diffusion transport of

[1] The purity of these two compounds was checked in the "Laboratoire de Chimie Organique I de la Sorbonne," and we want to express here our gratitude to C. Georgoulis, Director of the No. 138 C.N.R.S. Research Team, associated with the Universite de Paris VI, for his help.

chemical species. This rotation speed was measured by an electronic stroboscope (15) and was stable to better than 1%.

Plotting of the polarization curve and measurement of the impedance.—The plotting of the cathodic polarization curve and the measurement of the impedance were carried out under potentiostatic conditions. The current-potential curve was corrected for ohmic drop. This term was determined by an interruptor method (16), and from the high-frequency limit of the impedance.

We can obtain the electrode impedance by superimposing a sinusoidal potential of low amplitude on the continuous polarization potential. Some of the results were achieved by means of an impedance meter and an electronic potentiostat built in our laboratory (17). Joining this method to that of Lissajous, we were able to obtain the electrode impedance up to a frequency of about 0.1 Hz. However, when the pH varies with time during the electrolysis, measurements become more difficult at low frequencies. We performed them, in this case, by means of a digital transfer function analyzer (Solartron, J M 1600 Type) connected to a potentiostat which was built in our laboratory and which allowed measurements of electrochemical impedances in a frequency range between 10^{-5} Hz and 50 kHz (18).

Results and Discussion

Study of the polarization curve.—During the electrocrystallization of nickel, we studied the influences of the electrolyte pH and the metal ion concentration on the polarization curve. Such a study is more difficult in the case of cobalt because the pH varies with time during electrocrystallization. However, in this case, the current-potential curve does not obey Tafel's law at a pH of 4.2 ± 0.2. As a matter of fact, $\partial \log I/\partial V$ varies with the cathodic potential, and this variation is in agreement with a deposition mechanism implying several steps (6).

In the case of nickel, the current-potential curve remains the same when the electrolyte pH varies between 3.5 and 5.6. At a fixed pH (= 4.5), the ion metal concentration has an effect on the reaction rate, which is shown in Fig. 2. The concentrations c of Ni^{2+}, which correspond to curves 1 to 3, are 1.22M, 0.15M, and 0.063M, respectively. When the concentration of Ni^{2+} decreases from 1.22M, Ni^{2+} is progressively substituted in the electrolyte by Na^+, so that the concentrations of SO_4^{2-} and Cl^- remain constant (5). At high current densities, the current-potential curves have been discontinued either at a potential (about −1.2V/SCE) at which hydrogen evolution is no longer negligible, or at a current (about 150 mA) at which electrolysis conditions are no longer those for a steady-state.

Within the potential range studied here, (*i.e.* between −0.7 and −1.12V/SCE), the value of $(\partial \log I/\partial \log c)_V$ is 1 ±8%, which shows that the order of the reaction is one with respect to Ni^{2+}.

Consequently, Heusler's hypothesis (3) concerning an intermediate NiOH acting as a catalyst must be rejected, since, according to Eq. [1], the order of the over-all reaction should decrease from 2 to 1 when the cathodic polarization increases. On the other hand, our experimental results strongly support the mechanism put forward by Simonova and Rotinyan (4).

To conform with Eq. [6], which must be satisfied at each point of the polarization curve, each polarization curve presented in Fig. 2 has two asymptotes, and all these asymptotes form a family of parallel straight lines, at ±10%. When the cathodic polarization is low, the curve tends toward a straight line which represents the variation of current I_1 and whose slope is $b_1 = 23V^{-1}$. When the cathodic polarization is high, the asymptote represents the variation of current I_3 and its slope is $b_3 = 8.5V^{-1}$.

Analysis of the cathodic impedance.—This analysis

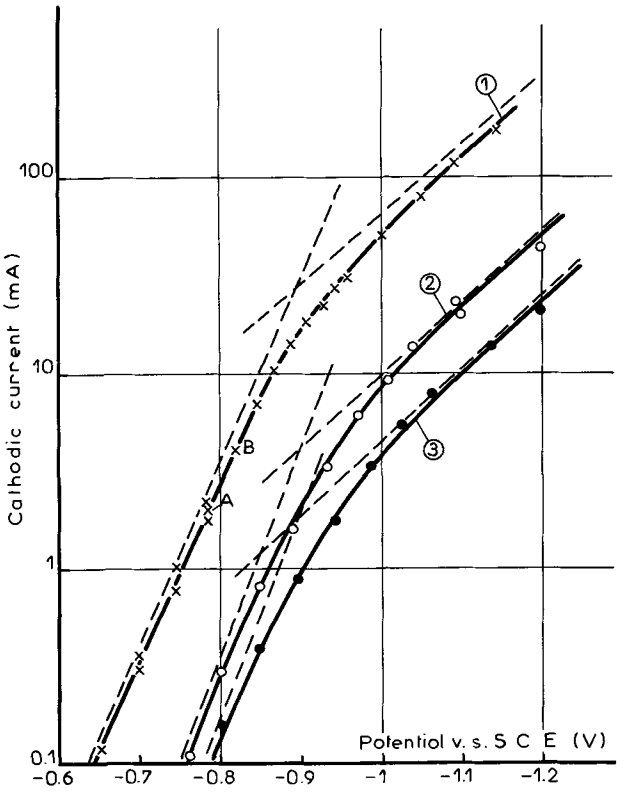

Fig. 2. Influence of the concentration (c) of Ni^{2+} on the steady-state current-potential curves corresponding to the electrocrystallization of nickel at a rotating disk electrode (area = 0.2 cm^2). (pH = 4.50 ± 0.05; temperature = 50° ± 0.5°C). X: Curve 1 where c = 1.22M and rotation speed = 2000 rpm; ○: Curve 2 where c = 0.15M and rotation speed = 9500 rpm; ●: Curve 3 where c = 0.063M and rotation speed = 8000 rpm. The continuous line represents experimental curves and the dotted line represents partial currents deduced from Eq. [4], [5], and [6]. A: I = 2 mA, V = −0.78 V/SCE; B: I = 4 mA, V = −0.82 V/SCE.

corroborates the results obtained from the plotting of the current-potential curve. When the cathodic polarization exceeds a certain value (about −0.96V/SCE, in the case of nickel), the impedance is capacitive at all frequencies. On the contrary, within the range of low cathodic polarizations, the electrode impedance presents an inductive character at low frequencies.

The impedance diagrams relative to the electrocrystallization of nickel, represented in the complex plane ($Z = R - jG$) on Fig. 3, correspond to this last range. They were obtained from the Watts solution under the same polarization conditions as those of points A and B in Fig. 2. We checked on the two diagrams (A) and (B) that the resistance obtained by extrapolating

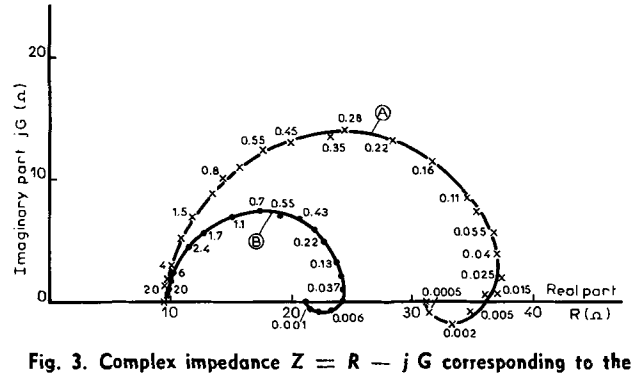

Fig. 3. Complex impedance $Z = R - jG$ corresponding to the electrocrystallization of nickel under the same conditions as for points A and B in Fig. 2. Frequencies are expressed in kHz.

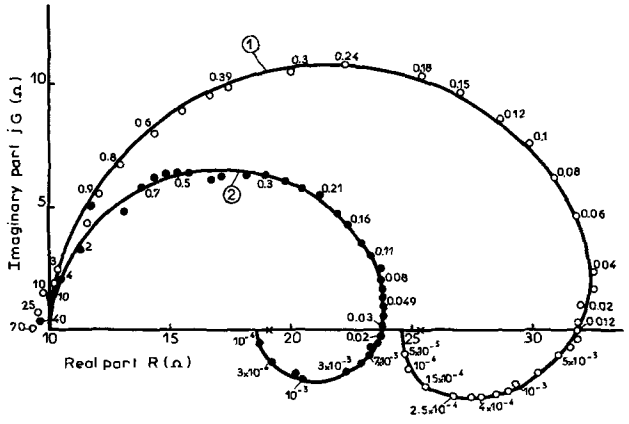

Fig. 4. Complex impedance $Z = R - jG$ corresponding to the electrocrystallization of cobalt, at a rotating-disk electrode (area = 0.2 cm²), from an electrolyte of the Watts type (concentration of Co^{2+} = 1.22M; pH = 4.2 ± 0.2; temperature = 50° ± 0.5°C). ○ Curve 1: I = 3 mA, V = −0.74 V/SCE; ● Curve 2: I = 6 mA, V = −0.81 V/SCE. Frequencies are expressed in kHz.

at zero frequency is equal to the reverse of the slope of the steady-state current-potential curve which corresponds to the points A and B in Fig. 2, respectively. At high frequencies, the faradaic impedance is shunted by the electrochemical double-layer capacity, and the electrode impedance is reduced to the electrolyte resistance R_e. At low frequencies, in conformity with the schema in Fig. 1, the impedance has an inductive character: the imaginary component G of Z becomes negative, while the real component R passes through a maximum.

During the electrocrystallization of cobalt, the same phenomenon is observed at low cathodic polarizations. As an illustration, Fig. 4 shows the diagrams obtained from the Watts solution under the following polarization conditions: I = 3 mA V = −0.74 V/SCE (diagram 1); I = 6 mA, V = −0.81 V/SCE (diagram 2).

Determination of the electrochemical double-layer capacity.—In order to define the concept of electrochemical double-layer capacity when an electrocrystallization process occurs at the electrode, we calculated by a least-squares method (19), the elements of the representative circuit of the impedance from experimental data. The confidence interval of the results was calculated on the 10% level of significance. All calculations were carried out on a 360/75 IBM computer.

A numerical calculation shows that we can account for our experimental results by assuming the faradaic impedance shunted by a constant capacity C. Tables I and II summarize the values of the parameters of Eq. [12] obtained under the same polarization conditions as those in Fig. 3 (for nickel) and in Fig. 4 (for cobalt), respectively. Under these polarization conditions, we

Table II. Electrocrystallization of cobalt

Experimental values of the parameters of the electrode impedance under the same polarization conditions as for diagrams 1 and 2 in Fig. 4. Notations are the same as for Table I.

Parameters	Polarization conditions 1	2
R_e (ohm)	10.43 ± 0.28	10.36 ± 0.27
R_t (ohm)	22.03 ± 0.39	13.64 ± 0.34
τ_{HF} (msec)	0.584 ± 0.015	0.372 ± 0.011
ρ (ohm)	49.2 ± 3.8	24.7 ± 2.1
τ (msec)	373 ± 49	142 ± 21

verified no frequency dependence of the electrochemical double-layer capacity C at high frequencies. Consequently, the concept of double-layer capacity can be used for the study of the action of organic inhibitors on the cathodic reaction.

Influence of organic inhibitors on the cathodic reaction kinetics.—Analysis of the impedance shows that the presence of either of the two inhibitors studied here causes a decrease, but no frequency dependence of the electrochemical double-layer capacity C. For instance, in the presence of 3.10^{-2}M sodium benzenesulfonate, this capacity changes from 70 to 45 μF/cm² at a current of 4 mA. Similarly at 6 mA, the addition of 8.10^{-3}M 2-butyne 1,4-diol leads to a capacity C of 50 μF/cm². These results are in agreement with those of the literature (9-11).

Not only do these inhibitors decrease the capacity C, but they also have a considerable influence on the kinetic parameters of the two Transfer Reactions [I] and [III] as shown by the current-potential curve (Fig. 5). Curve 1 was obtained from the Watts solution without inhibitor (concentration ç of Ni^{2+} = 1.22M). It can be seen (curve 2) that the addition of 4.10^{-3}M to 3.10^{-2}M sodium benzenesulfonate modifies neither the slopes b_1 and b_3 of the two asymptotes nor the partial current I_3, but diminishes the partial current I_1 at a given cathodic potential.

On the other hand, the presence of 2-butyne 1,4-diol (8.10^{-3}M; curves 3 and 4, Fig. 5) diminishes both I_1 and b_3. This is clearly shown on curve 4. The presence of this inhibitor also modifies the parameters of the impedance. It shifts indeed, toward the cathodic potentials, the limit of the polarization range within which the impedance is inductive, since this inductive character persists when the potential is −1.10 V/SCE (5). Table III gathers together the values of the elements of the equivalent circuit of the impedance obtained under the same polarization conditions as those of points C, D, E, and F in Fig. 5 in the presence of 8.10^{-3}M 2-butyne 1,4-diol in the electrolyte. At these cathodic polarizations, we can assume that reaction [I] is irreversible, and we can compare the experimental values of the impedance parameters with those that are calculated from Eq. [9], [10], [11] and which are shown in the last column of Table III. The value of β is assumed equal to the density of the nickel atoms in the (111) plane ($3.1\ 10^{-9}$ mole cm²) which forms at the metal surface during the growth of crystallites. There is a good agreement between experimental values and calculated values, except for the time-constant τ whose experimental value is systematically higher than the calculated value. These differences might be due to the fact that the hypothesis of an adsorption according to the Langmuir isotherm assumes a uniformly accessible surface for the electrode, but this condition cannot be satisfied with a textured deposit.

Conclusion

The shape of the polarization curves obtained in the absence of any convective diffusion transport, and the inductive character of the impedance at low frequencies lead to the conclusion that the electrocrystallization of nickel and cobalt occurs in several steps. By

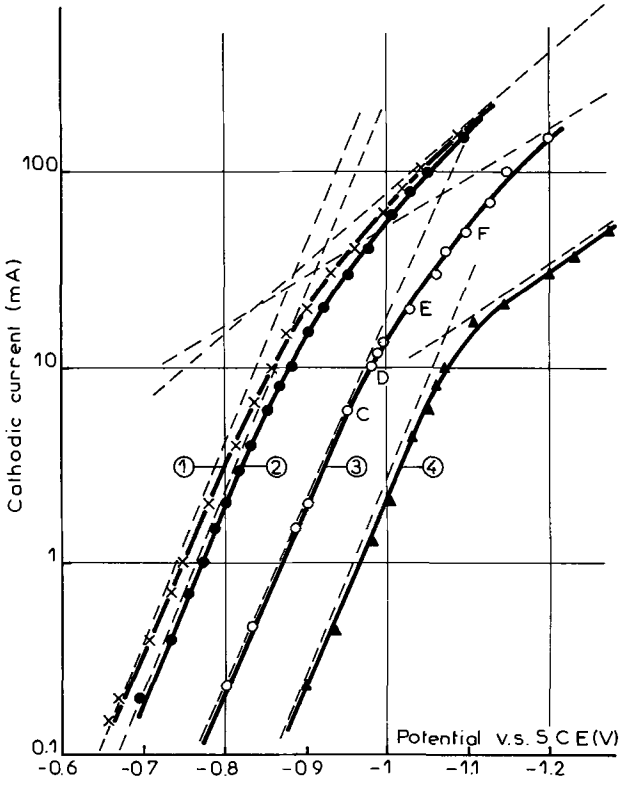

Fig. 5. Influence of organic compounds on the steady-state current-potential curve in the case of the electrocrystallization of nickel (pH = 4.5; temperature = 50° ± 0.5°C) at a rotating-disk electrode (area = 0.2 cm²). Curves 1, 2, and 3 are obtained with an electrolyte of the Watts type (concentration c of Ni^{2+} = 1.22M, rotation speed = 2000 rpm). For Curve 4: c = 0.15M. rotation speed = 9000 rpm. X Curve 1: without organic compound, ● Curve 2: with 3.10^{-2}M sodium benzenesulfonate, ○ Curve 3 and ▲ Curve 4 with 8.10^{-3}M 2-butyne 1,4-diol. The continuous line represents experimental curves and the dotted line represents partial currents deduced from Eq. [4], [5], and [6]. Polarization conditions for points C, D, E, and F are given in Table III.

calculating the elements of the equivalent circuit of the cathodic impedance, we were able to define the capacity of the electrochemical double-layer, which showed no frequency dependence, and to separate this capacity from the faradaic impedance. Unfortunately, in the case of cobalt, we could not further investigate the mechanism of the electrocrystallization, since the current-potential curve varied with the pH. On the other hand, in the case of nickel, the experimental results support a faradaic process implying two successive reactions, during which $(NiOH)_{ads}$ acts as an intermediate consumed at the electrode and not as a catalyst. Furthermore, the presence in the electrolyte of organic inhibitors, such as sodium benzenesulfonate or 2-butyne 1,4-diol, not only diminishes the capacity of the electrochemical double-layer, but also specifically modifies the rates of the two successive transfer reactions.

We hope that these two methods can be generalized for the study of the electrocrystallization of other metals. The two methods described in this article have indeed already been used for the study of the electrocrystallization of copper in an acidic solution (20).

Table III. Electrocrystallization of nickel

Comparison between experimental values and calculated values of the parameters of the electrode impedance. The polarization conditions are the same as for points C, D, E, and F in Fig. 5.

C	:	I = 6 mA	V = −0.95 V/SCE
D	:	I = 10 mA	V = −0.98 V/SCE

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

APPENDIX

We give here a detailed calculation leading to Eq. [1], [3], and [7].

$(MeOH)_{ads}$ acts as a catalyst.—Supposing that $(MeOH)_{ads}$ species cover a fraction θ of the cathodic surface, the forward reaction [I] will take place on a fraction $(1 - \theta)$, while the reverse reaction [I] and reaction [II] will occur on a fraction θ (21). Under steady-state conditions

$$K_1 (1 - \theta) [MeOH^+] = K_1' \beta\theta \quad [13]$$

Consequently

$$\theta = \frac{K_1 [MeOH^+]}{K_1 [MeOH^+] + K_1'\beta} \quad [14]$$

Reactions [I] and [II] lead to a current I obeying Eq. [15] (see Ref. 21).

$$\frac{I}{F} = K_1 (1 - \theta) [MeOH^+] - K_1'\beta\theta + 2K_2\beta\theta [MeOH^+] \quad [15]$$

Combination of Eq. [14] and [15] leads to Eq. [1]

[1]

$$I = \frac{2F K_1 K_2 \beta [MeOH^+]^2}{K_1 [MeOH^+] + K_1' \beta} \quad [1]$$

$MeOH_{ads}$ is an intermediate consumed at the electrode.—Reaction [I] (supposed here irreversible) takes place on a fraction $(1 - \theta)$ of the cathodic surface, whereas Reaction [III] occurs on a fraction θ. Under steady-state conditions

$$K_1 (1 - \theta) [MeOH^+] = K_3 \beta\theta [MeOH^+] \quad [16]$$

Consequently

$$\theta = \frac{K_1}{K_1 + K_3 \beta} \quad [17]$$

Current I is then given by Eq. [18]

$$\frac{I}{F} = K_1 (1 - \theta) [MeOH^+] + 3 K_3 \beta\theta [MeOH^+] \quad [18]$$

Equation [3] can be deduced from Eq. [17] and [18]

$$I = \frac{4F [MeOH^+] K_1 K_3 \beta}{K_1 + K_3 \beta} \quad [3]$$

According to Eq. [18], I is a function of θ and V; the faradaic impedance Z_f is consequently expressed by

$$-\frac{1}{Z_f} = \left(\frac{\partial I}{\partial V}\right)_\theta + \left(\frac{\partial I}{\partial \theta}\right)_V \frac{\Delta\theta}{\Delta V} \quad [19]$$

These two partial differentials can be calculated by differentiating Eq. [18] and using the value of θ given in Eq. [17]

$$\left(\frac{\partial I}{\partial V}\right)_\theta = -\mathbf{F}\,[\mathrm{MeOH}^+]\,\frac{K_1 K_3 \beta}{K_1 + K_3 \beta}\,(b_1 + 3b_3) \quad [20]$$

(Coefficients b_1 and b_3 are defined in Eq. [2])

and $$\left(\frac{\partial I}{\partial \theta}\right)_V = \mathbf{F}\,[\mathrm{MeOH}^+]\,(3K_3\beta - K_1) \quad [21]$$

The dependence of the superficial density $\beta\theta$ of $(\mathrm{MeOH})_{ads}$ with time is given by Eq. [22]

$$\beta\frac{d\theta}{dt} = K_1\,[\mathrm{MeOH}^+]\,(1-\theta) - K_3\,[\mathrm{MeOH}^+]\,\beta\theta \quad [22]$$

Using the following relation $d(\Delta\theta)/dt = j\omega\,\Delta\theta$ and the total differential of Eq. [22], we can obtain

$$\frac{\Delta\theta}{\Delta V} = \frac{K_1 K_3 \beta}{K_1 + K_3 \beta}\,[\mathrm{MeOH}^+]\,\frac{b_3 - b_1}{j\omega\beta + [\mathrm{MeOH}^+]\,(K_1 + K_3\beta)} \quad [23]$$

Equation [7] is readily obtained by combining Eq. [19], [20], [21], and [23], and introducing the expressions of currents I_1, I_3, and I given by Eq. [4], [5], and [6]

$$\frac{1}{Z_f} = \frac{I}{4}\left[b_1 + 3b_3 + \frac{(3I_3 - I_1)\,(b_1 - b_3)}{4\mathbf{F}j\omega\beta + I_1 + I_3}\right] \quad [7]$$

ABSTRACT

A study has been made of heat transfer in three types of internally cooled electrolytic cells employing a common nonaqueous electrolyte. The heat transfer surfaces were in part cathodic and evolved hydrogen gas. The gas evolution was utilized to promote rapid circulation of electrolyte. By varying the relative areas that were gas evolving and nongas evolving, the heat transfer coefficients through the bath side liquid film in contact with these surfaces could be estimated. The film coefficient is greatly enhanced by electrolytic gas evolution and is of the order of 2.5 to 3. Film coefficients appear to follow an exponential law, $h = k \cdot I^n$. Useful application of the effect for purposes of cell design is pointed out.

Most electrolytic processes, as conducted in real cells, evolve surplus heat which must be dissipated in one way or another. The sources of heat are of two kinds: surplus electrical energy and surplus chemical energy.

Surplus electrical energy: The net heat Q_e generated by passage of the current I is

$$Q_e = VI - \Delta H \cdot I/\mathbf{F}$$

If V is the actual cell voltage, which includes the emf E, the electrode overvoltages, and all other internal IR drops; I is the current in kiloamperes; ΔH is the heat absorbed for the over-all electrode reaction in kilojoules per gram equivalent, and 1 kj = 0.239 kcal; and $\mathbf{F}$ = 96.5 kilocoulombs per gram equivalent; then Q_e is in kilowatts, and 1 kW = 860 kcal/hr, or 3413 Btu/hr.

Key words: liquid film heat transfer, electrolytic gas evolution, film coefficients, electrolytic process, gas lift, hydrogen fluoride, potassium fluoride, pilot plant, enhanced heat transfer, scale-up self-cooling.

Surplus chemical energy.—This is the algebraic sum of all the chemical reactions (other than the electrode reactions) that also occur in the cell, *e.g.*: back reactions between anode and cathode products, and reactions between anode and/or cathode products and other materials either existing in or introduced into the cell as feed. This algebraic sum Q_c is usually exothermic.

In order to achieve a steady-state cell temperature, the total excess heat may be dissipated in a number of ways:

1. Positive difference in enthalpy between product streams and feed streams. This includes phase changes, such as partial vaporization of feed streams, including the solvent.
2. Loss of heat from cell to ambient surroundings via convection and radiation.
3. Forced rejection of heat from cell to coolants, generally via internal heat transfer surfaces.

Some large industrial cells require no internal heat transfer surfaces. In a diaphragm type chlor-alkali cell, the excess I^2R heat is balanced principally by the evaporation of water which is evolved with the chlorine and hydrogen. In a mercury type chlor-alkali cell, the excess I^2R is balanced principally by the increased enthalpy of the very large brine throughput.

Some types of cells require indirect cooling means, either internal or external to the cell. If external, the electrolyte is recycled back to the cell. In chlorate electrolysis, the electrode products NaOH and Cl_2 are allowed to react to form $NaClO_3$, and thus a large amount of excess chemical energy is released as heat. Cells of both types (internal and external cooling coils) are in common use.

Less common, but of increasing importance, are cells designed to carry out organic chemical syntheses by introducing organic feed streams which react with either or both of the electrode products as fast as they are formed. Halogenation of hydrocarbons at an anode can be conducted in this way, and even the subsequent hydrolysis of the halocarbons in the catholyte chamber, can also be conducted. The dissipation of heat in such operations can be a problem.

Assuming the cell designer is faced with the problem of providing auxiliary cooling, he has the choice of:

(*a*) Circulating the anolyte, the catholyte, or the common electrolyte if the cell is undivided, through an external heat exchanger and back to the cell. A pump is required. The engineering problems are many, and in some cases this turns out to be a difficult or expensive solution to the problem.

(*b*) Cooling the cell by providing internal heat exchangers. If gas is evolved at an electrode, the gas lift effect can be utilized for creating a strong circulation of the electrolyte. By placing the heat exchanger optimally with respect to the circulation, fairly good heat transfer can be realized. This solution dispenses with the moving parts (the pump) mentioned under (*a*).

Under (*b*), the cell designer has still another option: he might, for example, combine the separate functions of electrode and heat transfer, by cooling the electrode itself. This has two advantages:

1. It cuts cost, since no separate heat exchanger is needed, and this also conserves space.
2. The heat transfer coefficient between bath and a heat conducting surface is greatly enhanced if the surface is a gas-evolving electrode.

The idea is not new. Many patented chlorate cells (4-8) employ water-cooled cathodes, these being hydrogen evolving. In all cases, the gas evolution is utilized to promote electrolyte circulation. The fact that gas evolution promotes heat transfer is not new either and has been reported by several investigators (1, 2). The enhancement factor of the film coefficient may be in the range of 2 to 3 times.

The present authors have designed and operated, on a pilot scale, a variety of cells having cooled cathodes. These cells were built for the purpose of carrying out fluorination of hydrocarbon gases. The excess heat release was sufficiently large to create a major problem in scale-up to industrial size cells. Consequently, the heat transfer problem was studied in depth. The results of this study confirm the high enhancement factor for gas-evolving surfaces and has provided the basis for intelligent scale-up.

Experimental

In the experiments to be described, the common electrolyte approximates the composition KF·2HF (anhydrous) in liquid form at a temperature in the range 93°-110°C. The three cells used were of various shapes, rectangular and cylindrical, and, with the exception of the anodes, were fabricated entirely of carbon steel. Electrolysis of the bath resulted in depletion of its HF content, which was replenished regularly to maintain constant composition and operating bath levels. The electrodes were either parallel or concentric, and the anode-cathode gap was in the range of ½ to 1 in. Vertical height of electrodes ranged from 12 to 24 in. in the active area. The number of electrode pairs per cell ranged from 1 to 5, and these were arranged to take full benefit of the gas lift effect to promote circulation of electrolyte upward in the electrode gap. Return paths for degassed electrolyte were provided, as illustrated in Fig. 1-3.

During electrolysis, hydrogen gas (containing some HF vapor corresponding to the vapor pressure of the bath) was evolved at the cathodes. No gas whatever was discharged at the anode into the gap. The anode processes that did take place are immaterial to this heat transfer study. In some cases the cathodes were water-cooled; in others cooled with boiling methanol. Noncathodic heat transfer surfaces were cooled similarly.

With a power supply of 1000A d.c. total, cathode current density was varied over the range of 80 to 200 A/ft^2. Current efficiency was in all cases substantially 100%.

The cells were provided with numerous thermocouples for temperature measurement of bath, coolant, and metal wall on cathodic heat transfer surfaces. Coolant flow rates were accurately measured. In some cases, fluid bath velocities were measured directly by means of a pitot tube.

By varying the percentage of the total cooling surface that was cathodic, the over-all heat flux through

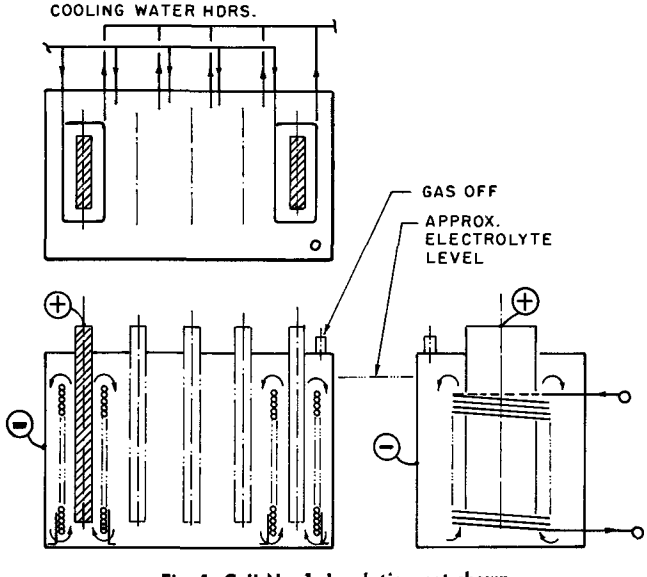

Fig. 1. Cell No. 1. Insulation not shown

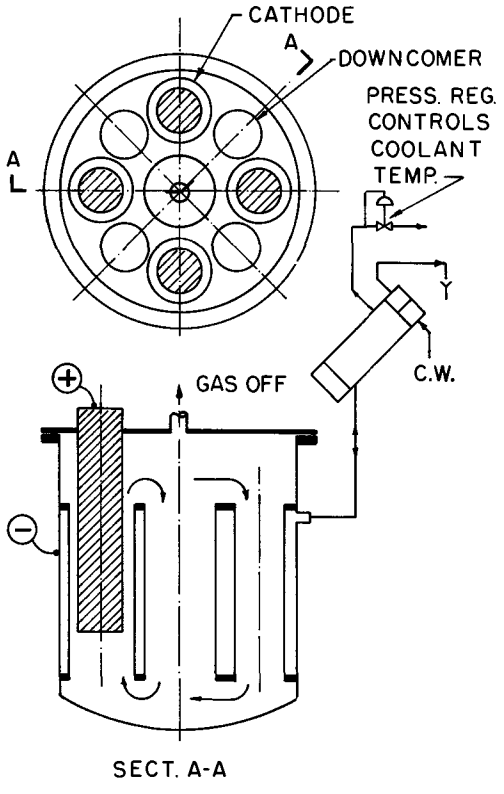

Fig. 2. Cell No. 2. Insulation not shown

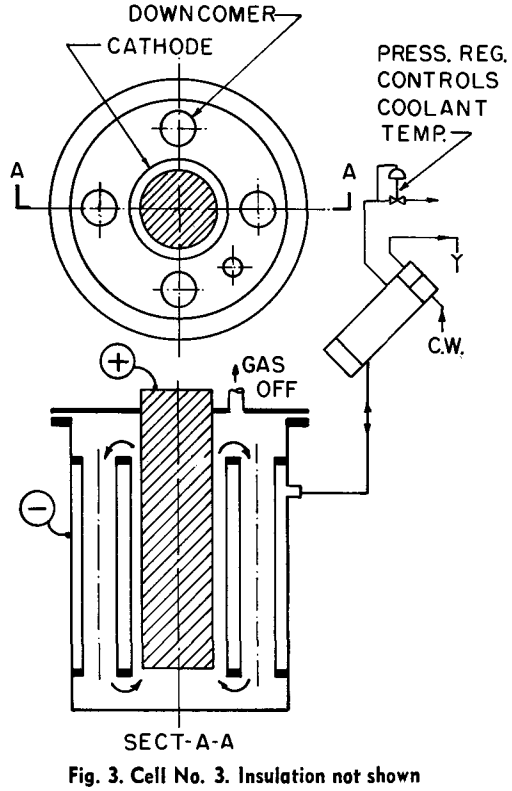

Fig. 3. Cell No. 3. Insulation not shown

cathodic and noncathodic surfaces could be differentiated, although these two paths for heat transfer were in parallel. Although the cell bodies were thermally insulated, some heat was lost to the surroundings, and this could be estimated with sufficient accuracy to permit fairly accurate estimates of the actual heat transferred through the cooling surfaces within the cell. See Appendix.

Film coefficients on the coolant side, and thermal conductivity of the steel walls of the heat transfer surface could be readily estimated. From these, and the over-all coefficient, the film coefficients on the bath side were calculated. Both over-all U's and bath-side film coefficients were found to be a function of cell current. Cell current, of course, determines H_2 gas evolution and indirectly, the bulk fluid velocity past the heat transfer surface. Schematic diagrams of the three types of cell used are shown in Fig. 1-3.

Results

Series I.—Rectangular Cell No. 1 contained five anode-cathode pairs. Cathodes of ⅜ in. OD tubing were wound into rectangular coils, adjacent coils touching. Cathodes were independently water cooled. These coils could serve either as gas evolving or nongas evolving coolers. Results are summarized in Table I.

Discussion.—1. Because these tubes touched, the areas used in calculating the U's are circumferential tube areas. It is possible that the effective area for heat transfer on the bath side is somewhat less, and the effective U's somewhat greater than shown in Table I. Effective current densities could also be somewhat higher for the same reason.

2. In any event, the enhancement ratio $R = h_c/h_{nc}$ is of the order 3.0.

Series II.—Cylindrical Cell No. 2 contained four cylindrical electrode pairs. One central and four surrounding pipe downcomers provided for return circulation and additional nongas evolving cooling surface. The central cathode and the downcomers were cooled with boiling methanol. The cell was operated with all downcomers open.

Series III.—Like Series II, but operated with the central downcomer open, all others closed.

The over-all U's at various current levels are summarized in Tables II and III for Series II and III, respectively.

Table I. Summary, cell No. 1, Series I

Subscript c, cathodic (gas evolving); nc, noncathodic (nongas evolving). All values of U and h refer to bath-side areas (geometric) in Btu/ft², hr, °F. I, amperes. i, A/ft². Average bath temperature, 202°F.

3	205.0	475	92.3	64.94	8.33	7.80
	Average					6.945 ± 0.308

Discussion.—1. On the assumption that U is an exponential function of I of the form

$$U = K \cdot I^n \qquad [1]$$

the data for Series II was processed for a least square best fit which gave $K = 8.736 \pm 0.892$ and $n = 0.2808 \pm 0.1379$.

The data for Series III was unsuitable for a meaningful regression analysis, since most of the data was taken at 950A, with insufficient data at low amperage.

In Series IV and V there is ample evidence for the exponential relation, with $n = 0.344$ approximately. We have therefore calculated the K's for Series II and III on this basis, as shown in Tables II and III. The average values of K are as follows:

Series	% Cathodic	K ($n = 0.344$)
II	32.9	5.780
III	49.4	6.945

If C = the fraction cathodic, and K_c and K_{nc} equal the values of K for cathodic and noncathodic conditions, respectively

$$K = C \cdot K_c + (1 - C)\, K_{nc} \qquad [2]$$

Solving the two sets of data gives

$K_c = 10.535$
$K_{nc} = 3.455$
$R_u = K_c/K_{nc} = 2.96$

where R_u is the enhancement ratio of the over-all coefficient U.

2. It is now possible to re-analyze the data, assigning a calculated heat flux through the cathodic and noncathodic areas independently. This results in the following values for the bath-side film coefficients

$$h = k \cdot I^{0.344}$$

Cathodic	k_c av	15.38
Noncathodic	k_{nc} av	5.43
R_h		2.83

Thus, the enhancement ratio for the bath film coefficient, $R_h = 2.83$ as compared to the over-all enhancement ratio $R_u = 2.96$. This confirms the known fact that the bath film is the controlling factor in heat transfer in these cells.

Series IV.—Large cylindrical cell No. 3 contained a single cylindrical electrode assembly and four peripheral pipe downcomers for return circulation and additional nongas evolving cooling surface. The central cathode and the downcomers were cooled with boiling methanol. The cell was operated with all downcomers open.

Table IV. Summary, cell No. 3, Series IV

Cooling surface, 43.15% cathodic. All downcomers open. Over-all U refers to the bath-side area, Btu/ft², hr, °F. I, amperes. i_c, A/ft² on cathode. Bath temperature T, as noted, °F.

Test No.	T_1	I	i_c	U	Log I	Log U	U calc.
7	219.7	900	224.5	68.83	2.9542	1.8378	69.30

Extrap.	210	(300)		(46.2)	2.4771	(1.6646)	45.67

Regression analysis gives log $K_u = 0.72018 \pm 0.01267$.
$K_u = 5.2500 \pm 0.155$, n, $= 0.37933 \pm 0.02462$.
Best fit: $U = 5.250 \cdot I^{0.3793}$.

Table V. Summary, cell No. 3, Series V

Cooling surface, 80.00% cathodic. All downcomers plugged. Circulation in electrode gap only. Over-all U refers to the bath-side area, Btu/ft², hr, °F. I, amperes. i_c, A/ft² on cathode. Bath temperature, T, as noted, °F.

Test No.	T_1	I	i_c	U	Log I	Log U	U calc.
6	217.9	600	149.7	80.3	2.7782	1.9047	80.8
2	211.9	500	124.8	74.1	2.6990	1.8698	73.8
4	210.8	400	99.9	67.4	2.6021	1.8287	66.2
3	211.7	300	74.8	56.8	2.4771	1.7543	57.4

Regression analysis gives log $K_u = 0.52967 \pm 0.00690$.
$K_u = 3.386 \pm 0.054$, $n = 0.49626 \pm 0.03069$.
Best fit: $U = 3.386 \cdot I^{0.4963}$.

Series V.—Similar to Series IV but with downcomers plugged. Restricted circulation both ways in the gap was still possible and confirmed by observation.

The over-all U's at various current levels are summarized in Tables IV and V.

Discussion.—In Fig. 4, log U is plotted against log I, for Series IV and V. Average values of U at each value of I are used. The slopes of these lines give n for the equation

$$U = K \cdot I^n$$

For Series IV, $n = 0.379$; for Series V, $n = 0.496$.

The regression line values of U, as read from Fig. 4, for several currents are given in Table VI.

These data are plotted in Fig. 5. The lines are extrapolated to 100% cathodic current to give values of U_c. With these values of U_c, the heat flux on the cathodic cooling surfaces can be calculated for Series V, and hence the bath side coefficients, as follows:

I, amperes	300	400	500	600
h_c (cathodic)	110.9	124.8	130.8	141.3

A plot of log h_c *vs.* log I in Fig. 6 gives the relation

$$h_c = k_c \cdot I^n$$

Table VI. Regression line values of U

Series % Cathodic		IV 43.15%	V 80.0%	U_c 100.0
I	300	45.67	57.40	63.7
	400	50.90	66.18	74.5
	500	55.50	73.84	83.8
	600	59.30	80.80	93.5
	700	63.00	87.40	100.7

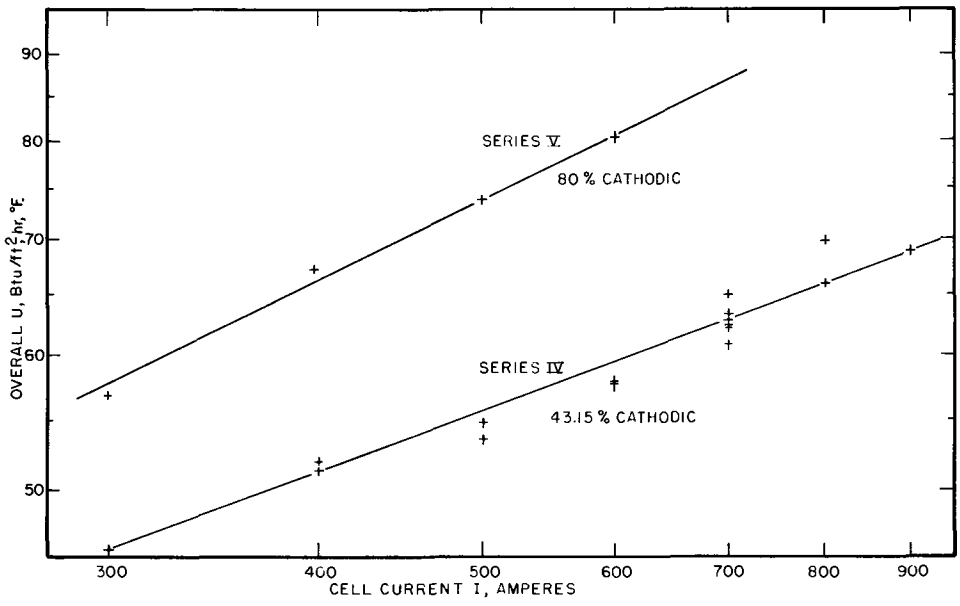

Fig 4. Over-all heat transfer coefficient U vs. current in cell No. 3. Series IV, 43.15% cathodic. Series V, 80.0% cathodic.

and with the best value of $n = 0.344$, the average value of k_c is 15.68.

The data of Series IV were then re-worked making various assumptions as to the value of R. The heat flux through the cathodic cooling surfaces for these values of R then yielded the corresponding values of k_c, the average values of which (for 19 runs) were as follows:

Assumed R	1.5	2.0	2.5	3.0	3.5	4.0
Avg k_c	12.10	13.91	15.31	16.50	17.48	18.30
Avg k_{nc}	8.06	6.95	6.12	5.50	4.99	4.575

A plot of this data is shown in Fig. 7.

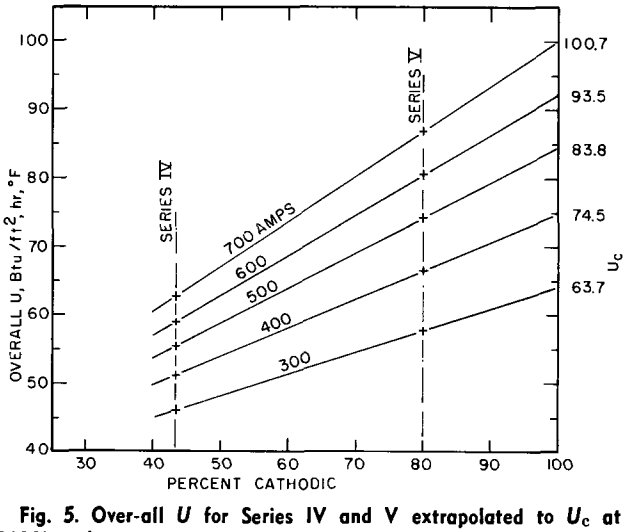

Fig. 5. Over-all U for Series IV and V extrapolated to U_c at 100% cathodic surface.

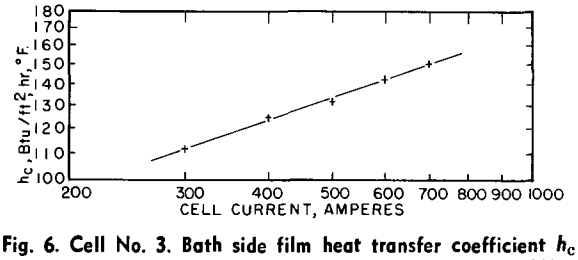

Fig. 6. Cell No. 3. Bath side film heat transfer coefficient h_c in cathodic region. Equation of this line is $h_c = 15.68 \cdot I^{0.344}$.

Assuming that the k_c is the same for Series IV (unrestricted circulation) and Series V (restricted circulation), and dependent only on $I^{0.344}$, then the k_c of 15.68 derived above, corresponds to an R value of 2.68 for Series IV. Since this assumption may not be strictly accurate, we can say that the enhancement ratio for the 19 runs of Series IV was at least 2.68.

Summary

The primary object of this paper was to present evidence that electrolytic gas evolution enhances the liquid film heat transfer coefficient by a factor of the order of 2.5 to 3.5, depending on the rate of gas evolution in the gap.

For purposes of design and scale-up, we have shown that the over-all heat transfer in a cell provided with a means of internal cooling, chiefly depends on two factors: the per cent of the total area that is gas evolving, and the rate of gas evolution, which is proportional to current.

Since the measurements of the bath-side film coefficients were made in several quite different types of cell and electrode geometries, it is worthwhile to see

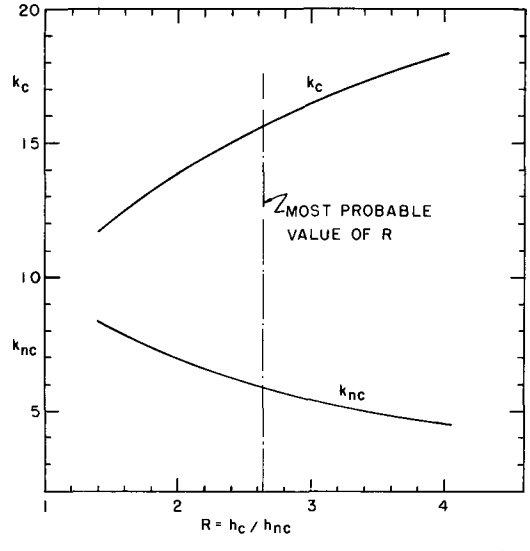

Fig. 7. Series IV runs. Values of k in the equation $h = k \cdot I^{0.344}$ for various assumed values of $R = h_c/h_{nc}$. If $k_c = 15.68$, as in Series V, the most probable value of R for Series IV is 2.64.

Table VII. Comparison of film coefficients in three different types of cell at the same current density, calculated from our data

i_c is cathodic current density, A/ft². h is bath film coefficient, Btu/ft², hr, °F. Subscript c, cathodic, gas evolving; nc, noncathodic, no gas evolved. R is enhancement ratio. h_c/h_{nc}.

Cell No.	Electrodes	Coolant	$i_c = 203$			$i_c = 101.5$		
			h_c	h_{nc}	R	h_c	h_{nc}	R
1	Multiple	Water	181.5	60.0	3.02	143.5	47.3	3.02
2	Multiple	CH_3OH	167.3	59.2	2.83	133.2	47.2	2.83
3	Single	CH_3OH	163.0	61.7	2.64	128.0	48.5	2.64
Average			170.6	60.3	2.83	134.9	47.7	2.83

how these coefficients compare. It is probably best to make the comparison at some arbitrary current densities on the gas-evolving electrode, as shown in Table VII. The concordance is quite good.

Effect of fluid velocity on film coefficient.—A direct measurement of velocity in the nongas evolving downcomers of No. 2 cell, during Series II runs, at a cathode current density of 194 A/ft², indicated a maximum velocity along the center line of a 5.5 in. ID pipe of 1.40 ft/sec, which when corrected for velocity profile, gives an average velocity of about 1.1 ft/sec.

The properties of the fluid were as follows:

ρ = 118 lb/ft³ (known)
μ = 14.2 cp = 0.00955 lb/ft-sec = 34.4 lb/ft-hr (known)
C_p = 0.685 (estimated)
k = 0.14 (estimated)

from which Re = 6230 and Pr = 169.

Using the Dittus-Boelter equation

$$Nu = 0.023\ Re^{0.8}\ Pr^{0.4} \qquad [4]$$

$$hD/k = 194.4 \text{ and } h = 59.5$$

This value of h is consistent with the h_{nc} shown in Table VII, column 1.

When the fluid velocities are not known, as in the case of a proposed cell design, these velocities can usually be calculated with sufficient accuracy. The principle involved (3) is to balance the gas lift head against the algebraic sum of the friction heads in the complete circuit of the circulating electrolyte.

Conclusions

1. Heat transfer from bulk electrolyte to a metal cooling surface is greatly enhanced when the surface is a gas evolving electrode. For the particular system studied, the enhancement ratio of the fluid film heat transfer coefficient is in the range 2.5-3.0.

2. Actual film coefficients, either gas evolving or nongas evolving, are affected by fluid velocity in the usual predictable manner. The gas lift effect can be utilized to promote circulation, hence fluid velocity. Since the gas evolved is proportional to the current, the heat transfer coefficients depend on the current exponentially, that is, $h = k \cdot I^n$. For the particular cells used in this study, $n = 0.344$ approximately.

3. Self-cooling of electrodes appears to be an economical way of cooling cells internally in those cases where cell cooling is necessary.

Manuscript submitted Jan. 25, 1971; revised manuscript received *ca.* May 17, 1971. This was Paper 172 presented at the Washington, D. C., Meeting of the Society, May 9-13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

APPENDIX

For each run, a careful heat balance was made to determine the total heat generated within the cell. Call this Q_1. It involves seven items in all. Let Q_2 be the observed heat removed by the coolant. The difference $Q_3 = Q_1 - Q_2$ is the heat lost to the surroundings. This is a small number, around 10% of Q_1.

Q_3 was then apportioned to Q_4, the loss from cell surfaces at bath temperature to ambient, and Q_5, the loss from cell surfaces at coolant temperature to ambient, in proportion to area and ΔT to ambient. Only Q_5 passes through the internal heat transfer surfaces. It was usually less than 5% of Q_1.

The total heat passed by the total heat transfer surfaces is $Q_6 = Q_2 + Q_5$. The total flux is Q_6 divided by ΣA. The over-all $U = Q_6/\Sigma A \cdot \Delta T$. The method of apportioning the total heat flux through nc and c surfaces is fully explained in the text.

Principles and Applications of A-C and D-C Rapid Polarography with Short Controlled Drop Times

A. M. Bond*

Department of Inorganic Chemistry, University of Melbourne, Parkville 3052, Victoria, Australia

ABSTRACT

The techniques of a-c and d-c rapid polarography employing short controlled drop times and fast scan rates of potential are discussed in detail. Particular emphasis is given to comparing the methods with conventional polarography in electroanalytical applications. The shapes and main characteristics of both a-c and d-c polarograms are essentially the same as in conventional polarography. Any differences encountered generally arise from the different time scales of the two techniques. Reversible, quasi-reversible, and irreversible electrode processes are considered. In analytical applications, the rapid methods are superior to conventional polarography because of the considerable time saving gained from the fast scan rates of potential. The reproducibility is also marginally better. In fundamental studies, such as in the characterization of electrode processes, rapid polarography is also shown to be particularly useful. The analogy of behavior akin to a streaming mercury electrode is considered, as are other phenomena and characteristics introduced by having short controlled drop times. It is concluded that the technique could be given wider usage than presently accorded.

One of the disadvantages of conventional polarography compared with other analytical methods has always been that the natural drop times of the dropping mercury electrode (DME)—usually between 2 and 8 sec—necessitate reasonably slow scan rates of potential, and the time required for recording a polarogram is correspondingly long. Scan rates of potential must be slow for two major reasons: (*A*) to avoid violating the constant potential-current conditions assumed for theoretical purposes, and (*B*) to provide a high degree of precision of measurement. Each drop represents one data point on the current-voltage curve, and especially over the steeply rising portion of a d-c polarogram or around the peak or summit potential of an a-c polarogram, a large number of data points is necessary. Obviously, the faster the scan rate, the fewer data points on the graph and this results in a decrease in precision. Thus, even if the theoretical constant potential-current requirement did not need to be met, there would still be an excellent practical reason why the scan rate cannot be increased beyond well-defined limits when natural drop times are used.

In electroanalytical methods with stationary electrodes, such as the hanging drop mercury electrode, platinum electrode, glassy carbon electrode, *etc.*, fast scan rates of potential are used routinely. The theory for stationary electrode voltammetry includes terms for the scan rate of potential and so restriction given as (*A*) above for polarography does not apply, nor does that given as (*B*), because a continuous current-voltage curve is obtained. Similarly, with streaming (mercury) electrodes, no restriction is placed on current-voltage curves. However, although voltammetric methods may be used with considerable time saving, they have several well-established difficulties and disadvantages compared with the polarographic method (1). Consequently, the dropping mercury electrode technique still remains in widespread use, especially in analytical studies, and in most cases voltammetry is used only when the polarographic method is inapplicable, *e.g.*, when the latter is not sufficiently sensitive, does not cover suitable potential range, *etc.*, or alternatively for theoretical or other reasons, where a stationary or streaming electrode should give different results from a DME, *i.e.*, involve a different product, different electrode mechanism.

If, for the polarographic method, time saving is required through shortening of the scan rate, then the only real possibility is shortening of the drop time. In principle this could be achieved by using suitable glass capillaries and increased lengths of mercury columns; but a much more convenient method is to mechanically knock or remove the mercury drop at selected time intervals to produce a short controlled drop time. This has been the preferred technique, and the one employed here.

In the theoretical or philosophical sense the drop time could be shortened indefinitely until the mercury drops become so close together that a streaming mercury electrode, rather than a dropping mercury electrode is obtained. Thus at some drop time or range of drop times, a transition between a DME and a streaming electrode should be encountered. The nature of electrode processes and the physical characteristics of a short drop time DME itself could also be expected to undergo certain transitions as the drop time is decreased.

Various features of short controlled drop time d-c polarography have been already reported in the literature [see Ref. (1)-(8), for instance]. Relatively little application of the rapid technique to a-c polarography has been made until recently, apart from these laboratories (9), although recent publications (8-11) show growing interest.

In addition to the obvious ones of time saving there are practical advantages in use of controlled drop times, if sufficiently short. Therefore experimental findings on the so-called "rapid" a-c and d-c polarographic methods in the drop time range 0.16 to 0.32 sec are presented critically. In particular, a detailed comparison and discussion of advantages relative to the conventional polarographic method are given. However, the outline of work based on results obtained in these laboratories over a number of years is deliberately comprehensive, and includes an account of the transition towards streaming mercury electrode behavior, the sensitivity of the method in the analytical sense and the changes in electrode processes relative to those obtained with conventional polarography.

Experimental

All chemicals used were of reagent grade purity. All measurements were made at 25°C, unless otherwise stated. Polarograms were obtained using the

* Electrochemical Society Active Member.
Key words: alternating and direct current rapid polarography.

Metrohm Polarecord E 261. A-C polarography was carried out using the Metrohm A-C Modulator E 393 with an applied a-c voltage of 10 mV, rms at 50 Hz. Rapid polarographic techniques with drop times between 0.16 and 0.32 sec for both the a-c and d-c work were obtained using Metrohm Polarographie Stand E 354. The ohmic *IR* drop was compensated for in the d-c polarography, using Metrohm *IR* Compensator E 446 and the three electrode polarographic method. No *IR* compensation was undertaken in the a-c polarography.

Results and Discussion

Recording, damping, and maximum scan rates of potential.—With conventional a-c and d-c polarography scan rates of potential are usually in the range 5-15 min per volt, depending on the drop time and accuracy of measurement required. Because of the large current fluctuations associated with each drop during the considerable period of growth, recorder damping is frequently necessary, particularly with low concentrations of depolarizer, and with a-c polarography (12). The possibility of distortion of the wave shape caused by damping must always be considered; however, with slow scan rates of d-c potential used with conventional d-c and a-c polarography, distortion is usually not significant.

In the case of rapid polarography, with an extremely short drop time, very little time is available for growth of the mercury drop. Hence current fluctuations are small and damping is completely unnecessary even with the lowest detectable concentrations of depolarizer. Figure 1 shows this with respect to a-c and d-c polarography at low concentrations. The removal of the need for damping is an extremely convenient feature of rapid polarography and facilitates ready measurements with minimum possibility of recorder distortion.

The recorder used in this work was an X-Y recorder with a response time of 1 sec for full scale deflection. This is by no means the fastest X-Y recorder available

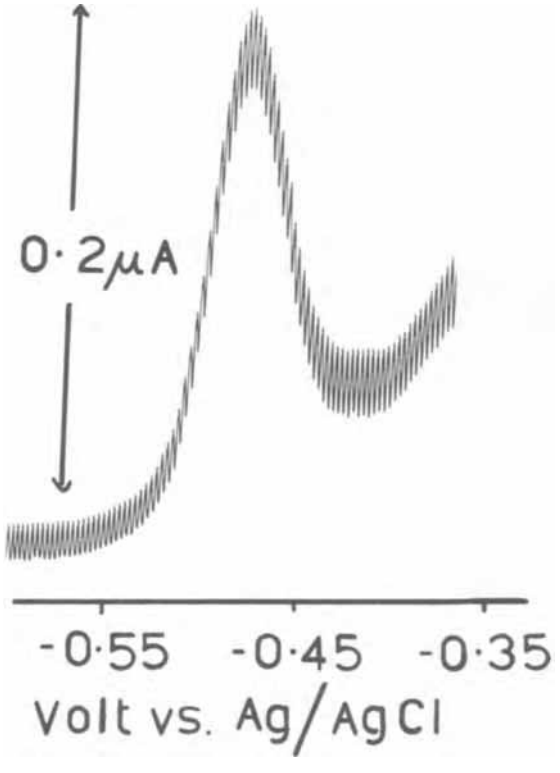

Fig. 1a. Rapid a-c polarogram of 2 x 10^{-5}M rhodium(III) in 0.02M NaBr/4M $HClO_4$. Scan rate of d-c potential is 0.5V per min. Zero damping is applied.

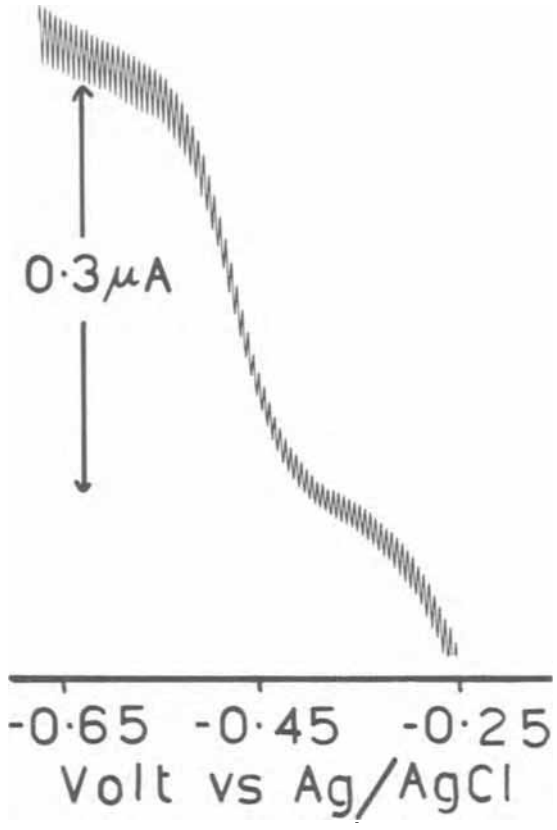

Fig. 1b. Rapid-dc polarogram of same solution as in Fig. (1a). Scan rate of d-c potential is 1.0V per min. Zero damping is applied.

but it is a typical response time for use in polarographic studies and the same as that used previously to consider the influence of scan rate and damping in a-c polarography (12). For rapid polarography, damping other than that inherently present in any recorder, is not used and damping is unlikely to give rise to recorder distortion, but scan rate could. Recorder distortion would certainly be encountered if $di/dt >$ response time of recorder. The equation of a reversible d-c wave is given by

$$E = E_{1/2^r} + \frac{RT}{n\mathbf{F}} \ln\left(\frac{i_d - i}{i}\right) \qquad [1]$$

The equation for a reversible a-c wave, provided the a-c voltage is sufficiently small, can be expressed as

$$E = E_{1/2^r} + \frac{2RT}{n\mathbf{F}} \ln\left\{\left(\frac{I_p}{I}\right)^{1/2} \pm \left(\frac{I_p - I}{I}\right)^{1/2}\right\} \qquad [2]$$

where E = d-c potential of the dropping mercury electrode, $E_{1/2^r}$ = reversible d-c half-wave potential, i and I are the direct and alternating current respectively, and i_d and I_p are the limiting direct current and maximum alternating current respectively. Other symbols are those used conventionally.

The shape of both a-c and d-c polarograms is governed by many variables. However, the gradient of current-voltage curves is in general greatest for reversible electrode processes where the steepness or gradient is directly proportional to the number of electrons involved in the charge transfer. Hence, in considering the maximum possible scan rate attainable without distortion of the wave, only equations for the reversible electrode process need be considered and these are the ones described by Eq. [1] and [2].

The maximum scan rate recordable can therefore be calculated as follows. For d-c polarograms

$$\frac{di}{dt} = \frac{di}{dE} \times \frac{dE}{dt} = \frac{di}{dE} v \qquad [3]$$

where $dE/dt = v$, the scan rate of d-c potential. The maximum value of $di/dE = (di/dE)_{max}$ occurs where $i = i_d/2$. Calculating di/dE from Eq. [1] and substituting $i = i_d/2$ into the expression gives

$$\left(\frac{di}{dt}\right)_{max} = -0.25\, i_d \left(\frac{n\mathbf{F}}{RT}\right) v \qquad [4]$$

Assuming i_d to be equal to the full scale of the recorder, which is close to the condition usually employed in experimental conditions, then at 25°C it follows that $(di/dt)_{max} = -9.74\ nv$ full scale deflections per sec. Consequently $(di/dt)_{max}$ will be less than the response time of recorder with a full scale deflection of 1 sec if $-9.74\ nv \leq 1$. That is, provided the scan rate is less than about $100/n$ mV per sec, no recorder distortion should be encountered in rapid d-c polarography.

With a-c polarography, using the same calculation procedure, it is found as shown previously (12) that

$$\left(\frac{dI}{dt}\right)_{max} \text{ is approximately } 0.4\, I_p \left(\frac{n\mathbf{F}}{RT}\right) v \qquad [5]$$

and therefore at 25°C, $(dI/dt)_{max} = 15.6\ nv$ full scale deflections/sec, which will be less than the response time of a recorder with a full scale deflection of 1 sec, if $15.6\ nv \leq 1$. Again, provided the scan rate is less than about $60/n$ mV per sec, no recorder distortion should be encountered in rapid a-c polarography.

Experimentally, results were found to be in excellent agreement with this theoretical treatment, and for $n = 1$, 2, or 3 it was found that scan rates of up to 30 mV per sec with rapid d-c polarography and 20 mV per sec with a-c polarography, could be used without any distortion. Furthermore, scan rates of 50 mV per sec were tried with $n = 1$ [$Tl(I) + e \rightleftarrows Tl(O)$], and with $n = 3$ [$In(III) + 3e \rightleftarrows In(O)$]; with the case of $n = 3$, distortion was observed as theoretically predicted. Figure 2 shows rapid a-c polarograms for $Tl(I)$ ($n = 1$) in 1M NaCl for various scan rates up to 50 mV per sec, and they can be seen to be of the same height. For comparison, Fig. 3 shows the "apparent" peak height of the $In(III)$ ($n = 3$) electrode process at the same scan rates. The recorder distortion at the highest scan rates can be seen.

In view of the above argument, if a normal X-Y recorder with a full scale deflection of 1 sec is to be used, the maximum scan rate of d-c potential that can be used satisfactorily is 20-30 mV per second if distortion is to be avoided. With a drop time of 0.16 sec this means that approximately 5 to 8 mV is covered per drop, which is about the minimum necessary if

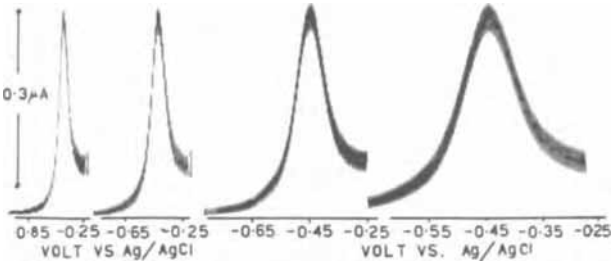

Fig. 2. Recording of a rapid a-c polarogram for the electrode process Tl(I) + e ⇌ Tl(O) in 1M NaCl at various scan rates of d-c potential. *(Right to left)* (a) 0.5 V/min (8.3 mV/sec), (b) 1.0 V/min (16.7 mV/sec), (c) 2.0 V/min (33.3 mV/sec), (d) 3.0 V/min (50.0 mV/sec). Concentration of thallium(I) is 8×10^{-5}M.

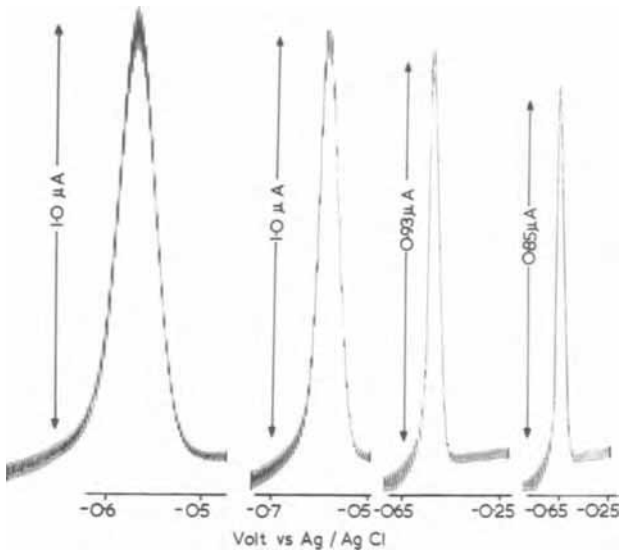

Fig. 3. Recording of a rapid a-c polarogram for the electrode process In(III) + 3e ⇌ In(O) in 1M NaCl at various scan rates of d-c potential. *(Left to right)* (a) 0.5 V/min (8.3 mV/sec), (b) 1.0 V/min (16.7 mV/sec), (c) 2.0 V/min (33.3 mV/sec), (d) 3.0 V/min (50.0 mV/sec).

marked loss in precision, due to lack of data points, is to be avoided in recording a polarogram. Hence, in the practical as well as theoretical sense, there is no advantage in using faster response recorders than the normal X-Y type, unless even shorter drop times than 0.16 sec are used. With a scan rate of 20 to 30 mV per sec, a complete a-c or d-c polarogram can be recorded in about 10 sec. In these laboratories, slower speeds of d-c scan rate are normally used than this maximum value. In routine analysis, where i_d and I_p values are the only parameters of interest, a scan rate of 1V per min is generally used. In electroanalytical applications where potential needs to be measured, the scan rate used is 0.5V per min. These scan rates still allow complete polarograms to be recorded well inside a minute, which is considerably faster than the conventional polarographic method. However, scan rates of up to 3V per min were used successfully when a glass DME was used in relatively concentrated glass corrosive hydrofluoric acid (10).

Reproducibility.—With any technique, reproducibility and precision of results are always of extreme importance. With the experimental arrangement used in these laboratories, working with a scan rate of d-c potential of 0.5V per min, six research workers (including the author) have always found that the reproducibility of the d-c i_d value is better than 0.5%, and that of the a-c I_p value is better than 1%. This reported reproducibility is based on at least six results for each of more than 100 solutions. For a full-scale deflection of 250 mm on the current axis of the X-Y recorder, a range of 2 to 3 mm has been usually encountered with i_d values and 2 to 5 mm with I_p values. Reproducibility of i_d and I_p values has been found to be marginally better than the conventional polarographic method, using a much slower scan rate of d-c potential (0.5V per 12 min), and a natural drop time of between 2 and 5 sec.

Measurements of the d-c $E_{1/2}$ values and a-c summit or peak potentials, E_s, have been carried out on even more systems by the same six workers. Attempting to read potentials to 0.2 mV, mean deviations for $E_{1/2}$ have been found to be in the range 0.9 to 1.1 mV; a-c E_s values on reversible systems have always been considerably superior, showing mean deviations of 0.6 to 0.8 mV. The reproducibility of potential parameters

as with current parameters, has always been found to be marginally better with the rapid method, using controlled drop time, than with the conventional polarographic method.

All results show conclusively that the considerable time saving obtained with the rapid polarographic method is not gained at the expense of reproducibility or precision, as is often the case when an attempt is made to increase the rate of measurement. In fact, an improvement in these vital factors is observed, making the technique highly attractive from two points of view, *viz.*, speed and reproducibility.

Dependence of i_d and I_p on Various Parameters

Dependence upon mercury column height and drop time.—Rapid d-c polarography.—The Ilkovic equation, $i_d = kcnm^{2/3}t^{1/6}D^{1/2}$, where i_d is the limiting or diffusion current, k is a constant, c is the concentration of depolarizer, n is the number of electrons involved in the charge transfer, m is the flow rate of mercury, t is the drop time, and D is the diffusion coefficient of the depolarizer, has been shown to be valid over drop times ranging from those used with the conventional DME down to the millisecond region (3, 7). In the drop time range of 0.16 to 0.32 sec, the predicted dependence of i_d on n, c, m, t, and D was found, and the validity of the Ilkovic equation with short controlled drop times was confirmed. Thus, this equation can be used for discussion purposes in this and subsequent sections.

As the Ilkovic equation is obeyed, it follows that increasing the mercury column height at constant drop time increases the flow rate of mercury and i_d increases accordingly.

The dependence upon $t^{1/6}$ predicted by the Ilkovic equation would indicate that the decrease in i_d, going from a drop time of 3 sec, say, in the conventional method, to $t = 0.16$ sec in the rapid method, would not be particularly large, because with $t = 3$ sec, $t^{1/6} = 1.2$ sec$^{1/6}$, and with $t = 0.16$ sec, $t^{1/6} = 0.74$ sec$^{1/6}$. At the shorter drop time of the rapid method, the value of $m^{2/3}$ is also decreased compared with the natural drop time. Over-all, the value of i_d with the rapid d-c method is therefore predicted to be slightly less for measurements made with the same concentration of depolarizer, and experimentally this has been confirmed on all systems measured. Increase in drop time at constant mercury column height over the drop times 0.16, 0.20, 0.24, 0.28, and 0.32 sec also increases i_d, as would be expected.

Rapid a-c polarography.—The value of I_p in a-c polarography is given by the expression

$$I_p = \frac{n^2 \mathbf{F}^2 AC\ (\omega D)^{1/2}\ \Delta E}{4RT} \sin\left(\omega t' + \frac{\pi}{4}\right)$$

where A = area of electrode, ω = angular frequency, ΔE = amplitude of applied alternating potential, t' = time. Other symbols are as used before.

The area of the electrode, A, is proportional to $m^{2/3}t^{2/3}$ and with natural drop time this is a constant, independent of mercury column height. Thus I_p is dependent only upon the particular capillary used with conventional a-c polarography, and not the mercury column height. However, with rapid a-c polarography, dependence on column height is predicted because t is now a constant, and as the height of mercury increases, $m^{2/3}t^{2/3}$ increases and therefore I_p does also. In fact, with t a constant, a similar dependence to d-c polarography should be found, and this is found experimentally.

The a-c dependence on $t^{2/3}$ rather than on $t^{1/6}$ as in d-c polarography would suggest that a-c currents found with the rapid polarographic method would be substantially less than with conventional a-c polarography. Taking the previous example of a drop time of 3 sec in the conventional method, gives a value for $t^{2/3}$ of 2.1 sec. By comparison, for a value of 0.16 sec in rapid polarography, $t^{2/3} = 0.29$ sec. This calculation illustrates that a marked difference in current magnitudes is expected. Experimentally, in agreement with theory, considerably lower currents are observed with the short drop time of rapid a-c polarography, and this lowers the concentration detection limit of the method compared with that of the conventional a-c method. Further discussion of this is given in the next section.

Increase of drop time at constant mercury column height for the values 0.16, 0.20, 0.24, 0.28, and 0.32 sec increases A, and hence I_p increases with increasing drop time as would be expected.

Dependence on concentration of depolarizer detection limits.—Figure 4 shows plots of i_d and of I_p *vs.* concentration of depolarizer for rapid and conventional polarography with both the a-c and d-c methods. The electrode process considered is

$$Sn(II) + 2e \rightleftarrows Sn \text{ (amalgam)}$$

in 5*M* HCl, and it is reversible (13).

In general, linear a-c and d-c plots are observed with the rapid polarographic method when the corresponding conventional method gives linear plots. However, in certain circumstances where the short drop time of the rapid polarographic method causes alterations to the electrode process (see later), it can be noted that this analogy between the rapid and conventional method does not necessarily follow.

The slightly lower currents obtained with the rapid d-c method and the markedly lower currents of the rapid a-c method, compared with their respective conventional d-c and a-c counterparts, are clearly il-

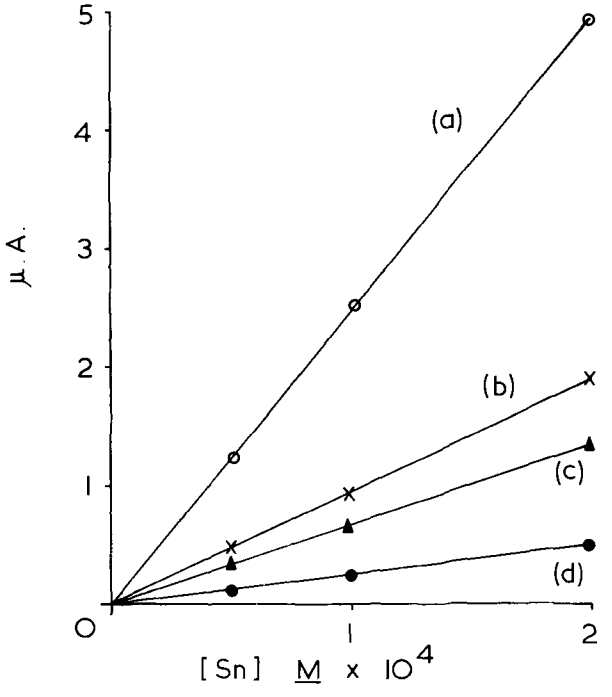

Fig. 4. Comparison of analytically used calibration curves in rapid and conventional a-c and d-c polarography for the electrode process Sn(II) + 2e ⇌ Sn(O) in 5M HCl. (a) I_p *vs.* concentration of tin using conventional a-c polarography, (b) i_d *vs.* concentration of tin using conventional d-c polarography, (c) i_d *vs.* concentration of tin using rapid d-c polarography, (d) I_p *vs.* concentration of tin using rapid a-c polarography.

lustrated in Fig. 4, which also verifies graphically discussion in the previous section on relative current magnitudes.

The limit of concentration detection of rapid d-c polarography in most cases has been found to be about $10^{-5}M$, a level very similar to that for conventional d-c polarography. In rapid a-c polarography, the limit of detection for reversible electrode processes has been found to be in the range 10^{-5} to 5×10^{-6}, somewhat less than the range 5×10^{-6} to $10^{-6}M$ found with a-c polarography. The slightly higher detection limit in rapid a-c polarography is considered to be almost entirely a function of the lower currents associated with the short drop time. The lower detection limit in the a-c polarography was primarily established by the double-layer charging current, rather than by noise, so the use of phase-sensitive a-c polarography, which discriminates against the charging current, should enable an improvement in the detection limit reported above.

Dependence on other variables.—The other variables to be considered in the Ilkovic equation are n and D. Values of D do not vary greatly with inorganic depolarizers, and as i_d is proportional to $D^{1/2}$, little variation from this term is observed from one system to another in conventional polarography. Examination of reduction of Zn(II), Pb(II), Cu(II), and Cd(II) in various electrolytes, with the same capillary at the same mercury column height showed that i_d/C is approximately the same for all systems. Furthermore, the order of magnitude of i_d/C for these systems was identical with that obtained with conventional d-c polarography.

Measurement of i_d/C values for the group Bi(III), Rh(III), Sb(III), In(III) showed i_d/C values to be in general slightly higher than for the group above, and for Tl(I) and U(VI) [$U(VI) + e \rightleftarrows U(V)$] the values were slightly lower. This trend reflects the dependence of i_d on n.

For reversible a-c electrode processes, I_p is proportional to n^2, and with the rapid a-c as well as with the conventional method, values of I_p/C are considerably greater as n increases from 1 to 3.

In summary, it can be seen that the equations describing each of i_d and I_p in terms of the various parameters, can be applied to the rapid polarographic method, with sufficient precision to enable successful predictions concerning the method and the shortened controlled drop time does not invalidate the main features of polarographic theory.

Influence of Rapid A-C and D-C Polarography on Various Electrode Processes

Charge Transfer Rate Determining

Because of the different time scale of the rapid polarographic method, an electrode process may exhibit different behavior from that observed with conventional d-c methods. Here, the simplest case is considered where charge transfer is considered as the rate determining step.

Reversible a-c and d-c electrode processes.—A reversible d-c electrode process should have certain characteristics, including the following: (*i*) The current-voltage curve can be described by the equation

$$E = E_{1/2} + \frac{2.303RT}{n\mathbf{F}} \log \frac{i_d - i}{i}$$

(*ii*) $E_{1/2}$ should be independent of concentration, (*iii*) $E_{1/2}$ should be independent of drop time.

For an electrode process with an extremely large value of the heterogeneous charge transfer rate constant, k_s, (*e.g.* $> 10^{-1}$ sec^{-1}) and for which the conventional d-c electrode process is entirely reversible, meeting all the requirements listed above, then under rapid d-c polarographic conditions the current-voltage curve has always been found to be fitted to a high degree of precision by the Heyrovsky-Ilkovic equation, given as condition (*i*).

The condition, that $E_{1/2}$ is independent of concentration, is also obeyed by reversible d-c electrode processes with rapid polarography.

The third condition that $E_{1/2}$ should be independent of drop time should theoretically mean that $E_{1/2}$ obtained should be the same as with conventional d-c polarography for reversible electrode processes. With extremely short drop times this was observed for cadmium (7). However, with measurements made on a large number of systems, this has in fact not been strictly observed in all cases in this work, although values are usually within several millivolts, and certainly always less than 10 mV. The small discrepancy can be rationalized in several ways by considering some different conditions applying at a rapidly dropping mercury electrode:

(*i*) Depletion at the mercury drop is likely to be encountered when drops are falling in such rapid succession.

(*ii*) Many of the measurements have been made in halide and other solutions where adsorption phenomena are likely to be present. $E_{1/2}$ values reflect in part the state of the solution near the electrode surface (double layer) as well as the bulk, and at shorter drop times it has been shown that adsorption phenomena are likely to be reduced (5-7, 14). Hence, slight differences in $E_{1/2}$ may arise because of the slightly different state of the electrode surface or double layer at the extremely short drop times of the rapid method.

(*iii*) Maxima present in conventional d-c polarography are frequently absent or altered with rapid polarographic conditions (5, 7). Polarograms for reduction of Sn(II) [Ref. (13)] provide an example where the maximum is eliminated. Maxima need not be removed, however, at the drop time used in this work, as is shown by the work of Wolf (2). However, the point to be made is that the measurement of $E_{1/2}$ in the presence of maxima, although reproducible, can be somewhat arbitrary as the value of i_d to be used is somewhat uncertain. Furthermore, comparison of a value of $E_{1/2}$ with that obtained on a rapid polarogram with a different maximum or no maximum may be expected to give slightly different $E_{1/2}$ values.

Delahay (15) has shown that for conventional d-c polarography with normal drop times, electrode processes with k_s values greater than 2×10^{-2} cm sec^{-1}, give rise to reversible electrode processes. Obviously, with the much shorter drop times of the rapid polarographic method, considerably higher k_s values would be needed for the observation of a reversible electrode process. Zinc(II) reduction in various media approaches quite closely to being reversible with very long drop times. However, as the drop time decreases, the departure of the electrode process from reversibility becomes more severe (16). With rapid polarography the electrode process is quasi-reversible (16, 17), and the nonreversibility of the electrode process is accentuated markedly. In fact, any electrode process which shows even a slight departure from d-c reversibility with conventional polarography will be easily recognized as being quasi-reversible on the time scale of rapid polarography. In addition to zinc, cited as an example above, tin(II) reduction in fluoride media (18) illustrates this clearly.

As with d-c polarography, the time scale of rapid a-c polarography is less than that for conventional a-c polarography. For a highly reversible a-c electrode

process the rapid a-c polarogram has exactly the same shape and characteristics as the conventional a-c polarogram (*i.e.* fits Eq. [2]). Furthermore E_s is independent of concentrations of depolarizer, has a value very close to $E_{1/2}$, and is similar in magnitude for both conventional and rapid a-c polarography. Any departure from a-c reversibility in the conventional method is also markedly accentuated at short drop times, as shown with zinc(II) and tin(II) (16-18).

Quasi-reversible and irreversible electrode processes. —As with reversible electrode processes, quasi-reversible and irreversible electrode processes exhibit the same features and are described by the same equations for both rapid and conventional a-c and d-c polarography. The time scale is again different of course, and a quasi-reversible electrode process measured by conventional methods may appear irreversible with short drop times.

The quasi-reversible electrode process in both a-c and d-c polarography is characterized by considerable drop time dependence. Hence, wave shapes and $E_{1/2}$ and E_s can be substantially altered with drop time. This contrast to reversible electrode processes occurs because with nonreversible electrode processes, kinetic terms are involved in determining many polarographic parameters. However, in the main, differences observed in rapid and conventional d-c polarograms, are just those expected because of different drop times.

An irreversible electrode process can often be described in terms of the charge transfer coefficient, α, by the equation

$$E = E_{1/2} + \frac{2.303RT}{\alpha n\mathbf{F}} \log \frac{i_d - i}{i} \qquad [6]$$

where (1)

$$E_{1/2} = E_{1/2}^{r} + \frac{RT}{n\mathbf{F}} \ln \frac{1.349\ k_s t^{1/2}}{D^{1/2}} \qquad [7]$$

If a conventional d-c polarogram fits Eq. [6], then unless the short drop time induces a different electrode mechanism, the rapid d-c polarogram has also been found to closely follow this equation. However, as shown by Eq. [7], a considerable negative shift in $E_{1/2}$ is observed. This feature in fact enables the ready distinction of nonreversible and reversible electrode processes. Furthermore, this feature certainly eliminates any possible ambiguity between, say, an irreversible electrode process with $n = 1$ and $\alpha = 0.5$ fitting Eq. [6], and a reversible electrode process with $n = 2$ being described by Eq. [1], both equations being identical with the set of parameters given. Some typical data to show the comparison of rapid and conventional d-c polarograms for irreversible electrode processes are given in Table I.

For irreversible a-c electrode processes, E_s is more negative than $E_{1/2}$, and as for d-c polarography, the wave shape is independent of k_s (19). The difference between E_s and $E_{1/2}$ depends principally on k_s, n, and α and E_s is also related to drop time in a similar fashion to $E_{1/2}$ (19). Hence with rapid a-c polarography, the behavior on decreasing the drop time gives rise to a more negative E_s value, the wave shape, however, remains essentially unaltered. Because both $E_{1/2}$ and E_s values for irreversible electrode processes are governed by the same drop time dependence, it could be anticipated that the shifts in going from conventional to rapid method would be virtually identical. Table I includes some typical experimental data which verify this and other features of rapid a-c polarography for irreversible a-c electrode processes.

Kinetically Controlled Electrode Processes—Analogy with A Streaming Mercury Electrode

In reduction or oxidation of inorganic complexes (or organic compounds), the electrode process can occur *via* a wide variety of mechanisms. By way of example, rearrangement and/or dissociation of a complex could occur prior to the charge transfer, and if both the initial complex and rearranged or dissociated complex are electroactive, two kinetically controlled pathways may be available for the electrode process.

It has been well established that a streaming mercury electrode can often discriminate between kinetically controlled and slow electrode processes. Thus, certain electrode processes observed with a dropping mercury electrode may not be apparent at a streaming mercury electrode. As mentioned in the introduction, a streaming mercury electrode can be considered as a rapidly dropping mercury electrode of extremely short drop time, and hence, as the drop time is shortened, the transition in behavior to that of a streaming mercury electrode should become apparent.

This phenomenon has been observed recently in the studies of Cover and Connery (5) on the formaldehyde system and in studies by Bond, Heath, and Martin (20, 21) on the polarographic behavior of some dithioacetylacetone complexes. In the latter work, for example it was shown that the palladium complex, $Pd(SacSac)_2$, in acetone, undergoes two reduction steps (21):

$$Pd(II) + e \rightarrow Pd(I)$$

and

$$Pd(I) + e \rightarrow Pd(O)$$

The first reduction step, $Pd(II) \rightarrow Pd(I)$, is reversible and identical using either the rapid or conventional polarographic method. The second reduction step, $Pd(I) \rightarrow Pd(O)$, however, varies substantially with the different techniques.

Figure 5 shows a comparison of rapid and conventional polarograms of $Pd(SacSac)_2$. The d-c polarogram for the complex using conventional techniques shows three distinct waves, the height of the two more negative waves being equal to the first reversible $Pd(II) \rightarrow Pd(I)$ wave. The rapid polarogram, however, shows only two reversible one-electron-reduction waves of equal height, corresponding to the consecutive reduction $Pd(II) \rightarrow Pd(I) \rightarrow Pd(O)$. Both these waves have the same $E_{1/2}$ values and electrode characteristics as the first two waves of the conventional d-c polarogram. The third wave of the conventional d-c

polarogram, not appearing on the rapid polarogram, is therefore an alternative kinetically controlled reduction process for Pd(I) $\rightarrow$Pd(O), and presumably results from partial dissociation or rearrangement of a Pd(I) complex, the product of the first electrode process. With the much shorter time scale of rapid polarography, insufficient time is available to produce a detectable concentration or the alternative Pd(I) complex, and hence only the two reversible waves are observed.

This example shows how rapid polarography can be used as a powerful tool in electrochemistry for the understanding of electrode processes, although to date it has not been used frequently in this area.

Determination of numbers of electrons in consecutive electrode processes.—In the previous section, it was shown how rapid polarography can be used in the study of electrode mechanisms. However, other electrochemical applications are also possible.

When a number of consecutive electrode processes are observed from the one complex at different potentials, and all are diffusion controlled, then according to the Ilkovic equation, the ratios of the various i_d values should be close to the ratio of the numbers of electrons involved in each electrode process. However, with the conventional method, the drop time is well known to be markedly potential dependent, as may be evidenced by the so-called electrocapillarity curves (1) commonly used to study electrode phenomena. Consequently $m^{2/3}t^{1/6}$ in the Ilkovic equation is potential dependent, and ratios of i_d values of two consecutive electrode processes, separated by a considerable potential dependence, may give a completely false idea of the relative numbers of electrons in the respective electrode processes. By contrast, in the rapid polarographic method, the drop time is controlled and therefore independent of the potential. This eliminates a variable usually encountered in polarography, and this can be useful in studies such as the one now under consideration.

Figure 6 shows a plot of drop time *vs.* potential of the conventional method in acetone, and Fig. 7 shows a conventional d-c polarogram for reduction of the complex RuNOCl(SacSac)$_2$. In acetone, two reduction steps with half-wave potentials of -0.27 and -1.43V *vs.* Ag|AgCl are observed. The i_d values are obviously quite different. Table II shows the ratios of i_d at various drop times. However, with the rapid polarographic method, the i_d values are equal, showing simply and conveniently that the same number of electrons [later shown to be one (21)] are involved in both electrode processes. The difference in i_d values of the two electrode processes resulted solely from the

considerable variation of $m^{2/3}t^{1/6}$ with potential, as shown by Fig. 6. The rapid polarographic method, however, quickly establishes that variations in i_d arise from this and shows that the same number of electrons is involved.

Figure 8 shows a comparison of rapid and conventional d-c polarograms for reduction of Pt(SacSac)$_2$ in acetone. A considerable difference in i_d values of the two electrode processes Pt(II) $\xrightarrow{e}$ Pt(I) $\xrightarrow{e}$ Pt(I)

is obvious with the conventional method, but as expected, they are almost equal with the rapid polarographic method, confirming simply and conveniently that equal numbers of electrons are involved in both electrode processes.

That this use of the rapid polarographic method is possible, confirms again the earlier findings that the Ilkovic equation can still be successfully used in applications of polarography with drop times as short as 0.16 sec.

Other applications.—The fast scan rates permitted by the rapid polarographic method have allowed other applications of the technique in glass corrosive hydrofluoric acid media (10, 18, 22, 23) and for the study of complexes formed in precipitating systems (24, 25) as described elsewhere.

Conclusion

The above discussion and results have been presented in an endeavor to demonstrate that the rapid polarographic method, with short controlled drop times, is an extremely useful electrochemical technique. In analytical applications it is markedly superior to the conventional polarographic method, because of the considerable time saving gained from the faster potential scan rates. Furthermore, a slight increase in precision and reproducibility is obtained. Thus, while maintaining all the advantages of having a dropping mercury electrode, the technique permits the use of routine and rapid polarographic methods on a time basis which is competitive with other methods.

When used in conjunction with conventional polarographic methods, rapid polarography can also be an extremely powerful tool in electrochemistry, and can often be successfully used to elucidate electrode processes and to provide information not readily accessible by the conventional method.

In the light of the above analytical and electrochemical uses of the method, it is concluded that the rapid polarographic method warrants considerably wider use than presently accorded.

A Computer Controlled Capillary Electrometer

John Lawrence[1] and David M. Mohilner*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80521

ABSTRACT

A completely automatic capillary electrometer controlled by an on-line digital minicomputer is described. This instrument is based on the maximum bubble pressure principle and is not subject to the systematic errors of the classical Lippmann electrometer in the presence of dilute solutions of weakly adsorbed electrolytes. Details of the interface hardware and the necessary software are given. The instrument is capable of producing very high quality electrocapillary data comparable to that which can be obtained with a capacitance bridge in the case of simple salt solutions and superior to bridge data in the case of the electrosorption of organic compounds which exhibit very high capacitance desorption peaks.

The interfacial tension (or interfacial free energy), γ, is the most fundamental property characterizing the equilibrium state of the electrical double layer at an electrode-electrolyte interface. Precise knowledge of this property as a function of temperature, pressure, electrode potential, and system composition permits all of the other thermodynamic properties of the double layer such as excess charge density, q^M, and relative surface excesses of system components, Γ's, to be calculated (1). In the case of solid electrodes, no reliable method has yet been devised for the direct measurement of γ, although some recent progress has been reported by Beck (2). In the case of liquid metal electrodes, especially mercury, direct measurements of γ date back to the original work of Lippmann (3) of nearly a century ago. The instrument invented by Lippmann for such measurements, which he named the "capillary electrometer," and to which we shall refer as the "Lippmann electrometer," was based on the capillary rise principle (4). It was the principal instrument used to study the electrical double layer in the first half of this century, and it has continued to be widely used although probably differential capacitance measurements at dropping mercury electrodes based on the principles first described by Grahame (5) have been more often employed for high-precision double-layer studies in recent years.

It is true that differential capacitance measurements, coupled with measurements of the potential of zero charge, can supply essentially all of the information required for a complete thermodynamic description of the electrical double layer in the presence of simple salt solutions. For the case of such solutions, differential capacitance may be said to provide a satisfactory substitute for interfacial tension measurements. However, in the case of the adsorption of organic molecules at electrode surfaces this is not true. In the first place, recent studies have shown (6, 7) that integration of differential capacitance under the very high desorption peaks characteristic of most organic sorbates fails to yield the correct thermodynamic value of the charge density even when the capacitance is extrapolated to zero frequency. Secondly, it appears now that it is the rule, rather than the exception, that the electrosorption of organic compounds is congruent neither with respect to electrode potential, E, nor with respect to charge density, q^M, *i.e.*, that the so-called lateral interaction parameter in the adsorption isotherm is not a constant, but rather is a function either of E or of q^M. When this is the case, there exist no known relationships which permit calculation of fractional surface coverage, θ, from charge density-potential curves. The known equations due to Frumkin (8) and to Parsons (9) which express either q^M at constant E or, alternately, E at constant q^M as linear functions of θ are now known to be both the necessary (9) and the sufficient (7) conditions for congruence of electrosorption with respect to electrode potential or charge density, respectively. Thus, when the electrosorption is noncongruent, neither of these relationships may be used to calculate θ. In such cases it appears that the only valid way to obtain correct electrosorption isotherms is to measure the interfacial tension of the electrode directly.

In the past, nearly all interfacial tension measurements have been made with the Lippmann electrometer. Unfortunately, until quite recently it was not realized that this classical instrument is subject, under certain conditions, to very serious systematic errors (10). As is true in the case of all types of capillary rise measurements (4), the Lippmann electrometer is reliable only when the contact angle at the three-phase boundary (mercury-solution-glass) inside the capillary is constant and preferably zero. When the contact angle is constant as is true, for example, in the case of aqueous 0.1M NaCl, very precise measurements of γ are possible with a Lippmann electrometer (11). In the case of such solutions the only serious drawback of this instrument is the extreme tedium[2] of using it. On the other hand, in the case of dilute solutions of weakly adsorbed electrolytes such as aqueous NaF solutions (10, 13, 14) a systematic negative error appears in the vicinity of and especially at potentials positive to the point of zero charge when the interfacial tension is measured with a Lippmann electrometer. This systematic error is shown to be present by comparison of the shape of the directly measured electrocapillary curve with that of the corresponding electrocapillary curve obtained by double integration of the differential capacitance. Such systematic errors have also been observed in the case of dilute solutions of other electrolytes, including HCl and KCl solution (15, 16). As was first shown by Schiffrin (15) and later verified in this laboratory (14), the replacement of the Lippmann electrometer by a capillary electrometer based on the maximum bubble pressure (MBP) principle entirely eliminates this source of systematic error. Since the maximum bubble pressure method is known to be independent of contact angle (4), these results support the contention (10) that the source of the systematic error in the case of the Lippmann electrometer is the development of a finite and potential-dependent contact angle at the three-phase boundary inside the capillary.

[1] Postdoctoral Fellow, 1969-1971. Present address: Bell-Northern Research, Ottawa, Ontario, Canada.

Key words: electrocapillary, interfacial tension, maximum bubble pressure, interface hardware, software.

[2] Recently Conway and Gordon (12) described a technique to relieve some of the tedium and strain on the operator's eyes by using a television camera focused through a microscope to view the meniscus inside the capillary of the Lippmann electrometer. With this modification, the operator watches a TV monitor instead of having to peer through the microscope.

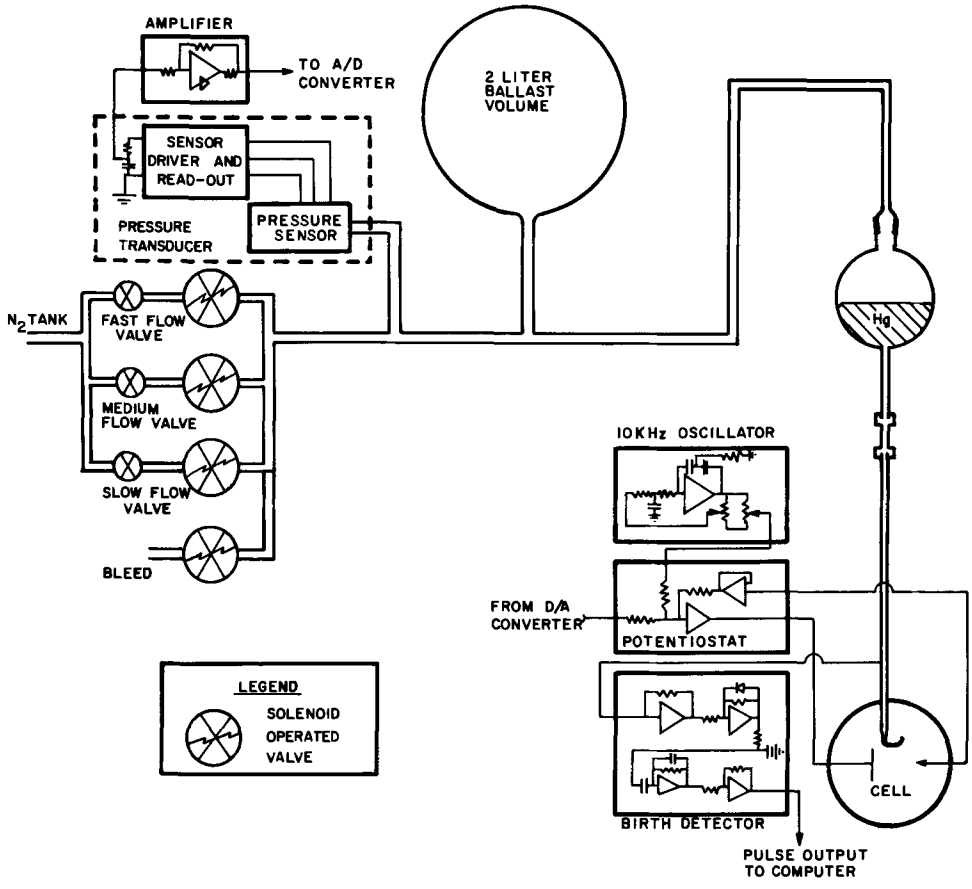

Fig. 1. Maximum bubble pressure apparatus.

Because of the systematic errors which may be present in measurements of γ with the Lippmann electrometer, and because it is not always possible from the Lippmann electrometer measurements themselves to detect whether or not these systematic errors are present in the data, we believe that a capillary electrometer based on the maximum bubble pressure (MBP) method provides the most realistic solution to the problem. Moreover, it is much simpler to automate a capillary electrometer based on the MBP principle than it would be to automate a Lippmann electrometer.

In the present paper we describe in detail the instrumentation which has been developed in this laboratory for a completely automatic capillary electrometer based on the MBP principle. This electrometer is controlled by an on-line digital minicomputer. The results of our experiments with this instrument indicate that the quality of the data it can yield, as determined by the agreement of the charge density-potential data obtained by differentiation of the electrocapillary curve with integrated differential capacitance data, is at least comparable to that which can be obtained with a capacitance bridge.

Experimental

General description of the instrument.—The maximum bubble pressure (MBP) apparatus (Fig. 1) consists of three main components: (*a*) the electrochemical cell with its associated potentiostat, (*b*) a gas pressure control and measurement system, and (*c*) the birth detector circuit (14) which determines when the maximum bubble pressure has been achieved. This apparatus receives control signals from, and transmits information to, the minicomputer[3] in a closed loop configuration.

[3] The minicomputer used in this laboratory is a Digital Equipment Corporation (DEC) Model PDP-8/I. It is equipped with an 8K core (12 bit words), 32K random access magnetic disk (DF-32), a high speed paper tape reader-punch (PC8/I), an ASR-33 teletype, analog-to-digital converter (ADC-1), and additional interface built in this laboratory from DEC digital logic modules (Flip-chips).

The MBP electrode is a fine capillary (10 to 14μ internal radius) which is drawn, after thorough cleaning, from 1 mm. ID borosilicate glass capillary tubing (6 mm OD). The capillary is bent into a U-shape (15) so that its orifice is directed upward. After being bent, the capillary is dewetted by sucking the vapor of dichlorodimethylsilane through it for approximately 3 min.[4] After the capillary is dewetted, its tip is recut as was recommended by Payne (17) for dropping electrodes. Figure 2 is a close-up photograph of an actual MBP capillary used in this study. The MBP capillary is sealed to a length of ¼ in. OD glass tubing. It is connected to a mercury reservoir by means of a stainless steel Swagelok union equipped with Teflon ferrules. The electrode is inserted into one compartment of the two compartment cell via a Teflon 10/30 standard taper thermometer adapter. The cell is provided with an outer jacket through which water from a thermostat is pumped. The auxiliary electrode is a mercury pool at the bottom of the same compartment into which the MBP electrode dips. The reference electrode dips into the other compartment of the cell. Figure 3 is a photograph of the assembled cell.

The potentiostat (Fig. 1) is an operational amplifier circuit with an adder configuration for two voltage input signals (18). The potential controlling amplifier is a Philbrick P-85AU, and the voltage follower is Philbrick P-25AU. The d-c voltage input signal to the potentiostat comes from a 12-bit digital-to-analog (D/A) converter which is a part of the computer interface. The value of the d-c potential is determined by a program command (*cf.* section on software below). The other voltage input signal to the potentiostat comes from a 10 kHz sine wave oscillator (18) which causes a controlled, 5 mV peak-peak a-c potential to be superimposed on the d-c potential of the

[4] An important precaution in the use of dichlorodimethylsilane vapor as a dewetting agent for capillaries is to insure that the inner wall of the capillary is first wet with a monolayer of water. We have found that a convenient way to insure this condition is to draw water vapor from above a beaker of warm water through the capillary for a few minutes immediately before dewetting.

MBP electrode. This signal is required for the operation of the birth detector. The MBP electrode is connected to the summing point of the current amplifier of the birth detector circuit (Fig. 1); it is therefore held at a virtual ground potential.

A detailed description of the birth detector has been published previously (14). It suffices here to say that this circuit detects the instant in time when the mercury, under slowly increasing pressure, has been pushed to the very tip of the up-turned capillary and has formed a protruding semidroplet or "bubble" whose surface has a minimum radius of mean curvature, and which has just started to expand. That is, this circuit detects the instant of "birth" of a mercury droplet at the tip of the capillary. The corresponding difference of pressure across the curved interface at the instant when the mercury droplet begins to expand is the "maximum bubble pressure," *i.e.*, the maximum pressure which can be exerted against the interfacial tension without starting a continual flow of mercury. Except for the fact that the fluid in the capillary is mercury instead of air, the experiment is exactly analogous to the maximum bubble pressure measurement of classical surface chemistry (4, 19), and, hence, the name. The maximum bubble pressure, Δp, is, according to the Laplace equation (4, 19, 20), directly proportional to the interfacial tension, γ. Thus

$$\Delta p = 2\gamma/r \qquad [1]$$

where r is the radius of mean curvature[5] of the surface of the protruding "bubble."

When the maximum bubble pressure has been reached, the birth detector produces a sharp voltage pulse which is transmitted to the computer interface and serves to signal the computer that it is time to record the pressure.

The pressure, Δp, is the sum of two components: one due to the mercury head above the tip of the capillary, the other due to nitrogen gas pressure exerted on the mercury in the reservoir (Fig. 1). The gas pressure is controlled by four solenoid actuated valves[6] which operate under computer control by program command. Three of these solenoid valves control nitrogen flow into the gas pressure system. The flow rate through each solenoid valve and into the system is determined by the setting of a needle valve[7] (Fig. 1). The gas pressure system contains a 2 liter ballast volume to smooth fluctuations during pressure increase. The fourth solenoid valve serves to bleed the gas pressure to atmospheric in order to stop the flow of mercury through the capillary after each measurement of the maximum bubble pressure.

[5] If the orifice of the capillary is perfectly circular, the protruding bubble of mercury will be a true hemisphere, and its radius will be identical with that of the capillary orifice. This would, of course, be the minimum radius which the mercury surface could assume. Therefore, according to Eq. [1], the corresponding pressure difference Δp across the curved interface will be the maximum which can be exerted if the interface is to be in mechanical equilibrium. Any infinitesimal increase of the applied pressure will cause the protruding hemisphere to begin to expand, and hence its radius and surface area will start to grow. The birth detector circuit actually detects the instant when the surface starts to expand.

If the orifice of the capillary is not a true circle, Eq. [1] is still valid but r is no longer the radius of the capillary. Rather r now stands for the radius of mean curvature (20) of the interface, and it is given by the following equation

$$\frac{1}{r} = \tfrac{1}{2}\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \qquad [2]$$

where R_1 and R_2 are the two principal radii of curvature of the surface.

[6] The valves used are Model V52D2100 normally closed, 2-way, "bubble tight" valves equipped with 24V d-c solenoids manufactured by Skinner Electric Valve Division, New Britain, Connecticut. The power for all four solenoids is provided by a single regulated d-c power supply, Model W-740, manufactured by Wescom, Inc., Downers Grove, Illinois. A single power supply is sufficient because only one of the solenoid valves is ever actuated at any given time.

[7] The needle valves for the fast and medium rates of pressure increase are miniature forged needle valves (Model 3212G4B), while the valve for the slow flow rate is a micrometer metering valve (Model 2PY280), all of which are manufactured by Hoke, Inc., Cresskill, New Jersey.

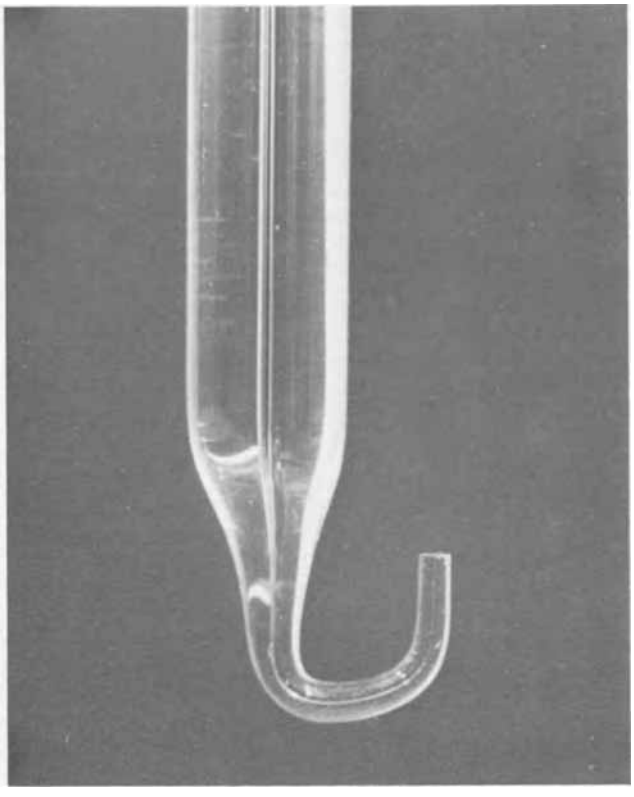

Fig. 2. Close-up photograph of typical MBP electrode. Diameter of capillary at orifice is about 20μ.

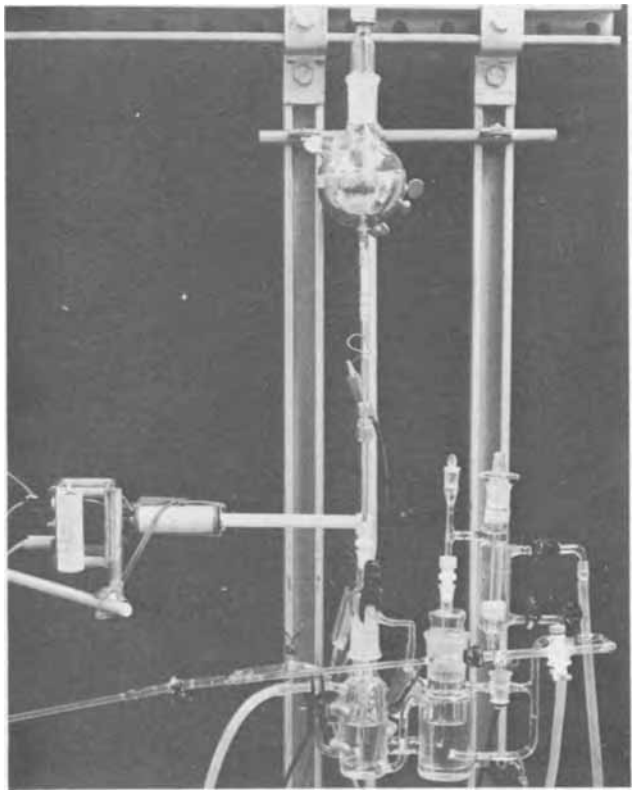

Fig. 3. Assembled MBP cell. Left compartment contains MBP electrode. Right compartment contains salt bridge for reference electrode. Reference electrode is water jacketed calomel. Drop knocker is on left of photograph.

The gas pressure is measured by a pressure transducer (Fig. 1) which consists of a Lion Research Corporation (Newton, Massachusetts) Model DC-303

differential, capacitive pressure sensor coupled to a Model PM-100A sensor driver and readout. The sensor, although originally calibrated over a range of 0-100 mm Hg, is capable of being operated safely over a range of 0-200 mm with no loss of precision. It is over this latter range that the sensor is used in the MBP apparatus. One side of the pressure sensor is connected to the gas pressure system, and the other side is left open to the atmosphere. The PM-100A then outputs an analog voltage which is the measure of the difference of pressure between the gas pressure system and the atmosphere. This analog voltage is then scaled by an operational amplifier (Philbrick Model 1700, chopper stabilized) before being input to the A/D converter. The purpose of the scaling is to insure maximum precision in the digital representation of the analog voltage. The pressure transducer and scaling amplifier combination is calibrated by connecting the pressure sensor to a separate, manually adjustable gas pressure system. The pressure in this latter system is read on a wide bore mercury manometer with the aid of a cathetometer calibrated to 0.01 mm. The scaled analog voltage output of the PM-100A is read to the nearest 0.1 mV with a Fluke Model 8300A digital voltmeter. The table of calibration data (pressure *vs.* voltage) is then fitted to a least squares 4th degree polynomial by digital computer (CDC 6400), and the five coefficients of this best-fitting calibration polynomial are then input to the PDP-8/I computer and stored in its memory. During the measurement of an electrocapillary curve, the digitized, scaled analog voltage from the PM-100A corresponding to each individual measurement of pressure is converted into a pressure by means of this calibration polynomial. Our experience indicates that recalibration of the pressure transducer need not be done more often than once a month.

Figure 4 is a block diagram of the complete, closed loop apparatus. The items on the right hand side of this diagram represent the MBP apparatus, proper (*cf.* Fig. 1). The large double rectangle on the left represents the computer. The items in the center of Fig. 4 represent the interface between the computer and the experimental apparatus. The arrows in the figure indicate the direction of information flow.

Interface hardware.—The interface required for communication between the MBP experiment and the computer consists (Fig. 4) of three digital-to-analog (D/A) converters, four relay drivers, one positive input converter, one bipolar output converter, and an analog-to-digital (A/D) converter. A complete list of all digital logic modules required is given in the Appendix. Every discrete type of operation of each interface device requires one-third of a hardware

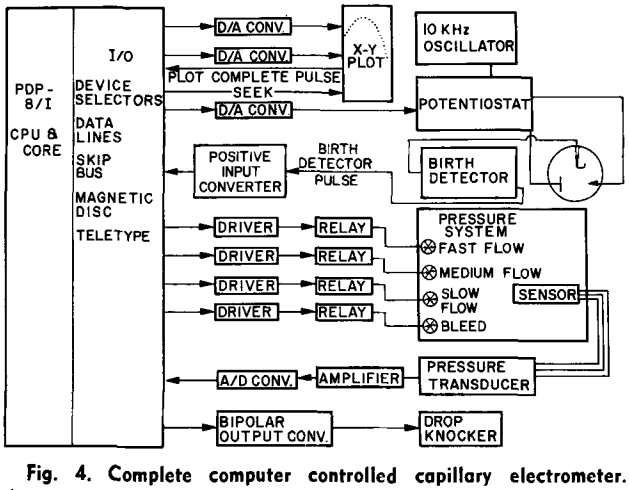

Fig. 4. Complete computer controlled capillary electrometer. Arrows in center section of drawing indicate direction of information flow.

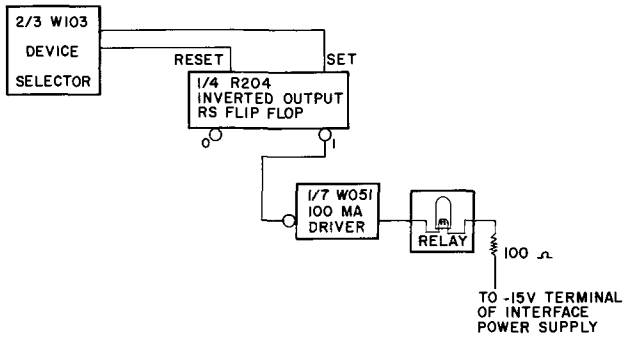

Fig. 5. Logic diagram for relay interface

device selector module (W103) to decode the corresponding program command and translate it into a voltage pulse which initiates the interface device operation (21, 22). D/A converters have only one type of operation, namely, to convert a binary number appearing in the accumulator of the computer into an analog voltage. Therefore, one W103 suffices for all three D/A's. Relay drivers require two device codes, one for energizing, the other for de-energizing the relay coils. Therefore, each relay driver requires two-thirds of a W103. The A/D converter requires three device codes, and, therefore, uses a whole W103 device selector module.

One of the D/A converters is used to provide the d-c voltage input signal to the potentiostat. The resolution of this converter is one part in 4095. This means that the d-c potential of the MBP electrode is controlled to better than 0.5 mV. The other two D/A converters are each 10-bit and are used only to operate an X-Y plotter[8] so that a graphical record of every measurement is produced. The resolution of the plot is one part in 1023. Examples of the plots obtained are shown in Fig. 11 and 13 below.

Each of the four solenoid valves (Fig. 1 and 4) which control the pressure in the gas pressure system is energized or de-energized on program command by the action of a relay (Clare Model RP 3718-G75) through whose contacts the current from the solenoid power supply[6] passes. Figure 5 shows the interface logic diagram for a relay. When the R-S flip-flop is in the "zero" state the relay is de-energized and therefore the current to the solenoid valve is cut off. When the flip-flop is changed to the "one" state the relay and, hence, the solenoid valve are energized. The device selector decodes the two program commands, "energize" or "de-energize" (SET or RESET respectively, *cf.* Fig. 5), and translates them into voltage pulses which cause the flip-flop to go to either the "one" or "zero" state.

When the maximum bubble pressure has been achieved, the birth detector produces a sharp analog voltage pulse (14). This analog pulse must be converted to the proper standard digital voltage level in order to interact with the computer. That conversion is accomplished by a W510 positive input converter. Figure 6 shows the logic diagram of the interface between the birth detector and the computer. When the positive voltage pulse from the birth detector occurs, the W510 switches (in 100 nsec) from ground to −3V. When this happens the R107 inverter applies a corresponding positive voltage level change (−3V to ground) to the "set" input of the R-S flip-flop which has previously been put in the "zero" state by a program command via the W103 device selector. This flip-flop serves the purpose of a "birth detector flag" whose state is continually tested by the computer which operates in a wait loop (duration 60 μsec) as the pressure is building up in the gas pressure system

[8] The plotter is a Hewlett Packard Model 7004A X-Y recorder equipped with two Model 17171A d-c preamplifiers, one Model 17173A null detector, and one Model 17012B point plotter.

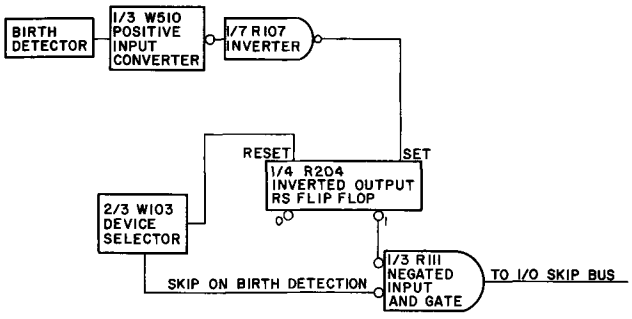

Fig. 6. Logic diagram for birth detector interface

prior to birth detection. When birth is detected by the hardware, the "one" output of this flip-flop enables one of the two inputs of the negated input AND gate (R111); otherwise this input is disabled. A statement in the waiting loop, "skip on birth detection flag," then causes the W103 device selector to enable the other input of this AND gate once each time around the waiting loop. If birth has been detected by the hardware during a pass through the waiting loop, the AND gate is enabled and outputs a voltage level which causes the skip bus of the computer to be driven to ground. When the skip bus is driven to ground, the computer skips the next instruction in the program and enters a routine to store the current value of the gas pressure in memory.

The analog voltage from the pressure transducer is converted by the A/D converter (Fig. 4) to a digital number at the beginning of each occurrence of the birth detection waiting loop. The A/D converter used is a single channel, 12-bit DEC ADC-1 successive approximation type converter which is equipped with a 150 nsec sample-and-hold amplifier (A400). (The analog voltage range of the A/D is ±5.000V.) In order to achieve maximum digital accuracy the analog output of the pressure transducer is scaled to give a maximum output voltage of −5.000V (Fig. 1).

In the early stages of development of this instrument it was observed that occasionally spurious low pressure measurements were produced. The cause of these spurious measurements was traced to the fact that sometimes the mercury droplet produced at the tip of the capillary did not fall off, but rather sat over the orifice of the upturned capillary (*cf.* Fig. 2). In order to preclude the occurrence of such spurious pressure readings, a simple solenoid actuated drop-knocker was interfaced to the computer. After each MBP measurement this drop-knocker twice raps the capillary sharply, thereby insuring that no droplet is left sitting over the orifice to interfere with the next measurement. (The rapping rod of the drop-knocker can be seen in Fig. 3.) The interface used is a DEC W602 bipolar output converter (Fig. 4). The output of the W602 saturates an NPN transistor which, in turn, activates a silicon controlled rectifier. The SCR serves as a switch to discharge a 200 μF capacitor, charged to 50V, through the solenoid coil of the drop-knocker. (Figure 7 is the logic diagram for the drop-knocker.) An alternative method of interfacing a drop-knocker would be to connect a solenoid driver (W040) directly to the drop-knocker solenoid.

Software.—The computer program for the automatic capillary electrometer is designed to operate with a DEC PDP-8/I computer having a single 4K memory core [4096 (decimal) 12-bit words] and one 32K random access magnetic disk (DF-32). The program[9] is written in the disk version, PALD, of the standard PDP-8 assembly language, PAL. This program, in its entirety, is too large to fit within the 4K memory and still to have room for the necessary data buffers. Therefore, in order to conserve the amount of memory actually occupied by the program at any one time, a disk overlay system is used. With this system, the program is divided into four parts: a main (or controlling) program which is resident in core at all times, and three overlay programs which are stored on the magnetic disk as system programs and which are called into core as they are required by the main program. Each overlay occupies the same portion of the memory as its predecessor. The idea of this programming system is illustrated in Fig. 8. In addition

[9] Listings of the assembly language program will be supplied upon request to the authors.

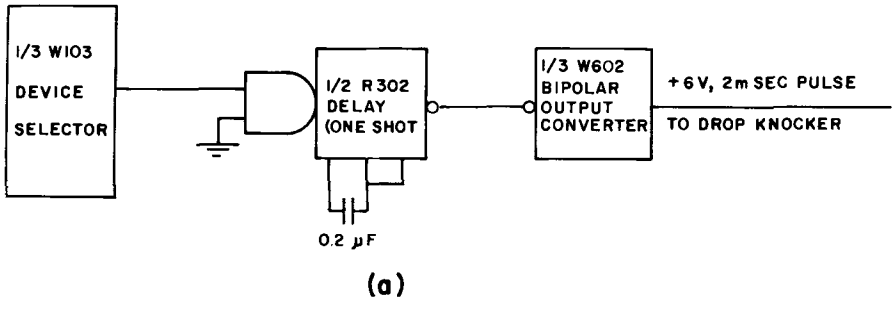

Fig. 7. Drop knocker. (a) Logic diagram for interface. (b) Circuit diagram for drop knocker.

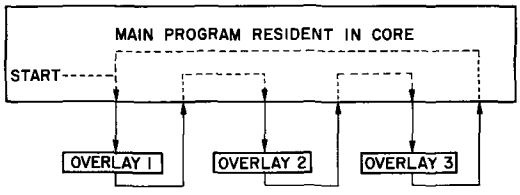

Fig. 8. General programming scheme

to the main program, it is also necessary to have the software floating point package and the disk monitor permanently resident in core. The floating point package contains all of the algorithms necessary for decimal arithmetic operations, and the disk monitor actually accomplishes the transfer of overlay programs from the disk into core after receiving the relevant disk file name from the main program. Figure 9 is a block diagram of the core allocation map. The fractional area of each block in that diagram is equal to the fraction of the memory occupied by the designated entity. The numbers in parenthesis in the block diagram give the range of memory addresses used for each purpose. (These addresses are expressed in octal arithmetic.)

The main program consists of subroutines for message writing on the teletype, plotting the electrocapillary curve on the on-line plotter, and overlay calling.

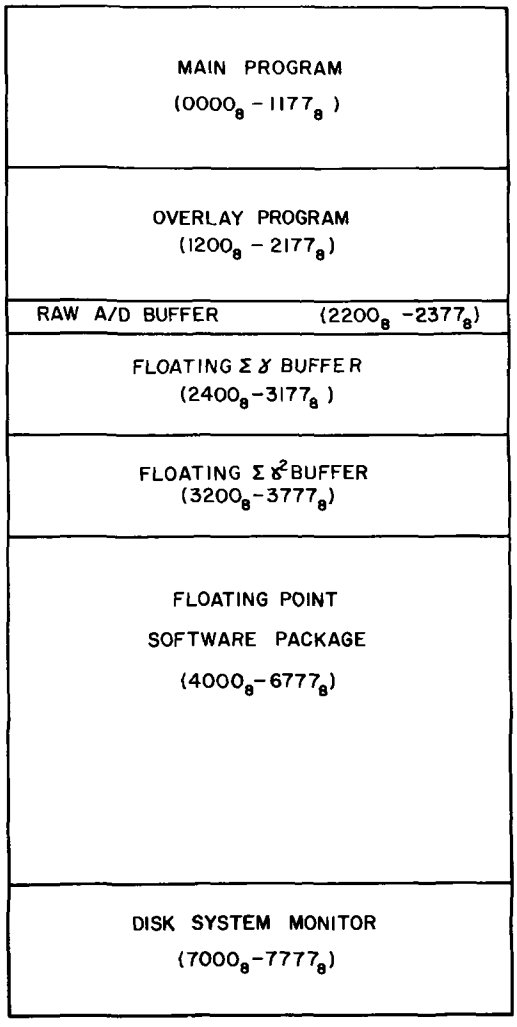

Fig. 9. Core allocation map. The fractional area of each block in this diagram is equal to the fraction of the computer memory used for the designated purpose. Actual address limits of each block of core are given in octal arithmetic.

In addition, it contains storage locations for various constants and variables required by the overlays. The actual control of the experiment is accomplished by the three overlays. As each overlay completes its task it returns control to a predetermined address in the main program (*cf.* Fig. 8). The main program then transmits the disk file name of the next overlay required to the disk monitor, and the disk monitor transfers the new overlay program into the same block of core occupied by the previous overlay (*cf.* Fig. 9).

The purpose of overlay 1 is to accept from the experimenter, via the teletype, the necessary input parameters for the performance of the experiment. These parameters include: the capillary calibration constant used to convert pressure measurements into interfacial tensions; the head of mercury above the capillary tip; the head of solution above the capillary tip (used for back-pressure correction); the number of electrode potentials (E) at which the interfacial tension (γ) is to be measured (maximum of 128 points per curve); the initial electrode potential; the potential increment between points; and the number of times the measurement of the complete electrocapillary curve is to be replicated.

Overlay 2 actually runs the experiment. The flow diagram for this overlay is shown in Fig. 10. The first task of this overlay is to make a rough run through the electrocapillary curve which will serve as a guide for the subsequent high precision measurements. For this purpose, only the medium flow rate of gas into the gas pressure system is used (*cf.* Fig. 1 and 4). The flow diagram for the steps required to make the rough run are given in the left hand part of Fig. 10. At each potential the 12-bit digital equivalent of the analog voltage output of the pressure transducer produced by the A/D at the instant of birth detection (*i.e.*, the maximum bubble pressure) is written in a memory buffer (denoted RAW A/D in Fig. 9). When the rough run through the electrocapillary curve has been completed, the high precision electrocapillary measurements are then made following the logic in the middle and right hand portions of the flow diagram in Fig. 10 starting at the point marked "A." In order to speed the measurements, the gas pressure is first increased rapidly using the fast flow valve (*cf.* Fig. 1 and 4). The A/D reading is checked continuously against the value which was stored at the same electrode potential in the RAW A/D buffer during the rough run. When the pressure is within 3 cm (Hg) of that required for birth detection during the rough run, the fast flow valve is closed and the medium flow valve is opened. The pressure is then increased at the medium flow rate until it is within 1.5 cm of the value stored during the rough run. At this time the medium flow valve is closed and the slow flow valve is opened. The pressure then increases very slowly until birth is detected. (In order to protect the A/D converter from receiving an analog voltage overload, a check is made to insure that the pressure has not exceeded 99% of full scale.) When birth is detected, indicating that the maximum bubble pressure has been achieved, the pressure increase is stopped and the current contents of the A/D register are stored in the same location in the RAW A/D buffer where the previous rough measurement had been stored. (The decision when to switch gas flow rates in the next repetition of the measurement will then be based on the value of the pressure stored in the RAW A/D buffer during the preceding high precision run.) The value of the gas pressure is then floated using the floating point package. Then the head of mercury above the capillary tip is added and head of solution above the capillary tip (expressed in equivalent cm Hg) is subtracted, and the net value of the maximum bubble pressure is multiplied by the capillary calibration constant (*cf.* Eq. [1]) to obtain the interfacial tension γ. The floating point decimal value

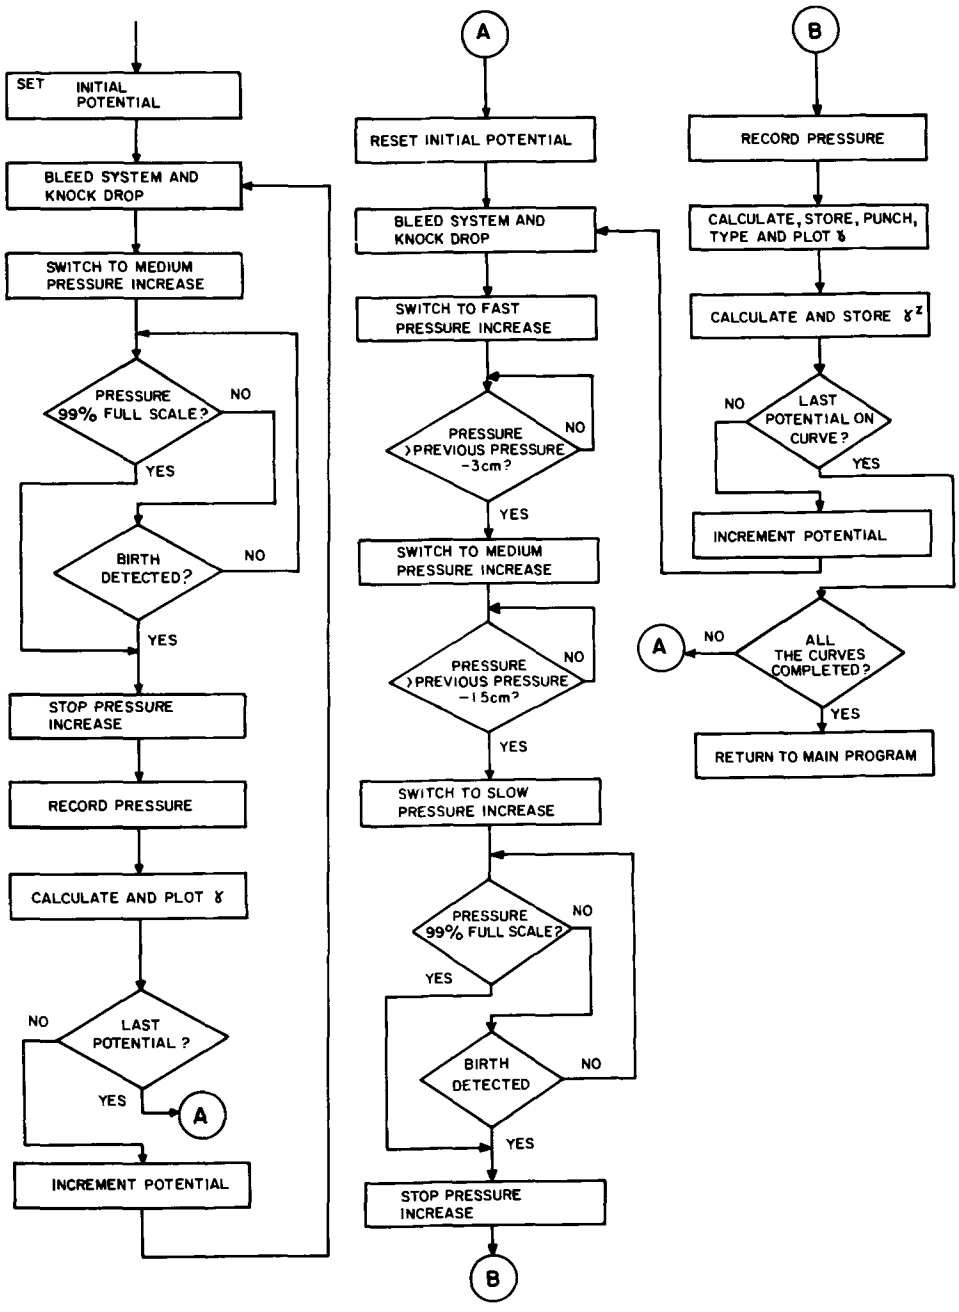

Fig. 10. Flow diagram for overlay program No. 2.

of the interfacial tension is punched on high speed paper tape for a permanent record and also typed by the teletype opposite the value of the electrode potential. The floating binary version of γ (expressed as three 12-bit words) is then stored in the floating buffer (denoted by FLOATING $\Sigma\gamma$ in Fig. 9). This buffer was filled initially with zeros by overlay 1. On each subsequent high precision measurement of γ the new value is added to the sum of the previous ones. This is necessary in order to be able to calculate the average value of γ at the completion of the experiment. Similarly, the sum of the squares of the interfacial tensions are accumulated in the buffer denoted FLOATING $\Sigma\gamma^2$ in Fig. 9 to permit later calculation of the standard deviation of γ at each electrode potential. When the high precision measurement of γ at each E has been repeated the desired number of times (typically, five times), overlay 2 returns control of the system to the main program which then causes overlay 3 to be brought into core.

The purpose of overlay 3 is to calculate the average value of γ at each electrode potential. These values are typed out on the teletype, punched on high speed paper tape, and plotted on a graph. The standard deviation of γ at each potential is also typed on the teletype. If the relative standard deviation exceeds a predetermined amount (*e.g.*, one part per thousand) the teletype also prints the message "EXAMINE!" to alert the experimenter to review the individual values of γ determined at the given potential in order to identify a possible spurious measurement for subsequent discard before proceeding with the thermodynamic analysis of the data.

Results and Discussion

Calibration.—The computer-controlled capillary electrometer is calibrated using an electrolyte solution for which the absolute value of the interfacial tension at the electrocapillary maximum is known from an independent method of measurement, namely: the sessile drop method. After calibration, the performance of the instrument was judged by comparison of the values of the surface charge density, q^M, calculated according to the Lippmann equation (1) by differentiation of the electrocapillary curve with respect to electrode potential with the corresponding values of q^M obtained by integration of the differential capacitance from the point of zero charge.

The calibration is based on the value, 426.2 ± 0.2 dyne cm^{-1}, of the interfacial tension of mercury in

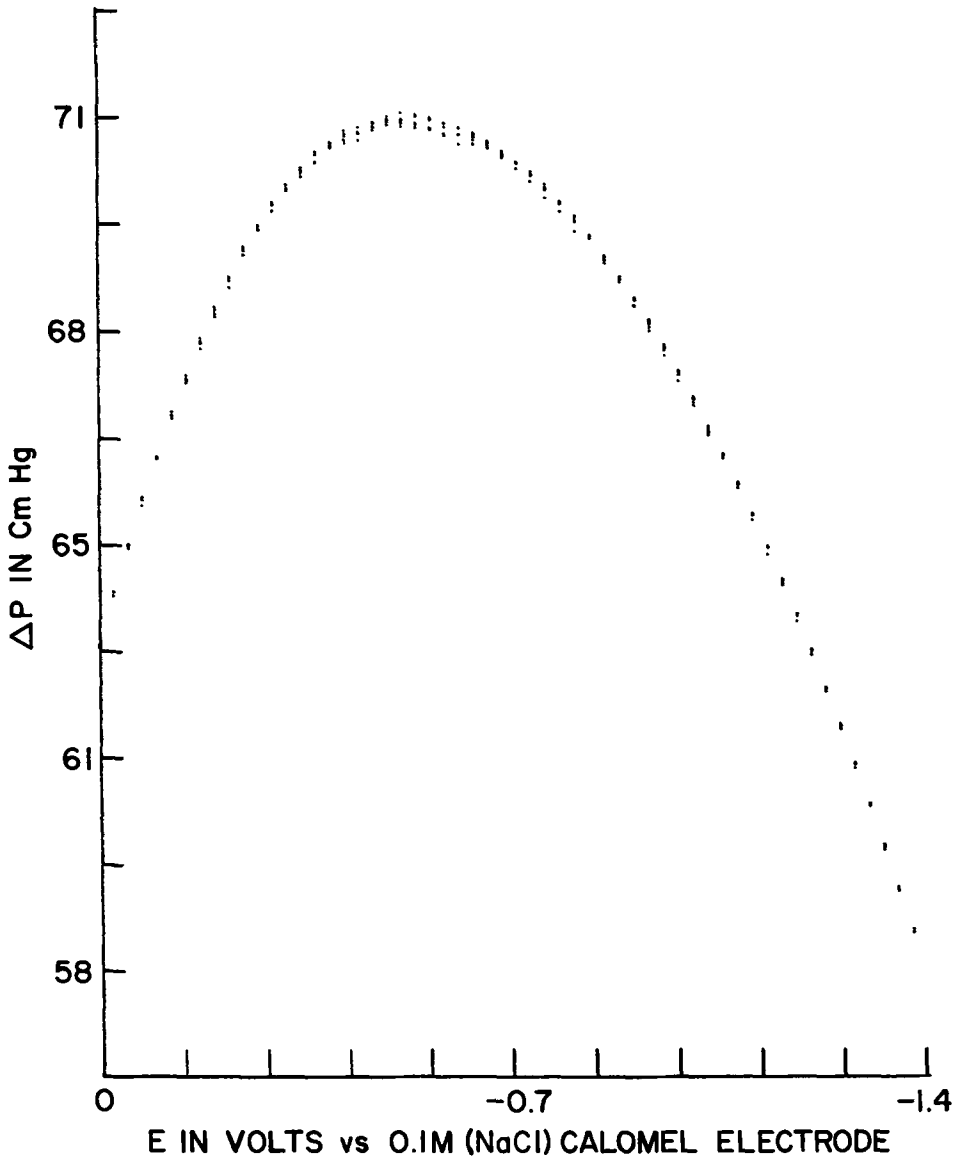

Fig. 11. Typical calibration experiment. Solution is 0.05M Na_2SO_4. Each dot represents an individual determination of the maximum bubble pressure. This experiment was repeated five times.

contact with 0.05M Na_2SO_4 at the electrocapillary maximum at 25°C determined by Smolders and Duyvis (23) by the sessile drop method in 1961. This determination is generally considered to be the most reliable absolute value of the interfacial tension of an ideal polarized mercury electrode which is available. Figure 11 shows the actual plot of the maximum bubble pressure Δp (in cm Hg) *vs.* electrode potential which was produced in a calibration experiment. The measurements were replicated five times (not counting the rough run), and the small scatter of the measurements can be seen from the graph. The average value of Δp at each of the 57 potentials was calculated and the data was smoothed on the CDC 6400 computer using the previously published (24) moving least squares technique with the "runs cutoff criterion." The value of Δp at the potential of zero charge, E_z, was found by computer interpolation. The value, 426.2 dyne cm^{-1}, was then assigned to Δp at E_z, and the calibration constant was calculated. (The calibration constant multiplied by Δp in cm Hg yields interfacial tension γ in dyne cm^{-1}.) All values of Δp were then multiplied by the calibration constant to obtain the γ-E curve which was then differentiated by the moving cubic fit routine (25) to obtain the charge density-potential curve. We measured the differential capacitance of a dropping mercury electrode in the same solution using a General Radio Model 1615-A transformer ratio-arm bridge, and we determined the potential of zero charge by the streaming electrode method of Grahame (26). (The potential of the isolated streaming electrode was measured with a Fluke Model 8300A digital voltmeter as a function of pressure and in accordance with the recommendation of Grahame, the most negative value found was accepted as the value of $E_z \cdot E_z = -0.532$V *vs.* 0.1M NaCl calomel electrode.) The differential capacitance was integrated by digital computer from E_z to obtain q^M. The values of q^M obtained by differentiation of the electrocapillary curve were then compared at each elertrode potential to the values of q^M obtained by integration of the differential capacitance curve. The results are illustrated in Fig. 12. For perfect agreement between the two methods of determining q^M, the points would lie on the solid line of unit slope. It can be seen that the actual agreement is quite good. The points in the centers of the small ovals are the actual experimental points. (In order to make the experimental points clearly visible, the ovals are drawn with their major axes about three times larger than the standard deviation of the experimental error.) The value of the standard deviation of the experimental error in the determination of q^M from the derivative of the electrocapillary curve (taking the values of q^M determined from integration of the differential capacitance as correct) was 0.12 μcoulomb cm^{-2}; the average value of the error was 0.03 μcoulomb cm^{-2}.

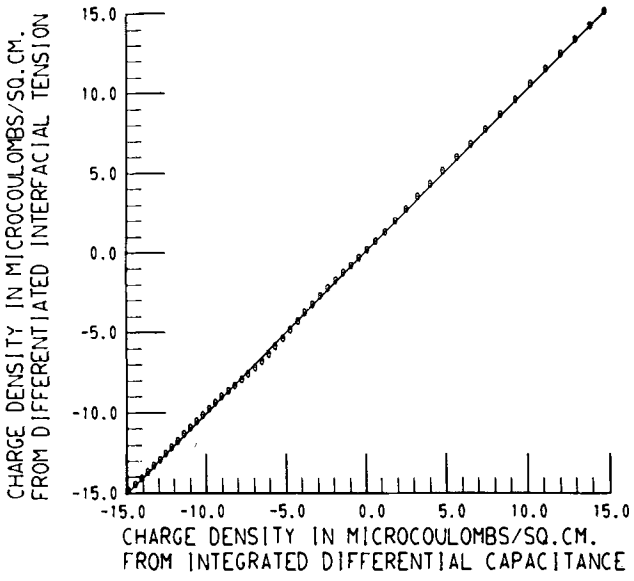

Fig. 12. Typical calibration graph for a capillary. (Results of experiment illustrated in Fig. 13.) Perfect correlation is given by solid line of unit slope.

Applications.—The apparatus has now been tested with a variety of salt solutions, and it is being used routinely in this laboratory for measurements of the electrocapillary curves of organic compounds in aqueous electrolyte solutions. Typical results are shown in Fig. 13 for the electrosorption of 2-butanol on mercury from aqueous 0.01M NaF. The points plotted in this figure are averages of five determinations. The points shown on the curve represent measurements at each of 57 electrode potentials for the 0.01M NaF base electrolyte (top curve) and for 14 different concentrations of 2-butanol ranging from 0.01 to 1.0M. It should be noted that measurements such as these could not have been obtained at all with a classical Lippmann electrometer because of the systematic errors to which that instrument is subject. (In the case of 0.01M NaF, the Lippmann electrometer shows negative errors slightly cathodic of the electrocapillary maximum, and these errors increase to more than 10 dyne cm^{-1} on the anodic branch.) The time and labor required to make this set of measurements was also very much less than would have been needed to make an equal number of measurements with a Lippmann electrometer even if it could have been safely used. The typical rates of pressure increase used with our instrument are (*cf.* Fig. 1 and 4): fast flow, 50 mm Hg/sec; medium flow, 7 mm Hg/sec; slow flow, 0.7 mm Hg/sec. With these flow rates it requires approximately 45 sec for the automatic electrometer to change the electrode potential, make the MBP measurement, and record the measurement on the teletype, paper tape, and plotter. This means that three repetitions of a 60 point electrocapillary curve requires

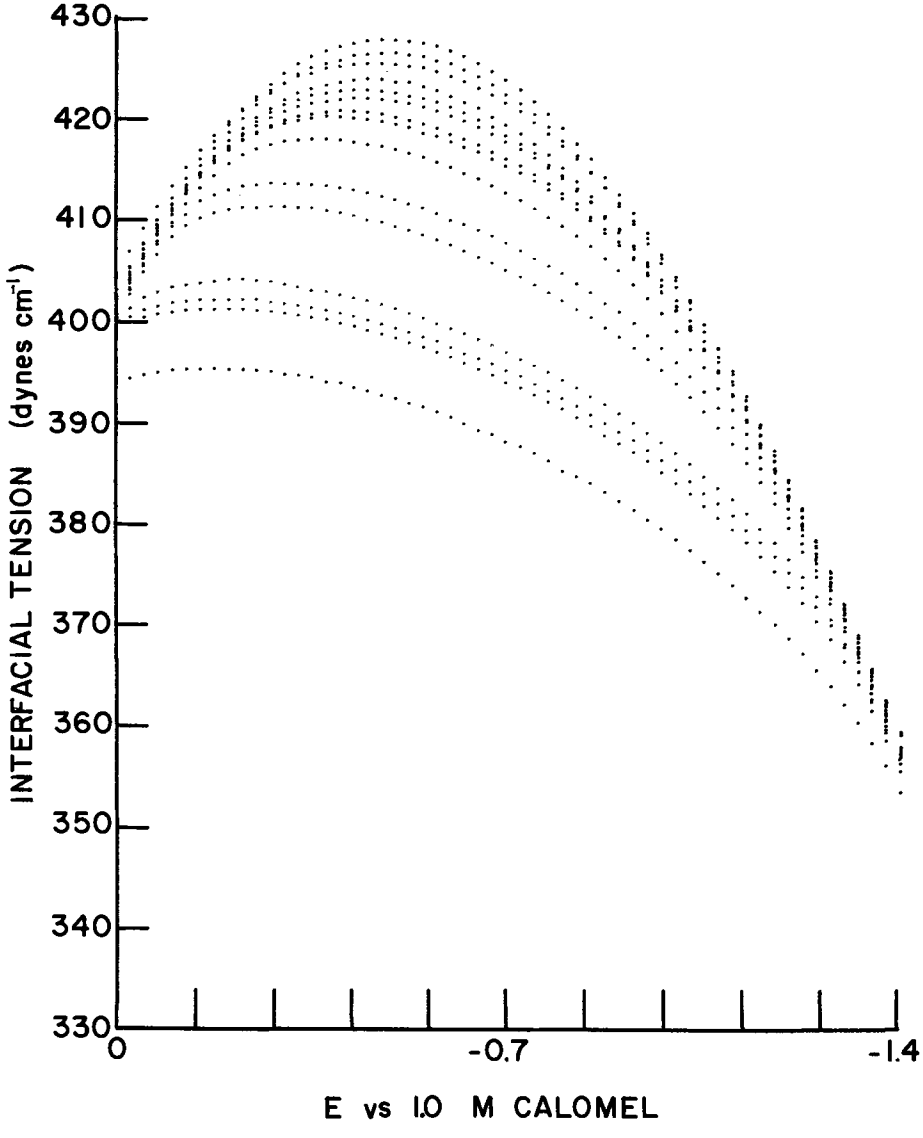

Fig. 13. Electrocapillary curves obtained by the computer controlled capillary electrometer for the electrosorption of 2-butanol on mercury from aqueous 0.01M NaF solution. Each point is the average of five determinations. Concentration 2-butanol (reading from top curve to bottom): 0.0M, 0.01M, 0.04M, 0.05M, 0.06M, 0.07M, 0.09M, 0.10M, 0.15M, 0.19M, 0.30M, 0.50M, 0.60M, 1.00M.

less than 3 hr. Since the operation of the experiment is completely automatic after setting up, the experiment requires no attention from the experimenter. The only work required from the experimenter is to prepare the solution and fill the cell, deaerate the solution, and enter into the memory of the computer via the teletype the necessary input parameters as required by overlay 1. The computer then starts the experiment, runs it the desired number of times, and records the data. When the measurements have been completed the electrocapillary data recorded on high speed paper tape are transferred to magnetic tape and the thermodynamic analysis is accomplished on the large digital computer[10] (CDC 6400) using the previously published methods (24, 25).

Minimal system requirements.—The minicomputer system employed in this laboratory makes the experiments with the computer-controlled capillary electrometer very convenient. However, it should be pointed out that it would be quite feasible to construct a workable instrument using a significantly less expensive minicomputer system having fewer peripherals, for example: a PDP-8/E with 4K core and no magnetic disk or high speed paper tape reader-punch. For a computer system with no magnetic disk, the program could simply be split into three separate programs, each corresponding to one of the overlays described above. Program 1 would accept the input parameters and punch them on low speed paper tape, *i.e.*, on the teletype. Program 2 would read the tape produced by program 1, run the experiment and punch out the results on low speed paper tape. Program 3 would perform the same task as our overlay 3. The only difference in the practical operation of such a system and the one described in this paper would be that the operator would have to load each of the three programs manually using the binary loader. The same interface (*cf.* Fig. 4 and Appendix) would, of course, be required, although one could dispense with the on-line plotter. Obviously, equivalent minicomputers of other manufacturers could also be used to construct this instrument.

Conclusions

The design of a completely automatic capillary electrometer controlled by an on-line digital minicomputer has been described. The performance of this instrument has been evaluated, and it was found that the quality of the electrocapillary data it can produce is comparable to that which can be obtained with a capacitance bridge in the case of simple salt solutions. In the case of solutions of organic neutral compounds the results are superior to those obtained with a capacitance bridge (7). Because this instrument is based on the maximum bubble pressure principle instead of the capillary rise principle it is completely immune from the systematic errors which render a Lippmann electrometer useless for measurements in dilute solutions of weakly adsorbed electrolytes such as 0.01M NaF. The instrument has been tested and is now being used routinely in this laboratory for the studies of the electrosorption of organic molecules at electrodes.

Acknowledgment

We are very grateful for support of this work by the Office of Naval Research under Contract No. N0014-67-0299-0007-AA, Project NR 359-493, and by the Air Force Office of Scientific Research, AFOSR (AFSC), USAF, under Grant No. AF-AFOSR-70-1887. We take pleasure in thanking Mr. Hisamitsu Nakadomari and Dr. Giorgio Papeschi of this laboratory for help with several of the experiments and Dr. Patricia R. Mohilner, Colorado State University Computer Center, for valuable advice on the computer programming.

Manuscript submitted April 13, 1971; revised manuscript received *ca.* May 28, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

[10] The reason a large digital computer is used for the thermodynamic analysis is that the computational floating point precision of the PDP-8/I (12 bits, sign and exponent, plus 24 bit mantissa) is not sufficient for the matrix inversion routines used in the smoothing program (24). The CDC 6400 has a 60 bit word length (21 bits, sign and exponent, plus 48 bit mantissa) which means that the analysis programs may be written in single precision FORTRAN. A 60 bit floating point package for the PDP-8/I computer is currently being written in this laboratory which should make it possible to carry out the thermodynamic analysis of the data on the minicomputer also.

APPENDIX

Table I is a list of the digital logic modules (DEC flip chips) used to construct the various interface components on the system described in this paper. The interface for this system is built from DEC "negative logic" (−3V and ground) discrete circuit component modules, *i.e.*, R, A, and W series digital logic modules. In order to aid in the selection of components for an interface based on "positive logic" (+3V and ground) we also give the nearest equivalents to our interface in terms of DEC M and A series integrated circuit digital logic modules. The number in parentheses immediately preceding the logic module model number is the number of modules of the indicated type required. It should be noted that the D/A converters also require a stable analog reference voltage source. We employ two Hewlett Packard Model 6215A power supplies for this purpose. The Model ADC-1 A/D converter is purchased as a single packaged unit installed at the factory.

Table I. List of digital logic modules

Interface device	Number needed	Negative logic modules per device		Positive logic modules per device	
12-bit D/A	1	(1)	A605	(1)	M613
		(2)	A604	(1/3)	M103
		(2)	A601	(2)	M206

Exchange in the Zn, Zincate, ZnO System

T. P. Dirkse,* L. A. Vander Lugt,* and N. A. Hampson[1]

Chemistry Department, Calvin College, Grand Rapids, Michigan 49506

ABSTRACT

The results of a radiochemical study of the system Zn/Zn(II), OH^-/ZnO are presented. It is shown that the exchange of tagged Zn(II) between solid ZnO and zincate ion is slow and appears to be negligible in zincate solutions based on 30% KOH. Commercial implications are discussed. Attempts to study the charge transfer reaction at a solid zinc electrode were unsuccessful due to the high parasitic corrosion rate.

Although considerable progress has been made in understanding the processes which occur at a solid zinc electrode in KOH solutions, some unsettled questions still remain. One of the reasons for this is that the nature of concentrated KOH solutions is not fully understood; the situation is further aggravated when zincate ion is present in the solution.

Zincate solutions may be prepared by dissolving ZnO in aqueous KOH. Two complex ions have been identified in the solution $Zn(OH)_3^-$, and $Zn(OH)_4^{2-}$ (1). It is generally agreed that the most common of these is $Zn(OH)_4^{2-}$ (2). A further complication with these solutions is the readiness with which "supersaturated" zincate solutions can be prepared, *i.e.* solutions in which the concentration of the dissolved Zn(II) species is greater (often by a factor of 2) than that of solutions in equilibrium with solid ZnO. Raman spectra (3, 4) and N.M.R. (5) have been used to study potassium zincate systems based on KOH solutions ranging from 4 to 15 mol l^{-1} and it has been concluded that the only significant anion is the tetrahedral $Zn(OH)_4^{2-}$. In more dilute solutions there were indications of "second coordination sphere" influences and indications of ion pair association.

Of special interest for power source applications and significance to the study of the zinc-alkali electrode process is the electrolytic production of supersaturated zincate electrolytes by the anodic oxidation of zinc in KOH (6). Practically nothing is known about such solutions except that the precipitate that forms extremely slowly appears to be composed mainly of ZnO. Above a certain concentration of zincate the Zn(II) appears to be electrochemically inactive (7). Raman spectra studies of supersaturated solutions indicate that above the equilibrium solubility limit Zn(II) species are not present as $Zn(OH)_4^{2-}$ (4).

The process of discharge of zinc electrodes (dissolution of zinc) occurring in energy conversion devices generally involves the ultimate production of ZnO as a solid phase. For the whole process, then, at least two exchange reactions occur involving Zn and Zn(II) species. These are: first, the charge transfer reaction (exchange of electrons and ions between electrode and solution); and second, the exchange between solution Zn(II) and lattice Zn(II) in ZnO.

The charge transfer reaction has been investigated using electrochemical methods and in the case of the zinc amalgam electrode the results have been confirmed using radiochemical techniques (8). Radiochemical techniques appear to offer the only method of studying the solution/oxide exchange equilibrium. Recently in this laboratory the exchange of Zn^{65} between soluble Zn(II) species in 7 mol l^{-1} KOH and solid ZnO has been investigated. It was reported in a preliminary communication (9) that the rate of exchange of Zn was so slow as to be virtually undetectable.

In this paper we present the detailed results of the investigation concerning the exchange of Zn^{65} between soluble Zn(II) species in electrolytes based on various concentrations of KOH and solid ZnO. We note the results of experiments on the electrolytic production of ZnO through the intermediacy of supersaturated potassium zincate solutions and also the results of an attempt to follow the Zn/Zn(II) exchange using the radiochemical technique.

Experimental and Results

Materials and general procedures.—The radioactive form of zinc used was Zn^{65} available as carrier-free $Zn^{65}Cl_2$. Radioactive zinc electrodes (1 cm x 1 cm) were prepared by electrodeposition onto platinum at a rate of 2 mA cm^{-2} from a dilute solution of $Zn^{65}Cl_2$. Zincate concentrations were determined by titration with EDTA, and samples (0.5 ml or 1.5g) were used

for radioactive counting. All work was carried out at room temperature, 23° ± 1°C.

Zincate/solid ZnO exchange.—Each mixture contained about 3g of undissolved ZnO, having a particle size of 0.3μ, suspended in 60 ml of KOH solution (10, 20, 30, and 45%) previously saturated with tagged ZnO. These mixtures were agitated on a mechanical shaker. The results are shown in Fig. 1. The amount of exchange was followed by noting the decrease in count rate of the solution and by measuring the uptake of Zn^{65} by the solid ZnO. The latter procedure was more inconvenient because of the problems associated with the washing of the solid ZnO.

In the case of the 30% KOH solution, no exchange occurred during the experimental time period. In the case of 10% and 20% KOH, a small amount of exchange occurred. This could not be ascertained from Fig. 1, but was determined from the count rate of the solid ZnO at the end of the run. The "time infinity" values on Fig. 1 are calculated values based on the assumption of complete exchange. It is clear that in no case were these values approached on the present time scale.

The system based on 45% KOH did not show a change in radioactivity of solution with time within the uncertainty limits inherent in the radiometric counting. To check this, the amount of undissolved ZnO in the system was increased to 12g. Figure 2 shows the results; a small but significant amount of exchange occurs.

As a check on the results shown in Fig. 1, the solid was removed from each system at the completion of the experiments and counted for radioactivity. The results are shown in Table I. For 30% KOH no exchange has occurred, the solid ZnO being free of tagged Zn. For 10% KOH the ZnO shows pronounced activity but the 20% and 45% KOH systems exhibit only weak activity.

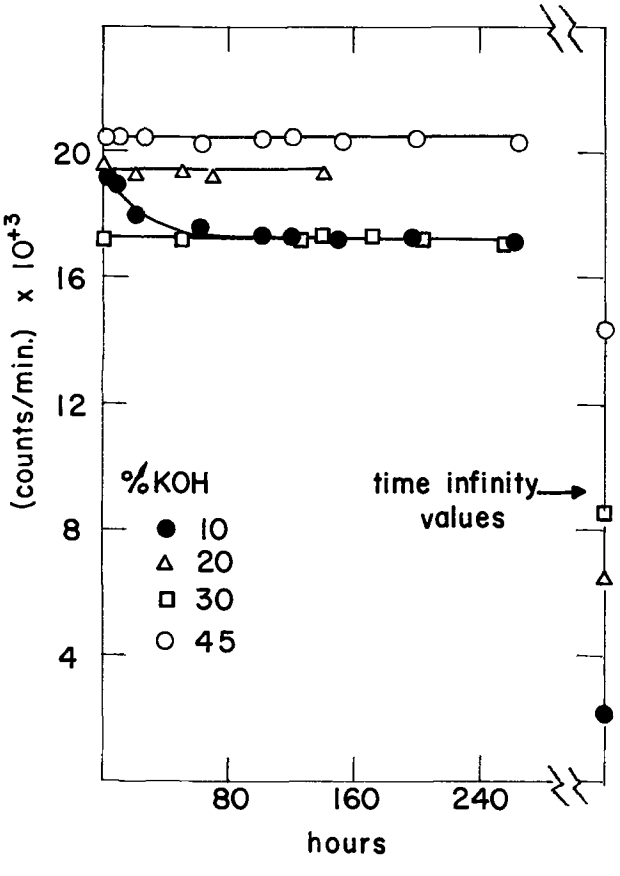

Fig. 1. Change in radioactivity of KOH solutions saturated with ZnO and in equilibrium with 3g excess ZnO. Counting rates in 10^3 counts per min.

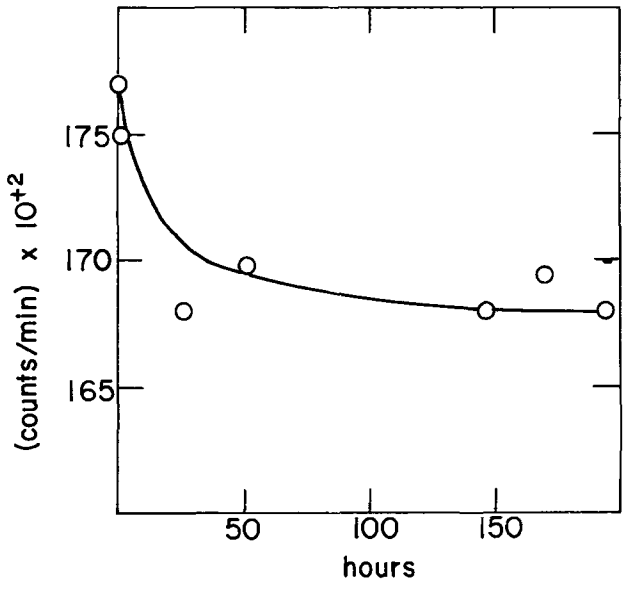

Fig. 2. Change in radioactivity of 45% KOH saturated with ZnO and in equilibrium with 12g excess ZnO. Counting rates in 10^2 counts per min.

Discharge of Zn into KOH saturated with tagged ZnO.—The electrolyte system consisted of KOH solutions saturated with tagged ZnO, zinc anodes, and cadmium oxide cathodes. As current passes through the cell the zinc dissolves and the cathode is reduced to cadmium metal. Charge was passed until a supersaturated solution of potassium zincate [2 to 3 times the equilibrium concentration of Zn(II)] resulted. This was verified by EDTA analysis. The supersaturated solution was stored until a precipitate of ZnO was deposited. This required about 2 days for the first signs of solid deposition to appear. From time to time throughout the precipitation period solution samples were removed, filtered, analyzed, and counted for radioactivity. In the 35% KOH solution, the supersaturated solution contained 0.1 mole Zn(II). At the end of the run, 2.4g of ZnO had precipitated.

The results of these experiments are given in Table II. The solution shows no change in the proportion of the atoms of zinc which are tagged.

Zincate/zinc metal exchange reaction.—Tagged solid zinc electrodes were suspended in untagged potassium

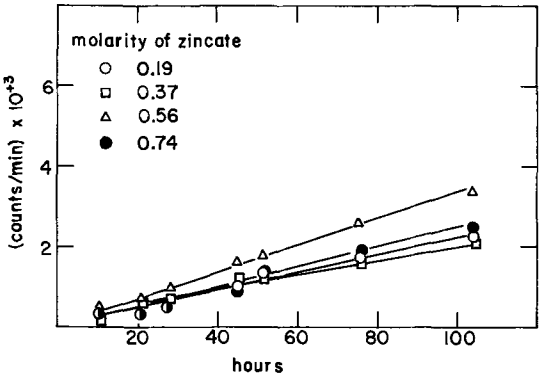

Fig. 4. Change in radioactivity of 35% KOH in contact with tagged zinc electrodes at room temperature. Counting rates in 10^3 counts per min.

zincate solutions. The change in the radioactive count for the solution was measured from time to time. Figure 3 shows the change in radioactivity for a zincate solution based on 45% KOH and Fig. 4 shows similar data for a solution based on 35% KOH. The solution radioactivity increased markedly. Examination of the electrode at this point revealed that the zinc deposit had been corroded to such an extent that the platinum base had become exposed. Data are tabulated in Table III. Calculation of the rate of corrosion by measuring the weight loss indicated a rate of 2×10^{-6} mol hr^{-1} cm^{-2}.

In a further series of experiments with solid electrodes, untagged zinc sheets were placed in tagged zincate solutions. Again no change in the radioactivity of the solution could be detected.

Discussion

The exchange between zincate and solid ZnO.—Saturated zincate electrolytes based on 30% KOH solutions in contact with ZnO exhibit rates of exchange of Zn too small to be measured in the present experiments. This effect may be an extension of the observation (9) that the rate of exchange decreases with increase in the pH of the electrolyte. However, this is not substantiated by the results obtained in 10, 20, and 45% KOH solutions. In the 10% and 20% KOH solution a small exchange rate was noted. In the 45% KOH system exchange was detected and confirmed only when the surface/volume ratio had been considerably increased to enhance the radioactive changes occurring in the electrolyte.

Table III. Zinc-zincate exchange in 35% KOH at room temperature

Run	Start of run: mg Zn	Start of run: (10^7 cts/min) g^{-1}	End of run: mg Zn	End of run: (10^7 cts/min) g^{-1}	For complete exchange: (10^6 cts/min) g^{-1}
1	77	1.45	39	1.33	8.8
2	76	1.52	32	1.31	17.5
3	85	1.24	31	1.39	5.7
4	78	1.39	15	1.35	4.5

No satisfactory theoretical explanation has yet been developed to account for the behavior of the ZnO/zincate system. The detection of a little exchange at the higher KOH concentration is a further perplexing aspect. A possible explanation is that below 30% KOH zincate ion is in some respect different from that in zincate solutions based on KOH of concentration greater than 30%. Further work in this area is urgently required.

The main concomitant of the present work is that in strongly alkaline solutions of zincate, in which energy conversion devices are conventionally operated, the mechanism cannot include any step which assumes a rapid equilibrium between zincate ion and solid zinc oxide. Such mechanisms apply in the case of microporous zinc electrodes operating in low electrolyte volume to active material ratio when electrolyte efficiencies well in excess of 100% are readily achieved. The nonestablishment of an equilibrium between products (ZnO) and the electrolyte may explain why this system is not subject to considerably more concentration polarization than is generally observed. The reduction of a ZnO-rich phase (discharged negative) may well be expected to go by a solid phase "direct" reduction in the absence of a rapid Zn(II) exchange between solution and ZnO. This latter aspect may explain the high microporosity of such zinc negative plates. The absence of a significant solution (or surface) diffusion step hinders the development of compact deposits on cycling (as occurs in the lead-acid battery but is far less marked in the zinc electrode in alkali).

The production of supersaturated zincate solutions.—The experiments indicate that Zn(II) produced electrochemically and zincate ion in solution are in equilibrium. There is evidence that supersaturated solutions produced by dissolving ZnO in KOH contain two solution species (4) in which case it follows from the present experiments that these two are themselves in equilibrium.

The zinc/zincate exchange reaction.—The results of the weight loss *vs.* time correlation, 2×10^{-6} mol hr^{-1} cm^{-2}, agrees very well with the reported rate of corrosion of zinc in alkaline solution in contact with the atmosphere (10). The result of the experiment with the untagged zinc sheets that no change in solution radioactivity occurs, further reinforces the idea that the exchange reaction at the Zn/Zn(II), OH^- interphase cannot be followed by radiochemical experiment due to the spontaneous corrosion of zinc in the electrolyte. The uptake of tagged zinc from solution in any case would be small and the parasitic dissolution of the electrode due to local action is difficult to suppress and has the effect of obscuring any atomic exchange. Carefully purified microelectrodes used in ultrapurified systems are not feasible where it is necessary to measure a significant reduction in radioactivity.

Energetics of Single Ion Solvation in Nonaqueous Solvents and the Effects on Electrode Kinetics

Mark Salomon

U. S. Department of Transportation, Transportation Systems Center, Cambridge, Massachusetts 02142

ABSTRACT

Individual ionic energies of solvation are estimated for solvation in methanol and in a 20% dioxane-water mixture. As found in a previous paper (1), these solvation energies are about 10 to 15 kcal/mole larger (more positive) than most previous estimates. A detailed discussion is presented on these differences. The medium effect is discussed in relation to the kinetics at electrode surfaces and it is proposed, and demonstrated, that the standard chemical free energy of transfer of the activated complex from water to an organic solvent is, effectively, zero. Based on this assumption, a new method is presented for the calculation of differences in surface potentials between water and an organic solvent.

In a previous paper (1) it was proposed that single ion solvation energies can be estimated from the empirical relation

$$d\,\Delta G^{o}_{conv} = \text{constant}/r - 2\Delta G^{o}_{solv}(RI) \quad [1]$$

In Eq. [1] $\Delta G^{o}_{solv}(RI)$ is the solvation energy of the reference ion and $d\Delta G^{o}_{conv}$ is the difference in conventional energies of solvation between a cation and anion of equal ionic (crystal) radius, r. For monovalent ions, the conventional energies, referred to the solvated proton, are given by

$$\Delta G^{o}_{conv}(M^+) = \Delta G^{o}_{solv}(M^+) - \Delta G^{o}_{solv}(H^+) \quad [2a]$$

$$\Delta G^{o}_{conv}(X^-) = \Delta G^{o}_{solv}(X^-) + \Delta G^{o}_{solv}(H^+) \quad [2b]$$

The constant term in Eq. [1] is therefore

$$\text{constant}/r = \Delta G^{o}_{solv}(M^+) - \Delta G^{o}_{solv}(X^-) \quad [3]$$

Izmailov (2) actually proposed the use of these relations some 10 years prior to the present use. However Izmailov proposed that $\Delta G^{o}_{solv}(M^+)$ and $\Delta G^{o}_{solv}(X^-)$ are accurately described by a function in $1/r$ or $1/n^2$ (n is the principal quantum number of the lowest vacant orbital of the ion) and that plots of $\Delta G^{o}_{conv}(M^+)$ and $\Delta G^{o}_{conv}(X^-)$ *vs.* $1/r$ should extrapolate to the same intercept; *i.e.* at $1/r = 0$, the common intercept is $\Delta G^{o}_{solv}(H^+)$. There are several objections to this assumption. If it is correct, then it follows that the choice of crystal radii will seriously effect the extrapolations as the intercepts will vary depending upon which set of radii are chosen (see below for numerical results). Also, this simple assumption regarding a common intercept is actually an acceptance of the Born equation. It is well established [see discussions in Ref. (1), (3-5)] that the leading electrostatic terms are really those for ion-dipole ($1/r^2$), ion-quadrupole ($1/r^3$) and dipole-dipole interactions ($1/r^3$) in the first solvation sphere. Other electrostatic terms such as ion-induced dipole ($1/r^4$), ion-induced quadrupole ($1/r^5$) and other multipole interactions are difficult to treat analytically and are often neglected as they are probably quite small. Nonelectrostatic terms such as those due to the London dispersion forces, hydrogen bonding, charge transfer and σ- and π-bonding require a quantum mechanical approach for their analytical treatment and it is highly unlikely that a simple $1/r$ plot, even if linear, would yield an intercept equal to $\Delta G^{o}_{solv}(H^+)$. In general (see below), the $1/r$ plots of Eq. [2a] give higher (more positive) intercepts than those of Eq. [2b]. In Izmailov's works (2) Eq. [2b] was used to obtain the intercept since this relation was found to be linear in $1/r$ and the plot for cations (Eq. [2a]), which was not linear, was subjected to a long extrapolation to the intercept obtained from the anion plot. In previous work (1) it was found that $1/r$ plots of Eq. [2a] and [2b] were linear (using more recent thermodynamic data for solvation energies) and that the intercepts were not identical. It was concluded that:

(1) A linear relation for ΔG^{o}_{conv} *vs.* $1/r$ is strictly empirical and that the intercepts contained residual energetic terms due to those forces which have a higher order dependence than $1/r$. The intercept of the $1/r$ plot of Eq. [2a] can be represented by the sum[1]

$$(\text{intercept})_a = -\Delta G^{o}_{solv}(H^+) + \sum_{j=1}^{n-1} a_j/r^n \quad [4a]$$

Similarly, for Eq. [2b], the intercept of the simple $1/r$ plot is

$$(\text{intercept})_b = -\Delta G^{o}_{solv}(H^+) + \sum_{j=1}^{n-1} b_j/r^n \quad [4b]$$

Key words: medium effects, solvent effects, single ion solvation energies, electrode kinetics, surface potentials.

[1] Born charging is omitted from this sum since it is really a function of $\{r(\text{ion}) + 2r(\text{solvent})\}^{-1}$ as discussed elsewhere (4, 5).

where $n = 2, 3, 4, \ldots\ldots$ and a_j and b_j are constants which are not necessarily equal.

(2) With the exception of the Born charging energy, all other electrostatic interactions are highly dependent upon structural properties; *e.g.* the number of solvent molecules in the inner solvation sphere and the alignment of their multipoles with respect to the radial direction of the ion. Both the enthalpy and entropy terms are very sensitive to these structural parameters (3-8) and a simple $1/r$ dependence for these terms could not be considered valid. Free energy relations are, however, considerably simpler since much cancellation occurs between the enthalpy and entropy terms (1, 6, 9) and in this context we have proposed earlier (1) that

$$\lim_{r \to \infty} \{\Sigma\, a_j/r^n - \Sigma\, b_j/r^n\} \to 0 \qquad [5]$$

Since the energies and enthalpies are not exact functions of $1/r$, there are no reasons to believe that the individual intercepts in Eq. [4] are equal to $\Delta G^\circ_{solv}(H^+)$. These intercepts are dependent upon the choice of crystal radii used in the calculation and it is more valid to consider differences in conventional energies (*i.e.* Eq. [1]) since the difference in intercepts is independent of the choice of radii as long as the sum of the cation and anion values equal the observed value. The assumption that the "neutral" part of the solvation energy or enthalpy is simply related to some function of the ionic radius (*e.g.* r^2 or r^4) has proved to be a popular approach in evaluating these single ion contributions (1-3, 8, 10, 11). It should be pointed out that this procedure may be invalid if, as discussed by Noyes (12), these neutral energies for the individual ions are more accurately related (identical) to the neutral energies for an iso-electronic rare gas molecule.

Data and Results

Table I lists conventional free energies for various ions referred to the proton in methanol and in a 20% (by weight) dioxane-water mixture. These data are based on the emf studies of Feakins *et al.* (15-17). Also included in this table are the reciprocals of the crystal radii obtained from Ref. (13) and (14). Figures 1 and 2 are plots of Eq. [1] for the 20% dioxane-water mixture using, respectively, Pauling's radii and Gourary and Adrian's radii. Plots of Eq. [1] for methanol and water have a similar appearance. The results for these three systems are summarized in Table II. For the aqueous system (1) the value of $\Delta G^\circ_{solv}(H^+)$ based on Eq. [1] is identical using either Pauling's or Gourary and Adrian's radii. The fact that $\Delta G^\circ_{solv}(H^+)$ in the nonaqueous solvents are, very slightly, dependent upon which set of radii are used (to within ± 1 kcal/mole) is attributed to the shorter range of linearity using the Gourary and Adrian radii which therefore leads to a greater uncertainty in the extrapolation to $r = \infty$. In the discussions below, the results for the nonaqueous systems based on Pauling's radii are compared with the aqueous data from Ref. (1). Table III summarizes the single ion solvation energies obtained

Table I. Conventional free energies and crystal radii[a,b]

by the author and several other investigators. A more complete review is given elsewhere (18). It has been noted in Ref. (18) that if more recent values for ΔG°_{conv}(ion) are used in the original Izmailov method (2), then it is found (for water) that $\Delta G^\circ_{solv}(H^+) = 251.5$ kcal/mole. It has also been observed here and in Ref. (1) that the cation plots of Eq. [2a] are linear [there is curvature for this plot around the point for Li^+ when the Gourary and Adrian radii are used; Pauling's radii lead to completely linear plots (1)]. Latimer, Pitzer, and Slansky (19) added a small constant factor (the δ-factor) of 0.10Å to all anion radii and a large constant factor of 0.85Å to all cation radii to obtain linear plots of Eq. [2a] and [2b] such that they had a common intercept. These δ-factors for water have been reported to be as high as 0.42Å for anions (23) and as low as 0.64Å for cations (24).

The medium effect for single ions is an important factor in studying solvation behavior. King (25) has given an excellent review on this subject and Popovich (21) and Criss and Salomon (18) have reviewed some more recent developments in this field. Feakins *et al.* (15-17, 22) have studied the alkali metal halides and acid halides in great detail and have proposed that the standard chemical free energies of transfer of ions from water to pure methanol or a methanol-water mixture can be obtained from

$$\Delta G^\circ_t = \Delta G^\circ_t(H^+) + k/r_- \qquad [6a]$$

and from

$$\Delta G^\circ_t = \Delta G^\circ_t(X^-) - m/r_+ \qquad [6b]$$

Here ΔG°_t is the measured standard chemical free energy of transfer of the halogen acid HX or the metal halide MX and k and m are constants. It was found that the $\Delta G^\circ_t(H^+)$ values obtained from Eq. [6a] and [6b] were significantly different and average values were used. Popovych (21) has determined ΔG°_t(ion) values for the transfer from water to methanol by assuming that ΔG°_t(large cation) = ΔG°_t(large anion). Alfenaar and DeLigny (10) suggested that the extrapolations based on [6a] and [6b] could be improved by first correcting for the neutral free energy of transfer, $\Delta G^\circ_{t,n}$, which is assumed to be a function of r^2. They assume the applicable relations for the evaluation of $\Delta G^\circ_t(H^+)$ are

$$\Delta G^\circ_t(HX) - \Delta G^\circ_{t,n}(X^-) = \Delta G^\circ_t(H^+) + a/r_- + b/r^2_- + c/r^3_- + \ldots. \qquad [7a]$$

$$\Delta G^\circ_t(H^+) - \Delta G^\circ_t(M^+) + \Delta G^\circ_{t,n}(M^+) = \Delta G^\circ_t(H^+) - a/r_+ + d/r^2_+ + e/r^3_+ + \ldots \qquad [7b]$$

The quantities on the LHS of [7a] and [7b] are known and plotted *vs.* $1/r$. The resulting curves were not linear and a long nonlinear extrapolation was made to a common intercept. The ΔG°_t(ion) values for the transfer from water to methanol and to the 20% dioxane-water mixture obtained from these various methods are given in Table IV. There is fairly good agreement between the present values and those of Feakins *et al.* The data of Alfenaar and DeLigny are in moderate agreement with these two sets of ΔG°_t(ion) values but Popovych's results are markedly different. The standard real free energies of transfer which were measured by Case and Parsons (20) are discussed below. The negative ΔG°_t(cation) values indicate that methanol is a stronger base than is the water molecule in pure aqueous solutions. It has been suggested recently (21) that the reverse situation exists; *i.e.* that the water molecule in pure water is a stronger base than is the methanol molecule in pure methanol. The basis of this conclusion rests in the calculation of positive ΔG°_t(cation) values. There are however several reasons why the positive ΔG°_t(cation) values of Popovych and Izmailov should be questioned (18, 26). Izmailov's results are based on a questionable extrapolation. Popovych has based his results on the assumption that the free energies of transfer of the triisoamylbutylammonium cation (TAB^+) is equal to that for the tetraphenyl boride anion (Ph_4B^-). The experimental free energies of transfer were obtained mainly from solubility data. TAB^+ and Ph_4B^- were chosen as reference ions because of the equality of the Stokes radii of these two ions in water and methanol. Besides the fact that the significance of Stokes radii are unclear (8), it has also been pointed out (18) that solubility measurements for large organic salts are very difficult to perform and are subject to the following possible sources of error:

1. The possible formation of ion pairs.
2. The possible formation of crystal solvates.
3. The possibility of complex ion formation.
4. The possibility of micelle formation.

Coetzee and Sharp (42) have recently found experimental (NMR) evidence showing that there is indeed specific solvation effects with large reference ions and suggest caution in accepting them as ideal solutes. Emf measurements, which can easily be corrected for non-ideal behavior, therefore yield the most accurate ΔG°_t(salt) values [cf. (18), (27)]. Table V illustrates

Table V. Experimental ΔG°_t (salt) values for HCl and KCl for the transfer from water to methanol and the sum $\Delta G^\circ_t(M^+) + \Delta G^\circ_t(X^-)$ at 25°C*

Salt	ΔG°_t (salt) (experimental)	$\Delta G^\circ_t(M^+) + \Delta G^\circ_t(X^-)$	ΔG°_t (ion) calc. from	Reference
HCl	5.36 (15, 16)	5.36	1/r plot	15, 16, p
		5.36	Reference ion	21
		5.59	1/r plot	2
KCl	6.29 (15, 16)	6.29	1/r plot	15, 16, p
		5.29	Ref. ion (solubility)	21
		4.09	1/r plot	2

* ΔG°_t values are in kcal/mole based on molal units; reference p indicates present results.

the accuracies in the reported ΔG°_t(ion) values by comparing the experimental value of ΔG°_t(salt) with the same quantity calculated from the sum of the individual ΔG°_t(ion) values.

Electrode Kinetics and the Medium Effect

The medium effect has been applied to acid base behavior (25), structural properties (15, 16, 18, 20, 21) and to nucleophilic substitution reactions (28). Very few studies are concerned with cation substitution or transfer reactions [cf. ref. (28)] and only one example dealing with the electrochemical proton transfer reaction in H_2O and MeOH-H_2O mixtures has been reported (29). The relative rates of ion substitution or transfer reactions is given by

$$k^{\circ}_w/k^{\circ}_s = \exp\{[\Delta G^{\circ}_t(\neq) - \Sigma\, \Delta G^{\circ}_t(r)]/RT\} \quad [8]$$

In this relation k° is the specific rate constant for water (w) and some organic solvent (s); $\Delta G^{\circ}_t(\neq)$ is the standard chemical free energy of transfer of the activated complex and $\Delta G^{\circ}_t(r)$ is that for a reactant ion or molecule. For anion nucleophilic substitution reactions, the rates in dipolar aprotic solvents are typically 10^6 times greater than they are in water and this has been shown to be due, mainly, to the large positive ΔG°_t(anion) values (28). If on the other hand, ΔG°_t(ion) is negative, as they usually are for the transfer of small cations from water to most organic solvents (18, 28), then one might "predict" that k°_w/k°_s will be greater than unity since the reactant would be in a lower free-energy state in the organic solvent. The fact that the rates of solvent molecule exchange between bulk solution and the inner solvation sphere of transition metal ions are orders of magnitude faster in pure water than they are in methanol or MeOH-H_2O mixtures has been offered as proof of this type of behavior (18). In the present paper, the relative rates of cation transfer at electrodes are considered. A general electrode reaction involving the transfer of cations is

$$M_h^+ + e_M^- \rightleftharpoons X^{\neq} \rightarrow M_M \quad [9]$$

where the subscripts h and M refer, respectively, to a hydrated species and a species located on or in the metal electrode. The ratio of standard exchange currents for reaction [9] in water and some organic solvent is given by (18, 29)

$$i_o(w)/i_o(s) = \exp\{[\Delta G^{\circ}_t(\neq) - \Delta G^{\circ}_t(M^+) + (1-\beta)(\psi_s - \psi_w)\mathbf{F} + \beta\mathbf{F}(\phi_s - \phi_w)]/RT\} \quad [10]$$

In Eq. [10], ψ is the potential at the outer Helmholz plane (specific adsorption is not considered here), ϕ is the absolute single electrode potential, and β is the transfer coefficient. Equation [10] is valid only if β has the same value in the two solvents under consideration. It is also convenient to define the following rate constant ratio (30)

$$i_o(w)/i_o(s) = k^{\circ}_a(w)/k^{\circ}_t(s) = [k^{\circ}_t(w)/k^{\circ}_t(s)]\exp\{(1-\beta)(\psi_s - \psi_w)\mathbf{F}/RT\} \quad [11]$$

where k°_a is the standard rate constant and k°_t is the standard rate constant corrected for double layer effects and is often referred to as the true heterogeneous constant. There are several complicating factors involved in dealing with these relations. One problem is concerned with the potential difference term $\phi_s - \phi_w$. It is not valid to equate this term with the standard chemical free energy of transfer of a single ion or ions as has been done previously (29). This potential difference term is however given exactly in terms of the standard real free energies of transfer (18, 20, 27, 31); *e.g.* for the reversible hydrogen electrode in two solvents we can write

$$\Delta\alpha^{\circ}_t(H^+) = \Delta G^{\circ}_t(H^+) + (\chi_s - \chi_w)\mathbf{F} = [\phi_s(H^+) - \phi_w(H^+)]\mathbf{F} \quad [12]$$

where χ is the surface potential for the indicated solvent. In this context it should be mentioned that methods of arriving at individual ionic contributions to the standard chemical free energies of transfer, ΔG°_t(ion), based on the assumption that an electrode reaction is independent of the nature of the solvent are basically incorrect because of the neglect of these χ terms. The χ terms do not enter into Eq. [8] as they cancel because we are considering differences in free energies between the initial and activated states. Thus in order to be able to "predict" relative rates of electrochemical reactions, the χ-potentials or the standard real free energies must be known. Another critical quantity in Eq. [8] and [10] is the free energy of transfer of the activated complex. In a previous paper (29) this term was adjusted empirically by use of the Born equation. Parker (28) has shown that a reasonable assumption for some S_N2 type reactions is $\Delta G^{\circ}_t(\neq) = 0$ and below it is shown that this assumption is satisfactory for electrochemical reactions. Since the χ-potentials are important quantities in these calculations, it is of interest to present some discussion on their evaluation.

Case and Parsons (20) have used Kenrick's method (32) to measure real free energy differences of ions between water and several organic solvents. Some of their results are included in Table IV. Only one paper (31) reports the measurement of an individual χ value which is based on the assumption that for very large hydrocarbon anions (R^-) and cations (R^+), the following relation holds

$$\lim_{r\to\infty}\ [\alpha_{R^+} - \alpha_{R^-}] \rightarrow 2\chi \quad [13]$$

Here α_R is the real free energy of solvation of a hydrocarbon ion. In this way the value of χ for acetonitrile (AN) was estimated to be -0.10V at 25°C. The negative value of χ corresponds to a surface orientation with the positive end of the solvent dipole (the hydrocarbon part of the molecule) directed towards the gas phase (31). From direct measurements of the standard real free energy of transfer of the Ag^+ ion from water to AN, $\Delta\alpha^{\circ}_t(Ag^+) = -10.1$ kcal/mole (20), one can estimate χ_{H_2O} using the reported values of $\Delta G^{\circ}_t(Ag^+)$ which vary from -3.1 to -7.5 kcal/mole (see 18, 28). From Eq. [12] we have

$$\chi_{AN} - \chi_{H_2O} \approx -0.113 \text{ to } -0.304\text{V at } 25°C \quad [14a]$$

and for $\chi_{AN} = -0.1$V we have

$$\chi_{H_2O} \approx 0.01 \text{ to } 0.20\text{V at } 25°C \quad [14b]$$

There is good evidence to show that the surface potential of water is about 0.1V (33-35) which is in good agreement with the value estimated above and indicates that the water molecules at the solution-air interface are preferentially oriented with the oxygen atom in the gas phase. For methanol the data in Table IV give $\chi_{MeOH} - \chi_{H_2O} = -0.137$V so that χ_{MeOH} is close to zero and is possibly negative indicating that the dipoles are directed with the hydrocarbon part of the molecule directed towards the gas phase.

We now have all the quantities required to predict the relative rates of proton discharge at mercury cathodes in water and in methanol with the exception of $\Delta G^{\circ}_t(\neq)$. This quantity can be empirically estimated by choosing an appropriate model of the activated complex as has been done previously (29). This method is unsatisfactory because by using the activated complex as a variable parameter, we can explain everything but predict nothing (38). In order to be able to predict relative rates of electrochemical reactions, it is proposed here that $\Delta G^{\circ}_t(\neq)$ for the transfer of large cationic activated complexes from water to any organic or mixed organic-water solvent is zero. To show that this approximation at least holds for the proton discharge reaction at Hg cathodes in methanol and water, we can use Eq. [10] to calculate

$\Delta G^o_t(\neq)$ as shown below. For this reaction, we have the following inputs to Eq. [10] at 25°C [see Ref. (29) for references to the original literature]

$$i_o(w)/i_o(s) = 0.56 \qquad \beta = 0.5$$
$$\Delta G^o_t(H^+) = -2.9 \text{ kcal/mole}$$
$$(\phi_{MeOH} - \phi_w)\mathbf{F} = -5.98 \text{ kcal/mole}$$
$$(\psi_{MeOH} - \psi_w)\mathbf{F} = -0.44 \text{ kcal/mole}$$

These data all refer to the molar concentration scale and making the appropriate substitutions into Eq. [10] gives $\Delta G^o_t(\neq) = -33.5$ cal/mole. Considering the uncertainties in the input data, the assumption that $\Delta G^o_t(\neq) = 0$ is certainly a good one. If this is indicative of general behavior, then Eq. [10] simplifies to

$$i_o(w)/i_o(s) = \exp\{[-\Delta G^o_t(M^+) + (1-\beta)(\psi_s - \psi_w)\mathbf{F} + \beta(\phi_s - \phi_w)\mathbf{F}]/RT\} \quad [15]$$

Thus $i_o(w)/i_o(s)$ can be estimated for any reaction providing enough free energy data are available. It is also interesting to note that Eq. [15] offers a new approach to the calculation of the $\chi_s - \chi_w$ term. Consider the electrode reaction

$$Li^+ + e^-_{Hg} \rightleftharpoons X\neq \rightarrow Li(Hg) \quad [16]$$

for which $k^o_t(w) = 0.02$ cm/sec (36) and $k^o_t(DMSO) = 2.9 \cdot 10^{-5}$ cm/sec (37). Taking $\beta = 0.70 \pm 0.05$ (36, 37) and for the transfer of Li^+ from water to dimethylsulfoxide we have $\Delta G^o_t(Li^+) = -6.0$ kcal/mole (molar scale) (28), all data being reported for 25°C. Making the appropriate substitutions into Eq. [11] and [15], it is found that $\alpha^o_{DMSO}(Li^+) - \alpha^o_w(Li^+) \approx -4.34$ kcal/mole and from Eq. [12] it is found that

$$\chi_{DMSO} - \chi_w \approx 0.072V \text{ at } 25°C \quad [17]$$

Thus χ_{DMSO} is about 0.17V which indicates that at the liquid-air interface, the hydrocarbon part of the molecule is directed towards the bulk of solution and the thionyl ($S = O$) group is directed towards the gas phase.

Conclusions

Any method employing a $1/r$ extrapolation for the evaluation of single ion contributions to solvation energies or energies of transfer must be cautiously regarded because of the long extrapolations involved. This is particularly true for nonlinear extrapolations. The use of reference ions is also associated with several difficulties as discussed above. Since detailed electrostatic-quantum mechanical calculations have not as yet given satisfactory results [cf. (18)] for these ion-solvent and solvent-solvent interaction energies, empirical methods still represent an important procedure for the evaluation of ΔG^o(ion) values. The empirical method used here and in Ref. (1) does at least give linear relations and does not make the questionable assumption that the cation and anion $1/r$ plots give identical intercepts at $r = \infty$. Considering single ion solvation, the only quantities known with some degree of confidence are the standard entropy of solvation of the proton in water (4-6, 9, 39, 40); the standard chemical and real free energies of transfer from water to methanol solutions; and possibly the sign of the surface potential of water (positive) and of acetonitrile (negative).

Gurney's aqueous value of -31.3 eu for $\Delta S^o_{solv}(H^+)$ (40) is generally accepted as the most reliable one (4, 5, 9, 39). If we take as an upper limit values of ~ -260 kcal/mole for $\Delta H^o_{solv}(H^+)$ as indicated in several recent works (7, 11), then this requires that $\Delta G^o_{solv}(H^+) \approx -251$ to -258 kcal/mole [cf. Ref. (5)]. Using Randles' elegantly measured value of $\Delta\alpha^o_{solv}(H^+) = -260$ kcal/mole (41), then from

$$\Delta\alpha^o_{solv}(H^+) = \Delta G^o_{solv}(H^+) + \mathbf{F}\chi_{H_2O} \quad [18]$$

we would have to conclude that χ_{H_2O} is negative regardless of the source of $\Delta G^o_{solv}(H^+)$. It is of course possible that our estimates of χ_{H_2O} above are in error and this only serves to indicate the need for additional work in this area.

Solvation of Alkali Metal Perchlorates in Water

Mark Salomon[1]

NASA, Electronics Research Center, Cambridge, Massachusetts 02142

ABSTRACT

The crystal lattice energies and the energetics of solvation of the alkali metal perchlorates are calculated from a combination of experimental and empirical (theoretical) data. The results indicate that the crystal radius of the perchlorate ion is 1.85Å. The free energy and enthalpy of formation of gaseous ClO_4^- are also estimated.

Perchlorates constitute an important class of salts for studies in solvation phenomena. Despite the wide use of these salts, little is known about several important properties such as the crystal radius of the ClO_4^- ion, the lattice energies and enthalpies of the salts and the free energy and enthalpy of formation of the gaseous ClO_4^- ion. In this paper, a method is discussed in which these properties may be evaluated. In this work only the alkali metal perchlorates are considered.

Entropies of gaseous ions.—The relation between the lattice free energy and enthalpy is given by

$$\Delta G^\circ_{lat} = \Delta H^\circ_{lat} - T\{\Sigma S^\circ_{i,g} - S^\circ_{cryst}\} \quad [1]$$

where $S^\circ_{i,g}$ is the entropy of the gas phase species i, and S°_{cryst} is the crystal entropy. All thermodynamic properties considered in this paper refer to standard conditions of 298.15°K and 1 atm.

For monatomic gaseous ions only the translational degrees of freedom contribute to the entropy so that

$$S^\circ_{i,g} = R\{5/2 + \ln (g(2\pi mkT)^{3/2}V/Nh^3)\} \quad [2a]$$

If the ground state of the electronic energy level is singly degenerate and there are no significant populations of excited states then $g = 1$ and the above equation reduces to

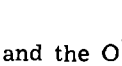
$$S^\circ_{i,g} = 25.930 + 6.8636 \log_{10}M, \text{ (cal/K.mole)} \quad [2b]$$

In these two equations M is the molecular weight of the gaseous ion in g/atoms and all other terms have their usual significance. For polyatomic molecules or ions, rotational and vibrational contributions to the entropy are evaluated from (1)

$$S_{i,rot} = R\{3/2 \ln T + 3/2 \ln I - \ln \sigma\} + 267.65 \text{ cal/K.mole} \quad [3]$$

$$S_{i,vib} = R \sum_i^n \{x(e^x - 1)^{-1} - \ln (1 - e^{-x})\} \quad [4]$$

Here I is the moment of inertia in g-cm^2; σ is the symmetry factor; $x = h\nu/kT = 1.4387\ \omega/T$ where ω is in cm^{-1}; and n is the number of vibrational degrees of freedom for the polyatomic ion composed of N atoms ($n = 3N - 6$ for a nonlinear molecule). For the gaseous perchlorate ion, $\sigma = 12$ which corresponds to a regular tetrahedron (1, 2) for which all three moments of inertia are identical so that $I = (8/3)\ m\ r^2$ where m is the mass (amu) of the oxygen atom. Taking



$r = 1.4$Å and the O Cl O angle as 110° (1, 2), then the fundamental frequencies listed in Table I are obtained using the force constants k (stretch) = 8.24 and k (bend) = 0.670 md/Å.

Lattice enthalpies and free energies.—Since lattice enthalpies or free energies cannot be measured for the perchlorates, other methods of estimating these quantities must be sought. Our first attempt involved the use of the empirical equation (in kcal/mole)

$$-\Delta H^\circ_{lat} = [600/(r_+ + r_-)]\ (1 - 0.4/(r_+ + r_-)) \quad [5]$$

which is claimed (3) to be accurate to within 1-2 kcal/mole. In Eq. [5], r_+ and r_- are, respectively, the crystal radii of the cation and anion in Å. The most accurate crystal radii are believed [*e.g.* see Ref. (4)

Key words: perchlorate ion, crystal lattice energies, crystal radii, solvation energies, solvation enthalpies, free energy and enthalpy of formation.

Table I. Properties of gaseous ClO_4^- and its (solid) salts*

For gaseous ClO_4^-					
Property	Value	Salt	$-\Delta G°_f$	$-\Delta H°_f$	$S°_{cryst}$
ω_1	935	$LiClO_4$	60.71	91.0	30.0
$\omega_2(2)$	462	$NaClO_4$	60.79	91.48	34.0
$\omega_3(3)$	1102	$KClO_4$	71.79	102.80	36.1
$\omega_4(3)$	628				
$I \times 10^{40}$	138.84				
$S°_{1,\,trans}$	39.64				
$S°_{1,\,rot}$	19.85				
$S°_{1,\,vib}$	3.04				

* Reference state is 298.15°K and 1 atm.
ω units are cm^{-1}; number in parenthesis is the degeneracy.
I units are $g\text{-}cm^2$.
S units are eu (cal/K·mole).
ΔH and ΔG are in kcal/mole; 1 kcal = 4.184 kJ.

and (5)] to be those of Gourary and Adrian (6). However values of r_- must often be estimated from "thermochemical" data, *i.e.* they are based on a theoretical calculation such as the Meyer-Born-Madelung treatment in which r is usually determined from the repulsive potential (7, 8). On this basis the crystal radius of ClO_4^- has been found (9, 10) to equal 2.45Å (average value). According to Pauling (2), this radius has a value of 2.0Å. The use of Eq. [5] for any of the alkali metal perchlorates does not yield consistent results with either of these radii and it is concluded that this relation is not valid for the salts presently under consideration (see below).

Free Energies and Heats of Solvation

In our previous work (11) it was found that the conventional enthalpies of OH^-, F^-, Cl^-, Br^- and I^- could be fit to a power series by the least squares method, *i.e.* (in kcal/mole)

$$\Delta H°_{conv}(\text{anion}) = -223.47 - 1945.8/(r_- + 1.38)^2 + 2304.9/(r_- + 1.38)^3 \quad [6]$$

Conventional enthalpies and energies for monovalent anions are defined by

$$\Delta H°_{conv}(x^-) = \Delta H°_{solv}(x^-, \text{absolute}) + \Delta H°_{solv}(H^+, \text{absolute}) \quad [7]$$

$$\Delta G°_{conv}(x^-) = \Delta G°_{solv}(x^-, \text{absolute}) + \Delta G°_{solv}(H^+, \text{absolute}) \quad [8]$$

In Eq. [6], the constant 1.38Å corresponds to the radius of the water molecule and the relation for $\Delta H°_{conv}$ was fit to a function in $(1/r^2 + 1/r^3)$ since they are the leading energetic terms (11-13). In previous work (11) it was postulated that the leading term in the plot of conventional free energies is that in $1/r$ and this is shown in Fig. 1 (neglect, for the moment, the point corresponding to ClO_4^-). The relation for this straight line, in kcal/mole,[2] is

$$\Delta G°_{conv}(\text{anion}) = -265.9 - 114.07/r_- \ (\pm 0.5) \quad [9]$$

The intercept (−265.9) does not represent the absolute solvation energy of the proton since it still contains major contributions from ion-dipole, quadrupole,

[2] 1 kcal = 4.184 kJ.

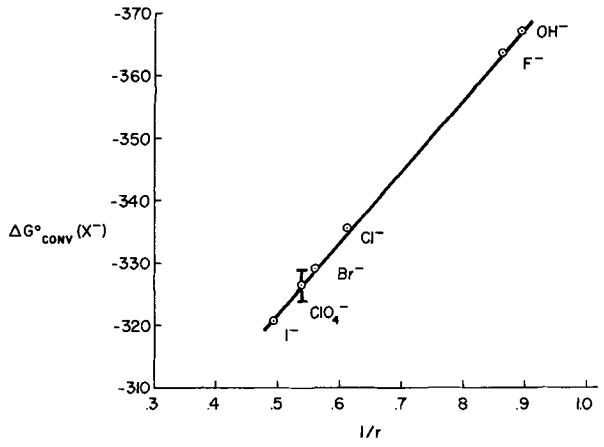

Fig. 1. Plot of convention free energy of solvation for anions vs. the reciprocal of the crystal radius.

etc., interactions (11), and Eq. [9] is therefore strictly empirical. The conventional terms are all (except for the perchlorates) experimentally available. The only experimental data available for alkali metal perchlorates are the heats of solution (14) and the solubilities (15). The free energies of solution for the moderately soluble K, Rb, and Cs perchlorates can be obtained from

$$\Delta G°_{soln} = -2RT \ln(m_\pm \gamma_\pm) \quad [10]$$

where $\ln \gamma_\pm$ is obtained from the Davies equation (16)

$$\ln \gamma_\pm = -Am^{1/2}/(1 + m^{1/2}) + 0.3Am \quad [11]$$

The relations between the heats and energies of solvation and solution are

$$\Delta H°_{solv} = \Delta H°_{lat} + \Delta H°_{soln} \quad [12]$$

$$\Delta G°_{solv} = \Delta G°_{lat} + \Delta G°_{soln} \quad [13]$$

The calculations proceeded as follows. Values of $r_{ClO_4^-}$ were assumed starting from 1.2Å up to 3.0Å and $\Delta H°_{conv}$ (ClO_4^-) was calculated from Eq. [6]. This result was used to obtain the enthalpies of solvation for the K, Rb, and Cs salts from

$$\Delta H°_{solv}(MClO_4) = \Delta H°_{conv}(ClO_4^-) - \Delta H°_{conv}(M^+) \quad [14]$$

Values of $\Delta H°_{conv}$ (M^+) are 180.1, 184.3, and 188.3 kcal/mole, respectively, for $M = K^+$, Rb^+, and Cs^+ (11) (for $M = Li^+$ and Na^+, $\Delta H°_{conv} = 137.2$ and 162.6). From these enthalpies of solvation, the lattice enthalpies were calculated using Eq. [13]. Adding the entropy terms (*cf.* Table I) the lattice free energy is obtained (Eq. [1]) and finally the free energy of solvation is obtained from Eq. [13]. For the three salts (K, Rb, Cs), the value for $r_{ClO_4^-}$ which best fit Eq. [9] is 1.85Å and the point for ClO_4^- shown in Fig. 1 was obtained in this manner. Using this value of −326.08 ± 2.5 kcal/mole for $\Delta G°_{conv}$ (ClO_4^-), the values for the Li and Na salts were obtained by the additivity requirement. The results are shown in Table II. Under

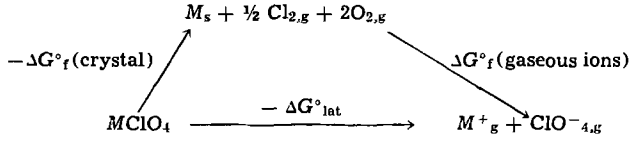
Table II. Thermal Properties (molal units) of alkali metal perchlorates at 25°C

(kcal/mole)

Salt	m_{sat}[b]	$\Delta H°_{soln}$[c]	$\Delta G°_{soln}$[d]	$-\Delta H°_{lat}$	$-\Delta G°_{lat}$	$-\Delta H°_{solv}$	$-\Delta G°_{solv}$
$LiClO_4$	—	−6.35	−9.5	198.7	(179.5)	(205.0 ±0.1)	(189.0 ± 2.5)
$NaClO_4$	—	3.32	−1.80	180.7	(161.7)	(177.4 ± 0.1)	(163.5 ± 2.2)
$KClO_4$	0.1491	12.20	2.40	169.7	150.8	157.5	148.4
$RbClO_4$	0.0849	13.56	3.04	163.9	145.1	150.4	142.0
$CsClO_4$	0.0688	13.25	3.29	156.6	138.4	143.4	135.1

[a] Those values given in parentheses were obtained using the additivity requirement.
[b] Molalities of saturated solutions are from Ref. (15).
[c] Ref. (14).
[d] Calculated from Eq. [10].

no conditions did Eq. [5] yield any consistent relation between $\Delta H°_{conv}$ and $\Delta G°_{conv}$. The free energy and enthalpy of formation of gaseous ClO_4^- is obtained by considering the cycle



where the subscripts g and s refer to solid and gaseous species, respectively.
Hence

$$\Delta G°_f(ClO^-_{4,g}) = -\Delta G°_{lat} + \Delta G°_f(\text{crystal}) - \Delta G°_f(M^+_g) \quad [15]$$

and

$$\Delta H°_f(ClO^-_{4,g}) = -\Delta H°_{lat} + \Delta H°_f(\text{crystal}) - \Delta H°_f(M^+_g) \quad [16]$$

Using the tabulated values for the heats and energies of formation of the crystals (17) for the three salts (K, Rb, Cs), it is found that $\Delta G°_f(ClO^-_{4,g}) = -36.3 \pm 0.3$ kcal/mole and $\Delta H°_f(ClO^-_{4,g}) = -56.3 \pm 0.2$ kcal/mole.

Conclusions

It should be pointed out that in the estimations of the thermal properties of the perchlorates, the choice of crystal radii for the anions OH^-, F^-, Cl^-, Br^-, I^- appear to be critical. The radii of Gourary and Adrian are chosen because they appear to be the more reasonable ones (4, 5, 19). It might still be argued that a readjustment of the radii back to the original Pauling values might also produce valid results. This does not appear to be the case since those values for $\Delta H°_{lat}$ calculated *via* Eq. [5] based on either Pauling's radii (2) or those quoted by Halliwell and Nyberg (3) still give solvation energies lower by 10-25 kcal/mole than those shown in Table II.

One should also note that the present method assumes that those thermodynamic properties associated with the perchlorate ion follow the same empirical relations (Eq. [6] and [9]) derived for the halide ions. Whether this is a valid procedure or not cannot be determined at present but this assumption is not without precedence (19).

Technical Note

The Charging of Cu in Organic Electrolytes

Stuart G. Meibuhr*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

The advent of high energy density batteries has focused research efforts on metal halide cathodes such as $CuCl_2$. This research has centered principally on the use of Lewis acid solutes in propylene carbonate solvent. Rao found (1) that the oxidation of Cu metal resulted in soluble CuCl rather than the slightly soluble $CuCl_2$. Eisenberg *et al.* obtained (2) an i_o value of 3-6 x 10^{-5} A/cm^2 for the room temperature reduction of $CuCl_2$ to Cu in the same type of Lewis acid electrolytes.

The study of $CuCl_2$ electrodes had been initiated in this laboratory by using two types of organic solvents: one in which the $CuCl_2$ was only slightly soluble (for example, propylene carbonate), and the other extreme in which the $CuCl_2$ was very soluble (for example, triethylene glycol dimethyl ether [TEGDME]). Initial polarization studies on porous $CuCl_2$ electrodes immersed in 1M $NaClO_4$ solutions of TEGDME containing 0.5M $CuCl_2$ showed that the charging polarization was unusually high—in the order of several volts. No such high charging polarization was observed in propylene carbonate. The cause of the high polarization was postulated as due to the forma-

* Electrochemical Society Active Member.
Key words: triethylene glycol dimethyl ether, triethylene glycol, polarization, cupric chloride, cuprous chloride film.

tion of a highly resistive, insoluble film. The verification of that postulate is the subject of this note.

The IR-free and the IR-included charging polarization was measured simultaneously with a Kordesch-Marko bridge as a function of time at a smooth Cu electrode (1 cm^2) immersed into either of two electrolytes made from TEGDME or triethylene glycol (TEG). These electrolytes both contained 1M $NaClO_4$, dried as previously described (3), and anhydrous $CuCl_2$. However, the solubility of CuCl was different in each solution; CuCl would be an intermediate product formed during the charging process (1). In TEGDME, the solubility of CuCl was found to be low whereas in TEG, the solubility was found to be high. A Cu wire reference electrode was located 2 mm from the working Cu electrode. Both solvents were vacuum distilled; Karl Fischer water analysis showed that TEGDME had a water content <20 ppm and TEG had a water content ~100 ppm.

The potential-time plots, which resulted from using the TEGDME solution, are shown in Fig. 1; curve A represents the *IR*-free data and curve B represents the *IR*-included data. Both sets of data were obtained at the low current density of 0.25 mA/cm^2. Higher current densities only served to develop the high polarization more quickly. The large voltage difference between the two curves indicates a large *IR* loss that cannot be attributed simply to solution resistance. The solution resistivity was determined to be 275 ohm-cm; this value corresponds to only 15 mV solution *IR* drop at this current density. Since CuCl was previously found to be insoluble in this solution, it appears highly likely that the high polarization was due to the formation of a highly resistive, insoluble film. Curve B exhibits three branches. The transition times (τ) corresponding to the first two branches are identical in length—85 min. These times each represent the passage of 1.275 coulomb. If one assumes that there exists 1 charge/site for the fcc Cu metal, the number of μcoulomb/cm^2 = 210. If one also assumes a surface roughness factor of 10, then τ_1 corresponds to the buildup of a film of about 600 layers thick. Its composition is postulated as solvated CuCl. Since the value for τ_2 is identical to the value for τ_1, we postulate that

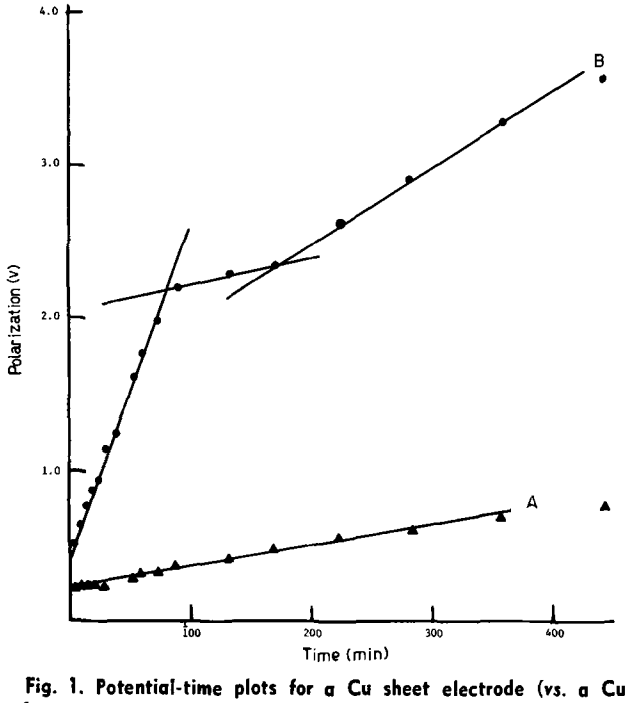

Fig. 1. Potential-time plots for a Cu sheet electrode (vs. a Cu reference electrode) in a TEGDME-1M $NaClO_4$ + 0.5M $CuCl_2$ solution at a constant charging current density of 0.25 mA/cm^2. Curve A, *IR*-free polarization; B, *IR*-included polarization.

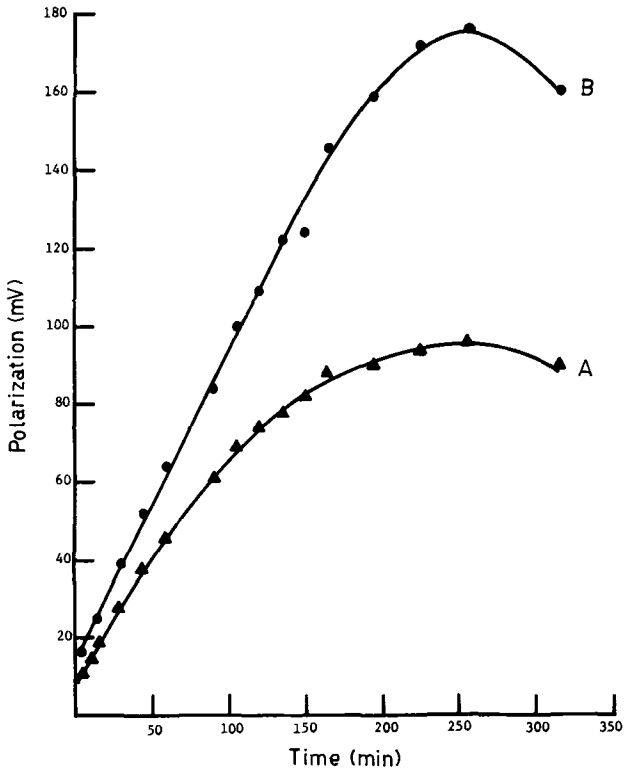

Fig. 2. Potential-time plots for a Cu sheet electrode (vs. a Cu reference electrode) in a TEG-1M $NaClO_4$ + 0.5M $CuCl_2$ solution at a constant charging current density of 0.25 mA/cm^2. Curve A, *IR*-free polarization; B, *IR*-included polarization.

τ_2 corresponds to the conversion of Cu(I) to insoluble Cu(II). The thick film was easily seen with the naked eye when the electrode was removed from the electrolyte.

The potential-time plots, which resulted from using the TEG solution, are shown in Fig. 2. Note the change in the voltage scale from Fig. 1; the two curves carry the same connotation as in Fig. 1. A much lower *IR*-drop occurred during the charging of Cu in this solution than in TEGDME. The *IR*-drop (the difference between curves A and B) can be entirely attributed to the solution resistivity. The low polarization obtained in TEG solutions supported the original hypothesis that a resistive film, probably CuCl was formed in TEGDME, a solution in which CuCl is soluble. Furthermore, no visible film was formed in TEG.

No transition times were observed in the TEG solution, probably because the intermediate product, CuCl, can migrate away from the electrode surface. In TEGDME, no such migration can occur because of its low solubility.

One explanation for the decrease in the potential values (Fig. 2) at times > 250 min could be that the reference potential value was not constant. If Cu(I) is formed in solution, the Cu reference potential would change to reflect this concentration change. The reference potential would no longer be determined exclusively by the Cu(0) $\rightleftarrows$ Cu(II) reaction, but also by the Cu(0) $\rightleftarrows$ Cu(I) and the Cu(I) $\rightleftarrows$ Cu(II) reactions. This potential shift at these long times does not affect the conclusions made regarding the film formation in TEGDME. The reason that no such potential decrease was observed in TEGDME solutions (Fig. 1) can be due to two causes: (*a*) the potential decrease was too small to affect the large observed potential, or (*b*) no such potential shift occurred because Cu(I) is not soluble in TEGDME solution.

These data show that: (*i*) a thick resistive film forms during the anodic charging of Cu in TEGDME

solution; (*ii*) the process of charging a Cu electrode proceeds stepwise in solvents in which the intermediate product, CuCl, is insoluble. Similarly, it may also proceed stepwise in solvents in which CuCl is soluble.

Preparation and Properties of Aluminum Oxide Films Obtained by Glow Discharge Technique

H. Katto and Y. Koga

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo, Japan

ABSTRACT

Amorphous aluminum oxide films have been deposited on silicon substrates by decomposing aluminum trichloride in an rf induced glow discharge of oxygen. Among various deposition parameters, it is shown that the reactant gas pressures affect greatly the deposition rate and the resultant film quality. The properties of these films such as infrared transmission, etch rate, film structure, resistivity, dielectric constant, and dielectric strength are described. Aluminum-aluminum oxide-silicon (MAS) structures were prepared and characterized by the positive values of flat band voltage, distortion of C-V curves, and a large, positive shift in flat band voltage under negative bias at an elevated temperature. The field effect electron mobility was as low as 70 $cm^2/V \cdot sec$, while it could be improved by the annealing at around 700°C, or by putting a thin layer of thermally oxidized silicon dioxide between the aluminum oxide and the silicon.

In the use of MOS transistors and high field devices, some limitations have been recognized in the use of silicon dioxide as a gate insulator or a passivating medium. In particular, attention has been drawn to the inability of the oxide to give positive values of threshold voltage and to stop fast diffusing alkali metals. Aluminum oxide is one of the materials that has been investigated in an attempt to overcome these problems, and the results concerning preparation and properties of aluminum oxide films have been published by several authors using the reaction of an aluminum halide with a hydrogen-carbon dioxide mixture at 900°C (1), thermal decomposition of an aluminum alkoxide at 420°C (2), plasma anodization (3), reactive sputtering (4), reactive vacuum evaporation (5), and r.f. sputtering (6).

In the present study, aluminum oxide films have been deposited by decomposing aluminum trichloride in a radio frequency glow discharge of oxygen. In the glow discharge deposition, adherent films up to several microns can easily be obtained at fairly low deposition temperatures; thus the technique offers the possibility of depositing films on a wide variety of substrate materials. A complete understanding of discharge reactions requires detailed studies. Here, a semi-empirical approach has been taken to optimize growth conditions, and to evaluate the properties of aluminum oxide films deposited by the r.f. glow discharge method for field effect devices.

Experimental

Deposition apparatus.—Figure 1 shows the general arrangement of the apparatus, which is similar to the one presented by Swann *et al.* (7), differing in that the silicon substrate is grounded through a platinum-rhodium (4:1) susceptor in order to obtain a larger deposition rate. A 400 kHz, 10 kW radio frequency generator; Model MA-1003H (Kokusai Electric), is used to supply energy for both the chemical reaction and substrate heating by means of a radio frequency coil surrounding a vertical fused silica tube with a diameter of about 60 mm. The susceptor temperature is measured by an infrared pyrometer: Thermodot Model TD 7B (Infrared Industries). The pressure of oxygen in the reactor chamber is controlled by a leak valve and monitored by a Pirani vacuum gauge. Aluminum trichloride is placed in an oxygen stream and heated up to 70°-120°C to get a pressure necessary for the deposition of aluminum oxide. The vapor pressure of aluminum trichloride was estimated by using the known vapor pressure curve (8).

The glow discharge is sensitive to the shape and arrangement of the metal susceptor and earth line, and is liable to concentrate on the sharpened or irregular points of metals disposed in the reactor tube. There-

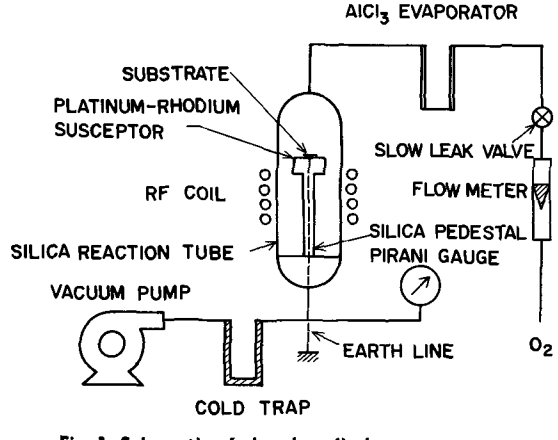

Fig. 1. Schematic of the glow discharge apparatus

Key words: dielectric, passivation.

fore, to get the glow discharge stable on the metal susceptor, the under side of the susceptor and the earth line are carefully shielded by a silica tube.

Fabrication and measurements.—Aluminum oxide films were deposited usually on (100) surfaces of p- or n-type silicon slices of resistivity 30-50 and 3-7 ohm-cm. P-type silicon slices of resistivity 3-7 ohm-cm were used for n-channel MAS or MAOS transistor fabrication. In general, the oxide deposition is independent of the silicon substrate resistivity.

Because of the mobility problem encountered by aluminum oxide-silicon structures (see later), aluminum oxide films were also deposited on silicon dioxide-silicon samples prepared by thermally oxidizing silicon in dry oxygen at 1000°C. The oxide thickness was up to 500Å. Postdeposition heat treatment in N_2, O_2, and H_2 have also been made. For the electric evaluation of the interface properties of aluminum oxide-silicon structure, MIS structures with a diameter of 1 mm were prepared by evaporating aluminum by the filament method using a metal mask.

The film thickness of aluminum oxide deposited on silicon was measured by observing the change in interference colors on the basis of the color chart made by interferometry for the aluminum oxide, similar to the one used for silicon dioxide (9). The infrared transmission curve was taken using a Model EPI-G2 Hitachi infrared spectrophotometer. Film structure was determined by reflection electron diffraction and electron micrography. Electrical and interface properties were studied by the MOS capacitance and conductance methods. Capacitance-voltage (C-V) measurements were made in the dark at 1 MHz using a semiautomatic recording apparatus. The d-c bias sweep speed was controlled manually between about 0.1 and 1 V/sec. The stability of the charge distribution was evaluated by applying positive and negative voltages to the gate electrodes of samples at 250°C. Field effect electron mobility was measured by constructing n-channel MAS and MAOS transistors with ring gates. The field effect electron mobility and the threshold voltage (V_{TH}) were obtained from the square-law characteristic of the transistors in the saturation region.

Results and Discussions

Growth rate.—In the glow discharge method, the deposition is dependent on the vapor pressures of reactants, the temperature of the substrate, the intensity and wave forms of discharge field, and the geometrical configuration inside the reaction chamber. The deposition is sensitive to the configuration of the susceptor and the rf coil, and the deposition rate is very low when the susceptor is set lower than the coil. It is suggested that, in order to obtain efficient deposition, the mixed reactant gases should not be exposed to the glow discharge field before they come close to the substrate. In the present study, therefore, the susceptor is always positioned higher than the coil.

Assuming this configuration and with other parameters fixed, the deposition rate of aluminum oxide films is dependent on the vapor pressure of oxygen and aluminum trichloride as shown in Fig. 2. When the temperature of aluminum trichloride is lower than about 80°C, the deposition rate is strongly dependent on the temperature of aluminum trichloride, that is, nearly proportional to its vapor pressure. If, however, the temperature of aluminum trichloride exceeds 80°C, the deposition rate is almost independent of the pressure of aluminum trichloride. It seems to indicate that, as far as aluminum trichloride is sufficiently supplied, the deposition rate is limited by the ionization of oxygen which is mainly determined by the oxygen pressure.

The deposition rate is largest at the oxygen pressure of about 1 or 2 Torr, when the vapor pressure of aluminum trichloride is held constant. As the oxygen pressure is made either lower or higher than 1-2 Torr,

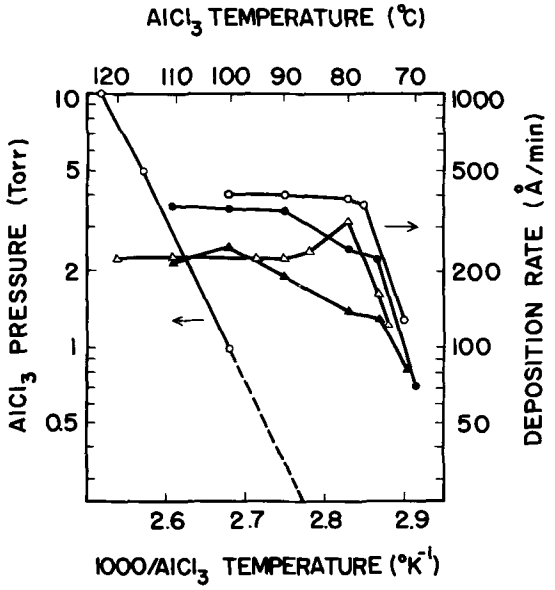

Fig. 2. Deposition rate of Al_2O_3 as a function of pressure of O_2 and temperature of $AlCl_3$. RF voltage, 4 kV; substrate temperature, 480°C. O_2 pressure: ▲ 3 Torr, ● 2 Torr, ○ 1 Torr, △ 0.5 Torr. Vapor pressure of $AlCl_3$ is also shown as a function of temperature.

the deposition rate decreases monotonically. This tendency can probably be interpreted by considering the degree of ionization of oxygen in the glow discharge field as a function of oxygen pressure. When the oxygen pressure exceeds about 3 Torr, the film thickness uniformity becomes poor. The deposition rate is completely independent of the flow rate of oxygen into the reaction chamber between 10 and 200 cc/min.

The dependence of deposition rate on the substrate temperature cannot be evaluated exactly because of the limitation of the deposition apparatus. In our apparatus, the substrate temperature is controlled mainly by the position of the rf coil and partly by the rf voltage. The change of temperature is always accompanied by the change of discharge field in the reaction chamber. In practice, however, the deposition rate does not seem to be strongly dependent on the temperature, and a fairly fast deposition rate can be obtained even at temperatures as low as below 100°C.

The dependence of deposition rate on the intensity of discharge cannot be evaluated exactly for the same reason as mentioned above because the coil supplies energy to both the susceptor and the gaseous reaction. Assuming, however, that the deposition is not so strongly dependent on the temperature, the deposition rate is found nearly linearly dependent on the rf voltage applied to the reaction chamber. This is analogous to the result obtained for the rf sputtering (6).

Film structure and composition.—Examination of the infrared transmission spectrum of the aluminum oxide films shows a broad absorption peak around 15μ, as shown in Fig. 3, very similar to the one for aluminum oxide films obtained by the thermal decomposition of aluminum triethoxide $Al(OC_2H_5)_3$. Electron diffraction patterns show that aluminum oxide films are amorphous unless they are annealed at about 800°C or over. The aluminum oxide films are transparent and visually very smooth, but electron micrographs show, as shown in Fig. 4, that the surface of aluminum oxide films becomes uneven as they are annealed at 700° or 800°C. The crystallization of aluminum oxide as evidenced by the electron diffraction pattern may have some connection with the unevenness of the film surface. But the degree of crystallization is considered low from the diffraction pattern, especially at 700°C, so the phenomenon is mainly attributed to the film structure change due to something like vaporization

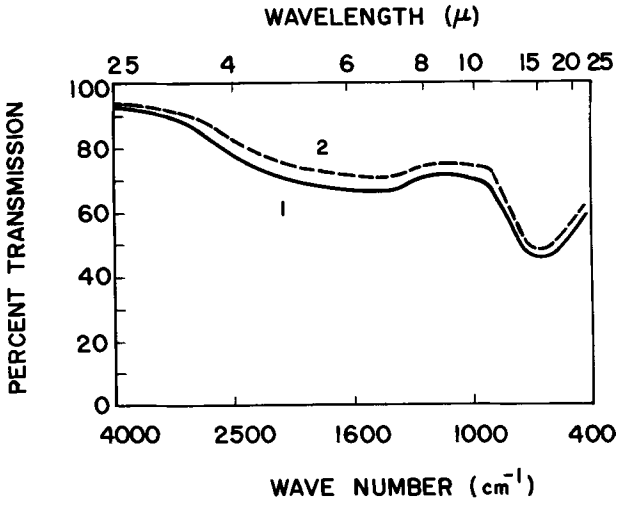

Fig. 3. Infrared absorption spectra of Al_2O_3 films deposited by: curve 1, glow discharge technique; curve 2, thermal decomposition of $Al(OC_2H_5)_3$.

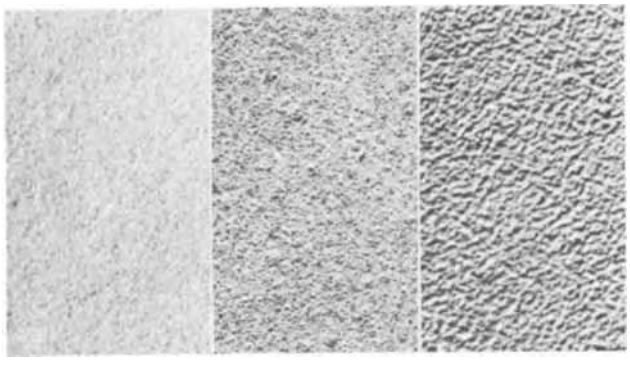

Fig. 4. Electron micrographs for Al_2O_3 films. Al_2O_3 films from left: as deposited at 400°C; annealed at 700°C in N_2 for 1 hr; annealed at 800°C in N_2 for 1 hr. Magnification *ca.* 25,000X.

or chemical reactions of some unknown impurities in the film.

Etch rate.—Etch rate studies have been made for the P-etch solution and for the conc phosphoric acid. As shown in Fig. 5, etch rates for the P-etch solution are normally about 10 Å/sec, and increases to over 100 Å/sec at lower rf voltages supplied during deposition. The discharge becomes unstable when the rf voltage is made a little lower than 2 kV in our apparatus, and the large etch rates of films deposited at lower rf voltages can be attributed to the insufficient intensity of the discharge for obtaining dense films. If the vapor pressure (temperature) of aluminum trichloride is as low as 0.03 Torr (70°C) during deposition, the etch rate of the film is unusually high, *i.e.* over 200 Å/sec by the P-etch solution, though the reason is not clear. Post-deposition heat treatment at 700°C in nitrogen for 1 hr results in the slight reduction of the etch rate. Heat treatment at temperatures over 800°C makes the film almost insoluble in the P-etch solution. For the conc phosphoric acid, the etch rate is dependent on the etch temperature as shown in Fig. 6 for both aluminum oxide films deposited at 400°C and annealed at 700°C in nitrogen for 1 hr. For these films, fine patterns can be etched by the phosphoric acid heated to around 70°C using an ordinary photoresist. Films annealed at 800°C for 20 min are much slower in being etched by the phosphoric acid, *i.e.* at the rate of 10 Å/sec at 85°C and 70 Å/sec at 120°C.

Electrical properties.—Electrical properties of aluminum oxide films deposited by the glow discharge

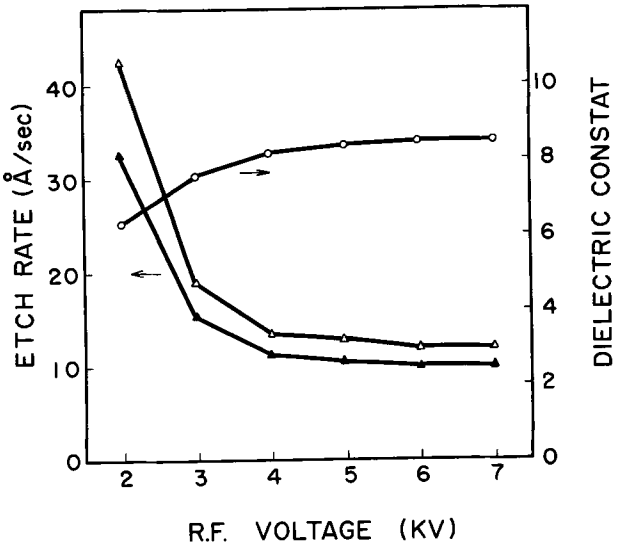

Fig. 5. Etch rate for P-etch solution and dielectric constant as a function of rf voltage during deposition. △ as deposited (480°C); ▲ annealed at 700°C in N_2 for 1 hr.

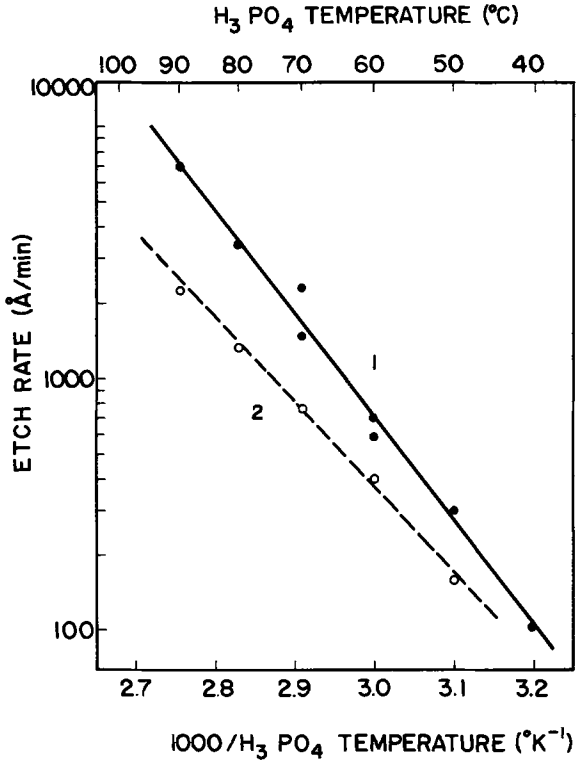

Fig. 6. Etch rate of Al_2O_3 in H_3PO_4 as a function of temperature. Curve 1, as deposited (34 Å/sec in P-etch solution); curve 2, annealed at 700°C in N_2 for 1 hr (18 Å/sec in P-etch solution)

method depend on deposition parameters, especially on the vapor pressures of the reactant gases. When the temperature of aluminum trichloride is as high as 110°C, or the pressure of oxygen is lower than about 0.5 Torr, deposited aluminum oxide films contain grainy spots and are electrically leaky, suggesting the incomplete reaction due to the insufficient oxygen concentration. Vapor pressures of about 2 Torr for oxygen and about 0.3 Torr (90°C) for aluminum trichloride are most conveniently used for obtaining flat and good insulating films with moderate deposition rates. In this condition, the dielectric constant of the deposited film is normally 8.5, with a decrease to about 6 at lower rf voltages, as shown in Fig. 5, prob-

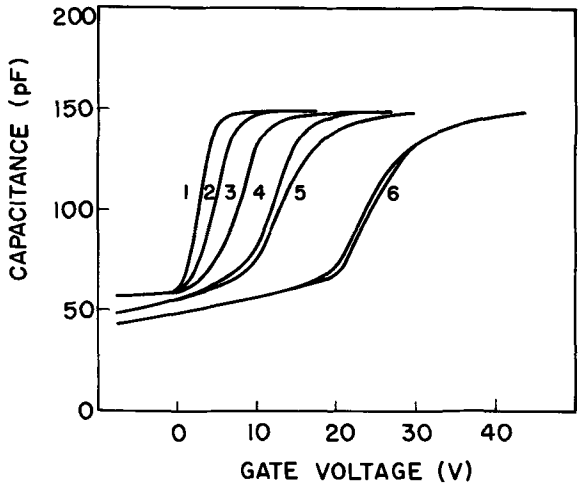

Fig. 7. Typical MAS capacitance curves for 4000Å Al_2O_3 films as a function of deposition rate. Deposition rate: curve 1, 255 Å/sec; curve 2, 350 Å/sec; curve 3, 480 Å/sec; curve 4, 580 Å/sec; curve 5, 605 Å/sec; curve 6, 680 Å/sec.

ably related to the low film density (10), and the tan δ is about 0.01 at 1 MHz. The dielectric strength, as defined by 0.05 μA per a 1 mm diameter spot, is usually over 5 x 10^6 V/cm by film thickness around 4000Å. The dielectric strength is slightly affected by the annealing at 700°C, but serious degradation can be observed when the film is annealed at 800°C or over, probably due partly to the crystallization of aluminum oxide and to the content of some unknown impurities in the film.

MIS Structures

C-V measurements.—Figure 7 shows typical C-V curves for 4000Å aluminum oxide films with the deposition rate as a parameter. The films are deposited at 480°C with an oxygen pressure 2 Torr and an aluminum trichloride temperature 90°C. The deposition rate is in this case controlled mainly by the rf voltage. The position of the rf coil is slightly moved to adjust the deposition temperature to 480°C. The flat band voltage, V_{FB}, is found positive in all cases, increasing with the deposition rate. The oxide charge as determined from the C-V curve is negative and found by the etching experiment to be located at or near the silicon-aluminum oxide interface. The V_{FB} value is affected by the postdeposition annealing, generally increasing by the 700°C annealing process, but reproducible data and interpretation could not be obtained. The distortion in the C-V curves of aluminum oxide films indicates the presence of fast interface states, which increases with the deposition rate, or the rf voltage. The distortion is not eliminated by annealing the films at 700°C under gas atmosphere N_2, O_2, or H_2, and it is suggested that the interface states were produced by the damage due to the glow discharge of oxygen. Hysteresis of the C-V curve is only slightly recognized, generally of the order of 0.1V. Only, the aluminum oxide film deposited very slowly with an aluminum trichloride temperature as low as 70°C is found to show the unusually large hysteresis, though the reason is not yet clear.

Drift of the MAS structures under BT stress.—Figure 8, curve 1 shows the V_{FB} shift of the aluminum oxide film, deposited at 480°C, under bias applied at 250°C. The V_{FB} increases considerably under the BT stress biased negative. Also, there is a tendency that V_{FB} increases (decreases) gradually as the positive (negative) bias is increased. Figure 8, curve 2 shows the V_{FB} shift under BT stress for the aluminum oxide film annealed at 700°C in nitrogen for an hour. It can be seen in the curve that the tendency vanishes for V_{FB} to shift positively (negatively) as the positive (negative) bias is increased. This kind of instability can be attributed to the polarization effect, which was discussed to be the main cause of the instability observed in the aluminum oxide film deposited by the thermal decomposition of aluminum triethoxide (11). From the fact that V_{FB} does not shift in the negative direction under the positive bias, the aluminum oxide film is free from the positive ion instability due to Na^+ ions and the like as observed in silicon dioxide films (12). The large positive increase of V_{FB} under negative bias is observed also in the aluminum oxide film deposited by the thermal decomposition of aluminum isoproxide and annealed in oxygen at 700°C (13). As discussed in (13), this can probably be attributed to some negatively charged particles like OH^- ions, by the analogy of Na^+ ions in the silicon dioxide film, or electrons injected into the aluminum oxide from the gate metal. The instability of these films is irreversible, that is, the V_{FB} value once attained by BT stress under some finite bias remains almost unchanged under another BT stress test with less or zero bias. The authors found this kind of irreversibility in the instability also in the silicon dioxide film deposited by the thermal reaction of silane and oxygen, so it may probably be common to films deposited at low temperatures. The phenomenon resembles the trapping instability found in vapor-deposited silicon nitride or silicon dioxide (14), but the direction of V_{FB} shift under BT stress is opposite. It probably indicates the presence of deep trapping centers for ions at the silicon-dielectric interface.

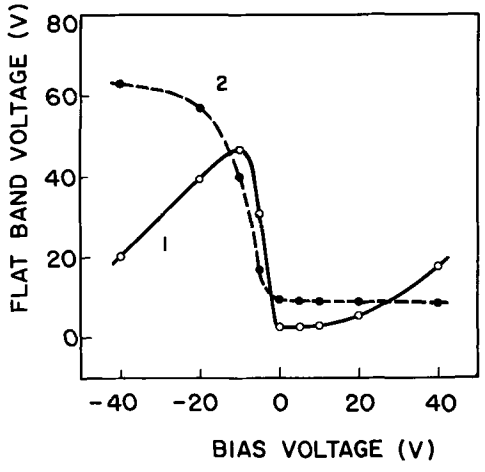

Fig. 8. V_{FB} shift under BT stress at 250°C for 15 min in air. Curve 1, as deposited; curve 2, annealed at 700°C in N_2 for 1 hr.

The instability of V_{FB} under negative bias is detected even at the room temperature. As shown in Fig. 9,

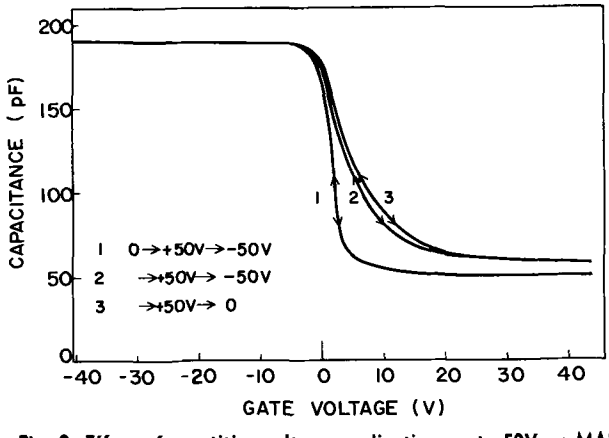

Fig. 9. Effect of repetitive voltage application up to 50V on MAS capacitance of the 3200Å Al_2O_3 film at room temperature.

Table I. Characteristics of MAS and MAOS transistors, using Al_2O_3 films deposited at 480°C
Heat treatment: 700°C, N_2, 1 hr

Al_2O_3 thickness, Å	SiO_2 thickness, Å	Heat treatment, N_2, 700°C, 1 hr	Threshold voltage, V	cm^2 V·sec Electron mobility,
3000	0	No	4.0	70
3000	0	Yes	6.0	140
3000	200	No	1.8	270
3000	200	Yes	0.5	350
3000	500	No	1.0	430
3000	500	Yes	0.1	530

the C-V curve of the aluminum oxide film deposited at 480°C is distorted after a large negative voltage (−50V) is applied to the film. The figure shows that the C-V curve traces quite the same path after +50V is applied, and so the application of positive voltages does not produce such instability effects.

Field effect mobility of electrons.—N-channel MAS and MAOS transistors were fabricated by using aluminum oxide films as a gate insulator to evaluate field effect mobility of electrons in the channel under the gate insulator. The transistors have the following dimensions: channel length, 14μ; channel width (periphery) 540μ. Substrate resistivity is 3 to 7 ohm-cm for (100) surfaces of p-type silicon wafers. The result is summarized in Table I.

The transistor having aluminum oxide as a gate insulator deposited directly onto the silicon surface at 480°C has the electron mobility around 70 $cm^2/V \cdot sec$. Annealing of the film at 700°C for an hour results in the increase of the electron mobility up to about 140 $cm^2/V \cdot sec$. Transistors whose gate insulator are made by depositing aluminum oxide on slightly thermally oxidized (up to 500Å) silicon surface shows larger electron mobilities, up to 530 $cm^2/V \cdot sec$ after the annealing at 700°C.

The authors found the same trend in the electron mobility when silicon dioxide films deposited by the decomposition of tetraethoxysilane $Si(OC_2H_5)_4$ in the glow discharge of oxygen were used as gate insulators of the transistors. The low electron mobility in the surface channel can partly be attributed to the intrinsic nature of the aluminum oxide/silicon interface, but is mainly due to the surface damage caused by the bombardment of charged particles (15). The damage due to the bombardment is evidenced by the fact that the thickness of silicon dioxide has influence on the magnitude of the electron mobility. In the aluminum oxide deposition process, the silicon dioxide/silicon interface can be influenced only by the charged particles' bombardment. It is known that the surface damage caused by electron bombardment is restored by the annealing at 500°C (15). So, in the glow discharge methods, the damage is caused mainly by the bombardment of ionized oxygen so that it cannot be restored completely even by the annealing at 700°C.

Conclusions

Decomposition of aluminum trichloride in the glow discharge of oxygen at moderately low temperatures results in amorphous aluminum oxide films. Among various deposition parameters, the reactant gas pressures affect greatly the film deposition rate and the resultant film quality. At the oxygen presure of about 2 Torr and the aluminum trichloride temperature of about 90°C, coherent, good insulating films are obtained at the deposition rate of a few hundred Å/min or over. The physical and electrical properties of these films compare favorably with those of films obtained by the thermal decomposition of aluminum alkoxides. The MAS capacitance shows the positive value of flat band voltage, V_{FB}, and a large positive shift of V_{FB} under negative bias at 250°C. Distorted C-V curves indicate the presence of fast interface states, which can not be eliminated by the annealing up to 700°C. MAS transistor characteristics show that the field effect electron mobility is as low as 70 $cm^2/V \cdot sec$, while it becomes much higher by the annealing at around 700°C, or when a thin layer of thermally oxidized silicon dioxide is put between aluminum oxide and silicon.

Properties of Aluminum Oxide Films Obtained from Nitrous Oxide and Aluminum Trimethyl

L. H. Hall* and W. C. Robinette*

Texas Instruments, Inc., Dallas, Texas 75222

ABSTRACT

Aluminum oxide (both amorphous and γ-Al_2O_3) have been deposited from the reaction of aluminum trimethyl and nitrous oxide at 650°C. The refractive index is 1.75 ± 0.02 and the dielectric constant is 8.5 ± 0.3. Films have a resistivity of 10^{14} ohm-cm at 10^6 V/cm. D-C current-voltage characteristics indicate a Poole-Frenkel model of conduction similar to that for Si_3N_4 films. Turn on voltage and MAOS capacitor flat band voltage stability of ±0.03V at 300°C and 10^6 V/cm has been attained.

A number of authors have reported on pyrolytic aluminum oxide films prepared from organoaluminum compounds (1-3). This paper deals with films prepared from the reaction of nitrous oxide and trimethylaluminum. Electrical characteristics, including d-c conduction and complex dielectric constant, and alumina-silicon interface properties have been studied as a function of applied electric field and temperature during measurement. Aluminum oxide was deposited on 4-8 ohm-cm, n- and p-type silicon substrates of several different crystal orientations. The film thickness was varied from 800 to 3800Å. Film thickness was measured using an ellipsometer with either a mercury arc source (λ = 5461Å) or a laser source (λ = 6328Å). Electrical measurements were made on capacitor (MAS, MAOS) structures. Metal (aluminum or gold) was evaporated on the alumina surface and capacitor dots ranging in area from 5 x 10^{-5} to 2 x 10^{-2} cm^2 were photolithographically defined.

Experimental

The deposition systems used were single slice and multislice vertical reactors. The aluminum trimethyl vapor, and nitrous oxide, both diluted with argon, were transported in separate inlet tubes so that the two gases are mixed only after entry into the reactor chamber. Although several different aluminum alkyls can be used, the trimethyl was chosen because it is a liquid at room temperature and has a vapor pressure of 8.4 mm Hg at 20°C. Nitrous oxide was chosen as the source of oxygen since it is not an oxidizing agent and is only appreciably thermally decomposed at temperatures of 600°C and greater. The highest grade purity commercially available for aluminum trimethyl and nitrous oxide was used without further purification. A constant temperature chamber was used to maintain a constant supply of aluminum trimethyl. The deposition rate of the aluminum oxide films was controlled by limiting the amount of reactant gases entering the reaction chamber.

The quality of the aluminum oxide films obtained is highly dependent upon the aluminum trimethyl reacting completely to give aluminum oxide. If a fast deposition rate is used there is generally a residue after etching of the film. Also these films had poor electrical properties. However, an interesting aspect of such a process is that the amount of excess aluminum can be controlled, and this may provide an interesting material.

Only a cursory examination of films which did not have a refractive index between 1.72 and 1.80 was made as the refractive index is a very sensitive measurement of the purity of deposited films. Electrical properties of amorphous and γ-aluminum oxide films showed no difference as long as the refractive index was the same.

Film deposition temperature was kept between 640° and 660°C as this was about the lowest temperature at which good electrical films were obtained with nitrous oxide. It was not desired to have a high-temperature process since aluminum oxide films become crystalline at high temperatures. Also there are a number of good high temperature processes for aluminum oxide. A slow deposition rate, <75 Å/min, gave γ-aluminum oxide films. Good amorphous films which etched at a uniform rate in Bell No. 2 were obtained in the single slice vertical reactor. This is a desirable property of oxide films which are to be used in semiconductor processing.

Results and Discussion

D-C conduction.—Direct current measurements were made using a resistance-programmed Kepco ABC 1000 voltage supply and a Hewlett-Packard 425-A micromicroammeter. Data were taken with samples in slice form on an unilluminated probe stage with a controlled ambient at temperatures between 250° and 575°K. Current measurements were taken after a stabilization period of ~ 5 min after field application. The percentage change in the current values after this time period was small (≤ 1%).

A ln I *vs.* $V^{1/2}$ plot at various temperatures for a representative high-resistivity alumina sample is shown in Fig. 1. From these data the high field conductance in the temperature range 250°-541°K may be expressed as

$$I \sim I_0 \exp\left(\frac{\beta V^{1/2} - \Psi}{kT}\right) \qquad [1]$$

where I is the measured current, V the applied voltage, β and Ψ are constants to be explored, k is Boltz-

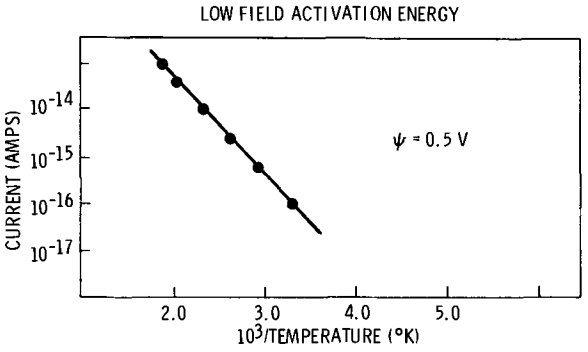

Fig. 2. Zero voltage current intercept (I_i) vs. reciprocal temperature.

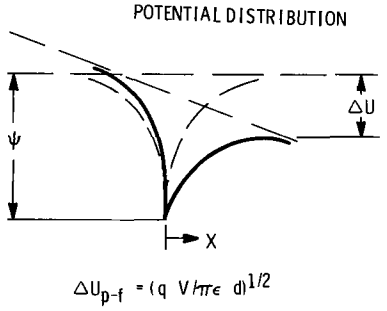

Fig. 3. Potential distribution acting on an electron escaping a donor-like trap.

mann's constant, T is the absolute temperature, and I_o is the extrapolated, zero voltage intercept.

The activation energy at low fields, Ψ, is found to be 0.5 eV in Fig. 2 by extrapolating the curves in Fig. 1 to the zero voltage intercept. This intercept I_o plotted *vs.* reciprocal temperature yields Ψ from the line slope.

Some samples deposited at other than ideal conditions exhibit very high conduction levels indicating very low activation energies. Due to the nonohmic conduction characteristics resistivities will be compared at a fixed field of 10^6 V/cm. Samples exhibiting high conduction levels have resistivities in the 10^6-10^8 ohm-cm range. Samples with activation energies of 0.5 eV have a resistivity of $1.0 \pm 0.1 \times 10^{14}$ ohm-cm.

None of the parameters studied were found to be dependent on electrode materials used.

Model.—The d-c current-voltage characteristics of the alumina films investigated are analyzed in terms of the Poole-Frenkel model of conduction discussed by Brown *et al.* (4) for silicon nitride films. A bulk, electronic conduction mechanism is proposed with the mechanism being field-aided thermal ionization of trapping levels in the film. The mechanism of Poole (5) and Frenkel (6) has been used by many workers including Vermilyea (7) (ZrO_2), Mead (8) (Ta_2O_5), Hartman *et al.* (9) (SiO); for Si_3N_4 in particular Brown *et al.* (4), Sze (10), Hu *et al.* (11), and Frohman-Bentchkowsky and Lenzlinger (12). The reader is referred to reference (4) for a more complete discussion of the model than will be given here. If an electron escapes a donor-like trap at an energy qU below the conduction band it is acted upon by both any external voltage applied and the field produced by the ionized donor. The potential distribution seen by the electron is shown in Fig. 3. The energy barrier is seen to be lowered by an amount $q\Delta U$.

$$\Delta U_{p\text{-}f} = \left(\frac{qV}{\pi \epsilon d}\right)^{1/2}$$

$$\Delta U_s = \left(\frac{qV}{4\pi \epsilon d}\right)^{1/2}$$

where U is the trap depth below the conductor band for Schottky or Poole-Frenkel emission, ϵ is the optical dielectric constant, and d is the film thickness.

The fact that $\Delta U_s = \Delta U_{p\text{-}f}/2$ due to image force effects is compensated for in the total conductivity expression by a factor of 2. This factor arises from a statistical description of electron population above the donor-like centers, assuming that at low temperatures all centers are filled (13).

The conductivity of a film arising from Poole-Frenkel emission was expressed by Frenkel (6) as

$$\sigma = \sigma_o \exp\left[-q(U_{p\text{-}f} - \Delta U_{p\text{-}f})/2kT\right]$$

However, if one assumes the electron deficiency of the donor-like centers to be greater than the excited electron density then

$$\sigma = \sigma_o \exp\left[q(\sqrt{qV/\pi \epsilon d} - U_{p\text{-}f})/kT\right] \quad [2]$$

The slope of a ln I *vs.* $V^{1/2}$ plot for this system would be twice as large as one for Schottky emission or the "normal" Poole-Frenkel effect. Mott and Gurney (14) have outlined the statistical derivation and point out that this electron deficiency might well be expected in a material which has an excess of metallic ions over its stoichiometric requirement. This could easily be the case in the films investigated here. Similar treatments have been reported by Mark and Hartman (15) and Simmons (16).

Application of model.—Equation [2] is of the same form as Eq. [1], with

$$\beta = [q^3/\pi \epsilon d]^{1/2} \text{ and } \Psi = qU_{p\text{-}f}$$

To establish the model proposed here the slope of the current-voltage characteristics is shown *vs.* oxide thickness in Fig. 4 for thicknesses of 850-3800Å. The slope of this plot is $-1/2$ as is predicted by the $(1/d)^{1/2}$ dependence of the theoretical slope value. The dashed line is the line predicted by the Schottky or "normal" Poole-Frenkel effect while the heavy line is calculated using the proposed Poole-Frenkel formulation.

In Fig. 5 the current-voltage slope is plotted *vs.* temperature. The higher temperature points follow a line of slope -1 as is expected for the model. The deviation of the lower temperature points from a line of slope -1 is not understood. A fitting of these data including Fowler-Nordheim conduction characteristics has not been possible. No study was made varying the index of refraction to test the ln I-$V^{1/2}$ slope dependence on this parameter ($\epsilon = n^2$).

Complex dielectric constant.—Dielectric data were obtained using a General Radio 1615A capacitance bridge, G.R. null detector, and a G.R. 1203-B function

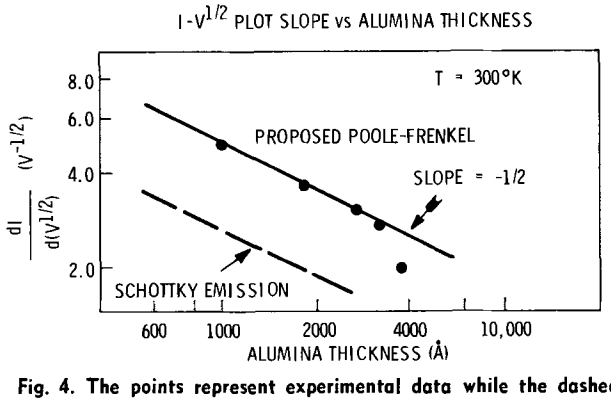

Fig. 4. The points represent experimental data while the dashed line is calculated from Eq. [2].

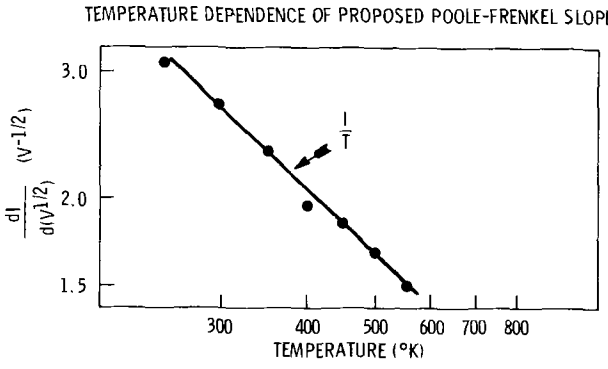

Fig. 5. 1/T dependence of proposed Poole-Frenkel slope

generator. Signal level was maintained at 100 mV and monitored with a Ballentine 861 a-c voltmeter. Capacitance-voltage measurements were made using a Moseley 20-2A x-y recorder, Boonton 71-A capacitance meter, Kepco ABC-1000 power supply, and a Hewlett-Packard 3300A function generator.

The real part, ϵ', of the complex dielectric constant is equal to 8.5 ± 0.3, at 100 kHz, very near the reported value of 8.6 for α crystalline Al_2O_3 (17). A variation of ϵ' between 7.7 and 9.2 was found for samples deposited at other than ideal temperatures and flow conditions.

The dielectric loss, ϵ'', varies from 0.009 to 0.1, at 100 kHz, but these values were found to be extremely dependent on substrate surface preparation. Localized surface imperfections and film imperfections as well as surface impurities prior to deposition might be expected to contribute to the variation in ϵ''. No trend could be seen relating dielectric loss to capacitor area or particular substrate cleanup. The substrates were not vapor etched prior to alumina deposition.

Surface electrical properties.—The silicon wafers were not etched *in situ* prior to silicon oxide growth or Al_2O_3 deposition, and again only films with Al_2O_3 refractive index of 1.75 were investigated. The well-known property of Al_2O_3 to cause a tendency toward a more p-type surface on both n- and p-type silicon was verified with these films. *N* channel enhancement mode field effect devices on 5 ohm-cm silicon were constructed. Turn-on voltage and MAOS capacitor flat band voltage stability of ±0.3V at a threshold voltage of +1V at 300°C and 10^6 V/cm has been attained. MAS capacitors with similar stability were fabricated.

Conclusions

It has been demonstrated that aluminum trimethyl and nitrous oxide can be used to chemically vapor deposit aluminum oxide films at 650°C of electrical quality similar to that of films deposited from the aluminum chloride, carbon dioxide, and water reaction at 900°C. The films prepared by this technique have resistivities in the 10^{14} ohm-cm at 10^6 V/cm. However, they can also have resistivities in the 10^6-10^8 ohm-cm range if the films contain a high impurity content. This is similar to data reported on films prepared by the low-temperature pyrolysis of aluminum alkoxides.

While it is important to accurately control the amount of the aluminum trimethyl vapor and the oxygen/aluminum ratio to obtain high quality electrical films, this method is interesting in that a controllable excess of aluminum in the aluminum oxide film may provide an interesting material for some novel applications in MOS technology.

High-resistivity aluminum oxide films prepared by the reaction of nitrous oxide and trimethylaluminum have been characterized as to d-c conduction, dielectric constant, and stability properties.

Films of 10^{14} ohm-cm resistivity at 10^6 V/cm have been found to exhibit a "special" mechanism of conduction previously reported for Si_3N_4 films (4). The applicability of this model has been demonstrated by detailed study of the variation of the magnitude of the ln I-$V^{1/2}$ slope expressed as

$$S_{p\text{-}f} = (q^3/\pi \epsilon d)^{1/2}/kT$$

This slope value is found to be twice as large as that of the "normal" Poole-Frenkel effect (6), thus implying a low-field thermal activation energy equal to the energy barrier height for electron emission instead of ½ of that height.

Stability of the flat band voltage for MAOS structures and field-effect transistors is ±0.3V at 10^6 V/cm and 300°C. The dielectric constant for high-resistivity films is found to be 8.5 ± 0.3.

Double Epitaxial Isolation Method for the Fabrication of Integrated Circuit Transistors

Kiyoshi Demizu

Mitsubishi Electric Corporation, Kita-Itami Works, Mizuhara 1-Chome Itami, Japan

ABSTRACT

A new fabrication method is proposed which eliminates the isolation process by introducing a p-type epitaxial layer into the I.C. fabrication process. The typical values of BV_{CEO}, BV_{CBO}, and h_{fe} of I.C. transistors made by this new method are 6.5 ~ 10V, 16 ~ 18V, and 20 ~ 60, respectively. This new method is suitable for the fabrication of high-density integrated circuits in view of its simple process and better transistor performance.

In the application of conventional I.C. fabrication methods to L.S.I., laterally spreading areas occupied by the isolation diffusion process are a space limiting factor to the fabrication design. To improve this matter, the C.D.I. (collector-wall diffusion isolation) method was proposed by Murphy and others (1, 2). They used a p-type epitaxial layer as the base, and eliminated the isolation diffusion. However, there are some difficulties in obtaining a high level of transistor breakdown voltage and in controlling the thickness of the epitaxial layer. The D.E.I. (double epitaxial isolation) method, which has some advantages in integrated circuit fabrication, is proposed in this paper.

Fabrication Method

A comparison of manufacturing processes between the D.E.I. method and the conventional method is shown in Fig. 1. The D.E.I. method starts with diffusion of n^+-buried layers into the p-type substrate in those regions that are to hold the finished transistors. This step is identical to the conventional process. Next, a 2-3μ p-type epitaxial layer is grown, and followed by an approximately 2μ n-type epitaxial layer. It should be emphasized that this epitaxial growth is one continuous process. The change from p-type to n-type is achieved by activating valves in the gas feed line at the appropriate times during processing.

During the heat cycles of epitaxial and base diffusion processing, there is an autodiffusion from the n^+-buried layer into the p-type epitaxial layer. This converts the conductivity type of the epitaxial layer above the buried layer from p-type to n-type. This inverted layer acts as the collector of the finished transistor.

The p-type impurity diffusion of 3.0μ in depth is simultaneously applied to the base and isolation regions. The p-type diffused base extends completely through the n-epitaxial layer, and then the actual base-collector junction is in the inverted epitaxial layer where the p-type epitaxial layer has been converted to n-type. The regions of the p-type epitaxial layer not over the n^+-buried layer are unaffected throughout the entire process. During the base diffusion, p-type isolation regions are diffused through the n-type epitaxial layer and into the p-type epitaxial layer, making the transistor's collector an isolated n-type island in a p-type sea. The transistor is completed by simultaneously diffusing the n^+-emitters and the n^+-collector contacts.

The D.E.I. method has many important advantages, because in this method the isolation is performed simultaneously with the base diffusion. The isolation diffusion depth is only as deep as the base. As shown in Fig. 2, both the isolation mask alignment and the isolation diffusion process are eliminated in the D.E.I. method. Since impurity diffusion proceeds about the same distance vertically and laterally, the shallower isolation diffusion yields narrower isolation regions. Thus, each transistor takes up less space.

A comparison of chip sizes of the Quad Nand circuits designed by the D.E.I. method with those utilizing the conventional method is shown in Fig. 3. As is evident from this figure, by using the D.E.I. method the chip size of the circuit is reduced by about 30%.

Transistors made by the D.E.I. method have compensated collector regions as a result of auto diffusing the n-type impurity from the n^+-buried layer into the p-type epitaxial layer. Thus, it was important to investigate how the autodiffusion influences the characteristics of transistors.

At first, the impurity distribution of the autodiffusion layer was studied in detail. As shown in Fig. 4, the p-type epitaxial layer is grown upon an n-type substrate with localized n^+-buried layers, and then the autodiffusion is brought about by heat treatment for 1-8 hr at 1215°C.

Key words: isolation, I.C. transistor, autodoping, epitaxial.

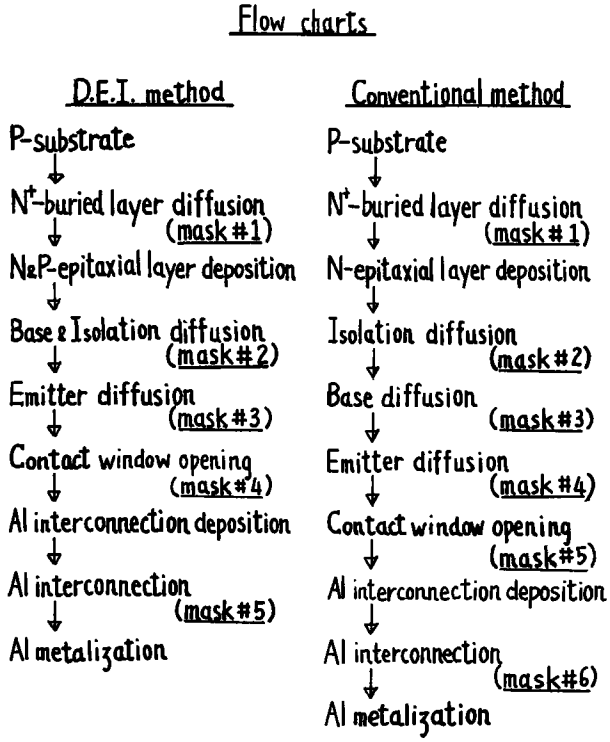

Fig. 2. Flow charts of the D.E.I. and the conventional method

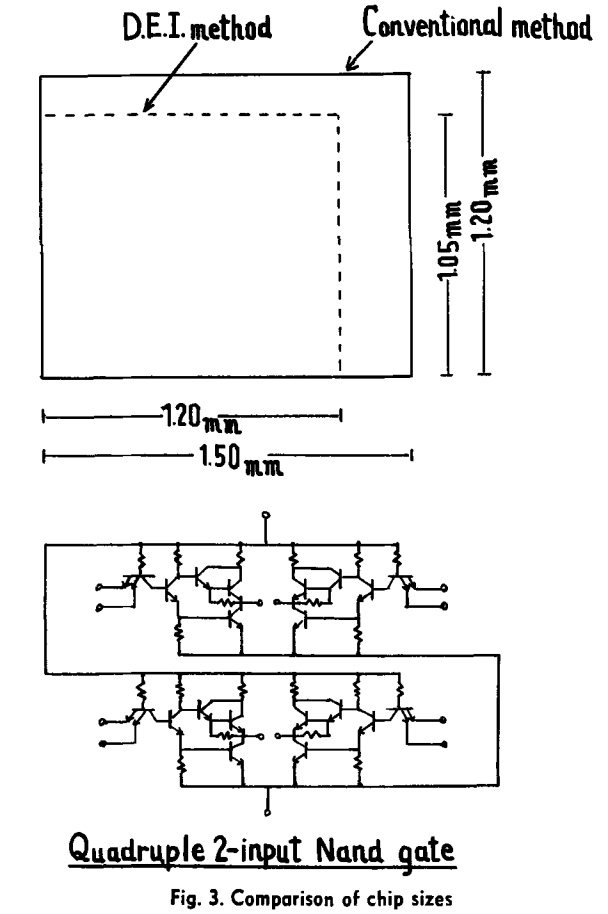

Fig. 3. Comparison of chip sizes

The p-n junction was observed by angle-lapping and stain-etching. Distances between the surface of the p-type epitaxial layer and the p-n$^+$ junction were measured. The experimental results are shown in Fig. 4, where the parameter is the resistivity of p-type epitaxial layer. The gradient of these lines is about

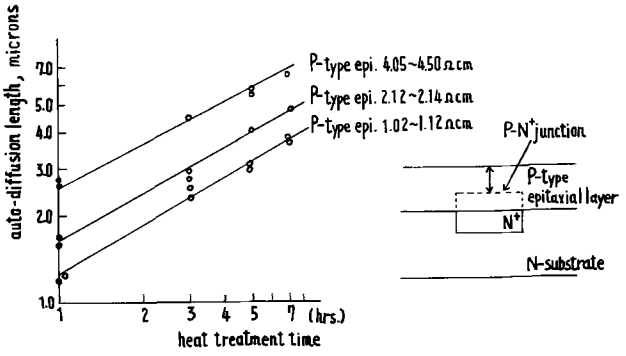

Fig. 4. The relation between heat treatment time and auto-diffusion length.

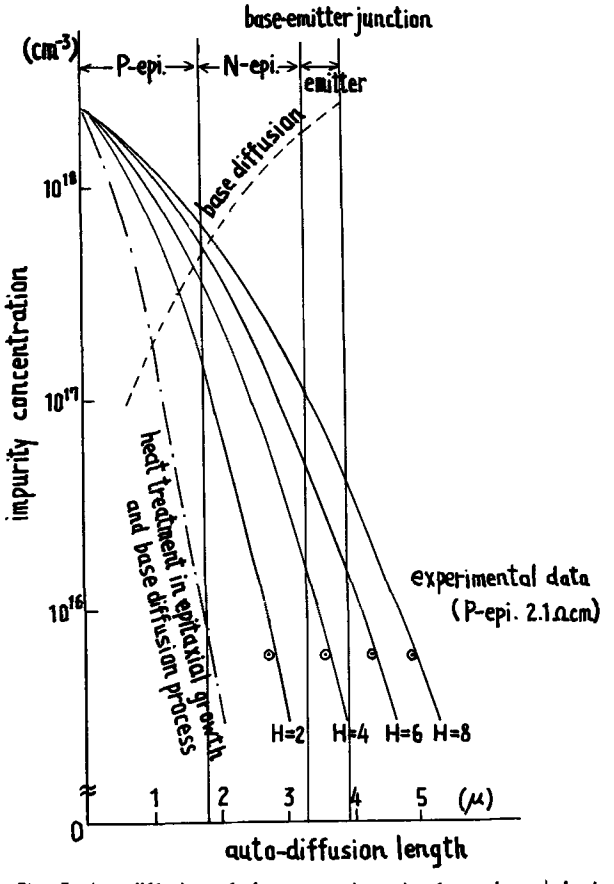

Fig. 5. Autodiffusion of the n-type impurity from the n$^+$-buried layer.

one-half, so these experimental data show that auto-diffusion from the n$^+$-buried layer is approximately given as error function.

Autodiffusion profiles of n-type impurity from the n$^+$-buried layer are shown in Fig. 5, where parameter H is the heat treatment time. In this figure $x = 0$ is the interface between the n$^+$-buried layer and p-type epitaxial layer before any heat treatment. The broken line in this figure is the impurity profile of the base diffusion given as error function. The emitter-base junctions are given as a step junction of 0.6μ in depth from the surface.

As is evident from Fig. 5, with increasing heat treatment time, the position of the base-collector junction is closer to that of the emitter-base junction, that is, the base width decreases. Also the maximum inverse breakdown voltage of the base-collector junction, BV_{CBO}, and the series resistance of the transistor, R_S, decrease. This means that the current gain of transistors becomes higher with increased heat treatment.

Experiments and Results

In the D.E.I. method a high breakdown voltage of the base-collector junction is maintained by controlling the thickness of the p-type epitaxial layer. Conditions for sample fabrication are summarized in Fig. 6.

The relation between BV_{CBO} and the heat treatment time is shown in Fig. 7. A heat treatment time of zero means that autodiffusion from the n^+-buried layer to the p-type epitaxial layer takes place only during heat treatments in the epitaxial growth (D_1t_1) and the base diffusion (D_3t_3). Inversion of the p-type layer into n-type material is essentially completed during epitaxial growth and base diffusion processes for sample TR-6, but requires more than three additional hours of heat treatment for sample TR-5 because of its thick p-type epitaxial layer. The values of BV_{CBO} of TR-6 hardly vary with heat treatment time, since impurity concentrations of base and collector regions are very high (from 10^{17} to 10^{18} cm^{-3}), while those of TR-5 vary considerably, since the impurity concentration density is in the range of 10^{16} to 10^{17} cm^{-3}. The broken lines in this figure give calculated values of BV_{CBO} based on McKay's data (3). The assumptions in this case are that the impurity profile of the autodiffusion layer is given as error function and the impurity distribution at the base-collector junction is step-shaped.

The structure of a transistor in which the p-type epitaxial layer is eliminated from the D.E.I. scheme is shown in Fig. 8. This fabrication method is tentatively named S.E.I. (single epitaxial isolation). Transistors made by the S.E.I. method have lower breakdown voltages, from 11 to 15V in TR-6 and TR-5 substrates. Hence, it is evident that the p-type epitaxial layer in the D.E.I. method plays a very important role in improving transistor breakdown voltage.

Deposition	Sample number	
	TR-5	TR-6
N^+-buried layer	17~23Ω/□, 7~8μ	17~23Ω/□, 7~8μ
P-type epitaxial layer	2.0~3.0Ωcm, 3.0~3.6μ	2.0~3.0Ωcm, 1.8~2.1μ
N-type epitaxial layer	0.7Ωcm, 2.4~2.7μ	0.3Ωcm, 2.1~2.4μ
Heat treatment time	3, 4, 6, 8 hrs.	0, 1, 2, 4, 6, 8 hrs.
Base & isolation diffusion	200Ω/□, 3.0μ	200Ω/□, 3.0μ

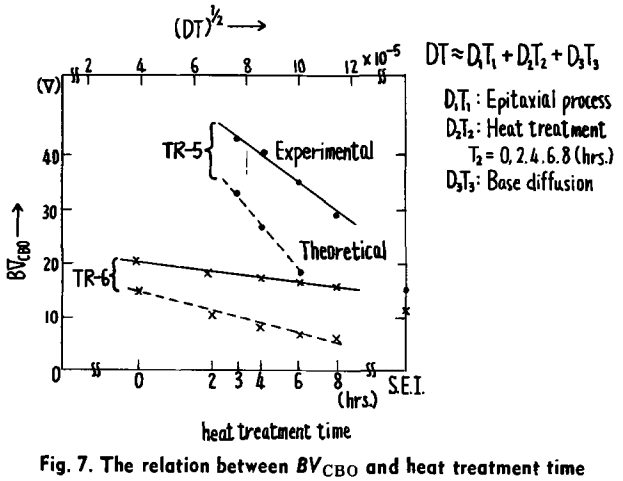

Fig. 7. The relation between BV_{CBO} and heat treatment time

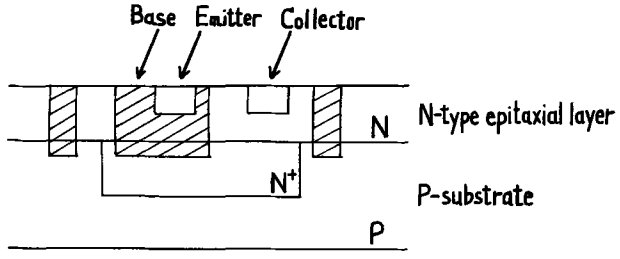

Fig. 8. S.E.I. transistor structure (p-type epitaxial layer is eliminated from D.E.I. structure).

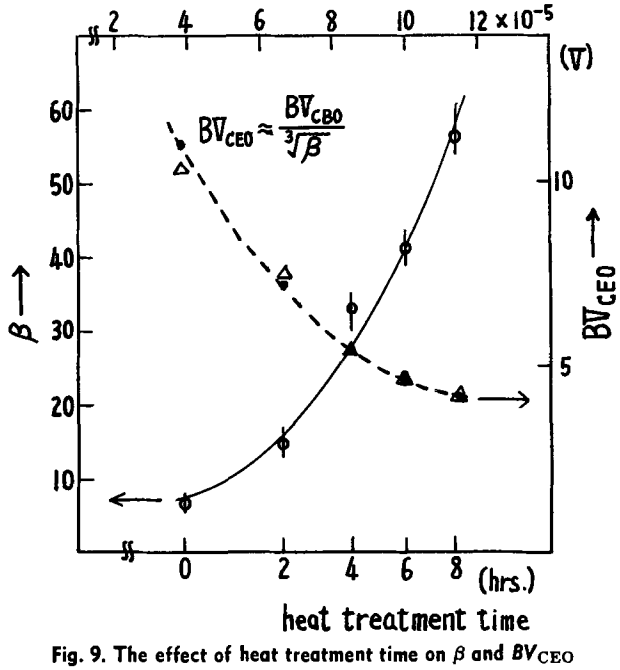

Fig. 9. The effect of heat treatment time on β and BV_{CEO}

The effect of heat treatment time on β and BV_{CEO} is shown in Fig. 9. Fabrication conditions of the samples for these experiments are the same as for TR-6, and emitter diffusion time is kept constant regardless of any heat treatment time. With increased heat treatment time, β increases and BV_{CEO} decreases to about 5V. As mentioned before, these facts mean that with increased heat treatment time, the base width is reduced. Generally speaking, there is a relation between BV_{CEO}, β and BV_{CBO} of transistors as follows

$$BV_{CEO} \approx \frac{BV_{CBO}}{n\sqrt{\beta}} \qquad n = 2 \text{ to } 6 \qquad [1]$$

Th broken lines in Fig. 9 give the values of BV_{CEO} calculated from measured values of β and BV_{CBO} for $n = 3$. These calculated values show good agreement with experiment.

The relation between collector series resistance, R_S, and heat treatment time for the D.E.I. method is represented in Fig. 10. With increased heat treatment time, as autodiffusion proceeds, the values of R_S become lower than those of transistors made by conventional methods. The series resistance, R_S, of I.C. transistors made by the D.E.I. method consists of four components

$$R_S = \eta\,(R_E + R_N + R_{C1} + R_{C2}) \qquad [2]$$

Here, η is a constant coefficient, and R_E and R_{C1} are resistances in the compensated region.

If ρ_S represents the mean value of sheet resistance in the compensated collector region, then the value of ρ_S may be estimated from the measured values of the R_S. The results are summarized in Fig. 11. The mean values of compensated collector region sheet resistance

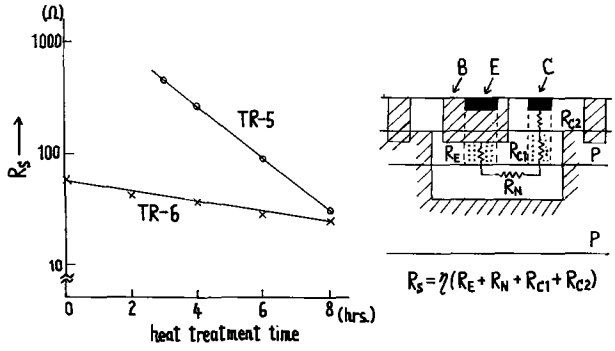

Fig. 10. The relation between heat treatment time and collector series resistance R_S.

decrease from 5.7 x 10^3 ohm/square to 2.5 x 10^3 ohm/square with increased heat treatment time. If this compensated collector region consisted of only n-type impurity, the impurity concentration in this layer would be from 1 to 2 x 10^{16} cm^{-3}.

Conclusion

A comparison of the fundamental characteristics of transistors made by various methods is shown in Fig. 12. The first and third columns of this figure give a comparison of conventional I.C. transistors and the D.E.I. I.C. transistors. Except for slightly lower values of breakdown voltage, the characteristics of D.E.I. transistors are quite similar to conventional ones. The value of BV_{CEO} given in the top row is sufficient for logic circuits; they are normally operated in the vicinity of 6V.

Storage time of the D.E.I. transistors is lower than that of conventional ones without gold-diffusion, because the impurity distribution in the collector pro-

Description	Conventional method	CDI method	DEI method	SEI method

Fig. 12. A comparison of the characteristics of transistors made by various methods.

duces a field that sweeps stored charge out of the collector as the transistor comes out of saturation. The fourth column of Fig. 12 shows the characteristics of transistors made by the S.E.I. process. It is simpler, but collector breakdown voltage tends to run too low even for logic circuits.

The second column of Fig. 12 presents characteristics of transistors with collector wall diffusion isolation. Although the breakdown voltage is higher than for a S.E.I. transistor, it is still marginal even for standard logic circuits.

In both the single epitaxial isolation and the collector wall diffusion methods, precise thickness control of an epitaxial layer is an important problem. There is much less of a problem in double epitaxial isolation transistors, because thickness can be adjusted by subsequent heat treatment. The D.E.I. method will be suitable for the fabrication of higher density integrated circuits in view of its simpler processes and better transistor performance.

Effect of Partial Dissolution During LPE Growth of $Al_xGa_{1-x}As$ on the Efficiency of Diffused Light-Emitting Diodes

K. K. Shih* and J. M. Blum*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Light-emitting diodes have been prepared by Zn diffusion to form p-n junctions in Te-doped $Al_xGa_{1-x}As$ layers grown by liquid phase epitaxy. When the growth process is interrupted by a partial dissolution cycle, the external quantum efficiencies for junctions formed in the material grown after dissolution are about five times greater than those obtained without a dissolution cycle. Efficiencies of about 1 x 10^{-3} have been measured at about 6750Å for uncoated diodes. Electron microprobe analysis shows that in the regrown material there is a sharp initial drop in Al concentration, after which the Al concentration gradient becomes considerably less than in layers grown without dissolution. In addition the dislocation density in the regrown layers is about a factor of two lower than in material grown without dissolution.

Efficient visible light emission has been obtained (1) from $Al_xGa_{1-x}As$ p-n junctions grown by the liquid phase epitaxial (LPE) method. It is important to develop a simple diffusion process as an alternative technique for making high efficiency $Al_xGa_{1-x}As$ light-emitting diodes. This would make it possible to prepare planar monolithic structures and therefore enable the economical fabrication of high density monolithic arrays. Linden (2) has made diodes by Zn diffusions into $Al_xGa_{1-x}As$ crystals grown by the LPE method, but these diodes had very low quantum efficiencies (about 10^{-5} at 7000Å).

We have studied the diffusion of Zn into $Al_xGa_{1-x}As$ epitaxial layers grown by the LPE method. By optimizing the diffusion processes and doping levels of the material, slight improvements of quantum efficiency in diffused diodes have been achieved. More important, a substantial improvement in efficiency has been obtained by using a dissolution cycle during the LPE growth of the material into which Zn is subsequently diffused to form the diodes. This cycle dissolves a thin surface layer of the epitaxial overgrowth prior to the regrowth of another thin layer. In order for the improvement in efficiency to be realized, the p-n junction must be formed in the regrown layer near the region where the dissolution takes place.

In order to grow $Al_xGa_{1-x}As$ crystals for diffusion studies the vertical growth method described by Rupprecht *et al.* (1) was employed. N-type GaAs single crystals with (100) orientation were used as substrates. Te was added as the n-dopant. A typical solution composition is 20g Ga, 3g GaAs, 3 mg Te, and a variable amount of Al depending on the desired composition. The cooling cycle I shown in Fig. 1 was used to grow one epitaxial layer. The solution was heated to 955°C and then cooled in contact with the GaAs substrate to about 860°C at a rate of about 0.4°C/min. The AlAs concentration of the epitaxial layer was about 50 mole per cent (m/o) at the interface with the substrate and about 25 m/o at the surface. To prepare diodes, this layer, which was about 60-80 μm thick, was etched into five steps at about 6 μm intervals as depicted in the insert in Fig. 1, and Zn was diffused into the surface of these steps at 700°C for 30 min. The diffusion junction depth is about 3-5 μm. The external quantum efficiencies and wavelengths of the diodes made from each step were measured at 300°K, and the data are plotted as solid circles in Fig. 2.

Cooling cycle II with a dissolution cycle during the growth process, as shown in Fig. 1, was used to grow another $Al_xGa_{1-x}As$ n-type epitaxial layer. In this case, the solution was first cooled at a rate of 0.4°C/min from 955° to 900°C. The temperature was then raised five degrees to 905°C, kept there for 5 min, and finally lowered to 860°C again at a rate of 0.4°C/min. (This cooling cycle is the same as the one which Woodall *et al.* (1, 3) used to grow $Al_xGa_{1-x}As$ p-n junctions with high efficiencies, but they added Zn during the process to form the grown junctions.) As before, the epitaxial layer was etched into five steps, and Zn was diffused into the surfaces of the steps at 700°C for 30 min. The diode results are shown by open circles in Fig. 2. In the region where dissolution had taken place, the diodes are substantially more efficient than those made from the epitaxial layer grown by cooling cycle I.

Key words: $Al_xGa_{1-x}As$, liquid phase epitaxy (LPE), dissolution, regrowth, diffusion, light-emitting diodes, III-V alloys.

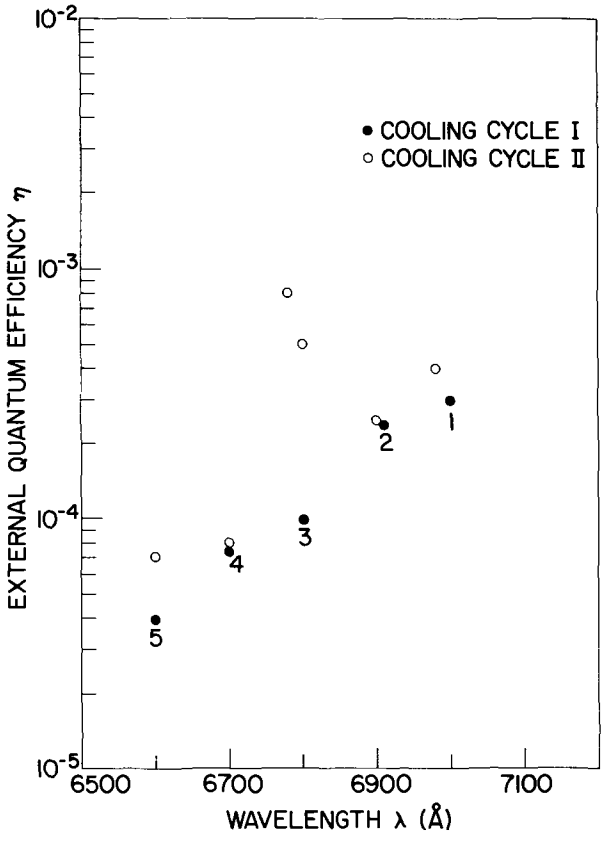

Fig. 2. The external quantum efficiency of $Al_xGa_{1-x}As$ diffused diodes as a function of diode emission energy at 300°K. Solid and open circles correspond to diodes made from epitaxial layers grown with cooling cycles I and II in Fig. 1, respectively.

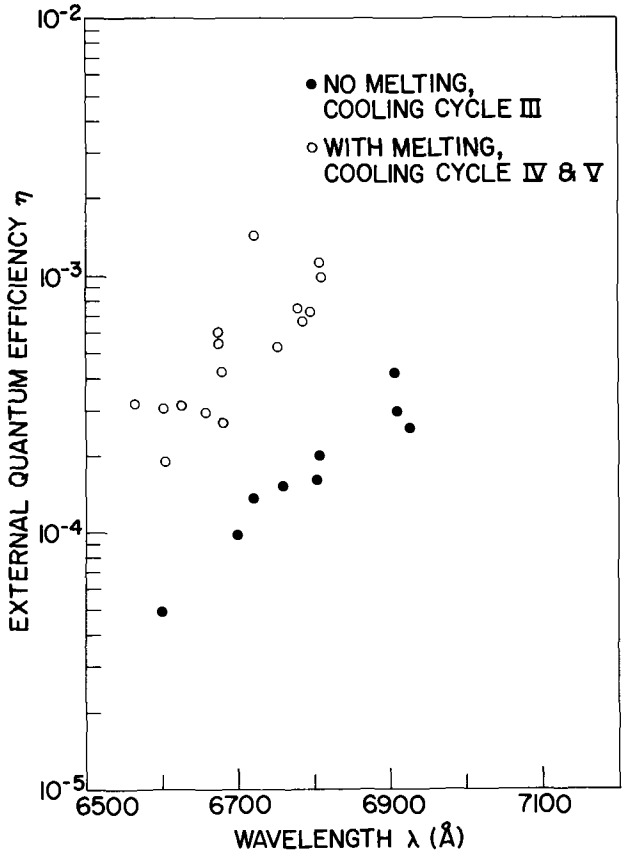

Fig. 3. The external quantum efficiency of $Al_xGa_{1-x}As$ diffused diodes as a function of diode emission energy at 300°K. Solid and open circles correspond to diodes made from epitaxial layers grown without and with a dissolution cycle, respectively.

In order to confirm that the dissolution cycle during the LPE growth of the $Al_xGa_{1-x}As$ is responsible for the improvement in the quantum efficiency of diodes made by subsequent diffusions, many additional layers using the same composition of solution but different amounts of Al have been grown by using the cooling cycles III, IV, or V shown in Fig. 1. In cooling cycle III the solution was heated to 955°C and cooled at a rate of about 0.4°C/min to 900°C. For layers grown with a dissolution cycle, after cooling to 900°C, the temperature was raised 5°C (cycle IV) or 10°C (cycle V). After 5 min at the higher temperature, the solution was cooled again to 900°C. The initial concentration of Al in each of the solutions was different. The AlAs concentration in the epitaxial layers varied between 50-54 m/o at the interface with the substrate and between 32-36 m/o at the surface, and the total thickness of the layers was about 30-50 μm. Zn was subsequently diffused into the surface of these layers at 700°C for 30 min. Figure 3 shows the external quantum efficiencies of the $Al_xGa_{1-x}As$ diffused diodes as a function of the diode emission energy, both measured at 300°K. Solid circles represent the diodes made from layers grown by using cooling cycle III, and open circles represent the diodes made from layers grown by using cooling cycles IV and V. The efficiency decreases as the wavelength decreases because the direct-indirect bandgap composition is approached. The efficiency of diodes made from material grown with a dissolution cycle is improved by a factor of about five, but this value is about a factor two lower than that of the grown junctions (1, 3).

The electron microprobe has been used to measure the composition profiles of epitaxial layers along the growth axis. The mole fraction of AlAs, x in $Al_xGa_{1-x}As$, is plotted in Fig. 4 as a function of dis-

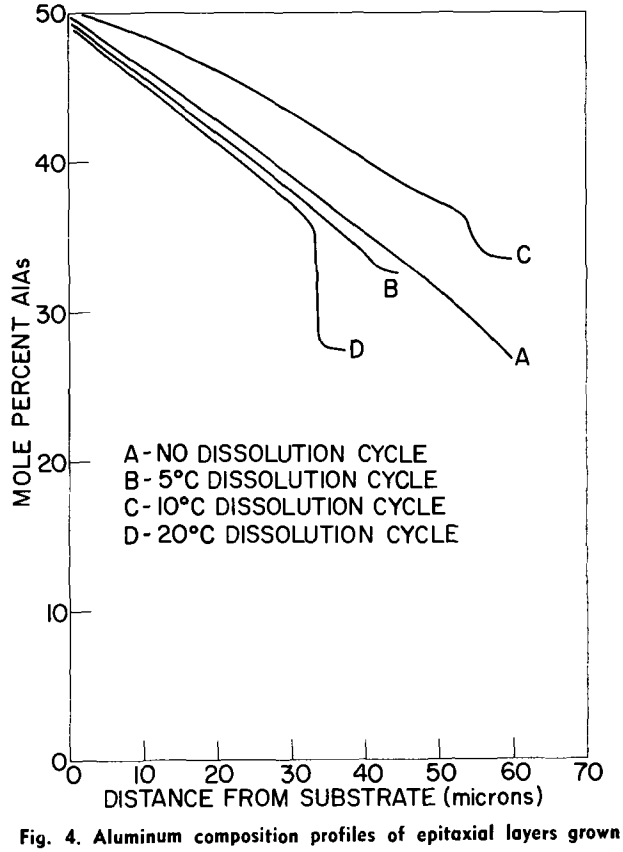

Fig. 4. Aluminum composition profiles of epitaxial layers grown with or without a dissolution cycle.

tance from the substrate for four representative layers. Because of the high segregation constant of Al (3), the concentration of Al decreases with increasing distance from the substrate. Curve A is a typical Al profile of a layer which was grown by using cooling cycle III in Fig. 1. Curves B and C are typical Al profiles of layers grown by using 5° and 10°C dissolution cycles, respectively, corresponding to cooling cycles IV and V in Fig. 1. It is apparent that consequences of dissolution on the material grown after this step are twofold: there is a sharp drop in Al concentration, after which the rate of decrease of the Al concentration with distance is much smaller than the rate of decrease prior to the dissolution cycle. An epitaxial layer with a 20°C dissolution cycle was grown and its profile (curve D) exhibits an even larger initial decrease in Al concentration. A kinetic effect must be responsible for the observed composition profiles, since under equilibrium conditions dissolution and regrowth would not cause any change in the Al concentration profile.

The two changes in the Al concentration profile are probably the major factors which contribute to the large increase in quantum efficiency of diodes made from material grown with a dissolution cycle. The regrown region is about 5 μm thick. The diffused p-n junction, which is about 3-5 μm deep, is normally located in the regrown region after the abrupt drop in Al concentration. Since the radiative recombination occurs on the p-side of the junction, the sudden decrease in bandgap due to the drop in Al concentration, which is about 0.02 eV for a 5°C dissolution step, may increase the radiative recombination by enhancing the injection of electrons and confining the holes in the p-region. The result would be similar to the effect observed in $Al_xGa_{1-x}As$-GaAs heterojunction lasers, where a marked decrease in current threshold is attained using the heterostructure to increase carrier confinement with suppression of the onset of hole injection (4-6).

The diode efficiency may also be increased by the flattening of the Al concentration profile in the regrown region. Because of this change in profile, the Al concentration and therefore the average bandgap are greater in this region (curves B, C, and D in Fig. 4) than in the corresponding region grown without a dissolution step (curve A in Fig. 4). This will reduce the fraction of the light emitted at the junction which is absorbed by the regrown region. In order to determine the degree of improvement one could expect from the flattening effect a rough estimate has been made of the degree to which the absorption is reduced. The photon energy emitted by $Al_xGa_{1-x}As$ diodes is approximately 0.03 eV less than the bandgap at the junction (7), and a 5°C dissolution step causes an increase of about 0.03 eV in the bandgap at the surface of the epitaxial layer. On the basis of these values, together with the slope of the intrinsic absorption edge for direct bandgap material such as GaAs and InP (8, 9), the average absorption coefficient at the emitted wavelength was assumed to be 5×10^2 cm^{-1} for the regrown region and 5×10^3 cm^{-1} for the corresponding region grown without a dissolution step. For a junction depth of 3 μm, the absorption by the regrown region would then be about one-fourth that of the region grown without dissolution. Such a reduction would make a significant contribution to the increase of about a factor of 5 in diode efficiency obtained by using a dissolution cycle.

The effect of the dissolution cycle on the dislocation density of the grown $Al_xGa_{1-x}As$ was also investigated. Dislocations were observed by using the etchant described by Abrahams and Buiocchi (10) to etch 5° angle-lapped surfaces which had been mechanically polished to a mirror finish. The dislocation density of the typical epitaxial layer is of the order of 10^4-10^5 cm^{-2}, and it decreases by about a factor of two in the regrown region. The dislocation density may be reduced in the regrown regions because the dissolution and waiting provides more time for establishing a better liquid-solid interface. This reduction in dislocation density may improve the quality of devices produced by subsequent diffusions.

In conclusion, it was found that the external quantum efficiency of $Al_xGa_{1-x}As$ diodes made by Zn diffusion into layers which were regrown after a 5°-10°C dissolution step is improved by about a factor of approximately five. This may be attributed to the abrupt change of Al concentration so that the injection of electrons into the p-side is enhanced, the leveling effect of the Al concentration gradient in the regrown region so that the absorption of emitted light is reduced, and the reduction in dislocation density.

Charge Injection in MAOS Systems

P. Balk[1] and F. Stephany

Institut für Halbleitertechnik, Technical University, Aachen, West Germany

ABSTRACT

A study of charge injection in metal-Al_2O_3-SiO_2-silicon (MAOS) structures has been made using the capacitance-voltage technique. Thin SiO_2 films were grown thermally on the Si substrates, whereas Al_2O_3 layers were obtained by pyrolytic deposition from $AlBr_3$ in a NO-forming gas mixture. Independent of the electrode material, negative charge is introduced into the oxide system when a positive voltage is applied to the metal. With Al electrodes, the oxide also becomes negatively charged under negative bias. Only for large negative voltages will a gradual loss of negative charge occur, leading to a net positive oxide charge. Charge injection under negative bias is not observed on O_2 annealed Al_2O_3 layers, or on samples with Au electrodes. The results are discussed in terms of a qualitative model.

Charge storage in metal-Si_3N_4-SiO_2-silicon (MNOS) structures has attracted considerable interest since the late sixties because of its potential for memory device application. For stressing voltages exceeding a threshold value carriers will, depending on the direction of the electric field, enter or leave traps near the Si_3N_4-SiO_2 interface, thus changing the state of charge of the system, and thereby the threshold voltages of IGFET devices incorporating such double layers as gate insulators (1-7). Particularly for very thin SiO_2 layers (<30Å), when the charging takes place by direct tunneling through this oxide film into the traps, these processes are quite fast. The field and time dependencies of the charging processes are determined by the trap energies and by the spatial distribution of the traps. These characteristics will depend, in turn, on the method by which the layers were prepared. The somewhat different results obtained in Ref. (5) and (6) (logarithmic increase in induced charge with time under electric stress *vs.* relatively rapid saturation of the charging process) must be related to details of the sample preparation process.

The discovery of such charge storage behavior in the MNOS system raises the question of similar effects occurring in sandwich structures with other insulators. Indeed, it has been reported recently that also in MAOS structures (A = Al_2O_3) with Al electrodes the charge can be varied easily in an electric field. However, here both positive and negative voltage stress tends to induce negative oxide charge. The behavior appears to be independent of the method by which the Al_2O_3 film was obtained: reactive evaporation of Al in O_2 (8), pyrolysis of trimethyl-Al in O_2 at 450°C (4) or of Al-isopropoxide in O_2 at 420°C (9), pyrolysis of $AlCl_3$ in CO_2-H_2 at 850°C (10), or of $AlBr_3$ in NO-H_2-N_2 at 900°C (11). Only for rf sputtered Al_2O_3 films does the injection of negative charge under negative bias on the metal appear to be absent (12). Although some authors (8, 10) have not mentioned the occurrence of SiO_2 in their insulator system, it appears likely that in all cases a layer of native oxide was present on the silicon wafers used as substrates for Al_2O_3 deposition.

In the present study we have explored the mechanism of charging in MAOS systems with Al_2O_3 films prepared by high-temperature pyrolysis of $AlBr_3$ in a NO-H_2-N_2 mixture. It is shown that electron injection from the Al electrode into the Al_2O_3 accounts for the introduction of negative charge under negative voltages. The effects of the nature of the metal electrode and of annealing the dielectric are demonstrated. A qualitative model is presented to explain the observations.

Experimental

Silicon substrates [1 and 10 ohm-cm p- and 1 ohm-cm n-type, (100) oriented, chemically-mechanically polished Wacker material] were cleaned in organic solvents, HNO_3, and water. Immediately after a final HF dip they were placed under N_2 flow in an rf heated oxidation and deposition apparatus. Very thin SiO_2 films (<30Å) were formed by oxidation at 900°C in forming gas (80% N_2, 20% H_2) with 2% NO (Deutsche l'Air Liquide). Thicker layers were obtained in O_2 at the same temperature. After oxidation, Al_2O_3 films were deposited in the same apparatus and at the same temperature from a 0.03% $AlBr_3$ (Merck)-2% NO-forming gas mixture (13) at a linear flow rate of 400 cm min^{-1}. The deposition rate was about 80 Å min^{-1}. Under these conditions, polycrystalline films of γ-alumina with a grain size of 100-200Å will form (13). Capacitor structures were completed by evaporation of metal (Al or Au) dots through a metal mask, without heating the substrate.

Ellipsometric SiO_2 thickness determinations on a series of samples, oxidized in NO-forming gas by the same procedure as used for our standard thin SiO_2 films, yielded a value of 13 ± 3Å. The layers formed in O_2 were at least 40Å, the thickness depending on oxidation time. Measurements of the capacitance-voltage characteristics of MAOS samples on n-type substrates with 13Å SiO_2 films and Al electrodes indicated that these were converted to p-type after exposing them to a 900°C heat treatment for an extra 15 min period. This suggests that Al readily penetrates the SiO_2 layer, possibly converting it into an aluminosilicate. For this reason one should consider the SiO_2 thickness value measured before Al_2O_3 deposition only as a semiquantitative indication of the thickness of the SiO_2 layer in the composite dielectric film. The Al_2O_3 thickness was obtained from the capacitance of the system, using a value of 9.8 for the dielectric constant (13).

Pulses of various amplitudes and lengths were applied using a HP 214A pulse generator. For pulse lengths ≥ 1 sec the voltages were switched on and off manually. The state of charging of a MAOS system was evaluated from its flatband voltage (V_{FB}), obtained from a capacitance-voltage (CV) measurement (14), generally made at 3 Mc. An attempt was made to estimate the density of interface states from the displacement of the CV curves between room temperature and liquid N_2 temperature (15). If such states occur, one expects a shift in negative direction for p-type substrates at the low temperature, and in positive direction for n-type samples. However, for samples of both conductivity types an increase in V_{FB} (by 0.1V to 1V) was obtained. This displacement did not change upon electrically stressing the samples. We cannot explain this observation at the present time.

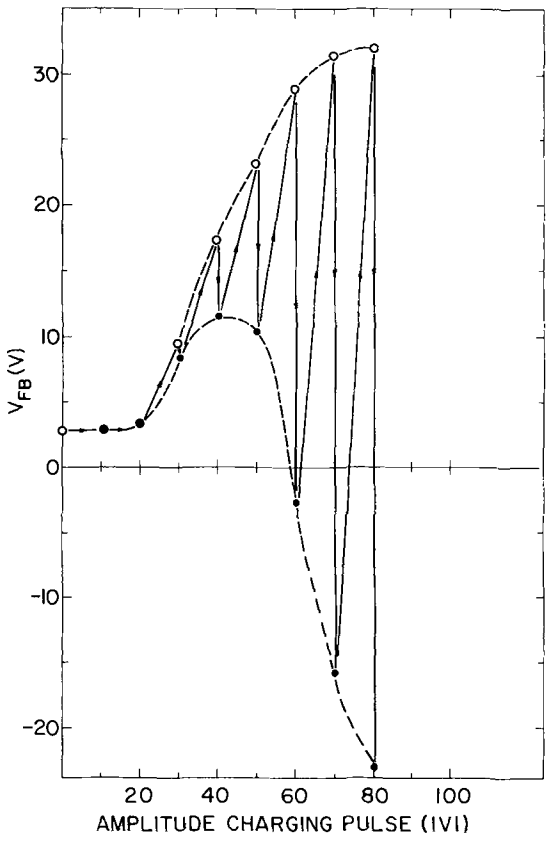

Fig. 1. V_{FB} shift under alternating pos. (○) and neg. (●) 1 sec pulses of increasing amplitude (see arrows). Sample: Al-Al_2O_3(1300Å)-SiO_2 (13Å)-Si [p-type, (100), 1 ohm-cm].

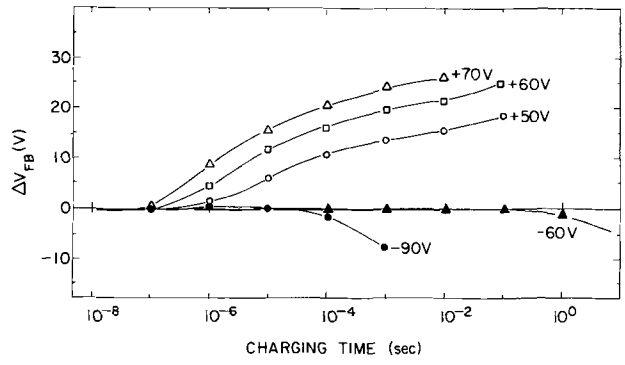

Fig. 2. Time dependence of V_{FB} shift (ΔV_{FB}) for various charging voltages. Sample: Al-Al_2O_3(1100Å)-SiO_2(13Å)-Si [p-type, (100), 1 ohm-cm]

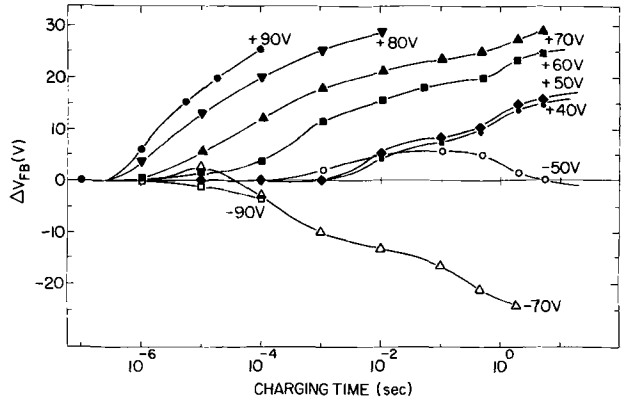

Fig. 3. Time dependence of V_{FB} shift (ΔV_{FB}) for various charging voltages. Sample: Al-Al_2O_3(1300Å)-SiO_2(40Å)-Si [p-type, (100), 1 ohm-cm].

Nevertheless, it appears reasonable to conclude that the interface state densities were always relatively small (approximately 10^{11} cm^{-2} or less), and that the V_{FB} values can thus be directly correlated with the charge in the oxide system.

Results and Discussion

Some characteristic features of the charging behavior of a MAOS system with Al electrode are illustrated in Fig. 1, which shows the effect on V_{FB} of alternating positive and negative pulses (pulse length: 1 sec) applied to the metal electrode. Before stressing, such capacitors exhibit a positive V_{FB} value, which implies the presence of negative charge in the oxide system. Small stressing pulses (<20V) do not change V_{FB}. Increasing the pulse amplitude beyond this threshold value first leads to an increase in V_{FB} both for positive and negative pulses, independent of the order of application. Thus, in both cases the negative charge in the oxide increases. For larger stresses, V_{FB} continues to rise under positive voltages, but decreases under negative voltages. This suggests that in the latter case a different charging process becomes dominant. When applying only voltage pulses of the same sense to the sample, one obtains curves which are qualitatively similar to the dotted lines connecting the positive and negative voltage points. A situation where the positive and negative V_{FB} shifts become of equal magnitude for applied voltages of opposite sign is only approached for very large stresses.

This point is also apparent in Fig. 2 and 3, which show the time dependence of the V_{FB} shift for large positive and negative voltages, obtained on samples with two different SiO_2 thicknesses. The shifts with positive voltage are roughly logarithmic with time, but show a tendency to saturate. Their dependence on oxide thickness is relatively small. Under negative stress two competitive processes appear to determine the shapes of the time dependence curves: first negative charge is introduced into the oxide, but somewhat later the negative charge content of the oxide system appears to decrease, as seen from the reversal of the direction of V_{FB} shift. The balance between these two processes tends to change in favor of the second one for larger voltages and thinner oxides. This complex behavior is only observed for larger negative voltages. As reported earlier (11), for voltages just above the charging threshold, V_{FB} will first increase but then remain constant. Rather similar charging characteristics were observed at liquid nitrogen temperature when stressing such MAOS structures in the enhancement direction.

A comparison of the dependence of V_{FB} on pulse amplitude (pulse length: 1 sec) for two different SiO_2 thicknesses, both obtained by oxidation of the substrate in O_2, is shown in Fig. 4. The data for the thicker composite film have been normalized to 1400Å, the thickness of the thinner one, in order to make a direct comparison of the curves possible. It may be seen that that threshold for V_{FB} change under negative voltage stress is not dependent on the SiO_2 thickness. Such behavior suggests that this initial increase in V_{FB} is determined by charge injection from the metal into the Al_2O_3 film. However, the subsequent decrease for larger negative voltages, and the increase under positive stress are both affected by the thickness of the SiO_2 film. From this, it may be concluded that in the latter two processes charge transport into or across the SiO_2 layer takes place. The weak temperature dependence appears to indicate that in both cases the rate-determining step involves a tunneling process.

From literature data for the bandgap of Si (16), the barrier energy for holes between Si and SiO_2 (17), the bandgap of SiO_2 (18) and the electron affinity of

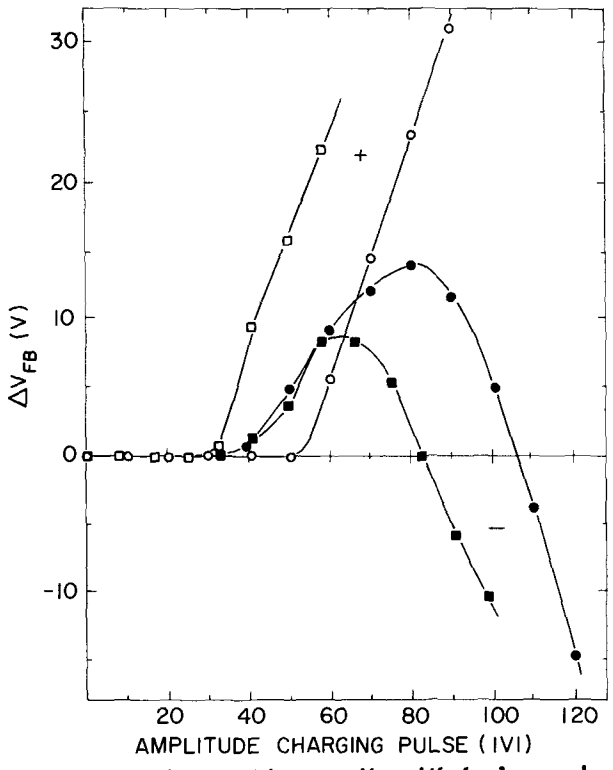

Fig. 4. Effect of SiO_2 thickness on V_{FB} shift for 1 sec pulses. Samples: □: Al-Al_2O_3(1700Å)-SiO_2(40Å)-Si [p-type, (100), 10 ohm-cm], data normalized to 1400Å; O:Al-Al_2O_3(1400Å)-SiO_2(73Å)-Si [p-type, (100), 10 ohm-cm].

this material (19), the bandgap of Al_2O_3 (20), the work function of Al (16), and the barrier energy for electrons between Al and Al_2O_3 (21), the energy band diagram shown in Fig. 5a may be constructed for the Al-Al_2O_3-SiO_2-Si system. Also indicated in this diagram are some trapping states, which occur in this material in relatively high densities compared to SiO_2 (22, 23). It must be stressed that such a diagram is necessarily tentative, since the data on the Al-Al_2O_3 barrier and those on the deeper traps most likely refer to amorphous material.

The relatively low threshold field (approximately 3 x 10^6 V cm^{-1}) suggests that under negative bias electrons tunnel directly from the Al electrode into the traps in the Al_2O_3 (Fig. 5b). In Fig. 5b-d, we made the assumption that the centers at approximately 1 eV below the Al_2O_3 conduction band play a dominant role in the charging effects, but the possibility that deeper traps also participate cannot be excluded. In comparison, Fowler-Nordheim tunneling of 10^{11} electrons cm^{-2} (this charge does not significantly affect the field across the oxide, thus permitting a simple calculation) in 10^{-3} sec would require a field of approximately 8 x 10^6 V cm^{-1}. This may be inferred from literature data on tunneling from a deposited Al electrode into an Al_2O_3 film (24), taking into account the built-in field of the film. One would thus expect that this tunneling mode only occurred for the highest stressing voltages in our MAOS samples. The electrons will drift further into the oxide *via* a field enhanced thermal excitation (Poole-Frenkel effect) or a field ionization mechanism, causing V_{FB} to shift in positive direction. At the same time, the accumulation of charge near the electrode reduces the local field at that interface, which results in a decreasing electron injection rate. Thus, for voltages just above the threshold the V_{FB} shift will saturate. At high voltages electron injection into the silicon, *via* tunneling into the SiO_2 conduction band, will gradually become the dominant process (Fig. 5c). This causes a decrease in the negative oxide charge, and consequently in V_{FB},

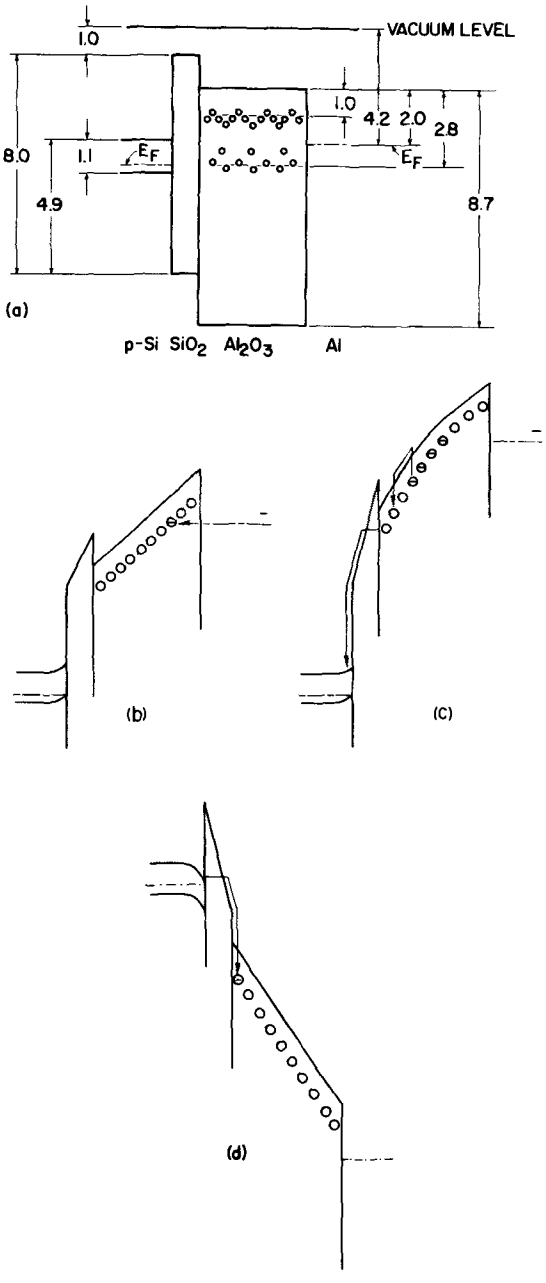

Fig. 5. (a) Energy band diagram for MAOS structure (energies in eV); (b) charge injection under moderate negative bias; (c) charge drift and emission under large negative bias; (d) injection under positive bias.

after the initial rise. The fact that V_{FB} attains negative values implies that the charge in the system has become positive. It is not possible to decide on the basis of the present data whether this means that positively charged centers are being created under application of negative voltages, or that such centers are always present in the films, but compensated by oppositely charged trapping states.

For positive-stressing voltages and thick SiO_2 layers (as exemplified by the capacitor with 73Å SiO_2 film in Fig. 4) Fowler-Nordheim tunneling of electrons into the SiO_2 conduction band (Fig. 5d), followed by drift into the Al_2O_3 conduction band and subsequent trapping, appears the only likely explanation of the data. The observed threshold voltage of approximately 55V is quite compatible with the value of nearly 50V, required for tunneling of 10^{11} electrons in 10^{-3} sec into the SiO_2 conduction band, estimated from Lenzlinger and Snow's work (25). The threshold field for this type of injection should be independent of SiO_2 thick-

ness, unless the SiO_2 films exhibit different internal field distributions, caused by different charge distributions before stressing. Such charge distributions may result from the before-mentioned Al penetration, which will particularly affect the behavior of the thinner SiO_2 layers. It is not clear whether the smaller threshold values, obtained on samples with thinner SiO_2 films, are caused by such a thickness dependence of the charge distribution, or that a new mechanism (direct tunneling into the traps) manifests itself in this case. Tsang *et al.* (26) have recently concluded that in a MAOS structure with Al electrode, very thin (approximately 20Å) SiO_2 film, and Al_2O_3 film prepared from $AlCl_3$ in CO_2-H_2, charge injection at both electrodes takes place by direct tunneling for the appropriate direction of field.

The above model implies that electron injection at the metal electrode can be suppressed by previously filling the traps in the region of the Al_2O_3 film near the electrode. In this case a negative V_{FB} shift should start immediately upon application of negative voltages larger than the threshold value. This conclusion is borne out by the data in Fig. 6, which shows the time dependence of the change in V_{FB} under negative voltage after the Al_2O_3 traps had been partially filled by application of a 1 sec pulse of +50V amplitude. The same effect is apparent in Fig. 7, which shows the hysteresis behavior of a MAOS sample for 1 sec pulses. Starting with the application of negative pulses to the Al electrode, one observes, as before, an initial rise in V_{FB}, followed by a decrease for larger negative voltages. Returning in the opposite direction, V_{FB} remains constant, until at the positive threshold of approximately +20V a steep increase begins. Traversing a complete counterclockwise loop, by varying the stressing voltage from positive to negative to positive again, the negative to positive return trace is again horizontal, and at the same V_{FB} value as before. It will be clear that the shape of such hysteresis loops depends on the pulse length.

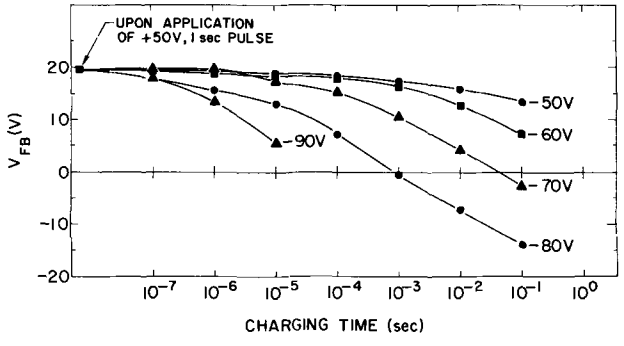

Fig. 6. Time dependence of V_{FB} shift under negative bias after application of 1 sec + 50V pulse. Sample: Al-Al_2O_3(1300Å)-SiO_2(40Å)-Si [p-type, (100), 1 ohm-cm]

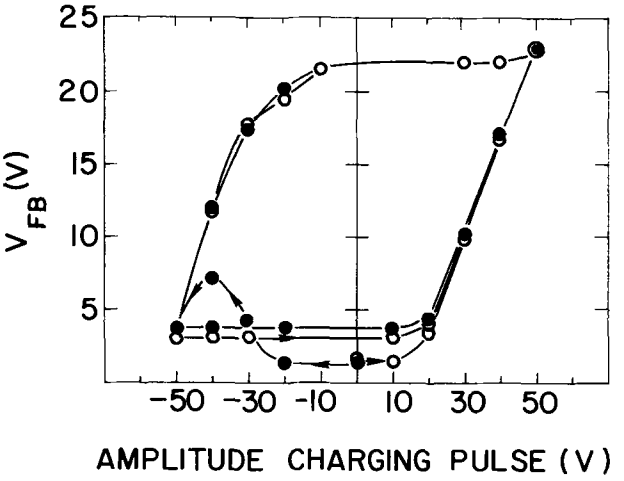

Fig. 7. Hysteresis behavior of MAOS capacitor with Al electrodes. Arrows indicate sign of initial stressing voltage (pulse length: 1 sec). Sample: Al-Al_2O_3(1300Å)-SiO_2(13Å)-Si [p-type, (100), 1 ohm-cm].

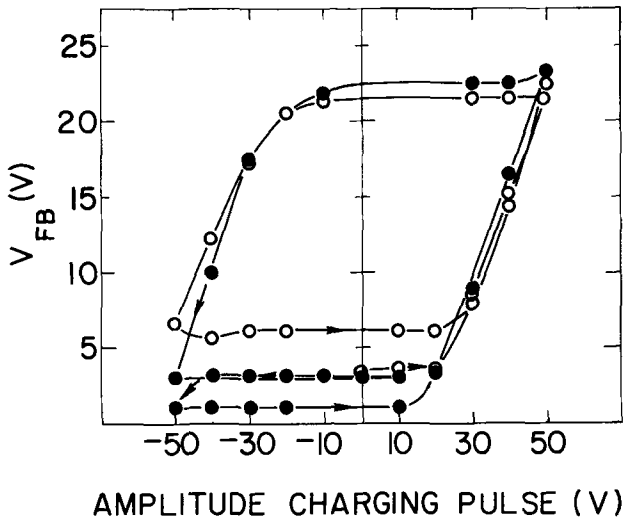

Fig. 8. Hysteresis behavior of MAOS capacitor with Au electrode. Arrows indicate sign of initial stressing voltage (pulse length: 1 sec). Same substrate as used in Fig. 7.

Since tunneling probabilities depend exponentially on barrier heights, the electron injection rate from the metal into the Al_2O_3 layer is only appreciable for electrode materials with a relatively low work function. Figure 8 shows that indeed for MAOS systems with an Au electrode [vacuum work function: 4.7 eV for Au, 4.2 eV for Al (16)] the hysteresis loop does not show the initial increase in V_{FB} for negative pulses as was the case with Al electrodes. In other respects the loop is rather similar to that for Al electrodes.

It is known (22) that annealing alters the trap density in Al_2O_3. Also, Kalter (27) has found that the negative charge in the thermal SiO_2-high temperature pyrolytic Al_2O_3 composite layer system decreases during annealing in O_2 at 900°C. The change saturates in approximately 1 hr. It appears likely that the charge centers are of the same nature as the trapping states discussed above in explaining the memory behavior of MAOS systems. Since high temperature pyrolytic Al_2O_3 films are commonly grown under only marginally oxidizing conditions such centers may be oxygen vacancies. It may be expected that O_2 annealing would reduce their concentration.

For these reasons the effect of such annealing treatment at 900°C on the charging of the oxide films was investigated. It was found that the increase in V_{FB} under negative bias has already been considerably reduced after 15 min annealing, and has disappeared completely in 1 hr. The V_{FB} hystersis loop in Fig. 9, obtained after 1 hr annealing, and measured with 1 sec pulses and Al electrodes, shows this effect. Note also that the magnitude of the positive and negative threshold voltages for V_{FB} shift have become quite comparable. Larger positive or negative pulses of equal magnitude yield V_{FB} shifts of opposite sign, but of comparable magnitude. The data appear to support the contention that O_2 annealing reduces the trap density in Al_2O_3, since the direct tunneling from Al into Al_2O_3 traps seems to be suppressed. In the case of O_2-annealed samples very similar results are obtained with Au electrodes.

Finally, it was observed quite generally on unannealed samples with Al electrodes that the capacitance-voltage characteristic developed a step-like dis-

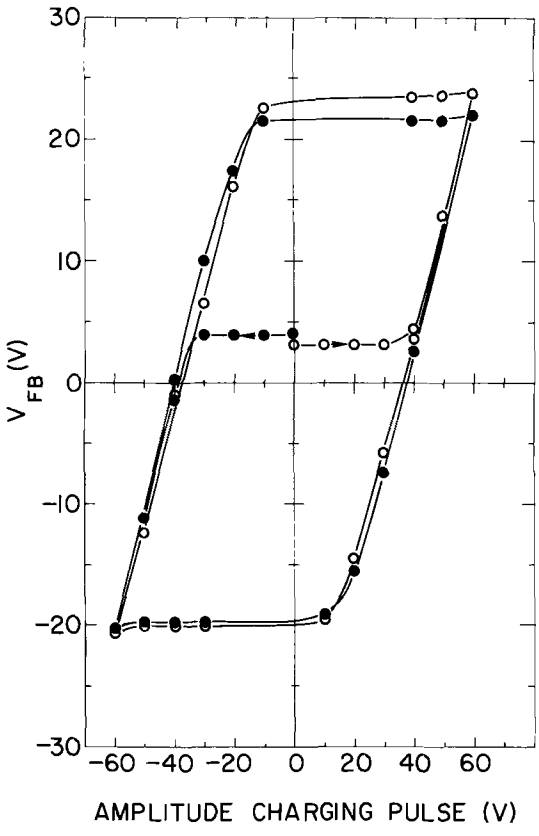

Fig. 9. Hysteresis behavior of MAOS capacitor with Al electrode. Arrows indicate sign of initial stressing voltage (pulse length: 1 sec). Sample: Al-Al_2O_3(1300Å)-SiO_2(13Å)-Si [p-type, (100), 1 ohm-cm], annealed for 1 hr in O_2 at 900°C before metallization.

tortion and a gradual flattening of the steep part in the curve during the increase of V_{FB} under negative voltage stress. This distortion would gradually disappear when the curves moved back (and V_{FB} decreased) at larger stressing times or upon application of positive voltages. Such effects were never observed on samples with Au electrodes, or on O_2-annealed structures. It appears likely that these distortions reflect a nonuniform rate of change of the surface potential under the electrode. This behavior could be caused by a varying electron injection rate under negative bias, which may imply a nonuniform trapping center density across the surface.

Conclusions

The present study confirms that negative charge builds up in MAOS systems with Al electrodes under application of negative voltages exceeding a certain threshold value. This behavior is most likely caused by injection of electrons into traps in the Al_2O_3 film by direct tunneling or possibly, at higher fields, also *via* Fowler-Nordheim tunneling into the Al_2O_3 conduction band. Thus, it can be suppressed by using an electrode material with a larger work function, like Au. Elimination of oxide traps should have a similar effect. Since O_2 annealing probably results in a reduced trap density, the absence of negative charge accumulation for a negatively biased Al electrode in O_2-annealed samples tends to confirm this model. The model also implies that the injected charge will drift across the oxide by a Poole-Frenkel mechanism or through field emission from the traps.

Exchange of charge between the silicon and the composite oxide film takes place *via* Fowler-Nordheim tunneling in the case of thick SiO_2 films. For very thin films our data do not allow us to decide between this mechanism and direct tunneling. In the thin SiO_2 case the situation is complicated by the interdiffusion of the film constituents. The high dielectric constant of Al_2O_3 tends to enhance the field in the SiO_2 layer, and thus yields relatively low threshold fields for charge injection at the silicon.

When operating under conditions where charge injection from the metal electrode is suppressed, the amount of oxide charge changes roughly logarithmically with time for both directions of voltage stress. This lack of distinctive saturation may be undesirable for memory device application.

Acknowledgments

The authors like to acknowledge continued support and interest in this work by Professor Dr. H. Beneking. They are also indebted to Dr. G. Ackermann (IBM Laboratory, Boeblingen) for a number of ellipsometric measurements of oxide film thickness, to Dr. P. J. Tsang (IBM Components Division, East Fishkill) for directing their attention to Ref. (20) and (21), and to Drs. N. J. Chou, P. J. Krick, and T. O. Sedgwick (IBM Thomas J. Watson Research Center, Yorktown Heights, New York) for helpful discussions.

Preparation and Properties of $In_xGa_{1-x}As$ Single Crystals by Solution Growth Technique

Kiyoshi Takahashi, Toyosaka Moriizumi, and Shinji Shirose[1]

Department of Electronics, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo, Japan

ABSTRACT

Single-crystalline $In_xGa_{1-x}As$ layers were grown epitaxially on GaAs substrates by the solution-growth technique. X-ray microanalyses showed that the value of "x" obtained in $In_xGa_{1-x}As$ was between 0.0 and 0.2. Hall measurements were made for undoped $In_xGa_{1-x}As$ crystals as a function of the composition x. The crystals were n-type and their mobilities varied little as x increased from 0.0 to 0.2. Doping of some impurities, such as Zn and Ge, was tried. Ge was found to be an amphoteric impurity in the $In_xGa_{1-x}As$ crystals, and a pn junction could be made in one solution-growth cycle.

Recently III-V ternary alloys have attracted much attention, because it is possible to change energy gaps or carrier mobilities by controlling the mixing ratio of two terminal compounds. In the case of InAs-GaAs alloys, several attractive properties have been reported; *e.g.*, coherent light emission with wavelengths between 0.84μ and 3.1μ (1) and thermoelectric properties with a high figure of merit (2). Moreover, in the devices for high-frequency and room-temperature operation, an $In_xGa_{1-x}As$ crystal has a great advantage because it is possible to make a semiconductor with a higher electron mobility than GaAs and with a wider energy gap than InAs.

Homogeneous, single-phase $In_xGa_{1-x}As$ alloys have been prepared by many investigators utilizing several kinds of growth techniques; *i.e.*, directional freezing (3), zone-leveling (4), vapor growth (5), Czochralski pulling (6), and solution-growth techniques (7). However, a single-crystal $In_xGa_{1-x}As$ alloy has been grown only within a limited range of x, although the vapor epitaxial experiments (5) were successful throughout the entire composition range.

In the present work, $In_xGa_{1-x}As$ crystals were prepared by Nelson's solution-growth technique (8). The crystalline nature, the composition ratio x, and the electrical properties of the grown crystals deposited on GaAs substrates were studied. Furthermore, the impurities were doped into $In_xGa_{1-x}As$ crystals, and the amphoteric properties of Ge therein were studied.

Crystal Growth

The solution-growth apparatus employed for this study was based on the work of Nelson (8). The crystal growth was carried out in a graphite boat, which was placed in a H_2 gas flow ($\sim$ 2 liter/min) atmosphere. The melt consisted of solvent metals (In + Ga, 500 mg) and of a GaAs polycrystal. The solvent metals, In and Ga, were six-9's pure. The GaAs polycrystal was an undoped n-type crystal with n $\simeq 10^{17}$ cm^{-3}, and its weight was heavy enough for the GaAs polycrystal to become saturated in the solvent: *i.e.*, 110 mg at the maximum growth temperature, T_M = 800°C, and 60 mg at T_M = 700°C. The In was etched in conc HCl, and Ga was etched in conc HBr. The GaAs polycrystal was etched in 2% Br_2-methanol solution. The GaAs substrate was a semi-insulating crystal with $\rho = 10^6$-10^8 ohm-cm at room temperature or an n-type wafer with electron concentration n $\simeq 10^{17}$ cm^{-3}. Its dimension was 5 mm x 5 mm x 0.5 mm, and its surface was usually the (111)B face. It was polished with 0.3μ Linde-Alumina powder and was chemically etched in a $H_2O + 3H_2SO_4 + H_2O_2$ solution.

In the preliminary stage of growth, the solvent and the GaAs polycrystal were mixed by heating to T_M. Then the GaAs substrate was set in a boat after the furnace was cooled to room temperature. For the crystal growth, the temperature program as shown in Fig. 1 was adopted. The substrate was dipped in the melt two minutes after the furnace was heated up to T_M, 700°C or 800°C. One minute later, the temperature was lowered with the constant cooling rate of 1°C/min or 15°C/min, and an $In_xGa_{1-x}As$ crystal began to grow on the substrate. At 400°C, the melt was removed from the grown layer by a quartz slider, and the boat was pulled out of the furnace.

Crystalline Nature

Crystal orientation of the substrate surface affects the crystalline quality of the grown layer. The surface of the grown layer was investigated through a microscope. Figure 2(a) and (b) show the surfaces of the layers grown on (100) or (111)A substrate, respectively. The former surface was rough like corn and was polycrystalline. The interface between the substrate and the grown layer was very rough in this case. The latter surface was terraced and easily broken into flakes. Hence, hereafter these substrates were not used, and only (111)B substrates were used. Figure 3 demonstrates the surface patterns of the layers which were grown on (111)B substrates cooled at the rate of 1°C/min or 15°C/min from T_M (= 700°C), in solutions of various atomic ratios of In to Ga. The atomic ratio of the solvent metals, In to Ga, which hereafter will be designated as AR, determined the surface patterns, the crystalline qualities, and the x values of the grown $In_xGa_{1-x}As$ layers. As shown in Fig. 3, when AR was

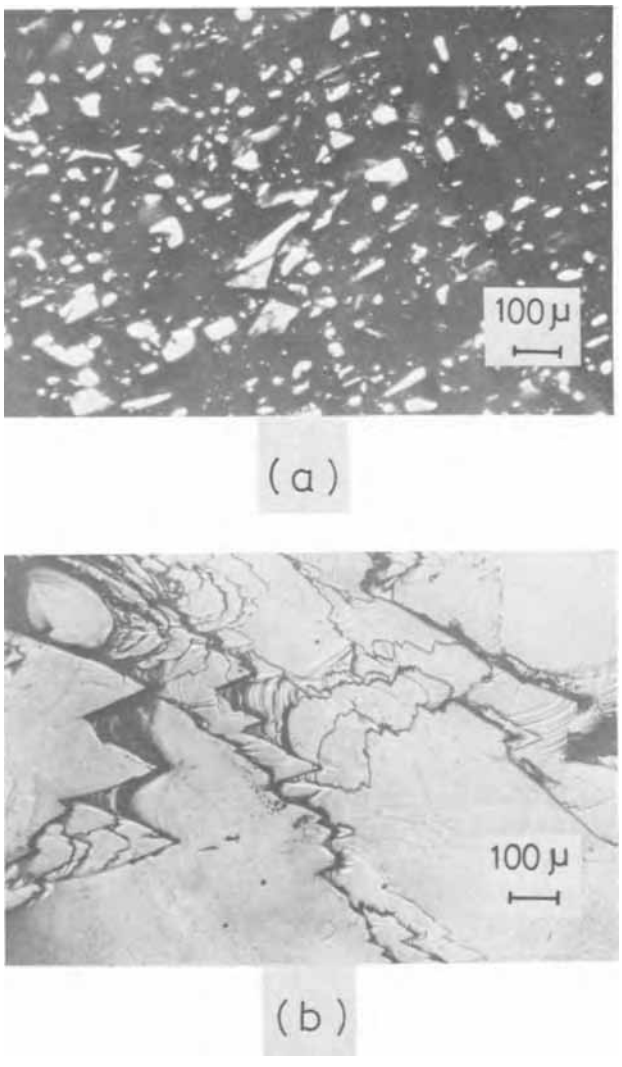

Fig. 2. Surfaces of the layers grown on (a) (100) and (b) (111)A faces of GaAs substrates.

smaller than 1.0, wavy patterns, which are peculiar to solution-grown crystals, were found. When AR was larger than 10, the surfaces were rough and dendritic. Besides the effects of AR, smaller cooling rates and higher maximum growth temperatures resulted in smoother surfaces, although their effects were much weaker than the effects of AR. As for the thickness d of the grown layer, it depended on T_M; *i.e.*, d is $\sim 80\mu$ for $T_M = 800°C$ and $\sim 40\mu$ for $T_M = 700°C$.

In order to clarify the crystalline quality of the grown layer, an electron diffraction study was performed. When AR was smaller than 30, a spot pattern as shown in Fig. 4 was observed, which indicated that the grown layer was a single crystal and had the (111) plane, the same orientation as that of the GaAs substrate. When AR was over 30, a Debye-Scherrer ring was observed, which revealed that the grown layer was polycrystalline.

The composition of the grown $In_xGa_{1-x}As$ layer was studied by two methods; *i.e.*, (a) using an X-ray Micro-Analyzer (X.M.A.) and (b) studying the photocurrent-spectrum of the pn $In_xGa_{1-x}As$ homojunction (9). In the first method, an electron beam microprobe ($\sim 2\ \mu\phi$) scanned the cross section of the grown layer at every 2μ. One example of the X.M.A. data is shown in Fig. 5 for the layer of AR = 10. From the data, the composition x in the grown layer was calculated as shown in Fig. 6, and the growth parameters used were as follows: AR = 10, cooling rate was 1°C/min or 15°C/min, and T_M was 700°C or 800°C. It is observed from Fig. 6 that the transition of the composition at the GaAs-$In_xGa_{1-x}As$ interface is almost abrupt and that x is almost constant in the middle of the layer and decreases toward the surface of the layer. In addition, a faster cooling rate and a lower maximum growth temperature (T_M) give a larger x-value. This is because a long growth time and a higher T_M result in the deficiency of As in the solution which makes the x-value low, as indicated in the phase diagram of $In_xGa_{1-x}As$ by Stringfellow and Greene (10). This is also the reason why the x-value was so small in the grown crystal, even when the AR-value was very large in the solution.

In the second method, a pn $In_xGa_{1-x}As$ homojunction was prepared by diffusing Zn into an undoped $In_xGa_{1-x}As$-grown layer. The Zn diffusion process was performed at 700°C for 0.5-1 hr in a closed quartz ampoule with the As vapor pressure of 1 atm. The photocurrent spectrum of the pn $In_xGa_{1-x}As$ homojunction had a sharp peak, as shown later in this paper. From the wavelength of the peak, the band gap, E_g, of the $In_xGa_{1-x}As$ layer was calculated. Then, x was deduced by assuming the linear relationship between E_g and x, although this assumption is a little inaccurate (2). In Table I, the obtained values of E_g and x were shown as a function of AR. In the table, the x-values for AR = 10 have been derived from the X.M.A. study shown in Fig. 6, while those for AR = 0.1, 1, 20, and 30 (in the brackets) have been deduced approximately from this assumption. When AR was over 30, the grown layer was found to be polycrystalline as mentioned previously. Hence, the upper limit of x in the present growth technique is 0.2 for $In_xGa_{1-x}As$ single crystal.

The 5° angle-lapped section of the interface between the (111)B substrate and the grown $In_xGa_{1-x}As$ layer was investigated after staining it in a HF(50 cm^3) + HNO_3 (1 or 2 drops) solution. As shown in Fig. 7, the interface was flat. The flatness was independent of the cooling rate, T_M, and AR-value. Furthermore, to study the crystalline imperfections at the interface and in the $In_xGa_{1-x}As$ layer, a (111)A bevel-lapped section that was at an angle of 70.5° to the (111)B surface of the grown layer and 35.2° to the (110) cleavage plane was etched in a $HF+3HNO_3+2H_2O$ solution. Figure 8 shows the distribution of etch pits which appeared on the etched (111)A face. There were less etch pits in the grown layer than in the substrate. It is evident, therefore, that the solution-grown $In_xGa_{1-x}As$ layer had a lower dislocation density and a better crystalline quality than the GaAs substrate crystal. However, a great many etch pits were found at the interface. These etch pits may in part result from the misfit dislocations which compensate the lattice mismatch between GaAs and $In_xGa_{1-x}As$, as reported by Grenning for GaAs-$GaAs_xP_{1-x}$ heteroepitaxy (11).

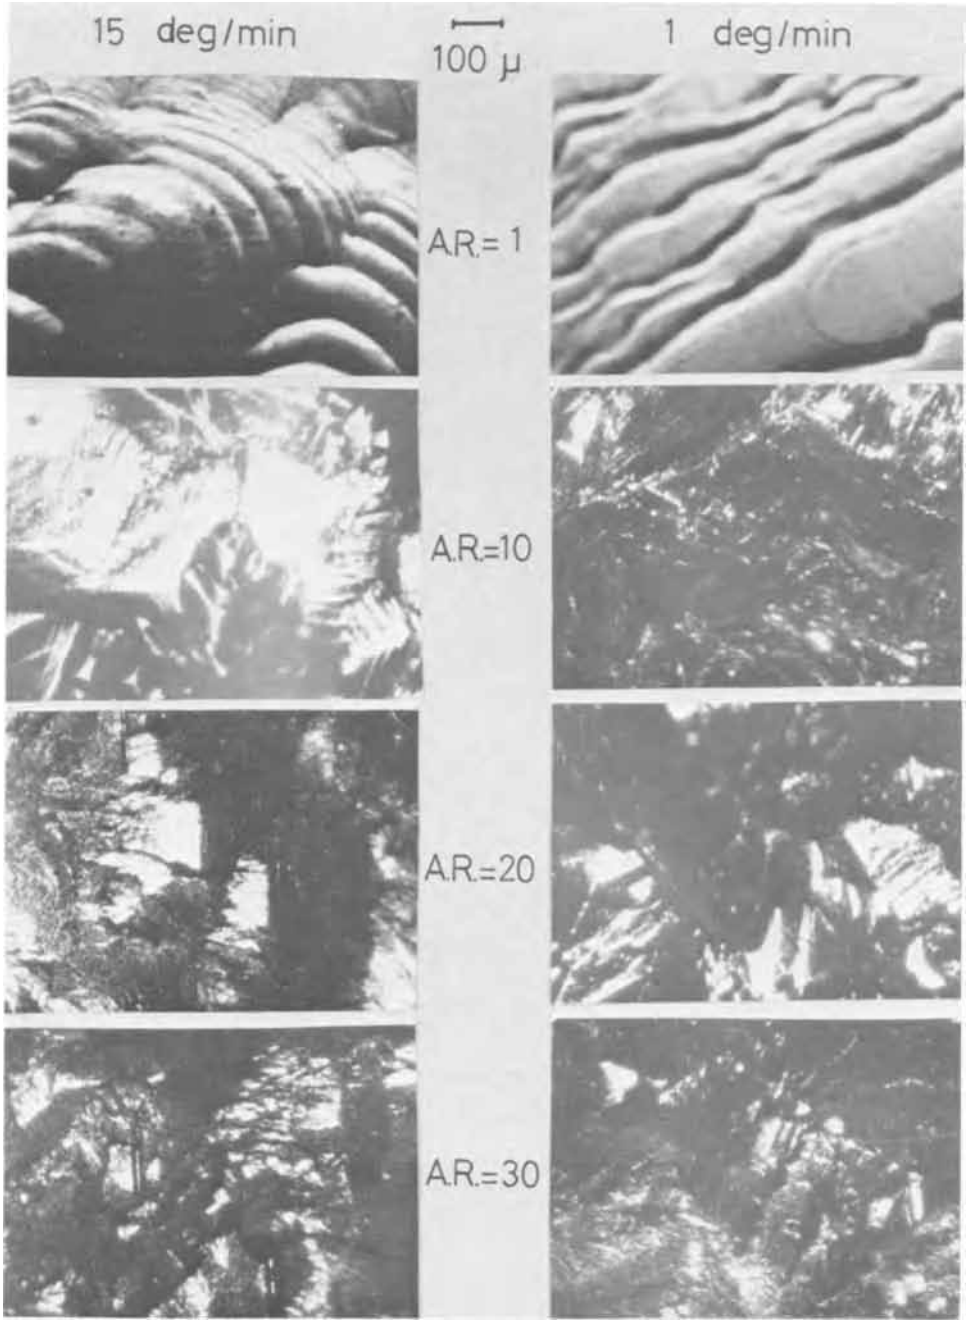

Fig. 3. Variations of the surfaces of the layers grown on (111)B substrates with the various In:Ga atomic ratios in the solution. The maximum growth temperature, T_M, was 700°C and cooling rate was 15 deg/min or 1 deg/min.

Electrical Properties

The electrical parameters of the $In_xGa_{1-x}As$ layer grown on a semi-insulating GaAs substrate—i.e., resistivity ρ, Hall mobility μ_H and carrier concentration n—were obtained from Hall measurements by the van der Pauw method at room temperature (12). The growth conditions were as follows: T_M was 700°C and the cooling rate was 15°C/min or 1°C/min. For accuracy of measurements, some humps on the grown layers were lapped off with No. 4000 abrasive and 0.3μ Linde-Alumina, and then mechanical-chemical polishing was performed. For the lead wires, 50 μ ϕ Au wires were spot-welded at four corners of the grown layer. The conduction type of the grown layers was found to be n-type. Figure 9 shows the results of electron mobility μ_H and electron concentration n which have been plotted as a function of AR. The electron concentration n decreased with the increase of AR, while μ_H remained almost constant. Although AR = 0-30 corresponds to x = 0-0.2, μ_H did not increase in this composition range in spite of the expectation mentioned previously. This is partially due to the impurity compensation effect, as deduced from the decreasing electron concentration with the increase of AR.

Impurity Doping

Attempts were made to dope acceptor impurities, Zn or Ge (10 mg, each), into the solution to obtain a p-type layer. When Zn was doped into the $In_xGa_{1-x}As$ layer which was grown on an n-type GaAs ($n \simeq 10^{17}$ cm^{-3}), a p · $In_xGa_{1-x}As$-n · GaAs heterojunction was formed. Its photoresponse will be taken up later in this report.

It has been reported that Si is an amphoteric impurity in GaAs (13-15) and a pn junction can be made in the solution-grown GaAs layer with Si as the dopant on both p- and n-type sides of the junction (14). On the other hand, although Ge is also an am-

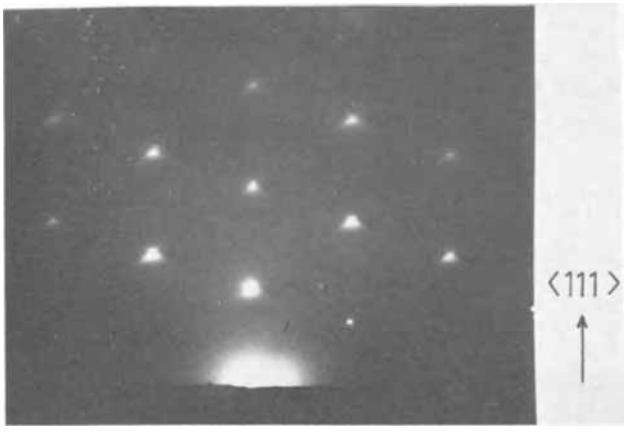

Fig. 4. Electron diffraction pattern of the (111)B surface of $In_xGa_{1-x}As$-grown layer. T_M = 700°C, AR= 10, and cooling rate = 15 deg/min.

photeric impurity, only a p-type layer can be obtained in the solution-grown Ge-doped GaAs (15, 16). However, the present work revealed that when Ge was doped into the $In_xGa_{1-x}As$ crystal, a pn junction appeared in the grown layer. Hence, the same effect as found upon doping Si in GaAs occurred upon doping Ge in $In_xGa_{1-x}As$. It has been suggested that for the solution growth of GaAs the arsenic vapor pressure in the solution determines which of the lattice sites Si atoms or Ge atoms enter (13, 14). If Si atoms or Ge atoms enter a Ga lattice site, an n-type is obtained, and similarly a p-type GaAs is obtained when Si atoms or Ge atoms enter an As lattice site. Moreover, as indicated by the present study, the addition of In to GaAs can also control the behavior of Ge. As In has a larger tetrahedral radius than Ga or As (17), Ge can enter an In site more easily than enter an As or a Ga site. It follows, therefore, that the increase of In atoms in $In_xGa_{1-x}As$ makes Ge enter a III-atom site as a donor, resulting in an n-type $In_xGa_{1-x}As$. However, as the furnace temperature is lowered, the arsenic vapor pressure in the solution is reduced so much that Ge substitutes as an acceptor into the arsenic site. Hence a p-$In_xGa_{1-x}As$ appeared at the end of the growth, and a pn junction was formed in the grown layer.

When T_M was lowered to 600°C, a p-type $In_xGa_{1-x}As$ could be grown directly on the substrate by doping with Ge. Thus, by the proper choice of T_M, a pn $In_xGa_{1-x}As$ homojunction or a p · $In_xGa_{1-x}As$-n · GaAs heterojunction can be made. The photocurrent spectra of both junctions are shown in Fig. 10 together with the spectra of the Zn-doped p · $In_xGa_{1-x}As$-n · GaAs heterojunction and the Zn-diffused pn $In_xGa_{1-x}As$ homojunction. The Ge-doped junctions had larger photoresponses at wavelengths ~ 1μ than Zn-doped junctions. This fact can be attributed to deep Ge acceptor levels, as observed in Si-doped GaAs pn junctions (15).

Conclusion

The epitaxial growth of the $In_xGa_{1-x}As$ layer on a GaAs substrate was achieved by Nelson's solution growth. The solution consisted of In, Ga, and polycrystalline GaAs. When AR (In:Ga atomic ratio) in the solution varied from 0.0 to 30, single-crystalline $In_xGa_{1-x}As$ of the composition x ranging from 0.0 to 0.2 was grown. When x was over 0.2, the grown layer was polycrystalline. The same result has been reported recently by Antypas (7), although the substrates used have (111)A faces of GaAs. In those cases, the x value was very small in the grown crystal in comparison with the value of AR in the solution. This is due to the deficiency of As in the solution.

The crystalline quality of the $In_xGa_{1-x}As$-grown crystal was found to be good from a microscopic ob-

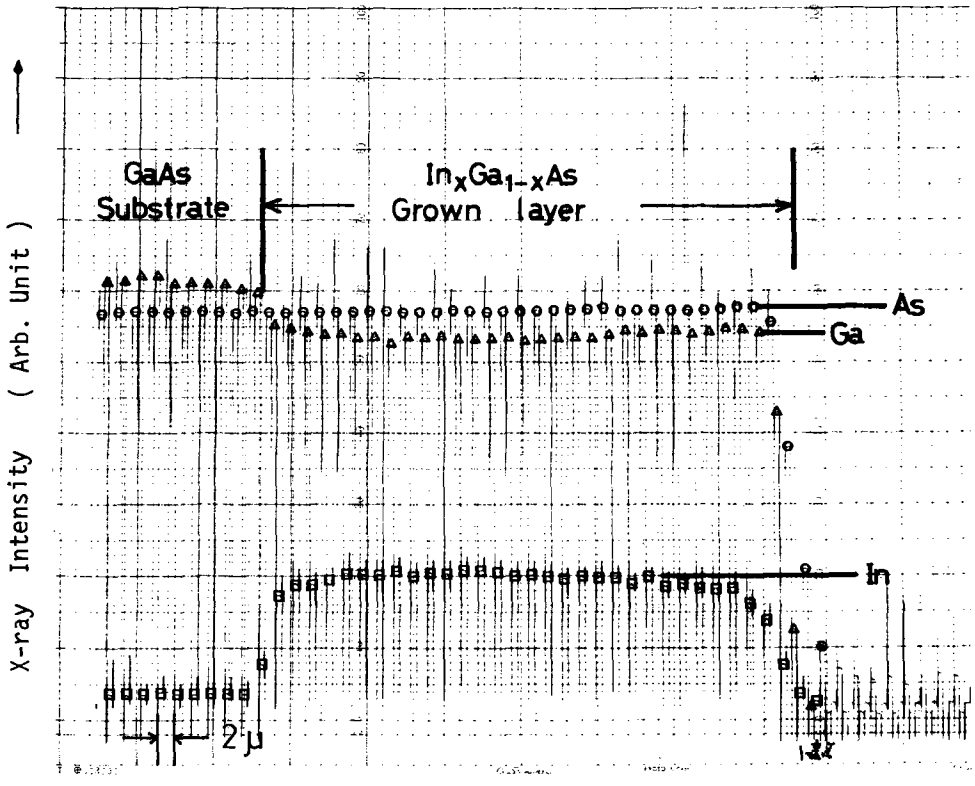

Fig. 5. X.M.A. data of the $In_xGa_{1-x}As$-grown layer when AR = 10, cooling rate was 15 deg/min and T_M = 800°C. Scanning spot: 2 $\mu\phi$. Scanning step: 2μ.

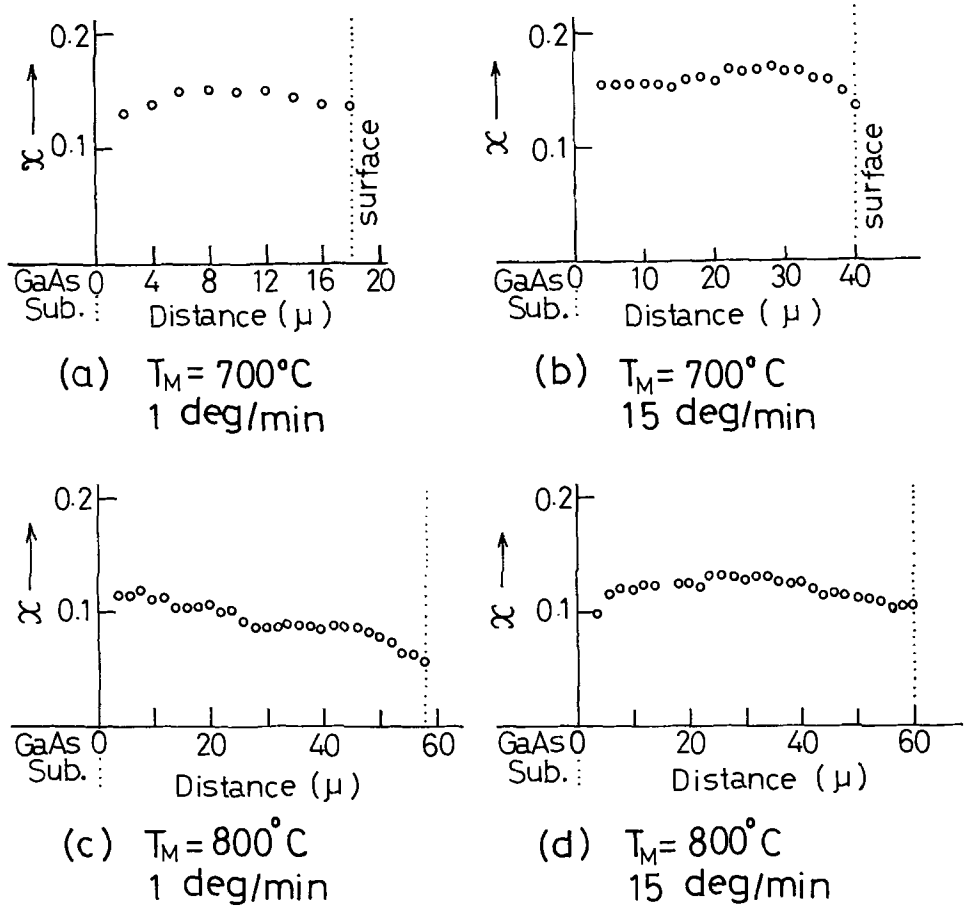

Fig. 6. Composition profiles of the grown layers obtained from X.M.A. data. The growth parameters were: AR = 10, cooling rate = 1 deg/min or 15 deg/min, and T_M = 700°C or 800°C. The In content, x, was shown as a function of the distance from GaAs substrate along the growth direction.

servation and an electron diffraction study. Moreover, etch pits distribution in the bevel-lapped section revealed that the number of defects was smaller in the grown layer than in the substrate. Hence, a good heteroepitaxy was achieved.

Hall measurements of the grown $In_xGa_{1-x}As$ layers were made, and the variations of the electrical parameters, ρ, μ_H, and n, as a function of AR were studied. It was found that an undoped $In_xGa_{1-x}As$ was of n-type, whose electrical parameters were $\rho \simeq 10^{-2}$ ohm-cm, μ_H = 4000-5000 $cm^2/V \cdot sec$, and $n \simeq 10^{17}$ cm^{-3} at room temperature and did not vary much with the increase of AR. To increase the electron mobility, it is necessary to improve the growth technique so that a larger x-value can be achieved.

Ge was found to be an amphoteric impurity in the solution-grown $In_xGa_{1-x}As$ crystal. By the proper choice of T_M, the layer containing a pn junction or a p-type layer was obtained by doping Ge. Moreover, it has been found that by changing x, a p-type or an n-type layer can be grown easily by doping a proper amount of Ge. It seems reasonable to suggest that Ge tends to enter into an In site and hence, x determines into which site more Ge atoms enter, a III-atom site or a V-atom site. The details of Ge-doped $In_xGa_{1-x}As$ will be reported later.

Analysis of Impurity Distribution in Homoepitaxial n on n^+ Films of GaAs. II

J. V. DiLorenzo*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The nature and cause of a high-resistivity region (*i* layer) at the interface of n-type GaAs on bulk n^+ GaAs have received the attention of many workers in the field. Our previous investigations of impurity distributions of n^+ GaAs films on n^+ bulk GaAs substrates by Direct Image Mass Analysis (DIMA) have correlated a high concentration of silicon with a high-resistivity region at the interface. Further analysis of the impurity distribution in epitaxial layers grown on bulk substrates and epitaxial layers grown on buffer layers (epitaxial layers doped to the mid-10^{17} cm^{-3} range) by vapor phase epitaxy and liquid phase epitaxy have been performed. The main conclusions of the present analysis are: (*A*) The buffer layer is effective in isolating the lightly doped n layer from segregated impurities at the buffer-substrate interface. (*B*) Group I and Group II elements have a great affinity for GaAs surfaces. (*C*) Preliminary observations on impurity "clusters" indicate that complicated impurity interactions may be present in GaAs. (*D*) The occurrence of a high concentration of silicon at the interface of epitaxial GaAs is definitely established.

We have recently reported (1) on the analysis of impurity distribution of n on n^+ epitaxial films of GaAs. The analysis was done using a Direct Image Mass Analyzer (DIMA). These films contained high resistivity regions between the epitaxial film and substrate (2-5). This region, called the *i* layer, was found to contain the localized impurities potassium, lithium, chlorine, iron, and silicon. A correlation was obtained between a high localized concentration of silicon at the interface and the appearance of the *i* layer.

In this paper we report on further analysis, using the DIMA, of the impurity distribution of several films of epitaxial GaAs doped in the mid-10^{15} cm^{-3} range grown by either vapor phase epitaxy (VPE) or liquid phase epitaxy (LPE). These films were grown on either bulk GaAs substrates or epitaxial GaAs substrates (buffer layer).

The data obtained confirm the previous conclusions that silicon, as well as other impurities, has a tendency to localize at the interface. In addition, several films showed the appearance of impurity "clusters," i.e. areas of high local concentration of an impurity. Definite correlations are obtained between absence or presence of impurities at the interface and the cleaning history of that wafer.

Experimental

Growth procedures.—The VPE layers of GaAs were grown using the $AsCl_3|Ga$ (saturated with GaAs)$|H_2$ synthesis system (6). Details of the handling and cleaning procedures have been previously given (1). The buffer layers, that is epitaxial layers doped to the 5×10^{17}-10^{18} cm^{-3}, and the lightly doped layers were grown in a continuous fashion. The buffer was doped with sulfur to the mid 10^{17} to 10^{18} cm^{-3} range.

The LPE film, LA039, was grown using a dipping system which has been previously described (7).

Substrates were either silicon, selenium, or tellurium doped boat grown or Czochralski grown ingots.

Analytical technique.—The DIMA technique has been previously described (1). Briefly, it is worth noting the three types of information which are obtained from this technique. Ion images are obtained which show the lateral distribution of a particular impurity and the continuous change in that distribution with depth (see Fig. 3-7). Secondly, in depth changes of the concentration of a particular impurity are read out as current on the y-axis and time, i.e. depth, on the x-axis (see Fig. 1 and 2). Finally, recorded mass spectra of elements from mass 1 through 70 at some depth greater than 1μ into the film were obtained. This is useful as a qualitative chemical analysis for impurities located at that depth.

Results

Film properties.—The properties of the films are listed in Table I. The net donor concentration of the films, n, and of the *i* layer, n_i, listed in Table I, were obtained by the continuous profiling technique described by Copeland (8). Two of the films (D185 and LA039), which were grown directly on bulk substrates, have *i* layers (defined as $[(n - n_i)/n] \times 100$) ranging from 0-13% for D185 to 15-45% for LA039.

Chemical analysis.—A total number of 39 craters (or "burns"), approximately 300μ in diameter were

made by sputtering with O_2^+. The minimum average number of burns for each sample was four.

A list of impurities found in the samples at the interface between the epitaxial layer and bulk substrate are presented in Table II. The impurities were observed either by recording a mass spectrum at a depth of approximately 2μ below the surface of the film or by observing the impurities visually by ion imaging. In the latter case the impurity is either noted by a *D* for diffuse in the film or by an *N* for nonuniform. In addition, in depth distributions of various elements were made as outlined in Ref. (1). Representative traces of the in depth distribution of various impurities are shown in Fig. 1 and 2. The numerical scale on the *x*-axis of each trace is the scale obtained by dividing the total crater depth by the total time of burn. Errors as large as 20% in the optical determination of the crater depth are possible (1). The vertical line between the words epi and substrate is the position of the interface as determined by angle lap and strain.

Impurities found.—Silicon and sodium.—In Fig. 1c the silicon signal from sample D185 is reproduced. The appearance of a large silicon signal at 4.5μ, in reasonable agreement with the interface, is apparent. As mentioned above, we believe the error in determining the crater depth accounts for the discrepancy between the peak and interface position. Note also the greater signal for silicon in the substrate compared to the epitaxial films. By similar determinations silicon signals for samples D185, D203, and J70 were observed at the interface. For samples D185, D203, E532, and J70, a

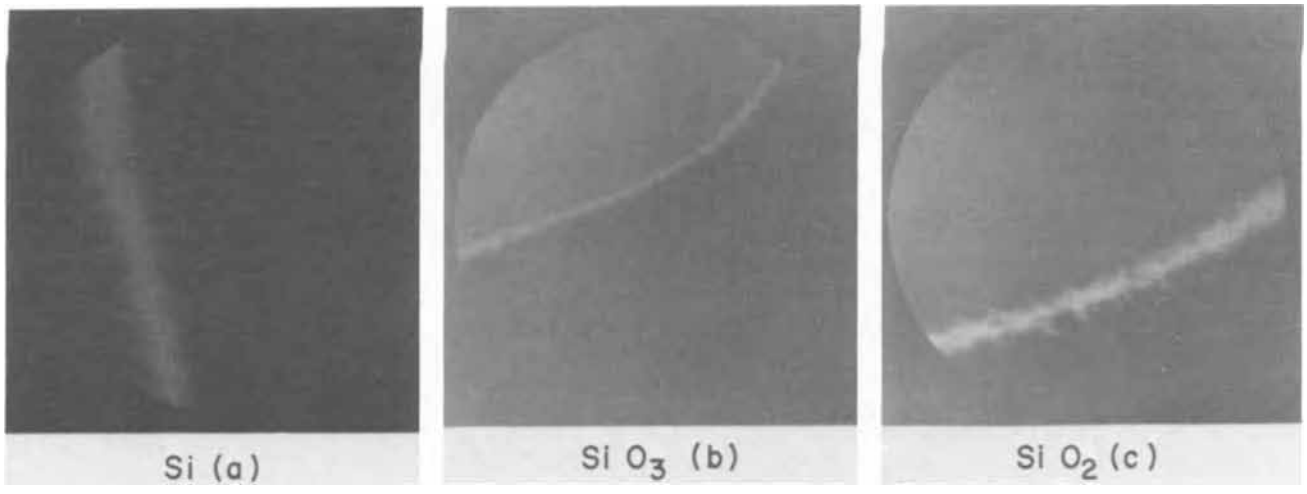

Fig. 4. Ion images from (a) Si^+, (b) SiO_3^-, and (c) SiO_2^- in samples D185.

high concentration of sodium occurs at the epi-substrate or buffer-substrate interface. The sodium concentration at the buffer-substrate interface of sample E532 is lower relative to the other samples.

Calcium.—A representative trace of the signal resulting from a localization of calcium at the interface of sample D185 is shown in Fig. 1b. Sample E532 shows no calcium at the interface both by in depth analysis and ion image analysis (see Table II). Sample LA039 shows the appearance of a high concentration of calcium at the interface ($\simeq 5\mu$) as well as an area rich in calcium ($\approx 1.5\mu$) below the surface.

Ion image analysis.—As discussed previously (1), the ion images appearing from an impurity localized at an interface appear as a white "band" of new moon-like character, defining the interface. Contrast effects on the concave side of the ring are due to the substrate while those on the convex side are due to the film.

In Fig. 3-5 ion images from various species located at the interface are presented. In Fig. 6 the appearance of "impurity clusters" in sample LA039 is shown. Figure 7 shows the aluminum nonuniformity in the substrate of sample J70.

J70	Yes	No	No

Discussion

Our previous observations (1) of a high concentration of silicon at the interface are further substantiated by the data shown in Fig. 1c and Fig. 4 for sample D185. Definite confirmation was obtained that the signal at mass 28 is Si^+ (and not CO^+ for example which has a mass 28). Oxygen sputtering was used and images corresponding to the masses for Si^+, SiO_2^-, and SiO_3^- species were obtained. (The compound negative ions SiO_2^- and SiO_3^- are assumed to arise chemically from a Si + O_2 reaction.) The ion images for these ions from sample D185 are shown in Fig. 4. The data clearly indicate that silicon is the impurity present at the interface.

We have observed a definite correlation between the cleaning history of a sample and impurity localization. The complete cleaning details of the samples D185, D203, J70, and E532 are given in the Appendix. The samples were given either of the treatments listed in Table III. The "chelation" step was performed because of prior work which suggested that this was useful to remove heavy metal surface contamination (4) (copper, iron, etc.).

From the data in Fig. 1-7 and Table II, the following conclusions concerning the contamination of elements at the interface for the samples were reached

D185 (Na,K,Ca) = D203 (Na,K,Ca)
> J70 (Na,K,Ca) > E532 (Na, low)

It seems clear that the introduction of the "chelating" step greatly increased the contamination of Group I and II elements at the interface. This is despite ex-

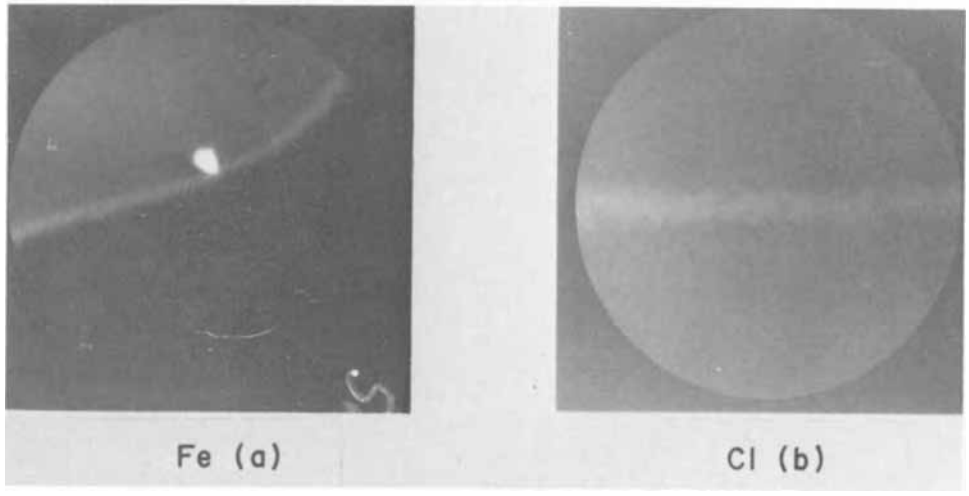

Fig. 5. Ion images from iron (Fe^+) and chlorine (Cl^-) in sample D185.

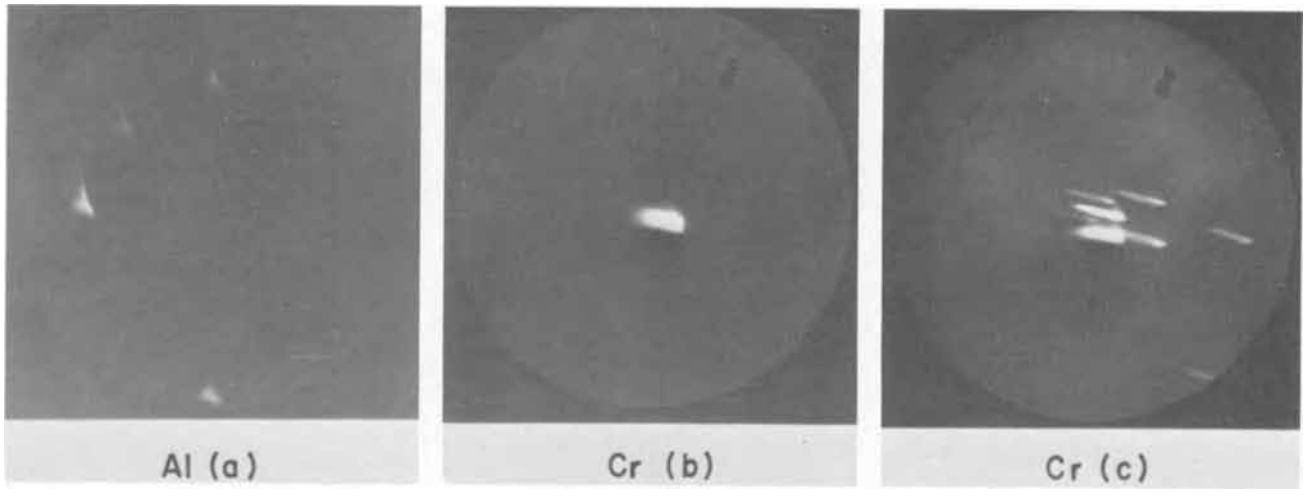

Fig. 6. Ion images from aluminum (Al^+) (a), chromium (Cr^+) (b) (c) in sample LA039.

tensive rinsing in 18 megohm-cm water after treatment. Also *in situ* etching greatly reduces the surface contamination as evidenced by the very clean interface of sample E532 compared to J70 (Table II and Fig. 3).

However, photoluminescence data (9) indicates that the order of copper contamination in these samples is

$$D185 < E532 < J70$$

Therefore, although we removed surface copper contamination by use of the chelation step, Group I and II element contamination was observed.

As assumed, the buffer layer is effective in providing a protective layer between the bulk substrate and lightly doped region for the impurities observed (see Fig. 2 for example).

The iron image shown in Fig. 5 shows three interesting features: (*A*) The high concentration of iron in the substrate contrary to the manufacturer's claim (10). (*B*) The localization of a high contamination of iron (white spot). (*C*) Buildup of iron at the interface. The cause of iron "clump" is not known.

Although preliminary, the data presented in Fig. 6 are quite interesting. Figure 6a shows aluminum ion images from sample LA039, while chromium images are shown in 6b and c. The results indicate that large ($\approx$10-30μ) "clusters" of aluminum or chromium rich

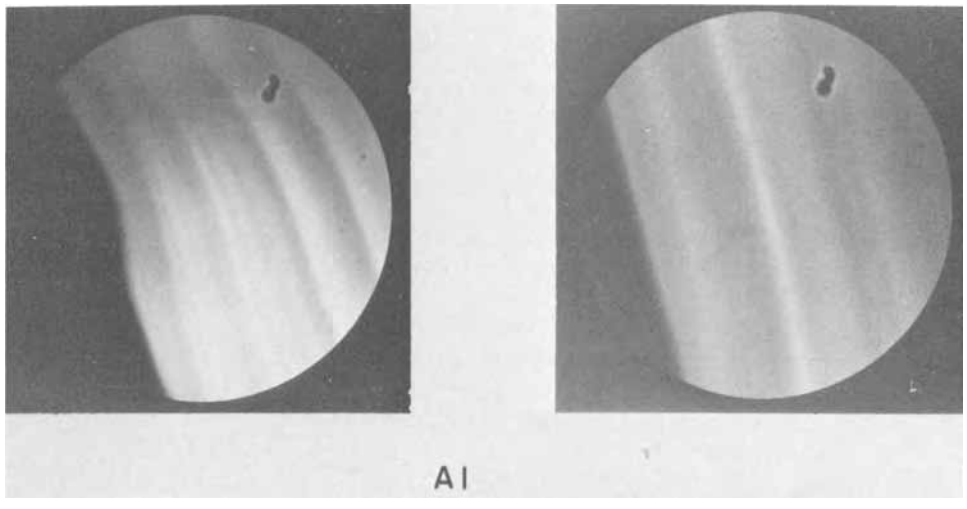

Fig. 7. Ion images from aluminum (Al^+) in substrate of sample J70.

areas are present. Note also the nonuniform distribution of chromium indicated by the nonuniform contrast in Fig. 6c. This data was obtained on only one sample, and the generality of this nonhomogeneous distribution is not known.

Also interesting is the nonuniformity of aluminum in the substrate of sample J70. This substrate was grown by the Czochralski process and was tin-doped. Presumably the impurity striations arise from impurity segregation known to occur in Czochralski crystals. Similar to the observation made on iron above, aluminum was not indicated by the manufacturers (11) as an impurity present in the ingot.

Summary and Conclusions

The continuing analysis of impurity distribution in epitaxial GaAs have led to the following conclusions: (*A*) The occurrence of a high concentration of silicon at the interface of epitaxial GaAs is definitely established. (*B*) The "buffer" layer is effective in isolating the lightly doped layer from segregated impurities at the interface. (*C*) Group I and II elements have a great affinity for GaAs surfaces. (*D*) Preliminary observations on impurity "clusters" suggest that complicated impurity interactions may be present in GaAs.

Acknowledgments

We wish to thank A. Machala for growing some of the epitaxial samples. We wish to especially thank R. Lewis, while at Bell & Howell for performing the analysis on the DIMA. We also wish to thank S. Knight for extensive discussion of these results, and also A. E. Blakeslee, L. R. Dawson, and W. A. Johnson for providing some of the epitaxial wafers.

Manuscript submitted Feb. 22, 1971; revised manuscript received June 1, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

APPENDIX

Preepitaxial Cleaning Procedures of Substrates for Samples D185 and D203

1. Boil in acetone 3 times.
2. Boil in trichloroethylene 3 times.
3. Boil in acetone 2 times.
4. Boil in isopropanol 3 times.
5. Rinse in 17-18 $\times$ 10^6 ohm-cm water 5 min.
6. Etch in $5H_2SO_4$: $1H_2O$: $1H_2O_2$ for 2 min.
7. Rinse in 17-18 $\times$ 10^6 ohm-cm water for 15 min.
8. Soak in 10% by weight solution of sodium ethylene-diamine-tetraacetate at (pH = 7) for 45 min.
9. Rinse in rapidly flowing 17-18 $\times$ 10^6 ohm-cm water for 20 min.
10. Immerse in isopropanol.
11. Load into the reactor from isopropanol wet and dry in hydrogen.
12. Etch *in situ* with HCl removing 7-10μ of substrate.

Preepitaxial Cleaning Procedures of Substrates for Samples E532 and J70

1. Acetone soak 5 min (ultrasonic agitation).
2. Cohben[1] boil for 3 min (ultrasonic agitation).
3. Rinse in methanol.
4. Boil in methanol 3 min (ultrasonic agitation).
5. Rinse in methanol 5 times.
6. Soak 1 min in concentrated HCl.
7. Rinse in methanol 10 times.
8. Etch 10 min. in $5H_2SO_4$: $1H_2O$: $1H_2O_2$.
9. Rinse in methanol 10 times.
10. Store in Cohben.
11. Load wet from Cohben.

Sample E532 was then etched *in situ* in the reactor. The amount of material removed was unknown. Sample J70 was not given the *in situ* etch.

Phosphosilicate Glass Stabilization of MOS Structures

L. H. Kaplan and M. E. Lowe

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The flatband voltage and stability of metal-glass-oxide-silicon (MGOS) systems were studied for phosphosilicate glass layers of varying thickness and composition. Thickness from 30 to 200Å and compositions from 1 to 6 mole per cent (m/o) P_2O_5 were used with a total insulator thickness of 500Å. Electrical properties were measured after contamination (before metallization) of 4 different levels of sodium ranging from approximately 10^{11} to 10^{14}/cm^2. The initial flatband voltage was found to be linear with both sodium contamination and PSG thickness. The ΔV_{FB} shift (due to +10V bias at 200°C for 10 min) is a decreasing linear function of the product of thickness and P_2O_5 concentration up to a value of (t_{PSG} x M%) sufficient to trap all sodium. At higher PSG levels, the ΔV_{FB} increases. For a desired level of Na protection, the thickness—mole per cent product needed, can be determined by the figures supplied.

The use of thin phosphosilicate glass (PSG) films to cover thermally grown SiO_2 layers on IGFET devices is well documented (1). Such films prevent the drift of cationic impurities, *e.g.* sodium, and the resultant instability in threshold voltage. The PSG layer acts as a getter for Na^+ ions, removing them from the SiO_2 layer and acting as a barrier to their entrance from the ambient. Although clean processing techniques tend to lower the Na^+ level greatly, the ever increasing performance requirements for microcircuits make

Key words: flatband voltage, flatband shift, sodium protection, MOSFET.

the use of stabilization system such as PSG almost mandatory.

The use of PSG systems has certain inherent limitations. The films, when of sufficient thickness and/or concentration, have exhibited polarization, which can itself increase threshold shifts (2, 3). Additionally, it has been shown (4) that, while PSG prevents migration of Na^+ ions through the oxide (the amount of Na^+ protection being dependent on PSG thickness and phosphorus concentration), the addition of the PSG layer causes an increase in the flatband voltage (V_{FB}), (negative), corresponding to a decreased threshold voltage (positive) for N-channel devices and to an increased negative V_T for P-channel devices.

For these reasons, it seemed appropriate to investigate the PSG system in an attempt to optimize PSG properties such that both a minimum thermal bias shift (ΔV_{FB}) and minimum flatband voltage might be realized.

Similar investigations of PSG thickness and concentration have been performed in the past (5, 6). However, these studies were concerned mainly with P_2O_5 concentrations above 4 m/o. Consideration of the polarization effects mentioned above, as well as of the increased demands for device stability necessitated by thinner gate insulators, make it advisable to extend this range.

Experimental

A matrix of PSG layers with varying thicknesses and P_2O_5 concentrations between 30 and 200Å and 1-6 m/o for a total SiO_2 thickness of 500Å was proposed for this study. Using a $POCl_3$ deposition system, considerable difficulty in obtaining all the desired PSG layers was encountered.

The PSG layers used were deposited on 500Å SiO_2 layers, thermally grown in dry O_2 on 2 ohm-cm, (100), p-type Si wafers. Deposition was performed by bubbling N_2 through $POCl_3$ and subsequent mixing with additional N_2 and O_2 at the furnace entrance. To achieve varying thickness and P_2O_5 concentrations, such variables as bubbler temperature and deposition temperature were altered. A method of diluting the $POCl_3$ saturated N_2 at constant volume was also utilized. Concentrations as low as 4 ppm were obtained by these methods. However, altering the $POCl_3$ concentration did not give predictable or reproducible results. The most reliable method for producing PSG layers of desired arbitrary concentrations was found to be by varying the temperature of the postdeposition anneal, while keeping the deposition parameters constant. Although all desired levels of thickness and P_2O_5 concentration were not achieved, a sufficient number of samples was obtained for a valid study. Properties of the PSG layers in the 17 sets of samples used were obtained by the well-known step etch technique (7) and are shown in Table I.

To determine the effectiveness of the various PSG layers against Na^+ contamination, four different Na^+ contamination levels were used for each PSG condition. The controlled contamination of the wafers was achieved by vacuum evaporation of the residue from measured small volumes of dilute NaCl solutions. The sodium levels were determined by MOS measurements on unstabilized oxides contaminated at the same time as the experimental samples. All samples were metallized with 10,000Å thick Al dots (using an electron-beam heated source), annealed in N_2 at 400°C for 20 min, and tested. V_{FB} and ΔV_{FB} were determined by CV measurements before and after thermal bias stressing for 10 min at 200°C with the Al electrode at +10V with respect to the Si substrate.

Results and Discussion

The behavior of the sodium ions in SiO_2/PSG systems is complex (4, 5). It is beyond the scope of this paper to explore most of the effects involved. The purpose here is to present a practical report of the variation of V_{FB} and ΔV_{FB} as functions of the PSG properties thickness and m/o of P_2O_5, as well as of the Na^+ contamination level. To this end, only such theory and only such models as will enable one to recognize trends, as they exist, will be presented.

Flatband voltage.—Assuming that $Q_{ss} = 0$ and that all charge is due to sodium, the expected flatband voltage may be arrived at by starting with the following well-known relationships.

$$Q_{eff} = \frac{-\epsilon_o \epsilon_{ox}}{t_{ox}} (V_{FB} - \Delta W_F) \quad [1]$$

$$Q_{eff} = Q_{ox} + Q_{ss} \quad [2]$$

and

$$Q_{ox} = \int_o^{t_{ox}} \frac{t_{ox} - x}{t_{ox}} q_{ox} dx \quad [3]$$

The final expression for V_{FB} will be determined by the functional dependence of q_{ox} upon x. For the method of contamination used in this work, it might be expected that all Na^+ is initially concentrated near the metal-PSG interface, with essentially zero concentration elsewhere in the oxide. Since, in this case, $X = t_{ox}$, Q_{ox} reduces to zero and $V_{FB} = \Delta W_F$ regardless of sodium level or PSG parameters. However, experimentally this was not found to be true. The flatband voltage before stressing (but after annealing at 400°C) was found in all cases to vary linearly with the concentration of deposited sodium, when plotted on a log-log basis. Figure 1 shows some typical examples for a variety of PSG thicknesses and concentrations. V_{FB} is shown in Fig. 2 to vary linearly with PSG thickness at each contamination level.

It seems clear that the functional dependence of q_{ox} upon x hypothesized is incorrect. If the Na^+ diffuses during the 400°C postmetallization anneal, the distribution may be assumed to consist of two parts. Because of the gettering effect of the PSG, the Na^+ should be localized in this layer to a point at which all available trapping sites are filled. Although the trapping process is recognized to be transient and

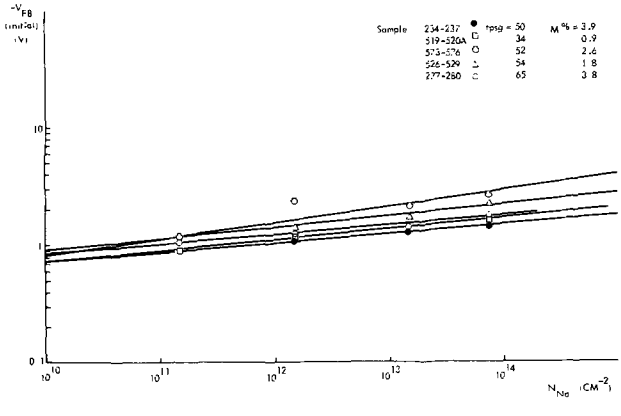

Fig. 1. Typical curves of V_{FB} vs. sodium concentration

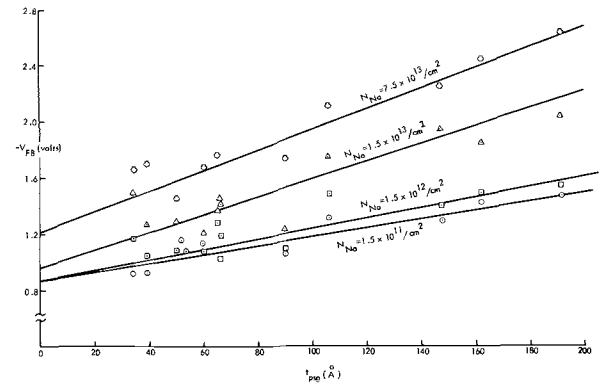

Fig. 2. Initial flatband voltage vs. PSG thickness for four levels of contamination.

merely constitutes a slowing-up of any motion imparted to the ions, at any given point in time, some Na^+ will be in a trapped condition and some in a mobile condition. The data of Fig. 2 strongly imply that the Na^+ distribution in the PSG layer is one of uniform density. The increase of V_{FB} with PSG thickness would rule out any major accumulation of trapped Na^+ at the Al-PSG boundary, since it indicates that thicker PSG layers have their sodium distributed closer to the Si/SiO_2 interface, on the average.

Any sodium ions in excess of those required to fill traps will be distributed in the PSG and SiO_2. The exact nature of this distribution is somewhat in doubt, since the radiochemical and neutron activation work (8, 9) done to establish such distributions has been on much thicker oxide films. The simplest functional dependence which could be assumed is, of course, constancy. As shown below, this assumption leads to fairly good agreement with the experimental data. It might be noted in passing, that a linear distribution ($q_{ox}/q = A + Bx$) was also investigated and found to bear no relation to the experiment.

Prior to any electrochemical stressing, q_{ox} may be considered as being made up of two parts; the charge densities due to trapped and mobile ions, respectively. For the uniform distribution in x indicated above

$$Q_{ox} = \int_o^{t_{ox}} \frac{t_{ox} - x}{t_{ox}^2} qN_{Nam}\,dx + \int_{t_{ox}-t_{PSG}}^{t_{ox}} \frac{t_{ox} - x}{t_{ox}t_{PSG}} qN_{Nat}\,dx \quad [4]$$

where the integration limits for the last term (corresponding to trapped Na^+) were changed to conform to the distribution of trapped sodium in the PSG. Integrating Eq. [4] and combining with Eq. [1] and [2], one obtains

$$V_{FB} = \Delta W_F - \frac{q\,t_{ox}}{2\epsilon_0\epsilon_{ox}}\left(N_{Nam} + \frac{N_{Nat}\,t_{PSG}}{t_{ox}}\right) \quad [5]$$

By definition, $N_{Nam} = N_{Na} - N_{Nat}$. Substituting and rearranging

$$V_{FB} = \Delta W_F - \frac{q\,t_{ox}}{2\epsilon_0\epsilon_{ox}}\left[N_{Na} + \left(\frac{t_{PSG}}{t_{ox}} - 1\right)N_{Nat}\right] \quad [6]$$

The number of Na^+ ions which can be trapped by a PSG layer (N_{Nat}) can be simply calculated, under the assumption that all traps are active, based upon the "nonbridging oxygen" model advanced by Eldridge and Kerr (5). The number of PO^- trapping sites is calculated from the density and m/o, and thickness of the PSG. After evaluating numerical constants, the expression becomes

$$N_{Nat} = 1.33 \times 10^{20}\ t_{PSG}\ m/o$$

Substituting for N_{Nat}, as well as for numerical constants, and assuming an oxide thickness of 500Å, one obtains, for the case where the PSG is insufficient to trap all of the sodium

$$V_{FB} = \Delta W_F - 1.053 \times 10^{-12} N_{Na} - (2.8 \times 10^{13}\,t_{PSG} - 1.4 \times 10^8)\,t_{PSG}\,m/o \quad [7]$$

If all the sodium is trapped, $N_{Nat} = N_{Na}$ and Eq. [6] reduces to

$$V_{FB} = \Delta W_F - \frac{q\,t_{PSG}N_{Na}}{2\epsilon_0\epsilon_{ox}} \quad [8]$$

As previously noted, Fig. 2 shows a linear relationship between V_{FB} and t_{PSG}. This is in direct agreement with Eq. [8], suggesting that, even for the highest levels of contamination, all sodium has become associated with trapping sites in the PSG.

Without offering any further interpretation of the above data, it is quite clear that the V_{FB} for systems containing PSG increases with PSG thickness for any given Na^+ level. This is in good agreement with previously described findings (6). Further, it seems evident from Fig. 3 that higher sodium concentrations produce higher initial flatband voltages with any given thickness of PSG.

Change in V_{FB} with electrothermal stress.—Consideration of the "nonbridging oxygen" model mentioned earlier would seem to indicate a linear relation between ΔV_{FB} and the product of PSG concentration and thickness. Figure 4 shows the variation observed experimentally between these variables. Plots of ΔV_{FB} against PSG concentration or thickness separately produced no clear relationship. The plot of Fig. 4 is in semilog format to allow the wide range of ΔV_{FB} to be shown in a single plot. A linear format, however, shows that each curve (for a given contamination level) has a decreasing linear region at low values of m/o x t_{PSG}, and a flat or increasing region at higher values.

The data described above are in agreement with an extension of the treatment used previously to predict V_{FB}. This treatment assumes that, for a given stress temperature and electric field, some of the sodium associated with the PSG behaves as mobile sodium due to emission from the traps. For all practical purposes, therefore, the total sodium content may then be classified as either mobile or trapped. However, because of the emission process, only a fraction of the available traps will contain "trapped" sodium. Since $\Delta V_{FB} = V_{FB}$ (after stressing) $- V_{FB}$ (before stressing), it is now necessary only to formulate an expression for V_{FB} (after stressing). For this, Eq. [4] must be modified by replacing its first term (corresponding to the mobile Na^+) to account for all mobile Na^+ being located at the interface.

Thus, $Q_{ox} = Q_{eff}$, which is defined as the charge which, if placed at the interface, would have the same effect as that of the distributed charge, q_{ox}. Since the real charge, qN_{Nam}, is now completely at the interface,

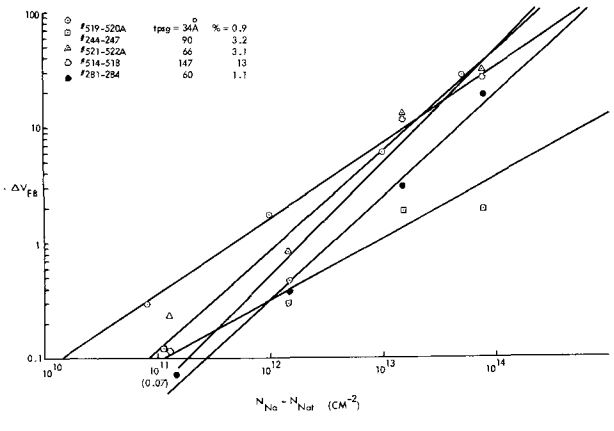

Fig. 3. Typical curves of ΔV_{FB} vs. sodium concentration

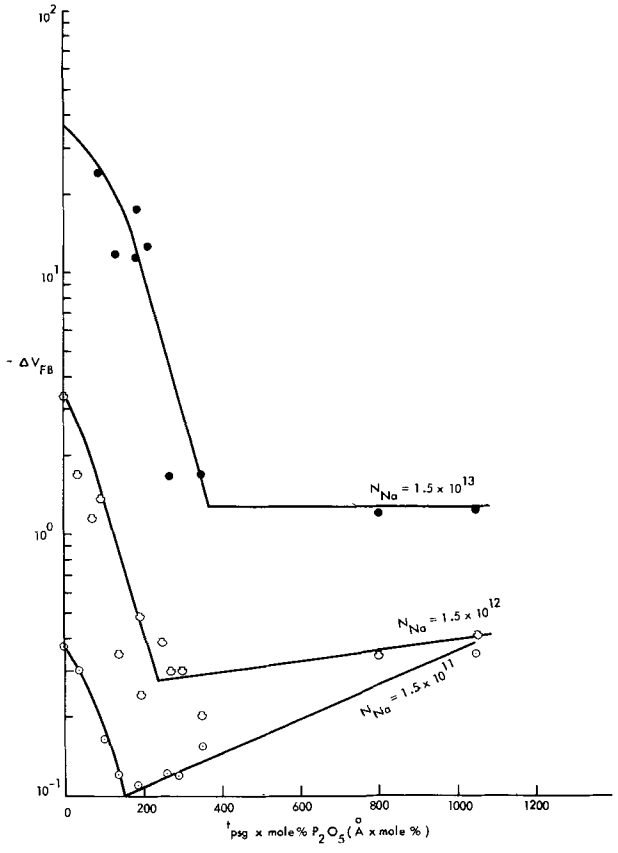

Fig. 4. Variation of thermal bias flatband voltage shift with thickness x m/o P_2O_5. (Thickness measured in Å.)

it is equal to the mobile charge contribution to Q_{ox}. Then, analogous to Eq. [4]

$$Q_{ox} \text{ (after stress)} = q N_{Nam} + \int_{t_{ox}-t_{PSG}}^{t_{ox}} \frac{t_{ox} - x}{t_{ox} t_{PSG}} q N_{Nat} dx \quad [9]$$

Analogous treatment to that of Eq. [5] and [6] gives

$$V_{FB} \text{ (after stress)} = \Delta W_F - \frac{q t_{ox}}{\epsilon_0 \epsilon_{ox}} \left[N_{Na} + \left(\frac{t_{PSG}}{2t_{ox}} - 1 \right) N_{Nat} \right] \quad [10]$$

Subtracting V_{FB} (before stress), as obtained from Eq. [6], one obtains for the saturation shift on thermal bias stress

$$-\Delta V_{FB} = \frac{q t_{ox}}{2\epsilon_0 \epsilon_{ox}} (N_{Na} - N_{Nat}) = 1.053 \times 10^{-12} (N_{Na} - N_{Nat}) \quad [11]$$

When the amount of PSG is insufficient to trap all sodium, $N_{Nat} = 1.33 \times 10^{20}\ t_{PSG} \cdot \text{m/o} \cdot G$ where G is some fraction which accounts for all available traps not being permanent. Therefore

$$-\Delta V_{FB} = 1.05 \times 10^{-12} N_{Na} - 1.40 \times 10^{8} \cdot t_{PSG} \cdot \text{m/o}\, G \quad [12]$$

This predicts the linear decrease in ΔV_{FB} with t_{PSG} m/o shown in the data of Fig. 4. As predicted by Eq. [11], $-\Delta V_{FB}$ was found, in each of the seventeen PSG types studied, to be linear with $(N_{Na} - N_{Nat})$. Figure 3 shows several typical log-log plots of this type for a variety of PSG characteristics.

Conclusion

The data presented allow the estimation of the degree of protection given by PSG films of various thickness/concentration combinations against the deleterious effects of Na^+ contamination levels which might be experienced during device fabrication. However, the sole criterion used here is the flatband voltage shift under bias of +10V (2 x 10^6 V/cm) at 200°C for 10 min. No attempt is made to correlate these shifts with in-use conditions. From Fig. 4, it appears that sodium concentrations higher than approximately 10^{12}/cm^2 create shifts of greater than 0.2V, regardless of the thickness and concentration of the PSG used. For shifts as low as 0.1V, it would seem necessary to maintain the Na^+ contamination at 10^{11}/cm^2.

It is interesting to consider the quantity G, introduced in Eq. [12]. By rearrangement of this equation, G may be expressed as follows

$$G = \frac{\Delta V_{FB} + 1.05 \times 10^{-12} N_{Na}}{1.40 \times 10^{8}\ t_{PSG}\ \text{m/o}} \quad [13]$$

Values for G calculated in this way are plotted in Fig. 5. The factor is evidently a function of PSG parameters as well as the Na^+ level and can have rather low values. The range of G values calculated for PSG films in this work is from 0.0003 to nearly unity. Another independent study in this laboratory shows the same effect (10).

Even if more permanent traps could be made available so that lower shifts could be obtained at high Na^+ density, the practical protection would still be limited by consideration of initial V_{FB} requirements. While the ΔV_{FB} was shown here to depend only on the product of t_{PSG} and m/o, (neglecting polarization effects), the V_{FB} is clearly seen (Fig. 2) to depend upon the thickness of PSG at a given Na^+ level. Figure 2 also demonstrates that the dependence grows more pronounced as the Na^+ concentration is increased. It is very likely, then, that the V_{FB} thickness dependence is actually caused by sodium trapped in the PSG layer. In any event, the optimum configuration of PSG would seem to consist of the minimum thickness consistent with processing considerations and a concentration of P_2O_5 sufficient to yield a (t_{PSG} x m/o) product which will protect against the Na^+ level of interest.

Finally, it should be noted that there are other modes of Na^+ contamination which might not be expected to yield results equivalent to the ones quoted. Sodium contamination during device fabrication may arise from several sources, among which are: incorporation during oxidation, contamination during photoresist processing, and contamination due to handling between all premetal process steps. Clearly, no one controlled contamination process can be expected to simulate all of these mechanisms. The vacuum deposition of NaCl most closely resembles the modes of contamination due to photoresist and handling. Other methods, such as treatment with boiling NaCl solution, would be expected to give somewhat different results. It is believed that the method of contamination used

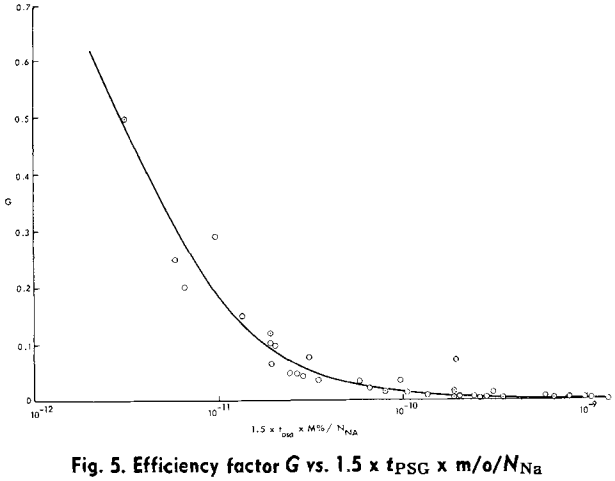

Fig. 5. Efficiency factor G vs. 1.5 x t_{PSG} x m/o/N_{Na}

here yields the most accurately controlled contamination levels and is a good substitute for the total contamination experienced in IGFET processing.

The Chemical Polishing of Sapphire and MgAl Spinel

A. Reisman,* M. Berkenblit,* J. Cuomo,* and S. A. Chan

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Based on air annealing studies at 1500°C, it appears that bulk and surface mechanical damage in sapphire and MgAl spinel ($MgAl_2O_4$) may be greatly minimized. Such annealed surfaces can then be effectively polished chemically leaving essentially featureless surfaces. Preannealed sapphire orientations can be polished at 285°C in a 1:1 H_2SO_4:H_3PO_4 mixture for 15 min while MgAl spinel orientations may be treated in a 3:1 H_2SO_4:H_3PO_4 mixture at 250°C for the same length of time. (111) MgAl spinel and $(10\bar{1}4)$ sapphire cannot be chemically polished by the procedures described but are presumably amenable to removal of most surface and mechanical saw and polish induced bulk damage via the high-temperature annealing process.

Sapphire and, more recently, MgAl spinel ($MgAl_2O_4$) have been employed extensively as single-crystal dielectric substrates for the epitaxial growth of a variety of materials. Wafers of these dielectrics are available only in mechanically polished form. Because of the damage introduced during mechanical preparation, a number of liquid- and gas-phase treatments have been applied prior to use to effect nonselective etching (chemical polishing) of the surfaces. Among these are included molten borax (1-4), heated phosphoric acid (2, 5-7), molten V_2O_5 (8), molten lead fluoride (9), heated vaporous sulfur fluorides (10), heated vaporous fluorinated hydrocarbons (11), HCl-H_2 at elevated temperatures (12), and H_2 annealing (2, 4, 5, 13, 14), among others. In fact, none of these approaches has been too satisfactory for a variety of reasons. Molten salt approaches are cumbersome, often are somewhat selective, and in common with others noted above are highly orientation dependent. The vapor-phase etchants are quite orientation dependent and sometimes exhibit low removal rates. Heated phosphoric acid has shown some promise but tends to leave insoluble residues behind. Further, because it dehydrates and polymerizes, its chemical behavior varies continuously with time at temperature. H_3PO_4 is also somewhat orientation selective and frequently results in dense pitting. H_2 annealing exhibits a vanishing low removal rate and was found by us not to eliminate polishing scratch damage when subjected subsequently to the liquid-phase portion of the polishing technique to be described below. Finally, where some modicum of success might be attributed to some of the methods mentioned above for sapphire, their applicability to Mg spinel is an unknown quantity.

* Electrochemical Society Active Member.

Key words: chemical polishing, sapphire chemical polishing, MgAl spinel chemical polishing.

Experimental Procedure

Sapphire and magnesium spinel wafers were obtained from Insaco Corporation (Quakertown, Pennsylvania) and Union Carbide Company (Crystal Products Division, San Diego, California) as 3/4 or 1 in. diameter sawed, lapped, and mechanically polished materials prepared from Czochralski-grown ingots. Several sapphire wafers cut from vapor-grown ingots, obtained from the Lexington Laboratories (Cambridge, Massachusetts), and mechanically polished by Insaco were also examined. The nominal sapphire orientations studied included (0001), $(10\bar{1}4)$, $(11\bar{0}0)$, $(11\bar{0}2)$, $(11\bar{2}6)$, and $(11\bar{2}0)$. X-ray analysis showed these to be within 1°-4.5° of these specified orientations. Spinel orientations examined included (111), (110), and (100) and were within 1°-2° from the specified planes.

Wafers were rinsed ultrasonically in acetone and deionized water, then dried in a filtered nitrogen stream. Microscopic examination prior to further treatment showed the presence of a variable number of random polishing scratches, the density being greatest at the wafer periphery.

The polishing procedures developed are of two kinds, an anneal in air at 1500°C, and a wet chemical polish effected in the temperature range 250°-300°C. The air anneal or the wet chemical technique may be utilized separately but when possible (namely when the wet chemical technique does not exhibit orientation dependence) were found to provide the most useful surfaces for epitaxy when applied in sequence. The high-temperature anneal serves to remove most if not all surface and induced bulk damage while the wet chemical technique removes retained surface debris and contaminants.

Annealing of the samples was conducted in air in a platinum wound resistance furnace using an Alundum furnace tube, Fig. 1. The samples were placed on a slab single-crystal sapphire support and loaded into the furnace at 750°C. The furnace temperature was raised to 1500°C and the samples were held at this temperature for varying periods of time. They were examined microscopically for evidence of residual scratch damage, then subjected to chemical polishing which was useful for revealing remnant bulk scratch damage.

The wet chemical polishing treatment involves nonselective etching of the sapphire or MgAl spinel wafers in sulfuric-phosphoric acid mixtures at 300°C or less. It was found that unlike the behavior of pure phosphoric acid which tends to polymerize when heated to form a practically water insoluble, extremely viscous fluid, H_2SO_4-H_3PO_4 mixtures do not thicken or become water insoluble. The H_2SO_4 appears to prevent degradation of the H_3PO_4. Equally important is the observation that with H_2SO_4-H_3PO_4 mixtures, insoluble residues do not form on the wafer surface nor is surface pitting a problem. While loss of H_2SO_4 does occur during a polishing cycle, the amount of volatilization is not great, due to the vapor pressure reduction resulting from dilution with phosphoric acid. Polishing of sapphire and spinel was studied in the temperature range 200°-300°C using various H_2SO_4/H_3PO_4 ratios contained in a platinum crucible, with and without wafer rotation. The wafers were held in a platinum basket. The apparatus employed is shown schematically in Fig. 2. In all studies, Mallinckrodt 85% H_3PO_4 Analytical Reagent and Mallinckrodt Sulfuric Acid Transist AR grade were employed. Fresh solutions were heated to temperature slowly to allow the H_3PO_4 to lose its absorbed water and highest vapor pressure water of hydration at *ca.* 185°C. Polishing solutions were replaced after two polishing cycles in practice, although regeneration to a given volume with either a 3/1 or stronger H_2SO_4/H_3PO_4 mixture appears to enable additional cycles without adverse effect.

Results and Discussion

Removal rate studies.—Preliminary studies were conducted over the temperature range 200°-450°C, where feasible, using pure sulfuric acid, sulfuric/phosphoric acid volume ratios of 9/1, 3/1, 1/1, 1/3, and

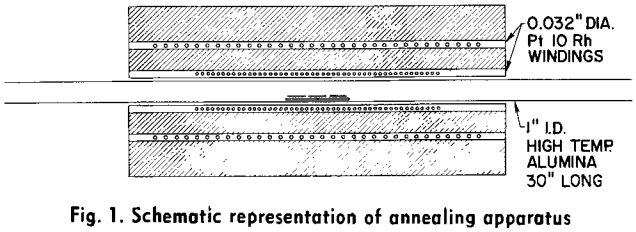

Fig. 1. Schematic representation of annealing apparatus

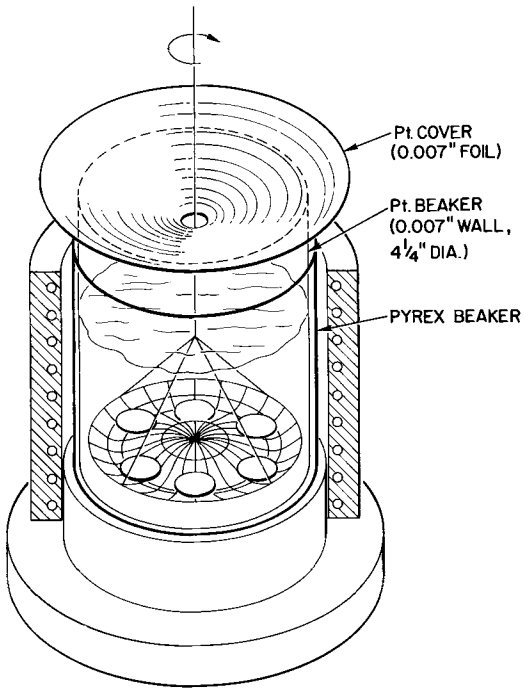

Fig. 2. Schematic representation of wet chemical polishing apparatus.

pure phosphoric acid. Rotation rates of 0, 0.5, 10, and 50 rpm were examined. In general, removal rates were independent of the rotation rates examined. Surface quality was, however, distinctly superior at the lower rotation rates and best when the samples were stationary. Table I tabulates all etching results obtained at 0.5 rpm. Figure 3 shows the variation of log {(0001) sapphire removal rate} as a function of T^{-1} °K^{-1} for pure phosphoric acid in the temperature interval 285°-450°C and for 9:1 H_2SO_4:H_3PO_4 mixtures in the temperature interval 250°-300°C (above 300°C the evaporation rate of the H_2SO_4 became too great in the 9:1 mixture to obtain reproducible results). Figure 4 shows the variation of log {(111), (110), and (100) magnesium spinel removal rate} as a function of T^{-1} °K^{-1} for 3:1 H_2SO_4:H_3PO_4 mixtures

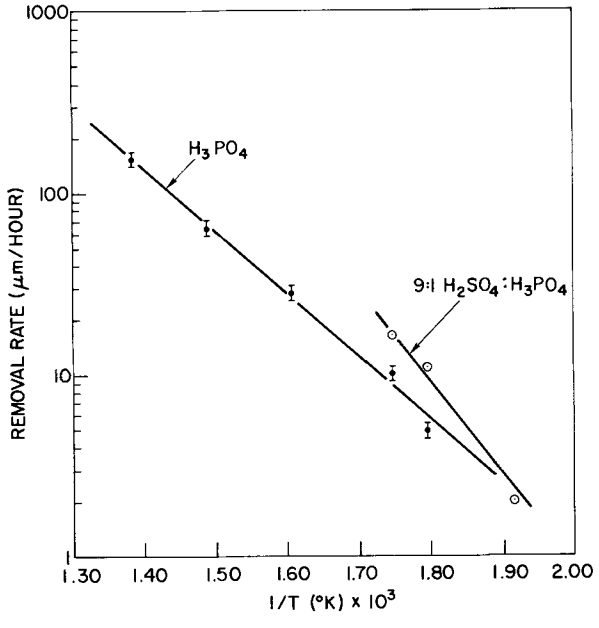

Fig. 3. Variation of log {(0001) sapphire removal rate} as a function of $T^{-1}[°K]^{-1}$ for 9:1 H_2SO_4:H_3PO_4 and H_3PO_4.

in the temperature interval 200°-300°C. Figure 5 shows the variation in etch rate of (0001) sapphire at 285° and 300°C in different H_2SO_4:H_3PO_4 mixtures and (110) magnesium spinel at 250°C in the same composition interval. Data for other sapphire orientations have not been plotted but can be obtained from Table I.

It is to be noted that removal rate data for pure sulfuric acid are not given. This is because the samples following such treatment were covered with a heavy deposit and weight gains occurred.

From Fig. 3 and 4 it is seen that linear semilog plots were obtained which in general exhibit somewhat different slopes. Such results indicate that the etching behavior observed occurs in a surface limiting regime and is representative of chemical rather than diffusion limiting kinetics. This explains the independence of removal rate on rotation rate. Based on these data, the removal rates of (0001) sapphire in phosphoric acid and in a 9:1 H_2SO_4:H_3PO_4 mixture as a function of temperature are given by Eq. [1] and [2], respectively

$$\log R_{(0001)\text{sapphire}}^{H_3PO_4} = \frac{-3.472 \times 10^3}{T[°K]} + 6.968 \quad [1]$$

$$\log R_{(0001)\text{sapphire}}^{9:1} = \frac{-5.050 \times 10^3}{T[°K]} + 10.037 \quad [2]$$

The removal rates of (111), (110), and (100) MgAl spinel in a 3:1 H_2SO_4:H_3PO_4 mixture as a function of T are given by Eq. [3]-[5], respectively

$$\log R_{(111)\text{spinel}}^{3:1} = \frac{-6.971 \times 10^3}{T[°K]} + 13.658 \quad [3]$$

$$\log R_{(110)\text{spinel}}^{3:1} = \frac{-5.524 \times 10^3}{T[°K]} + 11.350 \quad [4]$$

$$\log R_{(100)\text{spinel}}^{3:1} = \frac{-5.103 \times 10^3}{T[°K]} + 10.787 \quad [5]$$

In all instances R is the removal rate in μm/hr.

From Fig. 5 it is seen that the removal rate of (0001) sapphire increases with increasing H_2SO_4 concentration and tends to level off at high H_2SO_4 concentrations. However, (110) MgAl spinel shows its maximum removal rate in pure H_3PO_4 but does show a leveling off at high H_2SO_4 concentrations. These data indicate that over a rather broad composition range the removal rate is not too concentration dependent.

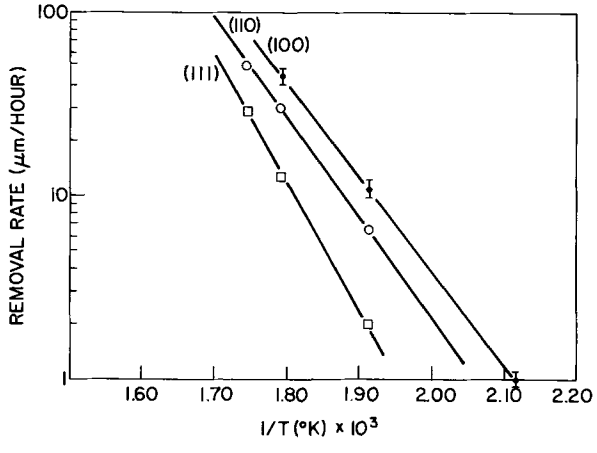

Fig. 4. Variation of log {(111), (110), and (100) MgAl spinel removal rate} as a function of $T^{-1}[°K]^{-1}$ for 3:1 H_2SO_4:H_3PO_4.

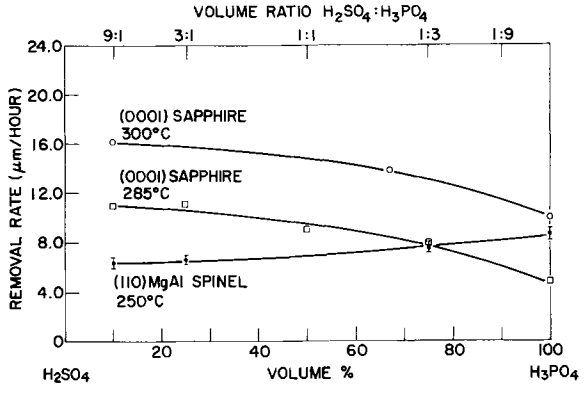

Fig. 5. Variation of removal rate with polishing solution composition for (0001) sapphire and (110) MgAl spinel.

While the polishing of certain sapphire and spinel orientations could be effected reasonably well in pure phosphoric acid, pronounced pitting and residue formation were problems, as were the changes in the properties of the H_3PO_4 with continued heating. For sapphire, the best polishing was achieved at a 1:1, H_2SO_4:H_3PO_4 ratio at a temperature of 285°C. While somewhat higher temperatures can be employed, 285°C provides a good practical working temperature from the point of view of removal rate and relatively low volatility of H_2SO_4 from the mixture. Neither pitting nor residue formation is a problem. In badly damaged wafers, chemical polishing alone requires the removal of a few mils of material which can be accomplished with minimal deterioration of surface planarity. However, a certain degree of etch propagation of scratch damage may occur which necessitates too much removal, from a practical point of view, to completely eliminate all traces of damage. In practice, when the chemical polishing alone was employed, only 0.5 mil was removed which left very faint traces of such scratch damage.

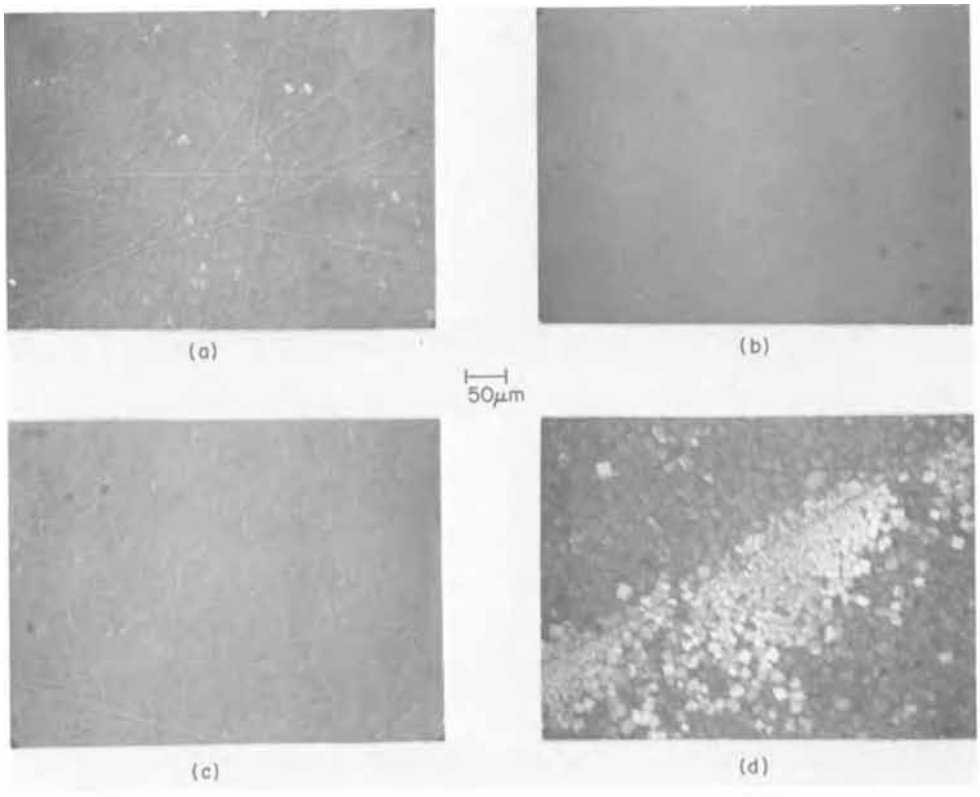

Fig. 6. Polishing behavior of (0001) sapphire, 90 min at 285°C. (a) H_3PO_4, (b) 1:1 H_2SO_4:H_3PO_4, (c) 3:1 H_2SO_4:H_3PO_4, (d) H_2SO_4.

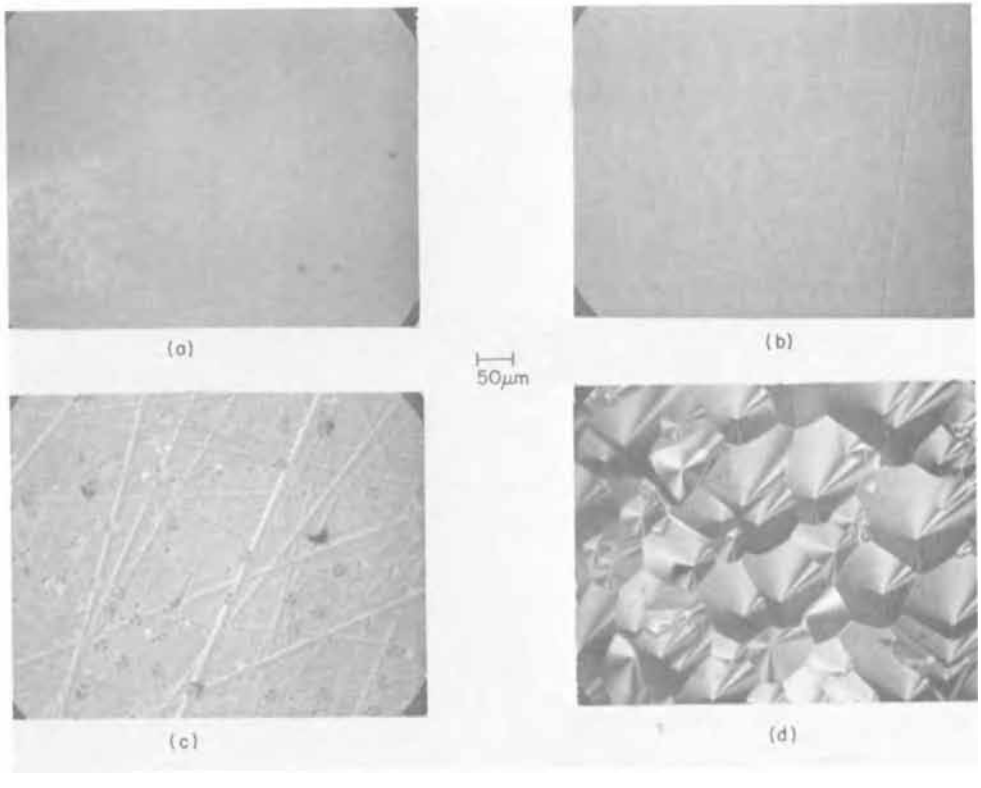

Fig. 7. Polishing behavior of MgAl spinel, 90 min, 3:1 H_2SO_4:H_3PO_4. (a) (100) at 250°C, (b) (110) at 250°C, (c) (111) at 250°C, (d) (111) at 300°C.

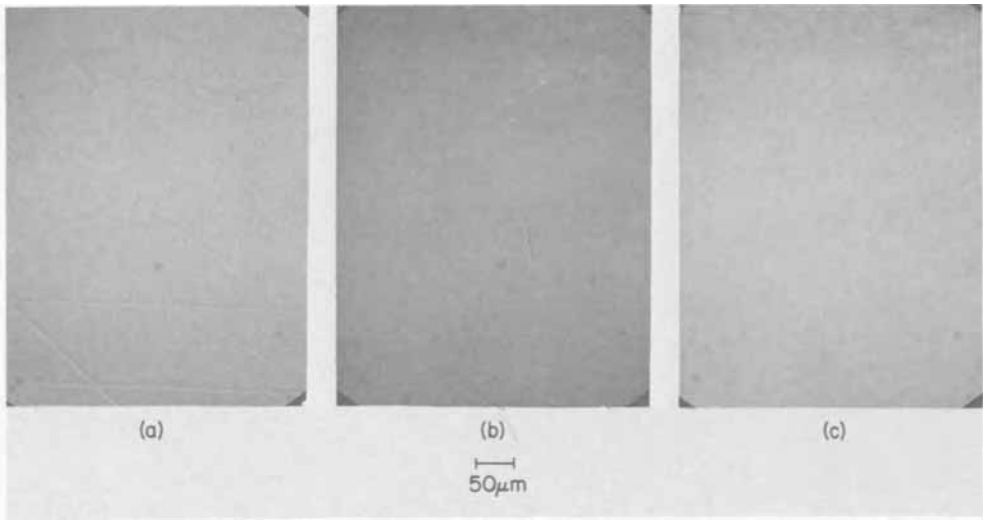

Fig. 8. Effect of preanneal of (110) MgAl spinel at 1500°C on chemical polishing behavior. (a) No anneal, (b) 1 hr anneal, (c) 4 hr anneal.

In Fig. 6a-d is shown the polishing behavior of (0001) sapphire. Figure 6a shows the effect of a 90 min etch in pure phosphoric acid at 285°C. Figure 6b shows a similar time-temperature polish in a 1:1 mixture. Figure 6c shows the behavior under the same conditions in a 3:1 H_2SO_4:H_3PO_4 mixture and Fig. 6d shows the results of a like H_2SO_4 treatment. Figure 6b is representative of a surface polished with the practical constraints mentioned. While visual damage is greatly minimized, as compared to pure phosphoric acid, or other H_2SO_4:H_3PO_4 compositions, the faint residual scratch evidence (real damage or etch propagated damage) mentioned above is present.

Of the other sapphire orientations examined, aside from the variation in removal rate with orientation (see Table I), all but the $(10\bar{1}4)$ could be polished successfully. The latter could not be polished either because the etching was selective or because massive scratch damage was present.

The behavior of MgAl spinel was similar to that of sapphire except in detail. A 3:1 H_2SO_4:H_3PO_4 mixture at 250°C provided the best surfaces although the composition range from 1:1-3:1 was quite adequate. In Fig. 7a-c the surfaces of (100), (110), and (111) spinel following 90 min treatments at 250°C in 3:1 mixtures are shown. Figure 7a shows a (100) surface and Fig. 7b a (110) surface. Figure 7c shows the (111) surface, from which it is evident that polishing could not be effected on this orientation. In Fig. 7d, the behavior of (111) spinel at 300°C in this same mixture shows even greater selectivity.

Annealing studies.—The effects of an annealing at 1500°C in air on damage were studied by heating the wafers for different periods of time, then following this annealing by chemical polishing. The effects were quite dramatic and unexpected. For example, if a mechanically polished (110) spinel wafer is chemically polished (3:1 H_2SO_4:H_3PO_4, 250°C) for only 15 min without a preanneal, the resulting surface, Fig. 8a, exhibits a very dense scratch pattern indicative of the region of heaviest damage. If such a wafer is annealed for 1 hr and then subjected to a 15 min chemical polish, Fig. 8b, surfaces result which exhibit minimal evidence of scratch damage. Finally, if a 4 hr preanneal is applied followed by a 15 min chemical polish, Fig. 8c, essentially featureless surfaces result. To allow for normal variation in the degree of mechanical damage, it was found adequate to anneal for 2-4 hr periods before applying the 15 min chemical polishing treatment. Similarly, a marked improvement was observed for the (100) spinel and the various sapphire orientations examined in this study following a preanneal in air at 1500°C and chemical polishing. Air annealing does not effect the chemical polishing behavior of the different orientations. Both spinel and sapphire wafers prepared by this process have been used successfully for deposition of epitaxial ZnO and Si.

Similar studies were conducted using vacuum annealing at 1500°C. While comparable results were obtained they were not quite as good as those obtained using the air annealing approach.

Nondestructive Determination of the Composition and Thickness of Thin Films of Pyrolytically Deposited Borosilicate Glass by Infrared Absorption

A. S. Tenney

Corporate Research and Development, General Electric Company, Schenectady, New York 12301

ABSTRACT

The compositions of thin films of pyrolytically deposited borosilicate glass were correlated with the infrared spectra of these films over the entire composition range. Although the composition has been related to the ratio, R, of the B-O absorbance maximum at about 1300 cm^{-1} to the Si-O maximum at about 1050 cm^{-1}, the relationship between R and composition was found to be dependent on deposition conditions for glasses of more than about 30 m/o (mole per cent) B_2O_3. Nevertheless, if R' is defined to be the ratio of the areas of the B-O and Si-O bands, respectively, the relationship between R' and mole fraction is independent of temperature and other deposition conditions. The composition dependence of the integrated intensity of these bands as well as of film density and refractive index and the temperature dependence of composition and deposition rate were determined also.

The "IR peak ratio" R, the ratio of the absorbance peak of the B-O vibrational band at about 1300 cm^{-1} ($\sim 7.5\mu$) to that of the Si-O band at about 1050 cm^{-1} ($\sim 9.4\mu$), has been correlated with the composition of thin films of pyrolytically deposited borosilicate glass (1, 2). The aim of the present work was to determine the relationship between R and composition with accuracy greater than had been achieved previously (2), to discover any dependence of this relationship on deposition conditions, and to extend this study to glasses of higher boron concentration.

Experimental

Most glasses were deposited on chemically etched 10 ohm-cm silicon wafers by pyrolytic oxidation of silane and diborane in either of two (geometrically different) vertical reactors as described by Brown and Kennicott (3). The rest were made in a horizontal Silox reactor. To keep glasses of more than about 25 m/o (mole per cent) B_2O_3 from absorbing water from the air, it was necessary to deposit a cover glass of 100-200Å pure SiO_2 on top of the usually about 6000Å of the glass to be studied.

The infrared spectra of these glasses were determined with a Perkin-Elmer Model 457 double-beam recording spectrophotometer on the "fast" scan mode (2000, 1000 cm^{-1}/min) with a slit setting of "N" (6). For samples with cover glass, a wafer of the same type and resistivity covered with 100-200Å pyrolytically deposited SiO_2 was placed in the reference beam; the reference for uncovered samples was a bare wafer. The base line was drawn to correct for oscillations due to interference of the thin films so that the relationships between spectra and composition are general for glasses of different thicknesses.

The thicknesses and refractive indices of these glasses were determined with a Gaertner ellipsometer.

Glasses were deposited on circular wafers approximately 1 in. in diameter, with a deviation of about 0.005 in. for a given wafer, as measured with a micrometer. The area of the film was taken to be the area of the wafer, and the film volume to be the area times the thickness.

Analysis

The film was dissolved in dilute HF solution (50 ml 50% HF/1 H_2O). Boron was determined colorimetrically by extracting methylene blue fluoroborate (4) with 1, 2-dichloroethane. The amount of boron in the glass film could be determined within ±2% except for glasses containing less than 5 μg boron for which the uncertainty was ±0.1 μg boron. The details of the boron analysis are presented elsewhere (5).

Silicon was determined with an Instrumentation Laboratories atomic absorbance spectrophotometer Model 153 in the range 0-40 ± 0.5 μg silicon/ml. This amounted to about a 2% error for most glasses. The silicon found was corrected for that in the cover glass, if present. Excess silicon (presumably etched from the wafer itself) was found if the wafer on which the glass was deposited were left in the dilute HF solution too long (>2 hr). It took a maximum of 5 min to etch the glass from the wafers and no excess silicon could be detected from wafers left in dilute HF for <10 min.

The film weights of several samples were determined by weighing the wafer before and after deposition of the glass (and again, as a check, after removal of the glass) using a Cahn recording electromicrobalance. The films were found to weigh 500-700 ± 15 μg.

The film weight and the B_2O_3 mole fraction $N_{B_2O_3}$ were calculated from the results of the analyses assuming boron and silicon to be present as B_2O_3 and SiO_2, respectively. It was found that within experimental error (2.5%) the weight thus calculated agreed with that found by direct weighing. With the precision of the boron and silicon analyses given above, $N_{B_2O_3}$ was determined in the range 0-1.0 within ± 0.005-0.02, the uncertainty depending somewhat on composition.

Results and Discussion

It was found that the relationship between the IR peak ratio, R, and $N_{B_2O_3}$ was dependent on temperature and other deposition conditions. In Fig. 1, R is shown as a function of $N_{B_2O_3}$ for glasses grown in three different reactors at temperatures from 250° to 500°C. The 300°, 350°, and 375°C lines are drawn to represent results from glasses grown in (vertical) reactor 1 only. The results from reactor 1 and (vertical) reactor 2 (open symbols) indicate that for a given R (or $N_{B_2O_3}$), $R/N_{B_2O_3}$ decreases with increasing deposition temperature in a given reactor. Also, the dependences of R on $N_{B_2O_3}$ for glasses grown in the different reactors at identical temperatures are found to be in disagreement. For instance, the results for R *vs.* $N_{B_2O_3}$ from reactor 1 at 350°C agree with those from (Silox) reactor 3 at 450°C and with those from reactor 2 at

Key words: borosilicate glass composition, IR peak ratio.

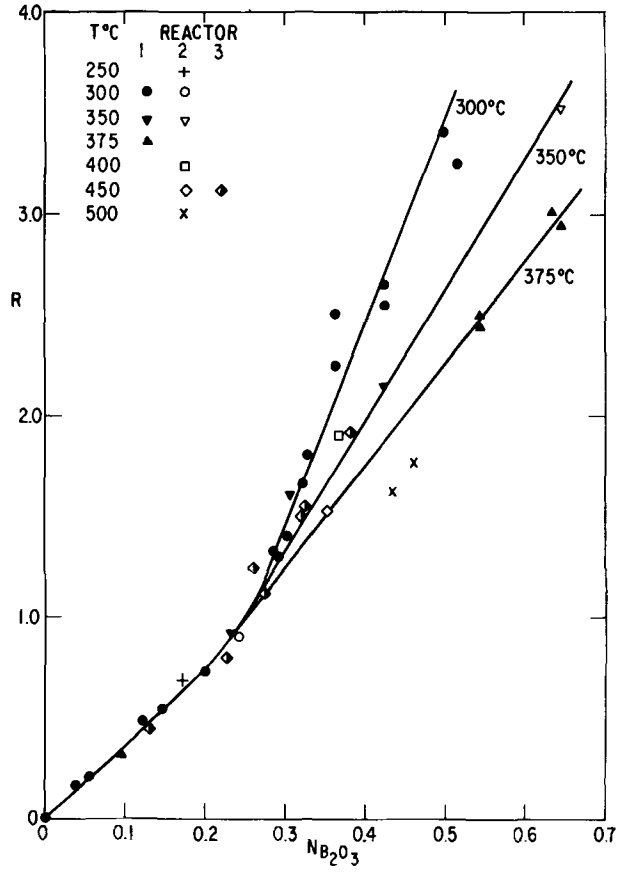

Fig. 1. Infrared peak ratio R vs. B_2O_3 mole fraction $N_{B_2O_3}$ for thin films of borosilicate glass pyrolytically deposited in vertical reactors 1 (closed symbols) and 2 (open symbols) of different geometry, and in horizontal Silox reactor 3 (half-filled symbols) at temperatures from 250° to 500°C.

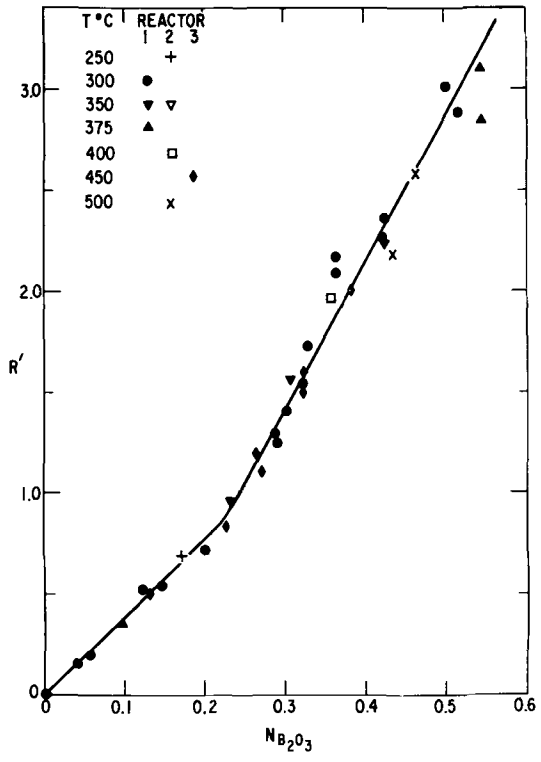

Fig. 2. Infrared band area ratio R' vs. B_2O_3 mole fraction $N_{B_2O_3}$ for thin films of borosilicate glass pyrolytically deposited in vertical reactors 1 (closed symbols) and 2 (open symbols) of different geometry, and in horizontal Silox reactor 3 (half-filled symbols) at temperatures from 250° to 500°C.

450°C > T > 400°C. Thus, the relationship between $N_{B_2O_3}$ and the infrared peak ratio is dependent not only on temperature but also on other deposition conditions (presumably related to reactor geometry). Although this relationship may be employed to determine the composition of borosilicate glasses from the infrared spectra, a calibration curve (of R *vs.* $N_{B_2O_3}$) must be generated for each glass reactor at each temperature (at least for glasses with $N_{B_2O_3} > 0.3$).

However, the relationship between $N_{B_2O_3}$ and R', the ratio of the integrated intensity or area of the B-O band to that of the Si-O band was found to be independent of deposition conditions. For simplicity (since the spectrophotometer employed records absorbance logarithmically) the area of a band is approximated by the product of the peak intensity in absorbance units times the bandwidth in cm^{-1} at half the peak height. In Fig. 2, this area ratio is shown as a function of mole fraction for the glasses whose peak ratios are shown in Fig. 1. The accuracy of the band area approximation should be suspected since neither band is symmetric. Nevertheless, when several spectra were replotted in linear absorbance units and the band areas determined with a planimeter, the results were found to agree with those shown in Fig. 2 with about the same precision. It is concluded that employing this approximation of the integrated intensities introduces little error at least in results involving area ratios. Most of the scatter seen in Fig. 2 probably results from stated imprecision of the chemical analysis.

Although the composition of thin films of borosilicate glass may be determined from their infrared absorbance spectra and the plot of R' *vs.* $N_{B_2O_3}$ shown in Fig. 2, R' must approach infinity as $N_{B_2O_3}$ approaches 1.0. In order to be able to correlate infrared results with $N_{B_2O_3}$ over the whole composition range, a quantity $N_{R'}$ is defined to be the area of the B-O band divided by the area of the B-O band plus the area of the Si-O band. This "area fraction," corresponding in some sense to an "optical mole fraction," approaches 0 and 1.0 as $N_{B_2O_3}$ approaches these values, respectively. Simple algebra shows

$$N_{R'} = \frac{R'}{1 + R'}$$

With an uncertainty of 0.01 absorbance in the peak heights and 5 cm^{-1} in the half-widths, it is found that $N_{R'}$ may be determined over the range 0-1.0 to a precision of better than ±0.03, the uncertainty being largest for glasses near the middle of the concentration range.

The composition of thin films of pyrolytically deposited glass may be determined nondestructively from the infrared spectra of these films and from Fig. 3, where the dependence of the infrared band area fraction $N_{R'}$ is shown as a function of the B_2O_3 mole fraction $N_{B_2O_3}$. This calibration curve is comprised of results on glasses deposited from 250° to 500°C in three different reactors: two vertical and one horizontal, all of different geometries.

A comparison of the results shown in Fig. 2 with those shown in Fig. 1 suggests that, while the integrated intensities of the infrared bands are insensitive to structural differences in glasses formed under various deposition conditions, the peak intensities reflect (and, in fact evidence) these differences. It is well known that the integrated intensity is a more reliable measure of concentration than is the peak intensity. However, the fact that the peak intensities depend on deposition conditions while the integrated intensities do not suggest (as indeed the data show) that the shape of at least one of the bands depends on deposition conditions.

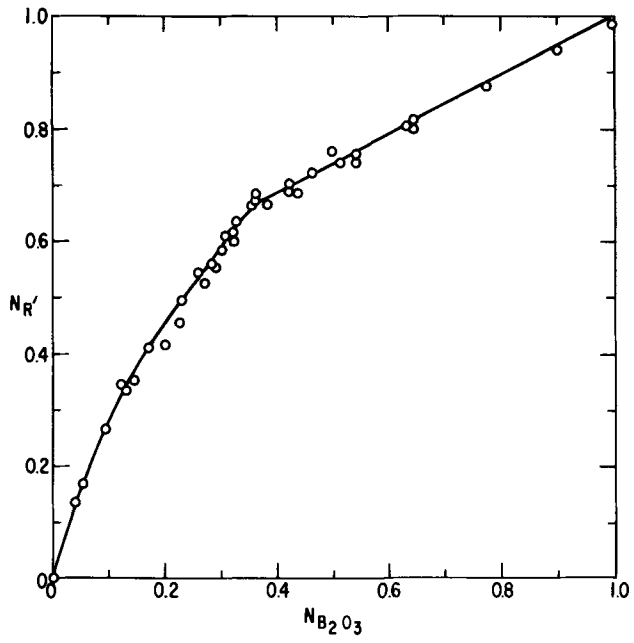

Fig. 3. Infrared band area fraction $N_{R'}$ vs. B_2O_3 mole fraction $N_{B_2O_3}$ for thin films of pyrolytically deposited borosilicate glass.

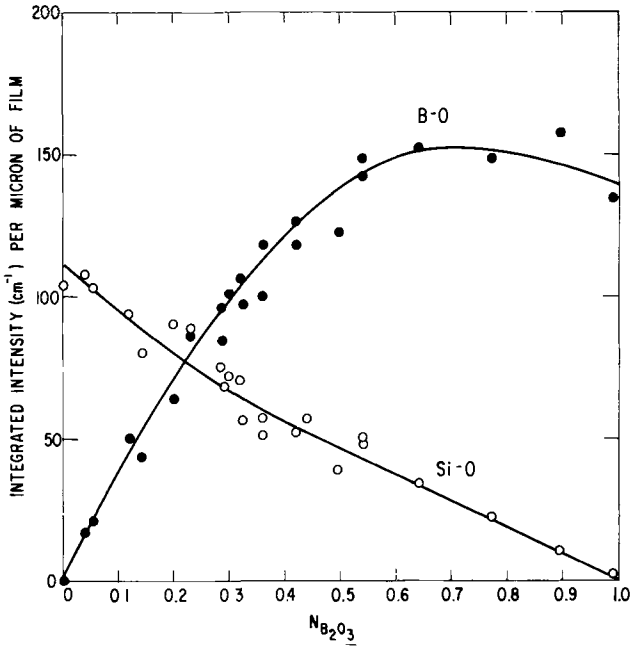

Fig. 4. Integrated intensity normalized to 1μ of film vs. B_2O_3 mole fraction for the major B-O and Si-O absorbance bands (at ~1300 and ~1050 cm^{-1}, respectively) in the borosilicate glass spectrum.

The linear absorption coefficient of a band may be calculated by dividing its peak height by the film thickness. This quantity was found to be temperature dependent for both the B-O and Si-O bands. However, like the area ratio, the integrated intensity is independent of temperature from 300° to 375°C. It should be pointed out that while quantities involving ratios of peak heights or areas such as R and R' are relatively insensitive to differences in spectrophotometer settings, the absolute values of peak heights or integrated intensities do depend on these settings. Thus absorbance coefficients reported here strictly apply only for the settings stated above.

The integrated intensity of each major band normalized to 1μ of film is shown as a function of B_2O_3 mole fraction in Fig. 4. From the glass composition, the band areas and the plots in Fig. 4, the thickness of the film may be determined. Although the area of either band may be used to measure film thickness, that of the larger band—which one this is depends on composition—gives more reliable results. This method is at best precise to ±5% for 6000Å of film making it about as accurate as using the interference colors. Nevertheless, it could be useful if thickness results did not accompany a spectrum or if the order of the color were not known.

Thus, employing Fig. 3 and 4, the composition and thickness of thin films of pyrolytically deposited borosilicate glass may be determined from their spectra alone.

The fact that the composition dependence of the integrated intensities is not linear suggests that the absorbance per mole or atom (of B and Si) is not independent of composition. This effect is particularly striking in the case of the B-O band whose absorbance is apparently greater for a glass of 60-70 m/o B_2O_3 than for pure B_2O_3. This composition dependence as

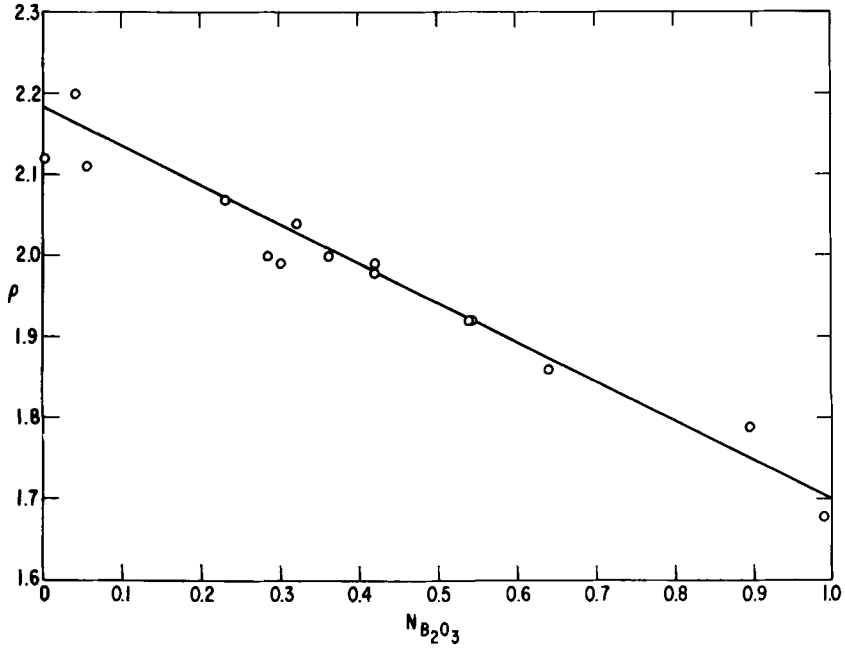

Fig. 5. Density ρ (as deposited) vs. B_2O_3 mole fraction $N_{B_2O_3}$ for thin films of borosilicate glass.

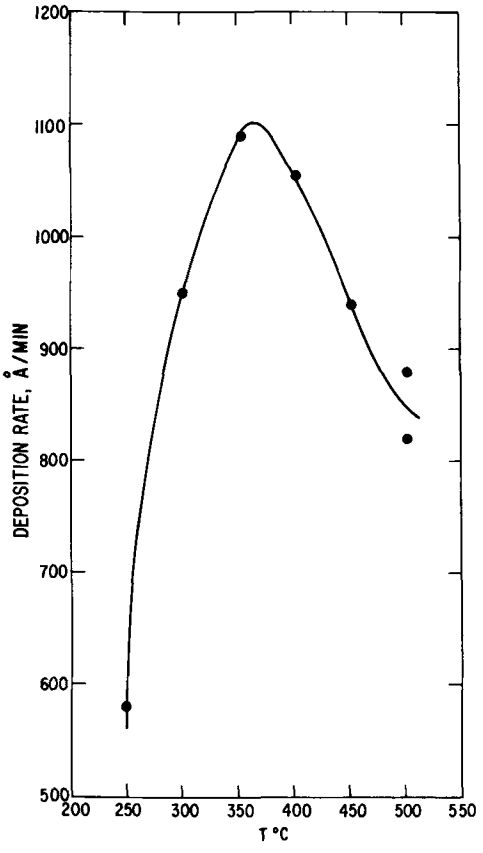

Fig. 6. Borosilicate glass deposition rate, Å/min (under constant reactant flows), vs. temperature.

well as the temperature (and composition) dependence of the band shapes mentioned above and several other characteristics of the IR spectra of these glasses will be considered further in a subsequent publication (6).

From the film volume and weight, the density ρ of the glass, as deposited, may be calculated. The densities found are plotted as a function of $N_{B_2O_3}$ in Fig. 5. It was found that

$$\rho = 2.18 - 0.48\, N_{B_2O_3} \pm 0.1$$

for glasses deposited from 300° to 375°C. The density of 2.18 obtained for pure SiO_2 agrees with those found in the literature for bulk glasses (7), while the value of 1.70 for B_2O_3 is lower than those previously reported (7-9). The scatter in the results shown in Fig. 5 is probably due largely to the uncertainty of the chemical analysis and to the as much as 5% variation in film thickness across a given wafer.

The refractive index was found to be 1.46 ± 0.01 for glasses as deposited from 300° to 375°C and within this experimental uncertainty to be independent of concentration and temperature of deposition. This value agrees with those reported for SiO_2 (7) and for B_2O_3 (9).

The temperature dependence of the glass growth rate and composition (for given gas flows) were found to be in agreement with the results of Kern and Heim (10). While the growth rate increases with temperature, reaches a maximum at 375°C, and then decreases as shown in Fig. 6, $N_{B_2O_3}$ increases continuously with temperature as shown in Fig. 7 for glasses deposited from a B_2H_6 to SiH_4 flow rate ratio of 0.5. Kern and Heim's results indicate a leveling off of $N_{B_2O_3}$ with temperature at about 450°C. The present data are in agreement with this conclusion. However, $N_{B_2O_3}$ apparently increases again for glasses grown from 450° to 500°C.

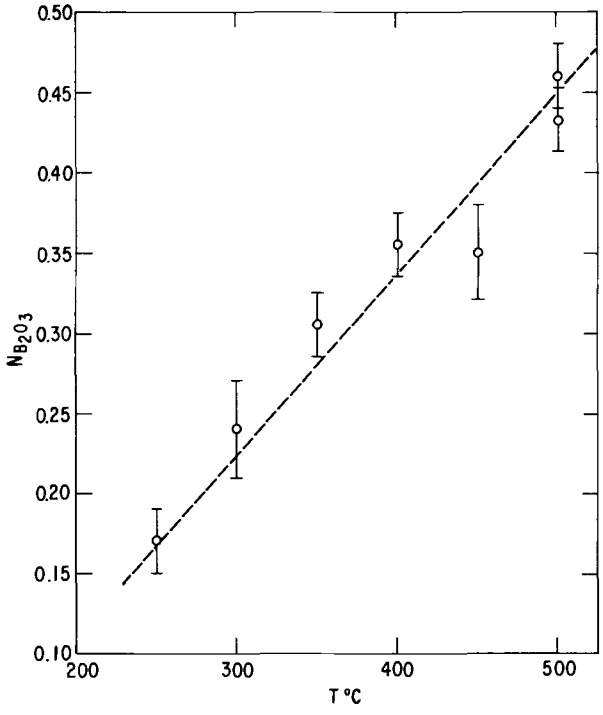

Fig. 7. B_2O_3 mole fraction vs. temperature for borosilicate glass deposited from a B_2H_6 to SiH_4 flow rate ratio of 0.5.

The Free Energy of Mixing in the Lithium-Germanium Binary System[1]

Gunter H. R. Kegel, Richard J. Laramee,[2] and Brahm D. Bhardwaj[3]

Lowell Technological Institute, Lowell, Massachusetts 01854

ABSTRACT

The free energy of mixing of the solid solution of Li in Ge has been measured for 250°C $\leq T \leq$ 420°C. An equilibrium method is used. Germanium samples are immersed in molten Li-Pb alloys of known lithium activity. After reaching equilibrium the lithium concentration in the samples is measured and the free energy of mixing is obtained from the lithium activity and the concentration. The partial molar heat and entropy of lithium in the solid solution are given.

Various techniques may be used to measure the free energy of mixing in binary systems. These procedures have been described by Lewis and Randall (1) and some of the results obtained by different workers for binary alloys have been collected by Hultgren, Orr, Anderson, and Kelley (2). Few if any, of these procedures are suitable in the case reported in this paper because the Li solubility in Ge is small, about a few parts per million, and the lithium diffusion coefficient is small at the low temperatures under consideration. In view of these restrictions a variant of an existing technique has been applied; lithium is diffused into germanium from an external phase consisting of a liquid alloy with known lithium activity. Once equilibrium is reached the Li activity in the alloy equals that in the germanium.

Ideally Ge should be insoluble in the external phase and vice versa. This requirement is approximated if lead is used as an external phase because the solubility of Ge in Pb is small [see, *e.g.*, Thurmond and Kowalchik (3)] and the diffusion coefficient of Pb in Ge is probably orders of magnitude smaller than that of Li (4). Li-Sn alloys were used by Reiss and Fuller to diffuse Li into silicon (5); they were found unsuitable because the germanium solubility in tin is too large (3).

Once equilibrium is established the lithium concentrations in the germanium and in the alloy have to be determined. The lithium activity in the alloy can be obtained from the Li-Pb phase diagram. These data give the partial molar free energy of Li in Ge and thence heat and entropy of mixing.

Experimental Procedure

Germanium samples were cut from horizontally grown, single-crystal material containing approximately 3 x 10^{14} cm^{-3} of gallium. Samples were about 2.7 cm long, 1.0 cm wide, and 0.13 cm thick. These pieces were ground and etched; tin plating, using an alkaline bath, was found to facilitate wetting with the Li-Pb alloy. For lithium diffusion a germanium sample and an adequate amount of alloy were placed in the diffusion apparatus, under vacuum, and were heated to the desired equilibration temperature. Diffusion times were chosen as follows: The time required to obtain a lithium distribution uniform to within 1% was computed, as outlined in Appendix A. This time interval is denoted by $t_{0.01}$. Actual diffusion times were substantially longer than $t_{0.01}$, assuring that the Li distribution would be uniform to 1% or better in the germanium samples. Diffusion times and temperatures, the parameters $t_{0.01}$, and other pertinent data are listed in Table I.

At the end of the diffusion period the alloy was drained and kept for analysis; the sample was cleaned and mounted in a conductivity measuring device. From the sample conductivity the lithium concentration was computed, as outlined in the next section.

The Li content of the alloy was determined by dissolving the alloy in Hg, extracting Li with water, and titrating the extract with HCl.

Data Reduction

Li dissolves in Ge as a donor (6) hence the conduction electron concentration and the sample conductivity are functions of the lithium concentration. Since our samples also contained gallium, an acceptor, we have to consider the following set of reactions

$$\begin{array}{ccc} Li \rightleftharpoons Li^+ & + & e^- \\ + & & + \\ Ga \rightleftharpoons Ga^- & + & e^+ \\ \Updownarrow & & \Updownarrow \\ Li^+Ga^- & & e^+e^- \end{array} \qquad [1]$$

At the measuring temperature of 60°C Ga and Li are almost fully ionized. The equilibrium constant for the reaction $Li^+ + Ga^- \rightleftharpoons Li^+ Ga^-$ has been evaluated by Reiss, Fuller, and Morin (6) and the constant for the reaction $e^+ + e^- \rightleftharpoons e^+e^-$ has been determined by Morin and Maita (7). These data can be used to obtain concentrations of Li^+, Ga^-, e^+, e^-, and Li^+Ga^-, all as functions of the total lithium concentration.

The conductivity σ is given by

$$\sigma = e\,(n\,\mu_n + p\,\mu_p) \qquad [2]$$

Here e is the electronic charge, n and p are concentrations of electrons and holes, respectively, and μ_n and μ_p are the corresponding mobilities. Mobility data are available in the literature (8) so that σ can be computed as a function of the lithium concentration. This function is shown in Fig. 1.

We should add here the diffusion of lead or tin into the sample can be neglected, as far as the sample conductivity is concerned. Lead and tin are Group IV elements and are not expected to be electrically active

Table I. Diffusion parameters

Sample	Diff. temp, °C	Diff. time, hr	Lithium concentration in sample, cm^{-3}	Lithium concentration in alloy, a/o	$t_{0.01}$, hr (see text)

in Ge, *i.e.*, they do not supply electrons or holes. As neutral impurities, lead and tin atoms contribute to the scattering of charge carriers so that the carrier mobilities will be attenuated. This effect is negligible because the depth of lead or tin diffusion is likely to be small. This question is examined in more detail in Appendix B.

Activity of Li in Li-Pb Alloys

The phase diagram of the Li-Pb system has been determined by Grube and Klaiber (9). In the range $235°C \leq T \leq 327°C$ both solid and liquid solutions are found at the Pb-rich end of the diagram. We assume that both solutions are regular, see *e.g.* Swalin (10), and we write for the excess free energy of mixing

$$\Delta G_m^{xs,L} = \Omega_{AC}^{L} X_A^{L} X_C^{L} \quad [3]$$

$$\Delta G_m^{xs,S} = \Omega_{AC}^{S} X_A^{S} X_C^{S} \quad [4]$$

Here X are atom fractions; subscripts A, B, and C refer to Li, Ge and Pb, respectively; superscripts L and S refer to liquid and solid phases. The Ω are interaction parameters (10).

From [3] and [4] the partial molar free energies of Li and Pb can be obtained. At a given temperature the partial molar free energy of Li at the liquidus is equal to that at the solidus, an analogous relation holds for Pb. These two conditions are used to obtain Ω_{AC}^{L} and Ω_{AC}^{S}. The result is

$$\Omega_{AC}^{L} = -2.69 \text{ kJ/mole} \quad [5]$$

$$\Omega_{AC}^{S} = \omega_{AC}^{0} + \omega_{AC}^{1} T \quad [6]$$

$$\omega_{AC}^{0} = 33.7 \text{ kJ/mole} \quad [7]$$

$$\omega_{AC}^{1} = -56 \text{ J/mole K°} \quad [8]$$

The liquidus and solidus calculated with these data fit the experimental results by Grube and Klaiber quite well, as shown in Fig. 2. This shows, that our assumption about the regular character of the solutions is consistent with the experimental data.

Results

It is convenient, though not essential, to assume that the solid solution of Li in Ge be regular. In this case the partial molar free energy of Li in Ge is

$$\Delta\bar{G}_A^{S} = (1 - X_A^{S})^2 \Omega_{AB}^{S} + RT \ln X_A^{S} + \Delta G_{fA} \simeq \Omega_{AB}^{S} + RT \ln X_A^{S} + \Delta G_{fA} \quad [9]$$

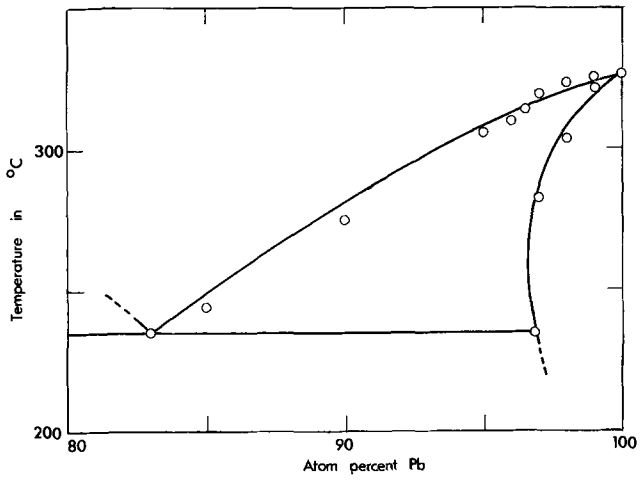

Fig. 2. Lead-rich end of the lithium-lead phase diagram. The points indicate the results by Grube and Klaiber (9). The liquidus and the solidus have been calculated assuming solid and liquid solutions to be regular.

Here we omitted X_A^{S} in the first term because $X_A^{S} \simeq 10^{-5} << 1$. The last term is the free energy of fusion of Li at temperature T. For the Li-Pb alloy we have

$$\Delta\bar{G}_A^{L} = (1 - X_A^{L})^2 \Omega_{AC}^{L} + RT \ln X_A^{L} \quad [10]$$

Equating $\Delta\bar{G}_A^{L}$ and $\Delta\bar{G}_A^{S}$ we obtain Ω_{AB}^{S}. These data are shown in Fig. 3.

A note should be added concerning the data at 285° and 330°C. The lithium concentration in these samples has reached the saturation value as measured by Morin and Reiss (11). In this case

$$\Delta\bar{G}_A^{L} > \Delta\bar{G}_A^{S} \quad [11]$$

and only an upper limit for Ω_{AB}^{S} is obtained.

It is interesting to compare our results with those obtained from the Li-Ge phase diagram. Pell (12) has calculated the liquidus assuming the liquid solution to be regular. The solidus has been determined by Reiss, Fuller, and Morin (6) and by Pell (12). These data may be analyzed in the same fashion as those for the Li-Pb phase diagram and Ω_{AB}^{S} can be obtained. The result is also shown in Fig. 3, it is consistent with our measurements.

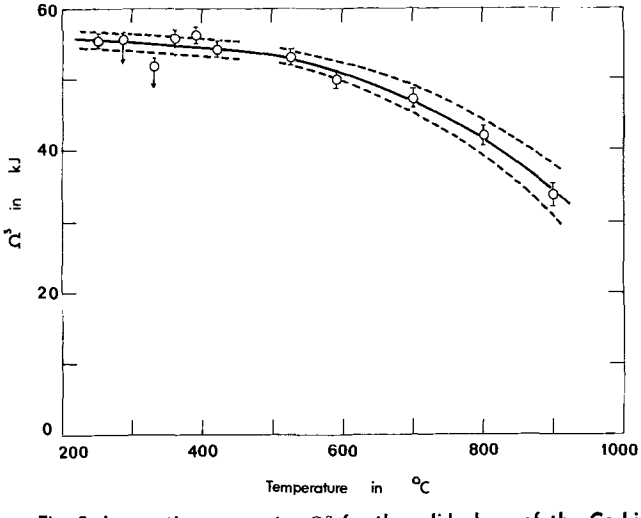

Fig. 3. Interaction parameter Ω^{S} for the solid phase of the Ge-Li system. Points with $T < 500°C$ were obtained from measurements reported in this paper; points with $T > 500°C$ were computed from data by Pell (12). Dashed lines indicate the range of systematic errors; random errors are shown by error flags.

In the temperature range covered by our measurements $\Omega_{AB}{}^{S}$ can be written as

$$\Omega_{AB}{}^{S} = 59.6 \text{ kJ/mole} - 7.7 \text{ J/(mole °K)}\ T \quad [12]$$

Equation [9] shows that

$$\Omega_{AB}{}^{S} = \Delta\overline{G}_{A}{}^{xs,L} \quad [13]$$

Hence the partial molar heat of lithium is

$$\Delta\overline{H}_{A} = 59.6 \text{ kJ/mole} \quad [14]$$

and the excess partial molar entropy

$$\Delta\overline{S}_{A}{}^{xs} = 7.7 \text{ J/(mole °K)} \quad [15]$$

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

APPENDIX A

Lithium Distribution

The lithium distribution in the samples can be calculated by solving the diffusion equation with appropriate initial and boundary conditions (13). In our case the sample thickness a ($a = 0.13$ cm) is much less than its width b ($b = 1.0$ cm) or length c ($c = 2.7$ cm), so that most of the lithium reaches the sample interior by diffusion in the x-direction. (See Fig. 4). If we neglect diffusion in y- or z-direction we have

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \quad [16]$$

Here $C(x, t)$ is the lithium concentration and D is the lithium diffusion coefficient. The initial and boundary conditions are $C(x, 0) = 0$; $C(0, t) = C(a, t) = C_0$.

It is apparent, that at all times during the diffusion cycle the lowest lithium concentration will be found in the sample center, $x = a/2$. Solving the diffusion equation, we find for $C(a/2, t)$

$$C(a/2, t) = C_0 - \frac{4}{\pi} C_0 \sum_{n=0}^{\infty} \frac{(-1)^n}{2n+1} \exp\left\{ - (2n+1)^2 \frac{t}{\tau} \right\} \quad [17]$$

where

$$\tau = \frac{a^2}{\pi^2 D} \quad [18]$$

The parameter $t_{0.01}$ is defined as the time required to obtain a lithium distribution which is uniform to within 1%. Thus.

$$C(a/2, t_{0.01}) = 0.99\ C_0 \quad [19]$$

Substituting [19] into [17] and solving for $t_{0.01}$ we get

$$t_{0.01} = 4.85\ \tau \quad [20]$$

Numerical values of $t_{0.01}$ are given in Table I; they were obtained using the lithium diffusion coefficients determined by Fuller and Severiens (14).

APPENDIX B

Tin and Lead Impurities

In this appendix we examine the influence of lead and tin impurities upon the sample conductivity. We consider tin first.

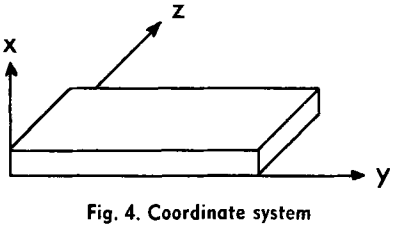

Fig. 4. Coordinate system

Table II. Tin diffusion

Sample	u_0, Eq. [21], cm	A, Eq. [28]	δ, Eq. [27], cm
P1	1.80×10^{-7}	5062	4.69×10^{-7}
P2	4.02×10^{-8}	5816	1.06×10^{-7}
P3	4.40×10^{-7}	4201	1.13×10^{-6}
P4	1.21×10^{-6}	4459	3.13×10^{-6}
P5	2.42×10^{-6}	4136	6.22×10^{-6}
P6	5.72×10^{-6}	3339	1.45×10^{-5}

The solubility of tin in germanium is large at the temperatures of interest: $X_{Sn} \simeq 5 \times 10^{20}$ cm^{-3} (15). The Sn diffusion coefficient in Ge, D_{Sn}, does not seem to be known. It is unlikely, however, that this diffusion coefficient differs substantially from that of the adjacent elements, Sb and In.

At the end of the diffusion cycle, the tin concentration in the sample, $C_{Sn}(u)$, at a depth u below the surface, is given by (13)

$$C_{Sn}(u) = C_{Sn}(0) \text{ erfc } \frac{u}{u_0} \quad [21]$$

$$u_0 = 2\sqrt{D_{Sn}\, t}$$

Here $C_{Sn}(0)$ is the Sn concentration at the sample surface and t is the diffusion time. If we assume that the Sb diffusion coefficients reported by Fuller (16) hold for Sn too, then we can compute u_0; the result is given in Table II.

Tin and lead act as neutral impurity scatterers in Ge; their action is accounted by introducing a neutral impurity mobility μ_N (8). For Sn and for electrons we have

$$\mu_N = \frac{1}{20} \frac{m^* e^3}{4\pi\epsilon\hbar^3} \frac{1}{C_{Sn}(u)} = \frac{\lambda}{C_{Sn}(u)} \quad [22]$$

where

$$\lambda = 2.32 \times 10^{22} \text{ (V sec m)}^{-1} \quad [23]$$

If we denote by μ_0 the electron mobility in the absence of tin, then the total mobility μ is given by (8)

$$\frac{1}{\mu(u)} = \frac{1}{\mu_N} + \frac{1}{\mu_0} \quad [24]$$

Our measurements depend on the average mobility, μ_{av}, which is essentially equal to $\mu(u)$ averaged over the interval $0 \leq u \leq a/2$

$$\mu_{av} \simeq \frac{2}{a} \int_0^{a/2} \mu(u)\ du \quad [25]$$

It is convenient to write

$$\mu_{av} = \mu_0 \left(1 - \frac{2\delta}{a}\right) \quad [26]$$

Here the parameter δ may be considered as the thickness of an equivalent layer with zero mobility. Combining Eq. [21] to [26] we obtain

$$\delta = u_0 \int_0^{\frac{a}{2u_0}} \frac{dv}{1 + (A \text{ erfc } v)^{-1}} \quad [27]$$

where

$$A = \frac{\mu_0}{\lambda} C_{Sn}(0) \quad [28]$$

The parameters δ have been computed assuming $C_{Sn}(0) = X_{Sn} = 5 \times 10^{20}$ cm^{-3}; the results are given in Table II. It is apparent that $2\delta/a$ is negligibly small, so that in very good approximation $\mu_{av} = \mu_0$. Similar results apply to the hole mobilities.

The solubility of Pb in Ge is much smaller than that of Sn, $X_{Pb} \leq 6 \times 10^{17}$ cm^{-3}, so that the role of this impurity is negligible too.

Nonstoichiometric Disorder in Single Crystalline MnO

N. G. Eror[1] and J. B. Wagner, Jr.*

Department of Materials Science and Materials Research Center, The Technological Institute, Northwestern University, Evanston, Illinois 60201

ABSTRACT

The electrical conductivity of single crystalline manganous oxide was investigated over the temperature range of 900°-1150°C while in thermodynamic equilibrium with oxygen partial pressures of 10^{-6}-10^{-21} atm. Results indicated that MnO may be either p- or n-type. Slopes of 1/6 and −1/6 are obtained from the log σ *vs.* log p_{O_2} data for the p- and n-type regions, respectively. Thermogravimetric measurements at thermodynamic equilibrium support the evidence of the electron mobility being much greater than that for electron holes in MnO. The enthalpies of formation of nonstoichiometric disorder and activated enthalpy of movement of electron holes in p-type MnO were determined to be −18 and 12 kcal/mole, respectively. The bandgap of MnO was calculated from the minima of the log σ *vs.* log p_{O_2} data to be 52.8 kcal/mole (2.3 eV).

Davies and Richardson (1) investigated the nonstoichiometry of manganous oxide at 1500°, 1575°, and 1650°C as a function of oxygen partial pressure. The concentration of excess oxygen was determined by chemical analysis for trivalent manganese. Calculations from the data of Davies and Richardson indicate that for large deviations from stoichiometry the manganese vacancy concentration is proportional to $P_{O_2}^{1/6}$. For this oxygen pressure range the nonstoichiometric disorder may be described by

$$\tfrac{1}{2}\,O_2 \rightleftarrows O_O + V_{Mn}'' + 2p \qquad [1]$$

where V_{Mn}'' and p refer, respectively, to doubly ionized manganese vacancies and electron holes.

Marion and co-workers (2) found that polycrystalline MnO may be either p- or n-type on the basis of electrical conductivity measurements as a function of oxygen partial pressure over the temperature range 900°-1200°C. Later measurements (3) at 1000°C of the electrical conductivity and Seebeck coefficient have been interpreted on the basis of ± 1/6 oxygen partial pressure dependence due to doubly ionized manganese vacancies (Eq. [1]) for the p-type region and Mn^{+2} interstitials for the n-type data. The metal excess disorder could be expressed by

$$Mn_{Mn} + O_O \rightleftarrows Mn_i^{\cdot\cdot} + 2n + \tfrac{1}{2}\,O_2 \qquad [2]$$

where $Mn_i^{\cdot\cdot}$ denotes a manganese interstitial. Tannhauser and co-workers (4) have also determined that MnO may be either p- or n-type at elevated temperatures. Electrical conductance, Seebeck effect, and thermogravimetric measurements on polycrystalline and single-crystal samples over the temperature range 1100°-1557°C have been interpreted on the basis of a predominantly metal deficit compound with the mobility of electrons much greater than that for electron holes. This mobility ratio was later calculated to be approximately 50 at 943°C on the basis of Hall effect measurements on a MnO single crystal (5). DeWit and Crevecoer (6, 7) have confirmed that the mobility of electrons is much greater than that for electron holes at elevated temperatures and report a ratio of approximately 1000 at 1100°C for polycrystalline MnO. Lacombe *et al.* (8) have measured the electrical conductivity and Mn diffusion in MnO and conclude that the atomic defects associated with the p- and n-type regions are doubly ionized manganese vacancies and triply ionized manganese interstitials, respectively. Price and Wagner (9), however, have reported Mn tracer diffusion data in single crystalline MnO that are in agreement with a model of doubly ionized cation vacancies for describing nonstoichiometric MnO.

Experimental

The experimental technique has been described previously (10) except that an Ainsworth semimicro vacuum recording balance for a 4g single crystal was also used for the thermogravimetric measurements. See Table I for chemical analysis of the single crystals.

Experimental Results and Discussion

The electrical conductivity of single crystalline MnO as a function of oxygen partial pressure derived from CO-CO_2 mixtures is shown in Fig. 1. As can be clearly seen the electrical conductivity of single crystalline MnO can be either n- or p-type over the temperature range 900°-1150°C. The n- to p-type transitions or minima in the isothermal log σ *vs.* log p_{O_2} plot are near the center of the log p_{O_2} *vs.* $1/T$ single-phase region and lie near a constant CO/CO_2 ratio of unity. Hed and Tannhauser (4) found the same type of behavior at higher temperatures and Marion and co-workers (2) report similar behavior for polycrystalline MnO.

Table I. Analyses of MnO crystals (as-received boule)

Analytical Laboratory "A" Impurity	Weight per cent
Aluminum	0.005
Iron	0.001
Molybdenum	0.001
Nickel	0.001
Vanadium	0.001
Chromium	0.0005
Copper	0.0005
Lead	0.0005
Silicon	0.0005
Silver	0.0001

As, Bi, Ca, Nb, Co, Cs, K, Li, Na, Hf, P, Rb, Sb, Sn, Ti, W, and Zr were not detected.

Analytical Laboratory "B"

Ca, Co, Fe, Si, V, Al, Cr, Cu, Mo, Ni, Ag, and Pb all < 1 ppm weight (Ti = 0.001 weight per cent).

The linear p-type log σ *vs.* log p_{O_2} data are limited to approximately two decades of oxygen partial pressure for each of the temperatures investigated. A slope of approximately 1/6 is found at the lower temperatures and nearly 1/5 for the higher temperatures. These data are given in Table II together with the probable error. This oxygen partial pressure dependence suggests that the disorder may be described by an expression of the form of Eq. [1] for the lower temperatures and by a transition to an expression of the form

$$\tfrac{1}{2}\,O_2 \rightleftarrows O_O + V_{Mn}' + p \qquad [3]$$

for the higher temperatures and oxygen partial pressures.

The electronic conductivity, σ, may be expressed by (10, 11)

$$\sigma = \text{const.}\ p_{O_2}^{1/2\,m} \exp\left[-\frac{\Delta H_f}{mRT} - \frac{\Delta H_p}{RT}\right] \qquad [4]$$

where ΔH_f denotes the enthalpy of dissolution of oxygen, m denotes the degree of ionization of the lattice defects, ΔH_p is the enthalpy of motion of the electronic carriers, and the other terms have their usual significance. Arrhenius plots for the electrical conductivity of p-type manganous oxide at constant oxygen partial pressures may be constructed from the data in Fig. 1. It is clear that only three temperatures correspond to any single oxygen partial pressure for which the p-type conductivity is linear in Fig. 1. For this reason the linear regions were extrapolated in order to provide additional data points in constructing the Arrhenius plots at constant oxygen partial pressure. The log σ *vs.* $1/T$ relationship for p-type manganous oxide at fixed oxygen partial pressures is given in Fig. 2 where the data obtained by extrapolation of the linear log σ *vs.* log p_{O_2} data has been denoted. The slopes of the Arrhenius data in Fig. 2 result in a value of 8 kcal/mole for the sum, $\Delta H_f°/m + \Delta H_p$. These data are given in Table III. The oxygen partial pressures were obtained from CO/CO_2 ratios and precise values for the oxygen partial pressure could only be obtained at temperatures above 900°C. It was not possible to obtain a constant concentration of disorder by quenching (10, 11) manganous oxide since even at 900°C the specimen was found to have equilibrated as rapidly as a homogeneous CO/CO_2 ratio could be established in the furnace reaction tube assembly.

Table II. Oxygen partial pressure dependence of the electrical conductivity

Temperature, °C	Oxygen partial pressure dependence of the electrical conductivity (with probable error) p-type	n-type
900	1/5.9 ± 0.3	−1/5.40 ± 0.05
950	1/5.9 ± 0.2	−1/6.14 ± 0.07
1000	1/5.7 ± 0.1	−1/5.92 ± 0.05
1050	1/5.4 ± 0.2	−1/6.23 ± 0.05
1100	1/5.2 ± 0.1	−1/6.42 ± 0.02
1150	1/5.4 ± 0.2	−1/6.42 ± 0.14

There was a departure from the linearity of the log σ *vs.* log p_{O_2} data for CO_2/CO ratios greater than approximately 200. Since the increase in electrical conductivity was identified with a specific CO_2/CO ratio rather than a particular oxygen partial pressure, it was possible to have a higher value of the electrical conductivity at temperature T_1, than at temperature T_2, where $T_1 < T_2$. Similar behavior at more elevated temperatures can be interpreted from the data of Hed and Tannhauser (4) for CO_2/CO ratios greater than 50. This behavior is not readily apparent since the published data (4) are reported on the basis of CO_2/CO values rather than oxygen partial pressure. Hed and Tannhauser (12) have interpreted our data on the basis of the decrease in concentration of cation vacancies with increasing temperature at constant oxygen pressure for the high oxygen compositions of MnO. The same behavior is also true for lower concentrations of nonstoichiometric disorder where the log σ *vs.* log p_{O_2} data are linear. Bransky (13), on the other hand, has made thermogravimetric measurements and has found

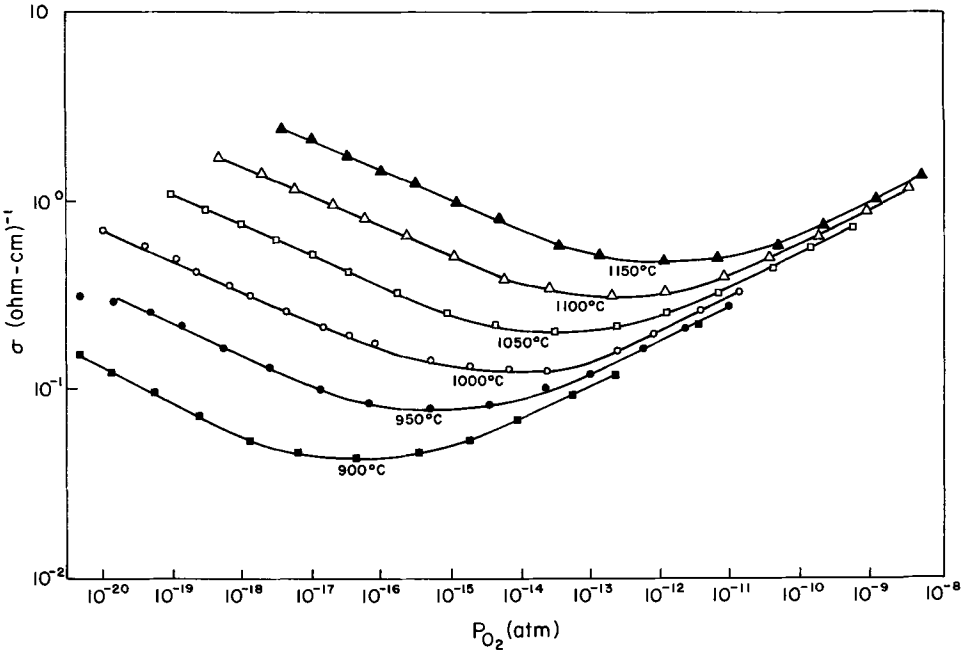

Fig. 1. Oxygen partial pressure dependence of the electrical conductivity of MnO showing the minimum in conductivity.

** Mobility data, see Fig. 5.

a ¼ power oxygen partial pressure dependence with no break in the weight charge data for p-type MnO. Bransky's data do not extend to CO_2/CO ratios of 200, however.

In the present study it was found that there were but small weight changes near the p- to n-type transition and at 1000°C one had to increase the oxygen partial pressure by four decades before significant weight changes were apparent (*e.g.*, $> 10^{-3}$ mole fraction). The isothermal weight change data were fitted to the integer, $2m$, that produced the best straight line as a function of $p_{O_2}^{1/2m}$ and extrapolated to $p_{O_2}^{1/2m} = 0$ for an estimate of the "stoichiometric weight" (10). The weight of the crystal at 1000°C as a function of $p_{O_2}^{1/6}$ is shown in Fig. 3. The similarity of Fig. 3 and Fig. 1 for the p-type electrical conductivity at 1000°C should be noted: both are linear over the same oxygen partial pressure range.

An oxygen partial pressure of 7×10^{-10} atm was selected for weight change measurements as a function of temperature because of the necessity of an oxygen partial pressure to produce significant weight changes and also intersect linear electrical conductivity-oxygen partial pressure dependence data as shown in Fig. 1. The log $[V_{Mn}'']$ *vs.* $1/T$ plot at an oxygen partial pressure of 7×10^{-10} atm is shown in Fig. 4. The slope of Fig. 4 yields a value of −5.9 kcal/mole for ΔH_f°. The activated enthalpy of movement of an electron hole, ΔH_p, is, therefore, 11.9 kcal/mole. These data are given in Table III.

The very small deviations from stoichiometry reported here are in agreement with the lower temperature results of Hed and Tannhauser (4). The immeasurably small deviations found for the n-type region, even when the sample was equilibrated with essentially pure CO, lends further support to the higher mobility electrons as the source of the n-type electrical conductivity. It is interesting to note that the parabolic oxidation of manganese to manganese oxide is independent of the oxygen partial pressure when the CO_2/CO ratio is less than one (14) (n-type region). Price and Wagner (9) on the other hand have measured the tracer diffusion coefficient of Mn^{54} in single crystalline MnO and did not observe any inflection in the diffusion data near the p- to n-type transition. This result (9) would indicate that the concentration of manganese vacancies is monotonically decreasing as the oxygen partial pressure is lowered and remains as the predominant nonstoichiometric atomic disorder.

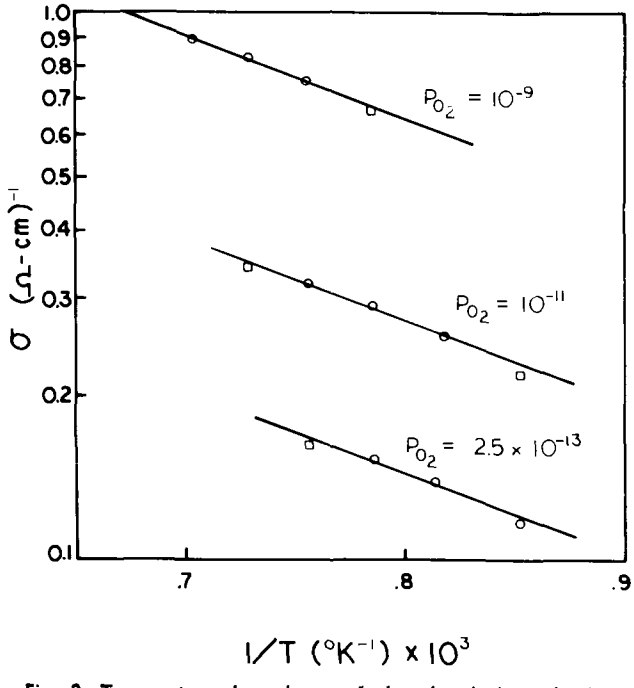

Fig. 2. Temperature dependence of the electrical conductivity of p-type MnO. The symbol, □, denotes data obtained by extrapolation as explained in the text.

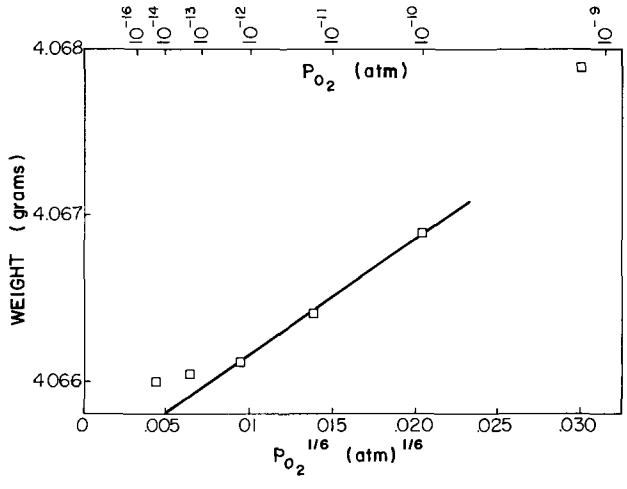

Fig. 3. Oxygen partial pressure dependence of the weight of p-type MnO at 1000°C. The values of the individual oxygen pressures are 7×10^{-10}, 7×10^{-11}, 7×10^{-12}, 7×10^{-13}, 7×10^{-14}, and 7×10^{-15} atm.

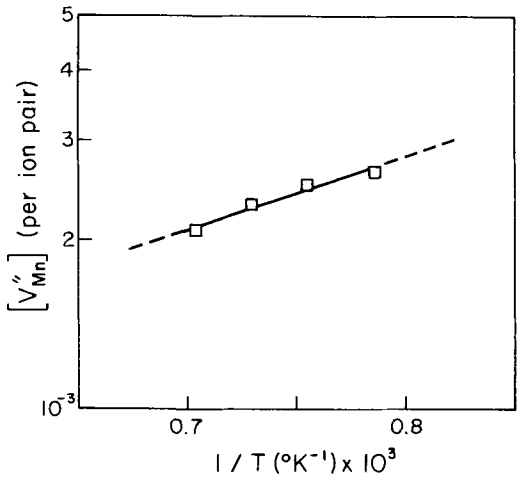

Fig. 4. Temperature dependence of the manganese vacancy concentration in MnO at constant oxygen partial pressure of 7 x 10^{-10} atm.

The thermogravimetric data may be combined with the electrical conductivity data in order to calculate the mobility of the electron holes. The mobility data may then be used to determine the activation energy of motion of an electron hole. The mobilities of the electron holes at an oxygen partial pressure of 7 x 10^{-10} atm have been calculated on the basis of two electron holes for each cation vacancy ($\sigma_p \propto p_{O_2}{}^{1/6}$) and are given in Table III. The temperature dependence of the mobility of the electron holes is shown in Fig. 5 and the resultant activation energy for motion of an electron hole is calculated to be 11.8 kcal/mole (see Table III).

The minima of the log σ *vs.* log p_{O_2} data may be used to determine the bandgap of MnO (15, 16). The log $\sigma_{min.}$ data as a fuction of $1/T$ are shown in Fig. 6. The data in Fig. 6 yield an activation energy of 63.4 kcal/mole (2.8 eV). Others (15, 16) have approximated this to be the bandgap at 0°K but it is actually given by

$$\frac{\partial \ln \sigma_{min.}}{\partial (RT)^{-1}} = \frac{-E_g}{2} + \frac{1}{2}\frac{\partial \ln \mu_p}{\partial (RT)^{-1}} + \frac{1}{2}\frac{\partial \ln \mu_n}{\partial (RT)^{-1}} \quad [5]$$

Since the p-type conductivity has a significant energy term associated with the mobility, the correction is an important one. For a calculated value of $[\partial \ln \mu_n]/[\partial (RT)^{-1}]$ of -1.3 kcal/mole at 1000°C based on $\mu_n \propto (kT)^{-1/2}$ and the measured value of $[\partial \ln \mu_p]/[\partial (RT)^{-1}]$ of 11.9 kcal/mole, the bandgap for single crystalline MnO at 0°K is calculated to be 52.8 kcal/mole (2.3 eV).

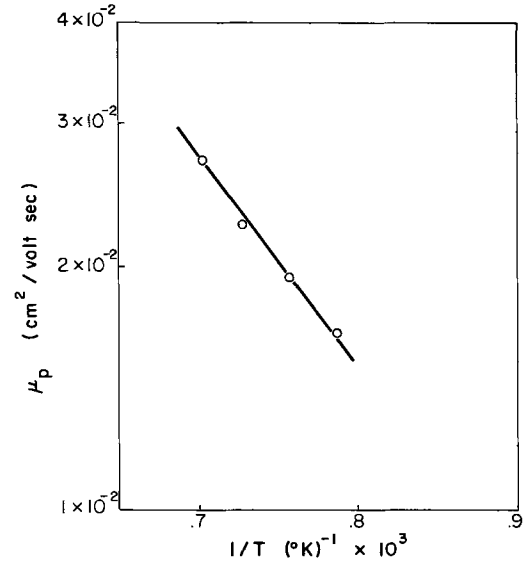

Fig. 5. Temperature dependence of the mobility of electron holes in MnO.

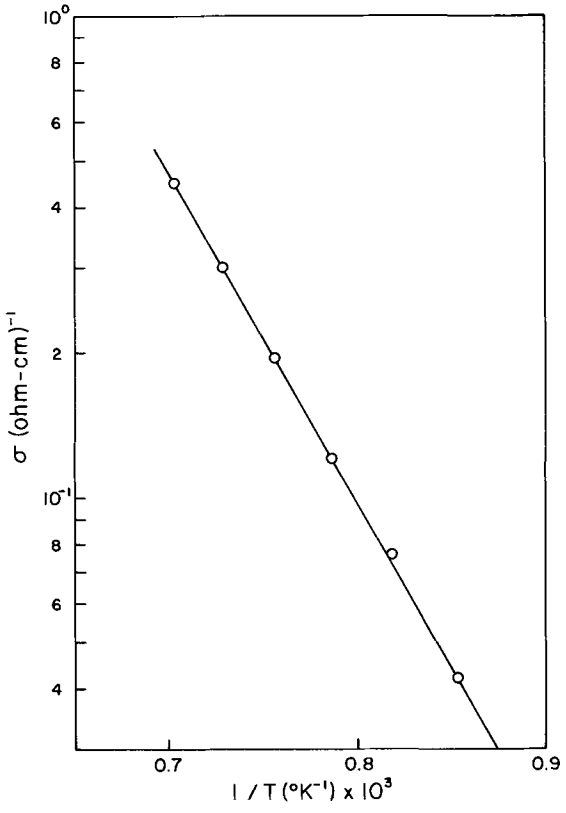

Fig. 6. Temperature dependence of the minima in conductivity obtained from the log σ *vs.* log p_{O_2}. See Fig. 1.

The electrical conductivity of n-type manganous oxide was found to be proportional to the $-1/6$ power of the oxygen partial pressure derived from CO/CO_2 mixtures over the temperature range of 900°-1150°C. These data are given in Table II.

For temperatures above 1000°C it was possible to employ CO/CO_2 ratios of 10^3 but at temperatures below 1000°C such large ratios resulted in values of the electrical conductivity that were insensitive to the calculated oxygen partial pressure. When the temperature was kept constant and the CO/CO_2 ratio was decreased after the electrical conductivity had been measured in the region which was insensitive to the oxygen partial pressure, it was found that the electrical conductivity tended to remain somewhat insensitive to changes in oxygen partial pressure. If, however, the temperature were raised to 1000°C the electrical conductivity values were found to correspond to the previous data measured at 1000°C. This behavior suggests the possibility of a phase change so the nonlinear, n-type electrical conductivity has been deleted.

It has been shown that the mobility of the electron is much greater than that for electron holes in MnO (5-7). This means that the predominant type of nonstoichiometric disorder is metal deficit at the p- to n-type transition and for at least some range of the n-type MnO. Simkovich (17) reports that carbon is a dopant in the ppm range in n-type MnO that has been equilibrated in CO/CO_2 atmospheres and may, therefore, contribute to the n-type electrical conductivity.

If the electrons responsible for the electronic conductivity result from the intrinsic electronic equilibria because of the decrease in electron holes, due to a decreasing cation vacancy concentration, then

$$\sigma = ne\mu_n = \text{const.}\ p_{O_2}^{-1/2m} \exp\left\{\left[\frac{\Delta H_{f_p}^\circ}{m} - \left(E_g + \frac{\partial \ln \mu_n}{\partial (RT)^{-1}}\right)\right] \Big/ RT\right\} \quad [6]$$

where $\Delta H_{f_p}^\circ$ is the enthalpy of formation of an ionized cation vacancy, E_g the intrinsic energy gap, and μ_n the mobility of an electron. The log σ *vs.* $1/T$ data for n-type MnO are shown in Fig. 7. The sum, $[(\Delta H_{f_p}^\circ/m) - E_g - (\partial \ln \mu_n)/(\partial (RT)^{-1})]$, is 52.6 ± 3.2 kcal/mole (see Table III) while the sum, $[E_g + (\partial \ln \mu_n)/(\mu (RT)^{-1})]$ is 51.5 ± 0.6 kcal/mole. $\Delta H_{f_p}^\circ/m$ is then calculated to be zero, within the experimental error.

If, on the other hand, the electrons that are responsible for the n-type electronic conductivity are due to doubly ionized cation interstitials then the measured activation energy for n-type electronic conduction may be represented by the sum, $[(\Delta H_{f_n}^\circ/m) + (E_1/m) + (E_2/m)]$, where $\Delta H_{f_n}^\circ$ is the enthalpy of formation of a cation interstitial and E_1 and E_2 are the first and second ionization energies, respectively, of the quasi-free electrons. The measured activation energy sum is 52.6 ± 3.2 kcal/mole (see Table III) and since m is equal to 3 the sum, $(\Delta H_{f_n}^\circ + E_1 + E_2)$, is found to be 158 kcal/mole (6.9 eV).

Stoichiometric compensation (18) of an acceptor dopant such as Li^+ may result in the creation of metal excess lattice disorder in MnO (the electronic disorder could still be p-type, however). This effect has probably been observed for the case of Li-doped CoO (19). Similar thermogravimetric and conductivity measurements are needed on Li-doped MnO as a function of p_{O_2} and temperature in order to estimate the concentration of interstitial manganese relative to the majority lattice defects, cation vacancies, in undoped MnO.

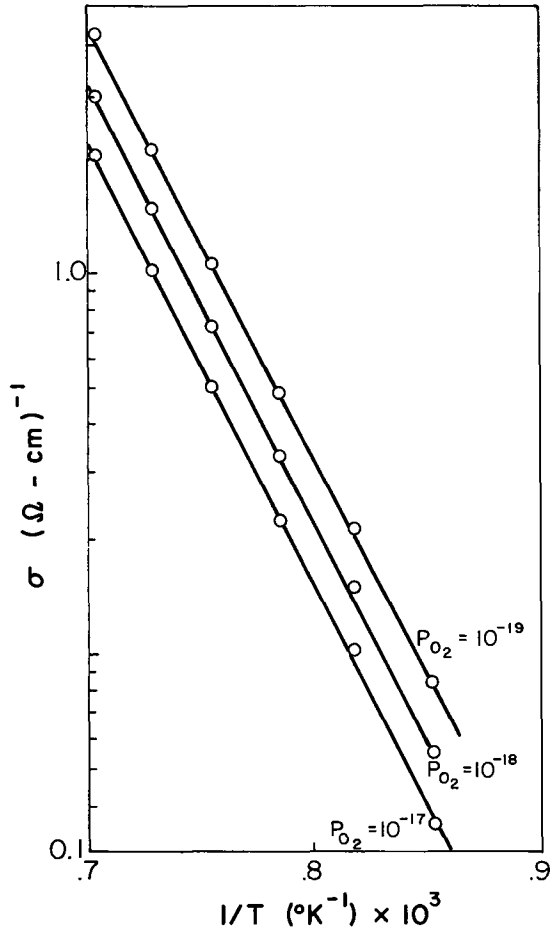

Fig. 7. Temperature dependence of the electrical conductivity of n-type MnO.

We have assumed that the electrical conductivity of manganous oxide is primarily electronic. Employing the value of approximately 1.0 x 10^{-9} cm^2/sec for D^* of the more mobile ion Mn, from the diffusion data of Price and Wagner (9) at 1032°C and an oxygen partial pressure of 10^{-11}, an appropriate electrical conductivity of 0.31 $(ohm\text{-}cm)^{-1}$, and p of 4.6 x 10^{22}, the transference number of the more mobile ion may be calculated from the Nernst-Einstein relation. The transference number of the more mobile ion at 1032°C and an oxygen partial pressure of 10^{-11} atm is found to be 8.3 x 10^{-4} which indicates that the electrical conductivity is primarily electronic.

Conclusions

1. Manganous oxide was found to exist as either p- or n-type from electrical conductivity measurements.
2. The p-type electrical conductivity was found to be proportional to the 1/6 power of the oxygen partial pressure. This oxygen partial pressure dependence suggests that the nonstoichiometric disorder in p-type manganous oxide may be described by

$$\tfrac{1}{2}O_2 \rightleftarrows O_O + V_{Mn}'' + 2p \quad [7]$$

3. The n-type electrical conductivity was determined to be proportional to the −1/6 power of the oxygen partial pressure. The n-type electrical conductivity was found to be consistent with high mobility electrons and metal deficit atomic disorder. If a portion of the n-type electrical conductivity is due to metal excess atomic disorder then

$$Mn_m + O_O \rightleftarrows Mn_i^{\cdot\cdot} + 2n + \tfrac{1}{2}O_2 \quad [8]$$

could describe the nonstoichiometry.

4. The sum of the enthalpy of formation of nonstoichiometric disorder and enthalpy of movement of the electronic defect was determined for both p- and n-type manganous oxide. The enthalpy of formation of p-type disorder and hence the enthalpy of movement of the electron holes were also determined. See Table III.
5. The bandgap of MnO was determined from the electrical conductivity minima at the p- to n-type transition to be 52.8 kcal/mole (2.3 eV).
6. Thermogravimetric measurements indicated that the departure from stoichiometry was small, ~3 x 10^{-3}, at 1000°C and 7 x 10^{-10} atm oxygen partial pressure for p-type manganous oxide and not detectable for n-type manganous oxide.
7. Mobilities of the electron holes were calculated from the thermogravimetric and electrical conductivity data at 7 x 10^{-10} atm oxygen partial pressure.
8. The transference number of the manganese ion at 1032°C and 10^{-11} atm oxygen partial pressure was calculated to be 8.3 x 10^{-4}.

Preparation of Beta-Rhombohedral Boron Whiskers[1]

Iqbal Ahmad and W. J. Heffernan

Benet Research and Engineering Laboratories, U. S. Army Watervliet Arsenal, Watervliet, New York 12189

ABSTRACT

Whiskers of beta-rhombohedral boron have been prepared by the reduction of BBr_3 and BCl_3 with hydrogen, involving a vapor-liquid-solid mechanism. The liquid forming impurities used were Au, Pt, Cu, and Ag. Gold was found to be the best. Optimum conditions for the whisker growth were: for BBr_3-1200°C, 25:1 H_2/BBr_3 molar ratio, and 100 cc/min flow rate; for BCl_3-1300°C, 1000:1 H_2/BCl_3 molar ratio, and 1000 cc/min flow rate. Whiskers from BBr_3 reduction were mostly circular in cross section, while those with BCl_3 were predominantly faceted.

In view of the current interest in beta-rhombohedral boron as an advanced structural material, it was considered of interest to prepare it in the form of high-strength filamentary single crystal whiskers. Two techniques were investigated: (*A*) Vaporization of elemental boron at high temperatures (1800°-1900°C) from BN crucibles, (*B*) Chemical vapor deposition (CVD) by the reduction of boron trihalides with hydrogen. With the first technique, whiskers 5-15μ in diam and up to 1 cm long with tensile strengths as high as 1.3 x 10^6 psi were obtained. The details of this work have already been published (1). Results obtained with the second technique are discussed in the present paper.

The formation of tetragonal boron whiskers, 2-3 mm long and 0.1 mm wide, as a result of the reduction of BCl_3 with H_2 (H_2/BCl_3, molar ratio of 100:1) over an inductively heated (1300°-1800°C) boron rod have been described by Olempska *et al.* (2). Sitarik and Ellis (3) have reported growth of alpha-rhombohedral boron whiskers by the reduction of BCl_3 with H_2 (1000°C, H_2/BCl_3 molar ratio of 1500:1.4, and flow rate 1.5 liter/min) on an amorphous boron substrate by a vapor-liquid-solid (VLS) mechanism (4). Platinum was used as the liquid-forming impurity. Some of the whiskers were 2 mm long and 25μ in diam.

To the best of the authors' knowledge, whiskers of beta-rhombohedral boron prepared by CVD have not been reported in the literature.

Experimental Details

CVD-H_2/BBr_3.—In the initial studies, formation of boron whiskers by simple chemical vapor deposition was investigated. BBr_3 was selected as a source of boron. As compared with BCl_3, it is relatively easier to purify (5). Prior to attempting whisker growth, rates of deposition of boron on resistively heated Ta strips at various molar ratios (H_2/BBr_3) and flow rates were determined. The apparatus is schematically illustrated in Fig. 1. Most of the runs were made at 1200°C, as below this temperature, alpha and tetragonal boron can also form. However, a number of runs were also made at higher temperatures. The temperature dependence of deposition rate at 12:1 molar ratio and 0.008 moles of BBr_3/cm^2 hour (total flow 100 cc/min) flow rate is shown in Fig. 2.

It is not proposed to give the details of the morphology of the deposits as a function of various variables. The major conclusions, however, were that higher temperature, higher molar ratio (H_2/BBr_3), and higher flow rate encouraged needle growth. Reproducible acicular growth of beta-rhombohedral boron was observed under the following conditions: temperature, 1200°C; H_2/BBr_3, 98:1, flow rate, 400 cc/min.

CVD-VLS:H_2/BBr_3 (Au, Pt, Cu, Ag).—From the above series of experiments it became obvious that, to promote whisker growth, a catalytic mechanism such as that provided by vapor-liquid-solid (4) was necessary. For the selection of liquid-forming impurities, the available phase diagrams were examined. Bates *et al.* (6), have studied the phase equilibria of Au-B, Pt-B, and Cu-B. Apparently none of these systems showed solid solubility of these elements in boron. Therefore, all of them were considered to be promising as liquid-forming impurities.

A tantalum strip was first coated with boron at a relatively low temperature (900°-1000°C). Particles of gold (−100 mesh) were then sprinkled over the boron deposits, the temperature of the strip was raised to 1200°C, and a gas mixture of H_2/BBr_3 (12:1) was allowed to flow at 200 cc/min. Whiskers were found to grow within a minute as shown in Fig. 3. Because of the low molar ratio, in some areas there was excessive

nucleation resulting in an "explosion" or "flower" effect (Fig. 4). Sometimes there was a secondary Au deposition on whiskers from which more whiskers nucleated giving a Christmas-tree-like growth. All of these whiskers were identified by x-ray diffraction as beta-rhombohedral boron.

In some runs, Pt, Cu, and Ag particles (−100 mesh) were used. Platinum gave encouraging results. However, with Cu and Ag, curly-type whiskers appeared and the growth was rough. Au was found to be the best.

The steep temperature gradient normal to the strip severely limited the length of these whiskers. To grow longer whiskers it was necessary to provide a better temperature gradient. Consequently, the apparatus was redesigned as shown in Fig. 5. In this apparatus, a graphite stick heater was used as a substrate. A Hoskin clamshell-type furnace was placed around the

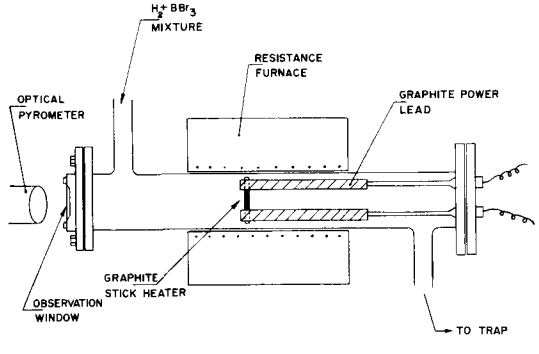

Fig. 5. Resistively heated graphite stick heater with clamshell furnace to provide shallow temperature gradient.

tube containing the substrate assembly. Unfortunately, because of the radiation losses, this furnace did not reach temperatures high enough to give the desired temperature gradient at 1200°C. Although whiskers of beta-rhombohedral boron with Au, Pt, and also Cu were obtained (Fig. 6a) in most cases they were not well-formed. At lower temperature regions (950°-1000°C), especially on the graphite leads, whiskers of tetragonal boron formed with both Au and Cu (Fig.

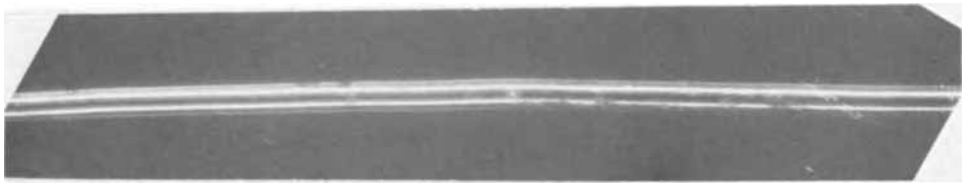

Fig. 6. Morphology of boron whiskers formed in graphite stick heater apparatus. (a, left) A beta-rhombohedral boron whisker (X385).

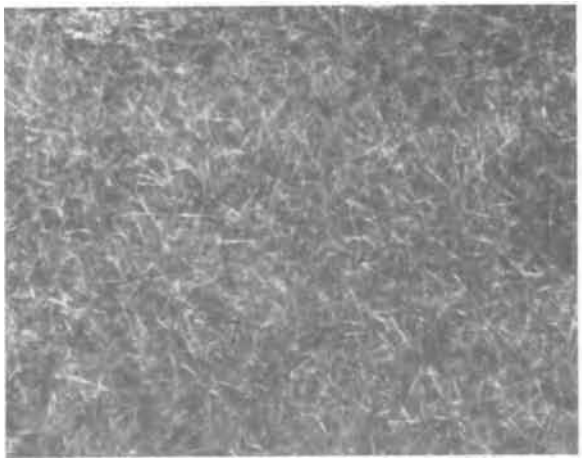

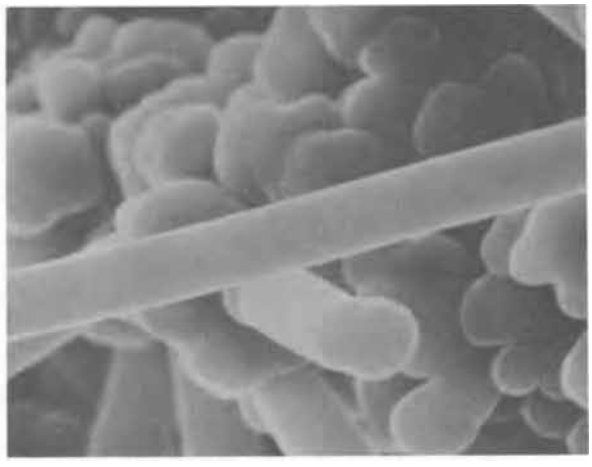

Fig. 6. Morphology of boron whiskers formed in graphite stick heater apparatus. (b, above left) A view of tetragonal boron whiskers formed on graphite leads (X120). (c, above right) Magnified view of (b). (d, left) Thread-like fibrous growth (X200).

6b). These whiskers were round in cross section (Fig. 6c) and had very smooth surfaces. Sometimes, very long thread-like fibers were also observed (Fig. 6d). In these experiments, even though a graphite heater was used, no evidence of the formation of B_4C was noted.

Finally, an apparatus shown in Fig. 7 was set up. In this apparatus a boron disk with metal particles sprinkled on it was positioned on a graphite base which, in turn, was placed in a graphite susceptor. In a few experiments, particles were also placed on the graphite base. Due to the geometry of the apparatus there was a preferential deposition of boron at the gas entrance side; however, at the middle of the substrate the deposition was less. The boron disk was positioned between these two regions to avoid excessive nucleation. With this setup, whiskers approaching 5 mm in length were obtained. The major observations were as follows:

(*A*) X-ray diffraction analysis showed that the majority of the black whiskers were beta-rhombohedral boron. However, sometimes minor amounts of tetragonal boron were also detected.

(*B*) At 1100°C, whiskers were observed only below 100:1 molar ratio. As the molar ratio was decreased, the time of growth reduced. At 25:1, the whiskers grew within 1 min.

(*C*) The best whisker growth was at 1200°C and a molar ratio of 25:1 (Fig. 8). They were predominantly round in cross section. At lower temperatures they were generally ill-formed. Occasionally, very fine straw-colored, apparently transparent whiskers, were also observed. X-ray diffraction analysis showed them to be predominantly B_4C.

Figure 9 is a trace of the microprobe analysis of the boron whisker grown from platinum, showing the concentration of platinum at the tip. Frequently, overgrowth was detected under high magnification, even on the apparently smooth surface of the boron whisker (Fig. 10). In one case a fractured whisker also showed a hollow core. The diameter of the whisker was 35μ while the core diameter was 25μ.

CVD-VLS:H_2/BCl_3 (Au, Pt).—In spite of considerable variation of the parameters such as flow rates, molar ratios, and the temperatures, the problem of the formation of nonfaceted whiskers could not be suc-

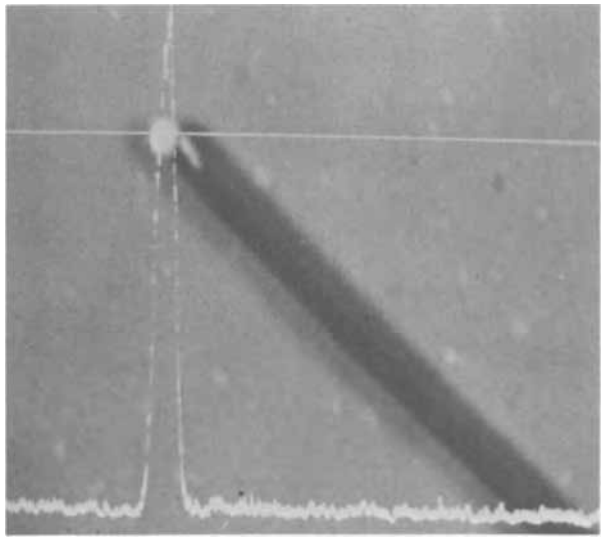

Fig. 9. Platinum distribution over tip of a whisker

cessfully solved. It was felt that circular cross section could have been due to the instability of the liquid-solid interface, caused by the fast reduction of BBr_3 under the conditions used. Thermodynamic considerations indicated that BCl_3 should be less easily reducible than BBr_3 at these temperatures from which a better control of the growth of whiskers could be expected. Therefore, in another series of experiments, BCl_3 instead of BBr_3 was used. In these runs a relative predominance of faceted whiskers was achieved. Whiskers of good quality (Fig. 11) were obtained at 1300°C at a molar ratio of 1000:1.

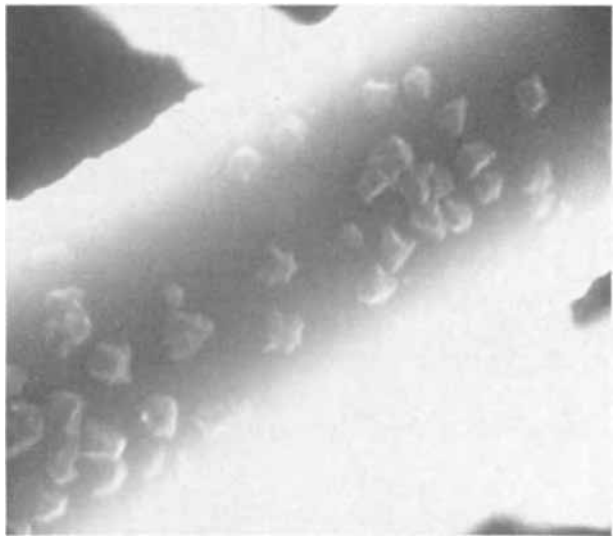

Fig. 10. Overgrowth on an apparently smooth surface of a whisker (X10,000).

Some runs were made without a boron disk. A graphite plate was used as a growth substrate. In these runs there was an evidence of very fine and long, apparently transparent, leader whiskers with liquid balls on their heads. They formed within a few minutes. When extended times were used, such whiskers, when on the gas entrance side of the substrate, either thickened or developed an overgrowth of polyfaceted, well-formed crystals as shown in Fig. 12. This overgrowth sometimes looked like beads on a thin string. Bushes of such whiskers without overgrowth were also observed at the exit end of the carbon substrate, as shown in Fig. 13. On x-ray diffraction they were found to be B_7C.

In one experiment, platinum was used in the form of a thin wire as a liquid-forming impurity. While only a very few whiskers of boron were obtained, in the region where the wire was positioned, golden-

Fig. 13. Bushes of leader whiskers grown at 1300°C, 500 cc/min, 500:1 ratio (X275).

colored whiskers were formed (Fig. 14). Under high magnification they appeared to be platelets and were identified as platinum boride.

Discussion

The main objective of this study was to produce beta-rhombohedral boron whiskers and characterize their physical and mechanical properties. The work reported here has shown the feasibility of the preparation of these whiskers by CVD involving VLS mechanism. However, the quality and size of the whiskers achieved so far are not suitable for the purpose of characterization.

It has already been mentioned that, although acicular growth of boron was achieved from simple CVD, it was found necessary to employ a VLS mechanism for the promotion of proper whisker growth. However, with BBr_3, apparently because of the considerably negative free energy of reaction of H_2 with BBr_3 in the temperature range of interest, it was not possible to establish a controlled whisker growth from the metal particles. This is apparent from the bushy growth obtained. Toward the gas entrance side there was invariably multinucleation from these particles.

It is also clear that, under the process conditions used, it was very difficult to control the temperature- and chemical-potential gradients in the substrate region. Some improvement was achieved by the use of BCl_3 in that more faceted whiskers formed. However, the growth and quality of whiskers were still unsatisfactory.

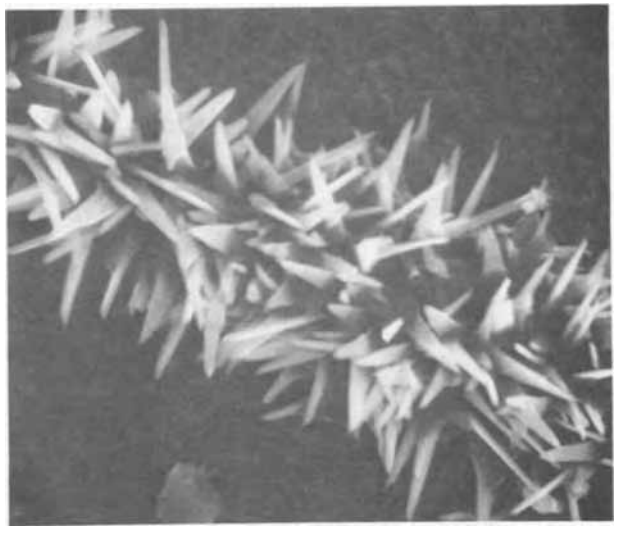

Fig. 14. Golden-colored whiskers of platinum boride (X1000)

This study, nevertheless, confirmed that alpha-rhombohedral and tetragonal whiskers can be obtained at temperatures below 1000°C. At temperatures of 1100°C or higher, this technique yielded essentially beta-rhombohedral boron. However, traces of tetragonal were also observed.

The formation of straw-colored boron carbide whiskers is noteworthy. The authors did not find any reference in the literature to a straw or orange-colored boron carbide phase. It appears that this phase in very fine size is not opaque. Analogous to this is the example of SiC, which in thick section is opaque black, while its whiskers are transparent and light green in color.

The formation of the leader whiskers can possibly be explained as follows. In the initial stages of heating, the molten metal particles pick up some carbon from the carbon substrate. When the $BCl_3 + H_2$ mixture is introduced, the dissolved carbon reacts with boron formed on the surface of the molten metal, resulting in the nucleation of fine boron carbide whiskers. Such whiskers in the gas inlet side then act as nucleation sites for the overgrowth of B, as structurally beta-rhombohedral boron is very similar to B_4C. In the exit-end side, boron in the reactants is depleted and therefore no boron overgrowth occurs. In the middle zone, boron whiskers form together with some B_4C whiskers.

Technical Notes

Magnetoelectret Effect in Shellac Wax

P. K. C. Pillai, Kamlesh Jain, and V. K. Jain

Department of Physics, Indian Institute of Technology, New Delhi-29, India

Eguchi (1) made the first thermoelectret from a mixture of carnauba wax, shellac wax, and beeswax. Many other workers studied the electret properties in different materials. Recently Bhatnagar (2) has developed a magnetoelectret by applying a magnetic field instead of an electric field. This new class of electrets also retains the surface charge for a very long time.

Experimental

In the present investigations, the powder of shellac wax was put into a cavity of mica sheet 1 mm thick and 4 cm^2 in area. A solid slab of the material was obtained in the mica holder by using the technique developed by Jain and Pillai (3) without the application of the field. The sample was kept in a desiccator for some time, until it lost all the surface charges due to stripping. A heating system was also made to heat both faces of the sample, when it was kept between the two pole pieces of an electromagnet. A thermocouple of copper constantan was fixed near the face of the sample for recording the temperature. The sample with the holder was mounted vertically between the pole pieces of the magnet, and the temperature of the sample was maintained at 70°C (softening point).

The distance of the poles was reduced to 1 in. to get the maximum magnetic field. The sample was polarized by heating and cooling under the same magnetic field strength. The magnetoelectret that was formed was taken out from the jig, and surface charge on both the surfaces was measured daily for about 28 days. The measurements were taken with the help of a d-c amplifier and electrometer (Type 1230A, Serial No. 1200) using a special measuring device (4, 5). The sample was short circuited with metallic foil after measurements and was kept under desiccated conditions for further studies.

Key words: Electret, magnetoelectret, polarization.

Results

In order to study this effect in detail, three series of samples were made with variation of polarizing time, temperature, and field.

In the first case, a series of the magnetoelectrets was made by applying a field of 4.75 kilo Gauss (kG) to 12 kG at a fixed temperature of 70°C for 75 min. From the surface charge decay characteristics (Fig. 1-3), it can be seen that both north and south faces of the electret show a permanent positive surface charge,

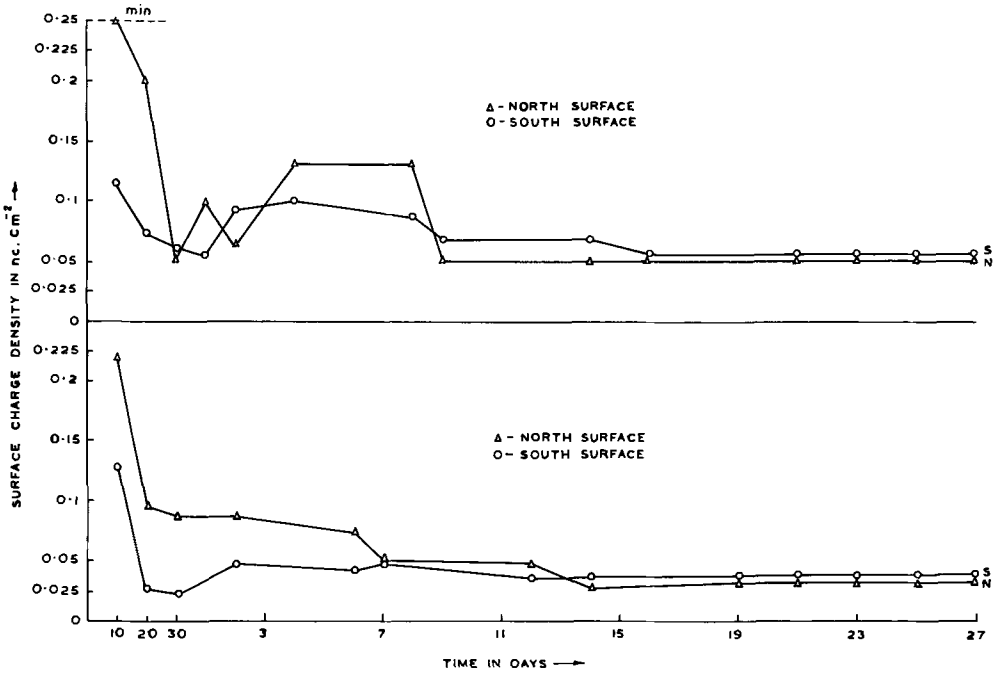

Fig. 1. (top) Variation of surface charge density vs. time for shellac wax electret formed at 12 kG/mm in 75 min polarizing time.

Fig. 2. (bottom) Variation of surface charge density vs. time for shellac wax electret formed at 8.75 kG/mm in 75 min polarizing time.

which decreases very quickly in the initial stage and then becomes constant. The final surface charges on the samples of this series increase with an increase of the polarizing field.

To confirm the presence of a magnetoelectret effect, a sample was also made without the application of a magnetic field under the same conditions. It was found that the sample showed some charges of low value due to the stripping and molding (6, 7). But the charges were not permanent and decayed to zero (Fig. 4) within a few days time.

Secondly, the effect of polarizing time was studied. The samples were made by applying 10.5 kG at 70°C and the heating time was varied from 15-60 min. Each sample was allowed to cool down to room temperature in 30 min under the magnetic field. It can be seen from the graphs (Fig. 5 and 6) that the surface charge increased with the increase of polarizing time. An increase in the final value of the surface charge was also found with an increase of polarizing time.

In the next case, the studies were made with the change of polarizing temperature from 70°C to room temperature (22°C). The samples were made at 55°C and at 22°C and the characteristics are shown in Fig. 6 and 7. It can be seen that at 55°C the final surface charge obtained is very low in comparison with the sample made at 70°C. The sample prepared at room temperature did not show any surface charge from the very beginning.

Discussion

The formation of the thermoelectret (8) can be explained on the basis of the contributions from different mechanisms such as (*A*) spray charge, (*B*) ionic displacement, (*C*) dipolar orientation, and (*D*) molding and stripping charges. But these phenomena are inadequate to explain the formation of a magnetoelectret state in solid materials.

In the present investigations, the effect of spray charge is completely ruled out as the dielectric is not

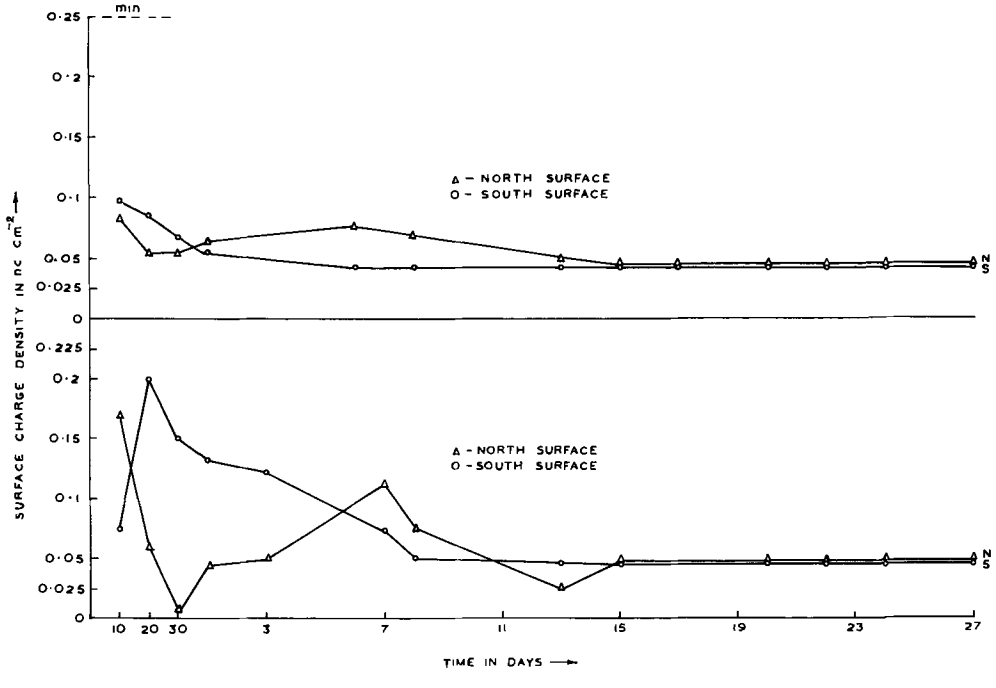

Fig. 5. (top) Variation of surface charge density vs. time for shellac wax electret formed at 10.5 kG/mm in 45 min polarizing time.

Fig. 6. (bottom) Variation of surface charge density vs. time for shellac wax electret formed at 10.5 kG/mm in 75 min polarizing time.

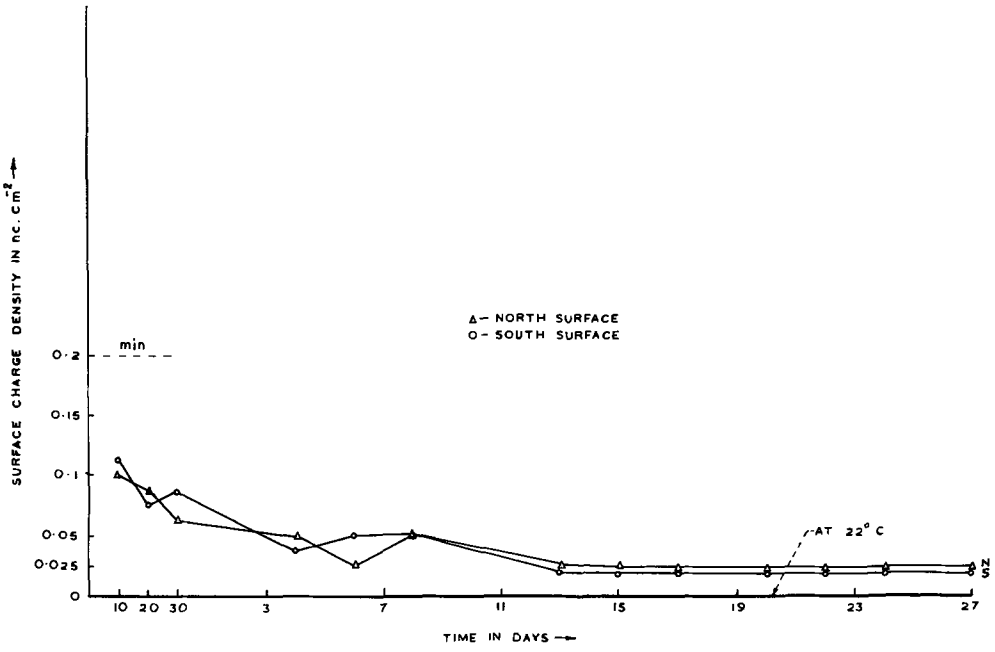

Fig. 7. Variation of surface charge density vs. time for shellac wax electret formed at 10.5 kG/mm in 75 min polarizing time at 55°C polarizing temperature.

being solidified under an electric field. The formation of magnetoelectrets may be due to the orientation of ionic charges or dipolar molecules or both which get frozen in the dielectric during its solidification.

The existence of polar molecules itself is insufficient to explain the development of charge on the magnetoelectret sample. But how a magnetic field causes dipoles to orient in their own direction is difficult to visualize.

The possibility of forming the magnetoelectret is confirmed by the results obtained by McMahon (9). He found that when certain organic compounds solidified in an electric field, the dielectric constant of these compounds in the solid state becomes higher than normal. The increase in the constant is isotropic and bears no relation to the direction of the field applied during the solidification. But in the case of a magnetic field, an anisotropic change takes place in the value of the dielectric constant, causing it to be greater than normal in the direction of the applied field and lower at right angles to this direction. McMahon postulated this mechanism of orientation of the molecules through diamagnetic coupling with the field. Diamagnetic anisotropy is observed in many aromatic ring compounds and according to Selwood (10), the principal susceptibility is generally perpendicular to the plane of the ring. Hence, in a magnetic field such molecules should tend to orient themselves so that the plane of the rings is parallel to the field and when the wax is solidified in a magnetic field, the molecules tend to orient with an axis of highest polarization in the direction of magnetic field.

Bhatnagar (11) has also mentioned that this explanation cannot directly be applied to the present case because the substance has an open chain structure; but according to Selwood, ring structure is not a necessary prerequisite for diamagnetic anisotropy, and chain compounds might also possess this property. Selwood says in open chain compounds "containing few or no multiple bonds, the maximum diamagnetic susceptibility corresponds to the greatest dimensions of the molecule." Thus it appears that McMahon's ideas may as well be extended to substances containing open chain compounds.

Although the above theory explains the nature and magnitude of the initial and final charges which appear on the electret surface, it fails to give a proper explanation for the appearance of a positive surface charge on the surface of the sample facing the north pole of the magnet. It can be due to the following two reasons (5, 6). First, due to the stripping after heating of the sample, positive charges were obtained on both the surfaces. Second, the dipoles oriented in the direction of the field in turn attract the excessive positive ions which are stuck on the surface when the sample is solidified from the bulk of the material. These ions are bound due to the attractive force of dipoles. The observed surface charge on an electret may therefore be written as

$$\sigma_{\text{eff}} = \sigma_D + \sigma_i + \sigma_m$$

where σ_{eff} = effective surface charge, σ_D = contribution of charge due to polar orientation, σ_i = component due to ionic polarization, and σ_m = contribution due to the molding and stripping.

The magnitude and nature of the effective charge depends of course, on the relative contributions of each one of these quantities and that varies from material to material and also depends on the polarizing conditions under which an electret is fabricated.

Acknowledgments

The authors wish to thank Professor S. C. Jain and Professor K. L. Chopra for the encouragement given to them during the course of this investigation. They are also grateful to Dr. A. K. Sreedhar, Dr. R. K. Jain, Dr. N. Chaudhri, and Dr. S. C. Gupta and their colleagues for the help given during the investigations.

The Mechanism of the Emission Color Shift with Activator Concentration in Eu^{+3} Activated Phosphors

Lyuji Ozawa and Philip M. Jaffe

Zenith Radio Corporation, Chicago, Illinois 60639

The emission of Eu^{+3} activated phosphors usually results from three excited states, namely $^5D_2$ (blue-green), $^5D_1$ (green-orange), $^5D_0$ (red) and the emission color shifts from yellow to red with an increase in activator concentration (1-3) and/or in the phosphor temperature (4-6).

In the case where the phosphor temperature is held constant, the emission color shift as a function of activator concentration is due to the difference in concentration dependence curves of the $^5D_2$, $^5D_1$, and $^5D_0$ emissions in the Eu^{+3} spectrum. However, only the concentration quenching mechanism of the $^5D_0$ emission is understood. The $^5D_0$ emission intensity depends on the concentration of isolated single activator ions which in turn depend on the crystal structure of the host and the mole fraction of activator (7). For weakly absorbed direct photoexcitation, the $^5D_0$ emission intensity per activator ion follows the equation

$$\frac{I_{ob}}{x} = (1 - x)^z \qquad [1]$$

where x is the activator concentration and z the weighted number of nearest neighbor cation sites.

Since the optimum activator concentration of the $^5D_1$ and $^5D_2$ emissions from many phosphors is around 0.01 mole fraction, electrostatic multipolar interaction may be involved in the concentration quenching. The quenching by multipolar interaction between rare earth ions has been studied by the change of decay time (8, 9). Van Uitert (8) indicates that the intensity of multipolar interaction can be also determined from the change of the emission intensity from the emitting level which has multipolar interaction. The emission intensity per one activator ion follows the equation

$$I_{ob}/x = (1 + \beta'(x)^{\theta/3})^{-1} \qquad [2]$$

where $\theta = 6$, 8, or 10 for dipole-dipole, dipole-quadrupole, quadrupole-quadrupole interactions, respectively, and β' is a constant for each interaction for a given host crystal.

For strongly absorbed exciting radiation, however, the observed concentration dependence curve, (I_{ob}/x) *vs.* x, deviates from the curves calculated by Eq. [1] and [2]. Equations [1] and [2] apply only to weakly absorbed exciting radiation used here (10).

Experimental

The Eu^{3+} activated phosphors studied in this paper are $(Y_{1-x}Eu_x)_2O_3$, $(Y_{1-x}Eu_x)_2O_2S$, and $Li(Y_{1-x}Eu_x)O_2$. The yttrium oxide and the europium oxide used were 6*N* and 3*N*, respectively. The preparation of the phosphors are reported in a previous publication (10).

The optical measurements were made on 2 mm thick powder samples, which were packed in planchettes. The concentration dependence of selected emission lines was determined by measuring their intensities as a function of activator concentration. The emission spectra of $(Y_{1-x}Eu_x)_2O_3$ and $Li(Y_{1-x}Eu_x)O_2$ phosphors were obtained with the 365 nm radiation from a mercury discharge lamp plus a Corning filter No. 7-54; for $(Y_{1-x}Eu_x)_2O_2S$, however, 395 nm radiation was used.

Results and Discussion

The concentration dependence curves studied were classified according to the ^5D_J emitting level. The emission lines quenched in the order $^5D_2$, $^5D_1$, and finally $^5D_0$ as the activator concentration increased. This order was independent of a change in either the exciting wavelengths or in the host. The relative intensities of the $^5D_2$, $^5D_1$, and $^5D_0$ emissions, however, were markedly different for a given host.

The I_{ob}/x *vs.* x curves of the $^5D_{0\text{-}2}$ emissions from $(Y_{1-x}Eu_x)_2O_3$ are shown in Fig. 1. The magnitude of the absorption coefficient was obtained by monitoring the $^5D_0$ emission because if the exchange interaction only was involved the I_{ob}/x *vs.* x curve of the $^5D_0$ emission would have followed Eq. [1] which applies for weakly absorbed exciting radiation. The data of the $^5D_0$ emission below $x = 0.1$ in $(Y_{1-x}Eu_x)_2O_3$ fitted on the calculated curves as shown in Fig. 1. These results indicate that below these activator concentrations Eq. [1] and [2] can apply to analysis of the experimental data. The I_{ob}/x data of the $^5D_1$ and $^5D_2$ emissions, over the activator concentration range of 0.01 to 0.1 mole fraction, fit on straight lines whose slopes are respectively 6/3 and 8/3 which indicate that dipole-dipole and dipole-quadrupole interactions are involved in the concentration quenching mechanism of the $^5D_1$ and $^5D_2$ emissions, respectively. The same results were obtained with $Li(Y_{1-x}Eu_x)O_2$ (10). The possible transitions involving the electrostatic multipolar interaction of Eu^{+3} are

Eu^{+3} (Excited)	Eu^{+3} (Relaxed)	
$^5D_2 \rightarrow {}^5D_1$;	$^7F_1 \rightarrow {}^7F_4$	(Q – D)
$^5D_1 \rightarrow {}^5D_0$:	$^7F_0 \rightarrow {}^7F_3$	(D – D)

The dependence of the quenching, I_q, upon the rate of transfer by electrostatic multipolar interaction is represented by the following equation (11)

$$I_q = A/(1 + r^{-\theta}) \qquad [3]$$

where r is the distance between activator ions and A is a constant.

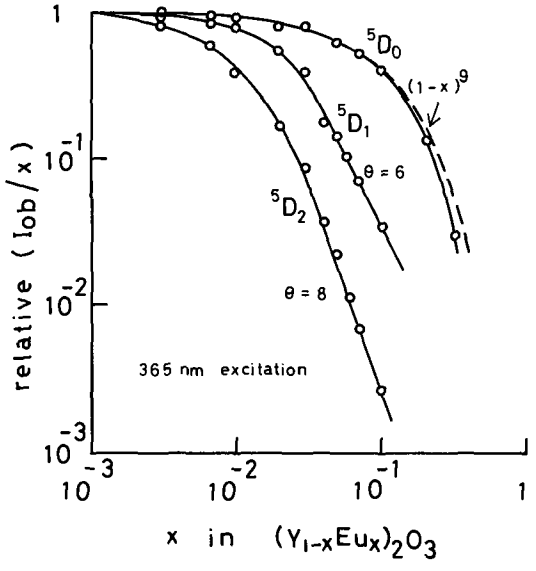

Fig. 1. Concentration dependence curves (I_{ob}/x *vs.* x) for $^5D_0$, $^5D_1$, and $^5D_2$ emissions from $(Y_{1-x}Eu_x)_2O_3$ under 365 nm ($4f^6$) excitation.

Key words: luminescence, phosphors, Eu^{+3} activation, concentration dependence.

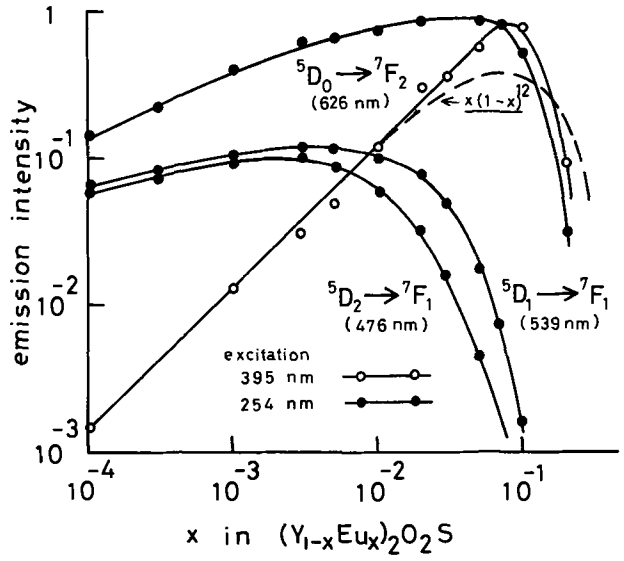

Fig. 2. Concentration dependence curves (I_{ob} vs. x) for $^5D_0$, $^5D_1$, and $^5D_2$ emissions from $(Y_{1-x}Eu_x)_2O_2S$ under 254 nm (host excitation ●) and 395 nm ($4f^6$ ○) excitations.

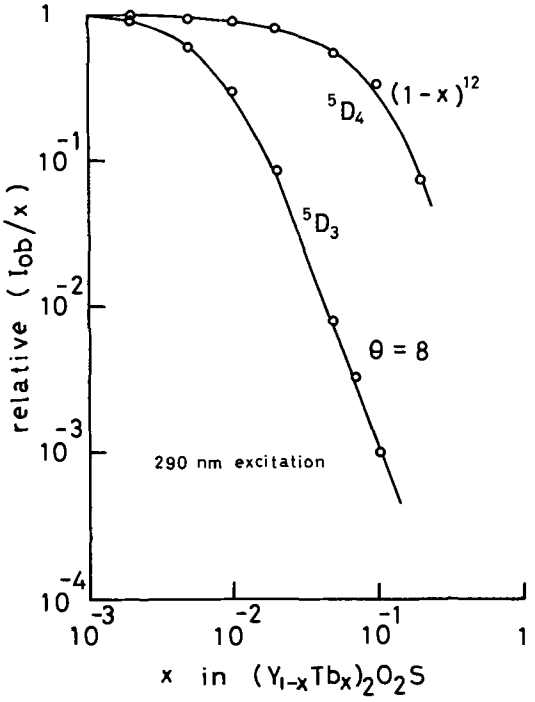

Fig. 3. Concentration dependence curves (I_{ob}/x vs. x) for $^5D_4$ and $^5D_3$ emissions from $(Y_{1-x}Tb_x)_2O_2S$ under 290 (f-d) excitation.

The concentration dependence curve of the $^5D_0$ emission from $(Y_{1-x}Eu_x)_2O_2S$ phosphor under the 395 nm exciting radiation ($4f^6$) had a positive deviation from the calculated curve, $x(1-x)^{12}$, as shown in Fig. 2. Therefore the concentration quenching mechanism of $(Y_{1-x}Eu_x)_2O_2S$ phosphor could not be exactly determined from the experimental data. Eu^{+3} seems to be a special case, however, since the I_{ob}/x *vs.* x curve of the $^5D_4$ Tb^{+3} in $(Y_{1-x}Tb_x)_2O_2S$ phosphor under the 290 (f-d) exciting radiation fitted on the calculated curve $(1-x)^{12}$ and the slope of the I_{ob}/x curve of the $^5D_3$ Tb^{+3} emission was 8/3 (see Fig. 3). Dipole-quadrupole interaction was estimated as the concentration quenching mechanism of the $^5D_3$ Tb^{+3} emission. These results agreed with the results of the other Tb^{+3} activated phosphors (12). From the results of $(Y_{1-x}Tb_x)_2O_2S$ phosphor, it is believed that in $(Y_{1-x}Eu_x)_2O_2S$ phosphor other quenching mechanisms may also be involved. However, the behavior of the concentration dependence curves of $(Y_{1-x}Eu_x)_2O_2S$ phosphor was qualitatively similar to those of $(Y_{1-x}Eu_x)_2O_3$ and $Li(Y_{1-x}Eu_x)O_2$ phosphors; *i.e.* the Eu^{+3} emission lines in the spectrum quenched in the order of $^5D_2$, $^5D_1$, and finally $^5D_0$ when the activator concentration increased. Therefore, the dominant mechanism of the concentration quenching of $(Y_{1-x}Eu_x)_2O_2S$ phosphor may be similar to those of $(Y_{1-x}Eu_x)_2O_3$ and $Li(Y_{1-x}Eu_x)O_2$ phosphors.

It is noted that the degree of the color shift over the same concentration range markedly depends on the phosphor host; well-known examples are white to orange to red with $(Y_{1-x}Eu_x)_2O_2S$, yellow to red with $(Y_{1-x}Eu_x)_2O_3$, and very little change with $(Y_{1-x}Eu_x)VO_4$. These color shift differences originate from the relative amounts of the $^5D_2$, $^5D_1$, and $^5D_0$ emissions at low activator concentrations. At low activator concentrations, where Eu^{+3} — Eu^{+3} interactions are unimportant, the $^5D_2$ to $^5D_1$, $^5D_1$ to $^5D_0$ relaxations and consequently the color shift are determined by host interactions. A phosphor which has a large amount of $^5D_2$ or $^5D_1$ emission at low concentration will show a large color shift as the activator concentration increases. Naturally, in order to study the color shift due to temperature effects the activator concentration should be very low, say, below 3×10^{-4} mole fraction.

An Improved Calcium Anode for Thermal Batteries

Robert P. Clark and Kenneth R. Grothaus

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

A technique is described for preventing electrical shorting resulting from the formation of $CaLi_2$ alloy in thermal cells employing a Ca anode and LiCl-KCl electrolyte. The cell employed in this work was Ca/LiCl-KCl-$CaCrO_4$/Fe. The method consists of immersing the Ca anode in an acetic acid solution, thereby forming a layer of $3Ca(CH_3COO)_2 \cdot 2CH_3COOH$ on the anode surface. This double salt decomposes to $CaCO_3$ either prior to or at the beginning of the cell discharge. The resulting high concentration of Ca^{++} at the anode-electrolyte interface retards the displacement by Ca of Li from the LiCl in the electrolyte. Cell and battery test results are given which demonstrate the improvement in performance resulting from application of this technique.

A thermal battery is a primary battery whose cells contain an electrolyte which is solid and virtually nonconductive at ambient temperatures, but which becomes highly conductive when heated to temperatures above its melting point. Because of its relatively low melting point, good thermal stability, and high electrical conductivity, the lithium chloride-potassium chloride eutectic is the most commonly used thermal battery electrolyte. The anode most often selected, calcium, is chosen for its large negative reduction potential, low equivalent weight, high melting point, low polarization and ready availability. Unfortunately, calcium displaces lithium from the molten electrolyte as shown in Reaction [1] (1).

$$Ca(s) + 2Li^+ \xrightarrow{352°C} Ca^{++} + 2Li(l) \qquad [1]$$

The molten lithium in turn reacts with additional calcium according to Reaction [2] to form a calcium-lithium alloy of composition $CaLi_2$ with a melting point of 230°C (2)

$$Ca(s) + 2Li(l) \xrightarrow{352°C} CaLi_2(l) \qquad [2]$$

The presence of an excess of a molten metal in a voltaic cell is obviously an undesirable situation because of the possibility of shorting. Electrical noise and cell degradation due to the $CaLi_2$ alloy have long been major problems in thermal batteries (3). Although thermal batteries can be overdesigned so as to be highly reliable, the unpredictable nature of this alloy results in poor reproducibility of performance especially with regard to activated battery life. Possible solutions to this problem are elimination of the Ca anode and/or the LiCl electrolyte. Unfortunately, the alternative materials often create more problems than they solve. Replacement of a Ca anode with Mg, for example, usually results in a reduced output voltage for a given thermal cell (1, 4). Unpublished results from this laboratory show that between 450° and 600°C, the output voltage for the cell M/LiCl-KCl-$CaCrO_4$/Fe is approximately 0.8V less for M = Mg than for M = Ca at current densities ranging from 0.11 to 120 mA/cm^2. Substitutes for the LiCl-KCl eutectic which possess the desirable combination of electrolyte properties previously mentioned for LiCl-KCl have not been found.

Key words: thermal batteries, anodes, calcium, batteries.

In the present paper, a technique is described for chemically treating the Ca anode such that $CaLi_2$ alloy formation is no longer a significant problem. The process involves the production of a high concentration of Ca^{++} ions at the anode-electrolyte interface, thereby greatly reducing the formation of Li (Reaction [1]). This is accomplished by depositing a layer of $3Ca(CH_3COO)_2 \cdot 2CH_3COOH$ on the Ca anode through the reaction between Ca and acetic acid. The double salt ultimately thermally decomposes to form $CaCO_3$. The existence of these salts has been shown with the aid of x-ray diffraction and thermogravimetric analysis.

Experimental

Materials.—All materials used were of a grade equivalent to that used in production thermal batteries. Anodes were: rolled sheet Ca pressed on an iron backing, or Ca vapor deposited on the backing.

The electrolyte consisted of reagent grade LiCl and KCl vacuum dried for 16 hr at 120°C, mixed in the eutectic ratio (5), fused at 400°C, cooled, and ground to a powder.

Baker and Adamson (Allied Chemical) technical grade $CaCrO_4$ was used as the cathodic depolarizer. Glacial acetic acid and acetone were both reagent grade. The cathode consisted of sheet iron.

Procedures

Calcium anodes used in the evaluation were of three types: control samples which had been cleaned with 5 volume per cent (v/o) HNO_3 in acetone, anodes which were cleaned and then immersed for 180 sec in 20 v/o CH_3COOH in acetone and anodes which were cleaned and immersed for 60 sec in 25 v/o CH_3COOH in acetone. All three anode types were tested in single thermal cell configurations and in five-cell thermal batteries.

Anodes treated with other acetic acid concentration-immersion time combinations, with acetic acid vapor and with acetic acid in Freon 113 (1,1,2 trichloro - 1,2,2 trifluoroethane), were evaluated but are not discussed here since these experiments lead to results equivalent to those reported in this paper.

Single cell tests.—The thermal cell was of the type Ca/LiCl-KCl-$CaCrO_4$/Fe. The over-all cell reaction is quite complex but may be written in simplified form as

$$3Ca + 2CaCrO_4 \rightarrow 5CaO + Cr_2O_3 \quad [3]$$

The LiCl-KCl eutectic electrolyte, the $CaCrO_4$ cathodic depolarizer, and an inert silica binder material were mixed and pressed into a homogeneous pellet configuration. The binder served to maintain the pellet dimensions even at temperatures above the electrolyte melting point. This depolarizer-electrolyte-binder (DEB) pellet was placed between a Ca anode and an Fe cathode to form a single cell. The cell was discharged by heating it between two electrically heated nickel platens from which the cell was electrically insulated. Constant platen temperatures of 450°, 500°, 550°, and 600°C were used in these investigations. These values are representative of actual temperatures experienced by cells inside an activated thermal battery during its operation (6). Cells were discharged through constant resistance loads ranging in value from 2800 to 2 ohms, corresponding to approximate current densities of 0.11 to 120 mA/cm². DEB pellets of various depolarizer, electrolyte, and binder concentrations were used in the tests. The single cell testing arrangement is shown in Fig. 1.

Dependent variables measured included peak cell voltage under load, cell capacity in amp · sec, the occurrence of electrical noise and weight of $CaLi_2$ alloy extruded from the Ca-DEB pellet interface.

Fig. 1. Single cell test arrangement

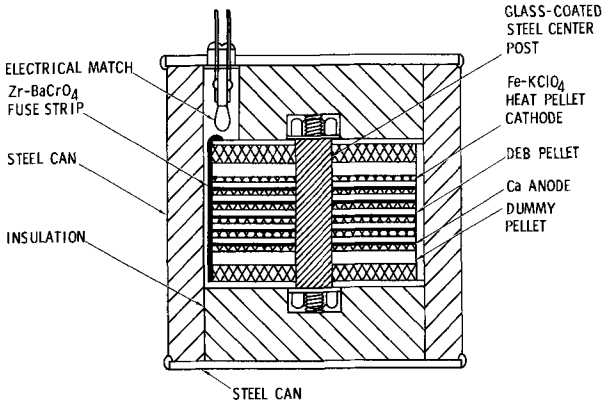

Fig. 2. Cutaway of thermal battery configuration

Battery tests.—Calcium electrodes of each of the three types were also evaluated in five-cell thermal batteries. The five cells were stacked in series with the anode of one cell in contact with the cathode of the next as shown in Fig. 2. Batteries were activated by means of an electrical match which ignited a zirconium-barium chromate fuze strip which in turn ignited iron-potassium perchlorate heat-generating pellets. The heat-generating pellets contained an amount of iron in excess of the stoichiometric mixture so that they also served as the cathodes. The cell stack was surrounded with insulation and hermetically sealed in a thin steel case. Batteries of this general type have been successfully used in the past to evaluate the effect of variables on performance (6).

Batteries were tested at seven ambient temperatures ranging from −54° to 71°C. Performance over this ambient temperature range is a common thermal battery requirement. Batteries were activated and discharged with a high impedance load (approximately 4 mA/cm²) for 120 sec followed by a heavier load for the remainder of the discharge. Approximate current densities after the first 120 sec ranged from 16 to 155 mA/cm². This type of discharge (high impedance load followed by a heavy load) is typical for thermal battery applications (3). If discharge rates are sufficiently high, much of the $CaLi_2$ which forms will be utilized electrochemically at the anode according to Reaction [4]

$$CaLi_2 \rightarrow Ca^{+2} + 2Li^+ + 4e^- \quad [4]$$

Consequently, under very light loads (as employed during the first 120 sec), the rate of $CaLi_2$ formation will be larger than the rate of electrochemical utilization, causing the shorting effects to be more pronounced. Voltage *vs.* time was monitored for each battery; electrical noise was noted and batteries were disassembled after testing to allow measurement of visible $CaLi_2$ alloy.

Results and Discussion

Cell tests.—Typical cell test results are shown in Table I. Data at each condition represent the average for at least three separate single cell discharges. These data show that cells with treated anodes exhibit reduced amounts of extruded $CaLi_2$ alloy and a corresponding absence of electrical noise. Within experimental error capacities of treated cells are equal to or greater than capacities of cells with untreated anodes. This is particularly significant at 450°C where any effect of increased cell *IR* which might be caused by the $CaCO_3$ layer on the anode surface would be most severe. This effect probably accounts for the differences in peak voltages observed at 450°C. No significant variation in peak voltage is observed at any other one temperature.

Some discussion of the relationship between $CaLi_2$ alloy weight and electrical noise is in order. The fact

600	25	60	0.11	2.87	0.87	49	No

that such a relationship does exist has been previously established (3). Also, in the present work it was possible to visually observe intermittent and/or permanent shorting caused by the bridging of molten $CaLi_2$ between anode and cathode. An inspection of discharged thermal batteries further verified $CaLi_2$ alloy as the cause of electrical noise. However, a quantitative correlation between alloy weight and electrical noise is not possible for two major reasons. First, the weight of extruded $CaLi_2$ alloy can be determined only semiquantitatively at best. The complete separation of the alloy from impurities (*e.g.* electrolyte, depolarizer, reaction products, etc.) is virtually impossible. Furthermore, in cases of prolonged cell shorting, the alloy often ignites, becoming partially or completely oxidized. Secondly, the nature of the extruded alloy is a function of the anode treatment. With untreated anodes, the $CaLi_2$ tends to form in a few very large globules. However, for anodes treated with acetic acid the alloy is extruded as many very small droplets. Consequently, the likelihood of resulting shorting is far greater for the larger globules even though the total weight of extruded alloy could be less.

Battery tests.—One of the difficulties associated with thermal batteries has been the inability to make accurate estimates of battery performance based on single cell data. Consequently, it has been the practice in thermal battery technology to use single cell tests primarily for rough screening evaluations. Any materials or processes selected on this basis must then be thoroughly tested in actual batteries. Because the present work has as its goal an anode for practical use in thermal batteries, an extensive evaluation of anodes in batteries was undertaken. Representative data for batteries are shown in Tables II and III. Each set of data represents the average of results for at least two separate batteries.

Table II shows discharge data as a function of temperature for batteries with each of the three Ca types. Comparison of untreated anodes with Ca anodes immersed for 180 sec in 20 v/o acetic acid and showed the following: treated anodes resulted in decreased weight of extruded alloy; a corresponding decrease in electrical noise was observed except at 71°C where both treated batteries were noisy while 7 of 10 untreated batteries exhibited noise; cell capacities were not significantly affected by the treatment. The results for batteries with anodes treated for 60 sec in 25 v/o acetic acid show that: alloy weight was further decreased; noise was eliminated and cell capacity was decreased markedly only at −54°C. This loss of capacity is due to *IR* at the anode-DEB pellet interface caused by the $CaCO_3$ layer on the Ca. The *IR* drop becomes significant for high-current densities at low temperature.

In order to determine the maximum current density which the treated anodes can sustain without large capacity losses, a comparison was made of test results at −54° and 71°C for untreated and treated Ca at a variety of current densities. The data are shown in Table III.

From this table it can be noted that the treated anodes result in less $CaLi_2$ extrusion with a corresponding decrease or, in these cases, absence of noise. For treated anodes peak voltages are low at −54°C for the higher current densities (147 and 155 mA/cm²) due to resistance of the deposited $CaCO_3$ layer. Battery capacity at 71°C is generally improved by the acetic acid treatment. Untreated anodes suffer losses due to intermittent or permanent shorting and also

because of loss of active anode material due to extrusion of $CaLi_2$. Capacity for treated cells at −54°C is only slightly less than for untreated, except at 155 mA/cm² where the decrease becomes very significant. Thus, treated anodes can be utilized over the complete temperature range −54° to 71°C without significant loss of capacity or peak voltage for current densities less than ~150 mA/cm².

Chemical reactions.—The chemistry of this treatment is explained with the help of thermogravimetric analyses and x-ray diffraction identification of compounds. The calcium anode and acetic acid react according to Reaction [5]

$$3Ca + 8CH_3COOH \rightarrow 3Ca(CH_3COO)_2 \cdot 2CH_3COOH + 3H_2\uparrow \quad [5]$$

The double salt was identified by x-ray diffraction. The existence of this compound ($3Ca(CH_3COO)_2 \cdot 2CH_3COOH$) has been previously established (7). This material decomposes very slowly at room temperature and very rapidly above 170°C to form calcium acetate.

Calcium acetate undergoes thermal decomposition at 400°-430°C to calcium carbonate (8) which is stable at the internal battery operating temperatures. Batteries may be assembled containing anodes coated with $3Ca(CH_3COO)_2 \cdot 2CH_3COOH$ or the anodes may be heated prior to assembly so that either a $Ca(CH_3COO)_2$ or a $CaCO_3$ coating exists.

The first compound adheres well to the calcium; however, the pressure generated within the battery due to the decomposition of the double salt during battery activation may be undesirable. In this case, the $Ca(CH_3COO)_2$ or the $CaCO_3$ coated anodes could be employed, although adherence to the anode is only fair with $Ca(CH_3COO)_2$ and poor with $CaCO_3$. In any event, once the cell is activated thereby reaching temperatures in excess of 450°C, the coating will consist of $CaCO_3$ which is moderately soluble in the LiCl-KCl eutectic electrolyte. (Rough measurements in this laboratory show that this solubility is approximately 5g $CaCO_3$/100g LiCl-KCl eutectic at 550°C.) Thus, a relatively high concentration of Ca^{++} ions will exist at the anode-electrolyte interface. This will cause the equilibrium in Reaction [1] to be shifted to the left, thereby retarding the formation of $CaLi_2$ alloy (Reaction [2]). Attempts to accomplish this same effect by adding Ca^{++} ion (as $CaCl_2$ or $CaCO_3$) to the electrolyte itself successfully reduced the rate of $CaLi_2$ formation; however, the melting point of the electrolyte was increased by this addition such that the conductivity of the electrolyte and output of the cell were severely degraded.

Conclusion

This work demonstrates the practical improvements in thermal batteries which resulted from reacting calcium anodes with acetic acid in a prescribed manner. The quantity of extruded $CaLi_2$ alloy was decreased, and the resulting electrical noise and shorting were virtually eliminated. No significant detrimental effect on cell capacity or voltage was noted except for discharges at 155 mA/cm² and −54°C. The particular acetic acid concentration and reaction time necessary for application of the technique are dependent upon the specific battery requirements. The method has been successfully applied to several commercial thermal batteries (9) and should find application to future thermal battery requirements.

The Corrosion Behavior of Zn-22Al Alloy Sheet

D. N. Williams, B. G. Koehl, W. E. Berry,* and E. S. Bartlett

Battelle Memorial Institute, Columbus, Ohio 43201

ABSTRACT

The corrosion behavior of three lots of annealed Zn-22Al sheet material was compared with that of 380 aluminum die-casting alloy using four accelerated corrosion test environments: 100% relative humidity at 120°F, 100% relative humidity at 120°F plus a trace of ammonia, 100% relative humidity at 120°F plus 100 ppm sulfur dioxide, and alternate immersion in 3½% sodium chloride solution at room temperature. Corrosion rates of the Zn-22Al materials as measured by weight change and metallographic evidence of subsurface attack were considerably less than observed in the 380 aluminum die-casting alloy. Intergranular attack was observed extending 2-4 mils beneath the surface in the Zn-22Al material exposed to high-humidity environments except when sulfur dioxide was present. Intergranular attack appeared related to the presence of a zinc-rich grain-boundary phase. Although the corrosion behavior of Zn-22Al material was not affected in most cases by exposure under stress, one material which was relatively free of intergranular attack when exposed without stress developed cracks when exposed under stress.

Zn-22Al alloy sheet is presently being considered for use in applications where extensive forming is required. When properly processed, this alloy shows superplastic behavior and is readily formed into complex shapes (1, 2). After forming, the alloy can be heat-treated to a nonsuperplastic condition having attractive strength and creep resistance. The postforming heat-treatment is designed to produce a lamellar eutectoid microstructure composed of the two terminal solid-solution phases. [See ref. (3) for a recent discussion of the phase diagram of the aluminum-zinc system.]

The present study was designed to examine the corrosion behavior of Zn-22Al alloy sheet in this final heat-treated condition. Since the alloy is expected to compete with aluminum die-cast components, at least in initial applications, the corrosion behavior was compared to that of the 380 die-casting alloy (Al-8.5Si-3.5Cu). All corrosion studies were conducted with accelerated-corrosion-test procedures.

Materials

Sheet material at about 50 mil thickness was used in this investigation. Three lots of material were evaluated, each of which had been processed somewhat differently.

One lot of sheet material was processed by a commercial supplier. This sheet, referred to as direct-chill material, was cast as a 14-in.-thick direct-chill ingot, scalped heavily to remove high-zinc surface segregates, and rolled to sheet on a commercial mill.

The other two lots of sheet materials were cast and fabricated to sheet in the laboratory. One lot, designated as tilt-mold material, was cast into a 1¼-in.-thick preheated tilt mold and scalped to remove 62 mils per side prior to rolling. The other lot, referred to as chill-mold material, was cast into a 1½-in.-diameter copper ingot mold and processed to sheet without scalping.

All three materials were hot rolled in the high-temperature single-phase field at about 650°F to an intermediate thickness. A final cold reduction of about 50% was used following quenching from the high-temperature phase field. This treatment placed the materials in a superplastic state. Following this treatment, all materials were heated to 650°F, held approximately 1 hr, and slow cooled at less than 30°F/min to below 450°F to place the material in an optimum use condition.

The direct-chill material showed evidence of alloy segregation in the central region as shown in Fig. 1. Electron-probe studies showed this region to be high in zinc. Noticeable grain-size differences were apparent among the three materials, the direct-chill material showing the largest grain size and the tilt-mold material the finest. The coarseness of the lamellar eutectoid structure also varied among the three materials. The direct-chill material appeared to have a coarser eutectoid structure than the other two materials. The eutectoid structure in this material is shown in Fig. 2. The differences in eutectoid coarseness were attributed to differences in the cooling rate following the 650°F anneal.

The chemical composition of the three materials is shown in Table I. The direct-chill material was of somewhat higher purity than the other two materials, and the chill-mold material was much lower in aluminum than desired: the intended range was 21.5 to 22.5. Tensile properties of the three materials shown in Table II indicated that processing and compositional differences among these three materials had a significant effect on strength and ductility.

The 380 aluminum alloy samples exposed in the corrosion study for comparison purposes were obtained

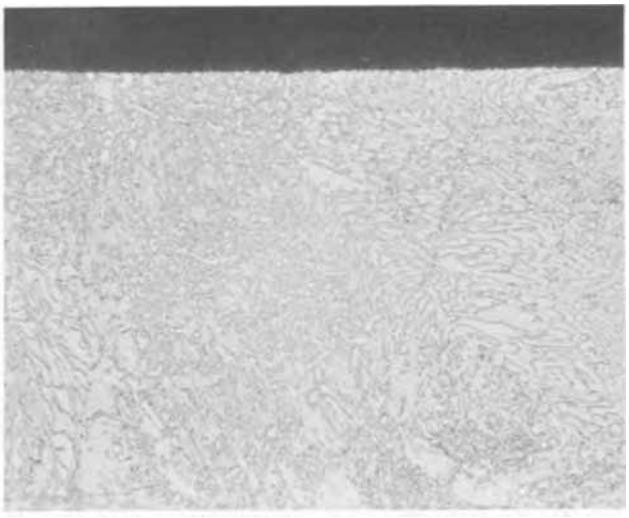

Fig. 2. Eutectoid structure in direct-chill alloy sheet adjacent to rolling surface. 540×.

from a thin-wall commercial die casting. Samples were cut from positions of the casting showing approximately 50-mil thickness and exposed with the as-cast surface intact. The 380 alloy has a nominal composition of Al-8.5Si-3.5Cu and typical tension properties as die cast of:

0.2% offset yield strength	24,000 psi
ultimate tensile strength	48,000 psi
elongation in 2 in.	3 %

Corrosion-Test Procedures

Four accelerated-corrosion test procedures were used to compare these materials:

1. Continuous exposure to 100% relative humidity at 120°F.
2. Continuous exposure to 100% relative humidity at 120°F with a trace of ammonia (1 ppm).
3. Continuous exposure to 100% relative humidity at 120°F with 100 ppm sulfur dioxide.
4. Alternate immersion in 3½% sodium chloride solution (10 min immersion followed by 50 min drying in ambient air).

Humidity tests were conducted in cabinets meeting Army-Navy-Aeronautical Specification AN-H-31. Duplicate samples measuring 1 x 2 in. were continuously exposed for 100, 250, 500, and 1000 hr in each environment and examined for weight change, visual appearance, and microstructural evidence of corrosion attack. Previous experience had shown that an adherent film formed on those specimens exposed to 100% relative humidity at 120°F. However, as will be noted later, some spalling occurred in humid air containing SO_2 and in 3½% NaCl solution. Because of the limited amount of material, replicate samples could not be removed at intermediate exposure periods for descaling to determine weight loss. Nevertheless, the weight changes for spalling specimens did show trends and the data are reported for this purpose.

Table I. Composition of three Zn-22Al materials

Material identification	Per cent by weight				
	Al	Fe	Si	Cu	Mg
Direct-chill	22.7	0.007	<0.005	0.001	<0.001
Tilt-mold	22.1	0.049	0.04	0.005	<0.001
Chill-mold	18.9	0.02	0.02	0.002	<0.001

Table II. Tensile properties of three Zn-22Al materials

Material identification	Tensile properties of 50-mil-thick sheet			
	0.2% Offset yield strength, psi	Ultimate strength, psi	Elongation, % in 2 in.	Reduction in area, %
Direct-chill	28,900	31,500	13	18
Tilt-mold	36,200	38,000	18	28
Chill-mold	29,200	30,300	16	16

The main criterion for evaluating corrosion performance was a metallographic examination of transverse cross sections (across the rolling direction). The entire periphery of the cross section was examined. Maximum depth of pitting or intergranular attack was recorded. If selective attack was observed, it was quite extensive. Only an occasional specimen exhibited an isolated area of selective attack.

Some corrosion studies were performed under stress. Cantilever-loaded bend samples measuring 6 x 1 x 0.05 in. were loaded so as to produce measurable creep during the test and were exposed to selected high-humidity environments. U-bend samples measuring 4 x 0.5 x 0.05 in. were bent over a ¾-in.-diameter mandrel and were exposed to alternate immersion in sodium chloride. The legs of the U-bend specimens were pulled up parallel using stainless steel nuts and bolts inserted through holes at either end of the specimen. Teflon washers were used to insulate the nuts and bolts from the specimens. The long axis of both types of specimens was parallel to the rolling direction of the sheet. Both types of bent beam specimens produced yield-strength stress levels in the outer fibers on the tensile side of the specimens.

Results

The corrosion behavior of the Zn-22Al material in 100% relative humidity at 120°F was not greatly affected by the presence of ammonia as shown by the results after exposure in both environments in Table III. Exposure to these environments resulted in the formation of an adherent gray film mottled with spots of white corrosion product. There was little tendency for spalling in these materials. A log-log plot of the weight-gain measurements for the tilt-mold material suggested that corrosion was following a cubic-rate law. Based on the weight-gain data, there did not ap-

Table III. Corrosion behavior of Zn-22Al material in 100% relative humidity at 120°F

380 Al alloy	No	131	105	97	110	0	3
380 Al alloy	Yes	100	116	124	125	0	3

[a] One area showing some intergranular attack was noted, but it was obviously an isolated occurrence.

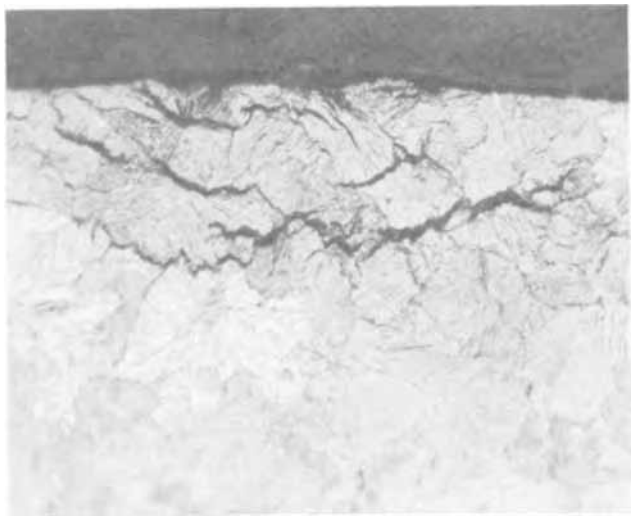

Fig. 3. Intergranular attack in the Zn-22Al sheet (tilt-mold material) after exposure to 100% relative humidity for 1000 hr. 345×.

pear to be a large difference in the rate of corrosion among the three Zn-22Al materials. All three were corroded to a lesser extent than the 380 aluminum alloy.

Metallographic examination of the corrosion samples after exposure showed two distinct types of attack, surface pitting and intergranular attack. The appearance of intergranular attack in a Zn-22Al material is shown in Fig. 3. Both types of attack were localized and were found under areas showing obvious corrosion product buildup. Measurements of the maximum depth of pitting and of intergranular attack after 1000 hr of corrosion are presented in Table III. The tilt-mold and chill-mold materials showed severe intergranular attack, but there was little evidence of this type of attack in the direct-chill material at the conclusion of 1000 hr of exposure. The aluminum alloy also showed intergranular attack. Pitting was about equally severe in the direct-chill and tilt-mold materials, but was not observed in either the chill-mold material or in the 380 aluminum alloy.

Backscatter scanning electron microscope studies suggested that intergranular attack in the Zn-22Al material was related to the presence of a zinc-rich grain-boundary phase. This technique readily distinguishes between zinc-rich and aluminum-rich phases. The zinc-rich phase fluoresces, appearing light in the micrographs, while the aluminum-rich phase remains dark. The appearance of the grain-boundary phase in the tilt-mold material is compared with that in the direct-chill material in Fig. 4. The chill-mold material also was found to contain a zinc-rich grain-boundary phase in the material adjacent to the surface. Zinc segregation in surface regions of these materials apparently occurred during casting and was not completely removed by scalping prior to rolling to sheet. Low aluminum, such as present in the chill-mold material, should have magnified this problem. The lesser depth of intergranular attack in chill-mold material was attributed to the form of the zinc-rich grain-boundary phase which, as shown in Fig. 5, was less continuous than that observed in the tilt-mold material.

After detection of intergranular attack in these materials, samples of the direct-chill and the tilt-mold materials previously exposed for 1000 hr in the 100% humidity environment containing ammonia were returned to the corrosive environment for an additional 500 hr to provide a total exposure of 1500 hr to determine if the depth of intergranular penetration would increase. Weight gains after 1500 hr were 62 and 80 mg/dm^2, respectively. Metallographic examination of these samples showed intergranular attack to a maximum depth of 4.4 mils in the tilt-mold material, not greatly different than the 4.2-mil depth of pitting observed after 1000 hr. A few intergranular penetrations were noticed after 1500 hr, up to 3.2 mils deep, in one side of the direct-chill material. Because of their localized nature, it is suspected that they resulted from a random high-zinc region rather than from the increased exposure time.

Cantilever-loaded bend samples of the Zn-22Al materials were stressed so as to produce measurable creep during exposure and were examined after 1000 hr of exposure to determine if stress accelerated intergranular penetration. Both the depth of pitting and the maximum depth of intergranular attack tended to be lower on the compression surface than on the tension surface, as shown in Table IV. Comparison with the data in Table III shows that stress did not increase the depth of intergranular attack in either the chill-mold or the tilt-mold material, but did result in intergranular attack in the direct-chill material which, in unstressed exposure, was relatively free of intergranular attack. Measurements of depth of pitting under stress did not compare well with those made on unstressed

samples. Based on one comparison, that for tilt-mold material, corrosion did not appear to affect the creep rate.

The corrosion product developed on zinc-base materials in a high-humidity environment containing sulfur dioxide is water soluble. As a result, as shown in Table V, the Zn-22Al material exposed to this environment exhibited a loss in weight. Pitting was more severe in this environment than observed in high-humidity environments free of sulfur dioxide. Based on depth of pitting, and on the weight gain measured for the 380 aluminum alloy, the sulfur dioxide-containing environment was more corrosive than the other high-humidity environments. However, no intergranular attack was observed.

The most corrosive environment examined was alternate immersion in a 3½% sodium chloride solution at room temperature as shown in Table VI. Heavy corrosion deposits were rapidly developed, and spalling occurred early in the test series. The weight gain exhibited by the 380 aluminum die-casting alloy was much greater than that observed in the two Zn-22Al materials. Although the difference was not large, the corrosion rate appeared somewhat greater in the tilt-mold than in the direct-chill material. Metallographic measurements suggested from 1 to 3 mils of general surface reaction occurred in the Zn-22Al materials during 1000-hr alternate-immersion exposure. Neither Zn-22Al material showed intergranular attack in alternate immersion, but deep surface pitting was observed. Metallographic examination of pits formed in Zn-22Al material showed some evidence of intergranular penetrations along the periphery of the corrosion pit. As shown in Table VI, severe intergranular attack was observed in the 380 aluminum alloy in this environment.

U-bend samples of the direct-chill and tilt-mold Zn-22Al materials were also exposed to alternate immersion in the 3½% sodium-chloride solution. The depth of surface pitting was less in the stressed condition, and no evidence of intergranular attack was observed as a result of exposure under stress.

Sheet material from the direct-chill ingot was also exposed to accelerated corrosion test environments in the superplastic condition, that is, prior to the final annealing treatment. In all cases, the amount of corrosion was less than that observed with annealed material as indicated both by weight gain and by visual appearance.

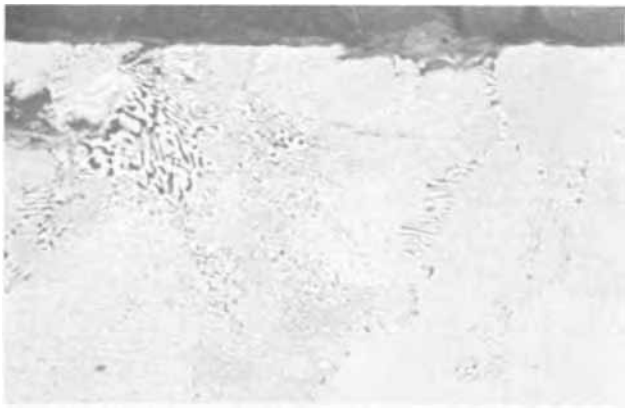

Fig. 5. Back-scatter scanning electron micrograph of the chill-mold material before corrosion exposure. 575×.

Conclusions

The conclusions resulting from these studies are as follows:

1. Zn-22Al sheet material in the nonsuperplastic use condition showed considerably less corrosion in several accelerated corrosion tests than did 380 aluminum die-casting alloy. The corrosion environments were 100% humidity at 120°F, including selected contaminants in two exposures, and alternate immersion in 3½% sodium-chloride solution. Alternate immersion was the most severe corrosion environment of those studied.

2. Surface pitting and intergranular attack accompanied corrosion. Intergranular attack was encountered in two of the three high-humidity environments studied, but not in alternate immersion. Intergranular attack appeared to be related to the presence of a continuous zinc-rich grain-boundary phase.

3. Stress did not increase the depth of intergranular attack in those materials showing this type of corrosion in unstressed tests, but did result in some intergranular attack in one Zn-22Al material which was relatively free of this attack in unstressed tests.

ABSTRACT

Aluminum was electrodeposited onto metallic substrates from a number of electrolytes consisting essentially of an $AlBr_3$ solute of commercial purity and technical grade alkyl benzene solvents or solvent mixtures.[1] Bright, fine-grained, adherent aluminum coatings were obtained at cathode efficiencies of the order of 70-85% and at anode efficiencies approaching 100%. Specific conductance of the electrolytes was 1-3 x 10^{-3} ohm^{-1} cm^{-1} while applied potentials of 3-6V provided current densities of 10 mA/cm^2. The most effective solvents were those of the ethylbenzene family. Ethylbenzene solvents are also effective in promoting plating with other solvents particularly benzene, toluene, and xylene. Technical grade solvents in equilibrium with atmospheric moisture were successfully employed throughout the tests.

Aluminum is in many ways almost ideal as a coating metal. While its coherent oxide film makes it highly corrosion resistant, it can be made even more resistant by anodizing it with coatings which may be dyed to attractive shades of color. Aluminum is a ductile metal with good electrical and thermal conductivities yet, by anodizing, a coating of higher insulating characteristics can be applied. It is not surprising, therefore, that many attempts have been made to deposit it onto other metals.

The electrodeposition of aluminum has proven to be extremely difficult and only limited commerical success has been attained. The principal reason is that aluminum, because of its high position in the electromotive series, is not easily deposited from aqueous solutions. Hydrogen gas is evolved before the applied potential is sufficiently high to deposit aluminum.

The well-known Hall process for the production of metallic aluminum avoids this problem by utilizing alumina dissolved in molten cryolite as the electrolyte. Similar fused-salt procedures have been devised for electroplating aluminum by which molten aluminum salts, usually the chloride or the bromide, are dissolved in various inorganic and organic salts such as potassium chloride, sodium chloride, and ethyl pyridinium bromide. Molten salt electroplating has not, however, found any large scale application due, most likely, to the complexity of the procedures and to uneven plating quality.

Some early investigators claimed that aluminum could be deposited from aqueous solutions (1-3). None of their findings could be verified, however, and no aqueous process has ever been successful. The analogy between ammonia and water led other workers (4) to attempt to electrodeposit aluminum from liquid ammonia. Again, no success was recorded from these systems.

It was soon recognized that moisture should be absent for the successful electrodeposition of aluminum. It was natural, then, to turn to organic solvents to provide a suitable room temperature electrolyte.

Investigations into aluminum electrodeposition from organic electrolytes up to 1967 have been comprehensively reviewed by Brenner (5, 6). In brief, the solvents and solutes employed to date can be classified as:

Solutes: (*a*) Aluminum halides.
(*b*) Aluminum organo compounds.

Solvents: (*a*) Ethyl bromide with or without an aromatic (7-14).
(*b*) Amino-aromatic (15-17).
(*c*) Ether (18-27).
(*d*) Amino or amide with or without ether (28-31).
(*e*) Aromatic (32-36).

The most successful electrolytes of each of these solvent groups are shown in Table I. All solvents and solutes used in the electrolytes, with the exception of the technical grade xylene used by Simanavicius were anhydrous and reagent grade.

As is indicated in Table I the electrolytes have been extremely reactive (ethyl bromide electrolytes), inflammable (ether and ethereal electrolytes), extremely sensitive to moisture or oxygen, or the plating quality has been rather poor. These drawbacks have prevented practical acceptance of the organic electrolytes.

It has been the object of the present work to continue the search for practical room temperature electrolytes for the deposition of aluminum.

Key words: aluminum, deposition, organic electrolyte, electrodeposition.

[1] Patent application filed (1970).

Table I. Summary of the most successful electrolytes based on previous solvent types

Type	Investigators	Solvent	Solute	Results and comments
Ethyl bromide	Blue and Mathers (10, 12)	Benzene Xylene Ethyl bromide	$AlBr_3$ $AlCl_3$	Gray aluminum deposits. Violent reaction during preparation. HBr evolution during electrolysis (18).
Amino-aromatic	Wier and Hurley (15)	Ethyl pyridinium Bromide + toluene	$AlCl_3$	Very conductive electrolyte but very sensitive to moisture and oxygen. Undergoes electrolytic decomposition (22). Deposits dark and brittle (18), solvent expensive.
Ether	Couch and Brenner (22)	Diethyl ether	$AlCl_3$ LiH	Excellent aluminum deposits. Electrolyte undergoes electrolytic decomposition (5) at the anode. Too inflammable for industrial uses.
Amino-ether	Menzies and Salt (31)	Butyl amino ether	$AlCl_3$	Bath difficult to prepare. Sublimation of the solute and complete exclusion of moisture from the solvent was required (31).
Aromatic	Simanavicius and Levinskiene (35, 36)	O-m-and P xylene	$AlBr_3$	Deposits were dark gray (36). Hydrogen evolution at the cathode.

Criteria for Potential Electrolytes

In choosing solvents potentially useful for plating aluminum, the two main criteria considered were: the ability of the solvent to dissolve an aluminum salt; and the ability of the electrolyte to release aluminum from its ion during electrolysis.

The dissolution of an aluminum salt into an organic solvent will take place through the formation of a mutual coordination bond between solvent and solute, *i.e.* the solute will act as a Lewis acid and the solvent as a Lewis base. Successful solvents will likely, therefore, be of this Lewis base type.

On the other hand, the electrolyte must be able to release aluminum from its ion during electrolysis and thus, solvents which can be used successfully to plate aluminum will be those containing relatively weak coordination centers (5), for example, the oxygen atom of an ether or the double bond of an aromatic hydrocarbon. Solvents with more unsaturated and hence stronger coordination centers such as nitrogen or carbonyl groups, will form too stable an aluminum complex, and aluminum will not be released from the complex upon electrolysis.

Solvents which have no coordination ability, *e.g.* aliphatic hydrocarbons, will not, however, form suitably conductive solutions.

The fact that aromatic hydrocarbons have suitably weak coordination centers and the evidence that some initial success had been obtained with xylene indicated that an investigation into alkyl benezene solvents would be in a logical direction. The most suitable solutes appeared to be the simplest, *i.e.* aluminum halides.

The investigation was centered upon finding practical electrolytes, and for this reason technical grade solvents and solutes were employed throughout the work.

Experimental

The experimental investigation was divided into two sections: (*a*) An exploratory program in which the suitability of a number of types of electrolytes for aluminum electrodeposition was investigated. (*b*) A more detailed study of two of the more effective electrolyte systems.

Exploratory Investigation

The exploratory investigation focused upon binary electrolytes consisting of an aromatic hydrocarbon and an aluminum halide, usually aluminum bromide. If the binary electrolyte appeared to be promising, a more common and less expensive solvent, *e.g.* benzene or toluene was added to the electrolytes and its behavior was tested.

In brief, the study consisted of a series of experiments in which aluminum was plated onto a copper cathode from an aluminum anode via the various experimental electrolytes. All experiments were carried out under near identical conditions so that the behavior of the electrolytes could be directly compared.

Apparatus.—The electrolytic cell consisted of a 180 ml electrolytic Pyrex beaker and a cover of transparent acrylic plastic (Fig. 1). The cover was machined and an "O" ring provided complete sealing of the cell.

The anode was 1 mm sheet aluminum in the form of a hollow cylinder 2 in. long and 1.27 in. ID, provided with regularly spaced 0.2 in. holes at ¼ in. intervals. An aluminum stem 5 in. long and ¼ in. wide held the anode in the beaker cover. A copper cathode 7 in. long, ½ in. wide, and 0.5 mm thick was placed centrally inside the anode.

Potentials applied during electrolysis were measured by a high impedence "Tacussel" (Solea, Lyon, France) electronic millivoltmeter Type 570AS, and currents

Table II. Summary of results of the exploratory investigation

Solvents	Gas evolution	Plating quality	Results and comments
Benzene	—	Nonmetallic	Only asphalt like material plated.
Bromobenzene	—	Nonmetallic	Only asphalt like material plated.
Toluene	None	Poor	Black deposits.
Xylene	H_2	Fair	Dark gray coatings.
Ethylbenzene	None	Very good	Cathode efficiency up to 80%.
Ethylbenzene-toluene (1:1)	None	Excellent	Improved electrolyte performance over ethylbenzene alone.
Ethylbenzene-benzene (1:1)	None	Good	
Ethylbenzene-xylene (1:1)	H_2	Good	
Ethylbenzene-cymene (1:1)	None	Good	
Ethylbenzene-bromobenzene (1:1)	None	Good	
Diethylbenzene	None	Very good	Cathode efficiency up to 75%.
Diethylbenzene-toluene (1:1)	None	Excellent	Improved electrolyte performance over diethylbenzene alone.
Diethylbenzene-benzene (1:1)	None	Good	
Triethylbenzene	None	Fair	Low cathode efficiency (20%).
Triethylbenzene-benzene (1:1)	—	Poor	Black coating.
Trimethylbenzene (mesitylene)	H_2	Good	Cathode efficiency up to 75%.
Trimethylbenzene-benzene (1:1)	H_2	Fair	
Tetramethylbenzene (durene)			
20% in toluene	H_2	Good	Durene is solid at room temperature.
20% in benzene	—	No plating	
Isopropylbenzene	None	Good	
Isopropylbenzene-benzene (1:1)	None	Good	
Isopropylbenzene-toluene (1:1)	None	Good	
Methylisopropylbenzene (cymene)	—	Poor	Black coating.
Cymene-benzene	—	No plating	

were recorded on a calibrated "Tacussel" milliammeter, Type MAR298.

Materials.—Copper cathode: Cold rolled copper sheet, manufactured to SAE71 (99.9+% copper). Aluminum Anode: Alcan aluminum sheet 2S grade (99+% aluminum). Aluminum Bromide: Anhydrous, technical grade. Alfa Inorganics Inc., Beverly, Massachusetts. Ethylbenzene: Technical grade. Matheson, Coleman and Bell, Norwood (Cincinnati), Ohio. Toluene: Commercial grade. Chemical division of the Esso Imperial Oil Company, Montreal. Benzene: Reagent grade. Fisher Scientific, Montreal. Diethylbenzene, Triethylbenzene, Trimethylbenzene, Cumene, Durene, Cymene, Xylene: Technical or practical grade. The Eastman Organic Chemicals, Rochester, New York. Argon: Technical grade, 99.99% Ar, 20 ppm N_2, 20 ppm O_2, 10 ppm H_2, L'Air Liquide Canada Ltée., Montreal.

Procedure.—The electrolyte was prepared by placing 50g of $AlBr_3$ in a dried electrolysis beaker followed immediately by the addition of 70 ml of solvent to give a solution of approximately 25 mole per cent (m/o) or 45 weight per cent (w/o) $AlBr_3$ for most electrolytes. A Teflon-covered magnetic bar was placed into the beaker, the cover and electrodes were fitted, and a flow of dry argon through the beaker was started. The solution was stirred until the $AlBr_3$ dissolved.

Contrary to the experience with the preparation of a number of previous electrolytes (18), no violent reactions occurred during preparation and no cooling was required.

The electrodeposition was carried out at 10 mA/cm^2 with 3-6V usually required to produce this current density. The plating was performed for 1½ hr while the solution was gently stirred. After electrolysis the cover was removed and the electrodes were immersed in a water and then an acetone bath. The electrodes were weighed before and after each experiment.

Operating conditions.—Conditions kept constant during the exploratory tests were: (*A*) Electrodes: Identical electrodes were used in all tests, immersed to the same depth in the electrolyte. The copper cathodes were cleaned in 1/3 HNO_3; 1/3 H_3PO_4; 1/3 CH_3COOH before all tests. (*B*) The electrolyte in each test was composed of 45 w/o $AlBr_3$ and 55 w/o solvent. Approximately 90 ml of electrolyte were used in each test. (*C*) Operating temperature: 25° ± 5°C. (*D*) Copper cathode immersion area: 10 ± 0.5 cm^2. (*E*) Current density: cathode current density was the operating parameter held constant in all exploratory tests. The current density was 10.0 ± 0.1 mA/cm^2 based upon the immersion area of the copper cathode at the beginning of each test.

Results.—The results of the exploratory tests are summarized in Table II. The appearance of the aluminum coatings from selected electrolytes is shown in Fig. 2. The thickness of the aluminum deposit on the ethylbenzene specimen is 0.5 mil.

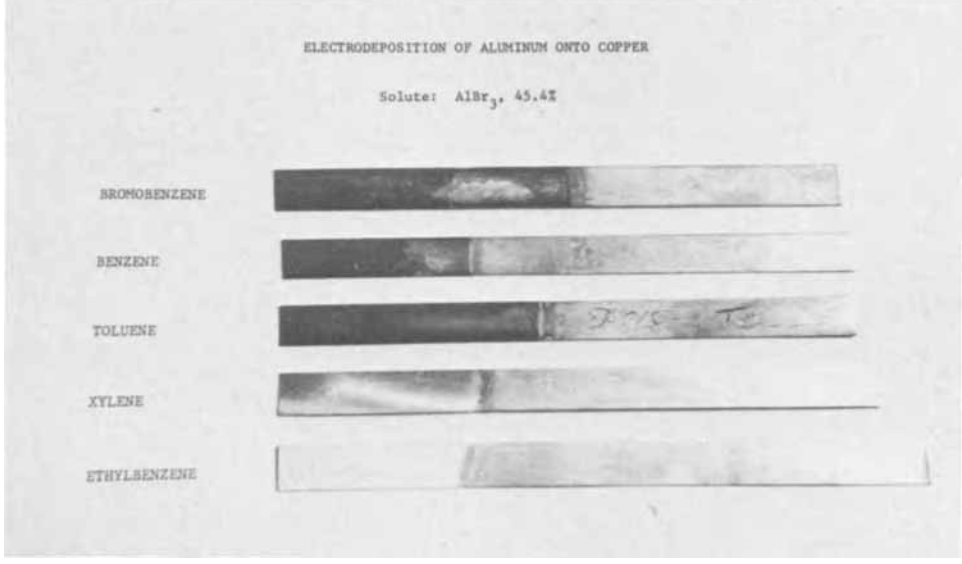

Fig. 2. Appearance of aluminum coatings from selected exploratory electrolytes.

The plating performance recorded in Table II is qualitative, and it has been estimated on the basis of appearance of the coating, its adherence to the substrate, and the consistency of performance of the electrolyte.

The tests clearly indicated that solvents in the ethylbenzene family are the most promising for aluminum plating. Plating quality has been the best with electrolytes based upon ethylbenzene and diethylbenzene, and a majority of electrolytes based on these solvents avoid gas evolution. Tests using alternative metal substrates (mild steel, brass, platinum, aluminum) were equally successful with these electrolytes.

Aluminum chloride and aluminum iodide were also tested in the exploratory program but both resulted in black deposits and cathode current efficiencies of less than 20%.

Detailed Study of Systems: Ethylbenzene-Xylene-$AlBr_3$ and Ethylbenzene-Toluene-$AlBr_3$

The ethylbenzene family of solvents was the most promising found during the exploratory experiments and thus a detailed study of ethylbenzene electrolytes was made. The main factors considered were plating quality, electrode efficiencies, and electrolyte conductivity, while the principal variables were electrolyte usage time, $AlBr_3$ concentration, and the effect of adding less costly solvents to ethylbenzene based electrolytes.

Apparatus.—The apparatus in the detailed study was similar to that in Fig. 1 with the exception that two flat aluminum anodes (1½ cm wide, 1 mm thick, and 18 cm long) were placed on either side of the copper cathode (1 cm wide, 0.5 mm thick, 18 cm long) through a Teflon cover. A 400 ml electrolysis beaker was employed, the usual electrolyte volume being 300 ml.

Conductivity determinations were made with a "Tacussel" direct reading conductimeter Type CD7A (Solea, Lyon, France) at a frequency of 5000 Hz using "Tacussel" conductivity cell CM .01/G. A silver coulometer was placed in series with the aluminum cell for determinations of electrode efficiencies.

Operating conditions.—The standard conditions in the detailed study were: (*A*) Electrodes: identical electrodes were used in all the tests. (*B*) Operating temperature: 25° ± 5°C. (*C*) Current density: cathode current density was the operating parameter held constant in all tests at 10 ± 0.1 mA/cm² based upon the immersion area of the cathode at the beginning of each test. (*D*) Plating time: 1½ hr starting with a new copper cathode. A plating time of 1½ hr at 10 mA/cm² with an anticipated 80% cathode efficiency would give an aluminum thickness of approximately 0.0005 in. United States Military Specification MIL-C-23217A (ASG) 1963 indicates that this thickness is the minimum coverage necessary for good corrosion protection.

The standard current density of 10 mA/cm² was chosen on the basis of a study (electrolyte: ethylbenzene-xylene 1:1; 53.4 w/o $AlBr_3$) of cathode efficiency *vs.* current density (Fig. 3). Each point in Fig. 3 represents a separate test in which 0.15 A-hr were passed starting with a new copper cathode. As shown in Fig. 3, cathode efficiency maximizes at a current density of about 10 mA/cm².

Results

An example result of the plating experiments is shown in Fig. 4 for the system ethylbenzene-$AlBr_3$. A graph of this type was obtained for each experimental electrolyte. Each point on the electrode efficiency curves represents an experiment of 1½ hr at 10 mA/cm² starting with a new cathode, and thus the graphs illustrate the performance of the electrolyte (under standard plating conditions) for considerable times of usage. The tests in Fig. 4 for example represent 42 hr total electrolysis time.

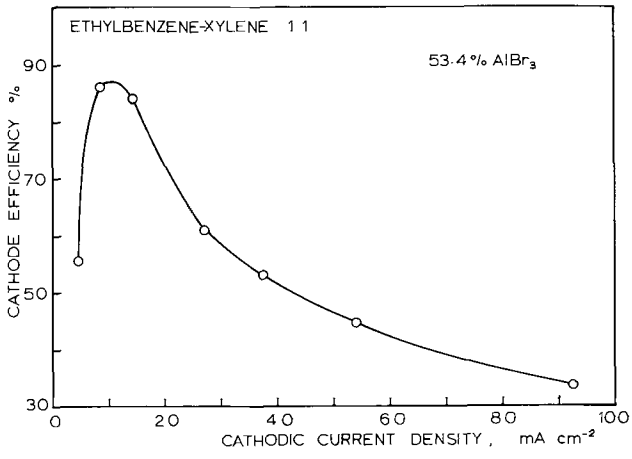

Fig. 3. Cathode efficiency as a function of current density; ethylbenzene xylene 1:1, $AlBr_3$ 53.4%.

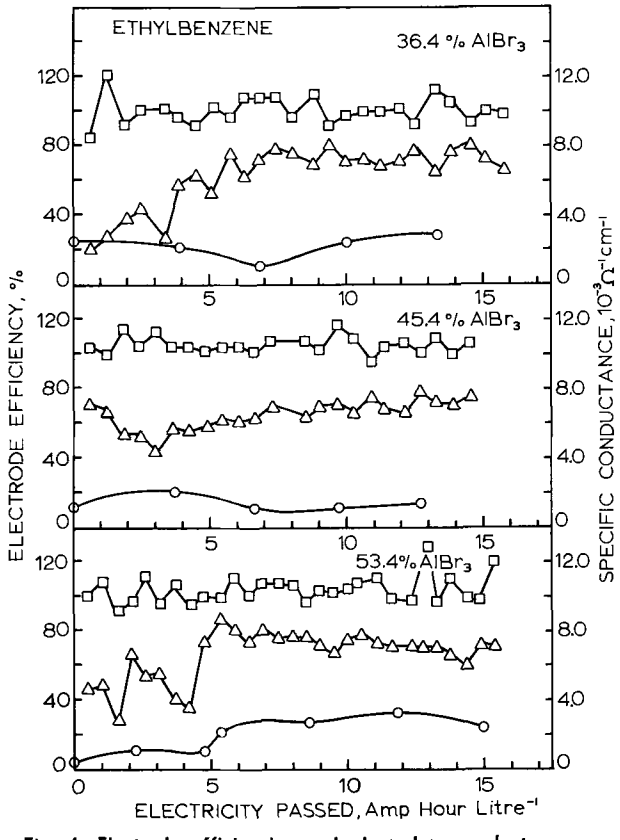

Fig. 4. Electrode efficiencies and electrolyte conductance as a function of electricity passed through electrolyte; ethylbenzene-$AlBr_3$ system. □ Anode efficiency, △ cathode efficiency, ○ specific conductance.

In common with all the electrolytes studied in detail, the anode efficiency is very nearly 100% with some scatter around this value. Cathode efficiency is much more variable, however, and a "working up" period of 3-4 hr is required before the cathode efficiency stabilizes, in this system, for example, at about 80% cathode efficiency. This "working up" period was not encountered in the case of the ethylbenzene-toluene electrolytes. The specific conductance of the electrolytes also required an initial period for stabilization. The performance of the electrolytes is summarized in Fig. 5-8.

It is clear that in terms of cathode efficiency the addition of ethylbenzene to toluene electrolytes markedly improves performance. Similar, though less pro-

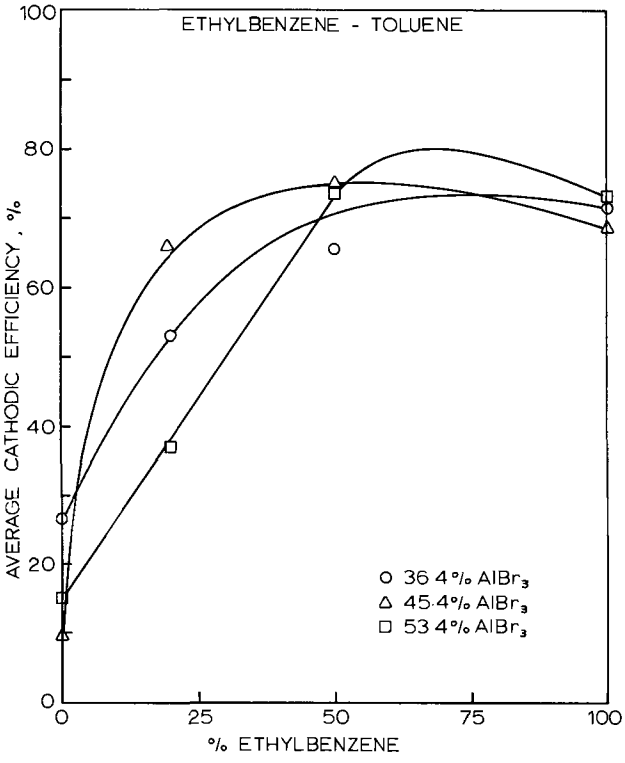

Fig. 5. Cathode efficiencies; ethylbenzene-toluene system

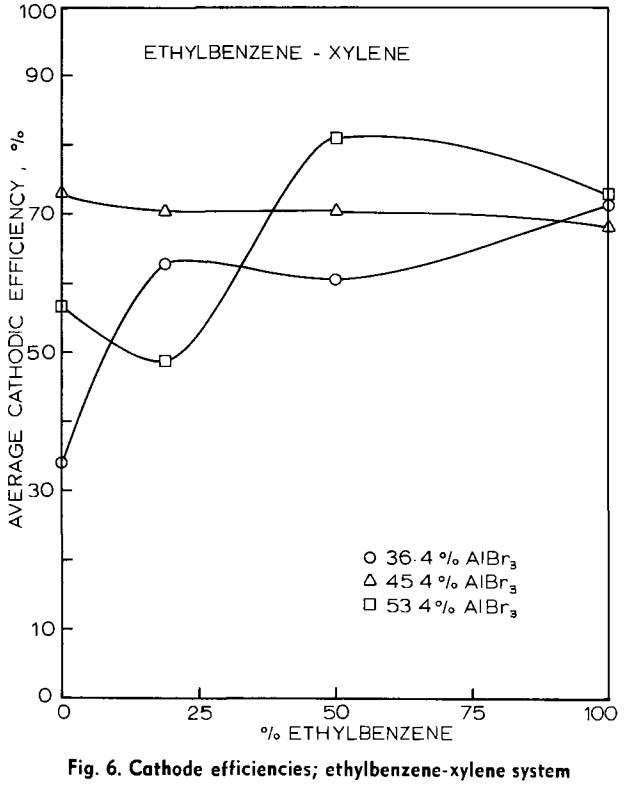

Fig. 6. Cathode efficiencies; ethylbenzene-xylene system

nounced behavior is obtained for the xylene electrolytes. Figure 7 shows, however, that there is some loss of electrolyte conductivity with the addition of ethylbenzene to toluene electrolytes. This means that the applied potential must be increased to maintain current density at a specific value.

The most marked indication of the effect of ethylbenzene was in plating quality from toluene electrolytes. Figure 9 shows that with toluene alone a very thin black deposit is obtained. On the other hand, an ethylbenzene-toluene electrolyte produces an attrac-

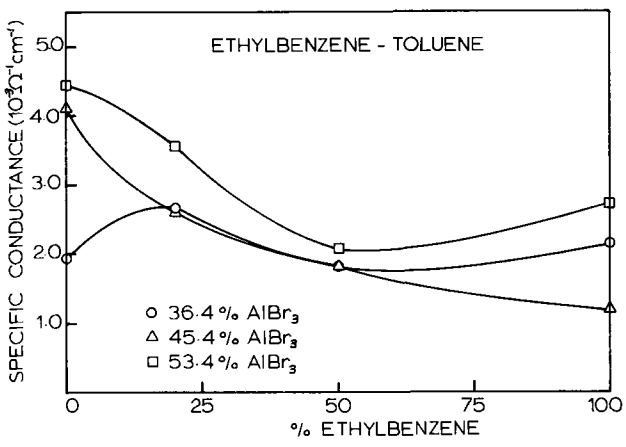

Fig. 7. Electrolyte conductance; ethylbenzene-toluene system

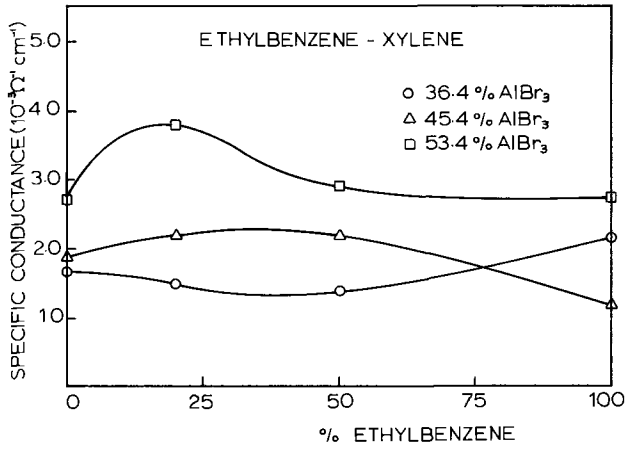

Fig. 8. Electrolyte conductance; ethylbenzene-xylene system

tive whitish gray aluminum deposit at 75% cathode efficiency. Figure 10 shows a similar though less pronounced situation for xylene electrolytes.

Comparison of the two systems indicates that the ethylbenzene-toluene electrolytes are preferable on the basis of quality of plating and the observation that hydrogen was evolved from each of the ethylbenzene-xylene electrolytes. Hydrogen evolution, though not as serious a problem as the evolution of HBr which had been obtained using ethyl bromide electrolytes, indicates a decomposition of the solvent, and places an upper limit on possible cathode efficiencies.

Plating quality.—The coherency of the aluminum coatings was tested by subjecting a number of aluminum plated samples to a bend test in which the aluminum plated samples were bent 90°, usually about 20 times, until failure. In all cases of plating from electrolytes containing ethylbenzene, the copper cathode broke before the aluminum layer became detached. The photomicrograph in Fig. 11 further indicates the excellent adhesion between the aluminum coating and the copper cathode (electrolyte: ethylbenzene-toluene 1:1, 45% $AlBr_3$). The thickness of the deposit in Fig. 11 is 0.5 mil. Other experiments at somewhat lower current efficiencies produced sound aluminum deposits of 2 mil thickness.

The grain size of the deposited aluminum (electrolyte: ethylbenzene-toluene 1:1, 45% $AlBr_3$) was analyzed by examining transmission-type x-ray diffraction spectra. The target aluminum coating was separated from the copper cathode by sanding off one side of the electrode to expose the copper base, and by then dissolving the copper in concentrated nitric acid. The resulting aluminum slice 1 cm wide, 5 cm long,

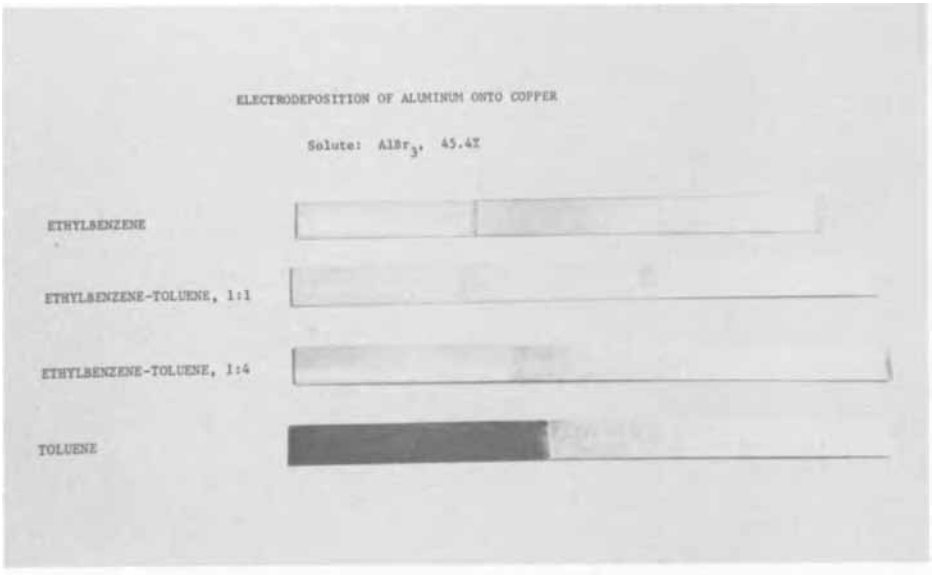

Fig. 9. Appearance of aluminum coatings; ethylbenzene-toluene system.

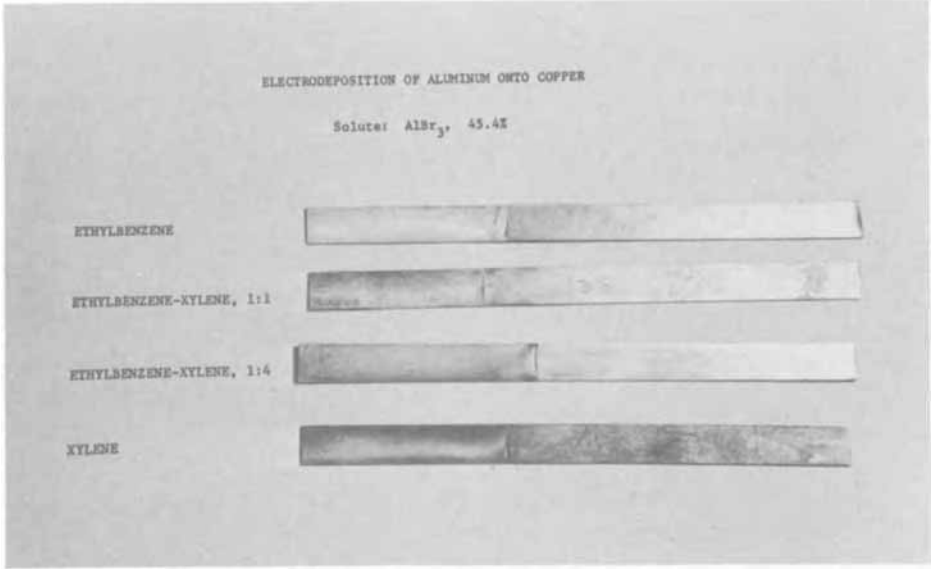

Fig. 10. Appearance of aluminum coatings; ethylbenzene-xylene system.

and 0.013 mm thick was exposed in a flat Phillips x-ray camera.

Figure 12 illustrates the resultant diffraction pattern in which the aluminum lines are clearly shown. The partially continuous nature of the lines indicates that the aluminum coatings are relatively fine-grained, *i.e.* in the order of 10^{-3} to 10^{-4} cm grain diameter. A spectrographic analysis of some aluminum deposits (electrolyte: ethylbenzene-toluene 1:1, 45% $AlBr_3$) showed that traces of metals more noble than aluminum present in the electrolyte were plated out on the first 2 or 3 cathodes. Subsequent coatings were of equal or higher purity than the anode material.

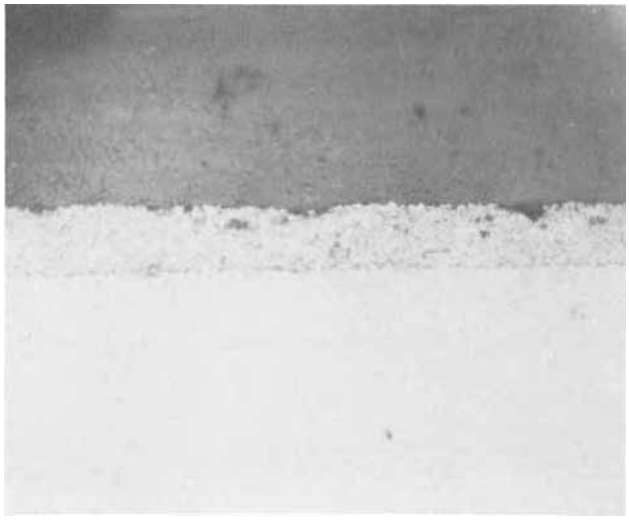

Fig. 11. Photomicrograph of aluminum coating on copper. Magnification 500X.

Discussion

Perhaps the most interesting result of the investigation has been that solvents which contain moisture can be successfully used in the electrolytes. There is some evidence which indicates that water is a beneficial component of the electrolyte as was demonstrated by a study of the system ethylbenzene-xylene 1:4 (45.4% $AlBr_3$) with the solvent in both anhydrous and hydrous form.

In the hydrous case (technical grade in equilibrium with the atmosphere) a good aluminum deposit was obtained at 5 applied volts. Attempts to plate aluminum from the same solvent, after drying overnight with P_2O_5 and redistillation, were not at all successful even after passing an electrical current for 20 hr. A reactive gas (presumably HBr) was evolved during the anhydrous experiment.

The electrolyte was a dark brown in the case of the moist solvent, while in the case of the dried solvent

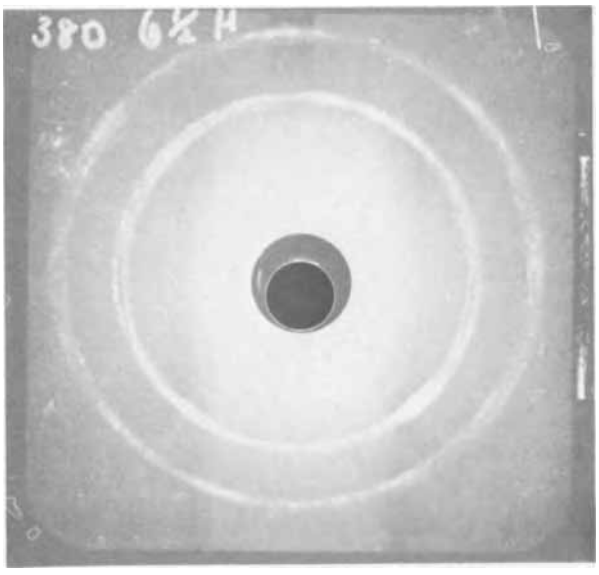

Fig. 12. Transmission x-ray diffraction spectrum from aluminum coating.

the complex was a scarlet color similar to that reported by Blue and Mathers (12) for the benzene-ethylbromide $AlBr_3$ system.

In addition the conductivity of the electrolyte from the hydrous solvent was considerably higher (some 5 times) than that of the anhydrous electrolyte, indicating that the presence of moisture improves electrolyte conductivity.

Mechanism of electrolysis.—Brown and Wallace (37) performed a series of vapor-pressure-composition-phase studies for the systems benzene-$AlBr_3$ and toluene-$AlBr_3$ from which they determined the existence of compounds of the type $Al_2Br_6 \cdot nArH$, where ArH represents an aromatic hydrocarbon. These authors attributed the conductivity of anhydrous organic solutions of these compounds to the formation of π complexes

$$Al_2Br_6 \cdot nArH \rightarrow \underset{(\pi \text{ complex})}{(Al_2Br_5 \cdot nArH)^+} + Br^-$$

Simanavicius and Levinskiene proposed a complex similar to the π type (36) and suggested that the mechanism of reduction of aluminum from solution for the system xylene-$AlBr_3$ involves the reaction

$$AlBr_2 \cdot nC_6H_4(CH_3)_2^+ + 3e^- \rightarrow Al^o + nC_6H_4(CH_3)_2 + 2Br^-$$

(π-type complex)

The equivalent anode reaction would be the reverse of the above equation.

In the present work, the presence of moisture in the solutions resulted in good aluminum plating and solutions of relatively high conductivity. It can be postulated that moisture in the system tends to displace bromine from the aluminum halide-aromatic compound due to the high affinity of OH^- for aluminum. For the case of ethylbenzene the complex formation would be of the type

$$2(Al_2Br_6 \cdot C_6H_5C_2H_5) + H_2O \rightarrow \underset{(\text{Hydroxy } \pi \text{ complex})}{(Al_2Br_4OH \cdot C_6H_5C_2H_5)^+} + Br^- + Al_2Br_7^- + \underset{(\sigma \text{ complex})}{(C_6H_5C_2H_5H^+)}$$

Thus, by this mechanism, the water would also act to form the σ complex previously reported (38, 39) to result from the reaction of HBr with aromatic hydrocarbon-$AlBr_3$ systems.

It is clear, however, that the quantity of moisture present in the solvent is insufficient to produce more than a limited concentration of hydroxy π complexes and σ complexes in the electrolytes.

Faced with the experimental result that anhydrous solutions of ethylbenzene-xylene (45.4% $AlBr_3$) failed to plate aluminum while hydrous electrolytes were successful, it appears that hydroxy π and σ complexes are essential to initiate the aluminum deposition even though they are present at low concentration.

The electrodeposition in the presence of moisture would be

$$C_6H_5C_2H_5H^+ + (Al_2Br_4OH \cdot C_6H_5C_2H_5)^+ + 6e^- \text{ ——— } 2Al^o + 4Br^- + H_2O + \underset{(\text{Ethylbenzene})}{2C_6H_5C_2H_5}$$

The anode reaction would be the reverse of this process.

The belief that the complexes formed from hydrous solvents are different from the anhydrous π complexes is reinforced by the fact that the color of complexes in the present work varied from brown to black as opposed to the red complexes previously reported for anhydrous electrolytes (12, 37). Further work has to be carried out to confirm this view.

It must be emphasized, however, that although water is a desirable ingredient in the electrolytes to a certain level, an excess of water will result in precipitation of the aluminum from the solution as $Al(OH)_3$, thus completely destroying the capability of the electrolyte.

Value of the electrolytes.—It would seem that the electrolytes presented in this paper are very promising, and that they warrant further investigation on a larger scale. The principal advantages are simplicity of preparation and cheapness of the solvents (technical-grade) along with good plating characteristics. In addition, the best electrolytes (for example ethylbenzene-toluene 1:1, 50% $AlBr_3$) give a uniform operation which is largely unaffected by changes in electrolyte composition or operating conditions.

Future work.—Experimental work to determine the most useful types of electrolytes is continuing and studies of mechanism and electrode potential have been initiated. Application of the electrolytes to the electrowinning of aluminum is also under investigation.

Conclusions

(*A*) A number of electrolytes, consisting essentially of an $AlBr_3$ solute and alkylbenzene solvents or solvent mixtures were developed for the electrodeposition of aluminum onto metallic substrates. Solvents of the ethylbenzene family appear to be the most useful for the electrolytes.

(*B*) Technical grade solvents and aluminum bromide of commercial purity are suitable for the electrolytes.

(*C*) Water up to a certain level is a desirable ingredient in the electrolytes as it improves electrolyte conductivity. Technical grade solvents in equilibrium with atmospheric moisture are good starting materials for the electrolytes.

(*D*) Extensive studies of ethylbenzene-toluene-$AlBr_3$ electrolytes and ethylbenzene-xylene-$AlBr_3$ electrolytes have shown that in both systems ethylbenzene improves electrolyte stability and plating performance.

Selective Electroless Metal Deposition Using Patterned Photo-Oxidation of Sn(II) Sensitized Substrates

J. F. D'Amico, M. A. De Angelo, J. F. Henrickson, J. T. Kenney, and D. J. Sharp

Western Electric Company, Engineering Research Center, Princeton, New Jersey 08540

ABSTRACT

Surface deposits containing hydrated Sn(II) species are generated when substrates are immersed in stannous chloride solutions, and then rinsed in water. These deposits, after a later immersion in an aqueous solution of $PdCl_2$, are capable of activating electroless plating baths to produce a metal deposit on the substrate. The Sn(II) species, however, can readily be photo-oxidized by exposure to ultraviolet light in air, yielding Sn(IV) and thereby destroying the latent catalytic surface. Thus, selective electroless metal deposits on a variety of substrates may be generated by exposure through an appropriate mask.

The generation of electroless metal photopatterns on dielectric substrates using an additive process called photoselective metal deposition (PSMD) was described in several earlier papers (1-4). Here we wish to present a more detailed explanation of the process chemistry, especially as it relates to the imaging capability.

PSMD combines conventional electroless (chemical) plating techniques (5, 6) with a photochemical imaging step; the substrate, sensitized with a divalent tin species and consequently catalytic to a chemical plating bath, can be rendered noncatalytic by exposure to ultraviolet radiation. Thus, positive images of a photomask can be generated on the substrate. The patterning capability extends to any metal for which a useful electroless plating bath is available; the present list would include Cu, Co, Pd, Ni, and Au.

Metal-patterned dielectrics have a variety of current uses, the most important of which, in terms of economic value, is the manufacture of printed wiring on a variety of both flexible and rigid substrates. In the current production, printed wiring is produced on Mylar, epoxy-composites, phenolics, or Kapton, with copper as the most widely used conductor. The present printed wiring technology is, by and large, based on a "subtractive" process; in its simplest form, a metal foil is laminated to the substrate, then selectively removed by an etchant to generate the desired pattern. The metal regions to be retained are protected by an etch resistant photo or printed mask.

Key words: pattern generation, photo-imaging, ultraviolet photochemistry.

An additive process such as PSMD can provide an alternative approach, useful in a variety of applications previously requiring resist and etch procedures. Moreover, in many applications a significant cost saving is possible since the cost of fabricating the initial metal-substrate laminate can be replaced by a less expensive plating of the PSMD pattern to build up the conductor. The PSMD process is applicable to a wide variety of flexible and rigid substrates and a broad range of metal deposition systems.

The Imaging Sequence

Substrates patterned by PSMD undergo the following basic steps, depicted schematically in Fig. 1:

(1) Substrate Preparation—The substrate is cleaned or etched as required to produce a clean and wettable surface.

(2) Sensitization—A light-sensitive layer containing Sn(II) species is deposited on the surface.

(3) Photo-Oxidation (Latent Image Formation)—Substrate is uv-light exposed in air through a mask. Exposed regions of the sensitizer are rendered inactive by photo-oxidation, while the unexposed regions retain their potential for subsequent activation of electroless metal deposition.

(4) Activation—On immersion into a solution of dilute $PdCl_2$, the unexposed regions of the sensitizer chemically reduce palladium ions to the metal, thus covering the active sensitizer sites with a micro-thin, discontinuous palladium deposit. Later this deposit will act to catalyze metal deposition. In the exposed regions, no Sn(II) sites remain, no palladium metal deposits, and thus no metallization can occur.

(5) Metallization—The surface is metallized by immersion in an appropriate electroless plating bath. When very thick deposits are required, an electroplating step may be added to increase the deposit thickness.

The PSMD process chemistry, as we reported earlier (1-4), follows the current technology for the blanket coating of plastics (5, 6). Thus, we will not elaborate on this aspect of the process, but will instead focus on how the light active deposits are formed (sensitization) and discuss various aspects of the photo-imaging reaction. Experimental details related to the sensitization and image formation are given in the Appendix.

Sensitization

The metallization of dielectrics requires the presence of catalytic sites at which the reduction of metal ions from solution may be readily initiated. Moreover, in useful electroless plating systems, the deposition, once begun, must be autocatalytic so that the metallization may continue after overcoating of the catalyst.

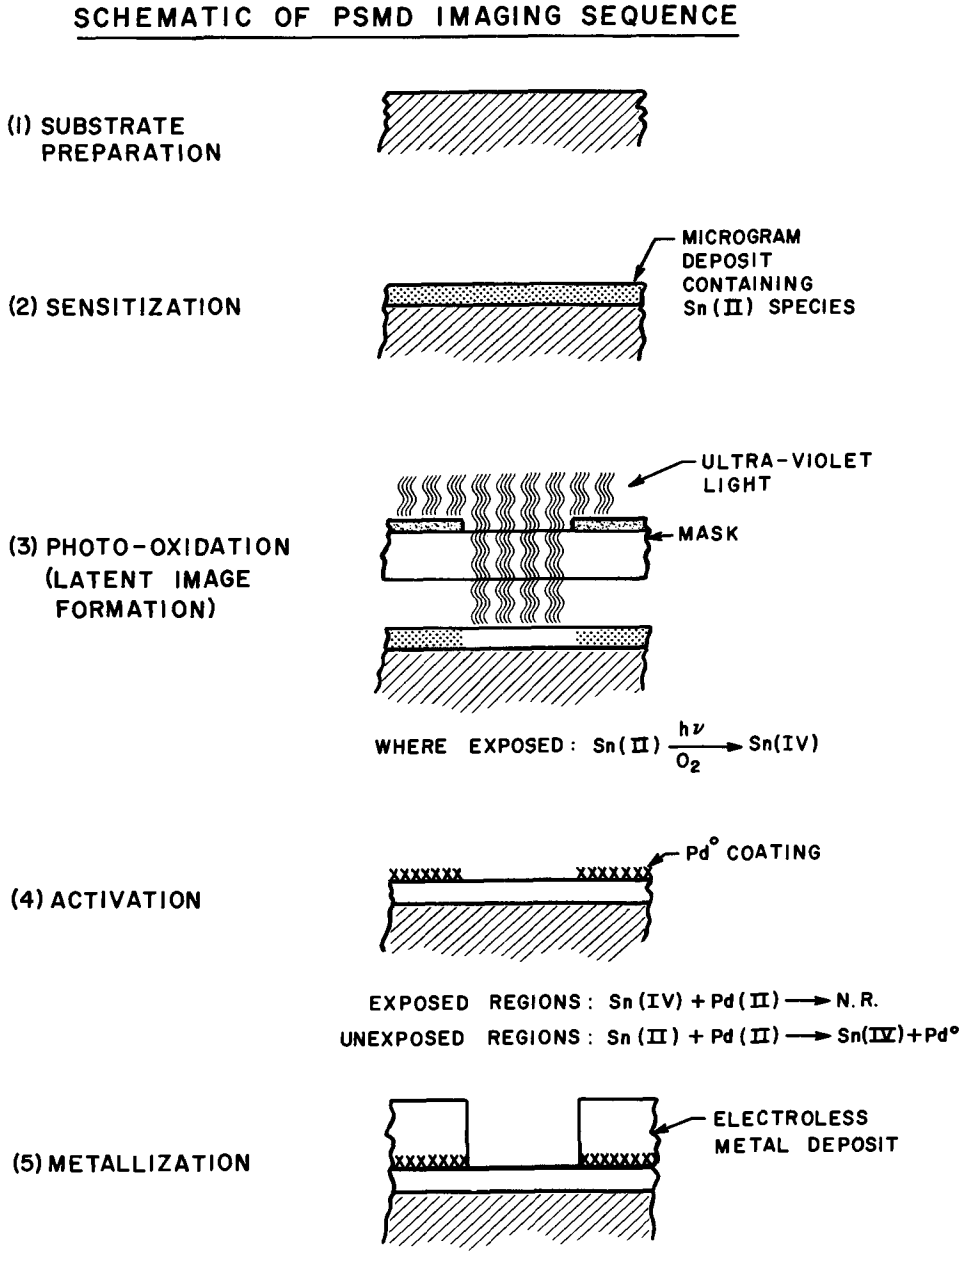

Fig. 1. Schematic of PSMD imaging sequence

The catalytic sites are usually provided by pre-application of a micro-deposit of a suitable metal referred to as the "activator." Palladium, gold, silver, and platinum have proved useful as activators for electroless baths (5), palladium being by far the most widely used.

The morphology of sensitizer deposits from solutions similar to those used in PSMD (we cite a typical formulation below) has been reported by several investigators, *e.g.* Marton and Schlesinger (7), Sard (8), and Sewall (9). Electron microscopy studies (8) show a typical sensitizer deposit to be composed of a particulate matter with the smallest resolvable particles 10-20Å in diameter and a tendency for these particles to agglomerate into clumps on the order of 50-100Å in diameter. The surface coverage of the deposits is found to be on the order of 50% to 70%. The activator deposits were found (7, 8) to replicate the sensitizer, and in turn, the depositing metal replicates the activator. The metal deposit then grows outward to cover the substrate and build up the conductor.

The generation of useful conductor deposits can be accomplished using a very wide variety of chemical formulations and process conditions, as is evident in reviewing the literature (10). This latitude becomes somewhat narrowed, however, if the generation of images rather than a blanket substrate metallization is desired. In PSMD, for example, the sensitizer deposit uniformity, and likewise its optical properties become important. The result is that somewhat more careful attention must be given to the process chemistry and associated preparative procedures than is customary in the current technology.

A typical sensitizer solution (10g of reagent grade $SnCl_2 \cdot 2H_2O$ and 10 ml conc HCl in a liter of water) is 0.044M in Sn(II) and 0.1M in HCl. The sensitizer deposit is formed by a brief immersion of the substrate into this solution followed by a gentle rinse in deionized water. This procedure generates an adherent deposit containing microgram/cm^2 quantities[1] of both divalent and tetravalent tin species. The tetravalent tin is the result of air oxidation of the reagent $SnCl_2 \cdot 2H_2O$ plus oxidation of divalent tin in both the solution and in the sensitizer deposit. The structure of the sensitizer deposit has not yet been fully determined; on polyimide (du Pont Kapton), however, it appears quite similar (11) to colloids formed in the sensitizer solution on standing. For our purpose, we will consider the active sensitizer species as consisting of a hydrated stannous oxide.

Our studies on the mechanics of the sensitization show that the deposit is the result of two distinct processes: (*a*) colloid formation in solution which is a consequence of air oxidation and hydrolysis of the divalent tin chloride, and (*b*) precipitation of soluble tin species from the liquid layer adhering to the substrate due to the rapid *p*H increase during the subsequent water rinse (1, 2). The interrelation of factors (*a*) and (*b*) and likewise the structural and chemical details of the generated sensitizer films depend very greatly on such solution factors as *p*H, concentration, and age. They also depend upon the substrate and its preparation, and finally on how the immersion and rinsing process is executed.

In generating the tin deposits, it is important that the aqueous sensitizer solution wets the substrate, otherwise a uniform sensitizer film will not be produced. When the substrates are hydrophobic, special pretreatments such as chemical etching may be available to render the surface hydrophilic and produce the desired wetting. An alternative is the use of a new class of wetting promoters (12) which permit the photosensitizer to be uniformly deposited on virtually any surface.

[1] Analytical determinations of total tin weight were made using x-ray fluorescence. This method was also used to determine palladium.

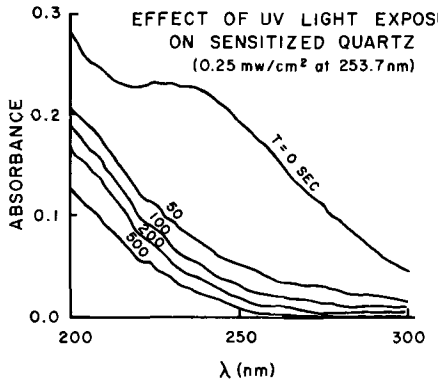

Fig. 2. Effect of uv light exposure on sensitized quartz (0.25 mW/cm^2 at 253.7 nm).

Photo-Oxidation (Latent Image Formation)

The image generation involves photo-oxidation of the divalent tin components of the sensitizer to their tetravalent state, thus rendering the substrate "noncatalytic" for metallization in those areas not shadowed by the photomask. The model which we proposed in the preceding section, namely, a photo-oxidation of Sn(II) plus galvanic reduction of palladium ions to the metal by the remaining Sn(II) is supported by considerable experimental evidence which is presented as follows:

(*A*) Early observations of the uv absorption spectrum of the sensitizer deposits on quartz (see Fig. 2) showed a systematic reduction in absorbance upon exposure. A similar behavior had been observed for dilute stannous chloride solutions in ~0.1M HCl. For these solutions, the uv absorption spectrum upon irradiation was found to approach that of an equally concentrated stannic chloride-HCl solution, indicating that the effect of the light was a conversion of the Sn(II) species to Sn(IV). A similar conversion of Sn(II) in the sensitizer deposit was assumed, despite likely differences in the exact species involved.

(*B*) More recent analytical determinations for Sn(II) in the sensitizer deposits on Kapton have been made using microcoulometry (13) and Mössbauer spectroscopy (11). Upon uv exposure in air, the fraction of Sn(II) was found to be systematically diminished or even reduced to zero depending upon the extent of exposure. A corresponding decrease in the palladium deposit[1] after activation of the exposed specimens was also observed.

(*C*) Solutions found to be active for catalyzing metallization were also found to contain a detectable concentration of Sn(II) (14). When solutions in which Sn(II) was no longer detectable were used for sensitization, no metal deposits could be generated. At the same time, the total tin weight[1] in the deposit remained undiminished.

(*D*) The Mössbauer spectra (11) show an essentially quantitative conversion of Sn(II) to Sn(IV) after the sensitized substrate is immersed for 30 sec in the palladium chloride activator solution. Thus, the palladium is reduced by the Sn(II) rather than merely adsorbed, as has been suggested as an alternative mechanism (15).

(*E*) The presence of oxygen is required for imaging. Light exposure in argon, in wet and dry nitrogen, and in vacuum did not deactivate the sensitizer (on Kapton). The extent of reaction (based on extent of image development at constant light exposure), on the other hand, was found to be quite sensitive to the partial pressure of the ambient oxygen.

We expect that the basic imaging characteristics for a given weight and type of sensitizer deposit should be independent of the substrate used. However, as we have already stated, the type and condition of the

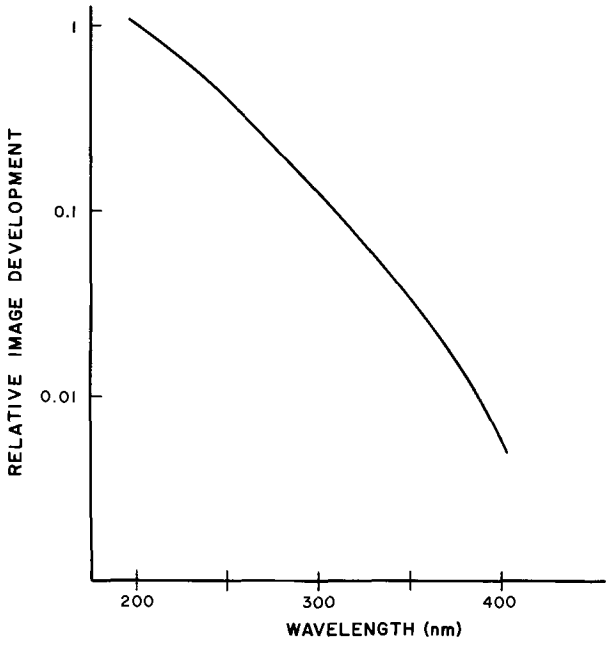

Fig. 3. Relative image development vs. wavelength. Light intensity constant at 0.2 mW/cm^2.

substrate surface can affect the nature of the tin deposit; thus potential substrate effects must be taken into account in the discussion and evaluation of the imaging.

Thus far, we have made PSMD images in copper on several substrates: Kapton, quartz, Mylar, glass, and several epoxy materials. Our most extensive evaluation of the imaging has been carried out on 2 and 3 mil Kapton which was processed as described in the Appendix. For this system, representative optical properties were found as follows:

(*A*) Relative Spectral Response, Fig. 3—These results are based on measurements of the light energy required at each wavelength to produce (approximately) complete image development.

(*B*) Incident Light for Image Development—22 millijoules/cm^2 at 254 nm, light intensity at 0.2 mW/cm^2. This energy is comparable to that required by KPR photoresist.

(*C*) Light Intensity Dependence—Over the useful wavelength range, the extent of image development was found to be nonlinear with respect to the incident light intensity (*i.e.* the reaction does not follow a photographic reciprocity law). The image development was found proportional to the nth power of light intensity, where $1/2 < n < 1$, implying that the photoactivated species participate not only in the tin oxidation, but also in one or more side reactions which do not contribute to the image development (16).

Conclusion

We have shown that dielectric substrates sensitized with Sn(II) species can be photo-oxidized by uv light exposure, and that this reaction can be used for generating electroless metal images. The process can be applied to produce a variety of components such as printed wiring, electroformed metal piece parts, fine metallic grids, photomasks. The method of fabrication and the process chemistry can be selected and adjusted to optimize each application. Both batch and continuous processing applications of this process have been successfully produced in our laboratory (1-4).

At present, the PSMD process technology is being rapidly expanded for use with a wide variety of substrates and pattern configurations, devoted mainly to the topic of printed wiring applications. In addition, basic studies of the important process steps are being carried out and will be reported in the near future.

Acknowledgments

The authors gratefully acknowledge the support and encouragement of many of our co-workers throughout the initial PSMD process development. Special acknowledgments are due to D. M. Lando and F. A. Litt for invaluable technical discussions, and to A. M. Ferrara, R. V. Dafter, R. M. Higgins, and B. R. Bell for technical assistance. We would also like to acknowledge the valuable services of D. A. Green who developed and calibrated the x-ray fluorescence methods for the tin and palladium analyses and performed many of the early determinations.

Manuscript received April 7, 1971; revised manuscript received June 3, 1971. This is a condensation and updating of Paper 136 presented at the Detroit Meeting of the Society, Oct. 5-9, 1969; and Paper 262 presented at the New York Meeting of the Society, May 4-9, 1969.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

APPENDIX

Experimental Procedures for Sensitization and Copper Imaging of Polyimide (Kapton) Substrates

Sensitizer Solution: 10g $SnCl_2 \cdot 2H_2O$ (Reagent Grade), 10 ml conc HCl/liter of deionized water.

Activator Solution: 0.5g $PdCl_2$, 5 ml conc HCl/liter of deionized water.

Substrate Preparation: Substrate etch in 10*N* NaOH, 10 min. Deionized water rinse, 10 min.

Sensitization: Immerse in Sensitizer Solution, 3 min. Deionized water-rinse, 5 min. Dry in nitrogen jet.

Exposure: Useful uv light sources: Low pressure Hg lamp (essentially monochromatic at 254 nm), high pressure xenon arc for continuum uv source. Photomasks: nichrome on quartz.

Activation: Immerse in activator solution, 30 sec. Water rinse, one min.

Metallization: Immerse in proprietary electroless copper 1.5 to 15 min as desired. We have found a number of proprietary solutions to be satisfactory, among them are solutions marketed by Enthone, Photocircuits and Shipley.

Electrochemical Delineation of Tungsten Films for Microelectronic Devices

Werner Kern* and J. M. Shaw

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

A process is described for delineating high resolution patterns in tungsten films on semiconductor device wafers. The process is based on high-speed anodic dissolution in alkaline ferricyanide electrolyte of exposed tungsten on a photoresist masked wafer. Slow chemical etching in the same solution occurs simultaneously with the electroetching to remove isolated residual areas of tungsten. The effects of important process variables are discussed, and optimized conditions are presented. The process is capable of accurately defining patterns in several-micrometer thick tungsten suitable for metallization and intraconnection patterns on transistor and integrated circuit wafers The technique is also suitable for patterning tungsten and molybdenum foils. The capability and applicability of the process is illustrated with photomicrographs of representative devices.

One of the steps in the fabrication of silicon integrated circuits is the formation of the metal patterns which serve to contact and intraconnect both the active and passive elements of the circuits. Aluminum is used most frequently for this purpose, but tungsten offers several significant advantages. Chemical vapor deposition of tungsten films from tungsten hexafluoride for microelectronic device applications has been described recently by Shaw and Amick (1). The present paper is concerned with delineating the high resolution patterns required to make these films useful as a metallization system for modern microelectronic device technology.

Tungsten can be etched with solutions of alkaline potassium ferricyanide, ammonium persulfate, hot hydrogen peroxide, or mixtures of nitric acid and hydrofluoric acid (2-4). Anodic dissolution of tungsten in strong sodium hydroxide solution is used to etch tungsten wire and to sharpen tungsten probes (2). However, etching simply to remove material or to polish the surface, and etching to delineate high precision patterns in films, are quite different problems.

Originally, we delineated device metallization patterns in tungsten films by chemical etching techniques. Severe problems were encountered with photoresist undercutting, poor pattern definition, and nonreproducibility of the etching. In the search for a better solution, we found that the anodic etching of tungsten films in caustic solutions can yield much better results than chemical etching. Development and optimization of this approach led to the present process which meets all normal requirements for pattern delineation in device metallizing. Transistor and integrated circuit metallization patterns in tungsten films now compare favorably with the best patterns of standard aluminum films produced in factory processing.

* Electrochemical Society Active Member.

Key words: etching, metallization, transistors, integrated circuits, sealing.

Description of the Process

Figure 1 shows a schematic diagram of the electrolysis circuit of the etching system. A photograph of the assembled laboratory apparatus with its associated equipment is presented in Fig. 2. The etch solution, prepared by combining separate stock solutions of appropriate concentrations, consists of the following mixture dissolved in deionized and distilled water:

5 w/o (weight per cent) potassium hydroxide (KOH pellets, 85%, cp)
5 w/o potassium ferricyanide ($K_3Fe(CN)_6$ crystals, cp)
1 w/o Tergitol[1] nonionic XD surface active agent.

The solution is vigorously agitated with a magnetic stirring rod during etching. A platinum sheet serves as the cathode. The tungsten-coated device wafer is first patterned with a suitable photoresist, such as KTFR (Kodak Thin Film Resist) by standard techniques. It is held in the reverse action tweezers shown in Fig. 3 so that the exposed anode contact touches the tungsten film on the wafer. Before applying a potential, the wafer is introduced into the electrolyte solution until it is completely submerged. Immediately following introduction in the bath the current density is adjusted to about 200 mA cm^{-2}. The progress of etching is monitored with a milliammeter as indicated in Fig. 1. The dual-channel current and voltage chart recorder[2] shown in Fig. 2 is a useful optional accessory. When the electrolysis current has dropped to 20-30% of its initial value, the wafer is pulled out of the bath and rinsed in water. The wafer is released from the holder, dried by centrifuging at low speed, and examined under the microscope for completeness of pattern etching. Additional etching is sometimes required to remove incompletely etched spots of tungsten or to sharpen up the definition of some parts in

the pattern. This is readily accomplished by immersing the wafer in the electrolyte, which now serves as a slow chemical etch, for an additional brief period of typically 5-10 sec with no potential applied. The photoresist mask is next stripped away with a suitable agent.[3] The wafer is rinsed in 6*N* HCl for several minutes and finally in deionized and distilled water.

Discussion

Shortcomings of chemical etch techniques.—The pattern delineation of tungsten films is based on selective masking with photoresist followed by removal of the exposed film regions. Removal by chemical etching is possible, but the definition of the resulting pattern is not sufficient for microelectronic circuit fabrication. The reason for this shortcoming lies mainly in the relatively poor adherence of the photopolymer resist films to the tungsten surface, resulting in undercutting with consequent degradation of the metal pattern. This situation is aggravated during prolonged exposure to etchants, or by the high temperatures required with chemical etchants that attack tungsten slowly. Attempts to improve the resist adhesion by changing the photoresist and etch processes, or by modifying the tungsten surface prior to etching were unsatisfactory. For best results, etching time must be minimized. Increases in the temperature and concentration of the chemical etchants minimized this exposure time by

[3] Hot chromic-sulfuric acid mixture is excellent for this purpose and does not attack the tungsten. Alternatively, less dangerous hot organic photoresist removing agents can be used, such as A-20 stripping solution, Electronic Grade, No. 2695 Baker & Adamson.

Fig. 2. Electroetching apparatus

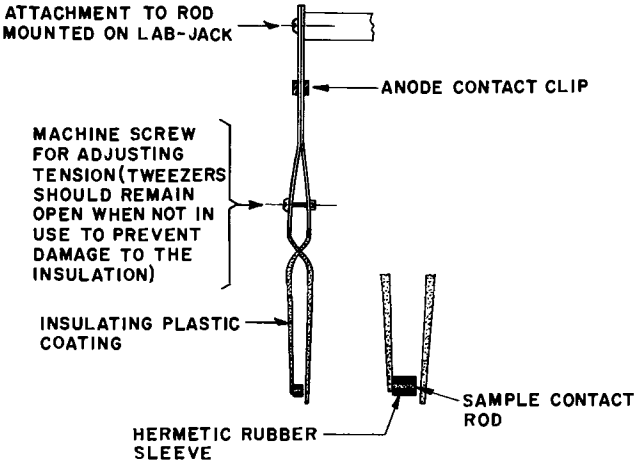

Fig. 3. Wafer holder and anode contact

speeding up the dissolution rate as expected, but also increased the rate of attack at the tungsten/polymer interface and made it difficult to stop the reaction precisely on completion of the etching.

Principle of electrolytic etch process.—For these reasons electrolytic etch methods with alkaline and acid electrolytes were investigated as a means of increasing the etch rate and to make the etching process self-limiting. However, a purely electrochemical process would be difficult to use because completion of the pattern delineation would have to coincide with beginning film discontinuity. Etching with a solution of a composition that effects both electrochemical etching at a high rate and chemical etching at a low rate was therefore chosen as the basis of tungsten removal.

Composition of the etch solution.—Strong caustic solutions containing ferricyanide were found best for this dual etching process. They are effective both as electrolytes for the anodic oxidation and for the direct chemical dissolution of the tungsten. Alkaline solutions are preferred over acids because of the greater solubility of tungsten salts at high *p*H, and because tungsten surfaces become passivated less easily in

alkaline media. Potassium hydroxide is preferable to sodium hydroxide from a standpoint of device contamination. Potassium ferricyanide also acts as an effective electrode depolarizer.

The addition of a suitable surface active agent was found beneficial. A low foaming, nonionic, water soluble, and alkali resistant surfactant compound which meets these requirements was selected from the polyalkylene glycol-ether types. The presence of this agent was found to improve the uniformity of the etching, to prevent the formation of tungsten islands, and to aid the electrolyte solution in wetting and penetrating into the smallest recesses of the photoresist patterns. Concentrations of mixture components were adjusted to yield a composite electrolytic plus chemical etch rate for optimum pattern etching.

Apparatus.—The special holding fixture shown in Fig. 3 was designed to allow submerging the entire device wafer in the electrolytic etch bath while making a sealed, insulated electrical contact between the tungsten film and the anode. The tungsten area that is covered by the tweezer contact, and that consequently will not be pattern etched, is typically a circular area of less than ⅛ in. diameter. For complete wafers this represents a very small loss in device yield, especially since the contact can be located near a wafer edge.

The electroetching apparatus was designed to afford simple, fast and accurate control over the process. A dual-channel current and voltage recorder with a chart speed of 6 in. min^{-1} was used for accurately following and recording the progress of the etching during development of the process, but the instrument is not required for routine etching applications. A dry cell or commercial d-c regulated power supply can be used as an external source of electromotive force.

Etch rate as a function of current density and type of tungsten.—Initial etching parameters were studied using smooth tungsten foils whose edges and backsides were masked, leaving exposed an area of 2.00 cm^2 on one surface. A minimum etch time of 100 sec was used and a minimum quantity of 25 mg of tungsten was removed per test to obtain reliable data. A fresh etch solution was used for each experiment. The uniformity of tungsten removal over the sample was monitored by thickness gauging, and the exact quantity of tungsten removed was determined by weighing on an analytical microbalance. A plot of typical data showing the etch rate at 25°C as a function of current density is presented in Fig. 4. The intersection of the linear curve with the abscissa at zero current density represents the chemical etch rate in the same etch bath for the same stirring conditions. The total etch rate at 25°C and at a current density of 200 mA cm^{-2} (of exposed tungsten area) is 380 Å-sec^{-1} of which 50 Å-sec^{-1} is by chemical dissolution. Electrochemical etching at this current density is thus approximately 87% by electrolytic action and 13% by chemical dissolution. The current efficiency of oxidizing the tungsten metal to hexavalent tungsten under these conditions is practically 100%. It is also seen from Fig. 4 that the tungsten foil and the tungsten deposited by chemical vapor reaction (1) etched at the same rate.

Smooth voltage and current curves were obtained up to 250 mA cm^{-2}. Higher current densities led to instabilities which appear to be caused by electrode polarization that, for the potassium ferricyanide concentrations used, becomes important at this threshold value. A value of 200 mA cm^{-2} was therefore chosen as a practical and controllable current density for the process.

Etch rate as a function of stirring, temperature, electrode spacing, and electrolyte composition.—Vigorous stirring is required to obtain reproducible etching. The positioning and spacing of the electrodes in the bath did not appreciably affect the electrolysis current, nor

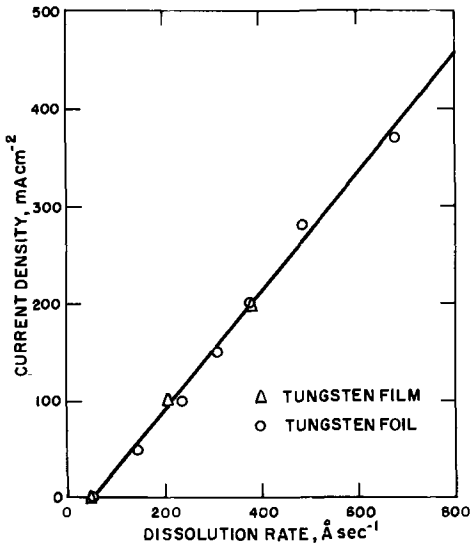

Fig. 4. Dissolution rate of tungsten foil and CVD film as a function of current density. Point at 0 mA cm^{-2} is the chemical etch rate; the line shown represents the total of the chemical and the electrolytic etch rates.

did changes of ± 5°C from the normal 25° bath temperature.

The effects of bath concentration on the electrolysis current and voltage stability were studied with concentrations of double, one-half and one-third of the concentration normally used. Increasing the concentration increased mainly the chemical etch rate, whereas dilution by two-fold or more caused electrolysis instability.

Termination of electroetching.—The approaching endpoint of electrolytic etching is manifest by the following changes: (*a*) an abrupt drop in current flow, (*b*) an abrupt rise of voltage, (*c*) a visually observable clearing of the metallization pattern, and (*d*) formation of oxygen bubbles on the device wafer. The most readily monitored criterion is the decrease of the current flow as measured with the ammeter. With the use of a strip chart recorder the etching process can

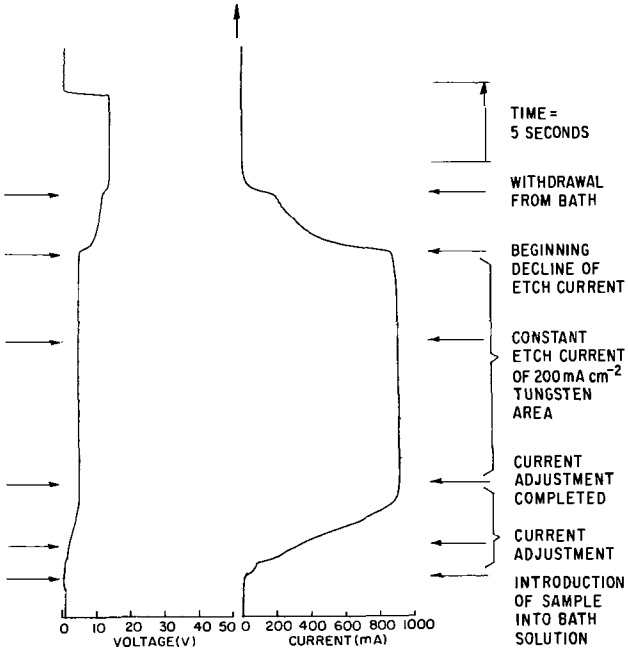

Fig. 5. Voltage and current recording obtained during electroetching a typical tungsten metallized device wafer.

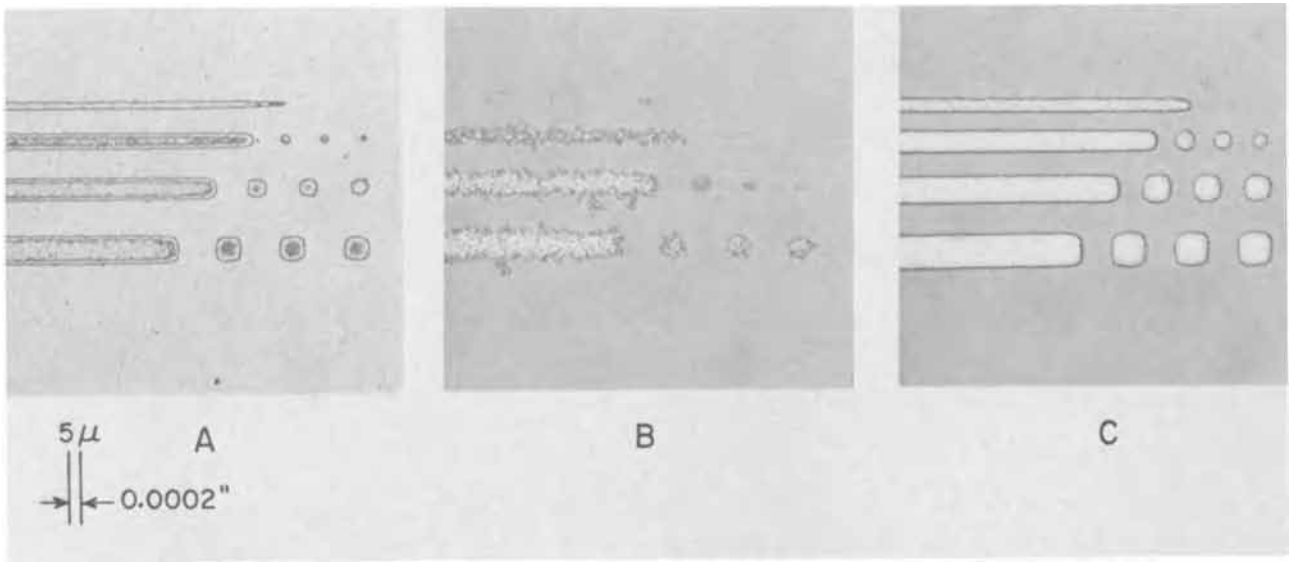

Fig. 6. Test patterns for tungsten etching resolution. A. Original photoresist pattern on tungsten film; B. Chemically etched pattern; C. Electroetched pattern.

be conveniently followed and traced for later reference or analysis. A typical current and voltage recording as a function of etching time obtained during the patterning of a 6000Å thick tungsten film is presented in Fig. 5. Etching proceeded at a uniform current density for 15 sec. The beginning decline of the current flow indicates that the continuity of the tungsten film is just becoming disrupted, meaning that the etching of the individual pattern parts is nearly completed. It can be seen from the curve that the steep decline in the current flow becomes less steep at about 50% of the full etch current. For optimum pattern resolution the best time to remove the wafer from the etch bath is at a value of 20-30% of the full electrolysis current. However, very accurate timing of the process is not necessary, since the "high-speed" electroetching stops automatically when the pattern becomes discontinuous.

Pattern resolution as a function of etching parameters.—The resolution of tungsten patterns obtained under various process conditions was tested with tungsten films of 5000Å thickness deposited on oxidized silicon wafers by chemical vapor phase reaction (1). Precision test patterns having lines and squares two, three, four, and five ten-thousandths of one inch width were used with standard KTFR processing. The surfactant in the etch solution was found to yield considerably cleaner patterns, free of grainy, residual tungsten islands observed without it. Photomicrographs of test patterns processed by the electroetching process *vs.* samples processed by chemical etching in the same solution at 40°C are presented in Fig. 6 for comparison.

Chemical surface cleaning of etched device wafers.—Following removal from the alkaline etch bath, the device wafer should be subjected to a thorough surface decontamination treatment designed to strip the photoresist layer and to remove adsorbed impurity ions. The resist layer is removed by a suitable stripping agent as described previously. Adsorbed ionic impurities are removed by desorption in 6*N* HCl for several minutes. It was shown previously by radiochemical tracer analysis that treatment with 6*N* HCl effectively desorbs alkali ions (5) and iron deposits (6) that are present after etching. Handling, rinsing, drying, storing, etc. of the wafers is best carried out by the techniques described in a separate paper on wafer cleaning (7). These treatments leave the surface in a state suitable for sealing with chemically vapor deposited silicon dioxide (8, 9), silicate glasses (9, 11), silicon nitride (12), or any desirable combination of these layers (12, 13).

Applications

The process has been applied for the delineation of tungsten films deposited on oxide-coated silicon device wafers, including discrete planar transistors, power transistors, integrated circuits, and multilayer crossover structures. The thickness of the tungsten films was usually in the 0.5-2 μm range, but films up to 5 μm have been patterned with excellent resolution.[4] Photographs of several representative devices are presented to illustrate the capability of the patterning process.

Figure 7 shows a 1¼ in. diameter silicon wafer with about 5000 tungsten-metallized planar NPN transistors on 0.015 in. centers patterned uniformly over the entire wafer area by electroetching. An enlargement of

[4] 12 μm thick films have been delineated by a two-step photoresist etch technique.

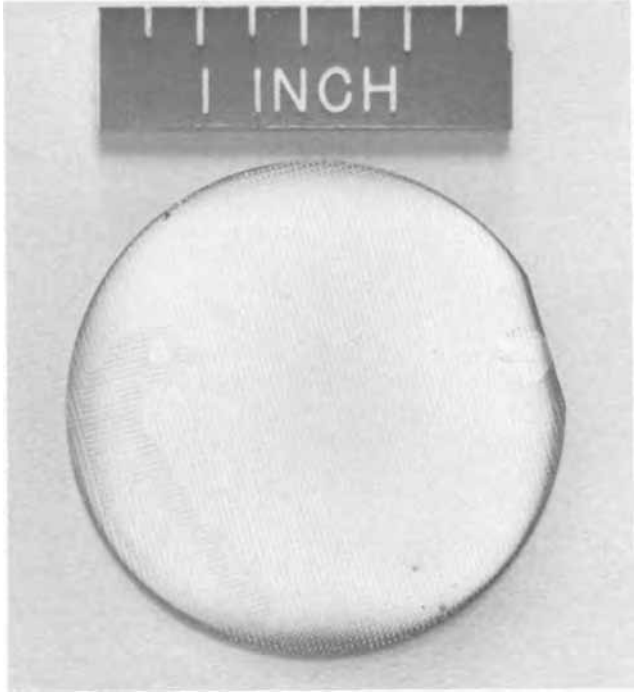

Fig. 7. Electroetched wafer with tungsten metallized planar transistor. Small area scribed "R" shows unetched portion masked by sample holder; (area on left is a nonuniformity in the oxide); wafer contains about 5000 flip-chip transistors.

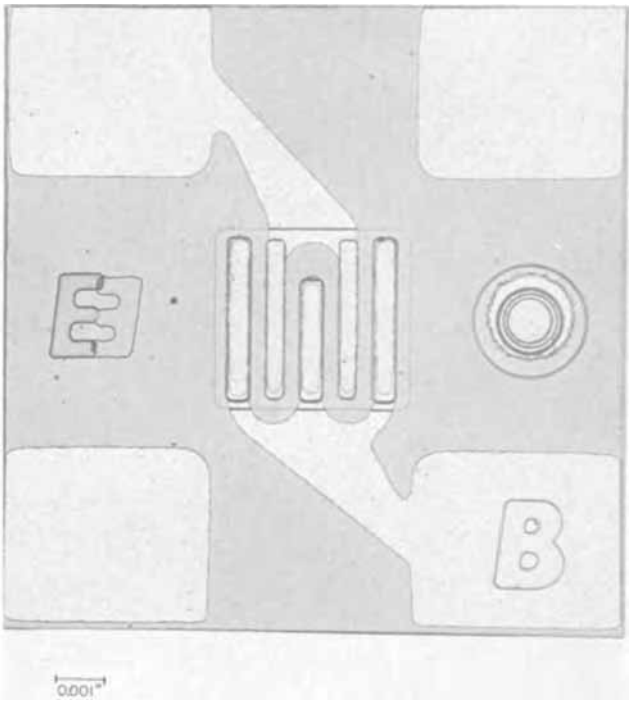

Fig. 8. Photomicrograph of flip-chip test transistor from wafer shown in Fig. 7.

one transistor from this wafer is presented in Fig. 8. The width of the emitter contact stripes of this experimental flip-chip transistor is 0.0004 in.

Figure 9 shows a photomicrograph of a high frequency power transistor taken with a scanning electron microscope at an angle of 65° at 1000-fold magnification. The 2.5-μm thick tungsten stripes exhibit excellent definition and follow the relief contour of the device surface with uniform thickness.

Details within an area of an integrated circuit chip metallized with 6000Å of tungsten are shown in Fig. 10. The width of the narrowest intraconnection leads is 0.0005 in.

Figure 11 finally shows a finished array of typical flip-chip integrated circuits metallized with tungsten

Fig. 9. Portion of a multiple contact power transistor examined by scanning electron microscopy at 1000X. The tungsten stripes are 2½ μm thick.

Fig. 10. Photomicrograph of central area of an integrated circuit chip. The narrow intraconnection tungsten stripes are 0.0005 in. wide.

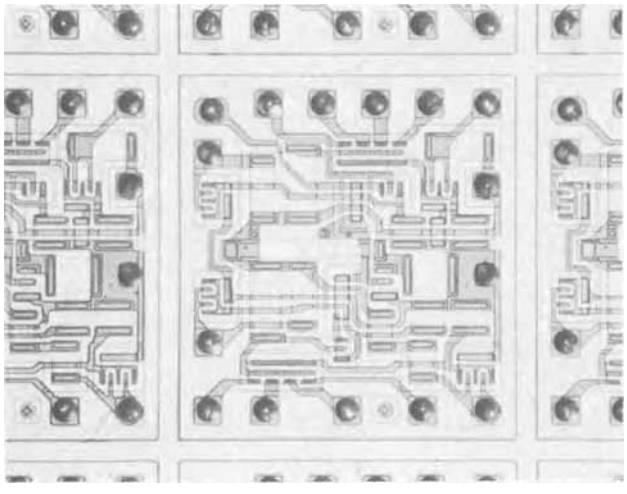

Fig. 11. Array of finished integrated circuits metallized with tungsten. Patterned by electroetching, sealed with silicon nitride, and provided with solder bumps for face-down bonding. The dimension of each IC is 0.050 by 0.055 in.

and patterned by electroetching. A high-temperature silicon nitride film seals the device surface. Openings were etched through the silicon nitride film to expose a circular area of the tungsten terminal pads which were provided with a solderable interface metal layer (14) and solder bumps.

Photographs of a tungsten-metallized and nitride/glass sealed integrated circuit chip (12), of a crossover pattern prepared using tungsten and vapor deposited SiO_2 (1), and of several "Decal" dielectric air isolated integrated circuits (15), all processed by the methods described, were presented in earlier publications.

In addition to the primary objective of delineating metallization patterns for semiconductor microcircuits, the process has been applied to the patterning of tungsten films of up to 12μ thickness on glass and ceramic

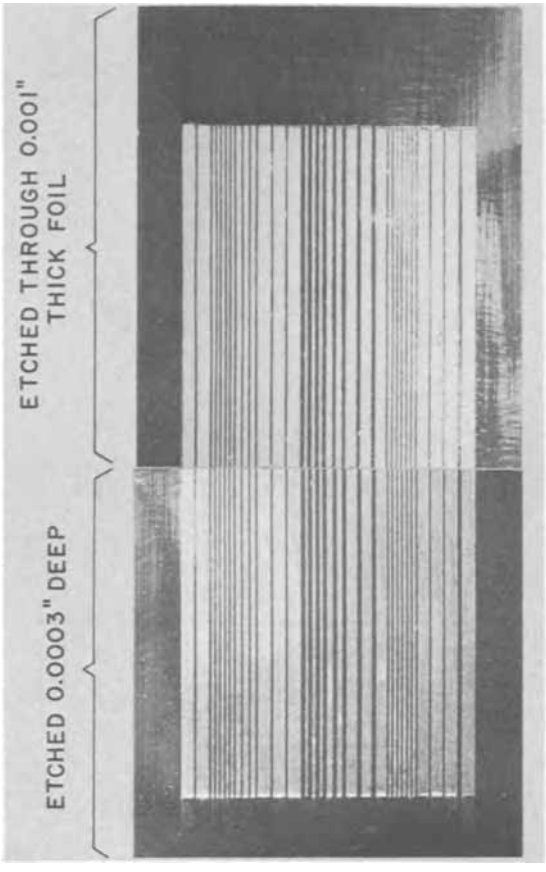

Fig. 12. Line pattern etched in tungsten foil masked by offset printing. Dark lines are elevated metal of 0.005, 0.010, and 0.020 in. width. White areas are etched tungsten (top picture) or background seen through the openings (bottom picture).

substrates. It has also been applied to creating patterns in tungsten foil. If the patterns are relatively large, the photoresist masking techniques can be replaced by more economic offset printing methods (16) with etch-resistant printing inks. Using this technique, lines down to 0.005 in. width and 0.0003 in. height were delineated with good resolution and with an etch factor of 1.0. These patterns were also completely etched through 0.001 in. foil as shown in the photographs in Fig. 12.

The same process of masking and electroetching is applicable also to molybdenum foil. The dissolution rate of molybdenum electroetched at 200 mA cm^{-2} is 392 Å-sec^{-1}.

Summary and Conclusions

A process has been devised for accurately delineating patterns in tungsten films for microelectronic device applications. It is based on combined chemical etching and electrolytic dissolution which proceeds rapidly at room temperature, allowing the photoresist mask to remain intact during etching. The composition of the etchant was designed to yield reproducible and smooth etching characteristics free of tungsten island formation. A special wafer holder was designed to allow the device wafer to be contacted to the anode and submerged during the electroetching. The process has been standardized to yield a chemical etch rate of 50 Å/sec, plus an electrolytic etch rate of 330 Å/sec at an optimum current density of 200 mA cm^{-2} exposed tungsten area. The high-speed electrolytic etching stops automatically when the pattern becomes discontinuous.

Resolution of the tungsten patterns in films up to 1μ thickness are limited essentially by the resolution that can be achieved in photoresist masking. Lines of 5μ width can easily be produced with resist films of 5000Å thickness. Films as thick as 12μ have been patterned successfully.

A post-etch chemical treatment effectively removes alkali ions and trace impurities from the device wafer surface, leaving the device surface in a condition suitable for the subsequent high-temperature sealing operations employing vapor deposited silicon nitride, oxides, or silicate glass layers.

The process has been demonstrated to be applicable also for delineating patterns in thick tungsten films deposited on glass and ceramic substrates, and for patterning foils of tungsten and molybdenum utilizing offset printing techniques for masking.

The principle of accelerating the dissolution of selectively masked films by electrolytic action superimposed on chemical etching appears to be generally applicable for a variety of metals.

Manuscript submitted Dec. 28, 1970; revised manuscript received May 28, 1971. This was Paper 71 presented at the Washington, D.C., Meeting of the Society, May 9-13, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Technical Notes

Effects of Various Additives in the Electrolyte on Oxygen Reduction at Ferric Phthalocyanine-Catalyzed Graphite Electrode

A. Kozawa,* V. E. Zilionis,* and R. J. Brodd*

Union Carbide Corporation, Consumer Products Division, Research Laboratory, Cleveland, Ohio 44101

Hemin and ferric phthalocyanine (FePc) were found to be good catalysts for oxygen reduction in saline solution and in blood (1-4), when a graphite or carbon was used as substrate (2). The activity of FePc-catalyzed graphite for oxygen reduction approached that of platinized Pt in 1M KOH (3). Platinum catalyst or a platinum electrode is known to be sensitive to various impurities. It has been shown that simple cations (Ca^{++}, Sr^{++}, Ba^{++}) and anions (Cl^-, Br^-) at a concentration of $10^{-4} \sim 10^{-2}$M significantly influence oxygen reduction at a platinum electrode (5). In this work, the influence of various additives in the electrolyte on oxygen reduction at FePc-catalyzed graphite electrodes was investigated. It is desirable to accumulate knowledge about what kind of impurities would deactivate the FePc catalyst for oxygen reduction especially during long-term operation in blood. Another reason is a basic interest in the interrelation of adsorption and electrode reaction rates. Unlike platinum catalysts (platinum black or platinized platinum on an electrode surface), FePc catalyst has a well-defined chemical structure, and the active center for oxygen reduction seems to be the iron atom in the molecule (2). Systematic data on the effect of various additives (anions, cations, complexing agents, etc.) would be meaningful in order to clarify some aspects of the electrode reaction in relation to adsorption.

Experimental

In our early work (1-4) isotonic saline solution (0.15M NaCl + 0.05M potassium sodium phosphate buffer, pH 7.15) or 0.05M sodium acetate solution (NaAc) was used. Here, 0.5M NaAc (pH 7.0) was primarily used as a base solution to provide a more desirable buffer action and to eliminate $PO_4^{\equiv}$ and Cl^- which would be strongly adsorbed on the Fe atom of FePc. The 0.5M NaAc (pH 7.0) base solution was prepared by adding concentrated acetic acid to 0.5M NaAc. Whenever 0.05M or 2M NaAc solutions were used; the pH was adjusted to desired values by adding HAc or NaOH.

Concentrated stock solutions of various additives (if possible 2M) were prepared and added to the base solution in concentrations of 0.01 to $\sim$ 0.1M. Since the $i-E$ curve was relatively sensitive to the pH of the solution, pH values of the solution after addition of the additives were measured. Unless otherwise noted, the pH remained 7.0 $\pm$ 0.1. Reagent grade chemicals and conductivity water were used throughout the studies.

A rotating disk-ring electrode technique was used in these studies (1). The disk electrode was made of a pyrolytic graphite and had an exposed surface of 0.196 cm^2. The disk radius was 0.25 cm and the platinum ring electrode had an inside radius of 0.277 cm and an outside radius of 0.360 cm. The collection efficiency measured experimentally ($N = i_r/i_d$, i_r = ring current, i_d = disk current) was approximately 0.39. FePc catalyst was applied on the surface of the pyrolytic graphite disk electrode. The electrode was always rotated at 120 rpm while taking the $i-E$ curves. The $i-E$ curves were taken in oxygen (1 atm) saturated solutions at 23°C $\pm$ 1°C at a sweep rate of 0.12 V/min. While sweeping the disk electrode potential toward the negative direction, the current at the ring electrode was measured at +0.62V *vs.* SCE. At this potential the H_2O_2 reaching the ring electrode is oxidized to O_2. Knowing the collection efficiency, N, of the ring electrode it is possible to calculate the fraction of the reaction current producing the hydrogen peroxide intermediate. The portion of the disk current which produces hydrogen peroxide is given approximately by $i_{H_2O_2} = i_r/N$ where i_r is the measured ring current. This calculation neglects the electrochemical reduction of H_2O_2 on the disk electrode as well as the possible self-decomposition of H_2O_2 in transit between the disk and ring electrode.

Results and Discussion

The main purpose of this note is to present various experimental facts and point out the behavior of various types of additives on oxygen reduction at a FePc catalyst graphite electrode. Current potential ($i-E$) curves presented in this paper were selected from a large number of experiments as representing significant behavior. Most of the effects caused by the various additives on the $i-E$ curve could be explained on the basis of adsorption on the catalyst surface.

A tentative model for adsorption of various types of additives on the FePc catalyst is useful when interpreting the results. FePc is essentially a large hydrocarbon molecule except for the Fe and nitrogen sites in the molecule. The hydrocarbon portion (pyrols) would adsorb $CH_3-\overset{\overset{O}{\parallel}}{C}-O^-$ or CH_3-CO_2H, since it may attract a methyl group. Nitrogen atoms would preferentially adsorb any metal ions since nitrogen can be an electron donor. Although in the FePc molecule, all the electrons of the nitrogen atom are used to bond with Fe, some attraction for other metal ions can be expected. The central Fe atom does have two free orbitals to accept any ligand, such as H_2O, Cl^-, Br^-, OH^-: O_2^-—R (oxyacid), etc. The FePc molecule requires one monovalent anion to balance the formal charge. This may contribute to the anion adsorption on the molecule. These three types of adsorption sites in FePc are shown pictorially in Fig. 1.

* Electrochemical Society Active Member.

Key words: oxygen reduction, ferric phthalocyanine-graphite, additives.

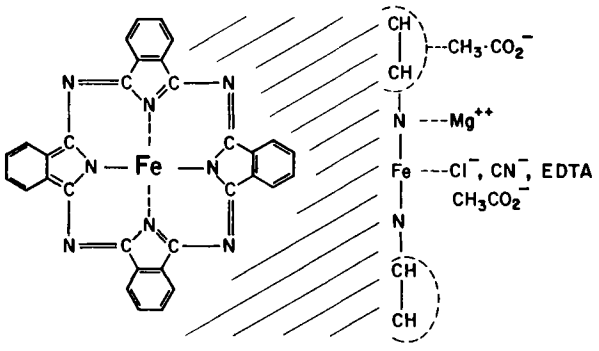

Fig. 1. Adsorption on ferric phthalocyanine

The nature of the oxygen reduction process at the electrode must also be considered. Oxygen is reduced by at least two kinds of electrochemical reactions, one produces H_2O_2 in a two-electron process and the other produces H_2O in a four-electron process

$$O_2 + 2H^+ + 2e^- \rightarrow H_2O_2 \quad [1]$$

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad [2]$$

Figure 2 shows the $i-E$ curves taken at a FePc-catalyzed graphite (FePc-Gr) electrode and also at an uncatalyzed pyrolytic graphite electrode in O_2-saturated 0.05M NaAc solutions (pH 6, 7, and 8). It should be noted that the FePc-Gr electrode is far better for oxygen reduction than is the uncatalyzed electrode. Practically no H_2O_2 is produced at the FePc-Gr electrode over the pH range studied, while at the uncatalyzed graphite electrode most of the disk current is due to an electrochemical reaction producing H_2O_2 (Reaction [1]). At the FePc-Gr electrode, the oxygen reduction reaction approximated a four-electron process (Reaction [2]). In fact the current value in the plateau ($-0.3 \sim -0.6$) region of the $i-E$ curve corresponds to the diffusion limited current for a four-electron reduction of dissolved O_2 under these rotational conditions. With the rotating disk ring electrode, approximate values for the current associated with each reaction path can be obtained as well as identification of a mechanism change. If the oxygen reduction current decreases at a certain potential with certain additives there are two possibilities. (*A*) The four-electron process changes to a two-electron process due to the influence of the nature of the adsorption on the various reaction paths. (*B*) The same four-electron process is taking place but a portion of the electrode (or catalyst) surface is simply blocked by the adsorbed material. If the first is the case, we should see an increase in the ring current and therefore, an increase in the fraction of current producing hydrogen peroxide. If the second is the case, the ring current should not increase.

Two-step $i-E$ curves for oxygen reduction are very frequently reported at various electrodes as the dropping mercury (6), graphite (2), gold and other electrodes. The first step is attributed to the reduction of O_2 to H_2O_2 and the second step to the reduction of O_2 to H_2O. At the FePc-Gr electrode, two-step $i-E$ curves of this type are obtained under certain conditions. The $i-E$ curve at pH 6 (curve 1, Fig. 2) has two steps, but the first step disappears as the pH value is increased (curves 2 and 3, Fig. 2).

The pH effect shown in Fig. 2 can be explained by the dissociation of HAc and its adsorption. Let us assume that undissociated HAc does not have the ability to complex or to be adsorbed on the Fe sites of the FePc catalyst as do Ac^- ions formed by dissociation. In acetate solution having low pH values there are more HAc molecules than dissociated Ac^- ions. Therefore, Ac^- adsorption is less; and the Fe sites of FePc have decreased blockage. But at high pH values, the Ac^- ion concentration is high and the Fe sites may be blocked by adsorption. Because of this situation at low pH, some oxygen reduction starts at more positive potentials and produces the first step in the curve. At more negative potentials all the Ac^- ions adsorbed on the Fe sites will be detached because of the charge repulsion, and the Fe sites then become available to catalyze oxygen reduction.

Figure 3 shows $i-E$ curves at FePc-Gr and uncatalyzed graphite electrodes in 0.05, 0.5, and 1.0M NaAc solutions. The height of the first step (see curves 1, 2, and 3) increases with increasing acetate concentration from 0.05 to 1.0M. The current value in the plateau region ($-0.2 \sim -0.7$ *vs.* SCE) of curves 1, 2, and 3

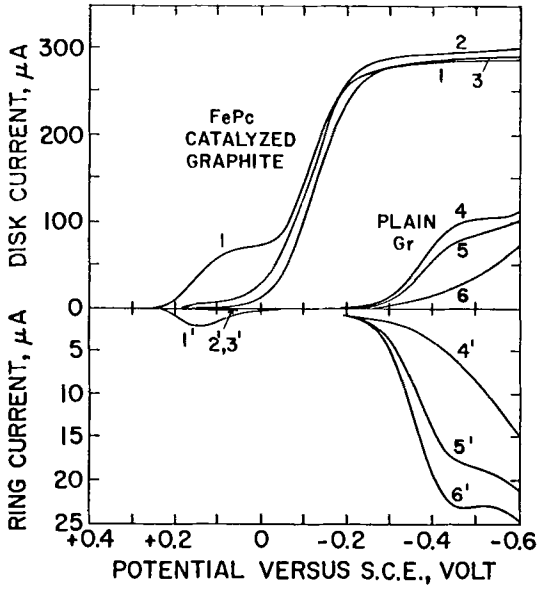

Fig. 2. Current-potential curves for FePc-graphite, curves 1-3, and graphite, curves 4-6, electrodes in the following solutions: Curves 1,4—0.05M sodium acetate pH 6; Curves 2,5—0.05M sodium acetate pH 7; Curves 3,6—0.05M sodium acetate pH 8.

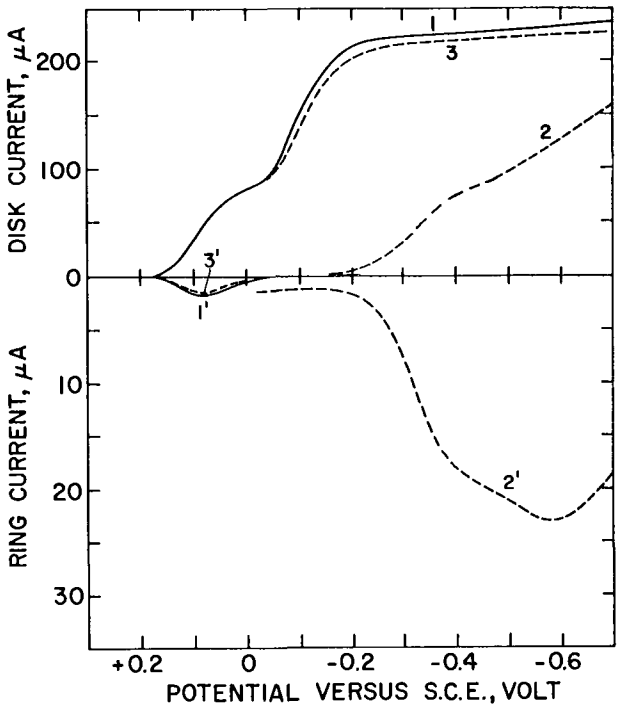

Fig. 5. Current-potential curves for FePc-graphite electrode in sodium acetate solution with and without cyanide additive. Curve 3 was taken after rinsing the electrode in Curve 2 with water: Curves 1,3—0.5M sodium acetate pH 7.0; Curves 2—0.5M sodium acetate + 0.01M sodium cyanide pH 9.25.

decreases with increasing acetate concentration, presumably due to a decrease in oxygen solubility.

Figure 4 shows $i-E$ curves taken in 0.2M Na_3PO_4 (pH 5, 7, and 9) and 0.2M NaAc (pH 5, 7, and 9) solutions at FePc-Gr electrodes. It is interesting to note that the curves in the phosphate solution shift toward the negative direction by approximately 33 mV/pH as the pH value increases, but in the acetate solution some unusual distortions are seen at pH 7 and 9 (see curves 4, 5, and 6). This may indicate that at pH 7 and 9 the acetate ion (0.2M) is adsorbed at the FePc electrode and hinders the O_2 reduction in this region (+0.2 ~ 0V). Another point to be noted is that the plateau current in the acetate solution decreases with decreasing pH from 7 or 9 to 5 (see curves 4, 5, and 6). It was shown previously (3) that in 0.1N H_2SO_4 solution, the plateau current of the $i-E$ curve is approximately half the value associated with the four-electron process. At pH 5, the behavior of the FePc-Gr electrode is approximately the same as that in 0.1N H_2SO_4. In acid solution (0.1N or 1.0N H_2SO_4), the activity of FePc for oxygen reduction deteriorated rapidly (3).

When $i-E$ curves were taken repeatedly at FePc-Gr electrodes, they were reproducible in most solutions indicating that the catalyst activity remains the same. In some solutions having pH values of 6 or less or in solutions containing certain anions *e.g.*, $PO_4^{\equiv}$ the shape of the curve changed rapidly because of deactivation of the FePc-catalyst. In 0.2M Na_3PO_4 solution, the repeated $i-E$ curves are reproducible at pH 9, but at pH 5 and 7, the electrode activity deteriorated rapidly on repeated sweeps.

Cyanide ions added to the acetate base solution greatly hinder the activity of the FePc catalyst for oxygen reduction as shown in Fig. 5. The $i-E$ curve for oxygen reduction in CN^--containing solution (curve 2) is very similar to that at a plain graphite electrode.

It is well known that the O_2-carrying ability of hemin is lost when cyanide ions are introduced in blood, since the CN^- ion is strongly adsorbed on the Fe atom of hemin. The results obtained here (Fig. 5) are analogous to the physiological effect of cyanide. However, the poisoning of FePc catalyst by CN^- is not permanent since, when the electrode which had been operated in CN^--containing solution was washed with water and operated in a CN^--free solution, the poisoning effect disappeared almost completely (see curve 3, Fig. 5). The inhibitive effect of EDTA (0.01M) is considerable and quite similar to that of CN^-. However, in this case the poison was more permanent. The electrode which was washed with water and tested in an EDTA-free solution did not recover its activity completely as in the case of CN^-. The activity of electrodes exposed to EDTA could be restored only after repeated rinsing with water. One explanation may be that the EDTA may remove the Fe from the FePc complex causing an irreversible loss of activity.

Cyanide ion and EDTA must be attached to the iron atom of the FePc catalyst. Their ability to form stable complexes with iron is well known. Therefore these additives are expected to hinder the oxygen reduction reaction. It is almost certain that iron in the FePc is the site for the electrochemical oxygen reduction, since among the various metal phthalocyanines tested, the catalytic activity is highly dependent on the kind of central metal ion; the active order among the active metal Pc's were Fe(III) > Fe(II) > Co > Cu, etc., (1). Increased peroxide formation was noted for CN^- and EDTA additives. Evidently they block the active sites of the iron for oxygen reduction.

Figure 6 shows the effects of adding small amounts of "Triton X-100" (a nonionic surface active agent-alkylaryl polyether alcohol), pyridine, and quinoline. These additives are typical materials which inhibit oxygen reduction at the FePc-Gr electrode. It should be noted that, although the disk current is greatly reduced in the presence of 0.002% quinoline (curve 4), the fraction of the current producing hydrogen peroxide is not greatly increased. This indicates that the inhibition effect does not necessarily change the oxygen reduction reaction from the four-electron process to the two-electron process.

In contrast to the behavior of $PO_4^{\equiv}$ and CN^- the effect of $SO_4^=$ addition to 0.5M NaAc is only slight. Also the addition of Cl^- and Br^- to 0.5M NaAc solution had little effect on the over-all behavior. The slight decrease in the plateau current was observed

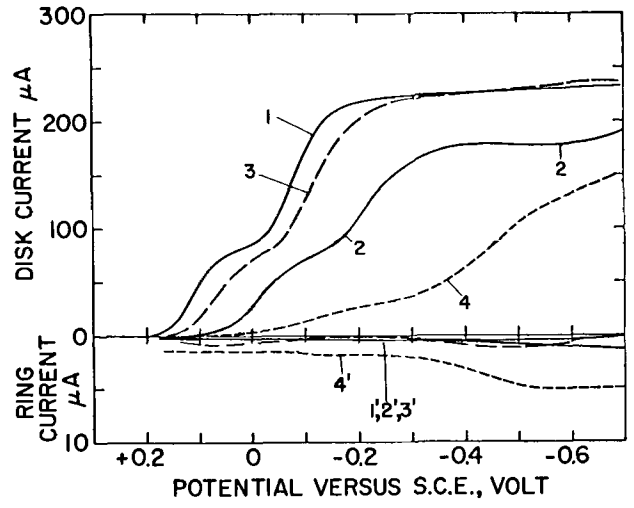

Fig. 6. Current potential curves for FePc-graphite electrode in sodium acetate solution plus the following additives: Curve 1—0.5M sodium acetate pH 7.0; Curve 2—0.5M sodium acetate + 0.01% "Triton X-100" pH 6.97; Curve 3—0.5M sodium acetate + 0.01% pyridine pH 7.1; Curve 4—0.5M sodium acetate + 0.002% quinoline pH 7.1.

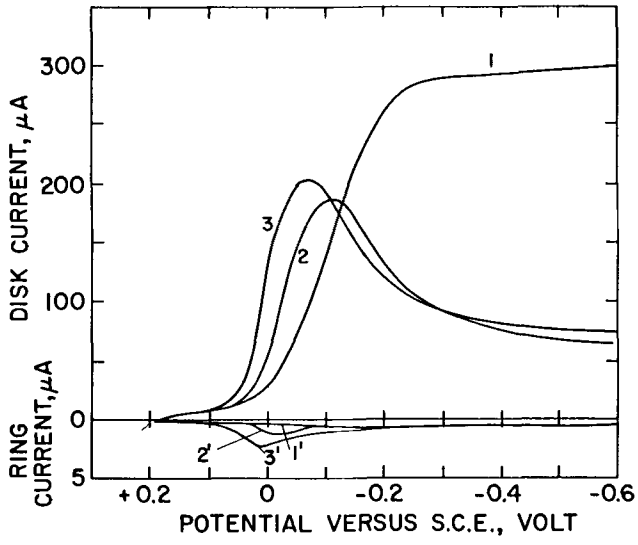

Fig. 7. Current-potential curves for FePc-graphite electrode in sodium acetate solution with and without magnesium additive: Curve 1—0.05M sodium acetate pH 7.0; Curve 2—0.05M sodium acetate + 0.1M magnesium nitrate pH 7.0; Curve 3—0.05M sodium acetate + 0.2M magnesium nitrate pH 7.0.

perhaps due to decreasing oxygen solubility. The following additives were found to have practically no effect on the $i-E$ curves: Na oxalate (0.01M, 0.02M), Na tartrate (0.01M, 0.1M), urea (0.01M, 0.1M), KNO_3 (0.01M, 1M).

In solution containing only bromide ion there was little effect of pH on the $i-E$ curves. Br^- ions must be strongly adsorbed on Fe sites, since the Fe(III)-halide complex is very stable. Such a Br^- adsorption should be influenced very little by a pH change in the solution. However, when a certain negative potential is imposed, the adsorbed Br^- on the Fe of FePc should be desorbed and consequently, oxygen reduction should take place when the potential becomes sufficiently negative.

When a Br^- solution containing no acetate ion was used, the Br^- effect was considerably different from the effect of Br^- added to the 0.5M NaAc solution. In the bromide solution the pH effect is very small in the pH range of 5-9, although in acetate solution the $i-E$ curve develops a pronounced second step at lower pH values.

The effect of divalent positive ions is not clear. Adding $Ca(NO_3)_2$ (0.01M, 0.1M), and $Sr(NO_3)_2$ (0.01M, 0.1M) has no notable influence on the $i-E$ curves. As shown in Fig. 7, addition of Mg^{++} produces a somewhat beneficial effect around $+0.1 \sim -0.1$V, since the current is larger with Mg^{++} additions than that in 0.05N NaAc solution. However, the current decreases considerably as the potential becomes more negative. At higher Ac^- concentration the plateau current is not depressed as much as in lower Ac^- solutions.

The only possible site for Mg^{++} adsorption is the nitrogen atom of FePc. Let us assume Mg^{++} ions are adsorbed on some N-sites. This adsorbed Mg^{++} would somehow promote oxygen reduction at the Fe-site of FePc. When a more negative potential is applied (or the electrode is swept toward more negative potential) Mg^{++} adsorption should be increased since the Mg^{++} is positively charged. If hydrated Mg^{++} ions would be adsorbed on two N-sites of FePc, oxygen reduction may be hindered physically since it is difficult for the O_2 molecule to approach the Fe site because of steric hindrance. This would account for the current decrease shown in Fig. 7 (curves 2 and 3).

The effect of Pb^{++} addition shown in Fig. 8 is quite similar to that of Mg^{++} in the potential range of $+0.2 \sim 0.1$V, but the plateau current remains steady at

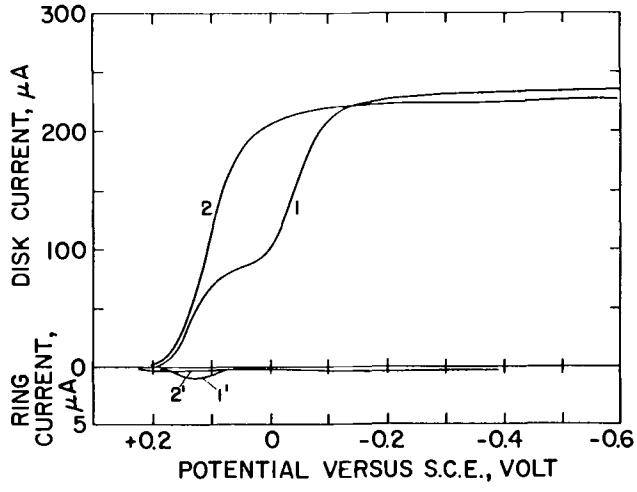

Fig. 8. Current-potential curves for FePc-graphite electrode in sodium acetate solution with and without lead additive: Curve 1—0.5M sodium acetate pH 7.0; Curve 2—0.5M sodium acetate + 0.01M lead nitrate pH 6.9.

negative potentials. This kind of beneficial action of Pb^{++} for oxygen reduction has been reported previously using dropping mercury electrode (6, 7) as well as various solid electrodes (8).

Electrical Resistivity of Magnetite Anodes

R. Itai, M. Shibuya, T. Matsumura, and G. Ishi*

The Japan Carlit Company, Limited, Shibukawa-shi, Gunma-ken, Japan

Considerable progress has been made in quality and economy of magnetite anodes, and they are now used not only in traditional chlorate cells, but also in such new fields as cathodic protection and electrodialysis.

Electrolytic manufacture of sodium chlorate with magnetite anodes has been described in a previous paper (1). Since they have relatively high electrical resistance compared with graphite, this should be kept as low as possible through quality control. Much work has been done with regard to factors which govern electrical resistance of commercial magnetite anodes. In the present paper, effects of composition, temperature, and some additives on resistivity of cast magnetite samples prepared from relatively pure mill scale, are described.

Experimental

Composition of magnetite and its raw materials may be expressed in terms of Fe(III)/Fe(II) atomic ratios (*AR*). Pure magnetite corresponds to an *AR* of 2.00.

Determination of AR.—Dissolve a weighed portion of a sample in 12*N* H_2SO_4, titrate it with 0.1*N* $KMnO_4$ which gives Fe(II). Dissolve another portion in 8*N* HCl, add $SnCl_2$ to reduce any Fe^{3+}, oxidize the excess $SnCl_2$ with a saturated solution of $HgCl_2$, add $MnSO_4$ and finally titrate it with 0.1*N* $KMnO_4$ to obtain the total iron which gives Fe(III) by difference.

Preparation of magnetite samples.—Mill scale of as high quality as was available was melted under conditions similar to the practical ones. Composition of the mill scale used throughout is shown in Table I. Purity was much better than that of hematite ore, a common raw material for commercial magnetite anodes. The feed was a mixture of unoxidized and partly oxidized mill scales in such a ratio as to give any target *AR* value in the final product.

Melting was carried out in a 15 kW resistor furnace. The melt was poured into a red-hot cast iron mold and was left cooling overnight in an annealing furnace preheated above 800°C. Samples, 15 mm wide, 75 mm long, and 8 mm thick, were ground out of ingots.

Electrical measurements.—A constant d-c current (10 to 200 mA) was led through a sample plated with Cu on both ends, and the voltage drop across a pair of silver knife edges on which it rested was measured by a potentiometer. For measurements at temperatures higher than 150°C, a thin silica tube, on which a pair of Cu wires were wound 30 mm apart, pressed tightly against a sample, provided potentiometric contacts. The unit was placed in a silica tube, 30 mm inner diam, inserted in a horizontal tube furnace with Ni-Cr resistors and swept by a stream of CO_2.

Results and Discussion

Effect of AR on resistivity.—Direct-current resistivity, ρ, at 25°C of cast magnetite as a function of *AR*, is shown in Fig. 1. The curve has a jump at $AR = 2.0$, corresponding to stoichiometric magnetite. As *AR* passed the stoichiometric point from the lower to the higher *AR* region, ρ increased 10^2-fold. The observed value of ρ at $AR = 2$ was about five times as high as that reported for pure single crystals of Fe_3O_4 (2, 3). The difference might be explained by the fact (4) that conductivity of polycrystalline magnetite is 10-20% of that of single crystals, and partly by the presence of small amounts of impurities in our samples.

From the practical point of view, it is obviously advantageous to keep *AR* of the anode products as close to the value of 2 as possible but never in excess of it.

Effect of temperature.—Resistivity of samples with different *AR*'s was measured between 2° and 900°C and log ρ was plotted against $1/T$ as shown in Fig. 2, where T is absolute temperature. Curves formed two groups, an upper and a lower. The curves for $AR \gtrless 2.0$ belonged to the latter. Below 300°C they roughly coincided with a curve reported for $FeO_{1.07}$ (4). The discrepancy at $AR = 2$ of the observed from the reported

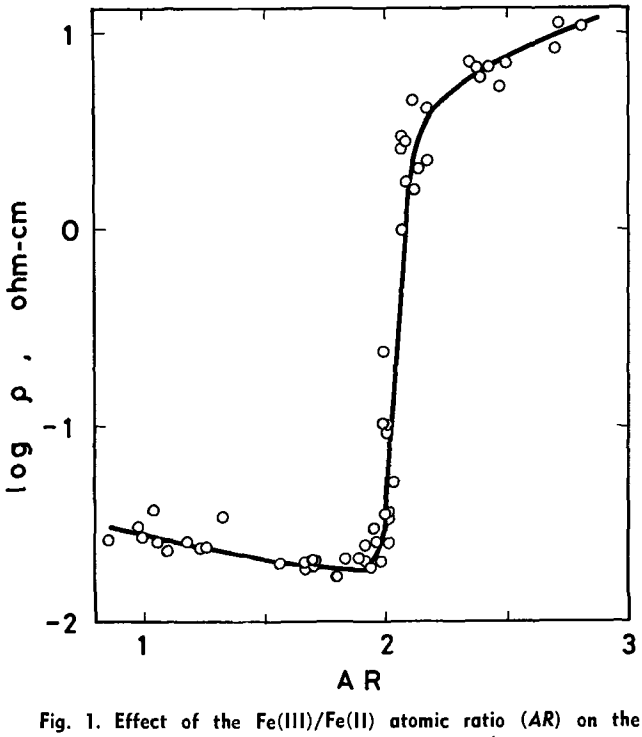

Fig. 1. Effect of the Fe(III)/Fe(II) atomic ratio (*AR*) on the electrical resistivity at 25°C of cast magnetite samples.

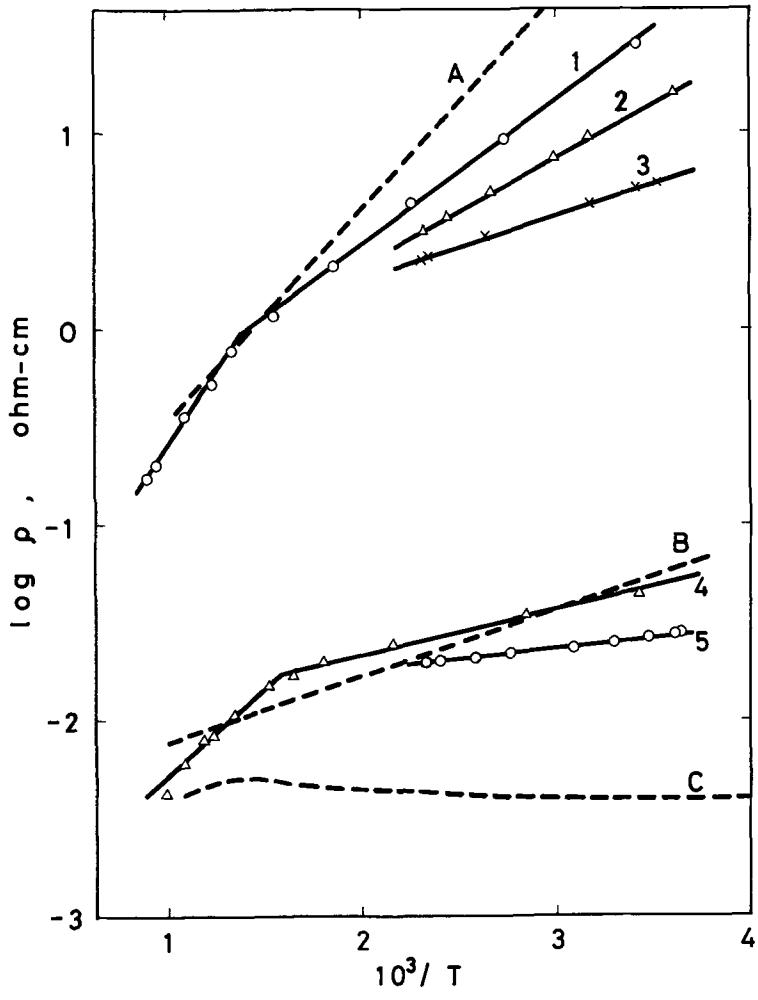

Fig. 2. Temperature dependence of the electrical resistivity of cast magnetite with various *AR*'s, compared with that of γ-Fe_2O_3, Fe_3O_4, and FeO: 1) *AR* = 2.72, 2) 2.44, 3) 2.11, 4) 1.03, 5) 1.97, (A) γ-Fe_2O_3, (B) $FeO_{1.07}$, (C) Fe_3O_4 (see text).

curve (3) could be attributed to the same reason as given above. The curves for $AR > 2$ formed the upper group. A curve for a preparation of epitaxially grown γ-Fe_2O_3 (5) is also shown. Curves for α-Fe_2O_3 presumably lie higher than those for γ-Fe_2O_3 (6). Curves for those samples with which the measurements extended up to 900°C had a kink at about 430°C.

Activation energy, *E*, for the low-temperature part, showed a minimum at the stoichiometric magnetite composition (Fig. 3). At this point, the temperature coefficient of resistivity at 25°C was about −0.2% per degree. The increase in *E* was much steeper towards the higher *AR* region than towards the opposite.

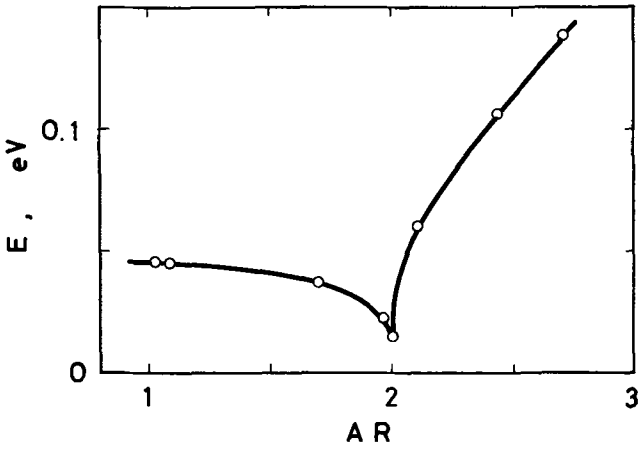

Fig. 3. Activation energy for the low-temperature part of the resistivity curves as a function of *AR*.

Microscopic observations.—Five samples with *AR*'s from 1.04 up to 2.70 were inspected microscopically (Fig. 4 a-e). The samples with $AR = 1.04$ and 2.70 showed two distinct phases, whereas those with $AR = 1.35$, 2.00, and 2.29 showed a single phase. In the $AR = 1.04$ sample, either wuestite or metallic iron appears as a separate phase, while in the $AR = 2.70$ sample, maybe α-Fe_2O_3 has segregated. In view of the poor solubility of wuestite or iron in magnetite (7), it is surprising that those samples having *AR*'s well below the stoichiometric value were found to be uniform, even though they had been anealed during preparation.

Effect of additives.—The commercial magnetite anodes contain certain amounts of impurities, such as silica, alumina, and lime (1). In order to study the

* Preparation was so difficult that only a few samples were available for measurements.

roles played by such impurities, certain elements of Group I and V were added to the mill scale as the corresponding oxides, except for potassium where the nitrate was used. Electrical measurements and microscopic observations were made on samples prepared as before. The critical *AR* at which the jump occurred, the associated value of ρ, and the number of phases observed near the critical value of *AR* are summarized in Table II. Typical examples of microscopic structures where the number of phases is one and two, respectively, are shown in Fig. 5a and b.

Potassium gave little effect except that it brought about a second phase. Elements of Group II caused more or less rises of the critical *AR*, that is, some shifts towards the higher *AR* region, but the corresponding changes in ρ were not substantial. CaO made cast magnetite so fragile that only a few pieces were available for measurements.

With Al_2O_3, only one phase formed in samples, and the critical *AR* lowered. The increase in the corresponding ρ was a little more enhanced than those observed with the Group II oxides.

Such changes in the critical values of *AR* may be postulated, at least qualitatively, as follows. Group II oxides might form corresponding spinels by joining with excess Fe_2O_3 within the lattice of $AR = 2$, causing rises of the critical *AR*. Similarly, alumina could combine with the interstitial Fe^{2+} to form $FeAlO_4$, lowering the critical *AR*.

This was no longer the case with SiO_2, for it went into a separate phase, having little influence on the

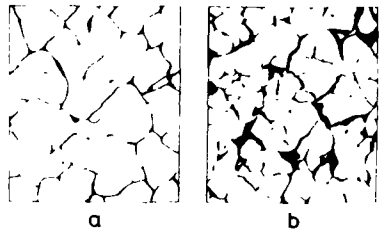

Fig. 5. Schematic representation of microscopic structures of magnetite containing additives (X269): (a) 5% Al_2O_3, $AR = 2.0$, (b) 5% SiO_2, $AR = 1.9$.

conduction process. The gradual increase in ρ as the addition level increased may be taken as being caused by the increasingly silica-rich matrix. P_2O_5 behaved quite like SiO_2.

Addition of TiO_2 was an intermediate case. It caused two separate phases to exist, while a lowering of the critical *AR* cannot be neglected. Partial solubility of TiO_2 in magnetite might be a possible answer, but no further discussion will be attempted here.

Generally, rises in the critical *AR* are favorable on account of conductivity, but other factors, such as thermal and mechanical properties as well as electrochemical performance, should also be considered.

Thus our resistivity measurements made on cast mill scale magnetite provided useful guidelines for the manufacture of commercially acceptable magnetite anodes.

Brief Communication

Electric Conductivity of Carbon Black Suspensions in Molten Sulfur

T. K. Wiewiorowski

Freeport Sulphur Company, A Division of Freeport Minerals Company, Belle Chasse, Louisiana 70037

Molten sulfur is a very poor electrical conductor. In certain applications it would be desirable to increase its electrical conductivity. For example, molten sulfur is being considered as the cathode reactant in sodium-sulfur and lithium-sulfur batteries, but its low electrical conductivity in these rechargeable batteries makes current collection at the cathode a very difficult task. The poor electric conductivity of molten sulfur

Key words: batteries, carbon black, conductivity—electric, sulfur, suspensions.

is undoubtedly one of the major technological barriers in the successful commercial developments of lithium-sulfur and sodium-sulfur batteries. In an effort to overcome this problem, the electrical current collection system at the cathode in one prototype lithium-sulfur cell consisted of an elaborate metal mesh to maximize its surface area and increase the current output of the cell (1). Although somewhat improved, this current output did not reach a sufficiently high level to render the system suitable for practical applications. Furthermore, the use of an extended metal mesh in the current collection system of a battery significantly increases the weight of the battery and consequently decreases its specific energy (energy per unit weight).

The performance of sodium-sulfur and lithium-sulfur batteries can be greatly enhanced by increasing the electric conductivity of the molten sulfur contained in the cathode compartments of these batteries. It has been found that compositions of matter consisting of molten sulfur and powderized carbon have electric conductivities substantially higher than that of pure molten sulfur.

The concentration of carbon used in preparing a particular composition depends primarily on the desired electrical conductivity of the melt and on the physical properties of the specific carbon employed, such as density, crystallinity, particle size, and porosity. The carbon content of the suspension may vary between 0.1% and 15% by weight.

The preparation of carbon-in-sulfur suspensions can be accomplished by blending carbon powder into molten sulfur, while providing sufficient agitation to achieve uniform distribution of the solid in the liquid phase. Carbons consisting of small porous particles form quite stable suspensions in molten sulfur and show little or no tendency to settle even after extended periods of time. This is important in applications where a uniform suspension is desired and where it is impractical to provide mechanical agitation in order to maintain such uniformity of suspension. It was quite surprising to observe that such suspensions have conductivities several orders of magnitude higher than that of pure molten sulfur, even though the carbon content of these compositions was only in the order of 0.1%-15%.

The physical properties of the suspension are strongly affected by the type and amount of carbon it contains. For example, suspensions of powderized carbon in molten sulfur in which the carbon content is below about 2% by weight have a fluidity similar to that of molten sulfur. In the case of finely divided carbons, these compositions gradually acquire the consistency of a paste as the carbon content is raised above about 2%.

A series of carbon black suspensions in molten sulfur was prepared and their electrical conductivities determined at 130°C using a direct current conductivity measuring circuit with a sensitivity of about 10^{-7} ohm^{-1} cm^{-1}. The results obtained are shown in Table I. In all cases tested, the electrical conductivity of the suspensions was at least three orders of magnitude higher than the conductivity of molten sulfur, which is reported to be in the order of 5×10^{-11} ohm^{-1} cm^{-1}. Note that the suspension containing 2.0% of Vulcan XC-72R carbon black, manufactured by the Cabot Corporation, had a conductivity in the order of 10^{-1} ohm^{-1} cm^{-1}. In this case, the enhancement in electrical conductivity resulting from the presence of the carbon black in the molten sulfur is about ten orders of magnitude.

In another experiment, a 5% by weight suspension of Vulcan XC-72R carbon black in molten sulfur was prepared by thoroughly mixing 25g of carbon black into 475g of molten sulfur. The mixture, contained in a glass beaker, was placed in a thermostatically controlled oven and maintained at 142°C without agitation. In order to evaluate the stability of the molten sulfur-carbon black suspension, conductivity readings were obtained over a period of ten days by immersing an electrical conductivity probe near the bottom, in the center, and near the surface of the suspension. The conductivity reading was not affected by the location of the conductivity probe, indicating that no settling of the carbon black occurred. The results shown in Table II demonstrate the excellent stability of this suspension. Throughout the entire testing period the electrical conductivity of the suspension remained about ten orders of magnitude higher than the reported conductivity of pure molten sulfur.

Preliminary tests intended to compare the performance of carbon-in-sulfur suspensions with pure molten sulfur in a lithium-sulfur cell indicate that the conductive suspensions will facilitate considerable simplification of the current collection system in lithium-sulfur and sodium-sulfur batteries.

The Adsorption and Reaction of Cyclic Olefins on a Fuel Cell Electrode

H. J. Barger, Jr., G. W. Walker, and R. J. York

Electrochemical Division, U. S. Army Mobility Equipment Research & Development Center, Fort Belvoir, Virginia 22060

ABSTRACT

The adsorption and reaction during cathodic pulse of 1,2- and 2,3-dimethylcyclopentene and 1,2- and 2,3-dimethylcyclohexene were studied. The *cis* to *trans* ratios of the reduced hydrocarbon products were analyzed by gas chromatography. In view of the large difference in reduced isomer ratios obtained for the different size ring systems, different modes of adsorption are postulated for each ring system. A π-bonded, aromatic, adsorbed intermediate is proposed for the dimethylcyclohexene system, since the *cis/trans* ratio is the same as that obtained upon pulsing an electrode which has been in contact with *ortho*-xylene. The cyclopentyl results are explained in terms of a less restricted adsorption geometry, with the relative thermodynamic stabilities of the reduced isomers contributing extensively to the *cis/trans* ratio observed.

The primary purpose of this investigation is the study of hydrocarbon adsorption at a fuel cell electrode in order to elucidate the electrooxidation process.

Brummer (1) has shown that the oxidation process involves adsorption on the electrocatalyst, followed by the rapid formation of the intermediates CH-α and O-type, with the subsequent slow oxidation of O-type to CO_2

$$\text{Adsorption} \xrightarrow{\text{Fast}} \text{CH-}\alpha \xrightarrow{\text{Fast}} \text{O-type} \xrightarrow{\text{Slow}} CO_2$$

It has also been shown that the reaction must occur by adsorption and that all intermediates are adsorbed on the electrocatalyst (2). A method of studying the adsorption process was adopted whereby an evolved product would retain the essential geometrical features of the reactant hydrocarbon. This method involved adsorption at fixed potential followed by a galvanostatic cathodic pulse (3) with subsequent trapping of the reduced hydrocarbons.

By proper choice of reactant, one can conceivably obtain some insight into the adsorption geometry on the electrocatalyst. Dimethylcycloolefins, for example, may yield both *cis*- and *trans*-dimethylcycloalkanes upon cathodic pulse, and the cycloalkane isomer ratio allows speculation as to the mode of adsorption. The olefins, 1,2-dimethylcyclopentene, and 2,3-dimethylcyclopentene were chosen for this study for several reasons: (*a*) this type, or quite similar types, of molecule occurs in substantial concentrations in hydrocarbon fuels which fuel cells may ultimately be able to utilize; (*b*) the molecules have been extensively studied under normal heterogeneous catalysis conditions (4-6) so the effect of electrocatalyst potential could be determined; and (c) the reduction products, *cis*- and *trans*-1,2-dimethylcycloalkanes, are readily separable by gas chromatography.

Key words: fuel cell, hydrocarbon adsorption, hydrogenation, aromatization, π complex, cycloolefin, isomerization, electroreduction.

Experimental

The electrochemical cell and circuitry used in this study have been previously described (7). The circular working electrode was an LAA25 American Cyanamid type consisting of 25 mg/cm^2 platinum black bonded with 25% Teflon on a tantalum screen, and having a geometrical area of 20.2 cm^2. The counterelectrode was of the same material but with an area approximately three times that of the working electrode. Potentials were measured against the dynamic hydrogen electrode (8) which was typically 40 mV cathodic to the normal hydrogen electrode in the same electrolyte. The electrolyte, 85% H_3PO_4, was maintained at 120°C and contact to the reference electrode compartment was effected through a Luggin capillary. Water vapor losses from the electrolyte, due to the elevated working temperature, were replenished by passing humidified inert gas into the cell. Reactants were introduced into the working electrode gas cavity in an argon stream by passing the inert gas at a known flow rate through a heated saturator containing the hydrocarbon of interest. The inert gas was first passed through copper turnings heated to 425°C to remove traces of oxygen.

Reactants[1] 1,2-dimethylcyclohexene (12DMCH), 2,3-dimethylcyclohexene (23DMCH), 1,2-dimethylcyclopentene (12DMCP), and 2,3-dimethylcyclopentene (23DMCP) were used as received from K & K Laboratories Inc. Baker spectroquality *ortho*-xylene was also used as received. Gas chromatographic analysis of each reactant showed them to be of 99% purity, with no impurity found in greater than 0.2% abundance.

[1] Reactants and products will be hereafter referred to by the abbreviations in parentheses.

Retention times of and instrument sensitivities to the above reactants were determined before each run. Calibration of the instruments for the product hydrocarbons was accomplished on known samples of *cis*-1,2-dimethylcyclohexane (*cis*-DMCH), *trans*-1,2-dimethylcyclohexane (*trans*-DMCH), *cis*-1,2-dimethylcyclopentane (*cis*-DMCP), and *trans*-1,2-dimethylcyclopentane (*trans*-DMCP) obtained from K & K Laboratories Inc. Separation and identification of the cyclohexyl derivatives were effected on three six-foot columns connected in series with a helium flow of 32 cc/min at 110°C using a Hewlett-Packard 5750 gas chromatograph. The column series consisted of a UCON LB-550X on Sil-O-Cel firebrick column between two squalane on diatomite columns. Separation and identification of the cyclopentyl compounds were accomplished with a Perkin Elmer 154D Vapor Fractometer on a six-foot squalane on diatomite column at 62°C with a carrier flow of 100 cc/min. All reported ratios and percentages have been normalized according to the instrument sensitivity measurements.

A potential step technique (9) was used to prepare a reproducible electrocatalyst surface.[2] In order to oxidize the catalyst surface and any adsorbed impurities, the working electrode was held at 1.35V until the observed current had decreased to 10 mA. Next the potential was stepped cathodically to 0.05V for 20 min to reduce the catalyst oxide film formed at 1.35V. The potential was then stepped to the adsorption potential and the hydrocarbon reactant was passed over the working electrode in the inert gas stream for approximately 1 hr. Flows of 4.8×10^{-6} moles/min for 12DMCH, 8.8×10^{-6} moles/min for *ortho*-xylene, and 1.4×10^{-6} moles/min for 12DMCP were used. These flows derive from the equilibrium vapor pressures of the hydrocarbons in the inert gas stream which had passed over the reactants at 8 cc/min and 40°C. The varying flows were offset by allowing the electrocatalyst sufficient reactant contact time to achieve steady state. The contact time necessary to achieve steady state was determined by measuring the charge accumulation with anodic, galvanostatic, charging curves. Steady-state conditions were assumed when the electrocatalyst surface coverage became constant. The 60 min contact time allowed more than enough time for each reactant to achieve steady-state coverage. The long equilibration time, although necessary to achieve steady state, does present some complications. As the time of electrosorption increases, the possibility of competing reactions and adsorption site migrations also increases. Such effects might tend to obscure the specific mechanism involved in the electrode reaction. However, the requirement to achieve reproducible electrode coverage before pulse necessitates the acceptance of the above factors. The lines and working electrode gas cavity were then swept with inert gas for 30 min. After this time, gas chromatographic analysis revealed only trace amounts of reactant remained in the gas cavity. The working electrode was then galvanostatically cathodically pulsed at 1.0A and the resulting evolved hydrocarbons were trapped in 2,2-dimethylbutane, octane, or passed directly into the gas chromatograph.

Results

Dimethylcyclopentenes.—Table I shows the *cis/trans* (hereafter designated C/T) ratios obtained with 12DMCP and 23DMCP as reactants. The close correspondence of results, independent of cyclopentyl reactant, was not surprising since it was observed that an equilibrium was established between 12DMCP and 23DMCP upon passing one or the other over the electrocatalyst surface (Table I). The attainment of an equilibrium condition occurred with or without a potential applied to the working electrode. Isomerization, however, only occurred when the cycloolefin contacted the working electrode, and was not a consequence of the elevated temperature. The mean C/T ratio obtained upon cathodically desorbing the cyclopentyl compounds from an electrode which had been held at a 0.30V adsorption potential was 0.52 ($cis = 1.25 \times 10^{-8}$ moles).[3] Cyclopentane and methylcyclopentane were obtained along with *cis*- and *trans*-DMCP upon cathodic pulse and accounted for approximately 15% of the total pulse products. Passage of either 12DMCP or 23DMCP over the working electrode under potentiostatic conditions of 0.05V resulted in a mean C/T ratio of 0.47 ($cis = 2.5 \times 10^{-8}$ moles). The apparently rather small potential dependence of the C/T ratio was supported by a mean ratio of 0.51 ($cis = 9.5 \times 10^{-9}$ moles) at an adsorption potential of 0.20V.

Table I. Isomer ratios for 1,2- and 2,3-dimethylcyclopentene reactants

Reactants	0.05V (C/T)[a]	0.20V (C/T)[a]	0.30V (C/T)[a]	During adsorp. at 0.30V[b]

[b] Ratio of 1,2-dimethylcyclopentene to 2,3-dimethylcyclopentene during reactant adsorption and before pulse.

Table II. Isomer ratios for dimethylcyclohexene and *ortho*-xylene

Reactants	0.05V (C/T)[a]	0.30V (C/T)[a]	0.50V (C/T)[a]	During adsorp. at 0.30V[b]
12DMCH	1.12	2.21	2.47	2.48
23DMCH	1.17	2.18	2.53	2.44
Ortho-xylene	1.51	2.20	2.54	—

[a] Ratio of *cis*-1,2-dimethylcyclohexane to *trans*-1,2-dimethylcyclohexane.
[b] Ratio of 1,2-dimethylcyclohexene to 2,3-dimethylcyclohexene during reactant adsorption and before pulse.

Although the study was continued at 0.50V, a competing reaction occurred at this more anodic adsorption potential which interfered with the accuracy of the C/T data, therefore these results are not reported here. This reaction involved a one carbon expansion of the cyclopentyl ring and is under further investigation (10).

Dimethylcyclohexenes.—Table II lists the isomer ratios obtained with 12DMCH and 23DMCH as reactants. As with the cyclopentyl reactants, an equilibrium was established between the 1,2- and 2,3-dimethylcycloolefin isomers upon passage of either isomer over the electrocatalyst surface. The isomerization required contact of the cycloolefins with the working electrode, with or without an applied potential. As a consequence of the equilibrium, the C/T ratios obtained at the three potentials of interest (0.05V, 0.30V, and 0.50V) were independent of cyclohexyl reactant.

In contrast to the cyclopentyl olefins, the C/T ratios obtained with 12DMCH and 23DMCH showed a high percentage of *cis* isomer upon cathodic desorption. Similar results, low C/T from cyclopentyl reactants and high C/T from cyclohexyl reactants, have been previously observed during studies of the dimethylcyclohexene isomers and the dimethylcyclopentene isomers under conditions of normal heterogeneous catalysis (4, 11). At adsorption potentials of 0.30V and 0.50V, the mean isomer ratio obtained was 2.2 ($cis = 2.9 \times 10^{-7}$ moles), respectively; whereas pass-

[2] The cell gas cavity was swept with an inert gas at a flow rate of 8-10 cc/min throughout the potential step sequence.

[3] Reported quantities are included to give orders of magnitude only, since the total amount of products varied as the electrode aged and underwent changes in surface area. However, the relative amounts of one product to another are reasonably constant. The estimated error for all reported C/T ratios is 5%.

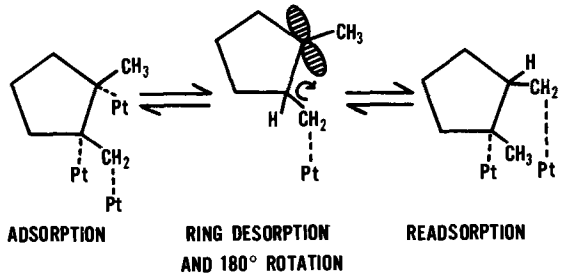

Fig. 1. Surface motion of intermediate

ing either dimethylcyclohexene isomer over the electrocatalyst potentiostated at 0.05V resulted in a C/T ratio of 1.12. The hydrocarbon products obtained during adsorption and after cathodic pulse are listed in Table III. As with the cyclopentyl reactants, monosubstituted cycloalkane and cycloalkane were obtained as pulse products and substantial quantities (2-10%) of the aromatic compound, *ortho*-xylene, were observed both during adsorption and after cathodic pulse at all potentials studied. The formation of *ortho*-xylene from 1,2-dimethylcyclohexene has also been observed during normal catalytic hydrogenation on reduced platinum oxide (11).

Ortho-xylene.—*Ortho*-xylene was studied under the same conditions as 12DMCH and 23DMCH to determine the effect of its hydrogenation on the reduced isomer ratios obtained with cyclohexyl reactants. At 0.05V, a potential at which the electrocatalyst sites should be covered by a monolayer of hydrogen or be actively evolving hydrogen, the aromatic reactant gave a higher C/T ratio than that obtained with cyclohexyl reactants. However, at 0.30V and 0.50V, the C/T ratios obtained with *ortho*-xylene as reactant were in good agreement with those obtained after reaction of the dimethylcyclohexenes.

Discussion

Although unactivated olefins and aromatic hydrocarbons are known to be difficult to reduce electrochemically (12), several investigators have reported reductions of these compounds at platinum electrodes by a variety of electrochemical methods (13-15). Little is known, however, about the nature of the adsorption process and adsorption geometry. The reduction of 12DMCP, 23DMCP, 12DMCH, and 23DMCH to their respective *cis*- or *trans*-dimethylcycloalkane seemed at first glance a simple means of studying the stereochemical aspects of electroreduction. The products and reduced isomer ratios obtained indicate that the processes occurring at the electrode are considerably more complicated than first imagined.

Dimethylcyclopentenes.—The C/T ratios obtained with 12DMCP or 23DMCP as reactants are not those expected if simple *cis* addition is to account for the mechanism of hydrogenation during cathodic desorption. By *cis* addition 12DMCP should give only *cis* product while 23DMCP should give both *cis*- and *trans*-DMCP. If the unlikely assumption is made that 23DMCP gives only the *trans* product upon pulsing, then from the 12DMCP/23DMCP equilibrium value a C/T ratio of approximately seven would be expected. Apparently the C/T ratio is not solely determined by the cycloolefin equilibrium, but is probably also a consequence of the adsorption geometry of the intermediate, and the thermodynamic stabilities of the reduced isomers (16).

To account for the high *trans* isomer percentage, the adsorption geometry must be such that the molecular motions of the adsorbed intermediate are not too severely hindered. A mechanism such as that shown in Fig. 1 could account for the *trans* isomer percentage. Adsorption of the dimethylcyclopentene reactant at the double bond and at one of the methyl groups would be the first step of this mechanism. The observation of the demethylated[4] compounds, methylcyclopentane and cyclopentane, supports the importance of electrocatalyst-methyl group interactions during the adsorption process. Such an interaction is not unexpected since the allylic positions in olefins, which the methyl groups occupy, are known to possess a high degree of reactivity. It has been postulated that olefins are capable of reversibly adsorbing by loss of a hydrogen atom at an allylic position as a mechanism for catalytic deuterium exchange (17). The next step of the mechanism would involve the addition of hydrogen to one end of the double bond followed by partial desorption, involving only the ring, and subsequent rotation of the ring 180° about the single bond between the ring and the platinum bound methyl group. Finally, readsorption of the ring would result in the plane of the molecule originally facing the electrocatalyst now facing away. Hydrogenation at this time would result in the *trans* isomer due to the two hydrogen additions occurring from opposite sides of the molecule.

Siegel and Smith (18) have proposed a mechanism for heterogeneous catalytic hydrogenation of dimethylcycloolefins whereby the migration of the double bond from the 1,2 to the 2,3 position followed by complete desorption and rotation of the molecule would yield the *trans* product. This process could not account for the high percentage of *trans* isomer obtained in this study. Since their mechanism is dependent on the cycloolefin equilibrium, a reasonable degree of correlation between the C/T and 12DMCP/23DMCP ratios would be expected. The mechanism proposed in this paper does not require any dependence of the C/T ratio on the dimethylcyclopentene equilibrium. Siegel and Smith's mechanism also differs from that proposed here in that their mechanism invokes complete molecular desorption whereas the proposed mechanism involves only partial desorption with retention of a methyl-platinum bond.

An alternate explanation of the observed results is that the C/T ratio is controlled only by the difference in activation energies between the reaction paths to the respective reduced isomers upon cathodic hydrogenation of a common adsorbed intermediate. As previously stated, olefins are believed to be capable of reversibly adsorbing by loss of a hydrogen atom at a reactive allyl carbon with direct formation of a 3-carbon π-bonded species (17). Formation of such an allylic π-bonded intermediate, as shown in Fig. 2, would not only provide a facile pathway for the observed cycloolefin isomerization, but also provides the common intermediate necessary to explain the C/T ratios on the basis of the thermodynamic stabilities of the reduced isomers. At present both alternatives

[4] The demethylation process, although not of major concern herein, might proceed via mechanisms similar to those which have been postulated to account for fragmentation in normal alkanes (3, 7). However, mechanistic interpretations based on demethylation fragments would have no significance, since it has been shown that C_1-C_6 fragments occur during the cathodic desorption of cyclohexane and benzene (23). Thus it would be impossible (unless isotopic labelling were used) to state whether any observed fragments were a result of the dimethylcycloolefin ring degradation or from demethylation of the intact ring.

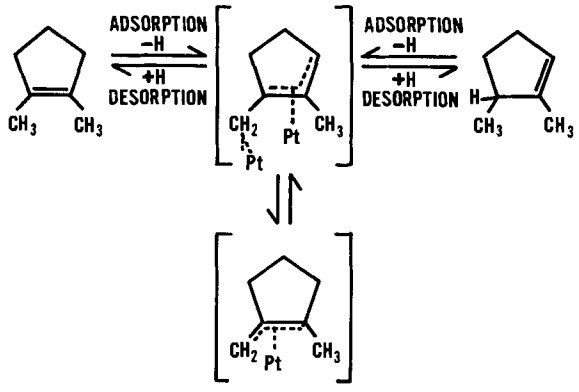

Fig. 2. Allylic cyclopentyl intermediate

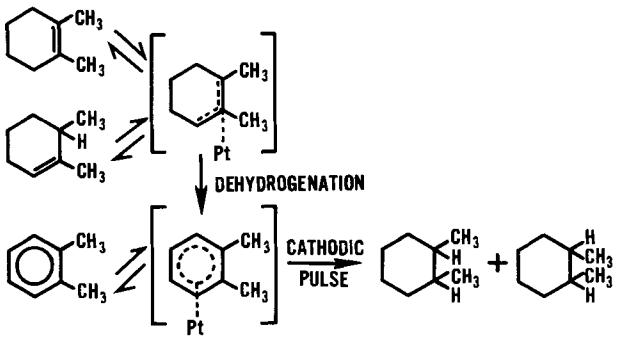

Fig. 3. Aromatic intermediate

appear equally plausible. A study of the temperature dependence of the C/T ratio now underway may ultimately determine the proper mechanism.

Dimethylcyclohexenes.—The C/T ratios obtained with 12DMCH and 23DMCH as reactants again do not appear to correspond to those expected if *cis* addition is to account for the mechanism of hydrogenation. Only in the extreme case of 23DMCH giving all *trans*-DMCH isomer could the C/T ratio be explained on the basis of the 12DMCH/23DMCH equilibrium observed during adsorption. It seems unlikely, however, that the 23DMCH adsorption geometry would be such as to make the cathodic hydrogenation stereospecific for the production of the *trans* isomer.

The presence of methylcyclohexane and cyclohexane (Table III) suggests the importance of platinum-methyl interactions and that the initial adsorption processes may be similar for both cyclopentyl and cyclohexyl reactants. If the proposed mechanism is to be applicable to both DMCP and DMCH reactants, the dimethylcyclohexene adsorption geometry must be able to be modified from the cyclopentyl adsorption geometry in such a way that desorption and rotation from the electrocatalyst surface is restricted. An increased interaction of the ring itself with the electrocatalyst could restrict its motion by effecting a stronger bond between the ring and the active surface. Such restricted ring motion could account for the higher *cis* percentages observed. In contrast to the DMCP results, the dimethylcyclohexene reactants give a C/T ratio which is markedly dependent on potential. The increase in the C/T ratio with more anodic potentials suggests that as the catalyst becomes more "electron deficient," the ring motion becomes more restricted. To account for this behavior the ring would have to possess some nucleophilic, or "electron rich," character.

The marked similarity in results obtained for 12DMCH, 23DMCH, and *ortho*-xylene suggests the existence of a common reaction path for both olefin and aromatic. It would then be required that both systems pass through a common intermediate while absorbed on the electrocatalyst. The formation of six individual carbon-platinum sigma bonds from each ring carbon to electrocatalyst sites hardly seems likely due to the steric requirements imposed on such a bond scheme. It also would seem doubtful that an energetically favored system, such as the aromatic *ortho*-xylene, could find such a surface reaction thermodynamically favorable. However an aromatic π-orbital interaction with the catalyst constitutes a distinct possibility. π complexes have been postulated for the interaction of olefinic and aromatic hydrocarbons with a platinum surface by other investigators (17, 19, 20) for deuterium exchange reactions. If the dimethylcyclohexenes adsorb by loss of a hydrogen atom from an allylic ring carbon with direct formation of a π-bonded species (16), the achievement of an energetically favored state, such as an aromatic system, could provide the impetus to dehydrogenate the cyclohexyl species. Figure 3 is a representation of the DMCH isomers and *ortho*-xylene reacting through a common π adsorbed aromatic intermediate to form *cis*- and *trans*-1,2-dimethylcyclohexane isomers. Evidence that such an aromatization is possible electrochemically can be found in the work of Luksha and Weissman (21) on anodic oxidation of various hydrocarbons at a porous platinum black, Teflon electrode. They observed that overpotential data obtained for cyclohexyl olefins were not consistent with that obtained for other olefins. Instead the cyclohexyl olefin results were close to those obtained for aromatic species. Such a similarity can be explained by dehydrogenation of the cyclohexyl compounds under anodic conditions to aromatics, with a resultant behavior more like aromatics than olefins (21). It might then be expected that under more cathodic conditions aromatization might not occur. This would explain the noncorrespondence of the C/T ratios of *ortho*-xylene, 12DMCH, and 23DMCH at 0.05V. Since the electrocatalyst would be "electron rich" at this potential, there would be no driving force to form a π-electron cloud within the adsorbed species. The increased C/T ratio with increased anodic potential might be expected for this type of intermediate, since the electrocatalyst would show increased electrophilicity as the potential becomes more anodic. Thus a stronger interaction would result between the "electron deficient" catalyst and the electron rich π-cloud of the aromatic intermediate.

Summary and Conclusions

The following similarities between the dimethylcyclohexene isomers and *ortho*-xylene have been observed upon adsorption and reaction at a fuel cell electrode. With 12DMCH or 23DMCH as reactant, *ortho*-xylene was observed both during adsorption and after cathodic pulse, suggesting a common reaction path for both species, and that the conversion from DMCH to the aromatic compound readily occurs. The C/T data obtained on cathodic pulse are virtually identical for both cycloolefin and aromatic reactants, again suggesting a common reaction path.

The differences in the data obtained for the DMCP isomers and the DMCH isomers clearly point to different processes occurring for the two ring sizes. With cyclopentyl olefins as reactants, the C/T ratio appears to be highly dependent on the ability of the adsorbed intermediate to partially desorb and rotate about the bond connecting the ring to the platinum bound methyl group. The apparent driving force is suggested to be the greater thermodynamic stability of the *trans*-1,2-dimethylcyclopentane over the *cis*-isomer (16).

The reduced product ratio obtained with the cyclohexyl reactants on the other hand appears to be controlled by a more complex interaction of the hydrocarbon with the electrocatalyst. Based on the similarities observed between the dimethylcyclohexene and

ortho-xylene reduction products, the interaction is postulated to be the formation of an aromatic π-bonded intermediate with little dependence on the thermodynamic stability of the *trans* reduced isomer over the *cis* (22).

The Role of Passivity in the Mechanism of Stress-Corrosion Cracking and Metal Dissolution of 18Cr-8Ni Stainless Steels in Boiling Magnesium and Lithium Chlorides

B. E. Wilde*

U. S. Steel Corporation, Applied Research Laboratory, Monroeville, Pennsylvania 15146

ABSTRACT

Electrochemical polarization measurements conducted on AISI Type 304 stainless steel in boiling lithium chloride have shown that the alloy exists in a stable state of passivity. Similar investigations in boiling magnesium chloride indicated a stable passive state, but the data were more ambiguous than the lithium chloride data because of the effect of pitting corrosion. Controlled potential corrosion studies and microchemical analysis in boiling magnesium and lithium chloride have indicated that Type 304 stainless steel is in a passive state at the potential where the alloy cracks under freely corroding conditions. Further, cation partial current density curves have shown clearly that nickel enrichment does not take place in either corrodent at the corrosion potential. The data presented strongly support the film-rupture model (slip-step dissolution) of crack initiation.

Much effort has been expended over the last 25 years to elucidate the mechanism of stress corrosion cracking (SCC) of austenitic stainless steels in chloride-containing environments (1-5). These efforts have resulted in several models proposed to explain the initiation and propagation stages of cracking and have been the subject of several recent reviews (6, 7). Two of the models rely on the presence of a film on the surface of the corroding steel and in the advancing crack tip, which subsequently affects the anodic dissolution of the metal.

Champion (8) and Logan (1) suggest that localization takes place by a rupture of a film on the surface where slip-step emergence occurs because of dislocation movement under plastic flow. Rapid anodic dissolution then occurs on the bare metal, followed by a refilming process that stifles the dissolution reaction. The propagation stage is envisaged as a repetitive repassivation and rupture process at the crack tip. This model has been criticized by various workers who believe that passivating films are not likely to form on austenitic steels in magnesium chloride (9, 10).

To overcome this criticism, Latanision and Staehle (6) have suggested that nickel enrichment may occur and result in a thin film of the relative noble nickel, which would decelerate anodic dissolution. They propose that initiation and propagation then take place by a similar film rupture and formation mechanism as proposed by Champion (8) and Logan (1). The nickel enrichment concept, although not proven, finds support from the experiments of Pickering (11), who demonstrated that such noble metal enrichment can take place in certain SCC environments on Cu/Au alloys, as a result of preferential copper dissolution.

Clearly, from the viewpoint of these two models, it is essential to establish whether or not a passive

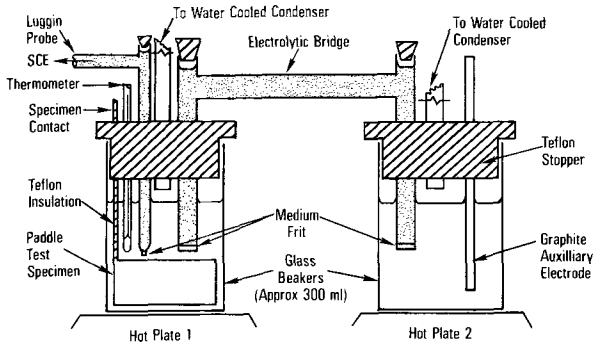

Fig. 2. Schematic representation of controlled potential corrosion apparatus.

film or nickel-rich film forms on austenitic steels exposed to concentrated chloride solutions. In an attempt to clarify these questions, Davis and Wilde (12) conducted electrochemical measurements on austenitic steels in boiling magnesium chloride and from transient polarization studies concluded that the electrode kinetic behavior of Type 304 stainless steel was consistent with the presence of a passivating film at steady state. These authors demonstrated that the shapes of cyclic polarization curves for this alloy in boiling $MgCl_2$ were identical to those obtained with the alloy in an unambiguous state of passivity; namely when exposed to oxygenated $1\overline{M}$ Na_2SO_4 acidified to *p*H 2 with H_2SO_4 at 25°C.

If the above interpretation is correct, the anodic and cathodic partial reaction rates should be similar to those depicted by the dotted lines in Fig. 1. Further, the applied current polarization behavior should be, and indeed is, as that represented by the solid lines in Fig. 1. Additional circumstantial support for this interpretation comes from the shape of the potential transients following immersion (9, 12), which are very similar to those reported elsewhere (13) for this alloy passivating in aerated dilute acid media.

A possible method to unambiguously establish the validity of this interpretation is the use of chemical analysis following corrosion at a controlled potential active to the corrosion potential, to demonstrate an active to passive transition in terms of the cation partial currents as suggested by Pickering and Byrne (14). These authors along with Condit *et al.* (15) have successfully employed this technique to construct cation partial rate curves for alloy dissolution in room-temperature electrolytes. The present communication describes the results of an attempt to extend this technique to higher temperatures and more complex electrolytes along with conventional polarization studies to establish the electrode kinetic nature of the surface of Type 304 stainless steel in boiling $MgCl_2$ (150°C) and boiling LiCl (146°C).

Materials and Experimental Work

The Type 304 stainless steel used in this study had the chemical composition shown in Table I. Specimens for electrochemical polarization studies were machined from bar stock after annealing at 1000°C for

Table I. Chemical composition of the steel used in this investigation

Composition (weight per cent)									
C	Mn	P	S	Si	Cu	Ni	Cr	Mo	N
0.052	1.25	0.023	0.018	0.52	0.08	9.75	18.8	0.36	0.036

30 min and water quenching. Cylinders (2 cm long by 0.625 cm diameter) were drilled and tapped to fit a Stern-Makrides type electrode holder (16), and were abraded down to 600 grit silicon carbide finish, ultrasonically cleaned in a detergent, washed in distilled water (7.63 megohm cm at 25°C), and hot-air-dried prior to use.

Polarization experiments were conducted with the procedures and equipment described elsewhere (17). All electrode potentials are expressed against the saturated calomel half-cell (SCE), and measured via a Luggin-Haber probe (filled with liquid and/or solid corrodent) which extended from the boiling flask to a beaker at room temperature containing a SCE in either 35% $MgCl_2$ or saturated LiCl at 25°C. No attempt was made to correct for Soret thermal potential errors (8) or those arising from liquid junctions (18, 19).

Specimens for controlled potential studies were cut out of 2 mm thick sheet stock having been heat-treated and surface-prepared as above. For maximum analytical sensitivity, the paddle specimens had a nominal surface area of 20 to 30 cm^2.

The magnesium and lithium chlorides used in this study were of reagent grade quality and were prepared as follows: (*A*) 850g $MgCl_2 \cdot 6H_2O$ were added to 70 ml water, resulting in a solution boiling at 150°C. (*B*) A saturated solution of LiCl was prepared with distilled water at 25°C. This solution boiled at 146°C.

Controlled potential corrosion tests were conducted in an apparatus shown schematically in Fig. 2. The apparatus was divided into two compartments, separated by an electrolytic bridge containing frits at both ends. By this facility the catholyte could be isolated conveniently to eliminate the effects of the chlorine liberated in the anolyte while maintaining electrolytic conductance. The porosity of the frits was such that approximately 300 mA could be passed through the bridge at 140° to 150°C. Samples were exposed for a suitable period of time to reach steady state, and approximately 100 ml of catholyte were removed by rapid pouring into a convenient beaker for analysis.

The precise analytical procedure employed is described in Appendix 1, but the following will be given in the interests of clarity. The hot catholyte sample was carefully poured into distilled water[1] to a final volume of 500 ml and cooled to room temperature. The cooled solution was transferred to the main part of the cyclic extraction vessel shown in Fig. 3. After addition of ammonium pyrolidine dithio carbamate, the complexes of iron, chromium, and nickel were precipitated by adjustment of the *p*H to 3.0, leaving the salts of magnesium and lithium in solution. The transition metal complexes were then extracted on a continuous 12 hr recycle basis into

[1] Note it is essential to pour the sample into water to avoid sputtering.

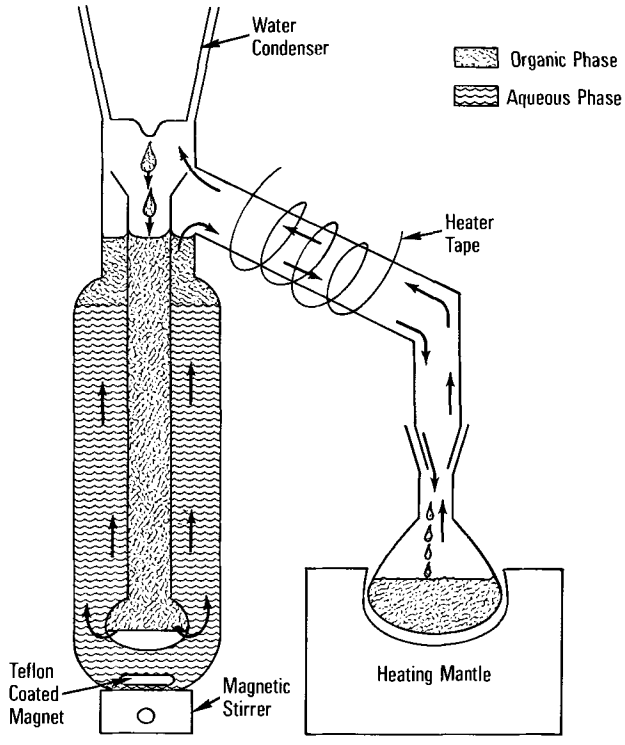

Fig. 3. Schematic representation of the continuous two-phase liquid extraction assembly used to extract Fe^{2+}, Ni^{2+}, and Cr^{3+} from $MgCl_2$ and LiCl.

methyl-isobutyl ketone. The organic extract was evaporated down to almost dryness on a hot plate, then finally to dryness in a room temperature circulating air cabinet.[2] The residue was oxidized with concentrated nitric acid three times, and evaporated to dryness to leave the nitrate salts of iron, chromium and nickel. These residues were dissolved in 5 ml concentration HNO_3 and diluted to a standard volume of 10 ml, thus effecting a concentration factor of 10.

The absorbance of the residue solutions was determined by atomic absorption spectrometric techniques (20) and compared with a standard graph to obtain the concentration of Fe, Cr, and Ni in the 10 ml aliquot. This latter figure was equal to that in the original 100 ml sample, which was converted to cation partial current densities as described in Appendix 2.

Results and Discussion

For simplicity of presentation the data will be developed and discussed in three sections: (*A*) polarization and analytical experiments in boiling $MgCl_2$, (*B*) polarization and analytical experiments in boiling LiCl, and (*C*) a brief review of how the present data fit into current mechanistic thinking.

$MgCl_2$—polarization studies.—Potentiodynamic anodic polarization curves obtained for Type 304 stainless steel in this corrodent evidenced an acceleration of the pitting observed at E_{corr}. Potentiodynamic cathodic polarization curves are shown in Fig. 4 at various sweep speeds. In all except the fastest sweep, an arrest or inflection was observed around −0.750 V_{SCE}. Recently Staehle *et al.* (21) have described the cathodic polarization behavior of some Fe-Cr-Ni alloys in boiling $MgCl_2$, where inflections and applied current minima were noted during potentiodynamic polarization. These authors have suggested that this behavior is consistent with what one would expect by cathodic polarization of a stable passive electrode, since i_{app} should decrease at the passivation potential because of the dictates of the mixed potential theory (22)

[a] It was found essential to adopt this procedure to avoid loss of the chromium chelate by distillation.

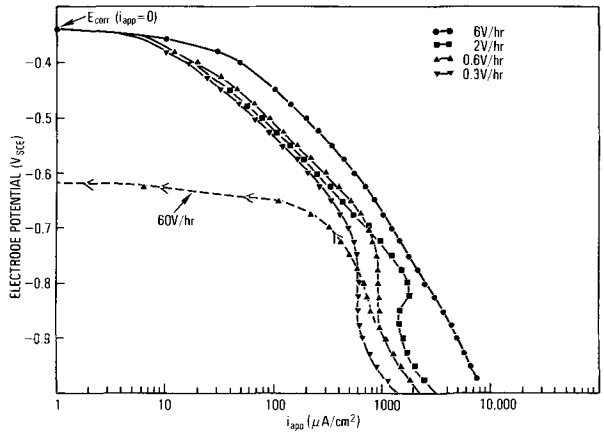

Fig. 4. Potentiodynamic cathodic polarization curves for Type 304 stainless steel in boiling $MgCl_2$.

$$i_{app} = \Sigma i_{red} - \Sigma i_{ox} \qquad [1]$$

where Σi_{red} represents the sum of all the operative cathodic partial processes and similarly Σi_{ox} represents the sum of the anodic reactions.

Since no significant minima were observed, and a wide range of potential independent applied current was found at −0.750 V_{SCE}, it must be assumed that the cathodic process has differing kinetics on the passive surface as compared with those on an active or nonpassive surface, and is not in fact represented by the one reduction process as depicted in Fig. 1.

A similar situation has been reported for the reduction of protons on an active and passive chromium surface. In this latter case Wilde and Hodge (23) have shown that one reduction curve (see Fig. 1) cannot be used to describe the electrode kinetic behavior of chromium. Significant differences were reported in exchange current density, Tafel slope, stoichiometric number and activation energy for the hydrogen evolution reaction. A typical galvanostatic cathodic polarization curve on passive chromium is shown in Fig. 5, which is similar to that obtained on Type 304 stainless steel in boiling $MgCl_2$ as shown in Fig. 6.

A possible reason for this behavior could be the changes in the transmission coefficient α_c, and exchange current density $i_{o(H_2)}$ when polarizing an initially passivated surface (which can support a limited rate of proton reduction) to a situation where the passive film becomes unstable and the surface shifts to an active state having a different α_c and $i_{o(H_2)}$.

To emphasize the existence of a passive state in $MgCl_2$, the 0.6 V/hr sweep was reversed after prolonged exposure at −1.0 V_{SCE}. As reported previously

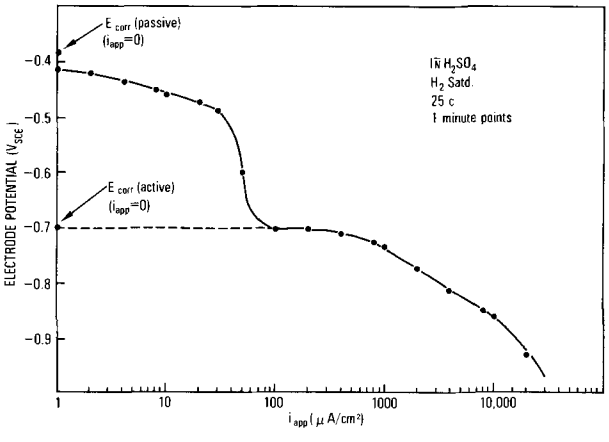

Fig. 5. Galvanostatic cathodic polarization curve on passive chromium in 1N sulfuric acid.

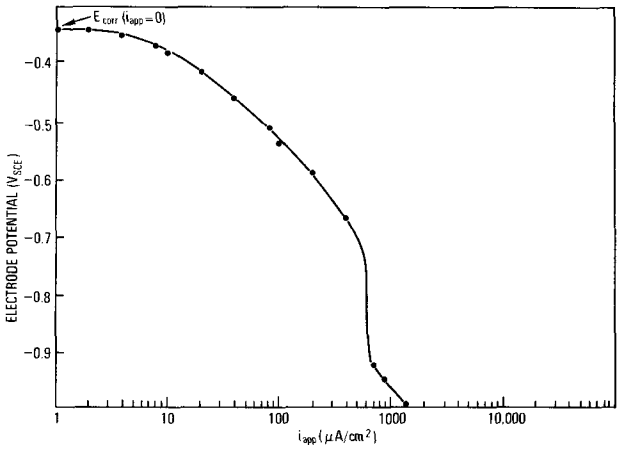

Fig. 6. Galvanostatic cathodic polarization curve for Type 304 stainless steel in boiling $MgCl_2$.

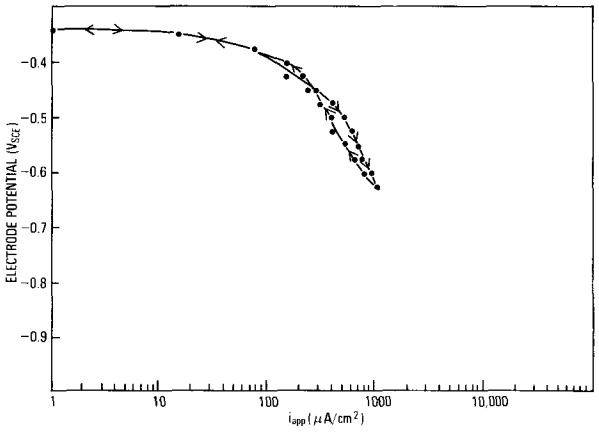

Fig. 7. Cyclic potentiodynamic cathodic polarization curve for Pt in boiling $MgCl_2$.

(12) a second more active mixed potential was noted at −0.715 V_{SCE}. Since the reverse sweep was conducted at 60 V/hr (a speed assumed to be faster than the repassivation kinetics), it is thought that this latter potential represents the corrosion potential of a film free surface. To verify that this behavior was not an experimental artifact, a cyclic cathodic-polarization experiment was conducted on a bright platinum electrode. These data are shown in Fig. 7, where virtual complete reversibility was observed with both sweeps going through the same mixed potential in contrast to the behavior of stainless steel.

Controlled potential corrosion studies.—Before the controlled potential corrosion tests, a series of synthetic standards was put through the analytical procedure to assess the efficiency of the Fe, Cr, and Ni extraction from $MgCl_2$. The results are shown in Table II along with equivalent data for LiCl. The standard solutions were prepared by suitable dilution of a stock solution containing 1.000g of pure Fe, Cr, and Ni metal dissolved in dilute HNO_3. Two significant facts are evident from Table II: first, the efficiency of recovery of pure standards was excellent for all three elements; and second, the impurity content of the $MgCl_2$ was rather high, being equivalent to the anticipated level of Fe, Cr, and Ni resulting from corrosion. This factor, although decreasing the inherent sensitivity of the measurement, did not affect the excellent recovery efficiency of standards added to $MgCl_2$ at the 50 μg level.

Table II. Check on analytical separation technique with synthetic standards

Sample	Concentration added, μg/10 ml Fe	Cr	Ni	Concentration found, μg/10 ml Fe	Cr	Ni

* Residue analyzed after extracting 100 ml of $MgCl_2$ and LiCl and expressed as total Fe, Cr, and Ni in final 10 ml volume.

The rate of dissolution of Type 304 stainless steel in boiling $MgCl_2$ at the steady-state corrosion potential was determined every 24 hr to steady state. These data are summarized in Fig. 8, from which it is clear that a steady state dissolution rate was attained after 72 hr. Since it was essential that a steady state be reached prior to analysis so as not to encounter effects resulting from one or more components being involved in film formation, all subsequent analyses were conducted as follows. The specimen was exposed at a fixed potential for 72 hr, after which the corrodent was discarded and replaced by a fresh batch for 24 hr, the latter being analyzed for Fe, Cr, and Ni.

During experiments conducted at potentials more negative than −0.600 V_{SCE}, precipitation of magnesium hydroxide occurred as a result of the local increase in pH at the metal/electrolyte interface during prolonged hydrogen ion reduction. Typical examples of this phenomenon are shown in Fig. 9. Also of interest in Fig. 9 is the pronounced stress-corrosion cracking that took place at the sheared edges of the specimen exposed at E_{corr}. However, although not clear from Fig. 9, the majority of the attack at E_{corr} took the form of elongated pits in the midst of apparently untouched shiny bright metal. This behavior strongly resembles the breakdown of passivity observed on similar steels in chloride media at lower temperatures (24). The nature of the deposits shown in Fig. 9 varied, with the applied potential being loose and gelatinous at −0.700 V_{SCE} and becoming hard and brittle at −0.800 V_{SCE} and −0.900 V_{SCE}. Although not clear from the figure, the covered area increased markedly as the applied potential became more negative.

The results of the controlled potential tests are given in Table III and summarized as cation partial current density polarization curves in Fig. 10.

At the steady-state corrosion potential, it is evident that although the partial current density for Ni^{2+} is less than that for Fe^{2+}, it is nevertheless greater by a factor of three than the partial current density for

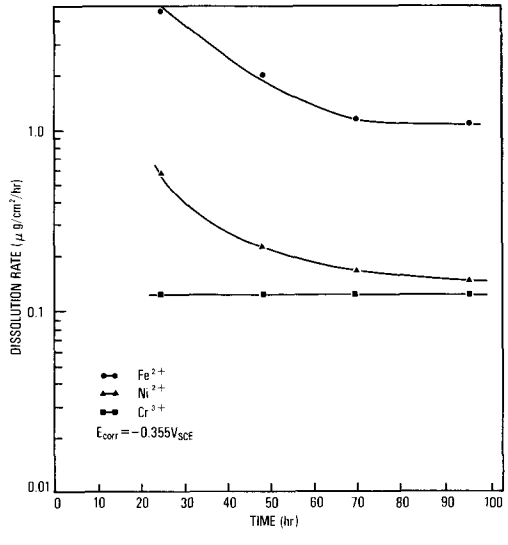

Fig. 8. The change in dissolution rate with time for Type 304 stainless steel at E_{corr} in boiling $MgCl_2$.

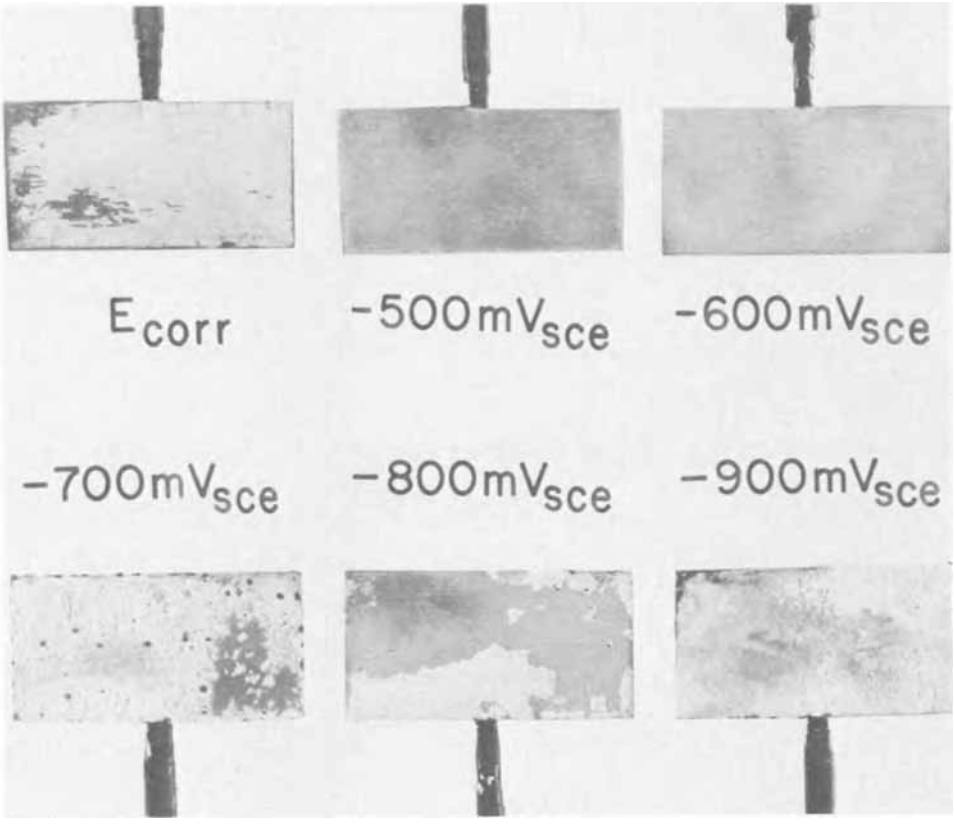

Fig. 9. Photograph of paddle specimens after exposure to boiling $MgCl_2$. Note cracks and pits at E_{corr} and $Mg(OH)_2$ deposit at potentials more active than -0.600 V_{SCE}.

Cr^{3+}. These findings are in conflict with the nickel-enrichment theory (6). Inspection of Fig. 10 indicates that a small, active-passive transition occurs at -0.700 V_{SCE}, which is shown better in Fig. 11 where the sum of the cation partial current densities is plotted. This value of the passivation potential is qualitatively very close to the potential where inflections were observed in the cathodic polarization curves (Fig. 4). In Fig. 11 a 200 mV wide passive range is shown at potential active to E_{corr}, which translates into a pitting situation at E_{corr} presumably due to the critical pitting potential E_c being more active than -0.355 V_{SCE}.

It is also of interest from the point of view of the mechanism of alloy dissolution to note the ratio at which the various components enter solution. A general summary is given in Fig. 12, where the dissolution fraction is calculated as the ratio of the cation partial current density to the total dissolution current density. Two points of interest emerge. First, during the process of passivation the dissolution fraction of Cr reaches a maximum at the passivation potential (-0.700 V_{SCE}) after which it progressively decreases as the passive film is formed to a value well below the stoichiometric level for Cr. This behavior strongly suggests that the Cr dissolution products are being incorporated into a passive film. Second, the dissolution fraction for nickel increases from the stoichiometric value at E_{corr}, passes through a maximum at -0.420 V_{SCE} and then decreases to a potential independent value (-0.600 to -0.900 V_{SCE}) of approximately 4%. It is clear from this behavior that although nickel enrichment occurs at active potentials, it does not at the steady-state corrosion potential. Therefore, it must be concluded that during stress-corrosion cracking under freely corroding conditions, nickel enrichment plays no role in the initiation of cracks.

The dissolution fraction for Fe evidenced a minimum at the passivation potential, after which Fe entered the corrodent in a manner close to the stoichiometric factor in the alloy. At the corrosion potential, however, (where pitting corrosion was observed) iron dissolves preferentially while nickel dissolves at the stoichiometric rate and chromium appears to be tied up in the passive film.

It must be pointed out that the above data should be considered as semiquantitative, in view of the experimental problems caused by magnesium hydroxide precipitation and the relative high Fe, Cr, and Ni impurity content of the $MgCl_2$. In the former case it was necessary to assume that the measured corrosion products resulted from the unfilmed area as measured with a planimeter. Implicit in this latter assumption

is the fact that the $Mg(OH)_2$ was an effective barrier through which dissolution could not take place.

LiCl-polarization studies.—Essentially the same experiments that were conducted in boiling $MgCl_2$ were conducted in boiling LiCl. It was felt that since this latter solution: (*i*) had a soluble hydroxide, (*ii*) was inherently of better chemical purity than $MgCl_2$, and (*iii*) caused cracking of Type 304 stainless steel in a manner identical to $MgCl_2$ and in times almost as short, experiments in this media would be less subject to the ambiguity encountered in $MgCl_2$. A summary of the stress corrosion behavior in both LiCl and $MgCl_2$ is given in Table IV along with typical cross-section metallography of cracks from both solutions in Fig. 13. Potentiostatic anodic polarization curves were constructed by using 25 mV steps every 3 min after an unstressed specimen had reached a steady-state corrosion potential. A typical curve is shown in Fig. 14, from which two points of interest emerge. First, unlike Type 304 stainless steel in $MgCl_2$, a wide range of passivity was observed. Second, at -0.360 V_{SCE} a distinct critical pitting potential (E_c) was noted. At a more noble potential than E_c rapid pitting of the specimen took place, as shown in Fig. 15.

These latter observations were of interest from the viewpoint of recent proposals which suggest that the stress-corrosion cracking of austenitic stainless steels in chloride media results from hydrogen embrittlement caused by absorption of hydrogen into the metal via proton discharge in pits (25). Although it is not possible to discount the above mechanism during crack propagation, it is clear from Fig. 14 that cracking initiated at potentials well active to E_c [where no pit-initiation was possible (26)] and it must be con-

Corrodent	Time to failure* (hr) 1	2	3	Mean
$MgCl_2$ (BP 150°C)	3.34	4.36	5.62	4.4
LiCl (BP 146°C)	11.55	15.36	21.3	16.1

* Specimens stressed to 75% of the room temperature engineering yield strength after immersion in the hot corrodent.

cluded that pitting corrosion is not a precursor of crack initiation, at least in boiling LiCl.

A typical galvanostatic cathodic polarization curve is shown in Fig. 16, where each point represents less than 1 mV change in 15 min. It is of interest to note the influence of immersion time. Although the steady-state corrosion potential was −0.495 V_{SCE} (a condition where one would expect film formation to be complete), the kinetics of the cathodic partial process were decreased by increasing the immersion time from 20 to 48 hr. Values of the Tafel constant increased from −0.087 V/decade to −0.095 V/decade.

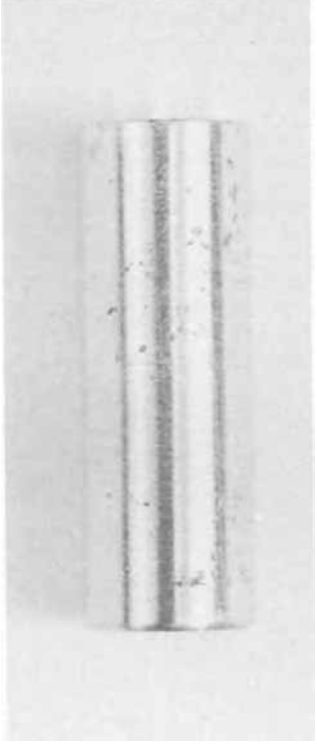

Fig. 15. Macrophotograph of anodic polarization specimen showing passivity breakdown and pit-initiation.

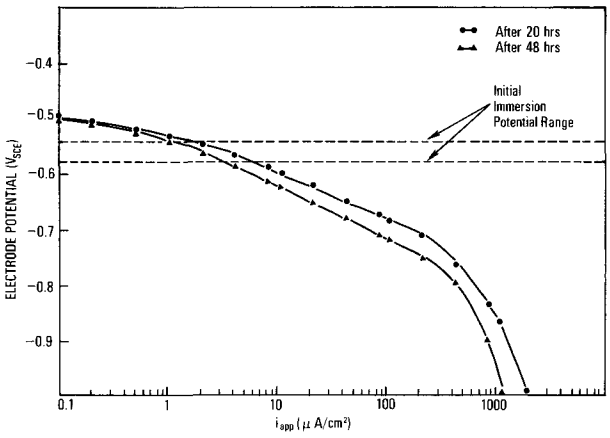

Fig. 16. Galvanostatic cathodic polarization curves for Type 304 stainless steel in boiling LiCl solution.

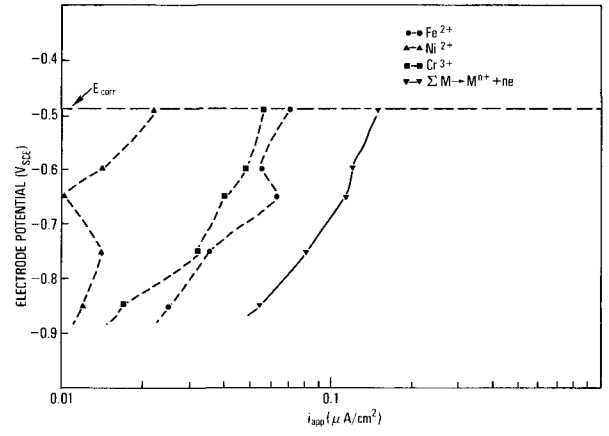

Fig. 17. Partial current dissolution curves for Fe^{2+}, Ni^{2+}, and Cr^{3+} from Type 304 stainless steel in boiling LiCl.

Potentiodynamic polarization measurements on Type 304 stainless steel in boiling LiCl at 1.5 V/hr sweep speed did not reveal any applied current minima nor the inflections noted with $MgCl_2$, and essentially duplicated the curves shown in Fig. 16. In view of the obvious state of passivity (Fig. 14) it must be concluded that the cathodic process is entirely supported on the passive film, and in this respect the electronic conductivity of the passive film formed in LiCl must be considerably different from that formed in $MgCl_2$ [possibly because of the incorporation of the cation into the film (12)].

Controlled potential corrosion studies.—The results of the controlled potential corrosion tests in boiling LiCl are summarized in Table V and Fig. 17. Unlike the situation with $MgCl_2$ no evidence of an active-passive transition was observed, indicating that Type 304 stainless steel in LiCl is in a stable passive state even at potentials as active as −0.900 V_{SCE}. By use of the data shown in Fig. 17, the component dissolution ratios were calculated as for $MgCl_2$ and are presented in Table VI.

Table V. Results of controlled potential corrosion tests in boiling LiCl

Control potential, V_{SCE}	Partial current density, μA/cm^2 Fe	Cr	Ni	$\Sigma M \rightarrow M^{n+} + ne$, μA/cm^2
−0.490 (E_{corr})	0.07	0.056	0.022	0.146
−0.600	0.055	0.048	0.014	0.117
−0.650	0.063	0.040	0.010	0.113
−0.750	0.035	0.032	0.014	0.018
−0.850	0.025	0.017	0.012	0.054

Table VI. Summary of cation dissolution fractions observed in boiling LiCl

Control potential, V_{SCE}	Percentage dissolution fraction Fe	Cr	Ni
−0.490	46.2	31.5	22.2
−0.600	47	41	12
−0.650	56	35.5	8.5
−0.750	43	39.5	17.5
−0.850	47.4	37.9	14.2
Mean	47.9	31.1	14.9

In contrast to the trends observed in $MgCl_2$, the percentage dissolution fractions for each cation were essentially constant over the potential range −0.400 to −0.850 V_{SCE}. Referring to the mean values, it appears that both Cr and Ni are dissolving at a rate higher than the stoichiometric level for the alloy. In addition, it would seem that Fe in this case is involved in film formation, in contrast to the chromium in the case of $MgCl_2$.

Mechanistic considerations.—The data presented indicate that Type 304 stainless steel in boiling $MgCl_2$ and LiCl exists in a stable state of electrochemical passivity. Furthermore, no evidence has been obtained to indicate that nickel enrichment occurs on the steel surface under freely corroding conditions. In view of these facts it appears that the initiation of stress corrosion cracks evolves from a passive film breakdown process. Although in boiling $MgCl_2$ pitting corrosion occurs in addition to cracking, it should not be concluded that the film breakdown process that leads to pitting is responsible for crack initiation. Evidence to support this point of view is presented in the boiling LiCl experiments where no pitting took place since E_c was more noble than E_{corr}.

The model recently proposed by Staehle *et al.* (21) for crack initiation involving slip-step dissolution is consistent with the experimental data obtained in this study. The picture regarding the propagation mechanism is less clear; consequently, only a limited review of the more important observations will be made.

It is becoming well established that the evolution of hydrogen from a growing crack is a common observation (27, 28). This observation indicates that at least a part of the cathodic partial process supporting crack growth occurs within the confines of the crack. These data can be understood on the basis of the observations of Marek and Hochman (29) who have reported considerable acidification of the corrodent in the crack tip when Type 304 stainless steel was cracked in boiling $MgCl_2$. This acidification process presumably occurs by a similar hydrolysis reaction to that described by Brown *et al.* (30) during crack propagation in high strength steels in sodium chloride, and allows proton reduction and hydrogen evolution to occur.

On the basis of the above evidence, it is not considered likely that the film-rupture model proposed for crack propagation by Champion (8) and Logan (1) is applicable because acid conditions at the crack tip would tend to destroy the passive film which has been shown to be stable on the surface at a bulk *p*H of 3 to 4.

Other authors have suggested that crack propagation occurs as a result of hydrogen absorption into the steel at the crack tip. Troiano and his school (31, 32) suggest that crack growth occurs because of a triaxial decohesion phenomenon essentially identical to that proposed for crack growth in high-strength steels. Unfortunately, this thesis as yet is not amenable to direct proof. However, although the absorption of hydrogen into Type 304 stainless steel under cathodic polarization in LiCl at lower temperatures has been demonstrated by electrochemical permeation experiments (33), and also during pitting corrosion of a number of stainless steels (34), it has not been established beyond doubt that a similar absorption process occurs at 146° to 150°C under freely corroding conditions. The answer to this latter question rests in the relative magnitude of the temperature coefficients of the absorption-rate constant (35) and the Tafel recombination rate constant (36), which to the best of the author's knowledge have not been determined. Another hydrogen absorption model has been proposed by Vaughan and Phalen (37) who suggest that crack propagation involves the formation of an unstable "hydride" phase under strain, which subsequently dissolves. However, there are several reported facts that are difficult to rationalize on the basis of a "hydrogen embrittlement" model.

First, Davis (38) has conducted experiments on stressed roll-bonded specimens consisting of a susceptible and a nonsusceptible steel in boiling $MgCl_2$. He demonstrated that crack propagation arrested at the interface, and changed to a lateral dissolution mode of attack along with severe crack blunting. The only difference between the two steels was 0.177% Mo and 0.014% P; the hydrogen diffusivity, corrosion rate, and corrosion potential[3] were identical when tested individually in boiling $MgCl_2$. It does not seem reasonable in view of the very similar mechanical properties and hydrogen diffusivities of the two steels that total crack arrest should occur if a bulk controlled crack propagation mechanism were operative.

Second, the fact that crack propagation can be arrested immediately on application of a cathodic current (a condition that may be expected to enhance hydrogen absorption) seems to preclude the applicability of crack growth by a "hydrogen embrittlement" mechanism. It seems more likely that although hydrogen evolution and possibly absorption does occur during crack propagation, the basic mechanism of crack growth must involve an electrochemical stage, to which hydrogen contributes little, if anything, in the case of austenitic stainless steels.

The author believes that the mechano-chemical model proposed by Hoar and Hines (9) for crack propagation remains the one most generally applicable. The acidification discussed previously would favor this latter model since it is based on the concept that deforming film-free metal (at the crack tip) dissolves more rapidly than nondeforming metal because of the effective increase in the metal exchange-current density resulting from surface disarray caused by dislocation emergence (39, 40).

Conclusion

The following conclusions may be drawn from the data presented.

1. Electrochemical polarization measurements on Type 304 stainless steel in boiling LiCl have shown that the alloy exists in a stable state of passivity.
2. Controlled potential corrosion studies and chemical analyses in boiling $MgCl_2$ and LiCl have confirmed that Type 304 stainless steel is in a passive condition.
3. Construction of cation partial current density curves has shown that nickel enrichment does not occur in the cracking or corrosion potential in either $MgCl_2$ or LiCl.
4. The data presented suggest that the probable mechanism of stress corrosion cracking of Type 304 stainless steel in boiling $MgCl_2$ and LiCl is as follows: (*a*) passive film rupture by a process of slip-step emergence. (*b*) crack propagation by a strain assisted anodic dissolution process. The basic crack propagation mechanism may be assisted by corrodent acidification with crack tip and the presence of a pre-existing susceptible path caused by metallurgical factors such as dislocation structure.

APPENDIX 1

1. Transfer 100 ml of the hot corrodent to a beaker containing 300 ml of distilled water, taking great care to avoid sputtering. Mix the solution thoroughly and cool to room temperature. Carefully transfer the contents by means of a funnel to the extraction unit through the center tube. Rinse the beaker with a further 100 ml of water and add to the extractor.
2. Accurately weigh 1g of ammonium pyrolidine dithiocarbamate (APDC), stir with 10 ml water, and add to the extractor via the funnel. Rinse out beaker and add to extractor.
3. Stir extractor slowly with magnet and carefully adjust pH to 3.0 with 10% HCl.
4. Add 185 ml methyl isobutyl ketone (MIBK) carefully down center tube. About 100 ml should overflow into boiling flask.
5. Attach condenser and extract for 12 hr.
6. Cool down and evaporate off MIBK out of boiling flask down to approximately 25 ml. Evaporate the remaining 25 ml in a room temperature forced-air cabinet.
7. Add 10 ml concentrated HNO_3 to residue and evaporate to dryness. Repeat with two more portions of HNO_3.
8. Add 5 ml conc. HNO_3, warm and cool. Transfer quantitatively to a 10 ml volumetric flask, using distilled water for the transfer.
9. Read absorption for Fe, Cr, and Ni using an atomic absorption spectrometer and read off concentration from a standard curve.

APPENDIX 2

For simplicity we shall consider the translation of M micrograms Fe obtained by analysis into an equivalent partial current on the assumption that the dissolution reaction proceeds with the formation of Fe^{2+}. Now

$$96{,}500 \text{ coulombs} \equiv 27.93 \times 10^6 \ \mu\text{gFe} \qquad [i]$$

thus M μgFe are equivalent to

$$\frac{M \times 9.65 \times 10^4}{27.93 \times 10^6} \text{ coulombs} \qquad [ii]$$

Since 1 coulomb $\equiv 10^6$ μA $\times$ 1 sec, and since M μgFe resulted from dissolution over a 24 hr period (8.65×10^4 sec), the partial current required to give the above number of coulombs is

$$\frac{M \times 9.65 \times 10^4 \times 10^6}{27.93 \times 10^{-6} \times 8.65 \times 10^{-4}} = M \times 0.0399 \ \mu\text{A} \qquad [iii]$$

Since M μgFe occurred by dissolution from a specimen of surface area Acm^2, then the Fe partial current density is simply

$$\frac{M \times 0.0399}{A} \ \mu\text{A/cm}^2 \qquad [iv]$$

In the case of the conversion of Cr and Ni analyses into partial currents, it was assumed that the dissolution products were Cr^{3+} and Ni^{2+}, thus requiring the use of 17.3 and 29.35, respectively, in the right hand portion of Eq. [i]. The factors to be used in Eq. [iv] are 0.0646 for Cr and 0.0381 for Ni.

Sectioning of Sputtered Tantalum Films by Anodic Oxide Growth in Fluoride Solutions

P. S. Wilcox

Bell-Northern Research Laboratories, Ottawa, Ontario, Canada

ABSTRACT

The growth of anodic oxides in fluoride solutions and the subsequent stripping away of this oxide has been used to section thin Ta films. The mass of tantalum removed can be controlled either by the total charge passed during anodization or by the anodization voltage. Control by the charge passed is limited by the presence of oxygen in the sputtered tantalum. This effectively makes the anodization current efficiency greater than 100%. Control using the anodization voltage method is limited by a possible difference in oxide growth field for different tantalum samples and the fact that there is an upper limit to the usable voltage. This upper limit to the anodization voltage depends on the electrolyte concentration. More concentrated solutions give a linear relation between anodization voltage and the mass of tantalum removed over a larger voltage range and is, therefore, more useful for sectioning films. However, the film thickness which can be removed is limited because the oxide growth becomes very nonuniform at higher voltages.

Anodic oxidation of tantalum in electrolytes containing fluoride ions results in an oxide film which does not adhere well to the tantalum and can be stripped easily from the metal. This property has been used to investigate diffusion near the surface in bulk Ta (1). It can also be used to section sputtered Ta so that the film properties may be determined as a function of depth into the film. The variation of resistivity, temperature coefficient of resistance, and oxygen content of sputtered Ta films has been obtained by anodization in citric acid (2). However, this technique is restricted to films up to 2000Å thick. The method of oxide stripping is a simple and rapid technique and, subject to certain limitations, is an accurate method of removing specific amounts of tantalum from the surface of a film of any thickness. The purpose of this paper is to describe the technique of oxide stripping and to discuss the limitations on the method.

Experimental

Tantalum films were sputtered onto cleaned glass (Corning 7059) substrates in a d-c diode sputtering system. The films were deposited at 3.5-4.5 kV. and 0.5 mA/cm^2 in a dynamic argon atmosphere at a pressure of approximately 30 mTorr, the deposition rate being about 200 Å/min. The films were 4000-5000Å thick with a resistivity of 170 to 250 μohm cm, consistent with their tetragonal β-Ta structure.

Film areas of approximately 16 cm^2 were anodized in solutions of HF, BaF_2, and NH_4F with concentrations ranging from 0.01 to 1.0% by weight using a platinum foil cathode approximately 1 in.^{2} in area. Unless otherwise specified the oxides were grown at a constant current density of 1 mA/cm^2 in unstirred solutions at room temperature.

The samples were weighed before anodizing (m_1), after anodizing (m_2), and after removal of the oxide (m_3) by sticking "scotch" tape to the oxide and stripping. Weights were obtained to an accuracy of 5 μg using a Mettler microbalance. Before each weight measurement the sample was rinsed in trichlorethylene and dried in a nitrogen jet.

Before the initial anodization, the samples were cleaned by ultrasonic agitation in a detergent solution followed by a deionized water rinse. Sample areas were defined on three sides by the substrate edge and on the fourth by a thick oxide stop-off grown in dilute citric acid using a Q-dope[1] mask.

Key words: tantalum, anodic oxide, oxide stripping, fluoride electrolyte.

[1] Manufactured by G. C. Electronics.

For each anodization step, the mass of tantalum stripped is given by the weight difference $m_1 - m_3$. The anodic film mass is $m_2 - m_3$ while the contribution of elements incorporated from the electrolyte during anodizing is $m_2 - m_1$. The oxide thickness was determined by stripping only part of the oxide from the tantalum and measuring the height of the resultant step using a Talysurf (Taylor Hobson Model 4). The oxide growth field was then calculated from the thickness and the voltage.

In addition to the sputtered Ta films, metallurgical grade Ta foil was sectioned in order to serve as a comparison to the sputtered films.

Results

Figure 1 shows the variation in the mass of tantalum $(m_1 - m_3)/Q$ removed per unit charge with the charge per unit area (Q/A) passed through the anodization cell. Curve b is the average of values obtained for ap-

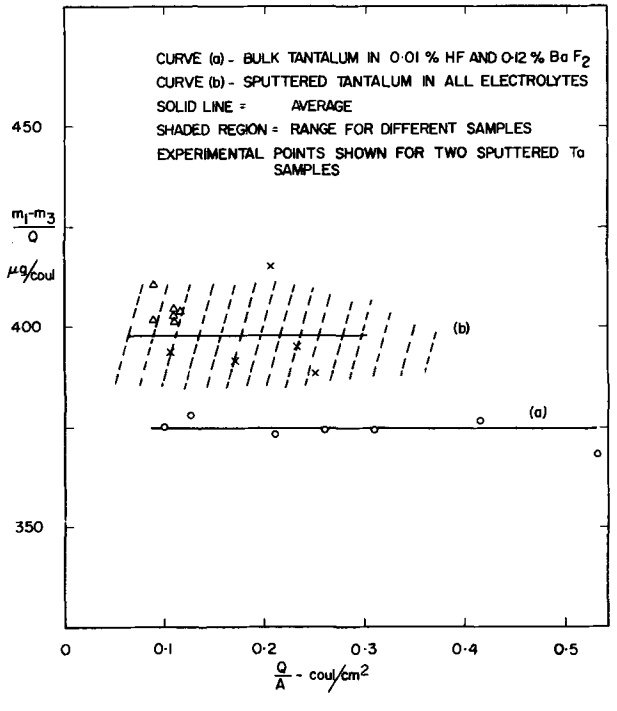

Fig. 1. Mass of tantalum removed per unit charge vs. charge density.

proximately five anodization steps on each of ten different samples. Samples were anodized in 0.01, 0.10, and 0.50% solutions of NH_4F and 0.01 and 0.12% solutions of BaF_2 (0.12% is the solubility limit of BaF_2). In some cases different solutions were used with the same sample. Experimental values are shown in Fig. 1 for two samples; the shaded region represents the mean range of values for all the different samples. No differences due to either the type or concentration of the electrolyte were observed. Curve a is the average of the experimental points obtained for anodization of tantalum foil in 0.01% HF and 0.12% BaF_2. The former electrolyte could not be used with the sputtered films because it etched the glass substrate.

For the tantalum foil, $(m_1 - m_3)/Q$ is constant at 375 μg/coulomb; whereas, the average value for sputtered films is 398 μg/coulomb.

Figure 2 shows the mass of tantalum removed per unit area per volt of anodization, $(m_1 - m_3)/AV$, plotted against the anodization voltage V. The anodization voltage is the anode-cathode potential less the ohmic voltage drop in the circuit, with no account being taken of the potential differences across the various interfaces. Curve a is the average of the values obtained for the tantalum foil which was anodized in 0.12% BaF_2. Curve b is the average of the values obtained for sputtered films anodized in all electrolytes except the 0.01% solutions of NH_4F and BaF_2. The results for the 0.01% solutions of NH_4F and BaF_2 are shown by curve c. Experimental points are shown for the same samples as in Fig. 1; the shaded region indicates the range of values for sputtered film samples anodized in all electrolytes except those of 0.01% concentration. The value of $(m_1 - m_3)AV$ for bulk tantalum is 0.98 μg/cm^2 volt. For sputtered films in stronger electrolytes the average value is 0.95 μg/cm^2 volt. The value for the sputtered films in the 0.01% electrolytes is 0.95 at $V < 60$ volts, but it decreases rapidly with increasing V.

Figure 3 shows the variation in weight gain per unit charge, $(m_2 - m_1)/Q$, on anodizing with the charge per unit area passed through the anodization cell. Curve a is the average of values for the tantalum foil anodized in 0.12% BaF_2. Curve b is the average of the values for sputtered films anodized in all electrolytes except the 0.1 and 0.5% NH_4F solutions; the average of the values for these two electrolytes is shown by curve c. Experimental points are shown for the same samples as in Fig. 1; but because of the small weights being measured, there is considerably more scatter here. The shaded regions represent the range of values for all the sputtered film samples. For all cases, no dependence of $(m_2 - m_1)/Q$ on Q/A was observed; but the values given by curves a, b, and c were 92, 83, and 60 μg/coulomb, respectively.

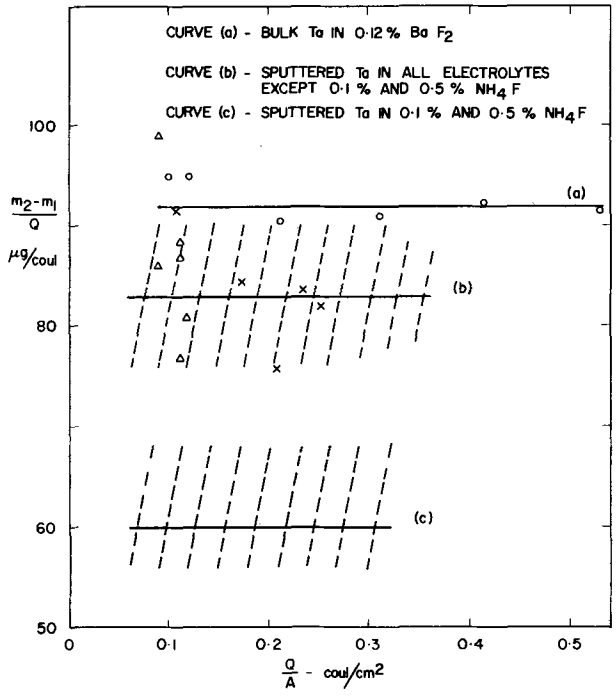

Fig. 3. Weight gain on anodizing per unit charge vs. charge density passed.

Discussion

Current efficiency.—If 100% current efficiency is assumed, then the tantalum removal rate calculated from Faraday's law is 375 μg/coulomb for the Ta foil. Since β-Ta contains about 7-15% oxygen (3) then the calculated tantalum removal rate is between 388 and 410 μg/coulomb for the sputtered films. These values agree with those shown in Fig. 1, thus the different values for bulk and sputtered Ta is due to the difference in their oxygen content. The differences between sputtered films is also probably due to differences in oxygen content.

There is a greater variation between samples when the mass of tantalum removed per unit area per anodization volt, $(m_1 - m_3)/AV$, is considered rather than the mass removed per unit charge. The maximum variation in $(m_1 - m_3)/AV$ is $\pm 6\%$, whereas the maximum variation in $(m_1 - m_3)/Q$ is $\pm 3\%$. Some of the variation in $(m_1 - m_3)/AV$ might be attributed to different oxide growth fields for the different samples. It has been observed that the field can range from 6.33 to 6.58 x 10^6 V/cm for growth in dilute citric acid (3). The higher value for bulk tantalum shown in Fig. 2 is consistent with the lower oxide growth field observed for tantalum foil. The oxide thickness measurements made with the Talysurf were accurate to only $\pm 5\%$; therefore, it could not be determined conclusively if the observed variations in the oxide growth field for anodization in dilute citric acid were carried over to oxide growth in fluoride solutions. Some of the variation between samples might also be attributed to the nonlinear growth effects and discoloration effects which are discussed in subsequent sections.

Assuming 100% current efficiency and that the weight gain on anodizing is due solely to the uptake of oxygen, then the value of $(m_2 - m_1)/Q$ should be 83 μg/coulomb. Since fluoride is incorporated in the film the actual value of $(m_2 - m_1)/Q$ should be higher.

The value of 92 μg/coulomb for bulk tantalum (Fig. 3) can be explained on the basis of part of the charge transfer being caused by fluoride ions. The average value of 83 μg/coulomb for the sputtered films, represented by curve b in Fig. 3, indicates that very little fluorine is incorporated during oxide growth on these films. It is not clear why more fluorine should be incorporated in oxides grown on bulk tantalum than on sputtered films.

The very low value of $(m_2 - m_1)/Q$, shown by curve c in Fig. 3, is peculiar to the 0.5 and 0.1% concentrations of NH_4F (but not to the 0.01% concentration). This low value cannot be attributed to a low current efficiency, because then the same effect would be observed in the value of $(m_1 - m_3)/Q$ (curve b in Fig. 1). Also, the solutions do not dissolve the substrate or tantalum under conditions of no applied voltage. One possibility is that, on anodizing, some of the tantalum or the oxide passes into the electrolyte. This would result in a low value of $(m_2 - m_1)/Q$ but would not affect the value of $(m_1 - m_3)/Q$. It is perhaps significant that the values of $(m_1 - m_3)/AV$ for 0.5% NH_4F were about 5% higher than for 0.1% NH_4F and 0.12% BaF_2. If part of the oxide is being dissolved, the anodization voltage will be reduced causing a higher value of $(m_1 - m_3)/AV$. A mechanism for the dissolution of the oxide is possible if it is assumed that some tantalum fluoride is formed, since tantalum fluoride is soluble in water. A similar effect might also occur in the other electrolytes. This possibly accounts for the difference between curve b in Fig. 3, and the value for bulk tantalum in curve a. However, it still cannot be explained why the values of $(m_2 - m_1)/Q$ should be higher for bulk tantalum nor why more concentrated solutions of NH_4F are more effective in lowering $(m_2 - m_1)/Q$.

Nonlinear anodization characteristics.—Some information on the anodization behavior can be obtained from the voltage-time (V-t) curves during the constant current anodization. For all 0.01% fluoride solutions and current densities between 0.1 and 5.0 mA/cm^2, the V-t plots for sputtered tantalum are linear to about 60V and then the voltage starts to increase faster with time. The sharply decreasing curve in Fig. 2 is a result of this. Since the amount of tantalum removed is more closely proportional to the total charged passed, $(m_1 - m_3)/AV$ will decrease when the voltage is increasing nonlinearly with time. The nonlinear V-t plots are a peculiarity of the sputtered tantalum; when tested as high as 200V, bulk tantalum does not show this effect.

Step height measurements indicated that the oxide growth field in the region of the linear V-t plots is close to that for oxide growth in dilute citric acid (*i.e.*, about 6.4 x 10^6 V/cm at 1 mA/cm^2). The nonlinear increase of voltage with time is not associated with a rapidly increasing oxide thickness but is due to an increasing average oxide growth field.

In more concentrated fluoride solutions the linearity of the V-t plots is extended to higher voltages. At the higher voltages there is, however, a tendency for the voltage to increase at a slightly lower rate with time. This is possibly indicative of increased electronic leakage. In some of the samples, it was observed that values of $(m_1 - m_3)/Q$ decreased slightly at higher voltages. This would be expected for a lowered current efficiency. In solutions of 0.12% BaF_2 and 0.1 and 0.5% NH_4F, the V-t plots for sputtered films are linear to between 130 and 140V.

The region of linearity in the V-t plots was sensitive to the properties of the sputtered material. For example, tantalum which did not adhere well to the glass substrate exhibited nonlinear V-t plots at much lower voltages. The V-t plots were also sensitive to sample history. This will be discussed under Discoloration effects.

The V-t curves are repeatable, even in the nonlinear region. For example, if an oxide is grown, stripped away, regrown, etc., several consecutive times, the V-t plots are identical for each growth stage. This repeatability was unaffected by the absence or presence of a cleaning step after each oxide stripping step. Thus, any fluoride left on the tantalum surface after stripping of the oxide seems to have no effect on the subsequent anodization. However, there is evidence that some fluoride remains on the tantalum surface. Two samples which had been anodized in 0.12 and 0.01% BaF_2, respectively, and the oxide stripped away were then anodized in dilute citric acid. The sample which had been previously anodized in 0.01% BaF_2 produced a clear colored adherent oxide, and the V-t plot was linear to at least 200V. This is what is observed when a freshly sputtered film is anodized in citric acid. For the sample which had been previously anodized in 0.12% BaF_2, the oxide was nonadherent and discolored. The V-t plot was nonlinear above 80V. When a sample was given a simple swabbing with trichlorethylene, after stripping of an oxide grown in 0.12% BaF_2, then the subsequent oxide growth in dilute citric acid exhibited V-t plots linear to a slightly higher voltage. The oxide was now more adherent (although still strippable). It was generally observed that oxides grown in the 0.01% fluoride solutions were more adherent than those grown in the concentrated solutions.

Discoloration effects.—The aforementioned repeatability of the V-t plots holds true only if no discoloration of the tantalum occurs. The type and degree of this discoloration depends on electrolyte concentration and the formation voltage. It is also associated with the discoloration of the oxide.

In all fluoride solutions with concentration of 0.1% or higher, and at voltages usually about 150V, the oxide becomes covered with circular patterns of different colored spots. It also takes on a generally splotchy and mottled appearance. In spite of this, the V-t plots are linear for the HF electrolytes. The stains left on the tantalum after removal of the oxide have a brownish appearance, and they are of a permanent nature as subsequent anodizations and strippings do not remove the stains. The V-t plots become nonlinear, for all electrolytes except HF, at lower voltages when the tantalum becomes discolored. Figure 4 is an electron micrograph of the tantalum surface, and it shows that discoloration is associated with a pitting of the surface. As indicated by the Talysurf, the top surface of the oxide is covered with bumps. This suggests accelerated oxide growth in localized regions resulting in pits in the tantalum due to excessive tantalum consumption. Vermilyea (4), on anodizing bulk Ta in a solution containing HF, found that after a time the oxide tended to separate from the metal. This may be the cause of some of the discoloration noted here.

Oxides grown in 0.01% fluoride solutions to high voltages develop a characteristic discoloration different from that of the more concentrated solutions. The oxide is smooth and uniform in appearance but has a "milky" color. The sharpness of the interference colors is reduced. This type of discoloration does not leave any stains on the tantalum surface, but examination with an optical microscope in the dark field mode indicated a very fine surface roughness on both the tantalum and the oxide. Figure 5 is an electron micrograph of the tantalum surface and it shows a uniform distribution of very small bumps. These bumps are probably associated with the fine oxide roughness which scatter the light and give the oxide its milky color. The causes of these surface roughness and discoloration effects are not known.

There is one other factor which can affect the V-t plots and that is the presence of a thick thermal oxide or an oxide formed in dilute citric acid. The effect of this initial oxide layer is to extend the linearity of the V-t plots to higher voltages and to prevent oxide stripping below a certain voltage. For example, with an initial 50V oxide (formed in dilute citric acid) it is

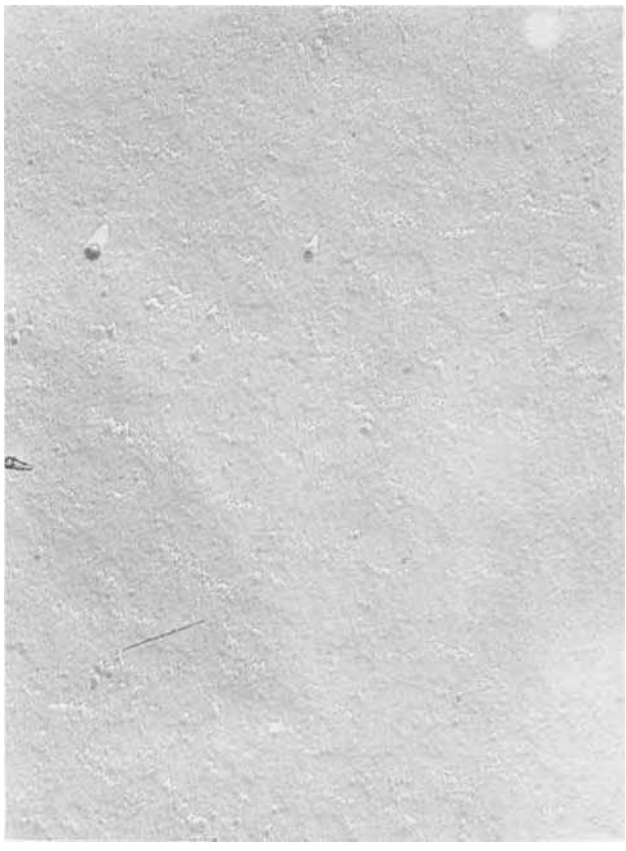

Fig. 4. Electron micrograph of a two-stage carbon replica showing pitting of a Ta surface after anodizing to >150 in 0.1% or stronger electrolytes. Latex sphere diameter, 880Å.

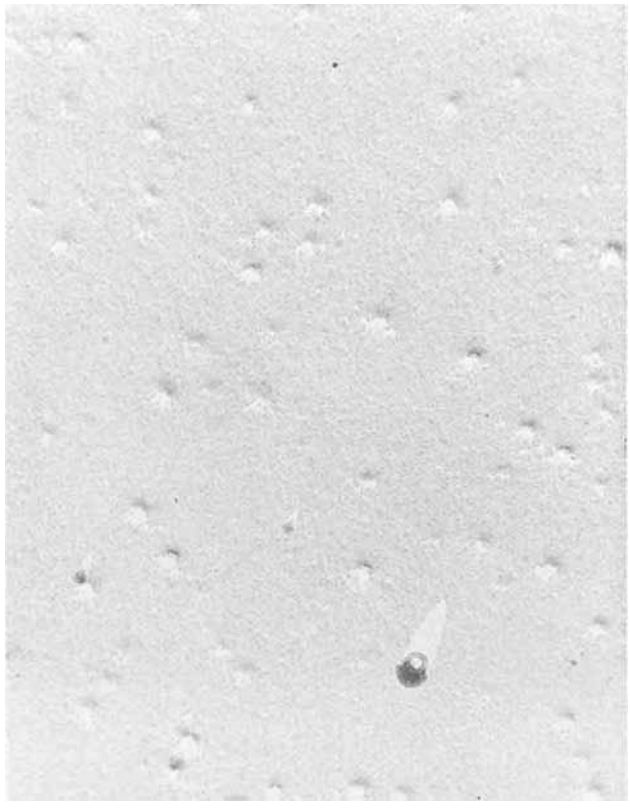

Fig. 5. Electron micrograph of a two-stage carbon replica showing bumps on a Ta surface after anodizing to high voltages in 0.01% electrolytes. Latex sphere diameter, 880Å.

necessary to anodize to about 180V in 0.1% HF before the oxide can be stripped. This upper voltage is lower for lower anodization current densities. This phenomenon might be useful in sectioning films in larger increments than is feasible by using only a fluoride solution. When using a straight fluoride solution, the largest feasible increment is about 100V. Higher voltages can result in discoloration and pitting of the tantalum. The increment could be doubled by growing an initial adherent oxide layer and subsequently anodizing it in a fluoride solution.

Conclusions

Sputtered tantalum films can be sectioned by anodizing in fluoride solutions and stripping of the anodic oxide. The mass per unit area of tantalum removed can be controlled by either the formation voltage or the total charge passed during anodization. The formation voltage is the more convenient method to control; the total charge passed method requires that the sample area be carefully defined. However, the total charge passed method, in comparison to the voltage method, is a more precise measure of the mass of tantalum removed. Also the charge passed method is less dependent on experimental conditions. The presence of oxygen in the tantalum affects the amount of tantalum removed as determined by the total charge passed.

A suitable electrolyte is a saturated (0.12%) BaF_2 solution. The electrolyte concentration is a major factor in the stripping technique. Solutions which are too dilute (<0.1%) result in nonlinear relations between the mass of tantalum removed and the formation voltage, while solutions which are too concentrated (≥0.1%) can result in excessive discoloration and pitting of the tantalum surface at higher voltages. The anodization voltage should not exceed 100V as higher voltages result in pitting of the tantalum surface which can effect subsequent anodizations.

Some Physical and Dielectric Properties of Hydrous Alumina Films

Robert S. Alwitt*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

Properties of pseudoboehmite films, produced by the reaction of aluminum foil with boiling water, were studied by a variety of techniques. For reaction times of 1-30 min the average film porosity decreased linearly with increasing film weight. The surface area of freshly prepared films was similar to that of alumina gel, but decreased on aging in air. Aging in 1*N* $NaNO_3$ inhibited the area decrease. The series capacitance decreased on aging in air or nitrate electrolyte. It was determined that with the sample immersed in electrolyte the measured dielectric properties were those of an inner region impermeable to electrolyte. This layer was not the same as a typical barrier oxide. The films exhibited a low frequency dielectric dispersion. From the temperature dependence of the loss maxima the activation energy and relaxation time for the process were found to be 13.4 kcal/mole and 6.2×10^{-15} sec. These are in the range found for other systems containing hydroxyl chains or bound water.

Films produced by the reaction of aluminum or aluminum oxide with water are of importance in corrosion (1), the sealing of porous anodic oxides (2), and the manufacture of electrolytic capacitors (3). A recent paper by Vedder and Vermilyea (4) has greatly extended our knowledge of the formation and physical properties of these porous hydrous films. They identified the film produced by reaction with boiling water as pseudoboehmite, a poorly crystallized oxide with a structure close to that of boehmite but containing more hydroxyl than corresponds to the formula AlOOH. The composition of the film will vary, but reaction at 100°C has always been found to result in an average water content of 27% (3, 5, 6).

Some new data on film thickness and surface area are presented here, but the primary purpose of this paper is to report on the dielectric properties of films produced by the reaction of aluminum with boiling water. This was of interest to us because these films are often incorporated into the dielectric layer of electrolytic capacitors (3). There may be more general interest in the comparison of the dielectric properties of this film with those of other materials such as boehmite, ice, and silica gel.

Procedure

The hydrous films were grown on 99.99% Al foil specimens that had been cleaned by chemical polishing in a mixture of 15 parts 70% HNO_3 + 85 parts 85% H_3PO_4 for 2 min at 85°C, followed by a 10 min etch in 1*N* NaOH at room temperature. The reaction with boiling, distilled deionized water was in Pyrex beakers for times up to 30 min. For reaction times of 3 min or less, two samples were prepared consecutively and then the water discarded. For longer reaction times fresh water was used with each sample.

Series capacitance and RC were measured with a resistance ratio arm bridge. The maximum amplitude of the a-c signal was 0.2V rms. A large capacitance (1300 μf) was in series with the signal generator to block the passage of d-c current through the measuring cell. Two measuring cell designs were used. For measurements at a frequency of 120 Hz the foil sample was held equidistant between two platinized electrodes spaced 7 mm apart and the gap was filled with electrolyte. With this cell, small deviations in sample alignment produced some measurement errors at higher frequencies (5-10 kHz). To eliminate these errors, measurements over a range of frequencies were made with the foil sample separated from platinized electrodes by single sheets of 0.001 in. thick Benares paper. This is a paper commonly used in electrolytic capacitors. The assembly was held between glass slides and impregnated with electrolyte. A comparison of measurements in the two cells showed that no unique effects were introduced by the paper (7). For both cells the measuring electrolyte was 5.9*N* $NaNO_3$. Preliminary experiments indicated no effect from dissolved CO_2 on dielectric properties, so all solutions were in equilibrium with ambient atmosphere.

The weight of aluminum reacted at several immersion times was determined directly from the weight loss of metal substrate. The hydrous film was stripped in CrO_3-H_3PO_4 solution at 85°C for 10 min (5).

Film thickness measurements were made using aluminum evaporated on glass slides. After evaporation, the slide was immersed in boiling water for the required time, dried, and then warmed sufficiently to melt Apiezon wax rubbed across the surface at several places. After the wax hardened, the slide was immersed in the CrO_3-H_3PO_4 solution at 60°C for 30 min to dissolve the exposed hydrous film. At these conditions no undercutting of the wax took place. The wax was then dissolved in warm toluene. The height of the oxide steps so produced was measured by interferometry using the method of fringes of equal chromatic order.

Surface areas were determined from the amount of N_2 adsorbed from a 10% N_2-90% He stream at liquid N_2 temperatures. The change in N_2 content of the gas stream passing over the sample was detected by the change in thermal conductivity. Areas were calculated from the linear region of a standard BET plot over the range of N_2 relative pressures 0.13-0.33. Prior to measurement, samples were outgassed in the N_2-He stream at 85°C for 2 hr. To increase the total sample surface area the hydrous film was developed on heavily etched foil normally used in electrolytic capacitors.

Results and Discussion

Physical properties.—The weight of aluminum reacted at several immersion times is shown in Fig. 1. The crosses were calculated from the results reported by Vedder and Vermilyea (4) assuming 27% water in the films. These authors report significant inhibition of film formation by impurities leached from Pyrex. Apparently no such effects were encountered at the short reaction times used in our experiments, except perhaps with a 30 min boil.

Key words: hydrous alumina film, pseudoboehmite, aluminum oxide, physical properties, dielectric properties.

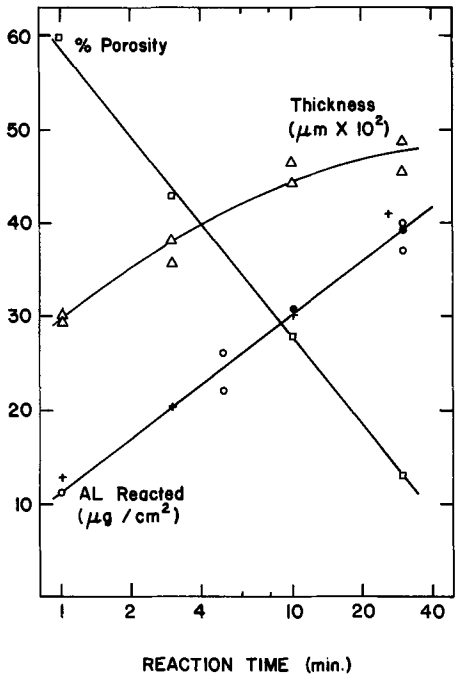

Fig. 1. Weight of Al reacted, film thickness (△), and porosity (□) of hydrous films from reaction of Al with boiling water. Weights determined with cleaned foil (○), evaporated Al on foil (●), and calculated from Fig. 18 of ref. 4 (+).

Measured film thicknesses are also recorded in Fig. 1. Vedder and Vermilyea (4) reported thicknesses of 0.3 and 0.5μ for films produced by reacting aluminum with boiling water for 9 and 40 min, respectively. They also found inhibiting effects from material leached from glass slides from some suppliers. A comparison of their values with the thicknesses in Fig. 1 suggests the absence of strong inhibiting effects in this work.

The porosity of the film was calculated from the thicknesses, weights, and specific film density of 2.4 g/cc (5). The decrease in porosity with increasing reaction time is shown in Fig. 1. The porosity decreased linearly with increasing film weight over the range covered. It would be risky to extrapolate this relationship to shorter or longer reaction times.

The surface areas of three freshly prepared oxide films (3 min reaction time) were in the range 133-154 m^2/g. This is about one-third of the values reported for pseudoboehmite precipitates (8), but within the range found for alumina gel and silica gel. Measurements on one of these samples showed the area decreased, on standing in air at 25°C and 30% RH, to 109 m^2/g after 17 hr and 78 m^2/g after 11 days. The surface area of hydrous alumina precipitate has been found to decrease similarly (9). In that case, vacuum storage prevented the area decrease but admission of water vapor produced a rapid reduction.

Because of changes in dielectric properties observed after aging in aqueous nitrate solutions, it was of interest to see what effect this treatment had on surface area. Three samples, prepared as above, were immersed in 1*N* $NaNO_3$ for 40 hr at 25°C. The surface areas were in the range 119-149 m^2/g. Thus, immersion in this electrolyte inhibited the aging process responsible for the area decrease. It might be noted that nitrate anion is not specifically adsorbed onto aluminum oxides.

Dielectric properties.—The series capacitance and resistance of a film grown during a 3-min immersion in boiling water and then aged in air at 25°C and 30% RH for about 4 hr are shown in Fig. 2. Measurements were made in 0.044*N* $NaNO_3$ (230 ohm-cm resistivity) and 5.9*N* $NaNO_3$ (10 ohm-cm). Also shown are the properties of a film grown during the aging period on a substrate that had not been exposed to

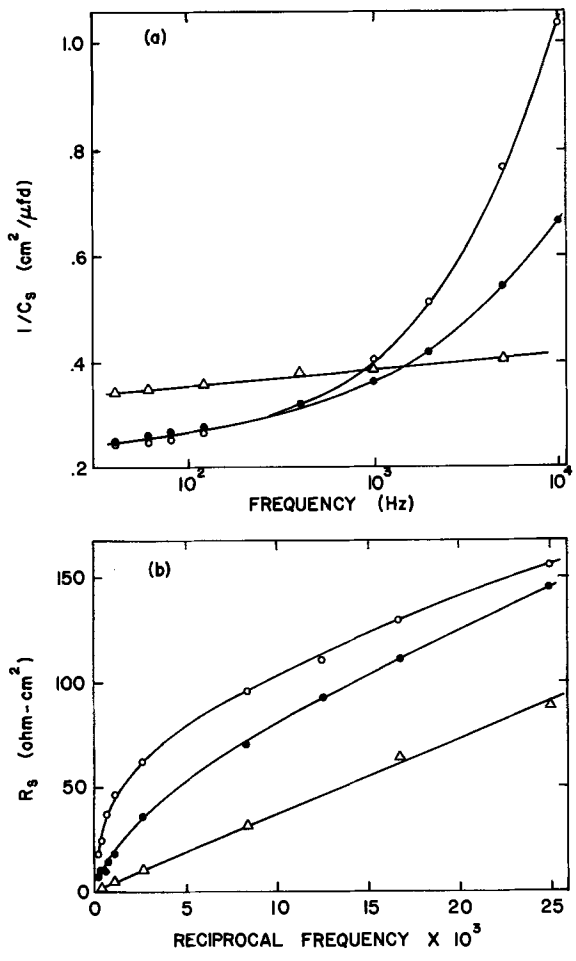

Fig. 2. Dielectric properties of oxide films in $NaNO_3$ electrolyte. Hydrous film grown during 3-min boil measured in 230 ohm-cm (○) and 10 ohm-cm (●) solutions. Air-formed oxide measured in 10 ohm-cm solution (△).

boiling water. The air-grown film exhibits the linear relationships usually found with amorphous oxide dielectric films (10) but the hydrous film does not.

The complex structure of the hydrous oxide made it necessary to establish what features of the film were reflected in the dielectric properties. First, it can be noted that for these electrolyte concentrations the smallest diffuse double layer capacitance would be about 10 $\mu f/cm^2$ (11). This is much greater than any values measured in this study. Thus, the observed capacitance is a property of the solid hydrous oxide.

The portion of the hydrous film that is permeable to electrolyte could contribute to C_s and R_s because of its colloidal properties (12), or it could contribute to R_s alone because of the tortuous electrolyte paths through the film. In both cases, R_s would be almost proportional to electrolyte resistivity at low frequencies. This was not found to be so. Instead of a 20:1 ratio, about the largest effect seen was a 15% difference (Fig. 2b). In some experiments no difference was found in R_s measured in the two solutions. This indicates that dielectric properties of the porous outer portion were not measured. The observed properties are those of a less permeable inner region. Vedder and Vermilyea (4) showed the existence of such a region but its thickness has not been established.

This compact region is obviously not the same as a typical barrier oxide, nor does it contain a layer that is the same as the air-formed oxide. The evidence for the latter point is the higher capacitance of the hydrous film at low frequencies. The only similarity noted between the hydrous and air-formed films was in the frequency dependence of R_s and C_s at low frequencies.

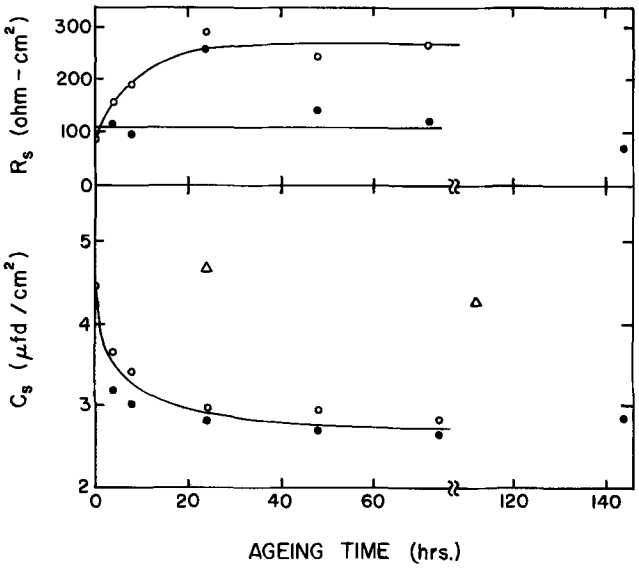

Fig. 3. Effect of aging on dielectric properties (120 Hz) of films produced in 3-min boil. Aged in air (○), 0.044*N* $NaNO_3$ (●), and vacuum (△).

The capacitance of hydrous films decreased on aging in air and in aqueous solutions (Fig. 3). Vacuum storage prevented this change. The series resistance was unchanged in the electrolyte but increased on aging in air.

The changes in the air-aged sample could be explained by a thickening of the inner compact region, although we have no knowledge that this occurred. Although there are some similarities between the changes of capacitance and surface area during aging, there is no exact parallel. This is not surprising since capacitance and surface area are properties of different portions of the hydrous oxide film. It might be noted that no changes in dielectric properties occurred on aging of anodic barrier films or air-formed oxides.

Specimens were aged for 40 hr at 25°C in nitrate electrolytes of different composition. Any changes in dielectric properties were independent of solute concentration (0.044-1.0*N* $NaNO_3$), small changes in *p*H (5.1-7.2), or cation species (Na^+, NH_4^+, R_3NH^+, R_4N^+).

The effect of a change of anion is shown in Table I. The ranges represent fifteen samples (1*N* $NaNO_3$), six samples (0.044*N* $NaNO_3$), and five samples (salicylate). The other results are the average for two specimens. The first six solutions listed had about the same effect on aging. Without more extensive tests it is not possible to say whether acetate and formate were significantly different. Borate exerted a profound effect on dielectric properties and this will be the subject of another report.

Dielectric dispersion curves were generated by calculating values for the parallel capacitance, C_p, and $C_p \tan \delta$ from the relations

$$C_p = C_s/[1 + (\tan \delta)^2] \quad [1]$$

$$\tan \delta = 2\pi f R_s C_s \quad [2]$$

Table I. Effect of anion on capacitance of aged films

Films produced by 3-min immersion in boiling water. Aged 40-48 hr at 25°C. Capacitance at 120 Hz.

Aging electrolyte	pH	C_s, μf/cm^2
1*N* sodium nitrate	6.0-6.2	2.3-3.6
0.044*N* sodium nitrate	6.0-6.2	2.3-3.7
0.1*N* sodium salicylate	6.3	2.6-3.8
0.1*N* sodium benzoate	6.3	3.0
0.1*N* ammonium tartrate	6.0	2.4
0.1*N* ammonium phosphate	6.5	2.3
0.1*N* sodium acetate	6.2	2.1
0.1*N* ammonium formate	6.4	2.0
0.2*N* ammonium borate	7.0	0.91

The real part (ϵ') and imaginary part (ϵ'') of the complex dielectric constant are

$$\epsilon' = (d/A\epsilon_r)\, C_p \quad [3]$$

$$\epsilon'' = (d/A\epsilon_r)\, C_p \tan \delta \quad [4]$$

where d and A are the dielectric thickness and area and ϵ_r is the permittivity of free space. Plots of C_p *vs.* log f and $C_p \tan \delta$ *vs.* log f are the usual dispersion curves with the ordinate multiplied by a constant.

Dispersion curves of films produced during 3- and 30-min immersions in boiling water and then aged for 40 hr in 1*N* $NaNO_3$ at 25°C are shown in Fig. 4. The lower capacitance for the 30-min film is probably the result of a thicker compact region. According to Fig. 1 the porosity of this film is only 13% compared with 44% for the 3-min film. An interesting feature of these results is the shift in the frequency of the maximum of $C_p \tan \delta$ (loss maximum).

Dielectric properties of films produced in a 3-min boil and then aged 40 hr in 1*N* $NaNO_3$ at 25°C were measured at temperatures down to −20°C in 5.9*N* $NaNO_3$. The activation energy (E_a) of the relaxation process responsible for the dielectric dispersion was obtained from the slope of a plot of log f_{max} *vs.* $1/T$ (Fig. 5), where f_{max} is the frequency of the loss maxi-

~1 monolayer H_2O on silica gel	11.3	5.9×10^{-15}	18

* Calculated from maxima in Fig. 1b. of ref. (17).

mum at each temperature (13). The value of E_a was 13.4 kcal/mole. The relaxation time (τ) is given by the expression

$$\tau = \tau_0 \exp (E_a/RT) \quad [5]$$

where τ_0 is a constant and $\tau \equiv (2 \pi f_{max})^{-1}$. The value of τ_0 was found to be 6.2×10^{-15} sec.

These values are close to those found for systems containing hydroxyl chains or an ordered water structure. Some examples are listed in Table II.

Mata Arjona and Fripiat (14) found that the low frequency dielectric absorption in boehmite was probably due to ion pair defects propagating along the OH chains. It is generally accepted that the low frequency relaxation process in ice is due to the movement through the lattice of orientational defects (Bjerrum defects) arising from the rotation of a proton about an oxygen position (13). There is no general agreement on the nature of the relaxation process responsible for the dielectric dispersion of ordered water layers on alumina and silica. Hasted (19) has suggested that the process may be similar to that in ice.

On the basis of E_a and τ_0 values it is not possible to choose between the above two mechanisms to account for the relaxation process in pseudoboehmite. Since pseudoboehmite has a high concentration of OH groups not constrained to the boehmite lattice, the structural factors that inhibit the propagation of Bjerrum defects in boehmite (14) may not be limiting in pseudoboehmite.

There is also a third possibility. The poor crystallinity of pseudoboehmite and its platelet structure probably result in a high density of grain boundaries in the compact inner region of the film. These could act as surfaces for termination of defect propagation. A higher charge density in these regions would produce a Maxwell-Wagner effect (13). The value of E_a would still be governed by the process for defect propagation, but τ_0 would depend on the properties and spatial distribution of grain boundaries.

Conclusions

1. Pseudoboehmite films undergo aging processes like those experienced by alumina gels.
2. The films have an impermeable inner region which determines the dielectric properties measured in aqueous electrolytes. This region does not contain a layer with the same properties as the barrier portion of an air-formed oxide.
3. The dielectric properties of the film are characteristic of systems containing hydroxyl chains or bound water.

The Effect of Boric Acid on the Dielectric Properties of Hydrous Alumina Films

Robert S. Alwitt*

Research and Development Laboratories, Sprague Electric Company, North Adams, Massachusetts 01247

ABSTRACT

Aging hydrous aluminum oxide films in boric acid solutions accelerated the surface area decrease and markedly changed the dielectric properties of the films. The effect on dielectric properties could be removed by immersion in a borate-free electrolyte. The observations were accounted for by a model in which adsorbed borate anions increased the relaxation time of a Maxwell-Wagner process occurring within a compact inner region of the films. It was postulated that borate anions penetrated to the interior of the oxide by diffusion along platelet surfaces. Borate was the only anion found to exert this particular effect on the hydrous oxide films.

In a previous paper we presented some information on the properties of pseudoboehmite films grown on aluminum in boiling water (1). It was noted that these hydrous oxide films attained a much lower capacitance when immersed in a borate electrolyte than when immersed in other salt solutions. In this paper we present the results of an investigation of the effect of borate species on some physical and dielectric properties of pseudoboehmite films. We think these results are of intrinsic interest. In addition, they are of practical importance because borate electrolytes are widely used for forming barrier anodic oxides on aluminum and as electrical contact in the measurement of dielectric properties.

Experimental Procedure

The general procedures and materials were the same as used previously (1). All hydrous oxide films were produced by reacting aluminum foil with boiling water for 3 min. Initial work was done in solutions of 50 g/liter H_3BO_3 with NH_4OH added to give a resistivity of 230 ohm-cm and a pH about 6.5. Subsequently, solutions of H_3BO_3 were used containing 1*N* $NaNO_3$ as supporting electrolyte and adjusted to pH 6.1 ± 0.1 with NaOH and HNO_3.

Results

Surface area and weight changes.—Hydrous oxide films aged in borate electrolytes for 40 hr at 25°C had about one-half the specific surface area of films aged in nitrate electrolytes. For example, samples aged in 1*N* $NaNO_3$ + 0.2M H_3BO_3 had a specific area of 61 m^2/g, and a specimen aged in 50 g/liter H_3BO_3 had an area of 66 m^2/g. This compares with 119-149 m^2/g for films aged in 1*N* $NaNO_3$ (1). On subsequent aging in a nitrate solution there was some increase in area of borate-aged samples. For example, the area of one of the above samples increased from 66 to 83 m^2/g after immersion for 40 hr in 0.04*N* $NaNO_3$.

A sample aged in air for 11 days had a specific area of 78 m^2/g (1). This is about the same as the specific area of films aged in borate for 40 hr. This suggests that the role of borate may have been to accelerate aging to some final state.

The weight change of samples aged for several days at 25°C was measured. Each foil specimen was coated with about 900 μg of hydrous oxide. Samples aged in nitrate electrolyte gained 12-42 μg and those aged in borate gained 7-60 μg. The weight gain did not appear to be affected by the composition of the electrolyte. The reason for the gain is probably the incorporation of water as pseudoboehmite aged to bayerite and gibbsite (2).

Dielectric properties.—With samples aged in nitrate solutions it was found that the dielectric properties measured were essentially those of a compact inner portion of the film (1). With borate-aged samples this was also found to be the case, as indicated by a series resistance that was little dependent on measuring electrolyte resistivity. For example, $NaNO_3$ was added to 25 g/liter H_3BO_3 to give solutions with resistivities of 17 and 230 ohm-cm; the series resistance of samples in these solutions differed by only 25%.

The changes in series capacitance and resistance on aging in a borate solution at 25°C are illustrated in Fig. 1. After 144 hr the sample was immersed in a nitrate electrolyte. There was a rapid recovery of capacitance and resistance to values typical of "normal" aging. The reversible nature of this property is in contrast to the essentially irreversible change in surface area. This is another indication that dielectric behavior is determined in a portion of the film that does not contribute to specific surface area.

Dispersion curves are shown in Fig. 2 for samples aged for 40 hr at 25°C in solutions containing different concentrations of boric acid. The effect of increasing boric acid concentration appeared to be to shift the curves to a lower frequency range.

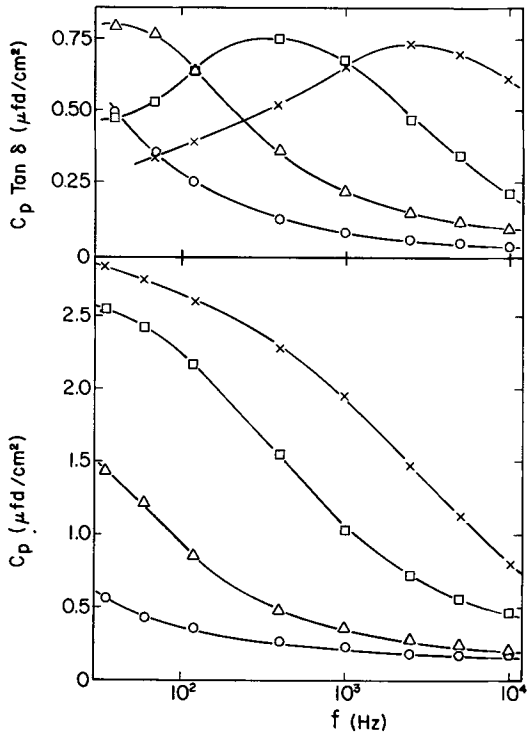

Fig. 2. Dielectric dispersion of hydrous oxide films after aging in 1*N* $NaNO_3$ containing 0.8M H_3BO_3 (○), 0.1M H_3BO_3 (△), 0.025M H_3BO_3 (□), and no H_3BO_3 (X).

It is sometimes possible to extract information about the dielectric dispersion process from a Cole-Cole diagram, which is a plot of real part *vs.* imaginary part of the complex dielectric constant, each point obtained at a different frequency (3). The data obtained at different boric acid concentrations were treated in this fashion. The results are illustrated in Fig. 3 for the data of Fig. 2. The locus of these points did not fit a simple curve, such as a semicircle or circular arc. But Fig. 3 does relate the important information that the data obtained at all boric acid concentrations, and in the absence of borate, fall on the same curve. This means that a single dispersion equation describes the dielectric behavior of these films, with the relaxation time (τ) a function of boric acid concentration. The presence of boric acid did not alter the nature of the relaxation process responsible for dielectric dispersion, but only increased the relaxation time for the process. The frequency at which maximum dielectric absorption occurs is proportional to $1/\tau$ ($2\pi f_{max} = 1/\tau$). The dependence of f_{max} on boric acid concentration is shown in Fig. 4.

Further evidence was obtained that boric acid had no effect on the nature of the relaxation process. The activation energy for the dielectric relaxation process was determined from the temperature dependence of f_{max}. Samples were aged 40 hr at 25°C in 1*N* $NaNO_3$ containing 1.25 x 10^{-2}M and 5.0 x 10^{-2}M H_3BO_3, pH 6.1. Dielectric properties were measured at several temperatures in 5.9*N* $NaNO_3$ adjusted to the same boric

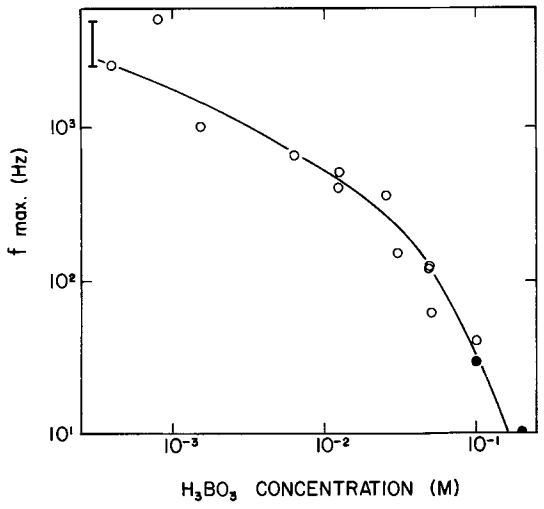

Fig. 4. Effect of boric acid concentration on f_{max}. Filled circles at lowest f_{max} represent extrapolated estimates. Vertical line to the left gives range obtained in the absence of boric acid.

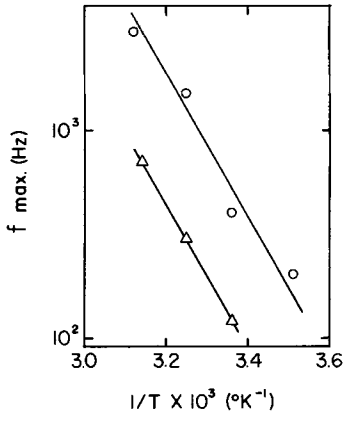

Fig. 5. Arrhenius plot for dielectric dispersion of films aged in 1*N* $NaNO_3$ containing 1.25 x 10^{-2}M H_3BO_3 (○) and 5.0 x 10^{-2}M H_3BO_3 (△).

acid concentration and *p*H as the aging solution. The results are shown in Fig. 5. At both boric acid concentrations the data could be fit by lines with a slope equivalent to an activation energy of 13.8 kcal/mole. This is not significantly different from the value of 13.4 kcal/mole obtained in 1*N* $NaNO_3$ (1). Thus, boric acid had no effect on the activation energy of the relaxation process.

In 1*N* $NaNO_3$ the *p*H of the aging solution, over the narrow range *p*H 5-7, had no effect on the dielectric properties (1). This was not the case in borate electrolytes. Samples were aged for 40 hr at 25°C in 1*N* $NaNO_3$ + 0.03M H_3BO_3 adjusted to several *p*H values. The value of f_{max} decreased with increasing *p*H as shown in Table I. A similar shift in f_{max} with *p*H was observed in 0.1M H_3BO_3.

Discussion

In a study of the point of zero charge (pzc) of pseudoboehmite (4) it was found that in the presence of borate species the pzc was shifted to more acid values. The data were interpreted as evidence for the

Table I. Effect of *p*H on f_{max}

specific adsorption of borate anions, both the monomer $B(OH)_4^-$ and the cyclic trimer $B_3O_3(OH)_4^-$.

It is very likely that adsorption of borate species was the cause of the marked change of dielectric properties in boric acid solutions. The species was desorbed readily in nonborate electrolytes, as judged by the reversible nature of the dielectric change (Fig. 1). If the effective adsorbed species was undissociated boric acid it would be expected that the surface would have become saturated at some concentration less than, say, 0.1M. No saturation behavior was observed, but rather there was an increased dependence of f_{max} on boric acid concentration at the highest concentrations. This suggests that adsorbed borate anions caused the observed behavior. Boric acid is only weakly dissociated; for example, at 0.2M H_3BO_3 and *p*H 6 there is less than 3% ionization. The effect of *p*H on f_{max} also supports the idea of anion adsorption controlling the dielectric behavior. With increasing *p*H the anion concentration increased and f_{max} decreased.

There is no evidence that surface charge had any effect on the measured dielectric properties. In the earlier study with nitrate solutions (1) it was found that varying *p*H and ionic strength, both of which alter surface charge, had no effect. It might be noted that the electric field induced in the oxide by a layer of adsorbed charge would be expected to be too weak to account for more than a small fraction of the observed effect [for example, see ref. (5)].

There was no general response to adsorbed anions. Phosphate and salicylate had no more effect than nitrate (1). Yet salicylate is adsorbed to about the same extent as $B(OH)_4^-$, as judged by its effect on pzc (4).

The premise that adsorbed borate anions increase the relaxation time of a process occurring within an oxide layer many atoms thick leads to interesting consequences. First, there must be some penetration of the oxide by anions. Borate anions are not particularly small so any regions open to these ions must also be penetrated by other species, ions such as nitrate which do not affect dielectric properties. Thus, the action of borate is not to affect some internal electric field but must be a localized structural effect.

Pseudoboehmite films consist of thin platelets, less than 300Å thick, extending from the metal surface (2). The platelet boundaries in the compact inner region can probably act as paths for easy diffusion into the oxide and are likely surfaces for anion penetration. It was previously suggested that increased charge density on these surfaces could give rise to a Maxwell-Wagner effect (1). Taking this into account leads to a model in which borate adsorbed on platelet surfaces increases the relaxation time of the Maxwell-Wagner effect.

For a heterogeneous dielectric consisting of a nonconducting matrix containing conductive inclusions, the relaxation time will increase if the dielectric constant of the inclusions is increased or if the conductivity of the inclusions is decreased (6). The relaxation time of the alumina/borate system varied over two orders of magnitude, so it seems more reasonable to assign the effect to a change in conductivity.

Progress falters at this point since the mechanism for conduction on the platelet surfaces is not known. Two structural features that may be important can be stated: First, the surfaces of pseudoboehmite platelets probably have the fundamental structure of the plane of OH groups in boehmite (2, 7). Second, the B-O bond distance in $B(OH)_4^-$ is given as 1.47Å by Pauling (8), so the OH-OH distance in this tetrahedral ion is about 2.42Å. This compares with 2.47 ± 0.07Å for the OHO distance in boehmite (7). Thus, it is possible for $B(OH)_4^-$ to adsorb onto two adjacent OH groups, possibly by hydrogen bonding. Other tetrahedral $>B<^{OH}_{OH}$ structures might also be bound in this fashion.

Borate solutions are widely used as electrolytes for the formation of anodic barrier oxide films on aluminum. They are unsurpassed in their ability to form to high voltages without breakdown occurring. Perhaps this is related to some unique surface properties provided by borate adsorption.

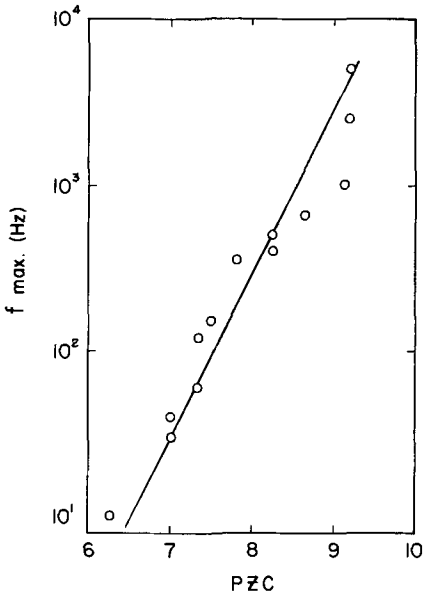

Fig. 6. Correlation between f_{max} of pseudoboehmite films and pzc of pseudoboehmite suspensions. Each point obtained at a different H_3BO_3 concentration.

Based on results at 10^{-3}M concentration, it is reported that boric acid does not inhibit the reaction of aluminum with water (9). It is our experience, corroborated by studies of Randall and Bernard (10), that at higher concentrations of boric acid this reaction is inhibited, although to a lesser extent than with phosphate. It is significant that at 10^{-3}M, boric acid does not yet affect the pzc (4) and has only a slight effect on f_{max}. This is too low a concentration for judging the interaction of boric acid with aluminum oxide.

There is a striking correlation between f_{max} of pseudoboehmite films and the pzc of pseudoboehmite suspensions. This is shown in Fig. 6. The data points are from Fig. 4 and the pzc corresponding to each boric acid concentration is from Fig. 2 in ref. 4. The line is drawn with a slope of one decade change in f_{max} per unit change in pzc. We interpret this as indicating that the dielectric relaxation time and pzc have the same functional dependence on the concentration of adsorbed borate anions.

Summary

Adsorption of borate anions onto hydrous oxide films accelerated the surface area decrease during aging and increased the relaxation time of the dielectric process in the compact inner region. It was inferred that the dielectric properties of pseudoboehmite films were governed by a Maxwell-Wagner effect and the adsorbed borate decreased the conductivity of oxide platelet surfaces.

Electrochemical and Structural Aspects of Gold Electrodeposition from Dilute Solutions by Direct Current

H. Y. Cheh[1] and R. Sard*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The electrochemical and structural aspects of gold deposition from dilute cyanide, citrate, and phosphate-buffered plating solutions were studied using rotating disk electrodes. Current-potential curves were recorded galvanostatically for 0.005M Au solutions at 60°C, and the morphology of deposits approximately 1μ thick, which corresponded to different regions of the i-V curves, was determined by scanning electron microscopy. Transmission electron microscopy was used to elucidate the early stages of growth (~0.1μ).

The cyanide system, which has an exchange current density of 0.82 mA/cm^2 and a transfer coefficient of 0.7, showed the greatest tendency to form an outward growth morphology consisting of fine features termed spikes. These features are responsible for the characteristic brown appearance of deposits plated under certain conditions. Increasing current density and decreasing rotation speed, in general, both favor the formation of spikes which occurs over a given range of potential (150 mV $< |\eta| <$ 300 mV) and not at a particular concentration of gold at the interface. The spikes, which are typically 0.1-1.0μ in size and $>10^8$/cm^2 in density, were also observed for deposits from the citrate system and to a much lesser extent in the phosphate system. At low overpotentials, a smooth, layer type of growth is formed.

The formation of the various morphological features is governed by the electrode potential below the limiting current density and by mass transport near or above limiting current.

The electrodeposition of gold is an extremely important aspect of electronics technology. Among the factors responsible for this development are the following beneficial properties of electrodeposited gold: high purity and conductivity, low porosity, high corrosion resistance, and the ability to form excellent thermocompression bonds. It is noteworthy that the successful device applications that utilize such properties have resulted primarily from empirical studies that were aimed at optimizing specific systems to meet certain engineering requirements (1). Consequently, there is relatively little available information regarding the electrochemical and mass transport phenomena that govern gold deposition. Moreover, the relationships between these phenomena and the structure of the resulting gold deposits have yet to be established. Such relationships are obviously important because of the well-known fact that film properties are, in general, structure sensitive (2).

The purpose of the present investigation is, therefore, to elucidate both the electrochemical and structural aspects of electrodeposited gold. The approach taken differs somewhat from previous studies of electrocrystallization (3-5) in several respects. First, all experiments were conducted on rotating disk electrodes in order to control the mass transfer characteristics of the system. Although the advantages of the RDE are well established in many fields of electrochemical research (6, 7) and some structural data were reported concerning the effects of addition agents in Ni (8) and Cu (9) deposition, it appears that this method has yet to be applied to a detailed structural study of electrocrystallization. Second, steady-state experiments under galvanostatic conditions were carried out in order to more closely approximate the type of plating carried out in device applications. Another reason for taking this approach is that the scale on which relevant physical changes occurred in the gold systems studied was on the order of 1μ or less. This precluded the use of *in situ* optical methods (10) for studying structure.

Unlike the more frequently studied systems for Cu and Ag deposition, relatively little is known about the mechanism of gold plating in various plating solutions. Maja (11) studied both the thermodynamic and electrochemical kinetic behavior of gold in cyanide gold solutions. Adsorbed $Au(CN)_2^-$ was suggested as a reaction intermediate for cathodic deposition. However, based on a recent study employing fast scan techniques, MacArthur (12) has postulated that the adsorbed intermediate species is AuCN. Polarization curves of citrate gold solutions containing $KAu(CN)_2$, citric acid, and KOH to control the pH were obtained by Taran *et al.* (13). No limiting current was observed in acid medium. This was attributed to the onset of hydrogen evolution before reaching mass transport limitations for gold deposition. Similar behavior was observed by Cheh (14) and by Visco (15).

In the present study, polarization measurements were obtained for three gold-plating systems: cyanide,

citrate, and phosphate. These data were used as a guide to study the structural aspects of electrodeposited gold which was accomplished by scanning and transmission electron microscopy.

Experimental

Electrochemical measurements.—Three dilute gold-plating solutions, of the type normally used in a strike process (16), were used for these experiments. The compositions of these solutions are given in Table I. Solutions were purged with nitrogen gas in order to minimize oxygen concentration. The *p*H, kinematic viscosity, and diffusion coefficient of $Au(CN)_2^-$ for these solutions, which were reported previously by Cheh (16), are also included in Table I.

Polarization curves were obtained galvanostatically on a gold RDE at 60°C. A copper cylinder of 0.635 cm diam was imbedded in an epoxy sleeve and gold-plated. A high-speed rotator[2] was used to drive the electrode at known constant speeds. A coil of platinum was used as the counterelectrode. A saturated calomel electrode was placed in the reference compartment of the cell, which is illustrated in Fig. 1. Constant currents were applied by connecting a decade resistance box and a 45V battery in series with the plating cell. The potential between the cathode and the reference electrode was measured and recorded on a Varian Model G 22A recorder with an input impedance of 1 megohm at 10V span.

Physical measurements.—A necessary requirement of any structural study involving metal deposition under a wide variety of conditions is that the substrate surfaces must be well defined, reproducible, and relatively easy to prepare. These considerations led to the adoption of the following procedure for preparing thin Cu or Au disks with mirror-bright surfaces. First, films approximately 2000Å thick of Cu (or Au) were thermally evaporated onto clean glass slides (1 × 3 in.) at about 1000 Å/min in a Varian PS10E vacuum system at ~ 1×10^{-5} Torr. The metallized slides were then masked with Teflon tape (*e.g.*, 3M Company No. 549) having 10 punched holes of 8 mm diam. Copper disks, approximately 20μ thick, were then plated in an electrolyte consisting of 0.5M $CuSO_4$ and H_2SO_4 at 6 mA/cm² at room temperature. After rinsing in distilled water and removing the tape, the disks were readily removed from the glass, dried in N_2, and stored in a vacuum desiccator. Immediately prior to use, the substrates were immersed in a 20% HNO_3 solution for a few seconds, rinsed, then placed on the electrode and secured with a Teflon screw cap as shown in Fig. 1. The mirror-bright surface of the disk was wet at all times to minimize the probability of trapping a gas bubble at the surface when the cell was raised to immerse the rotating electrode. No attempt was made to exclude oxygen from the system in these experiments. Current densities were preset to give the desired value as soon as the substrate entered the electrolyte.

In addition to the type of plating system used (Table I), the other variables considered were current density and rotation speed. Under most sets of conditions, two Cu substrates were plated for times which differed by an order of magnitude in order to yield deposits with calculated thicknesses in the vicinity of 0.1 and 1.0μ. The purpose of this was to determine whether any structural changes occurred over this interval and to facilitate direct observations of the microstructure formed at the early stages (~0.1μ) by transmission electron microscopy. Also, some experiments were carried out on Au surfaces to determine whether substrate effects could be detected on thicker films.

Scanning electron microscopy (SEM, Cambridge Stereoscan) was used to characterize the surface morphology of all the deposits generated in this study. Small, pie-shaped specimens were cut from each disk and mounted, usually 6-8 on a holder, for observation at 45° to the beam (21 kV, secondary electrons). The magnification range from 20 to 20,000 was surveyed and representative micrographs were taken, usually at 10,000X and at least one other magnification, using the *Y*-direction correction accessory. Suitable specimens for transmission microscopy were prepared by slowly dissolving the Cu substrate in a chromic-sulfuric acid solution (17). After rinsing the thin gold deposits in distilled water and absolute ethyl alcohol, these were examined at 100 kV by transmission electron microscopy (TEM, Siemens Elmiskop) and selected-area electron diffraction.

Thickness measurements were carried out with a Betascope, DZ800 instrument using a Promethium radioisotope that was calibrated with NBS thickness standards. The precision of the readings was estimated to be within ± 7%.

Reflectivity spectra over the range 4300-7500Å were recorded with a Perkin Elmer Model 402 Spectrophotometer using the specular reflectance attachment with a 2-mm mask. These measurements were carried out to determine whether this relatively simple macroscopic method, which was shown to be an effective means of characterizing electroless gold deposits (18), can be correlated with the microscopic structural information in a meaningful way.

Results and Discussion

Electrochemical behavior.—Alkaline cyanide gold solution.—Polarization curves for the alkaline cyanide gold solution at various rotational speeds are shown in Fig. 2. Due to the large excess of CN^- in the solu-

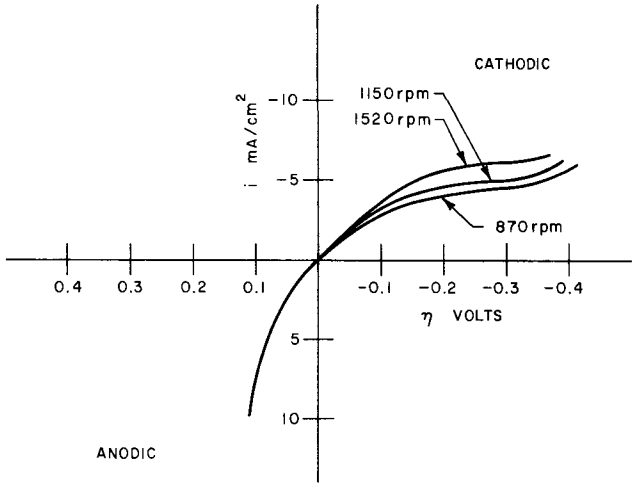

Fig. 2. Polarization curves for cyanide gold solution

tion, no anodic limiting current density is observed. Within the experimental uncertainty, the cathodic limiting current density varies linearly with the square root of rotational speed. The Volmer-Tafel equation for the present system can be expressed as

$$i = i_o \left[\exp\left(\frac{\alpha n\mathbf{F}}{RT}\eta\right) - \left(\frac{i_l - i}{i_l}\right) \exp\left(-\frac{(1-\alpha)\, n\mathbf{F}}{RT}\eta\right)\right] \quad [1]$$

where i is the applied current density, i_o is the exchange current density for the deposition process, i_l is the limiting current density for gold deposition, α is the transfer coefficient, η is the overpotential which is defined as the difference between the electrode potential (E_c) and the equilibrium potential (E^o), and n, $\mathbf{F}$, R, and T have their usual meaning. By differentiating Eq. [1] with respect to η and letting both i and η approach zero, an expression for i_o can be obtained

$$i_o = \frac{\left(\frac{di}{d\eta}\right)_{i,\,\eta\to 0}}{\frac{n\mathbf{F}}{RT} + \frac{\left(\frac{di}{d\eta}\right)_{i,\,\eta\to 0}}{i_l}} \quad [2]$$

The exchange current density is found from the experimental value of $\left(\frac{di}{d\eta}\right)_{i,\,\eta\to 0}$ and Eq. [2] to be 0.82 mA/cm². Based on the anodic portion of Fig. 2, the transfer coefficient is found to be 0.7, which is in agreement with the value obtained from the data given in Ref. (11). According to Maja, the cathodic rate is proportional to the square root of $Au(CN)_2^-$ concentration. This dependence would lead to an i_o value of 0.89 mA/cm² for this system.

The over-all reaction for gold deposition in the alkaline cyanide system is

$$Au(CN)_2^- + e^- \rightleftarrows Au + 2CN^- \quad [3]$$

The standard heterogeneous rate constant, k_s is calculated from the following equation

$$i_o = n\mathbf{F}k_s\, C_o^{\alpha} C_R^{2(1-\alpha)} \quad [4]$$

where C_o and C_R are the concentrations of $Au(CN)_2^-$ and CN^-, respectively. From Eq. [4], k_s was found to be 3.9×10^{-3} cm/sec.

Citrate gold solution.—Reproducibility of polarization measurements in the citrate gold solution was in general poor. Typical results are shown in Fig. 3. It is

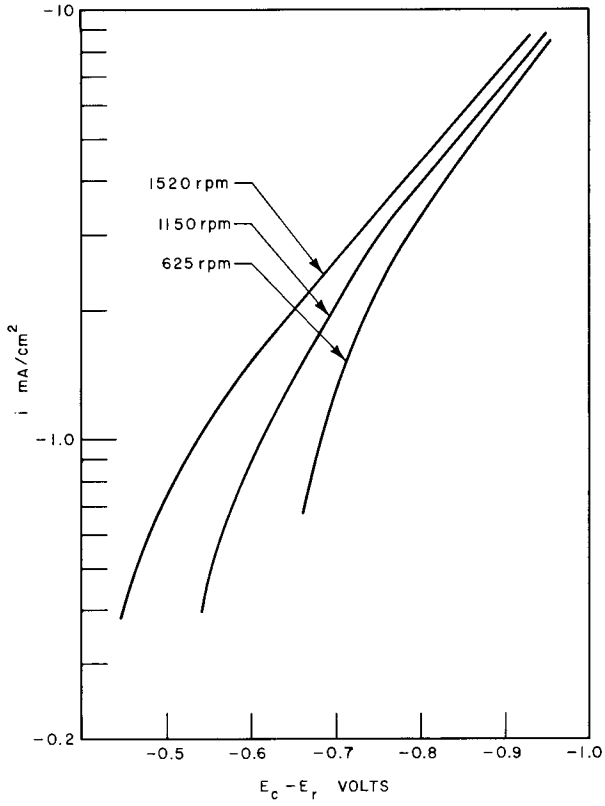

Fig. 3. Polarization curves for citrate gold solution

evident that no limiting step for gold deposition can be seen here due to the gradual onset of the H_2 evolution reaction. However, the limiting current density for deposition can be calculated from the transport properties of the system (16) and the following equation (19)

$$i_l = -\frac{0.554\, n\mathbf{F} D^{2/3}\, \nu^{-1/6}\, \omega^{1/2}\, C_o}{0.8934 + 0.316\,(D/\nu)^{0.36}} \quad [5]$$

where D is the diffusion coefficient of $Au(CN)_2^-$, ν is the kinematic viscosity of the solution and ω is the rotation speed. The values[3] were found to be 5.2 mA/cm² at a rotation speed of 1520 rpm and 4.1 mA/cm² at 870 rpm. It was not possible to extract kinetic parameters in this system.

Phosphate gold solution.—The results for the phosphate gold solution are shown in Fig. 4. Well-defined limiting current density is observed here. The values at various rotation speeds agree well with those obtained in an independent study based on current efficiency measurements (14). It was not possible to measure the equilibrium potential, presumably due to the small amount of free CN^- existing in the solution. Hence, no direct experimental information on the magnitude of i_o for this system can be obtained. However, if the anodic portion of Eq. [1] is neglected then the transfer coefficient can be calculated from the cathodic portion of the Volmer-Tafel equation

$$E_c - E_r = \frac{-RT}{(1-\alpha)n\mathbf{F}} \ln\left[\frac{-i}{i_o\left(1 - \frac{i}{i_l}\right)}\right] + (E^o - E_r) \quad [6]$$

[3] All current densities appearing in the text are cathodic; therefore the negative sign will be omitted.

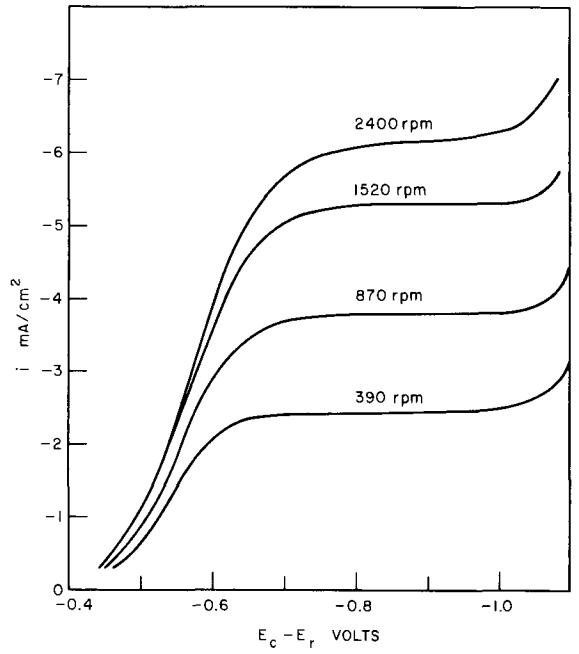

Fig. 4. Polarization curves for phosphate gold solution

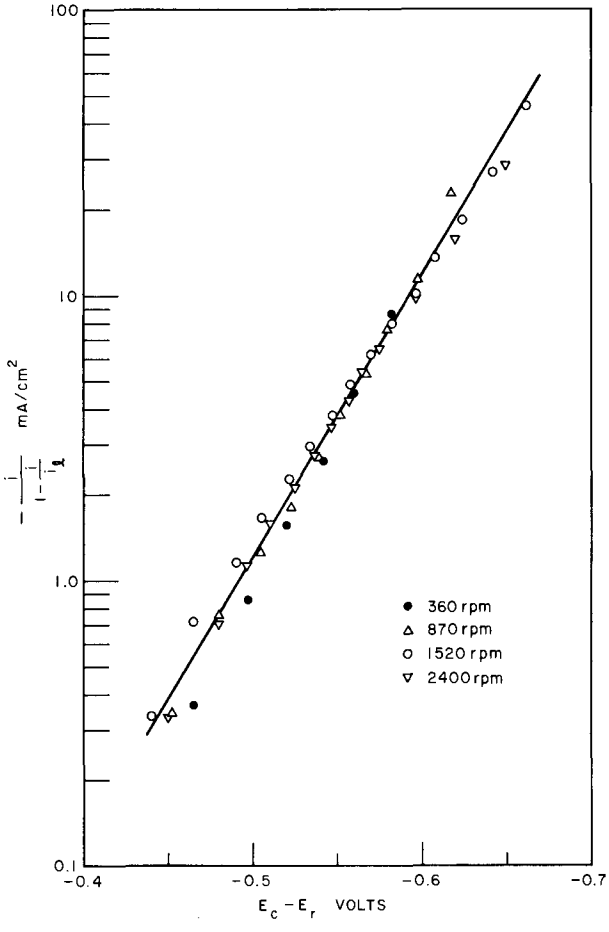

Fig. 5. Plot of ln $[-i/(1 - i/i_l)]$ vs. $E_c - E_r$ for phosphate system.

where $E_c - E_r$ is the potential difference between the cathode and the reference electrode. A plot of $\ln[-i/(1 - i/i_l)]$ *vs.* $E_c - E_r$ is presented in Fig. 5. The Tafel slope is measured to be 0.101V and this provides a value of 0.35 for the transfer coefficient.

In contrast to the cyanide system, the *p*H of the phosphate buffered solution is such that nearly all free cyanide is present as HCN. Hence, the electrode reaction can be written as

$$Au(CN)_2^- + 2H^+ + e^- \rightleftarrows Au + 2HCN \qquad [7]$$

The standard potential for this reaction is calculated to be 0.268V (*vs.* SCE) at room temperature based on the known values (20) of the dissociation constant for HCN and E^o for Eq. [3]. Following Delahay's treatment for irreversible i-V characteristics (21), Eq. [6] can be rearranged to give

$$E_c = \frac{RT}{(1-\alpha)n\mathbf{F}} \ln\left[\frac{i_l - i}{i}\right] + E_{1/2} \qquad [8]$$

where the half-wave potential is given by

$$E_{1/2} = E^o + \frac{RT}{(1-\alpha)n\mathbf{F}} \ln\left[\frac{k_s n\mathbf{F}C_o}{-i_l}\right] \qquad [9]$$

This treatment yields the heterogeneous rate constant $k_s = 6 \times 10^{-11}$ cm/sec based on the data in Fig. 4 and 5 and the room temperature value of $E^o = 0.268$V. Since the value of E^o for Eq. [7] at 60°C is unknown, the rate constant must be considered as an approximate result.

Physical behavior.—Alkaline cyanide solution.—This system yielded the greatest variation in deposit appearance, as surfaces ranged from bright yellow to dark brown depending on plating conditions. Tables II and III list the actual conditions studied together with thickness data obtained by calculation (μ_c) based on 100% current efficiency and by beta backscatter measurement (μ_β). A brief discussion of these data is given in the Appendix. Also listed in Tables II and III are reflectivity data (R_s) for these deposits. However, as discussed in the Appendix, this type of measurement is of limited usefulness in the cyanide system.

The SEM results in Fig. 6 illustrate the changes in morphology due to increasing current density at 760 rpm. The relatively smooth-faceted deposit formed at 0.63 mA/cm² (Fig. 6a) is yellow-gold in color and has a matte appearance. Increasing C.D. leads to the formation of outward growing features termed "spikes"; when these become sufficiently large and dense (Fig. 6c and 6d), the deposits are dark brown. In between the regions where these two types of deposits are formed is a transitional structure (Fig. 6b) which occurs at about 1.6 mA/cm² for these conditions. Similar structural features were also noted for thin deposits ($\sim 0.1\mu$); however, at this stage there was an increased tendency to form spikes, *e.g.*, they are evident at 1.6 mA/cm² for these conditions.

The same general behavior, *i.e.*, the transition to spikes, occurred at all rotation speeds. For example, at

higher rpm (1430-1520 rpm), the transition to spikes takes place at 3-4 mA/cm²; and at about 1.3 mA/cm², for thin deposits plated at 230 rpm. Under these last conditions, however, the thicker deposits did not exhibit spikes.

Experiments were carried out in a more concentrated cyanide solution (0.01M) to determine the effect of surface concentration. Applied C.D. values were chosen such that the surface concentration of $Au(CN)_2^-$ was identical to that in the dilute solution. To achieve these conditions, the surface concentration (C_e) was calculated from (19)

$$i = -\frac{0.554\, nFD^{2/3}\, \nu^{-1/6}\, \omega^{1/2}\, (C_0 - C_e)}{0.8934 + 0.316\, (D/\nu)^{0.36}} \qquad [10]$$

for C.D. values used with the dilute solution. Corresponding C.D. values for the concentrated solution (2 C_0) were then obtained using Eq. [10] with the appropriate ω values for each C_0.

It was found that different structures were formed at equivalent values of C_e in the two solutions. The experimental evidence for this statement is presented in Fig. 7 and the results are listed in Table III. Each micrograph in Fig. 7 should be compared with the corresponding one in Fig. 6 in order to see the different structures formed at equivalent C_e values (0.0044M, 0.003M, 0.0021M, and 0.0002M, respectively for a-d).

As indicated in Table III, the transition from a smooth-faceted type of growth to spiked was observed for deposits plated at 870 rpm. The C_e values for these conditions are 0.009M for the smooth deposit formed at 1.26 mA/cm², 0.0075M for the transitional structure at 2.52 mA/cm², and 0.006M for the spikes formed at 3.78 mA/cm². These data together with the results obtained at 1520 rpm provide additional evidence that the surface concentration of gold is not what determines which structure forms. At 1520 rpm, deposition at 2.52 mA/cm² (C_e = 0.0082M) yields well-defined spikes (similar to Fig. 7a) and increasng C.D. to 8.7 mA/cm²

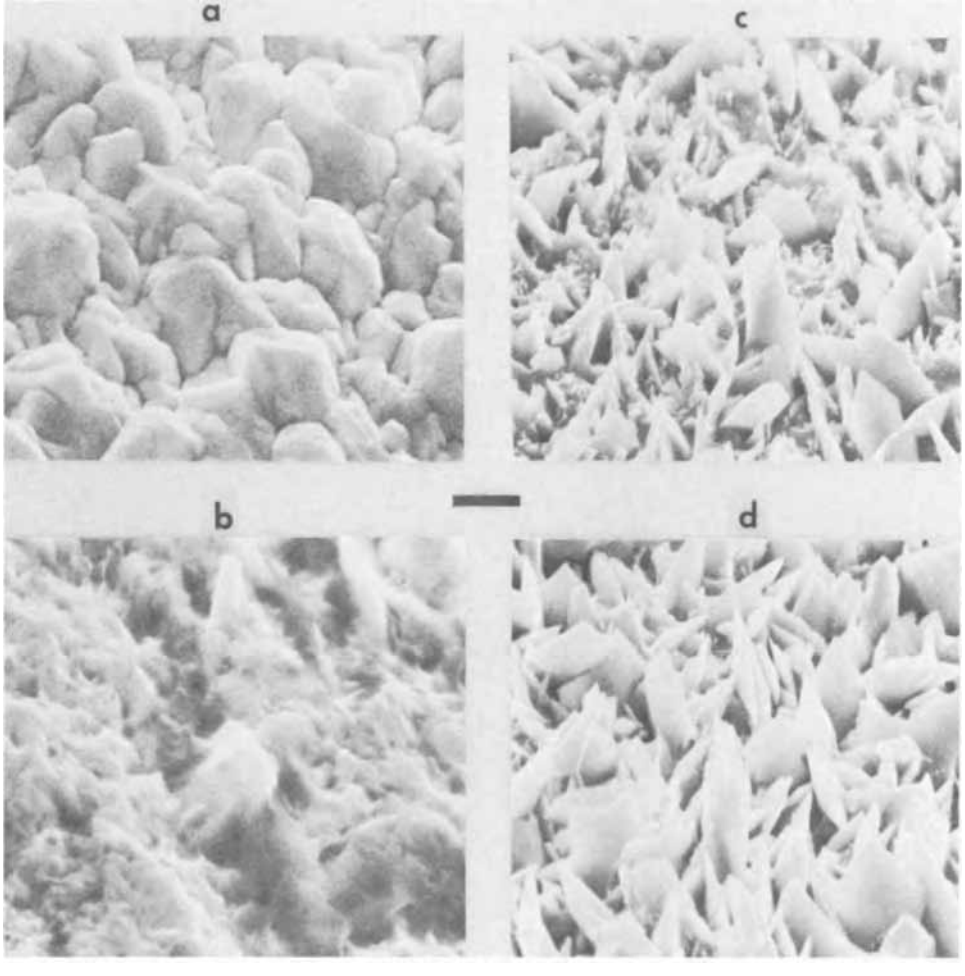

Fig. 6. Morphology of deposits plated in cyanide system (0.005M) at 760 rpm. a, 0.63 mA/cm²; b, 1.6 mA/cm²; c, 2.5 mA/cm²; d, 3.8 mA/cm². Scanning electron micrographs, magnification bar represents 1 μ in this and subsequent figures. 10,000X originally.

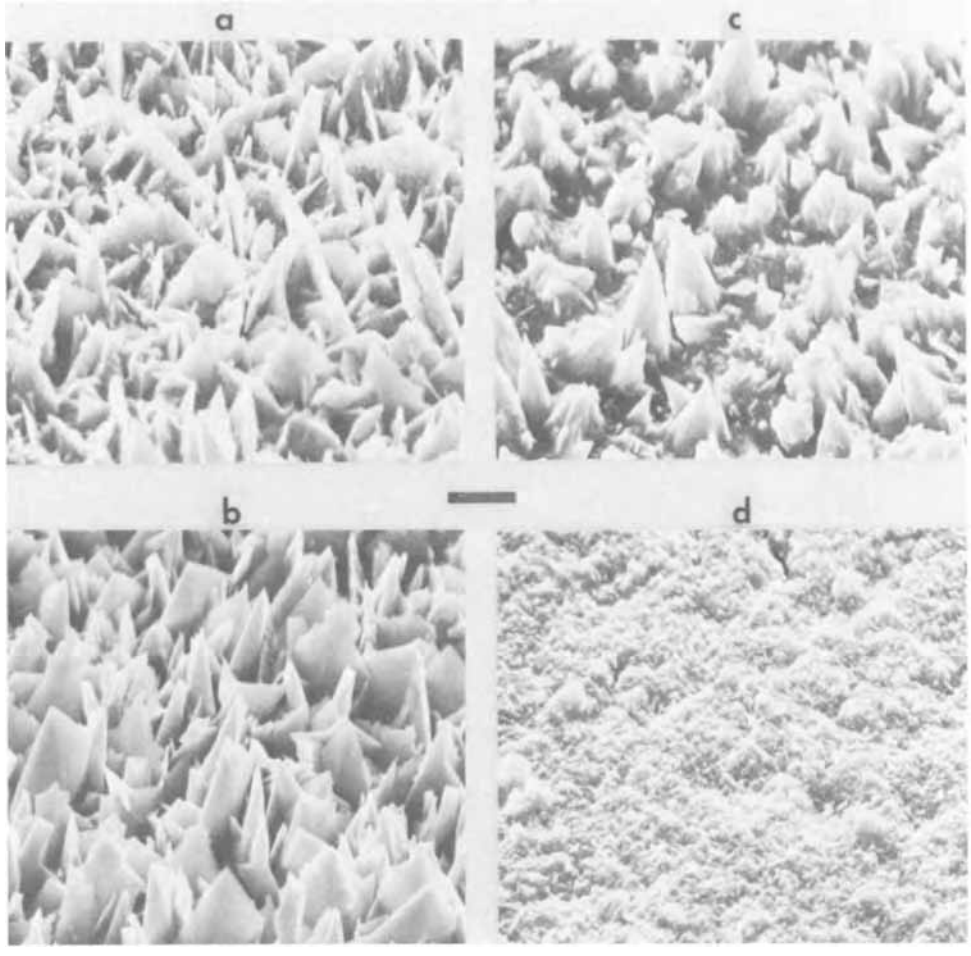

Fig. 7. Morphology of deposits plated in 0.01M $Au(CN)_2^-$ solution at 1520 rpm. Surface concentrations are equivalent to corresponding deposits in Fig. 6. a, 6.9 mA/cm^2; b, 8.7 mA/cm^2; c, 10.0 mA/cm^2; d, 11.9 mA/cm^2. Scanning electron micrographs, 10,000X originally.

causes very little change as the density of spikes increases approximately twofold to 2 x 10^8/cm^2 (Fig. 7b). Further increases in C.D. result in another transition (Fig. 7c) back to yellow-appearing deposits with a very fine grain size at about 12 mA/cm^2 (Fig. 7d), which is in the vicinity of the limiting C.D. (C_e = 0.0002M). Above this C.D. the formation of powderlike structures of the type discussed by Ibl (22) was observed, but no systematic study of the structures formed above i_l was carried out.

It appears on the basis of these results that morphology is not determined primarily by either the surface concentration or C.D. Hence, it is instructive to consider whether overpotential is controlling the formation of the various structures. The smooth, faceted surfaces which formed at 0.63 mA/cm^2 in the dilute solution (Fig. 6a) and at 1.26 mA/cm^2 in the more concentrated one correspond to overpotentials of less than ~50 mV in magnitude (Fig. 2). The transitional structures (*e.g.* Fig. 6b) were formed in the region from −50 to −100 mV. Spikes (Fig. 6c, d and 7a, b) appeared over the potential range from −150 to −300 mV. The previously mentioned transition to a fine-grained type of deposit (Fig. 7d) occurred at higher potential in the concentrated solution.

The results obtained from the alkaline cyanide system indicate that below i_l the formation of the different structures is governed by the potential[4] rather than by mass transport.

Citrate solution.—The deposits plated in the citrate solution were in many respects similar to those obtained in the cyanide system at low gold concentration. Results are given in Table IV and the transition from flat, faceted growth to the outward growing spikes is illustrated in Fig. 8 for deposits plated on gold substrates at 870 rpm. On Cu substrates similar results were obtained except that the transition region, which occurs at 2.5 mA/cm^2 on Au (which corresponds to ~ −0.75V according to Fig. 3), is displaced towards a lower value as these conditions yield a spiked structure like that in Fig. 8c. When the rotation speed is increased to 1520 rpm at 2.5 mA/cm^2, a smooth, flat, fine-grained surface similar to that in Fig. 8a (1.26 mA/cm^2) is formed. It is significant that either way, *i.e.* increasing ω (from 870 to 1520 rpm)

[4] Previous studies (23, 24) of Cu deposition onto stationary single crystal electrodes have also shown that different types of growth habit are associated with specific ranges of overpotential.

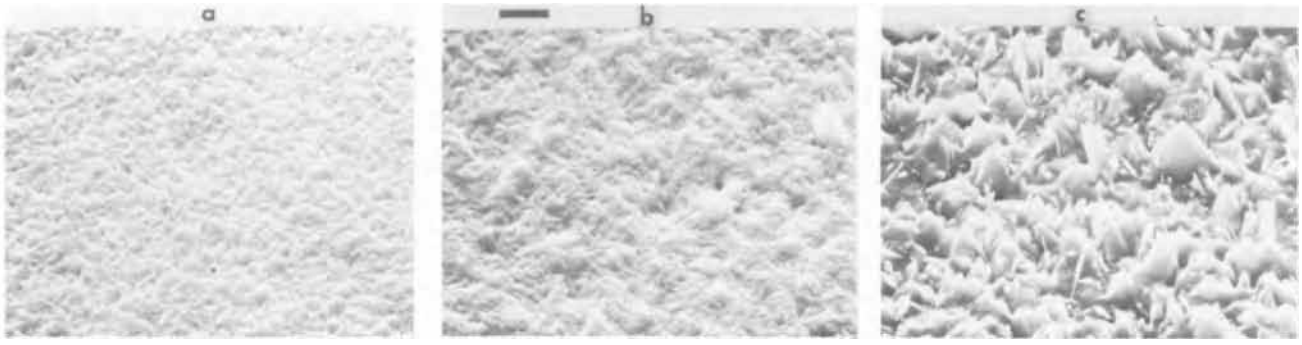

Fig. 8. Morphology of deposits plated in citrate system at 870 rpm. (Thickness, approximately 1μ). a, 1.3 mA/cm^2; b, 2.5 mA/cm^2; c, 3.8 mA/cm^2. Scanning electron micrographs 10,000X originally.

at constant i (2.5 mA/cm^2), or decreasing i (from 2.5 to 1.3 mA/cm^2) at constant ω (870 rpm), which both correspond to a potential decrease of about 60 mV in magnitude, the same structure is obtained. This result is in agreement with the previous discussion concerning the cyanide system. However, it must be recognized that increasing ω or decreasing C.D. have similar qualitative effects on mass transport. Specifically, at 1520 rpm 2.5 mA/cm^2 corresponds to $i_l/2$, whereas at 870 rpm 1.3 mA/cm^2 corresponds to $i_l/3$. Therefore, the available data do not permit a completely unambiguous determination of whether potential or mass transport is the controlling factor regarding the structures formed in this system.

The same general behavior was also noted for the thinner citrate deposits, except that the scale of structural features is significantly reduced. Thus, for example, the thin sample plated at 1.3 mA/cm^2 and 870 rpm exhibited an extremely fine grained microstructure consisting of crystallites approximately 300-500Å in size (as determined by TEM using dark-field images) and other particles about twice as large which were present on the surface. A two-fold increase in i led to the formation of spikes (Fig. 9a). The results obtained by TEM (Fig. 9b) indicate that the spikes protrude from a fine-grained, thin, continuous layer of gold. The spikes, which appear dark in transmission due to absorption, are seen to range from about 1000

to 2500Å in length and number about $2 \times 10^9/cm^2$. Increasing i to 3.8 mA/cm² yielded a similar structure with about 1.6×10^9 spikes per cm² and these range from 1000 to 4000Å in length.

The effect of increasing rotation speed to 1520 rpm at 2.5 mA/cm² is shown in Fig. 9c. No spikes are formed; instead there exists a heterogeneous surface consisting of relatively large ($\sim 1\mu$) regions of different contrast and an overgrowth of small particles (< 1000Å). TEM results (Fig. 9d) show that these large regions are, in fact, Au crystallites which apparently copied the surface structure of the Cu substrate and preceded the particle nucleation. At higher C.D. (5 mA/cm²), the transition to spikes was observed, but the large-grained, initial layer was quite similar to Fig. 9d. It is also evident from Fig. 9d (*e.g.* the regions denoted by arrows) that the particles nucleated preferentially at structural defects such as twin faults and grain boundaries. These results indicate that the initial deposition onto Cu is rather complex and consists of a substrate-dominated stage which results in an epitaxial[5] layer several hundred angstroms thick, followed by another stage where the type of growth is controlled by the deposition conditions. This latter stage is of primary concern here; the epitaxial stage will be the subject of a future paper.

The changes in reflectivity (R_s) correlate reasonably well with microscopic observations and show, in addition to the expected decreases with increasing i, t, and decreasing ω, that at lower current densities (1.3 and 2.5 mA/cm²) thick deposits plated on Au (Fig. 8a, b) are even more reflective than the thin ones plated on Cu. This effect is apparently a consequence of an increased surface roughness which results in the latter case. It appears that the change in reflectivity is a very sensitive indicator of morphological changes as the features protruding from the surfaces in Fig. 9 are on the order of 10% of the wavelength. In general, for a given set of plating conditions the reflectivity is greater for samples from the citrate system than for corresponding cyanide samples.

[5] The fact that the initial stage of Au electrodeposition onto Cu substrates is epitaxial (i.e. in parallel orientation) has been reported previously (25, 26) for other plating systems.

Phosphate solution.—Deposits from the phosphate system showed the least variation over the range of conditions studied and tended to be more reflective and yellow than the samples from the other systems. Results are given in Table V. Thicker deposits (1-2μ) are matte yellow in appearance due to the smooth, faceted features present on their surfaces (Fig. 10a). As discussed in the Appendix, such surfaces show reduced specular reflectivity; however, the R_s values, in general, were much higher for deposits from the phosphate bath than corresponding ones plated in the citrate system.

Increasing C.D. appears to cause a refinement in the size of surface features and a slight tendency towards outward growth (Fig. 10b, 4.4 mA/cm², 760 rpm). The thin deposit plated under these same conditions was the only nonyellow appearing one observed in this system and Fig. 10c clearly shows the formation of spikes on the surface.

The factors responsible for the greater tendency for spikes to form at shorter times, which was also noted previously for the other systems, have not been established conclusively. One observation which appears to be related to this phenomenon is that the potential-time curves (14) showed a maximum (of approximately 200 mV in magnitude above the steady-state value) at about 0.5 to 1 min, which corresponds to the conditions used for preparing the thin deposits. While it seems probable that this rise in potential is associated with the energy required for the initial stage of three-dimensional gold nucleation, no detailed study of this effect was carried out.

Additional information on the structure of thin deposits was obtained by TEM. Some bright-field micrographs showing the effect of C.D. at 760 rpm are shown in Fig. 11. At low C.D. (0.63 mA/cm², Fig. 11a), the structure is seen to be essentially a replica of the Cu substrate as the relatively large crystallites ($\sim 1\mu$) with numerous twin faults were also present in evaporated Cu films. As C.D. is increased to 1.3 mA/cm² the growth centers become more apparent due to the formation of thicker, three-dimensional nuclei. These appear as dark gray and black blotches about 0.5μ across in Fig. 11b. A similar structure was also

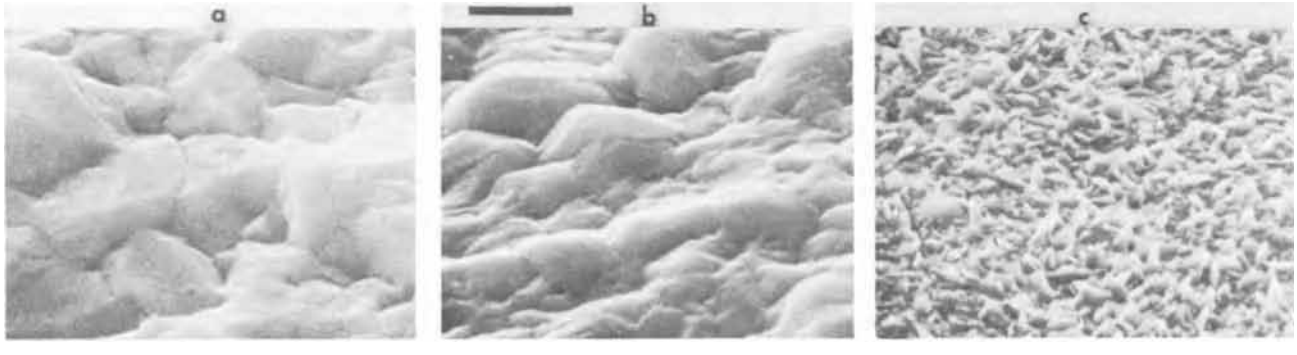

Fig. 10. Morphology of deposits plated in phosphate system at 760 rpm. a, 1.3 mA/cm²; 1.7μ thick. b, 4.4 mA/cm²; 1.1μ thick. c, 4.4 mA/cm²; 0.14μ thick. Scanning electron micrographs, 20,000X originally.

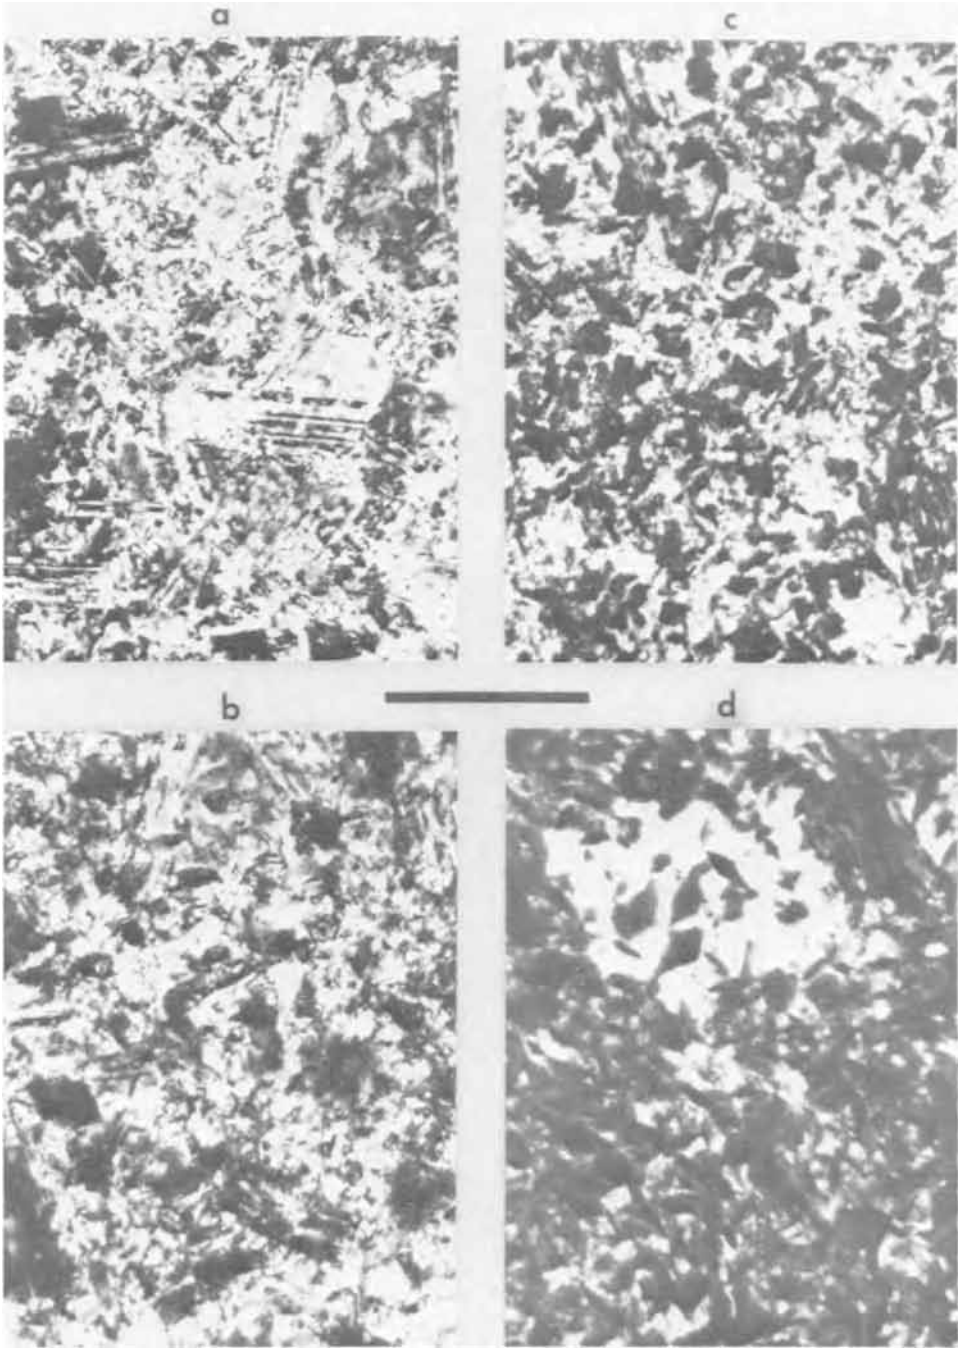

Fig. 11. Structure of thin deposits (~ 0.1μ thick) plated in phosphate system at 760 rpm. a, 0.63 mA/cm^2; b, 1.3 mA/cm^2; c, 3.6 mA/cm^2; d, 4.4 mA/cm^2. Transmission electron micrographs, 30,000X originally.

formed at 2.5 mA/cm^2. Dark-field images were used to aid interpretation of these structures, *i.e.* to differentiate between absorption contrast due to the thicker regions and diffraction contrast effects. In the vicinity of i_l, at 3.6 mA/cm^2 (Fig. 11c) spikes are present, and these become more numerous and regular at 4.4 mA/cm^2 (Fig. 11d). Apparently the spikes do not form directly on the Cu substrates but are supported by thin (few hundred angstroms) epitaxial Au layers which are white in Fig. 11c, d as the primary contrast here is due to absorption. Inspection of these and other similar micrographs indicates that the spikes are generally thin parallelograms in cross section. Although they appear in some cases to have a particular crystallographic orientation, and lie with their long axes parallel to <110> directions in the epitaxial Au layer, it was not possible to establish whether such behavior is general. Spikes were not formed when the rotation speed was increased by a factor of two at approximately this same deposition rate (4.7 mA/cm^2), which is consistent with the previous discussion regarding the citrate and cyanide systems.

Summary

This study of the electrochemical and physical aspects of gold deposition onto rotating disk electrodes has provided the following information.

Polarization data for the alkaline cyanide system (0.005M) yield an exchange current density of 0.82 mA/cm^2 and a transfer coefficient of 0.7. From these data k_s was calculated to be 3.9×10^{-3} cm/sec. This system showed the greatest tendency to form an outward growth morphology consisting of fine features termed spikes that are responsible for the characteristic brown appearance of deposits plated under a wide variety of conditions. By electron microscopy it was observed that the spikes are typically 0.1-1.0μ in size and $> 10^8$/cm^2 in density. Increasing C.D. and decreasing ω, in general, both favor the formation of spikes which occurs over a given potential range and not at a particular concentration of gold at the interface. At low overpotentials, a smooth, layer type of growth is formed.

The citrate system gave the most irreproducible polarization results and did not show a well-defined limiting step for gold deposition due to the gradual

nature of the hydrogen evolution reaction. Deposits showed the same general structural characteristics as for the cyanide system, and the formation of spikes also appears most likely to be governed by the potential of the reaction.

Polarization data for the phosphate system showed well-defined limiting current density and gave a Tafel slope of 0.101V; however, the insufficient quantity of CN^- in solution precluded determination of i_o. Following Delahay's treatment for irreversible electrode reactions, the k_s value for this system was calculated to be 6×10^{-11} cm/sec. These deposits were more reflective and yellow than corresponding ones from the other systems due to the decreased tendency to form spikes which occurred only in the vicinity of i_l for thin deposits (0.1μ). The transition from spikes in thin deposits to smoother surfaces at steady state, which was observed for all three systems in the potential region where the transitional structures formed, is associated with the maximum in the potential-time curves.

Finally, by transmission electron microscopy it was established that the initial stage of deposition is rather complex and consists of a substrate-dominated stage which results in an epitaxial layer several hundred angstroms thick, followed by another stage where three dimensional growth occurs. At the beginning of this stage, which is controlled by the deposition conditions, structural defects such as twin faults and grain boundaries in the epitaxial layer act as preferential sites for nucleation.

APPENDIX

Characterization of gold deposits by spectrophotometry.—The purpose of making reflectivity measurements on the gold deposits generated in this study was to determine whether this approach would facilitate more quantitative comparisons of the different morphologies. Spectra were recorded with the Perkin Elmer Model 402 Spectrophotometer which was used previously to study electroless gold deposits (18). Because of the small sample size, a 2-mm circular mask was inserted in the specular reflectance attachment. The instrument yields plots of relative absorbance *vs.* wavelength as illustrated in Fig. 12. These curves correspond to the deposits whose SEM results are given in Fig. 6-10. The method used to compare spectra of this type was to determine the relative separation of each curve from the specular gold reference at the arbitrarily selected value of $\lambda = 6500$Å. From this separation, the R_s values quoted in Tables II-V were computed as fractions of the value for the specular gold reference surface. Although the R_s values appear to correlate reasonably well with deposit morphology in most cases, they should be considered as semiquantitative data for the following reasons. First, while a single parameter is suitable for describing the separation of similarly shaped curves, it is evident that the spectra obtained from the gold deposits (Fig. 12) show both a displacement and change in slope at a given wavelength. Second, a relatively large number of surfaces (*e.g.* particularly those from the cyanide system) had a nonspecular or matte appearance, either orange or brown in color, and could not be measured as they gave no detectable signal. Finally, the R_s values are sensitive not only to the type of structure formed, but are significantly affected by subtle features like grain size and the amount of faceting both of which vary with thickness. Recent evidence obtained with electroless gold deposits (27) suggests that most of these difficulties can be overcome by measuring the total light reflected, *i.e.* diffuse plus specular, using an integrating sphere (28). It appears that this approach can be applied to a more quantitative study of gold deposits provided that larger area (> 1 cm^2) samples of equivalent thickness are compared.,

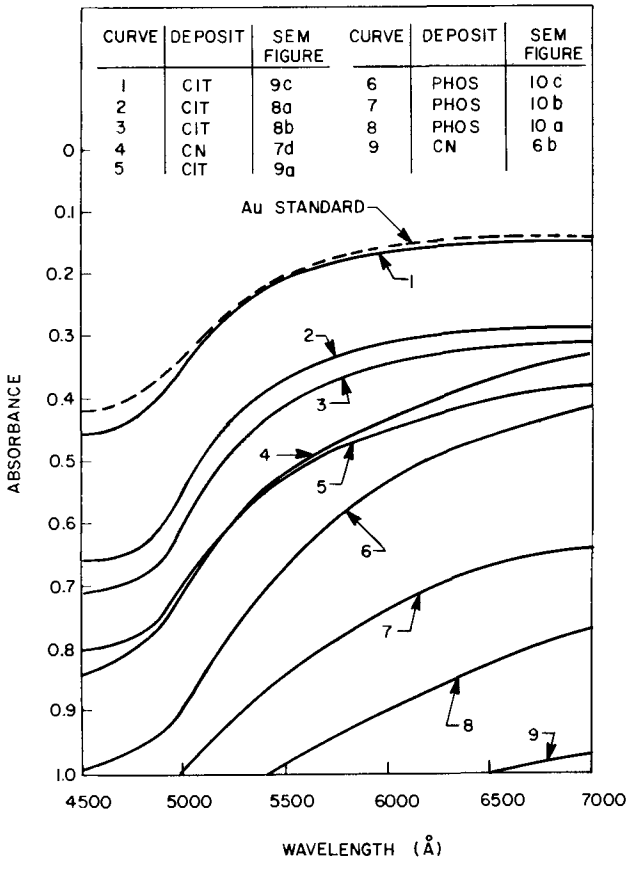

Fig. 12. Optical spectra of representative electrodeposited gold surfaces. Numbered curves correspond to deposits whose SEM results are given in Fig. 6-10.

Some comments regarding thickness data.—The efficiency of gold plating was not of major interest in this work. However, the thickness data (μ_c and μ_β values) presented in Tables II-V provide support for the following generalizations regarding efficiency: (*A*) For all three gold plating systems (0.005M), efficiency increases from less than 50% at low C.D. to more than 80% in the region below i_l. (*B*) The more concentrated cyanide system (0.01M) showed a significant increase in efficiency with most μ_β/μ_c values in the range from 0.95 to 1.0.

Both of these results appear to be related to the effects of oxygen which, as mentioned previously, was not excluded from the solution during these experiments. This interpretation is based on the excellent agreement between the present results and a recently completed quantitative electrochemical study (14) of the current efficiency of gold deposition in phosphate and citrate systems which were identical to those used in this work. The increased efficiencies noted for the more concentrated cyanide system probably result from a salting out effect which, in addition to the higher current densities used, acts to further diminish the oxygen reduction current.

LIST OF SYMBOLS

C_e	surface concentration of $Au(CN)_2^-$

Electrochemistry of Alloxan and Its N-Methyl Derivatives in Aqueous Solution

Barbara H. Hansen[1] and Glenn Dryhurst

Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

Alloxan, methyl- and dimethyl alloxan in aqueous solutions are reduced by way of three processes. The first cathodic wave (wave I_a), appears between *p*H 0-8 and is a kinetically controlled two-electron, one-proton reduction to the respective dialuric acid anion. Dehydration of the reducible carbonyl site is the kinetic factor. A second *p*H independent kinetically controlled reduction wave (wave I_b) is observed for 1.0 mM solutions of methyl- and dimethyl alloxan and for 10.0 mM solutions of alloxan between *p*H 0-3. The process involved is the transfer of two electrons to protonated alloxan molecules, again producing the dialuric acid anion. Wave II, detected only in the limited *p*H range of *ca.* 4.7-5.9, is a virtually *p*H independent, two-electron reduction of the hydrated form of alloxan to the dialuric acid dianion as the potential controlling process. This study indicates that wave II is not due to the further reduction of dialuric acid. Evidence is also given which refutes the view that alloxantin exists to a large degree in aqueous solutions.

Alloxan is produced upon electrochemical (1) and enzymatic (2, 3) oxidation of uric acid in weakly acidic solution. Dimethyl alloxan is an electrochemical oxidation product of theophylline (4) and caffeine (5). Methyl alloxan is an electrooxidation product of theobromine (5). Only alloxan itself has been studied electrochemically (6, 7) and is reported to show only two cathodic waves at the dropping mercury electrode (DME). The first wave (occurring at most positive potentials) has been shown to be a two-electron, one-proton reduction of alloxan to the anionic form of dialuric acid in a kinetically controlled electrode reaction (7). The reaction responsible for the other wave (wave II) that occurs at much more negative potentials over a very limited *p*H range has not been properly characterized, although it has been suggested that it is due to further reduction of the wave I product, dialuric acid, to barbituric acid or to other more highly reduced species (7).

Consideration of the structures of alloxan (I), alloxantin (II), and dialuric acid (III) suggests that alloxantin would be the most probable primary reduction product. The literature, however, contains conflicting

Key words: 2,4,5,6-trioxypyrimidine, alloxantin, dialuric acid.

reports on the stability of alloxantin (8-10). Struck and Elving (7) claim that alloxantin is not appreciably dissociated in solution (to alloxan and dialuric acid) and that it is polarographically active and gives rise to an anodic wave at the same $E_{1/2}$ as that of dialuric acid, and a small kinetically controlled cathodic wave at the same $E_{1/2}$ as that of alloxan. It was also claimed to give only a very small cathodic wave at potentials corresponding to alloxan wave II (7). In some recent work in this laboratory (4, 5) it become necessary to understand the details of the electrochemistry of alloxan and its N-methyl derivatives. It became clear that more study was necessary, first to clarify the involvement of the methylated alloxantins in the polarographic reduction of the alloxans, second to ascertain the nature of the wave II process, and third to explain the process responsible for a further small wave which was observed at low pH.

Experimental

Chemicals.—Dimethyl and methyl alloxan were prepared according to the method of Fischer (11). Alloxan was obtained from Nutritional Biochemicals, alloxantin from Eastman, and dialuric acid from Calbiochem. Buffer solutions had an ionic strength of 0.5. Argon used for deoxygenation was equilibrated with water.

Apparatus.—Equipment employed for polarography, voltammetry, and coulometry has been described elsewhere (4, 5, 12-14, 16, 19), with the exception that salt bridges in the electrochemical cells were composed of agar-potassium sulfate. The reference electrode was a saturated mercurous sulfate [0.40V *vs.* SCE (15)] and the counterelectrode was a cylindrical platinum gauze dipping in saturated potassium sulfate solution. All potentials are referred to the SCE at 25°C.

The DME had an M value of 1.375 mg sec^{-1} and $t = 5.08$ sec^{-1}, at open circuit with $h = 70$ cm.

The cell used for macroscale coulometric and preparative electrolysis contained three compartments and was adapted from that described previously (16), with the reference and counterelectrodes described above. All compartments were equipped with stoppers and bubblers to ensure complete deoxygenation.

Solutions.—Solutions of the alloxans were not stable so each test solution was made up in the desired buffer immediately prior to use. Solutions used for the pH study were normally about 1 mM in concentration.

Determination of coulometric n-values.—General procedures employed for the determination of coulometric n-values are described elsewhere. In most cases the electrolysis was considered complete when the quantity of acid added into a titration coulometer (15) per unit time matched that required for identical electrolysis of background solution. However, at the pH values where wave II is observed alloxan is very unstable. Electrolysis time was therefore limited to 30 min. The concentration of the remaining alloxan was determined polarographically by comparison with a calibration curve prepared as described below.

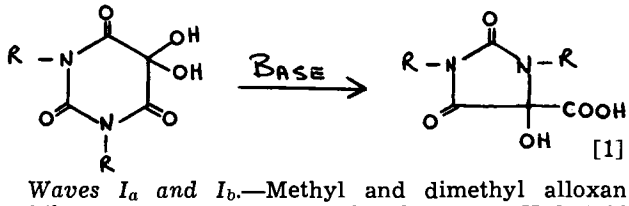
Polarographic i_l — C curves at pH 4.9 to 5.1.—Two consecutive concentration-decomposition studies were performed on each alloxan. Solutions of the respective alloxan were prepared (1.0 mM) in pH 4.9 or pH 5.1 McIlvaine buffer and 1, 2, 3, 4, and 5 ml aliquots immediately transferred into volumetric flasks containing the background solution giving a total 10 ml volume. The solutions were allowed to stand for 30 min. Immediately after this period polarograms from −1.2 to −1.6V were obtained. The solutions were scanned in the order 0.1, 0.5, 0.2, 0.4, and 0.3 mM. Background current at the potential of the limiting current of wave II was obtained as the average from several background polarograms and was subtracted from the average limiting current at each concentration.

UV spectrophotometric procedures.—Samples studied spectrally had to be maintained in an oxygen-free environment. All flasks, cells, and pipettes were flushed with nitrogen prior to use. Positive nitrogen pressure was used to transfer solutions from pipettes. Solutions used for dilution of the reduction product solution or for dissolution of alloxantin and dialuric acid were also thoroughly deoxygenated.

Alloxantin dissociation study.—A solution, 0.2 mM in alloxantin, was prepared in pH 4.7 acetate buffer as follows: a weighed quantity of alloxantin was placed in a volumetric flask which had been flushed with nitrogen and a deoxygenated solution of buffer added. Dissolution was accomplished by heating in a water bath (*ca.* 5 min) while a steady stream of nitrogen was passed through the solution. After cooling, an air-free transfer was made to the nitrogen-filled polarographic cell, and polarograms from −1.2 to −1.6V and then from +0.4 to −0.2V were recorded.

Results and Discussion

Aqueous solutions of methyl and dimethyl alloxan exhibit three cathodic waves at the DME. Wave I_a (the most positive wave) occurs between pH 0-8 and 0-7.1 for methyl and dimethyl alloxan respectively. Wave I_b appears between pH 0-3 and wave II between about pH 4.7-5.9 for both compounds. Above pH 4-5 alloxan and its N-methyl derivatives begin to decompose into the appropriate nonelectroactive alloxanic acids (Eq. [1]); this reaction becomes rapid at pH 7-8 (18).



[1]

Waves I_a and I_b.—Methyl and dimethyl alloxan exhibit waves I_a and I_b together between pH 0 (1M H_2SO_4, Fig. 1A) and pH 3. Above pH 3 wave I_b disappears (Fig. 1B). Wave I_a for both compounds shifts linearly more negative with increasing pH, $E_{1/2}$

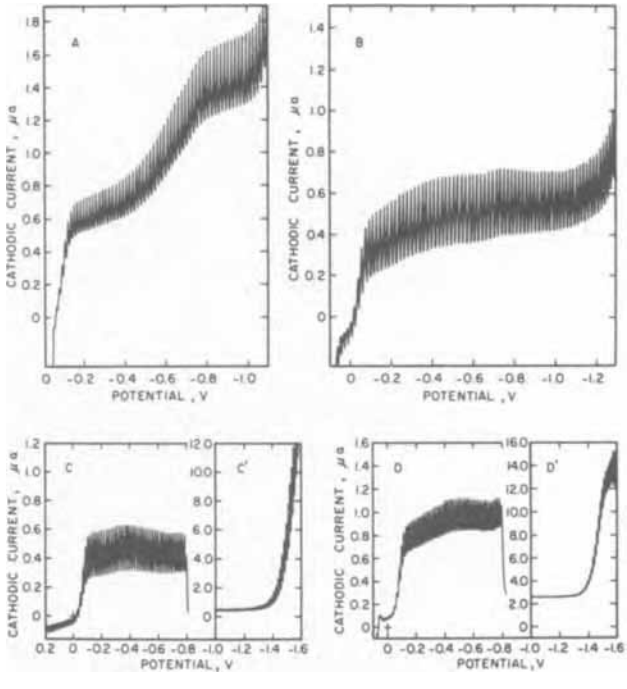


Fig. 1. Polarograms of dimethyl alloxan in A, 2M H_2SO_4; B, McIlvaine buffer pH 3.7; C, Acetate buffer pH 4.3; D, McIlvaine buffer pH 4.9. Concentration dimethyl alloxan A, 1.3 mM; B, 1.1 mM; C, 1.1 mM; D, 1.5 mM.

$= 0.10\text{-}0.033$ pH for methyl alloxan, and $E_{1/2} = 0.10\text{-}0.036$ pH for dimethyl alloxan. These equations compare favorably with that for the first wave of alloxan where $E_{1/2} = 0.060\text{-}0.031$ pH (7), and are in accord with that expected for a reversible process involving two electrons and one proton. The diffusion current constants ($I = i_l/Cm^{2/3}t^{1/6}$) for wave I_a of methyl and dimethyl alloxan are very small. Between pH 0-5.9 the mean diffusion current constant for methyl alloxan was 0.23 and for dimethyl alloxan was 0.30. The limiting current for wave I_a for both compounds was independent of the corrected mercury column height indicating that the electrode reaction was kinetically controlled. A temperature coefficient of 4.3% per °C (methyl alloxan) and 5.2% per °C (dimethyl alloxan) further confirmed the kinetic nature of the wave I_a process.

Wave I_b is essentially pH independent and occurs at -0.27 ± 0.03V for methyl alloxan and -0.34 ± 0.07V for dimethyl alloxan. The limiting current for wave I_b decreases significantly as the pH approaches 3. Above pH 3 wave I_b is not observed indicating that the species reduced exists only at low pH. The diffusion current constant for wave I_b of methyl alloxan (0.10 between pH 0-2) is considerably smaller than for wave I_b of dimethyl alloxan (0.17 between pH 0-2). The temperature coefficient of the limiting current for wave I_b of dimethyl alloxan, 1.2% per °C in chloride buffer pH 1.9, is smaller than that expected for a kinetically controlled process.

Polarograms of dimethyl alloxan in McIlvaine buffers above pH 2.2 (Fig. 1B, D) and in acetate buffers pH 3.4-5.3 (Fig. 1C) indicate that the shape of the current-potential curve for wave I_a at potentials immediately more negative than the half-wave potential differs between the two buffers. In McIlvaine buffers this region is more drawn out and the limiting current is reached at potentials approximately 0.3V more negative than with acetate buffers. This effect does not constitute a second distinguishable reduction wave. A similar phenomenon, *i.e.* a wave more drawn out than is generally expected, was reported (19) for parabanic acid and its N-methylated derivatives in McIlvaine buffers over a limited pH range. This was explained as the reduction of phosphate complexes, the structures of which were also proposed, of the respective parabanic acid. The arrangement of carbonyl groups in dimethyl alloxan is similar to those of the parabanic acids and, therefore, analogous complexes are plausible for a dimethyl alloxan phosphate interaction. The wave I_a reduction in McIlvaine buffer, pH $\geq$ 2.9, may represent, therefore, the reduction of both dehydrated dimethyl alloxan and the dimethyl alloxan-phosphate complex.

Wave II.—Wave II of methyl and dimethyl alloxan can be observed between pH 4.7-5.9 and is comparable to wave II of alloxan (7). Accurate measurement of the limiting current is complicated by the decomposition of the alloxans to the appropriate alloxanic acid. However, the limiting current appeared to be diffusion controlled as evidenced by its dependence on the corrected mercury column height. The diffusion current constant for wave II of methyl alloxan ranged from 3.8 at pH 4.7 to 1.7 at pH 5.9. For dimethyl alloxan over the same pH range the value changed from 2.8-1.6. The systematic decrease of the diffusion current constant with increasing pH reflects the increasing rate of decomposition of the alloxans to the alloxanic acids. Over approximately the same pH range alloxan itself gives an average diffusion current constant for wave II of about 3.6 (7).

The half-wave potential for wave II of methyl alloxan (-1.46 ± 0.01V) and dimethyl alloxan (-1.41 ± 0.01V) between pH 4.7-5.9 are pH independent. Between pH 4.6-6.6 wave II of alloxan is also virtually pH independent (-1.51 ± 0.02V) (7).

Table I. Coulometric determination of the number of electrons involved in the reduction of alloxan and n-methylated derivatives

Supporting electrolyte	pH	Controlled potential	n
		Dimethyl alloxan

[a] Mean of at least three determinations usually. Reproducibility of data ±5%.
[b] Values from work of Struck and Elving (7).
[c] At pH values of about 5 the decomposition of the alloxans was quite rapid and the reproducibility of data was ±10-15%.

Coulometry

Data from coulometric determinations of the number of electrons involved in the reduction of alloxan, methyl alloxan, and dimethyl alloxan at controlled potentials corresponding to waves I (includes I_a plus I_b in the case of the methylated compounds) and II respectively are summarized in Table I. Clearly, electrolysis of all alloxans at potentials corresponding to the crest of wave I results in the transfer of close to 2 electrons per molecule reduced. Complete electrolysis was not attempted at potentials corresponding to wave II because the alloxan solutions were not sufficiently stable at the required pH. The period of the electrolysis was therefore limited to 30 min. The concentration of the remaining parent compound was determined polarographically (see Experimental). Average coulometric n values of 2.3, 1.6, and 1.9 were obtained for alloxan, methyl and dimethyl alloxan respectively.

Identification of Reduction Products

It is clear that both waves I and II of alloxan species involve 2*e*. Because of our greater interest in dimethyl alloxan, product identification was limited to this compound; analogous products were assumed from the other alloxans.

Wave I.—Polarography of a 1*M* HOAc solution of reduced dimethyl alloxan revealed the presence of a single large anodic wave, $E_{1/2} = 0.01$V (Fig 2). Dialuric acid shows analogous polarographic behavior to this product (attempts to prepare dimethyl dialuric acid in this laboratory were unsuccessful).

Dialuric acid was isolated as a solid upon macroscale reduction of alloxan (7); dimethyl dialuric acid was not observed as a solid product under similar conditions upon reduction of dimethyl alloxan.

When aliquots of the electrolyzing solution were taken at intervals and examined spectrophotometrically a highly oxygen-sensitive species absorbing at $\lambda_{max} = 274$ mμ was observed which increased in concentration as the electrolysis proceeded; upon exposure to air the absorbing species disappeared. Under the same solution conditions alloxantin and dialuric acid show similar behavior, except that the absorption of the nonmethylated species occurs at $\lambda_{max} = 271$ mμ; only dialuric acid absorbs in these regions (20). Alloxantin does not itself absorb; its apparent absorbing properties therefore arise as a result of its disproportionation to alloxan and dialuric acid. The slight shift in the λ_{max} value for the methylated dialuric acid is readily understood by consideration of the spectra of methylated and nonmethylated ureido species such as the uracils which show shifts of similar magnitudes and direction (21).

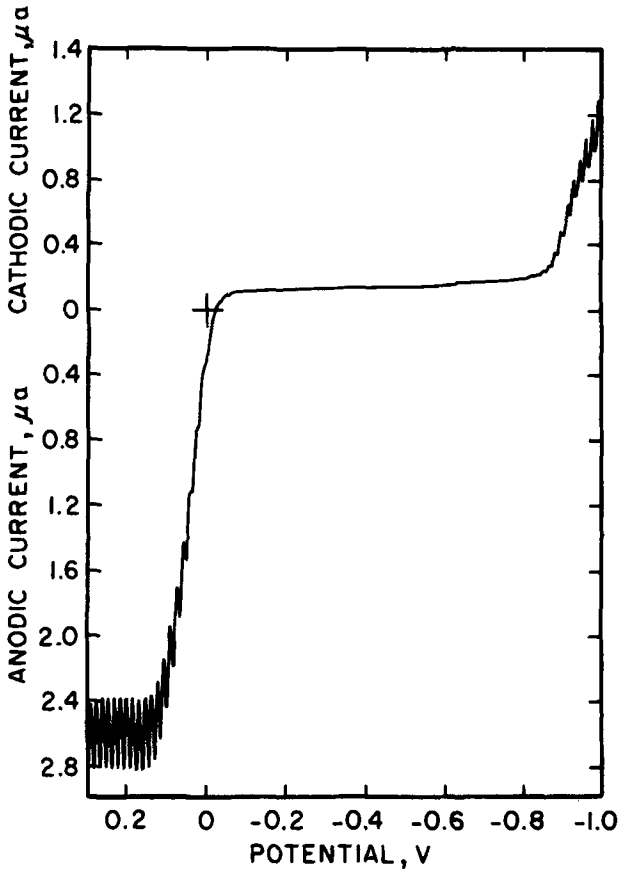

Fig. 2. Polarogram of reduction product of dimethyl alloxan electrolyzed at −0.4V (wave I) in 1M HOAc. Initial concentration dimethyl alloxan 1.0 mM.

Polarographic dissociation studies (7) have been reported to show that alloxantin does not exhibit wave II in a height comparable to that observed with alloxan itself, hence supporting the view that alloxantin is not highly dissociated. In our studies it was found that in acetate buffer pH 4.7 alloxantin does show wave II and that it is at least ten times the height of wave I. In order to obtain sufficiently accurate measurements of the current for waves I and II of alloxantin it was necessary to employ a concentration of at least 0.2 mM, which required warming of the solution (under air-free conditions) to achieve dissolution. These polarographic and spectrophotometric studies therefore support the view that alloxantin is rapidly dissociated in solution to give an equimolar mixture of alloxan and dialuric acid.

Wave II.—Polarography of the product of electrolysis of dimethyl alloxan in pH 5.1 McIlvaine buffer at potentials on the crest of wave II showed a well-formed anodic wave ($E_{1/2} = -0.09$V) (Fig. 3) which grew in height as the electrolysis proceeded; the height for cathodic wave II correspondingly decreased. The two-electron nature of the wave II process and the fact that the $E_{1/2}$ for its reduction product is identical with that from the wave I reduction and for wave I_a itself ($E_{1/2} = -0.09$V in both cases) (Fig. 3) suggests that the product for wave II is identical to that from wave I, *i.e.* dimethyl dialuric acid. That this is so is further confirmed by the susceptibility of the wave II product to air oxidation back to dimethyl alloxan and its uv absorption spectra ($\lambda_{max} = 276$ mμ), which is in the region expected for dimethyl dialuric acid (for dialuric acid at the same pH $\lambda_{max} = 273$ mμ).

Mechanism

The over-all electrochemical reduction of alloxan, methyl and dimethyl alloxan indicates the same number of electrons for their polarographic waves I and II, with similar current controlling factors and $E_{1/2}$ — pH equations; the basic polarographic processes are hence essentially identical for all compounds.

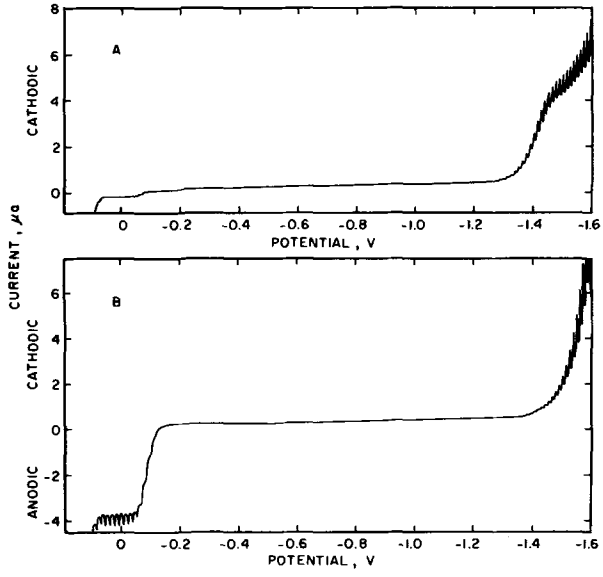

Fig. 3. Polarograms of A, 1.0 mM dimethyl alloxan and B, reduction product of 1.0 mM dimethyl alloxan after electrolysis at −1.40V (wave II). Background, McIlvaine buffer pH 5.1.

Wave I_a.—The kinetic step involved in wave I_a is undoubtedly dehydration of the carbonyl group at C-5, a process well characterized for several related systems (6, 22) (Fig. 4) and for alloxan itself (6, 7). The $E_{1/2}$ — pH relationships for all compounds (shift of *ca.* 30 mV per pH unit) is in accord with a two-electron, one-proton reversible process. Polarography and cyclic voltammetry of alloxan at a pyrolytic graphite electrode support the view that the process is virtually reversible (Fig. 5). In order to observe the anodic peak at *ca.* −0.1V in Fig. 5 it is only necessary to scan the first cathodic peak at $E_p = -0.2$V. A two-electron reduction process is indicated by coulometry, and the product is the respective dialuric acid. Accordingly, in support of the mechanism of Struck and Elving (7) wave I_a is a two-electron, one-proton reduction of the alloxan (II, Fig. 4) to the appropriate dialuric acid anion (III, Fig. 4). At this stage it is not possible to decide whether alloxantin is the primary product of the electrochemical reduction of alloxan because of the rapid dissociation of alloxantin in aqueous solution. These findings on the extent of dissociation are in accord with those of Hill and Michaelis (9).

Wave I_b.—Wave I_b is observed most distinctly for dimethyl alloxan; it is considerably smaller for methyl alloxan and, except at very high alloxan concentrations and very low pH, is not normally observed for alloxan itself. Wave I_b for methyl and dimethyl alloxan is under kinetic control and occurs at a more negative potential than wave I_a; its $E_{1/2}$ is essentially pH independent, and the height of the wave decreases with increasing pH and disappears above pH *ca.* 3. It is known that alloxans form protonated species at very low pH (10, 20) and reduction of this species no doubt results in wave I_b. Since both waves I_a and I_b below pH 3 occur to the positive side of the electrocapillary maximum (*i.e.*, the electrode is positively charged), then approach of a cationic species towards the electrode would be energetically more difficult than approach of a neutral species, hence wave I_b occurs at more negative potentials than wave I_a (23). The kinetic nature of wave I_b would normally be expected to result in a temperature coefficient of >5% per °C; however, that for wave I_b of dimethyl alloxan

is much lower (1.2% per °C at pH 1.9). Previous studies of other cationic acids (24, 25) has indicated that cationic acid dissociation constants increase with increasing temperature, *i.e.* the concentration of the cationic species is lower at 40°C than at 25°C (the temperatures employed in this work to evaluate temperature coefficients). Thus, although the temperature coefficient of wave I_b is of a magnitude normally associated with a diffusion-controlled process, it actually represents a kinetically controlled process modified by appreciable changes in the solution concentration of the electroactive species, *i.e.* the dimethyl or methyl alloxan cation.

Thus, in other words alloxan at low pH exists primarily in the hydrated form which is not electroactive at the wave I_a, I_b potentials. It is probable that an equilibrium mixture of protonated and nonprotonated hydrated alloxan exists (10, 20). Some alloxan however exists in the dehydrated form and again no doubt an equilibrium mixture of protonated and nonprotonated dehydrated alloxan exists. The nonprotonated dehydrated alloxan (II, Fig. 4) gives rise to wave I_a which at low pH is primarily kinetically controlled by the dehydration reaction (I → II, Fig. 4) but also no doubt to a much lesser extent by the deprotonation reaction (IV → II, Fig. 4). Wave I_b corresponds to reduction of protonated dehydrated alloxan which again is primarily kinetically controlled by the dehydration reaction but also possibly by the protonation reaction (II → IV, Fig. 4). The behavior of the dehydrated alloxan and its conjugate acid is polarographically analogous to the well-documented behavior of polarographically reducible weak acids (26), except that as a result of the electrode reaction occurring at a positively charged electrode and the positive charge of the acid the relative potentials of the acid and its conjugate base are reversed. Thus normally with a neutral weak acid (HA) and its conjugate base (A^-) reduction occurs at a negatively charged electrode so that the conjugate base (A^-) is reduced at more negative potential than the acidic species. The mechanism for wave I_b is presented in Fig. 4 where the structure of the cationic form of alloxan (IV, Fig. 4) is written in a general form.

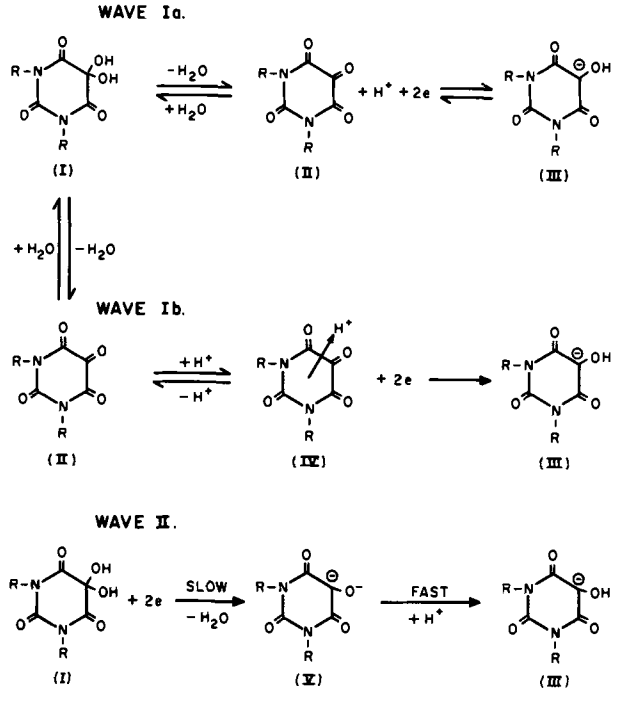

Fig. 4. Proposed reaction pathways for the polarographic reduction of the alloxans. I, hydrated alloxan; II, dehydrated alloxan; III, dialuric acid monoanion; IV, alloxan cation; V, dialuric acid dianion.

The current for wave I_b of methyl alloxan is much smaller than that for dimethyl alloxan. However, the inductive effect of an electron-releasing substituent, such as $-CH_3$, is similar, although less pronounced, to a negative charge on nitrogen (21). Thus, a methylated amide carbonyl is expected to be a more favored proton acceptor than a nonmethylated amide carbonyl. It is thus expected that dimethyl alloxan would be a better proton acceptor, or more readily form an alloxan cation than methyl alloxan. This is reflected in the magnitude of the wave I_b limiting currents. In the case of unsubstituted alloxan, the proton acceptor properties are the least of all three compounds so that even in 1*M* H_2SO_4 solution a 10 mM solution of alloxan is required before wave I_b can be observed.

Wave II.—The magnitude of the polarographic diffusion current constant and coulometry indicate that wave II is a 2*e* process for all alloxan species. Polarography and spectra indicate that the electrolysis product from dimethyl alloxan is identical to that produced from wave I, *i.e.*, dimethyl dialuric acid. Cyclic voltammetry indicates that the wave II process is not reversible. The computed αn_a values (26) for all three alloxans (1.07 ± 0.01) and the virtual pH independence of wave II supports the view that it involves a two-electron potential-controlling and over-all transfer of electrons to give the dianion of dialuric acid (V, Fig. 4). The only possible route by which this mechanism can proceed is by reduction of the hydrated form of alloxan (I, Fig. 4), the predominant solution species. In the case of all three compounds it is very unlikely that wave II is due to reduction of the dialuric acid as suggested by Struck and Elving (7). This is so because not only is dialuric acid not reduced at the wave II potential (or any

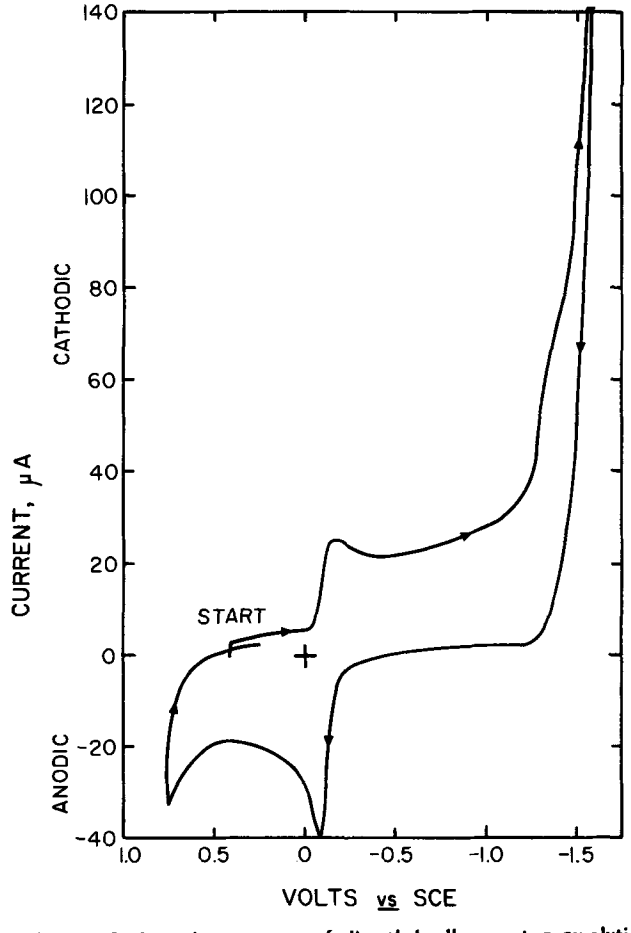

Fig. 5. Cyclic voltammogram of dimethyl alloxan at a pyrolytic graphite electrode in McIlvaine buffer pH 4.7. Scan rate, 200 mV/sec; electrode area, 10 mm².

other potential), but even if it was wave II should also be at least partly under kinetic control.

Dissociation of alloxantins in solution.— In view of the distinct contradiction between our study of alloxantin and that of earlier workers (7) a further discussion of their data and ours is presented.

The former workers indicate [Fig. 7, Ref. (7)] that a 0.25 mM solution of alloxantin in pH 4.0 acetate buffer gives almost exactly one-half the anodic current observed for a 0.5 mM solution of dialuric acid and about half the cathodic current (wave I) observed for a 0.5 mM solution of alloxan; the half-wave potentials for all waves being essentially identical. The cathodic currents for alloxantin and alloxan (wave I) are under kinetic control. This immediately suggests that alloxantin is completely dissociated in aqueous solution, especially so since it is very difficult to see an obvious way that the alloxantin process could be under kinetic control. The fact that we detect dialuric acid spectrally and via its anodic polarographic wave in solutions prepared from alloxantin, and also that alloxan wave II can be observed polarographically in such solutions at the appropriate pH, further supports the view that alloxantin is completely dissociated. Struck and Elving (7) further attempted to confirm the nondissociation of alloxantin by adding large excesses of alloxan to the polarographic solutions. If alloxantin were partially dissociated or the association constant were not too large, then the excess alloxan should have decreased the anodic wave if it was due to dialuric acid. The fact that it did not was taken to infer that alloxantin was not dissociated at all to dialuric acid. However, it is equally plausible to explain the effect if the dissociation constant for alloxantin is very large as our data suggest.

The Electrochemical Behavior of Technetium and Iron Containing Technetium

G. H. Cartledge

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

The electrochemical behavior of pure technetium and iron containing 0.1 weight per cent (w/o) technetium has been determined by polarization in sulfuric acid. Evolution of hydrogen on technetium has a Tafel slope approximating −40 mV/decade. At overvoltages noble to the hydrogen-evolution potential, oxidation of technetium or its surface oxides has a rate of *ca.* 10^{-6} A/cm^2 until the potential becomes high enough to form soluble pertechnic acid. The current density then rises rapidly. The presence of technetium in iron modifies the electrochemical behavior because dissolution of iron leads to enrichment of the surface in residual technetium. This causes the open-circuit potential to ennoble, with lowering of the overvoltage for evolution of hydrogen. Passivation is also rendered more difficult and much less effective in lowering the passive corrosion current density.

Recent studies showed that technetium forms hydrous oxides as surface films in which the element exhibits valencies of 1+, 2+, 3+, and 4+, as well as two hybrid oxides Tc_3O_4 and Tc_4O_7. The compounds were identified in both anodic polarization of the metal and cathodic reduction of $Tc(OH)_4$ deposited electrolytically on the metal. The measurements led to free energies of formation for all the compounds (1). The present paper gives the results of studies of the po-

Key words: technetium, hydrogen evolution, polarization, passivity, iron-technetium, electrode potential, technetium oxides, "unpolarizability."

larization of technetium and of an iron alloy containing 0.1% technetium. It was found that the contrasting electrochemical properties of iron and technetium give rise to some unusual behavior in polarization; the radioactivity of technetium permits a correlation of this behavior with the concentration of technetium in the surface during anodic polarization.

Experimental

Materials.—The technetium electrodes were similar to those described in connection with the thermodynamic measurements (1), namely, a 0.72g rf-melted pellet and technetium plated over platinum or gold substrates. In addition, a swaged rod of pure technetium was used as a check on the polarization. An iron master alloy was made by addition of 1 w/o of technetium powder to pure iron; this was then diluted to 0.1 w/o. The product was machined down to rods of 0.25 in. diameter, cut into 1 cm lengths, and these were tapped and threaded for attachment to the insulated stainless steel electrode assembly. The electrodes were then encapsulated in quartz tubes *in vacuo* and heat treated for 30 min at 700°C, with air cooling. The specimens remained in the capsules until the beginning of the measurements. (The author is indebted to the Metals and Ceramics Division for preparation of the alloy electrodes, and especially to Mr. Carl Koch for loan of a rod of pure technetium.)

Procedure.—Just prior to their first use, technetium electrodes were either reduced in H_2 at 425°C or cathodically polarized in 1*N* NaOH for 10 min at *ca.* 0.5 A/cm^2. They were then dipped into 12*N* HCl for a few seconds, rinsed, and at once put into the cell. In certain experiments a second cathodic polarization followed a complete cathodic and anodic series of measurements without intervening treatment of the electrode. The iron alloy electrodes were first electropolished in H_3PO_4:HNO_3:CrO_3 (80:20:excess) at *ca.* 80°C, treated with 6*N* NH_4OH containing H_2O_2 to convert superficial technetium or its oxides to soluble ammonium pertechnetate, then etched in 6*N* HCl containing a little H_2O_2, rinsed and at once transferred to the cell. This was an H cell holding 125 ml of electrolyte in each side. Hydrogen or helium purified by passage over copper at 425°C was aspirated through the solution, and the electrolyte could be renewed without access of air. Polarization was effected both galvanostatically from batteries and potentiostatically, as in (1). Potentials are expressed in mV referred to SCE. Measurements were made at 24°C.

Results

Technetium electrodes: cathodic polarization.—The anodic oxidation of hydrogen on a technetium surface is so rapid that cathodic polarization curves rarely indicate Tafel behavior until the current density is great enough to be significantly affected by both *IR* and concentration polarization. A fortunate circumstance, however, was the discovery that this anodic process has a rate which is approximately independent of the potential over a considerable range of overvoltage on both sides of the $\eta = 0$ axis. This behavior is shown in Fig. 1. Here, a platinum spiral was plated first with gold and then with technetium. The electrode was heated in hydrogen at 425°C to reduce any oxide in the film. The resultant electrode had a bright, silvery appearance. It was then polarized in 1*N* H_2SO_4 in an atmosphere of hydrogen. Polarization covered the range of overvoltage from −100 to +50 mV. It was found that application of an *IR* correction in the 10^{-3} decade (X's on the curve) indicated a probable Tafel line which crossed the $\eta = 0$ axis at about 9 x 10^{-5} A/cm^2. Such a Tafel was then tested on the positive side to evaluate the anodic current density. The X's on the anodic side of Fig. 1 show that this is between 9 x 10^{-5} and 1 x 10^{-4} A/cm^2 and that it varies little, if any, with overvoltage. An average value of 9.5 x 10^{-5} A/cm^2 was found to bring the measured cathodic current densities precisely up to the Tafel line indicated at higher current densities. The points denoted by X's in the 10^{-4} decade are calculated by application of this anodic correction. Concentration polarization is seen to begin at the highest negative potentials. This approximate constancy of the anodic oxidation of hydrogen made it possible to utilize polarization data in other experiments with equal success. It may be noted that Joncich, Stewart, and Posey observed a similar constancy in the polarization of rhenium (2).

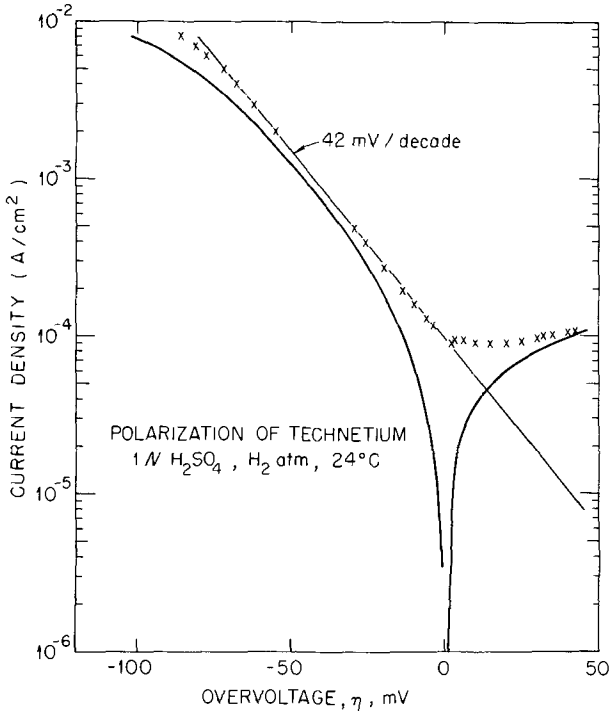

Fig. 1. Cathodic and anodic polarization of technetium in 1*N* H_2SO_4 in hydrogen. Curves show the consistency of the cathodic Tafel line with the assumption of a constant anodic current density of 9.5 x 10^{-5} A/cm^2.

The assumption of a constant anodic current density at overvoltages between 0 and −50 mV proved to be legitimate even in experiments in which helium was used as the purging gas. This circumstance arose from the further discovery that hydrogen, liberated at high negative overvoltages, is only slowly lost as the overvoltage is decreased. (This will be illustrated later.) For analyzing cathodic polarization curves, therefore, the procedure was to look for a possible Tafel line which would (*A*) parallel the polarization curve in the middle of the 10^{-3} decade and (*B*) cut the $\eta = 0$ axis at such a current density as would correct the cathodic data in the lower current densities up to a Tafel line consistent with the higher current densities when applied as a constant anodic current density. As a first approximation, the sum of the *IR* and concentration polarization corrections may be assumed to be proportional to the current density in the upper 10^{-3} and lower 10^{-2} decades. Then both the polarization correction, $j\,x$, and Tafel slope may be estimated algebraically from two equations of the form $(\eta_3 - j_3 x) - (\eta_1 - j_1 x) = -0.48T$, in which the subscript 3 refers to the overvoltage at a current density j_3 that is 3 times as large as that at j_1. T is the Tafel slope in mV/decade, x is the correction factor in mV/mA-cm^{-2}, and η is in mV. The estimate obviously becomes more exact when applied in the region in which the corrections for both anodic current and concentration polarization are as small as possible, that is, from the middle of the 10^{-3} decade to that of the 10^{-2} decade. The approximated Tafel line will usually have a slope that is numerically too small, but from its intersection on the $\eta = 0$ axis

it may be determined by trial what small shift in j_+ is needed to satisfy criterion (*B*) above.

Sixteen cathodic polarizations were conducted with the pellet or rod of technetium and with technetium plated over gold or platinum. In two instances, a film of corrosion product was deliberately formed by leaving the electrode in the cell overnight in an atmosphere of helium. The resulting open-circuit potential was very close to the reversible potential of the Tc-TcOH couple (1) when polarization was started. The curve in Fig. 1 is representative of 10 experiments with fully reduced electrodes, the average Tafel slope being -41.2 ± 1.8 mV/decade (37 to 44). The two coated electrodes agreed in having a Tafel slope of -80 mV/decade. When a cathodic polarization followed an anodic polarization to some 100 mV noble to the H.E.V., the cathodic Tafel slope was intermediate between these values (-47, -47, -48 mV/decade). By polarizing a given electrode both when fully reduced and, afterwards, when some anodic film had been formed, it was found that the correction for anodic current is considerably reduced by formation of film.

It is noteworthy that the j_+ value for the pellet electrode and for those in which technetium was plated over platinum was considerably larger than it was when a thin layer of technetium was plated over gold (*ca.* 10^{-3} *vs.* 10^{-4} A/cm²). For this reason, measurements with the different types of electrodes gave Tafel lines which span about 70 mV in their position on the axis of overvoltage. Although the absolute surface areas undoubtedly differed somewhat from the estimated areas, this variation could not be sufficient to account for the observed span. A possible factor may be the fact that platinum absorbs more hydrogen than does gold. Such an explanation would be consistent with other experiments in an atmosphere of helium. In these, it was observed that the current density at a given negative overvoltage decreases if the electrode is left on open circuit for some time and then polarized again at the same potential. The current density at this potential can be raised by holding the electrode at a higher negative potential to recharge the electrode fully with hydrogen and then restoring the original potential. It thus appears that the rate of the cathodic process is related to the concentration of hydrogen in the electrode. (The necessity to use helium in polarizations near or noble to the H.E.V. arises from the fact that oxidation of technetium begins in this region, although the current density is much lower than that for oxidation of hydrogen.)

Technetium electrodes: anodic polarization.—As was shown before (1), technetium forms a series of hydrous oxides as surface films when subjected to anodic polarization, or when $Tc(OH)_4$ precipitated upon the metal is reduced cathodically. The numerous couples between the metal and one of these oxides, or between two of the oxides, have normal potentials, V_H^o, covering the span between 0.031 and 0.768V. Anodic polarization therefore oxidizes both hydrogen, if present, and technetium or its oxides. A further complication in anodic polarization is the slowness of the transitions between the several couples formed by the insoluble oxidation products, hence the results of an anodic polarization are highly dependent upon the state of the electrode when polarization is started.

In discussing the analysis of cathodic polarization curves above, Fig. 1 was used to illustrate the constant rate of oxidation of hydrogen from the technetium surface on both sides of η_0. This behavior is further examined in experiments represented by Fig. 2. Curves 1 and 2 pertain to anodic scans at the rate of 48.3 mV/min, following cathodic polarization of the pellet electrode in 1*N* H_2SO_4 in hydrogen. After this initial polarization, the open-circuit potential was -263 mV, or within 3 mV of the calculated H.E.V. Helium then replaced hydrogen before beginning the scan at -400 mV. Curve 1 shows that the current density fluctuated somewhat during the first part of the experiment, but

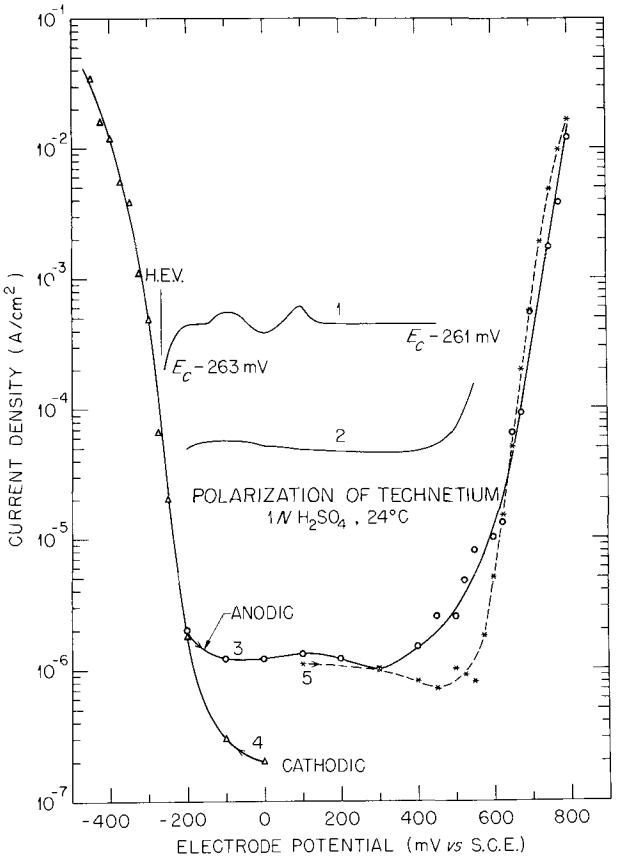

Fig. 2. Polarization of technetium electrodes in 1*N* H_2SO_4. Curve 1: Scan at 48.3 mV/min in helium after cathodic polarization. Curve 2: Second scan after 20 min on open circuit. Curve 3: Potentiostatic anodic polarization after holding potentials of -200 to 0 mV for 48 min to oxidize hydrogen. Curve 4: Cathodic polarization of electrode bearing film from curve 3. Curve 5: Anodic polarization following curve 4 and elimination of hydrogen at -100 and 0 mV (61 min).

then remained at 4.5×10^{-4} A/cm² until the scan was discontinued at +450 mV. During this interval (17.6 min), the open-circuit potential ennobled only 2 mV, thus indicating that the electrode still contained hydrogen.

The electrode was then left on open circuit for 20 min, during which time the potential rose and was still rising at -235 mV, when the scan was repeated, beginning at -200 mV. The result is shown in curve 2. The oxidation rate is an order of magnitude lower, but as the succeeding experiments showed, more drastic treatment is required to suppress the hydrogen reaction completely.

In the measurements represented by curve 3, the pellet electrode was given a rapid cathodic polarization (in helium), and when the current became anodic each potential was maintained potentiostatically until an approximately constant current density was realized. These times were 23 min at -200 mV, 17 min at -100 mV, and 8 min at 0 mV. Polarization was then continued to 800 mV. The valley in the curve then fell at around 10^{-6} A/cm². The great increase in the current density beginning at 400 mV corresponds to conversion of the oxide film into soluble $HTcO_4$; it was observed in several similar experiments always to begin in the vicinity of 400 mV. (The normal potential of the $Tc(OH)_4$-TcO_4^- couple, V_H^o, is 0.738V, or 0.493V SCE.) The electrode was left in the cell overnight on open circuit with helium passing. Upon renewing the solution, the electrode potential was found to be 249 mV, or within 3 mV of the reversible potential of the Tc(II-IV) couple (1).

The electrolyte from the anodic half cell was analyzed for pertechnic acid, $HTcO_4$. For this purpose, an aliquot was treated with excess of $BaCO_3$ to remove all solutes but $Ba(TcO_4)_2$. A small aliquot of this solution

was evaporated on a counting plate for measurement of the beta activity. The total solution contained 0.6 mg of technetium as a result of the oxidation.

The filmed electrode was next polarized cathodically from 0 mV to −450 mV and back to −300 mV, the results being shown in curve 4. This curve, when corrected, gives a Tafel slope of −80 mV/decade, in agreement with the result for another electrode bearing a corrosion film. The low rate of reduction of the film at 0 mV is clearly seen, although the thermodynamic data indicate that $Tc(OH)_4$ should be reduced at this potential.

Following this cathodic polarization, the same electrode was held at 0 mV and −100 mV until the current density indicated substantial elimination of excess hydrogen (13 min at 0 mV, 40 min at −100 mV, and 8 min again at 0 mV). Anodic polarization from 100 mV now gave results (curve 5) in close agreement with those of curve 3 for higher potentials.

The results, taken together, show that technetium and its surface films are oxidized with a rate approximating 10^{-6} A/cm² over a range of potentials from −200 to +400 mV; at higher potentials, oxidation to $HTcO_4$ occurs rapidly. The tenacity with which hydrogen is retained in the metal is also shown, together with the fact that oxidation of hydrogen is essentially independent of the potential over a wide range.

The iron-technetium electrode.—The alloy electrodes were polarized in 1*N* H_2SO_4 (*p*H 0.35) and a 1*N* mixture of H_2SO_4 and Na_2SO_4 at a *p*H of 2.7. The indicated pretreatment gave as nearly reproducible a surface as it seemed possible to obtain, since the initial cathodic polarization of different specimens gave closely agreeing results. Figure 3, curve 1 shows the results for two potentiostatic cathodic polarizations (○,□). Concentration polarization becomes important at the higher current densities, but a Tafel line with a slope of −110 mV/decade is apparently indicated, this being only slightly less, numerically, than that normally observed on pure iron. The corrosion potential, *ca.* −500 mV (SCE), is approximately normal, but the indicated corrosion current density appears to be slightly higher than that for pure iron. Curve 1 is representative of numerous measurements.

When potentiostatic polarization was carried to potentials noble to the corrosion potential, an anomalous anodic curve was always obtained. At overvoltages up to perhaps +50 mV, a maximum current was observed quickly when the potential was shifted to a more noble value; it then decreased slowly. Intermittent measurement of the open-circuit potential showed that this was shifting in the noble direction as anodic corrosion proceeded, hence, at a fixed applied potential, the overvoltage decreased with passage of current. Curve 2 in Fig. 3 shows the results for a typical electrode, the approximately stabilized current densities being plotted against the applied potential. It is seen that the electrode is almost unpolarizable at *ca.* −440 mV until the current density has risen to the order of 10^{-2} A/cm². After anodic polarization was terminated at 4.6×10^{-2} A/cm², cathodic polarization in renewed electrolyte gave curve 3. The open-circuit potential had shifted to −470 mV, as shown at E'_c, in Fig. 3. It may be seen that the cathodic Tafel slope is not significantly diminished in this instance, but that the overvoltage for a given rate of evolution of hydrogen is about 70 mV lower than it was for the freshly prepared electrode.

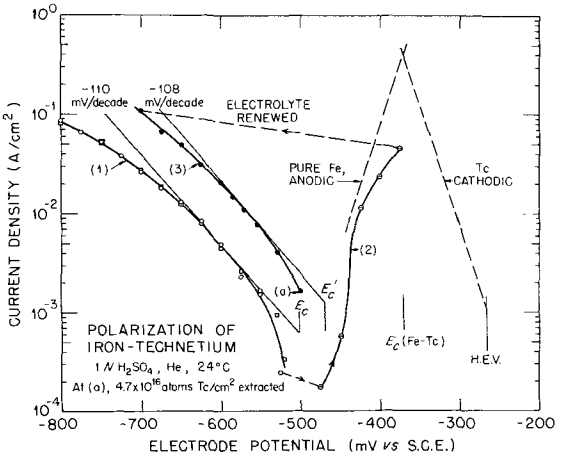

Fig. 3. Polarization of iron-technetium electrodes in 1*N* H_2SO_4 under He at 24°C. Curve 1: Two cathodic polarizations, ○, □, E_c, corrosion potential. Curve 2: Anodic polarization with shifting corrosion potential, $E_c \rightarrow E'_c$. Curve 3: Cathodic polarization after anodic polarization to 4.6×10^{-2} A/cm². The dashed curves represent Tafel lines for evolution of hydrogen on the technetium pellet and a typical anodic curve for pure iron, also in 1*N* H_2SO_4 (for subsequent consideration).

Examination of the electrolyte after similar anodic polarizations showed that little, if any, technetium passed into solution (beta count too small to be statistically significant), although at considerably more noble potentials surface technetium can be oxidized to soluble pertechnic acid, as was noted previously. That dissolution of iron during anodic polarization left technetium to accumulate on the surface was demonstrated analytically. It was found that a 10-min extraction of the electrode with 6*N* NH_4OH containing H_2O_2 oxidized the superficial technetium to TcO_4^-, the beta activity of which could be determined after evaporation of a small aliquot on a counting plate. Similar treatment of electrodes was employed to remove extractable technetium before their first use.

At the conclusion of the successive polarizations represented by curves 1-3 in Fig. 3 (point a), such an analysis showed the presence of 2.4 μg of extractable technetium from 0.306 cm², which corresponds to 4.7×10^{16} atoms per cm². In the original alloy, uniform distribution of technetium would correspond to the order of 10^{12} atoms per cm², hence the shift in the corrosion potential during anodic polarization is associated with an enrichment of the surface layer in the alloying element. Since the highest potential reached in the anodic polarization of Fig. 3 was 140 mV negative to the reversible potential of the Tc-TcOH couple in 1*N* H_2SO_4 (1), it must be presumed that the metal remained in elemental form. In numerous experiments, it was observed that residual technetium rose to the order of 10^{16}-10^{17} atoms/cm² during typical anodic polarizations.

In view of the early discovery of this constant change in the surface state, in later experiments, such as those represented by Fig. 3, the open-circuit potential was measured, in anodic polarizations, just prior to each change of the potential. In this way, ambient overvoltages were obtained and used for the curves in Fig. 4. The current densities plotted are those read just before taking the open-circuit potential and raising the potential. Curve (2η), in Fig. 4, represents the same data as those for curve 2 in Fig. 3. Comparison of the two curves shows that, while the current density rose from 10^{-3} to 10^{-2} A/cm², the potential was raised by 16 mV, but the overvoltage increased by only 4 mV. The "unpolarizability" depends upon the rate at which the potential is raised.

For further study of this anodic effect, a freshly cleaned electrode was polarized cathodically in 1*N* H_2SO_4, the first part of the curve being shown as 4 in Fig. 4. The entire curve was in close agreement with curve 1 in Fig. 3. Upon completion of the cathodic polarization, the electrode was left to corrode spontaneously in the cell, with helium passing. After *ca.* 16 hr, the cell solution was renewed and it was found that the open-circuit potential had shifted from −504 to −452 mV. An electrode of pure iron in the same solution was at −500 mV. The alloy electrode was then polarized anodically to a maximum current density of 16.3 mA/cm², during which time the open-circuit potential remained essentially constant (−452 to −450

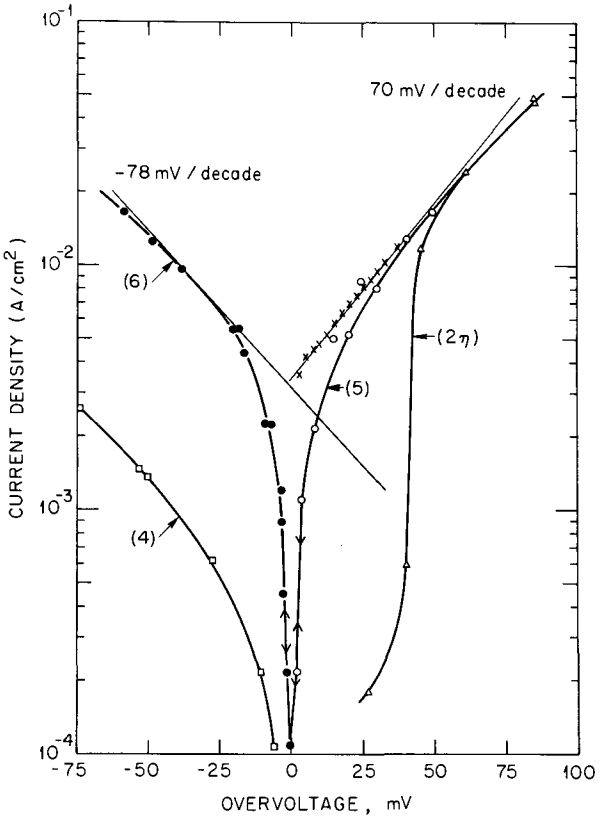

Fig. 4. Polarization of iron-technetium electrodes in 1N H_2SO_4 under He, plotted as overvoltages. Curve 2η: Data of curve 2 in Fig. 3 plotted as overvoltages against the measured ambient open-circuit potential. Curve 4: Portion of cathodic curve of a fresh electrode. Curve 5: Anodic curve for the same electrode after spontaneous corrosion for ca. 16 hr under He; x's calculated from subsequent cathodic curve 6. Curve 6: Repetition of cathodic polarization after anodic curve 5. Points on curves 5 and 6 were taken with both rising and falling potentials.

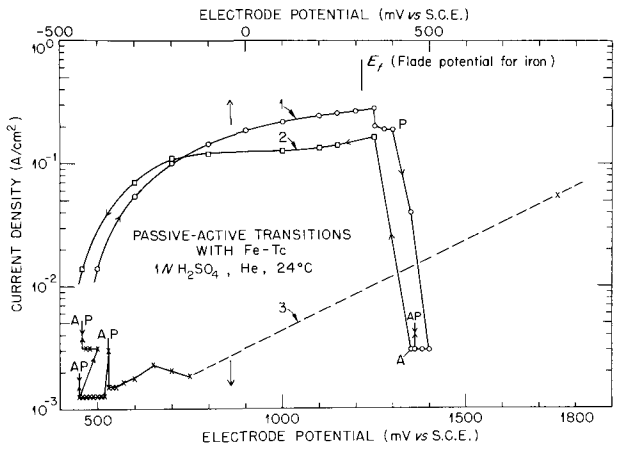

Fig. 5. Passivation (P) and activation (A) of iron-technetium electrodes in 1N H_2SO_4, 24°C, He. Curve 1: Anodic passivation at 400-500 mV; (upper scale). Curve 2: Activation at 450 mV; (upper scale) Curve 3: Fast passivation at 2V and activation at ca. 450 mV; (lower scale).

mV). The calculated overvoltages are therefore significant for a surface state already enriched in technetium to somewhat less than 4.6 x 10^{16} atoms/cm^2. (This was the value found after an additional anodic polarization in which a further slight ennobling of the corrosion potential occurred.)

The data for the initial anodic polarization of this electrode are given in curve 5 of Fig. 4. It is seen that there is no region of unpolarizability in this case, and that the curve merges smoothly into the linear part of curve (2η) obtained after the open-circuit potential had virtually stabilized at the more noble value in the previous experiment.

Polarization was next continued into the region of cathodic potentials and back to the open-circuit potential, with the results shown in curve 6 of Fig. 4. The apparent Tafel slope is distinctly less than that for the fresh electrode and indicates a substantial increase in the corrosion current density at the ennobled corrosion potential. On the anodic side, the curve represented by x's is calculated from the extrapolated cathodic Tafel and shows that the electrode, after overnight corrosion, is more polarizable than pure iron, which normally has a Tafel slope of +40 mV/decade. In repeated experiments, it was found that extraction of an anodically polarized electrode with ammoniacal peroxide caused a subsequently measured cathodic polarization curve to revert to that of a freshly prepared electrode. Hence this treatment effectively removes excess technetium from the surface.

On the right side of Fig. 3 the dashed curves represent the Tafel lines for anodic polarization of pure iron and cathodic polarization of the pellet of technetium, respectively, in 1N H_2SO_4. It is seen that, ideally, a couple between the two electrodes should have a potential of about −375 mV, if their areas were equal and there were no concentration polarization. Actually, concentration polarization causes the curves to bend over considerably (Fig. 5, curve 1 and Fig. 1). Hence their intersection would come at a lower local current density than that indicated by the dashed Tafel lines, but in the same region of potentials. This was verified experimentally. An electrode of Armco magnetic iron was directly shorted to the pellet in 1N H_2SO_4. The area of the iron electrode was 1.6 times that estimated for the pellet, but the potential of the couple came quickly to −372 mV. This figure is of interest in connection with the observation that the usual anodic polarizations caused the open-circuit potential to shift only to the region of −440 to −460 mV, although subsequent extraction of the superficial technetium indicated amounts sufficient to form a complete layer 10-100 atoms or more in thickness. It is therefore apparent that the thin layer of technetium on iron, if, indeed, the 10^{16}-10^{17} atoms/cm^2 are coalesced into a true layer, is quite unlike the surface of bulk technetium with respect to evolution of hydrogen. As was indicated previously for the technetium electrodes plated over gold, the solubility of hydrogen in the metal may be playing a role.

Passivation.—When the iron-technetium alloy was dipped into concentrated HNO_3, the results were visually the same as those observed with pure iron. Decided differences were found, however, in experiments on anodic polarization to high current densities. Polarization was effected potentiostatically at 24°C in 1N sulfate solutions at pH 0.35 (1N H_2SO_4) and 2.70, with helium passing through the solution. To obtain high current densities, the 0.25 in. electrodes were completely encased in "shrinkable vinyl" tubing and then a small hole was drilled through the tubing to expose the metal. For the two sets of measurements represented by Fig. 5, the holes had areas of 0.08 and 0.1 cm^2, respectively. Before being polarized, the metal was prepared by successive treatment with 6N NH_4OH plus H_2O_2, 6N HCl plus H_2O_2, and, finally, 12N HCl.

In none of several experiments did the decrease in current density indicative of passivation begin at the Flade potential of iron at either pH value. Figure 5 shows the results of two representative experiments in 1N H_2SO_4. For curve 1, the active electrode was polarized in steps from −400 mV. The current density decreased slightly at 350 mV, fell sharply at 400 mV, and further to a steady value at 500 mV. The current density, 3 mA/cm^2, however, was much greater than the 7 μA/cm^2 observed with pure iron (3). The current density just before passivation was approximately the

same as that for iron. When the potential was lowered slightly, the electrode remained "passive" down to 460 mV, when activation and repassivation ocurred. At 450 mV, the electrode activated sharply; the further polarization to lower potentials is shown in curve 2. The electrode was darkened, presumably by formation of oxidation products of technetium.

To minimize effects arising from insoluble oxidation products, a freshly cleaned electrode was polarized at once to a potential of 2V (not allowing for the *IR* drop). For 1.2 min, the electrode drew the maximum anodic output of the potentiostat (490 mA/cm^2). Passivation was then indicated visually by evolution of oxygen and a drop of the current density to 250 mA/cm^2. Also, excess technetium on the surface was presumably oxidized to $HTcO_4$. As shown in Fig. 5, curve 3, the current density at 1.75V was 56 mA/cm^2. The potential was then lowered to 750 mV in one step and the curve gives the subsequent results. Instability at 530 mV was followed by repassivation, which persisted to 450 mV. The two types of experiments agree in showing that active-passive transitions occurred between 450 and 500 mV, although the current densities of 1-3 mA/cm^2 are too large to be considered as truly passive in the usual sense of the term.

Discussion

The electrochemistry of technetium is chiefly characterized by the broad span of potentials over which it is almost inactive. In Fig. 2, it is seen that elimination of hydrogen reduces the anodic current density to the order of 10^{-6} A/cm^2, based on the estimated geometrical area. Consideration of roughness would certainly reduce this number by a factor of 3 or, perhaps, more. The exchange current for liberation of hydrogen on the pellet electrode is similar to that on platinum (*ca.* 10^{-3} A/cm^2) in 1*N* H_2SO_4, so that the minimal activity of the technetium itself does not measurably polarize the hydrogen electrode potential in an atmosphere of hydrogen. In cathodic polarization, the hydrogen overvoltage is less than it is on platinum, the Tafel slope being *ca.* −40 mV/decade, rather than −119 mV/decade. In Ref. (2), a low value for the Tafel slope was reported also for rhenium, though it would seem that the exchange current is considerably larger on technetium than it is on rhenium.

Figure 2 illustrated also the tenacity with which hydrogen is retained by technetium. The assumption that anodic oxidation of hydrogen proceeds at an essentially constant rate over an appreciable range of potentials is shown both in Fig. 2 and also in the analysis of polarization curves, such as that given in Fig. 1. This shows that the rate is at least partly controlled by a slow diffusion process within this region of potentials.

As shown previously (1), technetium forms couples with its hydrous oxides as films for which reversible potentials can be determined. For the lowest valence state, we have: $Tc + H_2O \rightarrow TcOH + H^+ + e^-$; $V_H^o = 0.031V$. This potential was observed repeatedly in an atmosphere of helium, the compound TcOH with a free energy of formation of −56.0 kcal mole^{-1} being identified in couples both with the metal itself and with the hydrous oxides formed at higher potentials. Potentials in the range of $V_H^o = 0.01$ to 0.02V were several times observed as brief halts in potential-time curves on open circuit when hydrogen was being displaced by helium. Since the lowest couple potential for technetium and its corrosion product is noble to the H.E.V., these cannot be considered as corrosion potentials. In the light of Fig. 2, they represent pseudostationary potentials of a hydrogen electrode on technetium at a diminished activity of adsorbed hydrogen. As shown in (1), spontaneous ennobling of the potential occurs slowly, presumably as a radiolytic effect (4), and often with an easily recognizable halt when the potential of the Tc(0-I) couple is reached.

Figure 2 shows that the rate of oxidation of TcOH and the other film components is less than 10^{-6} A/cm^2 until the potential is high enough to produce soluble pertechnic acid. It was observed further that the metal remains black at the most noble potentials shown in Fig. 2. It must therefore be presumed that under these conditions metal is oxidized more rapidly than the oxide film.

The polarization measurements show that the 0.1% addition of technetium to iron alters its cathodic behavior and initial corrosion rate very little. Under spontaneous corrosion or anodic polarization, however, irreversible accumulation of excess technetium on the surface reduces the overvoltage for liberation of hydrogen, with the consequent ennobling of the open-circuit potential. The apparent "unpolarizability" during an initial anodic polarization is thus of different origin from that observed in the presence of iodide ions and some other anions, in which a reversible change in the extent of adsorption of an inhibiting species occurs.

It may be significant that, in the experiments represented by Fig. 3 and curve 6 of Fig. 4, determination of extractable technetium gave essentially equal amounts. The cathodic polarization curves had different slopes, however, and the open-circuit potential had shifted in the noble direction by different amounts before cathodic polarization. The larger shift in the open-circuit potential coincided with the decrease in the numerical value of the Tafel slope. Both observations indicate that the surface of the electrode was more like that of pure technetium in the experiment of Fig. 4. It may be inferred that the difference arose from the fact that the technetium accumulated in a slow spontaneous corrosion in this case, whereas it was built up rapidly at a polarized potential in the other experiment. This difference might well cause the anodic attack to be of different type or distribution in the two cases.

That the presence of even low concentrations of technetium interferes with the complete passivation of iron need not be surprising, if it is noted that formation and oxidation of technetium surface compounds are shown by Fig. 2 to increase rapidly just above the potential at which passivation of iron might be expected to occur. Previous work has shown that even a considerable deposit of $Tc(OH)_4$ on an iron surface is not, in itself, protective in the absence of inhibiting pertechnetate ions in solution (5), although a very small amount, in combination with the film of passive iron, facilitates the processes leading to passivation in the presence of the inhibitor (6). Thus, the fact that the current density is decreased by 4.5 orders of magnitude in the passivation of iron but by only 2 orders when 0.1% of technetium is present may well be attributable to continuous rupturing of the film by formation and further oxidation of technetium components in the surface. These processes, in effect, would introduce porosity into the film. Alternatively, the oxidation of technetium components in the film may provide a mechanism by which electrons may be removed from the film more readily than by creation of electron holes in the fully oxidized film of iron, which was postulated to be the origin of real passivity (7).

Nonaqueous Electrochemistry of 1-Hydroxy-9,10-Anthraquinone and Its Conjugate Base

Ivan Piljac[1] and Royce W. Murray*[2,3]

Department of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514

ABSTRACT

The electrochemical behaviors of 1-hydroxy-9,10-anthraquinone (HOAQ) and its conjugate base (OAQ^-) have been compared in DMF and acetonitrile solvents. HOAQ is reduced in two one-electron steps to stable anion radical and dianion, while OAQ^- reduces in a single two-electron wave accompanied by a monoprotonation reaction. Addition of phenol as proton source to DMF solutions of OAQ^- forms a heteroconjugate acid-base dimer, $\text{Ø}OH \cdots OAQ^-$. This complex is reduced at a potential intermediate between that of HOAQ and OAQ^-, and interpretation of its reaction includes consideration of concomitant formation of $\text{Ø}OH \cdots O\text{Ø}^-$ homoconjugate dimer. The conjugate base OAQ^- is oxidizable by a one-electron reaction which is followed by rapid hydrogen atom abstraction to yield HOAQ as product. Combined thin-layer spectroelectrochemical and coulometric measurements form an important supplement to the conventional electroanalytical methods used in this study.

Among the extensive literature dealing with the electrochemistry of quinones, there are several reports (1-5) which give data, in aprotic media, on compounds bearing hydroxyl groups in positions conducive to hydrogen-bonding to quinone oxygen. This hydrogen-bonding is expected to stabilize the quinone against reduction. A greater hydrogen-bonding stabilization ensues, however, in the negatively charged semiquinone product of the charge transfer (2, 4). The net experimental result observed for such quinones is a polarographic $E_{1/2}$ for the first electron transfer step which is considerably more positive than the $E_{1/2}$ for the analogous reduction step for the parent (unsubstituted) quinone.

The present study was undertaken to compare the cathodic electrochemistry of one such hydroxyquinone, 1-hydroxy-9,10-anthraquinone, denoted HOAQ, with that of its conjugate base, denoted as OAQ^-, in N,N-dimethylformamide and other aprotic solvents. The intramolecular hydrogen-bonding effect is absent in the OAQ^- conjugate base. It was also of interest to examine the relative effects of added proton donors on the HOAQ and OAQ^- electrochemistries and to utilize in particular the advantages of combined thin layer coulometric and spectroelectrochemical experiments (6) to acquire a detailed picture of the protonation steps which might accompany charge transfer in the aprotic and added-proton situations. Several interesting effects came to light under this detailed scrutiny, a novel one of which is a demonstration of participation of homoconjugate and heteroconjugate acid-base dimers in an electrochemical reaction.

In addition to these cathodic studies, some data on an oxidation reaction of the phenolate OAQ^- species are presented.

Experimental

Chemicals.—Dimethylformamide (Baker and Adamson, reagent grade) was purified according to Brummer (7) and was kept under nitrogen. All solution preparations and manipulations were carried out in a dry nitrogen atmosphere. Acetonitrile (Eastman Spectrograde) was used as received. Propylene carbonate (Eastman Practical Grade) was purified and stored as described earlier (8).

1-Hydroxyanthraquinone (Aldrich Chemical Company, Red Label) was purified by vacuum sublimation; its solutions were yellow in color. The tetraethylammonium salt of HOAQ was prepared by adding a small excess of tetraethylammonium hydroxide to a solution of HOAQ in ethyl alcohol. The solution was boiled for several minutes and filtered through a medium sintered glass frit. The filtrate was evaporated almost to dryness, and the crystals formed were collected and washed by Soxhlet extraction with 3% ethyl alcohol in diethyl ether to remove any traces of parent HOAQ. The washed crystals were collected by filtration, dried *in vacuo* at 60°C for several hours, and stored in a dry atmosphere. Elemental analysis of the black-purple tetraethylammonium salt showed that it was a monohydrate: $(Et)_4N^+OAQ^- \cdot H_2O$: carbon, determ. 70.19 ± 0.10%, theor. 71.1%; hydrogen, determ. 7.96 ± 0.05%, theor. 7.81%; nitrogen, determ. 3.90%, theor. 3.77%; oxygen, determ. 17.51 ± 0.27%, theor. 17.25%. Potentiometric titration of this salt, carried out in glacial acetic acid (9), indicated an equivalent weight of 371 (theoretical 371.22). The potentiometric titration involved addition of an excess of standard $HClO_4$ and backtitration with sodium acetate. The tetramethylammonium salt of HOAQ could be prepared by the same procedure, but elemental analysis of the product showed that it was of unsatisfactory purity.

Tetraethylammonium hydroxide (Eastman Organic Chemicals; 50% solution in water), phenol (Baker Reagent Grade), and benzoic acid (Allied Reagent Grade) were used as received. Tetraethylammonium perchlorate (Eastman Organic) was recrystallized twice from water and dried at 110°C.

Gas-liquid chromatographic analysis of the water concentration in the DMF solvent gave a value of 0.040 molar as the probable worst case. The procedure

used was similar to one reported for analysis of propylene carbonate (10).

Solutions were prepared under nitrogen fresh for each experiment. Solutions of HOAQ are stable; those of OAQ^- are stable (violet color) if stored under nitrogen but tend to decompose (to HOAQ) when exposed to air.

Apparatus and procedure.—Figure 1 shows the optically transparent thin layer cell assembly, an elaboration of an earlier arrangement (6), employed in measurements of coulometric electrolysis charges and product spectra. A gold minigrid (500 lines/in.) was used in the all-glass cell, which had an electrode area of 1.58 x 0.9 cm and thin-solution layer thickness of 114 ± 1μ as measured by comparison to absorbances of both HOAQ and OAQ^- in a standard 500μ spectrophotometer cell. Correction of the spectral thickness, for the minigrid electrode volume, gives a solution thickness of 112μ to be used for calculations with coulometric data. The electrode was optically masked down to a window of 1.5 x 4 mm with black tape, slightly smaller than the optical beam dimension of the Cary Model 14 spectrophotometer employed for spectral measurements. The sample solution was transferred with nitrogen pressure from the 10 ml volumetric flask (in which it had been prepared and degassed with presaturated nitrogen) through glass tubing (with shrinkable Teflon joints at breakage-prone points) into the thin layer cell mounted in the Cary compartment. The cell was preflushed with nitrogen before the initial filling. It was found necessary, especially for extended spectral observations, to insert a Teflon stopcock immediately adjacent to the inlet tube of the thin layer cell. This stopcock was closed after filling the cell with fresh solution to prevent any slight solution flow through the cell caused by temperature gradients in the closed solution system. Such gradients, in the absence of this precaution, could cause slow and artifactual changes in the thin layer solution spectrum. The reference beam of the spectrophotometer was passed through an identical but empty thin layer cell made with 500 lines/in. gold minigrid. The same thin layer cell survived an extended series of spectroelectrochemical measurements.

For polarographic and cyclic voltammetric experiments, a previous cell (8) was modified so that the salt bridge compartment between the working and reference electrodes extended as a capillary tip terminating within 1 mm of the working electrode. This bridge compartment could be filled with degassed solution; this solution and that used in the reference electrode compartment was identical to the sample solution under study. An SCE with NaCl filler electrolyte was employed as reference electrode.

The hanging mercury drop electrode employed for cyclic voltammetry was prepared according to Shain *et al.* (11). Rotated Pt wire and stationary Pt or Au foil or wire electrodes were pretreated as recommended by Adams (12). A Pt mesh served as auxiliary electrode in all experiments.

The electrochemical instrumentation was based on a Philbrick Researches Model K7-A10 operational amplifier manifold using conventional passive circuitry. Data recording was by a Tektronix Model 564 oscilloscope, a Model 1005 Beckman 10" Recorder, and a Hewlett-Packard Model 7004A X-Y recorder. The maximum current was measured in polarographic experiments and was multiplied by the factor 6/7 for calculations of polarographic constants I_d (13).

Results and Discussion

Electrochemistry of 1-hydroxy-9,10-anthraquinone.—The results of a variety of electrochemical experiments on 1-hydroxy-9,10-anthraquinone (HOAQ) are summarized in Table I. The two reduction steps in DMF, CH_3CN, and propylene carbonate solvents, exemplified by the polarographic curve G of Fig. 2, are diffusion controlled by polarographic and chronoamperometric criteria. Both the values of $E_{1/2}$ for the two waves and their potential separation agree with earlier polarographic results in DMF (2, 4). Cyclic voltammetry of HOAQ in DMF at Pt and Au electrodes (Fig. 3, Curve 1) demonstrates chemical reversibility of both cathodic reactions through sweep-rate-independent unity peak current ratios. Similar results are obtained in CH_3CN and propylene carbonate solvents. On a mercury electrode in DMF, the two cathodic waves are well behaved, but the anodic cyclic voltammetric waves are "noisy" in a manner highly reminiscent of behavior ascribed in another system to streaming effects (14).

Curve A, OAQ^- only; curve B, added [ØOH] = 0.26 mM; curve C, [ØOH] = 0.38 mM; curve D, [ØOH] = 0.67 mM; curve E, [ØOH] = 0.96 mM; curve F, [ØOH] = 1.20 mM; curve G, 1.02 mM HOAQ only; curve H, 1.02 mM HOAQ with added [ØOH] = 0.78 mM.

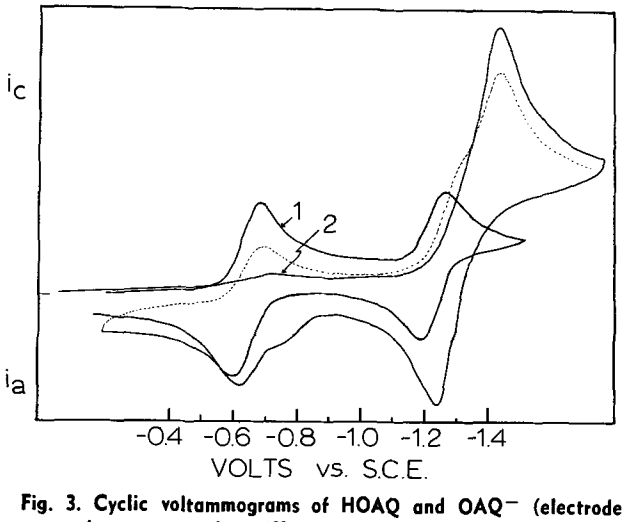

Fig. 3. Cyclic voltammograms of HOAQ and OAQ^- (electrode areas and current scales differ for curves 1 and 2). Curve 1, HOAQ on Pt in DMF; curve 2, OAQ^- on Pt in DMF, —— first cycle, . . . second cycle.

Thin layer potential step coulometry in DMF solvent (Au minigrid electrode) demonstrates that both HOAQ reduction steps involve single electrons. Spectra of both one- and two-electron products are stable in DMF over a one-hour observation period, and both charge and reactant spectra could be quantitatively recovered upon reverse potential stepping in the optically transparent thin layer cell.

Thus, reduction of HOAQ in DMF solvent on Au and Pt electrodes yields stable one- and two-electron products

$$HOAQ + e \rightarrow HOAQ^{\cdot-} \quad [1]$$

$$HOAQ^{\cdot-} + e \rightarrow HOAQ^{2-} \quad [2]$$

The absence of significant protonation accompanying the second reduction step, indicated by its chemical reversibility, is confirmed by other spectral results presented later. The apparent slight polarographic irreversibility of Reaction [2] is probably then a charge transfer rate effect (15).

Spectra of HOAQ, $HOAQ^{\cdot-}$, and $HOAQ^{2-}$ are presented in Fig. 4; band positions and intensities are: HOAQ, 400 nm ($\epsilon = 5.28 \times 10^3$); $HOAQ^{\cdot-}$, 388 nm ($\epsilon = 5.18 \times 10^3$), 462 nm ($\epsilon = 5.19 \times 10^3$), 540 nm ($\epsilon = 9.40 \times 10^3$); and $HOAQ^{2-}$, 462 nm ($\epsilon = 1.58 \times 10^4$), 544 nm ($\epsilon = 2.97 \times 10^3$).

Spectra of HOAQ and its one- and two-electron thin layer electrolysis products in CH_3CN solvent are blue-shifted from those in DMF by 5-10 nm but are otherwise similar. The spectra of the cathodic products decay in intensity (shape unchanged) with a half-life of about one-half hour, and charge recovery is incomplete upon reverse potential stepping in the thin solution cell. In propylene carbonate solvent, fairly rapid changes in spectral intensity and shape are observed for both reaction products. Thus, while the one- and two-electron products of the quinone reduction are stable in all three solvents on the time scale of cyclic voltammetry, on the slower thin layer electrolysis time scale, stability is observed only in DMF solvent. This solvent is accordingly emphasized in subsequent experiments in this report.

Cathodic electrochemistry of the conjugate base of HOAQ.—Solutions of the tetraethylammonium salt, $Et_4N^+OAQ^-$, of 1-hydroxy-9,10-anthraquinone exhibit a single cathodic wave at a potential somewhat more negative than the second of the two one-electron reactions of HOAQ. Figure 2, curve A, illustrates this wave in DMF solvent. Table II summarizes some data; the reaction is rather irreversible. The polarographic I_d for the quinone salt reduction is 84% of the sum of I_d's for the two one-electron steps for HOAQ; that n equals two for OAQ^- reduction is confirmed by potential step thin layer coulometry.

The reduction of OAQ^- is accompanied by a quantitative monoprotonation step; the stable product spectrum observed in the transparent thin layer cell is identical in band positions and intensities (±4%) to that of the two-electron product of HOAQ, itself, curve A, Fig. 4. The reaction is, thus, written

$$OAQ^- + HS + 2e \rightarrow HOAQ^{2-} + S^- \quad [3]$$

where HS is the medium proton source. If Reaction [3]

occurs through an ECE sequence, the protonation rate must be high, inasmuch as no deviation from diffusion control could be detected by either polarographic or chronoamperometric criteria.

Protonation also accompanies the two-electron reduction of OAQ^- in CH_3CN solvent, and the $HOAQ^{2-}$ product spectrum undergoes the same slow decay of intensity as that of $HOAQ^{2-}$ resulting from reduction of HOAQ in this solvent.

It is evident that the effect on the quinone reduction of removing the phenolic hydrogen is considerable; the $E_{1/2}$ for the first electron step for OAQ^- in DMF lies at least −0.72V negative of that of HOAQ. Several factors can contribute to this interesting difference; they are the differences in electronic substituent effects of the −OH and $-O^-$ groups, the intramolecular hydrogen-bonding present in HOAQ and $HOAQ^-$, and the negative charge of OAQ^-. Brodsky *et al.* (16) in a study of substituent effects for a series of 1-substituted anthraquinones in DMF, found a reasonable correlation of the polarographic $E_{1/2}$ of the first wave with Hammett σ_m substituent constants. The −OH and $-O^-$ substituents were not included in their study. Using σ_m values of +0.12 and −0.71 (17) for the −OH and $-O^-$ substituents, and taking account of apparent differences in junction potentials (by difference-referencing to our $E_{1/2}$ of −0.84V for anthraquinone as compared to theirs of −0.97V), approximate $E_{1/2}$ values of −0.83 and −1.15V, respectively, are predicted for HOAQ and OAQ^- from this earlier correlation line. Our measured $E_{1/2}$ for HOAQ (−0.64V) is more positive than this substituent-based prediction. The difference is attributable, from discussions by Peover (2) and Jones and Spotswood (4), to hydrogen-bonding, the negatively charged semiquinone ($HOAQ^-$) being stabilized to a greater extent than is the parent HOAQ. The measured $E_{1/2}$ of OAQ^- (−1.36V) is more negative than predicted from the Hammett approach. This latter difference can be regarded as having the same origin as the difference in reduction potentials of any sequence of one-electron reductions of a neutral quinone or aromatic hydrocarbon. The additional energy required for the second electron transfer can be attributed mainly to the repulsion energy of two electrons in the dinegative product (18). In the sense that the OAQ^- reactant already bears a negative charge at the quinone reaction center, an additional energy requirement is imposed on its reduction.

A second difference between the HOAQ and OAQ^- electrochemistries is the stability of the mono- and dinegative charge transfer products of HOAQ as compared to the immediate protonation of the charge transfer product of OAQ^-. Assuming that reduction of OAQ^- involves an ECE process, this means that the OAQ^{2-} species exhibits a higher basicity than $HOAQ^-$ or $HOAQ^{2-}$. This difference probably arises through the intramolecular hydrogen bonding stabilization of oxygen sites in the latter two species.

A number of reoxidation experiments were carried out on the $HOAQ^{2-}$ solutions resulting from OAQ^- reduction in DMF. It would be supposed that these solutions would exhibit the same two-wave oxidation pattern as that of a $HOAQ^{2-}$ solution derived from HOAQ reduction. This expectation is realized only in part. A cyclic voltammogram of OAQ^- on Pt (Fig. 3, curve 2) or Au in DMF displays, following the cathodic peak, anodic waves at −1.25, −0.76 (small), and −0.63V *vs.* SCE. The anodic wave at −1.25V bears neither 1:1 nor 1:2 peak current relation to its cathodic wave [$i_{p(a)}/i_{p(c)} = 0.70$]. If the $HOAQ^{2-}$ product of OAQ^- reduction in DMF is reoxidized at −0.8V in the thin solution cell, the spectrum resulting is mainly that of $HOAQ^-$ (bands at 388, 467, and 540 nm), but absorption at 568 nm clearly shows the presence of some OAQ^-. ($Et_4N^+OAQ^-$ absorbs at 568 nm with $\epsilon = 5.6 \times 10^3$). An increasing proportion of OAQ^- is observed upon prolonged electrolysis at this potential. Stepping further to 0V converts the spectrum to mainly that of OAQ^-, with a small amount of HOAQ evident by absorption at 400 nm. A potential step directly to 0V following OAQ^- reduction at −1.5V initially yields mainly HOAQ, but this spectrum is slowly converted to that of OAQ^- upon extended electrolysis.

These thin layer spectral results make it clear that Reaction [3] and the protonation step it involves can be reversed and provide inspiration for the following interpretation of the anodic cyclic voltammetric waves. The anodic wave at −1.25V (Fig. 3, curve 2) must be composed of two overlapping reactions: a direct one-electron oxidation of $HOAQ^{2-}$ to $HOAQ^-$ (reverse of Reaction [2]) and an oxidation of $HOAQ^{2-}$ accompanied by deprotonation and, consequently, transfer of a second electron to yield OAQ^- (reverse of Reaction [3]). Hence, $1.00 > i_{p(a)}/i_{p(c)} > 0.50$. The subsequent anodic waves at −0.76 and −0.63V are those of $HOAQ^-$ oxidation accompanied and not accompanied, respectively, by a rapid subsequent deprotonation step.

This pattern of anodic events is also observed in CH_3CN solvent, but the deprotonation step permitting the reversal of Reaction [3] is more quantitative than in DMF solvent. Thus, the cyclic voltammetric $i_{p(a)}/i_{p(c)}$ for the second wave is nearly unity in this solvent, and the two waves due to $HOAQ^-$ oxidation (−0.9 and −0.7V) are barely perceptible. The thin layer oxidation (at 0V) of $HOAQ^{2-}$ obtained from OAQ^- reduction yields a spectrum only of OAQ^-.

It is evident that the experimental data for $HOAQ^{2-}$ oxidation in both DMF and CH_3CN solvents require that the base S^- resulting from Reaction [3] either be a stable species or decompose to another stable strong base. Existence and reaction participation of such residual base products has been generally disregarded in organic electrochemical studies in nonaqueous, unbuffered media. The identity of the proton source HS in these experiments could not be established with certainty; from the general similarity of behavior in two solvent systems, it seems likely that it is either residual water impurity or the Et_4N^+ cation, with the Reaction [3] reversal then being caused by hydroxide ion or triethylamine.

Anodic electrochemistry of OAQ^-.—A well-defined anodic wave is observed for the $Et_4N^+OAQ^-$ quinone salt on Au or Pt electrodes in a variety of solvent media (Table III). Assignment of $n = 1$ to this reaction is made clear by thin layer coulometry and by comparison of anodic and cathodic limiting currents at the rotated Pt electrode. Quantitative matching (intensity and wavelength) of thin layer spectra clearly show that the reaction product is the parent acid species HOAQ. The reaction is formulated as a one-electron production of a neutral phenoxyl radical with subsequent hydrogen atom abstraction

$$OAQ^- - e \rightarrow [OAQ\cdot] \xrightarrow{HD} HOAQ + [D\cdot] \quad [4]$$

The rotated Pt electrode current-potential curves

[a] Ratio of limiting R.P.E. current for OAQ- oxidation to limiting current for two-electron reduction of OAQ- on same R.P.E.

for OAQ^- oxidation have a reversible shape (Table III); a similar result has been given by Vermillion and Pearl (19) for oxidation of other phenoxides. This is clearly a pseudoreversibility, however. Cyclic voltammetry of the anodic OAQ^- wave reveals no corresponding cathodic peak in any solvent at any potential sweep rate examined; the cathodic potential sweep cycle shows only waves for anodically generated HOAQ and fresh OAQ^-. Reconciliation of the voltammetry and cyclic voltammetry results requires that the rate of the hydrogen atom abstraction reaction be fast compared to the cyclic voltammetry time scale but slow in comparison to the rate of the primary charge transfer step (20).

The $Et_4N^+OAQ^-$ quinone salt also exhibits an anodic wave at a mercury electrode; this was briefly examined. In propylene carbonate solvent, the anodic polarographic wave has $E_{1/2} = -0.12V$ *vs.* SCE, $0.059/n = 60$ mV, and a diffusion current of magnitude 0.46 as compared to the cathodic OAQ^- reaction. In cyclic voltammetry, the anodic wave has a cathodic counterpart of approximately equal magnitude. These data indicate a fairly reversible one-electron/OAQ^- formation of a mercury complex.

Effects of proton donors on cathodic electrochemistry of OAQ^-: Heteroconjugate acid-base dimers in electrochemistry.—The influence of two proton sources, benzoic acid and phenol, on the reduction of the $Et_4N^+OAQ^-$ quinone salt was studied in DMF solvent. Addition of benzoic acid gave the trivial result of immediate, quantitative protonation to yield HOAQ. Addition of the weaker acid phenol gave, on the other hand, a rather interesting and novel result.

As shown by curves B-F of Fig. 2, addition of phenol to OAQ^- solutions generates two new cathodic waves, designated I and II, lying at potentials between those of the two cathodic waves of the parent acid HOAQ. These are polarographically diffusion controlled reactions (constant $i_d/h^{1/2}$); diffusion control in wave I was also ascertained by potential sweep chronoamperometry (constant $i_p^I/v^{1/2}$). Although the poorly defined plateau of wave II makes accurate measurements difficult, waves I and II appear to be of equal magnitude. The diffusion current of wave I is proportional to [ØOH]; for [ØOH]/[OAQ^-] = 0.31, 0.46, 0.63, 0.80, 0.98, and 1.15, i_d^I/[ØOH] = 1.06, 1.23, 1.15, 1.32, 1.08, and 1.25 $\mu A \cdot mM^{-1}$, respectively.

The basis for understanding of these electrochemical results is found in spectra of phenol-OAQ^- mixtures in DMF, examples of which are shown in Fig. 5. A small change in absorbance at 400 nm occurs upon phenol addition, and, for [ØOH]/[OAQ^-] $\geq$ 2, it appears that a small amount of proton transfer (to yield HOAQ) has probably taken place. At [ØOH]/[OAQ^-] $\leq$ 1, however, the spectral changes are inconsistent with a simple proton transfer. The original OAQ^- band at 568 nm undergoes a pronounced blue shift and a lowering of absorbance which is much larger than the absorbance change at 400 nm, and an isosbestic point becomes obvious at 523 nm. These effects demonstrate that in the presence of phenol an equilibrium between OAQ^- and another species is

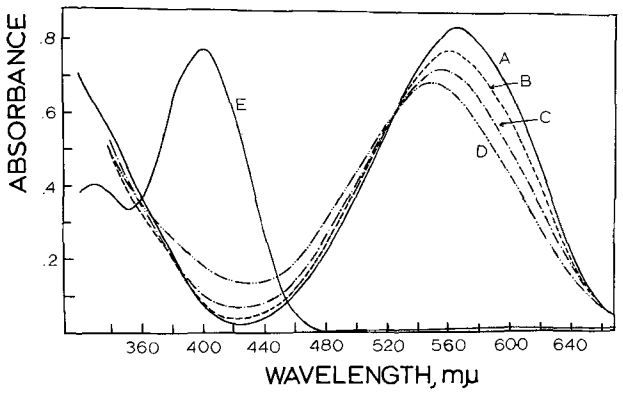

Fig. 5. Spectra in 0.1M TEAP-DMF. $l = 500\mu$. Curve A, 2.94 mM OAQ^-; curve B, 2.94 mM OAQ^- plus 1.5 mM ØOH; curve C, 2.94 mM OAQ^- plus 3.4 mM ØOH; curve D, 2.94 mM OAQ^- plus 5.7 mM ØOH; curve E, 2.93 mM HOAQ.

established. The new species in the phenol-OAQ^- mixtures must be their heteroconjugate acid-base dimer

$$\text{ØOH} + OAQ^- \rightleftharpoons \text{ØOH} \cdots OAQ^- \qquad [6]$$

An extensive literature has been developed by Kolthoff and co-workers and Coetzee (21-28) on interactions of weak acids with their conjugate bases and with other bases in nonaqueous solvents (homoconjugate and heteroconjugate acid-base dimers). Formation constants have been obtained in both CH_3CN and dimethylsulfoxide solvents; they are larger in the former solvent where, for instance, the ØOH $\cdots$ ØO^- homoconjugate has $K^f_{HA_2^-} = 11 \times 10^3$. While quantitative dimer studies do not appear to have been made in DMF solvent, the properties of this solvent are sufficiently similar to those of CH_3CN and DMSO that formation of acid-base dimers in DMF can be anticipated. By analogy with the data in CH_3CN solvent, it can also be anticipated that an order of dimer stability ØOH $\cdots$ ØO^- > ØOH $\cdots$ OAQ^- > QAOH $\cdots$ OAQ^- should occur. Consistent with this ordering is the fact that, in contrast to ØOH,OAQ^- mixtures, spectra and polarograms of HOAQ,OAQ^- mixtures in DMF show strictly additive relations between HOAQ and OAQ^- spectral bands and polarographic waves, respectively.

Recognizing that the phenol-OAQ^- mixtures in DMF actually constitute mixtures of OAQ^- and the dimer ØOH . . . OAQ^-, wave I in the polarograms of Fig. 2 must correspond to the reaction

$$\text{ØOH} \cdots OAQ^- + e \rightarrow [\text{Ø}O \cdots HOAQ]^{2-} \rightarrow HOAQ^{\cdot -} + \text{Ø}O^- \qquad [7]$$

Dissociation of the dimer charge transfer product $[\text{Ø}O \ldots HOAQ]^{2-}$ (OAQ^{2-} should be a much stronger base than ØO^-) yields phenolate ion, which can interact with unreduced ØOH $\cdots$ OAQ^- dimer to produce the more stable ØOH . . . ØO^- dimer

$$\text{ØOH} \cdots OAQ^- + \text{Ø}O^- \rightarrow \text{ØOH} \cdots \text{Ø}O^- + OAQ^- \qquad [8]$$

These reactions predict that for [ØOH]/[OAQ^-] $\leq$ 1, two phenol species are required to effect a one-electron reduction of one OAQ^- species at the potential of wave I. The i_d^I — [ØOH] proportionality is, thus, explained, as is the fact that for [ØOH]/[OAQ^-] = 1.0, the current for wave I is approximately one-fourth (0.20) of that of the original two-electron wave for OAQ^-. This interpretation of wave I is confirmed with certainty by thin layer electrolysis of an equimolar mixture of phenol and OAQ^- at −0.8V; the product spectrum is that of an equimolar mixture of $HOAQ^{\cdot -}$ and OAQ^-.

The second polarographic wave (wave II) caused by the addition of phenol to OAQ^- solutions in DMF corresponds to one-electron reduction of the one-half of the original OAQ^- remaining after Reactions [7]-[8].

(Recall that $i_d^{I} \simeq i_d^{II}$). The potential for this reaction is less negative than that for normal OAQ^- reduction owing to the presence of the proton source $\phi OH \cdots O\phi^-$

$$OAQ^- + e \rightarrow [OAQ^{2-}] \xrightarrow{\phi OH \cdots O\phi^-} HOAQ^{\cdot-} + \phi O^- \quad [9]$$

Reaction ceases at the one-electron stage since Reaction [9] occurs at a potential positive of that required to reduce $HOAQ^{\cdot-}$. In confirmation, thin-layer electrolysis of an equimolar mixture of phenol and OAQ^- at -1.0V gives a product spectrum quantitatively identical to that of the $HOAQ^{\cdot-}$ species obtained from one-electron reduction of HOAQ (Fig. 4).

The third wave in the phenol-OAQ^- mixture polarograms of Fig. 2 can be ascribed to overlapping reduction of OAQ^- and $HOAQ^{\cdot-}$. (A partial splitting is visible in curve D.) When $[\phi OH]/[OAQ^-] = 1.0$, this wave has $E_{1/2}$ equal to that of the second wave of HOAQ, as expected, and thin-layer electrolysis at -1.4V gives the spectrum of $HOAQ^{2-}$.

Thin-layer reoxidation, at 0V, of phenol-OAQ^- mixtures following reduction at -1.4V gives unity Q_{cath}/Q_{anod} charge ratios. A deprotonation similar to that discussed above for OAQ^- occurs (reverse of Reaction [3]), with ϕO^- in this case serving as the base $\underline{S}^-$. The OAQ^- spectrum reappears during the thin-solution oxidation much more rapidly than was the case in the absence of phenol.

The reduction of OAQ^- in DMF was also examined for further protonation of the two-electron reduction product ($HOAQ^{2-}$). The thin-solution spectrum following electrolysis at -1.4V for $[\phi OH]/[OAQ^-] = 2.0$ corresponds to a new species with bands at 412 nm ($\epsilon = 1.54 \times 10^3$) and 490 nm ($\epsilon = 4.48 \times 10^3$). This spectrum is identical to that observed for reduction of a 1:1 mixture of HOAQ and benzoic acid at -1.4V (Fig. 4) and must correspond to the diprotonated species H_2OAQ^-. Little further spectral change could be discerned in phenol-OAQ^- mixtures reduced at $[\phi OH]/[OAQ^-] = 3.0$.

A series of experiments on phenol-OAQ^- mixtures paralleling those above was carried out in acetonitrile solvent. Spectral changes similar to those of Fig. 5 were noted, but the spectra show that in these mixtures significant direct protonation to form HOAQ accompanies heteroconjugate dimer formation even at $[\phi OH]/[OAQ^-] < 1$. Polarograms of phenol-OAQ^- mixtures have split waves like those of Fig. 2, but the wave separations are small, precluding quantitative studies. Thus, Reactions [6]-[9] can only be qualitatively surmised to occur in acetonitrile solvent.

The wave splittings caused by acid-base dimer formations in these experiments are, in a sense, entirely analogous to nonaqueous titration curve splittings such as those reported by Harlow and Bruss (29). The possibilities for dimer participation in the numerous electrochemical experiments in which proton sources have been added to nonaqueous solutions of organic compounds appear, however, to have gone unrecognized in the electrochemical literature. The sole exception is a report by Fujinaga, Izutsu, and Takaoka (30) who explain a wave splitting of quinoline reduction in DMF by phenol in terms of a "hydrogen bonded phenol-quinoline complex." Neither coulometry nor spectral data are given to support the interpretation, which may, unfortunately, contain some error in its details owing to neglect of $\phi OH \cdots O\phi^-$ formation.

Although much further experimentation will be required to completely characterize the role of acid-base dimer formation in electrochemical processes, several generalities appear probable at this point. First, dimer formation upon proton source addition will be most common with basic samples and with proton sources whose conjugate bases have strength comparable to that of the sample. Second, the reduction potential for a sample involved in dimerization will lie between the reduction potentials of the completely protonated and nonprotonated forms of the sample. (From recent studies on phenols (31), a similar statement may also apply to oxidations.) Third, even though a sample may not itself participate in dimer formation, formation of species such as $\phi OH \cdots O\phi^-$ can complicate kinetic studies of anion radical protonation reactions. Last, the dimer formation event may provide a mechanistically useful perturbation in the study of organic electrode reactions; conversely, the electrochemical properties of dimers may provide further insight into the chemistry of the dimers themselves.

Effects of proton donors on cathodic electrochemistry of HOAQ.—The effects of added proton donors on sequential one-electron reductions of aromatic hydrocarbons and other substances have been reviewed by Peover (15). Mixtures of benzoic acid and 1-hydroxyanthraquinone in DMF exhibit a classical Hoijtink (32) pattern of polarograms; the first reduction wave for HOAQ grows at the expense of the second as benzoic acid is added in increasing concentrations. The chemical step of the ECE reaction occurring in the first reduction wave (protonation of $HOAQ^{\cdot-}$ by benzoic acid) appears to be essentially quantitative, as $[\phi COOH]/[HOAQ] = 1.0$ is sufficient to replace completely the two one-electron waves with a single two-electron wave. [A similar alteration of anthraquinone polarography in DMF by benzoic acid (15) has been reported to require a threefold excess of the acid.]

Spectra of thin layer electrolysis products parallel the polarographic results for benzoic acid-HOAQ mixtures. The bands of $HOAQ^{\cdot-}$ resulting from reduction at -0.8V are, as benzoic acid is added, proportionately replaced with those of the protonated two-electron product, H_2OAQ^- (whose spectrum at a $[\phi COOH]/[HOAQ] = 1.0$ ratio is shown by curve B of Fig. 4). As noted earlier, an identical spectrum results from reduction of a $[\phi OH]/[OAQ^-] \geq 2$ mixture.

Proton donors too weak to cause the ECE (Hoijtink) reaction for a substance polarographically reduced in two one-electron steps are without effect on the first one-electron wave but often produce a shifting of the second wave to less negative potentials. This effect is usually interpreted as a post-electron transfer protonation of the product of the second reduction step. Such behavior is observed upon addition of phenol to HOAQ solutions in DMF solvent but with the added feature that the second wave is not only shifted positively but is also split into two waves. Figure 2, curve H shows the polarogram obtained for a somewhat less than equimolar mixture of phenol and HOAQ; the more positive of the two new waves can be clearly seen here, and the second is poorly resolved from the second wave of the residual excess of HOAQ. The poor definition of both new waves preclude accurate wave height measurements, but they appear to be of equal height and to be proportional to the added phenol at less than equimolar ratios. These results are again interpretable by reactions involving formation of the $\phi OH \cdots O\phi^-$ homoconjugate dimer. Thus, in a 1/1 mixture of phenol and HOAQ, the wave at ~ -0.95V occurs from transfer of the second electron, the wave being shifted by subsequent protonation by ϕOH

$$HOAQ^{2-} + \phi OH \rightarrow H_2OAQ^- + \phi O^- \quad [10]$$

The ensuing formation of the homoconjugate $\phi OH \cdots O\phi^-$ means that only one-half of the phenol is available as such for Reaction [10], and, in the 1/1 mixture, the wave at -0.95V is approximately one-half of the height of the original second-electron wave. The second of the new waves caused by phenol is the same as Reaction [10] but with the less acidic $\phi OH \cdots O\phi^-$ acting as proton source, producing a smaller positive shift of reduction potential. We note finally that formation of a heteroconjugate $\phi OH \cdots HOAQ^{\cdot-}$ following the first charge transfer could provide an alternative interpretation of these results.

An Experimental Study of Mass Transfer on a Rotating Spherical Electrode

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Convective diffusion of electrolytic ions to a rotating spherical electrode has been investigated experimentally over the range of Reynolds numbers from 200 to 40,000, and Schmidt numbers between 920 and 37,000. The study was carried out by measuring the limiting currents for the reductions of ferricyanide and tri-iodide ions with a platinum hemispherical electrode. The results confirm the validity of a mass transfer theory reported previously for Reynolds numbers within the range 200-15,000. At Reynolds numbers above 15,000, the flow becomes turbulent, and the rate of mass transfer varies with $Re^{0.67}$. The characteristics of fluid flow around the spherical electrode were observed by generating dyes electrochemically near the pole of rotation.

In a previous paper (1), the rationale for the use of a rotating spherical electrode (RSE) was described. A mathematical model was formulated for the rate of ionic transfer to the spherical electrode in the laminar flow region.

An inherent limitation of a rotating disk electrode (RDE), used in metal dissolution studies, is that the disk would recede into the support and upset the fluid flow characteristics. Consequently, high rate dissolution reactions cannot be studied precisely with a RDE. The concept of a RSE is to replace the central disk electrode on the RDE with a spherical head electrode. The spherical head merely reduces in size during metal dissolution, and does not alter the flow characteristics. Owing to this geometrical advantage, the RSE has been proposed in this laboratory as an analytical tool for our investigations into the mechanism of electrochemical machining. For other applications, the new technique could also be used to study corrosion and high-rate electrodeposition reactions.

The present study was designed to check the transfer theory. Reductions of ferricyanide and tri-iodide ions in the presence of excess supporting electrolytes were used for the investigations. Details of these electrochemical reactions and their applications to the mass transfer studies have been reported elsewhere (2, 3). This paper describes an experimental setup for the use of such an electrode as well as the results of

* Electrochemical Society Active Member.
Key words: convective diffusion, limiting current.

limiting current measurements over an extended range of experimental conditions.

Experimental

Spherical electrode.—The electrode used was a RSE having a replaceable platinum hemispherical electrode. It was composed of three separate sections: a brass holder, an acrylic support, and a hemispherical head electrode. Figure 1 shows the construction details.

The acrylic support was a cylindrical rod, 2.5 cm diam and 8.2 cm long, having a 0.6 cm hole through the center. The lower end of the support was threaded to accommodate the electrode. Its upper end was machined to fit tightly into the brass holder. A neoprene gasket, 0.08 cm thick and 2.5 cm diam, was cemented to the lower end to prevent leakage of electrolytes into the interior of the RSE.

The brass holder was made from a 2.5 cm diam rod. It also had a central through hole to accommodate a copper wire used as the electrical connection to the head electrode. Its upper portion was precision machined to a No. 1 Morse taper to fit snugly into the spindle shaft of a rotating assembly (Fig. 2).

The electrode was electroplated with a layer of smooth platinum, 0.003 cm thick. Three such electrodes were prepared for the study; the radii of their hemispherical heads were 0.478, 0.645, and 0.772 cm. The electrical connection was made by soldering a copper wire to the tail end of each electrode. After the electrode was screwed into the acrylic support, the wire would extend to the top portion of the brass holder and was secured there with a set screw. The assembled RSE was approximately 16.5 cm long.

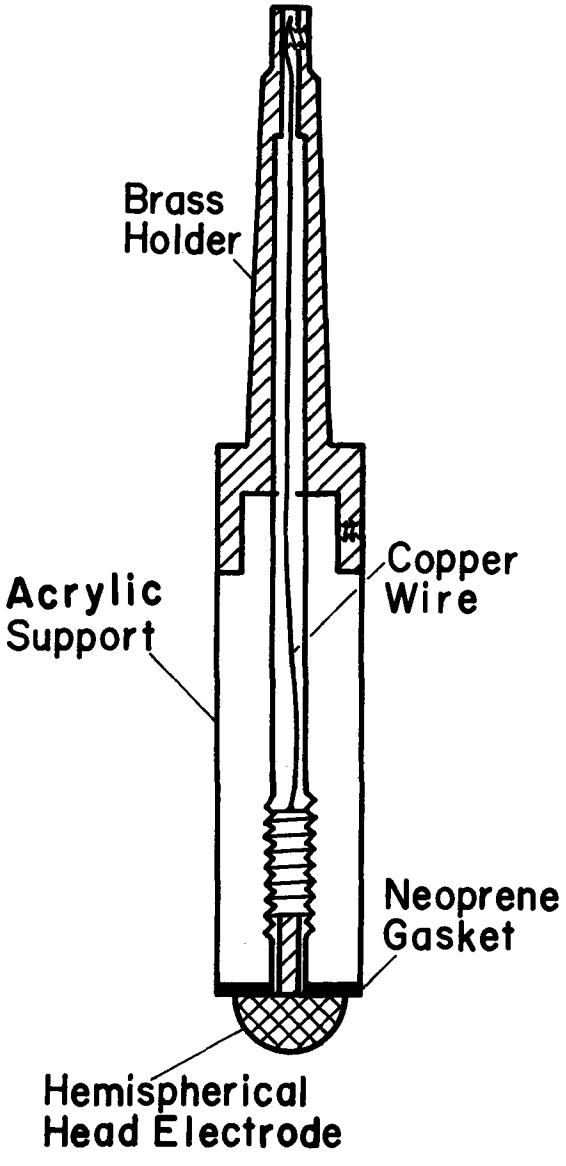

Fig. 1. Rotating spherical electrode

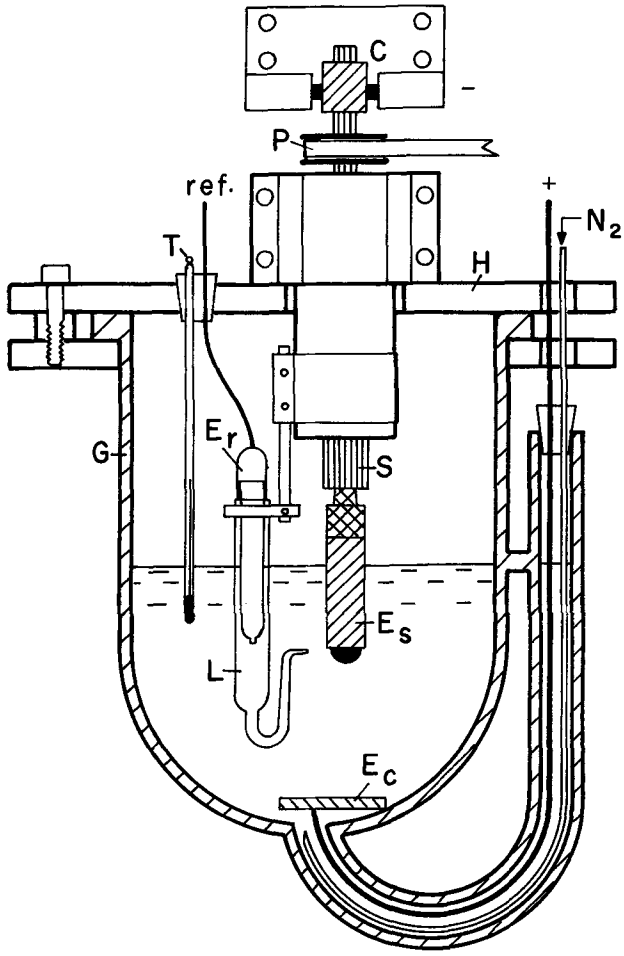

Fig. 2. Schematic diagram of cell arrangement. C, slip-ring contacts; E_c, counterelectrode; E_r, reference electrode; E_s, rotating spherical electrode; G, glass jar; H, cell cover; L, Luggin capillary tube; P, pulley and belt; S, spindle shaft; T, thermometer.

Solutions.—The ferricyanide electrolyte was composed of 0.01M potassium ferricyanide, 0.01M potassium ferrocyanide, and 2M sodium hydroxide. For the tri-iodide system, a solution containing 0.002M iodine and 0.1M potassium iodide was used. All the solutions were prepared by dissolving Baker analyzed chemicals in distilled water without further purification. Iodometric titrations were used to determine the concentrations of ferricyanide and tri-iodide ions. During some of the experimental runs, sucrose was added to the tri-iodide electrolyte to increase the solution viscosity and to decrease the diffusivity of tri-iodide ion; this allowed a variation in Schmidt numbers ranging from 920 to 37,000. The solution viscosity was measured with a falling ball viscosimeter. To determine the diffusivities for ferricyanide and tri-iodide ions, a platinum rotating disk electrode (0.635 cm diam) was employed, and the diffusivity computation was performed according to Levich's disk equation (4).

Cell arrangement.—Figure 2 is a schematic diagram of the cell arrangement. The cell was a Pyrex bell jar, 21.5 cm ID x 28 cm high. It had a ground glass flange to fit against the underside of an aluminum cell cover mounted on an aluminum frame. Connected to the bottom of the cell was a glass U-tube, which allowed insertion of an electric lead for the counterelectrode as well as a polyethylene tube for bubbling of nitrogen through the electrolyte.

A Gilman spindle assembly was attached directly to the aluminum frame and extended down into the cell. The spindle shaft had a tapered hole on the lower end to accommodate the RSE as shown in the figure. Electrical contact to the RSE was made by two carbon brushes which were spring loaded to ride on the rhodium-plated surface of a brass slip-ring mounted on the top of the spindle shaft. The whole spindle assembly was mounted eccentric to the center of the cell. This arrangement was necessary in order to avoid inducing swirling of the electrolyte at high rotational speeds.

A d-c motor secured on a separate frame was used to drive the rotating assembly. The connection between the pulleys on the motor and the spindle shaft was provided by a rubber timing belt. A Cole-Parmer 4420 electronic speed controller was used to control the speed of rotation.

A platinum-plated copper sheet, 4 × 4 cm, embedded in an epoxy block was used as the counterelectrode. It was located at the bottom of the cell. The reference electrode was a saturated calomel electrode placed in a Luggin tube. The tube was immersed in the electrolyte. To avoid disturbing the flow characteristics, the capillary tip was positioned at the downstream side of the spherical head as shown in Fig. 2.

Limiting current measurements.—Diffusion-limited currents were measured for the reduction of ferricyanide and tri-iodide ions over a speed range of 100-6000 rpm. All the experiments were performed at 24° ± 1°C. For each run, the RSE was first cleaned with methanol, and was cathodically treated at −1.5V for 2 min in a 2M NaOH solution followed by rinsing in distilled water. The clean electrode was then transferred quickly into the cell, and installed on the spindle of the rotating assembly.

The potential of the RSE was controlled by a Magna 4700M potentiostat. The current was measured using a standard resistor and the voltage drop was measured with a Keithley 610C electrometer. A Magna 4510 linear scan unit and a Honeywell 540 XYY′ recorder were used in conjunction with the potentiostat. For each run, current/potential curves over the entire anticipated potential range of interest were first plotted on the recorder to determine the limiting current range. A proper potential setting was then chosen for the potentiostat, and the limiting current readings were made with the electrometer at various rotational speeds. Normally, a potential of −0.3V *vs.* SCE was used for the reduction of ferricyanide ion. For the tri-iodide system, the potential setting varied from 0 to −0.2V *vs.* SCE, depending upon the sucrose concentrations.

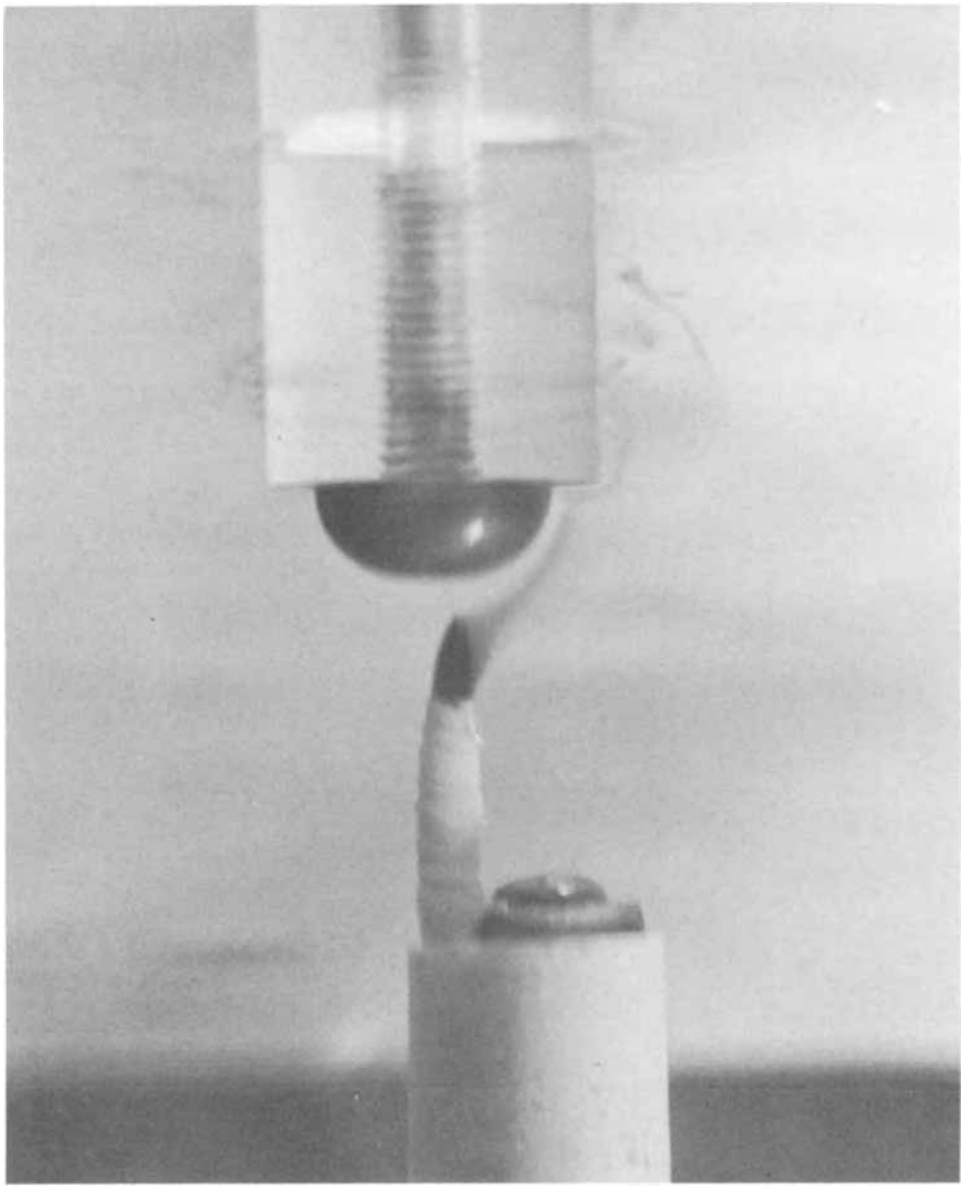

Fig. 3. Photograph of the flow pattern around a hemispherical electrode rotating at a Reynolds number of 1300.

The reproducibility of the measurements was within ± 5%.

To avoid a possible secondary reaction due to reduction of dissolved oxygen, high purity nitrogen was passed through the electrolyte before the start of each experiment. The gas was presaturated with water vapor and iodine vapor by passing it through a solution of the same composition as the test electrolyte. During the run, a nitrogen atmosphere was maintained by passing the gas over the electrolyte.

Flow observations.—The fluid flow around the spherical head was visually examined by generating dyes electrochemically near the pole of rotation. The dye generator was a small conical electrode, 0.026 cm diameter and 0.6 cm long, made from an AWG No. 10 copper wire, and was positioned about 0.3 cm below the RSE. The electrolyte used was a 2M sodium nitrate solution containing 0.01% thymol blue. When the conical electrode was made cathodic with respect to the counter-electrode located at the bottom of the cell, a blue stream was produced in the yellow electrolyte due to the increase in pH in the vicinity of the conical electrode. In this way, the flow induced by the RSE was made visible, and motion pictures of the flow pattern were taken with the aid of light sources behind the cell.

Results

Flow of electrolytes.—Figure 3 is a photograph showing the dye movement around the spherical electrode rotating at a Reynolds number of 1300. It was observed that under the laminar condition, the fluid was drawn in toward the spherical surface along the axis of rotation. From there, it was carried by the swirling motion toward the equator. In the neighborhood of the equator, the flow bent smoothly 90° toward the radial direction, and then moved along the support surface to the bulk of the electrolyte.

Limiting currents.—For the ferricyanide system, the limiting currents were measured with three different sizes of hemispherical heads. The results are given in Fig. 4, where the current is plotted against the square root of angular velocity. The electrolytic concentrations as well as the associated electrolyte properties are shown in the accompanying table. In the low speed region, the data points for each electrode fall on a straight line passing through the origin as predicted by the transfer theory (1). In the high-speed region, a break point occurs for the large electrodes, beyond which there is another linear portion with a larger slope. Presumably the break point signifies the beginning of the turbulent flow. The rotational speed at which the break point occurs increases with decreasing electrode size. For the 0.478 cm radius electrode, no break point was observed within the speed range investigated.

□	1.58	2.22	6.20	1.69

The tri-iodide electrolyte was used primarily for showing the effect of Schmidt numbers on the transfer measurement. The solution viscosity was increased by adding sucrose to the electrolyte. Figure 5 shows the results of limiting current measurements with a 0.772 cm radius electrode for various sucrose concentrations. The accompanying table in the figure gives the electrolyte concentrations as well as the solution viscosities and the diffusivities of tri-iodide ion. Again, a linear portion passing through the origin is obtained for all the electrolytes. The effect of viscosity is: (*A*) to increase the speed at which the break point occurs, and (*B*) to decrease the diffusivity and, hence, the limiting current.

Discussion

As shown in a previous paper (1), the theory for mass transfer to the hemispherical electrode in the laminar flow region is given by the following expression

$$\mathrm{Sh} = 0.474\,\mathrm{Re}^{1/2}\,\mathrm{Sc}^{1/3} \qquad [1]$$

Here Sh is the Sherwood number defined as Kr_o/D, Re is the Reynolds number based upon the electrode radius, and Sc is the Schmidt number. The mass transfer coefficient, K, is related to the limiting current, I_{lim}, by

$$K = \frac{I_{lim}}{A\,n\,\mathbf{F}\,C_\infty} \qquad [2]$$

where A is the surface area of the electrode, and C_∞

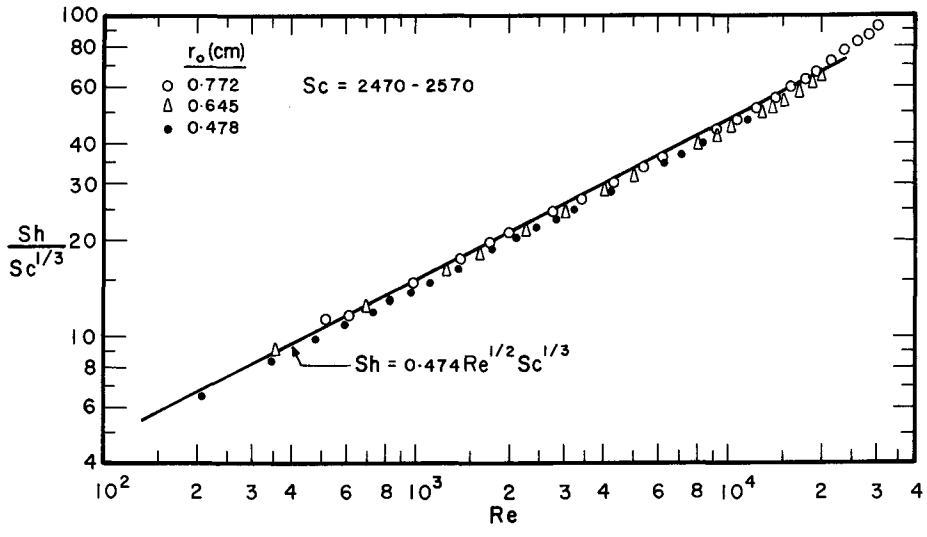

Fig. 6. Comparison with mass transfer theory for the ferricyanide data.

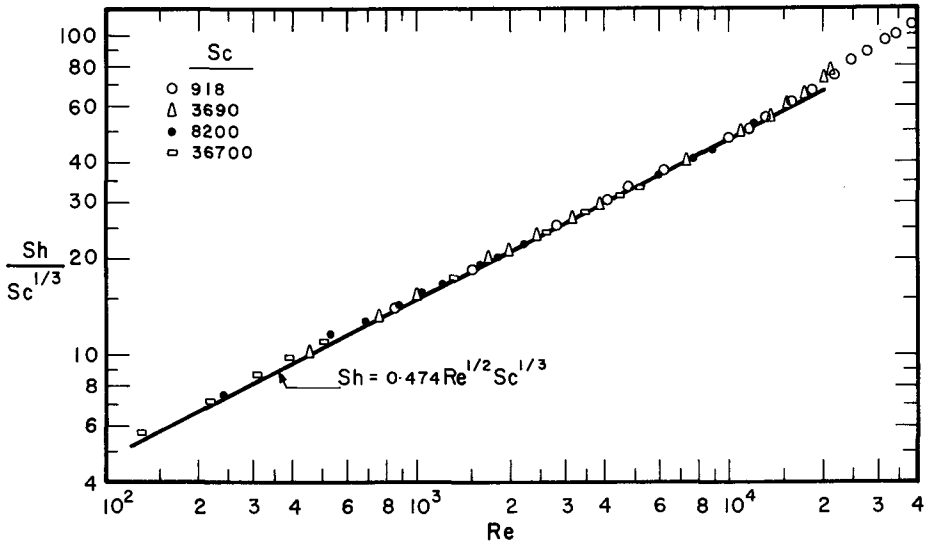

Fig. 7. Comparison with mass transfer theory for the tri-iodide data.

is the bulk concentration of the diffusing ion. Accordingly, a log-log plot of $Sh/Sc^{1/3}$ *vs.* Re would be expected to be linear with a slope equal to ½ for the limiting current results obtained in the laminar region.

Such plots are shown in Fig. 6 for the ferricyanide data, and in Fig. 7 for reduction of tri-iodide ion. The experimental points are indicated by the symbols ○, ●, △, and □. The solid line is the theoretical prediction given by Eq. [1]. The data replotted this way merge together into a single curve over the range of Reynolds numbers from 200 to 40,000. For Reynolds numbers less than 15,000, the data vary with the one-half power of Re, and the agreement with theory is apparent. An analysis of the laminar data gives an empirical proportional constant of 0.47 ± 0.02, as compared to the theoretical value of 0.474.

Poorer agreement is found for smaller size electrodes as shown in Fig. 6, where the results with the 0.478 and 0.645 cm electrodes lie about 7% below the theoretical line. This discrepancy can probably be attributed to an experimental uncertainty due to an edge effect imposed by the underside wall of the acrylic support. A close examination of Fig. 3 reveals that the flow beyond the equator of the hemispherical electrode is not a free stream as in the case of a rotating sphere (5, 6). The flow characteristics near the electrode edge would therefore deviate from the case considered in the theory. Ideally, a support having a radius equal to that of the spherical head should be used. For practical purposes, this situation is difficult to maintain, especially during dissolution reactions. It can be expected that the smaller the electrode size as compared to the support, the more apparent will be the edge effect. Presently, the exact nature of this edge effect is not known; further study on this aspect seems to be necessary.

Apart from the above considerations, the agreement between the theory and the experimental results is reasonably good, judging from the 5% reproducibility for the measurements. There is little doubt that the theory is valid in the laminar flow region over the range of Schmidt numbers reported in the present paper.

Figures 6 and 7 show that for Reynolds numbers larger than 15,000, the flow becomes turbulent, and the mass transfer characteristics deviate from the laminar theory. An analysis of the data within the range of Reynolds numbers from 15,000 to 40,000 reveals that the Sherwood number is proportional to $Re^{0.67}$. Interestingly, this 0.67 power coincides with the result of an earlier heat transfer measurement from a rotating sphere (5). Since there are fewer data points available in this region, no definite conclusion can be made regarding the Schmidt number dependence for turbulent flow.

An experimental investigation of heat transfer from a rotating sphere has been reported by Kreith, Robert, Sullivan, and Sinha (5) over the range of Prandtl numbers from 0.024 to 217. These authors also supplemented their experiments with a theory (5, 7) derived from Nigam's (8) incorrect velocity analysis. More elaborate thermal boundary layer computations have been performed by Banks (9) for Prandtl numbers equal to 0.7 and 1.0. Baxter and Davies (10) re-

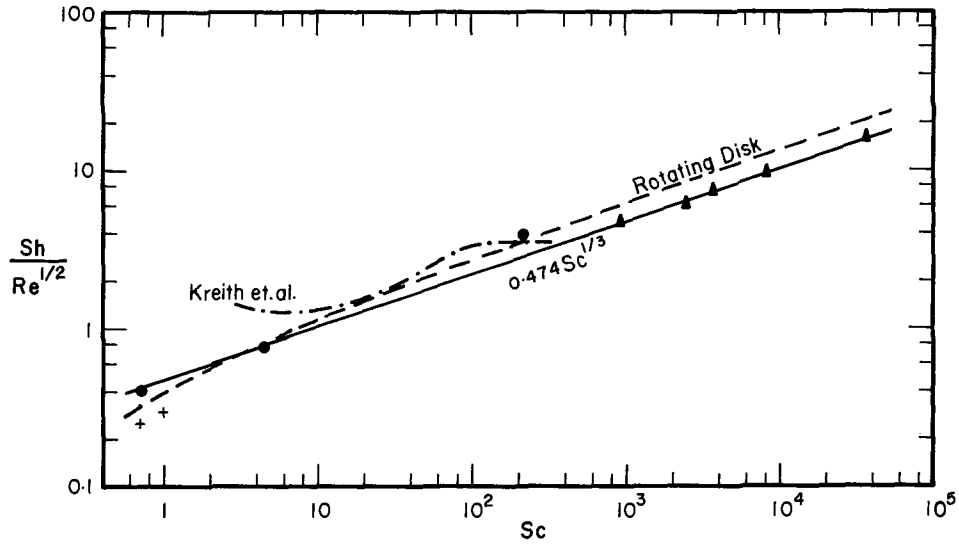

Fig. 8. Comparison with heat transfer results. The triangles are the limiting current data obtained in the laminar region (200 < Re < 15,000). The dots are the results of Kreith *et al.*'s heat transfer measurements. Banks' numerical computations are represented by the crosses.

ported an approximate theory for transfer to a rotating spherical cap at large Prandtl numbers; however, owing to the nature of the equations used, these authors were not able to carry out computations for the cases of a hemispherical cap or a sphere. Since the Prandtl and the Nusselt numbers of heat transfer are analogous to the Schmidt and the Sherwood numbers, respectively, used for the mass transfer studies, it seems desirable to compare the results of the present study with those reported previously. Such a comparison is given in Fig. 8, where $Sh/Re^{1/2}$ is plotted in a log-log fashion *vs.* the Schmidt number. The solid triangles are the present limiting current results obtained in the laminar region. The solid line is the theoretical prediction from Eq. [1]. Kreith *et al.*'s laminar data are indicated by the dots, and their theoretical analysis is shown as the dash-dot curve. Banks' results are indicated by the crosses. Also given in the figure is the rotating disk theory over the range of Schmidt numbers as calculated by Litt and Serad (11) with an analog computer.

It is seen that Kreith *et al.*'s theory does not correlate the data at all; Banks' computation, on the other hand, falls short of the heat transfer measurement. The rotating disk theory predicts a $Sc^{1/3}$ variation at large Schmidt numbers; it gives a transfer rate 32% too high for the case of a sphere or a hemispherical electrode. Only the solid line representing a $0.474\ Sc^{1/3}$ dependence is capable of following the experimental points over the extended range of Schmidt numbers. However, Eq. [1] represents only the asymptotic behavior of the transport process occurring at large Schmidt numbers; the agreement with the heat transfer data at small Sc may simply be fortuitous.

Conclusions

In summary, convective diffusion on a rotating hemispherical electrode has been studied experimentally over the range of Reynolds numbers from 200 to 40,000, and Schmidt numbers between 920 and 37,000. At Reynolds numbers below 15,000, the theory reported previously (1) appears to give a satisfactory correlation with the experimental data. For Reynolds numbers larger than 15,000, the flow becomes turbulent, and the rate of mass transfer varies with $Re^{0.67}$.

Technical Note

Interface Equilibrium Concentrations During Diffusion

S. M. Hu*

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

In the literature (1) it has been shown that, during the diffusion of a solute from a semi-infinite source into a semi-infinite sink, the interface concentrations of the solute in both phases are invariant with time. This was proved under the conditions that the diffusivities D_1 and D_2 in both phases are constant, and that the segregation of the solute between the two phases is described by $C_{2,0} = kC_{1,0}$ (where k is the segregation coefficient; C_1 and C_2 are the solute concentrations in the two phases, and the subscript 0 denotes the interface $x = 0$), provided that equilibrium is established at the interface and that the interface is not moving during diffusion. The latter condition means that there is no Kirkendall effect. This assumption is generally reasonable for diffusions in semiconductors in which highest concentrations seldom exceed a few atomic per cent, and in which the vacancy pump effect is negligible (2). The purpose of this note is to point out that the time-invariance of interface concentrations is still valid under the more general conditions that D_1 and D_2 are respectively functions of C_1 and C_2, and that the equilibrium between the two phases is described by $C_{2,0} = f(C_{1,0})$, where f is an arbitrary function.

This aspect is of practical importance in, for example, the diffusion of a solute from a doped oxide into a semiconductor at high concentrations. For generality, we assume the ratio between the surface areas of the two phases to be r, which is not necessarily unity except for the case of direct physical contact.

In the present case the concentrations at the interface in the two phases are nonarbitrary and must be determined as a condition of self-consistency, although in cases of diffusion in one semi-infinite medium the surface concentration is an arbitrary constant (or an arbitrary function of time). Hence, one may start by assuming that the surface concentrations are time-invariant, and then prove that the resulting solution is consistent with the boundary conditions including this assumption. Under this assumption, one can express the concentrations as functions of a single Boltzmann variable $u = x/2\sqrt{t}$. The continuity equations can be written

$$-2u\frac{dC_2}{du} = \frac{d}{du}\left(D_2\frac{dC_2}{du}\right) \qquad [1]$$

$$-2u\frac{d(C_s - C_1)}{du} = \frac{d}{du}\left[D_1\frac{d(C_s - C_1)}{du}\right] \qquad [2]$$

where C_s is the initial bulk concentration in the source, and D_1 is a function of $(C_s - C_1)$. The initial conditions are

$$(C_s - C_1) = C_s - C_{1,0}, \text{ at } u = 0$$
$$= 0, \text{ as } u \to -\infty \qquad [3]$$

and

$$C_2 = C_{2,0}, \text{ at } u = 0$$
$$= 0, \text{ as } u \to -\infty \qquad [4]$$

A solution to [1] is then obtainable from an iterative scheme (3) as

$$C_2 = C_{2,0}\left[1 - \frac{\int_0^u D_2^{-1}\exp\left(-\int_0^u 2uD_2^{-1}\,du\right)du}{\int_0^\infty D_2^{-1}\exp\left(-\int_0^u 2uD_2^{-1}\,du\right)du}\right] \qquad [5]$$

One obtains a similar expression for C_1, or equivalently $(C_s - C_1)$. At the interface, one has

$$C_{2,0} = f(C_{1,0}) \qquad [6]$$

$$C_{2,0}\left[\int_0^\infty D_2^{-1}\exp\left(-\int_0^u 2uD_2^{-1}\,du\right)du\right]^{-1} =$$
$$r(C_s - C_{1,0})\left[\int_0^\infty D_1^{-1}\exp\left(-\int_0^u 2uD_1^{-1}\,du\right)du\right]^{-1} \qquad [7]$$

The mass flows at the surfaces of the source and the sink are given by Eq. [7] since, from Eq. [5]

$$-\left(D_2\frac{\partial C_2}{\partial X}\right)_{X=0} = -\frac{1}{2\sqrt{t}}\left(D_2\frac{dC_2}{du}\right)_{X=0}$$
$$= -\frac{C_{2,0}}{2\sqrt{t}}\left[\int_0^\infty D_2^{-1}\exp\left(-\int_0^u 2uD_2^{-1}\,du\right)du\right]^{-1} \qquad [8]$$

and similarly for $-\left(D_1\frac{\partial C_1}{\partial X}\right)_{X=0}$

The definite integrals in Eq. [7] are independent of u, and hence, invariant with time. Since both Eq. [6] and [7], which together determine $C_{1,0}$ and $C_{2,0}$, do not contain u, $C_{1,0}$ and $C_{2,0}$ must be invariant with time. This in turn upholds the original assumption of $C_{1,0}$ and $C_{2,0}$ being time-invariant on which is based the application of Boltzmann transformation.

The solution of Eq. [6] and [7] requires the solution of [5] and its companion expression for $(C_s - C_1)$, and *vice-versa*. Hence, the actual numerical scheme involves a two-level iteration. For example, the first-level iteration involves searching $C_{1,0}$; then one obtains $C_{2,0}$ with Eq. [6]. This is followed by the second-level iteration, solving Eq. [5]. Fulfillment of Eq. [7] is the criterion for the first-level iteration. If the diffusivities in both media are constant, Eq. [7] reduces to

$$C_{2,0}/\sqrt{D_2} = r(C_s - C_{1,0})\sqrt{D_1} \qquad [9]$$

$C_{1,0}$ and $C_{2,0}$ are then obtainable from a straightforward algebraic solution of Eq. [6] and [9]. In the special case in which Eq. [6] reduces to $C_{2,0} = kC_{1,0}$ which, in combination with Eq. [9]

$$C_{1,0} = rC_s/(k\sqrt{D_1/D_2} + r) \qquad [10]$$

A Study of the Dissolution of SiO_2 in Acidic Fluoride Solutions

John S. Judge*,[1]

IBM, Components Division, Hopewell Junction, New York

ABSTRACT

Data are presented on the dissolution rates of SiO_2 films in a variety of acidic fluoride solutions. It is shown that the rate of dissolution is linearly dependent on the concentration of HF_2^- and HF in relatively dilute fluoride solutions. Both reactions have a similar temperature dependence characterized by an activation energy of 9.1 and 8.1 kcal/mole, respectively. The reaction with HF_2^- is about four to five times as fast as that with HF. Extrapolation to more concentrated solutions suggests that higher polymeric species of the type $H_xF_{x+1}^-$ may also be active in the dissolution process. Raman data indicates that no single product species is formed although the product spectrum is consistent with the presence of some SiF_6^{2-}.

The dissolution of glasses by acidic fluoride solutions is probably one of the most familiar of chemical reactions. Nevertheless, the chemistry of this process has received very little study. In recent years, this reaction has taken on new technological importance through its use in the manufacture of micro-miniature electronic devices. Many different fluoride solutions, from concentrated HF to solutions highly buffered with NH_4F, are being used for SiO_2 dissolution through photoresist masks. Recently, Dey, Lundgren, and Harrell (1) reported on the temperature and agitation dependence of the rate of SiO_2 dissolution in one of the buffered HF solutions whose composition they failed to specify. It is the purpose of this study to determine what species in solution may be responsible for the dissolution and how these depend on the formulation of the solution, *i.e.*, to begin to elucidate the chemistry involved in the dissolution of SiO_2 in acidic fluoride solutions.

Experimental

The SiO_2 used in this study was in the form of thin films, ~5000Å thick, produced by the thermal oxidation of single-crystal silicon wafers. These were Monsanto wafers (111) orientation, p-type, ~15 ohm cm. They were oxidized in an oxygen, water vapor atmosphere (mole fraction $H_2O = 0.373$) at 1100°C. (These conditions are mentioned here although the etch rate data does not appear to be particularly sensitive to the conditions of oxide formation.)

The thickness of the oxide film was measured by an interference technique (2). The dissolution rates were calculated from the thickness changes which were found to be linear with time in all cases. The dissolution rates were, in general, measured under quiescent conditions although mild agitation has no measurable effect on the rates.

Reagent grade chemicals were used in all cases. It was necessary to standardize the NH_4F stock solutions utilizing an Orion fluoride electrode and Orion standard fluoride solutions. A hydrogen electrode was used for pH measurements in these acidic fluoride solutions. Jarrel-Ash kindly furnished the Raman spectrum of several solutions run on their Laser-Raman Spectrophotometer.

Results and Discussion

In relatively dilute fluoride solutions, the only significant species present are related by Eq. [1] and [2].

$$K_1[HF] = [H^+][F^-] \quad [1]$$

$$K_2[HF_2^-] = [HF][F^-] \quad [2]$$

Farrer and Rossotti (3) conclude that these are the only species present up to at least one molar fluoride. The constants, K_1 and K_2, have been determined many times [summarized in ref. (4)]. The most recent values for 1M ionic strength solutions and chloride media were reported by Mesmer and Baes (5) to be:

	25°C	60°C
$K_1 =$	1.30×10^{-3}	6.57×10^{-4}
$K_2 =$	0.104	3.66×10^{-2}

Of course, these values will be a function of ionic strength and, therefore, cannot be used quantitatively in more concentrated media such as buffered fluoride etches, which are commonly 10 → 15M in fluoride. Nevertheless, it is instructive to consider how the concentrations of the various species will depend on pH.

Figure 1 is a plot of the calculated concentrations of HF and HF_2^- for solutions of 15F total F^- as a function of pH (or more precisely $-\log_{10}[H^+]$), assuming the noted values of K_1 and K_2 (6). The values on the ordinate are normalized to add up to 1.00, such that the fraction of free fluoride is the difference between 1.00 and the sum of the two plotted values. It is apparent that in the region of pH > 7 all of the fluoride exists as uncombined fluoride ion. As the pH is lowered, the $[HF_2^-]$ begins to increase and reaches a maximum in the region of pH 3. At the same time, HF becomes a significant species below a pH of 4 and increases monotonically as the pH is further lowered.

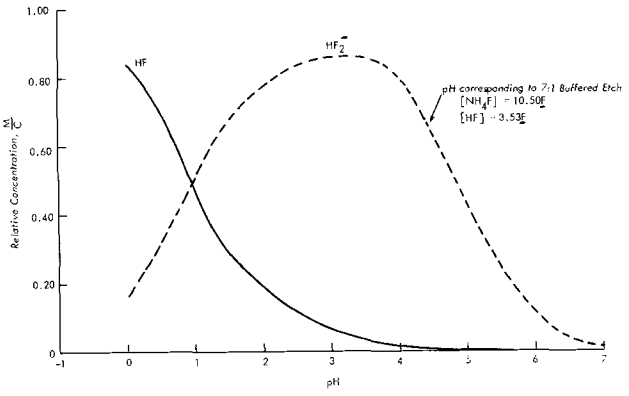

Fig. 1. Mole fraction of fluoride as HF and HF_2^-, calculated for 15M total F^-, and using the constants of Ref. (5). (——— mole fraction of fluoride as HF; - - - - - - - mole fraction of fluoride as HF_2^-).

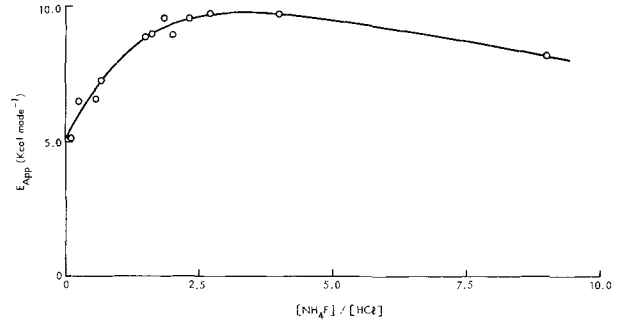

Fig. 2. Dependence of apparent activation energy on the ratio of NH_4F to HCl.

The pH of one commonly used buffered HF etchant composition is indicated on this figure. It is apparent that this composition would contain only HF_2^- and F^- and very little HF if higher polymeric species are not significant at these high concentrations.

In Table I, the etch rates and apparent activation energies in the temperature range 30°-60°C are listed for a selection of solutions made up of various amounts of NH_4F and HF. The ΔEapp values are calculated from relationship [3]

$$\text{Rate} = A \exp(\Delta E\text{app}/RT) \qquad [3]$$

assuming no change in the pre-exponential factor which includes concentration terms. It is apparent that ΔEapp tends to increase as the ratio of NH_4F to HF is increased. This suggests several parallel reaction paths of different activation energy.

In order to be able to treat the rate data more quantitatively, a series of solutions were prepared at a constant value of 1M ionic strength. The acidity of these solutions was varied using HCl and the fluoride

Table I. Effect of varying the concentration of NH_4F and HF on the apparent activation energy for the dissolution of SiO_2

Solution composition (F)				
NH_4F	HF	$[NH_4F]/[HF]$	ΔEapp. (kcal/mole)	Etch rate at 30°C (A/sec)
0	10.0	0	6.7	36.2
2.00	10.0	0.2	8.1	60.5
1.00	2.50	0.4	8.2	15.0
8.00	10.0	0.8	8.8	112
8.00	2.50	3.2	10.3	19.4
10.5	3.53	3.0 (7:1 buffered HF)	11.0	22.0
Dey *et al.* (1)	?	?	8.2	20

content, by including various amounts of NH_4F or NH_4Cl. Thus, the conditions of ref. (4) are met for these solutions and their values of K_1 and K_2 can be used to calculate the various concentrations. The composition and the calculated values of the concentrations of the various species are shown in Table II.

Again, the apparent activation energy for these solutions exhibited a similar dependence on the ratio of NH_4F to H^+ (or the pH). This relationship is shown in Fig. 2. It is apparent that the solutions with the greatest temperature sensitive rates have a composition with a ratio of NH_4F to HCl near three.

Although the solutions of Table II do not include one without added acid, such solutions have been investigated. They have a pH of ~7, and as can be seen from Fig. 1, contain essentially all fluoride in the unprotonated state. Such solutions exhibit essentially zero rate of SiO_2 dissolution, immediately allowing one to exclude free fluoride as one of the species responsible for the dissolution.

For these solutions then, the rate equation will have the general form

$$R = A[HF] + B[HF_2^-] + C \qquad [4]$$

where any of the values A, B, or C may become zero if the data so requires.

A least squares fit of the dissolution rate data to Eq. [4] yielded the following values for A, B, and C (with R in Å/sec and concentrations in molarity).

Temperature, °C	A	B	C
25	2.50	9.66	−0.14
60	10.4	48.6	−1.02

The linear fit of the rate data to relationship [4] with these values of the constants is shown in Fig. 3 and 4 where the experimental rates are plotted *vs.* $A[HF] + B[HF_2^-]$.

In general, these terms A and B will contain an exponential temperature dependence and a pre-exponential term. The temperature dependence is somewhat different for each term so that the over-all concentration dependent part of the rate equation for dilute fluoride solutions becomes as shown in Eq. [5].

$$R(\text{Å/sec}) = 5.0 \times 10^7 [HF_2^-]\, e^{-\Delta E_1/RT} + 2.2 \times 10^6 [HF]\, e^{\Delta E_2/RT} + C(T) \qquad [5]$$

Table II. Composition and calculated concentrations of various species in 1M ionic strength fluoride solutions

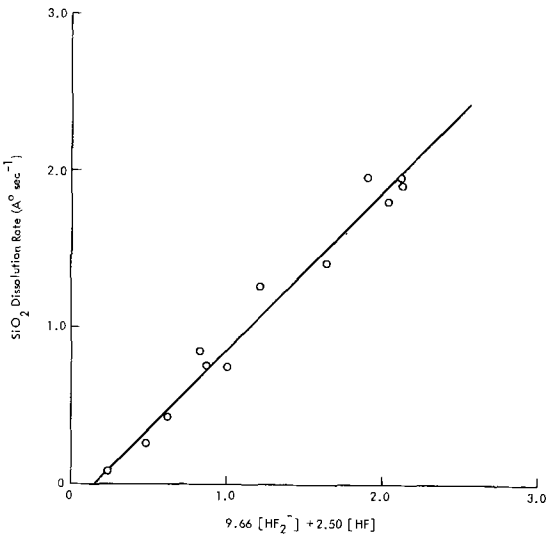

Fig. 3. Linear dependence of the dissolution rate of SiO_2 at 23°C on the plotted function of [HF_2^-] and [HF].

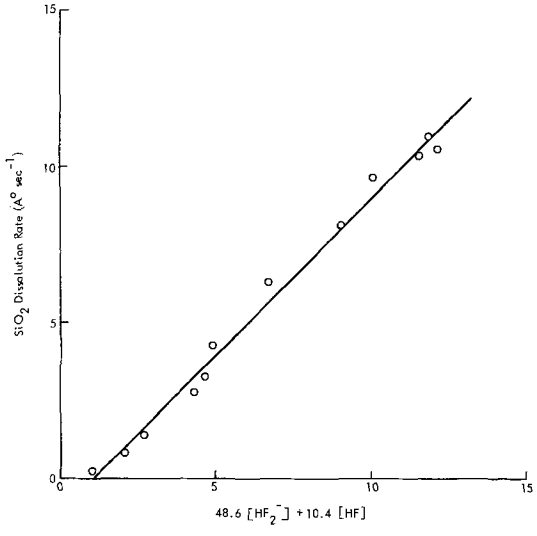

Fig. 4. Linear dependence of the dissolution rate of SiO_2 at 60°C on the plotted function of [HF_2^-] and [HF].

where

$$C(T) \sim 0.025\ (T\text{-}292)$$
$$\Delta E_1 = -9.1 \times 10^3$$
$$\Delta E_2 = -8.1 \times 10^3$$

It is now clear that the change in apparent activation energy with solution composition is in part a reflection of the change in the constants K_1 and K_2 with temperature which results in significant changes in [HF_2^-] and [HF] as can be seen from Table II. In all cases, the [HF_2^-] increases with temperature, whereas [HF] decreases for solutions containing relatively large amounts of HF_2^- and remains nearly constant for the more highly acidic solutions.

The fact that the value of C is not zero is at first surprising, but a much better fit of the data is obtained with these small but nonzero values. It might be expected that as the concentration is lowered, the concentration at the surface will become significantly lower than bulk concentration, *i.e.*, diffusion control becomes the case. This would result in the extrapolation of high concentration rates intersecting the zero rate point at some small but nonzero concentration, as is observed. In addition, as the temperature is raised, the value of this intercept should increase, as it does.

A test of the validity of this relationship can be made by comparing calculated rates from it to measured

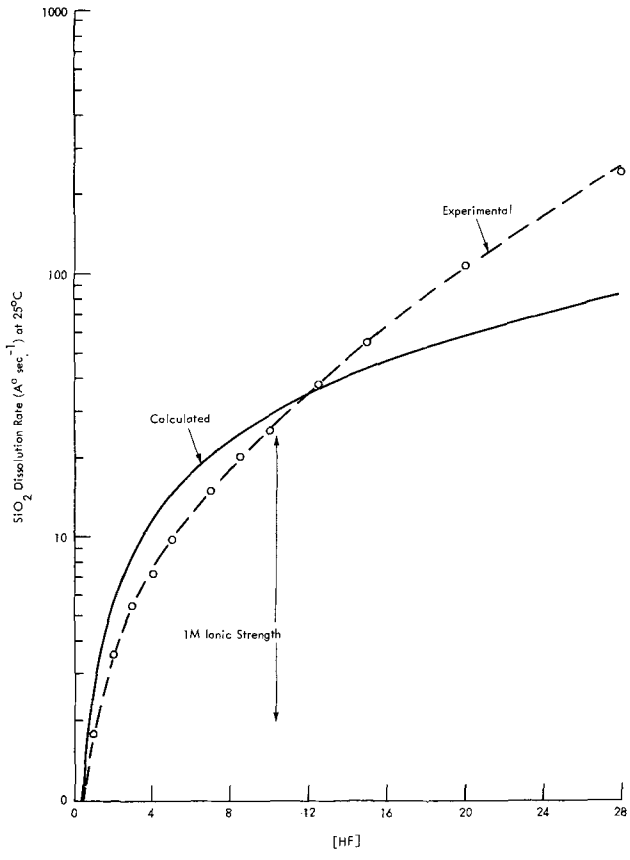

Fig. 5. Dependence of the dissolution rate of SiO_2 on the concentration of HF (——— calculated from Eq. [4], using K_1 and K_2 for 1M ionic strength; - - - - experimental).

rates in a slightly different system, namely, solutions of various concentrations of HF. The same one molar ionic strength values of K_1 and K_2 have been used to calculate the concentrations of HF and HF_2^- from which the rates in Fig. 5 are derived.

It is apparent that for the more dilute solutions, *i.e.*, solutions <10M, the measured and calculated rates are at least qualitatively in agreement. At high concentrations of HF, however, the rate of SiO_2 dissolution is significantly higher than would be predicted on this model. This suggests that other polymeric species may become of importance in chemically attacking the SiO_2 surface in these concentrated solutions, although the change in the nature of the media and the concomitant changes to be expected in the values of K_1 and K_2 could, perhaps, be sufficient to account for this deviation. In this connection, it is important to note that the agreement between the measured and calculated values is best near 1M ionic strength where the constants used will have the correct values. Evidence for higher polymeric species in more concentrated HF has been provided by Jones and Penneman (7). They found an infrared absorption at 1820 cm^{-1} in solutions greater than 6F in HF which is not due to HF_2^- or HF and is not shifted in D_2O. The ion $H_2F_3^-$ has been identified crystallographically in the solid state (8), and some phase rule studies (9) have indicated the presence of $H_3F_4^-$ and $H_4F_5^-$. The large positive deviation of the experimental rates from those calculated on the basis of dilute solution measurements may indicate that these higher polymeric species have a high activity in the dissolution of SiO_2.

The over-all reaction is often assumed to involve the formation of hexafluorosilicate ion in solution. It is most likely a gross over-simplification to assume that this is the exclusive product since aqueous H_2SiF_6 will itself dissolve up to 20 m/o (mole per cent) more SiO_2 (10). It has been proposed (11) that a series of products of the form $SiF_i(OH_2)_k$, where $i + j + k \leq 6$,

may form in the reaction of SiO_2 with H_2SiF_6. This would also probably apply to the solution of SiO_2 in HF.

A solution 10.5F in NH_4F and 3.5F in HF (commonly referred to as 7:1 buffered HF) was examined by Raman spectroscopy before and after dissolving SiO_2 in it by exposing a one inch quartz disk in a 500 cc volume of solution for two days. The solution which had no SiO_2 dissolved in it, exhibited no detectable absorptions in agreement with the work of Woodward and Tyrrell (12). The spectrum of the solution with the SiO_2 dissolved in it is reported in Table III. A very large number of peaks are observed, indicating the presence of multiple product species. The medium intensity peak at 656 cm^{-1} coincides with the Raman absorption reported previously for hexafluorosilicate ion in aqueous solution (13) and may indicate its presence as one of the product species.

Conclusions

It has been shown that the dissolution rate of SiO_2 in dilute acidic fluoride solutions depends on the concentration of HF_2^- and HF, but not free fluoride. The rate of attack of HF_2^- is about four to five times that of HF. The temperature dependence of the rate is similar for both species and is characterized by an activation energy of 9.1 and 8.1 kcal/mole, respectively. Quantitative characterization of the dissolution of SiO_2 in concentrated fluoride solutions must await the determination of the concentration dependence of the dissociation constants, K_1 and K_2, and identification of the role of higher polymeric species which are present in these solutions.

Acknowledgments

It is a pleasure to acknowledge the valuable assistance of Mr. M. J. Galindo in performing most of the experimental work and the Jarrel-Ash Company, Waltham, Massachusetts, for running the Raman spectra.

Flexure Measurements on a U-Nb-Zr Alloy During Oxidation and Temperature Cycling

R. E. Pawel* and J. V. Cathcart*

Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

As part of a general program to study the fundamental oxidation characteristics of a uranium-7.5 weight per cent (w/o) niobium-2.5 w/o zirconium alloy, measurements of the flexure of thin specimens reacting on one side were utilized to assess the extent of stress generation during oxidation. During the early stages of the reaction at 700°C, rapid flexing of the specimens was observed. Because the depth or thickness of the layer involved in this reaction was quite small, the stress within this zone must have been large to account for the observed bending stresses. The model relating flexure to a uniform stress in the growing oxide film appeared to be applicable and led to film stress values of the order of 10^6 psi. When the oxidation process was interrupted, the high stresses then dissipated rapidly as the reaction slowed. This behavior was analyzed in terms of a balance between stress generation and relief in both the oxide film and the substrate metal. We also used flexure measurements during thermal cycling of these specimens to study the kinetics of some of the structural transformations exhibited by this alloy. The presence of an elastic stress gradient was found necessary to promote significant flexure during the transformation period in these specimens, suggesting that shear forces play an important role in the transformations, particularly those involving the α'' structure.

The importance of mechanical effects on the over-all process of gaseous oxidation is generally acknowledged to be large for a number of metals. Many manifestations of these effects have been observed and their influence upon the over-all oxidation behavior discussed. Thus, stress buildup and the response of both the film and substrate metal to the stresses are regarded as important features in most oxidation processes and may be primary factors in determining whether or not an oxide film will be "protective."

The techniques which have been used to obtain quantitative data on stress development during oxidation have so far been limited to x-ray methods (1), optical methods (2), and methods which involve measurements of the macroscopic strain of the oxide film and/or the substrate. The latter category includes the "flexure" technique, in which the curvature of a specimen reacting on one side is measured. The first application of this procedure to an oxidation reaction was made by Dankov and Churaev (3) in 1950; variations of this method have since been utilized in high temperature gaseous oxidation studies of several pure metals (4-7) but few alloy systems (4c, 8, 9). In addition, some investigators have employed different types of measurements of the strain which occurred as a result of oxidation in order to obtain data from which to infer a stress distribution (10, 11). These results all indicate that significant, and in many cases dominant, stress systems and responses may arise during oxidation.

In the present paper we will consider the flexure behavior of a U-7.5 w/o Nb-2.5 w/o Zr alloy during oxidation at 700°C. During the course of this work we also found that the alloy exhibited some unusual flexure sequences upon temperature cycling. We will discuss these in terms of the structure of the alloy and the possibility of extending the uses of the flexure technique to the study of stress-sensitive transformations.

Background Information

The details of the oxidation characteristics of the alloy are being published elsewhere (12) and will not be presented here. However, it is useful to furnish a brief description of the alloy and its oxidation behavior in order to provide suitable background for our interpretation of the flexure data. A more complete picture is available in the literature (12-16.)

At 700°C, this ternary alloy has a single phase, body-centered-cubic structure (γ) which may be retained with minor modification by quenching. Aging of the quenched material at temperatures less than 400°C yields several transition structures; at temperatures between 400°C and the critical temperature, about 650°C, the equilibrium phases $\alpha + \gamma_3$ appear (α is the uranium-rich solid solution, γ_3 is niobium-rich). The time-temperature-transformation diagram determined by Dean (13) for this material is shown in Fig. 1. The metastable phases, γ^s, γ^o and α'' all have structures closely related to the parent γ, and have essentially the same density. Yakel (14) has discussed these structures and described the atomic displacements necessary for their formation. The observed changes for γ^s and γ^o did not involve a chemical ordering.

At 700°C with oxygen pressures of a few microns, the oxide films which form on the surface of electropolished specimens during the early stages of oxidation are generally very uniform in thickness. They consist mainly of a compact, columnar UO_2 matrix in which stringers of a metallic niobium-rich phase ex-

Key words: alloy oxidation, stresses in oxide film, uranium alloy oxidation.

tend normal to the metal surface into the oxide. The solubility of oxygen in the alloy is thought to be quite low, as is the case for pure uranium (15). Similarly, growth of the oxide layer is thought to take place primarily by anion diffusion, probably aided by the presence of a high density of short circuit paths.

Experimental Procedure

Specimens in the shape of 1 cm x 4 cm coupons were cut from 0.05 cm and 0.075 cm sheets of arc-cast, hot-rolled alloy. They were then annealed in vacuum for 2 hr at 800°C and quenched into ice water to retain the γ-bcc structure. The specimens were prepared by standard metallurgical grinding techniques, electropolished in a 5% perchloric acid-methanol solution, then vapor-coated on one side with a thin (~4000Å) layer of 3 Au-1 Al (by weight). This mixture has proved very effective in protecting this alloy from oxidation at temperatures of at least 700°C; it was also used with appropriate caution for a few experiments at 800°C and above. Specimens were mounted vertically in the apparatus, shown schematically in Fig. 2, by a small stainless-steel vise so that the bottom of a quartz fiber "transducer" could be viewed with a cathetometer. The deflection of the fiber is directly related to the curvature of the specimen. These deflection measurements could be obtained during the various oxidation, annealing, and temperature cycling experiments performed in the apparatus. The details of the apparatus, the flexure measurements, and procedures necessary for their interpretation have been discussed previously (7).

Results and Discussion

Stresses Generated During Oxidation

The fact that a significant stress system arises during the oxidation of this alloy was noted early in the investigation when it was observed that thin specimens increased dramatically in area during oxidation. In these experiments the metal was undergoing plastic deformation most probably as a result of compressive forces generated in the growing oxide and the associated tensile forces created in the metal. Lateral extensions of 40% were not unusual.

In order to ascertain the conditions under which it would be possible to obtain flexure measurements and to test the efficiency of the protective layer, we oxidized a series of 1 x 4 x 0.05 cm alloy specimens at 700° and 800°C at oxygen pressures up to 300μ. Several

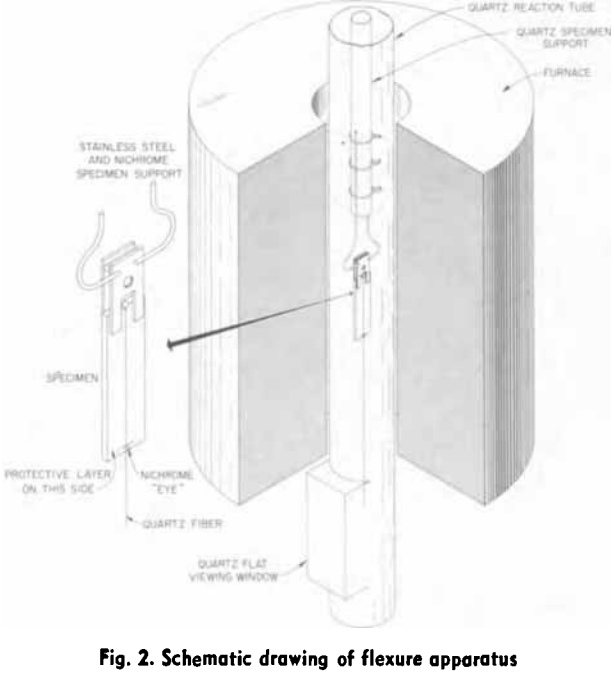

Fig. 2. Schematic drawing of flexure apparatus

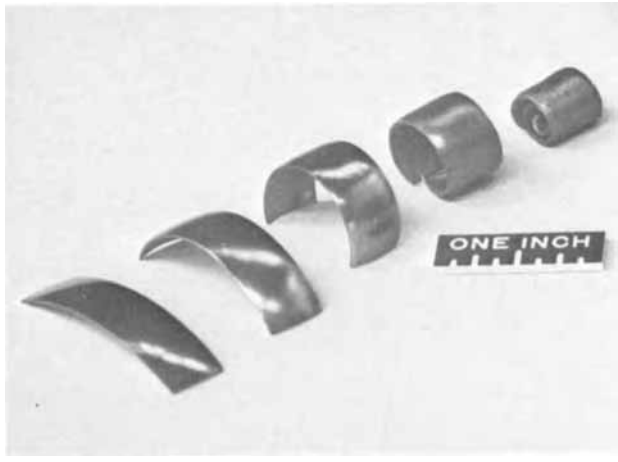

Fig. 3. U-7.5 w/o Nb-2.5 w/o Zr alloy specimens oxidized on top side at 800°C for the following times and oxygen pressures: 5 min at 100μ, 15 min at 100μ, 1 hr at 100μ, 2 hr at 150μ, and 3 hr at 200μ. (Exposures of 8, 25, 100, 300, and 600μ hr, respectively.)

materials were tried as protective layers (combinations of Al, Au, and Ag) before choosing the Au-Al mixture mentioned above. At these temperatures, oxidation invariably resulted in bending of the specimens, the bending becoming quite severe as oxidation continued. Fig. 3 shows a series of such specimens oxidized at 800°C. The degree of bending of these specimens is, of course, much more than that measured in a typical flexure measurement and is obviously associated with considerable plastic deformation of the metal. Similar behavior has been reported for extended oxidation of niobium (7b).

Flexure experiments.—Some of the typical characteristics of specimen flexure during the early stages of oxidation are illustrated in Fig. 4, which is a plot of fiber deflection as a function of time for a sequence of oxidation/anneal periods at 700°C. The deflection was quite rapid as the oxygen pressure was increased up to about 20μ during the first oxygen cycle. The bending occurred such that the oxidizing side was convex.[1] After only 2.3 min, the specimen curvature reached the limit measurable in our apparatus, and the oxygen leak valve was closed. As the pressure decreased, the degree of bending was observed to decrease quite rapidly. This cycle was repeated several times and each time less oxygen pressure was required to initiate comparable bending rates.

For ideal cylindrical bending, the fiber deflection measured in our apparatus (7) is directly related to the degree of curvature of the specimen (for small curvatures) by

$$\rho_x = \frac{LQ}{2Z} \qquad [1]$$

where ρ_x = radius of curvature in the long dimension. L = specimen length, Q = fiber length, and Z = lateral deflection of the end of the fiber. For all experiments reported in the present paper, L = 4 cm and Q = 25 cm. If the specimen deforms entirely elastically, the maximum stress level in the metal can be approximated[2] by the ideal maximum bending stress

$$\sigma_s = \pm \frac{hE}{2\rho_x} \qquad [2]$$

where h = specimen thickness and E = Young's modulus which, for this alloy, is thought to be at least 5 x 10^6 psi at 700°C (16). Thus, the largest maximum

[1] For convenience, we define "positive" (+) flexure as that bending which increases the convexity of the oxidized or nonprotected side of the specimen.

[2] A correction is necessary because of the fact that the neutral axis is not the specimen midplane for these oxidation experiments.

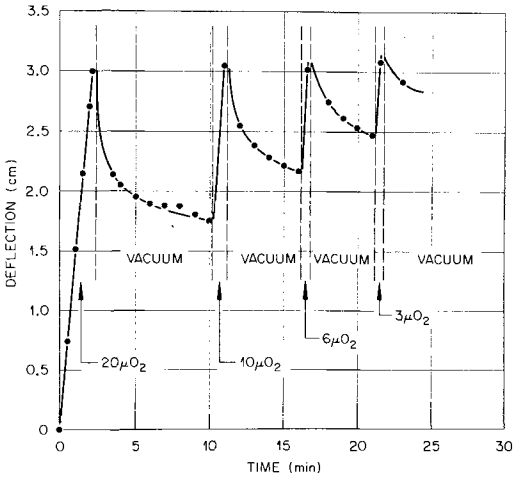

Fig. 4. Flexure characteristics during oxidation/annealing experiment at 700°C. Pressures listed above are maximum pressures reached during that part of cycle. Specimen thickness 0.041 cm; fiber length 25 cm.

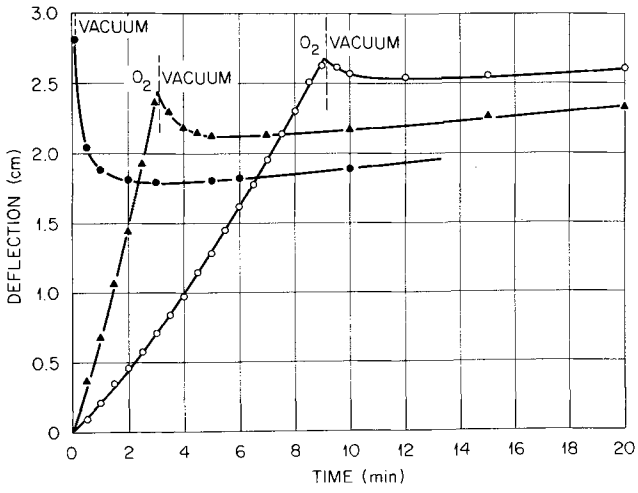

Fig. 5. Flexure of U-Nb-Zr alloy during oxidation/annealing cycles at 700°C. ● Specimen thickness 0.052 cm, oxygen pressure 100-200μ for about 20 sec; ▲ specimen thickness 0.061 cm, nominal oxygen pressure 5μ; ○ specimen thickness 0.061 cm, nominal oxygen pressure 2.5μ.

elastic bending stress obtained from the data of Fig. 4 is about 6000 psi. Tensile data (16b) indicate a yield stress for the alloy of about 5000 to 6000 psi at 700°C. However, the poor creep resistance of this alloy at this temperature, plus the very efficient stress generation mechanism operative during oxidation, leads to nonelastic behavior on the part of the alloy at a very early stage of oxidation. Caution must therefore be exercised in using the flexure data in calculations based on ideal elastic behavior.

For these reasons we confine our attention to the first minute of oxidation for the flexure curves shown in Fig. 4. The largest bending stress encountered is then only ~3000 psi, and the assumption that elastic behavior predominated in the metal seems more reasonable. In this region of the flexure curve, the average stress in the oxide may then be calculated from the simple film stress equation (3, 7b, 9)

$$\sigma_f = \frac{1}{3}\sigma_s \frac{h}{w} \qquad [3]$$

where σ_f is the average stress in an oxide film of thickness w, σ_s is the maximum bending stress given in Eq. [2], and h is the specimen thickness. The equation is accurate for $h>>w$. The oxide film formed in 1 min at 700°C at a pressure of 20μ is approximately 0.5μ thick; Equation [3] then shows that an average stress of about 800,000 psi compression must exist in the film. Comparable results were obtained from several similar experiments.

The very rapid unbending of the specimen during the subsequent vacuum annealing periods came as something of a surprise. Indeed, the unbending generally commenced as the pressure was falling—well before it could reach its limiting value. While this deflection-time behavior was reminiscent of that for tantalum and niobium under similar conditions (7a) in which the redistribution of oxygen in the metal was controlling the unbending, the possibility that the mechanisms are the same is remote. The low solubility of oxygen in this case, as well as the very high diffusivity necessary to account for the rate of unbending (greater than 10^{-6} cm²/sec), strongly suggests a different reason for the observed behavior.

An alternate mechanism is suggested by the deflection data presented in Fig. 5. In these experiments, the specimens were oxidized to about the same total flexure at different rates by changing the oxygen pressure. The degree of unflexing upon subsequent removal of the oxygen was found to depend very much upon the original flexing rate. These characteristics, coupled with the very high film stresses and maximum bending stresses which existed, pointed strongly to an interaction of elastic and plastic effects in both the oxide film and the metal as a basis for a model which may be proposed as follows: (*a*) During the early stages of oxidation, the total strain energy remains small, and elastic behavior predominates in the metal. However, stresses in the oxide film quickly reach values in the range of 10^6 psi and some forms of stress-relief become operative. During this part of the process, a "steady state" exists between the stress-generating and the stress-relieving mechanisms in the oxide film. (*b*) As the film thickness and, therefore, the total strain energy of the system increase, the maximum bending stress in the specimen becomes sufficiently high for stress relief in the form of plastic flow or creep to begin in the metal. As oxidation continues, bending will likewise continue, perhaps even at an increasing rate because of the relatively decreased resistance. (*c*) When the oxygen pressure is suddenly reduced, the means of stress-renewal in the oxide film is withdrawn (or becomes slower), the dynamic balance is broken, and the result is a rapid decrease in the stress level in the oxide. The remaining elastic components of the bending stresses in the metal react to the decreased stress level by partially "unbending" the specimen. This will take place rapidly as the effective stress in the oxide drops to a level where its rate of creep is negligible. (*d*) At 700°C creep in the metal is expected to continue even at comparatively low stress levels. Thus, for longer annealing times the remaining elastic stress in the oxide might be expected to exert its influence, resulting in additional flexure of the specimen at a rate governed essentially by creep of the metal. An example of this behavior is shown in Fig. 6 which shows some additional, but very slow, flexure for long annealing times.

The flexure behavior of this alloy during oxidation is therefore explained on two premises: first, there is a highly efficient stress-generation mechanism available in the form of anion diffusion in the oxide coupled with a large oxide/metal volume ratio. Second, we surmise that for a given rate of stress generation, the relative rates of stress relief in both oxide and metal play an important role in determining the details of flexure in a given experiment.

Flexure During Transformation

While the flexure of the alloy specimens during the isothermal oxidation and annealing experiments was reasonably self-consistent and reproducible, abnormally large changes in the final specimen curvature were generally observed after the specimens were

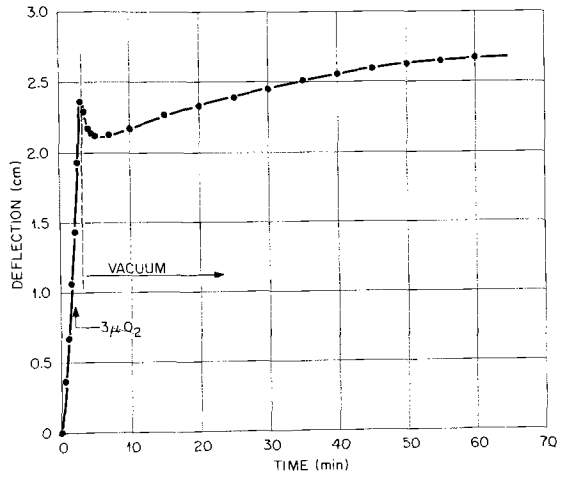

Fig. 6. Flexure of alloy specimen during oxidation/annealing experiment at 700°C. Specimen thickness 0.061 cm.

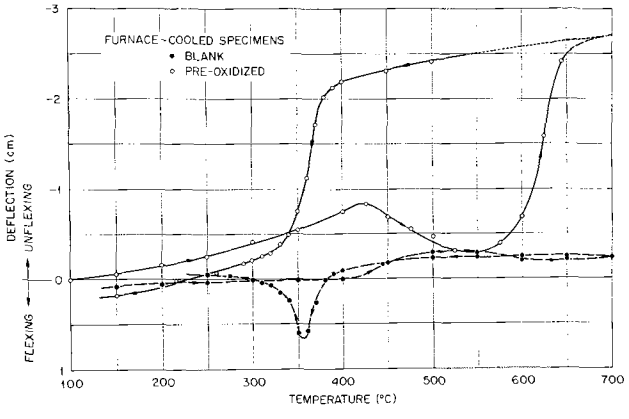

Fig. 7. Flexure during thermal-cycling in vacuum for unoxidized (●) and preoxidized (○) specimens. Initial radius of curvature for oxidized specimen was approx. 10 cm. Both specimens originally furnace-cooled from 700°C.

cooled and removed from the flexure apparatus. These anomalous changes were larger than those to be anticipated as a result of differential thermal contraction and/or differential transformation strain effects between the metal and the thin oxide film. We therefore conducted a series of temperature-cycling experiments in which these flexure effects were documented in detail.

Temperature cycling.—Specimens were prepared for these experiments as previously described, and several unoxidized ("blank") specimens were temperature-cycled from 30° to 700°C in vacuum (10^{-6} Torr) in the flexure apparatus. These specimens exhibited only minor bending effects over the complete temperature cycle regardless of the initial structural state of the specimen. Such behavior is shown in the "blank" run of Fig. 7 where a small deflection was observed on heating at about 450°C; a larger hump occurred on cooling starting at about 400°C. Undoubtedly such minor effects could be attributed to inhomogeneities in the specimen resulting in slightly different transformation rates from one side to the other; if the transformation were influenced by a free surface, the protective Au-Al coating on one side might also exert an effect.

When a specimen was lightly oxidized on one side at some stage of the experiment, however, the subsequent flexure characteristics during temperature cycling in vacuum were very much different. Typical behavior for a furnace-cooled preoxidized specimen is shown in Fig. 7 for direct comparison with the unoxidized sample. (In this case the oxidation treatment

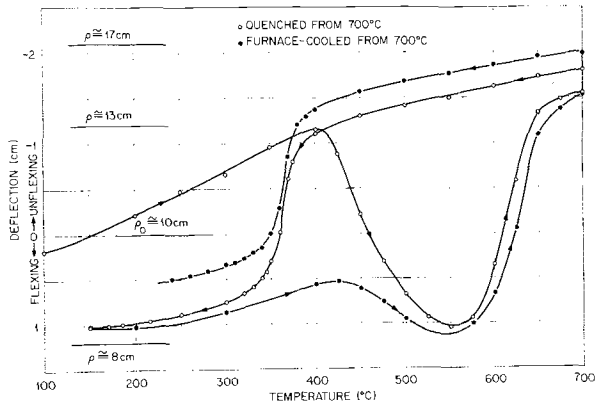

Fig. 8. Flexure during thermal cycling of oxidized and quenched alloy specimen. Initial radius of curvature, ρ_0, after quench from 700°C was approx. 10 cm. ○ First cycle (quenched condition). ● Second cycle (slow-cooled condition). Approximate specimen curvatures corresponding to the deflection values are shown in the figure.

consisted of 2.5 min at 5μ O_2 pressure at 700°C. The radius of curvature after oxidation, computed from the fiber deflection, was about 21 cm. After slow cooling it was measured directly as about 10 cm). Upon heating at a rate of about 10°/min, the specimen unflexed as the temperature was increased to 425°, flexed from 425° to 550°, and finally very rapidly unflexed from 550° to 650° to approach a radius of curvature of 21.7 cm. As the specimen was cooled, flexing occurred slowly until 400°C was reached; between 400° and 300°C the large increase in flexure returned the specimen virtually to its original shape. From the phase diagram and TTT curves (13) for this alloy, it appeared that a good correlation existed between this flexure behavior and the structural transformation of the alloy.[3] For instance, referring to Dean's transformation curves in Fig. 1, it is apparent that the large flexure which occurred during the cooling cycle shown in Fig. 7 parallels the formation of α'' from the matrix γ. (In our apparatus, cooling rates were sufficiently fast so that only the α'' transformation was involved.) On the other hand, the exact sequence of events during heating as the $\gamma^{s,o}$ and α'' phases revert eventually to the high-temperature γ phase is not so clear.

Information which helped to correlate further the flexure and structure data was obtained by making temperature-cycle flexure experiments on specimens heat-treated to yield different starting structures. For example, Fig. 8 and 9 illustrate the flexure behavior of specimens oxidized on one side, then heat treated to yield γ^s (quenched) and $\gamma_3 + \alpha$ (isothermally transformed) structures. While virtually identical cooling curves were obtained in both cases, the flexure during heating obviously depended upon the starting structures. In Fig. 8, the quenched specimen unflexed at a rapid rate during heating to 400°C, then exhibited a comparatively large dip—bending then unbending—as the temperature was increased to 700°C. On the other hand, (in Fig. 9) the isothermally transformed specimen consisting of essentially equilibrium $\gamma_3 + \alpha$ did not show either the initial rapid rate of unbending or the abrupt reversal at 400°C; it did however, show the large degree of unbending starting at about 600°. It is significant that quenched or transformed speci-

[3] These curvature changes were thought to be larger than those which would occur as a result of a uniform relative dilation between the alloy and the very thin oxide during transformation. Thus, in order for a transformation to influence significantly the curvature of such a specimen, it must occur "differently" on one side of the specimen compared to the other. If the flexure change is permanent, the difference must be one which involves "texture" or "extent" of the transformation rather than "rate" which would result in flexing, then unflexing, as the reaction went to completion. Also, a volume or shape change must be involved in the transformation to produce the necessary strain. Since the effect was not observed on annealed, unoxidized specimens, something connected with the oxidation of the specimens on one side created the condition which leads to this difference.

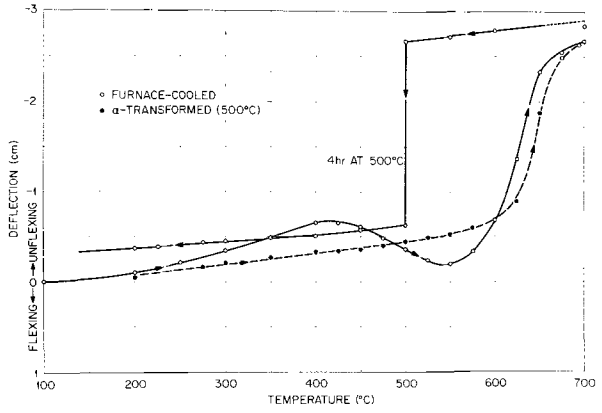

Fig. 9. Flexure during thermal cycling of oxidized specimen isothermally transformed 4 hr at 500°C. Initial curvature after cooling oxidized specimen was 8 cm. ○ Isothermal transformation cycle. ● Isothermally transformed specimen.

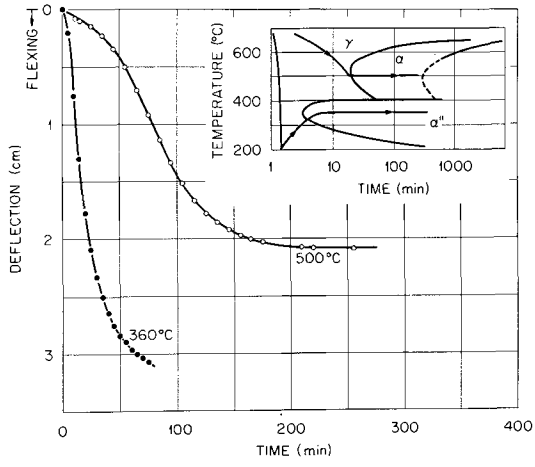

Fig. 10. Flexure during isothermal transformation at 360°C and 500°C for preoxidized specimens. Temperature schedule and time-temperature-transformation curves (13) shown in inset.

mens that had not been preoxidized did not react in this manner but rather behaved in the same way as the "blank run" of Fig. 7.

Summarizing these data, the fewest flexure variations on heating occurred with the specimen with the fewest expected variations in structure. The structure of the isothermally transformed specimen appeared to remain stable upon heating (Fig. 9) to about 600°C where we can associate this part of the flexure curve with the production of γ. Specimens having initial structures consisting of the metastable γ^s (Fig. 7) or $\gamma^{s,o}$ plus α'' (all furnace-cooled specimens) exhibited some intermediate transformations which depended heavily upon the heating rate. Reactions producing α'' or $\gamma_3 + \alpha$ from either γ or $\gamma^{s,o}$ phases resulted in further bending of an oxidized specimen, and vice versa. The increased rate of unflexing at low temperatures in the quenched specimen, for example, may have been associated with some intermediate stage of the reaction, perhaps the formation of additional γ^o.

Superimposed on all these possible transformation effects is the differential thermal contraction between the oxide film and the metal. For these specimens, the additional flexure from this source was small because the oxide layer was generally quite thin compared to the metal. However, the effect was measurable during heating and cooling in temperature ranges where transformations did not interfere. This permitted us to obtain estimates of both film and bending stress values which might result. According to the bimetal thermostat analysis of Timoshenko (17), a specimen oxidized on one side and typical of those under consideration here might be expected to exhibit maximum elastic bending stresses of 1500 psi or more, solely as a result of cooling or heating a few hundred degrees. Stresses in the oxide film due to this source could approach 35,000 psi.

Isothermal transformations.—With only slight modifications of the experimental procedures described above, we were able to use the flexure technique on preoxidized specimens to follow the isothermal transformation kinetics of this alloy. Examples of the flexure at constant temperature due to the $\gamma \rightarrow \gamma_3 + \alpha$ and $\gamma_s \rightarrow \alpha''$ transformations are shown in Fig. 10. The temperature schedule is superposed on Dean's TTT curves in the inset, and reasonable agreement is seen to exist between our data and those obtained by more conventional techniques. Long-time isothermal transformation experiments of this sort did not result in significant unbending of the specimen, which indicated that a differential texture or extent of the transformation is involved in this flexure.

Stress effects.—The item which is primarily responsible for the difference in the transformation behavior is thought to be the elastic stress gradient which exists in the specimens at the time of transformation. In specimens which have been oxidized on one side, the resulting stress system includes substantial bending stresses; even if these are reduced to some degree by annealing periods in vacuum, the action of the forces of differential thermal contraction alone could reestablish a significant stress gradient across the specimen during cooling.

The belief that elastic stress effects, rather than some other aspect of the oxidation treatment, were responsible for the observed transformation-flexure behavior was enforced by additional flexure measurements on specimens in which elastic stress gradients were imparted by strictly physical means. Unoxidized, unprotected specimens quenched from 800°C were deformed in bending at room temperature using an adjustable metal hose clamp to produce a uniform radius of curvature in the desired range. Sufficient uniform plastic deformation was induced into these specimens so that when they were released from the clamp, springback increased the radius of curvature only to about that value which had been observed in the oxidation experiments. Of course, the residual elastic stress distribution here is not a completely linear entity such as a pure bending stress. However, elastic stress gradients do exist in these specimens which might be expected to influence a stress-sensitive transformation.

The results of such an experiment with respect to the α'' transformation are shown in Fig. 11. A mechanically deformed γ-quenched specimen was heated in vacuum to 350°C, flexing only slightly during the 25 min heating period. Held at this temperature, flexure now occurred, decreasing the radius of curvature of the specimen from 12 cm to about 7 cm in a short period of time. The behavior was practically the same as that observed on specimens in which the original deformation was accomplished by oxidation and/or by differential thermal contraction. This specimen was then reheated to 800°C for 90 min to reform the γ phase and to anneal out the stresses left by the original room-temperature deformation. After quenching the specimen, the radius of curvature was found to be identical to that observed before the initial heating, 12 cm. Thus, the strain, in this case differential strain, caused by the formation or removal of the α'' was completely reversible. The curve shown by the open circles in Fig. 11 shows the flexure behavior observed when the annealed specimen was reheated to 350° and held for an extended period of time. No changes in flexure were found. The absence of flexure changes for a specimen in a condition completely identical to that in the first cycle—except for the presence of residual elastic stress gradients—is significant. This behavior indicates that

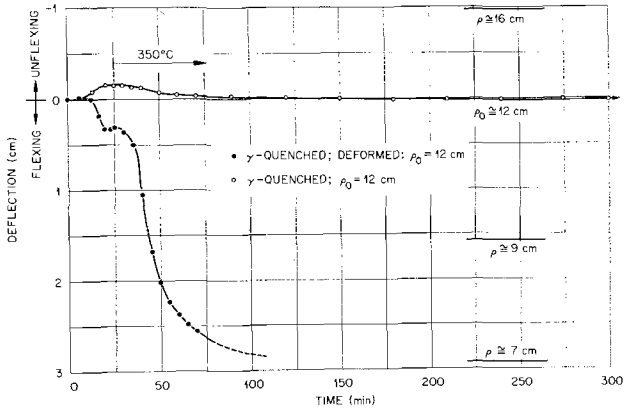

Fig. 11. Flexure of mechanically deformed specimen with initial radius of curvature of 12 cm. ● γ-quenched, deformed. ○ Same specimen, annealed 90 min at 800°C to relieve elastic stresses, γ-quenched; radius of curvature after quenching was 12 cm. Approximate specimen curvatures corresponding to the deflection values are shown in the figure.

the transformation is indeed affected by the presence of a stress gradient and strongly suggests that it takes place by a mechanism in which martensitic or shear processes play an important role. This is in accord with previous investigators (18) who have also concluded that shear transformation mechanisms are important in several uranium alloy systems.

Conclusions

The flexure technique was used to observe stress buildup during the oxidation of a uranium-7.5 w/o niobium-2.5 w/o zirconium alloy. These measurements indicated that the effective stress in the oxide film approaches 10^6 psi and were instrumental in the establishment of a mechanism accounting for the stress generation and relief behavior. This model furnishes an important facet in the complete description of the oxidation process.

The application of the flexure technique to the study of oxidation phenomena in an alloy system must be made with the realization that extraneous sources of flexure may be operative under certain conditions. Conversely, one may sometimes make use of flexure methods to investigate the nature of these "extraneous sources." For example, in this investigation we used such measurements to observe the kinetics of certain phase transformations in this alloy. The transformations were subject to a flexure measurement because they proved to be sensitive to the elastic stress gradients which could be imposed by either oxidation or mechanical means.

Acknowledgment

The authors express their appreciation to J. J. Campbell for his contribution to the experimental phases of this investigation. Discussions with H. L. Yakel and T. G. Kollie concerning the structure of the various alloy phases were very helpful.

Research was sponsored by the U.S. Atomic Energy Commission under contract with the Union Carbide Corporation.

Oxidation of Ni-Cr-Al Alloys Between 1000° and 1200°C

C. S. Giggins and F. S. Pettit

Pratt & Whitney Aircraft, Materials Engineering and Research Laboratory, Middletown, Connecticut 06457

ABSTRACT

The oxidation of Ni-Cr-Al alloys in 0.1 atm of oxygen has been studied at temperatures of 1000°, 1100°, and 1200°C. Twenty-one alloys with varying chromium [2-30 weight per cent (w/o)] and aluminum (1-9 w/o) contents were examined. It was found that all of the alloys initially underwent a period of transient oxidation before steady-state conditions were established. The transient period of oxidation usually did not exceed 1 hr and was characterized by rapid conversion of thin surface layers of the alloys to oxides with the subsequent formation of continuous layers of one of the following oxides: NiO, Cr_2O_3, or Al_2O_3. Steady-state conditions were established with the formation of these continuous oxide layers, and oxidation occurred by three different mechanisms which were characterized by the growth of an external layer of NiO over a subscale of Cr_2O_3 and Al_2O_3, the growth of an external layer of Cr_2O_3 over an Al_2O_3 subscale or the growth of a continuous, external layer of Al_2O_3.

Nickel-base superalloys are currently used in numerous high-temperature applications which require both mechanical strength and oxidation resistance. Virtually all such alloys in use today were developed empirically through a judicious selection of strengthening elements and elements required for oxidation resistance. Elements usually added to improve mechanical properties include Mo, W, Ta, and Nb through solid solution hardening and Al and Ti via formation of a γ' precipitate in a γ-nickel matrix. Carbon is used to improve grain boundary properties while Al and Cr are included to develop oxidation resistance. Finally, elements such as yttrium (1) as well as inert dispersoids (1, 2) have also been found to improve the oxidation resistance of alloys. In order to develop high strength nickel-base alloys with improved oxidation resistance, it is necessary to determine the influence of these types of elements upon oxidation properties. However, before it is possible to examine the effect of different elements on the oxidation behavior of nickel-base superalloys, it is essential to define the oxidation mechanisms for simpler but related alloys such as Ni-Cr-Al alloys.

Thermodynamic considerations have shown that Cr_2O_3 and Al_2O_3 are the stable oxide phases formed on Ni-Cr and Ni-Al alloys, respectively, whenever these alloys contain more than one part per million of chromium (3) or aluminum (4). In view of these conditions, Cr_2O_3 and Al_2O_3 should be the principal products formed on virtually all oxidized Ni-Cr-Al alloys. Furthermore, since the equilibrium constant for the following reaction is very small (*e.g.* 3×10^{-18} at 1100°C[1])

$$Al_2O_3 + 2Cr(\text{alloy}) = Cr_2O_3 + 2Al(\text{alloy}) \quad [1]$$

Al_2O_3 should be the stable oxide phase formed on Ni-Cr-Al alloys that contain more than 1 ppm aluminum. For example, when the activity of chromium and aluminum in the alloy is taken as 1 and 10^{-7} respectively, the mole fraction of Al_2O_3 in the Al_2O_3-Cr_2O_3 solid solution is 0.9997. Previous studies (6-9) on the oxidation of Ni-Cr-Al alloys show that much more than 1 ppm aluminum is required to form an external Al_2O_3 scale on these alloys and it is apparent that other parameters in addition to thermodynamic conditions must be considered when discussing the oxidation of such alloys. Although some experimental work (6-9) has been accomplished, a mechanistic description for the oxidation of Ni-Cr-Al alloys is not available. The purpose of the present study was to determine the oxidation mechanisms of Ni-Cr-Al alloys at temperatures between 1000° and 1200°C.

Key words: oxidation, Ni-Cr-Al alloys, mechanisms.

[1] Thermodynamic data obtained from Ref. (5).

Experimental

The alloys listed in Table I were prepared from high-purity metals by nonconsumably arc melting and casting as 100g buttons. These alloys were then given a preliminary annealing treatment in vacuum at 1000°C for 48 hr to promote homogeneity. Each button was cut into approximately 0.250 in. thick sections that were subsequently cold-rolled to 0.050 in. thicknesses and annealed in vacuum at 1000°C for 48 hr to provide a twinned, equiaxed γ matrix. Two of the alloys, Ni-10Cr-9Al and Ni-30Cr-6Al, were studied in the cast-annealed condition due to difficulties encountered during cold-rolling. Most of the alloys were single phase γ and the remainder exhibited either two phase, $\gamma + \gamma'$ or three phase $\gamma + \gamma' + \alpha$Cr structures in agreement with the Ni-Cr-Al phase diagram (10). Rectangular specimens were cut from the sheet and buttons to provide surface areas of approximately 2.5 cm^2. All specimens were polished through 600-grit SiC abrasive paper, ultrasonically agitated in ethylene trichloride and rinsed with ethyl alcohol.

The alloys were isothermally oxidized at temperatures of 1000°, 1100°, and 1200°C in static oxygen at 0.1 atm. Oxidation kinetics were determined by the weight-gain method using an automatic vacuum microbalance. The specimens were raised from the cold zone to the hot zone of the furnace after oxygen had been admitted to the system. The experimental apparatus and procedure have been described in a previous paper (4) and will not be included here.

Table I. Composition of alloys

Alloy designation	w/o chromium	w/o aluminum	Phases present
Ni-5Cr	4.9	—	γ
Ni-3Al	—	3.1	γ
Ni-2Cr-4Al	2.0	4.0	γ
Ni-2Cr-6Al	2.0	6.0	γ
Ni-3Cr-6Al	3.0	6.0	γ
Ni-5Cr-1Al	5.1	1.0	γ
Ni-5Cr-3Al	5.0	3.0	γ
Ni-5Cr-4Al	5.0	4.0	γ
Ni-5Cr-6Al	5.0	6.2	$\gamma + \gamma'$
Ni-5Cr-9Al	5.0	8.9	$\gamma + \gamma'$
Ni-10Cr-1Al	10.0	1.0	γ
Ni-10Cr-2Al	10.0	2.0	γ
Ni-10Cr-3Al	10.0	3.1	γ
Ni-10Cr-6Al	9.9	6.0	$\gamma + \gamma'$
Ni-10Cr-9Al	10.0	8.9	$\gamma + \gamma'$
Ni-15Cr-6Al	14.8	5.9	$\gamma + \gamma'$
Ni-20Cr-2Al	19.9	2.0	γ
Ni-20Cr-3Al	19.9	3.0	γ
Ni-20Cr-4Al	19.9	4.0	γ
Ni-20Cr-6Al	19.8	5.9	$\gamma + \gamma'$
Ni-30Cr-2Al	30.0	2.0	γ
Ni-30Cr-4Al	30.0	4.0	$\gamma + \alpha$Cr
Ni-30Cr-6Al	29.9	6.0	$\gamma + \gamma' + \alpha$Cr

Note: The impurity level of all alloys was less than 0.4 w/o.

Upon completion of the kinetic measurements, the oxidized specimens were examined optically to evaluate their surface topography. Transverse sections of representative specimens were subsequently prepared by standard metallographic techniques and examined optically at high magnifications. Some of the oxidized specimens were studied with a Cambridge Microscan electron probe-microanalyzer to determine the distributions of nickel, chromium and aluminum in the oxides and substrates in the same manner as described for nickel and chromium in a previous paper (3).

Standard x-ray diffraction techniques were employed for phase identification of the oxidation products. Oxides that did not spall during cooling were examined *in situ*. Spalled and extracted (10% Br-methanol) oxides were studied by the Debye-Scherrer method. Oxides formed during the initial period of oxidation, *i.e.* < 1 hr, were also extracted from selected specimens and examined by transmission electron microscopy with a Philips EM200 electron microscope.

Results and Discussion

The experimental results obtained for the oxidation of Ni-Cr-Al alloys in 0.1 atm of oxygen for 20 hr or more were found to fall into three distinct groups which correspond to three different oxidation mechanisms. The diagrams presented in Fig. 1 show the proposed compositional limits for these three oxidation mechanisms at 1000°, 1100°, and 1200°C. Construction of these diagrams was accomplished by evaluation of the kinetic data and characterization of the oxides formed via optical and electron metallography, x-ray and electron diffraction and electron probe microanalysis. Most of the surfaces of the alloys studied oxidized uniformly but a few alloys, with compositions close to the boundaries of the diagrams shown in Fig. 1, oxidized nonuniformly and appeared to be oxidizing by different mechanisms on different portions of their surfaces. These latter alloys will be referred to as transition alloys in the subsequent discussion.

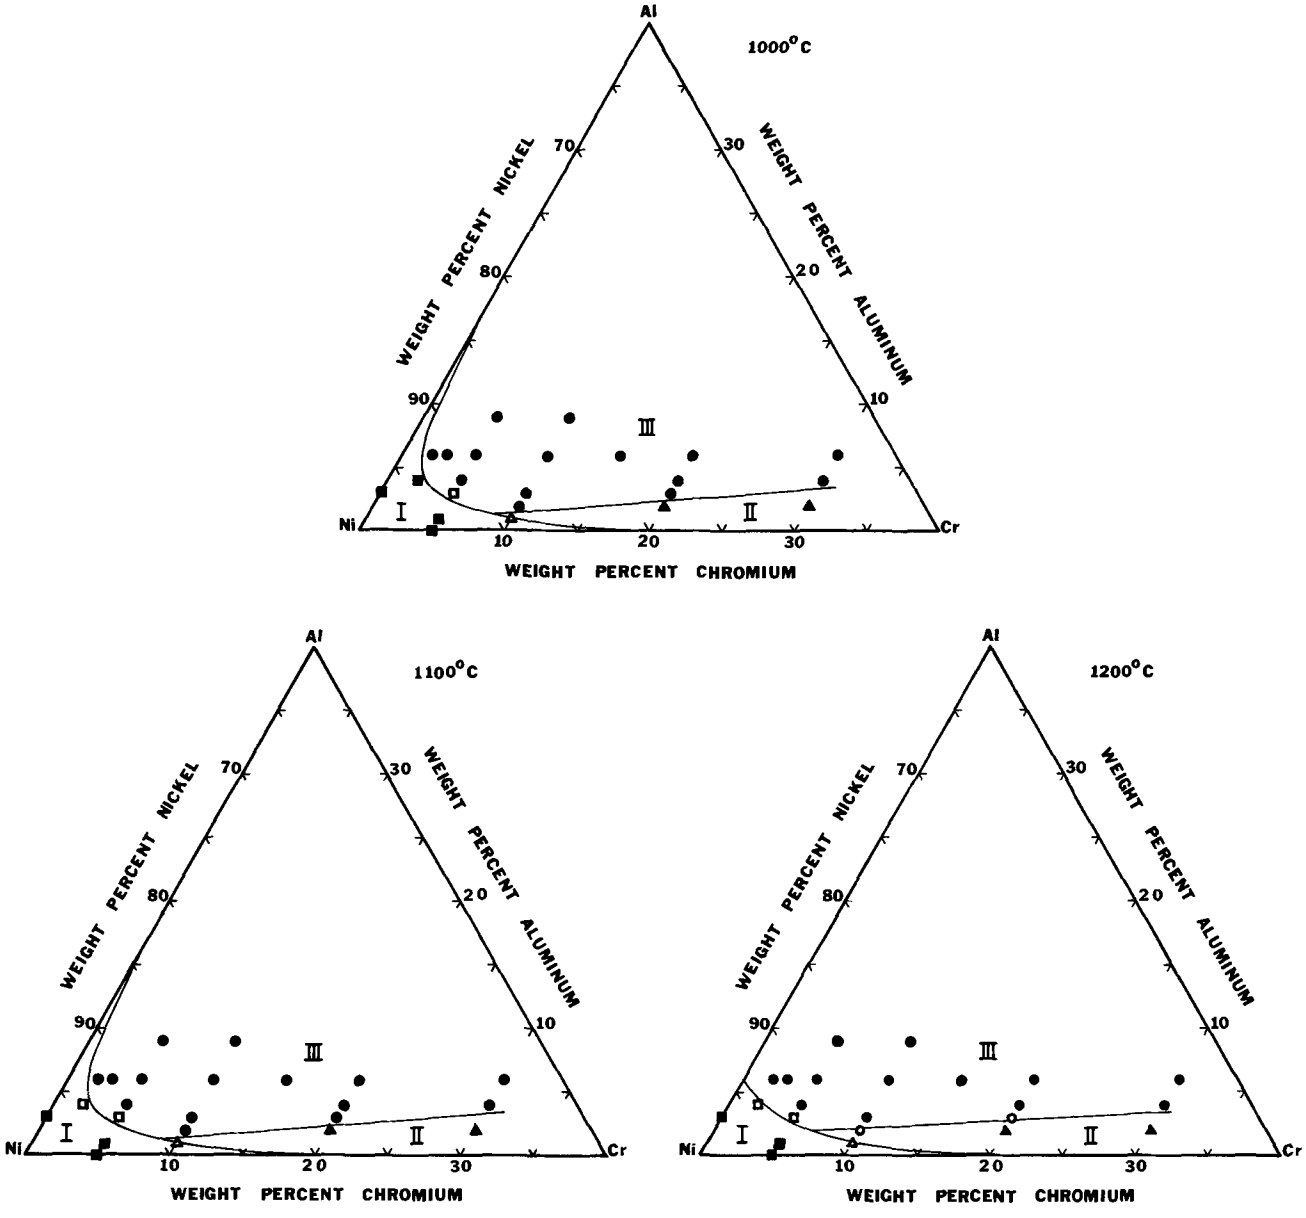

Fig. 1. Isothermal diagrams showing the compositional limits for the three oxidation mechanisms of Ni-Cr-Al alloys in 0.1 atm of oxygen at 1000°, 1100°, and 1200°C. (I) An external scale of NiO and a subscale of chromium and/or aluminum oxides is formed. (II) An external layer of Cr_2O_3 and a subscale of Al_2O_3 is formed. (III) Only an external layer of Al_2O_3 is formed. The data points in this diagram correspond to the compositions of the alloys studied. Solid squares, triangles and circles indicate alloys that conform to mechanisms I, II, and III respectively. Open symbols represent alloy compositions where evidence for mechanisms on both sides of the boundaries were observed.

Group I alloys.—The oxidation kinetics for all alloys with compositions corresponding to region I of Fig. 1 eventually obeyed the parabolic rate law. Usually this rate law was followed virtually from the beginning of the weight-increase measurements although in some cases conformance was not evident for up to 10 hr of oxidation. Typical results are presented in Fig. 2. The parabolic rate constants for alloys in this group were always about an order of magnitude greater than that for pure nickel oxidized under the same conditions, Fig. 3.

A photomicrograph of a transverse section through an oxidized specimen, typical of Group I, is shown in Fig. 4. A dense external scale is evident above a zone of internal oxide precipitates. X-ray analysis of *in situ* and extracted oxides showed that the outer scale was NiO while the subscale precipitate was composed of a mixture of Cr_2O_3, Al_2O_3, and $Ni(Cr,Al)_2O_4$.

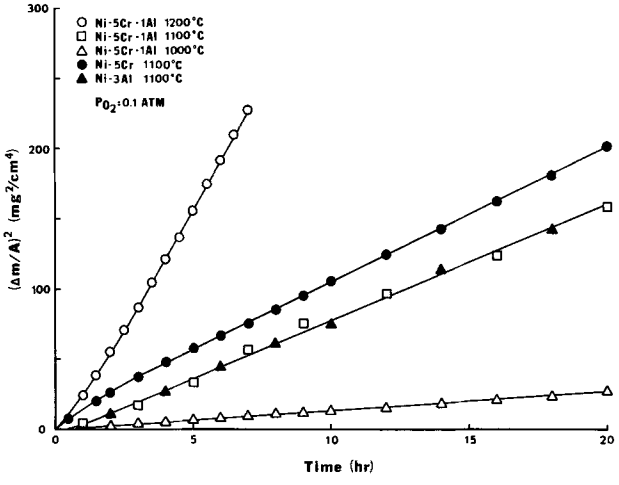

Fig. 2. Typical oxidation data for Group I alloys.

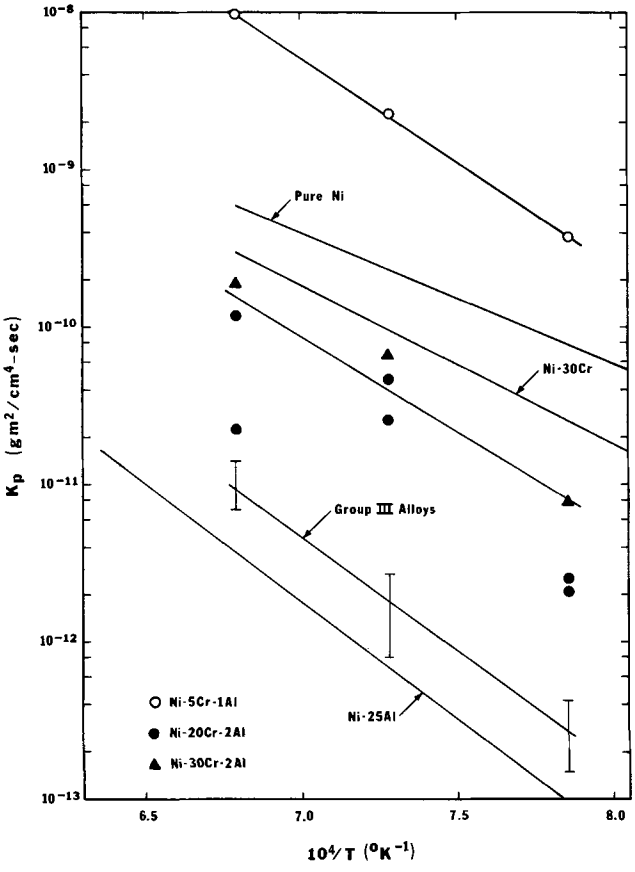

Fig. 3. Temperature dependence of the parabolic rate constants obtained for the oxidation of a typical Group I alloy (Ni-5Cr-1Al), Group II alloys (Ni-20Cr-2Al, Ni-30Cr-2Al), and Group III alloys. Parabolic rate constants for the growth of NiO on pure nickel (3), Cr_2O_3 on Ni-30Cr (3), and Al_2O_3 on Ni-25Al (4) are included for comparison.

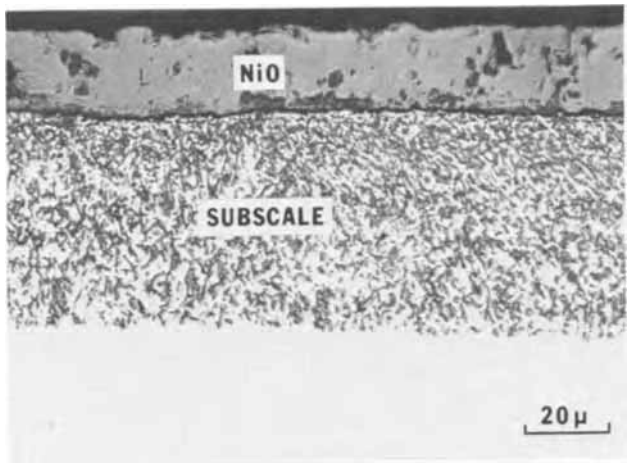

Fig. 4. Microstructure of Ni-2Cr-4Al after 20 hr of oxidation in 0.1 atm of oxygen at 1000°C. This structure is representative of oxidized Group I alloys.

The results show that nickel is oxidized externally to form a continuous scale whereas a discontinuous subscale of Al_2O_3 and Cr_2O_3 is developed by the internal oxidation of both chromium and aluminum. The oxidation rates of these alloys must therefore be controlled by transport through the NiO scale. The oxidation rates are greater than that for pure nickel probably because solution of chromium and aluminum from the alloy increases the cation vacancy concentration in the NiO scale (11). Furthermore, the apparent activation energy obtained from the parabolic rate constants for these alloys is greater than that for pure nickel since the solubility of chromium (12) and probably aluminum in NiO increases with temperature.

Group II alloys.—Typical weight-gain *vs.* time curves for alloys with compositions in region II of Fig. 1 are presented in Fig. 5. The oxidation kinetics for these alloys usually obeyed the parabolic rate law and the parabolic rate constants were close to those for the growth of Cr_2O_3 on nickel-chromium alloys (3) as shown in Fig. 3. In some experiments with alloys in this group the oxidation kinetics did deviate from the parabolic rate law. Occasionally the external oxide scale would crack during isothermal oxidation and

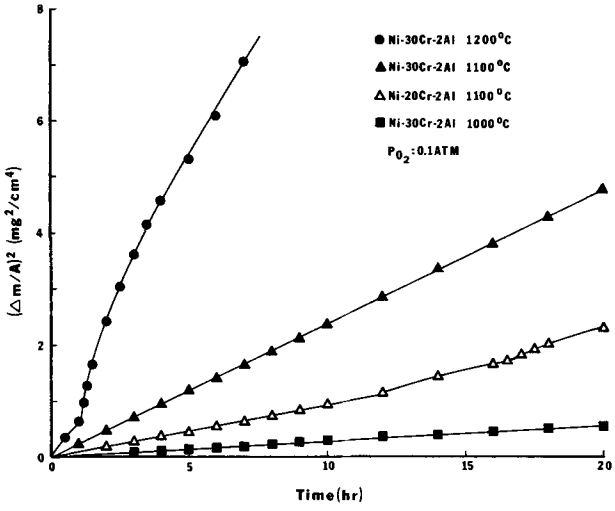

Fig. 5. Typical oxidation data for Group II alloys

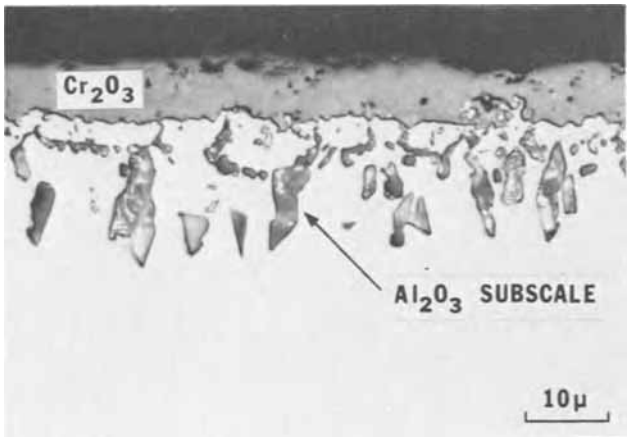

Fig. 6. Microstructure of Ni-20Cr-2Al after 21 hr of oxidation in 0.1 atm of oxygen at 1100°C. This structure is representative of oxidized Group II alloys.

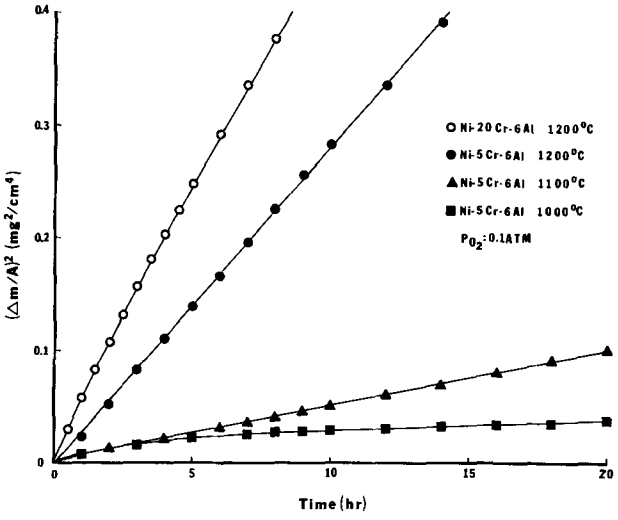

Fig. 7. Typical oxidation data for Group III alloys

the cracks would heal upon subsequent oxidation as shown for two of the curves presented in Fig. 5. In other cases, the instantaneous parabolic rate constant decreased gradually with the oxidation time and final values were found to be close to those for Group III alloys as can be seen in Fig. 3 for the Ni-20Cr-2Al alloy.

A cross-sectional view of the microstructure for a typical specimen from this group is presented in Fig. 6. X-ray analysis of spalled, *in situ*, and extracted oxides showed that the dense outer scale was Cr_2O_3 and the subscale precipitate was exclusively Al_2O_3. Quantitative compositional data obtained from an examination of this specimen with the electron probe-microanalyzer (EPM) further substantiated the preceding oxide characterization. For this group of alloys, the chromium and aluminum are selectively oxidized to form an external scale of Cr_2O_3 and an internal subscale of Al_2O_3. The oxidation rate is controlled by diffusion through the aluminum-doped Cr_2O_3 scale. The specimens, whose oxidation kinetics did not exactly obey the parabolic rate law but had a gradually decreasing parabolic rate constant, were found to have semicontinuous Al_2O_3 scales beneath the external Cr_2O_3 layers which probably caused the slower oxidation rates of these alloys.

The oxidation kinetics for this group of alloys can be influenced by formation of CrO_3 gas via the following reaction

$$Cr_2O_3(s) + \frac{3}{2}O_2(g) = 2CrO_3(g) \qquad [2]$$

However, even at 1200°C, the effect of CrO_3 formation is negligible compared to the weight changes produced by growth of the Cr_2O_3 scale for the oxidation times used in the present experiments which was usually 20 hr. In the case of alloys in this group where the oxygen pick up is decreased due to the formation of a semicontinuous Al_2O_3 scale, as occurred during oxidation of some of the Ni-20Cr-2Al specimens, weight losses caused by the formation of CrO_3 are not negligible and probably did affect the oxidation kinetics for these specimens.

Group III alloys.—Typical weight-gain *vs.* time curves for alloys with compositions corresponding to region III are presented in Fig. 7. The oxidation kinetics for alloys in this group obeyed the parabolic rate law virtually from the beginning of the weight-increase measurements. The rate constants were substantially smaller than those of the previous two groups and similar to those for the growth of Al_2O_3 on Ni-25Al alloys as shown in Fig. 3. A transverse section through an oxidized specimen, typical of this group, is shown in Fig. 8 where only an external scale

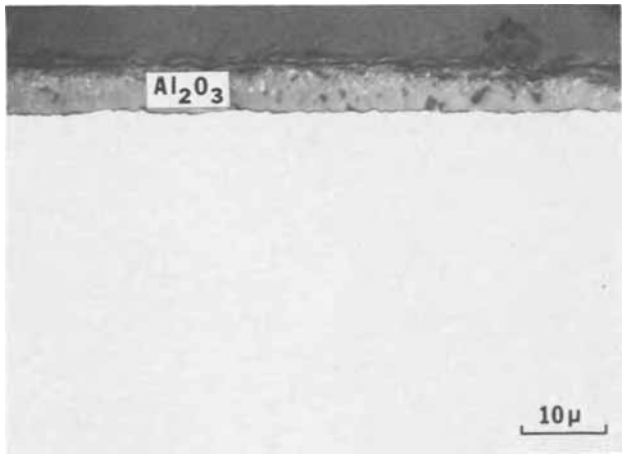

Fig. 8. Microstructure of Ni-20Cr-4Al after 20 hr of oxidation in 0.1 atm of oxygen at 1200°C. This structure is representative of oxidized Group III alloys.

is evident. This dense, continuous external scale did spall from localized areas during cooling. X-ray analysis of spalled, *in situ*, and extracted oxides indicated that the scales formed on the surfaces of this group of alloys consisted of only Al_2O_3. Quantitative EPM examination of this specimen also confirmed that the external scale was Al_2O_3 which contained a small amount of chromium in solution. The results obtained for this group of alloys show that the aluminum is selectively oxidized and the oxidation rate is controlled by diffusion through the external Al_2O_3 scale.

Transient oxidation.—The oxidation data presented thus far have been for the oxidation of alloys under steady-state conditions where virtually all features of the oxidation reactions are independent of time except for the thicknesses of the oxide layers which increased with time. It was found that before steady-state conditions were established, all of these alloys had a period of oxidation where the morphology and composition of the oxide layers changed with time. In addition the oxidation kinetics did not conform to any simple rate law. Chattopadhyay and Wood (13) have obtained similar results from studies on the oxidation of Fe-Cr and Ni-Cr alloys and have referred to this type of oxidation as transient oxidation to differentiate it from steady-state oxidation, *i.e.* oxidation under steady-state conditions. In the present study the duration of the transient oxidation period for most alloys was less than 1 hr from the beginning of weight-increase measurements and transmission elec-

tron microscopy was used to examine the thin extracted films that were formed. The transition alloys, which were defined previously, were the exception since localized transient oxidation occurred on these alloys for as long as 20 hr and these types of oxidation structures could be studied with conventional thick film techniques. The results obtained from examination of the microstructures of oxidized transition alloys were extremely useful in deciphering the latter stages of the transient oxidation process, in particular, the factors interrelating the three mechanisms observed for the oxidation of Ni-Cr-Al alloys under steady-state conditions.

To avoid confusion, it is important to emphasize the difference between use of the terms transient oxidation and oxidized transition alloys. Transient oxidation was observed on all of the alloys that were studied, however, in the case of the transition alloys localized transient oxidation persisted for extremely long periods of time. Finally, it should also be mentioned that since transient oxidation is nonuniform and involves the development of continuous layers of certain oxides as steady-state conditions are approached, it is not possible to determine oxide thicknesses at which transient oxidation ceases and oxidation under steady-state conditions begins.

Transition alloys.—The oxidation kinetics for the transition alloys did not obey any simple rate law since the surfaces of these alloys did not oxidize uniformly as shown in Fig. 9 and 10 and the structure of the oxide scales changed with the time of oxidation. In view of this condition meaningful data was obtained principally from examination of the microstructures of oxidized specimens.

A photomicrograph of a transverse section through an oxidized specimen with a composition near the boundary between regions I and II of Fig. 1 is shown in Fig. 9. The nonuniformity of the oxidation is obvious. In this photomicrograph one part of the alloy has developed an external layer of Cr_2O_3 with internal Al_2O_3 particles (*i.e.* mechanism II) whereas the other has formed an external scale of NiO with internal particles of both Cr_2O_3 and Al_2O_3 (*i.e.* mechanism I). At the boundary between these structures the internal precipitates of Cr_2O_3 and Al_2O_3 particles are observed to be continuous but aluminum is still oxidized internally beneath this duplex scale. This shows that the transition from mechanism I to II occurs when the volume fraction of internal Al_2O_3 and Cr_2O_3 particles is sufficient to establish a continuous, duplex oxide layer beneath the NiO scale which still allows sufficient diffusion of oxygen into the alloy to oxidize the aluminum internally.

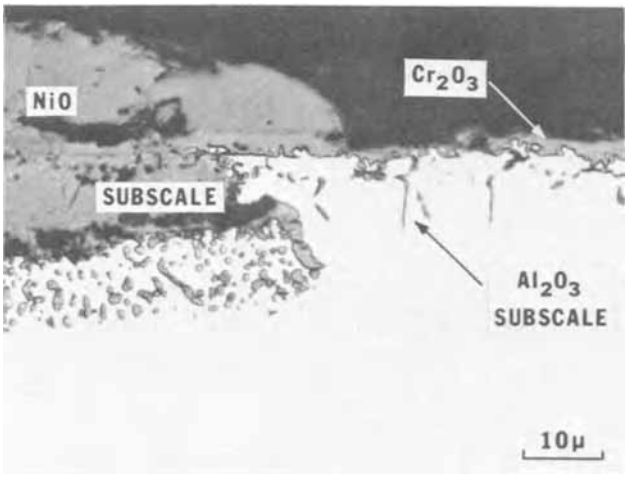

Fig. 9. Nonuniform oxidation morphology of Ni-10Cr-1Al after 20 hr of oxidation in 0.1 atm of oxygen at 1000°C. A portion of the alloy has oxidized as a Group I alloy whereas the remainder has oxidized as a Group II alloy.

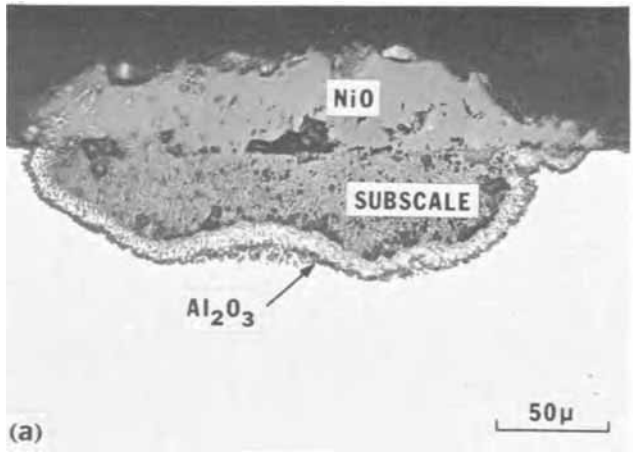

Fig. 10 (a). Nonuniform oxidation morphology of Ni-5Cr-3Al after 20 hr of oxidation in 0.1 atm of oxygen at 1100°C. A portion of the alloy has oxidized as a Group I alloy whereas the remainder has oxidized as a Group III alloy.

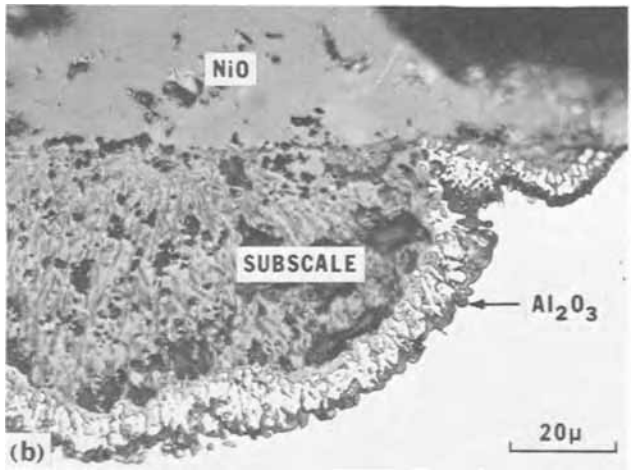

Fig. 10 (b). This high magnification photomicrograph shows that a continuous layer of Al_2O_3 has formed beneath a duplex layer containing both Cr_2O_3 and Al_2O_3 in the region where the alloy has oxidized as a Group I alloy.

A transverse section of an oxidized specimen with a composition near the boundary between regions I and III of Fig. 1 is shown in Fig. 10. Most of the surface of this specimen was covered with a thin, external Al_2O_3 scale, however, numerous mounds of NiO were also evident on the specimen surface. Figure 10(a) shows a typical nickel mound with the external Al_2O_3 scale at the edges. In Fig. 10(b) a continuous layer of Al_2O_3 is seen to have formed beneath the NiO mound at the subscale front. EPM results for this specimen have shown that the continuous layer of oxide immediately above the Al_2O_3 layer in Fig. 10(b) contained both Al_2O_3 and Cr_2O_3. These results show that the transition from mechanism I to III occurs by the formation of a continuous, duplex layer of Cr_2O_3 and Al_2O_3 beneath the NiO scale which inhibits the diffusion of oxygen into the alloy and thereby permits the development of the continuous Al_2O_3 layer.

Representative areas of a transverse section through an oxidized specimen typical of alloy compositions at the boundary between regions II and III of Fig. 1 are presented in Fig. 11. It is evident that a continuous, external layer of Cr_2O_3 is present on all of the sections, however, the morphology of the internal zone of Al_2O_3 is seen to vary from coarse particles to a con-

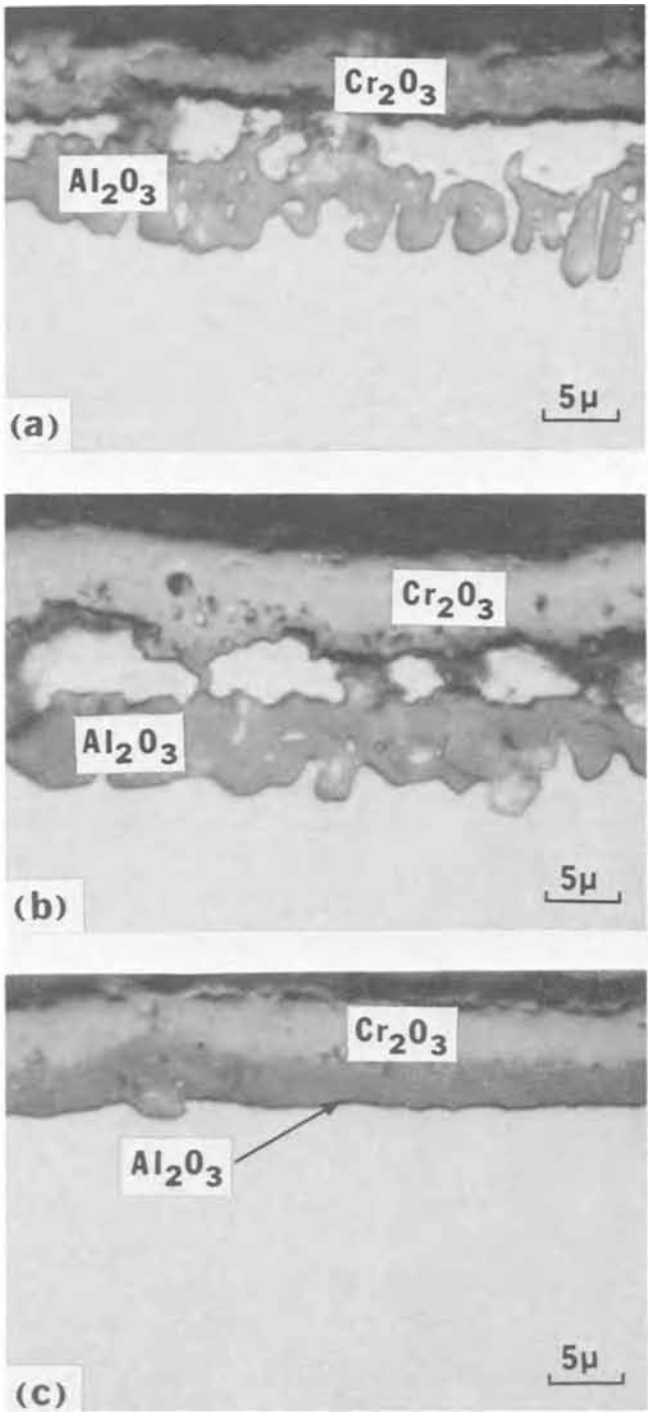

Fig. 11. Oxidation morphology for three different areas of Ni-20Cr-3Al after 20 hr of oxidation in 0.1 atm of oxygen at 1200°C. These microstructures show the different stages for the transition from Group II to Group III. (a) Formation of coarse, discontinuous Al_2O_3 particles beneath an external Cr_2O_3 scale. (b) The Al_2O_3 particles beneath the Cr_2O_3 scale are continuous. (c) No internal oxide particles are evident. The external layer is Cr_2O_3 at the oxide-gas interface and the internal layer is Al_2O_3 at the alloy-oxide interface.

tinuous layer. This shows that Al_2O_3 particles beneath an external Cr_2O_3 layer can coarsen and grow laterally to form a continuous Al_2O_3 layer.

Thin film studies.—In order to examine the transient oxidation of the alloys in which steady-state conditions were established after short periods of oxidation (*i.e.* Group I, Group II, and Group III alloys), the thin oxide films formed on a Ni-15Cr-6Al alloy after 1 min, 5 min, and 40 min of oxidation at 1000°C in 0.1 atm of oxygen were extracted by dissolving the alloy in 10% Br-methanol solution and examined with the electron microscope. Electron and x-ray diffraction indicated that after 1 min of oxidation $Ni(Cr,Al)_2O_4$, NiO, and Cr_2O_3 were present on the surface of this alloy. The spinel phase was the major phase. As the oxidation time was increased, the same oxide phases as well as α-Al_2O_3 were detected but evidence for the formation of layers in the film was observed, as shown in Fig. 12 where an inner layer of oxide is visible below a crack in the outer oxide layer. During preparation of one specimen for examination, this outer layer became delaminated as shown in Fig. 13. Comparison of the electron diffraction patterns for the total oxide and the exposed inner layer showed that the inner layer was Cr_2O_3 containing small particles of spinel whereas the outer layer was composed predominantly of NiO and spinel. It was not possible to examine the thin films which developed on this alloy for oxidation times greater than 40 min since the thicknesses of these films were too large for transmission electron microscopy. However, the oxide layer that was present on this alloy under steady-state conditions was predominantly Al_2O_3, (*i.e.* similar to that shown in Fig. 8) and therefore, in view of the results obtained from studies with the transition alloys, it can be concluded that an Al_2O_3 layer forms beneath the inner Cr_2O_3 layer during the latter stages of transient oxidation.

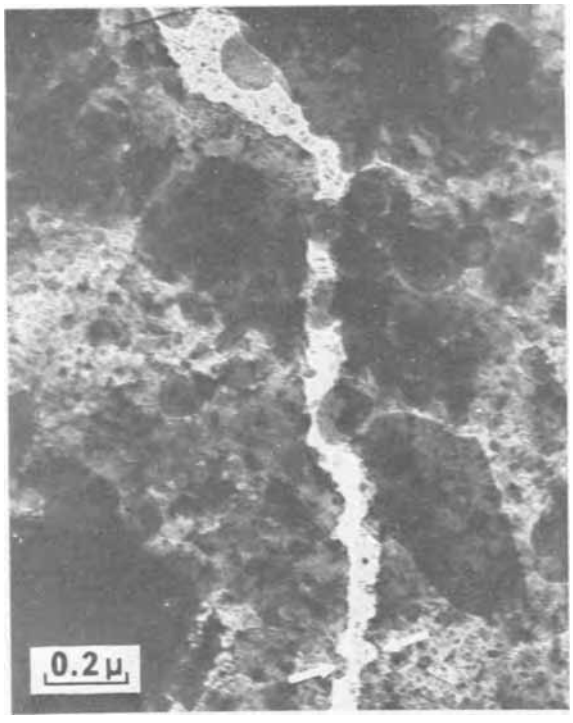

Fig. 12. Transmission micrograph of oxide scale formed on Ni-15Cr-6Al after 40 min in 0.1 atm of oxygen at 1000°C. This scale appears to be composed of two layers of oxide. The outer layer has cracked and exposed the inner layer. (Arrows indicate matching surfaces of cracked outer layer.)

The thin films formed on Ni-5Cr-6Al, Ni-10Cr-6Al, Ni-20Cr-6Al, and Ni-30Cr-6Al alloys after 1 min of oxidation at 1000°C in 0.1 atm of oxygen were also examined with the electron microscope. The oxide films obtained from these alloys were similar to those described for the Ni-15Cr-6Al alloy except that the proportions of the different oxide phases in these films varied with the compositions of the alloys. For example, the films from the Ni-30Cr-6Al alloy contained much more Cr_2O_3 than those extracted from the Ni-5Cr-6Al alloy.

Oxidation mechanisms for Ni-Cr-Al alloys.—The results obtained from the oxidation of Ni-Cr-Al alloys show that these alloys are oxidized under steady-state conditions by one of three different mechanisms and that the particular mechanism which prevails for a specific alloy is determined by the composition of the alloy. These oxidation mechanisms are always preceded by a transient oxidation period where a thin surface layer of the alloy is converted to oxide with little diffusion occurring in the alloy due to the rapid uptake of oxygen by the alloy. The latter stage of the transient oxidation period is characterized by the development of layers of certain oxide phases in the scale. The transient period of oxidation is usually completed after about 1 hr for most Ni-Cr-Al alloys. In the case of alloys with compositions where a transition in oxidation mechanisms occurs (*i.e.* boundaries in Fig. 1) localized transient oxidation has been observed after more than 20 hr of oxidation.

Considering all of the results that have been obtained in the present study, the following model can be constructed to describe the oxidation of Ni-Cr-Al alloys. At the beginning of oxidation of any Ni-Cr-Al alloy, the rapid uptake of oxygen converts the surface layer of the alloy to oxide. As illustrated in Fig. 14(a), this layer is predominantly $Ni(Cr,Al)_2O_4$ and NiO, however, the composition of this layer is determined by the composition of the alloy, since little diffusion takes place in the alloy and therefore significant amounts of Cr_2O_3 or Al_2O_3 would be present on alloys with sufficiently high chromium or aluminum contents.

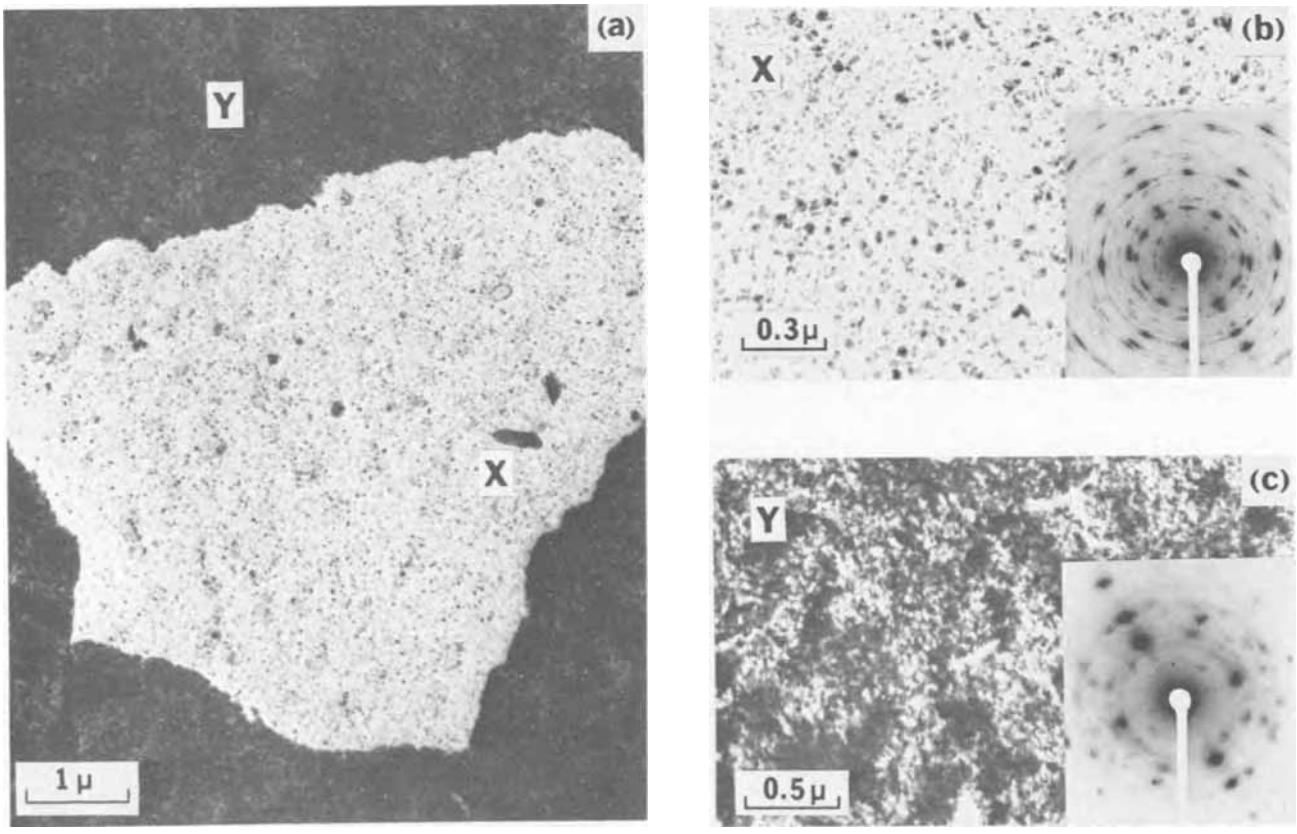

Fig. 13. Transmission micrographs and diffraction patterns of a different area of the oxide scale shown in Fig. 12. The area denoted by X is the inner oxide since the outer layer was delaminated. The diffraction patterns show that the inner layer is Cr_2O_3 with small particles of $Ni(Cr,Al)_2O_4$ while the outer layer, Y, contains substantial amounts of NiO and $Ni(Cr,Al)_2O_4$ in addition to a small amount of Cr_2O_3. In view of the compositions of the two layers, the inner layer must have been in contact with the alloy substrate.

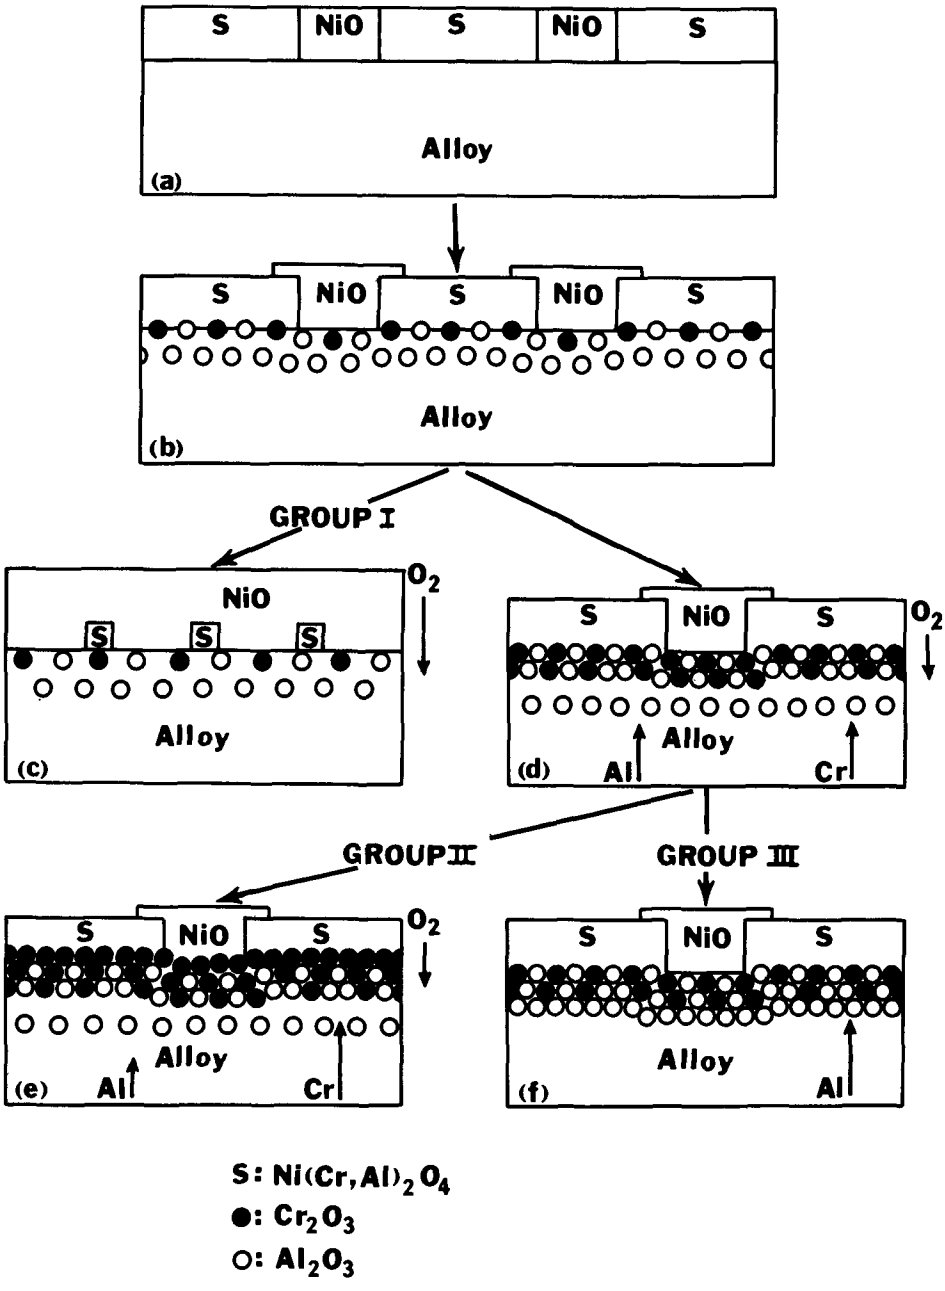

Fig. 14. Schematic diagram illustrating the oxidation mechanisms for Ni-Cr-Al alloys. (a) Conversion of a thin alloy surface layer to oxide by rapid uptake of oxygen. The oxide phases formed are determined by the composition of the alloy. (b) Diffusion within the alloy results in the formation of a Cr_2O_3 and Al_2O_3 subscale beneath the external scale. (c) For alloys with low chromium and aluminum concentrations, the subscale cannot become continuous and NiO in the external scale predominates (Group I). (d) For alloys with higher chromium and aluminum concentrations, the subscale becomes continuous but aluminum is still oxidized internally beneath this duplex internal oxide layer. (e) For alloys with smaller aluminum concentrations, the aluminum continues to be oxidized internally and the continuous duplex layer is enriched in chromium (Group II). (f) For alloys with larger aluminum concentrations, the Al_2O_3 subscale zone becomes continuous beneath the duplex oxide layer (Group III).

As the oxidation reaction continues, diffusional processes in the alloy begin to affect the oxidation reaction. Since the oxygen activity required to oxidize chromium and aluminum in the alloy is less than that established over the alloy by the NiO or spinel in the external scale, oxygen moves into the alloy and precipitates Cr_2O_3 and Al_2O_3 as illustrated in Fig. 14(b). The activity of oxygen required to oxidize the aluminum in the alloy is smaller than that required to oxidize the chromium and the particles of Al_2O_3 therefore extend deeper into the alloy than the particles of Cr_2O_3. If the combined volume fraction[2] of precipitated Cr_2O_3 and Al_2O_3 particles is not sufficient to restrict the movement of oxygen into the alloy, as is the case for Group I alloys, chromium and aluminum continue to be oxidized internally and form a discontinuous subscale of particles beneath the external scale. In the external scale the growth of NiO is much faster than that of any other oxide phase that can be present and NiO completely envelopes the other phases in the external scale as indicated in Fig. 14(c). When the NiO layer becomes virtually continuous, the oxidation reaction proceeds under steady-state conditions and is controlled by transport through the NiO layer (*i.e.* mechanism I). The oxidation rates of alloys that are oxidized by this mechanism are greater than that for pure nickel probably because some chromium and aluminum are dissolved in the NiO which increases the cation vacancy concentration of this oxide.

For alloys where the combined volume fraction of precipitated Al_2O_3 and Cr_2O_3 is sufficient to inhibit the movement of oxygen from the external scale into the alloy, as is the case for Group II and Group III alloys, diffusion of chromium and aluminum from the interior of the alloy results in the precipitation of additional Cr_2O_3 and Al_2O_3 in the subscale zone and a continuous layer of Cr_2O_3 and Al_2O_3 particles is formed beneath the external oxide layer as shown in Fig. 14(d). The formation of this continuous, duplex layer of oxides further reduces the flux of oxygen into the alloy since it establishes a lower oxygen activity over the alloy than that established by the nickel-rich external scale. Consequently, the volume fractions of precipitated Cr_2O_3 and Al_2O_3 are increased to still larger values. For the Group II alloys the flux of oxygen from the duplex scale into the alloy is still sufficient to oxidize the aluminum internally but not the

[2] Use of the volume fraction of precipitated oxides in oxidation processes as developed by Wagner (14) and by Rapp (15) has been discussed in a previous paper by the authors (3).

chromium. Chromium therefore diffuses from the alloy through the duplex scale to form Cr_2O_3 above the duplex scale as illustrated in Fig. 14(e). When the Cr_2O_3 scale becomes continuous, steady-state conditions have been achieved and the oxidation reaction is controlled by transport of chromium through the layer of Cr_2O_3 (*i.e.* mechanism II). In the case of the Group III alloys, the volume fraction of precipitated Al_2O_3 is sufficient to form a continuous layer beneath the duplex zone as shown in Fig. 14(f). Steady-state conditions are reached when the Al_2O_3 layer becomes continuous and the oxidation reaction is controlled by transport through the Al_2O_3 scale (*i.e.* mechanism III).

It is important to emphasize that the transient oxidation period for most Ni-Cr-Al alloys exists for less than 1 hr and the oxides that are formed prior to the formation of continuous Cr_2O_3 or Al_2O_3 layers on the Group II and Group III alloys are usually not evident after 20 hr of oxidation. Frequently the oxide phases formed during the transient period of oxidation could not be detected after 20 hr and it appears that these oxides have been dissolved in the continuous Cr_2O_3 or Al_2O_3 layers or their amounts were too small to be detected. Finally, the nonuniform oxidation of the surfaces of the transition alloys indicates that when the volume fractions of precipitated Cr_2O_3 and Al_2O_3 achieve values where a transition from one mechanism to another is imminent, local differences in surface preparation or impurity content may affect the amount of precipitated oxides whereby different portions of the alloy surface are oxdized by different mechanisms. When such conditions exist, localized transient oxidation will continue until one of the two oxidation mechanisms prevails.

Summary and Concluding Remarks

The particular oxidation mechanism by which a specific Ni-Cr-Al alloy is oxidized is determined by the combined volume fraction of Cr_2O_3 and Al_2O_3 precipitated within the alloy. Chromium allows a continuous, external layer of Al_2O_3 to be formed on Ni-Cr-Al alloys at lower aluminum concentrations than would be necessary if the chromium were not present in the alloy (see Fig. 1) by contributing to the volume fraction of precipitated oxide which reduces the movement of oxygen into the alloy. C. Wagner has proposed such an effect for chromium on the selective oxidation of aluminum in Fe-Cr-Al alloys (16). It is interesting to note that aluminum promotes the formation of continuous Cr_2O_3 layers on some Ni-Cr-Al alloys for similar reasons.

Acknowledgments

The authors wish to express their sincere appreciation to P. A. Scott, V. Nevins, and K. P. Gumz for technical assistance. They also wish to acknowledge that the electron microscopy studies were done with B. H. Kear, L. P. Lemaire, and D. E. Fornwalt. Finally, the authors wish to thank G. W. Goward for many helpful discussions.

Manuscript submitted April 30, 1971; revised manuscript received *ca.* June 18, 1971. This was Paper 114 presented at the Atlantic City Meeting of the Society, Oct. 4-8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Growth of Semi-Insulating Cadmium Telluride

Nanse R. Kyle

Hughes Research Laboratories, Malibu, California 90265

ABSTRACT

A modified Bridgman method for growing cadmium telluride is described. This method controls the composition of the melt, and thus the solid, by controlling the pressure of one of the components of cadmium telluride (CdTe) over the melt. The theory of equilibrium between solid-liquid-gas for this system indicates that the liquid acts only as a transferring medium between gas and solid. Thus the system may be treated as a gas-solid system with respect to defect chemistry. The synthesis and purification of CdTe is described in detail, and empirical results for producing large single crystals are given. Crystals grown by this system are compared with the defect chemistry presented by de Nobel.

D. de Nobel (1) has shown that cadmium telluride (CdTe) can undergo stoichiometric deviations, and that such changes in composition are caused mainly by lattice defects which determine the conductivity and type of conduction. Since cadmium telluride does show a deviation from stoichiometry, the constituents of the crystal itself can act as impurities. Figure 1 is a schematic phase diagram for a two-component system A-B, with one compound AB showing deviation from stoichiometry. For each point of the liquidus there is a corresponding pressure of the volatile component. If a

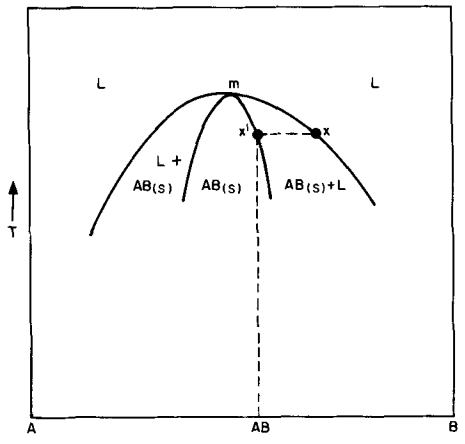

Fig. 1. T-X diagram of the system A-B where compound near AB can solidify at other than exact stoichiometric ratio.

specific vapor pressure of the component is maintained over the melt, the system has a tendency to remain at the composition corresponding to the vapor pressure applied. As solidification takes place, the segregation process tends to make the melt more and more concentrated relative to the excess component present. However, at this point, the liquid is no longer in equilibrium with the vapor, and a reaction between the vapor and melt sets in until equilibrium is again reached. The end result depends on the rate at which the composition changes as a consequence of the segregation, as compared with the rate at which atoms are transferred between the melt and the vapor. Eventually, a stationary state will be reached in which the crystals attain a composition between x' and m.

Because the composition of CdTe is a function of the chemical potential of one of the components when grown from the melt, it is desirab e to grow the crystals under conditions which control the chemical potential of one of the components. This is accomplished utilizing the Bridgman technique. By elongating the tube so that cadmium or tellurium can be placed high in the tube where its vapor pressure is controlled by a second furnace operating significantly below the crystal furnace temperature, the properties of the compound can be determined by the pressure of one of the components above the melt. Use of the elongated tube is referred to as the modified Bridgman system or technique. This system (*i*) controls the composition of the melt, and consequently the solid, by controlling the pressure of one of the components of CdTe over the melt; (*ii*) stops decomposition of the melt; and (*iii*) fixes the distribution coefficients of the dopants.

The theory of equilibrium between solid-liquid-gas for this system indicates that the liquid acts only as a transferring medium between gas and solid; thus the system may be treated as a gas-solid system with respect to defect chemistry. Cadmium telluride synthesis and purification are also described in detail, and empirical results for producing the large single crystals are given. Crystals grown by this system are compared with the defect chemistry presented by de Nobel (1).

Experimental

Equipment.—The equipment used for growing CdTe crystals by the modified Bridgman technique consists of a Marshall multitapped platinum-wound furnace and a Marshall multitapped Kanthal-wound furnace, plus a power supply and a digital temperature control unit for each furnace. The crystal is lowered out of the furnace on a metal support by a screw-driven apparatus whose speed can be varied. The temperature profile of the furnace is adjusted by controlling the power to each tap on the furnace by a series of variable autotransformers and stepdown transformers. Each autotransformer is adjusted individually until the desired profile is obtained. A large autotransformer than can handle the power of the system is used to raise or lower the temperature profile.

Purification.—Cadmium telluride has been synthesized by many processes, including the reaction of cadmium and tellurium previously purified by zone melting or sublimation, followed by crystal growth, as well as purification of the compound CdTe by zone melting. Some controversy exists regarding the purification of tellurium:

1. Weidel (2) determined that distillation and zone refining were unsatisfactory. He used thermal decomposition of H_2Te to obtain pure tellurium.
2. Shvartsenau (3) found that zone melting of tellurium in quartz under hydrogen at 6 cm/hr gave greater than 99.999% purity, although magnesium and silicon were not removed.
3. Blakemore (4) used several hundred zone passes through tellurium to attain extreme purity.

Multiple distillation has been used by several investigators (3-7) with and without zone refining:

1. Silvey *et al.* (8) found that distillation is very effective for purification of cadmium.
2. Aleksandrov and Verkin (9) used 15 zone passes at 15 mm/hr in agron.

Based on the above information and because the segregation coefficients (1, 10-12) of most impurities for solid-liquid purification (such as zone melting) of CdTe are of approximately 0.5 (magnesium = 1, aluminum > 1), purification by sublimation of CdTe was chosen. Zone refining would require that the material be subjected to a very large number of passes to remove the impurities. This would intensify the contamination problem because the melt would be in contact with the container at high temperatures for extended periods of time. Purification by sublimation is rapid, and less chance of container contamination exists; no melt is involved and sublimation temperatures are low. In addition, the compound recombines stoichiometrically according to the equation

$$CdTe_{(s)} \rightleftarrows Cd_{(g)} + \frac{1}{2} Te_{2(g)}$$

Therefore, any excess cadmium or tellurium is effectively segregated because the vapor pressure of both cadmium and tellurium is much higher than that of CdTe.

Purification by sublimation is based on a distribution equilibrium between the solid and gas phase. Impurities which are nonvolatile will be effectively segregated, and those which are volatile will be in equilibrium with the sublimate and condensate. Starting with the purest cadmium and tellurium available (99.9999% pure from Cominco), the components are reacted to form the compound CdTe and then sublimed to purify it. This is a one-step process which takes place in a closed evacuated tube (Fig. 2). When this technique is used, the starting material may consist of the compound CdTe or the pure elements cadmium and tellurium. In either case the material is placed in a long quartz tube which has been cleaned in electronic grade $HF-HNO_3$, washed in continuously deionized water in a closed system, and coated with pyrolytic carbon. The acid cleaned tubes, as well as the pyrolytic carbon coated tubes are continuously washed in this system until needed.

Once the tube is loaded, it is sealed off under a vacuum of 10^{-8} Torr. When using CdTe as the starting material, the pyrolytically coated tube is placed directly in the furnace so that the CdTe is in the flat zone of the temperature profile. The tube is withdrawn from the furnace at approximately 0.6 cm/hr. Excess cadmium or tellurium (which has a higher vapor pressure than CdTe) collects in the cool end of the tube, while CdTe collects in a much hotter sec-

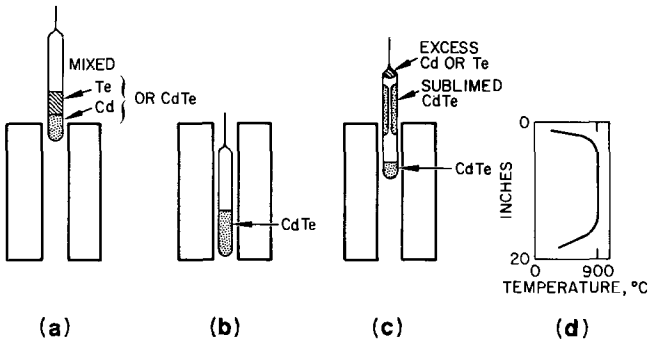

Fig. 2. Synthesis of CdTe and its purification by sublimation. (a) Cadmium and tellurium (or CdTe) are sealed in a pyrolytic carbon coated quartz tube and allowed to react. (b) The tube is lowered into the furnace. (c) The tube is slowly withdrawn from the furnace. (d) Temperature profile.

tion. Normally, two sublimations are sufficient for purification of the material.

When starting materials are cadmium and tellurium, near stoichiometric amounts are sealed at 10^{-8} Torr in a pyrolytically coated quartz tube. Initially, the tube is partially lowered into the furnace until the heat is sufficient to start the reaction between cadmium and tellurium. The reaction is exothermic and very rapid. When it stops, the tube is then lowered completely into the furnace and withdrawn at approximately 0.6 cm/hr, as mentioned.

For a series of sublimations, the tube sizes are graduated so that the coalesced material travels directly from one tube to another. No attempt is made to clean the material mechanically or chemically. This method also reduces the possibility of contamination by minimizing handling. In addition, the CdTe sublimate is heated in the sublimation tube under a hydrogen atmosphere to remove any oxides before the tube is sealed under vacuum. Removing the oxides prevents removal of the pyrolytic coating through reaction of the carbon with the oxides. If oxides are present, the quartz reacts with them, weakening the walls. (This has caused an implosion.) In addition, the CdTe is prevented from sticking to the quartz tube. It is important that molten material in crystal growth does not come into contact with the quartz container, since quartz has been found to be very soluble in CdTe and consequently a source of contamination. It has also been found that in spite of a heavy coating of pyrolytic carbon on the usual commercial quartz used for crystal growing, this coating did not stop impurities from coming through from the quartz although it was considerably reduced to approximately 20 ppma (parts per million atomic). Consequently, synthetic quartz, which has the lowest impurity content of any available quartz, is used to grow the crystals.

Mass spectrographic analysis (13) of crystals grown in synthetic quartz is tabulated in Table I. This is a typical impurity concentration in parts per million atomic for CdTe grown in synthetic quartz by the modified Bridgman technique. Impurities not shown were not detected, and thus have concentrations less than 0.1 ppma. Silicon, phosphorus, manganese, iron, nickel, copper, cesium, thorium, and uranium cannot be detected because they are interfered with by background lines of tellurium and cadmium. Emission spectrographic analysis was used to determine the concentrations of some of these elements, although giving only an upper limit.

The results of varying the cadmium pressure above the melt in commercial quartz containers in order to change the electrical properties of crystals grown by the modified Bridgman process were masked by the impurities from the quartz. Since beginning the use of synthetic quartz, the change in electrical properties has been observed as a function of cadmium pressure and the results have become reproducible.

Modified Bridgman system.—The Bridgman technique for growing CdTe has the advantages of producing uniform ingot size and more uniform distribution of impurities in the direction transverse to the direction of growth. The main disadvantage of the original Bridgman technique is that if the melt is not stoichiometric the composition of the melt changes continuously as solidification takes place, changing the composition of the solid as it grows. The change in composition of the melt affects the electrical properties of the crystal and causes the segregation coefficient of any dopants to change accordingly (10).

CdTe readily dissociates at high temperatures according to the equation

$$CdTe_{(l)} \rightleftarrows CdTe_{(g)} + \frac{1}{2} Te_{2(g)}$$

Therefore, growth of CdTe from the melt requires a closed system because of the dissociation and mass transport which occurs constantly through the vapor phase to lower temperature regions. The Bridgman method can be used to grow CdTe; however, the modified Bridgman method permits control over the composition of the crystal and consequently the electrical parameters.

In the modified Bridgman technique, the tube is elongated (Fig. 3) so that cadmium or tellurium can be placed in a reservoir high in the tube, where the

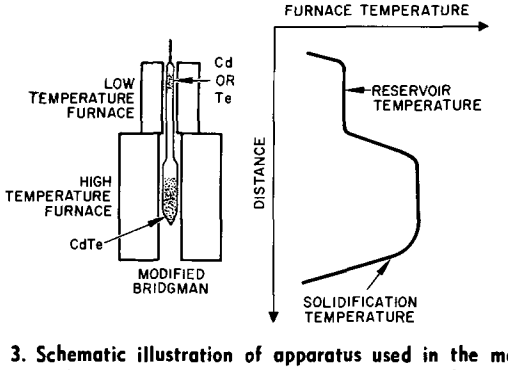

Fig. 3. Schematic illustration of apparatus used in the modified Bridgman technique for growth of single crystals, together with the temperature profile.

vapor pressure can be controlled by a second furnace operating significantly below the temperature of the crystal furnace. The pressure of one of the components above the melt effectively stops, or at least minimizes, vaporization of CdTe. Since this pressure is held constant, the composition of the melt and consequently that of the crystal is held constant. (In practice, the composition of the solid is determined by the composition of the solid-melt interface, which can be appreciably different from the average melt composition. However, in this system the solid-melt interface is also theoretically held constant, and thus the results are reproducible.) In addition, because the distribution coefficient of dopants is a function of the component pressure (10), it is also fixed. In theory, therefore, crystals of CdTe can be grown stoichiometrically, cadmium-rich or tellurium-rich, simply by changing the pressure of one of the components.

Equilibrium between vapor and liquid.—In the modified Bridgman technique, the vapor phase is in equilibrium with the liquid phase, which in turn, is in equilibrium with the solid phase. It is necessary to assume a model for the liquid which is equivalent to the normal crystalline model of the solid. Two types of models are used. One may be called the gas-like and the other the crystal-like model. In the gas-like model, the perfect liquid is assumed to consist of molecules and dissociation products of the molecules. Ionization may occur, which leads to additional imperfections. In the crystal-like model, the liquid is regarded as a crystal with an exceptionally large concentration of Schottky-Wagner or Frenkel-type defects. Intrinsic excitation and ionization are assumed to take place exactly as in a solid. Statistically, both models are equivalent and give the same results.

If α is defined as a defect in the liquid caused by addition of Cd_x (x indicates an uncharged atom in the liquid) and β is a defect in the liquid caused by the removal of Cd_x from the liquid, then

$$Cd_{(g)} \rightleftarrows Cd_{(l)} + \alpha$$

for small concentrations of α

$$K_1 = \frac{[\alpha]}{P_{Cd}} \qquad [1]$$

In addition

$$Cd_{(l)} \rightleftarrows Cd_{(g)} + \beta$$

for small concentrations of β

$$K_2 = [\beta][P_{Cd}] \qquad [2]$$

Under these conditions

$$K = P_{Cd}\, P_{Te}{}^{1/2} \qquad [3]$$

since

$$CdTe \rightleftarrows Cd_{(g)} + \frac{1}{2} Te_{2(g)}$$

Accordingly

$$[\alpha][\beta] = K_{\alpha\beta} \qquad [4]$$

or the composition of the liquid is a function of P_{Cd}.

Equilibrium between liquid and solid.—In the equilibrium between liquid and solid, reactions are needed to describe the transfer of atoms from one phase to another, as well as imperfections within each phase. Transfer of electrons or ions need not be considered because both phases remain neutral. If such particles are transferred, electrons and ions are transferred in equal concentrations, so that the final reactions may be expressed in terms of the transfer of neutral atoms and vacancies.

If a is a defect caused by removal of a tellurium atom from the solid and b is a defect caused by removal of a cadmium atom from the solid, then

$$M^x_{(s)} + \beta \rightleftarrows M^x_{(l)} + b$$

where M^x_s and M^x_l are un-ionized atoms in the solid and the liquid, respectively. For small concentrations of β and b

$$K_3 = \frac{b}{\beta} \qquad [5]$$

In addition

$$Te^x_{(s)} + \alpha \rightleftarrows Te^x_{(l)} + a$$

$$K_4 = \frac{[a]}{[\alpha]} \qquad [6]$$

and

$$[a][b] = K_{ab} \qquad [7]$$

Using [4], [5], and [6]

$$[a][b] = K_3 K_4 K_{\alpha\beta} = K_{ab}$$

The above theory was simplified by assuming that: (*i*) the liquid is always homogeneous; (*ii*) diffusion in the solid is slow, and thus the composition of the solid does not change after it has grown from the liquid; (*iii*) the gas phase equilibrium $CdTe_{(g)} \rightleftarrows Cd_{(g)} + (1/2)\ Te_{2(g)}$ is reached quickly, with CdTe molecules not present in any significant amounts; (*iv*) the distribution coefficients are constants which are independent of composition; and (*v*) the solid-liquid distribution is adjusted quickly. In the modified Bridgman system, the gas and solid phases are physically separated so that the liquid phase essentially acts as a communication medium, since the liquid phase composition is determined by the pressure of one of the CdTe components.

Optimum growth conditions.—Optimum growth conditions for producing large single crystals of CdTe (Fig. 4) were determined empirically by evaluating growth rate, crystal rotation, temperature gradients, and crystal size. Radioactive isotopes were especially useful in this evaluation because they revealed the shape of the solid-liquid interface during growth.

A primary problem in growing crystals from the melt is that of maintaining a shape convex (pointing in the direction of growth) or at least flat at the solid-liquid interface. This convex shape is obtained when the heat flows axially from the melt (*i.e.*, along the axis of growth) instead of radially. The convex isotherm formed under these conditions is considered ideal for single-crystal synthesis from the melt. If the solid-liquid interface becomes concave because of radial heat flow, the resultant cooling causes spurious nucleation. Radiotracer experiments indicate that our crystals are grown with a flat solid-liquid interface. In these experiments the melt was doped with radioactive indium (which was determined to have a segregation coefficient of 0.51 ± 0.04 under 1 atm cadmium). Under normal conditions an impurity is segre-

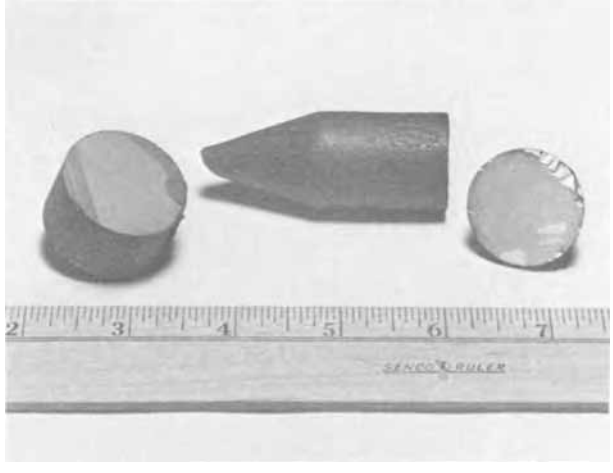

Fig. 4. Cadmium telluride crystals grown by the modified Bridgman technique, showing crystallinity.

gated uniformly from the growing crystal; by freezing in the indium at the solid-liquid interface at several points along the growth axis of the crystal, the shape of the interface could be determined by autoradiography.

As a result of these experiments, the following conditions for single-crystal growth are specified:

1. A sharp temperature gradient in the growth zone is necessary for an axial flow of heat. Crystals grown through a shallow gradient were invariably polycrystalline. We use a minimum gradient at the melting point of 20°C/cm.

2. A flat profile is required to minimize the radial flow of heat and thermal convection in the melt.

3. Slow growth is necessary to avoid rapid cooling of the surface, which would result in a concave solid-liquid interface. Thermal conductivity is the dominant factor determining growth rate. Therefore, for low thermal conductivity material, the growth must be slow. For CdTe, a concave shape was obtained for growth speeds much greater than 0.50 cm/hr. At speeds greater than 0.50 cm/hr the dislocation density [determined using the method of Inoue *et al.* (14) except that a 10% volume solution of bromine in methanol was used to chemically polish the material] rapidly goes into the thousands (Fig. 5). However, the rate which produces the least number of dislocations (in the order of 100/cm^2) is not the best rate for producing large single crystals for the seeds that form initially propagate linearly through the crystal along the growth axis, producing many crystals. The speed is too slow for one of the growing planes to dominate, so that large areas of a single-crystal material are produced. As a compromise, a speed of 0.25 to 0.50 cm/hr is used.

4. Large crystals of approximately 2.5 cm diameter minimize radial temperature fluctuations across the ingot by incorporating the properties of a large mass.

5. A large metal heat sink on the nose of the crystal assists in the axial flow of heat with subsequent statistical improvement in the number of single crystals, as compared with crystals grown without the heat sink.

Table II. Nondoped CdTe crystals grown under component atmosphere

Crystal number	Atmosphere	Pressure, atm	Resistivity, ohm-cm	Type	Electron mobility, M	Carrier concentration, N_h
12	Cd	1	10^7-10^9	—	—	—
14	Cd	1	10^5	—	—	—
16	Cd	1	10^7	—	—	—
17	Cd	1	10^6-10^8	—	—	—
11	Te	0.32	75-1300	p	—	—
5	Cd	2.6	4.6-1.7	n	957 997	1.4×10^{15} 3.8×10^{15}

6. The crystal must be rotated in asymmetrical furnaces. Rotation will smooth out the asymmetry of the furnace and also minimize radial fluctuations.

7. The solid-liquid interface can become concave if the melt temperature is well above the melting point of the material. A temperature of 5°-10°C above the melting point is ideal but not rigid.

8. The pressure of one of the components above the melt affects the crystallinity. In particular, when the cadmium pressure was much above or below 1 atm, the crystallinity degenerated. This may be related to Lorenz's work (15), which shows that for every set of fixed component pressures there are two points in phase-space where solid, liquid, and vapor are *in* equilibrium.

Relationship of crucible geometry to crystallinity.—In the Bridgman method the material is initially in the liquid state. As the material moves through the temperature gradient, chance nucleation takes place in the tip of the tube. There is no guarantee that nucleation will take place such that a 100% single crystal is formed each time. Seven different configurations of quartz crucibles were tested to determine whether the different methods of crystal nucleation and slopes of growth had any effect on the crystallinity of the material. Only one of the configurations offered any advantage in getting a single crystal start. This shape was a ball which grew into a neck constriction then expanded gradually into the big tube.

Defect chemistry of cadmium telluride.—The equations describing the reactions involving the various imperfections and the mass action relations resulting from it are given by de Nobel (1); they are used as a basis for the following discussion. The types of imperfections which appear in the solid and the manner in which their concentration varies with the preparation conditions depend on the energy levels of the imperfections and the values of the constants governing the reactions involving the various imperfections.

Pure cadmium telluride.—When CdTe is prepared under high cadmium pressure, cadmium is introduced into the crystal at interstitial sites (Cd_i), which ionize and give rise to an equal concentration of Cd_i^+ (cadmium atom which has lost an electron) and free electrons (n).[1] Decreasing the pressure lowers the electron concentration, until a transition point is reached in which the material changes from n- to p-type. This occurs when $(V_{Cd}') = (Cd_i^{\cdot})$ where (V_{Cd}') is a cadmium vacancy with a negative effective charge. Upon further reduction of the pressure, cadmium vacancies (V_{Cd}') dominate and the material becomes p-type.[2] The area of interest for high-resistivity material is where $(V_{Cd}') = (Cd_i^{\cdot})$. This transition range between n- and p-type is theoretically very narrow and thus is very sensitive to pressure changes.

Ingots No. 12, 14, 16, and 17 (Table II) were grown under a cadmium pressure of 1 atm, which corresponds empirically to the transition region discussed above. For comparison, ingots No. 5 and 11 were grown under

[1] High temperature measurements by Whelan and Shaw (16), Smith (17) and Zanio (18) indicate that the material is n-type due to the presence of a doubly ionized native donor (Cd^{++}).

[2] High-temperature measurements by F. T. J. Smith indicate that for compositions close to tellurium saturation the electrical properties are dominated by foreign impurities rather than by native defects.

Table III. Indium-doped CdTe crystals grown under component atmosphere and quenched or slow-cooled

Crystal number	Resistivity, ohm-cm	Indium, atoms/cm³	Cadmium atmosphere pressure, atm	Carrier concentration, N_h	Electron mobility, μ	Quench temperature, °C
21	10^7	2.4×10^{17}	1.0	—	—	>1000
22	10^8	2.5×10^{17}	1.0	—	—	>1000
24	10^7	2.5×10^{17}	1.0	—	—	>1000
25	10^5	5×10^{17}	1.0	—	—	>1000
01	10^5	1.9×10^{18}	2.1	—	—	>1000
23	0.93	2.5×10^{17}	1.0	—	—	<1000
02	0.63	2×10^{18}	2.1	1.64×10^{17}	603	Slow-cooled

a cadmium pressure of 2.6 atm and a tellurium atmosphere of 0.3 atm, respectively. All crystals were slow-cooled to room temperature during the growth process.

Cadmium telluride-indium.—When CdTe is doped with indium (a donor) and slowly cooled following solidification, the electrical properties of the crystal are determined predominantly by the amount of indium put in the crystal and the pressure of one of the components of the compound. If CdTe is doped with indium and rapidly cooled (quenched) from high temperatures, the electrical properties are no longer dominated by the indium content.

In the quenching process under an atmosphere of one of the components, it is assumed that all atomic positions of vacancies and foreign atoms remain unchanged, while only the electrons and holes are free to redistribute themselves over the crystal. Consequently, quenching under a high cadmium pressure would introduce cadmium interstitials as the dominant donor. As the pressure is lowered, the donor impurity (indium) becomes the dominant electron supplier. This n-type region ends at the cadmium pressure in which all electrons either recombine with holes or are trapped at deep-lying levels during the quenching process. The imperfections which trap electrons are thought to be V_{Cd}' centers.

As the cadmium pressure is lowered further, the V_{Cd}'' (cadmium vacancy with effective charge of -2) functions as a trap for the holes during the quenching process. The ionization energy of these V_{Cd}'' levels is too large to give appreciable conduction at room temperature. It is not clear whether these deep-lying energy levels consist of a double-negative charged cadmium vacancy or associates of cadmium vacancies with donors (1, 19, 20). However, the result is that the transition from n- to p-type material takes place over a wide range of atmospheres in which the crystal has an extremely high resistivity (Table III). The range showing low resistivity p-type conductivity is never reached. Consequently, high-resistivity material is obtained by this process without extremely critical limits on cadmium pressure, temperature of quench, rate of quench, or donor (indium) concentration. It is obvious that the high-temperature equilibrium state cannot be completely quenched, especially in our crystals with diameters on the order of 2.5 cm. However, the high-temperature disorder is maintained well enough that room-temperature resistivities are reasonably reproducible. If the cooling takes place slowly or if the quench occurs at a temperature that is too low, vacancies and foreign atoms are able to move to energetically more favorable positions; thus the Fermi level is no longer near the center of the forbidden energy zone, and something less than high-resistivity material is formed. This is evident in crystal 23, which was quenched at a lower temperature than the earlier ones.

A quantitative evaluation of quench temperature *vs.* electrical properties was made on crystal 25 (Fig. 6) in order to show more precisely the effect of quenching on large ingots. This crystal weighed 139g and had a diameter of 2.54 cm. The temperatures indicated in Fig. 6 are those along the ingot before it was removed rapidly from the furnace and allowed to air quench. The "distance, cm" gives the distance from the nose of the crystal that rods were taken from slices at that point and of the thickness indicated. This is in good agreement with the phase diagram (1), which indicates that indium-doped CdTe grown at a pressure of 1 atm should have high resistivity if it is quenched rapidly from 1000°C to room temperature.

According to the phase diagram, if the pressure of cadmium is lowered sufficiently, the indium-doped CdTe can be slow-cooled to room temperature and the result will still be high-resistivity material. It naturally followed that high-resistivity CdTe could be grown using the Bridgman process by adding an excess of tellurium to the melt with the indium. However, by this method the composition of the liquid is constantly changing as solidification takes place. Ingots 32, 35, and 39 (Table IV) grown by this method were slow-cooled or quenched. Ingots 37 and 38, grown by the modified Bridgman method, yielded similar results, as did ingot 34 which was solution grown (4:1 Te to Cd by weight).

Resistivity of rods taken transverse to ingots.—The resistivity of single-crystal rods from ingots grown under various conditions (Table V) was measured as a function of distance along the rods (Fig. 7). These rods were cut perpendicular to the growth axis of the crystal and had a cross-sectional area approximately

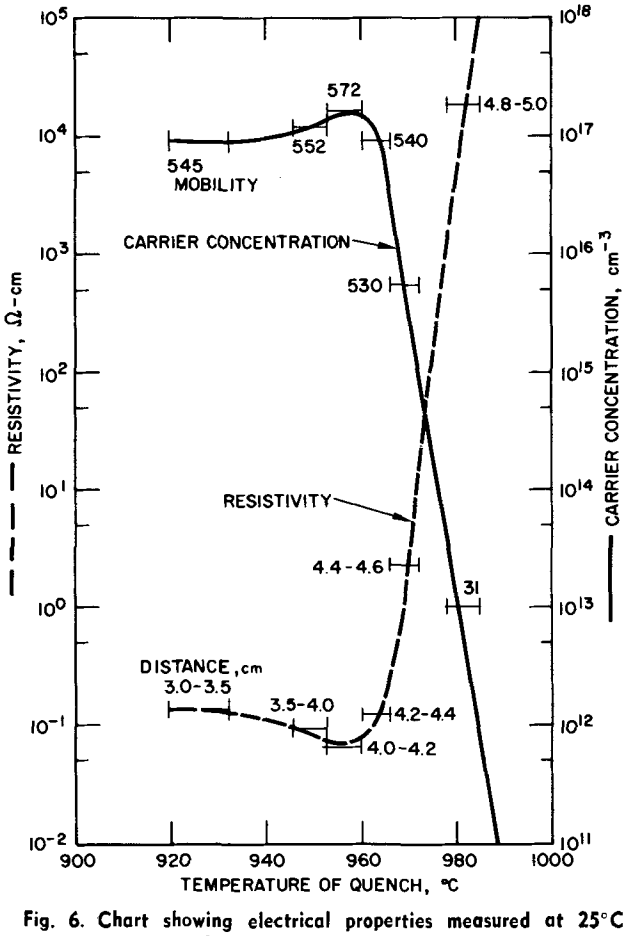

Fig. 6. Chart showing electrical properties measured at 25°C as a function of quench temperature.

Table IV. Indium-doped CdTe crystals grown with an excess of Te or under a Te atmopshere, slow-cooled or quenched

Crystal number	Indium, atoms/cm³	Weight CdTe, g	Weight Te (added), g	Resistivity, ohm-cm	Method of growth
39	3.6×10^{17}	174.41	3.41	10^5	Slow-cooled, Bridgman
35	1.7×10^{17}	135.54	2.68	10^8	Slow-cooled, Bridgman

37	2.5×10^{17}	307.6	Te atm = 0.84 atm	10^8-10^9	Slow-cooled, Bridgman
38	2.5×10^{17}	294.2	Te atm = 0.84 atm	10^6-10^7	Slow-cooled, Bridgman
34	7.8×10^{18}	58.4	91.3	10^5	Slow-cooled, solution

0.1 cm². They were cut from the ingots with a wire saw, polished in a 12% solution of bromine in methyl alcohol, and indium-silver electrical contacts made. CdTe polished in bromine-methyl alcohol does not show any of the surface conduction that has been observed with other polishing etchants. All resistivity measurements were made at room temperature in the absence of light and are precise to ±20%.

In Fig. 7, the rods show a wide variation in resistivity which at first glance may indicate great inhomogeneity. But at this level, the change in carrier concentration is extremely small. That is, a small change in carrier concentration can change the resistivity greatly. However, it is certain that this variation is due to different cooling rates between crystals as well as along a crystal. No two crystals were exactly the same size in dimension; *e.g.*, the weights varied from 150 to 300g. Also, the thickness of the quartz walls has a significant effect on the cooling rates. A more uniform distribution was achieved by growing very small, pencil-like crystals, or by heat-treating small volume pieces. However, since small crystals could not meet the requirements of the optical modulator, the emphasis has been on large crystals.

Discussion

The high-temperature quenching results for CdTe doped with indium are in good agreement with de Nobel's theory, especially considering that the ingots had diameters on the order of 2.5 cm and weighed approximately 300g. For the undoped crystals if they were pure, n-type material should be obtained at $P_{Cd} \sim 1$ atm according to the phase diagram. Since high-resistivity material is obtained at this pressure, it is obvious that the material is not really pure but that impurities are playing a role in obtaining the high-resistivity material.

Even if the material was pure, it is nearly impossible to grow a stoichiometric crystal with control of pressure since the pressure must be adjusted with temperature in order to stay on the stoichiometric line, if such conditions could be obtained in growing a crystal which must pass through a temperature gradient. For example, initially it would be easy to be in the high-resistivity range for the cadmium pressure range is 1.1 atm wide at 1000°C. As the temperature decreases to 700°C the stoichiometric line is only 1.28×10^{-3} atm wide. Thus a change in pressure of ±0.003 atm at 700°C would change the resistivity by a factor of 10^5. Even for solution growth in excess tellurium at 700°C high-resistivity pure cadmium telluride would be difficult to grow as the P_{Te_2} range is only 5×10^{-6} atm wide. On the other hand, a small amount of donor extends this range considerably. For example, at 1000°C the high-resistivity range is P_{Cd} 0.36 to 4.3 atm and at 700°C any cadmium pressure between 1.9×10^{-3} to 4.1×10^{-5} atm will give high-resistivity material. However, it would sublime before reaching 10^{-5} atm. Thus, for pure cadmium telluride there is no appreciable pressure range that will produce a small number of charge carriers. Whereas, for donor-doped CdTe there is a wide range in which the carrier concentration is extremely low. For acceptor-doped material, there occurs a change in conductivity from p- to n-type, but it also occurs without an appreciable width in which the charge carriers are very low.

Table V. Conditions of growth for crystals in Fig. 7

Crystal number	Indium, atoms/cm³	Atmosphere and pressure, atm	Method of cooling
22	2.5×10^{17}	Cd 1	Quenched
16	None	Cd 1	Slow-cooled
17 Nose	None	Cd 1	Slow-cooled
17 Tail	None	Cd 1	Slow-cooled
30	2.5×10^{17}	Cd 1	Quenched
32	2.5×10^{17}	Te 1	Quenched
29	2.5×10^{17}	Cd 1	Quenched

The modified Bridgman method was developed primarily to grow high-resistivity material for gamma detectors and optical modulators. It has been useful for growing material for the study of impact ionization (21) and superradiance (22) in CdTe where reproducibility is important. An example of this is in Fig. 8 in which $P_{Cd} = 0.8$ is plotted on a T-X diagram of the existence region. At this pressure the defect concentration as a function of temperature is given. If a donor is added to the melt, then the entire excess Te side becomes high resistivity. Reference to Fig. 8 also shows that if solution growth takes place on the excess cadmium side or excess tellurium side, retrograde solubility takes place. Thus as the crystal cools after growth, cadmium or tellurium atoms will have to precipitate out in the material. We have noticed that CdTe grown from cadmium solutions, tellurium solutions, and from the melt at 1 atm of cadmium pressure differ in the cell constant. For cadmium solution grown crystals a value of $a = 6.4794$Å was obtained. For tellurium solution, $a = 6.4823$Å and for melt growth at $P_{Cd} = 1$ atm, $a = 6.4805$Å.

Borsenberger *et al.* (23) and Woodbury *et al.* (24) suggest that the dominant Te defect is an electrical neutral interstitial defect which correlates with our increase in lattice size. An electrically neutral Te atom could fit in an interstitial site, causing an increase in cell size, easier than a negatively charged Te atom which is much larger. An antistructure configuration does not seem very logical in view of the difference in the atom sizes. Neither does the I-A or S-A structure seem possible. For the cadmium-rich side it is generally agreed by many authors that the dominant defect is a cadmium interstitial. A method currently

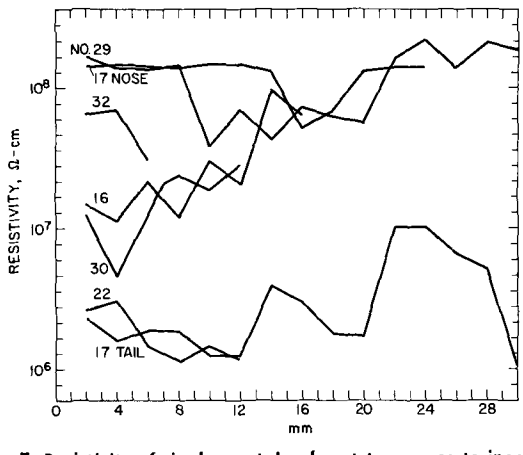

Fig. 7. Resistivity of single-crystal rods cut transverse to ingots

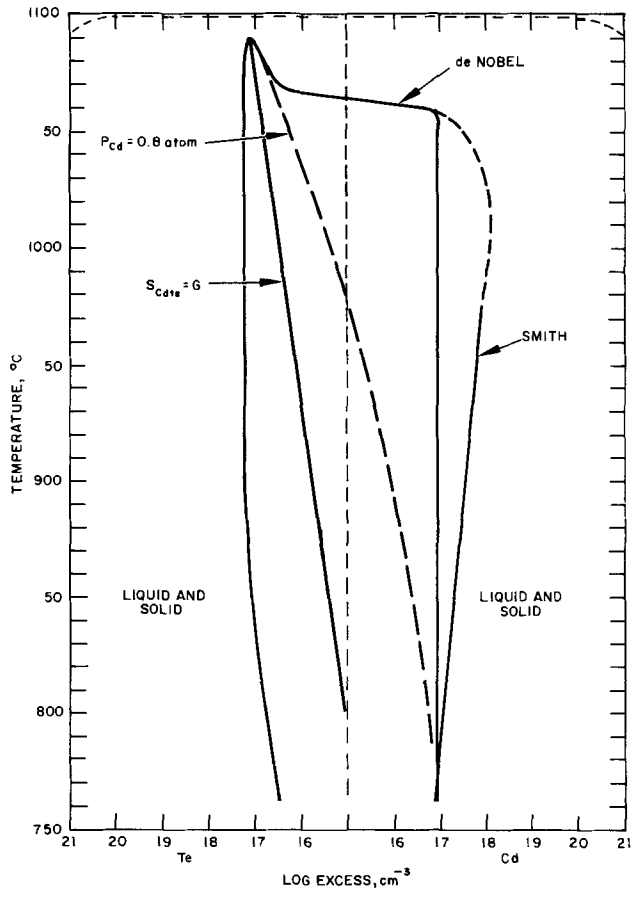

Fig. 8. Expanded phase diagram of CdTe

being investigated is vapor growth. The $S_{CdTe} = G$ line (Fig. 8) indicates that vapor growth takes place entirely in the existence region and depending on the temperature will approach stoichiometry. This method eliminates the high-temperature liquid phase, and bypasses the retrograde solubility curve with the added bonus of being low-temperature operational and self-purifying. As with any vapor growth, the greatest problem will be to make large single crystals. For gamma detector use the problem is not too severe, but for the optical modulator there is much to be done.

Acknowledgments

The author wishes to acknowledge the support of this work by the Atomic Energy Commission, the Office of Naval Research, The Air Force Flight Dynamics Laboratory, and particularly by the Hughes Research Laboratories. In addition, the assistance of Robert A. Walker in the preparation of the crystals is greatly appreciated.

Manuscript submitted Dec. 18, 1970; revised manuscript received *ca.* May 26, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Electrical Breakdown in Anodic Oxide Films on Zircaloy-2

N. Ramasubramanian* and T. Trottier

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

In Zircaloy-2/anodic oxide, 250 to 2500Å thick/gold structures, three types of electrical breakdown characteristics have been observed. By comparing the breakdown characteristics of oxide films grown on the alloy in the as-received condition and vacuum-cooled or quenched from the β phase conditions (Widmanstätten and martensitic type structures, respectively) it was possible to identify the location of a majority of the initial breakdown spots with that of a few of the second-phase particles.

A study of electrical breakdown in metal-insulator-metal structures is complimentary to electrical conductivity measurements. By suitable experimental procedures distinction can be made between the properties of weak spots in the insulator and those of the bulk (1). We have observed electrical switching in zirconia films, grown by thermal and anodic means on zirconium and a number of its alloys. Areas of impurity and intermetallic precipitates have been identified as

* Electrochemical Society Active Member.
Key words: Zircaloy-2, anodic oxide, second-phase particles, electrical breakdown.

localized paths for electron conduction in these oxide films (2). A study of the electrical breakdown characteristics of these films was undertaken to locate the weak spots present and to understand processes involved in the destruction and possible variations in behavior with changes in the oxide thickness. The results obtained on Zircaloy-2 are presented here.

Experimental

The hot-rolled Zircaloy-2 (Zr-1.5% Sn-0.1% Fe-0.1% Cr-0.05% Ni), *i.e.* as-received material was supplied by Wah Chang Corporation. Specimens 2 x 2 cm carrying a short stem were cut from 0.1 cm thick sheets, mechanically polished, pickled in a hydrofluoric-nitric acid mixture and washed in water. Some samples were given a heat treatment to produce different metallographic structures. These were either vacuum-cooled or water-quenched from the β phase to give Widmanstätten and martensitic type structures, respectively. Details of the technique can be found in a paper by Holt (3). Following the heat treatment the above procedure for surface preparation was followed.

Anodic oxide films were grown in saturated solutions of sodium nitrite and ammonium borate, 0.1% potassium hydroxide and 1*N* potassium nitrate solutions by fixed voltage anodization to various thicknesses. The maximum current density during a step was 1 mA/cm^2 and the current was allowed to decay to ~0.05 mA/cm^2. Oxygen evolution during the various anodizing steps was more vigorous (visual observation) on the heat-treated samples than on the as-received material. A growth constant of 28 Å/V was used for estimating the thicknesses (4). Gold counterelectrodes 3 and 6 mm in diameter and 1000-1500Å thick were evaporated through masks; in a single operation on four specimens at a time using a specimen to source distance of ~10 cm. Each specimen carried a minimum of four diodes. The diodes were tested in an evacuated, helium-filled tube and also in air on the stage of an optical microscope. The series resistance for measuring the current varied in the 10^2 to 10^4 ohm range. Conventional electronic equipment (Keithley electrometers and a Moseley x-y recorder) was used to trace the $i \times V$ curves and a Tektronix oscilloscope, Type 564 to trace $i \times t$ characteristics. The breakdown areas were examined on a scanning electron microscope.

Results

As-received Zircaloy-2.—Oxide films 250-2500Å thick were tested. The d-c resistivities of these films were $\geq 10^{12}$ ohm-cm. Their behavior could be broadly classified into three categories.

"Single-hole" breakdowns.—All the specimens tested (anodized to various voltages in the range 25-80V) showed "single-hole" breakdowns of the self-healing type (1), the first ones occurring at and above about 15V. In Fig. 1, $i \times V$ curves obtained is a typical case are shown; for the sake of clarity only a few of the tracings are included. The diode carrying a 50V (~1400Å) film was set up on the stage of an optical microscope. When the d-c voltage across the diode was gradually increased, a sudden current burst was observed at 37V and, simultaneously, light emission spots were seen on the gold surface. Microscopic examination showed the spots to be "single-hole" breakdowns where gold, oxide, and some of the alloy had been evaporated. The average frequency of the first spots to appear was 10/cm^2.

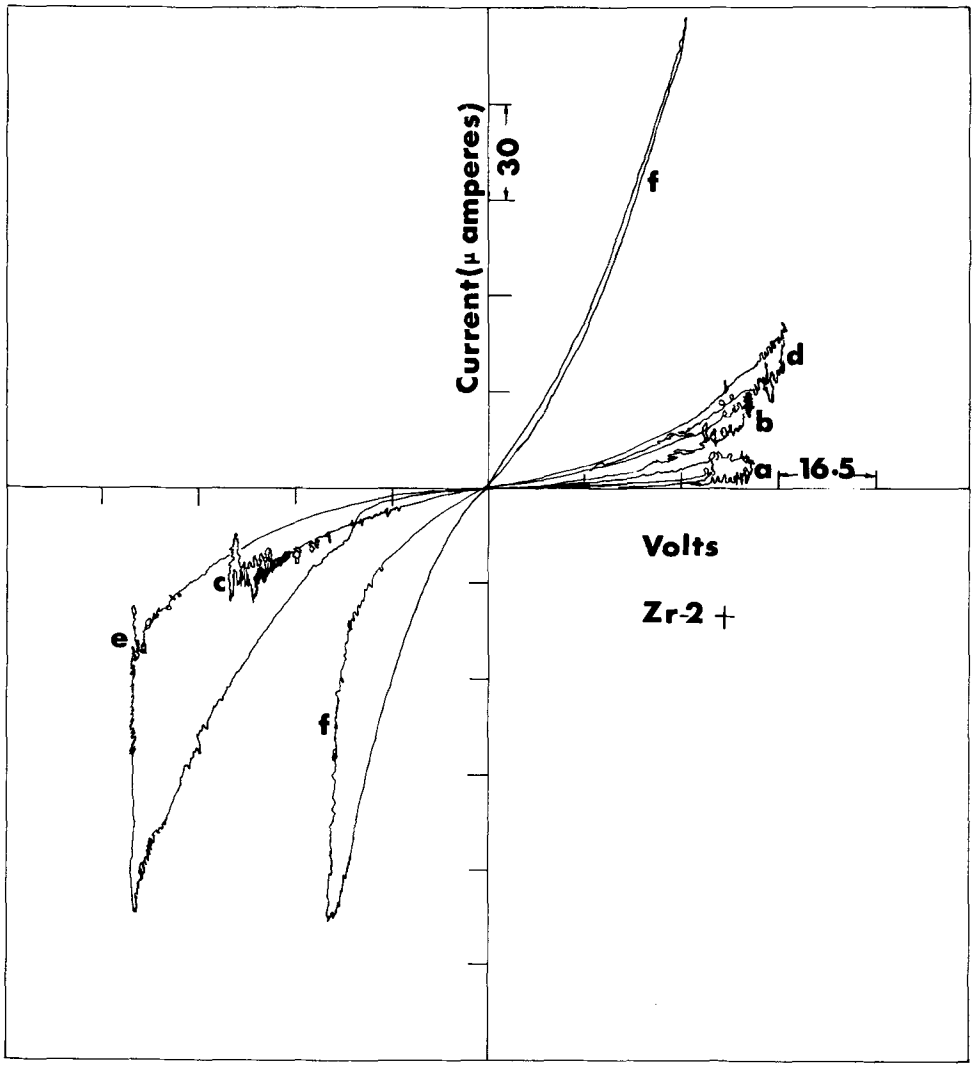

Fig. 1. Current bursts and increase in conductivity associated with "single-hole" breakdowns in Zircaloy-2/1400Å anodic oxide film, grown in KNO_3/gold (0.27 cm^2); tracing of x-y recorder plots: a, atmospheric conditions; b and c, in vacuum at room temperature: d, in helium at 190°K; and e and f, in helium at 80°K.

As the applied voltage was increased additional current bursts associated with light emission spots were observed and the current through the diode increased with the increasing number of breakdowns. The diode was then placed in the sample cell, evacuated and tested under vacuum at room temperature, then filled with helium and tested at 190 and 80°K. More breakdowns occurred over the range of 15-45V. The following characteristics were observed, in general, regarding the breakdowns and current bursts: (*i*) during a period when the applied voltage was being reduced current bursts and light emission still occurred, *i.e.* at lower voltages than during the preceding period of increasing applied voltage; (*ii*) similarly, during cathodic bias, breakdowns occurred at lower voltages than in the previous anodic step and vice versa and; (*iii*) the freshly produced breakdown spots spread in a radial fashion around a previously formed one.

The breakdown characteristics were all similar whether the test was carried out in atmospheric conditions, in vacuum at room temperature, or in helium at 80°-300°K. No effects of polarity on the Zircaloy was found. The impedance of the diode was checked on a GR 1680A automatic capacitance bridge at various stages during the testing. There were only small decreases in the capacitance readings, changing in the same fashion as the decrease in area of the gold electrode. The breakdowns were thus the self-healing "single-hole" type.

The micrographs of the breakdown areas and oscilloscope traces of the current rise during the breakdown are shown in Fig. 2. The breakdowns were mostly of the same size, 25 μm in diameter, and the density after a cycle similar to that in Fig. 1 was around $10^4/cm^2$. That a considerable amount of Zircaloy is evaporated during a breakdown is clearly evident from the scanning electron micrograph showing the ruffled structure of a light emission spot. The oscillogram was traced using a 560 ohm series resistance to measure the current. It is readily seen that the current bursts in the recorder tracings in Fig. 1 do not indicate the true current rises during breakdowns. The poor response of the electrometer to the speed of the process responsible for the current transients results in a mere jitter in recorder tracings. From the oscillogram a current density of 10^3 A/cm^2 during light emission, can be estimated assuming the area of current flow to be that of the whole breakdown region, and that the evaporated gold in that region was not destroyed (thus enabling the maximum current to be traced). The current rise and the fall to nearly half the maximum value occurred in a microsecond; a gradual fall to 5% of maximum occurred over 100 μsec.

Delayed breakdown.—With some diodes, carrying a 40-80V anodic oxide film, only the leakage current flow was detected at 80 and 190°K when applied potentials of both polarities were increased to near the forming voltage. Similarly at room temperature a positive bias on the alloy to near the forming voltage was without any influence on the current flow. Varying the time of holding at various applied voltages also did not result in any changes. But when the alloy was made negative to about 15V and held at that potential for ½ to 2 min current bursts associated with the appearance of a few light emission spots on the diode surface were noticed. The diode simultaneously became highly conducting. Breakdown areas had the same appearance as those shown in Fig. 2.

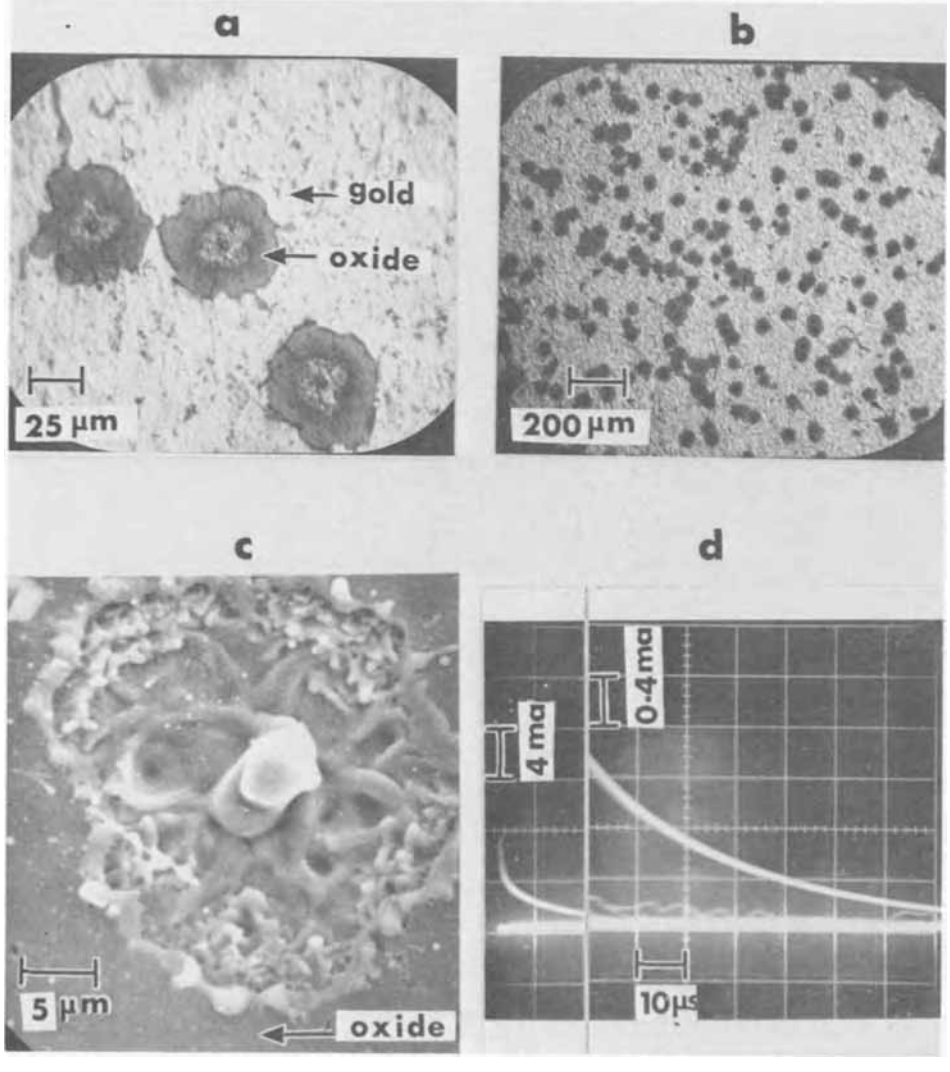

Fig. 2. Optical and scanning electron micrographs and current-time oscillograms of the single-hole breakdowns associated with the current bursts in Fig. 1. (a) First breakdown spots, (b) after tracing curve f in Fig. 1, (c) scanning electron micrograph of a breakdown and, (d) current transients during a breakdown.

Nondestructive breakdown.—This term is used to distinguish the current bursts which were not associated with any detectable microscopic changes on the gold surface from those involving "single-hole" breakdowns. The nondestructive breakdown was a chance occurrence and was detected only with a few diodes. In the temperature range of 80°-300°K these current bursts were observed at applied potentials of ±5 to 10V. With oxide films <750Å thick, the diodes invariably were highly conducting subsequently. The oscillograms of current rise were similar to that in Fig. 2 but the currents were two orders of magnitude less.

A total of 150 diodes distributed among 30 specimens were tested. The delayed type "single-hole" breakdowns were the most common; about 70% of the diodes exhibited this type. The nondestructive type of breakdown was a chance occurrence and was observed on ~10% of the diodes.

Heat-treated specimens.—Almost all the tin in the alloy is in solid solution in α zirconium in the as-received material. The alloying additions Fe, Cr, and Ni are precipitated as intermetallics of zirconium and are distributed uniformly through the alloy matrix in sizes ranging from ~0.5-2.5 μm in diameter. When the alloy is cooled in vacuum from the β phase (a nominal rate of 11°/sec from 1050°C), Widmanstätten morphology, with a parallel plate structure of α zirconium containing mostly tin in solid solution, is obtained. There is microsegregation of alloying additions; these are precipitated as intermetallics in between the α platelets. On quenching from the β phase a martensitic type structure results in which tin as well as the other alloying additions are in solution with no detectable microsegregation. An indication of a slight enrichment of iron at the grain boundaries was noticed in the electron microprobe analysis (3, 5).

In the as-received material carbon, phosphorus, and silicon are present in ppm quantities. These elements have very low solubilities in both the α and β phases of zirconium and probably exist as second-phase precipitates. These impurity precipitates, numbering about $10^3/mm^3$, are considered as the likely sites for nucleation of the α platelets (3).

Vacuum-cooled specimens.—A total of 30 diodes, the oxide thickness varying in the 1200-2500Å range, were tested. They all exhibited the delayed type of breakdown described previously. A typical set of data, $i \times V$ curves and scanning electron micrograph of one of the first breakdowns associated with the current bursts, is shown in Fig. 3. The potential across the diode was measured by direct connection to the oscilloscope's input; sample impedance was obviously higher than that of the scope's amplifier input and hence the larger current flow. The diode was first tested at 80° and 190°K; the Zircaloy was held for over 2 min at various potentials up to ±25V. Only the leakage current was measured. Then tracings in Fig. 3 were made at room temperature, the anodic bias being the first step. In the 13-19V region of negative bias on the alloy current bursts were observed following a waiting period of ~½ min at 13V. The gold surface showed two types of changes subsequent to the current bursts in the $i \times V$ tracing; a few darkened circular areas ~5 μm in diameter and a number of isolated "single-hole" breakdowns. The "single-hole" breakdowns were all centered on the boundaries between the α platelets.

The optical and scanning electron micrographs of the initial breakdowns in films of different thicknesses grown in 0.1% KOH solution are shown in Fig. 4. No variation of the breakdown voltage was found with changes in the anodizing voltage; all the initial breakdowns occurred when the alloy was biased negative to 18 ± 2V. The frequency of occurrence of these was on the average $10/cm^2$, same as that obtained with the as-received material. Isolated breakdowns were of the ordinary kind to be observed. The occurrence of a group of four or more breakdowns as shown in Fig. 4

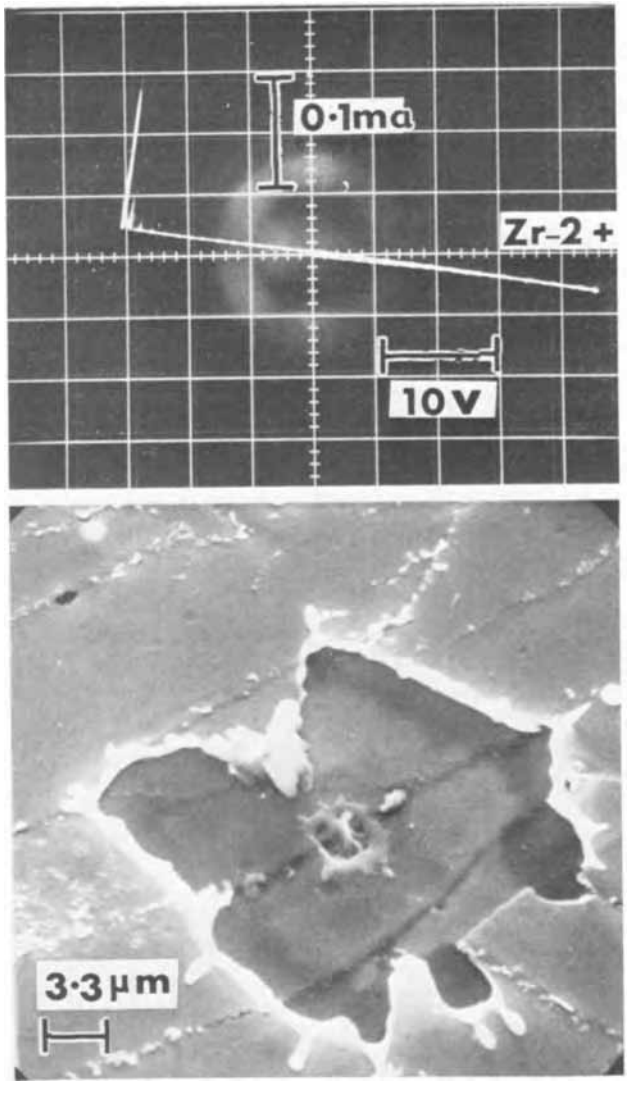

Fig. 3. Zircaloy-2 was vacuum cooled from the β phase (Widmanstätten morphology) and anodized to 80V in ammonium borate; current-voltage curves and scanning electron micrograph of one of the initial breakdowns when tested at atmospheric conditions.

(a) was uncommon and these forming any regular patterns was just accidental.

All these initial breakdowns (excepting a few which were located at the intersections of two or more boundaries) were centered on the boundaries between the α platelets.

The series resistance in the circuit influenced the occurrence or not of a breakdown. When this was of the order of a few hundred ohms, breakdowns occurred. However, when the resistance was ≥2K ohm the diodes invariably switched to a high conductivity ON state without resulting in any detectable changes on the gold surface. On turning the diodes OFF (high-impedance state) using a current pulse, breakdown spots were seen, centered on the boundaries between the α platelets.

In Fig. 5 scanning electron micrographs of vacuum-cooled samples in the pickled and anodized conditions are shown. Electrolytic anodization has resulted in the growth of porous oxide ridges along the α platelet boundaries. Films grown in nitrite solution showed extensive cracking along these oxide growths. However, the entire area along a boundary was not covered by these porous oxide growths; there were some portions where the anodic oxide growth had a similar appearance to that on the α platelet. The α platelet boundaries housing the segregated material are sites

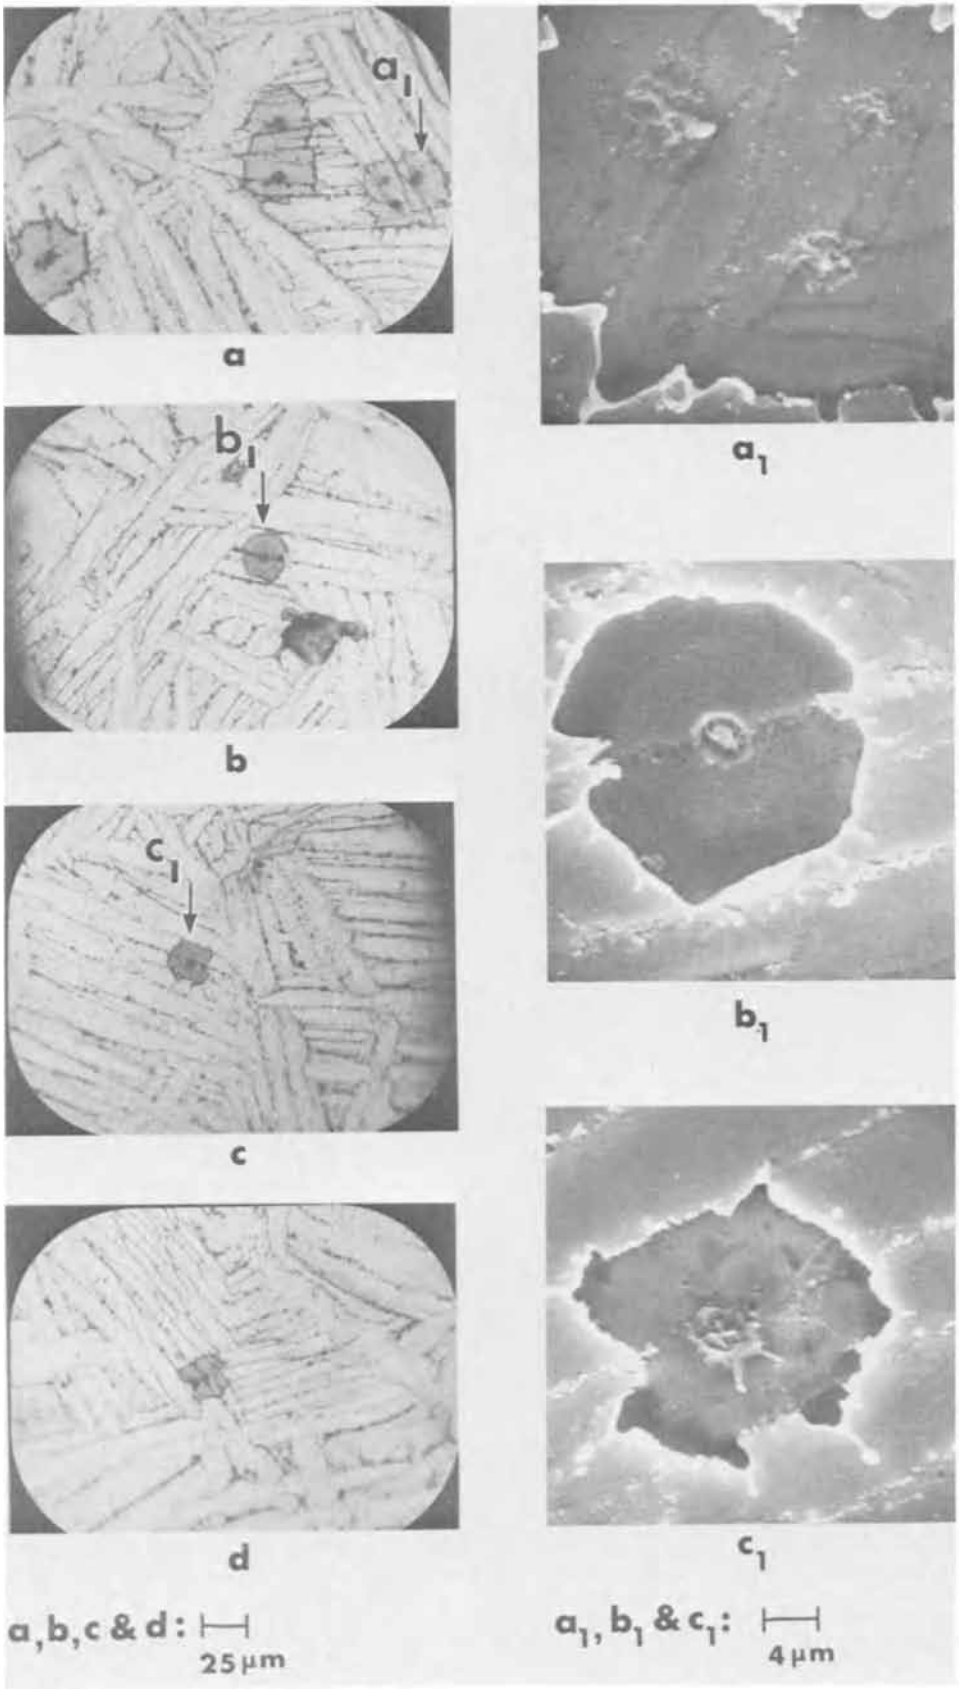

Fig. 4. Optical and scanning electron micrographs of initial electrical breakdowns in Zircaloy-2 (vacuum-cooled from the β phase)—anodic oxide grown in 0.1% KOH solution—gold structures; a, b, c and d—40, 50, 60, and 70V oxide films.

of heterogeneous oxide growth at lower anodizing voltages also is evident from Fig. 4.

Water-quenched specimens.—A typical set of data for a β-quenched sample tested at room temperature is shown in Fig. 6. After a holding time of 15 sec at −14V on the alloy current bursts were observed. Microscopic examination showed "single-hole" breakdowns with three out of a total of four located at the prior β grain boundaries.

With quenched samples a sensitivity towards nitrite and nitrate ions was noticed. The oxide films grown in $NaNO_2$ and KNO_3 solutions on these samples were highly heterogeneous with ridges of porous oxide growth. However, as in the case of as-received and vacuum-cooled samples, no specific correlation was

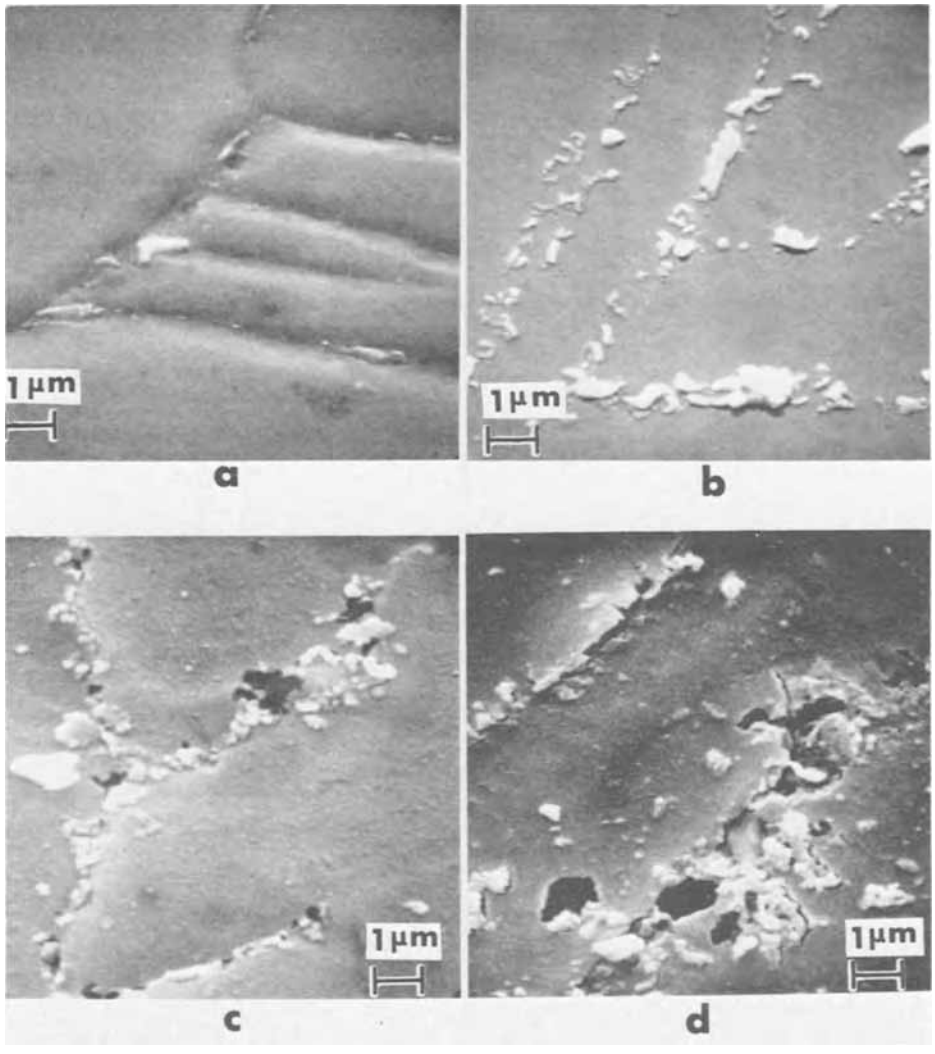

Fig. 5. Scanning electron micrographs of Zircaloy-2 vacuum-cooled from the β phase in (a) pickled and (b, c and d) anodized conditions; 80V films grown in (b) potassium hydroxide, (c) ammonium borate and, (d) sodium nitrite solutions.

found between the type of breakdown and the anodizing electrolyte used.

Discussion

Location of weak spots.—When the results obtained on the as-received and heat-treated materials are compared the advantages of using the Widmanstätten and martensitic type of structures for locating breakdown spots are obvious. In the as-received samples, because the second phase intermetallic and/or impurity precipitates are uniformly distributed and the breakdown areas are an order of magnitude larger in size (Fig. 7), it is difficult to identify the centers of the light emission and breakdown spots. In the case of oxide films on vacuum-cooled samples, there is a clear and definite indication that the boundaries between the α platelets are the location of first breakdowns. These boundaries house the second phase precipitates segregated during the nucleation and growth of the α platelets.

The composition and behavior towards anodization of the second phase particles in vacuum-cooled samples are likely to be different from those of the precipitates in the as-received material. However, the experimental observations, that the majority of the breakdowns in as-received material is the same delayed type as in the vacuum-cooled samples; that though the oxide films grown in nitrite and nitrate solutions are porous their breakdown characteristics are the same as those of the films grown in ammonium borate and potassium hydroxide; and that no systematic variation of breakdown voltage with oxide thickness is found, indicate the existence of a common source of weak spots in all cases. Moreover, in the case of anodic oxide films grown on the as-received material it has been shown that second phase precipitates are sites of localized electrochemical activity (2). Therefore, it is reasonable to assume that the conclusion reached in the case of vacuum-cooled samples regarding the delayed type of breakdown would be applicable to that of the as-received material also.

Areas of breakdown.—The intermetallic particles in Zircaloy-2 are either Zr-Fe-Ni or Zr-Fe-Cr phases. Information on the solid solubility of Fe, Ni, and Cr in zirconium oxide is not available and often the solubility in α zirconium is assumed to be applicable to the oxide case (6). In a detailed study on the growth of anodic oxide films on zirconium and Zircaloy-2, the importance of the oxide formed on the intermetallic particles in determining the current decay and leakage rate was pointed out by Cox (7). However, details regarding the nature of the oxide films formed on these particles and the mechanism of their growth are still largely in the speculative stage.

It is evident from Fig. 5 that thick porous oxide grows on the second phase particles in the α platelet boundaries during wet anodization. These boundaries for the most part are covered by such heterogeneous oxide growth. However, the average frequency of occurrence of the initial breakdowns is found to be only $\sim 10/cm^2$. Therefore it is unlikely that these porous oxides are the sites of first breakdowns. Moreover, in some experiments when the applied voltage was gradually increased the breakdowns occurring subsequent to the first ones were still isolated and their propagation along a boundary was not observed. Other than eliminating the possibility that the initial breakdowns occur in the pores of these oxide films, it is difficult at this stage, however, to correlate them with a specific type of oxide grown on the second-phase particles.

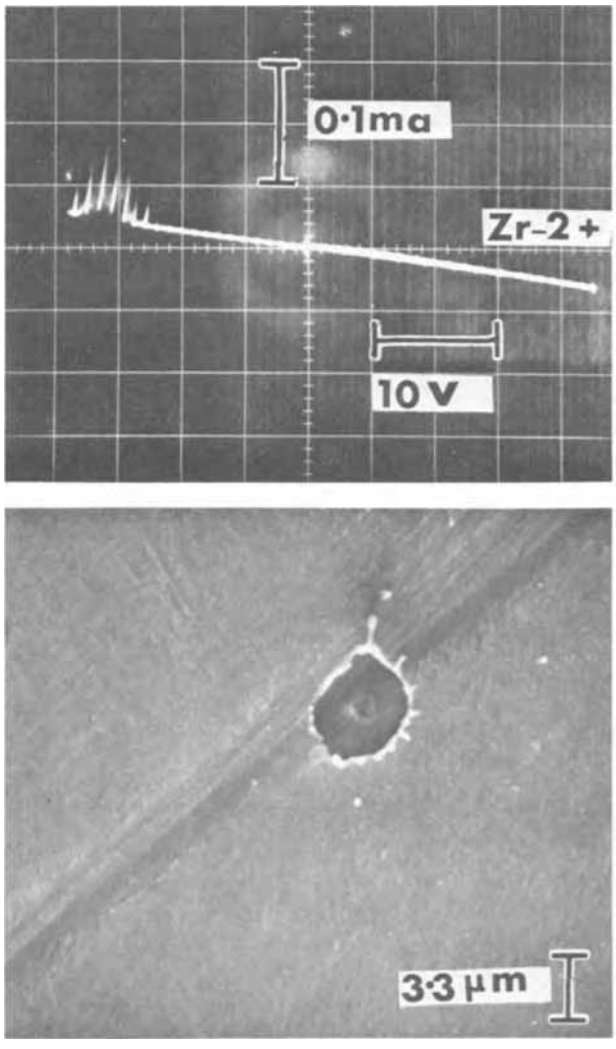

Fig. 6. β quenched Zircaloy-2 anodized in ammonium borate to 80V and tested at room temperature; current-voltage curves and scanning electron micrograph of one of the breakdowns.

Mechanism of breakdown.—The breakdown of these oxide films on the second phase precipitates is then considered to occur in two stages following the model suggested by Klein (1). A conducting channel is formed, which becomes thermally unstable, and triggers the breakdown by the discharge of the stored electrostatic energy. The "single-hole" and the nondestructive types of breakdown are obviously electronic in origin because they occur at liquid nitrogen and higher temperatures. The delayed breakdown does not occur at temperatures $<<300°K$ and is facilitated by a negative bias on the alloy. These characteristics and the necessity of a holding time indicate that an additional step of ionic migration is involved prior to the conducting channel formation. It is not clear at present, where the former two types of breakdowns occur in the as-received material.

During "single-hole" breakdowns in silicon dioxide breakdown spot current densities up to 10^{10} A/cm^2 have been estimated by Klein (1). Therefore the low current density of 10^3 A/cm^2 obtained in the present study might be due to two causes, *viz.* (*a*) gold at the breakdown site has partly evaporated and only part of the maximum current attained was recorded on the oscillogram and (*b*) the area of current flow at the instant of breakdown was smaller than the area observed subsequently. However, the conductivity change observed here agrees with that of Budenstein and Hayes (8) who reported in the case of silicon monoxide a change by a factor of 10^{10}. In this investigation a factor of 10^{11} is calculated for the rise in conductivity at the breakdown spot.

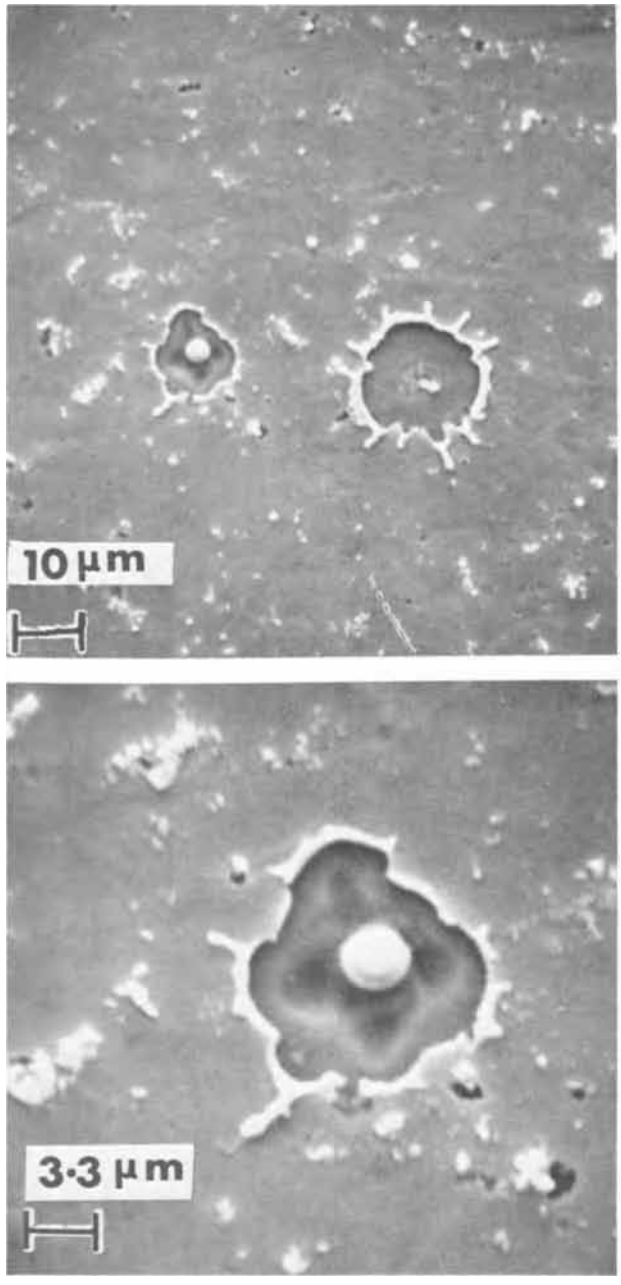

Fig. 7. Scanning electron micrographs of breakdowns in Zircaloy-2 (as-received material)—50V anodic oxide film grown in ammonium borate—gold structures.

Conclusions

Three different types of electrical breakdown are observed in anodic oxide films on Zircaloy-2: "single-hole" type at 80°-300°K associated with light emission and evaporation of the gold electrode, oxide and alloy material; delayed type at 300°K, the easy direction is with the alloy negative; nondestructive type at 80°-300°K and low voltages, without any evaporation of materials.

In oxide films grown on the as-received Zircaloy-2, more than 70% of the initial breakdowns is of the delayed type; these spots are identified with the location of a few of the second-phase precipitates in the alloy.

Acknowledgments

The authors wish to express their thanks to Mr. H. J. Arnal for his assistance with the scanning electron microscope and Dr. B. Cox for his encouragement and discussions.

The Chemical Polishing and Etch Pitting of Sapphire

R. G. Vardiman

Metallurgy Division, U. S. Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

Three dislocation etchants, H_3PO_4, KOH, and $KHSO_4$, and two chemical polishes, H_3PO_4 and $Na_2B_4O_7$ have been investigated as to their effective temperature and orientation ranges on sapphire. In addition the etchants are compared for effectiveness of dislocation pitting. It is found that the best pitting is obtained with $KHSO_4$ on the $\{2\bar{1}\bar{1}0\}$ plane, and KOH on the (0001) plane.

Sapphire (single crystal α-aluminum oxide) is an important and widely used material in modern technology. Characterization of its crystalline defects—in particular determination of the dislocation structure—is increasingly important in electronic, as well as mechanical applications. For those interested in observing the dislocation structure of sapphire by etch pitting, its high resistance to chemical attack creates some difficulties. Only a few etchants have been found which develop pits at dislocation sites, and these function only at rather high temperatures. They are further restricted as to their effective orientation range, although this has been defined in only one case (1).

The best known etchant for sapphire is phosphoric acid (H_3PO_4). Scheuplein and Gibbs (1) found dislocation pits for two types of sapphire surface orientations: within a few degrees of the basal plane (0001) at 320°C, and in the region of the $\{1\bar{1}01\}$ to $\{1\bar{1}02\}$ planes[1] at 375°C. Barber and Tighe (2) found that polishing and etching in phosphoric acid were highly temperature dependent; polishing for various planes occurred about 50°C above the etching temperature. They also used hot concentrated potassium hydroxide (KOH) for etching the basal plane. They observed that with both etchants the dislocation structure was often incompletely developed in subgrain boundaries. Alford and Stephens (3) used potassium bisulfate ($KHSO_4$) at 675°C to develop etch pits on the basal (0001) and prismatic $\{2\bar{1}\bar{1}0\}$ planes.

A number of chemical polishes have been reported. Besides the above mentioned phosphoric acid (2, 3), they include borax (4, 5) vanadium pentoxide (6), and potassium aluminum fluoride (3). Again, applicable orientation ranges are not well defined.

The present work compares the utility of the above three etches (H_3PO_4, $KHSO_4$, and KOH) in examining the dislocation structure of sapphire, as well as determining their effective orientation and temperature ranges. In addition, the polishing ranges of phosphoric acid and borax have been investigated.

Experimental Methods

Etching and polishing effects for specific planes were examined on sectioned rods or oriented disks obtained from Union Carbide or Hugo Keller Company. Orientation boundaries of etched or polished regions were determined by comparison of optical observations with Laue back-reflection x-rays on ⅜ in. diam spheres (obtained from Insaco). Although this method permits boundary positions to be defined to ±1°, there are two possible sources of variation. First, the distinction between adequate and inadequate etching or polishing represents a subjective judgment. Second, the boundary position may be a function of etching time and the procedure employed. To minimize this latter problem, all boundaries shown in this study define areas which appear adequately etched or polished after preheating the specimen in air and immersing it in the reagent for 3 min. Temperatures were measured with a chromel-alumel thermocouple, and were controlled to ±5°C. The handling of the various reagents is discussed in later sections.

With regard to the crystallography of sapphire, the hexagonal structural unit cell (7) ($c/a=2.73$) is used in this paper. Since the sapphire lattice has only threefold symmetry (Laue class $\bar{3}$m), some confusion is possible with the use of hexagonal indices. Therefore, orientation effects will be shown on stereographic triangles with strong x-ray reflections marked and indexed. This will distinguish between planes, such as $(10\bar{1}2)$ and $(1\bar{1}02)$, which have similar indices but are not identical as in the hexagonal system. As a guide to the stereographic triangles, some useful interplanar angles, as calculated from a computer program (8), are given in Table I.

X-ray topography was used as a check on the dislocation etching. Good resolution was obtained on the (0001) surface with the Berg-Barrett technique as described by Newkirk (9). With Cr radiation, the operative reflection on this case is $\{2\bar{1}\bar{1}6\}$.

Table I. Selected interplanar angles for sapphire ($c/a=2.73$)

	(0001)	$(2\bar{1}\bar{1}0)$	$(10\bar{1}2)$
$(1\bar{1}01)$	72.4°	34.4°	55.6°
$(1\bar{1}04)$	38.2°	—	47.0°
$(10\bar{1}2)$	57.6°	43.0°	—
$(2\bar{1}\bar{1}3)$	61.2°	28.8°	—

Key words: aluminum oxide, sapphire, dislocation, etch pits.

[1] Hexagonal structural unit cell, as used in this paper.

Surface Preparation

Mechanical polish.—All specimens obtained for this investigation had been initially mechanically polished in fine diamond paste to a scratch-free appearance. However, after treatment with one of the etchants (none of which dissolve sapphire at an appreciable rate at etching temperatures) the surface showed a highly scratched appearance. This effect has been noted by others (6). Hockey (10) has shown that after fine polishing, the surface is highly distorted and has a high dislocation density. Apparently this layer, less than 1μ thick, can be dissolved by the hot etchants to expose a surface which shows the effects of previous coarse grinding and polishing.

The simplest way to eliminate this effect is to vacuum anneal the specimen at about 1700°C for 2-3 hr. Some evaporation occurs during this treatment, and the resulting surface is sufficiently strain free that no scratch marks develop during etching. Only surfaces near the basal orientation are inappropriate for this treatment, as they tend to develop pits during evaporation.

Chemical polish.—The high temperature anneal described above is inappropriate for experiments involving nonequilibrium dislocation distribution. In this case, and also when the initial surface is not smooth, it is necessary to use a chemical polish which re-

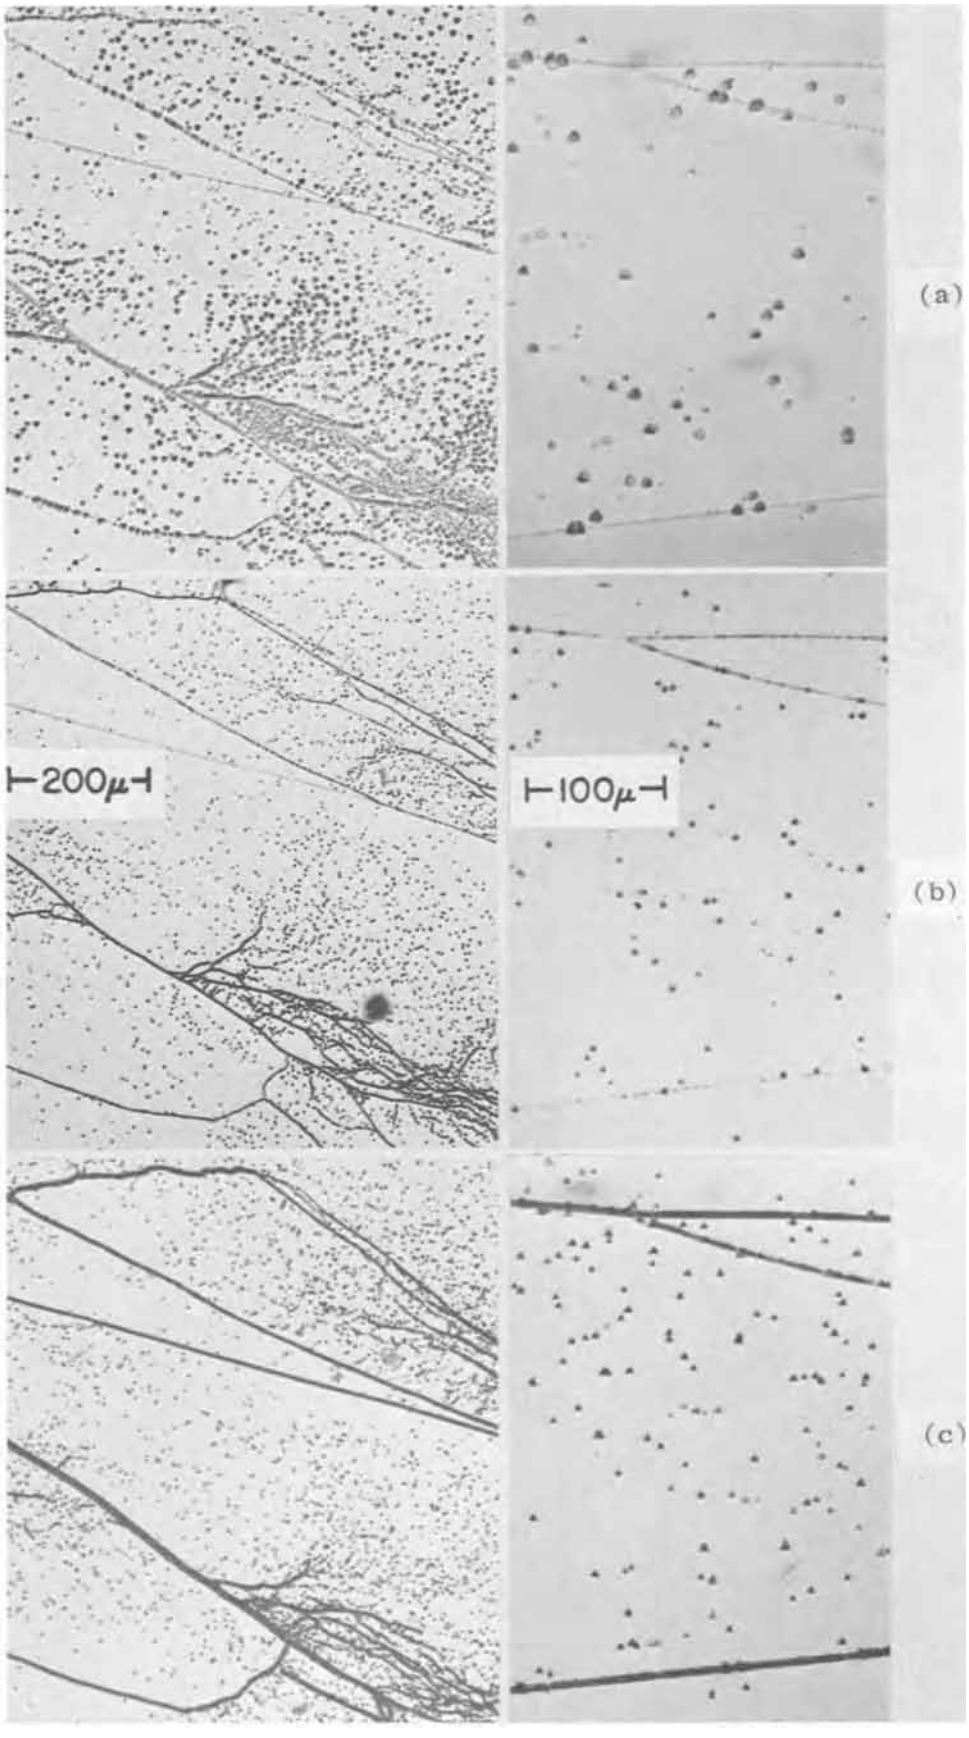

Fig. 6. (0001) surface of sapphire, etched 3 min in (a) phosphoric acid at 325°C; (b) potassium bisulfate at 500°C; and (c) potassium hydroxide at 350°C. Polished in phosphoric acid between etches.

moves material at a moderate rate. For most orientations (Fig. 1) good results can be obtained with molten sodium tetraborate, $Na_2B_4O_7$ (borax), above 800°C (5). The borax is melted in a platinum crucible. Material adhering to the specimen after polishing is then dissolved in boiling water, and any remaining surface film can be removed in dilute HCl. The dissolution rate of sapphire in borax varies little with orien-

tation, and the resulting surface is microscopically smooth, except for orientations where pitting or roughness develops. These are principally the area near the (0001) plane and a larger area around the $\{2\bar{1}\bar{1}0\}$ plane, as shown in Fig. 1.

For polishing (0001) surfaces, one may use concentrated phosphoric acid (85%) at 420°C (3). The rate of attack of this acid is highly orientation dependent. Figure 2 shows the orientation range of polished surfaces at 420°C. Remaining orientations show little evidence of attack (except for pitting). Because reaction products may adhere strongly to the surface at this temperature, the specimen must be vigorously agitated. Using a large volume of acid (200-300 cc) for polishing is also helpful in this respect. Because of chemical changes, fresh acid should be used for each treatment. At these temperatures a Pyrex beaker may be used, but must be changed frequently due to the slow attack of the acid. Higher temperatures might extend the orientation range of polishing (2), but would require a forced-flow apparatus such as that described in Ref. (11).

Dislocation Etchants

We will describe here the orientation and temperature effects of the three etchants, and the manner of their use. In the next section we will discuss the quality of pitting at various orientations, and the utility of each etchant for determining the dislocation structure.

Phosphoric acid.—Pitting with this etch is highly temperature dependent. The basal plane etches at 320°C. Etching in an area near $(1\bar{1}04)$ begins at about 335°C, and as the temperature is increased, the etched region extends towards $(1\bar{1}01)$. The extent of the well-etched areas at 350°C and 420°C are shown in Fig. 3. At 420°C, the basal plane polishes (see preceding section) whereas the region around $(1\bar{1}04)$ is simply overetched. Longer times or higher temperatures extend the 420°C area toward $(2\bar{1}\bar{1}0)$ (see Fig. 7b). The precautions given in the remarks on polishing apply in using phosphoric acid as an etch above 400°C.

Potassium bisulfate.—A relatively easy etch to use, a small amount may be melted in a platinum crucible, and renewed when necessary with additions of sulfuric acid and $KHSO_4$ while cool. Little general dissolution of the sapphire is found with this reagent. The extent of the etched regions around the basal and prismatic planes at 550°C is shown in Fig. 4. Adequate etching can be obtained at this temperature for both orientations, but the basal plane pitting is more easily controlled at 500°C, while it is helpful to go to 600°C for the prismatic area. Boundaries of the etched regions are not particularly temperature dependent.

Potassium hydroxide.—This etch was prepared by adding KOH crystals to a concentrated aqueous solution until boiling no longer occurred at 350°C. Etched regions observed with this concentration of reagent are shown in Fig. 5. Little etching is observed below 320°C. However, the small area near $(2\bar{1}\bar{1}3)$ which etches below 300°C, can be very useful, since the axes of many Verneuil-grown boules fall in this region. Large areas suddenly develop pits around 325°C, but in most of these the pits cannot be identified with the dislocation structure. The exception is the area along (0001)-$(1\bar{1}04)$, where sharp triangular pits develop well around 335°C (see Fig. 6c), although they are weakly developed even below 320°C. There are two centers to this region where the pits are equilateral, at (0001) and near $(1\bar{1}04)$.

Etching-Comparison

Although dislocation etchants have not been found for a substantial portion of the orientations as shown by the stereographic triangles of Fig. 3-5, the areas which can be etched allow a determination of the complete dislocation structure of most crystals, and the examination of any potential slip plane. Not all of the etchants are equally good, however, and a comparison of the pitting on the basal and prismatic planes, where more than one etchant may be employed, is instructive.

(0001).—All three etchants develop dislocation pits on the basal plane. In Fig. 6, the same areas have been etched with each reagent after repolishing. Both H_3PO_4 6(a) and $KHSO_4$ 6(b) show areas of incomplete etching. This is particularly noticeable in certain sub-boundaries, as has been observed previously (2) for H_3PO_4. A substantial improvement is seen for KOH, Fig. 6(c). Here, pit size is much more uniform, and most sub-boundaries are completely pitted. Incomplete etching is also found in the $\{1\bar{1}01\}$-$\{1\bar{1}04\}$ area for phosphoric acid. It is possible that this is partly an impurity effect, and might not be observed in sapphire of different origin. Nevertheless, these data indicate that KOH would be the etchant of choice for the (0001)-$(1\bar{1}04)$ orientation range.

$\{2\bar{1}\bar{1}0\}$.—Although borax and phosphoric acid pit this plane, the results are not entirely satisfactory, as may be seen in Fig. 7. The borax pits 7(a) are shallow and poorly defined, while the phosphoric acid pits 7(b) are elongated and uneven in size. The clear superiority of potassium bisulfate is shown in Fig. 7(c). No gaps show in the sub-boundaries, and pit size is even more uniform than for KOH on the basal plane (Fig. 6c). Since a $\{2\bar{1}\bar{1}0\}$ plane may be found to intersect basal, pyramidal, and prismatic slip planes, this combination of plane and etchant is recommended where only one surface is to be examined.

Discussion and Conclusion

The similarity of the etching patterns in Fig. 6 indicates that these etchants produce pits only at dislocation sites. Repeated etching by H_3PO_4 on the basal plane and $KHSO_4$ on the prismatic plane show no change in the pit pattern or increase in the number of pits. Finally, a comparison of an x-ray topograph of the basal surface with the etch pit pattern produced by KOH on the same area in Fig. 8 shows a satisfactory correspondence. Whether all dislocation sites pit is

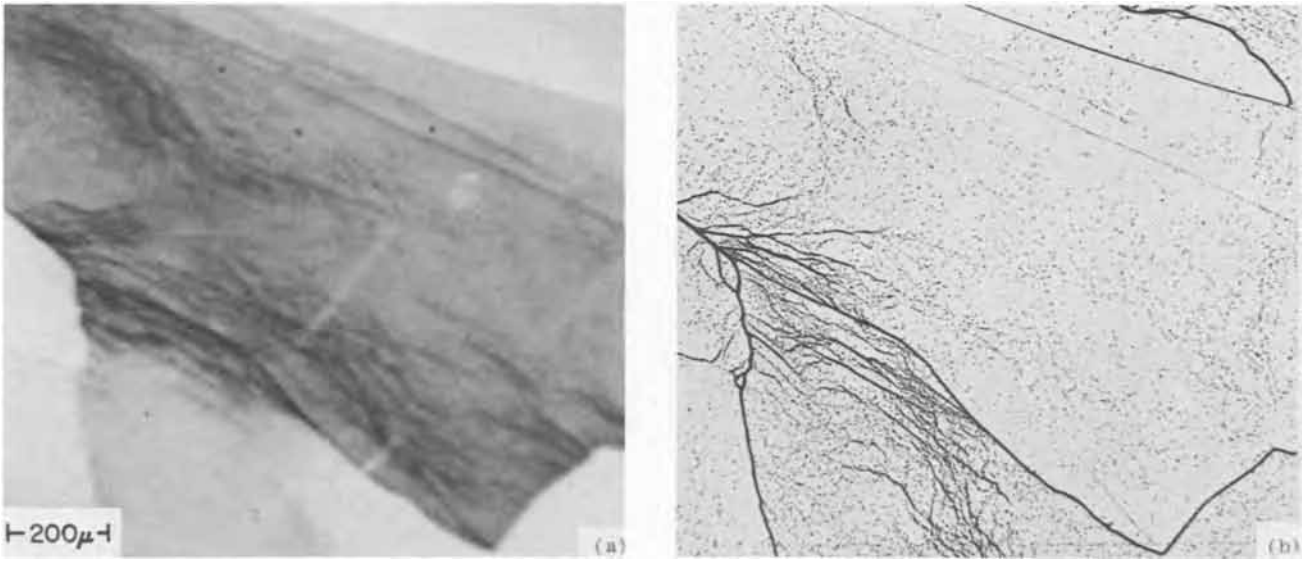

Fig. 8. (0001) surface of sapphire; (a) Berg-Barret x-ray micrograph, $\{2\bar{1}\bar{1}6\}$ reflection; (b) optical micrograph, etched 3 min in KOH at 350°C.

more difficult to determine. However, comparing Fig. 6 and 7, it would seem that uniformity of pit size and continuity in the sub-boundaries are good guides to an etchant's reliability. From this point of view, the dislocation structure of sapphire may be accurately determined by etch pitting with potassium hydroxide on planes in the range (0001)-{$1\bar{1}04$}, and by potassium bisulfate on planes in the vicinity of {$2\bar{1}\bar{1}0$}.

Acknowledgments

I wish to thank C. L. Vold, who made a number of x-ray topographs for these studies, and Dr. R. A. Meussner, who gave a very helpful critique of the manuscript. This work was supported by the Office of Naval Research and the Naval Air Systems Command.

The Morphology of Electrolytic Breakdown Products in Anodic Films on Silicon

J. Zahavi,[1] I. A. Blech, and J. Yahalom

Department of Materials Engineering, Technion—Israel Institute of Technology, Haifa, Israel

ABSTRACT

The local electrolytic breakdown regions in p-type Si were investigated. Large amounts of brittle material in the form of hills were seen to form during the breakdown. The material is amorphous, probably $SiO_2 \cdot (H_2O)_x$. The hills are severely cracked and have a residual tensile stress.

The morphology and crystallization of anodic oxide films under electrolytic breakdown voltage were previously reported for aluminum, tantalum, and titanium (1,2). It was found that the electrolytic breakdown of anodic films of aluminum and tantalum was associated with crystallization, whereas in titanium a crater-like morphology with a polycrystalline structure was revealed (1, 2). Vermilyea (3, 4) has found that some crystallization of tantalum anodic oxide films is observable after certain periods, depending on the anodizing conditions.

The structure and the effect of electrolytic breakdown of anodic oxide films on silicon were considered by some authors (5, 6). Schmidt and Owen (5) found that anodic films grown on silicon in phosphoric acid were of three types: completely structureless nonporous films, films with round spots of increased film thickness and films with round holes. Schmidt and Michel (6) found that electrolytic breakdown of anodic oxide films in p-type silicon was associated with severe damage to the oxides, when the voltage started to oscillate without rising any further. The present work is concerned with the morphology and structure of anodic films on silicon under electrolytic breakdown.

Key words: electrolytic breakdown, breakdown, silicon, silicon oxide.

Experimental Results

A (111) oriented p-type silicon wafer (~0.015 ohm-cm) was anodized in 0.8% and 80% wt H_2SO_4 without stirring at a constant current density of 20 mA/cm^2. The anodizing circuit has been described previously (7). In the concentrated solution, the cell emf increased with time, reached a value of 52V in about 10 sec, then dropped to 36V in another 10 sec, climbed slowly (24 sec) to 38V, after which it remained substantially constant (Fig. 1).

The cell emf in the dilute solution can also be seen in Fig. 1. The forming emf increased quickly (~2 sec) to 22V and more gradually to 70V in 8 min. During the next 12 min it dropped to 45V and then remained almost constant with a very slight decrease. No distinct breakdown voltage could be defined.

Anodizing for shorter periods than the first breaking point of the curve in Fig. 1 caused no apparent change

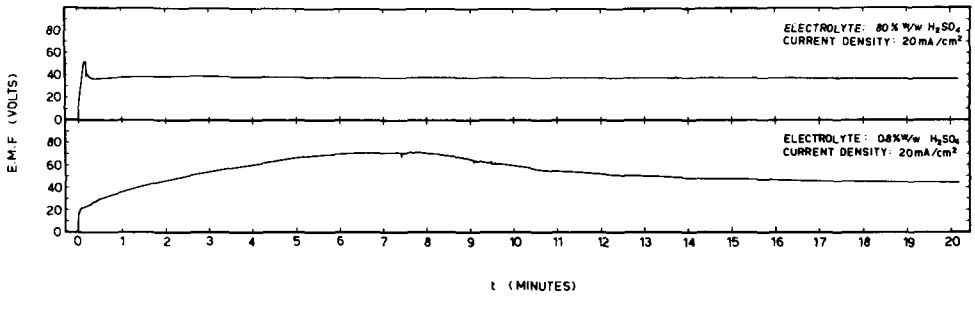

Fig. 1. Cell voltage transients during anodizing.

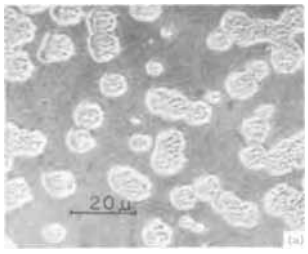

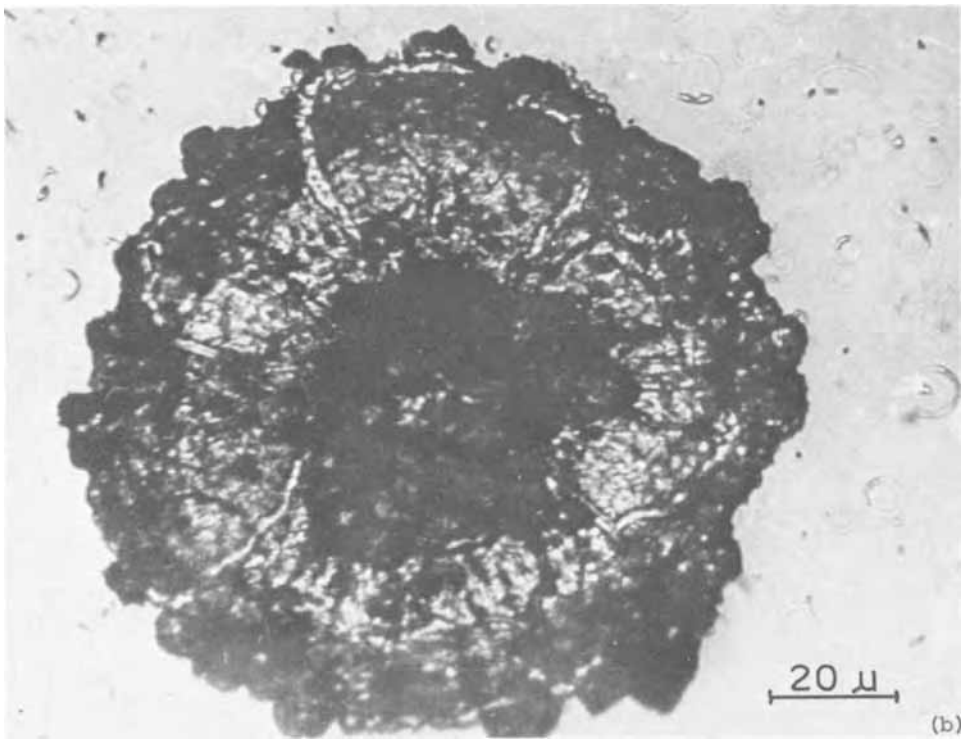

Fig. 2. Optical micrograph of breakdown regions after 15 min anodization. (a) 0.8% H_2SO_4, (b) 80% H_2SO_4.

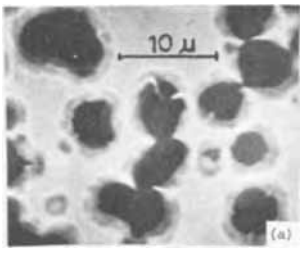

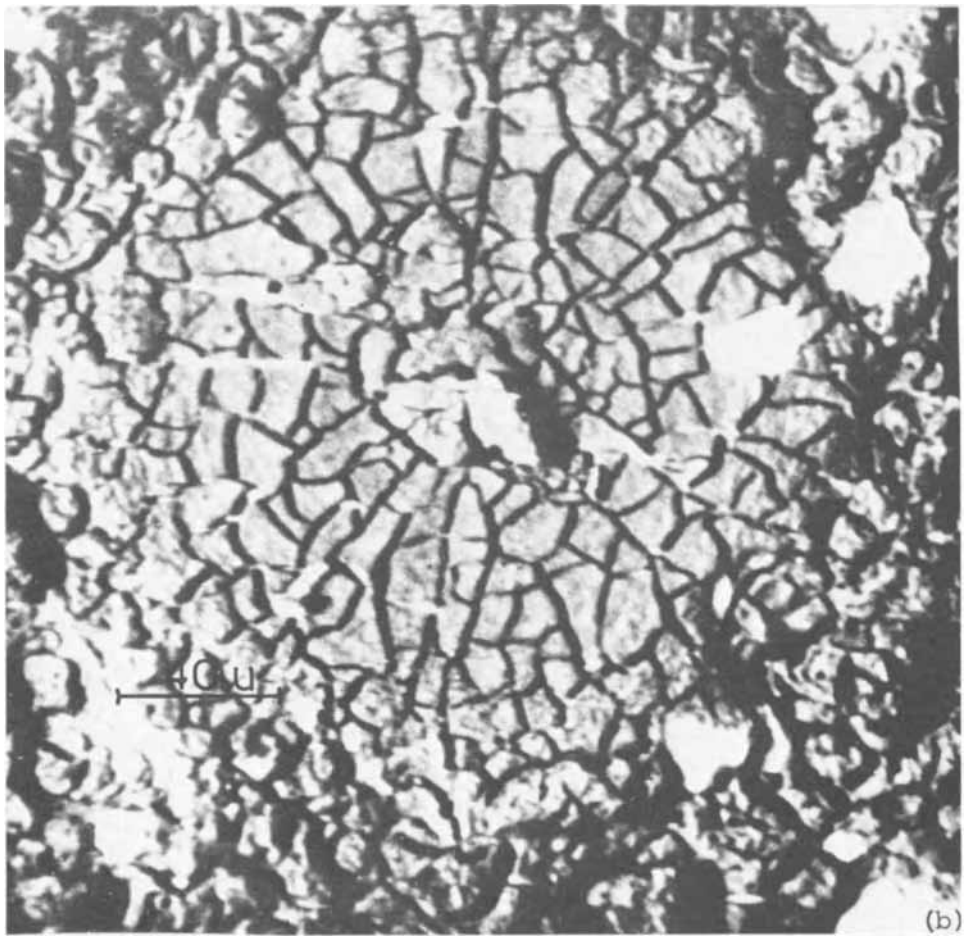

Fig. 3. Backscattered electron image of breakdown regions after 15 min anodization. (a) 0.8% H_2SO_4, (b) 80% H_2SO_4.

in the smooth nature of the film surface. However, anodizing for longer periods produced many areas of breakdown.

Photomicrographs of anodic films formed for about 15 min in dilute and concentrated solutions are seen in Fig 2a and 2b respectively. The effect of breakdown in these films was the creation of hills, the size of which depended on the solution concentration. The typical diameter of hills formed in the dilute solution was about 10μ, while that for the concentrated solution was about 100μ. The heights, measured by adjusting the focus of the objective lens, were 6μ and 10μ respectively. The anodic film thickness in the field was of the order of 0.1μ.

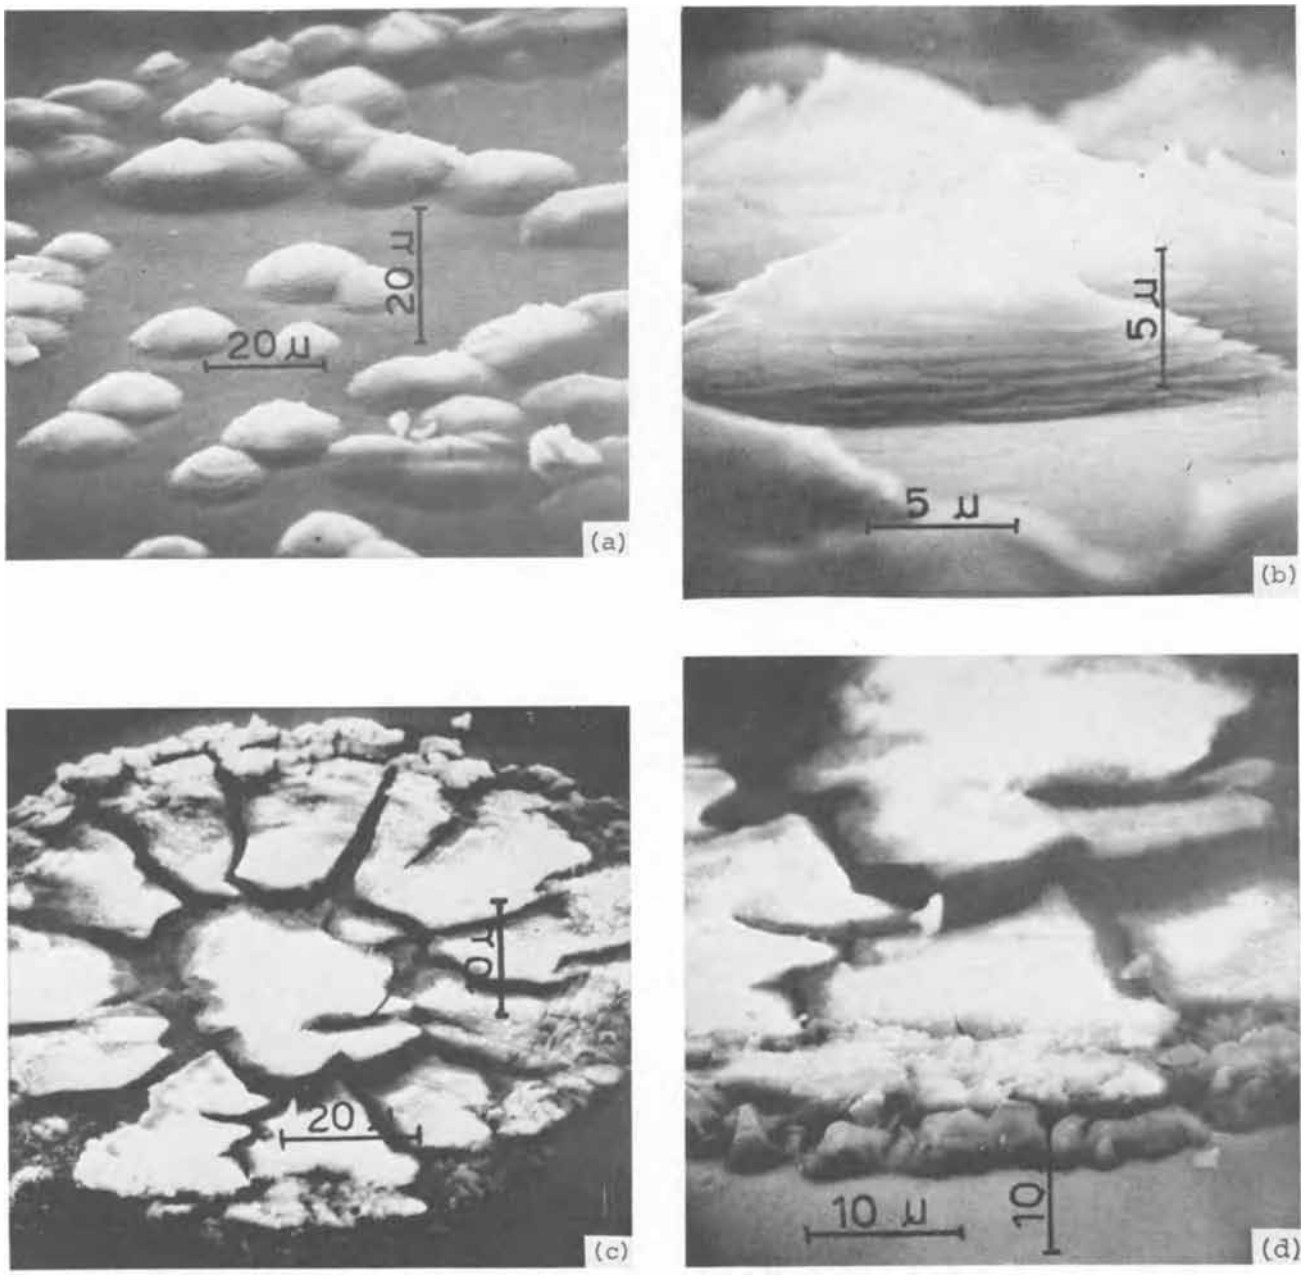

Fig. 4. Scanning electron micrographs of region of breakdown after 15 min anodization. (a) 0.8% H_2SO_4, (b) 0.8% H_2SO_4, (c) 80% H_2SO_4, (d) 80% H_2SO_4

The hills are typically round and their height decreases gradually from a central summit. The shape of the hills, formed in the dilute solution, can be seen in Fig. 3a, the backscattered electron image, obtained in the JEOL JXA-5 Microprobe. A better view of the breakdown regions is provided by scanning electron micrographs, Fig. 4a and 4b. Figures 3 and 4 reveal severe cracks in the hills, branching mainly from the hill's summit. A layered structure is also observed at the base of the hills. The shape of the hills, formed in the concentrated solution, is seen in the backscattered electron image, Fig. 3b, and in the scanning electron micrographs, Fig. 4c and 4d. The hills formed in the concentrated solution had severe cracks which have the appearance of "mud cracks." The white areas in Fig. 3b are due to flaking of the breakdown product. Craters, typically 1-2μ deep, remain in the underlying Si when the hills are chemically etched.

The hill material is probably thicker in the center of the hill, since most of the material remained attached to the Si in spite of the severe cracking around it (Fig. 3b). This conclusion is confirmed by the absorbed electron image of the breakdown regions in dilute and concentrated solutions, Fig. 5a and 5b respectively. The thicker breakdown regions absorb more electrons than the surrounding film. The hill material exhibits poor adhesion to the underlying Si, since it could be easily removed by scraping it with a sharp tool.

X-ray transmission topography furnishes further evidence for the existence of material in intimate contact with the Si inside the breakdown regions (Fig. 6). Diffraction contrast is seen inside the breakdown regions. Such contrast can be brought about if there is intimate contact between the hills and the substrate inside the breakdown region. The stresses in the hill are of a tensile nature as can be judged from the stronger x-ray intensity diffracted from the hill edge whose strain vector $\overline{H}$ is opposite to that of the diffraction vector $\overline{g}$ ($\overline{g}\cdot\overline{H}<0$) (8, 9) (Fig. 6). Since the material in the hills could be easily attacked by 1:20 HF, x-ray topographs were also taken of the surface after the dissolution of the film. This revealed that there are no residual stresses after removal of the hills, which implies that the stresses in the Si in the regions of breakdown are essentially elastic within the sensitiv-

ity range of the technique. X-ray topography of films before breakdown showed no local stresses.

Attempts to detect a crystalline structure were done both by x-ray diffractometry of the film after breakdown and by the powder method using the scrapings of the breakdown products. No sharp diffraction lines could be detected. Also, electron diffraction patterns taken by grazing the summit and the edge of the hills, were typical of an amorphous material.

X-ray microprobe analysis was done along the bright line shown in the backscattered electron image of the breakdown region in the concentrated solution (Fig. 7). In this image the region of breakdown is on the upper left side. The x-ray intensity records are shown in Fig.

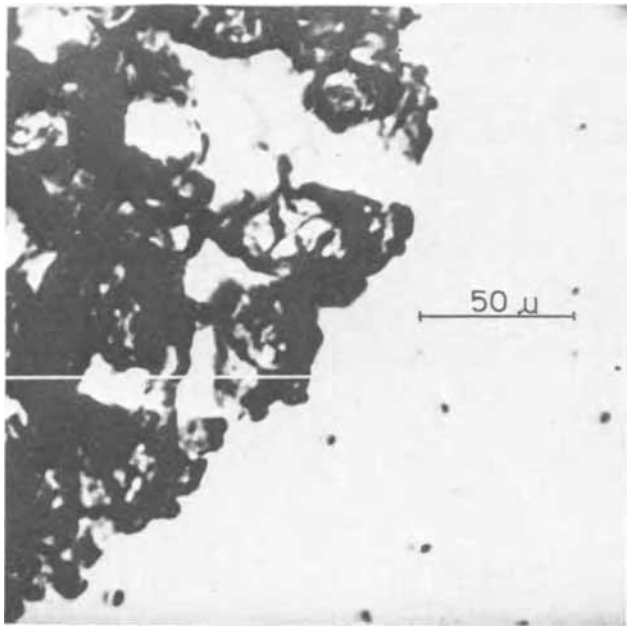

Fig. 7. Backscattered electron image of a breakdown zone and the adjacent intact anodic film 80% H_2SO_4 (15 min anodizing).

(a) background

(b) oxygen Kα

(c) silicon Kα

8. Above the background curve (a), the x-ray Kα intensities are seen for oxygen, curve (b), and silicon, curve (c).

The x-ray images for oxygen and silicon for the area shown in Fig. 8 are given in Fig. 9a and 9b respectively. The fractured regions are characterized by a higher silicon content (due to the underlying substrate wafer) while the breakdown product contains less silicon.

An excess of oxygen was detected in the breakdown region over the normal oxygen concentration in SiO_2. This excess may be explained by the formation of the amorphous hydrated oxides $SiO_2 \cdot (H_2O)_x$ in the regions of breakdown.

Conclusions

The morphology and composition of electrolytic breakdown products of anodic films was investigated. It is concluded that the breakdown region is comprised of a brittle material, probably amorphous $SiO_2 \cdot (H_2O)_x$. While previous evidence for the existence of water in anodic oxide films was obtained in infrared absorption studies (10), the present assumption about the composition can only be regarded as a hypothesis. The material is severely cracked and does not adhere well to the Si. This material is under residual tensile stress. The thickness of the breakdown regions is very large compared to the normal anodic film volume. It is proposed that the breakdown products form by a very rapid growth during the local heating produced by the breakdown (11).

The Optical Properties of Mn^{+2} in Calcium Halophosphate Phosphors

Westinghouse Lamp Division, Bloomfield, New Jersey 07003

ABSTRACT

A study of the optical properties of Mn^{+2} in commercial halophosphate phosphors has revealed that the Mn^{+2} is located on four distinguishable sites: on the simple Ca(I) site, on the simple Ca(II) site, on a Ca(II) site adjacent to an antimony-oxygen pair, and on a Ca(II) site adjacent to a chlorine ion in those phosphors containing chlorine. The Mn^{+2} fluorescence that results when the excitation is via energy transfer from antimony ions is primarily due to Mn^{+2} situated on a Ca(I) site, with smaller components due to Mn^{+2} located on the other sites observed.

During the twenty years that halophosphate phosphors have been utilized in fluorescent lamps many improvements have been made in their performance. These improvements have resulted in better maintenance, higher efficiency, and an increased selection of different spectral distributions. The technique used in improving the phosphors has been essentially trial and error guided by a sense of chemical intuition. It cannot be contested that this approach has been very successful in improving the phosphor. However, a basic understanding of many of the details of the operation of the phosphor has been lacking.

The difficulties in understanding the operation of the halophosphate phosphors have been due to the complexity of the halophosphate system. The commercial halophosphate phosphors form into the fluorapatite structure which has the hexagonal space group $P6_3/m(C_{6h}^2)$. This is a complicated crystal structure with 42 atoms in the unit cell. In pure calcium fluorophosphate there are two molecules of $Ca_5(PO_4)_3F$ per unit cell, with two inequivalent sites for the Ca^{+2} ions. The Ca(I) site has C_3 point group symmetry with each calcium ion having six oxygen nearest neighbors which form a twisted triangular prism about it. The Ca(II) site has C_{1h} point group symmetry. The Ca^{+2} ions on Ca(II) sites are situated at the corners of equilateral triangles with an F^- ion in the center. In "cool white" (CW), a typical commercial halophosphate phosphor, various additives are introduced which complicate matters even further. A CW phosphor may be viewed as being calcium fluorophosphate with about 10% of the fluorine ions replaced by chlorine, 2% of the calcium ions by manganese, and an additional 1% by cadmium. Antimony is believed to be incorporated as an antimony-oxygen pair replacing a calcium(II) ion and its adjoining fluorine ion (1-3). If this model is correct, an additional ½% of the calcium ions are replaced with antimony and an additional 2½% of the fluorine ions by oxygen.

In the operation of this phosphor in a fluorescent lamp the antimony absorbs the ultraviolet radiation present in the mercury discharge. The antimony either fluoresces in the blue region of the visible spectrum or transfers energy to the manganese ions. The manganese ions then fluoresce in the yellow. These gross features of the operation of the phosphor have been known for a long time. There have remained many mysteries, however, such as the mechanisms by which various phosphor additives cause wavelength shifts in the manganese fluorescence. For example, the incorporation of chlorine into calcium fluorophosphate shifts the manganese fluorescence emission to longer wavelengths (4). Several explanations have been proposed to explain this shift. Butler and Jerome (5) suggested that in halophosphate phosphors the manganese is located on the calcium(II) site which is adjacent to the halogens. Replacing some fluorines with chlorine might therefore shift the manganese fluorescence. Nagy, Wollentin, and Lui (6) ascribed the shift to a lattice distortion due to chlorine since the ionic size of chlorine is larger than the fluorine it replaces. Johnson (7) proposed that the manganese emission shift with addition of chlorine is due to a shift in preferred location of manganese from the calcium(I) position in pure fluorapatite to calcium(II) in the chloro-fluorapatite. There has been no way to choose between models such as these since no information on the precise locations and environments of manganese in halophosphate phosphors was available. This information could not be obtained because, in addition to the complicated apatite structure and the incorporation of relatively large amounts of antimony, manganese, cadmium, and chlorine, only powders were available for study.

After Johnson (8) succeeded in growing single crystals of calcium fluorophosphate it became possible to perform electron spin resonance measurements of the Mn^{+2} to compare with the optical properties of the Mn^{+2}. One could therefore identify specific environmental symmetries for Mn^{+2}. These could then be correlated with the optical spectra of Mn^{+2} at the various sites in the crystals. In a previous paper (9) we found that in fluorapatite, manganese is associated with at least four inequivalent environments; the Ca(I) site, the Ca(II) site, and two similar to the (I) and (II) sites but with "modified" environments. We labeled

"Cool white"	0.75	0.63	0.59	0.99	>0.6	<0.1	<0.05	~0.25

these sites the Mn(I), Mn(II), Mn(Im), and Mn(IIm). The Mn(I), Mn(II), and Mn(IIm) all possessed different optical properties that could be distinguished readily from one another by means of their characteristic excitation and fluorescence spectra, and decay times.

In this work we have used the techniques and results of our single-crystal experiments as a guide to understanding the sites of manganese and their related optical properties in the more complicated system of the real phosphor. We find this approach to be very successful in explaining many of the phenomena of manganese in commercial halophosphate phosphors.

Samples

While many different types of halophosphate phosphors were studied, three particular samples illustrated all of the phenomena observed and form the nucleus of this paper. The first is a single crystal of calcium fluorophosphate, fluorapatite, doped with manganese by pulling from a melt containing 10% manganese. The optical properties of this crystal have been previously reported (9). The other two samples are commercial phosphors, a "yellow halo" (YH) and a "cool white" (CW), produced by the Westinghouse Lamp Division at Bloomfield, New Jersey. They were prepared by firing raw mixes of luminescent grade calcium dibasic phosphate, calcium carbonate, calcium fluoride, ammonium chloride, cadmium carbonate, antimony trioxide, and manganous carbonate in an atmosphere of nitrogen. The YH was fired at 1130°C and the CW at 1180°C. The principal differences between YH and CW are that the former contains no chlorine and has a higher manganese concentration than CW. Analyses were done by x-ray fluorescence spectroscopy using a Norelco x-ray fluorescence spectrometer. The tungsten target x-ray tube was powered at 50 kV-20 mA. For manganese, a vacuum was pulled in the sample and dispersing chambers to increase sensitivity. For chlorine determinations, a PET crystal and flow counter were used to disperse and detect the radiation. Chemical analyses of the samples are listed in Table I.

Experimental Techniques

The optical excitation and fluorescence measurements were performed at 1.8°K with the samples immersed in liquid helium below the λ point to eliminate bubbling. The optical excitation and fluorescence envelopes were narrowed slightly at 1.8°K compared to 300°K. This made it easier to separate the contributions to the excitation and fluorescence spectra from the various types of Mn^{+2} present in the samples. Measurements performed at 77° and 300°K showed optical phenomena similar to those occurring at 1.8°K so that the conclusions we arrive at concerning the behavior of Mn^{+2} in our samples at 1.8°K apply to 77° and 300°K as well.

The powder phosphor samples presented an unusually difficult problem in measurement technique, particularly in the measurement of their excitation spectra. In measuring the excitation spectra of powders the strong diffuse reflectance of the excitation light into the fluorescence detector requires good rejection of the excitation wavelengths by the detector. Since the absorption of Mn^{+2} is due to a forbidden transition with an oscillator strength of less than 10^{-6} in calcium fluorophosphate (9), the ratio of excitation light intensity to fluorescence intensity was much higher than one commonly attempts to measure in powders. In addition, due to the presence of several types of manganese centers, we found it necessary at times to excite and view at the same, or nearly the same wavelength. This required a discrimination of the excitation light compared to the fluorescence light that could only be achieved by utilizing time resolved spectroscopy and sampling only the slowly decaying after-glow of the Mn^{+2} ions ($\tau \sim 8$ msec for all species) and not the excitation light.

Our time resolved spectra were obtained by using synchronous mechanical choppers for exciting and viewing. A block diagram of the system we developed is shown on Fig. 1. Here the coupling between the reference chopper and the synchronous chopper is electrical rather than the conventional mechanical coupling. This allows a greater flexibility in the arrangement of components. Under our experimental conditions this arrangement allowed no detectable excitation light to reach the fluorescence detector. This apparatus was used to obtain both the fluorescence and excitation spectra reported here.

The precise identification of the wavelengths of several of the sharp excitation peaks shown on the figures (such as the peaks at 4009 and 4037Å) was obtained by scanning a narrow wavelength range about these peaks at a much higher resolution than was used for obtaining the figures.

Optical Properties of Mn^{+2} in a Commercial "Yellow Halo" (YH) Phosphor

While we have studied the optical properties of manganese in a wide selection of commercial halophosphate phosphors two particular phosphors, the "YH" and the "CW," illustrate all of the phenomena observed. The major difference between the YH and CW phosphors is that the YH contains no chlorine and therefore is a somewhat simpler system to study, even though YH contains more manganese than CW.

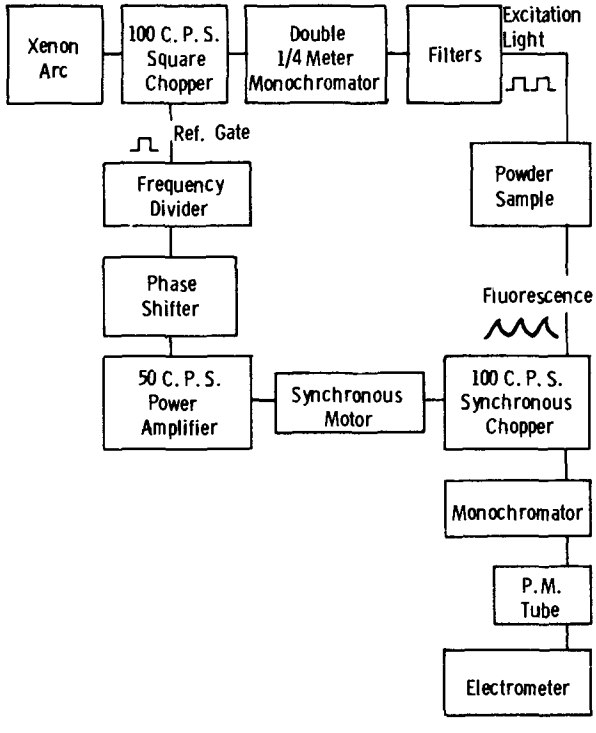

Fig. 1. Experimental arrangement for measuring the time resolved excitation and fluorescence spectra.

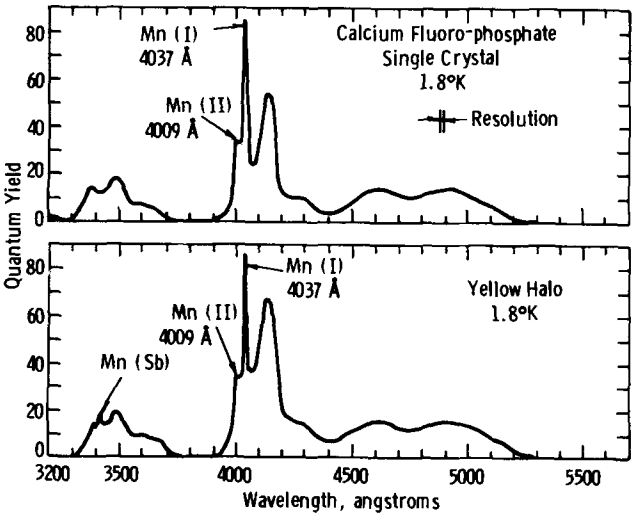

Fig. 2. 1.8°K excitation spectra of a calcium fluorophosphate single crystal and a "yellow-halo" phosphor.

Figure 2 shows the excitation spectrum of Mn^{+2} in YH along with the unpolarized excitation spectrum of Mn^{+2} in a single crystal of calcium fluorophosphate to which it is compared. In the calcium fluorophosphate crystal all of the resolved peaks shown are due to Mn(I) except for the peak at 4009Å which is due to Mn(II). The remainder of the Mn(II) excitation lines are lost in the Mn(I) envelopes. To obtain these excitation spectra all slowly decaying luminescence (in the order of milliseconds) emitted between 5000 and 8000Å was monitored. This wavelength range contains the fluorescences of all of the various Mn^{+2} types present in these samples. The Mn(I) and Mn(II) identifications are based on our previous single-crystal work (9). This crystal contains a concentration of 1.95 w/o (weight per cent) manganese which is in the same range of concentration as the phosphors measured which contained 1.67 and 0.75 w/o for the YH and CW phosphors, respectively. It is therefore considered to be a good crystal for comparing excitation and fluorescence spectra with the phosphors as the line widths due to concentration broadening would be similar.

The YH phosphor contains cadmium and antimony in addition to the manganese that the calcium fluorophosphate crystal contains. It can be seen that the crystal and YH possess essentially identical excitation spectra, the only difference being the appearance of a new minor excitation peak near 3425Å which has been labeled Mn(Sb). The Mn^{+2} in the YH phosphor is therefore behaving almost exactly like the Mn^{+2} in the crystal. In analogy to the crystal we therefore come to the following conclusions about the sites of Mn^{+2} in YH: most of the Mn^{+2} is situated on the Mn(I) site, with a small contribution on the Mn(II) site. An additional Mn^{+2} center is observed in a relatively small amount, Mn(Sb), which is associated with the presence of antimony in the phosphor. We term this center the "antimony associated" manganese center. It is not due to the presence of cadmium as we have prepared YH phosphors without cadmium that still show the presence of this center. We feel that it is due to manganese situated on a Mn(II) site with an antimony ion located on an adjacent Ca(II) site. Arguments supporting this assignment are presented later in the paper. An estimate of the relative occurrence of the various Mn^{+2} species in YH is given in Table I. In our previous single-crystal work such estimates were obtained from electron spin resonance measurements. Electron spin resonance measurements were of little value in studying the Mn^{+2} in our powders since at these high manganese concentrations the resonance lines are very broad (10). The powder estimates were

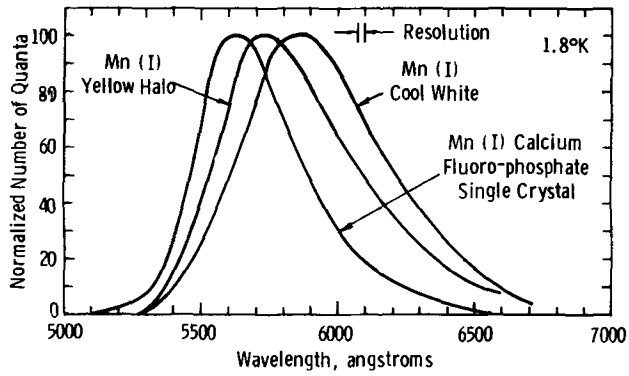

Fig. 3. 1.8°K fluorescence envelopes of the Mn(I) center in a calcium fluorophosphate single crystal, a "yellow halo," and a "cool white" phosphor.

therefore obtained by a comparison of the relative strengths of the excitation peaks of the various species of Mn^{+2} in our powders with the relative strengths of the excitation peaks of the various species of Mn^{+2} in single crystals of calcium fluorophosphate on which electron spin resonance measurements had been made. The assumptions must be made that all species have identical quantum efficiencies and that the oscillator strength of a given Mn^{+2} center in the fluorapatite crystals is the same as the comparable Mn^{+2} center in the phosphor. These assumptions introduce some uncertainty in the relative occurrence numbers stated in Table I for the powders.

The fluorescence envelopes of the Mn(I) centers in the calcium fluorophosphate crystal and the YH phosphor are shown in Fig. 3. They were obtained by pumping at 4037Å where only the Mn(I) species is strongly excited (9). The addition of cadmium and antimony to calcium fluorophosphate has shifted the 1.8°K Mn(I) fluorescence envelope about 100Å to longer wavelengths (the shift at 300°K is somewhat less). The Mn(Sb) fluorescence envelope was too weak to measure accurately, although it was determined that it fluoresces with an envelope that is shifted slightly to longer wavelengths than the Mn(I) envelope.

Optical Properties of Mn^{+2} in a Commercial CW Phosphor

Commercial CW phosphors contain chlorine in addition to all of the additives present in the YH phosphor. The presence of the chlorine (which represents about 10% of the total halogens) is found to create a new Mn^{+2} center associated with the presence of chlorine which we term the Mn(Cl) center. Its excitation spectrum is shown on Fig. 4 and its fluorescence envelope on Fig. 5. This fluorescence was obtained by exciting at 5450Å which pumps Mn(Cl) but not the other manganese types. The CW phosphor contains four easily identifiable types of Mn^{+2} centers. As they result in somewhat different fluorescence envelopes it is possible to accentuate the excitation spectra of the various centers by selectively viewing at certain fluorescence wavelengths. In Fig. 4 two excitation spectra are shown. The first excitation spectrum is that which results when viewing the fluorescence occurring at 5500Å. Viewing at 5500Å accentuates the Mn(I) and Mn(II) excitation peaks and so this excitation spectrum selectively displays the Mn(I) and Mn(II) components. It may be seen that this excitation spectrum is identical to that observed in the fluorapatite crystal in Fig. 2. The second excitation spectrum of Fig. 4 was obtained by viewing the fluorescence occurring at 6000Å which accentuates the Mn(Cl) and Mn(Sb) components. Some Mn(I) component is still visible, however, as there is still a sizable 6000Å component to the Mn(I) fluorescence.

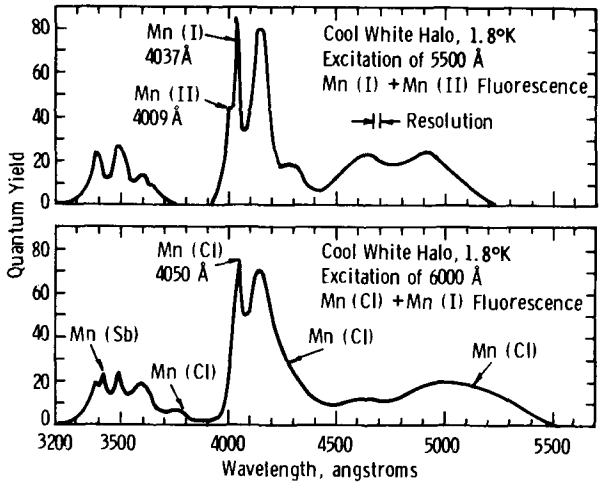

Fig. 4. 1.8°K excitation spectra of the Mn(I), Mn(II), Mn(Cl), and Mn(Sb) centers in a "cool white" phosphor.

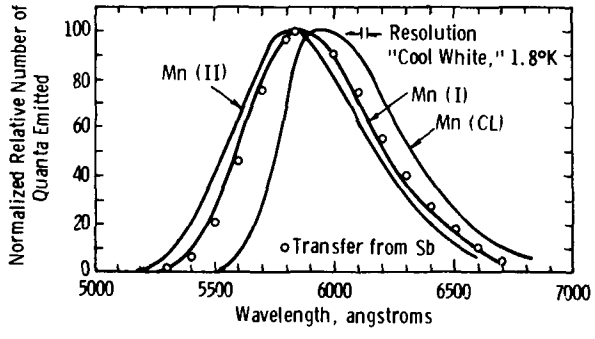

Fig. 5. 1.8°K fluorescence envelopes of the Mn(I), Mn(II), and Mn(Cl) centers in a "cool white" phosphor along with the Mn^{+2} fluorescence envelope that results when the excitation is due to transfer from antimony ions.

On Fig. 5 the normalized fluorescence envelopes of the Mn(I), Mn(II), and Mn(Cl) centers in CW are shown along with the fluorescence envelope that results when the antimony ions are pumped by 2537Å radiation and the Mn^{+2} is excited by energy transfer from the antimony. From Fig. 5 it is seen that the Mn^{+2} fluorescence envelope that results when energy is transferred from the antimony ions may be made up by a suitable combination of the various Mn^{+2} types present in the CW phosphor. On Fig. 6 we present the linear combination of the three major Mn^{+2} components that yields a composite envelope giving a "best fit" to the envelope resulting when excitation is via antimony. It occurs for approximately 70% Mn(I), 20% Mn, and 10% Mn(II). These component percentages lie within the probable error limits of the relative absorption (excitation) strengths of the various species. This implies that the various Mn^{+2} types receive relative amounts of energy from the antimony ions that do not differ greatly from their relative absorption strengths during excitation by external light. All three species therefore are active in the functioning of the CW phosphor in a fluorescent light and contribute to its composite manganese fluorescence envelope.

Discussion

The assignment of components in the optical spectra of our phosphor samples to Mn(I) and Mn(II) was relatively simple, as the Mn(I) and Mn(II) excitation and fluorescence spectra in the phosphors closely resembled their counterparts in single crystals of calcium fluorophosphate. No Mn(Sb) or Mn(Cl) centers were present in the calcium fluorophosphate crystals that we studied previously so that models for these

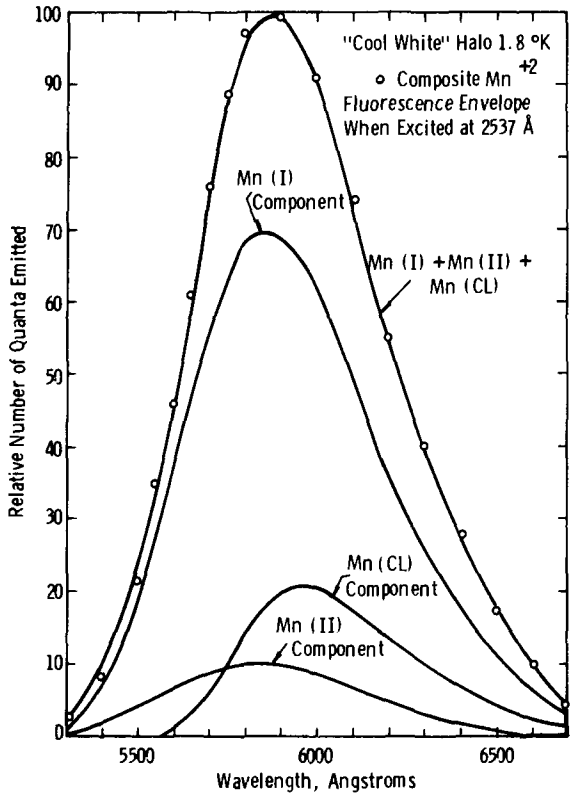

Fig. 6. Linear combination of the Mn(I), Mn(II), and Mn(Cl) centers that gives a best fit to the composite Mn^{+2} envelope that results when the excitation is due to transfer from antimony ions at 1.8°K. The combination is 70% Mn(I), 20% Mn(Cl), and 10% Mn(II).

centers must be derived from more indirect arguments. The models that we propose for these two centers are therefore somewhat speculative and represent what we believe the centers to look like, rather than what we can prove them to be.

In our previous single-crystal work we found that if our crystals were grown under certain conditions (a deficiency of fluorine and/or an excess of oxygen), defect centers would be formed along the halogen chains (9). These centers consisted of clusters of fluorine vacancies and oxygen ions substitutional for fluorine. They exhibited an attractive force on substitutional manganese ions which caused nonrandom pairing, forming centers such as the one we termed the Mn(II) "modified," or Mn(IIm) center. Our model for this center is that it consists of a manganese ion located on a Ca(II) site immediately adjacent to an oxygen vacancy complex. No corresponding center due to pairing of manganese ions located on Ca(I) sites with the defect centers was observed to occur. This is undoubtedly because the Ca(I) site is much farther away from the halogen chain than the Ca(II) site, and that an attractive force between the manganese ions and the defect centers would cause them to be located as closely together as possible, *i.e.*, with the Mn on the Ca(II) site.

Another observation we can make from the single-crystal data is that the Mn(I) and Mn(II) centers exhibit no observable modifications in their ESR or optical spectra due to the presence of the defects on the fluorine chains. Thus it appears that the excitation spectra of manganese ions are practically unaffected by the presence of defects unless they occur at a nearest neighbor position. We are therefore led to expect that the Mn(Cl) and Mn(Sb) centers, which exhibit characteristic excitation spectra that differ significantly from the Mn(I) and Mn(II) spectra, are formed by having a manganese ion located adjacent to the

chlorine ions and the antimony-oxygen complexes, respectively.

Since the chlorine atoms would most probably enter the lattice substitutionally for fluorine, one expects that in the Mn(Cl) center the manganese ion is located on a Ca(II) site adjacent to a chlorine ion. The presence of a manganese-chlorine attraction analogous to that found for the Mn(IIm) center may be seen from the distribution of the various types of manganese that occurs in CW. In the CW phosphor about 70% of those Mn^{+2} ions located on Ca(II) sites are Mn(Cl) centers. Since only 10% of the fluorine ions are replaced by chlorine, a random distribution of manganese and chlorine would predict that only 10% of the manganese ions on Ca(II) positions would be adjacent to chlorine ions and form Mn(Cl) centers, not 70%.

Piper has reported on ESR measurements of manganese in single crystals of calcium fluorophosphate, chlorophosphate, and mixed fluorochlorophosphates that lend support to our assignment of the Mn(Cl) center to manganese on a Ca(II) position adjacent to a chlorine. In his pure fluorophosphate crystals Piper observed only Mn(I) centers and no Mn(II) centers. In mixed crystals containing small amounts of chlorine he detected, in addition to Mn(I), a single type of Mn(II) associated with the presence of chlorine in the structure. This observation is consistent with our model of the strong interaction between manganese and chlorine ions that gives rise to the formation of the Mn(Cl) center. His failure to observe the Mn(II) center in calcium fluorophosphate is consistent with our observation that at low manganese it is incorporated as Mn(I).

Strong evidence suggests that antimony ions enter the apatite structure as antimony-oxygen pairs, with the oxygen located on a halogen site and the antimony on one of the three adjacent Ca(II) positions (1-3). We conclude that the Mn(Sb) center consists of a manganese ion located on a Ca(II) site adjacent to a antimony-oxygen complex. The Mn(Sb) center is such a minor center in CW that we are unable to determine whether the number of Mn(Sb) centers is greater than a random distribution of manganese and antimony would predict or not.

The shift in the emission envelope of the Mn(I) fluorescence to longer wavelengths as cadmium, antimony, or chlorine are added to calcium fluorophosphate is probably because these ions cause dimensional changes to the fluorapatite lattice. Norita (12) has suggested that the resultant change in the crystal field strength acting on the Mn^{+2} ions due to these dimensional changes would be expected to shift the Mn^{+2} emission envelope. While this effect is certainly present we do not feel that it is primarily responsible for the emission shifts observed. We observe no corresponding shift in the excitation spectra of Mn(I) in our phosphors when cadmium, antimony, or chlorine are added: only a shift in the emission, Norita's model would predict a shift in the excitation levels also due to the change in crystal field strength, particularly the broad excitation peak which corresponds to excitation to the fluorescence state. All of the shift appears after the Mn^{+2} ions are in their excited state, although a slight shift in the lowest lying excitation envelope with additives could easily be missed as the envelope is quite broad. That is, a larger Stoke's shift occurs to the Mn^{+2} ions when the various additives are present. We thus prefer to view the functioning of the additives as "softening" the lattice and allowing larger Stoke's shifts to occur. How this can happen may be seen from the following simple model. Figure 7 shows how a Stoke's shift is commonly pictured as occurring on an energy configuration-coordinate diagram. The ground and excited states of the ion are assumed to be parabolic, $E \sim \frac{1}{2} k Q^2$ where k is the lattice force constant, and to couple to the lattice modes with terms V_1 for the ground state and V_2 for the excited state.

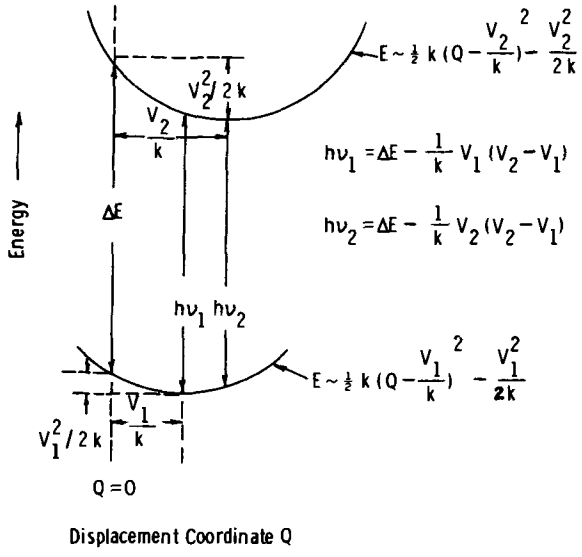

Fig. 7. Energy configuration-coordinate diagram for the Stoke's shift observed in the phosphors. The symbols are defined in the text.

The coupling to the lattice modes is assumed to yield an energy term that is linear in the lattice distortion so that coupling terms in Q^2 or higher are negligible. Adding this term to the parabolic term we have

$$E \sim \frac{1}{2} k Q^2 - QV$$

The Stoke's shift is then observed as the difference between the absorption and emission energies

absorption

$$h V_1 = \Delta E - \frac{1}{k} V_1 (V_2 - V_1)$$

emission

$$h V_2 = \Delta E - \frac{1}{k} (V_2 - V_1)^2 - \frac{1}{k} V_1 (V_2 - V_1)$$

where ΔE is the separation of the levels in the absence of coupling to the lattice modes. The difference in energy between the absorption and emission is thus the term, $\frac{1}{k} [V_2 - V_1]^2$. If k is reduced (the lattice gets softer), hV_2 shifts more than hV_1 by an amount approximately equal to

$$\left[\frac{V_2 - V_1}{k} \right]^2 \Delta k$$

where Δk is the change in the lattice force constant. If Δk is negative then the shift is toward longer wavelengths. In order for the absorption line to shift very little (the location of the center of the lowest energy excitation envelope in this case) while the emission line shifts a much greater amount, one requires that V_1 is small and that V_2/V_1 is large. It is a reasonable assumption that the excited state of the manganese ions would couple more strongly with many of the lattice modes than does the ground state. The observation of a Stoke's shift and the absence of a zero phonon line (9) already informs one that the coupling terms V_1 and V_2 are considerably different. While admittedly crude, this model does qualitatively explain the increased Stoke's shift observed as additives such as chlorine are incorporated into calcium fluorophosphate.

Conclusions

In commercial halophosphate phosphors, Mn^{+2} can find itself in four distinct environments: on the simple Ca(I) site, on the simple Ca(II) site, on a Ca(II) site

adjacent to an antimony-oxygen pair, and on a Ca(II) site adjacent to a chlorine ion in those phosphors containing chlorine. In the most commercially important phosphor of the group, CW, we find that between 60 and 70% of the manganese is present as Mn(I), between 5 and 10% as Mn(II), between 1 and 5% as Mn(Sb), and between 20 and 30% as Mn(Cl). The phosphor functions in the following manner in the fluorescent lamp. The antimony ions absorb the 2537Å radiation and either fluoresce or transfer energy to Mn^{+2} ions. Most of the Mn^{+2} fluorescence that results is due to Mn(I), with smaller components due to Mn(Cl) and Mn(II), and a very small component due to Mn(Sb). The fluorescence envelope of Mn(I) in CW is at longer wavelengths than Mn(I) in calcium fluorophosphate. This Mn(I) envelope shift is primarily responsible for the color shift observed in the CW phosphor relative to calcium fluorophosphate. The shift is not due to a redistribution between the Ca(I) and Ca(II) sites due to the introduction of Sb, Cd, and Cl as Johnson proposed (7), nor due to the formation of new Mn(Cl) centers as Butler and Jerome (5) proposed, although the formation of Mn(Cl) centers does occur to some degree and does cause a slight additional wavelength shift to the composite Mn^{+2} fluorescence envelope.

The Effect of Rapid Cooling on Divalent Manganese Ions in Calcium Fluoro-Chlorophosphate Phosphors

ABSTRACT

Quenching experiments were performed on manganese-activated calcium fluoro-chlorophosphate phosphors. Changes in the optical properties of the manganese ions due to quenching were studied in order to explain the manganese fluorescent envelope shift in quenched phosphors reported by other workers. We find that quenching causes a change in the nearest halogen neighbors of manganese ions located on the so-called "Ca(II)" positions. In slowly cooled phosphors these ions have mostly chlorine ions as nearest neighbors while in the quenched phosphors many of the chlorine ions are replaced with fluorine. It is shown that this redistribution will produce a shift in the manganese fluorescence envelope equal in magnitude to that experimentally observed.

Apple and Ishler (1) have observed that if chlorine-containing calcium halophosphate phosphors, activated by antimony and manganese, are cooled very rapidly (from 600°-1200°C) to room temperature, that the spectral distribution of the manganese fluorescent emission shifts to slightly shorter wavelengths while the antimony emission is unchanged. This effect was found to be reversible upon annealing and did not occur in calcium fluorophosphate. They proposed two alternative models to explain this effect. One explanation involved a redistribution of manganese among the various sites it may occupy in these phosphors, due to the quenching. Since one would expect somewhat different emission wavelengths for manganese located on different sites a shift in the composite emission envelope could result from such a redistribution.

Their second model involved changes in the location of the chlorine atoms in the crystal structure of the phosphors due to quenching. It was proposed that a rapid cooling could freeze the chlorine atoms into a more random arrangement than the equilibrium configuration at low temperatures.

At the time they published their paper, progress in understanding the structural and optical properties of the calcium halophosphate phosphors had not yet reached the point where these models could be tested. Since then, some progress has been achieved in characterizing the structural modifications that exist, the nature of the sites that manganese ions occupy in the calcium halophosphate phosphors, and the optical properties of the manganese ions on those sites. This

information has enabled us to conduct experiments which have clearly revealed the origin of the quenching effect.

Background

The pseudobinary system calcium fluorophosphate: calcium chlorophosphate includes almost all of the commercially important halophosphate lamp phosphors. There are two structures known to exist in this system. Calcium fluorophosphate forms in the hexagonal fluorapatite structure, space group $P\ 6_3/m$ (C_{6h}^2), with two molecules of $Ca_5(PO_4)_3F$ per unit cell. There are two inequivalent calcium ion sites in this structure. The Ca(I) site has C_3 point group symmetry with each calcium ion having six oxygen nearest neighbors which form a twisted triangular prism about it. The Ca(II) site has C_{1h} point group symmetry with each calcium ion situated at the corners of equilateral triangles with a fluorine ion in the center. These triangles and hence the fluorine ions are located on reflection planes. The fluorine ions are at (0,0,1/4; 0,0,3/4) positions in the unit cell as determined from precision x-ray structure measurements.

Calcium chlorophosphate has two known crystallographic modifications (2, 3). Above 200°C it exhibits the x-ray pattern expected for a hexagonal chlorapatite structure with the same space group as the fluorapatite. It has been proposed (4) that the structure of chlorapatite and fluorapatite differ, however; in particular that in chlorapatite the larger size of the chlorine ions relative to the fluorine ions causes them to be displaced from the reflection planes where they are located in the fluorapatite structure to positions midway between the reflection planes at (0,0,0; 0,0,1/2) positions. These positions also satisfy the symmetry requirements of the hexagonal apatite space group. A precise structure determination has not been reported on the chlorapatite structure, which would yield more precise information on the positions of the chlorine ions. One can therefore only state from the type of x-ray measurements that have been performed, that the positions of the chlorine atoms on the average satisfy the symmetry of the hexagonal apatite space group. Random displacements about either the (0,0,1/4; 0,0,3/4) or (0,0,0; 0,0,1/2) positions cannot be ruled out.

Below 200°C calcium chlorophosphate exists in a monoclinic form which appears to differ only slightly from a hexagonal structure. The monoclinic unit cell can be derived from a hexagonal unit cell by doubling the length of one hexagonal "a" axis. Viewing down the monoclinic "a" axis the chlorine atoms are thought to be displaced alternately up and down along the "c" axis, although the magnitude of the displacement has not been determined (3). It is the ordering of these displacements that distinguishes the monoclinic phase from the hypothetical disordered chlorapatite. Prener (3) has pointed out that the monoclinic to hexagonal phase transition observed by x-ray technique could be accomplished either by a simple disordering of the alternate chlorine displacements that exist in the monoclinic form or by a rearrangement in which all chlorine positions are equivalent.

This uncertainty in the positions of the chlorine atoms on a microscopic scale persists into the pseudobinary system. It is known that compounds with a fluorine to total halogen ratio of over 36% are "hexagonal apatites" with no low temperature transition to the monoclinic phase (3), but the exact positions of the chlorine atoms are not yet known.

More pertinent to this paper than structural considerations is information on the manganese ions which are located in these structures. We have previously reported on electron spin resonance (ESR) measurements of manganese in single crystals of calcium fluorophosphate (5). These measurements were compared with optical measurements, and we were able to identify the optical excitation and fluorescence spectra of manganese located on the Ca(I) site, termed Mn(I), on the Ca(II) site, termed Mn(II), and on a Ca(II) site adjacent to an oxygen-vacancy complex, termed Mn(IIm). In a later paper (6) we extended these investigations to calcium fluoro-chlorophosphate phosphors containing manganese. No single crystals of the mixed fluoro-chlorophosphates were available to us so that ESR measurements could not be used to aid in the identification of the manganese sites. The identification of the Mn(I) and Mn(II) optical excitation and fluorescence spectra in the mixed halophosphates was accomplished through their great similarity to the optical excitation and fluorescence spectra of the corresponding centers in calcium fluorophosphate. Two additional types of manganese centers were observed to occur in the mixed fluoro-chlorophosphates; a Mn(Cl) center which we identify as a manganese ion located on a Ca(II) site immediately adjacent to a chlorine ion, and a Mn(Sb) center which we identify as a manganese ion located on a Ca(II) site adjacent to a substitutional antimony-oxygen ion pair. The identification of these centers was accomplished through analogy to the Mn(IIm) center in the fluorophosphates and by use of other indirect evidence. We found that in the mixed fluoro-chlorophosphates almost all of the manganese located on Ca(II) sites was immediately adjacent to chlorine [forming the Mn(Cl) center] evidence of a strong manganese-chlorine attraction.

A typical commercial apatite phosphor is one called "cool white." It is a calcium fluoro-chlorophosphor activated with both antimony and manganese. It was found that all of these manganese centers could receive energy which was transferred from antimony ions when the "cool white" phosphor was excited with 2537Å radiation, and that the manganese emission envelope that resulted was a composite of the various manganese types present.

In view of the additional information about the types of manganese sites in "cool white" it appeared worthwhile to repeat some of Apple and Ishler's quenching experiments to determine what changes might be induced in the various types of manganese centers, due to rapid cooling. A report on the results of these investigations is the purpose of this paper.

Experimental

The "cool white" phosphor that was used in our quenching experiments was a commercial phosphor produced at the Westinghouse Lamp Division at Bloomfield, New Jersey. It was prepared by firing a raw mix of luminescent grade calcium dibasic phosphate, calcium carbonate, calcium fluoride, ammonium chloride, cadmium carbonate, antimony trioxide, and manganous carbonate in an atmosphere of nitrogen at 1180°C. A chemical analysis of the minor constituents in the fired material showed it to contain by weight 0.75% manganese, 0.63% antimony, 0.59% chlorine, and 0.99% cadmium.

We found that in order to obtain quenching effects comparable in magnitude to those reported by Apple and Ishler it was necessary to cool our samples in times considerably shorter than 20 sec and from the highest temperatures they reported. Our best results were obtained for samples contained in thin-walled quartz tubes with a bore size of 3 mm and a wall thickness of 0.5 mm. To obtain an adequate sample volume these tubes were made as long as our furnace could accommodate. The samples were sealed in one third atmosphere of argon at room temperature and heated to 1150°C in 1 hr and kept at temperature for 1 hr. The tubes were quenched by quickly dumping them into a container of water. No measurements of temperatures inside the tubes as a function of time after immersion were performed, but the incandescent glow from the samples disappeared almost instantly after immersion and all boiling ceased within about 2 sec. We feel that the material at the center of the tubes reached a temperature below 100°C in at most 5 sec. Even at this fast quenching rate the portion of the phosphor immediately adjacent to the quartz wall

showed a measurably greater quenching effect than the phosphor portion located at the very center of the tube where the cooling rate was lowest.

Every attempt to quench unencapsulated phosphors directly into water resulted in some pink body coloration of our phosphors which reduced their efficiency measurably. This pink color has been ascribed by Rabatin and Gillooly to Mn^{+3} in calcium orthophosphate, a second phase component often present in halophosphate phosphors (7). Since no such difficulty was reported by Apple and Ishler with their phosphors we surmise that their phosphors contained a smaller amount of calcium orthophosphate than ours. Possibly our unencapsulated phosphors lost enough chlorine during heating to induce the formation of the orthophosphate phase.

All of the excitation and most of the fluorescence measurements reported in this paper were obtained by directly exciting the manganese ions with external light rather than via transfer from antimony ions. These spectra were obtained through the use of time-resolved spectroscopy, a technique which has been described in detail in a previous paper (6). The fluorescence decay times of all manganese species reported here are essentially identical so that the relative strengths of their fluorescence and excitation spectra, obtained by time-resolved techniques, are equivalent to those obtained by the more standard d-c techniques. All spectra plotted on the figures are manganese concentration limited in their resolution.

UV-induced depreciation of the quenched samples was studied by exposing powder plaques of the phosphors to the radiation emitted by a mercury discharge lamp with a Suprasil quartz envelope, operated under discharge conditions identical to those in a 40W fluorescent lamp. The use of a Suprasil envelope for a mercury discharge lamp results in a much higher transmission of the 1849Å mercury line than ordinary quartz so that the radiation emitted from such a lamp closely resembled the energy distribution of radiation incident on the phosphor inside an actual fluorescent lamp. The lamp and phosphor samples were located inside a sealed chamber provided with a constant flow of nitrogen gas to eliminate absorption of the uv radiation by oxygen. The phosphor samples were positioned so that the uv flux incident upon them was closely equal to the flux incident upon the phosphors in a 40W fluorescent lamp. The temperature of the phosphors during the irradiation was approximately 30°C.

The samples were removed and their quantum efficiency measured under 2537Å excitation at various times during the depreciation exposure of 100 hr. These measurements were accurate to within ±2%.

Results

We will discuss now the changes which occurred in the types of Mn^{+2} centers present in a sample of "cool white" phosphor after a quenching of the type described in the experimental section of this paper. Figure 1 shows the fluorescence envelopes of the sample before and after the quenching. These envelopes were obtained by exciting the sample, kept at 300°K, with 2537Å radiation. Time resolved spectroscopy was not used for obtaining these envelopes as a time resolved fluorescence spectrum would reject the antimony emission component, since the antimony ions decay with a much faster decay time than the manganese ions (10 μsec *vs.* 7 msec). The shift in the manganese fluorescence envelope after quenching of approximately 40Å to shorter wavelengths may be seen in Fig. 1. This shift is similar to that reported by Apple and Ishler in their experiments on "cool white." We found this shift to be reversible upon annealing as they also reported.

The excitation spectra of the sample before and after quenching are shown in Fig. 2. Only selected regions of the excitation spectra are shown here in order to demonstrate the changes occurring due to the

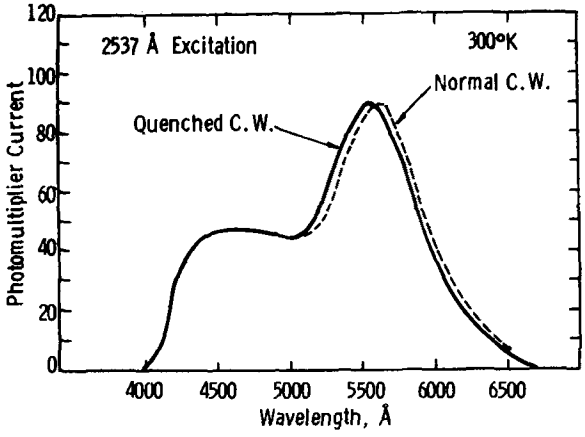

Fig. 1. Fluorescence envelopes of quenched and normal "cool white" phosphors at 300°K. Excitation is at 2537Å.

quenching. The two excitation spectra on the left hand side of the drawing show on an expanded wavelength scale the changes induced by quenching in the relative strengths of two important excitation peaks. The peak located at 4037Å is the dominant sharp line in the excitation spectrum of manganese ions located on the Ca(I) site, *i.e.* Mn(I). The peak located at 4009Å is the dominant sharp line in the excitation spectrum of manganese ions located on a Ca(II) site adjacent to a fluorine ion, *i.e.* Mn(II). These two peaks are made to be of comparable height in these two spectra by monitoring the fluorescence at a selected wavelength (5350Å) where both emissions are equally strong. This allows small changes in the ratio on Mn(II) to Mn(I) due to quenching to be seen more readily than would be possible if nonselective fluorescence viewing were employed for obtaining the excitation spectra. Normally the Mn(II) excitation peak is much weaker

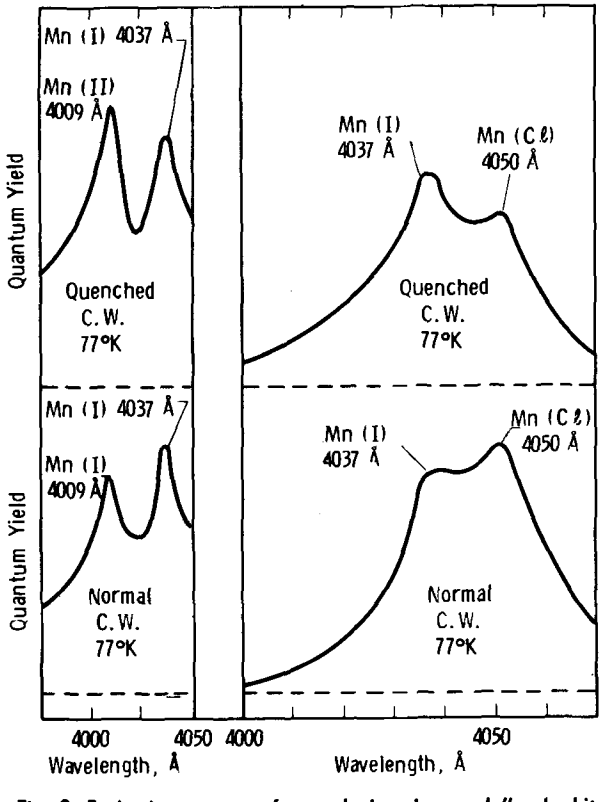

Fig. 2. Excitation spectra of quenched and normal "cool white" phosphors at 77°K. The growth in the number of Mn(II) centers following quenching may be seen on the left hand side of Fig. 2 and the decrease in the number of Mn(CI) centers on the right.

than the Mn(I) peak. It may be seen in Fig. 2 that quenching has increased the ratio of the Mn(II) to Mn(I) but that the strength of the Mn(I) excitation spectrum is unchanged. This means that the number of Mn(II) ions in the phosphor has increased upon quenching.

The two excitation spectra shown on the right hand side of Fig. 2 were obtained by selectively viewing the fluorescence emitted at 6000Å. This choice of wavelength accentuates the fluorescence due to manganese ions located on Ca(II) sites adjacent to chlorine [the Mn(Cl) center]. The dominant sharp line of the Mn(Cl) center is located at 4050Å compared to the Mn(I) line at 4037Å. It can be seen from the curves on the right hand side of Fig. 2 that the Mn(Cl) center has decreased upon quenching relative to the Mn(I) center. We thus find that quenching both reduces the number of manganese ions adjacent to chlorine and increases the number adjacent to fluorine. The decrease in the number of Mn(Cl) centers is numerically equal to the increase in the number of the Mn(II) centers to within our estimated experimental accuracy of 10%. The Mn(Sb) center is such a minor center that little can be said about the changes in its concentration that might occur due to quenching.

By comparing the relative areas under the excitation spectra of the three major species of manganese we find that prior to quenching the manganese is distributed as about 7.5% Mn(II), 65% Mn(I), and 25% Mn(Cl). After quenching, the distribution is changed to about 20% Mn(II), 65% Mn(I), and 12.5% Mn(Cl). From the known fluorescence spectra of each component and these percentages we can calculate the shapes of the composite envelopes to be expected both before and after quenching. They, and the individual components are shown in Fig. 3. The calculated composite Mn^{+2} envelope shifts by approximately 40Å to higher energy due to quenching. This is in good agreement with the shift of the manganese envelope observed for this sample shown in Fig. 1 and is an important confirmation of the validity of this treatment. The small Mn(Sb) components for both the quenched and normal samples were ignored in preparing Fig. 3.

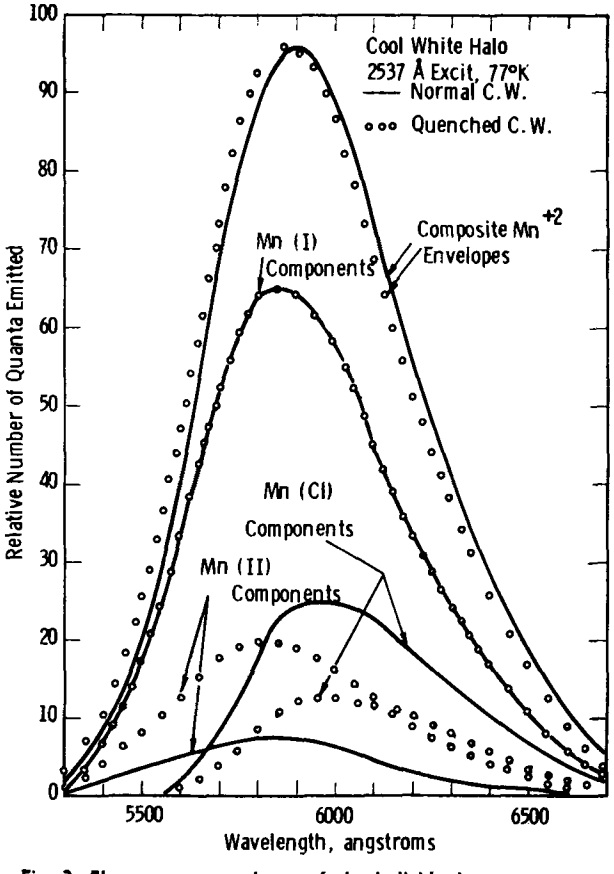

Fig. 3. Fluorescence envelopes of the individual components and the composite envelopes for a "cool white" phosphor before and after quenching.

Depreciation Results

Apple and Ishler reported that their quenched calcium fluorochlorophosphate phosphors were more resistant to depreciation by 1850Å irradiation than their unquenched phosphors. We have studied the depreciation of several samples of "cool white" quenched phosphor and compared the results with those obtained from normal "cool white" phosphor to determine if our phosphors showed the same effect. We found that, within our experimental accuracy of ±2%, quenching had no measurable effect on the depreciation rates of our phosphors up to our maximum depreciation time of 100 hr. The quantum efficiencies of our quenched and unquenched phosphors were identical before depreciation (although the luminous efficiencies of the quenched phosphors were slightly higher due to the manganese envelope shift). We conclude that the enhancement in irradiation resistance that Apple and Ishler observed in their quenched samples was due to a different mechanism than that responsible for the manganese fluorescence shift, and that the effect does not generally occur in quenched calcium halophosphate phosphors.

Discussion and Conclusions

The quenching induced shift in the composite manganese fluorescence envelope can be explained by a redistribution of the manganese ions over the various types of manganese centers present before quenching. In particular, quenching has the net effect of converting some of the Mn(Cl) centers into Mn(II) centers. Since the decrease in the number of Mn(Cl) centers after quenching is numerically matched by the growth of the Mn(II) centers, and no new manganese center appears, one must rule out the formation of new types of manganese centers due to quenching such as a center where the chlorine ion is frozen into an intermediate position in the lattice as was proposed by Apple and Ishler. In slowly cooled (normal) "cool white" most of the manganese ions situated on a Ca(II) position are adjacent to a chlorine ion. This is due to a pairing attraction between the manganese and chlorine ions. At high temperatures these pairs are broken up and the chlorine distribution is randomized. A rapid quench freezes in a more random distribution of chlorine than occurs if the phosphor is allowed to cool slowly.

Some details of this conversion from Mn(Cl) to Mn(II) deserve further comment. The center that we call Mn(Cl) consists of a manganese ion next to a chlorine ion which has replaced a fluorine, but we have not specified the next nearest halide. We have assumed that this center has optical properties that are not measurably altered by the type of halogens located immediately above and below the chlorine ion. Because this is not strictly true, the dominant sharp line in the excitation spectra of the Mn(Cl) center, located at 4050Å, is actually a very narrow envelope containing the sharp lines of all of the varieties of these Mn(Cl) centers corresponding to the different arrangements of halogen next nearest neighbors. An analogous situation occurs for the Mn(II) center.

A Mn(Cl) center with a fluorine ion located directly above or below it along the "c" axis transforms into a Mn(II) center by simply shifting the halogens by one position up or down along the "c" axis. This model does not require any movement or diffusion of the manganese ions and the presence of halogen vacancies would allow such arrangements to occur at relatively low temperatures.

In addition to the shift in the manganese emission envelope in the mixed chloro-fluorophosphates upon quenching, Apple and Ishler reported upon a similar shift after quenching calcium chlorophosphate phos-

phors doped with antimony and manganese. A different mechanism must be responsible for this shift as these phosphors contain no fluorine. In order to investigate this effect, we prepared and quenched some calcium chlorophosphate phosphors, and did observe the wavelength shift in the manganese fluorescence envelope that Apple and Ishler reported for this phosphor upon quenching. On the other hand, excitation spectra taken before and after the quenching revealed little change except that the dominant sharp line in the manganese excitation spectrum of the unquenched chlorophosphate phosphor was located at 4055Å while in the quenched phosphor it was located at 4060.

No analysis of this effect was possible because we had no background information on the optical properties of the various types of manganese present in calcium chlorophosphate phosphors. Such information should prove to be much more difficult to obtain in the chlorophosphate system than in the fluorophosphate system due to its greater structural complexity and the larger number of possible types of manganese sites.

Effects of the $AsCl_3$ Mole Fraction on the Incorporation of Germanium, Silicon, Selenium, and Sulfur into Vapor Grown Epitaxial Layers of GaAs

J. V. DiLorenzo* and G. E. Moore, Jr.

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

The effect of the $AsCl_3$ mole fraction on the incorporation of germanium, silicon, selenium, and sulfur in GaAs epitaxial layers has been studied. The layers were grown by vapor phase epitaxy (VPE) using the $AsCl_3|Ga|H_2$ synthesis system. Both room- and low-temperature Hall data as well as photoluminescence spectra were used to examine the incorporation of the impurities into grown layers. The results of these studies indicate that the incorporation of silicon and germanium decreases with increasing $AsCl_3$ mole fraction, and that the incorporation of sulfur and selenium is largely unaffected by changes in the $AsCl_3$ mole fraction. The results are interpreted using a model which proposes that the major background dopant in this system is silicon and that the mole fraction effect is due to the interaction of stable chlorides of silicon with hydrogen chloride in the reactor. A calculation of the activity of silicon as a function of the hydrogen chloride pressure is presented. The results compare reasonably well with the experimental data.

We have recently reported the variation of carrier concentration with the $AsCl_3$ mole fraction (1) of undoped, p-type vapor phase epitaxial (VPE) layers of GaAs. The layers were grown by the $AsCl_3 \mid Ga \mid H_2$ chemical vapor deposition system. The effect was originally reported by Cairns and Fairman (2) for n-type epitaxial layers with residual background doping present in the epitaxial reactor. The effect observed by Cairns and Fairman has now been observed by various other workers as well (3, 4). Cairns and Fairman (5) have also observed a variation in carrier density with $AsCl_3$ mole fraction for epitaxial crystals doped with silicon by transport of silicon from the gallium source.

In this paper, we report on the dependence of the incorporation of germanium, silicon, selenium, and sulfur into VPE GaAs on the $AsCl_3$ mole fraction. The carrier concentration and mobility of the doped layers were determined as well as the low-temperature photoluminescence spectra. In addition, the photoluminescence spectra of several silicon doped VPE GaAs samples were investigated.[1]

An analysis of these data has led to the conclusion that the incorporation of the Group IV dopants, silicon and germanium, into the epitaxial layers depends strongly on the $AsCl_3$ mole fraction. On the other hand, the dependence of the incorporation of sulfur and selenium on the $AsCl_3$ mole fraction was substantially different in that at the higher doping levels the concentration of sulfur and selenium (10^{16} cm^{-3}) is largely unaffected by the $AsCl_3$ mole fraction.

The results are interpreted using a model which suggests that the Group IV elements silicon and germanium, having stable chlorides, can chemically interact with HCl present in the reactor. On the other hand, the incorporation of sulfur and selenium, which do

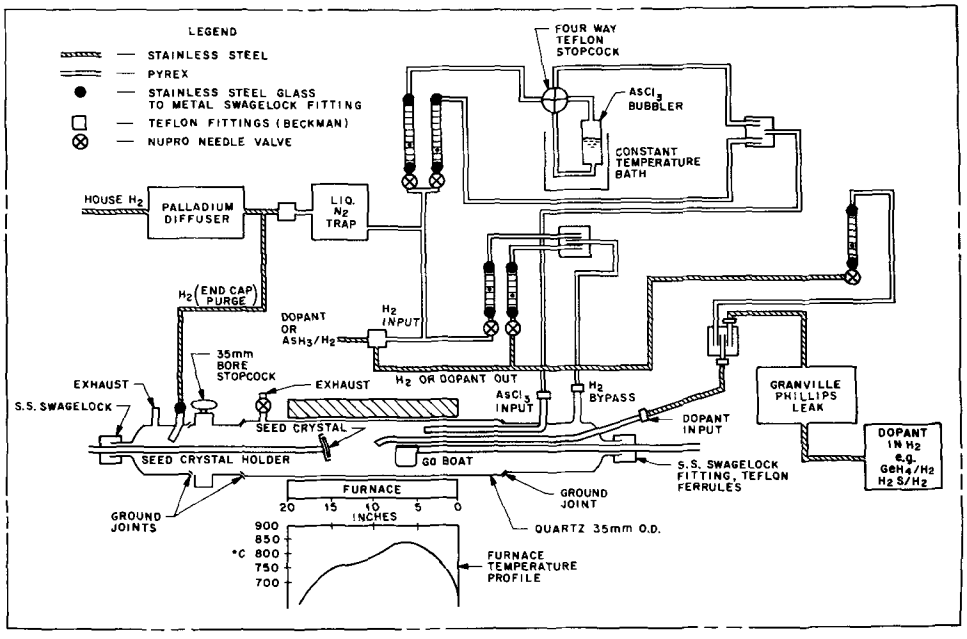

Fig. 1. Schematic diagram of the epitaxial deposition system.

not have stable chlorides at the epitaxial growth temperatures, is unaffected by the HCl concentration in the reactor.

Growth System and Procedures

Epitaxial reactor.—A standard $AsCl_3$ | Ga | H_2 synthesis system (6) was used to grow epitaxial crystals of GaAs substrates. A schematic diagram of the epitaxial reactor is shown in Fig. 1.

The materials used for the construction of the system are indicated in the legend in Fig. 1. The reactor tube, gallium boat, seed crystal holder, $AsCl_3$ input, and hydrogen bypass lines were constructed of high purity synthetic quartz. Epitaxial layers were doped in the 10^{15} to 10^{17} cm^{-3} range reproducibly by introduction of a mixture of either GeH_4, H_2Se, or H_2S in hydrogen through a variable leak, diluting the mixture further with hydrogen and passing it into the reaction zone. The concentrations of dopant gas relative to hydrogen present in the supply tanks were 5 ppm for GeH_4 | H_2, 5 ppm H_2Se | H_2, and 1000 ppm for H_2S | H_2.

The main reactor tube, boat, input glassware, substrate holder and output glassware were cleaned with aqua regia and given multiple rinses in 1.5 x 10^7 ohm-cm deionized water prior to assembly. The ground joints were greased with a minimum amount of a fluorocarbon grease to ensure a leak-free seal.

Starting materials and growth procedures.—Starting materials used were Ga (99.99999%, Eagle Picher Company); $AsCl_3$ (99.99999%, Mitsubishi Metal Mining Company) and Pd-diffused hydrogen. The O_2 contamination of the hydrogen was measured at all inputs to the main reaction tube by gas chromatography. The following results were obtained:

Output of Pd-diffuser: 0.6 ± 0.1 ppm O_2.
Input to liquid N_2 cold trap: 0.6 ± 0.1 ppm O_2.
$AsCl_3$ input to furnace: (0.9 to 2.0) ± 0.2 ppm O_2.
H_2 bypass input: (0.8 to 4.0) ± 0.2 ppm O_2.
Dopant input: 1.0 ± 0.2 ppm O_2.

Substrate materials were either chromium doped, boat-grown, semi-insulating ($\rho > 10^8$ ohm-cm at 300°K) GaAs, or tellurium-, selenium-, or silicon-doped, boat-grown, N^+ ($\rho \simeq 0.003$ ohm-cm at 300°K) GaAs. The substrates were cut as 30 mil thick slices orientated 2° off {100} towards {110}. After cutting, the substrates were chemically cleaned with a $5H_2SO_4$: H_2O: H_2O_2 etch, mechanically lapped, and finally chemically polished using Br_2/CH_3OH.

Prior to epitaxial growth the substrates were degreased in boiling trichlorethylene, rinsed in acetone and given multiple rinses in hot isopropanol. After degreasing, the substrates were etched for 2 min in $5H_2SO_4/H_2O_2/H_2O$ at room temperature and rinsed in deionized water. Following the etch, the substrates were soaked from 30 to 90 min in sodium ethylenediaminetetracetate, a complexing agent for metals, and rinsed for approximately 10 min in running deionized water.

The mole fraction of $AsCl_3$ was varied by changing the relative amounts of flow through the bubbler and H_2 dilutent, maintaining the total flow constant as closely as possible ($\approx$ 130 cm^3/min).

Measurements and Results

Growth parameters.—Ga/As ratio.—The marked dependence of the electrical properties of the epitaxial layers on the $AsCl_3$ mole fraction discussed below could be due to a varying ratio of Ga to As in the gas stream. Thus it was necessary to determine whether the concentration of Ga relative to As in the gas phase was constant as the concentration of $AsCl_3$ was increased.

A boat with a removable liner containing Ga saturated with GaAs was inserted into the furnace and positioned at the normal boat position. $AsCl_3$ was passed into the reactor under flow conditions similar to those of the growth experiments, and the weight loss of the material from the liner was measured to the nearest 0.1 mg to determine the transport of Ga from the boat.

The transport of $AsCl_3$ was determined by trapping the $H_2/AsCl_3$ stream at 77°K and measuring the volume of the liquid obtained in a specified period of time. The flow through the bubbler was 175 cm^3/min, approximately the highest flow used in epitaxial growth (equivalent to an $AsCl_3$ mole fraction of 6 x 10^{-3}). It was found that the bubbler completely saturated the H_2 gas with $AsCl_3$ (to within experimental error of measurement) at these conditions. Therefore, it was assumed that complete saturation of the H_2 with $AsCl_3$ occurred at lower flow rates through the bubbler.

The data obtained on the weight loss of material from the boat and the calculated transport ratio of Ga to As are listed in Table I. The data clearly indicate that the ratio of Ga to As, that is, the ratio of the number of moles of gallium relative to the number of moles of arsenic transported to the deposition zone, is

Table I. Experimentally determined ratio of Ga to As for $AsCl_3$ mole fractions from 1.52×10^{-3} to 5.82×10^{-3}

$AsCl_3$ Mole fraction $\times10^3$	Moles $AsCl_3$/min $\times10^5$	Temp (°C) Ga	Wt. Ga transported (g)	Ga/As ratio
1.52	2.08	858	0.0820	1.88
2.50	3.98	858	0.1513	1.82
4.78	8.58	858	0.3471	1.93
5.82	10.2	858	0.4223	1.84

not changing significantly over the range of $AsCl_3$ mole fractions used in these experiments.

Since, in an epitaxial growth system, the $AsCl_3$ mole fraction is the independent variable, all data have been analyzed in terms of the $AsCl_3$ mole fraction.

Characteristics of the epitaxial layers.—The thickness, the carrier concentration, and Hall mobility, at room temperature and at 77°K, and the photoluminescence of selected layers were measured in an effort to correlate characteristics of the grown layers with various growth parameters.

Electrical measurements.—Germanium doped layers.—In Table II the carrier concentration and Hall mobility at room temperature and at 77°K, the $AsCl_3$ mole fraction, and thickness of germanium-doped layers are listed. The variation in the thicknesses of these layers resulted mainly from different growth periods. We have observed (1) that the growth rate varies only by about 20-30% as the $AsCl_3$ mole fraction changes by as much as a factor of 6. This is consistent with the data of Cairns and Fairman (2).

The layers are divided into three groups. Group A was grown with a GeH_4 mole fraction of 10^{-10} in the vapor. Groups B and C were grown by introducing GeH_4 at mole fractions of 5×10^{-10} and 10^{-9}, respectively. The factor of ten change in the GeH_4 mole fraction produced a change in the carrier concentration of approximately a factor of ten as well. Sample D 225 was undoped and is characteristic of the background level present in the reactor at an $AsCl_3$ mole fraction of 2×10^{-3} prior to the growth of Group C.[2]

The carrier concentration of the germanium-doped layers decreases as the $AsCl_3$ mole fraction increases. This is shown graphically in Fig. 2 where n as a function of the $AsCl_3$ mole fraction for germanium-doped layers is plotted. The rate of decrease for the most lightly doped of the germanium layers, Group A, is greater than for Group B or C.

[2] The room temperature and liquid nitrogen mobilities of sample D225 are typical of the values obtained for undoped samples with $n \simeq 0.6 - 2\times10^{15}$ cm^{-3}.

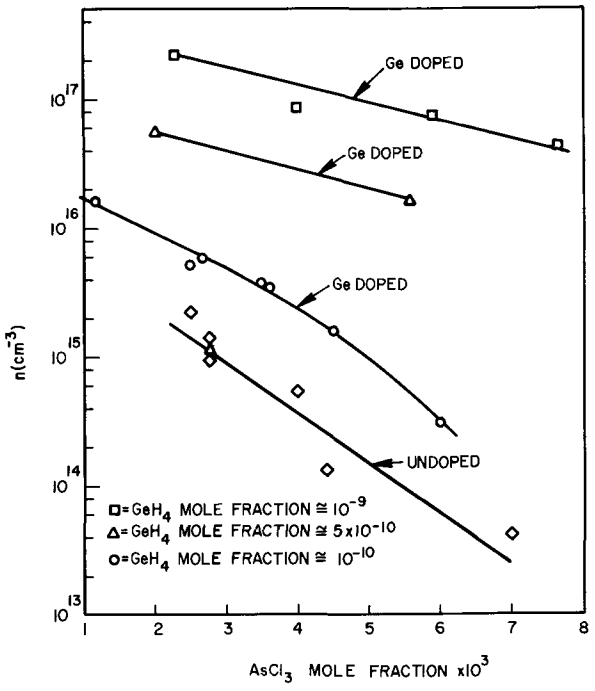

Fig. 2. The carrier concentration, n, of germanium-doped and updoped epitaxial layers plotted against the $AsCl_3$ mole fraction.

Included also in Fig. 2 is the dependence of the carrier concentration of undoped layers on the $AsCl_3$ mole fraction. This plot is representative of the type of variation we have observed although the curve can be displaced vertically from reactor to reactor.

Sulfur and selenium doped layers.—In Table III the thickness, $AsCl_3$ mole fraction, carrier concentration, and Hall mobility at 300°K and at 77°K, are listed for sulfur-doped layers while the same quantities for selenium-doped layers are contained in Table IV. The layers are divided into Groups D, E and F. Group D was grown at an H_2S mole fraction of approximately 10^{-9} while Group E was grown at a mole fraction of

approximately 5×10^{-10}. Group F was grown at an H_2Se mole fraction of approximately 5×10^{-8}.

In Fig. 3 the variation of n with $AsCl_3$ mole fraction for both groups of sulfur-doped layers and for selenium-doped layers is presented. From an analysis of the data in Tables III and IV and Fig. 3, it is apparent that the incorporation of sulfur and selenium is markedly different from that of germanium. There is litle variation in the doping level with $AsCl_3$ mole fraction for sulfur-doped layers having $n \simeq$ (2 to 5) $\times 10^{16}$ cm^{-3} over an $AsCl_3$ mole fraction range of (2 to 7) $\times 10^{-3}$. (Group D). Only a slight decrease in doping level with $AsCl_3$ mole fraction was observed for Group E.

For the layers doped with selenium, we have observed scatter in the value of n at a given mole fraction [see Fig. 3, n at a mole fraction of 2.5×10^{-3}]. This is due to the instability of a 5 ppm H_2Se/H_2 source for doping. For example, the carrier concentration observed at a mole fraction of 2.5×10^{-3} ranged over a factor of three (see Table IV and Fig. 2). We present the data for selenium-doped layers in order to indicate the trend of the variation of selenium incorporation with $AsCl_3$ mole fraction. The carrier concentration of these layers increases slightly with increasing $AsCl_3$ mole fraction. Like sulfur, the dependence of the incorporation of selenium on the $AsCl_3$ mole fraction is different from that of silicon or germanium.

In Fig. 4 the carrier mobilities at 77°K *vs.* $AsCl_3$ mole fraction for germanium-doped samples of Groups A and C, for sulfur-doped samples of Group D and for selenium-doped samples are presented. The increase in carrier mobility of the germanium-doped samples correlates with a decrease in the carrier concentration as the $AsCl_3$ mole fraction increases. The mobility of sulfur-doped samples is invarient with the $AsCl_3$ mole

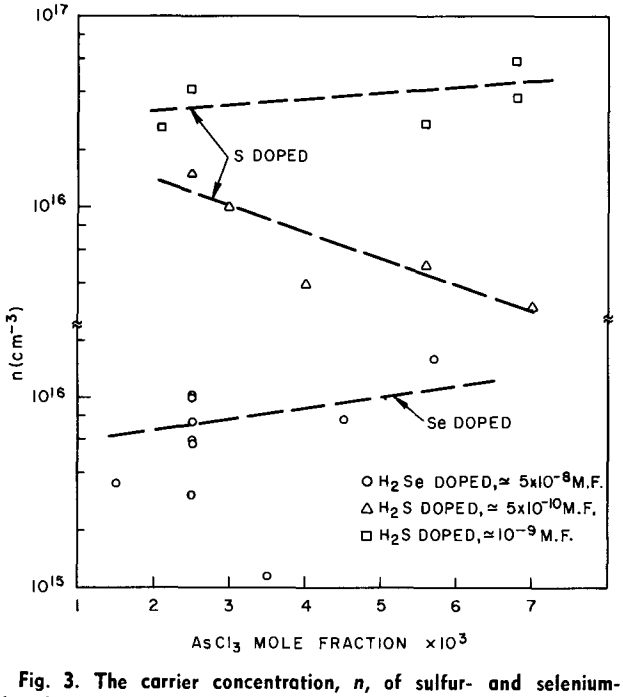

Fig. 3. The carrier concentration, n, of sulfur- and selenium-doped epitaxial layers plotted against the $AsCl_3$ mole fraction.

fraction, while the mobility of selenium-doped samples decreases with increasing $AsCl_3$ mole fraction.

Photoluminescence

The electrical measurements indicate that increasing the $AsCl_3$ mole fraction inhibits the incorporation of electrically active centers in the Ge- and Si-doped samples but has little effect in the Se- and S-doped crystals. Photoluminescence was used to identify the optically active impurities in the crystals in an attempt to compare their behavior as a function of the $AsCl_3$ mole fraction with that of the electrically active impurities.

A typical low-temperature photoluminescence spectrum of germanium-doped epitaxial GaAs is shown in Fig. 5. Three peaks, occurring at 1.514, 1.480, and 1.444 eV, are readily identifiable. The small rise centered at about 1.356 eV is due to copper, which is a common contaminant in GaAs (1). This peak was noted in only two of the samples studied, and the copper contamination is thought to be insignificant.

The 1.480 eV peak arises from transitions between the conduction band and the Ge acceptors (7, 8) (B-A transitions). Since the energy gap (E_G) for GaAs at 10°K is 1.520 eV (9), the Ge acceptor level lies 40 meV above the valence band. The 1.444 eV peak is the first LO phonon replica of the Ge acceptor peak and occurs 35 meV below the Ge acceptor peak [*i.e.* 76 meV from the valence band], in good agreement with the energy of the LO phonon in GaAs (10).

The higher energy peak at 1.514 eV may be due to a variety of processes. Since the luminescent energy is less than E_G by 6 meV, the recombination does not involve band-to-band transitions. There are two alternative explanations for the nature of the 1.514 eV peak: the recombination may be due to (*I*) donor-to-valence band transitions (D-B) or (*II*) annihilation of excitons bound to neutral or ionized donors (11).

Thus the photoluminescence spectrum consists of a high-energy peak assumed to be due to silicon or germanium donors (depending on the dopant), an acceptor peak (also associated with the germanium dopant), and its phonon replica. No other impurities, aside from slight amounts of copper in two of the crystals, appear in significant amounts. The silicon-doped samples exhibit identical spectra except that the germanium acceptor peak at 1.480 eV is replaced by a peak at 1.490 eV associated with silicon acceptors (12).

The above results indicate that Ge and Si are the only optically active impurities in the samples. The next step is to relate the intensities of the photoluminescence peaks to the concentrations of Si and Ge. To do this we will assume that these recombination paths exist: (*I*) donor-to-valence band (D-B) radiative recombination (the high energy peak in Fig. 5); (*II*) conduction band to acceptor (B-A) radiative recombination (the 1.480 eV peak in Fig. 5); (*III*) all other nonradiative (NR) recombinations.

The rate equation for the valence band then becomes

$$\dot{P} = G - \frac{P}{\tau_{DB}} - \frac{P}{\tau_c} - \frac{P}{\tau_{NR}} = G - \frac{P}{\tau_T} \qquad [1]$$

where P = free hole concentration, G = generation rate of free holes, τ_{DB} and τ_{NR} are the lifetimes for D-B and NR transitions, τ_c is the capture time for the acceptors, and τ_T is the total lifetime for the minority carriers (holes). Assuming equilibrium, we have $P = \tau_T G$.

For D-B transitions we can write (13, 14)

$$I_D = \frac{P}{\tau_{DB}} = \frac{\tau_T G}{\tau_{DB}} = \tau_T G B N^\circ_D \qquad [2]$$

where B is the mean capture coefficient and N°_D represents the number of neutral donors. B depends upon the effective mass, index of refraction, activation energy, recombination energy, and temperature (14). By holding the intensity of the exciting radiation and the temperature constant, we can hold G and B constant. Further, since (15)

$$N^\circ_D \simeq N_D - N_A \qquad [3]$$

for these temperatures, where N_D = the total number of donors and N_A = total number of acceptors, we can write

$$I_D = A\tau_T(N_D - N_A) \qquad [4]$$

Similarly, the rate equation for the acceptors will be

$$N^+_A = \frac{P}{\tau_c} - \frac{N^+_A}{\tau_{BA}} \qquad [5]$$

where N^+_A is the number of neutral acceptors and τ_{BA} is the lifetime of B-A transitions. At equilibrium we have

$$\frac{P}{\tau_c} = \frac{N^+_A}{\tau_{BA}} = I_{BA} \quad [6]$$

τ_c can be written as (16)

$$\tau_c^{-1} = \theta v_{th} N_A \quad [7]$$

where θ is the capture cross section for the center and v_{th} its thermal velocity. Both θ and v_{th} are constants under the experimental conditions and we have, combining Eq. [2], [6], and [7]

$$I_{BA} = C\tau_T N_A \quad [8]$$

Equations [4] and [8] indicate that if the experimental conditions, *i.e.* temperature, intensity of exciting radiation, *etc.*, are held constant for a series of crystals, I_D and I_{BA} will be proportional to $\tau_T(N_D - N_A)$ and $\tau_T N_A$, respectively. If we make the further assumption that τ_T is constant for these crystals, we arrive at the desired correspondence between the intensities of the photoluminescence peaks and the concentration of the various impurities. This last assumption implies that the limiting recombination process is unaffected by changes in the $AsCl_3$ mole fraction. This would be true if the limiting process were band-to-band recombination, for example.

Figure 6 illustrates the dependence of the integrated intensities of the donor (I_D) and acceptor ($I_{Ge} = I_{BA}$) peaks in Ge-doped GaAs on the $AsCl_3$ mole fraction. The data were taken under identical optical and thermal (10°K) conditions. On the same graph the values for N_A and N_D for the same crystals are plotted, using the results of Table II (17). The close correlation of the electrical and optical data leads to several conclusions: (*A*) the assumption that τ_T is a constant for this series appears to be valid; (*B*) the Ge_{donor} to $Ge_{acceptor}$ ratio is independent of the $AsCl_3$ mole fraction; and (*C*) the total number of Ge atoms incorporated decreases sharply as the $AsCl_3$ mole fraction is increased.

Figure 7 shows the same data for the Si-doped samples. The Si-doped samples were grown on N^+ substrates and Hall data could not be taken. Thus

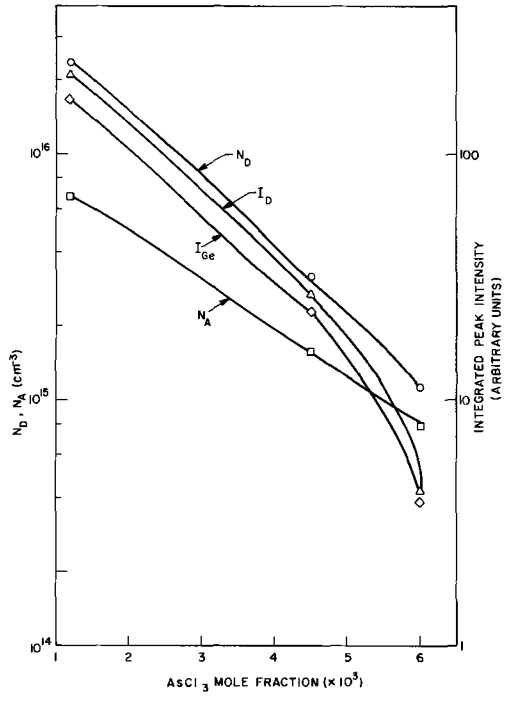

Fig. 6. The impurity concentrations, N_A and N_D, and integrated photoluminescence peak intensities, I_D and I_{Ge}, of Ge-doped GaAs plotted against the $AsCl_3$ mole fraction.

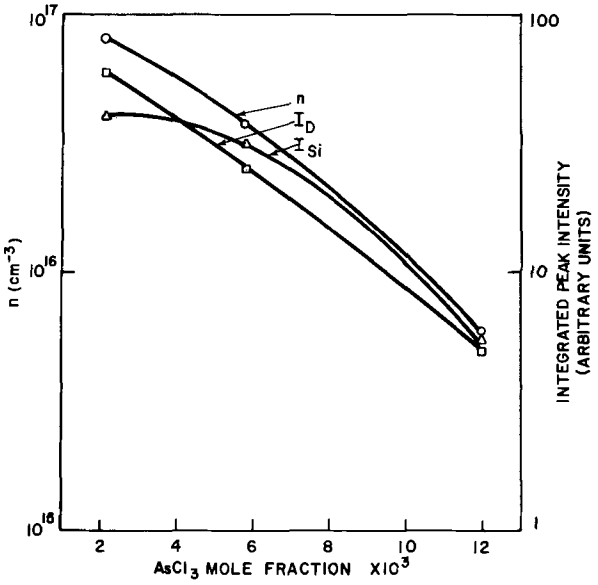

Fig. 7. The carrier concentration and integrated peak intensity of the near bandgap peak and silicon acceptor peak plotted against $AsCl_3$ mole fraction.

$n = N_D - N_A$ is plotted with I_D and I_{Si}. The conclusions are identical to those for Ga-doped crystals.

Discussion

In the discussion of these results it is most useful to keep in mind the data presented in Fig. 2-7. The conclusions which are reached concerning the incorporation of germanium, silicon, sulfur, and selenium are summarized as follows:

1. The incorporation of germanium decreases as the $AsCl_3$ mole fraction increases. This is based on the decrease of n with $AsCl_3$ mole fraction [Fig. 2], the increase in mobility with increasing mole fraction [Fig. 4], and the decrease in integrated peak intensities of germanium donors and acceptors in layers grown with increasing mole fraction [Fig. 6].

2. The incorporation of silicon decreases with increasing $AsCl_3$ mole fraction [Fig. 7].

3. The dependence of the incorporation of sulfur and selenium on the $AsCl_3$ mole fraction is substantially different from that of germanium or silicon. The carrier concentration of sulfur- and selenium-doped layers remains relatively constant as the $AsCl_3$ mole fraction increases [Fig. 3]. In addition, the mobility of these layers does not increase with $AsCl_3$ mole fraction [Fig. 4].

The significance of the above statements, we feel, is that they indicate the mechanism for the mole fraction effect observed in undoped $AsCl_3$/Ga/H_2 systems. The specific mechanism involves the interaction of the various impurities with HCl present in the system. Group IV elements, silicon and germanium, have stable chlorides at temperatures in the vicinity of 800°C. Group VI elements, sulfur and selenium, have only stable hydrides under reactor conditions. We can represent a general reaction between a Group IV element, *M*, and HCl in the presence of H_2 as follows

$$(n-2)H_2(g) + MCl_nH_{4-n}(g) \leftrightarrow M(s) + n\,HCl(g)$$

$$\text{at } P_{H_2} = 1 \text{ atm}$$

$$K = \frac{a_M P^n_{HCl}}{P_{MCl_nH_{4-n}}}$$

$$a_M = \frac{K P_{MCl_nH_{4-n}}}{P^n_{HCl}}$$

where n is an integer, K is the equilibrium constant and a_M is the activity of $M(s)$. The effects of $SiCl_2$,

$GeCl_2$, *etc.* have been neglected. Qualitatively we see that the activity of $M(s)$ varies inversely as P_{HCl} to P^4_{HCl} for the $MClH_3$ to MCl_4 compounds.

This model proposes that in an undoped $AsCl_3/Ga/H_2$ system exhibiting an $AsCl_3$ effect, the major background dopant is silicon, and that the degree of silicon incorporation depends strongly on the HCl pressure, which is proportional to the input $AsCl_3$ mole fraction X_{AsCl_3} [*i.e.* $P_{HCl} \propto P_{AsCl_3} = X_{AsCl_3} P_{total}$]. Using direct image mass analysis (18), we have identified silicon as a major contaminant of layers exhibiting high-resistivity regions (19-21) at the substrate-epitaxial interface. Silicon has been identified as an impurity in VPE films using photoluminescence (1, 12). Doping levels in undoped reactors have been reported as high as 2 to 3 $\times$ $10^{16}/cm^3$ at an $AsCl_3$ mole fraction of $\approx 2 \times 10^{-3}$. We have observed levels as high as 5 $\times$ 10^{17} cm^3 at the same $AsCl_3$ mole fraction. Therefore, it is necessary to determine whether sufficient concentrations of silicon halides are present to explain doping levels of 10^{16} to 10^{17} cm^{-3}.

The major chemical components of the growth system are: $HCl(g)/ H_2(g)/Ga(l)$ saturated with $GaAs/ H_2O(g)/AsCl_3(g)/SiO_2(s)$. The reactions leading to the formation and transport of GaAs in this system are as follows:

[1] $AsCl_3(g) + 3/2\, H_2(g) \rightleftarrows 1/4\, As_4(g) + 3HCl(g)$

[2] $Ga(l) + 1/4\, As_4(g) \rightleftarrows GaAs(s)$

[3] $GaAs(s) + HCl(g) \rightleftarrows GaCl(g) + 1/2\, H_2(g) + 1/4\, As_4(g)$

[4] $Ga(l) + HCl(g) \rightleftarrows GaCl(g) + 1/2\, H_2\,(g)$

therefore for $P^o_{AsCl_3} = P_{AsCl_3}$ (input)

$$P^o_{HCl} \simeq 3P^o_{AsCl_3} \text{ (before boat)}$$

$$P_{As_4} = 1/4\ P^o_{AsCl_3}$$

$$P_{HCl} = 1/3\ P^o_{HCl} \text{ (i.e. downstream of boat)}$$

Reaction [1] goes essentially to completion while reaction [2] produces a skin of GaAs over the gallium source when the saturation concentration of arsenic in gallium at 850°C is reached. Reaction [3] represents the over-all reaction for both transport of the GaAs skin at 850°C and the deposition reaction at the seed. Both of the reactions [2] and [3] are sensitive to the coupling of the influent gas stream containing $AsCl_3$ with the gallium boat. If the coupling is poor, the skin of GaAs will not be uniform and reaction [4] easily takes place. Assuming a well-saturated boat and

$$P^o_{AsCl_3} = 5 \times 10^{-3} \text{ atm}$$

then

$$P_{HCl(equilibrium)} \simeq 5 \times 10^{-3} \text{ atm}$$

downstream of the boat.

In the Appendix we have listed reactions between hydrogen, quartz, and HCl which lead to the formation of the volatile silicon compounds SiO, $SiClH_3$, $SiCl_2H_2$, $SiCl_3H$, and $SiCl_4$. The equations which are solved to obtain the pressures of these compounds are listed also. With the assumption that the hydrogen carrier gas is dry [$P^o_{H_2O} \leq 5 \times 10^{-7}$ atm] we calculate the following pressures of volatile silicon compounds and water for $P^o_{AsCl_3} = 5 \times 10^{-3}$ atm

$$P_{H_2O} = 1.3 \times 10^{-6} \text{ atm}; \quad P_{SiCl_4} = 3.8 \times 10^{-9} \text{ atm}$$

$$P_{SiCl_3H} = 1.2 \times 10^{-9} \text{ atm}; \quad P_{SiCl_2H_2} = 5.0 \times 10^{-9} \text{ atm}$$

$$P_{SiClH_3} = 6.3 \times 10^{-7} \text{ atm}$$

and the pressure of all chlorosilanes

$$\Sigma P_{SiClH_3} \rightarrow P_{SiCl_4} = 6.4 \times 10^{-7} \text{ atm}$$

Our calculations, which neglect $P^o_{H_2O}$ and P_{H_2O} resulting from reaction [A-1] listed in the Appendix, agree well with the more exact calculations of Weiner (22).

The calculated level of volatile silicon in the gas is approximately 0.6 ppm. Since P_{GaCl} and P_{As_4} is approximately 1000 ppm, the ratio of $P_{volatile\ silicon}$ to $P_{Ga,As}$ is approximately 10^{-3}. This level of silicon is sufficient to explain a doping level in an undoped system of 10^{16} to 10^{17} cm^{-3}. It can be seen from Eq. [A-7] and [A-8] in the Appendix that

$$P_{chlorosilanes} \propto \frac{1}{P^2_{H_2O}}$$

A calculation of this dependence by Weiner (22) shows that an input H_2 stream with $P^o_{H_2O} \simeq 5$ ppm reduces the silicon concentration by a factor of 10 relative to our assumption of $P^o_{H_2O} \leq 0.5$ ppm atm. This dependence on the $P^o_{H_2O}$ can explain why we have observed in different systems at the same mole fraction of $\simeq 1.5 \times 10^{-3}$ doping levels from (2 to 5) $\times$ 10^{17} cm^{-3} to as low as 5 $\times$ 10^{14} cm^{-3} (23). Cairns and Fairman's data show $n \simeq$ (2 to 5) $\times$ 10^{16} cm^{-3} for an $AsCl_3$ mole fraction of 1.5×10^{-3}.

In Fig. 8 we have plotted the activity of silicon, a_{Si}, at 750°C as a function of P_{HCl} downstream of the boat. This curve was obtained in the following manner: We assume that the pressure of all chlorosilanes, $\Sigma P_{chlorosilanes}$, by wall reactions at 850°C equals the pressure of chlorosilanes in equilibrium at 750°C with H_2, HCl, and Si at the substrate interface.

$$\Sigma P_{chlorosilanes}\text{, from wall reactions, 850°C} = P_{chlorosilanes}\text{, in equilibrium with HCl, } H_2\text{, Si}$$

$$\Sigma P_{chlorosilanes}\text{, wall} = (P_{SiCl_4} + P_{SiCl_3H} + P_{SiCl_2H_2} + P_{SiClH_3})$$

$$\Sigma P_{chlorosilanes} = \frac{a_{Si}P^4_{HCl}}{K_{SiCl_4}} + \frac{a_{Si}P^3_{HCl}}{K_{SiCl_3H}} + \frac{a_{Si}P^2_{HCl}}{K_{SiCl_2H_2}} + \frac{a_{Si}P_{HCl}}{K_{SiClH_3}}$$

$$\frac{\Sigma P_{chlorosilanes}}{\left[\frac{P^4_{HCl}}{K_{SiCl_4}} + \frac{P^3_{HCl}}{K_{SiCl_3H}} + \frac{P^2_{HCl}}{K_{SiCl_2H_2}} + \frac{P_{HCl}}{K_{SiClH_3}}\right]} = a_{Si}$$

For the curve plotted in Fig. 8, the HCl pressure is taken to be P_{HCl}, neglecting the production of HCl during the deposition according to reaction [3]. The

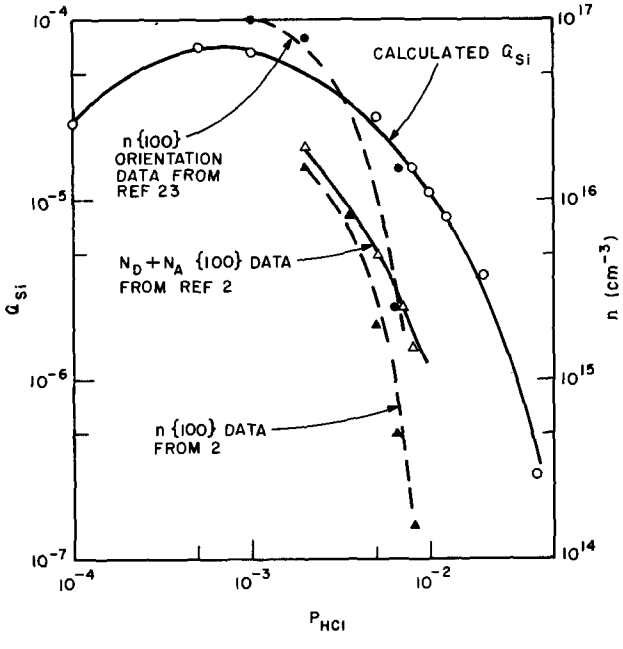

Fig. 8. The calculated activity of silicon, a_{Si}, and selected experimental carrier concentrations plotted against the pressure of HCl.

calculation indicates that the activity of silicon decreases with increasing P_{HCl}.

Also plotted in Fig. 8 are the experimental carrier concentrations, due to residual background doping, for samples grown on the {100} orientation. These curves were prepared from our own unpublished experimental results and from Cairns and Fairman's original data (2). Cairns and Fairman have calculated the total ionized-impurity concentration, $N_D + N_A$, from 77°K Hall mobilities. In Fig. 8 we have plotted their calculated values of $N_D + N_A$ as a function of the $AsCl_3$ mole fraction (note that $P_{AsCl_3} \simeq P_{HCl}$ for this plot). The slope of n *vs.* P_{HCl} is steeper than the calculated activity of silicon as a function of P_{HCl}. The slope of $N_D + N_A$ is in better agreement with the calculated curve. Since the actual silicon incorporation is characterized by $N_D + N_A$ and not $N_D - N_A$ (*i.e.* n), the better correlation is not surprising.

The model we have presented is based entirely on equilibrium thermodynamic calculations. Clearly, there may be kinetic effects operative as well as orientation dependences and growth-rate dependences (24). These effects are presently being investigated.

Conclusions

The investigation of the dependence of the incorporation of dopants into GaAs on the $AsCl_3$ mole fraction has lead to the following conclusions:

(*A*) The incorporation of silicon and germanium decreases as the $AsCl_3$ mole fraction increases.

(*B*) The incorporation of sulfur and selenium is largely unaffected by the $AsCl_3$ mole fraction.

(*C*) The behavior of n with $AsCl_3$ mole fraction for background doping can be explained by assuming that silicon is the major background dopant present in the reactor.

(*D*) The calculated vapor pressure of volatile silicon compounds generated by reactions between HCl(g), H_2(g), and SiO_2(s) is sufficient to explain the doping levels observed in undoped $AsCl_3/Ga/H_2$ systems.

(*E*) The calculated activity of silicon in equilibrium with HCl, H_2, and chlorosilanes at the substrate temperature decreases with increasing HCl pressure. This decrease is in reasonable agreement with the observed experimental decrease in n and $N_D + N_A$ with $AsCl_3$ mole fraction.

APPENDIX

Reactions leading to the formation of volatile silicon compounds.—Wall reactions leading to the production of volatile chlorosilanes in the $AsCl_3/Ga/H_2$ system are:

		ΔF° (Kcal/mole) 850°C	K(eq.) 850°C
[A-1]	$H_2(g) + SiO_2(s) \rightarrow SiO(g) + H_2O(g)$	+80.2	3.9×10^{-16}
[A-2]	$3H_2(g) + HCl(g) + SiO_2(s) \rightarrow SiClH_3(g) + 2H_2O(g)$	+80.5	2.0×10^{-16}
[A-3]	$2H_2(g) + 2HCl(g) + SiO_2(s) \rightarrow SiCl_2H_2(g) + 2H_2O(g)$	+79.5	4.1×10^{-16}
[A-4]	$H_2(g) + 3HCl(g) + SiO_2(s) \rightarrow SiCl_3H(g) + 2H_2O(g)$	+70.8	1.5×10^{-14}
[A-5]	$4HCl(g) + SiO_2(s) \rightarrow SiCl_4(g) + 2H_2O(g)$	+56.5	9.8×10^{-12}
and at the boat are			
[A-6]	$4Ga(l) + SiO_2(s) \rightarrow Si(s) + 2Ga_2O(g)$	+87.4	9.2×10^{-18}

The generated pressures of H_2O and chlorosilanes, P_{H_2O} and $P_{chlorosilanes}$, can be obtained by solving the following equations

$$[A\text{-}7] \quad P_{H_2O} = 2[P_{SiClH_3} + P_{SiCl_2H_2} + P_{SiCl_3H} + P_{SiCl_4}]$$

$$[A\text{-}8] \quad P_{H_2O} = 2\left[\frac{K(2)P_{HCl}}{P^2_{H_2O}} + \frac{K(3)P^2_{HCl}}{P^2_{H_2O}} + \frac{K(4)P^3_{HCl}}{P^2_{H_2O}} + \frac{K(5)P^4_{HCl}}{P^2_{H_2O}}\right]$$

The above equations assume: (*i*) P_{SiO} and P_{H_2O} from reaction [A-1] are small, (*ii*) that the contribution of silicon from the boat reaction [A-6] is small, and (*iii*) the vapor pressure of water in the input hydrogen, $P^o_{H_2O}$, is less than or equal to 5×10^{-7} atm.

The In-Ga-Sb Ternary Phase Diagram

G. M. Blom*,[1] and T. S. Plaskett*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The ternary phase diagram for In-Ga-Sb has been determined experimentally and has been verified by calculation. Liquidus compositions are measured along several isotherms together with several solidus compositions on the pseudobinary phase diagram. For the calculation both liquid and solid are assumed to be nonideal. The activity coefficients are calculated using a model with temperature dependent interaction parameters.

Several mixed III-V semiconductor compounds have, because of their band structures, certain advantages over the pure binary compounds. For example, the electronic properties of $In_xGa_{1-x}Sb$ are such that Gunn microwave oscillations can be observed in this material (1), while InSb and GaSb do not show this effect. $In_xGa_{1-x}Sb$ has been grown by liquid phase epitaxy from a nonstoichiometric melt, where the Sb fraction in the liquid does not equal 0.5. The desired solid composition can be grown from either an In-Ga-rich or an Sb-rich melt. Therefore, an understanding of the In-Ga-Sb ternary phase diagram is of major importance in devising crystal growth procedures.

We measured the compositions along isotherms in the In-Ga-Sb liquid and also calculated these isotherms from thermodynamic considerations. The computed isotherms turn out to predict the liquidus lines very well and also give the solidus isotherms. The model for the calculations is based on the known data for the binaries In-Sb, Ga-Sb, and InSb-GaSb. Both liquid and solid are assumed to be nonideal solutions, where an interaction parameter, α, is a measure for the departure from ideality. Similar calculations have been made for other III-V ternary alloys by Stringfellow and Green (2, 3), with a slightly different model and by Blom (4).

Calculation

The model for the calculation of the liquidus and solidus isotherms, for which a detailed description is given in ref. (2, 3, 6), is based on the assumption that equilibrium exists in the system; hence the chemical potentials in the liquid (μ^l) and solid (μ^s) phase are equal for both InSb and GaSb. For InSb, for example

$$\mu^s{}_{InSb}(T) = \mu^l{}_{InSb}(T) = \mu^l{}_{In}(T) + \mu^l{}_{Sb}(T)$$

The chemical potential for each element in the liquid phase can be related to its atomic fraction (N_i) and activity coefficient (γ_i). The chemical potential for the solid is related (5) to the changes in free energy which occur when heating the solid to its melting point, melting it, and cooling it down to the original temperature T, resulting in a supercooled stoichiometric liquid. The final expression for InSb which has to be solved is (2, 3, 6)

$$\gamma_{InSb}N_{InSb} = 4\frac{\gamma_{In}\gamma_{Sb}}{\gamma_{In}{}^{st}\gamma_{Sb}{}^{st}}N_{In}N_{Sb} \exp\left[\Delta S^f{}_{InSb}\left(T^f{}_{InSb} - T\right)/RT\right] \quad [2]$$

where N_{In}, N_{Sb}, and N_{InSb} are the atomic (molecular) fractions of In, Sb, and InSb, and γ_{In}, γ_{Sb}, and γ_{InSb} their respective activity coefficients, $\gamma_{In}{}^{st}$ and $\gamma_{Sb}{}^{st}$ the activity coefficients for In and Sb in a stoichiometric In-Sb melt, $\Delta S^f{}_{InSb}$ the entropy of fusion for InSb and $T^f{}_{InSb}$ its melting point. A similar relation can be written for GaSb. Letting the sum of the atomic fractions in the liquid and of the molecular fractions in the solid both be equal to unity, the equations describing the solid and liquid compositions as a function of temperature can be solved numerically provided that the melting points, entropies of fusion, and activity coefficients are known parameters.

It is the way in which the activity coefficients are determined that can give rise to discrepancies between different models. Obviously, neither the liquid nor the solid in the ternary system are *a priori* ideal ($\gamma_i = 1$) because they generally are not ideal in the binary compounds. Guggenheim (7) describes a lattice model wherein the interaction between nearest neighboring atoms is expressed in terms of the energy per atom and an interaction energy (E_{AB}), which is defined as the energy increase when interchanging two unlike neighboring atoms. An interaction energy equal to zero leads to an ideal solution ($\gamma_i = 1$).

For our calculations we assume a "zero order" approximation in the Guggenheim (7) approach, which means that the atoms in the liquid and the molecules in the solid are randomly distributed in spite of a nonzero energy of mixing. Little would be gained in using a higher order approximation, where no randomness in the distribution of the constituents is assumed, or taking also next nearest neighboring atoms or molecules into account, because the errors introduced in obtaining the interaction parameter α_{AB} are relatively large and of the same order of magnitude as the errors in the heat of fusion (ΔH^f). The interaction parameter α_{AB} is the sum of all the interaction energies E_{AB}. The interaction parameter is composition independent but is assumed, according to measurements on many binary systems, to be linearly dependent on temperature.

The activity coefficient for a binary system is given in terms of the interaction parameter as

$$RT \ln \gamma_{InSb} = \alpha_{InSb\text{-}GaSb} N_{GaSb}{}^2 \quad [3]$$

where $\alpha_{InSb\text{-}GaSb}$ is the parameter describing the interaction between InSb and GaSb molecules in the solid. For the ternary liquid the equivalent expression for the In activity coefficient, for example, is

$$RT \ln \gamma_{In} = \alpha_{In\text{-}Sb}N_{Sb}{}^2 + \alpha_{In\text{-}Ga}N_{Ga}{}^2 + (\alpha_{In\text{-}Sb} - \alpha_{Ga\text{-}Sb} + \alpha_{In\text{-}Ga})N_{Ga}N_{Sb} \quad [4]$$

where $\alpha_{i\text{-}j}$ represents the interaction parameter between unlike atoms i and j. Again when $E_{AB} = 0$ this results in an ideal solution ($\gamma = 1$). Values for $\alpha_{In\text{-}Sb}$ and $\alpha_{Ga\text{-}Sb}$ can be obtained from the binary phase diagrams of In-Sb (8) and Ga-Sb (9) and are assumed to be linear functions of temperature (5, 16). The interaction parameter $\alpha_{In\text{-}Ga}$ has been measured by Macur *et al.* (13).

The phase diagram for liquid and solid, which can now be calculated, does not give any information about the binary eutectic in the ternary system which is known from experimental data to exist. The eutectic composition at a certain temperature is obtained from the crossover point of the liquidus line, described by Eq. [2], and the liquidus line in the Sb region for

Table I. Parameters used in the calculations for the In-Ga-Sb ternary phase diagram

	T^f (°K)	ΔS^f (eu)	α (cal/mole)
In-Sb } (Liquid)	796 (12)	14.34 (12)	8000-16.68T (°K)
Ga-Sb } (Liquid)	985 (12)	15.81 (12)	6220-8.11T
In-Ga			1066 (13)
InSb-GaSb (Solid)			1500 (14)
Sb	903	5.72	

the same temperature. In the Sb region the isotherm can be written as

$$\gamma_{Sb}N_{Sb} = \exp\left[-\Delta S^f_{Sb}(T^f_{Sb} - T)/RT\right] \quad [5]$$

where ΔS^f_{Sb} and T^f_{Sb} are the entropy of fusion and melting temperature, respectively, for Sb. The activity coefficient γ_{Sb} can be calculated as described in Eq. [4].

Experimental

The liquidus isotherms were determined by a technique similar to that described by Hall (10). Essentially, the method consisted of submerging the end of a weighed bar of GaSb into a melt of Ga:In:Sb of known composition and at a constant temperature until saturation of the melt was obtained (about 3-4 hr). The bar was then lifted from the melt and from its weight loss the composition of the liquid was determined for that temperature.

The solidus line for the pseudobinary GaSb-InSb was also determined for two temperatures by the technique described by Foster and Scardefield (11). In this method crushed samples of GaSb and InSb are equilibrated in the two phase region, *i.e.*, between the solidus and liquidus curves for 2-3 weeks and then quenched in water. The samples were then sectioned and analyzed with an electron microprobe to determine the composition of the solid which was in equilibrium with the liquid prior to quenching.

Results and Discussion

The parameters needed for the calculation of the phase diagram for In-Ga-Sb are the entropies of fusion of InSb and GaSb, their melting points, and the interaction parameters between the constituents in the liquid and in the solid. They can all be obtained from the literature and are given in Table I. The interaction parameter for the solid (14) is obtained by fitting the experimental data for the pseudobinary from Woolley and Lees (15). The value for $\alpha_{InSb\text{-}GaSb}$ is affected by the choice for the interaction parameter for the pseudobinary liquid (B^l) (14) or by $\alpha_{In\text{-}Ga}$ (the connection between these parameters is described below). Because we use a different number for $\alpha_{In\text{-}Ga}$ than Foster and Woods for their interaction parameter in the pseudobinary liquid, their value for $\alpha_{InSb\text{-}GaSb}$ cannot be entirely applicable for our calculation. However, it is the only one available and, more important, the fit we find in the ternary phase diagram is such, as is pointed out later, that we are confident that $\alpha_{InSb\text{-}GaSb} = 1500$ gives a good description of the interaction in the solid.

The isotherms are calculated between 300° and 675°C and are plotted, together with the experimental data, in Fig. 1. The dashed line represents the binary eutectic valley in the phase diagram and the calculated isotherms for higher Sb concentrations are plotted as well; in this latter region only Sb solidifies on cooling. At any point along the binary eutectic line there is immiscibility in the solid, and thus $In_xGa_{1-x}Sb$ and Sb solidify simultaneously.

The endpoints of the binary eutectic line in Fig. 1 can be compared to composition and temperature with the eutectic points in the In-Sb and Ga-Sb binary phase diagrams. The agreement for Ga-Sb is very good: 88% Sb at 590°C as experimental data (9) *vs.* 89% Sb and 592°C for the calculated composition and eutectic temperature. On the In-Sb side of the phase

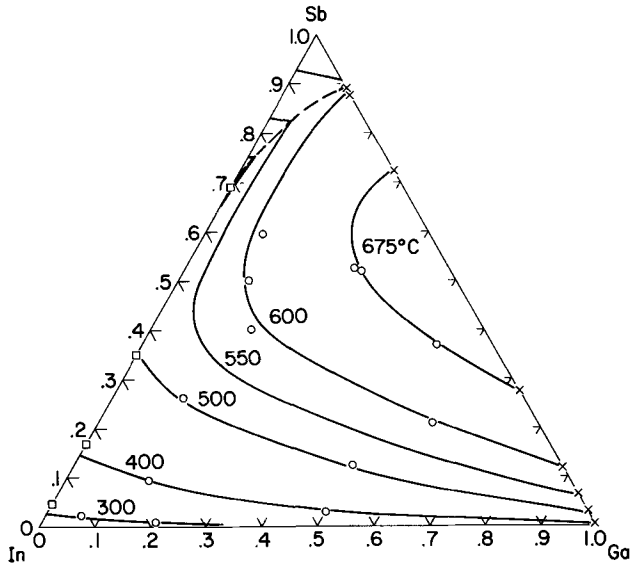

Fig. 1. Liquidus isotherms for the In-Ga-Sb ternary phase diagram. Solid lines: calculated curves; circles: our experimental data; □: ref. (8); x: ref. (9).

diagram again the composition agreement is good: 69% Sb experimental (8) and 71% Sb as calculated concentration. There is in this case, however, a discrepancy in the eutectic temperature of nearly 20°C with the published data; 476°C instead of 494°C (8).

The agreement in the entire phase diagram between the calculated and experimental isotherms is significant and shows that there is no need to adjust any of the parameters. This means that the lattice model seems well able to describe the interaction between atoms and molecules in liquid and solid and that the zero order approximation where only nearest neighbors are involved and a random distribution of the constituents is assumed, is adequate. We have to remember that, while the agreement between experiment and the model is sufficient, the calculation is still an approximation. The temperature dependence of the interaction parameters can be interpreted as due to an entropy contribution of the excess free energy of mixing. For the case that the whole temperature dependence of α contributes to the entropy term, it can be shown that $T\,\Delta S^M_{ex} > \Delta H^M_{ex}$, in contradiction with the model, which assumes only an enthalpy contribution to the excess free energy of mixing. The apparent contradiction between experiment and the predictions by regular or quasi-chemical theories leads to the conclusion that the present theories do not give an accurate chemical description for the III-V semiconductor systems, despite the significant agreement with experimental data.

Figure 2 shows the calculated solidus isotherms, where the GaSb concentrations in the solid are plotted as a function of the Ga concentrations in the liquid. As might be expected, the GaSb concentration in the solid decreases at a fixed Ga fraction in the liquid when the temperature increases, however, at high enough temperatures this trend reverses. We also notice a minimum in the GaSb fraction at $T > T^f_{InSb}$ which represents a point along the pseudobinary. The fact that there exists no Ga fraction smaller than 0.08 at 600°C can be understood from Fig. 1.

The InSb-GaSb pseudobinary phase diagram can be calculated as a special case from the ternary system, where the Sb fraction in the liquid remains constant at 0.5 and therefore in the solid also. The calculated pseudobinary is shown in Fig. 3 and is compared with experimental data. The two experimental liquidus points we determined are excellent fits to the calculated compositions, but they differ from the data of

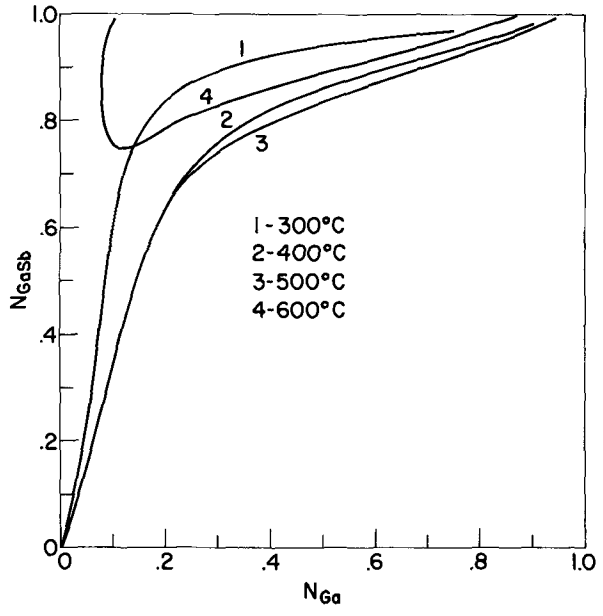

Fig. 2. Calculated solidus isotherms for the In-Ga-Sb system. The GaSb fraction in the solid is plotted as a function of the Ga fraction in the liquid for four different temperatures.

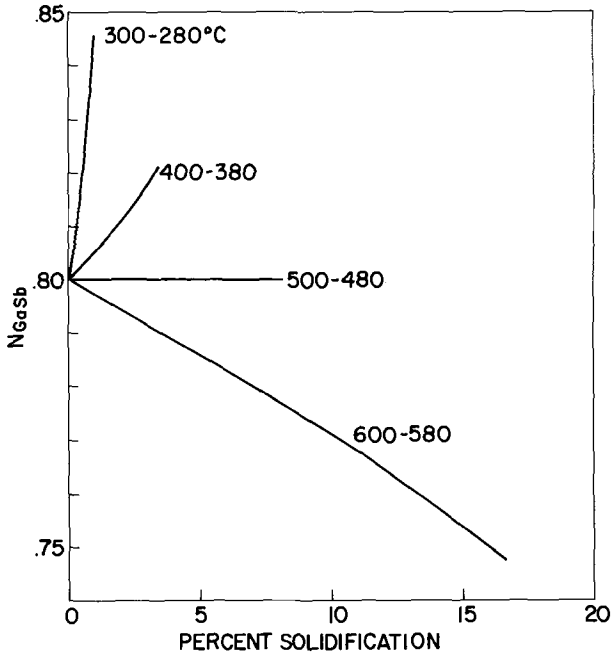

Fig. 4. GaSb fraction in the solid as a function of amount of solidification, thus proportional to the thickness of a liquid phase epitaxial layer, for several temperature ranges of growth.

Woolley and Lees (15) by 0-5% in absolute composition or 0-15°C in temperature. Calculating the ternary and the pseudobinary with the parameters from Table I, it appears that the ternary liquidus isotherms (Fig. 1) give a much better fit with our experimental data than with the pseudobinary liquid as determined by Woolley and Lees (Fig. 3). On the other hand, a shift in the α's such that the calculated curve fits the pseudobinary results in a poor fit in the ternary. The conclusion from these contradictory experimental results appears to be that the thermal analysis data (15) are not accurate enough.

Substituting in Eq. [2] for the pseudobinary case the expressions for the γ's derived from Eq. [3]-[4] gives the following expressions, where $N_{Sb} = 0.5$

$$N_{InSb} \exp[\alpha_{InSb\text{-}GaSb} N^2_{GaSb}/RT] = 2 N_{In} \exp[\Delta S^f_{InSb}(T^f_{InSb} - T)/RT] \exp[2 \alpha_{In\text{-}Ga} N^2_{Ga}/RT] \quad [6]$$

and

$$N_{GaSb} \exp[\alpha_{InSb\text{-}GaSb} N^2_{InSb}/RT] = 2 N_{Ga} \exp[\Delta S^f_{GaSb}(T^f_{GaSb} - T)/RT] \exp[2 \alpha_{In\text{-}Ga} N^2_{In}/RT] \quad [7]$$

It seems that, according to these equations, the only interaction parameters necessary to establish the pseudobinary are those for the solid and $\alpha_{In\text{-}Ga}$. This means that the pseudobinary liquid is independent of the interaction between In and Sb and Ga and Sb. In general, the pseudobinary liquid can in first order be described by the interaction between the two metals and is independent of the group V element. Hence, the InSb-GaSb, InAs-GaAs, and InP-GaP pseudobinary liquids are all determined by one and the same interaction parameter. The InP-GaP pseudobinary has been calculated this way (4) and shows good agreement with experimental data, while the InAs-GaAs system shows an agreement for the liquid within 15°C or 5% GaAs in absolute composition, while the solid fit is excellent.

An important application of the knowledge of the In-Ga-Sb ternary phase diagram is in predicting conditions for liquid phase epitaxial (LPE) growth. In general, $In_xGa_{1-x}Sb$ can be grown from an In-Ga-rich or Sb-rich solution. Growth from a metal-rich solution, however, will result in a smaller variation of the solid composition per unit thickness of the LPE layer. A calculation also shows that, when growing from an In-Ga solution, there is for each solid composition one temperature range where the composition of the solid is practically invariant along the growth axis. For a composition $In_{0.2}Ga_{0.8}Sb$ the variation of the solid composition as a function of the amount of solidification, which is directly proportional to the thickness of the overgrowth layer, is plotted in Fig. 4 for several temperature ranges. This shows that for greatest homogeneity $In_{0.2}Ga_{0.8}Sb$ should be grown in a temperature range of 500°-480°C.

The In-Ga-P Ternary Phase Diagram and Its Application to Liquid Phase Epitaxial Growth

G. M. Blom*[1]

ABSTRACT

From the procedure developed for computing the In-Ga-P ternary phase diagram the InP-GaP pseudobinary phase diagram is generated. The free energies for the ternary liquid and pseudobinary solid are calculated as a function of composition, which establishes the stability of the solid *vs.* the liquid and shows on what substrate liquid-phase epitaxial growth is possible. The composition variation of an $In_xGa_{1-x}P$ solid that is deposited during cooling in liquid phase epitaxial growth under various conditions is calculated.

The growth of III-V mixed alloy systems (1-5) is considered to be important because of possible advantages they have over the pure binary compounds. For example, $In_xGa_{1-x}P$ alloys offer the potential of direct recombination ($\Delta k = 0$) luminescence throughout the visible spectrum almost to the green. The understanding of the phase equilibria in the metal-rich ternary systems is of particular interest because the most efficient III-V alloy devices have been grown by liquid phase epitaxy (LPE) from such solutions.

Using the model which is described by Guggenheim (6) as the zero order approximation, and introducing temperature dependent interaction parameters, the ternary liquidus and binary solidus phase diagrams are calculated. The applications for LPE which can be derived from the knowledge of the phase diagrams are emphasized. An analysis of the free energies of liquid and solid as a function of composition is given, which gives insight into the stability and the behavior of a substrate in the ternary In-Ga-P liquid. Assuming equilibrium, the composition of the liquid and solid are calculated as a function of temperature and predictions are given for the composition variation as a function of the thickness of an $In_xGa_{1-x}P$ LPE layer.

Calculation of the Phase Diagram

Several calculations for deriving ternary III-V semiconductor phase diagrams are given in the literature (3, 7-10). They are, as far as the nonideal behavior is concerned, essentially based on the description given by Guggenheim (6). Ilegems and Pearson (7) and Mabbitt (10) determine the liquidus activity coefficient by introducing temperature dependent interaction parameters, but they assume the solid to be ideal, while it can be expected that the departure from ideality in the solid, due to strain, is larger than in the liquid. Stringfellow (9), in applying the quasi-chemical equilibrium (QCE) model, adopted a nonideal liquid and solid.

We use essentially the same model and mathematical description as Ilegems and Pearson (7) with the exception that the solid is assumed to be nonideal also. The linear temperature dependent interaction parameters are obtained from the binary systems (11-14). The entropies of fusion and melting points of InP and GaP are well known from the literature (12, 15, 16). All parameters are listed in Table I. The agreement with experiment for the calculated liquidus and solidus phase diagrams is just as good as Stringfellow (9) obtains with the more complicated QCE model. Thus the QCE treatment does not give a more accurate description of the chemical behavior of the constituents.

The InP-GaP pseudobinary phase diagram can be calculated from the ternary system as a special case, where the phosphorus fraction in the liquid equals 0.5. The equations which describe the concentration in liquid and solid as a function of temperature are

$$N_{InP} \exp[\alpha_{InP\text{-}GaP} N^2_{GaP}/RT] = 2N_{In} \exp[\Delta S^f_{InP}(T^f_{InP} - T)/RT] \exp[2\alpha_{In\text{-}Ga} N^2_{Ga}/RT] \quad [1]$$

and an equivalent one where In and Ga are permutated. N_i denotes the respective fractions in liquid and solid, ΔS^f_{InP} and T^f_{InP} the entropy of fusion and melting point, and $\alpha_{i\text{-}j}$ represents the interaction parameter between the constituents i and j. According to Eq. [1] the interaction parameters for the binary systems In-P and Ga-P do not affect the pseudobinary phase diagram.

Table I. Parameters used in the calculations of the In-Ga-P ternary phase diagram

	T^f (°K)	ΔS^f (eu)	α (cal/mole)
In-P }	1341 (12)	14.7 (15)	0 (12)
Ga-P } (liquid)	1758 (16)	16.0	(7900-7T) (11)
In-Ga }			1066 (14)
InP-GaP (solid)			(−681 + 2.79T) (13)
