Electret science is becoming an important branch of pure and applied physics. An electret is simply a dielectric material with remanent polarization. Thermoelectrets and photoelectrets are formed by simultaneous application of electric field and heat or light, respectively. Properties of naphthalene thermoelectrets were first discussed by Baldus (1) and then by Mascarenhas (2). Later Belyaev, Belikova, Fridkin, and Zheludev (3) reported on the thermo- and photoelectret effects in naphthalene and showed that these states are inseparable. Campos *et al.* (4) used the thermal depolarization technique to investigate trapped polarization in naphthalene thermoelectrets. The higher values of charge storage in naphthalene (3) led to further investigation. Depolarization current characteristics and contact electrification processes of naph-

Key words: organic semiconductor, naphthalene, photoelectret, dark depolarization current.

thalene photoelectrets, formed under different experimental conditions, have been studied in detail in this investigation.

Naphthalene is a photoconducting dielectric material with a permittivity of 2.7 and a band gap of 3.7 eV (5). This band gap value gives an optical absorption edge in solid naphthalene at 3400Å.

The naphthalene used in this investigation was obtained from British Drug Houses Ltd. (BDH) Laboratory Chemicals Division, Poole, England, and had a molecular weight of 128.17.

Experimental Conditions

About 25 naphthalene samples were prepared by solidifying melted naphthalene (mp 79.5°C) in mica cavities, 1 cm^2 in area and 1 mm thick, between two aluminum electrodes. Sample surfaces were made uniform by means of a remelting and resolidification technique; keeping a heated aluminum electrode over the surface and applying pressure to remove extra material. This special technique also helped to maintain a uniform thickness for all samples. To avoid the initial molding charge, the samples after preparations were kept in a desiccator under dry conditions for about 12 days. The samples were then placed inside a photoelectret jig specially designed for the application of forming field and polarizing light simultaneously.

Details of the photoelectret jig are shown in Fig. 1. It consists of a brass cylinder, 1, 3 in. in diameter, closed on both ends except for an aperture, 2, for light illumination. Another small cylinder, 3, 1 in. in diameter, is screwed into the aperture to obtain perfect darkness surrounding the sample. The sample, 4, is held tightly by means of a spring, 7, and a movable electrode, 11, between two aluminum electrodes, 5 and 6, and is placed inside the guard ring of mica, 8.

To illuminate the sample, one of the aluminum foil electrodes, 5, was made into a grid with 1 mm^2 holes spaced 1 mm apart. The other aluminum electrode, 6, was solid. A brass rod, 9, was attached to the spring through insulation, 10. A circular brass disk, 11, connected to this rod was used to apply uniform pressure to the sample. An insulated knob, 12, to adjust the pressure on the sample, is held by the cover. A door, 13, is provided for handling the sample. The casing and the shielding of all connecting wires are grounded.

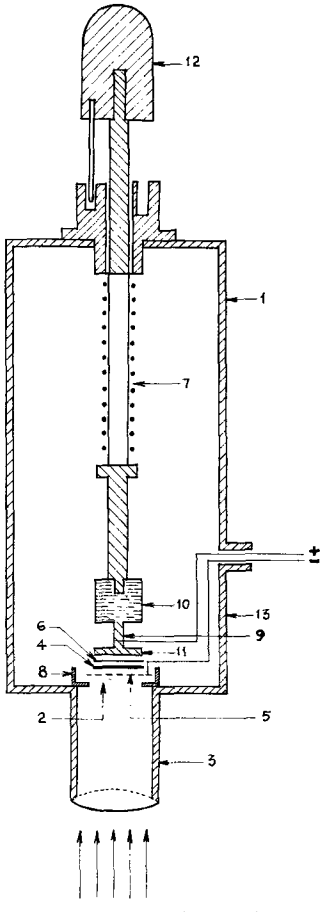

Fig. 1. Photoelectret jig

Aluminum electrodes make blocking contact with naphthalene monocrystal (6), but with polycrystalline material, the nature of contact is effectively ohmic due to the presence of surface states. Deviations from Ohm's law can occur at higher fields due to space charge effects.

To measure dark depolarization current, the sample was illuminated for 10 min with white light from a 100W, 220V, tungsten filament lamp, and a high polarizing field was applied simultaneously, keeping the perforated electrode negative. The field and illumination were then switched off, and the jig containing the sample was covered with a black cloth. Discharge current was measured by means of a microammeter E A 810A, supplied by Electronic Corporation of India; that can read current down to 10^{-12}A.

In another series of measurements the photoelectrets formed as above were kept short-circuited in complete darkness for half a minute, then re-illuminated with the same light intensity as used during polarization process. Photodepolarization current measurements were carried out simultaneously.

In the third series, photoelectrets were formed by the application of field and light for 10 min, then the field was continued for another 5 min after the illumination was switched off, *i.e.*, the sample was dark polarized for 5 min. After these polarization processes the samples were kept short-circuited in the dark for half a minute. The photodepolarization current measurement was taken while re-illuminating the photoelectrets. Measurements were carried out at room temperature, *i.e.*, 32° ± 2°C.

Experimental Results

Dark depolarization current measurements were carried out on ten different samples. A separate sample was used a each value of the field strength varying in steps of 0.9 kV/cm from 0.9 to 9 kV/cm. Results are shown in Fig. 2. The decay of dark depolarizing current with time is similar in each case. Illumination was kept constant in each of these measurements.

The results of experimental investigation of the second series of measurements are shown in Fig. 3. Initial values of currents in this case are much less than those of the photoelectrets processed without storing. Final values of the currents are slightly higher than the values without storing, indicating that the storing process stabilizes the traps. In Fig. 4 the results of the third series of measurement are plotted. Here the initial current is more than its corresponding value in the second series shown in Fig. 3. This suggest that the process of dark polarization for an extra 5 min after photopolarization for 10 min gives better results.

It can be seen from Fig. 2 and 3 that the initial value of depolarization current increases with increasing field strength. But the depolarization current curves cross at certain points due to different decay rates, which depend on the variation of temperature and humidity conditions during measurement, and also on the slight variation of thickness and structure from sample to sample. It has been observed that decay curve do not cross if a single sample is used at all field strengths under controlled conditions. Uncharged samples are used in this case at each field strength to preclude any effect of retention of previous charge on the measured value of current.

Five different samples were polarized by light and field at different field strength. Depolarization currents measured after re-illumination are shown in Fig. 5. Under similar experimental conditions, a single naphthalene sample was also polarized at each field

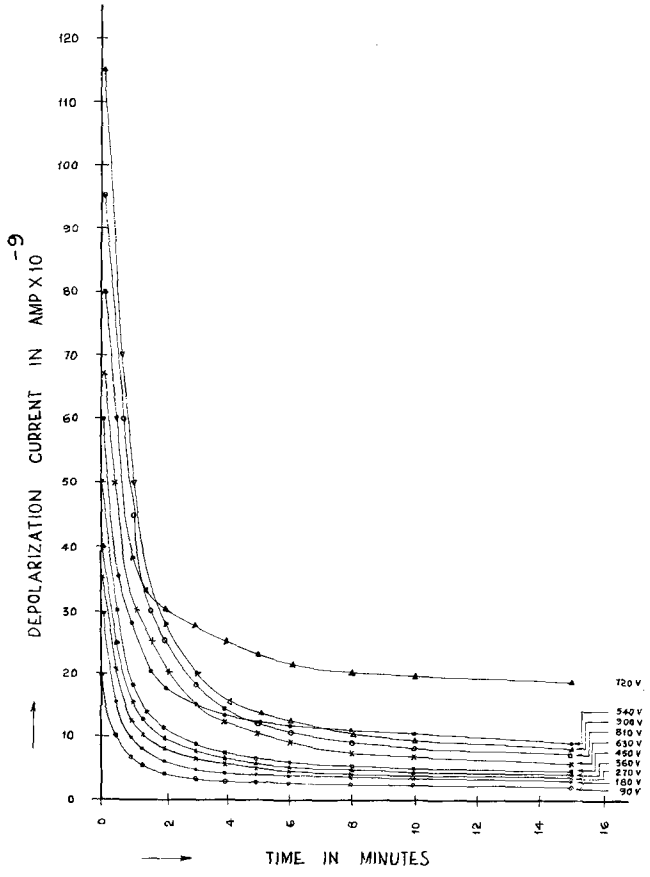

Fig. 2. Dark depolarization currents, for naphthalene photoelectrets formed in 10 min time at different field strengths varying from 0.9 to 9 kV/cm.

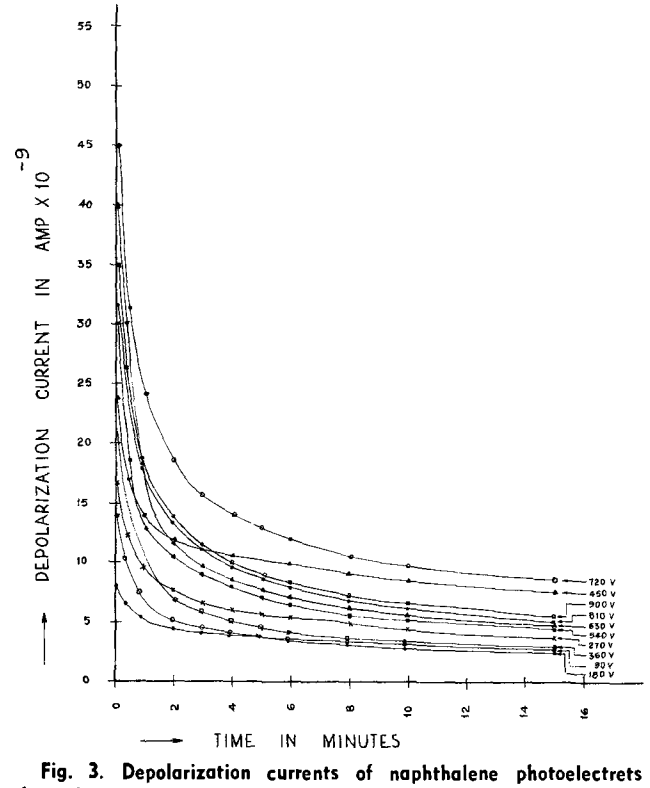

Fig. 3. Depolarization currents of naphthalene photoelectrets formed as in Fig. 2, but stored in dark for half a minute longer and then illuminated during measurements.

strength and depolarization current while re-illuminating was observed. Results are plotted in Fig. 6. The curves in Fig. 6 tend to converge while those in Fig. 5 are approximately equally spaced. This interesting

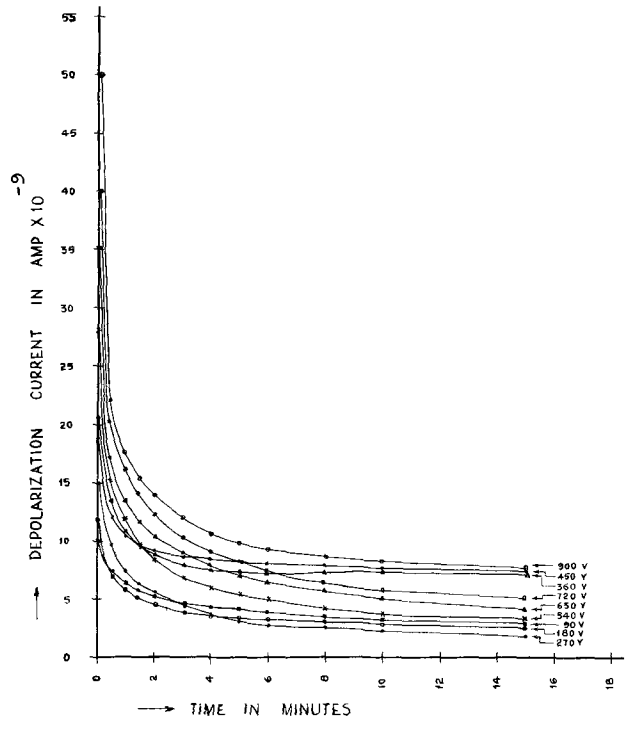

Fig. 4. Depolarization currents of naphthalene photoelectrets formed as in Fig. 2 and also dark polarized for another 5 min. The current measurements have been taken by re-illuminating the samples which were stored in dark for half a minute more.

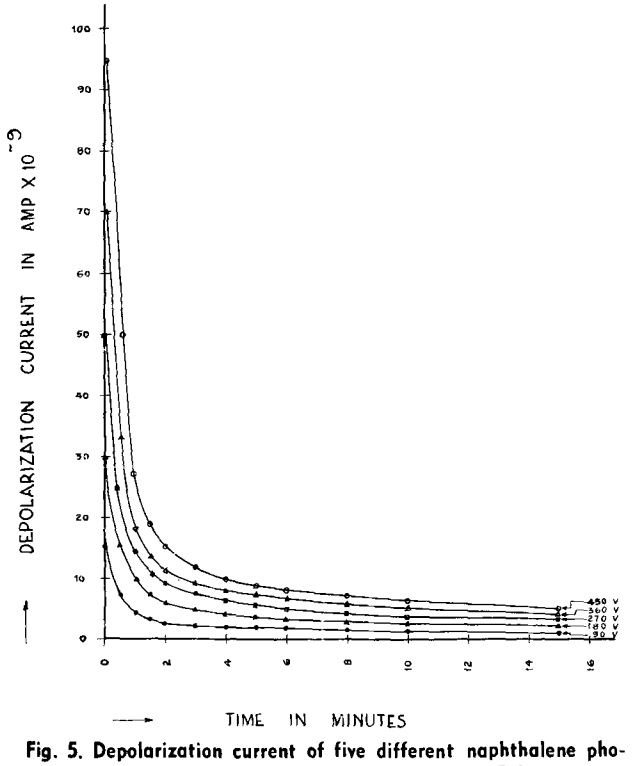

Fig. 5. Depolarization current of five different naphthalene photoelectrets for field strengths varying from 0.9 to 4.5 kV/cm.

phenomenon of convergence can be called the heat quenching effect (7).

In Fig. 7, current measurements on different fresh, unpolarized samples, *i.e.*, dummy samples, prepared under identical conditions without any application of field and illumination are shown. These stripping charges are introduced at the metal insulator contact during the molding of samples. It can be seen that currents on one side of the sample are always higher than those on the other side. High discharge currents are obtained on the side which solidifies on the alumi-

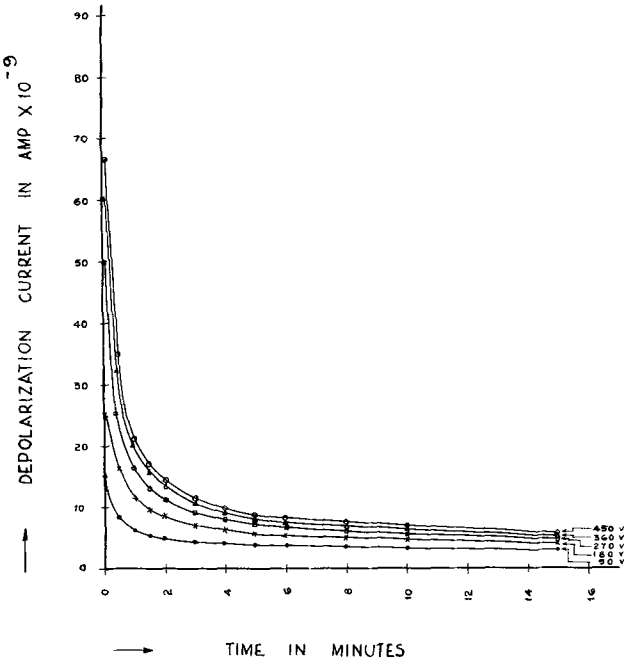

Fig. 6. Depolarization current of naphthalene photoelectrets prepared from the same sample at field strength varying from 0.9 to 4.5 kV/cm.

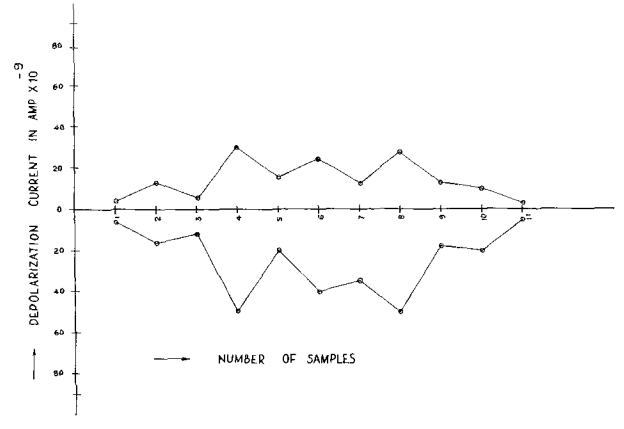

Fig. 7. Discharge current of different fresh samples formed without the application of field or light.

num electrode. The other side of the sample was treated by the remelting and resolidification process; reheating each time destroys the charge produced the previous time, and ultimately less current is observed on that surface. Such currents in samples left in open air, decay quickly in humid surroundings; however, in samples kept short-circuited by metallic foils in a desiccator, the currents retain their values for a longer time.

Depolarization current of a dummy sample and a polarized sample, prepared at 4.5 kV/cm, are compared in Fig. 8. For the dummy sample, depolarization current increases to a maximum value in 24 hr and then decays to a constant value in 3 days time (curve a). After 6 days it again starts decaying and ultimately becomes zero. Another sample was kept short-circuited for 24 hr (curve b) and then polarized. Current in this case increases from 50 x 10^{-9} to 130 x 10^{-9}A on the side subjected to illumination and from 110 x 10^{-9} to 150 x 10^{-9}A on the other side; it then falls sharply to a much lower value in the next 24 hr. Afterwards it decays slowly to zero in approximately 12 days. After measurements, samples were kept short-circuited in a desiccator for further studies. The high value of depolarization current in the dummy sample have been found to be associated with high humid environment.

Discussion

Kepler and Le Blanc (8, 9) have suggested that band structure model can be effectively applied to explain photoelectret phenomena in organic semiconductors. Incident light excites electrons and holes in the valence band of naphthalene, and when the condition of absorption is satisfied for any particular wavelength, electrons are excited either to the conduction band or to traps. Depolarization current is a maximum initially and then decays asymptotically due to the fact that the supply of trapped electrons is maximum in the initial stage and only a small number of electrons are available after some time. Excited electrons travel toward the positive electrode and holes toward the negative electrode, and the sample becomes polarized as shown in Fig. 9(a) (top) and (b) (bottom). If the number of electrons per unit volume in the trapping levels at the initial polarization state is N_0 and the number of electrons per unit volume contributing to depolarization current at any time t is n, then we can write

$$n = N_0 \exp(-t/\alpha) \quad \ldots \quad \ldots \quad \ldots \quad [1]$$

where α is the lifetime of electrons in electron traps. Similarly for holes

$$p = P_0 \exp(-t/\beta) \quad \ldots \quad \ldots \quad \ldots \quad [2]$$

where β is the lifetime of holes in hole traps. Values of α and β are of the order of several seconds for naphthalene crystal.

Total depolarization current density J at any time t is the current due to electrons as well as holes, which can be written as

$$J = ne\,\mu_e E + pe\,\mu_h E = J_{No} \exp(-t/\alpha) + J_{Po} \exp(-t/\beta) \quad \ldots \quad [3]$$

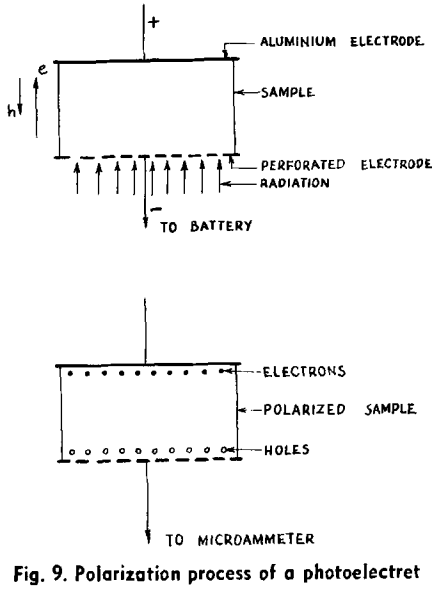

Fig. 9. Polarization process of a photoelectret

where E is the electric field and e the charge of the carrier; μ_e and μ_h are mobilities of electrons and holes, respectively,

$J_{No} = N_o\, e\, \mu_e\, E$, *i.e.*, initial electron current density
$J_{Po} = P_o\, e\, \mu_h\, E$, *i.e.*, initial hole current density

The decay of depolarization current, as shown in Fig. 2 to 6 can be explained by Eq. [3]. It is assumed that mobilities μ_e and μ_h do not change appreciably during illumination. The expression for depolarization current is valid for all values of electric fields except for one or two discrepancies. Since we do not know the exact contributions of electrons and hole, we cannot make exact calculations.

Dark depolarization current is the current due to thermal release of electrons; its decay is faster in the beginning and slow afterwards tending to become constant (Fig. 2). Dark depolarization current as a function of applied field is shown in Fig. 10, immediately after the formation of the electret. This initial depolarization current shows an almost linear increase from 20 x 10^{-9}A to 115 x 10^{-9}A with the applied field increasing from 0.9 to 9 kV/cm under constant illuminance (curve a). No saturation is observed in this case. Due to the application of field, electrons and holes are liberated from traps replacing conduction electrons which are already displaced by the applied field. The stronger the field the greater is the number of electrons displaced; this explains the rise of depolarization current with applied field. The fact that there is no saturation suggests that during formation of the photoelectret there is only partial filling of trapping levels by electrons. When short-circuited samples are stored in the dark for half a minute before photodepolarization current measurements, and then re-illuminated, charge carriers are excited from traps due to light induced transitions as well as due to thermally induced transitions. The initial depolarization current increases from 8 x 10^{-9} to 45 x 10^{-9}A for the same field values as above (curve b). The smaller value of initial discharge current in this case suggests that the phenomenon of recombination between electrons and holes is taking place during short-circuiting, thereby reducing the number of electrons in trapping levels and thus the density of conduction electrons. Discharge current increases with field from 10 x 10^{-9} to 50 x 10^{-9}A when the external field is applied for 5 min more after the illumination is switched off (curve c). Here an increase in the duration of the applied field has increased the initial depolarization current, indicating that more and more charge carriers are carried along by the field, depending on the duration of applied field.

Final depolarization current after 15 min, Fig. 11, curve a, shows a much shallower slope as compared to the slope of initial current as shown in Fig. 10. The dark depolarization current increases from 2 x 10^{-9} to 7.8 x 10^{-9}A for the field values from 0.9 to 9 kV/cm, except for a peak around 7.2 kV/cm where the current is 20.5 x 10^{-9}A. Depolarization current after storing (curve b) increases from 2.6 x 10^{-9} to 5.3 x 10^{-9}A and that after application of external field (curve c), from 2.9 x 10^{-9} to 7.5 x 10^{-9}A for the same field range. The small variation in final depolarizing current in these cases suggests that release of trapped electrons can take place at almost the same rate in all these cases. The data for Fig. 10 and 11 are taken from Fig. 2, 3, and 4.

The heat quenching effect, Fig. 6, occurs due to prolonged illumination of the sample with white light. The infrared component quenches electrons present in shallow traps without producing any further excitation. If separate samples are used at different field strengths, no such quenching effects occur, as shown in Fig. 5.

A dummy sample molded between two electrodes without any application of field and illumination also gives a depolarization current comparable to that of a polarized photoelectret (Fig. 8, curve a and b). This is associated mainly with the contact electrification of the sample.

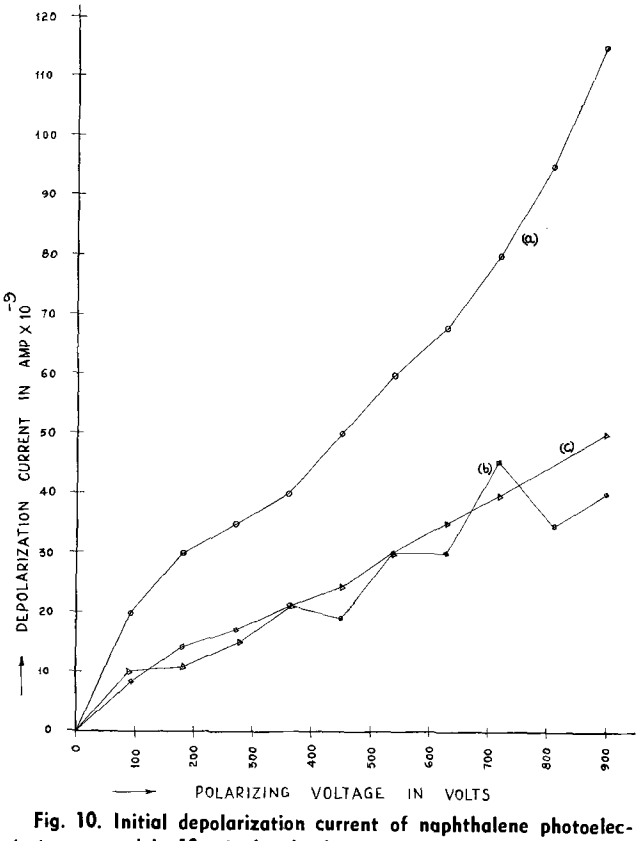

Fig. 10. Initial depolarization current of naphthalene photoelectrets prepared in 10 min by simultaneous application of field and illumination as a function of applied field strength: (a) immediately after formation of electret; (b) after dark storage, sample short-circuited; (c) external field maintained for 5 min after removal of illumination.

Summary and Conclusions

1. Naphthalene photoelectrets can be prepared in 10 min time with simultaneous application of an electric field and light.

2. Initial dark depolarization current increases almost linearly with increasing field; the final current after 15 min does not increase in the same proportion,

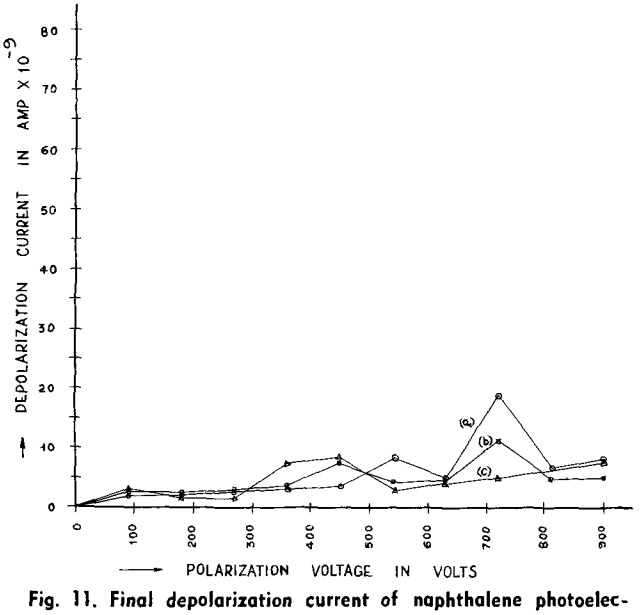

Fig. 11. Final depolarization current of naphthalene photoelectrets, prepared as in Fig. 10, after 15 min, as a function of applied field: (a) immediately after formation of electret; (b) after dark storage, sample short-circuited; (c) external field maintained for 5 min after removal of illumination.

indicating that decay is faster at higher voltages than at lower voltages.

3. When photoelectrets are stored in dark for 0.5 min, the depolarization current shows much more stability than it does in photoelectrets not stored.

4. The application of an external field after switching off the illumination increases the initial value of depolarization current; therefore this technique is advantageous for getting larger currents. The final current after 15 min is, however, not much affected by an extra field.

5. Prolonged illumination with the tungsten filament source produces a heat quenching effect and, therefore, the use of infrared filters is suggested for future work.

6. Contact electrification plays an important role in the behavior of a naphthalene photoelectret, especially under humid surroundings.

Acknowledgments

The authors are grateful to Professor M. S. Sodha, Head of the Department of Physics, Indian Institute of Technology, Delhi, for the encouragement given to them during the course of this investigation. Special thanks are also due to Mr. V. K. Jain for the useful suggestions and discussions at all stages of this experimental investigation. The authors are thankful to the Council of Scientific and Industrial Research, Government of India, for the research grant for carrying out this work.

Manuscript submitted Oct. 27, 1969; revised manuscript received *ca.* Oct. 22, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Behavior of Te in Vapor-Grown GaP

R. C. Taylor*

IBM Research Division, Yorktown Heights, New York 10598

During the course of recent photoluminescence studies of tellurium donors in vapor-grown GaP (1) it was found that dark, trigonally shaped patterns appeared in crystals grown in the (111)A direction at high tellurium concentrations. These dark areas were clearly visible at low magnification when the crystals were viewed with transmitted light. Similar findings were also made by Luther (2). Because of the importance of tellurium doping in GaP light-emitting diodes we attempted to gain a more quantitative picture of the nature of these dark areas and of the general behavior of Te in vapor-grown GaP, including the solubility of the electrically active species. To accomplish this a series of crystals was grown using radioactive Te as the dopant. The desired information was obtained from a correlation of the radiotracer data with the electrical measurements. Use was also made of transmission photomicrographs, autoradiographs, and electron microprobe analysis.

Experimental

The vapor-grown GaP crystals were prepared by a previously described Ga-PCl_3 transport method (3). The gallium source temperature was 900°C, the substrate temperature 800°C, and the PCl_3 bubbler temperature −30°C. The PCl_3 flux was maintained constant at 1×10^{-3} moles/hr for all runs by passage of 50 cm^3/min of hydrogen through the cooled bubbler. Radioactive Te was introduced into the system in the form of a Te pellet in the doping line. The Te vapor flux required to give the desired doping level was controlled by the pellet temperature and hydrogen flow over the pellet. The Te flux was determined by pellet weight loss. Total hydrogen flow in the system was 100 cm^3/min.

For the most part the substrates used were GaAs wafers oriented 5° off (111)A. This orientation was chosen because it had been found that high donor concentrations could be employed without significantly affecting growth rates and surface morphology of GaP growths as opposed to the case with growths on (111)B substrates (4, 5). Also the (111)A growths tend to reject the residual sulfur impurity that is present in PCl_3 (3) so that the electrical measurements should reflect only Te donor concentrations. A few (100) and 5° off (111)B substrates were used to determine whether the solubility of electrically active Te and the appearance of the discolored defect areas might be orientation dependent and to determine the $Te_{(111)B}/Te_{(111)A}$ orientation effect [the ratio of Te incorporated into (111)B growths to Te incorporated into (111)A growths under identical conditions].

The substrates were chemically polished with an H_2SO_4/H_2O_2 etch before use. After growth the GaAs was removed by a $3HNO_3/HCl$ etch. The radioactive Te was produced by neutron irradiation of six nines purity Te, and its concentration was determined in the GaP by gamma scintillation counting. Since the radiochemistry of Te is quite complex and several isotopes emit gamma radiation, the notation Te* will be used throughout this paper to indicate total Te concentration as determined by gamma counting of all radioactive Te species. A possible complication in determining Te in a sample by radiotracer methods is the decay of Te^{131} resulting in the growth of gamma activity in the daughter product I^{131}. The iodine being retained in the standard would not be incorporated into the growing GaP crystal and as a result erroneous radiotracer data would be obtained. Therefore the neutron-irradiated Te was not used until the I^{131} had decayed below the limit of detectability as determined by gamma ray spectrometry. In this way we were certain that all gamma activity from both sample and

Key words: tellurium segregation, donor solubility, substrate orientation effect.

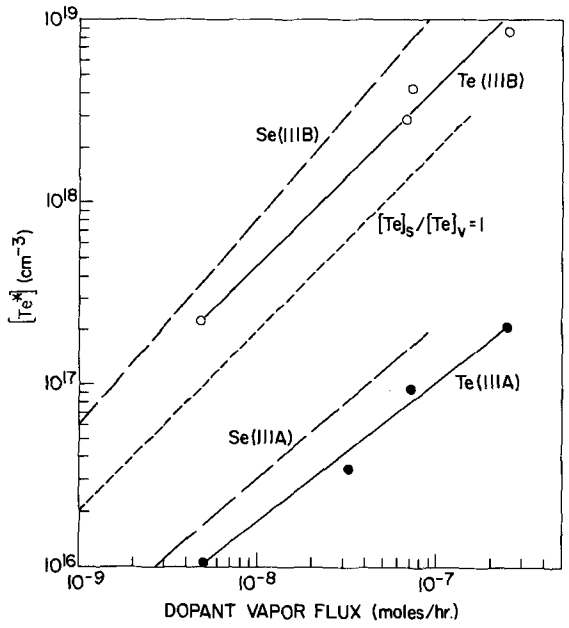

Fig. 1. The dependence of Te* concentration in (111)A and (111)B GaP crystals on dopant vapor flux.

standard was due exclusively to radioactive Te species. As a further check, the doped GaP samples were remeasured after a few weeks and were found to have the same Te concentration as compared with the standard. Electrical measurements were made by the Van der Pauw method. The GaP crystals were polished for the transmission photomicrographs, autoradiographs, and electron microprobe analysis. The autoradiographs were taken with Kodak R-X-ray film using 16-hr exposures.

Results and Discussion

Dependence of Te concentration on dopant vapor flux.*—The concentration of Te* in the GaP crystals as a function of dopant vapor flux is shown in Fig. 1. Previously obtained results for Se^{75} doping (4) are also shown for purposes of comparison. The Te concentration in the crystal shows an approximately linear dependence on dopant vapor concentration for both (111)A and (111)B growths. This was also found for Se doping and indicates that doping occurs under nonequilibrium conditions since under equilibrium conditions at an 800°C growth temperature the doping should reflect extrinsic behavior and the donor concentration should be proportional to the square root of the vapor phase concentration. A linear dependence has also been found by van der Does de Bye and Peters in an open tube GaP-HCl transport system (6). However Dyakonov (5) observed the expected extrinsic behavior in a closed-tube system, which lends itself more to equilibrium conditions than does an open system.

The orientation effect doping ratio, $Te_{(111)B}/Te_{(111A)}$, increases from about 20 at a dopant flux of 5×10^{-9} moles/hr to about 45 at a flux of 1×10^{-7} moles/hr. The same ratio is exhibited by Se-doped crystals, so it is apparently independent of donor species. We have explained this ratio previously for Se doping based on the fact that Se going onto a P site as a donor will form two surface bonds on a (111)B surface and only one on a (111)A surface and will therefore be more strongly held on the (111)B surface (4). Although the orientation effect ratio is independent of donor species, the distribution coefficient of the donor between solid and vapor is not. The distribution coefficient for Te is about one-half of that for Se. The difference decreases somewhat as lower dopant concentrations are approached. The distribution coefficient for Te is about 2 on (111)B face growths and about 0.05 to 0.1 on (111)A face growths.

Correlation of radiotracer and electrical data.—The results of radiotracer and electrical measurements on the Te-doped samples are given in Tables I and II and in Fig. 2. Table I shows the Te* concentration and the room temperature and 77°K electrical properties for (111)A growths. Table II gives similar results for (100) and (111)B growths. It should be noted that the Te* concentration at high concentrations is an average value due to segregation of the dopant.

In Table I all samples except A1 are n-type. The two principal effects illustrated by this table are those due to compensation and to impurity conduction. Compensation is indicated at Te* values below 10^{17} cm^{-3} by the discrepancy between the Te* concentration and the room temperature carrier concentration. This discrepancy becomes as large as 6 to 1 for sample A2 and decreases until a concentration 2×10^{17} cm^{-3} is reached (samples A5 and A6). Compensation is also reflected in room temperature and

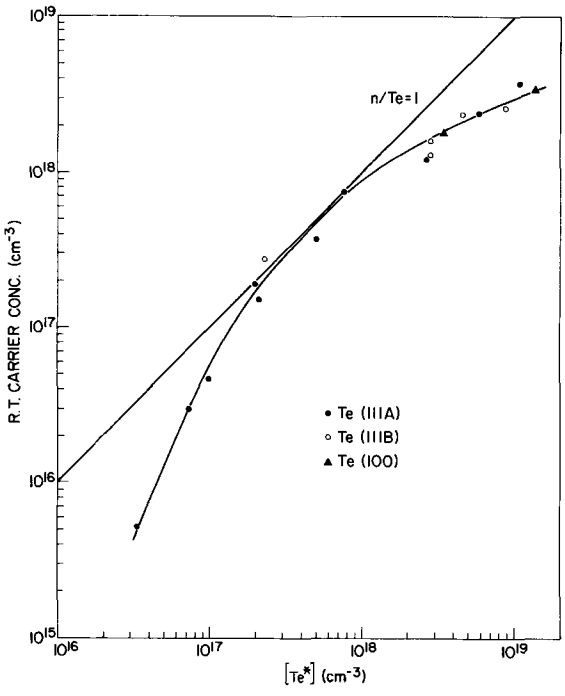

Fig. 2. The dependence of room temperature carrier concentration on Te* concentration in GaP crystals grown on (111)A-, (111)B-, and (100)-oriented substrates.

77°K mobility values, which peak at a Te concentration of 1 x 10^{17} cm^{-3} and fall off at lower concentrations. We have previously speculated (7) that this compensation is due to a Ga vacancy deep acceptor (triply ionized) at a concentration of about 1 x 10^{16} cm^{-3} which is introduced into (111)A growths to alleviate surface strain. Other investigators (6, 8) have calculated that a deep acceptor is present in (111)A growths at a level of 0.85 eV above the valence band, but they have failed to identify it.

The indication of impurity conduction is seen in the heavily doped samples (A10 and A11) where Te* is above the mid 10^{18} cm^{-3} range. Carrier freezout drops from three orders of magnitude for donor concentrations in the low 10^{16} cm^{-3} range to less than one order of magnitude at 10^{19} cm^{-3} (sample A11). Also at 10^{19} cm^{-3}, the mobility at 77°K is less than at room temperature. Table II shows the same tendency toward impurity conduction for (100) and (111)B growths as does Table I for (111)A growths and at the same donor concentration.

Figure 2 shows the experimental and n/Te = 1 curves for room temperature carrier concentration as a function of Te* concentration for three different substrate orientations. The previously mentioned compensation in (111)A growths is reflected on the divergence of the two curves at low Te concentrations. In the 10^{17} cm^{-3} range the two curves closely parallel each other. The fact that the (111)B point is above the n/Te = 1 line is perhaps due to the contribution of the sulfur impurity. At high concentrations the carrier concentration falls increasingly below the Te concentration due to increased donor ionization and the approach to saturation solubility of Te as an electrically active species. The points for high doping levels show the solubility limit to be independent of substrate orientation. Using the data if Montgomery (9) for Te binding energy *vs.* Te concentration and calculating the per cent ionization, it has been determined that for a sample with a Te concentration of 1 x 10^{19} cm^{-3} and a room temperature carrier concentration of 3-4 x 10^{18} cm^{-3} (upper limit of curve, Fig. 2) the donor concentration at exhaustion is about 6-7 x 10^{18} cm^{-3}, or about 60% of the Te concentration. This is probably the solubility limit for electrically active Te. This substantially agrees with the results of Trumbore (10), but is about three times the solubility determined by Dyakonov (5).

Tellurium segregation.—Figures 3-5 show transmission photomicrographs of the Te segregation which occurs at high concentrations. Figure 3 shows the most heavily doped (111)A and (100) growths. In (a) and (b) the view is along the (111) growth direction. The Te concentration in the sample of Fig. 3a (A10) is 6 x 10^{18} cm^{-3}, or about half that of the sample of Fig. 3b (A11) which is 1.1 x 10^{19} cm^{-3}. Both photomicrographs show the remnant of an as-grown surface pit not completely removed by polishing. The trigonally shaped dark areas appear to have their origin at the apex of these pits and display the three-fold symmetry of the (111) growth direction. The first signs of these defect areas appear at a Te concentration of about 2 x 10^{18} cm^{-3}. The number of trigonally shaped areas is considerably greater than the number of obvious pits in the as-grown surface, which suggests that the pits coalesce or fill in during growth. The filling in process has been observed by Luther (2). It is possible that the apex of each trigon is at a dislocation site either present in the substrate or generated to relieve heterojunction strain, the number generated increasing with increasing Te concentration. The reason for the shape of the trigon is probably that the pit walls are of an orientation which allows nucleation and retention of Te more readily than does the (111)A growth surface. Figure 3c is an autoradiograph of the sample in Fig. 3b. The clearly visible trigon in the center of the figure shows that the three blades of the trigon are truly Te rich. In Fig. 3d and 3e the view is along the (100) growth direction. The Te concentration in the sample of Fig. 3e(02) is 1.4 x 10^{19} cm^{-3}, or four times that in

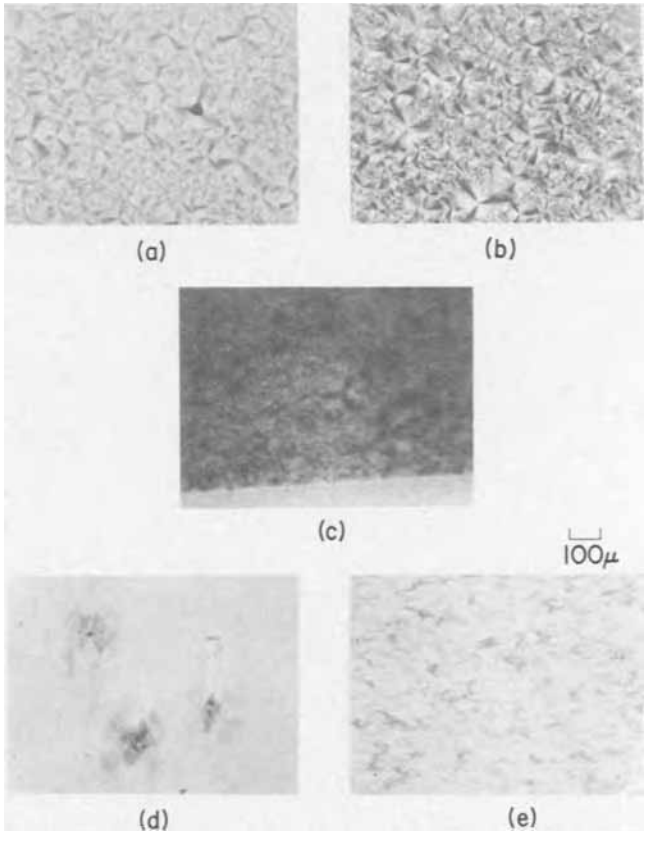

Fig. 3. (a) Transmission photomicrograph of sample A10 (t = 7 mils) viewed along (111)A growth direction. (b) Transmission photomicrograph of sample A11 (t = 7 mils) viewed along (111)A growth direction. (c) Autoradiograph of (111) surface of sample A11. (d) Transmission photomicrograph of sample 01 viewed along (100) growth direction (t = 4 mils). (e) Transmission photomicrograph of sample 02 viewed along (100) growth direction (t = 4 mils).

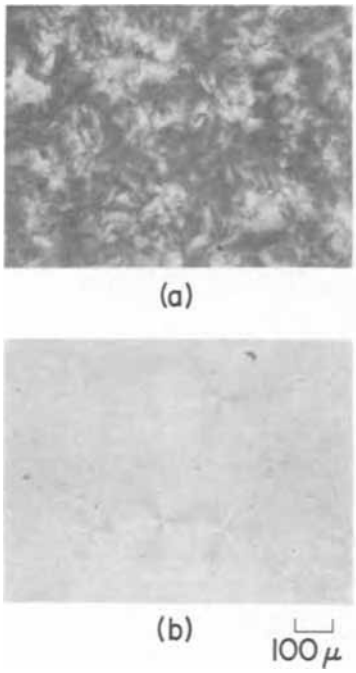

Fig. 4. (a) Transmission photomicrograph of Se-doped sample viewed along (111)B growth direction. (Se^{75}) = 1.3 x 10^{19}, n(RT) = 2.1 x 10^{18} cm^{-3}. (b) Transmission photomicrograph of Se-doped sample viewed along (111)A growth direction. (Se^{75}) = 3.2 x 10^{18}.

Fig. 5. Transmission photomicrograph of sample A12 (t = 8 mils) substrate and film viewed perpendicular to (110) cleavage plane and (111)A growth direction.

Fig. 3d(01) which is 3.5 x 10^{18} cm^{-3}. The typical "maltese cross" fourfold symmetry of the (100) plane is apparent in some of the areas. Precipitates are also evident.

Figure 4a is a transmission photomicrograph of a sample grown on a (111)B substrate, the view being along the (111) growth direction. The dopant here is Se^{75} at a concentration of 1.3 x 10^{19} cm^{-3}, but high Te doped samples look exactly the same. Figure 4b is a (111)A growth with an Se concentration of 3.2 x 10^{18} cm^{-3}. In contrast to (111)A growths the dark areas in (111)B growths show no distinguishable form. This is further evidence that the trigonally shaped areas are associated with pits since, while both (111)A and (111)B growth planes have the same threefold symmetry, there is never any pit formation observed in (111)B face growths. It may also be that the reason for the more drastic effect of high doping levels on growth rate and surface morphology of (111)B growths is the nonlocalized nature of the defect areas leading to a more highly strained surface.

In order to get a more quantitative idea of the Te distribution in heavily doped samples the electron microprobe was used on a cross section of one sample. Figure 5 is a transmission photomicrograph of a sample doped with nonradioactive Te (A12). The view is through a cross section of the film and the substrate (111A GaP) and is perpendicular to the (111)A growth direction and the (110) cleavage plane. The grown crystal is 1.5 mm in thickness. The room temperature carrier concentration in this sample is 3.1 x 10^{18} cm^{-3}. The complete set of electrical data for this sample (Table I) is almost identical to that of sample A10; thus it may be assumed that the average Te concentration is about 6-7 x 10^{18} cm^{-3}, as in A10. Electron microprobe analysis of this sample showed a Te concentration of 3 x 10^{19} cm^{-3} in the dark areas. It was below the limit of detectability (1 x 10^{19} cm^{-3}) in the light areas. From the electrical and microprobe data, the ionization energy data of Montgomery, and the previously calculated electrical solubility limit, it can be calculated that for a sample with an average Te concentration of 6-7 x 10^{18} cm^{-3} the Te is distributed at about 5 x 10^{18} cm^{-3} in the light areas (90% by volume) and 3 x 10^{19} cm^{-3} in the dark areas (10% by volume). Both light and dark areas would be expected to have a room temperature carrier concentration of 3 x 10^{18} cm^{-3} and an exhaustion region carrier concentration of about 5-6 x 10^{18} cm^{-3}. All of the Te in the light areas would be electrically active and only 1/6 or 1/5 of that in the dark areas. This is probably a fairly typical Te distribution for heavily doped samples.

Conclusions

It has been demonstrated that compensation occurs in lightly Te-doped GaP grown on (111)A substrates and that impurity conduction takes place at high Te concentrations. The effect of orientation on donor incorporation is the same for both Se and Te doping and in both cases doping occurs under nonequilibrium conditions. Visible segregation begins at an average Te concentration of 2 x 10^{18} cm^{-3}.

None of the studies made were capable of positively identifying the Te species in the dark areas in the Te-doped GaP crystals. However, in the light of previous work on Se- and Te-doped GaAs by other investigators (11-13) where precipitates appeared at high donor concentrations it is most probable that the dark areas observed in this study are either Ga_2Te_3-GaP solid solutions (with less than 1% Ga_2Te_3), or Ga_2Te_3 precipitates. In the Ga_2Te_3 structure, one-third of the Ga sites are unoccupied ($Ga_2V_{Ga}Te_3$). Thus when precipitation or solid solution formation begins there is one vacancy introduced for each three Te atoms. Since the Ga vacancy is a triply charged acceptor it compensates the three Te donors and the Te becomes electrically inactive (14, 15) above a concentration of 6 x 10^{18} cm^{-3}.

According to Saul (16), the number of dislocations generated at the substrate film interface is considerably greater in vapor phase epitaxy than in liquid phase epitaxy. It appears from this study that the dislocations lead to a growth morphology which promotes donor segregation due to the effect of orientation on donor incorporation. Thus on (111)A growths, for instance, the pit walls take on Te far more readily than the (111)A face, which leads to localized high Te concentrations and Ga_2Te_3 formation. This segregation is enhanced by the low growth temperature which prevents bulk diffusion of the Te to lower concentration regions. One possible consequence of this is the lower efficiency of vapor-grown GaP electroluminescent diodes as compared with that of diodes grown by liquid phase epitaxy. Precipitates such as Ga_2Te_3 can introduce strain and can also function as nonradiative recombination centers (12).

Polarity Dependence of Contact Angles between Liquid Gallium and {111} Surfaces of GaAs

B. E. Liebert and Z. A. Munir

Department of Materials Science, School of Engineering, San Jose State College, San Jose, California 95114

Although results of numerous sessile-drop measurements have been reported in the literature, apparently no attempt has been made to correlate these measurements with the crystalline orientation of the substrate materials. Aside from purely theoretical reasons, such information is of considerable practical interest since it relates directly to ohmic-contact phenomena and thus offers possible solutions to related problems in numerous device-oriented technologies. Because of these considerations, a study was initiated in order to investigate some of the parameters influencing contact angles between liquid metals and oriented surfaces of III-V and II-VI compounds. This note reports some initial observations of the dependence of contact angles made between liquid gallium and GaAs, on the polarity of the {111} planes of this compound.

Gallium arsenide, which crystallizes in the zinc-blende structure, has its (111) or A faces entirely populated by Ga atoms while the $(\bar{1}\bar{1}\bar{1})$ or B planes are occupied exclusively by As atoms. This polar nature of the {111} planes has been given as the reason for the anisotropic behavior of these planes with respect to chemical etch (1, 2), thermal stability and oxidation resistance (3), and the energetics of incorporation of impurity atoms (4).

Experimental

Contact angles between liquid gallium and GaAs were determined by the sessile-drop technique, which has been described in the literature (5) and is schematically represented in Fig. 1, in which γ is the surface energy vector between two adjacent phases (solid, liquid, or vapor).

The apparatus employed in the present study, schematically shown in Fig. 2, consisted of a horizontally positioned cylindrical tantalum heating element situated in the middle portion of an evacuated bell jar. Contained in this heating element is a graphite "dee" which served as a platform for the substrate wafers. To establish conditions approximating black-body radiation, the heating element was shielded around its major axis as well as at both ends. A small hole in the center of each end-shield provided openings for sighting on the liquid drop through one side, and for back-lighting the drop through the opposite side. The latter provision gave greater contrast between the sessile drop and its background. Power was introduced to the heating element by means of heavy-wall water-cooled copper tubing attached to the ends of the element. Measurements of contact angles between gallium drops and GaAs substrates were accomplished by

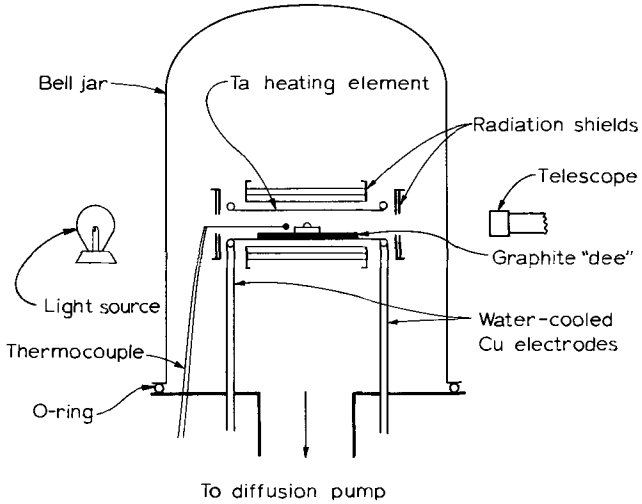

Fig. 1. Schematic of contact angle between liquid Ga and GaAs

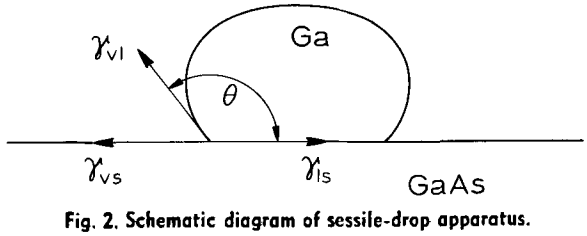

Fig. 2. Schematic diagram of sessile-drop apparatus.

Key words: sessile drop, interfacial interactions.

means of a telescope equipped with movable cross hairs and an especially designed goniometer capable of measuring angles to the nearest 0.25 degrees. All angular measurements were made under a vacuum of about 10^{-6} Torr, maintained by a liquid nitrogen-equipped diffusion pump.

To establish confidence in the angles measured by the telescope and to ascertain the absence of any significant contribution arising from optical distortion due to the wall of the bell jar, calibrations were made utilizing contact angle standards. The standards were stainless steel ball bearings with grounded facets representing mathematically calculated angles of contact from 33° to 180°. Telescopic determinations of these angles were made with and without the bell jar in position. The measured angles corresponded to the actual values to within ± 1° when the bell jar was removed and to within ± 2° when the jar was in place.

Crystals of semiconductor grade GaAs were cut along (111), (100), and (110) planes by means of a high-speed diamond saw. Laue patterns of the resulting 2 mm thick wafers indicated that deviations from the desired orientations were within about ± 1°. The surfaces of these wafers were then cleaned, chemically etched, and mechanically polished. Cleaning, whose purpose was to rid the samples of oil contaminants introduced during cutting and handling, was accomplished by successive washes with trichloroethylene, acetone, and deionized water. After drying with nitrogen gas, the wafers were chemically etched to remove surface layers believed damaged in the cutting process. The etchant used consisted of a hot mixture of 1:1 concentrated H_2SO_4 and 30% H_2O_2. Mechanical polishing was achieved by using 1μ diamond grit. Final treatment of the surface, which was performed just before their use in the contact angle measurements, included a wash with dilute HCl followed by water and acetone. Six-nine pure gallium pellets of approximately 2 mm diam were treated immediately before use in the sessile-drop experiments. This treatment, designed to eliminate any surface oxide layer, consisted of washing with dilute HCl followed by water and acetone. These pellets were then placed on the GaAs wafers which had already been placed on the graphite "dee" in the vacuum system. Using procedures suggested by Mariano and Wolff (2), chemical etch techniques were employed in order to identify the Ga and As faces of the {111} oriented wafers.

Temperatures were measured by means of a calibrated Chromel-Alumel thermocouple placed in contact with the substrate in the middle portion of the heating element. Calibration of this thermocouple was achieved *in situ* by observing the melting points of gallium and indium metals.

Results and Discussion

Table I gives the experimentally determined contact angles between drops of liquid gallium and substrates of GaAs, as a function of temperature and crystalline orientation. These measurements, which were made under identical experimental conditions, show a strong dependence of the contact angles on crystalline orientation and an apparent lack of dependence on temperature in the range investigated. The dependence on orientation is especially marked in the case of the {111} planes. A difference of about 30 degrees exists between contact angles measured on the A(111) side and those determined on the B($\bar{1}\bar{1}\bar{1}$) side, or about 25% of the former values. Apparently, therefore, a stronger interfacial interaction exists between liquid gallium and the Ga or A($\bar{1}\bar{1}\bar{1}$) surfaces than with the As or B($\bar{1}\bar{1}\bar{1}$) faces. Preliminary measurements using (110) oriented substrates of GaAs, which are composed of both Ga and As atoms, gave contact angle values of about 135° at 80°C. These values lie between those obtained for the surfaces populated exclusively by either of the two atomic species. Furthermore, contact angles on (100) oriented substrates were found to be about 150° at ~ 80°C.

Seemingly, the observations reported here indicate that the charge transfer model of Gatos and Lavine (6, 7) is not significant in contact angle considerations. However, results of this study cannot be exclusively interpreted in terms of differences of wetting of GaAs by gallium as related to the atomic nature of the surface atoms. The role of absorbed impurities, as influenced by the nature of the surface composition, cannot be overemphasized. Studies now in progress at our laboratories are aimed at determining the influence of such parameters as surface finish and orientation as well as the role of inert and semi-inert gaseous atmospheres on the wetting behavior between liquid metals and oriented substrates of several III-V and II-VI compounds.

Nonequilibrium Effects in Quasi-Static MOS Measurements

M. Kuhn and E. H. Nicollian*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

The low frequency MOS capacitance method first described by Berglund (1) has several advantages which make it useful for the study of the electrical properties of oxide-semiconductor interfaces. The two major advantages are: (*i*) it provides a method for measurement of the silicon surface potential over most of the bias range, and (*ii*) it is possible to extract the interface state density over most of the silicon energy bandgap. The major requirement which must be met to exploit these advantages is that the MOS capacitor must remain in thermal equilibrium over the entire bias range. This can be most easily satisfied by measuring the displacement current flowing through the MOS capacitor in response to a slow, linear voltage ramp (2-5). When the sweep rate (typically 5 to 100 mV/sec) is sufficiently slow so that both minority carriers and surface states can follow and the MOS capacitor remains essentially in thermal equilibrium, the response is directly proportional to the low frequency incremental capacitance. However, under certain conditions, the lowest practical sweep rates of about 5 to 10 mV/sec are not sufficiently slow to maintain thermal equilibrium over the entire bias range, and the resulting response is distorted. These conditions can occur at a room temperature for long lifetime silicon ($\tau > 100$ μsec), at low temperatures and also under illumination. The dominant effects observed are a peak in the response near weak inversion, and also a small voltage shift in strong inversion, when sweeping out of inversion. When deviation from thermal equilibrium is large, as for example at reduced temperatures, large distortions occur in the inversion region, as a result of the formation of a partial deep depletion condition when sweeping out of accumulation.

The purpose of this paper is to describe these effects and to show that they can be adequately explained in terms of well known minority carrier generation and injection effects (6, 7) in the field induced junction below the MOS field plate. They must be recognized and minimized in order to fully exploit the low frequency MOS capacitance technique.

Experimental Procedure

MOS capacitors were fabricated on 0.1 ohm-cm p-type epitaxial silicon and 5 ohm-cm n-type silicon by growing approximately 600 to 800Å of SiO_2 in steam under bias (8), and evaporating CrAu contact dots. The displacement current response, $i = C(V)\ dV/dt$, to a slow linear voltage ramp was measured. Under thermal equilibrium conditions, this ramp response is proportional to the low frequency differential capacitance (2). MOS ramp response measurements were performed using Keithley 602 electrometer, and an operational amplifier integrator was used to provide a low noise, slow, linear voltage ramp as described in Ref. (2). Measurements were made over the temperature range of 200° to 300°K with sweep rates varying from 0.01 to 1 V/sec with the sample in an atmosphere of dry nitrogen. The response for both sweep directions, from accumulation into inversion and the return sweep out of inversion toward accumulation was obtained and recorded on an x-y recorder.

Experimental Observation

A typical set of response characteristics are shown in Fig. 1, for both thermal equilibrium and nonequilibrium conditions and both sweep directions.[1] Curve 1 is the thermal equilibrium response when sweeping from inversion toward accumulation while curve 1′ is the thermal equilibrium response for the opposite sweep direction, from accumulation toward inversion. The ideal thermal equilibrium response would be symmetrical in sweep direction; the difference in scales of measured curve 1 and 1′ is due to a small difference in the magnitude of the sweep rate caused by the instrumentation. For comparison, curves 2 and 2′ show the typical nonequilibrium response measured at 270°K. The nonequilibrium characteristic, when sweeping from inversion toward accumulation shows a small shift in strong inversion and a peak near weak inversion. The nonequilibrium characteristics obtained when sweeping from accumulation to inversion (curve 2′) is similar.

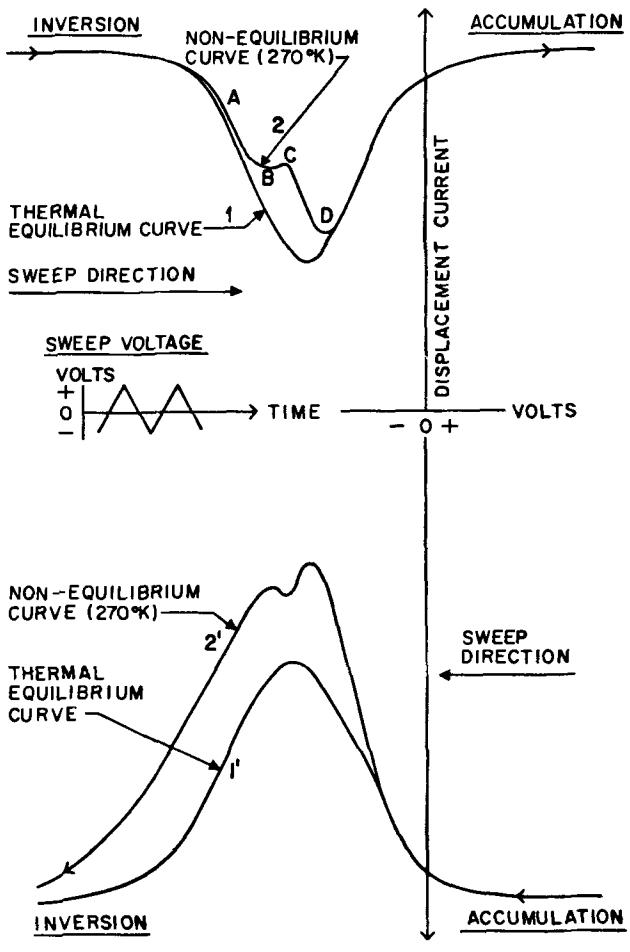

Fig. 1. Equilibrium and nonequilibrium response of an MOS capacitor to a triangular voltage sweep. The MOS capacitor was formed with 5 ohm-cm n-type Si, 800Å bias steam grown 7 oxide and Au-Cr contacts. The sweep rate was ±100 mV/sec.

Deviation from thermal equilibrium is due to those physical processes characterized by large time constants, *i.e.*, the inversion layer and the surface state response. The inversion layer response time constant (9, 10) and also the surface state time constants (10)

* Electrochemical Society Active Member.

Key words: surface states, silicon surfaces, inversion layers.

[1] Edge effects can be ruled out in these measurements because displacement currents scale linearly with gate area and the response characteristics are similar on both n and p type samples.

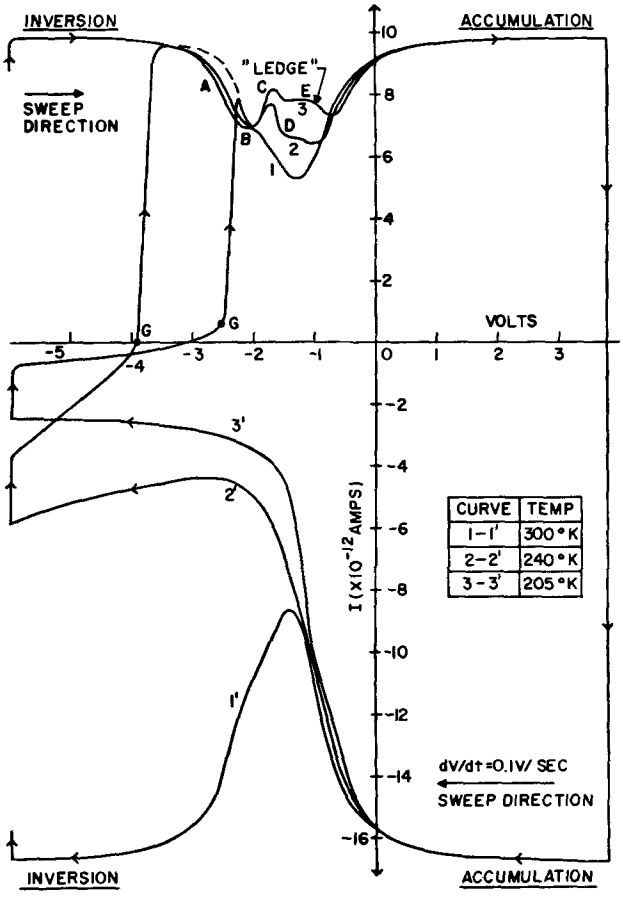

Fig. 2. Temperature dependence of the response of an MOS capacitor to a triangular voltage sweep. The MOS capacitor was 5 ohm-cm n-type Si, 800Å bias steam grown 7 oxide and Au-Cr contacts.

increase exponentially with decreasing temperature; therefore effects on the ramp response become dominant at low temperatures. A more detailed family of curves showing the temperature dependence of the ramp response of an MOS capacitor is shown in Fig. 2. The family of curves 1′ to 3′ show the temperature dependence of the response sweeping from accumulation toward inversion, and the family of curves 1 to 3 show the temperature dependence for the return sweep from inversion toward accumulation; a pair of curves such as 3 and 3′ is the ramp response to a triangular sweep at a fixed temperature.

We consider first the sweep direction from accumulation toward inversion (curves 1′ to 3′) in Fig. 1 and 2. Because the inversion layer formation is governed by generation of minority carriers, the system can remain in thermal equilibrium only if the maximum displacement current required by the sweep rate is much smaller than the generation current; that is $C_{ox}\, dV/dt << q\, n_i/\tau\, W$, where W is the depletion layer width, τ the minority carrier lifetime and n_i the intrinsic carrier concentration. At low temperatures, n_i and therefore the generation rate becomes small so that the above inequality can no longer be satisfied at normal sweep rates. Consequently, an equilibrium inversion layer cannot form, and the depletion layer expands more deeply into the bulk. The increasing space charge width results in a reduced displacement current and an increased generation current. Both of these effects tend toward restoring thermal equilibrium.[2] The peak in curve 2′ of Fig. 1 is due to surface state generation as the quasi-Fermi level passes through midgap at the surface. At lower temperatures, as in curves 2′ and 3′ of Fig. 2, surface state generation is so small that no peak is observed when sweeping toward accumulation.

When the sample is deeply depleted such as in curves 2′ and 3′ a net generation current flows, and minority carriers are stored at the semiconductor insulator interface. When the sweep direction is reversed, the generation current continues to flow, building up minority carrier charge at the interface while the depletion layer is being reduced by the sweep voltage. At the points G in Fig. 2 the silicon surface potential approaches that value required to hold the total minority carrier charge stored at the interface, in thermal equilibrium. At this point, the generation current abruptly ceases, and a field induced junction, in thermal equilibrium, is established below the field plate of the MOS capacitor. At lower temperatures, the equilibrium point G occurs at successively lower values of bias because the total minority carrier charge accumulating by generation at the interface becomes smaller at lower temperatures. Application of light increases the generation rate and will therefore move the equilibrium point G as if temperature were increased.

Sweeping through this equilibrium point towards accumulation a small forward bias V_F develops on the field induced junction. Initially this results in net recombination, in the depletion region, of minority carriers from the inversion layer with majority carriers from the bulk and occurs in region A of Fig. 1. This forward bias is necessary to sustain the displacement current and leads to a voltage shift between curves 1 and 2 in Fig. 1 and 2, given by $\Delta V = V_F + \Delta Q_s/C_{ox}$ where ΔQ_s is the excess minority carrier surface charge in the inversion layer and in the surface states. At room temperature and for typical sweep rates, ΔV is usually negligibly small (2). However, at lower temperatures a larger forward bias is required for a given recombination current density, ΔV can become appreciable, of the order of several tenths of a volt, as shown in region A of Fig. 2. In this region, the minority carrier surface charge and the surface potential are being reduced while V_F and ΔQ_s remain nearly constant as the ramp voltage decreases.

At point B in Fig. 1 and 2 the surface potential has been reduced sufficiently to make diffusion current dominant. The inversion layer charge is rapidly injected into the bulk, dissipating the excess minority carrier charge at the surface. The discharging of excess minority carrier surface charge ΔQ_s by injection produces the observed current peaks in region BCD of Fig. 1 and 2. The peaks at lower temperature are larger because ΔV and hence ΔQ_s is larger at lower temperature. At the lower temperatures, however, the reduced diffusion current density cannot restore equilibrium as rapidly, thus producing the ledge at E (15). The forward bias at which diffusion current becomes dominant is less in a field induced junction then in a metallurgical junction because in a field induced junction, inversion layer charge density is a function of V_F.

This observed peak is clearly a nonequilibrium effect and cannot be attributed to any particular surface state distribution. This peak would be observable in an ideal MOS capacitor without surface states. The magnitude of the peak however depends on the surface state density only through the excess minority carrier charge that may be stored in surface states.

The peak in weak inversion and the shift in strong inversion can be observed under illumination in both n and p-type MOS structures. An example of the effect of illumination on a p-type MOS capacitor is given in Fig. 3, showing C-V curves at room temperature in the dark and under room light. The response under illumination is essentially independent of the sweep direction.

[2] The response in this regime is determined by a complex dynamic equilibrium between the increasing voltage tending to increase the depletion layer width and minority carrier generation tending to reduce the depletion layer width and restore equilibrium. At temperatures as low as 77°K when the generation rate becomes negligible compared to the displacement current, the response is determined by the oxide capacitance, and yields the well known depletion characteristics (12, 13). These can of course be obtained at room temperature but a considerably faster sweep rate is required (14).

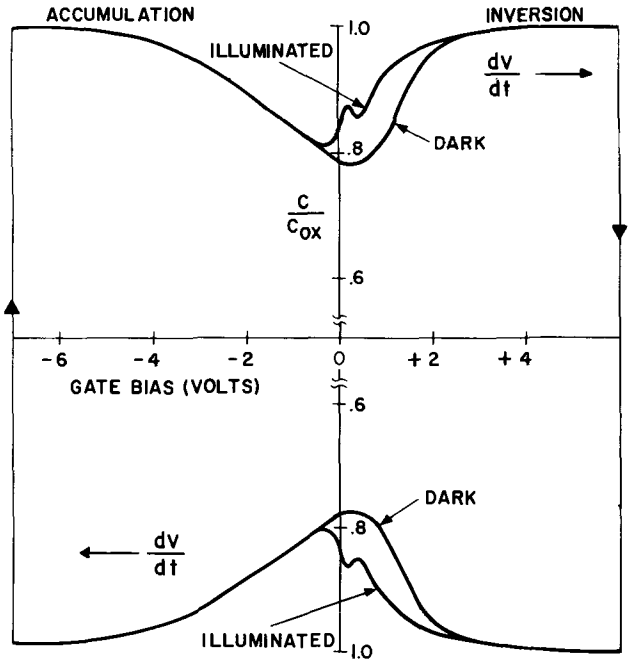

Fig. 3. Response at room temperature with and without illumination of an MOS capacitor to a triangular voltage sweep. The MOS capacitor was formed with 0.1 ohm-cm p-type, 600Å bias steam grown SiO_2 and Cr-Au contacts.

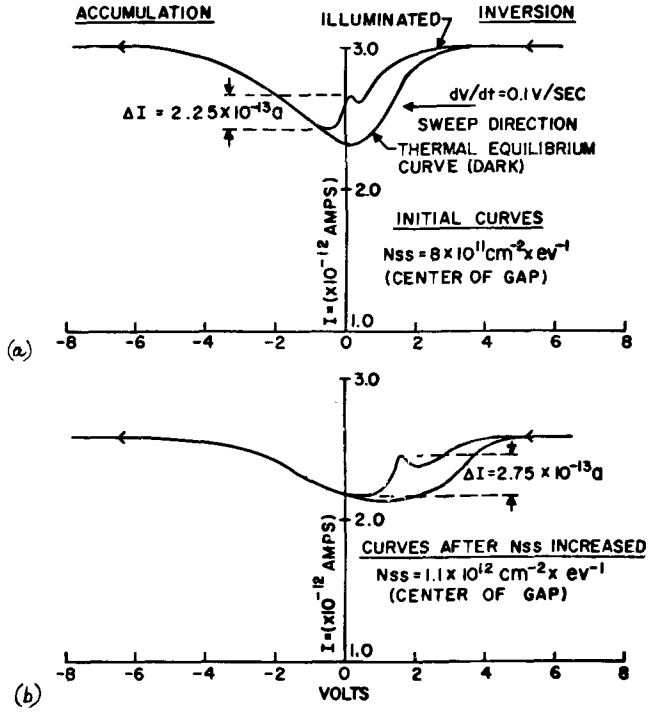

Fig. 4. Response at room temperature of an MOS capacitor to a linear voltage ramp with and without illumination before and after avalanche injection of minority carriers into the oxide. Sweep rate for upper curves was slightly greater than for lower curves. The MOS capacitor was 0.1 ohm-cm p-type, Si, 600Å bias steam grown SiO_2, and Cr-Au contacts.

Under illumination, the minority carrier concentration near the surface and beyond the field plate is increased and an excess minority carrier distribution is established below the field plate. This excess minority carrier concentration results in the shift of the *C-V* characteristics in strong inversion and also in the displacement current peak in the same fashion as described in the previous section.

Because the current peak observed under illumination is also produced by relaxation of the excess minority carrier surface charge, the magnitude of this peak is also expected to increase with an increase in surface state density. An experiment was devised to verify this dependence, and will be described below.

The quasi-static *C-V* characteristics with and without illumination shown in Fig. 4a, were obtained. Avalanche injection (16) of electrons was then carried out on this same sample in order to increase the surface state density, and the ramp response was measured with and without illumination. An example of the results is shown in Fig. 4b. From the shape of the *C-V* curves without illumination it is clearly evident that the surface state density after avalanche injection has increased, and that the peak under illumination has also increased. Additional measurements of the minority carrier lifetime and the surface recombination velocity using the Zerbst technique (17) also show that after avalanche injection the surface recombination velocity has increased.

An analysis of the quasi-static response was performed to determine the surface state distribution before and after avalanche injection. This showed that avalanche injection introduces surface states uniformly over a large part of the energy gap. The increase in the peak under illumination is also approximately proportional to the increase in surface state density.

Conclusions

Under some conditions, nonequilibrium effects can be encountered in low frequency capacitance-voltage measurements which can cause distortion of the response, even at the lowest practical sweep rates of 5 to 10 mV/sec. These conditions can occur even at room temperature for long lifetime silicon ($\tau > 100$ μsec), at low temperature, and under illumination. These nonequilibrium effects result in a small voltage shift of the inversion response and a peak near weak inversion when sweeping from inversion to accumulation and a partial deep depletion condition when sweeping from accumulation toward inversion. These effects have been explained in terms of field induced junction phenomena; they would still be observed in the absence of interface states. At most, interface states play a secondary role.

These nonequilibrium effects must be minimized in order to obtain meaningful results for surface potential and surface state density. They can be minimized and made negligible by using short lifetime silicon ($\tau \leq 1$ μsec), making measurements in the dark, and using sweep rates smaller than 100 mV/sec. Measurements on longer lifetime silicon can be performed by using elevated temperatures, normally not more than 100°C to avoid ionic drift.

Note on the Preparation of Rhenium Oxychlorides

Abner Brenner* and Harvey J. Anderson

National Bureau of Standards, Washington, D.C. 20234

Perrhenyl chloride, ReO_3Cl, is of potential interest for the chemical vapor deposition (CVD) of rhenium, as we have shown (1) that it readily reduces to the metal when passed with hydrogen over a substrate heated above 300°C. We found the methods given in the literature for the preparation of perrhenyl chloride unsatisfactory because of low yields and the inconvenience in the manipulations. We wish to report briefly on a simple procedure that yielded material of sufficient purity for use in experiments in chemical vapor deposition.

Brukl and Ziegler (2) first reported the preparation of the two oxychlorides, ReO_3Cl and $ReOCl_4$, which they obtained as a mixture by heating rhenium heptaoxide with rhenium chlorides (probably a mixture of $ReCl_3$ and $ReCl_5$). The product of the reaction was difficult to fractionate into its pure components. Briscoe, Robinson, and Rudge (3) heated rhenium with oxygen and chlorine or the mixed rhenium chlorides with oxygen. Geilmann, Wrigge, and Blitz (4) heated rhenium trichloride or rhenium pentachloride with oxygen and obtained a vigorous reaction which yielded a mixture of oxychlorides. No further work was published on the preparation until about 25 years later, when Wolf, Clifford, and Johnston (5) described a method consisting of the passage of chlorine over rhenium trioxide at 160°-190°C. The yield was 70%. The trioxide was prepared by thermally decomposing the adduct of rhenium heptaoxide and dioxane.

We did not have success with the earlier methods and only partial success with the method of Clifford *et al.* In four trials with the latter method we obtained one yield of 60%, which is in line with the stated yield, but in the other three trials the yields ranged from 0 to 20%. Apparently the method of preparing the trioxide affects its activity. The preparation of the trioxide is a drawback to the method since it adds a time-consuming step.

We prepared perrhenyl chloride by the direct passage of dry hydrogen chloride over rhenium heptaoxide. The reaction occurred even at room temperature but was facilitated by gentle warming, for example to 75°C.

$$Re_2O_7 + 2HCl \rightarrow 2ReO_3Cl + H_2O$$

The yields of the crude product were about 50%. Along with the formation of the perrhenyl chloride a more volatile compound of rhenium was formed, probably an adduct of ReO_3Cl and HCl.[1]

The simplest arrangement for conducting the reaction was to place the rhenium heptaoxide in a tap-funnel, which was in a horizontal position, and pass HCl through. The rhenium heptaoxide soon became transformed into a viscous blue liquid with a pale yellow fluid (perrhenyl chloride) above it. By chilling the side of the tap funnel with ice, the viscous blue layer was immobilized and the perrhenyl chloride was readily drained from the tap-funnel. This operation was repeated a number of times until the rate of formation of the oxychloride became too low for further operation of the process to be profitable. The reaction can also be carried out in an ordinary flask and the perrhenyl chloride distilled over in a current of hydrogen chloride.

We believe that the viscous blue liquid remaining in the reaction vessel consisted mainly of a solution of the heptaoxide dissolved in the water which was formed in the reaction along with some blue reduction products. The blue liquid can be treated with nitric acid and heated to about 200°C to regenerate the anhydrous heptaoxide which is used again. The yield of perrhenyl chloride (about 50%) together with the recovery of rhenium heptaoxide brings the utilization of the rhenium up to about 90%.

We attempted to improve the yield of perrhenyl chloride by using dehydrating agents to remove the water. In one procedure, the rhenium heptaoxide was dissolved in sulfuric acid heated to 200°-225°C and a rapid stream of HCl passed through. The yield was not improved over the simpler procedure already described and the lost rhenium was not readily recoverable. Other disadvantages were that the method was slow, requiring several hours to process 30g of the oxide, and the product collected was not pure enough to use for CVD. It contained sulfuric acid and had to be redistilled.

In another experiment, phosphoric acid was tried as a dehydrating agent, but apparently it formed too stable a complex with the rhenium. A partially successful method consisted in the suspension of rhenium heptaoxide in carbon tetrachloride. The passage of HCl through the system caused the oxide to turn quickly into a viscous blue liquid which settled out and the perrhenyl chloride formed went into solution. The perrhenyl chloride could be separated from the carbon tetrachloride by distillation.

Rhenium oxytetrachloride is also serviceable for CVD, although it has a higher boiling point (225°C) than perrhenyl chloride (130°C). Recently it has been prepared by Edwards and Woolf (6), who heated rhenium powder in a sealed tube with sulfuryl chloride, and by Bagnall, Brown, and Colton (7), who treated the heptaoxide with thionyl chloride. They reacted the materials at room temperature, then poured off the supernatant liquid from an adduct which had formed. They evaporated the supernatant liquid at 50°C in vacuo to obtain the oxytetrachloride. We found that simply refluxing the heptaoxide with thionyl chloride for an hour or two, followed by distilling off all volatile materials until the temperature reached the boiling point of the oxytetrachloride, sufficed to give a product usable for CVD without further purification. The yield was about 95%.

Key words: chemical vapor deposition, perrhenyl chloride, rhenium heptaoxide, rhenium oxytetrachloride.

[1] The evidence of the formation of an adduct of ReO_3Cl and HCl is as follows. At the start of the experiment, at room temperature, the reaction vessel filled with a yellow vapor which was too deep in color to be chlorine. Perrhenyl chloride (bp 130°C) is not sufficiently volatile at room temperature to produce vapor of this intensity of color. In the experiments the product of the reaction was first collected in a receiver cooled with ice. This receiver was backed up by a trap cooled with solid carbon dioxide, and this trap communicated with a mercury trap. All of the perrhenyl chloride should have condensed in the ice-cooled receiver. However, (as an example) at the conclusion of an experiment in which about 25g of perrhenyl chloride was prepared, a few grams of a yellow solid (chlorine would be a liquid at this temperature) were found in the carbon dioxide-cooled trap. As the yellow solid warmed up to room temperature it swelled, effervesced, and melted, giving off HCl. After the effervescence had ceased, the yellow liquid remaining was identified as perrhenyl chloride by its boiling point. The adduct must be slightly volatile even at the solid carbon dioxide temperature, since the mercury in the trap was discolored by the presence of rhenium compounds.

Testing Batteries for Vehicular Applications

III. Selection and Characterization of a Power Battery

Bernard Agruss*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The problem was to find an acceptable "power" battery (*i.e.*, a high power density battery to deliver short time acceleration pulses) for an electric commuter vehicle concept powered by a dual battery system. A number of batteries were tested, both Pb-acid and Ni-Cd. The best battery was a Ni-Cd aircraft starting battery. It could deliver 14 consecutive 1900W, 10 sec acceleration power pulses. It was calculated that about 180 lb of battery would be required for the particular power plant design envisioned. The high cost and scarcity of Cd militated against the use of a Ni-Cd battery. The next best candidate was a Pb-acid aircraft starting battery designed for high current drains for short time periods. It, too, delivered 14 consecutive 1900W, 10 sec pulses. In addition, it had sufficient energy capacity to provide some low speed range in the event of failure of the "base-load" energy battery. It had a power density of 70 W/lb at an energy density of 2 Whr/lb. About 270 lb of this battery would be required for the "power" battery pack. A Delco-Remy 2HN-11A military battery was tested to yield design data for the power plant. From these data, a battery was designed which would fit into an available lightweight container. Prior to this, a 2HN-11A modified battery was tested to confirm the design. Test results confirmed the designed capacities.

Several of the design batteries were built. Each consisted of seven cells containing 11 plates per cell. One of the batteries was tested. It delivered 15 consecutive 2500W acceleration power pulses to 10.5V. It weighed 32 lb; hence, the entire power pack would weigh 256 lb. Since the 11-plate cell performed so well, it was hoped that a 9-plate cell might just deliver adequate power. A 27 lb weight reduction would be realized. However, it could not deliver adequate power when tested. Nothing could be obtained at 2500W. The voltage fell immediately below 10.5. In fact, only 1.8 min were obtained at 1900W.

In a prior paper (1), a versatile test facility was described for testing batteries under actual operating conditions. In a following paper (2), a number of S.L.I. batteries were characterized. They could be called the energy batteries for a dual battery system since they were designed for energy capacity rather than power density. The system was a new, experimental, all G.M., electric car test bed, code named XEP, powered by two different kinds of batteries. To complete the dual battery system, a power battery had to be found. This paper presents the capacity data obtained on a number of commercially available Pb-acid and Ni-Cd batteries. It is shown how a battery was designed from the Pb-acid data for a power battery pack.

Experimental

All of the battery tests were carried out at ambient temperature. The test facility (1) described in a prior report was used for all of the tests. The tests performed were capacity at varying constant current discharges, constant power discharges at varying power levels, consecutive 10 sec acceleration power pulses to cutoff voltage, and charge discharge voltage *vs.* current at varying capacity levels.

* Electrochemical Society Active Member.

Key words: battery tests, storage batteries, lead-acid batteries, vehicular application tests, constant power capacity, acceleration power pulses.

Pb-acid aircraft starting battery results.—The first battery tested was an aircraft starting battery designed for lightweight and high current drains. Its nominal characteristics are given in Table I.

Figure 1 shows the results of the constant current capacity tests. These tests were for battery No. 2 and showed a nominal 5 hr capacity of about 29 A-hr. Typically lower capacities were obtained at higher current drains.

Figure 2 shows the constant power profiles for battery No. 1. Here the voltage is plotted against ampere-hours. As was shown in a prior report (2), it is better to plot voltage against time as in Fig. 3. The advantage comes in directly ascertaining by inspection range at any road load (power level) or number of acceleration power pulses. The most significant curve for the power battery for the XEP is the 1900W discharge. This is the power required from one battery for a 10 sec accelera-

Table I. Aircraft starting battery characteristics

	Pb-acid	Ni-Cd
A-hr capacity (5 hr)	29	8
Nominal volts	12	24
Cells/battery	6	20
Plates/cell	11	—
Battery weight (lb)	27	10

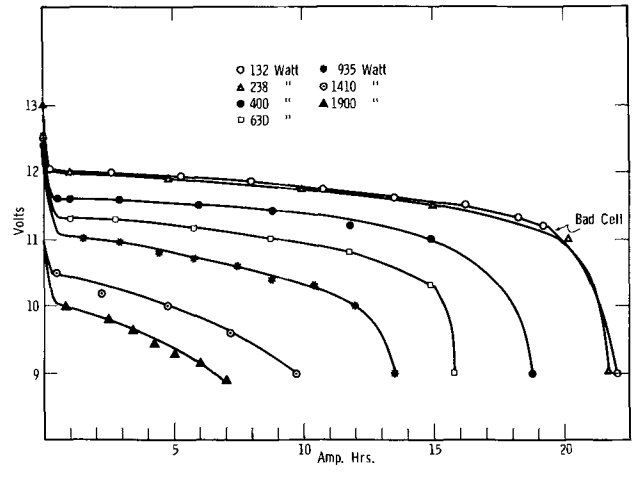

Fig. 2. Pb-acid aircraft starting battery No. 1, constant power discharge (A-hr).

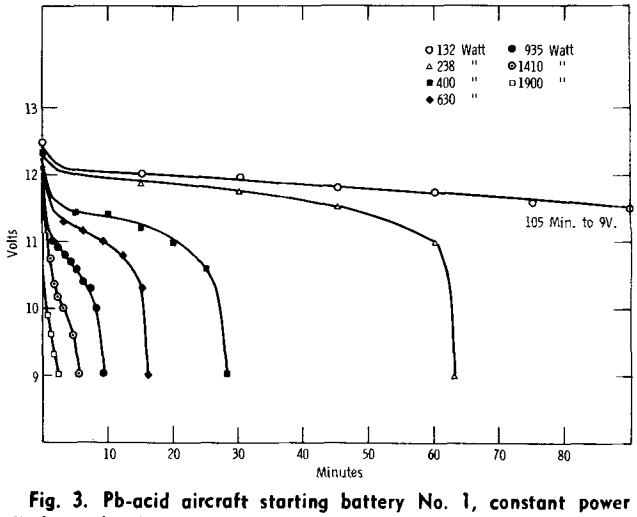

Fig. 3. Pb-acid aircraft starting battery No. 1, constant power discharge (min).

tion to 1.5 V/cell cutoff. It shows a capacity of 2.5 min to 9V. This is equivalent to fifteen 10 sec discharges.

It was noticed that one cell lost voltage rapidly and made the total battery voltage drop faster. It was felt that this might limit the capacity of the battery; hence, another battery was tested.

Figure 4 shows the power profiles for battery No. 2. This one discharged 3 min at 1900W equivalent to eighteen 10 sec discharges. All the capacities were just slightly better than battery No. 1. The difference, however, was not significant.

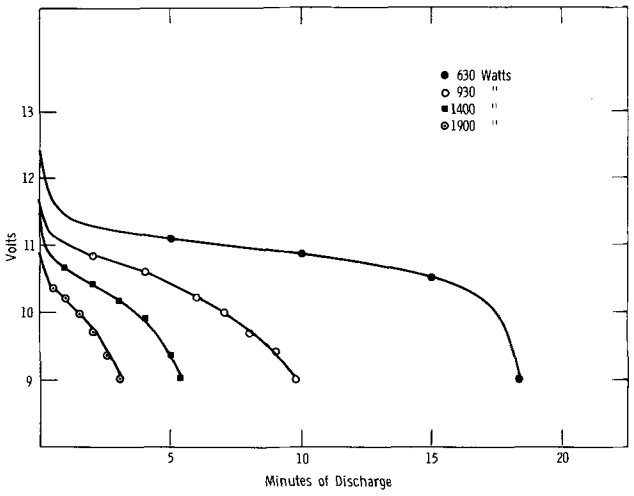

Fig. 4. Pb-acid aircraft starting battery No. 2, constant power discharge (min).

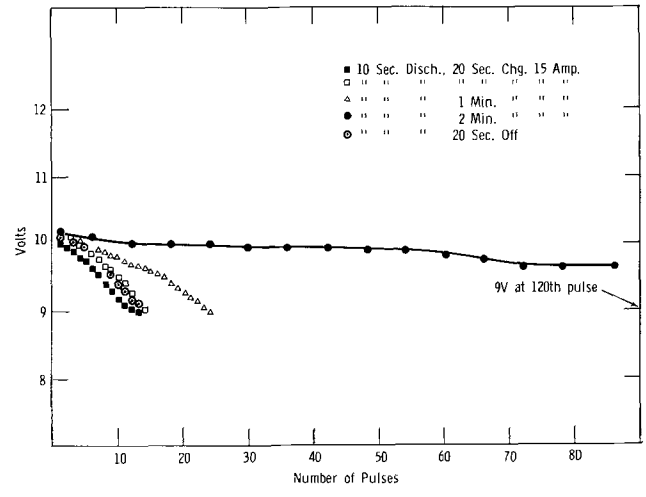

Fig. 5. Pb-acid aircraft starting battery No. 2, 1900W power pulses.

The number of consecutive 1900W, 10 sec pulses to 9V are shown in Fig. 5. Here, both batteries, No. 1 and 2, delivered 14 pulses. The constant power discharge predicted 15 and 18, respectively. Note that there was no change in the number of pulses whether the battery was charged at 15A or not charged during the 20 sec rest period. One minute and 2 min charge periods increase the number of pulses appreciably to 24 and 120, respectively.

For the voltage requirements, 10 of these batteries in series are needed. Each battery weighed 27 lb; hence, the total power pack would weigh 270 lb.

Useful range data may be derived from Fig. 4 by replotting as in Fig. 6. Using the principle of additivity (2), the range at any power level or a variety of power levels may be easily calculated. These curves may be of special interest to a systems analysis group.

Also for the benefit of systems and power plant design analyses are the charge-discharge, voltage *vs.* current plots at varying charge capacities shown in Fig. 7. These are useful in calculating charge-discharge efficiencies. They also give some indication as to what capacity the battery can be charged rapidly before the voltage efficiency deteriorates badly. Using a 15V upper limit, the battery can be charged at 100A to 50% capacity and to 75% capacity at 50A.

The discharge curves at all capacity levels have the same voltage-current characteristics. The slope is much less than the charge curves, except for the 50% capacity. Up to 50% capacity, the charge curve will be nearly a reflection of the discharge curve. Above 50% capacity, the charge curves have a much greater slope than the discharge curves. Apparently there is an increase

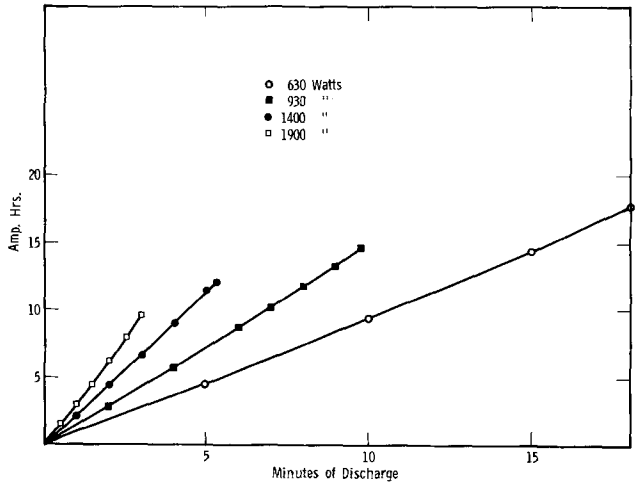

Fig. 6. Pb-acid aircraft starting battery No. 2, constant power discharge capacity vs. discharge time.

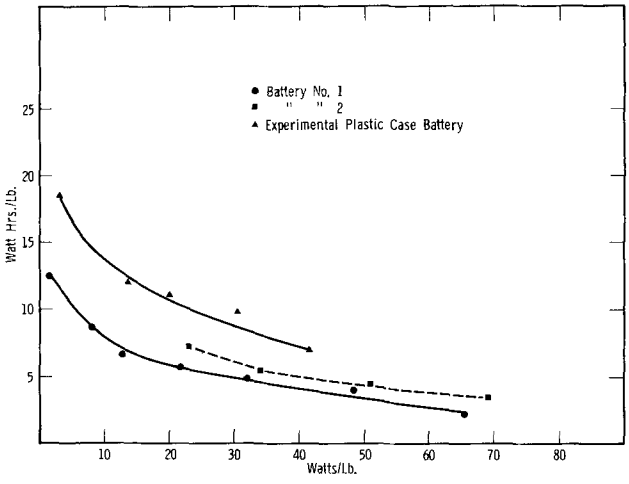

Fig. 9. Pb-acid aircraft starting battery, energy density vs. power density.

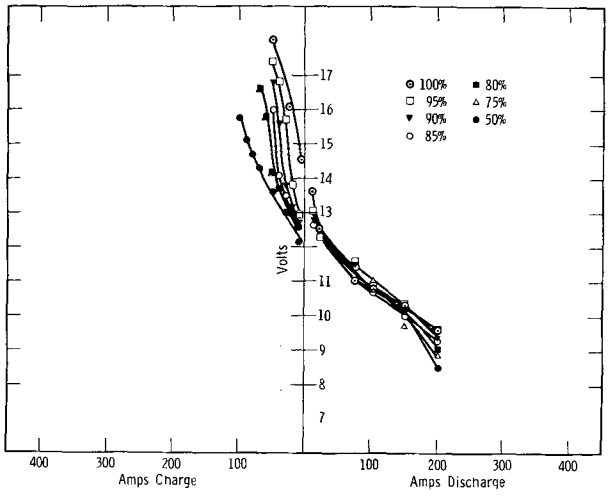

Fig. 7. Pb-acid aircraft starting battery, voltage vs. current

in polarization during charge after 75% capacity is reached. Usually, this is associated with the high hydrogen overvoltage on the Pb plate and the increased acid specific gravity in the pores of the plate.

The data in Fig. 8, taken from the power profiles, are given as an aid to systems analysis and power plant design. This shows the voltages under which the power plant will have to operate at any power level.

For purposes of analysis, also, the energy density *vs.* power density relation is important. This curve is shown in Fig. 9 and was derived from the power profiles. The bad cell in battery No. 1 depressed its energy density. It is interesting to note that this battery had a power density of 70 W/lb at an energy density of 3 Whr/lb.

Ni-Cd aircraft starting battery.—Table I lists the nominal characteristics of this Ni-Cd battery; Fig. 10 shows the constant power discharges. Since this battery was only a power battery, only high power discharges were made. At 2350W, only about two consecutive accelerations could be predicted. However, at the usual 1900W, about 12 consecutive accelerations would be predicted from the 1850W discharge to a 14V cutoff.

Figure 11 shows that 14 actually were obtained. A 2 min rest period between pulses increased the number to 18.

What is noteworthy, though, is that each battery weighed only 18 lb. It was calculated that 10 Ni-Cd batteries would be needed for the power package. This pack will weigh 180 lb, compared to the 270 lb of the Pb-acid pack. Also, the energy storage in the Ni-Cd battery is only 8 A-hr. But this amount of active material supplies the same acceleration pulses as 30 A-hr in the Pb-acid battery.

Figure 12 shows the charge-discharge voltage *vs.* current characteristics of the Ni-Cd battery. It is interesting that, between 50 and 95% capacity, the charge and discharge curves are very nearly continuations of one another. The rapid decrease in voltage during discharge for both 50 and 10% capacity at 50A is probably due to the increased polarization and resistance for the large amounts of $Cd(OH)_2$ and $Ni(OH)_2$ in the plates. The increase in resistance of the reacted forms of the active material may explain

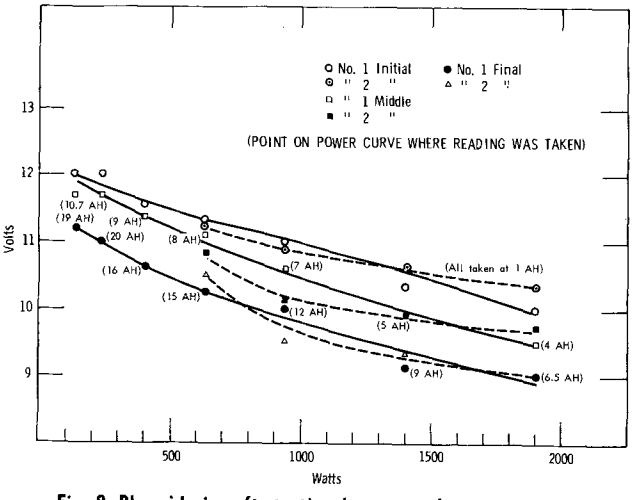

Fig. 8. Pb-acid aircraft starting battery, voltage vs. power

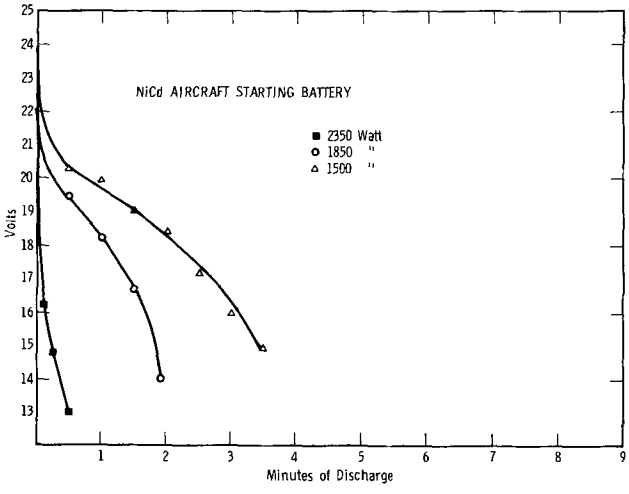

Fig. 10. Ni-Cd aircraft battery, constant power discharge

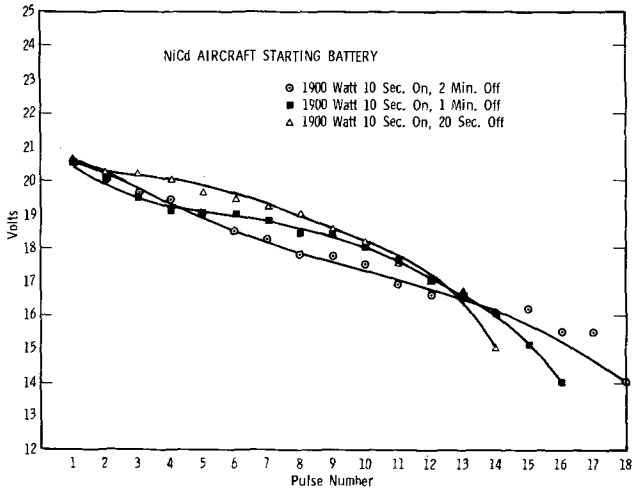

Fig. 11. Ni-Cd aircraft starting battery, consecutive acceleration power pulse discharge.

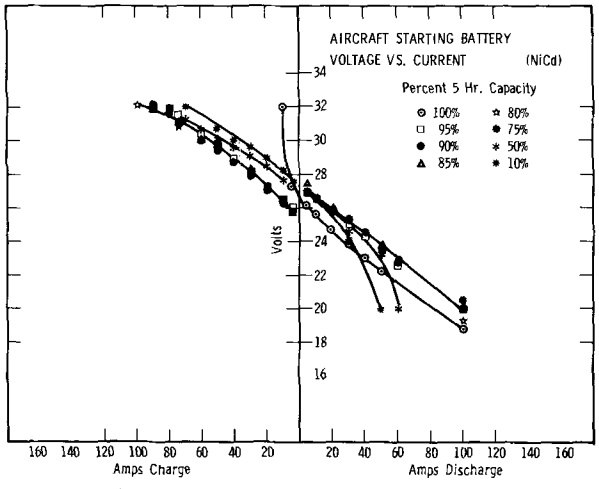

Fig. 12. Ni-Cd aircraft starting battery, voltage *vs.* current

the slightly higher charge voltage seen for the 10% capacity level. In contrast to the Pb-acid battery, the Ni-Cd battery may be charged to 95% capacity before the voltage rises precipitously. At 100A charge, the voltage is only 32V which is about maximum starting voltage for a Ni-Cd battery. This rate can be used until the battery is 95% charged before a reduction in charge rate is necessary. Thus, the Ni-Cd takes less power to charge.

Although range is not important for a power battery, range calculations can be made from Fig. 13 where capacity *vs.* discharge times are plotted.

The energy density-power density relationship is given in Fig. 14. For this battery, the relationship appears to be a linear one. At 2 Whr/lb, the power density is 130 W/lb, a significant improvement over the lead acid battery.

2HN-11A Pb-acid military battery.—The 2HN-11A battery is made by Delco-Remy for military use. Although of higher capacity than required, it could serve as a "power" battery. Discharge data were obtained from which an appropriate battery could be designed.

Figure 15 shows that this battery had more than sufficient capacity for a power battery. In fact, the capacity is nearly as good as some of the energy batteries previously tested (2). Based on the 1900W discharge, which is the power required for acceleration, this battery should deliver about 30 consecutive 10 sec acceleration pulses.

As shown in Fig. 16, 29 pulses were obtained. For this battery, resting between pulses for 1 or 2 min increased the number of pulses slightly. The battery for the 1 min test started at a higher voltage and came right off charge. For the others, they rested awhile before being tested. This could explain the reversed order of the two tests.

It is interesting to note from Fig. 9 and 17 that the energy density-power density curve for the 2HN-11A battery is about the same as the Pb-acid aircraft battery. Both showed about 70 W/lb at 2 Whr/lb. It was this similarity that brought to mind the use of 2HN plates for the power battery.

2HN-Thin plate (2HN-T.P.) Pb-acid battery.—Design considerations.—Table II shows the design data from which the final design was made for the DRX 47965-7 Pb-acid battery. The element weight divided

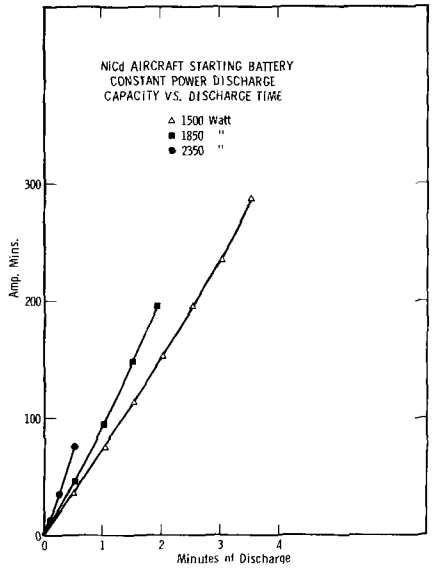

Fig. 13. Ni-Cd aircraft starting battery, constant power discharge capacity *vs.* discharge time.

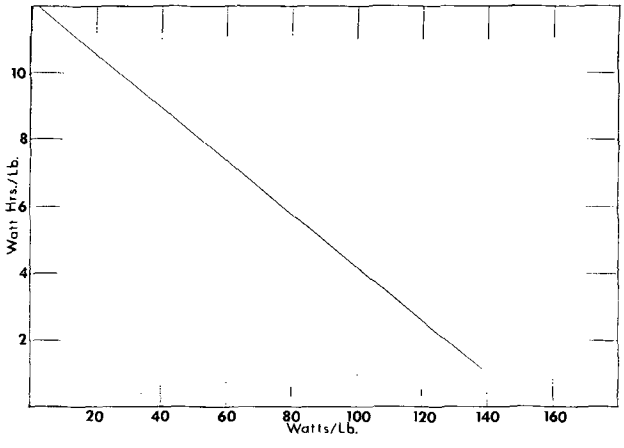

Fig. 14. Ni-Cd aircraft starting battery, energy density *vs.* power density.

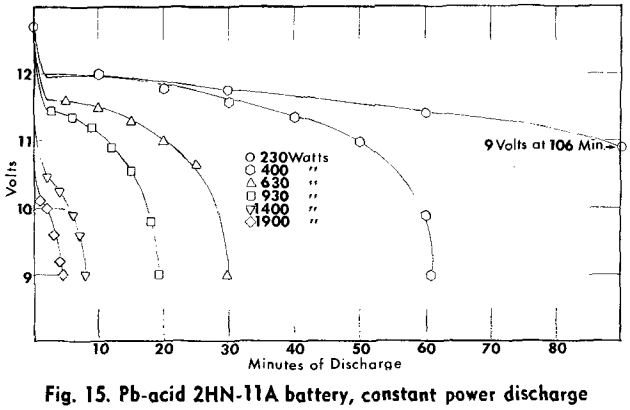

Fig. 15. Pb-acid 2HN-11A battery, constant power discharge

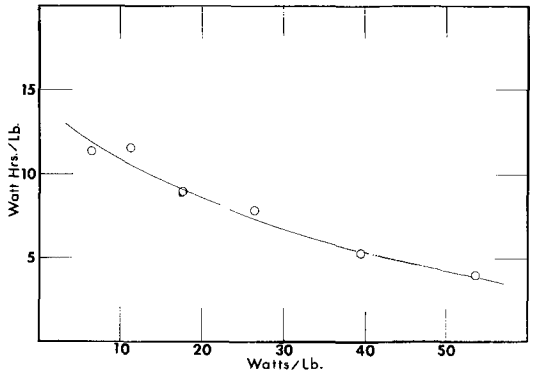

Fig. 17. Pb-acid 2HN-11A battery, energy density *vs.* power density.

by the volume of the plates gave the apparent density. The ampere-hour capacity divided by the element weight gave the specific capacity. From experience with other batteries, an apparent density of 0.2 lb./in.^{3} was assumed, from which the element weights and specific capacity were calculated.

A basic parameter was the amperes per square inch of positive plate surface. At the 1930W discharge, the maximum current was 215A. This is equivalent to about 1 A/in.^{2} for the 2HN-11A battery. Hence, a current density around 1 A/in.^{2} was fixed for the design.

It was also desired to use an available thin-walled, lightweight, hard rubber container. However, only seven plates of the 2HN-11A size could fit into a cell of this container. This design gave a positive plate current density of 1.5 A/in.^{2}. This increase in current density plus the large reduction in active material ruled out this design.

An alternative, proposed by Delco-Remy, was to press down the 2HN grids to 0.060 and 0.050 in. before pasting for the respective positive and negative plate thicknesses. Then, using standard 0.040 in. separators, 11 plates could be fitted into the thin-walled cell. The current density would be slightly less than 1 A/in.^{2}, and there would be a minimal reduction in the amount of active material.

The final design is given in the last column of Table II.

Table II. Battery design data

	2HN-11A	2HN-T.P.	DRX 47965-7
A-hr capacity	45	34	34

* For eight 7-cell batteries.

Evaluation tests.—Before proceeding to make any thin-plate batteries, it was decided to evaluate the thin-plate design in a standard 2HN-11A container. This was considered the fastest and easiest way to confirm the design.

Figure 18 shows the constant power discharge curves for this battery. It delivered 2 min at 1900W to 9V. This is equivalent to 12 consecutive 10 sec acceleration pulses to 9V.

Figure 19 shows that actually 13 consecutive 10 sec, 1900W pulses were obtained to 9V.

The voltage *vs.* current curves in Fig. 20 have the same general shape as the aircraft battery except possibly for a slightly better charge acceptance for the 2HN-TP. However, this might be an artifact caused by the large container.

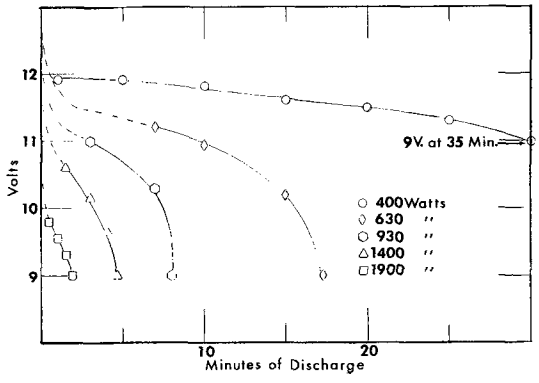

Fig. 18. Pb-acid 2HN-T.P. battery, constant power discharge

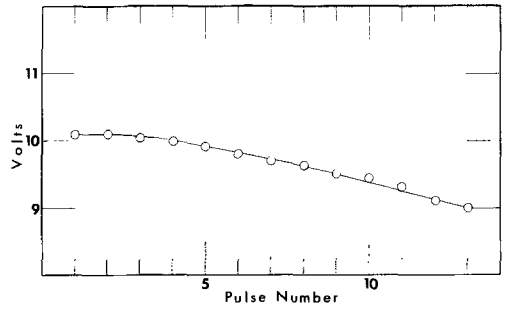

Fig. 19. Pb-acid 2HN-T.P. battery, consecutive acceleration power pulse discharge.

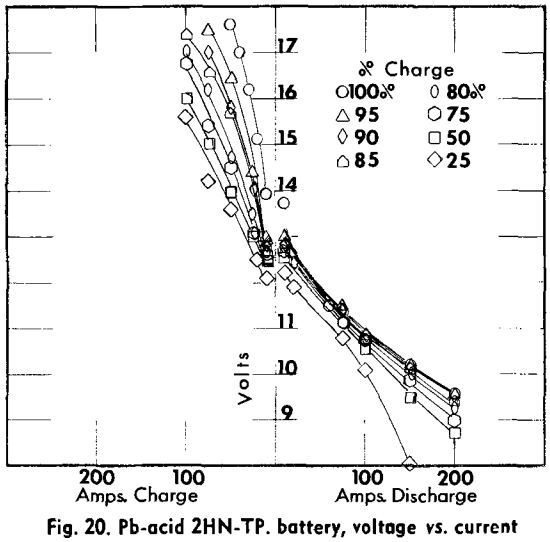

Fig. 20. Pb-acid 2HN-TP. battery, voltage *vs.* current

These evaluation tests confirmed the thin-plate design.

DRX 47965-7 Pb-acid battery.—The above designation was used for the battery made by Delco-Remy using thin 2HN-11A plates in the lightweight container. This battery contains seven cells instead of the usual six; hence, the nominal battery voltage is 14V instead of 12V. This increase in voltage meant that 2200W (1900 x 7/6) could be drawn from this battery and be equivalent to 1900W from a 12V battery. To provide acceleration power on this basis, 8.6 or 9 batteries would be required for the power pack. However, because of the good discharge characteristics of the 2HN plates, it was decided to use eight batteries instead of nine. This meant a current density slightly above 1 A/in.^{2}, which was tolerable. To provide some additional margin (*e.g.*, added accessories), the battery-proof test requirement was increased to 2500W.

Figure 21 shows how well the DRX 47965-7 battery performed. The design was seen to be conservative since 2 min were obtained at 2500W to 10.5V (1.5 V/cell). This is equivalent to 12 consecutive accelerations. By actual test, 15 were obtained. This means that eight batteries are sufficient for the power pack at 2500W per battery per 10 sec acceleration.

Figure 22 confirms the good charge acceptance of this battery. Large currents can be applied to this battery without a large voltage rise, up to 85% capacity. All the discharge curves have about the same slope. The same slope is shown by the Pb-acid aircraft and 2 HN batteries. The voltage starts to drop off more rapidly at high current drains, especially at the lower capacities.

The data in Fig. 21 are replotted in Fig. 23 so that the additivity principle can be applied to any projected duty cycle. This family of curves makes it easy to add up the discharge time at several different power levels.

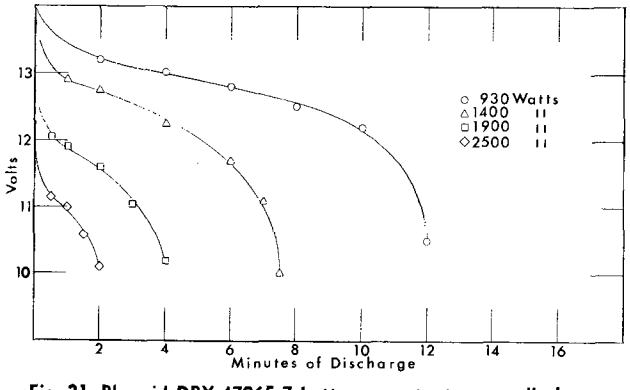

Fig. 21. Pb-acid DRX 47965-7 battery, constant power discharge

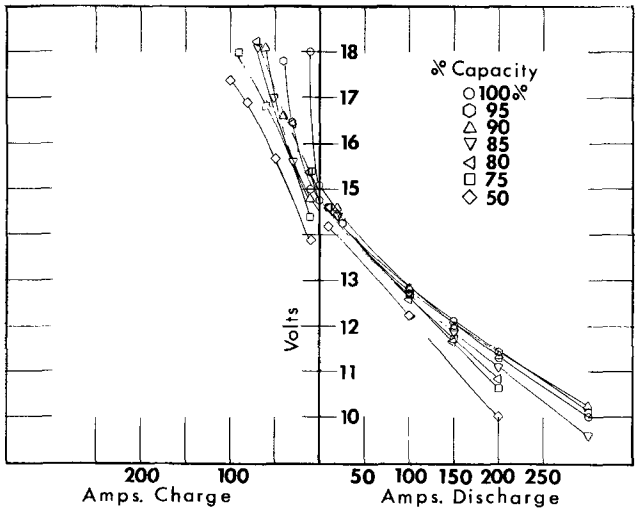

Fig. 22. Pb-acid DRX 47965-7 battery, voltage vs. current

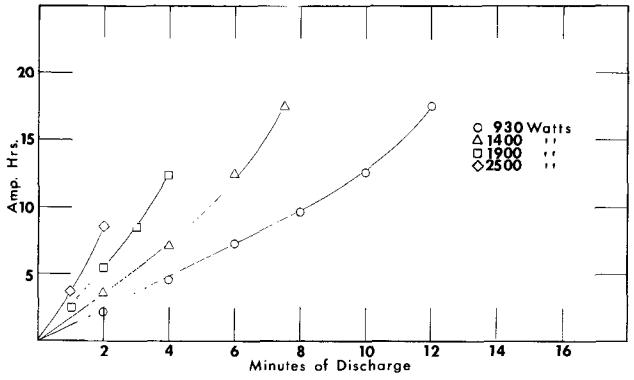

Fig. 23. Pb-acid DRX 47965-7 battery, constant power discharge capacity vs. discharge time.

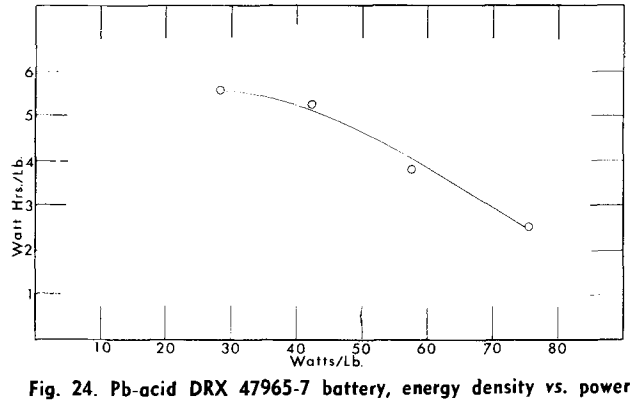

Fig. 24. Pb-acid DRX 47965-7 battery, energy density vs. power density.

Figure 24 shows the energy density-power density relationship for this power battery. It is definitely not an energy battery. It does show a relatively good power density for a lead acid battery, *viz.* 75 W/lb at 2.5 Whr/lb.

DRX 47965-26 Pb-acid battery.—In an effort to save weight and to take advantage of the excellent discharge characteristics of the 2HN plates, one battery was made using only nine plates per cell. Its constant power discharge curves are shown in Fig. 25. This battery was entirely inadequate. It does not even yield 2 min at 1900W, when at least 2 min are necessary at 2500W. No further tests were made on this battery.

Conclusions

A lead-acid power battery was designed by Delco-Remy and General Motors Research Laboratories, based on data obtained on commercially available batteries for the XEP electric car.

Eight batteries made up the pack which weighed 256 lb. Each battery had seven cells with 11 plates per cell.

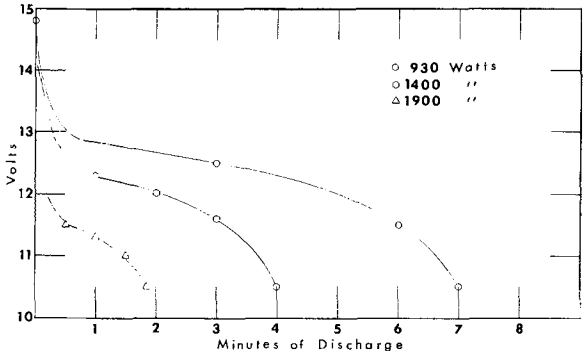

Fig. 25. Pb-acid DRX 47965-26 battery, constant power discharge

It was capable of 15 consecutive, 20 kW, 10 sec acceleration pulses before reaching 84V. It showed a power density of 75 W/lb at 2.5 Whr/lb.

Two alternatives are available. One is a lead-acid aircraft starting battery which gives the same characteristics as the Delco-Remy power pack and weighs 270 lb for ten batteries.

The second is a nickel-cadmium battery which has the same characteristics also but weighs only 180 lb for ten batteries. If volume and weight are at a premium, then this pack can be used. Otherwise, the scarcity and cost of cadmium rule out this battery.

Since the XEP was to be an all G.M. car, it was decided to use in it the specially designed Pb-acid power battery pack rather than use commercially available batteries.

ABSTRACT

A scanning electron microscope study of oxide replicas of aluminum electrolytic capacitor foils has provided information on tunneling produced by a given etch. Tunnel morphology depends on microstructure of the aluminum and on etching conditions. With increasing current density in an electrochemical etch, the number of etching tunnels per unit area increases and tunnel diameter decreases. A simplified model predicts the number of tunnels per unit area and the tunnel diameter needed for maximum capacitance for a given anodic Al_2O_3 film thickness.

Two of the present authors previously described a scanning electron microscope (SEM) method for revealing the complex morphologies produced during the etching of aluminum foils for electrolytic capacitors (1). A number of variables affect the etch morphology, and those of principal concern in the present paper are: (*a*) electroetching current density, (*b*) microstructure of the aluminum foil, (*c*) the substitution of a hot nitric acid etch for the last part of an electroetch, and (*d*) some additives to a 20% NaCl electrolyte. The effect of extent or degree of an etch and the effects produced by varying the composition of the aluminum are treated briefly. Use is made industrially of such etching variables to produce various kinds of electrolytic capacitors.

Regarding effects of current density and microstructure, Hunter (2) pointed out that the morphological detail became finer with increasing current density and this resulted in lower capacitance gains at high formation voltages. Hunter stated that microstructure was a variable. Bakish *et al.* (3) similarly reported that the morphological detail became finer with increasing current density and that this led to higher capacitance gains at low formation voltages. Later Bakish *et al.* (4) reported still finer morphologies and higher capacitance gains with the use of suitable hard aluminum foil [presumably the microstructure of such foil consists of subgrains of about 1μ size, *i.e.* the limiting subgrain size reported by Ball (5) for polycrystalline aluminum deformed at about room temperature; this is quite different from the microstructure of annealed aluminum foil]. Such results clearly indicated that current density and microstructure are important variables to be considered according to final use of the etched foil. Nothing specific was mentioned about a tunnel type etch morphology.

On the other hand, Burger *et al.* (6) had reported the tunneling character of suitable electrolytic etching methods and the production of tunnels ranging from 0.1 to 1μ in diameter. Edeleanu (7) discussed the nature of tunneling and showed that tunneling occurred in <100> directions in the aluminum. Altenpohl (8, 9) briefly discussed the tunnel morphology revealed optically in cross sections of etched foil. Additional detail about tunnel morphology, however, was revealed in SEM micrographs of oxide replicas of etched foil (1).

Two of the present authors (CGD and RBB) have developed a simple model of a tunnel morphology which leads to quantitative predictions of theoretical capacitance gains. The model is therefore useful in the discussion of morphologies of the kind obtained experimentally.

A Tunnel Model

Consider the specific model with N tunnels of radius ρ and length λ arranged in an hexagonal array normal to a flat surface of unit area (cm^2). This morphology implies a specific weight loss, w; a tunnel area or dimensionless area factor, f_A; and a tunnel capaci-

Key words: electroetch, etch-morphology, tunnel-etch-model, replica-oxides.

tance, C_t (μF/cm^2), after anodic film formation. Thus, in grams per square centimeter

$$w = 2.70\, N\pi\rho^2\lambda \qquad [1]$$

where 2.70 is the density of aluminum (g/cm^3). The factor $N\pi\rho^2$ in [1] is the fraction of surface area etched and the product $N\lambda$ is the total tunnel length (cm/cm^2). (The geometry places an upper limit on N for a given value of ρ, namely $N < \sqrt{3}/6\rho^2$). And, for the area factor

$$f_A = 2N\pi\rho\lambda \qquad [2]$$

Film formation to a thickness X may be expressed by

$$X = \alpha V \qquad [3]$$

where V is the formation voltage and α is a constant which depends on electrolyte temperature and holding time at the final voltage.

With this relationship one can then express a volt μF/cm^2 product in terms of X. Thus, for flat unetched aluminum with dielectric constant ϵ

$$V\, C_{flat} = 8.84\ (\epsilon/\alpha) \times 10^{-8} \qquad [4]$$

which is independent of X or formation voltage.

The corresponding product for the tunnel capacitance, C_t, is

$$VC_t = 5.55\, N\ (\lambda - X)\ X\ (\epsilon/\alpha)\ [\ln R/r]^{-1} \times 10^{-7} \qquad [5]$$

where R is the outer radius and r is the inner radius of the cylindrical oxide of thickness X, *i.e.* $R - r = X$. (The upper limit of N for a given value of R is $\sqrt{3}/6R^2$ and a number $N\pi R^2$ gives the fraction of original surface occupied by holes and cylindrical oxide). Equation [5] does depend on X.

If we neglect the contributions of flat areas, we obtain as a first approximation a dimensionless capacitance gain factor, $f_C = C_t/C_{flat}$, on combining [4] and [5]. Thus,

$$f_C = 2\,\pi N\ (\lambda - X)\ X\ [\ln R/r]^{-1} \qquad [6]^2$$

Since (ϵ/α) is a constant in [5], one notes that [6] differs from [5] only by a constant multiplying factor; therefore, [5] gives the functional form of [6]. However, for a given value of ρ it is necessary to express R/r in [5] in terms of ρ and X. The relationship is given in the Appendix.

For illustrative purposes we consider first two morphologies given by N, λ, ρ values of 6 x 10^8/cm^2, 35μ, 0.1μ and 6 x 10^6/cm^2, 35μ, 1.0μ, respectively. According to Eq. [1] the weight losses are the same (1.78 mg/cm^2). The area fractions, $N\pi\rho^2$, are also the same (about 0.19). According to Eq. [2] the morphologies represent tunnel area factors of 132 and 13.2, respectively. The total tunnel lengths are 21 and 0.21 km/cm^2, respectively. Taking the value of ϵ as 8.4 (10) and α as 13.7 Å/V and using [4] and [5], we obtained the curves shown in Fig. 1. Some minimum volt-microfarad products presently accepted for commercial foils, which are designated "M" in Fig. 1, were added for comparison purposes. At low voltages the 0.2μ diameter morphology (curve A) corresponds to excellent capacities approximately double those of the best foils currently available, but the 2.0μ diameter morphology (curve B) corresponds to capacities that are unacceptably low. At high voltages the situation is reversed; *i.e.*, curve B actually corresponds to acceptable capacities in the range above 200V since it lies above the M points, but the 0.2μ diameter morphology (curve A) is useless above 120V.

The model not only leads to simple predictions of possible capacity gains, as in these illustrated examples, but also predicts upper limits as shown in curves D and E in Fig. 2. Curves D and E are described more fully in the Appendix.

[2] f_C and f_A are compared in the Appendix (see footnote to Table AI).

Experimental

Current density and microstructure.—Specimens of commercial grade 99.99% aluminum foils, 84-90μ thick, from two lots—one annealed (0 temper) and the other hard (H19 temper)—were etched at either 77.5 mA/cm^2 or 775 mA/cm^2 (etching times, measured weight losses,

and calculated weight losses are listed in Table I). In certain instances one surface was masked to restrict etching to one surface and provide easy release of the oxide replicas for the transverse views of SEM samples. The electrolyte was a 20% NaCl solution at 90°C. Specimens which were etched completely in the NaCl bath were washed in deionized water, dried, immersed in a 25°C nitric acid solution (2 parts HNO_3 to 1 part H_2O) for 2 min, and washed again.

Current density and hot nitric acid.—Specimens of 0 temper foil were etched at either 77.5 mA/cm² for 210 sec or 775 mA/cm² for 21 sec, thus for the same coulombs per square centimeter. Specimens were washed, dried, and then chemically etched in an 8% nitric acid solution at 93°C until the weight loss was about 1.6 mg/cm² (see Table I).

Additives to 20% NaCl electrolyte.—Other specimens of the hard foil were etched in special baths as indicated in Table II.

Annealed 99.88% Al foil.—A specimen of 99.88% Al foil, 75μ thick, was etched at 77.5 mA/cm² for 300 sec in the 20% NaCl electrolyte, washed, and dried. The specimen was then chemically etched in the hot nitric acid bath for a weight loss of about 0.96 mg/cm².

Preparation of SEM samples.—The thickness of a reaction replica film should be kept as small as possible for best replication of the etch morphology, but the replica also needs to be relatively strong after separation from the aluminum matrix. Anodic oxide films meet these conditions better than boehmite films produced by hydration and were therefore used. The oxide replicas for the present paper were produced by formation to 50V generally in a 0.1% aqueous solution of $NH_4H_2PO_4$ at 90°C. Transverse views of the oxide replicas were obtained in the manner described previously (1). In order to obtain cross-section views showing the extent of tunneling into the foils, only partial removal of the aluminum matrix was required. This was accomplished by an electropolishing treatment that brought the oxide into relief (1). The surface view of the 50V oxide replica was obtained without removal of the aluminum matrix. All replicas were given a gold coating of about 500Å in the normal direction.

Preparation for capacitance measurements.—A cell containing 10% boric acid solution, adjusted to a pH of 4.3 and a resistivity of 560 ohm-cm at 90°C, was used in the formation of the dielectric film. Formation was accomplished in two steps, *i.e.*, constant current at 7.75 mA/cm² (projected area of one surface) and constant voltage with decreasing current until a density of 0.77 mA/cm² was reached. Another cell was used to measure a "65°C formation voltage" or the voltage, *V* appearing in the *VC vs. V* plot of data. Capacitance measurements were made at 120 Hz using a General Radio Capacitance bridge with the test specimen as one electrode in a low-resistance cell (37 ohm-cm ammonium tartrate).

Results and Discussion

Effects of current density and of hot nitric acid etch.—SEM micrographs of cross-section, transverse, and surface views of the oxide replicas of etched annealed 99.99 foils are shown in Fig. 3-8. Portions of Fig. 4 appear in Fig. 8 at higher magnifications. Transverse views corresponding to Fig. 3 and 4 appear in Fig. 5 and 6, respectively, but at a higher magnification. The surface views in Fig. 7 represent the same specimens as the transverse views in Fig. 5 (bottom) and Fig. 6 (bottom); clearly transverse views provide more information on etch morphology than do surface views.

Progress of the etches is displayed in Fig. 3-6 as follows: the center micrographs, the incomplete etches; the top micrographs, the complete electroetches; and the bottom micrographs, the etches completed with the hot nitric acid treatment. These micrographs show that more tunnels and smaller diameter tunnels occur for the high current density etch, but the distinction is not strong due to the wide variations in tunnel diameters. Observations made on the oxide replicas for the same number of coulombs (center micrographs in Fig. 3-6) revealed that low current density produced slightly greater penetrations into the specimens, while high current density produced more lateral tunneling. Rate of penetration (and tunneling) appeared to decrease with time (center and top micrographs in Fig. 3-6). The average penetration rate for the 21 sec electroetch at 775 mA/cm² was about

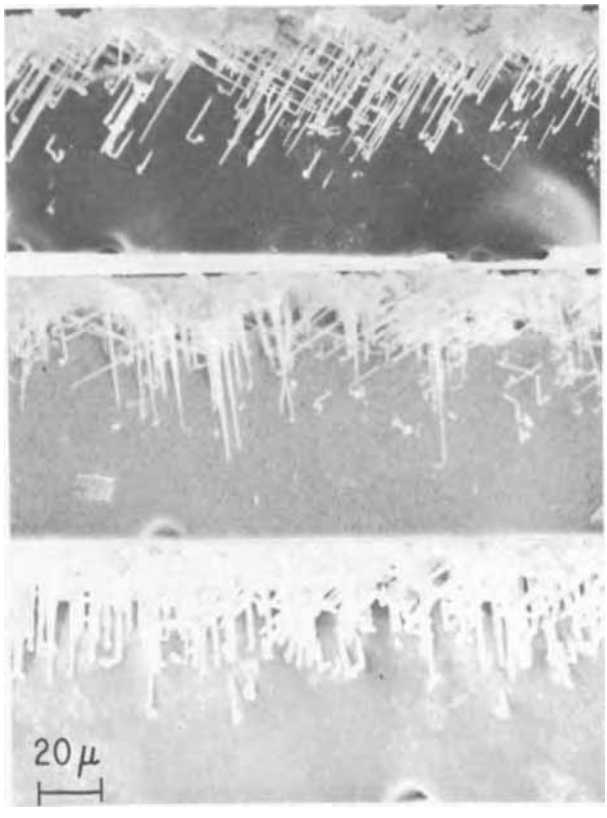

Fig. 3. SEM micrographs of annealed 99.99 foil after a one-surface etch at 77.5 mA/cm² as indicated. Cross sections showing 50V oxide replicas in relief. X400. Top, 432 sec; center, 210 sec; bottom, 210 sec plus 1.6 mg/cm² weight loss in hot nitric acid.

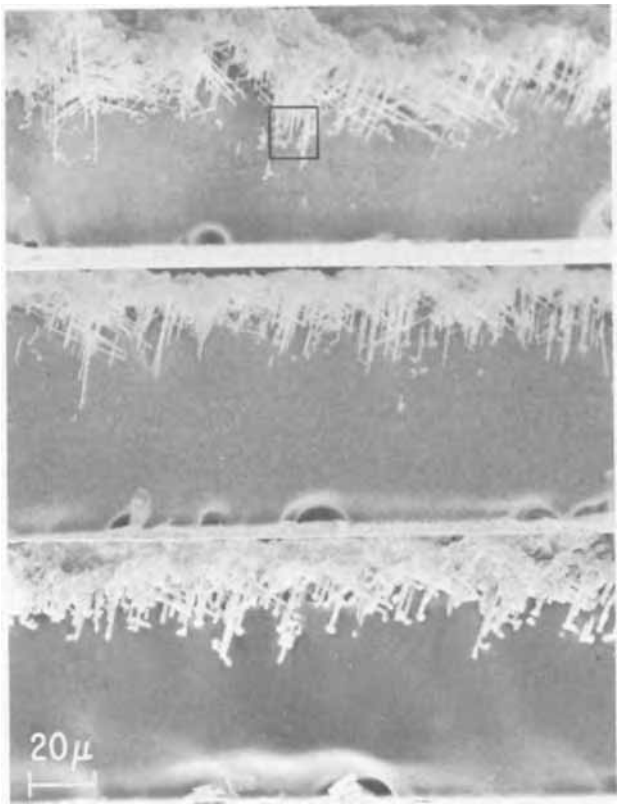

Fig. 4. SEM micrographs of annealed 99.99 foil after an etch at 775 mA/cm^2 as indicated. Cross section. X400. *Top*, 54 sec; *center*, 21 sec; *bottom*, 21 sec plus 1.6 mg/cm^2 weight loss in hot nitric acid.

2 μ/sec; the rate was below 1.5 μ/sec for the full 54 sec etch. Moreover, rates approaching 5 μ/sec were found for times below 10 sec. The estimated rates are in agreement with those reported by Edeleanu (6). The average penetration rates for etching at 77.5 mA/cm^2 were roughly a factor of ten lower than those for 775 mA/cm^2. Both low and high current density etches involved tunnel multiplication along with lateral tunneling and this resulted in oxide replica morphologies of the "jungle gym" type described previously (1).

It seems likely that some of the decrease in penetration rate with electroetching time is due to a relatively slow but uniform type of dissolution at tunnel walls, which may be characterized by definite rates of increase of tunnel diameters. Evidence of this appears in Fig. 5 since tunnel diameters for the complete etch (top micrograph) are larger than the tunnel diameters for the incomplete etch (center micrograph).

On the other hand, tunnel diameter growth may be obtained separately from tunneling; this aspect of etching is illustrated by the bottom micrographs in Fig. 3-6 for specimens partly electroetched then chemically etched in hot nitric acid. Larger diameter tunnels were obtained with the nitric acid etch (Fig. 6 bottom *vs.* Fig. 6 top) and this feature is needed for better high-voltage capacitance. For example, most tunnels are now sufficiently above 1μ diameter to make good contributions up to 700V, whereas parts of many tunnels in the complete electroetch are below 1μ diameter and contribute nothing above 600V. It is also interesting to note that the weight loss in nitric acid was less than the weight loss in the final 222 sec of the electroetch (Table I).

Although an increase in tunnel diameter may be needed for high-voltage applications, an increase in diameter after an initial high current etch (Fig. 7 bottom *vs.* Fig. 7 top) is less likely to be beneficial for low-voltage applications. First, the needed tunnel length $N\lambda$ may not develop in the electroetch step (compare appearances of Fig. 4 center with Fig. 4 top). Second, acid etching may reduce N (and $N\lambda$) as

Fig. 5. SEM micrographs of 50V oxide replicas of annealed 99.99 foil after a one-surface etch at 77.5 mA/cm^2 (same as Fig. 3). Transverse views. X1000. *Top*, 432 sec; *center*, 210 sec; *bottom*, 210 sec plus 1.6 mg/cm^2 weight loss in hot nitric acid.

Fig. 6. SEM micrographs of 50V oxide replicas of annealed 99.99 foil after a one-surface etch at 775 mA/cm^2 (same as Fig. 4). Transverse views. X1000. *Top*, 54 sec; *center*, 21 sec; *bottom*, 21 sec plus 1.6 mg/cm^2 weight loss in hot nitric acid.

neighboring tunnels merge together. Third, tunnels of tapered shape are usually produced, thus severely reducing the separation space and contributing to a

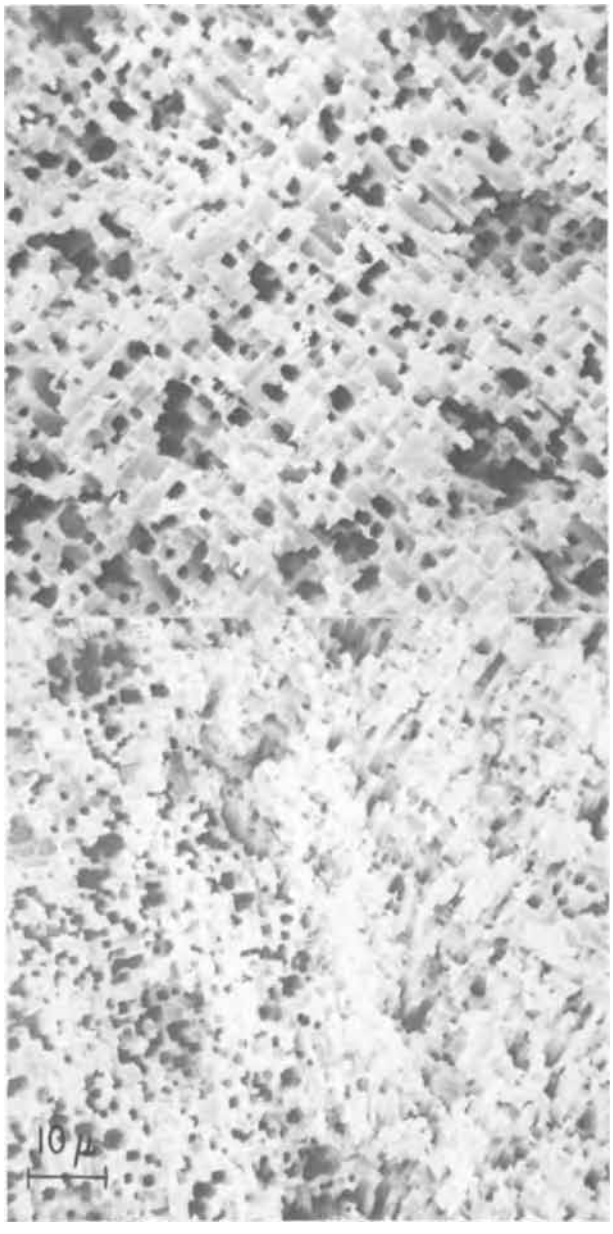

Fig. 7. SEM micrographs of the surfaces of annealed 99.99 foil after etches as indicated (also after formation to 50V). X1000. *Top*, 210 sec at 77.5 mA/cm^2 plus 1.6 mg/cm^2 weight loss in hot nitric acid; *bottom*, 21 sec at 775 mA/cm^2 plus 1.6 mg/cm^2 weight loss in hot nitric acid.

further reduction in $N\lambda$ with acid etching. In fact, capacitance data show that the complete electroetch generally produces higher gains at low voltages than the sequence of electroetch and acid etch. Theoretically, of course, with ideal geometry there could be significant gains with an increase in tunnel diameter (curve E of Fig. 2, described in the Appendix, gives upper limits for $N = 10^8$/cm^2; and f_A increases according to Eq. [2]).

Effect of microstructure and current density.—SEM micrographs of cross-section and transverse views of hard 99.99 foils are given in Fig. 9-11 and Fig. 12 (top). Views at different magnifications are given to show coarse and fine detail. It is clear that tunneling occurred in the heavily cold rolled foil. In Fig. 11 (center) there are many reasonably parallel tunnels for tunnel lengths $\sim 10\mu$, thus indicating a definite crystallographic feature to tunneling in this material. Bakish *et al.* (4), on the other hand, using optical methods found no clear evidence of crystallographic etching. The present morphology, however, appears to

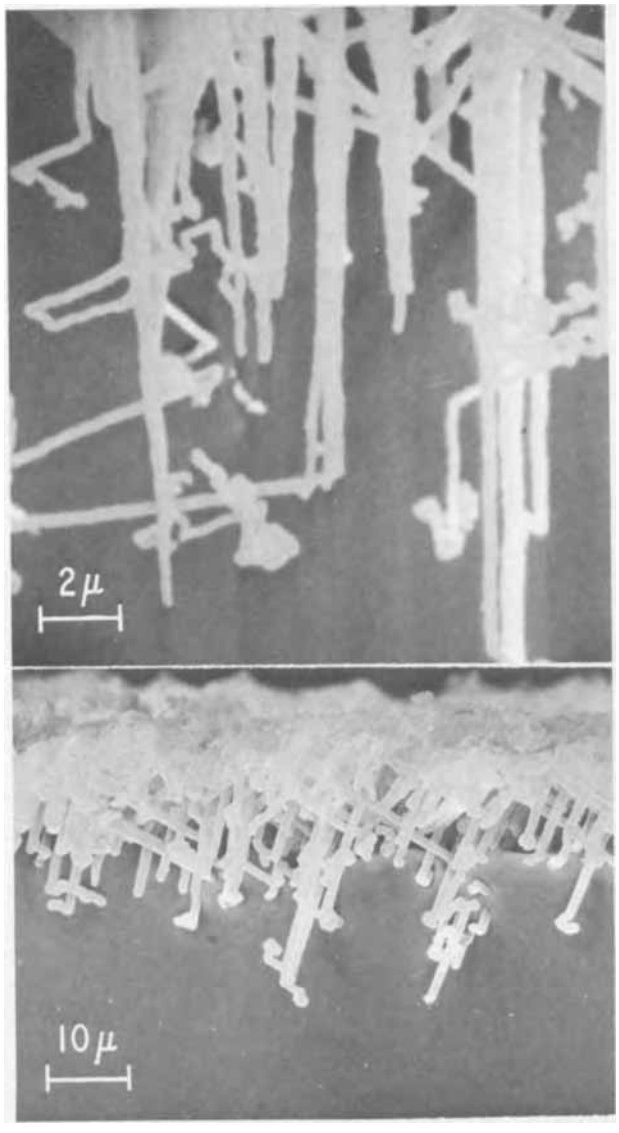

Fig. 8. SEM micrographs. *Top*, enlarged part of Fig. 4 top. X5000. *Bottom*, enlarged part of Fig. 4 bottom. X1000.

be consistent with <100> tunneling in a matrix with a strong (1$\bar{2}$3) [$\bar{5}$23] texture, the texture of heavily cold-rolled aluminum (11). The presence of tunnels that remain relatively straight over distances of about 10μ in a structure of subgrains of about 1μ size (5, 8) may be explained in terms of the very small disorientations of neighboring subgrains and the occurrence of mixed kinds of rotations, which tend to cancel out and keep the net amount of deviation small over a region of several subgrains' size.

Tunnel diameters were smaller for the hard foils than for annealed foils and were slightly smaller after etching at 775 mA/cm^2 than at 77.5 mA/cm^2. According to Eq. [1] and [2] the smaller tunnel diameters should produce larger area factors, f_A, if other factors are the same [in fact, capacitance measurements confirmed the effect of current density reported by Bakish *et al.* (4) because hard foil etched at 77.5 mA/cm^2 failed to meet the minimum acceptance levels, whereas the same material etched at 775 mA/cm^2 had acceptable qualities for low-voltage applications]. On the other hand, tunnel diameter differences may represent only part of the morphology difference. A comparison of micrographs in Fig. 11 (top) and Fig. 12 (top) indicates that the coarse features are far more uniform for the high current density etch. This difference in etch structure may favor greater etching efficiency and larger total tunnel lengths ($N\lambda$) in a layer of

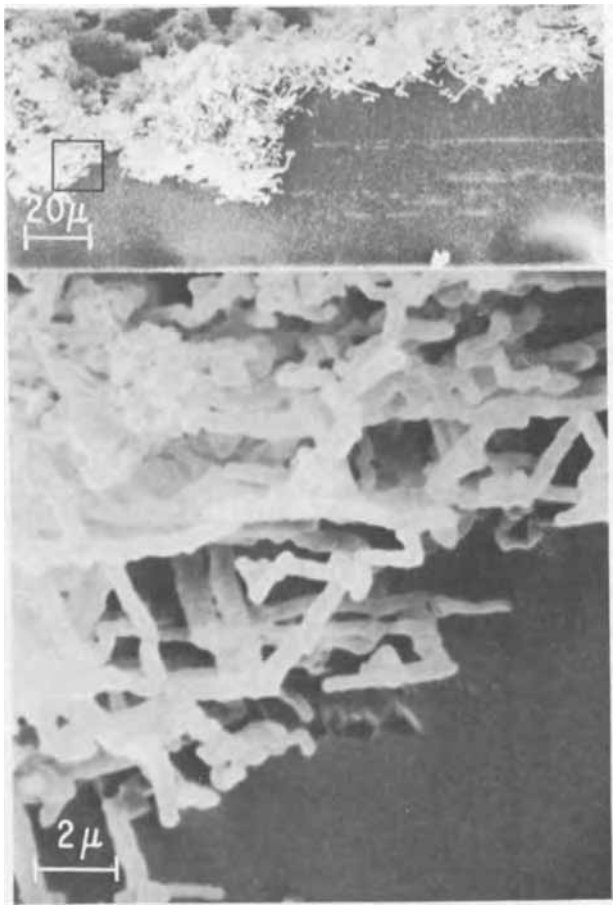

Fig. 9. SEM micrographs of hard 99.99 foil etched at 77.5 mA/cm^2 for 432 sec. Cross sections. *Top*, X400; *bottom*, enlarged area X5000.

depth λ; this point will be treated further in connection with effects of additives to the electrolyte.

Effects of additives to the NaCl electrolyte.—Etched structures.—Although both optical and SEM views of the etched surfaces at low magnification revealed large variations among the specimens etched in different electrolytes, the SEM micrographs of the transverse views of oxide replicas were rather similar in appearance (Fig. 12). Moreover, SEM observations at high magnifications revealed a fine tunnel structure which was also similar for specimens representing all four electrolytes. Qualitatively, there was little difference in tunnel diameters and only a small indication that all three additives decreased the tunnel diameters a very small amount. Rather extensive measurements and perhaps other etching conditions would be required for a more precise evaluation of the effect of these additives on tunnel diameters.

Capacitance results.—The volt μF products of one lot of 99.99 (H19) foil etched in the 20% NaCl electrolyte with various additives (Table II) are plotted in Fig. 13 as a function of formation voltage. (All samples were etched the same amount, *i.e.*, to 41.85 coulombs with measured weight losses 15-20% above the calculated values). At low voltages there is a higher etch gain with each additive; at 25V the etch ratio increases from about 44 to 65. For the particular amounts of additive used, the etch gain increases in the following order: HCl, CrO_3, and Na_2SO_4. There is a substantial increase in etch gain for the sulfate additive, and this confirms the claims of Martin (12). Present results also confirm those of N. V. Philips' Gloeilampenfabrieken (13) on CrO_3 additive.

Since the weight losses are approximately the same (Table II), the electrolyte additives apparently improve the efficiency of tunnel structure production.

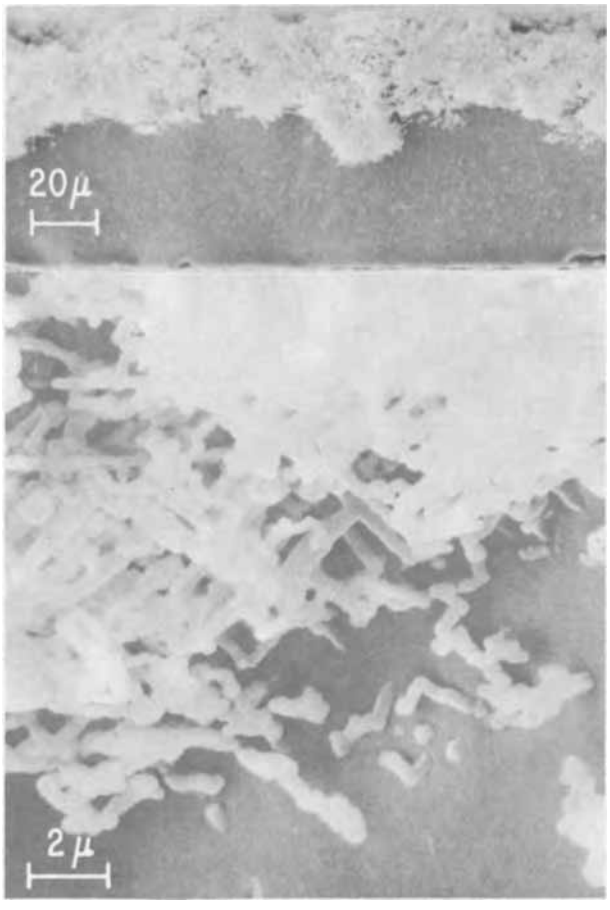

Fig. 10. SEM micrographs of hard 99.99 foil etched at 775 mA/cm² for 54 sec. Cross sections. *Top*, X400; *bottom*, X5000.

The weight losses are near 50% of the total mass in a layer 35μ deep. Such a fraction is higher than that for the points of curve D, which is constant at 38.6%. The higher fraction is within the 34.2-90.7% range for curve E (see Appendix and Fig. 2) where $N = 10^8/cm^2$ and the high values apply only to low formation voltages. A maximum fraction of about 30% would be the limit for a hexagonal array of conical tunnels which taper to zero diameter in a distance λ. A morphology involving truncated conical tunnels, however, would allow somewhat higher fractional weight losses before reaching the point of diminishing etch gains, but not as high as those for the cylindrical tunnel model.

All three morphologies have an area factor, f_A, given by Eq. [2], *i.e.*, $2\pi\rho N\lambda$ if ρ is replaced by the average radius $\bar{\rho}$. Values of $N\lambda$ obtained by the etches may be calculated if $\bar{\rho}$ and f_A are known. Actually, we may substitute the low-voltage etch gains, *i.e.*, 44-65, for f_A and take 0.30μ as a rough estimate of $2\bar{\rho}$ (see Fig. 10 bottom). These numbers yield tunnel lengths of 5×10^5 to 7×10^5 cm/cm². Such lengths divided into segments 35μ in length correspond to 1.3×10^8 to 2.0×10^8 tunnels/cm² (*i.e.*, values of N).

N may also be expressed as tunnel length per cubic centimeter; call this N^*. Since the above tunnel lengths average about 6×10^5 cm/cm² and are confined to volumes of 1 cm² $\times$ y, where $y \leq$ half the specimen thickness, N^* or its lower limit may be calculated. From Fig. 4(top) it is clear that $y \leq 45\mu$. Therefore, $N^* \geq 1.3 \times 10^8$ cm/cm³.

A uniform array of cylindrical tunnels with $N \geq 10^8$/cm² cannot contribute to the $V \cdot \mu F$ product above 400V (Fig. 2). However, the actual behavior of tunnels of varying size is clearly different from the behavior of one particular size (namely, $2\bar{\rho}$); without going into a detailed analysis, departures from uniformity should lead to decreasing $V \cdot \mu F$ products with increasing voltage, which is the case in Fig. 13, and the precipitous decline certainly is consistent with too many tunnels (N), and therefore unsatisfactory morphology, for high-voltage applications (compare with curves A and

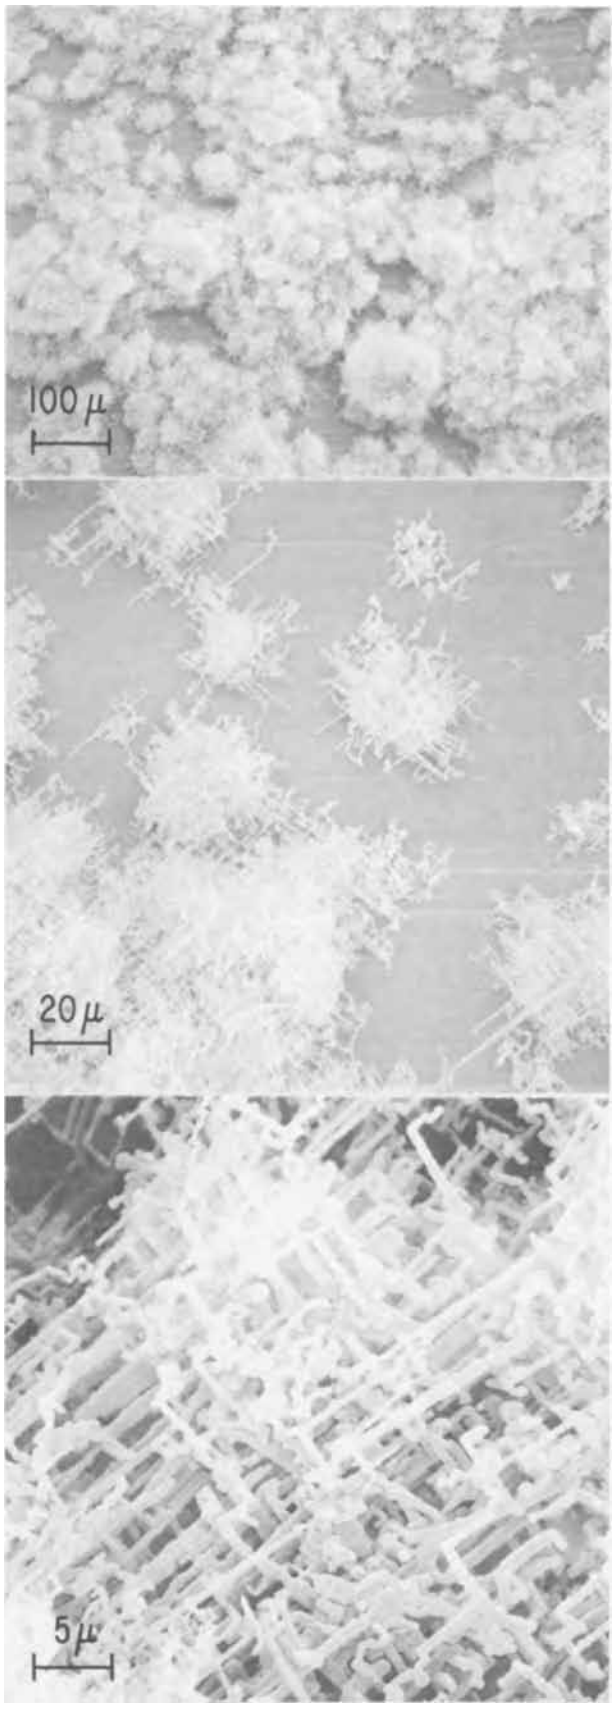

Fig. 11. SEM micrographs of 50V oxide replicas of hard 99.99 foil after a one-surface etch at 77.5 mA/cm² for 432 sec. Transverse views. *Top*, X100; *center*, X500; *bottom*, X2000.

E with $N \geq 10^8/cm^2$). The morphology needed for high-voltage applications involves larger diameter tunnels and greater separation distances, *i.e.*, features which are more easily obtained with annealed foil than with hard foil.

Effect of composition of the aluminum.—The etch gains of annealed 99.88% Al foil are similar, but generally somewhat lower, than those of annealed 99.99% Al foil (see Fig. 1 for some listed M points). The morphology produced by etching is also similar (compare Fig. 14 with Fig. 5 bottom). The SEM stereomicrographs in Fig. 14 show a typical "jungle-gym" structure of the oxide replica of the etch tunnels within a single-crystal grain of aluminum. Such three-dimensional structures are viewed best stereoscopically.

Summary and Conclusions

On the basis that tunnel diameter is a measure of "fineness of the etch morphology," present results confirm the earlier observations that increased current density produces a finer etch morphology (2, 3) and that hard foil etches to a finer morphology than soft foil (4).

More importantly, however, the observed morphologies not only confirm the presence of tunnel etching (6, 7, 1) but indicate that tunnel configurations are the principal features responsible for large etch gains. Therefore, in addition to tunnel diameters 2ρ, the description of a given morphology requires information on either the tunnel density, N (number per square centimeter), and average tunnel length, λ, or the tunnel density, N^* (total tunnel length per cubic centimeter), and the thickness, y, of the layer etched, where $y \cong \lambda$. The morphology parameters, ρ, N, and λ, in fact, are those needed for a "simple tunnel model." The model gives properties as functions of N, λ, ρ and X, where X is the thickness of the dielectric film. Only to a limited degree are N and ρ independent; also $\lambda \leq$ half the foil thickness.

The following conclusions were reached based on a "simple tunnel model" and experimental results.

1. Etched hard foil has a tunnel morphology, which is somewhat similar to that of etched soft foil; *i.e.*, there is a crystallographic feature which we believe arises from <100> tunneling.

2. Tunnel diameters of etched hard foil are smaller than those of etched soft foil, other factors being the same.

3. Slightly smaller tunnel diameters result from an etch at 775 mA/cm² than one at 77.5 mA/cm²; the more important morphology parameter is the product $N\lambda$ (tunnel length per square centimeter) according to the simple tunnel model.

4. Both SEM information on tunnel diameters and the simple tunnel model indicate that the maximum voltages for useful tunnel contributions to capacitance gains increases with tunnel diameter. The interdependence of tunnel diameter and tunnel density, however, places limits on tunnel diameter, especially if large etch gains are to be attained.

5. When electroetching produces a suitable tunnel density, but tunnel diameters of insufficient size for the formation voltage planned, chemical etching in a hot 8% nitric acid solution may be used to increase the tunnel diameters to the desired value.

6. Tunnel electroetching may be described in terms of increase in tunnel length and increase in tunnel diameter with time. The former has a high rate initially and decreases to almost zero toward the end of a long etch. The rate of tunnel diameter increase, or radial growth, on the other hand, is relatively low; the fraction of the current taken by radial growth appears to increase with time, perhaps approaching 100% in long etches.

7. Additives to the 20% NaCl electrolyte, such as Na_2SO_4, or CrO_3 or HCl in suitable amounts, increase the etch gains of hard foil for low-voltage capacitors (*e.g.*, etch gains of 44-65 after formation to 25V). SEM

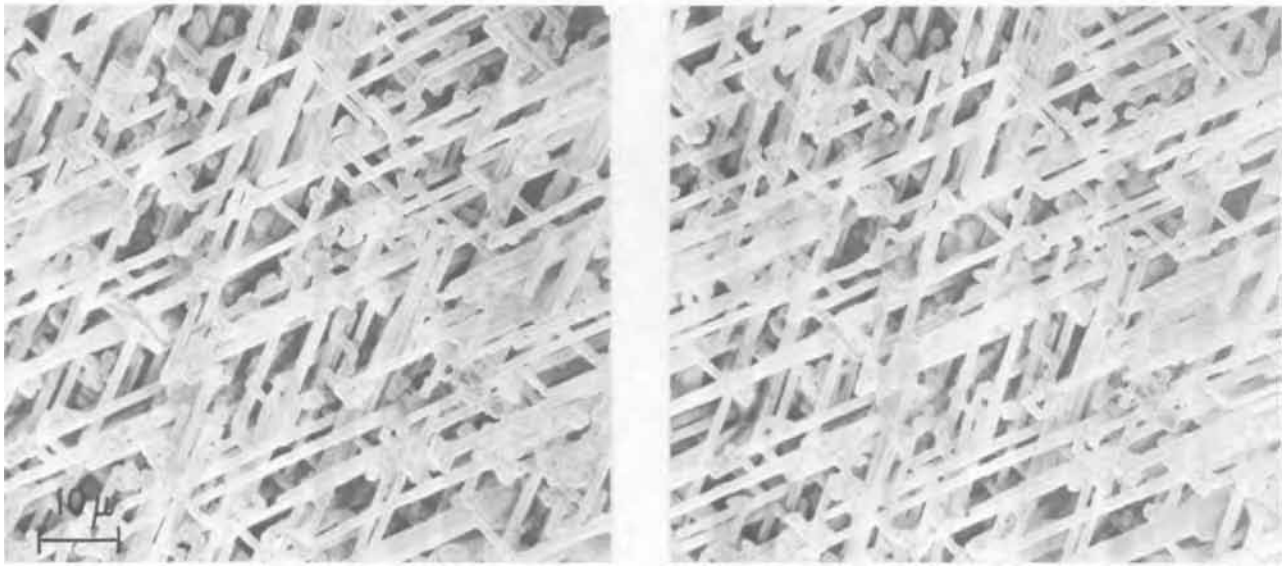

Fig. 14. SEM stereomicrographs of a 50V oxide replica of 99.88 soft foil. Transverse view. X1000.

data and calculations based on the simple tunnel model indicate that these additives increase the tunnel density, N^*, in a layer, y, where $y \leq$ half the foil thickness.

8. According to the tunnel model, etch gains of 44-65 and an observed tunnel diameter near 0.3μ indicate the production of tunnel lengths ($N\lambda$) of 5 x 10^5 to 7 x 10^5 cm/cm^2 (or 6 x 10^5 cm/cm^2 as an average) and tunnel densities, N, of 1.3 x 10^8 to 2.0 x 10^8 tunnels/cm^2. Alternatively, since half the specimens thickness (45μ) is the maximum depth of the etch a calculation of the tunnel density N^* for $N\lambda = 6 \times 10^5$ gives $N^* \geq 1.3 \times 10^8$ cm/cm^3.

9. The morphologies that gave etch gains of 44-65 at 25V (*i.e.*, $N\lambda$ values of 5 x 10^5 to 7 x 10^5 cm/cm^2) are unsuitable for use at high voltages according to the simple tunnel model. The tunnel densities for high voltages should be high, but not too high. N or N^* equal to 10^8 cm^{-2} is too high even for 400V; the properties of hard foil etched at 775 mA/cm^2 and formed to high voltages confirm this prediction.

Acknowledgments

The use of hot nitric acid and the experiments involving the HCl additive to the NaCl electrolyte were based on earlier investigations of R. A. Ruscetta. Mrs. Mary L. Mann carried out the etching and oxide-forming operations and made the capacitance tests.

Manuscript received Sept. 10, 1970. This was Paper 16 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

APPENDIX

Assuming 100% coulomb efficiency in the formation of the Al_2O_3 film on the tunnel walls, an Al_2O_3 density of 3.17 g/cm^3 (10), and $\lambda >> X$, it follows that

$$(R^2 - r^2)/(R^2 - \rho^2) = 1.6 \qquad [A1]$$

Also, since $R - r = X$, both R and r can be expressed as functions of X and ρ. Dividing R by r gives

$$R/r = \frac{X + \sqrt{2.56\rho^2 - 0.6X^2}}{-0.6X + \sqrt{2.56\rho^2 - 0.6X^2}} \qquad [A2]$$

Combining [A2] and [5] with $\epsilon = 8.4$ and $\alpha = 13.7 \times 10^{-8}$ cm/V gives an expression for VC_t in terms of X, which may be evaluated for given values of N, λ, and ρ.

N, λ, and ρ given.—Some calculated values of VC_t for curves A and B of Fig. 1 are listed in Table AI. Values of C_t/C_{flat} or f_C are also listed.

N and λ given but ρ variable to give the upper limit of VC_t.—Consider the case of curve E in Fig. 2 with $N = 10^8$/cm^2, $\lambda = 35\mu$, and ρ made just large enough that R approaches its upper limit of $\sqrt{\sqrt{3}/6N}$ or 0.537μ. For a given value of X in microns, r is equal to 0.537 − X, and the value of ρ needed is then determined by [A1]. Substituting $0.537/(0.537 - X)$ for R/r in [5] determines VC_t. The range of X is zero to 0.537μ (or zero to about 393V). The corresponding range of ρ is 0.537 down to 0.330μ with $N\pi\rho^2$ varying from 90.7

Table AI. Illustrative calculations of VC_t for curves A, B, and D in Fig. 1 and 2; also calculated values of f_C*

Voltage	A ($N = 6 \times 10^8$, $\rho = 0.1\mu$)		B ($N = 6 \times 10^6$, $\rho = 1\mu$)		D (N & ρ variable)	
	VC_t	f_C	VC_t	f_C	VC_t	f_C
5	720.4	133−	71.55	13.2	20,460	3770
10	724.3	133+	71.60	13.2+	10,230	1890
25	728.3	134	71.72	13.2+	4089	754
50	706.4	130	71.91	13.3−	2042	378
100	507.5	93.6	72.18	13.3	1019	188
300	0	0	71.91	13.3−	337	62.2
550	0	0	68.38	12.6	182	33.6
700			64.24	11.9−	142	26.2
900			55.52	10.2		
1000			49.0	9.0	98	18.1
1100			39.4	7.3		
2000			0	0	47	8.7

* Note that f_C approaches f_A, i.e., 132 for curve A and 13.2 for curve B according to Eq. [2] at low voltages and is equal to or greater than f_A over relatively wide voltage ranges.

to 34.2%. The fraction of aluminum remaining in the layer of thickness, λ, after anodic film formation is constant, i.e., $1 - N\pi R^2 = 9.3\%$.

Curve D: $\lambda = 35\mu$, both N and ρ variable for maximum VC_t.—Starting with Eq. [5] one replaces N with the upper limit value $\sqrt{3}/6R^2$ and r with $R - X$. One then finds the value of R that makes VC_t a maximum for any value of X (or V). The solution is given by $R/r = 3.51$. Therefore, $r = X/2.51$, $R = X\ 3.51/2.51$, and $\rho = 0.91X$. Table AI lists values of VC_t for curve D in Fig. 2. It is interesting to note that for each point of curve D the fraction $N\pi\rho^2$ is 38.6% and the fraction $N\pi R^2$ is 90.7%. Also, an increase of N from 6 x 10^8 to 1.23 x $10^9/cm^2$ with $\rho = 0.1\mu$ and $\lambda = 35\mu$ gives a VC_t curve similar to curve A, but above it with one, and only one, point common with curve D. For $\rho = 1\mu$ (like curve B), the value of N needed is 1.23 x $10^7/cm^2$. The unique combination needed for 700V to produce the upper limit, which is only a factor 2.2 above curve B, is $N = 6$ x $10^7/cm^2$, $\rho = 0.875\mu$, with $\lambda = 35\mu$. There is no hexagonal array of tunnels of constant radius and 35μ length that will produce a VC_t product above curve D. Corrections due to neglect of flat area contributions, or an increase in λ, or an increase in ϵ above 8.4, or a decrease in α in Eq. [5] from 13.7 Å/V could, of course, produce $V \cdot \mu F$ products above the limit set by the present model.

The Two-Level Effect in Sheet Resistance Measurements Made with a Four-Point Probe

Alvin H. Tong* and Andrew Dupnock

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Sheet resistance measurements by the four-point probe technique have been investigated on diffusions into opposite-type backgrounds with junction depths from 0.25 to 3.0 μm. Sheet resistances, measured with a probe each of whose four points was weighted with 30-60g and whose tips were five mils in radius, were independent of this loading between 34 and 1570 ohms/sq. As the voltage is varied, sheet resistances show a two-level effect, followed by a breakdown at 5.5V. The transition takes place, independent of the sheet resistance, at a constant voltage of 100 mV. This transition is explained by the correction factors for a four-point probe derived from the multilayer potential distribution theory.

Characterization of a diffused layer in silicon involves the following parameters: *Co*, the surface concentration; ρ_s, the sheet resistance; *xj*, the junction depth; *Cb*, the background concentration and the type of diffusion profile. A knowledge of these parameters is essential to the design, development, and manufacture of integrated circuits.

A complete profile of the diffused layer which contains all the above parameters can be obtained by the spreading resistance technique (1-3) with correction factors (4). Another widely used method is to measure ρ_s by the four-point probe technique, *xj* by the bevel and strain technique; and, assuming the profile to be either Gaussian or a complementary error function profile, *Co* can be obtained with a knowledge of *Cb* (5, 6).

Because of the need for fast devices, diffusion layers are being made shallower and shallower and the demand for accurate and reproducible sheet resistance measurement becomes more urgent. What follows is our investigation of the following important parameters in the four-point probe measurement of sheet resistance: probe loading, configuration and tip radius, and current levels.

It has been reported (7) that a different current level should be used for different resistivities to give the correct value in bulk materials. It was also noticed (8) that the resistivity measurement in silicon epitaxial layers is a function of the current level. For thin diffused layers, the current level is even more critical, and was therefore closely investigated.

Four-point probes that are commonly used in the semiconductor industry have two different configurations: in-line array and square array. Probe tip radii of 1.5 and 5.0 mils are most popular. Probe loadings are adjusted by the spring tension in the probe head. Because of the shallow diffusion layer involved in the sheet resistance measurement, a bad combination of probe loading, tip radius, and the velocity of impact of the probe can produce erratic readings caused by the penetration of the probe points through the diffused layer.

The diffused layer thicknesses investigated ranged from 0.25 to 3.0 μm. Sheet resistances range from 34 to 1570 ohms/sq. The substrate wafers are all 1 ohm-cm p<111> silicon. The diffusant is As, with *Co* ranging from 10^{18} cm^{-3} to 10^{20} cm^{-3}. The diffusion profiles are of the complementary error function type determined by the spreading resistance technique with correction factors.

Experimental and Results

The in-line array and square array configurations are shown in Fig. 1. A current, *I*, is sent through probe points 1 and 4, and the voltage difference, *V*, is measured between points 2 and 3. From the sample geometry and the measured resistance, the resistivity for bulk material and the sheet resistance (ρ_s) for diffused layers can be calculated (9).

Probe loading, configuration, and tip radius.—Table I lists sheet resistance values derived from different probe configurations and loadings. All measurements were made below 100 mV.[1] For the range of 30 to 60 g/point, sheet resistances measured by probe No. 1 are independent of the probe loading. A scatter is seen for probe No. 2 on sample No. 2 which has the highest sheet resistance of 1570 ohms/sq and a shallow junction of 0.5 μm. Probe No. 3 had a square-array probe which had a constant loading of 50 g/point and was not varied

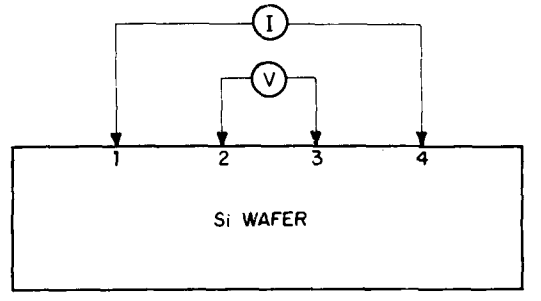
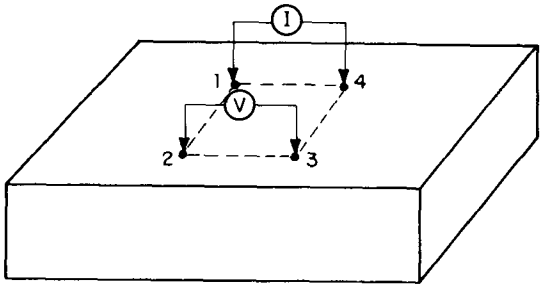
[1] This 100 mV limit is discussed later.



IN-LINE ARRAY



SQUARE ARRAY

Fig. 1. In-line and square array configurations of the four-point probe.

because of the design of the probe. Sheet resistances measured by this probe were lower than those measured by probes No. 1 and 2, especially on sample No. 2.

The reproducibility of probe No. 1 as a function of the probe loading is attributed to the broad point (the tip radius is 5.0 mils) as well as to the careful lowering of the probe points onto the wafer surface. (Since it is the "pressure," not the "velocity," that causes the probe points to make good contact, the probe points were lowered as slowly as possible.)

The scatter observed in the data from probe No. 2 could be caused by the combination of sharp probe point (tip radius of 1.5 mils), high sheet resistance, and shallow junction. Greater probe wander error reported for the square array technique (10) is a possible explanation for the deviation of sheet resistances measured by probe No. 3.

Probe No. 1 was used for the rest of the experiments; for convenience it was given a middle-of-the-range probe loading of 40 g/point.

* Each of these sheet resistance measurements represents an average of five readings.

I-V Characteristics

Room temperature.—Figure 2 shows a family of I-V characteristics taken at room temperature for different sheet resistance samples. There are three distinctive features: (*a*) all I-V curves are linear below 100 mV; (*b*) all I-V curves go through a transition region starting from 100 mV and then reach a different level where they are linear again; (c) finally, the voltage difference between the two inner probe points stays constant, independent of the current through the two outer probe points. (We refer to this effect as the "breakdown.")

At elevated temperatures.—To assure that heating is not the cause of the two-level phenomenon in the I-V characteristics mentioned above, we measured sample No. 5 at 125° and 175°C (Fig. 3). The heating introduces a shift in the I-V curve while maintaining the two-level effect. Also shown in this figure is the I-V curve measured at room temperature with a large heat sink underneath the silicon wafer. This curve is identical to the one measured without a heat sink. It is worth pointing out that the heating did change the voltage at the "breakdown." The "breakdown" voltage is lower for higher temperatures as reported by others (11).

Theoretical Model of the Two-Level Effect

A theoretical model may explain both the two-level and the "breakdown" mechanism.

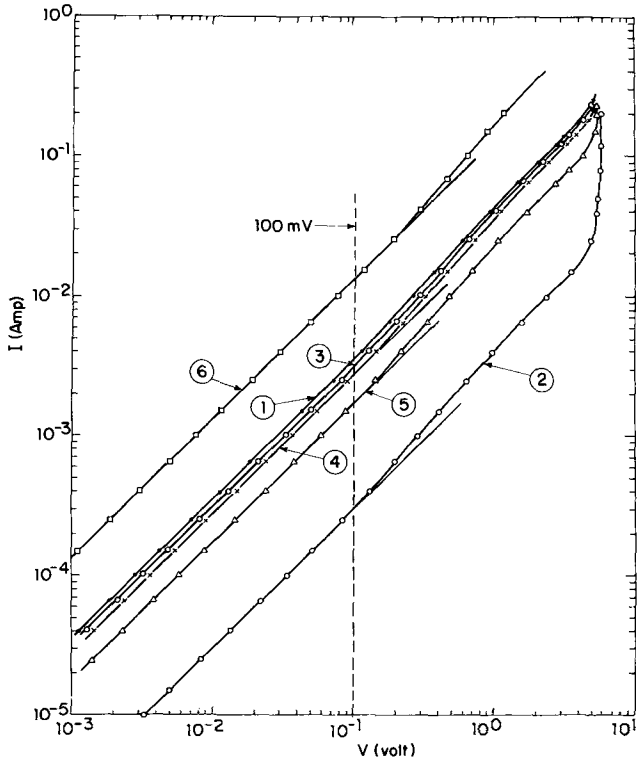

Fig. 2. I-V characteristics at room temperature for samples having different sheet resistances.

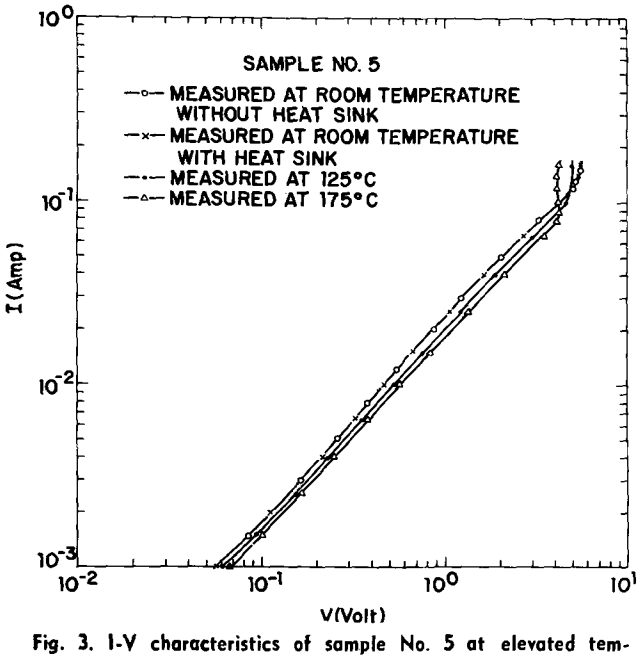

Fig. 3. I-V characteristics of sample No. 5 at elevated temperatures.

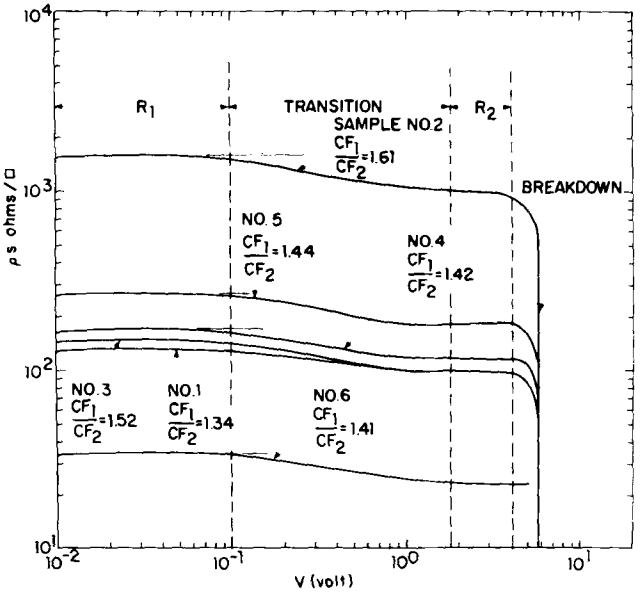

Fig. 4. Sheet resistance "breakdown" caused by varying the voltage. The two-level effect is reflected in the relationship between CF_1 (the correction factor at low voltage) and CF_2 (the correction factor at high voltage).

If we take the data of Fig. 2 and plot the sheet resistance *vs.* V, the results are shown in Fig. 4. The four sections of the curve are labeled R_1, transition, R_2, and "breakdown." Similar to the correction factors for spreading resistance reported by Schumann and Gardner (12), correction factors can also be derived for a four-point probe on a two-layer structure with uniform resistivity in both layers, as shown in Fig. 5. The relationship between V and I can be shown to be

$$V = \frac{I\rho_1}{2\pi S} \times \left[\frac{S}{a} \int_0^\infty \frac{[1 + 2\theta_1] \text{ Sin } (\lambda a)\ Jo\ (\lambda r)}{\lambda}\, d\lambda \right] \quad [1]$$

$$\theta_1 = \frac{K_1 e^{-2\lambda h_1}}{1 - K_1 e^{-2\lambda h_1}} \quad [2]$$

$$K_1 = \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1} \quad [3]$$

where a is the radius of the probe

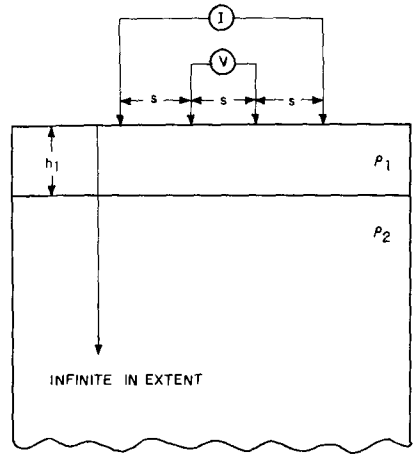

Fig. 5. Four-point probe correction factors for a two-layer structure.

$Jo(\lambda r)$ is the Bessel function of zero order
ρ_1 is the resistivity of the top layer
ρ_2 is the resistivity of the substrate
S is the probe spacing
h_1 is the thickness of the top layer

This equation can be written as

$$V = \frac{I\rho_1}{2\pi S} \times CF \quad [4]$$

where CF signifies the "correction factors" representing the expression in the bracket. When these correction factors are plotted against S/h_1 for various K_1 values, they are as shown in Fig. 6.

If the two layers have opposite conductivities (the result of an isolating junction), ρ_2 appears to be much greater than ρ_1, and therefore $K_1 = 1$. When $\rho_2 = \rho_1$, $K_1 = 0$ for the case of a bulk sample with infinite thickness. When the two layers are of the same conductivity but $\rho_2 > \rho_1$, K_1 has a positive value between "zero" and "one."

Suppose we have a structure of N+/N with $\rho_1 = 0.001$ ohm-cm (N $\simeq 10^{20}$ cm^{-3}) and $\rho_2 = 1$ ohm-cm. Then $K_1 = (\rho_2 - \rho_1)/(\rho_2 + \rho_1) = 0.999$, which corresponds to a correction factor of 1150, as indicated in Fig. 6. The probe spacing, S, is 1270 μm ($\simeq$ 50 mils) and the thickness, h_1, is 1 μm. If an isolating junction structure N+/P with the same ρ_1, ρ_2, S, and h_1 is used, then $K_1 = 1$, and the corresponding correction factor is 1800. The ratio of these two correction factors indicates the ratio of the two sheet resistances, which is

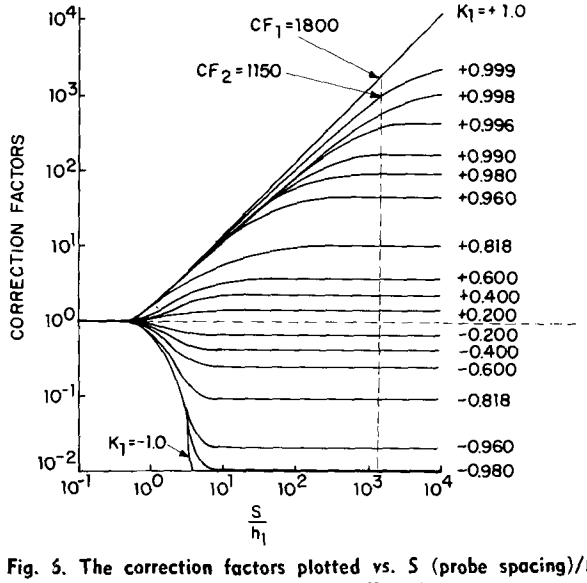

Fig. 6. The correction factors plotted vs. S (probe spacing)/h_1 (thickness of the top layer) for various K_1 values.

$$\frac{CF_1}{CF_2} = \frac{\rho_{S1}}{\rho_{S2}} = 1.56 \qquad [5]$$

So the sheet resistance, ρ_{S1}, of N+/P structure is 1.56 times higher than the sheet resistance, ρ_{S2}, of N+/N structure.

Our case is N+/P structure. Although the diffused layer does not have a uniform resistivity, ρ_1, the two-level sheet resistance effect can be explained by the difference in correction factors for an isolated and a "leaky" junction. When the current level, I (or voltage difference, V), is low, the relationship between V and I is

$$V = \frac{I\rho_1}{2\pi S} \times CF_1 \qquad [6]$$

because of the isolating junction. This is region R_1 in Fig. 4.

As I increases (or V increases), the isolating junctions underneath the two current probes start "leaking." This leakage current causes our N+/P structure to behave similar to that of a N+/N structure. Although the substrate resistivity, ρ_2, is still three orders of magnitude higher than ρ_1, K_1 is no longer "1" but "0.999." Therefore

$$V = \frac{I\rho_1}{2\pi S} \times CF_2 \qquad [7]$$

This is region R_2 in Fig. 4.

Since $CF_1 > CF_2$, sheet resistance values in R_1 are higher than those of R_2 (Fig. 4).

At this point, it is important to understand the voltage distribution under the current probe. When a current, I, is passed into the semiconductor, which has a two-layer structure as shown in Fig. 7, the voltage at a point (y, z) can be shown to be

$$V(y,z) = \frac{I\rho_1}{2\pi a} \times {}_2Q_1 \qquad [8]$$

where

$${}_2Q_1 = \int_0^\infty \frac{e^{-\lambda z} \sin(\lambda a)\, Jo(\lambda y)}{\lambda}\, d\lambda + \int_0^\infty \frac{\theta_1 (e^{\lambda z} + e^{-\lambda z}) \sin(\lambda a)\, Jo(\lambda y)}{\lambda}\, d\lambda$$

and θ_1 is the same as in Eq. [2].

In Fig. 7, ${}_2Q_1$ is plotted as a function of Y (or y/a) for the case of $h_1/a = 2$. The running parameter is Z or z/a. The curve indicated by $Z = 0$ is the voltage distribution on the surface of the semiconductor. The curve indicated by $Z = 2.0$ is the voltage distribution at the interface of this two-layer structure. For a distance of $Y \geq 5$ (or $y \geq 5a$), the voltage distribution

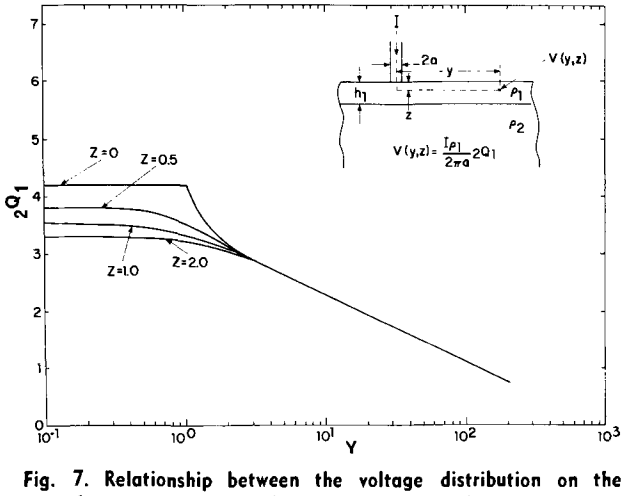

Fig. 7. Relationship between the voltage distribution on the semiconductor surface, Z = 0, and that at the P/N junction interface, Z = 2.0.

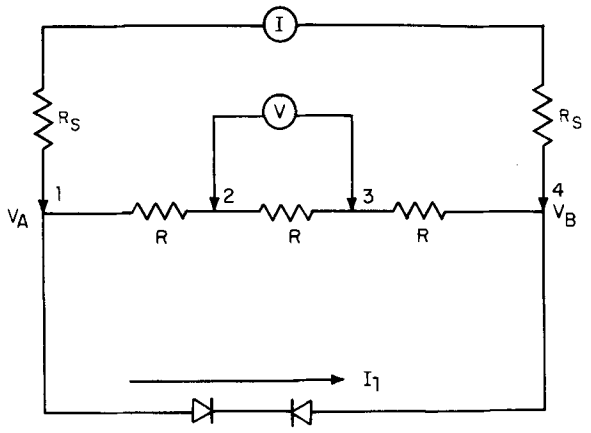

Fig. 8. A simplified equivalent circuit

on Z = 0 (the surface) and Z = 2.0 (the interface) are practically the same. In other words, the voltage difference measured on the surface of the wafer is no different than the voltage difference at the interface of the two layers.

To check that the condition $y \geq 5a$ is met, we calculated from the spreading resistance (12) measurement using this same current probe and obtained $a = 1.5$ μm.[2] The probe spacing, y, in our case is 1270 μm (50 mils) so the condition of $y \geq 5a$ is certainly satisfied. Therefore, the voltage difference measured on the surface can be thought of as the voltage difference at the P/N junction interface.

When I is increased further, the N-P junction underneath the two current probes breaks down and most of the current now flows through the substrate. A simplified equivalent circuit is shown in Fig. 8. The back-to-back diodes simulate the two N-P junctions underneath the two current probes. R represents the resistance of the thin layer. R_s is for the spreading resistance of the current probe. When the diodes break down, an increase in I from the constant current supply will increase I_1 through the diodes while maintaining a constant $\Delta V = (V_A - V_B)$ across the diode. A constant ΔV will in turn keep V between the two inner probes a constant. This "breakdown" situation is what we observed in Fig. 4.

Summary and Recommendations

The two-level effect is explained qualitatively by the correction factors for the four-point probe. The sample calculation shows $(CF_1)/(CF_2) = 1.56$. Calculated ratios of the two levels of the samples range from 1.34 to 1.61. This difference is due to the actual structure, which consists of diffused layers of different thicknesses.

The transition region starts at 100 mV, and the "breakdown" is around 5.5V. Both are independent of the sheet resistances, suggesting that this is an effect due to the nature of the N-P junction.

For reproducible sheet resistance measurements on thin diffusions, we recommend the following:

1. Use of a broad probe tip, since small tip radius might pierce through the diffusion and cause erratic readings.
2. Probe points should be loaded with between 30 and 60g and lowered as slowly as possible.
3. The current levels should be so adjusted that the voltage difference between the two inner probes is less than 100 mV.

Acknowledgments

The authors would like to thank Paul A. Schumann, Jr., for his many helpful discussions on the subject matter of this paper, and for the use of the correction factors curve constructed by him and E. E. Gardner.

[2] $R = \rho/4a$ is the relationship that exists between the spreading resistance (R), the resistivity of the sample (ρ), and the radius of contact (a) of the probe. For a sample with $\rho = 1.0$ ohm-cm, R was measured to be 1.68 kohm, which resulted in $a = 1.5$ μm.

The capacity of seawater activated batteries containing magnesium anodes is often limited by clogging. During discharge the space between the electrodes of the cells nearest to the negative terminal gradually fill with an insoluble precipitate that replaces the seawater electrolyte and reduces battery capacity.

The problem of clogging has been encountered in both high and low discharge rate batteries. In batteries designed for high rate (15 min) applications, the electrolyte is forced through each cell. In these applications, the flow of electrolyte is usually sufficient to flush the insoluble precipitate from the cells. However, Faletti and Nelson (1) found that the use of AZ61 magnesium anodes which had not been properly heat treated resulted in the formation of an adherent precipitate during high rate discharge. This precipitate could not be flushed from the affected cells and caused a reduction in battery capacity.

Clogging is usually more severe in batteries designed for low rate applications. In these batteries the electrolyte is not forced through the cells and there is a greater tendency for the precipitate to build up and reduce capacity. This problem was encountered during the development of a low rate (6 hr, 150 mA constant current discharge) 10 cell, 15V, AgCl/Mg seawater battery at the Naval Ordnance Laboratory, White Oak, Maryland. When prototype batteries were discharged in seawater, a flocculent adherent precipitate formed that gradually filled the space between electrodes in those cells nearest to the negative terminal of the battery. The precipitate also formed outside these cells and blocked the bottom water-entry holes. This condition limited the capacity to less than half of that theoretically available. However, when similar batteries were discharged in aqueous sodium chloride of equal salinity, a granular nonclogging precipitate was formed. This fine precipitate together with hydrogen gas escaped through the top port hole of each negative cell. As a result, the capacity of these batteries was two to four times greater than those discharged in seawater.

Key words: silver chloride/magnesium battery, seawater battery filter, control of $Mg(OH)_2$ formation.

This paper describes the experiments that were conducted to determine the cause for the formation of the flocculent clogging precipitate in seawater. The results of these experiments are discussed. Methods for controlling the formation of this precipitate are presented.

Experimental

The experimental battery model used in this study is shown in Fig. 1 and 2. It consisted of a clear Lucite

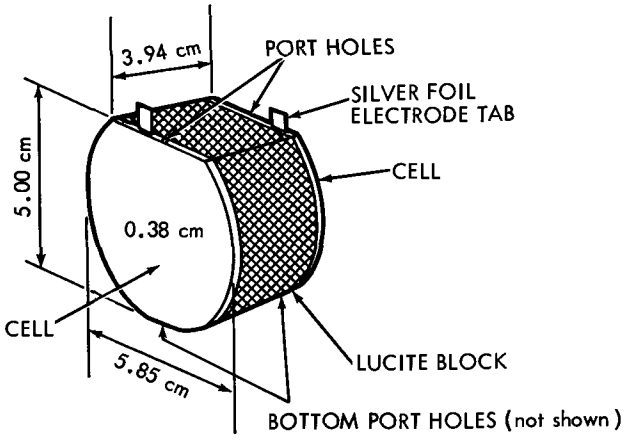

Fig. 1. Experimental battery model

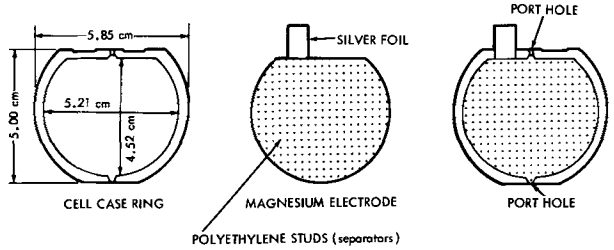

Fig. 2. Cell and electrode configuration of experimental battery model.

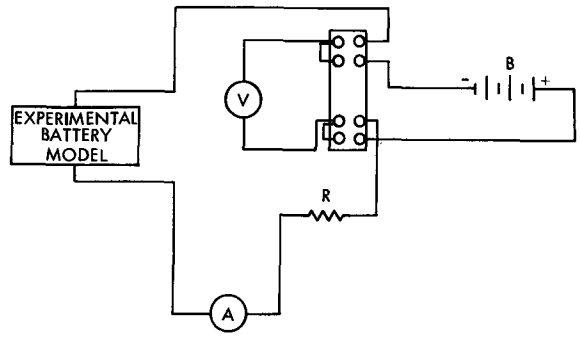

Fig. 3. Experimental apparatus and circuitry

block with a cell containing an AZ61 magnesium electrode attached to each end. The clear Lucite permitted *in situ* observations during the experiments. The configuration of the model was similar to the low rate, 10 cell, 15V battery that was being developed. When the model was immersed in an aqueous salt solution with a d-c voltage of 15.1 ± 0.1V impressed across the electrodes, the parasitic drain condition (2) similar to that occurring during the discharge of the 10 cell battery was simulated. A variable resistor was used to maintain the voltage between the desired limits. A Sensitive Research voltmeter (10,000 ohms/V) was used to monitor the voltage, and the current which represented the parasitic drain (2) was measured with a Weston milliammeter, Model No. 622. The circuitry is shown schematically in Fig. 3.

The experiments were conducted in various electrolytes: (a) in seawater obtained from the Gulf Stream near Ft. Lauderdale, Florida, which was representative of typical seawater, and (b) in other aqueous salt solutions of equal salinity (3.5%). The aqueous salt solutions were made up from ACS reagent grade salts and distilled water. These solutions contained varying proportions of NaCl, $MgCl_2$, Na_2SO_4, and $MgSO_4$. The ions contained in these aqueous salt solutions represented the four major ions found in seawater which are Na^+, Mg^{++}, Cl^-, and $SO_4^=$ (3-6). The composition of each electrolyte is given in Table I. The specific resistivity of the prepared salt solutions was similar to that of the Gulf Stream seawater which was 20.3 ohm-cm at 20°C (3-6). Before the start of each experiment, the *p*H of the electrolyte was measured and adjusted, if necessary, to 8.25 ± 0.05 with 0.1*N* Na_2CO_3. Upon the completion of each experiment, the *p*H was again determined. The volume of electrolyte used for each experiment was 1800 ml; the temperature was maintained at 23° ± 2°C. Experimental runs were usually of 3 hr duration, but some exploratory experiments ran for as long as 7 hr. The precipitate from each experiment was qualitatively analyzed using x-ray diffraction spectra.

Table I. Identification of electrolyte solutions

Electrolyte solution	Electrolyte composition 3.5% by weight:	Major ions present	Bulk *p*H initial	Bulk *p*H final
A	NaCl	Na^+,Cl^-	8.30	11.00
B	Na_2SO_4	Na^+,$SO_4^=$	8.25	10.90
C	32/39 NaCl & 7/39 Na_2SO_4	Na^+,Cl^-,$SO_4^=$	8.25	11.00
D	$MgCl_2$	Mg^{++},Cl^-	8.25	9.05
E	$MgSO_4$	Mg^{++},$SO_4^=$	8.25	8.50
F	32/39 NaCl & 7/39 $MgSO_4$	Na^+,Mg^{++},Cl^-,$SO_4^=$	8.25	9.90
G	32/39 NaCl & 7/39 $MgCl_2$	Na^+,Mg^{++},Cl^-	8.25	9.80
H	Gulf Stream seawater (salinity ~35‰)	Na^+ ~10.56 g/kg Mg^{++} ~1.27 g/kg Ca^{++} ~0.40 g/kg Cl^- ~18.98 g/kg $SO_4^=$ ~2.65 g/kg	8.30	9.65

Results

The data in Table II show that large flocculent agglomerates were formed only when magnesium salts were initially present in the electrolyte (solutions D, E, F, G, and H of Table I). This flocculent precipitate formed inside of the negative cell and also in the bulk electrolyte around the bottom inlet port of this cell. This condition was similar to that observed during the seawater discharge of the prototype batteries. However, in electrolyte solutions initially free of Mg^{++} ions (solutions A, B, and C of Table I) a granular precipitate was formed. This precipitate did not clog the negative cell and was flushed out into the surrounding body of electrolyte. These results indicate that the type of precipitate formed depends on whether Mg^{++} ions are initially present in the electrolyte.

The precipitates obtained from these experiments were analyzed by x-ray diffraction spectra. The spectrum of precipitates collected from solutions A, C, D, E, F, and G had only one readily identifiable component, $Mg(OH)_2$. In addition, there were two unidentified constituents found in these samples. One of these materials was probably free magnesium, for spalling of the anode was observed and metal was visible in the corrosion products. The precipitate from solution B was identified as being only magnesium metal. However, the concentration of this material may have been high enough to mask out any other constituents present, including $Mg(OH)_2$. The precipitate obtained from solution H (seawater) had only one identifiable component, $CaCO_3$. There were other materials present, but they were not identified. Although the results obtained from the x-ray diffraction analyses are somewhat limited, they seem to indicate that in most every case $Mg(OH)_2$ is formed as the principal corrosion product.

Table II also shows that the maximum simulated parasitic current value obtained for each experiment varied only slightly with the chemical composition of the electrolyte indicating that the conductivity of the different solutions was essentially the same. The values ranged from 47 to 65 mA. The lower values occurred when hydrogen gas bubbles were partially blocking the top port holes in each cell, and the higher values occurred when the holes were essentially free of gas.

Table I lists the *p*H values of each electrolyte at the end of a run. Electrolysis in those solutions initially free of Mg^{++} ions resulted in *p*H values of 11.0 ± 0.1 and granular precipitates. Is solutions to which mag-

Table II. Summary of electrolytic corrosion data

Electrolyte solution	Time of electrolysis (hr)	Maximum simulated parasitic current (mA)	Characteristics of insoluble precipitate
A	2.70	55	white, granular type
B	3.05	50	white, granular type
C	3.00	52	white, granular type
D	2.50	47	white, large flocculent agglomerates
E	2.35	47	white, large flocculent agglomerates
F	3.00	65	white, large flocculent agglomerates
G	3.00	50	white, large flocculent agglomerates
H	3.00	65	white, large flocculent agglomerates

nesium salts were added the resulting pH values were 9.4 ± 0.5 and the precipitates were flocculent. The pH values of these electrolytes agree with the results obtained by J. L. Robinson and P. F. King (7) and H. A. Robinson (8) who studied the electrochemical behavior of magnesium anodes in aqueous environments. They found that the pH of aqueous salt electrolytes decreases as the Mg^{++} ion concentration increases. However, they did not report the type of $Mg(OH)_2$ formed in these electrolytes.

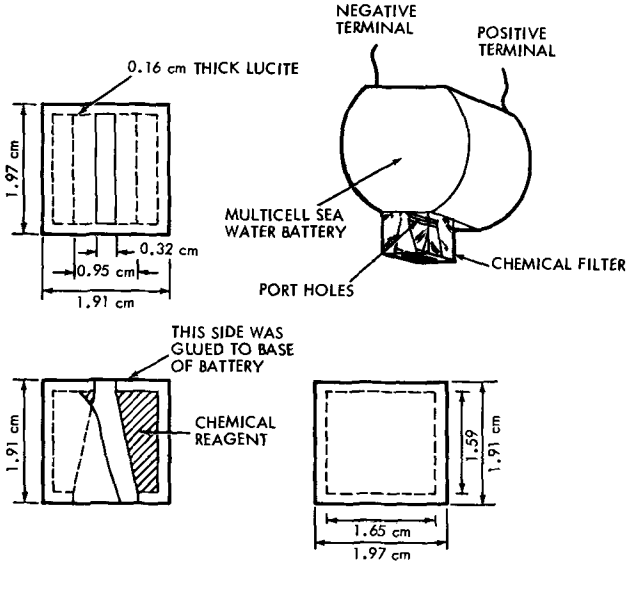
Control of $Mg(OH)_2$ Formation

The first approach that was investigated was the use of a chemical filter that would remove the Mg^{++} ions from the electrolyte entering the battery by precipitation in a nonflocculent form. Thallous fluoride (TlF), a white powdery compound that exhibits appreciable aqueous solubility (9), was used as the filter material. In aqueous solution, Mg^{++} ions may react with TlF according to the following reaction

$$Mg^{++} + 2TlF \rightarrow MgF_2 + 2Tl^{+} \quad [1]$$

and form MgF_2, a granular precipitate. Experiments were conducted in which a TlF filter was used during the low rate discharge of the 10 cell AgCl/Mg batteries in seawater. The filters used in these experiments were large enough to encompass the bottom inlet ports of the five cells nearest the negative terminal of the battery which was where the flocculent precipitate had previously formed. The filter was fabricated by compressing the TlF powder into the configuration shown in Fig. 4, and gluing the formed block into a four-sided Lucite case. Hence, the seawater electrolyte came in direct contact with the TlF before entering the five most negative cells. When batteries containing the TlF filter were discharged in Gulf Stream seawater, the capacity was about 15 per cent more than the controls which had no filter, and the amount of flocculent $Mg(OH)_2$ formed during discharge was reduced. Figure 5 shows typical voltage-time curves of AgCl/Mg seawater batteries discharged with and without the TlF filter.

A second approach was the use of a chemical filter that would remove the Mg^{++} ions from the electrolyte entering the battery by the formation of a soluble magnesium complex. Disodium ethylenediaminetetraacetate (disodium EDTA), a white crystalline compound that is moderately soluble in water, was used as the filter material. Disodium EDTA occurs with two molecules of water of hydration and is represented by the formula $Na_2H_2Y \cdot 2H_2O$. In aqueous



NOTE: SCALE 1:2

Fig. 4. Configuration of chemical filter

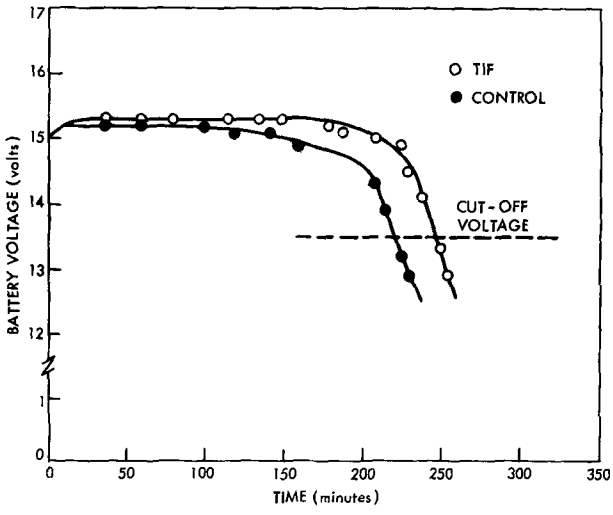


Fig. 5. The effect of a TlF filter on the capacity of a 10 cell AgCl/Mg seawater battery when discharged at a constant current of 150 mA.

solution $H_2Y^{=}$ is the complex forming ion and reacts with cations according to the following equation

$$Me^{+n} + H_2Y^{=} \rightleftharpoons MeY^{(n-4)} + 2H^{+} \quad [2]$$

where n ranges from 2 to 4 (10). One gram-ion of the complex forming ion reacts with one gram-ion of the metal without regard to its valence. The resulting complexes have the same composition but differ from one another in the charge they carry (10).

The complexes of the divalent metal ions (Me^{++}) occur as complex anions and are represented by the formula $MeY^{=}$. The stability of the complex is characterized by its formation constant (K). The larger the value of K, the greater the stability of the metal complex (11). In seawater there are two metal ions, calcium (Ca^{++}) and magnesium (Mg^{++}), that may form the $MeY^{=}$ complex. The formation constant of either complex, $CaY^{=}$ or $MgY^{=}$, is approximately of the same magnitude so that both complexes can occur (11).

Experiments were conducted in which disodium EDTA filters were used during the low rate discharge of 10 cell AgCl/Mg batteries in seawater. The filters used in these experiments were similar in design to the TlF filter shown in Fig. 4. However, since disodium EDTA is not compressible, the loose salt was placed within a Lucite case and sealed in with a Dynel-Webril paper of 0.00254 cm thickness. In aqueuos solution the resulting complex forming ions, $H_2Y^{=}$, were free to migrate through the thin paper and react with the Mg^{++} ions in the electrolyte prior to entering the five most negative cells. When batteries containing the disodium EDTA filter were discharged in Gulf Stream

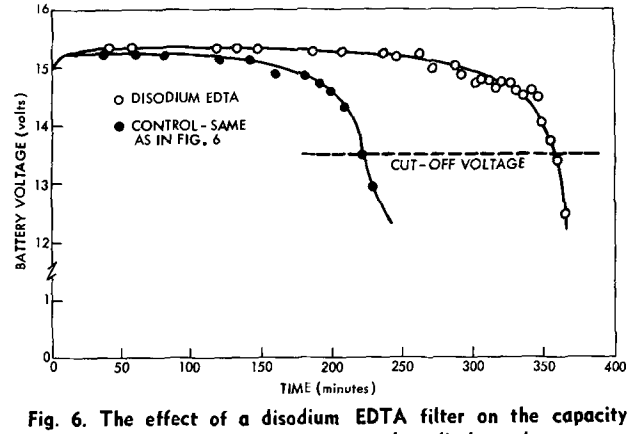

Fig. 6. The effect of a disodium EDTA filter on the capacity of a 10 cell AgCl/Mg seawater battery when discharged at a constant current of 150 mA.

seawater, the capacity was about 50% more than the controls which had no filter and the amount of flocculent $Mg(OH)_2$ formed during discharge was negligible. Figure 6 shows typical voltage-time curves of AgCl/Mg seawater batteries discharged with and without the disodium EDTA filter.

The results of these experiments demonstrate that the formation of flocculent $Mg(OH)_2$ during discharge of low rate AgCl/Mg seawater batteries can be controlled by using a filter. When disodium EDTA is used as the filter medium, the capacity of these batteries is significantly increased.

Acknowledgments

The authors wish to express their gratitude to Dr. G. Atkinson for his helpful suggestions and discussions throughout this study.

Oxide Films on Beta-Silicon Carbide

R. W. Bartlett*

Stanford Research Institute, Menlo Park, California 94025

Motzfeldt (1) has correlated the rate data of four investigators for oxidation of hexagonal α-silicon carbide (2-5) in dry oxygen and compared the results with Norton's data (6) for oxygen permeation of silica. He also correlated parabolic rate data for the dry oxidation of silicon (7-12). With one exception the results of these investigators are remarkably consistent. The absolute values of the parabolic rate constant for oxidation of silicon and α-silicon carbide agree within 1% at 1200°C and the activation energies agree within experimental error. It should be noted that the oxidation rate for both silicon and α-silicon carbide are for the formation of an amorphous silicon dioxide film. Jorgensen *et al.* (4) found that in the range of 1100° to 1300°C, there was a transition in the parabolic oxidation rate constant for α-silicon carbide after an initial oxidation period. This increase in oxidation rate was associated with a transition from an amorphous silica film to cristobalite and suggests that it is preferable to oxidize silicon carbide below 1100°C to avoid formation of a devitrified oxide film. They also found that water vapor promoted devitrification and accelerated the oxidation rate (13), as it does for silicon.

Growth of Insulating Oxide Films

The present note is concerned with oxide films on solution grown single crystals of cubic β-silicon carbide (14). The crystals used, which were platelets with a dominant {111} face, were cleaned in hydrofluoric acid, and rinsed in alcohol just prior to oxidation.

Several β-silicon carbide crystals were oxidized in dry oxygen or steam, both at 1 atm, to provide specimens for evaluation of the oxide films. Oxidation temperatures near 1000°C were used in conjunction with variable oxidation periods to obtain specimens with oxide film thicknesses from 500Å to over 3000Å. A polished silicon wafer was oxidized with each run and its oxide film thickness was determined to confirm the oxidation conditions.

The thicknesses of oxide films on transparent β-silicon carbide crystals were determined in two ways. The step height formed by etching part of the oxide film was measured with an interferometric microscope. This procedure required evaporating a thin reflecting film since silicon carbide is transparent. Interpretation was complicated by growth steps in the silicon carbide substrate surface, and the method was limited to thick oxide films. The oxide film thickness determinations for silicon carbide (dry oxidation) also agreed with the results of interferometric oxide film thickness measurements on the corresponding silicon monitor wafers. This was expected because of the identical oxidation rates for silicon and α-silicon carbide. In the most convenient technique, the oxide film thickness on silicon carbide was determined from a measurement of the oxide capacitance using the dielectric constant for silica, $k_o = 3.9$. This method was verified by comparing results with similar results obtained by the interferometric method on identical samples. Application was limited to insulating oxide films.

A few thermogravimetric oxidation rate experiments were made on β-silicon carbide platelets in dry oxygen at 0.2 atm and temperatures from 990° to 1220°C. Oxide film thickness is proportional to weight gain. During the first hour of oxidation weight increases were usually greater than predicted from the parabolic rate data (quasi steady state diffusion limited) for oxidation of silicon while the subsequent weight gain conformed with the parabolic oxidation rate of silicon. Evidently variable amounts of oxide are produced in the initial stages before a protective oxide (diffusion limiting) film is formed.

Several isolated aluminum field plates with dimensions of 10 mils by 10 mils were evaporated on each oxidized crystal. A 90% Au-10% Ta alloy fused on one end of each crystal made an ohmic contact with the silicon carbide crystal. The oxide films were tested for dielectric breakdown up to 50V using a point probe on the alloy contacts and a 4-mil-diameter gold spherical probe on the field plates. A Boonton 75C capacitance/conduction bridge with 0.001 μohm resolution was used.

The oxide films grown in dry oxygen were either sufficiently insulating to prevent measurable current flow or they exhibited negligible resistances. None of the oxide films resulting from the steam oxidation

* Electrochemical Society Active Member.
Key words: β-silicon carbide, oxidation, MOS structures.

Table I. Insulating properties of oxide films grown on β-silicon carbide crystals in dry oxygen at 1 atm

Oxidizing temperature (°C)	Oxidizing time (min)	Oxide thickness (Å)	Field plates shorted at 50 V
985	2790	7000	None
985	1030	3400	None
1000	795	3100	5%
980	275	1400	15%

were insulating. Some of the steam grown films were quite thick, equivalent to 24,000Å on a silicon monitor. Over 90% of the oxide films produced by the dry oxidation experiments and summarized in Table I were insulating if the thickness was 1400Å or greater. The measured oxide film thickness agreed with the thicknesses predicted from the parabolic oxidation kinetics. The yield of insulating 10 mil square films decreased for thinner oxide films and with a 500Å equivalent parabolic oxidation treatment, none of the oxide films tested were insulating.

Typical replica electron micrographs of the {111} surface of a crystal before and after dry oxidation are shown in Fig. 1. Growth steps in the crystal are replicated in the oxide surface. Although the texture of the oxidized surface is very similar to the unoxidized surface, there are more small pits, typically 500Å and all less than 1000Å in diameter, on the oxidized surface. It appears from these and other micrographs that lack of adequate oxide growth may cause dielectric breakdown of the oxide film at these depressions and at growth steps; however, it was not possible to differentiate between inadequate oxide growth and stronger adhesion of the replica film at growth steps.

Capacitance-Voltage Measurements

The metal-oxide-semiconductor structures (MOS) made of oxidized β-silicon carbide with evaporated 10 mil platinum field plates were tested by measuring the a-c capacitance at 100 kHz with a superimposed d-c bias voltage on the field plate, V_G, which was varied from +50V to −50V. The β-silicon carbide crystals were n-type. The reproducibility in capacitance change with d-c bias for three different field plates on the same crystal with an oxide film thickness of 1400Å is shown in Fig. 2. The variation in capacitance expressed as the ratio of measured capacitance under bias over the measured oxide film capacitance is plotted against the d-c bias.

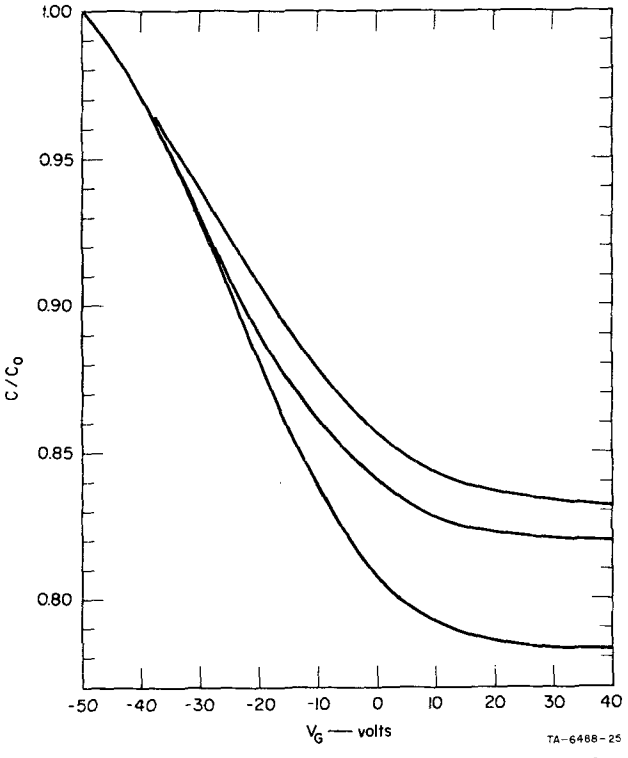

Fig. 2. Capacitance vs. gate voltage for MOS structure with n-type β-silicon carbide, $X_0 = 1400$Å.

The amount of variation in capacitance increases with decreasing carrier concentration in the underlying semiconductor and decreasing thickness of the oxide film. For the 1400Å oxide film shown in Fig. 2, the change in capacitance was greater than 20%. At a film thickness of 3000Å the change in capacitance was only 5%.

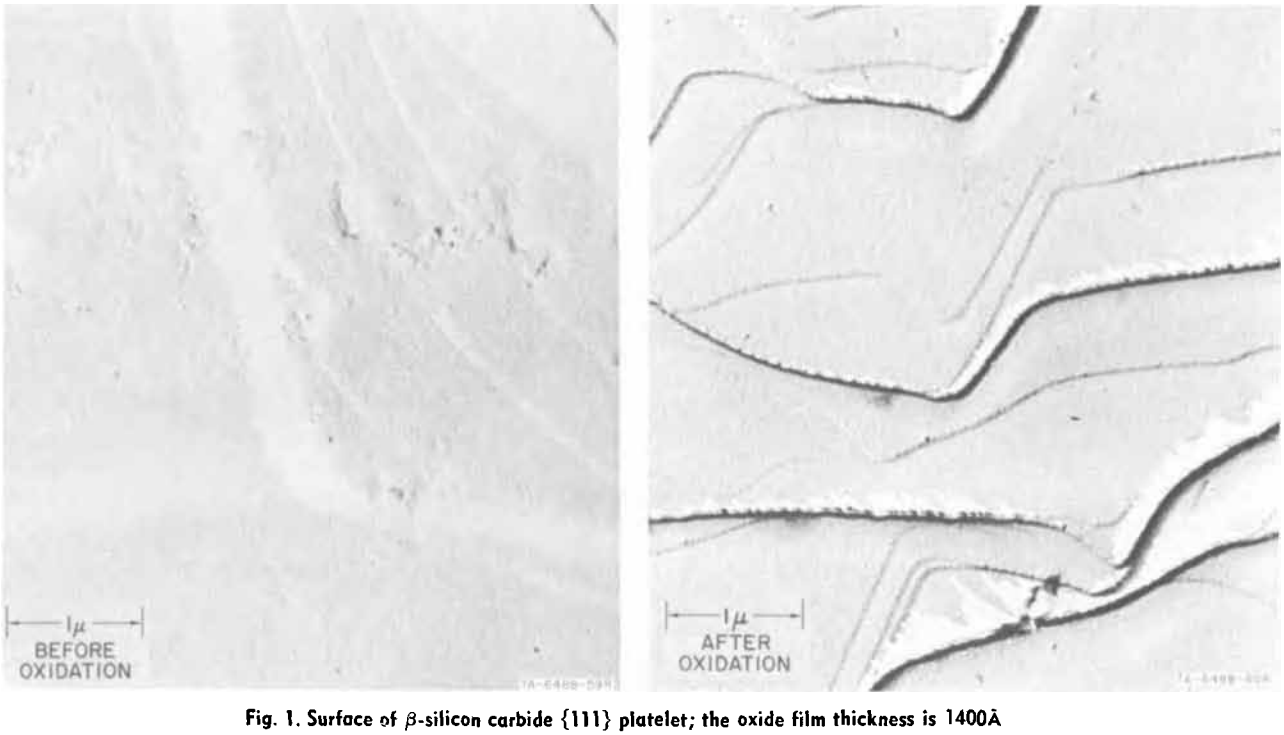

Fig. 1. Surface of β-silicon carbide {111} platelet; the oxide film thickness is 1400Å

The change in capacitance with applied d-c bias for an MOS structure has been discussed in several papers on thermally oxidized silicon surfaces. The paper by Grove *et al.* (15) gives a detailed description of the theory of an MOS structure. The variation in unit area capacitance, C, depends on the space charge within the semiconductor, since the total capacitance of both the oxide film and the underlying semiconductor space charge capacitance are being measured

$$C = \frac{1}{1/C_o + 1/(C_s + C_{ss})} \qquad [1]$$

where C_o is the oxide capacitance per unit area, C_s is the semiconductor capacitance per unit area, and C_{ss} denotes the capacitance per unit area of the surface states. Assuming that the surface state charge is constant, the surface state capacitance is zero and the capacitance of the MOS structure is

$$C = \frac{1}{1/C_o + 1/C_s} \qquad [2]$$

Calculating the space charge in the semiconductor is an involved process. For an MOS structure, the variation in energy bands and charge distribution in the semiconductor with distance in a direction normal to the semiconductor-oxide interface will depend on the d-c gate voltages, electric charge in the surface states, and the work function difference between the metal gate and semiconductor. However, for a given MOS specimen, only the gate voltage can be varied.

Biasing the gate voltage to deplete majority carriers in the semiconductor from near the oxide/semiconductor interface, without a sufficient field to accumulate minority carriers, will leave a space charge region of uncompensated acceptor or donor ions in the depletion region.

The effective width of the depletion region, X_d, can be defined from the charge distribution under a unit area of the semiconductor

$$Q_s = Q_p + q(N_D - N_A)X_d \qquad \text{(n-type)} \qquad [3]$$

where $(N_D - N_A)$ is the net donor concentration, Q_s is the total charge induced within the semiconductor, and Q_p is the charge associated with electron holes.

Plots of Q_s *vs.* Q_p for various $(N_D - N_A)$ have been calculated for silicon by integrating Poisson's equation with an appropriate Boltzmann relation for charge carrier concentration (15). Equation [3] can then be used to determine X_d as a function of Q_s and $(N_D - N_A)$. Similar curves have not been calculated for silicon carbide. Nevertheless, it was of interest to calculate the depletion mode semiconductor capacitance for undoped n-type solution grown β-silicon carbide crystals, using the maximum values of X_d as a function of $(N_D - N_A)$ determined for silicon

$$C_s = k_s\epsilon_o/X_d \qquad [4]$$

The following equation results when Eq. [4] and a similar equation for the oxide capacitance are substituted in Eq. [2]

$$C/C_o = [1 + (k_o/k_s)(X_d/X_o)]^{-1} \qquad [5]$$

where k_o is the oxide dielectric constant, X_o is the oxide thickness, and k_s is the silicon carbide dielectric constant. The dielectric constants are $k_o = 3.9$ and $k_s = 10.0$. The resulting values of $(N_D - N_A)$ *vs.* C/C_o for various oxide film thicknesses, X_o, on β-silicon carbide are plotted in Fig. 3.

These curves can be used to estimate net donor concentrations in the crystal. For example, the minimum capacitance values in Fig. 2, $C/C_o = 0.78$-0.82, measured with a 1400Å oxide film, indicate a net donor concentration of 1 x 10^{17} to 2 x 10^{17} cm^{-3}. The minimum C/C_o data measured for several β-silicon carbide MOS structures with oxide film thicknesses from 1400Å to 3400Å were analyzed using Fig. 3 to determine the net donor concentrations. In all cases the results indicated that $(N_D - N_A)$ was in the range 10^{17} to 10^{18} cm^{-3}.

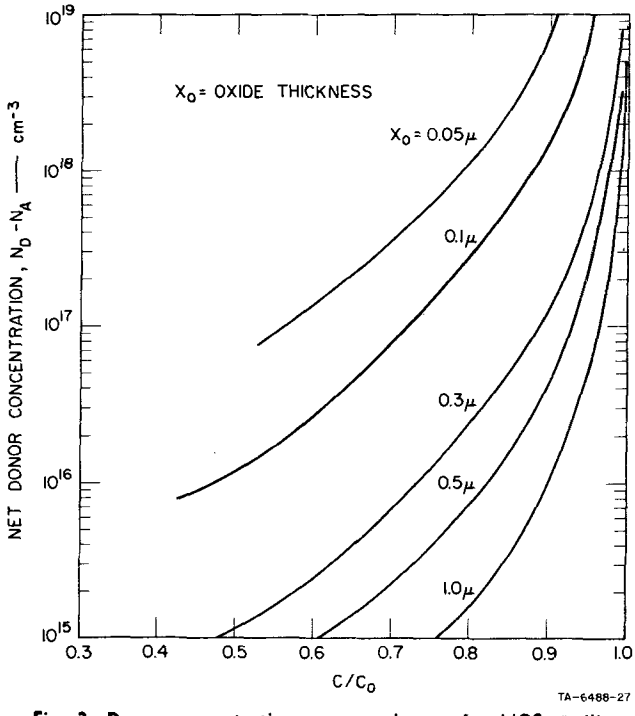

Fig. 3. Donor concentration vs. capacitance for MOS β-silicon carbide structures.

These results are in good agreement with net donor determinations from Hall measurements made on β-silicon carbide crystals grown in the same apparatus under identical conditions (14).

Although charge depletion near the surface of β-silicon carbide in MOS structures has been demonstrated, thinner insulating films than those grown by thermal oxidation, without leading to dielectric breakdown, are required before MOS devices can be developed using β-silicon carbide.

Electrodeposition of Boron

A. J. G. Maroto and J. Merlo Flores

Gerencia de Energia, Comisión Nacional de Energia Atómica, Buenos Aires, Argentina

A procedure has been developed to produce B^{10} deposits on aluminum disks used in ionization chambers. The method works equally well on Cu, brass, and stainless steel substrates.

The B^{10} is deposited from a colloidal suspension in anhydrous isopropyl alcohol which contains approximately 0.3 mg/ml of boron (1 μm particles) and 23 ppm of $MgCl_2$. A relatively high electric field of 900 V/cm is used (in our case the electrode spacing was 2 mm). The deposit should be well dried before handling.

The value of the electric field required was obtained by applying the model of E. J. Verwey and J. T. Oberbeek (1).

Figure 1 shows the percentage of deposited boron on an aluminum disk as a function of the deposition time.

Compared with the method described by Lange *et al.* (2), this method has the following advantages: (*a*) anhydrous conditions are not required, (*b*) the suspension is easier to prepare and is more stable, (c) no stirring is needed during deposition, (*d*) there is no need to cool the suspension.

In our case the deposit is cathodic in fluorine; in the Lange method it is anodic.

Procedure

1. Finely grind the boron in an agate mortar and mix with a small amount of anhydrous isopropyl alcohol.
2. Add $MgCl_2$, preferably in an anhydrous methanol solution.

Key words: electrodeposition, boron.

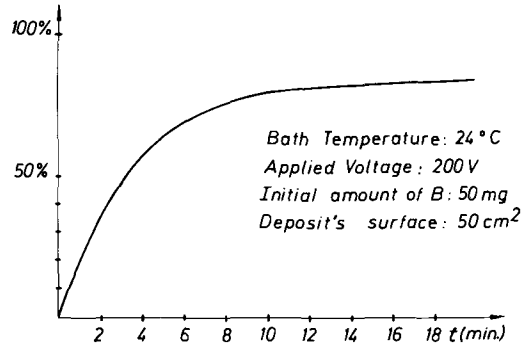

Fig. 1. Percentage of deposited boron on an aluminum disk as a function of deposition time.

3. Transfer the mixture to the electrodeposition cell containing the rest of the needed amount of isopropyl alcohol.
4. Stir thoroughly before commencing electrodeposition.

Manuscript received Sept. 8, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Brief Communications

Formation of Electrolytic Rutile Film Containing Barium

M. Yamazaki and H. Nozaki

Institute of Industrial Science, University of Tokyo, Tokyo, Japan

Thin insulating films of controlled thickness may be formed on a number of metals including aluminium, titanium, tantalum, zirconium, *etc.*, by anodization of the metal in a suitable electrolyte (1, 2), and anodic oxide films formed in this way have been widely used in electrolytic capacitors. It would be of interest in connection with electrolytic capacitors if the high dielectric constant material $BaTiO_3$ could be produced on titanium by anodization. In the present work we formed oxide films on titanium by applying either d-c or a-c current to a titanium electrode in an aqueous solution of barium hydroxide. It was found that the oxide film contained barium only when alternating current was used.

Key words: electrolytic capacitors, dielectrics, thin films.

The electrodes (1 x 20 x 40 mm) were prepared from Kobe Seiko Company KS-50 titanium (H_2, <0.01%; O_2, <0.20%; N_2, <0.05%; Fe, <0.20%). The surface of the electrodes was first treated in 16 weight per cent H_2SO_4 solution at 25°C, using alternating current (50 Hz) at 50 mA/cm² for 2 hr. Then, the oxide films were formed on the surface of the electrodes in two methods as follows.

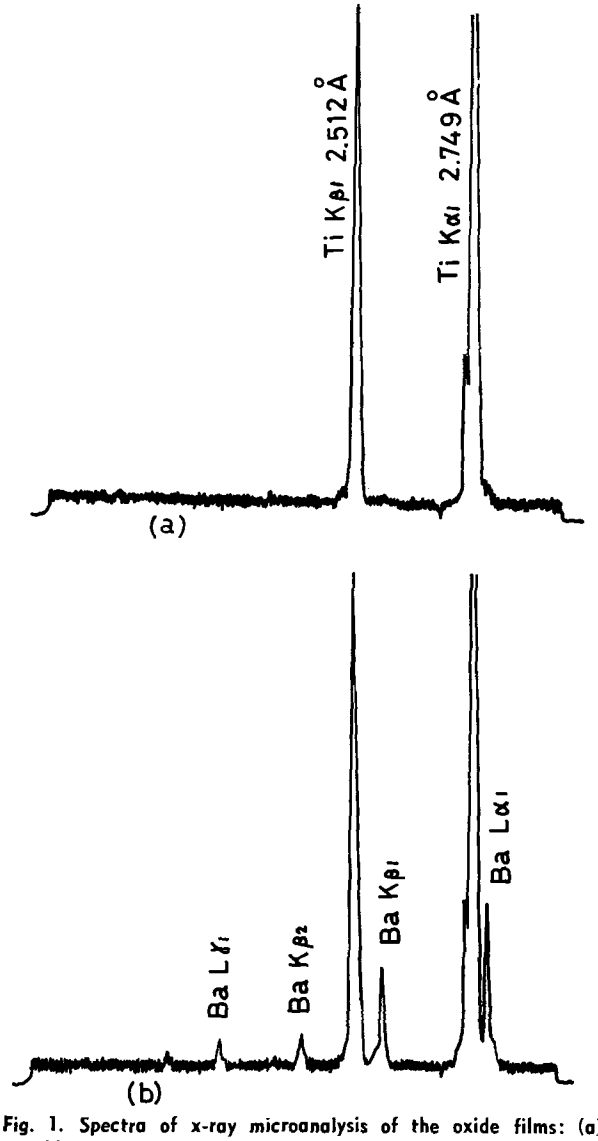

Fig. 1. Spectra of x-ray microanalysis of the oxide films: (a) oxide film formed by anodic current; (b) oxide film formed by alternating current.

(*A*) The electrode was anodized with direct current in a saturated solution of barium hydroxide for 1 hr at 25°C, at 5 mA/cm^2.

(*B*) The electrode was electrolyzed by applying alternating current (50 Hz) with the same solution first for 1 hr at 40 mA/cm^2 and next for ½ hr at 70 mA/cm^2. The procedure of electrolyzing with two levels of current density was useful in increasing the film thickness.

The films obtained were examined by x-ray microanalysis and by electron diffraction analysis. The surface of the oxide films was observed with an electron microscope.

X-ray microanalysis (Fig. 1) showed barium to be present only in the a-c film. Electron diffraction indicated that the d-c film contained anatase, while the a-c film contained rutile. According to the electron microscope both films were polycrystalline.

Capacitor-like Ti-oxide-Au samples were fabricated by the vacuum evaporation of gold onto the oxide films through a mask with slits of 5 x 5 mm^2. Then the capacitance of the samples was measured at room temperature with a bridge (Yokokawa Electric Work Company Model 4255 A). Film thicknesses were estimated from the capacitance of the samples as 0.5 ~ 1.0μ for the d-c film and 1.5 ~ 2.5μ for the a-c film. In these estimations, a value of 40 was used for the dielectric constant of the d-c film (3) and a value of 100 was used for the a-c film. It is reasonable to use 100 for the value of dielectric constant of the a-c film, since a small amount of barium in rutile hardly affects its dielectric constant (4).

Ethylene Diamine-Pyrocatechol-Water Mixture Shows Etching Anomaly in Boron-Doped Silicon

A. Bohg

IBM Laboratories, Boeblingen, Germany

Recently Greenwood (1) reported that the ethylene diamine-pyrocatechol-water etch described by Finne and Klein (2) etches only n-type silicon in samples containing p-n junctions. We found no preferential etching of p-n junctions, but an abrupt change in the etch rate with concentration for boron-doped silicon.

Finne and Klein had already studied the influence of boron doping on the etch rates for <100> silicon and found a constant etch rate of 50 μm/hr for the resistivity range between 10^{-1} and 10^2 ohm-cm, corresponding to boron concentrations from $2 \cdot 10^{14}$ cm^{-3} to $5 \cdot 10^{17}$ cm^3.

To study the influence of boron concentration above $5 \cdot 10^{17}$ cm^{-3}, a 1° bevel of a <100> sample was etched for 10 min. A glass refluxing system was used, with N_2 bubbling through the boiling solution (110°C). No drying tubes were used, as the etch times never extended over 10 min. The etch solution consisted of 17 ml ethylene diamine, 8 ml water, and 3g pyrocatechol. The boron concentration in the sample decreased with depth, the surface concentration being $5 \cdot 10^{20}$ cm^{-3}. The sample contained a background As doping of about 10^{17} cm^{-3}. The p-n junction was 7.7 μm under the surface.

The 10 min etch resulted in a sharp step on the bevel, as shown in Fig. 1. From the known concentration profile and the distance of the step on the bevel from the unattacked silicon surface, the critical concentration of electrically active boron atoms in silicon was estimated

Key words: semiconductor technology, preferential etching, boron doping.

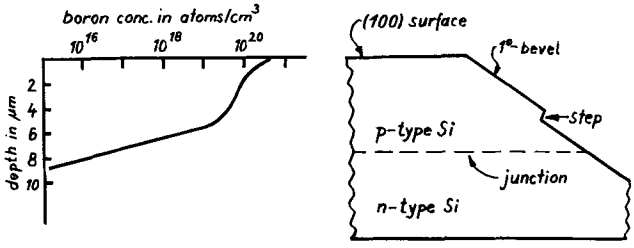

Fig. 1. Cross section of etched sample with correspondng boron concentration profile.

to about $7 \cdot 10^{19}$ cm^{-3}, corresponding to a resistivity of $1.7 \cdot 10^{-3}$ ohm-cm.

Silicon with a higher boron concentration remained completely unattacked. On the other hand, we could not find any influence of the junction itself on the etch rate. In the above example, the etching stopped at a depth of 4.8 μm, almost 3 μm above the junction.

With this result, Greenwood's observations can be easily explained. In his sample, the maximum boron concentration was above the critical value of $7 \cdot 10^{19}$ cm^{-3}. The etching occurred from the n-type side of the sample, etched away the junction region, and stopped within the p-type layer at the critical concentration level.

Electrochemical Preparation of Stannous Sulfate Using Periodically Reversed Direct Current

Chung-Chiun Liu* and Richard E. Horn

Chemical and Petroleum Engineering Department, University of Pittsburgh, Pittsburgh, Pennsylvania 15213

Stannous sulfate can be prepared by direct dissolution of metallic tin in sulfuric acid. However, tin dissolves only slowly in sulfuric acid, and the use of either excess acid or heat is not effective. The use of a periodically reversed direct current (1) has been employed in an electrolytic process to prevent or greatly retard the cathodic reaction. This method might be used to promote the rapid dissolution of a metal in the suitable electrolyte (2). This communication reports the experimental studies of the electrochemical preparation of stannous sulfate using periodically reversed direct current.

Solid-state circuitry was developed in this laboratory to operate a reversing relay which permitted applying alternate polarities to the cell over a frequency range from 0.5 to 120 sec/cycle. The circuitry to accomplish this is shown in block diagram form in Fig. 1.

The experimental assembly is conventional. The experimental cell used was a 600 ml Pyrex beaker, and 500 ml of electrolyte were used each time. Two strengths of sulfuric acid were used as electrolyte, namely 1*N* and 3*N* in concentration. The tin electrodes were made of grade A straits tin (Thisarco Brand) of 99.98+% purity. Tin was first melted and cast into bars which had a width of 0.635 cm, a length of 12.7 cm, and a thickness of 0.635 cm. The cast tin bars were then used as the electrodes and were submerged in the electrolyte to a depth of 7.62 cm, and the electrodes were placed approximately 7 cm apart in each run.

The operation temperature was set at 333° ± 1°K and remained at that value throughout the experiment. Constant stirring of the electrolyte was provided. The tin concentration in the electrolyte was analyzed using an atomic absorption spectrometer (Perkin-Elmer Corporation Model 290). Throughout this study, the current supplied was maintained at 3A. Thus, the current density employed was 0.155 A/cm^2. It should be noted that the potential supplied to the cell was not measured.

The dissolution rate was considered insignificant during the period of placing the electrodes in the electrolyte when no current was passed. The tin concentration in the electrolyte was considered zero initially. As time proceeded, samples were removed periodically from the electrolyte and analyzed for tin by the atomic absorption spectrophotometer.

The first set of experimental runs utilized 1*N* sulfuric acid. However, in 1*N* sulfuric acid, the reprecipitation of undesirable SnO_2 indicated that sulfuric acid of higher concentration should be used to inhibit the hydrolysis of stannous sulfate.

For the 3*N* sulfuric acid electrolyte, seven different intervals of time for the periodically reversed current were employed in this study, varying from 0.5 to 120 sec/cycle. At each cyclic time, the current was supplied for a period up to 60 min or more. Within this period of time, it was found that the dissolution of tin in the electrolyte became saturated throughout our experimental conditions. The experimental results are presented in Fig. 2 which is self-explanatory. Under the experimental conditions investigated, the best yield of stannous sulfate occurs at 11 sec/cycle. It was estimated that approximately a 3% saturated solution was achieved and was considerably better than a direct dissolution of tin in sulfuric acid.

Experimental results show the formation of stannous sulfate increases as the interval of time of the periodically reversed current changes from 0.5 to 11 sec/cycle and decreases as the interval of time changes from 11 to 120 sec/cycle. Qualitatively, it can be explained as follows.

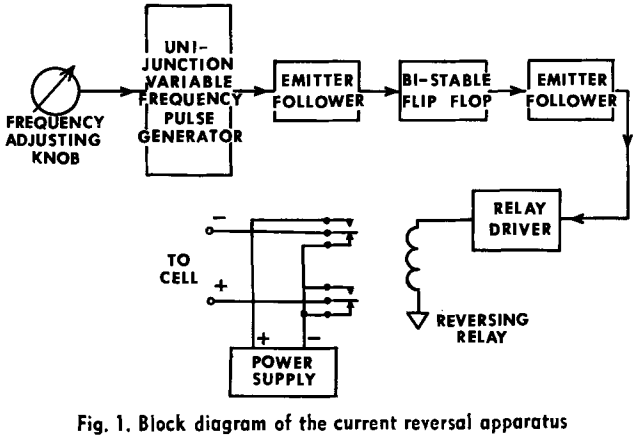

Fig. 1. Block diagram of the current reversal apparatus

* Electrochemical Society Active Member.

Key words: tin, a-c electrolysis, mass transport.

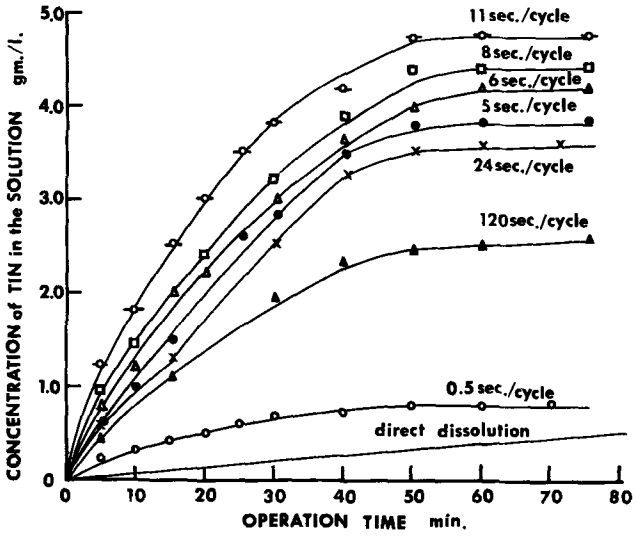

Fig. 2. Experimental results of preparation of $SnSO_4$ using periodically reversed direct current at 333°K.

At a value of 0.5 sec/cycle, the short time interval between cycles does not permit sufficient stannous ions to migrate from the tin electrode and dissolve in the electrolyte. On the other hand, at a longer interval of time of 24 or 120 sec/cycle, stannous ions plate on the cathode over this time interval similar to a d-c electroplating process. Thus, the optimum value of the time interval for the periodically reversed current would be the one which is long enough to permit sufficient stannous ions to migrate into the electrolyte but not long enough to allow the ions to be plated out. However, quantitative interpretation has not been made here.

Electrochemical Behavior of the Aluminum Electrode in Molten Salt Electrolytes

Betty S. Del Duca

Lewis Research Center, National Aeronautics and Space Administration, Cleveland, Ohio 44135

ABSTRACT

The kinetics for dissolution and deposition of solid aluminum in molten $AlCl_3$·NaCl and $AlCl_3$-$(LiCl\text{-}KCl)_{eut}$ electrolytes were studied by means of galvanostatic and potentiostatic techniques over a temperature range of 175°-313°C. The apparent exchange current densities varied from 1 to 56 mA/cm². Surface diffusion was found to be the rate-determining step at low overpotentials, and charge transfer the rate-determining step at high overpotentials. The most probable anodic rate-determining step was found to be $Al \rightarrow Al^+ + e^-$; the most probable cathodic rate-determining step was $Al^{+++} + e^- \rightarrow Al^{++}$ in $AlCl_3$-$(LiCl\text{-}KCl)_{eut}$ electrolyte and $Al^{++} + e^- \rightarrow Al^+$ in $AlCl_3$·NaCl electrolyte. Current efficiencies for dissolution were close to 100%.

For high-energy-density, rechargeable anodes, aluminum appears to be a promising choice for several reasons. It has low equivalent weight, is readily available and inexpensive, and exhibits a high potential. Its use in aqueous systems is hampered by passivity in most electrolytes or by corrosion in nonpassivating electrolytes. Zaromb (1) has discussed its application in aqueous primary and chemically rechargeable cells. Aluminum can be electrodeposited from nonaqueous organic solutions (2) and from molten salts (3). Molten-salt systems appear promising for three main reasons: (*i*) aluminum can be deposited from the electrolyte, (*ii*) the alkali halide-aluminum chloride mixtures have relatively low melting temperatures, and (*iii*) these melts have electrical conductivities in the range of 0.1-0.2 ohm^{-1} cm^{-1} (4), which is one to two orders of magnitude higher than those of the typical organic electrolytes.

The aluminum-cryolite system has been studied extensively (3, 5, 6), but the melting point of this electrolyte is greater than 725°C, which is unattractive for battery applications. Laitinen and Liu (7) have measured the potential of aluminum electrodes in the lithium chloride-potassium chloride (LiCl-KCl) eutectic relative to the Pt/Pt^{++} reference electrode. Piontelli and Sternheim (8) studied the current-potential behavior of aluminum electrodes in $AlCl_3$-NaCl at 200°C and found the charge transfer polarization to be negligible for both the anodic and cathodic reactions. More recently, King, Brown, and Frayer (9) found no measurable charge transfer or diffusion polarization at current densities as high as 1-2 A/cm² in 40 m/o (mole per cent) NaCl-60 m/o $AlCl_3$. Giner and Holleck (10) studied the electrochemical behavior of aluminum anodes in 67% $AlCl_3$-13.6% KCl-19.4% NaCl and 59% $AlCl_3$-17% KCl-24% NaCl at 157° and 105°C. "Passivation" was observed and was attributed to the partial freezing of the electrolyte at the electrode surface.

Key words: aluminum anode, molten chloride electrolytes.

In the present work, current-potential curves, current efficiencies, and the nature of the cathodic deposit were examined. The polarization measurements were carried out on solid aluminum electrodes using transient and steady-state galvanostatic and potentiostatic techniques. Tafel plots were constructed and interpreted in terms of the rate-determining steps for the anodic dissolution and cathodic deposition reaction. The electrolytes studied were mixtures of aluminum chloride with alkali halides melting between 110° and 160°C.

Experimental Procedure

Instrumentation.—Galvanostatic measurements.— Galvanostatic techniques were used to determine the ohmic (IR) drop of the solution and electrodes in the conventional manner (Fig. 1) and to obtain transient overpotential time data (Fig. 2). A potentiostat with a rise time specification of 1-3 μsec (±60V ±300 mA) was used to apply steady anodic and cathodic currents to the electrode. (Rise times of less than 10 μsec were

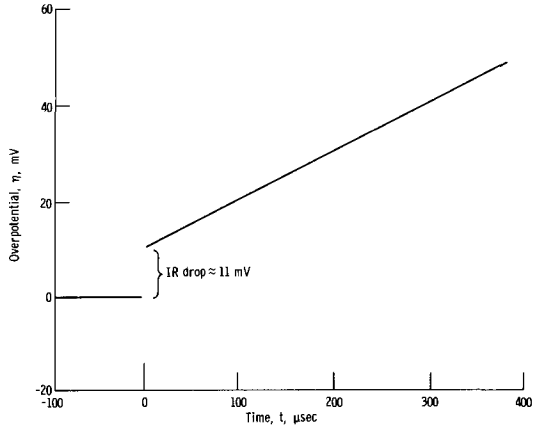

Fig. 1. Overpotential-time transient. Aluminum anode in 50 m/o $AlCl_3$-50 m/o NaCl; current density, 40 mA/cm².

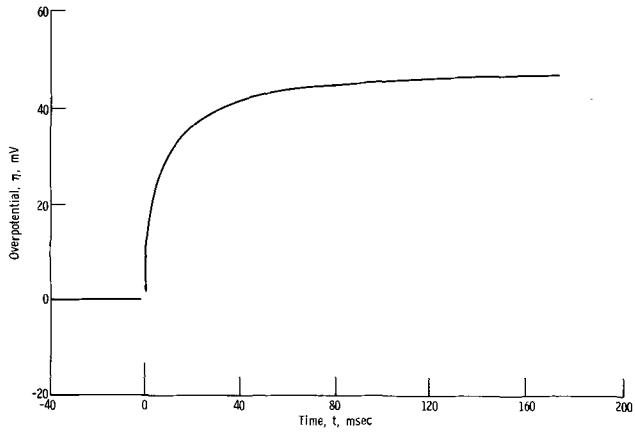

Fig. 2. Transient overpotential-time data. Aluminum anode in 50 m/o $AlCl_3$-50 m/o NaCl; current density, 9.1 mA/cm^2.

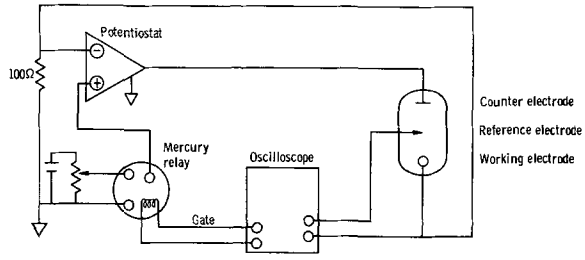

Fig. 3. Block diagram of circuit for galvanostatic measurements

obtained with this circuit applied to aqueous Cu/Cu^{++} system, indicating that the performance of the instrumentation is acceptable.) The block diagram is shown in Fig. 3. The control amplifier inputs (+, −) and output should be identified with the potentiostat terminals: "control potential," "reference electrode," and "counterelectrode," respectively. A mercury-relay pulse generator of conventional design supplied a potential pulse of selected length and magnitude to the control circuit of the potentiostat. This, in turn, controlled the potential across a precision resistor of 100 ohms, thereby establishing a constant current through the cell. The pulse was triggered by the gate output of a Tektronix 535A oscilloscope. The potential transients were displayed on the oscilloscope with a Type D differential amplifier and photographed (see Fig. 1 and 2 for typical traces).

Potentiostatic measurements.—Steady-state current-potential relations were determined by potentiostatically controlling the overpotential and observing the current on the potentiostat milliammeter after a time of approximately 30 sec. This time was chosen for two reasons: (*i*) at all potentials applied, the current density had reached a steady value within this time period; and (*ii*) it was relatively short so that very little electrolysis took place, thus minimizing electrode surface changes. It should be noted that the current density was not affected by concentration gradients since vigorous stirring (> 100 rpm) had no effect on the magnitude of the current density, and that the 30-sec, or steady, current density was only slightly higher than that observed in oscillographic traces recorded over a 10-sec time interval. All potentials were corrected for the IR drop determined from the galvanostatic transient. This correction for uncompensated resistance never exceeded 5% of the potential.

Electrochemical cell.—The cell used to obtain the electrochemical data is shown in Fig. 4. Forty-mil wires of 99.99% aluminum were washed with reagent-grade acetone to remove grease and were then mechanically connected to tungsten rods to form working, counter, and reference electrodes. Aluminum wire was used as a reference for the galvanostatic and potentiostatic measurements. This gives an open-circuit voltage of zero, and the applied or resultant voltage is thus the overpotential on the working electrode.

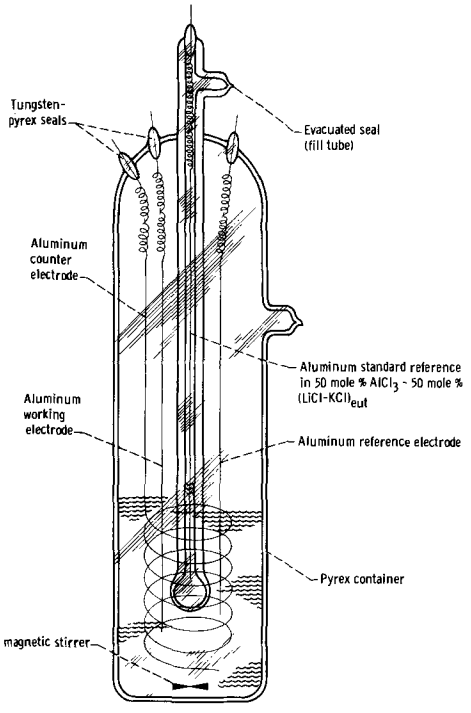

Fig. 4. Electrochemical cell

Equilibrium potentials of the aluminum anode in the various electrolytes were measured relative to a "standard" reference electrode of aluminum wire in $AlCl_3 \cdot (LiCl\text{-}KCl)_{eut}$. The reference electrode was made by sealing a piece of 8-mm Pyrex tubing so as to leave a micro-opening at the bottom.

The cell temperature was controlled within ±5°C by means of a thermostated oil bath. A magnetic stirrer was used to agitate the electrolyte when this was desired.

At the conclusion of the electrochemical experiments, all the melts were analyzed for metals by emission spectrographic methods. In all cases, compositions were within ±5% of the values listed in Table I.

Preparation of melts.—The lithium chloride-potassium chloride eutectic (41 m/o LiCl-59 m/o KCl), hereinafter referred to as $(LiCl\text{-}KCl)_{eut}$, and mixtures of $AlCl_3$ in the eutectic were obtained from Anderson Physics Laboratories in evacuated sealed vials. The former was certified as having a residual current not larger than 1.6 μA at 2V and 410°C. The $AlCl_3$-NaCl mixtures were prepared at this laboratory from reagent-grade chemicals which were dried at 110°C.

All samples containing $AlCl_3$ even though specified as "high purity" were found to be contaminated with organic materials which pyrolyzed on heating. The techniques used for purification varied depending on the concentration of aluminum chloride in the melt.

Equimolar mixtures [$AlCl_3 \cdot NaCl$, $AlCl_3 \cdot (LiCl\text{-}KCl)_{eut}$].—Melts in which $AlCl_3$ and alkali chloride were present in equal amounts had low vapor pressures (<1 Torr at 500°C). The organic impurities were removed by thermal decomposition. The mixture was heated in Pyrex tubes under flowing nitrogen. Vigorous bubbling began at 520°C and continued for one to several hours. When bubbling ceased, a clear straw-colored melt was obtained with a black carbon residue. The yellow coloration was attributed to the presence of small amounts of an oxychloride (private communication from Anderson Physics Laboratories, Inc.) and was removed by introducing an aluminum wire into the melt. A black precipitate formed on the wire and the melt became water-white. Presumably the oxychloride reacts with metallic aluminum to form

soluble aluminum chloride and insoluble aluminum oxide. The yellow coloration could be recreated by bubbling (undried) oxygen into the purified melt and could be removed again by the aluminum treatment. Other investigators have reported a yellow coloration due to iron impurities which were removed by sublimation (11) or by treatment with metallic aluminum (12). No iron was detected by spectrographic analysis (sensitivity, 0.03 ppm) of the melts used in the present work.

After purification, the clear melt was transferred under inert conditions to a dry, heated electrochemical cell, which was evacuated to 1 Torr and sealed off.

Mixtures containing more than 50 m/o $AlCl_3$.—It was not possible to thermally decompose organic material present in these solutions because of the high partial vapor pressure of aluminum chloride over the melts. The organic material and oxychloride were removed by heating at 250°C in the presence of metallic aluminum for several days. The organics slowly distilled into cold traps in an adjacent sidearm. A second sidearm was kept heated and used to transfer the purified melt into the attached electrochemical cell by tipping the apparatus. The melt was allowed to freeze, and the cell was sealed under reduced pressure.

Mixtures containing less than 50 m/o $AlCl_3$.—Three methods were used in an attempt to prepare melts of less than 50 m/o $AlCl_3$ in LiCl-KCl eutectic (13). All resulted in the formation of a multiphase system which was unaffected by heating to 550°C.

Preliminary experiments.—Experimental conditions considered initially included (*i*) the influence of the atmosphere within the cell (inert gas or vacuum) and (*ii*) the magnitude of changes in the measured polarization curves with time. With respect to the former, vacuum-sealed cells and cells open to an excess pressure of dry nitrogen gas gave identical results. With respect to the latter, marked effects were observed. This is shown in Fig. 5, where the log of current density i against overpotential η is plotted for an electrode held at constant temperature and tested at various times up to 48 hr. The observed changes, no doubt, partly reflect roughening of the electrode surface. Since it is difficult to evaluate and correct for this kind of change, only freshly prepared cells were used for each series of runs reported, and the time period over which data were recorded never exceeded 3 hr from the time of filling the cell.

Experimental variables considered.—Table I lists the compositions of the electrolytes used and the temperatures and current density ranges over which measurements were made. All current densities are based on the apparent geometrical area of the electrode.

Results and Discussion

Transient results.—In this work, rise times to the steady state were observed which were in excess of 10 sec at low current densities. This is much longer

	313	

than the 150 μsec rise-time calculated by the equation of Mehl and Bockris (14). The rise time was observed to decrease with increasing current densities. Figure 2 illustrates the potential rise for the first 180 msec at a current density of 9.1 mA/cm² in $AlCl_3$·NaCl electrolyte. The potential-time data are shown in Fig. 1 for times up to 375 μsec at a current density of 40 mA/cm². A linear relation is obtained for times which are longer than normally expected. A capacitance C calculated from the slope $\partial\eta/\partial t$ and current i in the equation

$$C = \frac{i}{\left(\frac{\partial\eta}{\partial t}\right)_{t\to 0}} = \frac{0.040 \times 10^{-3}}{0.104} = 385\ \mu\text{F/cm}^2 \quad [1a]$$

is too large to be a double-layer capacitance and is therefore apparently an adsorption capacitance. The surface diffusion model described by Bockris and Damjanovic (15) allows the concentration of adsorbed species C_o to be estimated, using this potential-time data at low potentials, by means of the equations

$$C_o = \frac{RT}{n^2\mathbf{F}^2} \frac{i}{\left(\frac{\partial\eta}{\partial t}\right)_{t\to 0}} \quad [1b]$$

$$C_o = \frac{RT}{n^2\mathbf{F}^2} C \quad [1c]$$

Equations [1b] and [1c] are derived by assuming (*i*) a small coverage of the surface by adions and (*ii*) a potential smaller than $RT/\alpha n\mathbf{F}$. Table II lists the concentration of adions calculated for the aluminum anode in 50 m/o $AlCl_3$-50 m/o NaCl at 220°C at various current densities. The average value is $(0.17 \pm 0.03) \times 10^{-10}$ moles/cm², which is the same order of magnitude as that reported for gallium in aqueous solution (16). Mehl and Bockris (17) report C_o values of 4×10^{-10} moles/cm² for silver in aqueous solution, and Reddy (18) reports $C_o = 9 \times 10^{-10}$ mole/cm² for silver in molten $(LiCl\text{-}KCl)_{eut}$.

An adion concentration of 0.18×10^{-10} moles/cm² corresponds to a surface coverage of only 0.001 if the radius of the adion is assumed to be the crystal radius of trivalent aluminum [0.5×10^{-8} cm (19)].

Table II. Concentration of adions, surface diffusion rate, and exchange current density as calculated from surface diffusion rate for aluminum anode in $AlCl_3$·NaCl at 220°C

Current density, i, mA/cm²	Concentration of adions, C_o, moles/cm²	Surface diffusion rate, $n\mathbf{F}v_o$, mA/cm²	Calculated exchange current, $i_{o,calc}$, mA/cm²
6.5	0.15×10^{-10}	3.7	1.52
8.5	0.16	3.2	1.48
12.0	0.15	3.7	1.72
25.5	0.20	5.5	2.46
40.0	0.19	5.7	2.66
Average	$0.17 \pm 0.03 \times 10^{-10}$	4.3 ± 1.4	1.97 ± 0.47

The diffusion rate of adions on the surface $n\mathbf{F}v_o$ may be obtained provided the time dependence of overpotential as it approaches the steady state is measured experimentally. The appropriate equation (15) is

$$n\mathbf{F}v_o = -\frac{d\ln(\eta_\infty - \eta)}{dt} n\mathbf{F}C_o \qquad [2]$$

Values of η_∞ were obtained potentiostatically and are discussed further under Steady-state results. Table II summarizes values of the surface diffusion rates obtained for aluminum anodes in $AlCl_3$·NaCl at 220°C. As expected from the long rise times observed, the diffusion rates which average 0.0043 A/cm² are slower than those reported for silver either in aqueous solution [0.015 A/cm², (16)] or molten salts [3.3 A/cm², (18)]. They are, however, larger than the value reported for the dissolution of gallium in aqueous solution at the same current density [0.0003 A/cm², (16)].

In their monograph, Bockris and Razumney (20) indicate that the surface diffusion rate and the steady-state overpotential may be used to calculate an exchange current $i_{o,calc}$ which generally agrees with experimental exchange currents obtained from Tafel plots to within ±30%. Values of $i_{o,calc}$ obtained from the equation

$$\eta_\infty = -\left(\frac{RT}{n\mathbf{F}}\frac{i}{i_{o,calc}} + \frac{RT}{n^2\mathbf{F}^2}\frac{i}{v_o}\right) \qquad [3]$$

at various current densities i are also summarized in Table II. The average value is 1.97 mA/cm², which agrees well with the experimental value of 1.88 mA/cm² obtained from a Tafel plot.

All transient data discussed so far were taken in the 0 to 250-μsec time period. Similar analyses of data in the 0 to 20-msec range gave smaller values for $i_{o,calc}$.

It appears then that the nonsteady-state data for aluminum at low current densities (so that $\eta < RT/\alpha n\mathbf{F}$) fit reasonably well into the surface diffusion model described by Bockris and co-workers. Aluminum in $AlCl_3$·NaCl melts appears to be quite similar to solid gallium in alkaline aqueous solutions as far as the surface diffusion parameters are concerned.

Bockris and Razumney (20) conclude that probably all metals undergo deposition and dissolution at planar sites on the surface with subsequent diffusion along the surface to other sites. This is based on calculations of the heats of activation for transfer of silver ions to different kinds of sites on the surface: that is, planar surface, edge, kink, vacancy in an edge, and vacancy in a surface. The rate constant for transfer to a planar site is 10^6 times greater than to any other type of site. The rate-controlling process then becomes the diffusion on the surface either to or from this planar site. These same authors point out that there is a transition from surface diffusion control to another rate-controlling mechanism, such as charge transfer at higher current densities or overpotentials, and that a limiting current due to the surface diffusion occurs at still higher overpotentials.

Steady-state results.—Figure 6 is typical of the Tafel plots constructed from steady-state measurements. This particular plot is for aluminum in a 75 m/o $AlCl_3$-25 m/o $(LiCl\text{-}KCl)_{eut}$ mixture at 235°C. A region of linearity is observed for both the anodic and cathodic branch extending from 80 mV on the anodic side and 170 mV on the cathodic side.

The deviations from linearity are attributed partly to normal deviations from Tafel behavior caused by the increased importance of the back reaction at low overpotentials and partly by the surface diffusion effects already discussed. Since deviations from straight-line behavior resulting from the back reaction usually occur around 60 mV, the existence of surface diffusion effects might well not be evident from inspection at a Tafel plot such as Fig. 6.

No evidence of a limiting current density is found at potentials as high as ±350 mV. In one experiment,

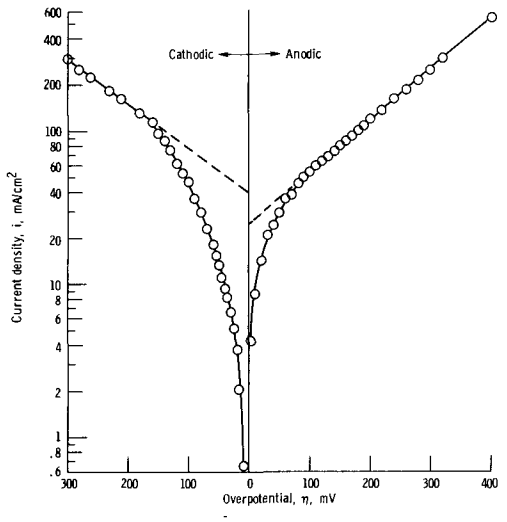

Fig. 6. Tafel plot for aluminum in 75 m/o $AlCl_3$-25 m/o $(LiCl\cdot KCl)_{eut}$. Temperature, 235°C (508°K).

however, the potential was increased to several volts in the anodic direction. An apparent limiting current density of about 1 A/cm² was observed, the value of which did not oscillate with time or vary with the rate of stirring. This suggests a limiting current density not caused by mass transport in the molten salt (23) but perhaps caused by chemical reaction or surface diffusion phenomena (22). This result is not conclusive, however, as the surface undergoes rapid changes at these high current densities.

The Tafel slopes in Fig. 6 are $b_a = 2.3\ RT/0.29\mathbf{F}$ and $-b_c = 2.3\ RT/0.29\mathbf{F}$, for the anodic and cathodic reactions, respectively. The respective exchange current densities are 26 and 39 mA/cm².

Results for the other temperatures and electrolytes studied are summarized in Table III. The standard deviations obtained for the exchange current densities and

Table IV. Calculated Tafel slopes

Mechanism	Rate determining step (RDS)	Tafel slope	
		Anodic, b_a	Cathodic, $-b_c$
I, II	$Al^0 \rightarrow Al^+ + e^-$	$\frac{2.3\,RT}{\beta F}$	$\frac{2.3\,RT}{(3-\beta)F}$
I	$Al^+ \rightarrow Al^{+2} + e^-$	$\frac{2.3\,RT}{(\beta+1)F}$	$\frac{2.3\,RT}{(2-\beta)F}$
I, III	$Al^{+2} \rightarrow Al^{+3} + e^-$	$\frac{2.3\,RT}{(\beta+2)F}$	$\frac{2.3\,RT}{(1-\beta)F}$
III	$Al^0 \rightarrow Al^{+2} + 2e^-$	$\frac{2.3\,RT}{2\beta F}$	$\frac{2.3\,RT}{(3-2\beta)F}$
IV	$Al^0 \rightarrow Al^{+3} + 3e^-$	$\frac{2.3\,RT}{3\beta F}$	$\frac{2.3\,RT}{3(1-\beta)F}$
II	$Al^+ \rightarrow Al^{+3} + 2e^-$	$\frac{2.3\,RT}{(2\beta+1)F}$	$\frac{2.3\,RT}{2(1-\beta)F}$

Tafel slopes were less than ±10% in most cases. While the uncertainty within one set of data was usually ±2 to ±3%, the reproducibility of one fresh cell to another varied as much as ±10%.

Note that the anodic exchange current densities in Table III range from a value of 1.3 mA/cm² for the 50 m/o $AlCl_3$-50 m/o NaCl electrolyte at 175°C to a value of 56 mA/cm² for the 75 m/o $AlCl_3$-25 m/o (LiCl-KCl)$_{eut}$ electrolyte at 265°C. For all $AlCl_3$-(LiCl-KCl)$_{eut}$ mixtures, the anodic and cathodic Tafel slopes are similar and vary with composition from about 2.3 $RT/0.25F$ to 2.3 $RT/0.5F$. In contrast, for the $AlCl_3$·NaCl electrolyte, the anodic slope is comparable to the others, but the cathodic slope is about a factor of 5 smaller.

The activation energies from a plot of log i_o against $1/T$ (Fig. 7) for both the anodic and cathodic processes in the $AlCl_3$·NaCl electrolyte are 7.3 ± 1.0 and 5.3 ± 0.6 kcal/mole, respectively. These lie a little below the values of about 10 kcal/mole usually encountered (18).

In order to determine which processes are rate determining at high overpotentials (*i.e.*, Tafel region), it is necessary to calculate Tafel slopes for various postulated sets of reactions and compare them with experiment. Fraser and Barradas (24) have described a simple method for carrying out these calculations.

The mechanism chosen for analysis consisted of consecutive steps and did not consider the possibility of parallel processes. They are as follows, written for the anodic process

$$\text{I} \quad Al^0 \rightarrow Al^+ + 1e^- \rightarrow Al^{+2} + 1e^- \rightarrow Al^{+3} + 1e^- \quad [5]$$

$$\text{II} \quad Al^0 \rightarrow Al^+ + 1e^- \rightarrow Al^{+3} + 2e^- \quad [6]$$

$$\text{III} \quad Al^0 \rightarrow Al^{+2} + 2e^- \rightarrow Al^{+3} + 1e^- \quad [7]$$

$$\text{IV} \quad Al^0 \rightarrow Al^{+3} + 3e^- \quad [8]$$

For the cathodic process the reactions are reversed. The use of simple bare-ion symbolism does not imply the absence of ligand coordination with Cl^- for example.

The calculated Tafel slopes for various rate-determining steps are presented in Table IV. By comparing these expressions for the Tafel slopes with the experimental values in Table III, it is possible to select the most probable rate-determining steps consistent with the data (Table V).

Table V. Most probable rate-determining steps for charge-transfer reaction

Electrolyte, m/o	Anodic rate-determining step	Anodic true transfer coefficient, β	Cathodic rate-determining step	Cathodic true transfer coefficient, β
50 $AlCl_3$-50 LiCl · KCl	$Al^0 \rightarrow Al^+ + e^-$	0.31	[a]	[a]
67 $AlCl_3$-33 LiCl · KCl	$Al^0 \rightarrow Al^+ + e^-$	0.59	$Al^{+++} + e^- \rightarrow Al^{++}$	0.60
75 $AlCl_3$-25 LiCl · KCl	$Al^0 \rightarrow Al^+ + e^-$	0.29	$Al^{+++} + e^- \rightarrow Al^{++}$	0.71
50 $AlCl_3$-50 NaCl	$Al^0 \rightarrow Al^+ + e^-$	0.20	$Al^{++} + e^- \rightarrow Al^+$	0.75

[a] No analysis performed.

For the anodic reaction in all electrolytes, the most probable rate-determining step is the one-electron transfer constituting the first step in mechanisms I or II

$$Al \rightarrow Al^{+} + 1e^{-}$$

For this step, reasonable values of the true transfer coefficient β from 0.20 to 0.59 (Table V) are obtained. The variation of β with composition should be noted. This implies structural changes, possibly, as the concentration of $AlCl_3$ is changed relative to the concentration and nature of the cations. Similar effects have been noted by Morrey (25, 26) in spectroscopic studies in these media.

For the cathodic reaction in the $AlCl_3$-$(LiCl\text{-}KCl)_{eut}$ mixtures, the most probable rate-determining step is

$$Al^{+++} + 1e^{-} \rightarrow Al^{++}$$

with true transfer coefficients β of 0.60 and 0.71. All other possibilities give values for β which are very close to 1 or larger. The cathodic reaction in the $AlCl_3$·NaCl electrolyte clearly has a different rate-determining step than for the other solutions. Four possible rate-determining steps which give reasonable values for β are

$$Al^{++} + 1e^{-} \rightarrow Al^{+} \qquad \beta = 0.75$$

$$Al^{++} + 2e^{-} \rightarrow Al^{0} \qquad \beta = 0.90$$

$$Al^{+++} + 2e^{-} \rightarrow Al^{+} \qquad \beta = 0.375$$

$$Al^{+++} + 3e^{-} \rightarrow Al^{0} \qquad \beta = 0.583$$

The first of these reactions is proposed as the most probable rate-determining step since the activation energy for a multi-electron transfer is very high (> 100 kcal/mole) and therefore improbable (20). It should be noted, though, that above 650°C in fluoride melts, a three-electron transfer has been observed (27). The most probable rate-determining steps and the corresponding values for β are presented in Table V.

That the rate-determining step for the cathodic reaction in the $AlCl_3$-$(LiCl\text{-}KCl)_{eut}$ melts is different from that in the AlCl·NaCl melt is not surprising in view of recent Raman results on the structure of the $AlCl_4^-$ complex ion in $AlCl_3$·KCl and $AlCl_3$·NaCl melts (28). A regular tetrahedral symmetry T_d is found in the Na^+-containing melts, while a distorted tetrahedral (C_{2v}) symmetry is found in the K^+-containing melts. These structural differences could influence the relative rates of the steps in the reduction reaction.

In closing this discussion of the most probable rate-determining steps, it should be mentioned that a recent paper by Rangarajan (29) has criticized the analysis of Bockris and co-workers used in the present work. Very briefly, Rangarajan concludes that in cases where surface diffusion is rate limiting at low overpotentials, the Tafel slope at higher overpotentials is equal to twice the "true" slope (for charge transfer) and the observed exchange current is larger than the true exchange current. The present results are not adequate to settle this theoretical dispute. In the present work, the Bockris treatment of surface diffusion has been employed since there is some evidence in the literature which experimentally supports it. Rangarajan's approach would lead to

$$Al^{+} + e^{-} \rightarrow Al^{0}$$

as the most probable rate-determining step for the cathodic reaction in $AlCl_3$·NaCl electrolyte. Both anodic and cathodic reactions in $AlCl_3$ $(LiCl\cdot KCl)_{eut}$ and the anodic reaction in $AlCl_3$·NaCl electrolyte remain the same as predicted by the Bockris treatment.

In addition, Rangarajan's treatment does not predict a limiting anodic current which was observed in at least one electrolyte in this study and has been observed by others for gallium (16). The Bockris approach predicts such a limiting current.

Table VI. Anodic and cathodic efficiencies of Al in LiCl·NaCl

Anodic		Cathodic	
Current density, mA/cm²	Efficiency, %	Current density, mA/cm²	Efficiency, %
0.3	100 ± 1	0.1	>83
0.5	98 ± 2	0.5	>62

Current efficiencies.—Current efficiencies determined for aluminum anodes and cathodes in the AlCl·NaCl melt by passing a known number of coulombs and measuring the weight loss of the anode and the weight gain of the cathode are summarized in Table VI. The cathode efficiency could not be determined accurately because of the loss of some material during the repeated washings which were necessary to remove all traces of electrolyte from the electrode. While the apparent inefficiency of the cathode is not considered to be real, it should be noted that these are preliminary results and further study is indicated.

Photographs at an enlargement of X14 were taken of both an anode and a cathode after electrolysis. The smooth surface of the anode with visible grain boundaries may be seen in Fig. 8a. The crystallites of aluminum deposited on the cathode are seen in Fig. 8b. These crystallites greatly increase the surface area. While some crystallites were mechanically removed during vigorous washing procedures, the deposit appears to adhere well enough to the surface that it would not create a problem in secondary cell applications. Very high current densities (10 A/cm²) do produce a dendritic deposit and would not be suitable for use in a cell unless measures were taken to prevent such growth.

Conclusions

Aluminum appears to show promise of being a suitable negative electrode for a secondary battery when charged and discharged in alkali chloride-aluminum chloride molten salts at temperatures less than 250°C. The apparent exchange current densities for discharge (dissolution) vary from about 2 to over 20 mA/cm² as the concentration of $AlCl_3$ in the KCl-LiCl eutectic is increased from 50 to 75 m/o. The apparent exchange current densities for charging (deposition) vary from about 10 to 40 mA/cm² over the same range of composition.

On the basis of an analysis of steady-state and transient overpotential data using the theoretical framework of Bockris *et al.*, the following rate-determining steps for the anodic and cathodic reactions in the various electrolytes can be proposed:

1. At low overpotentials, less than 70 mV anodic and 170 mV cathodic, the rate-determining step is the diffusion of adions on the metal surface. The concentration of adions was found to be 0.2 x 10^{-10} moles/

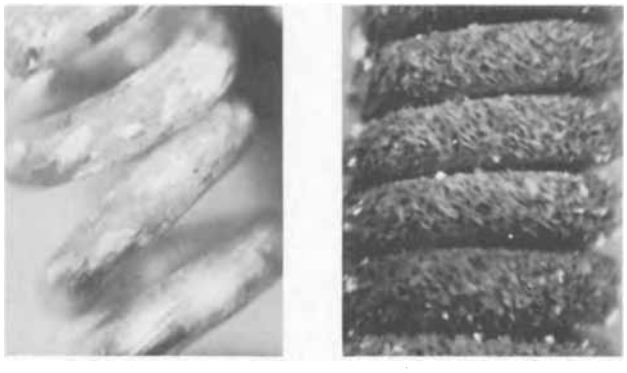

Fig. 8. Nature of electrode surface. X14. a (left) Anode, electrolyzed at 0.3 mA/cm². b (left) Cathode, electrolyzed at 0.1 mA/cm².

cm^2 and the surface diffusion velocity 0.0043 A/cm^2 in $AlCl_3$·NaCl melts.

2. At higher overpotentials the rate-determining steps are charge transfer. In the anodic reaction, for all electrolytes, the most probable rate-determining step is $Al \rightarrow Al^+ + e^-$. For the cathodic reaction, the most probable rate-determining step is $Al^{+++} + e^- \rightarrow Al^{++}$ in the $AlCl_3$-(KCl-LiCl) eutectic mixtures and $Al^{++} + e^- \rightarrow Al^+$ in the $AlCl_3$·NaCl melts. These conclusions about the charge-transfer steps cannot be considered unambiguous as they are deduced from a consideration of Tafel data and are based on the assumption that the true transfer coefficient should be between 0.20 and 0.80 and that one-electron transfers are most probable.

Current efficiencies for dissolution were close to 100% at current densities up to 0.5 mA/cm^2. The measurements were inaccurate for deposition, but a strong adherent deposit was obtained at low current density. Dendrites were observed at current densities larger than 10 A/cm^2.

Acknowledgment

The author gratefully acknowledges the assistance of Dr. Jacob Greenberg who constructed the electrochemical cells and carried out the purification of all materials used in these experiments.

LIST OF SYMBOLS

a	Tafel slope, mV
C	double-layer capacitance, μF/cm^2
C_o	concentration of adions, moles/cm^2
F	faraday, 96,500 coulombs
i	current density (anodic+, cathodic−), mA/cm^2
i_o	apparent exchange current, mA/cm^2
n	number of electrons transferred in over-all reaction
$n\mathbf{F}v_o$	surface diffusion velocity, mA/cm^2
R	gas constant, 8.314 Vc/mole deg
T	temperature, °K
t	time, sec
v_o	surface diffusion flux, mole/(cm^2) (sec)
Z	number of electrons transferred in charge-exchange rate-determining step
α	anodic, cathodic apparent transfer coefficient
β	true transfer coefficient
η	overpotential (anodic +, cathodic −), mV
η_1	steady-state overpotential

Potential Measurements on a Si,SiO_2 Electrode Using a ThO_2-Y_2O_3 Electrolyte

F. J. Salzano,* H. S. Isaacs,* and B. Minushkin

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

A series of emf *vs.* temperature measurements were made on the cell

$$Si,SiO_2|ThO_2\text{-}15\ w/o\ Y_2O_3|Pt|ThO_2\text{-}15\ w/o\ Y_2O_3|Ni,NiO$$

in order to establish the ionic range of ThO_2-15 w/o Y_2O_3 (ThO_2-17 m/o $YO_{1.5}$) at very low oxygen activities. The use of platinum between the ThO_2-15 w/o Y_2O_3 disks extended the useful life of the cell. In the temperature range 600°-1000°C the emf falls progressively below the expected thermodynamic value with increasing temperature. These data were found to be reproducible in several different cell configurations. The apparent ionic transference number, t_i, at the Si,SiO_2 electrode is given by

$$t_i = \{1 + 6.64 \times 10^{13} P^{-1/4} \exp[-99{,}800/RT]\}^{-1}$$

where P is the partial pressure of oxygen, T is the absolute temperature, and R is the gas constant. The fall off in emf from the thermodynamic value is not predictable from measurements of the ionic range of ThO_2-Y_2O_3 reported by other workers. Some possible factors responsible for the fall off in emf from the thermodynamic value are discussed.

Solid anionic conducting oxide electrolytes have been used extensively to measure the thermodynamic properties of oxides and metal alloy systems (1-3). The properties of these electrolytes have been studied, but the results differ due to the presence of impurities in these ceramics, variations in experimental techniques, and the possibility of complicating electrode electrolyte interactions (4-7).

At present, high-temperature oxygen activity monitoring devices are being applied to industrial processes (8-10). In liquid sodium coolant systems it is necessary to monitor and control the chemical activity of oxygen in order to avoid excessive corrosion. A device has been developed to monitor continuously the chemical activity of oxygen in sodium coolant systems (8, 9). This device is based on the cell

$$Na(O)|ThO_2\text{-}15\ w/o\ Y_2O_3|^{oxygen}_{reference} \qquad (I)$$

where Na(O) represents sodium containing dissolved oxygen. The ThO_2-15 w/o Y_2O_3 (w/o, weight per cent) electrolyte in these cells is in the form of a closed end tube (test tube). The sensitivity and accuracy of the device depends on the value of the ionic transference number at the sodium electrode. The oxygen activity in these systems is as low as 10^{-50} atm at 400°C with respect to oxygen gas at 1 atm pressure and limits the usefulness of some solid electrolyte compositions. The present work was initiated to establish if the ionic transference number of ThO_2-15 w/o Y_2O_3 is unity at oxygen activities corresponding to those in liquid sodium.

The cell chosen for study was

$$Ni,NiO|ThO_2\text{-}15\ w/o\ Y_2O_3|Si,SiO_2 \qquad (II)$$

since the ionic transference number at the Ni, NiO electrode has been established to be unity (2, 4-6) and the oxygen activity of the Si, SiO_2 electrode is close to and slightly below the values found in practical sodium-oxygen systems (11). Furthermore, the thermodynamic properties of NiO and SiO_2 are known and ThO_2-15 w/o Y_2O_3 was found to be inert to the metal species of the electrodes even at 1100°C.

In preliminary experiments it was noted that the Ni, NiO electrode lost weight while the cell was operating. This is very likely due to transport of oxygen through the cell as a result of the electronic conductivity of the electrolyte (12). We believe that this transport process was affecting the stability and reproducibility of the cell as a result of the inability of Si, SiO_2 to consume or Ni, NiO to supply oxygen and maintain their respective equilibrium oxygen activities. Several techniques were tried which could partially block or otherwise alter the oxygen flux through the cell. The most successful technique utilized cells of the type

$$Ni,NiO|ThO_2\text{-}15\ w/o\ Y_2O_3|\chi|ThO_2\text{-}15\ w/o\ Y_2O_3|Si,SiO_2 \qquad (III)$$

where χ is a barrier placed between two ThO_2-15 w/o Y_2O_3 disks to reduce the oxygen flux through the cell. This cell had an additional advantage in that the ThO_2-15 w/o Y_2O_3 disk on the Si, SiO_2 side could be changed without changing the disk at the Ni, NiO reference electrode.

Theory

The useful range of a solid oxide electrolyte is determined by the onset of electron or positive hole conduction due to changes in stoichiometry.

At very low oxygen activities electronic conductivity may appear in a solid oxide electrolyte according to the reaction

$$O_l \rightarrow 1/2\ O_2(g) + V_{O=} + 2e' \qquad (a)$$

where O_l is an oxygen ion at a normal oxygen lattice site, $V_{O=}$ is a doubly ionized oxygen vacancy, and e' is an excess electron (6). These excess electrons lead to enhanced electronic conductivity in the electrolyte which decreases the ionic transference number, t_i, defined as the ratio of ionic conductivity to the sum of the total ionic and electronic conductivities.

If the electrolyte in an electrochemical cell exhibits significant electronic conductivity at either one or both electrodes, the ionic transference number is less than unity and is dependent on the chemical potential of oxygen at the electrode-electrolyte interface. The emf of the cell is lower than the thermodynamic value and is given by (4, 6)

$$E = -\frac{1}{4F}\int_{\mu_1}^{\mu_2} t_i(\mu)\, d\mu \qquad [1]$$

* Electrochemical Society Active Member.
Key words: Si, SiO_2 electrode; ThO_2-Y_2O_3 electrolyte; ionic domain of ThO_2-Y_2O_3; anionic conducting oxides.

where E is the emf, $t_i(\mu)$ is a function which expresses the ionic transference number at any value of μ; μ_1 and μ_2 are the chemical potentials of diatomic oxygen at the respective electrodes, and **F** is the Faraday constant. If the ionic transference number is unity, Eq. [1] reduces to the familiar expression

$$E_O = \frac{\mu_1 - \mu_2}{4F} \quad [2]$$

where E_O is the theoretical emf.

Based on a model described by Lasker and Rapp (6)

$$t_i(\mu) = (1 + KP^{-1/4})^{-1} \quad [3]$$

where P is the partial pressure of oxygen and is related to μ by the expression

$$P = \exp[(\mu - \mu^\circ)/RT] \quad [4]$$

where the reference state is oxygen at 1 atm pressure. K is given by

$$K = K_O \exp[E_a/RT] \quad [5]$$

where K_O and E_a are constants. K^4 is the oxygen partial pressure where the excess electronic and ionic conductivities are equal. It is equivalent to the parameter P_θ given by Schmalzried (13). Substituting Eq. [3] into [1], integrating, and assuming that t_i at μ_1 is unity, we obtain

$$E = E_O + \frac{RT}{F} \ln(1 + KP_2^{-1/4}) \quad [6]$$

where P_2 is the partial pressure of oxygen at the electrode (Si, SiO_2) where t_i is less than unity. Thus, from measurements of the emf *vs.* temperature behavior of a cell and the known thermodynamic properties of the electrodes we can calculate K_O and E_a and determine $t_i(\mu)$.

Experimental

Materials.—The ThO_2-15 w/o Y_2O_3 (ThO_2-17 mole per cent Y_2O_3) was in the form of ¾ in. OD by ⅛ in. disks and was purchased from the Zircoa Corporation, Solon, Ohio.

The Ni and NiO were standard reagent-grade material obtained from the J. T. Baker Chemical Co., Phillipsburg, New Jersey. The silicon metal powder was obtained from Alfa Inorganics, Beverly, Massachusetts. The SiO_2 was prepared by firing reagent-grade silicic acid ($SiO_2 \cdot xH_2O$) in air at 850°C.

Procedure.—In order to establish that the ionic transference number at the Ni, NiO electrode is unity as reported (6) and to test the apparatus, a series of emf *vs.* temperature measurements were made using ThO_2-15 w/o Y_2O_3 electrolyte and Ni, NiO and Cu, Cu_2O electrodes in the same apparatus. The results of these measurements were in agreement with the data reported for these electrodes using ZrO_2-CaO electrolytes in the temperature range 350°-850°C (1). This indicates that the ionic transference numbers of ThO_2-15 w/o Y_2O_3 for both Ni, NiO and Cu, Cu_2O electrodes is unity since ZrO_2-CaO is known to have a unity transference number at these oxygen partial pressures. This result is in agreement with data reported previously for various ThO_2-Y_2O_3 compositions at oxygen activities up to 1 atm (2, 4-6).

All of the cell configurations studied were in the form of stacks of disks having the general form

SS|Pt|Ni,NiO|ThO_2-15 w/o Y_2O_3|χ|ThO_2-15 w/o Y_2O_3|Si,SiO_2|SS (III)

where χ was either empty (disks in direct contact), 1 mil platinum foil or Al_2O_3, and SS represents the 304 stainless steel parts of the cell assembly.

The Ni, NiO electrodes were pressed disks ⅜ in. OD x ⅜ in. thick and contained 25 v/o nickel. These electrode disks were pressed in a 304 SS die at ≈5000 psig and sintered in vacuum (10^{-6} mm Hg) at 850°C for 4 hr. Before loading into a cell the surface of each disk was ground on medium fine emery paper using a figure-eight motion to assure a flat surface, and the loose powder was removed with a clean, coarse brush.

The Si, SiO_2 electrodes were prepared from two compositions: (*i*) a 50 v/o mixture of Si and SiO_2 powders and (*ii*) pure Si powder plus its normal surface oxide film. These electrode disks were ⅜ in. OD x ⅜ in. thick and were pressed in a 304 SS die at ≈1000 psig. Disks prepared from both compositions were fragile and had to be carefully handled until vacuum sintered at 950°C for a minimum of 4 hr. The ThO_2-15 w/o Y_2O_3 disks were also ground flat on medium fine emery paper and vacuum fired before assembly into a cell.

The cells studied were assembled on a 304 SS block which contained a ⅜ in. OD depression on top for the Ni, NiO reference electrode and a ⅛ in. OD 304 SS thermocouple sheath which was inserted in the bottom and which served to support the block. The stack of disks was held together with a 200g 304 SS weight which rested on top of the stack and contained a ⅜ in. OD depression for the Si, SiO_2 electrode. Each cell was enclosed in a quartz envelope, further enclosed by a 304 SS sheet metal electrical shield which was electrically connected to ground and to the Ni, NiO electrode. The voltage developed by the cell was measured with a high impedance electrometer (Cary Model-30CV) and a precision reference voltage source (General Resistance Model-DA45D), and the signal was continuously recorded.

Each cell was operated with a continuous purge of helium obtained from the boil off from a 50-liter liquid helium Dewar. No effort was made to isolate the electrodes from their common helium purge. The flow rate was controlled by means of a heat leak into the Dewar to give a flow rate ≈100 cm^3/min. The emf was independent of gas flow at rates from approximately 50 to 200 cm^3/min.

These cells were run for various periods ranging from several days to three weeks. The time to reach equilibrium varied from several hours at the high temperatures to one or two days at the lower temperatures.

Results

Emf *vs.* temperature data were obtained for the following cells

SS|Si,SiO_2|ThO_2-15 w/o Y_2O_3|Pt|ThO_2-15 w/o Y_2O_3|Ni,NiO|Pt|SS (IV)

SS|Si,SiO_2|ThO_2-15 w/o Y_2O_3|Al_2O_3|ThO_2-15 w/o Y_2O_3|Ni,NiO|Pt|SS (V)

SS|Pt|Si,SiO_2|ThO_2-15 w/o Y_2O_3|ThO_2-15 w/o Y_2O_3|Ni,NiO|Pt|SS (VI)

SS|Si,SiO_2|ThO_2-15 w/o Y_2O_3|Pt|ThO_2-15 w/o Y_2O_3|Ni,NiO|Pt|SS[1] (VII)

The data obtained from cell (IV) in the temperature range 600°-1000°C are shown in Fig. 1. The upper line is the thermodynamic value, *i.e.*, $t_i = 1$, and to a good approximation is independent of temperature (11). It is evident from Fig. 1 that at low temperatures the emf approaches the thermodynamic value and at temperatures above 700°C shows large deviations which are approximately linear to 900°C. The data from these cells did not show hysteresis, were reproducible at temperatures above 750°C, and showed little scatter. The data for temperatures below 750°C were difficult to reproduce and showed greater scatter, especially as the cells aged.

The emf *vs.* temperature data from cells (V), (VI), and (VII) are shown in Fig. 2. The data from cell IV are also shown in Fig. 2 for comparison.[1] All of the emf data from the cells studied, *i.e.*, (IV), (V), (VI), and (VII), show the same behavior with temperature

[1] All the Si, SiO_2 electrodes, with the exception of cell (VII), were prepared from mixture (*ii*), i.e., with pure silicon powder and its normal impurity oxygen without addition of SiO_2.

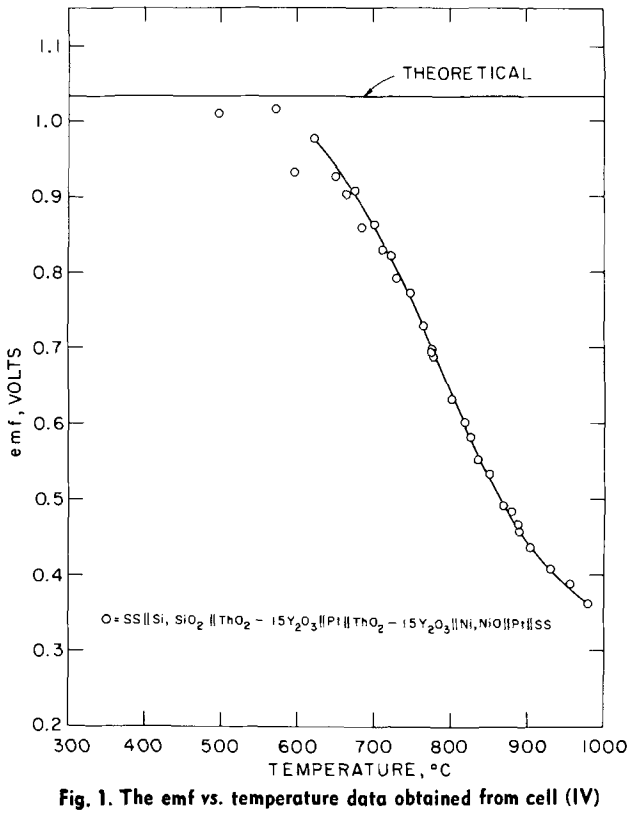

Fig. 1. The emf vs. temperature data obtained from cell (IV)

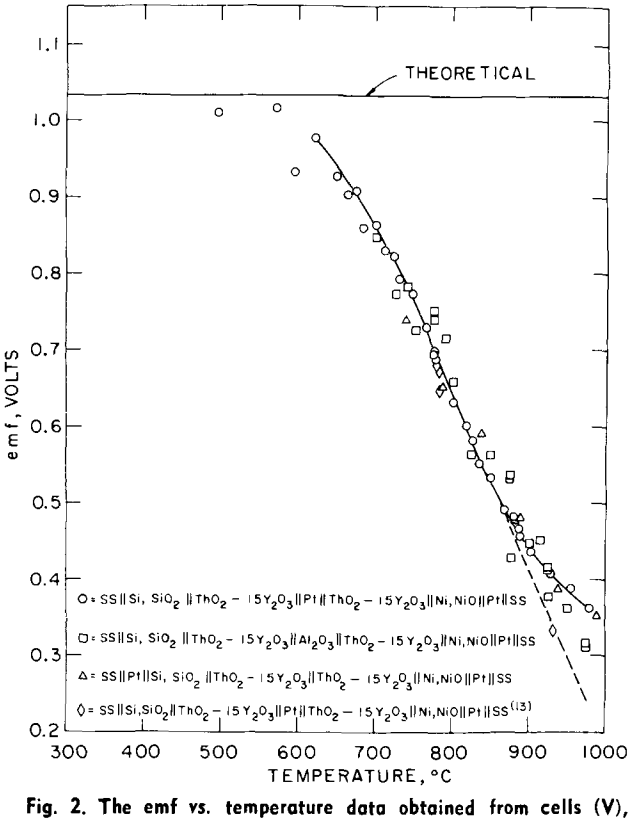

Fig. 2. The emf vs. temperature data obtained from cells (V), (VI), and (VIII).

and are in good agreement. The data from cells (V), (VI), and (VII) show more scatter than the data from cell (IV), but all the data fall uniformly around the average line drawn through the data from cell (IV).

Using Eq. [6] and the available data on the thermodynamic properties of NiO and SiO_2 (11), the values of K were calculated from the line of best fit through the emf *vs.* temperature data. The values of K obtained in the temperature range 650°-1000°C are plotted as log K *vs.* the reciprocal temperature in Fig. 3.

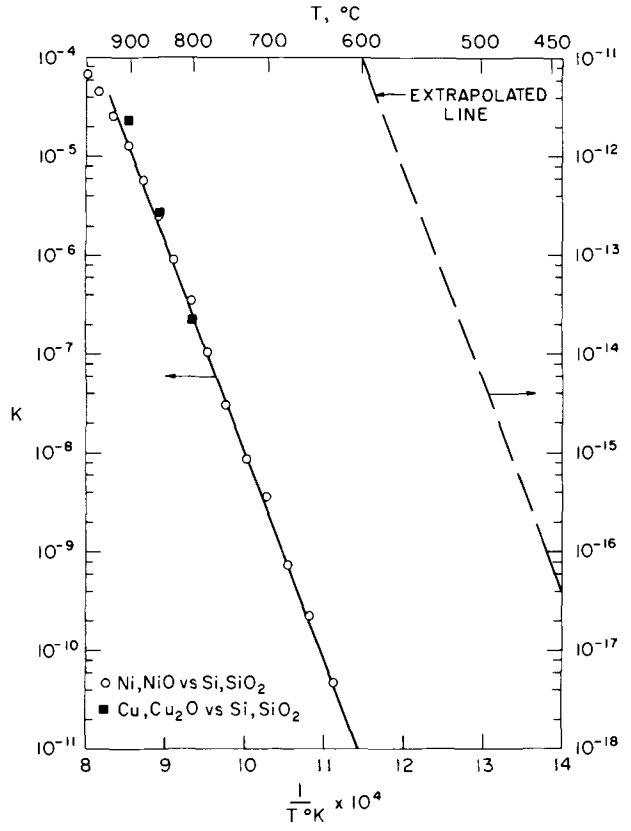

Fig. 3. Plot of log K vs. the reciprocal absolute temperature from which the values of E_a and K_O were derived.

Plotted in this form the data are linear and show a slight tailing off above 900°C.

A limited amount of data from the cell

$$SS|Si,SiO_2|ThO_2\text{-}15 \text{ w/o } Y_2O_3|ThO_2\text{-}15 \text{ w/o } Y_2O_3|Cu,Cu_2O|Pt|SS \quad \text{(VIII)}$$

are also shown in Fig. 3. These data are in good agreement with the data obtained from the cells which used Ni, NiO reference electrodes.[2]

The expression

$$K = 6.64 \times 10^{13} \exp [-99{,}800/RT] \quad [7]$$

where T is the absolute temperature and R is the gas constant, was calculated from the data shown in Fig. 3. Assuming the observed emf fall off is due to electronic conduction effects, the t_i value at any temperature and at oxygen activities up to Cu, Cu_2O can be calculated using Eq. [7] and [3]. However, other effects may be responsible for the fall off as explained below. If this is the case, Eq. [7] and [3] cannot be used to calculate t_i.

Discussion

Preliminary measurements using cell (II) demonstrated that spontaneous loss of oxygen was occurring from the Ni, NiO reference electrodes, causing this cell to give poorly reproducible data. Similar behavior was observed in cells with Cu, Cu_2O reference electrodes. This spontaneous loss of oxygen could not be accounted for by transport into the gas phase since electrochemical measurement of the oxygen activity in the helium indicated it was in the range of 10^{-6} to 10^{-7}. Thus, the hydrogen content was also low and was estimated from vapor pressure data to be ~4 x 10^{-7} mm Hg. The transport of oxygen could only be between the Ni, NiO and Si, SiO_2 electrodes through the electrolyte. It results from the finite electronic conductivity present in this electrolyte at the low oxygen partial pressures corresponding to Si, SiO_2 (12).

[2] We were reluctant to use Cu, Cu_2O as the reference electrode since this mixture readily fuses to the ThO_2-15 w/o Y_2O_3 disk and could only be removed by grinding the surface of the disk, but some data were obtained with Cu, Cu_2O (see Fig. 3).

The arrangement of cell (III) with a metal or Al_2O_3 barrier between the electrolyte tablets was devised to minimize the oxygen flux. It is obvious that in all of the cells studied a flux is still present since the oxygen activity in the helium purge gas is higher than at either of the two electrodes. However, the transport of oxygen is expected to be from the gas phase (helium) directly to each of the electrodes and is believed to be slight since we obtain theoretical emfs in Cu, Cu_2O *vs.* Ni, NiO cells. However, the direct oxidation of the Si, SiO_2 electrode may not be as slight. In any case the use of the barrier resulted in cells which were reproducible and remained so for a longer period of time than cells without the barrier.

In principle, the junction between the two electrolyte tablets will have no effect on the emf of the cell provided $t_i(\mu)$ is unity and that μ is the same in both electrolyte barrier interfaces.[3] We believe that both these conditions were satisfied, (*a*) since the composition of the two disks was the same and (*b*) measurements of t_i at high oxygen activities, *i.e.*, corresponding to the oxygen activity in the helium indicate that t_i is close to unity at an oxygen activity of 10^{-6}, *i.e.*, at both platinum electrolyte interfaces (13). In order to evaluate the possible importance of the transport of oxygen or that the nature of the electrolyte-electrolyte junction was not seriously affecting the results, a series of emf *vs.* temperature measurements were made on cells with different internal resistances, resulting from the use of different barrier materials, which would be expected to transport oxygen at different rates, *i.e.*, cells (IV), (V), (VI), and (VII). Agreement between the data from all the cells suggests that transport through the cells and the nature of the junction did not have a significant effect on the measurements.

Comparison with other data.—The model described by Lasker and Rapp (6) has been used to calculate the value of $t_i(\mu)$ from the experimental data. Equation [7], which is derived from the experimental data, has the same form as Eq. [5]. The experimental emf *vs.* temperature data is, as predicted from Eq. [6], approximately a linear function of temperature at high temperatures, *i.e.*, where $KP^{-1/4} > 1$. Thus, the empirical form of the data is predicted by the model. These results are also qualitatively in accord with reported measurements of the ionic range of ThO_2-Y_2O_3 at low oxygen activities which indicate that the electronic conductivity increases at a faster rate than the ionic conductivity with increasing temperature (14, 15). However, the magnitude of the relative increase is substantially in disagreement with results reported by previous investigators (14-16).

Based on results obtained in this study with Si, SiO_2 electrodes (cell III) cell (I) should give theoretical emfs at 550°C and oxygen concentrations in sodium as low as 1 ppm. However, we observe t_i for cell (I) at the Na(O) electrode to be less than unity at 550°C, at oxygen concentrations in sodium in the range of 1 to 10 ppm oxygen. Tretyakov and Muan (14) and Hardaway *et al.* (15) have measured values of K by means of a technique which does not depend on knowledge of the exact partial pressure at the low oxygen activity electrode. Their results predict similar behavior for the Na, Na_2O system, *i.e.*, cell (I). Both investigations measured K at oxygen activities where t_i is effectively zero. Their results predict that there should be no readily observable deviation in the emf of cell (III) from the calculated emf until 1000°C. Furthermore, Fruehan (16) claims he does not see the emf fall-off in the cell

$$Si,SiO_2|ThO_2\text{-}Y_2O_3|Cr,Cr_2O_3$$

at 1600°C. This disagrees with the extrapolated values of Tretyakov and Muan (14) and Hardaway *et al.* (15) whose results predict significant falloff in the emf at this temperature. Thus, it appears the deviation in emf from the calculated value of a particular cell system can depend on other factors such as the nature of the physical surface or chemical interactions between the electrode and the electrolyte in addition to the onset of electronic conduction. However, we found that using solid polished or pressed porous silicon did not have a significant effect on the emf *vs.* temperature behavior of cell (III). Furthermore, there were no obvious chemical interactions between Si, SiO_2 and ThO_2-15 w/o Y_2O_3. The effect of gas phase impurities can also be ruled out because they would not give the rapid fall-off of emf with increasing temperature observed. We cannot rule out the possibility of forming SiO_2 or some other oxide layer at the Si, SiO_2-electrolyte interface whose properties could effect the behavior of the cell. Thus, it appears that the behavior of a particular cell combination is not always predictable from measurements of the inherent ionic domain of a solid oxide electrolyte. We suggest that further investigations to define the useful oxygen activity range of ThO_2-Y_2O_3 be made at oxygen activities in the vicinity of the ionic domain boundary predicted by Tretyakov and Muan (14) and Hardaway *et al.* (15) using a variety of metal-metal oxide systems. We believe that the use of the barrier technique described in this paper will facilitate these studies by extending the useful life of the cells.

[3] In calculating the emf of this composite cell, Eq. [1] must be applied to each electrolyte disk with its adjacent contacts and the emfs summed for each disk.

Acknowledgments

This is to acknowledge the contribution of W. Kalinowski who constructed the experimental apparatus and helped solve many of the technical problems which developed during the initial phases of this work. We would like to thank Dr. L. Newman and Dr. D. H. Gurinsky for their encouragement and helpful discussions during the course of this study. This work was performed under the auspices of the United States Atomic Energy Commission.

Manuscript submitted Feb. 24, 1970; revised manuscript received *ca.* Nov. 17, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Ionic Range of ThO_2-15 w/o Y_2O_3 at High Oxygen Activities

F. J. Salzano,* C. Auerbach, H. S. Isaacs,* and B. Minushkin

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The ionic transference numbers (t_i) of ThO_2-15 w/o Y_2O_3 was determined at oxygen activities corresponding to approximately 1 atm by (*a*) emf measurements utilizing air-O_2 and air-Pb/PbO cells and (*b*) four-point resistance measurements, both as a function of temperature. The expression

$$t_i = \left[1 + 8.3 \times 10^{-2} P^{1/4} \exp\left(\frac{3420}{RT}\right)\right]^{-1}$$

was deduced from the emf measurements. The resistance data are in good agreement with these results, but the latter technique is not sensitive enough to discriminate easily between cases where $t_i < 1$ and where ionic and electronic contributions to the resistance are of comparable magnitude.

Yttria doped thoria is being used extensively as a solid oxide electrolyte in oxygen activity monitors for liquid sodium coolant systems (1). These applications require that the ionic transference number of the electrolyte either be unity, *i.e.*, that the electrolyte be a purely ionic conductor, or be readily reproducible. Since air or gaseous oxygen electrodes have shown advantages as reference electrodes over the solid metal-metal oxide system used heretofore, it was necessary to study the electrolyte at high oxygen activities. The behavior of ThO_2-15 w/o Y_2O_3 at low oxygen activities has been studied by some of the present authors to determine the ionic transference number (2). In this paper we report pertinent emf measurements on the following pairs of cells

$$Pb(l),PbO(s)\,|ThO_2\text{-}15\text{ w/o }Y_2O_3|O_2(0.21\text{ atm}),Au \quad (I)$$

$$Pb(l),PbO(s)\,|ZrO_2\text{-}CaO|O_2(0.21\text{ atm}),Au \quad (I')$$

and

$$Au,O_2(0.21\text{ atm})\,|ThO_2\text{-}15\text{ w/o }Y_2O_3|O_2(1\text{ atm}),Au \quad (II)$$

$$Au,O_2(0.21\text{ atm})\,|ZrO_2\text{-}CaO|O_2(1\text{ atm}),Au \quad (II')$$

The ZrO_2-CaO electrolyte is known to be a purely ionic conductor at all oxygen activities considered in this work, and the oxygen activity determined by the Pb-PbO system falls well within the 99% ionic conductivity range of ThO_2-15 w/o Y_2O_3 (3). In addition, four-point conductivity measurements, taken over a wide temperature and oxygen partial pressure range, are reported and discussed in the light of the emf data.

Results

Measurements on cells (I) and (I') were carried out using electrolyte tubes filled with a 9:1 Pb-PbO mixture. The tubes were coated on the outside with a porous gold film and rested inside a furnace on a bed of platinum gauze to which contact was made, air being allowed to circulate through the furnace and over the gold film. A piece of iridium wire served to make contact with the lead mixture. The cells were studied over the 500°-700°C temperature range; below 500°C cell (I) was excessively slow in reaching equilibrium. The results shown in Fig. 1 indicate that cell (I') gave values in close agreement with calorimetric data, in accord with previous work (4), while the values for cell (I) were noticeably lower. If $E_{(I')}$ and $E_{(I)}$ are the respective emf's, it may be shown based on the model described by Lasker and Rapp (5, 2), that

$$E_{(I)} - E_{(I')} = \frac{RT}{F} \ln t_i \qquad [1]$$

In this equation t_i is the value of the ionic transference number of ThO_2-15 w/o Y_2O_3 at the electrolyte-air interface ("point value"). Values of t_i calculated from Eq. [1] ranged from 0.66 at 500°C to 0.76 at 700°C. Similar results were obtained by comparing emf measurements on the cell

$$Cu(s),Cu_2O(s)\,|ThO_2\text{-}15\text{ w/o }Y_2O_3|O_2(0.21\text{ atm}),Au$$

with appropriate thermochemical data.

Cells (II) and (II') were studied in analogous fashion, air and oxygen being allowed to flow over the

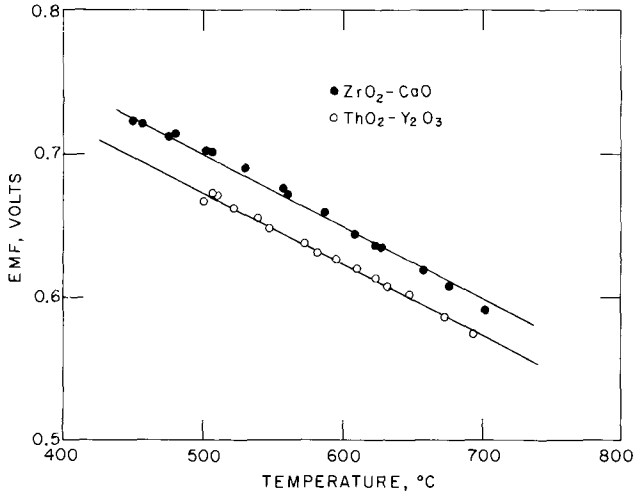

Fig. 1. Emf *vs.* temperature data obtained from cells (I) and (I').

* Electrochemical Society Active Member.

Key words: oxide electrolytes, ThO_2-Y_2O_3 electrolytes, ionic domain of $ThO_2Y_2O_3$, anionic conducting oxides.

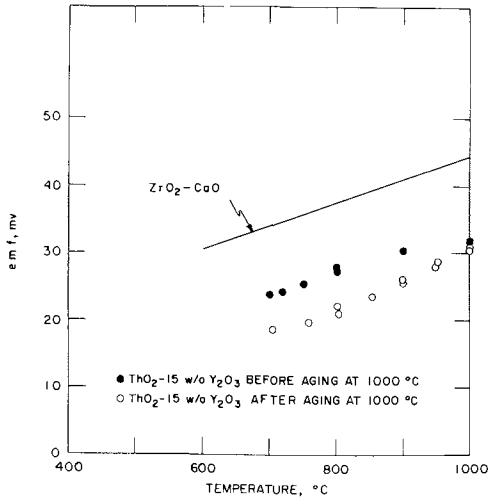

Fig. 2. Emf *vs.* temperature data obtained from cells (II) and (II').

outside and inside, respectively, of both tubes. Results are shown in Fig. 2; it is seen that aging the gold-coated ThO_2-Y_2O_3 tube at 1000°C has a marked effect on $E_{(II)}$. In the case of cells (II) and (II'), the average ionic transference number, $\bar{t}$, given by

$$\bar{t} = \frac{E_{(II)}}{E_{(II')}} \qquad [2]$$

may be considered to represent the point value, t_i, at each electrode, since the oxygen activity difference between the two electrodes is very small. Using Eq. [2], $\bar{t}$ at 700°C was found to be 0.7 for a freshly coated ThO_2-15 w/o Y_2O_3 tube and 0.5 for a tube aged at 1000°C. This constitutes satisfactory agreement with the results obtained from cell (I). The following explanation may account for the decrease of t_i (increase in $E_{(II)}$) on aging. In the above experiments the films consisted of porous gold, as in cells (I) and (I'), and sintering of such films is likely to occur at 1000°C. This would reduce the three-phase contact area (gas-gold-electrolyte) and thereby alter the polarization phenomena which may occur as a result of the partial electronic conductivity present in ThO_2-15 w/o Y_2O_3. Such a hypothesis is supported by the observation, made in prior experiments, that the same tube, equipped with a 1/16 in. solid gold button contact gave even lower emf values than were observed with the aged porous film.[1]

Four-point resistance measurements were made on a ThO_2-15 w/o Y_2O_3 ceramic sample cut from a sodium oxygen meter electrolyte tube (4 cm long by 1.3 cm wide by 0.15 cm thick) (1). The sample was placed in a quartz apparatus which in turn was enclosed in a 304 SS sheet metal electrical shield. Various gases could be passed through the vessel to control the oxygen activity of the sample. Four leads, numbered 1, 2, 3, and 4, were attached equally spaced on the long axis of the sample. The technique employed was that of brazing on four 1/16 in. diameter gold button contacts at 1100°C and subsequently brazing four platinum lead wires to the gold contacts. Contacts 1 and 4, attached to the ends of the sample, served to carry the current into and from the sample. The other two contacts, 2 and 3, served as potential probes. Measurements were made using Keithley Electrometers, Model 602. Each resistance measurement was made over as broad a range of current as allowed by the sensitivity of the electrometers. The resistance was always independent of the current.

Data were obtained in the temperature range 800°-200°C at three typical oxygen activities: dry hydrogen

[1] A ZrO_2-CaO tube equipped with the same solid gold button contacts gave theoretical emfs in a cell of the type (II') at temperatures down to 600°C.

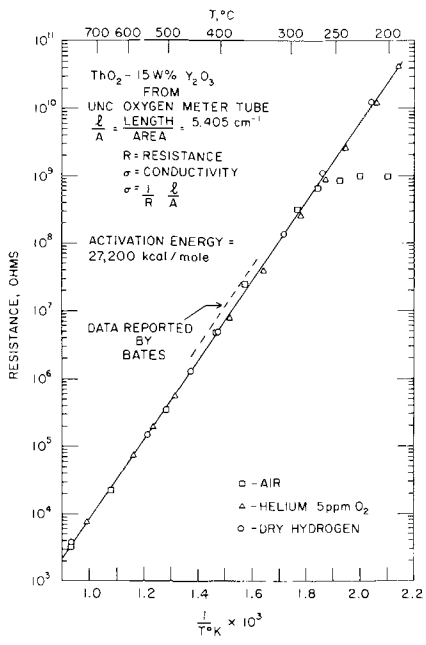

Fig. 3. Temperature dependence of the resistance of ThO_2-15 w/o Y_2O_3 taken from a UNC oxygen meter tube (1).

(<10 ppm H_2O, $\approx 10^{-28}$ atm O_2 at 800°C), 5 ppm O_2 in helium, and air. The data obtained are shown in Fig. 3 as a plot of log resistance *vs.* the reciprocal absolute temperature, and are seen to fall on a single straight line.

From these data the activation energy for the observed conductance was found to be −27,200 cal/mole, in good agreement with the values previously reported (3, 6). Two-point resistance measurements on the cells

$$Na,Na_2O|ThO_2\text{-}15\ w/o\ Y_2O_3|Na(O)$$
$$Cu,Cu_2O|ThO_2\text{-}15\ w/o\ Y_2O_3|Na(O)$$

give similar values for the activation energy.

Discussion

The emf measurements clearly indicate that ThO_2-15 w/o Y_2O_3 does not behave as a purely ionic conductor at the high oxygen activities considered in this work. Based on the work of Lasker and Rapp (5) and others one can define the parameter K by the equation

$$t_i = \left(1 + \frac{p^{1/4}}{K}\right)^{-1} \qquad [3]$$

where p is the oxygen partial pressure corresponding to t_i. Note that K raised to the fourth power represents the oxygen partial pressure corresponding to $t_i = 0.5$.[2] Values of K based on the data from cells (I) and (I') are plotted in Fig. 4 and yield the relationship

$$K = 12 \exp\left(-\frac{3420}{RT}\right) \qquad [4]$$

The fact that all the conductivity data may be represented by the same straight line, independent of pressure and temperature over a wide range, might at first sight indicate a t_i value of unity even at high oxygen activities, in contradiction to the potentiometric findings and the results of Bauerle (7). The measurements of Bauerle were limited to 1000°C, and he observed only a 25% change in conductivity at the highest Y_2O_3 composition he studied (4.5 w/o Y_2O_3) in the pressure range 10^{-6} to 1 atm pressure. His results show that the percentage change in conductivity decreases with increasing Y_2O_3 content. It is evident from these results that in ThO_2 containing more than three times as much Y_2O_3 (15 w/o Y_2O_3), changes in conductivity in this pressure range are expected to be very small

[2] Note the difference between this Eq. [3] and Eq. [3] in ref. (2). This is done so that the units of K will be (pressure)$^{1/4}$ in both cases.

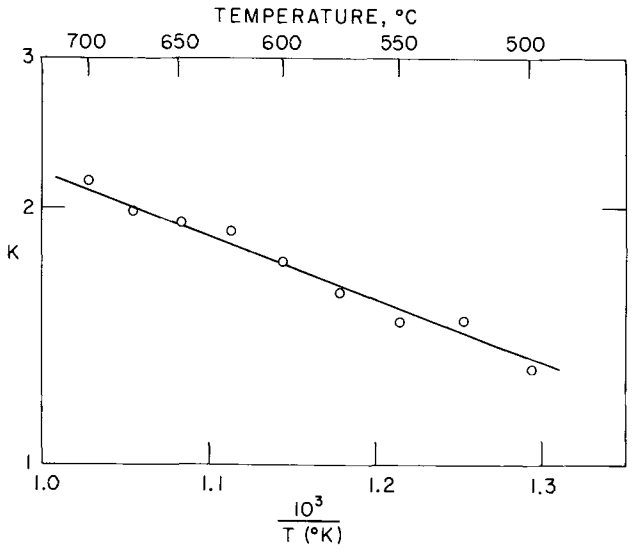

Fig. 4. Temperature dependence of K is obtained from emf measurements on cells (I) and (I').

and thus not easily detectable with techniques used in this study. The following considerations will show that there is no inconsistency between the emf and conductivity results reported in this paper. Since the ionic conductivity (σ_i) and the positive hole conductivity (σ_e) are given by the expressions

$$\sigma_i = \sigma_{io} \exp\left(\frac{-\Delta E_i}{RT}\right)$$

and

$$\sigma_e = \sigma_{eo} p^{1/4} \exp\left(\frac{-\Delta E_e}{RT}\right)$$

respectively, and since

$$t_i = \left(1 + \frac{\sigma_e}{\sigma_i}\right)^{-1}$$

it follows from Eq. [3] that

$$K = K_o \exp\left(\frac{\Delta E_e - \Delta E_i}{RT}\right) \qquad [6]$$

where the ΔE's represent the respective activation energies and

$$K_o = \frac{\sigma_{io}}{\sigma_{eo}}$$

Comparing Eq. [4] and [6] one finds that $\Delta E_e - \Delta E_i = -3420$ cal. If one makes the reasonable assumption that the slope of the plot in Fig. 3, which traverses a very low oxygen pressure range, is a measure of ΔE_i, *i.e.*, that $\Delta E_i = -27{,}200$ cal, one concludes that ΔE_i and ΔE_e differ by less than 15%. It is therefore not surprising that the temperature dependence of the conductivity continues to be constant, reflecting largely ΔE_i, even at appreciable oxygen pressures where σ_e is large enough to make $t_i < 1$. A slight drop in R is observed in air at the low temperature end, as predicted qualitatively from the oxygen partial pressure dependence of σ_e. However, no attempt was made in this work to study the pressure dependence in detail.

The reaction primarily responsible for the onset of hole conductivity at high oxygen activities is

$$\tfrac{1}{2}\, O_2(g) + V_o'' \rightleftarrows O_o + 2\oplus$$

where V_o'' is a doubly ionized oxygen vacancy, O_o is an oxygen ion on an oxygen site, and $\oplus$ represents the concentration of positive holes (5). We can estimate the value of the heat of reaction for the above equilibrium from the temperature dependence of K (2). According to the model

$$K^{-1} \propto \frac{k^{1/2}}{\mu_V}$$

and we expect

$$\Delta E_i - \Delta E_e \cong \frac{E_k}{2} - E_v$$

where k is the equilibrium constant for the above reaction, μ_v is the mobility of vacancies, E_k is the heat of reaction for the above equilibrium, and E_v is the activation energy for vacancy migration. Using the value $+3420$ cal/mole for $E_k/2 - E_v$ and the value E_v, $-27{,}200$ cal/mole obtained from the conductivity measurements, we calculate E_k to be $-47{,}500$ cal/mole. Thus, the heat of reaction for the above equilibrium is of the order of 50,000 cal/mole. The results obtained in this work have shown that t_i is less than unity at oxygen pressures close to 1 atm. In more quantitative terms, the ionic conductivity range corresponding to $t_i \geq 0.99$, may be defined by a limiting oxygen partial pressure, $p_{0.99}$, at which $t_i = 0.99$. Based on Eq. [3] and [4] it may be shown that

$$p_{0.99} = 2.07 \times 10^{-4} \exp\left(-\frac{1.37 \times 10^4}{RT}\right) \qquad [7]$$

Conductivity measurements on ThO_2-15 w/o Y_2O_3 do not contradict this finding but simply cannot easily discriminate between cases where σ_i and σ_e are of comparable magnitude, *i.e.*, $t_i < 1$, and $\Delta E_i \approx \Delta E_e$. Air or oxygen electrodes may nevertheless be used as reference electrodes in oxygen activity meters for sodium provided appropriate allowance is made for deviations of t_i from unity.

Acknowledgments

The authors are indebted to W. Kalinowski and G. Kissel for their substantial aid in construction of the apparatus and solution of other mechanical problems. They would like to thank Dr. L. Newman and Dr. D. H. Gurinsky for their encouragement and helpful discussions during the course of this study. This work was performed under the auspices of the United States Atomic Energy Commission.

Free Energies of Formation of Silver Sulfide and Lead Sulfide by Electromotive Force Measurements at High Temperature

W. T. Thompson[1] and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto 5, Ontario, Canada

ABSTRACT

The Gibbs free energy of formation of Ag_2S and PbS were measured in the temperature range 500°-800°C. The measurements were made with an electrochemical formation cell employing a sulfur vapor electrode and a fused chloride electrolyte saturated with the sparingly soluble sulfide. For the reaction

$$2Ag_{(solid)} + \tfrac{1}{2}S_{2(gas,\ 1\ atm)} \rightarrow Ag_2S_{(solid)}$$

$$\Delta G^\circ = -21{,}000 + 8.85T \text{ cal/g-mole}$$

For the reaction

$$Pb_{(liquid)} + \tfrac{1}{2}S_{2(gas,\ 1\ atm)} \rightarrow PbS_{(solid)}$$

$$\Delta G^\circ = -40{,}000 + 22.5T \text{ cal/g-mole}$$

An accurate knowledge of the Gibbs free energy of formation of sulfides, particularly base metal sulfides at high temperature, is of considerable importance in metallurgical process design. Although it is possible to determine free energies of formation at high temperatures by applying the appropriate heat capacity and enthalpy of transformation data to enthalpies and entropies of formation at 298°K, it is desirable to circumvent the cumulative errors of such calculations by directly measuring the free energies of formation at the temperatures of interest whenever this is feasible. Of the procedures available for such measurements, electrochemical methods are perhaps the most reliable and accurate when suitable electrolytes are available.

For the oxides with low free energies of formation, an electrochemical technique employing a solid ZrO_2-CaO solution as electrolyte has been particularly successful in yielding thermodynamic data at high temperature of high accuracy (1). An analogous procedure for the study of sulfides has not been possible because no similar solid sulfide electrolyte is at present well enough understood to yield emf data of unquestioned thermodynamic significance. The electrochemical procedure described in this paper, therefore, involves a fused salt electrolyte saturated with sulfide. This type of solution is suitable as an electrolyte since sulfide saturation is reached at a sufficiently low level that the salt solution still conducts current exclusively by ionic transference (2-4).

Of equal importance to the present electrochemical procedure has been the development of a reversible sulfur vapor electrode (5). In a previous publication, the reversibility of this electrode was demonstrated by measurements of the cell

$$-Ag \left| \begin{matrix} AgCl \\ Ag_2S \end{matrix} \right| S_{vapor},\ C+$$

When the mole fraction of Ag_2S was less than 0.1, the melt conducted ionically (4) and Nernst behavior was observed with respect to Ag_2S concentration and partial sulfur pressure in the temperature range 490°-860°C.

Experimental

The cell used to measure the free energy of formation of Ag_2S may be represented schematically as follows

$$-Ag \left| \begin{matrix} Ag_2S\ (satd.) \\ AgCl \\ ACl \end{matrix} \right| S_{vapor},\ C+$$

where ACl is molten alkali chloride (KCl or a KCl-NaCl mixture). The PbS formation cell may be similarly represented. The important physical features of these cells are shown in Fig. 1 and 2. The upper Pyrex portions of these cells containing sulfur were connected to a lower quartz portion containing the fused electrolyte. The entire cell was located in a two compartment furnace assembly such that the temperature of the sulfur and the electrolyte could be independently controlled.

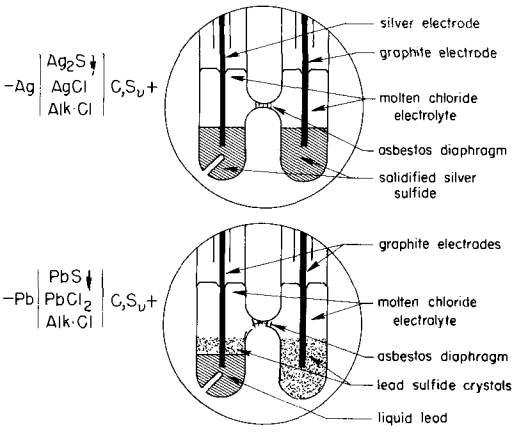

Fig. 2. Details of lower parts of sulfide formation cells

A gas mixture of fixed partial sulfur pressure was created by bubbling dry, oxygen-free preheated argon through the molten sulfur. The bubbling action tended to reduce temperature gradients in the sulfur and assure saturation of the argon. The sulfur for this purpose was laboratory reagent grade; purification by repeated sublimation was not performed since the impurities consist chiefly of insoluble matter known not to affect the sulfur pressure (6). The sulfur-argon mixture was led down and over the sulfide electrolyte and then passed to a sulfur condenser from which sulfur-free argon was expelled to the atmosphere.

In order to be certain that the temperature of the liquid sulfur in the bulb would control the sulfur pressure over the electrolyte, it was necessary to heat all tubing conducting the vapor from the bulb to the condenser. This was accomplished by wrapping the tubing with auxiliary chromel heating elements. Electrode connections were made using tungsten leads sealed in urania glass, the electrodes being threaded or silver soldered to the tungsten. The metal exposed to the sulfur rapidly formed a thin sulfide layer which rendered the connections immune to further vapor attack. The saturation of the argon with sulfur was verified by approximate dew point measurements taken on the tube leading from the bulb; by slowly reducing the power to the heating element on the tube while peering through a small inspection window in the upper furnace, sulfur was observed to condense at temperatures only 4° or 5°C cooler than the sulfur bath temperature. The flow rate of argon is important in this connection. At high flow rates, the argon does not become saturated with sulfur vapor. On the other hand, at very low flow rates thermal diffusion in the gas mixture may occur. This would account for the slight decrease in cell potential when the argon flow was stopped entirely. Preliminary experiments, however, showed that the cell voltage was insensitive to changes in argon flow rate in the range 20-100 ml/min. Accordingly for all subsequent experiments, the flow rate was adjusted to fall approximately in the middle of this range and no further attention was given to this experimental variable.

The two electrode compartments were separated by an asbestos diaphragm but contained melts of the same composition. The diaphragm was made by collapsing quartz tubing around a small prefired strand of asbestos fibers. The capillaries formed between the interstices of the fibers allowed electrolytic contact but prevented significant diffusion of dissolved sulfur to the metal electrode. This is a most important feature of the cell design if the results are to have thermodynamic significance.

The metal electrodes were fine silver rods or graphite rods dipping through the electrolyte into pools of high purity lead. The metal electrodes in each case were slowly flushed with argon during the course of an experiment. The inert electrodes for the sulfur side of the cell were ⅛-in. diameter spectroscopic grade graphite rods. Prior to use, these were heated in vacuum at 1000°C for about 24 hr to remove volatile matter. This did not result in any observable difference in the magnitude or stability of the cell potential. To test its reactivity, a small section of graphite rod was heated in a flowing sulfur-argon mixture for 48 hr at 850°C; an insignificant weight loss indicated that graphite was essentially inert to sulfur at temperatures below 850°C.

The Ag_2S was prepared by precipitation from an aqueous $AgNO_3$ solution using ammonium sulfide solution. The precipitate was thoroughly washed in distilled water then dried in vacuum at 150°C. Lead sulfide was prepared by reacting stoichiometric quantities of high purity lead with doubly distilled sulfur in sealed quartz capsules that were slowly raised to 1000°C (2). The reacted material was then melted and crystallized in a double walled evacuated quartz capsule. The reagent grade chloride salts were all vacuum oven dried but were otherwise untreated.

Considerable glass blowing was involved in preparing cells for an experiment. The entire cell was therefore carefully evacuated and maintained in this state at an elevated temperature for several hours to remove accumulated water vapor. It was only after this procedure that the electrolyte was fused and the argon admitted. In the case of the experiments with Ag_2S, the electrolyte temperature was raised initially above the melting of Ag_2S and then lowered to assure crystallinity of this component.

The temperatures of both the sulfur and sulfide melts were measured with chromel-alumel thermocouples constructed from calibrated wire. The hot junctions of the couples were in good thermal contact with the liquids by locating them in small wells blown directly into the glass cell.

Results

The emf measurements are presented in Tables I and II. Based on temperature fluctuations during the

temperature-controlling cycle, and the accuracy of the thermocouples, the reported sulfur bath temperatures, T_B, and the electrolyte temperatures, T_E, are considered accurate to 1° and 2°C, respectively. The composition of the electrolytes reported in the tables refers to the composition before sulfide saturation. However, sulfide saturation in alkali chloride-rich melts is known to be very small (2, 7), and as a result the concentrations of the chloride components in the electrolyte when actually saturated with sulfide should not differ appreciably from the values reported in Tables I and II. It was observed that several hours were required to reach a stable cell potential (±1 mV for 2 hr) when the electrolyte temperature was altered. This was attributed to the sluggishness in saturating the chloride melt with sulfide. It will be noted that a much more extensive study was undertaken of the Ag_2S formation cell. This was done to check the sulfur pressure dependence of the cell emf. In the light of the measurements on the Ag_2S formation cell, it was considered unnecessary to perform a similar study on the lead sulfide formation cell. In the case of measurements on the Ag_2S cell, a thermoelectric voltage was created by the dissimilar electrode materials. The leads from the potentiometer to the tungsten connectors were both of silver; as a result, the temperature of the cold junction for the +Ag/C− thermocouple effect was nearly that of the liquid sulfur. The true electrochemical voltage, reported in Table I, was computed by adding the thermoelectric voltage to the measured voltage, taking the cold junction temperature to be T_B. The output of the +Ag/C− thermocouple was measured as a function of temperature in an argon atmosphere. The results fitted by the method of least squares gave the equation

$$V = 4.36 - 8.80 \times 10^{-2}T + 1.29 \times 10^{-2}T \ln T \quad [1]$$

where V is the output in mV relative to 25°C and T is the hot junction temperature in °K.

Discussion

Sulfur vapor equilibria.—If sulfur were a simple vapor that could exist only in one molecular form, the sulfur pressure at the electrode would be equal to the vapor pressure of sulfur in equilibrium with the liquid in the bulb. It is known however that sulfur in the vapor phase is a complex mixture of various molecular species ranging essentially from S_2 to S_8, the concentration of each being temperature and pressure dependent. For this reason the relative concentration of the various molecules will be different at the electrode than in the bulb and, if diffusionless flow of sulfur saturated argon is assumed, then the total sulfur pressure will be increased as the gaseous solution is increased in temperature. If the vapor passes through the temperature gradient from the sulfur bulb to the electrode while at all times preserving local equilibrium, it is possible to calculate the composition of the sulfur vapor at the electrode when both bulb and electrode temperatures are known.

The assumption of local equilibrium is reasonable; the number of sulfur collisions per unit time is large in the pressure range of this investigation, and the time constants for dissociation and association processes of sulfur molecules are small (8). Therefore, before a sulfur molecule can move an appreciable distance within the temperature gradient, it will enter the equilibrium required by the temperature and total sulfur pressure in the new position. Furthermore, the partial pressure decrease in argon, as sulfur dissociates, is relatively small. There is thus very little tendency for argon diffusion. The small relative change in the argon pressure is a consequence of the fact that sulfur generally represents only a small fraction of the total volume of the gas phase.

For calculation purposes let a volume element V_B at temperature T_B, the temperature of liquid sulfur in the bulb, contain argon at pressure $(P_A)_B$ and sulfur at pressure $(P_{S\bar{v}-})_B$ where

$$(P_{S\bar{v}-})_B = \sum_{v=2}^{8} (P_{S_v})_B \quad [2]$$

Since the total gas pressure is fixed experimentally at 1 atm by the exit bubbler, the argon pressure in the bulb is

$$(P_A)_B = 1 - \sum_{v=2}^{8} (P_{S_v})_B \quad [3]$$

In passing from the sulfur bulb to the electrode compartment, the volume element V_B gradually expands to V_E as the sulfur vapor dissociates into lighter molecules and the molecules acquire more kinetic energy at the higher temperature. The total sulfur pressure within this element is now

$$(P_{S\bar{v}-})_E = \sum_{v=2}^{8} (P_{S_v})_E \quad [4]$$

However the total gas pressure remains at 1 atm. The argon pressure in element V_E is thus

$$(P_A)_E = 1 - \sum_{v=2}^{8} (P_{S_v})_E \quad [5]$$

Since diffusionless flow is being assumed, no net mass can leave the volume element and so the ratio of argon atoms to sulfur atoms in volume elements V_E and V_B are the same. Therefore

$$\frac{\left[1 - \sum_{v=2}^{8} (P_{S_v})_E\right](V_E/RT_E)}{\left[\sum_{v=2}^{8} (vP_{S_v})_E\right](V_E/RT_E)} = \frac{\left[1 - \sum_{v=2}^{8} (P_{S_v})_B\right](V_B/RT_B)}{\left[\sum_{v=2}^{8} (vP_{S_v})_B\right](V_B/RT_B)} \quad [6]$$

or

$$\frac{1 - \sum_{v=2}^{8} (P_{S_v})_E}{\sum_{v=2}^{8} (vP_{S_v})_E} = \frac{1 - \sum_{v=2}^{8} (P_{S_v})_B}{\sum_{v=2}^{8} (vP_{S_v})_B} \quad [7]$$

Comprehensive thermodynamic data on the equilibrium composition of sulfur vapor has been calculated from mass spectrometric studies (9, 10) assuming the vapor species to be ideal. These investigations showed that only the species S_2 to S_8 were significant contributors to the total sulfur pressure; S, S_9, and S_{10}, though observed, existed only in exceedingly small

quantities. For equilibria of the type

$$S_2 \leftrightharpoons 2/v\ S_v \qquad [8]$$

the equilibrium constants have the form

$$K_v = \frac{P_{S_v}{}^{2/v}}{P_{S_2}} \qquad [9]$$

In these equations v is an integer varying from 3 to 8. The relative populations of vapor molecules at various temperatures and total sulfur pressures, obtained from the existing mass spectrometric data, allow log K_v to be expressed as a linear function of reciprocal temperature. The work of Detry *et al.* (10) gives the following equations

$$\log P_{S_3} = 1.50 \log P_{S_2} + \frac{2.91 \times 10^3}{T} - 4.11 \qquad [10]$$

$$\log P_{S_4} = 2.00 \log P_{S_2} + \frac{6.16 \times 10^3}{T} - 8.00 \qquad [11]$$

$$\log P_{S_8} = 4.00 \log P_{S_2} + \frac{21.2 \times 10^3}{T} - 24.1 \qquad [12]$$

$$\log P_{S_5} = 0.625 \log P_{S_8} - \frac{2.79 \times 10^3}{T} + 2.88 \qquad [13]$$

$$\log P_{S_6} = 0.750 \log P_{S_8} - \frac{1.37 \times 10^3}{T} + 1.66 \qquad [14]$$

$$\log P_{S_7} = 0.875 \log P_{S_8} - \frac{1.26 \times 10^3}{T} + 1.57 \qquad [15]$$

These equations constitute six independent relationships involving partial sulfur pressures. For vapor in equilibrium with liquid sulfur at temperature T_B. The evaluation of the partial pressures in Eq. [10] to [15] is possible because the total vapor pressure [11] provides a seventh independent equation

$$\log \sum_{v=2}^{8} (P_{S_v}) = -\frac{4830}{T_B} - 5.0 \log T_B + 21.00 \qquad [16]$$

The partial pressures of sulfur species over liquid sulfur at temperature T_B determine a value for the right hand side of Eq. [7] and hence a value for

$$\frac{1 - \sum_{v=2}^{8} (P_{S_v})_E}{\sum_{v=2}^{8} (vP_{S_v})_E}$$

This relationship among partial pressures at the electrode is independent of Eq. [10] to [15] that can be written for temperature T_E. It is therefore possible to calculate all the partial pressures over the sulfide melt at the sulfur electrode at temperature T_E for a given liquid sulfur temperature T_B.

The actual solutions to the simultaneous equations for measured experimental conditions of T_B and T_E were accomplished by an iteration method using a digital computer. The forms of the various equations that lead to solution of these simultaneous equations are shown graphically in a previous paper (5). The calculated logarithms of the S_2 partial pressure over the sulfide electrolyte are listed in Tables I and II. The S_2 pressures are estimated to be accurate to about ±5%.

Electrochemistry of sulfur vapor electrode.—In the Ag_2S formation cell, the expected primary cell process is

$$2Ag + 1/vS_v \rightarrow Ag_2S \qquad [17]$$

In this reaction pure silver is solid, S_v is gas (the mean value of v being a function of temperature and total sulfur pressure), and Ag_2S is in a state of unit activity with respect to pure solid. When reaction [17] is the primary cell process two conditions must be observed experimentally: the cell emf must be independent of the electrolyte composition so long as Ag_2S is saturating it, and the cell voltage must vary in the Nernst manner with respect to partial sulfur pressure.

The Nernst expression for the proposed cell reaction is

$$E = E_{S_v}{}^\circ + \frac{RT}{2v\mathbf{F}} \ln P_{S_v} - \frac{RT}{2\mathbf{F}} \ln a_{Ag_2S} \qquad [18]$$

where v may assume any integral value from 2 to 8. The choice of this value affects both the numerical value of the partial sulfur pressure and $E_{S_v}{}^\circ$ in such a way that E is independent of the choice. This is consistent with the assumption of local equilibrium made in the previous section. Since S_2 is the predominant molecule in sulfur vapor at temperatures above 500°C, v will be taken to be 2 in all subsequent calculations making S_2 gas at 1 atm pressure the standard state for sulfur. In accord with Eq. [18], plots of E against log P_{S_2} must be linear with a slope of $4.575T/2n\mathbf{F}$ where n is the number of Faradays of charge associated with the formation of a mole of Ag_2S. These plots are shown in Fig. 3 at four temperatures. The slopes were determined by the least squares method and values of n were calculated; these are shown on each line, the mean value, $\bar{n}$, being 2.01. This is in good agreement with the required value of 2 considering the complexity of the sulfur vapor equilibria.

It should be noted that the same value for n is observed with electrolytes of different composition. This suggests that the process responsible for the cell voltage depends only on the activity of Ag_2S, this being fixed at unity with respect to pure solid, and in no way on the concentrations of the other components of the electrolyte.

The cell potentials for both the Ag_2S and PbS formation cells given with respect to a standard S_2 electrode are listed in Tables I and II. The corrections from the experimental conditions of measurements involved the addition of

$$-\frac{4.575T}{4\mathbf{F}} \log P_{S_2}$$

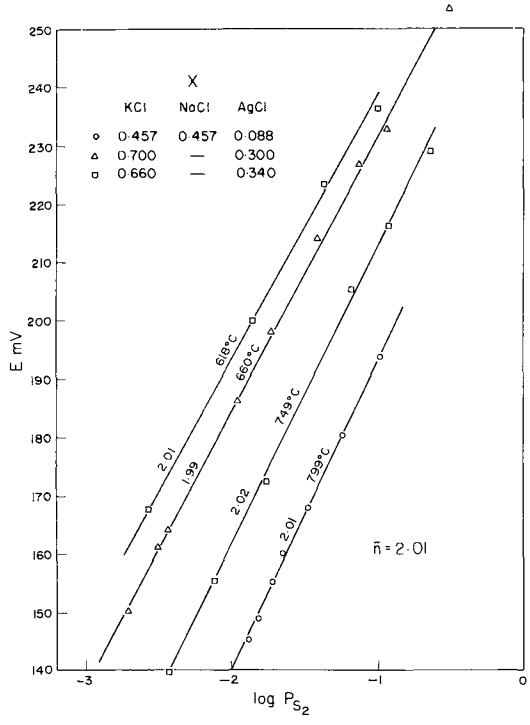

Fig. 3. Variation of emf with respect to calculated partial S_2 pressure for solutions saturated with Ag_2S.

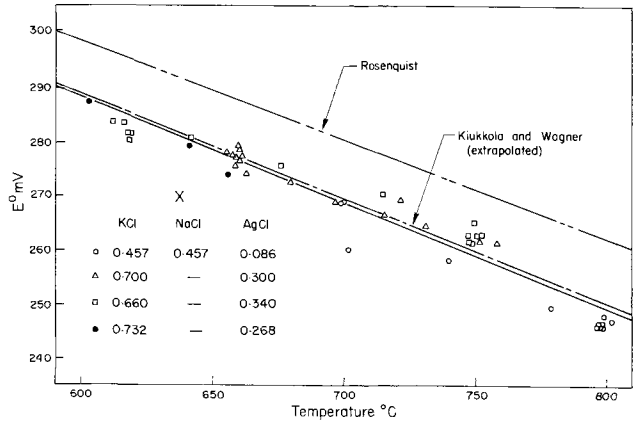

Fig. 4. Variation of standard potential of Ag_2S formation cell with respect to temperature. All solutions are saturated with Ag_2S.

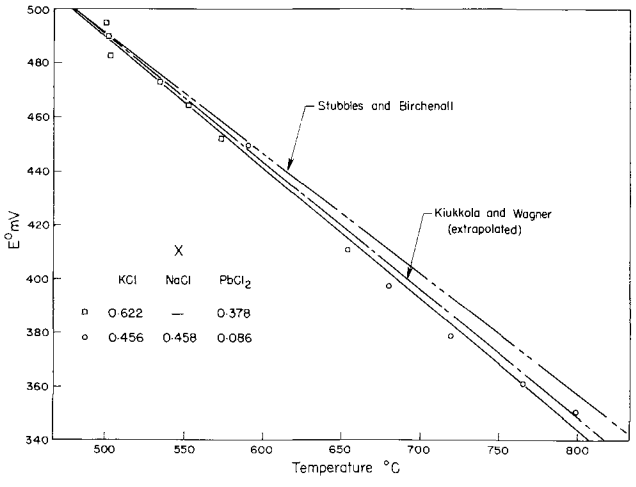

Fig. 5. Variation of standard potential of PbS formation cell with respect to temperature. All solutions are saturated with PbS.

to the measured cell voltages. The corrected voltages are plotted in Fig. 4. Within a few millivolts, it is apparent that the measurements are independent of the composition of the sulfide saturated electrolytes.

It should be noted that all electrolytes contain the chloride salt of the corresponding base metal sulfide. This was found to be essential if cell voltages were to correspond to the free energy of formation of the sulfide and to satisfy the requirements of the Nernst equation. Apparently the solubility of base metal sulfide in alkali chloride is insufficient to yield enough base metal ions to establish a reversible potential at the metal electrode. In addition, the concentration of base metal ion may be limited by incomplete dissociation of the dissolved base metal sulfide in pure alkali chloride.

Thermodynamic calculations.—The least squares equation for the line through the data for the Ag_2S formation reaction shown in Fig. 4 is

$$E^\circ = 455.3 - 0.1919T \quad [19]$$

or equivalently

$$\Delta G^\circ = -21{,}000 + 8.85T \quad [20]$$

where E° is the potential in millivolts relative to a standard S_2 electrode, ΔG° is the standard free energy of formation in cal/mole Ag_2S, and T is temperature in °K. The standard deviation is 3.2 mV or 152 cal/mole. The results of Rosenqvist (12), determined using H_2-H_2S mixtures, are shown for comparison in Fig. 4. His results are given with an error limit corresponding to 10 mV. There is better agreement between the present work and the extrapolated results of Kiukkola and Wagner (13). Their measurements were made at lower temperatures using a solid AgI electrolyte and a liquid sulfur electrode and are reported to be accurate to 1 mV in the temperature range 150°-425°C. The extrapolation involves changing the standard state of sulfur to S_2 gas at 1 atm pressure. This procedure is outlined in the Appendix.

The standard electrode potentials for the PbS formation reaction are shown in Fig. 5. The least squares equation representing the line through the points is

$$E^\circ = 867.4 - 0.4884T \quad [21]$$

or equivalently

$$\Delta G^\circ = -40{,}000 + 22.5T \quad [22]$$

where E° is the potential in millivolts relative to a standard S_2 electrode, and ΔG° is the standard free energy of formation in cal/mole PbS. The standard deviation is 4.5 mV or 207 cal/mole.

The experimental procedure of having a lead sulfide saturated melt in contact with molten lead results in the dissolution of a maximum of 4 m/o (mole per cent) sulfur in the lead (14). The lead electrode therefore is not at unit activity. Assuming ideal solution behavior of sulfur in lead the activity of lead is about 0.96 at 800°C. This effect reduces the cell voltage by about 1.9 mV from the value it would have at 800°C if the lead were pure. This difference is within the uncertainty of the experimental measurements; as a result no corrections for sulfur dissolution in the lead were applied to the measurements.

Stubbles and Birchenall (15) carefully studied the H_2-H_2S equilibrium over lead-lead sulfide mixtures. The line shown in Fig. 5 was calculated from their measurements; the suggested error in their free energy is equivalent to 10 mV. The results of the present study are just below their suggested lower limit of accuracy. The comparison with the extrapolated measurements of Kiukkola and Wagner (13) is better. However, since the accuracy of their measurements was only 4 mV, the extrapolation is less certain than in the case for Ag_2S.

Recently in this laboratory, the enthalpy contents of PbS and Ag_2S were measured using a sapphire calibrated drop calorimeter (16). These make possible comparisons of the present high-temperature electrochemical measurements with data available at 298°K using the Σ function.

When the difference in the molar heat capacity of the reactants and products of a chemical process can be expressed in the form

$$\Delta C_p = \Delta a + \Delta bT + \Delta cT^{-2} \quad [23]$$

the Σ function is

$$\Sigma = \frac{\Delta G^\circ}{T} - \Delta a + \Delta a \ln T + \frac{\Delta b}{2} T + \frac{\Delta c}{2} T^{-2} \quad [24]$$

When written in this form Σ is a simple linear function of temperature given by

$$\Sigma = \frac{\Delta H^\circ_0}{T} - \Delta S^\circ_0 \quad [25]$$

where ΔH°_0 and ΔS°_0 are integration constants.

Figure 6 shows the Σ plot for the Ag_2S and PbS formation reactions. The values for Σ were calculated using the electrochemically determined free energies of formation, the thermal data for the sulfides listed in Table III, and the heat capacities for the elements tabulated by Kelley (17). It is apparent that Σ is a linear function of temperature for both reactions as required by Eq. [25].

In the case of the formation reaction to produce γ-Ag_2S, the integration constants determined by a least squares analysis are

$$\Delta H^\circ_0 = -24.03 \text{ kcal/mole} \quad [26]$$

$$\Delta S^\circ_0 = -40.68 \text{ cal/°K mole} \quad [27]$$

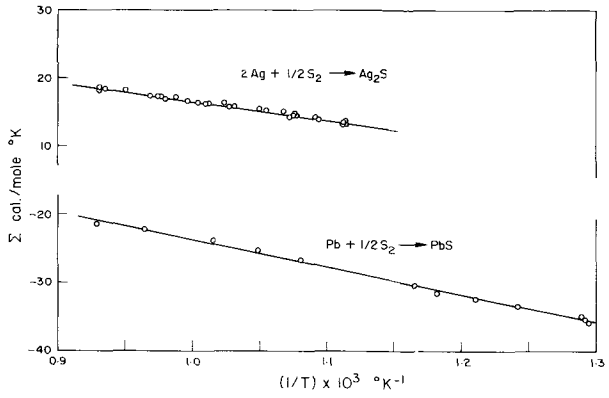

Fig. 6. Sigma plot for silver and lead sulfide formation reactions

Performing the integrations, care was taken to account for the two solid state transformations of Ag_2S

$$\Delta H°_{298} = -23.52 \text{ kcal/mole} \quad [28]$$

$$\Delta S°_{298} = -13.81 \text{ cal/°K mole} \quad [29]$$

$$\Delta G°_{298} = -19.40 \text{ kcal/mole} \quad [30]$$

These properties apply to the formation of α-Ag_2S from pure silver and S_2 gas at 1 atm pressure. At 298°K, however, sulfur is a solid; accordingly, rhombic crystal is used as the standard state for purposes of expressing enthalpies and entropies of sulfide formation reactions. The enthalpy and entropy for the formation of 1 mole of S_2 gas at 1 atm pressure from rhombic crystal at 298°K is calculated in the Appendix. Using these values, the thermal properties for the formation of α-Ag_2S from rhombic sulfur and silver are

$$\Delta H°_{298} = -8.57 \text{ kcal/mole} \quad [31]$$

$$\Delta S°_{298} = +4.73 \text{ cal/°K mole} \quad [32]$$

$$\Delta G°_{298} = -9.98 \text{ kcal/mole} \quad [33]$$

These data compare with N.B.S. values (18) of

$$\Delta H°_{298} = -7.79 \text{ kcal/mole} \quad [34]$$

$$\Delta S°_{298} = 6.48 \text{ cal/°K mole} \quad [35]$$

$$\Delta G°_{298} = -9.72 \text{ kcal/mole} \quad [36]$$

In the case of the reaction to form PbS, the integration constants determined from the Σ plot are

$$\Delta H°_0 = -40.17 \text{ kcal/mole} \quad [37]$$

$$\Delta S°_0 = -16.43 \text{ cal/mole °K} \quad [38]$$

Integrating and taking account of the freezing of lead at 327°C, the thermal properties associated with the formation of solid PbS from solid lead and S_2 gas at 1 atm at 298°K are

$$\Delta H°_{298} = -39.67 \text{ kcal/mole} \quad [39]$$

$$\Delta S°_{298} = -20.08 \text{ cal/mole °K} \quad [40]$$

$$\Delta G°_{298} = -33.68 \text{ kcal/mole} \quad [41]$$

With respect to formation from rhombic sulfur these become

Table III. Thermal data for Ag_2S and PbS

	$C_p = a + bT$ cal/mole °K		
	a	$b \times 10^3$	Temp. range, °K
αAg_2S	14.80	12.1	298-449
βAg_2S	19.44	0.702	449-859
γAg_2S	19.77	—	859-1103
PbS	10.78	2.72	298-1281

$(\Delta H_t)^{440}_{Ag_2S} = 940$ cal/mole
$(\Delta H_t)^{859}_{Ag_2S} = 120$ cal/mole

$$\Delta H°_{298} = -24.72 \text{ kcal/mole} \quad [42]$$

$$\Delta S°_{298} = -1.54 \text{ cal/mole °K} \quad [43]$$

$$\Delta G°_{298} = -24.26 \text{ kcal/mole} \quad [44]$$

These quantities compare with N.B.S. values (19) of

$$\Delta H°_{298} = -24.0 \text{ kcal/mole} \quad [45]$$

$$\Delta S°_{298} = -1.3 \text{ cal/°K mole} \quad [46]$$

$$\Delta G°_{298} = -23.6 \text{ kcal/mole} \quad [47]$$

Only fair agreement exists between the high-temperature measurements reported in this investigation and values reported at 298°K. It must be recognized, however that a large quantity of thermodynamic data was required in order to effect this comparison. The possible errors in the enthalpy and entropy of formation of S_2 gas from rhombic crystal alone, could readily account for most of the discrepancy in the previous comparisons.

Conclusion

A sulfur vapor electrode has been used in sulfide-saturated multicomponent chloride electrolytes to measure the standard Gibbs free energy of formation of silver sulfide and lead sulfide.

In the temperature range 876°-1075°K, for the reaction

$$2Ag_{(solid)} + \tfrac{1}{2}S_{2(gas,\ 1\ atm)} \rightarrow Ag_2S_{(solid)}$$

$$\Delta G° = -21{,}000 + 8.85T$$

The standard deviation of the experimental points from this line is 152 cal/mole.

In the temperature range 773°-1071°K, for the reaction

$$Pb_{(liquid)} + \tfrac{1}{2}S_{2(gas,\ 1\ atm)} \rightarrow PbS_{(solid)}$$

$$\Delta G° = -40{,}000 + 22.5T$$

The standard deviation of the experimental points from this line is 207 cal/mole.

APPENDIX

The free energy of formation of S_2 gas from liquid sulfur, ΔG, may be represented by

$$2S_{(liquid)} \rightarrow S_{2(gas,\ 1\ atm)} \quad [A\text{-}1]$$

At the same temperature, the free energy for the process

$$S_{2(gas,\ P_{eq})} \rightarrow 2S_{(liquid)} \quad [A\text{-}2]$$

is zero, P_{eq} being the partial pressure of S_2 in equilibrium with pure liquid sulfur. The free energy for the process represented by Eq. [A-1] is thus equal to that for the reaction

$$S_{2(gas,\ P_{eq})} \rightarrow S_{2(gas,\ 1\ atm)} \quad [A\text{-}3]$$

that is

$$\Delta G = \int_{P_{eq}}^{1} V\,dP \quad [A\text{-}4]$$

Assuming the S_2 to be ideal

$$\Delta G = RT \ln (P_{S_2})_{eq} \quad [A\text{-}5]$$

The partial pressure of S_2 gas in equilibrium with liquid sulfur may be evaluated at temperatures from 119° to 444°C by solving Eq. [10] to [15] with Eq. [16]. In this way, the free energy of formation of S_2 from liquid sulfur can be calculated at any temperature. This calculation was employed to convert the data of Kiukkola and Wagner (13) to correspond to sulfide formation from S_2 gas.

At 400°K

$$\Delta G^{400} = 15{,}132 \text{ cal/mole } S_2 \quad [A\text{-}6]$$

By calculating the free energy at other temperatures near 400°K. it was possible to evaluate the temperature dependence of this free energy at 400°K. The enthalpy and entropy for process [A-1] were then evaluated at this temperature as follows

$$\Delta H^{400} = \frac{d(\Delta G_1/T)}{d(1/T)} = 28{,}640 \text{ cal/mole } S_2 \quad [A\text{-}7]$$

$$\Delta S^{400} = -\frac{d(\Delta G_1)}{dT} = 33.77 \text{ cal/°K mole } S_2 \quad [A\text{-}8]$$

Using the data of Kelley (17), the enthalpy of formation of S_2 at 298°K from rhombic crystal is

$$\Delta H^{298} = 2\,(H^{400}_{S,\text{liquid}} - H^{298}_{S,\text{rhombic}}) + (\Delta H)^{400} - (H^{400}_{S_2,\text{gas}} - H^{298}_{S_2,\text{gas}}) = 29{,}900 \text{ cal/mole } S_2 \quad [A\text{-}9]$$

Similarly, the entropy of formation is 37.1 cal/°K mole S_2 at 298°K.

Electrical Conductivities of Molten $AlBr_3$-NaBr Mixtures

C. R. Boston[1]

Atomics International Division of North American Rockwell Corporation, Canoga Park, California 91304

ABSTRACT

The electrical conductivities of $AlBr_3$-NaBr mixtures have been measured from 25 to 98 m/o (mole per cent) $AlBr_3$ at temperatures ranging from 140° to 1000°C. A minimum in the equivalent conductance *vs.* composition diagram was observed near 33 m/o $AlBr_3$ and a maximum near 50 m/o $AlBr_3$. With increasing temperature, conductivities increased linearly at low temperatures and gradually went through a maximum at high temperatures. The maximum was actually reached for only one composition; namely, that corresponding to the compound $NaAlBr_4$ at a temperature of 800°-900°C. Arrhenius coefficients were lower than those observed for the $AlCl_3$-KCl mixtures but showed a similar pattern of behavior with composition.

Conductivity measurements previously reported (1) for the $AlCl_3$-KCl system gave rather interesting results, the most outstanding being the effect of composition. With increasing $AlCl_3$ at constant temperature the equivalent conductance first went through a pronounced minimum near 33 m/o (mole per cent) $AlCl_3$ followed by an equally pronounced maximum at 50 m/o $AlCl_3$.

The choice of $AlBr_3$-NaBr for this study was based primarily on the availability of a reasonably detailed phase diagram (2) since the conductivity behavior for the $AlCl_3$-KCl system appeared to be related in a qualitative way to phase equilibria occurring in the system. The $AlBr_3$-NaBr system had the additional advantage of normal consolute behavior in the two-liquid region. This permitted conductivity measurements in the 80 to 100 m/o AlX_3 region which was not possible for the $AlCl_3$-KCl system.

Experimental

$AlBr_3$ was prepared by two methods. The first method was essentially the same as that described (3) for $AlCl_3$ except that high-purity HBr instead of HCl was reacted with aluminum metal. The HBr was prepared by bubbling H_2 through Br_2 and passing the mixture over a platinum catalyst.

The second method was a purification of commercial $AlBr_3$ (anhydrous, technical grade, Matheson, Coleman and Bell). This was done by digesting the $AlBr_3$ at 230°-250°C with aluminum metal followed by two distillations. The apparatus consisted of a three-chamber Pyrex tube. The chambers were about 13 cm long x 4.1 cm in diameter and separated from each other by sintered glass disks. The first chamber was also separated from the remaining chambers by a break-off tip. Before loading, the entire apparatus was baked out under a vacuum of 10^{-5} mm Hg to remove surface moisture. The second and third chambers were then evacuated and sealed off and the first chamber was loaded with $AlBr_3$ and aluminum metal (99.9999%, Cominco Products, Inc.). This end of the apparatus was then evacuated and sealed off. The entire apparatus was held in a rocking furnace at 230°-250°C for several days. At first the crude $AlBr_3$ had a deep red color, but as digestion proceeded it became colorless and a black precipitate formed. The latter was presumably carbon resulting from the decomposition

[1] Present address: Metals and Ceramics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830, which is operated by Union Carbide Corporation for the U.S. Atomic Energy Commission.

Key words: conductivity, molten, electrical, aluminum bromide, sodium bromide.

of organic impurities. Distillation was started by breaking the break-off tip and allowing the material to distill into the second chamber. The first chamber was then sealed off and the final product distilled from the second into the third chamber. $AlBr_3$ samples prepared by these two methods gave identical conductivity results.

Anhydrous NaBr was prepared from reagent grade material by a method similar to that used by Boston and Smith (4) for the purification of LiCl-KCl eutectic. The $AlBr_3$-NaBr mixtures were weighed into the conductivity cells in a dry box purged with high-purity argon.

The apparatus and methods for measuring electrical conductivities of volatile molten salts have been described by Grantham and co-workers (5-7). As in the case of $AlCl_3$-KCl mixtures, the tungsten electrodes were found to be inert to corrosive attack by $AlBr_3$-NaBr mixtures at temperatures as high as 1000°C. To prevent cell rupture, external pressures were applied to the conductivity cell for the more volatile mixtures, 80, 92, and 98 m/o $AlBr_3$.

Results

The specific conductivities (κ) against temperature are shown in Table I and Fig. 1 and against composition at 600° and 800°C in Fig. 2. Although measurements were made up to 1000°C, only the 600° and 800° isotherms are shown since they are representative and show quite adequately the trend with temperature. Equivalent conductivities were calculated at 600°C using the density data of Boston and Ewing (8) and are shown plotted against composition in Fig. 3. Again, the effect of temperature was quite similar to that shown for specific conductivities in Fig. 2 so a single isotherm was considered adequate. The 600°C isotherm should be the most reliable since it required the minimum amount of extrapolation of density and specific conductivity data.

The points in Fig. 2 and 3 which are represented by open circles or squares were obtained by extrapolation of the linear portions of the conductivity *vs.* temperature curves and the solid points by direct measurement. At 0 and 25 m/o $AlBr_3$ the open circles represent extrapolations to temperatures below the liquidus. Such low-temperature extrapolations should be reliable since the curves are linear in this region. At higher $AlBr_3$ compositions open points represent extrapolations to temperatures above those where the

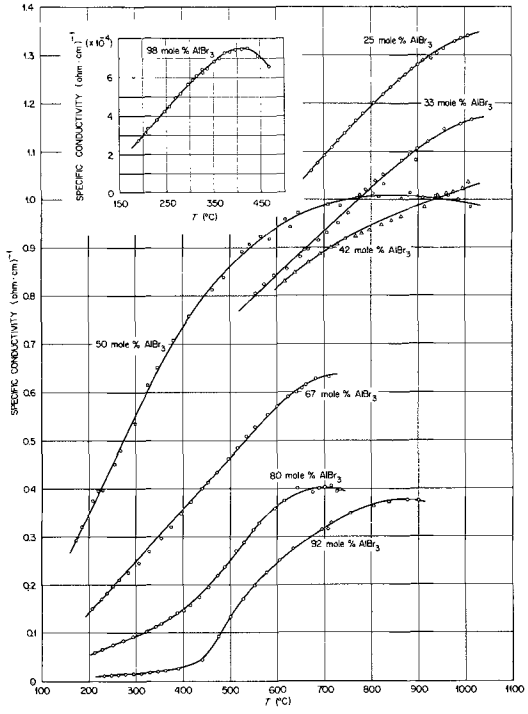

Fig. 1. Specific conductivity *vs.* temperature for the $AlBr_3$-NaBr system.

conductivity *vs.* temperature curves are linear. At 42 and 50 m/o $AlBr_3$ both measured and extrapolated points are shown. The extrapolated points produce more pronounced maxima as shown by the dotted curves but otherwise do not change the general shapes of the curves.

The unusual shapes of the 80 and 92 m/o $AlBr_3$ curves were presumably due to changes in composition of the liquid as significant amounts of $AlBr_3$ moved into the gas phase. The conductivity of the NaBr enriched liquid phase thus increased more rapidly than would be expected for temperature increase alone. To test this possibility the 92 m/o $AlBr_3$ composition was repeated using a larger melt volume which reduced the vapor volume by about one half. This produced about a 50° increase in the temperature at which the conductivity curve began its sharp increase which

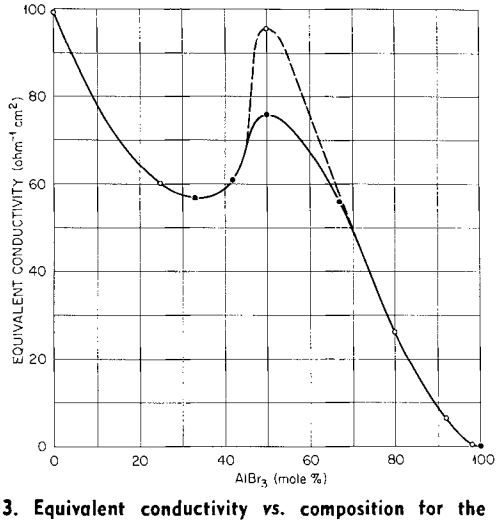

Fig. 3. Equivalent conductivity *vs.* composition for the $AlBr_3$-NaBr system.

supports the presumption that the increase is due to loss of $AlBr_3$ from the liquid phase. The low-temperature, linear portions of these curves were extrapolated to obtain the values shown in Fig. 2 and 3.

Arrhenius coefficients for electrical conductivity were calculated from the slopes of log κ *vs.* $1/T$ (°K) plots and are shown plotted against composition in Fig. 4. The coefficients usually decreased with increasing temperature. The term "Arrhenius coefficient" as used here corresponds to the activation energy for conductance. However, the latter term implies temperature independence which is definitely not the case here so Arrhenius coefficient is used instead. The values shown in Fig. 4 were obtained from the low-temperature region of the log κ *vs.* $1/T$ curves where linearity was usually observed. Arrhenius coefficients for the $AlCl_3$-KCl system are also shown in Fig. 4 for comparison.

Discussion

The effect of temperature on conductivity for the $AlBr_3$-NaBr system is shown in Fig. 1. As in the case

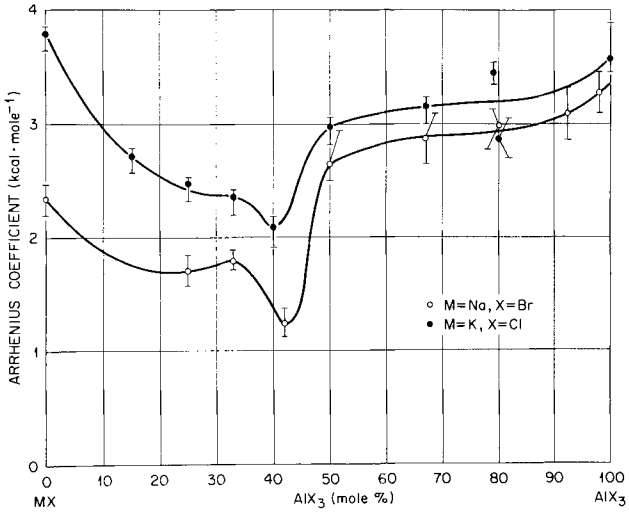

Fig. 4. Arrhenius coefficient *vs.* composition for the $AlBr_3$-NaBr system.

of pure compounds, the conductivity increases linearly at low temperatures and eventually goes through a maximum as the temperature increases. The temperature of maximum conductivity, T_{max}, was reached only for the 50 m/o mixture corresponding to the compound $NaAlBr_4$. The observed value of T_{max} at this composition was about 850°C. The maxima observed for 80 and 92 m/o $AlBr_3$ are due to the compositional changes mentioned earlier. Grantham and Yosim (6) have shown that a rough correlation exists between the heat of vaporization and T_{max}.

The compositional effects on conductivity are shown in Fig. 2 and 3. Minima in specific and equivalent conductivities occurred near 40 and 33 m/o $AlBr_3$, respectively. A pronounced maximum in both specific and equivalent conductivities occurred at 50 m/o $AlBr_3$. This behavior pattern is quite similar to that observed for $AlCl_3$-KCl mixtures (1). The conductivities are generally somewhat higher for the bromide system.

As pointed out in the chloride study (1), the 1:1 compound is so stable that it may be more reasonable to consider the NaBr-$AlBr_3$ system as consisting of the two systems, NaBr-$NaAlBr_4$ and $NaAlBr_4$-Al_2Br_6. When this is done, instead of a conductivity maximum, one finds negative deviations from additivity for NaBr-$NaAlBr_4$ and both negative and positive deviation for $NaAlBr_4$-Al_2Br_6. The latter effect is discussed below and the former effect has been discussed in some detail in the chloride study (1) and will not be repeated here.

In treating compositional effects in binary systems Delimarskii and Markov (9) suggest that qualitative correlations exist between deviations from additivity of conductance and degree of association in the melt as may be indicated by the complexity of the phase diagram. In analyzing several systems he has found that deviations tend to increase both in number and magnitude as one progresses from phase diagrams showing solid solutions to those showing eutectics and finally to those having congruently melting compounds. Both the $AlCl_3$-KCl and the $AlBr_3$-NaBr systems fit into this qualitative picture quite well since they both exhibit extremely stable 1:1 compounds (existing even in the vapor phase) and both have large conductivity deviations.

The most noticeable difference in compositional behavior between the two systems was observed for AlX_3-rich mixtures. A plot of equivalent conductivity *vs.* composition for the $NaAlBr_4$-Al_2Br_6 systems shows a negative deviation from additivity in the region of immiscibility (> 60 m/o Al_2Br_6-$NaAlBr_4$) and a positive deviation at lower Al_2Br_6 compositions. This

in contrast with the $KAlCl_4$-Al_2Cl_6 system where only positive deviations were observed. For example, at 60 m/o Al_2X_6 and 600°C, a positive deviation of 55% was found for the chloride system while for the bromide system a negative deviation of 20% was observed. It was suggested that the large positive deviation in the $KAlCl_4$-Al_2Cl_6 system was due to the drastic changes in melt structure when the nonconducting Al_2Cl_6 molecules reacted with $AlCl_4^-$ ions to form conducting ionic species such as $Al_2Cl_7^-$. [Evidence for the species $Al_2Cl_7^-$ in KCl-$AlCl_3$ (10) and NaCl-$AlCl_3$ (11) melts has recently been obtained by means of Raman spectroscopy.] From this point of view, then, the reversal in behavior for the $NaAlBr_4$-Al_2Br_6 system may indicate a less drastic change in melt structure on addition of $NaAlBr_4$ to Al_2Br_6 and a greater compatibility of Al_2Br_6 with anionic species such as $Al_2Br_7^-$ than is the case for the $KAlCl_4$-Al_2Cl_6 systems. This might be expected from a consideration of relative polarizabilities of chloride and bromide with the bromoaluminates being more molecular in nature than the chloroaluminates and thus more compatible with the corresponding aluminum halide. The phase diagram (2) for the bromide system shows a narrower miscibility gap and lower consolute temperature than does the chloride system as perhaps further indication of less pronounced changes in melt structure in the bromide system.

Compositional effects on Arrhenius coefficients are shown in Fig. 4 for the $AlCl_3$-KCl and $AlBr_3$-NaBr systems. This information was not presented in the previous study (1) on $AlCl_3$-KCl since the behavior pattern did not seem particularly significant in the light of inherent uncertainty limits. However, when the points for $AlBr_3$-NaBr are plotted as shown in Fig. 4 the striking similarity of the two systems adds considerable credibility to the results. The Arrhenius coefficients at first decrease with increasing AlX_3 composition, undergo a sharp drop near 40 m/o AlX_3 and then gradually increase beyond this point. The sharp drop near 40 m/o AlX_3 is close to the conductivity maxima observed for these systems (Fig. 2 and 3) and may reflect the pronounced changes in melt structure occurring in this composition range.

A Correlation of the Solution Properties and the Electrochemical Behavior of the Nickel Hydroxide Electrode in Binary Aqueous Alkali Hydroxides

E. J. Rubin* and R. Baboian*

Metallurgical Materials Division, Technical Center, Texas Instruments Inc., Attleboro, Massachusetts 02703

ABSTRACT

The electrochemical behavior of the nickel hydroxide electrode in binary aqueous alkali hydroxide solutions was investigated in the temperature range —40°-60°C. Maxima were observed in the electrode capacity *vs.* temperature curve for each electrolyte. The nature of the interaction of the alkali metal ion has a marked effect on the charge acceptance of the electrode. At the higher temperatures, the charge acceptance is greatest with the LiOH-H_2O electrolyte. At the lower temperatures, the charge acceptance is greatest with the RbOH-H_2O and CsOH-H_2O electrolytes. The results correlate with the variation in solution properties at these temperatures.

The role which the electrolyte plays in the nickel-cadmium battery is extremely important and complex. In addition to providing a current-carrying medium, the electrolyte participates in the half-cell reactions and is involved in the transfer of material to and away from the electrodes. The nature of the electrolyte and the factors influencing the properties of the electrolyte have marked effects on the behavior of the nickel-cadmium battery. However, the nature of these effects is not clearly understood because of the complexity of the problem.

In this initial study, we have investigated the behavior of the nickel-hydroxide electrode in binary,

* Electrochemical Society Active Member.

Key words: electrode, nickel hydroxide, alkali hydroxide solutions, electrolytic battery interactions.

aqueous, alkali hydroxide solutions. A correlation of this behavior with the properties of the electrolyte solutions is made in the temperature range −40°-60°C.

Experimental

The LiOH, NaOH, and KOH solutions were prepared using reagent grade chemicals and deionized water. The purity of the RbOH used was 99.9%. Cesium hydroxide solutions (>99% purity) of 50 w/o (weight per cent) were diluted to the appropriate concentration with deionized water. Precautions were taken to prevent the introduction of CO_2 during the preparation and use of these solutions.

All solution property measurements were made using alkali hydroxide resistant polypropylene containers. Sealed systems at atmospheric pressure were used wherever possible. For the conductivity measurements, a Beckman Instruments' Model CEL-K10 conductivity cell and an Industrial Instruments' conductivity bridge were used. The cell constant for the conductivity cell was determined using the method of Jones and Bradshaw (1). Viscosity measurements were made using a Brookfield Model LTV viscometer. The instrument was calibrated with distilled water using the published data of Swindells *et al.* (2). The desired temperature for all measurements was maintained using a Lauda Model TK-30 temperature bath.

The behavior of the nickel hydroxide electrode particularly oxidation potentials and the efficiency of the oxidation (charging) process were studied using the apparatus as shown in Fig. 1. The electrochemical cell was made from alkali hydroxide resistant Lucite with three interconnected compartments. The center compartment contained the test electrode (NiOH/NiOOH deposited into the pores of a porous sintered nickel plaque), with known theoretical capacity. An Hg/HgO and a partially discharged nickel hydroxide electrode served as the reference electrodes. The outer compartments contained conventional sintered plaque cadmium hydroxide plates as counterelectrodes with approximately ten times the capacity of the test electrode.

The experiments were carried out in the flooded condition with the appropriate electrolyte. The temperature was varied from −40° to +60°C and was controlled to ±0.5°C in a Tenney environmental chamber. In each case, the total charge input was 150% of the theoretical capacity of the test electrode. After each charging cycle, the cells were discharged at constant current to determine the charge acceptance of the nickel hydroxide electrode.

To determine the point of incipient gas evolution, the cell shown in Fig. 1 was connected to a manometer and gas buretts. Gas pressures produced in the cell displaced a conducting liquid in the manometer which actuated an electronic sensor, thus indicating the time of pressure rise. Immediately after gas evolution was detected, the manometer was bypassed and the evolved gas was collected in the buretts.

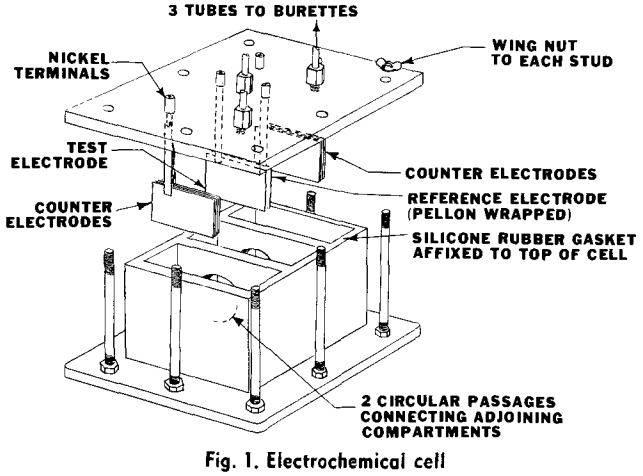

Fig. 1. Electrochemical cell

The accuracy of the apparatus was determined by electrolytically generating gas using an unimpregnated nickel plaque. Gas evolution was detected within 2 A-min after start of the test. The total gas evolved was greater than 95% of the volume (after STP corrections) predicted by Faraday's law. Deviations from the theoretical values were attributed to experimental error, gas adsorption on the plaque, and the quantity of gas necessary to overcome the water leg of the manometer. In actual operation, these effects were minimized by precycling the test electrode in the apparatus thus pressurizing the system and saturating the electrolyte with oxygen.

Results

Solute-solvent interactions.—Ionic solvation has been the subject of numerous articles. Bockris (3) suggested that the term "primary solvation" be used to refer to the number of solvent molecules near to an ion which have lost their translational degrees of freedom and move as one entity with the ion. Secondary solvation was used to refer to solvent molecules which interact with the primary solvated ion.

The magnitude of the hydration numbers for various ions reported in the literature vary widely because the methods used to measure these values include primary and secondary hydration contributions. For example, the values of the hydration number for Na+ reported in the literature vary from 2 to 70 (4).

The data in Table I show that the crystal radius of the alkali metal ions increases in the order of their atomic number.

The small lithium ion has a high charge density and should interact more strongly with surrounding water molecules than does the rubidium ion. This is reflected in the magnitude of the experimental mean primary hydration numbers $h_{meas.}$ in Table I. The values decrease for the alkali metal ions in going from Li+ to Rb+.

Also listed in Table I are the hydration numbers (h_{calc}) derived from activity-coefficient measurements. These values are thought to be the lower limit of hydration numbers because the method used to obtain them tends to emphasize the primary hydration. The calculated ionic radii (r_h) resulting from these measurements show the effect of solvation on the size of the ions in solution. In contrast to the trend of the crystal radii, the solvated ion size decreases in going from Li+ to Cs+.

The model used most frequently to describe the hydrated alkali metal ion is shown in Fig. 2a. The alkali metal ion polarizes the water molecules orienting them so that the oxygen end of the dipole is nearest the ion.

A number of authors have found, in aqueous solutions, that the hydroxide ion is strongly hydrated. This conclusion was based on heat capacity measurements (5), calculations based on activity coefficient data (6), Raman spectra (7), infrared spectra (8), and ionic entropy data (9). The formula $[OH(H_2O)_3]^-$ has been used most frequently to represent the state of the hydroxide ion in solution. The models proposed for such a species are shown in Fig. 2b and c. In Fig. 2b, all three water molecules are bound to the oxygen of

Table I. Ionic properties of alkali metals

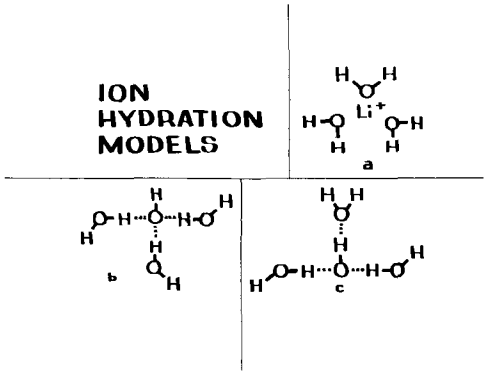

Fig. 2. Ion hydration models

the hydroxide ion. In Fig. 2c, one of the water molecules is bound to the hydrogen of the hydroxide ion. The former model is favored because the high-frequency O-H mode of the Raman spectrum remains unchanged (7) when an alkali hydroxide is dissolved in water. In concentrated alkali hydroxide solutions, the magnitude of the interactions in the trihydrated hydroxide ion depends on the nature of the alkali metal cation.

Solute-solute interactions.—The degree of ion association in solution depends on the nature of the anion, cation, and solvent. Concentration, temperature, and pressure have a marked effect on this parameter. At high concentrations the calculated separation of ions is small. Therefore, depending on the extent of interaction with the solvent, the ion solvation spheres may overlap interacting with one another.

This model for ion association in water is adequate for interpreting the magnitude of the activity coefficient for most alkali metal solutions. The values for most electrolytes of the alkali metal family decrease in the order lithium to cesium (10).

This is consistent with the increasing hydration of the cation from cesium to lithium (Table I). The reverse is true for the alkali metal hydroxides. The activity coefficients decrease in the order cesium to lithium (10).

To account for the low activity coefficient found for lithium hydroxide, Robinson and Harned (10) postulated the existence of water-bridged ion-pairs. The model in Fig. 3a shows that in the hydration shell surrounding the lithium ion, the water molecule is highly polarized with protons directed away from the cation. The proton then interacts with the oxygen of the hydroxide ion. In concentrated solutions, the model in Fig. 3a would best describe ion association in lithium hydroxide solutions because of the high charge density of the lithium ion. Ion association in cesium hydroxide solutions may be more direct as in Fig. 3b because the cesium ion is not bound by a sheath of highly polarized water molecules.

Solution properties.—Aqueous solutions in which the ions are strongly hydrated and/or have strong electrical forces between the ions in adjacent layers, have high viscosities. The viscosities measured at 25°C for LiOH, NaOH, KOH, RbOH, and CsOH solutions are

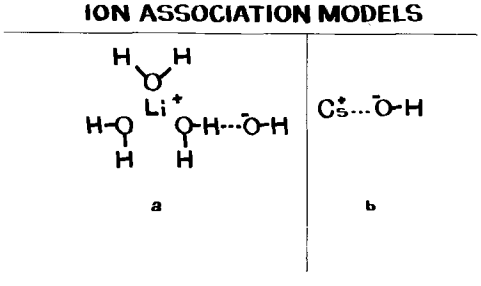

Fig. 3. Ion association models

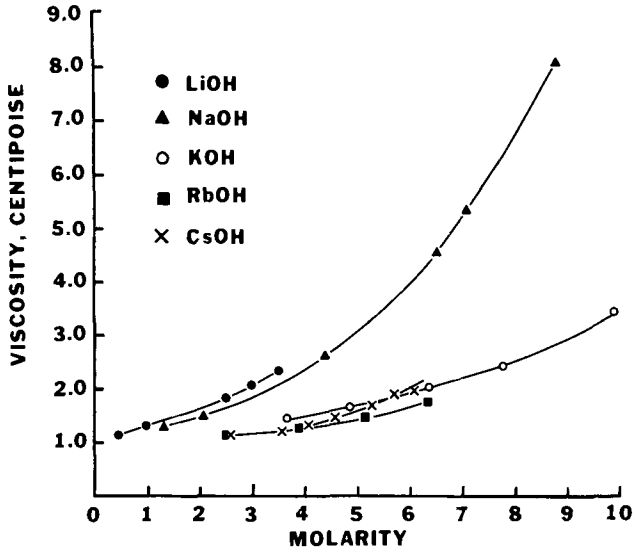

Fig. 4. Viscosity of alkali metal hydroxide solutions at 25°C

plotted *vs.* concentration in Fig. 4. In the concentrated region, the viscosities rise rapidly with concentration due to increased ion association. The highest viscosities are measured for LiOH and NaOH solutions in which ion hydration and water bridge ion pairing is appreciable.

The specific conductivities at 25°C for solutions of the alkali metal hydroxides are plotted *vs.* concentration in Fig. 5. In the dilute region, the increase in conductivity with concentration is due to the increase in the population of ions per unit volume. The decrease in conductivity at high concentrations is due to increased ion association which is characteristic for these 1:1 electrolytes. The lowest conductivities are found for the LiOH and NaOH systems. This is due to the effect of ion hydration and water bridge ion pairing and is in agreement with the viscosity measurements.

The phase diagrams (11) for the binary alkali metal hydroxide-water systems are shown in Fig. 6. Notice that the eutectic temperature decreases in the order LiOH through CsOH and that the compositions of the eutectic and the conductivity maximum at room temperature correspond closely for the KOH-H_2O system whereas marked differences are observed for the other systems. The specific conductivities are strongly temperature dependent because they are sensitive to the types of interactions which prevail. Conductivity

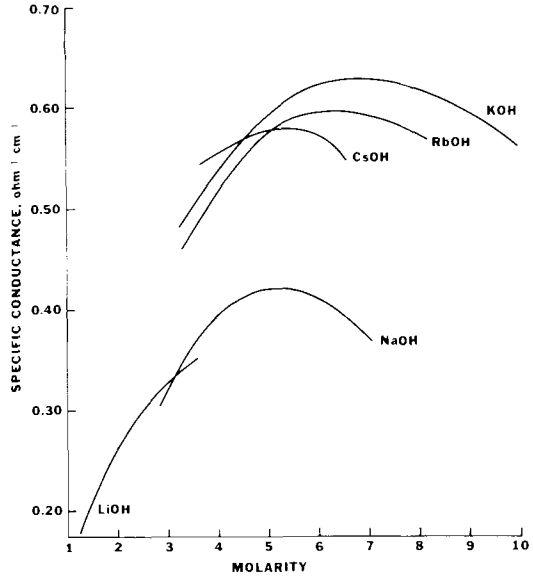

Fig. 5. Specific conductance of alkali metal hydroxide solutions at 25°C.

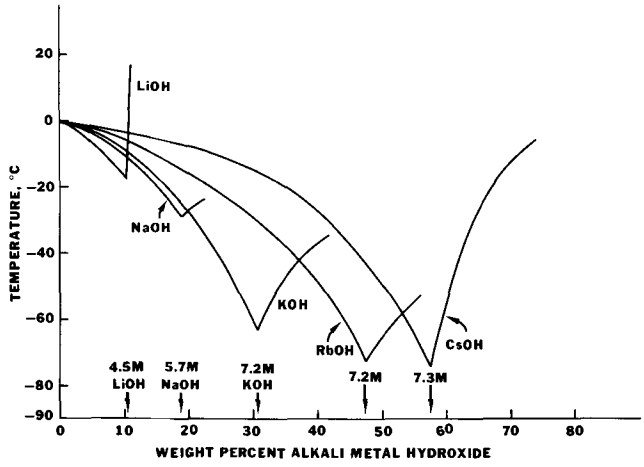

Fig. 6. Alkali metal hydroxide-water phase diagrams

maxima, therefore, shift with temperature. For example, the conductivity maximum in the KOH-H_2O system was found to occur below 4M at −15°C, about 6M at 0°C, and 6.7M at 25°C.

The electrolytes chosen for the comparative investigation were those having the highest specific conductivity at 25°C. In the case of lithium hydroxide, the liquidus is so steep beyond the eutectic composition that this concentration could not be used. A 3.0M LiOH solution was used for this system. In Fig. 7, the specific conductivities of these solutions are plotted *vs.* temperature. Below 0°C, the CsOH solution has the highest conductivity. At −10°C the order is

$$\text{LiOH} < \text{NaOH} < \text{KOH} < \text{RbOH} < \text{CsOH}$$

At 25°C the KOH solution has the highest conductivity and the order is

$$\text{LiOH} < \text{NaOH} < \text{CsOH} < \text{RbOH} < \text{KOH}$$

This data can be compared to the viscosity data and the freezing points listed in Table II. To some extent, the behavior of the electrolytes correlate; however, the lowest viscosity electrolyte is shifted to RbOH at 25°C and the order is

$$\text{NaOH} > \text{KOH} > \text{CsOH} > \text{RbOH}$$

Nickel hydroxide electrode behavior.—The oxygen-free capacities of the nickel hydroxide electrode developed in the various electrolytes are plotted as a function of temperature in Fig. 8 and 9. In Fig. 8 the

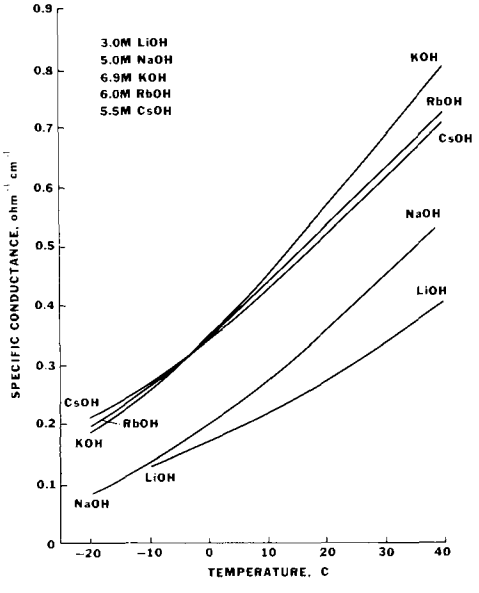

Fig. 7. Temperature dependence of specific conductance of alkali metal hydroxide solutions.

Table II. Solution properties

Solution (conc.)	Freezing point, °C	Specific conductance, ohm^{-1}-cm^{-1}, 25°C	Viscosity, centipoise 25°C	Viscosity, centipoise −10°C
LiOH (3M)	−11	0.33	2.0	—
NaOH (5M)	−23	0.42	3.0	6.9
KOH (6.9M)	−64	0.63	2.1	3.8
RbOH (6M)	−50	0.59	1.6	3.1
CsOH (5.5M)	−43	0.57	1.7	2.9

values were obtained at the c/5 charge rate and the c/2 discharge rate. In Fig. 9 the values were obtained at the c charge and the c/2 discharge rate. The oxygen-free capacities are similar for the two charge rates except at low temperatures where they are higher at low charge rates. In Fig. 10 and 11 the delivered capacities are plotted as a function of temperature for the various electrolytes. Figure 10 shows the results of the low charge rate and Fig. 11 shows the results of the fast charge rate.

Discussion

The dependence of oxygen-free capacity and delivered capacity of the nickel hydroxide electrode on electrolyte type is significant. At temperatures where the oxygen-free capacity is high the delivered capacity is correspondingly high so that the capacity maxima occur at the same temperature. The capacities are high with the sodium and lithium electrolyte at high temperatures, are high with the potassium electrolyte at intermediate temperatures, and are high with the rubidium and cesium electrolytes at low temperatures. Specifically, the delivered capacity is highest with the

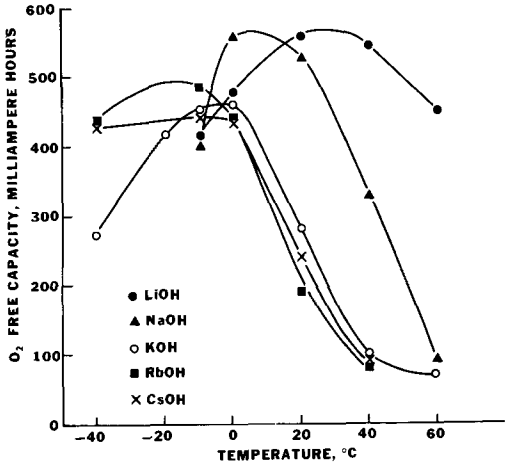

Fig. 8. Nickel hydroxide electrode oxygen-free capacity (112 mA charge rate).

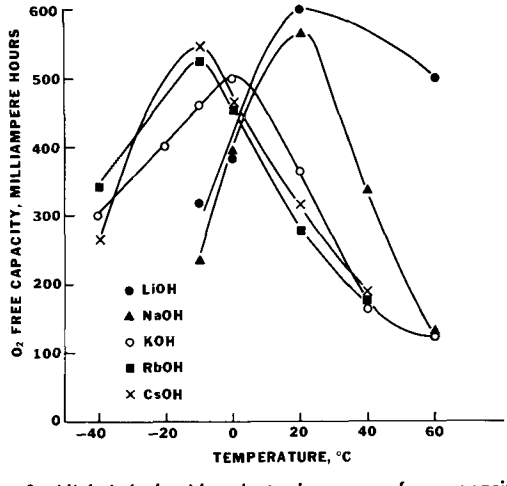

Fig. 9. Nickel hydroxide electrode oxygen-free capacity (500 mA charge rate).

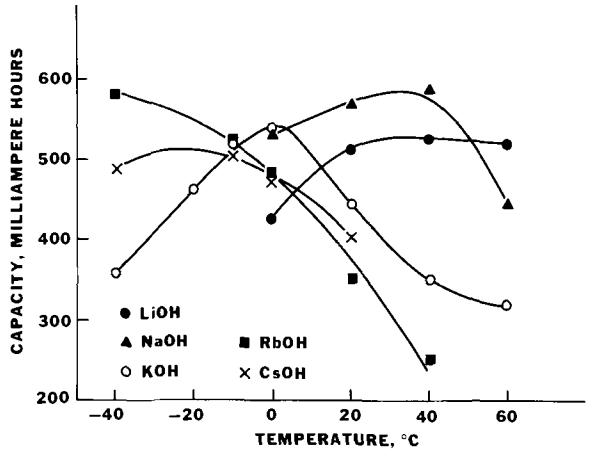

Fig. 10. Nickel hydroxide electrode capacity (112 mA charge rate).

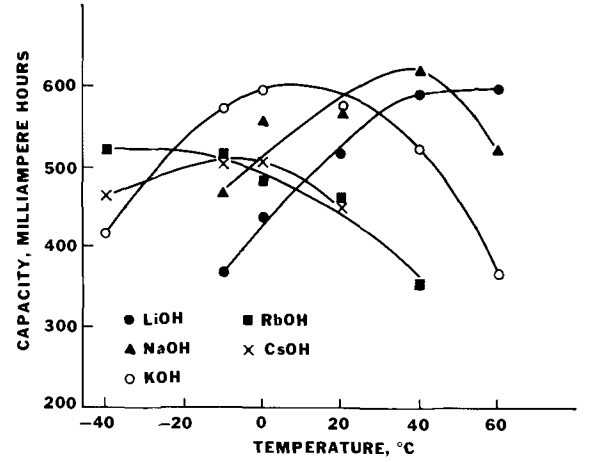

Fig. 11. Nickel hydroxide electrode capacity (500 mA charge rate).

rubidium hydroxide electrolyte at −40°C, with the KOH electrolyte at 0°C, with the sodium hydroxide electrolyte at 40°C, and with the lithium hydroxide electrolyte at 60°C.

In general, this same trend is observed for the specific conductance of these electrolytes with temperature. Since the solution compositions used in this study are the ones with the highest specific conductance (Fig. 5) at 25°C, some degree of correlation is expected. However, the correlation is surprisingly good over a wide temperature range.

The magnitude of the difference in isothermal electrode capacities with the various electrolytes cannot be totally explained by differences in electrolyte properties and suggests that structural changes occur in the electrode. Bode (12) has reported that alkali metal cations present in the nickel hydroxide crystal lattice have an effect on the stability of the higher nickel oxidation states. The stability varies with the alkali metal cation and therefore leads to variations in electrode capacity with electrolyte type. This effect has been studied extensively and has been reported previously (13, 14).

For a given electrolyte over the temperature range investigated the structure of the nickel hydroxide electrode does not change significantly enough to explain the maxima observed in the electrode capacity *vs.* temperature curves (Fig. 8-11). However, the results can be explained by consideration of electrolyte interactions.

In Table III, differences in nickel hydroxide electrode potential during charging and end-of-charge (oxygen evolution) electrode potential are listed at various temperatures. For each electrolyte, this difference in potential decreases rapidly with increasing temperature. This indicates that electrode polarization is reduced as the temperature is increased and follows the trend of increasing conductance (Fig. 7) and decreasing viscosity (Table II) with increasing temperature.

Table III. ΔE plateau oxygen evolution-nickelous hydroxide oxidation (500 mA charge rate)

Temp, °C	LiOH	NaOH	KOH	RbOH	CsOH
−10	268	230	145	130	115
20	195	143	87	65	93
40	155	101	30	33	50
60	105	26	10	—	—

Table IV. ΔE (mV) incipient O_2 evolution-nickelous hydroxide oxidation (500 mA charge rate)

Temp, °C	LiOH	NaOH	KOH	RbOH	CsOH
−10	38	22	10	7	41
20	84	43	27	3	27
40	93	15	13	0	2
60	28	0	10	—	—

The differences in nickel hydroxide electrode potential and the potential at which incipient oxygen evolution occur at the nickel hydroxide electrode are listed in Table IV. These data include not only effects of electrode polarization, but also tendency toward oxygen evolution. The latter effect is dependent on the nature of electrolyte interactions represented diagrammatically in Fig. 2b and c, and 3a and b. The magnitude of these electrolyte interactions decrease with increasing temperature.

In Table IV, the trend (ΔE *vs.* temperature) is the same as that observed for electrode capacity *vs.* temperature. The maxima in Table IV and in Fig. 8-11 appear at approximately the same temperature for each electrolyte. This indicates that the capacity maxima are a result of superimposed effects of variations in electrode polarization and oxygen evolution with temperature.

When ΔE values in Table IV are very low the electrode should become unstable or inefficient. For rubidium hydroxide and cesium hydroxide electrolytes, the ΔE values are zero and two millivolts respectively at 40°C. Spontaneous decomposition of charged nickel hydroxide electrodes in these electrolytes was observed.

The effect of charge rate on the nickel hydroxide electrode oxygen free capacity is significant since the results support the above interpretation of observed capacity maxima. The lower temperatures yield delivered capacities which are higher at slow charge rates. This effect is not observed at the higher temperatures due to reduced electrode polarization.

The Anodic Dissolution Reaction of InSb: Etch Patterns, Electron Number, Anodic Disintegration, and Film Formation[1]

M. E. Straumanis* and Lih-da Hu

Department of Metallurgical Engineering and Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

The etching behavior of the inverse {111} planes of undoped, semiconducting, n-type, InSb single crystals was explored. Depending upon the etchant, including anodic dissolution, various etch patterns were obtained on the inverse planes. In general the etch pits on the In{111} plane were round, and the face was shiny, whereas the face of the inverse plane was dark and rough. The rates of dissolution in the electrolytes used were very low, especially in absence of oxidizers. The components dissolve as In^{3+} and Sb^{3+}. At current densities above 40 or 60 mA cm^{-2} (on Sb{$\bar{1}\bar{1}\bar{1}$} or In{111}), growth of a black, collodial film of $Sb_4O_5Cl_2$ containing very fine metallic Sb particles occurs on both planes. The Sb particles result from the partial disintegration of InSb. Upon heating the film in vacuum, recrystallization occurs and the Sb aggregates to form larger particles. An explanation is offered for the different behaviors of the inverse {111} planes.

The chemical and anodic dissolution reactions occurring on various planes of III-V semiconductors in several electrolytes have been studied by Gatos *et al.* (1, 2), Pleskov (3), Dewald (4), Gerischer (5, 6), Harvey (7), Straumanis *et al.* (8, 9), and others. Dewald attempted to explain why the {111} inverse faces of InSb in an aqueous solution of KOH behave differently. Anodic oxide films of varying composition with the ratio of Sb:In close to one at the surface of the crystal planes were formed during electrolysis.

The aim of the present investigation was, therefore, to check once more the etch patterns formed on the inverse {111} faces of InSb, to determine the valences of the ions (In and Sb) going into solution in acidic electrolytes, to look for disintegration phenomena and film formation, and determine the composition of the films.

Electrodes and Their Treatment

The electrodes were prepared as for GaAs by mounting InSb wafers (~ 2 mm thick and 8 to 12 in diameter) into Teflon holders provided with a screw cap and Cu lead wires (9). The wafers were cut from single InSb crystals obtained from the Monsanto Company (St. Louis, Missouri), grown in the [111] direction by the Czochralski or the gradient-freeze technique. They were n-type with no intentionally added dopants, and the impurity level was less than 1 ppm. The {111}, {110}, and {100} directions were established from Laue x-ray back reflection patterns. Deviations from these faces were adjusted by successive grinding to give the desired orientation on the Laue patterns.

These faces had a mirror-like appearance after mechanical polishing (Fig. 1a). To remove mechanical surface damage, they were subsequently treated with CP-4 (2, 4) (mixture of concentrated acids HNO_3, HF, and CH_3COOH) for 2 sec, washed, and dried. Although still mirror-like, the faces showed a slight undulation in the interference microscope (Fig. 1b).

This etchant and several others, including anodic dissolution, were used to check the previous results and to determine which of the {111} faces was In {111} and which Sb {$\bar{1}\bar{1}\bar{1}$.} The distinction is based on x-ray work and its comparison with the results obtained by etching (1, 10, 11).

Results

Etching.—The two inverse {111} planes of InSb, following etching for 5 or more sec in CP-4, showed the expected results: one side of the wafers was glossy, exhibiting round, flat etch pits—(In{111}), and the other was dark and rough—(Sb{$\bar{1}\bar{1}\bar{1}$}).

The HNO_3-HF etchant (1:1 of the concentrated acids) worked similarly: rounded etch pits appeared on the glossy side, as on the Ga{111} side of GaAs (8) but on the inverse Sb{$\bar{1}\bar{1}\bar{1}$} side, irregular triangular etch pits appeared (Fig. 5).

The HCl-$FeCl_3$ etchant produced a different kind of pattern, especially after prolonged treatment (Fig. 2a and b and Fig. 3).

Anodic etching led to round or rounded, triangular pits on the In{111} face. These pits grew in size with the time of etching and finally merged together as observed by Gatos and Lavine (1). The anodic dissolution in 2*N* HCl lasted 15 to 45 min (10 mA/cm^2) and 60 min in 1*N* HNO_3 containing 1*N* tartaric acid. Figure 4 shows a surface which displays merging, round etch pits.

The Sb{$\bar{1}\bar{1}\bar{1}$} plane becomes rough after etching displaying irregular triangular etch pits (Fig. 5) and frequently pits within pits.

Key words: inverse {111} planes, self-dissolution rates, $FeCl_3$ etchant, colloidal Sb, $Sb_4O_5Cl_2$.

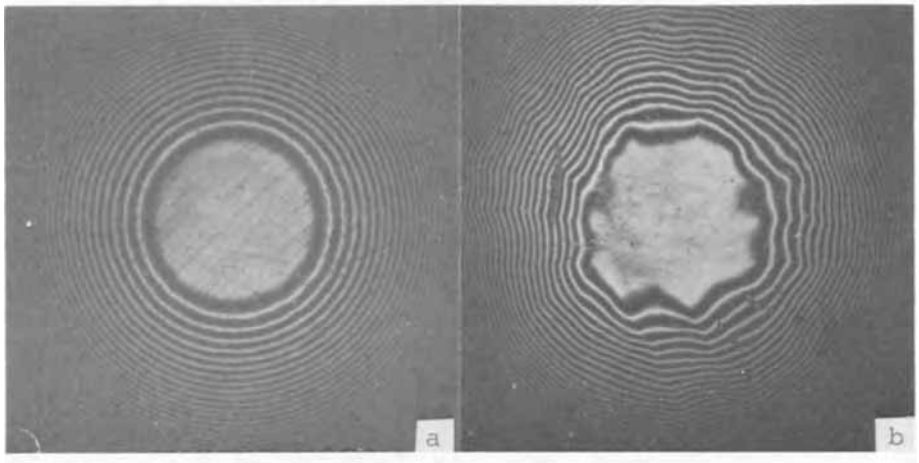

Fig. 1. Interference rings on InSb faces, 165X; a—highly polished; b—etched with CP-4 for 2 sec.

Fig. 2. a—In{111}, etchant: 6*N* HCl-0.2*N* $FeCl_3$; 20 min; 80°C; 970X. b—In{111}, etchant: 2*N* HCl-0.5*N* $FeCl_3$, 24 hr; 25°C; 90X.

Anodic or chemical etching, excepting $FeCl_3$ additions, produced round pits on In{111} faces. The latter were then treated with the HCl-$FeCl_3$ etchant. Dense triangular etch pits, as pictured on Fig. 2a, developed on these faces; even the walls of the deep round pits (Fig. 4) consisted of triangular steps. Thus, submicroscopic steps, which might have been present on the walls of the round pits were developed to microscopic size by the HCl-$FeCl_3$ etchant. No superimposed pattern was observed on the Sb{$1\bar{1}\bar{1}$} face.

The main characteristic in distinguishing the two inverse faces is, therefore, the shiny appearance of In{111} and the dark, rough one of the inverse face. Consideration of etch pits only for recognition may be misleading as the etch pattern changes with the nature of the etchant, its concentration, and time of etching.

Apparent electron number of InSb.—Since some of the anodic dissolution experiments were continued up to 24 hr, it was necessary to know the self-dissolution rate of the InSb used in the various electrolytes. These rates are summarized in Table I, which clearly shows that the self-dissolution rate of InSb in pure 2*N* HCl is nearly zero. It increases considerably in the presence of oxidizers. There is some difference in the dissolution rates of the inverse {111} planes.

The electron number determinations were, therefore, carried out in 2*N* HCl and in tartaric-HNO_3 acid (Table I). The results can be read from Fig. 6, which

Table I. Self-dissolution rates of InSb in various electrolytes in air
Estimated accuracy: ±0.02

Face	Electrolyte	Time, hr	Self-dissolution rate, mg cm^{-2} day^{-1}
In{111}	2*N* HCl	24	0.00
Sb{$\bar{1}\bar{1}\bar{1}$}	2*N* HCl	24	0.00
In{111}	1*N* $H_2C_4H_4O_6$ + 1*N* HNO_3	30	0.07
Sb{$\bar{1}\bar{1}\bar{1}$}	the same	30	0.04
In{111}	2*N* HCl + 0.005*N* $FeCl_3$	45	1.06
Sb{$\bar{1}\bar{1}\bar{1}$}	the same	45	1.33
In{111}	2*N* HCl + 0.01*N* $FeCl_3$	37	2.25
Sb{$\bar{1}\bar{1}\bar{1}$}	the same	37	2.60

indicates that up to current densities below 50 mA cm^{-2} the electron number is 6.00 within error limits. Since In goes into solution as In^{3+} (12, 13), Sb must do the same. The In{111} face seems to be more resistive than the inverse and the {110} and {100} planes, as it tolerates current densities up to 60 mA cm^{-2}. At higher current densities, the apparent electron number decreases, that is more In or Sb goes into solution than predicted by Faraday's law. This can be attributed to the formation of ions of lower valency (14), increased local corrosion and/or anodic disintegration (15-18). However, no particles were observed separating from the InSb anode, only the formation of a film at current densities above 40 to 60 mA cm^{-2}.

Anodic film formation and disintegration.—The films formed on the anode at elevated current densities were nearly black, but displayed a mother of pearl luster. They had a stratified structure (Fig. 7) and were colloidal in nature as they did not produce x-ray diffraction lines. The electron diffraction method was not used.

The same kind of film was produced on both inverse {111} planes. The film could usually be removed from the crystal surface by a soft brush. The substrate side of the film appeared more even than the electrolyte side (Fig. 8a and b).

To investigate the composition of the films, fragments were heated in vacuum at 350°C for about 2 hr. As a result of this treatment, an x-ray diffraction pattern consisting of many sharp lines was obtained. The position of these lines coincided with those of a powder resulting from anodic dissolution of pure Sb in 2*N* HCl and with those of a precipitate obtained by (aqueous) hydrolysis of $SbCl_3$. According to Mellor (19) and the ASTM cards, the composition of the white precipitate is $Sb_4O_5Cl_2$. Since the Sb is trivalent in this compound, this is a further confirmation for the trivalency of Sb ions going anodically into solution from InSb.

The above x-ray patterns exhibited some weak, additional lines. To identify them, the black anodic

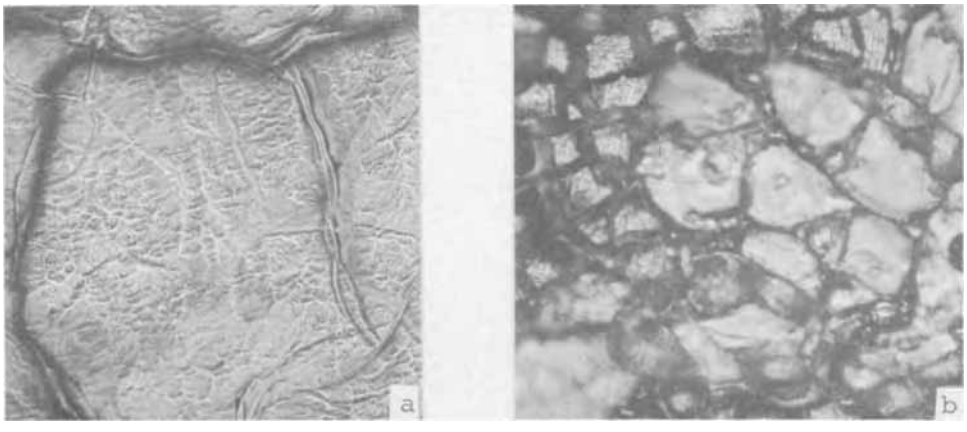

Fig. 8. Black film resulting from anodic dissolution of the In{111} face of InSb in 2*N* HCl at 70 mA cm^{-2}; 970X. a—Substrate side; b—Electrolyte side.

film fragments were heated in vacuum above 650°C (melting point of Sb-630°). At that temperature the black and the white material separated. The latter proved to be $Sb_4O_5Cl_2$, while the former appeared as molten spheres, identified as metallic Sb.

Discussion

Since no reducing species were in the black anodic deposits, metallic Sb must have already been present as very fine particles.

The explanation of the anodic behavior of InSb is then as follows. Both components dissolve anodically as trivalent ions

$$In \rightarrow In^{3+} + 3e \quad [1]$$

$$Sb \rightarrow Sb^{3+} + 3e \quad [2]$$

Although the In^{3+} pass directly into solution, the Sb^{3+} ions hydrolyze, particularly at increased current densities (above 40 to 60 mA cm^{-2}), as a sufficient amount of H^+ cannot penetrate to the surface of the anode

$$Sb^{3+} + H_2O + HCl \rightleftharpoons Sb\begin{matrix}=O\\ \diagdown Cl\end{matrix} + 3H^+ \quad [3]$$

or complete hydrolysis may occur

$$2Sb^{3+} + 3H_2O \rightleftharpoons Sb_2O_3 + 6H^+ \quad [4]$$

The oxychloride as well as the oxide or hydroxide $Sb(OH)_3$ are relatively insoluble and adhere to the anode as layers consisting of crystallites of colloidal dimensions. A further reaction may occur on the surface and after heating

$$Sb_2O_3 + 2SbOCl = Sb_4O_5Cl_2 \quad [5]$$

Simultaneously, during heating, the colloidal product is converted into a crystalline one, detectable by x-ray diffraction.

Since metallic Sb is much more noble than In, the Sb atoms of the InSb have a tendency to retain their valence electrons whereas In is readily oxidized and goes easily into solution. Consequently, especially at increased current densities, the In atoms surrounding the Sb atoms dissolve and some of the latter embed themselves into the oxychloride film (Eq. [5]), which is simultaneously formed according to Eq. [3] and [4] by a part of Sb^{3+}. The oxychloride film prevents the Sb atoms from collecting into particles larger than colloidal (20). As a consequence, the white, possibly transparent film turns dark, and the electron number (or the apparent valency) drops. Thus, partial disintegration of the Sb on the surface of the InSb occurs, and the resulting product does not produce x-ray interference lines. The film formation process may proceed periodically, starting where there is a weakness in the thin film or where a breakdown of the film takes place. A film of stratified structure results (Fig. 7). Upon heating in vacuum, the colloidal particles of the oxychloride and the Sb grow separately to form larger entities which can now produce x-ray diffraction lines.

That the Sb{111} is more susceptible than In{111} to partial Sb disintegration (Fig. 6) depends evidently on the characteristic structure of these inverse planes. According to Galaev and Gorelik (21), the bond strength on the Sb{$\bar{1}\bar{1}\bar{1}$} plane should be weaker than on the In{111} plane. Consequently, the former is easier to destroy; its hardness is less; and the outer Sb atoms are more remote from the In atomic layer than on the inverse side (21). This explains why the partial Sb disintegration on Sb{$\bar{1}\bar{1}\bar{1}$} and on {110} and {100}) planes starts at lower anodic current densities than on In{111}.

Finally the weaker bond strength on Sb{$\bar{1}\bar{1}\bar{1}$} suggests that this plane should be attacked by etchants at a faster rate than the inverse plane. Table I shows the correctness of this conclusion. The difference in the rates of corrosion of the two inverse {111} planes in HNO_3-tartaric acid is, however, within the limits of error.

Anodic Dissolution of N^+ Silicon

Ronald L. Meek

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

An experimental study has been made of the anodic dissolution of silicon in aqueous HF solution with emphasis on heavily doped n-type. Current-voltage curves, the effective dissolution valence, and the critical current density have been determined for n, n^+, and p samples. Since n^+ silicon has a resistivity less than 0.05 ohm-cm, it can be electropolished while higher resistivity material exhibits a current saturation effect although breakdown occurs at only a few volts. Minority carrier generation within the space charge region does not account for the magnitude of the saturation current for n-type and extensive attack was evident at the surface of n-type which had received prolonged anodic treatment. The critical current density for n^+ samples was found to be a function of the resistivity.

Numerous applications (1) of electrochemical processes in semiconductor technology have been proposed and utilized since the paper of Brattain and Garrett (2) established the field of semiconductor electrochemistry. Many of these utilize selective etching or staining effects exhibited by the semiconductor electrode dependent on resistivity, type, potential, and the nature of the solution. In particular, it is well known that n^+ and p silicon electrodes are readily anodically dissolved, electropolished, in HF solution, whereas those of n material are not. While the behavior of p-type, and to a lesser extent n-type, has been thoroughly investigated, the behavior of n^+ silicon in aqueous HF has not been widely studied and consequently is poorly understood.

Anodic Dissolution of Silicon

The anodic dissolution and electropolishing of silicon in aqueous hydrofluoric acid solutions was first accomplished by Turner (3) and has recently been studied by Memming and Schwandt (4). The dissolution mechanism for semiconductors in general and silicon in particular has been discussed by numerous authors (3-9), the over-all reaction being most simply written as

$$Si_{(solid)} + 6F^- + (4 - n)h^+ \rightarrow SiF_6^{=}{}_{(soln.)} + ne^- \quad [1]$$

where quadrivalent dissolution has been assumed and n is a number between zero and four. (h^+ represents a hole-valence band charge transfer, and e^- an electron-conduction band charge transfer.) The physical picture behind Eq. [1] is that the primary reaction (perhaps the initial breaking of covalent bonds) requires holes and that these reaction products are unstable allowing electrons to go into the conduction band (2). This leads naturally to current saturation on n-type anodes (2). The importance of valence band charge transfer has been well established by the multitude of experiments which have shown the dissolution current to be increased by any process which increases the supply of holes (2, 5, 8).

As might be expected from its form, Eq. [1] reveals little of the dissolution chemistry. Its vagueness becomes apparent once it is realized that n is not an integer and in general depends on the material resistivity and the current density (2, 5). Part of the difficulty is that effectively divalent dissolution has not been considered and, as will be seen shortly, a significant fraction of the semiconductor atoms always enter solution divalently. Although it is not certain that they are present, if the formation of divalent silicon compounds is allowed, say SiF_2, the disproportionation

$$2SiF_2 + 2F^- \rightarrow Si + SiF_6^{=} \quad [2]$$

or, in general, polymerization

$$(1 + x)SiF_2 \rightarrow Si_xF_{2x+2} + Si \quad [3]$$

reactions must be accounted for.

In principle, analysis of the elementary steps

$$Si^{+m} + h^+ \rightarrow Si^{m+1} \quad [4a]$$

or

$$Si^{+m} \rightarrow Si^{m+1} + e^- \quad [4b]$$

where $m = 0$ to 3, should be undertaken. (In writing [4a] and [4b] it is understood that silicon atom is bonded to and complexed with the crystal lattice and/or appropriate solution species.) Then allowing for any other reactions such as are illustrated by [2] and [3] and for any larger aggregate dissolved species would yield an over-all description of the dissolution if the appropriate concentrations and rate constants (energy barriers and their tunneling probabilities) were known. From the data on n- and p-silicon it can be concluded that reaction [4a] is favored over [4b] for $m = 0$ (the initiating step). Reaction [4b] presumably becomes more competitive as m successively increases to 1, 2, and 3. The numerous possible reaction paths clearly allow n in Eq. [1] to have a noninteger value even if no divalent dissolution occurs.

Any hypothetical mechanism must account for the fact that heavily doped n-type semiconductors can pass large currents and be electropolished quite nicely (10, 11). Gereth and Cowher (12) have concluded from measurements of the corrosion potential, I-V curves in alkaline solution with and without added oxidizing agents, and the temperature dependence, that dissolution of heavily doped n-type germanium does not depend on holes but goes entirely by a conduction band mechanism. The details of what occurs are not at all clear.

It must not be supposed that n^+ material becomes "just like a metal" since the bonds are still covalent, as opposed to the metallic bonding and consequent indistinguishability of charge transfer paths for a metal. A detailed semiconductor dissolution mechanism must deal with the electrons in these localized covalent bonds. Evaluation of possible current flow mechanisms in light of capacitance-voltage measurements of the n^+ silicon-electrolyte interface will be made in a separate paper.

Experimental Method

All current-voltage data reported herein were taken using thick (6 mm) silicon slices about 3 cm in diameter which were held vertically in the Teflon sample holder shown in place in a thermostated electrolyte bath in Fig. 1. The electrolyte was 5 w/o (weight per cent) aqueous HF (2.5N) which is in about the center of the practical range of concentrations for electropolishing silicon (1-5N) (13). The area of the slice exposed to the solution was 1.27 cm^2 and, unless stated

Key words: silicon electrochemistry, anodic dissolution, n-type silicon.

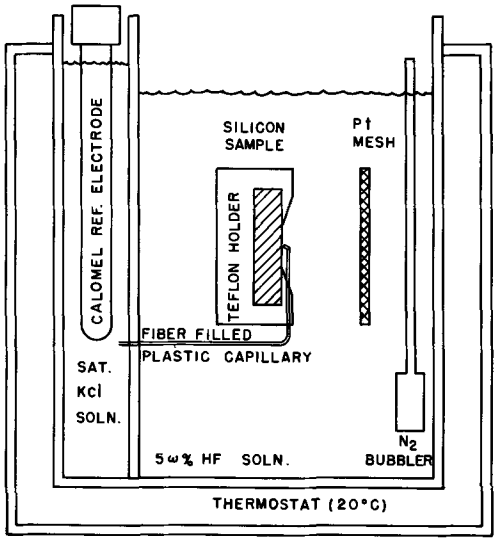

Fig. 1. Experimental arrangement for current-voltage measurements.

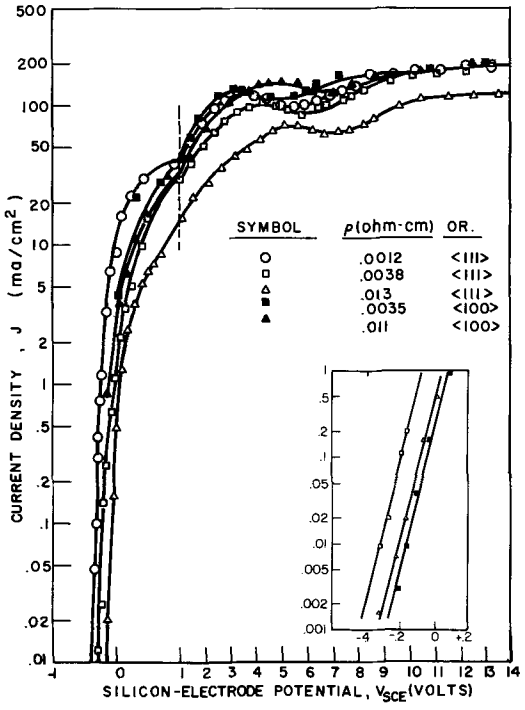

Fig. 2. Current density *vs.* silicon electrode potential for n^+ silicon. (Note change of scale at +1V.)

otherwise, all experiments were performed at 20°C and in the dark. The cell configuration and dimensions were chosen to simulate as closely as possible the conditions used for an electrochemical process of technological interest. The electrolyte was purged with nitrogen before data were taken and during experimentation nitrogen very slowly bubbled through the solution near one wall of the cell which was kept under a nitrogen cover. The silicon samples of <111> and <100> orientation were of n- and p-type doped with As and B, respectively, and were initially chemically etched and silica-sol polished.

The silicon sample was held at a set potential relative to a platinum mesh auxiliary electrode having a projected area of 25 cm². This electrode is placed 2 cm from the exposed silicon surface and the tip of the capillary which connects to the reference electrode chamber is about 1 mm removed (see Fig. 1). The cell potential, the silicon electrode potential *vs.* the saturated calomel reference electrode, and the current are recorded on a point to point basis (as opposed to sweeping through a potential range).

For the case of silicon samples that could be electropolished (n^+ and p), the surface was prepared before each measurement by electropolishing. This was found to give reproducible results whereas simply going from one cell potential value to another yielded a hysteresis effect at intermediate current densities. In the case of n-silicon, which cannot be electropolished, reproducible data could be taken by step-wise increasing of the cell potential. Selected values of potential and current which were taken in this way were checked by repeating the measurement at the same cell potential using a fresh silica-sol polished surface.

Only anodic currents are considered here. Attempts to measure cathodic currents showed that two rather reproducible current values were obtained for a given cell potential depending on whether the surface was electropolished or had received an extended cathodic treatment at relatively large negative potential (several volts). Furthermore, the two values do not approach one another for current densities less than a few milliamperes per square centimeter even after many tens of minutes. [Similar effects have previously been observed for both Ge and Si (5).] Clearly some sort of hydrogen pretreatment of the electrode is involved, but since it was not of direct interest to the present study this phenomenon was not investigated further.

Experimental Results

Current voltage relation for n^+ silicon.—Current density as a function of the silicon potential (relative to the saturated calomel reference electrode) has been measured on samples having resistivities in the range 0.001-0.01 ohm-cm with <111> and <100> surface orientations. The results are summarized in Fig. 2. The open-circuit potential, $V_{SCE}(J = 0)$, is in the range −0.3 to −0.4V for these heavily doped samples as well as for lightly doped n and p specimens to be discussed shortly. The value, however, is not too reproducible (±20 mV) although in general most negative for n^+ and p samples being usually somewhat less negative for n silicon. For current densities below a few tenths of a milliampere per square centimeter a Tafel relation applies, the slope being about 0.1V/decade in agreement with other measurements on silicon anodes (8).

For descriptive purposes attention is focused on one of the curves of Fig. 2, −0.0012 ohm-cm, <111>-orientation. Above a few tenths of a milliampere per square centimeter the experimental curve departs from the Tafel line and below 17 mA/cm² a film forms on the silicon surface. (This "critical" current density will be discussed further in a subsequent section.) Above this current density no film is formed. As the potential is further increased, the current goes through a maximum of about 120 mA/cm² at 3V. Below this potential, dissolution with no film formation occurs but the surface is not electropolished; for greater potentials, a bright electropolished surface is produced.

Figure 3a shows a surface after extensive anodic dissolution at a current density only slightly greater than that at which film formation is observed. Numerous small pits are observed and the surface appears almost as if sand blasted. At a somewhat greater current density, Fig. 3b, the surface exhibits the familiar "orange peel" appearance often observed on chemically etched surfaces. This figure also displays one of the conical pits which are sometimes observed at these intermediate current densities. When such a surface is etched with a dislocation revealing etch, a pit is usually formed at the site of the electroetched pit and it is suggested that they are due to dislocations.

As the potential is further increased beyond the point corresponding to the current maximum, electropolishing of the surface takes place and the current density first goes through a minimum and then steadily increases with applied potential. This maximum/minimum behavior is presumably due to change in

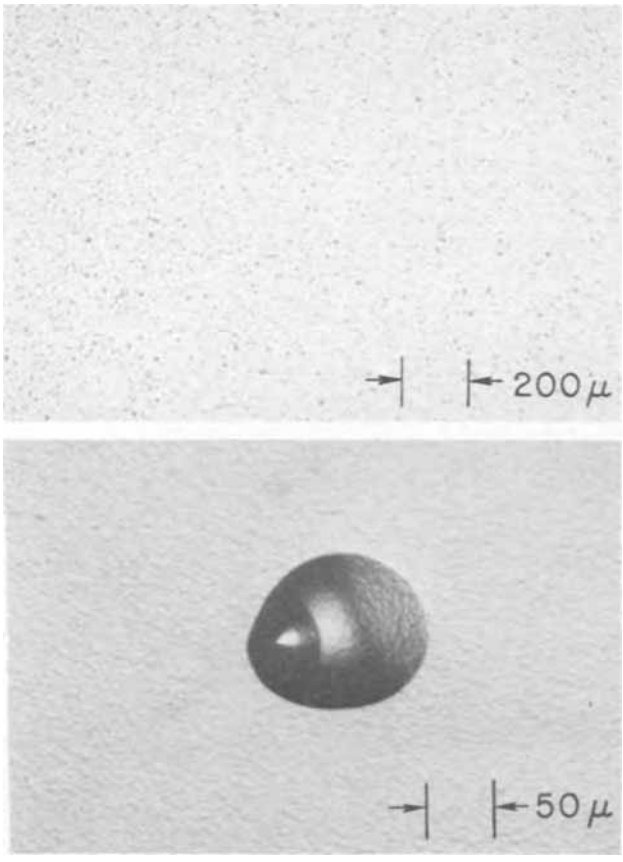

Fig. 3. n^+ Silicon surfaces after anodic dissolution at low current densities. (a) (top) $J \simeq 1.1\ J_c$; (b) (bottom) $J \simeq 50$ mA/cm^2.

structure of the silicon/solution interface; that is, development of the "polishing film."

At a given silicon potential, the current density is seen to be a function of the material resistivity and orientation. <100> surfaces draw a greater current density than <111> surfaces for the same resistivity. That this is to be expected can be argued from the number and accessibility of the surface bonds. Such orientation effects have been well documented (8). Also, for a given potential and surface plane, the current density decreases with increasing resistivity. The curves could be made to coincide only by shifting along both the current and potential axes since the maximum and minimum occur at different potentials for different silicon resistivities. Clearly, this J-V behavior cannot be explained in any detail until the dissolution mechanism can be clarified. Measurements on samples where the dopant was Sb or P rather than As showed the J-V relation to be independent of the dopant atom.

In Fig. 4 J-V data are presented for p silicon in the resistivity range 0.01-1 ohm-cm and of <111> and <100> orientation. The general behavior of the current voltage curve is the same as was observed for n^+ samples, the current density magnitude being comparable to that for the most heavily doped n material. While <100> surfaces may draw slightly more current than <111> surfaces at the same potential, there is no resolvable dependence on the material resistivity. It is tempting to explain this resistivity effect by arguing that for p silicon of any resistivity all the holes that could possibly be consumed are readily available at the surface whereas for n^+ silicon a barrier to current flow exists and that the magnitude of this barrier decreases with decreasing resistivity. The orientation dependence for n^+ would seem to imply that bond accessibility is also important in determining this barrier.

Effective dissolution valence and critical current density.—An effective dissolution valence, ν_e, is defined

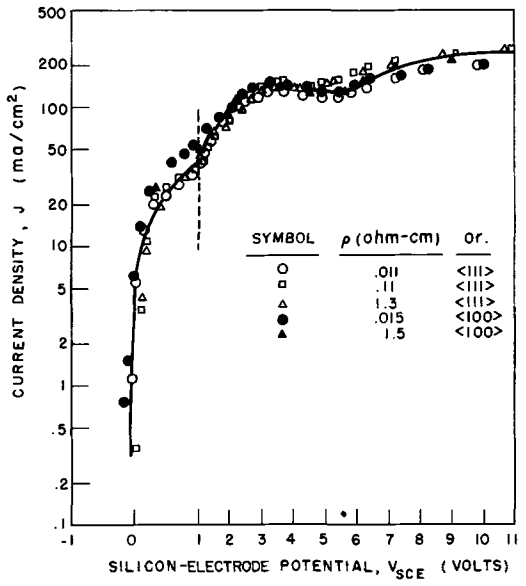

Fig. 4. Current density vs. silicon electrode potential for p silicon. (Note change of scale at +1V.)

as the number of electronic charges passing through the external circuit per atom of silicon entering solution. If both divalent and quadrivalent dissolution are allowed, then the ratio of the number of atoms going into solution as Si^{+2}, N_2, to those as Si^{+4}, N_4, is

$$\frac{N_2}{N_4} = \frac{4 - \nu_e}{\nu_e - 2} \qquad [5]$$

The experimental data for heavily doped n-type silicon are given in Fig. 5 where the effective valence has been plotted *vs.* the silicon-electrode potential. The range of potentials covered is from at or very slightly below the potential at which surface film-formation is observed to well into the electropolishing region. Even for large potentials and current densities (~200 mA/cm^2) a significant fraction ($N_2/N_4 \simeq 0.1$) of the silicon goes into solution in the effectively divalent form. When ν_e drops much below 3 ($N_2/N_4 = 1$) formation of a surface film is observed. Figure 5 may be used with the J-V curves to obtain the electropolishing (or etching) rate.

It has been observed by a number of authors, but in particular by Turner (3), that below some characteristic current density a thick brown film forms on anodically biased silicon electrodes, which film was thought to be amorphous silicon (13). Based on the facts that this characteristic, or critical, current density increased with increasing temperature, with increasing concentration of HF in solution, and with decreasing solution viscosity, Turner (3) concluded that the phenomenon was due to the HF concentration

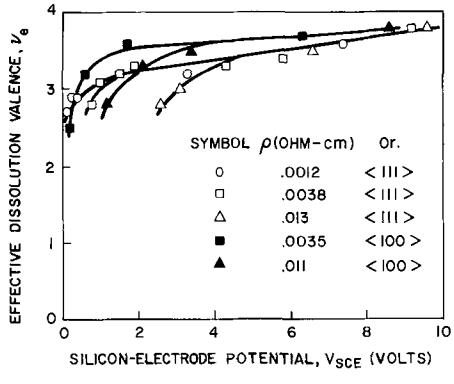

Fig. 5. Effective dissolution valence vs. silicon electrode potential for n^+ silicon.

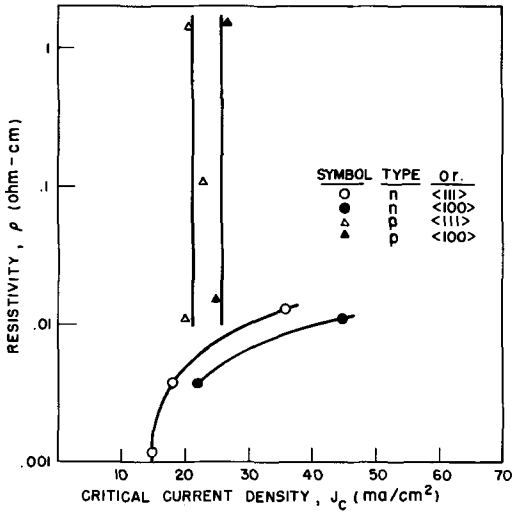

Fig. 6. Critical current density for brown film formation as a function of resistivity, conductivity type, and orientation.

at the silicon-solution interface increasing above some critical value.

The present determinations of this critical current density, J_C, are presented as Fig. 6 for various resistivities and orientations of n^+ and p silicon. The HF concentration, as in all experiments, was 5 w/o. The first rather startling observation to be made is that this current density is definitely a function of resistivity and apparently also of surface orientation for n^+ material. This is not explicable on the basis of a limiting surface concentration of some species transported from the bulk of the solution. For p silicon, the critical current is independent of resistivity and the apparent orientation dependence is hardly greater than the experimental uncertainty.

Turner (3) found for horizontal p-type electrodes facing up and conditions otherwise the same as the present experiments that $J_{c(H)} = 55$ mA/cm² whereas the present determination is $J_{c(V)} = 20$ mA/cm² for a vertical surface. For some species transported from the solution bulk to the interface

$$W_H = k_H(C_s - C_i) \quad [6a]$$

and

$$W_V = k_V(C_s - C_i) \quad [6b]$$

where W is the mass flux to the surface, k is the mass transfer coefficient, and $C_s(C_i)$ is the bulk solution (interface) concentration of the species in question. The subscript H(V) specifies a horizontal (vertical) electrode. At steady state, and if this diffusing species enters the dissolution reaction it is to be expected that

$$J \propto W \quad [7]$$

Thus the conclusion is that

$$J \propto k$$

or

$$\frac{J_V}{J_H} = \frac{k_V}{k_H} \quad [8]$$

The free convection problem for the vertical surface has been solved (14) but not that for the horizontal one. Appeal can be made however, to the well-known similarity between the mass-transfer and heat-transfer problems (14, 15). For free convection heat transfer from plates to fluids (15) it is known that the coefficient is less for the vertical than the horizontal plate. In addition, the present experimental arrangement is not fully equivalent to the vertical surface as the sample is considerably set back in the holder, further reducing the mass transfer coefficient (increasing the boundary layer thickness) relative to a horizontal surface. Thus from Eq. [8] it is expected that the critical current density in the present experiments should be less than that measured by Turner (3), as was in fact found to be the case.

The present results then support the earlier conclusions (3), but for n^+ silicon other factors must also be of importance. This difference appears to be related to the interface barrier which for p silicon is independent of resistivity but on n^+ silicon depends on the doping level.

Some further comments on the nature of the thick surface film are in order. First, the film in no sense passivates the surface. After a few minutes, the film thickness appears to reach a constant value and neither the current density nor the silicon electrode potential change with time even while the film is developing. Second, it is often stated that the films produced react vigorously, even explosively, with strong oxidizers (HNO_3,H_2O_2). Silicon samples, upon which such films were grown, have been placed in nitric acid and hydrogen peroxide solutions for 24 hr and no reaction whatsoever has ever been observed. If, however, the film is removed and placed in the oxidizing solution, it disintegrates immediately. (Dissolves or reacts do not seem to be appropriate descriptions.) Apparently the latter observation is the result of some change induced in the film when it was removed from the silicon (by raising the potential and polishing out the underlying silicon so that the film floated off).

The chemical composition of the films which form on silicon when anodized at low current in HF solution or when etched in HF:HNO_3 mixtures, very dilute in HNO_3, is uncertain. Mass analyses (13, 19) have indicated the films are 90+ w/o silicon and Turner (13) postulated that they were amorphous silicon while Archer (19) proposed that they were silicon hydrides at least in the case of films formed in HF:HNO_3 mixtures. Yoshioka (20) and Beckmann (21) have studied the films formed in HF:NO_2 gas mixtures (20), anodically in HF, and in HF:HNO_3 (21) by infrared spectroscopy (20, 21) and omegatron mass analysis (20) and have found them to be mostly silicon hydrides. It is felt that in the anodic case the film is probably at least partially silicon hydrides and that it is in fact the presence of hydride films which passivates silicon surfaces to direct attack by HF which would be expected thermodynamically. It may be mentioned that hydride films are known to be formed on the surfaces of some metals dissolving in hydrofluoric acid (22).

Current voltage relation for n silicon.—Silicon of n-type resistivity greater than 0.05 ohm-cm shows current saturation as the potential is increased. Figure 7 presents the J-V data measured for n-type samples. Up to a current density of about 50 μA/cm² the current remains at a constant value for at least an hour. Here again, it must be noted that no passivation occurs and some slow dissolution is always taking place. However,

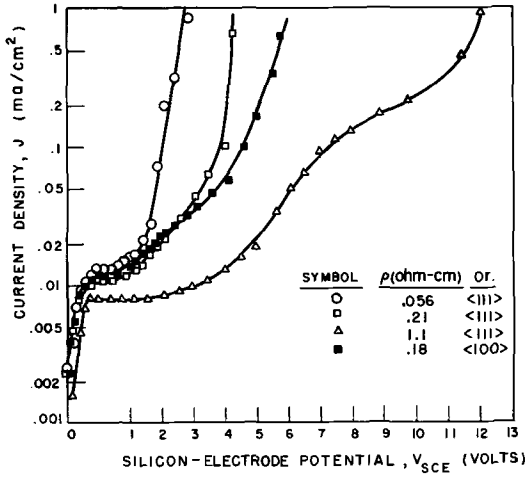

Fig. 7. Current density vs. silicon electrode potential for n silicon.

a measurable uniform etching of n-type has never been observed, rather pitting occurs. For somewhat greater potentials (but current densities less than 1 mA/cm²) the current stabilizes at a constant value for about the first minute after the potential is applied (it is this point that is plotted in Fig. 7) and then slowly increases over a period of about an hour to a second value of the current density (but with larger fluctuations, 10-20%, about the mean) of about 2 to 5 times the initial value. Beyond the range plotted in Fig. 7 (that is, currents greater than 1 mA/cm²) the fluctuations in current are so large and erratic that no meaningful measurement can be made. This may indicate the breakdown of a surface film and the existence of a second current voltage relationship in its absence. The saturation currents observed, about 10 μA/cm², are comparable to those measured by Flynn (16) for silicon. The present data, however, show lower saturation currents for the higher resistivity material, whereas the opposite is observed for Ge (17). This could be due to differences in the concentration of generation centers from sample to sample. For silicon, the saturation current is said to be dominated by the space charge generation current (8), I_g where

$$I_g \propto N_g \sqrt{\rho} \qquad [9]$$

N_g is the density of generation centers and ρ the resistivity. It is not unreasonable to suppose that N_g is greater for the more highly doped material due to incorporation of greater amounts of foreign substances which do not affect the resistivity and due to the expected increase in crystallographic defects.

However, from the observed saturation current, an effective lifetime may be estimated from (8)

$$J_{gen} = \frac{en_i}{2\tau_0} W \qquad [10]$$

where e is the electronic charge, n_i the intrinsic carrier density, W the space charge width, and τ_0 the lifetime. For the 1.1 ohm-cm sample, for which the current density is 8 μA/cm², τ_0 is, from Eq. [10], 7 $(10)^{-9}$ sec; whereas the actual lifetime was determined to be 3 $(10)^{-8}$ sec by use of the MOS deep depletion technique. A low-temperature plasma oxide was used so the lifetime would not be changed by high-temperature processing. Therefore, the currents observed cannot be explained on the basis of space charge generation alone. It would appear that other factors such as surface generation and injection may also be important, and there may be localized areas of high current density at the surface connected with the localized breakdown examined next. As will be discussed later, the silicon is observed to be nonuniformly attacked after extensive anodic dissolution above the saturation current region.

As has been observed also for germanium (17), saturation breakdown occurs at a voltage an order of magnitude less than would be expected from abrupt junction avalanche considerations. Breakdown is not uniform, but occurs at numerous isolated spots on the surface. This results in a heavily pitted surface, to be discussed further in the following section, and would appear to be due to local electrochemical attack. The breakdown has not been studied in detail but it is possible that it occurs at crystal defects or points of impurity segregation (8, 18). The apparent explanation for the initial and final steady currents observed for the initial current values greater than 50 μA/cm² is that the initial value is characteristic of the smooth polished surface and the final value corresponds to the pitted surface. It has been observed (8) that for 1 ohm-cm n silicon in KOH and H_2SO_4 solutions, breakdown does not occur until potentials of 70 or 80V are applied, but it seems likely that a significant portion of this voltage appears across an anodic oxide film.

Figure 8 illustrates the familiar increase in saturation current due to illumination of the surface. When

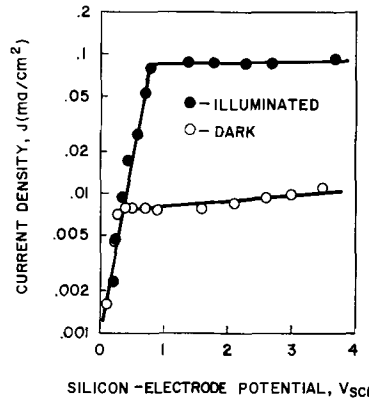

Fig. 8. Current density, potential relation for n silicon (ρ = 1.1 ohm-cm <111>) in the dark and illuminated.

the same light is shined on n+ samples no effect is observed over the entire range of current densities.

Effect on n silicon of prolonged anodic treatment.— Due to the large and erratic currents which n silicon was observed to draw at relatively low potentials and the fact that an electrochemical process of interest allows n material to be exposed to the solution at significant potentials for extensive times, it was deemed necessary to ascertain the effect of prolonged anodic treatment. A total charge of 0.2 coulomb was passed through the samples at various cell potentials, and the surface was microscopically examined. This was followed by a 10-sec etch (white etch-1HF:3HNO_3) examination, a 2 min-etch, and a final observation of the surface. The surfaces subsequently to be described are all of <111> orientation.

Figure 9a shows the surface of a sample for which the (initial) current density was 0.2 mA/cm² (well above the saturation current) after anodization. The surface is very densely and harshly pitted and is somewhat reminiscent of a mechanically damaged one. After the 10-sec etch a curious phenomena is observed as illustrated by Fig. 9b which shows the surface to be covered by a dense brownish-black adherent layer. This cannot be wiped or even scraped off and always covers all of the area which was exposed to the electrolyte. A subsequent 2-min etch removes this film and

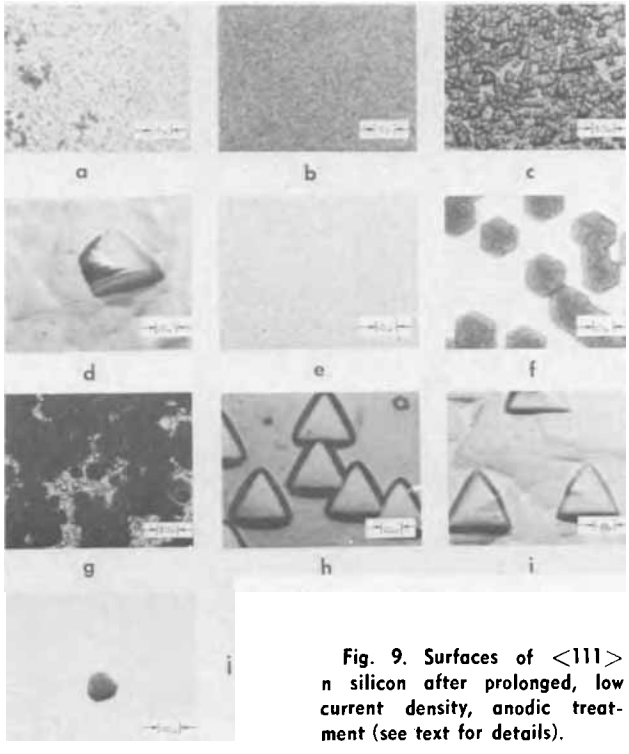

Fig. 9. Surfaces of <111> n silicon after prolonged, low current density, anodic treatment (see text for details).

produces a densely pitted surface, Fig. 9c. Most of these pits are not further resolvable, but in some places pits as shown in Fig. 9d are found. At or slightly above the saturation current, 10 to 20 μA/cm^2, the surface after anodic treatment appears as in Fig. 9e. The small shallow pits produced are of a surprisingly regular size and spacing. A 10-sec etch produces the hexagonal features of Fig. 9f and g and it is at once realized that 9b consisted of a complete coverage of the surface by these features which appear to be shallow pits, the bottoms of which are filled with the brownish-black matter. Figure 9f is for saturation current and Fig. 9g for a current twice the saturation value. When the 2-min etch is performed, the surface is again observed to be covered with pits as shown in Fig. 9h and i. Those of Fig. 9h are much more common than the more structured pits of 9i. (It must be emphasized that no pitting occurs on portions of the sample not exposed to the electrolyte.) When the current is below the saturation value, in particular 2 μA/cm^2, no resolvable features are observed after 0.2 coulomb are passed. However, after a 10-sec etch, of the order of 10 of the hexagonal features as shown in Fig. 9j are observed per square centimeter of surface. For <100> surfaces the same behavior is observed except that the hexagons become squares. It is apparent then that if usable n-type silicon is to be reclaimed after it has been anodically exposed that careful attention must be paid to the process parameters such as silicon potential and exposure time. Clearly, this also introduces limitations on the structures which may be produced by electroetching processes.

Summary

The details of the mechanism of anodic silicon dissolution are at present rather obscure especially for heavily doped n-type samples. More information will be needed before a thoroughly convincing model can be constructed because the properties of the interface region where the relevant electrochemical reactions take place are largely unknown.

Current-voltage curves, the effective dissolution valence, and the critical current density have been measured for silicon of various orientation, type, and doping level. The n$^+$ silicon of resistivity less than 0.05 ohm-cm can be electropolished and the J-V relation, which depends on the resistivity and orientation, may be divided into three regions. Below a critical current density, which itself is a function of orientation and resistivity, a steady current passes at constant cell potential but the well-known thick brown film forms on the electrode surface. It has been found, as a supplement to previous observations, that the film does not react at all with strong oxidizing agents if it is not removed from the silicon. This also applies to films formed on p silicon for which the resistivity has no effect on the critical current density value.

The second portion of the J-V curve extends from the critical current density to a maximum in the J-V curve observed at a silicon electrode potential of a few volts and $J \simeq 100$ mA/cm^2. In this range dissolution occurs without any film formation but the surface is rough and pitted; this is an etching, as opposed to electropolishing, regime. Beyond the maximum, bright electropolishing occurs. Measurements on p samples show the J-V curve to be independent of resistivity, the general features being the same as for n$^+$.

From measurement of the effective dissolution valence it is seen that even at large potentials a significant portion, 10%, of the material enters solution effectively divalently. The thick brown film apparently forms once the effective valence drops much below three, that is when more than half of the dissolution is divalent. It appears that for n$^+$ silicon a factor in addition to the surface HF concentration is involved in the critical current density determination.

The n-type silicon having resistivity greater than 0.05 ohm-cm exhibits current saturation but breakdown occurs at only a few volts even for 1 ohm-cm material. The breakdown is not uniform but occurs at localized points on the surface and causes extensive damage to it at least for <111> and <100> surfaces. Prolonged anodic bias at currents above saturation has been shown to result in extensive attack at the surface.

Acknowledgments

The author would like to thank R. H. Braun for assistance with the measurements and P. J. Boddy and M. P. Lepselter for valuable discussions. G. W. Reutlinger determined the lifetime quoted and J. R. Ligenza grew the low-temperature plasma oxide involved.

Corrosion and Passivation of Thin Molybdenum Films

L. H. Lee* and V. Y. Doo*

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Corrosion behavior of thin molybdenum films was investigated in the environments of air, fluorochemical liquid coolant ($C_5F_{11}NO$), and deionized (DI) water in the 70°-100°C temperature range. A striking similarity both in kinetics and mechanism was observed for the corrosion of molybdenum film in dry air and dry coolant ($C_5F_{11}NO$), as well as moist air and wet coolant ($C_5F_{11}NO/H_2O$). Molybdenum remains inert in dry environments and corrodes in the wet media. In addition, molybdenum forms a nonprotective, porous corrosion film and dissolves in DI water at 85°C. The simultaneous presence of water and oxygen in these environments is the controlling factor on the corrosion of molybdenum films. An effective passivation of thin molybdenum films can be provided by either a single layer of silicon dioxide or a composite layer of silicon nitride over silicon dioxide on the metal film.

For the past decade, metal and insulating thin films have received increased attention principally for their broad application in microelectronic components. Metal thin films serve as ohmic contacts and interconnections in integrated circuits, and insulating films serve as diffusion masking and surface passivation. To have good performance and reliability, the metal films require low-resistance ohmic contacts, good adhesion to oxide and silicon, and resistance to deterioration at the temperature and conditions of use. Among the limited materials (1) which meet these criteria, molybdenum has been suggested (2) for integrated circuits because of the unique combination of such properties as good thermal stability, reasonably high electrical conductivity, and good adhesion to oxide and silicon. However, limited information on the corrosion of molybdenum is available (3, 4). For a fuller understanding of molybdenum corrosion behavior in the environments of air and several commonly used coolants including water and fluorochemical liquid ($C_5F_{11}NO$), accelerated corrosion tests were conducted in these environments to study the kinetics and mechanism of corrosion. A method of passivating the molybdenum films by pyrolytic silicon dioxide and silicon nitride films was also developed.

Experimental

Materials.—A 6000-7000Å layer of silicon dioxide was thermally oxidized on 1¼ in. diameter silicon wafers. Two 12,800Å thick molybdenum films were deposited on the silicon dioxide, the first by RF sputtering and the second by chemical vapor deposition. Molybdenum blanket films were produced by the RF sputtering process at a rate of 500 Å/min at 500°C. The pyrolytic molybdenum films were deposited by the hydrogen reduction of $MoCl_5$, followed by the formation of a photolithographic pattern. For passivated samples, pyrolytic silicon dioxide of various thickness was deposited at 475°C at a rate of 350 Å/min using an O_2:SiH_4 ratio of 10:1; silicon nitride films were produced by RF glow discharge at 450°C. All samples were degreased in acetone and air dried before testing. Fluorochemical liquid coolant ($C_5F_{11}NO$), air, and DI water were employed as the basic environments for corrosion study.

Exposure details.—Liquid coolant was used with water ($C_5F_{11}NO/H_2O$) and without ($C_5F_{11}NO$) as a second phase. When the tests were performed in aerated condition, specimens were enclosed in a mechanically sealed 50 ml Pyrex tube. Each tube contained one specimen along with 25 ml of $C_5F_{11}NO$ which had been saturated with compressed air by bubbling for 10 min. An additional 5 ml of DI water was added to the tube whenever required. For the tests in deaerated $C_5F_{11}NO$, the liquid was degassed by an alternating freeze/melting vacuum technique (5). Specimens were vacuum sealed in a heavy-walled Pyrex tube which contained one specimen and 5 ml of $C_5F_{11}NO$, plus 1 ml of DI water. By deaeration, the oxygen concentration in $C_5F_{11}NO$ was reduced from 84 to 18 μg/ml. All test tubes were placed in the conventional laboratory ovens in such a position that the specimens were completely immersed in $C_5F_{11}NO$. Unless otherwise stated, aerated $C_5F_{11}NO$ and $C_5F_{11}NO/H_2O$ were employed. During the experiment, specimens were removed alternately for the measurements and carefully handled to eliminate any direct contact with water. When the tests were conducted in DI water, a similar procedure was employed. Test temperature was accurately controlled and maintained constant within ±1°C. For the tests in dry air, a laboratory oven was used; in moist air, a temperature-humidity cabinet[1] was employed. The specimens were handled in glass cradles to permit air circulation.

Methods of evaluation.—The corrosion of molybdenum films was determined by several measuring techniques. The method chosen depended entirely on the characteristics of the corrosion film. The gravimetric method was used when the corrosion film was thick and visible to the naked eye. Ellipsometry was employed when the corrosion films were thin and invisible. Both measurements were made in the atmosphere at room temperature.

The gravimetric method has long been favored for conducting laboratory corrosion experiments. Samples were weighed with a microbalance[2] which gives accurate readings to ±5 μg. The changes in weight per unit area were recorded.

Ellipsometry is the measurement of the changes in the state of polarization of light when reflected from a surface. By determining and comparing the optical properties of a film-free and a film-covered metal surface, the film thickness can be determined with accuracy. The principle and application of the ellipsometer[3] have been detailed elsewhere (6-8). Metallographic examination and statistical evaluation were also employed to study the corrosion and passivation of molybdenum films.

Results

Corrosion of thin molybdenum films.—$C_5F_{11}NO$ was used as an effective coolant for high-power electronic devices (9). Sputtered films exposed to $C_5F_{11}NO$ at

temperatures of 70°, 85°, and 100°C remained shining with no measurable weight change after 2000 hr immersion. Electron diffraction showed the presence of oxides, but their exact composition was not identified. Figure 1 shows the increase of oxide film thickness as a function of time. It was observed that all specimens oxidized slowly, reaching a film thickness less than 35Å after 2000 hr immersion. Tests in dry air gave similar results. Note that good agreement both in magnitude and curve shape was obtained in these two environments. The oxide film grew linearly with the logarithm of time. A distinct break was observed on these curves corresponding to a two-stage oxidation. The film thickness increased with increasing temperature and the critical time for the transition of the oxidation rate decreased with increasing temperature. Generally, the logarithmic rate relationship prevails at low temperatures for thin oxide films (10).

During the ellipsometer measurements, it is difficult to determine the optical constants of the clean metal surface without any superficial oxide film. In this investigation, we assume that the clean metal surface gives a minimum value of the measured azimuth φ and a maximum value of the phase difference Δ. The theoretical values of Δ and φ were plotted and compared with those experimental data obtained from various periods of the surface film growth (11, 12). A trial curve fitting gave a refractive index of 2.3.

In $C_5F_{11}NO$, the influence of dissolved water on molybdenum corrosion was studied with the presence of water as a second phase. Molybdenum formed a nonprotective porous corrosion film in aerated $C_5F_{11}NO/H_2O$ from 70° to 100°C. Figure 2 shows that the sputtered molybdenum films reacted at a continuously increasing rate with time and temperature. Further, the corrosion film tended to disintegrate and flake off after reaching a critical thickness or critical time as indicated by the arrows. In this instance, the corrosion film served no protective purpose and did not reduce the corrosion rate. Comparing the results obtained in $C_5F_{11}NO$ with those in $C_5F_{11}NO/H_2O$, the corrosion rates differed by three orders of magnitude. In addition, the character of the film changed from protective to nonprotective. There is no doubt that water exerts a significant effect on the corrosion of molybdenum in $C_5F_{11}NO/H_2O$. Attempts have been made to analyze the dissolved water concentration in $C_5F_{11}NO$ and $C_5F_{11}NO/H_2O$. The results obtained by the Karl Fischer Spectrometric method showed that the water concentration in $C_5F_{11}NO$ was less than 23 μg/ml at 70° and 85°C. However, the water concentration in $C_5F_{11}NO/H_2O$ increased to 133 μg/ml at 70°C and to 261 μg/ml at 85°C.

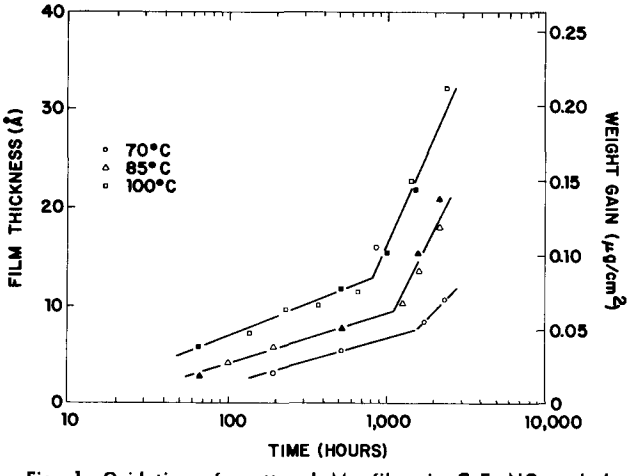

Fig. 1. Oxidation of sputtered Mo films in $C_5F_{11}NO$ and dry air. Weight gain data were calculated from the oxide film thickness, assuming the film is MoO_2 (density = 6.47 g/cc). Solid symbols indicate dry air environment.

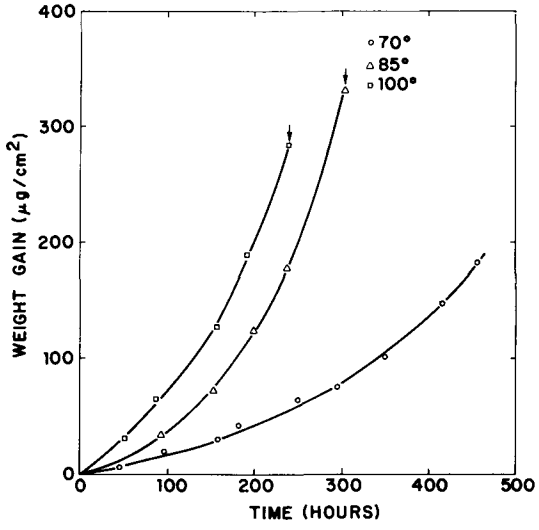

Fig. 2. Corrosion of sputtered Mo films in $C_5F_{11}NO/H_2O$

The pronounced influence of water was further verified by a simple experiment: specimens were partially contaminated by water droplets before exposure to $C_5F_{11}NO$. Rapid destruction was observed locally only at contaminated points, while the rest of the specimen remained unattacked. However, tests in deaerated $C_5F_{11}NO/H_2O$ showed no measurable weight change and no visible discoloration of molybdenum films after 2000 hr exposure at 100°C. Obviously, water is important for the corrosion of molybdenum only when oxygen is present. In other words, both oxygen and water are the major corrosive ingredients in the corrosion of molybdenum in $C_5F_{11}NO$. Neither aerated $C_5F_{11}NO$ nor deaerated $C_5F_{11}NO/H_2O$ corrodes molybdenum to any practical extent. To demonstrate the importance of relative humidity on the atmospheric corrosion of molybdenum, samples were also exposed to moist air at 85°C/85% RH. It was observed that molybdenum oxidized linearly with time and gave a constant rate of 2.3 μg/cm^2 hr. A similar rate relationship in moist air was reported by other investigators (3, 4). In moist air at 85°C, a critical relative humidity exists at 60%, below which the corrosion of molybdenum is nil. In $C_5F_{11}NO/H_2O$, molybdenum produced a water-soluble, porous corrosion film and discolored successively yellow, brown, blue, and black with increasing time exposure. This discoloration is most likely associated with the changing film thickness, oxidation state of the corrosion film, and test temperature. A similar corrosion film was obtained in moist air at 85°C/85% RH. X-ray diffraction analysis of the corrosion film showed no diffraction pattern; the film was practically amorphous in nature.

The destructive action of aerated water and the corrosion of molybdenum has been reported (4). Further tests in DI water at 85°C demonstrated the progressive deterioration of molybdenum film. Pyrolytic molybdenum films on oxidized silicon wafers were employed with subetched patterns. Figure 3 shows the degree of corrosion after various periods of immersion in DI water at 85°C. The samples clearly showed uniform corrosion after 24 hr, cracking after 40 hr, and disintegration along the cracks after 53 hr. Since the corrosion product is water soluble, molybdenum completely dissolved in DI water at 85°C after 65 hr immersion.

Passivation of thin molybdenum films.—Insulating films have become important for the surface passivation of electronic devices. In this investigation, insulating films such as pyrolytic silicon dioxide and silicon nitride were employed over pyrolytic molybdenum film with various thicknesses.

For the tests in moist air (85°C/85% RH), molybdenum-patterned silicon wafers containing 1000 units

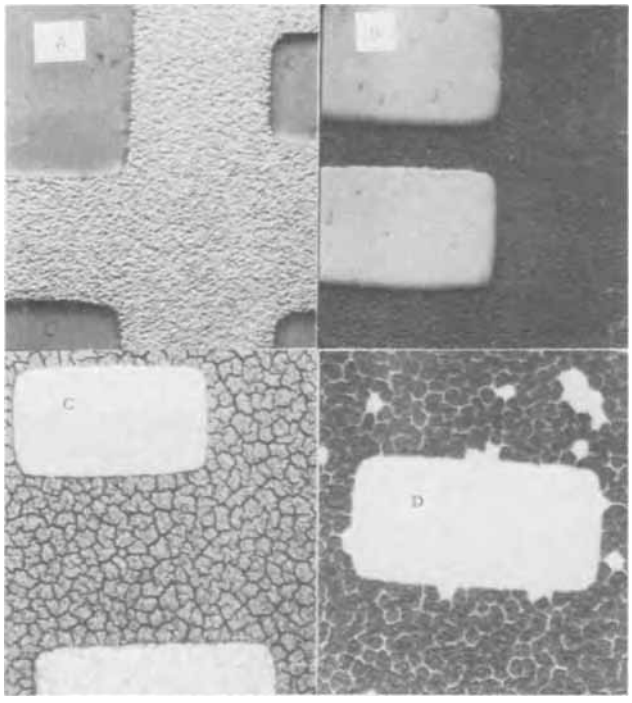

Fig. 3. Corrosion of bare pyrolytic Mo films in DI water at 85°C (525X): A, initial appearance; B, uniform attack after 24 hr; C, cracking after 41 hr; D, disintegration after 53 hr.

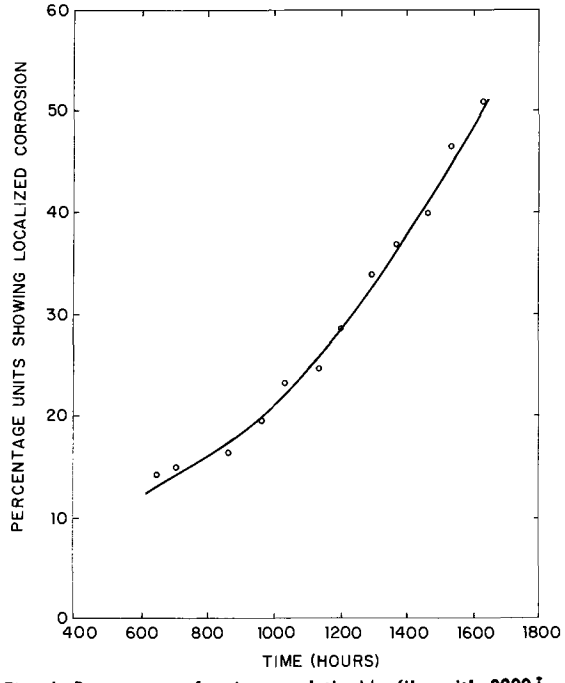

Fig. 4. Percentage of units, pyrolytic Mo film with 8000Å pyrolytic SiO_2 overlay, showing localized corrosion as a function of immersion time in 85°C DI water.

were used to determine the effective thickness for passivation. The percentage of corrosion is defined as the number of units corroded among the total number of units examined. It was observed that all units showed corrosion after 1500 hr with a 350Å silicon dioxide overlay. Corroded units were less than 10% after 2180 hr with 1750Å silicon dioxide overlay. No corrosion was noted on any of the units after 2360 hr exposure with 3500-7000Å silicon dioxide coatings. Samples with a composite layer of 770Å silicon nitride over 400Å silicon dioxide had corrosion on only 5% of the units after 1150 hr exposure.

For the tests in DI water at 85°C, the passivated samples with 400Å silicon dioxide overlay exhibited slight discoloration after 67 hr, localized corrosion at sharp corners after 85 hr, uniform corrosion along all film edges and narrow molybdenum stripes after 120 hr, and disintegration after 165 hr. The corrosion of molybdenum was delayed up to three times longer. A composite layer of 770Å silicon nitride over 400Å silicon dioxide tended to delay corrosion onset six times longer than a single layer of 400Å silicon dioxide, and 20 times longer than the bare molybdenum film. When these units were overlaid with 8000Å silicon dioxide, corrosion was detected after 500 hr immersion in DI water at 85°C; only localized corrosion was noted with increasing immersion time.

Figure 4 illustrates the increase of localized corrosion recorded among a total of 268 units examined. On every corroded site, there was evidence of incomplete protection caused by the presence of 4-8μ dust particles. Comparing the results on bare and passivated molybdenum films in DI water, the lifetime of 12,800Å molybdenum films was increased about 3X by adding 400Å pyrolytic silicon dioxide, approximately 20X by a composite layer of 770Å silicon nitride and 400Å pyrolytic silicon dioxide, and about 60X by 8000Å pyrolytic silicon dioxide overlay.

Discussion

A similar corrosion behavior of molybdenum films was observed in $C_5F_{11}NO$ and dry air, and in $C_5F_{11}NO/H_2O$ and moist air. In $C_5F_{11}NO$ and dry air molybdenum reacts with oxygen, forming molybdenum oxides. However, the reaction rates are so slow molybdenum is essentially inert. Our observations support earlier reports (12, 13) that molybdenum retains its brightness up to 200°C and forms an oxide film of 1-3 atomic layers after 70 days exposure at room temperature. In contrast, molybdenum corrodes in $C_5F_{11}NO/H_2O$ and moist air and dissolves in DI water (85°C) after 65 hr immersion. As described previously, the presence of water in aerated $C_5F_{11}NO/H_2O$ plays an important role in the corrosion of molybdenum. Similarly, relative humidity controls the atmospheric corrosion of metal films. It is believed that in $C_5F_{11}NO/H_2O$ and moist air, the corrosion of molybdenum proceeds electrochemically:

1. Water and oxygen diffuse to the metal-liquid interface where reaction occurs forming a nonprotective porous corrosion film.
2. The spongy corrosion film serves as an electrolyte; oxygen and water migrate freely toward the bare metal film and corrosion continues.

The over-all reaction includes the dissolution of metallic molybdenum to molybdenum ions and the reduction of oxygen to hydroxide ions.

$$\text{Oxidation:} \quad Mo \rightarrow Mo^{+n} + ne$$

$$\text{Reduction:} \quad O_2 + 2H_2O + 4e \rightarrow 4\,OH^-$$

Charge conservation is maintained so each electron released is immediately consumed by oxygen reduction. In DI water free of oxygen, the cathodic reduction is a hydrogen evolution reaction which is very slow in neutral solution. Since the rate of oxidation depends on the rate of reduction, this can be speeded by dissolved oxygen. This explains why the simultaneous presence of oxygen is required to corrode molybdenum in $C_5F_{11}NO$, air, and water. This type of corrosion is characterized by porous corrosion film forming and reacting continuously until the metal is completely consumed. Determination of the exact composition of the corrosion film was extremely difficult. Numerous investigators (3, 4, 15) were not wholly successful for two reasons: (*i*) molybdenum oxides exist in different valence states ranging from 2 to 6; and (*ii*) slight changes in test condition may change the coordination number. From the literature (16), the most stable oxides are MoO_2 and MoO_3; hydroxide exists as $Mo(OH)_3$, or as $MoO(OH)_3$. Moreover, water-soluble molybdenum blue exists as $MoO_{2.5\text{-}3} \cdot XH_2O$, whose

composition is still not exactly defined. It is also reported that molybdenum exists as MoO_2 in air and dissolves in solution with a valence of six (17).

The effectiveness of passivation of molybdenum film is directly related to the pinhole density and moisture permeability of the passivative film (18). A pyrolytic silicon dioxide film less than 1000Å thick has a high pinhole density. For 1000Å films and thicker, the pinhole density decreases linearly with increasing film thickness; it approaches zero for oxide films with 6000 to 7000Å thickness. There is no doubt that the corrosion of passivated molybdenum film is greatly suppressed by increasing the silicon dioxide film thickness, *i.e.*, decreasing the pinhole density of the film. As described elsewhere (19), pyrolytic silicon dioxide has low pinhole density and good edge conformity, although its moisture absorption is relatively high. However, this disadvantage can be overcome by covering with silicon nitride film, which is known for its greater density, low moisture permeability, and excellent chemical inertness (20). It is expected that a composite layer of silicon dioxide and silicon nitride exhibited better performance than a single layer of silicon dioxide. Therefore, we conclude that molybdenum can be protected from corrosion by covering it with passivating films.

Summary

1. In $C_5F_{11}NO$ and dry air, molybdenum forms a thin oxide film that reaches a thickness less than 35Å after 2000 hr exposure at temperatures of 70°, 85°, and 100°C. The oxidation follows a logarithmic rate law.

2. In moist air (85°C/85% RH), molybdenum corrodes at a linear rate. In $C_5F_{11}NO/H_2O$ (70°-100°C), molybdenum reacts at a continuously increasing rate with time and temperature. In both media, molybdenum forms a nonprotective, porous corrosion film. The reaction is electrochemical in nature.

3. In DI water at 85°C, molybdenum films (up to 12,800Å) dissolve completely after 65 hr immersion.

4. Water and oxygen are the major corrosives in these environments.

5. Comparing the results on bare and passivated molybdenum films in DI water, the lifetime of 12,800Å molybdenum films was increased about 3X by adding 400Å of pyrolytic silicon dioxide, approximately 20X by a composite layer of 770Å silicon nitride and 400Å pyrolytic silicon dioxide, and about 60X with an 8000Å pyrolytic silicon dioxide overlay.

Electrolytic Reductive Coupling

XIX.[1] Effect of Counterions in Cathodic Reactions of 1,2-Diactivated Olefins

John P. Petrovich and Manuel M. Baizer*

Central Research Department, Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

Certain 1,2-diactivated olefins XCH=CHY (I) in which X and Y are electron-withdrawing groups not themselves reduced under the conditions used were electrolyzed in the presence of counterions (M^+) chosen from the group Li^+, Na^+, K^+, Rb^+, R_4N^+. Cyclic voltammetric techniques permitted the measurement of the change in rate of decomposition of the anion radical as M^+ was varied. Bulk electrolyses yielded reduced coupled products whose identity and distribution varied with changes in M^+.

In a previous paper in this series (2) we reported that reductive coupling of olefins I (in which X and Y are electron-withdrawing groups not themselves reduced under the conditions of the electrolysis) in the presence of quarternary ammonium cations led to the formation of reduced dimers mainly by path [1] rather than by path [2]. That is

$$\underset{\text{I}}{\text{XCH—CHY}} \xrightarrow{e^-} \underset{\text{II}}{(\text{XCHCHY})^{\cdot-}}$$

$$(\text{XCH=CHY}) \longrightarrow (\text{XCHCHY})_2^{=}$$

$$\xrightarrow[2\text{H}_2\text{O}]{e^-} \text{XCH}_2\text{CHYCHXCH}_2\text{Y} + \text{YCH}_2\text{CHXCHXCH}_2\text{Y} \quad [1]$$

$$\underset{\text{I}}{2\text{XCH=CHY}} \xrightarrow{2e^-} \underset{\text{II}}{2(\text{XCHCHY})^{\cdot-}} \rightarrow (\text{XCHCHY})_2^{=}$$

$$\xrightarrow{2\text{H}_2\text{O}} \text{XCH}_2\text{CHYCHYCH}_2\text{X} \quad [2]$$

the intermediate anion radical II led to products more likely by an ECE mechanism than by an EC mechanism. The supporting evidence presented was based on an analysis of the cyclic voltammetry data and on the determination of the structures and distribution of the products obtained in macroelectrolyses.

Now II is always in the presence of a counterion and the ensemble anion-radical-counterion-solvent is present in a medium whose polarity may, within certain limits, be varied. It was of interest to determine whether varying these parameters judiciously would make it possible to direct the reaction of II toward either route [1] or route [2], both of which could be then regarded as limiting cases of anionic and free radical behavior, respectively. It was anticipated that the results would also have a bearing on the question of the mechanism(s) whereby anion radicals enter into other reactions, *e.g.*, the formation of "living" dianions (3) and the condensation with alkyl halides (4). As will become apparent the "directive" influence of the counterion may be offset by steric factors in the monomer which may be more decisive in blocking path [1] or path [2].

Experimental

Materials.—Dimethylformamide (DMF) was purified as described previously (1). Tetramethylammonium, tetraethylammonium tetrapropylammonium, tetrabutylammonium, lithium, sodium, potassium, and rubidium perchlorates, were recrystallized from appropriate solvents and dried immediately before use. Tetraethylammonium *p*-toluenesulfonate was purified as described previously (1). Sodium and lithium *p*-toluenesulfonate were recrystallized from acetic acid and dried before use.

Olefins.—Diethyl fumarate, cinnamonitrile, and α-phenylcinnamonitrile were obtained commercially.

The saturated analogs of these olefins, required as VPC references, were prepared by reduction of the corresponding olefin with hydrogen over palladium on carbon with ethanol as solvent using a Parr shaker at room temperature.

Cyclic voltammetry.—The cyclic voltammograms were obtained as described previously using anhydrous DMF as the solvent (2).

Preparative electrolysis.—The apparatus used for the preparative electrolysis has been described (5). A mercury cathode, area 55 cm^2, was used throughout.

General electrolysis method.—The anolyte consisted of either a saturated aqueous solution of tetraethylammonium *p*-toluenesulfonate, 2*M* aqueous solution of lithium *p*-toluenesulfonate or 2*M* aqueous solution of sodium *p*-toluenesulfonate depending on the electrolyte used in the catholyte. The catholyte consisted of 0.2 mole of the depolarizer, 0.03 mole of the electrolyte and 5 ml of water diluted to 150 ml dimethylformamide. The electrolyses were conducted at a constant current of 2A as described previously. The yields of electrolysis products, the relative yields of dihydro and hydrodimeric products as well as the isomer distribution are given in Table I.

Electrolysis of cinnamonitrile in the presence of lithium ion.—The products were isolated and identified as described previously (2). The only dimeric product isolated was 3,4-diphenyladiponitrile (16.9g). VPC analysis[2] indicated the presence of *ca.* 2% 2-benzyl-3-phenylglutaronitrile. Distillation gave 5.9g of 3-phenylpropionitrile.

Electrolysis of N,N-dimethylcinnamamide (1) *in the presence of lithium ion.*—The main dimeric product was purified by crystallization from benzene-methanol, 16.6g, mp 126°-128° [lit. (7) N,N,N',N'-tetramethyl 3,4-diphenyladipdiamide, 127°-129°]. The yield of N,N-dimethyl-3-phenylpropionamide was estimated by VPC.[2]

Electrolysis of α-phenylcinnamonitrile in the presence of tetraethylammonium ion.—A solid product formed during the electrolysis and was subsequently removed by filtration, 5.6g. VPC analysis[2] indicated

that this was a mixture of two dimeric isomers.[3] Recrystallization from dimethylformamide gave a pure isomer A, mp 346°-347°.

Anal.—Calcd. for $C_{30}H_{24}N_2$: C, 87.10; H, 5.86; N, 6.81. Found: C, 87.30; H, 5.86; N, 7.26.

Mass spectra of isomer A showed the parent ion peak at m/e 412 with fragment peaks in decreasing order of intensity at m/e of 180 ($\phi CH=CH\phi$), 116 ($\phi CHCN$), 218 ($\phi CH=C\phi CHCN$), and 296 ($\phi CHC\phi HC\phi CNH$). Of the possible dimeric products only 2,3,4,5-tetraphenyladiponitrile would be expected to have all of these peaks.

Work-up of the electrolysis mixture in the usual manner gave an oily product. VPC analysis[2] of this product showed none of the isomer A but a mixture of a dimer B and the starting olefin. The oily product was chromatographed on activated alumina using benzene as the solvent. The solid dimer (28.1g) obtained was recrystallized from acetone, mp 222°-223°.

Anal.—Calcd. for $C_{30}H_{24}N_2$: C, 87.10; H, 5.86; N, 6.81. Found: C, 87.22; H, 5.74; N, 6.97.

Isomer B is apparently identical with Wawzonek's reported imine.[3]

Electrolysis in the presence of sodium cation.—The electrolysis products were worked up as described above. Isomer A, 13.6g, was isolated by crystallization. Isomer B was obtained by VPC analysis.[2]

Electrolysis in the presence of lithium cation.—The electrolysis products were worked up as described above. The products distribution was found to be 17% saturated monomer and 83% dimer mixture which was 89% Isomer A' and 11% Isomer B. Isomer A' was isolated and recrystallized from DMF (mp 255°-258°). The VPC retention time[2] (4.3 min) and mass spectrum of this material were identical to those obtained for Isomer A in electrolysis described above. The difference in melting points is probably due to different diastereoisomers (four asymmetric carbon atoms)

Anal.—Calcd. for $C_{30}H_{24}N_2$: C, 87.10; H, 5.86, N, 6.81. Found: C, 87.07; H, 6.12; N, 7.00.

Results and Discussion

We have used (8) the relation between the peak current and the scan rate from cyclic voltammetry as a means of distinguishing between an EC and an ECE mechanism (essentially an irreversible charge transfer due to dimerization of II) (9). The expected dependence of $i_p/V^{1/2}$ *vs.* $V^{1/2}$ is shown in Fig. 1, along with the observed behavior of diethyl fumarate (III) and α-phenylcinnamonitrile (IV) using both the alkali metal cations and the tetraethylammonium cation. It is clear that, in the presence of the sodium cation, α-phenylcinnamonitrile behaves as expected for an EC mechanism.[4] However, in the presence of the tetraethylammonium cation, IV shows an intermediate behavior between an EC and an ECE mechanism, indicating that both paths, Eq. [1] and [2], are taken in this case. In the case of diethyl fumarate the $i_p/V^{1/2}$ behavior is not as conclusive. A trend, however, is apparent. On changing from the tetraethylammonium ion to the lithium ion, the curve shifts from the curve expected for an ECE process toward the expected curve for an EC process, indicating that both paths are taken in the decomposition of the anion radical from diethyl fumarate in the presence of the lithium ion. However, there is essentially no change in the rate of decomposition of the anion radical from diethyl fumarate (lithium counterion) in the presence of 1*M* acrylonitrile,[5] indicating that the anion radical dimerization path, Eq. [2], predominates.

In each of these cases olefins III and IV reduce well before the background electrolyte cations discharge.

From the cyclic polarograms, the rate constants, k_{obs}, for the decomposition of the anion radicals electro-

[2] A 6 ft 10% SE-30 Ultraphase on 80-100 mesh Chrom W-HP column programmed from 200°-300° at 15°/min. This column was used throughout.

[3] S. Wawzonek *et al.* (6) reported obtaining a dimeric nitrile and the cyclic imine formed from it by a Ziegler-Thorpe reaction on electrolysis under similar conditions.

[4] Similar experiments using the lithium cation were inconclusive due to a preadsorption wave.

[5] By contrast, in the presence of the tetraethylammonium ion, a substantial rate increase was observed with added acrylonitrile (8).

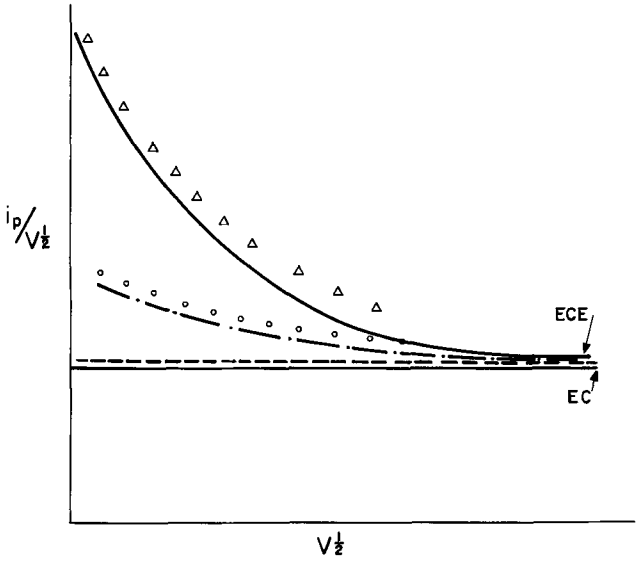

Fig. 1. Plot of $i_p/V^{1/2}$ *vs.* $V^{1/2}$ as indicator of EC or ECE mechanism. ———— Expected curves for EC and ECE mechanisms; — — — observed behavior of α-phenylcinnamonitrile with the sodium ion; —·—· observed behavior of α-phenylcinnamonitrile with the tetraethylammonium ion; o o o observed behavior of diethyl fumarate with the lithium ion; △ △ △ observed behavior of diethyl fumarate with the tetraethylammonium ion.

chemically generated from the diactivated olefins were calculated by the method of Nicholson (10). In each case, the decomposition rate is faster in the presence of the alkali metal cations than in the presence of the tetraethylammonium ion. In typical nucleophilic reactions, where no charge is formed in the transition state, *i.e.*, only a reorganization of charge occurs, the rate of attack of the nucleophile on an aceptor (analogous to Eq. [1]) would be expected to decrease on changing the cation from larger tetraethylammonium to the smaller sodium or lithium due to ion-pairing considerations (11). The anion radical/sodium or lithium ion pair should be less nucleophilic than the essentially free anion radical which is present when the tetraethylammonium ion is the counterion

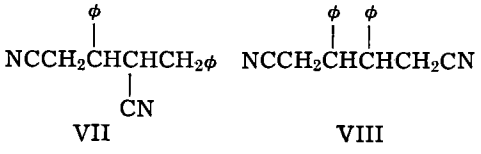
$$XCH{=}CRY \xrightarrow{e^-} (XCHCRY)^{\cdot-} \xrightarrow[\text{proton source}]{k_1} \xrightarrow{k^2} (XCHCRY)^{\cdot-} \xrightarrow{k^3} XCH{=}CRY$$

$k_{obs} = k_1 + k_2 + k_3$, assuming the concentration of the second reactant is a constant. Therefore, the effect of changing the cation from tetra-alkylammonium to an alkali metal cation should be a decrease in k_{obs} due to a decrease in k_3. The increase in k_{obs} is indicative of an increase in k_2. The final result k_{obs} in any particular case will be a blend of these three reactions.

Furthermore, these same ion-pairing considerations would tend to favor the dimerization of two anion radicals, Eq. [2], because of the neutralization of the negative charge by the relatively small cations. It would be expected that the dimerization of two free anion radicals would be disfavored by charge repulsion. However, in a tight ion pair, the charge is essentially absent and the typical radical reactions can occur.

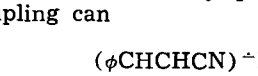
In these systems, especially for olefins (III) and (IV), both limiting cases were observed as well as the intermediate case. With olefin III, k_3 dominates in the presence of the tetraethylammonium ion, and with olefin IV, k_2 is the main path in the presence of the sodium ion. Both paths (k_2 and k_3) are taken by olefin III with lithium ion and possibly by olefin IV with tetraethylammonium ion.

On macroelectrolysis, the isomer distribution of dimeric products as implied by the rate constants depends on the cation of the electrolyte, Table I. Cinnamonitrile (V) gave a mixture of isomers. The main product, 57%, was 2-benzyl-3-phenyl glutaronitrile VII in the presence of the tetraethylammonium ion (1) and almost exclusively 3,4-diphenyladiponitrile VIII in the presence of the lithium ion.



VII VIII

In the ion pair, consisting of the anion radical of cinnamonitrile and the lithium counterion, the lithium ion is probably associated with the electron-rich nitrile group, IX. The most likely pseudo-radical through which coupling can



IX

occur is the benzylic-type radical. Coupling $\beta,\beta-$ to the nitrile is indeed what is observed.

Similar dual behavior was observed in the macroelectrolysis of N,N-dimethylcinnamamide VI. Olefin VI gave N,N,N',N'-tetramethyl 2,3-dibenzylsuccinamide in the presence of the tetraethylammonium ion and N,N,N',N'-tetramethyl 3,4-diphenyladipamide in the presence of the lithium ion.

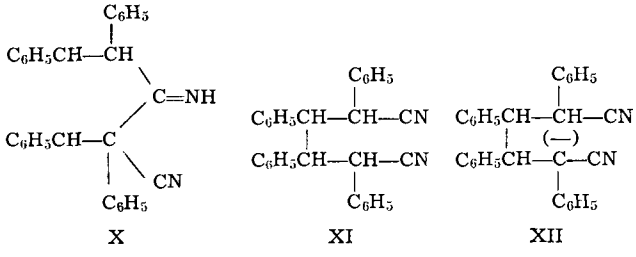
[c] ±10% reproducibility.

For olefins V and VI, the $i_p/V^{1/2}$ behavior was not obtainable because the current peak comes too close to the background electrolyte discharge. The rate constants were estimated but, because of the proximity of the background discharge, are probably not very accurate.

The macroelectrolysis of α-phenylcinnamonitrile (IV) gave 86% of dimer X and 14% of dimer XI in the presence of the



X XI XII

tetraethylammonium ion, while, with sodium as the counterion, about equal amounts of these two isomers were obtained. In the case of the lithium ion 89% of the dimeric product was XI.[6] Since the final intermediate leading to both X and XI must be the anion XII, these results again illustrate (12) the differences in effect of the hydrated alkali metal cations and the unhydrated quaternary ammonium cations: in the former case XII is immediately hydrated to XI; in the latter case XII escapes hydration long enough to be able to engage in the intramolecular reaction leading to X.

We find this hypothesis useful: In the limiting cases a small counterion may form an intimate ion-pair (perhaps a covalent bond when X or Y contains oxygen) with II whereby the ensemble behaves like a free radical; a large counterion well separated from II by a polar solvent favors anionic behavior of II. In most cases, particularly in electrolytic experiments in which solvents of some polarity are required and the choice of counterions is not always free, an admixture of both behaviors is to be expected. This interpretation of counterion effects is applicable to an explanation of the merger of two polarographic waves of benzil into one when Li^+ is the counterion (13); the changes in equilibrium constant between dimer dianion and mono anion radical of benzophenone with counterion (14); and the course of some polymerization reactions depending on the metal initiator used (15). This hypothesis must be tested in additional systems. Controversies concerning the mechanism of anion radical reactions which do not simultaneously take into consideration the counterion and the medium are fruitless.

[6] It is an interesting observation, for which we do not presently have explanation, that different diastereoisomers of XI were formed in the presence of lithium and of sodium cations.

Electrolytic Reductive Coupling

XX.[1] Mixed Reductive Couplings with Acrylonitrile

Reductions at the Cathode Voltage Required for the More Difficultly Reduced Partner

Manuel M. Baizer* and John L. Chruma

Central Research Department, Monsanto Company, St. Louis, Missouri 63166

ABSTRACT

Acrylonitrile has been reductively coupled with acetone, styrene, 1,1-diphenylethylene, benzophenone, and benzaldehyde. When the reduction is carried out at the cathode voltage required for the more difficultly rather than the more easily reduced partner (*a*) current efficiencies for the mixed products are increased, (*b*) couplings which otherwise fail can occur, (*c*) by-product polymer formation may be suppressed, and (*d*) when either of two by-product hydrodimers must be accepted, the more useful one may be chosen.

It has been pointed out before (2) that mixed reductive coupling between two different types of activated olefins A and B (in which A as arbitrarily the most easily reduced species) provides a convenient route to the synthesis of molecules **4** with two different functions. When the cathode

$$\underset{\mathbf{1}}{A} + \underset{\mathbf{2}}{B} \xrightarrow[H_2O]{F} \underset{\mathbf{3}}{HAAH} + \underset{\mathbf{4}}{HABH} + \underset{\mathbf{5}}{HBBH} \qquad [1]$$

voltage can be controlled at a value required for the reduction of A but not of B, only products **3** and **4** are formed (2); the more negative the cathode voltage can be made without reducing B[2] the higher the ratio of **4** to **3** (3). Even under the latter circumstances, however, if the reduction potentials of A and B are more than *ca.* 0.4V apart, **3** is formed along with very little,[3] if any, **4** (4).

The maximization of the yield of **4** at the expense of **3** and **5** is a challenging synthetic goal since the latter two can be made individually by electrolytic hydrodimerization of **1** and **2**, respectively, while the former is usually very difficult to prepare by alternate means.

This paper reports the results obtained in attempting to increase the yield of **4** by carrying out the reductive couplings of Eq. [1] at cathode voltages negative enough to reduce B. Further, in view of Sugino and Nonaka's (6) successful reductive coupling of acetone[4] and acrylonitrile at −1.9V in the presence of tetraalkylammonium salts in neutral or alkaline medium, the carbonyls acetone, benzophenone, and benzaldehyde were also included here as representatives of A or B.[5]

Possibly related work, involving the anodic oxidation of cyclohexane (more positive voltage) in the presence of chloride, has been published (7).

Previous papers in this series have pointed out the difficulties in establishing the mechanism whereby **4** is formed when only A is reduced (Eq. [1]). When the coupling is carried out at the (more negative) voltage for the reduction of B, the elucidation of the routes to **4** becomes formidable. This paper poses, but does not grapple with, these mechanistic problems.

Experimental

Reagents.—The purification and/or quality of tetraethylammonium *p*-toluenesulfonate, diethyl maleate

* Electrochemical Society Active Member.

[1] For Part XIX see (1).

Key words: potentiostatic electrolyses, cross coupling, hydromerization.

[2] It was observed (3) that, when the cathode voltage was negative enough to reduce 2 also, the ratio of 4 to 3 increased even further, but now some 5 was also formed.

[3] In addition to the work cited in (4) it may be mentioned that our attempt several years ago (5) to couple acrylonitrile with styrene at 1.9V *vs.* SCE resulted in only a very small yield of 5-phenylvaleronitrile.

[4] Benzophenone was reported (6) to be unsuitable as a coupling partner.

[5] The carbonyls are electroreducible but obviously are not activated olefins.

(DEM), DMF, and acrylonitrile (AN) have been described before (3). The acetone was Mallinckrodt reagent grade. Styrene (Eastman, practical grade) was distilled *in vacuo* and stored over a trace of *p*-nitrosodimethylaniline. Benzophenone (Fisher, reagent grade) and 1,1-diphenylethylene (Aldrich, technical grade) were used as received.

Equipment.—Except where otherwise specified, the assembly previously described was used (3); the salt bridge was positioned directly under the alundum cup diaphragm which contained the anode. A mercury cathode of 55 cm^2 was used throughout.

Synthesis of reference compounds.—5-Hydroxy-5-methyl-valeronitrile and γ,γ-dimethylbutyrolactone were made according to the literature by the electroreduction of a sulfuric acid solution of acetone in the presence of acrylonitrile (6). The preparation of the 5-phenyl-valeronitrile has been described (5). 4-Phenylvaleronitrile was prepared from 4-phenylvaleric acid (Aldrich) by conventional means *via* the acid chloride and amide, bp 85° (0.2 mm) [reported (8) 125° (13 mm)], chromatographically pure, ir spectrum consistent with structure. 1,1,4,4-Tetraphenylbutane was prepared by the electrohydrodimerization of 1,1-diphenylethylene, mp 120°-121° [reported (9) 122°].[6] 1,3-Diphenylbutane and *meso*- and *dl*-2,3-diphenylbutane were prepared according to (11). 4,4-Diphenylbutyrolactone was prepared by the method of (12). The benzyl 2-cyanoethyl ether was prepared by cyanoethylating benzyl alcohol (13).

Procedures.—Except in the case of experiments done for comparison purposes, the general electrolysis procedure involved dissolving B, the most difficultly reducible component, in a solution of water-DMF-tetraethylammonium *p*-toluenesulfonate, deaerating with purified nitrogen for at least 15 min, presetting the cathode voltage by potentiostat at the desired value, starting the electrolysis and shortly thereafter beginning the addition of component A either neat or dissolved in DMF or B. The pH was kept at *ca.* 7-8 by occasional addition of acetic acid dropwise to the catholyte. At the end of the electrolysis the catholyte, if necessary, was neutralized with acetic acid and poured onto ice. After separation of the mercury, the mixture was filtered, if necessary, and the filtrate extracted several times with methylene chloride. The extracts were washed with water, dried, filtered, and analyzed by the methods described below. Isolation of products involved fractional distillation or crystallization as appropriate. The electrolysis data are gathered in Table I; the products obtained are given in Table II.

Analytical methods.—Gas chromatography employing the F and M Hewlett Packard Model 5750 instrument was used throughout. The preliminary treatment of the sample and the choice of chromatographic column depended on whether it was desired to analyze for both "low" and "high" boiling products. (*A*) When "low boilers" analysis was required the methylene chloride and other relatively volatile products were removed by distillation at $< 100°$ and collected in a chilled receiver. The distillate was analyzed on a 6 ft 10% Carbowax 20M on Chromosorb W (80-100 mesh) column[7] (No. 1) isothermally at 70° or on a 1 ft Par 1 (80-120 mesh) column (No. 2) isothermally at 100°. (*B*) When only "high boiler" analysis was required, the more volatile materials were removed on a hot water bath *in vacuo* and the residue analyzed on column No. 1 programmed from 100° to 210° at 15°/min or on column No. 2 programmed at 200° to 240° at 6°/min or on column No. 3 (10 ft 3% OV-225 on Chromosorb G, 80-100 mesh) programmed 150° to 300° at 15°/min. When pure samples of expected products

[6] Wawzonek and Fan had reported (10a) no reductive coupling under polarographic conditions; Funt and Gray (10b) found no hydrodimerization under cyclic voltammetric conditions using tetrabutylammonium perchlorate.

[7] Occasionally, the crude catholyte was directly analyzed for low boiling components.

[a] Infrared and elemental analyses indicated that no moiety derived from benzophenone had been incorporated, See ref. (14).
[b] MP 57°-58°. Calcd. for $C_{17}H_{17}N$: C, 86.76; H, 7.28; N, 5.95. Found: C, 86.80; H, 7.11; N, 5.86.
[c] MP 95°-95.5° (2 × from alc.), bp 180°-190° (0.03 mm). Calcd. $C_{16}H_{15}NO$: C, 81.02; H, 6.32; N, 5.90. Found: C, 81.19; H, 6.33; N, 5.81. The infrared spectrum showed OH (2.9μ), CN (≯45μ) C_6H_5 (13.4μ) and no >CO or R-O-R absorption.
[d] BP 155° (0.3 mm). Calcd. for $C_{13}H_{14}N_2O$: C, 73.0; H, 6.52; N, 13.10. Found: C, 72.75; H, 6.76; N, 13.17. The infrared spectrum showed no OH, CN (4.5μ), no >CO, ether (9.1μ), C_6H_5 (13.3 and 14.5μ).

were available, analysis was carried out using dimethyl terephthalate or octadecane (runs 13 and 14) as the internal standard. Otherwise, semiquantitative analyses were obtained using corrected area percentages.

The infrared spectra were obtained on a Beckman Microspec spectrophotometer. The nmr spectra were obtained on Varian A-60 and T-60 instruments.

Discussion of Results

In reductive couplings according to Eq. [1], the parameters that can be controlled are cathode voltage, mode of addition of **1** and **2** to the catholyte, and, within certain limitations (3), concentration of proton donor (water). If the cathode voltage is controlled so as to be close to the value required for the reduction of **1** but not of **2**, it is clear from a comparison of the results of runs 1 and 2 that slow addition of **1** to the catholyte favors the formation of mixed product **4** at the expense of **3**. We have frequently [*e.g.*, (3)] employed this strategy. When the cathode voltage is negative enough to reduce **2** (run 4)[8] the ratio of **4** to **3** + **5** is maximum.

In runs 1-4, involving the acrylonitrile-acetone system, it is significant that, when the acceptor is acetone rather than an activated olefin, cross-reductive coupling occurs [runs 1 and 2 and ref. (6)] even though the separation of cathode voltage between AN and acetone is *ca.* 0.5V; if the acceptor had been an activated olefin which reduces at *ca.* the acetone cathode voltage, cross-reductive coupling would not have been expected to occur (4). This point is, indeed, verified in runs 5 and 8. Comparison with runs 6 and 9, respectively, however, illustrates that electrolysis at the more negative voltage does produce type **4** products.[9]

The data thus far discussed illustrate that electrolyses at the more negative voltage (*a*) increase the ratio of cross-coupled to self-coupled products and (*b*) permit couplings to occur which fail at the more positive voltage.

The experiments (runs 10-12) with the AN-benzophenone system illustrate additional features of the electrolyses at negative voltages. Benzophenone was reported (6) not to couple with AN and we have verified this result [at −1.73V, run 10]. Sugino and Nonaka did not report what did occur in their experiment. We obtained some adiponitrile and, in spite of the presence of a quantity of water ordinarily sufficient to arrest anionic polymerization/oligomerization (15), a large quantity of polyacrylonitrile together with AN hydrotrimer and α-methyleneglutaronitrile. The polymer was carefully examined for the presence of benzophenone-derived end-groups: none were found. The polymer may be free radical-initiated and may have arisen by electron-transfer to acrylonitrile from benzophenone dianion *ex* benzophenone radical anion (14). The possibility (16) that polymerization was initiated by $CH_2{=}\bar{C}CN$, also an intermediate to α-methyleneglutaronitrile, is not consistent with the fact that increasing the quantity of water in the catholyte (run 11 *vs.* run 10) while maintaining a constant concentration of the hydrophobic quaternary ammonium cations did not decrease the yield of polymer, although it did reduce the quantities of AN hydrotrimer and of α-methyleneglutaronitrile.

Cross-coupled products between AN and benzophenone were formed at −2.00V (run 11) and at −2.20V (run 12)[10] together with major amounts of adiponitrile. In this case, then, cross-coupling occurred at a negative voltage which failed at a more positive voltage and, in addition, by-product polymer formation could be avoided by operating at a very negative voltage.

A comparison of runs 13 and 14 shows that again type **4** product is maximized at the more negative

[8] At the beginning of the experiment the background current and the current in the presence of acetone were determined to establish that the latter was, indeed, being reduced.
[9] It is an interesting fact that the 2-cyanoethyl moiety was joined to the α-(→ 4-phenylbutyronitrile) as well as the β-(→ 5-phenylvaleronitrile) carbon atoms of styrene, that the 5-isomer predominated considerably, and that its ratio to the 4-isomer increased even more at the more negative voltage (run 7 *vs.* run 6).
[10] At this voltage very little polymer was formed, presumably because any free radical initiators were immediately reduced and anionic polymerization was aborted by the proton donors. The possibility cannot be ruled out that benzophenone dianion participated in the coupling.

voltage. In addition, since hydrodimer **5** rather than hydrodimer **3** is formed as the major[11] bimolecular by-product, and since one must usually accept **5** or **3** as a by-product in the synthesis of **4**, one can, by choice of cathode voltage, select the more useful by-product.

Benzaldehyde coupled reductively with AN both at −1.575V (run 15) and at −1.95V (run 16). The current efficiency for the formation of coupled product was higher at the more negative voltage but at the expense of forming adiponitrile as a by-product. It is interesting that because of difficulty in preventing the catholyte from becoming too alkaline, as evidenced by the formation of bis-(2-cyanoethyl) ether, both C and O cyanoethylation of benzaldehyde occurred

$$C_6H_5CHO + 2CH_2{=}CHCN \xrightarrow[2H_2O]{2e^-} C_6H_5CH(OCH_2CH_2CN)\text{-}CH_2CH_2CN \quad [3]$$

This result finds a certain analogy in the report (17) that a small quantity of the ethyl ether of ethylphenylcarbinol was formed during the electrolysis of benzaldehyde[12] in the presence of ethyl iodide

$$C_6H_5CHO + 2C_2H_5I \xrightarrow{2e^-} C_6H_5CH(OC_2H_5)C_2H_5 \quad [4]$$

Mechanistic Problems

When only reactant B (together with supporting electrolyte and solvent) is present in the catholyte, electrolysis at a cathode voltage sufficient to reduce B is started and A is added in gradually, the following situation obtains initially. B is reduced to its radical anion or derived anion.[13] The reduced intermediate may anionically attack proton donor to yield dihydro **B**, or **B** to yield eventually its hydrodimer or incoming A to yield eventually the cross-coupled product **4**. However, B anion radical (say from benzophenone) may also disproportionate and the resulting dianion (or even the initial anion radical) may transfer an electron to readily reducible A, so that coupling may be of the radical combination type. If A has acquired one electron from the reduced intermediate formed from B, radical combination of two A radicals would lead to **3**; reduction of A radical *via* the electrode or by relay *via* the B-reduced species would lead to A anion and then to **3** and **4**; if the electron-transfer to A had occurred under circumstances under which A radical could not be reduced, free radical-initiated polymerization could occur.

As B is being reduced and its concentration at the electrode surface diminished, new B and competitively A reach the electrode surface. If A is electroreduced, then the couplings described in our previous papers occur.

To study the mechanistic phenomena in an ideal system would require precise control of pH, proton donor concentration, and rate of addition of A in the vicinity of the electrode surface. Current density adjustment would be required so that the rate of reaction of reduced B with A, in conjunction with all other processes in which reduced B participates, was just sufficient to prevent any direct reduction of A. It appears that there will be some delay before this can be achieved.

Manuscript submitted Aug. 24, 1970; revised manuscript received Nov. 9, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

[11] The complete elimination of tetraethyl butanetetracarboxylate in run 14 is a fortuitous result.

[12] On the other hand, benzophenone and ethyl iodide yielded only the C-ethylated product (18).

[13] Following protonation and a second reduction. Depending on the stability of the radical anion (19) and the proton paucity near the electrode these processes may be relatively slow.

and Wallace Kesselman**

Chemical Engineering Department, Shell Development Company, Emeryville, California 94608

ABSTRACT

Integral transform methods are used to obtain analytic solutions for the current density (J) and potential distributions on a disk in an infinite plane for the four limiting cases of: (i) uniform potential disk-insulating plane; (ii) uniform J disk-insulating plane; (iii) uniform J disk-uniform potential plane and; (iv) uniform potential disk-uniform potential plane. Examples of applications of results are drawn from electrochemical engineering problems related to fuel cell design, corrosion enhancement due to inclusions, and rotating disk systems.

Advances in the mathematical treatment of current density problems have been made recently through the use of machine computation methods (1, 2). Analytic results remain attractive because of their generality, although the mathematical effort for all but the simplest geometries becomes excessive. Methods usually associated with idealized two-dimensional fields become increasingly complex for three-dimensional problems related to practical electrode geometries. However, the cylindrical field geometry may be treated in terms of two space coordinates when angular symmetry prevails, *i.e.*

$$\nabla^2 V = \frac{\partial^2 V}{\partial z^2} + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial V}{\partial r}\right) = 0 \qquad [1]$$

The resulting simplification permits solutions to be obtained by integral transform methods which provide insight to practically important situations. For full utilization of analytic solutions to Eq. [1], the result should be processed to yield additional useful information. It is customary to obtain the local gradient of potential in order to evaluate the variation of current density along electrodes. For the constant potential electrode type of boundary condition, the current density so obtained represents the limiting case of primary distribution in the absence of electrode overpotential. This bound on the current density may be useful in estimating worst possible cases. For example, in electroplating, a highly nonuniform, nearly primary current distribution will result in wasting possibly expensive metal in order to obtain a specified plate thickness in the central region of a flat electrode.

A second type of practical information available from the solution to Eq. [1] concerns the ohmic resistance associated with an electrode configuration. The virtual resistance of electrolyte between two electrodes may be found by application of Ohm's law using the total potential difference between electrodes and the total current, obtained by integrating the current density along the surface of the electrode with respect to area. When potential varies at the interface with an electrode, the area average potential may be used. Bounds to the resistance obtained from limiting cases of constant potential and constant current density electrodes are useful in applications such as electrolytic cell design and studies of corrosion enhancement due to impurity inclusions.

Additional useful information may be derived from the variation of the field in a few principal directions. The "range" in which the potential and current distributions become negligibly small permits the application of already obtained results to different electrode configurations. For example, it could be estimated how far away sidewalls must be in order for them not to affect the current distribution through a "shielding" effect.

Background

Nobili (3) in 1827 refers to a laboratory curiosity in which rings of color are produced on metallic sheet anodes facing a wire cathode. This curiosity became known as a "metallochrome" and clearly derived from a combination of nonuniform current distribution and interference effects (Newton's rings) in thin oxide layers. The interest of mathematicians in the "metallochrome" led to many mathematical developments. Thus, Riemann (4) solved the "metallochrome" current distribution problem in 1855, and Weber (5), using some of Riemann's results, derived the solution for the primary current distribution on an isolated disk in an insulating plane as well as the resistance for the disk electrode in 1873, using certain "discontinuous integrals." The equivalent electrostatic problem was worked out by Green (6) in 1832. Later (1887) Schafheitlin (7) generalized the result for these discontinuous functions in a thorough fashion so that these integrals of products of Bessel functions are known as Weber-Schafheitlin integrals. [These integrals are of the form

$$\int_0^\infty \frac{J_\mu(at)\,J_\nu(bt)}{t^\lambda}\,dt$$

and can be evaluated in terms of the hypergeometric function with μ, ν and λ as parameters and a/b as the independent variable (8)].

Fortunately, hypergeometric functions often reduce to well-known elementary functions. The use of these functions, coupled with the Hankel (Fourier-Bessel) transformation of Laplace's equation, facilitates the solution of certain problems of direct application in electrochemical engineering [see, for example, Watson (9) and Sneddon (10) for reviews].

Although there is no *a priori* scheme for the selection of one calculational method over another, recent researchers (1, 11, 12) have favored the use of rotational elliptic coordinates for disk problems. It is, however, satisfying in the present study, to extend and reapply mathematical methods originally inspired by electrochemical problems.

Mathematical

The Hankel transform (as used in this paper) of a function $V(r)$, is defined as follows

$$\mathbf{H}_\nu[V(r)] \equiv \overline{V}_\nu(p) = \int_0^\infty r J_\nu(pr) V(r)\, dr \qquad [2]$$

where J_ν is the Bessel function of the first kind and of order ν, and p is the transformed variable.

Mathematical details regarding Hankel transforms may be found elsewhere (13). It will suffice here to show just two formulas which will be useful in our development. The first is the inversion theorem

$$V(r) = \int_0^\infty p J_\nu(pr) \overline{V}_\nu(p)\, dp \qquad [3]$$

which allows us to get the potential from its transform. The other property is, as can be shown by methods of elementary calculus (14), that

$$\mathbf{H}_\nu \left[\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial V}{\partial r} \right) - \frac{\nu^2 V}{r} \right] = - p^2 \overline{V}_\nu(p) \qquad [4]$$

Equation [4] is especially important in the case where $\nu = 0$, since it reduces Laplace's equation (Eq. [1]) in cylindrical coordinates to an extremely simple form.

Applying Eq. [4] to Eq. [1] with $\nu = 0$, we obtain

$$\frac{d^2\overline{V}}{d^2 z} - p^2 \overline{V} = 0 \qquad [5]$$

Equation [5] is an ordinary differential equation, with the convenient solution

$$\overline{V} = A_1(p) e^{-pz} + A_2(p) e^{+pz} \qquad [6]$$

For the presently treated class of problems with remote counterelectrode, in order that the transform not become infinite for large z, we must have $A_2(p) = 0$. Applying the inversion formula, Eq. [3], we have finally the direct result for the potential

$$V(r,z) = \int_0^\infty p A_1(p) J_0(pr) e^{-\nu z} dp \qquad [7]$$

with $A_1(p)$ to be determined from the boundary condition at $z = 0$, *i.e.*, the problem is to find $A_1(p)$ in either Eq. [8] or Eq. [9] (or both)

$$V(r) = \int_0^\infty p A_1(p) J_0(pr)\, dp \qquad [8]$$

$$J(r) = \kappa \int_0^\infty p^2 A_1(p) J_0(pr)\, dp \qquad [9]$$

since Eq. [9] is obtained from Eq. [7] by use of Eq. [10]

$$J(r) = -\kappa \left. \frac{\partial V}{\partial z} \right|_{z=0} \qquad [10]$$

For subsequent convenience, we define a p-multiplied coefficient as

$$A(p) = p A_1(p) \qquad [11]$$

so that Eq. [8] and Eq. [9] become

$$V(r) = \int_0^\infty A(p) J_0(pr)\, dp \qquad [12]$$

$$J(r) = \kappa \int_0^\infty p A(p) J_0(pr)\, dp \qquad [13]$$

Depending on the types of boundary conditions given, two types of problems are encountered.

Mixed boundary conditions.—Case 1, Constant potential disk.—For the classic case of the disk at constant potential in an insulating plane, we must solve Eq. [12] and [13] as a set fitting the conditions

$$V(r) = V_0 \; ; \; r < a \qquad [14]$$

$$J(r) = 0 \; ; \; r > a \qquad [15]$$

To solve this set of equations for $A(p)$, it is convenient to use the dual integral equation formulation

$$\int_0^\infty y^\alpha f(y) J_\nu(xy)\, dy = g(x) \qquad 0 < x < 1$$

$$\int_0^\infty f(y) J_\nu(xy)\, dy = 0 \qquad x > 1 \qquad [16]$$

whose solution is known (15) to be

$$f(x) = \frac{2^{-\alpha/2} x^{-\alpha}}{\Gamma(1 + \tfrac{1}{2}\alpha)} \Bigg[x^{1+1/2\alpha} J_{\nu+1/2\alpha}(x) \int_0^1 y^{\nu+1} (1 - y^2)^{1/2\alpha} g(y)\, dy + \int_0^1 u^{\nu+1} (1 - u^2)^{1/2\alpha} du \int_0^1 g(yu) (xy)^{2+1/2\alpha} J_{\nu+1+1/2\alpha}(xy)\, dy \Bigg] \qquad [17]$$

Applying this to the disk problem, described by Eq. [12], [13], [14], and [15], we have

$$A(p) = \frac{2V_0}{\pi} \frac{\sin ap}{p} \qquad [18]$$

Combining Eq. [18] with Eq. [11], [7], [8], and [9] gives us an integral representation of the potential field and current distribution as

$$V(r,z) = \frac{2V_0}{\pi} \int_0^\infty \frac{\sin (ap) J_0(pr)}{p} e^{-pz} dp \qquad [19]$$

$$J(r, z = 0) = \frac{2\kappa V_0}{\pi} \int_0^\infty \sin (ap) J_0(pr)\, dp \qquad [20]$$

The integral in Eq. [19] may be evaluated in terms of elementary functions from tables of Laplace transforms for $r = 0$ [since $J_0(0) = 1$]; for $z = 0$, Eq. [19] and [20] are special cases of the previously mentioned Weber-Schafheitlin discontinuous integral, and may be expressed (8) in terms of the hypergeometric function, which in turn is often expressible in terms of elementary functions. In this case, the integral in Eq. [19] is known for all z (16), and the well-known results for the primary distribution are

$$V(r,z) = \frac{2V_0}{\pi} \sin^{-1} \left\{ \frac{2}{[(r/a-1)^2 + (z/a)^2]^{1/2} + [(r/a+1)^2 + (z/a)^2]^{1/2}} \right\} \qquad [21]$$

$$V(r, z = 0) = V_0 \qquad ; \; r < a \qquad [22a]$$

$$V(r, z = 0) = \frac{2}{\pi} V_0 \sin^{-1} (a/r) \qquad ; \; r > a \qquad [22b]$$

$$V(z, r = 0) = \frac{2}{\pi} V_0 \tan^{-1} (a/z) \qquad [23]$$

From Eq. [20], using the area average current density

$$J_{ave} = \frac{\int_0^a J(r) 2\pi r dr}{\pi a^2} \qquad [24]$$

we get

$$\frac{J(r)}{J_{ave}} = \frac{1}{2} \frac{1}{\sqrt{1 - (r/a)^2}} \qquad [25]$$

where

$$J_{ave} = \frac{4}{\pi} \left(\frac{\kappa V_0}{a} \right) \qquad [26]$$

The primary current distribution Eq. [25] has long been known (6, 5). The ohmic resistance for such a system is easily shown by Ohm's law to be

$$R = \frac{\Delta V}{I} = \frac{V_0}{J_{ave} \pi a^2} = \frac{1}{4\kappa a} \qquad [27]$$

From Eq. [21], [22], and [23], it is possible to calculate the range of the field, *i.e.*, the distance over which the field of the disk will vary significantly. For example, from Eq. [22b] it may be seen that the potential has fallen to 10% of its value on the disk at

$$a/r = \sin \pi/20 = \sin 9° = 0.15643$$

or $r/a = 6.393$ (roughly 3 diameters away). Similarly, along the centerline ($r = 0$) the potential falls to 10% at $a/z = \tan \pi/20 = \tan 9° = 0.15838$ (again, roughly 3 diameters away). This ranging effect has been used in discussions concerning reference probe placement for the rotating disk electrode (12) and occurs frequently in related problems. For example, Ellison (17) has recently found that in electroplating elliptical cylindrical wires, the presence of the wire anodes has very little effect on the field at the substrate when they are located 10 semi-minor-axes away.

Dirichlet and Neumann type boundary conditions.—Case 2, Constant current density disk.—When either the potential or its gradient is given on the entire boundary, a different procedure may be employed to solve for $A(p)$ in Eq. [12] or [13]. This problem is typified by the case of the disk with uniform current distribution embedded in an insulating plane. For this situation, the boundary conditions when substituted in Eq. [13] give

$$\int_0^\infty pA(p)J_0(pr)dp = J_D/\kappa \quad ; r < a$$
$$\int_0^\infty pA(p)J_0(pr)dp = 0 \quad ; r > a \qquad [28]$$

By comparing Eq. [28] with Eq. [2] and [3], it may be seen that the unknown $A(p)$ may be obtained by application of the Hankel transform inversion formula, giving

$$A(p) = \left(\frac{J_D a}{\kappa}\right)\frac{J_1(pa)}{p} \qquad [29]$$

Combining Eq. [29], [7], and [11], gives the integral representation for the potential field, which, for $z = 0$, may be solved from the Weber-Schafheitlin integral formulas. As before, the result is in terms of hypergeometric functions which, in this case, finally reduce to complete elliptic integrals of the first and second kind. The potential near the surface of the disk is as follows

$$V(r,z=0) = \begin{cases} \frac{2}{\pi}\left(\frac{J_D a}{\kappa}\right)\mathbf{E}\left(\frac{r}{a}\right) & ; r < a \quad [30a] \\ \frac{2}{\pi}\left(\frac{J_D a}{\kappa}\right)\frac{r}{a}\left\{\mathbf{E}\left(\frac{a}{r}\right) - \left[1-\left(\frac{a}{r}\right)^2\right]\mathbf{K}\left(\frac{a}{r}\right)\right\} & ; r > a \quad [30b] \end{cases}$$

as previously reported by Nanis (18). Numerical values for the radial field variation which closely match Eq. [30a] have also been computed by Newman for a limiting case which insures uniform current distribution, *i.e.*, large variation of overpotential with current density for mass transport limitation. Along the central axis of the disk, the potential may be found by combining Eq. [29], [7], and [11] and setting $r = 0$

$$V(z,r=0) = \left(\frac{J_D a}{\kappa}\right)\left\{\left[1+\left(\frac{z}{a}\right)^2\right]^{1/2} - \left(\frac{z}{a}\right)\right\} \qquad [31]$$

The range of the field may be found using Eq. [30] and [31]. For simplicity, the truncated series approximation for the elliptic functions (19) may be used to obtain

$$\frac{V(r,z=0)}{(J_D a/\kappa)} = \frac{V}{V_{max}} = \frac{1}{2}\left(\frac{a}{r}\right) + \frac{1}{16}\left(\frac{a}{r}\right)^3 + \ldots \qquad [32]$$

The potential drops off to 10% of its peak value at $a/r \cong 0.2$ or $r/a \cong 5$, *i.e.*, at a distance of only 2.5 diameters from the center of the disk. Similarly, along the axis of the disk, using binomial expansion, Eq. [31] becomes

$$\frac{V}{V_{max}} = \frac{1}{2}\left(\frac{a}{z}\right) - \frac{1}{8}\left(\frac{a}{z}\right)^3 + \ldots \qquad [33]$$

Again, the potential has dropped to 10% of its peak value at $r/a \cong 5$, roughly 2.5 diameters from the center of the disk in the vertical direction.

The resistance associated with the constant current density disk configuration may be calculated by introducing the concept of average potential in the electrolyte at the plane $z = 0$. By stipulating constant current density as a boundary condition, it is implicitly assumed that for a given solution conductivity and disk size, the slope of the overpotential *vs.* current density curve is sufficiently great so as to insure uniform current density on the disk, *i.e.*, good "throwing power." It should be noted that the overpotential conditions thus assumed at the electrode-electrolyte interface are located (in the mathematical sense) at $z = 0$, whereas the solution to Eq. [1] applies to the region $z > 0$ (strictly, $z \to 0^+$). Definition of the resistance associated with the constant current density case requires an analysis equivalent to that given by Jeans (20). Such a treatment in the present notation is given in the Appendix. Integrals of complete elliptic integrals used in potential averaging are known (19, 16). Use of Ohm's law yields

$$R = \frac{\Delta V}{I} = \frac{V_{ave}}{J_D \pi a^2} = \frac{\frac{8}{3\pi}\left(\frac{J_D a}{\kappa}\right)}{J_D \pi a^2} = \frac{8}{3\pi^2 \kappa a} \qquad [34]$$

Thus the ohmic resistance for constant current density on the disk is about 8% greater than the resistance associated with the constant potential (primary distribution) disk (Eq. [27]). (Results for the various cases are summarized in Table I.)

A comparison between radial potential at the plane $z = 0$ for the primary and uniform current distribution is shown in Fig. 1, where Eq. [30a, b] have been normalized by the average potential (*cf.* Eq. [34]).

Case 3, Constant J disk, constant potential plane.—Another boundary condition which proves useful in the treatment of corrosion problems concerns a disk at constant current density in a constant potential plane, *i.e.*

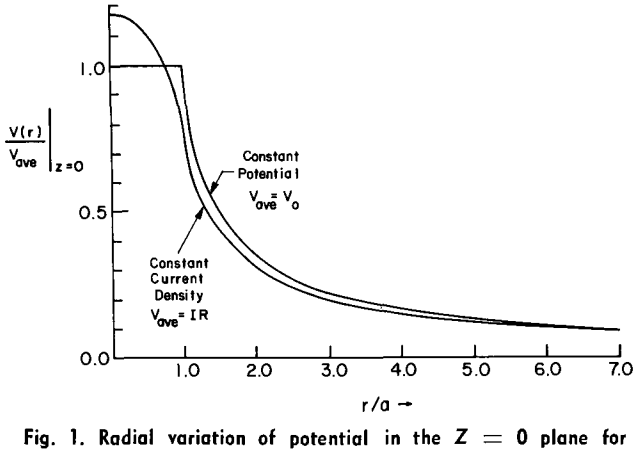

Fig. 1. Radial variation of potential in the Z = 0 plane for limiting cases of constant potential and constant current density on disk.

Table I. Field parameters

Equation No. for variation of	Current	[25]	—	[40]	[44]
	Potential	[21], [22], [23]	[30], [31]	[39], [41]	[45]
Resistance, ($\times \kappa a$)	$R_\kappa a$	$\frac{1}{4}$	$\frac{8}{3\pi^2}$	$\frac{4}{3\pi^2}$	0

$$\frac{\partial V}{\partial z} = \frac{J_D}{\kappa} \; ; \; r < a \qquad [35a]$$

$$V = 0 \; ; \; r > a \qquad [35b]$$

The solution of the Laplace equation with boundary conditions given in Eq. [35] is readily obtained by applying the dual integral equation approach (Eq. [16], [17]). Equation [35a] combined with Eq. [13], and Eq. [35b] with Eq. [12] become

$$\int_0^\infty pA(p)J_0(pr)\,dp = J_D/\kappa \quad ; \; r < a \qquad [36a]$$

$$\int_0^\infty A(p)J_0(pr)\,dp = 0 \quad ; \; r > a \qquad [36b]$$

Solution for $A(p)$ using Eq. [17] leads to the result

$$A(p) = \frac{2}{\pi}\frac{J_D}{\kappa}\left[\frac{\sin(ap) - ap\cos(ap)}{p^2}\right] \qquad [37]$$

which may also be written as

$$A(p) = \sqrt{\frac{2a}{\pi}}\frac{J_D a}{\kappa}\left[\frac{J_{3/2}(pa)}{p^{1/2}}\right] \qquad [38]$$

By substitution of Eq. [38] into Eq. [12] and Eq. [13], results are obtained in terms of an integral representation which may be reduced by use of the Weber-Schafheitlin formula to tabulated elementary functions or directly (21). For the plane $z = 0$

$$V(r,z=0) = \begin{cases} \frac{2}{\pi}\frac{J_D a}{\kappa}\sqrt{1 - \left(\frac{r}{a}\right)^2} & ; \; r < a \\ 0 & ; \; r > a \end{cases} \qquad [39]$$

$$J(r,z=0) = \begin{cases} J_D & ; \; r < a \\ \frac{2}{\pi}J_D\left[\sin^{-1}\frac{a}{r} - \frac{1}{\sqrt{(r/a)^2 - 1}}\right] & ; \; r > a \end{cases} \qquad [40]$$

Along the axis ($r = 0$), Eq. [38] together with Eq. [7] and [11] result in

$$V(z,r=0) = V_{max}\left[1 - \frac{z}{a}\tan^{-1}\frac{a}{z}\right] \qquad [41]$$

Levich and Frumkin (11) used elliptical cylindrical coordinates to arrive at Eq. [39] and [40] in terms of Legendre polynomials [a procedure later used by Newman (1, 12)]. Levich and Frumkin treated the resistance as a function of radius. It is difficult to assign a physical meaning to such a radial resistance function. By the methods used previously (cf. Eq. [34]), we can calculate a resistance based on the average potential along the disk (from Eq. [39]) as

$$R = \frac{\Delta V}{I} = \frac{V_{ave}}{J_D \pi a^2} = \frac{\frac{4}{3\pi}\left(\frac{J_D a}{\kappa}\right)}{J_D \pi a^2} = \frac{4}{3\pi^2 \kappa a} \qquad [42]$$

It is interesting to note that Eq. [42] indicates a resistance which is just one-half that for the constant current-density disk in the insulating plane (Case 2). It is also interesting to note that the range for such a situation is much smaller than for Cases 1 and 2. Inspection of Eq. [40] and [41] show that the current density drops to 10% of the value on the disk, J_D, at $r/a = 1.52$ and the potential along the centerline similarly decays to 10% of its peak value at $z/a = 1.66$, both less than a diameter away. This reduced range is because of a variation of potential as the inverse square of distance for large r and z compared with an inverse distance variation for Cases 1 and 2.

Case 4, Constant potential disk, constant potential plane.—For completeness, the limiting case of the constant potential disk in the constant potential plane has been treated. The boundary conditions for this case may be stated as

$$V = \begin{cases} V_o & ; \; r < a \\ 0 & ; \; r > a \end{cases} \qquad [43]$$

This boundary condition is of the Dirichlet type and may be solved following an inversion procedure (Case 2). Two difficulties encountered by this procedure reflect the "short circuit" indicated by Eq. [43]. First, current density is described by an integral of the form

$$\int_0^\infty pJ_1(pa)J_0(pr)\,dp$$

which can be shown to neither diverge nor converge (in the limit, the integrand approaches an undamped sine function). Hence the integral must be evaluated in the limit from the Weber-Schafheitlin formulas (8) as a special case involving the principle of summability of integrals (22). Second, the result so obtained (Eq. [44]) exhibits a "strong" infinity at $r = a$, so that an infinite current is obtained upon applying Eq. [24]. Waber (23) has encountered similar difficulties in considering the analogous case of a strip of fixed potential embedded in a conducting plane at a different potential. Despite difficulties in determining the average current density, the results for the local current density are

$$J(r,z=0) = \begin{cases} \dfrac{2}{\pi}\dfrac{\kappa V_0}{a}\dfrac{\mathbf{E}\left(\dfrac{r}{a}\right)}{1-\left(\dfrac{r}{a}\right)^2} & ; r<a \quad [44a] \\ \dfrac{2}{\kappa}\dfrac{\kappa V_0}{a}\dfrac{a}{r}\left[\mathbf{K}\left(\dfrac{a}{r}\right) - \dfrac{\mathbf{E}(a/r)}{1-(a/r)^2}\right] & ; r>a \quad [44b] \end{cases}$$

For $r/a = 0$, Eq. [17] and [11] yield the simple form

$$\frac{V(z,r=0)}{V_0} = 1 - \frac{z/a}{\sqrt{(z/a)^2+1}} \qquad [45]$$

From Eq. [45], it may be seen that the range for 10% potential remaining is about one diameter ($z/a = 2.06$) and, from Eq. [44b], the dimensionless current $J(r)/(\kappa V_0/a)$ drops to 0.1 at $r/a = 1.92$ (in the $z = 0$ plane).

Results derived from the field solutions for the bounding cases treated above are summarized in Table I.

Applications

Fuel cell technology.—For the application of general field solution characteristics to complex engineering problems, we consider the internal resistance of a fuel cell of the type treated by Gorin and Recht (24) and later discussed by Fick and Eisenberg (25). The system consists of an electrolyte matrix contacted on both sides by wire mesh screen electrodes (Fig. 2a). Their exact mathematical analysis of constant potential screen contact points results in an answer (Eq. [46]) consisting of several slowly converging series

$$\frac{R_{eff}}{R} = 1 - \left[4/\pi^2 r(h/d)\right]\sum_{m=1}^{\infty}\left[\frac{1}{m^2}\sin m\pi(1-r)\cdot\cos m\pi\tanh(m\pi h/d)\right] + \left[4/\pi^3 r^2(h/d)\right]\cdot\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\left[\sin m\pi(1-r)\sin n\pi(1-r)/mn\sqrt{m^2+n^2}\right]\cdot\cos m\pi\cos n\pi\tanh\left[\sqrt{m^2+n^2}\,\pi\,(h/d)\right] \qquad [46]$$

where $r = \Delta/d$, R_{eff} is the effective ohmic resistance, and R is the resistance of the matrix in contact with continuous sheet electrodes. In view of the present development of "range" and of individual electrode

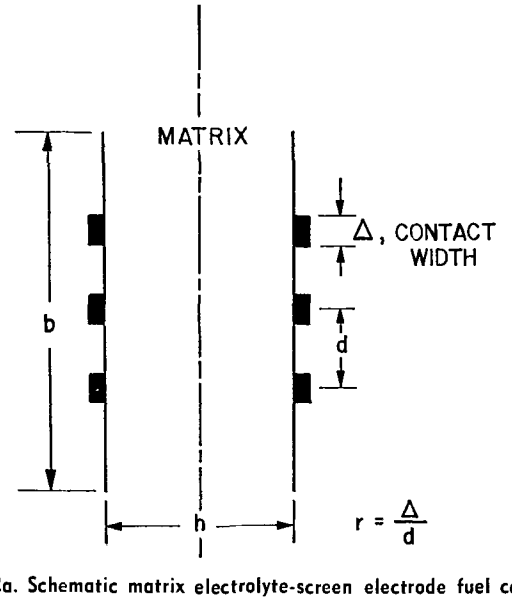

Fig. 2a. Schematic matrix electrolyte-screen electrode fuel cell

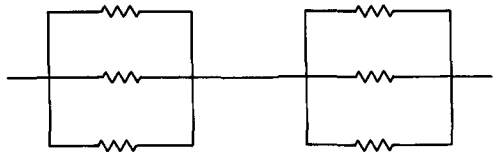

Fig. 2b. Equivalent circuit, individual resistances according to Eq. [47].

resistance, each contact may be considered (as a first approximation) as a disk of radius $\Delta/2$. By considering all of the screen mesh points on one side of the matrix as an array of individual disks in a parallel resistance circuit, the approximate equivalent circuit will be as shown in Fig. (2b), where each contact point is represented by the ohmic resistance for an isolated disk, R_i. From Eq. [27]

$$R_i = \frac{1}{4\kappa(\Delta/2)} = \frac{1}{2\kappa\Delta} \qquad [47]$$

where κ is the conductivity of the matrix (ohm^{-1} cm^{-1}). For the matrix of thickness h, assuming a square of edge b, the true resistance is

$$R = \frac{1}{\kappa}\frac{h}{b^2} \qquad [48]$$

For the equivalent circuit of Fig. 2, the over-all resistance, R_{eff}, is determined by

$$\frac{1}{R_{eff}/2} = \Sigma\frac{1}{R_i} = 2\kappa\Delta\frac{b^2}{d^2} \qquad [49]$$

since the number of contact points is b^2/d^2 in a square array of dimension b, and since each screen contributes to R_{eff}. Thus the resistance of the screen-matrix combination may be simply represented in terms of the two naturally resulting dimension ratios in Eq. [50]. The upper limit for each mesh point (and thus the entire system) may be based on the result for constant current density (Eq. [34]) so that the bounds are given as

$$\frac{d}{\Delta}\frac{d}{h} \leq \frac{R_{eff}}{R} \leq 1.08\frac{d}{\Delta}\frac{d}{h} \qquad [50]$$

From previous discussion of the range of a potential distribution, Eq. [50] will be most accurate when the contacts are spaced so that their fields do not interact, requiring that

$$\frac{d}{\Delta} > 6 \quad \text{and} \quad \frac{h}{\Delta} > 6$$

The tabulated values of Fick and Eisenberg are shown in Fig. 3 together with the lines representing the lower limit of Eq. [50] for comparably selected values of d/h. Note that agreement extends well beyond the limits imposed by range considerations. Clearly, where fields interact, the limit $R_{eff}/R = 1$ is ultimately to be expected, *i.e.*, as mesh spacing decreases and contact points increase in size to resemble a continuous sheet electrode.

Effect of inclusions in corrosion.—The effect of minor inclusions or sites with relatively large exchange current density for cathodic processes is associated with several practical problems. For example, in chlorine production cells, particles detach from the graphite anode and fall on the mercury cathode. The resulting local cell can result in production of unwanted hydrogen. Similarly on a single electrode, an iron impurity site on a zinc surface can provide a location for cathodic action (*i.e.*, hydrogen production), with corresponding enhanced corrosion of the zinc.

We may idealize such corrosion situations by considering the impurity to be a disk at constant current density imbedded in an infinite plane at constant potential (Case 3). This approximation may be made

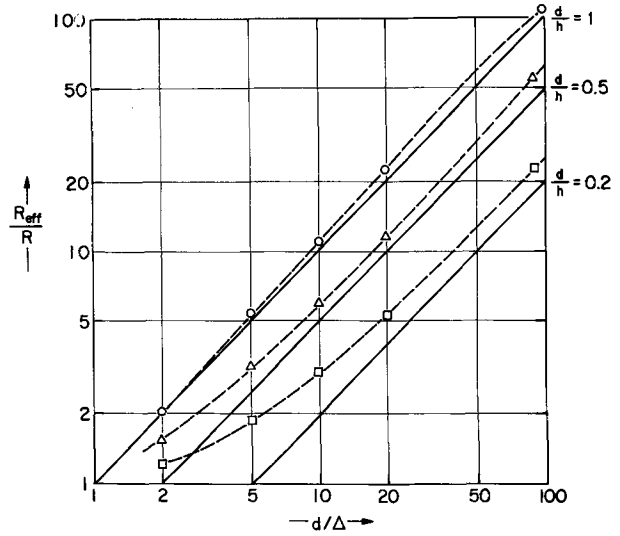

Fig. 3. Comparison of points according to Eq. [46] (ref. 6) and Eq. [50] (approximate model).

since the lateral range of the disk field does not extend much beyond $r/a = 1.5$. The same is true for the vertical range (see Eq. [41]), in general agreement with the computations of Simmons *et al.* (2) for the effect of electrolyte depth in a related problem.

In order to determine the corrosion current for the disk-plane system, it is necessary to locate the point of intersection of the two curves describing the overpotential-current relation for each of the half reactions involved. In addition, although not usually considered in such computations, the ohmic resistance of the system must be included. This tends to decrease the corrosion current, in much the same fashion as the internal resistance of a battery. Thus, the *IR* drop associated with the cathodic process (disk) will determine a lower corrosion current than would be expected if resistance were ignored (see Fig. 4) That is, if the anode and cathode reactions are described by general current-potential function such as

$$I_C = I_1(E_C) \qquad [51a]$$

$$I_A = I_2(E_A) \qquad [51b]$$

then we can rewrite Eq. [51] in terms of inverse functions as

$$E_C = I_1^{-1}(I_C) \qquad [52a]$$

$$E_A = I_2^{-1}(I_A) \qquad [52b]$$

By including the *IR* drop, Eq. [52] leads to

$$\frac{I_2^{-1}(I_A) - I_1^{-1}(I_C)}{I} = -R \qquad [53]$$

which must be solved for I, the corrosion current. Equation [53] is a restatement of the requirement that the sum of the potential drops in a closed circuit must equal zero (Kirchoff's rule).

As an example, consider a 1 cm² spot of iron impurity on a 100 cm² sheet of zinc, which will result in metal corroding to zinc ion and hydrogen evolution on iron as the two half-cell reactions. If we first calculate a corrosion current neglecting ohmic drop, we will have

$$|J_C| = 2 \times 10^{-6}\, e^{-FE/2RT} \qquad [54a]$$

$$J_A = 3 \times 10^{-4}\, e^{F(E+0.763)/RT} \qquad [54b]$$

The value of exchange current density for the hydrogen reaction (Eq. [54a]) is taken from the review of Kita (26) and the value for zinc dissolution from the work of Piontelli and Poli (27). Reversible potentials of −0.763V and 0.000V for zinc and hydrogen, respectively, in a solution of 1*N* H_2SO_4 + 1*N* $ZnSO_4$ are used as a basis. Equation [54a] is multiplied by the cathode area (1 cm²) and Eq. [54b] by the anode area (99 cm²) and are equated to solve for a corrosion current of 0.968A (uppermost intersection, 1000 mA, Fig. 4).

Using Eq. [53], the calculation of corrosion current for the case where the resistive potential drop is included is now considered. For the resistance associated with a single cathode site we may use Eq. [42] with an experimentally determined (28) conductivity of 0.157 ohm^{-1} cm^{-1}, which yields $R = 1.525$ ohms. Equation [53] reduces to

$$\frac{0.002 + 0.1777 \log I}{I} = -1.525 \qquad [55]$$

which must be solved by trial and error to yield a new corrosion current density of 1.10 mA/cm², almost a 90% decrease from the value of 9.7 mA/cm² obtained neglecting resistance. Clearly, the resistance associated with the cathodic sites must be included in such calculations.

We may now consider the important question concerning the physical dispersion of the low hydrogen overpotential sites. That is, would one 1 cm² patch of Fe produce the same corrosion current as one hundred 0.01 cm² patches? The answer may be deduced from Eq. [53] by representing $I_2^{-1}(I_A)$, $I_1^{-1}(I_C)$ and R as functions of area, and treating each site as an isolated spot. Equation [53] then becomes

$$\frac{0.1777 \log I + 0.1206 - 0.05922 \log \frac{A_A}{A_C} - 0.1777 \log A_C}{I} = -\frac{1.525}{\sqrt{A_C}} \qquad [56]$$

where I is the corrosion current, and A_A and A_c are the anodic and cathodic areas, respectively. Equation [56] shows that the corrosion current depends on the size of the corrosion spots (A_c) and also on the fraction of total area occupied (A_A/A_c). If we maintain the 99:1 ratio used previously, then Eq. [56] reduces to

$$\frac{0.1777 \log J_C + 0.0024}{J_C} = -1.525\sqrt{A_C} \qquad [57]$$

Hence, for a finer dispersion, corrosion current density goes up to 4.21 mA/cm². This effect may be rationalized if we recall that the finely dispersed particles, although

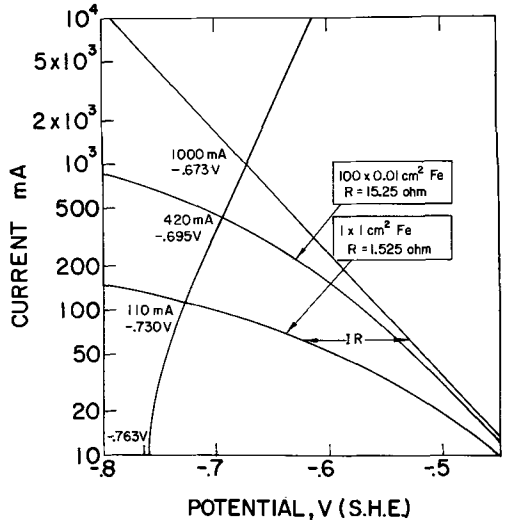

Fig. 4. Effect of impurity dispersion on internal cell resistance and corrosion rate. Zinc area, 99 cm²; iron area, 1 cm². Anode reaction: $Zn \rightarrow Zn^{++} + 2e^-$, $J_0 = 3 \times 10^{-4}$A cm^{-2} (1*N* $ZnSO_4$). Cathode reaction: $2H^+ + 2e^- \rightarrow H_2$, $J_0 = 2 \times 10^{-6}$ A cm^{-2} (1*N* H_2SO_4). Cathode site resistance $R = \frac{4}{3\pi^2\kappa a}$ with $\kappa = 0.157$ ohm^{-1} cm^{-1}.

having higher individual resistances ($R\alpha A_c^{-1/2}$), are in a parallel circuit which lowers the total resistance.

Placement of electrodes.—In the recent literature on rotating disk systems there has been some discussion (29, 12) on the proper placement of probes to measure the potential near rotating disk electrodes. Thus, Newman (12) suggests remote placement of the probe so as not to distort the field near the disk combined with estimation of the ohmic potential drop (unavoidably included in the measurement), based on the resistance of a disk at constant potential in an insulating plane. In a later paper, Hsueh and Newman (30) do indeed locate the reference probe in the plane of the electrode (10 radii away) and estimate the ohmic contribution to the potential from the equivalent of Eq. [22]. However, from present considerations it may be considered that the use of the probe is then rendered superfluous. All that need be measured in such a situation is the potential between the disk and a large remote unpolarized counterelectrode with the ohmic drop being approximated from either Eq. [22b] or [30b] as limits.

In this regard, Newman, in a later paper (1), recognizing that potential varies near the surface of the disk, defines a dimensionless effective resistance based on the group (in our notation)

$$\frac{V(r = z = 0)4\kappa a}{J_{ave}\pi a^2}$$

and uses this as a correction factor for Eq. [27]. In so doing, he finds that, when summing calculated overvoltage and resistive (IR) drops, the current-potential data of Hsueh and Newman (30) on a rotating disk are well fitted. However, use of his effective resistance approach requires that the ohmic resistance associated with a disk change by a factor of as much as 27.3% ($4/\pi = 1.273$; see Eq. [30a]) for the uniform current distribution, whereas we have seen that, in reality, the change of resistance is only on the order of 8% when changing from the uniform potential to uniform current distribution.

APPENDIX

Resistance of Nonisopotential Disk

As indicated by Jeans (20) and also Levich (31), the thermal energy, W, generated due to current flow in a medium of conductivity κ is given by the volume integral (for unit time)

$$W = \int\int\int \vec{J} \cdot \vec{E} d\tau \qquad [58]$$

where

$$\vec{J} = -\kappa \nabla V \qquad [59]$$

$$\vec{E} = -\nabla V \qquad [60]$$

Furthermore, Gauss' theorem for two arbitrary scalar quantities u and w is (32)

$$\int\int\int \nabla u \cdot \nabla w d\tau + \int\int\int u \nabla^2 w d\tau = \int\int u \frac{\partial w}{\partial n} dA \qquad [61]$$

where n indicates component normal to the bounding surface A. If we associate u and w with V, the potential, *i.e.*, let

$$\nabla u = \vec{J} = -\kappa \nabla V \qquad [62]$$

$$\nabla w = \vec{E} = -\nabla V \qquad [63]$$

then, since

$$\nabla^2 V = 0 \qquad [1]$$

combination of Eq. [1] with Eq. [58] to [63] yields

$$W = \kappa \int\int V \frac{\partial V}{\partial n} dA \qquad [64]$$

In the cases treated in the present cylindrical coordinate system

$$\frac{\partial V}{\partial n} \equiv -\left.\frac{\partial V}{\partial z}\right|_{z=0} \quad \text{and} \quad dA = 2\pi r dr$$

and since $W = I^2R$ (*cf.* Eq. [58]), Eq. [64] becomes

$$I^2R = -\kappa \int_0^\infty V(r) \left.\frac{\partial V(r)}{\partial z}\right|_{z=0} 2\pi r dr \qquad [65]$$

Equation [65] describes the system resistance in terms of arbitrary potential and current distributions on the plane $z = 0$. If, for $r > a$, we have an insulation or zero potential condition, and $\partial V/\partial z$ is constant on the disk then

$$I^2R = -\kappa \left.\frac{\partial V}{\partial z}\right|_{z=0} \times \int_0^a V(r) 2\pi r dr \qquad [66]$$

or finally

$$R = V_{ave}/I \qquad [67]$$

(*cf.* Eq. [34], [42]) where V_{ave} is based on area.

Technical Note

Note on an Organic-Electrolyte Cell with a High Voltage

Abner Brenner*

National Bureau of Standards, Washington, D. C. 20234

In the course of some experiments directed toward the electrodeposition of lithium, I chanced on a cell which delivered the unusually high back emf of 5.2V. I believe that this is the highest voltage which has been reported for a single cell. The voltage approaches the theoretical voltage of about 5.9V that can be obtained by the combination of lithium and fluorine. It is approximately equal to the voltage that would be obtainable from lithium and chlorine trifluoride, which combination is about the most active that could be considered feasible for operation as a cell near room temperature and atmospheric pressure (ClF_3 boils at 12°C).

Experimental

The electrolyte consisted of a 10% solution of lithium fluoborate in sulfolane or 3-methyl sulfolane. The latter is easier to use, because it is a liquid at room temperature, whereas the former is a solid. The solution of lithium fluoborate in sulfolane, however, is fluid at room temperature, although somewhat viscous. Smooth, gray coatings of lithium were readily electrodeposited from these electrolytes.

A combination of three materials was required in the cell to obtain the voltage of 5.2. These were: sulfolane or its methyl derivative, a fluorine-containing lithium compound, either the fluoborate or hexafluorophosphate, and a graphite anode. A series of qualitative experiments showed that replacing any one of the three materials led to a lower voltage. For example, a solution of lithium fluoborate in tetrahydrofuran or dimethylsulfoxide when electrolyzed yielded good deposits of lithium, but the back emf ranged between 4.3 and 4.5V. Use of platinum or a few other metals as anode in place of the graphite anode in the sulfolane electrolyte yielded a back emf of only about 3.7V. The electromotively active material was not in solution, as replacement of the polarized graphite rod by a fresh rod did not yield the high voltage. Substitution of lithium fluoborate by lithium bromide, in the sulfolane electrolyte, yielded an electrolyte which did not give a satisfactory deposit of lithium and the back emf (with graphite anode) was only 3.8V. Lithium hexafluorophosphate was a less satisfactory solute than the fluoborate, because it did not yield a satisfactory lithium deposit on electrolysis, and to obtain the back emf of 5.2V it was necessary to start the electrolysis with a lithium cathode (along with the graphite anode).

The back emf of 5.2V was obtained after only several minutes of electrolysis and in repeated experiments was reproducible to about 0.1V. On open circuit the voltage slowly decreased to about 5.0V in the course of a minute or two and then more slowly. A graphite anode, which had been polarized for a longer period of time, stored up some of the electromotively active material, as when the polarized cell was shorted through a milliameter the initial current was more than 10 mA/cm^2 and then slowly decayed. As a basis of comparison, a fresh, unpolarized graphite electrode with a lithium electrode in the sulfolane electrolyte initially had a voltage (open circuit) of 3.4 and yielded only about 1 mA/cm^2. The electromotively active compound was not too evanescent, as a graphite electrode was removed from the cell, rinsed in water, dried with a cloth and replaced and yielded a back emf of 4.3V, as compared with the voltage of an untreated graphite electrode of 3.4.

A matter of secondary interest, but still rather unusual was the electromotive activity of graphite and its deterioration in the solutions when used as an electrode. Graphite was not attacked by simple immersion. As an anode it was rapidly eroded away. With a lithium counterelectrode it behaved as a positive plate

* Electrochemical Society Active Member.
Key words: lithium deposition, high energy density cell, organic electrolyte, graphite electrode.

(cathode) in the sulfolane electrolyte and delivered a small current for a day or two. The initial current was about 1 mA/cm^2 which dropped down to about 0.2 mA/cm^2 after 24 hr. The graphite was somewhat etched.

The electromotive activity and disintegration of graphite was more pronounced in an electrolyte consisting of a 10% solution of lithium chloride in dimethylsulfoxide. Although this cell (with lithium and graphite electrodes) did not produce as high a back emf as the sulfolane-fluoborate cell previously described, it exhibited more reactivity with graphite electrodes, and for that reason is described here in a little more detail. All types of graphite utilized were rapidly disintegrated when made anodic in the DMSO solution. These included ordinary graphite rods, purified graphite obtained from the AEC, and pyrolytic graphite. The latter disintegrated into lamellae about 0.01 in. thick. Even more suprising was the rapid disintegration of graphite rods when used as the positive plate of a current producing cell. A graphite rod ¼ in. in diameter, for example, when used as part of a current delivering cell in DMSO-LiCl with a lithium anode completely disintegrated into a sludge after about 24 hr operation. The currents initially were about 1 mA/cm^2 of graphite surface and slowly dropped down to about 0.5 mA/cm^2.

In these experiments, a divided cell was not used. A test tube sufficed. The sulfolane and dimethylsulfoxide were used as received.

Conclusion

I do not suggest that the cells described herein have any utility in their present form as a high energy density battery. However, if the reactive material, that gives the sulfolane-fluoborate-graphite system the high back emf of 5.2V when the graphite is made anode, can be isolated or identified, perhaps such substances can be synthesized in quantity by other means and made available for the construction of cells. Also, the functioning of graphite in the organic electrolyte as a positive plate in the discharge of the cell is an unusual phenomenon and worthy of further investigation.

Brief Communication

The Low-Temperature Passivation of Cadmium in 8M KOH

Hong Yol Kang*

P. R. Mallory & Co. Inc., Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

It has been reported (1) that cadmium anodes have desirable properties for their use in primary alkaline cells at low temperatures. The discharge of cadmium electrodes is normally terminated by the onset of passivation. Although the passivation of cadmium in alkaline solutions has been studied by a number of authors (2-10), little data have been reported for the low-temperature range. In the present work measurements of cadmium passivation at low temperatures were carried out to provide the data necessary for an analysis of the intrinsic rate capabilities of cadmium at low temperatures. The behavior of flat cadmium electrodes was studied in order to avoid the uncertainties associated with the interpretation of passivation data on porous electrodes. Eight molar KOH solution was used as the electrolyte to cover a wider range of temperatures. The position of the cadmium (bottom) and the range of current densities (low) were chosen to minimize the effect of convection. The results fitted a kinetic expression proposed in the literature based on a dissolution-precipitation mechanism.

KOH solutions were prepared from a Fisher polypac 45% solution and stored under CO_2 free conditions. Cadmium sheet with a purity of 99.995% supplied by Alpha Inorganics, Inc., was degreased, treated with dilute acid, and cathodically reduced at 3 mA/cm^2 for 5 sec prior to anodization. The passivation cell consisted of a threaded Lucite block and a plug to form an electrolysis compartment. The Lucite block also had an opening for the reference electrode. The cadmium anode was tightly pressed by the plug in a horizontal position at the bottom of the cell, the area exposed to the electrolyte being exactly 1 cm^2. The conductor in contact with the working electrode was a platinum sheet welded on a nickel disk. The counter-electrode was a platinum wire and the reference electrode was a HgO/Hg electrode in the same KOH solution. The whole cell was covered by a lid to prevent an extensive change of the electrolyte composition by carbonation during the cooling down period. The amount of the KOH electrolyte was 5 ml and the cell was cooled in an Associate Testing Labs SK2101 temperature control chamber. The passivation measurements were made at constant currents supplied by a H/P Harrison 6200B d-c power supply combined with resistance regulators. The passivation time was determined from the time of closing the circuit to the instant at which the anode potential increased rapidly.

The passivation time of the flat cadmium electrode was measured at several current densities in 8M KOH at various temperatures ranging from 25° to −60°C. Results are shown in Table I. The values in the table are the average of 3-6 measurements, the reproducibility of the data in terms of the standard deviation being about 15% throughout the ranges of current and temperature.

There have been two different mechanisms proposed in the literature for the anodic reaction of cadmium

* Electrochemical Society Active Member.

Key words: cadmium, temperature dependence of passivation, vitreous point and passivation.

in alkaline solutions: the dissolution-precipitation mechanism (2-4, 8-10) and the film growth mechanism (5, 7). Recent investigations (8-10) appear to favor the former more than the latter. The data obtained in the present work fitted reasonably well the kinetic expression (8, 15) based on a dissolution-precipitation mechanism involving a competing reaction. This mechanism was characterized by the linear dependence of $i\tau^{1/2}$ on i at low current densities, where τ is the passivation time at constant current density i

$$i\tau^{1/2} = a + b\,i \qquad [1]$$

Figure 1 shows the i *vs.* $i\tau^{1/2}$ plot at various temperatures. Although further investigation is required to establish detailed reaction schemes, the data seem to indicate that under the conditions of this work cadmium is indeed anodically passivated through a mechanism satisfying the above kinetic expression.

1.0	15.86	16.78	13.04	12.59	7.02	7.00

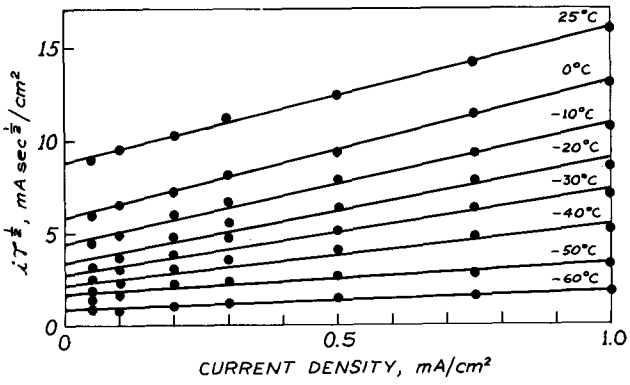

Fig. 1. i *vs.* $i\tau^{1/2}$ plot at various temperatures

If the above mechanism is the case, the passivation time is controlled by the rate of precipitation and/or the rate of mass transfer of the dissolved cadmium species (8, 15). Thus, a temperature dependence of the Arrhenius type is expected of the passivation time τ and thus $i\tau^{1/2}$. In considering the temperature dependence the concept of the vitreous point T_o (12-14) was introduced since the mechanism involves the movement of ions. The vitreous point T_o is the temperature below which mobility of ion in the electrolyte ceases (14). Then Eq. [1] can be expressed by

$$i\tau^{1/2} = \mathrm{A}\exp\left(-\frac{E_a}{T - T_o}\right) + B\,i\exp\left(-\frac{E_b}{T - T_o}\right) \qquad [2]$$

or

$$a = A\exp\left(-\frac{E_a}{T - T_o}\right) \qquad [2a]$$

$$b = B\exp\left(-\frac{E_b}{T - T_o}\right) \qquad [2b]$$

T_o was determined by Laurent and Tarrousseau (14) to be 165°K for 8M KOH. Based on the data in Table I parameters a and b were computed at different temperatures, and the values of A, B, E_a, and E_b were computed by the regression method. The results are: $A = 24.35$, $B = 33.70$, $E_a = 160.0 \pm 10.9$, and $E_b = 168.8 \pm 14.7$. E_a and E_b are equal within the standard error of statistical computation, and Eq. [2] can be expressed as

$$i\tau^{1/2} = (24.35 + 33.70\,i)\exp\left(-\frac{164.4}{T - 165}\right) \qquad [3]$$

The observed values of $i\tau^{1/2}$ were compared with the calculated ones based on Eq. [3] in Table II. The experimental data agree reasonably well with the calculated values. Although the fundamental significance of this equation, if any, depends on further study of the system, the expression may be interesting in suggesting a certain model of the passivation mechanism.

Investigations of the Variations of Dielectric Constant and Surface Charge of Polyvinyl Chloride Electrets with Time

P. K. C. Pillai, V. K. Jain, and Meenakshi Kamdar

Department of Physics, Indian Institute of Technology, New Delhi 29, India

ABSTRACT

This paper deals with the charge formation, decay characteristics, and variation of dielectric constant of thermoelectrets of SR_8 (polyvinyl chloride) and SR_{10} (polyvinyl chloride) prepared at different voltages with different polarizing times. It has been found that polarizing time has a major influence in determining the initial as well as the final surface charge and also the final value of the dielectric constant. The results also show that surface charge formation is due not only to dipolar orientation but also to some other charging mechanism, which in turn affects the dielectric constant of the sample. Studies of variation of dielectric constant prove the pulsatory nature of the charge decay and also show qualitatively the orientation effect obtained by x-ray diffraction studies of electrets.

Electrets have been known for many years but have recently become a subject of considerable interest. Heaviside (1) used the word electret to denote a permanently electrified material having electric charges of opposite sign at its extremities. Eguchi (2) has shown from his experimental investigations that electret effect is a volume effect and not merely a surface effect.

Many other workers (3-7) in this field have studied the characteristics of electrets prepared from different materials by measuring their surface charge, charging and discharging current, and dipole movement. In this investigation, measurements have been made on the variation of the dielectric constant of the polarized samples along with the surface charge studies. Useful information about the variations in the surface charge and dielectric constant have been obtained from these studies.

Experimental Details

The materials used for these investigations were SR_8 (vinyl) and SR_{10} (vinyl) manufactured by the Rajasthan Vinyl and Chemical Industries, Kota, India. These are PVC compounds with different physical properties and are available in powder form with different particle sizes. Although these materials are copolymers and do not show any definite melting point, most of the ingredients of these compounds are molten at about 160°C.

Samples were molded by using these powders in a mica cavity of 1 mm thickness and 1 cm^2 size in between two aluminum electrodes, keeping the device inside an electric oven at 190°C. During formation, the upper electrode was connected to the positive terminal of a d-c source and the lower electrode to the negative of the d-c supply in all cases. The heating and cooling of the sample were done under the influence of the electric field for the required polarizing time. The sample formed in this manner was taken out of the electrode assembly for surface charge and dielectric constant measurements. After the measurements, the electret was wrapped with a metallic foil and kept in a desiccator for further measurements.

Another series of samples were prepared in 15 min polarizing time by the application of low polarizing voltages, keeping the device on a regulated heater. In this case, the temperature gradient between the two surfaces was found to have a significant effect on the characteristics of these types of electrets. The variation of surface charge and dielectric constant with time of these samples was also measured, and the results obtained from these investigations show some useful information about the variation of dielectric polarization with time in such electrified samples.

Method of Measurement

The surface charge of the polarized sample was measured by a Lindemann Electrometer and a specially made measuring device using the induction method. After charge measurement on either side, the electret was short-circuited by a metallic foil and kept in a desiccated condition for further studies.

For the measurement of the variation in the dielectric constant of the polarized sample, another instrument was developed with the help of a spherometer. A metallic circular electrode was screwed into the central leg of a spherometer and the other three legs were fixed on a plane ebonite plate. At the center of the ebonite plate, just below the upper electrode, another circular metallic plate with a guard ring was fixed so that the arrangement would act as a variable guard ring condenser. By this arrangement the capacitance of the air space between the two parallel electrodes or the sample could be measured very accurately, as the least count of the spherometer was

0.005 mm. The two electrodes of this device (Fig. 1) were connected to the Picro Farad (PF) meter with the help of two short leads for capacitance measurement. With the help of this PF meter the capacitance can be measured directly in picrofarads, using the bridge method principle. The capacitance of the condenser was measured by keeping the polarized sample between the two electrodes. After removing the sample, the capacitance of the air condenser of the same thickness as that of the electret was also observed to determine the dielectric constant. If C is the capacitance measured with the polarized sample and C_o with the air between the plates, then the dielectric constant, ϵ, of the polarized samples can be written as

$$\epsilon = \frac{C}{C_o}$$

Using this relation and the above-mentioned technique, the variation of the dielectric constant with time of the electrets was measured for more than 30 days.

Results and Discussion (8, 9)

Figures 2-7 show the charge decay characteristics, and change in dielectric constant with time, of the electrets of SR_8 prepared to 10, 12, and 14 kV/cm in 4 and 6 hr of polarizing time. It has been observed from these curves that the cathode side of the samples prepared in 4 and 6 hr of polarizing time initially give homocharge which decays and reverses to a permanent heterocharge. From an analysis of these curves it can be seen that existence of the initial homocharge of samples prepared in 4 hr time decreases with the increase of the polarizing voltages (15 days for the sample prepared at 10 kV/cm; 2 days and 1 day for the samples prepared at 12 and 14 kV/cm, respectively). The same also happens with the anode surface, and the time varies from 13 to 2 days with increase of voltage as shown in Table I.

The charge retention characteristics of the anode and cathode sides of the series of electrets prepared at different polarizing voltages with 6 hr of polarizing time have been shown in Table I and in Fig. 2, 4, and 6. From this it can be seen that the cathode of these samples shows a reversal of charge from homo to hetero in a few days as indicated, whereas the anode side shows only a homocharge without any reversal.

The presence of heterocharge can be explained on the basis of the two-charge theory given by Gross (10), which has been accepted by most of the recent workers in this field. Wiseman and Feaster (11) considered the electret assembly as a three-layer capacitor and explained the experimental results by giving the analytical expressions. Cross and Hart (12) have shown that the current in the medium is $i = GE$, where G is the electrical conductance and E is the electric field in the medium. The current through the surface layers in therefore $i_1 = G_1E_1$. The current

through the main body of the sample is given by $i_2 = G_2E_2$. In general

$$G_1E_1 + G_2E_2$$

Here there is an accumulation of charge at the interface between the surface layer and main body and can be given as

$$\sigma_{\text{hom}}{}^{\gamma} = G_1E_1 - G_2E_2 = -\sigma_{\text{het}}{}^{\gamma}$$

This equation shows that the nature of the initial charge depends on the relative magnitude of G_1E_1 and G_2E_2.

Although the above theory explains the nature and magnitude of the initial and final charges appearing on the electret surface, it fails to give a proper explanation for the appearance of initial homocharge and reversal of homo to heterocharge. The presence of initial homocharge on the cathode side of the SR_8(PVC) electret may be due to the existence of excessive negative ions in the bulk of the material, and under high-temperature conditions they may be aligned on the cathode side of the electret. In the study of the thermal degradation of polyvinyl chloride, it was found that the weakest C-Cl bond will be ruptured at temperatures above 165°C (13). This is followed by an abstraction of a hydrogen atom from an adjacent carbon and formation of a double bond in the chain. Therefore, above 165°C negative ions are produced in PVC which in turn will be collected near the cathode side due to the attraction of the dipoles. Similarly, positive ions from the decomposed products collect near the anode side due to the action of the dipolar field.

When a field is applied in the molten state of the material, the dipoles will be oriented in the direction of the field and these oriented dipoles in turn will attract the ions of opposite polarity from the bulk of the material, which will stick to the surface when the sample is solidified. This can be seen also by observing the decay curve of initial homocharge on the cathode, as well as on the anode, side of the samples (Fig. 2-7) (14). As the field increases, decay time of initial homocharge decreases considerably as shown in Table I. When the field increases more, more dipoles are oriented in the direction of the field; consequently, the charge due to dipolar orientation will be much more than what is obtained at lower fields.

It has been observed that polarizing time is a major influence in giving the polarity of charge. Samples prepared in 6 hr give permanent homocharge at the anode side. It shows that the predominance of ionic charge increases with time of preparation.

Figure 8 shows the charge decay characteristics and change in dielectric constant of an electret prepared at 8 kV/cm in 4 hr of polarizing time with SR_{10} (PVC) material. SR_{10} is again a PVC compound with different compositions. It has lower dielectric constant than SR_8 (PVC). This material also shows similar behavior.

In the next part of this paper, characteristics are given of three samples prepared from SR_{10} vinyl at 15,

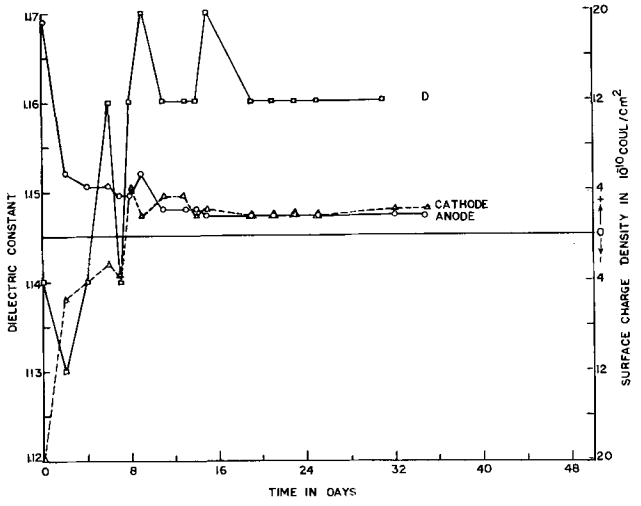

Fig. 7. Variation of dielectric constant and surface charge density vs. time for SR_8 electret formed at 14 kV/cm in 6 hr polarizing time.

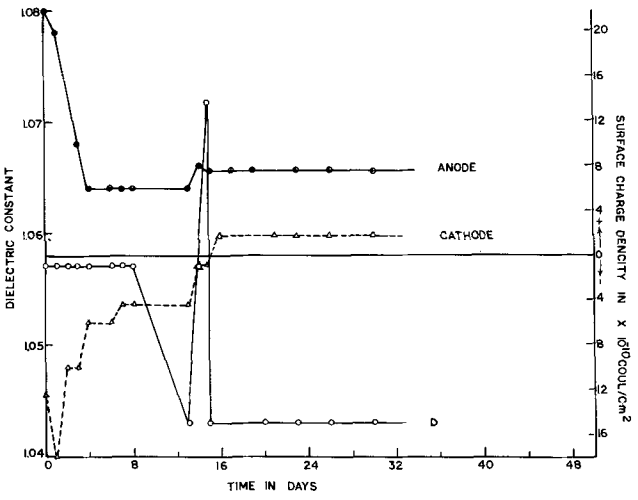

Fig. 8. Variation of dielectric constant and surface charge density vs. time for SR_{10} (PVC) electret formed at 8 kV/cm in 4 hr polarizing time.

360, and 720 V/mm, in 15 min polarizing time, following the method adopted by Jain and Pillai (15).

Here again the cathode side shows behavior similar to that of the high-voltage samples. It shows that, even at 15 V/mm, ions are collected on the negative side to give rise to homocharge, although the lifetime is much less than that of the high-voltage samples. It can be seen again that the lifetime of these initial homocharges is longer at higher voltages up to 720 V/mm.

The decay curves of the low-voltage electrets (Fig. 9-11) show that the charge decay is rather smooth in this case, which indicates that the rapid reorientation of dipoles may not be taking place at these low voltages. The curves (Fig. 9-11) showing the variation of the dielectric constant with time also show that the changes are not as significant as in the case of high-voltage samples.

Therefore, it is apparent that the formation of charge in thermoelectrets is not merely a contribution from the volume polarization taking place in the bulk of the sample, but is also due to the contribution from external polarizations. At high voltage it is possible to have spray charge from the electrode to the surface of the sample. The magnitude of this may depend on the work function of the electrode material, the interspace gap, and the gas in the interspace. In addition to these, another possible contribution is due to the molding and stripping charges which are also dependent on temperature and on the type of surface contact. To account for all these, Pillai, Jain, and Vij (16, 17) have given the following expression for the effective charge of an electret.

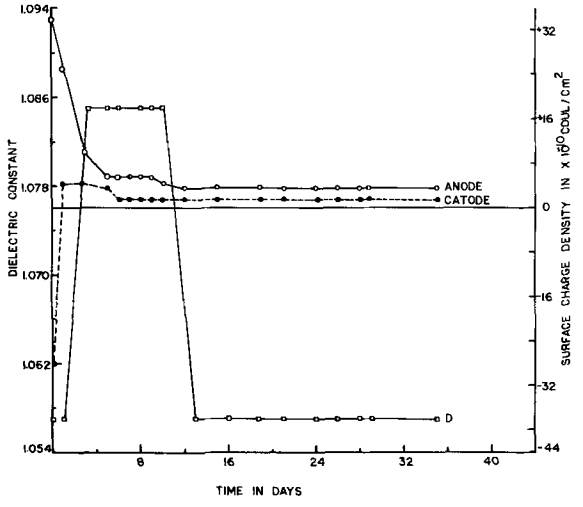

Fig. 9. Variation of dielectric constant and surface charge density vs. time for SR_{10} (PVC) electret formed at 15 V/mm in 15 min polarizing time.

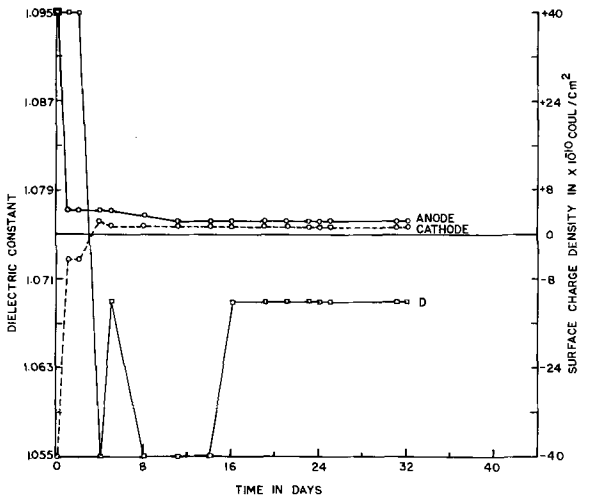

Fig. 10. Variation of dielectric constant and surface charge density vs. time for SR_{10} electret formed at 360 V/mm in 15 min polarizing time.

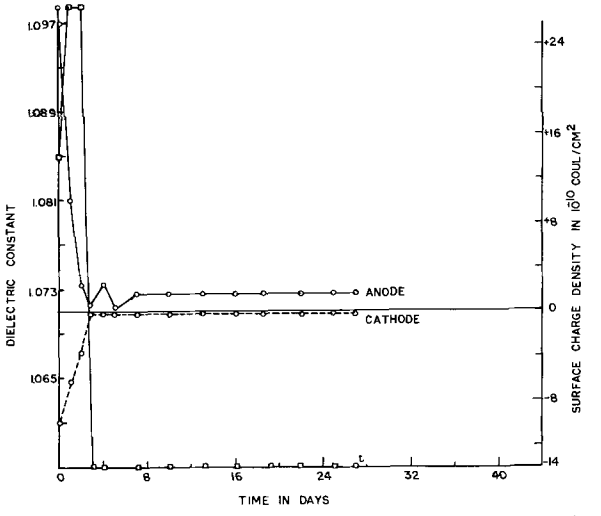

Fig. 11. Variation of dielectric constant and surface charge density vs. time for SR_{10} electret formed at 720 V/mm in 15 min polarizing time.

$$\sigma_E = \sigma_D + \sigma_i + \sigma_{hom} + \sigma_M$$

where σ_E is the effective surface charge of the electret
σ_D is the contribution of charge due to dipolar orientation
σ_i is component due to ionic polarization
σ_{hom} is contribution due to external polarization like spray charge
σ_M is charge due to molding and stripping

In every figure from 2 to 11 the variation of dielectric constant has also been plotted with surface charge to see both the effects simultaneously. Figure 12 shows the variation of dielectric constant with time in SR_{10} (PVC) electrets prepared at different voltages and also in different polarizing times.

From Fig. 2 to 7 and 12 it can be seen that the dielectric constant changes with time and reveals some peaks in the beginning. It shows that the dipoles aligned in the direction of the field slowly start reorienting in other directions. This gives rise to a change in dielectric constant as well as a change in surface charge. It can also be observed from these figures, 2-8, that the variation of dielectric constant takes place only in the initial few days and thereafter

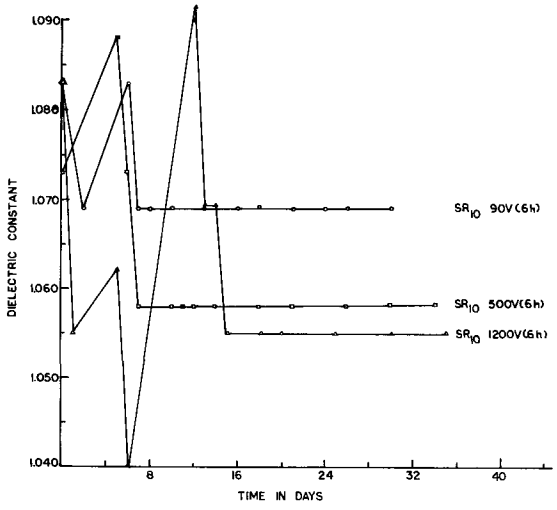

Fig. 12. Variation of dielectric constant vs. time for SR_{10} electrets prepared at 90, 500, and 1200 V/mm in 6 hr polarizing time.

it becomes constant almost simultaneously with the surface charge which also starts showing constancy.

On the application of the field in the molten condition of the material, only a fraction of the dipoles orient in the direction of the field and a larger portion orients randomly in all other possible directions. Alignment of the dipoles in the parallel direction increases the dielectric constant. The orientation of dipoles depends on the polarizing voltage, temperature, and time of the sample. In the initial stage, there are some peaks in the curves of the dielectric constant *vs.* time curve for all the samples prepared at high voltages. It clearly shows that the maximum reorientation of dipoles takes place in the initial stage. Surface charge measurements also show drastic charge density variation in the initial stage. But the phenomena of surface charge and variation of dielectric constant cannot be correlated directly, as the surface charge is not merely a dipolar phenomena; it also includes other mechanisms of charge formation. Other charging mechanisms also affect the dielectric constant variation. The dipoles are also bound by the presence of ions over the surface due to spraying, molding, and stripping. As soon as the surface loses some of these ionic charges, oriented dipoles become disturbed due to an unbalanced force which causes the variation in the dielectric constant.

After a few days time, there is no variation in dielectric constant as well as in surface charge. This clearly shows that there is no reorientation of dipoles at this stage. The permanent value of surface charge of the samples shows that presence of polarization. The dielectric constant of an unpolarized sample of SR_8 prepared under similar conditions is 1.181. But the final value of the dielectric constant of the polarized samples, Fig. 2-7, is not always higher than this value. It may be due to the fact that, on application of the field in the molten condition of the material, some dipoles were aligned in the parallel direction and some in the other directions. Moreover the contribution due to external polarizations varies from sample to sample, which also affects the variations from the normal value observed in the dielectric constant.

From Fig. 9 to 11 it can be seen that the variation observed in the dielectric constant *vs.* time curves for the electrets prepared at low voltages in 15 min time is not appreciable. Figure 12 shows the dielectric constant variation of samples of SR_{10} prepared at different voltages in 6 hr time. It can be seen from these curves that the variation of the dielectric constant in the initial stage is more for higher voltages. But the final value of the dielectric constant decreases with increase of polarizing voltages.

The present investigations show that the value obtained for the apparent dielectric constant is very low (1.1-1.2) in comparison to the value quoted in the literature for this material. The dielectric constant given for PVC is 3-5. The sample used in the present investigations is of much lower density than the standard sheets prepared under high-pressure conditions. In the present studies the microcrystallites cannot be packed closely, as the samples were made just between the two mica sheets without high pressure. The low apparent dielectric constant measured here is attributed to the low density of these specimens, which was measured to be about 0.6 g/cc, whereas the resin has a density of about 1.4.

This investigation thus confirms the pulsatory nature of surface charge decay as observed by Kojima and Kato (18). This also shows that the variation of the surface charge of an electret is intimately related to the variation of the dielectric constant of the polarized sample. In addition, the studies of variation of the dielectric constant of a polarized dielectric provide another important technique for investigating the characteristics of an electret.

Summary and Conclusions

The results obtained from these experimental investigations show that SR_8 (PVC) and SR_{10} (PVC) are good materials for electret preparation.

Polarizing time has a major influence in determining the initial, as well as final, surface charge of an electret and also on the final value of the dielectric constant.

It also shows that surface charge formation in electrets is not merely a dipolar phenomenon but includes other charging factors, which in turn affect the dielectric constant of the polarized samples.

Phase Equilibria in the $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ System and Eu^{2+}-Activated Luminescence of $Sr_3(PO_4)_2$ and Related Phases

James R. Looney[1]

Chemical and Metallurgical Division, Sylvania Electric Products Incorporated, Towanda, Pennsylvania 18848

and Jesse J. Brown, Jr. [1,*]

Department of Metals and Ceramic Engineering, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT

The phase equilibria relationships in the $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ system were established in air using DTA and melting point data obtained from compositions previously equilibrated by solid-state reactions. In addition to the previously reported rapid, reversible $\alpha \rightleftarrows \beta$-$Sr_3(PO_4)_2$ polymorphic inversion at 1305°C (1), a second rapid reversible transition $\beta \rightleftarrows \gamma$-$Sr_3(PO_4)_2$ was found to occur at 1410°C prior to melting at 1620°C. $Cd_3(PO_4)_2$ is soluble in: (*a*) α-$Sr_3(PO_4)_2$ to a maximum of 1 or 2 m/o (mole per cent), (*b*) β-$Sr_3(PO_4)_2$ to a maximum of 21 m/o at 1075°C with 12 m/o sufficient to stabilize the β-phase to room temperature, and (*c*) γ-$Sr_3(PO_4)_2$ to a maximum of 31 m/o at 1125°C. A eutectoid reaction exists at 1075°C where β-$Sr_3(PO_4)_2$ solid solution, γ-$Sr_3(PO_4)_2$ solid solution, and a ternary compound $Cd_2Sr(PO_4)_2$ are in equilibrium. $Sr_3(PO_4)_2$ is soluble in $Cd_3(PO_4)_2$ to a maximum of about 3 m/o at 1050°C. The luminescence of Eu^{2+}-activated $Sr_3(PO_4)_2$ is very dependent on composition and the polymorph present at the reaction temperature. Small additions of $Cd_3(PO_4)_2$ to all $Sr_3(PO_4)_2$ polymorphs rapidly quench the luminescence. Although both high-temperature forms of $Sr_3(PO_4)_2$ revert to the α-modification upon cooling to room temperature, phosphors prepared by solid-state reaction in the temperature stability range of β-$Sr_3(PO_4)_2$ possess superior brightness levels.

In recent years considerable interest has been directed toward the discovery and characterization of Eu^{2+}-activated phosphors (1-9). One of the most efficient phosphors in this class is $Sr_3(PO_4)_2$ (10, 11). Strontium orthophosphate is known to exhibit polymorphism on heating and cooling (12); however, the effect of this phase change on luminescence has not been investigated previously.

In the present investigation the polymorphism of $Sr_3(PO_4)_2$ is re-examined and the effect of polymorphism on luminescence is studied. The scope of the investigation is also expanded to include phase equilibria studies in the $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ system. This is especially relevant because of the similarity in ionic sizes between Sr^{2+} (1.27Å), Cd^{2+} (1.06Å), and Eu^{2+} (1.24Å) and the previously reported stabilizing effect of Cd^{2+} for Sr^{2+} substitutions in β-$Sr_3(PO_4)_2$ (13).

Related Literature

The luminescence of Eu^{2+}-activated $Sr_3(PO_4)_2$ has been described by Nazarova (10) and Levshin *et al.* (11). More recently, Shaffer (14) reported that $Sr_3(PO_4)_2$:Eu^{2+} possesses a characteristic peak emission at 408 nm, with a band width of 42 nm at half the peak intensity. The phosphor is approximately equally efficient to ultraviolet and cathode-ray excitation. The emission has saturated blue color coordinates at $X = 0.162$ and $Y = 0.016$ and is relatively fast decaying.

Sarver, Hummel, and Hoffman (12) demonstrated the polymorphic nature of $Sr_3(PO_4)_2$. The low-temperature (α) modification undergoes a rapid, reversible transition to β-$Sr_3(PO_4)_2$ at 1305°C. The high-temperature (β) polymorph crystallizes with the β-$Ca_3(PO_4)_2$ (Whitlockite) structure. Kreidler and Hummel (15) more recently established the melting temperature of $Sr_3(PO_4)_2$ at 1620°C. Powder x-ray diffraction data for $Cd_3(PO_4)_2$ were presented previously by Brown and Hummel (16).

Experimental Procedure

The phase equilibria relationships in the $Cd_3(PO_4)_2$-$Sr_3(PO_4)_2$ system were established using the 17 compositions listed in Table I. The raw materials used were C.P. grade $CdCO_3$, $SrCO_3$, and $NH_4H_2PO_4$. The batch materials were weighed to ±0.1 mg on an analytical balance and mixed to dryness under acetone in a glass mortar and pestle. The preparations were slowly heated to 900°C and reacted at this temperature for 2 days with one intermittent mixing. Weight loss experiments carried out in platinum crucibles in air indicated that no significant loss of CdO, SrO, or P_2O_5 occurred during the preparation process.

All single-phase regions were activated by substituting 0.01 mole of europium for the alkaline earth cation. The europium was added as Eu_2O_3 obtained from Michigan Chemical Corporation. The preparations were slowly heated to the desired reaction temperature in air and allowed to react for 12-24 hr. The reduction of Eu^{3+} to Eu^{2+} *in situ* was carried out by a second heat treatment in a mullite tube furnace under an atmosphere of approximately 95% N_2-5% H_2. All preparations were heat treated in the reducing atmosphere for 1½ hr and allowed to cool in a protective atmosphere of N_2.

X-ray diffraction data were obtained using CuKα ($\lambda = 1.5418$Å) radiation from a Norelco diffractometer operated at 40 kV and 15 mA. Precise lattice spacings were obtained using silicon powder ($a_0 = 5.4305$Å) as

[1] At the time this work was initiated, both authors were employed by Sylvania Electric Products Incorporated, Towanda, Pennsylvania. Abbreviations:
C_2SP = $Cd_2Sr(PO_4)_2$
C_3P = $Cd_3(PO_4)_2$
S_3P = $Sr_3(PO_4)_2$
DTA = differential thermal analysis.

an internal standard and a diffractometer scanning rate of ¼°-2 θ/min.

Differential thermal analysis (DTA) data were obtained using a Model 12BC2 apparatus manufactured by Robert L. Stone Company, Austin, Texas. A heating rate of approximately 10°C/min was used. Melting point determinations were made using a TemPres platinum strip furnace and a calibrated optical pyrometer.

Luminescence spectra were measured using an Aminco-Bowman Spectrophotofluorimeter. Spectra were compared with a standard $Sr_3(PO_4)_2$:Eu^{2+} phosphor.

Experimental Results

Phase equilibria studies.—The phase relationships for the $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ binary system as shown in Fig. 1 were established from the experimental data listed in Table I.

The $Sr_3(PO_4)_2$ rapid reversible $\alpha \rightleftarrows \beta$ polymorphic transition previously reported (12) at 1305°C was confirmed by DTA experiments. Upon heating β-$Sr_3(PO_4)_2$ to still higher temperatures, a second sharp reproducible heat effect at 1410°C was observed (see top curve in Fig. 2). Because this heat effect was observed on both heating and cooling through this temperature range, it was interpreted to indicate a second rapid reversible polymorphic transition for $Sr_3(PO_4)_2$. The high-temperature $Sr_3(PO_4)_2$ polymorph is designated γ in Fig. 1.

The $\beta \rightleftarrows \gamma$-$Sr_3(PO_4)_2$ transition apparently was not observed by previous investigators because they did not carry their DTA experiments to temperatures above 1350°-1400°C. An x-ray diffraction characterization of γ-$Sr_3(PO_4)_2$ was not obtained because of the temperature limitations of the x-ray diffraction furnaces available. Attempts to stabilize γ-$Sr_3(PO_4)_2$ to room temperature by chemical substitutions, as was done with β-$Sr_3(PO_4)_2$, were unsuccessful.

Upon addition of $Cd_3(PO_4)_2$ to $Sr_3(PO_4)_2$, three solid solution regions are developed. A very small amount of $Cd_3(PO_4)_2$ is soluble in α-$Sr_3(PO_4)_2$, apparently less than 2 m/o. Approximately 12 m/o $Cd_3(PO_4)_2$ dissolved in β-$Sr_3(PO_4)_2$ is sufficient to stabilize this polymorph to room temperature. This result is in good agreement with the previously reported results of Koelmans and Cox (13). The β-$Sr_3(PO_4)_2$ solid solution is relatively narrow below 1000°C, with a maximum solubility of 21 m/o $Cd_3(PO_4)_2$ at 1075°C. A

maximum solid solubility of 31 m/o $Cd_3(PO_4)_2$ in γ-$Sr_3(PO_4)_2$ was observed at 1125°C.

A ternary compound, $Cd_2Sr(PO_4)_2$, ($2CdO \cdot SrO \cdot P_2O_5$), was isolated and definitive x-ray diffraction data are listed in Table II. DTA experiments indicated that this compound does not exist in more than one crystalline modification and that congruent melting occurs at 1145°C.

DTA data clearly indicate two reaction isotherms between the $Sr_3(PO_4)_2$ solid solution phases and the ternary compound $Cd_2Sr(PO_4)_2$. At 1075°C a eutectoid reaction isotherm exists where β-$Sr_3(PO_4)_2$ solid solution, γ-$Sr_3(PO_4)_2$ solid solution, and $Cd_2Sr(PO_4)_2$ are in equilibrium. The intensity of the heat effect is very weak for compositions near $Cd_2Sr(PO_4)_2$ and becomes more and more intense as the $Sr_3(PO_4)_2$ content increases. Maximum intensity was observed near the eutectoid point. The existence of this eutectoid reaction substantiates the previous evidence for the existence of a third polymorph of $Sr_3(PO_4)_2$.

A second series of DTA heat effects in this compositional range were observed at 1125°C. These heat effects become more intense as the eutectic point at 60 m/o $Cd_3(PO_4)_2$ is approached. The equilibrium phases on the eutectic isotherm are γ-$Sr_3(PO_4)_2$ solid solution, $Cd_2Sr(PO_4)_2$, and liquid.

On the $Cd_3(PO_4)_2$ side of $Cd_2Sr(PO_4)_2$ a eutectic reaction was observed at 1125°C. A maximum of about 3 m/o $Sr_3(PO_4)_2$ is soluble in $Cd_3(PO_4)_2$ at this temperature. Liquid, $Cd_2Sr(PO_4)_2$, and $Cd_3(PO_4)_2$ solid solution are in equilibrium along this eutectic isotherm. Several weak unidentified heat effects between the solidus and liquidus temperatures were observed for compositions containing 80 and 90 m/o $Cd_3(PO_4)_2$.

Because the $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ system is not glass forming, all liquidus temperatures were determined by DTA and visual methods and are accurate to ±10°C. The liquidus temperature decreases rapidly from 1620°C as the $Cd_3(PO_4)_2$ content increases to the eutectic at 1125°C and 60 m/o $Cd_3(PO_4)_2$. The liquidus curve then increases to 1145°C at $Cd_2Sr(PO_4)_2$, then decreases to the second eutectic at 1050°C and 72 m/o $Cd_3(PO_4)_2$. The liquidus curve increases again to 1180°C, the melting point of $Cd_3(PO_4)_2$.

Luminescence studies.—All single-phase regions in the $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ system were investigated for Eu^{2+}-activated luminescence. $Cd_2Sr(PO_4)_2$:Eu and $Cd_3(PO_4)_2$:Eu were found to be inert. In addition, substitution of Cd^{2+} for Sr^{2+} in $Sr_3(PO_4)_2$ was observed to quench the Eu^{2+}-activated luminescence. Stabilized β-$(Sr,Cd)_3(PO_4)_2$ was a very weakly emitting blue phosphor.

As pointed out previously, both the $\alpha \rightleftarrows \beta$ and $\beta \rightleftarrows \gamma$ transitions of $Sr_3(PO_4)_2$ are rapidly reversible. Because of this nonquenchable characteristic, α-$Sr_3(PO_4)_2$ is always obtained at room temperature in phosphor preparations. The substitution of 1.0 m/o Eu^{2+} for Sr^{2+} in pure $Sr_3(PO_4)_2$ significantly lowers the inversion temperatures as shown in the DTA curves at the top of Fig. 2 The two sharp peaks for $Sr_3(PO_4)_2$ illustrate the characteristic heat effects of the two polymorphic transitions at 1305° and 1410°C. The corresponding two heat effects for the phosphor, $(Sr_{0.99}, Eu_{0.01})_3(PO_4)_2$, occur at temperatures of 125°-150°C

lower. In addition, the two peaks are not nearly as sharp, indicating the presence of a two-phase region.

Phosphors of composition $(Sr_{0.99},Eu_{0.01})_3(PO_4)_2$ were prepared by reaction in air at 1000°C for 2 days. The preparations were divided into smaller portions and reduced at temperature from 1000° to 1400°C. Extreme care was taken to assure that each phosphor was exposed to identical reducing conditions. In other words, only temperature was changed. Table III summarizes the results of these experiments.

Upon cooling, all samples contained α-$Sr_3(PO_4)_2$ as the major phase. In addition, the photoluminescent spectra for all preparations were identical. The only significant difference in the samples was in the peak emission intensities (brightness). The variations of the brightness values are illustrated in the bottom curve in Fig. 2. There is a very marked difference in the brightness of the phosphors depending on the $Sr_3(PO_4)_2$ polymorph present at the reducing temperature. This can be seen by comparing the brightness *vs.* temperature curve with the DTA curve for the phosphor.

Discussion

Luminescence.—In view of the data presented, it appears that the photoluminescent brightness of Eu^{2+}-activated $Sr_3(PO_4)_2$ is extremely dependent on the polymorph of $Sr_3(PO_4)_2$ present at the reducing temperature. Maximum brightness is obtained only when β-$Sr_3(PO_4)_2$ is present at these high temperatures. Moreover, in Fig. 2 it can be seen from the DTA curves that the stability range of β-$Sr_3(PO_4)_2$ solid solution decreases with increasing europium content.

These results indicate that the Eu^{2+} activator enters different cation lattice sites in the $Sr_3(PO_4)_2$ lattice, depending on the polymorph present at high temperatures. It seems likely that the Eu^{2+} is quenched into these sites upon cooling. The low temperature (α) form of $Sr_3(PO_4)_2$ is known to have two nonequivalent Sr^{2+} sites in the crystal lattice (17). It would seem reasonable to suspect one of these sites to be a more efficient luminescence center than the other. When α-$Sr_3(PO_4)_2$ is the polymorph present at the reducing temperature, Eu^{2+} enters the less efficient cation site. When β-$Sr_3(PO_4)_2$ is the polymorph present, the Eu^{2+} enters a lattice site, which upon cooling corresponds to the more efficient site in the α-$Sr_3(PO_4)_2$ lattice. Cooling quenches Eu^{2+} into this lattice position. Finally, when γ-$Sr_3(PO_4)_2$ is the polymorph present at high temperatures, the Eu^{2+} appears to enter a lattice position which upon cooling corresponds to the less efficient site in α-$Sr_3(PO_4)_2$.

Summary

1. A third polymorph of $Sr_3(PO_4)_2$ has been isolated which is stable only above 1410°C.

2. The $Sr_3(PO_4)_2$-$Cd_3(PO_4)_2$ phase diagram contains four solid solution regions. A very small amount (1 or 2 m/o) of $Cd_3(PO_4)_2$ is soluble in α-$Sr_3(PO_4)_2$. Approximately 12 m/o $Cd_3(PO_4)_2$ stabilizes β-$Sr_3(PO_4)_2$ to room temperature. The β-$Sr_3(PO_4)_2$ solid solution region is very small below 1000°C. A eutectoid reaction isotherm at 1075°C indicates substantial solid solution of $Cd_3(PO_4)_2$ in γ-$Sr_3(PO_4)_2$, probably as much as 30 m/o. Slight solid solubility of $Sr_3(PO_4)_2$ in $Cd_3(PO_4)_2$ exists.

3. A ternary compound, $Cd_3Sr(PO_4)_2$, was discovered which melts congruently at 1145°C.

4. Efficient Eu^{2+}-activated $Sr_3(PO_4)_2$ is obtained only when the reducing heat treatment is carried out in the temperature stability range of β-$Sr_3(PO_4)_2$.

Luminescence of $xZnO \cdot (1-x)\ MgF_2 \cdot y\ SiO_2 \cdot zGeO_2$:Mn Solid Solutions

W. A. McAllister*

Westinghouse Electric Corporation, Bloomfield, New Jersey 07003

ABSTRACT

Manganese-activated zinc germanate, and solid solutions with zinc silicate, have been synthesized and exposed to high-energy ultraviolet radiation in plaques and lamps. Replacement of germania by silica, and/or zinc oxide by magnesium fluoride, gave improved phosphor maintenance, the best output-maintenance combination being for phosphors having equal germania and silica concentrations. The influence of these substitutions on reaction sequence and product purity, surface characteristics of the phosphor, and the output-temperature behavior were considered and related qualitatively to the bonding properties of the cation species present.

Although zinc orthosilicate:Mn has been investigated in some detail and found useful in lamps and cathode-ray tubes, the corresponding zinc germanate has not been extensively considered since the early work of Schulman *et al.* (1) on the emission and excitation spectra of the ortho-zinc compound and its beryllium derivative. Absorption and emission characteristics of the zinc silicate and germanate are similar, with the latter having better luminosity and being responsive to a wider range of ultraviolet wavelengths (1, 2). Since the maintenance of the silicate in fluorescent lamp application has been a problem, a similar propensity may exist for the germanate also. To explore this possibility, we have made zinc germanates and solid solutions with silica and examined the maintenance characteristics; output-temperature relations were also considered.

Experimental

Solid-state reactions among oxides, carbonates, and halides were used, firing 2 hr at 1200°C in air, then 1 hr in nitrogen at 1100°C with grinding between firings, to effect phosphor formation. Products were identified by powder diffraction patterns and plaque maintenance measured by exposure to the radiation from a 40W Sterilamp having a Suprasil envelope. Both samples and lamp were housed in an outer jacket which was flushed with nitrogen prior to exposure in static nitrogen atmosphere. Plaque output was measured using a Spectra Brightness Spot Meter, which also was used, in conjunction with a hotplate, for the temperature dependence measurements on thick powder samples.

Results

The products from firing the raw mix compositions in Table I were found to have poor plaque maintenance when zinc oxide, germania, and manganese carbonate were the only constituents. Replacement of some zinc oxide by magnesium fluoride was found to give relatively large gains in output and maintenance at 100 hr time. However, even the best of these was still inferior to the commercial zinc silicate:Mn standard used for comparison. Subsequent substitution of silica for germania gave generally improved resistance to degradation until roughly half the germania was replaced. Thenceforth, both the output and maintenance stabilized at values higher than the commercial zinc silicate:Mn phosphor.

Since extraneous phases were detected in compositions with no fluoride (ZnO) or 0.5 mole fluoride ($MgGeO_3$), only the silicate-germanate solid solutions having 0.3 mole MgF_2 were considered in greater detail. In Table II, the variation in output and maintenance with manganese concentration is shown to be generally downward with increasing manganese concentration for each solid solution series. Use of zinc fluoride or magnesium oxide (added as the basic carbonate) as alternates to magnesium fluoride indicates better, and comparable, maintenance for the magnesium compounds (Table III).

Lamps were made using phosphors containing the magnesium fluoride modification, at several Ge/Si levels, with the small additions of lead and arsenic customary for zinc silicate:Mn type phosphors. The readings presented in Table IV follow closely those of the plaque data and again indicate best output and maintenance for solid solutions on the silica-rich side of the midpoint.

The plaque output-temperature relations were examined for each Ge/Si ratio at different fluoride levels and *vice versa*. Representative curves for the former variation are in Fig. 1, the Ge/Si ratio being 0.6/0.4 here. Though the fluoride confers some benefit up to 150°C, the curves converge to a similar quenching temperature thereafter. More pronounced is the change in output with temperature for $MgF_2 = 0.3$ mole (Fig. 2), it being generally true that initial output decreases, quenching temperature increases, as silica replaces germania. A similar statement applies to the influence of manganese concentration, shown for the Ge/Si ratio of 0.8/0.2 in Fig. 3, while curves abstracted from the previous three show best temperature dependence for low germania and manganese, poorest behavior for the high germania-high activator combination (Fig. 4).

Discussion

Substitution of magnesium fluoride for zinc oxide gives willemite solid solutions with improved resistance to degradation and, for modest halide concentrations, without extraneous phases. Without halide there is unreacted zinc oxide for all solid solutions, while high fluoride gives $MgGeO_3$ as second phase. Since the latter is the product of a reaction in competition with the desired one giving solid solution, the products of reactions among various combinations of the raw mix constituents were examined by powder diffraction methods, using the 0.3 molar halide composition found to give only solid solution.

The data in Table V show that orthosilicate or germanate form in reactions involving these oxides with zinc oxide and magnesium fluoride; the silica-halide combination alone also gives an orthosilicate, Mg_2SiO_4. However, the companion reaction of fluoride and germania produces the $MgGeO_3$ already noted in the complete firing mix. MgF_2-GeO_2-SiO_2 combinations were fired also and found to have the metagermanate as the sole reaction product until the Ge/Si ratio was ¼. Though the phase diagram of the MgF_2-MgO-GeO_2 (3) shows no fluoride-germania interaction, conversion of the fluoride to MgO in our firing conditions leads to the reaction forming $MgGeO_3$, the stable phase at 1200°C. Its persistent occurrence in mixes containing

Table V. Interactions among silicogermanate raw mix constituents

Composition (moles)				Phases identified
ZnO	MgF_2	GeO_2	SiO_2	
1.7	0.3	1.0	—	Zn_2GeO_4, ZnO
—	0.3	—	1.0	Mg_2SiO_4
—	0.3	1.0	—	MgF_2, $MgGeO_3$
—	0.3	0.8	0.2	$MgGeO_3$, MgF_2
—	0.3	0.5	0.5	$MgGeO_3$, SiO_2
—	0.3	0.2	0.8	Mg_2SiO_4, $MgGeO_3$, $MgSiO_3$, SiO_2

silica, as well as germania, can be explained by noting that the latter melts at 1116°C (4) giving it an advantage over silica in the competition for MgO in mixes having no zinc oxide or low (1.5 moles) concentrations thereof. With zinc oxide present the magnesium metagermanate was not detected, however, and, while this is largely due to the greater tendency for zinc orthogermanate formation, there may be contributions from vapor-phase reactions like those in Table VI. Such would consume both MgF_2 and GeO_2 needed for $MgGeO_3$ formation and, concurrently, effect transport of reactants like silica and germania, not especially noted for mobility in conventional solid-state reactions. It is likely that, as written, the reactions are oversimplified since gaseous oxyhalides of the Group IV elements could also be present and contribute. Indeed, such species as $SiOF_2^+$, $SiOF^+$, and $Si_2OF_5^+$ have been detected by mass spectrometry over reaction mixes of zinc oxide and silica having $NaZnF_3$ as flux (5).

It is a well-known fact that silica, in excess of that amount required for zinc orthosilicate stoichiometry, is used to assure complete reaction of the zinc oxide raw material (6). It is thus not surprising that, in our solid solutions without magnesium fluoride, there is always unreacted zinc oxide. In replacing some zinc by magnesium, one effectively alters the Zn/Si (Ge) ratio, the silica (germania) being in excess now even though the over-all metal ion concentrations are in the orthosilicate ratio.

In addition, the magnesium fluoride (and magnesium oxide) confer improved plaque output and maintenance properties when such substitution is made. Now Harrison (6) has associated the instability of zinc silicate:Mn with a surface phase different from that of the bulk material and has presented electron and x-ray diffraction results suggesting a spinel surface modification. In our phosphors the presence of magnesium, specifically its site preference tendencies, could be an important factor in the surface properties. For example it is known that magnesium, though found in tetrahedral sites in some host lattices (7), is most frequently in sixfold coordination (8). Thus magnesium orthosilicate has the olivine structure with silicon in fourfold, magnesium in sixfold, coordination. Although magnesium silicate is soluble in zinc orthosilicate to some extent without changing the phenacite structure of the major constituent (9), the unique conditions at surfaces could favor existence of a phase having the olivine structure. The relative strengths of octahedral (2.9) and tetrahedral (2.0) bonds (10) should result in lowered mobility of surface oxygens and protect against oxidation of manganese during cooling of the fired phosphor; the tan and white body colors of phosphors without and with magnesium fluoride, respectively, support this. Further, there is no visual evidence of the gray body color, ascribed by others (6, 11) to reduction or photolytic decomposition of zinc, in our plaque tests. This, too, suggests relative scarcity of zinc atoms at the phosphor surface, *i.e.* a magnesium-rich layer.

Improved plaque and lamp maintenance (Tables I, IV) also attended substitution of silica for germania, optimum performance being that for near-equal concentrations of these constituents. The lower luminosity expected for increased silica must be balanced by some beneficial effect. One clue may be the temperature behavior, quenching temperature increasing with silica concentration. Since the rate at which output drops with temperature reflects the influence of lattice

Table VII. Size and electron distribution for ionic species

Ion	Electron configuration	Orbital radius (Å)
Zn^{+2}	$3d^{10}$	0.292
Mg^{+2}	$2p^6$	0.246
Ge^{+4}	$3d^{10}$	0.260
Si^{+4}	$2p^6$	0.201
Mn^{+2}	$3d^5$	0.388

vibrations on the luminescence center, this means relatively greater isolation of the latter as silica increases in the solid solution. Since this coupling ultimately resides in chemical bond characteristics, consideration of these is merited.

For this purpose, the orbital radii (12) and electron configurations of the cation species involved in this system are presented in Table VII. It is apparent that simultaneous replacement of Zn^{+2} by Mg^{+2} and Ge^{+4} by Si^{+4} involves substitution of large ions by smaller. [In all phosphors, the activator manganese (Mn^{+2}) is the largest cation.] More important are the electron configurations, $3d^{10}$ for Zn^{+2} and Ge^{+4}, $3d^5$ for Mn^{+2}, and $2p^6$ for Mg^{+2} and Si^{+4}. Although, to a first approximation, all the cation sites in willemite are equivalent (13) and tetrahedral, the hybrid orbitals giving this tetrahedral orientation must meet both symmetry and energy requirements. Combinations of s with either the three p orbitals or three of the d orbitals (T_2) are allowed by symmetry (14) and doubtless a mixture of sp^3 and sd^3 hybrids is used in most situations.

For zinc, germanium, and manganese, the energies of the 3d, 4s, and 4p orbitals are quite similar, favoring the p-d mixing in the hybrids forming the primary (σ) tetrahedral bonds. However, the energies of the lowest d orbitals (3d) available to magnesium and silicon, may still be too high for their effective participation in bonding, *i.e.* the sp^3 set constitutes the hybrid responsible for the tetrahedral bonds between silicon or magnesium and oxygen.

In addition to the primary σ bonds, π bond formation is also possible between metal p,d or p-d hybrid orbitals and oxygen p orbitals. Symmetry considerations again limit the possibilities for bond formation (14), in this case to combinations of the two d orbitals belonging to the E representation with either or both T_2 sets used for the σ orbitals. Thus both σ and π bonds require the use of T_2 orbitals, but if the magnesium and silica use chiefly sp^3 hybrids for the σ bonds, they have only the d orbitals available for π bonding. If, as was suggested above, the d orbitals are too high in energy for effective utilization, then the degree of π bonding is negligible. This is not so for the other host species, zinc and germanium, or the activator manganese, where 3d, 4s, and 4p orbital energies are nearly equal.

A property of π bonds is delocalization of the electrons involved, a factor of some possible importance in the phosphors described here. Consider several adjacent tetrahedra occupied by zinc, germanium, and manganese and sharing a common oxygen ion (see Fig. 5). The three cations are disposed in a plane about the oxygen at the center (15) permitting extensive π bond formation among the positive ions and the 01 oxygen. Extension to the lattice as a whole provides considerable host-activator coupling and poor shielding of activator center from lattice vibrations, *i.e.* low quenching temperature. Progressive replacement of zinc and germanium by magnesium and silicon serves to limit the π bonding and improves the resistance to thermal quenching. This presumed lability of electrons in predominantly zinc germanate members of the solid solution series is also probably responsible for their rapid degradation. Electrons raised to excited states can be lost to the lattice in these members of the solid solution series and subsequently trapped at defects. The existence of traps is qualitatively demonstrated in

the persistent phosphorescence observed in both phosphors and unactivated host materials. Only the zinc orthosilicate materials have no visually detectable afterglow, supporting the suggestion that silica inhibits electron migration and the attendant damage.

Cathodoluminescence of $CaS:Ce^{3+}$ and $CaS:Eu^{2+}$ Phosphors

W. Lehmann* and F. M. Ryan

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Data are presented on green-emitting $CaS:Ce^{3+}$, red-emitting $CaS:Eu^{2+}$, and doubly activated $CaS:Eu^{2+},Ce^{3+}$, including spectra, efficiency, and decay characteristics. Green $CaS:Ce^{3+}$ rivals the best green ZnS-type phosphors in efficiency, color, and brightness at low beam current and is appreciably better at high current. Red $CaS:Eu^{2+},Ce^{3+}$ is better than $YVO_4:Eu^{3+}$ in terms of efficiency but, because of the less favorable emission spectrum, only about equal to it in brightness.

Calcium sulfide has been known for a long time as an excellent and versatile phosphor host material. Nevertheless, calcium sulfide phosphors seem to have suffered some disrepute in recent years; they are almost completely neglected now compared to the vast amount of research done in other phosphor systems. One reason for this decline of interest may be the relatively poor reproducibility, and the uncertain compositions, of so-called "Lenard Phosphors" (1). This prejudice may have been valid in earlier days but we believe it to be invalid now since it has been demonstrated many times that well-defined CaS and related phosphors can be very well and reproducibly prepared (2-6).

Another and more serious objection to alkaline earth sulfide phosphors is their chemical instability against atmospheric carbon dioxide and water, which in most cases requires special precautions during storage and use. This is doubtlessly the case for MgS, BaS, and, to a lesser degree, SrS. CaS phosphors are comparatively stable when consisting of well-grown particles, however, and they can freely be incorporated into various devices with only a minimum of precaution.

Red-emitting $CaS:Eu^{2+}$ phosphors are already described in the literature (5, 7-9) although their cathodoluminescence does not seem to have been investigated before. Luminescence due to trivalent cerium has been reported in MgS (10, 11) and in SrS (12, 13). Also, work on doubly activated CaS:Bi,Ce and CaS:Sm,Ce (mainly glow curves) is reported (14) but, peculiarly, publications on green-emitting CaS:Ce do not seem to exist (15) although this phosphor certainly is one of the most efficient we are aware of.

Experimental

The nominal composition of a good $CaS:Ce^{3+},Cl$ phosphor is CaS(100%):Ce(0.03%),Cl(2%) where the numbers indicate the concentrations on a molar basis added before firing. Starting materials used in our in-

Cathodoluminescence of $CaS:Ce^{3+}$ and $CaS:Eu^{2+}$ Phosphors

W. Lehmann* and F. M. Ryan

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Data are presented on green-emitting $CaS:Ce^{3+}$, red-emitting $CaS:Eu^{2+}$, and doubly activated $CaS:Eu^{2+},Ce^{3+}$, including spectra, efficiency, and decay characteristics. Green $CaS:Ce^{3+}$ rivals the best green ZnS-type phosphors in efficiency, color, and brightness at low beam current and is appreciably better at high current. Red $CaS:Eu^{2+},Ce^{3+}$ is better than $YVO_4:Eu^{3+}$ in terms of efficiency but, because of the less favorable emission spectrum, only about equal to it in brightness.

Calcium sulfide has been known for a long time as an excellent and versatile phosphor host material. Nevertheless, calcium sulfide phosphors seem to have suffered some disrepute in recent years; they are almost completely neglected now compared to the vast amount of research done in other phosphor systems. One reason for this decline of interest may be the relatively poor reproducibility, and the uncertain compositions, of so-called "Lenard Phosphors" (1). This prejudice may have been valid in earlier days but we believe it to be invalid now since it has been demonstrated many times that well-defined CaS and related phosphors can be very well and reproducibly prepared (2-6).

Another and more serious objection to alkaline earth sulfide phosphors is their chemical instability against atmospheric carbon dioxide and water, which in most cases requires special precautions during storage and use. This is doubtlessly the case for MgS, BaS, and, to a lesser degree, SrS. CaS phosphors are comparatively stable when consisting of well-grown particles, however, and they can freely be incorporated into various devices with only a minimum of precaution.

Red-emitting $CaS:Eu^{2+}$ phosphors are already described in the literature (5, 7-9) although their cathodoluminescence does not seem to have been investigated before. Luminescence due to trivalent cerium has been reported in MgS (10, 11) and in SrS (12, 13). Also, work on doubly activated CaS:Bi,Ce and CaS:Sm,Ce (mainly glow curves) is reported (14) but, peculiarly, publications on green-emitting CaS:Ce do not seem to exist (15) although this phosphor certainly is one of the most efficient we are aware of.

Experimental

The nominal composition of a good $CaS:Ce^{3+},Cl$ phosphor is CaS(100%):Ce(0.03%),Cl(2%) where the numbers indicate the concentrations on a molar basis added before firing. Starting materials used in our in-

* Electrochemical Society Active Member.

vestigation were pure CaS (16), Ce_2S_3, NH_4Cl, and sulfur. They were intimately mixed (dry) in the desired ratios and fired in capped quartz tubes, surrounded by a flow of argon, at 1200°C for 2 hr.

The addition of a halide (Cl may be replaced by F, Br, or I) to the phosphor is essential as it strongly enhances the otherwise very weak or completely absent Ce^{3+} emission. While it is relatively certain that all added cerium stays in the phosphor during firing, it is equally certain that most of the volatile halides "boil out" so that the halide content after firing is much smaller then the starting amount. The addition of some free sulfur to the raw material is not essential. It only serves to provide a sulfurizing atmosphere surrounding the phosphor during firing and protecting it from oxidation to $CaSO_4$. At the high firing temperature, the sulfur vaporizes and drives all air out of the quartz tube. It is then carried away by the flowing argon gas.

The preparation of red-emitting CaS:Eu^{2+},Cl phosphor is completely analogous to that of green CaS:Ce^{3+},Cl only with Ce_2S_3 replaced by Eu_2S_3. Presence of a halide is also essential here. Europium is unique among the rare earth elements as it appears to enter the CaS lattice only as divalent ion. Thus all attempts to prepare CaS:Eu emitting in the typical orange to red line spectrum of Eu^{3+} were without success (17) in agreement with similar experience reported by Jaffe and Banks (8) and by Brauer (7). The measurement techniques used to determine the phosphor properties are described elsewhere (16).

Properties of CaS:Ce^{3+}

Trivalent cerium produces two partly overlapping emission bands in all alkaline earth sulfides. In CaS their peaks are at about 2.10 and 2.37 eV, respectively (λ = 590 and 523 nm). The spectral energy distribution of these bands is plotted in Fig. 1. The energy difference between these two peaks is almost precisely the same as the difference of 0.28 eV reported for the two lowest states ($2F_{5/2}$ and $2F_{7/2}$) of the single 4f electron of Ce^{3+} (18) so that, with a high degree of certainty, the electronic transition responsible for the luminescence terminates in these two states. The point of origin of the electronic transition is open to speculation. The transition yielding the high-energy peak of the emission is invariably the stronger of the two. The two peak positions vary only very little with the cerium concentration or with temperature, and the intensity ratio of the two bands ($\approx$ 65/100 in terms of quanta) seems to be completely independent of all preparational parameters and of the conditions of excitation. The green color of the emission corresponds closely to that of a (Zn,Cd)S:Ag phosphor containing 30 m/o (mole per cent) of CdS (Fig. 2).

The optical absorption spectrum of CaS:Ce^{3+} is also plotted in Fig. 1. It corresponds closely to its excitation spectrum and is characterized by a fairly well-defined absorption band with a single peak at 2.73 eV (λ = 454 nm) in the blue, giving the material a greenish-yellow body color. The green cerium emission is excited well by blue light and by ultraviolet in the vicinity of the optical absorption edge of CaS ($\approx$ 4.8 eV) but, for lack of absorption, not by near-ultraviolet of a high-pressure mercury discharge lamp ($\approx$ 3.4 eV).

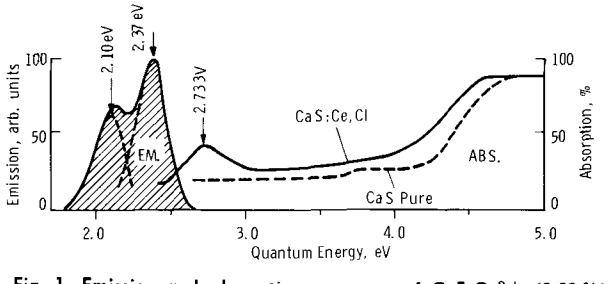

Fig. 1. Emission and absorption spectrum of CaS:Ce^{3+} (0.03%), Cl.

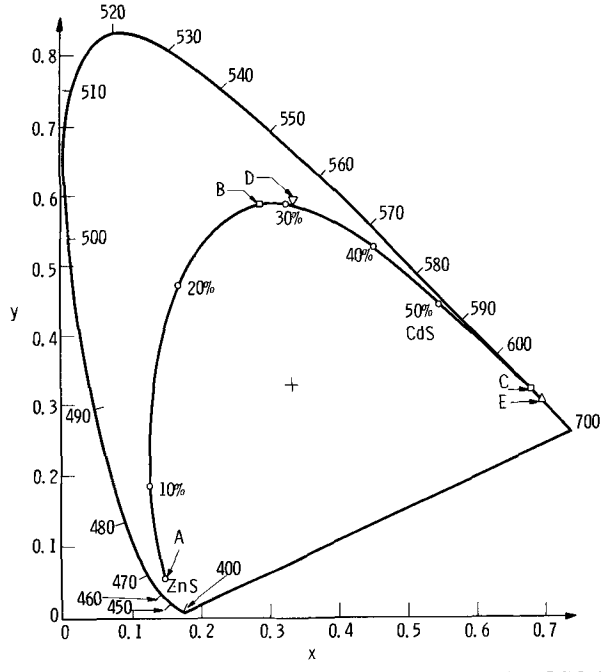

Fig. 2. ICI diagram containing the colors of various (Zn,Cd)S:Ag phosphors (circles), blue ZnS:Ag (point A), green (Zn,Cd)S:Ag (point B), red YVO_4:Eu^{3+} (point C), green CaS:Ce^{3+} (point D), and red CaS:Eu^{2+} (point E).

The influence of the cerium concentration on the intensity of cathodoluminescence of CaS:Ce^{3+},Cl is shown in Fig. 3. Quasi-infinitely thick powder samples of the phosphor were excited in a demountable system by 10 kV electrons of constant low current density ($\sim 10^{-6}$ A/cm^2). The light output was measured from the excited side by a selected silicon photo diode of flat quantum response over the visible range and compared to that of the best available green (Zn,Cd)S:Ag phosphor (P-22) used in color TV picture tubes. Such comparison is accurate and reproducible to about ±5%. Since there are very little differences either in the mean wavelength or in the luminosity factor between the two phosphors, the measured quanta can very approximately be considered to express also the differences in energy efficiency and in visible brightness. Figure 3 shows efficiencies measured in this way to have a flat maximum between about 0.02 and 0.03 m/o of cerium but decreasing only very little up to 0.1% of cerium. The energy efficiency at the optimum cerium concentration is about equal to that of the green P-22

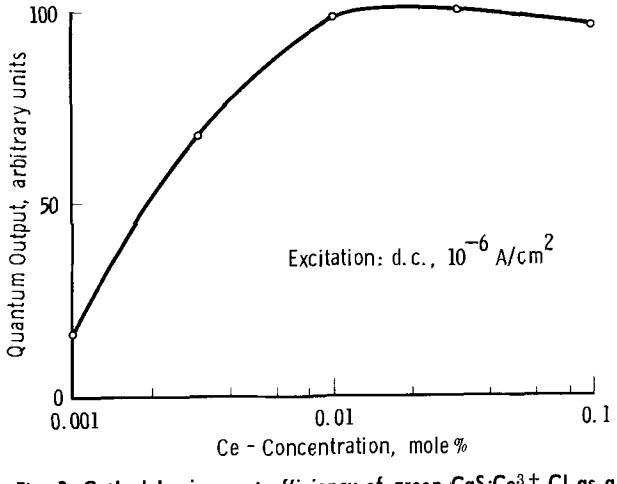

Fig. 3. Cathodoluminescent efficiency of green CaS:Ce^{3+},Cl as a function of the cerium concentration.

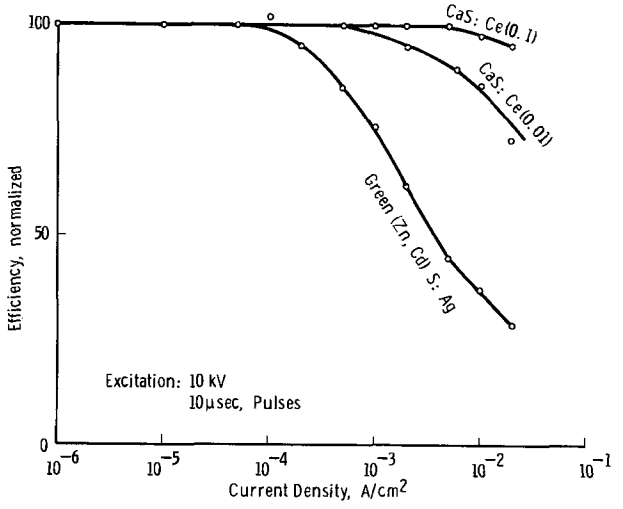

Fig. 4. Current saturation of two samples of CaS:Ce^{3+},Cl excited by 10 kV electron beam pulses of 10 μsec widths, compared to green (Zn,Cd):Ag.

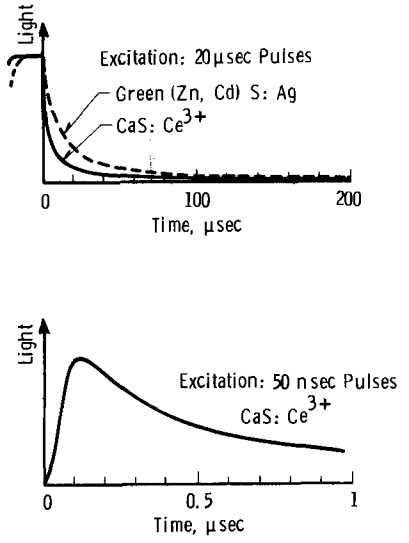

Fig. 5. Decay curves of cathodoluminescence of green CaS:Ce^{3+},Cl and of green (Zn,Cd)S:Ag.

phosphor whose efficiency was estimated to be about 22%.

The influence of the current density on the efficiency was tested on thin phosphor layers spread on glass with little binder and aluminized on top. The phosphors were excited by 10 kV electron beam pulses of 10 μsec length and the emission was observed through the glass. The results in Fig. 4 show the measured efficiencies (actually the ratios quantum output/current density) as functions of the current density during the pulse; all curves in Fig. 4 are normalized to 100 units at low currents. The three phosphors corresponding to the three curves are about equally efficient at low current but they differ considerably at high currents. CaS:Ce^{3+} phosphors saturate much less at high currents then the standard green P-22 phosphor so that the former is superior over the latter, at high currents, by an appreciable margin. It can also be seen that the saturation in CaS:Ce^{3+} is less pronounced for the higher cerium concentrations. This is indicative that the saturation of CaS:Ce^{3+} is caused by exhaustion of available unexcited Ce^{3+} ions in the phosphor (19).

Cerium-activated oxygen-dominated phosphors are well known to be relatively fast, typically with decay times between about 10^{-8} and 10^{-7} sec (example: P-16). We observe the decay of green CaS:Ce^{3+} phosphors, after excitation by an electron beam pulse at room temperature, to be slower and to consist of (at least) three components:

(*a*) The first decay, immediately after cessation of the pulse, is approximately exponential with a τ of $\sim 10^{-7}$ sec.

(*b*) A slower decay follows with a τ of a few 10^{-4} seconds.

(c) A very slow decay finally extends over several seconds.

Typical observed decay curves are shown in Fig. 5. Components (*b*) and (c) are nonexponential. Components (*a*) and (*b*) are observable after electron beam excitation; the slowest component (c) requires photoexcitation to be observed. Time-resolved spectra have shown that all three components of the decay result in the same identical cerium emission spectra. We believe all observed decay components to be due to traps thermally releasing carriers to the cerium ions. One must assume several trapping energies (or a range of trapping energies) to explain all observed decay phases at room temperature. Cooling of the phosphor to 77°K results in a nearly perfectly exponential decay with a τ of about 80 nsec which probably is the intrinsic recombination time within the Ce^{3+}-ion in CaS.

Properties of CaS:Eu^{2+}

Divalent europium is well known to produce a single, relatively narrow, but diffuse emission band in all alkaline earth sulfides. Its peak is near 1.90 eV ($\lambda = 652$ eV) in CaS at room temperature, almost independent of the europium concentration but somewhat dependent on the temperature. The emission shifts slightly to lower energies with decreasing temperature. At room temperature, the emission color is somewhat deeper red than that of YVO_4:Eu^{3+} (Fig. 2). Its spectral energy distribution is plotted in Fig. 6.

The optical absorption spectrum of CaS:Eu^{2+},Cl contains as its main feature a broad absorption band uniformly extending from about 2.1 (yellow) to 3.0 eV (violet) causing the characteristic pink body color of this phosphor. The red Eu^{2+} emission is well excited by optical irradiation within this band and by ultraviolet near the optical absorption edge of CaS but only weakly by the near ultraviolet of 3.4 eV ($\lambda = 365$ nm) of a high-pressure mercury lamp. Its optical absorption spectrum is plotted in Fig. 6.

The efficiency of cathodoluminescence of red CaS:Eu^{2+},Cl as a function of the europium concentration follows about the same concentration dependence as shown in Fig. 3 for CaS:Ce^{3+},Cl with the optimum located at about 0.05% europium. However, this optimum is lower than that of CaS:Ce^{3+},Cl. Even in the best materials it comes only to about 10-12%. This lower value (compared to the $\sim$ 22% observed in CaS:Ce^{3+}) cannot be completely explained by the lower mean quantum energy of the emission of CaS:Eu^{2+} and we have to assume the existence of a nonradiative recombination mechanism in CaS:Eu^{2+} which is not, or to a lesser degree, present in CaS:Ce^{3+}.

We have observed a drastic improvement of the efficiency of cathodoluminescence of red CaS:Eu^{2+} by incorporating small amounts of cerium into the phosphor, too small to let the green Ce^{3+} emission appear noticeably besides the red Eu^{2+} emission. Some re-

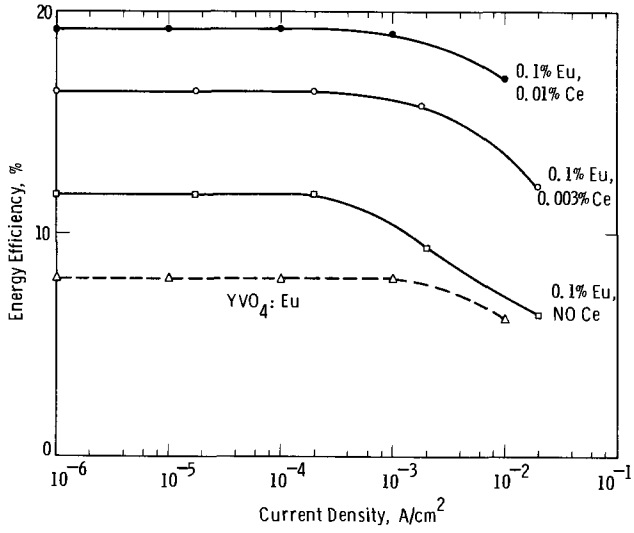

Fig. 7. Energy efficiencies of cathodoluminescence of CaS: Eu^{2+},Cl of CaS:Eu^{2+},Ce^{3+},Cl and of YVO_4:Eu^{3+} as functions of the current density. Excitation by 10 kV electron beam pulses of 10 μsec widths.

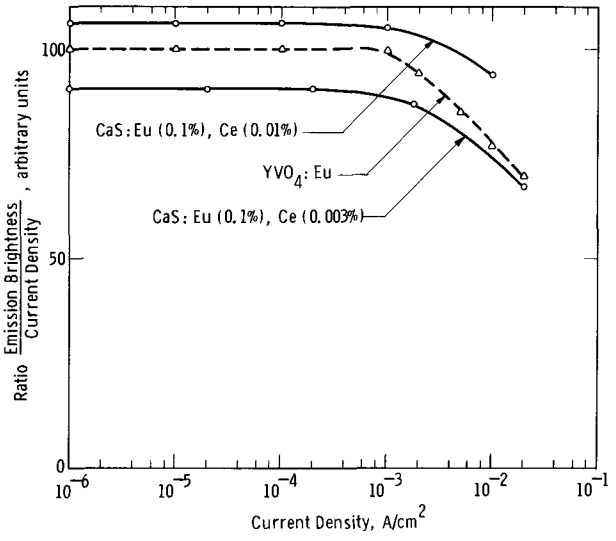

Fig. 9. Visible brightness of cathodoluminescence of CaS: Eu^{2+},Ce^{3+},Cl as a function of current density (compared to YVO_4:Eu^{3+} = 100 at low currents).

sults measured on these phosphors compared to that of commercial YVO_4:Eu^{3+} are shown in Fig. 7-9.

The efficiency of singly activated CaS:Eu^{2+},Cl compares well to that of YVO_4:Eu^{3+} in terms of energy (Fig. 7) but not in terms of brightness because of the less favorable emission spectrum. Increasing amounts of cerium added to CaS:Eu^{2+},Cl improve the low-current efficiency from about 12% (no cerium) to about 18% (0.01% cerium) which we believe to be about the maximum that can be obtained from this phosphor.

The saturation of singly activated CaS:Eu^{2+} at high current density decreases with increasing europium concentration (Fig. 8). We conclude that the saturation probably is caused by exhaustion of available unexcited Eu^{2+} ions in the phosphor (19) similar to the case of green CaS:Ce^{3+},Cl. At a given europium concentration, the saturation is decreased yet further by the addition of small amounts of cerium. It may be stressed here that all CaS:Eu^{2+},Ce^{3+},Cl phosphors of Fig. 7-9 emit only in the red Eu^{2+} band. There is no green Ce^{3+} emission contribution of noticeable intensity.

Figure 9 shows the emission brightness (actually the ratio of brightness/current) of two representative red-emitting CaS:Eu^{2+},Ce^{3+},Cl phosphors compared to that of YVO_4:Eu^{3+}. While the former are much superior to the latter in terms of energy (Fig. 8), the higher luminosity factor of the line emission of YVO_4:Eu^{3+} ($\sim$ 0.33) compared to the band emission of CaS:Eu^{2+} ($\sim$ 0.15) offsets this advantage. Therefore, the luminous efficiencies of the two phosphors are about equal. Cathodoluminescent decay curves of red CaS:Eu^{2+},Cl (no cerium) and YVO_4:Eu^{3+} for comparison are shown in Fig. 10. As to be expected, the allowed 5d→4f electron transition responsible for the emission of Eu^{2+} is much faster then the forbidden 4f→ 4f transition within the Eu^{3+} ion. A closer inspection of the decay curve of CaS:Eu^{2+} at room temperature reveals three components approximately equal to those observed in CaS:Ce^{3+}. All three components are nonexponential and are believed to be due to thermal trap emptying. The most striking difference between the decay characteristics of CaS:Ce^{3+} and CaS:Eu^{2+} is observed when those phosphors are cooled below room temperature. While CaS:Ce^{3+} decays fast and near-exponential already at 77°K, CaS:Eu^{2+} phosphors are nonexponential and very slow, slower than at room temperature, down to about 13°K. Details permitting an understanding of this difference are not yet known.

Discussion

One of the factors determining the efficiency of cathodoluminescence of a phosphor is the width of the forbidden band gap of the host material; the wider the

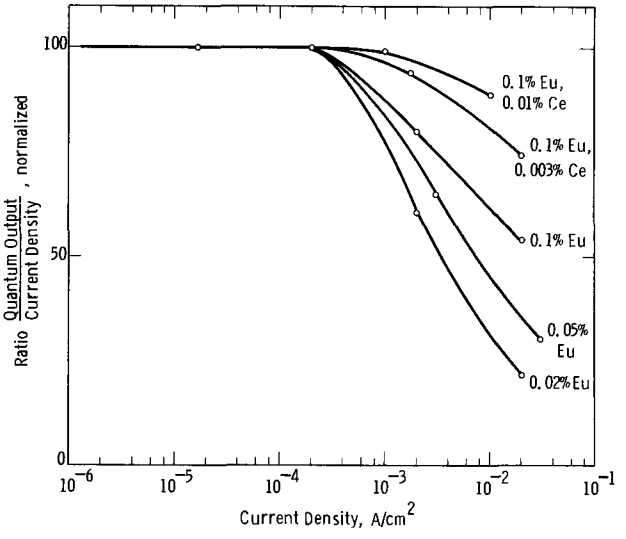

Fig. 8. Current saturation of red CaS:Eu^{2+},Cl and CaS: Eu^{2+},Ce^{3+},Cl (all normalized to 100 at low currents).

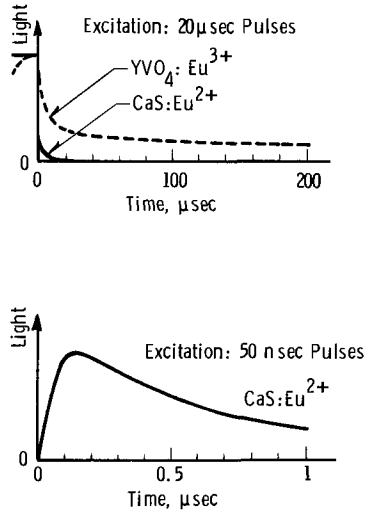

Fig. 10. Decay curves of cathodoluminescence of red CaS: Eu^{2+},Cl and of YVO_4Eu^{3+}.

gap, the lower the efficiency (all other factors kept constant). It came somewhat as a surprise, therefore, to observe the very high efficiency obtainable with CaS which, in the case of CaS:Ce^{3+}, about equals that of the best (Zn,Cd)S-type phosphors despite the much wider band gap of CaS (~4.8 eV) over that of (Zn,Cd)S (~3.0-3.7 eV dependent on the Zn/Cd ratio). This interesting observation may be discussed separately (20).

The action by which the addition of small amounts of cerium to red-emitting CaS:Eu^{2+} cathodoluminescent phosphors increases their efficiency probably involves optical cascading. The green Ce^{3+} emission (Fig. 1) coincides with the broad, strong absorption band of Eu^{2+} (Fig. 6) and any emission emanating from a Ce^{3+} ion will immediately be reabsorbed by a neighboring Eu^{2+} ion and reappear as red Eu^{2+} emission. In this mechanism, the Eu^{2+} ions are partly excited by relatively low-energy (< 2.6 eV) light quanta and it seems that this low-energy excitation of the Eu^{2+} ion is more efficient than excitation by the much higher energies available in the avalanches of free carriers during direct excitation by an electron beam. Whatever the details are, we can consider the enhancement effect as a case of sensitization of cathodoluminescence; the emission intensity by the europium is enhanced by the presence of cerium.

The puzzle least understood at the moment is a chemical one. It is our experience that none of the rare earth elements yields a luminescence worth speaking of if, under rigorously clean conditions, all other impurities are carefully avoided or if coactivation is attempted by addition of an alkali metal (Li, Na, K). The rare earth emission does appear, however, if either a halide (F, Cl, Br, I) or a group-V impurity (P, As) is added to the material before firing. This observation includes, besides the various line emitters (Sm^{3+}, Tb^{3+}, *etc.*), also the activators Ce^{3+} and Eu^{2+}. We have tried to clear up the situation with several experiments which may briefly be described here:

(*a*) A good green-emitting CaS:Ce^{3+} (0.05%), Cl phosphor was refired in an open boat, in flowing H_2S, at 1200°C for several hours. The H_2S gas can be expected to remove some of the volatile chlorine out of the phosphor under these firing conditions and, accordingly, the material was nearly nonluminescent afterwards. Addition of new chlorine (added as NH_4Cl) and refiring this near-dead material in a capped tube at 1200°C for 1 hr completely restored the green Ce^{3+} luminescence in full intensity. This cycle can be repeated several times with always the same results. Also, red-emitting CaS:Eu^{2+} tested in the same way behaves similarly. Hence, the halide does not simply act as a flux promoting particle growth. It is more actively involved in the luminescent process.

(b) A larger batch of CaS:Ce^{3+} (0.05%) was first fired without any second impurity and, afterwards, split into many small samples to which predetermined amounts of NH_4Cl were added. After refiring in tightly capped (but not sealed) tubes at 1200°C for 1 hr, the green Ce^{3+} emission appeared in full intensity in all samples to which 0.2 m/o or more Cl was added. The amount of chlorine actually retained in the phosphor after firing probably is still lower than that. A molar ratio of Ce:Cl = 1/1 in the phosphor is suggestive, although we have no reliable evidence for this yet (21).

(c) X-ray examination of CaS: samples fired in capped tubes at 1200°C for many hours with the addition of 10 m/o of either cerium or europium, and either without or with addition of 10% of $CaCl_2$, gave results which are summarized in Table I (22). The extremely large amounts of added cerium or europium may be the reason why, in these cases, even the samples made without chlorine were luminescent. The concentration of cerium dissolved in the CaS lattice is estimated to be between 1 and 10% if Cl was present but much below 1% if no Cl was present. The corresponding numbers for europium are 10% with Cl and much below 1% without Cl.

Table I. Some properties of CaS:Ce(10%) and CaS:Eu(10%) made without or with addition of 20%Cl

	10% Ce		10% Eu	
	No Cl	20% Cl	No Cl	20% Cl
Body color	Light green	Dark yellow-green	Light pink	Dark brown-red
Luminescence	Green	Yellowish	Red	Deep red
Undissolved Ce_2S_3 or Eu_2S_3	Much	Little	Much	None
Increase of lattice constant	0.007%	0.051%	0.005%	0.204%

The conclusions from these three experiments are that the solubilities of cerium and of europium in CaS are very enhanced by the presence of a halide, and that the ratios of Ce/Cl and Eu/Cl in good luminescent CaS:Ce^{3+},Cl and CaS:Eu^{2+},Cl phosphors are not far from unity. This strange behavior is completely in line with equal oddities observed in CaS phosphors made with many other activators. It cannot readily be understood on the basis of charge compensation which is so well established for ZnS-type phosphors, and a plausible explanation is still missing.

Manuscript received Sept. 23, 1970. This was Paper 49 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

21. Chemical analysis for chlorine actually retained in fired samples of CaS:Ce^{3+},Cl phosphors gave no conclusive results; molar ratios of Cl:Ce from about 2:1 to 10:1 were observed. Part of this

chlorine may be present as separate $CaCl_2$ phase so that the amount of Cl actually dissolved in the CaS lattice is uncertain.

22. This experiment was made jointly with M. Rubenstein of this laboratory. Free Ce_2S_3 or Eu_2S_3 was observed microscopically, clearly distinguishable from the CaS by the dark body colors. The lattice constants were checked by x-ray analysis.

The Effect of Exciting Wavelength on Optimum Activator Concentration

L. Ozawa,* H. Forest, P. M. Jaffe,* and G. Ban

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

The concentration dependence curves of several Eu^{+3}-, Tb^{+3}-, and Pr^{+3}-activated phosphors for different excitations have been studied. The optimum activator concentration was found to be a function of the number of excited activator ions as well as the exciting wavelength. For exciting radiation having a high absorption coefficient, the optimum activator concentration of a given phosphor shifted to low concentration. The concentration dependence curves of $(Y_{1-x}Eu_x)_2O_3$ and $(Y_{1-x}Pr_x)_2O_2S$ phosphors under cathode-ray excitation are almost identical to the curves obtained with host photoexcitation.

The emission intensity of many phosphors as a function of activator concentration initially increases proportionately with activator concentration and then decreases, going through a maximum at some concentration. The emission intensity decrease at high activator concentration is referred to as concentration quenching. Dexter and Schulman (1) have reported that concentration quenching in nonphotoconductive inorganic phosphors (many commerical phosphors are of this type) is due either to an electrostatic multipolar interaction or to a magnetic dipole interaction (exchange coupling). In a phosphor where concentration quenching is mainly due to exchange coupling between nearest neighbors, the emission intensity as a function of activator concentration depends on the concentration of isolated single activator ions which is given by $C(1 - C)^z$ (2-4) where C [1] is the activator concentration in molar fraction and z is related to the number of nearest neighbor cation sites. For quenching arising from electrostatic multipolar interactions, the emission intensity as a function of activator concentration is proportional to $C\{1 + \beta' (C)^{\theta/3}\}^{-1}$ (5) where $\theta = 6$, 8, or 10 for dipole-dipole, dipole-quadrupole, quadrupole-quadrupole interaction, respectively, and β' is a constant for each interaction for a given host crystal.

However, these expressions apply only when the exciting radiation is weakly absorbed by the activator. For practical phosphors, where the exciting radiation is strongly absorbed by the activator or absorbed by a "sensitizer," the optimum activator concentration is found to be lower than the calculated results. A point commonly overlooked in concentration quenching studies on phosphors is the importance of the absorption coefficient for the exciting radiation as well as the type of excitation. In this paper the optimum activator concentration is found to depend not only on the luminescent activator ions but also on the type of excitation; for example, weakly absorbed, strongly absorbed, sensitized, or cathode-ray.

Experimental

The phosphors studied were Eu^{+3}-activated Y_2O_3, $LiYO_2$, and YVO_4, and Eu^{+3}-, Tb^{+3}-, and Pr^{+3}-activated Y_2O_2S. The yttrium oxide and the rare earth oxides used to prepare the phosphors were 5*N* and 3*N* pure, respectively. The rare earth oxides as host and activator were dissolved in hot nitric acid and precipitated with oxalic acid. The oxide phosphors were prepared by firing the oxalates at 1200°C for 2 hr in oxygen. The vanadate phosphors were prepared by firing the proper mixture of the oxalates and 10% excess ammonium vanadate at 1000°C for 2 hr in air. After firing the samples were washed, first with 6*N* HCl and then with concentrated NH_4OH, rinsed several times with hot deionized water, and finally dried at 110°C. The oxysulfide phosphors were prepared from the oxide by a flux technique: a mixture of the proper rare earth oxide, sulfur, and sodium carbonate in the molar ratio 1:3:1, respectively, which was fired at 1100°C for 2 hr in a nitrogen atmosphere. After firing, the samples were washed with hot deionized water and dried. The lithium yttrium oxide phosphors were prepared as reported earlier (6).

The optical measurements were made on 2 mm thick powder samples, which were packed in planchettes. The emission spectra for various exciting wavelengths were obtained with a monochromatized light source consisting of a 200W d-c xenon lamp and a Bausch and Lomb grating monochromator (1300 lines/mm). Since the luminescence intensity for direct excitation in the visible is very weak, it is necessary to remove all stray uv excitation which can produce a significant emission. By proper choice of filters the emission from the desired excitation can be determined.

Results

In general, the emission of rare earth activated phosphors can be optically excited in three ways: by (*a*) indirect host excitation, (*b*) direct excitation into associated activator-host absorption (charge transfer) bands, and (*c*) direct excitation into the narrow $4f^n$ absorptions. The terms "direct" and "indirect" refer, respectively, to the classes of phosphors in which the absorption of the exciting radiation involves either an activator or a "sensitizer."[2] The dominant excitation for cathodoluminescence falls in the indirect class. Only (*a*) and (*b*) correspond to strongly absorbing excitations and are of practical interest; the $4f^n$ excitations are very weak.

* Electrochemical Society Active Member.

Key words: concentration quenching, concentration dependence, absorption coefficient, excitation, emission, phosphors.

[1] $C = n_a/(n_a + n_h)$ where n_a is the number of activator ions and n_h is the number of host cations.

[2] The host-matrix in many phosphors can act as a sensitizer.

Table I. Exciting wavelengths for the phosphors studied

Phosphor	Exciting wavelengths (nm)		
	Host excitation	Charge transfer	$4f^n$ or 4f-5d excitation*
YVO_4:Eu	320	—	467
$LiYO_2$:Eu	—	254	467 and 365
Y_2O_3:Eu	214	254	467 and 365
Y_2O_2S:Eu	254	320	467
Y_2O_2S:Tb	254	—	290
Y_2O_2S:Pr	254	290	460

* Only Tb^{+3} has a 4f-5d excitation.

The exciting wavelengths used for each of the phosphors studied are listed in Table I by type of excitation. The concentration dependence of selected emission lines was determined from the emission spectra by measuring their intensities as a function of activator concentration. The concentration dependence curves, including the one for cathode-ray (CR) excitation, are shown in Fig. 1-6. The optimum activator concentration for each photoexcitation and for cathode-ray excitation is shown in Table II. The optimum activator concentrations, as shown in Table II, were determined from linear concentration dependence curves (not shown). A linear representation was used because it was easier to determine the optimum activator concentration from this than from the usual log-log dependence curves. The log-log representation, however, is preferable for large concentration ranges and is used in the figures. The reproducibility of the data, which was checked by measuring three series of samples, is within ±5%.

For the weakly absorbing $4f^6$ Eu^{+3} direct excitation, the optimum activator concentration for $^5D_0$ emission of each phosphor exactly coincided with the concentration calculated by the exchange model, as shown in

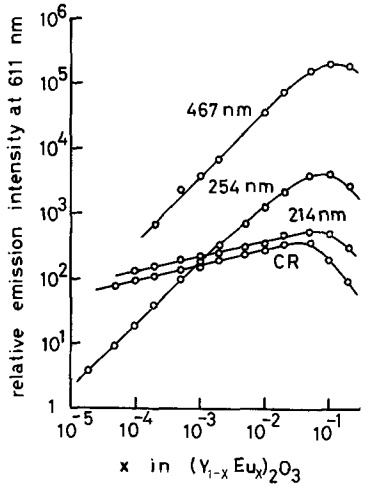

Fig. 1. Concentration dependence curves of $(Y_{1-x}Eu_x)_2O_3$ phosphors excited by 214 nm (host), 254 nm (charge transfer), and 467 nm ($4f^6$) radiation and by cathode rays. The 611 nm emission line was monitored.

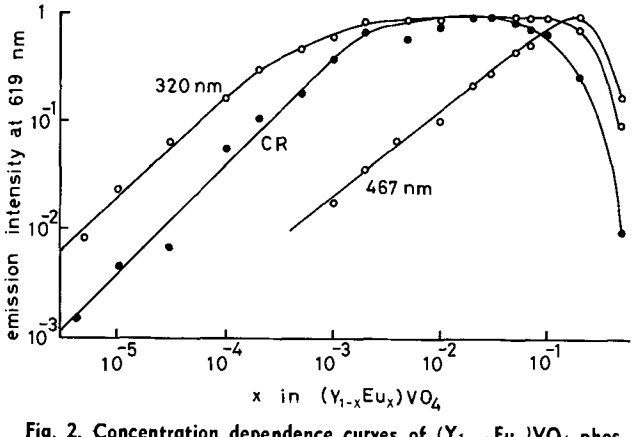

Fig. 2. Concentration dependence curves of $(Y_{1-x}Eu_x)VO_4$ phosphors under excitation by 320 nm (host) and 467 nm ($4f^6$) radiation and by cathode rays. The 619 nm emission line was monitored.

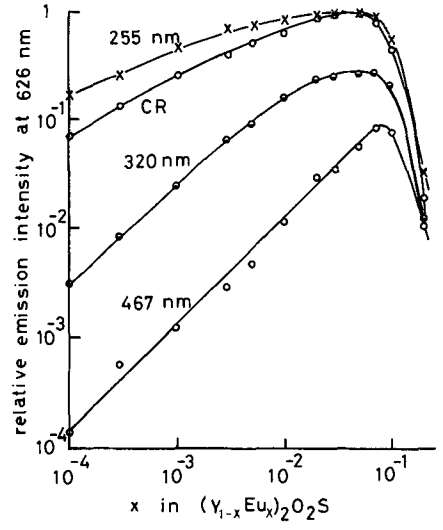

Fig. 3. Concentration dependence curves of $(Y_{1-x}Eu_x)_2O_2S$ phosphors under excitation by 255 nm (host), 320 nm (charge transfer), and 467 nm ($4f^6$) radiation and by cathode rays. The 613 nm emission line was monitored.

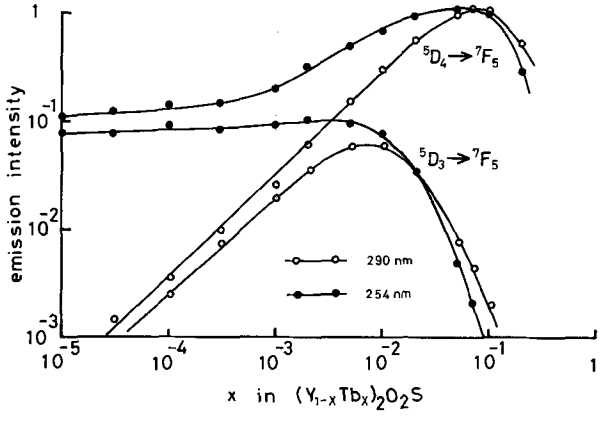

Fig. 4. Concentration dependence curves of $(Y_{1-x}Tb_x)_2O_2S$ phosphors under 254 nm (host) and 290 nm (direct) irradiation. $^5D_4 \rightarrow {}^7F_5$ (542 nm) and $^5D_3 \rightarrow {}^7F_5$ (416 nm) emission lines were monitored.

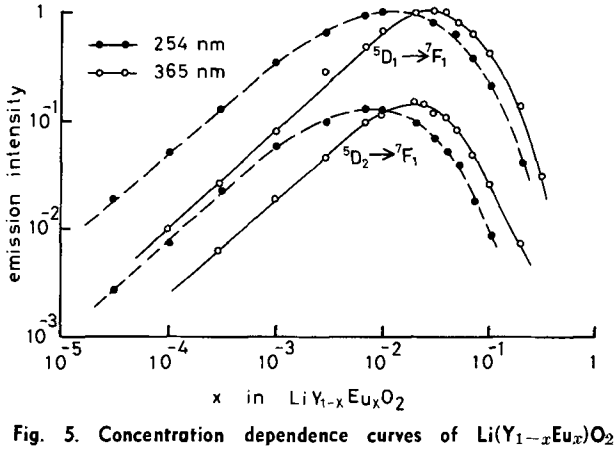

Fig. 5. Concentration dependence curves of $Li(Y_{1-x}Eu_x)O_2$ phosphors under excitation by 254 nm (charge transfer) and 365 nm ($4f^6$) radiation. $^5D_1 \rightarrow {}^7F_1$ (540 nm) and $^5D_2 \rightarrow {}^7F_1$ (476 nm) emission lines were monitored.

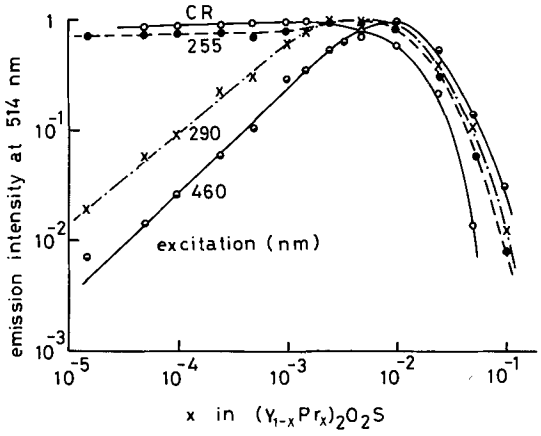

Fig. 6. Concentration dependence curves of $(Y_{1-x}Pr_x)_2O_2S$ phosphors under 255 nm (host), 290 nm (charge transfer), and 460 nm ($4f^2$) radiation and cathode-ray excitation. The 514 nm emission line was monitored.

Table II. However, the emission of $(Y_{1-x}Pr_x)_2O_2S$ and all of the $^5D_1$ and $^5D_2$ Eu^{+3} emissions quenched at considerably lower concentrations, indicating that the quenching is probably due to an electrostatic multipolar interaction (1).

In all cases, whether the quenching is due to exchange coupling or electrostatic multipolar interaction, the optimum activator concentration for a particular emission shifts to lower concentration as the excitation varies in the following sequence: $4f^n$ excitation, charge transfer excitation, host excitation, and finally cathode-ray excitation.

Discussion

In order to discuss the results, it is necessary to consider the dependence of the emission intensity from a packed powder on the absorption of the exciting radiation. Two cases are discussed: (*a*) where the scattering is large compared to the absorption (direct excitation) and (*b*) where the scattering is negligible (indirect excitation). For either case the observed emission intensity, I_{ob}, is given by the rate of formation of excited activator ions (ΔI) multiplied by the probability that an excited activator ion will undergo emission (η). This can be expressed by

$$I_{ob} = \Delta I \eta \qquad [1]$$

For a thin single crystal of a phosphor, ΔI can be obtained from Lambert absorption law as follows

$$\Delta I = I_o - I_t \qquad [2]$$

where I_o is the incident radiation intensity and I_t is the transmitted radiation intensity. But $I_t = I_o e^{-ad}$, where a [3] is the fractional decrease in the intensity per unit length due to absorption and d is the path length in the crystal, so that

$$\Delta I = I_o(1 - e^{-ad}) \qquad [3]$$

Now, Eq. [3] can also apply to a packed powder, but the path length must be modified to take into account the scattering. When an incident radiation beam encounters a packed powder, it is surface scattered through Fresnel reflections and the remainder penetrates the powder undergoing absorption as well as further scattering. The depth of penetration into the powder depends on both the scattering and the absorption. For extremely high absorption the penetration will be small, just as the case for a single crystal and Eq. [3] will apply except for the Fresnel surface losses. As the absorption decreases, the penetration will increase to the scattering limit which depends on the particle size of the powder. For 5μ particles, which includes most phosphors, the scattering limited penetration depth (*i.e.*, no absorption) is less than 1 mm. As a result of the scattering, the actual path length of the incident beam may be greater than the penetration depth. Therefore, Eq. [3] can be used for powders, in general, provided the path length can be properly determined.

In the present paper, the concentration quenching curves under various excitations are compared for a particular phosphor. The thickness of the powder samples was 2 mm to insure that none of the exciting radiation would be transmitted through the sample.

Direct excitation.—In the case of direct excitation, it is assumed that the penetration is limited by the scattering, so that the path length of the exciting radiation is fixed. This is certainly true for the weak $4f^n$ absorptions and is probably true for the charge transfer excitations at low activator concentrations. This means that Eq. [1] can be used to describe the emission intensity of a packed powder for a fixed penetration depth as follows

$$I_{ob} = I_o\,(1 - e^{-ad})\eta \qquad [4]$$

Only the qualitative features of the absorption factor are used in this paper since the path length is difficult to estimate.

For the quenching, there are two kinds of mechanisms to consider: exchange coupling and electrostatic multipolar interactions. For a phosphor in which the concentration quenching mechanism is due only to exchange coupling, the probability for emission η is proportional to the fraction of isolated single activator ions which is given by

$$(I - C)^z \qquad [5]$$

For electrostatic multipolar quenching, the probability for emission is given by

$$\{1 + \beta'\,(C)^{\theta/3}\}^{-1} \qquad [6]$$

Then, the following expressions for I_{ob} under direct excitation as a function of activator concentration (neglecting energy transfer from single ions to paired ions) are obtained:

For exchange interaction

$$I_{ob} = AI_o\{1 - \exp(-kCd)\}\,(1 - C)^z \qquad [7]$$

For multipolar interaction

$$I_{ob} = AI_o\{1 - \exp(-kCd)\}\{1 + \beta'\,(C)^{\theta/3}\}^{-1} \qquad [8]$$

The last factor in Eq. [7] and [8] merely depends on the crystal structure. Equations [7] and [8] both have a common factor which depends on the exciting wavelength. Therefore, the effects of exciting wavelength are qualitatively similar for each expression. For this reason, Eq. [7] is mainly discussed in this paper.

Figure 7 shows the calculated curves of Eq. [7] for three arbitrary values of kd, namely 1, 10, and 100, for Eu^{+3} occupying the C_2 yttrium site in Y_2O_3 where z

[3] $a = kC$, where k is expressed in cm^{-1} and depends only on the oscillator strength of the absorption, and C is the concentration expressed in molar fraction.

Table II. Optimum activator concentration of Eu^{+3}-, Tb^{+3}-, and Pr^{+3}-activated phosphors under various excitation modes

Phosphor	Emission from ^5D_j	Emission from ^3P_j	Excitation modes: Cathode ray	Host	Charge transfer	$4f^n$	Calculated $C^*_{opt} = \frac{1}{1+z}$

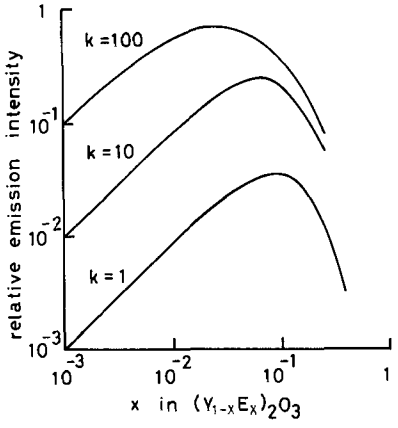

Fig. 7. Calculated concentration dependence curves for $(Y_{1-x}Eu_x)_2O_3$ with three arbitrary absorption coefficients, k, namely 1, 10, and 100.

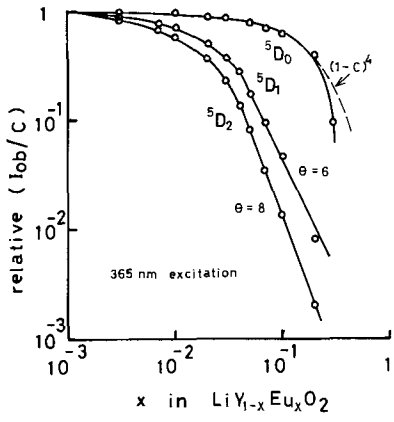

Fig. 8. Concentration dependence curves (I_{ob}/C vs. C) for the $^5D_1$ and $^5D_2$ emissions from $Li(Y_{1-x}Eu_x)O_2$ under 365 nm ($4f^6$) excitation.

is nine. These curves are relative since the constant AI_0 has not been evaluated. It can be seen that, for a fixed value of the penetration depth (d), the optimum activator concentration shifts to lower concentration as k increases. The shift is due to the saturation of the $\{1 - \exp(-kCd)\}$ factor in Eq. [7] which is linear with concentration only for small values of kCd, and as k increases the deviation from linearity occurs at successively lower concentrations.

As shown in Fig. 1-6 and Table II, regardless of the mechanism responsible for the concentration quenching, the optimum activator concentration changed with a change in the exciting wavelength. It was difficult to determine quantitatively the absorption by the phosphor powder; however, the experimental results agreed qualitatively with the results predicted by Eq. [7] and [8].

For a weak absorption, $kC << 1$, Eq. [7] becomes

$$I_{ob} = AI_0\, kCd\, (1 - C)^z$$

or

$$I_{ob} = BC\, (1 - C)^z \qquad [9]$$

where B is a constant for a given exciting intensity and penetration depth (d). Equation [9] has commonly been used as the concentration dependence equation (2-4). Therefore, if the excitation is made with radiation that is weakly absorbed, the data should fit Eq. [9].

The concentration dependence curve for the $^5D_4$ Tb^{+3} emission from $(Y_{1-x}Tb_x)_2O_2S$ for 290 nm excitation (4f-5d) was found to coincide exactly with the calculated curve using Eq. [9] (Fig. 4). Except for $(Y_{1-x}Eu_x)_2O_2S$, all of the $^5D_0$ Eu^{+3} data showed some discrepancies at concentrations greater than the optimum value. In the case of $(Y_{1-x}Eu_x)_2O_2S$, the $^5D_0$ Eu^{+3} emission curve between $x = 0.02$-0.08 showed an additional positive deviation from the calculated curve.

From Eq. [9], the optimum activator concentration C_{opt}, is given by (4)

$$C_{opt} = 1/(1 + z) \qquad [10]$$

Since z is four in YVO_4 and $LiYO_2$, nine in Y_2O_3, and twelve in Y_2O_2S, the optimum activator concentration should be, respectively, at $C = 0.2$, 0.1, and 0.08. As indicated in Table II, the observed optimum activator concentrations for the $^5D_0$ Eu^{+3} and $^5D_4$ Tb^{+3} emissions under direct excitation exactly coincide with the calculated values.

The optimum activator concentrations of the $^5D_3$ Tb^{+3} emission, $^5D_1$ and $^5D_2$ Eu^{+3} emissions, and Pr^{+3} emission, however, are at 0.01, 0.02, and 0.01, respectively; electrostatic multipolar interactions are responsible for the quenching of these emissions.

If kCd is small, Eq. [8] becomes

$$I_{ob} = BC\{1 + \beta'\,(C)^{\theta/3}\}^{-1} \qquad [11]$$

or expressed as emission per activator ion

$$I_{ob}/C = B\{1 + \beta'\,(C)^{\theta/3}\}^{-1} \qquad [12]$$

The value of θ can be estimated from Eq. [12]. Figure 8 shows the concentration dependence curves (I_{ob}/C vs. C) for $^5D_1$ and $^5D_2$ Eu^{+3} emissions from $Li(Y_{1-x}Eu_x)O_2$ under 365 nm excitation. Between 0.04-0.2 molar fraction, the curves are linearly decreasing with a slope of 6/3 and 8/3, respectively. These results indicate that dipole-dipole ($\theta = 6$) and dipole-quadrupole ($\theta = 8$) interactions are involved in the quenching. For the $^5D_3$ Tb^{+3} emission from $(Y_{1-x}Tb_x)_2O_2S$ under 290 nm excitation, it is found that the dipole-quadrupole interaction is responsible for the quenching, which agrees with other Tb^{+3}-activated phosphors (7).

Indirect excitation.—With indirect excitation, the incident energy is absorbed by a sensitizer or donor, for example the host lattice, and transferred to the activator or acceptor. This excitation process is more complicated than the direct case since it involves additional energy transfer steps. Perhaps it is for this reason that there is such a sparsity of theories and data for indirect excitations of so-called oxygen-dominated phosphors, such as oxides and oxysulfides. Even though our knowledge is too limited to describe indirect excitation by an analytical expression, it is possible to present a qualitative picture for the dependence of the emission intensity on activator concentration.

For host photoexcitation, a constant fraction of the incident radiation is absorbed which is independent of the activator concentration. This is unlike the direct excitation case where the absorption increased with activator concentration. Since host absorptions are very intense ($\sim 10^5$ cm^{-1}), the penetration depth is less than the dimensions of a single particle.

In the absence of an activator, the absorbed energy will be degraded by various mechanism (radiative and nonradiative) which can collectively be referred to as the "sink." As the activator concentration increases, the activator competes with the "sink" for the excitation until all of the absorbed energy is ultimately transferred to the activator at some "critical" concentration. Beyond this concentration the activator emission will no longer increase but will remain constant until concentration quenching begins. Therefore, the dependence of the emission intensity on activator concentration for host photoexcitation can be expected to show an initial rise, a flat region, and finally a decrease due to concentration quenching. The concentration dependence curves for host photoexcitation reported in this paper (see Fig. 1-4 and 6) show some similarities to this qualitative description. For the $^5D_3$ and $^5D_4$ Tb^{+3} emissions (Fig. 4) and the Pr^{+3} emission (Fig. 6) in Y_2O_2S, the host-to-activator energy transfer is apparently very efficient since the "critical" concentration is less than 10^{-5} mole fraction.

Under cathode-ray excitation, all of the excitations are involved; however, the dominant one is most likely

host excitation. Then, the concentration dependence curves for cathode-ray excitation and host photoexcitation should be similar. In $(Y_{1-x}Eu_x)_2O_3$ and in $(Y_{1-x}Pr_x)_2O_2S$ phosphors, the concentration dependence curves obtained by cathode-ray excitation (CR) are almost identical to the concentration dependence curves obtained for the host photoexcitation as shown in Fig. 1 and 6. However, the concentration dependence curves for the other Eu^{+3}-activated phosphors under cathode-ray excitation deviate from the host photoexcitation curve at high europium concentrations. This deviation may be due to the direct excitation of Eu^{+3} under cathode-ray excitation, which can occur at high europium concentrations.

Conclusion

Under direct excitation, an expression for the emission intensity as a function of activator concentration can be derived for the case where the exciting radiation is weakly absorbed. For this type of excitation, the optimum activator concentration of a phosphor, in which the quenching is due to an exchange interaction, exactly coincided with the value calculated from the isolated single activator ion concentration. Where the absorption coefficient is not negligible the number of excited activator ions saturates, causing the optimum activator concentration to shift to lower concentrations.

Under cathode-ray excitation and host photoexcitation the concentration dependence curves are similar, indicating common excitation mechanisms.

Concentration of Zinc in Gallium Arsenide Crystals Grown by Slowly Cooling Gallium-Rich Solutions[1]

S. F. Guo,[2] C. D. Thurmond,[3,*] and G. L. Pearson

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

Gallium arsenide crystals were grown from Ga-rich solutions having initial compositions near the 900°C isotherm of the Ga-As-Zn ternary phase diagram. They were grown over the temperature range from 900° to 700°C. The concentration of Zn in GaAs appears to vary linearly with the Zn atomic fraction in the liquid at lower doping levels and with the square root of the atomic fraction of Zn in the liquid at higher doping levels. In fitting the experimental data to the theoretical expression for the solid solubility, the intrinsic carrier concentration of GaAs was found to be about 8×10^{17} cm^{-3}. The corresponding temperature has been estimated to be 825°-850°C.

The solid solubilities of Zn in GaAs crystals grown from solutions along the 1000°C isotherm of the Ga-As-Zn ternary phase diagram have been obtained by Panish and Casey (1). Chang and Pearson (2) have made several solid solubility measurements at 900°C from diffusion curve extrapolations.

The objective of the experiments reported here is to obtain the dependence of the Zn concentration in GaAs on the liquid phase concentration. Ideally, such experiments should be done at a particular temperature. However, the expected temperature dependence of solubility (1, 2) is small. A crystal grown over a temperature range from 900° to 700°C should have about a factor of 3 variation. This should be true for most of the extrinsic range. The variation in concentration for intrinsic crystals should be smaller. Since the solid concentration will be varied by 4 orders of magnitude in the experiments represented here, the small variation with temperature will not obscure the concentration dependence.

Self-nucleated crystals were grown in sealed and evacuated ampoules by cooling slowly from solutions (3) containing Ga, GaAs, and Zn. The Zn concentration in the GaAs crystals was determined from Hall measurements. In addition, radioactive tracer measurements, electron beam measurements, Schottky barrier, and p-n junction diode capacitance measurements were made on certain samples.

Experiments

The materials used in these experiments were Asarco undoped polycrystalline GaAs containing a donor impurity of 3.5×10^{16} cm^3, Eagle Picher seven 9's Ga, and Cominco five 9's Zn. Radioactive ^{65}Zn was used in one experiment.

The starting composition of solutions was chosen to be near the 900° isotherm of the liquidus surface of the Ga-As-Zn ternary phase diagram presented by Panish (4). The atomic fractions of Ga, As, and Zn used in each run are given in Table I.

Table I. Composition of solutions

Run No.	Atomic fraction Ga	As	Zn
1	0.919	0.081	1.2×10^{-4}
2	0.94	0.06	8.7×10^{-4}
3	0.935	0.065	8×10^{-7}
4	0.83	0.07	0.1
5	0.93	0.06	0.01
6	0.94	0.06	9.2×10^{-7}
7	0.94	0.06	2.5×10^{-5}
8	0.50	0.13	0.37
9	0.24	0.24	0.52
10	0.96	0.04	9.3×10^{-6}

The materials were loaded in a clean quartz tube. The tube was evacuated to about 10^{-5} Torr and sealed. The volume of the ampoule was about 3 ml. The ampoule was put into a vertical furnace and heated to a temperature above the liquidus curve of the phase diagram for a few hours. The solution was then cooled slowly at a rate of 27°C/day. Single platelets were recovered.

The hole concentration obtained from Hall measurements at room temperature can be used to determine the Zn concentration in GaAs. The van der Pauw method was used for crystal plates of arbitrary shape (5). From the data of Ermanis and Wolfstirn (6) and this work, a relation between Zn and hole concentrations is established up to 5×10^{18} cm^{-3} as shown in Fig. 1. The zinc concentration is larger than the hole concentration by the factor 1.3. Electron beam microprobe analysis shows that the correction factor is unity at a concentration of 10^{20} cm^{-3}. We have chosen to make the small 1.3 correction to the Hall measurement below 5×10^{18} cm^{-3} and no correction at higher concentrations.

The junction capacitance method was used to measure the hole concentration in lightly doped GaAs; n^+-p junction diodes were formed either by alloying Sn dots directly on the p-type GaAs wafer in a forming gas atmosphere or by evaporating and alloying procedures in a vacuum system. Ohmic contacts to the p-type bulk were made by alloying Au-Zn alloy to the sample.

The resistivity ρ (ohm-cm), mobility μ_p (cm^2/V-sec), and hole concentration p (cm^{-3}) obtained from Hall measurements are given in Table II. The Zn concentrations obtained from the Hall measurements and from measurements used are also included in Table II.

Results and Discussion

The measured concentration of Zn in GaAs, grown from solutions with initial compositions near the 900°C isotherm of the Ga-As-Zn ternary phase diagram, is shown in Fig. 2. The results of Chang and Pearson (2) for 900°C are also shown in the figure. The concentration of Zn in GaAs appears to vary linearly with the atomic fraction of Zn in the liquid at the lower doping levels and with the square root of the atomic fraction of Zn in the liquid at the higher doping levels. This result is in good agreement with the theoretical expression discussed below.

From the thermodynamic equilibrium relation for the incorporation reaction of Zn atoms in the liquid with Ga vacancies in the solid to form singly ionized Zn acceptors and free holes in the solid and from the charge neutrality condition and the electron-hole mass action relation, the Zn concentration in GaAs can be expressed as

$$N_{Zn} = KX^{l}_{Zn}/(KX^{l}_{Zn} + n_i^2)^{1/2} \quad [1]$$

Here n_i is the intrinsic carrier concentration, K is proportional to the thermodynamic equilibrium constant for the incorporation reaction, and X^{l}_{Zn} is the atomic fraction of Zn in the liquid. Equation [1] applies to solutions sufficiently dilute to assure that the activity coefficients of Zn in the liquid and solid, the activity of arsenic in the liquid, and the activity coefficient γ holes in the solid are not functions of composition. The proportionality constant is $\gamma^{l}_{Zn}\gamma^{l}_{As}/\gamma_p\gamma^{s}_{Zn}$.

At low doping levels, $X^{l}_{Zn}K << n_i^2$, the Zn concentration is proportional to the atomic fraction of Zn in the liquid

$$N_{Zn} = (K/n_i)X^{l}_{Zn} \quad [2]$$

At high doping levels, $X^{l}_{Zn}K >> n_i^2$, the Zn concentration is proportional to the square root of the Zn fraction in the liquid

$$N_{Zn} = (KX^{l}_{Zn})^{1/2} \quad [3]$$

The experimental results, plotted in Fig. 2, appear to follow these relations quite well. It can readily be shown from Eq. [2] and [3] that the value of N_{Zn} at the point of intersection of the linear and square root lines is n_i and, to fit the data shown, has a value of 8 x 10^{17} cm^{-3}. The theoretical curve shown in Fig. 2 was obtained by plotting Eq. [1] in terms of reduced variables on a log-log scale and finding the best fitting position over the experimental points plotted on the same scale. Only points below 5 x 10^{19} cm^{-3} were used. The uncertainty in n_i from data scatter is about 30%. At concentrations higher than 5 x 10^{19} [4] it is expected that the experimental curve will depart from the square root line in the direction shown in the figure (1).

The above analysis assumes a constant temperature. In fact, the experimental results have been obtained from crystals grown over a 200°C temperature range. However, the variation in concentration of Zn in a grown crystal is expected to be about a factor of 3, as obtained from the temperature dependence of the Zn distribution coefficient (1, 2), about 12 kcal. Since the variation due to concentration dependence is much larger, the concentration dependence of Fig. 1 should be a good approximation to a single isotherm.

A temperature corresponding to the average measured composition can be estimated. At a particular starting composition at 900°C, the Zn concentration in GaAs can be calculated as a function of the fraction of GaAs crystallized between 900° and 700°C. The fraction crystallized is a known function of temperature. The curves obtained for various assumed values of the distribution coefficient, its temperature dependence, and the initial composition of the liquid were found to give an average concentration for the 900°-700°C temperature interval that fell in the range of 825°-850°C.[5] These estimates apply to extrinsic solid solutions. Intrinsic solid solutions are expected to have a temperature coefficient of solubility appreciably smaller than the temperature coefficient for extrinsic solutions. The temperature coefficient of n_i subtracts from that of the extrinsic solutions as can be shown to follow from Eq. [1]. Near cancellation occurs.

The value of n_i obtained from Fig. 2 can be compared to an estimate of n_i from band structure information.

[4] Early work (1) suggested that the hole activity coefficient began to change in the 5 x 10^{18} cm^{-3} range, but more recent work (7) indicates 5 x 10^{19} cm^{-3} or higher is required.

[5] A. S. Jordan (14) has recently evaluated the available solid solubility information for Zn in GaAs and has constructed a thermodynamically concise set of solubility isotherms. His 800° and 900°C isotherms, in the square root region, bracket the isotherm we have found to fit our measurements, shown in Fig. 2.

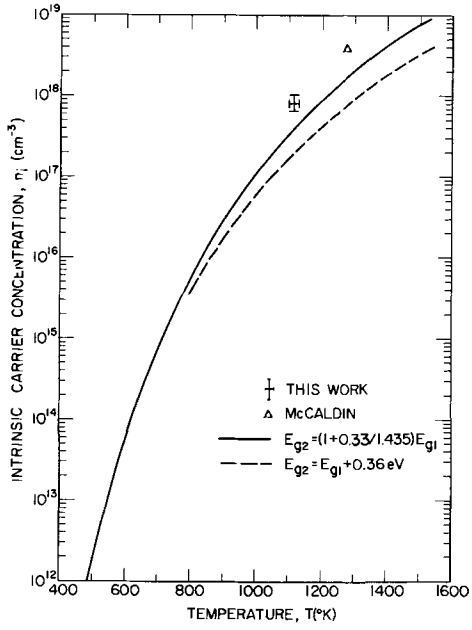

Fig. 3. Intrinsic carrier concentration of GaAs vs. temperature

For a multivalley semiconductor it can be written as

$$n_i = 4.9 \times 10^{15}T^{3/2} \sum_j (m_p m_{nj}/m_o^2)^{3/4} \exp(-E_{gj}/2kT) \quad [4]$$

The density-of-state effective mass of holes in GaAs is

$$m_p = (m_{p1}^{3/2} + m_{p2}^{3/2})^{2/3} = 1.03\, m_o \quad [5]$$

where the theoretical values (8) $m_{p1} = m_o$ and $m_{p2} = 0.1\, m_o$ have been used for the heavy and light hole masses, respectively. The <000> conduction band minimum has an effective electron mass (8) $m_{n1} = 0.084\, m_o$. The energy gap as a function of temperature is (9)

$$E_{g1} = 1.522 - 5.8 \times 10^{-4}T^2/(T + 300) \quad [6]$$

The second lowest minimum <100> has a density-of-state effective electron mass (10) $m_{n2} = 1.2\, m_o$. Hall and Racette (11) have calculated n_i by taking $E_{g2} = E_{g1} + 0.36$ eV. Recently, James and Moll (12) have found that the energy difference between the two minima is 0.33 eV at 300°K and 0.35 eV at 80°K. These data show that the energy difference is a function of temperature in the same manner as Eq. [6]. Thus the second energy gap can be written as

$$E_{g2} = E_{g1}(T)\,[1 + 0.33/E_{g1}(300°K)] \quad [7]$$

The results obtained from the calculation of the two-band model are given in Fig. 3. The experimental value of n_i falls a factor of 2 higher than that given by the theoretical curve. The result of McCaldin (13) at 1000°C is also shown in the figure and it is a factor of 2 above the theoretical curve.

Conclusions

The solid solubility data obtained in this work fit the theoretical expression given in Eq. [1]. The singly ionized substitutional acceptor model of the incorporation reaction seems to be correct. A value of n_i of 8 x 10^{17} cm^{-3} at a temperature in the range of 825°-850°C has been obtained.

New Optical Quenching Bands in CdS Crystals

Mamoru Oshima and Ryoji Takahashi

Engineering Research Institute, Faculty of Engineering, University of Tokyo, Tokyo, Japan

ABSTRACT

The effects of bombardments with pentavalent ions on the photoconductivity and optical quenching of photoconductivity in CdS single crystals have been investigated. A striking effect of bombardment with P, As, Sb, and Bi ion, each with an energy of 5 keV, is a considerable reduction in long wavelength, extrinsic response. As a result, optical quenching starts at very short wavelengths. At the high-energy side of the optical quenching band, in addition to two well-known bands situated at 0.9 and 1.4μ, respectively, we observed a new band with long wavelength cutoff at about 0.8μ (1.55 eV). This band has its maximum at about 0.63μ (1.97 eV), 0.64μ (1.94 eV), 0.66μ (1.88 eV), and 0.68μ (1.82 eV) for P, As, Sb, and Bi, respectively. These bands, as well as the 0.9μ band, are observable at temperatures as low as 77°K. Measurements of the thermally stimulated current show that relatively large numbers of vacancies of both sulfur and cadmium are produced in the bombarded region. It is believed that pentavalent ions in CdS crystals are substituted for sulfur ions forming the new acceptor levels related to the third band phenomena. The third band probably corresponds to excitation of trapped holes from these levels directly to the valence band.

It is well known that the spectral distribution of infrared quenching of photoconductivity in CdS shows two bands with maxima at 0.9μ and 1.5μ, respectively (1-5). A number of investigators have discussed the origin of these two bands, and by many reporters it was regarded as excitation of holes from two different types of hole traps, *i.e.*, "sensitizing centers," and successive recombination of the released holes with free electrons at certain recombination centers (1, 6, 7). The fact that optical quenching is observable in any kind of crystal, except for very insensitive ones, whether crystals were doped or undoped and, moreover, independently of impurity elements, naturally leads to the suggestion that some intrinsic imperfections of the crystals should be connected with the sensitizing centers, for instance Cd vacancies, which can act as acceptors in CdS crystals. Bube and Barton (8) suggested the formation of Cd vacancies for charge compensation in their report on highly photosensitive CdS crystals in which iodine was incorporated. Excitation in those crystals did not extend far beyond the absorption edge, and strong quenching was observed at higher energies than for the common ones with long wavelength response. Thomas and Hopfield (9) proved the presence of a single characteristic acceptor imperfection in CdS crystals by investigating recombination radiation from bound excitations. The presence of intrinsic acceptor-like defects in CdS crystals is also supported by other evidence (10-12). On the other hand, for the last ten years, various particle bombardments on semiconductors have been employed by several workers to investigate the effects of crystal defects on the electrical and photoelectric properties of the materials. Kulp and Kelley (13) showed that the threshold for the production of vacancy-interstitial pairs of sulfur atoms in CdS by electron bombardment is 115 ± 5 keV and that the center for the green edge emission in CdS is the interstitial sulfur atom. They also observed (14) the photoconductive peaks at 0.67, 0.9, and 1.4μ in 150 keV electron bombarded CdS crystals; the first one gave electronic conduction and the latter two gave hole conductivity. Bombardment by 100 keV electrons partially removed the 1.4μ quenching band and also removed the edge emission. Therefore, they concluded that the center for the 1.4μ quenching band is the interstitial sulfur. Im and Bube (15) reported that the ratio of quenching in the 1.4μ band to that in the 0.9μ region decreased continuously with increasing energy of irradiating electrons from 75 to 400 keV.

Various impurities, particularly the pentavalent ones, which are to be treated here, have been studied as dopants in the II-VI compounds by a number of workers (16-24). However, their effect on the electrical or optical properties were often not very pronounced. Originally most of the experiments dealt with thermal equilibrium situations. More recently, however, Anderson and Mitchell (25) and Chernow and co-workers (26), succeeded in forming highly conductive p-type CdS by P and Bi ion bombardment, respectively, and ion implantation, essentially a nonequilibrium process, was established as a new doping technique.

We bombarded CdS single crystals by various kinds of ions to investigate the effects of defects and, at the same time, we studied the effects of those impurity ions on optical quenching. Bombardment by almost all other kinds of ions with an energy of 5 keV had no influence on the optical quenching bands.

Key words: photoconductivity, CdS crystals, ion bombardment (P, As, Sb, Bi), thermally stimulated currents, optical quenching.

Pentavalent ions with this same energy, however, drastically changed the properties of the surfaces of the crystals (about 1μ in depth); namely, it (*a*) made the surface region highly resistive, *i.e.*, almost intrinsic, and (*b*) diminished extensively the long wavelength response, almost exactly the effects reported for CdS:I by Bube and co-workers (8). The cut off of photoconduction occurred at about 0.7μ, and quenching started at about 0.57μ. Especially in Sb ion-bombarded CdS crystals, the optical quenching band clearly showed three peaks with maxima at 0.65, 0.9, and 1.45μ, respectively; in crystals bombarded with other pentavalent ions, the third band at 0.65μ was more or less obscured under the foot of the broad band at 0.9μ. In this paper we deal mostly with the third band through measurements of spectral photoresponse, optical quenching of photoconductivity, temperature dependence of optical quenching, etc., and we come to a significant conclusion with regard to the center related to the third band.

Experimental

The CdS crystals used in this experiment were single crystals which were grown by the vapor phase technique at our laboratory. These crystals showed a bright red emission under uv stimulation at liquid nitrogen temperature, with the center of the band at 6200Å. This band has previously been associated with a silver center (27). Actually, spectrographic analysis showed the presence of 0.1 ppm Ag as an impurity besides Si, Mg, and Ca of the order of 1 ppm. The crystal rod (15 mm in diameter) was cut at right angles to the c-axis into 1 mm thick slices, which were then polished to an optical finish. Etching by dilute hydrochloric acid removed the very thin ($\sim$ 100Å) amorphous layer at the surface of the crystal which was caused by polishing. After preheating at 350°C for 20 min in argon gas of 1/2 atm pressure, the crystals were bombarded by ions at room temperature in a vacuum of 3 x 10^{-5} mm Hg. Various ions were produced and accelerated in an ion bombardment chamber by applying the "exploding wire" technique[1] which has been developed at our laboratory (28). Carbon, Al, P, Cl, Mn, Fe, Ni, Cu, Zn, As, Ag, In, Sb, Au, and Bi ion bombardments, each with an energy of 5 keV, were performed. The cross section of the ion beam incident on the target was limited to 0.03 cm^2 by a baffle with a circular window. The bombardment density was measured (29) at least 10^{12} ions/cm^2 for Cu. Estimated bombardment densities for the various ions are summarized in Table I. The bombarded crystals were heated at 400°C for 1 hr under 200 kg/cm^2 argon gas pressure in an autoclave, thus preventing the vaporization of the implanted ions from the surfaces. Both directly after the bombardment and after heating, the red emission became weaker for the 3.5 keV bombardment and entirely vanished for the 5 keV bombardment, no matter what kind of ions were used.

[1] "Exploding wire" phenomenon is an explosive evaporation of a metallic wire in the air resulting from a big electric current through the wire. We utilized the ionization of the metallic wire and the applied high voltage realized in the phenomenon for the ion bombardment performances.

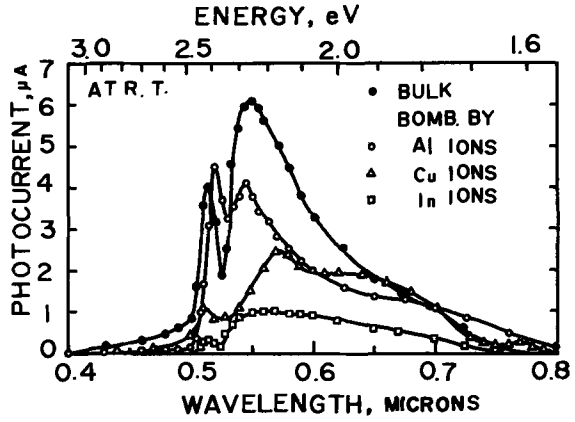

Fig. 1. Spectral response curves for CdS crystals bombarded by various kinds of ions, with an energy of 5 keV, compared with that for the nonbombarded crystal. The dark resistivity of the original crystal is 1 x 10^4 ohm·cm; those of the crystals bombarded by Al, Cu, and In ions are 3 x 10^3, 1.5 x 10^5, and 7 x 10^3 ohm·cm, respectively. (Curves marked "bulk" refer to nonbombarded crystals.)

Photoelectric measurements were carried out in a cryostat, which was kept evacuated at a pressure of 10^{-3} mm Hg during the experiments. The primary excitation was effected by an incandescent lamp with a 5200Å interference filter. The second beam of infrared light used for the measurement of optical quenching was obtained from a Hitachi EPU-2 type monochromator. Measurements were made with indium amalgam surface contacts, which showed ohmic characteristics for both nonbombarded and bombarded surfaces of the crystals through the whole range of voltage used. The dark resistivity of the crystal before bombardment was about 1 x 10^4 ohm·cm. A small change was detected in the resistivities of the specimens bombarded with C, Al, Cl, In, Zn, Cu, Ag, Mn, Fe, and Ni ions; for example for Al the resistivity was reduced to one-third of that before bombardment; for Cu the resistivity increased ten times. Also no marked change was observed in the spectral photoresponse curves, except for a somewhat impurity-dependent unevenness between 0.55μ and 0.80μ. Figure 1 shows this for crystals bombarded with various ions as well as for the nonbombarded crystal. Figure 2 shows the corresponding optical quenching spectra at room temperature. Each quenching band starts at about 0.75μ showing the usual two bands with maxima between 0.9 and 0.95μ, and between 1.35 and 1.50μ, respectively.

The effects of P, As, Sb, and Bi ion bombardments on the photoresponse and optical quenching are given in Fig. 3 and Fig. 4, respectively. There is a relatively larger decrease in response for extrinsic excitation at longer wavelengths than near the absorption edge. For crystals bombarded with Sb and Bi, the dark resistivity increased to 10^7 and 10^5 ohm·cm., respectively. The depth of the high resistivity layer, measured by direct microscopic observation of sections of the specimens, was found to be about 1μ. In Fig. 4 it may be noted that

Table I. Summary of densities of the various ions implanted into CdS crystals

Elements to be implanted	C	Al	Fe	Ni	Cu	Ag
Densities of ions implanted, ions/cm^2	$\sim 10^{13}$	2 x 10^{15}	3 x 10^{15}	2 x 10^{15}	1 x 10^{15}	2 x 10^{15}

Au	P, Cl, Mn, As, In, Sb, or Bi	Sb,Al or Sb,In
5 x 10^{14}	$\sim 10^{14}$	each of $\sim 10^{14}$

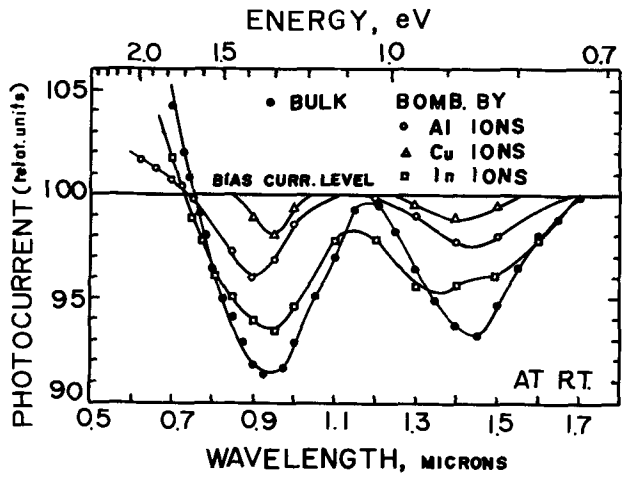

Fig. 2. Optical quenching spectra for the photoconductivity for CdS bulk and the surfaces bombarded by Al, Cu, and In ions, each corresponding to Fig. 1.

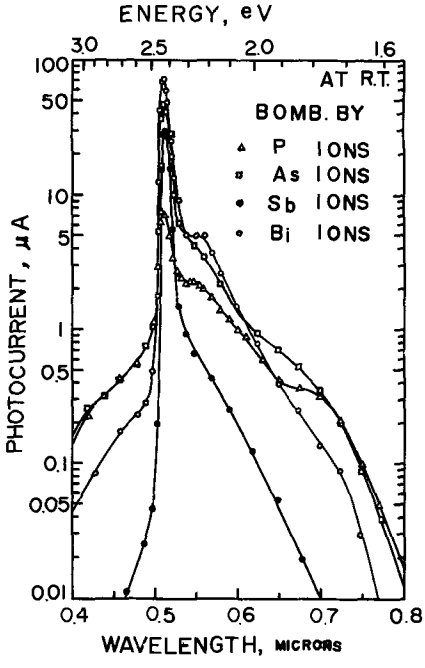

Fig. 3. Spectral response curves for CdS crystals bombarded by various pentavalent ions. An ion energy of 5 keV was used in each case. The dark resistivities of the crystals bombarded with P, As, Sb, and Bi, are 5 x 10^4, 8 x 10^4, 3 x 10^7, and 1 x 10^5 ohm·cm, respectively. An extremely large reduction of response is seen in the extrinsic region at longer wavelengths (compare with Fig. 1).

in addition to the well-known two quenching peaks, a third band appears with maxima at about 0.66 and 0.68μ for Sb and Bi, respectively. In the case of P and As, the total current in the third band region is larger than the bias current because excitation overcomes quenching. To investigate the effects of two kinds of ions on quenching we carried out the bombardment of CdS crystals using a special wire, which was prepared by simultaneous evaporation of a pair of metals onto a quartz tube (1 mm in diameter). Thus, almost equivalent numbers of two sorts of ions. *e.g.*, Sb and Al, or Sb and In, (10^{14} ions/cm^2), were simultaneously implanted in CdS crystals. We use the notation "Sb,Al" or "Sb,In" to represent such an ion bombardment. The spectral response of photoconductivity and the optical quenching spectra at room temperature for samples resulting from those bombardments are shown in Fig. 5 and Fig. 6, respectively. As one notices, the longer wavelength response from 0.6 to 0.8μ is thoroughly removed. More striking, however, are the results of

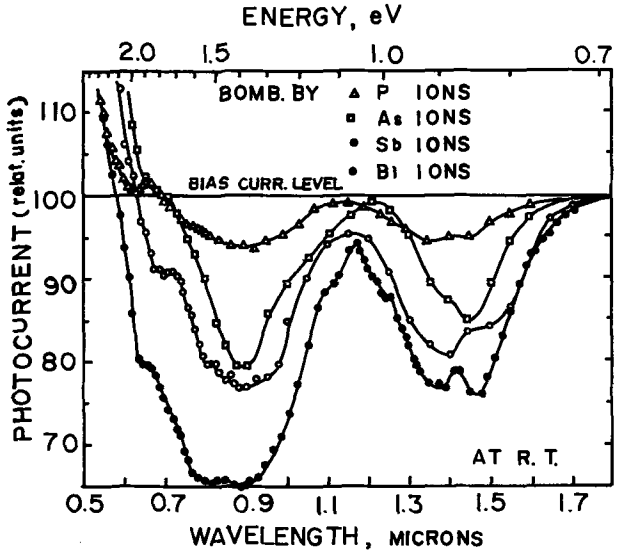

Fig. 4. Spectral distribution of quenching of photoconductivity in CdS crystals bombarded with various pentavalent ions for which Fig. 3 showed the spectral response curves. The third bands appear with maxima at 0.63μ (1.97 eV), 0.64μ (1.94 eV), 0.66μ (1.88 eV), and 0.68μ (1.82 eV) for P, As, Sb, and Bi, respectively. Subbands can be observed at about 0.75μ (1.65 eV) for P and at about 0.80μ (1.55 eV) for Sb and Bi.

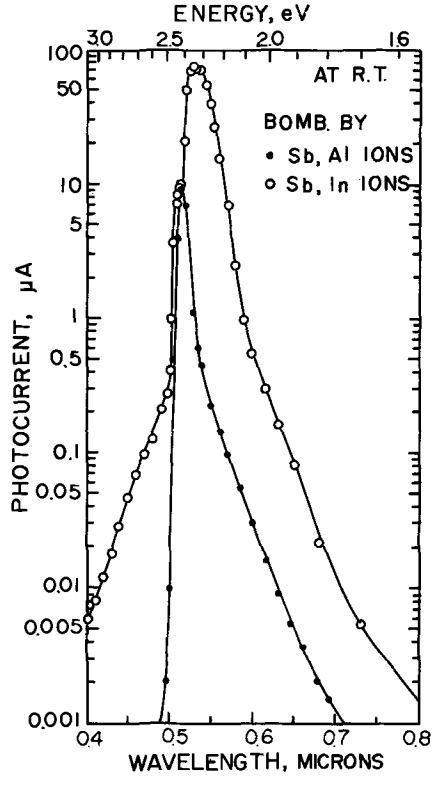

Fig. 5. Effect of simultaneous bombardments with two kinds of ions, Sb and Al, or Sb and In, on the spectral response curves. The dark resistivities of these crystals are $\gtrsim$ 10^8 and 1 x 10^7 ohm·cm for Sb,Al and Sb,In, respectively. A reduction of response similar to those shown in Fig. 3 is seen in the extrinsic region.

measurement of the quenching effects. Over the entire wavelength range from 0.58 to 1.60μ, at least 30% of the primary photocurrent is quenched. The third band asserts its existence showing a new clear peak in the samples bombarded with Sb and Al, with a maximum quenching percentage of 90%. For the nonbombarded crystal the quenching percentage is about 10%; in the crystals bombarded by ions of P, As, Sb, or Bi the quenching effect at the maximum of the 0.9μ band was

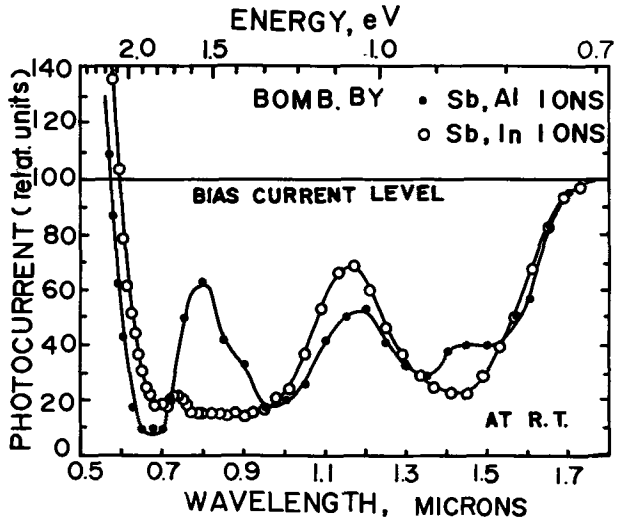

Fig. 6. Optical quenching spectra for CdS crystals bombarded by Sb,Al and Sb,In ions, correspondingly to Fig. 5. For Sb,Al, the third band forms a clear peak with maxima at 0.66μ (1.88 eV) and with longer wavelength cutoff at about 0.80μ (1.55 eV). At about 0.85μ (1.46 eV) for "Sb,Al' a subband can be seen.

a little higher. It may be pointed out that besides the third bands with the maxima at 0.63μ (1.97 eV), 0.64μ (1.94 eV), 0.66μ (1.88 eV), and 0.68μ (1.82 eV) for P, As, Sb, and Bi, respectively, several subbands are observed, *e.g.*, a group of bands at 0.75μ (1.65 eV) for P, 0.80μ (1.55 eV) for Sb and Bi, and 0.85μ (1.46 eV) for Sb,Al and another group of bands at 1.1μ (1.12 eV) and 1.2μ (1.03 eV) for Sb. Generally, in contrast with electron bombardment (14-15), no decrease of the ratio of quenching in the 1.4μ band to that in the 0.9μ one by ion bombardment was observed.

At low temperature, quenching effects in the region of the third band can still be detected, though the effects become considerably weaker. Figure 7 shows the results of experiments at 77°K. Because of the similarity in behavior of this band and the 0.9μ band, we believe that in accordance with the model (4) for the latter, 0.65μ radiation excites trapped holes from the new centers, the third hole traps, directly to the valence band. We notice that not only the 1.4μ band but also the 0.75-0.80μ subbands have vanished at low temperature.

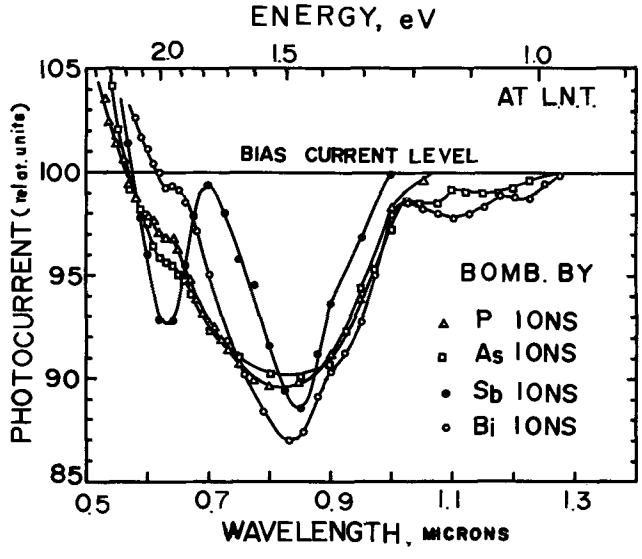

Fig. 7. Optical quenching spectra at liquid nitrogen temperature for CdS crystals bombarded by various kinds of pentavalent ions. In each case the third bands do exist in addition to the 0.9μ one. Subbands at 0.75-0.80μ on the other hand have disappeared together with the 1.4μ band.

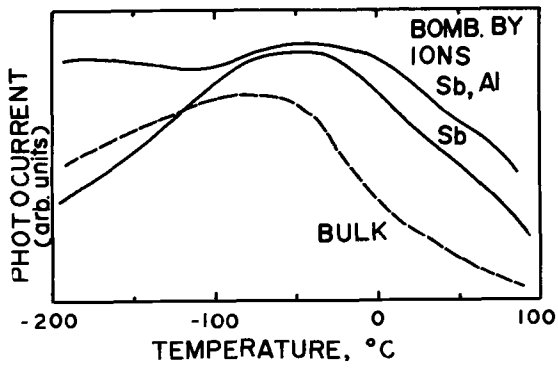

Fig. 8. Temperature dependence of photocurrent, excited by band gap light excitation, for CdS crystals bombarded by Sb and Sb,Al ions, as well as for the nonbombarded crystal. Thermal quenching sets in at higher temperature for the Sb-ion bombarded crystals than for the nonbombarded crystal.

In Fig. 8 we show the temperature dependence of the photocurrent, under band gap light excitation, for Sb and Sb,Al in contrast to that for the nonbombarded crystal. In the surfaces of the ion-bombarded crystals, thermal quenching of photoconductivity sets in at a higher temperature than in the nonbombarded inside. This means that the distribution of hole traps has moved to higher energies, *i.e.*, nearer to the conduction band.

Figure 9 shows the observed thermally stimulated current curves. It may be noted that the shallow traps, the depth of which ranged from 0.18 to 0.30 eV, are enhanced relative to the deeper ones near room temperature. Woods and Nicholas (30-31) have assigned traps at 0.25 and 0.30 eV to sulfur and cadmium vacancies, respectively. The results shown in Fig. 6 therefore suggest that a considerable number of defects are produced near the surface by bombardment and remain after heating.

Discussion

The existence of a third band of optical quenching in CdS crystals was suggested for the first time by Taft and Hebb (1) in 1952; Yoshizawa (32) found this band in phosphorus doped CdS. However, this crystal did not show a well-defined peak, but only a shoulder with the edge at 2.15 eV (0.577μ). Our experimental results show that the new bands have their maxima at 1.97 eV (0.63μ), 1.94 eV (0.64μ), 1.88 eV (0.66μ), and 1.82 eV (0.68μ) for P, As, Sb, and Bi, respectively; perhaps these energies give the position of new levels in the forbidden gap relative to the top of the valence band. More important than the peak is the wavelength cutoff of the band. For Sb,Al, the new band shows a cutoff at about 1.55 eV (0.80μ). These level positions are illustrated in Fig. 10. The greater part of the dif-

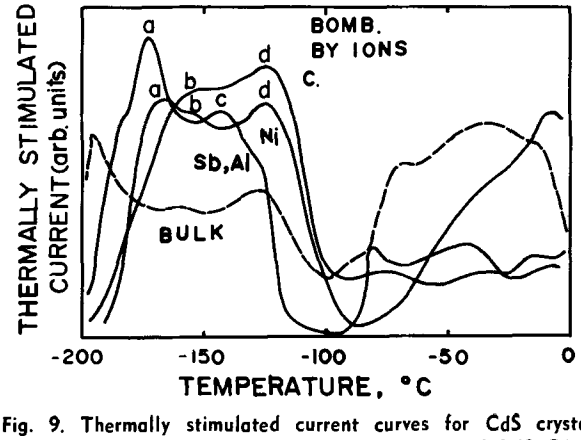

Fig. 9. Thermally stimulated current curves for CdS crystals bombarded by various kinds of ions. Heating rate of 0.43°C/sec. Peaks a, b, c, and d correspond to the depths of traps 0.18, 0.22, 0.25, and 0.30 eV from the conduction band, respectively.

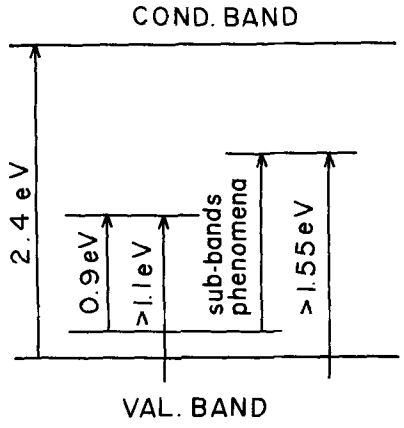

Fig. 10. A possible interpretation for the third band phenomenon in optical quenching. The levels for the two common centers are drawn as proposed by Hemila and Bube (35); for the higher energy center, the energy does not refer to the peak but to the long wavelength cut off of the 0.9μ band. In a similar way, the level of the third quenching band for Sb is based on the long wavelength cutoff of the third quenching band. For P, As, and Bi, the corresponding levels will be slightly different, the difference with the Sb level being perhaps in proportion to the differences of the energies of the third band peak from Sb. The figure shows the subbands as the excitation of trapped holes from the third center level to the lowest level of the common quenching centers.

ference in the maximum energies reported for phosphorus doped CdS by Yoshizawa and by us is thought to be attributable to the difference in quantity and/or properties of imperfections. In Yoshizawa's crystals the defects are essentially native ones; in our experiments we purposely set out to create an excess of defects within the surface layer of the crystal concurrently with the addition of impurities. According to a simple law of impulse and energy conservation (33), the thresholds (13) of 115 and 290 keV for the production of vacancy-interstitial pairs of sulfur and cadmium atoms, respectively, in CdS by electron bombardment, correspond to several tens of electron volts for almost all the ions with which we bombarded our crystals, from carbon to bismuth. The energy of 5 keV used by us will be more than enough to form both sulfur and cadmium vacancies, as is proved by the thermally stimulated current curves shown in Fig. 9. The disappearance of the red emission after 5 keV ion bombardment is probably more complex than a simple annihilation of silver centers.

If the third band phenomenon is caused only by the defects newly produced by the bombardment in the surface layer of the crystal, it ought to be independent of the nature of the bombarding ions. However, in the crystals bombarded by many kinds of ions, other than pentavalent ones, no quenching effect was detected before the wavelength of the second light exceeded 0.75μ. The third band, in consequence, must be due to pentavalent ions.

A possible interpretation of the doping mechanism in the processes of our ion bombardments and successive annealing is as follows: (*i*) a large number of vacancies is produced within the surface layers of the crystals in a depth of about 1μ, and (*ii*) implanted ions stop at interstices or lattice points which are vacant. (*iii*) After heat-treatment, pentavalent ions enter into the active sites, *i.e.*, sulfur vacancies, to form a new sensitizing center, while (*iv*) trivalent ions occupy cadmium vacancies. The last process, we believe, greatly promotes the third band by charge compensation, just as Apple (34) showed in his paper on P-, As-, and Sb-doped ZnS, that in addition to acting as activators, pentavalent atoms could also act as coactivators in the presence of Cu, presumably substituting for Zn as trivalent ions. The new sensitizing centers reported in this paper are possibly not identical with the ones introduced by Sb-doping in ZnS, the levels of which were investigated by Bube and Lind (21) who concluded that they are situated in the forbidden gap, 0.7 and 1.3 eV from the top of the valence band, respectively; levels which, as suggested by the contributors, could be related in part to vacancies rather than the Sb. The reason is that even if the new hole traps at 1.82-1.97 eV correspond to the 1.3 eV level, the subbands observed in the optical quenching at 1.65 eV for P, 1.55 eV for Sb and Bi, and 1.46 eV for Sb,Al are at too large an energy to correspond to the 0.7 eV level. It is more reasonable to interpret the subbands as the excitation of trapped holes from the level of the third center to the lower level of the usual two hole traps; the energies of the subbands region, for instance 1.46 eV for Sb,Al, fit fairly well with the energy difference between those two levels (see Fig. 10). This assignment finds further support in the fact that, as shown in Fig. 7, the quenching in the subbands vanishes at low temperature together with the disappearance of the 1.4μ one. Another group of subbands at 1.03-1.12 eV are at times also observed in undoped CdS; the origins of these are unknown. The slight differences, 0.15 eV at the most, between the energies of the peaks of the third bands from ion to ion are thought to be due to the differences between their ionic radii. The fine structure which can be seen in the 1.4μ band for Sb and Sb,Al, consisting of two peaks with maxima at about 1.35 and 1.45μ, respectively, has been interpreted by Hemila and Bube (35) as the effect of spin-orbit and crystal-field splitting of the levels concerned in the 1.4-μ quenching. perhaps the larger splitting of the level nearer to the valence band.

Acknowledgments

The authors are greatly indebted to Takao Tuno for completion of the ion bombarding system.

Technical Notes

Surface Properties of Oxidized Germanium-Doped Silicon

P. Balk

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

Oxidized silicon surfaces have a strong tendency toward n-type behavior. This has generally been attributed to the presence of positive charges in the SiO_2 layer and at the SiO_2-silicon interface (1). It is also known that GeO_2 rather readily becomes oxygen deficient, which gives rise to deep electron traps (2). Therefore, one might expect that incorporation of germanium into the SiO_2 film, obtained by thermal oxidation of silicon, could result in negative surface charge, and consequently a p-type space charge layer in the silicon. Such p-type surfaces on oxidized silicon have so far only been obtained by adding elements such as Ga (3) or Au (4, 5), which also appreciably affect the electronic characteristics of the substrate. On the other hand, the only substrate effect to be expected from adding germanium to silicon samples is a gradual decrease of the bandgap with increasing germanium concentration (6). It thus appeared convenient to use germanium-doped silicon alloys as substrate materials for the present investigation.

The samples were prepared from <111> oriented, 5 ohm-cm, n- and p-type Dow-Corning silicon, with a nominal germanium concentration of approximately 0.1, 1, and 2.5 w/o (weight per cent). These wafers were etched and then oxidized in O_2 at various temperatures (from 700° to 1100°C) in a resistance heated furnace. Upon oxidation, they were rapidly removed from the hot zone of the furnace and allowed to cool in the oxidation ambient. The resulting oxide thicknesses were determined either with an ellipsometer (7) or by the VAMFO method (8). The oxidation rates for germanium-doped and undoped samples were identical, within experimental accuracy. Table I shows that the oxide films do indeed contain germanium, and at a level which is only slightly lower than that of the starting material. The films grown on the 0.1 w/o germanium samples were not analyzed because of their low dopant concentration.

The characterization of the electrical surface properties of oxidized specimens was carried out by means of the MOS capacitance-voltage (C-V) technique (11). The shape of the C-V curves and the change of their position with measurement frequency indicated a considerable fast state density over an appreciable part of the forbidden gap, particularly for structures prepared at lower oxidation temperatures. However, the displacement of the C-V curves, measured at room temperature and 1.5 Mc, with respect to the curves for surfaces free of charge and interface states, always indicated the presence of positive surface charge.

Key words: oxidation of Ge doped Si, defects in SiO_2-GeO_2 alloys, C-V measurements, interface states.

Table I. Germanium content of oxide film and substrate of oxidized germanium-doped n-type silicon samples

Substrate				
Ge content (w/o)*	0.8	0.8	0.8	2.2
Oxide				
Oxidation temp. (°C)	1100°	800°	800°	800°
Oxide thickness (Å)	6110	2180	3950	1970
Oxide wt (μg)	1135	450	1015	415
Ge wt (μg)†	2.0	1.5	3.0	2.5
$\frac{\text{Ge wt}}{\text{Si wt}} \times 100$	0.4	0.7	0.6	1.2

* Determined by manitol titration (9); accuracy 0.1 w/o.
† Determined using phenylfluorone method (10); accuracy 10%.

A convenient indicator of the number of interface states was obtained by measuring their density (N_{ss}) between the room and liquid nitrogen temperature Fermi levels, according to (12)

$$N_{ss} = \frac{C_{ox}}{q} [V_{FB}(\text{room temp}) - V_{FB}(\text{liq. } N_2 \text{ temp})]$$

where C_{ox} is the oxide capacitance, and V_{FB} the (apparent) flatband voltage at 1.5 Mc. Data for films approximately 1000Å thick are shown in Fig. 1. All results were obtained after aluminum electrodes had been evaporated onto the surfaces, and the samples had been annealed for 5 min at 500°C in dry N_2. In agreement with earlier observations (13) this procedure was found to reduce the interface state density below 4×10^{10} cm^{-2} for germanium-free samples, oxidized in parallel with the doped substrates. The same result was obtained on samples with 0.1 w/o germanium. The annealing was applied in the present case since the flatband voltage for some of the p-type substrates with higher Ge doping could not be observed without this heat-treatment. Subsequent treatment in H_2 (14) at 500°C did not significantly affect N_{ss}.

Three conclusions stand out upon inspection of the data in Fig. 1: (*i*) The density of fast states (N_{ss}), not removable by Al (N_2) or H_2 annealing at 500°C, as detected by the present method, is strongly dependent on the oxidation temperature. It appears to reach a maximum around 800°C, and becomes quite small at

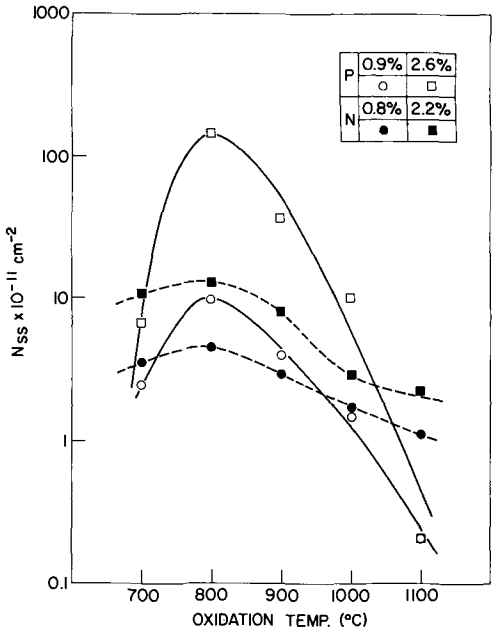

Fig. 1. Interface state densities in n- and p-type germanium doped silicon samples, oxidized at various temperatures. Germanium concentrations, determined by manitol titration (9), are indicated.

1100°C. (*ii*) Larger N_{ss} values are observed near the valence band on p-type samples than near the conduction band on n-type samples for substrates oxidized between 800° and 1000°C. This difference cannot be attributed to the slightly higher germanium concentrations in the p-type substrates (see Fig. 1). (*iii*) The N_{ss} values are strongly dependent on the germanium concentration in the substrate.

The interface states observed on germanium doped silicon are different in nature from those observed on undoped specimens, which are readily removed by low temperature H_2 annealing (14). However, the centers on germanium-doped silicon samples could be completely eliminated by heating in N_2 at temperatures over 900°C, followed by a post-metallization annealing at 500°C.

In view of the different behavior of n- and p-type germanium-doped substrates, it appears that the distribution of interface states is not symmetrical with respect to the middle of the forbidden gap. In drawing this conclusion, the assumption was made that this distribution is not dependent on conductivity type (12). The data show that the centers are related to the presence of the germanium dopant. There is no indication at the present time what the exact nature of these centers is and why the expected surface charge effects are absent. A similar difficulty to introduce negative oxide charge was reported by Sedgwick (15) for SiO_2-passivated germanium surfaces, which most likely contain a thin, residual germanium oxide film. In this case negative surface charge was only observed upon H_2 annealing at 700° or 800°C. However, for bulk GeO_2 the formation of deep electron traps takes place in this ambient already at 400°C (2). The H_2 annealing at 500°C in the present study had not the expected effect. Exposure to H_2 at higher temperatures was not attempted, since such treatments on silicon, according to our experience and that of others (16), lead to large positive surface charge.

Solidus Boundary in the InAs-AlAs Pseudobinary System

L. M. Foster* and J. E. Scardefield

IBM Research Division, Yorktown Heights, New York 10598

The $In_xAl_{1-x}As$ semiconductor alloy system is of interest for the fabrication of new electronic and electroluminescent devices. By varying the composition of the alloy the forbidden energy gap, which is one of the fundamental parameters that determine semiconductor behavior, can be varied from that of InAs (0.36 eV) to that of AlAs (2.16 eV). Direct radiative transitions ($k = 0$) of high quantum efficiency would be expected in alloys with AlAs content up to about 68 m/o (mole per cent), which is the crossover point of the direct band edges (1). Knowledge of the equilibrium T-x phase diagram is important when devising crystal growth practices for a new alloy system. The determination of the solidus boundary of the InAs-AlAs system is reported here.

The experimental procedure was that described by the authors for the InP-GaP system (2). In brief, a pellet pressed from a finely ground mixture of the two components is held at a constant temperature, T which is chosen so that the composition of the mixture falls within the two-phase region of the diagram between the liquidus and solidus boundaries. This could be assured by making up the starting composition to

* Electrochemical Society Active Member.
Key words: phase diagrams, III-V compounds, electron microprobe.

lie approximately along the straight line between the melting points of the two separate components. After allowing sufficient time for equilibrium to be attained, the sample consists of particles of a solid solution whose composition corresponds to the intersection of the isotherm, T, with the solidus boundary, suspended in a liquid whose composition corresponds to the intersection with the liquidus boundary. After quenching the sample, an electron microprobe analysis of the solid solution phase gives the composition of the point on the solidus corresponding to the equilibration temperature. By equilibrating a sufficient number of different starting compositions at the appropriate temperatures, the entire boundary can be determined.

The preparation and encapsulation of the pellets were described in the earlier paper (2). Departures from that procedure, which was developed for InP-GaP, were the shortening of the time at temperature to 3 days to minimize devitrification of the quartz capsule that occurred at these higher temperatures and the taking of precautions to avoid contact of the reactive AlAs with moisture.

Six experimental points were determined. The data are given in the following table:

Temp. (°C)	AlAs (m/o)
999	0.306
1040	0.547
1110	0.736
1212	0.850
1450	0.956
1513	0.967

The solidus boundary is shown in Fig. 1. The melting point of InAs (937°C) is from Lichter and Sommelet (3). The melting point of AlAs (1770°C) was determined in these laboratories by Chicotka (4). This system is seen to exhibit strong positive deviation from Raoult's law of mixing. Although numerical comparison with other systems cannot be made in the absence of liquidus data, it appears that the deviation is greater than in the InP-GaP system that was reported previously. This probably reflects the greater lattice mismatch between the two separate components of the InAs-AlAs system.

Low-Temperature Cathode Performance of Porous Ag/Ag_2O Electrodes

E. G. Gagnon[1,*] and L. G. Austin*

Department of Materials Science, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

The performance of porous, silver-silver oxide electrodes decreases rapidly below 0°C, and galvanostatic discharge curves show several different regions. Most of the work reported here was done on thin Ag/Ag_2O electrodes, prepared by electrodeposition or by powder pressing. An attempt is made to explain the regions in the discharge curves, and the apparent Tafel parameters, from a plausible kinetic mechanism. The application of theories of porous electrode behavior is demonstrated by results from thick electrodes made by stacking thin electrodes together. The use of the information in designing electrodes is discussed, as is future work.

It is well known that the performance of Zn|KOH| silver oxide cells decreases considerably at temperatures less than 0°F. Preliminary results on thin, porous electrodes (1), supplied by Harry Diamond Laboratories, Army Materiel Command, indicated that the major loss of performance was caused by increased polarization at the silver oxide electrode. It was decided, therefore, to perform a detailed half-cell study of the behavior of silver oxide electrodes in KOH eutectic [31 w/o (weight per cent)], concentrating at first on $Ag|Ag_2O$ electrodes to avoid the complexity of mixed $Ag_2O|AgO$ compositions during discharge.

Although the formation of Ag_2O and AgO on silver by anodic charging has been studied at room temperature (2, 3) using a variety of electrochemical techniques, cathodic discharge at low temperatures has not been widely investigated. The form of the anodic charge of solid silver at constant current is well known: polarization increases rapidly by double-layer charging until Ag_2O is formed on the surface, then polarization decreases somewhat to a plateau. After some time, polarization increases from this plateau to the AgO formation potential, passes through a peak, and again decreases to a higher plateau corresponding to continued AgO formation from Ag_2O and Ag; polarization eventually increases to oxygen evolution. There is good evidence (4) that thick, continuous films are not formed on anodic charge and that silver is removed from the surface and redeposited in the form of attached crystallites of Ag_2O, followed by disappearance of these crystals and the appearance of discrete AgO crystallites on the surface. Similarly, on discharge, massive rearrangement of the molecules occurs to give new crystal forms. The growth size of the crystallites is a function of rates of charge and discharge, being small at high current densities; lower current densities give fewer, but larger, crystallites.

The effect of porosity of practical battery electrodes can give added complexity to interpreting results. The reactions involve transfer of ions dissolved in the electrolyte contained in the pores of the electrode, and potential gradient is required for this transfer. This has the effect of making polarization greater at the exterior of the electrode (5-7). This effect is more pronounced for thicker electrodes, and it is possible during charge for potential in the interior to correspond to the $Ag|Ag_2O$ reaction, and potential at the exterior to correspond to $Ag_2O|AgO$. These effects are enhanced at low temperatures: for example, the specific resistance of eutectic KOH goes from 1.9 at 60°F to 33 ohm-cm at −60°F.

Experimental Techniques

A 250 ml beaker with a Lucite cover was used as the electrochemical cell (8). The Lucite cover contained five holes: three for the test, counter, and reference electrodes; one for nitrogen gas used to deaerate the electrolyte; and one hole for a glass U-tube which was used to remove trapped gas bubbles that occasionally formed on the surface of the electrode during a run. The electrolyte was a 31 w/o aqueous KOH solution, prepared from a 45% w/w Fischer reagent (Cat. No. SO-P-236) and distilled water that had been obtained from a Barnstead still (Model No. SM-5). The temperature of the cell was controlled by a Tenney Jr. test chamber (Model TJR) capable of controlling temperatures between −100° to 350°F to within ±1°F; electrical contacts were made through a terminal board on one of the walls of the chamber. The temperature within the chamber was measured with chromel-P-alumel thermocouple in conjunction with a Keithley d-c differential voltmeter (Model 660).

The test electrodes had a plane surface area of 0.317 cm^2 and were obtained by using a punch and die, where the die opening was 0.25 in. The electrode disks were press fitted into a Teflon collar where the opening had been machined about 1 mil less than the diameter of the electrode disk. The Teflon collar con-

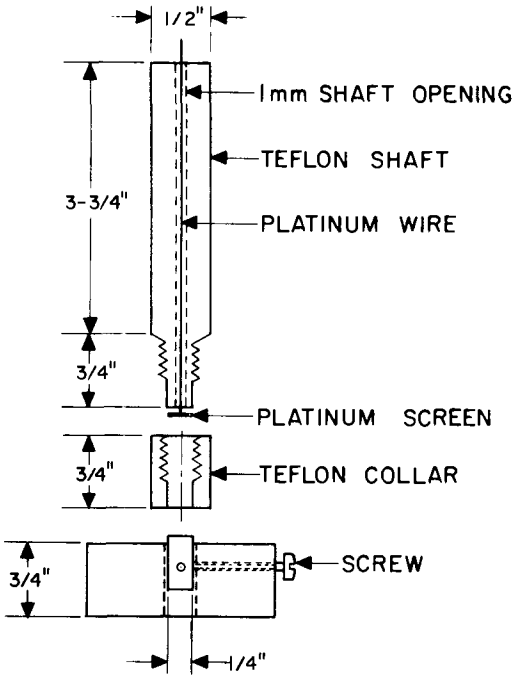

Fig. 1. Electrode holder

taining the electrode was then screwed onto a Teflon shaft as shown in Fig. 1, and the electrode pressed tightly against the current collector using the adjustable ¼ in. rod shown, which was then removed. A platinum screen was used as a current collector, positioned between the electrode and the solid Teflon shaft. An external contact wire was connected to the screen and passed up through the center of the Teflon shaft. The electrode holder thus exposed one face of the electrode to the electrolyte and insured uniform current density through this face. A coil of silver wire was used as counterelectrode, and the surface of the wire was periodically cleaned of reaction products by dipping the wire into an HNO_3-distilled water solution (1:1) for several seconds and then thoroughly rinsing the electrode in distilled water.

A Hg/HgO/31 w/o KOH reference electrode was used and was prepared as described by Hamer and Craig (9). A salt bridge filled with 31 w/o KOH was placed between the test and reference electrodes. One end of the salt bridge ended in a fine capillary (Luggin capillary) which was positioned close to the surface of the test electrode.

The cell was assembled in the test chamber with the test electrode raised above the level of the electrolyte, and the test chamber set to the appropriate temperature. The test electrode was then lowered into the electrolyte. Steady-state, open-circuit voltages *vs.* the Hg/HgO reference electrode were measured before steady-state and unsteady-state galvanostatic measurements, with a Fairchild digital multimeter (Model 7000). Constant current measurements were made using the rapid-switching circuit described by Austin and Almaula (10) in conjunction with a Nesco (Model JY120A-2) chart recorder. The desired current flowing through the cell was determined by the known voltage generated from a Harrison (Model 6206B) d-c power supply and the value of the precision resistor in the control circuit of the galvanostatic circuit. A Potter and Brumfield Hg-wetted contact relay (Type JMY-115-22) was used to eliminate switching transients.

A Tektronix Type RM564 storage oscilloscope (Type 3A3 differential amplifier and Type 2B67 time base) and Polaroid camera (Model C-12) were used to record voltage-time traces up to a few seconds. On initiation of a current, a vertical blanked-out portion of the trace showed the immediate establishment of an ohmic potential change, referred to hereafter as *IR* polarization. This polarization includes the resistance of the ionic current path in electrolyte between the face of the electrode and the Luggin tip, and electronic resistance in the current path through the test electrode, current collector, and wire to the point of attachment of the lead from the oscilloscope. During galvanostatic discharge, currents were interrupted and the decay of polarization *vs.* time measured with the oscilloscope. The blanked-out parts of the trace on break and make of the current were again used to indicate *IR* polarization at that stage of the discharge.

Test Electrodes

One of the electrodes (HDL) shown in Table I was prepared by Whittaker Corporation according to the procedures developed by the Harry Diamond Laboratories. The procedures as supplied by Harry Diamond Laboratories are as follows.

An Ag_2O-deionized water slurry was extruded onto an expanded metal screen (Exmet 5AG5-5/0), sintered, and anodically charged (using both faces of the electrode) in a 9-10% $NaHCO_3$ solution for 60 min at a current density of 0.125 A/in.^{2} The electrode material was then:

1. Discharged in $NaHCO_3$ solution at 0.125 A/in.^{2} for 60 min
2. Rinsed in deionized water for 30 min
3. Allowed to drain for 30 min
4. Dried at 165°F in a recirculating type oven for 30 min
5. Charged in 5% KOH at 2.5 A/in.^{2} for 20 sec
6. Rinsed in deionized water for 30 min
7. Allowed to drain for 30 min
8. Placed in a 160°F dry vacuum chamber for 4 hr
9. Stored in dry nitrogen gas

It will be noted that this procedure may leave some silver carbonate and AgO on the electrode, although at room temperature the electrode rapidly comes to the reversible potential of the Ag/Ag_2O reaction on immersion in electrolyte. The electrode is about 70% porous and contains silver (apart from the screen) and Ag_2O in approximately equal weights.

In order to test whether certain of the results were due to the electrolytic formation of the HDL electrode, and to provide more flexibility in the variation of important electrode properties, a number of the electrodes were prepared in the laboratory as follows: Ag_2O powder (Fischer reagent grade) was well mixed with an equal weight of Ag powder (Fischer reagent grade) in a mechanical shaker. Some of this material was used to fabricate electrodes, while another part was mixed with minus 400 mesh $NaNO_3$ to give a mixture containing 35 w/o of the salt. Electrodes were manufactured using the work of Morrell and Smith (11) as a starting point.

Silver expanded metal screen was etched in concentrated nitric acid for 30 sec and well rinsed in distilled water. This roughened the surface and promoted adhesion between powder and screen. A 0.25 in. diameter die of hardened steel was fitted with a bottom punch also of hardened steel, and a layer of the powder spread evenly on the face of the punch. A 0.25 in.

Table I. Characteristics of 50:50 w/o Ag-Ag_2O electrodes (TD is silver from thermal decomposition of silver oxalate)

Code No.	% Porosity	Silver type	Thickness, mm	Observed discharge capacity, coulombs/cm^2
HDL	70	Electroformed	0.25	15.4
16-TD	16	T. D.	0.312	70.5
65-TD	65	T. D.	0.405	45
63-TD	63	T. D.	0.262	19.5
63-F	63	Fischer	0.51	57
20-F	20	Fischer	0.34	57
81-F	81	Fischer	0.70	27

diameter portion of screen was cut from the roughened screen with a paper punch and placed on the surface of the powder. This was covered with another layer of powder, a top punch placed in the die, and the contents in the die were cold-compressed at 55,700 psi for 2 min. The electrode prepared in this way without $NaNO_3$ filler was about 20% porous and was mechanically strong. When the filler was present, the electrode was placed in 200 ml of distilled water and left for 3 days, with water replacement every day; the filler dissolved and slowly diffused out without mechanical rupture of the electrode structure. The electrode was then washed, and dried in a dessicator. This procedure gave an electrode of about 63-66% porosity. Similarly, an electrode of 80% porosity was prepared using 60% $NaNO_3$ and a pressure of 65,000 psi.

In an attempt to make electrodes containing high internal silver area, electrodes were made from Ag powder prepared by thermal decomposition of silver oxalate, following the procedure of Schroeder *et al.* (12). However, BET measurements on this powder showed it had areas of only 0.45 m^2/g instead of the 5 m^2/g expected.

Results

It was found that the test electrodes reached a stable, open-circuit potential after a few minutes of immersion in the electrolyte at room temperature, but took longer times at lower temperatures; for example, stabilization times were up to 1 hr at −70°F. The open-circuit potential was always within ±10 mV of the expected theoretical value. Figure 2 shows the variation of the effective resistance (times three) obtained from the initial blanked-out portion of the oscilloscope trace as a function of temperature, for an undisturbed position of the Luggin capillary. Also shown is the specific resistance of the electrolyte (solid line). The two sets of results are in reasonable agreement at the various temperatures, indicating that the resistance is due primarily to the mean electrolyte path between the electrode and the tip of the Luggin capillary. This mean path length can be calculated from $r = \rho l/A$, r being measured resistance, ρ specific resistance, l path length, and A the plane area of the electrode; thus, l is approximately 1/9 cm, which appears to be reasonable from the dimensions and position of the Luggin capillary. The data at −52°F show typical spread of results of repositioning the Luggin. There were sometimes differences between the effective resistances determined initially and at some later stage in discharge, but these differences were usually small, except as noted later.

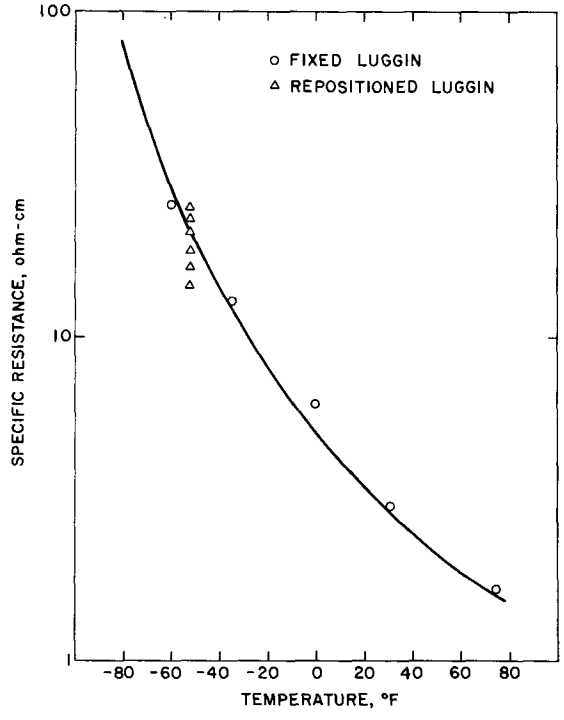

Fig. 2. Specific resistance of 31 w/o KOH (solid line) and effective resistance (times three) between test electrode and the Luggin capillary.

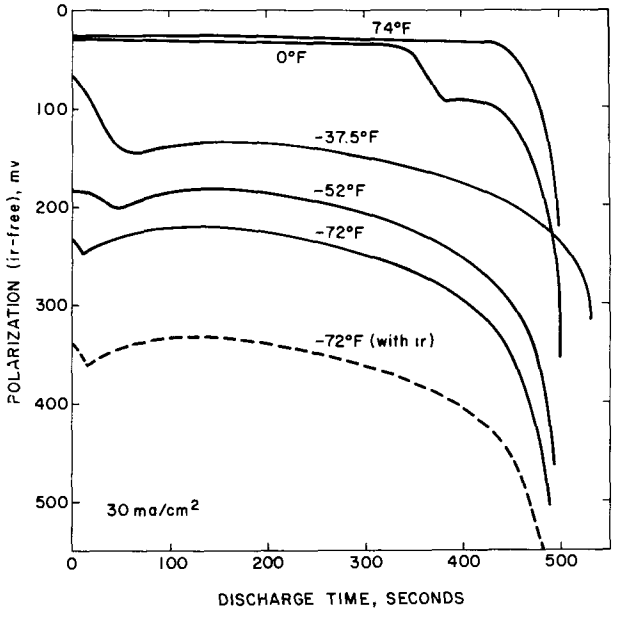

Fig. 3. Galvanostatic discharge at 30 mA/cm^2: HDL electrodes

Figure 3 shows typical results of polarization *vs.* time for HDL electrodes, discharged at 30 mA/cm^2 (27.9 A/ft^2), as a function of temperature. The results were corrected for *IR* polarization determined at 150 sec; the broken curve also shows the uncorrected values at −72°F, where the *IR* correction was maximum for this set of results. At room temperature, there is a small amount of polarization (about 20 mV), which is almost constant until the electrode is almost completely discharged. At 0°F, there is again a small amount of polarization at first, but it increases significantly after the electrode is about two-thirds discharged. The reason for the sudden increase in polarization preceding the final discharge of the electrode is not known. As temperature decreases, the polarization increases, and the shape of the curve becomes more complex. Figure 4 shows the polarization after 150 sec of discharge (about 30% discharged), which corresponds to the almost flat discharge regions; a marked increase in polarization below 0°F is apparent. Since the correction for the *IR* effect was also made at this time, the data are corrected reasonably well for *IR*.

The capacity of the HDL electrodes is somewhat variable, which is to be expected for such small electrodes (1/3 cm^2) stamped out from larger sheet sam-

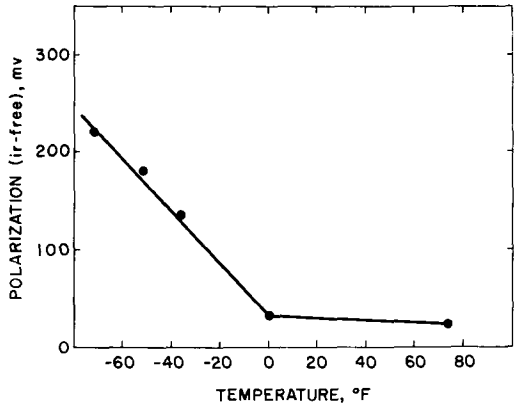

Fig. 4. Polarization (*IR*-free) at 30 mA/cm^2, measured at about 4.5 coulombs/cm^2 of discharge.

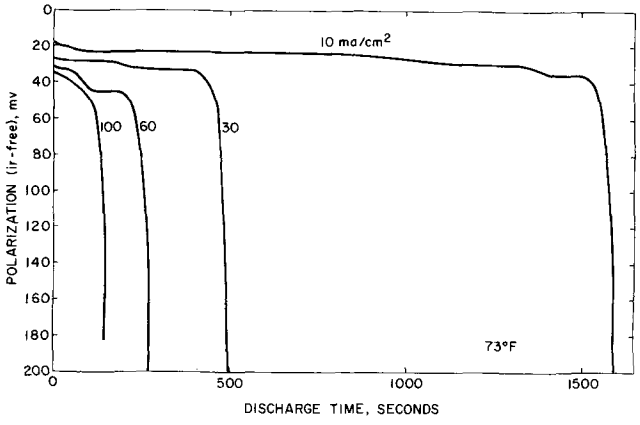

Fig. 5. Galvanostatic discharge at various current densities: HDL electrodes at room temperature.

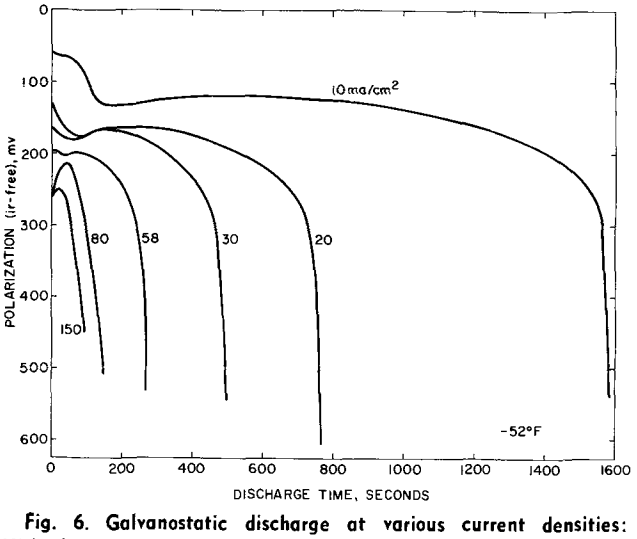

Fig. 6. Galvanostatic discharge at various current densities: HDL electrodes at −52°F.

ples, since the Ag/Ag_2O cannot be perfectly distributed over the Exmet support. The mean value was 4.89 coulombs (for area of 0.316 cm^2), with extremes of about ±5%. The capacity results were random in variability and showed no trend with temperature or with current density.

Figure 5 shows typical galvanostatic discharge curves (HDL electrodes) at 73°F, and Fig. 6 shows curves at −52°F. Values were corrected for *IR* assuming that the value measured at 1.42 coulombs of discharge applied over the whole curve. This point of discharge corresponds to a region between 1/4 to 1/3 of total coulombs, and corresponds to the minimum polarization in the plateau region following the initial peak polarization. Figure 7 shows Tafel plots of polarization *vs.* log current density at this point. The values for lower current densities were obtained by discharging the electrode at 10 mA/cm^2 until it reached the plateau, then changing the current density to low values and measuring steady polarization at the low

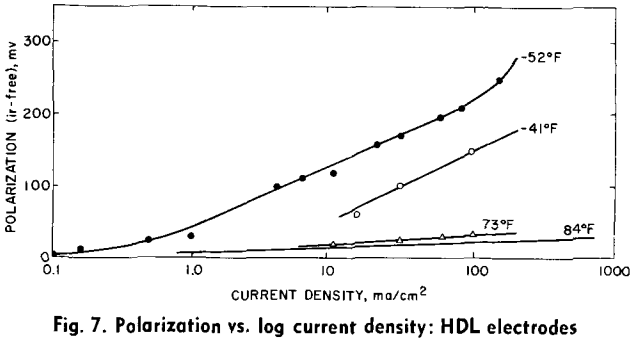

Fig. 7. Polarization vs. log current density: HDL electrodes

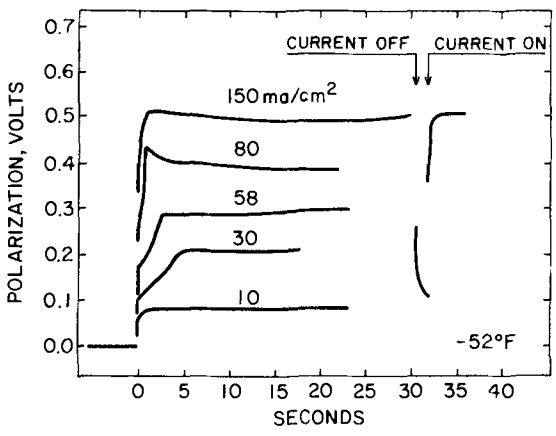

Fig. 8. Oscilloscopic traces showing the initial discharge characteristics of the curves shown on Fig. 6.

currents. A range of current from 0.1 mA/cm^2 to 5 mA/cm^2 was accomplished within the next coulomb of discharge. It was noticed that the initial parts of the curves of Fig. 6 were variable from sample to sample. For example, the 30 and 58 mA/cm^2 curves sometimes looked like the 80 mA/cm^2 curve shown, with a high initial polarization peak.

Recorder plots such as in Fig. 6 do not show fine detail at short times and Fig. 8 shows oscilloscope traces for the first few seconds of discharge. Again, the initial peak was more pronounced in some samples than in others. The 58 mA/cm^2 line in Fig. 6 contains all of the general features; there is evidence for an initial polarization peak occurring within 5 sec. followed by a slowly-developing second peak, followed by rapid increase of polarization as the electrode approaches complete discharge. At higher current densities, the two peaks fuse, while at lower current densities the first peak does not develop.

Since the presence of peaks and plateaus varied between samples the HDL electrodes and since the electrodes were prepared by electrolytic charging, it was decided to charge electrodes with anodic current and then perform discharge tests. Figure 9 illustrates typical results of cathodic discharge immediately after anodic charging; the broken line indicates the "normal" values, as found in Fig. 8, for example. The regions in the curve can be described by: a is the *IR* jump; b is a rapid rise of polarization due to double-layer charging; c is a plateau of discharge followed by a shallow peak at d; e is a plateau of discharge followed by rapidly increasing polarization as the electrode approaches complete discharge in region f. By prior anodic charging, at potentials more anodic than the $Ag_2O|AgO$ equilibrium potential, the plateau at c is lengthened proportionately to the coulombs of charge, to c′ as shown. In addition, a pronounced peak is developed after b′. The polarization level at e and f is virtually unchanged. If such a charged electrode is left standing at open circuit in the electrolyte, the

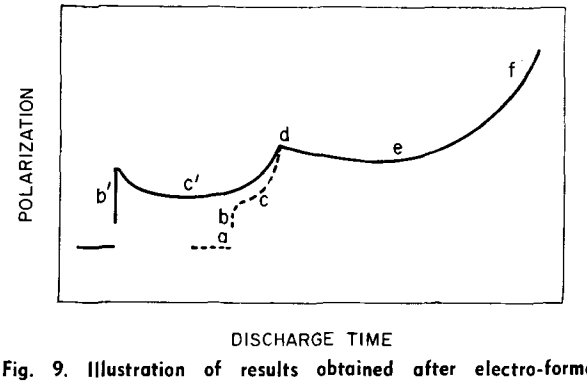

Fig. 9. Illustration of results obtained after electro-formed electrodes were anodically charged prior to discharge.

length of plateau c' decreases with time and comes back to normal values after standing overnight at −54°F. Alternatively, if a normal electrode is discharged to region e just after peak d, allowed to return to open circuit potential, then discharged again at the same current density, the coulombs in region c is shortened. Then if the electrode is left for some time at open circuit, the length of region c increases again to usual values.

Table I shows the characteristics of a group of electrodes prepared from silver and Ag_2O powder, as described previously. The BET area of the constituents were 0.57 m^2/g for Fischer silver, 0.45 m^2/g for T. D. silver, and 0.60 m^2/g for Fischer Ag_2O. These correspond to equivalent spherical diameters of 1.01μ, 1.3μ, and 1.0μ, obtained using the expression $D = 6/Bd$ where D is the equivalent spherical diameter (microns); B is the BET area (m^2/g); d is the density of the powder (g/cc). On galvanostatic discharge at 30 mA/cm^2, −52°F, it was observed that some electrodes gave high initial IR jumps. After some discharge, IR values measured at various points in the discharge were almost constant and usually comparable to previous results, see Table II. (Although electrode 63-TD gave an effective resistance of 11 ohms which is high compared to the usual values of 4 to 8 ohms, its discharge curve after correction for this value was similar to that of 65-TD.) It must be remembered that these values include the resistance of the electrolyte between test electrode and Luggin capillary (see Fig. 2). It can be concluded that high initial IR values decreased to normal values after no more than 2% of discharge. It is also concluded that these normal values of IR polarization did not increase even when electrodes were 95% discharged.

Figure 10 shows polarization *vs.* degree of discharge, corrected for IR. The marked effect of porosity is apparent; for example, comparing 63-F with 20-F, the 20-F electrode contains more Ag_2O and Ag and is thinner, yet operates at 75 to 200 mV more polarization. There was no correlation between high initial IR values and later performance. Figure 11 shows typical initial time results for the electrodes. A significant polarization peak was observed, similar to that found with the electro-formed HDL electrodes, but more pronounced. For some of the electrodes, 81-F for example, part of this peak was due to a high initial IR value which decayed during discharge. Even after

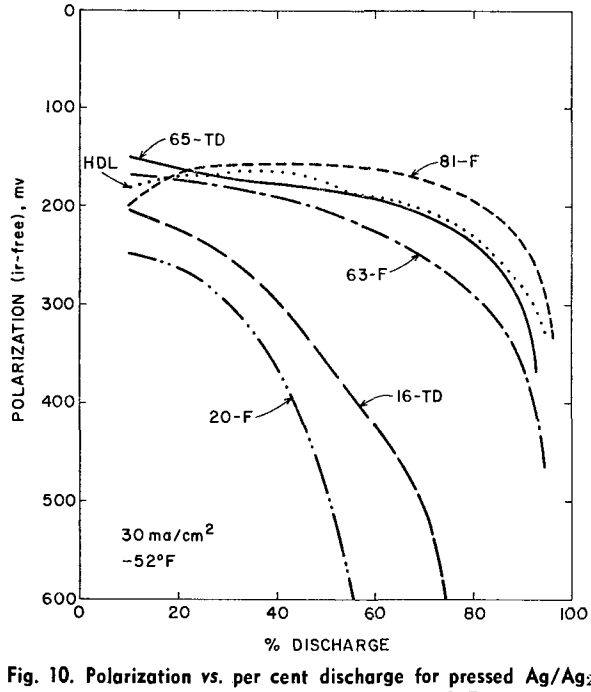

Fig. 10. Polarization *vs.* per cent discharge for pressed Ag/Ag_2O powder electrodes of different porosities at −52°F.

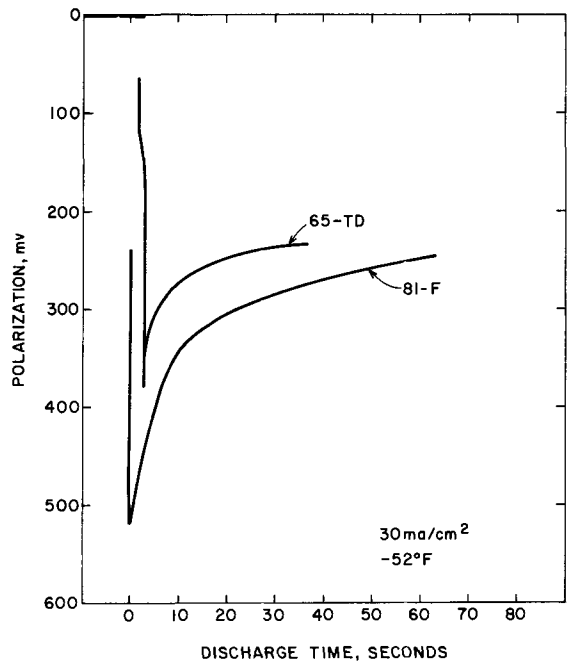

Fig. 11. Oscilloscopic traces showing initial discharge characteristics of electrodes 65-TD and 81-F.

allowing for this, a pronounced peak is still present, and it is also present in cases, 65-TD for example, where the initial and steady IR values were nearly the same. The shape of the initial polarization curve, when it is not obscured by a high initial IR, contains the a, b, c, d, e, regions discussed previously. The reason for the high IR values obtained with some of the pressed powder electrodes as compared to the electroformed electrodes is not known, but it is possible that because of the manner in which the Ag and Ag_2O particles are pressed together, good electrical contact throughout some of the electrodes is not achieved.

The effect of the porous nature of the test electrodes was investigated by making thicker electrodes from 5 of the 10 mil HDL electrodes stacked together. The stack was mounted in the electrode holder in the usual way with only one face exposed. Some preliminary tests, and some theoretical calculations (see Discussion) suggested that 30 mA/cm^2 at −52°F should give a small but significant amount of reaction at the back section and a lot of reaction in the first section. It was also found that there was some evidence for poor electronic contact between the sections, therefore a fine dusting of silver powder was applied between the sections before compressing in the holder. The stack was discharged to about 45% of total capacity,

disassembled and discharge completed on each of the sections. Knowing the average coulombic capacity of the sections, the amount of the coulombs discharged in each section during the first discharge was readily calculated. The results are shown in Fig. 12. Distribution of reaction through the 50 mil thick stack is clearly evident.

Figure 13 shows the polarization of this thick electrode during discharge. If reaction were uniformly distributed through the electrode, a current density of 30 mA/cm^2 would be 6 mA/cm^2 per section. On the other hand, if reaction were concentrated in the outer section, polarization would be similar to that for just one section at 30 mA/cm^2. As expected from Fig. 12, polarization lay between these two extremes. Of interest is the more rapid increase in polarization with amount of discharge for the thick electrode.

Figure 14 shows polarization for the remainder of discharge for each section. It can be seen that partial discharge develops the pronounced peak of polarization seen previously at higher current densities. This peak decays on further discharge so that each curve fuses into a common curve nearer completion of discharge.

Discussion

Considering first the HDL electrodes produced by electro-forming of sintered silver powder, and considering the internal surface of the electrode before

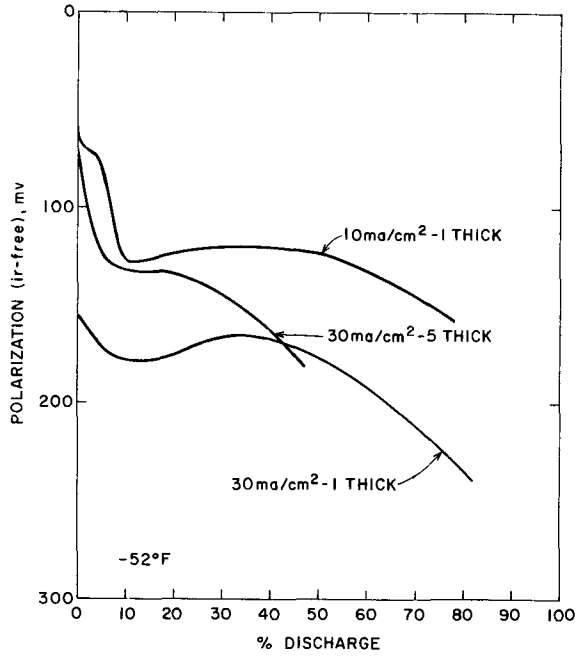

Fig. 13. Galvanostatic discharge for various thicknesses of HDL electrodes; 30 mA/cm^2 and −52°F.

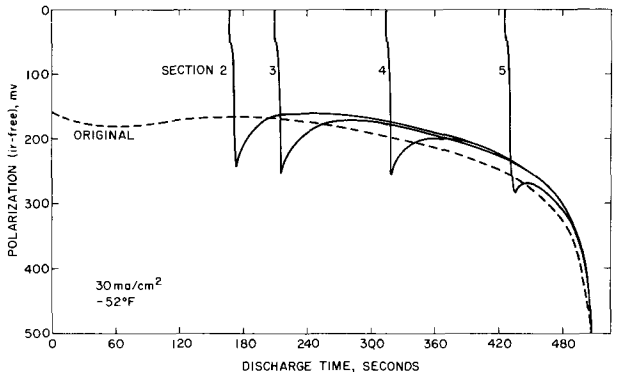

Fig. 14. Galvanostatic discharge of individual electrodes used in the stacked electrode experiment.

charge to be like an extended solid surface of silver, there are two possible forms in which Ag_2O can be produced. First, the entire surface of the silver can be covered with a tight layer of Ag_2O which grows by solid state film growth. BET measurements on these electrodes give an area of 0.4 m^2/g of silver, which is approximately 300 cm^2 of internal area per cm^2 of electrode. Thus at 30 mA/cm^2, the true current density would be about 0.1 mA/cm^2. A continuous film of Ag_2O of 0.1μ thick would give a resistance of 10^3 ohm cm^2 and an *IR* polarization of 100 mV, taking the specific resistance of Ag_2O to be 10^8 ohm cm. This is an order of magnitude higher than the experimental electronic *IR* values for these electrodes and it must be concluded that if a continuous film of Ag_2O covers the silver it must be less than 100Å in thickness. It seems more logical to conclude, from the experiments described by Thirsk (13), that the major part of the Ag_2O formed is in discrete crystallites (which can grow to about 1μ in size on solid silver) attached to the silver surface thus leaving relatively bare silver present to take and supply electrons. It can be argued that whatever is the mechanism of anodic formation or discharge of Ag_2O, it cannot involve charge transfer through thick crystallites or solid layers of Ag_2O, since no large electronic resistance is present.

The plateau of discharge at c in Fig. 9 indicates that there is some material which discharges more readily (at lower polarization) than the major amount of Ag_2O present. In the electro-formed electrodes this might be ascribed to silver carbonate or silver peroxide, but the typical S shape of b, c, d, is also clearly apparent in the other electrodes made from reagent grade Ag_2O. One explanation is that thin, continuous layers of Ag_2O cover the silver in the electrode and that these layers are more active than the bulk crystallites of Ag_2O. Assuming that a monolayer has roughly 0.2 mcoulombs/cm^2 of capacity, 300 cm^2 of internal surface would give 0.06 coulombs/cm^2 of electrode. Estimates of the amount of charge in region c under normal conditions gives about 0.1 coulombs/cm^2, thus the layers might be only a few molecules thick. After anodic charge at low temperature, region c is increased, possibly representing thickening of the layer. However, on soaking in electrolyte at open circuit, the charge in region c returns to about 0.1 coulombs/cm^2, indicating that there is an equilibrium amount of surface film in the Ag/Ag_2O/KOH system of a few angstroms thick. The solubility of Ag_2O is too small for the plateau to be due to discharge of dissolved oxide in the pores of the electrode. Possibly, this S shape, with a plateau of c, has not been observed in room temperature measurements because operation at low temperatures accentuates the polarization peak at d, thus clearly separating it from the plateau region. It is interesting that similar results at low temperature have been obtained with the cathodic discharge of a solid silver sheet anodized to Ag_2O formation (14), although the current density to obtain similar voltage-time curves is re-

duced from 30 mA/cm² for HDL electrodes to 0.3 mA/cm² for the anodized sheet.

Whatever the cause of this initial region of discharge, it caused variability in the first time interval of discharge of HDL electrodes which made it difficult to observe quantitative results on the magnitude of peak d as a function of current density and temperature. A general pattern is evident, however; the peak at d is more pronounced at higher current densities and at lower temperatures. If the electrode is partially discharged, allowed to rest at open circuit, and then further discharged, the peak is clearly evident (see Fig. 14). Alternatively, the peak is clearly present in the pressed powder electrodes (Fig. 11). It is not due to the porous nature of the electrodes because it is observed on discharge of anodized silver sheet (14). On the other hand, fairly rapid break-and-make of the current to perform *IR* measurements show no peak on make (see Fig. 8). It can be concluded that the peak reappears only after some stand time.

Three obvious explanations for peak d come to mind. First, by analogy with anodic charging, the peak could be a nucleation polarization. This would fit in with the dependence on current density and temperature. It is not clear, however, what is being nucleated. It could be dissolved silver deposition on pre-existing silver by

$$Ag_2O(s) + H_2O \rightarrow [Ag_2O \cdot H_2O] \rightarrow 2Ag^+ + 2OH^- \quad [1]$$

$$Ag(s) + Ag^+ + e^- \rightarrow 2Ag(s) \quad [2]$$

Equation [2] would be the nucleated step. Polarization produces growth of nucleation centers which are still present after rapid break-and-make of the circuit. On stand, the growth centers become poisoned by impurity adsorption or decay by molecular rearrangment to a non-nucleating structure.

Second, if the reaction in Eq. [1] were slow at low temperature, then the concentration of Ag^+ would decrease with current, giving concentration polarization in reaction [2]. The rate of dissolution of Ag_2O could be voltage dependent, increasing with cathodic polarization. The polarization overshoot would then be ascribed to the removal of surface impurities which slow down dissolution, or initial removal of stable surface layers leaving more reactive, freshly formed surface underneath. Third, if Reaction [2] had charge transfer polarization, the production of silver during discharge would have an autocatalytic effect. However, the large polarization overshoots would indicate at least a tenfold increase in silver area as the polarization decreases to the plateau at e, whereas there is 50% of unreacted silver present initially in the electrodes. In addition, silver area produced during discharge does not presumably disappear on stand, whereas the peak is reinstated after stand at open circuit. This last fact could be explained by postulating that on stand at open circuit the silver becomes covered with a continuous film of Ag_2O. However, it has already been argued that plateau c before peak d corresponds to the discharge of a surface film. It is planned to test the autocatalytic hypothesis by making double-layer capacity measurements during periods c, and in the regions d to e to f, since the double-layer capacity will be primarily due to metallic silver.

Further information can be deduced from Fig. 4 if it is assumed that electrodes at different temperatures can be compared in the plateau region, with only temperature as the prime variable. Figure 7 indicates that a Tafel-type relation exists and assuming

$$i = I_A \exp(\alpha \mathbf{F}\eta/RT) \quad [3]$$

$$I_A = k \exp(-\Delta H^{\ddagger}/RT) \quad [4]$$

the apparent activation enthalpy can be obtained from

$$\eta = \frac{\Delta H^{\ddagger}}{\alpha \mathbf{F}} + \frac{2.3RT}{\alpha \mathbf{F}} \log (i/k)$$

Applying this relation to the irreversible line in Fig. 4, with i constant, gives $\Delta H^{\ddagger} = \eta \alpha \mathbf{F}$ at absolute zero temperature; assuming $\alpha = 0.5$, $\Delta H^{\ddagger} = 14.5$ kcal/g-mole. The apparent exchange current density at −52°F from Fig. 7 is 0.3 mA/cm². From these data, the values of exchange current density at various temperatures are shown in Table III, with values of $b = 2.3RT/\alpha\mathbf{F}$. It must be clearly understood that the data presented here are not sufficient to prove the existence of a charge transfer-controlled reaction with the determined kinetic parameter. However, since Eq. [3] appears to describe the results fairly well, it can be used as a basis for the discussion of distributed reaction in the next section.

Equation [1] shows that water is the reactant to be transported from the bulk of the electrolyte through the pores of the porous electrodes to the interior. Even at 31 w/o of KOH, water is still present in high molar concentration in the electrolyte, and application of the Austin ϕ criteria (6) shows that distributed reaction will be due principally to ohmic effects. This greatly simplifies analysis of the system because an analytical solution exists for this case when η is large enough for the reaction to be considered irreversible. The basic equation (6) for a plane, porous electrode in which the pores are small compared to the thickness of the electrode is

$$d^2\eta/dx^2 = i_o S\rho\{(R/R_b) \exp(\alpha\eta/b) - (P/P_b) \exp[-(1-\alpha)\eta/b]\} \quad [5]$$

This equation relates the polarization η at a position x (measured from the back face of the electrode) to the distance x, where η is a function of x,η (x); S is the electroactive area per unit volume of electrode, cm²/cm³; ρ is the effective specific resistance of electrolyte in pores, ohm cm; i_o is the true exchange current density A/cm² at a reactant concentration of R_b and R is the concentration at x, g-moles/cm³; P_b, P are the corresponding product concentrations. Since water is present in high concentration, $R/R_b \sim 1$, and for the second term of Eq. [5] negligible

$$d^2\eta/dx^2 = i_o S\rho \exp(\alpha\eta/b) \quad [6]$$

The solution to this equation has been given elsewhere (15) and only the results of significance to the present work will be given. At low values of η (but still large enough for irreversible reaction), the total current density is approximated by

$$i = I_A \exp(\alpha\eta/b) \quad [7]$$

where

$$I_A = i_o SL$$

Thus a normal Tafel region may be seen with an apparent exchange current density, I_A, which represents complete utilization of the interior of the electrode. On the other hand, when reaction is concentrated toward the electrolyte face

$$i = I_0 \exp(\alpha\eta/2b) \quad [8]$$

where

$$I_0 = \sqrt{2i_o Sb/\rho\alpha}$$

Thus a Tafel slope of double the normal value is predicted, and L does not occur in the apparent current density as expected if the deep interior of the elec-

trode is not contributing to the current-producing reaction. The simple relations of Eq. [7] and [8] are quite useful even though they are only approximations. For example, the current at which these two Tafel lines cross can be called the cross-over current, i_c, and

$$i_c = 2b/\alpha L\rho \qquad [9]$$

This is an important relation because it does not contain the kinetic parameters of i_o and S and it can be fairly accurately estimated knowing the porosity of the electrode. If the actual current density is much less than i_c, reaction is uniform through the electrode; if it is much greater than i_c, distributed reaction occurs, and Eq. [8] applies.

Figure 15 shows plots of the complete solution to Eq. [6] compared with the approximate solutions represented by the two Tafel lines. Polarization is plotted in dimensionless form $\eta/2.3b$, where 2.3b is the (log base 10) Tafel coefficient, that is 0.12V at room temperature, $\alpha = \frac{1}{2}$. The zero of the polarization scale is arbitrarily taken at $i/i_c = 1$; in practice this point would correspond to a definite polarization which would be higher for a lower exchange current, and the zero of the scale is shifted accordingly (15). The maximum deviation in polarization of the complete solution from two Tafel lines is about 2.3b/4, that is, 30 mV at room temperature.

It is not claimed that the current-polarization relation is given exactly by two straight Tafel lines or by the curve in Fig. 15, since the equations are derived for an idealized system. However, it seems likely that the equations will apply well enough to aid in deciding what thickness of electrode should be used for a given duty, even if they cannot predict the exact shape of the current-polarization relation.

Table IV shows values of $I(O)/I(L)$, $I(\frac{1}{2})/I(L)$ *vs.* i/i_c, where $I(O)/I(L)$ is the ratio of the specific currents at $x = 0$ and $x = L$, $I(\frac{1}{2})/I(L)$ the ratio of specific currents at $x = L/2$ and $x = L$. These represent the relative rates of reaction at these positions, obtained from the solution of Eq. [6] with the appropriate boundary conditions (15). As expected, as i/i_c increases, reaction is less and less uniform throughout the electrode.

Considering the conditions for the data in Fig. 12, the specific conductivity of electrolyte is 20 ohm-cm, and L is 50 mil = 0.127 cm. The labyrinth factor (q/θ) can be taken as about 2 giving $\rho = 40$ ohm-cm. From the Tafel slope of 85 mV, $b/\alpha = 0.085/2.3 = 0.037$V. Thus $i_c = 14.6$ mA/cm², and Table IV predicts that a current density of 30 mA/cm² would give $I(O) : I(\frac{1}{2}) : I(L) :: 0.22 : 0.3 : 1$. Figure 12 gives the relative rates of reaction as roughly 0.25:0.4:1. This is a remarkable agreement bearing in mind that the reactive surface is undergoing change during the discharge, and that the transfer factor may also be changing during discharge. A more exact way of comparing theoretical with experimental results is as follows. The solution to the equation enables the fraction of the reaction occurring between 0 and x to be calculated, or the fraction between x_1 and x_2, for any value of i/i_c.

In a later and more complete paper, extensive tabulated solutions will be given which will enable the appropriate data to be readily picked out. The specific solution to be used here is that the fraction of reaction, $i(x)/i$, occurring between 0 and x is related to the total current density (i), the cross-over current (i_c), and fractional position in the electrode (x/L), by

$$i/i_c = X \tan X \qquad [10]$$

$$i(x)/i = \tan\left(\frac{x}{L}X\right) \Big/ \tan X \qquad [11]$$

X is an intermediate in the calculation, defined by Eq. [10]. Values of $i(x)/i$ can be compared directly with the experimentally determined fraction of reaction occurring in the various slices making up the electrode. Table V gives results for electrodes made of two sections.

It can be seen that agreement between predicted and experimental is good. The percentage of reaction occurring in each section of the 50 mil stack of Fig. 12 were predicted to be 11.6, 13, 16, 22, 38; the experimental values were 11, 13, 17, 25, 34.

The above results indicate that it is possible to predict the effect of distributed reaction for one electrode thickness. At −52°F, the estimated value of i_c for the 10 mil thick HDL electrode is 73 mA/cm². For 30 mA/cm², i/i_c is 0.41 which corresponds to $I(O)/I(L)$ of about 0.7; the predicted increase of polarization above a uniform reaction condition is about 11 mV. Thus at 30 mA/cm², a distributed reaction effect is present but it is not very great. At higher temperatures or at lower current densities, the distributed reaction effect is negligible for the HDL electrodes. Similar reasoning can be applied to the electro-forming of the 10 mil electrodes, which was carried out at 200 mA/cm² on each side of the electrode; this corresponds to an electrode used with current on one face with thickness 5 mils. At room temperature, the effective specific resistance of electrolyte can be estimated at about 10 ohm-cm, giving an estimate of i_c of about 500 mA/cm². Again the value of i/i_c of 0.4 corresponds to a greater rate of production of Ag_2O at the electrolyte face than in the interior and the ratio of Ag_2O to Ag in the outer face will be somewhat higher than the average of 50:50, while it will be somewhat less in the interior.

The above calculations also go some way in explaining the effect of porosity shown in Fig. 10. The more porous electrodes will avoid distributed reaction

Table IV. Calculated values of $I(O)/I(L)$, $I(\frac{1}{2})/I(L)$ *vs.* i/i_c

at these conditions, whereas the 20% porous electrodes will be undoubtedly in the completely distributed reaction condition and will have higher polarization at a given state of discharge because only part of the electrode interior is being utilized. When the reaction is concentrated at the outer face, a layer of fully discharged material will build up over the electrolyte face and this layer will grow thicker into the electrode as discharge proceeds. Figure 13 indicates that at the point where discharge of the 50 mil stack was stopped, polarization was increasing quite rapidly. Figure 12 shows that this corresponded to complete discharge of the outer face of the electrode. It is possible that this fully discharged layer is relatively impermeable, giving an additional *IR* polarization for ionic transport. Because of the double-layer capacity of this porous layer, this type of *IR* polarization will not disappear instantaneously when current is interrupted. (This postulate will be tested in future work by fully discharging a 10 mil electrode, making it the outer face of a 50 mil stack, and discharging the stack.)

Again, the concept of distributed reaction goes part of the way to explaining region f in the discharge. The evidence is that polarization increases more rapidly with the state of discharge when the reaction is concentrated toward the outer face. At lower currents and higher temperatures, a more extended plateau of region e is seen, followed by sudden development of region f at high percentage discharge. As current is increased or temperature decreased, region f starts at a lower per cent of discharge and is more spread out.

There are probably several reasons for the increase of polarization in region f. Certainly, much increased polarization is expected when the state of discharge has progressed to the point where the active area of Ag_2O present in the electrode is too small to support current. However, the Tafel relation indicated in region e suggests that a simple, charge-transfer reaction is rate-controlling. It has already been argued that this cannot involve a reaction occurring on an Ag_2O crystal, since the Ag_2O is nonconductive, would not have a simple double-layer on its surface, and would not give simple Tafel-type rate relations. Thus it appears that the reaction of Eq. [2] is the likely candidate.

$$Ag(s) + Ag^+ + e^- \rightarrow 2Ag(s) \qquad [2]$$

(This will be examined further by varying the area of silver by orders of magnitude keeping other parameters constant, and determine the effect on polarization.) The influence of Ag_2O would occur only via its production of dissolved Ag^+. If the rate of dissolution of Ag_2O from the crystallites (electro-formed electrodes) or powder (pressed electrodes) of Ag_2O is large, the concentration of Ag^+ in electrolyte in the pores of the electrode would be maintained constant until almost all of the Ag_2O had been reacted.

If the above postulate is correct, increased activation polarization can be obtained (at low temperatures where the polarization corresponds to irreversible reaction) by decrease in the concentration of Ag^+. This could arise from a slow rate of dissolution, or from a slow rate of mass transfer to the conductive silver matrix. Examining this last hypothesis, it is difficult to give a mean diffusion path from the surface of an Ag_2O particle to the surface of an adjacent Ag particle (16). In electro-formed material, the crystals of Ag_2O are presumably in contact with Ag, and the mean distance must be of the order of 1 micron or less. In the powder electrodes, if the elementary particles of Ag_2O and Ag are well mixed, the distance will again be of the order of 1 micron. However, if an agglomerate of Ag_2O particles touches an agglomerate of Ag particles, the mean diffusion path might correspond to the agglomerate size rather than the particle size.

Using the solubility-diffusivity results of Miller (17), the room temperature values are about $(3)(10^{-4})$ moles Ag_2O/liter and $(3)(10^{-6})$ cm²/sec. Taking a value of 100 cm² as a conservative estimate of the internal area of 1 cm² plane of the electrode, the steady-state limiting current due to mass transfer of Ag_2O across a diffusion path of 1 micron is

$$i_L \simeq (10^2)(2)(96500)(3)(10^{-7})(3)(10^{-6})/(10^{-4}) \text{ A/cm}^2$$
$$\simeq 180 \text{ mA/cm}^2 \text{ plane}$$

As temperature decreases, the diffusion coefficient will decrease comparably to the increase in electrolyte resistivity and the solubility may also decrease. Thus the order-of-magnitude calculation shows that region f at the higher current densities and lower temperatures might involve mass transfer limitations of dissolved silver between an Ag_2O surface and an adjacent silver surface within the electrode. This mass transfer effect would not be altered by stirring the electrolyte except inasmuch as stirring could move electrolyte within the micropores of the electrode. Presumably this mass transfer effect becomes more important as the electrode discharges because, the smaller particles of Ag_2O are consumed first leading to an increased mean diffusion path.

Conclusions

At low temperatures the galvanostatic discharge curve in general contains five regions of polarization with time; a, b, c, d, e, f. Region a represents an immediate *IR* polarization, due primarily to the electrolyte path between the test and Luggin tip. Region b is double-layer charging, and is followed by a short plateau c which corresponds to discharge of some active material. Region c progresses into a polarization peak at d, and is probably a nucleation overpotential. After the peak, a plateau at region e is obtained which appears to correspond to an activated, charge transfer reaction, possibly $Ag(s) + Ag^+(aq) + e^- \rightarrow 2Ag(s)$. In this region the active area of silver is not changing very much.

Finally, the polarization again increases as the electrode tends to more complete discharge, region f, which again is not due to an increased electronic *IR* effect. If the electrode current density and temperature are such as to cause distributed reaction, the electrode reacts more toward the face, giving increased polarization and a more rapid onset of region f. The increased polarization in region f may be due to layers of discharged material formed at the electrode face and to mass transfer of dissolved Ag_2O from Ag_2O surface to Ag surface.

Although the work in this paper is obviously not a comprehensive picture of how this electrode behaves at low temperature, the plateau region for steady discharge can be fairly quantitatively considered. First, the current density-polarization relation is the Tafel relation

$$\eta = b \log i - b \log I_A \qquad [12]$$

where I_A is given by

$$I_A = i_o SL$$

and the temperature coefficient of i_o is $\exp(-14.5/RT)$. In order to get lower polarization (loss of ideal potential) at a fixed temperature, the apparent exchange current I_A must be increased. This can be done by increasing the thickness L (but see below), or by increasing the specific reactive area S by using very fine Ag and Ag_2O powder. The thickness L should be less than a value L_c defined by

$$i_m < i_c < 2b/\alpha L_c \rho \qquad [13]$$

where $\alpha = \frac{1}{2}$ for the results reported in this paper, and i_m is the maximum current density of operation. Thicker electrodes will give lower polarization when $i << i_m$, but the value of i_c is reduced. When $i_m \geq i_c$, the reaction is concentrated toward the outer face, and polarization increases rapidly with increased i.

It is essential to design electrode thickness and porosity to avoid entering into region f at the outer

face when the electrode is only slightly discharged in the interior, for then the polarization increases rapidly with time during discharge. The effect of porosity is contained within the factor ρ, which is the effective specific resistance of electrolyte within the electrode. This factor appears to increase rapidly as porosity is decreased, thus causing a smaller i_c. To avoid this effect, porosities of 60 to 80% should be used. These high porosities reduce the value of S and the coulombic capacity of the electrodes so, again, a balance must be made between the various factors dependent on the conditions of operation and the duty required.

ABSTRACT

A unique electrochemical sensor is described for quantitatively detecting hydrogen in gas mixtures containing electrochemically inert species. Limiting diffusion current measurements in the range of +0.25 to 0.65V *vs.* a platinum electrode in the same acid solution are proportional to the hydrogen content in the bulk phase. When active species, such as oxygen, are present in binary or ternary gas mixtures, the hydrogen content of the gas phase is determined by maintaining a working electrode potential of +1.06V (oxygen or air rest potential on Pt black in acid) at which hydrogen is immediately ionized even in the presence of oxygen on the electrode surface. The feasibility of detecting carbon monoxide and hydrocarbons in oxygen-containing atmospheres using the electrical biasing technique is demonstrated. The limitations and practical applications of the sensing devices are discussed.

The electrochemical oxidation of hydrogen takes place at high rates and low anodic overvoltages in most aqueous electrolytes, even at room temperature. The process is accelerated by noble metal electrocatalysts such as platinum or palladium which display rather large kinetic constants (high exchange current densities). These anodic overvoltages are limited by potentials at which surface oxidation of the metal may take place, followed eventually by oxidation of the water in the electrolyte. Over a large potential region the electrode surface can be considered as clean, *i.e.* the surface concentration of hydrogen is essentially zero (Nernst's equation can be used to predict extremely low equilibrium partial pressures of hydrogen), and simultaneously the surface concentration of metal oxide is nearly zero. If the working electrode is maintained at potentials corresponding to the region of zero-surface coverage, all hydrogen arriving on the electrode will be instantaneously ionized. The rate of hydrogen ionization measured as a Faradaic current is then equal to the rate of hydrogen diffusion to the electrode. Under these conditions the rate of diffusion is proportional to ΔC (hydrogen concentration difference between the bulk gas phase and the electrode surface, $\Delta C = C_b - C_E$). However, since C_E is essentially equal to zero, the measured current is proportional to the hydrogen concentration in the bulk gas phase.

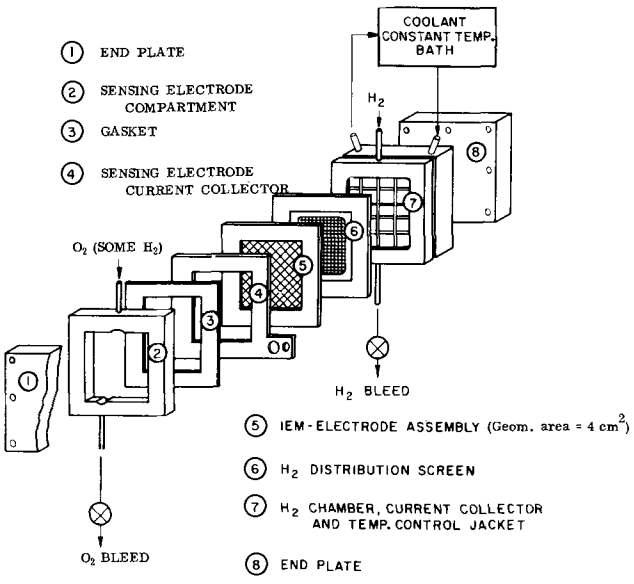

Fig. 1. Electrochemical hydrogen sensor

In the presence of oxygen, the situation is more complex since the electrode will tend to stabilize around the oxygen electrode rest potential. The detection of hydrogen in oxygen-containing atmospheres is accomplished by electrically biasing the platinum black sensing electrode at +1.06V [1] *vs.* a Pt/H_2 electrode in the same solution. The principles underlying the choice of the biasing potential and the unique features of the detector are as follows.

The rest potential of a hydrogen/oxygen acid fuel cell is 1.06V. When a potentiometer or similar device for applying a constant d-c voltage is used to counter the 1.06V, no current will flow in an external circuit. If hydrogen or other oxidizable gas is present in the oxygen stream and the applied potential is maintained at 1.06V, the following reactions will occur assuming hydrogen as the oxidizable gas.

Electrode	Atmosphere	Electrode reactions
Sensing	Some H_2 in O_2 stream	$H_2 = 2H^+ + 2e$
Counter-reference	Pure H_2	$2H^+ + 2e = H_2$

The current flowing in the external circuit is directly proportional to the quantity of hydrogen present in the oxygen stream. The novelty of the concept is that the electrical bias potential is exactly equal to the rest potential of the Pt/O_2 electrode; thus, making the device insensitive to oxygen and the utilization of a stable counter-reference electrode. Pure H_2 is passed over the hydrogen evolution counter-reference electrode to insure a quasi-constant potential of 0.0V. A diagram of the sensor is given in Fig. 1.

Experimental

All work on the development of a hydrogen sensor was conducted using a sulfonic acid cation exchange membrane (AMF-C 311) as the electrolyte. Teflon treated, platinum black electrodes (5 mg/cm^2 of Pt) having gold screen current collectors were attached to the membrane. The geometric area of the electrodes was 4.0 cm^2. A diagram of the device which is essentially an electrically biased cation exchange membrane fuel cell is given in Fig. 1. For complete cells, the hydrogen electrode served as a combination counter-reference electrode. For potentiostatic half-cell measurements, a reference Pt/H_2 electrode which contacted the membrane through a H_2SO_4 solution ($pH = 0$) was used as a third electrode. During the half-cell measurements, air was in contact with the counter-electrode. All cells were run at 25°C unless specified otherwise.

[1] All voltages are referred to a Pt/H_2 electrode in same solution unless otherwise specified. Signs for half-cell reactions are those discussed by Licht and de Bethune (1).

Experimental investigations were conducted on half and complete cells under controlled conditions, to determine the magnitude of the sensing electrode response when exposed to binary H_2-N_2 gas mixtures (limiting diffusion current measurements) and gas mixtures containing an oxidant, *i.e.* H_2-O_2 or H_2-N_2-O_2 (Faradaic hydrogen ionization current at oxygen electrode potentials).

Simultaneously, response times were measured to determine the time necessary before stabilization of the measured variable could be achieved. Half-cell measurements were necessary because of the technique used and also to avoid possible interference of the counterelectrode on the output signal. An oxygen electrode (as a possible counterelectrode in a hydrogen sensor) frequently displays potential fluctuations depending on variables such as electrolyte concentration, oxygen partial pressure, *etc.* These problems were alleviated by using potentiostatic techniques or quasi-reversible counterelectrode such as pure H_2 electrodes.

Relation between voltage and limiting currents.—The electrochemical oxidation of H_2 (pure or in presence of inert gases as nitrogen) takes place at high rates and low anodic overvoltages up to conditions where a rate-controlling process limits oxidation rates or up to a potential where oxygen deposition occurs on the electrode surface. Figure 2 displays this behavior on a 4.0 cm^2 platinum black anode operating with a binary H_2/N_2 mixture. In this instance, a 3 v/o (volume per cent) H_2 in N_2 was used in order to limit the maximum observable current. At anodic potentials between +0.25 and 0.65V, the limiting diffusion current is potential insensitive. Beyond +0.70V, oxygen deposition reduces the current progressively until the oxygen rest potential is observed. For purpose of comparison, a polarization curve for cathodic oxygen reduction is also presented in Fig. 2. From these results, it can be concluded that an anode operating in the range of +0.25 to 0.65V should display limiting diffusion currents (at low hydrogen partial pressures) essentially insensitive to the potential. Based on these observations, experimental investigations were started to determine the electrode current as a function of hydrogen partial pressure and the response time required to observe current stability.

Effect of partial pressure on limiting diffusion currents.—Half-cell measurements were conducted at a fixed potential of +0.45V as a function of hydrogen partial pressure in binary H_2/N_2 mixtures. The results plotted in Fig. 3 show linearity between current and partial pressure

$$i = KC(H_2) \qquad [1]$$

where i = maximum observed current in mA, $C(H_2)$

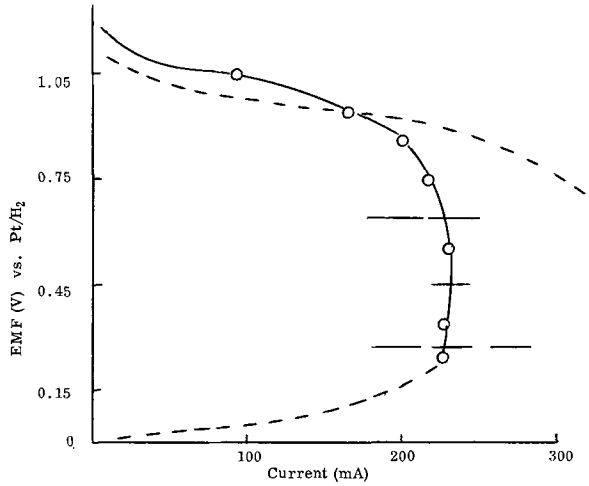

Fig. 2. Voltage-current relationship, ○ for increasing anodic potentials (H_2-N_2 oxidation), - - - for cathodic oxygen reduction.

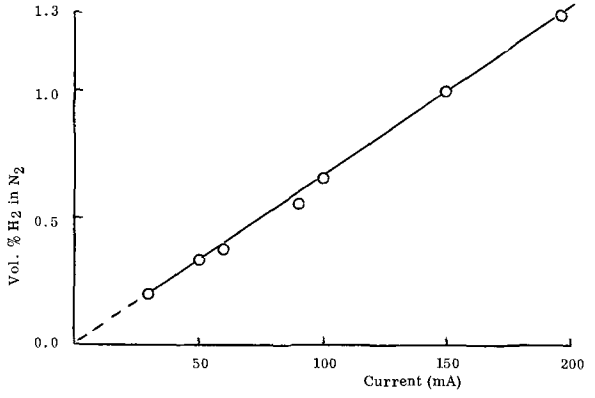

Fig. 3. Effect of hydrogen partial pressure in H_2-N_2 mixtures on limiting currents.

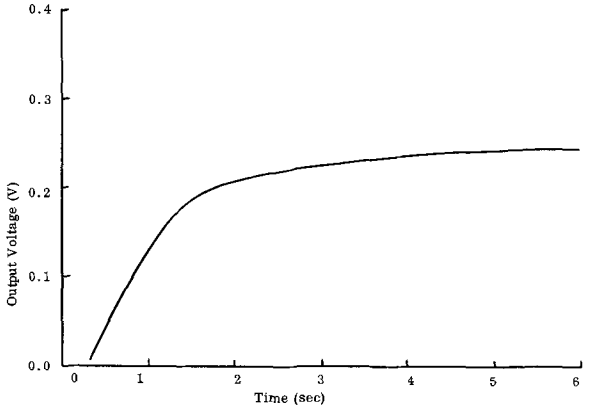

Fig. 4. Voltage (or current)—time response of the hydrogen sensing electrode.

= v/o H_2 in the gas phases, and the proportionality constant $K = 40$ with a maximum variance of ±3%.

Current time response.—Measurements on half cells and complete cells show that current read-out becomes stable within 4.5 to 6 sec. Figure 4 illustrates a representative current time behavior of a binary H_2/N_2 mixture. Response time at any fractional current (or equivalent potential) read-out can be estimated from the relationship

$$(i - I)/i = e^{t/\tau} \qquad [2]$$

where I = current observed at time t, sec
τ = time constant = 1 sec

The time constant will be somewhat sensitive to cell design, size, geometry, etc.

Hydrogen/oxygen (air) gas mixtures.—The rest potential of a Pt/O_2 half cell in acid solution at 25°C is approximately +1.06V, and currents observed in absence of hydrogen at this potential are only of the order of microamperes. Under these potential conditions, any current observed after exposure of the electrode to a hydrogen-containing gas mixture is related to the rate of hydrogen oxidation. This condition is favorable for hydrogen sensing since: (*i*) chemical surface oxidation of hydrogen is essentially avoided, (*ii*) the surface concentration of hydrogen is always maintained at an extremely low value, and (*iii*) hydrogen is electrochemically oxidized as soon as it appears on the surface. Comparative results for hydrogen/oxygen and hydrogen/air mixtures are presented in Fig. 5. Currents at various concentrations of hydrogen in oxygen and air were observed for flow rates of 1 ml/sec at a fixed potential of +1.06V. Flow rates of 3 ml/sec were also studied to show that the observed currents are not influenced by appreciable variations of hydrogen partial pressure along the electrode surface. Results between 1 and 3 ml/sec are identical. Again the currents

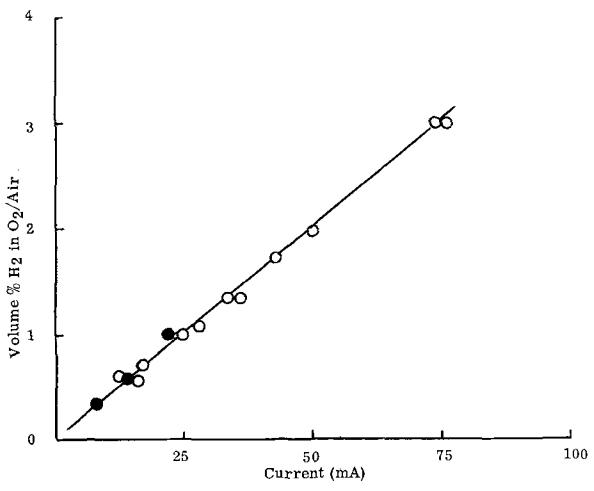

Fig. 5. Effect of hydrogen partial pressure in H_2-O_2 (air) mixtures on currents in: ○ half cells and • complete cells.

are proportional to the hydrogen partial pressure and can be expressed by Eq. [1]. If (*i*) is in mA, the constant $K = 25$ with a maximum variance of ±2%.

Results on complete cells.—To show applicability of the approach to an ion exchange membrane fuel cell, the current read-out was determined for a complete cell. Now it was essential to keep the counterelectrode at a quasi-constant potential (since this approach does not include the presence of a reference electrode), and thus be able to apply a cell and working electrode potential of +1.06V.

This can be accomplished by flowing hydrogen over the counterelectrode and keeping the electrode potential at nearly 0.0V. Applying 1.06V to the cell by means of an external constant voltage device insures a working electrode potential of approximately +1.06V since the hydrogen evolution counterelectrode is nearly reversible. Under these conditions, the fuel cell should behave essentially in a manner comparable to a half cell. All the results obtained on half cell and complete cells for H_2/O_2 and H_2/air mixtures are presented in Fig. 5. Linearity between current and partial pressure was observed in all cases.

Detection of Carbon Monoxide in Oxygen/Air.—The electrical biasing technique was extended to the detection of CO in oxygen-containing atmospheres. An optimization was made of the sensing electrode structure, electrolyte, and electrolyte concentration to obtain reproducible stable currents of less than 1.0 mA. A reversible metallic counter-reference system was substituted for the Pt/H_2 electrode. Studies entailed an investigation of the temperature characteristics of the sensor when detecting carbon monoxide in oxygen.

In the development of the hydrogen sensor, a sulfonic acid ion exchange membrane (IEM) served as the electrolyte. The problem with the (IEM) system is that it is difficult to find a reversible counter-reference electrode other than Pt/H_2, and water management is difficult. A sulfuric acid electrolyte was investigated due to its good conductivity, and also many reversible metal/sulfate couples exist. A 63% by weight sulfuric acid solution was chosen because of its very low vapor pressure at 25°C, 2.4 Torr, making it insensitive to flow of gases, which affects the concentration and temperature changes due to water evaporation.

A constant voltage source kept the carbon monoxide sensing electrode at a fixed potential *vs.* a stable metallic electrode which served both as a counter and reference electrode. An Alford-Niedrach (2) platinum on boron carbide electrode containing 3.4 mg/cm² platinum and a tantalum current collector served as the sensing electrode at a fixed potential *vs.* a stable kept at 0.18 cm² to insure a fast response time and minimal polarization of the counter-reference electrode,

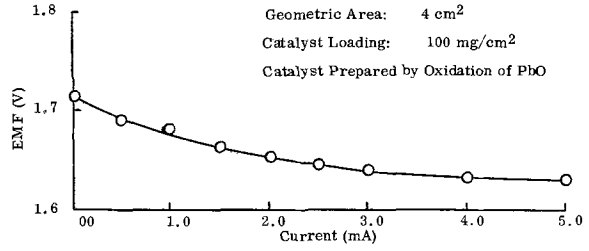

Fig. 6. Polarization of PbO_2 electrode in 63% H_2SO_4

i.e. observed currents were less than 1.0 mA. Of the metallic couples investigated as counter-reference electrodes, the $PbO_2/PbSO_4$, H_2SO_4 was most compatible with the system under investigation exhibiting minimal polarization when undergoing a reduction process in the sensor. The polarization characteristic of the lead peroxide electrode is demonstrated in Fig. 6 where a current-voltage curve is given for the cell

$$Pt/H_2, H_2SO_4\ (63\%), PbSO_4/PbO_2$$

The oxidation of CO on platinum black has been a subject of recent review (3, 4). Carbon monoxide adsorbs strongly on platinum, and appreciable reaction in acid only occurs at voltages greater than +0.70V as can be seen in the current voltage curve given in Fig. 7 for oxidation of CO on platinum black. At +1.06V the electrochemical oxidation of CO to CO_2 on platinum black occurs immediately, thus it can be expected at this voltage faradaic currents proportional to bulk concentration of CO will be observed.

The prototype sensor for detection of CO consisted of a Pt on B_4C electrode (3.4 mg Pt/cm²) with a sensing area of 0.18 cm², H_2SO_4 (63%) and PbO_2 counter-reference electrode containing 100 mg/cm² PbO_2 with geometric area of 4 cm². Tantalum current collectors were employed for both electrodes. When the Pt electrode was exposed to oxygen, the observed $\Delta E(V_r - V_1)$ was 0.71 for the cell

$$Pt/O_2, H_2SO_4\ (63\%), PbSO_4/PbO_2$$

When this voltage was exactly matched with a constant voltage source, no current flowed. When CO was present in O_2/air and the applied potential was maintained at 0.71V, a current proportional to the CO in the bulk phase was observed. The results plotted in Fig. 8 show linearity between current and partial pressure

$$i = KC(CO)$$

where C(CO) = v/o CO in O_2/air, the proportionality constant $K = 0.19$ with a maximum variance of ±6%. The stability and reproducibility of the sensor was examined by introducing three times daily a fixed concentration of CO in O_2. For a CO in O_2 sample, a 0.42 ± 02 mA reading was obtained for over a three-week period.

An investigation was conducted on the temperature characteristics of the sensor when detecting carbon monoxide in oxygen. An Arrhenius plot of log i *vs.* $1/T$ was found to be linear (Fig. 9). The observed current for oxidation of CO in O_2 approximately doubles for each 10°C increase in temperature. The described sensor appears to be a stable, low-cost sensitive instrument for detecting carbon monoxide in air or oxygen from 20° to 80°C.

Detection of hydrocarbons.—The CO sensor operating at room temperature is insensitive to hydrocar-

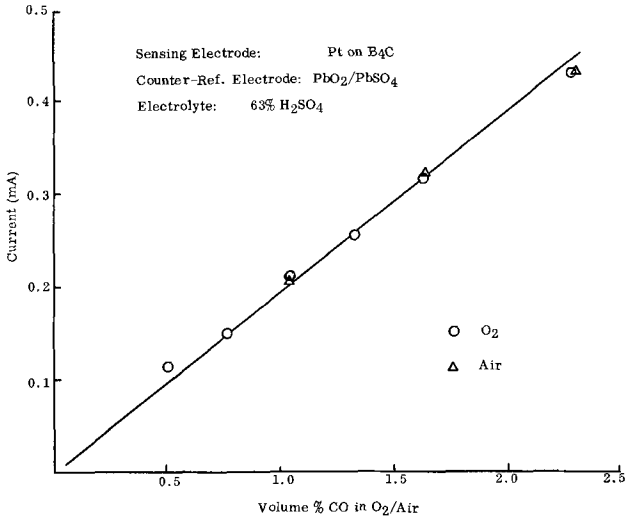

Fig. 8. Effect of CO partial pressure in CO-O_2/air mixtures on currents.

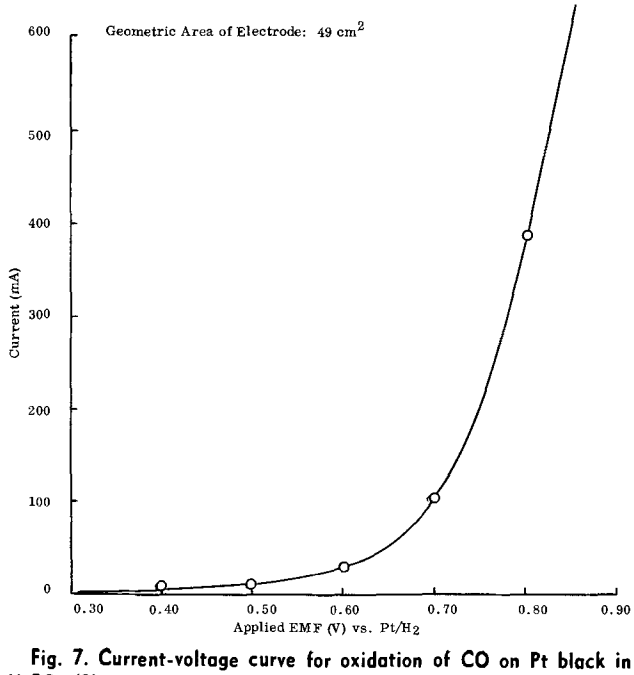

Fig. 7. Current-voltage curve for oxidation of CO on Pt black in H_2SO_4 (3).

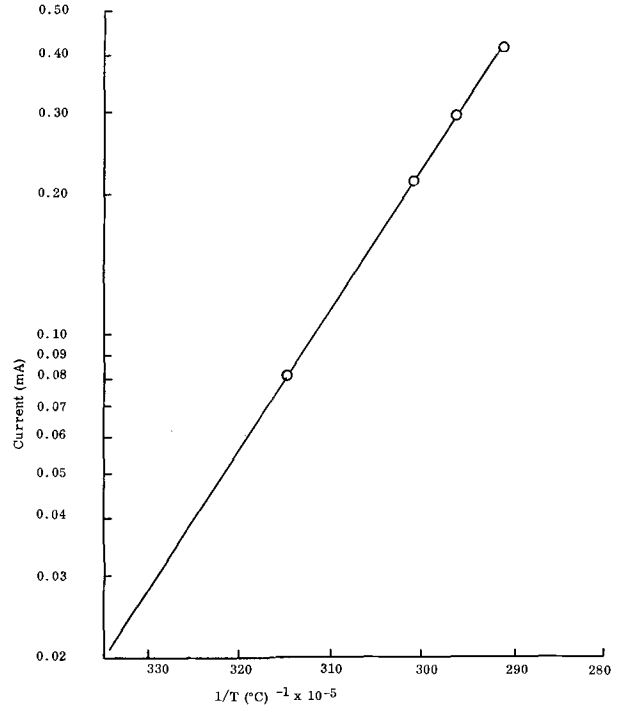

Fig. 9. Effect of temperature when oxidizing a fixed concentration of CO in O_2.

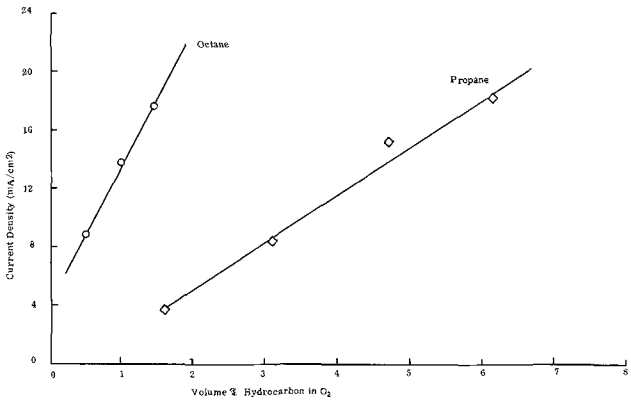

Fig. 10. Hydrocarbon gas detection with phosphoric matrix at 150°C.

bons. At elevated temperatures, however, the sensor will respond to hydrocarbons. The detection of hydrocarbons in O_2 was demonstrated with a fuel cell device consisting of a zirconium phosphate matrix saturated with H_3PO_4, at Pt black sensing electrode and a Pt/H_2 counter-reference electrode. A linear relationship was found between current and partial pressure of propane or octane in oxygen when the device was operated at 150°C as can be seen in Fig. 10. Of particular interest is the characteristic curve obtained for propane and octane. The novelty of the device is the insensitiveness to air or O_2 because of the biasing potential of +1.06V *vs.* Pt/H_2 applied to the sensor electrode.

Characteristics of the sensing devices.—The electrochemical sensors described have a lower limit of detection of approximately 500 ppm based on a volume basis. The prototype sensor described for detection of CO which uses a PbO_2 counter-reference electrode is a practical device for detecting easily oxidizable species such as H_2 and CO in O_2 and air streams. Some practical applications include use of the device as a gas leak detector to avoid the formation of an explosive mixture such as H_2 in air and buildups of toxic levels of CO in air. Novel features of the device are low cost, portability, and simplicity. At the current stage of development, the detector cannot be used directly for trace analysis which is best done by spectroscopic techniques (5). A reasonable goal is to reduce the detection limit to 100 ppm by more accurate control of electronic circuitry and electrode manufacturing process. With an applied biasing potential of +1.06V, the sensing electrode is not readily poisoned by species which normally adsorb strongly on platinum at low anodic potentials such as CO at low temperature ($\leq$80°C) and hydrocarbon intermediates at high temperature ($\geq$100°C). At an anodic potential of +1.06V, these species are readily oxidized to CO_2. This was evidenced by a 3-week life test at 25°C for a CO in O_2 gas mixture and a 2-day run at 150°C for a propane in O_2 mixture.

Manuscript received August 24, 1970.

Any discussion of this paper will appear in a Discussion section to be published in the December 1971 JOURNAL.

Desalting by Means of Porous Carbon Electrodes

A. M. Johnson and John Newman[1]

The Marquardt Company, Van Nuys, California 91409

ABSTRACT

A porous electrode model is developed and analyzed for ionic adsorption on porous carbon. In the absence of concentration variations, the system behaves like a distributed network of resistances and capacitances. Experimental results support the basic model and show a preferential adsorption of divalent ions. Consideration is given to the optimization of operating parameters.

A process for desalting water can be based on periodic sorption and desorption of ions on the extensive surfaces of porous carbon materials. Blair and Murphy (1) have described early work. Electrodialysis, ion exchange, and the present method of ion sorption remove the electrolyte from the solution and should be economically suited to waters of moderate salinity. Processes like evaporation and reverse osmosis, which remove the solvent should be preferable for dealing with high salinities. In addition to the practical aspects of desalting, the present work is relevant to the analysis of the behavior of porous electrodes. Experimental verification obtained here would be a reflection on the basic validity of models commonly used for porous electrodes. The present system should also provide a convenient means to study parametric pumping (2, 3). Porous carbon electrodes can also be used for storage of electrical energy and for ion exchange processes.

Key words: porous electrode, desalination.

Concepts of Charge Sorption

At any interface between an electrolytic solution and another medium, there is generally present an electric double charge layer, the interface as a whole being electrically neutral. On the solution side of the interface, the double layer consists of an excess of cations or anions from the electrolytic solution itself. It is the adsorption of the electrolyte here which is responsible for the desalting accomplished by this process. Porous carbon materials contain large interfacial areas, on the order of several hundreds of square meters per gram, and consequently it is possible to store a significant amount of salt in these electrical double layers. For our purposes, it is not particularly important to distinguish between ions of the solution which are tightly bound to the surface and those which exist in the diffuse layer adjacent to the surface.

It is presumed here that no charge passes directly from the carbon into the solution, and consequently a flow of current into the carbon is compensated by an

equal and opposite magnitude of charge on the solution side of the interface. In this case, the interface is similar to a simple electrical capacitor. Because of the small distances involved here, the double layer capacity can be quite high, on the order of 30 $\mu f/cm^2$. [The measurements of Evans (4) on porous carbons are of interest is the present application.] Grahame (5) has developed these concepts of the double layer in detail and gives sketches of the distributions of charge and potential near an interface as well as experimental results for double layer capacities and surface concentrations at mercury-solution interfaces.

The surface concentrations of the ions depend on the potential of the electrode, measured with respect to a suitable reference electrode. As the electrode is made more negative, it attracts cations and repels anions, and conversely. The absolute magnitude of ion adsorption is difficult to ascertain at solid electrodes. However, it is the variations in the amounts of adsorbed ions which are important in a process for desalting water. These can be represented by the quantity

$$f = \frac{dq_+}{dq} - \frac{dq_-}{dq} \qquad [1]$$

plotted in Fig. 1 as calculated from the data of Grahame (5) for the interface between mercury and a 0.3*M* NaCl solution. The potential is relative to a calomel electrode in the same solution.

The dashed curve in Fig. 1 is an idealization of the actual behavior and corresponds to a sharp change from sorption and desorption of cations at potentials more negative than V_z to sorption and desorption of anions at potentials more positive than V_z. In contrast, an increase in the net charge in the double layer can actually be accomplished by a combination of adsorption of cations and desorption of anions. The potential V_z indicates the potential at which the electrode changes from anion responsiveness to cation responsiveness. Strictly speaking, it does not represent the point of zero charge, which can be measured only with difficulty on solid electrodes.

We see from Fig. 1 that f can be less than -1 for positive potentials. This is due to specific adsorption of anions with a consequent adsorption of cations in the diffuse layer. The result is that more ions can be adsorbed than would be predicted from simple concepts of the double layer.

Porous Electrode Model

For the present system, the macroscopic model of porous electrodes (6) should be modified to account for the capacitive adsorption of ions. This is the only change which needs to be introduced. Two potentials are used, the potential Φ_1 of the porous matrix and the potential Φ_2 of the solution in the pores. Similarly, two current densities i_1 and i_2 are defined; these current densities are referred to the projected area of the electrode rather than to the areas of the individual phases. The concentrations c_i of species in the solution are referred to the volume of the solution phase; thus the concentration per unit volume of the electrode is pc_i where p is the porosity of the electrode. The fluid velocity v will be referred to the over-all area.

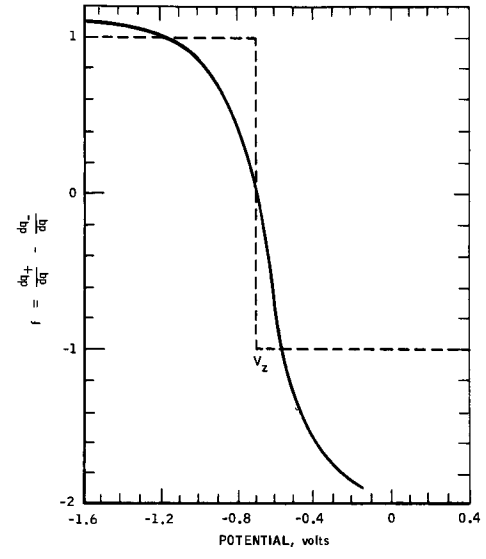

Fig. 1. Change of total ion sorption with potential, for the interface between mercury and a 0.3*M* NaCl solution.

The electrode consists of carbon particles with void spaces in between, but each particle is itself quite porous, with micropores which are much smaller than the particles. This accounts for the large surface area of porous carbons. The fluid flows between the particles but not through them, while the electric current in the fluid phase may or may not flow through the particles. At any rate, the surfaces of the micropores are electrically accessible to the solution phase. Material desorbed inside the particle will have to diffuse to the surface of the particle before it can enter the flowing stream. One could define a microporosity p_μ (corresponding to the void volume within the particles relative to the volume of particles) and a macroporosity p_M (the void volume between the particles divided by the total volume) as well as the over-all porosity p. These are related by

$$1 - p = (1 - p_M)(1 - p_\mu) \qquad [2]$$

At the interface between the matrix and the solution, the rate of change of the double layer charge (per unit volume of electrode) is

$$\nabla \cdot i_1 = -\nabla \cdot i_2 = -aC\frac{\partial(\Phi_1 - \Phi_2)}{\partial t} \qquad [3]$$

where C is the capacity per unit area and a is the interfacial area per unit volume. $\nabla \cdot i$, is the divergence of the current density in the matrix and represents flow of current from the solution to the matrix. This equation represents the major assumption of the model, that ionic adsorption can be approximated as a capacitive process, that the kinetics of adsorption do not limit the rates, and that faradaic reactions are negligible.

Let N_+ and N_- be the fluxes of cations and anions in the solution phase based on the over-all area of matrix and solution. We confine our attention to a solution with two types of ions; the rigorous treatment of complex waters is complicated, but their behavior can be adequately discussed on the basis of simple extensions of the present treatment of a binary electrolyte. A material balance for the ionic species reads

$$p\frac{\partial c_i}{\partial t} = -\nabla \cdot N_i - \frac{dq_i}{dq}\frac{\nabla \cdot i_1}{z_i\mathbf{F}} \qquad [4]$$

In the pore phase, the fluxes of ionic species can be expressed as

$$N_i = -z_i u_i \mathbf{F} p c_i \nabla\Phi_2 - D_i p \nabla c_i + c_i v \qquad [5]$$

Mobilities u_i and diffusion coefficients D_i are approximately equal to their values in a free solution except for tortuosity factors; that is, there is no need for an additional porosity factor. In the matrix, the current density obeys Ohm's law

$$i_1 = -\sigma\nabla\Phi_1 \qquad [6]$$

where σ is the effective conductivity of the matrix phase. The current density in the solution phase is due to the charge carried by ionic species

$$i_2 = \mathbf{F}\sum_i z_i N_i \qquad [7]$$

Finally, we adopt the electroneutrality equation for the solution phase

$$\sum_i z_i c_i = 0 \qquad [8]$$

Combination of Eq. [4], [5], and [8] yields an equation for the solution concentration

$$p\frac{\partial c}{\partial t} + v \cdot \nabla c = D\nabla \cdot (p\nabla c) - \frac{\nabla \cdot i_1}{z_+\nu_+\mathbf{F}}\left(t_- \frac{dq_+}{dq} - t_+ \frac{dq_-}{dq}\right) \quad [9]$$

if the mobilities and diffusion coefficients are taken to be constants and the fluid is incompressible. Here

$$D = \frac{z_+u_+D_- - z_-u_-D_+}{z_+u_+ - z_-u_-} \quad [10]$$

is the effective diffusion coefficient of the electrolyte

$$t_+ = 1 - t_- = \frac{z_+u_+}{z_+u_+ - z_-u_-} \quad [11]$$

is the cation transference number, and the solution concentration is

$$c = c_+/\nu_+ = c_-/\nu_- \quad [12]$$

where ν_+ and ν_- are the numbers of moles of cations and anions per mole of electrolyte.

Substitution of Eq. [5] into Eq. [7] yields an equation relating current and potential drop in the pore phase

$$i_2 = -\kappa\nabla\Phi_2 - z_+\nu_+\mathbf{F}(D_+ - D_-)p\nabla c \quad [13]$$

where

$$\kappa = z_+\nu_+pc\mathbf{F}^2(z_+u_+ - z_-u_-) \quad [14]$$

is the effective conductivity of the solution phase.

Assumptions in the Model

The fundamental Eq. [3] through [8] describe the porous electrode. For a solution of a binary electrolyte, Eq. [4], [5], [7], and [8] can be replaced by Eq. [9] and [13]. Thus, Eq. [3], [6], [9], and [13] represent five equations for the determination of the quantities c, i_1, i_2, Φ_1, and Φ_2.

These equations are typical of those used to analyze the behavior of porous electrodes, and the assumptions inherent in them are discussed in the literature (6, 7). Experimental verification with the present system would help to substantiate these models.

Here the transfer of charge from the solution to the matrix is assumed to occur by means of the capacity of the electric double layer. The effect of concentration changes on the potential relationships has been neglected in writing Eq. [3]. A similar assumption is involved if dq_i/dq in Eq. [4] is supposed to depend only on the potential difference $\Phi_1 - \Phi_2$ and not on the concentration. Thus, the charge and potential are assumed to be the main factors determining ionic adsorption, and the dependence of electrolyte adsorption on concentration is effectively ignored. One consequence of this assumption is that the velocity of a concentration wave through the bed is equal to the velocity of nonadsorbed solvent, whereas in a bed with concentration-dependent adsorption, this wave velocity is different (usually less) than the fluid velocity.

The double layer itself is assumed to be in local equilibrium at the appropriate concentration and potential difference $\Phi_1 - \Phi_2$. One might imagine that highly mobile ions (for example, hydrogen ions) would be preferentially adsorbed on the basis of transport considerations. Actually, equilibration times for the double layer (8) are quite short compared to the time scales involved here. The preferential adsorption of divalent ions from complex waters, mentioned later, is further evidence for equilibration of the double layer since divalent ions have lower mobilities, in general, than monovalent ions.

Faradaic or charge transfer reactions, also ignored here, could manifest themselves in three ways. First, they detract from the current used to charge the double layer. These can safely be ignored except at large applied potentials. Second, they can oxidize or reduce the surface, forming surface compounds or oxidizing the carbon matrix itself, and lead to a gradual change in the character of the electrodes. Finally, they can lead to a gradual change in the net charge on a pair of carbon electrodes used for desalting. This will degrade the performance if operating conditions had previously been optimized for the initial state of the electrodes.

The porous electrode model assumes that the concentration and potential Φ_2 in the solution phase are essentially uniform across a pore cross section (6, 7), which effectively means in the solution inside a porous particle as well as in the space between particles. Actually, as mentioned earlier, the electrolyte must diffuse from within a porous particle to the surface before it can reach the flowing stream. The time required for a particle of radius R to become 90% depleted by diffusion with an effective diffusion coefficient D is (9) 0.43 R^2/D or 3.2 min for R = 0.06 cm and D = 0.8 x 10^{-5} cm^2/sec. Furthermore, with a solution flowing between the particles, the distance in the direction of flow required for the solution concentration to reach 90% of the concentration at the surface of the particles is roughly (10) 0.037 d^2v/p_MD, where d is the equivalent diameter of the passages between the particles. For d = 0.02 cm, v = 1 cm/min, and p_M = 0.25, this gives a distance of 0.124 cm.

Under most conditions, it should be possible to neglect the diffusion terms $D\nabla \cdot (p\nabla c)$ in Eq. [9]. This is in harmony with the concepts that there is little upstream propagation of effects and only the inlet concentration to a bed need be specified, not the outlet concentration. Note that if the transference numbers are equal, the last term in Eq. [9] is simply related to f defined by Eq. [1] and plotted in Fig. 1 for a mercury surface. Even without this assumption, the quantities dq_+/dq are, in principle, measurable for a solid electrode. In the absence of cosorption of anions and cations, dq_+/dq = 1 and dq_-/dq = 0 for a cation responsive electrode, and dq_-/dq = 1 and dq_+/dq = 0 for an anion responsive electrode.

Analysis in the Absence of Concentration Variations

A simple system for desalting water by the process described here might consist of porous carbon electrodes through which the solution flows axially, alternate electrodes being connected together electrically [see also ref. (11)]. To achieve desalting, one set of electrodes should be displaced toward more positive potentials so that they will adsorb anions, and the other set, being displaced toward negative potentials, will adsorb cations. To regenerate the electrodes, the potential relationships would be reversed, so desorbed anions and cations would be put back into the solution and carried out with the waste water. For maximum efficiency, it is essential that one set of electrodes should operate in a potential range where cations are sorbed and desorbed and the other set of electrodes should be operated in a potential range where anions are sorbed and desorbed.

If concentration variations are negligible, then Eq. [9] can be ignored for the present, and Eq. [13] reduces to

$$i_2 = -\kappa\nabla\Phi_2 \quad [15]$$

A pair of electrodes can then be represented by the equivalent circuit in Fig. 2. The double layer capacity is represented here as connecting the electrode matrix and the solution in the pores. R_A represents the distributed resistance to the flow of electrons in the porous carbon matrix of one electrode, and R_C represents the distributed resistance to the flow of ions in the pore solution within the same electrode. These are connected to each other by the distributed double layer capacity. The other electrode is similarly represented by the electrode matrix resistance R_B and the pore solution resistance R_D. The two electrodes are connected to each other through the power source connected between the two electrode matrices and through

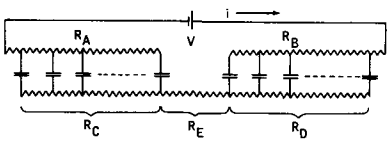

Fig. 2. Equivalent circuit of two porous electrodes and a separator

the solution by means of, for example, a porous cloth separator represented by the resistance R_E.

When the applied potential is changed, a current flows from the power source into the electrode matrices. This current consists of the flow of electrons within the electronically conducting portion of the circuit. The current flows from the matrices through the double layer capacity into the solution in the pores, resulting in a change in the double layer composition and the solution composition. The current is then carried from one electrode to the other by the ions of the electrolytic solution in the separator.

For constant values of σ, κ, and aC, Eq. [3], [6], and [15] can be rewritten as

$$Y = -\nabla\theta \text{ and } \frac{\partial\theta}{\partial t} = -\alpha\nabla \cdot Y \qquad [16]$$

or

$$\frac{\partial\theta}{\partial t} = \alpha\nabla^2\theta \text{ and } \frac{\partial^2 Y}{\partial t} = \alpha\nabla\nabla \cdot Y \qquad [17]$$

where

$$Y = i_1/\sigma - i_2/\kappa, \quad \theta = \Phi_1 - \Phi_2, \quad \alpha = \kappa\sigma/aC(\kappa + \sigma) \qquad [18]$$

Equations [17] are then analogous to the equations for heat conduction or diffusion in solids, and α might be termed the "electrical diffusivity," having the value 5×10^{-6} cm^2/sec for $\kappa = 4.3 \times 10^{-4}$ ohm^{-1}-cm^{-1}, $\sigma = 0.068$ ohm^{-1}-cm^{-1}, and $aC = 83.5$ f/cm^3.

Consider two electrodes having identical values of σ, κ, and aC, each of half thickness L, with a separator of effective thickness L_s and conductivity κ. At present there is no compelling reason to consider electrodes having different values of these parameters. We treat the case where the current is zero and the applied potential is $V = V_0$ for times $t < 0$. The values of Y and θ within the electrodes do not change discontinuously at the instant when the potential is changed.

The analysis is conveniently carried out by means of Laplace transforms. The most interesting result is the relationship between the Laplace transform $\mathcal{V}(s)$ of the applied potential and the Laplace transform $\mathcal{I}(s)$ of the resulting current density

$$\frac{\mathcal{V} - V_0/s}{\mathcal{I}} = R_1\left[1 + \frac{1/\sqrt{s\tau_1}}{e^{2\sqrt{s\tau_2}} - 1}\left(e^{2\sqrt{s\tau_2}} + 1 + \frac{4\kappa\sigma}{\kappa^2 + \sigma^2}e^{\sqrt{s\tau_2}}\right)\right] \qquad [19]$$

where

$$R_1 = \frac{2L}{\sigma + \kappa} + \frac{L_s}{\kappa}, \quad \sqrt{\tau_1} = \frac{R_1}{2\sqrt{\alpha}}\frac{(\kappa + \sigma)\kappa\sigma}{\kappa^2 + \sigma^2}, \quad \tau_2 = \frac{L^2}{\alpha} \qquad [20]$$

The system has associated with it two characteristic times, τ_1 and τ_2. For $L = 0.32$ cm, $L_s = 0.015$ cm, and the values of α, κ, and σ given below Eq. [18], we obtain

$$R_1 = 44.2 \text{ ohm-cm}^2, \quad \tau_1 = 18.4 \text{ sec}, \quad \tau_2 = 5.68 \text{ hr}, \quad \kappa\sigma/(\kappa^2 + \sigma^2) = 6.31 \times 10^{-3} \qquad [21]$$

The two characteristic times have quite different values. We illustrate their significance by considering two special cases.

For short times, the capacity of the electrodes is utilized only near the separator and near the current collector. Thus, when $e^{\sqrt{s\tau_2}}$ is large, Eq. [19] simplifies to

$$\frac{\mathcal{V} - V_0/s}{\mathcal{I}} = R_1\left(1 + \frac{1}{\sqrt{s\tau_1}}\right) \qquad [22]$$

If the applied potential is changed at $t = 0$ from V_0 to $V_0 + \Delta V$ and then maintained at the new value, the resulting current density is

$$i = (\Delta V/R_1)\, e^{t/\tau_1} \operatorname{erfc}(\sqrt{t/\tau_1}) \qquad [23]$$

For large values of t, this expression gives

$$i\sqrt{t} \to \frac{\Delta V}{R_1}\sqrt{\frac{\tau_1}{\pi}} = \frac{\Delta V}{2\sqrt{\pi}}\frac{\kappa + \sigma}{\kappa^2 + \sigma^2}\sqrt{aC(\kappa + \sigma)\kappa\sigma} \qquad [24]$$

Equation [23] is plotted in Fig. 3.

On the other hand, if the applied potential is maintained long enough, the capacity of the electrodes will eventually be used up. To illustrate this, we assume that σ is very large, and we neglect the resistance of the separator. Then Eq. [19] reduces to

$$\frac{\mathcal{V} - V_0/s}{\mathcal{I}} = \frac{R_1}{\sqrt{s\tau_1}}\frac{e^{2\sqrt{s\tau_2}} + 1}{e^{2\sqrt{s\tau_2}} - 1} \qquad [25]$$

The response to a step change in potential is shown in Fig. 4.

When $\tau_1 << \tau_2$, the two curves represented by Fig. 3 and 4 can be superposed to give a complete picture of the current response to a step change in potential. Equation [24] then applies over a considerable portion of the charging period. In this case, the current is independent of the values of L and L_s. At zero time, the current density cannot be infinite; it is limited by the resistance of the electrodes and the separator.

$$i = \Delta V/R_1 \text{ at } t = 0 \qquad [26]$$

Thus, for values of t on the order of τ_1, the values of L and L_s are important, and the current density is less than the value predicted by Eq. [24]. For values of t on the order of τ_2, the value of the electrode half thickness L again becomes important because the electrode capacity depends upon this parameter. As the electrode capacity becomes saturated, the current density again drops below the value predicted by Eq. [24].

The preceding analysis applies to a single step change in potential, whereas a desalting system would be operated with periodic changes alternating between ΔV and $-\Delta V$. Because the current due to a po-

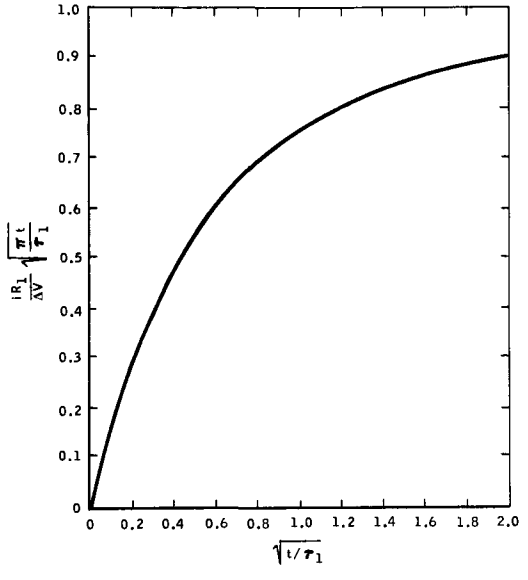

Fig. 3. Current response to a step change in potential, before the penetration layers begin to interact.

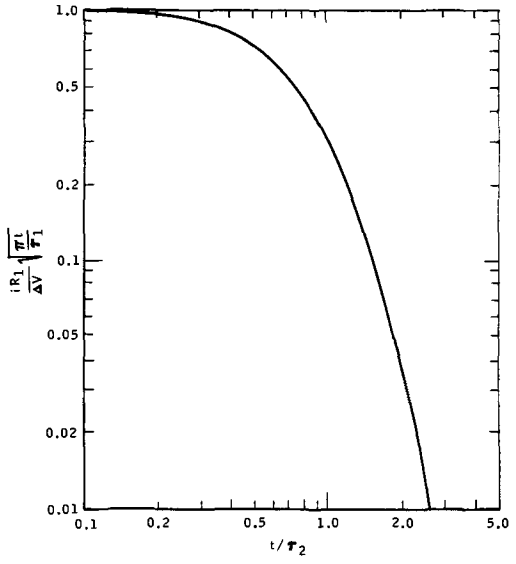

Fig. 4. Current response to a step change in potential, showing the approach to saturation of the capacity of the electrodes.

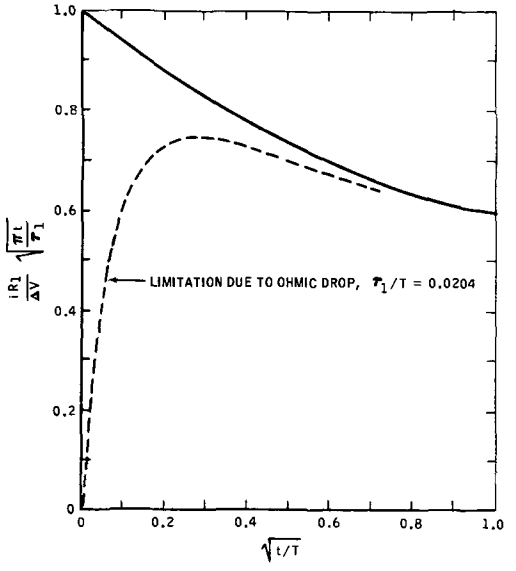

Fig. 5. Current response after extended cycling. The duration of each half cycle is T.

tential step decreases roughly as $1/\sqrt{t}$, the effect of previous changes will persist into a given cycle. Figure 5 indicates the magnitude of this effect. The solid curve was calculated by assuming that Eq. [24] is applicable to each potential change. Thus, for a single potential change, the ordinate value would be unity. The dashed curve represents the expected behavior when one accounts for the fact that the current cannot become infinite at $t = 0$. Here, the current resulting from the most recent potential change was determined according to Fig. 3 with $\tau_1/T = 0.0204$.

Let us now calculate concentration changes, assuming that the current density is given by the preceding considerations. In Eq. [9] we drop the diffusion term and average the last term over two electrodes, with $dq_+/dq = 0$ for one electrode and $dq_-/dq = 0$ for the other electrode. This gives

$$p\frac{\partial c}{\partial t} + v \cdot \nabla c = \frac{i}{2Lz_{+}\nu_{+}\mathbf{F}} \qquad [27]$$

where i is the current density, positive for regeneration and negative for desalting. If $i\sqrt{t}$ can be regarded as constant over a half cycle, the effluent salinity for steady cycling is given by

$$\left.\begin{aligned} c_{out} - c_{in} &= (I_{avg}\sqrt{T}/z_{+}\nu_{+}\mathbf{F}p)\,(\sqrt{t} - \sqrt{T} \\ &\quad + \sqrt{t + T - t_{res}}) \text{ for } t < t_{res}, \\ c_{out} - c_{in} &= (I_{avg}\sqrt{T}/z_{+}\nu_{+}\mathbf{F}p)\,(\sqrt{t} - \sqrt{t - t_{res}}) \\ &\quad \text{for } t > t_{res} \end{aligned}\right\} \qquad [28]$$

where I_{avg} is the average stack current per unit of active volume of the stack

$$I_{avg} = \frac{1}{2nLT}\int_0^T nidt \qquad [29]$$

and the residence time is given by

$$t_{res} = 2nLp/v \qquad [30]$$

Here n is the number of faces between electrodes; for example, $n = 5$ for a stack with six electrodes. The porosity p enters into the expression for the residence time on the assumption that the particles have time to equilibrate with the flowing stream. These calculations are carried out for $t_{res} < T$, the only practical case. The assumption, that $i\sqrt{t}$ is constant corresponds to Eq. [24]. Furthermore, it is good approximation for a half cycle as shown in Fig. 5. The effluent concentration predicted by Eq. [28] is plotted in Fig. 6 for $t_{res}/T = 0.2$.

Finally, one might like to have a more complete idea of the potential distribution within the electrode. We take the case where σ is large, L_s is negligible, there is a step change in the applied potential of ΔV, and t is small enough that the capacity of the electrodes is not used up. Then, in one electrode

$$\theta = \Phi_1 - \Phi_2 = \theta_0 \pm \tfrac{1}{2}\Delta V \operatorname{erfc}(y/2\sqrt{\alpha t}) \qquad [31]$$

where y is the distance from the face of the electrode into its interior. Under these conditions, one half of the applied potential step is applicable to each electrode, and the capacity of the electrodes becomes charged progressively starting at its face and proceeding into the electrode in such a way that the charge distribution is given by the similarity variable $y/2\sqrt{\alpha t}$ according to Eq. [31]. The thickness of the region of charged capacity is thus proportional to $\sqrt{\alpha t}$. This behavior should be representative of the potential distribution in the electrodes under conditions where Eq. [24] is applicable.

Efficiency of the Process

All of the current passed is not used effectively for desalting. This leads one to define the current efficiency

$$\eta = \frac{z_{+}\nu_{+}\mathbf{F}v}{2nLI_{avg}T}\int_{t_{b1}}^{t_{b2}} \Delta c dt \qquad [32]$$

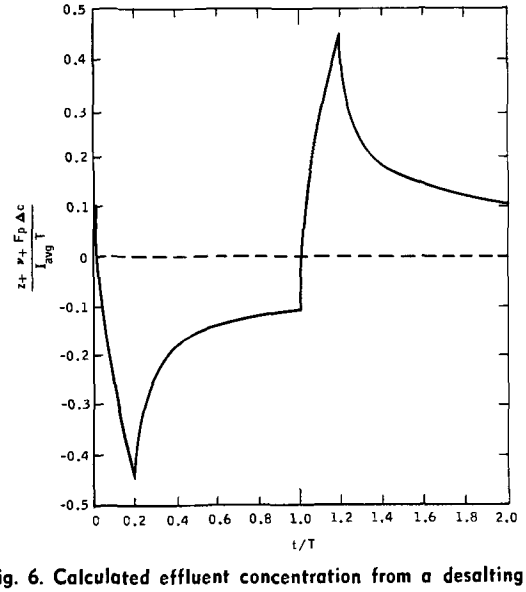

Fig. 6. Calculated effluent concentration from a desalting stack, for $t_{res}/T = 0.2$.

where Δc is the difference between the effluent concentration and the feed concentration and t_{b1} and t_{b2} are successive values of t at which the effluent concentration is equal to the feed concentration, it being presumed that the feed concentration is the point of demarcation between product water and waste water. The effective current density is then the product of the average current density and the current efficiency and is a quantity which should be maximized since it represents the rate of desalting per unit area of the electrodes.

A number of factors can contribute to the inefficiency of the process. For example, if the cycle time is too short compared with the residence time in the stack, water which is partially desalted will then be reconcentrated because it has not had a chance to leave the stack. An efficiency factor for this effect, indicated in Fig. 7, can be obtained by integrating Eq. [28] according to Eq. [32].

If $i\sqrt{t}$ is constant for a half cycle, use of the flow efficiency in Fig. 7 shows that the effective current density is maximized when the half-cycle time is 1.5 times the residence time. Consideration of the limitation of the current at short times (see Fig. 3 or 5) indicates that the optimum is shifted to roughly $T = 1.8t_{res}$. The diffusion within the particles will also favor a larger optimum value for T.

Another source of inefficiency is the cosorption of ions on the same electrode. Two possible charge-potential curves for a set of electrodes are indicated in Fig. 8. The electrode with the larger value of the zero point potential, which might be the result of a suitable chemical treatment, will be denoted as the cation responder, and the other electrode as the anion responder. Positive values of q are assumed to correspond to adsorption of cations, and negative values to anions. Figure 8 indicates a set of potentials which might apply to the desalting and regenerative parts of a cycle. When the two electrodes are shorted together, the potential is V_{sc}, relative to a suitable reference electrode. For desalting, the two electrodes are displaced from the potential V_{sc} in opposite directions, the cation responder increasing its charge and the anion responder decreasing its charge. On regeneration, the cation responder is displaced positively, and the anion responder is displaced negatively on the potential scale. If, on regeneration, the potentials are displaced too

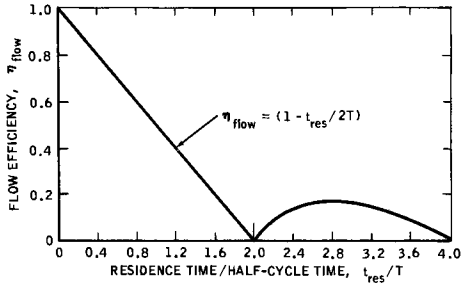

Fig. 7. Dependence of calculated flow efficiency on flow rate for equal durations of desalting and regeneration.

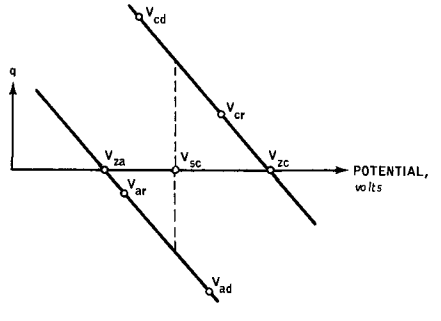

Fig. 8. Idealized charge-potential relationships for a set of electrodes with different zero points.

far, the zero points are exceeded, and, for example, the anion responder will begin to adsorb cations instead of desorbing anions. This represents a loss in efficiency for the desalting process, expressed by the cosorption efficiency η_{co}.

Let the fraction of cation responsiveness of the electrodes denote the charge of cations sorbed or desorbed during a half cycle divided by the total charge transferred during a half cycle. For the linear charge-potential relationships in Fig. 8, this can be represented as

$$\left.\begin{aligned} F_c &= (V_{cd} - V_{zc})/(V_{cd} - V_{cr}) \\ F_a &= (V_{ar} - V_{za})/)\,(V_{ar} - V_{ad}) \end{aligned}\right\} \quad [33]$$

but restrict F_a and F_c to lie between 0 and 1. Then the cosorption efficiency is

$$\eta_{co} = |F_c - F_a| \quad [34]$$

These formulas could be refined by a more detailed consideration of the potential distribution within the electrodes, for example, that given by Eq. [31].

The potentials which can be set are the applied desalting potential

$$V_d = V_{ad} - V_{cd} \quad [35]$$

the applied regeneration potential

$$V_r = V_{ar} - V_{cr} \quad [36]$$

and the short-circuit potential V_{sc}, which can be adjusted by charging both electrodes together by means of an auxiliary electrode. For electrodes symmetric in σ, κ, aC, and L, the potential variations in cyclic operation will be equal and opposite for the two electrodes and F_a and F_c can be re-expressed is terms of the operating variables

$$F_c = \frac{2(V_{zc} - V_{sc}) + V_d}{V_d - V_r} \text{ and } F_a = \frac{2(V_{za} - V_{sc}) - V_r}{V_d - V_r} \quad [37]$$

but where F_a and F_c are still restricted to lie between 0 and 1.

If, for such electrodes, the value of $(V_d - V_r)\eta_{co}$, analogous to the effective current density, is maximized while unnecessary power consumption is avoided, then the short-circuit potential V_{sc} should optimally lie halfway between the zero points of the anion and cation responders, and the minimum value of the regeneration potential should be such that the zero points of the electrodes are not exceeded

$$V_r = -(V_{zc} - V_{za}) \quad [38]$$

Under these conditions, the cosorption efficiency will be unity. Acceptable desalting potentials are not limited in the same way as regeneration potentials. The desalting potential may, in practice, be limited by current losses through faradaic reactions or by a change in the character of the electrodes due to these same reactions. Some faradaic reactions may be tolerable, merely leading to a drift of V_{sc} (faradaic rectification) which can be compensated for by a small charging current by means of an auxiliary electrode.

It may also be possible to change V_{zc} and V_{za} by chemical treatment. Then Eq. [38] suggests that these zero points should be as different as possible in order to maximize the magnitude of the optimum regeneration potential.

This model, relating desalting to the charging of the double layers of the electrode surfaces, leads to a method of analyzing the behavior of porous carbon electrodes and suggests how to achieve efficient operation by utilizing the correct range of potential. In particular, the displacements of potential from the short-circuit potential need not be symmetric on the desalting and regeneration parts of the cycle. For example, two basically identical sets of electrodes can be used. By using unequal times for desalting and regeneration,

and particularly by using unequal potentials, it has been possible to operate such electrodes with an overall efficiency better than 50%.

Other sources of inefficiency include

1. faradaic reactions which produce no desalting but consume current;
2. shorting of the electrodes through the separator;
3. axial dispersion, which tends to mix the product water and the waste water;
4. diffusion of electrolyte from within the porous carbon particles to their surface where it enters the flowing stream.

Experimental Results

For a description of the experimental program, see ref. (11). (This report also contains some cost analysis.) Only results which have a direct bearing on the analysis thus far presented will be cited here. Figure 9 shows the effluent salinity from a stack and can be compared with Fig. 6. The sharp concentration variations in Fig. 6 corresponding to the residence time are, in the experimental results, smoothed out by axial dispersion and the fact that the current is not infinite at the point of switching the potential. Furthermore, the experimental curve is not symmetric with respect to the desalting and regeneration half cycles. This can be attributed to conductivity changes associated with concentration variations. On regeneration, higher concentrations are produced, resulting in initially higher current densities and a sharper regeneration curve. This suggests that the regeneration half cycle can profitably be made shorter than the desalting half cycle. Despite the higher concentrations on regeneration, the amount of charge passed in the two half cycles is generally the same.

Figure 10 shows the product of current and the square root of time plotted against the square root of the ratio of the time to the half-cycle time. This curve compares favorably with Fig. 5. In order to improve the agreement, currents for the desalting and regeneration half cycles are averaged to produce Fig. 10. This eliminates the effect of the asymmetry of the two half

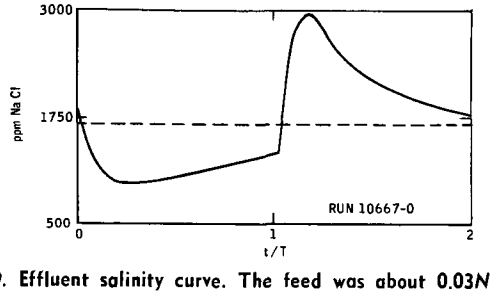

Fig. 9. Effluent salinity curve. The feed was about 0.03*N* NaCl flowing at a rate of about 5.6 g/min. Periods of 15 min each were allowed for desalting and regeneration at potentials of 1.0 and −1.0V, respectively.

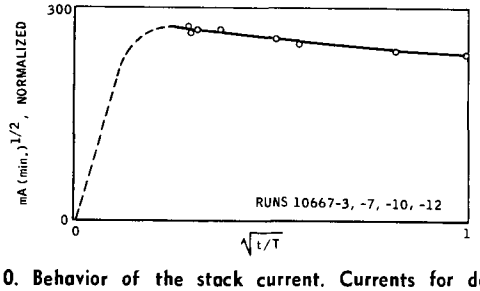

Fig. 10. Behavior of the stack current. Currents for desalting and regeneration were averaged to improve agreement with Fig. 5. The electrodes and conditions were the same as for Fig. 9 except as noted. The composition of the complex feed water is given in Table I. Average potentials were ±0.85V; average flow rate was 4.8 g/min.

Table I. Composition of complex feed water (pH = 5)

	ppm		ppm
Sodium	295	Calcium	150
Potassium	31	Magnesium	44
Chloride	750	Sulfate	178

cycles due to concentration variations, as alluded to in the preceding paragraph.

Experiments with complex water of the composition shown in Table I show preferential adsorption of divalent ions, with a separation factor of about 2.3 relative to univalent ions. This is in harmony with the theory of the diffuse layer and has important implications for the softening of complex waters.

Discussion and Conclusions

Porous carbon materials can be used to desalt water by periodic adsorption of ions. How many ions can be adsorbed depends on the electrical capacity of the double layer, the interfacial area available, and the applied potential. How fast they can be adsorbed depends on the rate of transport of charge to these surfaces and hence on the ohmic potential drop in the solution and the carbon matrix, since the kinetics of ion sorption are generally not rate determining. Equation [24] is useful for estimating these rates. For dilute solutions where $\kappa << \sigma$, this equation shows that the capability of the process should be approximately proportional to the square root of the salinity. It is important that the electrodes be operated in potential ranges where one electrode sorbs and desorbs cations while the other electrode sorbs and desorbs anions. The process shows a preference for adsorption of divalent ions over univalent ions, which is in accord with the double layer model.

Figure 10 shows that $I\sqrt{t}$ has a value of about 250 mA-min$^{1/2}$ for an electrode area of 25.3 cm^2 and a potential change of about 1.7V. With $\kappa = 7.3 \times 10^{-4}$ mho/cm and $\sigma = 0.068$ mho/cm, and with the assumption that this value of $I\sqrt{t}$ is 70% of that corresponding to a step change in applied potential (compare Fig. 5), Eq. [24] yields $aC = 69$ f/cm^3. For a double layer capacity of $C = 30$ μf/cm^2, the effective interfacial area per unit volume would be $a = 230$ m^2/cm^3. This calculation shows that much of the internal surface area of the porous carbon must be available for adsorption.

For processes which do not depend critically on the passage of a faradaic current, the appropriate property of the interface is the electrical capacity of the double layer. A "reversible electrode" has a clearly defined equilibrium potential, and a steady current is passed when the potential is shifted from this value. In contrast, an "ideally polarizable electrode" can be at equilibrium over a range of potentials; after a shift of potential, within this range, the steady current will drop to zero. The double layer capacity is a macroscopic property which describes the charge-potential relationship for such an ideally polarizable electrode and does not depend in its definition upon the detailed mechanism of charge sorption at the interface. The capacitive model is appropriate for analyzing the present process, where faradaic reactions constitute only a small part of the current and the depletion of electrolyte shows a potential dependent saturation of the sorbent. This double layer model can be contrasted with the electrochemically controlled ion exchange model of Evans and others (12-15).

If faradaic reactions were negligible, porous carbon electrodes could store significant amounts of energy. At a potential of 1V with a capacity of 69 f/cm^3, this would amount to about 1 Whr/lb, which, however, is not large enough to be interesting.

The potential dependent adsorption of ions on carbon surfaces should allow these materials to behave as ordinary ion exchangers. A negatively charged carbon in NaCl solution has adsorbed sodium ions. These can

be exchanged, without the flow of current, with calcium ions from a $CaCl_2$ solution. Conversely, a positively charged carbon should be an anion exchanger.

Discharge Profiles in a Porous Cadmium Electrode

P. Bro* and H. Y. Kang*

P. R. Mallory & Company Inc., Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

Porous cadmium electrodes were discharged galvanostatically at current densities between 2 mA/cm² and 200 mA/cm² in 30% KOH at 25°C, and the discharge profiles were determined by chemical analyses of thin sections sliced from the electrode. The discharge profiles were given by $q/q_0 = A \cosh B(1 - X)/\cosh B$, where A is the state of discharge at the front of the electrode and B is an electrochemical Thiele parameter. The retention of the discharge product in the electrode affected the discharge noticeably. The discharge efficiency was limited by both faradaic processes and mass transfer.

The discharge of battery electrodes is accompanied by structural changes in the electrodes; solid phases are both consumed and generated. The changing morphology poses a formidable mathematical problem which has not yet been solved for any practically useful systems.

Investigations of porous electrodes range from analyses of idealized invariant electrodes (1-3), which are useful as a first approximation, to theoretical and experimental studies of model systems comprising both simple pores, serially coupled electrodes, and actual electrodes (4-7). The work of Alkire, Grens, and Tobias involving a changing geometry is the most advanced, and it is hoped that it will be extended to systems of practical interest. The studies of Euler, Brodd, and Austin are significant in their focus on practical electrode structures, and they have given useful insights into the operation of cathodes used in practical cells.

We have found that data obtained on model configurations cannot be extrapolated to practical systems with any degree of confidence, and that, in fact, detailed experiments on actual battery electrodes are necessary. As part of our studies we have developed and used experimental techniques which introduce a minimal perturbation on the normal functioning of a battery electrode, and we describe our methods here. The work reported in this paper pertains to what must still be considered a model system since an excessive amount of electrolyte and a low specific surface area powder were used. However, the techniques are directly applicable to actual cells without these limitations, and data on such systems will be reported later.

Experimental Techniques

Conventional electrochemical techniques were employed, and we describe only their adaptation to our particular problem. Analytical grade reagents were used throughout the work.

The cadmium powder was obtained from the American Smelting and Refining Company, and it had a stated purity of 99.994% cadmium. Microscopic observations indicated that the powder consisted of nearly spherical particles. The particle size distribution was determined by measuring and counting particle images on photomicrographs, and they were found to have a mean diameter of about 7μ and to be represented by a nearly Gaussian distribution. Calculations from the smoothed distribution curve indicated that the surface area of the powder was 502 cm²/g on the assumption that all the particles were spherical.

The porous cadmium anodes were made by sintering loose powder compacts in 3N HCl (8). This resulted in reasonably strong sintered pellets. The anodes were rinsed in distilled water and stored under distilled water before use to avoid air oxidation. They were 0.20 in. thick and had a diameter of 0.444 in. The porosity of the anodes was calculated from their size and weight to give the values shown in Table I.

The test cell has been described elsewhere (9). It was maintained at 25°C, and the experiments were performed in the presence of a stoichiometric excess of deaerated 30% (wt) KOH. The anode potentials were recorded with respect to a Hg/HgO reference electrode in the same electrolyte, and they were measured with a Keithley Model 610B electrometer and a Moseley Model 680 strip chart recorder. All the dis-

charges were performed under constant current conditions using a Harrison Model 6200B power supply.

The anode holder fitted into a fixture with a micrometer advancing screw which allowed the slicing of about 0.015 in. thick sections from the anodes with a razor saw blade. The transfer of the anodes from the cells to the microtome, the slicing operation, and the transfer of the slices to the analysis vessels were performed inside an argon filled glove bag to avoid air oxidation of the cadmium.

The analysis of Cd^{+2} and unreacted Cd was carried out as follows: Each anode slice was transferred to a standard 20 ml Cu^{+2} solution in a 1.0*N* HAc-NaAc buffer. The displacement reaction

$$Cd + Cu^{+2} \rightarrow Cd^{+2} + Cu$$

was allowed to proceed to completion (20 hr), and argon was bubbled through the solution to prevent air oxidation of the copper. The copper powder and the supernatant solution were separated by decantation and distilled water washings of the powder were combined with the supernatant solution. The latter was diluted to 250 ml and a 5 ml aliquot was diluted to 100 ml with a 1.0*N* HAc-NaAc buffer and used for the polarographic determination of Cd^{+2} and Cu^{+2}. The total amount of Cd^{+2} found by analysis corresponded to the total amount of Cd and Cd^{+2} in the anode slice, and the consumption of Cu^{+2} corresponded to the amount of unreacted Cd in the slice. Thus, the state of discharge of the various sections of the anodes could be calculated.

The accuracy of the method was checked by the material and charge balances illustrated in Table I. The chemical analyses underestimated the total cadmium content by about 5%, which may be attributed, in part, to cutting losses even though attempts were made to collect all the cuttings with the slices. The depths of discharge calculated from the chemical analyses were about 5% greater than the values determined from the galvanostatic discharge curves. Although these inaccuracies will lead to some uncertainties in the interpretation of the data, it is believed that the data provide a reasonably faithful description of the true behavior of the electrodes.

Experimental Results

The end of the constant current discharges of the porous cadmium electrodes was well defined, Fig. 1. The electrode potentials remained nearly constant or increased slowly until a point was reached where the potentials increased quite sharply. This point was used to define the end of the discharge process; the resulting discharge efficiencies are shown in Fig. 2. It may be seen that the electrodes discharged efficiently at low integral current densities where values of about 70% were obtained. At higher integral current densities the discharge efficiencies decreased markedly and reached a value of about 4% at 200 mA/cm^2. The term

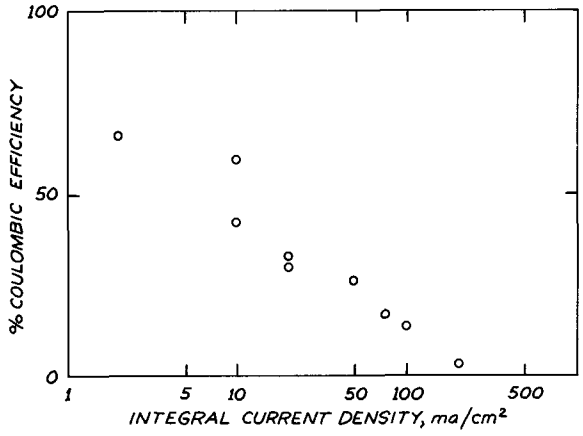

Fig. 2. Coulombic discharge efficiency of the porous cadmium electrode.

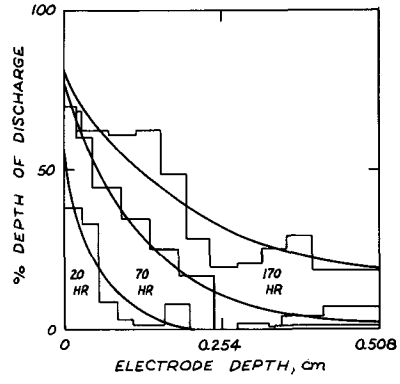

Fig. 3. Typical discharge profile histograms at 2 mA/cm^2

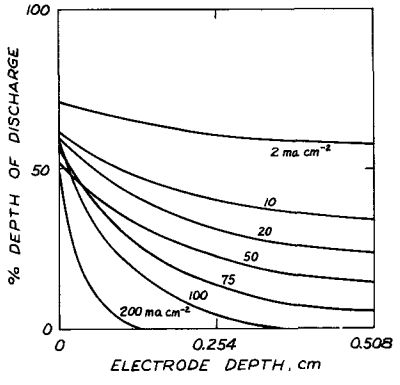

Fig. 4. Discharge profiles at the end of discharge

"integral current density" designates the total current to the electrode per unit front surface area.

The analyses of the anode slices gave rise to discharge profile histograms.[1] Three representative histograms are shown in Fig. 3 and the smooth curves fitted to the histograms to facilitate the comparison of the discharge profiles. The correlations we used are discussed in the next section. It may be seen from Fig. 3 that the chosen correlation represented the data well.

The discharge profiles in the electrodes at the end of discharge are shown in Fig. 4. At low integral current densities the porous electrodes reacted uniformly throughout their thickness. At 2 mA/cm^2 the depth of discharge at the rear of the electrode, 60%, was almost as great as at the front of the electrode, 70%. As the integral current density increased the discharge profiles became increasingly distorted, and the rear of the electrodes gradually ceased to participate in the discharge. However, the front surface of the electrodes

[1] Complete data tables are available from the author on request.

discharged almost as deeply as at the lower integral current densities. For example, at 200 mA/cm² the front surface discharged to about 50%, but the rear three fourths of the electrode did not discharge at all.

Two series of experiments were done to explore the time course of development of the discharge profiles at 2 and 50 mA/cm². Results are shown in Fig. 5 and 6. Although the experimental data gave rise to some crossovers in the profiles, the general reaction patterns are well defined. The initial discharge was confined to the front of the electrodes, and, subsequently, the discharge penetrated into the interior of the electrodes. The differences between the low and the high current density profiles are those expected from the profiles at the end of discharge; the interior and rear sections of the electrodes discharged much less at the higher than at the lower integral current density. The data show that the front surface tended to discharge quite extensively at the onset of the discharge, and the rear sections did not contribute much until the discharge was about half completed.

Discussion

The discharge of the cadmium anodes terminated when the electrode potentials increased abruptly at the end of the discharges. Several factors need to be considered in the analysis of this phenomenon. The most difficult factor to quantify is the changing geometry of the anodes during discharge, and we have not been able to develop any reasonable models which can be solved mathematically. The equations presented by Alkire *et al.* (6) pertain to a dissolving anode and cannot be used for our case where a precipitate is formed. We chose to pursue an heuristic approach in the search for an equation to describe the behavior of the porous anodes.

The behavior of finite networks is generally described in terms of hyperbolic functions, and, it turns out, it is possible to make a particular choice of hyperbolic functions and arrive at an adequate description of the discharge profiles in the porous cadmium anodes. As a guide, we note that the front surface of the electrodes generally reacted to a high and almost constant degree, and the rear of the electrodes participated to varying degrees depending on the current density and the fractional extent of discharge.

* Obtained by least square fitting of q/q_0 as a function of X to Eq. [1].

The hyperbolic functions should be chosen to reflect these characteristics. The following expression appears to satisfy these requirements

$$q/q_0 = A\ (\cosh B\ (1 - X))/\cosh B \qquad [1]$$

q = discharge density, mAh/cm³
q_0 = stoichiometric charge density of fresh anode, mAh/cm³
A, B = parameters
X = fractional depth in anode from front surface.

We used Eq. [1] to describe the discharge profile histograms with the results shown in Table II. Representative comparisons of some experimental data and Eq. [1] were given in Fig. 3. The data fit the hyperbolic expression with an average standard deviation of about 6% over the entire range of integral current densities and discharge times. Thus, whether or not the expression has any fundamental significance, it represents the data reasonably well, and it may be useful in suggesting the mathematical forms that should be sought in model considerations.

An examination of Eq. [1] indicates that A may be defined most simply as the depth of discharge at the front of the electrode. The effect of the integral current density on A at the end of discharge is shown in Fig. 7. The depth of discharge at the front of the electrode reached a value of about 54%, and it remained constant over the greater part of the integral current density range. It increased at integral current densities below 20 mA/cm², and as the integral current density approached zero the depth of discharge of the front surface approached 70% at the end of discharge. Some of the scatter in the data may be attributed to varia-

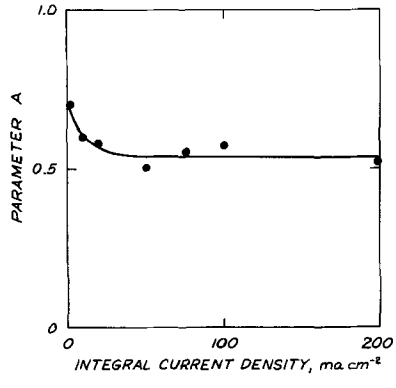

Fig. 7. Effect of the integral current density on parameter A in Eq. [1] at the end of discharge.

tions in the porosity of the anodes. Assuming the applicability of the mean initial porosity of 64% to all the low integral current density anodes, we find that the depths of discharge of 54% and 70% correspond to residual porosities of 38% and 30%, respectively, at the end of discharge. Such changes in the porosities imply a considerable blocking of the pores in the anodes, especially at the lower integral current densities.

The evolution of the state of discharge of the front surface during discharge is given in Fig. 8 for the integral current densities of 2 and 50 mA/cm^2. The best linear fits of the data are given by

$$2\ \text{mA/cm}^2\ \text{data: } A = 0.527 + 0.00103t \quad [2]$$

$$50\ \text{mA/cm}^2\ \text{data: } A = 0.281 + 0.0765t \quad [3]$$

t = time since start of discharge in hours.

At the lower integral current density the front of the electrode reached a high state of discharge at the very beginning of the discharge process, 53%, and it increased gradually to a value of 81% at the end of discharge. The discrepancy of the latter value from the earlier value of 70% obtained from $A(i)$ in Fig. 7 is attributable to their different origins which are those of a current correlation and a time correlation, respectively. The high value merely confirms that the front of the electrode becomes quite dense. At the higher integral current density the front of the electrode appeared to attain a lower initial depth of discharge, 28%, and it increased to only 51% at the end of the discharge. Although the latter value corresponds to some densification of the front of the electrode, it represents a much less blocked pore structure than obtains in the low integral current density anodes at the end of discharge.

There may be some question regarding the validity of the linear A-t equations, especially for the 2 mA/cm^2 data. If a nonlinear representation be employed, as indicated in Fig. 8, the initial depth of discharge at the front of the 2 mA/cm^2 electrode would be about 30% and the final value about 75%. The initial value would be, therefore, the same for the electrodes regardless of the integral current density. This appears to be more reasonable, but more data are needed to settle the question. Deviations from linearity are small for the 50 mA/cm^2 data.

A tentative interpretation of B can be obtained by a consideration of some analogies. Integration of Eq. [1] over the entire thickness of the electrode gives

$$q/q_o = (q/q_o)_{x=0}\ (\tanh B)/B \quad [4]$$

This equation has been used by Selim (10) to correlate the performance of a variety of batteries and electrodes. It was derived from a distributed network model, and in some simple cases the quantity B could be reduced to

$$B^2 = (\text{Ionic impedance})/(\text{Faradaic impedance}) \quad [5]$$

A similar quantity has been used by de Levie (11). Equation [4] is well known in chemical kinetics for the description of first order reactions in catalyst pellets (12) where the factor $(\tanh B)/B$ is referred to as an "effectiveness factor." It is equally to be considered an effectiveness factor for porous electrodes since it measures the extent to which the average discharge of the electrode approaches the discharge of the front surface of the electrode. In chemical kinetics B^2 is the Thiele parameter (13), and it is a measure of the ratio of the rate of the chemical surface reaction and the rate of diffusion into the porous structure. We arrive at a consistent description, therefore, if we identify B^2 as the Thiele parameter for electrochemical systems.

The Thiele parameter contains the effects of the geometry of the electrode, the degradation of the electrode, the operating parameters, as well as the effects of the electrochemical characteristics of the system. We restrict our discussion to the effects of the integral current density on B and the changes in B during the discharge.

The experimental data showed that B decreased noticeably during the evolution of the discharge process. Several correlations were tried to express B as a function of t, the time of discharge, and the exponential expressions

$$B_2\ (2\ \text{mA/cm}^2) = (245/t)^{0.898} \quad [6]$$

$$B_{50}\ (50\ \text{mA/cm}^2) = (6.45/t)^{0.806} \quad [7]$$

appeared to be the most satisfactory. They are shown in Fig. 9. The changes in B during discharge agree with our interpretation of the Thiele parameter, although the simple equality of B^2 and the ratio of the ionic and faradaic impedances is considered an oversimplification. The decrease of B with time at both the high and the low integral current densities reflects the gradual displacement of the reaction to the interior of the electrode. We know that the porosity decreases during discharge and the diffusive conductance should, therefore, decrease as well, making B^2 larger. However, the faradaic conductance decreases even more since the front regions of the electrodes approach passivation. We shall see later that the true current density at the front surface vanished near the end of the low integral current density discharges, but not so at the higher integral current densities. We would expect, therefore, a much greater decrease in B^2 during discharge for the former, and values of B^2 (initial)/B^2 (final) were found to be 282 and 16.7, respectively, for the two sets of data, in agreement with expectations. We conclude that the definition of B^2 as a Thiele parameter leads to a consistent interpretation of the data.

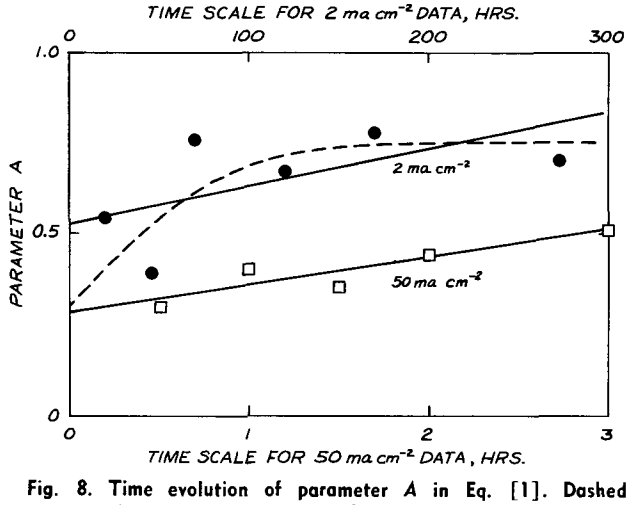

Fig. 8. Time evolution of parameter A in Eq. [1]. Dashed curve: an alternate fit of 2 mA/cm^2 data.

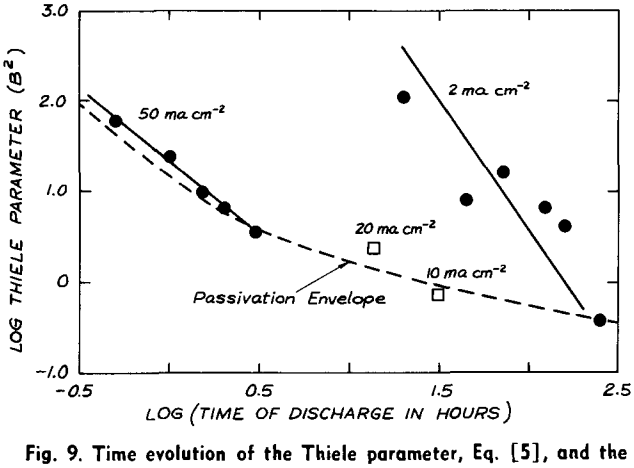

Fig. 9. Time evolution of the Thiele parameter, Eq. [5], and the Thiele parameter at the end of discharge.

The experimental data were used to obtain the $B(t)$ curve at the end of discharge for the entire integral current density range, and it is shown in Fig. 9. The near equality of the slopes of the log B *vs.* t curves at 2 and 50 mA/cm^2 suggests that it may be possible to interpolate and extrapolate from Fig. 9 to obtain the $B(t)$ values for other integral current densities and, thus, to obtain the detailed discharge profiles for electrodes operating over a wide range of integral current densities. The $B(t)$ curve at the end of discharge serves to delimit the interpolations.

The effect of the integral current density on B at the end of discharge may be expressed by

$$B = 0.445 \exp (0.244\, i^{1/2}) \qquad [8]$$

B increased with the integral current density, reflecting the progressive confinement of the reaction zone to the front of the electrode. In terms of the Thiele parameter interpretation, the ionic impedance became more significant relative to the faradaic impedance at the higher integral current densities.

From an operational point of view it is of interest to predict when the end of discharge will occur for any given integral current density. This follows directly from Eq. [4] using the A values from Fig. 7 ($A = (q/q_0)_{x=0}$) and the B values from Eq. [8]. The mean deviation of the efficiencies (in per cent) calculated from these expressions is 2.5% relative to the observed efficiencies (in per cent).

It is instructive to consider the true current distribution in the electrodes during the discharge. The smoothed discharge profile data were differentiated with respect to time to give the current distributions shown in Fig. 10 and 11. The specific surface area of 502 cm^2/g, and the average porosities were used to calculate the current densities. The internal surface areas change during the discharge, and the true current densities would differ somewhat from the values shown as t increases. Although it is possible to use the $q(x,t)$ values to estimate the area changes and to obtain a better estimate of the true current densities this refinement is not considered to be necessary since the given curves in their present form represent the essential features of the process.

The 2 mA/cm^2 data illustrate the advancement of the reaction zone into the electrode. During the early part of the discharge the current is concentrated near the front of the electrode. As the discharge continues the current wave advances into the interior of the electrode and moves gradually to the rear of the electrode. As it does so, the front of the electrode ceases to participate in the discharge altogether. At the higher integral current density of 50 mA/cm^2 there is also a high initial concentration of the current near the front of the electrode, and as the discharge proceeds the current wave moves into the electrode. However, the rearward advancement of the current wave is strongly damped, and the front surface remains active during the entire discharge.

Another effect associated with the discharge process is the accumulation of the reaction product inside the porous structure. Since the amount of Cd^{+2} recovered by analysis agreed reasonably well with the measured electrical charge it may be concluded that the $Cd(OH)_2$ remained inside the electrode where it would obstruct mass transfer and the flow of current. The discharge profiles were used to calculate the choking patterns shown in Fig. 12 and 13. It was assumed that the expansion of the anodes during discharge could be ignored.

The choking patterns are given in terms of a choking factor, F, that can be defined as a first approximation with reference to the Bruggeman-Baron equation (14) for the electrolytic conductivity of a porous body

$$K_p = K_s\,(1 - f)^{3/2} \text{ (Bruggeman-Baron)} \qquad [9]$$

K_p = conductivity of porous body
K_s = conductivity of solution in the pores
f = volume fraction of solids in the body

$$F = (1 - f)^{3/2}{}_{t=0}/(1 - f)^{3/2}{}_{t=t} \text{ (Choking factor)} \qquad [10]$$

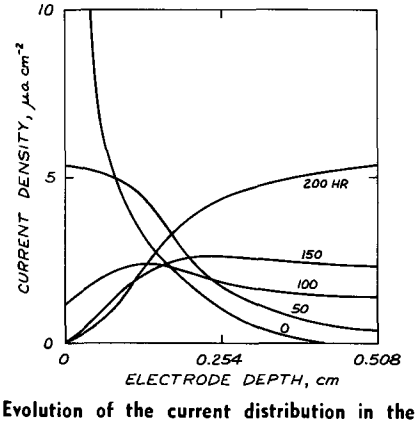

Fig. 10. Evolution of the current distribution in the electrodes at 2 mA/cm^2.

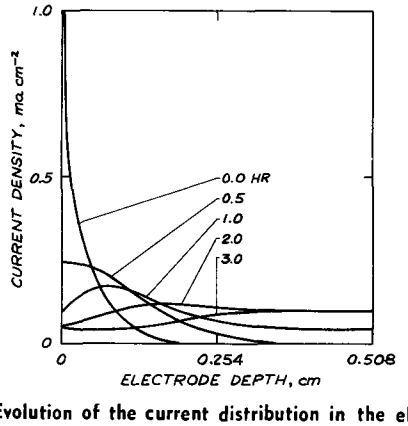

Fig. 11. Evolution of the current distribution in the electrodes at 50 mA/cm^2.

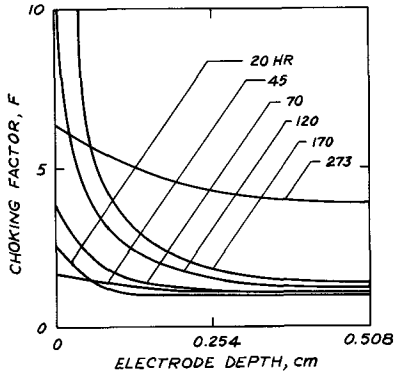

Fig. 12. Development of the choking patterns at 2 mA/cm^2

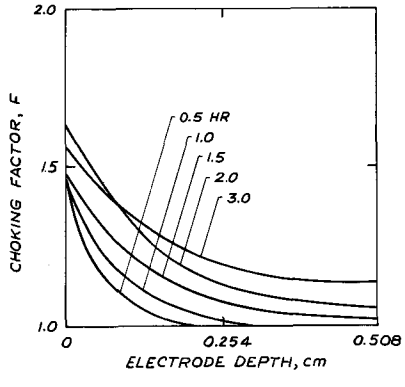

Fig. 13. Development of the choking patterns at 50 mA/cm^2

The choking factor is simply the ratio of the resistance of the porous body at any time, t, and the initial resistance of the porous body.

The curves in Fig. 12 show that the electrodes operating at 2 mA/cm^2 experienced an appreciable choking effect throughout their entire thickness near the end of discharge. The electrolytic resistance near the front of the electrode had increased about sixfold; near the rear it had quadrupled at the end of discharge. The electrodes operating at 50 mA/cm^2, Fig. 13, experienced a smaller choking effect. The electrolytic resistance had increased 55% near the front surface when the electrode ceased discharging, and at the rear it had increased 12%.

The choking factor and the current distribution provided an indication of the processes involved in the polarization of the anode. Since the faradaic current density vanished at the front of the electrode at the low integral current density, the front of the electrode may have reached passivation, and the ionic transfer path to the active region of the anode must have increased correspondingly. The concomitant increase in the choking factor would inevitably lead to an excessive mass transfer impedance and the anode would polarize. At the greater integral current density there was no front surface passivation, but the faradaic current density decreased markedly there, indicating an appreciable increase in the local faradaic impedance, sufficient to displace the current to the interior of the electrode, leading again to an increase in the mean ionic transfer path and an increase in the mass transfer polarization.

Calculations of the resistive polarization due to conductance choking during the discharge, using the faradaic current densities and their time change to obtain the pore current distribution and using the Bruggeman-Baron equation for the effective conductivity, predicted a gradual increase in the overvoltage with time but not the observed, abrupt increase in polarization at the end of discharge. The failure of the calculations to predict the terminal polarization curve may be attributed, in part, to an inadequate analysis of the choking effect. The choking is probably locally inhomogeneous, and complete choking may occur before the residual porosity vanishes. Since no satisfactory theory is available on the topography of conductance choking in electrodes undergoing structural transformations, a rigorous discussion of this phenomenon is not yet possible.

Another consideration is the coarseness of the cuts used to slice the electrodes. The implied averaging may have obscured a much more extensive choking of the front surface of the electrodes than was indicated by the values obtained from the experimental data. If such were the case, the terminal polarization would be explained.

An alternate hypothesis is that local passivation may have occurred in the electrodes to a greater extent than indicated by the current distribution curves. This possibility needs to be examined in more detail, both by obtaining more extensive current distribution curves and by doing passivation studies on flat electrodes using the observed local current-time profiles.

It was assumed in the polarization calculations that the bulk conductivity of the electrolyte remained constant in the anode. However, OH^- ions are consumed during discharge, and at the lower integral current densities the total amount of OH^- consumed exceeds that initially present inside the anode and that provided by electrical transport from the external solution. Some OH^- are also lost by electrolyte expulsion due to the densification of the anode. At the higher integral current densities less OH^- is consumed than is present initially. Local OH^- depletion would occur, therefore, in the anodes with a concomitant decrease in the electrolyte conductivity and an increase in the anode polarization. It is conjectured that the OH^- depletion may have contributed significantly to the terminal polarization of the anodes.

Conclusions

The experimental work shows that it is possible to determine the discharge profiles of porous electrodes by slicing the electrodes into thin sections parallel with their front surfaces and by analyzing the individual sections chemically to obtain histograms of the discharge profiles. Our study was limited to the effect of the integral current density on the discharge profiles of porous cadmium electrodes.

The discharge profiles could be described by a hyperbolic cosine function and the mean electrode efficiency by a hyperbolic tangent function. The latter is equivalent to the effectiveness factor used in chemical kinetics, and it is a function of an electrochemical Thiele parameter that depends on the relative magnitudes of the transport and reaction impedances in the electrode. The effectiveness factor measures the extent to which the discharge zone penetrates into the electrode. The given correlations provide a means for calculating the efficiency and the discharge profiles at any particular integral current density.

The product formed during the discharge of cadmium electrodes remains inside the electrode and causes the eventual choking of the porous structure. A choking factor was introduced to provide a quantitative description of the geometric choking effect. It was most pronounced at the low integral current densities near the end of discharge where a high degree of discharge had occurred. It was less pronounced at the higher integral current densities.

The discharge of the cadmium anodes was affected by both the faradaic and the transport limitations of the electrode. The increase in the faradaic impedance near the front of the electrode forced the current into the interior of the anode, and this extension of the transfer path combined with the increase in the transport impedance due to the choking effect led to the polarization of the anode. Although the exact cause of the terminal increase in the polarization could not be ascertained, it is believed to be due to an excessive choking effect near the front of the electrode and the depletion of OH^- ions inside the anode.

Crystallization of $PbSO_4$ on Anodes of Lead-Antimony Alloy

Jeanne Burbank*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20390

ABSTRACT

The morphologies of crystals of $PbSO_4$ depositing on 5% antimonial lead alloy in 1.25 sp gr H_2SO_4 were examined by electron microscopy. The crystals formed on open circuit stand and during discharge of PbO_2 coatings, developed by electrochemical cycling, were examined. Well developed prisms, dendrites, and hopper crystals were observed. The discharge of the antimonial coatings appeared to be limited by the crystal growth rate.

Individual particle morphology is directly related to the stability of polycrystalline masses (1, 2). Especially in the case of porous conglomerates, this factor is of supreme technological importance when the body is required to serve usefully in practical applications. Recent studies of the positive active material of the lead-acid cell have emphasized the relation of the crystal morphology to plate function and durability (3, 4).

Antimony is normally present in the cell as an alloying agent to stiffen the grids used to support the active materials. It is further recognized that it contributes significantly to successful cycle operation of the positive plate (5-7) where it appears to act as a nucleating catalyst for the PbO_2, promotes intercrystal bonding, and modifies the crystal size and habit. As a continuation of the investigation of the mechanism of the action of antimony in the positive plate, it was of interest to examine the habit of $PbSO_4$ crystallizing on anodes of lead-antimony alloy.

The modification of the crystal habit of $PbSO_4$ by addition agents in the negative plate of the lead-acid cell has been recognized by Willihnganz (8), and the morphology of $PbSO_4$ crystallizing on pure lead anodes in H_2SO_4 has been examined by electron microscopy (9-12), however crystallization on lead-antimony alloys has not been investigated.

Lead sulfate, occurring natively as the mineral anglesite, crystallizes in the orthorhombic system with unit cell parameters of $a_o = 8.5$, $b_o = 5.4$, and $c_o = 6.99$Å containing four molecules. The space group is Pnma, and the structure, made up of distinct Pb and SO_4 ions, has recently been refined by Sahl (13). It is isostructural with $BaSO_4$ and $SrSO_4$.

Shannon and others (14-23) have described the numerous crystal habits of $PbSO_4$ is many mineral and synthetic specimens. The frequently observed diamond-shaped platelet is the basal pinacoid//(001), prismatic with {210}. It may be modified by other prisms and domes. Older descriptions characterize {210} as {110} because of the axial ratios chosen for the optical measurements prior to the establishment of the crystal structure by x-ray diffraction which, in effect, doubled the a_o axis. The earlier optical designations of the {h01}, {hk0} and {hkl} forms must be corrected accordingly.

Lead sulfate also frequently grows in columnar prisms parallel to a_o, b_o, and c_o terminated with pyramidal and dome faces. The pinacoids (100) and (010) are often small or absent. The habit of synthetic material may be modified by impurities in and composition of the solutions from which it is precipitated (17, 20), and it has been reported that crystal size is increased by the presence of hydronium ion (23). Changes in habit and crystal size are generally attributed to preferential adsorption processes that alter the relative growth rates of the crystallographic directions.

Because of its sparing solubility $PbSO_4$ has been used extensively for studying crystal nucleation and growth rates (17, 19, 23, 24). Owing to the complexities of the processes that take place during a crystal deposition reaction, the fundamental theories presently available are somewhat restricted in application. Recent reviews of the field are found in VanHook, Botsaris *et al.*, and others (25-28). The necessary steps involved in crystallization are often conceived to be: the clustering of a few ions or particles into a unit called a crystal embryo, structural arrangement of the particles into a lattice network accompanied by addition of material to form a critical nucleus, growth of this nucleus into a crystallite, which may then grow into a typical crystal. Any one of these steps may be rate determining, however, in most instances the nucleation processes appear to be retarded, requiring an activation energy manifested by the phenomena of supercooling, supersaturation and, in electrocrystallization, polarization. The activation energy required for heterogeneous nucleation is usually less than in homogeneous cases, and most instances fall into the former category. Growth of the crystallites may also be very slow, and the rate may vary with the crystallographic direction. In general, but not always, a crystal will grow most rapidly in directions perpendicular to the lattice planes having the highest reticular density (29). Because the different crystallographic directions grow at different rates, the fastest growing planes become smaller in area, and, given time, disappear from the crystal surface. The rates of growth of the remaining enclosing faces are slower. For these reasons, the growth rate varies with time. The final shape of the crystal is determined by the various rates of growth in the different crystallographic directions as well as by the influence of factors such as adsorption of foreign material, mechanical restrictions, temperature, time allotted for growth, and degree of perfection of the crystal structure.

In order for a crystal to grow, the solution must be supersaturated, and the surface of the growing crystal must offer sites for the accretion of new structural units (ions or molecules). Present theories postulate deposition at emergent screw dislocations, kinks, and similar flaws in the crystal structure.

Complex as the crystallization process is, electrochemical crystallization adds further parameters that must be taken into consideration (30-36).

The reaction at the positive plate of the lead-acid cell is particularly complicated because it involves dissolution and crystallization of two solid phases, PbO_2 and $PbSO_4$ as well as the two electron exchange reaction. The plate reaction takes place by way of solution in the H_2SO_4 electrolyte (37, 38), and the solubilities of $PbSO_4$ and PbO_2 are limited. Despite these complexities, the electrode performs very well at relatively high current densities. Willihnganz, following the work of Kapitza (39-41), concluded that the charge exchange reaction is not the limiting step in the discharge reaction at current densities as high as 3.5 A/cm^2.

In discharge of a β-PbO_2 electrode in H_2SO_4 at constant current, the potential passes through a minimum

* Electrochemical Society Active Member.

Key words: lead-acid-cell, $PbSO_4$, crystal morphology, lead-antimony alloys, anodic coatings.

(42). This is reflected in the cell voltage and is known as the coup de fouet of spannungssack. It is during this period that supersaturation of Pb^{2+} in the electrolyte is built up, and the critical nuclei of $PbSO_4$ are formed (43, 44). Growth of the $PbSO_4$ crystals then follows at a lower polarization. This behavior is fairly typical of nucleation and growth kinetics in many electrocrystallization reactions (33, 34).

Antimony is coprecipitated with $PbSO_4$ to such a degree that it interferes with the gravimetric analytical procedure (45), and separation from lead is required for accurate results. The chemistry of antimony has been summarized by Maeck (46) and Sidgwick (47). Dawson *et al.* (48, 49) recently suggested that in H_2SO_4 solutions, antimony is present as the anions $Sb(SO_4)_2^-$, $SbOSO_4^-$, and $Sb_3O_9^{3-}$. Strong adsorption on the $PbSO_4$ surface may occur, and result in alteration of habit, growth rates, and lattice substitution in the growing crystals.

Experiments

Aged castings of nominal 5% lead-antimony alloy were used for this study. The specimens measured approximately 6 x 3 x 0.4 cm and fit the sample holder of the x-ray diffractometer so that x-ray patterns could be registered without destruction of the sample. Immediately prior to use, the specimens were washed in saturated ammonium acetate solution and thoroughly rinsed in distilled water. While wet with the final rinse, they were assembled in beaker cells containing two sheet lead cathodes, a Hg, Hg_2SO_4 reference electrode, and 1.2549 sp gr H_2SO_4. The cells were allowed to stand on open circuit for 30 min before the anodic current of 1 mA/cm² of apparent surface was applied. The cell voltages and anode potentials were continuously recorded and frequently checked manually with a potentiometer. Experiments were run in triplicate. The cycled samples were discharged at 1 mA/cm² to a potential of 0.75-0.8V *vs.* the reference electrode, recharged at the same current density, and anodization continued between discharges.

The electrodes were cycled to develop electrochemical capacity of approximately 2 mA-hr/cm². During discharge the interval known as the coup de fouet had a duration of approximately 5 min under these conditions and the minimum was reached at 3.25 min. Discharging electrodes were examined at 0.5, 2, 3.25, 4, and 5 min and at 1 hr (half discharge capacity) and at the knee of the curve. X-ray diffraction patterns were registered using CuKα radiation and the diffractometric method (50) with a scanning speed of 2°/min. Specimens for electron microscopy were removed following the 30-min presoak in H_2SO_4, and at the above indicated intervals during the discharge of the anodic coatings. They were blotted dry, and replicated for electron microscopy.

Two-stage polystyrene-carbon replicas were used (51-54). Dissolution of the particles embedded in the primary plastic replica proved to be tedious because of the tendency of antimony to hydrolize to the very stable hydrous oxides (45-47) which then could not readily be removed from the replica. Cleaning these replicas remains an art. By using oxalic acid to reduce the PbO_2, and tartrates to complex the antimony, the replica may be cleared. It was necessary to use occasional dips in H_2SO_4 to precipitate $PbSO_4$, which could then be removed in saturated ammonium acetate solution. By alternately treating with these reagents, rinsing with distilled water between the various baths, the formation of the curdy antimony oxide could be minimized. When all the PbO_2 had been reduced, HCl containing tartaric acid was used as a final treatment. It is, of course, the very stable insoluble hydrolytic product that gives rise to the chemical replica of lead antimony alloys (55) and interferes with the analytical chemistry of antimony (45).

Results

The $PbSO_4$ coating formed during open circuit stand for 30 min was made up of rhomboidal crystals of $PbSO_4$, Fig. 1. At some intercrystalline boundaries, clusters of radiating acicular crystals appeared. The larger crystals were several microns in diameter and appeared to be implanted in a bed of smaller crystals ranging in size down to approximately 0.1μ. These coatings are very similar to those observed by Feitknecht and Pavlov (9-12) on pure lead surfaces.

At 0.5 and 2 min discharge, no $PbSO_4$ crystals or nuclei could be identified in the electron micrographs, and the coating had the same appearance as the fully charged electrode (54). This is not unexpected because the critical nuclei or $PbSO_4$ are very small, about 11Å diameter (24).

Once the critical nuclei are formed, however, they grow very rapidly. These initial crystals are parallel growths of the basal pinacoid, Fig. 2. The larger crys-

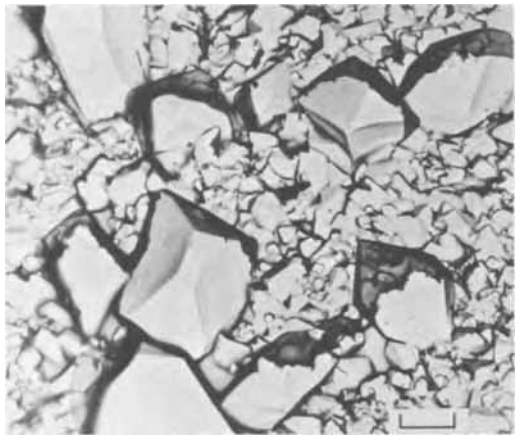

Fig. 1. Lead sulfate coating formed on lead antimony alloy on open circuit for 30 min in 1.2549 sp gr H_2SO_4. Larger prismatic crystals are implanted in a layer of smaller crystals. In the lower right hand corner, the bed of small crystals is seen through the "overhang" of the replica of the larger crystal, and the line of contact between the two types of crystal is visible. Magnification marker on all electronmicrographs = 1μ.

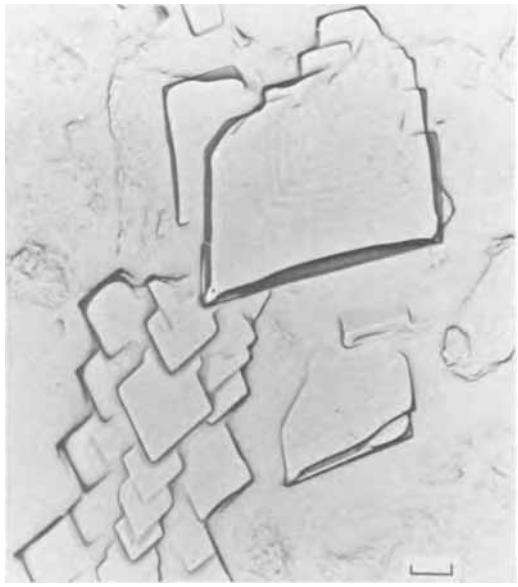

Fig. 2. $PbSO_4$ crystals formed on the discharging electrode at 5 min, immediately following the coup de fouet. The large crystal has a hopper type of face development. In the string of smaller crystals several interplate bridges are visible, and one of the basal pinacoids is modified by the {201} domes. These crystals stand out in relief from the layer of PbO_2 and only the most prominent features of this layer are replicated here.

tal has a hopper type of face development, and the overlapping plates in the string can be seen to be connected by bridges. When viewed from the side, Fig. 3, it is seen that the {210} prism faces are not developed, the platelets are usually less than 0.5μ thick, and the interplate attachments are small bridges that may have resulted from growth in the [201] and [011] directions. It is concluded that growth in the [001] direction is inhibited and may be the result of adsorption of an antimony species on the (001) face. Although domes appear on some of these basal plates, the pinacoids (100) and (010) are absent, indicating that growth in these directions was most rapid. Although an effort was made to observe these crystals at an earlier stage when they could be expected to display these faces, they had grown themselves out of existence by the time the electrodes were examined, *i.e.*, at 3.25 and 4 min.

When discharged to 0.8V *vs.* the reference electrode, corresponding to the cut off voltage of the positive plate of the lead-acid cell, the $PbSO_4$ crystals exhibited a different morphology, Fig. 4. These appear to be typical prisms parallel to the crystallographic axes, described for many mineral specimens, and resemble the crystals forming on self discharge of pure lead anodes (10). These lie implanted in the PbO_2 layer and could not have grown from the original strings of basal plane crystals formed on the electrodes, Fig. 2. It is possible that those platelets lying in the electrode surface on their sides in the manner shown in Fig. 3, grow into the prisms appearing at the end of discharge, Fig 4. On the other hand, some residual basal pinacoids were observed, Fig. 5. The appearance of these crystals suggests that during discharge, this crystal form became energetically unstable, and began to dissolve, hence few remain at the end of discharge. This is further suggested by the appearance of the electrode when half discharged, when the surface appeared to be more completely covered with $PbSO_4$ than at the termination of discharge. It appears possible that some of the anomalies associated with aging of chemically prepared $PbSO_4$ may result from similar transformations (17, 23, 56).

It is seen in the micrographs that the $PbSO_4$ crystals are several orders of magnitude larger than the PbO_2 crystals and $PbSO_4$ does not completely cover the elec-

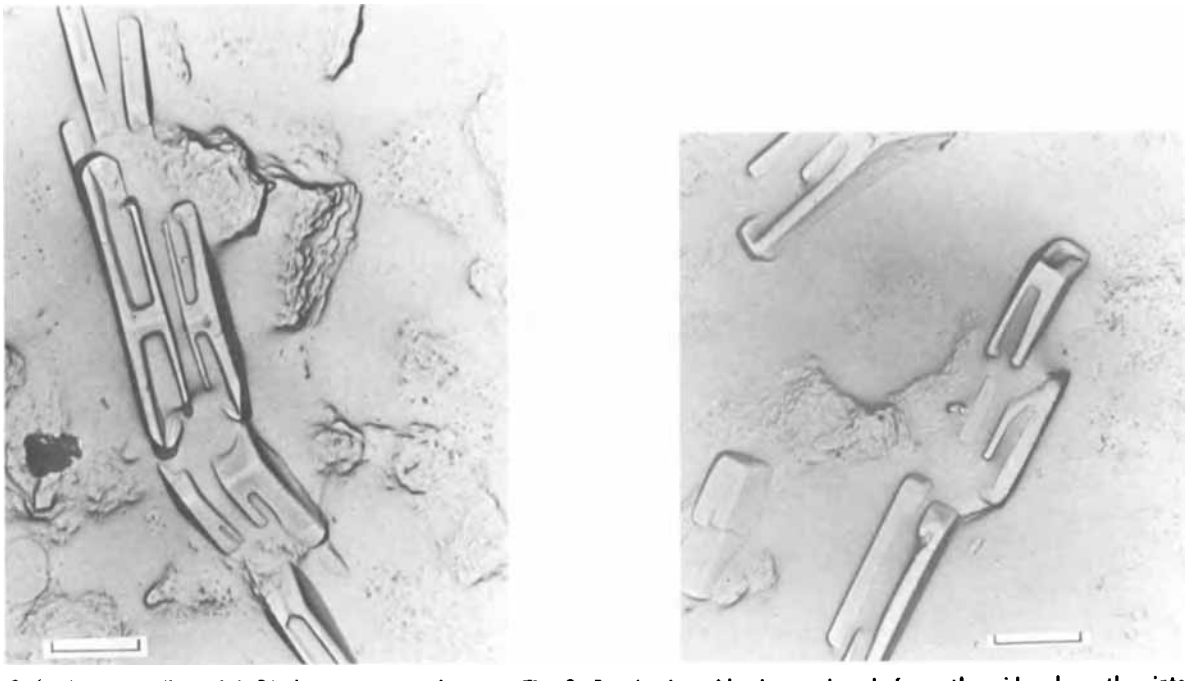

Fig. 3 (a, left) and (b, right) Discharging electrode as in Fig. 2. Basal pinacoid plates viewed from the side show the interplate bridging and the poor development of the {210} prism faces indicating inhibited growth in the c_0 direction. Most of these platelets are less than 0.5μ thick.

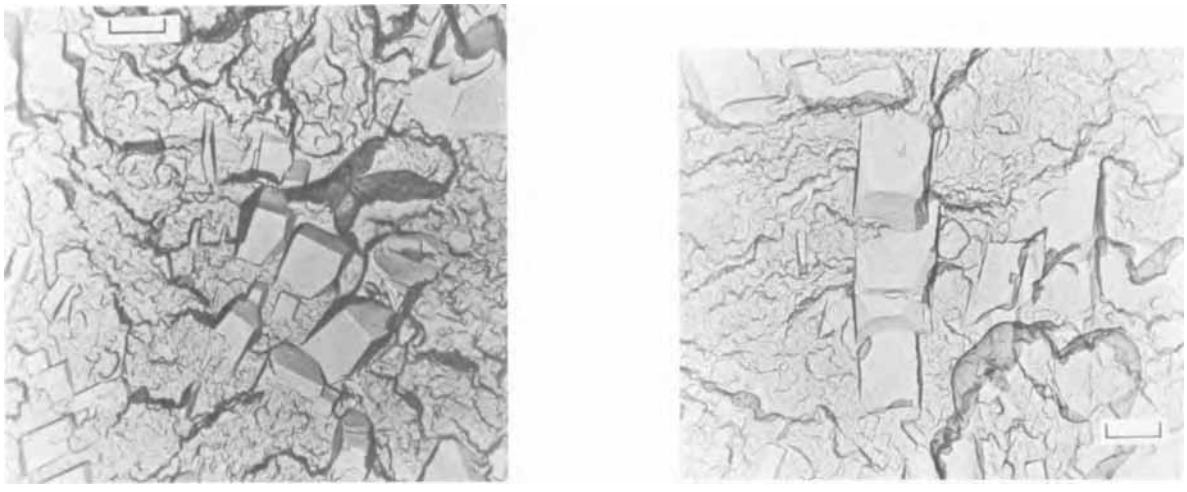

Fig. 4 (a, left) and (b, right). $PbSO_4$ crystals on the surface of electrode discharged to 0.8V *vs.* the Hg, Hg_2SO_4 reference. At the end of discharge the $PbSO_4$ crystals are implanted in the PbO_2 coatings. Much of the PbO_2 surface appears to remain available for discharge.

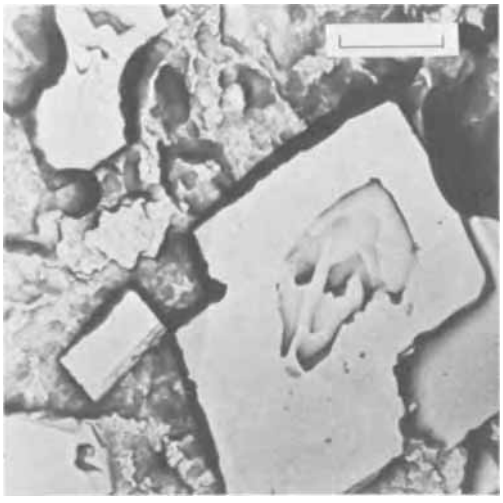

Fig. 5. Basal pinacoids remaining on the surface at the end of discharge. The etched appearance of the edges of these crystals, and the labyrinthine interior suggests that these crystals have been dissolving during the discharge, rather than growing. The PbO_2 is heavily pitted in the immediate vicinity of these $PbSO_4$ crystals. This would be expected if the reaction takes place by way of solution.

trode surface at the end of discharge. The observations of this study support the conclusions of other investigators (37, 38, 57) that the reaction takes place by way of the solution. It has been suggested that the end of discharge of PbO_2 on pure lead anodes is a result of a covering over of the surface by $PbSO_4$ (37). In the case of PbO_2 discharging on lead-antimony alloy, the electron micrographs, Fig. 4, suggest that nucleation and growth of the $PbSO_4$ crystals take place at "active centers" and that termination of discharge might be said to result from an "exhaustion or covering over of the active centers."

Another possible cause of the termination of discharge on the alloy may be the limited growth rate of the $PbSO_4$ crystals themselves. As indicated earlier, it is the slow growing faces that ultimately enclose a crystal. If the growth rate is significantly retarded, it is possible that accretion of additional material cannot keep pace with the electrochemical reaction, supersaturation of Pb ions would increase and the nucleation overvoltage associated with less active centers may require excessive polarization. The discharge would then be terminated in order to avoid secondary electrochemical reactions and homogeneous nucleation of $PbSO_4$ in the solution. The possibility that the crystal growth rate may limit the discharge is further supported by the fact that additional discharge capacity is usually available from the electrode at reduced current densities. A crystal-growth control mechanism has been established for the deposition of $PbSO_4$ on pure lead in $2N$ H_2SO_4 (34, 58). Similar potentiostatic studies of the discharge of the PbO_2 electrode on antimonial lead would be of interest to further clarify the mechanism.

Manuscript submitted Sept. 10, 1970; revised manuscript received Nov. 9, 1970. This was Paper 50 presented at the Atlantic City Meeting of the Society, Oct. 4-9, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Concerning the Critical Pitting Potential

David A. Vermilyea*

Research and Development Center, General Electric Company, Schenectady, New York 12301

ABSTRACT

The critical pitting potential, defined as the least positive potential at which pits can be grown, may be that potential at which the metal salt of the aggressive ion in solution is in equilibrium with the metal oxide. Such an equilibrium may be achieved when the activity of the anion in the pit has been increased by the potential difference between the inside and outside of the pit. The theory successfully predicts the critical pitting potentials for aluminum, magnesium, iron, and nickel, but fails for zirconium, titanium, and tantalum.

Passive metals are susceptible to localized attack by pitting when polarized above some potential in a solution containing aggressive ions, usually halides. The potential E_c above which pitting starts has been referred to as the "critical pitting potential." For a particular alloy the critical pitting potential is known to be a function of temperature and of the nature and concentration of the aggressive ion. The experimental determination of E_c is difficult because of a variety of kinetic effects, and the values are not reliable to less than a few tenths of a volt. In this paper a new theory, based on thermodynamic considerations, is presented for the calculation of E_c. The objective is only to make a rough estimate of E_c; the current understanding of the nature of concentrated aqueous solutions precludes more precise predictions. It is the intent of the theory to predict the *minimum* E_c, which would presumably be observed at an infinitely slow increase of potential. The minimum E_c may be equal to the so-called "protection potential" at which a growing pit would become repassivated on lowering the potential.

Vetter (1) has proposed that pitting occurs when the normally protective oxide is in equilibrium with the salt of the metal and the aggressive anion. In order for such equilibrium to occur it is usually necessary for the free energies of the oxide or of the salt layer or of both layers to deviate widely from the values for the bulk compounds. As an example, the reaction

$$AlCl_3 + 3/2\ H_2O \rightarrow 1/2\ Al_2O_3 + 3HCl_{(aq)} \qquad [1]$$

results in a free energy decrease of 45.4 kcal. In order for the $AlCl_3$ and Al_2O_3 to be at equilibrium the free energy for that reaction would have to be zero, and that could be true if the solid phases were nonstoichiometric or contained aluminum with an unusual valence. Since the standard free energies of $AlCl_3$ and $\frac{1}{2}$ Al_2O_3 are -150.2 and -188.4 kcal/mole, respectively, it is clear that very large changes of some kind are required. In view of the strong preference of aluminum for a valence of $+3$ it is debatable whether such large free energy changes are reasonable.

Other investigators (2, 3) have proposed that the critical pitting potential is that potential at which adsorption of the aggressive anion becomes favored over adsorption of oxygen. At present such theories do not permit a prediction of the critical pitting potential.

The present theory of the critical pitting potential is based on changes in the free energies of substances in the aqueous solution. Consider a pure passive metal corroding at potential E_1 in a solution containing an aggressive anion. Imagine that the passive film becomes ruptured locally so that the metal starts to dissolve rapidly, forming metal ions according to

$$M \rightarrow M^{+z} + ze \qquad [2]$$

where z is the valence of the metal. If E is below E_c, repassivation occurs, while above E_c repassivation fails and the ruptured area continues to corrode according to [2]; consider the latter condition. If reaction [2] were entirely reversible and if no other reaction occurred in the pit, the local potential would fall to E_M, the value of the metal-metal ion potential appropriate to the concentration of metal ions in the pit. Actually some overvoltage is required to drive reaction [2]. If the activation overvoltage, η, is taken as the difference between the local specimen potential and E_M, then

$$\eta + \Delta\phi = E_1 - E_M \qquad [3]$$

where $\Delta\phi$ is the potential difference between the Helmholtz plane in the pit and the bulk solution.

Under the influence of $\Delta\phi$, anions move into the pit until a concentration gradient is established so that their net flux is zero. Under these conditions the electrochemical potentials of the anions inside and outside the pit are equal, so that

* Electrochemical Society Active Member.
Key words: corrosion, passivation, reaction products.

$$\mu_p + z\mathbf{F}\phi_p = \mu_b + z\mathbf{F}\phi_b \quad [4]$$

where the subscripts p and b refer to the pit and bulk solutions, respectively. From [4] it can be seen that the chemical potential of anions inside the pit is greater than that in the bulk solution by $z\mathbf{F}\Delta\phi$.

Now consider the repassivation of the ruptured area. Passivation may occur when the metal potential rises to that required to form an oxide on the surface according to

$$M + z/2\ H_2O \rightarrow MO_{z/2} + zH^+ + ze \quad [5]$$

A possible competing reaction is the formation of a solid salt on the surface according to

$$M + zX^- \rightarrow MX + ze \quad [6]$$

It is proposed that if reaction [6] becomes thermodynamically favored over reaction [5] the ruptured area will not be repassivated but will continue to corrode at a high rate. When the metal is covered with a highly soluble salt the corrosion rate can be very high even if the solution near the surface is nearly saturated with respect to the salt. For instance, if the undersaturation is 10% and the solubility 10M the diffusion-limited corrosion rate based on a stationary layer 10^{-2} cm thick would be 10^{-1} A/cm^2. For simplicity it is assumed that the normal oxide and salt are the compounds of interest. The nonprotective layer could as well be some kind of oxy-salt.

The formation of salt will be favored because of the increased chemical potential of the anion. The formation of oxide will be impeded because of the decreased chemical potential of water in the concentrated solution and possibly because of the increased chemical potential of protons caused by hydrolysis of the cations of the metal. The decreased chemical potential of water results from the fact that, at very high salt concentrations, much of the water in the solution is closely associated with the ions as water of solvation. Hydrolysis of metal ions in concentrated salt solutions can readily produce proton activities which are much higher than expected by extrapolation from dilute solutions.

While it is not possible to calculate the chemical potentials of all the species in reactions [5] and [6], it is possible to measure them and hence to test the underlying principle. While such data are not readily available, some estimates can be made to demonstrate the plausibility of the theory.

As an example, consider aluminum in chloride solutions. The standard potential for forming $AlCl_3$ according to reaction [6] is -0.84V (all potentials are on the standard hydrogen electrode scale). For the oxide the normal potential is -1.5V, and the Al/Al^{+3} standard potential is -1.66V. The pH of a saturated solution of $AlCl_3 \cdot 6\ H_2O$ was measured to be -0.3. The vapor pressure of water over such a solution is not known, but might be lower than that over pure water by a factor of 10. The equilibrium potential for forming Al_2O_3 according to reaction [5] in such a solution would be -1.45V. Because of the change of chemical potential of anions obtained from [4], the corresponding potential for $AlCl_3$ is $-0.84 - \Delta\phi$ and hence, for a bulk solution with unit chloride ion activity, salt and oxide are equally stable when $\Delta\phi = 0.61$V. The activity of aluminum ions cannot be calculated. However, the chloride ion concentration must be very high if $AlCl_3$ is to be formed, and the Al^{+3} concentration must also be high to keep the solution neutral. The activity of Al^{+3} in the pit will probably be of the same order of magnitude as that of Cl^-. With that assumption $E_M = -1.66 + \Delta\phi/3 = -1.46$V. Equation [3] then gives $E_1 = -0.85 + \eta$. The overvoltage cannot be calculated, but for the large current densities associated with pitting it is probably a few tenths of a volt. Thus the theory predicts a pitting potential somewhere in the vicinity of -0.6V; aluminum is actually observed to pit at about -0.5V. The predicted pitting potential is close enough to the observed values to be intriguing and to suggest that there is some validity to the theory.

A similar analysis for magnesium shows that pitting should occur at about -1.5V, again in reasonable agreement with observations. For iron and nickel the chlorides should form at -0.2 and -0.05V, respectively, which are lower than the corresponding potentials for the oxides in acid solutions. Iron and nickel do pit in chloride solutions at potentials just above those at which the chlorides become stable.

The theory fails badly for some metals, however. Zirconium is predicted to pit at $E_1 = 0.9 + \eta$, while pitting is observed at about $+0.4$V. About 10V must be applied to cause titanium to pit, and tantalum can be anodized in chloride solutions to at least 100V without pitting. It is not known why these metals of higher valence do not pit at lower potentials. The answer may lie in the details of the molecular processes which yield the halides and oxides.

Discussion

According to this theory the pitting potential must always be sufficiently positive to the metal-metal ion potential to make equal the free energies of formation of the oxide and the salt. Thus a minimum pitting potential is a clear prediction of the theory. The actual pitting potential may exceed the minimum because of a variety of kinetic factors but, if this theory is valid, may not be less than the predicted minimum.

Experimental determination of the critical pitting potential appears to be very difficult, for values reported by different authors for the same system often differ greatly. Evidently the critical potential is a function of time, film history, and metal surface preparation. The theory predicts a change of the critical pitting potential by about 0.059V per decade of concentration at 25°C. A recent paper by Leckie (4) reports a variation of 0.070V per decade for stainless steel in chloride solutions in reasonable agreement with the theory. Kolotyrkin (5) has quoted results by Gilman which show such a dependence of critical pitting potential of zirconium on chloride concentration, but as pointed out above the theory does not seem to work well for zirconium. Studies on alloys (6, 7) and on nickel show that the critical pitting potential changes by 0.2-0.4V per decade of anion concentration, in conflict with the prediction above. However, the experiments reported often used a supporting electrolyte, which provides a complication not easy to resolve, and the behavior of an alloy may be different from that of a pure metal. Studies using pure metals in solutions containing only one anion are required to test the theory, and care must be taken to minimize contributions from convection and resistive potential drops in the bulk solution (outside the Nernst layer).

Some of the examples above led to the conclusion that potential differences as large as several tenths of a volt might be present in the solution. For reasonably concentrated solutions such potential differences are probably possible only with some kind of restricted geometry. For example, the growing section of the pit may be covered with a perforated layer of the passive film which originally covered the metal. Such films have been reported by many investigators.

Prediction of the ions which will act in an aggressive manner is not straightforward. The theory proposed above predicts the formation of a concentrated solution of any anion and, presumably, the precipitation of the salt of that anion. Whether the ion will be aggressive or not depends on the next step: Will the salt layer simply dissolve at a high rate and prevent passivity or will it be converted in some way to a passive layer? The answer to that question requires a more complete understanding of the mechanism of the active-passive transition. It is worth noting, however, that the most aggressive ions do not contain oxygen. Possibly films containing oxyanions can more easily be

converted to passive layers than can films containing halides, cyanides, sulfides, and other aggressive anions.

The Electrochemical Oxidation and Reduction of Gold

Kotaro Ogura,,[1] Shiro Haruyama, and Kyuya Nagasaki**

Chemistry of Metals Laboratory, Faculty of Engineering, Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT

Anodic film was formed on a gold electrode by the potentiostatic technique and then reduced cathodically. The amounts of charge needed for anodization, Q_a, were evaluated by graphical integration of transient currents, and the amounts of charge, Q_c, needed to reduce the film were obtained from the chronopotentiogram. In weak acidic solutions, log Q_a was proportional to E_a, and the auric hydroxide could grow continuously at noble potentials without the accompanying evolution of oxygen. In strong acidic solutions, however, log Q_a was not proportional to E_a but log $(Q_a - Q'_{a\ 1600\ mV})$ was proportional to E_a at noble potentials. In these strong acidic solutions, oxygen evolved on the auric oxide, and this oxide layer grew only to a fixed thickness. On galvanostatic reduction of the oxide film, an arrest was observed in the chronopotentiogram. It was concluded that the potential determining reaction at this arrest potential varied according to the pH ranges as shown in the following reactions

$$Au_2O_3 + 6H^+ + 6e \rightarrow 2Au + 3H_2O$$

(in strong acidic solutions)

$$Au(OH)_3 + 3H^+ + 3e \rightarrow Au + 3H_2O$$

(in weak acidic solutions).

The electrochemical formation and reduction of oxide films on noble metals, especially platinum, have been actively investigated (1-5). The surface oxide formed on platinum has been reported to have the ability to transfer electric charge from the metal to a reactant in the solution without an appreciable increase in film thickness; that is, the oxide film on platinum is an electronic conductor.

However, in the case of a gold electrode, the anodic film can grow thicker than a monolayer; a charge transfer reaction always accompanies this increase in film thickness. This means that the oxide film on gold is ion conducting rather than electron conducting.

Noble metals have been considered to be inert. However, two different types of oxide may exist on these noble metals and may affect electrochemical reactions in different ways. Also, there may be some differences in polarization behavior among the noble metals. In this sense, the gold electrode was studied in this work.

Some investigators (6-10) have studied an oxide film on gold by means of the galvanostatic technique of oxidation and/or reduction. Recently, some work has been performed using the potentiostatic technique combined with galvanostatic measurements (11, 12). This process is potentiostatic oxidation and galvanostatic reduction; however, the results of these latter studies do not always agree with each other. The investigators who used the potentiostatic technique paid attention not to the amount of charge passed during oxidation, Q_a, at constant potential, but to the amount of charge, Q_c, needed for cathodic reduction after charging the circuit to the galvanostatic technique. There is no experimental evidence that Q_c can be considered to equal Q_a; rather data reported in this paper and supported by Vetter and Berndt (6) show that they do not coincide.

In the present work, the amount of charge needed for potentiostatic oxidation was evaluated by a graphical integration of current-times curves. Also, the kinetics of the oxidation and reduction of a gold electrode were studied by the combination of potentiostatic and galvanostatic techniques. The oxygen evolution reaction on gold and the manner in which it is affected by the oxide formed during anodization are also discussed.

Experimental

Sample.—The electrode used in this study was a 99.99% gold foil 0.1 mm thick and 0.9 cm^2 in apparent area. The specimen was abraded with emery paper. Electropolishing was tried at first to obtain minimum roughness but had to be abandoned because of preferential attack at the edges. The foil was connected through a piece of gold wire to a tungsten wire, which was sealed in a glass tube. Only the foil and the lower part of the gold wire were immersed into the electrolytic solution during experiments.

Electrolytic solution.—The solution was prepared to 0.1 m/l in $HClO_4$ by perchloric acid of analytical grade and water redistilled from a basic permanganate solution. The pH of the solution was adjusted from 0.5 to 7.6 with sodium hydroxide solution. The solution was deaerated with purified nitrogen which was passed through a column of active copper heated at 200°C.

[1] Present address: Department of Chemistry, Rice University, Houston, Texas 77001.

Key words: oxidation, reduction, gold, amount of charge, rest potential.

The final solution was pre-electrolyzed for 48 hr. This was carried out at a current density of 80 $\mu A/cm^2$ so that the impurities would be eliminated but no H_2O_2 would be formed.

Cell.—Electrochemical measurements were made with a three-electrode system composed of a gold test electrode, a platinum counterelectrode, and a hydrogen reference electrode which was connected to the working electrode through a Luggin capillary. The counterelectrode was a cylindrical platinum foil sealed into a cylinder of 3 cm diameter. The reference electrode was put in a separate compartment which was connected to the test cell through a stopcock. The electrolytic solution in which the reference electrode was immersed was the same as the test solution. Potentials were measured with respect to the reversible hydrogen electrode (RHE) unless otherwise noted.

Method.—The specimen was polished with emery paper and was cathodically reduced to eliminate the oxide film or adsorbed oxygen formed on it in air. The cathodic current density was 22.4 $\mu A/cm^2$. Cathodic reduction was stopped when the potential reached 0 mV (RHE) in order that the effect of hydrogen evolution during cathodic reduction might be minimized. In order to obtain reproducible results, the cleaned specimen was pre-anodized at a constant potential of 600 mV (RHE) for 1 min. The amount of charge needed for the pretreatment was small enough to be neglected.

The specimen was then anodically oxidized by means of a potentiostat (Nichiya NP 250 Type) for a measured length of time. The change of current with time after application of the constant potential was followed by recording the ohmic drop across a standard 100 ohm resistor inserted in the polarization circuit. The amount of charge passed during anodization was evaluated by graphical integration of transient currents. This was performed with a planimeter. The oxidized gold electrode was reduced electrochemically at a constant current density. The change of potential with time was monitored by means of a recorder equipped with a preamplifier having an input impedance of 10^9 ohms.

The experiments were carried out at 16° ± 2°C in an atmosphere of purified nitrogen gas. Solution agitation was accomplished by bubbling nitrogen gas through a capillary tube placed beneath the test electrode.

Results and Discussion

Anodic oxidation.—Oxidation at less noble potentials.—The amount of charge passed, Q_a, at various constant potentials was calculated by graphical integration. Q_a was increased by shifting the potential to more positive values, as shown in Fig. 1 and 2.

From these figures, it can be seen that Q_a also increased by increasing the anodizing time and that Q_a is generally larger in higher *p*H solutions, from a comparison of Fig. 1 and 2. The following process may be envisioned to interpret these figures: a *p*H dependent chemical species adsorbs on the electrode surface

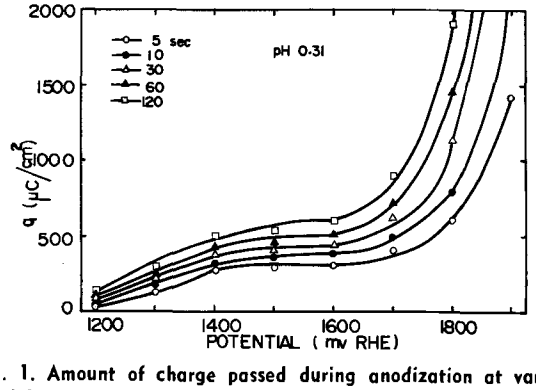

Fig. 1. Amount of charge passed during anodization at various potentials.

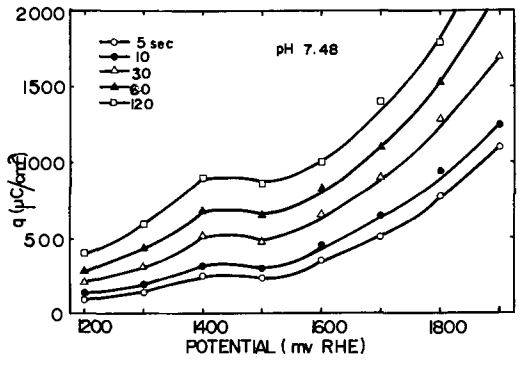

Fig. 2. Amount of charge passed during anodization at various potentials.

at less noble potentials; a stoichiometric compound of this species forms at about 1450 mV. At potentials more positive than about 1600 mV, either this compound continues growing or some other electrochemical reaction like oxygen evolution occurs. In the following sections, these assumptions are discussed in relation to additional experimental results.

In Fig. 3, values of Q_a obtained at various set potentials are plotted against the logarithm of time. Q_a can be seen to increase in proportion to log t_a at potentials less than or equal to 1300 mV. At potentials greater than or equal to 1400 mV, the linear relation between Q_a and log t_a is divided into two parts. It may be considered that a single reaction occurs at constant potentials less than or equal to 1300 mV.

As shown in Fig. 4, Q_a at lower *p*H values is independent of *p*H but does become *p*H dependent at higher values. This means that the single reaction which occurs at less noble potentials is *p*H dependent. The following equation holds for the more negative potential range

$$Q_a = \log t_a{}^n + m \qquad [1]$$

In weak acidic solutions, n and m are constants at fixed values of potential and *p*H. In the initial period

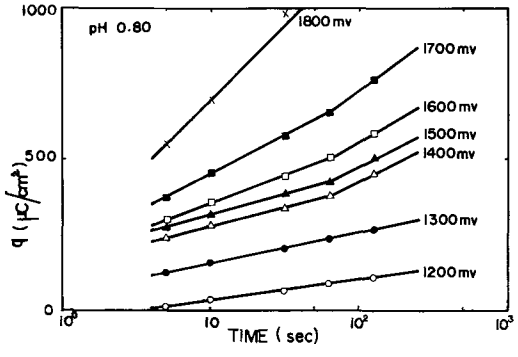

Fig. 3. Amount of charge as a function of time at various potentials.

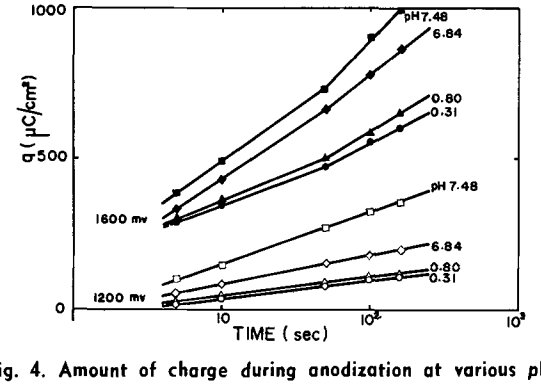

Fig. 4. Amount of charge during anodization at various *p*H's

of time (within a few seconds in this experiment), n of Eq. [1] depends only on potential as shown in Fig. 4. At lower pH, Q_a was essentially independent of solution pH. It is reasonable to assume that oxygen is adsorbed in the potential range in which the linear relationship between Q_a and log t_a holds. As shown in Fig. 1, Q_a increases with potential and has an arrest at about 1450 mV; these effects may be due to the adsorption of oxygen and auric oxide formation. The following process may be considered upon anodization at lower pH: $Au \rightarrow AuO \rightarrow Au_2O_3$. Oxygen evolution follows this process and is discussed in the next section.

As shown in Fig. 4, Q_a is pH dependent in weak acidic solutions. Figure 2 shows an arrest of Q_a at about 1450 mV. These results can be interpreted by considering OH radical adsorption followed by complex hydroxide formation and a stoichiometric layer of $Au(OH)_3$, as illustrated in the following process: $Au \rightarrow AuOH \rightarrow Au(OH)_x \rightarrow Au(OH)_3$. After $Au(OH)_3$ is formed on the surface of gold, Q_a increases again continuously with potential, as shown in Fig. 2. However, oxygen could not be visibly observed even at high anodic potentials (about 1900 mV); therefore, at least within the limits of these experiments, $Au(OH)_3$ could grow without the accompanying evolution of oxygen.

Oxidation at noble potentials.—As shown in Fig. 5, log Q_a increases in proportion to the set potential, E_a, in high pH solutions. Based on the linearity between log Q_a and E_a, it may be assumed that only a single reaction occurs under the experimental conditions used in this section. In the former section, the formation of $Au(OH)_3$ was assumed to occur in high pH solution. This same assumption can be used to interpret the results shown in Fig. 5; that is, $Au(OH)_3$ may grow in the range from 1500 to 1900 mV. By comparing Fig. 2 and Fig. 5, it can be determined that $Au(OH)_3$ which formed at about 1450 mV continues to grow at more noble potentials without the accompanying evolution of oxygen.

A similar plot of log Q_a *vs.* E_a was tried for strong acidic solutions; however, there was no linearity between log Q_a and E_a in this case. This lack of linearity means that the oxide film on gold in low pH solutions does not continue to grow at more noble potentials. However, the logarithm of the amount of charge, $(Q_a - Q'_{a1600\ mV})$, which is the charge that passed at 1600 mV, $Q'_{a1600\ mV}$, subtracted from the total charge passed, Q_a, was proportional to the set anodizing potential, E_a, as shown in Fig. 6 and 7. $Q'_{a1600\ mV}$ can be regarded as the amount of charge used in the formation of a fixed amount of Au_2O_3 film on gold. Thus, $(Q_a - Q'_{a1600\ mV})$ must be considered to be the amount of charge which was used for the other charge transfer reaction. This reaction is oxygen evolution as described earlier. The effect of solution agitation is shown in Fig. 6. The slope, $(Q_a - Q'_{a1600\ mV})/E_a$, did not change, but the magnitude of $(Q_a - Q'_{a1600\ mV})$ increased at each potential. If the Au_2O_3 film was continuing to grow, then the effect of agitation would be negligible, because the growth of this film is the reaction between

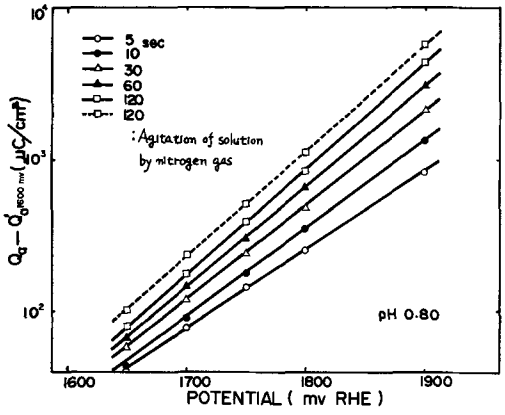

Fig. 6. Logarithmic dependence of charge on potential

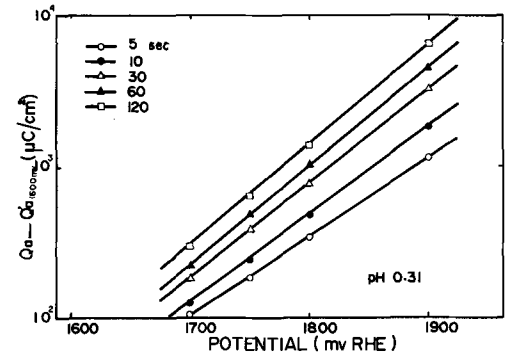

Fig. 7. Logarithmic dependence of charge on potential

two solid phases. However, experimentally, the effect of agitation is not negligible; therefore, the charge transfer reaction is not the growth of the oxide, Au_2O_3, but oxygen evolution at potentials more positive than 1600 mV. It may be concluded that Au_2O_3 is a better electronic conductor than $Au(OH)_3$, and conversely, $Au(OH)_3$ is a better ionic conductor than Au_2O_3. Oxygen evolves on Au_2O_3 without being affected by its presence; however, the oxygen evolution reaction on $Au(OH)_3$ is concealed by the growth of the oxide, $Au(OH)_3$. At pH values intermediate between extreme values used in this study, the growth of oxides occurs simultaneously with the occurrence of oxygen evolution.

Cathodic reduction.—At low pH solutions.—The gold specimen was anodized for an arbitrary length of time at constant potential and then was quickly cathodized by a constant current in order to reduce the oxide film on it. The chronopotentiograms obtained are shown in Fig. 8. These reduction curves have the same arrest potential and, indeed, are very similar in shape. A typical chronopotentiogram has an arrest potential at 1200 mV. This arrest potential was not affected either by the anodizing potential or by agitation of the

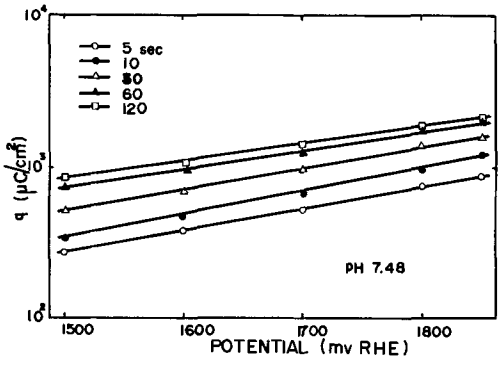

Fig. 5. Logarithmic dependence of charge on potential

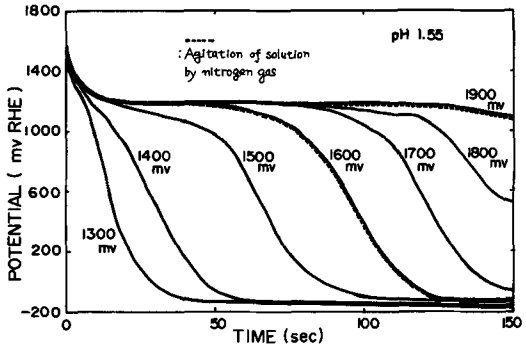

Fig. 8. Cathodic reduction curves

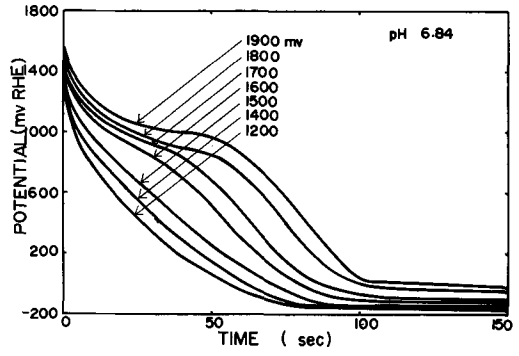

Fig. 9. Cathodic reduction curves

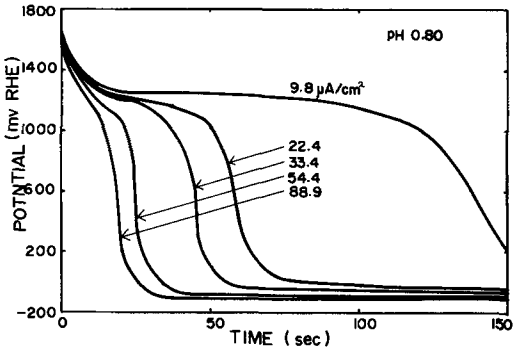

Fig. 10. Cathodic reduction curves

solution; therefore, the compositions of the oxide formed at various potentials in these low pH solutions are all the same. The arrest potential may be due to the reduction of Au_2O_3; this is discussed in a later section.

At high pH solutions.—In weak acidic solutions, the arrest potential shifts in a more cathodic direction as the anodizing potential is decreased, as shown in Fig. 9. This shift of potential may be interpreted as being caused by a change in activity of the $Au(OH)_3$ film; that is, the activity of $Au(OH)_3$ layer may decrease with the shift of the set anodizing potential toward the more cathodic direction. In a strong acidic solution, however, the arrest potential does not depend on the anodizing potential, possibly because the activity of oxide, Au_2O_3, is scarcely changed by the set anodizing potential.

Dependence of the arrest potential[2] *on current density.*—As shown in Fig. 10, the potential arrest shifts in a more cathodic direction as the reduction current density is increased. This dependence can be interpreted as the current dependent shift of overpotential. In Fig. 11, the arrest potential is plotted in the SCE scale *vs.* the logarithm of current density. The resulting plot shows that the potential-current density relationship obeys the Tafel relation

$$E_c = a + b \log i \qquad [2]$$

The value of b was found to be approximately 60 mV. The arrest potential, E_c, depended on the pH; however, the Tafel relation held in all of the experimental conditions.

Dependence of the arrest potential on pH.—From Fig. 12, it can be seen that E_c shows two different pH dependencies, one for weak acidic solutions and one for strong acid solutions. However, in both pH ranges, E_c was proportional to pH; this slope was approximately 60 mV/pH. This result corresponds very closely to the value of 59.2 mV/pH obtained by Vetter and Berndt (6). The reaction occurring at the arrest potential can be inferred from the dependence of E_c on pH in the following manner. Considering only the contribution

[2] This potential was measured at high sensitivity by changing the range of the recorder (±0.5 mV) in the region of the inflection.

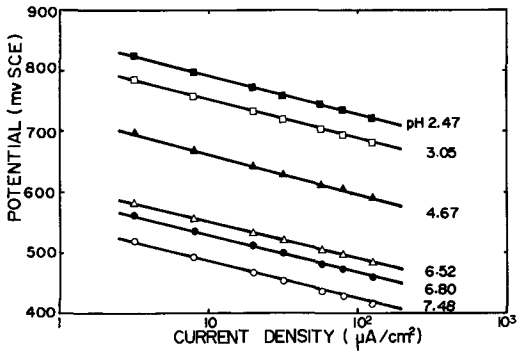

Fig. 11. Dependence of the arrest potential on cathodic current density.

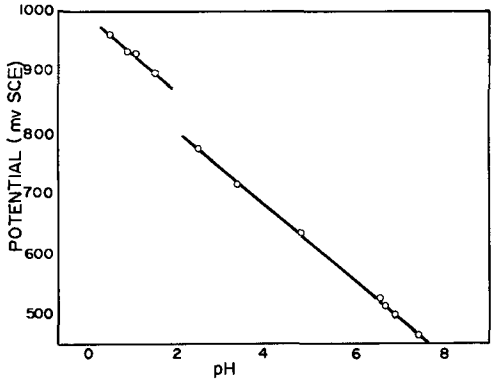

Fig. 12. Dependence of the arrest potential on pH

of H^+, the potential may be expressed by the following equation

$$E_c = E'_c + RT/n\mathbf{F} \log (H^+)^{n'} \qquad [3]$$

where n' is the number of moles of hydrogen ions which participate in the potential determining reaction. Differentiating Eq. [3] by pH

$$\partial E_c/\partial \mathrm{pH} = -2.30\, n'RT/n\mathbf{F} \qquad [4]$$

Since $\partial E_c/\partial$pH was experimentally found to be −60 mV/pH, n' equals n. Therefore, the number of electrons which participated in the reaction must be equal to the number of moles of hydrogen ion.

A metallic ion in solution can be assumed not to participate in this potential determining reaction, because the potential was not affected by the agitation of solution as was shown in Fig. 8. Accordingly, the potential determining reaction must be a solid-solid reaction involving hydrogen ions. It is reasonable to assume the following reactions for the potential arrest in strong and weak acidic solutions

$$Au_2O_3 + 6H^+ + 6e \rightarrow 2Au + 3H_2O \qquad [5]$$

(in strong acidic solutions)

$$Au(OH)_3 + 3H^+ + 3e \rightarrow Au + 3H_2O \qquad [6]$$

(in weak acidic solutions)

The equilibrium potential was calculated to be 1.511V for Eq. [5] and 1.457V for [6] (13).

Q_c and ratio of Q_c/Q_a.—The amounts of charge, Q_c, needed for cathodic reduction were calculated from the chronopotentiograms and were found to depend on the set potentials as shown in Fig. 13. Similar results have been reported by other investigators (11, 12). In strong acidic solutions, there are two discontinuous points, but in weak acidic solutions there is only one continuous point. There seems to be certain relations between these experimental results and the anodizing process; that is, the three linear parts in the Q_c-potential diagram in strong acidic solutions may correspond

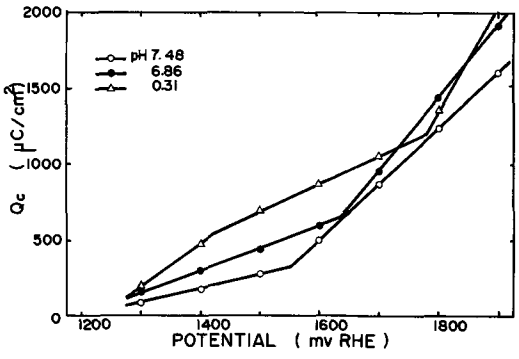

Fig. 13. Relation between the amount of charge needed for cathodic reduction and anodizing potentials.

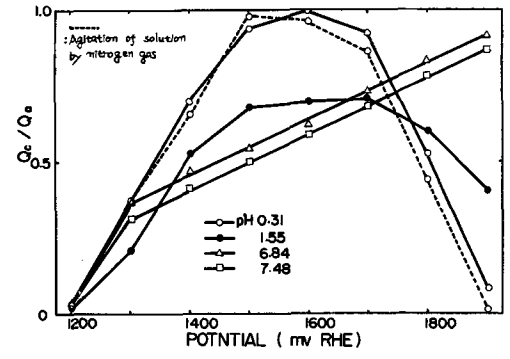

Fig. 14. Relation between Q_c/Q_a and anodizing potentials

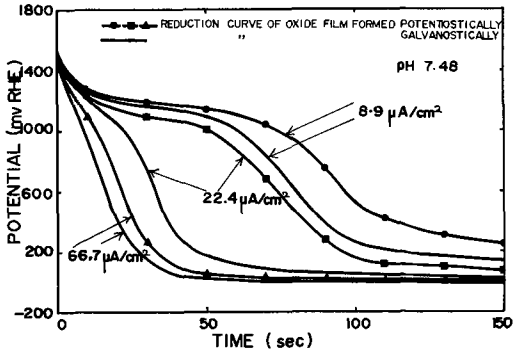

Fig. 15. Cathodic reduction curves

to the formation of a monolayer, the growth of Au_2O_3, and the evolution of oxygen, respectively. The two linear parts in the case of weak acidic solutions can be considered to correspond to the formation of non-stoichiometric $Au(OH)_x$ and the growth of $Au(OH)_3$, respectively.

The ratio of Q_c to Q_a has been reported to have values from unity to 0.5 (6) or to be unity (10). However, in this study, the relation between Q_c/Q_a and potential in several solutions with different pH values is shown in Fig. 14. In strong acidic solutions, Q_c/Q_a increased with increasing potential until about 1600 mV but then decreased on shifting the potential to values more positive than 1600 mV. In weak acidic solutions, Q_c/Q_a always increased with increasing potentials. It is clear that the decrease of Q_c/Q_a in the case of strong acidic solutions is due to the oxygen evolution reaction. In the anodizing process, some excess change may have been used for the formation of molecular oxygen in addition to that used for the oxide film on gold. In the reduction process, it may be difficult for an oxygen molecule which has desorbed from the electrode surface to be reduced, because the oxygen can diffuse away from the electrode surface. This view was also supported by the effect of agitation of solution. At potentials more positive than 1600 mV, Q_c/Q_a on solution agitation was always smaller than for the case in which the solution was not agitated. The desorption of molecular oxygen from the electrode surface became easier as a result of solution agitation; therefore, Q_a increased. In the case of weak acidic solutions, Q_c/Q_a increased continuously with potential as the result of the growth of $Au(OH)_3$ which may occur at all ranges of potential used in this experiment. When the set anodizing potential was shifted to more positive potentials, the amount of charge which participated in the oxidation process seems to approach that which participated in the reduction process.

Galvanostatic oxidation and reduction.—In the above section, the oxide film on gold produced by the potentiostatic technique was discussed; in this section, oxide film produced galvanostatically is discussed. The oxidized gold was reduced at a constant current density, and the change of potential with time was measured as shown in Fig. 15. The cathodic chronopotentiograms were compared with the results obtained for the specimen anodized at constant potential. It is found from Fig. 15 that the arrest potential during reduction was the same regardless of whether the gold electrode was anodized potentiostatically or galvanostatically. The oxide film formed by the two different techniques can be considered to be identical at the same pH. Accordingly, it is reasonable for the present results to be compared with the galvanostatic oxidation results obtained by others (6-10).

Kinetics of Anodic Processes on Iron in Alkaline Solutions

S. Asakura* and Ken Nobe*

School of Engineering and Applied Sciences, University of California, Los Angeles, California 90024

ABSTRACT

Anodic transients of iron in 1*N* KOH solution have been investigated. After the electrode was maintained at a potential E_R until steady state was achieved, either an anodic potential step or a potential sweep were imposed. For a potential step, the current transient i_a followed the relations

$$i_a \alpha 1/t, \text{ for } E_R < -1.1\text{V } vs. \text{ SCE}$$

and

$$i_a \alpha 1/\sqrt{t} \exp\left(-\frac{FE_R}{7RT}\right), \text{ for } E_R > -1.0\text{V}$$

where t is the time after the imposition of the potential step. For a potential sweep of sweep rate, λ, a peak current i_p was observed where

$$i_p \alpha \sqrt{\lambda} \exp\left(-\frac{FE_R}{6.5RT}\right), \text{ for } E_R > -1.0\text{V}$$

For $E_R < -1.1$V the current transients for both potential step and potential sweep polarization were interpreted in terms of the logarithmic growth of an oxide. For $E_R > -1.0$V, a duplex structure of the oxide layer, Fe/Fe_3O_4/ mixed oxide/solution, was assumed, where the mixed oxide consisted of Fe(II) and Fe(III) oxy compounds. The current transient behavior was attributed to composition changes in the mixed oxide layer due to diffusion of Fe(II). The experimental results can be satisfactorily interpreted by assuming the existence of the complex ions, $Fe(OH)_6^{4-}$ and $Fe(OH)_6^{3-}$, in the oxide film.

It is known that iron is easily passivated in alkaline solutions. However, Weil (1) did not observe a Flade potential during the decay after anodic polarization of iron in 1*N* NaOH. Kabanov, Burstein, and Frumkin (2) reported that iron in NaOH oxidized to $Fe(OH)_2$ and $Fe(OH)_3$. Initially, Fe oxidized readily to $Fe(OH)_2$ until the formation of a passive oxide layer. Burstein (3) found that small amounts of oxygen activated rather than passivated iron. Hurlen (4) observed that galvanostatic anodic transients of iron in alkaline solutions exhibited potential arrests at about the reversible FeO/Fe_2O_3 or $Fe(OH)_2/Fe(OH)_3$ and Fe_3O_4/Fe_2O_3 potentials. He concluded that active iron dissolution in both acidic and alkaline solutions followed the same mechanism since the same anodic Tafel slopes and the reaction orders were obtained. Foley, Kruger, and Bechtoldt (5) examined anodic surface films on iron by electron diffraction and concluded that the passive film was γ-Fe_2O_3; the non-passive film did not contain γ-Fe_2O_3; in 0.1*N* NaOH solution, the film consisted of Fe_3O_4 or a mixture of γ-Fe_2O_3 and Fe_3O_4 at -1.0V (*vs.* SCE), γ-Fe_2O_3 at $+0.5$V and Fe_3O_4 in the transpassive region at 1.0V.

Shepherd and Schuldiner (6) examined the steady state potentiostatic polarization of iron in NaOH and LiOH solutions. Their experiments were conducted in a highly pure gas tight system. Under these conditions, iron did not corrode significantly and behaved like an inert noble metal. This behavior was not observed for solutions containing small amounts of chloride ions. An examination of the literature indicated that, in general, iron in alkaline solutions exhibited rather unstable steady state behavior. In addition, reproducible surface conditions were very difficult to attain. Although transient studies could provide additional information, few such studies have been reported. In this study, the anodic transient behavior of pure iron in alkaline solution was studied by means of the potential step and potential sweep methods. While the steady state experiments usually yielded irreproducible results, the transient results were reproducible.

Key words: corrosion, oxide, oxidation.

Experimental

1*N* KOH solution deaerated with purified nitrogen was used as an electrolyte. The electrodes which were made of Ferrovac E iron with a purity of 99.91% was sealed in Teflon tubing. The electrode surface was polished with 2/0 emery paper and washed with water, degreased, and rinsed several times with benzene. The potential steps were provided by an electronic step function generator and a potentiostat. A function generator was used for the potential sweep experiments. Potentials were measured with respect to the saturated calomel electrode.

Results

Potentiostatic experiments.—The electrode was oxidized briefly at the potential where oxygen evolution was first observed and then set at a more negative potential, E_R, until a steady state current was attained. Then, an anodic or positive potential step, E_a, having a value more positive than E_R, was imposed. A few examples of current transients are given in Fig. 1 and 2. As can be seen in the log-log plots of Fig. 1 and 2, log

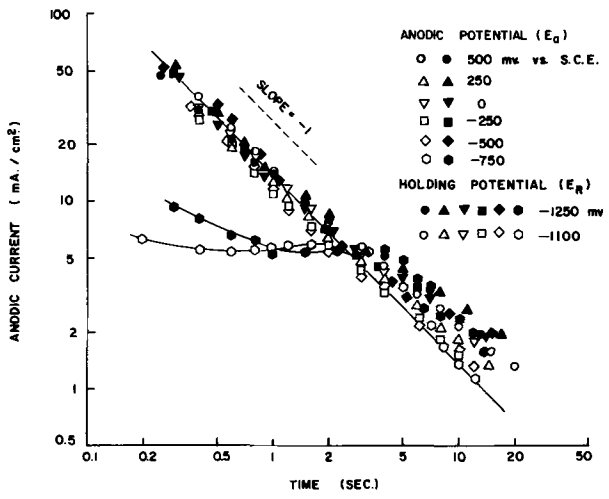

Fig. 1. Current transients of potential steps. $E_R < -1.1$V

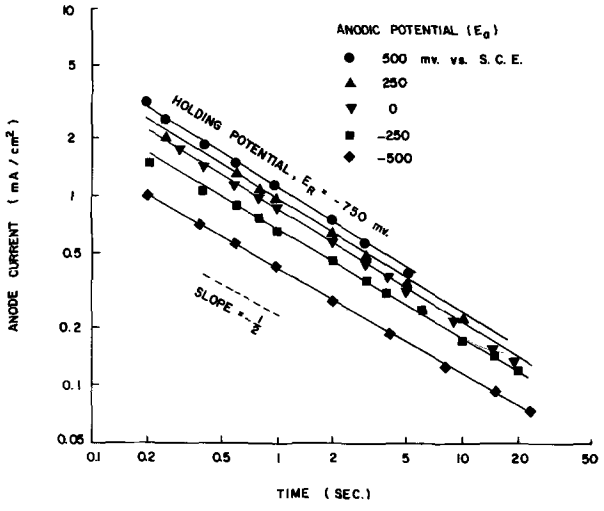

Fig. 2. Current transients of potential steps. $E_R > -1.0V$

current decreased linearly with log time except for a few cases which will be discussed later. The current i is related to time t as follows

$$i = k\,t^p \qquad [1]$$

where k and p are functions of E_a and E_R. The variation of p with respect to E_R and E_a is shown in Fig. 3.

It is found that p is indepedent of the anodic potential and changes from -1 to about -0.5 at approximately -1050 mV.

$$\begin{aligned} p &= -1 \text{ for } E_R < -1100 \text{ mV} \\ p &= -0.5 \text{ for } E_R > -1000 \text{ mV} \end{aligned} \qquad [2]$$

In the region, $E_R < -1100$ mV, the current transient was not affected by the anodic potential as long as E_a was positive enough. However, when E_a is not positive enough relative to E_R, for example, $E_a = -750$ mV as in Fig. 1, the current initially stays at a fairly constant value and then follows the same relation as other curves.

In the region $E_R > -1000$ mV, the current was dependent on the anodic potential, E_a. In Fig. 4, the current at $t = 1$ sec was plotted *vs.* E_a for two different values of E_R. These plots show that the current tends toward limiting values. The current at $t = 1$ sec and $E_a = 500$ mV was plotted *vs.* E_R in Fig. 5. A linear relation was obtained between the log of the above current and E_R with the slope of -425 mV/ decade.

$$\left(\frac{\partial E_R}{\partial \log i}\right)_{t=1,\,E_a} = -425 \text{ mV/decade}; \; E_R > -1000 \text{ mV} \qquad [3]$$

Thus, the current transients can be expressed by

$$i = k_1/t \text{ for } E_R < -1100 \text{ mV} \qquad [4]$$

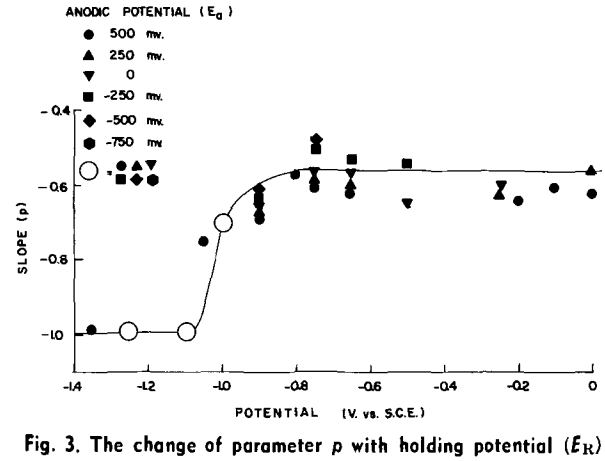

Fig. 3. The change of parameter p with holding potential (E_R)

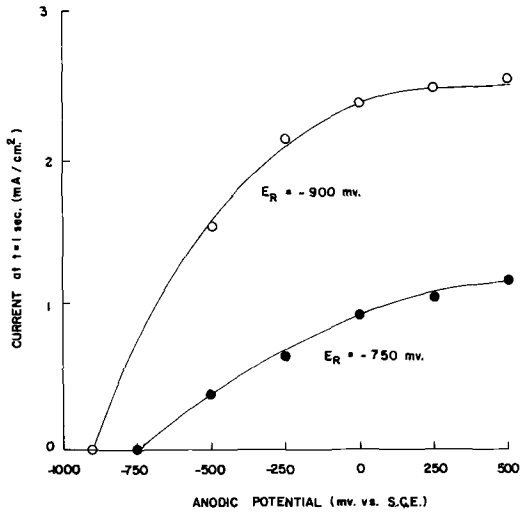

Fig. 4. Dependence of current at $t = 1$ sec on anodic potential (E_a). $E_R > -1.0V$

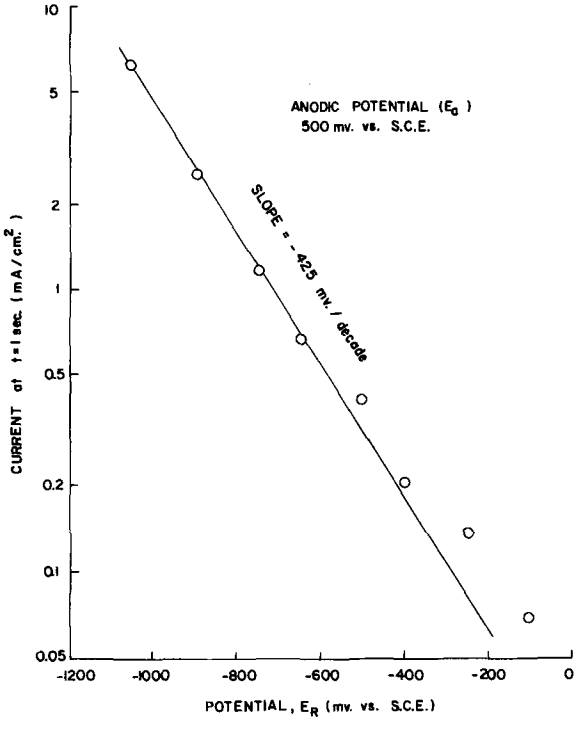

Fig. 5. Dependence of current at $t = 1$ sec on the holding potential (E_R).

$$i = k_2/\sqrt{t}\exp\left(-\frac{mF}{RT}E_R\right) \text{ for } E_R > -1000 \text{ mV} \qquad [5]$$

where k_1 and k_2 are constants and $m \approx 1/7$.

Potential sweep experiments.—After the electrode was maintained at E_R until the steady state was reached, a potential sweep in the positive potential direction was imposed. A few examples of the potential-current behavior are shown in Fig. 6 and 7. As seen in these figures, the potential-current characteristics for the holding potentials above -1000 mV and below -1100 mV are different. The peak potential E_p is defined as the potential at the maximum or peak current i_p, in the potential-current curves shown in Fig. 6 and 7. The peak potentials are plotted against E_R in Fig. 8. While E_p was constant for $E_R < -1100$ mV, it increased linearly with E_R for $E_R > -1000$ mV.

$$\partial E_p/\partial E_R \approx 1 \text{ for } E_R > -1000 \text{ mV} \qquad [6]$$

It should be noted that E_p is a minimum at approximately $E_R = -1050$ mV.

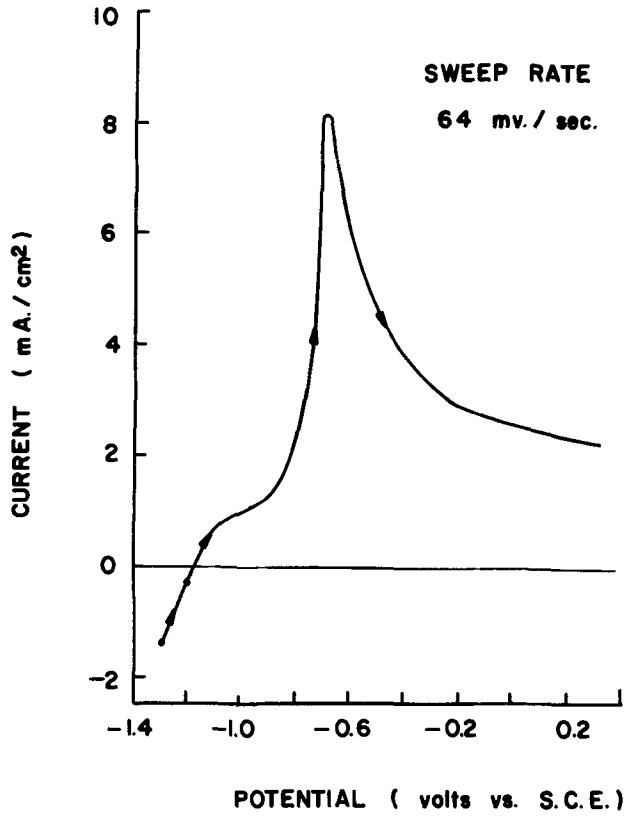

Fig. 6. Potential-current curve for a potential sweep polarization. $E_R < -1.1V$.

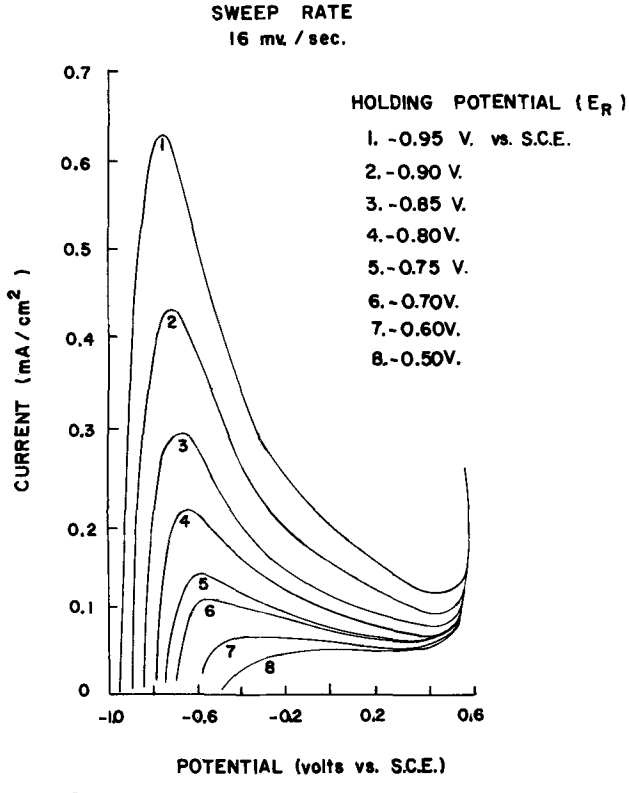

Fig. 7. Potential-current curve for a potential sweep polarization. $E_R > -1.0V$.

A Tafel plot of the ascending part of the $E_a - i_a$ curve in Fig. 6 is shown in Fig. 9. The Tafel slope was approximately 120 mV/decade

$$\frac{\partial E_a}{\partial \log i_a} \approx 120 \text{ mV/decade for } E_R < -1100 \text{ mV} \quad [7]$$

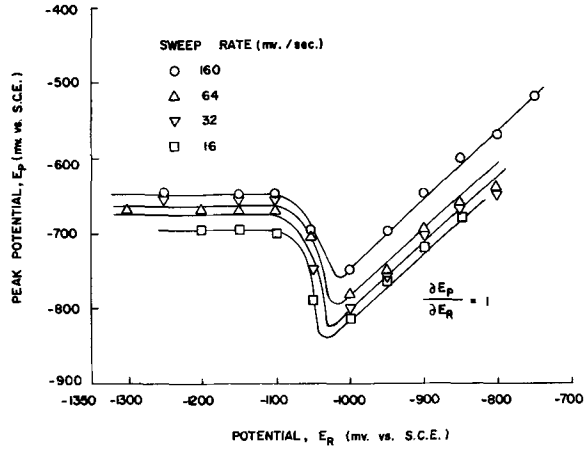

Fig. 8. Dependence of peak potential on holding potential (E_R)

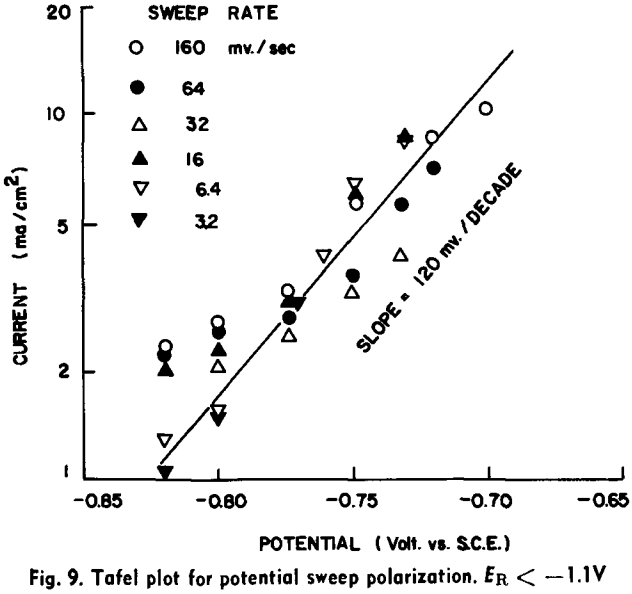

Fig. 9. Tafel plot for potential sweep polarization. $E_R < -1.1V$

The peak current, i_p, was plotted as a function of E_R in Fig. 10. For the potential region, $E_R < -1100$ mV, i_p is independent of E_R and only a function of the sweep rate, λ, as shown in Fig. 11. Therefore

$$i_p = k_3 \lambda^{\alpha} \text{ for } E_R < -1100 \text{ mV} \quad [8]$$

where k_3 and α are constants. On the other hand, for $E_R > -1100$ mV, i_p varied with both E_R and λ. A linear relationship was obtained for the log i_p *vs.* E_R plot as shown in Fig. 10.

$$\frac{\partial \log i_p}{\partial E_R} \approx -390 \text{ mV/decade for } E_R > -1000 \text{ mV} \quad [9]$$

A log-log plot of peak current at $E_R = -800$ mV and λ is shown in Fig. 11. A linear relationship with a slope of ½ was obtained. Thus

$$i_p = k_4 \sqrt{\lambda} \exp\left(-\frac{MF}{RT} E_R\right) \text{ for } E_R > -1000 \text{ mV} \quad [10]$$

where $M \approx 1/6.5$ and k_4 is a constant. In both potentiostatic and potential sweep experiments, stirring the solution did not affect the transient current. Furthermore, no measurable dissolution of iron was observed. The steady state current at E_R was less than 10 μA/cm² in the potential region from −1.2V to +0.55V.

Discussion

Thermodynamic consideration.—The experimental results indicate that anodic characteristics of iron are

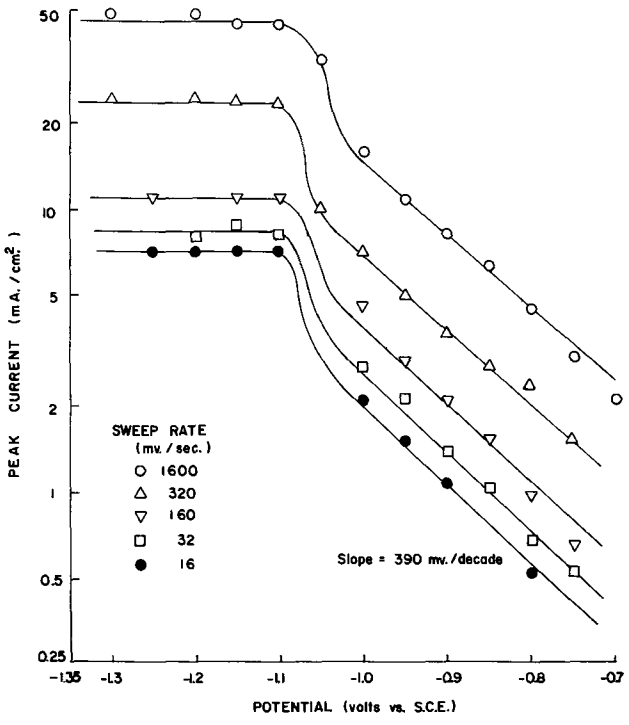

Fig. 10. Peak current *vs.* holding potential (E_R)

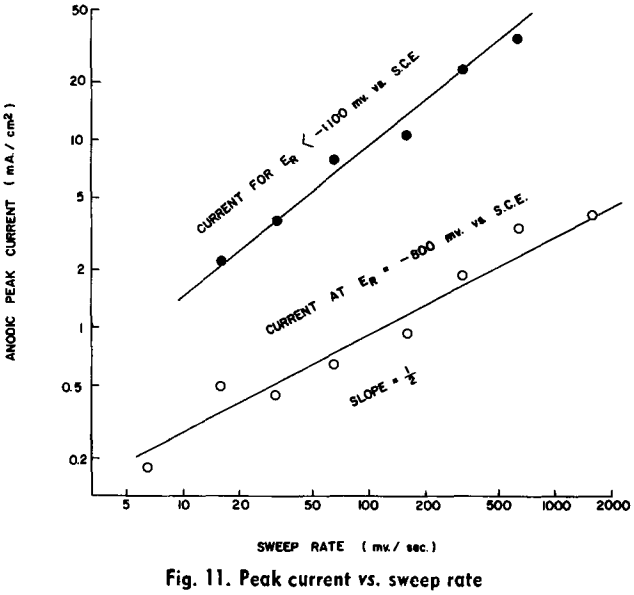

Fig. 11. Peak current *vs.* sweep rate

different for $E_R < -1100$ mV than for $E_R > -1000$ mV. It was observed that the transient behavior for $E_R < -1100$ mV was not affected by E_R, but varied with E_R for $E_R > -1000$ mV. The former case suggests that the iron surface is either unoxidized or covered with an irreducible iron oxide. The equilibrium electrode potential of the Fe/Fe_3O_4, Fe/Fe_2O_3, $Fe/Fe(OH)_3$ reactions at pH = 13.8 are (7)

Fe/Fe_3O_4: $E^e = -1142$ mV *vs.* SCE (anhydrous) [11]

Fe/Fe_2O_3: $E^e = -1110$ mV (anhydrous) [12]

Fe/Fe_2O_3: $E^e = -1000$ mV

(hydrated Fe_2O_3-equivalent to $Fe(OH)_3$ [12a]

For $E_R > -1000$ mV, the surface is covered with a mixture of Fe_3O_4 and Fe_2O_3 or $Fe(OH)_3$, and its composition is a function of E_R.

Oxide growth mechanism on iron reduced at $E_R < -1100$ mV.—In neutral solutions, the rate of growth of a thin oxide on iron has been shown to follow the logarithmic law. This rate equation can also be applied to the growth of a thin oxide on iron in alkaline solutions.

Potentiostatic polarization.—According to Sato and Cohen (8), the current can be expressed by Eq. [13] when the metal surface is anodically oxidized by a logarithmic rate equation.

$$i = k_5 \exp(\beta E_a - Q/B) \quad [13]$$

where E_a is the anodic potential, Q is the charge associated with formation of the oxide on the electrode, and k_5, β, and B are constants.
Since

$$i = dQ/dt \quad [14]$$

Eq. [13] becomes

$$dQ/dt \exp(Q/B) = k_5 \exp(\beta E_a) \quad [15]$$

Under potentiostatic conditions, the solution of Eq. [15] is

$$Q = B \ln\left[\frac{k_5 t \exp(\beta E_a)}{B} + \exp(Q_o/B)\right] \quad [16]$$

where Q_o is the value of Q at $t = 0$. Therefore

$$i = \frac{k_5 \exp(\beta E_a)}{k_5 \exp(\beta E_a)\, t/B + \exp(Q_o/B)} \quad [17]$$

For

$$k_5 \exp(\beta E_a)\, t/B >> \exp(Q_o/B) \quad [18]$$

$$i = B/t \quad [19]$$

Equation [19] is in accord with Eq. [4]. Empirically, $B = 15$ mc/cm² which is two orders of magnitude greater than that obtained in neutral solution (8). The same relation as Eq. [19] or [4] was reported by Nagayama and Cohen (9) for iron in neutral solutions. For comparatively long time duration, the deviations of the plots in Fig. 1 from Eq. [19] may be due to a change in mechanism of oxidation.

When the applied positive potential step E_a, as in the plots of $E_a = -750$ mV, was not large enough, deviations from Eq. [4] or [19] were also observed in Fig. 1. However, these deviations were due to Eq. [18] being invalid. Equation [17] can be transformed to Eq. [20]

$$i = \frac{1}{t/B + (1/i)_{t=0}} \quad [20]$$

As shown in Fig. 12 the plots obtained experimentally are approximated reasonably well by Eq. [20]. Thus, the transient behavior for relatively small values of

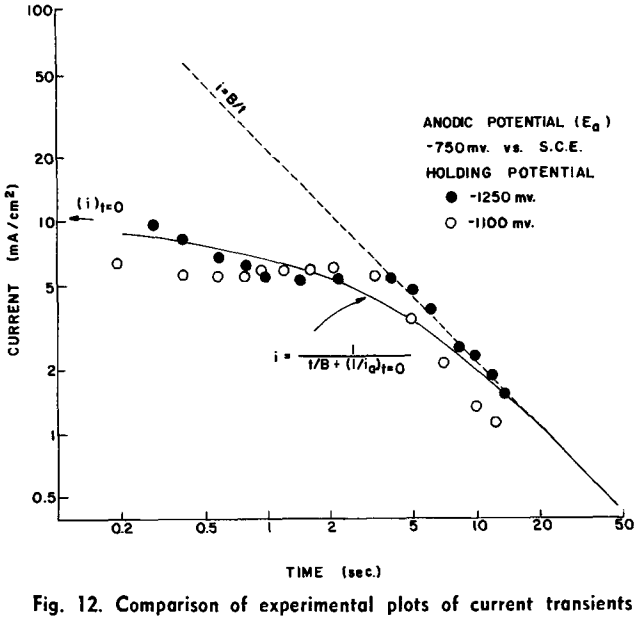

Fig. 12. Comparison of experimental plots of current transients with theory for potential step polarization.

E_a can also be interpreted in terms of logarithmic film growth.

Potential sweep polarization.—The solution of Eq. [15] can be obtained with the condition

$$E_a = \lambda t + E_R \quad [21]$$

where λ is the sweep rate. The solution for Eq. [15] is then

$$Q = B \ln \left[\frac{k_5 \exp(\beta \lambda t) \exp(\beta E_R) + c}{(B\beta\lambda)} \right] \quad [22]$$

where $c = B\beta\lambda \exp(Q_o/B) - k_5 \exp(\beta E_R)$
Therefore

$$i = \frac{B\beta\lambda}{1 + c/[k_5 \exp(\beta E_a)]} \quad [23]$$

It is of interest to determine the two limiting forms of Eq. [23]. First, for E_a sufficiently large such that

$$\exp \beta E_a >> \left[\frac{B\beta\lambda}{k_5} \exp\left(\frac{Q_o}{B}\right) - \exp \beta E_R \right]$$

Eq. [23] simplifies to

$$i = B\beta\lambda \quad [24]$$

On the other hand, for E_a sufficiently small such that

$$\exp \beta E_a << \left[\frac{B\beta\lambda}{k_5} \exp\left(\frac{Q_o}{B}\right) - \exp \beta E_R \right]$$

Eq. [23] becomes

$$i = \frac{k_5 \exp(\beta E_a)}{\exp\left(\frac{Q_o}{B} - k_5 \exp \beta E_R\right)} \quad [25]$$

Since $\exp(\beta E_a) = \exp \beta(E_R + \lambda t) > \exp \beta E_R$, $\exp \beta E_R << B\beta\lambda/k_5 \exp Q_o/B$. Therefore, Eq. [25] simplifies to

$$i = k_5 \exp\left(\beta E_a - \frac{Q_o}{B}\right) \quad [26]$$

Equation [26] shows that i is independent of λ and is the same form as $(i)_{t=0}$ for potentiostatic polarization (see Eq. [17]). Equation [26] gives

$$\frac{\partial E_a}{\partial \log i} = \frac{2.303}{\beta} \quad [27]$$

The parameter β can be determined by comparing Eq. [7] and [27]. Thus

$$\beta \approx 19.2 \text{ volt}^{-1} \quad [28]$$

This value of β is in accord with the one obtained by Sato and Cohen (8).

Transient behavior for $E_R > -1000$ mV. Potentiostatic polarization.—The variation of current with time for an anodic potential step in the region $E_R > -1000$ mV is proportional to $1/\sqrt{t}$ which suggests that the reaction process is diffusion controlled. Since there was no effect by stirring the electrolyte, the diffusion controlling process was considered to occur within the oxide layer. Since the iron oxides Fe_2O_3, $Fe(OH)_3$ are known to react with Fe to form Fe_3O_4 at room temperature (10), the oxide adjacent to Fe should always be Fe_3O_4. The oxide layer is assumed to have a duplex structure as previously proposed for iron in neutral and acidic solutions (9, 11). The following assumptions are made: (*i*) The outer layer is composed of Fe(II) and Fe(III) and is an ionic conductor. (*ii*) Since the magnetite is an electronic conductor, electron transfer for the Fe(II)/Fe(III) reaction occurs at the I/II interface. (*iii*) The charge transfer step is fast. Thus, the composition of layer II at the I/II interface is determined by the applied potential. (*iv*) The change in composition of layer II with E_a, occurs by diffusion of Fe(II) and Fe(III). Since the steady state current at E_R is very low, the concentration gradient in layer II at E_R is small. Thus, prior to the potential step, E_a, layer II has a uniform composition which is a function of only E_R. When the anodic potential step is imposed on the electrode, the concentration of the oxidant, C_{ox}, and of the reduced species, C_{Red}, is increased and decreased, respectively. Since for high anodic potentials, E_a, $C_{Red} \to 0$ at the I/II interface, a limiting current is obtained and should follow the following relation (12)

$$i = k_7 (C_{Red})_{ss}/\sqrt{t} \quad [29]$$

where k_7 is a constant and $(C_{Red})_{ss}$ is the steady state value of C_R at E_R.

By comparing with Eq. [5]

$$(C_{Red})_{ss} = \frac{k_2}{k_7} \exp\left(-\frac{mF}{RT} E_R\right) \quad [30]$$

Potential sweep polarization.—The potential-current curves in Fig. 7 are similar to those obtained for reversible electrode reactions where the potential is a function of C_{ox} and C_{Red} (12). For the anodic reaction

$$E = E^o - \frac{RT}{nF} \ln (C_{Red})_o \quad [31]$$

where $(C_{Red})_o$ is the value of C_{Red} at the I/II interface.

If E_a is related to $(C_{Red})_o$ by Eq. [31] and independent of C_{ox}, the peak current and peak potential, as shown by Delahay (12), can be expressed as

$$i_p = k_8 (C_{Red})_{ss} \sqrt{\lambda} \quad [32]$$

$$E_p = E_p^o - RT/nF \ln (C_{Red})_{ss} \quad [33]$$

where k_8 and E_p^o are constants. Comparison of Eq. [32] with Eq. [10] gives

$$(C_{Red})_{ss} = \frac{k_4}{k_8} \exp\left(-\frac{MF}{RT} E_R\right) \quad [34]$$

Combining Eq. [33] and [34]

$$\frac{\partial E_p}{\partial E_R} = \frac{M}{n} \quad [35]$$

is obtained. Since C_{Red} is uniform throughout layer II under steady state conditions at E_R

$$E_R = E^o_R - \frac{RT}{nF} \ln (C_{Red})_{ss} \quad [36]$$

Equations [34] and [36] give $M = n$. Thus, $\partial E_p/\partial E_R = 1$ is obtained. Equations [30] and [36] show that

$$n = m = M \quad [37]$$

Reacting species in the outer layer.—A comparison of Eq. [37] with Eq. [5] or [10] gives

$$n = \frac{1}{6.5} \text{ or } \frac{1}{7} \quad [38]$$

It may be assumed that the outer layer consists of Fe^{++}, Fe^{+++}, OH^-, $O^=$. Since iron has a tendency to form complex ions with six ligands like $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$, it seems reasonable that the complex ions, $Fe(OH)_6^{3-}$ and $Fe(OH)_6^{4-}$ are present in the outer layer. It is postulated that the potential difference across the I/II interface is determined by the redox couple

$$Fe(OH)_6^{3-} + e \rightleftharpoons Fe(OH)_6^{4-} \rightleftharpoons Fe^{++} + 6OH^- \quad [39]$$

Thus

$$E = E^o_1 + \frac{RT}{F} \ln \frac{[Fe(OH)_6^{3-}]}{[Fe^{++}][OH^-]^6} \quad [40]$$

Since the dissociation constant of $Fe(CN)_6^{4-}$ is much larger than $Fe(CN)_6^{3-}$, $Fe(OH)_6^{4-}$ should be less stable than $Fe(OH)_6^{3-}$. Therefore, the concentrations

of Fe^{++} and OH^- are related by

$$[OH^-] = 6[Fe^{++}] \quad [41]$$

If the main iron component of the outer layer is Fe(III), the concentration of $Fe(OH)_6^{3-}$ is much higher than the concentrations of Fe^{++}, OH^-, and $Fe(OH)_6^{4-}$ and is not appreciably affected by concentration changes in Fe^{++} or $Fe(OH)_6^{4-}$.

$$E = E^\circ_2 - \frac{7RT}{F} \ln [Fe^{++}] \quad [42]$$

or

$$E = E^\circ_3 - \frac{7RT}{F} \ln [OH^-] \quad [43]$$

Thus, if it can be assumed that either Fe^{++} or OH^- is the reduced species discharged at the I/II interface, $n = 1/7$.

Radiotracer Studies of Metal-Metal Ion Exchange Inhibition Using Organic Corrosion Inhibitors

David S. Newman,* Janet McCarthy, and Michael Heckaman

Department of Chemistry, Bowling Green State University, Bowling Green, Ohio 43403

ABSTRACT

The exchange between cadmium and its ions and between silver and its ions has been studied with radiotracers in solutions containing organic corrosion inhibitors. The inhibitors were butane 1,4 diol, cis-2-butene 1,4 diol, and 2 butyne 1,4 diol. The organic inhibitors reduced the rate of exchange by adsorbing onto the metal surface and this diminution in rate of exchange was correlated with the structure of the metal solution interfacial region. In the cadmium system the diols adsorbed parallel to the surface while in the silver system they seem to be adsorbed perpendicular to the surface. Free energies of adsorption and inhibition efficiencies were calculated.

When a solid metal, M, is placed in a solution containing M^{n+} ions and a comparatively inert anion such as ClO_4^- or Cl^- an exchange between M and M^{n+} ions occurs. This exchange can be followed by making the M^{n+} ions in solution radioactive and measuring the increase in radioactivity of M as a function of time. The rate of exchange, R, is obtained by dividing the total activity of M by the time of immersion and is therefore a measure of the mean flux at the metal surface. Re-exchange is undoubtably occurring but is not observed by this technique. R does however, represent the minimum rate of exchange and can be thought of as a fundamental property of the metal-solution system. As a consequence, this rate may be affected by several factors including changes in the structure of the metal-solution interfacial region, changes in crystal orientation, nature of the negative ion, variation in temperature, and changes in pressure. When all variables, except the structure of the metal-solution interfacial region, are held constant then variations in the exchange rate can be used to help elucidate this structure. Certain organic molecules can reduce the exchange rate by either adsorbing onto the metal surface, forming complexes with the metal ions in solution, or both. By selecting a series of organic compounds in such a way that a particular structural feature varies from molecule to molecule within the series while all other molecular parameters are held relatively constant and noting the decrease in R as a function of this feature, these molecules become sensitive probes of the metal-solution interfacial region. Proper use of molecular models allow further inferences to be drawn concerning the metal-solution interface.

The decrease in R can be measured using radiotracers, by comparing the radioactivity of a metal specimen that had been immersed in an inhibited solution for a period of time with a specimen that was in a similar solution with no inhibitor for the same period of time.

The metal-metal ion systems chosen for this investigation were $Cd\text{-}Cd^{++}$ and $Ag\text{-}Ag^+$. Each of these systems has been studied in the absence of inhibitors (1-3) and many of the important steps in the exchange mechanism are known (4). Furthermore, in the solid state, silver and cadmium differ from each other profoundly considering their close proximity to one another in the periodic table. For example, cadmium exhibits a positive Hall effect while silver, like most metals, has a negative Hall effect (5). This difference,

* Electrochemical Society Active Member.

Key words: inhibition, adsorption, diffusion, metal-metal ion exchange.

while not easily explained in detail, certainly implies a significant difference in the structure, and shape of the Fermi surface which in turn suggests that each metal might interact qualitatively differently with its environment.

The organic molecules selected for this study were butane 1,4 diol, cis-2-butene 1,4 diol, and 2 butyne 1,4 diol. These compounds were shown to inhibit the corrosion of iron in acid solution (6) and it was therefore thought that they would also decrease the rate of exchange in the systems under investigation by adsorbing onto active sites on the surface of the metal.

In all of the studies, the ratio of metal ion to inhibitor was one hundred to one. This ratio insured that a sizable decrease in the exchange rate had to be due to adsorption of the inhibitor onto the metal surface rather than complexing between metal ion and inhibitor in solution. The kinds of inference that can be drawn from these studies are illustrated by the following examples. If the organic molecules adsorb onto the metal parallel to the surface then the inhibition efficiency, given by the equation

$$I = 100\ (R_u - R_i)/R_u \qquad [1]$$

where R_u and R_i are the rates of exchange in the uninhibited and inhibited solution, respectively, should vary in the order —butyne— > —butene— > —butane— > uninhibited. This order of efficiency presumes metal inhibitor interaction is both through the two oxygen atoms and, in the case of —butene— and —butyne—, through the π electrons. If the inhibitors are oriented perpendicular to the metal surface and adsorption is through the oxygen atom then the efficiency should follow the order butane $\approx$ butyne $\approx$ butane > uninhibited.

Experimental Details

General experimental techniques.—The glass cell used for each of the experiments is described elsewhere (4). In each series of metal-metal ion exchange experiments, one solution contained no inhibitor, and each of three others was 0.001M in inhibitor. Reagent grade inhibitors were used and care was taken to see that no measurable decomposition occurred during an experiment.

The radiation was measured with a Beckman liquid scintillation counter (Model LS 133) using the standard PPO-POPOP-toluene scintillation cocktail. Because of the way in which the standards were prepared, and the fact that the instrument is sensitive to light, the γ rays were counted in essentially the same way as were the β rays.

The disks were immersed in methanol immediately upon removal from the reaction vessel and then washed in a stream of water. Two minutes of washing sufficed to remove all adsorbed material from cadmium while 5 min were required to insure that all material was removed from silver. Presumably, the $AgNO_3$ adsorbs more strongly onto the silver surface than the $CdCl_2$ adsorbs onto the cadmium surface.

The edge of each disk was coated with Paraffin wax. The disk was then suspended in the solution by means of a platinum wire which was wrapped around the edge and held in place by the wax. This procedure left two surfaces of each disk free to exchange.

The disks were carefully weighed prior to and after immersion to determine if dissolution or deposition occurred to any great extent. In no experiment for which data was recorded was the change in weight greater than 0.1 mg.

The average molecular area covered by each of the organic inhibitors was obtained with Stuart-Briegleb models by a method similar to that of Aramaki and Hackerman (7).

Cadmium-cadmium ion exchange.—Single-crystal disks of cadmium were immersed in solutions of 0.1M reagent grade $CdCl_2$. The radiotracer was Cd^{115m}, a β emitter, with a half life of 43 days. The solutions were deaerated and stirred with dry nitrogen, and maintained at a temperature of 25°C in a constant temperature bath. The electropolishing technique for the preparation of the disks and the method for preparing the standard for converting counts per minute to gram atoms exchanged so as to account for sample quenching are described elsewhere (1). The crystal of cadmium was oriented so that the surface of each disk was parallel to the 0001 plane of the crystal. Each disk had a diameter of approximately 18.5 mm and a thickness that varied between 3-4 mm. The disks were suspended in solution for periods of not less than 12 hr and not more than 72 hr. The ambient pH of the solutions was approximately 5.6.

Silver-silver ion exchange.—Single-crystal disks of silver were immersed in solutions of 0.1M $AgNO_3$. Ag^{110m}, a γ emitter with a half life of 270 days served as the tracer. The solutions were maintained at 25°C and stirred with nitrogen gas. The silver disks were approximately the same size as the cadmium disks.

The silver disks were mechanically cut from a large single crystal, etched back with dilute HNO_3 until no traces of a polycrystalline or amorphous materials formed by the cutting process remained. Laue diffraction patterns of every third disk were taken and in each case a single crystal was shown to be present. The crystal of Ag was oriented so that the surface of each disk was parallel to the 111 plane. The surfaces were prepared by using 25% HNO_3 as an etching bath and chromic acid-HCl as a polishing solution in a manner similar to that used by Tingley (3). The disks were then annealed for 12 hr at 850°C to insure that strains and other distortions were minimized. The ambient pH of the solutions was between 5.3 and 5.5. Because of the comparatively low rate of penetration of radioactive silver into solid silver the disks were left in solution for periods exceeding 100 hr in order to acquire enough activity to be accurately counted.

The standards for converting cycles per minute to gram atoms exchanged were prepared by depositing an accurately weighed amount of radioactive silver solution of known concentration on the surface of a polycrystalline silver coupon and allowing the coupon to dry. The activity of the coupon was measured and the counts per minute per gram atom silver computed. The single-crystal disks were immersed in similar solutions to those deposited on the coupons. Differences in rate of penetration into single-crystal silver and into polycrystalline silver were not important because measurable sample quenching by the silver does not occur.

Results and Discussion

The results of the cadmium-cadmium ion exchange studies together with the structure of each inhibitor are shown in Table I. The total activity, a_t, acquired by the disk is given by the equation

$$a_t = 2C_o\ (Dt/\pi)^{1/2} \qquad [2]$$

where C_o is the concentration of metal ions at the surface, t is the time, and D is the self-diffusion coefficient of the metal.

Equation [2] is a solution to the "mass transfer" analogue of the linear "heat flow" equation for a semi-infinite solid (8)

Table I. Rate of exchange and inhibition efficiency values for $Cd\text{-}Cd^{++}$ exchange

Compound		R, g-atoms/cm² sec × 10^{11}	I (%)
butane 1,4 diol		1.91	21.1
cis-2-butene 1,4 diol		1.15	51.8
2 butyne 1,4 diol		1.07	55.4
uninhibited		2.42	—

$$\frac{D\partial^2 C}{\partial x^2} = \frac{\partial C}{\partial t} \qquad [3]$$

where C is the concentration, D is the diffusion coefficient, x is the distance from the surface, and t is the time.

The equation is solved subject to the boundary conditions at $x = 0$, $C(0,t) = C_o$ = constant and $x = \infty$, $C(\infty,t) = 0$. This model applies because the initial radioactivity of the disk is zero and the distance of penetration into the disk is very small relative to its thickness. The values for R were obtained by dividing a_t in units of gram atoms exchanged/cm², by the total immersion time and averaging the results of a minimum of six different experiments with each solution.

The data in Table I indicate that the three organic compounds are efficient exchange inhibitors and adsorption of the organic molecule onto the metal surface is the primary inhibition mechanism. If complexing did contribute significantly to the inhibition and if each cadmium ion were tying up as many as one inhibitor molecule, a value for I of only 1% would result. The relative values of I imply that the two unsaturated molecules are adsorbed onto the metal surface primarily via their π electrons but that adsorption through the oxygens is a significant contributing factor because the butane 1,4 diol has an I value of 21.1% but no π electrons.

The three inhibitors are therefore assumed to be lying flat on the metal with the oxygens and, in the unsaturated compounds, the π electrons directed toward the metal surface.

The observed I values for the unsaturated alcohols are fairly close, indicating factors other than the number of π electrons play a role. The cis configuration of the butene diol possibly presents a favorable geometry for bidentate-like adsorption which is presumably stronger than the monodentate-like adsorption postulated for the butyne diol. At the same time, the four π electrons of the butyne diol probably repel each other slightly at the metal surface because of crowding so that they would bond slightly less than twice as strongly with the metal surface as would two π electrons.

The percentage of the disk covered by inhibitor may be computed from the equation

$$S_i = 100\,[1 - (C_{oi}/C_{ou})^{2/3}] \qquad [4]$$

where C_{oi} and C_{ou} are the surface concentrations of metal ion in an inhibited and uninhibited solution, respectively. C_{oi} and C_{ou} are calculated from Eq. [2] using a value of 3.6×10^{-15} cm²/sec for D_{Cd} (3).

In the inhibited solution the competition for active sites upon which to adsorb is between Cd^{++} and inhibitor and presumably one wins out at the expense of the other. Therefore, the chemical equation that best describes the adsorption process is

$$Cd^{++}\ (ads) + In\ (sol) = In\ (ads) + Cd^{++}\ (sol) \qquad [5]$$

The standard free energy of adsorption is given by the equation

$$\Delta G^o = -RT \ln \frac{[X_{In}\ (ads)]\,[X_{Cd++}\ (sol)]}{[X_{Cd++}\ (ads)]\,[X_{In}\ (sol)]} \qquad [6]$$

where the X's are the mole fractions of the various species in a two dimensional cross section area and are, in turn, given by the equation

$$X_{In} = \Gamma_i/(\Gamma_i + \Gamma_{Cd++}) \qquad [7]$$

Where the Γ_i's are the surface concentrations in gram atoms/cm².

In order to calculate Γ_i a roughness factor of 1.1 was assumed for the polished cadmium surface. The measured geometric area of the metal disk was multiplied by this roughness factor to give the "correct" area. A monolayer of adsorbed substrate was assumed to cover the fraction of this corrected metal surface area given by Eq. [4]. The total area covered by each inhibitor was then divided by the average area of the inhibitor molecule as computed by the Stuart-Brieglieb models. Γ_{Cd++} was calculated directly from $(C_o)^{2/3}$.

Errors in estimating the roughness factor will tend to cancel because nearly the same "roughness" is seen by both cadmium ions and inhibitors. A further justification for assuming a roughness factor near unity lies in the fact that C_{ou} is very close to the best value for the average bulk density of cadmium. This value for C_{ou} also serves as an internal check on the experimental method since it is the expected value if a single layer of Cd^{++} is adsorbed onto the metal surface or if the surface concentration of metal atoms has equilibrated. Values for S_i, $(C_o)^{2/3}$, ΔG^o, area of molecule, and X_{In} (ads) are listed in Table II.

The results of the Ag-Ag^+ experiments are shown in Table III. The data were obtained in the same way as in the Cd-Cd^{++} system.

The measured rate of exchange, R_u, in the uninhibited system compares very favorably with the value obtained by King, Simmons, and Berlin (9) in their exchange studies. When their results are cast in the same units as ours a value of 4.2×10^{-14} gram atoms/cm² sec obtains. Considering the difference in concentrations, difference in crystal orientation and the fact that they used a G.M. counter rather than a scintillation counter the values are in excellent agreement.

The relative values of I once more indicate that the alcohols are efficient exchange inhibitors and that adsorption is the primary inhibition mechanism. However, the data also implies that there is probably a qualitative as well as a quantitative difference in the mode of adsorption onto the two metal surfaces. In the Ag-Ag^+ system, the alcohols seem to be adsorbing "end on" or perpendicular to the plane of the metal. This interpretation most reasonably accounts for the fact that in this instance, the inhibition efficiencies of the three molecules are nearly the same. A possible reason for cis-2-butene 1,4 diol being slightly better at preventing exchange than the other two diols is because it has a cis configuration which can place two OH groups near the metal surface.

The generally greater efficiency of the three inhibitors in the silver system is difficult to account for in detail. The most obvious reason is that the metal inhibitor bond is stronger in silver than in cadmium. However, many other interesting explanations are possible. Evidence strongly suggests that NO_3^- is adsorbing onto the metal surface, blocking active sites, and thus preventing exchange (10, 11). Therefore a particularly intriguing idea is that a synergistic effect between NO_3^- and inhibitor is occurring similar to that described by Aramaki and Hackerman (12) in the case of medium sized polymethylenimine rings in the pres-

Table II. Surface coverage, free energy of adsorption, and average area of inhibitor in the Cd-Cd^{++} system

2 butyne 1,4 diol	3.7	70
uninhibited	21.0	

ence of I^-. That this synergistic effect is likely to be present can be inferred from the fact that NO_3^- like I^- is an exceedingly efficient "structure breaker" in aqueous solution (13) and can be expected to "break up" the water sheath about the inhibitor, thus making it more efficient.

Another strong possibility is that the difference between the mode of penetration of Ag atoms into solid Ag and the mode of penetration of Cd atoms into Cd causes an apparent increase in inhibitor efficiency. At 25°C Ag atoms penetrate single-crystal silver via a grain boundary mechanism. The grain boundary mechanism implies the existence of dislocation pipes, the diameter of which can be shown to be nearly equal to that of a Ag atom (14). If the inhibitors should block dislocation pipes then the only means of penetration into the disk would be volume diffusion. Since the diffusion coefficient for volume diffusion is some twelve orders of magnitude smaller than the "dislocation pipe" diffusion coefficient (14) the inhibitors will appear to be much more efficient even if they do not bond significantly more strongly.

In this discussion it has been assumed that there is a continuous dynamic competition for adsorption sites between metal ion and inhibitor so the efficiency, in a given system, can be thought of as being a function of the strength of the metal-inhibitor interaction despite the method of penetration. As this strength increases the efficiency will increase because the entrances to the dislocation pipes will be covered a greater percentage of the time. The fact that the efficiencies observed in the silver system are similar, therefore, implies that the inhibitor-metal interactions are similar and the most reasonable explanation for this similarity is that the inhibitors are adsorbing perpendicular to the surface. However, it should be noted that if an inhibitor blocks a dislocation pipe and there is virtually no other means for the metal to penetrate it is impossible to tell, without some additional assumptions, whether the "blocking" molecule has adsorbed perpendicular or parallel to the surface. In either case, the efficiencies will be similar. Therefore, without an independent measurement the orientation of the molecules is still open to question.

The uninhibited solution as well as each of the inhibited solutions are 0.1M in NO_3^- so the presence of the NO_3^- is not felt in these experiments unless it manifests itself in the form of a synergistic effect. The "net" reaction seen by the exchange experiments is described by the equation

$$Ag^+ \text{ (ads)} + \text{In (sol)} \rightleftharpoons Ag^+ \text{ (sol)} + \text{In (ads)} \quad [8]$$

and the free energy of adsorption is computed from the equation

$$\Delta G^\circ = -RT \ln \frac{[X_{\text{In}} \text{ (ads)}]\,[X_{Ag+} \text{ (sol)}]}{[X_{Ag+} \text{ (ads)}]\,[X_{\text{In}} \text{ (sol)}]} \quad [9]$$

where the X's are defined as in Eq. [7].

The percentage of the disk's surface covered by the inhibitor, S_i, the "measured" surface concentration, free energy of adsorption, average area of adsorbed molecule, and mole fraction of inhibitor at the surface are given in Table IV. In addition, a quantity C_o', the theoretical surface concentration, is given. A value of 2.1×10^{-21} cm²/sec was used for D in Eq. [2] (3, 9).

The average number of Ag atoms in the 111 crystal plane is 1.4×10^{15}. This number was multiplied by 1.1, the estimated roughness factor, to obtain a theoretical value for the surface concentration, C'_{ou}. This value for C'_{ou} was used as the basis for calculation of the mole fractions appearing in Table IV.

It is easily seen that the values of C_{ou} are too high unless a roughness factor approaching ten is assumed. It is more likely, based on King's data (9), Tingley's data (3), and our own experience that no single diffusion coefficient can accurately describe the penetration of radioactive Ag atoms into single-crystal Ag at room temperature. At least two diffusion coefficients are necessary, one for diffusion through the surface layers, and one for diffusion into the bulk of the crystal. In other words, the rate of diffusion of Ag atoms into the crystal of solid silver is a function of penetration distance. Therefore, while Eq. [2] is satisfactory for the calculation of C_{ou} and C_{oi} to be used to calculate S_i, it is not satisfactory for the calculation of the mole fractions.

Table IV. Surface coverage, free energy of adsorption and average area of inhibitor molecule in the Ag-Ag^+ system

Molecule	S_i, %	$C_o^{2/3}$ × 10^{-15} atoms/cm²	ΔG°, kcal/mole	Average area of inhibitors, Å²	X_{In}(ads)	$C_o^{2/3}$ × 10^{-15} atoms/cm²
—butane—	64	5.4	−5.7	30.4	0.70	0.56
—butene—	75	3.8	−11.2	27.4	0.90	0.38
—butyne—	68	4.6	−6.9	28.6	0.76	0.45
uninhibited		14.9				1.5

The assumption that C_o in Eq. [2] is equal to the bulk metal concentration was made because it generates the known diffusion coefficient for Cd and a reasonable one for Ag. Moreover, using the correct diffusion coefficient for Cd and an acceptable one for silver gives a value of C_o equal to the bulk metal concentration in Cd and a value greater than the bulk metal concentration in Ag. The high value in silver is easy to understand if the diffusion pipe mechanism is working. Using the solution concentration in either system gives absurd results.

Discussion of Errors

The data obtained from experiments with the Cd-Cd^{++} system are estimated to range in absolute accuracy from ±10% for the inhibition efficiencies to ±20% for the quantities that involve average area covered by the organic molecule. This estimate, for the error in I, includes the counting error of approximately 3%. Although our knowledge of the surface roughness contains a minimum of ±10% error, the variation in surface area from one cadmium disk to the next will differ by much less than ±10%. The estimate for the error in X_{In} and ΔG°(ads) assumes a ±10% error in the average surface area covered by the organic inhibitor as well as miscellaneous smaller errors such as not having an exact value for D_{Cd} in the 0001 plane. The errors involved in the silver-silver ion exchange experiments are slightly larger than in the cadmium-cadmium ion experiments primarily because of the uncertainty in D_{Ag}.

Conclusion

Radiotracer studies of exchange inhibition using organic inhibitors have been shown to yield information about the mode of adsorption, free energy of adsorption, and structure of the metal solution interfacial region. The errors involved in the experimental technique are smaller than those encountered by other authors attempting to study the adsorption of organic molecules on metal surfaces. Bockris and Swinkles estimate an absolute error of nearly ±65% for their measurements of the adsorption of n-decylamine on solid metal electrodes (15). These authors tagged their organic molecules with C^{14} which leads to a much larger counting error than occurs in our experiments. It is interesting to note however, that our values for ΔG°(ads) are well within the same order of magnitude as their values for the same quantity.

The hypothesis that a bidentate linkage between the butene diol and the metal surface exerts a significant effect on the efficiency of the butene needs further testing. The simplest way would be to study the inhibition efficiency of the trans compound. Presumably its efficiency should be less than that of the cis compound.

Finally, radiotracer studies of metal-metal ion exchange inhibition offer a potentially powerful tool for obtaining information about the interfacial region of

many heterogeneous systems where exchange occurs at a significant rate.

LIST OF SYMBOLS

I	inhibition efficiency, %
R_u	rate of exchange in uninhibited solution
R_i	rate of exchange in inhibited solution
a_t	total activity acquired by the disk
C_o	surface concentration, atoms/cm^3
D_{Cd+}	self diffuson coefficient of cadmium
D_{Ag+}	self diffusion coefficient of silver
S_i	percentage of surface covered by inhibitor
ΔG^o	standard free energy of adsorption
X_{1n}	mole fraction of species i in a two dimensional cross sectional area
Γ_i	surface concentration of adsorbed species in moles/cm^2
t	time in seconds
T	temperature

Electrochemical Characteristics of Iron in H_2SO_4 Containing Benzotriazole

Robert J. Chin and Ken Nobe***

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The effect of benzotriazole on the corrosion of iron in H_2SO_4 has been studied. The experimental data are consistent with the slow proton discharge step for the hydrogen evolution reaction on iron. No change in mechanism was observed by the addition of benzotriazole, but a significant decrease in the rate of hydrogen evolution was observed. The inhibitor concentration had a significant influence on the behavior of the open-circuit capacitance. Surface coverages determined from capacitance and corrosion rate data were consistent and found to fit a Langmuir adsorption isotherm.

Benzotriazole is an effective corrosion inhibitor of copper and copper alloys (1). It has also been shown to be a corrosion inhibitor of steel (2). Up to the present time there has not been a systematic study of the effect of benzotriazole on the electrode processes of active iron. This investigation examines the effect of benzotriazole on the hydrogen evolution reaction on iron in acidic solutions.

Experimental

Cylindrical electrodes (0.5 in. in diameter and 0.375 in. in length) were machined from Ferrovac E iron rod. The cross-sectional surface was exposed to the electrolyte. This surface was polished with increasingly fine grades of aluminum oxide paper, followed by degreasing with boiling benzene in a soxhlet column for several hours. After degreasing the electrode was annealed at 700°C for 1 hr in a vacuum. The electrode was then encased in shrinkable Teflon to prevent leakage of electrolyte and mounted in a Teflon holder. The details of the Teflon electrode holder are given elsewhere (3).

A three-electrode cell of Teflon and Pyrex glass was used in the experiment. A saturated calomel electrode and a platinized platinum electrode were used as the reference and auxiliary electrodes, respectively. The auxiliary electrode was separated from the test cell by fritted glass. A Luggin probe was used for the reference electrode.

Solutions of different *p*H (0.3, 1.0, and 1.9) were obtained by adding KOH to 1*N* H_2SO_4 prepared from doubly distilled water and reagent grade acid. The benzotriazole was supplied by the Maumee Chemical Company. Solutions were deaerated with prepurified nitrogen for several hours before introducing the test electrode.

The test electrode was activated in 5*N* H_2SO_4 for 10 min and then rinsed in distilled water before immersion in the electrolyte. The d-c pulse technique was employed for capacitance measurements. Galvanostatic polarization was utilized to study the hydrogen evolution reaction. Capacitance and polarization measurements were made periodically at various electrode immersion times. Each electrode was immersed approximately 72 hr. Capacitance measurements were also made during cathodic polarization of uninhibited iron. For cathodic polarization, one minute current pulses were utilized. Steady-state polarization was achieved in less than one minute.

Results

The cathodic polarization of iron was dependent on inhibitor concentration, solution *p*H, and immersion

* Electrochemical Society Active Member.

Key words: corrosion inhibition, hydrogen evolution.

time. In all cases constant polarization curves were reached within 40 hr after immersion. Cathodic polarization of iron in 1*N* H_2SO_4 at various concentrations of benzotriazole is shown in Fig. 1. Increasing the concentration of benzotriazole shifted the polarization curves toward more negative potentials. Similar behavior was observed for *p*H 1.0 and 1.9 solutions. This means that the rate of the hydrogen evolution reaction is decreased by the organic compound. An increase in the *p*H shifted the polarization curves of uninhibited iron toward more negative potentials as shown in Fig. 2. This behavior was observed for both uninhibited and inhibited iron. A cathodic Tafel slope of 100 ± 5 mV was obtained regardless of the *p*H or inhibitor concentration.

The corrosion current was determined by the intersection of the corrosion potential and the extrapolation of the cathodic Tafel line. The corrosion current as a function of immersion time of iron in 1*N* H_2SO_4 is shown in Fig. 3 for different inhibitor concentrations. Uninhibited iron reached steady state within 10 hr of immersion. In general, steady-state corrosion currents were obtained within 30 hr of immersion.

It is seen that the addition of 4.16 mM benzotriazole reduced the corrosion current of iron in 1*N* H_2SO_4 from 1.0 to 0.02 mA/cm^2. An additional increase of the inhibitor did not lower the corrosion current further. The effect of benzotriazole on the corrosion current up to this concentration is shown in Fig. 4.

The open-circuit capacitance increased with immersion time for uninhibited iron in H_2SO_4 as observed by others (3, 4). As the inhibitor concentration increased, this capacitance increase with immersion time decreased. The time to reach a steady-state capacitance decreased with increase in inhibitor concentration. The open-circuit capacitance of iron in 1*N* H_2SO_4 at various inhibitor concentrations is shown *vs.* immersion time in Fig 5. The capacitance of uninhibited iron in 1*N* H_2SO_4 did not achieve a steady-state value during the duration of the experiment. After 96 hr of immersion, the capacitance of uninhibited iron in 1*N* H_2SO_4 was 210 μf/cm^2 and still increasing. Table I presents the values of the initial open-circuit capacitance (at 30-min immersion) and the steady-state values for *p*H 0.3, 1.0, and 1.9 at various inhibitor concentrations.

The steady-state capacitance values (C_{ss}) were related to the steady-state corrosion current as shown in Fig. 6, *i.e.*,

$$\frac{\partial \log I_{corr}}{\partial \log C_{ss}} = \text{constant} \qquad [1]$$

* Estimated.

The reaction order with respect to the hydrogen ions can be determined from a plot of log I_c *vs.* pH at constant potential in the Tafel region as shown in Fig. 7 for inhibited and uninhibited iron in 1*N* H_2SO_4. The results show that

$$\frac{\partial \log I_c}{\partial \text{pH}} = -1 \qquad [2a]$$

regardless of the concentration of inhibitor in the solution. Also for uninhibited iron

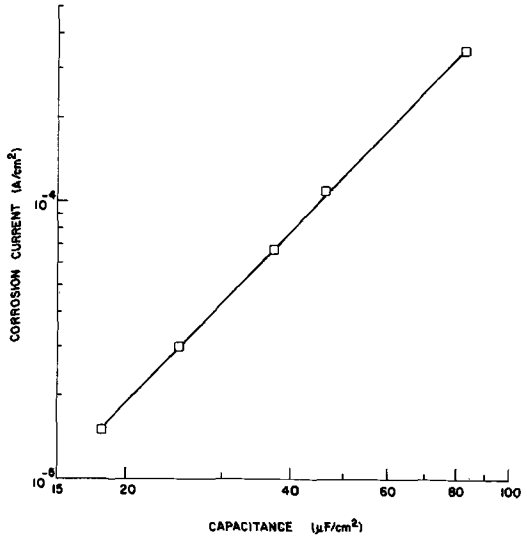

Fig. 6. Log-log plot of steady-state open-circuit capacitance *vs.* corrosion current of iron in 1*N* H_2SO_4.

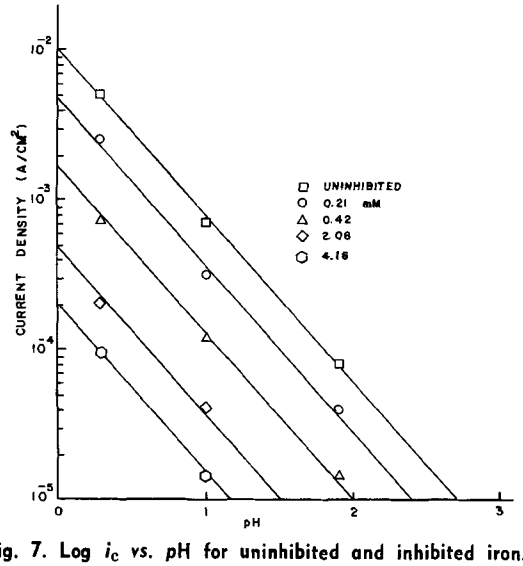

Fig. 7. Log i_c *vs.* pH for uninhibited and inhibited iron. ϕ = 600 mV.

$$\frac{\partial \log I_{corr}}{\partial \text{pH}} = -0.55 \qquad [2b]$$

$$\frac{\partial \phi_{corr}}{\partial \text{pH}} = -0.060\text{V} \qquad [2c]$$

and

$$\left(\frac{\partial \phi}{\partial \text{pH}}\right)_I = -0.11\text{V} \qquad [2d]$$

These results are in accord with those reported by Bockris *et al.* (4) and Kelly (5).

The absence of pseudocapacitance of uninhibited iron throughout the range of cathodic polarization was in accord with the results of Devanathan (6).

Discussion

The mechanism of the hydrogen evolution reaction in acidic solutions is assumed to be as follows

$$H^+ + e^- \rightarrow H \text{ ads} \qquad [3]$$

$$H \text{ ads} + H^+ + e^- \rightarrow H_2 \qquad [4]$$

or

$$H^+ + e^- \rightarrow H \text{ ads} \qquad [3]$$

$$H \text{ ads} + H \text{ ads} \rightarrow H_2 \qquad [5]$$

The experimental data obtained in this study for uninhibited iron are consistent with the results of Bockris (4), Kelly (5), and Devanathan (6) indicating that the discharge step is the rate-determining step. In the presence of benzotriazole, the rate of the h.e.r. is decreased. However, the cathodic Tafel slope and the reaction order with respect to the hydrogen ions is the same for iron in the absence and presence of the organic inhibitor. This result indicates that the inhibition of the h.e.r. by benzotriazole is by the simple adsorption mode and that the mechanism of the h.e.r. on uninhibited and inhibited iron in H_2SO_4 is the same.

If the above is valid, the apparent corrosion rate of inhibited iron is proportional to the surface area not covered by benzotriazole and it follows that

$$\theta_I = \frac{I^o_{corr} - I_{corr}}{I^o_{corr} - I^m_{corr}} \qquad [6]$$

where I^o_{corr} is the corrosion rate of uninhibited iron, I_{corr} is the corrosion rate of inhibited iron and I^m_{corr} is the limiting corrosion rate of inhibited iron, and θ_I is the fraction of the surface covered by adsorbed inhibitor. Furthermore, for the simple adsorption mode of inhibition, the surface coverage of inhibitor may also be determined from the differential capacitance of inhibited and uninhibited iron, since the apparent double layer capacitance is also proportional to the surface area not covered by the organic. Thus

$$\theta_I = \frac{C_o - C}{C_o - C_m} \qquad [7]$$

where C_o, C, and C_m are the steady-state capacitance of uninhibited iron, inhibited iron of surface coverage θ_I and inhibited iron of surface coverage $\theta_I = 1$, respectively. Equation [7] has been previously used by Hackerman (7) for adsorption of organics on solid electrodes. The experimental data indicate that maximum surface coverage is attained at a benzotriazole concentration of 4.16 mM.

Values of θ_I determined by Eq. [6] and [7] are given in Table II. As shown in Table II, good agreement is obtained between θ_I determined by Eq. [6] and [7]. Sufficient experimental data was not obtained for iron in pH 1.9 to determine θ_I.

A correlation between θ_I and C_I, the concentration of inhibitor in the electrolyte can be achieved with the Langmuir adsorption isotherm

$$\theta_I = \frac{KC_I}{1 + KC_I} \qquad [8]$$

Table II. Surface coverage of benzotriazole on iron in H_2SO_4

H_2SO_4 pH	Inhibitor conc, mM	Surface coverage Eq. [6]	Surface coverage Eq. [7]
0.3	0.21	0.66	0.69
	0.92	0.90	0.87
	0.83	0.94	0.91
	2.08	0.98	0.97
	4.16	1.00	1.00
1.0	0.21	0.88	0.69
	0.42	0.94	0.84
	2.08	0.97	0.97
	4.16	1.00	1.00

Rearranging Eq. [8]

$$\frac{C_I}{\theta_I} = \frac{1}{K} + C_I \qquad [9]$$

Several other isotherms correlated the adsorption data reasonably well for the higher surface coverages, but correlations were not obtained for the lower θ values in Table II. Only the Langmuir isotherm correlated all the $\theta - C_I$ data. Figure 8 is a plot of Eq. [9] and shows that the Langmuir adsorption isotherm correlates the experimental data for pH 0.3 and 1.0 well. The constant, $K = 10^4 M^{-1}$, and indicates that benzotriazole is strongly adsorbed on the iron surface.

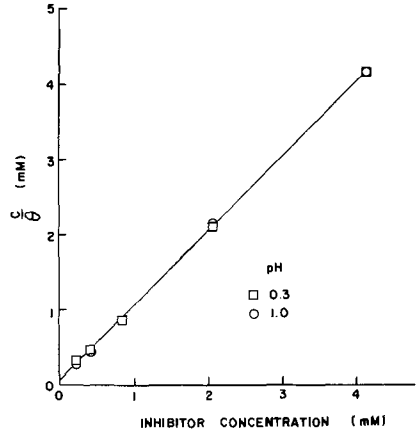

Fig. 8. Langmuir adsorption isotherm for adsorption of benzotriazole on iron in H_2SO_4.

Electrodeposition of Manganese Using Amide Solutions

M. A. Qazi[1] and J. Leja

Department of Mineral Engineering, The University of British Columbia, Vancouver, British Columbia, Canada

ABSTRACT

Laboratory study on electrodeposition of manganese was carried out in a diaphragm cell using an amide solution of $MnCl_2$ as catholyte and an aqueous solution of NH_4Cl as anolyte. Metallic manganese of approximately 98% purity was deposited at a current efficiency of 76%. The effects of several variables were investigated, and the optimum conditions were found to be: 10-15 g/liter Mn in formamide at pH 7.5 with 90-100 g/liter NH_4Cl anolyte solution at pH 2.5, cathode current density ~50 mA/cm^2 and temperature about 35°C.

Electrolytic production of manganese from aqueous solutions of manganese sulphate or chloride, containing large quantities of ammonium salts as buffer, in a diaphragm cell, has been investigated for several decades (1-3). The U. S. Bureau of Mines (4) developed a process for the electrowinning of manganese from aqueous solutions.

Very little work appears to have been done on the electrowinning of manganese from nonaqueous media. Dirkse and Brisco (5) reported on work which included deposition of manganese from ethers, acetones, and alcohols. The present paper deals with deposition of Mn from amide solutions; this topic has been investigated by Qazi (6) as a final step in recovering Mn metal from low-grade iron-manganese ore (from New Brunswick, Canada).

Schneider (7) electrolyzed amides and detected the presence of cyanuric acid in the electrolyte. This was confirmed later by Couch (8) who, in addition to cyanuric acid, identified secondary and tertiary amines in the amide solution after electrolysis.

Key words: metallic Mn deposition, nonaqueous electrodeposition, formamide catholyte.

Experimental

The laboratory cell for the electrodeposition of manganese is illustrated in Fig. 1; it is an H-type, two-compartment cell with a sintered glass separating disk. The volumes of catholyte and anolyte used were ~30 ml each. Direct current was obtained using a Sorensen Model 560 BB rectifier.

The anode was a rod of a spectrograde graphite and the cathode was an 18/8 stainless steel strip of 3 cm^2 area. The current was determined using a copper coulombmeter in series with the cell. Oxygen dissolved in the electrolyte was removed by bubbling nitrogen through the cell.

Manganese ($Mn^{++}/Mn = -1.18V$) readily evolves hydrogen from aqueous solutions unless buffered with large quantities of ammonium salts (~100-150 g/liter). The disadvantages of using aqueous electrolytes in

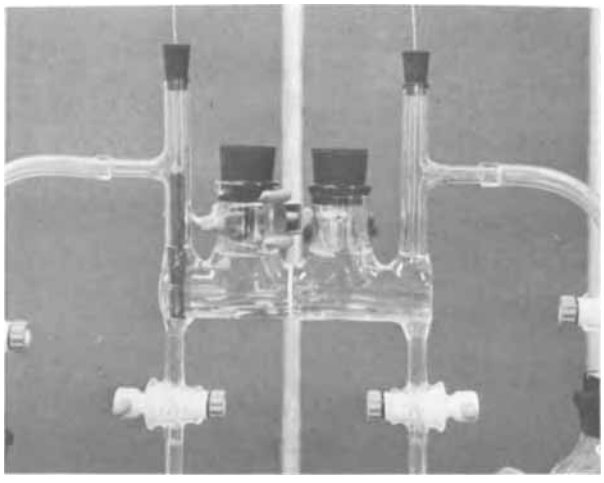

Fig. 1. An H-type two-compartment (separated by a fritted disk) laboratory cell for electrodeposition of manganese.

manganese depositions are: low current efficiency (~65%), low Mn concentration in catholyte, redissolution of some of the deposited manganese due to the lowering of pH (as the electrolysis proceeds).

The organic solvents which were used in the exploratory electrolysis tests for manganese deposition are listed in Table I.

$MnCl_2$ was found to be more soluble than $MnSO_4$ in most of the organic solvents, but even so the solutions of $MnCl_2$ in dimethyl sulfoxide, pyridine, and nitrobenzene were found poorly conducting and yielded brown or black, apparently nonmetallic, deposits (although presence of metallic manganese was detected qualitatively). Only the electrolysis of $MnCl_2$ in amides produced a dark, metallic deposit of manganese.

When the anolyte and catholyte products were allowed to mix, a brown coloration was produced around the anode with the result that the cathode product began to dissolve. The decomposition of amide at the anode meant the loss of valuable electrolyte. This problem was solved by using a diaphragm separating the cell into compartments and replacing amide in the anode compartment with an aqueous ammonium chloride; in this way the pH control of the cell and the quality of the deposited manganese were improved.

Results

The chemical analyses of the electroplated manganese from the catholytes containing 18 g/liter Mn as $MnCl_2$ in formamide, dimethylformamide, and dimethyl acetamide at a pH around 7.2, and using anolyte containing 90 g/liter NH_4Cl and 20 g/liter HCl, at a current density of 40 mA/cm² are given in Table II. The manganese deposited from a formamide bath was smoother and brighter, more metallic in appearance, than that from other organic electrolytes.

The conductivity of formamide (1.12×10^{-5} mho cm^{-1}) increases on dissolving manganous chloride, as plotted in Fig. 2. The abrupt change in the slope at ~3% $MnCl_2$ indicates the formation of some complex of the type $MnCl_2 \cdot n(HCONH_2)$. The solubility of anhydrous $MnCl_2$ in formamide was found to be 82.6 g/liter (~7.3%).

Table I. Physical properties of organic solvents

Solvent	Density, g/ml	Viscosity, C.P.	Spec. cond., mho cm^{-1}	Dielec. const.
Formamide	1.129	0.330	1.12×10^{-5}	109.50

* Analyses by Schwarzkopf Microanalytical Laboratories, New York, N. Y.

The data showing the effects of the variation of anolyte pH on the current efficiency at different NH_4Cl concentrations in anolyte solutions are plotted in Fig. 3. The optimum conditions for maximum current efficiency appear to be ~90 g/liter NH_4Cl and pH ~2.

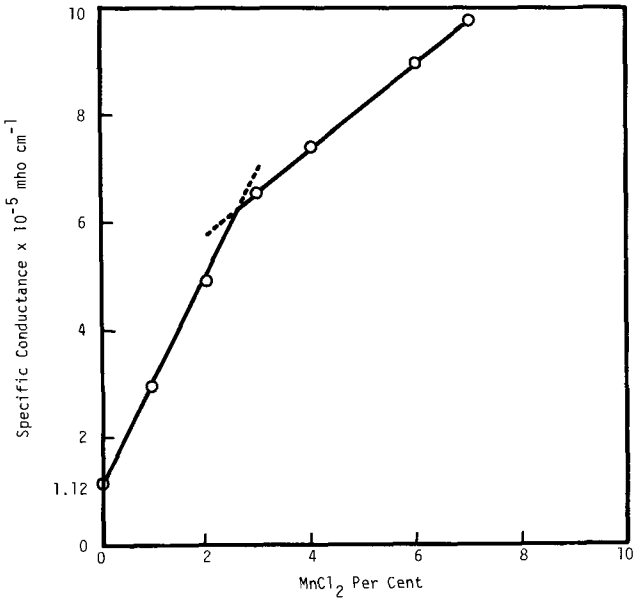

Fig. 2. Specific conductance of $MnCl_2$-formamide solutions at 25°C.

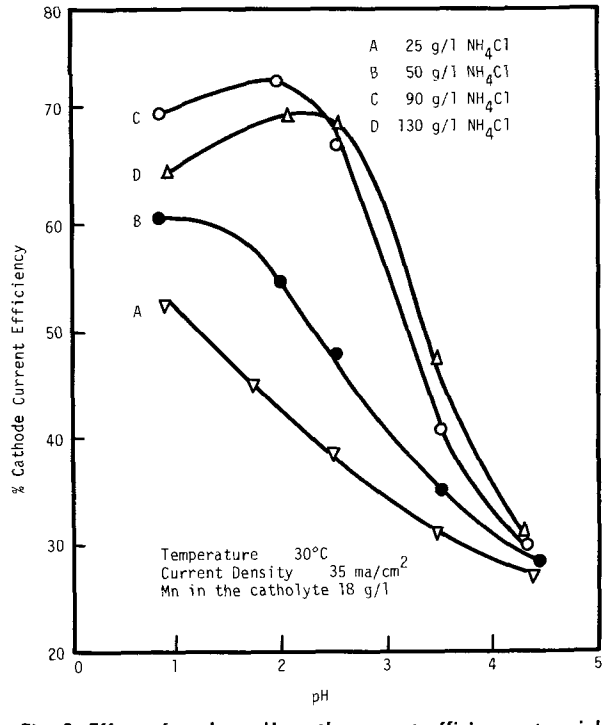

Fig. 3. Effect of anolyte pH on the current efficiency at variable NH_4Cl concentrations.

Manganese deposited at anolyte pH greater than 2.5 was black, flaky and tended to fall off the cathode.

Catholyte composition and pH.—It was found that even 40 g/liter $MnCl_2$ dissolved in formamide was gradually reacting with O_2 dissolved in the liquid giving a brown $Mn(OH)_2$ colloidal suspension in a few hours. When the formamide was made slightly acidic by HCl addition with 1 g/liter NH_4Cl the formation of $Mn(OH)_2$ was prevented for 3-4 days. An addition of a reducing agent, 0.4 g/liter of sodium ethyl xanthate, prevented the formation of $Mn(OH)_2$ indefinitely, *i.e.* after 30 days the solution was still colorless.

The results obtained on varying pH with various $MnCl_2$ concentrations in the catholyte containing 0.4 g/liter sodium ethyl xanthate are plotted in Fig. 4. The anolyte contained 80 g/liter NH_4Cl and its pH was adjusted at 2.5. After 90 min of electrolysis, pH of anolyte dropped to 0.8. It is seen that the critical pH of catholyte for a maximum in current efficiency decreases with the increase in the manganese concentration of the catholyte. Also, the current efficiency increases with the decrease in the manganese concentration. When the pH of catholyte was adjusted to pH 7.2, it changed after 90 min of electrolysis to pH 7.8.

Figure 5 shows the appearance of manganese of approximately 99% purity, (analyzed polarographically) chipped off on flexing the cathode. The maximum overall cathode current efficiency achieved was 76%. When a higher catholyte concentration was used, *e.g.* 20 g/liter Mn, a nodulized deposit was obtained as in Fig. 6, and the current efficiency decreased. Analysis of Mn deposit obtained in several batches of testing indicated a nearly constant C content (~1%) and O_2 content varying from 1-2.5%.

Manganese could be deposited from the formamide baths using a wide range of current densities with only a slight variation in the current efficiency. At higher current densities, however, the cathode current efficiency increased until the formation of nodules or trees occurred (as shown in Fig. 6), then it steadily decreased (see Fig. 7).

Temperature.—Using a current density of 50 mA/cm^2 and catholyte containing 16 g/liter Mn at pH 7.3, with anolyte containing 90 g/liter NH_4Cl at pH 2.4, an optimum cell temperature of 35°C was established, as given by the results in Table III.

Stirring of the electrolyte improved the rate of manganese deposition, presumably due to a more uniform distribution of the electrolyte at the electrode surface. The nature of the deposit was not affected.

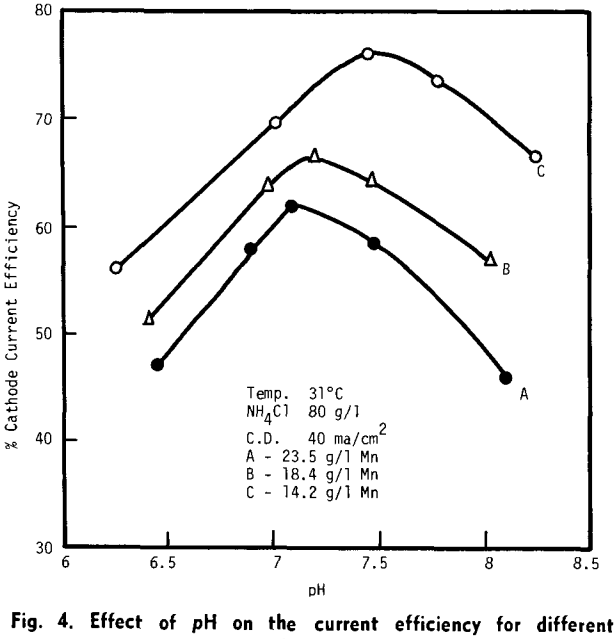

Fig. 4. Effect of pH on the current efficiency for different manganese concentrations in the catholyte.

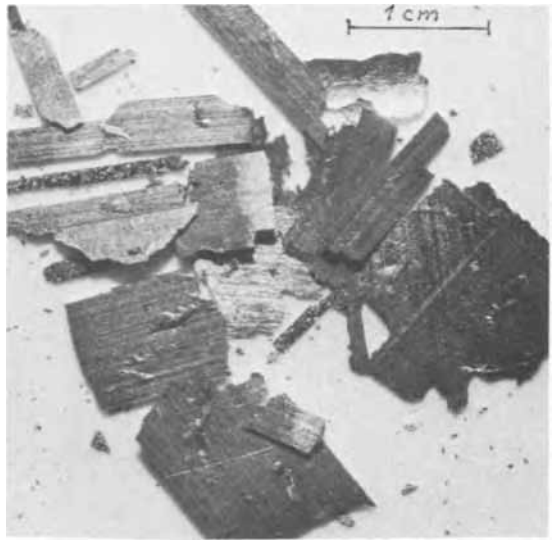

Fig. 5. Approx. 98% Mn flakes chipped off from stainless steel cathode, obtained at 14.2 g/liter Mn in catholyte.

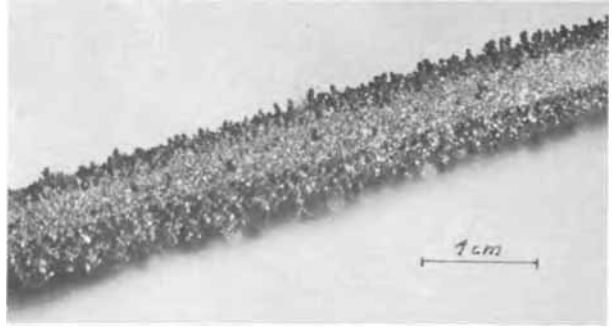

Fig. 6. Mn nodules and trees formed on the cathode when manganese concentration in catholyte was increased to 20 g/liter.

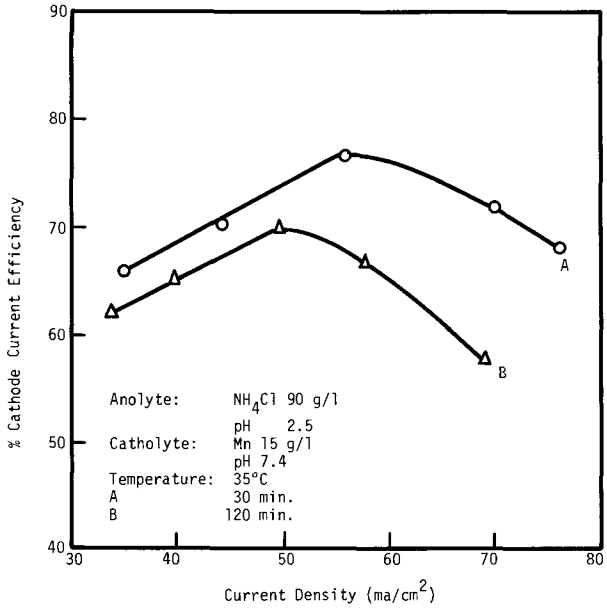

Fig. 7. Effect of current density on current efficiency

Electrode reactions.—Formamide and other alkyl amides coordinate through oxygen with metal ion, as Lewis acid, decreasing the force constant for C=O. The complex can be broken on electrolysis liberating the metal and regenerating the ligand. Cryoscopic

Table III. Effect of temperature on the current efficiency

Cell temperature, °C	Mn plated, mg	Cell, pH	Cell voltage	Cathode current efficiency, %
28.6	81.6	7.30	6.30	74.6
35.5	83.5	7.35	6.20	77.4
40.3	82.3	7.50	6.05	76.2
45.0	78.6	7.75	5.95	71.6
51.4	71.6	7.90	5.80	66.9

determination indicated that on the average 2-4 moles of ($HCONH_2$) are involved in the complex with $MnCl_2$. The solution, therefore, may contain $Mn(HCONH_2)_2Cl_2$ and $Mn(HCONH_2)_4Cl_2$.

On the dissociation and electrolysis, the reaction at the anode should involve liberation of chlorine

$$2Cl^- \rightarrow Cl_2 + 2e^-$$

Anode gas evolved during 90 min of electrolysis of 30 ml of catholyte (containing 40 g/liter $MnCl_2 \equiv 17.5$ g/liter Mn in formamide, with 0.4 g/liter sodium ethyl xanthate and 1 g/liter NH_4Cl, pH 7.2) amounted to 21 ± 1 ml. It was analyzed with a Pye gas chromatograph and showed ~1% Cl_2, ~7% O_2, balance N_2. The reaction of Cl_2 with NH_4Cl (100 g/liter NH_4Cl in water at pH 2.5) would be expected to involve

$$2NH_4Cl + 3Cl_2 \rightarrow N_2 + 8HCl$$

The volume of N_2 generated at 120 mA for 90 min should be ~25 ml. The lowering of anolyte pH from 2.5 to 0.8 did confirm the acidification of anolyte. However, the presence of O_2 must have resulted from the reaction

$$H_2O \rightarrow 2H^+ + \tfrac{1}{2}O_2 + 2e$$

Cathode gas has been collected during several tests; its volume exceeded slightly the volume of the anode gas. Its composition, as determined with a Pye chromatograph, showed ~4% O_2, balance H_2. In addition, qualitative tests and infrared spectroscopy of the catholyte after electrolysis showed presence of primary, secondary, and tertiary amines. Also, catholyte pH became slightly more alkaline (pH 7.2 → 7.8) at the end of the tests instead of becoming acidic, as expected theoretically. The details of the over-all reactions remain to be ascertained.

Conclusions

Electrolysis of 1-1.5% Mn as $MnCl_2$ in formamide resulted in the deposition of ~98% Mn, if the decomposition of the solvent and the undesirable side reactions were eliminated. These conditions were achieved by using a diaphragm cell and an aqueous solution of ammonium chloride (90-100 g/liter NH_4Cl at a pH around 2.5) as anolyte, with a current density of 50 mA/cm², and catholyte pH of about 7.5; a maximum current efficiency of 76% was obtained.

Compared with the electrolytic process using aqueous $MnCl_2$, the formamide solution of $MnCl_2$ results in a higher conductivity and higher current efficiency, enables higher pH of the catholyte to be used (up to about 8.0) without precipitating $Mn(OH)_2$.

Electrodeposition of Gold by Pulsed Current

H. Y. Cheh*[1]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

A diffusion model was developed to calculate the rate of deposition of metals by a periodically pulsed current. The results indicate that although the magnitude of the instantaneous applied current for deposition can be considerably higher than that of direct current plating under suitable conditions, the limiting over-all plating rate was in general lower. Experimental confirmation was established using the phosphate, citrate, and cyanide gold solutions. The diffusion coefficient of the complexed gold cyanide ion ($Au(CN)_2^-$) was measured. The values were 1.63 x 10^{-5} cm²/sec, 1.67 x 10^{-5} cm²/sec, and 1.68 x 10^{-5} cm²/sec at 60°C for the phosphate, citrate, and cyanide solutions, respectively. The pH value, specific conductance, and kinematic viscosity of these solutions were also measured and tabulated. The rate of chemical dissolution of gold in the cyanide solution was also investigated.

Electrodeposition of metals by a periodic variation of the applied current has been practised by a growing number of electroplaters. Jernstedt (1) obtained fine-grained deposits from a copper cyanide solution at high current densities by periodically reversing the polarity of the applied current (p-r plating). Similar observations were also reported by applying pulsed currents (p-c plating) in acid copper solutions by Popkov (2) and by Ozerov *et al.* (3). Hickling and Rothbaum (4) observed a decrease in deposit roughness in copper cyanide solutions by applying p-r plat-

Key words: electrodeposition, gold.

ing under suitable conditions. Most recently, Avila and Brown (5) presented a discussion on applying pulsed current to gold plating in the semiconductor industry.

Two advantages were most frequently cited by investigators in this field. First, in contrast to applying a direct current (d-c plating), it is claimed that a higher instantaneous cathodic current density for deposition can be applied to the plating system because of the higher concentration of metal ion in the diffusion layer. Second, more fine-grained deposits can be obtained. Although higher cathodic current density for deposition has been confirmed in the plating literature, confusion exists concerning the over-all plating rate which involves an integration of the current over the total cyclic period. From theoretical considerations, Ozerov *et al.* (3) claimed that the rate of deposition could be increased indefinitely in p-c plating by decreasing the duration of the pulsed current. A closer examination of their derivation revealed that their diffusion model was completely unrealistic for a practical plating system, and, in fact, they presented no experimental confirmation of an increased over-all plating rate. Hickling and Rothbaum (4) presented results of a careful experimental study on the rate of deposition of silver by both p-r and p-c plating. An increase of instantaneous cathodic current density for deposition but a decrease in the over-all plating rate was observed in both cases. A simple model of mass transport of the metal ion was suggested which showed satisfactory agreements with the periodic reversal of current experiments but failed completely to describe the pulsed current experiments.

In this paper, we present a realistic mass transport model to calculate both the limiting instantaneous cathodic current density for deposition and the limiting over-all rate of deposition by pulsed current. Results are then compared with the rate of deposition of three gold plating solutions.

Theoretical Analysis

We assume that a planar cathode is situated in a well-stirred plating solution. The cathode-anode distance is large as compared to the thickness of the diffusion layer so that the anode can be considered to be far away for the present model. The number of coulombs passed during a plating experiment is assumed to be so small that the depletion of the metal ion in the solution can be neglected. In other words, the concentration of the reacting species at the outer edge of the diffusion layer remains unchanged. The deposition process is assumed to be controlled by the mass transport of metal ion and current density is the controlled variable. Both the nonfaradaic component of the applied current and the electrical migration of the metal ion are considered to be negligible due to the relatively high conductivity of most plating solutions. Let the outer edge of the diffusion layer be located at $x = 0$ and the cathode at $x = \delta$. Under these conditions, the concentration of metal ion is governed by Fick's second law of diffusion

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2} \qquad [1]$$

with the following boundary conditions

1. $c = c_o$ for $t = 0$ and all x [2]
2. $c = c_o$ for $t > 0$ and $x = 0$ [3]
3. $D\left(\frac{\partial c}{\partial x}\right) = \frac{i}{n\mathbf{F}}$ for $t > 0$ and $x = \delta$ [4]

where c is the concentration of the metal ion, c_o is its concentration in the bulk of the solution, D is the diffusion coefficient of the metal ion, δ is the thickness of the diffusion layer, n is the number of electrons transferred during the deposition process, $\mathbf{F}$ is Faraday's constant, t is the time, and i is the applied current density which is negative for cathodic deposition.

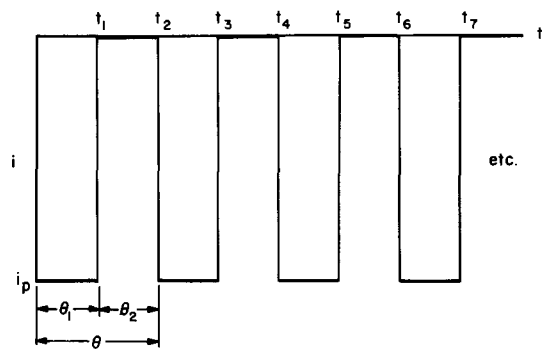

Fig. 1. Schematic diagram of a pulsed current

If we let the cyclic period for the pulsed current be θ, the time when the current is on in a period be θ_1, and the time when the current is off in the same period be θ_2, the form of the pulsed current density can be shown schematically in Fig. 1. Consequently, the pulsed current density in Eq. [4] can be expressed as

1. $i = i_p$ for $0 < t \leq t_1$, $t_2 < t \leq t_3$, etc. [5]
2. $i = 0$ for $t_1 < t \leq t_2$, $t_3 < t \leq t_4$, etc. [6]

and the cyclic period θ is given by

$$\theta = \theta_1 + \theta_2 = t_2 = (t_4 - t_2) = (t_6 - t_4), \text{etc.} \qquad [7]$$

where i_p is the pulsed current density and t_n is defined in Fig. 1.

Equation [1] subject to the boundary conditions, Eq. [2] to Eq. [6] was originally solved by Rosebrugh and Miller (6). The results for the surface concentration of the metal ion are

1. during periods when the current is on

$$\frac{(c_i - c_o)n\mathbf{F}D}{i_p\delta} = 1 - \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{\exp[-(2j-1)^2a\tau]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2a\theta] - \exp[(2j-1)^2a\theta_1])}{(\exp[(2j-1)^2a\theta] - 1)} - \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{\exp[-(2j-1)^2at]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2a\theta_1] - 1)}{(\exp[(2j-1)^2a\theta] - 1)} \qquad [8]$$

2. during periods when the current is off

$$\frac{(c_i - c_o)n\mathbf{F}D}{i_p\delta} = \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{\exp[-(2j-1)^2a\tau]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2a\theta] - \exp[(2j-1)^2a\theta_2])}{(\exp[(2j-1)^2a\theta] - 1)} - \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{\exp[-(2j-1)^2at]}{(2j-1)^2} \cdot \frac{(\exp[(2j-1)^2a\theta_1] - 1)}{(\exp[(2j-1)^2a\theta] - 1)} \qquad [9]$$

where

$$a = \frac{\pi^2 D}{4\delta^2} \qquad [10]$$

$$\tau = t - N\theta \qquad [11]$$

c_i is the surface concentration of the metal ion, and N is the number of cycles of current already passed. Equation [8] and Eq. [9] indicate that the surface concentration of the metal ion during p-c plating con-

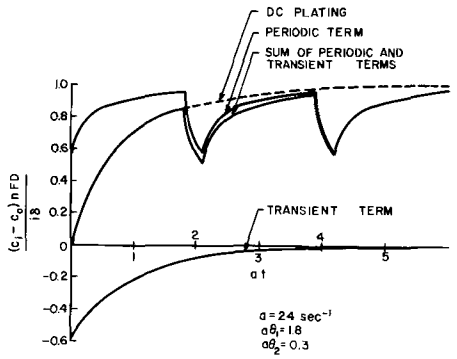

Fig. 2. Surface concentration of metal ion during p-c plating

sists of two periodic terms (first two terms in Eq. [8] and first term in Eq. [9]) and a transient term (third term in Eq. [8] and second term in Eq. [9]).

It is of interest to note that Eq. [8] can also be extended to calculate the surface concentration of the metal ion for d-c plating by letting $a\theta = a\theta_1$. Therefore, for d-c plating

$$\frac{(c_i - c_o)nFD}{i_{d\text{-}c}\delta} = 1 - \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{\exp\left[-(2j-1)^2 at\right]}{(2j-1)^2} \qquad [12]$$

where $i_{d\text{-}c}$ is the applied direct current density.

Numerical calculations for the surface concentration of metal ion for both p-c and d-c plating were performed using $i_p = i_{d\text{-}c}$, $a = 24\ sec^{-1}$, $a\theta_1 = 1.8$ and $a\theta_2 = 0.3$. These conditions are often used in practice. The results are shown in Fig. 2. Since i_p is negative for cathodic deposition, a comparison of these results indicates that the surface concentration of the metal ion in p-c plating is always higher than that in d-c plating after the first pulse. Consequently, in order to make the lowest surface concentration in p-c plating which occurs at the end of each pulse after the transient term has completely vanished equal to that from d-c plating at steady state, the instantaneous current density employed in p-c plating must be higher than that in d-c plating. If the instantaneous pulsed current density which causes the lowest surface concentration to reach zero is defined as the limiting current density for p-c plating, the ratio of the limiting current density to that of d-c plating can be calculated by dividing the steady-state term in Eq. [12] by the periodic terms in Eq. [8] and letting $c_i = 0$ and $\tau = \theta_1$

$$\frac{(i_p)_l}{(i_{d\text{-}c})_l} = \frac{1}{1 - \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{1}{(2j-1)^2}\cdot\frac{(\exp\left[(2j-1)^2 a\theta_2\right] - 1)}{(\exp\left[(2j-1)^2 a\theta\right] - 1)}} \qquad [13]$$

where $(i_p)_l$ and $(i_{d\text{-}c})_l$ are limiting current densities for p-c and d-c plating, respectively. The asymptotic form for $a\theta << 1$ is, therefore[2]

$$\left[\frac{(i_p)_l}{(i_{d\text{-}c})_l}\right]_{a\theta<<1} = \frac{\theta}{\theta_1} \qquad [14]$$

Numerical results from Eq. [13] and Eq. [14] for various values of $a\theta$ and θ_1/θ are plotted in Fig. 3. The results indicate that high limiting current densities can be obtained by decreasing the value of either $a\theta$ (shorter pulse periods) or θ_1/θ (shorter duration of pulsed currents).

[2] In deriving Eq. [14], the mathematical identity $\sum_{j=1}^{\infty}\frac{1}{(2j-1)^2} = \frac{\pi^2}{8}$, was used.

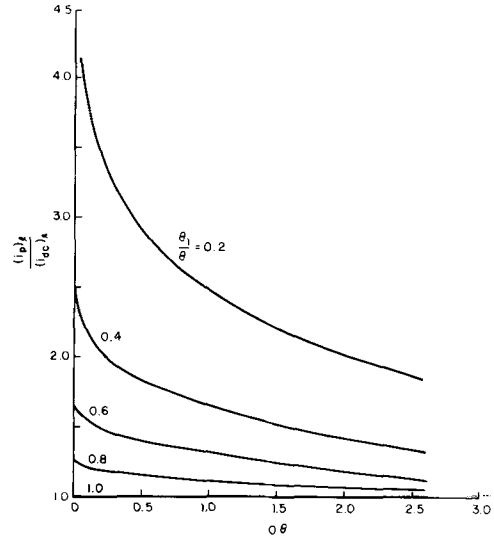

Fig. 3. Limiting current density for p-c plating

In order to calculate the over-all rate of plating, however, the pulsed current must be integrated over the entire cycle. Multiplying both sides of Eq. [13] by θ_1/θ, the following result is obtained,

$$\frac{\text{Max over-all rate of p-c plating}}{\text{Max rate of d-c plating}} = \frac{(i_p)_l\theta_1}{(i_{d\text{-}c})_l\theta} = \frac{\theta_1/\theta}{1 - \frac{8}{\pi^2}\sum_{j=1}^{\infty}\frac{1}{(2j-1)^2}\cdot\frac{(\exp\left[(2j-1)^2 a\theta_2\right] - 1)}{(\exp\left[(2j-1)^2 a\theta\right] - 1)}} \qquad [15]$$

Consequently, the asymptotic form for large values of $a\theta$ is

$$\left[\frac{(i_p)_l\theta_1}{(i_{d\text{-}c})_l\theta}\right]_{a\theta>>1} = \frac{\theta_1}{\theta} \qquad [16]$$

Numerical results of Eq. [15] are given in Fig. 4. It is clearly indicated here that even though the pulsed current can be made considerably higher than that of direct current, the limiting over-all rate of p-c plating simply cannot exceed that of d-c plating.

In order to determine the applicability of this model, experimental investigation was carried out using three different gold plating solutions.

Experimental Results and Discussion

Gold plating solutions were chosen to compare with the theoretical calculations for two reasons. First, gold deposition is of extreme importance in the modern semiconductor industry and little basic information is available for the gold plating processes. Second, the

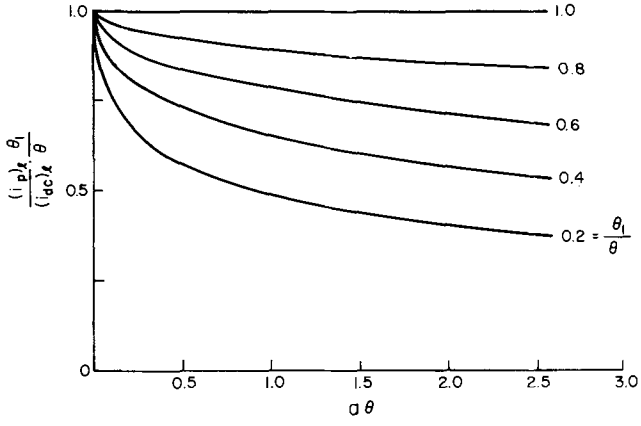

Fig. 4. Limiting over-all rate of deposition during p-c plating

Table I. Properties of gold plating solutions at 60°C

	pH	Specific conductance, κ, ohm^{-1} cm^{-1}	Kinematic viscosity, ν, cm^2/sec	Diffusivity of $Au(CN)_2^-$, D, cm^2/sec	Schmidt number, ν/D
Phosphate gold solution	7.5	0.159	0.00604	1.63×10^{-5}	370
Citrate gold solution	5.0	0.0548	0.00518	1.67×10^{-5}	310
Cyanide gold solution	10.8	0.105	0.00469	1.68×10^{-5}	279

electrochemical behavior of various gold plating solutions is rather different one from the other. For instance, the classical alkaline cyanide gold solution is a relatively reversible system with an exchange current density for the deposition process in the range of 1 mA/cm^2. Both the neutral phosphate gold and acid citrate gold solutions are highly irreversible systems. A detailed discussion on the electrochemical aspects of gold deposition will be published in the near future (7).

The composition of the three gold plating solutions used in the experiments were

1. Phosphate gold solution

$KAu(CN)_2$	1.3 g/l
K_2HPO_4	120 g/l
KH_2PO_4	30 g/l

2. Citrate gold solution

$KAu(CN)_2$	1.3 g/l
$(NH_4)_2HC_6H_5O_7$	50 g/l

3. Cyanide gold solution

$KAu(CN)_2$	1.5 g/l
KCN	35 g/l

Although these relatively dilute gold solutions are not full strength gold plating solutions, they can typically be used as gold strike solutions.[3] The reason for choosing to study these dilute solutions is because of their better defined tranport properties. The pH, specific conductance, and kinematic viscosity of these solutions were measured at 60°C by a Beckman Expanded Scale pH meter, a Type RC Conductivity Bridge by Industrial Instruments, Inc., operating at a bridge current of frequency 1000 Hz and a Cannon-Fenske Viscosimeter of cell constant of 2.194×10^{-5} cm^2/sec^2, respectively. Results are tabulated in Table I.

In order to test the proposed model, the diffusion coefficient of $Au(CN)_2^-$, the diffusion layer thickness at the cathode, the limiting current density of d-c plating and finally, the limiting current density of p-c plating must all be measured. Fortunately, all of this information can be obtained using a rotating disk electrode.

Limiting current density of d-c plating.—A high speed rotator[4] described by Napp and Bruckenstein (8) was used to drive the electrode. A platinum disk of 0.635 cm diameter (0.317 cm^2 area) imbedded in a Teflon sleeve was used as the rotating electrode. A platinum coil was used as the counterelectrode. Plating was performed in all three solutions at constant total current of −5 mA (or a current density of −15.8 mA/cm^2) at 60°C and 1520 rpm for 10 min. Gold stripping was carried out in a 0.1M KCN solution at room temperature, 1520 rpm, and a total current of 2 mA. Current efficiency and consequently the limiting current density were then calculated by a comparison of the number of coulombs passed in plating to that in stripping. The values obtained were −4.95, −5.39, and −6.00 mA/cm^2 for the phosphate, citrate, and cyanide solutions, respectively.

[3] A strike solution in the plating industry refers to a dilute metal solution used in preplating. By applying high current densities for a short duration in a strike solution, the adhesion and possibly other physical properties of subsequent deposits on the substrate surface are generally improved.

[4] Supplied by the Pine Instrument Company, Grove City, Pennsylvania.

Diffusion coefficient of $Au(CN)_2^-$ and thickness of the diffusion layer.—The problem concerning mass transport to a rotating disk was originally solved by Levich (9) for asymptotically large Schmidt number. Gregory and Riddiford (10) empirically improved the Levich derivation to include the effect of finite Schmidt number and presented the following equations

$$(i_{d\text{-}c})_l = \frac{-0.554\, nFD^{2/3}\nu^{-1/6}\omega^{1/2}c_0}{(0.8934 + 0.316\,(D/\nu)^{0.36})} \qquad [17]$$

and

$$\delta = 1.80\left(0.8934 + 0.316\left(\frac{D}{\nu}\right)^{0.36}\right)\left(\frac{D}{\nu}\right)^{1/3}\left(\frac{\nu}{\omega}\right)^{1/2} \qquad [18]$$

where ν is the kinematic viscosity of the solution and ω is the rotational speed.

The limiting current densities for the three gold plating solutions were measured at a number of rotational speeds using the same technique mentioned in the last section. Results were plotted in Fig. 5. The diffusion coefficients were then calculated by Eq. [17] and the results summarized in Table I. Due to experimental uncertainties, the third significant figure of D for the citrate gold solution is probably not meaningful. Knowing D and ν, the thickness of the diffusion layer can easily be calculated by Eq. [18].

Rate of deposition by pulsed current.—Similar experimental procedures for limiting current density measurements by d-c plating were used to study the rate of deposition by p-c plating. The magnitude of the pulsed current was 6 mA (*i.e.*, 18.9 mA/cm^2) and the total duration for a pulsed experiment was 10 min for all solutions. All experiments were carried out at 60°C and 1520 rpm. Five $a\theta$ values (0.5, 1.0, 1.5, 2.0, 2.5) and four θ_1/θ values (0.2, 0.4, 0.6, 0.8) were used. Values of δ and a for the phosphate, citrate, and cyanide solutions at 1520 rpm were calculated from Eq. [18] and Eq. [10] to be 0.00144 cm, 19.5 sec^{-1}, 0.00142 cm, 20.6 sec^{-1}, 0.00140 cm and 21.2 sec^{-1}, respectively. The pulsed current was supplied by feeding the square-wave voltage pulse from a Tacussel GSTP2 function generator to a fast-rise Wenking Model 61 RS potentiostat and converting the final output to the galvanostatic-control mode. The pulse was recorded on a Tektronix Model 564B oscilloscope. The rise time for the pulse was found to be less than 10 μsec for all cases.

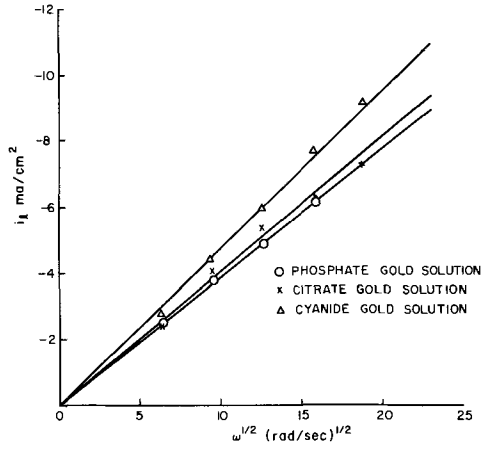

Fig. 5. Limiting current densities in phosphate, citrate, and cyanide gold solutions.

The rate of deposition and consequently the limiting current for p-c plating were then calculated from the same stripping experiments described earlier. The experimental data points for the phosphate and the citrate solutions are given in Fig. 6 to Fig. 9. Good agreement is observed between the proposed model and experimental results for both the phosphate and citrate solutions.

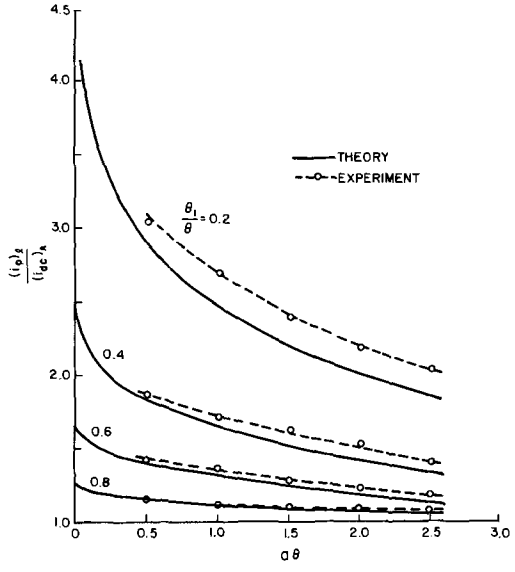

Fig. 6. Limiting current density for p-c plating in a phosphate gold solution.

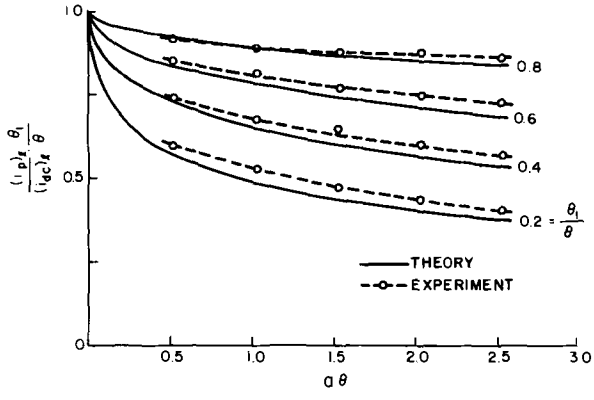

Fig. 7. Limiting over-all rate of deposition for p-c plating in a phosphate gold solution.

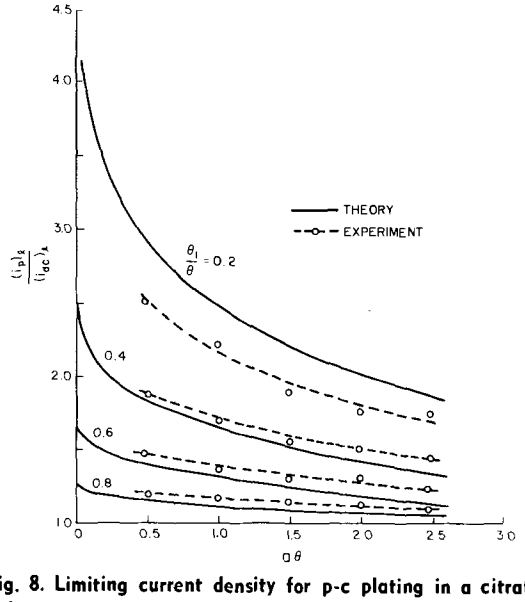

Fig. 8. Limiting current density for p-c plating in a citrate gold solution.

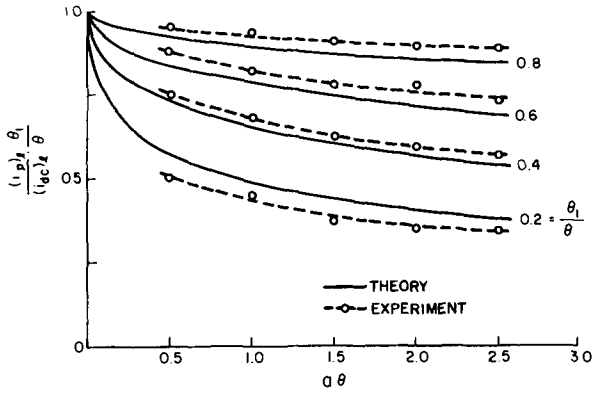

Fig. 9. Limiting over-all rate of deposition for p-c plating in a citrate gold solution.

Initial results from the alkaline cyanide bath indicated that the measured limiting current density and rate of deposition were considerably lower than those predicted from the theory. These are shown in Fig. 10 and Fig. 11. Turner (11) suggested the possibility of chemical dissolution of gold in a solution containing a large amount of cyanide ion and oxygen. This chemical dissolution process was studied using the same rotating disk electrode arrangement. Gold was plated onto the rotating platinum cathode at -15.8 mA/cm^2

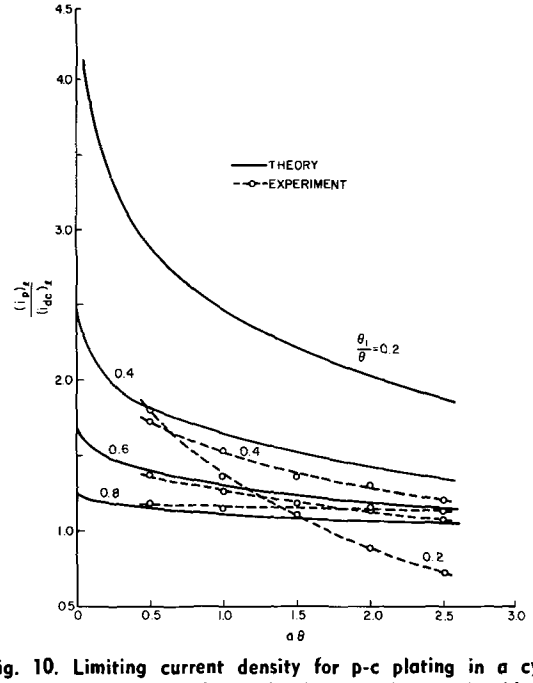

Fig. 10. Limiting current density for p-c plating in a cyanide gold solution; uncorrected for chemical dissolution of gold.

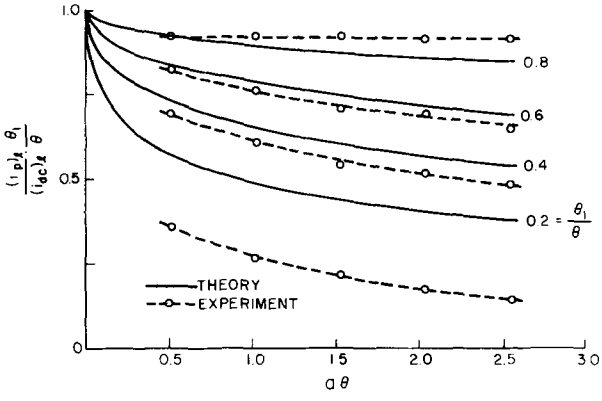

Fig. 11. Limiting over-all rate of deposition for p-c plating in a cyanide gold solution; uncorrected for chemical dissolution of gold.

and 1520 rpm for 10 min. At the end of the plating period, the electrode was disconnected electrically, but rotation was continued for 10 min to provide chemical dissolution. A stripping experiment was then performed to determine the amount of gold left on the electrode. The rate of chemical dissolution was calculated from the difference in amount of gold plated and gold stripped. The experiment was repeated changing only the rotational speed during chemical dissolution. Results are shown in Fig. 12. With this dissolution information, the results for p-c plating in the cyanide solution were corrected and shown in Fig. 13 and 14. In view of the relatively complex nature of the experiments, the agreement can also be considered to be satisfactory for the alkaline cyanide solution.

Chemical dissolution of gold in the cyanide solution is in itself an interesting problem. In an alkaline medium, the dissolution proceeds according to the reaction

$$2Au + 4CN^- + \tfrac{1}{2}O_2 + H_2O \rightarrow 2Au(CN)_2^- + 2OH^- \quad [19]$$

Little is known about the rate of this process. In the present study, the rate of this process was needed only as a correction factor. Consequently, no measurements of the oxygen concentration in the solution were made, and the present study was probably not accurate enough to calculate the reaction order and the rate constant of the dissolution process. Levich (12) discussed the application of the rotating disk electrode to study kinetics of surface reactions. Comparing

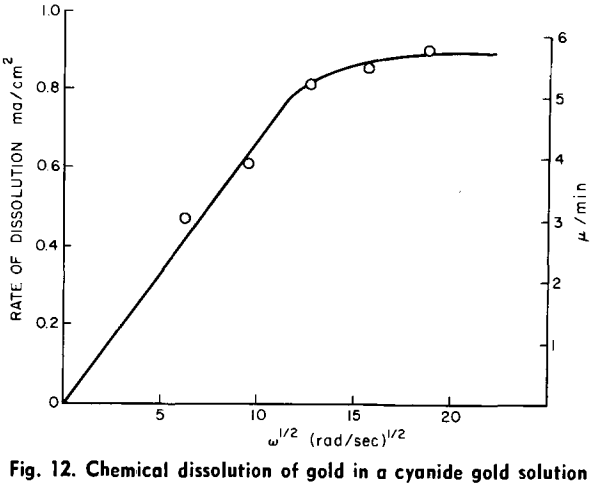

Fig. 12. Chemical dissolution of gold in a cyanide gold solution

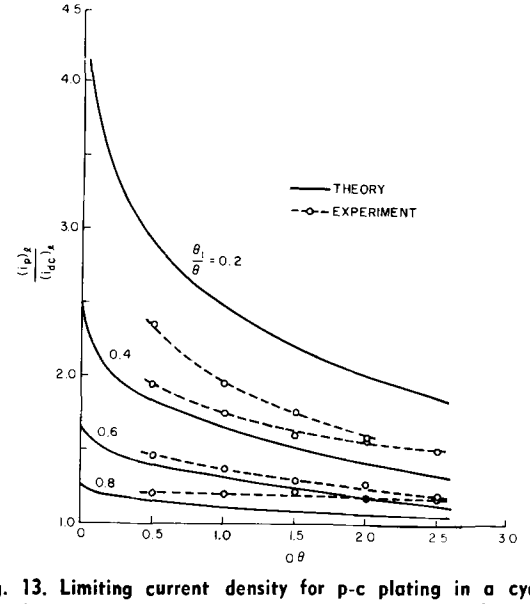

Fig. 13. Limiting current density for p-c plating in a cyanide gold solution; corrected for chemical dissolution of gold.

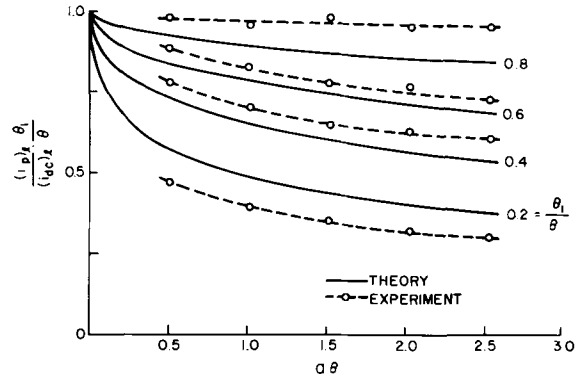

Fig. 14. Limiting over-all rate of deposition for p-c plating in a cyanide gold solution; corrected for chemical dissolution of gold.

Levich's theory and the experimental results, it can be concluded qualitatively that the chemical dissolution of gold is controlled by mass transport of oxygen at low rotational speeds, but is controlled by surface kinetics at high rotational speeds.

The only data on the diffusion coefficient of $Au(CN)_2^-$ were measured by Kakovskii *et al.* (13) in KCN solutions by the method of diffusion through a porous diaphragm. At infinite dilution the value was reported to be 1.60×10^{-5} cm²/sec at 25° C. A direct comparison of this information to the present data is not possible because of the different temperature where these data are presented. However, the difference is probably not significant.

Conclusions

A simple diffusion model was suggested to calculate the rate of deposition by p-c plating. In contrast to several claims made in the literature, the results indicate that although the limiting value of the instantaneous pulsed current for deposition can be considerably higher than that of d-c plating, the limiting over-all plating rate is lower than that of d-c plating.

Experimental investigations were carried out in three gold plating solutions. Results agree satisfactorily with the theoretical model.

The diffusion coefficient of $Au(CN)_2^-$, specific conductance, kinematic viscosity, and *p*H values for all three solutions were measured.

In conclusion, the advantage of applying pulsed current during electrodeposition is not to increase the limiting over-all plating rate but to raise the limiting current density; thereby possibly improving the physical properties through structural modifications of the electrodeposits.

LIST OF SYMBOLS

- a, a diffusion parameter, $a = \pi^2 D/4\delta^2$ (sec^{-1})
- c, concentration of the metal ion, moles/cm³
- c_i, c_o, concentration of the metal ion at the electrode-solution interface and at the bulk, respectively, moles/cm³
- D, diffusion coefficient of the metal ion, cm²/sec
- F, Faraday's constant, coulomb/equiv
- i, current density, A/cm²
- $i_{d\text{-}c}$, i_p, current density for deposition for d-c plating and for p-c plating, respectively, A/cm²
- $(i_{d\text{-}c})_l$, $(i_p)_l$, limiting current density for d-c plating and for p-c plating, respectively, A/cm²
- N, number of cycles passed during p-c plating
- n, number of electrons transferred in an electrochemical reaction
- t, time, sec

t_1, t_2, etc., time periods during p-c plating defined in Fig. 1, sec
x, distance coordinate, cm
δ, thickness of the diffusion layer, cm
θ, period of a pulsed current, sec
θ_1, θ_2, portion of the period when the current is on and portion of the period when the current is off, sec
κ, specific conductance of a solution, $ohm^{-1}\ cm^{-1}$
ν, kinematic viscosity of a solution, cm^2/sec
τ, a time parameter, $\tau = t - N\theta$, sec
ω, rotational speed, rad/sec

The Thermodynamics and Electrode Kinetic Behavior of Nickel in Acid Solution in the Temperature Range 25° to 300°C

R. L. Cowan*,[1] and R. W. Staehle*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

The electrode kinetic behavior of nickel was studied by potentiokinetic, potentiostatic, and potential decay techniques in sulfate solutions of *p*H 1.3, 3.4, and 6.3 adjusted to constant 0.1*N* ionic strength by K_2SO_4 additions. The active-passive transition characteristic of the room temperature behavior of nickel was found to be absent at temperatures above 100°C. However, at temperatures above 250°C, indications of oxide formation were found although there was little contribution to passivity therefrom. In addition, the temperature stability of passive films and these oxides seems to be *p*H dependent. Theoretical potential-*p*H diagrams were also constructed for the nickel-water systems for the temperature range used in these experiments.

The vast majority of electrode kinetic data reported in the literature for aqueous solutions have been determined at 25° ± 15°C, and very few data are reported for temperatures above 100°C. In view of this state of affairs, this study was initiated to investigate systematically the effect of temperature on the electrode kinetic behavior of nickel in acid solutions through the temperature range 25° to 300°C.

Nickel was chosen as the test material for three reasons: (*i*) Nickel serves as the base element for many alloy systems used industrially for corrosion resistance at high temperatures. (*ii*) The electrode kinetic behavior of nickel at 25°C is well documented (1-11) and could serve as a useful basis for interpreting higher temperature results. (*iii*) Nickel shows an active to passive transition which is typical of many corrosion resistant industrial alloys.

The experimental work on electrode kinetics involved potentiodynamic determinations of anodic and cathodic behavior, current decay at constant potential, and potential decay. To supplement the understanding of the kinetic results, the effect of temperature on the equilibrium thermodynamic behavior of nickel-water reactions was calculated, and potential-pH diagrams were constructed over the temperature range 25°-300°C. These thermodynamic calculations are discussed first to provide a basis for interpreting the subsequent kinetic behavior.

Potential—pH Diagrams

In electrochemical thermodynamics the standard hydrogen electrode (SHE) is defined as the zero potential [*i.e.*, $\mu^\circ_{H^+} = 0 \neq f(T)$] at all temperatures. The standard electrode potential, E°, of any other half-cell reaction is then given by the whole cell voltage of the cell shown in Eq. [1].

$$H_2\ (1\ atm)/H^+ || (aq., a = 1)$$
$$[\text{Half-cell in question, } a \text{ (all species)} = 1] \quad [1]$$

The standard electrode potential of such a cell is a thermodynamic quantity that can be measured accurately by experiment (12-15). Unfortunately, the determination of E° values for one reaction over a range of temperature is a long and arduous process, *i.e.*, see Greeley (16). If it is desired to construct potential-*p*H diagrams over a significant temperature range, *i.e.*, 25°-300°C, the experimental data for E°_T are not available at present for any system, and the needed data must be determined theoretically.

By using the relation $\Delta F^\circ = -nFE^\circ$, the standard electrode potential of any half-cell reaction at any temperature T can be referred to its standard value at 25°C by the use of Eq. [2], derived from thermodynamics by

$$\Delta F°_{T_2} = \Delta F°_{T_1} + \int_{T_1}^{T_2} \Delta C_p dT - T_2 \int_{T_1}^{T_2} \frac{\Delta C_p}{T} dT - \Delta T\, \Delta S°_{T_1} \quad [2]$$

Unfortunately, the C_p data required for Eq. [2] are not available for most ionic species (17-21) and attempts by Lewis (22) at solving it by assuming that the C_p value of ionic species are zero do not correspond with experimental data, as is shown in Table I, and the need for ionic C_p data is clear. Recently Criss and Cobble (23-25) have devised a theoretical method for solving Eq. [2]. Their method rests on what they call the "Correspondence Theory of Ionic Entropy," and their procedure (which is the one used herein) is described as follows. The absolute entropy of the hydrogen ion at 25°C, $S°_{H+}$ (25°C), is estimated to be −5.0 eu. Criss and Cobble normalize all of the literature values of the ionic entropy at 25°C to the absolute scale as follows by the relationship

$$S°_{25}\ (i,\text{abs}) = S°_{25}\ (i, \text{conventional}) - 5.0\ Z \quad [3]$$

where $S°_{25}$ (i,abs) = absolute entropy of i at 25°C, Z = ionic charge (with sign) of i, and where the conventional scale is based on $S°(H^+) = 0$ at any temperature. Criss and Cobble show that Eq. [3] is valid for any temperature, T_2.

$$S°_{T_2}\ (i,\text{abs}) = S°_{T_2}\ (i, \text{conventional}) - S°_{T_2}\ (H^+, \text{abs})\ Z \quad [4]$$

The problem then remains to relate $S°_{T_2}$ (i,abs) to $S°_{25}$ (i,abs). Criss and Cobble show that this can be done by the following relationship which they call the Correspondence Principle of Ionic Entropy.

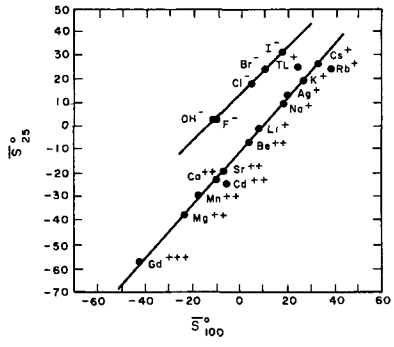
$$S°_{T_2}\ (i,\text{abs}) = a(T_2) + b(T_2)\ S°_{25}\ (\text{abs}) \quad [5]$$

The basis for Eq. [5] rests on Criss and Cobble's analysis of the available experimental data in the literature. For each temperature T_2 they found that only one assigned value of $S°_{T_2}$ (H^+, abs) could be used in Eq. [4] to give a linear relationship between $S°_{T_2}$ (i,abs) and $S°_{25}$ (i,abs) for every ion type. An example of their analysis is shown in Fig. 1 for T_2 equaling 100°C. The Correspondence Principle does have some theoretical justification, and the reader is referred to Criss and Cobble's papers (23-25) for its discussion and justification.

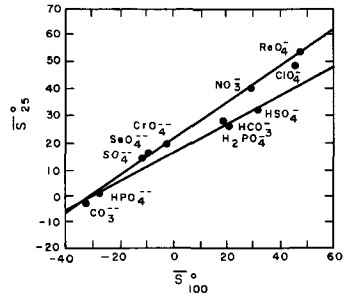
To calculate values of $\Delta F°_{T_2}$ from Eq. [2] using the Correspondence Principle it is convenient, following Criss and Cobble, to use the following definitions

$$\overline{C_P}\Big|_{T_1}^{T_2} = \text{average value of the heat capacity}$$

$$\overline{C_P}\Big|_{T_1}^{T_2} = \frac{\int_{T_1}^{T_2} \overline{C_P} dT}{\int_{T_1}^{T_2} dT} = \frac{\int_{T_1}^{T_2} C_p d \ln T}{\int_{T_1}^{T_2} d \ln T} \quad [6]$$



(a)



(b)

Fig. 1. Diagram illustrating the linear relationship between the absolute entropies of (a) simple cations and simple anions and (b) oxyanions and acid-oxyanions at 25° and 100°C, from Criss and Cobble (23).

Thus from Eq. [2]

$$\Delta F°_{T_2} = \Delta F°_{T_1} - \Delta T \Delta S°_{T_1} + \overline{\Delta C_p}\Big|_{T_1}^{T_2} \left[\Delta T - T_2 \ln \frac{T_2}{T_1}\right] \quad [7]$$

For nonionic species $S°$ and $C°_p$ values are easily found in handbooks such as Wicks and Block (26). For ionic species, $\overline{C_p}\Big|_{T_1}^{T_2}$ is calculated from the entropy data of Criss and Cobble by the following relation

$$\overline{C_p}\Big|_{T_1}^{T_2} = \frac{S°(T_2) - S°(T_1)}{\ln (T_2/T_1)} \quad [8]$$

To employ Eq. [7] for the calculation of potential-pH diagrams at elevated temperatures, one must write the whole cell reaction in Eq. [2] with the half-cell reaction in question written in the reduction direction. For example, if one were to consider the half-cell reaction $Ni \rightarrow Ni^{++} + 2e^-$ the whole cell reaction corresponding to Eq. [2] for use in Eq. [7] would be

$$Ni^{++} + H_2 = Ni + 2H^+ \quad [9]$$

The $\Delta F°_T$ value calculated from Eq. [7] would then be converted to $E°_T$ by using the usual relationship

$$E°_T = -\frac{1}{n\mathbf{F}} \Delta F°_T$$

If T_2 is greater than 200°C, the right-hand side of Eq. [8] will be in some error if 25°C is taken as the base temperature because of the averaging method used in Eq. [6]. To circumvent this problem the $\Delta F°$ value for 200°C should be calculated and then 200°C should be used as the base temperature T_1, when using Eq. [7] and [8]. A similar procedure should then be employed for each 50°C increment.

The question now is the validity of the method. A comparison of the $E°$ values for the Ag/AgCl half-cell reaction as calculated by the method of Criss and

Cobble and the experimentally determined values reported by Greeley (16) are shown in Table I. The agreement is excellent and suggests that it is reasonable to use for calculating $E°$ values of electrochemical reactions in aqueous solutions at elevated temperatures.

The use of C_p data to calculate $\Delta F°$ for reactions in aqueous solutions over a range of temperatures is not strictly valid since the changing vapor pressure of the solvent in a closed system causes a pressure change. This is especially true as the temperature nears the critical point. Pressure can influence the chemical equilibrium in the following three ways.

1. The activity of water will change, and this introduces an additional free energy change of the type

$$\Delta F = \int_1^P V dp$$

p = vapor pressure of H_2O at temperature T.

2. Changes of the partial molal volumes will introduce a free energy change of the type

$$\Delta F = \int_1^P \overline{\Delta V} dp$$

3. The pressure change will also affect the activity coefficients of dissolved species by

$$\frac{\delta \ln \gamma}{\delta P} = \frac{V_i \quad V_o}{2RT}$$

Criss and Cobble have shown that these effects are important, but can be ignored up to 300°C since the magnitude of the errors introduced are within the limited accuracy of the data used to formulate the Correspondence Principle.

After calculating $E°_T$ values for all of the reactions being considered for a metal-water system, the potential-pH diagram can be constructed as described by Pourbaix (27). Townsend (28) was first to adopt the method of Criss and Cobble and has recently determined the potential-pH diagram for iron at temperatures to 200°C using the method of Criss and Cobble.

The potential-pH diagrams for the nickel-water system are shown for the temperatures 25°, 60°, 100°, 150°, 200°, 250°, and 300°C in Fig. 2-5. These diagrams are based on the half-cell reactions and corresponding potential-pH equations shown in Table II. The thermodynamic data used to calculate the diagrams are shown in Table III. Because values of $S°_{25°C}$ and C_P are not reported in the literature for Ni_3O_4, Ni_2O_3, and NiO_2, values were assigned to oxides of elements nearest nickel in the periodic table with similar crystal structures and free energies of formation as is noted in

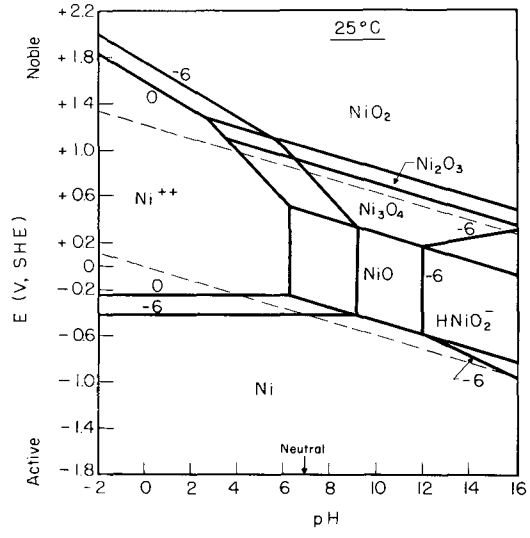


Fig. 2. Potential-pH diagram of nickel-H_2O system at 25°C

* pH values for ion concentrations = 10^{-6} moles/liter and coexistence of condensed phase.

dicates the H^+/H_2 equilibrium for $p_{H_2} = 1$ atm and the upper dotted line indicates the $2H_2O = O_2 + 4H^+ + 4e^-$ equilibrium for $P_{O_2} = 1$ atm. The solid lines indicate the coexistence between the nickel species. The activities of condensed phases were chosen as unity. Lines shown for coexistence between solid and ionic species are given for ionic activities of both unity and 10^{-6}M.

The most significant feature of these diagrams is the increasing stability of the nickel oxides in the acid range with increasing temperature. The range of pH over which the oxides are stable reaches a minimum at about 100°C and then increases with increasing temperature. At the high pH end of the diagram, the range of stability of the nickel oxy-anion, $HNiO_2^-$, increases greatly with increasing temperature. The absolute value of the slope, dE/dpH, of all lines increases with increasing temperature by the term $2.3RT/n\mathbf{F}$ from the Nernst equation. On each diagram, the neutral pH of pure water for the given temperature is indicated.

From a corrosion point of view, the range of stability of NiO as a potentially protective oxide film has shifted from a pH range of 9-12 to a pH range of 5-9. Thus, with increasing temperature, a basic pH that could have been quite protective at low temperatures might give rise to larger corrosion rate at high temperatures, especially if excess oxygen were present to raise the potential substantially above the hydrogen equilibrium potential. The diagrams also show that if the predominant reduction reaction is hydrogen ion discharge, the corrosion potential at 300°C will be such that corrosion of nickel will be impossible between the pH values of 5 and 10. The driving force for corrosion in this case will also be very small for the pH ranges 2-5 and 10-13, and lower rates should be expected. This observation probably explains the excellent corrosion performance of nickel base alloys (*e.g.*, Inconel 600) in pressurized water nuclear reactors that are overpressured with hydrogen gas and operated in the pH range 7-10. At 300°C in high pH solutions (>10) the $HNiO_2^-$ ion is the only species stable over the range of potential of water stability. This fact might in part explain the susceptibility to stress corrosion cracking of high nickel alloys in caustic solutions. Protective films formed at lower temperatures, when ruptured by stress, offer sites for rapid dissolution.

The detailed application and significance of potential-pH diagrams such as the one calculated here should be applied with some caution. The limitations therein are well known. For example, it is well known (1-11) that the region of thermodynamic stability of Ni^{++} at 25°C on a potential-pH diagram actually exhibits a wide range of effective passivity. The kinetic data reported in this study for the room temperature range are in agreement with these findings. However, the fundamental basis for passivity which produces this "anomalous" passivity is far from clear at present.

Experimental

The experimental system for obtaining kinetic data consisted of a high-temperature electrochemical cell and the supporting instrumentation necessary for electrode kinetic measurements. A schematic diagram of the experimental system is shown in Fig. 6. Electrochemical kinetic measurements in aqueous solutions at elevated temperatures are difficult for two reasons. First, the high pressure (over 1000 psi at 300°C) requires special seals and a high strength vessel. This is usually solved by some type of autoclave arrangement (29-34). The second problem is finding a suitable reference electrode arrangement that will give a half-cell potential that is thermodynamically meaningful (32-38).

Cell design.—A standard one liter double ended autoclave supplied by Autoclave Engineers (Erie, Pennsylvania) served as the electrochemical cell. The cell was constructed of Hastelloy B and employed a high-purity alumina liner to insure that corrosion from

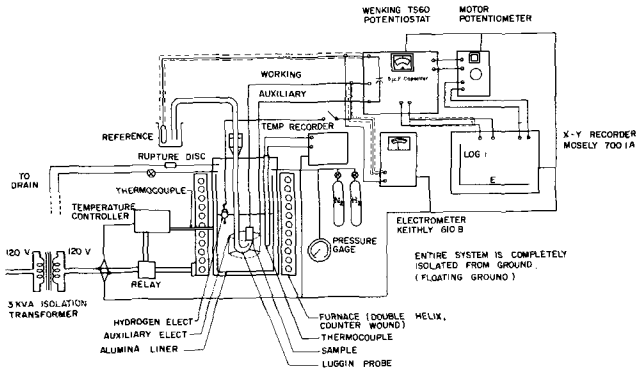

Fig. 6. Schematic diagram of experimental system used for high-temperature electrochemical measurements.

the hot solutions would neither harm the structural integrity of cell nor contaminate the test solution. Conax fittings were installed in the top head of the autoclave to seal the electrodes and thermocouple. Fittings were also provided on the body for the pressure gauge, rupture disk assembly, and gas inlet and outlet. The cell was heated by a 3 kW anti-induction wound resistance heater. A temperature controller regulated the outside temperature of the autoclave using a thermocouple held firmly against the autoclave wall by a spring. The temperature within the autoclave was controlled constant to within ±1°C. However, temperatures were only reproducible to ±5°C. The solution temperature was measured with a tantalum sheathed iron-constantan thermocouple. At temperatures below 100°C, the heat transfer characteristics of the cell were such that the temperature of the solution could not be controlled effectively, and all data below 100°C were obtained using a glass cell.

Electrode design.—The hydrogen electrode was a 1 in. piece of platinized platinum, replatinized for each run, suspended from a silica float as described by Greeley (36). The electrode could then "see" both the solution phase and the gas phase. The working electrode design was similar to that described by Wilde (32-33). The nickel specimen is the only metallic part of the electrode assembly that "sees" the solution. The nickel sample was a ¼ x ½ in. cylinder. The sample was screwed snugly to a rod and then was pulled tightly against a Teflon washer and alumina support tube. The Luggin probe solution bridge assembly was similar in design to those described by others (31-34). The probe was made of clear quartz capillary tubing. An external reference electrode of saturated calomel was used. Thus, it was possible to compare the behavior of an internal and external reference. To establish ionic conduction to the reference electrode during the low temperature experiments, a 200 psi overpressure of nitrogen was admitted to the cell to force solution through the cellulose plug. A thread was used in the Luggin probe to act as a wick to maintain electrolytic conductor through bubbles that sometimes formed in the lower temperature (but high-pressure) part of the bridge. A piece of 45 mesh platinum gauze 1 in. in width and 2¾ in. diameter served as the auxilliary electrode.

Electronic apparatus.—A Wenking potentiostat (Model 66TS10) was used for all potentiostatic work. For potentiokinetic scans, a Wenking motor potentiometer was employed to drive the potentiostat. Polarization curves were recorded directly on a Mosley 7601A recorder. Although shielded twisted cable was used in all electrical leads as well as the other usual precautions, a-c pickup on all electrodes was a major difficulty and caused instability in the potentiostat. A combination of an isolation transformer and 10 μF capacitive shunt between the reference and auxiliary electrode terminal solved the problem. A Keithley

610B electrometer and L&N potentiometer were used for potential measurements. The thermocouple output voltage from inside the cell was monitored throughout each test by a recorder.

Test materials.—Nickel 270 (99.97% Ni) supplied by the International Nickel Company was used in all experiments. The nickel stock material was solution annealed at 1090°C for 1 hr to assure homogeneity. Tests solutions were prepared from distilled water, analytical grade sulfuric acid and analytical grade potassium sulfate. The composition of these solutions was as follows:

pH 1.3	$0.050N$ H_2SO_4 + $0.05N$ K_4SO_4
pH 3.4	$0.001N$ H_2SO_4 + $0.099N$ K_4SO_4
pH 6.3	0.100 K_4SO_4

The hydrogen used to saturate the solution and the atmosphere over the solution was ultra high purity and contained less than 1 ppm O_2. The nitrogen used to provide overpressure contained less than 1 ppm O_2.

Experimental procedure.—The nickel specimens were degreased in acetone, rinsed copiously in distilled water, and polished successively with 280, 400, and 600 grit paper. The specimen was then screwed to the working electrode. The Luggin probe was adjusted until the tip was 1 mm away from the sample. A piece of filter paper was ground and wet with the test solution and then used as packing for the solution bridge assembly. The head and all fittings were tightened into place, and the system was pressure tested with nitrogen. Hydrogen was then bubbled through the test solution for twelve hours by means of a Hastelloy-B capillary inserted in the thermocouple fitting. The thermocouple was replaced and the plenum was flushed with hydrogen to remove the last tracers of oxygen. If the run was to be at a temperature below 175°C, a 200 psi of nitrogen was introduced to provide sufficient pressure across the cellulose plug to assure proper operation of the solution bridge. A glass solution bridge connected the solution bridge assembly to the calomel reference electrode which was maintained at 25°C and room pressure.

Results and Discussion

Measurement of potential.—To insure that the results determined in the high-temperature electrochemical cell were the same as those obtained by the conventional glass cell, the anodic polarization curve of Ni 270 was determined in each system at 25°C in $1N$ H_2SO_4. The two curves were practically identical, especially in the passive region, except that the curve determined in the autoclave was displaced in the noble direction by about 70 mV on the potential axis. This behavior was expected since the potential of the sample in the autoclave was measured through the high-pressure salt bridge by a standard calomel electrode at ambient pressure. This increment in potential is produced by the streaming potential and junction potential resulting from the 200 psi internal pressure acting across the cellulose plug.

Since it is desirable to avoid gross inaccuracies in the measurement of potentials over the range of experimental conditions, a standard procedure was developed for adjusting experimentally measured potentials. This procedure involves using a calculated correction obtained as follows. Since the hydrogen activity of the solution was known by the pH of the solution ($pH = -\log a_H$) and the partial pressure of hydrogen in the cell was set at 1 atm, the redox potential of the hydrogen electrode could be calculated by the Nernst equation.

$$E(H^+/H_2, \text{calc.}) = 0 - \frac{2.3RT}{nF} \log \frac{(pH_2)^{1/2}}{a_{H^+}} \quad [10]$$

Thus, the measured corrosion potential of the nickel electrode could be changed to the standard hydrogen scale by

$$E_{corr} = E(\text{corr, meas.}) - E(H^+/H_2, \text{meas.}) + E(H^+/H_2, \text{calc.}) \quad [11]$$

where:

E_{corr} = true corrosion potential on the SHE scale

E(corr, meas.) = corrosion potential of the nickel sample in the autoclave as measured through the solution bridge

$E(H^+/H_2, \text{meas.})$ = hydrogen redox potential of the floating hydrogen electrode as measured through the solution bridge

$E(H^+/H_2, \text{calc.})$ = calculated hydrogen redox potential from Eq. [1].

When the corrosion potential determined for nickel in the autoclave was adjusted by this calculation it agreed within 5 mV [E_{corr} (autoclave) = −0.045V, (SHE) of the value as determined in the glass cell (E_{corr} (glass cell) = −0.040V, SHE)] in which there was neither a streaming potential nor significant junction potential in the salt bridge.

This same technique was used to determine the corrosion potential on the standard hydrogen scale in the tests at elevated temperatures. Equation [10] was calculated for the temperature and pH of the test. Then $E(H^+/H_2, \text{calc})$, E_{corr} (measured) and $E(H^+/H_2, \text{measured})$ were substituted into Eq. [11] to determine the actual value of E_{corr} on the SHE scale at the test temperature. Using this technique, the corrosion potential, and thus the potentials of the polarization curves were on the same thermodynamically meaningful scale, SHE at T, as the calculated potential-pH diagrams. This technique for correcting measured potentials assumes that a_{H^+} and pH_2 do not change with temperature, *i.e.*, in this calculation we assume that a_{H^+} calculated at 25°C pH and $pH_2 = 1$ do not change with temperature. Greeley (36) has shown that indeed there are some small changes in a_{H^+} and pH_2 with temperature for a closed hydrogen saturated acid solution. However, since these two quantities are in the log term of Eq. [10], small changes should not affect $E(H^+/H_2, \text{calc.})$ appreciably.

Values of E_{corr} (measured), $E(H^+/H_2, \text{measured})$, $E(H^+/H_2$ calculated) and E_{corr} for the different test pH's and temperatures are given in Table V. These

are the initial values measured after 1 hr at the test temperature. One noticeable feature in Table V is that there is very little difference between $E(H^+/H_2$, measured) and E_{corr} (measured) at every pH and temperature. This is surprising since nickel has a relatively active standard potential of $E^\circ = -0.250$; E_{corr} should lie somewhere between $E(H^+/H_2)$ and $E(Ni^{++}/Ni)$. However, the Ni/Ni^{++} half-cell reaction is quite irreversible, having a relatively low i_o value and thus behaves approximately as a hydrogen redox electrode in acid solutions (27). With increasing pH, the difference between $E(H^+/H_2)$ and $E(Ni/Ni^{++})$ also decreases owing to the pH dependence of the former. In addition, as the temperature increases, the E° values of nickel changes in the positive direction with respect to the SHE, and thus one would expect the corrosion potential to remain near the hydrogen redox potential. Both of these effects are shown in the potential-pH diagrams.

Polarization behavior.—The polarization behavior of nickel 270 was determined in dilute H_2SO_4-K_2SO_4 solutions of pH 1.3, 3.4, and 6.3 over the temperature range 25°-300°C. The polarization curves were determined by the potentiokinetic technique at a scan rate of 2000 mV/hr. Anodic curves were determined in both the active to noble and noble to active directions while the cathodic curves were determined only in the noble to active direction. Figures 7 to 11 show the data obtained at pH 1.3. Both active-noble and noble-active anodic scans are shown at pH 1.3 since substantial differences between the two were observed. Figures 12 to 15 show the active-noble anodic scans determined at pH 3.4 and 6.3. The noble to active anodic curves

were quite similar and are therefore omitted. The reduction kinetics are included for the pH 1.3 case, Fig. 10 and 11, but for brevity are omitted for the other two solutions.

The most significant feature of the anodic polarization curves is the abrupt loss of an active to passive transition at temperatures in the range of 100°-150°C. The exact temperature at which passivity is no longer apparent is a function of both the scan direction and the solution pH. For a given pH the noble to active scan shows remnants of passivity at slightly higher temperatures than the active to noble scan, as shown in Fig. 7 and 9. The temperature at which passivity breaks down increases with increasing pH, although the effect is not a strong one. There is a noticeable hysteresis effect between the active-to-noble and the noble-to-active scans in the passive region at the lower temperatures. The passive current density is about an order of magnitude smaller for the noble-to-active scan at the same pH and temperature. Osterwald and Uhlig (8) found this same effect for nickel in 1*N* H_2SO_4 at 40°C. At the temperatures where passivity is no longer present, the potentiostatic curves obtained in both scanning directions are virtually the same.

As the temperature is increased above that at which passivity is no longer present, the anodic curves have the shape expected for a diffusion-controlled process. However, as temperatures approach 300°C the current density in this region begins to decrease. This latter behavior can be explained by the potential-pH plots in Fig. 2 to 5. With increasing temperature at a given pH, the range of stability of the bulk oxides increases with increasing temperature. Thus, the slight but significant reduction of limiting current density above a certain critical temperature can be attributed to the formation of bulk oxide on the surface. The temperature at which the current reaches a maximum decreases in going from pH 3.4 to pH 6.3 as would be expected from the potential-pH diagrams. For the experiments at pH 1.3 the bulk oxides are not stable over the temperature range except for the 300°C case at high potentials where we see the expected drop in current as an oxide is formed. Note that the potential-pH diagrams tell only whether an oxide phase is stable and provide no information as to the reduction of anodic current density. The exact conditions for the onset of passivity will depend on the local Ni^{++} concentration close to the surface. Since the concentrations are generally high at high potentials, precipitation of an insoluble product would be expected somewhat earlier than predicted from bulk concentration. Qualitatively, the diagrams do agree well with the experimental results.

The temperatures above which passivity was no longer observed is shown below as a function of pH and scan direction

pH	Active to noble, °C	Noble to active, °C
1.3	100	125
3.4	125	150
6.3	130	155

Since the results from potentiokinetic experiments are not exact relative to potentiostatic measurements, the above values should be taken as approximate. It is clear however that a critical temperature for loss of passivity does exist and is in the range of 75°-150°C. Myers *et al.* (11) have reported an inflection point in the Arrhenius plot of log minimum passive current density. This inflection point is a function of *p*H and is characterized by the equation $1/T \times 10^3 = -0.11$ pH + 3.04. The inflection point calculated for the *p*H values of the experiments reported herein would be T(pH 1.3) = 72°C, T(pH 3.4) = 102°C, and T(pH 6.3) = 153°C, which is the range of temperature at which passivity is no longer observed.

An Arrhenius plot of the current density at a constant potential of +0.800V SHE for the active to noble anodic scans is shown in Fig. 16. This potential is well into the passive region for all three solutions at 25°C. Above the critical temperature, the current density required to maintain the potential of +0.800V SHE increases two orders of magnitude. Obviously, there are separate processes operating over the experimental temperature range at the lower temperatures where passivity is present the kinetics seem to be activation controlled (although the data have too much scatter for the determination of a significant value for the activation energy). At the higher temperatures, the anodic current is insensitive to temperature over a broad range and may be indicative of a diffusion-controlled process. At the highest temperatures the current decreases with increasing temperature. A possible explanation for this latter behavior will be presented in conjunction with the potential decay measurements.

The corrosion current, i_{corr}, was determined by extrapolation of the cathodic Tafel region to the corrosion potential. These corrosion currents are plotted *vs.* $1/T$ in Fig. 17 and an activation energy of $\Delta G^* = +3.30 \times 10^{+3}$ cal/mole is obtained. The process to which the ΔG^* refers may be deduced by recalling that the corrosion potential was very close to the hydrogen equilibrium potential as shown in Table V. Thus the corrosion current density is approximately equal to the exchange current density for the reaction $H_2 = 2e^- + 2H^+$ on the nickel surface. The exchange current density is as follows

$$i_o = z\mathbf{F}fC_sV_L \exp(-\Delta G^*/RT) \qquad [12]$$

Assuming that f, C_s, and V_L are not a function of temperature

$$\frac{\log i_o}{1/T} = -\frac{\Delta G^*}{R} \qquad [13]$$

Thus, a plot of log i_{corr} *vs.* $1/T$ for the case of nickel should give a straight line of slope $= -\Delta G^*/R$ where ΔG^* will be the activation energy for the hydrogen redox reaction on nickel. The best straight lines through the points of each *p*H give the same slope, each line displaced from the other slightly with the *p*H 1.3 line being uppermost and the *p*H 6.4 line being lowest. This behavior agrees with Eq. [12] in that C_s, the hydrogen ion concentration in the double layer, will be less at the higher *p*H values and thus the curve should be displaced down for higher pH values. The activation energy calculated by the slope of the lines is $\Delta G^* = +3.30 \times 10^{+3}$ cal/mole. This compares fairly well with the value $\Delta G^* = 5.7 \times 10^{+3}$ cal/mole for the hydrogen reaction on nickel in 0.12*N* NaOH as determined by Bockris and Potter (39).

The reproducibility of polarization results was excellent. The anodic active-to-noble curves determined at 25°C agree within the scatter of the data of previous investigations (1-11). The curves determined at 25°C were the object of a rather intense study of the reproducibility of the polarization behavior. If the same sample was used for repeated curves at the same *p*H, the curves were identical. If different samples were used, the passive region was still identical, but the active region showed some variation. This type of behavior has been found by others in nickel (7) as well as in iron (40) and stainless steel (41). Since the object of this research was to characterize the effect of temperature on the polarization response of nickel at different temperatures, only selected checks of reproducibility were made. One of these checks involved determining the anodic polarization behavior of one sample in the same solution from 25° to 300°C. The anodic polarization curve was determined at one temperature; the temperature was then increased and

another curve was determined, etc. This procedure was followed for a test at each pH. The curves obtained in this manner agreed well with the data reported herein. In every case, the temperature at which passivity became absent was in exact agreement.

Decay of potential and decay of current at constant potential.—The presence of a passive film can usually be detected by appropriate decay experiments. When the potential is held constant and the current measured, a constant high current indicates that no film exists. A steady decay in current indicates that a film exists and is improving its protective quality. When the potential is first brought to a high value and allowed to decay, an immediate return to the corrosion potential indicates the absence of a protective film. When there is an intermediate arrest(s) before returning to the corrosion potential the presence of a protective film is indicated. In the constant potential experiments and for temperatures and pH combinations at which passivity was expected, the overpotential selected was such that the potential was well into the passive region. For temperatures and pH values at which passivity was not expected, the potential was selected to be in the diffusion controlled region. A summary of the experimental results from the measurements of current decay at constant potential is shown in Table VI.

For those cases in which passivity was expected, the current fell exponentially to values corresponding closely to the minimum passive current density found by the potentiokinetic scans. The steady-state ($t = 30$ min) passive current densities are summarized in Table VI and are compared with the values obtained potentiokinetically. The agreement is excellent. For those intermediate temperatures in which passivity was absent in the potentiokinetic curves, the agreement was good within an order of magnitude. In this latter case, the current did not change with time as can be seen by comparing $i(t = 30$ sec) and $i(t = 30$ min) in Table VI. At 300°C, where the potentiokinetic data and the potential-pH diagrams indicate that an oxide(s) of nickel is present for the pH 3.4 and 6.3 solutions, the current did decay somewhat with time, indicating that some diffusion barrier, probably an oxide, was inhibiting nickel dissolution. For the pH 1.3 case at 300°C, this behavior was not observed, as was expected from the 300°C potential-pH diagram.

In the case of the potential decay experiments the specimen was held for 30 min at constant potential, the potentiostat was turned off and the open-circuit potential of the sample was recorded as a function of time. The potentials were those used for the current decay studies. For the temperatures and pH values at which the potentiokinetic polarization curves indicated passivity, there was an abrupt arrest in the decay curve. The arrest should occur near but slightly below the equilibrium redox potential of nickel and the oxide composing the passive film, Ni/NiO_n, or at some redox potential of two oxides, NiO_n/NiO_m.

A listing of the experimentally observed arrest potentials is given in Table VII. At the lower temperatures at which passivity was present in the potentiokinetic curves, a potential arrest was observed. At the intermediate temperatures no arrests were found, but at 300°C arrests were observed for the pH 3.4 and 6.3 cases. Two exceptions in the above general behavior were the 75°C cases at pH 1.3 and 3.4. Although the decay curves for these cases were markedly different from the higher temperature cases, no clear arrest potential could be determined. At those temperatures for which neither passivity nor an oxide was present, the time for decay to the corrosion potential was practically instantaneous. In Table VII, an attempt is made to compare the observed arrest potentials with all the possible Ni/NiO_n and NiO_n/NiO_m redox potentials of the bulk oxides. These redox potentials were calculated in the same manner as the coexistence lines of the potential-pH diagrams described earlier. For those temperatures at which passivity was observed, the arrest potentials were close to the Ni/Ni_3O_4 equilibrium in the pH 1.3 and 3.4 cases. This behavior would be in good agreement with the Bockris, Reddy, and Rao (1) result that the passive film is composed of $NiO_{1.5\text{-}1.8}$. For the pH 6.3 case, at the temperatures where passivity was observed, the arrest potentials were very close to the Ni/NiO equilibrium. This latter

result was expected since the potential-pH diagram, Fig. 2, shows that NiO should be stable at the overpotentials in question. This result does not necessarily imply that NiO causes passivity at this pH, for the bulk NiO present probably obscures the redox arrest potential of the passive agent.

The arrest potentials at 300°C for the pH 3.4 and 6.3 agree best with the Ni/Ni_3O_4 equilibrium potentials. This behavior is not easily explained, since in both cases the applied overpotential should have produced NiO according to the potential-pH diagram of Fig. 5. In any event, the presence of an arrest potential did imply that an oxide was on the surface, in agreement with the potentiokinetic curves.

In summary, both the constant potential and potential decay experiments agreed well with the behavior expected from consideration of the potentiokinetic curves. The possibility of the presence of a stable oxide at the higher temperatures in the pH 3.4 and 6.4 solutions was also strengthened.

The question not answered by the present work is why the active-to-passive transition in nickel seems to disappear abruptly above a critical temperature that is only slightly pH dependent. One possible explanation is that the dissolution kinetics of the passive film are such that at the critical temperature the dissolution rate of the film is equal to the rate of film growth. Another possibility is that the precursor film described by Bockris, Reddy, and Rao (1) is not stable above the critical temperature. Since they conclude that this film is necessary, but not sufficient, for the formation of passivity, its absence would preclude any chance for the formation of the passive state. Whatever the cause, the observed phenomenon is not predicted by any current theory of nickel passivity.

Conclusions

Significant conclusions and observations from this study are:

1. The active-to-passive transition in nickel is absent at temperatures above the 90°-125°C range for the solutions studied.
2. Potential-pH diagrams for $Ni-H_2O$ were calculated over a range of potentials and indicate that the range of stability (with respect to pH) of the oxide phases of nickel in the acid region increases with increasing temperature.
3. At temperatures above the presence of an active to passive transition, the anodic polarization curves have the appearance of a film free diffusion-controlled process. At 300° in the pH 3.4 and 6.3 solutions, bulk oxide forms during anodic polarization as predicted by the potential-pH diagrams.
4. A hydrogen electrode within the autoclave can be used effectively to determine potentials on the standard hydrogen scale at test temperature.
5. Potential decay experiments suggest the presence of Ni_3O_4 (pH 1.3 and 3.4) and NiO (pH 6.3) during decay from the passive region at temperatures where "anomalous" passivity is present. At temperatures and pH where bulk oxide formation is present, potential decay experiments indicate the presence of Ni_3O_4.
6. The corrosion potential of nickel is always near the hydrogen redox potential at all temperatures and pH, indicating that nickel is acting as a hydrogen electrode. An Arrhenius plot of i_{corr} gives an activation energy of 3.3×10^3 cal/mole which is close to the activation energy for the hydrogen redox reaction on nickel.

ABSTRACT

A number of compounds of the transition elements with B, C, H, N, P, S, and Si have been screened for corrosion resistance and catalytic activity for anodic hydrogen oxidation in M H_2SO_4. Only WC and alloys of WC with TaC were found to be active. A plot of apparent activation energy against overpotential was linear in the range 200-500 mV The activity of WC is discussed in the context of (*a*) surface defects acting as active centers and (*b*) the formation of hydrogen tungsten bronzes.

Several articles have been published recently on the use of tungsten carbide as an alternative electrocatalyst to noble metals for the anodic oxidation of hydrogen in aqueous acid fuel cells (1-3). Tungsten carbide is, however, only one of a large range of similar interstitial compounds which can be prepared from reaction of the transition metals with boron, carbon, phosphorus, and silicon. A number of these compounds exhibit metallic conduction and have excellent corrosion resistance, even in the presence of strong acids. There seemed to be no known reason why the electrocatalytic activity for anodic hydrogen oxidation should be confined to tungsten carbide, and therefore a study was made of a range of similar compounds. This study was made in two parts: (*a*) a screening program to examine the compounds for bulk corrosion and catalytic activity for anodic hydrogen oxidation in M H_2SO_4, and (*b*) analysis of selected compounds to attempt to relate catalytic activity with measured physical-chemical parameters.

Experimental

Test samples were obtained from various suppliers as outlined in Table I. Hydrophobic gas diffusion test electrodes were prepared from these samples as follows: 60 mesh nickel wire gauze was cut into 1 cm squares, degreased in hot trichlorethylene, and a gold wire spot welded to one edge. The nickel gauze was then electroplated with gold (Johnson, Matthey and Company Ltd., G.88 plating solution) at 5 mA for 4 hr to produce electrodes which did not corrode in M H_2SO_4 over the potential range used. The catalyst sample was mixed with a polytetrafluoroethylene (PTFE) emulsion (Fluon G.P.1., I.C.I. Ltd.), to give a final PTFE: catalyst ratio of 1:3 (w/w); the slurry so formed was applied onto the electrodes which were then subsequently dried at 100°C before sintering in air at 300°C (±5°C) for 30 min.

Electrodes were tested in a typical half-cell arrangement. Each electrode was floated on the surface of the electrolyte and a Luggin capillary placed directly beneath it. A dynamic hydrogen electrode (4) in the same solution was used as reference electrode. The counterelectrode was a large piece of platinum gauze separated from the test electrode by a glass frit. Gas sparge tubes were fitted to each cell compartment.

All glassware was thoroughly degreased and cleaned with (*i*) alcoholic potash and (*ii*) a 1:1 mixture of concentrated nitric and sulfuric acids, and was finally washed in triply distilled water immediately before use. The electrolyte was prepared from AnalaR sulfuric acid and triply distilled water. All measurements were made at ambient temperature (22°-25°C), unless otherwise stated.

Steady-state measurements were made with the solution and atmosphere in the cell saturated with either nitrogen or hydrogen. Current readings were taken at 50 mV steps, allowing at least 10 min at each step for equilibrium to occur.

A selected number of samples were analyzed for the following information: phase composition, crystallinity of the various phases, impurity elements, and particle size distribution and average particle size.

Phase composition and crystallinity were determined by x-ray diffraction. Impurity elements were identified by x-ray fluorescence, and the average particle size and particle size distribution were estimated by optical and electron microscopy.

Results

Table I lists the compounds screened and shows the corrosion current and hydrogen oxidation current at 200 mV. Where measured, the average particle size is shown; in other cases the average particle size was larger than 3μ. Table IIa is a summary of the analytical results, set out to facilitate the correlation of the measured parameters with the hydrogen oxidation current. A number of ternary compounds and tungsten carbide samples, on which a full analysis was not made but which show catalytic activity or are otherwise especially interesting, are listed in Table IIb.

Figure 1 shows I-V plots at a number of temperatures for the most catalytically active sample tested. This was tungsten carbide (WC) which had an average particle size of 0.45μ (see Table IIb, sample 10).

Key words: hydrogen electrode, electrocatalysis, transition elements.

Apparent activation energies, calculated from Fig. 1 and similar plots, showed a characteristic linear variation with potential from 19.8 kJ $mole^{-1}$ at 500 mV to 27 kJ $mole^{-1}$ at 200 mV.

Discussion

In this comparison of the performance of hydrophobic gas electrodes prepared from various compounds, for the anodic oxidation of hydrogen, a number of reservations must be made. The performance of these electrodes is known to be dependent on their microstructure and method of preparation (5); Tantrum and Tseung (6) have shown that for oxygen reduction on PTFE bonded carbon electrodes, the performance of an electrode is related to the size of the particle aggregates rather than their surface area (measured by BET method). Clearly, when using submicron and ultrafine materials one may expect that there is an optimum particle size for maximum activity. But, as a result of differences in the surface energies of the catalyst materials, this optimum particle size may vary from compound to compound.

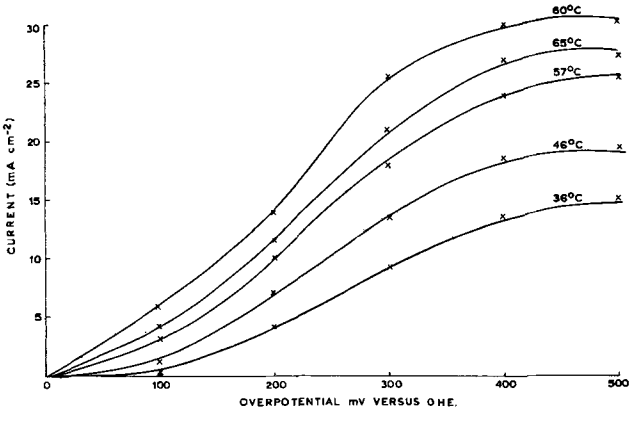

Figure 1. Current voltage curves at a series of temperatures for WC, particle size 0.45μ (sample 10, Table IIb).

The ratio of PTFE to catalyst for optimum activity may also be dependent on the particle size of the catalyst and its composition and cannot be ignored when comparing results. Tests in these laboratories with WC of particle size 0.45μ showed that 25% w/w PTFE gave the best results for this material, and this value was used in the fabrication of all the electrodes.

From the initial screening program two points immediately became apparent:

1. The borides of all the elements tested dissolve or corrode badly at anodic potentials in M H_2SO_4 and are therefore unsuitable for use in acid fuel cells.
2. Useful levels of catalytic activity are unlikely unless the average particle size of the catalyst is less than 1μ.

Results from Tables IIa and IIb show that the particle size is the most significant parameter for correlation with catalytic activity. Best results were obtained with WC with an average particle size of 0.45μ. This is very close to the figure of 0.3μ which Bohm (2) claims for optimum activity. The lower level of activity observed with the WC sample of smaller particle size is thought to be associated with the higher surface energy of these fine powders. Because of this surface

energy the particles show a strong tendency to cluster when in suspension, resulting in large aggregates.

The highly catalytic WC electrodes produced elsewhere (2) were prepared by carburizing tungsten particles in either CH_4 or CO gas streams with the lowest temperatures and shortest reaction times possible. Since the results both here and elsewhere do not appear markedly dependent on the stoichiometry, the increased activity may be due to an increase in the concentration of surface defects which are more probable with low-temperature short-duration preparations. Surface defects have been proposed as creating active centers and are therefore an important parameter effecting catalytic activity (7).

In an attempt to strain the host WC lattice, thus introducing surface defects, we tested a number of specially prepared ternary compounds based on WC. Of the ternary compounds tested the solid solution of TaC in WC (2% TaC/WC) might be expected to introduce surface defects, resulting from the difference in lattice parameters between TaC and WC. Catalytic activity of this solid solution was at least as good as that of the WC samples of similar particle size (1.1μ). Unfortunately, it was not possible to reduce the particle size of this compound further by grinding.

Binder *et al.* (3) have proposed that the catalytic activity of WC is due to the formation of hydrogen tungsten bronzes on the surface of the WC, as a result of oxidation of surface tungsten atoms in a hydrogen environment. Recently, we have shown (9) that the analogous sodium tungsten bronzes are completely inactive for anodic hydrogen oxidation. Also the plot of apparent activation energy against overpotential for WC (calculated from Fig. 1) showed a linear variation between 200 and 500 mV, while the value at 200 mV (27 kJ $mole^{-1}$) was consistent with those found elsewhere (2, 3). This linear variation is not indicative of the formation of a different surface on the electrode. It seems therefore unlikely that the reason for catalytic activity of WC is due to the formation of surface bronzes.

Ion Selective Electrochemical Sensors—Fe^{+3}, Cu^{+2}

Charles T. Baker* and Isaac Trachtenberg*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Ion selective electrochemical sensors which respond to Fe^{+3} and Cu^{+2} have been developed. The sensor material consists of a chalcogenide glass (60% Se, 28% Ge, and 12% Sb) doped with Fe^0, Co^0, or Ni^0. Response has been observed at concentrations as low as 10^{-6} moles/liter (0.056 ppm Fe) in both membrane and electrode configurations. Nernstian behavior is observed in the 10^{-5} to 10^{-1} moles/liter concentration range. Interference tests demonstrate good selectivity for Fe^{+3} in the presence of most cations, particularly Fe^{+2}. Potential response behavior supports a redox potential mechanism rather than the ion exchange mechanism.

Within the past five years, research and development in analytical potentiometry has increased. The impetus for this effort is due mainly to the simplicity of analysis offered by ion selective electrochemical sensors. The application of such sensors can result in the control required to insure water quality, attain optimum yields in chemical processes, maintain the critical K^+ balance of patients undergoing surgery, and, in general, obtain rapid analysis at low cost.

A general survey of the field of ion-selective electrodes was given by Rechnitz (1), who categorized the sensors into three major classes: glass electrodes, solid-state electrodes, and liquid-liquid membrane electrodes. In a review article by Toren and Buck (2), electrodes in each class were presented and pertinent references regarding electrode characterization, applications, and theory of operation were given. Lakshminarayanaiah (3) discussed the transport phenomena in membranes, and the excellent format of this work offers the physical and biological scientists a well-organized presentation of background material regarding theoretical treatments and experimental results of membrane phenomena. The history, theory, applications, limitations, compositions, and construction of ion selective glass electrodes have been presented in a book edited by Eisenman (4). The fixed anionic site ion exchange model has also been used by Buck (5) to study the transient electrical behavior of glass membranes. Solid-state membranes viewed in light of the fixed site ion exchange model have been treated by Buck (6). Eisenman (7) compared the similarities and differences between liquid and solid ion exchanges. In a book edited by Durst (8) the views and specialties of a number of scientists in the ion selective electrode field have been presented.

This investigation discusses the preparation, characterization, and tests of a doped chalcogenide glass as the active material in ion-selective electrochemical sensors for Fe^{+3} and Cu^{+2}.

perimental work (hereafter referred to as 1173 glass) was 60% selenium, 28% germanium, and 12% antimony. Undoped 1173 has a resistivity of 2 x 10^{14} ohm-cm and is not usable as a sensor. Doping 1173 glass with elemental iron, cobalt, or nickel lowers the resistivity and yields a material suitable for use in a sensor.

A standard compounding procedure was used in the preparation of the sensor materials. High-purity elements (five nine's or better Se, Ge, and Sb; and three nine's Fe, Co, or Ni) were weighed and sealed in an evacuated quartz ampoule. The ampoule was placed in a rocking furnace and heated slowly to 900°-1000°C. The melt was allowed to mix and/or react for 16 to 24 hr, then air-quenched to solid and annealed for 2 to 3 hr at 275°C to remove strain.

The success of the doping process was determined by visual examination and by the d-c resistivity of the material. Information about the vitreous nature of the sample, its ruggedness, and rejection of dopant was obtained by visual examination and optical microscopy. Additional information regarding the glassy nature of the material or the dispersion of crystallites in the glass was obtained from the infrared transmission of the sample. More detailed work on the infrared transmission characteristics of 1173 glass and Fe^0-doped 1173 has been reported by Johnson, Haisty, and Brown (9).

One of the more important physical properties of the material for sensor use is resistivity. Resistivity measurements indicate the effectiveness of the doping process and can be used to determine the homogeneity of the material as well as the reproducibility of preparation. Resistivity measurements were employed as a screening procedure to eliminate certain samples from further consideration as sensor elements.

Material samples (glass disks 1.1-1.2 cm in diameter, 0.04-0.06 cm thick) were prepared for resistance measurement by polishing each surface to a mat finish. The disk was rinsed thoroughly in deionized water and left to dry in air. Gold was evaporated onto each side of the disk, and the edges were ground to remove any traces of gold, which could short the sample.

Each prepared disk was placed in a shielded can, pressure contacts were made to the gold on each side of the disk, and the shielded can was evacuated. A voltage was applied to the sample by a Harrison Laboratories 6264A d-c Power Supply, and the current was monitored by a Keithley 610B Electrometer used as an ammeter. The resistance of the sample was calculated from current-voltage data. The current-time behavior was recorded on a Texas Instruments Model 341 function/riter®, which was connected to the output of the Keithley 610B Electrometer.

Two configurations (Fig. 1) have been used in testing the response of the sensors to specific ions. In the first, the glass is used as a membrane or solid electrolyte like the glass in a conventional *p*H electrode. The sensor element is sealed in the end of a Plexiglas tube with one surface of the disk exposed to the test solution and the other to the internal reference solution. The internal reference solution is composed of a concentration of the ion being measured (usually 10^{-3} *M*) in 0.1*M* KNO_3. A saturated calomel reference electrode (SCE) or a Ag/AgCl reference electrode makes contact with the internal reference solution and completes the assembly for the membrane configuration. The second configuration is an electrode in which gold is evaporated on one side of the glass disk, and a Pt-wire lead makes contact with the gold by Silver Micropaint. The lead side of the glass electrode is isolated from test solutions by sealing the glass disk in a Plexiglas tube.

The responses of each sensor were investigated by measuring the potential *vs.* a SCE or a Ag/AgCl reference electrode with a Keithley 610B or C electrometer. The unity-gain output of the Keithley electrometer was fed into a Hewlett-Packard 3440A digital voltmeter

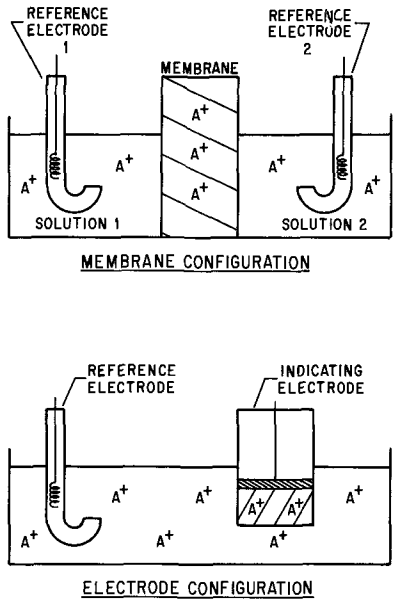

Fig. 1. Sensor configuration

equipped with a Hewlett-Packard 3443A high gain/auto range unit for digital display of potentials. During continuous run experiments, the unity-gain output of the electrometer was fed into a Sargent Model SR recorder.

All test solutions were prepared from reagent grade chemicals using deionized water. Varying concentrations of a given ion were prepared by volumetric dilution of the stock solution.

Results and Discussion

In the preparation of doped 1173 glass, there was no observable difference in the properties of samples prepared by compounding from prereacted 1173 glass and those of the same doped glass prepared from the elements. All materials discussed in this investigation were made by doping prereacted 1173 glass.

For the Fe-doped 1173 glasses, samples of 0.8, 1.6, 2.0, and 2.4 at. w/o Fe^0 were studied. The materials were uniformly vitreous, at the 0.8 and 1.6% Fe^0 level, with the Fe^0 remaining in solution when the glass was quenched. At 2.0% Fe^0 some totally glassy samples were prepared, but inhibiting the formation of a second phase was quite difficult. The presence of a second phase dispersed in a glassy matrix was always observed at doping levels above 2.0% Fe^0. The number and size of the second phase clusters were dependent on dopant concentration. If crystallites were present in the cluster phase, they were not detectable with x-ray diffraction or the scanning electron microscope, but analyses with the electron microprobe showed that the cluster phase and the glassy phase have the same elemental composition.

Electron spin resonance (ESR) spectra of undoped 1173, 0.05% Fe^0-1173, and 0.8% Fe^0-1173 confirmed that Fe^{+3} was present in the Fe-doped 1173 glasses. Qualitative analyses for the oxidation states of Fe in 1173 were made on a 1.6% Fe^0-1173 glass sample. The sample was dissolved in 10% KOH, acidified with H_2SO_4, and filtered. The filtrate was tested for the presence of Fe^{+3} and Fe^{+2}. Spot tests with $K_4Fe(CN)_6$ and KSCN indicated that Fe^{+3} was present, and the presence of Fe^{+2} was confirmed by a positive spot test with ferroin. From the results of cyclic voltammetry and controlled potential electrolysis experiments with a 2.4% Fe^0-1173 glass electrode, it was concluded that probably all the oxidation states of Fe (Fe^0, Fe^{+2}, and Fe^{+3}) were present in the Fe-doped samples which had clusters. These electrochemical techniques were applicable to the 2.4% Fe^0-1173 glass electrode because of the low resistivity of the cluster phase. These quali-

tative results indicated that Fe^{+2} and Fe^{+3} were present in doped 1173 glass samples when the doping level was less than 2% Fe^0; and Fe^0, Fe^{+2}, and Fe^{+3} were present when the doping level was greater than 2%. The relative concentration of each oxidation state of Fe in the Fe^0-doped 1173 glasses could not be stated conclusively.

Samples of 1173 glass doped with 1.5% Ni^0 and 1.5% Co^0 were studied. Physically, the materials consisted of a glassy matrix in which crystals were uniformly dispersed. The resistivities of these materials were of the order of 150 ohm-cm.

The effect of dopant concentration on the resistivity of Fe^0-doped 1173 glass is shown in Fig. 2. As the concentration of Fe in the glass is increased, the resistivity decreases significantly. The large drop in resistivity between 2.0 and 2.4% Fe^0-1173 is related to the cluster phases, which increase in size as the doping level of Fe^0 increases above the 2.0% Fe^0 value. When the diameter of individual clusters approaches the thickness of the sensor disk, or when the density of clusters increases so that clusters touch each other, the glass matrix is essentially shorted by the more conductive cluster phase. The Fe^0-1173 glasses exhibited ohmic behavior at all doping levels. At a given applied voltage, the current flow through the glasses was independent of time, indicating that the major conduction mechanism is electronic rather than ionic.

The case for an electronic conduction mechanism was further substantiated by an electrolysis experiment with a 2.0% Fe^0-1173 glass sensor in the membrane configuration. With 0.1*M* KNO_3 on each side of the membrane and large-area laboratory saturated calomel electrodes making contact with the KNO_3 solutions by means of 4% agar-saturated KNO_3 salt bridges, current was passed through the membrane. Gas bubbles formed at one membrane-electrolyte interface, and at the other membrane-electrolyte interface a brown product diffused away from the membrane into the bulk of the solution. Reversing the current caused the same reactions to occur at the opposite interfaces. The direction of the current in each case suggests that H_2 was the gas evolved, and the brown product was formed by the dissolution of the membrane. This electron transfer at the membrane-electrolyte interfaces is consistent with an electronic conduction mechanism.

Both the membrane and the electrode configuration were evaluated for potential responses to various ions. In the membrane configuration, the potential would ideally be related to

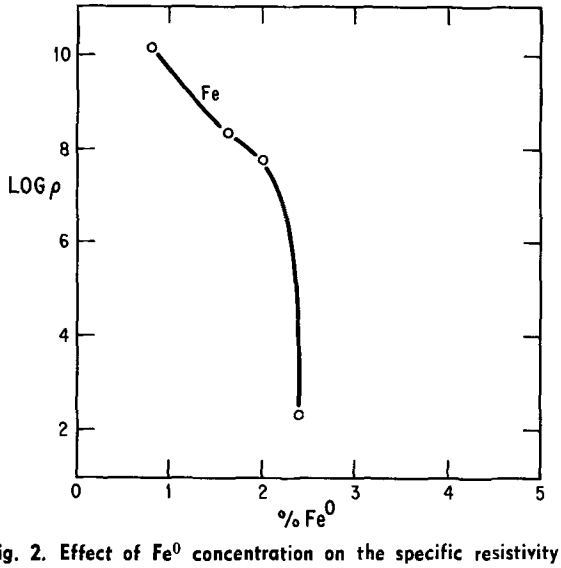

Fig. 2. Effect of Fe^0 concentration on the specific resistivity of doped 1173 glass.

$$E = E_a + \frac{2.3RT}{n\mathbf{F}} \log \frac{[M_1]}{[M_2]} \quad [1a]$$

or

$$E = E_a + \frac{2.3RT}{Z\mathbf{F}} \log \frac{[M_1]}{[M_2]} \quad [1b]$$

where E_a in [1a] is related to the asymmetry of the redox processes occurring on each side of the membrane. In [1b], E_a is the asymmetry potential for the ion exchange processes occurring at the two interfaces. For the ion exchange case, [1b] assumes that the diffusion potential contributions on each side of the membrane cancel out and the potential changes observed are related to changes in the phase boundary potential. The n in [1a] is the number of electrons transferred in the redox process, and Z in [1b] is the charge of the ion involved in the exchange process. $[M_1]$ and $[M_2]$ are the activities of ion M in solution on each side of the membrane.

For the electrode configuration, the potential equations take the form of

$$E = E_R + \frac{2.3RT}{n\mathbf{F}} \log \frac{[M^{+n}]}{[M]} \quad [2a]$$

and

$$E = E_1 + \frac{2.3RT}{Z\mathbf{F}} \log \frac{[M^{+Z}]\text{sol.}}{[M^{+Z}]\text{glass}} \quad [2b]$$

for redox and ion exchange processes, respectively. In the redox equation, [2a], E_R is a constant containing the standard potential for reduction of ion M^{+n} to M, the potential for any redox process occurring in the glass itself, and the metal-glass junction potential on the backside of the glass sensor element. For the ion exchange equation, [2b], E_1 is an analogous type constant which includes a diffusion potential, redox potential in the glass associated with the conduction mode changing from ionic to electronic, and the metal-glass junction potential mentioned above. $[M^{+Z}]$sol. and $[M^{+Z}]$ glass represent the activities of ion M^{+Z} in the solution and the glass, respectively.

Samples of 1173 glass doped with 0.8, 1.6, 2.0, and 2.4% Fe^0 were tested in the membrane and electrode configurations for potential response to changing Fe^{+3} concentration. All Fe^0-1173 sensors were responsive to Fe^{+3}, and the potential behavior was linear and reproducible in the concentration range from 10^{-5}-10^{-4} to $10^{-1}M$. The Fe^{+3} test solutions were prepared by diluting the 0.1*M* $Fe(NO_3)_3$ stock with 0.1*M* KNO_3 and adjusting the pH to ~1.7 (pH of the 0.1*M* Fe^{+3} stock solution). In this way wide variations in ionic strength were avoided so that the relationship between the potential and the concentration of Fe^{+3} could be used. Figure 3 shows the potential response of an electrode and a membrane of 2.0% Fe^0-1173 to Fe^{+3} concentration. For both configurations, a linear response is observed from $10^{-5}M$ to $10^{-1}M$ Fe^{+3}, and the slope in each case is approximately 60 mV. In view of Eq. [1a] and [2a], the slope of 60 mV per order of magnitude change implies that a redox potential involving the Fe^{+3}/Fe^{+2} couple is potential determining. If this is the case, then the Fe^{+2} must either be in the glass or generated at its surface. Ion exchange involving Fe^{+3} at the solution-glass interface is ruled out, since a slope of 20 mV is predicted from Eq. [1b] and [2b].

In Fig. 4, the potential response of an 0.8% Fe^0-1173 glass in the electrode configuration to Fe^{+3} and Fe^{+2} is shown. The slope of the E-log$[Fe^{+3}]$ is 53 mV from $<10^{-4}$ to $10^{-1}M$ Fe^{+3} and is consistent with the Nernst expression for a redox process. The response to Fe^{+2}, however, was suspicious because the potential shift is in the wrong direction when considered with respect to Eq. [2b]. Spot tests with $K_4Fe(CN)_6$ and KSCN confirmed the presence of Fe^{+3} in our Fe^{+2} test solutions. Therefore, the response in the Fe^{+2} solution was actually a response to the contaminant, Fe^{+3}. Our E-log $[Fe^{+3}]$ curve indicated Fe^{+3} was present at

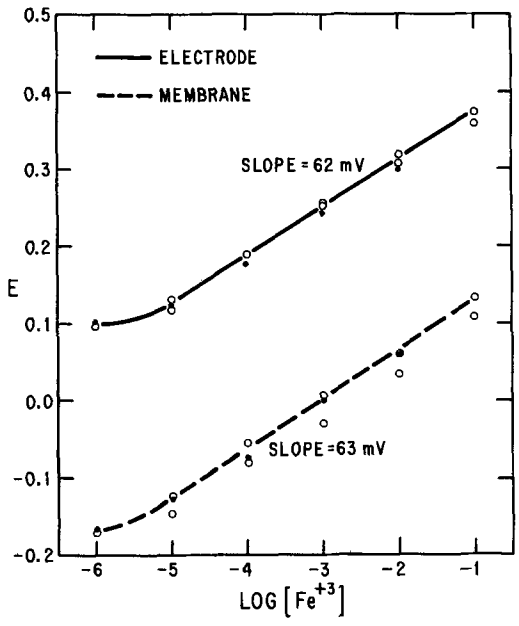

Fig. 3. Potential response of electrode and membrane of 2.0% Fe^0-1173 glass to Fe^{+3} concentration. All solutions are 0.1M in KNO_3 and pH = 1.8

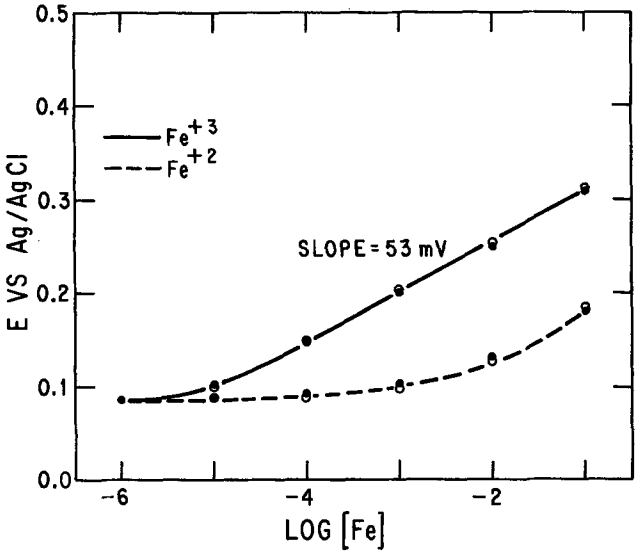

Fig. 4. Effect of Fe^{+3} and Fe^{+2} concentrations on the potential of a 0.8% Fe^0-1173 glass electrode. All solutions are 0.1M in KNO_3 and pH = 1.67.

a level that was less than 1% of the given Fe^{+2} concentration.

Additional support for the sensor response being independent of the Fe^{+2} concentration in the bulk of solution was gained from experiments in which the ratio of $[Fe^{+2}]/[Fe^{+3}]$ was varied from 0.1 to 100. The potential did not vary linearly with the log $[Fe^{+3}]/[Fe^{+2}]$, but was linearly related to log$[Fe^{+3}]$. When the ratio of $[Fe^{+3}]/[Fe^{+2}]$ was held constant, but the total iron concentration varied by dilution, the potential decreased as the concentration of Fe^{+3} decreased. These results indicated that the Fe^0-doped 1173 sensor was insensitive to Fe^{+2} in the bulk of solution.

Although Nernstian behavior has been observed for all the Fe^0-1173 glasses tested, the optimum doping level for potential stability, response time characteristics, and Nernst response is approximately 2.0% Fe^0-1173. At the lower doping levels, the high resistivity of the sensors is undesireable. With the heavily doped samples, more deviations from Nernstian behavior are recorded.

The potential response of the Fe^0-doped 1173 glasses to changing Fe^{+3} concentration is fairly rapid. A limited investigation of the potential-time characteristics suggested that establishment of equilibrium (stable potential) is mass transport controlled.

Several interference tests were made with the Fe^0-1173 glass sensors. As mentioned earlier, the sensors do not respond to Fe^{+2}. In addition, the sensor potential was independent of concentrations of Na^+, K^+, NH_4^+, Ca^{+2}, Ba^{+2}, Mg^{+2}, Mn^{+2}, Zn^{+2}, Cr^{+3}, and NO_3^-. Figure 5 shows results of some of the interference tests in which the contaminant concentration varied and the test solution remained 0.1M in KNO_3, 0.001M in Fe^{+3}, and at pH 1.6. As noted, Ag^+ represents a major interference. A decrease in potential is observed as the concentration of Cl^- and $SO_4^=$ is increased. In the absence of Fe^{+3}, however, the potential response is independent of these anion concentrations. Complexing of the Fe^{+3} by the anions is responsible for the potential shift noted in Fig. 5. These Fe^0-1173 glass sensors are sensitive to free Fe^{+3} concentration, and this coordination shifts the electrode potential negatively, as would be predicted by the Nernst expression. In the presence of excess Cl^- (Fig. 6), a 2.0% Fe^0-1173 glass electrode still exhibits close to Nernstian behavior to Fe^{+3} in the 10^{-4} to 10^{-1}M range. The apparent electrode sensitivity has decreased by an order of magnitude. In actuality, the free Fe^{+3} concentration is approximately an order of magnitude less than the total Fe^{+3} concentration.

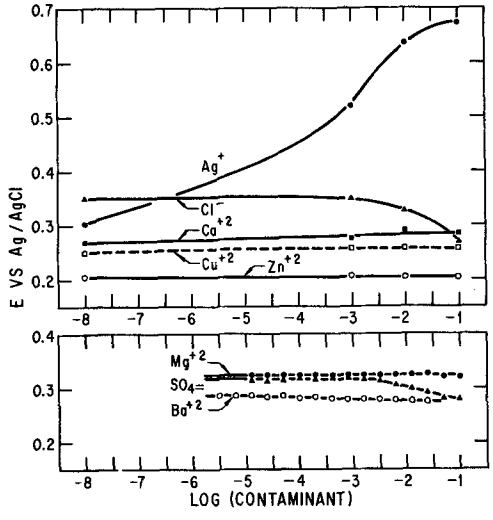

Fig. 5. Effect of contaminant concentration on the potential of a 2.0% Fe^0-1173 glass electrode. All solutions are 0.1M in KNO_3, 0.001M in Fe^{+3}, and pH = 1.6.

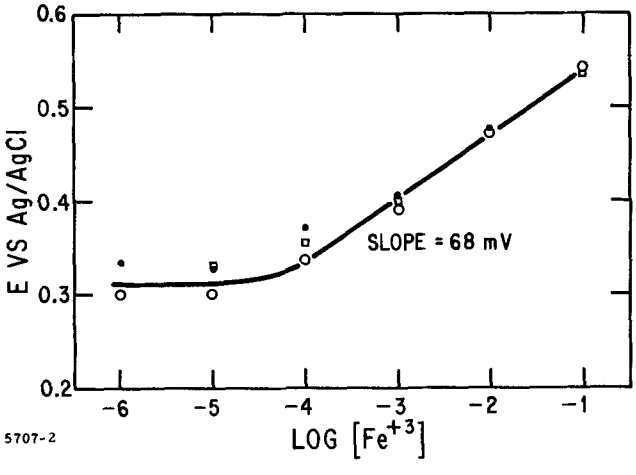

Fig. 6. Response of 2.0% Fe^0-1173 glass electrode to Fe^{+3} concentration in an excess Cl^- medium. All solutions are 1.0M in KCl and pH = 1.7.

One further comment with regard to Fig. 5 is necessary. When Fe^{+3} is present in the test solution, no potential response to Cu^{+2} is observed, even when the Cu^{+2} concentration is 100 times greater. Figure 7 is a plot of the potential behavior of 1.6% Fe^0-1173 and 2.0% Fe^0-1173 glass electrodes to Cu^{+2} in nitrate and chloride media in the absence of Fe^{+3}. The E-log $[Cu^{+2}]$ curves for Cu^{+2} in 0.1M KNO_3 (27 mV) have the slopes that would be expected for a $2e^-$ redox process or an ion exchange reaction involving a cation with a +2 charge. In the chloride medium, slopes of 53 and 62 mV for the 1.6% Fe^0-1173 and 2.0% Fe-1173, respectively, are indicative of a $1e^-$ redox process, especially since Cu^{+1} is known to be relatively stable in an excess Cl^- medium (10). These results suggest that the Cu^{+2} response in the nitrate medium was due to a $2e^-$ redox process. This redox type behavior for Cu^{+2} further supports the $1e^-$ redox potential mechanism for Fe^{+3}.

The redox potential mechanism for the response to Cu^{+2} raises some interesting questions. Since Cu is not present in the Fe^0-1173 glasses, how is the other half of the redox couple generated? In addition, must Fe be incorporated in 1173 to obtain a response to Fe^{+3}?

With these questions in mind, sensors of 1.5% Co^0-1173 and 1.5% Ni^0-1173 in the electrode configuration were prepared and evaluated. No response to Co^{+2} or Ni^{+2} was measured. The sensors exhibited a potential response to Fe^{+3} (Fig. 8) over the entire concentration range tested, with Nernstian behavior displayed from 10^{-5} to $10^{-1}M$ Fe^{+3}. The presence of Fe in the 1173 glass appears not to be a prerequisite for potential responses to Fe^{+3}. Figures 9a and 9b show the response of the 1.5% Co^0-1173 and 1.5% Ni^0-1173 electrodes to Cu^{+2} in nitrate and chloride media. In the NO_3^- medium the response to Cu^{+2} is linear in the 10^{-5} to $10^{-1}M$ range with a slope of ~30 mV. The slope increased to 54 mV in a Cl^- medium. These results, like those for the Fe^0-doped 1173 electrodes, indicate that the potential determining process shifts from a $2e^-$ mechanism to a $1e^-$ mechanism in going from a NO_3^- medium to a Cl^- medium.

The responses to Fe^{+3} and Cu^{+2} indicate the redox processes involved are

$$Fe^{+3} + e^- \leftrightharpoons Fe^{+2} \quad [3]$$

$$Cu^{+2} + 2e^- \leftrightharpoons Cu^0 \quad [4]$$

$$Cu^{+2} + e^- + 3Cl^- \leftrightharpoons CuCl_3^{-2} \quad [5]$$

and the lower oxidation state of each redox couple is generated at the electrode surface. Furthermore, the activity of the lower oxidation state of the particular redox couple must remain constant at the sensor surface for the linear E-log[Ox] curve to be displayed.

With the redox mechanism established, it appeared that there should be other ions associated with a reversible redox couple that could be measured with the Fe^0-, Ni^0, or Co^0-doped 1173 glass sensors. These sensors were found to be insensitive to Cd^{+2}, Co^{+2}, Ni^{+2}, and Pb^{+2}, but responsive to Cu^{+2} (excess Cl^-), Cu^{+2}, Fe^{+3}, Ag^+, Hg^{+2}, Mn^{+3}, and Ce^{+4}. The potential response is related not only to reversible redox couples, but also to the position of the redox couple in the emf series. In the emf series, the single electrode potential

for the reducing agent in the doped 1173 glass is between −0.12 and +0.18V.

Generation of the lower oxidation state for an ion which can be measured with the doped 1173 sensors, therefore, involves a redox reaction between the higher oxidation state of the reversible redox couple and the reducing component of the glass. Possibly due to limited reduction sites of the glass, the activity of the lower oxidation state is held constant while the higher oxidation state of the redox couple varies from 10^{-5} to $10^{-1}M$ in the bulk of solution.

Summary

Ion selective electrochemical sensors were prepared containing Fe^0-, Co^0-, and Ni^0-doped chalcogenide glasses (28% Ge, 60% Se, 12% Sb) as the active material. The potential responses of these sensors support a redox potential mechanism rather than the ion exchange mechanism. The sensors respond only to the higher oxidation state of reversible redox couples, and the response is dependent on the standard electrode potentials of the redox couples. The sensing element of doped 1173 glass does not appear to be inert, but acts as a reducing agent which generates the lower oxidation state of the redox couple and maintains it at a constant activity.

While the redox response characteristics greatly limit the applicability of the sensors to certain ions, they also eliminate many of the interferences. Interferences may be expected only from the higher oxidation state of redox couples other than the specific ion of interest or from ions (usually anions) which complex the specific ion to be determined.

Concentration Reversion in Potentiostatic Electrode Kinetics

C. A. Johnson,[1] S. Barnartt,* and F. D. Glasser[2]

Edgar C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Monroeville, Pennsylvania 15146

ABSTRACT

Coupled diffusion of two substances taking part in a potentiostatic electrode reaction can lead to a maximum concentration change at finite time for one of the substances. It is shown that this phenomenon can occur at spherical and cylindrical electrodes, with first-order and with higher-order reactions, but not at planar electrodes.

In heterogeneous chemical kinetics it is known (1-4) that the coupled migration of two substances to or from an interface can result in one substance (A) exhibiting a maximum change in concentration. Thus the concentration c_A can change from its initial value c_A^0 to a maximum or minimum value, and then revert back (in the direction of c_A^0) to attain an intermediate steady-state value as $t \to \infty$. We shall refer to such concentration-time behavior as "concentration reversion." [3]

This phenomenon has been observed in the sulfurization of iron by a calcium aluminosilicate slag containing sulfur (1). In that system, which involved the coupled diffusion of sulfur and silicon, the sulfur concentration at the slag side of the interface passed through a minimum. Good evidence has been given for carbon concentration reversion during diffusion across welds of an Fe-Si-C alloy to Fe-C or to Fe-Mn-C alloys (2, 3). Another example is the sulfur-concentration maximum produced near the surface of a ferrous silicate melt during simultaneous sulfurization and oxidation of the melt by a CO-CO_2-SO_2 atmosphere (4). In the latter study it was possible to correlate a portion of the concentration-time curve quantitatively with the equilibrium oxidation state of the melt.

The present paper deals with concentration reversion in electrochemical kinetics, specifically in electrode reactions carried out at constant potential. The concentration changes which can occur in a potentiostatic reaction are limited, and a knowledge of the maximum possible concentration changes is very useful. Such knowledge helps the experimenter to design

Key words: concentration polarization, coupled diffusion, concentration-time curves.

[3] This term was suggested by L. S. Darken. The term implies only that concentration changes reverse direction. It should not be inferred that the direction of diffusion changes; diffusion always proceeds in the direction of decreasing chemical potential.

experiments which permit only moderate concentration changes: (*a*) to avoid side reactions which contribute to the observed current or passivate the electrode, and (*b*) to permit accurate analysis of current-time curves (5-7). We can often calculate maximum concentration changes as those for the condition $t \to \infty$, provided concentration reversion does not occur. The aim of this study, therefore, was to determine under what potentiostatic conditions and with what electrode geometries concentration reversion is possible.

We demonstrate below that concentration reversion can indeed occur in the case of first-order reactions at spherical electrodes. In this case the reaction conditions that give rise to concentration reversion can be specified, and the entire concentration-time curve can be described by an exact closed-form equation. The possibility that concentration reversion can occur with higher-order reactions at spherical electrodes, or with electrode reactions of any order at planar and cylindrical electrodes, is also examined.

The generalized higher-order electrode reaction to be treated is fomulated as

$$\mathrm{bB}^{z+} + \mathrm{xX} + ne^- = \mathrm{yY}^{[(bz-n)/y]+} + \mathrm{wW} \qquad [1]$$

The charge-transfer mechanisms are restricted to those in which the electrical work involved all occurs during the rate-determining step. The solution is assumed to contain an excess of supporting electrolyte and high concentrations of substances X and W, so that only one reactant and one reaction product exhibit significant changes in concentration. For these conditions the rate of reaction [1] in the anodic direction (right to left), as a function of the concentrations at the electrode surface, may be expressed as current density at time t by (8)

$$i(t) = i_o \left(\frac{c_Y}{c_Y{}^o}\right)^{y/\nu} \exp\left[(1-\beta)\frac{n}{\nu}\epsilon\eta\right] - i_o \left(\frac{c_B}{c_B{}^o}\right)^{b/\nu} \exp\left[-\beta\frac{n}{\nu}\epsilon\eta\right] \qquad [2]$$

Here i_o is the exchange current density, β the transfer coefficient, and ν the stoichiometric number of the charge-transfer mechanism. Also η is the overpotential and $\epsilon \equiv \mathbf{F}/RT$, where $\mathbf{F}$ is the Faraday, R the gas constant and T absolute temperature. The concentrations of Y and B in the solution at the electrode surface are the bulk values $c_Y{}^o$, $c_B{}^o$ at time $t = 0$, and are written c_Y, c_B (without added notation) for time t. The reaction order (defined at constant potential) is y/ν with respect to Y and b/ν with respect to B.

It is assumed that the electrode is initially at the reversible potential, so that the potential step applied to begin the reaction is equal to η. At first sight we might expect the concentration ratio of the anodic reactant, $c_Y/c_Y{}^o$ in Eq. [2], to decrease continuously with time and the product ratio $(c_B/c_B{}^o)$ to increase continuously with time, each of these effects causing the current to decrease continuously with time. Although the current is a measure of the over-all reaction and decreases monotonically, the coupling of c_Y and c_B at the electrode surface through Eq. [2] means that one of c_Y, c_B is required to change monotonically, but not necessarily both. Coupled migration of this type makes concentration reversion possible but does not assure its occurrence, as is demonstrated later.

Mass transfer of Y or B to the electrode surface is restricted to diffusion only. The fundamental problem is then a boundary-value diffusion problem. The flux at the electrode boundary is given by Fick's first law as

$$i(t) = (n/y)\mathbf{F}D_Y(\partial c_Y/\partial x) = -(n/b)\mathbf{F}D_B(\partial c_B/\partial x) \qquad [3]$$

where $i(t)$ is the current in Eq. [2]. This boundary-value problem varies in detail for planar, spherical, and cylindrical electrodes, but the mathematical details need not be discussed here.

Planar Electrodes

The general diffusion problem for planar electrodes has been examined in a previous paper (5). By application of a powerful theorem of Mann and Wolf (9), rigorous proof was given that the concentration of anodic reactant Y at the electrode surface (c_Y) must decrease monotonically for all $t > 0$, and that c_B must increase monotonically. This proof encompasses higher-order as well as first-order electrode reactions. Therefore, concentration reversion will not occur at planar electrodes.

Spherical Electrodes

First-order reactions.—In the case of spherical electrodes, it is expedient to consider first-order reactions separately, because there exists an exact analytical solution of the general boundary-value problem only for reactions of first-order. The concentration-time curves for first-order reactions are given by (10)

$$c_Y(r=a,t) = c_Y{}^o - \frac{i_{t=0}}{n\mathbf{F}\sqrt{D_Y}(\xi-\mu)}\left\{\frac{\sqrt{D_B}}{a}\left(\frac{1}{\mu}-\frac{1}{\xi}\right)+\left(1-\frac{\sqrt{D_B}}{a\mu}\right)C[\mu\sqrt{t}] - \left(1-\frac{\sqrt{D_B}}{a\xi}\right)C[\xi\sqrt{t}]\right\} \qquad [4]$$

$$c_B(r=a,t) = c_B{}^o + \frac{i_{t=0}}{n\mathbf{F}\sqrt{D_B}(\xi-\mu)}\left\{\frac{\sqrt{D_Y}}{a}\left(\frac{1}{\mu}-\frac{1}{\xi}\right)+\left(1-\frac{\sqrt{D_Y}}{a\mu}\right)C[\mu\sqrt{t}] - \left(1-\frac{\sqrt{D_Y}}{a\xi}\right)C[\xi\sqrt{t}]\right\} \qquad [5]$$

Here D_Y and D_B are the diffusivities of Y and B, respectively: $i_{t=0}$ is the charge-transfer controlled current density, which is given by Eq. [2] with $c_Y = c_Y{}^o$ and $c_B = c_B{}^o$; also a = electrode radius, and

$$C[x] \equiv \exp(x^2)\,\mathrm{erfc}(x) \qquad [6]$$

$$\xi \equiv \frac{1}{2}\{\lambda + (\sqrt{D_Y}+\sqrt{D_B})/a + \sqrt{\psi}\} \qquad [7]$$

$$\mu \equiv \frac{1}{2}\{\lambda + (\sqrt{D_Y}+\sqrt{D_B})/a - \sqrt{\psi}\} \qquad [8]$$

$$\psi \equiv \lambda^2 + (\sqrt{D_Y}-\sqrt{D_B})^2/a^2 + (2/a)(\lambda_Y\sqrt{D_Y}-\lambda_B\sqrt{D_B})(\sqrt{D_Y}-\sqrt{D_B}) \qquad [9]$$

$$\lambda \equiv \lambda_Y\sqrt{D_Y} + \lambda_B\sqrt{D_B} \qquad [10]$$

$$\lambda_Y \equiv \frac{i_o \exp[(1-\beta)n\epsilon\eta]}{n\mathbf{F}\,c_Y{}^o D_Y}, \lambda_B \equiv \frac{i_o \exp(-\beta n\epsilon\eta)}{n\mathbf{F}\,c_B{}^o D_B} \qquad [11]$$

The corresponding current-time relation is

$$\frac{i(t)}{i_{t=0}} = \frac{1}{1+a\lambda_Y+a\lambda_B} + \frac{1}{\xi-\mu}\left\{\frac{(\sqrt{D_Y}-a\xi)(\sqrt{D_B}-a\xi)}{a^2\xi}C[\xi\sqrt{t}] - \frac{(\sqrt{D_Y}-a\mu)(\sqrt{D_B}-a\mu)}{a^2\mu}C[\mu\sqrt{t}]\right\} \qquad [12]$$

In examining Eq. [4] for possible concentration reversion, we note first that normal behavior requires the derivative $\partial c_Y/\partial t$ at $r = a$ to be negative and to decrease in absolute magnitude with time. A sufficient condition for reversion is that this derivative be posi-

** Compare $\sqrt{D_B/D_Y} - 1 = 2.16$.

tive and approach zero (steady-state condition) as $t \to \infty$. The general form of the derivative, as obtained from Eq. [4] for $r = a$, is

$$\frac{\partial c_Y}{\partial t} = -\frac{i_{t=0}}{n\mathbf{F}\sqrt{D_Y}(\xi-\mu)}\left[\left(1-\frac{\sqrt{D_B}}{a\mu}\right)\left\{\mu^2 C[\mu\sqrt{t}] - \frac{\mu}{\sqrt{\pi t}}\right\} - \left(1-\frac{\sqrt{D_B}}{a\xi}\right)\left\{\xi^2 C[\xi\sqrt{t}] - \frac{\xi}{\sqrt{\pi t}}\right\}\right] \quad [13]$$

For large values of t this may be simplified by use of the asymptotic expansion

$$C[x] = (1/\sqrt{\pi})x^{-1} - (1/2\sqrt{\pi})x^{-3} + 0(x^{-5}) \quad [14]$$

to yield

$$\frac{\partial c_Y}{\partial t} = \frac{i_{t=0}}{2\,n\mathbf{F}(\pi D_Y)^{1/2}t^{3/2}(\xi\mu)}\left[1 - \frac{(a\lambda_Y\sqrt{D_Y}+\sqrt{D_Y})+a\lambda_B\sqrt{D_B}+\sqrt{D_B}}{(a\lambda_Y\sqrt{D_Y}+\sqrt{D_Y})+a\lambda_B\sqrt{D_Y}}\right] \quad [15]$$

Noting that $(\xi\mu)$ must always be positive, we see from the term in square brackets that the derivative at long times is always negative when $D_Y = D_B$ or when $D_Y < D_B$. If $D_Y > D_B$, however, the derivative becomes positive for the condition

$$\sqrt{D_Y/D_B} - 1 > 1/a\lambda_B \quad [16]$$

Thus the concentration-time curve for reactant Y exhibits reversion when simultaneously $D_Y > D_B$ and $a\lambda_B$ is sufficiently large. The latter condition requires a moderately rapid electrode reaction and is favored by low bulk concentration of product B; also, the electrode radius must not be too small.[4]

Similar differentiation of Eq. [5] reveals that only normal $c_B - t$ curves can occur when $D_Y = D_B$ or when $D_Y > D_B$. This result tells us formally that the $c_B - t$ and $c_Y - t$ curves can never both exhibit concentration reversion in a single experiment. A sufficient requirement for obtaining reversion of a $c_B - t$ curve is found, as above, to be

$$\sqrt{D_B/D_Y} - 1 > 1/a\lambda_Y \quad [17]$$

Examples of first-order reactions which satisfy condition [16] are tests 1 and 2 of Table I. In each case the concentration of reactant Y at the electrode passes through a minimum at a finite time, t_m. Relative concentration changes

$$u_Y \equiv (c_Y - c_Y^0)/c_Y^0, \quad u_B \equiv (c_B - c_B^0)/c_B^0 \quad [18]$$

are tabulated for comparison purposes. The time t_m corresponding to the maximum concentration change was determined to better than ±1% accuracy from listings of u_Y and u_B as functions of time, obtained by computer from Eq. [4], [5]. Table I lists the minimum in u_Y (shown underlined), as well as the values of u_B and $i/i_{t=0}$ corresponding to it. Also tabulated are the ultimate values $u_{Y,\infty}$ and $u_{B,\infty}$ corresponding to $t \to \infty$. Examples of first-order reactions satisfying condition [17] are tests 3 and 4 of Table I; here the maximum value of u_B was determined and is shown underlined.

By way of illustration, curves of u_Y, u_B, and $i(t)/i_{t=0}$ as functions of time, calculated from Eq. [4], [5], [12], are plotted for test 1 of Table I in Fig. 1. The existence of a minimum in the $u_Y - t$ curve has no effect on the monotonic decrease of current or on the monotonic increase of u_B. This curve exhibits the characteristically slow rate of recovery of concentration after the maximum concentration change is passed. In this case the maximum concentration change exceeds the ultimate change ($t \to \infty$) by 21%. Many other reaction conditions gave relatively larger percentage changes, *e.g.*, 41% for test 2 and 52% for test 6 of Table I.

Higher-order reactions.—No exact analytical solution of the general diffusion problem for higher-order reactions at spherical electrodes has appeared as yet.

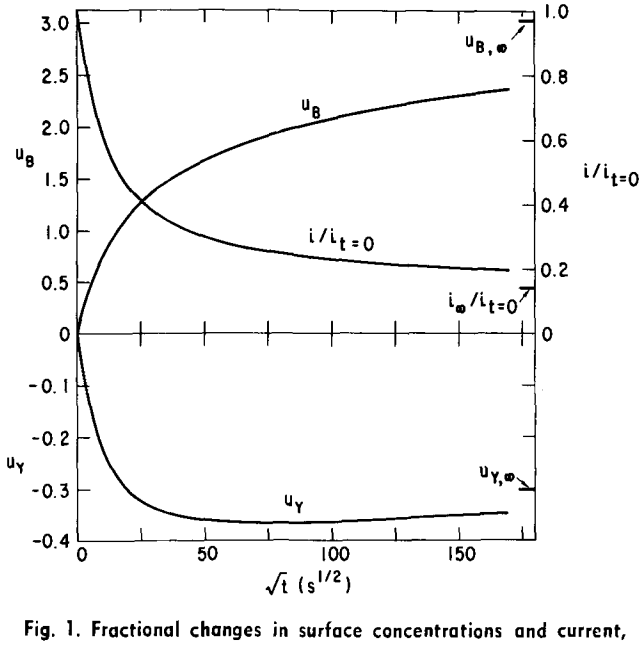

Fig. 1. Fractional changes in surface concentrations and current, first-order reaction at spherical electrode, test 1 of Table I.

[4] We are indebted to a referee for bringing to our attention the work of R. W. Lyczkowski, D. Gidaspow, and C. W. Solbrig, *Chem. Eng. Progress Symp. Series No. 77, 63*, 1 (1967). These authors showed that concentration reversion can occur with chemical reactions taking place on a catalytic surface. The surface constraints on their reacting system are essentially similar to those in the present paper. The criteria which we find, for the occurrence of concentration reversion in potentiostatic reactions, are similar to those which they found for catalytic chemical reactions.

* Compare $\sqrt{D_Y/D_B} - 1 = 2.16$.

** Compare $\sqrt{D_B/D_Y} - 1 = 2.16$.

A first approximation has been obtained by solving the general problem after linearizing Eq. [2] with respect to concentrations (11). The resulting $c_Y - t$, $c_B - t$ and $i - t$ relations are the same as Eq. [4], [5], [12], provided λ_Y and λ_B are redefined to include the reaction orders

$$\lambda_Y \equiv \frac{(y/\nu)^2 i_0 \exp[(1-\beta)(n/\nu)\epsilon\eta]}{(n/\nu)\mathbf{F}\, c_Y^0\, D_Y},$$

$$\lambda_B \equiv \frac{(b/\nu)^2 i_0 \exp[-\beta(n/\nu)\epsilon\eta]}{(n/\nu)\mathbf{F}\, c_B^0\, D_B} \quad [19]$$

This result indicated to us that Eq. [16] and [17], which are conditions for concentration reversion with first-order reactions, might lead us to higher-order reactions which show this phenomenon, if reversion is indeed possible in higher-order systems. Accordingly we selected several particular reactions which were second order in anodic reactant Y and first order in B; some of these obeyed Eq. [16] and the others Eq. [17]. For each case, the true $c_Y - t$, $c_B - t$, and $i - t$ curves were determined numerically on a computer following the Schmidt method (12). The solution was carried out sufficiently far in time to include the maximum concentration change. In each of the particular cases examined concentration reversion was found; a small sampling of these results is included in Table I. Tests 5 and 6 represent reaction conditions obeying criterion [16], and each exhibits a minimum in c_Y. Tests 7 and 8 obey criterion [17] and exhibit maximum c_B. The values of $u_{Y,x}$ and $u_{B,x}$ tabulated for these higher-order cases were calculated from equations previously developed (11).

Cylindrical Electrodes

In a potentiostatic experiment, the electrode reaction rate decreases monotonically with time whether the electrode is planar, spherical, or cylindrical. At planar electrodes the two coupled concentration changes, u_Y and u_B, stand in constant ratio at all times (5). At spherical electrodes the ratio of these concentration changes is initially ($t \to 0$) the same as at planar electrodes, because the diffusion layer thickness is small with respect to electrode radius, but as the reaction proceeds this ratio changes (10, 11). Cylindrical electrodes also behave initially like planar electrodes but, as with spherical electrodes, the ratio u_Y/u_B varies with time. Such time variation is a necessary condition for concentration reversion to occur. Although this is not a sufficient condition, it motivated us to look for concentration reversion at cylindrical electrodes. In addition, the success of Eq. [16], [17] as criteria for revealing concentration reversion in higher-order reactions at spherical electrodes encouraged us to apply these criteria to cylindrical electrodes, for both first-order and higher-order reactions. The admittedly tenuous rationale behind such application to cylinders is the fact (6, 13) that, for an appreciable time starting at $t = 0$, a constant-potential reaction exhibits almost the same kinetics at a cylinder of radius a as it does at a sphere of radius $(8/3)a$.

Several particular cases of first-order reactions at cylindrical electrodes were selected initially, on the basis of Eq. [16], [17], and the true curves of $c_Y - t$, $c_B - t$, and $i - t$ were obtained by solving the boundary value problem numerically on a computer. Again the Schmidt procedure (12) was followed, the boundary conditions on the concentration gradients being handled by a method also ascribed to Schmidt [ref. (14), designated Method II]. Concentration reversion was found to occur, as is shown by the group I tests in Table II (maximum relative concentration changes are underlined). Equation [16] was successful as a criterion for revealing c_Y reversion; tests 1 and 2 are typical examples. Equation [17] led to c_B reversion, *e.g.*, tests 3 and 4.

Next the two criteria were applied to particular reactions second-order in reactant Y and first-order in B as examples of higher-order reactions. In each case true concentration-time and current-time curves were generated numerically as above. Again Eq. [16] led us to c_Y reversion, *e.g.*, tests 5 and 6 of Table II; and Eq. [17] led to c_B reversion, *e.g.*, tests 7 and 8.

Conclusions

In electrode reactions at constant potential, the coupled concentration changes of two substances involved in the reaction can lead to concentration reversion, *i.e.*, the absolute value of the concentration change of one substance passes through a maximum at some finite reaction time. This phenomenon occurs at spherical and cylindrical electrodes, both with first-order and higher-order reactions, but it cannot occur at planar electrodes. In the case of first-order reactions at spherical electrodes, the known closed-form solutions for the concentration-time behavior permit one to predict experimental conditions that give rise to the reversion phenomenon.

Interferometric Study of the Concentration Change at High Cathodic Current Densities

Aladar Tvarusko* and Laurence S. Watkins[1]

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

ABSTRACT

The refractive index change, Δn, *i.e.*, the concentration of the solution at a vertical cathode was studied by a Lloyd mirror laser interferometer during the electrodeposition of copper from $CuSO_4$ solutions with and without tenfold excess of H_2SO_4. The initial galvanostatic transients were studied below the limiting current density and above to the start of H_2 bubble formation. It was found that the concentration decreased linearly with $it^{1/2}$ for both solutions. The effect of an assumed linear refractive index gradient on the measured value of Δn is discussed in addition to the influence of the H_2SO_4 supporting electrolyte.

The change of the refractive index, *i.e.*, concentration of the solution in the diffusion layer during electrochemical processes, has been extensively studied by interferometry, mainly at low current densities (1). At high current densities, the refractive index change of the solution cannot usually be obtained from the various interferograms because the beam of light is deflected due to the presence of large refractive index gradient in the diffusion layer (2, 3). Similar observations were made also in interferometric heat transfer studies (4). The complex light deflection errors were treated by several workers (2, 4-6).

We have described separately (2) a Lloyd mirror laser interferometer for the determination of the refractive index gradient. The optical path length change of the reflected ray was measured as a function of time, incidence angle, and electrode displacement (2). The refractive index gradient is calculated from the measured optical path length change (2) by an iterative solution of the derived equation (7) on a digital computer. The change of refractive index is obtained by multiplying the refractive index gradient with the diffusion layer thickness (2, 3).

The electrodeposition of copper from 0.24M $CuSO_4$ solutions without and with tenfold excess of H_2SO_4 was studied by a Lloyd mirror laser interferometer at high constant current densities ($\leq$90 mA/cm^2). We shall describe the interference fringe behavior especially above the limiting current density, the optical path length change as a function of time at various current densities, and the refractive index change as a function of $it^{1/2}$.

Experimental

The experimental setup was described separately in detail (2). Figure 1 shows schematically the electrolysis cell and the Lloyd mirror laser interferometer. A diverging laser beam is partially reflected off the electrode producing an interference pattern between the reflected and unreflected part of the beam. In the experiment, fixed photo devices are used to monitor the movement of the interference fringes and their outputs are recorded on oscillographs. The interference fringes move past the detectors after the current addition because the optical path length of the reflected beam changes in the developing diffusion layer (2, 7). The distance between neighboring maxima or minima of the sinusoidal signal (Fig. 2) correspond to the movement of one fringe and the optical path length change of the deflected beam equals the wavelength of the laser light (632.8 nm).

Results and Discussion

The sinusoidal oscillograph traces are basically the same in the beginning of the galvanostatic experiments regardless of the current density but not the number of cycles, *i.e.*, fringes and the frequency of the waveform, *i.e.*, number of fringes per second (compare Fig. 3). Below the limiting current density the sinusoidal waveform becomes smooth when the steady state is reached, whereas it abruptly ends after a certain time above the limiting current density. Figure 2 shows the latter for a 0.24M $CuSO_4$-2.36M H_2SO_4 solution and the signal undergoes a large rapid change which is followed by a slow recovery. The traces eventually become randomly rough due to the evolving hydrogen gas bubbles.

The aforementioned large change of the signal occurs first at large θ angles (θ is the complementary angle of incidence) and proceeds toward shallower angles with time (in less than 1 sec, depending to a

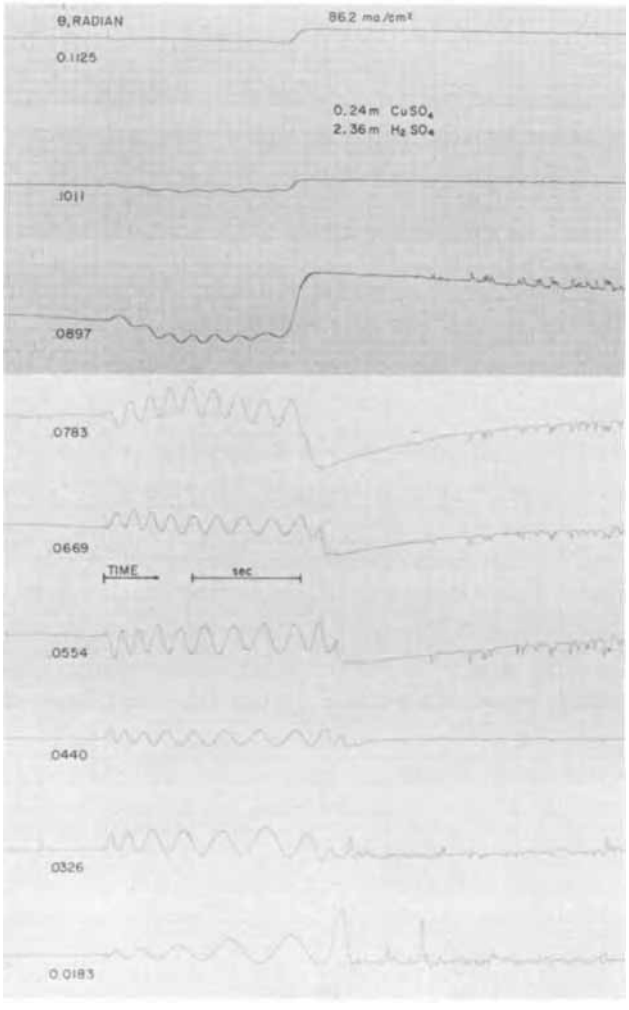

Fig. 2. Oscillograph record of the photodevice array output at various complementary angles of incidence (θ) before and after the addition of 86.2 mA/cm^2 which is well above the limiting current density. The solution is 0.24M $CuSO_4$-2.36M H_2SO_4.

certain degree on the current density). This large change of the trace coincides with the movement of a brighter spot of the interfering laser beam across the photodevice array from larger to smaller θ values. The random signal excursions, on the other hand, begin at the lowest θ value after the aforementioned large rapid change of the signal has already occurred at higher θ values.

The time dependence of the transition of the large change could be explained by the deflection of the ray on various segments of the diffusion layer normal to the cathode, if the diffusion layer is assumed to be uniform along the cathode. It is clear from initial appearance of the large signal change at large θ angles that the phenomenon responsible for it occurs first in a segment of the diffusion layer adjacent to the cathode. This phenomenon extends with progressing electrolysis time toward the diffusion layer/bulk solution interface. High-speed color motion pictures of the laser beam in the diffusion layer and on the cathode showed no visible change until the H_2 bubble formation. The H_2 bubbles were very clearly visible in the path of the ray and the ray was randomly bounced off the bubbles.

The aforementioned large change and its time dependent propagation through the diffusion layer are caused by the processes occuring in the immediate vicinity of the cathode. Let us see what happens at the cathode and in the diffusion layer during galvanostatic transient above the limiting current density. Cu^{++} are discharged in the beginning at the cathode until its concentration at the cathode/solution interface decreases to zero when the H^+ present in the solution will start to be neutralized at the cathode simultaneously with the Cu^{++}. The electrodeposited copper will be very rough and the H_2 will dissolve in the solution adjacent to the cathode. According to the unsteady-state model of electrolytic bubble growth (8), first developed by Hsu (9) for a boiling liquid at a heated wall, there is a waiting time before a gas bubble forms. During this waiting time the continuously generated hydrogen gas diffuses away from the cathode due to the concentration gradient and the gas concentration increases in the solution adjacent to the cathode until it reaches a critical value at a specific distance from the cathode. Then, a gas bubble will start to grow from the supersaturated solution at a nucleation site.

Glas and Westwater (8) found that the waiting times for hydrogen bubble formation from pure H_2SO_4 solutions were usually much less than 1 sec but were up to 30 sec on nickel at 40 mA/cm^2. The elapsed time in Fig. 2 for the large change between the largest and smallest θ angles is 0.42 sec and elapsed times of 0.4 to 0.7 sec were found for Cu cathodes during the electrodeposition of copper from both $CuSO_4$ solutions. The delayed appearance of gas bubbles, *i.e.*, randomly rough signal trace after the large change of the signal and its time dependent propagation toward the bulk solution could be assigned to the H_2 dissolution and supersaturation phase during the waiting time. Unfortunately, there are no experimental data available on the refractive index of electrolytes supersaturated with gases under comparable conditions and the aforementioned possible correlation cannot be ascertained on the basis of Lloyd mirror interferometric experiments. It is interesting to note that the diffusion layer thickness (determined from Mach-Zehnder interferograms) increased rapidly during the corresponding time before the visible H_2 bubble evolution in the presence of tenfold excess of H_2SO_4 (3). Another possible explanation for the time dependent large change would be the formation of submicroscopic hydrogen gas bubbles which are slowly growing from the solution rapidly becoming supersaturated.

The large change of the signal in 0.24M $CuSO_4$, *i.e.*, in the absence of tenfold excess of H_2SO_4, is present also but at approximately twice the previous current densities (due to the influence of migration). In the absence of H_2SO_4 the random signal excursions start practically immediately after the disappearance of the sinusoidal signal at all angles in contrast to the absence of these random traces at large θ angles with the tenfold excess of H_2SO_4. If they are present, they cannot be detected because of the aforedescribed large change of the signal.

It is hoped that a future interferometric study of the initial galvanostatic transients of gas evolution in aqueous acid and alkaline solutions will answer whether or not these large signal changes are present in absence of simultaneously occurring metal deposition and are caused by the supersaturation of the solution or by others.

Figure 3 shows the optical path length change of the deflected beam in terms of fringes at a recommended (2) higher θ angle ($\theta = 0.0807$ radian) as a function of time for various current densities. It can be clearly seen that (*a*) the optical path length change develops faster at higher current densities; and (*b*) the number of fringes increases with current density, but starts to decrease approximately above the limiting current density. The same is true for the change of the optical path length at low θ angle ($\theta = 0.0193$ radian, not reproduced here) but the number of fringes is not sensitive to current density ($\gtrsim$5 mA/cm^2). The reason for this current independence of the optical path length change at low θ angles is as follows: At shallow angles the beam penetration is quite small and so a change in the refractive index does not alter much the optical path of the beam through the diffusion layer; the beam will be very close to the edge of the diffusion layer.

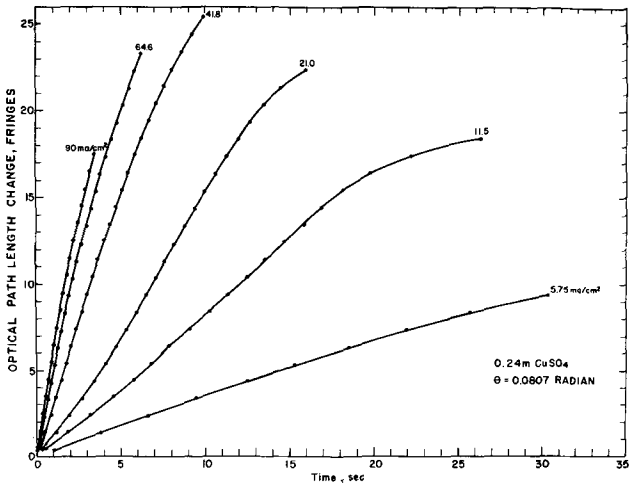

Fig. 3. The optical path length change of the deflected beam at higher complementary angle of incidence as a function of time at various current densities in 0.24M $CuSO_4$.

A change in the diffusion layer thickness, however, will alter the optical path length significantly since the diffusion layer edge has moved.

The refractive index gradient is calculated from the measured optical path length change (2) by an iterative solution of the derived equations (7) on a digital computer. The change of the refractive index at the cathode/solution interface, Δn during the current flow is obtained by multiplying the refractive index gradient with the diffusion layer thickness (2, 3). The refractive index change in our case is practically linearly dependent on the concentration change of the solution, Δc (refractive index change of 1.10^{-4} equals 3.68×10^{-6} mole $CuSO_4/cm^3$). Thus, a linear relationship should be obtained between Δn (Δc) and $it^{1/2}$ in $CuSO_4$ solutions with and without tenfold excess of H_2SO_4 (10).

Figure 4 shows Δn as a function of $it^{1/2}$ at various current densities in 0.24M $CuSO_4$. It can be seen in the left half that the linear regression fits the data well (the coefficient of correlation, R, is high) but the regression line (fitted by the least squares method) does not go through zero. The highest Δn value is 40×10^{-4} which is significantly below the expected value of 69×10^{-4} if the concentration of $CuSO_4$ at the cathode surface is zero at and above the limiting current density.

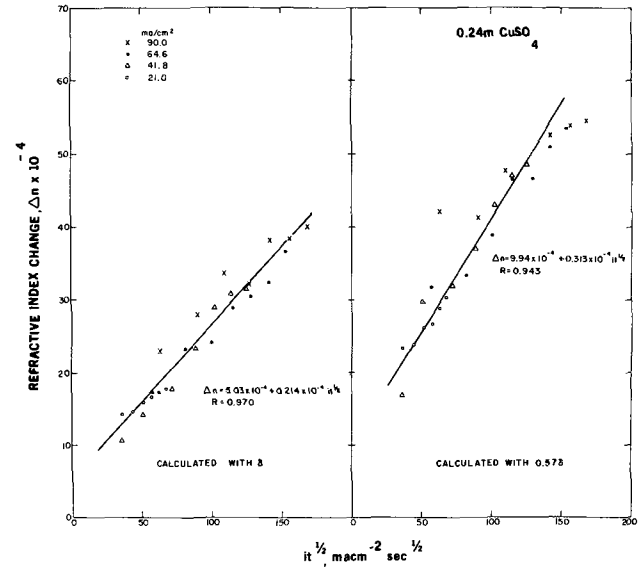

Fig. 4. The refractive index change as a function of $it^{1/2}$ at various current densities in 0.24M $CuSO_4$. Δn is calculated with the actual diffusion layer thickness, δ, and the idealized Nernst diffusion layer thickness (0.57 x δ), respectively.

The derived correlations (7) assume, as a first approximation, that the refractive index gradient is linear over the entire diffusion layer (idealized Nernst case). Interferometric measurements have shown that the gradient is linear over a substantial part of the diffusion layer (11) and the change of refractive index is exponential near the edge of the diffusion layer. The diffusion layer thickness, δ used for the calculation of Δn in Fig. 4, was obtained from Mach-Zehnder interferograms (1, 3) and is a measure of the diffusion layer thickness to its outside edge. If this δ is used to calculate the refractive index gradient, a much lower value of Δn results because the average linear value of the gradient over the entire diffusion layer is smaller (7). To obtain a more accurate value of Δn, a value of 0.57δ, derived by Ibl (11), should be used instead of the full δ values since the average gradient for this shorter distance more closely approximates the actual gradient at the cathode (7). We have recalculated Δn with 0.57δ and the result is shown in the right half of Fig. 4. The linear correlation is slightly lower and the highest Δn is within approximately 15% of the expected value. Thus, a better agreement is obtained with the expected value through this simple correction.

As mentioned, δ was obtained from Mach-Zehnder interferograms (1, 3). This requires another experimental setup and a time consuming interpretation of the interferograms. An empirical diffusion layer thickness, δ_θ was described separately (2, 7) and is obtained from the computer printout of the refractive index gradient calculation (7). Δn calculated with δ_θ was found to increase linearly with $it^{1/2}$ (similarly to Fig. 4) and the value of Δn is about half of the expected one. Since δ_θ corresponds to a point near the edge of the actual diffusion layer, we can use again $0.57\delta_\theta$ and Δn was found to increase markedly but it is still slightly lower than the expected value. The advantage of using δ_θ is that it yields an approximate value of Δn without an additional experimental setup.

During the electrodeposition of copper from $CuSO_4$ solution, the sulfate ions remain in the diffusion layer and must react with water to preserve the electroneutrality and HSO_4^- and/or H_2SO_4 forms. The presence of H_2SO_4 in the vicinity of the cathode would likely falsify the calculated Δn value and lower Δn values would be obtained. In view of this, we have measured the optical path length change in 0.24M $CuSO_4$ with a tenfold excess of H_2SO_4. Figure 5 shows

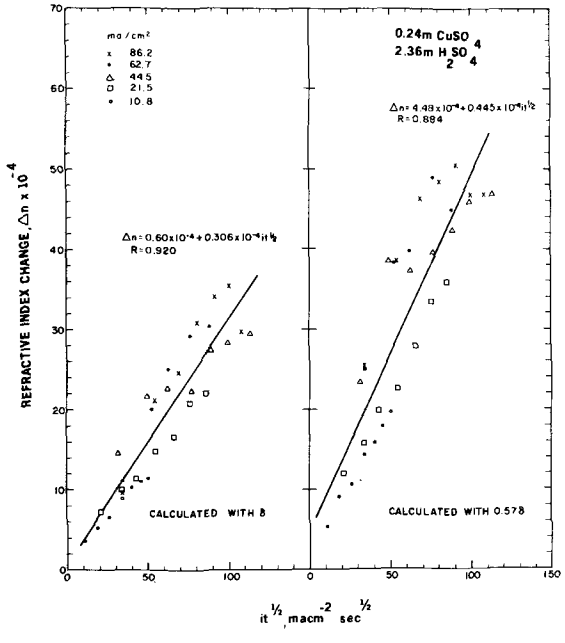

Fig. 5. The refractive index change as a function of $it^{1/2}$ at various current densities in 0.24M $CuSO_4$-2.36M H_2SO_4 solution. Δn is calculated as in Fig. 4.

that the calculated Δn values are approximately the same as in the absence of H_2SO_4 (Fig. 3) and the coefficients of correlation are smaller in the presence of the tenfold excess of H_2SO_4 then in its absence. The Δn values calculated with the empirical diffusion layer thickness values are similar to those obtained in the absence of H_2SO_4.

The slope of Δn-$it^{1/2}$ regression line is markedly larger, *i.e.*, Δn develops faster in the presence of tenfold excess of H_2SO_4 than in pure $CuSO_4$ (Fig. 4, 5). The ratio of the slope in pure 0.24M $CuSO_4$ solution, s_m, to that in the presence of tenfold excess of H_2SO_4, s_d, equals to 0.70. In view of the practically linear relationship between Δn and Δc, the s_m/s_d ratio can be calculated for the $CuSO_4$ solutions from

$$\Delta c = \frac{2(1 - n_c)}{z\mathbf{F}\,(\pi D)^{1/2}}\, it^{1/2} \qquad [1]$$

where n_c is the cation transference number, and the others have their usual significance (10). Using $D_{salt} = 5.6 \times 10^{-6}$ cm^2/sec (12), $n_c = 0.34$ (12) for the $CuSO_4$ binary electrolyte and $D_{Cu++} = 7.2 \times 10^{-6}$ cm^2/sec (13), $n_c \approx 0$ (14) for the $CuSO_4$ with large excess H_2SO_4, we obtain 0.748 for the s_m/s_d ratio which compares favorably with the aforementioned experimentally obtained s_m/s_d ratio of 0.70. These results clearly demonstrate that the change of the slope is due to the effects of migration.

Earlier (1) we have determined Δc by Mach-Zehnder interferometer as a function of $it^{1/2}$ in the presence of small amount of supporting electrolyte at low current densities and practically the same $CuSO_4$ concentration (0.25M). For these experiments $s_m/s_d^* = 0.77$ (s_d^* is the slope of Δc-$it^{1/2}$ regression line in the presence of 0.11M H_2SO_4) which is higher than the experimentally determined ratio for the presence of large excess of H_2SO_4. Unfortunately, independently determined values of D and n_c are not available for this solution and the slopes cannot be calculated.

Newman (15) studied the effect of H_2SO_4 addition on the limiting current for copper deposition from $CuSO_4$ solutions. If we assume that Newman's results are applicable also below the limiting current densities then we can compare them with our results. The $s_m/s_d^*/s_m/s_d$ ratio is preferred because thus any possible influence of the different interferometric techniques is eliminated and it equals 0.77/0.70 = 1.10. Newman's concentration ratio, r, for the 0.25M $CuSO_4$-0.11M H_2SO_4 solution is 0.3055 ($r^{1/2} = 0.553$) and we obtain 1.27 from his Fig. 3 and Table II for the I_L/I_D, *i.e.*, the ratio of limiting currents in the presence and absence of migration, respectively. Since Newman's results are valid for a disk electrode, we have to convert 1.27 for a plane electrode (our case) by dividing it by 1.1198 (Newman's Eq. [36]) and the result is 1.13. This value compares very favorably with our interferometrically determined ratio of 1.10. Unfortunately, we have no additional data at the present for further verification at other H_2SO_4 concentrations.

It should be noted that the Δn values obtained from Mach-Zehnder and Lloyd mirror interferometer measurements at low current densities (~10 mA/cm^2) agreed well.

Technical Note

An Automated Procedure for Obtaining Steady-State Current-Potential Relationship

G. Belanger*

Hydro-Quebec Institute of Research, Varennes, Province of Quebec, Canada

In the experimental investigations on the mechanism of activation-controlled electrode reaction, the relevant data are partly gathered by measurement of steady-state current-potential relationships (1-3). The current-potential curves thus obtained provide quantitative values of Tafel slopes, exchange current densities, reaction orders, apparent heats of activation, and, under favorable conditions, stoichiometric numbers. In addition to these parameters, a great deal of

* Electrochemical Society Active Member.
Key words: automation, measurement of current-potential curves.

other useful information may also be obtained in some cases from these curves, *e.g.*, inhibition inflections and associated negative Tafel slopes, mechanism change as a function of potential as deduced from abrupt changes in the Tafel slopes caused by parallel or consecutive reactions, and, some other general features of the over-all current-potential plots. In short, a variety of useful details, which are indispensable to the elucidation of the reaction mechanism, are obtained from these curves.

The usual procedure of obtaining these curves, is the point-by-point measurement (either potentiostatic or galvanostatic) which is quite tedious and time-consuming. A recent alternative has been proposed to measure a slow potentiodynamic curve, which in most cases, yields current-potential relationships very similar to those obtained by the steady-state procedure. The potentiodynamic method, even at slowest speed, is still open to the objection that the true steady state is never achieved since the potential is being continuously varied.

Here, an attempt has been made to describe a procedure which may be used to obtain true steady-state relationship in a fully automated manner. In most cases, the present method would yield results very similar to those obtained by a slow potentiodynamic sweep. However, in several cases in which a knowledge of the true steady-state current-potential relations is necessary for a precise mathematical analysis of the kinetic data (2), the present procedure may be used to acquire the data in an automated manner.

Experimental

Measurements were made in a conventional three-compartment Pyrex cell (Fig. 1A). The hydrogen reference electrode in the same solution was used, and the test electrode was studied under helium atmosphere. The gases used were purified by the usual techniques (4).

The electronic equipment used is commercially available; only a slight modification to one of the component, as described below, was required to put the system into operation.

Figure 1 gives the block diagram of the experimental arrangement. The potentiostat (B), Tacussel Model PRT 20-10, controlling the electrochemical reaction was regulated by a motor driven potentiometer (C): the potentiometer of the potentiostat was by-passed. The potential between the working and reference electrode was controlled by this mechanical device (Tacussel's Servovit pilot scanner Model 9B): the advantage of this particular instrument is that it can be controlled remotely by an appropriate switching program. To achieve this programming, a series of microswitches activated by cams (D), Industrial timer, series MC was used in our experiment. The potential span is regulated by the time the scanner is on and by the speed at which resistance of the potentiometer is made to vary. The current is measured by a logarithmic amplifier (E) whose voltage output is proportional to the logarithm of the input current (Tacussel's logalex, Model 100B). The lower limit of current measurement is 0.1 μA. The log i is fed to the X axis of X-Y recorder (F). The potential between the working and reference electrode is recorded on the Y axis. The pen of the recorder is activated by a switch closure provided by the cam system (D).

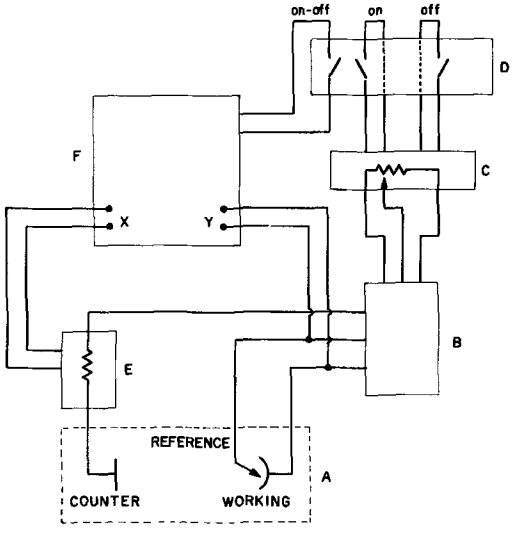

Fig. 1. Block diagram of the experimental set up: A, three-compartments cell; B, potentiostat; C, motor-driven potentiometer; D, microswitches and cam assembly; E, logarithmic current amplifier; F, X-Y recorder.

In Fig. 2 we present the schematic potential-time sequence to which the working electrode was subjected. In this figure, τ_1 represents the time the scanner is on: this time gives us the voltage span, ΔV. For a given time τ_2, the potential is kept constant: τ_2 is chosen long enough for the electrochemical steady-state to be established. Just before a new increment of potential is applied to the working electrode, one cam closes the switch, thus activating the pen of the X-Y recorder. This is illustrated as τ_3 in Fig. 2.

As mentioned above, slight modifications to the relay circuits of the Servovit scanner were made so that potentiostatic cycles could be performed (*i.e.* starting at 2V anodic going to zero and back at 2V or any other program). The modified circuit of the Servovit scanner is given in Fig. 3. The nomenclature and arrangement in Fig. 3 refer to the blue print of the instruction manual. Two double-pole double-throw relays (A and R) of this original instrument were replaced by two quadrupole double-throw relays. The relay (RT) originally used as a marker, is now used in conjunction with the new circuit. The remote control wiring diagram is also given in Fig. 3.

Other types of scanner could be used for the same purpose. The Wenking scanning potentiometer, Model S M P 69 would be equally suited for this experimental procedure.

Results

Figure 4 shows an example of the use of this procedure for the case of anodic oxidation of 5M methanol in 1*N* H_2SO_4 on bright platinum electrodes. This curve was plotted over a 24-hr period. The potential span is 10 mV, and the fixed potential was retained for 3.75 min at every point in order for the steady state to be achieved.

Detailed interpretation of this curve will be presented elsewhere, but some features can be compared with previous results (5, 6). The maxima on the ascending curve at 0.95 and at 0.7V on the descending

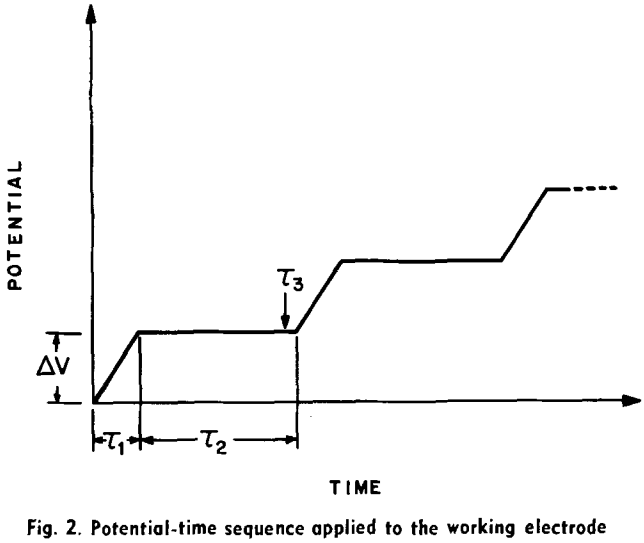

Fig. 2. Potential-time sequence applied to the working electrode

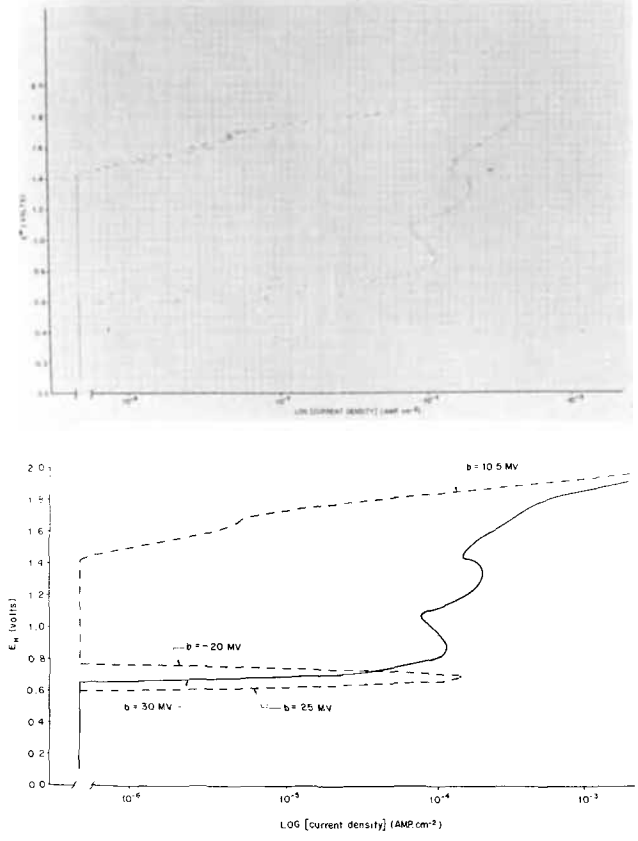

Fig. 4. Steady-state potentiostatic plot of 5M methanol in InH_2SO_4. (A) (top) Raw data from the recorder; (B) (bottom) final forms: – – – descending and ——— ascending directions of potential.

curve agree roughly with those obtained potentiodynamically by Gilman and Breiter (6). However, our rates are lower than those reported by them (6), since a steady state was not achieved in their work.

It may be mentioned that the same procedure was also used (7) for the investigation of hydrogen evolution reaction and found to be quite satisfactory.

After 2 min at a given potential, the current variations with time were very small at most potentials so that the 3.75-min interval was sufficient for the steady-state conditions to be achieved. However, in the low current region (10^{-6}A) it appears that some irregular oscillation of the currents occurred, due mainly to the oxidation, it is believed, of some residual impurities. These oscillations produced straight dashes (Fig. 4A) instead of points in the log current-potential relationship. By the addition of cams to the microswitch system (Fig. 1) several points could be recorded during the constant potential time interval (τ_2 in Fig. 2). This could give us an idea on the log current-time variations at a given potential.

The direct recording of the current-time variations could not be achieved directly with the instruments used in the experiment. The difficulty of matching the impedances between the different instruments produced meaningless results specially at low current values (10^{-7} to 10^{-6}A). This limitation does not appear to be intrinsic, however.

Conclusion

The advantage of this automated procedure is evident when a great number of such curves have to be obtained. Studies of certain variables in a given experimental condition can be made on a continuous basis, *e.g.*, variation of concentration to determine reaction orders, addition of certain poisons or accelerators in a given solution, etc.

Further extension in the automation of this simple system can be easily forseen: instead of recording the data on a X-Y recorder, they could be fed directly into a computer (with the appropriate interfaces). The format of the results could then be either digital or/and graphical. In this case the logarithmic amplifier could be replaced by a resistance, and the voltage drop across it would thus be the measure of the current.

Among further developments of this automated procedure, our attention will be focused on the means of defining and reaching the "true steady-state" conditions. This goal could be achieved by measuring the change of the current with time at a given potential and recording the value of the current only when this variation becomes less than a preset value (*i.e.*, less than 1%). This procedure implies comparison of data sampled at a given time interval and, to achieve this goal efficiently, the use of an automatic data acquisition and treatment system will be essenital.

By minor modifications of our scanner, other forms of potential time program can also be achieved.

Dielectric and Optical Properties of Stoichiometric Magnesium Aluminate Spinel Single Crystals

C. C. Wang* and P. J. Zanzucchi

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Stoichiometric magnesium aluminate spinel ($MgAl_2O_4$) single crystals grown by the flux, Czochralski, and Verneuil methods have been characterized for their dielectric and optical properties. Dielectric properties were determined from capacitance measurements in the frequency range 10^2-10^5 Hz. The dielectric constant and loss tangent of $MgAl_2O_4$ spinel crystals grown by the various methods are comparable. At 1 kc the $MgAl_2O_4$ spinel has a dielectric constant of 8.4 and a loss tangent of 10^{-4}. Optical transmission and reflection measurements were made in the wavelength range uv to IR (0.2-40 μm). Optical characteristics of the $MgAl_2O_4$ crystals are highly dependent on the method of growth. Chromium-doped $MgAl_2O_4$ spinel single crystals have also been grown by a flux technique. Optical emission and absorption characteristics of Cr^{+3} in flux-grown $MgAl_2O_4$ spinel have been studied. The results are compared with those of Cr^{+3} in natural spinel and synthetic spinel crystals prepared by the Czochralski and Verneuil methods.

The use of single crystal magnesium aluminate spinel as an insulating substrate material for epitaxial semiconductor devices has recently been reported (1-4). It is also reported to be of potential use in passive ultrasonic delay line application (5, 6). This has stimulated considerable interest in obtaining high quality, single crystalline spinel which is difficult to grow because of its high melting point, wide solid solubility range, and its tendency toward heterogeneous composition through a complicated precipitation phenomena (7, 8). In the past few years significant progress was made on the growth of stoichiometric spinel of large sizes (>½ in. diameter) by the Czochralski (9-12), Verneuil (1), and flux (13, 14) methods. Many important physical properties of single crystal spinel remain to be characterized. In this paper research results are presented on the dielectric and optical properties of single crystal stoichiometric spinels ($MgAl_2O_4$) grown by the various methods. Chromium doped $MgAl_2O_4$ crystals were also grown by a flux technique. Emission and absorption characteristics were studied, and these results are compared with those obtained from crystals grown by other methods.

Experimental

Crystal growth.—Crystal growth of stoichiometric spinel by a flux technique, both undoped and chromium doped, was carried out using a PbF_2 flux-solvent and B_2O_3 as a liquid encapsulant. Vaporization of the flux at constant temperature was used for the generation of supersaturation to promote the crystal growth. A schematic drawing of the growth apparatus is presented in Fig. 1. The furnace was constructed from insulating brick and SiC globar heating elements. Feed nutrients were prepared from mixtures of MgO (reagent grade from Fischer Scientific Company and Optran grade from B.D.H. Labs.) and Al_2O_3 (type A alumina from Linde Company and Optran grade from B.D.H. Labs.). Doping was achieved by using feed prepared by calcining at 1050°C coprecipitated mixtures of ammonium alum and chrome alum (both Baker analytical reagent grade) so that 0.5% by weight of Cr_2O_3 is added to the $MgAl_2O_4$ spinel. The nutrients were mixed with the PbF_2 flux (extra pure and Optran grades from B.D.H. Labs.). A degree of filling of 70-90% by volume was attained by premelting the initial charge in a platinum crucible at about 900°C followed by refilling with more of the mixture. A thin layer (1-2% by weight of flux) of B_2O_3 (reagent grade from

Fischer Scientific Company) was generally added on top of the mass as a liquid encapsulant to control the vaporization of the flux. The crucible was sealed with a platinum cover having a circularly shaped opening and heated at the growth temperature (~1250°C) for the desired period of time. The furnace temperature was regulated by a West temperature controller. To prevent the reaction between the flux vapor and the globar heating elements, argon gas was used during the growth to carry the flux into the cool zone of the furnace. After the desired period of growth, the spinel crystals were recovered, after cooling, by leaching the flux in the crucible with hot nitric acid. The growth process is controlled by three factors: (*i*) the growth temperature, which governs the vapor pressure of the PbF_2 flux-solvent and the solubility of the nutrient, (*ii*) the size of the crucible opening and the thickness of the B_2O_3 liquid encapsulant layer, which limit the vaporization rate of the flux, and (*iii*) the initial composition of the melt. Typical growth conditions are (*a*) composition of melt: 2350g PbF_2 flux, 81g MgO and 204g Al_2O_3 feed nutrient, 40g B_2O_3 liquid encapsulant; (*b*) growth temperature: 1250°C; (*c*) growth time: 500 hr; and (*d*) crucible dimension: volume of 1000 cc and opening of ¼ in.

In addition to the flux grown crystals, stoichiometric spinel single crystals were grown from melt using the Verneuil and Czochralski techniques. Details on the growth processes and techniques were reported (1, 9-12, 15). The Verneuil crystals were grown by flame fusion using a three-tube, post-mix Verneuil burner (16) with critical dimensions to avoid sharp turbulent mixing zones. This burner produces a wide flame pattern which minimizes turbulence and allows larger diameter crystals to be grown. Feed materials were prepared by calcining coprecipitated mixtures of ammonium alum and magnesium sulfate (both Baker analytical reagent grade). Crystals were grown at a rate of ¼ in./hr. The Czochralski growth of $MgAl_2O_4$ spinel crystals were carried out[1] by pulling from melts contained in rf inductively heated iridium crucibles. The spinel melts were prepared from mixtures of the oxides. Crystals were grown on (110) or (111) seeds at pull and rotation rates within the ranges 0.1-0.3 in./hr and 0 to 20 rpm respectively.

Characterization.—The spinel single crystals were analyzed by wet chemical, emission spectroscopic, and x-ray diffraction methods for the gross composition, impurity contents, dislocation densities, and lattice parameters. Chemical analyses[2] were performed by alkali fusion of the spinel crystals followed by volumetric techniques. A mixture of sodium borate and sodium carbonate (ratio of 3 to 1 by weight) was used for the decomposition of the spinel. After decomposition the melt was treated with HCl, after which an excess of EDTA (ethylene-diaminetetraacetic acid) is added and heated to boiling to complex the Al. The Al content was determined by back titrating with a standard lead solution at *p*H 5.5-6.0 using Xylenol Orange as indicator. By adding 2,2′,2″-nitrilotriethanol as a masking agent for Al, Mg was directly titrated with EDTA at *p*H 10.0 using Eriochrome Black T as indicator. The dislocation density of the crystals was determined by the Lang x-ray topographic technique (17). The accurate lattice parameters were determined using x-ray diffraction (Cu/Ni radiation) Debye-Scherrer powder patterns.

The bulk crystals were oriented, cut, and polished in the form of wafers (surface area of ½ to 1 cm^2) of about 20 mil thick for measurements. Orientation for cutting was determined by the x-ray Laue back reflection method, and wafers were prepared by cutting the oriented crystals using a standard type diamond wheel. An accuracy of better than ±¼° was maintained through the operation. Most wafers used in this study were (111) oriented, although (100) and (110) oriented wafers were also measured. No dependence of dielectric and optical properties on orientation has been observed. The spinel wafers were mechanically lapped and polished to produce a flat, smooth surface. Lapping was carried out with about 30-μm boron carbide abrasives to obtain a flat coplanar surface. The lapped suface was further polished using successively finer grades of alumina, generally ending with the 0.3-μm grade.

The dielectric properties of stoichiometric spinel crystals grown by the three methods were determined using polished single-crystal wafers with evaporated gold electrodes (0.4 μm thick). The dielectric constant and dissipation factor were derived from capacitance measurements after edge corrections (18). The measurements were made using a General Radio Model 1615 capacitance bridge in the frequency range 10^2-10^5 Hz. Optical properties of spinel crystals grown by the three methods were measured in the range uv to IR. Transmission measurements were made in the wavelength range 0.2-7 μm using a Cary Model 14 spectrometer and a Perkin Elmer Model 457 spectrometer. Reflection measurements were made in the range 7-40 μm using the Perkin Elmer Model 457 spectrometer and a Wilks Model 9 reflection attachment.

Emission and absorption characteristics of Cr^{+3} in flux grown $MgAl_2O_4$ crystals were determined in the visible range. The fluorescence spectra were measured using a Spex Model 1700-1 spectrometer under ultraviolet stimulation using a Bausch and Lomb Model 33-86-40-01 monochromator and a 500W Hg arc lamp as the light source.

Results and Discussions

Crystal growth and crystallinity.—Flux grown $MgAl_2O_4$ single crystals up to 1 in. on an edge were obtained under the conditions cited above. The as-grown crystals are octahedral in shape with well-developed (111) facets (Fig 2). The crystals are transparent and free from macroscopic flux inclusions. They resemble closely their natural counterparts in habit and appearance. It was found that there is a limited crystallization temperature range for the $MgAl_2O_4$-PbF_2 system. Below about 1100°C, MgO reacts with the flux, and MgF_2 needles and α-Al_2O_3 platelets precipitate from the solution. Above 1293°C, the boiling point of PbF_2, the evaporation rate of PbF_2 is excessive, and the quality of the crystals is poor. Because of the restricted temperature range for crystallization, the technique of slow cooling, which is most commonly used in flux growth, is not feasible for the growth of spinel crystals from PbF_2 solvent. Beside the evaporation technique, growth of $MgAl_2O_4$ single crystals was reported (19) by a flux hydrolysis method.

Several Verneuil $MgAl_2O_4$ crystals (up to ⅝ in. diameter) were successfully grown under closely controlled growth conditions with no cracking[3] occurring during and/or after growth. The size of the crystals is appreciably larger than those (~¼ in. diameter) of flame fusion $MgAl_2O_4$ crystals reported previously (15). The crystals were grown in the <100> directions and have well-developed facets. They are clear, transparent, and free of macroscopic bubbles. Czochralski spinel crystals (about ½ in. diameter) of good optical and crystallographic qualities were grown using an iridium crucible (1.8 in. diameter x 2.3 in. height). Details on the growth of $MgAl_2O_4$ spinel by the Verneuil and Czochralski methods were reported (1, 9-12, 15). The gross composition impurity content, dislocation density, and lattice parameter of spinel crystals grown by the three methods were determined. Typical results are presented in Table I.

[1] The Czochralski $MgAl_2O_4$ single crystals employed in this study were prepared in-house by A. D. Morrison of RCA Laboratories.

[2] The analyses were made by B. L. Goydish and K. L. Cheng of RCA Laboratories. Details will be reported separately.

[3] The ease of growing spinel crystals (1) by the Verneuil method increases with increasing Al content in the material. Commercial spinel has an approximate composition of $MgO{:}3.3Al_2O_3$ and can be most easily prepared by the Verneuil method. Various investigators have reported (15, 20-22) the difficulty (cracking) involved in growing Verneuil stoichiometric spinel.

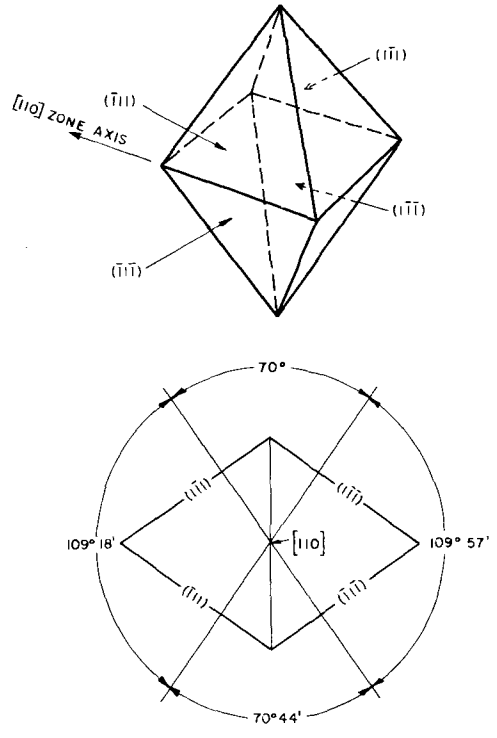

Fig. 2 a and b. Growth shape and habit of flux $MgAl_2O_4$ single crystals. Fig. 2a (top). As-grown $MgAl_2O_4$ octahedron. Fig. 2b (bottom). Growth habit.

It is seen from Table I that the experimentally determined Mg and Al contents are, within the range of experimental error, in agreement with the theoretical values for stoichiometric $MgAl_2O_4$ spinel. The melt grown (Verneuil and Czochralski) crystals may have slight Mg deficiencies due to the incongruent vaporization (20) of $MgAl_2O_4$ with preferential loss of Mg constituent at high temperatures. The flux grown spinel crystals seem to have a slightly lower lattice parameter than the melt grown crystals. The difference may be ascribed to the difference of the two kinds of crystals in ion distribution, impurity content, and gross composition.

The flux grown spinel crystals exhibit much less dislocations than the melt grown spinels because of the low growth rates and temperatures (~1200°C). The low temperatures are thermodynamically favorable for the growth of stoichiometric spinel from the phase behavior of the MgO-Al_2O_3 system (23). An interesting aspect of the flux spinel crystals is that they resemble

the natural stoichiometric spinel in growth habit and shape. It is likely that the natural spinel was also grown by a flux solution process at temperatures much lower than the melting point (2105°C) of spinel.

Dielectric properties.—The dielectric properties of $MgAl_2O_4$ spinel crystals grown by the three methods were determined in the frequency range 10^2-10^5 Hz. Typical results on the dielectric constant and dissipation factor (tan δ) are presented in Fig. 3 and 4. It is seen that in the frequency range measured the dielectric constant of $MgAl_2O_4$ spinel crystals grown by the three methods is comparable. The values are virtually the same. The dielectric constant falls slightly with frequency, and exhibits a change of about 0.1% per frequency decade over the measured frequency range. The dissipation factor also depends on frequency. The initial drop at lower frequencies is due to dissipation in the parallel leakage resistance, and the rise at higher frequencies is caused by loss in the series electrode resistance. The internal loss in the spinel dielectric is low and has values on the order

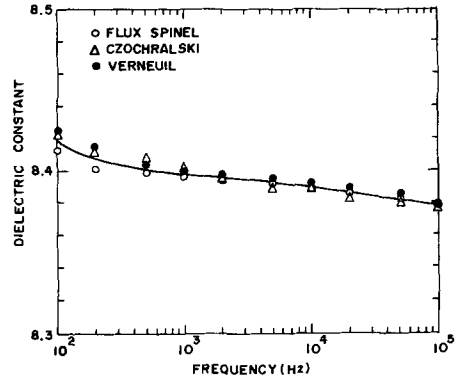

Fig. 3. Dielectric constant of flux, Czochralski, and Verneuil grown single crystal spinel.

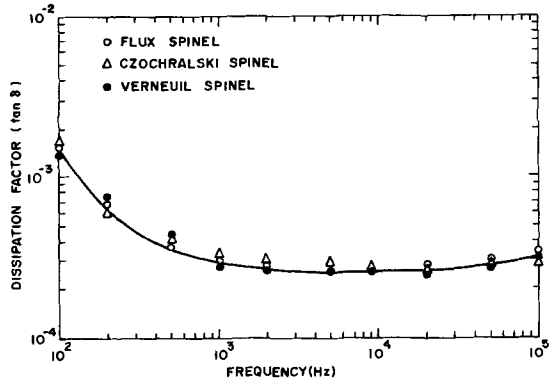

Fig. 4. Dissipation factor of flux, Czochralski, and Verneuil grown single crystal spinel.

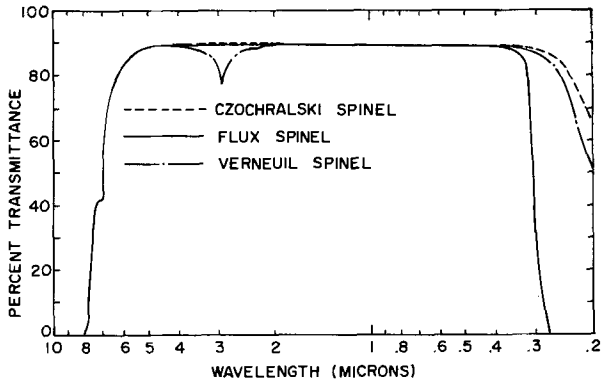

Fig. 5. Transmittance of flux, Czochralski, and Verneuil grown single crystal $MgAl_2O_4$ spinel.

of 10^{-4} in the measured frequency range. The minimal permittivity dependence on frequency and the low dielectric loss properties in a wide frequency range are characteristic generally of refractory insulating oxides.

Optical properties.—Transmission characteristics of stoichiometric spinel.—Transmission spectra of stoichiometric spinel single crystals (cut to an average thickness of 0.020 in.) grown by the flux, Czochralski, and Verneuil methods are shown in Fig. 5. It is seen that the spinel crystals are generally transparent from about 0.3 to 7.0 μm. In this region, the small apparent absorption of the variously grown crystals is largely due to Fresnel reflection losses (24) consistent with a refractive index of 1.70-1.72 for spinel (21). In the uv region, between 0.200 and 0.300 μm, the transmission of Czochralski and Verneuil grown crystals begins to decrease slightly, while the transmission of the flux grown crystals decreases sharply around 0.280 μm (as shown in Fig. 5). The strong uv absorption in the flux grown crystal may be due to impurities, most probably Fe, incorporated into the spinel lattice during the crystal growth. In the infrared region near 3 μm, an absorption band is present for the Verneuil $MgAl_2O_4$ spinel. This band has not been observed for the flux and Czochralski grown spinel crsytals. It is therefore not an intrinsic property of spinel. This absorption band occurs at 3360 cm^{-1} suggesting the presence of hydroxyl groups or water in the spinel lattice (21, 25). Since an oxyhydrogen flame is used in the Verneuil method, hydroxyl ions or water molecules are present in the flame, and these ions or molecules can be incorporated into the spinel lattice during the crystal growth (1, 21). Verneuil grown rutile has been reported to contain hydroxyl groups (26).

The O-H absorption characteristics at 3360 cm^{-1} of stoichiometric ($MgAl_2O_4$) and aluminum-rich ($MgO:1.5Al_2O_3$) spinels are compared in Fig. 6. It is seen that the band in the stoichiometric Verneuil spinel but not in the aluminum-rich spinel is somewhat broadened on the long wavelength side of the band. The band broadening suggests that some hydrogen bonding is occurring (27-28) among the hydroxyl groups in the Verneuil grown $MgAl_2O_4$ spinel. A significant structural difference (23) between the stoichiometric and the aluminum-rich spinels is that in the aluminum-rich phases the aluminum excess in the lattice is accompanied by cation vacancies. Because of the presence of vacancies, the hydrogen ions in the aluminum-rich spinels may be accommodated differently from those in the stoichiometric spinel. Extensive studies (29) reveal that the absorption characteristics of Verneuil grown spinel crystals are highly dependent on the aluminum content in the lattice. Details will be reported (29) separately.

Spinel grown by either of the three growth methods absorbs infrared radiation at approximately 6.6-7.0 μm, just before the transmission cutoff shown in Fig. 5. This absorption band is probably due to the presence of

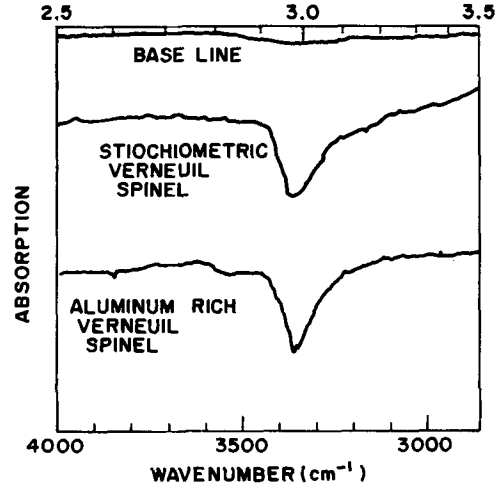

Fig. 6. Comparison of absorption band at 3360 cm^{-1} in Verneuil grown stoichiometric and aluminum-rich single crystal spinel.

carbonate groups in the spinel lattice originated from carbon dioxide or carbonate impurities.

Reflection characteristics of stoichiometric spinel.—Beyond 10 μm spinel lattice vibrations strongly absorb radiation. Transmission measurements were reported (30, 31) using Verneuil $MgAl_2O_4$ powder samples in wavelength to 30 μm. In the present work, reflection and transmission measurements were made in wavelength to 40 μm using, respectively, single crystal wafers and powder disks (KBr binder). Reflection spectro of flux, Czochralski, and Verneuil grown stoichiometric spinel and of Verneuil grown aluminum-rich spinel ($MgO:1.5Al_2O_3$) are shown in Fig. 7. The wavelengths of single crystal reflection bands and powder transmission bands are summarized in Table II.

It is seen that the Czochralski, Verneuil, and flux grown stoichiometric crystals have very similar reflection spectra. The observed lattice bands correlate with vibrations (30, 31, 34-37) occurring at the tetrahedral and octahedral sites for the spinel lattice with symmetry properties of the O^7_h space group (33). The absolute reflectivity of the flux grown spinel is somewhat

lower than that of the Czochralski or Verneuil grown spinel. This may be due to the impurities in the flux grown spinel, e.g., the lattice band for PbO occurs between 18 and 40 μm. Reflection losses have also been associated with surface damages (32, 33). Since a unique surface preparation of spinel wafers was made, this effect is not likely to be an important one. The reflection spectrum changes somewhat with changes in the composition of spinel. As shown in Fig. 7 and Table II, three sharp reflection bands appear in the spectrum of aluminum-rich spinel. The differences between the reflection spectra can be used to readily distinguish stoichiometric spinel from aluminum-rich spinel.

Absorption and emission characteristics of Cr-doped stoichiometric spinel.—Absorption spectra of chromium-doped flux grown spinel crystals were obtained in the visible region. A plot of optical density *vs.* wavelength is shown in Fig. 8. The spectra are very similar to those of ruby (38) and hence arise from the transition of Cr^{+3} in octahedral symmetry (39). There are two broad absorption bands observed with peaks at 5480 and 3910Å, corresponding to transition from the ground state to the $^4T_2$ and $^4T_1$ excited states, respectively. The absorption peaks of the spectra, as shown in Table III, are in general agreement (with slight differences in peak positions) with those reported for Cr^{+3} in natural (40) stoichiometric spinel and in stoichiometric spinel grown by Verneuil (41) and Czochralski (11) methods. A sample was annealed at 1000°C for ½ hr. After annealing, no change in position and intensity of the $^4T_2$ band, as reported for natural spinel (40), was observed.

Emission spectra of the chromium-doped spinel crystals were also measured in the visible region. A spectrum is shown in Fig. 9. The emission has vibrational fine structure with peaks at 6750, 6875, 6980, 7075,

and 7165Å. The principal component at 6875Å is the sharpest. The width of this component is considerably wider than that of natural spinel (42, 43), but is similar to those reported on Verneuil (41) and Czochralski (11) grown stoichiometric spinel crystals. The sharp line components of Cr^{+3} in Czochralski spinel was not observed. The emission characteristics of $MgAl_2O_4$:Cr crystals grown by various methods are compared in Table IV.

Conclusions

The growth of single crystal stoichiometric magnesium aluminate spinel has been successfully achieved in recent years by the flux, Czochralski, and Verneuil methods. Some physical properties of this material are not critically sensitive to the method of growth. These include the lattice parameter, dielectric properties, lattice vibration characteristics, emission and absorption properties of Cr^{+3} in $MgAl_2O_4$, and thermal properties (44). On the other hand, the crystalline perfection and the optical transmission properties are highly dependent on the growth methods. A pronounced difference is seen between the synthetic and natural $MgAl_2O_4$ spinel crystals. The Cr^{+3}:$MgAl_2O_4$ emission band widths of the synthetic spinels are con-

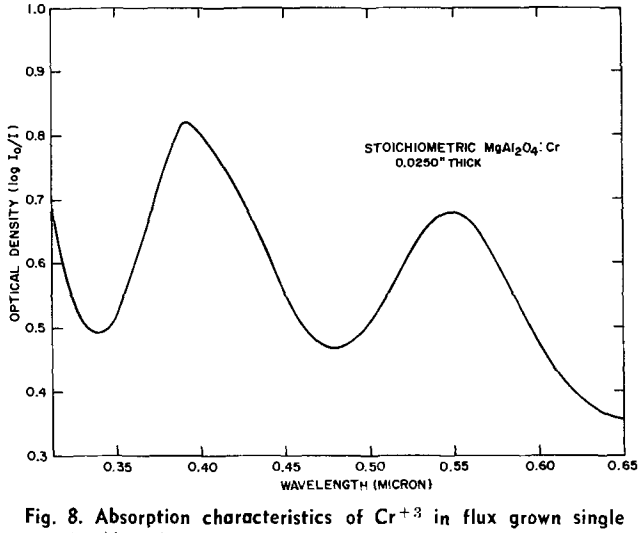

Fig. 8. Absorption characteristics of Cr^{+3} in flux grown single crystal $MgAl_2O_4$ host.

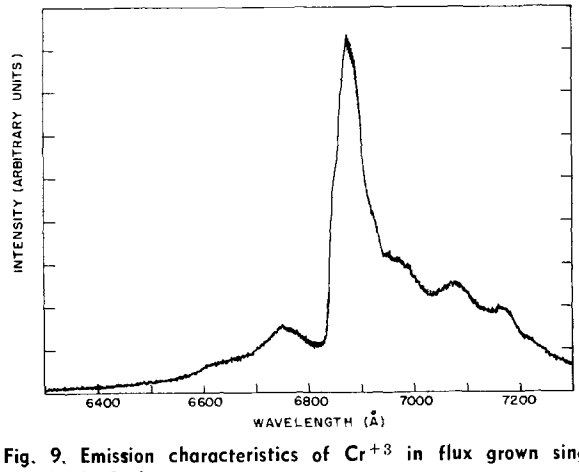

Fig. 9. Emission characteristics of Cr^{+3} in flux grown single crystal $MgAl_2O_4$ host.

siderably wider than that of the natural material. This fact rules out the potential of using the synthetic spinel as a laser host material.

Acknowledgments

The Czochralski spinel crystals were provided for this work through the generosity of A. D. Morrison. The authors wish to express their indebtedness to R. Bates for the Verneuil and flux crystal growth experiments. They also wish to thank B. L. Goydish and H. H. Whitaker for wet chemical and emission spectroscopic analyses. Thanks are also due to R. J. Paff for the x-ray work and to J. Gerber for optical measurements. Research reported in this paper was sponsored jointly by the Air Force Materials Laboratory, Wright-Patterson Air Force Base, under Contract No. F33615-68-C-1025 and RCA Laboratories, Princeton, New Jersey.

Manuscript submitted Sept. 10, 1970; revised manuscript received Dec. 3, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Some Charge Phenomena in D-C Reactively Sputtered Alumina Films on Silicon

Mao-Chieh Chen*

Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The charge behavior of d-c reactively sputtered Al_2O_3 films has been studied with MOS techniques. Both positive and negative oxide surface charges were observed in the Al_2O_3-Si structure in separate cases. This may be due to positive and negative oxygen ions which were created during the sputtering process and were then adsorbed by the silicon surface and by the deposited Al_2O_3 layer. Bias temperature stress revealed that both ion migration and carrier injection-trapping polarization participate in the charging phenomenon. The injection process appears to dominate the migration process at high applied electric fields. The trapping time constant is very large at low temperatures, but becomes smaller at higher temperatures. Change in the shape of the capacitance-voltage curves during a series of bias temperature stress tests was observed, notably whenever the carrier injection-trapping becomes the dominant instability mechanism.

The study of aluminum oxide (Al_2O_3) and its various properties, as well as its applications such as surface passivation of semiconductor devices, has been gradually drawing greater attention. These Al_2O_3 films are considered amorphous. There have been a variety of methods reported for the preparation of aluminum oxide films: by anodization (1-3), by evaporated deposition (4-10), by d-c reactive sputtering (11), and by rf sputtering (12).

Key words: charges in alumina MOS.

The metal-oxide-semiconductor (MOS) technique of studying the passivating properties of oxide films has proved to be a convenient and effective method. There have been reports concerned with the MOS study of aluminum oxide (10, 13), as well as the alumina/silicon dioxide (MAOS) system (13). A carrier injection phenomenon has been observed (10, 13). Both positive and negative flat-band voltages were observed in one case (10), while in the other case only positive flat-band voltages were detected (13). Prolonged annealing treatment reduced the positive flat-band voltage, and it eventually became negative after 15 hr of treatment at 200°C in air (13).

In this paper, along with the experimental procedure, we report the observed oxide surface charges and the results of various bias and temperature stresses on Al_2O_3 films. This is followed with a brief discussion on the introduction of oxygen ions from the sputtering plasma into the oxide.

Experimental Technique

Epitaxial n-type silicon wafers of 10 and 40 ohm-cm, both (111) orientated, were used as substrates in the fabrication of the test samples. Prior to oxide deposition, the silicon wafers were cleaned in trichloroethylene and acetone, and rinsed in ultrasonically agitated, flowing, deionized water for at least 10 min. The aluminum oxide (Al_2O_3) films were then deposited by d-c reactive sputtering in a pure oxygen atmosphere.

The deposition of aluminum oxide was performed under two different sputtering conditions using two separate d-c reactive sputtering systems. Sputtering conditions "A" were: cathode potential 1200V, cathode current density 2.4 mA/cm^2, and (pure) oxygen gas pressure 300 mTorr (300μ). An aluminum disk target 2.8 in. in diameter was used as a cathode, and a cathode current of 120 mA was recorded during the sputtering process. The substrate was a 10 ohm-cm silicon wafer. This substrate was set on a substrate holder which was electrically floating and placed underneath the cathode for downward sputtering. The spacing between the cathode and the substrate was approximately 2 cm, and the spacing between the cathode and the anode was approximately 10 cm. Another d-c sputtering system was used for the deposition of Al_2O_3 under conditions "B," which were: cathode potential 700V, cathode current density 1.6 mA/cm^2, and oxygen gas pressure 150 mTorr. An aluminum disk target 5.5 in. in diameter was used and a cathode current of 250 mA was maintained during the sputtering process. Silicon wafers of 40 ohm-cm were used as substrates. In this apparatus, upward sputtering was used, and the substrate was clamped to the plate and was electrically grounded to the system. The spacing between the cathode and the substrate was 2 cm. The oxide films deposited under condition "A" for 30 min were 1250Å and those deposited under condition "B" for the same period of time were about 400Å. For convenience hereafter, the oxide deposited under condition "A" will be referred to as "sample A," and that deposited under condition "B" as "sample B."

For annealing treatments, the Al_2O_3 deposited wafers were quartered, and each was subjected to a different annealing schedule, except that one of the quarter wafers was reserved for use as a "control" sample. The annealing was carried out in a helium atmosphere. The wafers were set in a furnace through which helium gas was flowing. The helium gas passed through a liquid nitrogen "trap" before it was admitted to the furnace. The trap eliminated oxygen and water vapor contamination.

Aluminum gate electrodes were applied to the control and to the annealed oxide films, using evaporated deposition and photomasking. Gate areas were 3.44 x 10^{-3} cm^2 (26 mils diameter aluminum dot). Individual devices were diced out, die bonded, and lead bonded to TO-5 headers.

MOS Device Characteristics

MOS capacitance and effective surface charges.— Samples A and B demonstrated different behavior in their MOS capacitance-voltage characteristics. The MOS capacitance was measured at 1 MHz and all the measurements were made at room temperature unless otherwise specified. Figure 1 shows the experimentally observed typical C-V characteristics of sample A for the control and the 500°C annealed specimen, along with the corresponding theoretical curve. In this experiment, four sets of samples were prepared: control samples and three annealed samples each subjected to annealing treatments in a He atmosphere for 1 hr at 300°, 500°, and 750°C, respectively. The resultant C-V characteristics show no obvious change for the 300°C annealed sample from that of the control sample, although the various C-V curves from the randomly selected 300°C annealed samples disperse a little bit more. The C-V curves also show no obvious change between those of the 500° and 750°C annealed samples, although the variation of the C-V curves of the randomly selected samples is a little bit larger for the 750°C annealed samples. The flat-band voltage of the control sample is −4.1V and that of the 500°C He gas annealed sample is −1.5V. The negative flat-band voltages indicate that positive surface charges were in the oxide.

Figure 2 shows the typical C-V curves of sample B as well as the corresponding theoretical characteristic. In this experiment, a 40 ohm-cm n-type silicon wafer was coated with Al_2O_3. Since annealing at 300°C showed no obvious effect and 500° and 750°C annealed samples make no obvious difference, the annealing treatments here were chosen at 500°C for 1, 2, and 3 hr, respectively. Several devices from each of the treatments were randomly picked and their C-V characteristics measured. It is seen that all four curves show a positive flat-band voltage indicating that negative, effective oxide surface charges are present. The flat-band voltages for each case are: 0.42V for control sample, 0.68V for the 1 hr annealed sample, 0.60V for the 2 hr annealed sample, and 0.55V for the 3 hr annealed sample.

The effective oxide surface charge density for the various oxide specimens was evaluated from the flat-band voltage. The results are tabulated in Table I. It is clear that the positive oxide surface charge of sample A is greatly reduced upon annealing. In the other case, however, the negative oxide surface charge of sample B increased upon annealing and then decreased somewhat during a prolonged annealing period. It has been observed (13) that a prolonged annealing treatment (at 200°C in air) reduces the positive flat-band voltage and eventually changes it to negative. In our

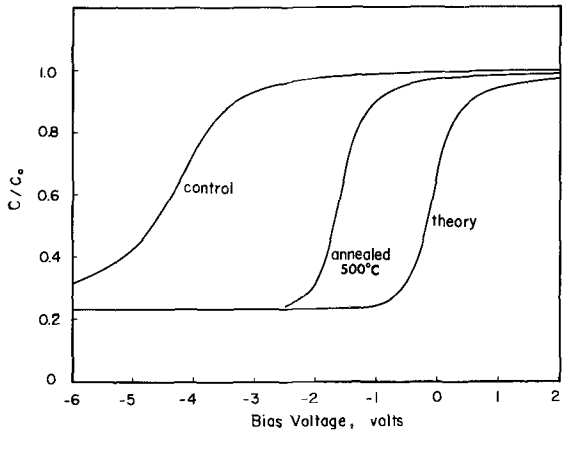

Fig. 1. Theoretical and experimental MOS C-V characteristics of sample A measured at 300°K and 1 MHz. The substrate wafer is 10 ohm-cm n-type silicon. The oxide thickness is 1250Å. The sample was annealed at 500°C in He atmosphere for 1 hr.

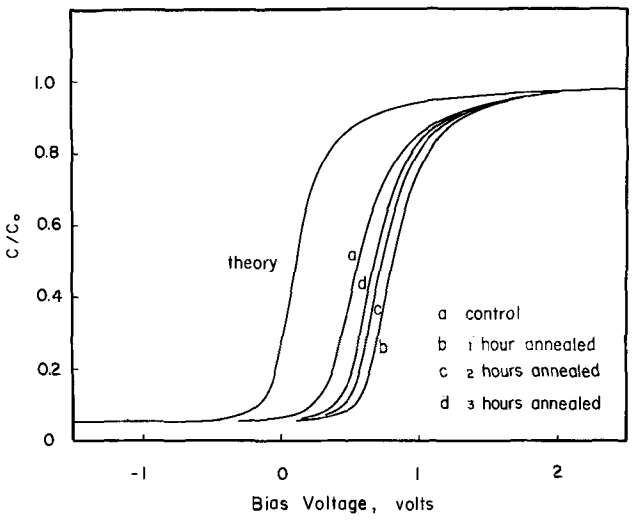

Fig. 2. Theoretical and experimental MOS C-V characteristics of sample B measured at 300°K and 1 MHz. The substrate wafer is 40 ohm-cm n-type silicon. The oxide thickness is 400Å. Annealing was performed at 500°C in He atmosphere.

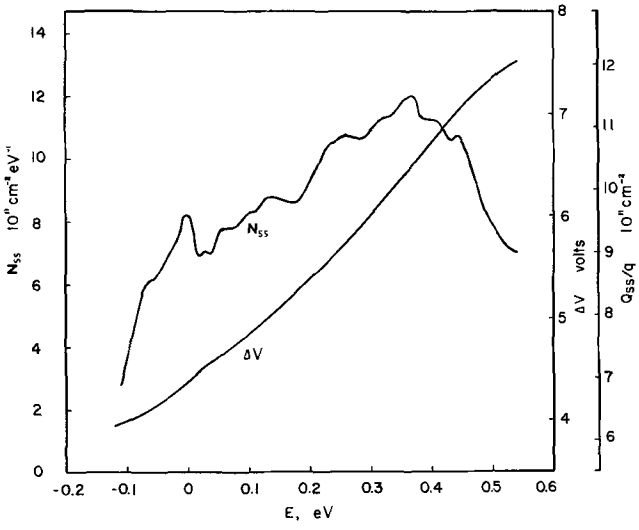

Fig. 3. Density of states of the interface states and the effective surface charge density vs. energy of sputtered oxide (sample A) on n-type silicon substrate. Reference for energy, E, is chosen at the intrinsic Fermi level in the bulk silicon.

case, the increase in the positive flat-band voltage upon annealing during the first hour might be due to a faster and greater elimination of the positive oxide surface charges, causing an effective increase in the effective negative oxide surface charges. The subsequent prolonged annealing further reduced negative oxide surface charges and shifted the C-V curve in the negative voltage direction. However, the exact mechanism is not yet understood.

Interface state density.—Comparison of the three C-V characteristics in Fig. 1 reveals that the C-V curve of the annealed sample, within the resolution of our measurement, is essentially parallel to the theoretical curve over the entire range of the variation in the capacitance. On the other hand, the C-V curve of the control sample is not just a parallel shift of the theoretical curve along the voltage axis. The curve exhibits a broader shape. This reveals, therefore, that the annealing effect has not only reduced the positive oxide surface charge but also the fast interface states as well. The parallel shift in the C-V curve of the annealed sample indicates that the charge in the oxide film is independent of the surface potential in the range of measurement at room temperature.

Figure 3 depicts the results of the investigation of Fig. 1 for sample A. This figure shows ΔV (the difference in voltage between the measured and the ideal C-V curve), effective oxide surface charge density, and the numerically calculated density of interface states *vs.* energy. The reference for energy, E, is chosen at the intrinsic Fermi level in the bulk silicon. The oxide surface charges are positive. The curve near the valence band edge is not shown because of limitations of MOS techniques on n-type silicon substrates (14). The interface state density shows a continuous distribution and seems to be increasing from near the middle of the silicon energy gap toward the conduction band, but drops near the conduction band edge. No clear high density peak was observed.

Table I. Effective surface charge density for various oxide specimens. Samples A are 1250Å and samples B are 400Å in thickness. Annealing is done in He atmosphere at 500°C

Unit	Effective surface charge density (No./cm²)	Sample	Remarks
1126-25-2	6.94×10^{11}	Control	Samples A
1126-33-2	2.47×10^{11}	1 hr anneal	Positive charges
1158-50-1	1.31×10^{11}	Control	
1158-55-1	2.68×10^{11}	1 hr anneal	Samples B
1158-59-2	2.26×10^{11}	2 hr anneal	Negative charges
1158-61-2	1.97×10^{11}	3 hr anneal	

Examination of the C-V curves in Fig. 2 shows that the four curves, a, b, c, and d, are almost parallel to one another. These experimental curves also show a slight broadened shape as compared to the theoretical curve, indicating the existence of a small amount of interface state charge. However, for the densities less than 10^{11} cm^{-2} eV^{-1}, the resolution of the present technique limits the meaningful derivation from these curves.

The technique of cooling samples to 77°K and measuring the resultant shift in flat-band voltage has been shown to be an excellent method of detecting and measuring the approximate total number of fast interface states between the 300° and 77°K Fermi levels (15-17). The results of this measurement show that the number of interface states is around 2×10^{11} cm^{-2} for all samples whether annealed or not. The 300°K bulk Fermi level (E_F) for 40 ohm-cm silicon is 0.225 eV below the conduction band edge. At 77°K, E_F is very close to the band edge. Investigations on the density of SiO_2-Si interface states have shown that fast interface states acting like acceptors and donors in nearly equal numbers exist near the conduction band and valence band, respectively (15, 18, 19). These are states perturbed from the nearby intrinsic silicon bands as was suggested by Gray and Brown (19) . We would, therefore, also expect a high density of states near both band edges in the case of the Al_2O_3-Si interface, and the above measured number of interface states would approximately represent the total number of interface states in the upper half of silicon's forbidden band. Unfortunately, at these low values of interface states, the distribution of the interface state density near the conduction band edge could not be measured by MOS techniques on samples B.

Bias and temperature stresses.—The devices were stressed at a given bias and temperature (BT) for 12 min. They were then cooled to room temperature with the bias still applied for about 1 hr. Subsequently, the C-V curves were taken, and the flat-band voltages were measured.

Devices from sample A.—Figure 4 shows the flat-band voltage *vs.* the gate voltage under repetitive bias cycling for both the control and the annealed samples. The annealing condition was 500°C in a He atmosphere for 1 hr. Both samples show essentially the same pattern of flat-band voltage variation, except the pattern of the annealed sample shifts to a less negative

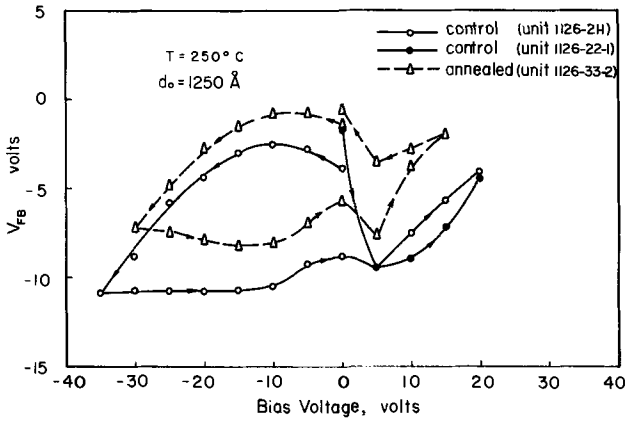

Fig. 4. Flat-band voltage *vs.* gate voltage at 250°C for sample A under repetitive bias cycling.

voltage position indicating a smaller effective, positive oxide surface charge. The devices were first subjected to negative bias, increasing in 5V steps up to −35V (or −30V for the annealed sample), then returned to zero volts in 5V steps. The procedure was repeated for positive bias. Under negative bias at about −10V, the flat-band voltage showed a little shift toward the positive direction and then shifted back to a more negative value when a negative bias of more than −10V was applied. When the stress direction was reversed, the flat-band voltage first shifted to a more negative value at low positive biases up to about +5V and then shifted back in a positive direction when a positive bias larger than +5V was applied. This phenomenon is more clearly depicted by a sample (unit 1126-22-1) which was subjected to positive bias from an initially unstressed condition. The flat-band voltage *vs.* temperature with gate voltage as a parameter during the BT stress is illustrated in Fig. 5.

The shift in the flatband voltage, for low-voltage stresses, is believed to be caused by a migration of charged ions in the Al_2O_3 films under the applied electric field (20). This is shown in Fig. 4 wherein the flat-band voltage shifts toward more negative values for small positive bias stresses (<5V), and toward more positive values for small negative bias stresses (<−10V). The much larger negative shift with positive bias as compared to the small positive shift with

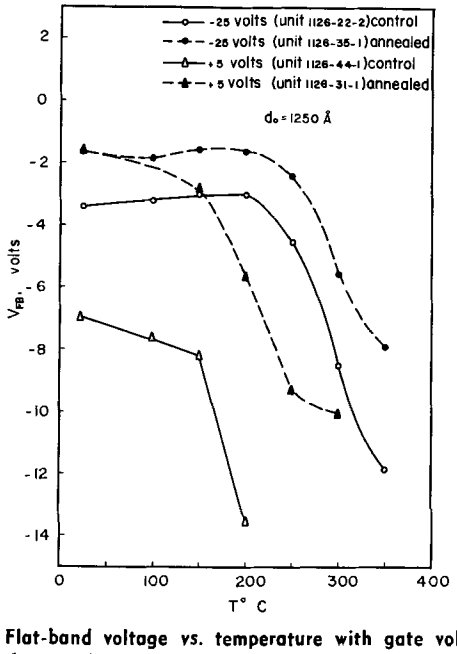

Fig. 5. Flat-band voltage *vs.* temperature with gate voltage as parameter for samples A.

negative bias is most probably because most of the positive ions released at elevated temperature (250°C) do not come from the region close to the Al_2O_3-Si interface. In Fig. 5, the flat-band voltage under +5V BT stress became more negative at higher temperatures and clearly indicates the ion migration. At higher temperatures, more positive ions can be released in the oxide and drift to the Al_2O_3-Si interface under the positive field.

At higher bias stress, however, the instability is characterized by positive shifts in flat-band voltage during applied positive bias greater than 5V and negative shifts in flat-band voltage during applied negative bias greater than 10V as shown in Fig. 4 and 5. This is the phenomenon that carrier injection-extraction would explain. The carrier injection-extraction phenomenon has been observed in Si_3N_4 films (21, 22), thermally grown SiO_2 films (23, 24), d-c reactively sputtered SiO_2 films (25), and reactively evaporated Al_2O_3 films (10, 13). Under applied high electric field, electron injection or extraction would occur across the barrier at the oxide-silicon interface. This mechanism was found to be thermally activated (23). This shifts the flat-band voltage in the direction opposite to what would be expected from ion migration and constitutes the slow trapping instability. In Fig. 5, with −25V bias, the flat-band voltage remains almost unchanged or shifts in a positive direction very slightly up to the temperature of 200°C during the BT stress. This slight positive shifting probably results from the competing effects of ion migration and carrier injection-extraction polarization. For temperatures above 200°C, however, the flat-band voltage starts to shift substantially in a negative direction. This would be expected since the slow trapping time constant is very large at low temperature and becomes smaller at higher temperatures (23). The involvement of the trapping time constant was tested in that, with −25V bias at a given temperature, prolonged BT stress did shift the C-V curve toward a more negative position. With +15V bias, however, it shifted more and more in a positive direction as the period of BT stress increased. In addition, a trapping (or injection) type hysteresis (10, 17, 26) was also observed in the C-V curve.

The shifting of the flat-band voltage under BT stress indicates that the effect of ion migration under negative applied bias is small, where under positive applied bias the effect is quite large. The shifting with −25V and 350°C BT stress is therefore presumed to be essentially due to the slow trapping instability. At room temperature, the device subjected to this stress condition remains stable; *e.g.*, the flat-band voltage measured two weeks after BT stress did not show any obvious change. On the other hand, ion migration is believed to be dominant under +5V BT stress. After a device was subjected to this positive bias BT stress and cooled back to room temperature, it was observed that the device was very unstable. For a device from the control sample, under +5V and 250°C BT stress for 12 min, the flat-band voltage was measured to be −24V. The device was open-circuited at room temperature for 22 hr. The flat-band voltage shifted to −10V. This is due to some sort of recovery ion migration. After being released at an elevated temperature, the ions were driven toward oxide-silicon interface under positive field. Some ions were trapped when the device was cooled to room temperature, and others remained relatively free. After removal of the positive bias, the positive ions repelled each other and moved away from oxide-silicon interface. Some of those ions staying near the interface may combine with injected electrons and become neutralized.

Devices from sample B.—Illustrated in Fig. 6 and 7 are the measured results for devices from sample B. Figure 6 shows the flat-band voltage *vs.* the gate voltage under repetitive bias cycling for both the control and the annealed (2 hr in He atmosphere at 500°C) samples.

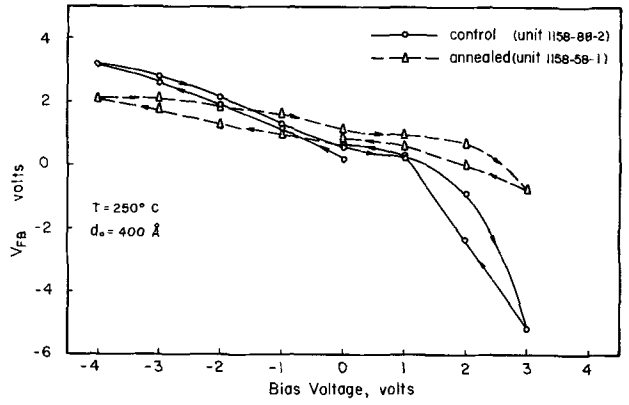

Fig. 6. Flat-band voltage vs. gate voltage at 250°C for sample B under repetitive bias cycling.

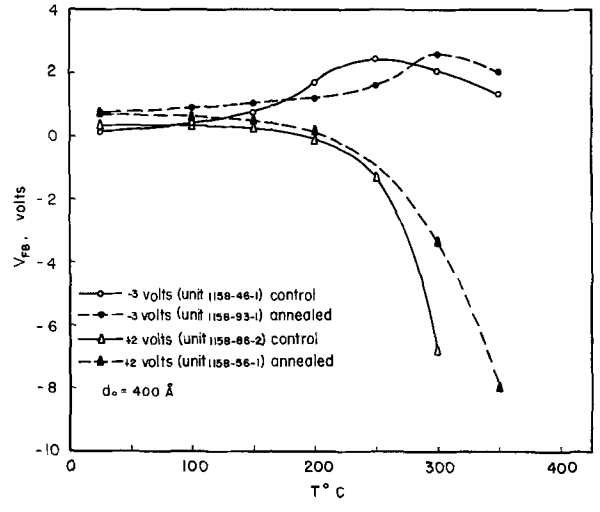

Fig. 7. Flat-band voltage vs. temperature with gate voltage as parameter for samples B.

The flat-band voltages of the original devices are positive, indicating a net negative oxide surface charge. The devices were stressed in the same way as in the previous experiment. Both the control and annealed samples exhibit essentially the same characteristics; however, the annealed sample shows a smaller shift in its flat-band voltage under the BT stress. The positive shift for negative bias and the negative shift for positive bias clearly indicates that the shifting of the flat-band voltage is due to ion migration. Figure 7 shows the flat-band voltage *vs.* temperature with the gate voltage as parameter for both the control and annealed samples. Under positive bias stress, the flat-band voltage decreased and became negative at temperatures beyond 200°C. The change of sign indicates that, in addition to ion migration which originates from the initial ion distribution, a lot of additional positive ions were released in the oxide at the higher temperatures and they migrated to the Al_2O_3-Si interface. The original ion distribution, *i.e.* before BT stress, is believed to consist of both the positive and negative ions. However, their number and distribution are such that the oxide charge is effectively negative. The negative ions are probably due to negative oxygen ions trapped in the oxide during sputtering which was performed in a pure oxygen glow discharge. The existence of negative oxygen ions has also been reported in reactively sputtered SiO_2 (25).

Under negative bias (−3V in the present case), the shifting of the flat-band voltage shows the increasing effect of ion migration as the temperature increased. However, when the temperature is increased beyond 250°C for the control sample and 300°C for the annealed sample, the flat-band voltage reverses shifting direction and shifts toward the negative direction. This indicates that the effect of slow trapping instability has dominated the effect of ion migration. This is also similar to the previous observation and would involve the temperature dependence of the trapping time constant.

Discussion

Oxygen ions in the sputtered oxide.—The different charge polarities of ionic species in the reactively sputtered Al_2O_3 as observed from the sign of the measured flat-band voltages can be attributed to the formation of positive and negative oxygen ions in the sputtered Al_2O_3. It is considered that the location of the substrate in the glow discharge chamber during the sputtering process is the most sensitive factor in determining the oxide charge contamination, with the effects of the sputtering parameters such as cathode voltage, gas pressure, *etc.*, having secondary importance (27). It would be better if in the experiment the only difference between conditions A and B were the substrate location. However, the configuration of our sputtering systems limited this effort. The substrate for sample A was sitting in the cathode dark space which is a region of high positive ion density. These positive oxygen ions can be adsorbed on the substrate upon collision with the surface or be accelerated to the cathode and subsequently reflected and adsorbed by the substrate (25, 28, 29). Of course, we should also admit to the very likely possibility that some positive oxide charges, most probably from alkali ions, will also be present.

On the other hand, we observed negative oxide charges in sample B, from the positive flat-band voltage of measured C-V curves. In this case, the substrate was sitting right on the anode which is 2 cm away from the cathode. Under this sputtering condition, the substrate was quite likely sitting in plasma where a large population of slow electrons exists (30). The low-energy, slow electrons in the plasma would likely favor the electron attachment process when they collide with oxygen molecules. The process in which O^- ions are formed through $O_2 + e \rightarrow O^- + O$ has been studied by Lozier (31), Hagstrum (32), Craggs *et al.* (33), and Chanin *et al.* (34). The negative oxygen ions may diffuse through the plasma and be adsorbed on the substrate.

Interface state instability.—Under certain bias temperature stresses, a third instability characterized by a change in shape of the C-V curve was observed. The characteristic of this instability is broadening or "smear-out" of the C-V curve. Under positive BT stress, the C-V curves became more broad as the positive bias increased. The phenomenon is quite prominent and was observed in the devices made from sample A. For the devices made from sample B, the broadening of the C-V curves is not obvious, probably because the change is below the sensitivity of our measurement. Under negative BT stress, similar phenomena were also observed, although to a smaller degree. Refer to Fig. 4. Under the repetitive bias cycling at 250°C, the observed change of C-V curve was as follows. At first, the curve had little change at low negative bias BT stress. As the negative bias was increased to the point where the flat-band voltage starts to shift toward the negative voltage direction, *i.e.*, when the slow trapping instability becomes dominant as was discussed in the previous section, the C-V curve began to show a clear change in its shape. The curves became broadened. This shape then remained in the subsequent repetitive cycling stress until the stress condition was brought back to the point where the flat-band voltages started to shift toward the positive direction again, *i.e.*, around −10V in our case. The broadened C-V curves then became sharp again.

The only obvious change in the shape of the C-V curves observed in the devices made from sample B occurred on the two following occasions. These are, referring to Fig. 7, at −3V and 300° and 350°C BT

stress for the control and annealed sample, respectively. As the stressing process proceeded from low temperature step by step, the shape of the C-V curve remained roughly unchanged until the above indicated temperatures were reached or exceeded. Above these temperatures, the curves showed an obvious broadening.

The observed broadening of the C-V curves described above was shown to coincide with the observation of the slow trapping instability. However, for a clear understanding of the reported phenomena, further effort should be pursued.

Conclusion

In d-c reactively sputtered aluminum oxide, oxide surface charges of both polarities were observed in the Al_2O_3-Si structure. The effective oxide surface charge densities are in the order of 10^{11} cm^{-2}. For the sample containing positive oxide surface charges, an annealing treatment in a He atmosphere at 500°C for 1 hr reduced the charge density, both in the oxide and in the interface states. However, this effect was not observed in the sample containing negative oxide charges. The density of the interface states in the semiconductor forbidden gap was evaluated in one case, but was limited by the MOS technique in the other.

Different polarities of the observed oxide surface charges can be attributed to the positive and negative oxygen ions which are created during the sputtering process and are then adsorbed in the silicon surface and in the deposited Al_2O_3 layer. Contamination of positive or negative ions in the oxide seems to be greatly determined by the location of the substrate in the glow discharge during the oxide deposition process. Bias temperature stress revealed that both ion migration and carrier injection-trapping polarization effects are present. The latter process dominates the former process at higher applied electric fields. The trapping time constant is quite large at low temperatures, but becomes smaller at high temperatures. During the series of BT stress, broadening of the C-V curves was observed, notably whenever the carrier injection-trapping becomes the dominant instability mechanism.

Acknowledgments

Low-Energy Electron Irradiation of Thin Paraffin Hydrocarbon Films[1]

W. B. Berry*

Department of Electrical Engineering and the Radiation Laboratory, University of Notre Dame, Notre Dame, Indiana 46556

ABSTRACT

Low-energy photoelectrons are excited through thin paraffin hydrocarbon films at 77°K. The photocurrent is measured as a function of film thickness which is increased in steps of 20-80Å. The attenuation length or range for electrons of approximately 1 eV initial energy is 65Å for 3-methylpentane, 59Å for hexane, and 55Å for nonane. The mean free paths determined from Baraff Theory are of the order of 12Å.

Interest in stopping power and range theory has been revived in recent years with the advent and promise of ion implantation in electron device technology (1). While the fundamental question addressed here is the stopping power, that is, the particle range, the particle under consideration is the electron, not an atom, ion, or molecule. This particular subject has been of interest to radiation chemists for at least the past decade. The basic questions evolve around the lifetime and range of electrons once they have been freed from their parent atoms or electron states. Ionizing radiation may impart energies from several electron volts to several mega electron volts and, therefore, the study can be divided into three parts involving high-, intermediate-, and low-energy exchange. In this study, electrons of low initial energy, *e.g.* 1 eV above the substrate free energy, are photoexcited into amorphous thin films of organic materials, alkanes, which have been condensed onto the substrate (cathode) surface. While the energies of these electrons are not subexcitational in an absolute sense, the cross sections for subexcitational exchange are considered to be dominant. Therefore, the problem reduces to consideration of the hot electron.

The excited electrons have an initial energy equivalent to that of the absorbed photon, if the assumption is made that only Fermi electrons are excited. To be emitted into the film, the electrons must overcome the effective work function of the cathode, which, for the source employed, results in electrons of 2 eV maximum, if the film-emitter interface is assumed to have a negligible effect on the cathode work function, no barrier potential exists, and film charging can be neglected. The energy diagram is given in Fig. 1. The magnitude of this extra energy is such that the electron is subexcitational. The equivalent total energy is considerably greater if one assumes that the amorphous film has an equivalent Fermi energy, work function, and band structure, but still subexcitational. The vibrations which can be excited are intramolecular, rotational, and intermolecular excitations. Each of these has a finite probability of occurring, but the cross section for intermolecular excitation is expected to dominate (2). In general, the one dimensional photoelectron flux is measured to attenuate exponentially with increasing film thickness. This compares well with Crowell's hot electron theory (3) which is typical of that found in most solids (4).

Experimental

As outlined above, the objective of this study was to determine whether or not a thin hydrocarbon film would significantly resist penetration by low-energy electrons. In the initial phase, the study has been restricted to paraffin hydrocarbons, such as 3-methylpentane, nonane, and hexane, to avoid significant charging of the film itself. To assist in this determination, the data chamber of Fig. 2 was designed. The controlled inputs required for the chamber design are vacuum, radiant energy, vaporized sample inlet, temperature control, and electrical sensing.

[1] The Radiation Laboratory is operated by the University of Notre Dame, under contract with the Atomic Energy Commission. This is AEC Document No. COO-38-749.

Key words: range theory, low-energy electron irradiation, attenuation length, mean scattering length, stopping power.

A mercury vapor diffusion pump was used to establish the vacuum. Two liquid nitrogen traps were inserted between the diffusion pump and the data chamber. The vacuum of the manifold to which the data chamber was connected was monitored with either a McLeod gauge or a CVC discharge gauge. The vacuum was maintained at approximately 2 x 10^{-5} Torr.

The sample was admitted to the data chamber in vapor phase, in calibrated units at established pressure and volume, through the valve shown at the lower left of Fig. 2. The volume of the controlled sample was 11 cc and the pressure was in the range of 10-100μ. Upon opening the valve, the vapor passed into the lower chamber, along the guide tube, through the tungsten mesh, and into contact with the silver-plated, liquid nitrogen cooled cathode onto which it condensed. By admitting controlled samples of the hydrocarbon, the thickness of the condensed film could be increased in steps and the transmission of electrons through the film could be measured as a function of the film thickness. The separation between the end of the guide tube and the cathode was about 1 mm. This separation was kept reasonably small to insure that the hydrocarbon condensed on the cathode bottom surface. A Consolidated Engineering Micromanometer was employed to monitor the pressure of the vapor in a storage chamber from which the calibrated sample was drawn.

The source of photons for the generation of photoelectrons was a mercury vapor lamp positioned below the window at the bottom of the data chamber. The window was Suprasil-2 quartz which admitted both 2537 and 1849Å quanta into the chamber. The radiant energy passed through the tungsten mesh anode, through the condensed film, and into the cathode. The tungsten mesh had a transmission coefficient of 0.85.

The photoemitted electrons which penetrated through the condensed film were collected by the positively biased anode. The bias voltage was approximately 100V and the electrode separation about 1 cm. The photocurrent of the collected electrons was recorded with the aid of a Cary vibrating reed electrometer and Varian Graphic Recorder. Bare cathode currents were of the order of 10^{-9} to 10^{-10} A. The noise level was normally three or four orders of magnitude below the bare cathode response.

Samples of 3-methylpentane, hexane, and nonane were dried by passing the liquids through an 8 ft column of silica gel. The material was then stored in a glass container until used. After these samples were inserted into the system, they were outgassed by a repetitive freeze-pump-thaw procedure. Prior to cooling the cathode for condensation of the film, the data chamber and preceding stages were flushed out with vapors from the outgassed sample.

Results

Typical photoresponse data are presented in Fig. 3 which shows the dependence of the photocurrent on the number of film layers for 3-methylpentane films. In the figure, δ represents the layer thickness which was varied in successive experiments by controlling the pressure of the vapor in the calibrated inlet chamber. The film thickness was increased in increments of 20-80Å and the photocurrent recorded following each incremental increase. The response saturated at a level approximately two orders of magnitude below the bare cathode response. A reasonably good fit to the data curves is obtained by assuming simple exponential attenuation as a function of film thickness. This attenuation continues until a residual signal level is reached which is independent of film thickness. The relative magnitude of this residual response is represented on the figure by the "A" value. The initial layer attenuation was always significantly greater than that for subsequent film layers. A brief discussion of the probable reason for this is given below.

As mentioned above, the functional form of the photoresponse can be represented by the equation:

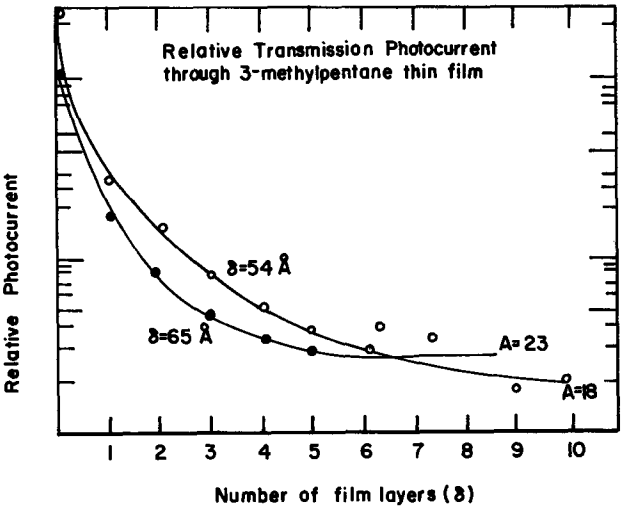

Fig. 3. Raw photoemission data for 3MP films

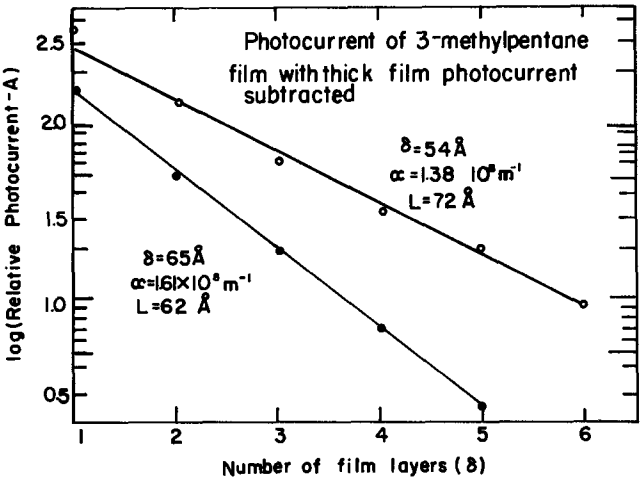

Fig. 4. Replotted 3MP photoemission data to obtain attenuation length.

$I = A + I_0 \exp(-n\delta/L)$, where A is the final value of the response as n becomes reasonably large, $(I_0 + A)$ is the initial value of the photoresponse, $\alpha = 1/L$ is the extinction coefficient, L is the mean attenuation length, δ is the layer thickness, and n is the number of layers. By plotting $\log[(I - A)/I_0]$ against n, as in Fig. 4, the magnitude of α and L can be determined. The figure presents data for different layer thickness, *i.e.*, inlet pressure, for 3-methylpentane. The determined value for L was, on the average, 64Å. The data, which are presented for contrast, represent the extremes in data obtained. Calculated values of mean attenuation length for hexane and nonane are also presented in Table I and are discussed below.

The data presented in Fig. 3 and 4 represent response to 1849Å radiation, since 2537Å radiation from the mercury lamp resulted in negligible collectable emission from the cathode. The principal reason for this stems from the fact that the work function of silver is approximately 4.7 eV and 2537Å photons have approximately 4.8 eV. While the 2537Å emission could be detected from the bare cathode, a film of 20Å or less reduced the photocurrent below the noise level.

Table I. Comparison of attenuation lengths and mean free scattering lengths for three materials

Material	Attenuation length	Mean free length
Hexane	59	12.5
3-Methylpentane	65	14
Nonane	55	12

The 1847Å radiation, which is significantly weaker for the lamp employed, resulted in very strong emission despite the fact that the photon intensity was an order of magnitude lower. To insure that this emission was due to 1849Å photons, a Corning 7910 filter was inserted between the source and the sample chamber at each film thickness. When this was done, the photocurrent dropped below the detection level. These emitted electrons have an average energy of approximately 1 eV above the work function of the cathode and an anticipated spectrum of approximately uniform density from 0 to 2 eV. The actual electron energy distribution was not determined. The fact that a very thin film eliminated the photoemission due to the 2537Å line and that the attenuation for the initial layer was, in all cases, greater than that which would have been anticipated from the data for subsequent layers indicated that the thin hydrocarbon film affected the work function of the metal surface, a not too surprising result. The effective increase was not measured, but the 2537Å data suggest that it was at least 0.1 eV. The fact that this initial attenuation took place for initial layers of 20Å or less supports the assumption of uniform thickness.

The potential applied between the electrodes is assumed to have negligible effect on the emission. The electric field, 100 V/m, is too small to significantly alter the image force potential out to a film thickness of 1000Å, which is beyond the maximum thickness of the films on which these data were taken. The boundary conditions for the film, *i.e.*, at the metal-film and film-vacuum interfaces, are essentially unchanged for each incremental thickness increase. Therefore, the measured change in photoresponse is a measure of internal losses alone.

Discussion

The elementary technique employed in the evaluation of the data in the previous section leads one to postulate a rather simple range model for the electrons. To minimize obvious complications, the model to be discussed assumes near-charge neutrality throughout the film. The elementary model simply implies that an electron which is scattered returns immediately to the cathode or else induces another electron to do so. Since the film is constantly in the flux of the complete radiation spectrum of the lamp, there are photons of lesser energy which are sufficiently energetic to excite electrons from traps which can migrate through the film and thereby readily return to the cathode, maintaining a near-neutral film.

There are two emission phenomena which must be considered. The first of these is emission from the cathode and subsequent transmission through the film. Second, some electrons will be assumed to be excited from the film itself, either from low-lying traps or by two-photon processes.

The form of the first emission phenomenon simply assumes that N_0 electrons are emitted per second per unit area from the cathode and collide with molecules, losing energy in increments along the path. Those electrons which lose sufficient energy to fall below the work function of the film are captured and returned to the cathode. Those which retain a portion of their initial energy over and above the work function are transmitted and collected by the cathode. Then the decrease in N is proportional to the stopping probability, *i.e.*, $dN/dx = -pN$, where N represents the number of electrons transmitted to the position x per unit area per second and p is the stopping probability. From this equation, $N = N_0 \exp(-px)$, where $p = \alpha = 1/L$ and $x = n\delta$ when comparison is made with the previous section. The photocurrent due to cathode-emitted electrons becomes $I_c = eN = eN_0 \exp(-n\delta/L)$.

Electrons which are excited from the film itself are transmitted from the point of excitation with the same probability as electrons emitted from the cathode through a film of that thickness. This emission is dependent on the absorption coefficient of the film for whichever process, single or double absorption, dominates. Even if this absorption coefficient is $10^6\ m^{-1}$, the film would have to be at least 1000Å in thickness for the absorption not to be considered as uniform throughout. The films considered here seldom exceed 500Å and, therefore, uniform excitation is a reasonable approximation. The exact emission for electrons excited from the film is formulated as

$$I_f = \frac{eP}{2} \int_0^{n\delta} \alpha \exp(-\alpha x) \exp(-x/L)\, dx$$

where $P\alpha\exp(-\alpha x)$ represents the number of electrons, per unit area per second, excited at x, and $\exp(-x/L)$ represents the probability that these electrons will be transmitted. The factor 1/2 is included since the excited electrons will have velocities both toward and away from the cathode in equal numbers. Integration of this equation yields

$$I_f = \frac{e}{2} [P\alpha L/(1 + \alpha L)]\, [1 - \exp(-[1 + \alpha L]n\delta/L)]$$

Since $L \sim 100$Å, and $\alpha \sim 10^{-4}$ Å^{-1}, then

$$I_f = \frac{e}{2} P\alpha L\, (1 - \exp[-n\delta/L])$$

which is the uniform excitation response. The total photocurrent is obtained by combining these two results. That is,

$$I = I_{f_x} + (I_{co} - I_{f_x}) \exp(-n\delta/L)$$

where $I_{f_x} = e/2\, P\alpha L$ represents the excitation from the film alone, that is, a very thick film, and $I_{co} = eN_0$ represents the bare cathode emission. A comment should be added here on the completeness of this relation because of the obvious strong reflection at the metal film interface. The reflected photons will indeed increase the excitation from the film. However, only the magnitude of I_f will be changed. The functional form will be essentially unchanged as long as wavelengths with sufficiently small absorption coefficients are used. I_{co} must be the bare cathode current adjusted to account for the metal-film interface potential.

The data fit this model which lends itself to a satisfactory explanation thereof. However, further examination and interpretation are necessary to gain some knowledge of the physical phenomena surrounding the determination of L. There are several items which one must consider such as the effects of trapping and therefore charging of the film, the scattering mechanism, which for subexcitational electrons is elastic or inelastic, and the adequacy of this model. The inelastic scattering results in the generation and annihilation of intermolecular vibrations or phonons.

The last item will be discussed first. Let the primed currents, I'_x, represent the three-dimensional model currents. If one were to consider a three-dimensional isotropic emission model for electrons emitted by both the cathode and the film, then the following photocurrents would be observed. These currents are determined by counting all electrons which would penetrate the film to the region to the right of the film in Fig. 1.

$$I'_c = I_{co}\, g_f\, (1 + x/L) \exp(-x/L)$$

$$I'_f = I_{f_x}\, g_f\, [(1 - \exp(-x/L)) - (x/L) \exp(-x/L)]$$

The geometrical factor, g_f, is actually an effective area factor which implies that the emitting area is proportional to L^2 rather than a unit area. The total current has the form

$$I' = g_f I + g_f (I_{co} - I_{f_x})\, (x/L) \exp(-x/L)$$

where the unprimed currents represent those for the one-dimensional model.

The additional current term would not be sufficiently significant for films of the thicknesses observed. The

dependence of the exponential coefficient varies much more slowly than the exponential term itself, especially when the data are plotted on a semilog scale. A comparison of the two shows that the maximum error in estimating the slope would be about 15%.

The question does arise as to whether this scattering model is appropriate since the electron would be expected to experience many elastic scattering events and therefore proceed by diffusion or random walk. The elastic scattering model which describes the electron's path must include the constraints of capture at the cathode surface and emission at the film surface. In one dimension, such a model leads to a reciprocal film-thickness dependence which does not fit the data.

If the film were charged, then that charge would inhibit the transmission of electrons. This possibility was investigated by observing the response for various radiation intensities. The emission from the cathode is proportional to the incident radiation, and transmission through the film was observed to be proportional to the incident radiation also. Incident intensity was varied by inserting neutral density filters between the lamp and the quartz window.

The spectral output of the lamp is quite broad. Since the electron traps in 3-methylpentane are known to be both deep and shallow, that is, capable of being emptied by infrared and uv radiation, it is expected that the lifetime of electrons in these traps is very short. Attempts were made to determine whether or not post emission occurred after the source was interrupted. However, the signal level was too small to be certain that such emission was actually present.

The scattering mechanism proposed above limits scattering to intermolecular vibrations since the electron energies are subexcitational. At least it is certain that intramolecular excitation would be accomplished in the first 20Å of travel or in the first layer of the film (2). The data support this analysis through the initial decrease in photocurrent which exceeds that for further increases in film thickness. Rotational excitations are ruled out for these nonpolar materials. The remaining, at least dominant, scattering mechanism is the intermolecular vibration or phonon. Raman spectra for the materials in question, in the liquid phase, indicate a vibrational range of 30-80 cm^{-1} or 0.004-0.01 eV. In the analysis and results of the calculations presented in Table I, the latter is used.

The analytical model proposed in the previous section assumes that a good fit to the data is obtained by exponential attenuation of the photoemitted carriers, or that the probability for a sufficient number of energy loss collisions to occur in a given distance is constant. This assumption is in good agreement with the range theory for hot electrons in metals (5) and electrons excited into materials where the dominant scattering is by optical phonons (6). In the latter reference, Baraff's attenuation length (range) is related to the initial average electron energy, 3 $kT_e/2$, the energy of the scattering phonon, E_r, and the mean scattering length, l, by the relation

$$l = L(3E_r/kT_e)^{1/2}$$

This relation leads to the values of l shown in Table I for the hydrocarbons mentioned above. On the average, an electron travels about three molecular diameters between scatters, if one assumes an energy loss of 0.01 eV for each occurrence. An electron will travel a distance of 1500Å in losing 1 eV. This agrees reasonably well with random walk theories (7) for total distance of travel. An additional advantage of the Baraff model is its independence of electron source energy distribution.

In the former reference, Sze *et al.* (5) treat metal films and electrons of energy above the Fermi energy but below the work function. The functional dependence of the response in this reference agrees with those of this effort, but the range is found to be energy dependent for electrons of energy near the top of the barrier over which they are collected. While the energy dependence of this theory is in general agreement with the Baraff theory, it lacks the incremental energy loss as an integral part of the range determination.

Application of Triangular Voltage Sweep Method to Mobile Charge Studies in MOS Structures

N. J. Chou

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The present paper examines the theoretical aspects of the triangular voltage sweep (TVS) technique and describes the development of a unified quasi-equilibrium approach wherein various polarization processes in an MOS capacitor structure subjected to the changing applied field are evaluated in terms of their contributions to the externally observed current. It is shown that a self-consistent experimental and analytical approach must be used when the TVS technique is applied to mobile charge studies in MOS structures.

The triangular voltage sweep (TVS) technique has been widely used by electrochemists to investigate anodic reactions in fuel cells (1). It is basically a voltammetric method where the voltage applied to a system $[V(t)]$ is made to follow a triangular waveform. Application of this technique to mobile charge studies in metal-oxide-silicon structures was first proposed by Yamin (2). More recently, Kerr (3) has reported that the method can be used to detect mobile Na^+ concentrations as low as 10^9 ion-cm^{-2} in SiO_2 films. So far, however, the capabilities and limitations of the TVS technique for analyzing various polarization processes in MOS structures at elevated temperatures have not been fully explored.

In the present paper a unified quasi-equilibrium analysis is developed wherein various electrical and electrochemical effects in an MOS capacitor are evaluated in terms of their contributions to the total current flow in the external circuit. It is shown that, under certain conditions, a faradaic polarization process may take place whose contribution will be superimposed on the polarization current normally attributed to the displacement of mobile charge in the insulator. A self-consistent analytical and experimental approach must therefore be used when the TVS technique is applied to mobile charge studies in insulating films. Extensive current-voltage measurements have been conducted in an electrochemically symmetrical Si-SiO_2-Si structure, and the results demonstrate that such an approach is indeed necessary. Experimental data in this simple structure indicate, for example, that the quasi-equilibrium analysis of mobile charge polarization in thermally grown SiO_2 films is applicable only in a limited range of temperature and voltage sweep rate. Indiscriminate use of the TVS technique may thus lead to erroneous interpretation of experimental data.

Quasi-Equilibrium Analysis of Polarization Currents

For a thin film sandwiched between two large electrodes, the current flow may be regarded as unidirectional and it is generally dependent in a complex way on $V(t)$ at elevated temperatures. The externally observed current density, j_{ex}, will be composed of various bulk and interfacial components and their interactive terms. In practice, where the interactions are negligible, the remaining components can be treated additively. Since the MOS structure constitutes a solid electrolyte cell at elevated temperatures (4), j_{ex} measured during the voltage sweep may contain: (*a*) a steady-state electronic component, j_e, due to the bulk conduction of the insulator; (*b*) a faradaic component, j_f, associated with the ions of reacting species; (*c*) a capacitive component, j_c, resulting from the charging and discharging of the MOS capacitor structure; (*d*) a polarization current, j_p, associated with slow-moving ionic defects in the insulator; and (*e*) a faradaic polarization current, j_{fi}, which may arise from the electrochemical reactions at the interfaces even when the faradaic current is negligibly small ($j_f \cong 0$). For convenience, these components are summarized in Table I. A typical current-voltage or I(V) characteristic obtained by the TVS method is also shown in Fig. 1, which demonstrates how various components of j_{ex} are superimposed.

Key words: insulator, solid electrolyte, MOS structure, ionic transport, triangular voltage sweep technique.

Table I. Various bulk and interfacial components of the externally observed current density: $j_{ex} = j_e + j_c + j_p + j_{fi} + j_f$

Component	Nature	Origin	Parameters affecting its magnitude
j_e	Steady-state, particle current	Electronic	Applied field, conduction mechanism
j_f	Steady-state or non-steady-state particle current	Electrochemical, ionic	Overpotential and rate of electrolysis
j_c	Displacement current	MOS capacitor charging; interface state polarization	Sweep rate, oxide capacitance, interface state concentration
j_p	Displacement current	Mobile charge polarization	Sweep rate, mobile charge concentration
j_{fi}	Displacement current	Faradaic polarization	Sweep rate, characteristics of transfer layer at the interface

For a given applied voltage, the magnitude of j_c depends on the specific conduction mechanism brought

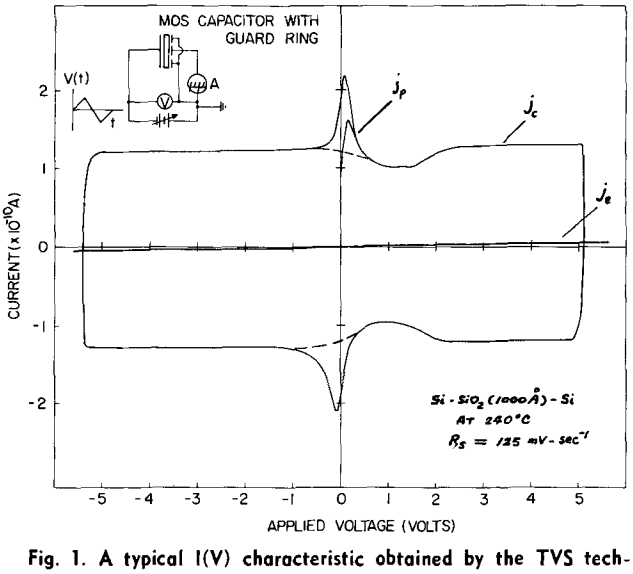

Fig. 1. A typical I(V) characteristic obtained by the TVS technique. Note that in the absence of faradaic polarization, j_{ex} is composed of j_e, the steady-state electronic component; j_c, the MOS capacitor charging component; and j_p, the mobile charge polarization component. Since j_e is independent of sweep rate, R_s, it constitutes the bisecting line for the j_c loop.

about by the applied field. The faradaic component, j_f, on the other hand, is determined by the rate-limiting step in the over-all reaction of the solid electrolytic cell. When the cell reaction becomes eventually diffusion controlled at sufficiently high temperatures, interactive effect of j_f on various polarization processes cannot be ignored. At these temperatures, ions of reacting species will be injected at one electrode and/or removed at the other in appreciable quantities. As a result, the polarization processes in the SiO_2 layer may become very complicated. For mobile charge studies, which are aimed at obtaining quantitative information about the extrinsic and intrinsic ionic defects in the the insulating film (*i.e.*, impurity ions and/or thermally generated vacancies and interstitials of constituent ions), the TVS measurements should be made in the temperature range where the electrodes are completely blocking ($j_f = 0$).

In the following analysis, the j_c, j_p, and j_l components will be estimated separately by postulating a state of quasi-equilibrium for each of their associated polarization processes. Provided that j_f is negligibly small and j_{ex} is not predominantly composed of j_c during the entire potential sweep, this quasi-equilibrium condition can be realized experimentally by varying two common external parameters (*i.e.*, potential sweep rate and temperature) either jointly or independently in the appropriate temperature range. It will be seen that the onset of electrode reactions in the MOS systems, usually undetectable by ordinary experimental techniques, sometimes manifests itself in the occurrence of a component, j_l, on the TVS plot. This component j_l, with its distinctive features, can often be used to define a suitable temperature range for mobile charge polarization studies.

Interface state polarization.—Component j_c is associated with the charging or discharging of the MOS capacitor which takes place concurrently with the formation of space charge in the semiconductor and also the capture or emission of charge carriers by the surface states or oxide traps[1] near the SiO_2-Si interface. When an external voltage is applied across the MOS structure, the surface charge of the metal electrode (σ_1) is balanced by the charges in the surface states (Q_{ss}) and in the space charge region (Q_{sc}): $\sigma_I = Q_{sc} - Q_{ss}$. Furthermore, the applied voltage is taken up by the surface potential of the semiconductor, ψ_s (*i.e.*, the potential rise or drop from the semiconductor bulk to its surface) plus the potential difference (V_{ox}) across the insulating layer and the work function difference (ψ_{ms}) between the metal and silicon electrodes (5)

$$V = \psi_s + V_{ox} + \psi_{ms} = \psi_s + (Q_{ss} - Q_{sc})/C_{ox} + \psi_{ms} \quad [1]$$

where C_{ox} is the oxide capacitance. Consequently, the capacitive current contribution is

$$j_c = d\sigma_I/dt = \left(\frac{\partial Q_{sc}}{\partial V} - \frac{\partial Q_{ss}}{\partial V}\right)\frac{dV}{dt} + \frac{\partial Q_{sc}}{\partial t} - \frac{\partial Q_{ss}}{\partial t} \quad [2]$$

or, by virtue of the relationship in Eq. [1]

$$j_c = C_{ox} R_s (1 - \partial\psi_s/\partial V) + (\partial Q_{sc}/\partial t - \partial Q_{ss}/\partial t) \quad [2a]$$

where dV/dt has been replaced by the constant sweep rate, R_s. When the system is stable and in a state of quasi-equilibrium such that the space charge and surface state population can readily follow the changing applied field, $\partial Q_{sc}/\partial t$ and $\partial Q_{ss}/\partial t$ vanish, and j_c reduces to

$$j_c = C_{ox} R_s (1 - \partial\psi_s/\partial V) \quad [3]$$

In the absence of other polarization processes, therefore, j_{ex} can be equated to j_c, and the $j_{ex} - V$ curve obtained by the TVS technique can be identified with the low-frequency capacitance *vs.* voltage characteristic of the MOS structure, as has been shown by previous investigators (6).

When the system is in a state of quasi-equilibrium, the following relationship holds (7)

$$\partial\psi_s/\partial V = \left[1 - \frac{1}{C_{ox}} \cdot \left(\frac{dQ_{sc}}{d\psi_s} - \frac{dQ_{ss}}{d\psi_s}\right)\right]^{-1} \quad [4]$$

At voltages corresponding to the accumulation and inversion regions for the semiconductor, the space charge term predominates and $\partial\psi_s/\partial V \approx 0$; in the depletion region, the value of $\partial\psi_s/\partial V$ depends on the relative magnitude of both the space charge and surface state terms. If a high surface state density is present such that $\partial\psi_s/\partial V$ will vanish when the Si surface is depleted, component j_c will describe a rectangular loop on a TVS plot as if the MOS structure consisted of an insulating film between two metal electrodes. In case the surface state density is not very high, $\partial\psi_s/\partial V$ will be less than unity in the depletion region. Then a surface state contribution will be superimposed on the ideal low-frequency $C(V)$ characteristics (*i.e.*, interface-state free). It is important to note that, at elevated temperatures, this contribution is usually negligible in comparison with others discussed in this paper.

On the other hand, if the potential sweep is so fast that the system is no longer in a state of quasi-equilibrium, the non-steady-state term in Eq. [2] often produces one or more current peaks of substantial magnitude on the I(V) plot at voltage values determined by the time constant and the energetic spectrum of the surface states (8). Appearance of such peaks obviously complicates the interpretation of the TVS plots.

In MOS specimens usually encountered in practice, a large interface state concentration often manifests itself in a small asymmetry in the $j_c - V$ curve with respect to the voltage axis. These states cannot be quantitatively evaluated without concurrent high-frequency $C(V)$ measurements (6).

Mobile charge polarization.—Redistribution of mobile charge centers in an insulator induces a change of surface charge (σ_I) on the metal electrode while contributing a component, j_p, to the externally measured current flow. Since σ_I depends implicitly on V and t during the potential sweep

$$j_p = d\sigma_I/dt = \frac{\partial\sigma_I}{\partial V} \cdot \frac{dV}{dt} + \frac{\partial\sigma_I}{\partial t} \quad [5]$$

For an arbitrary space charge distribution, $\rho = \rho(V, x, t)$, in an insulating film of thickness l, the instantaneous surface charge $\sigma_I(V, t)$ induced on the electrode (at $x = 0$) can be concisely expressed by (9)

$$\sigma_I(V, t) = Q(V, t)\,[1 - \overline{X}(V, t)/l] \quad [6]$$

where $Q(V, t) = \int_0^l \rho(V, t, x)dx$ is the area of the space charge profile (or the total space charge) between the two electrodes; and $\overline{X}(V, t) = \int_0^l \rho x dx / \int_0^l \rho dx$ is the coordinate of centroid for the space charge profile with respect to the axis at $x = 0$.

The polarization current is therefore

$$j_p = \left\{\frac{\partial Q}{\partial V}\left(1 - \frac{\overline{X}}{l}\right) - \frac{Q}{l}\left(\frac{\partial\overline{X}}{\partial V}\right)\right\}\frac{dV}{dt} + \left(1 - \frac{\overline{X}}{l}\right)\frac{\partial Q}{\partial t} - \frac{Q}{l} \cdot \frac{\partial\overline{X}}{\partial t} \quad [7]$$

When the system is in a state of quasi-equilibrium (*i.e.*, when the charge redistribution can readily follow the changing voltage), both $\partial Q/\partial t$ and $\partial\overline{X}/\partial t$ will vanish if the electrodes are blocking with respect to the moving ionic species. The polarization component, j_p,

[1] Oxide traps are regarded as effective surface states (5).

thus reduces to

$$j_p = R_s \left[dQ/dV \left(1 - \overline{X}/l\right) - (Q/l)\, d\overline{X}/dV \right] \quad [8]$$

where dV/dt has been replaced by R_s. When the total charge is independent of the applied voltage (*i.e.*, there is no field generation of mobile charge), $dQ/dV = 0$ and Eq. [8] simplifies to a more manageable form

$$j_p = -R_s\, (Q/l)\, d\overline{X}/dV \quad [9]$$

Analysis of the polarization current can now be treated as an electrostatic problem which essentially involves solving for static charge profiles in an insulating layer subjected to an applied field and determining the centroid of charge mass and its voltage derivative as a function of the applied potential. In addition, such solutions can be readily found by numerical calculations since Eq. [9] usually cannot be evaluated in a closed form (see Appendix I).

Component j_p obviously has a maximum at a voltage, V_m, for which $d^2\overline{X}/dV^2 = 0$. In an electrochemically symmetrical cell such as Si-SiO_2-Si, the polarization current peak will appear at zero applied voltage. In an asymmetrical cell, j_p will still peak when the mobile charge becomes uniformly or, more correctly, symmetrically distributed in the insulator. However, it should be noted that this distribution does not necessarily prevail when V is equal in magnitude and opposite in sign to the open-cell potential E^o (or equivalently, the work function difference, ψ_{ms}) of the MOS structure.[2] In Pt-SiO_2-Si structures, for example, V_m has been found to vary with the oxide thickness while other parameters were held constant (10).

Faradaic polarization.—When the electrode reactions occur but the faradaic component remains negligibly small ($j_f \cong 0$) during the whole potential sweep, the MOS structure can be treated as an electrolytic cell at virtual equilibrium. That is to say that, provided that the applied potential sweep rate is sufficiently slow, the concentration change in the transfer layers immediately adjacent to the electrode-insulator interfaces may be considered to be realized in an infinite number of perfectly reversible steps for which $j_f = 0$. Under appropriate conditions, a polarization component, j_l, associated with this concentration change may appear in the external circuit if, during the sweep, ionization-discharge is the rate-determining step of the electrode reactions.

Depending on the relative magnitudes of various parameters in the system under investigation (see Appendix II), j_l may exhibit any one of the following characteristics.

(*a*) When one of the interface reactions predominates, j_l has a maximum at

$$V_m = \frac{1}{\epsilon}\left(E^o - \frac{RT}{zF} \ln K_i\right) \quad [17]$$

where E^o is the equilibrium cell potential, ϵ the correction factor, K_i the equilibrium constant for the prevailing electrode reaction, and other symbols have their usual significance. In this case, j_l cannot be separated from j_p since ϵ and K_i are usually unknown.

(*b*) When the extent of both interfacial reactions is comparable, j_l appears double peaked with well-defined maxima at

$$V_1 = \frac{1}{\epsilon}\left(E^o - \frac{RT}{\delta_{1z}F} \ln K_I\right)$$

and

$$V_2 = \frac{1}{\epsilon}\left(E^o - \frac{RT}{\delta_{11z}F} \ln K_{II}\right) \quad [18]$$

where δ's are overpotential distribution factors.

[2] If the initial distribution of uncompensated mobile charge centers has the shape of a delta function at one of the interfaces, as postulated by Snow *et al.* (11), then quasi-equilibrium condition cannot be achieved throughout the course of the potential sweep. As the mobile charge leaves the boundary layer at low applied voltages, the diffusion and drift terms in the transport equation will be of the same sign, and the quasi-equilibrium condition does not hold until a concentration gradient is built up in the bulk of the insulator.

(*c*) For more intermediate cases, j_l exhibits a primary and a secondary peak, which are often difficult to resolve on a TVS plot. Nevertheless, double-peaked faradaic polarization current has been observed in both Cr-SiO_2-Si (12) and Pt-SiO_2-Si (10) structures.

The magnitude of the current peaks for j_l, normalized with respect to sweep rate R_s, is proportional to the equilibrium constant and the number of activated sites in the corresponding transfer layers (Appendix II). If a single peaked j_l is mistaken for j_p in the mobile charge studies, the error involved can therefore be several orders of magnitude. On the other hand, the appearance of a double-peaked component on a TVS plot can be taken as indicative of the onset of electrode reactions, and consequently sets an approximate temperature limit for ideally blocking electrodes.

For example, the j_l component observed in Pt-SiO_2-Si systems at 390°C indicates that the silicon electrode is no longer ion-discharge blocking above this temperature ($j_l \neq 0$) (see Fig. 2).

Mobile Charge Studies by TVS Technique

It is evident from the preceding discussion that meaningful data for mobile charge analysis can be obtained only when one has experimentally established that: (*a*) the system is in a state of quasi-equilibrium during the TVS measurement, and (*b*) the observed polarization component is solely attributable to the mobile charge excursion (*i.e.*, $j_l = 0$). Intuitively, either an increase in ambient temperature or a decrease in voltage sweep rate should eventually bring about the desired equilibrium. However, a continued decrease in sweep rate will lower the external current below the level of detectability, whereas an excessive temperature increase introduces complicating effects (*e.g.*, the electrodes become nonblocking and $j_l \neq 0$). A plausible experimental approach is therefore to determine the temperature limit by monitoring the occurrence of j_l on the TVS plot. After establishment of this temperature regime, the following three quantities associated with the mobile charge polarization current can then be used as self-consistent criteria to test the onset of quasi-equilibrium, as well as the validity of the various assumptions in the quasi-equilibrium analysis.

1. *Normalized area:* For voltages exceeding some value, $\pm|V_o|$, where mobile charge profile can be ap-

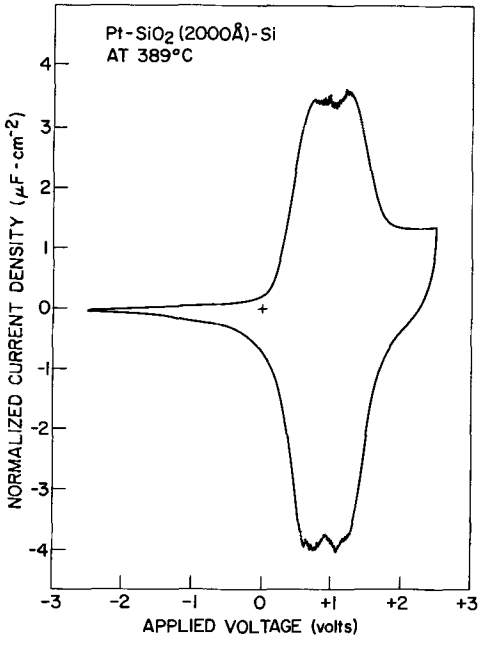

Fig. 2. Experimental evidence showing the occurrence of a double-peaked faradaic polarization current, j_l, in a Pt-SiO_2-Si cell. The TVS plot was taken at a sweep rate of 41.7 mV-sec^{-1}.

proximated by a delta function at each electrode (*i.e.*, $\bar{X}_2 - \bar{X}_1 \approx l$) the area under j_p on the TVS plot can be normalized with respect to R_s to yield

$$\frac{1}{R_s}\int_{\leq -|V_o|}^{\geq +|V_o|} j_p dV = -(Q/l)\int_{\bar{X}_1}^{\bar{X}_2} d\bar{X} \approx Q = \text{const} \quad [19]$$

Upon the onset of quasi-equilibrium, therefore, the normalized area should be independent of the sweep rate and the number of sweeps and should remain virtually constant for voltage sweeps exceeding $\pm|V_o|$.

2. *Normalized peak current*: Transposing Eq. [9] gives

$$(j_p)_{max}/R_s = -(Q/l)\,(d\bar{X}/dV)_{j_p=(j_p)_{max}} \quad [20]$$

Consequently, the normalized current peak should also be rate- and field-independent in the quasi-equilibrium regime.

3. *Voltage corresponding to current peak*: The equilibrium position of the current peak, V_m, is defined by the condition $d^2\bar{X}/dV^2 = 0$. Upon the onset of quasi-equilibrium, V_m should become rate independent and assume the value determined by static charge profile calculations.

In order to properly apply the quasi-equilibrium analysis of mobile charge polarization, it is therefore mandatory to determine the above-mentioned quantities at a given temperature over a wide range of R_s values. If the rate dependence of these quantities indicates that quasi-equilibrium has been achieved, the subsequent detailed analysis follows directly. The procedure consists of determining the charge profile (ρ) as a function of V, extracting therefrom the centroid of charge mass $\bar{X}(V)$ and its voltage derivative $d\bar{X}/dV$, and constructing a theoretical I(V) plot for j_p according to Eq. [9]. Since the charge profile can be determined under a variety of assumed conditions (13), a particular set of conditions which yields the best agreement between the calculated and observed polarization current will not only define the concentration of mobile charge centers but also supply insight into some of their physical properties. Furthermore, by repeating this type of experiment over a suitable temperature range, an activation energy for thermal generation of mobile ions can be quantitatively determined.

Experimental results and discussion.—Virtually symmetrical Si-SiO_2-Si guard-ringed capacitor structures were fabricated. Polycrystalline silicon counterelectrodes (with matched resistivities)[3] were deposited from an E-gun heated source, through 0.041 cm^2 mask holes onto SiO_2 films of various thicknesses, which were previously grown in dry O_2 on (100)-oriented, p-type, 1000 ohm-cm substrates. The specimens were annealed for 30 min at 1100°C in dry N_2 in order to crystallize the amorphous Si counterelectrodes while improving the electrochemical symmetry of the insulating layer at the interfaces. The final symmetry was verified both by $C(V)$ measurement and by a steady-state I(V) measurement after the electrical breakdown of oxide layer has occurred.

Since silicon electrodes have been found to be no longer ion-discharge blocking at 390°C, mobile charge polarization in these structures was investigated in the temperature range from 145° to 365°C. The TVS measurements were taken with sweep rates ranging from 1 mV/sec to 1 V/sec in a vacuum of 10^{-3} Torr. The field dependence of mobile charge concentration was checked by repeating the potential sweep to increasingly higher voltages at each temperature (see, for example, Fig. 3). The rate dependencies of the normalized area, the normalized peak current and the peak voltage, extracted from I(V) plots for various

[3] Polycrystalline silicon, obtained by E-gun deposition, usually has a high resistivity (10^4-10^6 ohm-cm). In our experiment, resistivity matching was achieved by using high-resistivity substrates and a highly B-doped evaporation source.

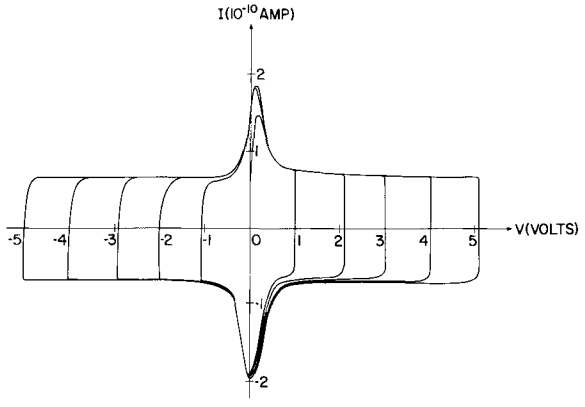

Fig. 3. Experimental evidence of the field independence of mobile charge concentration in a Si (poly)-SiO_2 (2000Å)-Si(100) capacitor structure. This I(V) plot was obtained at 247°C at a sweep rate of 41.7 mV-sec^{-1}.

sweep rates and temperatures, are shown in Fig. 4, 5, and 6, respectively. Below 145°C, the onset of quasi-equilibrium cannot be discerned experimentally by further lowering of the sweep rate since the currents cannot be accurately differentiated from the background noise (compare 145° curves in Fig. 4, 5, and 6). Somewhat above approximately 307°C, the total charge and peak current were found to increase with increasing voltage and decreasing sweep rate, suggesting thermal and field generation of new mobile charge species ($dQ/dV \neq 0$ in Eq. [9]) (see, for example, 307° and 365° curves in Fig. 5 and 6). Clearly, our quasi-equilibrium model of mobile charge polarization is self-consistent only in a limited temperature range below 300°C, where the normalized area and current cease to be rate dependent when the current peak assumes the theoretically predicted position of $V_m = 0$ (compare 192° and 247° curves in Fig. 4, 5, and 6). In this range the total mobile charge appears to be independent of temperature.

A computer program has been developed to determine mobile charge profiles under various boundary conditions which are considered appropriate for a symmetrical Si-SO_2-Si structure (see Appendix I).[4] Based on the assumption of blocking electrodes and

[4] The program was written by H. P. Crowder.

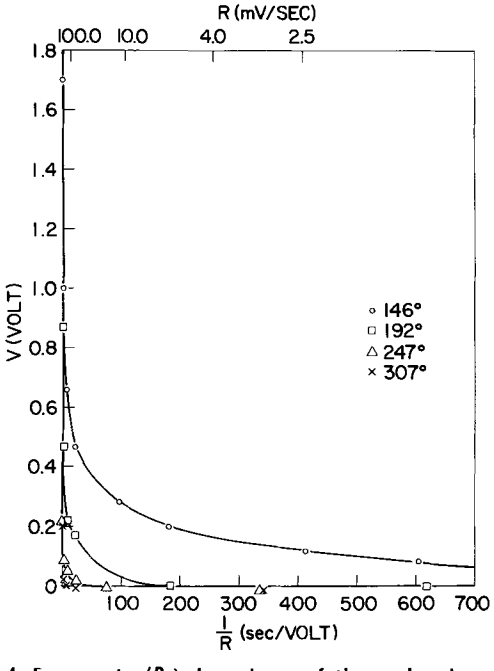

Fig. 4. Sweep rate (R_s) dependence of the peak voltage (V) of the polarization component measured at various temperatures.

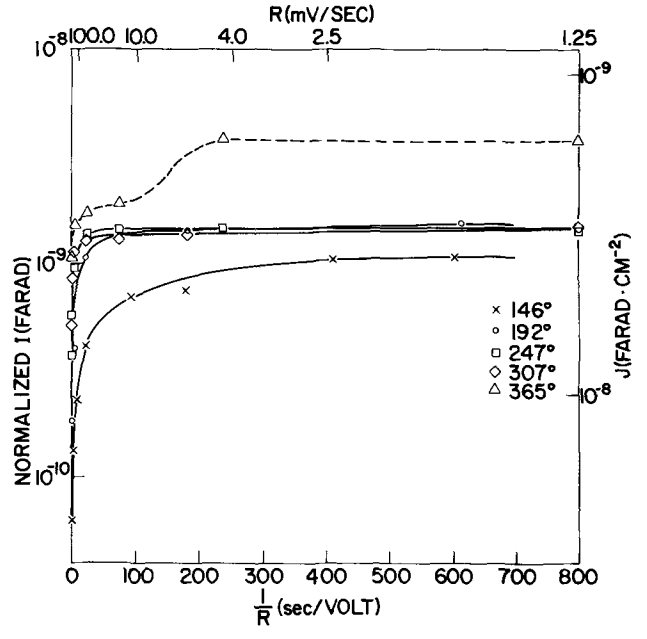

Fig. 6. Rate dependence of normalized peak current, I (or normalized peak current density, J), for various measurement temperatures.

one-carrier polarization, this program permits the polarization current to be calculated for any given temperature and oxide thickness, using the initial mobile charge concentration ($N_0 = Q/l$) as a disposable parameter. A detailed comparison was made between the calculated and observed polarization current based on the data obtained at 247°C for a 2000Å oxide specimen. At this temperature, the normalized area gives an initial concentration of $N_0 = 4.4 \times 10^{15}$ q-cm^{-3}. This value of N_0 was used as a starting point for the static charge computation. After a few trials, the best agreement between the calculated and the observed polarization was obtained for $N_0 = 5 \times 10^{15}$ q-cm^{-3}. The final results of this computation are shown graphically in Fig. 7, where $\bar{X}$ and its derivative $d\bar{X}/dV$ are plotted as a function of V. The theoretical polarization current was constructed in accordance with Eq. [9] and shown as a dotted line superimposed on the observed polarization component in Fig. 8. Since, in the absence of faradaic polarization, the normalized area should tally with the normalized current peak (compare Eq. [19] and [20]), the agreement between the

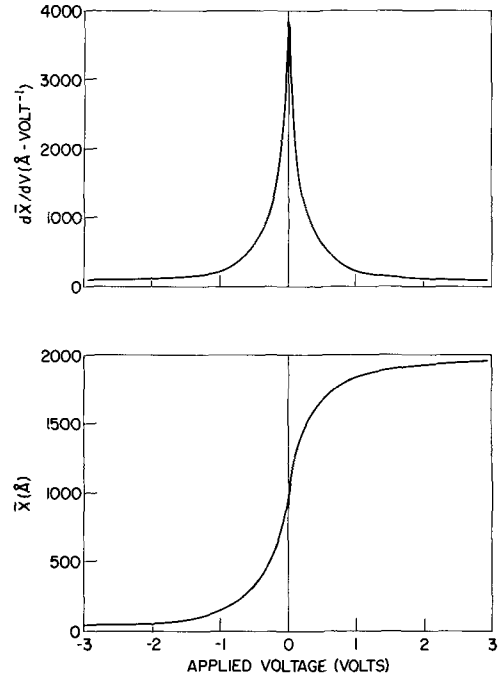

Fig. 7. Voltage dependence of $\bar{X}$, the center of mass, and its derivative $d\bar{X}/dV$, extracted from the space charge profiles which have been calculated with the following parameters: $T = 247$°C; $l = 2000$Å. $N = 5 \times 10^{15}$ q/cm^3. It should be noted that the $\bar{X}$ vs. V curve exhibits a kink near 0.1-0.2V, which has been deliberately smoothed out.

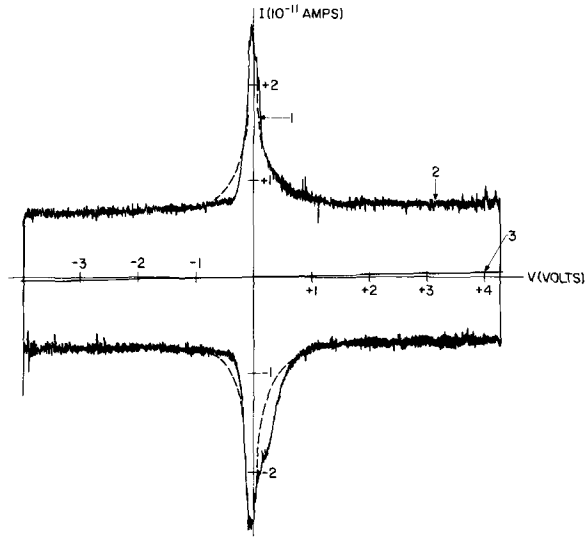

Fig. 8. Calculated and observed j_{ex} for the same capacitor structure as in Fig. 2. The TVS plot was obtained at 247°C at $R_S = 12.5$ mV·sec^{-1}. j_{ex} can be resolved into: (a) polarization component, 1; (b) capacitive component, 2; and (c) steady-state component, 3. Note the dotted line, which represents the polarization current calculated on the basis of a quasi-static model. The difference between the dotted line and the actual curve in the lower half of the plot is attributed to interface effects (see text). Note also the difference between the two polarization components in Fig. 2 and 8. This is due to the fact that quasi-static equilibrium was not quite achieved at the sweep rate of 41.7 mV-sec^{-1}.

calculated and observed currents is probably the most convincing evidence attesting the validity of the quasi-static model of mobile charge polarization.[5]

The asymmetry of the observed polarization current with respect to the voltage axis suggests the

[5] Yamin, for example, has found that at 500°C the charging peak was much higher than that calculated from the expected impurity concentration of 10^{18} ions-cm^{-3}. He attributed the discrepancy to the electrochemical effect, which is quantitatively analyzed in this paper.

presence of interface states at one of the interfaces [see the lower portion of the I(V) plot, Fig. 8]. In the light of the discussion on interface state polarization, it seems likely that these states reside near the interface between the oxide and the counterelectrode since, on the return sweep, the semiconductor surface of the counterelectrode goes from the accumulation to inversion regime.

When the total mobile charge was determined under quasi-equilibrium conditions for oxide specimens of various thicknesses, it exhibited no thickness dependence (Fig. 9). Since these specimens have been prepared under virtually identical conditions, the absence of thickness dependence strongly suggests that the mobile ionic species were introduced into the oxide layers not during the film growth, but either by surface contamination or by some process wherein the ionic species in the surface layer were rendered mobile (14). In view of the fact that stable Si-SiO_2-Si devices have been fabricated, it may be concluded that the observed mobile charge is due to external contamination.

Summary

Various bulk and interface effects in an insulator sandwiched between two electrodes have been shown to contribute to the anomalous charging current observed during a potential sweep at elevated temperatures. A unified quasi-equilibrium analysis indicates that a careful separation of these effects is necessary when the voltage sweep technique is used in either mobile charge or electrochemical studies in a solid electrolytic cell.

Observation of the double-peaked charging component, j_i, in the Pt-SiO_2-Si structure has established the temperature ranges ($T \leq 390°$) where the silicon electrode is blocking. The TVS measurements made in Si-SiO_2-Si structures in this temperature regime indicate that our quasi-equilibrium model for mobile charge analysis is applicable only up to 250°C. Above this temperature both field and thermal generation of new mobile charge species seem to have occurred, which is not accounted for in our model. However, in the range where the model is valid, excellent agreement has been obtained between the calculated and observed polarization currents. In this regime, the mobile charge concentration in the thermally grown oxide appears to be independent of temperature and applied field. This implies that the mobile charge in question is most likely associated extrinsic defects such as impurity ions in the SiO_2 film, which requires little or no activation energy for thermal generation. Such contention is further supported by the thickness data, which suggest that the mobile ionic species do not originate from thermal oxidation, but from surface contamination.

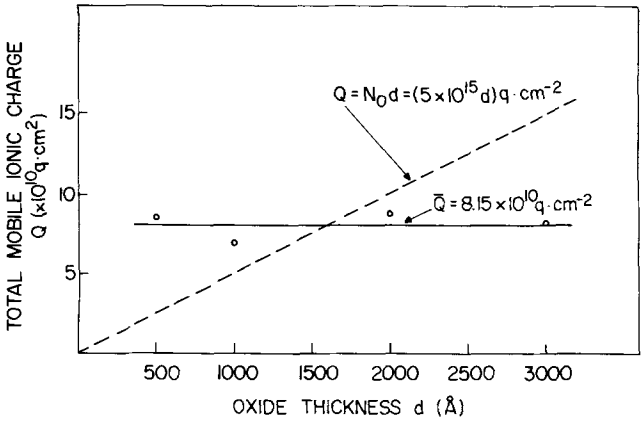

Fig. 9. Total mobile ion concentration in thermal SiO_2 films of various thicknesses, which have been prepared under virtually identical conditions. The dotted line indicates the thickness dependence which would have been observed if the mobile charge was not due to surface contamination or surface layer effect (see text).

Acknowledgments

The author is indebted to R. Hammer for his valuable assistance in the experimental work; to H. P. Crowder for developing the computer program used in the mobile charge analysis; to J. M. Eldridge, T. Sedgwick, and Y. van der Meulen for their critical reading of the manuscript; and to T. Hickmott for furnishing his prepublication data on low-frequency $C(V)$ measurements.

Manuscript submitted June 8, 1970; revised manuscript received Oct. 11, 1970. This was Paper 25 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

APPENDIX I

For an electrochemically symmetrical cell, which has neither emf nor work function difference, we shall assume that:

(*a*) The insulator thickness, *l*, is sufficiently small as compared to the electrode diameter so that the problem may be formulated one-dimensionally.

(b) At a given temperature, the concentration of dissociable charge pairs in the insulator is a fixed value.

(c) Application of external field can dissociate the charge pairs but creates no new pairs.

(d) Only one of the dissociated charge species is mobile under the influence of the applied field. Furthermore, it will not be compensated (recombined) because of the lack of oppositely charged centers in the new location it has moved into.

(*e*) The electrodes are ideally blocking: *i.e.*, no charge transfer or ionic charge injection takes place at the metal-insulator interfaces.

The electric field, E, in the specimen is related to the net space charge by Poisson's equation

$$\frac{\partial E}{\partial x} = \frac{4\pi q}{\epsilon}(\rho_p - N_o) \qquad [A\text{-}1]$$

where q is the electronic charge, ϵ the permittivity, ρ_p the mobile charge density, x the spatial coordinate of the insulator, and N_o the number of initial dissociable charge pairs per unit volume.

Since the electrodes are blocking, there is no mobile charge flow across the boundary

$$D\left(\frac{\partial \rho_p}{\partial x}\right) - \mu E \rho_p = 0 \text{ for } x = 0, l \quad [A\text{-}2]$$

where D and μ are the diffusivity and drift mobility of the mobile charge.

For a given applied voltage, V_a, a static equilibrium is established when

$$\frac{\partial \rho_p}{\partial t} = D\frac{\partial^2 \rho_p}{\partial x^2} - \mu\frac{\partial (E\rho_p)}{\partial x} = 0 \text{ for all } x\text{'s} \quad [A\text{-}3]$$

Integrating Eq. [A-3] between 0 and x gives

$$D\left(\frac{d\rho_p}{dx}\right)_{x=x} - D\left(\frac{d\rho_p}{dx}\right)_{x=0} = \mu(E\rho_p)_{x=x} - \mu(E\rho_p)_{x=0} \quad [A\text{-}4]$$

Application of the boundary conditions yields the important relationship

$$D\left(\frac{d\rho_p}{dx}\right) - \mu(E\rho_p) = 0 \text{ for all } x\text{'s} \quad [A\text{-}5]$$

Standard substitution of $y = \ln \rho_p$ (13) gives

$$D\frac{dy}{dx} = \mu E \quad [A\text{-}6]$$

and

$$D\frac{d^2y}{dx^2} = \mu\frac{dE}{dx} \quad [A\text{-}7]$$

By virtue of Eq. [A-1]

$$D\frac{d^2y}{dx^2} = \frac{4\pi q}{\epsilon}\cdot\mu(\rho_p - N_o)$$

or

$$2\frac{d^2y}{dx^2} = \frac{1}{L_D^2}(P - 1) \quad [A\text{-}8]$$

where

$$P = \frac{\rho_p}{N_o}$$

and

$$L_D^2 = \left(\frac{8\pi q}{\epsilon_{ox}}\frac{\mu}{D}N_o\right)^{-1}$$

have been substituted.

Setting $dy/dx = v$, [A-18] may be reduced to

$$L_D^2\, d(v^2) = (e^y - 1)\,dy \quad [A\text{-}9]$$

when the frequently used relation

$$2\frac{d^2y}{dx^2} = \frac{d}{dy}\left[\left(\frac{dy}{dx}\right)^2\right]$$

is applied.

Consequently

$$\int_{v_o}^{v} L_D^2\, d(v^2) = \int_{y_o}^{y} (e^y - 1)\,dy$$

or

$$L_D^2 v^2 = L_D^2 v_o^2 + e^y - e^{y_o} - (y - y_o) \quad [A\text{-}9a]$$

or

$$L_D\frac{dy}{dx} = [L_D^2 v_o^2 + e^y - e^{y_o} - (y - y_o)]^{1/2} \quad [A\text{-}9b]$$

Integration of [A-9b] results in

$$\int_{y_o}^{y} [L_D^2 v_o^2 + e^y - e^{y_o} - (y - y_o)]^{-1/2}\,dy = \frac{x}{L_D} \quad [A\text{-}10]$$

giving y or $\ln \rho_p$ in terms of x.

In addition, since

$$\int_o^l P\,dx = \int_o^l \frac{\rho_p}{N_o}\,dx = \frac{1}{N}\int_o^l \rho_p\,dx = \frac{N_o l}{N_o} = l$$

[A-8] can be integrated to give

$$\frac{dy}{dx_{x=l}} - \frac{dy}{dx_{x=0}} = \frac{1}{2L_D^2}\int_o^l (P - 1)\,dx = 0$$

or

$$v_l = v_o \quad [A\text{-}11]$$

From the relationship in [A-6]

$$\int_{y_o}^{y_l} dy = \int_o^l \frac{\mu}{D} E\,dx = \frac{\mu}{D}\int_{V_o}^{V_l} dV$$

or

$$y_l - y_o = \frac{\mu}{D}V_a \quad [A\text{-}12]$$

where $V_a = V_l - V_o$ is the applied voltage.

[A-19a] now gives

$$e^{y_o} = \left(\frac{\mu}{D}V_a\right)\Big/\left[\exp\left(\frac{\mu}{D}V_a\right) - 1\right] \quad [A\text{-}13]$$

and [A-9b] may be integrated between y_o and y_l to give

$$\int_{y_o}^{\left(y_o + \frac{\mu}{D}V_a\right)} [L_D^2 v_o^2 + e^y - e^{y_o} - (y - y_o)]^{-1/2}\,dy = l/L_D \quad [A\text{-}10a]$$

Equations [A-10], [A-10a], and [A-13] constitute the solution to our problem of space charge distribution.

Equation [A-10] cannot be integrated in a closed form. A computer program has been developed by H. P. Crowder to integrate [A-10] numerically by a trial-and-error scheme. y_o, l/L_D, and μ/D are determined from the initial charge concentration, temperature, applied voltage, and insulator thickness; v_o is chosen as a variable parameter subject to

$$[L_D^2 v_o^2 + e^y - e^{y_o} - (y - y_o)]_{\min} \geq \zeta$$

where ζ is a prefixed small value such that the integrand in [A-17] will not become infinite or imaginary. Integration of [A-10a] is carried out with v_o altered recursively until

$$\int_{y_o}^{y_o + \frac{\mu}{D}V_a} [L_D^2 v_o^2 + e^y - e^{y_o} - (y - y_o)]^{-1/2}\,dy = \frac{l}{L_D} < \epsilon$$

where ϵ is another predetermined tolerance.

When v_o and y_o are thus established, the space charge profile for a given voltage is obtained by integrating [A-10] with their established values.

APPENDIX II

Consider the SiO_2 film in an MOS capacitor as a solid electrolyte containing the metal ions of electrodes I and II. At equilibrium ($j_f = 0$), the over-all cell reaction may be written as

$$M^{z+}(\text{I}) + \gamma\text{M}(\text{II}) = \text{M}(\text{I}) + \gamma M^{z'+}(\text{II}) \quad [A\text{-}14]$$

where $\gamma = z/z'$ is the stoichiometric factor, and I and II refer to the electrodes. The open-cell potential, E^o, can be determined from the condition that the chemical potential changes associated with the reactants transversing the transfer layers is balanced by the electrical potential changes

$$E^o = E^o{}_{1-3} - \gamma E^o{}_{2-3} = -\frac{\Delta G_I}{z\mathbf{F}} + \gamma\frac{\Delta G_{II}}{z'\mathbf{F}} \quad [A\text{-}15]$$

where ΔG's are free energy changes, and $E^o{}_{1-3}$ and $E^o{}_{2-3}$ are equilibrium electrode potentials at I and II, respectively (see Fig. 10a). When an external voltage ($|V| > E^o$) is applied to the cell, potential drops (V_i) different from those of equilibrium values may appear in three regions of the electrolytic cell, i.e.

$$V = V_I + V_{III} - V_{II} \quad [A\text{-}16]$$

or

$$V = \zeta_I V + \zeta_{III} V - \zeta_{II} V$$

where ζ's denote the potential distribution factors. A detailed examination of the potential distribution in

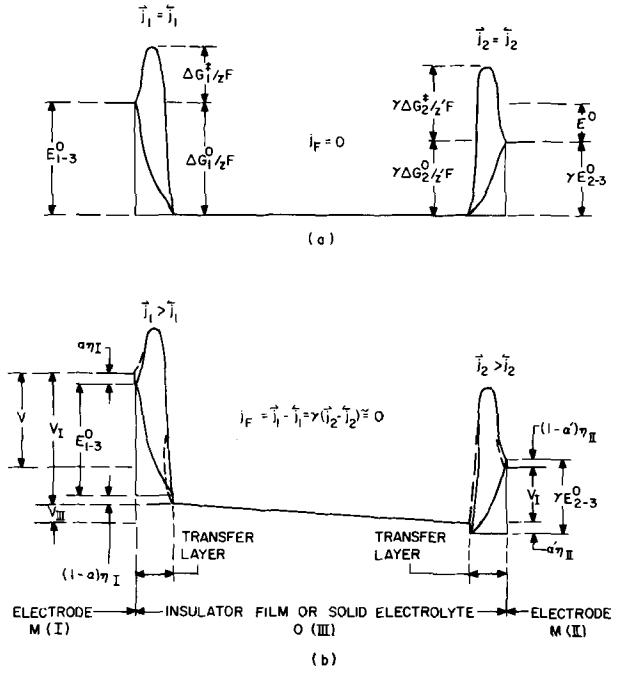

Fig. 10. Schematic representation of electrical activation in a solid electrolytic cell: *(a)* at equilibrium ($j_f = 0$)—there is no electrical activation, and the cell potential is $E^\circ = E^\circ_{1-3} - \gamma E^\circ_{2-3} = -(\Delta G^\circ_I - \gamma \Delta G^\circ_{II})/zF$; *(b)* potential distribution in the case of electrical activation—at electrode I $\eta = \delta_I V - E^\circ_{1-3}$; at electrode II $\eta_{II} = \delta_{II} V - \gamma E^\circ_{2-3}$. Note that the activation energy is represented by $\Delta G^{\neq}/zF$, which, according to the absolute rate theory, is associated with the free energy change between the reactants and the activated complex.

the electrolytic cell (Fig. 10b) shows that

$$V = [\alpha\eta_I + E^\circ_{1-3} + (1-\alpha)\eta_I] + V_{III} + [\alpha'\eta_{II} - \gamma E^\circ_{2-3} + (1-\alpha')\eta_{II}] \quad [A\text{-}17]$$

where α and α' denote the transfer coefficients, and, η_I and η_{II} the effective overpotentials for the two electrodes. Comparison of Eq. [A-16] and [A-17] yields the following relationship

$$\eta_I = \delta_I \eta = \zeta_I V - E^\circ_{1-3}$$

$$\eta_{II} = \delta_{II}\eta = \gamma E^\circ_{2-3} - \zeta_{II} V$$

and

$$\eta = (1 - \zeta_{III})\, V - E^\circ = \epsilon V - E^\circ \quad [A\text{-}18]$$

where η denotes the effective overpotential for the electrolytic cell, δ_I and δ_{II} are overpotential distribution factors, and ϵ may be regarded as the correction factor for the potential drop in the oxide bulk.

If the faradaic current, j_f, remains negligibly small during the voltage sweep, the concentrations of metal ions in the electrolyte adjacent to the transfer layers do not change and the total numbers of ions and atoms in the transfer layers which participate in the reaction (*i.e.*, total number of "activated sites" n_o and n_o') may be considered to be constant in spite of the passage of j_f. Consequently, the concentrations of the atoms $[C_{M(I)}, C_{M(II)}]$ and ions $[C_{Mz+}$ and $C_{Mz'+}]$ in the transfer layers can be related by

$$C_{Mz+} = \tilde{n} - C_{M(I)};\ C_{Mz'+} = \tilde{n}, - C_{M(II)} \quad [A\text{-}19]$$

where $\tilde{n} = n_o/\bar{N}_o$ and $\tilde{n}' = n'_o/\bar{N}_o$ are the ratios of n_o and n'_o to Avogadro's number, $\bar{N}_o$, respectively.

When ionization and discharge are the rate-limiting step of the electrode reactions, a pseudocapacitive component, j_l, appears in the external circuit during the voltage sweep even though j_f may be negligibly small. This component, j_l, can be evaluated by invoking a state of quasi-equilibrium for the rate-determining step. The quasi-equilibrium in this case is taken to mean that, while C_{Mz+} and $C_{Mz'+}$ are realized in an infinite number of reversible steps in which $j_f = 0$. Application of the theory of overpotential (17) and the absolute rate theory (18) yields

$$\frac{C_{Mz+}}{\tilde{n} - C_{Mz+}} = \frac{\vec{k}}{\overleftarrow{k}} \exp\left(\frac{zF\eta_I}{RT}\right) = K_I \exp\left(\frac{zF\eta_I}{RT} \exp\frac{zF\eta_I}{RT}\right) \quad [A\text{-}20]$$

and

$$\frac{C_{Mz'+}}{\tilde{n}' - C_{Mz'+}} = \frac{\vec{k}'}{\overleftarrow{k}'} \exp\left(\frac{z'F\eta_{II}}{\gamma RT}\right) = K_{II} \exp\left(\frac{z'F\eta_{II}}{\gamma RT}\right)$$

where k's and k''s are forward and reverse rate constants, and K's are the equilibrium constants for the rate-determining step of the electrode reactions. The change in C_{Mz+} ($C_{Mz'+}$) is accompanied by a corresponding change in the surface charge, σ_I (σ_{II}), on electrode I(II). In a mathematical approach analogous to that given by Srinivasan and Gileadi (19), one finds that the resultant polarization current is

$$j_l = R_s \left(\frac{zF}{RT}\right) \left\{ \exp\left(-\frac{zF\delta_I\eta}{RT}\right) \cdot \frac{k_I K_I}{\left\{\exp\left(-\frac{zF\delta_I\eta}{RT}\right) + K_I\right\}^2} + \exp\left(-\frac{zF\delta_{II}\eta}{RT}\right) \cdot \frac{k_{II}K_{II}}{\left\{\exp\left(-\frac{zF\delta_{II}\eta}{RT}\right) + K_{II}\right\}^2} \right\} \quad [A\text{-}21]$$

where $k_I = zqn_o$ and $k_{II} = zqn'_o$ convert the concentration changes into the changes in surface charge on the advancing or receding electrode-electrolyte interfaces. The exponential nature of the two terms in Eq. [A-21] suggests that the faradaic polarization component, j_l may exhibit two peaks at voltage values for which $K_I = \exp(-zF\delta_I\eta/RT)$ and $K_{II} = \exp(-zF\delta_{II}\eta/\gamma RT)$, respectively.

The magnitude of these two peaks can be evaluated by substituting the preceding expressions into Eq. [A-21]. Thus

$$(j_l)_{max} \cong \frac{z^2F}{RT} n_o\, qK_I \cdot R_s$$

and

$$(j_l)'_{max} \cong \frac{z'^2F}{\gamma RT} \cdot n'_o\, qK_{II} \cdot R_s$$

Synthesis of Gallium Phosphide

C. M. Ringel

Bell Telephone Laboratories, Incorporated, Reading, Pennsylvania 19604

ABSTRACT

An open-flow synthesis system for the production of polycrystalline GaP, using PH_3 flowing over Ga in a temperature gradient, has been investigated with regard to purity of the product and yield of GaP in terms of the elements Ga and P. This material is suitable as starting material for single-crystal growth by the liquid-encapsulated Czochralski technique. Optimization of the synthesis time, flow rate, and temperature gradient resulted in a P reaction efficiency of 50-55% and a GaP yield of 35-38g per 50g of Ga. A mechanism involving the formation of a reaction barrier over the Ga was used to explain the increase in P reaction efficiency and GaP yield with decreasing PH_3 flow rate. Both an increased reaction efficiency and GaP yield were observed with increasing temperature gradients, indicating a diffusion-controlled reaction. It was found that 1.5×10^{19} Si atoms cm^{-3} were incorporated in the GaP when pyrolytic boron nitride boats and silica liners were used. When He was substituted for H_2 as the carrier gas, the Si contamination dropped to about 5×10^{18} cm^{-3}. Silicon contamination of about 1×10^{19} atoms cm^{-3} was observed using an all silica system. When water vapor was introduced in small amounts to He in the pyrolytic boron nitride-SiO_2 system, the GaP yield was reduced by about 10% but the material produced was found to have an optically active Si content of about 10^{16} cm^{-3}. These results indicate the dominance of the vapor transport mechanism for Si contamination of GaP. Material grown in an all-pyrolytic boron nitride system, where the boats were physically separated from hot silica, had a Si contamination of less than 5×10^{16} cm^{-3}.

Considerable interest in polycrystalline gallium phosphide has been stimulated by the introduction of liquid-encapsulated Czochralski (LEC) crystal growth as a means to mass produce large-area gallium phosphide single crystals (1). If GaP electroluminescent devices are to be competitive relative to incandescent lamps, manufacturing expenses including the cost of polycrystalline starting material need to be minimized.

One method for preparing polycrystalline GaP was initially suggested by Grimmeiss *et al.* (2) and Frosch and Rao (3). In this method, polycrystalline GaP is prepared in an open-tube system in which Ga-containing boats, positioned in a liner, are placed in a temperature gradient. Gallium phosphide is formed by the reaction of phosphorus, obtained from the decomposition of PH_3, with Ga. The GaP dissolves in the excess Ga and, because of the temperature gradient, precipitates at the cooler ends of the boats. This high-purity GaP, precipitated in the form of porous polycrystalline ingots, has been used to produce LEC substrates (4). The present study is concerned with optimizing yields while maintaining or improving the purity of the GaP produced by this open-tube synthesis technique.

In the Experimental section of this paper, the experimental work is discussed. The effects of PH_3 flow rate and temperature gradient on the GaP yield, P and Ga reaction efficiencies, and length of run using pyrolytic boron nitride (PBN) system are the subjects of the following section.

The remaining part of the paper is concerned with the purity of the GaP and the effects of liner and boat materials and gaseous ambients. The possible mechanisms which can contaminate the GaP with Si and the results obtained using PBN and vitreous silica (SiO_2) liners and boats are discussed first. The interest in SiO_2 liners and boats stems from the considerable cost reduction that would result if these could be used rather than the quite expensive PBN liners and boats. Finally, the results obtained when He, with and without water, is substituted for H_2 as the PH_3 carrier gas in a SiO_2 liner-PBN boat system are presented.

Experimental

Raw materials.—The Ga used is commercially available 99.9999% pure delivered in sealed ampoules.[1] The

Key words: gallium phosphide, synthesis, growth.

[1] Supplier: Alusuisse.

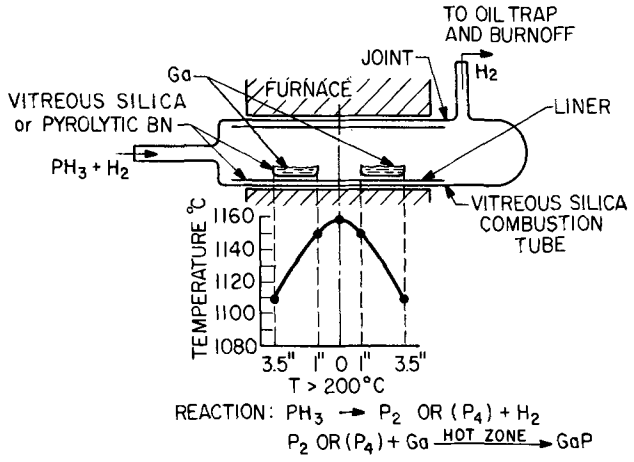

Fig. 1. Diagram of synthesis system with components and typical temperature gradient.

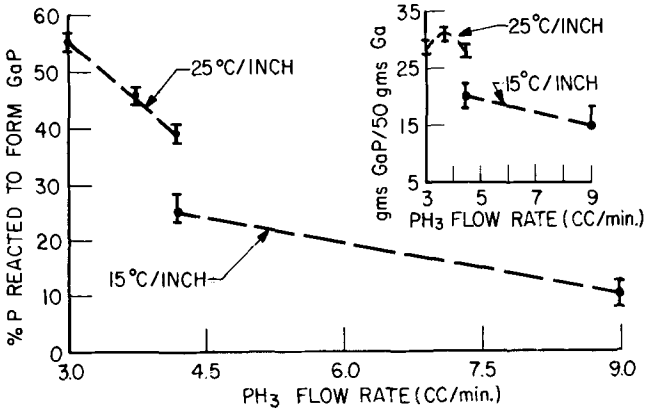

Fig. 2. Effect of PH_3 flow rate on average P reaction efficiency and GaP yield using temperature gradients of 15° and 25°C/in.

PH_3 used has been either a 3 or 5% PH_3 mixture in H_2 and has a total impurity content of less than 10 ppm.[2] For some experiments, He was substituted for H_2 as the carrier gas.

Furnace.—Figure 1 shows a diagram of the furnace, boats, and flow system, as well as a typical temperature gradient. The synthesis is carried out in a 1½ in. ID, three-zone resistance heated furnace with each zone controlled independently. The maximum temperature is controlled by a Pt-Pt 10% Rh thermocouple in the center zone. This furnace is capable of producing temperature gradients from 0° to a maximum of 40°-50°C/in. across the Ga-containing boats. Maximum temperatures of 1150°-1200°C were attainable with this furnace.

Boat and liner materials.—SiO_2 was always used as a combustion tube. One system used an SiO_2 liner and SiO_2 boats, the second system used an SiO_2 liner and PBN boats, and the third system used a PBN liner and PBN boats. The PBN liner used in this system was extended into the cooler ends of the furnace (600°-800°C) to minimize the formation of SiO in the vicinity of the reaction vessels.

Synthesis.—After cleaning the PBN and SiO_2 components in *aqua regia*, rinsing in D. I. water and alcohol, and drying, the SiO_2 combustion tube is placed into the furnace. The boats are loaded with 25g of Ga each and positioned in the liner. The liner is placed in the furnace in a position such that each boat extends from 1 to 3½ in. on either side of the center of the furnace. Helium, followed by hydrogen, is introduced to purge and clean the system. The PH_3 reaction mixture is then introduced. At the completion of the run, the PH_3 flow is stopped and He purge gas is introduced. The liner and boats are then removed from the system, while under He flow, and the Ga-GaP products are taken out of the boats and etched in hot HNO_3. After removal of the excess Ga by this acid treatment, the GaP is washed in D.I. water until no trace of acid is left. The GaP is dried and then baked out at 1-10 μm of vacuum at 300°-400°C to remove water.

Optimization of GaP Yield and P and Ga Reaction Efficiencies

Flow rates and length of run using an all-PBN system.—The reaction efficiency of P[3] to form GaP and the yield of GaP were examined as a function of flow rate. The reaction efficiencies are averaged over the total length of the run. The range of PH_3 flow rates examined was between 3 and 9 cc/min. The data are shown in Fig. 2. A nearly linear increase in P reaction efficiency as a function of decreasing PH_3 flow rate is observed for two different temperature gradients. At the same time, the GaP yield[4] is shown to reach a maximum of 29-32g at about 3.75 cc of PH_3/min with a 25°C/in. temperature gradient. Since a constant time interval is used with different flow rates, an increased P reaction efficiency does not necessarily mean an increased GaP yield. When either a 3 or 5% PH_3 mixture in H_2 was used to produce an equivalent PH_3 flow rate, the P reaction efficiency to form GaP and the GaP yield was found to be quite similar and relatively independent of the total H_2 flow rate used. The following explanation may be offered for the increased P reaction efficiency with decreasing flow rate.

When material was examined during the early stages of growth, it was found that upon cooling a crust of GaP had formed over the Ga. The crust formation is due to the lower density of GaP compared to Ga. Additional P can efficiently react with the Ga only when solution and diffusion of the reaction barrier from the hot end toward the cooler end of the boat are no longer rate controlling. Hence, increasing the PH_3 flow rate over that necessary to form the reaction barrier and maintaining a positive P pressure above the GaP will result in decreased over-all P reaction efficiency during a run.

An optimum time of about 72 hr was used for the synthesis. We found that this time resulted in a proper balance between total GaP yield, which does not increase significantly after this running time, and efficient conversion of P and Ga for a given flow rate and temperature gradient.

Temperature gradients using an all-PBN system.—In order to examine the relative importance of the solution and diffusion steps, yields were determined as a function of temperature gradient using the optimum flow rate for this system, 3.75 ± 0.3 cc of PH_3/min, and a 72 hr synthesis time. The concentration gradient is the driving force for the diffusion of the more soluble GaP at high temperature and its precipitation at lower temperatures. Increased diffusion of the dissolved GaP and its subsequent precipitation at the low-temperature end of the boat will consequently increase the reaction rate of P with Ga at the higher temperature to form more GaP. Symmetrical temperature gradients were examined over a 2½-3 in. length, the approximate length of the boats, on either side of a 2 in. center zone held at 1160° ± 10°C. Gradients of 15°-40°C/in. were investigated. Figures 3, 4, and 5 show the effect of temperature gradients on P and Ga reaction efficiency[5] and GaP yield.

For a flow rate of 3.75 ± 0.3 cc of PH_3/min, the GaP yield increased from 15 to 17.5g at a gradient of 15°C/in. to 35-38g with a 40°C/in. gradient. The corresponding increase in P and Ga reaction efficiencies were from 20-25 to 50-55%. Since only the temperature gradient was changed, not the maximum temperature

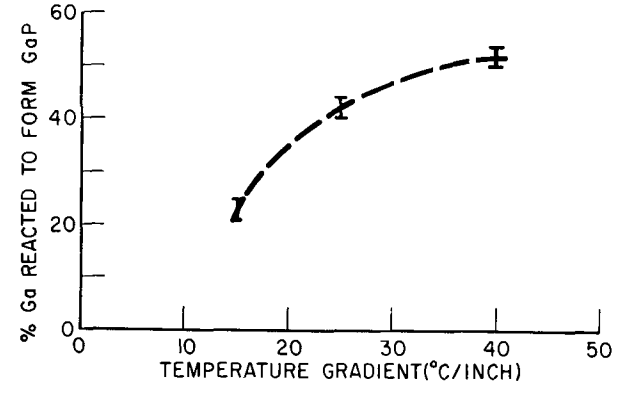

Fig. 4. Effect of temperature gradient on average Ga reaction efficiency.

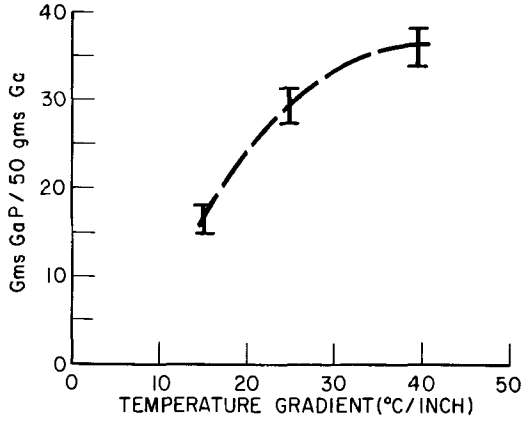

Fig. 5. Effect of temperature gradient on GaP yield

at the hot end of each boat (1150°C), the increased yield and conversions would suggest a diffusion-controlled reaction.

As seen from Fig. 3, 4, and 5, the increases in yields and reaction efficiencies tend to level off at the higher gradients. The deposition requires the diffusion of GaP from the hot end of the boat to the cooler end. By increasing the temperature gradient, and thereby the concentration gradient at the hot end of the boat, the diffusion rate should be proportionately increased. The data shown in Fig. 3-5 would then suggest the increased importance of the vapor-liquid interface reaction and/or the solution steps in the control of the reaction kinetics.

Due to furnace limitations, temperatures higher than 1200°C were not investigated. At these higher temperatures, higher PH_3 concentrations would be needed because of the higher dissociation pressure of GaP. If too high a temperature is used, an open-flow system becomes impractical because the P dissociation pressure could exceed atmospheric pressure and any yields would be drastically reduced.

Purity of GaP

Effect of liner and boat materials on purity.—All-PBN system.—The impurity content of the GaP using H_2 as a carrier gas in an all-PBN system was examined by: near band gap low-temperature optical absorption (5), a special analytical technique for Si (6), spark source mass spectroscopy (7), and inert gas fusion (8). Optically (5), the only substitutional impurity of the group N, S, Se, and Te found was nitrogen in concentrations of 3-6 x 10^{16} cm^{-3}. By HCl transport of a fixed quantity of GaP and weighing the SiO_2 residue, the total Si content was found to be less than 5 x 10^{16} cm^{-3} which is the detectability limit of this method (see Table I) (6). Mass spectroscopy (7), which is most sensitive for elements other than oxygen, nitrogen, and carbon, indicates that As and S probably derived from the PH_3 [6] are the only substantial impurities (see Table II). Inert gas fusion shows a concentration of total nitrogen and oxygen of about 10^{18} atoms/cm^{-3}.

Single crystals pulled from this material were usually n-type with carrier concentrations $\leq 10^{15}$ cm^{-3}, and electron mobilities in excess of 170 cm^2/V-sec, as determined by Hall measurements.

Silicon contamination.—If the PBN liner and boats are replaced by SiO_2 components, increased contamination by silicon is to be expected. In view of the potential cost reduction that is possible if SiO_2 material is used, the effects of such components on the purity of the GaP were examined.

Thermodynamics.—Some of the interactions to form Si, Si-SiO_2(SiO_x) in the GaP synthesis system are shown below (9).

The direct interaction of SiO_2 with Ga is given by:

$$SiO_2 + 2Ga \rightleftarrows SiO + Ga_2O \qquad [1a]$$

The equilibrium constant, K, for this reaction is defined as

$$K_{[1a]} = \frac{A_{SiO}\, A_{Ga_2O}}{A_{SiO_2}\, A_{Ga}}$$

where A = activity.

The activities of SiO_2 and Ga are unity. The reaction of SiO and Ga is

$$SiO + 2Ga \rightleftarrows Ga_2O + Si \qquad [1b]$$

The Si or the SiO (SiO_x solid) formed by reactions [1a] and [1b] or the sum of reactions [1a] and [1b] could then be incorporated into the Ga and GaP.

[6] As and S are not major contaminators of PBN, SiO_2, or Ga.

Table I. Si contamination in GaP(6)

*** Linear extrapolation of above data.

Another set of reactions involving a vapor-transport mechanism is also possible. In this set of reactions, direct contact of SiO_2 with Ga is not needed and we have instead

$$SiO_2 + H_2 \rightleftarrows SiO + H_2O \qquad [2a]$$

The equilibrium constant for this reaction is

$$K_{[2a]} = A_{SiO} A_{H_2O}/A_{H_2} \qquad [2a_1]$$

since $A_{SiO_2} = 1$.

The reaction of SiO from Eq. [2a] with Ga would then be the same as Eq. [1b] and Si or SiO could subsequently be incorporated in the Ga and GaP.

The water vapor formed by reaction [2a] can also interact with Ga and GaP as follows

$$H_2O + 2Ga \rightleftarrows Ga_2O + H_2 \qquad [3a]$$

$$H_2O + 2GaP \rightleftarrows Ga_2O + P_2 + H_2 \qquad [3b]$$

Free energy (ΔF) compilations for Eq. [1a], [1b], [1a] + [1b], [2a], [2a] + [1b], and [3a] are presented in Table III at different temperatures. The approximate equilibrium constants at 1073°, 1373°, and 1423°K for reactions [1a], [2a], and [3a] are also shown in Table III. Equilibrium constants for both the direct reaction of SiO_2 with Ga (Eq. [1a]) or the reduction of SiO_2 by H_2 (Eq. [2a]) are about 10^{-9} to 10^{-10} at 1150°-1100°C for both reactions. SiO mole fractions of approximately 10^{-5} can then be expected and some Si or SiO_x contamination of the GaP in measurable quantities seems reasonable. Due to the open-flow system and volatility of the reaction products, the kinetics of these reactions should be relatively high.

All-SiO_2 system.—In this system, both reactions [1] and [2] are applicable. The direct interaction of SiO_2 with Ga, the reaction of H_2 with SiO_2, and the possible solution of SiO in Ga or reduction of SiO by Ga can occur. Therefore, one would expect that synthesis in this system would result in the highest level of silicon contamination. As seen from Table I, the level of Si contamination is quite similar to the PBN boats-SiO_2 liner system. Thurmond and Kowalchik (10) found that Si in concentrations of 10^{20} cm^{-3} can be incorporated into GaP at 1050°C.

Since the solubility of Si in GaP has not been exceeded, it seems that reaction [2], the hydrogen reduction of SiO_2, may be of equal or greater importance than the direct reaction of SiO_2 with Ga in the incorporation of Si or SiO_x in GaP using this synthesis system.

SiO_2 liner—PBN boats.—In this system, the only mechanism for incorporation of Si into GaP is *via* reaction [2a]. The level of Si contamination was found to be 1.5×10^{19} atoms cm^{-3}. Since Luther and Verleur give an accuracy of ±30% for their analytical results (6), the Si contamination is about the same for this system as was obtained for the all-SiO_2 system. Therefore, no reduction in the level of Si contamination can be expected using boats other than SiO_2 when using an SiO_2 liner.

Effect of carrier gas on purity of GaP using a SiO_2-PBN system.—A distinct cost advantage can be realized using SiO_2 liners. Since high levels of Si contamination were observed using H_2 as a carrier gas in the SiO_2 liner-PBN boat system, an examination of the effect of the gaseous environment of that system to reduce the equilibrium SiO concentration was made. The equilibrium constant for reaction [2a], the vapor transport mechanism for Si contamination, is given by Eq. [2a$_1$]. If the H_2O pressure is increased using a constant H_2 pressure, the concentration of SiO will decrease. One can thus reduce the Si contamination by increasing the H_2O pressure (9), *i.e.*, by adding water vapor to the carrier gas. But from Eq. [3b], it follows that the addition of H_2O will increase the loss of GaP by the water-vapor transport reaction. Another method for reducing the Si contamination is to change the carrier gas from H_2 to He. By substituting He for H_2 according to Eq. [2a], the concentration of SiO should be reduced. However, some H_2 will be present because the reacting gas is PH_3. If the hydrogen pressure is 0.98 atm for the 95% H_2 gas mixture, by substitution of He for H_2 the H_2 gas pressure will be reduced to about 0.07 atm.

If X is the initial mole fraction of H_2 (0.98 or 0.07) and Y is the mole fraction of SiO or H_2O formed by reaction [2a], then $X - Y$ is the final mole fraction of H_2. Let the total pressure be P. If it is then assumed that the thermodynamic equilibrium constant, K, is equal to the one based on partial pressure, Eq. [2a$_1$] becomes

$$K_{[2a]} = \frac{Y^2 P^2}{(X - Y)P} = \frac{Y^2}{X - Y} \text{ since } P = 1 \qquad [4]$$

Since $K_{[2a]}$ is quite small (see Table III), Y is much less than X and therefore $X - Y \simeq X = 0.98$ or 0.07 depending on whether H_2 or He is used as the carrier gas. Equation [4] can then be simplified to

$$K_{[2a]} \simeq \frac{Y^2}{X} \text{ and } Y = (KX)^{1/2} \qquad [5]$$

If we then substitute the two values of the initial mole fractions of H_2, we obtain

$$\frac{Y_1}{Y_2} = \left(\frac{0.98}{0.07}\right)^{1/2} = 3.75 \qquad [6]$$

This value is quite similar to the threefold increase observed experimentally (see Table I) when 95% He is replaced by 95% hydrogen using the PBN boats-SiO_2 liner system. This result also substantiates the mechanism of reaction [2] and indicates that the kine-

tics of this reaction are reasonably rapid. The use of He as a carrier gas, rather than H_2, thus reduces the SiO concentration to about 1/3 and the Si content in GaP by a similar value. However, since the reactant gas contains PH_3, the H_2 mole fraction can be reduced only by about two orders of magnitude when using He. Therefore, the reduction of the SiO concentration by a factor of 10 is the maximum obtainable, which still leaves the Si content of the GaP at too high a value.

With water vapor, much greater reductions in SiO concentration can be realized although some oxygen doping of GaP may occur.[7] The use of He and water vapor should be more efficient in keeping the SiO concentration low than the H_2 and water vapor system, since less water vapor would be needed in the He system.

The addition of water vapor to the He carrier gas changes Eq. [4] to

$$K_{[2a]} = 2 \times 10^{-10} = \frac{YZ}{X - Y} \qquad [7]$$

where $X = 0.07$ is the mole fraction of H_2, Y is the SiO mole fraction, and Z is the H_2O mole fraction, equal to Y plus the water vapor added to the carrier gas. An H_2O mole fraction of 2×10^{-3} was added to the carrier gas. Hence, the resultant SiO mole fraction will be $Y \simeq 7 \times 10^{-9}$ under these conditions.

When the same calculation is made using hydrogen as the carrier gas, Y becomes 1×10^{-7}. Thus, using the same amount of water in the He system will reduce the SiO mole fraction by a factor of about 15.

GaP was prepared in an SiO_2 liner using PBN boats with a 95% He-5% PH_3 gas mixture containing about a 2×10^{-3} mole fraction of H_2O vapor. The material produced looked quite similar to that produced in an all-PBN system. The material was examined by optical fluorescence (11) and was found to have an optically active Si concentration of about 10^{16} cm^{-3}. The GaP yield obtained in these experiments was about 10% lower than comparable runs made without water.

Summary

Polycrystalline GaP was prepared in an open-flow system using the reaction of PH_3 with Ga to form GaP in pyrolytic boron nitride boats and liners in a temperature gradient. The spectrographic analysis of the material is shown in Table II. Optimization of synthesis time, PH_3 flow rate, and temperature gradient increased the P reaction efficiency from 10 to 50-55%, the Ga reaction efficiency from 20 to 50-55%, and the GaP yield from 15g/50g of Ga to 35-38g/50g of Ga. The increased P reaction efficiency and GaP yield with decreasing PH_3 flow rate was explained by the formation of a reaction barrier layer over the Ga. The increased yield and reaction efficiency with increased temperature gradient were suggested to be due to the solution of the reaction barrier layer and an increased driving force for the rate-controlling diffusion of GaP in Ga.

Pyrolytic boron nitride and water-free vitreous silica were used alone and in combination as liners and reaction vessels for the synthesis. It was found that the hydrogen reduction of SiO_2 produced as much, if not more, silicon contamination of the GaP as did the direct interaction of SiO_2 with Ga.

Since this hydrogen reduction reaction is so prevalent, experiments were performed to lower the Si contamination by examining this reaction. There are two ways to lower the SiO concentration: (*a*) increase the H_2O content of the gas and/or (*b*) decrease the H_2 content of the gas. The first method would decrease the GaP yield because of the water-vapor transport reaction with GaP. Therefore, the second method was investigated first by substituting He instead of H_2 as the carrier gas in the PBN boat-SiO_2 liner system. The use of He resulted in a threefold reduction of the Si contamination and produced material with a Si concentration of 5×10^{18} cm^{-3}. This reduction in Si is quite close to that theoretically calculated.

Since the H_2 content of the reactant gas cannot be lowered more than one to two orders of magnitude, the addition of water vapor to the carrier gas was examined in the SiO_2-PBN system. It was found that the optically active Si concentration in the GaP was reduced to about 10^{16} cm^{-3} when a 2×10^{-3} mole fraction of H_2O was introduced to the He-PH_3 gas mixture. Under the above conditions, the GaP yield was reduced by about 10% when water was added to the reactant gas. Thus, GaP of low Si content can be prepared in the presence of SiO_2.

[7] Water vapor may react with the PBN boats increasing the amount of nitrogen in the GaP. Analysis of crystals pulled from materials grown using water vapor in the SiO_2-PBN system indicated an optical nitrogen content similar to that obtained using an all-PBN system without water.

Acknowledgments

ABSTRACT

Determinations of the hydroxyl content of anodically and thermally grown silicon dioxide films by internal reflection spectroscopy in the infrared show that hydroxyl and silicon hydride are already incorporated into these films during their formation. The concentration, as well as the distribution, of these compounds within freshly formed anodic and thermal films is given.

In the investigation of silicon dioxide films which act as diffusion masks and protective coatings on semiconductor devices, the importance of the chemical purity of these films with respect to such applications has been shown [for review see (1)]. The chemical and electrical properties of thermally produced films, which have found wide applications in semiconductor device technology, have been investigated as well as those of anodically grown silicon dioxide films. The formation of relatively dense silicon dioxide films by anodization had been described by Schmidt and Michel (2). The electrical properties and the etching behavior, as well as other properties, were investigated by Schmidt and Rand (3) and by Pliskin and Lehman (4). These authors concluded that the insulating properties of such films depended highly on their hydrogen content. Dreiner (5) observed changes in the capacitance of the system silicon/anodic oxide/electrolyte, which depended on the time of exposure of the system to aqueous or water-containing electrolytes. From this he concluded that water or some hydrogen compound diffused into the anodic film at room temperature. Nannoni (6) reported changes of the electrical properties and also of the capacitance of the system silicon/anodic oxide/metal upon exposure to room air, which he also ascribed to the migration of hydrogen or hydrogen compounds into the oxide.

Studies of the influence of heat treatments in different ambients on the electrical properties of the silicon/silicon dioxide interface led several authors to the conclusion that hydrogen or hydrogen compounds might diffuse into the oxide (mostly thermal oxides) at elevated temperatures there forming hydrides or hydroxides [see (1, 7, 8)]. Radiotracer measurements of the distribution of hydrogen within silicon dioxide films thermally grown in tritium-tagged steam revealed high concentrations of hydrogen within these layers (9). By the same technique it was also shown that protons from ethanol adsorbed at the surface of thermal silicon dioxide films could be forced to migrate into the film at elevated temperatures by applying a bias between the silicon substrate and a metal electrode on top of the oxide (10). These methods could only reveal the presence of hydrogen within the oxide films, while no direct determination of the compound into which it was incorporated could be performed. Schmidt and Rand (3) and Pliskin and Lehman (4) reported an OH absorption band in the infrared absorption spectrum of anodically grown silicon dioxide, and Villemant and Kover (11) detected by the same method the presence of OH groups in films grown in wet oxygen and in those produced by hydrolysis of $SiCl_4$. These infrared spectroscopic investigations, however, were not sensitive enough to allow quantitative determinations of the concentration of these compounds.

For the above reason we performed quantitative measurements of the content of hydrogen compounds of anodic and thermal silicon dioxide films produced in different ways and after various postoxidation treatments. We used ellipsometry for the determination of film thickness and measured the infrared absorption by internal reflection spectroscopy (IRS) which offers a much higher sensitivity for measurements of the absorption by thin films than a simple transmission technique.

Experimental

The anodic films were grown on wafers of p-type silicon (15 ohm-cm) with optically polished faces (unoriented) in a 0.25*N* solution of KNO_2 in tetrahydrofurfuryl alcohol (THFA). In order to remove the polished layer and to achieve a well-defined crystalline state of the faces, all polished wafers were first covered with an oxide film several microns in thickness by thermal oxidation. This film was then removed by etching prior to the formation of the first anodic film to be measured. The growth of the anodic films was performed at constant current (10 mA cm^{-2} in most cases). The constant current generator used allowed a certain voltage to be preset, at which it automatically switched over to constant voltage operation (crossover). This voltage was set according to the film thickness wanted. After crossover the current was in most cases allowed to decrease to one tenth of its original value, which took approximately 10 min for a film thickness of 300Å and 25 min for 1000Å. During this period of constant voltage operation the film continued to grow, however, with a growth rate decreasing with time. After this time the wafer was removed from the electrolytic cell, rinsed in methanol, and dried in a stream of warm air. The thermal films were formed in an oxygen atmosphere or in oxygen saturated (at 85°C) with water vapor, at temperatures between 1050° and 1200°C.

The thicknesses of these films and the indexes of refraction were determined ellipsometrically with a Rudolph 43603-200 E thin film ellipsometer. The calculation of the film thickness and refractive index from the ellipsometer data was performed on a computer by using Fresnel's equations and the exact expression for the amplitude reflection coefficients of a thin film.

The infrared absorption by these thin films had to be measured by using the technique of internal reflection spectroscopy (IRS) as developed by Harrick (12), because of the small film thickness and the low number of absorbing bonds. We used a differential setup as shown in Fig. 1. A beam of monochromatic infrared radiation is split into two by a beam splitter (BS) (silicon plate). The transmitted portion is focused on the entrance face of the oxdized wafer which

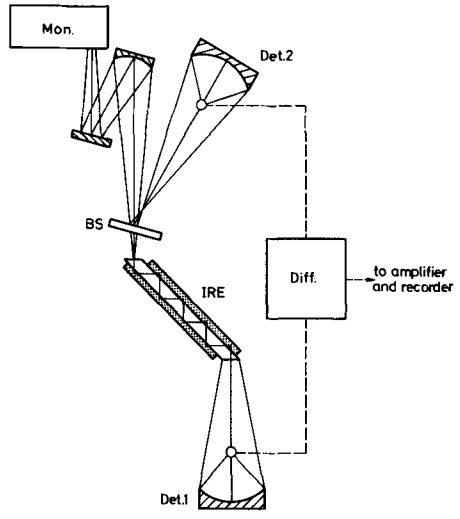

Fig. 1. Setup for the differential measurement of the infrared absorption spectrum of a thin film on a substrate (internal reflection element, IRE) by internal reflection spectroscopy (IRS). (Mon: monochromator; BS: beam splitter; Det: ellipsoidal mirror-detector unit; Diff: unit for the attenuation of the electrical signals and for the formation of the differential signal.)

is shaped in a trapezoid form so that it acts as an internal reflection element (IRE) [see (12)]. At the totally reflecting silicon/silicon dioxide interface, absorption of radiation occurs at those wavelengths at which absorption bands of the molecules incorporated into the oxide film exist. Since the beam suffers a great number of total reflections before leaving the wafer, the attenuation of the light intensity by absorption processes within the thin oxide film is amplified. This can be seen by comparing the two ordinate scales of Fig. 2. In the investigation of anodic films we used 60 reflections, and with thermal films 180 reflections were employed. Thus, absorption signals much larger in strength than those which could be obtained by one normal transmission through the films on both sides were obtained. After leaving the wafer the light of intensity, I, is focused on a thermocouple (Det. 1). That part of the incident beam (I_0) which is reflected at the beam splitter (BS) (reference beam) is focused on a second thermocouple (Det. 2). By this differential technique the relatively high level

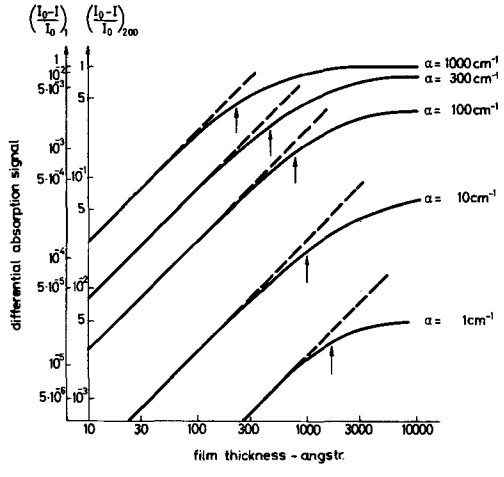

Fig. 2. Calculated dependence of the differential absorption signal for 1 (left vertical scale) and 200 (right vertical scale) reflections on film thickness for different magnitudes of the thin film's absorption coefficient. The other optical parameters needed for the calculation are those of the system silicon/silicon dioxide film ($\lambda = 3$ μm). The dashed lines give the slope of the same curves for the case of normal transmission through the films.

of the signal corresponding to the light intensity incident on the detectors can be suppressed. Thus, it is possible to choose the highest possible electronic amplification for the differential absorption signal. If absorption peaks due to the oxide film appear in the spectrum, this differential signal is thus proportional to the change in transmittance ($I_0 - I$) of the film-covered IRE. Since the magnitude of the intensity of the light in the wafer beam at the wavelength of absorption, I_0, is also determined by measuring the single beam spectrum at much lower electronic amplification, the expression $(I_0 - I)/I_0$ can be calculated.

Quantitative Evaluation

For a quantitative determination of the absorption constant from the transmission spectrum, the path length of the radiation within the absorbing medium has to be known. Since the spatial distribution of the energy flow within the rarer medium during total reflection follows a complicated pattern (13), no path length of the radiation within the absorbing medium can be defined in this case. On the other hand the validity of the concept of effective thickness (14) is limited to small values of the absorption coefficient. We therefore used for the evaluation of the absorption signals Fresnel's equations and the exact expressions for the reflectivity of a thin film on top of a substrate [see, *e.g.*, (15)]. By these relations the energy distribution within the rarer medium as well as the boundary conditions, *etc.*, are being properly taken into account. Since these relations cannot be solved for the absorption coefficient, this quantity was determined by a trial-and-error procedure on a computer.

To calculate from a measured absorption peak the number of absorbing bonds, the effective charge of the oscillating group has to be known. From this magnitude the strength of absorption per concentration unit of the oscillating group (absorption cross section, molar absorbance or molar extinction) may then be calculated. These values have been determined experimentally for the case of hydroxyl in fused quartz (16-18), but these data show only a poor agreement. In this publication we use the relation between the integrated absorption and the number of absorbing groups as given by Kats (16).

This relation, however, refers to the case of free oscillating OH groups. It is known that in the case of hydrogen bonding the integrated absorption at the fundamental frequency may be increased by a factor of up to 10 (19). One can see that the OH vibration within anodic oxide films at 3375 cm^{-1} (2.98μ) has a half-width of 435 cm^{-1}, whereas that within thermal oxide at 3600 cm^{-1} (2.78μ) has a half-width of 130 cm^{-1} (see Fig. 3). As we have proved by measuring the deuteration shift, both vibrations are due to the

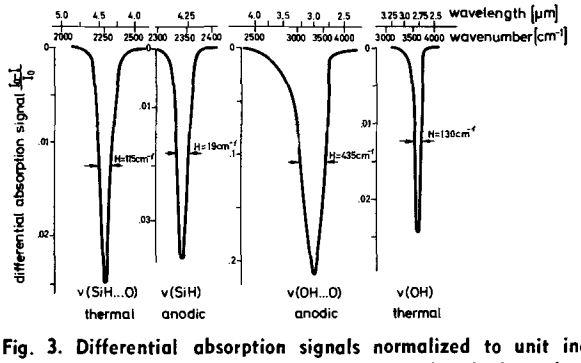

Fig. 3. Differential absorption signals normalized to unit incident intensity for four absorption peaks obtained with thermal and anodic silicon dioxide films. ν(OH), Fundamental O-H stretching vibration in thermal films; ν(OH. . .O), fundamental O-H stretching vibration in anodic films (hydrogen bridging); ν(SiH), fundamental Si-H stretching vibration in anodic silicon dioxide films and ν(SiH. . .O) of hydrogen-bonded silicon hydride as found in thermal films.

fundamental OH stretching vibrations. Therefore the difference between the two wave numbers measured with differently produced films as well as the increase in half-width demonstrates that the anodic film contains hydrogen bonding OH groups, whereas the OH vibration in thermal oxides occurs relatively free.

It has been found that in the presence of hydrogen bonding the integrated absorption by the fundamental vibration increases with the frequency shift, due to the same effect (20). Since quantitative results concerning these relations in the case of hydroxyl groups within an oxide lattice do not exist, we can only assume that this increase in the integrated absorption is a function of the frequency shift. In the system phenol/diethyl ether, a frequency shift of 270 cm^{-1} and an increase in the integrated absorption by a factor of 6.9 has been observed (21). Since we found a shift of 225 cm^{-1} due to hydrogen bridging, we assume an increase in the integrated absorption by a factor of 5. This relation looks reasonable also in view of the fact that the half-width of the stretching vibration band of hydrogen-bridged OH is 3.35 times greater than that of the "free" OH (see Fig. 3). Therefore we corrected the expressions given by Kats (16) for this influence of hydrogen bonding on the strength of absorption. The equation for estimation of the concentration of OH groups per cubic centimeter in the presence of hydrogen bonding reads

$$N_{OH\ldots O} = 0.4 \cdot 10^{16} H \alpha_{max} \quad [1]$$

where H, the half-width and α_{max}, the absorption coefficient at the fundamental frequency, are given in cm^{-1}. In the absence of hydrogen bonding, this equation becomes

$$N_{OH} = 2 \cdot 10^{16} H \alpha_{max} \quad [2]$$

There are, however, no literature data available concerning the absorption cross sections of the silicon-hydrogen valence vibration ν(SiH). We therefore calculated the partial charge resident on the hydrogen atom of SiH incorporated into a SiO_2 lattice using data given in the literature (22), and with this value the calculation of the specific absorption (23) could be performed. In this calculation the index of refraction of the thin film was taken as 1.4. This leads to the relation for unbonded SiH

$$N_{SiH} \approx 7.5 \cdot 10^{17} H \alpha_{max} \quad [3]$$

where H and α_{max} have the same meaning as is Eq. [2], now referring only to the SiH absorption band.

Comparing the SiH absorption bands shown in Fig. 3 one has also to conclude that SiH may be subjected to hydrogen bonding, since with thermal oxide we observe a band shifted to greater wavelengths and increased in half-width with respect to that obtained with anodic oxide. Referring to the arguments used in the calculation of the OH vibrations, we take the increase in half-width as a measure for the increase in the specific absorption. Thus, we may use for the estimation of the SiH concentration

$$N_{SiH\ldots O} \approx 10^{17} H \alpha_{max} \quad [4]$$

Since the magnitudes inserted into the relations [1-4] contain several uncertainties, these determinations can with respect to the absolute value of the SiH concentration be regarded only as an estimation of the order of magnitude. For the relative values, however, a greater accuracy can be claimed (±50%).

When determining the absorption coefficient by using Fresnel's equations for a boundary between different media, it is implied that these media and the thin film which are involved in this process of total reflection are homogeneous, especially that the absorption coefficient is constant throughout the film. Since the concentration of the absorbing groups will be calculated from the absorption coefficient thus determined, a constant distribution of the oscillators within the thin film is also assumed. As is seen from the results, this is not always the case. This is the reason the concentration thus determined is called the average concentration.

The question remains, what information can be obtained regarding the distribution of these oscillators within the film from measurements of the *IR* absorption. If we assume that the concentration, c, of the groups to be studied varies with the distance, x, from the silicon/silicon dioxide interface, $c = c(x)$, and that—as in a transmission experiment—the whole radiation passes through the whole film, then we could define the average concentration measured by one such experiment

$$c_{av}(t) = \frac{1}{t} \int_0^t c(x)\, dx \quad [5]$$

where x indicates the distance from the Si/SiO_2 interface and t the film thickness. If we reduce the film thickness stepwise by successive etching of the film and if we measure the *IR* absorption after each etching process, we may determine $c_{av}(t)$ as a function of the remaining film thickness, t. To calculate from this plot the dependence of the (local) concentration, $c(x)$, on the distance from the Si/SiO_2 interface for the original film, we derive from [5]

$$c(x) = \frac{d}{dt}(t\, c_{av}(t)) = c_{av}(t) + t \frac{dc_{av}(t)}{dt} \quad [6]$$

or, in a difference expression, if $c(t_1)$ and $c(t_2)$ are the concentrations found with thicknesses t_1 and t_2, for $x = (t_1 + t_2)/2$

$$c(x) = \frac{t_1 c_{av}(t_1) - t_2 c_{av}(t_2)}{t_1 - t_2} \quad [7]$$

(local concentration)

However, these relations apply only when the radiation penetrates practically through the entire film. Since in the case of total reflection—which is applied in IRS—the intensity of the light within the rarer medium shows an exponential attenuation with distance from the silicon/silicon dioxide interface even in the absence of absorption, the applicability of Eq. [6] and [7] has to be checked.

This has been done in Fig. 2. This figure shows a plot of the change in the intensity transmitted by the IRE normalized to unit incident intensity, $(I_o - I)/I_o$ (as defined in Experimental), calculated on a computer by using the exact equations, as a function of film thickness for different values of the absorption constant, α, for 200 total reflections, $(I_o - I/I_o)_{200}$, and (left scale) for one reflection, $(I_o - I/I_o)_1$. The dashed line gives the slope of the same expression *vs.* film thickness for one normal transmission of the film; that means for the case where the whole film contributes fully to the absorption signal. The absolute values—to which the left scale refers—are slightly smaller in this case because of the smaller path length. As long as there is no appreciable difference between the corresponding dashed and full drawn curves, we may assume that also in the case of total reflection practically the entire film contributes fully to the absorption signal so that relations [5-7] remain applicable. The arrows indicate the film thicknesses at which the contribution to the absorption of the region more distant from the Si/SiO_2 interface is 25% smaller than the contribution of that part adjacent to that interface. We wish to emphasize that this is taken into account exactly in the calculation of α for the case of a constant α throughout the film. If in the case of thicker films the outer region has a greater absorption constant than the inner, the average concentration of absorbing groups thus determined will be smaller, and in case of smaller absorption constant in the more distant part it will be larger than the concentration determined from a transmission measurement.

Finally, the total number of absorbing groups is defined as the number of absorbing groups within the whole film per square centimeter area.

Since all the measurements had to be performed in room air, some difficulty arose due to the adsorption of water and hydrocarbons at the surface of the IRE during the measurements which led to absorption bands at 3355 cm^{-1} (2.98μ) for the OH- and at 2857 cm^{-1} (3.50μ) for the CH-stretching vibration (24). Since the bands of adsorbed and of OH-groups built into the film occur at the same wavelength, a correction was required, especially with very thin anodic films ($t < 50$Å).

Since we found with, *e.g.*, very thin thermal films into which no hydroxyl groups had been built in that the ratio of the amount of hydrocarbons to that of water adsorbed at the surface was practically constant, we took the strength of the CH-absorption band as a measure of the degree of adsorption. The contribution of the adsorbed species to the optical absorption could thus be subtracted from the measured signal.

Results

Figure 3 shows the absorption bands which were recorded with anodic and thermal silicon dioxide films. As already pointed out in the preceding paragraph, the anodic films contain hydrogen bonding hydroxyl, whereas these groups are relatively "free" in thermal oxide. This assignment could be proved by deuteration of these groups which led to absorption peaks at approximately 1.4 times the original wavelength. The assignment of the peaks near 4.25 and 4.5 μm to the SiH stretching vibrations could not be checked directly by this method since the deuteration of these compounds would shift the absorption peaks to 6.0 or 6.3 μm, respectively. In this wavelength region certain combination vibrations of the oxide lattice occur so that the transmission of the internal reflection element is very low. We could perform only an indirect deuteration check, since these peaks decreased in strength upon heat treatment in deuterium gas, and they increased again upon subsequent heat treatment in hydrogen. Furthermore, it has been shown (23) that the SiH stretching vibrations in an oxidic lattice are positioned near $\lambda = 4.4\mu$.

The dependence of the initial average OH concentration of anodic films on several parameters of the film formation is shown in Table I. The given average concentrations are the mean values obtained with several films. We wish to point out that the error in these determinations is about ±50%.

We see from lines *a*, *b*, and *d* of Table I that the OH content of the anodic oxide films is reduced by keeping the film at the crossover voltage for some time. For an estimation of the relative concentration of these groups in the oxide lattice, one should bear in mind that, *e.g.*, fused silica contains 2.3 x 10^{22} SiO_2 groups/cm^3. By forming the anodic films in a solution the water content of which had been reduced from 300 ppm to 60 ppm with the aid of molecular sieves, a lower OH concentration may be achieved. Thus the water present in this electrolyte has to be regarded at least as one of the sources for the OH groups incorporated into the film. Line *e* of Table I indicates that during anodization [see (3)] the number of hydroxyl groups does not increase, as can be seen from line *f* of this table where are given the data of the thermally produced film prior to anodization.

Thermal films produced in wet oxygen at 1050°C contain 10^{19} OH groups/cm^3. No OH groups could be found with films produced in "dry" oxygen (which contained 60 ppm H_2O). For this reason the smallest amount detectable with our apparatus is inserted in lines *i*, *k*, *l* as the upper limit of a possible OH content. By a heat treatment at 530°C in wet nitrogen (this gas was saturated with H_2O at 85°C), the concentration can be increased with both oxides to approximately 2 x 10^{19}. This seems to be the saturation concentration for heat treatment at this temperature, since a prolonged annealing did not result in a further increase of the concentration.

Table II gives the concentrations of the silicon hydride groups found in different oxides. The most surprising result is that, after formation of the oxide film in a "dry" oxygen atmosphere, such a high concentration of silicon hydride groups has been found. Determinations of the water content of this oxygen gas, however, demonstrated that the humidity amounted to 60 ppm. We see from Table II that the silicon hydride concentration may be increased by subsequent heat treatment in hydrogen, whereas this process has practically no influence on the concentration of the hydroxyl groups. Silicon hydride groups in anodic films can be made to disappear by heat treatment at 300°C. Such a treatment only results in a small reduction (by 30%, approximately) of the hydroxyl content. Annealing the anodic films at 500°C in dry N_2 leads to a shift of the OH absorption band to $\lambda \approx 2.78$ μm. This indicates that the hydrogen bonds are being broken at this temperature.

Figure 4 shows the dependence of the average concentration of OH within anodically grown films on the remaining film thickness during step etching. One of these films had been kept at the crossover voltage in the forming solution for about 10 min, until the current had decreased to one tenth its original value. The other film was kept at this voltage for 24 hr. The local concentrations have been calculated by using Eq. [7]. The fact that the local concentration is smaller than the average concentration at greater distances from the interface indicates that there must be a very high

Table I. Initial average concentrations, c_{av}, of OH-groups determined immediately after formation

	Type of film	Kind of formation + treatment given after formation	Thickness, A	c_{av}, cm^{-3}
a	Anodic	Pulled out at crossover[1]	130	$8 \cdot 10^{20}$
b	Anodic	Normal[2]	330	$2 \cdot 10^{20}$
c	Anodic, in dry THFA[3]	Normal[2]	330	10^{20}
d	Anodic	24 hr kept at crossover[4]	327	$3 \cdot 10^{19}$

For explanations see Table I.

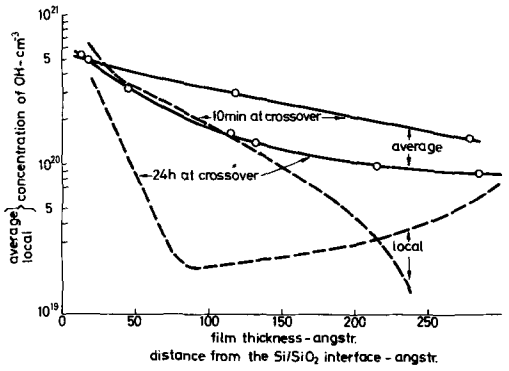

Fig. 4. Variation of the average concentration, c_{av} (vs. film thickness), and local concentration, c_{loc} (vs. distance), of hydroxyl determined from the absorption peak at 2.98 μm within anodic oxide films produced in a 0.25*N* solution of KNO_2 in tetrahydrofurfuryl alcohol. The solution was dehydrated by molecular sieves. Film formation at 10 mA cm^{-2}.

concentration of absorbing groups near this interface. One observes that an appreciable reduction of the local concentration happens almost throughout the film upon keeping it for 24 hr at crossover voltage, whereas a steep increase of this density can be seen near the Si/SiO_2 interface.

As has been stated in Table I, there are practically no OH groups present in thermal oxide films formed in "dry" oxygen, but they contain a great number of silicon hydride groups. Their distribution within the film is shown in Fig. 5. Since this film was 10,000Å thick, the outer regions are only weakly coupled to the evanescent wave. For this reason there is an increasing uncertainty in the concentration thus determined above 1000Å as has been described in the paragraph "Quantitative Evaluation."

Figure 6 shows the distribution of hydroxyl groups in an oxide film thermally produced in an oxygen

atmosphere which has been saturated with water vapor at 85°C. The distribution of the silicon hydride groups within the same film is shown in Fig. 7.

Conclusions

As has been found earlier, there exist structural differences between thermal and anodic silicon dioxide films (3). Nevertheless it is surprising that in anodic films hydroxyl groups show hydrogen bonding and silicon hydride does not, whereas with thermal films one observes hydrogen bonding SiH and nonbonded hydroxyl. This at least indicates that hydroxyl, as well as hydride groups occupy well-defined sites in both oxides.

From the results reported here, nothing can be said concerning the kind of compound into which the OH groups detected are incorporated; *i.e.*, whether they belong to SiOH or H_2O. The characteristic combination vibrations by which this question could be answered could not be detected by us.

The mean values of our results are summarized in Tables I and II and indicate that one of the sources for hydroxyl groups found with anodic films might be water present in the electrolyte, since we obtained a smaller average concentration of OH with an electrolyte dehydrated by molecular sieve. The fact that the OH concentration (see Fig. 4) within anodically grown films is markedly reduced throughout the film by keeping it for 24 hr at the crossover voltage (Fig. 4) indicates a consumption of hydroxyl at this anodic polarization. The increase of the concentrations toward the silicon-silicon dioxide interface points out that there must be a migration of the OH groups to the Si/SiO_2 interface under the action of the applied field which finally results in the further oxidation of silicon at the interface. In this reaction the oxidation process must be the rate-determining step thus leading to a higher concentration near the interface with respect to the interior of the film. In addition, however, one has to state that the supply with OH from the electrolyte is also reduced at the crossover voltage, since otherwise the over-all decrease of the hydroxyl concentration could not be explained.

The results obtained with thermally produced films are in good agreement with the data published after radiotracer measurements of the hydrogen content of such films (9, 10). A comparison of our findings with the concentrations published in these papers allows the conclusion to be drawn that at least an appreciable fraction of the hydrogen atoms present in such films is incorporated as hydroxyl or as silicon hydride.

A consumption of hydroxyl groups during the thermal oxidation process, too, is indicated by Fig. 5, 6, and 7. The decrease of the OH and the increase of the SiH groups near the interface may be explained by a reaction of silicon atoms with hydroxyl leading to silicon oxide and to some extent also to silicon hydride bonds. The same refers to the "dry" oxide since we have already mentioned that the oxygen used for oxidation contained some water.

Further experiments which may yield some insight into the diffusion mechanism of hydrogen or hydrogen compounds in anodic films, as well as such which may give additional information regarding the influence of hydrogen and its compounds on the electrical properties of the Si/SiO_2 interface [see, *e.g.*, (1) and (7)] are being undertaken.

Acknowledgments

The authors gratefully appreciate the assistance of Ing. Th. Tempelmann and Ing. C. Wiech in the performance and evaluation of the measurements. Thanks are due to Dr. E. Kooi and Ir. J. J. H. Schatorjé from Philips Research Laboratories, Eindhoven, for the growth of the thermal films. They also express their gratitude to Dr. R. Memming for valuable discussions.

Manuscript submitted April 20, 1970; revised manuscript received Aug. 24, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Video Display of X-Ray Images

I. X-Ray Topographs

Eugene S. Meieran

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

This paper discusses in detail the direct viewing of x-ray topographs via a secondary electron conduction (SEC) vidicon system. The various geometries used to record large area topographs, the theoretical and experimentally obtainable resolutions, and the applications of the different geometries for obtaining information about the defects within crystals are illustrated. Finally, some qualitative comparisons of a practical nature are made with other video systems used for recording x-ray topographs.

Approximately thirteen years have passed since Lang first described the transmission x-ray topographic technique for studying nearly perfect crystals, the technique that now bears his name (1, 2). Subsequently, several hundred papers concerned with both theoretical and experimental aspects of Lang topography have been reported. However, although there have been numerous modifications to the technique for particular applications (3-5), Lang topography in most common use today remains essentially the same as when first introduced.

In Lang topography, a crystal oriented for diffraction from a set of crystal planes is translated or scanned through a narrow characteristic incident x-ray beam; an x-ray sensitive film fixed to the (moving) crystal and normal to the diffracted beam records the diffracted beam intensity as a function of translation position, and is the Lang topograph of the crystal. In the topograph, defects appear as dark images on a gray background, since the defective areas of the otherwise perfect crystal diffract more integrated x-ray intensity than do the surrounding perfect areas, during the scan of the crystal through the incident beam. The film used to record the topograph is generally a high-resolution nuclear tracking plate with a thick emulsion (for example, Ilford nuclear plates, emulsion L-4, 50 μm thick). However, in spite of this thick emulsion, the recording of a topograph requires a long exposure as well as film processing time; in general, several hours pass before a topograph of even a small crystal can be viewed. Faster films can be used with a significant reduction in exposure time; this results in lower resolution topographs that still require some exposure time as well as film processing time. Furthermore, the films must be enlarged photographically for viewing, since the Lang topograph is recorded at unit magnification.

X-ray topography has provided much valuable information about the defects within semiconductor crystals. This information is useful for showing the possible effect of defects on devices made from the crystals. However, due to the time delay before an x-ray topograph can be viewed, Lang's method has found its way into production or quality control use only on a limited basis, since for these purposes large numbers of topographs need to be taken and viewed within a short period of time. Often a permanent record of the topograph is not required; all that is

Key words: x-ray topography, Laue patterns, television systems, semiconductor crystals, crystal defects.

necessary is a go, no-go analysis of the topograph. Consequently, there have been several attempts by semiconductor manufacturers to develop rapid methods for imaging topographs via video display techniques. While the reports of these efforts are rather superficial, they have shown that there are several ways of converting an x-ray signal into an instantly viewable television image, with reasonable resolution. Although this resolution must be improved by at least an order of magnitude before it can compete (in resolution) with film recording, the results to date are nonetheless encouraging. A topograph that may require several hours to record and process on film may now be viewed instantly, with reasonable magnification. So far as contrast is concerned, the video display does not compare to film recording, since the dynamic range of the video system is limited compared to the best x-ray films. However, the contrast does compare favorably to some of the faster, lower resolution films.

Four different systems for displaying x-ray topographs on a television monitor have been described within the past year. These are the PbO plumbicon, used in conjunction with an extremely high intensity x-ray source (6), the silicon diode array (7, 8), the cascaded image intensifier (9), and the combination image intensifier-SEC vidicon camera (10). The latter three systems use conventional x-ray sources. Other x-ray vidicon systems used for converting x-rays to a television picture, used primarily for radiography or medical fluoroscopy, are not suitable for x-ray topography due to a lack of sensitivity to the low intensity diffracted x-ray beams, or to low resolution.

This paper discusses in more detail the SEC (secondary electron conduction) vidicon system reported earlier (10). Special attention is paid to details of the optical system and geometrical arrangements used, and to factors affecting image quality. Finally, examples of the application of the television system to the study of defects in silicon crystals are shown. In the following paper (Part II), use of the television system for the orienting of silicon wafers or crystals via transmission or back reflection Laue patterns is illustrated.

Imaging System

The imaging system described here consists of four major components: a standard x-ray tube supplying characteristic x-rays, a diffracting crystal mounted on an x-ray camera, an x-ray sensitive phosphor screen that converts the diffracted x-rays into a visible light image, and an L^3-TV (low light level television) system that transforms the optical image into a television picture displayed on a monitor. Each portion of this over-all system will have some effect on the quality of the final image, and will be discussed separately.

X-ray source.—Geometry.—There are three general geometrical arrangements for taking large area x-ray topographs, and each arrangement has different advantages, disadvantages, and geometrical resolutions.

First, a topograph may be taken in transmission or reflection geometry by using a small point focus x-ray source and a set of collimating slits, and scanning the crystal through the narrow beam in a direction parallel to the surface of the crystal. The collimating slits limit the diffracted beam to a single component of the $K\alpha_1$-$K\alpha_2$ doublet. In transmission geometry (the normal Lang technique), a second set of slits must be placed between crystal and film, which is scanned synchronously with the crystal, in order to prevent the transmitted direct beam from exposing the film. The scanning method has high resolution, since the x-ray focal spot is small, and the imaging phosphor or film can be placed reasonably close to the sample (11). The only inconveniences of this geometry are the necessity of scanning the crystal and film continuously during exposure, and the long exposure times. Virtually every crystal orientation can be imaged by this

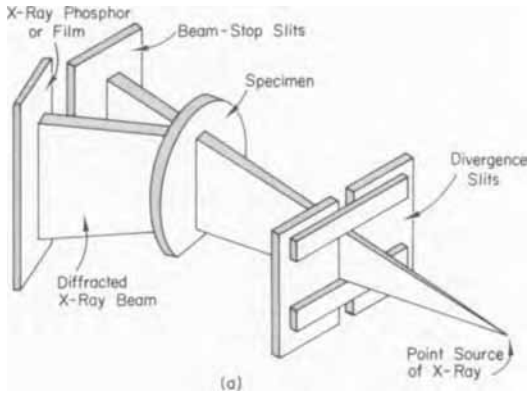

Fig. 1a. Schematic illustration showing geometry of x-ray topographic arrangement: scanning method using a point source of x-rays, transmission geometry.

arrangement, which is schematically shown in transmission geometry in Fig. 1a. This method may be slightly modified by holding the film stationary and scanning only the crystal at an angle ϕ with respect to the normal scan direction, *i.e.*, at an angle to the surface of the crystal. By choosing the appropriate angle ϕ, a width W on the crystal will expose a width W on the stationary film, giving an angularly undistorted large area picture (12). While the vertical resolution is not constant over the scan, since the crystal-to-film distance varies during the exposure, the fact that the film or other x-ray sensitive screen is stationary makes the technique valuable for high resolution direct viewing topography.

A point source of x-rays and set of collimating slits to limit the diffracted beam to the $K\alpha_1$ component are also used in the second arrangement. However, the sample geometry is selected such that the narrow beam of incoming x-rays impinges on the sample at a very shallow angle to the surface, and the diffracting planes and x-ray radiation wavelength are chosen to give diffraction angles 2θ of about 90°. Due to the shallow incidence angle, even the narrow beam illuminates a large area of the sample, which consequently need not be scanned through the incident beam (13). Since the diffracted beam is almost at right angles to the incident beam, the beam-stop slits are not necessary, and as an added advantage, the image of the surface is almost undistorted angularly, as shown in Fig. 1b. This geometry has high resolution and provides large area undistorted topographs of stationary crystals, and with relatively short exposure times. The major inconvenience of this method is that only particular x-ray wavelengths and crystal planes are usable; most common wafer orientations do not satisfy the geometrical conditions.

The third arrangement is to use a horizontal line source of x-rays, along with the geometry of Fig. 1a. Since an area of a wafer as wide as the line focus of

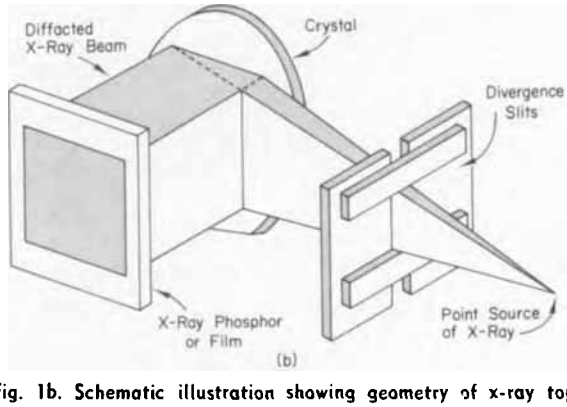

Fig. 1b. Schematic illustration showing geometry of x-ray topographic arrangement: stationary method using a point source of x-rays and a specially oriented crystal, reflection geometry.

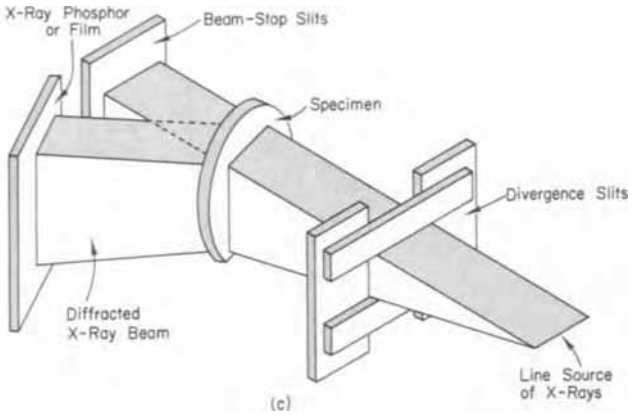

Fig. 1c. Schematic illustration showing geometry of x-ray topographic arrangement: stationary method using a line source of x-rays, transmission geometry.

x-rays is long can diffract at any instant, the sample does not have to be continuously scanned (14, 15); however, in order to examine a larger crystal, a simple mechanism for sample translation must be provided. This geometry can be used for transmission or reflection topographs of most common wafer orientations. The resolution of this method is poor compared to the previous methods, since, in general, the $K\alpha_1$ as well as the $K\alpha_2$ image appears and the x-ray detector must be placed far from the crystal in order to spatially separate direct and diffracted beams. The geometry of method 3 is shown in Fig. 1c.

These three geometrical arrangements are not completely distinct from one another; for example, methods 1 and 2 merge if the Bragg angle θ approaches 45° and the area of the crystal irradiated at any instant becomes large enough to display all the information desired. Similarly, methods 3 and 2 overlap if the Bragg angle is such as to give separate $K\alpha_1$ and $K\alpha_2$ images, irrespective of focal spot size.

For all work reported here, General Electric CA-7 Cu or Mo target x-ray tubes with a 1 mm spot or 1 mm x 10 mm line, were employed. The tubes were operated at 45 kV, 15 mA, with suitable $K\beta$ filters. The filters helped prevent stray ghost images which would strike the x-ray sensitive screen and contribute to background noise.

Resolution.—The geometrical resolution of x-ray topographs, arising from the finite size of the x-ray focal spot and divergence of the incident beam, can be separated into vertical and horizontal components (11). For a first approximation, the horizontal resolution is considered to be dependent only on the separation of the $K\alpha_1$-$K\alpha_2$ doublet and on the distance of the x-ray film from the crystal. If the $K\alpha_2$ component is suppressed, a geometrical horizontal resolution of about 2 μm results. However, if the $K\alpha_2$ component contributes to the image, double images of separation $D\Delta\theta_{1\text{-}2}$ are observed, where D is the distance of the imaging screen or film from the crystal, and $\Delta\theta_{1\text{-}2}$ is the angular separation of the $K\alpha_1$ and $K\alpha_2$ components. This gives an apparent resolution on the order of 40 μm, for most applications. (The true spatial resolution in a topograph containing double images due to the $K\alpha_1$ and $K\alpha_2$ components is still a few microns; however, for the purposes described here, the apparent resolution given by $D\Delta\theta_{1\text{-}2}$ will be used, since the double images appear as if a single smeared image.) The vertical resolution depends on the height h of the x-ray focal spot, the distance L of the crystal from the focal spot, and on D, and is given by $R = Dh/L$. For all geometries described above, h is generally small and L is large, and the vertical resolutions are on the order of a few microns.

For the first and second geometries above, the horizontal resolution is also on the order of a few microns, since the $K\alpha_2$ image is suppressed, the x-ray focal spot is small and is distant from the crystal, and the imaging screen or film can be placed close to the crystal. The third arrangement has low horizontal resolution due to the large D (on the order of 5 cm) and the wide beam divergence leading to the appearance of both $K\alpha_1$ and $K\alpha_2$ images; this point will be discussed later.

Table I. Resolutions of various x-ray geometries

	L, cm	Focal spot, mm × mm h	l	D, cm	Resolution, μm Vertical	Horizontal	2θ
Method 1							
(220) Si, Mo $K\alpha$, transmission	100	1	1	1	10	3	21°
	50	0.1	0.1	1	2	3	
(440) Si, Cu $K\alpha$, reflection	100	1	1	0.5	5	5	105°
	50	0.1	0.1	0.5	1	3	
Method 2							
(440) GaAs, Cu $K\alpha$, reflection	100	1	1	0.5	5	5	95°
	50	0.1	0.1	0.5	1	3	
Method 3							
(220) Si, Mo $K\alpha$, transmission	50	0.1	0.1	5	10	40	21°
(440) Si, Cu $K\alpha$, reflection	50	0.1	10	1	2	40	105°

Values of D, h, L, and approximate geometrical vertical and horizontal resolutions for the three geometries discussed are given in Table I, for some useful x-ray radiations and crystal reflections.

Crystal and camera.—The diffracting crystal and x-ray camera used have little effect on the resolution of the final image. The only requirement for the camera is that it have the movements necessary to allow the entire crystal to be aligned and imaged. For method 1, the camera must be a normal Lang camera, complete with precision scan system, precision incoming and direct beam-stop slits, and accurate specimen goniometer. For the second method, the beam-stop slits can be eliminated, and an accurate scan system is usually not necessary. For the third method, the precision incoming beam slits can be replaced by a simple slit, and only a rudimentary specimen holder is required. A sample scanner may be included in the latter two methods to allow large crystals to be imaged in their entirety; for example, most x-ray focal spots are only about 1 cm long and hence allow only a 1 cm topograph of perhaps a 7 cm wide crystal to be taken by arrangement 3. The sample scanner need not be very accurate; any simple slide mechanism will suffice, since a large portion of the crystal is visible at any one time.

Virtually all crystal reflections are suitable for methods 1 and 3, in both transmission and reflection geometries. Most commonly, {220} transmission topographs of (111) Si wafers are taken, using either Ag or Mo $K\alpha$ radiation. In reflection geometry, the {333}, {400}, {311}, and {440} reflections from (111) and (100) wafers are taken using Cu $K\alpha$, Fe $K\alpha$, or Cr $K\alpha$ radiation. For reflection geometry, the thickness of the crystal is immaterial, since only the first few microns near the surface contribute to the image. In transmission geometry, the crystal thickness t_o and x-ray radiation must be chosen to give $\mu_o t_o \sim 1$, where μ_o is the linear absorption coefficient of the crystal.

For method 2, only special reflecting planes can be used for (111) or (100) crystals, since both 2θ and the crystal position are restricted. Otherwise, the crystals must be cut to order, a somewhat inconvenient procedure that cannot be applied to production quantities of wafers.

X-ray sensitive phosphor.—In the system described here, the x-ray phosphor is the single most important component affecting final image quality. This phosphor must satisfy two conflicting requirements: it must transform x-rays into light with high efficiency, and

Table II. X-ray properties of experimental phosphors

Phosphor	Backing thickness, μm	Phosphor thickness, μm	I/I_0 Mo	I/I_0 Cu	I/I_0 Fe	Effective absorption, μ Mo	Effective absorption, μ Cu	Effective absorption, μ Fe	Resolution, μm	Light efficiency*

* 1 = bad, 10 = good.

it must have good resolution. For the former, thick phosphors are desired in order to absorb sufficient x-rays; for the latter, thin phosphors with small grain sizes are required. In all cases, the phosphor must be uniform in coating thickness.

In the present study, several types of phosphors have been examined. The one found most satisfactory was selected solely on the basis of experimentally observed resolution; the light output was boosted artificially if necessary by the SEC vidicon, by using long integration times. The resolution of all phosphors was determined by examining video displays of x-radiographs of fine wire meshes used as electron microscope grids; the best result obtained is from the U.S. Radium Corporation Radelin PTB-4-155-17, a blue-light emitting phosphor which actually showed a resolution of about 15 μm. This particular phosphor screen is about 65 μm thick, with a 10 μm grain size; it was coated on a 75 μm plastic backing. As will be seen, the phosphor resolution limits the final image resolution. All phosphors used were coated on the back with a flash of Al in order to reflect light back through the phosphor to the front side, light that would otherwise be lost. The phosphor side of the screen was placed facing the television camera, so that the x-rays entered on the screen through the aluminized back side.

A comparison of some of the experimentally available physical characteristics of several phosphors along with their measured resolutions and relative light emitting efficiencies are given in Table II.

Some comments are in order here concerning the properties of the fluorescent screens used in the present work. The properties listed in Table II were all experimentally determined; other properties that can be of interest, primarily phosphor grain size, were generally unavailable. The screens used were all commercially available, and while some attempt was made to obtain high resolution combined with good light output, no effort was devoted to improving screen quality experimentally. Consequently, the results discussed here are typical of the screens used, but probably could have been improved somewhat had special attention been paid to optimizing screens. None the less, the resolutions shown in Table II, which in many cases are surprisingly small fractions of the screen thicknesses, were observed experimentally. These resolutions were obtained using the x-ray tubes and operating conditions mentioned earlier. Unfortunately, the incident x-ray energies, which are known to affect screen resolution (16) were not determined.

L^3-TV system.—The television camera used here is a commercially available image intensifier-SEC vidicon combination L^3-TV.[1] The final image is displayed on a Sony 9-in. low persistence screen monitor for normal viewing, or a Conrac 15-in. long persistence screen monitor for recording via Polaroid film. The video system is unmodified from normal television operation except for the choice of optical lenses. The camera is equipped with automatic gain control in order to prevent burning of the SEC target or video screen.

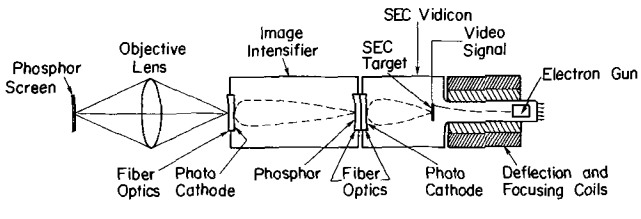
[1] Quantex Corporation, a subsidiary of Commercial Electronics, Inc., Mountain View, California.

The video system takes the light image formed in the phosphor and transmits it via a system of optical lenses and fiber optic bundles onto the photocathode of an image intensifier. The electrons formed by the photocathode are accelerated by an electric field and are reconverted into a brightened light image as the output of the image intensifier; this intensified light image is transferred by a fiber optic faceplate to the input photocathode of an SEC vidicon tube. The electrons formed by this photocathode are accelerated, and impinge on an SEC target, which emits large numbers of secondary electrons for each incident high energy electron. Since the target is of high resistivity, it retains its resulting charge as a function of position, until it is neutralized by a scanning electron beam. The variation of stored charge as a function of position is sensed by the scanning beam and is electronically processed and transferred to a video monitor. The gain of the over-all camera is on the order of 10^5. A schematic diagram illustrating the operation of the SEC camera is shown in Fig. 2. Details of the operation of SEC tubes may be found elsewhere (17, 18).

The optical resolution of the televison camera portion of the over-all system is determined by the number of television lines per inch of displayed field. The input to the photocathode of the image intensifier is 0.6-in. high and is read out of the SEC vidicon using 525 lines. For a one-to-one image transferred from the phosphor to the input photocathode, a television line resolution of 0.6 in./525 ~ 30 μm results. If a different set of lenses is used to transfer a 0.3-in., twice magnified image to the input photocathode, the television line resolution becomes ~ 15 μm, and if a four-times magnified 0.15-in. image is transferred, the television line resolution is about 7 μm.[2] Consequently, a phosphor whose resolution is 15 μm can be read out on the television monitor by the proper choice of magnification lenses to give better than 15 μm television line resolution.

The light level of the phosphor is, of course, important, but for the purposes discussed here, with a high signal-to-noise ratio even for low intensity x-rays, does not appreciably affect resolution. The L^3-TV system is not noise-limited by the electronics, but by the x-ray statistics. For the low power x-ray tubes used in these experiments, x-ray quanta fluctuations are occasionally observed on the screen, but

[2] These calculated resolutions must be divided by the Kell factor (19) of about 0.7, in order to give measurable resolution. Hence the calculated resolutions above become about 43, 21, and 10 μm, respectively.



OPTICS AND ELECTRON OPTICS

Fig. 2. Schematic diagram showing operation of SEC camera

reasonable quality images can then be obtained by integrating the image, via a time exposure on the Polaroid film, or by allowing the SEC target to store information for longer times before readout. In general, for the photographs shown, total integration times of up to 1 min were required for Polaroid Type 55, ASA 50 speed film. The television image can be integrated and stored on a disk recorder and then played back

continuously, eliminating the periodic flashes that would otherwise occur.

In order to gather sufficient light from the phosphor, high aperture lenses are used to transfer the phosphor image to the photocathode of the L^3-TV. For the one-to-one image, two back-to-back 50 mm f/0.95 lenses were used. For the two-to-one magnified image, either a 50 mm f/0.95-100 mm f/2 combination or a 25 mm f/1.4-50 mm f/0.95 combination was used. For the four-to-one magnification, a 25 mm f/1.4-100 mm f/2 combination was used. Better lenses are available; a 25 mm f/0.75 would provide considerably more light than the 25 mm f/1.4 lens actually used. In order to take topographs of large crystals, the various lenses can be reversed, giving two-to-one or four-to-one reduced images, covering larger fields of view with lower televison line resolution. More recently, fiber optic coupling of the phosphor screen to the input photocathode has been used, with a large gain in light collection. However, results quoted in the following sections were mainly obtained using the lenses rather than fiber optics, due to the restricted fields of view and magnifications available with presently available fiber optic bundles.

Results

Resolution, magnification, and field of view.—As discussed earlier, resolution and field of view are related, as is final image magnification. In order to observe a large 3-in. diameter wafer at one time, the 3-in. image height must be reduced to the 0.6-in. size of the first photocathode window; this is read off with 525 lines and displayed on any size monitor, with a television line resolution of ~60 μm. Hence, for this application, both the $K\alpha_1$ and $K\alpha_2$ components can be used to form the image, without affecting the resolution, and method 3 provides the best results. However, the image width viewable at any one time is restricted to about 1 cm, the length of the line focus of the x-ray tube, and the crystal is slowly scanned through the incident beam in order to observe the entire wafer.

With a resolution of ~60 μm, only gross defects such as microcracks or large dislocation arrays can be seen. Examples of both of these are given in Fig. 3a and 4, topographs taken by method 3. This type of topograph can only be used in production areas such as crystal growing, in order to sort out grossly imperfect wafers; the resolution is not satisfactory to be used for experimental Lang topography or to examine fine details. However, the resolution is sufficient to observe contrast asymmetries due to strain fields on opposite sides of oxide stripes on Si wafers (20, 21). Figure 5 shows a (220) video display topograph of a Si wafer containing several oxide stripes, with oxide thicknesses ranging from 0.1 to 1 μm. The contrast asymmetries of an oxide stripe as thin as 0.3 μm can

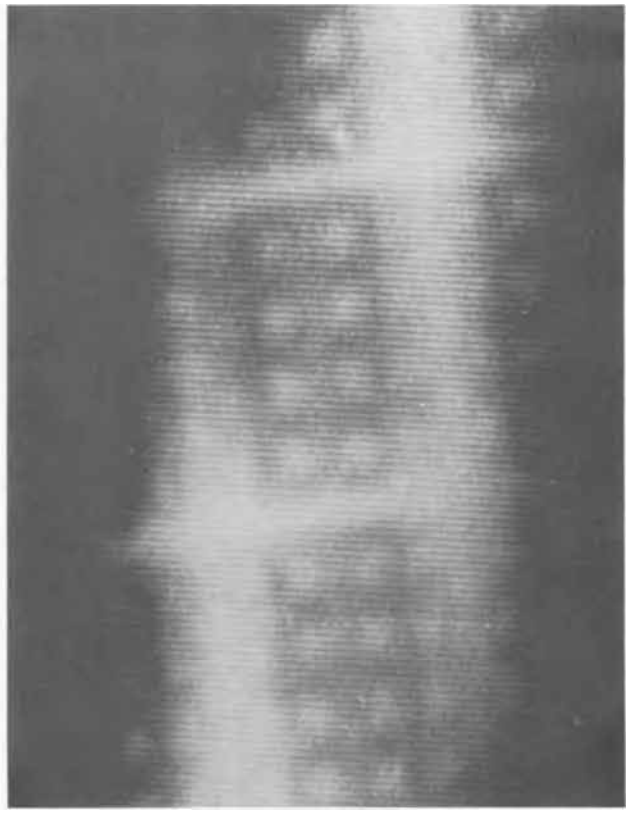

Fig. 6b. Method 1, nonscanning, reflection geometry. Magnification 15X.

be seen, even though the resolution is about 40 μm due to the combination of $K\alpha_1$ and $K\alpha_2$ images.

If the field of view can be restricted, *i.e.*, entire wafers need not be viewed, better resolution is obtainable. This is clearly shown in Fig. 3; the microcrack seen in Fig. 3a is shown at different magnifications and fields of view in Fig. 3b and 3c. Also included for comparison is a dental x-ray film topograph of the same area, taken by method 1, Fig. 3d.

When resolution better than that obtainable with the $K\alpha_1$-$K\alpha_2$ doublet is required, the $K\alpha_2$ component must be suppressed. Hence, method 3 becomes unusable, unless $K\beta$ radiation rather than $K\alpha$ radiation is used (22); this is sometimes impractical because strong $K\alpha$ images may overlap the weaker $K\beta$ image. On the other hand, if method 1 is used, as it was to take Fig. 3b and 3c, the image recorded at any instant is narrow due to the narrow incoming beam. The television camera itself can be scanned along with the crystal and integrated over the entire image (9), or the crystal only can be scanned at an angle to the diffraction vector (12), in order to obtain large area topographs. Also, narrow images themselves can be used, if they include the desirable information, Fig. 3d. A possible application of this type is in the imaging of section topographs (23); here, large fields of view are not required, but higher resolution is desirable.

As the magnification increases from Fig. 3a to Fig. 3c, the same amount of light is being spread over larger areas, and hence the x-ray intensity available becomes a critical factor. Figure 3a required about 1/10 the exposure on the Polaroid film that Fig. 3c required.

Another example of resolution *vs.* field of view is shown in Fig. 6. In Fig. 6a, a large area of a Si wafer with a device pattern is shown in reflection geometry. For the (111) Si wafer, Cu $K\alpha$ radiation, the {440} peak is at $2\theta = 107°$, so the diffracted x-ray beam is not quite perpendicular to the wafer surface. This angle is too great to obtain a large image via method 2, so method 3 was used. However, the $K\alpha_2$ component is then included and the image shown in Fig. 6a therefore has low resolution. If the $K\alpha_2$ component is suppressed by using a point source of x-rays, colli-

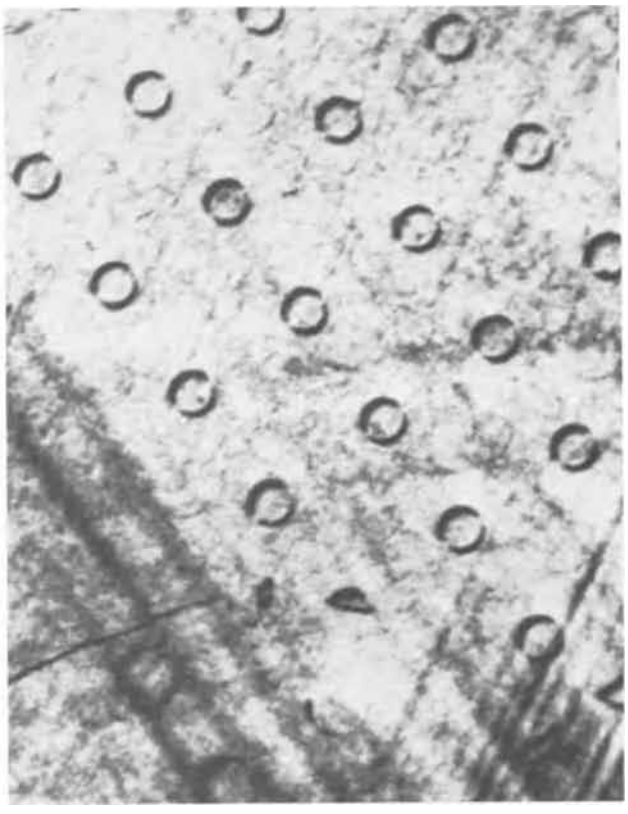

Fig. 7b. Dental film, scanning. Magnification 15X

mated by a divergence slit (method 2), the image appears sharper, Fig. 6b, but is much smaller in area. This image can then be magnified more on the television screen by selecting a different lens system, giving an enlarged view of a small part of the wafer, Fig. 6c.

A similar series of reflection topographs of a Si wafer is shown in Fig. 7; the contrast asymmetries arising from strain fields surrounding the boron diffused diodes are clearly visible (20).

The best examples of x-ray topographs are taken using method 2; these are the most convenient topographs to take since a stationary crystal is used and the television camera can be placed very close to the diffracting crystal. In addition, the diffracted beam can be limited to the $K\alpha_1$ component. However, as pointed out previously, only selected crystal reflections are usable. For example, {311} reflections from (100) Si or GaP are usable with Cr $K\alpha$ radiation, but there are no other very good reflections. With GaAs {400} Cu $K\alpha_1$ reflections from (111) or (100) crystals are obtainable, the intensities are high, the angles are ideal to give large area undistorted topographs without scanning, and the distance from the crystal to the television camera face can be less than 1 cm. For all the reasons given above, video display experimental x-ray topographs are most applicable to method 2; all conditions are favorable. Useful images of Si and GaP can be made with method 2 using reflections other than {311} (*i.e.*, nonscanning method 1) if the restriction of a narrow image and some angular distortion can be accepted.

Fig. 7c. Video display, nonscanning. Magnification 30X

Comparison with Other Video Systems

In comparison with other television systems for displaying x-ray topographs, the SEC vidicon has certain practical advantages, but also some disadvantages. For all practical purposes, the SEC vidicon is similar in operation and performance to Lang's cascaded image intensifier L^3-TV (9), so all comparisons made with the PbO plumbicon (6) and diode display (7, 8) apply equally well to his method. Some qualitative comparisons between the optical performances of SEC *vs.* a cascaded intensifier have been made by Emberson (24) and by Whitmell and Southon (25).

Field of view.—L^3-TV offers the only method whereby crystals larger in diameter than the x-ray window of the television camera can be imaged in

their entirety. Since optical lenses are used to transfer the image formed on the phosphor to the L³-TV window, virtually any size crystal can be displayed. Both the plumbicon and diode array camera read the information directly off the x-ray target, so the final image is restricted in size to that of the target window. The L³-TV can easily record a topograph of a 3-in. diameter crystal, while the other two methods are restricted to less than 1-in. diameter crystals.

Resolution, contrast, and magnification control.—The resolution of the L³-TV is at present limited by the x-ray sensitive phosphor. Since the optical image can be magnified (or demagnified) by the lenses to any desired size before it is focused on the input photocathode, the television line resolution can always be made better than the phosphor resolution, presently about 15 μm.

In the diode array, the ultimate resolution depends on the diode spacing, also about 15 μm. As new arrays are made, this resolution will be improved, to probably better than 10 μm. At high magnification, the image quality of the diode array is visibly better than that of the L³-TV, mainly due to better contrast. Comparison of resolution or contrast with the PbO plumbicon is difficult, since entirely different crystals, x-ray sources, geometries, etc., were used (6).

In the L³-TV, magnification is controlled by the choice of optical lenses. This system works well, so long as high aperture lenses are used. If interchangeable lenses are used for magnification control, provision must be made for focusing the lenses mechanically.

Magnification is easier to control in the diode array and plumbicon, since the magnification is determined electronically by varying the area of the target scanned by an electron beam. Since the image is displayed on a uniform-size screen monitor, the magnification is simply the ratio of the monitor screen size to the area of the target scanned. This also relates to resolution; the television line resolution in these two systems is determined by the number of scans per centimeter that are made by the electron beam on the target. Both the diode array and plumbicon can be zoomed electronically; zoom lenses can also be employed in the L³-TV system.

In the L³-TV, a 0.6-in. field is read off with 525 lines, as mentioned previously. This number of lines can be increased by perhaps a factor of 2 before other factors starting limiting resolution; for example, the fiber optics or SEC target (17). Hence, a one-to-one image can be read in the L³-TV with a maximum of $0.6/1050 \sim 15$ μm resolution. Therefore, direct imaging of x-ray topographs on the fiber optic input to the photocathode is impractical from a field of view viewpoint; the image cannot be magnified before it reaches the photocathode, and the resolution would be limited to about 15 μm, with a maximum field of view of 0.6-in. However, image intensifier-SEC vidicon systems with large input photocathodes can be used for imaging low resolution Laue patterns or fluoroscope displays directly on the input photocathode (26, 27). Also, use of fiber optic coupling from a phosphor to the input photocathode leads to significant advantages in light collection compared to lens coupling.

Sensitivity to x-rays.—In all television systems, the x-rays fall on some target, which transforms the x-rays into a signal which is electronically sensed and displayed as a television picture. The efficiency of the target depends on how much of the x-ray beam is absorbed by the target, and on how well the absorbed x-rays are converted into the proper signal.

In the L³-TV, x-rays are converted into visible light. As shown in Table II, the various x-ray wavelengths are absorbed differently by the assorted screens, and have different light output efficiencies. However, all screens emit sufficient light to be intensified and displayed, for the objective lens magnifications attempted.

For the diode array camera, soft x-rays are required, since the thin Si crystal into which the diodes are diffused is almost transparent to hard x-rays. The softer x-rays are absorbed reasonably well, the hard x-rays hardly at all.

This dependence on x-ray wavelength is reflected in the potential use of the various kinds of cameras. Soft x-rays are generally used for reflection topography, while hard x-rays are used for transmission topography. Hence, the diode array camera is best suited to reflection geometry, where it can provide instantaneous, good quality topographs of small areas of semiconductor crystal surfaces. The L³-TV is better suited to larger area transmission as well as reflection topographs, but can be used for higher resolution, smaller area topography as well.

Consequently, it appears that the L³-TV and diode array systems are complementary with some area of overlap, rather than directly competitive. L³-TV has certain advantages in some situations, while the diode array has advantages in other situations.

While it is difficult to directly compare the PbO plumbicon to the diode array or L³-TV, for reasons previously stated, it would appear that both systems would be useful for reflection or transmission geometry, since the PbO would absorb both hard and soft x-ray. However, the PbO system is limited due to its sensitivity; only extremely high intensity x-ray sources have been used (6).

Conclusions

On the basis of the foregoing, it is clear that instantaneous video display of x-ray topographs is possible, but that considerable room for improvement remains before the method becomes truly competitive with film techniques. It appears that perhaps two different types of television systems will be required in order to achieve the two ends of the topography spectrum: the high-resolution small field of view, and the low-resolution large field of view. The high resolution end seems to be covered at present by the diode array camera; however, this system is not sensitive to high energy Mo or Ag Kα x-rays. Consequently, the L³-TV system with its slightly lower resolution appears to be more versatile. On the large field of view end, the L³-TV has little competition from the diode array or PbO plumbicon systems discussed above, since any image size can be accommodated by proper choice of optical lenses. Most effort should be directed toward improving the phosphor for L³-TV, since this element has the largest effect on image quality. Lang (28) discusses this subject in some detail, and suggests that single crystal phosphors may provide better resolution than polycrystalline phosphors.

There are several obvious immediate applications for L³-TV. First, and most important from the point of view of experimental x-ray topography, the system can be used as an x-ray detector, replacing the scintillation or geiger counter, for aligning crystals in the Lang camera for subsequent film recording. Since the topograph can be viewed instantly unwanted ghost reflections and image inhomogeneities can easily be eliminated. Second, the system can be used in production for quality control to separate grossly imperfect wafers from reasonably good ones; high resolution is not necessary for this application. Similarly, the system can be used for low resolution topographical application, for example, observation of Moiré fringes (28) or double crystal "zebra" patterns (29). Third, the system can be used for Laue orientations of Si crystals; this subject is discussed in the paper that follows (Part II). With suitable improvement in the systems, however, video display of x-ray topographs may replace film techniques for many applications.

Acknowledgments

The author wishes to thank John Landre and Paul Mengers, of Commercial Electronics Corp., Mountain View, California, for providing the SEC camera used in this work, and for giving generously of their time and effort in endless discussions. He also wishes to thank Frank Masi, of the United States Radium Corporation, and Professor Andrew Lang, of the University of Bristol, for supplying the various x-ray sensitive phosphors. Finally my appreciation to Mike Callahan for his valuable laboratory assistance.

Video Display of X-Ray Images

II. Laue Patterns

Eugene S. Meieran

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The SEC vidicon system described in Part I has been adapted to display Laue orientation patterns. In this paper, the geometries of both transmission and symmetrical back reflection video display Laue patterns are illustrated.

Although Laue patterns have been used for many years for orienting single crystals via film techniques, only recently has it been possible to view them directly with image intensifiers or video system displays (1-4). These recent results have been due mainly to the development and improvement of low light level image intensification systems, generally for night vision applications.

The first Laue patterns so displayed were imaged directly from the fluorescent screen onto the intensifier photocathode and were then brightened sufficiently to be observed directly. Consequently, the patterns were generated in transmission geometry, since the x-ray tube itself would be in the way of the intensifier for back reflection geometry. Symmetric back reflection Laue patterns can be displayed only if high gain intensifiers are used, and if the Laue pattern can be transferred optically to the intensifier photocathode to provide room for the x-ray tube.

In Part I of this paper, an SEC (secondary electron conduction) video system capable of imaging low-intensity x-ray topographs was described. This same system is directly applicable to the display of both transmission and back reflection Laue patterns, since a large enough field of view to cover an entire pattern is optically transferred to an extremely high sensitivity television camera. To observe Laue patterns, the television camera is unmodified compared to normal television viewing or to topographic imaging, except for minor changes to the optical lens system. The camera is basically an L^3-TV (low light level television) camera which displays the image of a phosphor screen that has converted the x-ray signal into a visible light pattern (5). A schematic drawing of the system is given in Fig. 2 of Part I.

There are a number of reasons why direct display of Laue patterns is desirable (1, 2):

1. Detection of rapid phase changes or transient phenomena.
2. Identification of low-symmetry crystal Laue patterns, where large numbers of patterns must be taken to obtain correct orientations.
3. Remote display of x-ray patterns.
4. Low-cost display and storage via video tapes of very large numbers of patterns, where the cost of Polaroid film eventually becomes greater than the capital expenditure for the television camera.
5. Display of extremely large numbers of patterns, where the time required to take a film exposure becomes prohibitive.

Key words: x-ray topography, Laue patterns, television systems, semiconductor crystals, crystal defects.

As stated, Laue patterns are recorded on film in transmission geometry, or more commonly for semiconductor crystal growing industries, in back reflection geometry (6). For transmission geometry, the television camera needs no modification from topographic imaging, except for the proper choice of optical lenses to give the desired field of view. For back reflection geometry, the front end of the camera must be adapted to provide access for the x-ray tube. An asymmetrical back reflection Laue pattern can be taken without this adaptation (5); however, the resulting pattern is considerably distorted angularly, as seen in Fig. 1, and is difficult to interpret. The remainder of this paper is devoted to a qualitative description of transmission or symmetrical back reflection Laue display, since these geometries are used most often and are most convenient to interpret. Details of the theory and measurement of Laue patterns are not included, since they are adequately covered by textbooks such as ref. (6).

Geometry

Back reflection patterns.—A mirror is used in conjunction with the normal television camera optics in order to display an undistorted symmetrical back reflection Laue pattern. The geometry of this arrangement is shown schematically in Fig. 2a. The Laue pattern is first imaged on a phosphor screen which has been placed at right angles to the television camera axis and normal to the primary x-ray beam. A mirror with a small hole cut in it to allow passage of the primary beam is placed at 45° to the camera axis; this mirror reflects the Laue pattern through a demagnifying lens onto the television camera input photocathode. The collimator from a normal film Laue camera is used to define the x-ray beam; this collimator is about 8-cm long, in order to pass through the SEC camera front end, and has a pinhole diameter of 0.8 mm. The collimator passes through the mirror and also through the phosphor screen in order to cut down background fluorescence due to scattering from the air in the immediate vicinity of the screen.

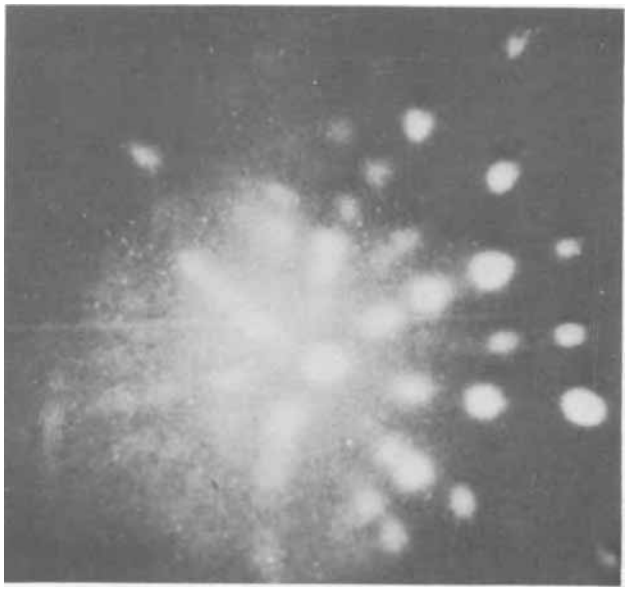

Fig. 1. Asymmetric back reflection Laue pattern

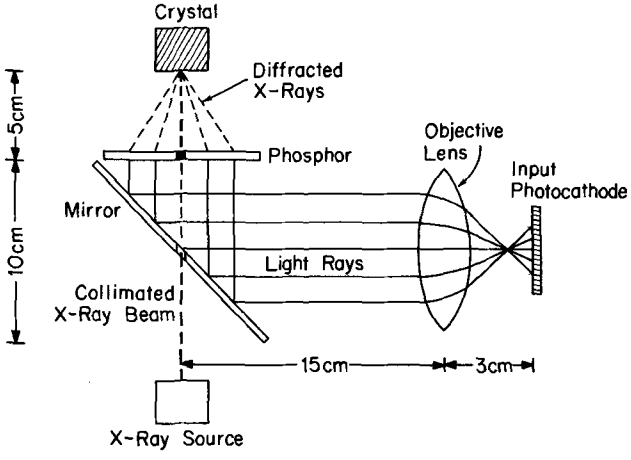

Fig. 2 a and b. Schematic diagrams showing geometry of direct display of Laue patterns. Fig. 2a. Symmetric back reflection geometry.

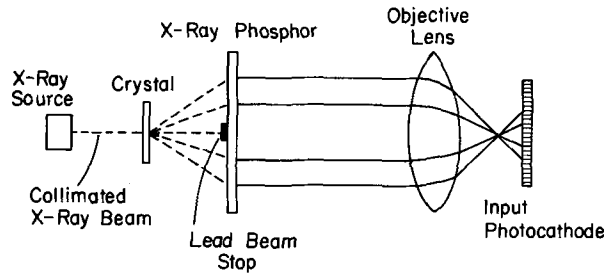

Fig. 2b. Symmetric transmission geometry

A normal Laue pattern is recorded at a distance of 3 or 5 cm from the diffracting crystal (6), and for general purposes, the same dimensions can be used for the video system display. The diffracted x-ray beams cover a total angular spread of about 50°, giving rise to a 6- or 10-cm wide Laue pattern, respectively. This width must be reduced to the 0.6-in. width (1.5 cm) of the input photocathode of the SEC camera; for the purposes described here, a single 50 mm f/0.95 lens was used. The approximate dimensions of the optical system are given in Fig. 2a.

A back reflection Laue pattern of a (111) Si crystal, recorded from a Sony 9-in. monitor, is shown in Fig. 3a. This pattern was integrated by the SEC camera for 10 sec before display; the image was stored on a disk recorder and then played back. Figure 3b shows a normal film Laue pattern for comparison, taken with the Polaroid XR-7 holder; it required 10 min of exposure. Both patterns were taken using a CA-7 W target x-ray tube, operating at 25 kV and 30 mA. Back reflection Laue patterns are useful for all crystal orientations, but are especially useful for crystals that are too thick to orient by transmission techniques.

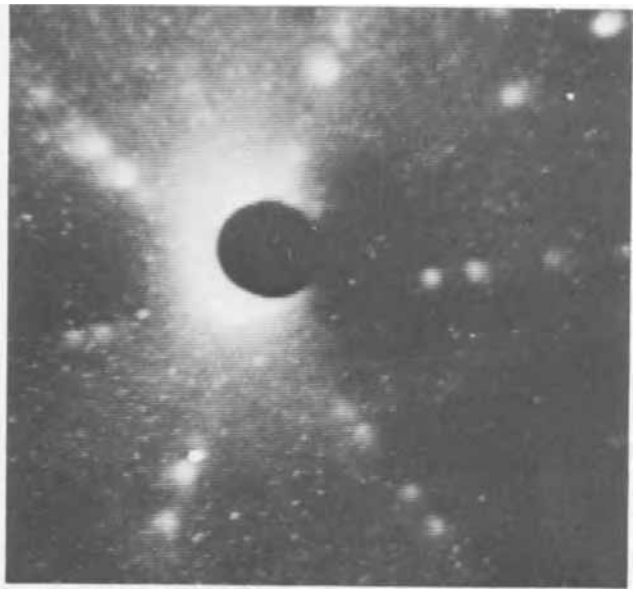

Fig. 3 a and b. Back reflection Laue patterns. Fig. 3a. Video display, 10-sec exposure.

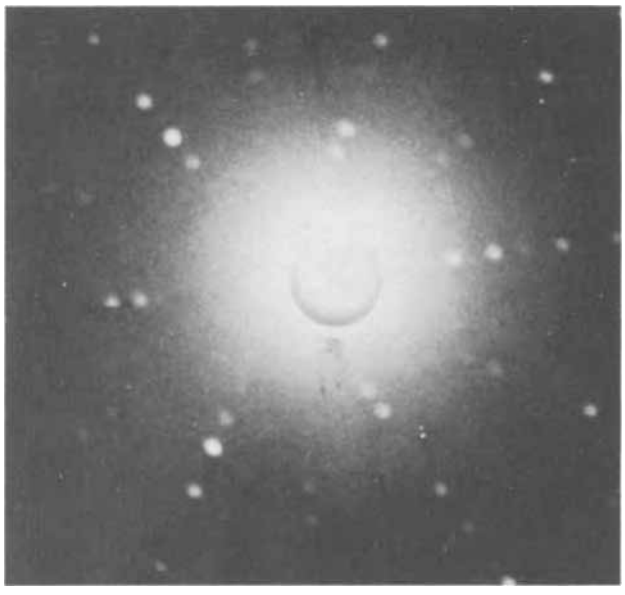

Fig. 3b. Film display, 10-min exposure

Transmission Laue patterns.—Transmission Laue patterns are taken using the geometry schematically shown in Fig. 2b. Since the direct x-ray beam transmitted through the crystal is so intense compared to the diffracted beams that it could burn the SEC target or television screen if the gain is set to allow viewing of the diffracted beams, it must be stopped from striking the x-ray phosphor. This is accomplished by using either a small lead beam stop, or by cutting a hole in the phosphor and trapping the beam behind it.

The transmission Laue patterns are useful for orienting single wafers, for example, to check out a wafer-sawing operation for accuracy. The dimensions of the system are similar to that of the back reflection technique; approximately 6-10 cm field of view is necessary, with a crystal placed 3-5 cm from the phosphor. A video display of a transmission Laue pattern of a Si wafer is shown in Fig. 4a, compared to the Polaroid pattern, Fig. 4b. The times of exposure for transmission geometry are about half that required for back reflection patterns.

X-Ray Sensitive Phosphor

The requirements for the x-ray sensitive phosphor used to image Laue patterns are substantially different from those needed for topography, described in the previous paper. Resolution is not as critical, since the original incident beam and Laue spot sizes are on the order of millimeters in diameter. Considerable light output by the phosphor is desirable and is obtained by using thicker screens. The most efficient screen of those tested that combines reasonable resolution with efficient light output is FG-3M05-005,[1] with the properties listed in Table II of Part I, although other screens are comparable. Much effort has been devoted to determining optimum phosphors for film and direct recording of Laue patterns (7-9); the results shown in this paper could probably have been improved if other phosphors had been used.

Measurement of Patterns

A 9-in. Sony monitor has an intrinsic magnification factor compared to the 0.6 in. diameter of the input photocathode window of $9/0.6 \sim 15$. Since the initial image formed on the phosphor is demagnified by about a factor of 5 by the optics, the final image on this monitor is about three times as large as a Polaroid film pattern recorded under the same conditions. Thus each Laue spot is about 3 mm in diameter.

[1] Supplied by the United States Radium Corporation, Morristown, New Jersey.

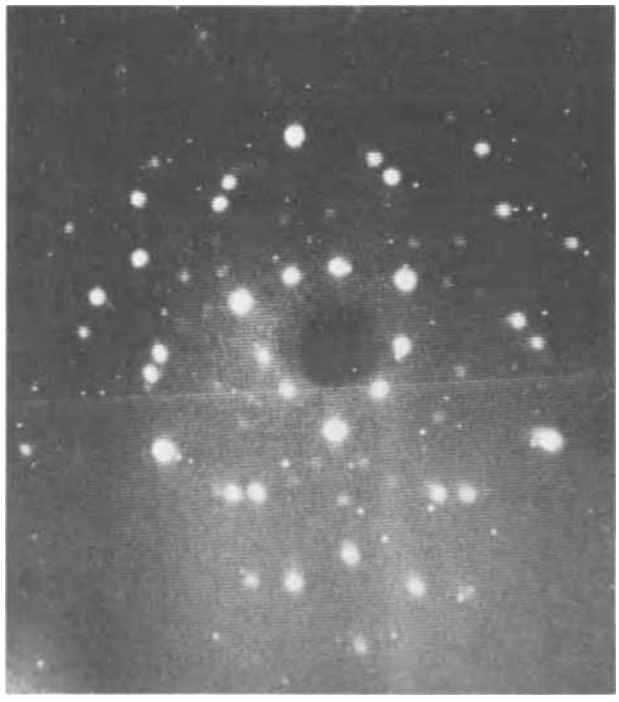

Fig. 4 a and b. Transmission Laue patterns. Fig. 4a. Video display, 2-sec exposure.

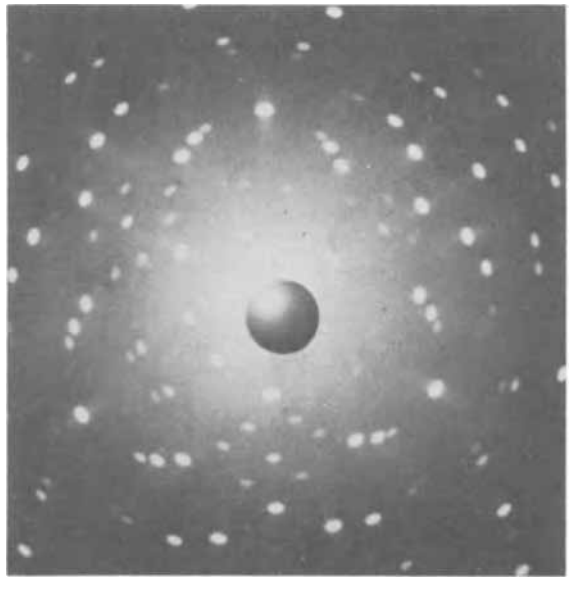

Fig. 4b. Film display, 4-min exposure

Measurement of the pattern to within 0.5° becomes measurement of the position of a Laue spot located at the edge of the pattern to within about 1 mm, one-third of the spot diameter. Often the Laue pattern is viewed in direct time, and corrections to the crystal orientation can be made visually. For less intense patterns, the image can be integrated for a short period of time and stored on a disk or tape; this pattern can then be displayed at will and measured.

Conclusions

L^3-TV is suited to the display of Laue patterns because of the use of optical transfer of the pattern to the input photocathode, the large field of view that can be obtained, the high light-sensitivity of the camera, and the capability of integrating the image for long periods of time before readout, if necessary. Since a significant capital expenditure for equipment is necessary, the system pays for itself in terms of the cost of Polaroid film and time savings only if large

numbers of patterns need to be taken. Although the quality of directly displayed Laue patterns does not yet compare to film recording, the speed of video display makes the method valuable for many applications.

Solid-Liquid Phase Equilibria for the Ternary Systems Li(F,Cl,I) and Na(F,Cl,I)[1]

Carl E. Johnson and Ellen J. Hathaway

Argonne National Laboratory, Argonne, Illinois 60439

ABSTRACT

The solid-liquid phase equilibria for the ternary systems Li(F,Cl,I) and Na(F,Cl,I) have been determined using thermal analysis techniques. The binary mixtures which make up the ternary system are all eutectic in nature. The diagram of the crystallization surface for each ternary consists of three areas, one for each of the pure components in the system. At the intersection of these three fields lies the minimum in the system; for the Li(F,Cl,I) system, a ternary eutectic of 11.7 m/o (mole per cent) LiF-29.1 m/o LiCl-59.2 m/o LiI melting at 340.9°C, and, for the Na(F,Cl,I) system, a ternary eutectic of 15.2 m/o NaF-31.6 m/o NaCl-53.2 m/o NaI melting at 529.4°C.

In searching for electrolytes suitable for use in energy conversion devices, criteria such as high conductivity, stability with respect to the anode metal, and low melting point have been applied. When using alkali metals as the anode, fused alkali halides generally meet these requirements. Experimental efforts have focused on the determination of the solid-liquid equilibria for ternary alkali halide systems suitable for use in cells employing either a lithium or sodium anode. The systems studied, Li(F,Cl,I) and Na(F,Cl,I), are simple eutectics with no apparent solid solution formation.

Experimental

Thermal analysis has been used to define the temperature-composition solid-liquid equilibrium characteristics in the binary and ternary mixtures. The thermal analysis apparatus used in this work has been described in detail elsewhere (1). Reagent grade lithium chloride and lithium iodide were purified by modification of the procedure described by Laitinen *et al.* (2) in which the anhydrous hydrogen halide was used to remove the last traces of water from the molten salt. The halide melting points were: lithium chloride, 606.8°C, and lithium iodide, 469.2°C. Single-crystal lithium fluoride, having a melting point of 848°C, was used without further purification. Reagent grade sodium fluoride, sodium chloride, and sodium iodide were heated to 130°C to drive off any moisture before use. The melting points of the pure reagents were: sodium fluoride, 990.0°C; sodium chloride, 801.0°C; and sodium iodide 659.3°C.

[1] Work performed under the auspices of the U.S. Atomic Energy Commission.

Key words: fused salts, eutectics, lithium halides, sodium halides, fused halide systems.

Temperatures were sensed with a Pt/Pt-10% Rh thermocouple, which was calibrated against NBS pure Zn (mp 419.5°C) and NBS pure Al (mp 660.0°C). The accuracy of the absolute value of the temperature was estimated to be ±0.3°C.

The amounts of the pure crystalline salts required for a given composition were weighed into a SS-347 sample capsule; all operations were carried out in a high purity helium atmosphere box. After being placed in the thermal analysis apparatus, the sample was heated to a temperature high enough to insure complete melting, and was held in the liquid state for about 1 hr. Preliminary cooling and heating cycles were then executed until reproducible first breaks in the cooling curves were obtained. Only then were complete cooling and heating curves recorded. Cooling rates were set in the range of 0.5-1 centigrade deg/min, thereby maintaining close control of the heat flow into and out of the sample. The sample composition was calculated from the weights of the pure materials; however, periodic checks were made by chemical analysis on selected samples. The above experimental melting points are in excellent agreement with the most reliable experimental data which is found in JANAF tables (3).

Except for the direct measurement of the melting point of pure sodium fluoride at 990.0°C, the upper experimentally measured temperature in the sodium systems was restricted to 850°C. This restriction was imposed primarily to conserve time, because it took about as long to heat the apparatus from 850° to 1000°C as it did to heat it from room temperature to 850°C. In all the systems studied, both binary and ternary, solid solutions were not observed for the mixtures in either thermal analysis or in x-ray diffraction analysis of selected solid samples.

Discussion

Temperature-composition data for the LiF-LiI binary system were obtained over the composition range of 10-95 m/o LiI. These data are given in Table I and in Fig. 1 where the other binary systems of interest here (LiCl-LiI and LiF-LiCl) are given for completeness. A eutectic composition of 83.5 m/o LiI in LiF melting at 410.9°C was observed.

The LiCl-LiI binary system was investigated by Johnson and Hathaway (4) and has a eutectic composition of 34.6 m/o LiCl in LiI melting at 368.2°C. The LiF-LiCl binary system was investigated by Haendler, Sennett, and Wheeler (5) who reported a eutectic composition containing 30.5 m/o LiF in LiCl melting at 501°C. These data have been confirmed by studies carried out in this laboratory.

Temperature-composition data for the NaF-NaCl, NaCl-NaI, and NaI-NaF binary systems are given in Table II and Fig. 2. In the NaF-NaCl binary system, a eutectic composition of 33.0 m/o NaF was observed melting at 680.4°C. Many investigators have studied this system, obtaining results which varied over an 8 centigrade deg range for the eutectic temperature and a 1.6 m/o range in composition. Plato (6) reported a eutectic temperature of 679.8°C at 34.6 m/o NaF; Rassonskaya and Bergman (7) obtained 674°C as the eutectic temperature at 33 m/o NaF; at a eutectic composition of 33.2 m/o NaF, Kuvakin and Kusakin (8) found the temperature to be 682°C.

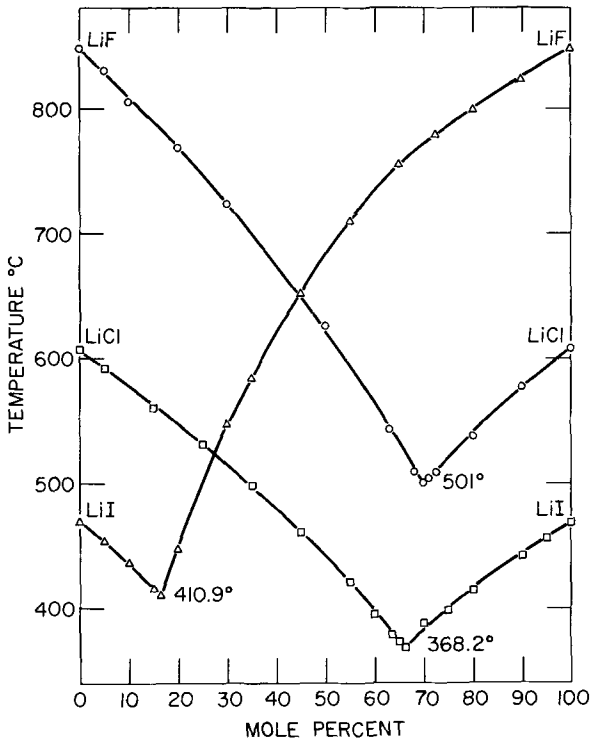

Fig. 1. Binary systems LiF-LiCl, LiF-LiI, and LiCl-LiI

For the NaCl-NaI binary system, we found a eutectic composition of 38.5 m/o NaCl melting at 572.9°C. Amadori (9) reported the eutectic temperature as 578°C at 37 m/o NaCl, and Ilyasov and Bostandzhiyan (10) published data giving the eutectic temperature as 585°C and the composition as 37.5 m/o NaCl.

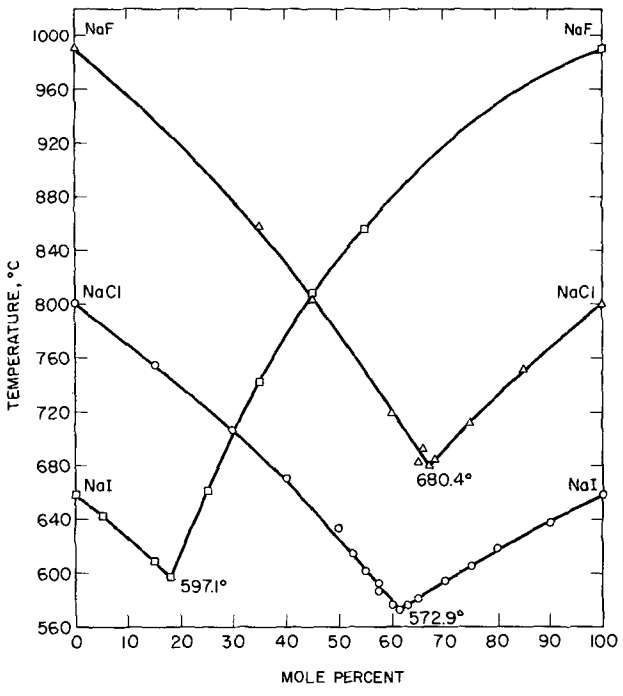

Fig. 2. Binary systems NaF-NaCl, NaCl-NaI, NaI-NaF

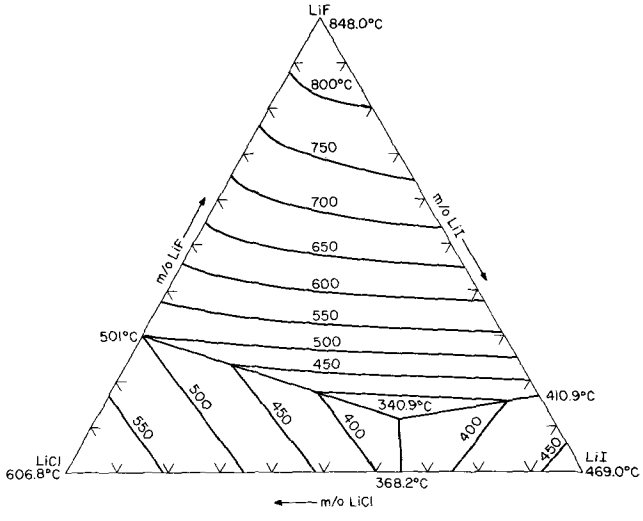

Fig. 3. LiF-LiCl-LiI ternary system

For the NaI-NaF binary system, we found a eutectic composition of 18.0 m/o NaF melting at 597.1°C. Ruff and Plato (11) reported a eutectic temperature of 620°C at a composition of 20 m/o NaF. Dombrovskaya (12) reported the eutectic at 603°C and 18 m/o NaF.

In characterizing the liquidus surface for the two ternary systems, Li(F,Cl,I) and Na(F,Cl,I), tempera-

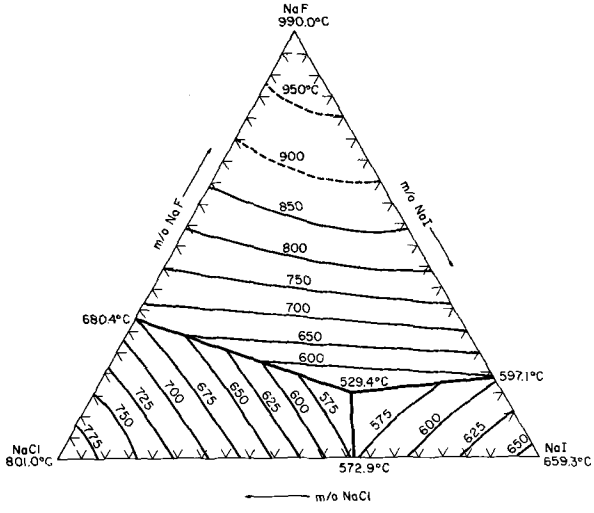

Fig. 4. NaCl-NaF-NaI ternary system

ture-composition data were obtained for various quasi-binary systems within each ternary system. For the Li(F,Cl,I) system, data were obtained for various LiCl:LiI mole ratios radiating from the LiF corner of the ternary field. The experimental compositions investigated and the equilibrium temperatures at which inflections and halts were observed are given as Series I to V of Table III. A contour diagram of the liquidus isotherms for the ternary system, given in Fig. 3, was constructed using the quasi-binary systems described in Series I-V. Similarly, for the Na(F,Cl,I) system, liquidus-solidus temperature data were obtained for various NaCl:NaI mole ratios radiating from the NaF corner of the ternary field and are given as Series VI-X in Table IV. An additional quasi-binary cross section, the 8.5:1.5 mole ratio of NaI-NaF, radiating from the NaCl corner was studied in order to describe more completely the area of the minimum temperature in this system. These data appear as Series XI in Table IV. A contour diagram of the liquidus isotherms for the ternary system, given in Fig. 4, was constructed from the quasi-binary systems described in Series VI-XI. The solid line isotherms are based on experimental data, while the dotted line isotherms result from extrapolations of the experimental data.

Inspection of the liquidus surface for both systems indicates that each is a simple eutectic with three fields of crystallization, one for each of the pure components in the system. The Li(F,Cl,I) system has a ternary eutectic with a composition of 11.7 m/o LiF-29.1 m/o LiCl-59.2 m/o LiI melting at 340.9°C, and, for the Na(F,Cl,I) systems, a ternary eutectic composed of 15.2 m/o NaF-31.6 m/o NaCl-53.2 m/o NaI melting at 529.4°C was found.

Technical Notes

Gas-Phase Etching of Silicon With Chlorine

J. P. Dismukes*,[1] and R. Ulmer

RCA Laboratories, Princeton, New Jersey 08540

Clean, smooth silicon substrates are of prime importance in achieving high quality epitaxial growth of silicon on silicon. For this purpose, *in situ*, gas-phase etching of silicon substrates at high temperatures with hydrogen halides has been extensively investigated (1-7). In contrast, very little work has been reported on etching of silicon with halogens, and the meager information available (1, 8) suggested that these reagents give only rough or preferentially etched surfaces. In this work, etching of silicon surfaces with dilute concentrations of chlorine in helium has been investigated over the temperature range 900°-1100°C, and the surfaces have been studied by scanning electron microscopy. The results showed that chlorine is a more efficient etch than HCl and gives smooth surfaces above 1000°C.

Experimental

Silicon wafers supported on a SiC-coated graphite susceptor were etched with chlorine in 10 l/min He carrier gas using the quartz chamber of 4 cm^2 cross section shown schematically in Fig. 1. The susceptor was heated by a 5 kW, 450 kHz, Lepel RF generator, and temperature was monitored by an optical pyrometer calibrated at the melting point of germanium, 937°C. In most cases the silicon wafers were <111> orientation, 8 mils thick, low resistivity p-type, and Lustrox polished.

To convert traces of oxygen in the Ultrapurity helium to water, the helium together with 0.1 vol % palladium-diffused hydrogen was passed through a Deoxo purifier containing platinum catalyst. The water and other trace impurities in the helium stream were removed in a series of two traps containing Linde 5A and Linde 13X molecular sieves cooled to liquid nitrogen temperature. Prior to etching, the thin oxide layer on the silicon was removed by heating in palladium-diffused hydrogen for 30 min at 1100°C. After switching to helium, etching was conducted for about 30 min at temperatures in the range 900°-1100°C, and

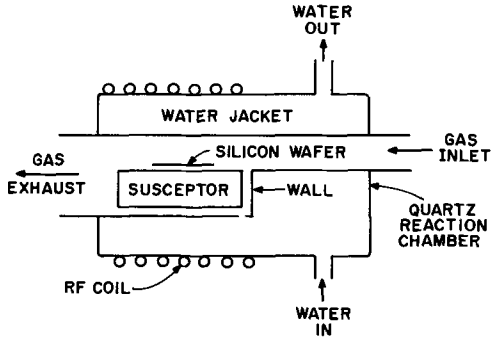

Fig. 1. Water-cooled quartz reaction chamber used for gaseous *in situ* etching of silicon.

etch rates were determined from weight loss using a balance sensitive to 0.01 mg.

The etched surfaces were first examined visually and by optical microscopy for gross features. To resolve features of surface morphology less than a few microns, the surfaces were studied using a scanning electron microscope operated in the emissive mode (9).

Results

Table I gives representative data for etching of silicon with chlorine in helium over the temperature range 900°-1100°C and as a function of concentration. These data show that the etch rate varies approximately as the first power of chlorine concentration over the range of conditions studied. The efficiency of the most probable etching reaction

Table I. Etching of silicon with Cl_2 in helium

Temp, °C	Concentration of Cl_2, %	Etch rate, μ/min	Surface appearance

$$Si + Cl_2 \rightarrow SiCl_2 \quad [1]$$

is 2% at 900°C and 4% at 1100°C. A plot of the etch rate for 0.2% Cl_2 as a function of reciprocal temperature yields an apparent activation energy of +10 kcal/mole.

For 0.2% Cl_2 concentration, smooth, reflecting surfaces were obtained in the temperature range 1000°-1100°C. For higher concentrations of Cl_2 and at temperatures below 1000°C rough surfaces were obtained. As indicated in Table I, the roughness is due to steps and pits, examples of which are shown in Fig. 2 and Fig. 3, respectively, for a sample etched at 900°C with 0.2% Cl_2. The pits (Fig. 2) are about 5μ on an edge, while the steps (Fig. 3) are about 0.3-0.5μ in height and 3μ in width. In most experiments no other surface features were observed. However, in several experiments in which leaks occurred, the silicon surface was severely roughened and was covered with small particles of carbon, apparently due to the attack of the SiC susceptor by Cl_2 gas in the presence of oxygen (10).

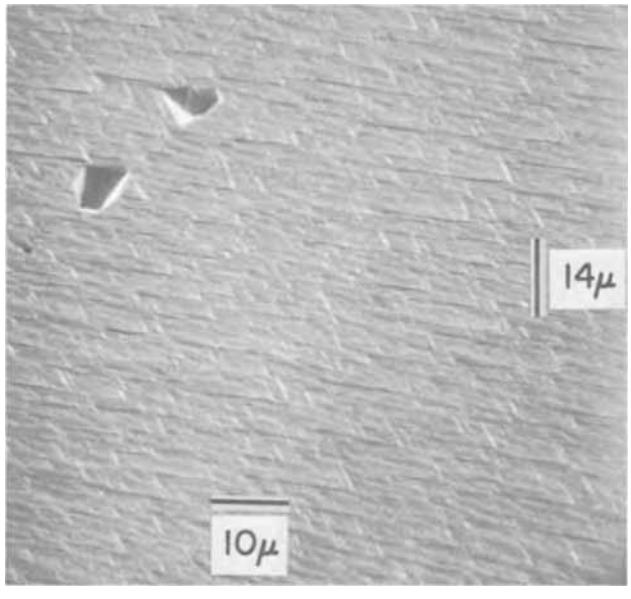

Fig. 2. Scanning electron micrographs at 45° incidence showing etch pits on a silicon surface etched with 0.2% Cl_2 at 900°C.

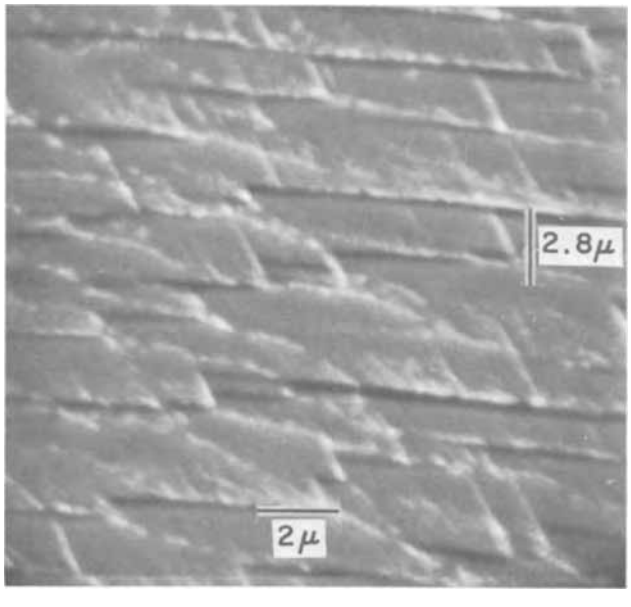

Fig. 3. Scanning electron micrograph at 45° incidence showing step pattern on a silicon surface etched with 0.2% Cl_2 at 900°C.

Discussion

The over-all kinetics in a gas phase reactor such as that shown in Fig. 1 can be quite complex, since the gas stream is not heated uniformly and since the residence time in the reactor depends on the gas flow velocity. Nevertheless, from experimental data it is often possible to distinguish one of the following three processes (11) as the rate-limiting step: (*i*) transport of the reactants to the reaction zone; (*ii*) diffusion of reactants and products to and from the reaction surface; and (*iii*) chemical reaction, which includes the separate steps of adsorption of reactants on the surface, reaction on the surface, and desorption of products from the surface. For large flow velocities such as employed here, case I can be neglected, so that the problem reduces to distinguishing between diffusion (case II) and chemical reaction (case III) as the rate-limiting processes.

The rate of gaseous diffusion (12) increases with temperature as T^n, where n is between 1.5 and 2, whereas the rate of etching increases with temperature approximately as T^4 in the temperature range 900°-1100°C. Therefore diffusion appears not to be rate limiting.

The calculated free energy change (13, 14) for the reaction in Eq. [1] at 900°C is −49 kcal/mole, in contrast to the observed activation energy of +10 kcal/mole determined from the data in Table I. This result indicates that Eq. [1] does not represent the rate-limiting step in the attack of silicon by chlorine gas, although it may well represent the over-all chemical reaction. But one of the elemental detailed steps (case III) of the total reaction could be rate limiting.

Conclusions

Chlorine is a more rapid and efficient etch for silicon than hydrogen chloride (7) between 900° and 1100°C, and gives smooth surfaces above 1000°C for concentrations $\leq$1% Cl_2. Preferential etching, characterized by pits and steps, occurs at temperatures below 1000°C. The rate-limiting process in the attack of silicon by chlorine appears not to be diffusion, but instead chemical reaction.

Mechanism of Cu_2O Tarnish Formation on Cu/30Zn: A $_{29}Cu^{64}$ Tracer Study

Stuart S. Birley and Desmond Tromans

Metallurgy Department, University of British Columbia, Vancouver 8, British Columbia, Canada

The mechanism of black tarnish film formation on the surface of alpha-phase copper-based zinc alloys immersed in either aqueous ammoniacal solutions of copper sulfate (pH ~ 7) or concentrated ammoniacal solutions containing dissolved copper is uncertain. It is generally agreed that the tarnish is composed primarily of Cu_2O (1-6). However, it is debatable whether or not the formation of Cu_2O proceeds by preferential dissolution of zinc accompanied by solid-state diffusion processes to produce Cu_2O (7), or whether both copper and zinc atoms are simultaneously dissolved with subsequent deposition of Cu_2O from solution (8). Recent kinetic studies on Cu_2O tarnish formation suggest that the mechanism involves dissolution of copper and zinc atoms followed by deposition of Cu_2O (5). The present work reports a more direct study involving the use of a radioactive copper tracer, $_{29}Cu^{64}$.

Experimental Procedures

The essence of the present technique involved the formation of Cu_2O on alpha Cu-Zn in the presence of an ammoniacal solution of copper sulfate containing $_{29}Cu^{64}$. Consequently, if Cu_2O formation entails dissolution of copper atoms from the alloy, and their subsequent deposition as Cu_2O, once these atoms enter solution they become chemically indistinguishable from the radioactive $_{29}Cu^{64}$ already in solution. Hence, Cu_2O formed by deposition should contain a mixture of both the normal copper isotopes ($_{29}Cu^{63}$ and $_{29}Cu^{65}$) and the tracer $_{29}Cu^{64}$, and should be measurably radioactive.

The tarnishing solution consisted of 0.04M $CuSO_4$ and 1.57M $(NH_4)_2SO_4$ with a pH of 7. This was of similar composition to that used in previous studies (4, 6). Two solutions were prepared, one containing the radioactive isotope $_{29}Cu^{64}$, and the second a control solution containing normal unirradiated copper. The radioactive solution was prepared by irradiating 1.27g of coiled copper strip (99.99% purity) for 1 min in a flux of 4.4×10^{13} thermal neutrons $\cdot$ cm^{-2} $\cdot$ sec^{-1} in the WR-1 Pneumatic Capsule Facility of Atomic Energy of Canada Ltd. The irradiated copper was subsequently dissolved in 63 cc of boiling 12.8M H_2SO_4 solution, the solution cooled, and neutralized with 104 cc of 15M NH_4OH. The volume of the resulting solution was raised to 500 cc by addition of distilled water and the pH adjusted to 7.0 by addition of 2M NH_4OH. All individual solutions were oxygenated prior to final mixing to prevent the aging and precipitation phenomena sometimes encountered in ammoniacal copper sulfate solutions (4, 9). The control solution was prepared in an identical manner except that the copper was unirradiated.

The alpha-brass employed for the studies consisted of Cu-29.38 w/o (weight per cent) Zn, and was of identical composition to that used previously (6). The actual specimens were in the form of squares of annealed strip 0.75 mm in thickness and 12 mm square. Prior to tarnishing the squares were degreased in trichlorethylene, cleaned in 45 v/o (volume per cent) HNO_3, washed in distilled water, and allowed to dry.

Tarnishing was conducted at room temperature in both the radioactive and control solution by placing 5 squares in a 150 cc aliquot of the active solution and 5 squares in a 150 cc aliquot of the control solution. Immersion time was 15 hr during which the solutions were stirred continuously. This procedure yielded tarnish films of 8μ thickness (as revealed by subsequent optical microscopy on sectioned specimens). After immersion, the tarnished squares were removed singly from the radioactive solution, agitated vigorously for 5 min in fresh distilled water to remove residues of solution, and allowed to dry. In the case of the nonradioactive control solution, 2 tarnished brass squares were removed, washed, and dried as before, and 3 brass squares were removed and further immersed for 5 sec in a 150 cc aliquot of fresh radioactive solution and again washed and dried in a similar manner. The further-immersion treatment allowed radioactive solution to penetrate any pores (1, 5) present in the Cu_2O tarnish and facilitated assessment of the residual radiation arising from entrapment of residues of radioactive solution within such pores. The 5 sec further-immersion treatment was of insufficient duration to produce appreciable growth of tarnish in the presence of the radioactive solution, as confirmed by subsequent comparison of the tarnish thickness with the 2 control specimens which did not undergo a further-immersion treatment.

All tarnished squares exposed to the radioactive solution were sealed in polythene bags and the intensity of the γ-radiation spectrum of $_{29}Cu^{64}$ determined for each specimen. The radiation was measured with a NaI scintillation detector, recorded autographically, and tabulated. The area beneath the low energy intensity peak of the γ-spectrum (*i.e.*, the integrated activity), corresponding to the 511 keV positron annihilation, was taken as a relative measure of the amount of $_{29}Cu^{64}$ present in the Cu_2O tarnish film. The 511 keV was chosen as this is the highest intensity peak in the spectrum and is more sensitive to measurement. The count corresponding to the area of the peak was corrected to a reference time as contingency for the different degree of radioactive decay in the tarnish films during the counting period.

Observations and Discussion

An example of the low-energy γ-spectrum peak for a specimen tarnished for 15 hr in the radioactive solution and an example of the same peak for a specimen immersed 15 hr in the nonradioactive control solution followed by 5 sec further immersion in radioactive solution are shown in Fig. 1. The γ-radiation intensity

Key words: ammoniacal, dissolution, deposition, irradiation, stress corrosion.

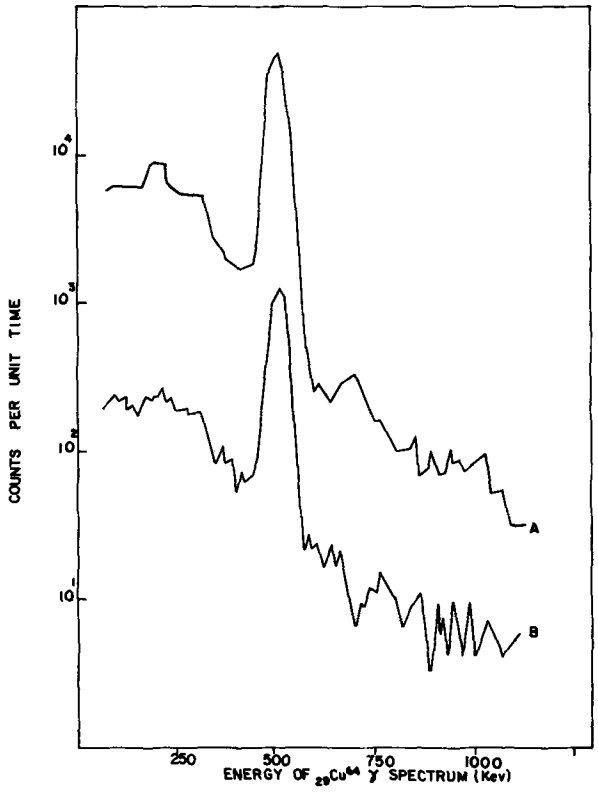

Fig. 1. An example (A) of the low energy γ-spectrum peak for a specimen tarnished for 15 hr in the radioactive solution, and an example (B) of the same peak for a specimen immersed 15 hr in the unirradiated control solution followed by 5 sec further immersion in radioactive solution.

(counts per unit time) is plotted on a log scale and it is readily seen that the area (integrated activity) beneath the γ-peak of the control specimen is considerably smaller than the area beneath the peak of the specimen exposed to the radioactive solution for 15 hr. This suggests that the activity of the latter arises principally from the presence of $_{29}Cu^{64}$ chemically combined in the actual Cu_2O tarnish and not from residues of $_{29}Cu^{64}$ solution entrapped in pores within the tarnish. The corrected areas beneath the γ-peak for all specimens are shown in Table I. It is seen that the integrated activity (counts per minute, c.p.m.) of the γ-peak for specimens tarnished 15 hr in the radioactive $_{29}Cu^{64}$ solution is ~40 times larger than the integrated activity of the γ-peak of the control specimens. Thus, the results suggest that the mechanism of Cu_2O tarnish formation on alpha-brass in the presence of aqueous-ammoniacal copper sulfate solutions involves the deposition of Cu_2O from solution. This has far-reaching implications in the field of ammoniacal stress-corrosion cracking of alpha-brass where Cu_2O tarnish films are believed to play a role (1, 2, 5-7, 10), because the kinetics of stress-corrosion cracking may now be considered in terms of the kinetics of the Cu_2O deposition process.

Table I. Activity of tarnished specimens

Tarnished specimens	Integrated activity of γ-peak (c.p.m.)
15 hr immersion in radioactive $_{29}Cu^{64}$ solution	
Spec. 1	2.4×10^6
Spec. 2	3.2×10^6
Spec. 3	2.5×10^6
Spec. 4	1.7×10^6
Spec. 5	2.5×10^6
	Average, 2.5×10^6
Control specimens	
Spec. 1	3×10^4
Spec. 2	7×10^4
Spec. 3	8×10^4
	Average, 6×10^4

c.p.m. = counts per minute.
Control specimen immersed for 15 hr in unirradiated tarnishing solution, followed by further immersion for 5 sec in radioactive $_{29}Cu^{64}$ solution.

Silicate Oxyapatites: New High-Energy Storage Laser Hosts for Nd^{+3}

R. H. Hopkins, G. W. Roland, K. B. Steinbruegge, and W. D. Partlow

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

Materials with the apatite structure, space group $P6_3/m$, are widely used as fluorescent-ion hosts (1, 2). One of these materials, fluorapatite (FAP), $Ca_5(PO_4)_3F$, has the highest long-pulse efficiency and lowest threshold of any known Nd^{+3}-doped crystalline laser material (3), properties which are attributed to the broad absorption spectrum and unique site

Key words: optics, fluorescence, oscillator, rare earth, infrared.

symmetry of Nd^{+3} in the structure. The high gain of the FAP:Nd^{+3} laser, although beneficial in long-pulse and CW applications, severely limits its use in Q-switched operation, and for this reason we sought other apatite varieties in which the local ionic environment of the fluorescing ion (*e.g.*, Nd^{+3}) could be altered to enhance the energy storage capabilities while still retaining the high-efficiency characteristic of FAP.

We developed a series of new hosts, the silicate oxyapatites (4, 5). A general chemical formula for these compounds can be written $MeLn_4(SiO_4)_3O$, where Me is a divalent alkaline earth ion, Mg^{+2}, Ca^{+2}, Sr^{+2}, etc., and Ln is a trivalent rare earth ion, Y^{+3}, La^{+3}, Gd^{+3}, etc. Since a large fraction of the ions in silicate oxyapatites are trivalent, doping of these hosts with trivalent fluorescing ions should be appreciably easier than in the case of FAP where charge compensation must accompany rare earth substitution for calcium (6). We synthesized polycrystalline samples of various silicate oxyapatites doped with Nd^{+3} and other activators and grew single crystals of the more promising hosts by Czochralski pulling.

This paper describes the crystal growth, characterizes the quality of the early crystals, and presents typical physical, optical, and laser properties for the crystals. For the sake of brevity, we have chosen to discuss only the compounds $SrLa_4(SiO_4)_3O$ and $CaLa_4(SiO_4)_3O$ as representative members of the material class.

Reactant material was prepared from 99.99% purity rare earth oxides (American Potash and Chemical Co.) and standard Luminescent Grade alkaline earth carbonates (Mallinckrodt) weighed according to the stoichiometric formulas. The doping ion, *e.g.* Nd^{+3}, was substituted in oxide form for the rare earth host constituent, La^{+3}. Charges were melted by induction heating in an iridium crucible protected from oxidation by a flowing argon atmosphere. Silicate oxyapatites melt congruently and are therefore amenable to growth by the Czochralski method; the pulling apparatus we used is essentially that described by Mazelsky *et al.* (6, 7). It was suitably modified with zirconia refractories to support the high temperatures required for growth of $SrLa_4(SiO_4)_3O$ and $CaLa_4(SiO_4)_3O$ (melting points about 2180°C by uncorrected pyrometer reading). Crystals were pulled at rates between 1 and 5 mm/hr with crystal rotation in the range of 70-90 rpm. Crystals as large as 12.5 cm long x 0.64 cm diameter have been grown with Nd^{+3} doping levels as high as 3% of the total (Ca^{+2} + La^{+3}) sites in the structure.

Typical crystals grown in the *a* or c direction have poorly developed facets, and the crystal surfaces are somewhat wrinkled. This may be due to selective volatility of one of the components (8), and apparently does not seriously impair crystal quality. By comparing decay times for Nd^{+3} measured in polycrystalline samples of known composition with those measured for single crystals, as well as by chemical analysis, we place the value of effective distribution coefficient of Nd^{+3} in $CaLa_4(SiO_4)_3O$, K'_{Nd}, in the range 0.8-1.0.

Single crystals of $CaLa_4(SiO_4)_3O$ were studied by means of a Buerger precession x-ray camera using both MoKα and CuKα radiation. The only systematic absences are reflections of the type $000\underline{l}$ with $\underline{l}$ odd. The Laue class is $6/m$ and diffraction aspect $P6_3/*$ so that either $P6_3$ or $P6_3/m$ are possible space groups. $P6_3/m$ is chosen on the basis of etch pits (see below) which clearly show the presence of a mirror plane normal to *c* in the structure. The relative intensities of spots from single-crystal x-ray patterns confirm that this silicate oxyapatite is essentially isostructural with FAP, although it is unclear whether La^{+3} substitutes randomly or preferentially on either the CaI and CaII sites in the fluorapatite structure. Debye-Scherrer x-ray powder photographs from polycrystalline samples were indexed on the basis of a hexagonal cell with dimensions slightly larger than those of FAP. The lattice dimensions for $SrLa_4(SiO_4)_3O$ and $CaLa_4(SiO_4)_3O$ are $a = 9.645 \pm 0.003$Å, $c = 7.215 \pm 0.004$Å, and $a = 9.631 \pm 0.004$Å, $c = 7.133 \pm 0.004$Å, respectively.

We qualitatively evaluated the perfection of $CaLa_4(SiO_4)_3O$ crystals by studying etch pit arrays on chemically polished surfaces and by Twyman-Green interferometry with a He-Ne laser. Immersing crystals of $CaLa_4(SiO_4)_3O$ in a fused eutectic mixture of NaF and KF at 350°C produced smooth polished surfaces on both *a* and c faces, though the quality of polish was better on *a* faces. Etching crystals with *aqua regia* for 1-3 min revealed well-defined etch pits displaying the symmetry characteristic of the etched face. The etch pit density on the *a* face of crystals pulled in the c direction was about 6 x $10^4/cm^2$. Etch pits in FAP correspond to dislocation sites (9, 10) and, although we did not verify this for silicate oxyapatites, we assume the etch pit density is representative of the dislocation content. A Twyman-Green interferogram (Fig. 1) taken through 4.6 cm of a $CaLa_4(SiO_4)_3O$ crystal containing 3% Nd^{+3} (pulled at 5 mm/hr) shows approximately seven fringes across a 0.64 cm diameter. We consider that the crystal quality is quite good considering that the rapid growth rate promoted the formation of second-phase inclusions along the rod center. The circular nature of the fringes is not indicative of a "core" or facet defect, from which the crystals are apparently free, but is related to variations of dopant distribution about the centrally located inclusions. When viewing crystals in the optical microscope, we occasionally observed 3-5 μm sized particles having color and shape similar to iridium oxide flakes (11) which are often present in high-melting Czochralski-grown crystals.

We measured the spectroscopic properties of Nd^{+3} in polycrystalline and single-crystal silicate oxyapatite samples. Typically, the primary transition at 1.06 μm is 50-60Å broad, Fig. 2, and only slightly polarized with a π to σ ratio of about 1.3. The net radiative branching of $^4F_{3/2}$ into this transition is similar to that for FAP:Nd^{+3} which has a 6Å line width and $\pi/\sigma = 2.6$ (3). The lifetime of the $^4F_{3/2}$ state of Nd^{+3} in the silicate oxyapatites is 200-250 μsec at low dopant concentrations. Thus the peak gain per excited Nd^{+3} ion in $CaLa_4(SiO_4)_3O$:Nd^{+3} and $SrLa_4(SiO_4)_3O$:Nd^{+3} should be down by nearly an order of magnitude, and energy storage capabilities increased by the same factor, relative to FAP. Energy storage for Nd^{+3}-doped

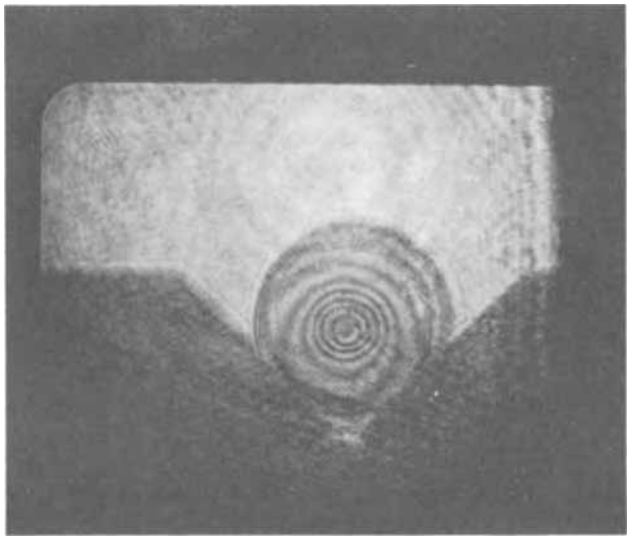

Fig. 1. Twyman-Green interference pattern observed with He-Ne laser traversing a 4.6 cm length of 3%Nd-doped $CaLa_4(SiO_4)_3O$. Crystal is 0.64 cm in diameter.

Table I. Comparison of long-pulse laser test data (298°K) for various Nd laser hosts

Laser material	Fluorescence peak (Å)	Fluorescence line width (Å)	Rod size (cm)	Distributed loss coefficient (cm^{-1})	Maximum slope efficiency, %	Threshold 99-99% Refl* (joules)
$CaLa_4(SiO_4)_3O$:3% Nd	10,613	~53	0.64 × 4.6	0.010	1.9	5.5
$SrLa_4(SiO_4)_3O$:2% Nd	~10,580	~53	0.43 × 7.5	0.016	2.1	3.2
FAP:2% Nd	10,629	6.6	0.64 × 3.8	0.045	1.53	2
YAG:1.5% Nd	10,637	7.1	0.64 × 3.8	0.017	1.05	3.3

* Both external mirrors had 99% reflectivity, peaked at 1.06 μm.

n_e	1.8227	1.7637	1.631	—

silicate oxyapatite will also exceed that of YAG:Nd^{+3} but by a smaller amount than it exceeds FAP:Nd^{+3}.

Concentration quenching of Nd^{+3} fluorescence is relatively weak in the silicate oxyapatite specimens we have examined. For example, when 2% Nd^{+3} is added to a crystal, the $^4F_{3/2}$ lifetime in $CaLa_4(SiO_4)_3O$:Nd^{+3} is reduced by only 15% from the low concentration value. This fact, combined with the large value of $K'_{Nd^{+3}}$ in silicate oxyapatite, indicates that it is practical to obtain high laser slope efficiency in these materials by using high Nd^{+3} concentrations.

Our first laser tests of $CaLa_4(SiO_4)_3O$ and $SrLa_4(SiO_4)_3O$ have verified for the most part the behavior predicted from our spectroscopic data. The test setup and methods used here were the same as described in ref. (3), although it was not necessary to use an aqueous sodium nitrite solution to prevent the coloring of the silicate oxyapatite rods during testing. The results of long pulse tests on the first crystals grown and tested are summarized in Table I. No attempt was made to optimize the growth conditions or laser test setup to obtain these data. While it is difficult to draw direct comparisons due to the variation in laser rod diameter, doping level, and quality among the hosts, the high efficiency, relatively low threshold, and low loss coefficient for these early silicate oxyapatite crystals are evident. Preliminary tests indicate that the slope efficiency of these lasers is essentially the same in the long-pulse and Q-switched modes of operation.

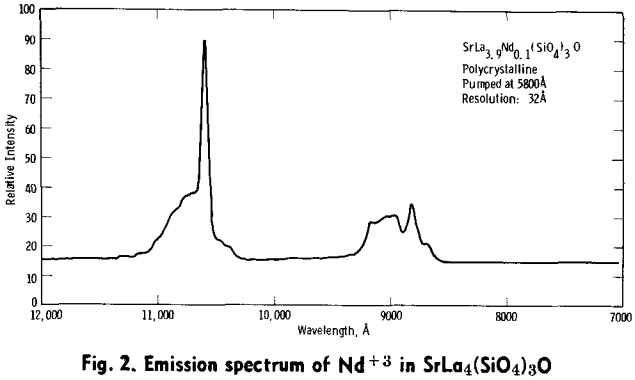

Fig. 2. Emission spectrum of Nd^{+3} in $SrLa_4(SiO_4)_3O$

Table II summarizes some of the other properties of the silicate oxyapatites, pertinent to laser performance, which we have measured to date. The indexes of refraction were determined by the normal incidence method on single-crystal wedges of the various materials. We find that the hardness of silicate oxyapatites lies between those of FAP and YAG, though closer to YAG. Silicate oxyapatites should, therefore, be much more resistant to distortion and fracture at high pump power levels than is FAP.

Acknowledgments

We would like to thank Mr. R. L. Remski, Air Force Avionics Laboratory, for performing the Twyman-Green analysis of our crystals; Dr. J. D. Feichtner for measuring the indexes of refraction; Mr. A. M. Stewart who contributed to all phases of the crystal-growth studies; and Mr. R. Perevuznik who carried out some spectroscopic measurements.

A Comparison of the Hole Mobility and Early Growth of Epitaxial Silicon on Flame Fusion, Flux, and Czochralski Spinel

G. W. Cullen* and C. C. Wang*
RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

Sapphire has been investigated more extensively than magnesium aluminate spinel as an insulating substrate material for the heteroepitaxial growth of silicon (1). This has been due more to the commercial availability of high quality flame fusion sapphire (2) than to the inherent properties of the two materials. The lattice match between the cubic spinel and cubic silicon is closer than the match between rhombohedral sapphire and cubic silicon (3-5), and the silicon epitaxially deposited on flame fusion spinel has proved to be less contaminated by substrate constituents than silicon deposited on sapphire (6).

The heteroepitaxial growth of silicon on spinel was initially demonstrated (5) on commercially available flame fusion spinel with a composition of $MgO \cdot 3.0\text{-}3.5Al_2O_3$. Material of this composition, however, is unstable at temperatures commonly employed during integrated circuit processing (7), and therefore the development of epitaxial silicon on the commercial flame fusion spinel was not pursued. The thermal stability of the flame fusion spinel has proved to be inversely proportional to the alumina content within the composition range $MgO \cdot Al_2O_3$ to $MgO \cdot 3.5Al_2O_3$ (7). Unfortunately, the ease of growth has proved to be directly proportional to the alumina content (7). A workable compromise between ease of growth and thermal stability has been established within the composition range $MgO \cdot 1.5Al_2O_3$ to $MgO \cdot 2.5Al_2O_3$ (7, 8), and relatively high hole mobilities have been realized in silicon deposited on this material (9-11). Flame fusion spinel within this composition range is not at present commercially available.

The stoichiometric ($MgO \cdot Al_2O_3$) flux grown spinel (12, 13) has also been investigated as a substrate material (14). A disadvantage to the use of the flux spinel is that it commonly contains constituents of the flux from which it was grown. Although methods have been developed for the removal of the impurities (14), the flux spinel has not been emphasized for silicon substrate use because of the inconvenience of using these procedures. Interest has recently been renewed in the flux spinel because the microwave attenuation in this material is lower than in other materials measured to date (15, 16). For a number of device applications, it would be advantageous to have epitaxial silicon on a microwave delay line material.

A number of investigators have reported on the Czochralski growth of stoichiometric spinel (17-19), and this material has recently been made commercially available (2). There is little information to be found in the literature, however, on the electrical properties of silicon on Czochralski spinel.

In this communication the magnitude of the hole mobilities before and after thermal oxidation and the nature of the film growth prior to complete coverage of the substrate are compared in silicon on flame fusion, flux, and Czochralski spinel. The characteristics of silicon on spinel are also compared with those of silicon on flame fusion sapphire.

Hole Mobilities in Silicon on Spinel

The hole mobility, which is highly dependent on both the crystallographic structure and the impurity content of the silicon films, has been used both as a means to compare the quality of the films epitaxially deposited on the various substrates and to anticipate the applicability of the films in device structures. The hole mobility is also a strong function of thermal treatment and film thickness. Therefore the mobility was measured in the as-deposited film and also after exposure to dry oxygen for 1 hr at 1100°C. This treatment is approximately equivalent to the total oxidation employed during the processing of an MOS transistor.

[While it is convenient and rapid to use the Hall mobility to monitor the film quality, this results in a pessimistic evaluation of the silicon films for use in MOS transistor structures. The field effect mobility of a completed MOS device is measured only in ~500Å of the silicon most remote from the silicon-substrate interface. In 1.5μ thick silicon on sapphire with hole mobilities ~30% of bulk, MOS field effect mobilities have been measured which are ~70% of the values measured in devices fabricated in bulk silicon (20)].

The thickness of all the silicon on spinel films discussed in this communication is $1.5 \pm 0.1\mu$. Diborane diluted with hydrogen was used as the dopant source. As-deposited hole concentrations of the films are between 1 and 5×10^{16} cm^{-3}. Within this range, for comparative purposes, the differences in the hole concentrations may be normalized by reference to a curve (21) of experimentally determined bulk silicon hole mobility *vs.* hole concentration (*i.e.*, per cent of bulk mobility values are compared). The silicon was deposited by the pyrolysis of silane in a hydrogen ambient, the substrate was heated by contact with an inductively heated pyrolytic carbon coated carbon susceptor, and the growth ampoule was water cooled. The film thickness was measured both during growth (22) and after deposition by interferometry. Details of the apparatus and procedures have been previously reported (9).

The hole mobilities realized on flame fusion, flux, and Czochralski spinel are compared in Table I. The hole mobility of 330 cm^2/V-sec ($n_a = 1.8 \times 10^{16}$ cm^{-3}) is typical of many 1.5μ thick samples prepared on (111) flame fusion spinel (9). This film was deposited at a temperature of 1100°C and a growth rate of 0.8 μ/min. The substrate was hydrogen prefired for 20 min at 1150°C to remove the work damage introduced by mechanical polishing. Single crystal low angle electron diffraction patterns are obtained on hydrogen etched flame fusion spinel surfaces. In this carrier

Table I. Hole mobilities in silicon epitaxially deposited on flame fusion, flux, and Czochralski spinel

Substrate	Thermal treatment	Hole concentration, cm^{-3}	Hole mobility, cm^2/V-sec	Per cent of bulk mobility
Flame fusion	As-deposited	1.8×10^{16}	330	100
$MgO \cdot 2.2Al_2O_3$	Oxidized	1.1×10^{16}	320	92
Flux	As-deposited	1.3×10^{16}	200	58
$MgO \cdot Al_2O_3$	Oxidized	2.8×10^{16}	200	60
Czochralski	As-deposited	4.2×10^{16}	250	80
$MgO \cdot Al_2O_3$	Oxidized	4.2×10^{16}	220	70

Deposit thickness: $1.5 \pm 0.1\mu$.
Oxidation: Dry oxygen, 1 hr; flame fusion—1200°C, flux and Czochralski—1100°C.
Substrate and film orientation: (111).

* Electrochemical Society Active Member.
Key words: silicon thin films, semiconductor thin films, insulating substrates, silicon on insulating substrates, chemical vapor deposition.

concentration range the hole mobilities are degraded by less than 5%, and the magnitude of the degradation is relatively insensitive to the growth rate (9). The after-oxidation hole mobility of 320 cm^2/V-sec (n_a = 1.1 x 10^{16} cm^{-3}) is ~92% of the bulk reference value.

Using hydrogen etching and deposition conditions identical to those used with flame fusion spinel, a hole mobility of 200 cm^2/V-sec (n_a = 1.3 x 10^{16} cm^{-3}) was obtained in a 1.5μ thick silicon film on (111) flux spinel. Flux impurities were gettered by deposition of silicon, removal, and redeposition of the silicon. The hole mobilities increased with each deposition to the value reported, which is a typical value after the third deposition. The substrate impurity content may also be reduced by vacuum firing of the substrate wafers (14). The mobilities in silicon on flux spinel, within this carrier concentration range, are also not significantly degraded during thermal oxidation. The after-oxidation mobility of 200 cm^2/V-sec (n_a = 2.8 x 10^{16} cm^{-3}) represents 60% of the bulk reference value. A mobility of 300 cm^2/V-sec in a 2μ thick film has been previously reported (14). The relatively low hole mobility in the 1.5μ thick silicon on flux spinel is attributed to contamination of the silicon films by flux impurities (lead compounds) from the substrate.

If the hydrogen prefiring and deposition conditions used with flux and flame fusion spinel are employed for epitaxial growth on Czochralski spinel, high resistivity films are obtained. The resistivities are relatively insensitive to the amount of added dopant (diborane), and doping levels must be used which are more than an order of magnitude greater than are required to obtain the same hole concentration in silicon on flame fusion spinel. The hole mobilities of these films are less than 100 cm^2/V-sec (n_a ~ 5 x 10^{16} cm^{-3}), and therefore it appears that the added dopant is compensated by, and the mobility degraded by, impurities introduced as the result of interaction with the substrate. Similar properties were obtained using substrate wafers cut from in-house and commercially available (2) Czochralski spinel crystals.

Silicon gettering procedures employed with the flux spinel were not effective in improving the properties of silicon on Czochralski grown material. After testing a variety of conditions for the growth of silicon on Czochralski spinel in a hydrogen ambient, it was found that the highest mobilities were obtained on substrates which had been exposed to a minimum of thermal treatment. The highest as-deposited hole mobility achieved to date in 1.5μ thick films was 250 cm^2/V-sec (n_a = 4.2 x 10^{16} cm^{-3}). This value decreased to 220 cm^2/V-sec (n_a unchanged) during thermal oxidation. The after-oxidation value represents ~70% of the reference bulk value. It has been found that under conditions where thermal pregrowth treatment in hydrogen of the substrate must be minimized, the electrical properties of the epitaxial silicon are highly sensitive to small variations in the surface polishing and cleaning procedures.

Higher hole mobilities have been observed in (111) silicon on (111) spinel than in (100) silicon on (100) spinel (9). But the mobilities of thin (100) silicon on the $(1\bar{1}02)$ sapphire have been higher than in (111) silicon on (0001) sapphire (23). After-oxidation hole mobilities of 150 cm^2/V-sec (n_a = 1 x 10^{16} cm^{-3}) have been typically observed in 1.7μ thick (100) silicon on sapphire (24, 25).

Nature of Silicon Growth Prior to Complete Coverage of Substrate Surface

Silicon was simultaneously deposited on (111) flame fusion and Czochralski spinel and on $(1\bar{1}02)$ flame fusion sapphire in a single growth run, and on (111) flux spinel in a separate run. The samples were all hydrogen prefired, and the silicon was deposited for 5 sec under conditions which give an over-all growth rate of 0.8 μ/min. Scanning electron micrographs of the surfaces are shown in Fig. 1.

The geometry of the incomplete films and the per cent of the surface coverage are similar on the flame fusion (Fig. 1a) and Czochralski spinel (Fig. 1b). The most obvious difference between the deposits on these two materials is that substrate reaction products are seen on the exposed areas of the Czochralski spinel. It also appears, from the nature of the silicon surface,

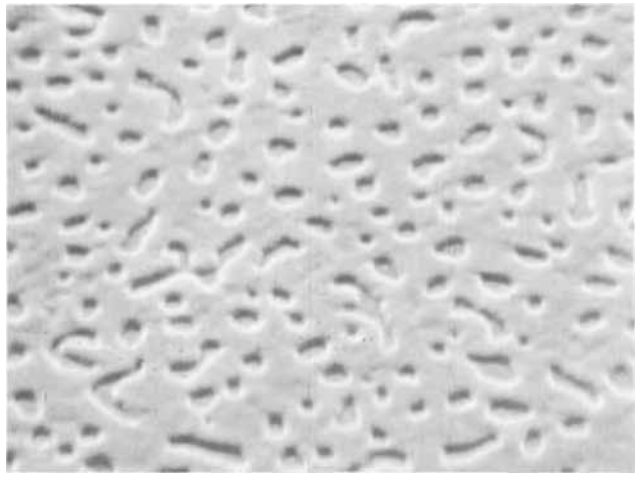

Fig. 1a-d. Scanning electron micrographs of silicon after deposition for 5 sec at 0.8 μ/min. Magnification 10,000X, beam sample angle 45°. Fig. 1a. On flame fusion spinel.

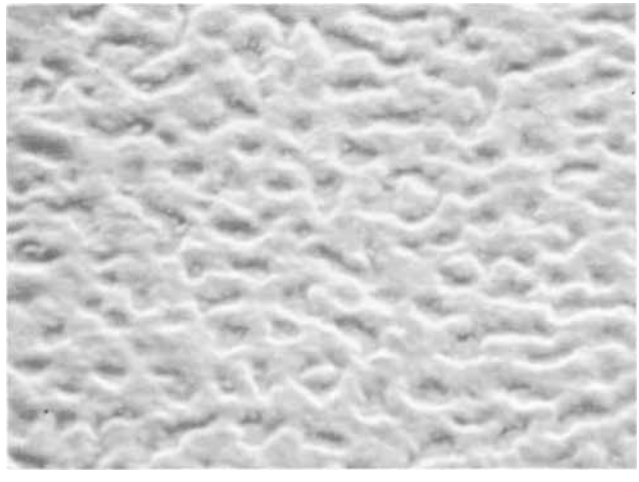

Fig. 1b. On Czochralski spinel

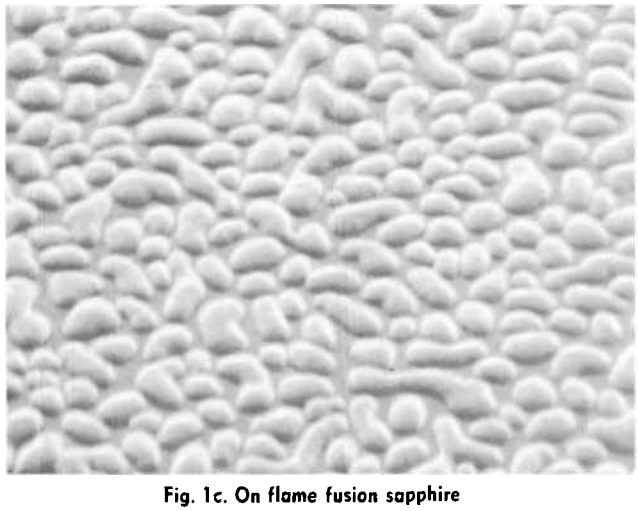

Fig. 1c. On flame fusion sapphire

Fig. 1d. On flux sample

that the reaction products have been incorporated into the growing film. The difference between the deposits on the flame fusion and Czochralski spinel may be seen in more detail at double the magnification and at a sample-beam angle more nearly normal to the surface (Fig. 2a and b). The geometry and per cent of surface coverage of silicon on flame fusion sapphire (Fig. 1c) are considerably different. The nature of the incomplete growth on the flux spinel (Fig. 1d) is more similar to that on sapphire than to the growth on the other two spinel samples. The appearance of the growth on flux spinel and sapphire is similar to that observed on flame fusion spinel during an earlier stage of growth prior to coalescence of the individual silicon islands. The lack of coalescence on the flux spinel can be attributed to a slight difference in growth duration, but the silicon on flame fusion sapphire was deposited in the same run as on the flame fusion and Czochralski spinel. Thus it appears that, under the same growth conditions, the surface coverage is more rapid on spinel than on sapphire.

Scanning electron micrographs are shown of the flame fusion (Fig. 3a), and Czochralski spinel (Fig. 3b), and the flame fusion sapphire (Fig. 3c) after removal of the silicon with an aqueous HNO_3-HF etch.

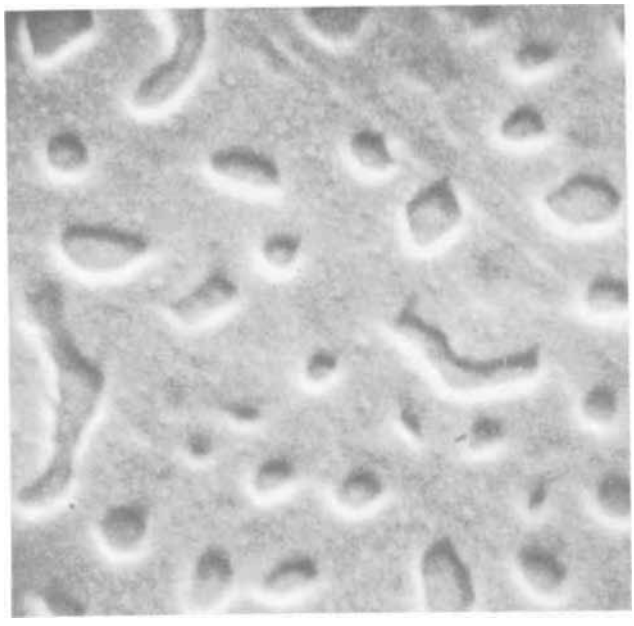

Fig. 2a and b. Scanning electron micrographs of silicon after deposition for 5 sec at 0.8μ/min. Magnification 20,000X, beam sample angle 70°. Fig. 2a. On flame fusion spinel.

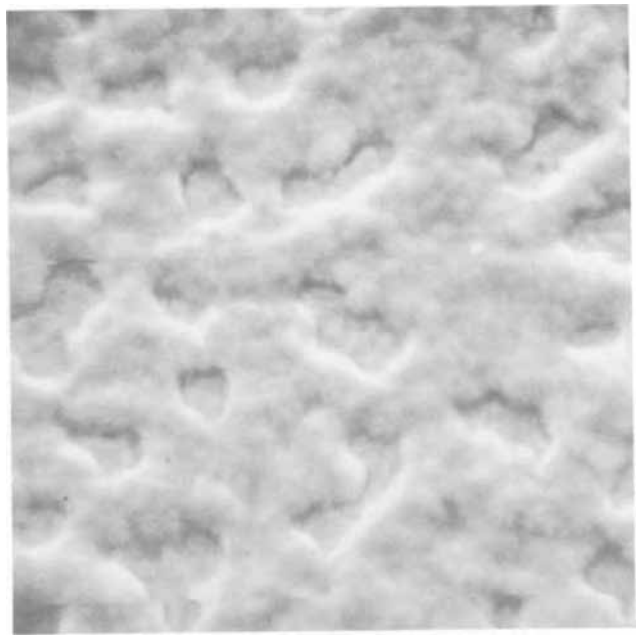

Fig. 2b. On Czochralski spinel

Fig. 3 a, b, c. Scanning electron micrographs of the substrate surfaces after the chemical dissolution of the silicon deposit. Magnification 10,000X, beam sample angle 45°. Fig. 3a. Flame fusion spinel.

Fig. 3b. Czochralski spinel

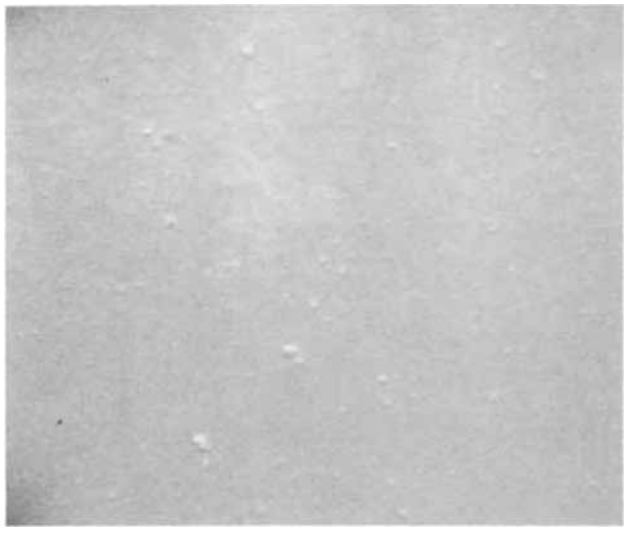

Fig. 3c. Flame fusion sapphire

The flame fusion substrate has been eroded at work damaged areas. This surface is characteristic of a hydrogen etched spinel which was not sufficiently polished to remove work damage introduced during the lapping step. Electron microscopic examination of hydrogen fired substrates has been adopted as a means to evaluate the mechanical finishing procedures.

The surface of the Czochralski spinel from which the silicon has been removed is uniformly and relatively deeply eroded. The surface of this spinel had been polished using the same procedures employed for polishing the flame fusion spinel, but the erosion appears to have extended deeper than the work damage. The surface of the sapphire is free of work damage erosion. Some residues remain on the surface which were not removed by the HNO_3-HF etch. These residues have been identified as highly nonreactive aluminum silicates.

Discussion

The defect density decreases, but the impurity content increases, in spinel crystals grown by the three methods in the following order: flame fusion — Czochralski — flux. This is due to the relative steepness of the thermal gradient and the chemical ambient in which the crystals are grown. It is interesting to note that no difference has been observed in the electrical properties of silicon deposited on flame fusion and Czochralski sapphire (26). The nature of silicon on sapphire appears to be dominated more by the lattice mismatch than by the defect density of the substrate.

It has been demonstrated in this communication that the properties of silicon on spinel are a strong function of the method by which the substrate crystals are grown, even for crystals of nominally the same composition. The lattices of the silicon and spinel are more closely matched than those of silicon and sapphire, but as with silicon on sapphire, the differences observed in the electrical properties of silicon deposited on spinel prepared by the three methods cannot be related to differences in the defect densities of the substrates. The highest hole mobilities have been realized on the relatively imperfect flame fusion spinel. The relatively low mobility of silicon on the flux spinel can be attributed to the incomplete removal of constituents of the flux from the substrate, but the impurity content of the flame fusion and Czochralski spinels is similar.

The most obvious difference between the Czochralski and flame fusion spinel is that the flame fusion crystals used in this study contain alumina considerably in excess of the stoichiometric composition. It is difficult, however, to associate the observed mobility-substrate effect with the presence of excess alumina. Both on the basis of lattice match and autodoping effects it is anticipated that the electrical properties of epitaxial silicon would be degraded with increasing alumina content. The lattice constant decreases, and the mismatch between the spinel and silicon lattice increases, with increasing alumina content. Since it has been demonstrated that silicon deposited on flame fusion spinel is less autodoped than silicon on sapphire (6), decreasing the alumina content should, if anything, lead to a decrease in the autodoping. Further evidence for the lack of involvement of the excess alumina *per se* is the observation that different deposition conditions are required for epitaxial growth on the two stoichiometric materials (flux and Czochralski), while the same conditions may be used to deposit on the low-alumina-rich flame fusion and the stoichiometric flux spinels. It is evident from examination of scanning electron micrographs of partially covered substrate surfaces that a difference in surface chemical reactivity is the source of the differences in electrical properties observed in silicon on flame fusion and Czochralski spinel. The surface reactivity is strongly influenced by the thermal treatment immediately prior to epitaxial growth. The highest mobilities have been obtained in silicon on Czochralski spinel which has been exposed to a minimum of annealing, while optimum properties are obtained in silicon on flame fusion spinel and flame fusion or Czochralski sapphire which has been annealed in hydrogen at or above the growth temperature. The surface conditioning-ambient-growth characteristic relationship of silicon on the Czochralski spinel is not well understood and requires further study.

The origin of the difference in the surface reactivity of the two substrate materials is not obvious. Two possible sources are proposed. While excess alumina does not degrade the use of spinel as a substrate, it is possible that excess magnesia influences the surface reactivity (27). The alumina:magnesia ratio is difficult to determine accurately by wet chemical procedures, and the lattice constant is insensitive to small deviations from stoichiometry on the magnesium rich side (28). The difference in surface reactivities may also be the result of the differences in the chemical ambient during crystal growth. The flame fusion crystals are grown in a highly oxidizing ambient in the presence of water (the reaction product in a hydrogen-oxygen flame), while the Czochralski crystals are grown in a dry neutral, or slightly oxidizing, ambient. These conditions affect the hydroxyl content and the arrangement of the magnesium and aluminum on the crystal lattice sites (7). Both of these factors may have a significant influence on the surface reactivity. The relatively high surface reactivity of the nominally stoichiometric Czochralski spinel has been observed specifically under conditions commonly employed for the epitaxial growth of silicon on Czochralski sapphire and flame fusion spinel. Crystal growth, surface conditioning, and epitaxial growth conditions are currently being sought to suppress the surface reactivity and optimize the electrical properties of silicon on Czochralski spinel.

Acknowledgment

The silicon growth and electrical measurements were carried out by F. C. Dougherty, and the scanning electron micrographs were taken by B. J. Seabury. The flame fusion spinel was grown by H. Temple and A. J. Wasielewski, the flux spinel was grown by R. F. Bates, and the "in-house" Czochralski spinel was grown by A. D. Morrison.

The Use of Metal-Organics in the Preparation of Semiconductor Materials

II. II-VI Compounds

H. M. Manasevit and W. I. Simpson*

Autonetics Division of North American Rockwell Corporation, Anaheim, California 92803

Based on a continuing program to examine the use of metal-organics in the preparation of films of semiconductor materials, this paper describes the formation of II-VI compounds on insulating substrates using this approach. The effort on II-VI compounds was first undertaken and successfully demonstrated several years ago in our laboratories and has recently been expanded to include several additional II-VI compound materials. The advantages of the metal-organic approach to semiconductor formation over other CVD processes have been demonstrated in prior studies involving the formation and properties of several epitaxial gallium-group V compounds (1-4) and aluminum-group V compounds (5). For example, the process requires only one hot temperature for the formation and growth of the semiconductor directly on the heated substrate, it simplifies the growth procedure for II-VI's considerably, it is halide-free, and it makes compound semiconductor film growth compatible with the equipment used for the growth of elemental semiconductors.

The studies with II-VI compounds to date have been limited to feasibility studies of the growth process and require further investigation for the optimization of the process; but with the increasing interest being shown in the area of photoconductors, phosphors, and electroluminescent devices, it seems appropriate at this time to report the successful use of the metal-organic technique for the preparation of the selenides, sulfides, and tellurides of zinc and cadmium.

The II-VI films described here were produced by reacting diethylzinc (DEZ) or dimethylcadmium (DMCd) with hydrogen selenide, hydrogen sulfide, or dimethyltellurium (DMT), using essentially the same apparatus previously described (2, 6) for the formation of GaAs and other III-V compounds (Fig. 1). It consists principally of a vertical 60-mm OD quartz reactor containing a side arm and a center tube extending to about 1-2 in. from a rotatable SiC-covered carbon pedestal which can be heated inductively; stainless-steel bubblers containing the liquid metal-organic compounds; appropriate flowmeters for monitoring the carrier gas and the H_2Se and H_2S flows; a burn-off area for hydrogen; and a manifold made from ¼-in. stainless steel tubing. Provisions are made for evacuation of the apparatus and reactor and for bypassing the reactor and keeping the reactants separate until they are to be mixed within the reactor. The hydrides and DMT in a carrier gas are usually intro-

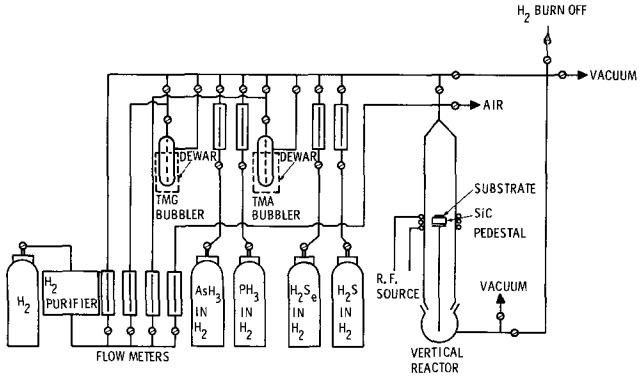

Fig. 1. Schematic of CVD apparatus used in growth studies

Key words: heteroepitaxy, chemical vapor deposition, single crystal insulating substrate.

duced into the reactor through the side arm prior to admitting the group II-metal-organic in its carrier gas via the center tube. The product of their mixing is then decomposed at the heated pedestal to produce the II-VI compound. Total gas flow rates in the range of 2-3 l/min were used in these experiments.

By handling the metal-organics in steel tanks and using adequate ventilation, the reactivity and toxicity problems which are reported for the metal-organics and hydrides are minimized. Only during the studies of telluride formation were extra precautions in ventilation considered necessary to remove the obnoxious odors.

Mechanically polished wafers of Verneuil Al_2O_3 and Czochralski $MgAl_2O_4$ and the naturally occurring facets of flux-grown BeO were used as substrates after a thorough degreasing in trichloroethylene and cleaning in water and methanol. Although this cleaning process is not considered optimum, it was sufficient for providing the films indicated and to establish the feasibility of the process.

Growth temperatures at the SiC-covered pedestal were estimated by comparing the readings of an infrared thermometer with those of an optical pyrometer at pedestal temperatures greater than 750°C (uncorr), establishing an average emissivity value for the system, and then extrapolating the infrared thermometer signal readings to still lower temperatures. The readings are made just prior to the actual deposition. Deposition temperatures in these studies were varied to accommodate the stability of the particular II-VI compound in H_2 or to be consistent with ordered growth and epitaxy. The temperatures reported should not be considered optimum without further experimentation.

Table I. ZnSe epitaxial relationships

Substrate surface plane	Parallel plane in ZnSe film
$(0001)Al_2O_3$	(111)ZnSe
$(11\bar{2}3)Al_2O_3$	(111)ZnSe
$(10\bar{1}4)Al_2O_3$	(111)ZnSe
$(01\bar{1}2)Al_2O_3$	(111)ZnSe
$(10\bar{1}1)$BeO	(111)ZnSe
$(10\bar{1}0)$BeO	(100)ZnSe
(0001)BeO	(111)ZnSe
$(111)MgAl_2O_4$	(111)ZnSe

The structural nature of the deposits, which were several microns thick, was examined first by viewing them in an optical microscope and then by x-ray diffraction and/or electron diffraction analysis. Because of the preliminary nature of these experiments, no measurements of the electrical properties of the films were made.

Single crystal films of ZnSe were grown on single crystal α-Al_2O_3, $MgAl_2O_4$, and BeO at 725°-750°C by decomposing on the heated substrate the product formed by mixing DEZ with H_2Se. Typical ZnSe surface structures are shown in Fig. 2. Growth on a number of orientations of these substrate materials supplied the heteroepitaxial relationships given in Table I. These results are consistent with the growth orientations of GaAs on these substrate planes (6) and, therefore, suggest a similar growth mechanism. Goodman (7) also obtained (111)ZnSe growth on $(01\bar{1}2)$ Al_2O_3 but by using an evaporation technique.

The nature of the surface of ZnS growth on Al_2O_3, $MgAl_2O_4$, and BeO is recorded in Fig. 3. Some crazing can be observed in the films grown on $(0001)Al_2O_3$

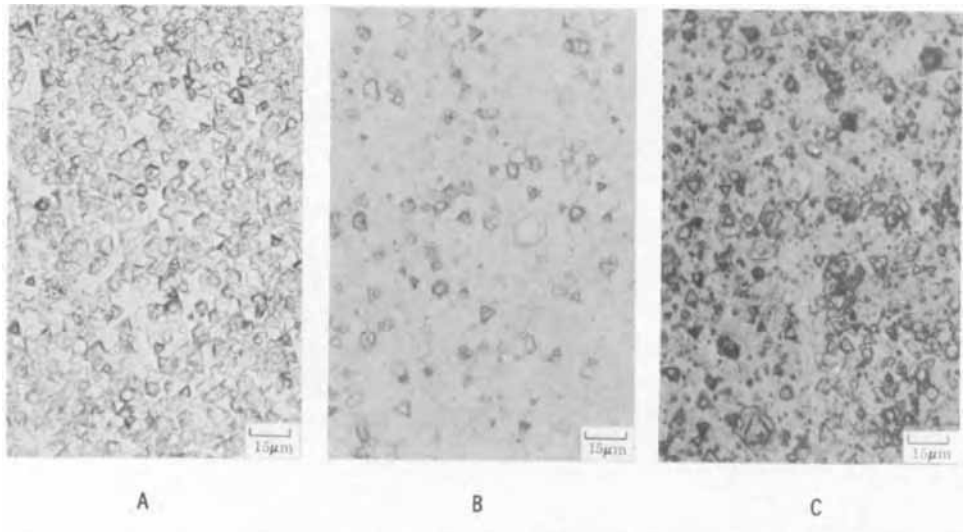

Fig. 2. ZnSe growth on: (a) (left) $(0001)Al_2O_3$; (b) (center) $(111)MgAl_2O_4$; (c) (right) $(10\bar{1}1)$BeO.

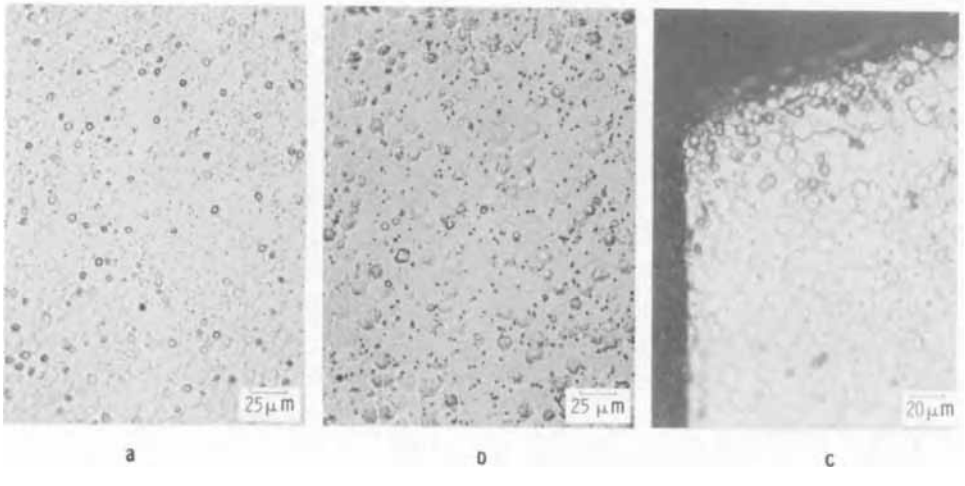

Fig. 3. ZnS growth on (a) (left) $(0001)Al_2O_3$; (b) (center) $(111)MgAl_2O_4$; (c) (right) $(10\bar{1}1)$BeO.

and (111) spinel. The films were grown at about 750°C from DEZ and H_2S.

Single crystal films of ZnTe were produced on Al_2O_3 by reacting DEZ with DMT at about 500°C. The nature of the surface and a Laue pattern of the composite is shown in Fig. 4. The growth shown is (111)ZnTe on (0001)Al_2O_3.

Replacing the DEZ with DMCd led to the formation of the corresponding Cd-group VI semiconducting compounds. The overgrowth of the yellow film of CdS obtained on (0001)Al_2O_3 by reacting DMCd with H_2S at 475°C is shown in Fig. 5. The order seen in the hexagonal structure found on regions of the substrate suggests that heteroepitaxial growth was achieved in those areas.

The growth of CdSe on (0001)Al_2O_3 also displayed a high degree of hexagonal order (Fig. 6). This dark, almost black, film was grown from DMCd and H_2Se at a pedestal temperature of about 600°C.

Specular single crystal films of CdTe were produced at about 500°C from DMCd and DMT on several orientations of Al_2O_3, $MgAl_2O_4$, and BeO. Evidence for the growth of (111)CdTe on $(11\bar{2}6)Al_2O_3$ is shown in Fig. 7, in which a hexagonal and symmetrical array of spots due to the CdTe are distinguishable from those due to the Al_2O_3 substrate, which does not possess this predominant Laue spot configuration.

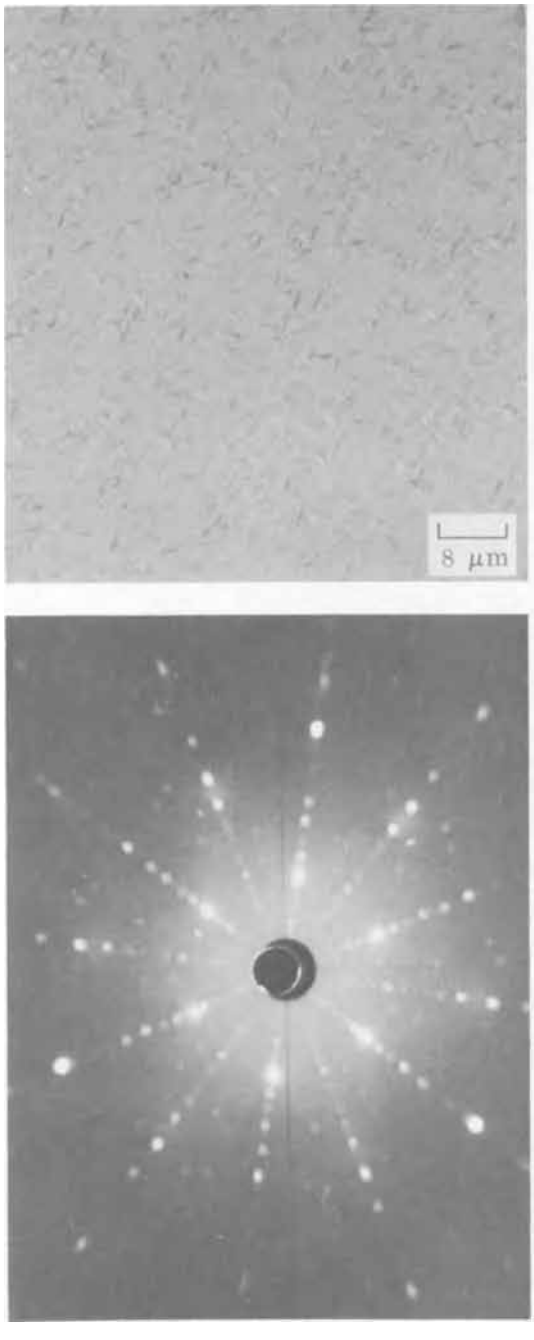

Fig. 4. (111)ZnTe growth on (0001) Al_2O_3; (a) (top) surface structure; (b) (bottom) Laue of composite.

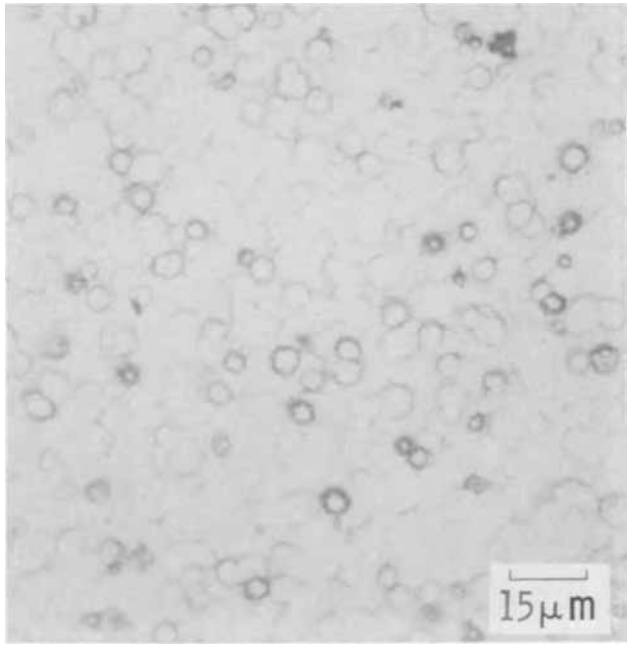

Fig. 5. Growth features of CdS on (0001) Al_2O_3

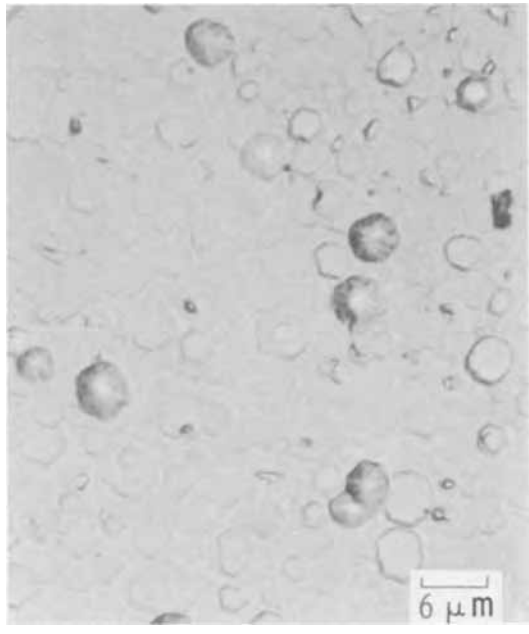

Fig. 6. Growth features of CdSe on (0001)Al_2O_3

Growth studies of the group II tellurides had not been undertaken until quite recently mainly because H_2Te, which might have been the preferred source of tellurium, was essentially unavailable commercially, probably because of instability and handling difficulties. Therefore, an alternate to H_2Te for producing group II Te compounds, *i.e.*, a low molecular weight alkyl telluride, specifically DMT, was obtained and used in these studies. Further studies will be required to determine whether the alkyl selenium and sulfur compounds are to be preferred over H_2Se and H_2S, respectively, in preparing the II-VI compounds.

In summary, the use of metal-organics for the formation of a number of II-VI semiconductor com-

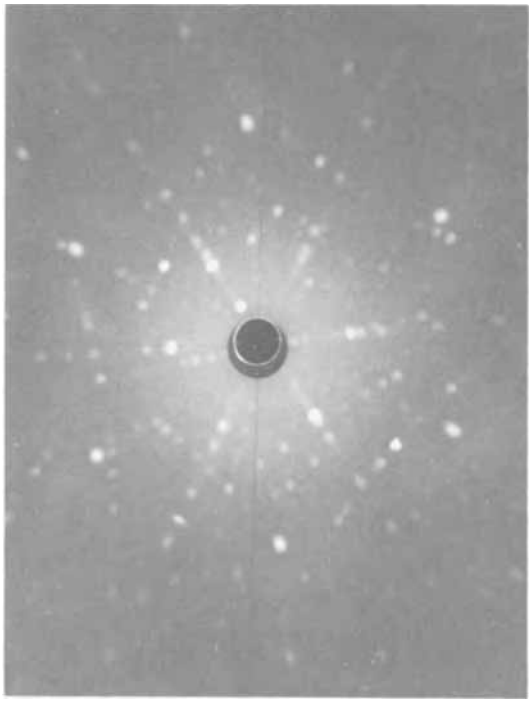

Fig. 7. Laue pattern for (111)CdTe growth on $(11\bar{2}6)Al_2O_3$

pounds on insulating substrates has been demonstrated. The advantages and ease of this approach for the formation of these compounds, either singly or in multilayer structures on insulators or semiconductors, suggest that the method should be exploited vigorously.

The Use of Metal-Organics in the Preparation of Semiconductor Materials

III. Studies of Epitaxial III-V Aluminum Compound Formation Using Trimethylaluminum

H. M. Manasevit

Autonetics Division of North American Rockwell Corporation, Anaheim, California 92803

In 1968 it was first demonstrated that metal-organics and hydrides can be used successfully in chemical vapor deposition (CVD) processes for the production of single-crystal layers of III-V semiconductor compounds (1, 2). GaAs was formed on GaAs, Ge, and a variety of single-crystal insulators such as sapphire (Al_2O_3), spinel, and BeO by reacting triethylgallium (TEG) or trimethylgallium (TMG) and arsine (AsH_3) in H_2 at an rf heated pedestal. The addition of various amounts of phosphine (PH_3) to TMG-AsH_3 mixtures led to the formation of single-crystal films of mixed $GaAs_{1-x}P_x$ alloys. GaP was produced by decomposing TMG-PH_3 mixtures. $GaAs_{1-x}Sb_x$ was produced from TMG, AsH_3, and SbH_3 mixtures.

This new approach to epitaxial film formation eliminated many of the drawbacks of the usual two- or three-temperature-zone methods and is also compatible with CVD processes used for the formation of elemental semiconductors.

Rai-Choudhury (3) has since also used this process to produce films of GaAs on GaAs, and Thomas (4) produced single-crystal GaP on Si by the thermal decomposition of a gas-phase mixture of TEG and triethylphosphine.

Key words: heteroepitaxy, chemical vapor deposition, insulating substrates, gallium aluminum arsenide, aluminum arsenide.

This note reports the successful use of trimethylaluminum (TMA) in the production of single-crystal films of AlAs and mixed III-V aluminum compounds, materials of interest for optoelectronic devices. The studies represent a series of feasibility experiments and are, therefore, far from complete; but the results again demonstrate the simplicity and flexibility of this process for thin-film epitaxial growth. A schematic of the apparatus is shown in Fig. 1.

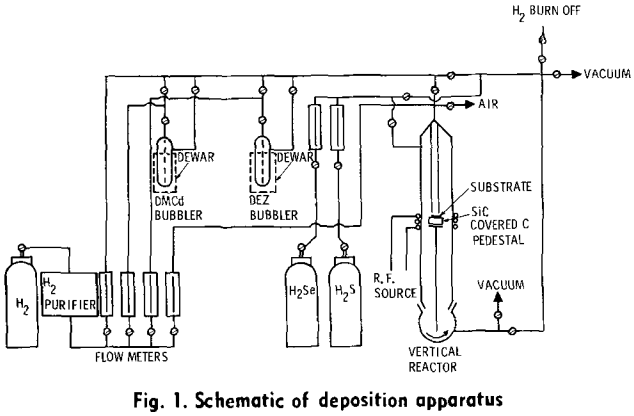

Fig. 1. Schematic of deposition apparatus

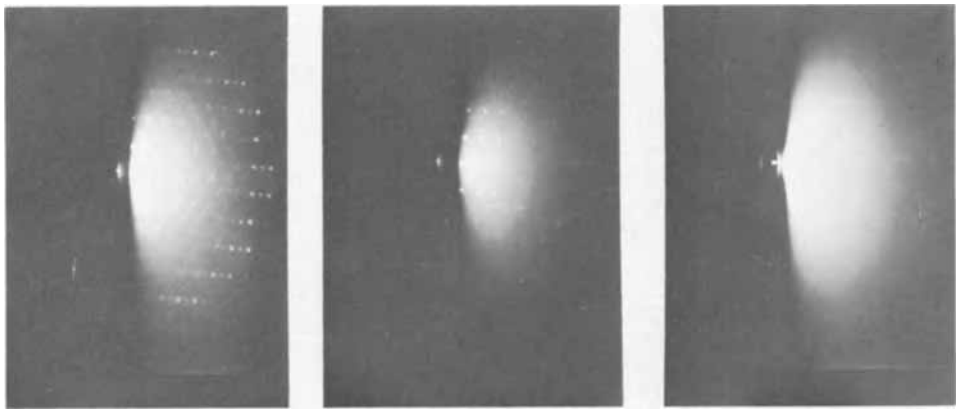

Fig. 2. The instability of (111) AlAs on (0001) Al_2O_3 in moist air, as followed by reflection electron diffraction patterns: (left) after 1 min; (center) after 3 min; (right) after 6 min.

The experimental deposition techniques are essentially those previously described (2). The TMA was kept at ambient room temperature, the bubbler being immersed in a dewar containing distilled water. For these experiments, total carrier gas flows of about 1500 ccpm were used.

Aluminum Arsenide

By pyrolyzing TMA and AsH_3 in a H_2 atmosphere at about 700°C, single-crystal films of AlAs have been formed on GaAs and on single-crystal insulating substrates. But the surface of the AlAs, yellow in thin-film form, was found to be unstable in the laboratory atmosphere. The instability of this film (<1 μm thick) was followed by reflection electron diffraction techniques. The results are recorded in Fig. 2. The pattern shown in Fig. 2 (left) was obtained within 1 min after the composite was removed from the CVD reaction chamber. Single-crystal spots and fairly strong Kikuchi lines are evident for this (111) deposit on (0001) Al_2O_3. This surface appeared stable under the vacuum of the electron microscope. However, after 3 min of its exposure to the laboratory air, the Kikuchi lines had faded [Fig. 2 (center)], the diffraction pattern spots became weaker, and indications of some twinning were observed. Only very faint spots were discernible after 6 min [Fig. 2 (right)], and the single-crystal diffraction patterns completely disappeared within about 10 min of exposure to the laboratory atmosphere. A back-reflection Laue x-ray pattern for an AlAs film on (0001) Al_2O_3 obtained during a half-hour exposure is shown in Fig. 3. Two hexagonally arranged sets of broad and diffuse spots are found, symmetrical to the center of the Laue pattern. They seem to suggest a high degree of strain in the AlAs film, which was decomposing at the surface during the x-ray exposure.

Other means were used for examining the epitaxial nature of the film. This was accomplished by growing multilayer heteroepitaxial films on Al_2O_3 and GaAs, *i.e.*, first growing a film of AlAs on the substrate and then switching from TMA to TMG and encapsulating the AlAs film with GaAs. The surface of a ~10.5 μm thick film of GaAs/AlAs on (0001) Al_2O_3 is shown in Fig. 4 (top); its back-reflection Laue pattern, Fig. 4 (bottom). The surface displays considerable order; and, from the parallel and triangular structure, one might infer essentially a (111)-oriented overgrowth. The Laue pattern displays strong spots typical of a single-crystal composite with heavy twinning present.

AlAs was then grown sandwiched between GaAs grown on Al_2O_3 and a final GaAs surface layer. Since the surface of a GaAs/AlAs/GaAs/(0001)Al_2O_3 composite grown under essentially the same deposition parameters appeared almost identical to Fig. 4(a), it is probable that the AlAs surface is the (111)"A" face with bonding through As atoms to Al_2O_3 and to Ga in GaAs, as was suggested by the (111) GaAs/(0001)-Al_2O_3 studies (2).

The quality of multilayer growth on bulk GaAs was found to be very surface- and orientation-sensitive, the GaAs/AlAs appearing to grow better on (100) and (110) than on the (111)"A" face of GaAs. The positions of sandwiched 0.8 and 1.5 μm layers of AlAs were revealed by angle-lapping the (110)-oriented III-V composites with a glycerin-Al_2O_3 slurry (Fig. 5).

Aluminum Phosphide

An attempt was made to produce AlP by the pyrolysis of TMA in H_2 at 700°C in an atmosphere containing excess P formed by decomposing phosphine (PH_3). The resulting film (~1 μm thick) was not stable in the laboratory atmosphere, even during the minute it took to transfer the wafer to the electron microscope chamber. Reid *et al.* also observed reaction at the AlP surface on exposure to moist air (5) for films formed at 900°C. Some of the unexpected optical effects observed by Richman for AlP films (6) may be related to this instability. No attempt has yet been made to encapsulate the AlP with GaAs or GaAs/AlAs multilayers. This will await future experimentation.

One experiment was performed with the intention of forming a GaAs/AlAs$_{1-x}$P$_x$/AlAs/(0001)Al_2O_3 composite. Based on the time of deposition, it is estimated that the approximate thicknesses of the layers are 15 μm GaAs, 3 μm AlAs$_{1-x}$P$_x$, and 0.5 μm AlAs. The surface characteristics of this composite film,

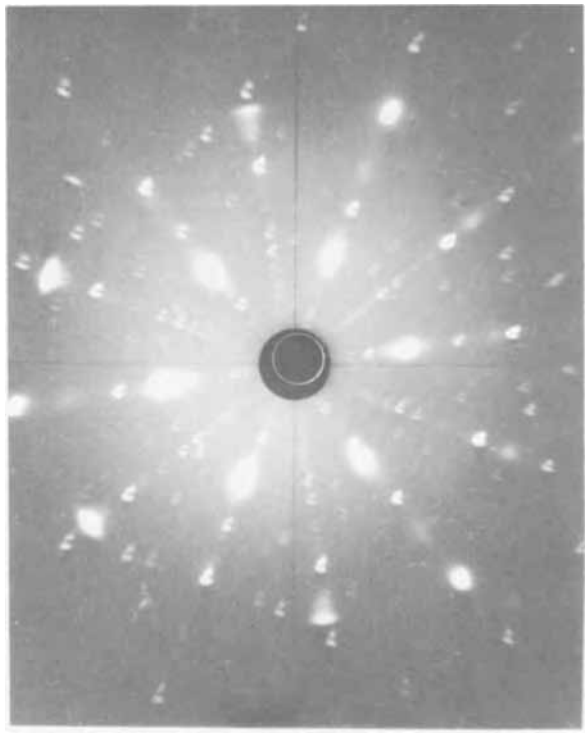

Fig. 3. Back-reflection Laue x-ray pattern for AlAs on (0001) Al_2O_3.

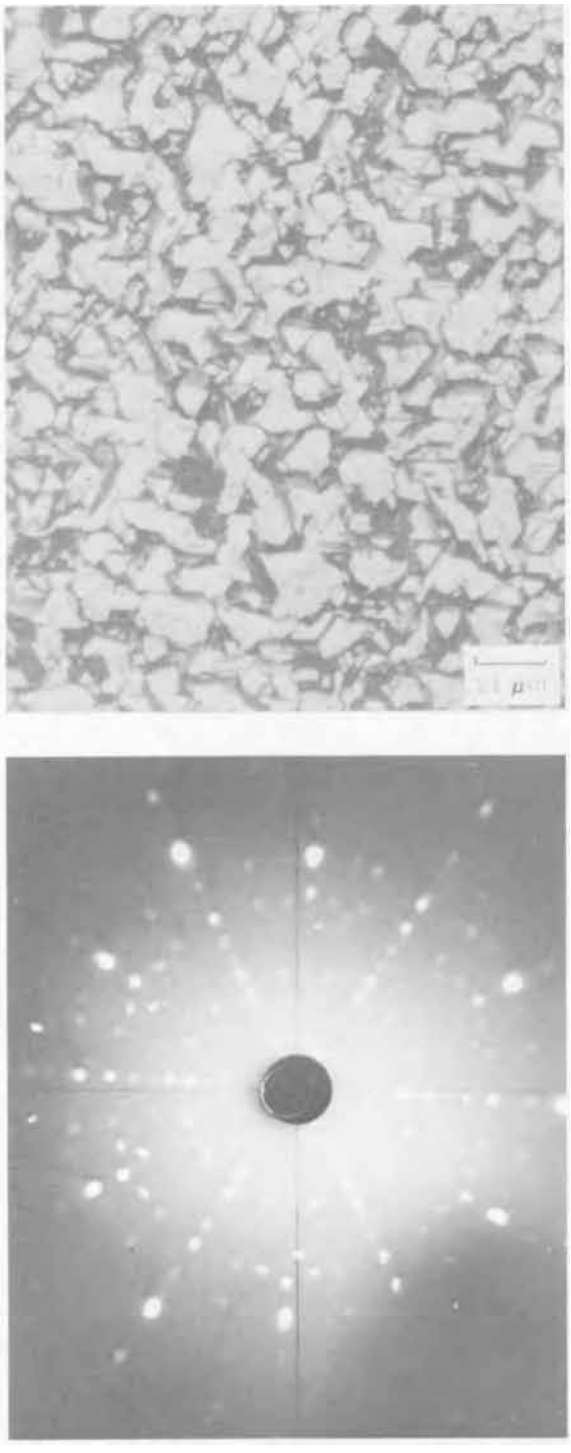

Fig. 4. (Top) Surface structure of 10 μm GaAs film grown on 0.3 μm layer of AlAs on (0001) Al_2O_3; (bottom) back-reflection Laue pattern for composite.

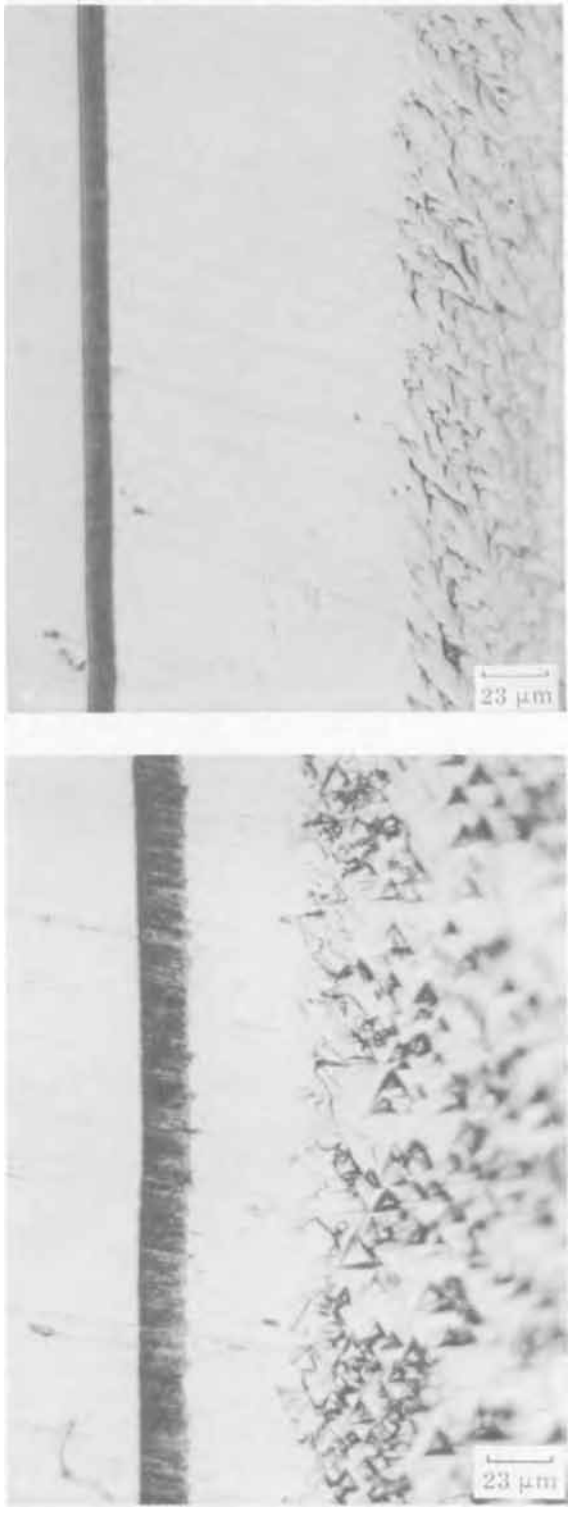

Fig. 5. The position of GaAs/AlAs/GaAs interfaces as revealed by angle lapping: (top) 0.8 μm AlAs, 7.7 μm GaAs; (bottom) 1.5 μm AlAs, 4.4 μm GaAs.

shown in Fig. 6, suggest a high degree of order exists throughout the multilayer structure.

$Ga_xAl_{1-x}As$

Alloys of $Ga_xAl_{1-x}As$ were relatively easily prepared by mixing different quantities of TMA and TMG and reacting these with AsH_3 at the heated pedestal. Alloys in the composition range $Ga_{0.1}Al_{0.9}As$ to $Ga_{0.8}Al_{0.2}As$, as analyzed with the electron microprobe, have been prepared on Al_2O_3 and GaAs substrates at 700°C.

The effect of arbitrarily changing the flowmeter settings of the H_2 carrier gas bubbled through the liquid TMG and TMA on film composition is reported in Table I.

Figure 7 is the back-reflection Laue pattern obtained for a 4.4 μm thick layer of $Ga_{0.8}Al_{0.2}As$ on (0001) Al_2O_3. Many of the spots shown can be identified as characteristic of the alloy film and not of the substrate.

Summary

The use of metal-organics for semiconductor compound formation has again been demonstrated, this time in the formation of III-V Al compounds and their alloys. Trimethylaluminum was the source of the Al. The feasibility of producing alloys of the III-V compounds was shown by reacting AsH_3 with various

mixtures of TMA and TMG, forming Ga$_x$Al$_{1-x}$As, with x varying from 0.1 to 0.8. Both Al$_2$O$_3$ and GaAs substrates were used as hosts for the epitaxial growth of these alloys and AlAs. The process is compatible with the growth of elemental semiconductors and can be applied to the formation of various combinations of III-V compounds.

Effect of Nitrogen Purity on the Nitriding of Metals Using Purity Controlled Nitrogen

J. Aubry and R. Streiff*,[1]

Laboratoire de Metallurgie et Chimie du Solide associé au CNRS, Faculté des Sciences, Nancy, France

Many studies in the oxidation of metals have shown that the impurity concentration, as low as a few ppm, can have considerable influence on the oxidation behavior (1). However, the effect of small amounts of impurities in the gas phase has been usually neglected. Usually, former investigators only considered very high ratios of foreign species in the oxidizing atmosphere, *e.g.*, steam in oxygen with a partial pressure close to the water vapor pressure at room temperature. The concentrations have to be regarded as gas mixtures rather than impurities. If the effect at these percentages can be important, the effect of smaller

Key words: nitrogen purity influence, nitriding kinetics.

amounts of impurities in the gas phase (in the ppm region) cannot be neglected, especially for very reactive metals. Thus, a former study of calcium nitriding (2) has shown that the usual method of removing oxygen or water from nitrogen is ineffective and that the kinetics of the reaction can be considerably altered by residual traces of those impurities. This led us to perfect a means of preparing pure nitrogen by decomposition of sodium azide. This pure nitrogen was used for nitriding studies, and the results were compared with those of nitriding studies which used nitrogen purified in the usual manner, *i.e.*, passage of commercial grade N_2 through dryers and cold traps. Thus we were able to study the effect of impurities on the nitriding kinetics of calcium and magnesium.

Preparation of Nitrogen

The nitrogen is obtained by decomposition of sodium azide under vacuum as follow

$$2N_3Na \rightarrow 2Na + 3/2N_2$$

This reaction as nitrogen supply is well known (3), but no indications are available up to now on the purity of the nitrogen from that source.

The generator is very simple (Fig. 1). The azide is contained in a glass tube connected to a storage volume through a trap filled with glass wool. The latter traps the sodium vapors generated by the decomposition reaction. A manometer located near the storage flasks gives the pressure of nitrogen. Finally, the assembly is connected to a vacuum system and to the nitriding reaction chamber. The whole device must be constructed of glass or metal.

The sodium azide is carefully dried in a dry box and then is outgassed by heating under high vacuum inside the decomposition chamber at a temperature slightly less than the decomposition temperature. The decomposition is initiated by local heating with a Bunsen burner. It starts at about 275°C. Any later purification is unnecessary since the last traces of oxygen or water are removed by the sodium which behaves as a getter.

The oxygen partial pressures were measured with a calibrated calcia stabilized zirconia galvanic cell. They were equal to 10^{-6} to $10^{-5.6}$ atm, corresponding to an oxygen concentration in the range 1-3 ppm. After three decomposition runs, the concentration of residual oxidizing impurities decreased to an average value of 0.1-0.2 ppm. No traces of CO_2, CO, or NH_3 have been revealed by mass spectrometry analysis.

In comparison, the nitrogen purified in the conventional manner (passed first over copper at 480°C, then over magnesium perchlorate and phosphoric acid, and finally through a trap cooled by a mixture of dry ice and acetone) contained 100-200 ppm of oxygen. These latter values are higher than those determined by other studies which used the same procedure (4, 5). This lack of reproducibility can be ascribed to the joint tubes of plastic or rubber present in assemblies used for purification of N_2 in the conventional manner (4).

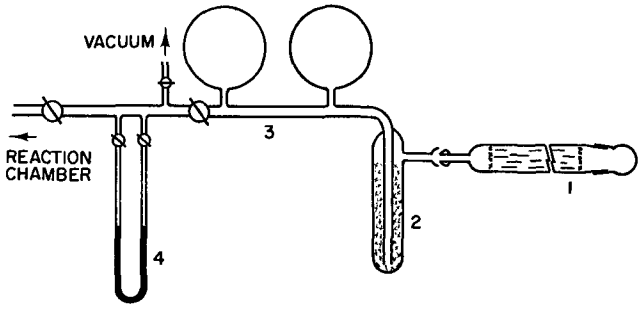

Fig. 1. Apparatus: 1, decomposition tube; 2, trap filled with glass wool; 3, storage flasks; 4, manometer.

Effect of Nitrogen Purity on the Nitriding of Metals

The most successful application of this nitrogen preparation has been the study of the effect of nitrogen purity on the nitriding kinetics of calcium and magnesium.

These studies have been carried out by thermogravimetric measurements. The reactions were followed by recording the weight gains with an automatic MacBain microbalance of cylindrical specimens with approximate dimensions 0.5 cm diameter by 2.5 cm. The surfaces of specimens were prepared by mechanical polishing. In the case of calcium, this polishing was followed by a high-temperature vacuum treatment with sublimation of a fixed amount of metal. This sublimation treatment involves a controlled break of the pre-existing oxide film on the surface metal. The sublimation of the metal is permitted by high vapor pressure of calcium at high temperatures (2).

The effect of the impurities in the nitrogen was determined by comparison of data from the nitriding with conventionally purified nitrogen and from nitriding with pure nitrogen prepared as detailed above. Three kinetic parameters are affected by the presence of impurities in the gas phase: the reaction threshold, the rate, and the type of reaction kinetics.

The nitriding of calcium begins at about 200°C in pure nitrogen whereas it commences at room temperature in undried commercial nitrogen. After a few days, such a specimen is covered by a dark scale of nitride exhibiting white spots of hydroxide. The same behavior can be observed by exposing the sample to the atmosphere of the laboratory. It would appear that traces of water vapor behave as an initiator of the reaction probably by transformation of the compact preoxidation film to a porous hydroxide. In pure nitrogen, calcium remains bright indefinitely at room temperature. Identical observations have been made by Fromont (6) for the nitriding of lithium.

In dry nitrogen the residual oxygen produces an important reduction in the nitriding rate and even a change in the type of kinetics. The results of nitriding by dried commercial nitrogen and pure nitrogen are shown for calcium at 600° and 675°C and magnesium at 510°C (Fig. 2, 3, and 4, respectively). The nitriding of calcium at 600°C corresponds to the formation of the tetragonal form of the nitride. At this temperature the kinetics of nitriding by pure nitrogen followed a parabolic law. Traces of residual oxygen in commercial nitrogen lower the reaction rate considerably (Fig. 2). Nitriding at 675°C corresponds to the formation of the cubic form of the nitride. In this case,

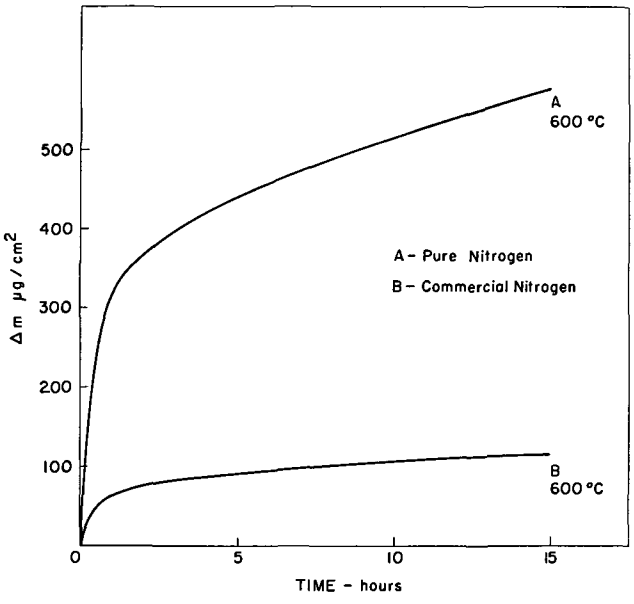

Fig. 2. Nitriding of calcium at 600°C

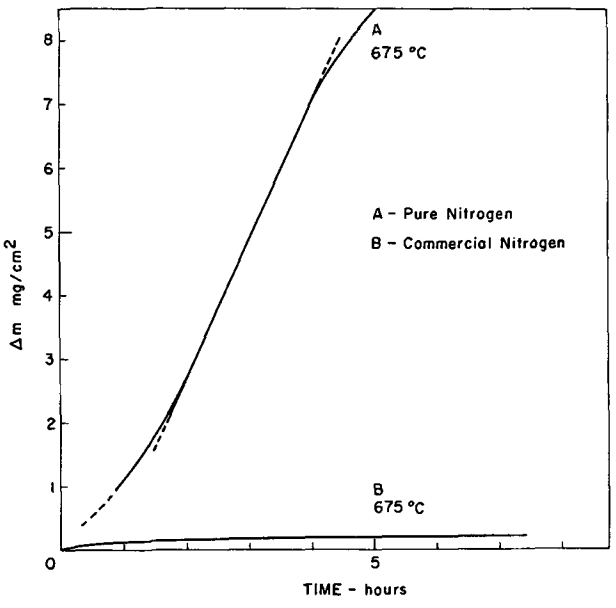

Fig. 3. Nitriding of calcium at 675°C

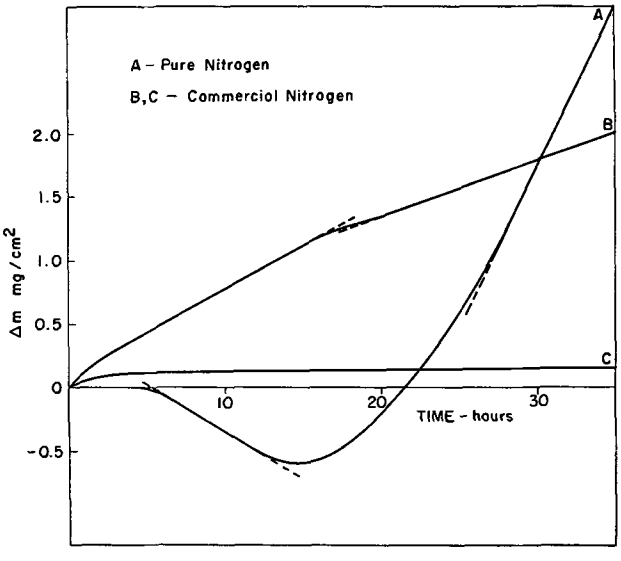

Fig. 4. Nitriding of magnesium at 510°C; curve A, by pure nitrogen; curve B, by flowing commercial nitrogen; curve C, by static commercial nitrogen in a closed system.

the reaction rate is lower in the presence of impurities, and the kinetics are also modified. The kinetics pass from a linear regime in pure nitrogen to a parabolic regime in commercial nitrogen (Fig. 3). It is significant that the formation of the two crystallographic forms of calcium nitride correspond to two types of kinetics (2). In both former experiments with commercial nitrogen, the specimens exhibit an inner dark compact scale covered by an external white porous scale. The compact scale has been found to be identical to the oxynitride scale formed during reaction of calcium with air (7). The white scale is pure CaO. On the other hand, in pure nitrogen the product of the reaction is only nitride without any traces of oxide. It therefore appears that the calcium reacts preferentially with the residual oxygen in the nitrogen to form a compact scale, resulting in an important decrease in the reaction rate.

This feature is identical in the case of nitriding of magnesium. In Fig. 4, two kinds of experiment for nitriding of magnesium by commercial nitrogen are shown. The first one (curve B) was done by reaction in flowing nitrogen, the second one (curve C) in a closed system. Both involve a significant decrease of the reaction rate compared with the nitriding by pure nitrogen (curve A). After reaction, the specimens exposed to commercial nitrogen are covered by a double scale of an inner compact layer, mainly of black non-stoichiometric oxide, and an outer porous layer of white MgO (8). Thus, as in nitriding of calcium, the residual oxygen in the nitrogen reacts preferentially with the metal forming a protective layer which decreases the reaction rate. This is particularly evident in a closed-system experiment where the reaction stops when all the initial impurities have been absorbed by the metal (curve C). Finally, the kinetics of nitriding of magnesium by pure nitrogen (curve A) show that sublimation of metal occurs simultaneously with the surface reaction. These kinetics are very different from those observed in previous investigations (9). These latter results are always more or less similar to the kinetics observed here for reaction of magnesium with commercial nitrogen.

Summary

The preparation of pure nitrogen by decomposition of sodium azide allowed a study of the effect of impurities in the gas phase on the nitriding of calcium and magnesium. It has been found that the residual oxygen in nitrogen reacts preferentially with both metals, and that in pure nitrogen the kinetics of nitriding of these metals are very different from those formerly ascribed to these reactions. A wide range of applications for this supply of high-purity nitrogen has also been found in nitrides syntheses (10-12) or would be possible in any reactions involving nitrogen atmosphere, such as the study of nitrogen diffusion in nitrides by solid-gas exchange method.

Safety Recommendations

Drying and decomposition of sodium azide are the two most dangerous steps in this nitrogen preparation technique. A too-rapid decomposition may involve the explosion of the decomposition tube and projection of hot sodium. In order to prevent nitrogen over-pressure, this tube is closed at one end by an ejectable glass joint. Also, the heating of the decomposition tube has to be slow and localized and directly controlled by the operator.

Chemical Polish and Etch for Lithium, Sodium and Potassium

R. N. Castellano and P. H. Schmidt

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

A survey of various alcohols has been made to determine the surface conditions that occur on immersion of lithium, sodium, and potassium. Alcohols are often used in the laboratory to polish and etch these alkali metals. Bowers *et al.* (1) report that a bath of 98% xylene and 2% isopropyl alcohol is a simple method of etching sodium. Grimes (2) notes that potassium is etched in a bath of 99% xylene and 1% isopropyl alcohol. Both solutions require critical surface conditions and timing prior to and during etching before grain boundary delineation is observed. A bath of 2-6% secondary butyl alcohol in xylene has been reported to be an effective etch for potassium metal (3-4).

Other polishes and etches of alkali metals employ the use of chemicals other than alcohols. Methyl ethyl ketone is a satisfactory polish for potassium (5), and (1) has reported using diethyl ether as an etch for lithium after first polishing the metal in methanol.

The surfaces of lithium and potassium are polished to a high luster with certain nondiluted alcohols used in the survey. Excellent grain boundary delineation on the surfaces of lithium and sodium is observed after only 30 sec.

The results of this survey indicate that these alcohols are superior to other chemicals in producing a strain free etch and/or polish of the alkali metals investigated. The surfaces of these metals exhibit a brilliant metallic luster and are smooth and free of pits (minute indentations of the surface). These alcohols are now commonly used in the preparation of bulk samples of lithium, sodium, and potassium for the investigation of certain phenomena such as conduction electron spin resonance (CESR) and cyclotron resonance.

Key words: alkali metals, alcohols.

Method

Lithium, sodium, and potassium were cut under mineral oil with a razor blade and were then placed in heptane to dissolve the oil and prevent oxidation of the metal by moist air. After immersion in the alcohol, the metal was taken directly to a beaker of tetrahydrofuran in order to stop the reaction and to dissolve the alkali metal alcoholate (alkoxide) which formed. The following reaction occurred

$$\underset{\text{alcohol}}{ROH} + \underset{\text{metal}}{M} \rightarrow \underset{\text{alcoholate}}{RO^{-}{}^{+}M} + 1/2\,H_2 \qquad [1]$$

The reaction of the alkali metals with alcohols decreased with increasing molecular weight of the alcohol due to the decreasing solubility of the alcoholate in the alcohol.

The metal was placed in a petri dish containing tetrahydrofuran and observed visually and then optically with a microscope.

The surface conditions of lithium, sodium, and potassium observed after immersion in the alcohols used in this investigation are explained in Table I.

Results

The best polish (the removal of material due to the nonpreferential cutting of the various {hkl} planes) for lithium is obtained using methanol. 2-Propanol is as effective as ethanol to produce a brilliantly polished surface on potassium. The reaction is less rapid with 2-propanol, however, and there is less risk of an explosive reaction.

Table I. Surface conditions observed after immersion in alcohols

Alcohol used	Lithium*	Sodium	Potassium
Methanol CH_3OH MW 32.04	Surface had a high luster and was smooth after 30 sec	Grain boundary delineation was observed. Some {hkl} planes brilliant, some dull, but all are pitted	Violent reaction
Ethanol CH_3CH_2OH MW 46.05	Grain boundary delineation was observed after 30 sec. Some {hkl} planes brilliant and smooth	Grain boundary delineation was observed. Some {hkl} planes brilliant, some dull, but all are pitted	Surface brilliant and smooth after 3 sec
2-Propanol $CH_3CHOHCH_3$ MW 60.10	Grain boundary delineation was observed after 30 sec. Most {hkl} planes dull	Grain boundary delineation was observed. Some {hkl} planes brilliant, some dull	Surface brilliant and smooth after 10 sec
3-Pentanol $CH_3CH_2CHOHCH_2CH_3$ MW 88.15	Surface became black after 30 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. All {hkl} planes brilliant, but razor marks still observed	Surface became dull after 30 sec
1-Heptanol $CH_3(CH_2)_5CH_2OH$ MW 116.20	Surface became dull after 30 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. Most {hkl} planes brilliant, but all are pitted	Surface became dull after 30 sec
1-Octanol $CH_3(CH_2)_6CH_2OH$ MW 130.23	Surface became dull after 30 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. All {hkl} planes were dull and pitted	Surface became dull and pitted after 30 sec
2-Octanol $CH_3CHOH(CH_2)_5CH_3$ MW 130.23	Surface became dull after 30 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. All {hkl} planes were dull and pitted	Surface became dull and pitted after 30 sec
2,4-Dimethylphenol $(CH_3)_2C_6H_3OH$ MW 122.17	Surface became dark after 15 sec even after preliminary methanol polish	Surface became dull and pitted after 30 sec	Surface became dull and pitted after 30 sec
Nonyl $CH_3(CH_2)_7CH_2OH$ MW 144.26	Surface became dark after 15 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. Most {hkl} planes brilliant and smooth	Surface became dull and pitted after 30 sec
α-Propylbenzyl $C_6H_5CHOH(CH_2)_2CH_3$ MW 150.22	Surface became dark after 15 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. Some {hkl} planes brilliant	Surface became dull and pitted after 30 sec
p-iso-propylbenzyl $(CH_3)_2CHC_6H_4CH_2OH$ MW 150.22	Surface became dark after 15 sec even after preliminary methanol polish	Grain boundary delineation was observed after 30 sec. Some {hkl} planes brilliant	Surface became dull and pitted after 30 sec
α,α-Dimethylphenethyl $(CH_3)_2COHCH_2C_6H_5$ MW 150.22	Surface remained brilliant for several min after preliminary methanol polish	Surface became dark after 30 sec	Surface turned purple after 30 sec

* Immersion of lithium metal in methanol was required to remove the oxide layer prior to immersion in the higher molecular weight alcohols.

Bowers *et al.* (1) reports that the reaction rate for the chemical etch (the removal of material due to the preferential cutting of the various {hkl} planes) for sodium requires several minutes. Superior results are obtained using nonyl alcohol, and excellent grain boundary delineation is observed after 30 sec. Ethanol is a very effective etch for lithium.

Conclusion

A survey of various alcohols has been made to determine the surface conditions that occur on immersion of lithium, sodium, and potassium. Only a few seconds are required to polish the surfaces of lithium and potassium to a high luster using methanol and 2-propanol respectively. Excellent grain boundary delineation on the surfaces of lithium and sodium is observed after immersion of the metals in ethanol and nonyl alcohol respectively for 30 sec. The results of this survey indicate that these alcohols are superior to other chemicals in producing a brilliant polish and/or etch of the alkali metals investigated.

Manuscript submitted Sept. 25, 1970; revised manuscript received Dec. 9, 1970.

The Role of Homogeneous Reactions in Chemical Vapor Deposition

Karl J. Sladek

Department of Chemical Engineering and Electronics Research Center, The University of Texas, Austin, Texas 78712

Chemical vapor deposition (CVD) finds increasing use in the fabrication of thin films for solid-state devices, as well as films for optical and protective coatings. For all of these applications, control of stoichiometry and structure is essential. A knowledge of the detailed mechanism of CVD would be very helpful in devising means to control these critical properties.

Most previous investigators of CVD processes have assumed that deposition reactions are heterogeneous; that is, they occur as catalytic reactions in an adsorbed layer on the surface of the growing film. Interpretations of CVD have accordingly been based on heterogeneous models. For example, Joyce and Bradley (1) discuss their measurements on epitaxial Si growth from SiH_4 in terms of a catalytic mechanism.

There is, however, a large body of evidence which suggests that homogeneous reactions play an important role in CVD. The purpose of the present work was to evaluate the possible importance of homogeneous reactions in CVD. Some qualitative evidence for homogeneous reactions is described next.

Evidence for Homogeneous Reactions

It is helpful to consider first the effect of temperature on homogeneous and heterogeneous reactions. One useful rule, which appears to be rather generally true, is that a catalyst serves to lower the activation energy, E, of a reaction. This suggests that heterogeneous reactions are favored at lower temperatures, while homogeneous reactions are favored at higher temperatures. For the many CVD reactions that take place in the neighborhood of 1000°C, one might expect *a priori* that homogeneous reactions would be favored.

The nonspecificity of substrates for CVD reactions should also be mentioned. By analogy with most catalytic reactions, one would expect that very few materials would serve as effective catalysts for a particular reaction under a given set of conditions. However, it is found in a variety of CVD experiments that solid product is deposited not only on the substrate but also on all hot surfaces which are exposed to the reactant stream. This observation is significant only for the very early stages of growth, since, after a coherent film has appeared, the reactants are exposed only to the surface of the deposited material. However, if no homogeneous formation of product occurred, then growth could not be initiated on noncatalytic substrates.

Key words: chemical vapor deposition, homogeneous reaction model, Si_3N_4, thin films.

Regarding experimental evidence, many investigators have observed formation of a solid precipitate in the gas phase above a heated substrate. For example, Joyce and Bradley (1) observed that precipitation of Si particles was favored by high SiH_4 pressures. Schaffer (2) reports that the use of lower operating pressures prevented formation of Al_2O_3 particles during CVD of that material from $AlCl_3$-H_2O mixtures. Grieco, Worthing, and Schwartz (3) observed the precipitation of NH_4Cl on the cold wall of a reactor during a study of the growth of Si_3N_4 from $SiCl_4$-NH_3 mixtures on a hot Si substrate. Evidently, the NH_4Cl was formed as an intermediate or byproduct in a homogeneous reaction. A similar effect was noted by Joyce and Bradley (1), who observed very thin films of product on the cold walls of their reactor.

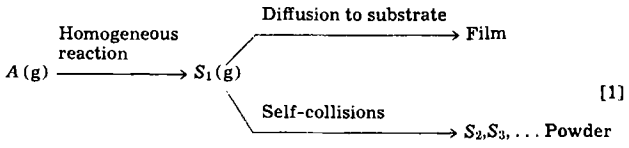
All of these observations can be explained by assuming that the reaction occurs in the gas phase and that the product then diffuses to the substrate and forms a film, or instead condenses in the gas phase to form powder.

Homogeneous Reaction Model

The features of a homogeneous CVD reaction can best be considered by treating the limiting case wherein the substrate is completely noncatalytic and serves only as a site for condensation of the solid product, S. For this case, single molecules of S, denoted as S_1, will be formed by the gas phase reaction. If a hot substrate is exposed to a cold reactant stream, as is usually done, then the reaction zone in which S_1 is formed will be localized in a thin region very near the hot substrate; most of the S_1 will then diffuse to the substrate and undergo condensation to form a film. There is, however, a competing process which can

cause powder formation in the gas phase. If the gas phase concentration of S_1, which will be called C_1, becomes too large, then the rate of S_1-S_1 collisions will become appreciable. This will lead to the formation of polymers, S_2, S_3, . . . S_n, in the gas phase, or, in other words, to powder formation.

For the case of a single gaseous reactant, A, these two processes are summarized as follows



[1]

To quantify this model, a parallel flow geometry is chosen as shown in Fig. 1. Gas at velocity, v, and entrance temperature, T_∞, flows along the substrate, which is maintained at temperature, T_0. Heat transfer occurs, producing a temperature field, $T(x,y)$. Product molecules, S_1, are produced in the gas phase at a local rate depending on $T(x,y)$. Once formed, S_1 can diffuse in the $-x$ direction toward the substrate, or can accumulate along the y direction, or, if C_1 becomes large enough, S_1 dimerizes to S_2 (concentration C_2), and addition of further molecules eventually produces powder particles in the gas phase. A material balance on S_1 follows.

Production = Diffusional Transport + Accumulation + Condensation to Powder

$$k'e^{-E/RT(x,y)} = -D\frac{\partial^2 C_1}{\partial x^2} + v\frac{\partial C_1}{\partial y} + k_{11}C_1^2 + k_{12}C_1C_2 + \ldots \quad [2]$$

The production term consists of a reactant concentration dependent function, k', and an Arrhenius function with activation energy, E. The diffusional transport term represents the rate of change of the flux of S_1 with x. The powder condensation terms represent collisions of S_1 with S_1, with S_2, and so on. As this equation is rather complicated in its original form, some simplifications are in order.

The function k' depends on reactant concentration C_A. To simplify the equation, only situations in which C_A is constant for all x and y are considered here. This applies to cases in which the fractional conversion of A is small and the mass transfer coefficient of A is large. To evaluate the accumulation term, $v\,\partial C_1/\partial y$, an approximate boundary layer analysis was carried out, and this term was found to be negligible. Neglect of this term amounts to a steady-state approximation. The concentration of S_1 is always very small; the S_1 that is formed at a point either diffuses away or undergoes condensation to powder.

The powder condensation terms involve polymers S_n with $n = 1, 2, \ldots$. Material balances can be written for diffusion and growth of every S_n, but this leads to a very complicated set of equations. A considerable simplification is achieved by including only the term for formation of dimers, S_2. Qualitatively, when dimers have been formed, they will diffuse more slowly than S_1, since they are larger, but they will grow more rapidly than S_1, again because they are larger. For this reason, it is suggested that if the dimerization rate becomes significant, not only dimers but also solid particles will be found.

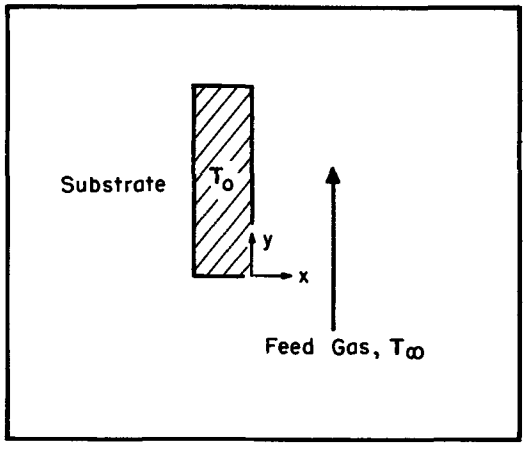


Fig. 1. Coordinate system

With these simplifications, Eq. [2] becomes

$$k'e^{-E/RT(x)} = -D\frac{d^2C_1}{dx^2} + k_{11}C_1^2 \quad [3]$$

The boundary condition at the substrate is $C_1 = 0$ at $x = 0$. This condition assumes that the growing film is sufficiently refractory that it exerts a negligible vapor pressure; that is, every molecule of S_1 that arrives at the film sticks to it. A similar assumption allows the calculation of k_{11} from a hard sphere kinetic theory model; it is assumed that S_1-S_1 bonds are sufficiently strong that S_2 has no tendency to dissociate. The "critical nucleus" is then just one molecule and every S_1-S_1 collision results in dimerization. The rate of removal of S_1 is then twice the S_1-S_1 collision rate

$$k_{11} = 2\left(\frac{4\pi kT}{m}\right)^{1/2}\sigma^2 \quad [4]$$

where σ is the collision diameter of S_1

The parameter of most interest is the film growth rate, which is equal to the flux of S_1 at the wall, J_0

$$J_0 = D\left(\frac{dC_1}{dx}\right)_{x=0} \quad [5]$$

As is shown presently, J_0 depends on the temperature gradient at the substrate, T_0'

$$T_0' = \left|\frac{dT}{dx}\right|_{x=0} \quad [6]$$

This quantity depends on the fluid mechanical and thermal properties of the flow and can be calculated by well-known methods; an example is given later.

Equation [3] now applies to each point, y, along the substrate. Normal to each point there is a gas phase temperature distribution, $T(x)$. However, as pointed out earlier, the reaction rate is localized very near the substrate because the Arrhenius term varies so steeply with temperature. This allows linearization of $T(x)$ and $1/T(x)$ near $x = 0$, with little loss of accuracy.

$$\frac{E}{RT(x)} = \frac{E}{RT_0}\left(1 + \frac{T_0'}{T_0}x\right) \quad [7]$$

The relative importance of film condensation and powder formation can be shown by incorporating Eq. [7] and converting Eq. [3] to dimensionless form using the following definitions

$$X \equiv \left(\frac{E}{RT_0}\right)\left(\frac{T_0'}{T_0}\right)x \quad [8]$$

$$Y \equiv \frac{D\left(\frac{E}{RT_0}\right)^2\left(\frac{T_0'}{T_0}\right)^2}{k_0}C_1 \quad [9]$$

$$k_0 \equiv k'e^{-E/RT_0} \quad [10]$$

The resulting equation is

$$e^{-X} = -\frac{d^2Y}{dX^2} + MY^2 \quad [11]$$

$$M \equiv \frac{k_0k_{11}}{D^2\left(\frac{E}{RT_0}\right)^4\left(\frac{T_0'}{T_0}\right)^4} \quad [12]$$

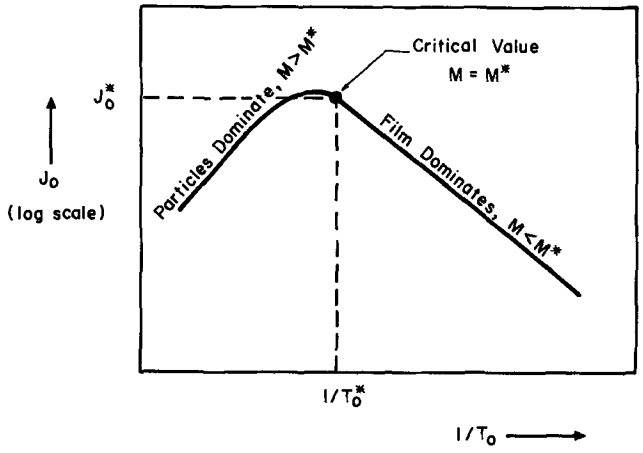

Fig. 2. Interpretation of growth rate curves

All the physical parameters now appear in the single dimensionless group, M. The size of M determines the importance of powder formation.

A typical growth rate-temperature curve is sketched in Fig. 2, along with the interpretation of the present model. At low temperatures, M is small and powder formation is negligible. For this condition, solution of Eq. [11] without the last term gives

$$J_o = \frac{k_o}{\left(\frac{E}{RT_o}\right)\left(\frac{T_o'}{T_o}\right)} \qquad [13]$$

As T_o increases, M increases rapidly until the rate of dimerization becomes comparable with the rate of film formation. Dimers are followed by larger clusters, and at higher M most of the reaction product is in the form of particles rather than film. The transition from film to particle formation occurs rather suddenly at a critical value, M^* (with associated values, J_o^* and T_o^*), which is taken to be the point at which the curve begins to deviate from a constant slope. The exact value of M^* has not been determined, but approximate solutions to Eq. [11] indicate that M^* is of order unity.

Substituting Eq. [13] into Eq. [12] gives the limiting film growth rate J_o^* above which particle formation becomes important

$$J_o^* = M^* \frac{D^2 \left(\frac{E}{R}\right)^3 (T_o')^3}{k_{11}(T_o^*)^6} \qquad [14]$$

Since the purpose of a CVD process is to grow a film, the value of J_o^* represents an approximate upper limit on the useful growth rate. From the form of Eq. [14] one can predict, for example, that J_o^* can be increased by increasing the diffusivity of S_1 through the gas mixture; D would be increased, for example, by lowering the total pressure.

In order to test Eq. [14], several sets of Si_3N_4 growth rate data were interpreted as shown in Fig. 2. An example calculation is described in the Appendix. Calculated results are given in Table I.

Comparison of J_o^* with the last quantity in Table I shows agreement with Eq. [14] to about an order of magnitude, if M^* is taken to be unity. However, the values of J_o^* cover less than an order of magnitude and, consequently, this is not a very strong test of the equation. Considering the uncertainties required in all the estimates, the agreement is at least encouraging.

Discussion

It has been suggested that homogeneous reactions often play an important role in CVD processes. A quantitative model was developed for the limiting case in which reaction occurs only in the gas phase. After some simplifications and approximations, it was shown that the relative importance of film *vs.* powder formation is controlled by a dimensionless group containing all the physical parameters of the system. Literature values of maximum film growth rates of Si_3N_4 showed order of magnitude agreement with the predicted behavior.

CVD processes can be expected to cover a broad range, including completely homogeneous, completely heterogeneous catalytic, and intermediate or mixed mechanisms. It is likely that many of the CVD processes which have previously been assumed to arise from heterogeneous catalytic reactions are, in fact, the result of homogeneous reactions. The present work provides one means of evaluating this possibility.

APPENDIX

As a sample calculation, use of the data of Chu, Lee, and Gruber (5) is described. Curve A in Fig. 2 of that reference gives a value of J_o^* of 250 Å/min at $10^3/T_o^*$ of 0.85. Converting the units using the observed product density of 2.8 g/cm^3 gives 830 x 10^{-12} moles/cm^2-sec. To estimate k_{11}, Eq. [4] was used, with a collision diameter for Si_3N_4 of 5.06Å, which was estimated from the density (3.44 g/cm^3) of the crystalline solid. The same type of estimate of σ is incorporated into the Gilliland Equation (7), which was used to find D, the diffusivity of Si_3N_4 in NH_3. Since D and k_{11} are both relatively insensitive to temperature, a fixed value of 1000°C was used in these calculations.

The temperature gradient at the surface, T_o', was estimated using known results for heat transfer in laminar boundary layers (8). Using the reported reactor size and gas flow rate (5) and estimates of properties of NH_3 at 1000°C (7), the Reynolds Number was estimated to be 10.2, and the Nusselt Number, averaged between $y = 0$ and $y = 1$ cm, was found to be 2.0. Using $T_o = 1180$°K and $T_\infty = 298$°K gave a T_o' of 1770°K/cm.

The other sets of data (4, 6) were treated in the same way. In these studies, H_2 was the carrier and consequently D was larger. For the data of Yoshioka and Takayanagi (6) flow was transverse instead of parallel to the substrate. For this case, T_o' was estimated from equations for heat transfer to a sphere (8).

It should be clear from all the estimates required that the test of the model shown in Table I is only a rough approximation.

Brief Communication

Preliminary Results on the Oxidation of GaAs and GaP during Chemical Etching

B. Schwartz*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Most of the studies on chemical etching of semiconductors have concentrated on systems used for silicon and germanium (1), while relatively little effort has been expended in studying etchants used on compound semiconductors (2). As part of a program to study chemical etching of GaAs and GaP, it was decided to examine first the oxidation step of the etching process. This communication describes results obtained on exposing clean GaAs and GaP surfaces to a number of different oxidizing reagents. All samples were prepared using a bromine-methanol (3) solution (2 ml to 4 l, respectively for GaAs and 1½ ml to 4 l when GaP was being polished) on a rotating assembly containing a Pellon-W face cloth. Both (100)- and ($\bar{1}\bar{1}\bar{1}$)-oriented, irregularly shaped samples of heavily doped ($\sim 10^{18}$) n-type and high-resistivity semi-insulating material were used for this study. After being polished and cleaned, the samples were placed in a test tube containing 25 to 50 ml of the desired concentrated reagent; the test tube was lightly corked and then allowed to stand for the desired time. For the high-temperature exposures, the samples were immersed in a heated Pyrex beaker containing the reagent. Just before measurement (in some instances the day before) the samples were carefully removed from the test tube, blot dried with the edge of a piece of filter paper, and then allowed to air dry further at room temperature in a laminar flow hood. In only one case, the H_2SO_4-treated samples, was heat used for drying the samples; the maximum temperature reached was about 250°C.

After drying, the samples were examined by powder pattern x-ray diffraction and by electron diffraction to determine the structure and composition of the surface films. Those samples which were still highly reflecting were then evaluated by ellipsometry.[1] The refractive index of a deposited film was determined and one sample of oxidized GaAs was analyzed further with an electron beam microprobe.

The results of these experiments are shown in Tables I and II for GaAs and GaP, respectively. The following is a brief summary of some of the more important aspects of these results.

1. $Ga_2O_3 \cdot H_2O$ is a major intermediate in the etching of GaAs and GaP in aqueous systems.

2. H_2O is an important oxidant for GaAs, and H_2O_2 is an important oxidant for GaP.

3. H_2O also serves as the solvent for As_2O_3 or P_2O_5 in the formation of $Ga_2O_3 \cdot H_2O$ as the principal component of the as-grown native oxide film (4).

4. The solubility of As_2O_3 in H_2O depends strongly on the pH of the system.

5. Residual oxide layers of 25 to 50Å are always present on GaAs and GaP after being etched in bromine-methanol.

6. Oxide layers of less than a few hundred angstroms grown on both GaAs and GaP appear to be amorphous when examined by x-ray or electron diffraction.

The Crystallography of Formed and Cycled PbO_2 Electrodes

A. C. Simon*

Naval Research Laboratory, Electrochemistry Branch, Washington, D. C. 20390

and S. M. Caulder*

International Lead-Zinc Research Organization Research Associate at the Naval Research Laboratory

ABSTRACT

The discharge-recharge cycle process of the lead dioxide electrode was followed by means of optical microscopy. The lead dioxide microstructure obtained from the original formation, using cured electrode materials consisting of a mixture of PbO and basic lead sulfates, was different from that obtained by recharge from an electrode reduced to normal lead sulfate. The lead dioxide electrodes, obtained from various sources and with various microstructures in the original as-formed condition, all converted to practically the same microstructure after receiving only a few cycles. Although the microstructure underwent further change with increasing cycling, the plates from different manufacturers continued to resemble one another after any given number of cycles.

The purpose of this investigation was to explore the possible relationship between the microstructure produced by electrolytic forming and that developed during cycling of the PbO_2 electrode, in particular as to whether such a relationship increased battery longevity. Microscopic examination, made in this laboratory, of large numbers of samples had revealed that there was considerable variation in microstructure among cured or formed plates obtained from different manufacturers. In addition, the microstructure of the formed PbO_2 electrode was also found to be determined by the prior structure of the cured plate of the same manufacture.

Factors which were found to influence the structure of the cured plate were: the type of oxide used in the preparation of the paste, the method by which the acid was added to the paste, how the paste was dried (cured), the temperature and humidity used in curing, and the amount of free lead remaining after curing. Battery manufacturers have found by experience that variations in these factors have a strong effect both on the service life and the available capacity.

It seemed logical to assume that the type of microstructure produced in the formed PbO_2 electrode was the actual end product of these various controlling factors and was therefore important in determining performance. Although random examination had been made of cycled $PbO_2/PbSO_4$ electrodes, no information was available as to whether the microstructure underwent systematic change during cycling. The following experiment was set up to obtain this information and to test the correctness of the above assumptions concerning the relationship between formed and cycled plate structures.

Source and Preparation of the Examined Material

For this examination to be significant, it was necessary that commercial plates of different initial microstructures be examined at intervals during cycle testing. Since NRL is not a manufacturer of batteries, it would obviously not be significant to test and cycle batteries of our own inexpert construction, nor would the microstructure produced necessarily be representative of any commercial battery.

With the cooperation of several manufacturers, four different series of cycled plates were obtained. Two of these series were obtained from manufacturers in the U.S.A., the other two were obtained outside of this country. Two of the series, while consisting of proprietary plates, were cycled in the laboratory of the company of manufacture. The other two series were taken from the assembly line and cycled routinely for life testing.

The only unfortunate result of obtaining plates in this fashion is that, because of the proprietary nature of the product, one is not at liberty to divulge details of preparation, formulation, and curing. Also, in routine plant cycling, significant factors are not always recorded.

After cycling the cells were disassembled in the charged state and the plates were washed and dried according to our specifications and shipped. When the plates were received at NRL, samples were cut from them which were then impregnated with a polyester resin. After this had hardened, the samples were sectioned and the sections polished for microscopic examination.

Observations

The most important observations are stated below.

1. Although the as-formed electrodes obtained from different manufacturers differed in microstructure,

with similar cycling treatment all of the electrodes were found to develop the same type of microstructure. This similarity in structure was observed in the first comparison at 50 cycles, although it probably represented a gradual development from earlier cycles.

2. The microstructure continued to change with additional cycling but remained comparable for each series of cycled plates at an equal number of cycles.

3. Between the 1st and 50th cycle, there was a large change in the electrode structure that transformed the active material to a more or less continuous and interconnected network, which was surrounded by void spaces that were large and of nearly equal size.

4. The large, featureless, and irregularly shaped particles of the electrode structure originally present were gradually replaced by much smaller, more uniformly shaped particles which had the actual appearance of crystals and which were formed along the surfaces of the network as the larger particles were replaced.

5. Electrode failure was accompanied by a breakup of the network structure and a dispersion of the small crystals composing it.

Structure of the formed, dry charged electrodes.— The plates of series A were made from a non-leady oxide, containing a mixture of basic sulfates and which was presumably a furnace product. Series B plates were made from a ball mill oxide containing approximately 25% of free lead. In addition, this oxide had been blended with 25% of Pb_3O_4. The plates of series C were made from a Barton pot oxide which contained 15% of free lead and had also been blended with 5% of Pb_3O_4. Series D was also a Barton pot oxide containing 15% of free lead but had not been blended with another oxide.

There was considerable difference in the way the paste was prepared by the four manufacturers, in the relative amounts of water and sulfuric acid used, and in the method by which these ingredients were added. There was very little difference in the curing of B, C, and D. These three series were stack cured for 72 hr at 90-100% humidity and at uncontrolled room temperature. The method of cure used with series A was not given. Because of the lack of free lead, it was probably an oven-cured product. This material, as cured, also contained large quantities of well-formed tetrabasic crystals, so was probably cured at high temperature and humidity. The grids of the plates were in all cases of an Pb-Sb alloy.

Despite these considerable differences in manufacture, series B, C, and D had a greater similarity in structure after formation than was expected. However, the structures were only superficially the same. Very noticeable in B was the different structure surrounding the sites where filaments of free lead had been present in the uncured plate. In series C and D this was much less noticeable because the free lead particles had been much smaller and spherical, as well as being present in a smaller amount. Two types of particles were evident in B and C, one which was formed from the Pb_3O_4 and the other representing the usual type of PbO_2. A difference in reflectivity, as well as in shape, indicated that the two types of particles were not the same material. A portion of the Pb_3O_4 thus appeared to have gone through the formation unchanged. Other differences were noted when polarized light was used in the examination. Series A was, of course, considerably different from the others and even after formation contained considerable quantities of basic oxides. The types of structures found in the four series of plates after electrolytic formation are shown in Fig. 1-4.

With the exception of series A, the formed but uncycled electrodes were found to have a surface layer with a microstructure that was quite different from that found in the interior of the electrode. This is illustrated by Fig. 5 and, at higher magnification, by Fig. 6. The blurred nature of some portions of Fig. 6 is produced by a combination of the very limited depth of focus at this magnification and by the small curvature of the specimen surface at the intersection of the hard PbO_2 and the soft supporting plastic. Here the PbO_2 forms the elevated portion, while the more depressed areas consist of the plastic impregnant.

The exact cause of this surface layer of different microstructure has not been definitely determined but

it is suspected that the cause lies in the chemical change that occurs during the period of time that the cured electrodes are immersed in acid electrolyte before the electrical circuit can be completed for the purpose of electrolytic formation. In this case the surface layers would be converted from basic to normal lead sulfate and this and the surrounding acid environment may be responsible for the changed microstructure.

Changes following a single discharge and recharge.—A series D sample was available that had been given a single discharge and recharge after the original forming. The microstructure of this recharged electrode (Fig. 7) had changed considerably from that of the formed, but uncycled, electrode (Fig. 4). In this recharged plate the microstructure had a finer and more uniform texture, with smaller particles of PbO_2 and with the particles in closer contact with one another than was the case in the formed, uncycled plate. The over-all effect of a single discharge-recharge cycle was to produce a plate with a much more uniform structure and one in which most of the characteristics of the as-formed plate had been removed. It was evident that reformation of PbO_2 from $PbSO_4$ produced a different structure than when formed from the basic sulfate paste of the original manufacture.

Changes during the first 50 cycles of charge-discharge.—Series B, C, and D were compared in the charged state after approximately 50 cycles of operation. Areas were present in each series which contained large residual $PbSO_4$ crystals. However, most areas of the plate contained only PbO_2. The most notable feature of each electrode was the increase in the size of voids within the plate. From structures such as shown in Fig. 1-4, where the voids were relatively small and the PbO_2 particles uniformly distributed, there had been a change to a structure like that shown in Fig. 8. After 50 cycles the void spaces were found to be much larger and somewhat elongated. The PbO_2 had separated into clumps or agglomerates that seemed to be interconnected at one or more points yet mostly surrounded by void.

At 50 cycles there was also a gradient in the electrode structure. The elongated void spaces and chain-like agglomerates of PbO_2 were most evident near the surface of the plate and less evident near the center, so that at the center there was still a uniform structure like that shown in Fig. 7. The three series examined near 50 cycles all showed this opening up of the structure and agglomeration of the PbO_2 particles. Plates of all three series showed the same increase in void size and agglomeration of particles into clumps, as well as an unchanged central portion. When examined in areas where change had occurred, however, all three showed remarkedly similar structure. Compare, for example, Fig. 8 (series D) and 9 (series C).

In addition to the opening up of the structure in the manner just described, there was also a change in the

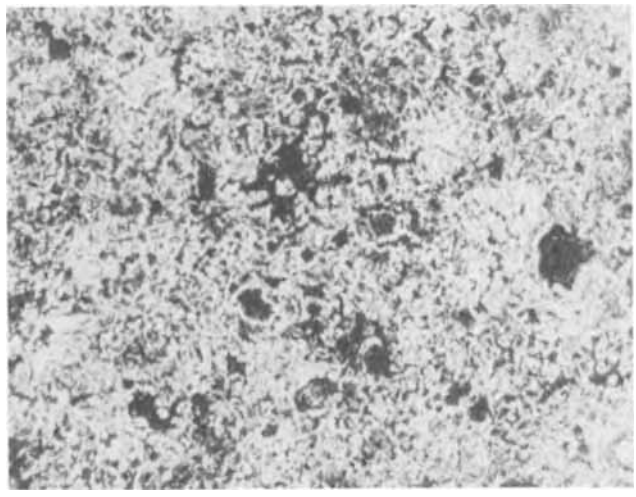

Fig. 7. Structure of plate D after a single discharge-recharge cycle. Compare with Fig. 4. Magnification 600X.

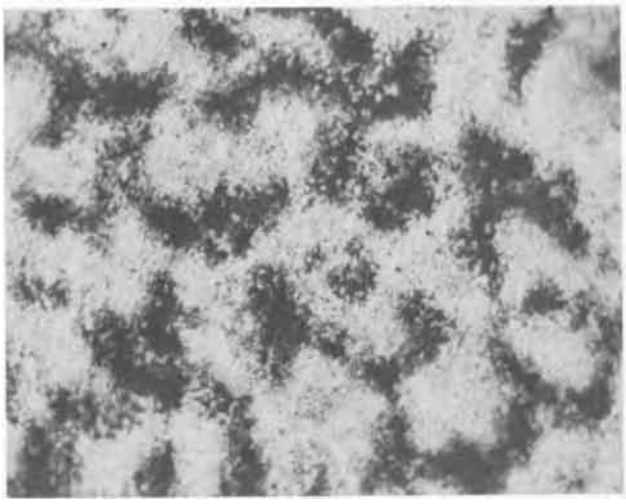

Fig. 8. Structure of plate D after 53 discharge-recharge cycles. Magnification 600X.

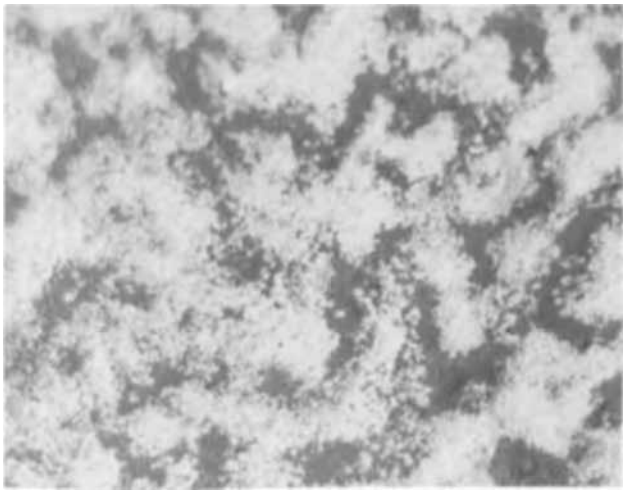

Fig. 9. Structure of plate C after 50 discharge-recharge cycles. Magnification 600X.

appearance of the PbO_2 particles in the reacted portions of the structure. Instead of the small, cell-like structure of PbO_2 formed after one discharge-charge cycle as in Fig. 10 (series D) or the rather nondescript particles found in the formed plate of series C (Fig. 11), for example, all of the plates now showed a structure similar to Fig. 12, in which the agglomerated particles of PbO_2 seemed to be very much smaller and more densely packed.

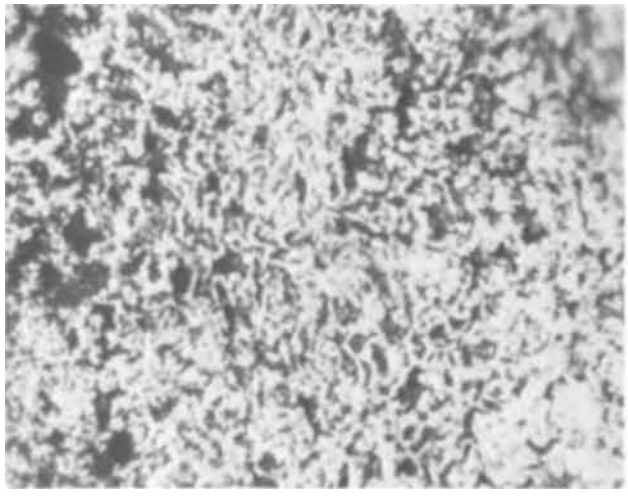

Fig. 10. Structure of plate D after a single discharge-recharge cycle and at a magnification of 1520X.

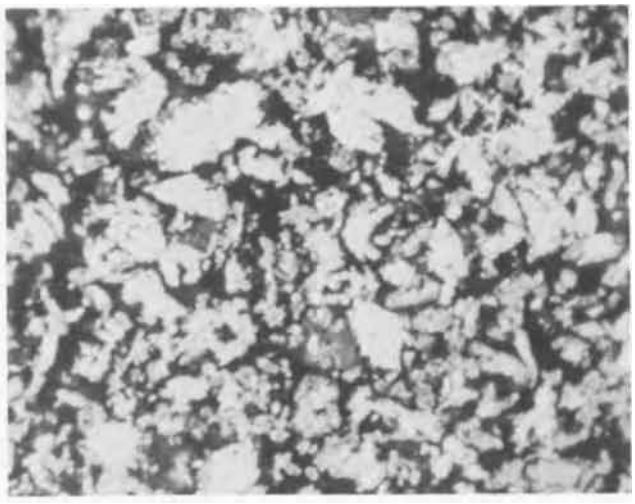

Fig. 11. As-formed structure of plate C at a magnification of 1520X.

Changes occurring between 50 and 100 cycles.—With continued cycling the voids became larger and the amount of material in the agglomerates smaller. The average diameter of the agglomerates decreased and there were less points of apparent contact. The average density of packing of the small particles of PbO_2 in the agglomerates appeared to be about the same as in plates with 50 cycles (Fig. 12).

This was true of series B, C, and D which all looked much as did Fig. 13, but series A was slightly different. A sample of this plate was not available with 50 cycles but at 100 cycles it was found to resemble Fig. 14 in most areas. It will be noted that, while the tendency to form large voids is about the same as in other plates, the agglomerates of the PbO_2 particles have a greater diameter, principally because the particles are less densely packed. The particles making up the agglomerates, however, were only slightly larger than those found in the other series. The size and general shape of the PbO_2 particles in all of the series remained the same in appearance as had been the case at 50 cycles (Fig. 12). A few areas of the series A plate had not yet opened up into the voids like those shown in Fig. 14, but these areas nevertheless had the same structure as that shown in the agglomerates of Fig. 14.

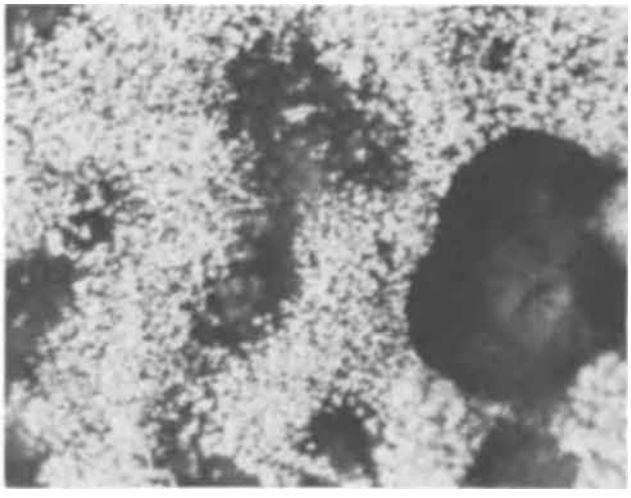

Fig. 12. Appearance of positive active material of plate D after 53 cycles and at a magnification of 1520X.

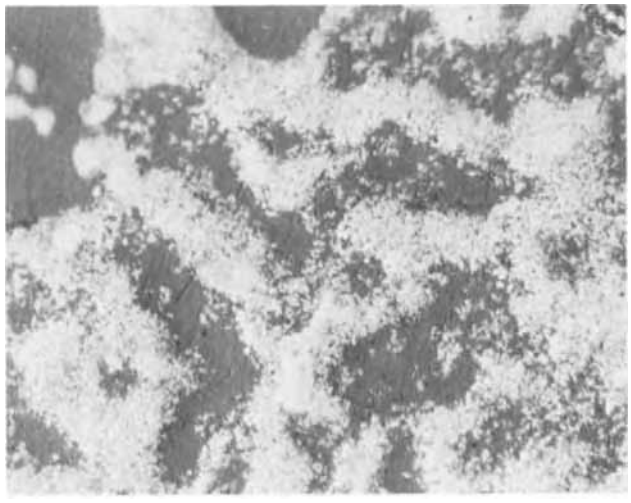

Fig. 13. Microstructure of plate D after 115 cycles and at a magnification of 600X.

Fig. 14. Appearance of plate A after 100 cycles and at a magnification of 600X.

Another distinguishing characteristic of this series A plate was a fairly uniform distribution of small sulfate crystals, absent in the other series. It is true that occasional large sulfate crystals were found in the other plates but they were much less numerous, larger, and very randomly distributed. Since all plates examined had been removed at the end of a charge cycle, these residual sulfate crystals must have represented material no longer in electrical contact, or else material that had reacted too slowly to have been converted in the time available.

It has also been mentioned that the as-formed plate had a different structure at its surface than in the interior (Fig. 6). This type of structure was still found at 50 cycles but had completely disappeared at 100 cycles. It was not clear whether this material near the surface had been converted to the same structure as the remainder of the plate or whether it had simply been removed by the gradual shedding of the active material.

The gradient in structure noted at 50 cycles, where the interior had no large voids, had also disappeared at 100 cycles and the structure throughout the plates was similar to Fig. 12 in plates B, C, and D.

Changes beyond 100 cycles.—Beyond 100 cycles, in the plates of all the series, an increasing number of particles appeared in the former void space surrounding each agglomerate. These particles appeared to be unattached but it is believed that they were really in the electrical circuit and attached to the main aggregate for the following reasons: (*a*) they had survived the washing to remove acid, which was necessary before the plastic impregnation could be made; (*b*) they were not swept away or compacted by the entrance of the fairly viscous imbedding resin; and (*c*) they disappeared from the voids on the discharge cycle and reappeared with the following recharge. With an increasing number of cycles, the number of such PbO_2 particles in the voids correspondingly increased. The former voids were gradually filled with a low-density distribution of such particles. Meanwhile the agglomerate particles formed less densely packed structures with each cycle. These simultaneous processes eventually filled the whole area with uniform but scattered particles (Fig. 15).

Although it would seem from Fig. 15 that no contact existed between particles, examination by polarized light revealed loosely piled crystals, roughly spherical. Only a portion of these were intersected by the plane of cutting, so that the crystals appeared smaller and further apart than was the actual case. The fact that these crystals had survived washing, drying, and impregnation indicated a more coherent structure than appears to be the case in Fig. 15.

After prolonged cycling the amount of lead sulfate remaining in the charged electrode also increased. This sulfate was found in fairly large areas as an almost continuous impregnant and it had encapsulated much of the PbO_2 remaining in these areas. It seemed unlikely that such encapsulated PbO_2 was continuing to take part in further reaction.

Discussion

There are several points brought out by this investigation that require further discussion.

Change in as-formed microstructure following a single discharge-recharge cycle.—It is not surprising to find that the mechanisms of formation and recharge are essentially different in the positive plate. During formation the plate structure is initially much more dense than when beginning recharge. In addition, the plate composition at the beginning of formation is nonuniform and contains many areas of mixed sulfates, residual PbO and Pb. After the first discharge, microscopic examination shows that only $PbSO_4$ and residual PbO_2 remain and the plate is found to have become much more porous than at the start of the forming process. PbO_2 is also present to nucleate the recharge process, which is not true at the beginning of formation (unless red lead, Pb_3O_4, has been used in the original mixing).

It is also quite usual to employ an electrolyte of considerably lower specific gravity during the formation than is used in actual service. Metzler and

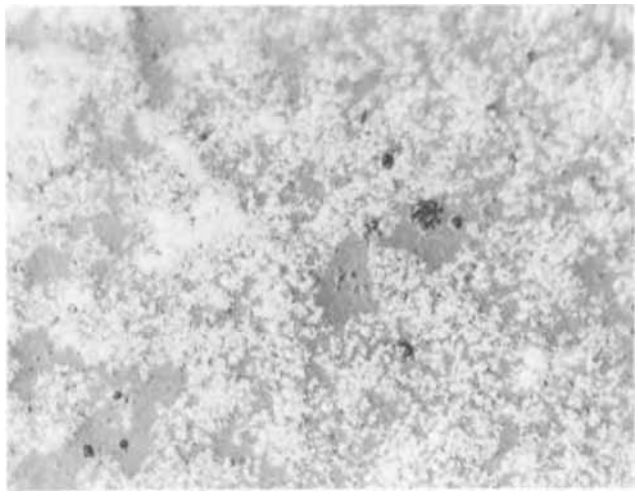

Fig. 15. Type of structure developed in positive plate after several hundred cycles. Magnification 600X.

Schwarz (1) have shown that the $PbSO_4$ crystals formed on soft lead in sulfuric acid of 1.12 sp gr were three times larger than those formed in 1.28 sp gr acid. While we are unaware of a similar study having been made for the $PbSO_4$ in active material, it is probable that a similar relationship exists. The different solubility of $PbSO_4$ in varied concentrations of H_2SO_4 may also be a factor.

It has also been shown by Simon and Jones (2) and Pierson (3) that many features of the unformed positive plate were reproduced in the formed plate, despite a change in chemical composition. In particular, it was observed that certain acicular or needlelike crystals which were found in the cured but unformed plate were preferentially converted to PbO_2. The normal $PbSO_4$ formed on discharge has a considerably different form, which also may be a factor in the difference in the recharged and as-formed plates.

It is assumed that, had samples of the other three manufacturers' plates with one discharge-recharge cycle been available for study, they would have also shown the same difference between as-formed and recharged microstructure.

Change in plate structure within the first 50 cycles.—The plates underwent further change in microstructure somewhere between the 1st and 50th cycle. Not only did the microstructure change from that developed after one cycle but the active material developed large internal voids, separated by nearly continuous walls of PbO_2, which formed a cell-like structure. Since no samples were available for study between the 1st and the 50th cycle, it is not known how many cycles were actually required to obtain the observed structure and whether the change occurred abruptly or gradually. From the fact that a gradual continuation of the process was observed beyond 50 cycles, it is assumed that the process was gradual in the initial stage as well. It was not possible, with the samples on hand, to determine the source of the change in structure. The rearrangement of the microstructure seemed to be brought about by a combination of the repeated change in chemical composition during cycling and the strictly physical effect of gas generation within the structure during the charge cycle. Although the structure found suggested the formation of cells, it is more likely that channels were being formed through which gas was able to escape to the surface of the plate. The escape of this gas would be accompanied by the removal of a certain portion of the more loosely held PbO_2 particles from the channel walls.

Some may object to the idea that gas could act as a pore former in the positive plate, preferring to believe that the pores are due only to the rearrangement and repeated change that occurs during cycling. At the beginning of the investigation we also supported this idea. It is obvious that growth of large sulfate crystals would be at the expense of the surrounding PbO_2 structure, and observation has also shown that upon recharge the PbO_2 structure appears more compact. The growth of large $PbSO_4$ crystals and their dissolution followed by the regeneration of PbO_2 must therefore be a contributing factor in opening up the structure. However, if this were the only or major cause, then one would expect the amount of $PbSO_4$ found in these pores to increase markedly as the pores become larger. This was not the case, for neither the size nor number of the $PbSO_4$ crystals within the pores changed with increasing cycling time.

Gas is generated and released, not only at the surface of the plate, but also on the inside of the electrode. When direct observation was made of the electrode surface while in a microcell, it was observed that gas bubbles repeatedly issued from the same pores in the electrode surface, even after several cycles. Such bubbles of gas increased to a diameter many times that of the original pore before leaving the surface so that they seemed to originate at the surface. However, microscopic observation revealed that, immediately after departure of the large bubbles, new ones were already forming within the original pores.

Hauel (4) reported an increase in negative plate permeability during repeated cycling, presumably because of an increase in number or size of pores or voids. This work was based on repeated measurement of the flow rate of electrolyte under constant pressure through the plate structure and extended over a considerable period of cycling. Unfortunately, no similar study appears to have been done on the positive plate.

Dittman and Sams (5) have shown that the apparent density of the active material decreased during service and have published a curve which indicates that the apparent density of the positive plate continued to decrease over a period of 16 weeks of SAE cycling. The work of Dittman and Sams, however, describes a phenomenon other than porosity. Dittman and Sams measured the apparent plate density in the following manner. The dried plate was weighed and then the amount of water displaced by the weighed plate was measured. Approximately 2/3 of the active material was then removed from the plate and, after again drying, the plate was reweighed. The volume of water displaced by this residual plate was again measured. From the results the apparent density was calculated.

It is obvious that the results would not be affected by a change in pore size or volume, provided that all the pores were open to the surface. The ease with which the samples used in our investigation were impregnated by a fairly viscous polyester, and the absence of unfilled pores, indicates that all pores were open. Only the development of pores into which water could not penetrate or an actual change in chemical composition would account for the decreased density noted by Dittman and Sams. Since their measurements were always made with the batteries in the same apparent state of charge, the only chemical change would seem to be in that portion of the $PbSO_4$ crystals that were unconverted by the charge process and no longer able to take part in the cell reaction. The statements that storage of the charged plate in sulfuric acid, overcharging, and cycling all decreased the apparent density, and that deep cycling caused more decrease in density than shallow cycling, all indicate that what Dittman and Sams actually measured was the increase in residual $PbSO_4$ left at the end of charge. Microscopic studies made in this laboratory confirm that residual $PbSO_4$, in the form of unreactive crystals, increases under the same conditions for which Dittman and Sams reported a specific gravity decrease.

Consideration of volume change as a cause of active material disintegration.—Because the specific volume of $PbSO_4$ is greater than that of PbO_2, it has frequently been suggested that the formation of $PbSO_4$ during discharge produces stresses not only within the active material but also against the grid bars. This explanation sounds attractive and reasonable until an actual microscopic examination is made of the changes that occur during charge and discharge. It has been shown that even the initial formation of the plate produces a PbO_2 microstructure that is full of voids and in which the PbO_2 uses only a portion of the available space.

In a previous paper (6) it was shown that the growth of $PbSO_4$ crystals during discharge occurs within some of the voids of the plate and that this growth of the $PbSO_4$ crystals takes place with a simultaneous disappearance of the PbO_2. During the entire process of discharge, the $PbSO_4$ crystals seemed to be surrounded by a considerable amount of void space and were not in close contact with surrounding PbO_2. Because the $PbSO_4$ grew as compact, regular crystals and because the original PbO_2 active material was very porous and therefore less dense than expected, it was decided that the increase of specific volume caused by the growing $PbSO_4$ crystals was more than compensated for by the original high porosity of the mass of PbO_2 active material. Therefore, no pressure

could have been exerted on the mass by the growing $PbSO_4$ crystals.

Possible factors contributing to the loss of capacity.—As the number of cycles increased, the positive active material developed a network of large voids and the PbO_2 structure itself became made up of very small crystals. There was some evidence that the formation of the large voids by gas evolution had also caused compacting of the surrounding PbO_2 particles into a denser agglomerate than might otherwise have been the case. It seems likely that gas evolution, with accompanying movement of electrolyte in the channels, would be sufficient to dislodge many of the more loosely attached PbO_2 particles along the channel walls and carry them to the surface.

This view is supported by the fact that the diameters of the agglomerates of PbO_2 particles decreased with increasing number of cycles. If this deduction is correct it presents a somewhat different picture than commonly accepted. The usual view is that softening takes place at the plate surface and that particles are loosened and carried away by the "washing" action of the gas bubbles rising along its face.

In the later stages of the cycling, it is evident that the plate has become so porous that channels are no longer necessary for the escape of the gas and that therefore the gas can escape without so much erosion of the plate's internal structure. At the same time contacts between particles have become much more limited and internal resistance must be higher.

A second consideration is the agglomeration of the PbO_2 particles and the formation of very small particles that takes place after a few cycles. While these agglomerates appear to be porous, the pores are very much smaller than those that were present in the as-formed plate or one with only a single discharge-recharge cycle. The pores formed after considerable cycling are very small. It would seem that penetration of the reaction into such small, relatively deep, pores would be limited to very short distances at the usual rates of discharge.

The increasing number of large-size $PbSO_4$ crystals that encapsulated many areas of remaining PbO_2 particles were at least a partial factor in capacity loss. It was not evident why these unreactive crystals should form and grow to large size, but it was suspected that in such areas there was no electrical contact with the rest of the electrode.

Development of a cycled structure independent of the original as-formed structure.—The most definite information obtained from this investigation was that plate structures from all sources investigated were quite similar after cycling and seemingly independent of the structures that had been developed during either curing or cycling. While this does not seem to agree with the known fact that different paste formulations produce plates with different performance characteristics and service lives, it is nevertheless significant. It indicates that the structure developed in the plate is evidently a function of the mode of operation and of such factors as gas formation, current density, and rate and habit of crystal growth. More subtle changes such as variations of the Pb/O ratios in the PbO_2 lattice, α- and β-PbO_2 ratios, introduction of crystal growth modifying additives from the separators or the expander of the negative, or destruction of nucleation sites, are very likely factors that not only determine the life of the plate but that would also be strongly influenced by paste formulation. Such factors as the above cannot readily be proven by microscopy, although their presence may be indicated by changes in color, hardness, or reflectivity. In such cases other methods of investigation are necessary.

Other evidence for increasing similarity in active material, in plates of different manufacture, with increasing cycle time.—A differential thermal analysis of the active material of the plates used in this investigation has confirmed some of the conclusions arrived at here. This differential analysis is the subject of a following paper.

Acknowledgments

The various battery companies that have contributed samples for this and other of our investigations prefer anonymity but we gratefully acknowledge their assistance. We also wish to thank the Naval Research Laboratory for its support of this joint investigation and for permission for publication of this work. Appreciation is also expressed to the International Lead-Zinc Research Organization, Inc., which has assisted in this and other investigations by maintaining the position of Research Associate for one of the authors at the Naval Research Laboratory.

Electrical Conductivity Measurements in Anhydrous Hydrogen Fluoride[1]

Robert P. Clark

Sandia Laboratories, Albuquerque, New Mexico 87115

and James R. Moser*

Catalyst Research Corporation, Baltimore, Maryland 21209

ABSTRACT

The specific conductivities of LiF, NaF, $KF \cdot 2H_2O$, SrF_2, and KNO_3 in distilled anhydrous hydrogen fluoride were measured over the temperature range −75° to 0°C. Standardization of the Teflon conductivity cells was made with a 0.100*N* solution of NaI in CH_3OH. Conductivities are presented for five concentrations of each solute ranging from saturation at −75°C to 1/10 of this concentration. An empirical equation has been developed which relates the specific conductivity to concentration and temperature. A table of constants is given which applies the equation to a particular solute.

Until recently, anhydrous hydrogen fluoride (HF) as a battery electrolyte has essentially been overlooked. In many ways, this seems reasonable because of its toxic and chemically corrosive properties. On closer examination, one finds that anhydrous HF passivates many metals in much the same way that oxygen passivates aluminum. Metals such as copper, nickel, and magnesium are passivated readily, as would be expected from the solubilities of their respective fluoride salts (1-3). Suitable materials are available for containers, and the problem of toxicity can be minimized by using sealed battery cases.

Previous use of anhydrous hydrogen fluoride as an electrolyte solvent has been limited. Koerber and DeVries (4) determined emf values and free energies of formation using cells of the type M, $MF_2(s)$/ $HF(NaF)/Hg_2F_2(s)/Hg$. Krefft (5) measured the potential of the cell Pt, $H_2/HF(KF)/F_2$, Pt and evaluated the free energy of formation of HF. Clifford and co-workers (6, 7) conducted potentiometric studies of several systems in liquid HF. More recently, Jasinski (8) has reported on studies of Cu/CuF_2 reference electrodes in anhydrous HF.

To the authors' knowledge, only one other group has undertaken any research aiming toward the development of a practical primary cell with anhydrous hydrogen fluoride as a main component of the electrolyte (9, 10).

Narrow ranges of specific conductivities have been measured by various workers. Simons (1) reports data at low concentrations for KF and KNO_3 and Fredenhagen (3) also studied the same solutes. Quarterman *et al.* (11) have published the specific conductivity of many organic solutes in anhydrous HF over an extensive concentration range but over a restricted temperature range, 0°-25°C. It appears that no comprehensive conductivity literature exists over a wide range of temperature and concentration for inorganic fluorides dissolved in anhydrous hydrogen fluoride.

In an over-all plan of battery development, the availability of an electrolyte with sufficient conductivity to minimize undesired *IR* losses must be ascertained. This study was designed to provide some of the necessary information for such an evaluation.

Experimental

The chemicals used were: $KF \cdot 2H_2O$, Fisher certified reagent; NaI, Fisher certified reagent; NaF, Fisher reagent; KNO_3, Fisher certified reagent; KCl, Fisher certified reagent; SrF_2, Mallinckrodt analytical reagent; CH_3OH, Fisher 99.5% min; "anhydrous" HF, Allied Chemical 99.7% min. Water used in the preparation of KCl solution was distilled. All operations were conducted in a glove box within a "dry room" at less than 1% relative humidity (300 ppm H_2O at 25°C). Water concentrations inside the glove box were not monitored. Any increase in conductivity resulting from moisture absorption is insignificant, as discussed in a later section.

The HF was purified by a single distillation with all-Teflon apparatus to rid it of traces of water and iron, the latter impurity originating from the shipping container. HF, which boils at 19.6°C (12), was vaporized at room temperature (~24°C), passed through Teflon cooling coils, and collected in a Teflon receiver at −25°C. The as-received tank of HF had a specific conductivity of 1.7×10^{-2} ohm^{-1} cm^{-1} at 0°C. After a single distillation, the specific conductivity had decreased to 5.0×10^{-4} ohm^{-1} cm^{-1} at 0°C. A second distillation resulted in no further decrease in specific conductivity. Further purification by electrolysis, using the method of Evans *et al.* (13), resulted in an increase in conductivity due to the dissolution of nickel fluoride which was formed at the nickel anode. Singly distilled HF was used in all further experiments.

The latter conductivity value is identical to that obtained by Fredenhagen (14) at −15°C. Efforts to duplicate the results of Schmidt and Schmidt (15) (7.5×10^{-6} ohm^{-1} cm^{-1} at −15°C) or Runner, Balog. and Kilpatrick (16) (5.7×10^{-6} ohm^{-1} cm^{-1} at 0°C) were not considered practical or necessary since the conductivities of the solutions being investigated were approximately 2-3 orders of magnitude higher than that of the HF solvent. Runner *et al.* (16) have demonstrated the impracticality of maintaining a specific conductivity less than 10^{-4} ohm^{-1} cm^{-1}.

Measurements were made at 1 kHz using a General Radio Type 1650-A impedance bridge. The conductivity cell constructed of Teflon is shown in Fig. 1. Platinum wire electrical connections to the electrodes were made through small pinholes in the end plugs. The platinum wire leads were spot welded to circular platinum electrodes.

The Pt electrodes were platinized using a 5% solution of chloroplatinic acid containing 0.02% lead acetate. A current density of 84 mA/cm^2 was employed for 3 min with current reversals each 30 sec. The electrodes were platinized *in situ* and rinsed clean of the plating solution with five washings of distilled HF. The test solutions were introduced through two 1.27 cm diameter holes. A calibrated chromel-alumel

Key words: electrical conductivity, hydrogen fluoride, specific conductivity.

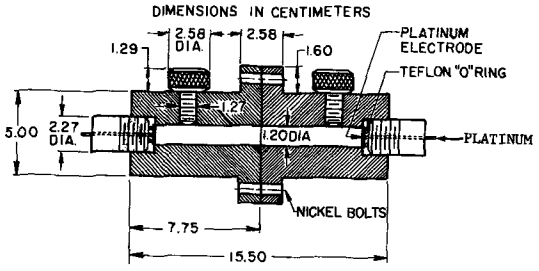

Fig. 1. Conductivity cell

thermocouple encased in a Teflon sleeve was used to monitor the temperature of the solution but was always removed immediately prior to making a conductivity measurement.

The Teflon cells were standardized with a 0.100*N* NaI solution in methanol. The conductivity of this solution was itself determined using a Pyrex "U" tube conductivity cell which was previously standardized with a 0.100*N* KCl solution at 25°C. Since Pyrex has a low coefficient of thermal expansion, 3.6 x 10^{-6} deg^{-1} (17), the Pyrex cell constant (13.07 cm^{-1}) determined at 25°C was assumed to apply over the temperature range of −75° to 25°C.

A Revco ULT-903 cold box was used to maintain temperature for these experiments. Temperatures were controlled to ±0.2°C. Conductivity data for electrolyte systems over the temperature range of −75° to 0°C are nonexistent; consequently, the conductivity of a solution of 0.100*N* NaI in CH_3OH was determined over this range. The conductivity measured for this solution between −75° and 0°C is given in Table I.

Since Teflon has a relatively high coefficient of linear thermal expansion, 10.0 x 10^{-5} deg^{-1} (18), the conductivity cell was standardized throughout the range −75° to 0°C. The cell constant (k) varied linearly according to the equation

$$k = 0.00437\,t + 12.69$$

where t is temperature in degrees centigrade and k is the cell constant in cm^{-1}.

Solution preparation.—The minimum solubility for each of the five salts studied occurs at the lowest temperature studied, *i.e.* −75°C. These data are shown in Table II. Salt concentrations were chosen such that solubility at −75°C was not exceeded.

The solubility of the salts at −75°C was determined as follows. One hundred grams of HF were placed in a Teflon beaker and solute was added from a previously weighed quantity until no more would dissolve with stirring. The solution was filtered through a Teflon filter, and the excess salt in the filter was dried and weighed. The quantity of salt dissolved was determined by difference.

Because the density of HF varies by approximately 20% over this temperature range (19), it is appropriate to express the solute concentrations in molality units.

The precision of these conductivity measurements is ±1.5%. The irreproducibility resulted from temperature variations (±0.2%), solubility measurement reproducibility (±0.1%), cell constant error (±0.2%), and bridge precision (±1.0%).

Results and Discussion

Figures 2 through 6 show specific conductivity as a function of concentration and temperature for LiF, NaF, $KF \cdot 2H_2O$, SrF_2, and KNO_3, respectively. Curves represent conductivity values calculated from the empirical equations which are discussed later in this article. Experimental data points are also shown in the figures.

It will be observed in Fig. 3 that specific conductivity values for NaF decrease at higher concentrations. Values for 5.83*M* (molal) NaF are: less than those for 4.31*M* NaF at all temperatures measured, less than those for 2.92*M* NaF at −20°C and below, and less than those for 1.46*M* NaF at −50°C and below. Although viscosity has not been determined for these solutions, this effect is probably the result of increased viscosity at the higher concentration in accordance with the Walden Rule.

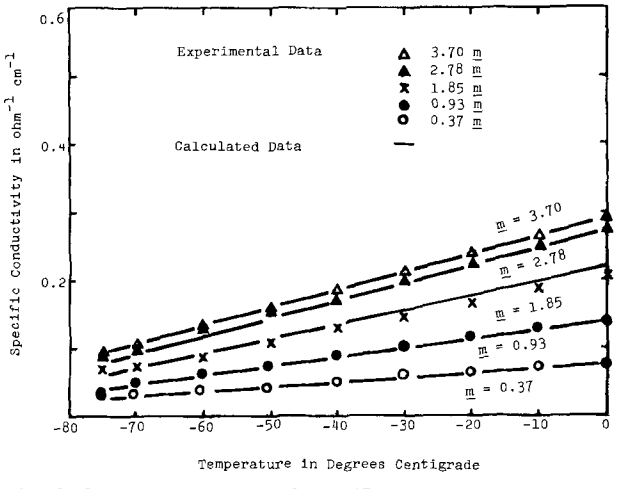

Fig. 2. Specific conductivity of LiF/HF solutions vs. temperature. Molality range, 0.37-3.70*M*.

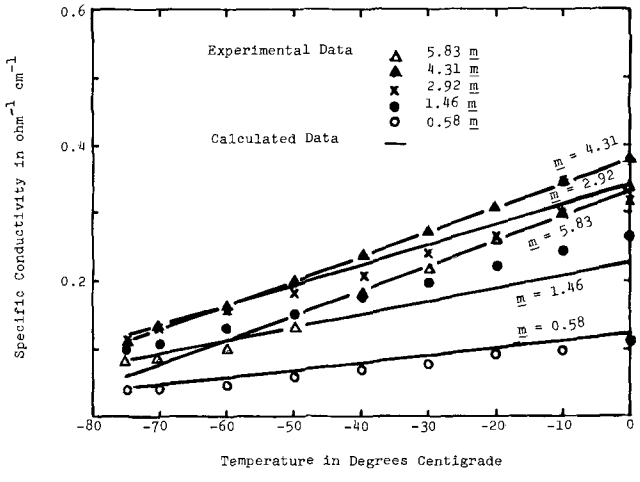

Fig. 3. Specific conductivity of NaF/HF solutions vs. temperature. Molality range, 0.58-5.83*M*.

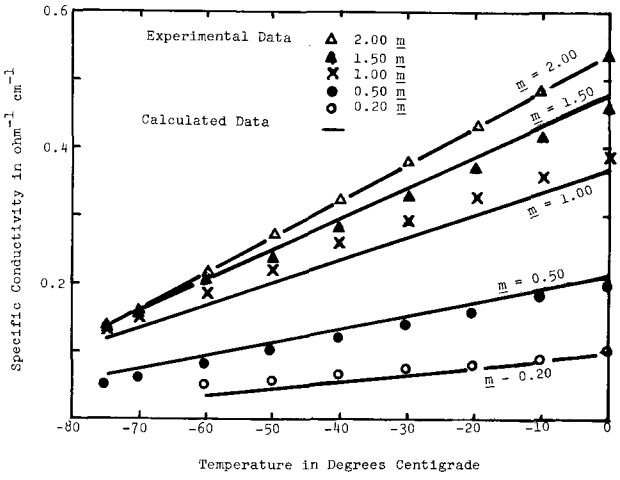

Fig. 4. Specific conductivity of $KF \cdot 2H_2O/HF$ solutions vs. temperature. Molality range, 0.20-2.00M.

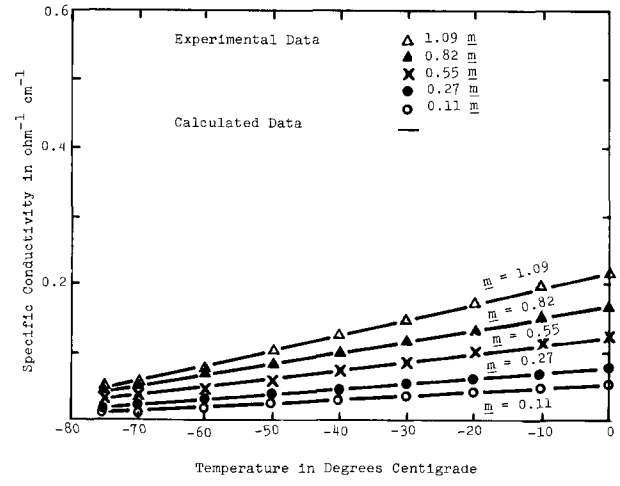

Fig. 5. Specific conductivity of SrF_2/HF solutions vs. temperature. Molality range, 0.11-1.09M.

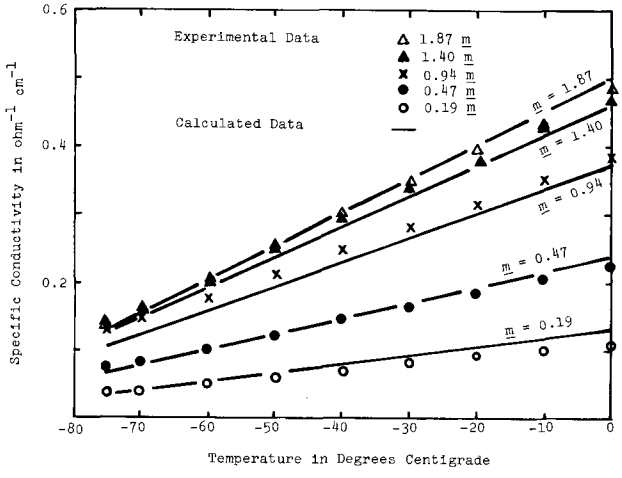

Fig. 6. Specific conductivity of KNO_3/HF solutions vs. temperature. Molality range, 0.19-1.87M.

The use of $KF \cdot 2H_2O$ (Fig. 4) produced conductivities twice as high as those reported by Simons (1) and Fredenhagen (3) for anhydrous KF. These values are included to show the effect of water of hydration.

Figure 7 shows the conductivity *vs.* temperature for singly distilled HF used in the preparation of the electrolyte solutions. These data were reproducible after several weeks' storage in the glove box indicating that no significant amounts of water were absorbed by the HF. Since the salt solutions exhibited conductivities several orders of magnitude greater than the values measured for HF itself, it is even less likely that water impurities have affected the conductivity data for the solutions.

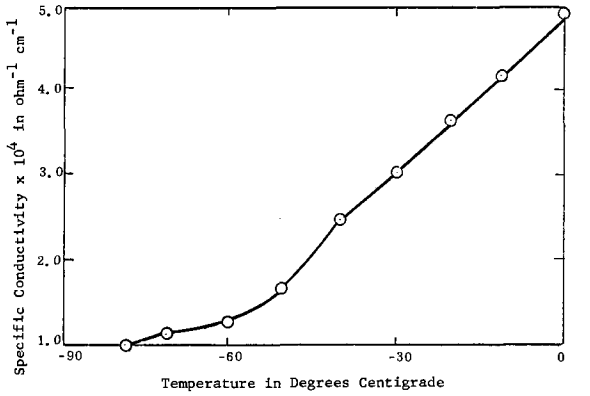

Fig. 7. Specific conductivity of singly distilled HF vs. temperature.

Conductivity *vs.* temperature curves for the solutions are straight lines and can be represented by the general linear equation

$$\kappa = at + b \qquad [1]$$

where κ is specific conductivity in ohm^{-1} cm^{-1}, a is the slope of the curve, t is temperature in degrees centigrade, and b represents the y-intercept at 0°C. Both the slope, a, and the intercept, b, are dependent on the concentration of the solution. Plotting a and b *vs.* concentration results in parabolic curves opening downward. The general equation representing these curves is

$$(m - c)^2 = -d\,(y - e) \qquad [2]$$

where m is the solution concentration in molality; y is either a or b from the previous linear equation; and c, d, and e are constants. Solving the general parabolic equation successively for a and b and substituting these results into the general linear equation give an equation relating specific conductivity to the solution temperature and concentration of the form

$$\kappa = (Am^2 + Bm + C)t + Dm^2 + Em + F \qquad [3]$$

where A, B, C, D, E, and F are constants. The constants were determined for each of the five salts using a least-squares analysis.

The results are shown in Table III.

Manuscript submitted Aug. 13, 1970; revised manuscript received Dec. 7, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1971 JOURNAL.

Epoxide-Containing Polymers as Highly Sensitive Electron-Beam Resists

Takako Hirai, Yoshio Hatano, and Saburo Nonogaki

Central Research Laboratory, Hitachi Limited, Kokubunji, Tokyo, Japan

ABSTRACT

High sensitivities to electron beams have been found in epoxide-containing polymers such as epoxidized polybutadiene, epoxidized polyisoprene, and poly(glycidyl methacrylate). The sensitivities of these polymers to electron beams are 50-300 times higher than those of the commercial photoresist KTFR. Epoxidized polybutadiene, with the highest sensitivity, becomes insoluble upon an electron beam exposure of 2 x 10^{-8} coulombs/cm^2 at an accelerating voltage of 15 kV; the *G* value for crosslinking was calculated to be about 200. These polymers can be used as resists for the etching of chromium and aluminum, as well as of oxide layers formed on silicon wafers.

In recent years, several investigations have been made on the application of electron beams to the fabrication of semiconductor devices. Using electron-beam scanning equipment, Hatzakis (1) made transistors with a 1μ wide emitter which is difficult to make by ordinary photoetching techniques. Where the electron-beam process is applied to the fabrication of semiconductor devices, electron-beam resists are usually used. Electron-beam resists are generally organic polymers which become insoluble (negative working resists) or soluble (positive working resists) in particular solvents. Polymers examined up to now as electron-beam resists include polymethacrylates (2, 3), commercial photoresists (4, 5), silicone resins (6), *etc.* As far as the authors know, the highest sensitivity reported to date is that of silicone resins, an exposure of charge density of about 3 x 10^{-6} coulombs/cm^2 being sufficient to insolubilize the resins. This sensitivity, however, still seems to be insufficient for rapid scanning by electron beams. Use of electron-beam resists with higher sensitivity will shorten the exposure time.

In the present investigation, electron-beam resists with high sensitivity have been sought in connection with the development of an electron-beam drafting machine (7) for IC photomask making. A preliminary study was made with the purpose of finding groups to make polymers sensitive to electron beams. The results indicated that epoxy groups  and the azide group ($-N_3$) are highly sensitive to electron beams (8).

Key words: electron beam resists, epoxide-containing polymers.

On the basis of this result, we synthesized epoxide-containing resists. The epoxy group was preferred to the azide because of its insensitivity to light.

Experimental

Material.—Epoxidized polybutadiene.—Polybutadiene (JSR BRO1, obtained from Japan Synthetic Rubber Co., cis content 97%, intrinsic viscosity [η] 2.8 in toluene) was epoxidized as follows. Polybutadiene (6g) was dissolved in 160 ml of toluene and epoxidized for 30 min at 45°C with 160g peracetic acid solution (0.9M) which was prepared from 30% hydrogen peroxide and acetic anhydride by the method of Findley (9). After 150 ml of cyclohexanone were added, the reaction mixture was washed repeatedly with water and aqueous sodium bicarbonate. The epoxidized polymer was precipitated from the solution by adding methanol; it was then dissolved in cyclohexanone. The epoxide content of the polymer, as determined by the hydrochloric acid procedure, was 6.0 mmoles/g. The intrinsic viscosity [η] was 3.0 in toluene at 25°C.

Epoxidized polyisoprene.—Polyisoprene (Cariflex IR 309, Shell Chemical Corp.) was masticated at 30°C for 60 min. Then 3g of the masticated polyisoprene ([η]

1.86 at 25°C in toluene) were dissolved in 60 ml of toluene and epoxidized with 40g of peracetic acid solution at 35°-38°C for 20 min. The epoxidized polymer was washed acid free and stored as a cyclohexanone solution. Epoxide content of the polymer was 6.2 mmoles/g.

Poly(glycidyl methacrylate).—The monomer, freed from inhibitor by distillation under reduced pressure in nitrogen, was polymerized in a sealed tube at 65°C for 20-35 min with 0.2% of α,α'-azobisisobutyronitrile as a catalyst. The polymer was purified by repeated precipitation from methyl ethyl ketone by addition of methanol and stored as a methyl ethyl ketone solution. The epoxide content was 7.2 mmoles/g.

Infrared spectra.—*IR* absorption spectra of polymers were obtained using a Hitachi Infrared Spectrophotometer EPI-2. Polymers coated on silicon wafers were exposed to an electron beam at an accelerating voltage of 35 kV. Their *IR* spectra were taken before and after exposure to the electron beam.

Insolubility characteristics.—Thin layers (0.3-1.0μ) of the polymers were laid on silicon wafers by spin-coating from 3 to 5% solutions and exposed to an electron beam at an accelerating voltage of 15 kV. After the exposure, the polymer layers were developed with cyclohexanone and the thicknesses of the layers remaining on the exposed areas were determined with an interferometer.

Resistance to etching solution.—Substrates (*e.g.*, oxidized silicon wafer) were coated with the polymer, exposed to electron beams through a mechanical mask (fine copper mesh), developed with cyclohexanone, baked, and etched. The substrates were then inspected with an optical microscope to check whether the etching had proceeded correctly or not.

Application to IC-mask making.—Chromium-evaporated glass plates were coated with the polymers and exposed in an electron-beam drafting machine (7) specially designed for the purpose of drafting the patterns of IC photomasks. The exposed plates were developed with cyclohaxanone, heated at 180°C for 10 min and then etched with NaOH-$K_3Fe(CN)_6$ etchant (Kodak Etch Bath EB-5) for 2-3 min.

Results

Electron-beam exposure characteristics of the epoxidized polymers are compared with those of unepoxidized polymers in Fig. 1. As is readily seen, the epoxidization increases sensitivities of the polymers by factors of 10-30. The sensitivity of a polymer depends on both its type and its molecular weight. It is known that the crosslinking sensitivity is proportional to molecular weight (10, 3). However, no significant change in the degree of polymerization by the epoxidization was observed; for example, [η]'s of epoxidized and unepoxidized polybutadiene are 3.0 and 2.8, respectively. Therefore, the high sensitivity in the epoxidized polymers is attributed to the existence of the epoxy groups in the polymers. The sensitizing effect of the epoxy group was also observed in poly (glycidyl methacrylate) PGMA. As shown in Fig. 2, PGMA is much more sensitive than Lucite 45, whose epoxy-free structure resembles that of PGMA.

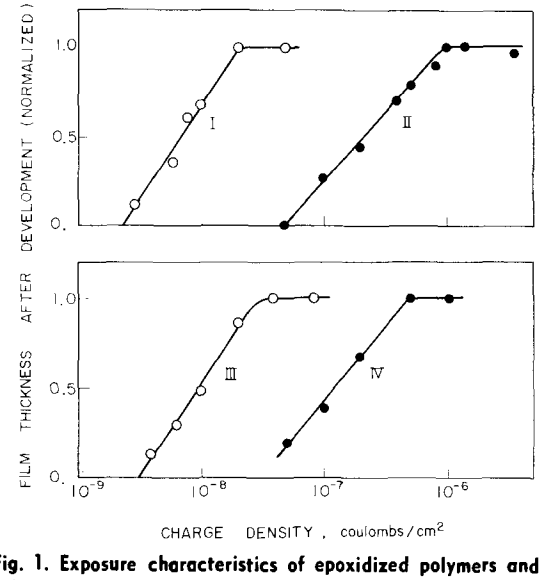

Fig. 1. Exposure characteristics of epoxidized polymers and their starting polymers: I, epoxidized polybutadiene; II, polybutadiene; III, epoxidized polyisoprene; IV, polyisoprene.

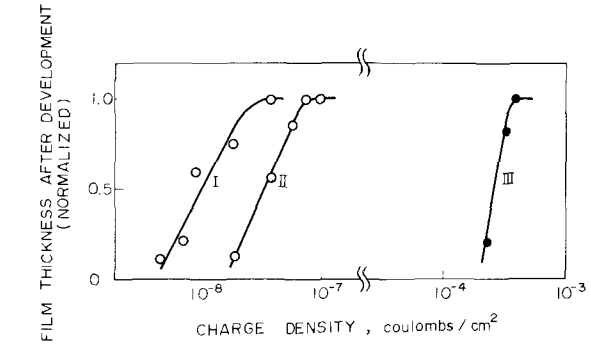

Fig. 2. Exposure characteristics of poly(glycidyl methacrylate) and Lucite 45: I, poly(glycidyl methacrylate) [η] = 1.94; II, poly(glycidyl methacrylate) [η] = 1.28; III, Lucite 45 (polyisobutyl methacrylate) [η] = 1.02.

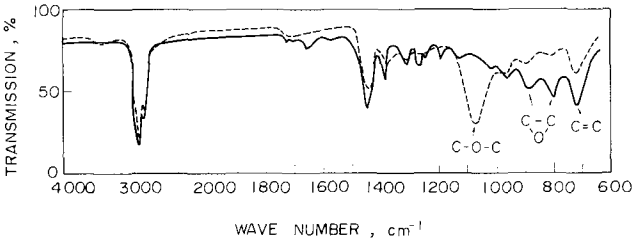

Fig. 3. Infrared spectra of epoxidized polybutadiene before and after exposure: ——, before exposure; - - -, after exposure (3 x 10^{-5} coulombs/cm².)

Figure 3 shows the infrared spectra of epoxidized polybutadiene before and after an exposure of 3 x 10^{-5} coulombs/cm². In the case of exposure, the absorption peaks at 810 and 900 cm^{-1}, corresponding to the epoxy group CH$\overset{O}{\diagup\!\!\diagdown}$CH, almost disappeared, a new peak at 1075 cm^{-1} assignable to the ether linkage C—O—C appeared, and no other significant changes were observed. This indicates that, through an electron-beam irradiation process, the epoxy ring opens only to give crosslinks.

In Fig. 4 is plotted the change in epoxy and ether contents of epoxidized polybutadiene in *IR* spectra as a function of irradiation dose. As the figure shows, the rates of ring opening of the epoxy groups and of formation of the ether bonds almost coincide.

The resistance of the epoxide-containing polymers to chemical etch was examined. It was found that thin layers of the polymers insolubilized on substrates are, after being improved in adhesion and chemical resistance by baking at 180°C for 10 min, capable of protecting the substrates from etch solutions. Thus, oxide layers on silicon wafers and evaporated chromium layers can be etched lithographically using these polymers as electron-beam resists.

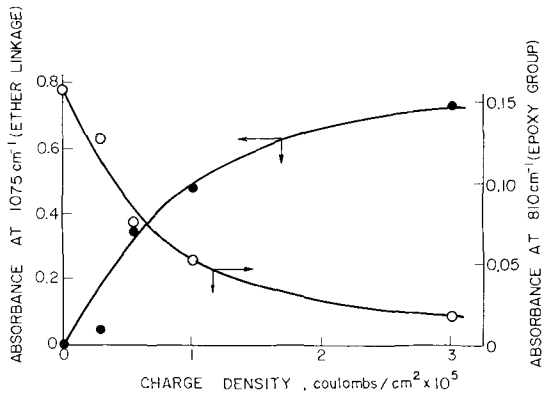

Fig. 4. Change in absorbance for ether linkage (●) and epoxy group (○) in epoxidized polybutadiene as a function of exposure.

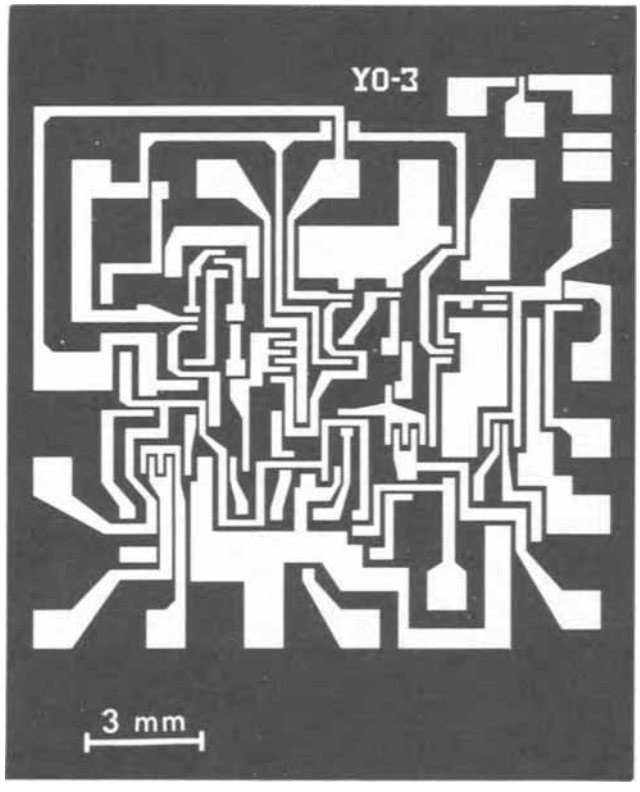

Fig. 5. Chromium mask for IC

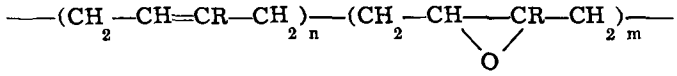
Chromium patterns are made with an electron-beam drafting machine and with the electron-beam resists prepared in the present study. An example of the patterns of these masks is shown in Fig. 5. This pattern (14.8 x 15.0 mm) was drafted directly by computer-controlled, electron-beam scanning. The electron-beam diameter used in this drafting machine is not small enough to determine the resolution capability of these resists. To examine the line definition of the resists, further experiments using a scanning electron microscope are now being carried out.

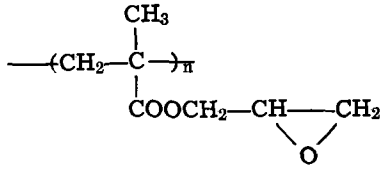
Discussion

As described above, we found that epoxide-containing polymers are highly sensitive to an electron beam. For example, epoxidized polybutadiene starts insolubilizing at a charge density of 2×10^{-9} coulombs/cm^2, whereas a charge density of 7×10^{-7} coulombs/cm^2 is necessary for the commercial photoresist KTFR (8).

The structures of epoxidized polybutadiene or polyisoprene and PGMA are shown below.



[1]



[2]

where R is H or CH_3.

The radiation sensitivity of a system is expressed in terms of the G value, which is defined as the number of chemical changes of a given kind produced per 100 eV absorbed. The G values for crosslinking of the epoxidized polymers can be calculated in two ways.

In the first, G is derived from the insolubilization data. According to Charlesby (10), three-dimensional network formation first starts occurring at the crosslinking density of one crosslinked unit per weight average molecule. This point, usually called gel point, corresponds to the threshold of charge density for insolubilization with exposure characteristics shown in Fig. 1. The number of crosslinks produced in the polymer per unit area at the gel point is equal to $0.5\ d\rho N/M$, where d, ρ, N, and M are the thickness, the density of the polymer, Avogadro's number, and the weight average molecular weight of the polymer, respectively. The energy absorbed in this case, at the accelerating voltage of V volts, is expressed as $Q_g V \alpha d$, where Q_g and α are the charge density at the gel point in coulombs/cm^2, and the energy absorption coefficient, respectively.

G is then expressed as follows

$$G = \frac{\rho N q}{Q_g \alpha V M} \times 50$$

where q is the electronic charge.

M's of polybutadiene and polyisoprene are calculated using Eq. [3] and [4], respectively (11).

$$[\eta] = 11.0 \times 10^{-4} M^{0.62} \quad [3]$$

$$[\eta] = 4.9 \times 10^{-4} M^{0.64} \quad [4]$$

The M's of the epoxidized polymers are corrected for the weight increase caused by the epoxidization. As the value of α is difficult to obtain by direct measurement, it is roughly estimated from the data obtained by Ehrenberg and King (12) to be 0.28 per μ at $V = 15{,}000$ for all the polymers considered here.

The G values calculated by use of Q_g and M thus obtained are shown in the second column of Table I.

In another way, G is calculated from the IR-spectrum data. By plotting the IR absorbance against the radiation dose, as shown in Fig. 4, we obtain the charge density required to decrease the epoxide content by a definite percentage, say 1%. It has been ascertained, as described previously, that the ring opening of the epoxy group leads to the formation of ether linkages almost exclusively. So we can assume that one crosslink is formed by one opened epoxy ring. And G then becomes

$$G = \frac{\rho N q}{Q_{0.01} \alpha V E}$$

where E and $Q_{0.01}$ are the epoxide equivalent (*i.e.*, the weight of the polymer containing 1 mole of epoxide)

Table I. G values for the crosslinking of the epoxidized polymers

Materials	G values: From insolubility data	G values: From IR data
Epoxidized polybutadiene	190	200
Epoxidized polyisoprene	160	70

and the charge density necessary to decrease the epoxide content by 1%, respectively. E is calculated from the epoxide content determined analytically. α is again estimated to be 0.070 per μ at $V = 35{,}000$. The G values obtained from $Q_{0.01}$ and E are shown in the third column of Table I.

It is seen from Table I that the G values of the epoxidized polymers are extraordinarily large compared with those of ordinary polymers. For example, G values for KPR and KTFR are reported by Broyde (5) to be 0.65 and 1.20, respectively. If a chain reaction is assumed to take place by an electron-beam exposure to produce three-dimensional structures, high G values of crosslinking can be explained. However, it is uncertain that such a chain reaction occurs smoothly in relatively rigid polymer layers. It may also be worthwhile considering that the highly exothermic character of crosslinking reactions contributes to the large G values. Bond-energy data show that heat of about 35 kcal/mole evolves in the crosslinking process with one epoxide-ring opening. Although we do not have data for further discussions, it may be possible to regard this exothermic character as one of the reasons for the high sensitivities of the epoxidized polymers to electron beams.

Conclusion

Selected polymers having large molecular weights and containing epoxy groups in high concentration are more sensitive to electron beams than any known negative resist. These polymers are: epoxidized polybutadiene, epoxidized polyisoprene, and poly (glycidyl methacrylate). They become insoluble by an exposure of 15 keV electron beams with charge density between 10^{-8} to 10^{-7} coulombs/cm^2. G values for crosslinking of the epoxidized polymers are calculated to be about 200. These high sensitivities and high G values are attributed to the presence of epoxide structures in the polymers. By use of these polymers as electron-beam resists, we can etch selected areas of chromium-coated plates and oxidized silicon wafers. Owing to their high sensitivities, these polymers shorten the exposure time when used in electron-beam techniques.

Acknowledgments

The authors are grateful to H. Morishita for his assistance with the etching tests and in making the chromium masks, and to A. Maekawa for his help with an electron-beam drafting machine.

A Continuous Manufacturing Process for Solid Tantalum Capacitors Based on the Powder-on-Foil Concept

Gerhart P. Klein*

P. R. Mallory & Company Incorporated, Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

ABSTRACT

A manufacturing process for solid tantalum capacitors in the lower CV range based on the use of a continuous tape approach eliminates the handling of individual parts through the most critical stages of the process and thereby eliminates mechanical damage, operator error, and reduces the labor requirements drastically. The process extends from the initial phase of anode fabrication by sintering to lead attachment and encapsulation. High process yields and very uniform device parameters can be achieved through the mechanization of all process operations. The process lends itself to complete automation and operation by means of a process control computer.

Problems in solid tantalum capacitor (STC) manufacturing that result from contamination and physical damage due to the use of organic binders, mechanical pressing, and individual parts handling are eliminated in the new powder-on-foil (POF) process (1). In it, tantalum foil in the form of a continuous tape serves both as the substrate which supports the powder compact and as an interconnecting means between a multitude of sintered anodes. The foil substrate contains depressions which serve as receptacles for Ta powder which is deposited dropwise in the form of a slurry of powder in water. After drying, the powder is fused to itself and the foil in a single sintering operation in inert atmosphere.

Tantalum tape with integral sintered anodes can be processed into solid tantalum capacitors with high processing yields, consistently low leakage currents, and superior reliability (2). The POF process is par-

* Electrochemical Society Active Member.
Key words: solid tantalum capacitors, continuous tape manufacturing process, binderless anodes, powder dispensing and measuring apparatus, continuous tape sintering furnace, continuous anodizing apparatus.

ticularly well suited to smaller types of STC's with radial leads in the range to about 200 $\mu f \cdot V$.

STC's in the conventional process are manufactured by batch processing techniques. Anodes are pressed individually, presintered in bulk, provided with leads individually, sintered in bulk, and are then fixtured and arranged in processing heads. The heads are taken through the process either manually or at various degrees of mechanization.

Various schemes for single-file continuous processing have been proposed (2, 3) for parts of the STC process. Obviously, the initial phase of the process is the most difficult to translate into a continuous process. Pressing of anodes with binder and sintering in vacuum are serious obstacles to any such attempt. Sintering must be done in vacuum because the binder cannot be removed reliably in inert gas sintering. A linear vacuum sintering process is expensive both from the point of view of initial equipment cost and its operation because of low loading density.

Other problems such as how to press and attach individual anodes to a common carrier before sintering and, after sintering, process them into good capacitors and separate them from the carrier at the end of the process without damaging them are equally far from a solution.

The advantages of a continuous process are as obvious as are the difficulties of achieving this goal by way of the conventional STC process.

A linear continuous process is defined as one in which the parts to be manufactured move through subsequent stages of the process in single (or multiple) file. Materials continuously enter the process line, pass through all stages without holdup, and finished devices come off the line continuously. This mode of operation provides for identical processing conditions for all parts. Manual labor is eliminated as are handling of individual parts and the chance of physical damage. The process variables can be controlled tightly and human error is largely eliminated. This can be the basis for full automation and computer control.

The POF process, in addition to providing an alternative to the pressing of anodes with binders which by itself leads to a significant improvement in product quality, provides at the same time an ideal basis for a continuous manufacturing process for STC's. The purpose of this paper is to report some of the work that was done toward this latter goal. A flow diagram of a continuous POF process (5) is shown in Fig. 1.

Description of Manufacturing Process

Tape preparation.—Any continuous process requires that individual parts be interconnected in some way such that they are aligned in single or multiple file. In the POF process, this is accomplished by means of tantalum foil which serves both as a substrate for a porous pellet and as an interconnecting carrier tape.

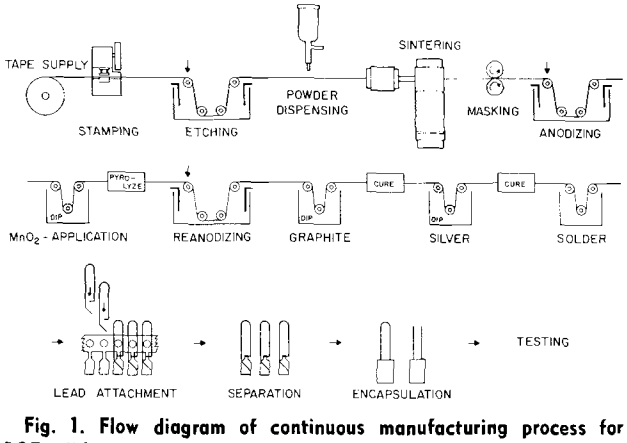

Fig. 1. Flow diagram of continuous manufacturing process for POF solid tantalum capacitors.

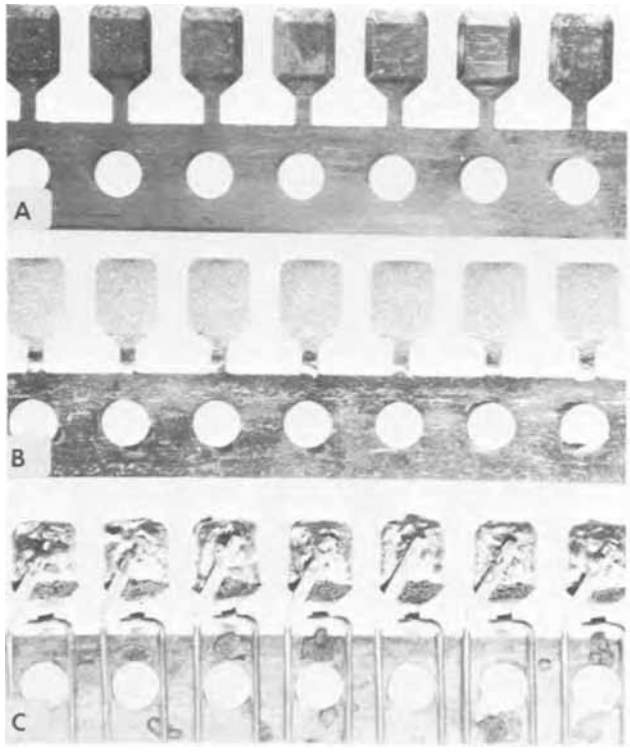

Fig. 2. POF tantalum tape. A, stamped; B, sintered after masking; C, finished capacitors with leads before separation and encapsulation.

The tape can have any number of configurations, one of which is shown in Fig. 2A. In the stamping operation (Fig. 1), a configuration with rectangular projections to one side and a continuous carrier strip with circular indexing holes are produced. The rectangular appendages are connected to the carrier by means of an integral narrow neck which serves as the contact to the substrate metal after the completion of the device. The appendage is made with a slight depression to provide a receptacle for the tantalum powder to be deposited in a subsequent operation. The use of tape with individual substrates projecting to one side greatly facilitates the design of process equipment and facilitates the cutting of the finished device from the tape at the end of the process. The indexing holes are provided to allow tape transport through the process by means of a sprocket drive

A cleaning operation is used to remove any surface contamination from the tantalum substrate and to remove impurities introduced during the stamping operation. After washing with deionized water followed by drying, the tape is fed to the next operation.

Powder dispensing.—In the powder dispensing operation, a measured amount of wet Ta powder is deposited in the appendages projecting from the tape. This dispensing technique is based on the discovery that Ta powder in a liquid carrier can be dispensed dropwise in measured amounts. The amount of powder dispensed per drop is determined by the geometry of the tip and the surface tension which holds a drop at the tip from which the slurry is being released. The principle underlying this dispensing technique has been described previously (2).

A dispensing apparatus on the basis of this principle which is suitable for controlled continuous operation (6) is shown schematically in Fig. 3. It consists of a reservoir (a) which is filled with firmly packed wet powder and water and is closed at the top with an airtight cover plate (b). The reservoir extends into a dispenser tube (c) which terminates in a tip (d) of special design. A closely metered stream of water enters the dispenser tube at (e). The flow is deter-

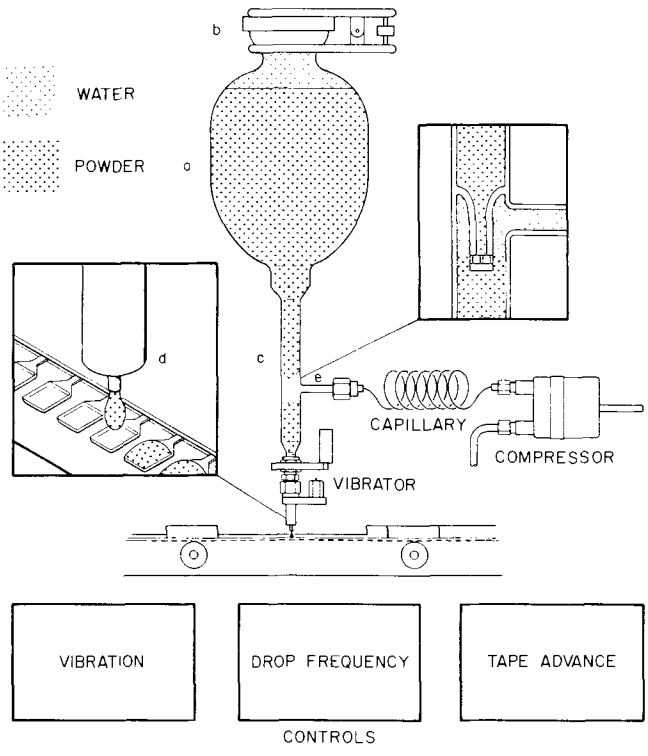

Fig. 3. Powder dispensing apparatus

mined by a water compressor in conjunction with a stainless steel capillary. Vibration is applied at the tip of the dispenser tube in order to provide for the smooth flow of powder in this part of the apparatus.

The size of the powder droplets is determined by the geometry of the tip. The ratio of diameter to length determines the ratio of water to powder. The droplets must contain a sufficient amount of water to spread out on the substrate. The amount of powder that can be dispensed dropwise is of the order of a fraction of a gram. Several drops have to be dispensed on the same substrate area if larger amounts of Ta powder are required.

The dropping frequency is determined by the rate of flow of water into the dispenser tube. Controls have been provided to insure continuous operation within narrow tolerances of dropping frequency and drop weight. The falling drop, sensed by a photocell, actuates the tape drive to advance the tape to the next position.

Both the short- and long-term stability of the dispensing apparatus have been found to be satisfactory. Drop weights fall well within the $\pm 10\%$ bracket of the average drop weight. This is within the specifications for STC's which normally require the capacitance to be within $\pm 20\%$ of the nominal capacitance.

Sintering.—Tantalum anodes for use in solid tantalum capacitors are commonly sintered in vacuum at temperatures between 1900° and 2200°C. However, vacuum sintering on a continuous basis with the material to be sintered moving in and out of the furnace continuously presents problems which can be overcome only at high cost.

We found sintering in inert atmosphere to be equally effective and selected this method because it could be adapted more readily to the sintering of tantalum tape.

The sintering equipment is shown in schematic form in Fig. 4. It consists of a furnace in two sections: A short horizontal presinter furnace is used to fuse the powder to itself and to the substrate, thereby removing the restraint from the tape orientation that required the tape to remain in horizontal position in order to avoid disturbing the loose and dry powder. After presintering, the tape can be wound through a

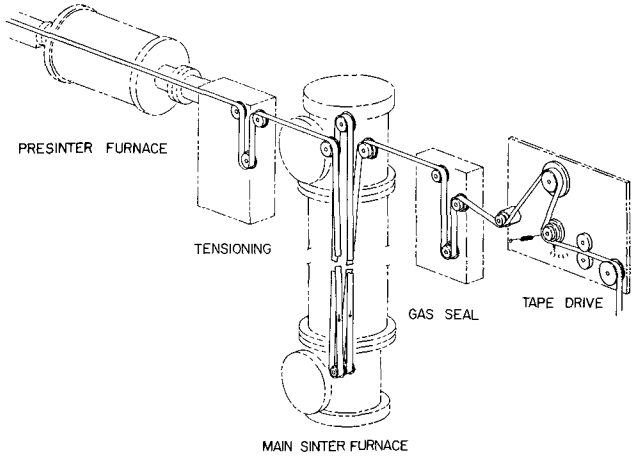

Fig. 4. Furnace for sintering POF tantalum tape

vertical sinter furnace of special design. The tape passes through the main furnace in two full loops for better utilization of the heat zone.

The furnace system is continuously being flushed with inert gas. The tape enters the furnace through a long tube in order to minimize the back-diffusion of the ambient atmosphere. A mercury-filled gas seal is used at the exit to block the flow of gas and force it out through the entrance tube.

The movement of the tape through the sinter furnace is paced by the dispensing apparatus.

Masking.—In the operations following sintering, it is important to limit the build-up of materials to areas where no ill effects will be found to occur in later process operations. In particular, the deposition of manganese dioxide and other cathode materials must be limited to those areas that have been covered with anodic oxide and that will not be subject to physical strain during lead attachment and encapsulation. For this reason, a narrow band of silicone adhesive is applied across the neck of each appendage (Fig. 2B), effectively suppressing creepage of solution over this part and limiting the build-up of cathode materials to the appendage proper. The neck area remains sufficiently clean for the positive lead to be welded to the riser at a later stage in the process.

The major operations after sintering and masking are: anodic oxidation, application of manganese dioxide, application of additional cathode materials, lead attaching, and encapsulation.

The discussion of the process steps is limited to those aspects that cannot be considered trivial adaptations from batch processes to an endless tantalum tape with anodes projecting at right angles from a continuous carrier tape.

Anodic oxidation.—In this operation, an insulating oxide film which is to serve as the dielectric of the finished capacitor is generated on the substrate metal by anodic oxidation. The tape is immersed in a suitable electrolyte, *e.g.* dilute phosphoric acid, and a potential is applied between the tape (positive) and a counterelectrode (negative). Anodic oxidation is carried out preferably at elevated temperature and with controlled current density. The voltage to be reached during anodization depends on the operating voltage of the finished capacitor and does not normally exceed 300V in the case of tantalum.

Anodizations are conventionally done in tank systems. Ta anodes are formed in batches, a mode which poses few problems with regard to controlling the critical parameters. The rate of voltage increase, in particular, can be programmed readily. Continuous tape anodization is widely practiced with aluminum foil and suggests itself for use with tantalum strip as well. However, problems arise with tantalum which require special solutions. In continuous tank forma-

tions, the current to the whole strip undergoing anodization has to be supplied at the entrance to the tank. The current required depends, among other factors, on the desired rate of formation, the loading of the tape (amount of powder per inch), and the tape speed (production rate). In the case of POF tantalum tape, the cross section of the carrier strip is far too small to supply the required current without overheating and intolerably high voltage drop along the tape under formation. The cross section of the tape cannot be increased at will because of the cost of tantalum. In addition, the anodization of porous anodes requires controlled current density which cannot be achieved readily in a tank formation system.

The shortcomings of the conventional tank anodization techniques have been overcome in the cascade formation which is illustrated in Fig. 5. The tape is suspended with its plane vertical between pairs of idlers and sprockets which guide the tape and serve as contacts for grounding the tape at the same time. Between contact wheels, the tape passes through electrolyte cascades which emerge from two rows of metallic nozzles alongside the tape path. The cascades have been subdivided into sections with electrolyte discontinuity between adjacent sections. Electrolyte is fed to each nozzle from a reservoir by means of insulating spaghetti tubing. The nozzles of each section have been interconnected electrically and serve as counterelectrode within a given section. Sections between the entrance and exit points of the tape are connected to power sources so that each one is more negative in potential than the preceding one by a fixed amount. The positive terminal of the power supply as well as the contact wheels are grounded. The tape is thus exposed during its travel through the formation system to a series of electrolyte cascades which are consecutively polarized at stepwise decreasing potentials by means of the counterelectrode nozzles. The magnitude of the potential step between adjacent sections as well as their length are determined such that optimal formation of a given type of anode is obtained. In the limit of small potential steps, formation will approach constant current formation. Large steps correspond to constant voltage formation.

The electrolyte is heated and thermostatically controlled in a tank and circulated through the formation system by means of pumps. Electrical isolation between electrolyte flowing to different nozzle sections is a requirement that is best met by long electrolyte paths. Grounded auxiliary electrodes have been placed in the electrolyte reservoirs to suppress cross currents which might otherwise flow between sections by way of the tank and the connecting tubing and cause corrosion in anodically polarized sections.

The continuous carrier strip is not being anodized to permit electrical contact to be made to the tape during anodization. Contact rollers are spaced such as to keep the current flow per contact within acceptable limits. The electrolyte is prevented from creeping up the neck by the silicone adhesive barrier applied earlier.

The rate of formation can be controlled by proper selection of the magnitude of the voltage steps, of the electrolyte conductivity, the cascade configuration, and the speed of the moving tape.

The anodization process can be programmed externally by selecting the number of sections at the same voltage and the magnitude of the voltage step according to the requirements of the rating being processed. The programmability facilitates the change-over between different ratings and minimizes the loss of tape between changes.

High formation rates become possible because of improved heat transfer between the electrolyte and the anodes in a flow system.

The same kind of equipment can be used for formation to voltage, stabilization at voltage, and reformation after the deposition of manganese dioxide.

Deposition of manganese dioxide.—After the generation of an insulating oxide film on the tantalum substrate which serves as the dielectric of the finished capacitor, a counterelectrode of manganese dioxide is deposited on the inner and outer surfaces of the porous tantalum slug. Conventionally, this is done by impregnating the porous slug with a concentrated solution of manganese nitrate in water and converting the manganese nitrate by heating it in air at temperatures between 200°-400°C. The operation is repeated several times in order to provide a dense, highly conducting layer of manganese dioxide.

The whole operation consists of a sequence of dipping and heating steps which pose no particular problems when applied to a continuous tape, and includes one or more reanodizations between MnO_2 applications. Obviously, the depth of immersion of the tantalum slugs must be controlled carefully in order to limit the build-up of manganese dioxide to those parts that have been coated with anodic oxide. The earlier masking step is an essential precondition for control of the build-up in the neck area.

A device which was found to permit dipping with the tape in the horizontal position is illustrated in Fig. 6. A metallic or plastic rod was provided with a hori-

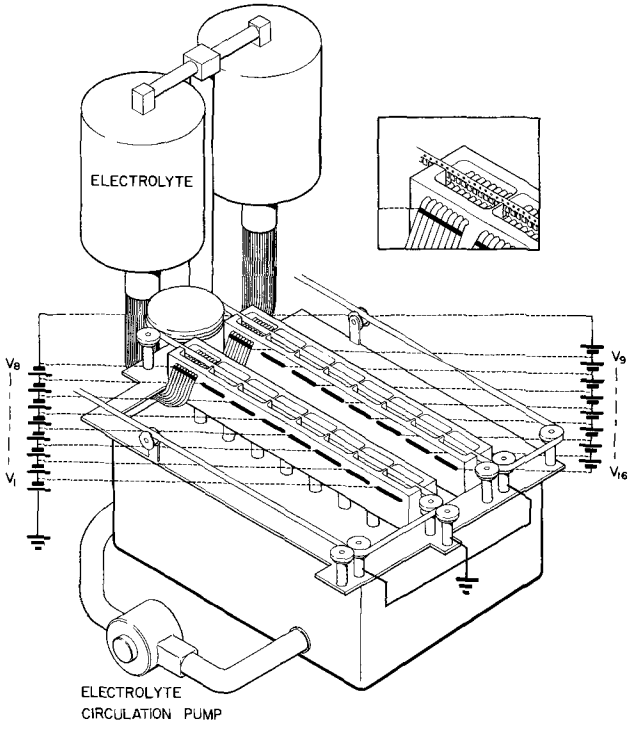

Fig. 5. Cascade anodization system

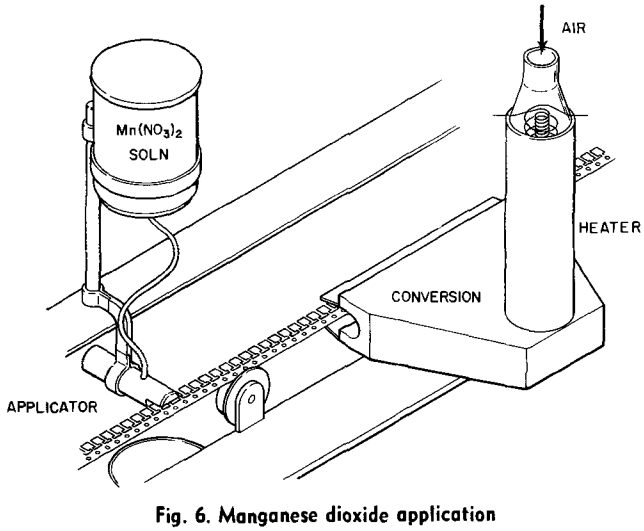

Fig. 6. Manganese dioxide application

zontal slot and a passage to permit feeding manganese nitrate solution to this slot. The solution is held in the slot by surface tension. A reservoir is thus provided from which the tantalum slugs can pick up the solution. The solution is pumped into the slot from a reservoir to which excess solution is returned.

Following dipping, the tape passes through hot gas which converts the manganese nitrate to oxide. The gas is heated by means of a cartridge heater with proportional control.

The preceding operations are repeated until an optimal coating with manganese oxide has been obtained. Reanodizations are carried out in an anodization system as described in the previous section.

Additional cathode contact layers.—Following manganese dioxide application, additional coatings of colloidal graphite and silver paint are applied in order to provide ohmic contact to the manganese dioxide semiconductor and to provide solderability. Both materials are applied by dipping, followed by drying and heat curing. The dipping is most conveniently done using the same applicators as used for manganese nitrate. Their use is particularly advantageous in the case of fast-drying materials, such as silver paint, because of the minimal surface area exposed to the atmosphere and the continuous replenishment of the small volume of solution which exists in the slot of the applicator. It has been found desirable to coat the silver layer with a layer of solder prior to lead attachment. Dipping of the whole strip in a pool of solder such as is generated in wave solder equipment is suitable for this operation.

Lead attachment.—The application of solder prior to lead attaching makes it feasible to attach the anode by welding and the cathode lead by reflow soldering. The anode lead is attached to the neck portion of the appendage using capacitor discharge or resistance welding. The negative lead is attached to the cathode contact by heating a section of the negative lead extending across the capacitor part and fusing it with the solder coating (Fig. 2C).

Separation from continuous tape and encapsulation.—Following lead attachment, the capacitor is severed from the tape by cutting the neck between the positive lead and the continuous tape. The capacitors are then transferred to fixtures for encapsulation which may be by means of transfer molding, dip coating, or hermetic sealing in metal cans, or other means depending on the use of the device.

Conclusions

In the POF process, a combination of novel techniques makes it possible to overcome the limitations inherent in the conventional process. The usual pressing of powder with binder has been replaced by the deposition of a powder slurry in water on a substrate of the same material which is sintered continuously in inert atmosphere. The special configuration of the substrate eliminates the requirement of attaching individual anodes to processing fixtures after sintering. The anodes thus made are of high purity and uniformity.

Truly continuous processing of tantalum capacitors with continuous flow of material through the line without any direct handling of individual capacitors has been achieved. The POF process can be mechanized and lends itself to automation and computer control.

Contamination and physical damage which could affect the final product quality through the presence of imperfections in the anodic oxide film have been minimized. Every device encounters processing conditions as nearly the same as possible. Operator influence on product quality and uncontrolled holdups during processing have been eliminated. As a result, uniformity of device parameters, near optimal electrical characteristics, and high yields can be expected.

Potentiostatic Anodic Pickling of Stainless Steels

G. Bombara,* A. Tamba, and N. Azzerri

Centro Sperimentale Metallurgico S.p.A., 00129 Rome, Italy

ABSTRACT

Surface Cr-depletion beneath the oxide scale in heat-treated stainless steels plays a determining role in both functions of acid pickling which are: (*i*) scale detachment or descaling proper and (*ii*) restoration at the metal surface of the base Cr content, *i.e.* of the highest passivity properties. As the anodic behavior of the impoverished alloy is quite different from that of the base alloy, definite advantages may be obtained by potentiostatically polarizing the steel during pickling in a potential range where the anodic dissolution of the Cr-depleted alloy is kinetically favored over that of the base alloy. Experimental evidence is given for AISI Type 304 steel in both HNO_3-HF and simple H_2SO_4 baths, showing the attractiveness of potentiostatic pickling in allowing the replacement of the usual nitric-hydrofluoric acid pickles with less toxic and cheaper sulfuric baths.

Rolling of stainless steels requires the quick and complete removal of oxide scales formed in hot rolling, for which temperatures below 900°C are unadvisable as well as during solubilizing heat-treatments carried out at 1050°-1100°C. Oxide scales of high-alloy steels are much more impervious and adherent than those of nonalloyed or low-alloy steels. Scales formed on Cr and Cr-Ni steels have a complex structure owing to the oxidation mechanism of these oxidation-resistant alloys. In fact, because of the higher oxidizability of chromium, the main step consists in the formation of

* Electrochemical Society Active Member.

Key words: acid pickling, Cr-depletion, descaling, fluoronitric pickle, passivity evaluation, potentiostatic treatments, sulfuric pickle, stainless steels.

a highly protective Cr-rich oxide layer which inhibits outward diffusion of iron. However, on growing, the oxide layer undergoes mechanical ruptures allowing the rapid oxidation of the underlying alloy which is less oxidation resistant because of the Cr impoverishment. The succession of low-rate (parabolic) oxidation stages under a continuous Cr-rich oxide layer and high-rate (linear) oxidation stages under a ruptured oxide layer results in the formation of stratified scales with alternate layers of Cr-rich and Fe-rich oxides (1, 2). The final situation of an oxidized surface (Fig. 1) will show the prevalence of a Cr-depleted alloy under an adherent and compact layer of Cr-rich oxides together with the presence, to a much lower extent, of surface areas of less Cr-impoverished alloy under a much more porous and strongly adherent layer of Fe-rich oxides. The resulting subsurface alloy is Cr depleted up to a depth of a few microns (3). Such a depletion is of the utmost importance in the acid pickling of rolled sheets and strips. A previous electrochemical investigation (3) showed indeed that the main descaling mechanism does not consist in disintegrating the scale by direct dissolution, but rather in detaching and exfoliating the scale *via* dissolution of the Cr-depleted surface alloy supporting the most adherent scale. Such an alloy has an electrochemical behavior much different from that of the base alloy. This led to the idea, preliminarily experimented and patented (4, 5), of increasing the rate and efficiency of stainless steel acid pickling through the electrochemical control of the anodic dissolution of the subscale layer in such a way as to accelerate the rate of attack on the Cr-depleted alloy over that of the undepleted material. So far as final cold-rolled products are concerned, the restoration at the steel surface of the base Cr content (giving the maximum "passivability," *i.e.* resistance, to the general and localized corrosion) depends on the complete removal of the depleted alloy. Indeed, the reduction in chromium, which is less noble thermodynamically than iron and nickel but highly contributing to the "kinetic nobility" (*i.e.*, passivity), produces, accordingly, a substantial enlargement of the activity range in the anodic polarization curve of the alloy together with a definite shift of the anodic peak potential in the noble direction and a marked increase of passive current densities. Besides, dechromization makes the active-passive transition less sharp, enlarging the region of incomplete passivity. All these effects are shown schematically in Fig. 2.

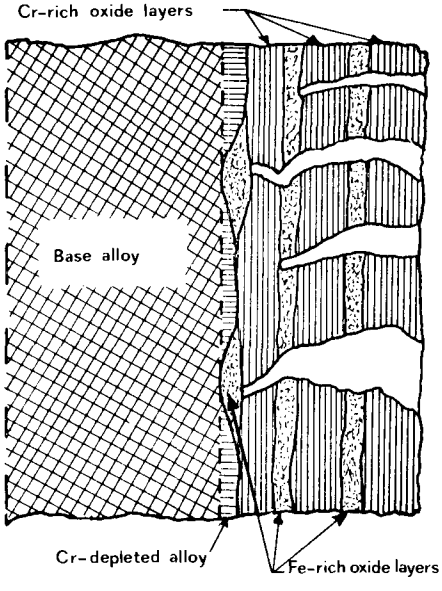

Fig. 1. Schematic picture of an oxide-scaled, high-Cr steel

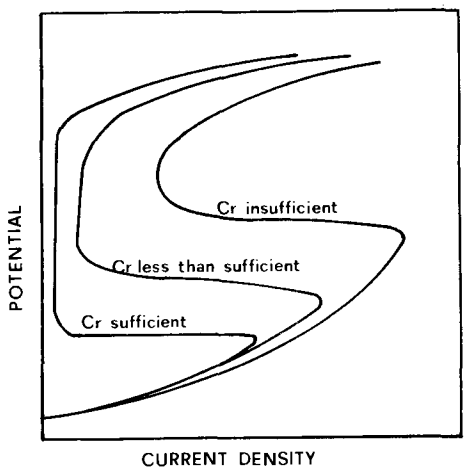

Fig. 2. Influence of Cr content on anodic polarization curve of Cr steels.

From such considerations it can be easily shown that the anodic polarization curve of an oxidized stainless steel, *i.e.* of a broadly dechromized steel surface, will give both the primary peak of the base alloy and a dissolution peak of the Cr-depleted alloy at more positive potentials (Fig. 3). A marked broadening of the active dissolution range will result, as well as an increase in passive current density. The mechanism of ordinary acid pickling of stainless steels may now be explained. If the pickle contained nitric acid only, owing to the oxidizing power of this acid, the working potential of the steel would shift quickly to the passivity range where the dissolution rate would be negligible on nondechromized areas and minimal on Cr-depleted areas. When hydrofluoric acid is present with the nitric acid, the strong activating power of F^- ions confers on the medium a definite depassivating character which affects the polarization behavior in the same way as lowering the Cr content in the alloy to insufficient levels. As indicated in Fig. 4, active dissolution rates increase remarkably, and the working potential of the steel keeps close to the zero current value.

The principle of potentiostatic anodic pickling lies in maintaining the steel potential polarized by a potentiostat within the range (shown in Fig. 4) where the anodic dissolution rate of the Cr-depleted alloy is at its maximum.

Experimental and Results

Specimens.—All tests were carried out on strip specimens, 8 x 3 cm, of AISI Type 304 steel from commercial sheet, 1 mm thick, with a standard finish No. 2B. A necessary prerequisite was the production of a

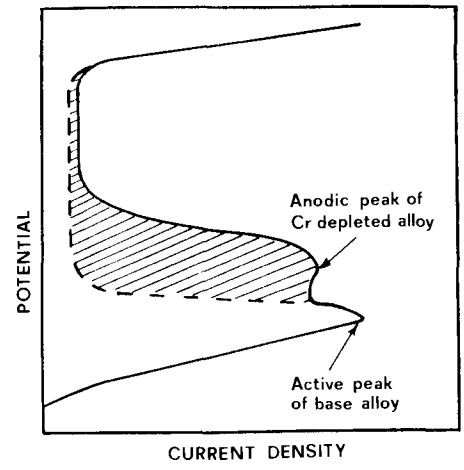

Fig. 3. Typical potentiodynamic anodic polarization curve for an oxidized Cr steel in acid solution.

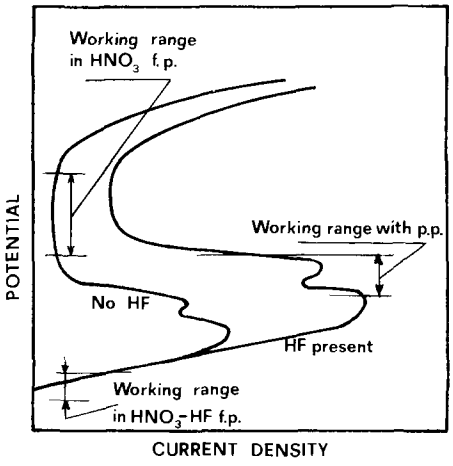

Fig. 4. Influence of HF on anodic polarization curve in HNO_3; working position for potentiostatic pickling.

uniform oxide scale sufficiently reproducible from one specimen to another. Satisfactory results were obtained by accurately controlling in each experiment both the surface preparation and the final oxidation treatment. The following succession of operations to be carried out on one specimen at a time was adopted: (*i*) prolonged pickling in (HNO_3 (d 1.4) vol. 20% + HF (d 1.15) vol. 2%) at 60°C for 20 min, aiming at leveling the metal surface microgeometrically and chemically; (*ii*) accurate rinsing in running water and dipping in a passivating HNO_3 (d 1.4) vol. 46% solution at room temperature for 30 min; (*iii*) drying in a current of air at 80°C (*iv*) oxidizing at 1050°C for 20 min in air flowing at 60 liters/ hr in a vertical tubular furnace (6 cm diameter); (*v*) final rapid cooling in air at room temperature.

For the oxidizing treatment each specimen was placed in a definite position within the furnace by means of a special supporting device, to prevent the specimen from any contact or impact with the furnace wall (especially during the final air quenching) which could possibly lead to scale scratching or detaching. Specimens so treated presented uniform, adherent oxide layers and gave reproducible results with regard to the electrochemical behavior. Scales, however, were much thicker and more uniform than those produced in practice, where heat treatment is much shorter.

Evaluation of pickling.—It was necessary to set up suitable technique for assessing the efficiency of any pickling treatment tested from the standpoint of descaling proper and passivability restoration.

Descaling was evaluated by measuring with a special photodiode device the average reflectivity of the pickled surface, assuming a conventional linear scale ranging from 0 to 100. The figure 100 was assigned to a blank consisting of a deeply pickled surface (20 min in nitric-hydrofluoric acid mixture at 60°C), whereas the figure "zero" was given to a surface oxide scaled by treating in the furnace as described above. Such values were determined as the average of measures on 20 specimens for each extreme condition.

The second criterion of evaluation, aimed at assessing the stainless quality of pickled surface, was strictly electrochemical and was based on the determination, in a deaerated 20% H_2SO_4 solution at 30°C, of the tensiodynamic anodic polarization curve of the pickled specimens. The area of the passivation peak, being inversely proportional to the passivability, gave a measure of residual Cr depletion at the surface, *i.e.*, of the extent at which pickling succeeded in restoring the proper base composition at the surface.

In order to minimize the effect of minor variations in scale properties from one specimen to another, the comparison between the efficiency of each experimental potentiostatic pickling (p.p.) and that of a free pickling (f.p.) was made on each specimen. Namely, while a half specimen was pickled freely, the other half was pickled under potentiostatic control, at the same bath temperature and for an equal time, and a direct reflectometric and electrochemical comparison was made of the two halves.

Potentiostatic pickling in HNO_3-HF.—On the basis of preliminary tests, a mixture [HNO_3 (d 1.4) vol. 10% + HF d 1.15 vol. 1%] was adopted as the pickling solution to be operated at 30°C. Such a low temperature gave descaling kinetics slowly enough to allow an easy comparative evaluation; *i.e.*, a definite differentiation could be made between the time dependence of p.p. and f.p.

Figure 5 shows the trend of successive polarization curves obtained by scanning the same oxidized area in the pickle chosen. Potentials are referred to a Hg/Hg_2SO_4 electrode in K_2SO_4 saturated solution (SMSE). The progressive decrease in current densities and the clear tendency of the active dissolution peak to split on repeating the scanning can be seen.

Descaling.—The results obtained are presented as reflectivity-pickling time curves at different polarization potentials (Fig. 6) and as plots of the per cent advantage of p.p over f.p. *vs.* pickling time at various constant potentials (Fig. 7) and *vs.* potential at various constant pickling times (Fig. 8). Each experimental point was obtained as the average for four different

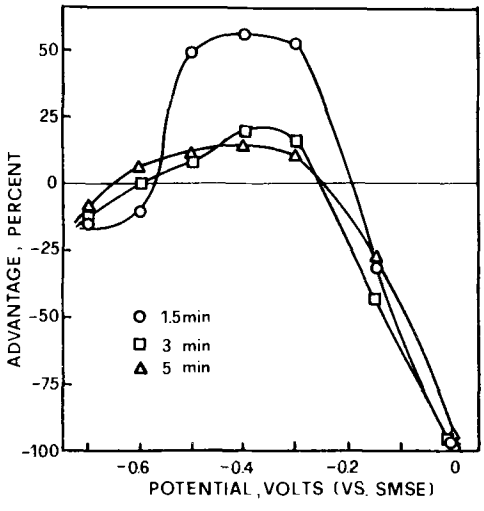

Fig. 8. Potential dependence of descaling improvement by p.p. over f.p. in HNO_3-HF.

specimens. Figure 6 shows that, by polarizing at −300 to −500 mV (SMSE), the descaling rate was faster with p.p. than with f.p. At −600 mV, only for relatively long pickling times was the descaling efficiency of f.p. surpassed, while at the other potentials tested a marked inferiority of p.p resulted.

The superiority of p.p. was particularly marked in the potential range corresponding to the active dissolution peak of the Cr-depleted alloy (Fig. 5). The equivalence between f.p. and p.p. at −600 mV may be explained by considering that free corrosion potentials of oxidized specimens ranged between −590 and −625 mV. At −150 and at 0 mV only an incomplete descaling was obtained since the steel worked in the passivity region (Fig. 5). Also, at potentials (−700 mV) more negative than the free corrosion potential, descaling was inferior to that with f.p.

The beneficial effects of p.p. are seen in Fig. 7 in terms of gain in reflectivity as a function of pickling time. The highest advantages (over 50%) were obtained for short pickling times at potentials ranging from −500 to −300 mV. For longer times, obviously, the difference reduced since f.p. is also completely efficacious. Figure 8 represents the gain in descaling rate as a function of working potential at different constant times, showing again that the optimum working range was −300 to −500 mV.

The practical profit of the potentiostatic control can be simply expressed as the shortening of the time required to reach the maximum reflectivity obtainable with f.p. Since in this way descaling could be considered accomplished in 3 min while an equal reflectivity was reached in about 1.5 min with p.p. (at −300 to −400 mV), the practical time profit in terms of descaling rate was about 100%.

Cr restoration.—The results obtained are presented as: (*i*) passivation charge-pickling time curves at different constant potentials and (*ii*) plots of the per cent advantage of p.p over f.p. Figure 9 shows the curves in (*i*) drawn from polarization curves obtained by anodic scans in 20% H_2SO_4 at 30°C as mentioned above. For short pickling times a definite differentiation appears, depending on the potential. F. p. always gave passivation charges higher than those for p.p. at proper potentials. This demonstrates the superiority of p.p. in Cr restoration at the steel surface.

The advantages obtained with p.p. over f.p. are reported in Fig. 10 in terms of lowering the electric charge for passivating. For short pickling times (0.5 min), the gain was about 65% at −300 mV, while somewhat lower figures resulted at −400 and −500 mV. For longer times the gain reduced gradually as f.p. also worked and in 3-5 min almost completely restored the base Cr content at the surface..

Figure 11 presents the plot of the per cent advantage *vs.* polarized potential at three different constant pickling times. It appears that there is a broad potential range (about 400 mV large) in which p.p. is bene-

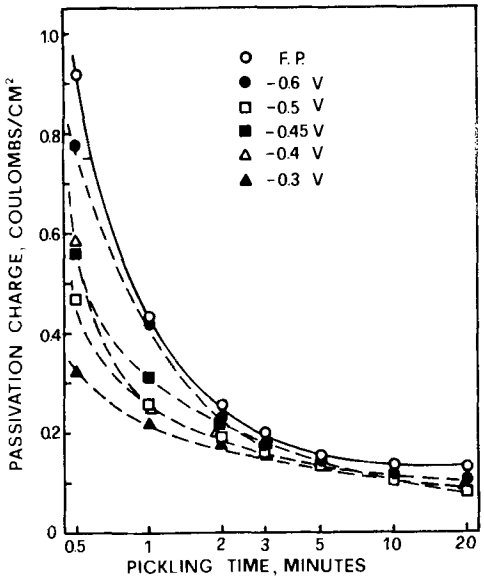

Fig. 9. Time dependence of electrical charge for passivation of specimens potentiostatically pickled and free pickled in HNO_3-HF.

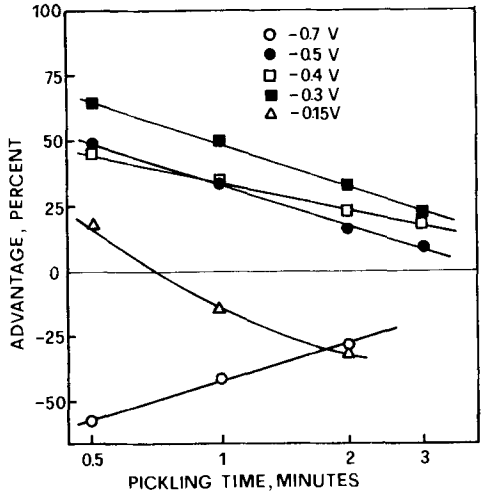

Fig. 10. Time dependence of Cr-restoration improvement by p.p. over f.p. in HNO_3-HF.

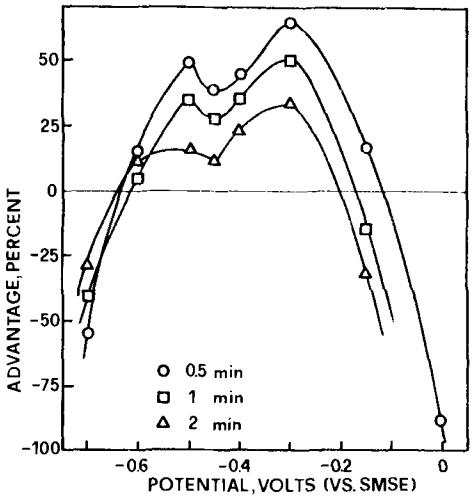

Fig. 11. Potential dependence of Cr-restoration improvement by p.p. over f.p. in HNO_3-HF.

ficial. The optimum conditions appear to coincide with those for the descaling proper. A practical profit figure can also be drawn for the Cr restoration rate. In accordance with the above criterion, assuming 3 min to be the time required with f.p. to reach the maximum passivability, this same result could be obtained in about 1 min by p.p. at −300 to −400 mV. This leads to an over-all time profit of about 200%.

Potentiostatic pickling in H_2SO_4.—An attractive possibility offered by the introduction of potentiostatic techniques in stainless steel pickling lies in substituting simple sulfuric acid solutions for ordinary nitric-hydrofluoric acid baths. This would allow substantial lowering of direct costs such as those of chemicals used in the bath, as well as indirect ones such as those connected with the abatement of nitrous vapors from the bath and the neutralization of exhausted pickles prior to discharging. Further, owing to the stability of sulfuric acid, lower evaporation losses would result, and many problems could be avoided connected with handling such a toxic chemical as hydrofluoric acid. The essential function of the potentiostatic control in sulfuric pickling would be in substituting the depassivating action of hydrofluoric acid allowing the steel to work constantly in a range of active dissolution. In this connection, in order to outline the right potential range, an anodic potentiodynamic scan was carried out in 20% H_2SO_4 on an oxidized specimen (Fig. 12). The

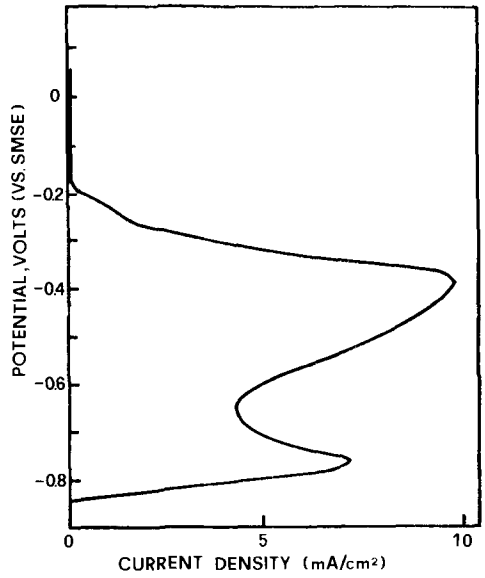

Fig. 12. Potentiodynamic anodic curve of oxidized AISI Type 304 steel in 20% H_2SO_4 at 30°C.

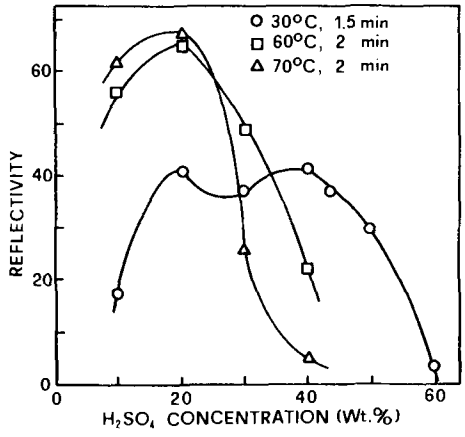

Fig. 13. H_2SO_4 concentration dependence of reflectivity for specimens potentiostatically pickled at −600 mV (SMSE).

curve obtained clearly displays the two dissolution peaks of the base alloy and the Cr-depleted alloy.

Prior to experimenting in sulfuric acid baths, exploratory potentiostatic pickling tests at −600 mV (SMSE) were carried out, aimed at determining the most suitable temperature and acid concentration. Figure 13 shows a plot of descaling efficiency (measured through reflectivity) *vs.* H_2SO_4 concentration, at three constant temperatures. It appears that the highest efficiencies were obtained with 20% H_2SO_4 at 60° and 70°C and, because of the essential equivalence of the two temperatures, the lower one was adopted for all p.p. tests.

Owing to the insufficiency of descaling by f.p. in H_2SO_4, the f.p. in HNO_3 (d 1.4) vol. 20% + HF (d 1.15) vol. 2% mixture at the same temperature of 60°C was chosen as the reference. As for p.p. experiments in nitric-hydrofluoric bath, each experimental p.p in H_2SO_4 was carried out on one-half of an oxidized specimen, while on the other half f.p. in the above HNO_3-HF reference pickle was carried out, time and temperature being equal.

Descaling.—The experimental results were plotted as a function of pickling time at various constant potentials, each point being the average for four specimens (Fig. 14). It appears that the efficiency of ordinary HNO_3-HF f.p. can be approached under certain con-

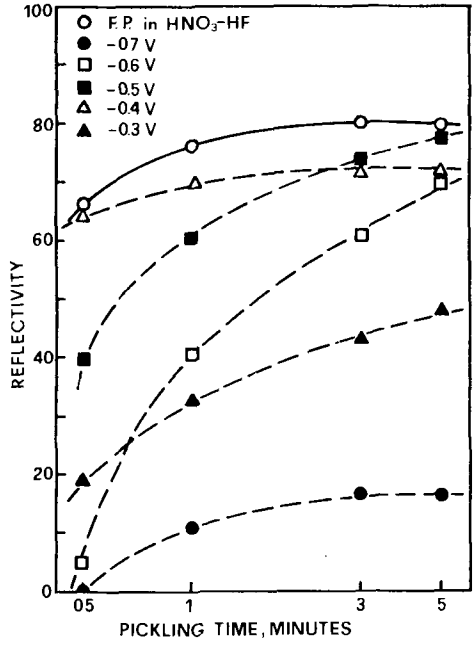

Fig. 14. Reflectivity *vs.* pickling time for surfaces potentiostatically pickled in 20% H_2SO_4 at 60°C.

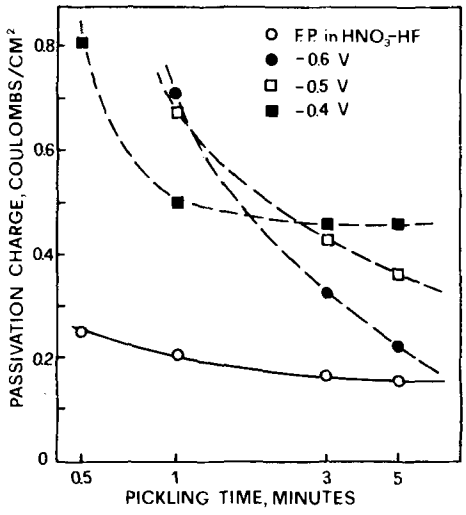

Fig. 15. Time dependence of passivation charge for specimens potentiostatically pickled in 20% H_2SO_4 at 60°C.

ditions by that of p.p. in H_2SO_4. In fact, p.p. at −400 mV (SMSE) in short times (0.5-1 min) or at −500 to 600 mV in longer times (3 and 5 min, respectively) gave descaling degrees almost equivalent to those with HNO_3-HF f.p.

Cr restoration.—The efficiency of p.p. in H_2SO_4 in removing the Cr-depleted alloy from the steel surface was evaluated by the coulometry of the residual passivation peak (in 20% H_2SO_4) in comparison with that obtained with f.p. in the reference HNO_3-HF mixture, time and temperature being equal. The results obtained are plotted in Fig. 15 showing that in this respect p.p. in the simple sulfuric solution tested was inferior to the ordinary pickling in nitric-hydrofluoric acid bath. Comparable results between the two, however, were obtained with p.p. at −600 mV prolonged for 5 min at least. This indicates that, under particular operating conditions and of course at lower speed, p.p. in H_2SO_4 could give about the same final surface quality of ordinary pickling baths.

Conclusions

With necessary reservations about the particular conditions of laboratory treatment and the special techniques for evaluating descaling and Cr restoration, the experimental results presented in this paper have definitely shown the potentiality of the potentiostatic control of nitric-hydrofluoric pickling in terms of both descaling acceleration and surface quality improvement, as well as of possible replacement of nitric and hydrofluoric acids with cheaper and less toxic sulfuric acid. In this latter respect, however, H_2SO_4 p.p. appeared to compete with ordinary HNO_3-HF pickling in descaling efficiency while being somewhat inferior as to the stainless quality of the pickled surface. However, this point seems to be easily surmountable by means of suitable additions to the bath, or by raising the operation temperature, or, perhaps, by a final "flash" dipping in HNO_3-HF pickle.

Other aspects of practical interest such as those regarding the other stainless grades, the metal losses, and the life of baths, require further systematic investigations in order to draw out useful information on the over-all economy of the potentiostatic treatment.

Technical Note

Gold Plating on Copper Substrates from Gel Electrolytes

H. Y. Cheh[1,*]

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

Thin deposits of gold are often applied on substrate surfaces of electronic parts to protect the parts from corrosion and to provide a conducting path between devices. Additionally, the concept of gold plating on selected areas is interesting, often mandatory and economically most attractive because of the high intrinsic values of the yellow metal.

In this paper, preliminary investigations on one means of selective plating, namely, gold plating from gel electrolytes, are described. In principle, a gel electrolyte can be shaped to any desirable geometry for selective plating. However, many practical questions must be answered in order to demonstrate the feasibility of plating through a gel electrolyte. For instance, no convection exists in a gel electrolyte. The transport of ions must be accomplished by diffusion and electrical migration alone. Little is known about the diffusion of ions in a gel. Consequently, a study on the rate of deposition in a gel is crucial. When the current efficiency for gold deposition is low, hydrogen bubbles generated at the substrate surface tend to adhere to the surface and shield off, to a large extent, further deposition. The contact, or wettability, between the gel electrolyte and the substrate surface is another important parameter to consider. Nonuniform contact be-

Key words: plating, gel electrolyte, gold.

tween the two phases yields a nonuniform deposition which also affects the porosity of the electrodeposit. Experiments designed to study both the current efficiency of the plating process and the porosity of the gold deposits are reported here.

Experimental

An acid citrate gold bath (1) which contained 21.3 g/liter potassium gold cyanide and 50 g/liter ammonium citrate (dibasic) and a neutral phosphate gold bath (2) which contained 20 g/liter potassium gold cyanide, 30.5 g/liter potassium phosphate (dibasic), and 10 g/liter potassium phosphate (monobasic) were chosen for these experiments. A number of gelling agents were considered, but only two proved satisfactory for this application. These were the high viscosity sodium carboxymethyl cellulose and hydroxyethyl cellulose.

A circular OFHC copper disk and gold disks with diameters of 0.78 cm were used as cathode and anode, respectively. The cell container was a glass tube (ID 0.8 cm) 4 cm long.

In order to find the optimum composition of gel electrolytes, several solutions containing various amounts of gelling agents were prepared. It was subsequently found that electrolytes containing 5 to 10 w/o (weight per cent) gelling agents were most suitable for performing the deposition experiments. When the concentration of the gelling agent was less than 5 w/o, the resulting solution did not solidify. At concentrations above 10 w/o, gelling occurred spontaneously, and uniform mixing became a difficult task. It was also found that hydroxyethyl cellulose dissolved much more readily in the gold solution than the sodium carboxymethyl cellulose.

Prior to plating, the copper cathode was cleaned and degreased using acetone and trichloroethylene, respectively. It was then bright-dipped for approximately 10 sec in a solution containing 250 ml H_2SO_4, 125 ml HNO_3, 4 ml HCl and 250 ml water, then rinsed with distilled water and dried. The gel electrolyte was injected into the plating cell by a plastic syringe. To ensure uniform current distrbution, the cathode and anode were placed at two ends of the cell facing each other. Plating was then carried out under constant current density condition. The rate of deposition was then calculated by comparing the weight increase of the cathode after the deposition process. Depending on the applied current density, the duration of plating was varied between 10 min to 3 hr for optimum weighing. The porosity of the electrodeposit was measured by an electrographic porosity tester.[2] Deposits 0.5μ thick were used in the test. A voltage of 5V and a pressure of 800 lb/in.^{2} were applied for pore printing. The results were then compared with a standard deposit which was also 0.5μ thick and was plated from the aqueous acid citrate gold bath at 60°C and a current density of 4 mA/cm^2.

Results and Discussion

The results from measurements of current efficiency are summarized in Table I-IV. The product of the applied current density and current efficiency for gold deposition ($i \cdot E$) represents the current density for gold plating. This quantity is directly proportional to the rate of deposition. The current density for gold deposition observed in these experiments varies between 0.15 mA/cm^2 to 0.50 mA/cm^2, and this corresponds to a deposition rate of 0.6 μ/hr to 2 μ/hr. This relatively fast rate of deposition in a convection-free medium can be explained by a consideration of electrical migration and diffusion of ions in a gel. It is known that the electrical conductivity of a gel electrolyte does not change appreciably from its aqueous solution with no gelling agents in it (3). In other words, the mobility of an ion is not hampered during a gel formation. The theory that a gel contains a network of capillary spaces filled with unchanged solvent and the "micro-viscosity" of the system remains unchanged is often suggested in the literature (3). The mean free path of a cation in a gel electrolyte is in the order of 1Å. This is often much smaller than the size of the structure introduced into the system during a gel formation. Consequently, the diffusion coefficient of a cation in a gel is of the same order of magnitude as that in an aqueous solution. The transport of ions due to electrical migration can be ignored because of the relatively high electrical conductivity of the system. Assuming diffusion as the only means of transporting ions and using a semi-infinite model, the concentration of the reacting species has the following form (4)

$$c = c_0 - \frac{iE}{n\mathbf{F}} \sqrt{\frac{4t}{D}}\, i\,\mathrm{erfc}\,\frac{x}{2\sqrt{Dt}} \qquad [1]$$

where c is the concentration of the cation in the system, c_0 is the initial concentration of the cation, n is the number of electrons transferred for the deposition reaction, $\mathbf{F}$ is Faraday's constant, t is the time, D is the diffusion coefficient of the cation and x is the distance from the electrode surface. The concentration of the cation at the electrode-solution is therefore

$$c_{x=0} = c_0 - \frac{iE}{n\mathbf{F}} \sqrt{\frac{4t}{\pi D}} \qquad [2]$$

The transition time τ is defined as the time when $c_{x=0}$ becomes zero. From Eq. [2]

[2] Supplied by Sel-Rex Corporation, Nutley, New Jersey.

$$\tau = \frac{\pi c_o^2 n^2 F^2 D}{4i^2 E^2} \quad [3]$$

c_o for the plating system is 7×10^{-5} moles/cm^3. iE, as shown in Tables I-IV, varies between 0.15 mA/cm^2 to 0.50 mA/cm^2. Assuming a diffusion coefficient of 5×10^{-6} cm^2/sec, τ is 8×10^3 sec for an iE of 0.15 mA/cm^2 and 720 sec for an iE of 0.50 mA/cm^2. Comparing τ with the duration of the deposition experiment, it is confirmed that the concentration of the cation at the electrode-solution interface was never depleted completely for all the experiments. This explains both the fast rate of deposition and the increase of deposition rate at higher applied current density.

The electrographic porosity test provides a qualitative rather than a quantitative measurement. The preliminary results indicate that pore formation is due largely to hydrogen bubbles which are generated during the deposition and trapped at the interface. The porosity of the bulk of the deposit is similar to that plated from an aqueous solution.

Conclusions

Preliminary investigations on gold plating from gel electrolytes are presented. The rate of deposition is found to be sufficiently rapid to render the deposition process worth considering. The feasibility of such a process will depend largely on future efforts in either eliminating or separating hydrogen gas bubbles from the electrode-solution interface thereby reducing porosity of the deposit.

Film Formation and Hydrogen Evolution on the Alkaline Zinc Electrode

R. W. Powers*

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The duplex structure of anodic films formed in concentrated KOH solutions with convection nearly absent—a hydrodynamic condition present near a battery plate in proximity to a separator—has been confirmed on high-purity polycrystalline zinc and to a more limited extent on some polycrystalline zinc alloys as well. Previously, the use of a very slow potential scan with simultaneous microscopic observation of single-crystal zinc electrodes showed that a precipitated coating of ZnO particles (type I film) overlies a more coherent film also of ZnO (type II). The experimental conditions required for following stages in the formation of the precipitated film, the one most difficult to observe, are defined more explicitly in this paper. Evidence is presented that the type II film serves as a catalyst for hydrogen evolution at potentials anodic to the zinc/zinc oxide equilibrium value. Hydrogen bubbles, whose formation is so catalyzed, can mechanically dislodge overlying passivating film to cause reactivation of the electrode. The presence of complex tin or lead anions at concentrations about 10^{-3}M (molar) in KOH solutions gives rise to very smooth, almost imperceptible, films of metallic tin or lead over the zinc electrode surface. Such films are made visible, though, during zinc dissolution as they rumple and eventually gather into a wad after being undercut. These foreign metal films inhibit the dissolution of zinc to an extent that depends on the particular complex anion, its concentration, and exposure time to the zinc surface. Lead films can be made sufficiently inhibitive that zinc dissolution is reduced to such a rate that very little precipitation of ZnO occurs.

Studies of the anodic films that form on pure zinc electrodes in concentrated alkaline electrolyte under different hydrodynamic conditions—their composition, the mechanism of their formation, their effects on the current density-electrode potential curve, and some aspects of their relationship to the problem of passivation and to the problem of dendrite formation during subsequent cathodic deposition—have been reported previously (1-3). In particular, when convection is nearly absent, a hydrodynamic situation present near a battery plate in proximity to a separator, the anodic film is shown to be duplex. A precipitated film of zinc oxide covers a more coherent skinlike film, also of zinc oxide. Recently, the notion of anodic film formation by precipitation from a layer of electrolyte supersaturated with electrode dissolution product has been questioned (4). It is perhaps a little surprising that the formation of the outer film, the one that forms by precipitation according to this author, is the more difficult one to document. Its observation does, however, require considerable attention to some experimental problems.

In this paper, the special experimental conditions required for viewing successive stages in the formation of this film are defined more explicitly. They are illustrated in part by presenting evidence for the formation of the duplex film structure on polycrystalline zinc. Such photomicrographic documentation both confirms and complements that presented previously for single-crystal zinc electrodes. Finally, this concept of the duplex film is shown to be useful in relating the phenomenon of electrode reactivation to hydrogen evolution and in explaining some effects associated with the presence of small concentrations of lead and tin anions in the KOH electrolyte.

A rather lengthy discussion of past anodic studies on the alkaline zinc electrode has been presented previously (1). Consequently, only a very brief recounting of past work on this topic and on others relevant to this study is given below.

Anodic Film Formation

In 1965, the Russian chemists, Vozdvizhenski and Kochman, reported two peaks in the current potential curve for zinc between the rest potential and that potential at which the electrode remains passive, using solutions 2M and 5M in KOH. They speculated that the different peaks might be associated with the formation of various oxides with different degrees of hydration, structure, and solubility (5). The results of Vozdvizhenski and Kochman differed markedly from those reported by other workers (6, 7). These differences were resolved by Powers and Breiter, who found that the course of passivation, as reflected in the current-potential curve, as well as the structure of the

* Electrochemical Society Active Member.

Key words: anodic films, hydrogen evolution, zinc oxide films, zinc passivation.

passivating films depend strongly on the hydrodynamic conditions in the electrolyte near the zinc electrode. Two peaks can be observed in the anodic current if convection is nearly absent and if the potential scan rate from the rest value is very small, typically 0.05 mV/sec (1).

The first peak, near −1.27V *vs.* a mercury-mercuric oxide reference electrode, is associated with the formation of a white, particulate film by precipitation from a saturated layer of electrolyte adjacent to the electrode surface. The saturated layer is produced by dissolution of the electrode. This precipitated, so-called type I film was later identified as ZnO by x-ray diffraction (2). Shortly after formation of the precipitated coating, another film, more coherent and skin-like than type I, becomes evident. It forms directly on the electrode surface beneath the precipitated film. This so-called type II film has also been identified as ZnO, using electron diffraction (2). It can be strongly light absorbing and is believed to contain an excess of zinc. In the presence of convection, ony the type II film was observed to form on the electrode surface (1). These findings about the nature of the anodic films forming under different hydrodynamic conditions are summarized in Fig. 1.

Hydrogen Evolution

Zinc is probably the most active metal whose oxidized species can be reduced back to the metallic state in good yield in an aqueous solution. Because the equilibrium potential of a zinc electrode is over 0.4V more active than that of a hydrogen electrode in the same KOH solution, the oxidation of zinc by the electrolyte is a spontaneous process. The complementary electron-accepting step to zinc oxidation, the reduction of water with the evolution of hydrogen, is usually sufficiently hindered that hydrogen evolution takes place at a rather slow rate. However, this latter reaction can be catalyzed.

Catalysts for hydrogen discharge on zinc can be divided into two general classes. The first is much better known and is comprised of a number of metals noble to zinc. Those of the second class are generated electrochemically and have been recognized only recently. They are based on anodic zinc oxide films.

Most metals will catalyze hydrogen evolution to some extent when in both electrolytic and electronic contact with a zinc specimen. Iron, nickel, and platinum are particularly effective, while on the other hand, mercury, thallium, lead, and tin are not catalytic. In fact, mercury and thallium impede this reaction; *i.e.*, they increase the overvoltage for hydrogen evolution on zinc (8, 9). Impurity catalysts can appear on the surface of a zinc specimen either by incorporation with the metallic zinc as impurities or alloy addition agents or by way of the electrolyte. The oxidized species of a metal noble to zinc can be reduced spontaneously to the metallic state on the zinc surface. Iron impurities in KOH solutions were found, very early in this study, to be particularly troublesome in this way.

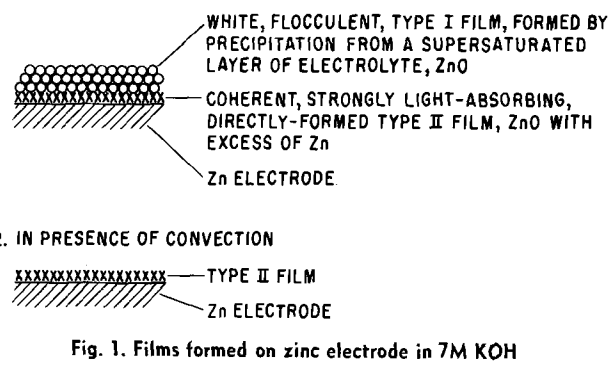

Fig. 1. Films formed on zinc electrode in 7M KOH

Although zinc oxide catalysis of hydrogenation reactions has long been known in organic chemical technology, an awareness of the catalytic activity of anodic zinc oxide films for hydrogen evolution is an achievement of only the last decade. To bring out better the nature of the phenomenon under consideration, some electrode potentials need to be cited. That for zinc in equilibrium with 0.25M zincate is −1.36V when measured against a mercury/mercuric oxide reference electrode in the same alkaline solution. That for the equilibrium between zinc and a solution saturated with respect to either zinc hydroxide or zinc oxide is −1.34V, while that for the reversible hydrogen electrode is −0.93V. Although hydrogen evolution is theoretically possible then at any potential below −0.93V, it is usually negligible in filtered 7M KOH at −1.36V. When the potential is shifted toward more positive values, the driving force for hydrogen evolution is reduced. Yet in the range from about −1.25 to −1.0V, the gas evolution rate is usually much greater than at −1.36V. The only apparent way to understand such a phenomenon is to assume the existence of a catalyst on the zinc electrode that was not present at −1.36V.

Sanghi and Fleischmann in 1959 were the first to present some evidence for the existence of this kind of catalysis (6). On applying an increasingly positive potential to a zinc electrode in a very dilute (0.01-0.1M) KOH solution, the current was anodic from the rest value until passivation ensued. However, it became cathodic over a region of more positive potentials between that for passivation and that corresponding to the hydrogen equilibrium. The current became anodic again at still more positive potentials. The cathodic current was attributed to the discharge of hydrogen catalyzed by the presence of an anodic film formed at lower potentials. Similar experimental results were observed by Kaesche working with dilute solutions of NaOH and $NaHCO_3$. Furthermore, Kaesche confirmed the existence of an electroreducible film on zinc, presumed to be zinc oxide, at potentials just slightly more positive than that for the equilibrium of zinc and zinc oxide (10). J. Oxley observed that, on subjecting zinc dendrites to a couple of hundred millivolts of anodic overpotential in 6M KOH, the dendrites turned black and a gas was evolved on them. He also observed similar phenomena on smooth zinc surfaces (11).

Tin and Lead Additions in KOH Solutions

Tin and lead salts dissolve in alkaline solutions to form the complex anions, $HSnO_2^-$ and $HPbO_2^-$, according to Garrett and his students (12). About twenty years ago, N. T. Kudryatsev reported that only millimolar concentrations of these anions in alkaline zincate baths were required to suppress zinc dendrite formation, a finding confirmed recently by Diggle and Damjanovic (13, 14). Mansfeld and Gilman report these additives give rise to microscopically smooth lead and tin films on the zinc electrode. They have observed small coral-like zinc crystallites at 200 mV of cathodic overvoltage in place of the dendrites which would otherwise have been deposited (15).

Experimental Procedure

The main technique used in this work was the observation of changes on the zinc electrode with a microscope during the passage of electric current. The experimental cell and auxiliary equipment used for simultaneous *in-situ* microscopic observations and the measurement of current density-potential curves under carefully controlled conditions have been described previously (16).

Nevertheless, the hydrodynamic conditions in the viewing cell deserve comment here. In this cell, the

specimen electrode caps the lower end of a hollow, 7.9 mm ID, Teflon polymer cylinder filled with electrolyte. The electrode is viewed through a thin window at the top of this cylinder. The specimen electrode lies in a horizontal plane facing upward with the boundary of the area exposed to electrolyte defined by the wall of the Teflon polymer cylinder. When the electrolyte is not forcibly stirred, mass transport occurs almost entirely by diffusion alone. There is little natural convection during anodic dissolution because the denser layer of solution produced by dissolution remains beneath the bulk electrolyte. Precipitation takes place from this denser layer when saturated—with little change, however, in the concentration of dissolved zincate in the bulk of the electrolyte. Thus, the hydrodynamic situation near a battery plate in proximity to a separator is simulated in the viewing cell (1, 17).

Much of the work in the present study was concerned with somewhat thicker anodic films than those studied previously (1, 2). For this reason, a Wild stereomicroscope was adapted for use with the viewing cell to complement the metallurgical microscope used exclusively in the past. The new instrument allows observation with a depth of focus and a sense of depth perception impossible with a metallurgical microscope. In addition, the ability to change magnification and size of field rapidly is most helpful in observing gas evolution. However, it has not been possible in a practical sense to photograph stereoscopically. Most of the photomicrographs shown in this paper were taken using a Leitz Ortholux microscope equipped with dark field objectives, largely because of the higher magnifications possible.

The major problems of adaption of the stereoscopic microscope were getting sufficient illumination for observing the strongly light-absorbing films that form on the alkaline zinc electrode and making provision for suitable photomicrography. A modified high-pressure mercury arc lamp, a CSI lamp, was most often used to provide the necessary high-intensity illumination. The horizontal beam from this source was projected onto the specimen in the viewing cell by means of a plane mirror and a condensing lens. In situations where less intensity was required, a quartz-iodine illuminator was used. A Leitz camera provided with a Polaroid camera back for taking 8.9 x 11.4 cm photomicrographs was suspended from a framework independent of the microscope. This type of suspension reduced vibration caused by shutter motion and eliminated the need for frequent refocusing caused by the weight of a large camera bearing down on the body tube of the microscope.

The compositions of the various electrode materials used in this study, as furnished by the suppliers, are given in Table I. Measurements and observations have been carried out on two different series of polycrystalline materials, one made up of different grades of nearly pure zinc and the other of various zinc alloys. Specimens were prepared by punching ⅞ in. diam disks from sheet stock. The surfaces of all specimens were cleaned prior to electropolishing in a 20% sulfuric acid bath. This electropolishing procedure has been described in detail elsewhere (18). While the nearly pure zinc specimens acquire a beautiful mirror finish by this procedure, the surfaces of the zinc alloys are marred by the presence of fine pits. This pitting is due to the evolution of oxygen on the alloy specimens. The last step in the polishing procedure involves subjecting a specimen to an overvoltage of nearly 8V in order to remove a gray anodic film responsible for smoothing. At this overvoltage, oxygen evolution occurs on the alloys but not on the nearly pure zinc specimens.

Because of their extraordinary mirrorlike quality which facilitates the observation of film formation, some studies were also carried out on the basal plane of single-crystal material. Such surfaces were prepared by cleavage of specimens about 3 mm thick from a larger single crystal immersed in liquid nitrogen.

Measurements were carried out with 7M potassium hydroxide solution prepared from reagent-grade chemicals and distilled water. Zinc oxide at a concentration of 0.25 mole/liter was dissolved in this solution to fix the initial zinc electrode potential and to inhibit chemical corrosion of the zinc specimens when first exposed to electrolyte. The electrolyte was filtered through Gelman Acropor microporous polymer membranes of 0.45μ pore size to remove the larger particles of iron compounds present. Experiments were carried out at 23°-25°C.

Solutions containing electrolyte additions of complex tin or lead anions were usually prepared by thorough mixing of a weighed quantity of a lead or tin salt with 100 ml of stock alkaline solution. This operation was carried out in a separate vessel equipped with a magnetic stirrer before introduction of the solution into the viewing cell. The salts used were the oxides, chlorides, and acetates. The concentration of the addition agent varied from 0.0005 to 0.01M.

The zinc electrode potentials were measured against mercury-mercuric oxide reference half cells in 7M KOH. The potential was controlled by means of a Jaissle potentiostat. The voltage required for the very low speed scanning of the zinc potential was taken from a simple potential divider network comprised essentially of a Zener diode and a multiturn potentiometer driven by a clock motor. Current-potential curves were registered on a Moseley Model 2D-2A X-Y recorder.

Experimental Results and Discussion

The results of this study are discussed under three headings: problems in observing a precipitated anodic film on zinc electrodes; hydrogen evolution and electrode reactivation; and the effects of tin and lead ions in the electrolyte on dissolution, film formation, and hydrogen evolution on zinc.

Problems in observing a precipitated film on zinc electrodes.—One of the more important findings of previous work is that the convective conditions in the electrolyte near the zinc electrode have a decisive influence on the current-potential curve and on the nature of the passivating film. Particularly relevant is the notion that passivation can be brought about by very localized precipitation of zinc oxide from a layer of electrolyte saturated with zincate without the bulk

Monocrystals, Inc. The single crystal was grown from zinc better than 99.999% pure.

of electrolyte in the cell being saturated. Documentation of the precipitation phenomenon has improved with time and additional experience now permits a better definition of the best conditions for its observation.

Two principal observations support the interpretation that the formation of a precipitated film gives rise to the first peak in the current observed near −1.27V (*vs.* the mercury-mercuric oxide electrode) when the potential is scanned very slowly from the rest value in a more positive direction, with convection in the electrolyte nearly absent. The first observation is that the formation of a white coating composed of very small particles coincides with this peak. On the other hand, if the electrolyte is strongly stirred, this peak is eliminated and such a white film is not observed. The latter fact is consistent with the interpretation of the first. With appreciable forced or natural convection, the formation adjacent to the electrode surface of a layer of electrolyte saturated with the dissolution product is prevented. The whole bulk of the electrolyte in the test cell would need to be saturated before precipitation could occur. The second major observation is that of slow motion of some of the small white particles or light-scattering centers. When observed, a large number of closely spaced particles can be seen traveling in the same direction. This observation indicates the particles are in the electrolyte and are propelled by small convection currents. It eliminates the possibility that these small light-scattering centers originate by direct electrochemical reaction at various numerous sites over the electrode surface.

However, both of these critical experimental facts require considerable attention to detail for their really satisfactory observation. Successful viewing of the individual particles, which when present in sufficient density form a white coating on the electrode surface, requires a special optical background. Since such particles need to be viewed under dark-field conditions, a smooth mirrorlike surface is required to provide this dark background. It is important that the darkness of the background arises from the smoothness of the surface and not because of strong light absorbance by the surface. For instance, when precipitate particles move across the electrode surface, they are almost lost from view when they cross over portions of the surface covered with so-called type II anodic film, a strongly light-absorbing electrochemically formed film. Most of the earlier work on this project was carried out with cleaved single-crystal specimens because they most nearly met this background requirement. Even with single crystals, though, there exists considerable variation in the ease with which individual precipitate particles can be documented by photomicrography. If the anodic dissolution of the specimen, required of course to produce a supersaturated layer of electrolyte, gives rise to dissolution facets on too fine a scale, light scattering from such facets makes detection of individual particles difficult. The relatively inferior documentation of precipitation provided in Ref. (1) compared to that in (2) can be attributed in part to this factor.

It has been found that chloride ion additions at low millimolar concentrations in KOH solutions cause the bunching of dissolution steps on the basal plane of zinc single crystals. This ion appears to act as a poison which reduces the rate of vertical etching of dissolution pits. Very shallow, flat-bottomed pits are produced with steep vertical walls. No other effect of chloride ion was detected. The photomicrograph shown in Fig. 2 was taken near −1.29V during an anodic scan very shortly after the motion of precipitate particles was first observed in the viewing field. An electrolyte, 0.002M in chloride ion, was used in this experiment. Some particles perhaps can be seen on the left side of this photograph against the dark field provided by the smooth bottom of the dissolution pits. This photomicrograph shows the importance of a good dark field

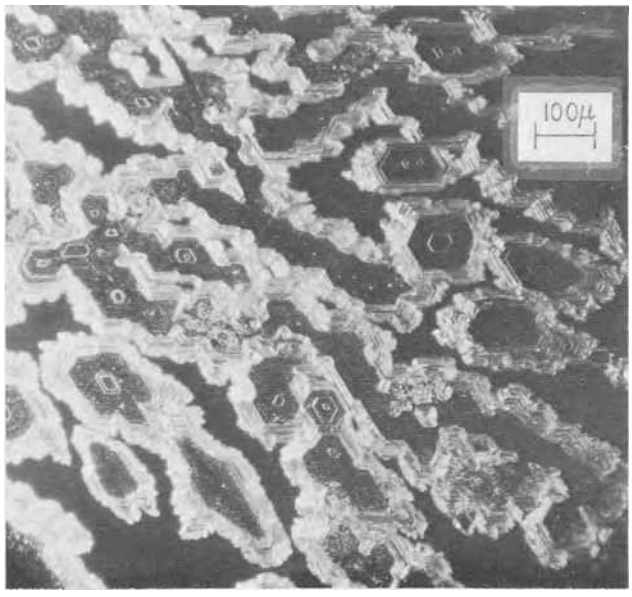

Fig. 2. Dissolution step structure on zinc single crystal associated with low concentrations of chloride ion. Dark field. 75X.

background for satisfactory viewing of the very early stages of precipitation. Since 7M potassium hydroxide prepared from reagent-grade KOH may be slightly in excess of 0.001M in chloride ion impurity, possibly the flat-bottomed dissolution pits shown in Ref. (2) owed their existence to the adventitious presence of these impurity ions (19).

Documentation of the early stages of precipitation of ZnO on polycrystalline zinc electrodes has been slightly inferior to the best obtained on single crystals. Some difficulties arise from the fact that, although electropolishing of zinc in a sulfuric acid bath produces a surface that is mirrorlike to the eye, under the microscope at about 100X, light scattering from small imperfections on such polished surfaces interferes to an extent with that from the precipitate particles. The point is illustrated below.

The ease of observation of the motion of precipitate particles varied from specimen to specimen. With some, motion could be seen in all fields of the specimen. At the other extreme, on one or two of dozens of specimens of nearly pure zinc, no motion at all was detected. It became evident that the ease of observation of particle motion was intimately related to the height of the first current peak. At the potential scan rate used in most experiments, 0.05 mV/sec, about one half of the measured heights of the first anodic peak fell in the range 42-47 mA/cm^2. However, the remainder were larger and reached 70 mA/cm^2 in a few cases. The ease of observation of the motion of precipitate particles was greatest in those cases where the peak height was large. Clearly, the small-scale natural convection, made evident by particle motion, stirs the electrolyte sufficiently to cause a larger current. Near the potential for the first current peak, −1.27V, the current is limited by the transport of zincate ions away from the electrode surface. The slight convection arises because the specimen surface is not perfectly flat. It is nearly impossible to cleave a single crystal of zinc without introducing a cleavage step. The density gradient across such a step, typically 100μ high, is evidently sufficient to produce a small convection current as particle motion is usually easiest to observe adjacent to such a surface discontinuity. Furthermore, a 2-3 mm thick single-crystal specimen is usually slightly bent during cleavage. In a few instances, the complex motion of precipitate particles was clearly associated with the small elevations and depressions in the surface associated with such bending. With polycrystalline specimens, the preferential dissolution of grain boundaries

is the largest factor giving rise to an uneven electrode surface.

In summary, the ideal conditions for observing the particles that in mass constitute so-called type I film are a mirrorlike electrode surface, a dissolution pattern that leaves large areas of electrode surface unetched or otherwise very smooth, and a small amount of convection so that motion of precipitate particles at velocities of the order of microns per second occurs over much of the electrode surface. Such velocities are smaller by a factor of 100-1000 than those usually associated with natural convection along vertical electrodes (20).

To illustrate a number of points discussed above and to introduce some new findings as well, the results of an experiment with a polycrystalline zinc specimen, 99.9999% pure, are presented in Fig. 3 and 4. These include a current-potential curve along with photomicrographs taken at different potentials. In this run, the potential was scanned in the positive direction starting at the rest value at the very slow rate of 0.05 mV/sec. The photomicrographs shown in Fig. 4 were taken with a metallurgical microscope on the same specimen field with Polaroid Type 52 film (ASA speed rating of 400) at 1 sec exposure time. Figures 4(a)-4(j) were taken with the same incident light intensity.

The initial state of the surface at the rest potential after approximately 10 min exposure to electrolyte is indicated in Fig 4(a). Even though the electropolished specimen is very smooth and appears mirrorlike to the eye, fine-scale etching is evident. This mars the dark-field background and interferes with the observation of the precipitation process to a limited degree. Figures 4(b)-4(e), which correspond to potentials along the steeply ascending portion of the current-potential curve, show that anodic dissolution occurs preferentially at the grain boundaries. These are gradually widened and deepened with time. The attack exposes macrosteps and ledges, many of which reflect so much light into the camera that individual steps are not easily discernible although they can often be seen by eye. Some, however, are so aligned that they appear black on the photomicrographs.

The first evidence of precipitation was noted shortly before the photomicrograph shown in Fig. 4(f) was taken. Figures 4(f)-4(i), taken near the first peak on the current-potential curve, show the manner in which the fine precipitate particles eventually coat the entire electrode surface. The increase in particle density on successive photomicrographs should be noted. The coating is most readily seen over the interior of the grains as illustrated over the large grain adjacent to the right border of the photographs. Actually, the grain boundaries are also coated with this precipitated type I film, although the coating there is more difficult to discern because light is so strongly absorbed at the grain boundaries.

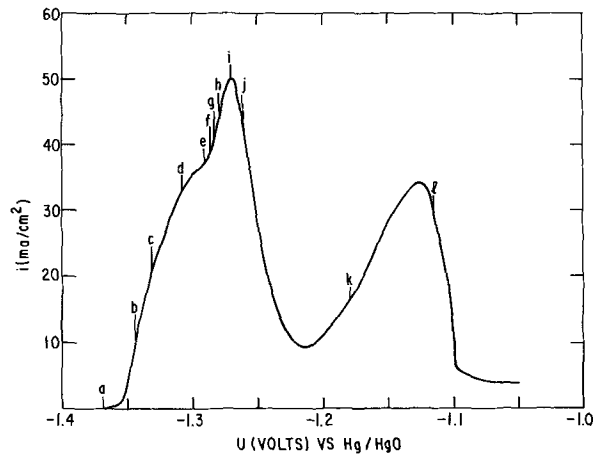

Fig. 3. Current density-potential curve for polycrystalline zinc taken during an anodic sweep at 0.05 mV/sec under nearly convectionless conditions.

In fact, the major feature of interest about the grain boundaries is their gradual darkening as shown in successive photomicrographs, Fig. 4(g)-4(j). Darkening can be noted very soon after the onset of precipitation. In experiments similar to the one under discussion, the potential scan was stopped at approximately −1.23V and the electrolyte was stirred. Stirring removes the overlying type I film on the grain boundaries and reveals the presence of another anodic film that is responsible for the grain boundary darkening. This strongly light-absorbing anodic film we have previously called type II. It is usually possible to lift up small portions of this skinlike film off the surface at irregular intervals along the grain boundaries by stirring the electrolyte. The small pieces then become particularly obvious as they flap about in the electrolyte. The sizes of pieces of type II film that have been lifted from polycrystalline specimens are very much smaller than those from single-crystal surfaces as documented previouly (1, 2). Because of the relatively good separation at 144X between areas of the specimen surface undergoing dissolution, *i.e.* the grain boundaries, and those left unattacked, *i.e.* the grain interiors, one can readily see that the formation of dark, type II film occurs only on portions of the specimen undergoing active dissolution. While this point has also been observed on single-crystal specimens, documentation is usually much more difficult because of the smaller size of active and inert areas.

Some type II film is likely present on zinc at all potentials above the zinc/zinc oxide equilibrium value. In experiments in which the electrolyte was stirred, film formation, as evidenced by multihued tinting of the specimen surface, was noted at potentials only 20 mV above this equilibrium value. These observations do pose the question whether the precipitated film is the direct or the indirect cause of the first passivation, the decline in current following the peak near −1.27V. Stated otherwise, does passivation occur by the blockage of active sites by precipitated particles or is the underlying dark type II film responsible? Conceivably, the precipitated coating could so shelter the underlying film that the formation rate of the latter exceeds its rate of dissolution. Thus, it could thicken or otherwise change its characteristics to reduce the available current. The information available does not permit a clear choice between these alternative mechanisms.

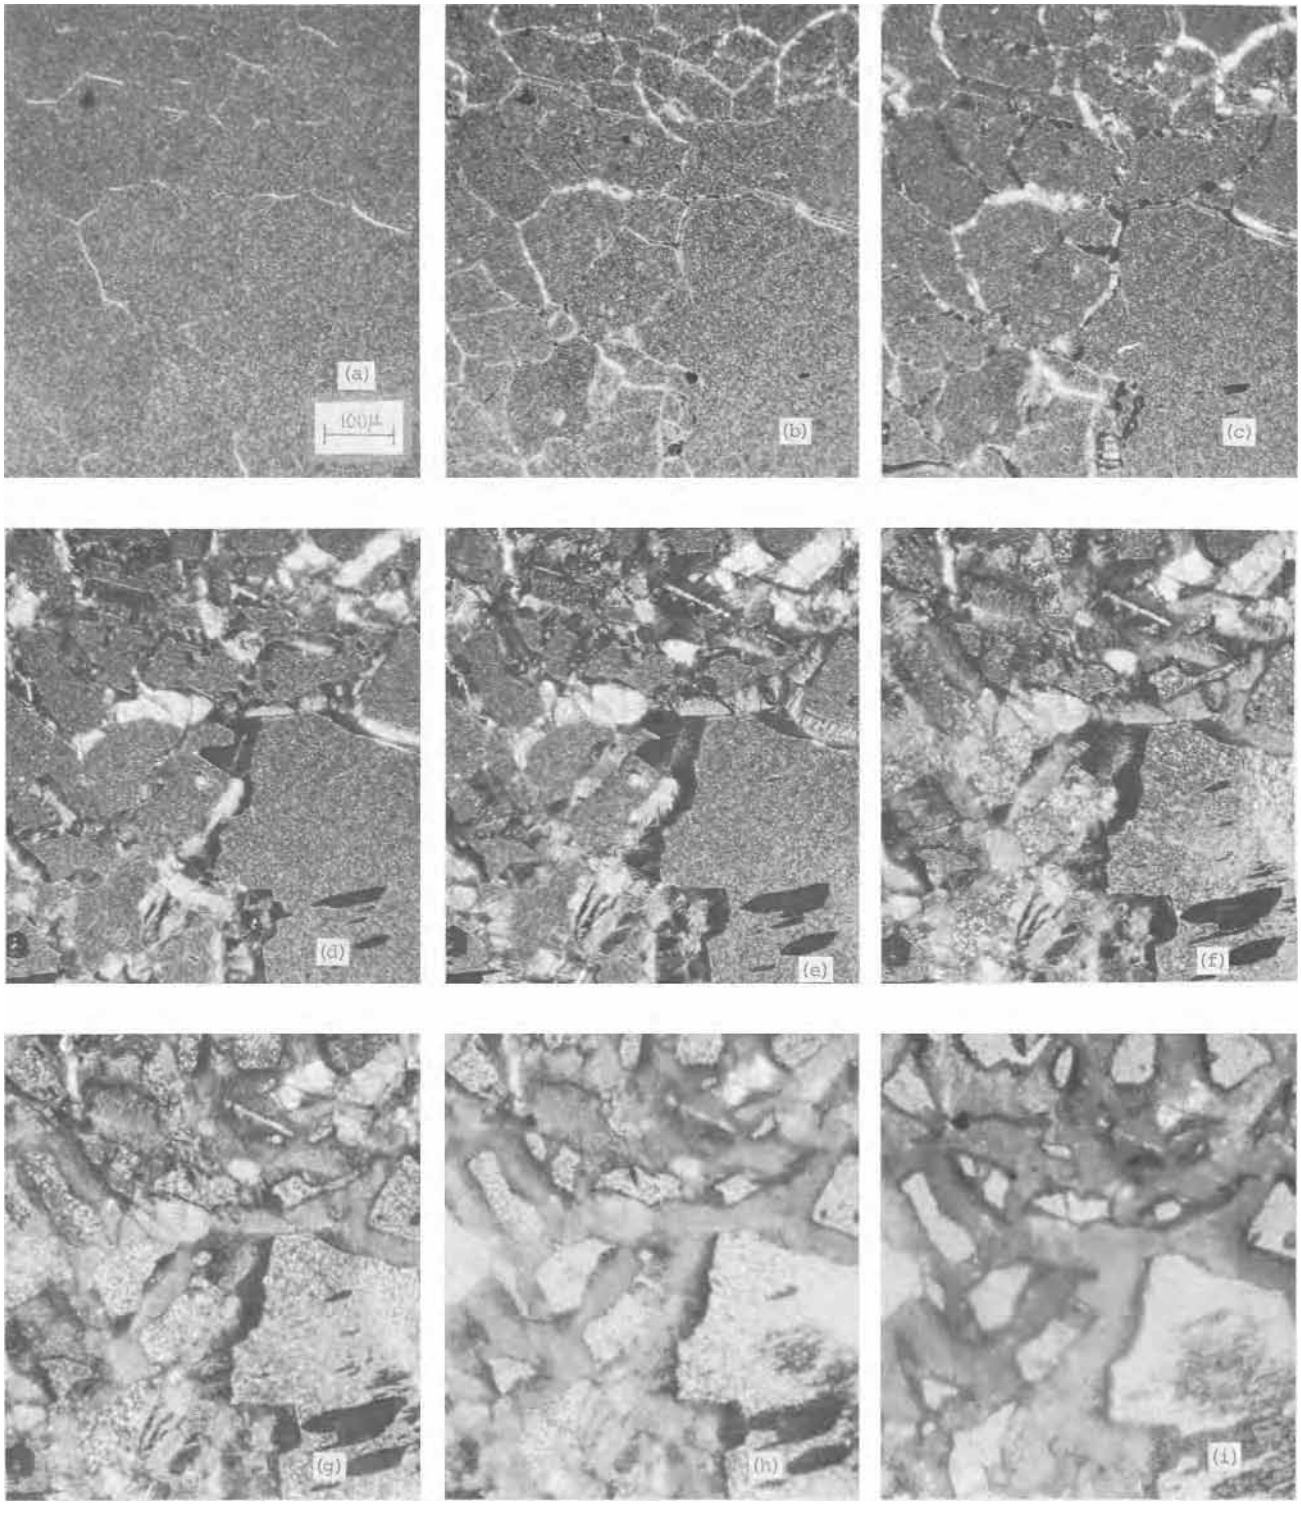
The incident light intensity needed to be increased considerably to obtain the photographs shown in Fig. 4(k) and 4(l). Two points are noteworthy and are discussed in greater detail subsequently. One is that the outermost film coarsens with time and develops considerable porosity. Many more cracks and holes are evident in Fig. 4(l) than in Fig. 4(k). The other is evidence of hydrogen evolution. Two spherical gas bubbles appear in the field in Fig. 4(l). The behavior of other grades of nearly pure polycrystalline zinc listed in the table is indistinguishable from that for 99.9999% zinc as discussed above.

Throughout this paper, the gas evolved on a zinc electrode in the potential range from approximately −1.36 to −1.00V *vs.* the Hg/HgO electrode is assumed to be hydrogen. From thermodynamic considerations, the evolution of hydrogen is possible in the range of potential under consideration. On the other hand, the potential is much too low for the gas to be oxygen. The materials deliberately added to the system comprise metallic zinc (or zinc alloys in some experiments), distilled water, reagent-grade ZnO, reagent-grade KOH, and small quantities of argon used to deoxygenate the alkaline solution. Since gas evolution has been observed to continue at an apparently unabated rate for a period of hours, it seems unlikely that the gas is derived from an impurity. Attempts to obtain a positive identification for hydrogen gas were not successful. This analysis involves working with approxi-

mately 10^{-7} moles of gas in the presence of an aqueous solution.

Hydrogen evolution and electrode reactivation.— After the surface of a zinc electrode has darkened as illustrated in Fig. (4j), the amount of additional information on film formation that can be obtained with a metallurgical microscope is usually limited. The photograph shown in Fig. 4(l) is somewhat unusual in that the film surface lies sufficiently in a horizontal plane to allow much of the field to appear in focus. However, with a stereomicroscope, more information can often be obtained both on subsequent changes in the precipitated film with time, as well as on hydrogen evolution at higher anodic potentials. Since hydrogen evolution takes place at random isolated sites over the electrode surface, it is expeditious to view it at low magnification in order to survey the entire specimen. Higher magnifications are preferred, though, for observing film formation.

Oxide film on pure zinc electrodes often appears blue to the eye. The stereomicroscope has been of great utility in examining this film property. If after the second passivation the electrolyte is circulated to dissolve the anodic film slowly, the precipitated film can be seen to have consolidated into pieces of deep-blue material. These pieces are sometimes surrounded by more reflecting type I precipitate and other times not. These consolidated masses of film substance give rise to the over-all bluish appearance of the outer film on the electrode surface. The conversion of the precipitated film into blue oxide begins near the electrode surface and proceeds away from that surface. Its for-



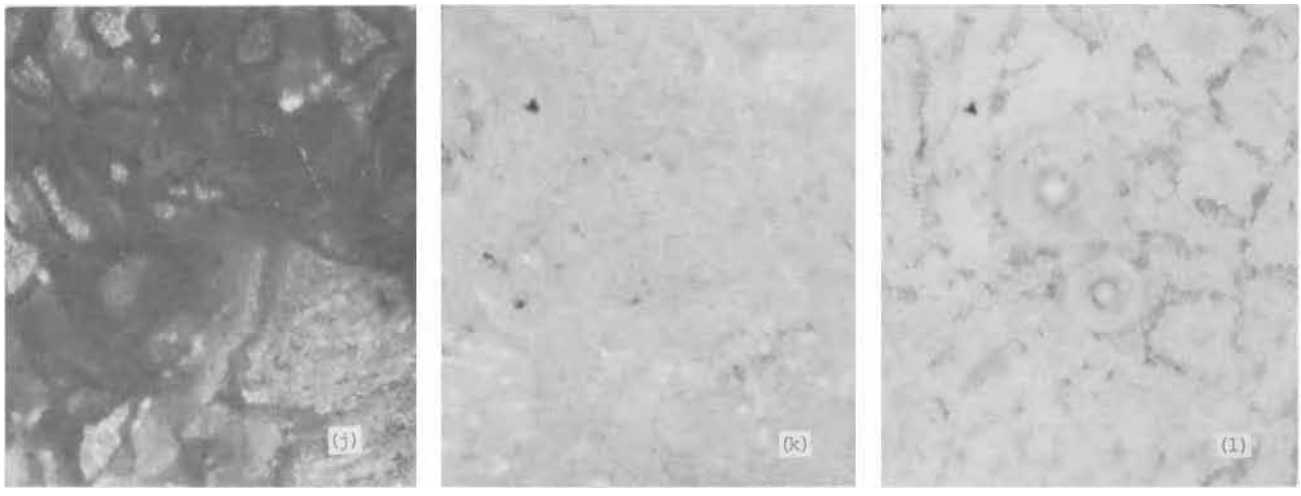


Fig. 4. Changes on a polycrystalline zinc electrode during an anodic sweep. Dark field. 90X. Letters on photomicrographs correspond to potentials indicated in Fig. 3: (a) initial surface; (b) −1.343V; (c) −1.330V; (d) −1.309V; (e) −1.292V; (f) −1.285V; (g) −1.283V; (h) −1.280V; (i) −1.273V; (j) −1.262V; (k) −1.178V, light intensity increased; (l) −1.114V, light intensity increased.

mation has often been noted in association with appreciable hydrogen evolution.

As discussed in a previous section, it is an interesting fact that after the zinc electrode is passivated near −1.24V with a coating of precipitated film it can be reactivated at still higher potentials; *i.e.*, the anodic current increases again. Surely, some change must take place in the coating to permit this to occur. One possibility is that recrystallization of the precipitate takes place to produce a more porous coating. However, on examining photomicrographs such as Fig. 4(k) and 4(l), it seems that this process takes place too late or at too high a potential to account for reactivation. The dislodging of film by the evolution of hydrogen bubbles seems the more likely cause. Hydrogen bubbles are usually first noted at a potential slightly above that for the current minimum. With but a few exceptions, this observation was noted in over a dozen runs in which an effort was made to note carefully the first appearance of gas evolution. The exceptions mainly involved runs in which the evolution rate was very low. Specimens included electrodes both of nearly pure zinc, as well as of zinc alloys. The rate of hydrogen evolution increases with potential at least up to the second current maximum. Near this potential, the accumulation of hydrogen bubbles under the window of the viewing cell often makes further microscopic observation difficult. The small bubbles so refract light that a good focus is nearly impossible. In one run in which the bubbles drifted away from the window, it was possible to observe that the rate of hydrogen evolution decreased again at still higher potentials when the electrode was passivated for the second time. Such a phenomenon is expected—the rate of hydrogen discharge must go to zero as the equilibrium potential for hydrogen at −0.93V is approached.

The underlying type II film is believed to be the catalytic site of hydrogen evolution. Bubbles must then move through the outer film before emerging from a hole in the surface. This motion is indicated in Fig. 5 where a number of only "partial" gas bubbles can be seen, owing to their incomplete emergence from holes. Many of the pores and channels evident in Fig. 4(l) were created by the motion of hydrogen bubbles. The displacement of film by bubbles has been noted frequently.

Two maxima were usually observed on the current-potential curve for the various zinc alloys studied. For example, the i-U curve for a specimen of N2263 alloy is shown in Fig. 6. From the similarity of this curve to that in Fig. 3, one would infer that duplex anodic films form on zinc alloys much as observed on nearly pure polycrystalline and single-crystal zinc electrodes. However, only indirect evidence, mostly related to the effects of hydrogen evolution, could be obtained to support this interpretation.

During the initial rapid rise in current density with potential, selective etching of grain boundaries was not observed on the alloys, but rather a more general attack took place at both grain boundaries and grain interiors. The etching of pits, without exposure of brightly reflecting crystallographic facets, could be

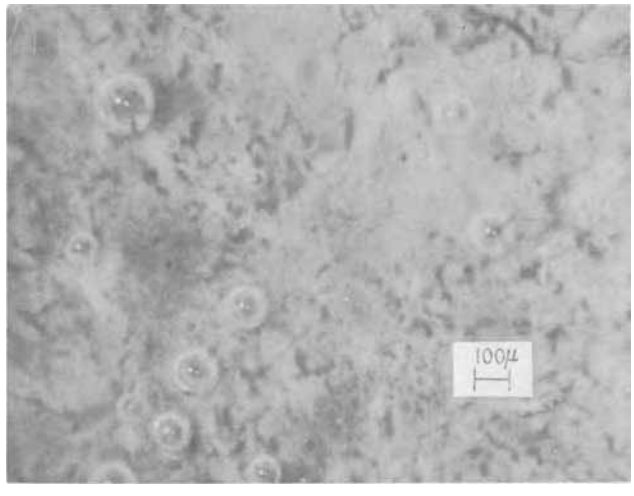

Fig. 5. Emergence of gas bubbles from overlying film. 44X

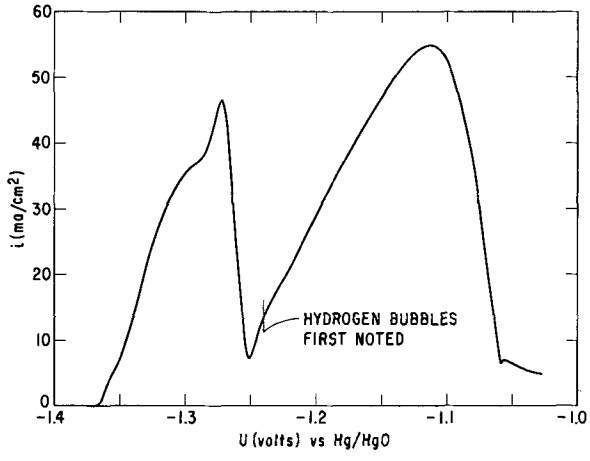

Fig. 6. Current density-potential curve for N2263 zinc alloy taken during an anodic sweep at 0.05 mV/sec under nearly convectionless conditions.

seen with the stereomicroscope but was very difficult to photograph satisfactorily. At about 80 mV above the rest potential, the initial formation of a film on the electrode was sensed. However, this film was not reflecting (white) as is the type I film formed on nearly pure zinc and, when present at some depth, channels and holes were not evident as illustrated in Fig. 4(1) for pure zinc. The outer film appeared nearly uniformly dark with little structure evident. It gradually filled the etched pits and eventually covered the electrode surface very evenly. As for specimens of nearly pure zinc, gas evolution usually was first evident near the minimum in the current potential curve. The above features were common to all the alloys studied. Nonetheless, there were differences in the behavior of individual alloys.

Films on N2262 alloy, for example, tended to blister. In one run as the second passivation was approached, observations in the stereomicroscope revealed that the film over the entire electrode surface was assuming a domed shape. When a large crack formed in the blister, the current increased and passed through a third maximum. The i-U curve taken during this run and a photomicrograph of the crack in the blister are shown in Fig. 7 and 8. This is good evidence that, as with pure zinc, hydrogen is not generated within nor at the top surface of the outer film, but rather underneath it.

The rate of hydrogen evolution on the specimens of N2262 was roughly comparable to that observed from specimens of nearly pure polycrystalline zinc. That, however, for N2263, an alloy containing about 0.3% each of cadmium and lead, appeared to be significantly less. In a run with this material, the outer film developed a small blister which did not crack, however. Following the voltage scan, the blister was punctured and a small piece of the outer film was overturned, exposing the underside to view. In contrast to the topside, the surface of the underside contained a large number of cavities as shown in Fig. 9. Such cavities were really fine channels, the mouths of which appear as dark spots on the photomicrograph. They were apparently the escape paths of small bubbles. A bubble of hydrogen still clinging to the underside of the film appears in the upper left portion of the photomicrograph. Here is additional evidence that the generation of hydrogen occurs at sites underneath the outer film.

The hydrogen evolution rate was significantly greater for the N2264 alloy, a material containing 0.6% copper, than for any other composition studied. Bubbles appeared just prior to the current minimum. The rate of evolution was sufficiently high near the second current peak that a scan of potential to the second passivation could never be completed. Hydrogen bubbles

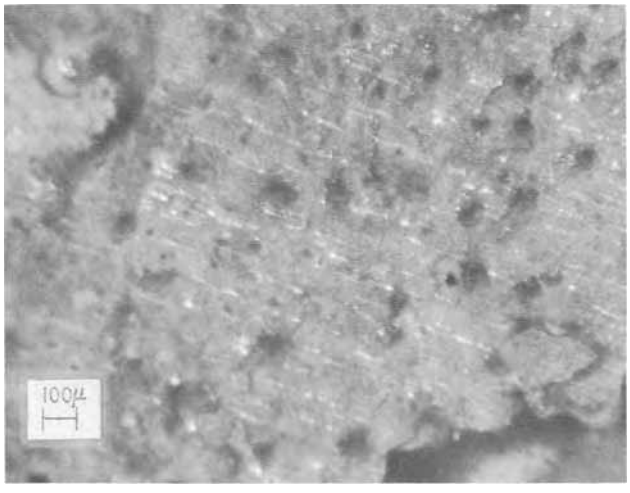

Fig. 9. Cavities in underside of anodic film on N2263 alloy. 44X

entered the sidewall capillary leading to the reference electrode compartment in the viewing cell and opened the circuit between the reference and working electrodes (16). Of course, the potentiostat could not function under this condition. Removal of the gas led very quickly to another blockage. Every run with this alloy had to be aborted near the second current peak. An indication of the gas evolution from this alloy is provided by Fig. 10, which shows the bubbles trapped below the window of the viewing cell. This photograph was obtained when the electrode potential corresponded to the second current maximum. The dark background arises from the exceedingly strong light absorption of anodic films on N2264 alloy specimens. Unlike the other alloys, this film was readily removed from the electrode surface. A bright metallic surface was found beneath it. These observations support the notion that copper in the zinc alloy enters the lattice of the type II film and thereby enhances catalysis of hydrogen evolution. It likely affects other electronic properties of this film as well. Kaesche has presented evidence that the presence of copper in anodic films on passivated zinc makes this electrode an efficient cathode for oxygen reduction in hot water (10).

When the polarization source was removed after an anodic scan on either a pure zinc specimen or on one of the alloys studied, the electrode potential dropped to that for the Zn/ZnO couple. The gas evolution rate decreased markedly from that observed near the second current peak although some hydrogen evolution continued to be noted. Much of this was likely due to gas previously trapped in the anodic coating. If this film was scratched with a pointed glass rod,

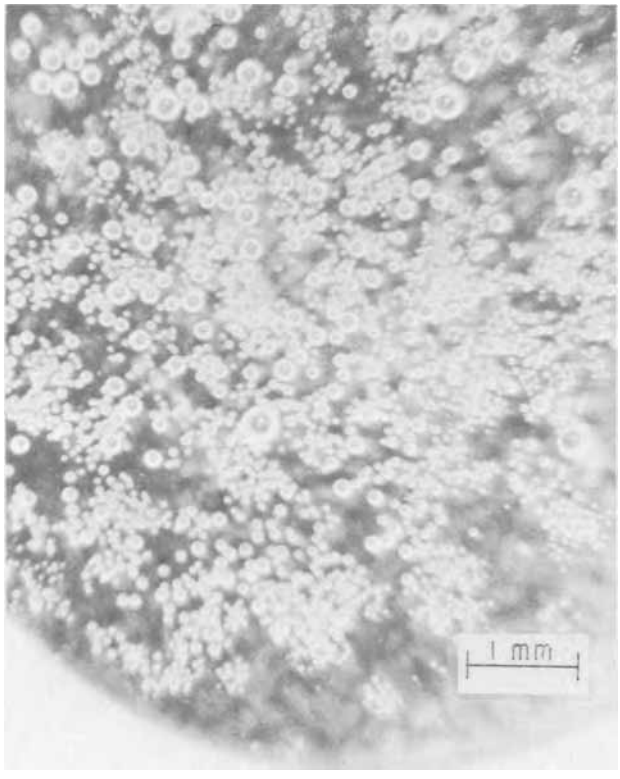

Fig. 10. Hydrogen bubbles trapped below window of viewing cell. 15X.

the release of a very large number of small bubbles could be noted under the microscope.

The viewing cell was not designed for measuring rates of hydrogen evolution. Nonetheless, a very crude estimate of the rates under consideration in this report can be obtained from the amount of gas accumulated under the window of the cell. They correspond to current densities in the range 1-10 $\mu A/cm^2$, a quantity insignificant in comparison to the rates of anodic oxidation in 7M KOH. Thus, it seems that hydrogen generated at a rate corresponding to microamperes per square centimeter can affect anodic currents about 10,000 times greater through its mechanical action on anodic films.

The effects of tin and lead anions in the electrolyte on anodic dissolution, film formation, and hydrogen evolution.—The utility of the notion that anodic films on zinc can form both by precipitation from a supersaturated layer of electrolyte adjacent to the electrode surface, as well as by a direct electrochemical mechanism on the zinc surface, is exemplified further by observations on the effects of lead and tin additions to the KOH electrolyte. The current potential curves shown in Fig. 11, along with photomicrographs corresponding to one of these curves shown in Fig. 12, indicate the sensitive effects of small concentrations of such addition agents. The three current-potential curves were obtained in KOH solutions to which various amounts of PbO were added to give the concentrations of $HPbO_2^-$ indicated in Fig. 11. The presence of lead ions in the electrolyte has practically eliminated the anodic peak near −1.27V associated with the formation of a precipitated coating.

Figure 12(A) shows a representative photomicrograph of a portion of a single crystal specimen taken before any appreciable amount of dissolution occurred. The metallurgical microscope equipped with a dark-field objective was also used to obtain the series of photographs presented in Fig. 12. The surface, which contains the basal plane, is marred by only a few traces of slip planes and by a cleavage step running from the lower left corner to the middle of the right edge of the photograph. It is not evident that the

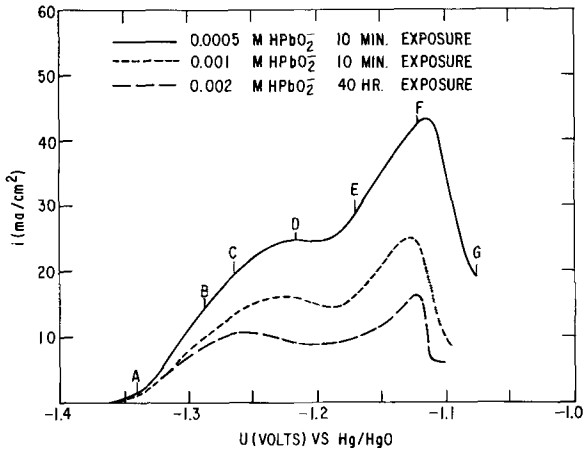

Fig. 11. Current density-potential curves for zinc single crystals taken during anodic sweeps at 0.05 mV/sec under nearly convectionless conditions with various concentrations of $HPbO_2^-$ in electrolyte.

surface is covered by a thin film of lead although the presence of such a film was indicated by x-ray diffraction carried out on another single-crystal specimen which had been immersed in a solution similar to that used in this run. In Fig. 12(B), there is a very slight indication of dissolution along the clevage step and of lifting of the lead film there. In Fig. 12(C), these events are much more evident. Just prior to taking this photograph, precipitate particles were noted moving away from the cleavage step, above which the electrolyte is saturated, toward the top of the photomicrograph. These are easy to see against the nearly perfect dark-field background. In Fig. 12(D), further spreading of precipitate particles can be observed. However, the much lower density of the particles in this coating compared to that shown in the series of photomicrographs in Fig. 4 should be noted. The lead film evidently has so restricted the amount of dissolution that a truly passivating precipitated coating does not form. Some wrinkling and buckling of the lead layer can be seen in the lower right portion of this photomicrograph.

Thus far in this series of photomicrographs, evidence of so-called type I (precipitated film) and of the lead film has been presented. In Fig. 12(E), the exposure time was increased threefold to secure evidence for the presence of type II also. The narrow areas along the cleavage step and the small, nearly circular, areas adjacent are very black because they are light absorbing. Some dissolution has occurred in these places and they are now coated with a light-absorbing film. The area in the center of this photomicrograph just above the cleavage step does not appear to have such an intense black hue. It is light reflecting because it is still coated with a smooth lead film. In Fig. 12(F), it can be seen that the circular areas have expanded. In addition, the previously wrinkled metal film in the lower right corner has gathered into a wad. In Fig. 12(G), still further spreading of the areas covered with type II film can be noted. The area in the center portion of the field has become intensely bright because the previously smooth lead film has wrinkled. Presumably, in this experiment, the passivation of the electrode surface is associated with the presence of type II film. The ability of this film to passivate a zinc electrode without the presence of a precipitated coating was shown previously in experiments where the electrolyte was stirred. Higher potentials are required, though, than those associated with a precipitated film (1).

Larger concentrations of lead ions in solution or longer exposure times of the specimen to electrolyte before the start of an anodic scan produced presumably less porous and certainly more inhibitive lead

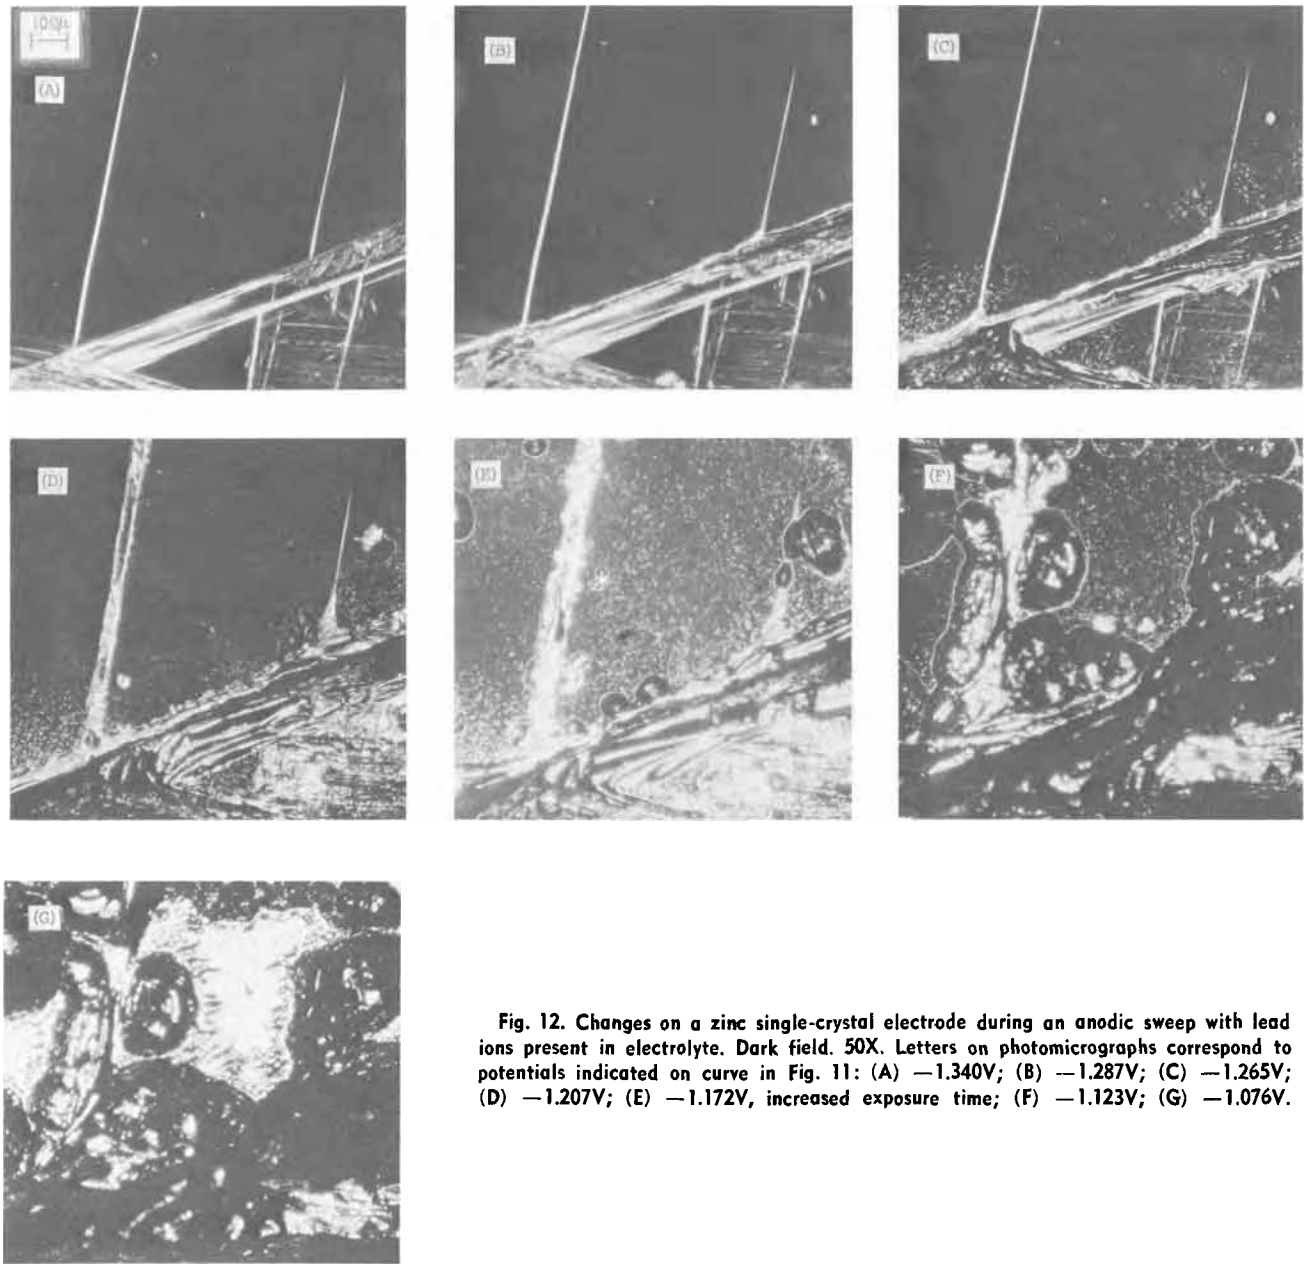

Fig. 12. Changes on a zinc single-crystal electrode during an anodic sweep with lead ions present in electrolyte. Dark field. 50X. Letters on photomicrographs correspond to potentials indicated on curve in Fig. 11: (A) —1.340V; (B) —1.287V; (C) —1.265V; (D) —1.207V; (E) —1.172V, increased exposure time; (F) —1.123V; (G) —1.076V.

films as shown on Fig. 11. When a specimen was exposed to a 0.002M lead solution for 40 hr, fine lead dendrites in addition to a smooth lead coating were noted on the zinc surface. The presence of lead dendrites suggests a lead reduction process sufficiently rapid that transport of lead ions is rate limiting. Consequently, concentrations of lead ions in excess of 0.002M were not investigated. Polycrystalline zinc specimens were usually not as effectively inhibited by a given concentration of lead ions as were single crystals.

The disintegration of tin films appeared rather similar to that for lead. They first wrinkled and then gathered into a wad. Tin films, however, were never found to be as inhibitive as those of lead. Even films, formed in 0.01M $HSnO_2^-$ after 24 hr exposure to electrolyte, did not suppress the first anodic peak as illustrated in Fig. 11 for lead films, nor correspondingly did they suppress formation of a precipitated coating. Tin films often disintegrated at much lower anodic potentials than those of lead. For example, the rumpling of a layer of tin on a zinc single crystal at —1.32V is shown in Fig. 13. This tin layer was formed by exposing a single crystal to a solution, 0.0015M in $HSnO_2^-$, for 24 hr. Actually, the rumpling of tin films has been observed at potentials below —1.34V, *i.e.* in a range of potential where type II film cannot form.

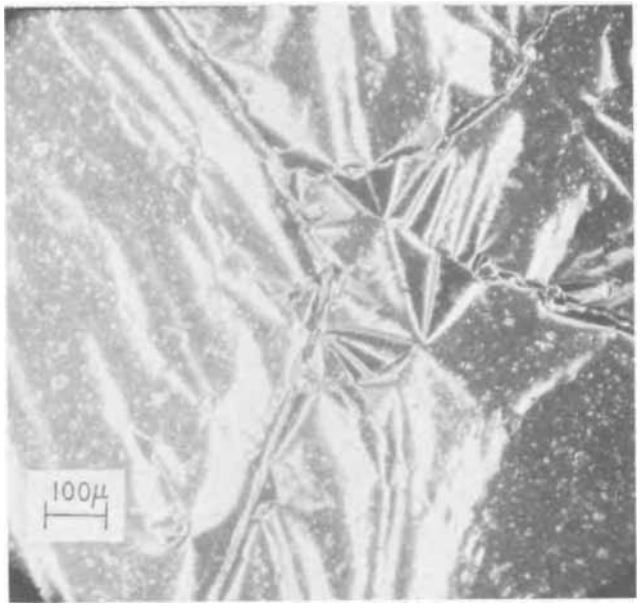

Fig. 13. Rumpling of tin layer on zinc single crystal. Dark field. 75X.

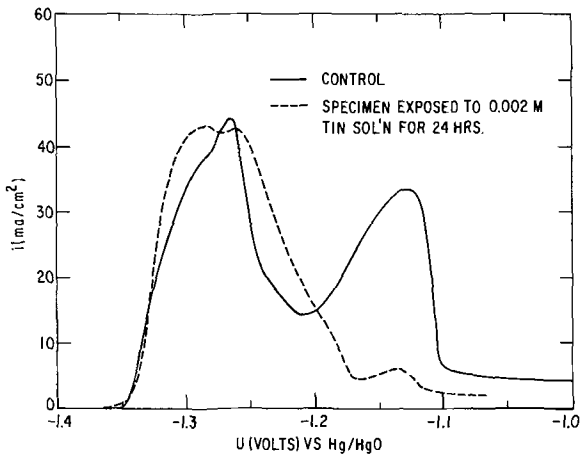

Fig. 14. Current density-potential curves for zinc single crystals taken during anodic sweeps at 0.05 mV/sec under nearly convectionless conditions with and without tin ions in the electrolyte.

The point is of some importance because type II ZnO, while very light absorbent at higher potentials, is much less so at potentials close to the zinc/zinc oxide equilibrium value. Under these conditions, it may have a metallic sheen. Consequently, care must be exercised to distinguish type II ZnO films from those of tin.

Thus, lead and tin additions to alkaline electrolyte function mainly by giving rise to smooth inert films over the zinc electrode surface. Such films inhibit dissolution until they are undercut. Apart from some effects associated with hydrogen suppression, anodic film formation on active portions of the zinc surface seems otherwise unaffected by the presence of these foreign metal anions in the electrolyte. In most of the experiments with tin anions in the electrolyte, the amount of hydrogen evolution near the second current peak appeared to be somewhat less than in control experiments. In a few, hydrogen evolution seemed to be nearly completely suppressed and the second anodic peak practically disappeared. The result of one such experiment is shown in Fig. 14. Current-potential curves are presented there for a single-crystal specimen exposed to 0.002M tin solution for 24 hr prior to the scan, as well as for a comparable specimen not exposed to tin. The results are, of course, consistent with the interpretation of electrode reactivation given above. If hydrogen evolution is suppressed, mechanical dislodging of precipitated film should not take place. Nor should electrode reactivation occur. The converse statement is not true though. In several runs, a normal second peak was observed but only a limited amount of hydrogen evolution was noted. This anomaly seems attributable to the trapping of gas inside the film as discussed above. The mechanism of this hydrogen suppression is not understood.

The findings of this paper with regard to the formation of an anodic film by precipitation are not in disagreement with those of Hull, Ellison, and Toni if the conclusions of these authors are understood to apply only to experiments with considerable forced or natural convection (4). Hull *et al.* used zinc rotating disk electrodes or vertical 0.76 mm wire electrodes. The work of Ibl has demonstrated the effectiveness of natural convection as a means of stirring electrolyte along vertical wire electrodes as well as vertical plane electrodes (21). Perhaps it should be stressed again that the notion of duplex film formation as used in this paper is applicable only to a hydrodynamic situation in which there is very little convection. Although this condition requires somewhat special arrangements to achieve in laboratory test cells, nonetheless it is of importance to battery technology where a plate is located in close proximity to a separator (21, 17).

Acknowledgments

Partial financial support for this work was provided by the International Lead Zinc Research Organization, Incorporated, New York City. Dr. M. M. Wright of Cominco Limited provided zinc sheet of different levels of purity. Dr. C. B. Tennant and Mr. S. R. Dunbar of the New Jersey Zinc Company supplied sheet stock of various zinc alloys. Doctors F. Mansfeld and S. Gilman kindly furnished the author copies of their manuscripts prior to publication.

Chemical Iron-Phosphorus Films

C. Ruscior and E. Croială

Polytechnic Institute of Jassy and Research Center for Physics, Jassy, Romania

ABSTRACT

Iron-phosphorus deposits on copper substrates were obtained using Brenner's method. The films (0.03-3 μm) were prepared in a bath containing ferrous ammonium sulfate, sodium citrate, and sodium hypophosphite by immersion of the copper substrate in contact with an aluminum strip. The deposition takes place at bath temperatures in the range of 25°-95°C and a *p*H higher than 9.5. For bath temperatures between 25° and ~60°C, only phosphorus-free Fe deposits are obtained. The plating mechanism is an electrochemical process due to the Cu-Al galvanic couple. Fe-P films are obtained at bath temperatures in the range of ~60° to 95°C. For these films, the plating mechanism is a combination of galvanic and chemical deposition due to reduction of the Fe cation by the hypophosphite anion accompanied by phosphorus codeposition. For the Fe-P deposit obtained at 80°C and *p*H = 10.5, the phosphorus content is 3%. The deposition conditions and some magnetic properties of the Fe-P films are investigated.

The chemical (electroless) method for the preparation of Ni-P and Co-P films, based on reduction of the Ni and Co cations by means of hypophosphite anions, was discovered by Brenner and Riddel (1) more than 20 years ago. Numerous papers have been published concerning the properties of these films. However, a method of depositing Fe-P films in this way has not yet been reported. Electrolytically obtained Fe-P films, exhibiting low coercivities (<1 Oe), are presented in (2). Ternary Ni-Fe-P films, both electrodeposited (3) and prepared by electroless technique (4), are also known.

The present paper describes a method for obtaining Fe-P deposits by chemical reduction with hypophosphite. As shown below, the Fe-P films can be obtained if the chemical reaction occurs simultaneously with an electrochemical deposition of Fe. The effects of certain plating parameters on the film thickness and some magnetic properties of these films are examined.

Experimental

Preparation of deposits.—The Fe-P films were obtained using an aqueous solution of the following composition: (*a*) ferrous ammonium sulfate, $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, 30 g/liter; (*b*) sodium citrate, $C_6H_5O_7Na_3 \cdot 5H_2O$, 45 g/liter; (c) sodium hypophosphite, $NaH_2PO_2 \cdot H_2O$, 30 g/liter.

The above solution was optimized after making attempts with various solution component concentrations such as (*a*) between 10 and 40 g/liter, (*b*) between 25 and 45 g/liter, (c) between 25 and 40 g/liter.

Since the deposition takes place only at a *p*H higher than 9.5, ammonia was added to increase the *p*H of the solution.

The films were plated on copper sheets (50 mm x 5 mm), after mechanical cleaning with Carborundum powder and degreasing with sodium hydroxide. To obtain the deposition, it is necessary for the copper sheet to be in contact with an aluminum, zinc, or magnesium strip. In the present work, only aluminum was used. The aluminum strip, cut from a sheet 0.5 mm thick, is clamped to the copper sheet as shown in Fig. 1. This couple is then immersed in the deposition bath (100 cm^3), whose temperature was varied from 25° to 95°C.

Under these conditions the deposition may start even at room temperature, but in this case the plating rate is very slow. The deposition rate increases with increasing bath temperature. Concurrently, the aluminum strip corrodes and Al ions pass into the solution. The same aluminum band can be used for several successive depositions.

Key words: iron-phosphorus films, magnetic coatings, electroless plating.

Thickness measurement.—The thickness was determined by the mass-density relationship assuming a bulk density of 7.8 g/cm^3 for the deposits obtained.

Analytical.—The film composition was determined by qualitative spectrographic analysis. For this purpose, the Fe-P film, deposited on pure electrolytic copper sheet, was first dissolved together with the substrate in *aqua-regia*. After evaporation, the residue was spectrochemically analyzed by means of the d-c carbon arc.

The phosphorus content was determined spectrophotometrically, using the molybdenum blue method (5).

Magnetic measurements.—In order to determine the magnetic parameters, a 50 cycle hysteresis loop tracer (6) having a maximum driving field of 300 Oe was used. The measured parameters were the coercivity, H_c, the remanence, M_r, and the magnetization, M_m, corresponding to the maximum driving field. At 300 Oe, full saturation was not attained.

Results

Film composition.—The spectrochemical analysis of the samples shows that the deposited films contain only iron as the major metallic component. The presence of aluminum was not observed, although this metal could be detected as low as 0.2% concentration in the film.

The photocolorimetric analysis showed the presence of phosphorus only for the films plated at bath temperatures in the range of ~60° to 95°C. Therefore, the films deposited below approximately 60°C are Fe films free of phosphorus, whereas those obtained above this temperature are Fe-P films. The phosphorus content of these films depends on bath temperature and *p*H. Thus, the films deposited at 80°C and *p*H = 10.5 con-

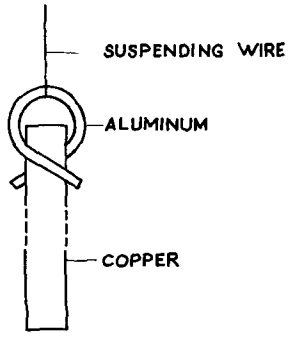

Fig. 1. Schematic drawing of the copper-aluminum couple

tain 3% P, whereas those obtained at the same temperature but at a pH = 11.4 contain only 1% P.

Properties of the Fe-P films.—The films obtained in the thickness range of 0.03-3 μm are uniform and adherent to the copper substrate. They are gray, but their aspect changes with increasing film thickness. Thus, the films below ~0.4 μm are smooth, bright, and do not oxidize in open air (during a period of many months, they did not lose their metallic luster); the films in the thickness range of ~0.4 to ~1 μm are less bright, whereas those over ~1 μm are dull and become oxidized in a few weeks.

The thickness of the deposited films depends on the plating time, bath pH, bath temperature, and the geometrical area of the copper and aluminum sheets. The effects of these parameters on the film thickness are analyzed below.

Effect of plating time.—The film thickness increases linearly with increasing plating time, at constant values of the other plating parameters. Figure 2 shows the dependence of the Fe-P film thickness on plating time, for the deposition obtained at 80°C, pH = 10.5, S_{Al} = 2 cm². In this case, the average plating rate is 2 μm/hr.

Effect of bath pH.—As mentioned above, the deposition takes place in alkaline solutions only, when pH > 9.5. At this pH value, the plating rate is small but it increases with increasing bath alkalinity. Figure 3 shows the dependence of the film thickness on the bath pH at 80°C and constant deposition time (30 min). A plating rate of 0.6-5 μm/hr is obtained as the pH varies from 10 to 11.4.

Effect of bath temperature.—The deposition takes place at bath temperatures in the range of 25°-95°C. Increasing bath temperature leads to increased deposition rate. In Fig. 4, the film thickness is plotted against bath temperature, the other plating parameters having the constant values mentioned in this figure. Two distinct temperature intervals are to be noticed with respect to plating rate change. The first one, including temperatures from 25° to ~60°C, is marked by a relatively small change of the deposition rate (0.02 μm/hr/deg). In this interval, Fe films free of phosphorus are deposited. The second interval, comprising temperatures from ~60° to 95°C, is characterized by a greater plating rate change (0.07 μm/hr/deg). In this temperature range, the Fe-P films are obtained.

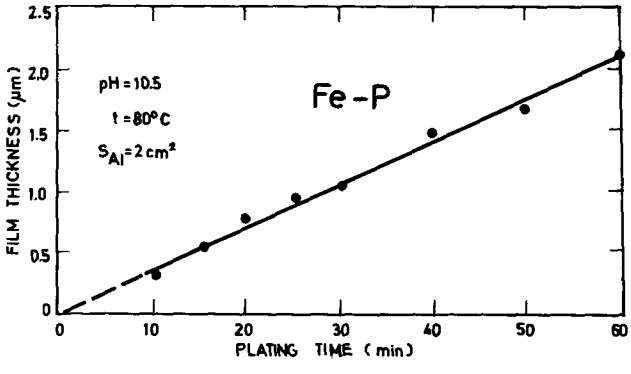

Fig. 2. Thickness of Fe-P film vs. plating time

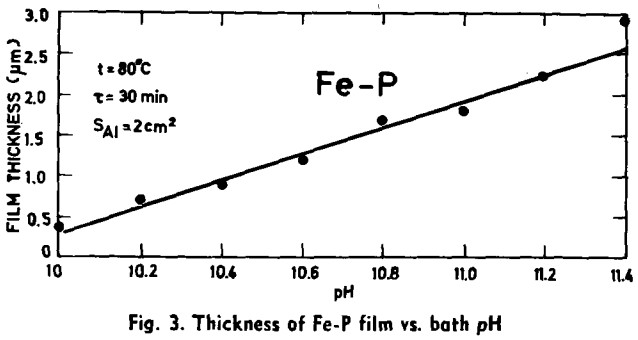

Fig. 3. Thickness of Fe-P film vs. bath pH

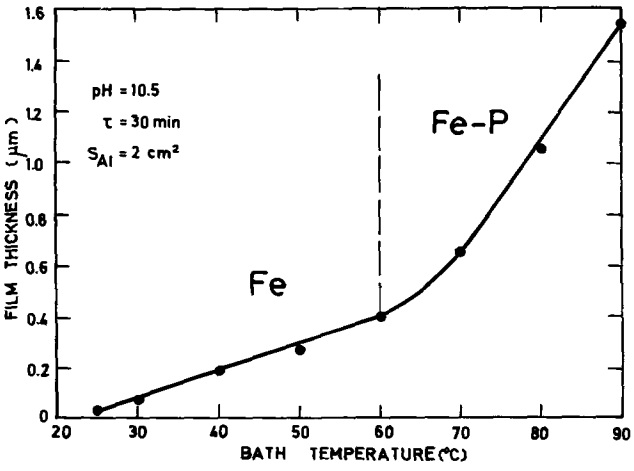

Fig. 4. Film thickness vs. bath temperature

Aluminum strip.—In order to obtain the deposition, it is necessary to bring the copper sheet in contact with metals more electronegative than Fe, *i.e.* Zn, Al, or Mg. As mentioned, only aluminum has been used in this work. During the plating process, Al passes into solution as shown by weighing the aluminum strip before and after deposition.

It is important to note that, if the aluminum contact is removed during the plating process, the deposition stops and the previously deposited film dissolves. In this respect, the Fe-P films differ from the Ni-P and Co-P films obtained on copper substrates. Indeed, for starting the deposition of these films, it is also necessary to bring the copper sheet in contact with more electronegative metals, as Al or others, but after initiation the deposition continues even if the contact is removed. In the case of Fe-P deposition, the contact between the two metals must be maintained.

The plating rate of the deposited Fe-P films depends on the area ratio of the aluminum and copper surfaces. Figure 5 shows the film thickness as a function of S_{Al}/S_{Cu} for the deposition obtained at 80°C, pH = 10.5 and τ = 30 min. It can be seen that the plating rate increases with increasing area ratio, tending to a constant value of about 3 μm/hr for area ratio higher than ~1.

Magnetic properties.—The Fe-P films deposited are ferromagnetic. The coercivity, H_c, depends on the film thickness, having high values for thin films (under ~0.5 μm) as shown in Fig. 6. For the indicated plating parameters, H_c increases from 25 to 145 Oe as the film thickness decreases from 1.2 to 0.03 μm.

In contrast with coercivity, the remanence, M_r, and the maximum value of the magnetization, M_m, increase with increasing film thickness, tending to constant values for films over ~0.5 μm. Thus, M_r approaches an almost constant value of 1100 Gs, whereas M_m reaches

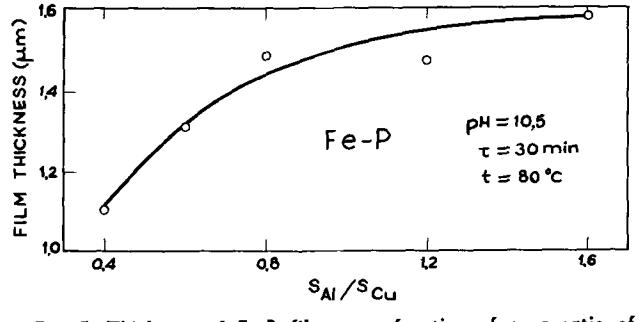

Fig. 5. Thickness of Fe-P film as a function of area ratio of aluminum and copper surfaces.

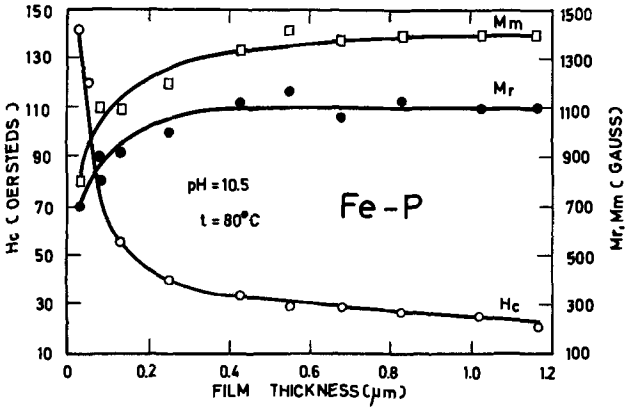

Fig. 6. Coercivity, H_c, remanence, M_r, and magnetization, M_m, at $H = 300$ Oe vs. thickness of Fe-P film.

1400 Gs. As mentioned before, full saturation is not attained at $H = 300$ Oe.

Discussion

The method of Fe-P plating described above raises the question of the mechanism of film deposition, which was investigated by performing two experiments. The first was a Fe-P deposition achieved in the usual manner, by dipping the copper substrate in contact with the aluminum strip into a plating bath containing ferrous ammonium sulfate, sodium citrate, and sodium hypophosphite. The second was a Fe deposition achieved under similar conditions, but using a bath with no hypophosphite. In Fig. 7 the masses of the two deposits obtained in this way are plotted against bath temperature, at constant plating time (30 min). As shown in this figure, for temperatures below ~60°C both depositions have practically the same mass. They are iron films free of phosphorus. For bath temperatures above ~60°C, when Fe-P and Fe films are obtained, the masses of the two deposits differ: the plating rate of the Fe-P film is higher than that of the Fe film, and it increases with increasing bath temperature. Concurrently, in both experiments the amount of aluminum dissolved can be considered identical, as shown in Fig. 8.

The results of these two experiments may be interpreted as follows.

The mechanism of the Fe deposition, obtained both from the bath containing hypophosphite and from the bath with no hypophosphite, is an electrochemical process. Indeed, the two metals, Cu and Al, connected inside the deposition bath form a galvanic couple which gives rise to internal electrolysis. As a result, the Al cations leaving the aluminum anode pass into solution and the Fe cations are reduced at the copper

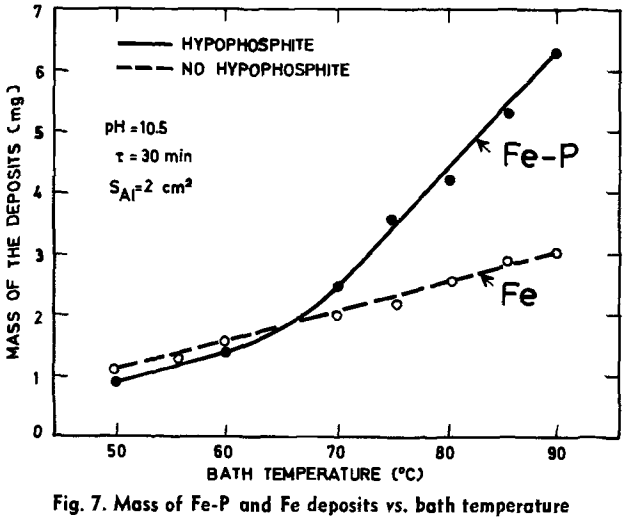

Fig. 7. Mass of Fe-P and Fe deposits vs. bath temperature

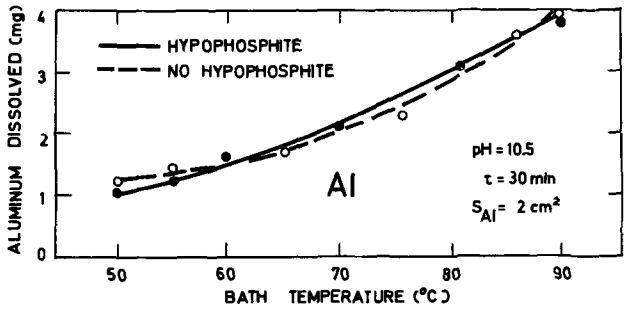

Fig. 8. Mass of aluminum dissolved vs. bath temperature

cathode forming the Fe film. This process occurs at any temperature between 25° and 95°C, the yield increasing linearly with temperature (Fig. 7).

The Fe-P deposits, obtained from the bath containing hypophosphite at temperatures in the range of ~60° to 95°C only, result as a superimposition of the above-described electrochemical process with a purely chemical process, due to reduction of the Fe cations by $PO_2H_2^-$ anions, accompanied by phosphorus codeposition. Actually, the plating rate of the Fe-P films is higher than that of the corresponding Fe films (Fig. 7) although the amount of Al ions present in the two solutions is the same (Fig. 8). Therefore, the additional deposit, leading to formation of the Fe-P films in the plating bath containing hypophosphite, must be obtained by another process which gives rise to a new iron deposition and codeposition of phosphorus, *i.e.* a chemical process.

The amount of Fe-P deposit chemically obtained depends on bath temperature, as is seen from Fig. 7. It increases linearly with increasing temperature and reaches ~50% of the total deposit at 90°C, the rest being galvanically plated iron.

The necessity of the electrochemical reduction of Fe ions as a prerequisite for the chemical reduction shows that the electrochemically plated Fe is required for the autocatalytic reduction of Fe ions by hypophosphite at temperatures greater than 60°C and a $pH > 9.5$. Consequently, the continuous electrochemical reduction of iron is necessary only to provide catalytic iron. Thus, removing the aluminum foil results in immediate dissolution and/or oxidation of the iron which eliminates the necessary catalyst for the autocatalytic reduction of iron ions by hypophosphite.

Conclusion

It has been shown that, to obtain Fe-P films by chemical reduction with hypophosphite, a concomitant electrochemical Fe deposition is necessary. It can be concluded that chemical iron-phosphorus plating is an autocatalytic process, provided that a fresh or active iron surface is present.

Primary Products of Electrochemical Oxidation of Uric Acid in Aqueous and Methanolic Solution

Glenn Dryhurst

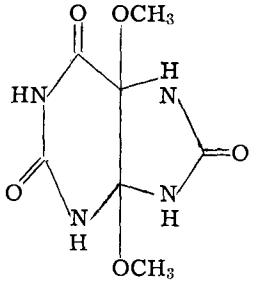
Department of Chemistry, University of Oklahoma, Norman, Oklahoma 73069

ABSTRACT

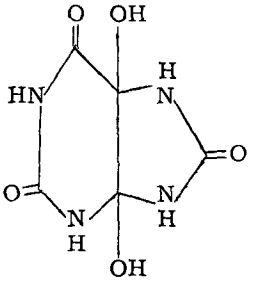
Uric acid is oxidized in aqueous and 50% methanolic acetate buffer *p*H 3.7 in a two-electron process. In aqueous solution the primary product is uric acid-4,5-diol, which is unstable and fragments predominantly to allantoin, but a very small fraction is further oxidized to parabanic acid. In the presence of appreciable quantities (*i.e.*, 50% v/v) of methanol the greater nucleophilicity of methanol results in formation of 4,5-dimethoxyuric acid, which is apparently quite stable and cannot be further oxidized to parabanic acid, and it appears to be reasonably stable to the rather drastic conditions of hydrolysis used to determine allantoin. The results presented further confirm the site and nature of the primary product of the electrochemical oxidation of uric acid.

Uric acid (2,6,8-trioxypurine) is readily oxidized at the pyrolytic graphite electrode. Struck and Elving (1) carried out coulometry and product identification and found that in 1*M* HOAc solution a little more than two electrons were transferred in the electrochemical process and that a mixture of alloxan, allantoin (or an allantoin precursor), urea, carbon dioxide, and parabanic acid was produced. The primary product of the oxidation was proposed to be a dicarbonium ion formed by removal of two electrons from the 4,5-double bond of uric acid. Hydrolysis of the dicarbonium ion gave rise to allantoin, alloxan, CO_2, and urea, while partial further oxidation gave parabanic acid and urea. Subsequent studies (2) using fast sweep cyclic voltammetry revealed that the primary product was not a dicarbonium ion but a more stable species, probably uric acid-4,5-diol, which could be detected as a reduction peak after having first oxidized uric acid, and provided the voltammetric sweep rate was sufficiently rapid. Other purines gave a similar type of behavior which was also attributed to formation of a primary 4,5-diol product formed after having previously oxidized any unoxidized 2 or 8 position in the purine nucleus (3, 4). It has also been shown that enzymatic (5, 6), photodynamic (7, 8), and radiolytic (9, 10) oxidation of uric acid could proceed through a similar primary product to give similar ultimate products to those observed electrochemically.

Recently Matsuura and Saito (11) found that photodynamic oxidation of 1,3,7,9-tetramethyluric acid in methanol gave 4,5-dimethoxy-1,3,7,9-tetramethyluric acid which was sufficiently stable to be isolated. This, of course, provides very nice confirmatory evidence for the nature of the primary product formed in aqueous solution. A 4,5-dimethoxy (I) primary purine oxidation product would be expected to be very much more stable than the corresponding 4,5-diol (II),



(I)



(II)

since the 4,5-diol is capable of readily decomposing to smaller stable molecular fragments, whereas the 4,5-dimethoxy- compound is not.

Accordingly, the electrochemical oxidation of uric acid in methanolic solutions has been reinvestigated with a view to understanding further the nature of the primary product in the electrochemical process.

Key words: uric acid-4,5-diol, 4,5-dimethoxyuric acid, bioelectrochemistry, pyrolytic graphite, 2,6,8-trioxypurine.

Experimental

Chemicals.—Uric acid was obtained from Nutritional Biochemicals. The *p*H 3.7 acetate buffer was prepared by diluting acetate buffer *p*H 3.7 having an ionic strength of 1*M* with an equal volume of water or with an equal volume of methanol. The *p*H 4.7 buffer used for cyclic voltammetric studies was prepared by diluting a 1*M* ionic strength solution with an equal volume of appropriate mixtures of water and methanol. All uric acid solutions were saturated in the particular background medium employed. Deaeration was accomplished with water-saturated Linde Argon without further purification.

Apparatus.—Cyclic voltammetry was accomplished with the apparatus described by Dryhurst *et al.* (12), with the triangular voltage sweeps supplied by an Exact Electronics Model 502 function generator. Current-voltage curves were recorded on a Tektronix Model 502A dual beam oscilloscope equipped with a C-27 polaroid camera. A water-jacketed three-compartment electrochemical cell was used maintained at 25° ± 0.1°C containing a saturated calomel reference electrode (SCE) to which all potentials are referred; a platinum gauze counterelectrode in saturated KCl was employed.

For controlled potential electrolysis a Wenking Model 66TA1 potentiostat was employed; current integration was performed by the usual voltage-to-frequency converter-frequency counter method. The cell used for controlled potential electrolysis and preparation of the pyrolytic graphite electrodes have been described elsewhere (13, 14).

Results and Discussion

In an attempt to define at least qualitatively the effect of methanol on the electrochemical oxidation of uric acid fast-sweep cyclic voltammetry was first performed. Although the most detailed electrochemical study has been carried out in 1*M* HOAc background (1), it was found that in the presence of appreciable amounts of methanol that the resistance of the solution was too high to permit fast-sweep cyclic studies. The most definitive data was obtained in acetate buffer *p*H 4.7 and is presented in Fig. 1, although parallel behavior was observed in acetate buffer *p*H 3.7 (Fig. 2). At a clean electrode no cathodic peaks are observed on the initial negative-going sweep. An anodic peak (peak

I_a) at *ca.* 0.6V is observed on the first positive-going sweep due to the two-electron, two-proton oxidation of uric acid (I, Fig. 1) to the corresponding 4,5-diol (II, Fig. 1). Provided the sweep rate is sufficiently rapid, part of the 4,5-diol can be reduced back to uric acid (peak I_c), the remainder being fragmented to allantoin or further oxidized to parabanic acid. The latter compound gives rise to the second cathodic peak (peak II_c) at *ca.* −0.8V, which is due to the two-electron, two-proton reduction of parabanic (III, Fig. 1) acid to 5-hydroxyhydantoin (15) (IV, Fig. 1). Upon addition of only 5% v/v of methanol the height of peak I_c (B, Fig. 1, 2) is clearly significantly reduced and at the 20% methanol level and above peak I_c is completely eliminated. Up to the 10% methanol concentration level the parabanic acid peak (peak II_c) is virtually unaffected, but at above 20% methanol concentrations peak II_c also disappears. However, peak I_a remains essentially unaffected; the slight decrease in the current value for peak I_a is no doubt related to the decreased solubility of uric acid in the mixed solvent. Thus, increasing concentrations of methanol decreases the amount of 4,5-diol produced and the amount of parabanic acid produced, although the methanol concentrations required to make these two species undetectable by cyclic voltammetry is greater in the case of the latter compound.

In order to investigate further the mechanism of the processes, coulometry of uric acid was carried out in acetate buffer *p*H 3.7 in the absence of methanol and in 50% v/v methanol solution. The *p*H of 3.7 chosen for this study was selected because alloxan, one of the products found in 1*M* HOAc electrolyses (1), is unstable above *p*H 4. After complete electrolysis, analyses were performed only for allantoin, parabanic acid, and alloxan. Data are presented in Table I where it is clear that in aqueous solution close to 90% of the uric acid oxidized results in allantoin formation with only a very small amount of parabanic acid being produced. In the 50% methanolic solution only about 20% of the uric acid oxidized results in allantoin formation, and no parabanic acid is produced. In neither the completely aqueous nor the 50% methanol solution was alloxan detected, although at *p*H 3.7 alloxan in either medium gives rise to only a very small kinetically controlled polarographic wave; accordingly, small amounts of alloxan could go undetected by the polarographic method at *p*H 3.7. Nevertheless, since experiment showed that alloxan, parabanic acid. and allantoin were reasonably stable in the 50% methanolic solution, then the bulk of the oxidized uric acid must be present in a form which cannot be produced in aqueous solution. The only reasonable major product formed is, therefore, 4,5-dimethoxy-uric acid.

Mechanism

Uric acid is clearly oxidized in aqueous and 50% methanolic acetate buffer *p*H 3.7 in a two-electron process. In aqueous solution the oxidation proceeds via a primary uric acid-4,5-diol product which predominantly simply fragments to allantoin, although a

small portion is further oxidized to parabanic acid.[1] On addition of methanol to the solution cyclic voltammetry indicates that the amount of 4,5-diol is drastically decreased so that at the 50% methanol level no 4,5-diol can be detected. Under cyclic voltammetric conditions parabanic acid formation is also repressed by addition of methanol, but not at such low methanol concentrations as are required to repress the 4,5-diol detection. At the 50% methanol concentration level parabanic acid is not formed.

The mechanism of the process can thus be rationalized by assuming that, under the voltammetric conditions, the greater nucleophilicity of methanol [or methoxide ion] (19) results in preferential formation of 4,5-dimethoxy-uric acid, rather than the uric acid-4,5-diol. Since the cathodic parabanic acid peak can be observed cyclic voltammetrically even when the 4,5-diol cathodic peak is completely eliminated, then presumably most of the 4,5-diol that is produced is further oxidized to parabanic acid. At the 50% methanol concentration level no parabanic acid is observed, indicating that little or no 4,5-diol is produced in the primary oxidation process. That some allantoin can be produced (under conditions of exhaustive controlled potential electrolysis) probably result from partial hydrolysis of 4,5-dimethoxy-uric acid under the rather drastic conditions of the allantoin determination to allantoin or glyoxylic acid, which is the species actually spectrophotometrically determined (16).

It is of some interest to note that under cyclic voltammetric conditions at the stationary PGE that the cathodic parabanic acid peak (peak II_c) is much larger (Fig. 2A) relative to the principal uric acid oxidation peak (peak I_a) than would be expected on the basis of the analytical concentration of parabanic acid determined at the end of an exhaustive controlled potential electrolysis. Struck and Elving (1) found that at pH 2.3, 30% of uric acid was oxidized to give parabanic acid, *i.e.*, the lower the pH the greater the amount of parabanic acid produced. Under cyclic voltammetric conditions the peak I_a process (A, Fig. 1, 2) clearly involves liberation of protons, which must at least momentarily decrease the surface pH and presumably aid the formation of parabanic acid. Under conditions of controlled potential electrolysis the vigorously stirred solution would not be as susceptible to large changes in surface pH and, accordingly, less parabanic acid is produced.

[1] Work now in progress is being carried out with a view to elucidation of the processes leading to the uric acid-4,5-diol or 4,5-dimethoxy derivative.

Influence of the Faradaic Process on Nonfaradaic Resistance Compensation in Potentiostatic Techniques

Arthur A. Pilla*

ESB Incorporated, Research Center, Yardley, Pennsylvania 19067

ABSTRACT

The theoretical justification for the use of IR compensation in potentiostatic techniques when a faradaic reaction is present is considered in detail. It is shown that the stability of the system indeed depends on potentiostat and all electrode parameters, *i.e.*, both the double layer and faradaic time constants contribute. Under certain conditions, the faradaic contribution is not significant; however, it is difficult to determine even in an *a posteriori* manner the remaining uncompensated resistance R_u. It is concluded that IR compensation can only be employed unambiguously in the time and classical a-c frequency domains if the critical damping frequency is accurately known and the frequencies employed are sufficiently lower than this frequency. IR compensation can however be advantageously employed in combination with the transient impedance technique over the entire accessible frequency range (even those above τ_{min}) and which allows the system to be unmasked experimentally from the effects of nonfaradaic resistance. This permits the necessary kinetic and double-layer information to be extracted from the final results with a precision increased at least two orders of magnitude above the uncompensated system when high-speed circuitry is employed.

In a previous study (1), the general problem of the incorporation of IR compensation via positive feedback in a potentiostatic circuit was considered for an electrochemical system exhibiting double-layer behavior only. The system was analyzed in terms of frequency domain stability criteria and a characteristic parameter, the minimum time constant, τ_{min} was derived. This quantity is the minimum stable over-all time constant exhibited by the potentiostat-cell combination in the presence of positive feedback. It represents the maximum IR compensation beyond which damped and finally undamped oscillations may occur; τ_{min} is, in general, the sum of time constants involving both the electrochemical cell and the potentiostat, rendering the unambiguous evaluation of both the remaining uncompensated nonfaradaic resistance, R_u, and the double-layer capacitance, C_d, difficult in the time or classical (a-c) frequency domain. In addition, since τ_{min} is always a finite quantity, overcompensation in the absolute sense (*i.e.*, achieving the proper response to charge C_d in the absence of any series resistance) is physically impossible, even with the fastest state of the art potentiostats.

IR compensation is most often employed in the presence of a faradaic reaction. Essentially, the desire is to charge C_d as rapidly as possible and unmask the faradaic process for further analysis at the shortest possible times. For an extensive bibliography on IR compensation the reader is referred to ref. (1). The effect of faradaic parameters has not explicitly been considered previously. However, it has been stated that the stability of the system would most probably be increased when a faradaic reaction is present (2). This could be interpreted to mean that the degree of positive feedback might be increased above that allowable in the absence of faradaic reaction. Another approach (3, 4) has been to obtain the fastest stable system response with positive feedback at an electrode potential at which no appreciable faradaic current flows, *e.g.* at the bottom of the polarographic wave. Once this has been accomplished it is then considered that the same degree of positive feedback accomplishes the same amount of compensation when a faradaic reaction is also present. In an effort to clarify this situation and to make a previous study (1) more generally applicable an attempt will be made here to elucidate the effect of the faradaic process on the stability conditions of the total system (*i.e.*, on τ_{min}). In addition, criteria will be presented to provide guidelines for the use of IR compensation in the most general cases.

Theoretical

In order to establish a working model for the general application of IR compensation in potentiostatic techniques the same basic model as previously employed for a system exhibiting double layer behavior only will be utilized (1). This involves considering the electrochemical system as linear which allows the concept of impedance to be utilized permitting the system to be represented in shorthand notation by an aperiodic equivalent circuit (5). This circuit is then appropriately coupled to a potentiostat thereby constituting the total control circuit. Among the various types of potentiostats (3, 6) which have commonly been employed, the optimum choice when using positive feedback for high speed applications has been shown (1) to be the single amplifier variety. The incorporation of IR compensation in this type of potentiostat is achieved by voltage feedback of part of the output signal to its noninverting (+) input.

Utilizing the above considerations, a general model may now be constructed as shown in Fig. 1. Here, the electrochemical cell is shown as a series resistance, R_e, representing the electrolyte and/or working electrode nonfaradaic resistance. The working interface is shown as an arbitrary impedance, Z_E, which is valid for any electrochemical system under linear conditions. The amplifier, A_1, is the potentiostat, and A_2 is the positive feedback amplifier which is essentially a voltage follower with gain. R_o represents both the counterelectrode impedance and output impedance of A_1. IR compensation is accomplished outside the negative feedback loop of A_1 by sampling a portion of the voltage across R_1 (Fig. 1) thereby keeping τ_{min} as small as possible. This point has been discussed previously (1) and is based on the fact that the closed loop time constant of the potentiostat is smaller if the current sampling resistor is outside the negative feedback loop.

* Electrochemical Society Active Member.

Key words: positive feedback, potentiostat amplifier, impedance, frequency domain.

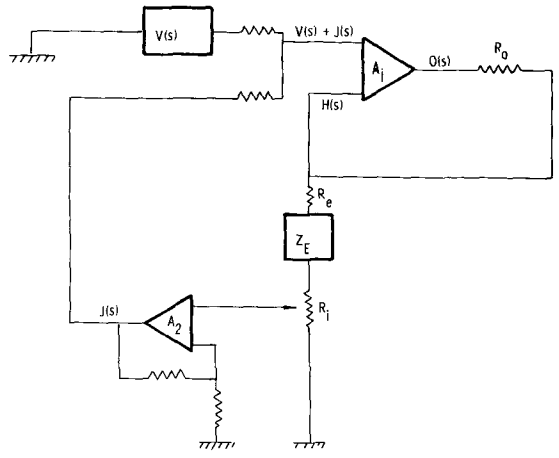

Fig. 1. Single amplifier potentiostat circuit with compensation outside the negative feedback loop: for generalized linearized electrochemical system.

All voltage signals in this model are represented in terms of their Laplace transforms (7) since this procedure allows simple algebraic expressions to be obtained which are sufficient to describe the frequency response of the system (1). The quantity necessary to examine this property is its transfer function which is defined as the ratio of the output voltage $O(s)$ (Fig. 1) to the input voltage $V(s)$ (Fig. 1). This is given by (1, 7).

$$\frac{O(s)}{V(s)} = \frac{G_1(s)}{1 + [H(s) - J(s)]\,G_1(s)} \qquad [1]$$

where $G_1(s)$ is the gain frequency function of the potentiostat, $H(s)$ is the negative feedback, and $J(s)$ is the positive feedback voltage functions. This expression takes into account the interaction of both the main and positive feedback amplifiers. Since $H(s)$ is defined as the fraction of the output voltage which is fed back to the inverting (−) input of the potentiostat, it is given by

$$H(s) = \frac{R_e + R_i + Z_E(s)}{R_o + R_i + R_e + Z_E(s)} \qquad [2]$$

The voltage at the output of A_2, which is the IR compensation signal $J(s)$ (Fig. 1) is

$$J(s) = \frac{R_i G_2(s)}{R_o + R_i + R_e + Z_E(s)} \qquad [3]$$

where $G_2(s)$ is the gain function of the IR feedback amplifier.

The essential requirements for optimum IR compensation are to keep the system order in terms of the Laplace variable s and the associated time constants as low as possible (1). For this, it is sufficient to examine the denominator of either the transfer function (Eq. [1]) or the output current, $i(s)$, or the control voltage $E(s)$ since these quantities may be obtained from the transfer function. The frequency functions which must be made explicit and which are the key factors in determining the system order are $G_1(s)$, $G_2(s)$, and $Z_E(s)$. Obviously very little can be done with $Z_E(s)$ since this is an inherent property of the electrode under study. However, the value of the time constants in $Z_E(s)$ which prevail in any given experiment are determined by the surface area of the electrode. Thus the double-layer capacitance, C_d, is smaller, as is well known, the smaller the electrode area. The same is true for parameters of the faradaic impedance such as the charge transfer resistance, R_t, adsorption capacitance, C_a, etc. It is, therefore, desirable to keep the electrode time constants as low as possible to enable optimum IR compensation conditions to be obtained.

The gain functions $G_1(s)$ and $G_2(s)$ can be determined to a certain extent by appropriate choice of amplifiers. The ideal gain function would be $G(s) = K$ indicating constant gain at all accessible frequencies. Unfortunately, in the case of the potentiostat amplifier, this function cannot be obtained since, *e.g.*, the potentiostat is not an infinite current source at infinite frequency. The various gain functions which potentiostat amplifiers may exhibit have been discussed elsewhere (1, 4). The most desirable is that of lowest order since this allows the total system order to be kept to a minimum. A first order gain function is given by

$$G_1(s) = \frac{K}{s\tau + 1} \qquad [4]$$

where K is the open loop d-c gain and τ the open loop time constant, the value of which depends on amplifier design. The fastest available potentiostats have been shown to exhibit this gain function (1). In addition external phase compensation which affects the value of τ without modification of the form of the gain function is highly desirable since this allows the total system to be stabilized without changing the over-all system order. If the positive feedback amplifier is utilized at relatively low gain and is at least one order of magnitude faster than the potentiostat amplifier under these conditions, it is then possible for it to exhibit the simple gain function $G_2(s) = K_2$. An amplifier having this characteristic when utilized for high speed IR compensation has previously been described (1).

In view of the above considerations, the transfer function now becomes, using [2], [3], and [4], and maintaining arbitrary $Z_E(s)$

$$\frac{O(s)}{V(s)} = \frac{K}{K+1}\left[\frac{R_o + R_e + R_i + Z_E(s)}{R_T\tau_p s + Z_E(s)[1 + \tau_p] + (R_T + R_u K)/(K+1)}\right] \qquad [5]$$

where

$$R_T = R_o + R_e + R_i \qquad [6]$$

$$R_u = R_e + R_i - R_i K_2 \qquad [7]$$

$$\tau_p = \tau/(K+1) \qquad [8]$$

It is convenient at this point to develop expressions for both $i(s)$ and $E(s)$. Thus

$$i(s) = O(s)/[R_o + R_e + R_i + Z_E(s)] \qquad [9]$$

from which, using [5]

$$i(s) = V(s)\frac{K}{K+1}\left[\frac{1}{R_T\tau_p s + Z_E(s)[1 + \tau_p] + (R_t + R_u K)/(K+1)}\right] \qquad [10]$$

The voltage appearing at the potentiostat control points, $E(s)$, is

$$E(s) = O(s) - i(s)R_o \qquad [11]$$

which gives, using [5]

$$E(s) = V(s)\frac{K}{K+1}\left[\frac{R_e + R_i + Z_E(s)}{R_T\tau_p s + Z_E(s)[1 + \tau_p] + (R_T + R_u K)/(K+1)}\right] \qquad [12]$$

relating the input voltage to that actually appearing across the working and reference electrodes. As has been shown previously (1, 5), the use of the transient impedance technique allows Eq. [12] to be divided by Eq. [10] in the most general case thereby markedly reducing the contribution from all parameters except those actually appearing across the potentiostat control points.

Examination of Eq. [5], [10], and [12] shows that $O(s)$, $i(s)$, and $E(s)$ are subject to the same stability conditions, as is to be expected. These conditions are determined by the roots of the denominator of the respective expressions. These roots contain, in an appropriate manner, all of the time constants present in the system including those in $Z_E(s)$. It is therefore obvious that, in the general case for which the present model is valid, the combination of time constants prevalent at the critical damping point of the system includes both potentiostat and all electrode parameters, *i.e.*, both double-layer and faradaic processes contribute.

In order to illustrate this in a somewhat more specific manner, an electrochemical system exhibiting both double-layer behavior (C_d) and charge transfer (R_t) as the faradaic process will be considered. In this case

$$Z_E(s) = \frac{R_t}{1 + R_t C_d s} \qquad [13]$$

This expression is the complex impedance of an aperiodic RC parallel electric circuit which represents a relatively classical electrochemical system [8]. Using this in, *e.g.*, Eq. [10] for $i(s)$, the following is obtained

$$i(s) = V(s)\,\frac{K}{K+1}\left[\frac{C_d s + 1/R_t}{\tau_c\tau_p s^2 + [\tau_u + \tau_c/(K+1) + \tau_p(1 + R_T/R_t)]s + 1 + 1/R_t(R_T/(K+1) + R_u)}\right] \qquad [14]$$

where

$$\tau_c = (R_e + R_i + R_o)C_d \qquad [15]$$

$$\tau_u = (R_e + R_i - R_i K_2)C_d \qquad [16]$$

and R_T, R_u, and τ_p are defined by Eq. [6], [7], and [8], respectively. Examination of [14] shows that it represents a second order system which closely resembles the result for $i(s)$ previously obtained (1) for a system exhibiting double-layer behavior only. The result is reproduced here for convenience.

$$i(s) = V(s)\,\frac{K}{K+1}\left[\frac{C_d s}{\tau_c\tau_p s^2 + [\tau_u + \tau_c/(K+1) + \tau_p]s + 1}\right] \qquad [17]$$

Comparison of [14] and [17] shows that they differ only in terms containing R_t. This difference, however, is essential since the critically damped behavior allowable for both systems is not identical. Thus, the minimum time constant, τ_{min}, corresponding to [14] is

$$\tau_{min} = \sqrt{\tau_c\tau_p[1 + 1/R_t(R_T/(K+1) + R_u)]} \qquad [18]$$

which is to be compared to τ_{min} for [17]

$$\tau_{min} = \sqrt{\tau_c\tau_p} \qquad [19]$$

Equation [18] clearly shows that, at critical damping, *i.e.*, just at the onset of damped oscillations, faradaic parameters play a role whereas these parameters are, of course, nonexistent in [19].

The above results indicate that the total electrode behavior must be taken into account when evaluating results obtained from potentiostatic techniques incorporating IR compensation. In particular, [18] and [19] clearly show that, even for the simplest of electrode systems, it is not allowable to adjust for optimum compensation in the absence of a faradaic reaction and assume that results will be unaffected in its presence. The conditions under which minimum error is made when performing the above can, however, be established by consideration of [18]. It is clear that the larger R_t is, *i.e.*, the slower the charge transfer process, the more identical [18] and [19] become since as $R_t \to \infty$, $1 >> 1/R_t[R_T/(K+1) + R_u]$. This shows that the slower the faradaic process, the less τ_{min} will be affected by it, which is entirely reasonable since this essentially means that all faradaic time constants are large compared to both the effective double-layer charging time constant, R_uC_d, and the potentiostat time constant, τ_p.

The above result may be generalized by allowing $Z_E(s)$ to be given by

$$Z_E(s) = \frac{Z_F(s)}{1 + Z_F(s)C_d s} \qquad [20]$$

which considers the faradaic impedance, $Z_F(s)$, to be arbitrary and in parallel with C_d, a valid model for many electrode systems. Using [20], $i(s)$ is then

$$i(s) = \frac{K}{K+1}V(s)\left[\frac{C_d s + 1/Z_F(s)}{R_T[C_d s + 1/Z_F(s)]\tau_p s + [R_u + R_T/(K+1)][C_d s + 1/Z_F(s)] + \tau_p s + 1}\right] \qquad [21]$$

Equation [21] reduces to that for pure double-layer behavior (Eq. [17]) when $C_d s >> 1/Z_F(s)$, which occurs if frequencies (or times) may be achieved such that the overwhelming majority of current which flows serves only to charge the double layer. It is thus only when the above condition is met that IR compensation may be employed validly in an electrochemical system exhibiting a faradaic process. Note that, in principle, a frequency range may always be achieved such that $C_d s >> 1/Z_F(s)$; however, this range may be entirely too high to be within the upper limit of stability set by τ_{min}.

It is appropriate at this point to examine the criteria which might allow the unambiguous use of a potentiostat with IR compensation in the time or classical (a-c) frequency domain. To do this, consider $Z_E(s)$ to be given by Eq. [13], *i.e.*, charge transfer in parallel with C_d. The desired current response in the absence of any potentiostat parameters is

$$i(s) = V(s)\left[\frac{C_d s + 1/R_t}{\tau_u s + 1 + R_u/R_t}\right] \qquad [22]$$

where R_u and τ_u are defined by Eq. [7] and [16], respectively. This equation allows for the fact that the potentiostat cannot be an infinite current source (1) by the existence of some uncompensated nonfaradaic resistance (R_u). Comparison of [22] with [14] shows that many conditions must be met before the two relationships become identical. However, the essential factors underlying these conditions are the speed of the potentiostat and of the faradaic reaction. Thus, [14] shows second order behavior while [22] is first order. It is therefore necessary that the term $\tau_c\tau_p s^2$ in [14] be negligible. This can be done by proper cell design and with a fast potentiostat. Cell design affects τ_c by reducing R_o (Eq. [15]) and the speed of the potentiostat affects τ_p (Eq. [8]) and R_o. It can therefore be seen that the smaller the closed loop time constant, τ_p, of the potentiostat, the more the system will behave as a first order system as predicted by [22]. Inspection of the remaining portions of [14] shows that it is essentially the relative values of potentiostat parameters which allow undesirable terms to be neglected. Thus, if the open loop d-c gain is high (>1000), the following conditions can be established: $K \cong K + 1$, $\tau_u >> \tau_c/(K+1)$ and, therefore, $R_u >> R_T/(K+1)$. The term $\tau_p(1 + R_T/R_t)$ is negligible if τ_p is small compared to τ_u and τ_c, *i.e.*, very fast potentiostat, and if $\tau_u/\tau_p >> R_T/R_t$. The latter condition is valid only if the charge transfer process (or the faradaic reaction

in general) is relatively slow and the potentiostat relatively fast. Note that when all of these conditions are met, it would not matter whether a faradaic reaction were present since the potentiostat itself no longer influences the results obtainable. It is to be remembered, however, that as critical damping is approached, indeed if present at all, then the above conditions cannot be met since a first order electrochemical system as considered here (Eq. [22]) does not predict critical damping behavior. This can be understood by considering the fact that as more and more positive feedback is employed, both τ_u and R_u become smaller, eventually rendering it more and more difficult to eliminate potentiostat parameters, *e.g.*, τ_u may approach the same order of magnitude as τ_p. In general, therefore, it is never possible to use the critical damping point as detection for optimum IR compensation in the presence or absence of a faradaic reaction if the results are to be interpreted in the time or classical a-c frequency domains at frequencies close to the critical damping frequency. The exception to the above occurs in those cases for which faradaic parameters do not contribute to τ_{min} or for sufficiently low frequencies and it is not desired to evaluate C_d in the presence of the electrode reaction. If this is so, it is then indeed advantageous to employ IR compensation so as to unmask the faradaic process for study at shorter times than possible otherwise since the upper frequency limit is higher when IR compensation is employed.

Experimental and Results

In order to illustrate the effect of the faradaic process on IR compensation, the basic circuit shown in Fig. 1 was employed. The electrode impedance Z_E is that found applicable for an electrode process involving adsorption (5) and is shown in Fig. 2. Here, the adsorption coupled charge transfer is given as a charge transfer resistance, R_t, in series with an adsorption capacitance, C_a. These are placed in parallel with the double-layer capacitance C_d. The details of the potentiostat circuit (Fig. 1) have been given in detail elsewhere (1).

Initial experiments were performed on an electrical equivalent circuit with $R_e = 500$ ohms, $R_i = 100$ ohms, $R_t = 50$ ohms, $R_o = 0$, $C_d = 0.15$ μF and $C_a = 1$ μF. The response at τ_{min} was compared with the faradaic components (R_t and C_a) both present and removed from the circuit. Representative current response curves to a potential step are shown in the photograph in Fig. 3. Here, the horizontal axis is 10 μsec per major division and the vertical axis is 20 μA per major division. The curves were obtained in the following sequence: τ_{min} was achieved with the faradaic parameters initially absent from the circuit (lower curve, Fig. 3). Note that this is normally the manner in which τ_{min} would be adjusted in an actual system, *i.e.*, in a region of the i-v curve exhibiting double-layer behavior only (3). With τ_{min} adjusted, the faradaic components were then placed in the circuit giving the upper curve in Fig. 3. It can be seen that some ringing is present indicating that the degree of positive feedback is too high. This damped oscillation is particularly

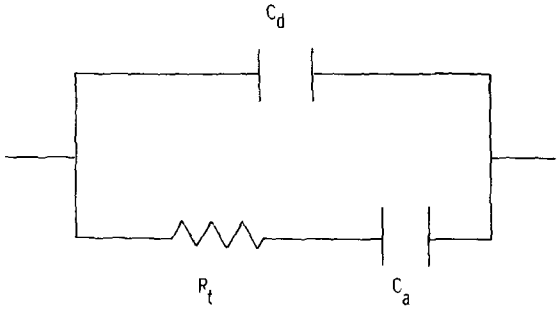

Fig. 2. Aperiodic equivalent circuit for an electrode exhibiting double layer behavior and adsorption coupled charge transfer.

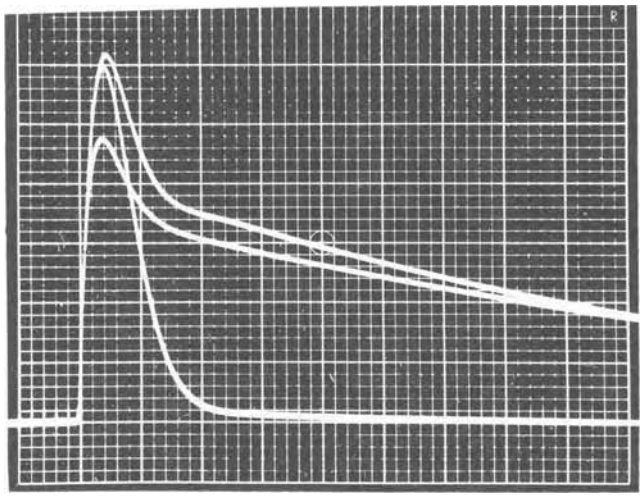

Fig. 3. Oscilloscope traces of current-time response curves to a voltage step input. Lower trace, τ_{min} with Z_F removed; upper trace, τ_{min} with Z_F replaced; center trace τ_{min} adjusted for most stable response (see text for details).

visible because a step function input perturbation [V(s)] was employed. It would be much less evident if a standard triangular or, in particular, a sinusoidal waveform were employed. In the latter case, a distortion analyzer would be needed to detect excitation of the ringing frequency, otherwise this effect would remain unnoticed with the use of, *e.g.*, standard phase sensitive detectors. The center curve in Fig. 3 is that for τ_{min} with no visible ringing in the presence of the faradaic components. It was achieved by reducing the amount of positive feedback by approximately 10% as predicted by the analysis in the previous section. The above results show that τ_{min} is indeed affected by faradaic parameters, particularly when there is significant reaction current at the ringing frequency, *i.e.*, the faradaic time constants are excited at τ_{min}.

In order to further illustrate the influence of the faradaic time constants upon IR compensation, consider the following. If τ_{min} is composed only of double layer and potentiostat parameters, then, in principle, at times longer (or frequencies lower) than τ_{min}, the system should behave as though the potential were constant across the faradaic impedance and the remaining uncompensated resistance (R_u). Thus for the circuit considered above, at all frequencies below those corresponding to τ_{min}, the impedance should appear as if it were given by

$$Z(s) = R_u + R_t + \frac{1}{C_a s} \qquad [23]$$

instead of its complete form which is

$$Z(s) = R_e + R_i + \frac{R_t C_a s + 1}{R_t C_a C_d s^2 + (C_d + C_a)s} \qquad [24]$$

The use of Eq. [23] to generate a usable $i(t)$ function requires that C_a receive no significant charge during the time required to achieve τ_{min}. In addition the time required to achieve constant potential conditions across the circuit represented by Eq. [23] must be taken into account. For this a true step function [$V(s) = V_o/s$] cannot be assumed as the input perturbation. It is, in fact, difficult to determine the exact function for this quantity, however, for evaluation of the results in the time domain, an explicit function must be employed. To a first approximation exponential behavior can be assumed. In this case $i(t)$ should be given by, for all times after the peak current (see Fig. 3)

$$i(t) = \frac{V_o}{R_u + R_t}\left[1 + \frac{1/(R_u + R_t)C_a}{a - 1/(R_u + R_t)C_a}\right] \exp\left(-\frac{t}{(R_u + R_t)C_a}\right) \quad [25]$$

where a is the reciprocal of the time constant for the rise of $V(t)$ to V_o at the current peak. Inspection of [25] shows that a linear ln $i(t)$ *vs.* t plot should be obtained having an intercept at the time of the current peak which is complex enough to render the desired quantities R_u, R_t, and C_a difficult to obtain in the most general case. In any event, linearity in ln $i(t)$ *vs.* t should be sufficient indication that faradadic contribution to τ_{min} is negligible provided that the linearity extends to times relatively close to those corresponding to τ_{min}.

In view of the above, Eq. [25] was tested for the circuit given earlier using the $i(t)$ curves shown in Fig. 3. The remaining uncompensated resistance R_u was evaluated in the absence of Z_F (lower curve, Fig. 3). This could be done with Eq. [19] as described previously (1) giving $R_u = 14$ ohms (where initially $R_e + R_i = 600$ ohms). The faradaic parameters were then inserted and ln $i(t)$ *vs.* t examined. Note that at all times from the current peak to that at which the current changes slope, this plot is not valid for the circuit corresponding to Eq. [23] since double-layer charging is also taking place during this time interval. In addition, ringing occurs in the region of slope change indicating that all times before this point relate to τ_{min}. It is, however, valid to consider that constant potential has been achieved at the current peak as far as the faradaic process is concerned. With these points in mind, it is important to note the shortest time at which nonlinearity in the ln $i(t)$ *vs.* t plots occurs. This can be seen in Fig. 4 (curve for $C_a = 1$ μF) where deviation from linearity is visible at approximately 15 μsec which is very close to that time at which $i(t)$ changes slope (see Fig. 3). The parameters calculated using Eq. [25] were $R_u + R_t = 66$ ohms and $C_a = 0.95$ μF, which is in fairly good agreement with their known values ($R_u + R_t$ should be 64 ohms). It is to be noted, however, that the most accurate results could only be achieved using the center curve in Fig. 3, *i.e.*, the most stable system response. This required, as indicated earlier, reduction of the amount of positive feedback from that for which stable response could be achieved in the absence of Z_F. Naturally, in this case the amount of positive feedback could be rendered identical; however, in an electrochemical system, this approach is not possible.

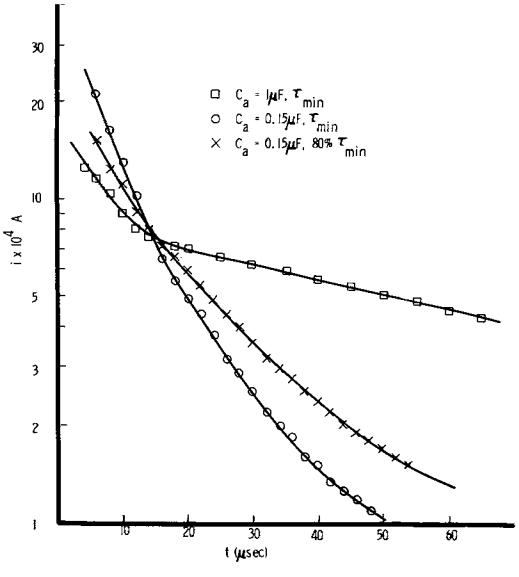

Fig. 4. ln $i(t)$ *vs.* t plots at τ_{min} for system with electrode impedance as shown in Fig. 2.

A further test of this analysis was made on the same circuit as previously employed with $C_a = 0.15$ μF, effectively changing Z_F by one order of magnitude as compared to the previous case. The procedure for determination of R_u was as above, however, as the semilogarithmic plots in Fig. 4 show, linearity was not obtained at τ_{min} or at 80% τ_{min}. This indicates the large influence of Z_F on both the over-all system stability and its response at a degree of positive feedback considerably below the ringing frequency.

The above appears to illustrate the conditions for which the faradaic contribution to τ_{min} are negligible; however, the situation is more complex than could be expected from these results. Thus, as the first case ($C_a = 1$ μF) shows, R_u was not negligible compared to R_t requiring its evaluation for meaningful values of R_t and C_a. The problem is then to evaluate R_u in every case (which would also allow knowledge of C_d). This cannot be done from a knowledge of τ_{min} alone. Thus an attempt to evaluate R_u and C_d from time domain ln $i(t)$ *vs.* t plots even in the case of pure double-layer behavior was unsuccessful (1). This is to be expected since a simple RC series circuit does not exhibit ringing except under conditions of positive feedback when potentiostat parameters become involved, as indicated earlier. The situation is even more serious when classical (a-c) impedance techniques are employed since τ_{min} is difficult to detect without distortion analysis. In principle, however, when correct detection techniques are employed R_u and C_d could be separately evaluated provided potentiostat contribution, *e.g.*, τ_p, can also be determined.

In addition to the above it is quite certain, as can be seen from Fig. 3, that τ_{min} varies somewhat, even in the best of cases, from that obtainable in the absence of Z_F. Further, since C_d generally varies with potential, τ_{min} cannot be expected to remain constant throughout the potential region of interest even when Z_F contributes negligibly. Thus as Eq. [19] shows, τ_{min} varies with τ_c which contains C_d. An example of this phenomenon has been reported recently for the $C_d(NO_3)_2$ system (9).

As can be seen from the preceding results, the use of IR compensation is subject to a great deal of ambiguity whether or not the faradaic process contributes to τ_{min}, even in the relatively simple case examined here. As the system becomes more complex, it would be necessary to derive expressions for $i(t)$ (for time domain analysis) allowing $Z_E(s)$ to take every possible form. This, of course, can be done. However, the resulting equations rapidly become unmanageable in a practical sense and would not in any case provide a good working method for the use of positive feedback. Further, in order to even develop working equations in the time domain, it is necessary to accurately know the analytical form of the input perturbation which may in general be difficult to estimate.

The above difficulties can be eliminated to a large extent by the use of the Transient Impedance Technique which allows $Z(s)$ to be examined. This quantity is obtainable in terms of the present study by the division of Eq. [12] for $E(s)$ by Eq. [10] for $i(s)$. The resulting expression is

$$Z(s) = \frac{E(s)}{i(s)} = R_e + R_i + Z_E(s) \quad [26]$$

in which it can be seen that only those quantities appearing across the potentiostat control points appear in the final results, positive feedback having no influence. This approach has been described in detail elsewhere (1, 5).

Conclusion

The above study indicates that the use of IR compensation in the presence of a faradaic reaction must be carried out with extreme caution. In general, faradaic time constants do contribute to the over-all system stability although under certain conditions their

contribution is not significant. It is, however, difficult to determine, even in an *a posteriori* manner, the amount of remaining uncompensated resistance, R_u. Thus experiments with a known system show the expected range of faradaic influence (involving considerable error even in this case if R_u had not been known); however, an unknown system certainly cannot be anticipated in such a manner. The problem now reduces to whether or not IR compensation should ever be employed. The answer depends on the manner in which the experiments are performed and, in particular, the way in which the results are interpreted. Thus, in time domain experiments, IR compensation should only be employed if it is known that the faradaic process is relatively slow and R_u can be unambiguously evaluated by using, *e.g.*, 80% τ_{min}. Note, however, that the slower the electrode reaction, the less necessary IR compensation becomes. In the classical (a-c) frequency domain, it has already been shown (1) that the use of the input perturbation $[v(s)]$ for phase reference necessitates the use of frequencies at least two orders of magnitude lower than that corresponding to τ_{min} for minimum error. This problem becomes more complex in the presence of Z_F. The use of positive feedback is rendered less ambiguous, particularly at high frequencies, if the results are interpreted using the Transient Impedance Technique (5). This is so since potentiostat parameters can conveniently be eliminated from the final impedance expression while the system is unmasked experimentally from the effects of R_e. Note that when this approach is employed, R_e is not reduced in any way in the final result; however, the experimentally accessible information content of the response function is greatly increased allowing much higher precision in the final results.

Structural Transition in Strong-Acid Membranes

R. A. Wallace* and B. K. Jindal

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

To illustrate the effects of glass transition on ion transport in polystyrenesulfonate cation-exchange membranes, membrane d-c conductivities have been measured over a wide temperature range. Membranes were loosely crosslinked with 1% divinylbenzene and contained up to 10% by weight of styrene-sulfonic acid. Membrane conductivity obeys the Arrhenius equation with apparent activation energy values ranging from 11 to 16 kcal/mole in the glassy membrane and 15 to 22 kcal/mole in the rubberylike membrane. Computed diffusion coefficients of hydrogen ions increase with sulfonic acid content and are appreciably higher in the rubbery than in the glassy membrane states.

Membranes are widely used in electrodialytic desalting processes and electroseparation processes as ion-selective membranes and in fuel cells as solid electrolytes. Structural changes within membranes would likely cause marked changes in their mechanical and electrochemical properties. A very important structural transformation of amorphous materials, such as sulfonated polystyrene membranes, is glass transition. The temperature at which amorphous polymers when cooled solidify to a glass is called the glass transition temperature, T_g.

Above T_g, the polymeric membrane is soft and liquidlike because the chains are mobile; below T_g, it is hard and brittle on account of freezing in of chain segmental motion. Knowledge of membrane T_g and its influence on molecular rate transport might serve as a guide in improving membrane function and processes. In this paper, we present results of our T_g measurements and illustrate the effects of this structural transition on electrical transport within sulfonated polystyrene membranes of varying degrees of sulfonation.

* Electrochemical Society Active Member.

Key words: phase transition in membranes, cation-permeable membrane, hydrogen-ion transport.

For purposes of illustration, we prepared cation-exchange membranes containing up to 10% by weight of styrenesulfonic acid by sulfonating polystyrene films which were loosely crosslinked with 1% by weight of divinylbenzene. In these solid membranes, ion transport, under a d-c field, occurs primarily by migration of hydrogen ions resulting from dissociation of sulfonic acid groups (1). In correlating membrane T_g and ion conduction, the passage of mobile hydrogen ions under the influence of external electric field is considered as hopping from one sulfonate anion exchange site to the next. Ionic conduction is treated as a molecular diffusion process and is interpreted from a kinetic and thermodynamic view.

Experimental

Sulfonated polystyrene membranes containing up to 10% by weight of styrenesulfonic acid were prepared by casting a 20% solution of polystyrene (viscosity-average molecular weight of 500,000) in benzene on glass plates followed by sulfonation by the method of Chen *et al.* (2). Test membranes, 2 cm in diameter and 0.03 cm in average thickness, were dried under vacuum at 80°C prior to testing.

Membrane conductivities were measured over the temperature range 70°-170°C using a Keithley electrometer Model 610-Q, a Trigon Electronics d-c power supply Model HR40-750, and a guarded brass electrode assembly. The electrode assembly was placed in an electric oven maintaining temperatures within ±0.3°C. Membrane d-c conductivity σ was calculated from the equation $\sigma = (tI)/VA$ where t, I, V, and A are sample thickness, current, voltage, and electrode area, respectively. Tests were run at constant voltage of 10V d.c. Membranes were heated at a rate of 1°C per 2 min. Once a steady temperature was reached, current was recorded.

Results and Discussion

Membrane conductivity increases exponentially with temperature and is expressed by

$$\sigma = \sigma_0 \exp(-E_a/RT) \quad [1]$$

where E_a is the apparent activation energy of conduction and σ_0 a pre-exponential constant. Figure 1 shows the results of several membrane conductivity runs with sulfonic acid content as a parameter. Over the temperature and concentration range used, membrane conductivity obeys Eq. [1]; however, a break in the log σ *vs.* $1/T$ plot occurs to signify glass transition. Because the rate of increase of conductivity with temperature is faster above T_g than below T_g, E_a is greater in the liquid than in the glassy membrane states.

Table I lists values of apparent activation energies for the membrane ionic conduction process. These values vary from 11 to 16 kcal/mole in the glassy region and from 15 to 22 kcal/mole in the liquid region. Comparison with ionic conduction in liquid glasses yields good agreement (3). For AMF C-60 (polystyrenesulfonic acid entrapped in a polyethylene matrix) membranes, E_a is reported as 22 kcal/mole between 28° and 54 °C (1). In this temperature range, polyethylene is well above its T_g and explains why the reported E_a values agree well with our results.

Membrane T_g and conduction.—The influence of sulfonic acid concentration on membrane conduction is illustrated in Fig. 1. Membrane conduction increases with sulfonic acid content, apparently due to increasing concentration of hydrogen ions. On the other hand, membrane T_g rises with sulfonic acid content on account of progressively higher dipolar attractive forces within the membrane. T_g values are in good agreement with our correlation (2) obtained dilatometrically which is given by

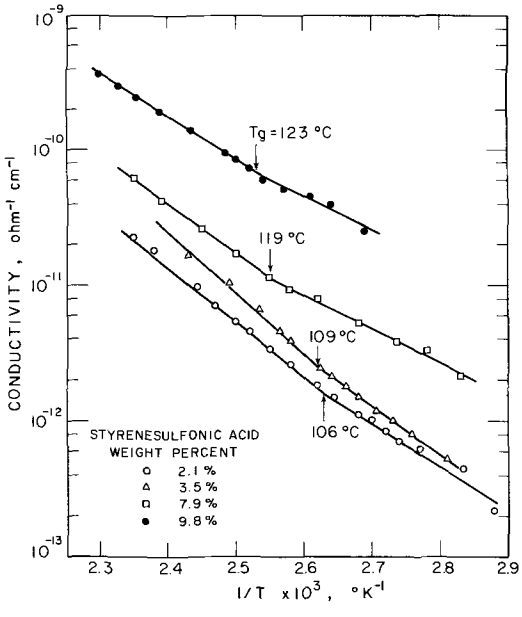

Fig. 1. Dependence of conductivity of sulfonated polystyrene membranes on temperature.

Table I. Apparent activation energies for conduction process below and above membrane T_g

Membrane T_g, °C	w/o of styrenesulfonic acid	E_g, kcal/mole	E_l, kcal/mole
100	0.0	16.4	21.0
106	2.1	14.2	17.9
109	3.5	16.3	21.8
118	8.1	15.8	21.6
119	7.9	11.2	17.5
123	9.8	11.3	15.7

$$T_g = T_{gB} + 200\, w_A \qquad (w_A < 0.15) \quad [2]$$

where T_{gB} is the glass transition temperature of loosely crosslinked polystyrene matrix and w_A is weight fraction of styrenesulfonic acid.

Ion conduction process.—The exponential temperature dependence of σ can be developed by treating the ionic diffusion process as a special case of the more general reaction rate theory for activated processes (4). Conduction under a unidirectional field involves the migration of hydrogen ions along the sulfonated polystyrene chains by hopping from one sulfonic acid site to the next. Midway between these two positions is the activated state, and hence the individual reaction to form the activated complex is: hydrogen ions (stable) → hydrogen ions (activated). Reaction rate theory provides us with the relation for diffusion coefficient of hydrogen as defined by Fick's law

$$D = \bar{\lambda}^2 \frac{RT}{Nh} \exp(\Delta S^{\ddagger}/R) \exp(-\Delta H^{\ddagger}/RT) \quad [3]$$

where λ, $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and N are effective jump distance of hydrogen ions in the direction of diffusion, enthalpy of activation, entropy of activation, and Avogadro's number, respectively. Combining Eq. [3] with the Nernst-Einstein relation (5) yields the expression for conductivity

$$\sigma = \frac{ce^2\bar{\lambda}^2}{h} \exp(\Delta S^{\ddagger}/R) \exp(-\Delta H^{\ddagger}/RT) \quad [4]$$

with c, e, and h as concentration of mobile hydrogen ions, electronic charge, and Planck's constant, respectively. The concentration of hydrogen ions depends on the degree of dissociation which, in turn, varies with moisture content and temperature. Dissociation is difficult for the membranes at hand because they contain only trace amounts of water. From Eq. [4] and the expression of Fuoss (6) for ion-pair equilibrium constant, we get

$$\sigma = \frac{\sqrt{c_0 K_0}\, e^2\bar{\lambda}^2}{h} \exp(\Delta S/R) \exp\left(-\frac{\Delta H^{\ddagger} + U/2}{RT}\right) \quad [5]$$

where c_0 is the total sulfonic acid concentration, K_0 is a constant, and U is the molar energy required in ion-pair separation in a dielectric. It should be noted that Eq. [5] predicts the conductivity-temperature relationship as given by Eq. [1] with

$$\sigma_0 = \frac{\sqrt{c_0 K_0}\, e^2\bar{\lambda}^2}{h} \exp(\Delta S^{\ddagger}/R) \quad [6]$$

and

$$E_a = H + U/2 \quad [7]$$

Using Eq. [6] we have estimated the transport entropy of activation of hydrogen ions (listed in Table II) in terms of the jump distance. To compute $\Delta S^{\ddagger}$, estimated values of $\bar{\lambda}$ should be used. For pure polystyrenesulfonic acid, Grubhofer (7) measured a value of 8.2 x 10^{-8} cm as the distance between adjoining sulfonic acid group. Since the chains are randomly distributed, $\bar{\lambda}$ in this case would be approximately 8.x

Table II. Estimated values of activation entropy for the membrane conduction process

T_g, °C	w/o of styrenesulfonic acid	$\bar{\lambda}^2 \exp(\Delta S^{\ddagger}/R)$ Below T_g	Above T_g
106	2.1	1.76×10^{-10}	1.81×10^{-8}
109	3.5	2.47×10^{-9}	3.9×10^{-6}
119	7.9	7.5×10^{-12}	2.51×10^{-8}
118	8.1	2.18×10^{-9}	3.32×10^{-6}
123	9.8	9.1×10^{-12}	1.08×10^{-8}

Table III. Calculated values of diffusion coefficients of hydrogen ions below and above T_g

Membrane T_g, °C	w/o of styrenesulfonic acid	$D\phi$, cm²/sec Diffusion coefficient × degree of dissociation $T = T_g - 30$°C	$T = T_g + 30$°C
106	2.1	7.4×10^{-16}	3.1×10^{-14}
109	3.5	6.8×10^{-16}	3.1×10^{-13}
119	7.9	2.5×10^{-15}	4.2×10^{-13}
118	8.1	1.2×10^{-15}	5.6×10^{-14}
123	9.8	1.4×10^{-14}	1.6×10^{-12}

$\times 10^{-8} \cos 45°$. On the assumption that the distance between sulfonic acid sites is roughly linearly proportional to sulfonic acid content, the effective jump distance in partially sulfonated membranes can be approximated. Thus for a membrane containing 9.8% of styrenesulfonic acid, $\bar{\lambda}$ is 7×10^{-7} cm and $\Delta S^{\ddagger}$ is 6.7 cal/mole $-$°K below T_g and 20.8 cal/mole $-$°K above T_g.

The highly positive values of entropy of activation of hydrogen ions within the solid charged membrane in its essentially dry state suggests that the activated state is much less ordered than the stable state. Furthermore, as pointed out by Boyd and Soldano (8), ionic diffusion may be accompanied by breakage of van der Waals bonds when $\Delta S^{\ddagger}$ is highly positive. Segmental motion above T_g would then explain the increase in $\Delta S^{\ddagger}$ as the membrane goes through its glass transition. For the wet membrane, on the other hand, ΔS tends to decrease. This is due in part to the negative contribution from the electro-restriction of water accompanying the separation of charge in forming the activated complex (8).

Table III lists values of diffusion coefficients of hydrogen ions in terms of degree of dissociation of sulfonic acid groups estimated from the Nernst-Einstein equation. These values show a rising trend in diffusion coefficients with greater sulfonic acid concentration. Glass transition results in an appreciably higher D value in the liquid state than in the glassy membrane. An estimate of D can be obtained by approximating ϕ using Fuoss's developed relation (6). For instance, for a membrane with 9.8% sulfonic acid content, setting the dielectric constant equal to 6, ϕ is 1.7×10^{-6} and D is 8×10^{-7} cm²-sec^{-1}.

Electrode Studies in Nonaqueous Electrolytes

III. The Sodium Electrode in $NaClO_4$-Propylene Carbonate Solutions

Stuart G. Meibuhr*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The exchange current density (i_0) of smooth Na electrodes immersed in propylene carbonate solutions containing $NaClO_4$ or $NaPF_6$ was determined by galvanostatic methods. In 1*M* $NaClO_4$ the ΔH_0^* value = 14.6 kcal/mole. The i_0 value was strongly dependent on the Na^+ ion concentration, approximately 2 orders of magnitude decrease in i_0 with 1 order of magnitude decrease in Na^+. The results showed that the kinetics of the Na/Na^+ reaction in propylene carbonate are, at best, about equivalent to those for the Li/Li^+ electrode.

The number of studies of negative electrode materials in organic solutions recently has increased owing to the interest in nonaqueous electrolyte batteries. Lithium, magnesium, calcium (1-3), aluminum (2), and beryllium (4), all have been proposed and tested as negative electrode materials. Lithium amalgams in dimethylsulfoxide (DMSO) (5, 6) and calcium amalgams in propylene carbonate (PC) (7) were examined to determine both the activity of the metal in the amalgam and the standard electrode potential measured against a suitable reference electrode.

Electrode kinetic studies also have received attention. Kinetic studies of the $Li(Hg)/Li^+$ reaction in DMSO (8) yielded the standard rate constant in LiCl-DMSO solution at 25° of $(2.9 \pm 0.2) \times 10^{-5}$ cm/sec, a transfer coefficient value, α, of 0.75 ± 0.02, and an enthalpy of activation of 7.9 kcal/mole. Examination (9-11) of the solid Li/Li^+ electrode in $LiClO_4$-PC solutions resulted in values for the exchange current density (i_0) at 23° of about 0.7 mA/cm² (10, 11); α had a

Table I. The i_0 values for different experimental conditions

$NaClO_4$ concentration (M)	Temperature (°C)	i_0 (mA/cm²)
1.0	19	0.21
	37	0.90
	52	2.6
	66	6.77
0.5	19	0.012
0.1	19	0.0005

temperature independent value of two-thirds. These values occurred only at passivated electrodes (at low current densities). It has also been shown (12, 13) that these values are typical of Li electrodes which have been immersed into the solution for periods up to about 30 min regardless of the solute; i_0 values determined within 1 sec after a freshly cut Li surface was exposed to the solution showed higher i_0 values (12). At active electrodes, (higher current densities), i_0 was found to be equal to 1.78 ± 0.33 mA/cm² (11).

This note gives the results of a kinetic study of the previously ignored Na/Na^+ electrode in $NaClO_4$-PC solutions under experimental conditions that yielded reproducible polarization data.

Experimental

The PC solvent was purified by distillation as described before (14). The $NaClO_4$ solute was of the highest purity available (G. F. Smith Chemical Co.); it was dried at 120° in a vacuum for 4 days, cooled, and promptly transferred to a dry box. The $NaPF_6$ (Alfa Inorganics, Inc.) was used without further purification. The experimental procedure for the solution preparation, and the procedure and equipment used in making the galvanostatic polarization measurements have already been reported (10). The sodium electrodes were prepared in a dry box, manufactured by Vacuum Atmospheres Corporation, in a manner similar to a technique used for making a Pb electrode (15). A freshly polished Fe wire was used as the lead. Three such electrodes (0.06 cm²), served as test, counter, and reference electrodes.

The exchange current density was calculated for every current value with a computer program from the equation

$$i_0 = iRT/\eta_{(iR\text{-free})}F \qquad [1]$$

Reproducible i_0 values were obtained on new Na electrodes only after they were anodized for 10 min at 2 μA/cm². Electrodes so treated gave reproducible data for about 4 days before another anodization became necessary. The potential between the working and reference electrodes at open circuit remained <0.5 mV.

Results and Discussion

Figure 1 displays the linear anodic iR-free polarization data for a Na electrode in 1M $NaClO_4$-propylene carbonate solution for temperatures from 19° to 66°C. Duplicate runs yielded slopes that agreed with one another within 15%, which is somewhat poorer reproducibility than noted for the Li/Li^+ reaction (10). The i_0 variations with temperature and Na^+ ion concentration are recorded in the table. Note that the i_0 value decreased very sharply with a decrease in Na^+ ion concentration, approximately 2 orders of magnitude decrease in i_0 with 1 order of magnitude decrease in Na^+ ion. This decrease is greater than was observed for the Li/Li^+ reaction in ClO_4^- solution (10).

The solute $NaPF_6$ was considerably less soluble than the $NaClO_4$ and only very low i_0 values were obtained at Na electrodes in $NaPF_6$-PC solutions. At saturation, (about 0.3M), the i_0 value was 0.002 mA/cm² at 21°. The low i_0 values were not due to a high concentration of water because the Karl Fischer analysis showed that these solutions contained less than 30 ppm. Thus, the rapid decrease of i_0 with Na^+ ion concentration appears to be a real function of the concentration and not an artifact of some impurity such as water.

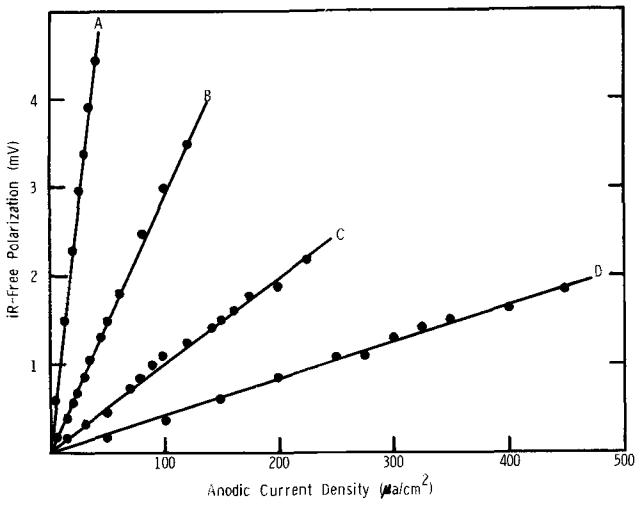

Fig. 1. Current density-iR free polarization data for a 1M $NaClO_4$ solution. Curve A, 19°C; B, 37°C; C, 52°C; D, 66°C.

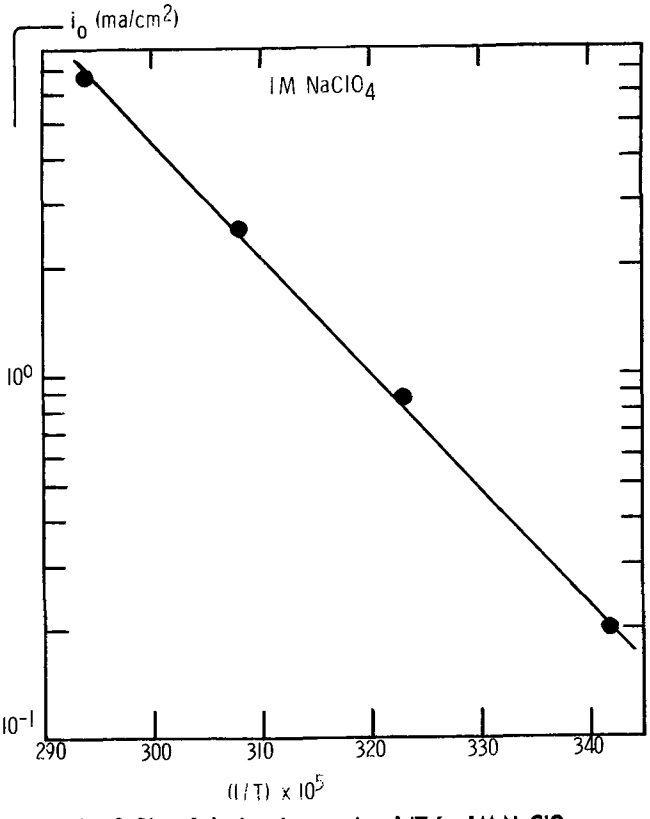

Fig. 2. Plot of the i_0 values against 1/T for 1M $NaClO_4$

The enthalpy of activation at zero polarization (ΔH_0^*) was calculated from the results of the temperature variation using the equation

$$\frac{\partial \ln i_0}{\partial (1/T)} = \frac{\Delta H_0^*}{R} \qquad [2]$$

A plot of the log i_0 against 1/T is exhibited in Fig. 2. The value for ΔH_0^* was 14.6 kcal/mole. This value, being somewhat higher than expected for metal dissolution (~10 kcal/mole), suggests that there may occur (a) reduction of the organic solvent or some other organic component such as ethylene carbonate; (b) adsorption of the solvent at the Na electrode interface; (c) some other process. However, no evidence of chemical degradation of the solvent was apparent at any temperature during the course of these experiments. No color change in the solvent, no blackening of the electrode, no gas evolution, all indicate that no chemi-

cal degradation occurred. Consequently, the unusually high ΔH_0^* value may be either real or due to adsorption.

To obtain reproducible polarization data on Na, it was necessary to anodize the test electrode. Electrodes, when immersed into the ClO_4^- solution, gave nonreproducible and very low i_0 values. A brief anodization (10 min at 2 $\mu A/cm^2$) activated the Na, perhaps by removing an oxide or hydroxide, and allowed reproducible data to be made. Subsequent brief cathodic pulses (for periods up to 10 min) did not destroy the active Na surface.

These results showed that the kinetics of the Na/Na^+ reaction in PC, at best, are about equivalent to those for lithium but are much more dependent on the Na^+ concentration than is the case for the Li reaction.

Technical Notes

Differential Capacitance Study of Stress-Annealed Pyrolytic Graphite Electrodes

Jean-Paul Randin[1] and Ernest Yeager*

Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

In recent years, high-pressure stress-annealed pyrolytic graphite has become available. This material has a near perfect orientation along the c-axis, and its structure is much more defined than that of the pyrolytic graphite used by prior workers (1). The basal plane of this material provides a rare opportunity to study the electrochemical properties of a surface in which all the surface valencies are satisfied in the plane of the surface.

The present study has been directed to the study of the differential capacity of this surface in aqueous solutions using an a-c impedance bridge.

Experimental Section

The stress-annealed pyrolytic graphite used in this study[2] showed a rocking curve whose mosaic spread is approximately 0.3° to 0.4° width at half-maximum intensity of the (002) x-ray diffraction line. The measured 2d interplanar spacing is 6.713 ± 0.002Å compared with 6.7078 ± 0.0002Å for the single crystal. The graphite electrodes were machined under compression into circular disks with a diameter of 5 mm. These graphite disks, backed with nickel to increase their mechanical strength, were then press-fitted into a Teflon holder. A fresh electrode surface was exposed for each experiment by placing a piece of plastic adhesive tape, cut to the exact size, in contact with the graphite surface and then peeling off a layer of graphite with the tape. Care was taken not to contaminate the Teflon surrounding the graphite disk with the adhesive on the plastic tape. The graphite surface so exposed had the appearance of a black mirror, and no plane other than the basal plane has been observed by microscopic examination under 800× magnification.

The electrochemical cell was made entirely of Teflon. The main compartment contained the working electrode and a 99.99% gold disk-shaped counterelectrode (9 cm diam, 0.01 cm thick), located parallel to the working electrode at a distance of about 4 cm with one side against the bottom of the Teflon cell. This electrode was used for only the a-c impedance measurements. Gold was chosen for the counterelectrode since it should not dissolve in helium-saturated sodium fluoride solutions. Two separate compartments were connected to the central compartment for the auxiliary and reference electrodes. The auxiliary electrode was used for the d-c polarization of the working electrode. Both the auxiliary and reference electrodes were 99.99% palladium foil (2.9 cm diam, 0.01 cm thick) over the rear of which was passed purified hydrogen. The reference electrode compartment was connected to the main compartment via a Luggin capillary, and the auxiliary compartment was connected to the main compartment by a short tube (1 cm diam, 5 cm long), filled with the same solution as the main compartment. The auxiliary and reference Pd electrodes were charged with hydrogen (purified with an Englehard

Industries Pd-Ag alloy diffuser) in order to form a stable H-Pd alloy, the β-phase (2).

The experiments were performed in a nitrogen atmosphere glove box to reduce contamination by atmospheric components and to minimize possible incorporation of dust and dirt in the cell. Nitrogen was continuously purged through the box.

The solutions of sodium fluoride (Baker Analyzed Reagent) were prepared by dissolution in nitrogen-saturated triple distilled water (second distillation from alkaline permanganate). Trace contaminants were removed by treatment of the electrolyte with purified active charcoal and *in situ* pre-electrolysis performed with a 50 cm^2 gold cathode in the main compartment polarized to $-0.9V$ *vs.* the H/β-Pd reference for at least 24 hr with helium bubbling. The helium was purified with copper turnings maintained at about 450°C and molecular sieves (Linde Type 3A and 13X). This gas was bubbled through the solution before and during the measurements.

The measurements of the equivalent series capacitances and resistances were carried out at 25°C with an a-c bridge and polarization circuit. This bridge has been checked with standard resistance and capacitance components and found to contribute a negligible error over the range of frequencies covered in this paper (100 Hz to 20 kHz). The a-c voltage applied to the cell did not exceed a few millivolts.

All capacitances are given in terms of apparent electrode area. The true area has not been taken into account, but the ratio of the true to apparent area should be essentially unity for the basal plane of stress-annealed pyrolytic graphite.

Results and Discussion

In a recent paper, Bauer, Spritzer, and Elving (1) studied the differential capacity of a pyrolytic graphite disk electrode whose structural characteristics were not defined in the paper. These authors observed a frequency dependence of both the series capacitance and resistance. Bauer *et al.* suggested that this frequency dispersion might be at least in part the result of the electrode geometry, since the distribution of current at a disk electrode is not uniform across the surface.

Preliminary measurements in the present study also showed a frequency dispersion. Consequently, an attempt was made to minimize the nonuniform current distribution on the disk solid electrode surface by using a Teflon hood of the type shown in Fig. 1. A circular lip, which made a line seal with the graphite electrode, was incorporated in the Teflon hood. The internal diameter of the hood (4 mm) was smaller than that of the graphite disk (5 mm). The depth of the hood was chosen to be the same as its diameter, *i.e.*, 4 mm. Preliminary tests showed that this dimension had no significant effect on the frequency dispersion.

Beside providing a more uniform current distribution on the electrode, the hood restricted the effective area of the electrode to the center of the disk and hence minimized problems associated with orientations other than the basal plane, present along the periphery of the disk where it fitted into the Teflon holder. Measurements on the edge orientation (plane perpendicular to the basal plane) indicate capacities of at least one order of magnitude higher than on the basal plane and hence even a small fraction of the surface other than the basal orientation can lead to a serious error.

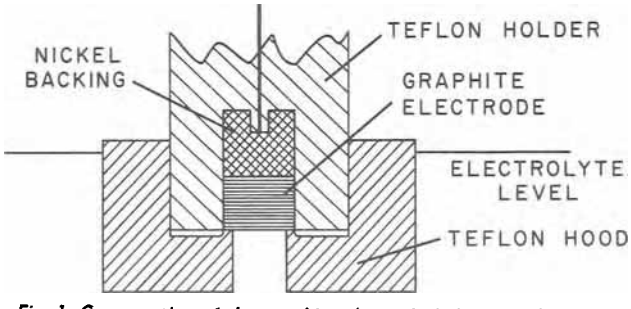

Fig. 1. Cross section of the graphite electrode holder and hood

The frequency dispersion for the basal plane of stress-annealed pyrolytic graphite in 0.9*M* NaF is shown in Fig. 2. Without the hood, the magnitude of the dispersion is comparable with that reported by Bauer *et al.* (1), although not as large. With the Teflon hood the frequency dispersion is negligible (see Fig. 2), provided the hood is slipped onto a freshly peeled dry electrode. On the other hand a small frequency dispersion is evident (see Fig. 2) if the hood is slipped onto a wet electrode, prepared by peeling off a layer from the basal plane under the surface of electrolyte in a separate container and then transferred wet within the N_2-filled glove box into the cell. This frequency dispersion is attributed to the electrolyte film between the graphite surface and the Teflon hood. When the two surfaces are dry, the small gap between the hood and the portion of the graphite covered by it does not normally fill with electrolyte because of the hydrophobic properties of the two surfaces.

Usually the capacity measured on the electrode peeled off dry was lower than that of the same electrode peeled off under the electrolyte. The reproducibility of the capacity at a given frequency also was less with electrodes peeled in either air or the nitrogen within the glove box rather than under the surface of the electrolyte. Under extreme conditions, the variation in capacity was as much as 100% with the electrodes peeled dry as compared with a variation of only 5% for electrodes peeled wet. Consequently all further measurements reported in this paper have been carried out with electrodes peeled off under electrolyte and the hood subsequently slipped on.

The lack of any appreciable frequency dispersion in 0.9*M* NaF on the basal plane of stress-annealed pyrolytic graphite with the Teflon hood is to be expected for a solid electrode provided the surface roughness is small. The mirrorlike appearance of the surface with direct visual examination as well as microscope examination (800×) both imply that surface roughness is very small. In the case of a semiconductor electrode (see the following discussion), the lack of frequency dispersion at audio frequencies also implies either that the surface electronic states contribute very little to the observed capacity on the basal plane or that the surface electronic states have very short or very long relaxation times.

The capacity measured at a fixed potential on the basal plane also decreased slowly with time. This decrease was usually smaller than 3% in 15 min with electrodes peeled wet while the series resistance remained virtually constant. This rate of decrease did not vary significantly with the applied potential in the range $+0.5$ to $-0.5V$ re NHE, with the frequency in the range 100 Hz to 20 kHz, or with stirring. The rate

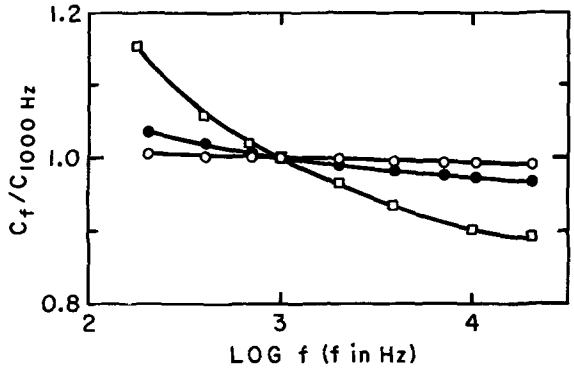

Fig. 2. Frequency dependence of capacity for the basal plane of stress-annealed pyrolytic graphite in 0.9M NaF at 25°C at a potential of +0.2V *vs.* NHE: □ without hood, layer peeled off under electrolyte; ○ with hood, layer peeled off dry; ● with hood, layer peeled off under electrolyte.

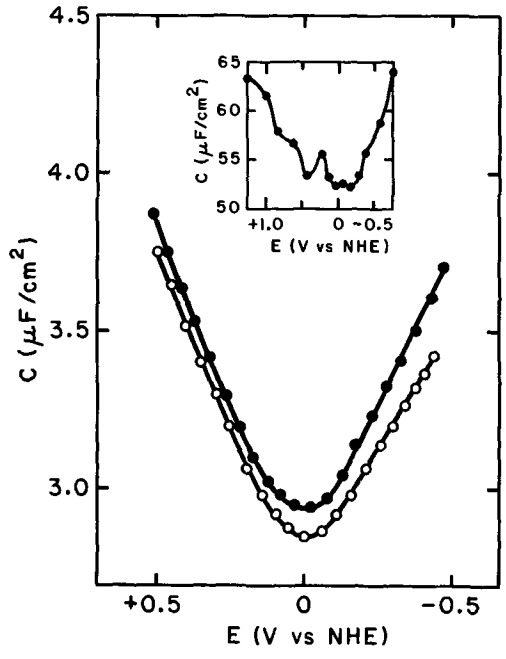

Fig. 3. Capacity-potential curves for the basal plane of stress-annealed pyrolytic graphite in NaF (pH $\simeq$ 6) at 25°C and 1000 Hz. With hood, layer peeled off under electrolyte: ●, 0.9M NaF; ○, 0.1M NaF. Insert figure: Bauer, Spritzer, and Elving (1) data in 0.5M KCl; resurfaced by polishing; frequency: 1000 Hz.

of decrease was smaller with electrodes peeled off under electrolyte than peeled dry.

Since the time dependence of the capacity on the basal plane of wet peeled electrodes was so small, the capacity-potential curves measured point by point were essentially the same regardless of whether the values were measured with increasingly anodic or cathodic potentials. The values indicated in Fig. 3 were recorded point by point with potential increasing in the anodic direction. The shape of the capacity-potential curve is nearly symmetrical with respect to the minimum, is independent of the concentration of the electrolyte at concentrations in the range 0.01 to 1.0*M*, and does not exhibit the hump usually observed on metallic electrodes. The shape of the capacity-potential curve does not depend significantly on the way the electrode surface has been renewed (peeled wet or dry).

The series equivalent resistance was also measured but is not reported. Within the accuracy of the measurements, the data showed no significant variation with potential (*i.e.*, a variation of approximately 1 to 3 ohms out of 100 ohms over the potential range +0.5 to −0.5V *vs.* NHE).

The value of the apparent capacity at the minimum of the capacity-potential curve is low, *i.e.*, ~3 μf/cm^2, compared with values usually higher than 15 μf/cm^2 for metallic electrodes. In contrast, the apparent capacity at the minimum of the capacity-potential curve is about 16 μf/cm^2 for the polished basal plane of ordinary pyrolytic graphite ($\Delta\theta_{1/2} \simeq 40°$). Furthermore, the minimum capacity is 50 to 70 μf/cm^2 for the polished edge orientation of stress-annealed pyrolytic graphite ($\Delta\theta_{1/2} \simeq 0.4°$).

Table I compares the capacity data for ordinary and stress-annealed pyrolytic graphite obtained by Bauer *et al.* (1) and in the present study. Bauer *et al.* (1) reported values ranging from ~12 μf/cm^2 for the surface prepared by cleaving to ~60 μf/cm^2 for the polished basal plane of ordinary pyrolytic graphite measured at 1000 Hz. The insert in Fig. 3 gives the capacity-potential curve based on the data reported by these authors. The minimum value of the capacity as well as the potential dependence reported by these authors deviate substantially from that found on the

basal plane of stress-annealed pyrolytic graphite in the present study. The minimum value of the capacity reported by Bauer *et al.* for the polished basal plane of ordinary pyrolytic graphite, *i.e.*, ~60 μf/cm^2, should be compared with ~16 μf/cm^2 found in the present study for the same orientation of polished ordinary pyrolytic graphite. The different origin and preparation of the sample are probably responsible for the discrepancy.

The capacity measured on the basal plane of the graphite specimens with very small rocking angles (*e.g.*, $\Delta\theta_{1/2} \simeq 0.4°$) should approach the value for this plane on single crystal graphite. The minimum capacity of ~3 μf/cm^2 observed on the basal plane of such stress-annealed pyrolytic graphite is far too low to be explained on the basis of the usual ionic double layer structure within the electrolyte.

The differential capacitance of a semiconductor or semimetallic electrode-electrolyte interface is composed of three series components: the capacitance of the space charge layer within the semiconductor, that of the compact double layer, and that of the diffuse ionic layer of the electrolyte. For electrolytes of high concentrations, *e.g.*, 1*M*, the capacitance of the diffuse ionic layer is usually large, *i.e.*, >100 μf/cm^2, compared with the other two components. In this case, its contribution to the total capacitance is therefore negligible. The capacitance associated with the compact layer is expected to have a value of 10 to 20 μf/cm^2 in the absence of surface states on the basis of the values encountered with metal electrodes. The capacity of the compact double layer on the basal plane of graphite may differ appreciably from this value due to the nonpolar nature of the graphite surface, but it seems quite unlikely that this difference would amount to almost an order of magnitude. Consequently, the low observed capacity is best attributed to the space charge component within the graphite.

Unfortunately, the electrical properties (resistivity, carrier concentrations, and mobilities) are not known specifically for the materials used in the present study. For similar stress-annealed pyrolytic graphite, Spain *et al.* (3) have reported a resistivity in the basal plane of ~40 μohm/cm and a charge carrier mobility of 1.2 10^4 cm^2/V-sec at room temperature. In contrast, along the c-axis the resistivity of the same material is 0.15 ohm-cm according to the same authors. For heat-treated pyrolytic graphite without stress-annealing, the charge carrier mobility along the c-axis has been reported (4) to be ~3 cm^2/V-sec at room temperature. Also at room temperature, the following total carrier concentrations have been reported: for naturally occurring graphite single crystals, 9.9 to 10.1 · 10^{18} carriers/cm^3 (5); for heat-treated pyrolytic graphite, 1.2 · 10^{19} (4), 1.1 · 10^{19} (6), and 1.4 · 10^{19} carriers/cm^3 (7). The ratio of the mobility of the electrons to that of the holes ($b = \mu_e/\mu_h$) was found to be 1.1 at room temperature (3, 5, 6) for both heat-treated and stress-annealed pyrolytic graphite.

The theory of semiconductor electrodes indicates that the capacitance of the space charge layer in a pure intrinsic semiconductor should exhibit a minimum value given by the expression (8)

$$C_o = \left[\frac{2\epsilon\epsilon_o e^2 c}{kT}\right]^{1/2} \qquad [1]$$

with the dependence of the capacity on potential given as:

$$C_{sc} = C_0 \cosh\left(\frac{\phi e}{2kT}\right) \quad [2]$$

where ϵ = dielectric constant
ϵ_0 = permittivity
e = absolute value of electronic charge
c = electronic charge carrier density
k = Boltzmann's constant
T = absolute temperature
ϕ = potential at the surface

The only values apparently available for the dielectric constant are those from optical measurements rather than at audio frequencies. According to Ergun *et al.* (9) the value of ϵ at 5461Å in the basal plane is 2.61 and along the c-axis is 3.28.

Using the value of 6.10^{18} carriers/cm^3 (mean value from Ref. 4, 6, and 7) for the electronic carrier concentration and 3 for the dielectric constant (9), C_0 is 4.5 μf/cm^2 as compared with $\sim$3 μf/cm^2 for the experimental value.

The comparison of the calculated C_0 value with the experimental value is reasonable, considering the uncertainty as to c and ϵ. The potential dependence of the space charge capacity represented by Eq. [2], however, is much greater than that observed experimentally in Fig. 3. Possible factors responsible for this discrepancy are (I) Imperfections on the exposed basal plane that give rise to sites other than those with completely satisfied valencies and result in degenerate surface electronic states. In the case of germanium electrodes, Gerischer (10) has given a theoretical treatment which shows that the space charge capacity depends relatively little on polarization in the potential region of surface degeneracy. (II) The applicability of the presently available semiconductor theory to a system such as graphite with a total carrier concentration as high as 10^{19} carriers/cm^3 and hence with Debye lengths comparable to the lattice dimensions is open to serious question.

In order to explore further the importance of the semiconductor properties of graphite in controlling the observed differential capacitance, measurements are being undertaken with boronated stress-annealed pyrolytic graphite which exhibits p-type semiconducting characteristics. Studies involving the effect of anions which normally specifically adsorb on ordinary electrodes, for example, iodide, are also in progress and will be reported later.

The data included in this paper show that the differential capacitance of the basal plane of stress-annealed pyrolytic graphite-electrolyte interface is quite abnormal and that the space charge characteristics of graphite must be taken into account in examining the electrochemical properties of this material.

Acknowledgment

The authors are pleased to acknowledge the support of this research by the U. S. Office of Naval Research. One of the authors (J.P.R.) thanks the Stiftung für Stipendien auf dem Gebiete der Chemie, Basel, Switzerland, for the award of a research fellowship. The authors also express appreciation to the Union Carbide Technical Center, Parma, Ohio and to Dr. A. Moore of that laboratory for providing the various pyrolytic graphites used in this study.

The Hydrostatic Pressure Dependence of the Ionic Conductivity of β-Aluminas

R. H. Radzilowski and J. T. Kummer

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

Single crystals of Na β-alumina with the idealized formula $Na_2O \cdot 11Al_2O_3$ exhibit a specific conductivity of $\sim 3 \times 10^{-2}$ (ohm-cm)$^{-1}$ at 25°C (1) due to the rapid two-dimensional diffusion of Na^+ ions in a direction perpendicular to its hexagonal c-axis. The two-dimensional motion of the Na^+ ions takes place in a slot formed by two close-packed oxygen layers which are perpendicular to the c-axis and are held 4.76Å apart by Al-O-Al bridges. Based on the measured diffusion coefficient for various ions in ion-substituted β-alumina (1) it appears that for ions larger than Na^+ the monovalent cation diffusion coefficient is smaller than for Na^+ and the activation energy for diffusion is larger. This can be explained qualitatively by repulsion between the electron clouds of the ion and the oxygen ions above and below the mobile monovalent cation as that cation moves in the lattice. The larger the cation, the lower the diffusion coefficient. Thus, the K^+ ion diffuses slower than the Na^+ ion, and the Rb^+ ion diffuses slower than the K^+ ion. For the Li^+ ion, however, the diffusion coefficient also is smaller than for Na^+ ion. In this case the evidence (1) is that the Li^+ ion does not sit near the midplane position equidistant from the close-packed oxygen planes above and below the cation as Na^+ and the larger ions do, but because of its smaller size is located close to one or the other oxygen planes in a potential well formed by its three nearest oxygen neighbors. This position leads to an increase in the c-axis dimension, as can be seen in Table I,

Key words: potassium β-alumina, lithium β-alumina, high-pressure apparatus.

Table I. Lattice constants of β-alumina and ion-substituted β-alumina (1)

Ion radii A	Ion	a (A)	c (A)
0.60	Li^{+a}	5.593	22.570
0.95	Na^+	5.594	22.530
1.33	K^+	5.596	22.729
1.40	$O^=$		

[a] The lattice constants of Li-substituted β-alumina were determined under anhydrous conditions and differ from Ref. (1).

since the maximum force pulling the two oxygen planes together is obtained when the monovalent cation is midway between the two oxygen planes.

The motion of the Li^+ ion through the slot made by the two oxygen planes would experience, in addition to the electrostatic barriers seen by the Na^+ ion, an additional energy barrier required to move the Li^+ ion from the potential well formed by its three nearest neighbors. This picture is in agreement with the lower diffusion coefficient and higher activation energy for the Li^+ ion than for the Na^+ ion found (1) experimentally for diffusion in the β-alumina structure. This picture would also lead to the conclusion that hydrostatic pressure applied to β-alumina should decrease the diffusion coefficient or ionic conductivity of the ions larger than Na^+, which experience electron cloud repulsion when moving through the lattice, and increase the diffusion coefficient or ionic conductivity of the Li^+ ion because a closer arrangement of the two oxygen layers would enable the Li^+ ion to sit less tightly in its potential well and move towards the midplane position.

This paper reports some experiments made in an effort to support this picture by measuring the effect of hydrostatic pressure on the ionic conductivity of single crystals of Na β-alumina and K and Li ion-substituted β-alumina.

Experimental Section

The single crystals of β-alumina used in this work were obtained from fusion cast bricks, Monofrax H, Harbison Carborundum Co., Falconer, New York. The K- and Li-substituted β-aluminas were made by the ion exchange of Na β-alumina in a melt of KNO_3 and Ag-substituted β-alumina in a eutectic melt of LiCl-$LiNO_3$, respectively, as described by Yao and Kummer (1). An analysis of the crystals by atomic absorption and x-ray fluorescence spectroscopy showed that the exchanges were 99% complete. The Li-β-alumina was found to be extremely hygroscopic, and thus the crystals were handled under argon gas dried with molecular sieves.

The crystals of β-alumina were prepared for resistivity measurements by attaching Pt wire leads to the crystals (2 mm wide × 3 mm long × 0.2 mm thick) with a thin film of platinum. The platinum electrodes were formed by coating the opposite edges of a crystal with Engelhard platinum resinate solution and baking the crystal in air at 400°C for one hour. This procedure was repeated after applying a small droplet of Engelhard liquid gold over the platinum electrodes to insure good electrical contact. Excess platinum was removed from the crystals by scratching or sanding the surface of the crystals.

Hydrostatic pressures up to 4100 atm were produced by a hydraulic press acting on the piston of the assembly shown in Fig. 1. Kerosene dried with Linde molecular sieves acted as the pressure transmitting fluid. The pressure produced in the 10 cm^3 cavity of the cell was monitored with a manganin coil calibrated against the freezing pressure of mercury at 0°C. In a test run a Fe-Cu thermocouple was mounted in place of the manganin coil and the changes in temperature in the kerosene-filled cavity were followed at intervals of 500 atm up to 4000 atm of pressure. A close-fitting aluminum block surrounded the steel cell in order to help dissipate the heat generated during the compression of the kerosene. The temperature rose 3°-8°C at each pressure interval but dropped to the block temperature within 12 min. In actual runs, the manganin coil was activated for only a few seconds after the system reached equilibrium in order to prevent a rise in temperature, calculated to be small even if the coil were left on because of heat generated by the current-carrying coil. The temperature of the steel block was measured during runs with a chromel-alumel thermocouple placed in a kerosene-filled well in the top of the block.

The resistivity and capacitance of the crystals were measured on a Wayne Kerr radio frequency bridge, Type B.601 with a Tektronix Type 190B constant amplitude signal generator operated in the frequency range of 0.55-1 MHz. A tuned null detector, General Radio Type 1232-A, coupled with the IF circuit of a communications receiver, Allied Model A-2515, allowed precise balancing of the bridge. The specific resistivity of a crystal of Na β-alumina containing 5 w/o (weight per cent) Na was 44 ohm-cm at 23° with the Au-Pt electrodes. This resistivity measured at 1 MHz was 7% lower than that found at 0.55 MHz. The specific resistivities of Li- and K-substituted β-alumina at 1 MHz and 23° were 1200 and 5200 ohm-cm, respectively. The capacitance of the crystals with

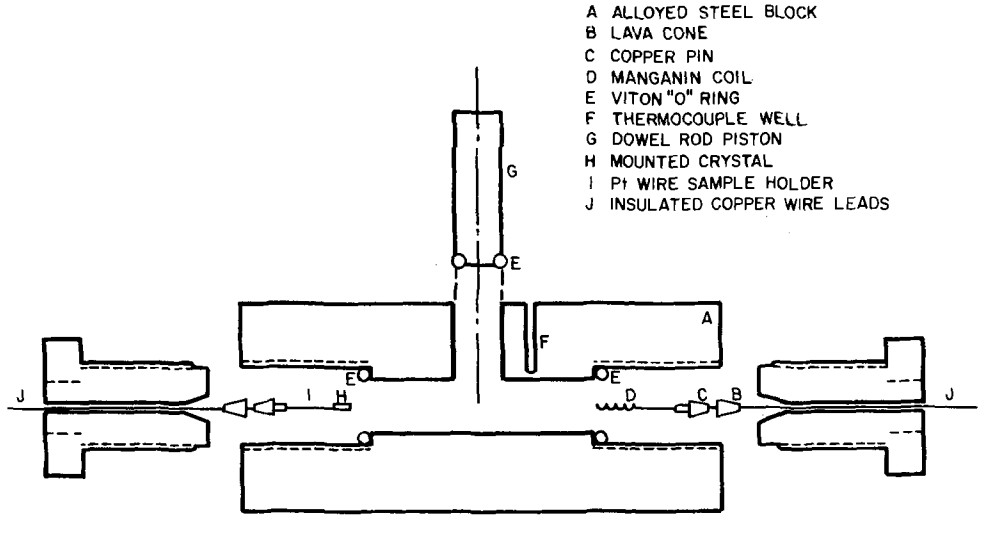

Fig. 1. A sectional view of the pressure cell

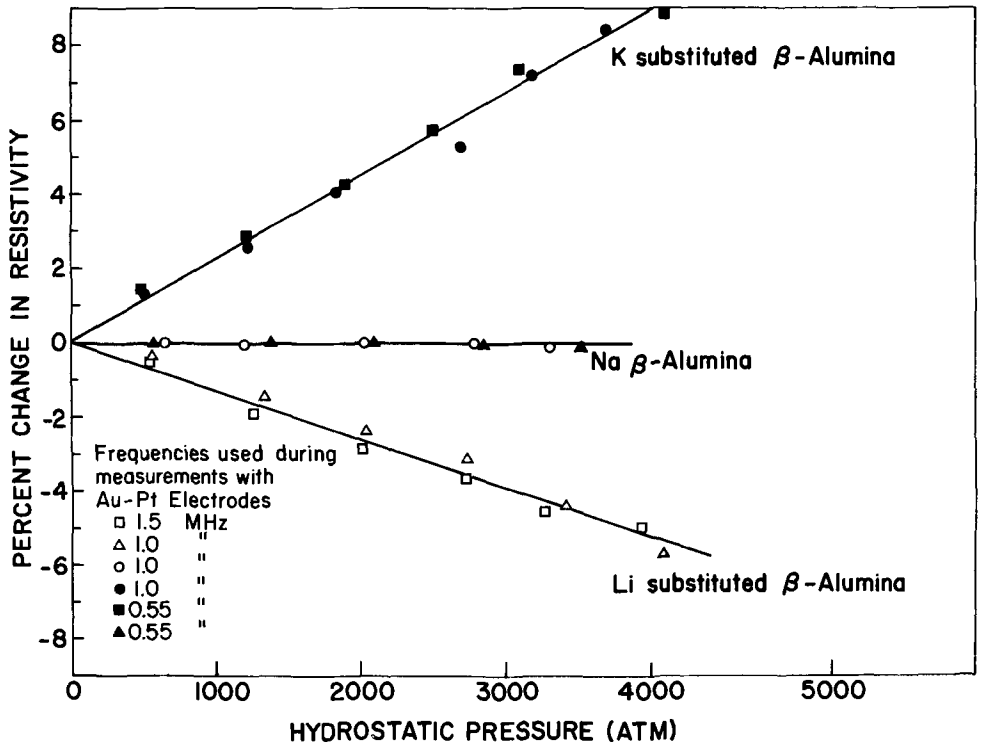

Fig. 2. The change in ionic resistivity of β-alumina and ion-substituted β-alumina with pressure

platinum wire leads varied between 9 and 23 pF at at 1 MHz.

Results and Discussion

The pressure dependence of the ionic conductivity of Na β-alumina and of the two ion-substituted β-aluminas is shown in Fig. 2. The results are qualitatively in agreement with what was expected. The activated state theory of reaction rates as applied to ionic diffusion (2) uses the concept of an activation volume of motion associated with the jump of a cation from site to site. This activation volume is the volume change due to the dilatation or contraction of the crystal lattice in the vicinity of the mobile cation when the diffusing ion sits in the saddle-point configuration.

In order for a monovalent cation to move through the β-alumina structure, it must move through the crystallographic site which is in the center of an equilateral triangle formed by nearest-neighbor normal cation sites. This point in the motion of the cation from cell to cell produces the smallest oxygen to cation distance. There are two oxygen ions above and below the cation as it moves through this site, 4.76Å apart for Na β-alumina and 4.86Å apart for K-substituted β-alumina. The Na^+ ion with an ion size of 0.95Å moves through this site without serious steric hinderance, whereas the K^+ ion (1.33Å) requires lattice expansion. The curves in Fig. 2 indicate a positive activation volume for K-substituted β-alumina and a 0 activation volume for Na β-alumina. Li-substituted β-alumina has a negative activation volume. In its motion from cell to cell it moves some distance out of its potential well toward the midplane, causing a local contraction of the lattice.

A quantitative explanation of the results in Fig. 2 cannot be made since we know only one compressibility (Na β-alumina's c-axis compressibility is $\sim 2 \times 10^{-7}$ atm^{-1}) and we lack an adequate theory. In addition, although the Pt electrodes seem quite adequate it would be desirable to cross-check the results with some electrodeless conductivity (or diffusion) measurement if this could be devised.

ABSTRACT

The anodic oxidation of silicon and tantalum in organic solvents containing small quantities of dissolved salts (KNO_2 and KNO_3) and water has been studied. The source of oxygen in the oxide layer has been determined using O^{18}-labeled materials. The isotopic exchange of oxygen between the various components of the electrolyte under thermal and electrolytically induced conditions was measured using mass spectrometric analysis and found to be extremely slow. Nuclear methods of analysis of isotopic oxygen were used to determine the source of oxygen in the oxide layer on both metals. It was found that over 80% of the oxygen of the oxide comes from water, the rest from the salt. The small extent of incorporation of nitrogen-containing anions in the oxide layers was also measured by a nuclear method.

A detailed study of the anodic oxidation of silicon has been undertaken in order to elucidate the phenomena occurring both in the electrolyte and in the growing oxide film. These phenomena have already received considerable attention in the literature and were first studied in 1957 in N-methylacetamide[1] solutions of KNO_3 and other salts by Schmidt and Michel (1). Since then, Duffek *et al.* have studied this process both in NMA (2) and in glycol (3) for various salt and water concentrations. In addition to the classical methods of investigation used by these authors we have resorted to a special technique developed to study anodic oxidation, *i.e.*, microanalysis by means of nuclear reactions (4-7). The latter enables the precise determination of the oxygen content of oxide films and the investigation of the mechanisms of formation using O^{18} as a tracer.

Our study was aimed primarily at determining the source of the oxygen contained in the films. This can be the solvent, the salt, or traces of water in the solution, or a combination of these. Either NMA or glycol were used as solvents, containing small quantities of KNO_3 and water. For some experiments in glycol, KNO_2 was used. Either the water or the KNO_3 used were labeled with O^{18}.

Key words: anodic oxidation, silicon, tantalum, oxygen source, O^{18} tracing, isotopic exchange, organic solution, water, salt.

[1] In what follows, the abbreviation NMA will be used for N-methylacetamide.

In addition to the anodic oxidation of silicon, the same process on tantalum was also studied in order to investigate the similarities and differences in behavior of the two metals. The reasons for using tantalum are its ready oxidation in the above electrolytes, the high current efficiency of the oxidation process, and low field of formation as compared to silicon.

Once the source of the oxygen in anodic oxidation has been determined, the mechanisms of ionic transport in the films can be elucidated. This will be the subject of a further paper, although preliminary results on field-induced self-diffusion in anodic silicon oxide has been published recently (6). The aim of the present work was also to help in determining the optimal conditions of oxide film formation so as to make anodic oxide film production competitive with thermal growth methods.

Experimental

Preparation of samples to be oxidized.—Samples of p-type silicon were used, with a resistivity of about 0.1 ohm·cm. The surface of the silicon wafers polished by a mechano-chemical process, was cleaned before oxidation using classical methods: degreasing with trichloroethylene, rinsing, removal of the oxide layers with hydrofluoric acid, and finally rinsing with hot water (of resistivity greater than 15 megohm·cm) and air drying. The tantalum samples were cut from 0.2 mm thick rolled sheets with a highly polished surface,

supplied by Fansteel Corporation, with a stated purity 99.9%. The tantalum samples were cleaned with trichloroethylene, washed with methanol, and air dried.

Preparation of labeled compounds.—O^{18}-enriched water from the Isotope Separation Plant of the Weizmann Institute was used. This water, obtained by fractional distillation, is also highly enriched in deuterium. In order to eliminate both chemical and nuclear isotope effects this water was "normalized" so as to contain less than 0.1% deuterium by the method of Zhavoronkov [see ref. (8), p. 38]. In all cases, the water was purified by distillation first from permanganate and then under reduced pressure in silica vessels. For the anodic oxidation experiments the water used had the approximate isotopic concentration 88% O^{18}, 0.5% O^{17}, 11.5% O^{16}. Various high O^{18} concentrations were used for exchange experiments.

O^{18}-labeled potassium nitrate was prepared by acid catalyzed exchange with water, by the method of Anbar *et al.* (9), and contained 77% O^{18}. The salt used was shown to be free of any O^{18}-labeled water by dissolving it in the minimum quantity of water depleted in O^{18} [*i.e.*, containing 0.007 a/o (atom per cent) oxygen^{-18}, thirty times less than natural abundance]. On distilling the water and analyzing it for O^{18}, it was found to be unchanged in isotopic content.

In certain experiments made in order to examine the effect and quantity of residual water in "dry" solvents, "washed NMA" and "washed glycol" were prepared. In each case *ca.* 2 ml highly enriched H_2O^{18} was added to *ca.* 50g organic solvent of the best quality available and the solvent dried by repeated fractional distillation, the final product having a water content of less than 0.05%.

Preparation of organic solutions.—Most of the solutions used contained 0.4% water and 0.4% salt by weight. This salt content insures that the solution has a resistivity (which appeared to be independent of the water content) convenient for easy oxidation. In addition, preliminary studies showed that the optimal water content for the formation of high-quality silicon oxide films for semiconductor devices is in the vicinity of 0.4%.

When isotopically enriched materials were used, the weight of labeled components was increased in proportion to their molecular weight, so as to insure that the same number of molecules were present in both labeled and unlabeled solutions.

In all NMA solutions KNO_3 was used. However, difficulties were encountered in oxidizing tantalum in glycol using KNO_3, when the water content was less than 2%. In particular, it was impossible to reach high anodic voltages, since breakdown occurred at about 20V. These difficulties could be overcome by using KNO_2, as was done in a number of experiments with glycol solutions.

The solvents used (NMA from Eastman Kodak and glycol from Merck) were purified by double fractional distillation at reduced pressure through a column of molecular sieves. NMA was distilled at 60° ± 0.5°C, and glycol at 55° ± 0.5°C. The final product, containing less than 0.02% by weight of water (see later), was distilled directly into the electrolytic cell. The KNO_3 was dried on a vacuum line at 100°C for 24 hr; the less stable KNO_2 *in vacuo* at room temperature for several days.

It should be noted that very small traces of impurities such as fluorides may have a deleterious effect on the anodic oxidation of silicon. These trace contaminants are not removed by the purification processes described above, so that certain batches of solvents had to be rejected, especially in the case of glycol.

Electrolyte solutions containing known quantities of O^{18}-labeled water had to be prepared with great care, since any water accidentally introduced will immediately dilute the isotopic content of the enriched water.

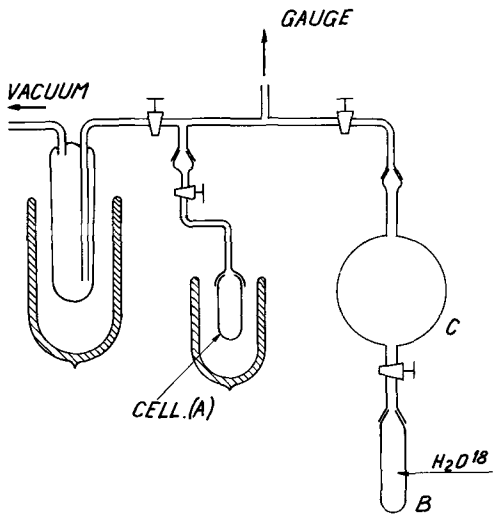

Fig. 1. Vacuum line used for transfer of O^{18} labeled water. A is electrolysis cell; B, H_2O^{18} reservoir, C, bulb for determining the quantity of water.

This could happen easily, since the solvents used were found to be very hygroscopic. It was, therefore, essential to transfer all distillable liquids on the vacuum line shown in Fig. 1. The dried, weighed salt (KNO_3 or KNO_2) is placed at the bottom of an electrolytic cell (A), which is then filled first with *ca.* 30 ml of "dry" solvent by distillation. The solvent is then carefully degassed and a given quantity of labeled water (determined by the volume of the bulb C and the saturation pressure of water at the temperature of the reservoir B maintained at 26°C) is transferred from the reservoir (B) to (A) by cooling the latter in liquid nitrogen. To prevent condensation of water vapor on other surfaces, the entire apparatus is kept at about 28°C. This enables the transfer of 60 mg of ordinary water (or its labeled equivalent) in each operation; the desired water content being obtained by repeating the above operation as many times as necessary. The problem of residual water in the solvent will be discussed later. The cell is then filled with dry argon, the cathode and samples to be oxidized are placed in position in a dry box, and the cell is ready for use.

For solutions of natural isotopic oxygen composition or for those containing an O^{18}-labeled salt, water was simply added using a microsyringe. In all cases, the total quantity of water in the electrolyte was determined just before oxidation as described below.

Method of oxidation.—The samples to be oxidized were placed as anodes opposite a platinum cathode. The solution was stirred magnetically and its temperature controlled by a thermostat. The Pyrex oxidation cell is sealed with a cover fitted with a spherical ground glass joint which supports the leads to the electrodes. Seven electrodes were placed in each cell so that successive oxidation of six samples could be performed without opening it (Fig. 2). Condensation of liquids on the walls of the cells was prevented by heating those parts not in contact with the bath.

Owing to the problems associated with maintaining electrical contact with silicon and tantalum foils, some details of the electrical connections will be given. In electrolytes where tantalum is easily oxidized (NMA + KNO_3; glycol + KNO_2) a special tantalum clamp, previously oxidized to 300V is used [see ref. (10)] with the sample totally immersed in the liquid. When glycol and KNO_3 is used to oxidize silicon, the clamp is kept above the surface of the liquid.

Oxidation was performed at a constant current of 1 mA/cm^2 up to a predetermined voltage (of up to several hundred volts), followed by a stage at constant voltage. The final current was allowed to decrease down to about 10 μA/cm^2 for all samples. The duration of this stage varied from 2 to 4 hr for silicon and 10

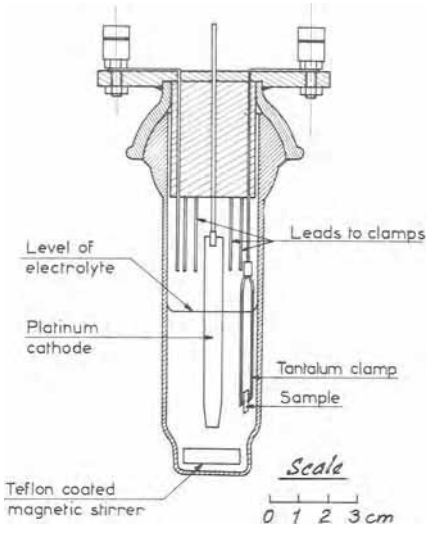

Fig. 2. Single compartment cell for successive oxidation of six samples without opening.

to 15 min for tantalum. The temperature of the solutions was maintained at about 20°C for glycol and, to avoid solidification, at around 35°C for NMA. After oxidation the samples were rinsed at 20°C in acetone, alcohol, and finally high resistivity water.

Under these conditions the thickness of SiO_2 films was measured by optical and nuclear methods and found to be about 6 Å/V, and that of Ta_2O_5 films about 16 Å/V. No gas evolution was observed at the anode during oxidation of either silicon or tantalum (see Discussion).

It was found that after a number of oxidations of silicon in glycol or NMA (consuming more than 1000 coulombs), further silicon samples cannot be oxidized satisfactorily. The solution apparently becomes poisoned by unknown decomposition products. For this reason the solutions, both isotopically labeled and unlabeled, were renewed frequently.

Exchange experiments.—Thermal isotopic exchange of oxygen between O^{18}-labeled water and glycol (or NMA) with or without added KNO_3 was examined. Various mixtures of the components of the system were heated in a sealed Pyrex tube in an oil or water bath for given times. In some cases the nitrate was labeled with O^{18}. The components were then separated and analyzed for their isotopic content, as described below.

The experiments on exchange during electrolysis were conducted at room temperature in a classical three-compartment cell with platinum electrodes. The cell consists of two electrode compartments (20 ml) and a middle compartment (15 ml), separated by sintered glass of porosity No. 1 (100 to 150μ pores). Each compartment was stirred by means of Teflon-coated bar magnets and the temperature measured by a separate thermometer. After a given number of coulombs (usually 1000) had been passed through the cell, the components of the electrolyte were separated and analyzed for their isotopic content as described below.

Chemical analysis of the solutions.—Water was determined by the Karl Fischer method. Great care was taken during the transfer of the liquids for analysis: all manipulations were done in a dry box, using oven-dried syringes and injecting the sample directly into the titration chamber through a rubber stopper. The analysis was done by back-titration. Using these precautions, the limiting sensitivity was about 0.02% (by weight) of water in NMA or glycol; reproducibility was of the same order of magnitude.

The formation of nitrite in the nitrate solutions was determined by means of the Greiss reagent. The chemical identification and analysis of other decomposition products was not attempted.

Isotopic analysis of the constituents of the solutions.—Separation of labeled compounds.—Water was removed from mixed solvents (from both exchange and electrolysis experiments) by distillation at atmospheric pressure using a 30 cm Vigreux fractionating column. The water was then redistilled in a micro still. Only when the NMA contained more than 2 ml water per 30g solvent could sufficient water of high purity for isotopic analysis be obtained. It was more difficult to isolate water from glycol, due to the formation of an azeotrope.

The organic solvent was then fractionally distilled (NMA at 80°C/4 mm; glycol at 65°C/10 mm). In order to eliminate the effect of traces of highly enriched O^{18} water in the isotopic analysis, a small quantity of unlabeled water was deliberately added to the distilled solvent and then removed by another distillation as described above. This procedure was repeated twice and the NMA or glycol dried with molecular sieves. Owing to the slow rate of isotopic exchange between NMA or glycol and water at room temperature, this procedure does not affect the isotopic content of the organic solvent at the low O^{18} concentrations found. Traces of residual water (<1%) do not affect the analysis of these isotopic concentrations.

The KNO_3 remains as a solid residue from the first fractional distillation. For the thermal exchange experiments, the heating of KNO_3 during distillation has only a negligible effect as compared to the previous much more drastic heat treatment. For the exchange during electrolysis the results on thermal exchange show that the effects of our distillation procedure was also negligible. To eliminate traces of H_2O^{18} in the salt the latter was washed and recrystallized twice with water. It was known that there is negligible isotopic exchange of oxygen under these conditions. It should be noted that recent experiments (7) using highly labeled KNO_3 in 30-times O^{18}-depleted water showed that the isotopic exchange between KNO_3 and water under similar conditions is not detectable. The traces of KNO_2 formed in the electrolytic experiments using KNO_3 are mostly removed on crystallization and do not affect the analytical result. Attempts to separate the nitrate from the organic solvent by thin layer chromatography were not successful.

For mass spectrometric analysis at least 5 mg of any compound is required for a single isotopic analysis. Quantities smaller than this give irreproducible results, due in part to exchange with traces of moisture, impurities, etc., in the glassware.

Mass spectromic analysis.—Water was analyzed by mass spectrometry using conventional methods. At low enrichments the "bromine" method was used by means of which water is converted to molecular oxygen by alkaline hypobromite (11). At high enrichments the water is equilibrated with carbon dioxide (12); at very high enrichments O^{18}-labeled CO_2 is used to avoid too great an isotopic dilution. The oxygen or carbon dioxide was analyzed by mass spectrometry. Attempts to equilibrate CO_2 directly with water mixed with either NMA or glycol were not successful.

Potassium nitrate was analyzed by two methods: a general method for pyrolysis of inorganic materials to carbon dioxide by means of a mixture of mercuric chloride and mercuric cyanide (13) and a specific method for nitrate in which the oxygen is converted to nitrous oxide by pyrolysis with ammonium chloride (14). Both methods gave the same result.

Glycol and NMA were analyzed for their isotopic content by conversion to carbon dioxide by the pyrolytic method described above. However, in order to obtain reproducible results great care must be taken to purify the carbon dioxide before mass spectrometric analysis. The gas was first passed through a column of benzoquinoline crystals in order to absorb HCl and

other acidic substances and then distilled from −80°C (dry ice acetone) to a liquid nitrogen trap. CO_2 purified in this manner gave reproducible results.

Attempts to analyze the oxygen isotopic content of NMA and glycol nondestructively by means of infrared (O^{18}) or NMR (O^{17}) were not successful owing to the low sensitivity of these methods.

Isotopic analysis of the anodic oxide films.—O^{16} was measured by the O^{16} (d,p) O^{17*} reaction and O^{18} by the O^{18} (p,α)N^{15} reaction. The technical details of these nuclear methods, devised for the study of anodic oxidation processes, are described in ref. (4) and (5). Other applications to anodic oxidation were described in ref. (6) and (7).

Results

Chemical Changes in the Electrolytes

The effects on the electrolyte of the electrochemical processes taking place during anodic treatment depend on the nature of the currents injected into the electrodes. At the cathode, by choosing a platinum electrode, we insured that this current is purely electronic. At the anode both electronic and ionic currents may pass through the oxide layer being formed. In what follows we shall discuss the various effects of the anodic current in terms of "electronic" and "ionic," it being understood that this refers to its nature in the oxide layer.

Since the current efficiency of the anodic oxidation of silicon is of the order of only 2%, it would appear that most of the current is used up in decomposing the solution, as is illustrated by the poisoning effects mentioned above. Some of the products of anodic processes have been studied by Duffek *et al.* (2, 3), who showed that the amount of silicon lost to the electrolyte is a small fraction of that contained in the oxide film formed. They also found that water was formed during the electrolysis. We have investigated some of these phenomena including the formation of water, both by effective drying of the solvents before use and also by using O^{18} as a tracer.

Measurements in a single-compartment cell.—In order to simulate the electronic current, corresponding to the small current efficiency of silicon oxidation, a given quantity of electricity was passed between platinum electrodes in the above solutions. The cell used is shown in Fig. 2. The formation of water was studied as a function of the components of the solution and of the current passed. A new solution was used for each measurement, so that each experiment is influenced in the same way by traces of water accidentally introduced. The total amount of water thus introduced into a 20 ml solution from outside sources (*i.e.*, before electrolysis) is estimated to be about 5 mg.

Figure 3 shows the results for NMA and glycol solutions containing 0.4% KNO_3. The presence of traces

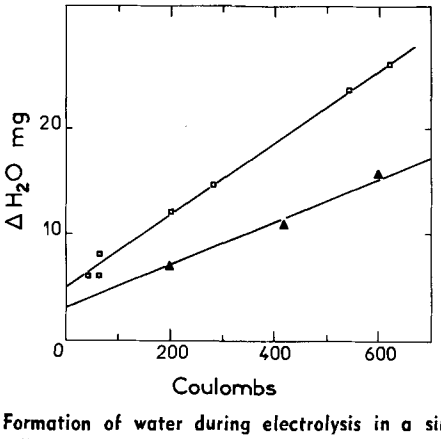

Fig. 3. Formation of water during electrolysis in a single compartment cell, as measured by Karl Fischer method: □ glycol, ▲ NMA.

Table I. Water formation in a single compartment cell

H_2O formed	Glycol	NMA
mg/1000 coulomb	40	20
mole/Faraday	0.2	0.1

of water from outside sources is shown by extrapolating the straight lines to the origin. The proportionality constant between the net increase in the amount of water and the charge passed can be deduced from these results for various solutions (Table I). The results for glycol and KNO_2 system are very similar to those for KNO_3. Thus, these two salts appear to be equivalent from this point of view.

These experiments were repeated in glycol solutions with a silicon anode, with results identical to those obtained above with platinum. This confirms that the effects in the oxidation process of silicon were indeed due to an electronic current.

Measurements in a three-compartment cell.—In order to investigate the formation of water in more detail, measurements were carried out in a three-compartment cell, using either NMA or glycol solutions containing 0.4% KNO_3 and platinum electrodes. Only hydrogen was evolved at the cathode as verified by mass spectrometry, the yield obtained by coulometric measurements being exactly 1 g-atom/Faraday. Although under normal circumstances no gas evolution was observed at the anode, precise coulometric experiments at high current densities performed with a special cell indicate that small amounts of gas may be evolved.

In NMA, after the passage of 1000 coulombs, an increase in the *p*H at the cathode was observed, which has been attributed to the formation of KOH [see ref. (2)]. Simultaneously, the *p*H at the anode fell to about 5. Further results are given in Table II.

The reduction of nitrate to nitrite is negligible as the total amount of nitrite formed corresponds to the consumption of only 0.3 coulombs, 3×10^{-4} of the quantity passed. The presence of nitrite in the anode and middle compartments can be attributed to a migration process from the cathode. Similar results were obtained in glycol. Duffek *et al.* (2, 3) also found traces of nitrite after anodic oxidation but did not estimate the extent of this process.

The amount of the water formed varies from compartment to compartment. The increase in the water content of the middle compartment could be due to transport phenomena by electrolytic migration or spontaneous diffusion from the anode compartment. Experiments have shown that the quantity of water is independent of the porosity of the sintered glass partitions for porosities of between 1 and 4 (*i.e.*, 120-10μ) indicating that migration is probably preponderant. The total amount of water formed in all three compartments is significantly greater than that found in a single-compartment cell under similar conditions for both NMA and glycol solutions. As will be discussed later, this suggests that water is probably formed at the anode and destroyed at the cathode. This suggestion is supported using O^{18} tracers and nuclear analysis of the oxide films (see below). Direct methods such

Table II. Decomposition products in a three-compartment cell

	Anode	Middle	Cathode	Total
		(a) NMA		
KNO_2 formed:

as these eliminate the uncertainties due to transport phenomena.

Isotopic Changes in the Electrolytes

Since all the components of the solutions contain oxygen, tracer experiments by O^{18} labeling of one of the constituents can only be simply interpreted if the changes in the isotopic compositions throughout the experiment are relatively slow. Therefore the isotopic oxygen exchange between the components of the solution was studied in detail first by mass spectrometry and these results will be presented now. They will be followed by those on the labeling of the films obtained by oxidation.

Temperature induced exchange.—Solutions of NMA and glycol containing either water or nitrate labeled with O^{18} were heated to 100°C or more for times of up to 720 hr. The isotopic composition of each constituent was analyzed in a mass spectrometer before and after heating. The absolute errors on the results are taken as ±0.02% for concentrations at or near the natural abundance of O^{18} and ±0.5% for higher concentrations. The results obtained are given in Table III, where the calculated exchange ratios of the various constituents are shown. These ratios were calculated for the exchange between two constituents as follows. Since the kinetics of the isotopic exchange obey a first order kinetic law (15), the exchange ratio, ρ, after a heating time t, may be written as

$$\rho = \frac{C(o) - C(t)}{C(o) - C(\infty)} = 1 - e^{-t/\tau}$$

where $C(o)$ is the initial concentration of isotope in the constituent examined, $C(\infty)$ the concentration of isotope at equilibrium for a total exchange, and τ the mean life, characteristic of the exchange. In the three component systems (NMA + H_2O + KNO_3) the calculations were made separately for the pairs NMA + H_2O, KNO_3 + H_2O, neglecting the effect of the third component, since the extent of the exchange is small. The results indicate that in all cases studied, the exchange ratios are less than 2%. Those calculated for each constituent in glycol are in good agreement with one another, but in the case of NMA the water could not be analyzed. The mean life τ deduced from ρ is shown in Table IV.

From these results the following conclusions may be drawn:

Exchange in NMA.—The results indicate that there is a very slow isotopic exchange of oxygen between NMA and water at 100°C. Both with and without added KNO_3 the exchange ratio is of the order of 0.5%, corresponding to a mean life of 1.5 x 10^5 hr; a mechanism for isotopic exchange of oxygen between amides and water in dilute solution is known [see ref. (16)] and may operate here. The exchange at 100°C between KNO_3 and water dissolved in NMA occurs at a slightly higher rate. This exchange is known to occur but is acid catalyzed; under the drastic conditions of the experiment, the presence of traces of acid (from hydrolysis of NMA for instance) cannot be excluded. Under the considerably milder conditions used for anodic oxidation, (*i.e.*, a few hours at room temperature) thermal exchange of oxygen between the various components in the NMA system can be ruled out.

Exchange in glycol.—The isotopic exchange of oxygen between water and glycol is somewhat faster than with NMA as shown by the isotopic analysis of each component after 148 hr at 100°C. Various dehydration, hydration, and substitution mechanisms for this exchange can be posulated, but at the present time there is insufficient evidence for deciding which mechanism operates. There is virtually no exchange between glycol and nitrate, as might be expected. Here again the thermal isotopic exchange of oxygen is so slow as not to be taken into account under the considerably milder conditions of anodic oxidation.

Electrochemically induced exchange.—The isotopic labeling of a component in an electrolyte mixture under the influence of an electric current passing through the cell, could be the result of various processes:

1. the formation by electrolytic decomposition of products which can exchange oxygen rapidly with the other components of the solution;
2. the formation of nonlabeled species, chemically identical to the labeled ones; causing isotopic dilution;
3. exchange induced by the electrolysis itself.

The experiments carried out were on NMA solutions where isotopic analysis of all the components was possible, and on glycol solutions where only the glycol could be analyzed. The results obtained in the three-compartment cell may also be affected by transport phenomena; their effect on the accuracy of the results for water is smaller here than in the experiments on thermal exchange in the electrolyte, since larger quantities of labeled water are used.

The NMA-KNO_3-H_2O system.—The results of the mass spectrometric analysis are summarized in Table V. They show that:

1. there is no change in the isotopic content of the water from the middle and cathode compartments, within experimental error;
2. the isotopic content of oxygen in the water in the anode compartment decreases markedly;
3. the isotopic content of oxygen in the NMA hardly changes;

Table III. Temperature induced exchange

4. the isotopic content of oxygen in the nitrate is unchanged (this analysis was made on KNO_3 from a solution where 500 coulombs have been passed to oxidize silicon samples). These results are compatible with those obtained is the preceding section.

In the anode compartment the change in the isotopic content of oxygen in the water does not correlate quantitatively to the change in the opposite direction of isotopic content of the NMA and nitrate. This is not, therefore, the result of exchange phenomena, but of isotopic dilution, in agreement with the production of water indicated earlier. The decrease in O^{18} content of the water in the anode compartment from 68 to 60% can be accounted for by the creation of 5×10^{-3} moles of water per 100 coulombs, *i.e.*, about 0.5 mole/Faraday. This last figure is in agreement with that obtained by the classical methods previously described. The interpretation of this result will be discussed later.

The glycol-KNO_3-H_2O systems.—Similar experiments in glycol have lead to the results given in Table V. The isotopic analysis of oxygen in glycol shows that there is again a slight change, varying from one compartment to the other.

It appears that apart from the dilution effect due to the formation of water at the anode there is little isotopic exchange between the constituents of both NMA and glycol solutions even after 1000 coulombs have been passed through the solution. Since less than 200 coulombs are required for the formation of an anodic oxide film on silicon, electrochemically induced isotopic exchanges can be neglected.

The formation of water and consequent changes in isotopic oxygen content can be examined by analyzing the oxide layers formed. Once it has been established that the isotopic exchanges between the components of the solutions are very slow, and can be neglected, one can determine the source of oxygen and the production of water with greater accuracy and care by the nuclear methods outlined above.

Isotopic Analysis of the Oxide Films

The oxygen necessary for the formation of tantalum and silicon oxides can be provided by any of the components of the solution. It is unlikely that the source of oxygen is dissolved molecular oxygen (see Discussion). The relative contribution of oxygen from each of the constituents of the solution to the oxide layer was evaluated by using labeled H_2O^{18} and $KNO_3{}^{18}$, which have been shown not to undergo isotopic exchange under a wide variety of conditions.

Both tantalum and silicon were oxidized. Because of the high yield in the anodic oxidation of tantalum and consequent minimal decomposition of the solution, tantalum oxides were considered to be characteristic of the isotopic composition of the solution at various stages. In order to verify that current density does not affect the process investigated, some experiments were made at 5 mA/cm² on silicon, in addition to all those made at 1 mA/cm². No difference was observed between them.

Table V. Electrochemically induced exchange

Bath		% O^{18} initial	Charge passed through, coulombs	% O^{18} final		
				Anode	Middle	Cathode
NMA	30g	0.2	1000	0.32	0.33	0.44

* Single compartment cell, silicon anode.

In what follows the isotopic O^{18} content, *i.e.*, the $O^{18}/(O^{16} + O^{18})$ ratio, of the oxides will be called C. In the calculations the O^{17} content, always less than 0.5%, was neglected. The quantity of interest is often the isotopic oxygen content normalized to 100% enrichment of the labeled species. This quantity will be written C^*.

O^{18}-labeled water.—It should be emphasized that during anodic oxidation it is the total amount of water produced which contributes to the isotopic dilution, since stirring mixes water from various origins completely before destruction at the cathode. In order to minimize the errors caused by dilution, the oxide layer formed in a fresh solution at the beginning of a series of oxidations (immediately after the Karl Fischer analysis) was analyzed for its O^{18} content. From this result the proportion of oxygen originating from the water can be calculated. Then, by following the isotopic content of subsequent oxide layers on a series of anodes, in the same solution, the dilution effect was measured and the rate of creation of water determined.

Experiments were carried out in the following solutions

$$\text{Glycol} + 0.4\%\ H_2O^{18} + 0.4\%\ KNO_2{}^{16}$$

$$\text{NMA} + 0.4\%\ H_2O^{18} + 0.4\%\ KNO_3{}^{16}$$

The water added to the "dry solvent" had a concentration of 88% O^{18}, but the introduction of traces of water during handling operations (as determined by the Karl Fischer method) reduced the actual isotopic concentration of the water in the solution at the start of the oxidations to 76 ± 2% O^{18}. In both NMA and glycol and for both silicon and tantalum oxidations, the isotopic content C of the first oxides produced in repeated experiments on fresh solutions was 67 ± 1%. The SiO_2 films were formed at 150V (consuming 40 coulombs) and the Ta_2O_5 films at 50V (with a consumption of less than 0.5 coulomb). A tantalum foil was oxidized before and after each silicon oxidation. Dilution of the O^{18} content due to the 40 coulombs used for the first silicon oxidation was less than 2%. When O^{18}-washed solvents (see above) were used, identical results were obtained, confirming the efficiency of our drying and analytical techniques. Calculation of the normalized isotopic content C^* shows that 88 ± 3% of the oxygen in the oxides (both silicon and tantalum in NMA or glycol) comes from the water in these conditions.

The isotopic oxygen content of a series of films formed in successive oxidations in the same bath was examined. The solutions used were similar to those decribed in preceding experiments. Ta and Si samples were alternately oxidized in NMA solutions, the cell being opened only after three pairs of oxidations. For glycol solutions the procedure was somewhat different. Si and Ta were oxidized in separate solutions. Between each oxidation of Ta, the effect of the oxidation of Si was simulated by letting a current flow between Pt electrodes so as to consume 180 coulombs. This checked the equivalence of the electrolytic effect due to the passage of electronic current with silicon or platinum anodes.

Results are shown in Fig. 4 and 5. It was found convenient to plot in these figures the quantity $\Delta(W_o{}^{18}/C)$ (where $W_o{}^{18}$ is the total amount of O^{18}-labeled water molecules present initially in the fresh solution) as a function of the number of coulombs passed through the cell. The theoretical basis for the choice of this plot is discussed below. It should be noted however that were the water the only source of oxygen and were there no destruction of water, one would have

$$C = \frac{W_o{}^{18}}{W_o{}^{18} + W^{16}}$$

where W^{16} is the amount of unlabeled water in the solution at any instant. Then

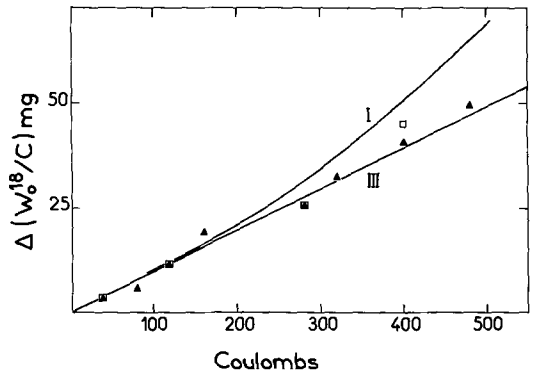

Fig. 4. Change in the isotopic content C of the oxide layer during oxidation in an NMA bath containing O^{18} labeled water. □ Silicon, ▲ tantalum. The calculated curves correspond respectively to cases I and III.

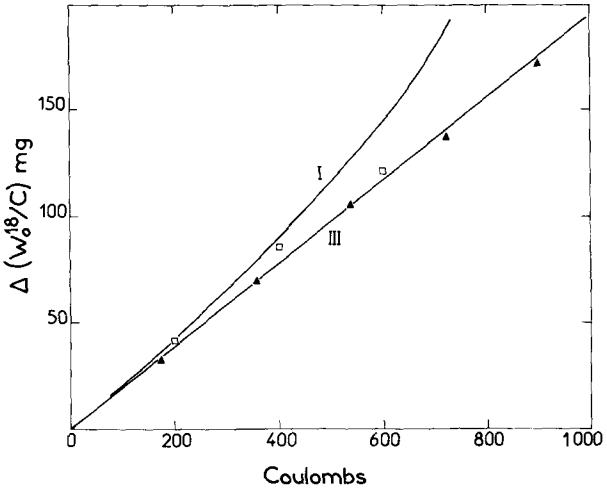

Fig. 5. Change in the isotopic content C of the oxide layer during oxidation in a glycol bath containing O^{18} labeled water. □ Silicon, ▲ tantalum. The calculated curves correspond respectively to cases I and III.

$$\Delta\left(\frac{W_o^{18}}{C}\right) = \Delta W^{16} \qquad [1]$$

and the water production could be simply deduced from Fig. 4 and 5 by measuring the slope. A more sophisticated interpretation of the results would require experiments using O^{18}-labeled KNO_3.

It is seen from Fig. 4 and 5 that the results for both silicon and tantalum oxide films fall approximately on a single line, suggesting that the source of oxygen is the same for the oxidation of both anodes.

O^{18}-labeled KNO_3.—Solutions of $KNO_3{}^{18}$ (enriched to 77% O^{18}) in either NMA or glycol and water (all of natural isotopic composition) were used to further investigate the sources of oxygen for the oxidation of silicon and tantalum.

Alternate oxidations of Si and Ta were carried out in the same NMA solution by the procedure previously described. The highest normalized O^{18}-content C* of the films obtained (both Si and Ta) in a freshly prepared 0.4% $KNO_3{}^{18}$ + 0.4% H_2O + NMA solution was 10.6 ± 1%. This value is discussed below. After a series of Ta-Si pairs of oxidations in the same solution where the change in isotopic content was very slow, successive injections of unlabeled water were added to the solution between each Ta-Si pair in order to elucidate the effect of salt to water ratio. Each injection added an increment of 0.2% of water to the system. The results are shown is Fig. 6 where the inverse of the normalized isotopic content C* of the oxides is shown as a function of the quantity of water

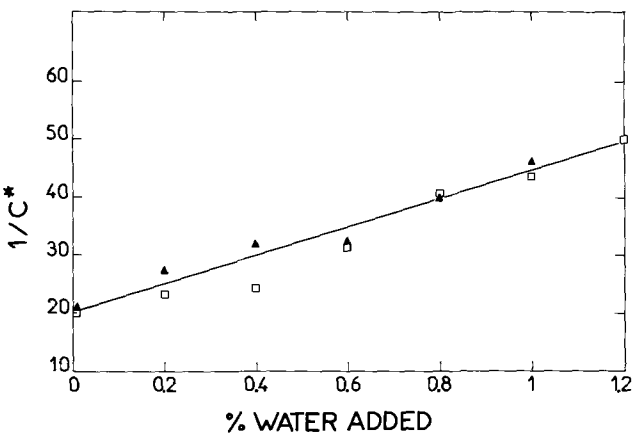

Fig. 6. Dependence of the normalized content C* of the anodic oxides on the amount of water added to NMA solutions containing O^{18} labeled KNO_3. □ Silicon, ▲ tantalum.

added (the effect of electrochemically produced water being neglected). It is seen again that the isotopic content of the silicon and tantalum oxides is very similar. The straight line obtained indicates that the relationship between O^{18} content and water added is homographic.

Similar results were obtained for SiO_2 films produced in glycol indicating that the nature of the solvent does not play a critical role in the function of the salt as a source of oxygen. On the other hand, Ta_2O_5 films produced in glycol contained slightly more O^{18} than SiO_2 films. This discrepancy may be due to the difficulties in oxidizing tantalum in glycol containing KNO_3 which produces films of bad quality and ill-defined composition, even when formed at voltages near 20V.

Incorporation of nitrate in the anodic oxide films.—One obvious reason for the presence of O^{18} in anodic oxides from labeled KNO_3 could be the direct incorporation of NO_3^- or NO_2^- anions into the film [as discussed in a similar case in ref. (7)]. It was therefore important to determine the nitrogen content of oxide films formed in NMA and glycol solutions containing 0.4% KNO_3 and 0.4% water. Nitrogen was measured using nuclear reaction microanalysis, by means of the N^{14} (d,α)C^{12} reaction as described in ref. (17). This sensitive analytical technique allowed us to assign an upper limit to the nitrogen content of the films. This limit was set by the presence of traces of nitrogen on the samples before anodic oxidation. The SiO_2 films formed in both glycol and NMA solutions were found to contain less than 0.2% nitrogen, per oxygen atom. The tantalum oxide films formed in NMA contained less than 0.8% nitrogen per oxygen atom. However, those formed in glycol containing KNO_3 contained a significant amount of nitrogen up to 2.5%, but as stated above, these films are of poor quality and results are probably not reliable.

It thus appears that direct incorporation of nitrogen containing anions accounts for less than 0.6% of the oxygen in SiO_2 and less than 2.4% in Ta_2O_5. In order to account for the 11% oxygen originating from nitrate found, a more complex mechanism of oxygen transfer from salt to oxide must be considered.

Quantitative Interpretation of Results

Empirical relationships for the sources of oxygen.—Let α, β, and γ be the relative contributions to the source of oxygen of the salt, the water, and of the solvent, respectively. We have

$$\alpha + \beta + \gamma = 1 \qquad [2]$$

For equal weights of salt and water it was found experimentally that in all cases

$$\alpha = 10.6 \pm 1\% \quad \text{and} \quad \beta = 88 \pm 3\%$$

hence

$$\alpha + \beta = 98.6 \pm 3\%$$

This shows that γ is negligible, *i.e.*, that within the experimental error the oxygen of the solvent does not constitute a direct source of oxygen.

The laws governing the contributions α and β as a function of salt and water concentrations in the solutions may be deduced from Fig. 6, using certain simple assumptions. Let V_0 be the quantity of solvent used in the labeled KNO_3 experiment, S and W the amounts of salt and water (expressed in moles) at various stages. The isotopic O^{18} content of the oxide films is

$$C = \alpha\eta$$

where η is the isotopic content of the oxygen of the salt (77% in this case). We have shown that η is constant throughout the experiment. Whereas S is constant, $S = S_0$, W varies as water is added to the solution. Hence

$$\alpha = f(W, S_0)$$

where S_0 is a fixed parameter. From Fig. 6 one can deduce, since here $C^* = \alpha$ that

$$\frac{1}{f(W, S_0)} = KW + l$$

K and l being constants.

This formula may be written in the form

$$\frac{1}{f(W, S_0)} = k\frac{W}{S_0} + l \qquad [3]$$

where k and l are now dimensionless constants.

The value of k may be obtained from Fig. 6: $k = 1.8 \pm 0.2$. Using this value and the value $10.6 \pm 1\%$ for C^* for equal weights of salt and water, one may obtain the value of l, which is not far from unity. However, this value is not well defined since it is deduced by extrapolation over a wide interval. If we assume $l = 1$, one may write

$$\alpha = f(W, S_0) = \frac{S_0}{kW + S_0} \qquad [4a]$$

and since $\alpha + \beta = 1$

$$\beta = \frac{W}{k^{-1}S_0 + W} \qquad [4b]$$

Thus, assuming $l = 1$, the amount of salt S_0 is equivalent to an amount $W_e = k^{-1}S_0$ of water. A slightly different value of l would give a more complex homographic relation for α and β, without changing the numerical values appreciably.

The above calculation was based on the hypothesis that $S = S_0$, and in principle k (like l) depends on S. If the simple equivalence law found above applies in a limited range of values of S and W (for given V_0), it is most probable that k is independent of S. This implies, in fact, the assumption that the source of oxygen depends only on the ratio W/S of the water to salt concentrations, and not on the absolute concentrations with respect to the solvent. Whereas no detailed experimental proof of the general validity of Eq. [4a] and [4b] can be given, some measurements made with 0.2% of salt by weight of solvent have confirmed the validity of these laws within the range of experimental conditions studied. Further discussion of this result is given below.

Equations [4a] and [4b] may be tested for the values of α and β measured for equal weights of salt and water with $k = 1.8 \pm 0.2$ and, assuming that $l = 1$. One finds that

$$\alpha = 9 \pm 1\% \quad \text{and} \quad \beta = 91 \pm 3\%$$

which compare well with the values $\alpha = 10.6 \pm 1\%$ and $\beta = 88 \pm 3\%$, found experimentally by independent experiments.

The production and destruction of water.—The experimental results on the production and destruction of electrolytic water (measured using O^{18}-labeled water), shown in Fig. 4 and 5, cannot be interpreted by means of the simple formula [1], since the following facts must be taken into account.

(*i*) A quantity of $q\theta$ of water is produced by θ coulombs (the number of coulombs passed through the cell), with isotopic composition identical to that of the solvent, *i.e.*, natural abundance.

(*ii*) A quantity $\hat{q}\theta$ of water is destroyed by θ coulombs; the isotopic composition of the water destroyed is the same as that of all the water in the solution, assuming isotopic homogeneity due to good stirring.

(*iii*) The O^{18} contained in the destroyed water molecules remains in the solution since the oxygen evolved as a gas at the cathode and the anode is negligible.

(*iv*) The source of oxygen is the water and the salt according to Eq. [4a] and [4b]. The water equivalent $W_e = k^{-1}S_0$ does not participate in the production or destruction phenomena and is of natural isotopic composition throughout (the salt is not labeled in this experiment).

It appears at this stage that in order to interpret the experimental results an additional assumption on the role of the O^{18} atoms which are removed from water is needed. Water is here considered to be all species detected by the Karl Fischer method in the solution. Three simple cases may be considered:

Case I. The new compounds which contain O^{18} do not oxidize the anode and do not undergo isotopic exchange with water. Hence, the corresponding O^{18} atoms do not play a role in further anodic processes.

Case II. The new compounds behave like water for anodic oxidation but are not detected by Karl Fischer titrations. In this case the amount of O^{18} atoms to be considered remains constant.

Case III. The new compounds do not act as a direct source of oxygen but are in isotopic equilibrium with the water in the solution.

The real situation may be a mixture of these various possibilities. In order to interpret our results we have calculated the theoretical curves corresponding to those three models, the calculation being given in the Appendix. The curves corresponding to case I and case III were drawn for NMA in Fig. 4, and for glycol in Fig. 5.

It thus appears that case I is not supported by the experimental results, whereas case III is in excellent agreement with the experimental points for both Ta and Si. Case II gives rise to two possibilities:

Case IIa. That the quantity W in formula [4a] and [4b] represents the total amount of oxygen-supplying compounds. In this case it appears as if there is no water destruction at all and that the phenomenon obeys Eq. [1].

Case IIb. The quantity W in Eq. [4a] and [4b] is the water detected by the Karl Fischer method. Then as shown in the Appendix, the calculated curve is identical with that of case III. These assumptions are discussed below.

It should be noted that case III leads, in the range of values studied, to a nearly linear relation, and the only difference between case III and case IIa is in the calculated value of the rate of water production.

The following rates of water production (q) are thus obtained:

Case III: 9.05 g/**F** in NMA; 17.9 g/**F** in glycol.

Case IIa: 9.85 g/**F** in NMA; 19.3 g/**F** in glycol.

Discussion

The results may be best discussed is relation to two well-defined classes of phenomena: changes induced in the electrolyte by electronic current and the anodic oxidation processes induced by ionic current.

Action of the electronic current on the electrolyte.—First, a choice should be made between case IIa and

case III which give slightly different values for the rate of water production. Case IIb, which gives the same results as case III, seems less likely as, if the decomposition products behave like water for oxygen supply they should also behave like water with respect to the salt. We have no experimental evidence to decide between cases IIa and III. However, it seems less likely that a compound behaves exactly like water for oxygen supply in anodic oxidation and not in titration by the Karl Fischer method. On the other hand, experiments have shown that in the organic solutions used, KOH is detected as water by the Karl Fischer method within experimental error, in agreement with ref. (18) (1.251). As a result the concentration of KOH is included in the amount of water formed when describing our phenomena. Under these conditions (with a 10% error if case IIa is the correct one), our results may be summed up with the statement that approximately 0.5 mole of water per Faraday is created in NMA by the electronic current and 1 mole/Faraday in glycol.

Any mechanism for this process must therefore account for the following facts:

(*a*) about 0.5 mole/Faraday of water is created at the anode in NMA, and 1 mole/Faraday in glycol; in both cases about 80% of the water produced is destroyed at the cathode.

(*b*) H^+ is produced at the anode and OH^- at the cathode.

(c) Hydrogen is evolved at the cathode. Negligible gas evolution is observed at the anode during anodic oxidation of Si and Ta.

(*d*) Slight decomposition of the nitrate into nitrite was measured.

(*e*) Isotopic exchange of oxygen between nitrate, water, and solvents is negligible. However, a very small isotopic exchange between water and the solvents was observed, mainly at the cathode.

The reactions occurring can be discussed in terms of those related to the cathode and those to the anode.

Reactions at the cathode.—The primary reaction at the cathode is probably

$$H_2O \xrightarrow{+e^-} \tfrac{1}{2}H_2 + OH^- \qquad [5]$$

Some of the hydroxide ions formed attack the organic solvent causing it to hydrolyze. While no direct evidence for hydrolysis products could be obtained, the rapid poisoning of the system quoted above may indicate the liberation of such species.

There is some evidence for nucleophilic attack of hydroxide on NMA from the slight exchange of O^{18} observed, by the mechanism involving reversible addition of OH^- to the carbonyl bond as suggested by Bender and Ginger (19). In glycol solutions there is no evidence as to the nature of the exchange reactions.

In the presence of an electric current there is the possibility of the formation of aldehydic species: acetaldehyde in the case of NMA and either acetaldehyde, formaldehyde, or a related compound in glycol. The formation of such species would account for the existence of a compound with one oxygen which rapidly undergoes isotopic exchange with the water in the solvent [ref. (8), p. 55; and ref. (20)]. Carbonyl compounds are not easily analyzed by Karl Fischer titrations and in fact formaldehyde is unaffected by the analytical reagent [ref. (18), p. 147]. Although no positive evidence for an aldehydic species has been obtained, the presence of these entities would account for most of the experimental observations.

The reduction of nitrate to nitrite at the cathode takes place according to the reaction

$$\tfrac{1}{2}NO_3^- + \tfrac{1}{2}H_2O \xrightarrow{+e^-} \tfrac{1}{2}NO_2^- + OH^- \qquad [6]$$

The quantitative measurements of nitrite showed however that this reaction accounts for such a small proportion of the current (3×10^{-4}) that its effect as a pathway for the loss of water is negligible.

Reactions at the anode.—The main reaction at the anode which must be considered is the production of water. It can be assumed that the oxygen of this water comes from the organic solvents in each case, since the only other source, nitrate, can be eliminated from the O^{18}-labeling experiments. Various condensation reactions of organic compounds (both amides and alcohols) can be suggested to account for water production (21). However, in the absence of isolatable products, no mechanism for the production of water can be suggested at the present time. It should be noted that the yield of water in glycol where there are two oxygen atoms is exactly double that in NMA where there is only one. This may be related to the mechanism, but the possibilities of a coincidence cannot be excluded. The most important reaction at the anode is of course the anodic oxidation of silicon and tantalum.

Anodic oxidation processes.—The phenomena investigated may be described as follows:

(*a*) Although their oxidation current efficiencies are very different, in all these experiments silicon and tantalum behaved in an identical manner. It therefore seems very likely that the reactions induced by the electronic current do not affect the mechanism for the supply of oxygen for anodic oxidation. Since in silicon oxidation water is produced, the similarity to tantalum indicates that this water must be immediately mixed with the bulk of the solution, so as to insure isotopic equilibrium.

(*b*) The source of oxygen in anodic oxidation does not depend on the nature (NMA or glycol) of the solution.

(c) The organic molecules do not act as a direct source of oxygen in anodic oxidation. The contribution of the two identified oxygen sources, water and nitrate, depend on their relative concentrations according to Eq. [3] and [4a] and, at least at low absolute concentrations, not on the nature of the solvent. The over-all equations for the reaction with water, which is the main source of oxygen, may be written as

$$Si + 2H_2O \rightarrow SiO_2 + 4H^+ + 4e^- \qquad [7]$$

$$2Ta + 5H_2O \rightarrow Ta_2O_5 + 10\,H^+ + 10\,e^- \qquad [8]$$

(*d*) The nitrate is also a supplier of oxygen as a direct source, since no incorporation of nitrogen or isotopic exchange with water was observed.

External molecular oxygen can play no role in the reaction since all solutions were carefully degassed before use. As was mentioned above, in cells of special geometry, some molecular oxygen may be evolved at the anode during oxidation. This however is not likely to be a source of oxygen by means of electrochemical reactions at the anode.

A tentative mechanism for the direct participation of nitrate in anodic oxidation is the following. The protons formed by the reaction [7] and [8] (and in the case of silicon, also those formed by the electronic current) could react with nitrate ions near the surface of the anode. The reaction will loosen the oxygen to nitrogen bonds possibly through a nitronium type of reaction (22), thereby providing another source of oxygen for oxide formation, the reaction being of the following type

$$NO_3^- \overset{+H^+}{\rightleftharpoons} HNO_3 \overset{+H^+}{\rightleftharpoons} (H_2NO_3)^+ \rightarrow NO_2^+ + (H_2O) \qquad [9]$$

the water species immediately reacting with the anode to form an oxide. The high local concentration of protons near the anode is such that a fixed fraction of the nitrate ions undergoes this process, independently of absolute water concentration and current density. This dependence on local protonation makes these reactions

very sensitive to possible acidity of the salt and to the environment. The two competing sources of oxygen contribute in proportion to the relative concentration of water and salt (assuming that the concentrations are the same near the anode as in the bulk of the solution). The weighting factor k of Eq. [4a] is determined by the fraction of the nitrate ions which undergoes reaction [9]. Whatever the mechanism is, the fact that k is the same for silicon and tantalum is not surprising considering their similar electrochemical properties, the oxidation reduction potentials, for reactions [7] and [8] being 0.86 and 0.81V, respectively, on the hydrogen scale.

APPENDIX

One may calculate the O^{18} content $C(\theta)$ of the oxide films as a function of the charge θ passed through the cell using Eq. [4a] and [4b] and the assumptions corresponding to cases I, II, and III. The calculations enable one to extract from Fig. 3, 4, and 5 the value of the rate of production and destruction of water, knowing the initial total water content (in moles) W_o of the solution, and the initial number of moles, W_o^{18} of the O^{18}-labeled water molecules. The total water content is for any θ

$$W(\theta) = W_o + (q - \hat{q})\theta \qquad [A\text{-}1]$$

This relation was used to extract the values of $(q - \hat{q})$ from Fig. 3, listed in Table I, which were used in the calculations below.

In all cases one may write for any θ, neglecting the O^{17} content

$$W(\theta) = W^{16}(\theta) + W^{18}(\theta) \qquad [A\text{-}2a]$$

Moreover, the new decomposition products formed contain a number of moles U of oxygen where

$$U = \hat{q}\theta \qquad [A\text{-}2b]$$

We may write

$$U(\theta) = U^{16}(\theta) + U^{18}(\theta) \qquad [A\text{-}2c]$$

and we have

$$U^{18} + W^{18} = W_o^{18} = \text{constant} \qquad [A\text{-}2d]$$

since the total number of O^{18} atoms is conserved.

Case I.—Here the only source of oxygen^{-18} is the water, and

$$C(\theta) = \beta(W)\frac{W^{18}(\theta)}{W(\theta)} \qquad [A\text{-}3]$$

where $\beta(W)$ is the fraction of oxygen in the oxide originating from the water, for fixed salt content S_o and variable water content W. We may write from [4b]

$$\beta(W) = \frac{W}{W_e + W} \qquad [A\text{-}4]$$

and

$$C(\theta) = \frac{W^{18}(\theta)}{W_e + W(\theta)} \qquad [A\text{-}5]$$

The destruction of water may be described by the equation

$$\frac{dW^{18}(\theta)}{d\theta} = -\hat{q}\frac{W^{18}(\theta)}{W(\theta)} \qquad [A\text{-}6]$$

according to assumption (*ii*) (Section on Production and destruction of water).

(*a*) If $\hat{q} = q$, $W(\theta) = W_o$ = constant and from [A-6]

$$W^{18}(\theta) = W_o^{18}\exp\left[-\frac{\hat{q}\theta}{W_o}\right] \qquad [A\text{-}7]$$

(*b*) If $\hat{q} < q$, from [A-6] and [A-1]

$$\frac{dW^{18}(\theta)}{d\theta}\Big/W^{18}(\theta) = -\frac{\hat{q}}{W_o + (q - \hat{q})\theta}$$

Simple integration yields

$$W^{18}(\theta) = W_o^{18}\left[\frac{W_o}{W(\theta)}\right]^{\frac{\hat{q}}{q - \hat{q}}} \qquad [A\text{-}8a]$$

The closer $\hat{q}$ is to q, the closer $W^{18}(\theta)$ is approximated by an exponential.

$C(\theta)$ may be conveniently expressed from [A-5] and [A-8a] by writing

$$\frac{W_o^{18}}{C(\theta)} = \left[\frac{W(\theta)}{W_o}\right]^{\frac{\hat{q}}{q - \hat{q}}}[W_e + W(\theta)] \qquad [A\text{-}8b]$$

This expression was used to calculate the curves labeled I in Fig. 4 and 5.

The values of q and $\hat{q}$ to be used in [A-8b] are readily determined by noting that from [A-8b]

$$\left.\frac{d\left[\frac{W_o^{18}}{C(\theta)}\right]}{d\theta}\right|_{\theta=0} = q + \hat{q}\frac{W_e}{W_o} \qquad [A\text{-}9]$$

Hence the second term of Eq. [A-9] is determined by measuring the initial slope in Fig. 4 and 5. Knowing $q - \hat{q}$, q and $\hat{q}$ are calculated.

Case II.—Case IIa is described by Eq. [1] as mentioned above.

Case IIb is described by assuming that the new compounds formed behave for anodic oxidation like a quantity of water U, whereas β is still given by [A-4]. Hence,

$$C(\theta) = \beta\frac{W^{18} + U^{18}}{W + U}$$

Using [A-2d] we may write

$$\frac{W_o^{18}}{C(\theta)} = \left[1 + \frac{W_e}{W}\right](W + U) \qquad [A\text{-}10a]$$

and from [A-1] and [A-2b]

$$\frac{W_o^{18}}{C(\theta)} = \left[1 + \frac{W_e}{W}\right](W_o + q\theta) \qquad [A\text{-}10b]$$

It can readily be shown that the slope of this curve for $\theta = 0$ is also given by Eq. [A-9]. Hence both case I and IIb lead to the same values of q and $\hat{q}$. On the other hand the expression [A-10b] is nearly linear in the range of values of θ considered here, as shown in Fig. 4 and 5.

Case III.—The isotopic equilibrium between the oxygen in the new compounds and the water in the solution, is expressed by

$$\frac{W^{18}}{W} = \frac{U^{18}}{U} = \frac{W_o^{18} - W^{18}}{U} \qquad [A\text{-}11]$$

the last term being deduced using [A-2d]. Solving for W^{18} one gets

$$W^{18} = \frac{W_o^{18}\,W}{U + W} \qquad [A\text{-}12]$$

and as [A-3] and [A-5] fully apply here also, according to assumption (*ii*) (Section on Production and destruction of water)

$$C(\theta) = \frac{W}{W_e + W}\frac{W_o^{18}}{U + W} \qquad [A\text{-}13]$$

hence

$$\frac{W_o^{18}}{C(\theta)} = \left[1 + \frac{W_e}{W}\right](W_o + q\theta)$$

which is identical with [A-10b]. Thus case III and IIb lead to the same result as stated above.

Acknowledgments

We wish to acknowledge the assistance of J. Diaz, P. Paimblant, and R. Venard of the SESCOSEM on

making many of the measurements reported here and of E. d'Artemare for his help in operating the Van der Graaff accelerator of E.N.S. In addition, we are grateful to Dr. J. Siejka for many enlightening discussions. The work was supported by CNRS (RCP No. 157), DGRST, and DRME.

A Study of the Oxygen Growth Laws of Anodic Oxide Films on Aluminum and Tantalum Using Nuclear Microanalysis of O^{16} and O^{18}

J. Siejka, J. P. Nadai, and G. Amsel

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Tour 23-9, Quai Saint-Bernard, Paris 5ème, France

ABSTRACT

The oxygen growth laws of anodic oxide films on aluminum and tantalum were studied using the nuclear microanalysis of the O^{16} and O^{18} isotopes. The influence of current density and surface preparation on the growth laws has been demonstrated. The correlation of the results of nuclear microanalysis of O^{16} and of coulometric measurements allowed the determination of the dissolution current density during anodic oxidation of aluminum. This dissolution current was shown to be purely electrochemical. The values of the intercepts with the potential axis of the linear growth laws show that the overpotentials at the interfaces are smaller than 0.1V for current densities from some $\mu A/cm^2$ to 10 mA/cm^2. Measurements of isotopic exchange of oxygen using O^{18} as a tracer allowed direct estimation of the oxygen exchange current without applied field. The results show that oxygen transfer at the oxide-solution interface, enhanced by field-induced oxygen vacancies, is responsible for the growth of the anodic film.

The growth laws of anodic barrier layers on aluminum and tantalum have been carefully investigated by numerous authors (1-8) using various methods. The published results clearly indicate that the growth laws of the anodic layers are strongly dependent on the experimental conditions of sample surface preparation and of film formation, illustrating the complicated character of the mechanisms involved. It appears that the direct measurement of the oxygen content of the anodic films as a function of various parameters could contribute to the elucidation of some of the aspects of these growth mechanisms. In addition the use of tracing techniques applied to the isotopes of oxygen may yield further information, which cannot be provided directly by classical methods, on the electrochemical processes taking place during anodic treatments.

Key words: oxygen, aluminum, tantalum, anodic oxidation, growth rate, O^{18} tracing, nuclear microanalysis, exchange current, interface, surface treatment.

In this work we applied the microanalysis of the isotopes of oxygen by means of nuclear reactions to a detailed study of the anodic oxidation of aluminum and tantalum in aqueous solutions. The isotope O^{16} (natural abundance 99.758%), determined by the nuclear reaction $O^{16}(d,p)O^{17*}$, was monitored to measure the oxygen content of films formed in solutions of natural isotopic composition. In the absence of long-lived radioactive isotopes of oxygen, O^{18}-enriched compounds may be used for tracing experiments, the $O^{18}(p,\alpha)N^{15}$ reaction allowing the determination of the O^{18} isotope (natural abundance 0.204%) contained in the films. Several recent publications (9-12) deal with the application of this method to anodic oxidation processes. The techniques themselves are described in detail in ref. (13-15) and will not be pre-

sented here. These microanalytical techniques allow the determination, with a precision of the order of 1% even for oxide films some 10Å thick, of the number of O^{16} or O^{18} atoms/cm^2 they contain, with respect to an absolute oxygen standard. As an absolute oxygen standard we used here an anodic oxide film formed on tantalum in well-defined conditions, as described in ref. (9); it was shown in this reference that precise coulometric measurements allow in this case the absolute determination of the number of oxygen atoms/cm^2 in the standard with a precision of about 3%.

The oxygen growth laws were measured in both natural and O^{18}-labeled solutions for various sample surface preparation procedures. The results clarify the influence of the initial layer on the metal on the growth of the anodic films. Furthermore we have tried to estimate the value of the sum of the overpotentials at the metal-oxide and oxide-solution interfaces, by measuring the intercept of the oxygen growth law with the potential axis for various oxidation currents. For tantalum, Young (1) and Vermilyea (2) found very small overpotentials, which seems to imply a high ionic exchange current at the oxide-solution interface. We have therefore attempted to measure this exchange current directly by studying the isotopic exchange of O^{18} in order to correlate its value with those of the overpotentials, found by the nuclear method, for the two metals. In addition we have tried by the nuclear method to demonstrate the existence on the samples of layers of high ionic conductivity for various methods of surface preparation and, when such layers exist, to relate their presence to the changes observed in the corresponding oxygen growth laws. We have not attacked here the problem of the mechanism of ionic transport in the oxide itself. This was dealt with in ref. (10) and will be further studied, by O^{18} tracing, in a future publication.

Sample Preparation

The aluminum used was in the form of bright rolled and annealed sheets 0.6 mm thick, of purity 99.9%. Taking into consideration on the one hand that electrochemical polishing of aluminum is known to leave on the surface of the metal a thin film which may differ in its properties from anodic barrier layers (6, 16, 17), and on the other hand that unpolished samples, although free of contamination by chemicals, might present a less well-defined state of the surface, both polished and unpolished aluminum samples were systematically studied in this work. Unpolished samples were cleaned with acetone in a vapor degreasing set-up according to the classical procedure described by Holland (18). Electropolishing of the samples was carried out so as to avoid the deleterious effects on the anodic oxidation of aluminum of contamination by chlorine (17) or by chromates (6). On the other hand, as Godard reports that SO_4 anions are less "aggressive" to aluminum than chlorine (19) we used sulfuric acid as the main polishing agent. The procedure used consisted in: (*a*) etching in a sodium hydroxide solution (10% by weight, 10 min); (*b*) dipping into a solution containing 15% trisodium phosphate and 20% disodium carbonate (10 min); (c) anodic polishing in a solution containing 20% sulfuric acid (1 min, 5 mA/cm^2); (*d*) dipping for 10 min into the above solution; and (*e*) rinsing in triply distilled water. This procedure is used in industry and yields a highly brilliant surface; the corresponding results on anodic oxidation showed a high degree of reproducibility.

The tantalum used, 99.95% pure, was in the form of unannealed rolled sheets 0.2 mm thick. As in ref. (9) the samples were degreased with acetone and chemically polished for 15 sec in a mixture of 5 volumes of 95% H_2SO_4 2 volumes of 53% HNO_3, and 2 volumes of 45% HF. As suggested by Young (1) the samples were then dipped for 5 min in boiling tridistilled water. The assumption of Young, according to which this leaching removes fluorine traces from the surface of polished tantalum, was recently confirmed in our laboratory using nuclear microanalysis of F^{19} (20). Although for tantalum the polishing process seems to have less influence on the subsequent anodic behavior than for aluminum, here again polished and unpolished samples were compared in some cases.

All the samples were punched into 2 cm^2 rectangles by a special tool (9) insuring the reproducibility of the area. The electrical contact with the samples was made by a 0.5 mm wire as described in ref. (9) or by a special tantalum clip used by Croset (21).

The unlabeled solutions were prepared with triply distilled water of resistivity 0.5 x 10^6 ohm-cm, and high-purity salts provided by Merck. Oxidations were carried out at 22° ± 1°C in aqueous solutions of 5% by weight ammonium citrate of *p*H 6. These solutions were prepared by dissolving diammonium citrate and by adjusting the *p*H with ammonia. This yields a mixture of di- and triammonium citrate solution with good buffer characteristics.

In the tracer experiments water of nonnatural isotopic composition of oxygen was used[1]: either enriched to 80% in O^{18} (and about 0.7% in O^{17}) or depleted 30 times in O^{18} (0.007%). The isotopic composition of hydrogene was normalized near to the natural abundance (deuterium content <0.1%). The first O^{18}-labeled anodic oxide films on aluminum were produced by Amsel and Samuel (10). They encountered difficulties in oxidizing aluminum in small volumes of O^{18}-enriched water and succeeded to do so only by a massive adjunction of ammonia, up to *p*H 9 (22). It was found in this work that these difficulties were due to impurities introduced in the labeled water during the enrichment procedure: careful purification allowed the anodic oxidation of aluminum to be carried out in conditions identical to the nonlabeled case. The handling of the labeled water was carried out using a vacuum line; this allows repeated loss-free transfers of the expensive enriched water, easy purification, and prevents any isotopic exchange with the constituents of the atmosphere (23). The first stage of the purification consists of eliminating dissolved gases. The sealed ampula containing a given quantity of labeled water is broken inside a cell connected to the distillation line. This cell is placed in a mixture of solid carbon dioxide and acetone; once the water has frozen, the greatest part of the dissolved gases (O_2, CO_2, H_2, N_2) are removed by pumping. In the second stage, to eliminate traces of halogens, in particular, the water was distilled over sodium contained in a glass capillary (following the procedure developed by Dostrowsky (24) at the Weizmann Institute) from ambient temperature to that of melting ice. The transfer must be carried out in several stages, between which the hydrogen formed is pumped off at CO_2-acetone temperature. The water is then distilled from the resulting sodium hydroxide solution at ambient temperature into the oxidation cell containing the necessary quantity of salt, at the temperature of melting ice.

Salts of natural isotopic composition were used both in the O^{18}-enriched and depleted solutions: preliminary experiments using ammonium citrate enriched to 70% in O^{18} showed that at least 98% of the oxygen contained in the films formed on aluminum and tantalum in our experimental conditions come from the water in the solution used (25). In addition it was shown by Samuel (26) at the Weizmann Institute that the isotopic exchange between ammonium-citrate and water is negligible at room temperature. O^{18}-labeled solutions at *p*H 6 were prepared in the following way. Ammonium citrate was dissolved in an ammonia solution of *p*H 8 in the oxidation cell. This solution was evaporated and the remaining salt dried for 6 hr in high vacuum at room temperature. The labeled water was then distilled on the salt. This procedure yields a solution of *p*H 6-6.5. The final adjustment of the *p*H,

[1] Supplied by the Weizmann Institute, Rehovot, Israël.

if necessary, may be achieved by adding a minute amount of dry citric acid.

In all the experiments with nonnatural water a special 5 cm³ cell [described in ref. (22)] was used due to the high cost of enriched or depleted water. A special sample holder was used, described in (27), with a platinum wire cathode encircling the sample. The oxidations were carried out under atmospheric pressure, the contact with the ambients being kept to a minimum. In these conditions the drop in enrichment of the 80% O^{18} water was negligible during the duration of the experiments.

The anode potential was measured with respect to a reference electrode using a high impedance voltmeter (Keithley 610B, 10^{14} ohms). To avoid contamination of the solutions by chlorine ions from a calomel reference electrode, a mercury sulfate electrode was used. To further minimize any contamination the reference electrode was separated from the solution by a double junction of sintered glass.

For electrolytes enriched in O^{18}, reference electrodes were not used, to avoid any possibility of isotopic exchange. The anode potential was measured with respect to a platinum cathode whose current-potential characteristics had previously been measured with respect to a reference electrode.

Most of the oxidations were carried out at constant current densities, in the range of 1-10 mA/cm², using a Harrison 6209B power supply. Once the potential V_{ox} between the anode and the reference electrodes reaches a preset value, an electronic arrangement cuts the circuit. A digital current integrator (Brookhaven Instruments Corporation, Model 1000) connected to a counting scale, gives the number of coulombs consumed during the oxidation. This integrator, designed for accelerator beam current measurements, insures a precision and absolute calibration better than 10^{-3}.

In order to operate at low current densities, below 10 μA/cm², after a constant current stage (5 mA/cm²), the potential V_{ox} was maintained constant for fixed times (10 min for tantalum, 20 min and 50 min for polished and unpolished aluminum, respectively) allowing the current to decay to small final values. This procedure kept the duration of these experiments reasonably short while minimizing the perturbing effects arising at low current densities of oxidation for aluminum, which result in the formation of porous oxide or hydroxide layers as reported in ref. (4, 28, 29) (see below).

Results and Interpretation

Nuclear microanalysis gives the numbers N_{O16} or N_{O18} of oxygen atoms per square centimeter fixed on the surface of the sample; O^{17} will be neglected and hence the total number of oxygen atoms per square centimeter N_O is given in any oxide film by $N_O = N_{O16} + N_{O18}$. It should be noted that when results from nuclear microanalysis are compared with coulometric results obtained on the same sample, the effects of roughness cancel out, as has been pointed out in ref. (9). For a homogeneous oxide it is possible to introduce an equivalent geometric thickness L deduced from N_O, by assigning known values to the stoichiometry and the density of the chemical compound formed as well as to the roughness factor of the underlaying surface. Under such assumptions we may write

$$L = \lambda N_O \qquad [1]$$

where λ is a constant. This relation allows the comparison of our results on growth laws with those obtained by other authors, who measured the thickness of the films formed by various methods such as capacitance, optical, gravimetric, etc., measurements. Let us remark that the determination of the intercepts of the growth laws with the potential axis does not depend on a given normalization of the thickness, and hence neither on the roughness factor nor on the absolute oxygen standard.

Oxygen growth laws.—General characteristics.— Figures 1, 2, and 3 show the curves $N_O = f(V_{ox})$ obtained at various final current densities between some μA and 10 mA/cm², on polished tantalum and unpolished and polished aluminum, respectively. The values of the potentials are expressed in the hydrogen scale, in volts. The oxidations were carried out in unlabeled solutions; N_O is therefore given by N_{O16}. It should be noted that the quantities of oxygen in the initial layer

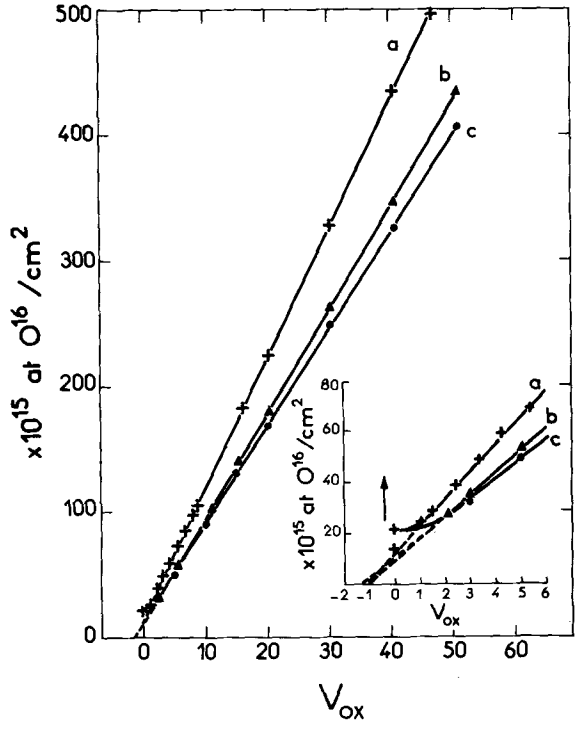

Fig. 1. $N_{O16} = f(V_{ox})$ for polished tantalum for various final current densities: curve a, of the order of 1 μA/cm² (constant potential); curve b, 1 mA/cm²; curve c, 10 mA/cm². The insert shows the detail near the origin.

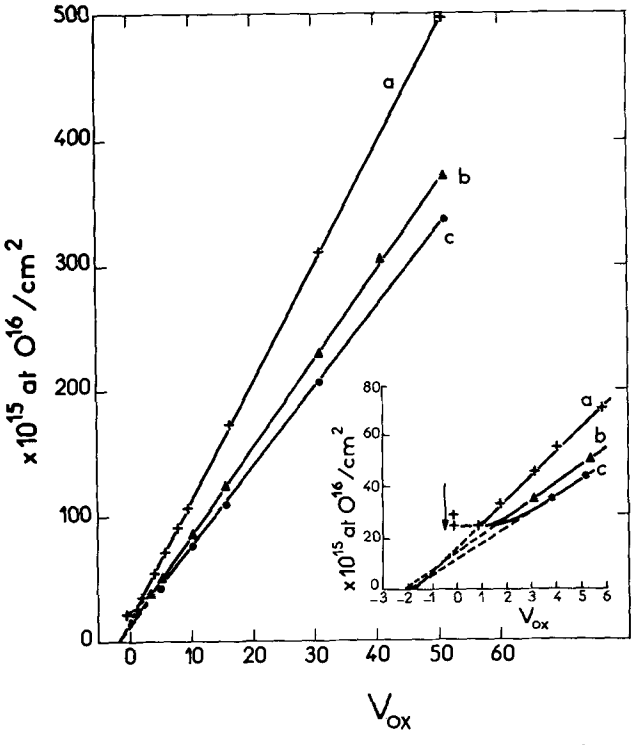

Fig. 2. $N_{O16} = f(V_{ox})$ for unpolished aluminum: curve a, below 10 μA/cm² (constant potential); curve b, 1 mA/cm²; curve c, 10 mA/cm². The insert shows the detail near the origin.

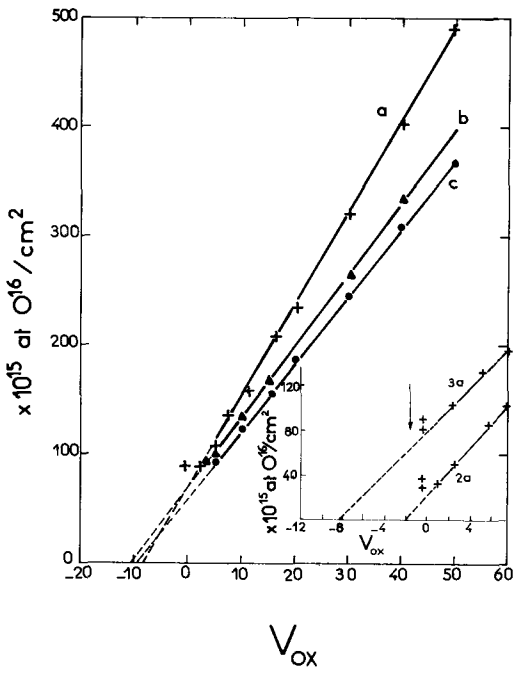

Fig. 3. $N_{O16} = f(V_{ox})$ for polished aluminum: curves a, b, c see Fig. 2. The insert compares in detail the growth laws at constant potential for unpolished (curve 2a) and polished aluminum (curve 3a).

change when the sample is immersed in the solution, before any potential is applied. This variation is shown in these figures (direction of the arrow).

The anode potential V_{ox} satisfies, according to Young (1), the relation

$$V_{ox} - V_{eq} = \eta_m + \eta_s + \eta_{ox} \qquad [2a]$$

throughout the oxidation, where η_m is the overpotential at the metal-oxide interface, η_s that at the oxide-solution interface, and η_{ox} that in the oxide. V_{eq} is the anode equilibrium potential; this potential is equal to the thermodynamic potential V_{th} for the formation of the oxide (1-3) for which the over-all reaction can be written

$$M + H_2O \rightleftarrows MO + 2H^+ + 2e^- \qquad [3a]$$

where M represents the metal.

If all the oxygen on the sample surface is contained in a highly insulating oxide film which behaves as an anodic barrier layer, we may write

$$\eta_{ox} = \lambda E_{ox} N_O \qquad [2b]$$

where E_{ox} is the electric field of formation of the oxide. If the film contains a region of high ionic conductivity, with oxygen content N_O^c, we have

$$\eta_{ox} = \lambda E_{ox}(N_O - N_O^c) \qquad [2c]$$

Hence, in the most general case we have

$$V_{ox} - V_{eq} = [\eta_m + \eta_s - \lambda E_{ox} N_O^c] + \lambda E_{ox} N_O \qquad [3b]$$

The intercept $V_{ox}(0)$ of the curve $N_O = f(V_{ox})$ with the V_{ox} axis for $N_O = 0$ is given for constant N_O^c by

$$V_{ox}(0) - V_{eq} = \eta_m + \eta_s - \lambda E_{ox} N_O^c \qquad [3c]$$

It is clear from Eq. [3c] that in the case when an initial layer of high ionic conductivity is present on the sample surface, the curve $N_O = f(V_{ox})$ is shifted toward the negative potentials. Moreover, if $N_O^c = 0$ the curves $N_O = f(V_{ox})$ for various current densities (hence various E_{ox}) intersect at one and same point, the intercept $V_{ox}(0)$ yielding the sum of the overpotentials.

In order to determine with precision the values of the parameters of Eq. [3b] it is advantageous to operate in conditions such that the curves $N_O = f(V_{ox})$ are linear. In particular E_{ox} and the overpotentials should be constant; this was insured by taking into account the following considerations. The final current density J may be decomposed in the oxide according to

$$J = J_i + J_e \qquad [4]$$

where J_i is the ionic and J_e the electronic current density, respectively. It is known that one to one relations exist between E_{ox} and J_i and between the overpotentials and J_i; furthermore these relations are of the logarithmic type. Hence E_{ox} and the overpotentials are constant if J_i is, and are nearly constant even if J_i varies slightly, owing to their logarithmic dependence on the latter. In the case of oxidations at constant current ($1 \leq J \leq 10$ mA/cm^2) J_e was always less than 5% of J (see below); this insures a good constancy of J_i by simply controlling J itself. In the case of oxidation at constant potential, at the low final current densities reached, J_e may be a large fraction of J. In this case we have no precise estimation of J_i and it appears that the control of the duration of the anodic treatment leads to a better constancy of J_i than the control of J, as illustrated by additional results below. Figures 1 to 3 clearly illustrate that operation according to these principles leads to the linear relations expected.

The experimental values of the slopes of the straight lines in Fig. 1, 2, and 3 and of the intercepts $V_{ox}(0)$ were determined by a method of least squares; they are listed in Table I. In our experimental conditions the thermodynamic potential V_{th} for the formation of tantalum oxide is equal to -1.15V (30) and for the formation of hydrated aluminum oxide or anhydrous aluminum oxide to -1.9 and -1.84V, respectively (31); over the whole range of currents investigated for polished tantalum and unpolished aluminum the values $V_{ox}(0)$ are very close to these theoretical values of V_{th}. The mean value of the difference with V_{th} is -30 mV for Ta_2O_5, and -13 or -73 mV for Al_2O_3,

Table I. Characteristic constants of the growth laws

Metal	Surface preparation	J, mA/cm^2	$dN_O/dV_{ox} = \frac{1}{\lambda E_{ox}}$ $\times 10^{15}$ at./cm^2 V	$V_{ox}(0)$ deduced from $N_O = f(V_{ox})$*	$V_{ox}(0)$ deduced from $\hat{N}_O^{18} = \hat{g}(V_{ox})$

with a statistical standard deviation of 80 and 170 mV, respectively. It can be deduced that the sum of the overpotentials $\eta_m + \eta_s$ is statistically zero with the standard deviation indicated. By contrast the straight lines corresponding to polished aluminum are considerably translated toward negative potentials with respect to those for unpolished aluminum, as is shown in detail on Fig. 3. Moreover the initial layer contains about three times more oxygen on polished aluminum than on unpolished aluminum. In view of Eq. [3c] this result strongly suggests that the anodic oxides on the polished aluminum samples contain a layer of high ionic conductivity; it seems likely that this layer originates in the initial oxide layer left on the samples after the polishing procedure.

It appears also that when the growth law curve is shifted toward negative potentials the corresponding slope decreases. In the case of aluminum the ratio of the slopes for polished and unpolished samples varies between 0.98 to 0.86 as the current density varies between 10 mA/cm^2 and some μA/cm^2.

Control experiments carried out at constant potential, in electrolytes containing 0.5% by weight of salt (*i.e.*, 10 times less than above), produced the same results as those of Fig. 1-5 and Table I, within experimental error. This shows that the influence of salt concentration on the growth laws is very small, if any.
