The calculated InP-GaP pseudobinary is shown in Fig. 1 and is compared with the experimental solidus curve from Foster and Scardefield (17) and values obtained from extrapolated In-Ga-P ternary data (3) for the liquid. The computed solidus gives a perfect fit with the experimental compositions, while the calculated liquid line indicates GaP fractions which are 5 m/o (mole per cent) too high or a temperature 20°C too low. Adjusting $\alpha_{\text{In-Ga}}$ to 2000 cal/mole and increasing the interaction parameter for the solid slightly by 80 cal/mole results in an agreement with the experimental data within the experimental accuracy. It is felt that it is not the uncertainty in $\alpha_{\text{In-Ga}}$ obtained by Macur *et al.* (14) which gives rise to the discrepancy between the experimental liquidus line and the one as calculated and shown in Fig. 1, because the fit is within 2 a/o (atomic per cent) for the rest of the ternary system and becomes worse in varying the respective α's. It might be the application of the lattice model as described by Guggenheim (6), which is questionable for III-V semiconductors. This model was originally derived and applied to organic mixtures where the temperature variations are much smaller than for the In-Ga-P system.

Foster and Woods (13) compared the predictions given by the QCE or zero order approximation treatments for several III-V pseudobinaries with the experimental results. They indicated that the relative magnitude of the enthalpy (ΔH^{M}_{ex}) and entropy (ΔS^{M}_{ex}) term in the excess free energy of mixing (ΔF^{M}_{ex}) are such that in theory $\Delta H^{M}_{ex} > T\Delta S^{M}_{ex}$. This should mean for the interaction parameter $\alpha = a - bT$, which is directly related to ΔF^{M}_{ex} that $a > bT$. Experimentally, however, the ternary and pseudobinary can only be described with an interaction parameter with $a < bT$. Hence there exists a serious contradiction, for the experimentally determined excess free energy is nearly entirely an entropy term ($T\Delta S^{M}_{ex}$), while theory predicts it should be mainly an enthalpy (ΔH^{M}_{ex}).

Application to Liquid Phase Epitaxy

A major application from the knowledge of the In-Ga-P phase diagrams for liquid and solid is in predicting conditions for LPE growth. Only phosphorus fractions smaller than 0.5 are considered because only they have any current application because of the otherwise very high vapor pressures involved.

The criteria for LPE growth under equilibrium conditions are the absence of miscibility gaps in solid and liquid and the stability of the solid in the presence of the liquid. The existence of miscibility gaps comes straightforwardly from the calculations of the isotherms in the In-Ga-P system, when no solution of the equations describing solid and liquid is possible. The stability of a solid, for example a substrate, in a ternary liquid can be expressed in terms of their respective free energies. The free energy for the liquid phase can be written as

$$F^{l} = \mu^{l}_{In}N_{In} + \mu^{l}_{Ga}N_{Ga} + \mu^{l}_{P}N_{P} \quad [2]$$

and for the solid as

$$F^{s} = \mu^{s}_{InP}N_{InP} + \mu^{s}_{GaP}N_{GaP} \quad [3]$$

The atomic and molecular fractions (N_i) in liquid and solid are obtained from the calculation of the phase diagram. The chemical potentials are obtained from the equivalent equations derived by Ilegems and Pearson (7). The entropies of fusion for the pure elements, needed to calculate the chemical potential for the pure elements are $\Delta S^{f}_{P} = 1.9$ eu, $\Delta S^{f}_{In} = 1.8$ eu, and $\Delta S^{f}_{Ga} = 4.4$ eu (18).

Equilibrium is established when the free energy-composition curves of a solid and liquid phase have a common tangent line. Figure 2 is a schematic diagram of the free energies of the ternary In-Ga-P liquid and binary $In_xGa_{1-x}P$ solid phases as a function of composition. Any solid in this system with a higher free energy than for that solid which is in equilibrium with a specific liquid composition will, when brought into contact with that liquid, dissolve isothermally in order to minimize the free energy of the total system from this nonequilibrium situation. For the same reason, isothermal crystal growth will occur if a solid with a lower free energy is introduced into the liquid. The difference in free energy between the equilibrated solid and new introduced one is the driving force for isothermal dissolving or crystal growth.

The free energies for liquid and solid which establish equilibrium at 900°C, calculated according to Eq. [2] and [3], are plotted in Fig. 3, both as a function of the Ga fraction in the liquid; similar curves exist for other temperatures. As expected for equilibrium conditions the free energy for the solid is smaller than that for the liquid at each composition. As is observed in Fig. 3 the free energy of pure InP is always higher than the solid which is in equilibrium with an In-Ga-P ternary melt. Accordingly an InP substrate will tend to decompose in any In-Ga-P melt, while a GaP substrate is stable. Approaching equilibrium dissolving is indeed experimentally observed after exposure of InP to an In-Ga-P melt while LPE of $In_xGa_{1-x}P$ on GaP substrates has been done in many laboratories. When growing under highly dynamic conditions, hence when equilibrium conditions may be disregarded, it might

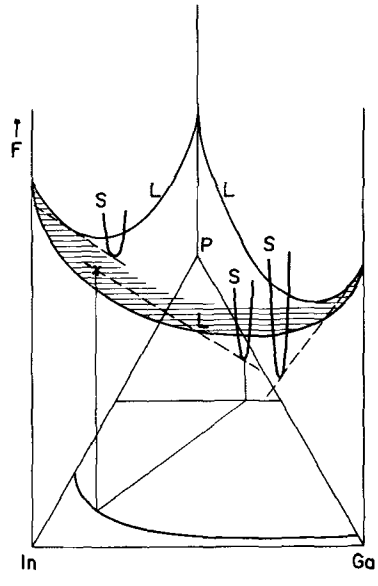

Fig. 2. Schematic diagram of the free energies for liquid and solid as a function of their compositions. The dashed lines represent lowest common tangent lines. L = liquidus lines, S = solidus lines.

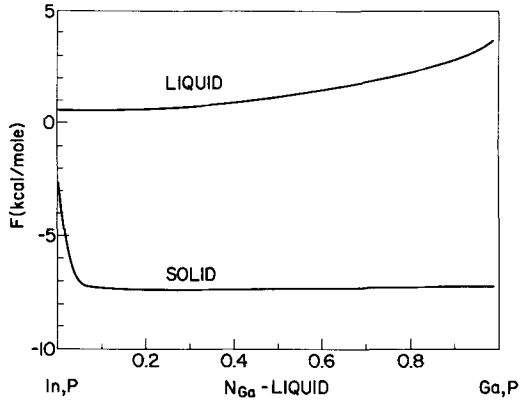

Fig. 3. Calculated free energies which establish equilibrium at 900°C for the liquid and the solid phase both as a function of the Ga fraction in the liquid. Note that the free energy in the solid is not plotted as a function of the composition of the solid, but as a function of the composition of the liquid with which it is in equilibrium.

be possible that heterojunction structures on "wrong" substrates, as for example $In_xGa_{1-x}P$ on an InP substrate, can be grown despite the fact that the difference in free energy is large, as is therefore the driving force for dissolving the substrate.

After establishing the potential possibilities for LPE of $In_xGa_{1-x}P$, from the knowledge of the phase diagrams, the predicted composition variation of a deposited LPE layer is described as a function of the growth temperature, assuming equilibrium. For a melt containing 50 a/o phosphorus, this is known from the pseudobinary phase diagram. When we grow from the In-rich corner of the ternary system the P as well as the Ga atomic fraction in the liquid will decrease upon cooling because the distribution coefficient (C_s/C_l) is for both elements larger than unity. From a numerical calculation on the phase diagram one can determine how, under thermodynamical equilibrium conditions, the composition in liquid and solid vary upon cooling and also how much of the liquid will solidify. Using as an example, a first-to-freeze composition of $In_{0.3}Ga_{0.7}P$, which is nearly the highest Ga content where direct bandgap electroluminescence is possible, we can compare the changes in composition and the amount of solidification (*i.e.*, weight percentage) for various temperature ranges of crystal growth. The results are summarized in Table II. It is shown that in equal temperature changes (ΔT) the highest starting growth temperature, for which we choose the pseudobinary, provides the largest amount of crystallization and also the largest change in solid composition. It is also shown that for equal percentages of solidification, hence for equal thicknesses of a liquid phase epitaxial layer, the composition variation in the solid for various starting growth temperatures is very small and can be neglected for practical LPE purposes. This means that the ratio of the amount of crystallization and composition variation in the solid is nearly independent of temperature. For practical applications under equilibrium conditions there are certain advantages in growing at relatively low temperatures, where the same solid can be achieved in a larger cooling cycle and at lower phosphorus partial vapor pressures.

Table II. Summary of the composition variation and temperature conditions to achieve an $In_{0.3}Ga_{0.7}P$ crystal

T (°C) (starting growth temp)	ΔT (°C)	$1-x$ (after cooling ΔT°C)	Weight % solidification	Ga at. fraction in starting liquid
1168	20	0.62	3.2	0.058
	5	0.68	0.8	
1000	20	0.66	1.4	0.053
	11	0.68	0.8	
900	20	0.68	0.8	0.045

In Table II are also shown the Ga atomic fractions in the liquid prior to growth. It turns out that the Ga concentration is nearly the same in all three cases to achieve a first-to-freeze GaP concentration of 70% in the solid. Hence when we replace P by In it means we can work at lower temperature and grow equally homogeneous $In_xGa_{1-x}P$ crystals. This characterization of a nearly temperature independent Ga concentration in the liquid to achieve a certain GaP fraction in the solid is not restricted to the 70% solid but holds over a wide region in the phase diagram.

The Effect of Trace Amounts of Water Vapor on Boron Doping in Epitaxially Grown Silicon

J. Bloem*

Semiconductor Development Laboratory, N. V. Philips Gloeilampenfabrieken, Nijmegen, Holland

ABSTRACT

It was found that silicon epitaxy from silane (SiH_4) can tolerate unexpectedly high water concentrations in the gas phase before deterioration of the growing layer sets in. The extent of boron doping from B_2H_6, however, is shown to be strongly influenced by water vapor concentrations in the ppm region. It is shown that HCl gas at partial pressures greater than 10^{-3} atm has a similar influence on the extent of boron doping and that it makes the system less susceptible to small variations in water vapor concentrations. The results can be explained by consideration of the various gas phase equilibria at or near the silicon-gas interface.

In the epitaxial growth of silicon layers it was discovered early that the presence of oxygen or water vapor has a detrimental effect on the quality of the epitaxial layers (1). In doping the silicon layers, boron doping (using B_2H_6 as the doping agent) appeared to be a more difficult operation than doping with P, As, or Sb compounds. The water content of a well-purified gas was seen to lie in the order of 1 ppm or less (10^{-6} atm in the 1 atm open-tube system used); this value is orders of magnitude higher than the B_2H_6 concentration of 10^{-10} atm used in doping. Because the varying results in boron doping were thought to be explained by small differences in the efficiency of the gas purification, by small leaks in the gas-handling system, or by residual moisture on the surface of the quartz reactor, it seemed appropriate to study the effect of trace amounts of water vapor on boron incorporation.

Experimental Procedure

The horizontal, air-cooled epitaxial reactor consisted of a quartz tube 80 cm in length, of rectangular cross section (10 × 2.5 cm^2) into which a SiC-coated graphite susceptor (9.5 × 24 × 1.0 cm^3) was placed. The susceptor was loaded with 10 silicon slices of 38 mm diam in two parallel rows and was R.F.-heated. The main gas stream for all runs was 75 liters hydrogen per min. The silicon substrates were (111)-oriented, mechanically and chemically polished, with dislocation densities less than 500 dislocations per cm^2. The surface quality of the slices was such that under normal conditions a heat treatment prior to epitaxial growth of the slices in hydrogen at 1250°C for 15 min was sufficient to obtain layers free of spikes and stacking faults. The resistivities of the epitaxial layers were measured both by the four-point probe technique (2) on reference slices of opposite resistivity types and by spreading resistance measurements (3). When p-type doping was studied, higher resistivity (about 2 ohm-cm) n-type substrates were placed on the susceptor along with the low-resistivity (0.007 ohm-cm) n-type substrates. It appeared that lower resistivities were the same on both types of substrates within the experimental error (±15%). By tilting the susceptor (1°30′) and slightly adjusting the temperature over the susceptor (leading edge about 20° cooler than end section), depletion of the gas phase was counteracted in such a way that both thickness and resistivity variations were minimized (±5% for thickness, ±15% for resistivity). Thickness and resistivity values on slices 4 and 10 cm from the leading edge were taken to be representative for the run.

The thickness of the grown layers was measured by the infrared interference technique (4). For the thickness measurements layers grown on Sb-doped substrates (resistivity 0.007 ohm-cm) were used. The thickness of the epitaxial layers was monitored from 10 to 20 μm. Unless otherwise stated, the silicon growth rate was kept at about 1 μ/min ($p_{SiH_4} = 10^{-3}$ atm). The values from the *IR* interference technique were in accord with those obtained by the bevel and stain method. The temperature of the substrates was measured with an optical pyrometer, and the readings were corrected for the emissivity of silicon (5).

The starting silane and diborane (4% SiH_4 in H_2, 1% B_2H_6 in H_2) were diluted with hydrogen to the wanted partial pressures using calibrated flowmeters. The water vapor was obtained from an evaporation cell filled with water at constant temperature (20°C). By passing a small hydrogen stream (0-100 cm^3) over the surface of the liquid and mixing this with the main gas stream (75 liters/min) the water vapor concentration in H_2 was varied from 0 to 50 ppm (0-50 × 10^{-6} atm). In separate runs analysis with a Beckmann moisture meter showed the measured water content of the gas to be in good agreement with the amount calculated from the vapor pressure of water. Epitaxial runs without diborane doping were performed, and silicon layer resistivities higher than 20 ohm-cm, n-type, were consistently obtained. On the addition of water vapor the resistivity remained on this level. Prolonged annealing of the layers at 500°C shows the donor activity expected from the oxygen content (6). The addition of HCl showed the resistivity to decrease; for the highest HCl concentration (2 × 10^{-2} atm) the resistivity dropped to 3 ohm-cm (1.6 × 10^{15} donors/cm^3). Where necessary, corrections for this additional doping effect were applied.

Experimental Results

Influence of water vapor on silicon epitaxy.—Epitaxial runs at 1150°C with increasing amounts of water vapor showed that up to 40 × 10^{-6} atm of water vapor in the gas did not cause stacking faults in the layers, provided that the slices were preheated for 15 min in hydrogen at 1250°C before the introduction of silane. For $p_{H_2O} \approx 10 \times 10^{-6}$ atm small pits become visible on the Si surface. This is an aftergrowth effect: when the silane flow is terminated the freshly grown layer is etched slightly by the water vapor present in the hydrogen. On further cooling, the formation of SiO_2 could be expected; this is not observed presumably because the cooling period is too short. For values of p_{H_2O} greater than 10 × 10^{-6} atm the onset of gas phase reactions gave a brown deposit on the relatively cold upper wall of the reactor. This deposit was accompanied by a decrease in epitaxial layer thickness; the farther the substrate from the leading edge of the susceptor, the greater the decrease. With $p_{H_2O} = 40 \times$

* Electrochemical Society Active Member.
Key words: chemical vapor deposition, silicon thin films, gas phase doping, surface reactions.

10^{-6} atm, deposition of silicon was present only on the first row of silicon slices.

Influence of water vapor on boron doping.—In order to examine the boron content of the grown layers as a function of the silicon growth rate, the partial pressure of diborane ($p_{B_2H_6}$) was kept constant whereas p_{SiH_4} and consequently the growth rate was varied. The variation of growth rate with p_{SiH_4} is shown in Fig. 1, and the boron concentration as a function of growth rate is depicted in Fig. 2. The scatter in the results shown in Fig. 2 decreased considerably after checking the apparatus for minor leaks and careful drying of the quartz tube used. Subsequent experiments then showed the same behavior, *i.e.* no distinct increase or decrease of the concentration of boron incorporated in the layers as long as $p_{B_2H_6}$ is kept constant; only for the highest growth rates a slight decrease in boron concentration is found.

The boron concentration in the layers varies linearly with $p_{B_2H_6}$ (Fig. 3). If the water vapor pressure is increased for a fixed value of $p_{B_2H_6}$ and p_{SiH_4}, a decreasing boron concentration is found; this effect occurs for various diborane concentrations (Fig. 4). For higher values of p_{H_2O} the decrease is proportional to $(p_{H_2O})^2$ (Fig. 4).

The boron concentration in the epitaxial layers is temperature dependent; contrary to the findings for n-type dopants (7) the concentration increases with increasing temperature (Fig. 5). There is some indication of a decreasing influence of water with increasing temperature.

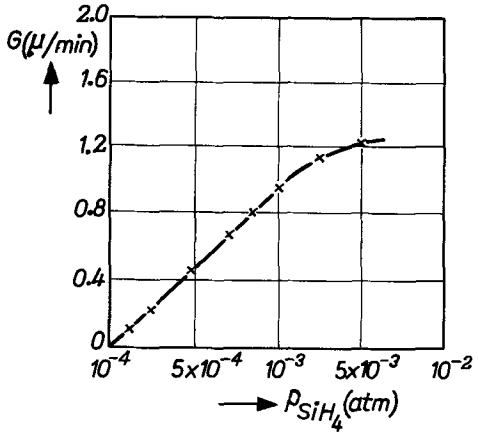

Fig. 1. Growth rate of silicon as a function of the partial pressure of silane in the gas phase.

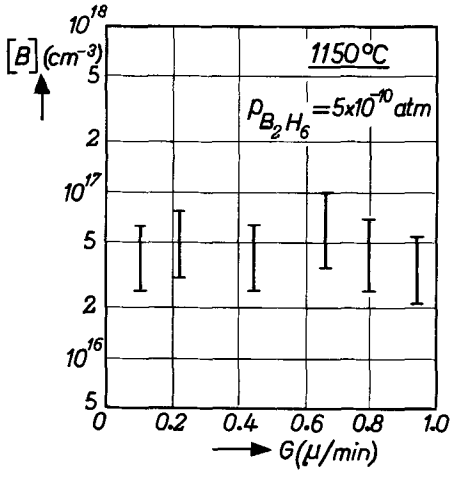

Fig. 2. Boron concentration in the epitaxial layers as a function of silicon growth rate (constant partial pressure of diborane in the system).

Influence of HCl on boron doping.—The introduction of HCl in the epitaxial reactor shows only a small influence on silicon growth rate (8): a ratio p_{HCl}/p_{SiH_4} of 1 reduces the silicon growth rate by 0.4% and a ratio of 4 gives a reduction of 6%. The presence of HCl also counteracts the incorporation of boron in the growing silicon (9).[1] The influence of the introduction of HCl on the acceptor concentration is pronounced if no water vapor is added (Fig. 6, curve $p_{H_2O} = 0$). For an HCl concentration greater than 10^{-3} atm (p_{HCl}/

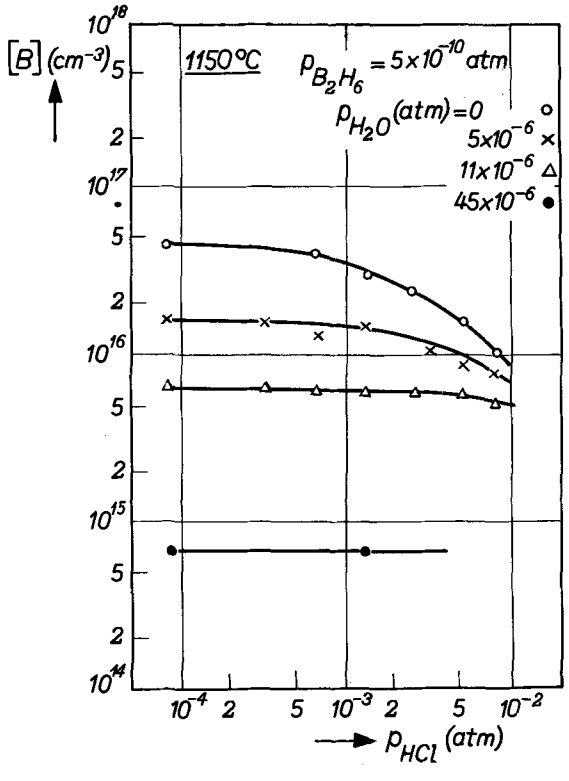

Fig. 6. Boron concentration in epitaxial silicon as a function of the amount of hydrochloric acid added in the gas phase, with the water vapor content as parameter.

$p_{SiH_4} = 1$) the boron concentration in the grown layers is seen to decrease with p_{HCl}.

For gas mixtures containing H_2O, HCl, B_2H_6, and SiH_4 in hydrogen the result is depicted in Fig. 6 and 7. At low values of p_{HCl} the influence of water vapor is more pronounced than at higher values of p_{HCl}.

Discussion

In this section the influence of water and hydrochloric acid vapor on the silicon growth rate and on the boron doping will be treated, starting from possible

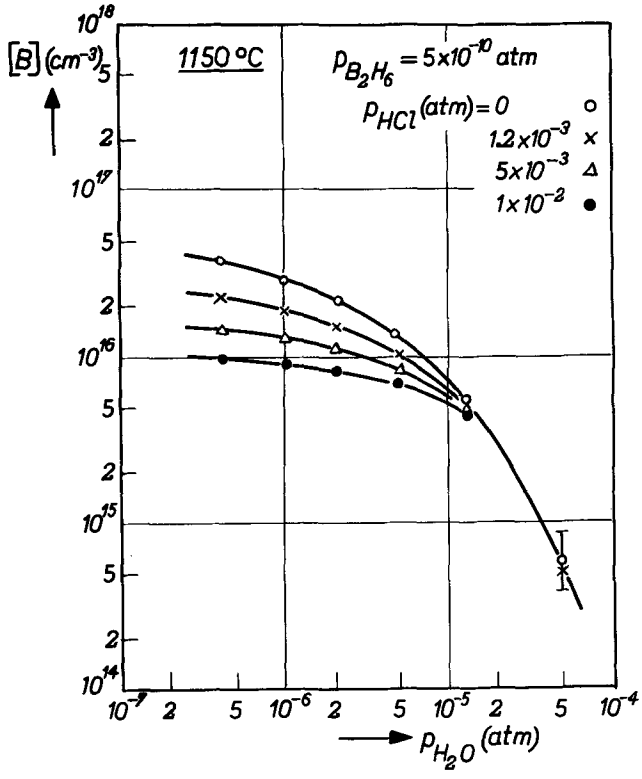

Fig. 7. Boron concentration in epitaxial silicon for a constant vapor pressure of diborane vs. the water vapor pressure, with the hydrochloric acid content as parameter.

reactions in the gas-phase and at the gas-silicon interface. From existing thermochemical data the predominant reaction products can be inferred, the main object being to relate the variation of the boron concentration in silicon to the variations in the gas phase composition. It will be assumed that the reactions are surface catalyzed, *i.e.* the reactions are thought to proceed to equilibrium, the equilibrium constants not being altered by the presence of the surface.

Influence of water vapor on silicon epitaxy.—Two reactions on the silicon surface are of importance, *viz.*

$$Si_{(s)} + 2H_2O_{(g)} = SiO_{2(s)} + 2H_{2(g)}$$
$$K_1 = (p_{H_2O})^{-2} \text{ for } p_{H_2} = 1 \quad [1]$$

$$Si_{(s)} + SiO_{2(s)} = 2\,SiO_{(g)}$$
$$K_2 = (p_{SiO})^2 \quad [2]$$

and the combination of [1] and [2]

$$Si_{(s)} + H_2O_{(g)} = SiO_{(g)} + H_{2(g)}$$
$$K_3 = p_{SiO}/p_{H_2O} \quad [3]$$

If equilibrium [3] at the silicon surface is reached sufficiently rapidly, the value of K_3 being about 30 at 1400°K (10), then the equilibrium vapor pressure of water near the surface will be lower than in the main gas phase. For a diffusion-controlled reaction rate the water vapor pressure at the surface is reduced by a factor K_3, assuming the diffusion coefficients of H_2O and SiO to be the same. In Fig. 8 water and SiO vapor pressures according to Eq [1] and [2] are given (10), *i.e.* values of $K_1^{-1/2}$ and $K_2^{1/2}$ as a function of temperature for $p_{H_2} = 1$. In the regions II and III, formation of SiO_2 is expected (Eq. [1]); whereas in region I the silicon surface will be free from surface oxides. In region II, however, the SiO_2 formed on the surface reacts with silicon to form volatile SiO (Eq. [2]) and the value of p_{H_2O} at the surface is reduced below the value corresponding to the lower curve in Fig. 8 at the temperature studied. It is only for water vapor pressures higher than the value on the upper curve ($K_2^{1/2}$) that the whole surface will be covered by SiO_2, that

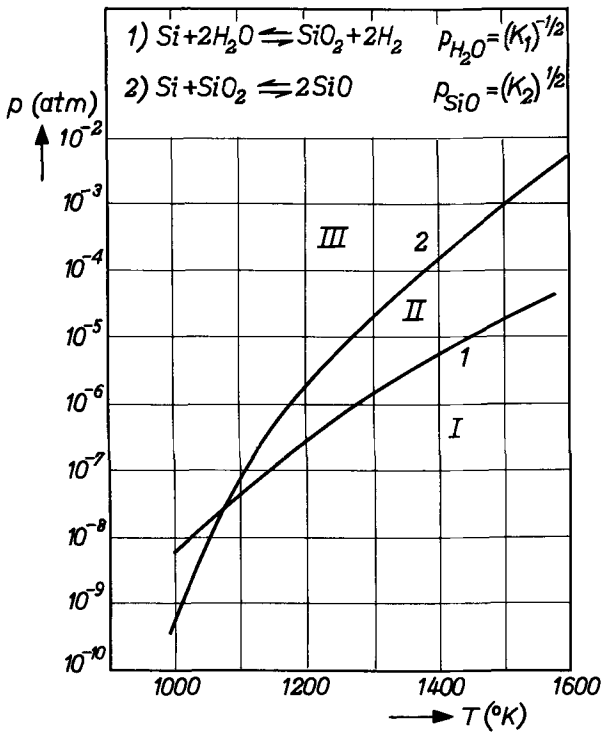

Fig. 8. Water vapor pressures that can be allowed in the gas phase growing epitaxial silicon layers. Curve 1 gives the water vapor pressures at the silicon surface in equilibrium with solid silicon dioxide as a function of temperature. Curve 2 gives the vapor pressure of silicon monoxide in equilibrium with solid silicon and silicon dioxide. For water vapor pressures in region II the formation of volatile SiO prevents the formation of solid SiO_2 on the silicon surface.

is, the actual water vapor pressure at the surface then has reached the critical value indicated by the lower curve. From reaction [1] it would be expected that at 1400°K water vapor pressures greater than 4 ppm would cause the formation of SiO_2. In practice, with up to 50 ppm no deterioration of the layers was observed because of reaction [2]. Epitaxy becomes impossible, however, because of another reason, *i.e.* excessive gas phase reactions.

Water vapor can react with silane in the gas phase or etch the silicon surface. In both cases gaseous SiO is formed. It is postulated that this SiO diffuses into colder parts of the gas stream and decomposes according to

$$2SiO = Si + SiO_2$$

As the vapor pressures of Si and SiO_2 are low, the gas phase is easily supersaturated giving rise to gas phase nucleation of the corresponding compounds. Subsequently decomposition of SiH_4 occurs on the solid nuclei leading to a serious depletion of silane in the gas phase.

Boron doping.—In Fig. 2 it is shown that the boron concentration in the epitaxial layers does not depend on the silicon growth rate under the prevailing conditions.

The silicon growth rate is diffusion-controlled in the range of temperatures studied (8), but for the incorporation of boron in the growing layer diffusion control is not indicated, because otherwise increasing growth rates due to increasing concentrations of SiH_4 would give a decreasing boron concentration. The same number of boron atoms has to be incorporated in increasingly thicker silicon layers.

B_2H_6 is reported to decompose rapidly at elevated temperatures into BH_2 (11) and BH_3 (12). This explains the slope of the curve in Fig. 3, which is about unity. If B_2H_6 were stable, a slope of 0.5 would be expected. The incorporation of boron in silicon can be given as

$$B_2H_6 = 2BH_3(g) \qquad K_4 = 7.0 \quad \text{at } 1400°K \text{ (13)} \qquad [4]$$

$$BH_3(g) = B(g) + 3/2\ H_2(g) \qquad K_5 = 3.2 \times 10^{-8} \quad \text{at } 1400°K \text{ (13)} \qquad [5]$$

$$B(g) = B_{Si} \qquad K_6 \qquad [6]$$

$$B_{Si} = B^-_{Si} + p \qquad K_7 \qquad [7]$$

The gas phase segregation coefficient of boron is best defined as the equilibrium constant of the reaction describing the incorporation of elemental boron in silicon giving ionized acceptor centers.[2]

$$\gamma_B = \frac{p_B}{[B^-]_{Si}} = \frac{p}{K_6K_7} = \frac{n_i}{K_6K_7} \qquad [8]$$

As the acceptor may be assumed to be fully ionized, and the value of p is equal to the intrinsic carrier concentration, n_i at the temperature of the experiment, for B concentrations well below n_i (approximately 10^{20} cm^{-3} at 1400°K or $2 \cdot 10^{-3}$ acceptors per Si atom), K_7 is a constant giving the number density of states in the valence band of silicon. As the ambient pressure is unity, p_B in Eq. [8] is equal to the mole ratio of boron in the gas phase close to the silicon surface. The concentration of acceptor centers in silicon will further be denoted by the symbol [B].

A practical segregation coefficient relates the concentration of dopant in the system ($p_{B_2H_6} = p_o$) to the resulting acceptor concentration in the grown layer. With Eq. [4]-[7] we find, in the absence of water or HCl

$$\gamma_{B_2H_6} = \frac{p_o}{[B]} = \frac{1}{2}\gamma_{BH_3} = \frac{1}{2K_5}\gamma_B \qquad [9]$$

In the gas phase B_2H_6 is dissociated completely into BH_3, and therefore $p_{BH_3} = 2\,p_o$.

Influence of water and HCl concentration on doping.—If water vapor and HCl are present in the gas phase, then reactions with the highly reactive boron hydrides can be expected. According to thermodynamic data (13), the most probable reaction products are BHO_2, BCl, and BClO.

$$BH_3 + 2H_2O = BHO_2 + 3H_2 \qquad K_{10} = 2 \times 10^{11} \quad \text{at } 1400°K \qquad [10]$$

$$BH_3 + HCl = BCl + 2H_2 \qquad K_{11} = 20 \quad \text{at } 1400°K \qquad [11]$$

$$BCl + H_2O = BClO + H_2 \qquad K_{12} = 1.5 \times 10^6 \quad \text{at } 1400°K \qquad [12]$$

from [10] and [11] we obtain

$$H_2 + HBO_2 + HCl = BCl + 2H_2O \qquad K_{13} = 10^{-10} \qquad [13]$$

moreover

$$2\,p_o = p_{BH_3} + p_B + p_{BHO_2} + p_{BClO} + p_{BCl} \qquad [14]$$

With Eq. [1]-[14] the resulting equilibrium can be estimated for any initial gas composition. As all equilibria are coupled it is sufficient to take one boron compound as the source of elemental boron in order to obtain the amount of boron incorporated in the growing layers. It is convenient to select BH_3. According to Brouwer (14), simple linear relations are obtained by splitting Eq. [14] into a number of limiting cases; *e.g.*

[2] The segregation coefficient is often defined as $\alpha = \left(\frac{B}{Si}\right)_{gas} / \left(\frac{B}{Si}\right)_{solid}$. This definition is only meaningful if B and Si are incorporated in the same manner; otherwise α depends on the value of p_{SiH_4} and thus on the silicon growth rate.

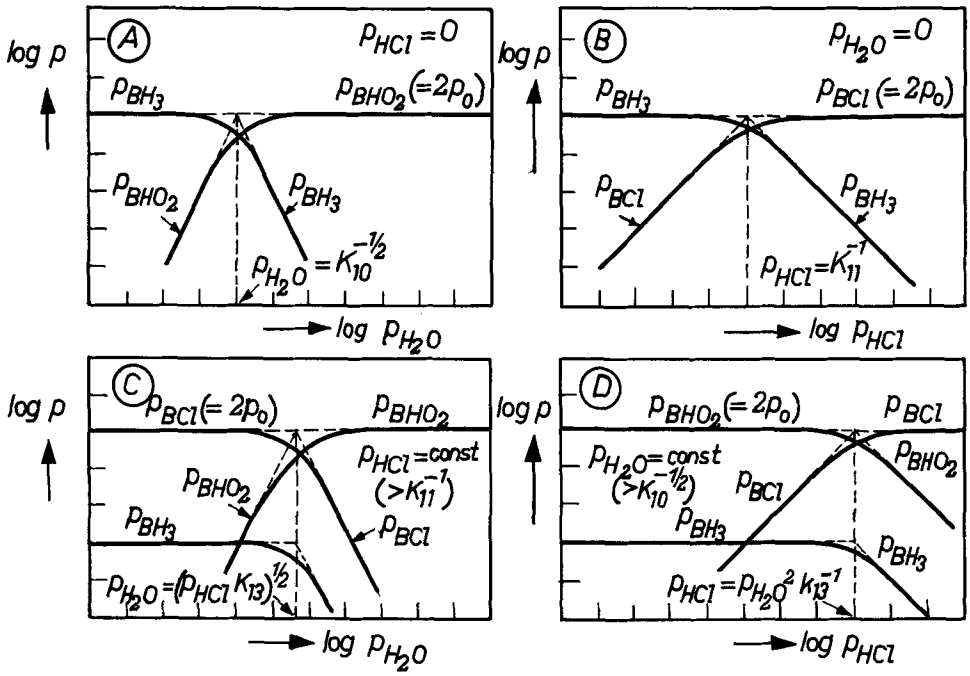

Fig. 9. Schematic representation of the variation of the partial pressures of boron compounds in the gas phase as a function of the water and/or hydrochloric acid content of the gas: A = variation with p_{H_2O} for p_{HCl} = 0, B = variation with p_{HCl} for p_{H_2O} = 0, C = variation with p_{H_2O} for p_{HCl} = constant ($> K_{11}^{-1}$), and D = variation with p_{HCl} for p_{H_2O} = constant ($> K_{10}^{-1/2}$).

$2p_o = p_{BH_3}$; $2p_o = p_{BHO_2}$ in the presence of water or $2p_o = p_{BCl}$ if sufficient HCl is present. In doing this and introducing the values in Eq. [10]-[13] the interrelations can be depicted as in Fig. 9. The acceptor concentration in silicon is proportional to the value of p_{BH_3}. In Fig. 9c and 9d it is seen that p_{BH_3} is constant for not too great values of p_{H_2O} or p_{HCl}. If BClO would be present in greater concentrations and a region $2p_o = p_{BClO}$ would appear, then in Fig. 9c the value of p_{BH_3} would be decreasing with p_{H_2O} even in the low-water vapor concentration range. As this is not apparent in Fig. 7, it is expected that the value of K_{12} has to be lower than calculated. In order to bring the calculated and experimental results into accord, the value of K_{10} and K_{11} have to be taken higher than given with Eq. [10] and [11] together with a lower value of K_{12}. These corrections are well within the accuracy of the thermochemical data (*e.g.* heat of formation of BH_3 given as 25.5 ± 10 kcal mole^{-1} (12) for BH_2 as 48 ± 15 kcal mole^{-1} (13).) In total we expect

$$p_{BH_3} = \frac{2p_o}{1 + K_{10}p_{H_2O}^2 + K_{11}p_{HCl}} \qquad [15]$$

By definition, $\gamma_{BH_3} = p_{BH_3}/[B]$; also, the actual water vapor pressure at the interface is lower than in the main gas by a factor K_3. p_{HCl}, however, will have the same value at the interface and in the main gas (8). Therefore

$$[B] = \frac{2p_o}{\gamma_{BH_3}\left\{1 + K_{10}\left(\frac{p_{H_2O}}{K_3}\right)^2 + K_{11}p_{HCl}\right\}} \qquad [16]$$

The value of [B] can be transformed into a concentration per cm^3 by multiplication with 5×10^{22}, the number of atoms per cm^3 of silicon. The experiments at 1150°C can then be explained with $\gamma_{BH_3} = 10^{-3}$, $K_{10} = 2 \times 10^{13}$, $K_3 = 30$, $K_{11} = 10^3$; with Eq. [9] we find $\gamma_{B_2H_6} = 5 \times 10^{-4}$.

In conclusion it can be stated that the influence of varying amounts of water vapor and HCl in the gas phase on the boron concentration in the silicon can be explained semiquantitatively by assuming the gas phase reactions to come to equilibrium at the silicon interface. The main features of the experimental results are in accord with the predictions given in Fig. 9.

Thick Epitaxial Films of Cubic ZnSe and ZnS by Vapor Phase Transport

P. Vohl, W. R. Buchan, and J. E. Genthe

Itek Corporation, Lexington, Massachusetts 02173

ABSTRACT

Films of cubic ZnSe and ZnS have been grown epitaxially on [100] oriented GaAs substrates by vapor phase transport in flowing hydrogen. Thicknesses up to 200 μm over areas up to 5 cm^2 have been obtained. The ZnSe films are superior in crystalline quality to the ZnS films. The films exhibit low birefringent strain, good optical transmission, high resistivity, and near-bulk electro-optic constants. These properties make them suitable for use in information storage devices utilizing the longitudinal linear electro-optic effect.

The objective of this work was to produce cubic ZnSe and ZnS of quality suitable for use in electro-optic information storage devices. These devices are designed to have a laminar structure for utilization of the longitudinal linear electro-optic effect in the spectral range of visible and near ultraviolet light (1). For this mode of operation their geometrical specification calls for an area at least 1 cm^2 oriented in the [100] direction and a film thickness sufficient to prevent excessive current flow at the required operating voltage. The operating requirements for these devices impose quite stringent conditions on the properties of the film. The material must be free of optical defects and birefringent strain. The intrinsic absorption edge must be sharp and the resistivity high. Bulk ZnSe and ZnS do not have the required properties. High resistivity bulk ZnSe is generally strained and contains an undesirable number of twins and low angle grain boundaries. The crystal quality of bulk ZnS is even worse. This material is characterized by stacking faults for a wide range of growth temperatures, probably because of a hexagonal to cubic phase transition which is reported to occur around 1020°C (2). Such structures constitute optical defects and would degrade the electro-optic performance of the device. Thus the requirement for unstrained cubic phase material imposes the condition of low temperature growth for these compounds. This and the plate-like form of the device make epitaxial film growth an attractive approach. Vapor phase growth methods for preparing epitaxial films of ZnSe and ZnS have been reported in the literature (3-7).

After considering possible substrates it was decided to try Si, Ge, and GaAs. In a few preliminary experiments on growing ZnSe and ZnS, the best indications of epitaxy were obtained for films grown on GaAs. It was then concluded that GaAs was more suitable for use as a substrate than either Si or Ge.

In this paper the procedure used for the growth of epitaxial films of ZnSe and ZnS on GaAs by vapor transport are outlined. The effects of different film growth parameters on epitaxial quality are described. The methods used to evaluate the crystalline properties of the films are listed along with the results obtained. Finally, the results of optical absorption, electrical and electro-optic measurements on these films are presented. Concurrently with using vapor phase growth methods, vacuum deposition of epitaxial ZnS films was accomplished by M. E. Behrndt and S. C. Moreno of these laboratories, with the same device objectives. Their results are reported separately (8).

Growth of Epitaxial Films

Method.—The vapor transport method used in this work is simple and highly efficient. Approximately 1/3 to 1/2 of the source material lost by vaporization is deposited on the substrate. A schematic design of the transport chamber incorporated into a modified Pensak furnace is shown in Fig. 1. A vertical quartz cylinder ~2 cm in diameter by ~1 cm high is positioned on a flat source heater. The heater consists of a notched ceramic disk wound with 0.018 in. platinum heater wire. The source is placed on the heater within the quartz cylinder. The cylinder has three supports upon which the substrate is placed, partially enclosing the transport chamber.

There is no separate substrate heater. The substrate is heated by convection from the source heater, and its temperature is substantially uniform because of the excellent thermal convection of the hydrogen carrier gas. The amount of gas-vapor exchange between the ambient environment and the inner chamber is varied by changing the length of the quartz supports. This spacing is generally varied between 0.1 and 2.0 mm. A shelf in the cylinder acts as a baffle to deflect the direct vapor flow away from the outer edge of the substrate, so that in this region the vapor flow is parallel to the substrate, while at the center the flow remains nearly perpendicular to the substrate. A thermocouple is pressed against the back of the substrate. The transport chamber of Fig. 1 is placed inside a Pyrex enclosure on a metal base containing all the gas and electrical feedthroughs. Provisions exist for evacuating the chamber in order to operate at reduced pressure. The ambient gas is normally high-purity hydrogen although a dilute mixture of H_2S in hydrogen has been tried. The hydrogen flows continuously.

The ZnSe source is a wafer cut from a crystal grown in these laboratories (9). The ZnS source is Kodak Irtran II, a hot-pressed ZnS plate. It is believed to contain some halide and metal impurities. To remove any apparent dirt, the surface is cleaned by a dilute nitric acid etch and rinsed with distilled water.

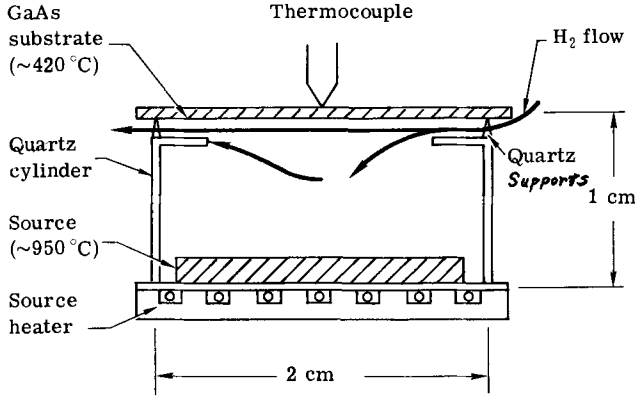

Fig. 1. Schematic drawing of the vapor transport chamber for epitaxial growth of ZnSe and ZnS.

Key words: epitaxy, electro-optic effect, birefringent strain, film growth, II-VI semiconductors, single crystal.

The substrates are [100] oriented single-crystal wafers of n- or p-type, commercially obtained, GaAs. This is the orientation which exhibits the longitudinal linear electro-optic effect. The wafers are either mechanically polished and then etched in methanol-bromine solution or chemically polished. They are between 0.010 and 0.020 in. thick. An optically reflecting scatter-free surface is desirable, although generally some dust particles, scratches, and pits remain after processing.

The source and substrate are dried and installed in the furnace. Prior to film deposition the furnace is evacuated and flushed with hydrogen. The desired hydrogen pressure and flow rates are then established. Films have been grown at hydrogen pressures ranging from 50 Torr to 1 atm, but the best results were achieved at pressures between 100 and 300 Torr, and hydrogen flow rates around 10 cm^3/min. The source heater is raised to a temperature of about 950°C. The substrate temperature is between 400° and 500°C. Under these conditions the films grow at a rate which ranges between 3 and 5 μm/hr. Growth times are between 25 and 40 hr to yield films between 75 and 200 μm thick. The reaction is believed to be $ZnX + H_2 \rightleftarrows Zn + H_2X$ (where X = Se or S). The presence of the hydrogen is probably not important except possibly for serving as a reducing agent or as a carrier gas because vapor transport occurred at about the same rate in the presence of an inert gas.

Effect of growth conditions on epitaxial quality.—Five ZnSe films followed by 30 ZnS films have been grown on (100) GaAs substrates. Both types of film have been grown to thicknesses of 200 μm over areas up to 5 cm^2. The epitaxial quality of the individual films was evaluated primarily by means of microscopic studies of the film surfaces and of cleavage sections. These studies were initially checked against x-ray and electron diffraction results.

Of the ZnSe films, the first was partly epitaxial, and the fourth and fifth were completely epitaxial. The initial deposit of pratically all the ZnS films is epitaxial, but as the thickness increases beyond about 10 μm the tendency toward polycrystalline growth increases. Good reproducibility of thick (>25 μm) ZnS films of high crystalline perfection has not yet been achieved. Of the 30 ZnS films, about five were completely epitaxial. About 20 were partly epitaxial, with epitaxy always occurring in a ring at the outer edge of the substrate, where the vapor flows fast and parallel to the substrate. The centers of these films contained polycrystalline pockets amid the epitaxial material. About five ZnS films were mainly polycrystalline.

During the experiments on ZnS film deposition, a number of growth parameters were varied to determine their effect, if any, on the epitaxial quality of the films. The observations made are summarized in Table I. Of the parameters listed, it was found that hydrogen pressure (c) hydrogen flow rate (d), and especially chamber geometry (g) could be varied to improve the quality of the films. These results imply that the partial pressure and concentration of the vapor species have a pronounced effect on epitaxy, and therefore that the degree of supersaturation is important. Low supersaturation is generally the desired condition for avoiding fast nucleation on the substrate of many misaligned nuclei. The vapor pressure over the source material, for a given temperature distribution, H_2 pressure, and flow rate, is controlled mainly by the pressure drop across the chamber opening. This in turn depends on the spacing as determined by the length of the quartz supports. With "large" spacing, enough vapor is carried out of the chamber to make thick film growth very inefficient. With virtually no spacing, *i.e.*, a closed chamber, the vapor pressure is apparently sufficient to cause enough supersaturation at the substrate to prevent epitaxial growth. At some optimum spacing (with the chamber geometry described this was about 1.0 mm) the vapor pressure established a low enough supersaturation to provide for epitaxy at a reasonably high growth rate. This might be the explanation for epitaxy occurring preferentially at the outer edge of the substrate where the degree of supersaturation is likely to be low because of the pressure drop in this region. Polycrystalline defects increase with film thickness instead of "growing out," suggesting that the amount of supersaturation tends to increase with film thickness. However, no satisfactory explanation for this result has been found.

Table I. Effects observed with variation of ZnS film growth parameters

Parameter	Condition or setting	Effect on epitaxial quality
(a) Substrate preparation	Etching Chemical polishing Outgassing	No marked effect
(b) Substrate temperature	400°-500°C	For a given thickness, film surfaces are rougher with increase in substrate temperature
(c) Hydrogen pressure	100-760 Torr	Lower pressure enhances epitaxy
(d) Hydrogen flow rate	1-10 cm^3/min	Higher flow rate enhances epitaxy
(e) Growth rate	3-5 μm/hr	No marked effect
(f) Cool down time	1-4 hr	No marked effect
(g) Chamber geometry	The spacing for vapor flow out of the transport chamber was varied by changing the length of the quartz supports	Discussed in test

Evaluation of Crystalline Properties

X-ray and electron diffraction.—X-ray diffractometer traces showed strong reflections only from (100) planes. Laue back-reflection photographs were taken on films at least 75 μm thick. These revealed the fourfold symmetry as shown in Fig. 2 and 3 for ZnSe and ZnS, respectively. Electron diffraction patterns of the as-grown surface of a 70 μm thick ZnS film are shown in Fig. 4a and 4b.

Surface morphology.—Figures 5a and 5b are photomicrographs of the as-grown surfaces of a ZnSe and ZnS film, respectively.

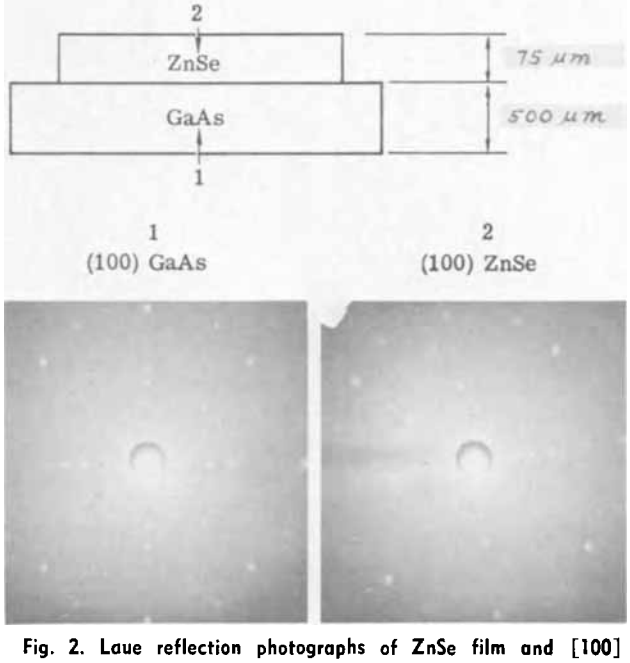

Fig. 2. Laue reflection photographs of ZnSe film and [100] oriented GaAs substrate. The apparent rotation of the ZnSe was caused inadvertently by sample rotation.

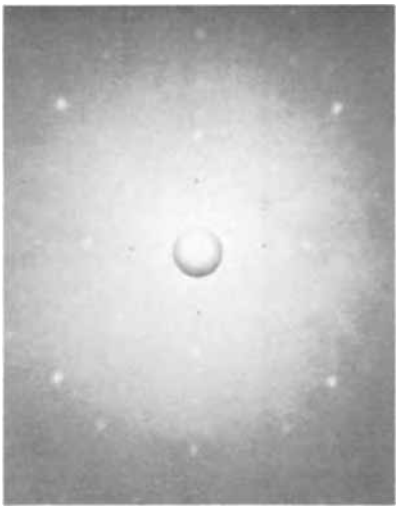

Fig. 3. Laue reflection photograph of ZnS film on [100] oriented GaAs substrate. Film thickness, 100 μm.

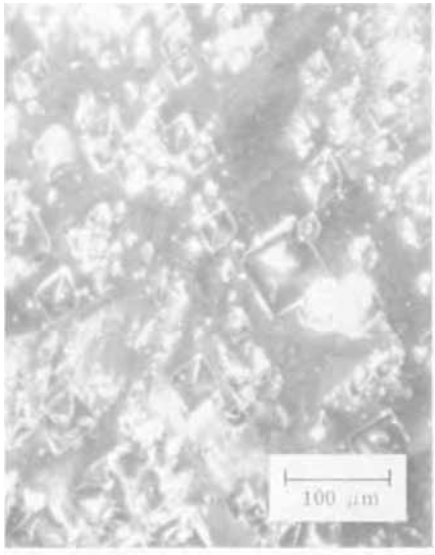
Fig. 4. Reflection electron diffraction of as-grown ZnS film on (100) GaAs. a) [100] direction. b) [110] direction at 45°.

ZnSe.—The film is 75 μm thick and was deposited at a substrate temperature of 450°C. The surface is characterized by growth pyramids. The four-fold symmetry of the (100) plane is quite apparent, although a slight elongation of some of the growth pyramids has occurred. On other pyramids, extra planes of higher order are visible. The pyramids are formed by (110) planes which intersect the surface at (100) planes. Steps are



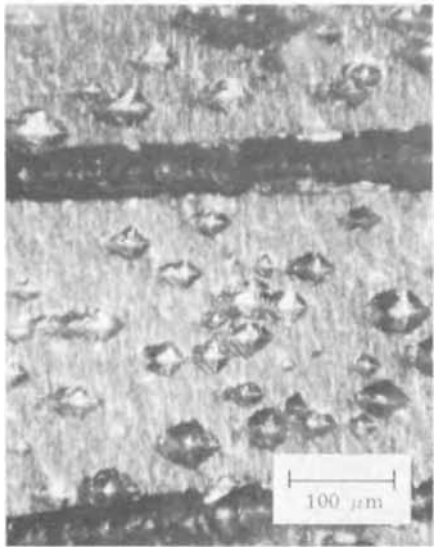


Fig. 5. As-grown surfaces of epitaxial films. (a) 75 μm thick ZnSe film characterized by four-fold growth pyramids. (b) 80 μm thick ZnS film characterized by four-fold pits.

visible on some of the sides; however, it could not be determined whether or not they are spirals. The surface between the pyramids is fairly smooth; the main features are very slight ripples which run parallel to the [110] direction.

ZnS.—The film is 80 μm thick and was deposited at a substrate temperature of 430°C. The surface is characterized by pits of predominately tetragonal shape. Ideally, the pits are inverted growth pyramids and exhibit the four-fold symmetry of the (100) plane observable in the photomicrographs, but actually many of them are elongated and some are even rhombohedral in shape. The two dark horizontal bands are "troughs" which grew from scratches in the surface of the GaAs substrate. The surfaces of ZnS films between the pits are rougher than those of the ZnSe films. In general, the surfaces of ZnSe were smoother and the growth features more nearly four-fold symmetric than those of ZnS for films of similar thickness grown under similar conditions.

Cleavage.—The epitaxial films and the GaAs substrates can be cleaved along (110) planes. A photomicrograph of an epitaxial ZnS/GaAs edge cleaved along a (110) plane is shown in Fig. 6. The film thickness of 80 μm was measured by means of the calibrated eyepiece of the microscope. The junction is directly observable, since the epitaxial film transmits visible

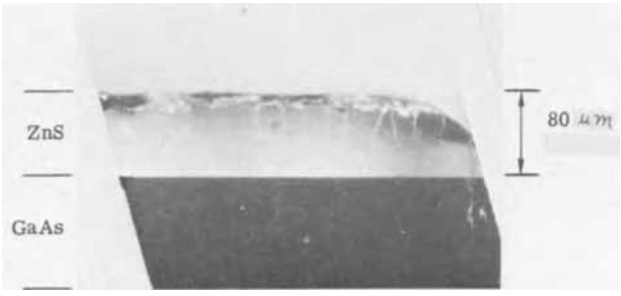

Fig. 6. (110) Cleavage edge of ZnS/GaAs. The ZnS film is brightened by microscope light transmitted through it.

light. Cleavage lines and "broken out" positions of the edge are visible in the photomicrograph. The cleavage lines change direction as they cross the interface. Cleavage defects appear to be more numerous in the top 40 μm of the film. Beyond about 30 μm from the substrate, tiny polycrystalline boundaries become apparent. These seem to flare with increasing thickness, and eventually form the pits which are characteristic of the surface morphology. It is speculated that the defects originate at the surface of the GaAs, are propagated through the film, flare with thickness, and eventually tend to dominate the structure. Beyond 80 μm the epitaxial quality of such films can be substantially degraded. The 4% lattice mismatch at the interface could subsequently induce fiber growth to account for such defects.

Cleavage surfaces of nonepitaxial films are rough. The edges are jagged and not along (110) planes. They scatter light in contrast to the edges of smooth epitaxial films, which reflect light specularly. This effect provides a convenient test for epitaxy because of its good correlation with x-ray and electron diffraction results. Cleaved (110) planes of epitaxial films of ZnSe/GaAs are generally smoother and contain fewer cleavage lines than those of ZnS/GaAs.

Birefringent strain.—The films were further evaluated with a beam splitting Glan-Thompson prism by viewing the reflected light from the GaAs/ZnS or GaAs/ZnSe interface after the top surface of the film was polished to an optical finish. This gives the optical equivalent of viewing between crossed polarizers. Low birefringent strain was readily observed in this manner, together with light scattered from point defects at the top surface of the films. The birefringent strain in the films was compared with that in a number of naturally occurring cubic ZnS crystals in the form of ~125 μm thick wafers, most of which exhibited considerable strain. Almost all of the films showed less strain than even the best natural crystals. Strain was lower in the ZnSe films than in the ZnS films. The light scattering point defects are believed to be polycrystalline "columns" growing up through the film from the GaAs to the surface.

Other Measurements on Epitaxial Films

Optical absorption of a ZnS film.—For this measurement a ZnS film was separated from the GaAs substrate. This was accomplished by first polishing the top surface of the film and then etching away the GaAs with a solution of 2 ml H_2O, 8 mg $AgNO_3$, 1g CrO_3, and 1 ml HF (10), which leaves the ZnS intact. An optical absorption spectrum of the ZnS film at room temperature is shown in Fig. 7. It compares quite well in the steepness of the absorption edge and in the transmission at wavelengths beyond the edge with a spectrum obtained on high-purity, hexagonal single-crystal ZnS.

Current-voltage characteristics of a ZnS film.—Current-voltage characteristics were measured on an unpolished 50 μm thick film of ZnS on a p-type GaAs substrate. A Ga-In "point" contact was made to the ZnS, such that the area to thickness ratio was about 1 at the Ga-In contact and much greater than 1 at the GaAs substrate. Positive and negative polarities were applied to the GaAs. Because of the small contact area at one electrode compared to the ZnS film area, surface leakage is considered to be negligible. The current was recorded with a Cary electrometer. A large transient current flows through the sample upon application of the voltage. It increases with increasing applied voltage and consists of a polarization current and an injected electron current. Some of the injected electrons are subsequently trapped. The transient component of the electron current is about an order of magnitude higher than the final steady-state current. The measurement was made when the transient current was negligible, *i.e.*, about half an hour after the voltage was applied.

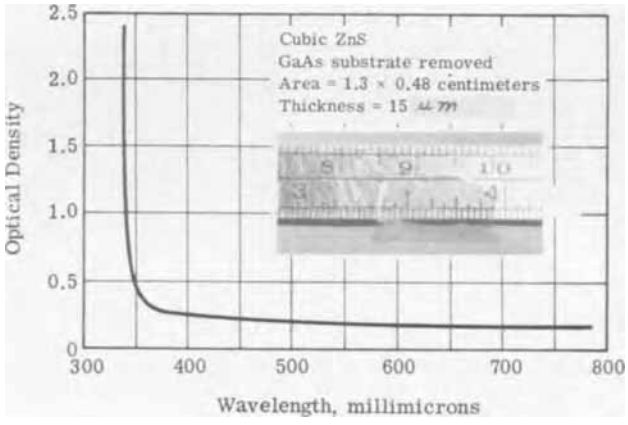

Fig. 7. Optical absorption spectrum of ZnS film at room temperature. Inset shows ZnS film removed from the substrate.

Figure 8 is a plot of ln I *vs.* ln V. Below 400V the slope gradually changes from about 1 to about 9. The observed I-V characteristics may be due to space

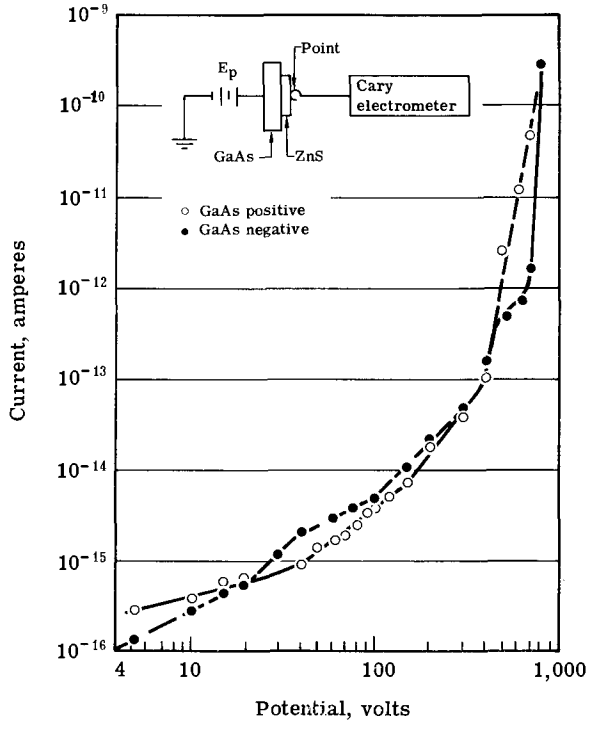

Fig. 8. I-V characteristic of 50 μm thick ZnS film on p-type GaAs substrate. A 3 x 10^{-3} cm^2 area Ga-In contact is made to ZnS top surface.

charge limited currents or field-induced breakdown through hot carrier effects.

Electro-optic measurements.—The ZnS and ZnSe epitaxial films both showed the linear electro-optic effect (Pockels effect) characteristic of materials with $\bar{4}3$ m symmetry.

The electro-optic constants (r_{41}) of one ZnSe and two ZnS films were determined by first measuring the Pockels constant $k = \frac{n_o^3 r_{41}}{\lambda}$ and then measuring the refractive index, n_o, at the same wavelength, λ. The Pockels constant was found by using a calibrated electro-optic light modulator (EOLM) between polarizers in the same optical path as the film being measured. The arrangement is shown in Fig. 9. The films were oriented so that the plane of reflection coincided with the plane defined by two of the cube ($\bar{4}$) axes, and the incident light was linearly polarized perpendicular to the plane of reflection [*i.e.*, parallel to one of the cube ($\bar{4}$) axes]. The retardation introduced by applying a known voltage across the film was balanced by applying a voltage to the EOLM to introduce an equal but opposite retardation. The light intensity transmitted by the system is then

$$I = I_o \sin^2 \pi (\Gamma_1 + \Gamma_2) \quad [1]$$
$$= 0, \text{ when } \Gamma_1 + \Gamma_2 = 0, 1, 2 \ldots$$

where I_o is the incident light intensity and Γ_1 and Γ_2 are the retardations in the film and the EOLM, respectively. Thus, the photomultiplier provided a signal for detecting the null when

$$\Gamma_1 = \Gamma_2$$

i.e.

$$2k_1 V_1 \cos \phi = -k_2 V_2$$

$$k_1 = \frac{|V_2|}{2|V_1|(V_2)_\lambda \cos \phi} \quad [2]$$

where k_1, and V_1 and k_2, and V_2 are the Pockels constants of and voltages applied to the film and the EOLM, respectively, $(V_2)_\lambda$ is the full wave voltage of the EOLM, and ϕ is the angle of refraction in the film. The angle of incidence was 11° for all the measurements so that the angle ϕ was about 4½°; the approximation $\cos \phi \approx 1$ was therefore made. The factor, 2, in the denominator arises from the double pass of light through the film.

The refractive index, n_o, of each film was found by measuring Brewster's angle. The measurements of the Pockels constants and the refractive indices were all made at 633 nm using a 1 mW He/Ne laser source. Voltages of either polarity were applied. The current through the ZnSe film at 40V was 10^{-7}A. For the ZnS samples the currents were always less than 10^{-10}A.

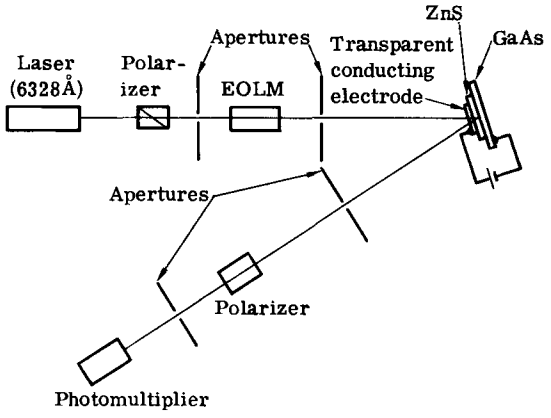

Fig. 9. Schematic of optical arrangement for measuring phase retardation in epitaxial films.

Since the maximum value of V_1 was limited to about 100V by the thickness of the films, the maximum value of Γ_1 was of the order of 10^2. The optical system therefore had an extinction ratio of 10^5 which gave distinct nulls when balancing Γ_1 and Γ_2.

Voltage across the film was applied between the GaAs substrate and a 2 mm diameter transparent conducting platinum electrode evaporated onto the polished surface of the II-VI film. The GaAs/ZnS or GaAs/ZnSe interface acted as a reflector of about 5% efficiency which gave two light passes through the film and double the birefringence. A natural crystal of cubic ZnS was also measured in the same way by using a layer of evaporated Al as the reflecting electrode. The polished surfaces of the films and of the natural ZnS wafer were slightly nonparallel so that the relatively strong reflection from the platinized top surface was excluded by the apertures used.

The results of the measurements along with values for bulk crystals reported in the literature are listed in Table II. The figures for k_1 in column 4 are the average values obtained from Eq. [2] over the range of applied voltage given in column 3. There was no consistent difference between the values obtained with opposite polarities at the same voltage or with different voltages. For the samples studied, the refractive indices in column 5 were used to derive the values for r_{41} in column 6. The accuracy of the Pockels constants is ±2% and that of the refractive indices ±0.4%. The accuracy of r_{41} is therefore about ±3%.

The value of r_{41} obtained for the natural ZnS crystal agrees quite well with that given by Namba (12). The epitaxial films all gave values for r_{41} slightly lower than the values for the bulk crystals although the value for the ZnSe film is very close to the bulk value. The values of r_{41} obtained for the ZnS films are respectively 92% and 83% of the value obtained for the natural crystal. The refractive indices of the films are about 98% of the values for the bulk crystals.

The half-wave voltages calculated from the Pockels constants are 13-14 kV for the epitaxial ZnS films, 10 kV for the epitaxial ZnSe film, and 11.3 kV for the natural ZnS crystal.

Conclusions

GaAs was found to be the most suitable substrate for vapor deposition of [100] oriented cubic ZnSe and ZnS films. Epitaxial films have been grown to thicknesses of 200 μm over areas up to 5 cm². With the ambient hydrogen flow method employed, it was found that the ambient pressure and flow rates affect the epitaxy of the deposited films. The greatest effect on epitaxial quality of the ZnS films was produced by the geometrical arrangement of the transport chamber, which is apparently important in controlling the degree of supersaturation of the vapor species. The best epitaxy is in the initially deposited layers. With increasing thickness, polycrystalline pockets tend to form. The 4% lattice mismatch at the interface could be the origin of subsequent fiber growth. The surfaces of the films are characterized by four-fold growth pyramids in the case of ZnSe and four-fold pits in the case of ZnS. It has been concluded that epitaxial ZnSe films on GaAs are superior in crystalline quality to the ZnS films.

Table II. Measured values of Pockels constant, refractive index, and electro-optic coefficient at 633 nm

Sample	Thickness (μm)	Voltage range (V)	Pockels constant, k_1 ($V^{-1} \cdot 10^{-5}$)	Refractive index, n_o	Electro-optic coefficient, $r_{41} = \frac{\lambda k_1}{n_o^3}$ (10^{-12} m/V)
ZnS/GaAs	40	20-100	3.85	2.30	2.00
ZnS/GaAs	20	20-100	3.63	2.33	1.82
ZnS (natural)	400	20-200	4.44	2.35	2.16
ZnS (bulk)	—	—	—	2.354 (11)	2.1 (12)
ZnSe/GaAs	20	10-40	5.00	2.52	1.98
ZnSe (bulk)	—	—	—	2.580 (13)	2.0 (14) [546 nm]

The optical absorption spectrum of epitaxial ZnS films is similar to that of bulk ZnS. Birefringent strain is far less in these films than in naturally occurring cubic ZnS. The resistivity of ZnSe films is around 10^{11} ohm-cm and that of ZnS is greater than 10^{14} ohm-cm. The Pockels constant of the ZnS films is approximately 85% of the value for natural ZnS crystals. For the ZnSe films it is very close to that reported for bulk ZnSe crystals.

Acknowledgments

We wish to thank W. F. Bolza for his help with the film growth and R. G. Dykeman for the film polishing. We would like to acknowledge J. R. Howley and J. F. Washeba for the x-ray and electron diffraction data and W. A. Simmons for his help with the electro-optic measurements. We also thank R. R. Addiss, who read and criticized the manuscript.

Anneal Behavior of Cd Ion Implanted GaAs

R. G. Hunsperger and E. D. Wolf

Hughes Research Laboratories, Malibu, California 90265

ABSTRACT

The high temperature anneal behavior of lattice damage produced by 60 keV Cd^+ ion implantation of GaAs has been measured for <111> substrates implanted at 77° and 300°K. Measurements of relative lattice disorder were made by the Coates-Kikuchi pattern technique, which employs a scanning electron microscope. Damage produced by ion doses $\geq 10^{14}/cm^2$ was observed to anneal gradually in the temperature range from about 400°-700°C. There was no significant difference in the anneal behavior of samples implanted with the substrate at 77°K and those implanted at room temperature. Hall measurements of surface carrier concentration, average mobility, and sheet resistivity in the implanted layers showed that the electrical properties follow essentially the same trends as the damage anneal curves. Annealing at approximately 800°C or higher was required to obtain maximum electrical activity of the implanted ions and maximum carrier mobility, although a p-type layer could be produced by annealing at temperatures as low as 600°C. Samples implanted with relatively low ion dose ($\sim 10^{13}/cm^2$) exhibited damage anneal stages at temperatures below 500°C, but still required annealing at 700°C or greater to produce a measurable p-type layer.

Ion implantation has been used to dope gallium arsenide with both p- and n-type dopants. The electrical properties of p-type layers have been reported for Zn (1-4), Cd (2, 4), and C (5) implantations, while Se (6), Te (1), S (4, 5), and Si (5) have been shown to form n-type layers. In general, implantation must be performed at temperatures greater than 400°C or must be followed by annealing at such temperatures to eliminate implantation-caused lattice damage and to cause implanted dopant atoms to move to electrically active lattice positions. The relation between lattice damage annealing and the electrical properties of implanted layers depends on a number of variables including ion type, ion energy, substrate temperature during implantation, ion dose, and dose rate. This paper is concerned with the high temperature (>500°C) anneal behavior of lattice disorder produced by 60 keV Cd ion implantation of GaAs at room temperature and its correlation with the electrical properties of the implanted layers, as previously reported (4). The anneal behavior of doped layers produced by implantation of 60 keV Cd ions into GaAs substrates held at 77°K is also described, with respect to both lattice damage and electrical properties of the layers.

Key words: Coates-Kikuchi analysis, lattice disorder, ion-implantation doping.

Experimental

The samples were prepared from gallium arsenide <111> oriented (±3°) wafers approximately 15 mils thick, with the "B" face etch polished in a solution of methyl alcohol and bromine to remove sawing and lapping damage prior to ion-implantation. Ion-implantation was performed, with the substrates either at room temperature, or at 77°K, using a 60 kV magnetically-mass-separated Cd^+ ion beam. The substrates were tilted ~8° off axis to minimize ion channeling effects. Ion dose rate was $\sim 10^{-7}$ A/cm^2. Prior to annealing the samples were coated with a sputtered layer of SiO_2 about 2000Å thick to prevent outdiffusion of dopant atoms and decomposition of the GaAs. Annealing was performed in a nitrogen atmosphere.

The p-type dopant Cd was implanted into n-type substrates so that the resulting p-n junction would provide electrical isolation of the implanted layer during measurement. Substrate background impurity concentration was approximately 1 x $10^{16}/cm^3$. The electrical characteristics of the implanted layers (sheet

resistivity ρ_s, effective surface carrier concentration N_s, and effective mobility μ) were determined using the van der Pauw-Hall measurement technique (7). Square-shaped Hall samples (approx. 4 mm on a side) were diced from the ion-implanted substrate wafers prior to annealing. All Hall measurements were made at room temperature, after the samples were quenched in air from whatever temperature at which they were annealed. The maximum possible error in the Hall measurements is estimated to be approximately 10%. This maximum error could occur only in cases in which the sheet resistivity is large ($>10^4$ ohm/□) and hence the Hall voltage is difficult to measure because of background noise voltage. Otherwise the error is limited to the accumulative instrument error of approximately 3%.

The measurements of implantation-caused lattice disorder were made by the "Coates-Kikuchi" pattern technique, which employs a scanning electron microscope as the measuring instrument. This method is relatively new, and hence a brief description of it is provided even though it has been described elsewhere (8-10).

When a collimated, monochromatic beam of electrons enters a crystal at a well-defined angle with respect to the surface and the lattice, certain Bloch waves are excited in the crystal. The anisotropic backscattering of these coherent waves through single and multiple events can be displayed as a function of the incident beam angle by utilizing a collimated scanning electron beam and a sensitive detector to collect the high energy backscattered electrons (11). Figure 1 (top) is a schematic representation of the experimental method and Fig. 1 (bottom) is an idealized one-dimensional line scan orthogonal to the (110) lattice planes.

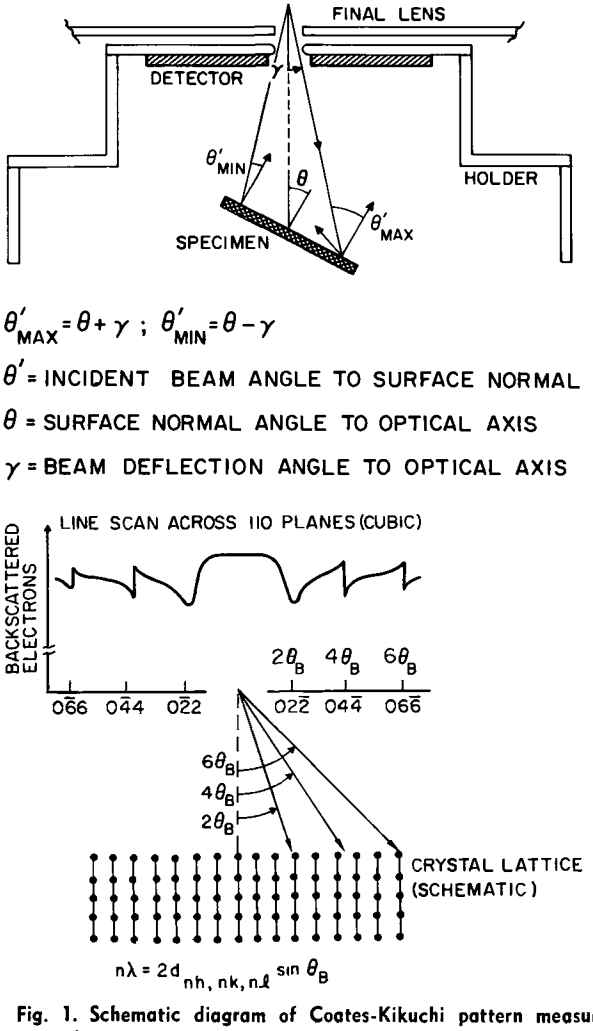

Fig. 1. Schematic diagram of Coates-Kikuchi pattern measurement technique.

The ion-implanted specimens were cleaned in HF to remove the surface oxide and were placed in the scanning electron microscope along with a clean nonimplanted GaAs wafer which served as a reference standard. It should be noted that regions of the samples that were masked from the ion beam during implantation (by the spring clips that held them in place in the apparatus) also served as nonimplanted reference areas. These areas were, of course, SiO_2 coated and annealed along with the rest of the sample. Since the Coates-Kikuchi patterns for these areas were the same as that for the nonimplanted, nonannealed reference standard, the heat treatment can be ruled out as a possible source of lattice disorder. The relative backscattered electron intensities were recorded as illustrated in Fig. 2 [from Ref. (9)] using an annular semiconductor diode detector. The fractional change in intensity ($\Delta I/\Delta I_{ref}$) across the $0\bar{4}\bar{4}$ band edge (line) was determined by dividing the change observed for an ion-implanted sample ΔI by the intensity change for the reference sample ΔI_{ref}. A Faraday cup was used to measure the beam current. The beam current was typically 1×10^{-8} A and did not change between measurements of the unknown and the standard, nor were any other conditions allowed to vary during the measurements. This fractional intensity change ($\Delta I/\Delta I_{ref}$) has been defined earlier (8) as the normalized pattern quality I^*, and is a measure of the lattice perfection (or lack of).

Results and Discussion

The data shown in Fig. 3 give the anneal behavior of implantation-caused lattice disorder, as indicated by the parameter I^*, for implantation performed with the substrate held at either room temperature or 77°K. (The data corresponding to samples implanted at room temperature and annealed at 450°C or below have been previously published (9), but are included for completeness and to allow comparison with the data for samples implanted at 77°K.) For samples implanted with ion dose greater than 1×10^{14}/cm² a gradual annealing of lattice disorder was observed in the temperature range from about 400°-700°C, with relatively little additional improvement after heat treatment at higher temperatures. This same trend was evident in the electrical characteristics of the implanted layers, as shown by the resistivity data of Fig. 4. Hall measurements could not be made for samples annealed below 600°C because there was not sufficient electrical activity to produce a p-type region and resultant p-n junction to isolate the implanted layer from the substrate. There was no significant difference in the anneal behavior of samples implanted with the substrate at 77°K and those implanted at room temperature; in this respect GaAs behaves differently from silicon. For example, a 60 keV Cd ion dose $\geq 10^{14}$/cm² exceeds the level required to form a region of saturated damage in the GaAs, as determined by Rutherford backscattering measurements (13). Davies (14) has found that silicon <111> oriented samples, implanted at 77°K with greater than the saturation dose of 200 keV boron, exhibit an abrupt anneal stage at a temperature several hundred degrees below that required to cause the same change in resistivity in samples implanted at room temperature with the same ion dose. Other authors (15, 16) have also reported what appears to be damage-enhanced annealing in silicon. The difference between the anneal behavior in these particular cases of ion-implanted layers in GaAs and Si indicates that reordering of the lattice depends not just on the over-all degree of lattice damage but also on the particular lattice defects involved. Very little is known about the detailed nature of lattice defects created in either GaAs or Si by ion implantation. However, the different lattice structures of the two materials can reasonably be expected to yield different defect types. For example, di-vacancies have

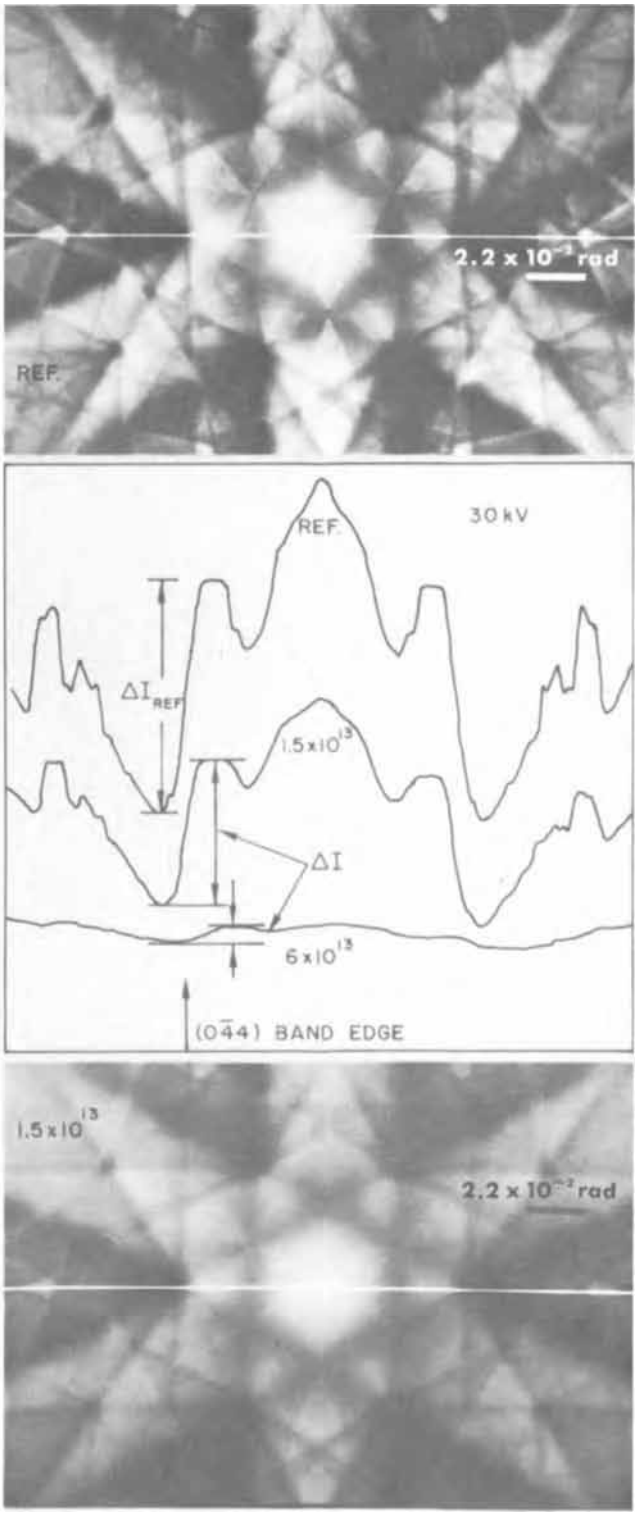

Fig. 2. Coates-Kikuchi patterns for Cd^+ ion implanted GaAs

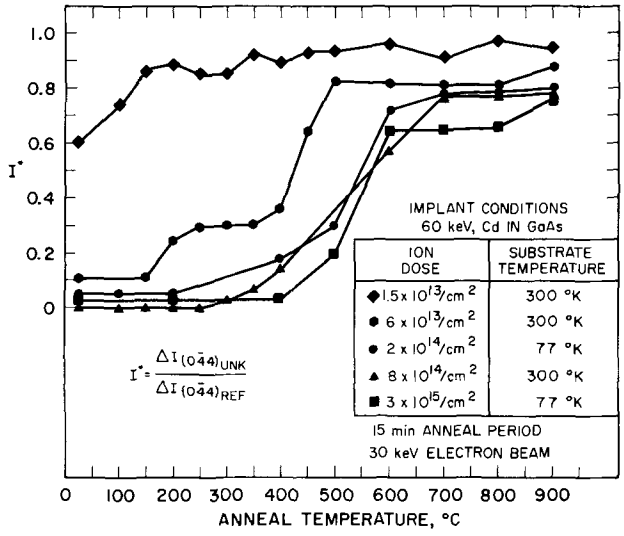

Fig. 3. Normalized pattern quality I^* for implanted and annealed GaAs.

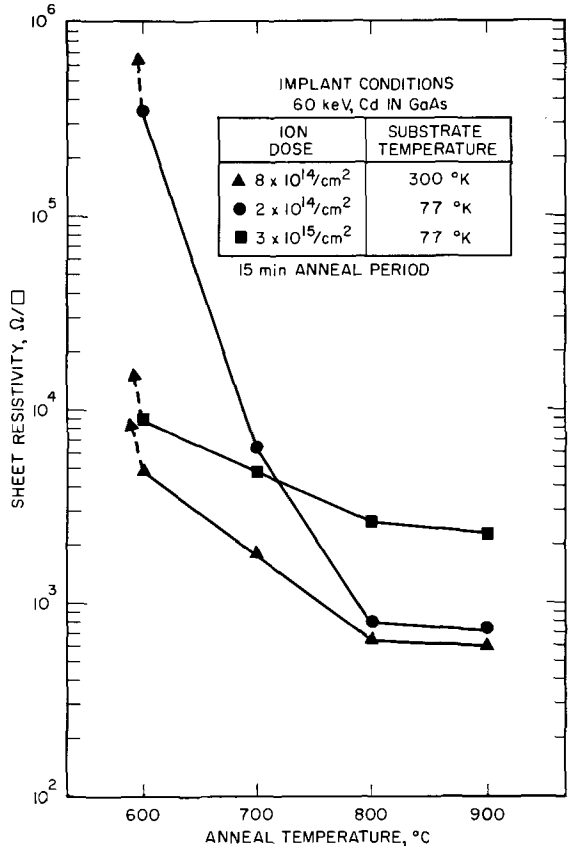

Fig. 4. Dependence of sheet resistivity on anneal temperature

been identified in ion-implanted Si (17), while vacancy-dopant atom complexes appear to form in GaAs (18, 19).

It is interesting to note from the data of Fig. 3 that even after annealing at 900°C, complete recovery was not observed in any sample. There was always a residual disorder, which was greater for the samples implanted with larger ion dose. From a practical viewpoint it is thus desirable to avoid very large doses, for the largest surface carrier concentration that could be produced in any sample after annealing at temperatures up to 900°C was approximately 1-2 x 10^{14}/cm², even in samples with implanted ion doses as high as 3 x 10^{15}/cm². Implantation of more than 2 x 10^{14} ions/cm² served only to reduce carrier mobility and did not result in increased carrier concentration, as shown by the data of Fig. 5 for the samples implanted at 77°K. Similar results were obtained for samples implanted at room temperature (4). For ion doses $\leq 10^{14}$/cm² 100% electrical activity of the implanted ions was observed after annealing at 800°C or higher. The upper limit to the carrier concentration seems to result merely from reaching the solubility limit of Cd in GaAs, which Goldstein (20) has reported to be 2 x 10^{19}/cm³ for the case of diffusion at 900°C from a vapor source. Angle section and stain measurements have shown that the p-type, Cd implanted layer is approximately 0.1μ thick; thus the peak Cd ion concentration per cm³ is $\sim 10^{19}$/cm³ for a sample implanted with 1 x 10^{14} ions/cm².

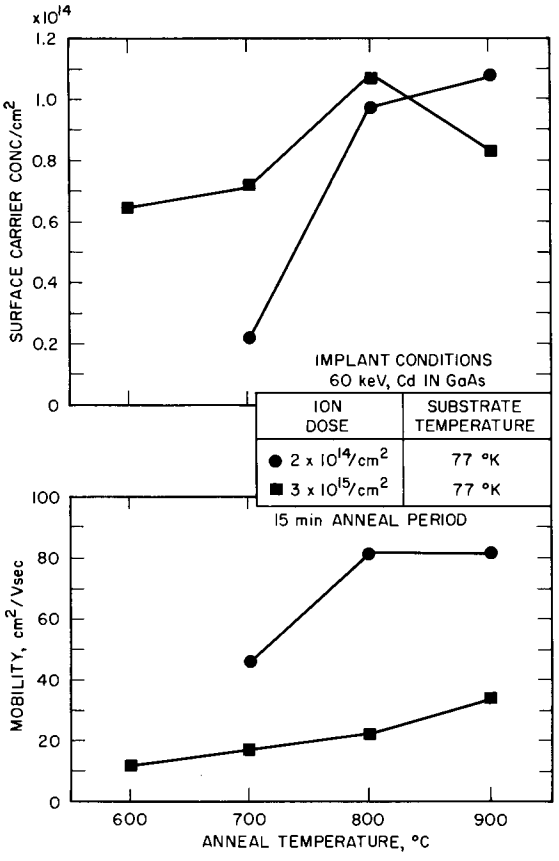

Fig. 5. Dependence of carrier concentration and mobility on anneal temperature.

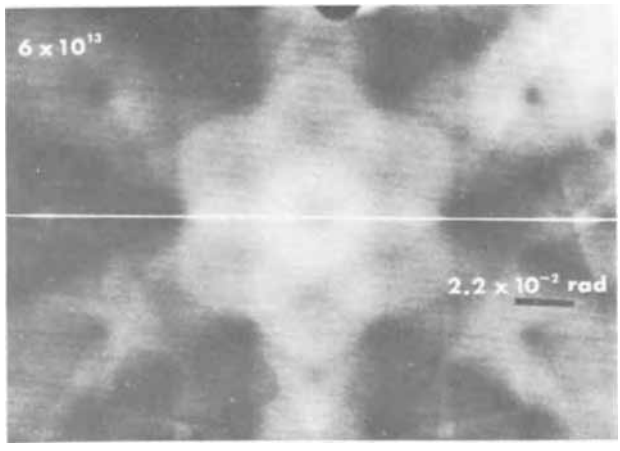

Fig. 6. Coates-Kikuchi pattern for 6 x $10^{13}Cd^+/cm^2$ implanted GaAs after 300°C anneal.

(The concentration *vs.* depth profile for the implanted ions is roughly Gaussian, rather than being uniform.) The exact nature of the residual lattice disorder cannot be determined from the Coates-Kikuchi pattern analysis. However, transmission electron microscopy applied to 40-100 keV Ne implanted GaAs by Mazey and Nelson (21) has shown that networks of small dislocation loops remain following annealing at 700°C. It should be emphasized that the effect of residual lattice damage on the electrical properties (carrier concentration and mobility) of samples implanted with $\leq$ 1 x $10^{14}Cd^+/cm^2$ and annealed at $\geq$800°C is negligible (4).

The anneal behavior of lattice damage in samples implanted with smaller ion dose than that required to produce a layer of saturated disorder is different from that considered thus far for saturation doses. For example, referring again to the data of Fig. 3, the samples implanted with 1.5 x 10^{13} Cd^+/cm^2 exhibited almost complete recovery after annealing at only 150°C. Similar results have been obtained by Weisenberger, Picraux, and Vook (22), who observed that the lattice damage produced by implanting GaAs with low doses of either 140 keV Zn or 150 keV Xe (at 99° and 93°K respectively) was almost completely eliminated by annealing at 125°C for 15 min. It must be emphasized, however, that recovery of the lattice does not necessarily imply that the implanted ions will assume substitutional positions and become electrically active. In the case of the samples implanted with 1.5 x 10^{13} Cd^+/cm^2 it was necessary to perform annealing at 700°C before a p-type layer was observed, and at 800°C before 100% of the implanted ions were electrically active (4).

The samples implanted with 6 x 10^{13} Cd^+/cm^2 (which is approximately the threshold for damage saturation in the case of room temperature implantation of 60 KeV Cd ions) exhibited a small anneal stage between 150° and 250°C and a large anneal stage between 400° and 500°C, separated by a range of anneal temperature within which lattice disorder apparently remained unchanged (Fig. 3, 6 x $10^{13}/cm^2$ dose anneal curve). The Coates-Kikuchi pattern characteristic of this anneal state (shown in Fig. 6) is unusual in that it shows high contrast for the (220) bands but very little fine detail, whereas heavily damaged unannealed crystals or very thin amorphous films exhibit more general over-all diffuseness with no enhanced principal direction scattering. This suggests partial anneal with preferred order in the (110) directions, but with slight random misalignment of the microscopic-damaged zones in other directions which destroys the long range order or fine detail in the reciprocal lattice displays. A similar effect has been observed in certain instances for ion-implanted silicon (23).

Summary

Measurement of the lattice disorder in annealed, 60 keV Cd^+ ion implanted GaAs by the Coates-Kikuchi pattern technique has shown that damage produced by ion doses $\geq$ $10^{14}/cm^2$ anneals gradually in the temperature range from about 400°-700°C. There is no significant difference in the anneal behavior of samples implanted with the substrate at 77°K and those implanted at room temperature. The damage in samples implanted with smaller ion doses anneals at lower temperatures. However, complete recovery was not observed in any sample, even after annealing at 900°C. Hall measurements indicate that ρ_s, N_s, and μ follow essentially the same trends as the damage anneal curves. Annealing at approximately 800°C or higher is required in order to obtain maximum electrical activity of the implanted ions, as well as high mobility, although a p-type layer can be produced by annealing at temperatures as low as 600°C.

Acknowledgments

The authors are grateful to R. Wilson, D. Jamba, and their associates for performing the ion implantations. They would also like to thank P. Coane for making the scanning electron microscope measurements.

The Elimination of Vacancy-Cluster Formation in Dislocation-Free Silicon Crystals

A. J. R. de Kock

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

In dislocation-free silicon crystals grown by the floating-zone technique vacancy clusters are formed. The influence of crystal growth conditions on the cluster formation is studied. Methods for the prevention of vacancy cluster formation during growth, based on a nucleation model, are discussed. In crystals grown by one of these methods vacancy clusters could not be detected.

Up to now relatively little attention has been paid to the influence of point defects on the crystal perfection of as-grown silicon crystals. The main emphasis has been on the prevention of the formation of dislocations and impurity precipitates. For some time now it has been possible to grow silicon single crystals by floating-zone techniques in which no planar or line defects are present. Furthermore, because of the high purity of this material, impurity precipitation will not take place.

However, it has been reported (1, 2) that in dislocation-free floating-zone silicon crystals clustering of vacancies occurred, leading to a poor lattice perfection. Plaskett (1) investigated such crystals, grown in helium, by copper decoration and infrared microscopy. The precipitates present after copper diffusion were attributed to vacancy clusters decorated with copper. Abe and Maruyama (3) investigated similar microdefects in dislocation-free vacuum floating-zone silicon. They attributed these defects to oxygen precipitation. However an explanation for oxygen precipitation in dislocation-free low oxygen-content silicon could not be given. De Kock (2) obtained further evidence that these defects are vacancy clusters. He determined the distribution and concentration of the vacancy clusters in commercial silicon crystals. Two types of vacancy clusters, differing in size, were found to be present. A model was presented which elucidates both the formation and nature of these defects. In this model it is assumed that during cooling of the as-grown dislocation-free crystal vacancy-oxygen complexes are formed acting as nucleation sites for the supersaturated amount of vacancies. Corbett, Watkins, and McDonald (4) have found with their E.P.R. and infrared spectrometric studies of electron-irradiated silicon that complexes of oxygen atoms and a vacancy are readily formed. The temperature T_c below which these complexes are stable depends on the number (n) of oxygen atoms per complex. The A-center ($n = 1$) was found to be stable below 300°C. The complex with $n = 2$ anneals at about 450°C, whereas the complex with $n = 3$ is probably stable below 600°C. It is known (5) that large oxygen complexes taking the form of precipitates are stable up to a temperature of 1350°C. Applying the results of Corbett *et al.* (4) to crystal growth conditions, the formation of stable vacancy-oxygen complexes in different stages of the cooling procedure can be expected. The first stable complexes containing n_1 oxygen atoms will begin to form at about $T = T_{c1}$. This leads to the formation of large clusters, whereas the formation below T_{c2} ($< T_{c1}$) of complexes containing n_2 ($< n_1$) oxygen atoms gives rise to the nucleation of smaller vacancy clusters. Henceforth the large clusters will be called A-clusters, the small ones B-clusters.

In the present paper the vacancy cluster distribution as related to the crystal growth conditions is studied. In particular it will be shown that vacancy cluster formation can be prevented by crystal-growth methods which apparently retard the formation of vacancy-oxygen complexes.

Key words: silicon crystal growth, vacancy clusters in Si, nucleation in Si, nucleation of point defects in Si.

Detection Methods

Vacancy clusters in silicon can be detected by several techniques. The preferential etching of polished surfaces, using *e.g.* HF (50%) : CrO_3 (33% aqueous solution) = 1 : 2 reveals vacancy clusters in the form of etch pits. These etch pits are clearly visible under a normal light microscope (2, 3, 6). In x-ray transmission topographs using the normal Lang technique, the relatively small strain fields around the vacancy clusters cause no detectable contrast for most of the crystals investigated. In some cases only an extremely weak contrast pattern was detected.

A very sensitive detection method (2) has been recently developed. In this method the vacancy clusters are decorated with copper. This is done by heating the sample up to a temperature of about 950°C for 30 min in an argon stream in which copper is evaporated, fol-

lowed by rapid cooling in a nitrogen-argon flow. Subsequently the sample is etched in order to remove possible copper precipitation on the surface. X-ray transmission topographs of the decorated sample are then made. The strain field around the decorated clusters is large enough to cause strong direct image contrast.

Experimental Results of Normal Dislocation-Free Silicon Crystals

Dislocation-free silicon crystals were grown in purified argon (pressure of 1 atm) using the pedestal-pulling technique (7). The crystal growth rates were between 1 and 3 mm/min. Dislocations were eliminated by growing a thin neck at the beginning of the crystal (7, 8). Polycrystalline high-resistive starting material was used. Phosphorus was added up to a concentration of 10^{16} at. cm^{-3}. Figure 1 shows a detail of a preferentially etched longitudinal section of such a crystal. The A-clusters give rise to the formation of etch pits located in a striated pattern. The shape of the pattern indicates that the vacancy-cluster formation mainly occurs in thin layers, being closely related to the solid-liquid interface present during growth. However investigation in the transmission electron microscope of carbon replicas made of preferentially etched surfaces proved a similar distribution of very small vacancy clusters (B-clusters) to be present, which could not be seen in the light microscope. These small ones are also located in a striated pattern and are present in a higher concentration than the larger clusters.

The concentration and actual distribution were determined by x-ray topographs of copper-decorated slices. Figures 2, 3, and 4 show such topographs of longitudinal and cross-sectional slices, cut from crystals with diameters between 23 and 25 mm. In all topographs shown, $MoK\alpha_1$ radiation was used. The direct images of the decorated clusters, black on the original nuclear plate, are visible on these photographs as white dots. The over-all bulk concentration of the A-clusters in our crystals, as determined from these topographs, varied between $5 \cdot 10^5$ cm^{-3} and $5 \cdot 10^6$ cm^{-3}. The concentration in the layers containing the clusters is about one order higher. In crystals grown in the <111> and <100> direction under identical conditions equal cluster concentrations were found. The previously reported (2) dependence of cluster concentration on orientation of the crystals grown by other manufacturers probably originated from differences in growth conditions. The dope concentration and the crystal growth rate had no influence on the defect density.

In contrast with crystals grown in the <100> direction, dislocation-free crystals grown in the <111> direction have a noncircular cross section (Fig. 3). This effect, which is related to the shape of the solid-liquid interface during growth, was reported by Ciszek (9).

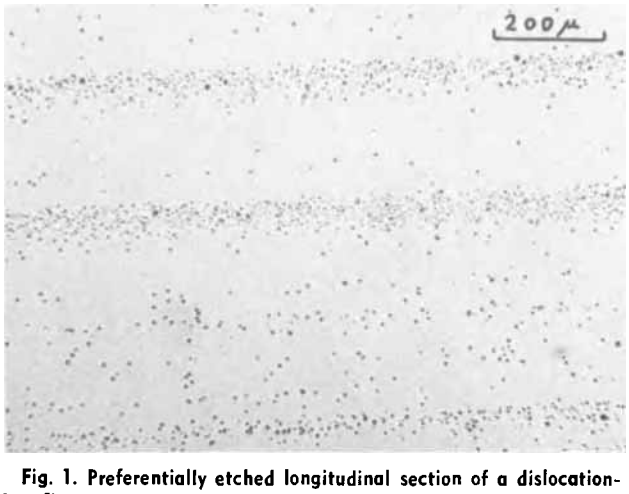

Fig. 1. Preferentially etched longitudinal section of a dislocation-free floating-zone silicon crystal.

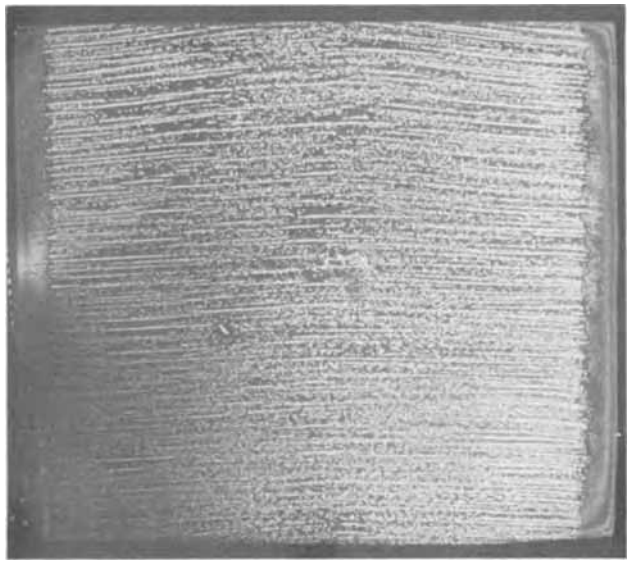

Fig. 2. (111) x-ray transmission topograph of a decorated longitudinal slice. Slice thickness: 2.4×10^{-2} cm. Crystal growth rate: 1 mm/min. Growth direction: <111>.

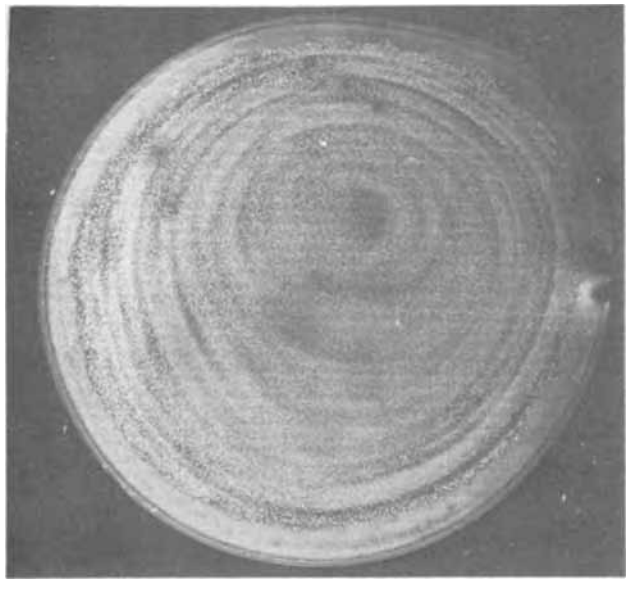

Fig. 3. ($2\bar{2}0$) x-ray transmission topograph of a decorated cross-sectional slice. Slice thickness: 2.0×10^{-2} cm. Growth rate: 3 mm/min. Growth direction: <111>. A-cluster concentration: 1.6×10^6 cm^{-3}.

The distribution of decorated clusters as present in a longitudinal section of a crystal grown in argon is schematically drawn in Fig. 5. The cluster concentration generally exhibits a minimum in the central area of the crystal. No A-clusters are found in a crystal surface layer about 2 mm thick. In some vacuum-grown crystals, received from other manufacturers, this surface layer was completely cluster-free.

Discussion

The striated cluster distribution can be explained with the aid of the described nucleation model. A periodic variation in oxygen concentration (rotational striations) caused by growth rate variations results in a very pronounced variation in complex concentration [see (2)]. For crystals grown in argon A-clusters were absent in a surface layer of about 2 mm (see Fig. 5). This is probably due to the vacancy sink action of

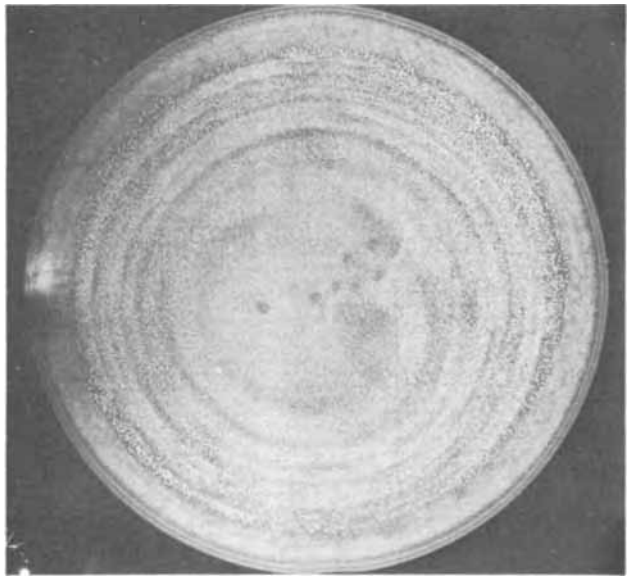

Fig. 4. ($\bar{2}20$) x-ray transmission topograph of a decorated cross-sectional slice. Slice thickness: 2.1×10^{-2} cm. Growth rate: 1 mm/min. Growth direction: <100>. A-cluster concentration: 2.2×10^{6} cm^{-3}.

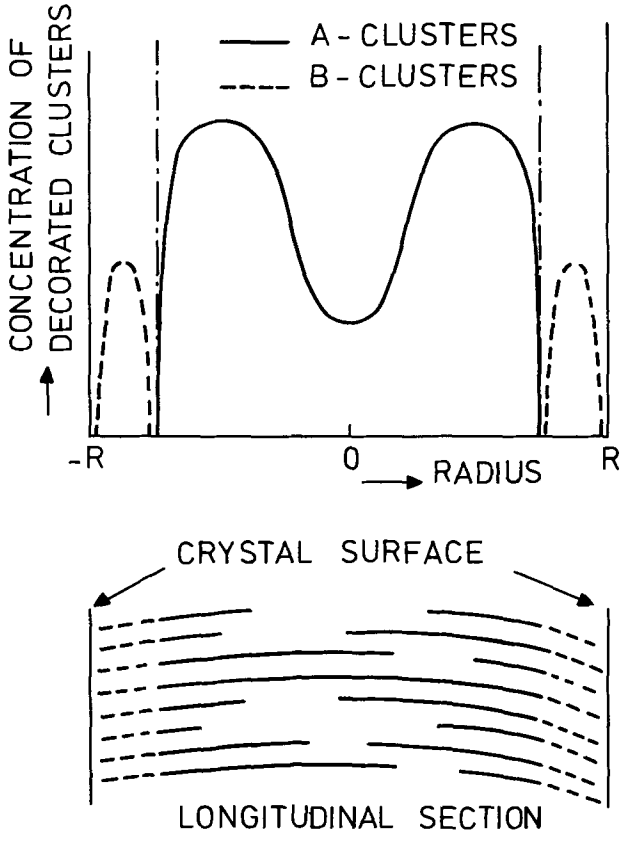

Fig. 5. Distribution and concentration profile of decorated vacancy clusters.

the crystal surface. B-clusters are still present in this layer indicating that they form more readily than the A-defect. This is in agreement with the fact that the over-all concentration of B-clusters is several orders higher than that of the A-type defect. The occasional absence of B-clusters in this region in vacuum-grown material may be caused by a lower oxygen concentration in this area as a result of evaporation of oxygen from the melt in the form of SiO. This effect was found by Kaiser and Keck (10) for crucible-grown material.

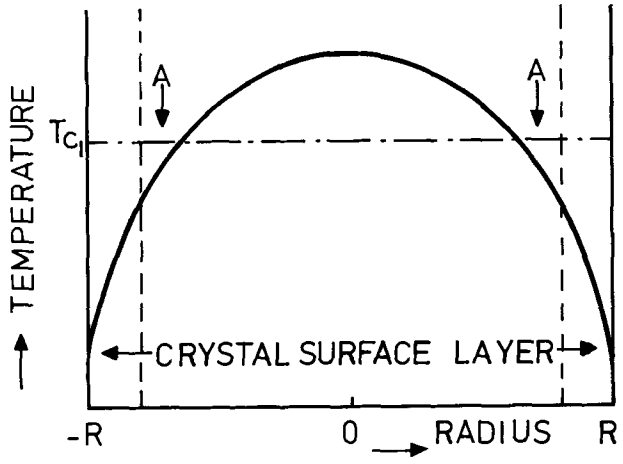

Fig. 6. Temperature distribution in the crystal area where the formation of vacancy-oxygen complexes begins (region A).

Two different processes combine to cause the minimum in the vacancy cluster concentration in the central part of the crystal (Fig. 5). First, the rotational striations decrease in passing from the periphery to the interior of the crystal (11). Furthermore, during cooling of the as-grown crystal the first vacancy-oxygen complexes and consequently the first clusters will be formed in region A (Fig. 6), where T drops below T_{c_1} first. On their way to the surface the excess vacancies from the crystal interior will nucleate here on clusters already formed or contribute to the formation of new nucleation sites. Finally, the temperature over the entire cross section will be below T_{c_1} and the resulting vacancy-cluster distribution will show a minimum in the crystal center.

Prevention of Vacancy Clustering During Growth

Vacancies in silicon are mobile below 150°K with migration energies between 0.18 and 0.33 eV (12, 13). This means that the excess vacancies present during cooling of the as-grown crystal should be able to diffuse out to the surface under normal growth conditions if no nucleation sites (vacancy-oxygen complexes) were formed. Therefore, the growth of vacancy cluster-free silicon should be possible as soon as complex formation is prevented. In principle, this can be achieved in several ways. One method could be based on reduction of the oxygen concentration (C_{ox}). This will lead to a decrease in the probability of complex formation. In floating-zone silicon crystals C_{ox} is generally low (10^{15}-10^{16} at. cm^{-3}) (14, 15). A further reduction will require the use of extremely pure starting material combined with very clean crystal growth conditions (*e.g.* high vacuum). In some crystals having slightly different values of C_{ox}, as measured by infrared absorption at 9μ wavelength at low temperatures, the lowest vacancy cluster concentration was indeed found in crystals having the lowest C_{ox}. However, in addition to the average C_{ox}, the probability of formation also depends greatly on the periodic variation in C_{ox} (2). A reduction of this periodic variation will decrease the probability of formation. The growth rate should therefore be kept as constant as possible.

In the case of very high oxygen concentration the vacancy clustering becomes more complicated. In dislocation-free crystals grown by the Czochralski method, usually containing large amounts of oxygen and carbon, the formation of vacancy-oxygen complexes can also be expected. During cooling of the as-grown crystal, however, the material becomes supersaturated not only with vacancies but also with oxygen and carbon. This will lead to simultaneous precipitation of vacancies, oxygen, and carbon. Besides homogeneous nucleation of the impurities, precipitation of oxygen and carbon

on the vacancy clusters is likely to occur. Indeed it is found that in dislocation-free crucible-grown silicon crystals after annealing at 900°-1300°C oxygen and carbon precipitate in a striated distribution similar to that found for vacancy clusters in floating zone material (16, 17). Batavin (17) in particular presented evidence that vacancy clusters might act as nucleation sites for oxygen and carbon. The precipitates of oxygen and carbon in crystals containing dislocations were found on the dislocations and randomly distributed in the crystal (16).

Another method for preventing vacancy clustering during growth is based on a reduction of the complex formation rate. This can in principle be achieved by adding to the crystal an impurity, which reacts with the oxygen atoms present. The oxygen-impurity bonds formed may lower the effective oxygen mobility in the silicon lattice and therefore the vacancy-oxygen complex formation rate. If this effect is combined with a sufficiently fast growth rate (cooling rate), not enough time will be available for complex formation, giving the extremely mobile vacancies the opportunity to diffuse out to the crystal surface. To be bound to oxygen atoms this impurity should have a strong affinity to oxygen, while it should also possess a high diffusion coefficient in silicon in order to make a fast reaction with oxygen possible. An impurity matching these conditions is hydrogen, which can be added to the crystal by growing the latter in an atmosphere containing hydrogen.

Some evidence for an interaction between oxygen and hydrogen in the silicon lattice was reported by Yukimoto, Hirano, and Sugioka (18, 19). Crystals pulled from the crucible in hydrogen atmosphere exhibited a lower infrared absorption at 9μ compared with crystals pulled in argon. This was thought to be due to the formation of oxygen-hydrogen complexes resulting in a reduction of the total number of Si-O bonds.

Furthermore the diffusion coefficient of hydrogen in silicon is high (*e.g.* $D = 1.70 \times 10^{-4}$ cm^2 sec^{-1} at 1092°C) as measured by van Wieringen and Warmoltz (20).

The two methods described above for eliminating vacancy clusters can, of course, be combined for optimum results.

Experimental Results and Discussion of Vacancy Cluster Elimination

A series of dislocation-free crystals were grown in the <111> direction by the pedestal pulling method in an atmosphere of purified argon to which 10% hydrogen had been added. The total pressure was 1 atm. High-resistivity starting material was used with an oxygen concentration below 10^{16} at. cm^{-3}. The diameter of the crystals varied between 23 and 25 mm. Increasing the growth rate and consequently the cooling rate of the crystal resulted in a continuous decrease in vacancy cluster concentration. This is demonstrated with a series of x-ray topographs of decorated cross-sectional slices (Fig. 7-10). With a growth rate of 1 mm/min (Fig. 8), the cooling rate of a crystal surface layer is already high enough to prevent cluster formation in this area. In the crystal grown at 2 mm/min (Fig. 9) the B-clusters, usually detectable with carbon replica techniques only (2), now become detectable by copper decoration as well. The reason for this is threefold. Firstly, because of the low concentration of A-clusters (7×10^4 cm^{-3}), more copper is available for decoration of the B-type defects. Secondly, the average B-cluster concentration is also reduced (3×10^6 cm^{-3}) by several orders of magnitude compared with material grown in argon. Finally, the B-clusters are probably larger in this case because, as a result of the low cluster concentration, they will capture more excess vacancies per defect. In the slice shown in Fig. 10, which has been cut from a crystal grown at 3 mm/min, no A-clusters were found whereas in the entire sample 107 B-clusters were counted. In all the crystals grown at this rate the A-clusters were totally eliminated. This result indicates that hydrogen not only decreases the formation rate of vacancy-oxygen complexes but apparently also causes an incubation time for complex formation. A reproducible elimination of the B-clusters was found to be more difficult. This again proved that B-defects are formed more readily than A-defects. In some experiments the temperature gradients in a limited region near the solid-liquid interface were reduced by application of a special rf coil construction, resulting in a decrease of the interface curvature. Generally this will cause a decrease of the periodic variation in growth rate. In crystals grown in Ar + 10% H_2 at 3 mm/min using such a coil, zero concentrations of both A- and B-clusters were obtained. In Fig. 11 the cluster concentration as a function of crystal growth rate is plotted. The formation of A- and B-clusters is prevented by growing at a rate of 3 mm/min. This indicates that the incubation time for formation is of the same order for both defects.

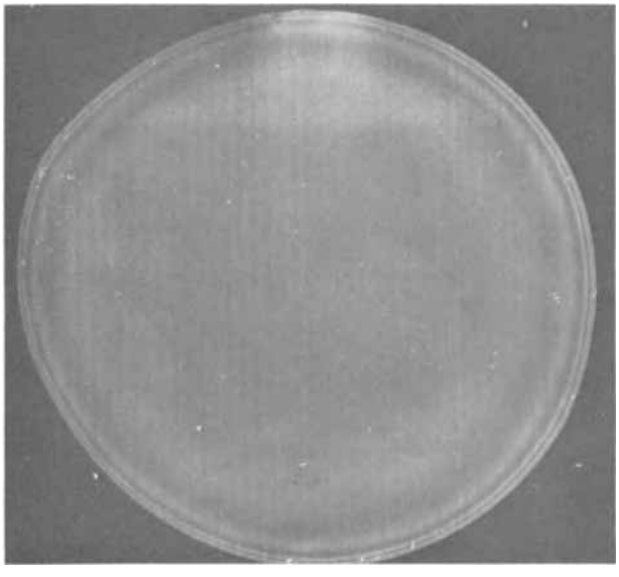

Fig. 10. ($2\bar{2}0$) x-ray transmission topograph. Growth rate. 3 mm/min. A-cluster concentration: 0.

Crystals with various phosphorus dope concentrations (up to 10^{16} at. cm^{-3}) were grown. No influence of the dope on the elimination of clusters was found.

As reported by Yoshimatsu, Sugita, and Yukimoto (21, 22, 19, 20), hydrogen in silicon can give rise to the formation of crystal defects. These defects caused anomalous etching effects and were often detectable in x-ray topographs. Sugita (22) found that in his floating-zone apparatus at least 25% hydrogen in the argon flow was necessary to introduce these defects. We, however, found that in our set-up precipitation of hydrogen in the interior of the crystal occurred with as little as 10% hydrogen. This caused anomalous etching effects. During nonpreferential etching, *e.g.* using HF-HNO_3 etchants, holes were formed at the sample surface. The hydrogen precipitation greatly depends on the crystal perfection and the radial temperature gradient. In a crystal in which the radial temperature gradient was enlarged by an Ar-H_2 flow against the growing crystal, the hydrogen precipitates, formed in the central part of the crystal were large

enough to give contrast in x-ray topographs. The upper part of the crystal was dislocation-free and contained vacancy clusters (growth rate 1 mm/min) (Fig. 12), while dislocations were introduced in the lower part (Fig. 13). The hydrogen was found to precipitate on

the vacancy clusters or on the dislocation lines. The strain fields around these precipitates were up to 100μ in diameter in this case. It proved possible to dissolve these precipitates again by annealing at 550°C for about 3 hr. However, in dislocation-free crystals grown under such conditions that vacancy clusters are not present, hydrogen precipitation could not be detected either by etching or by x-ray transmission topography. Obviously, if no crystal defects acting as nucleation sites for hydrogen are present, hydrogen diffuses out to the crystal surface.

Acknowledgments

The author wishes to express his gratitude to Mr. P. J. Roksnoer for growing the crystals and Mr. P. G. T. Boonen for his active assistance with the crystal characterization.

Preparation of Hafnium-Tantalum Nitride Films by Reactive Alloy Sputtering

L. D. Locker,* C. L. Naegele,[1] and F. Vratny*

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Thin films of hafnium nitride and tantalum nitride with resistivities of 10^{10} and 10^{4} ohm-cm, respectively, have been deposited by rf + d-c reactive sputtering. By sputtering hafnium-tantalum mixtures in pure nitrogen at 7.0×10^{-2} Torr, the complete range of resistivities is obtained, with a linear increase between 10^{5}-10^{9} ohm-cm, corresponding to a relative hafnium content of 40-70%. For a fixed Hf:Ta ratio, the resistivity, deposition rate, and nitrogen content of the films depend on the pressure and substrate temperature. For pure tantalum a dinitride (TaN_2) is deposited, but for pure hafnium the dinitride has not been obtained. An alloy nitride containing 60% Hf can be represented by the formula $Hf_{0.6}Ta_{0.4}N_x$, where x increases from 1.2 to 1.4 as the substrate temperature increases from 225° to 400°C. A sequence of reaction steps on the substrate surface is proposed to explain the deposition rates observed in reactive sputtering.

In the d-c reactive sputtering of tantalum in nitrogen, the transition from tantalum to tantalum nitride occurs as the nitrogen pressure is increased from 10^{-5} to 10^{-2} Torr. The phases Ta_2N, TaN, and TaN_2 have been reported previously (1-4). Corresponding increases in the resistivity of the films occur, with a maximum of 10^{4} ohm-cm. Some of the same compositional and electrical changes are known to occur with reactively sputtered hafnium (5). High-resistivity (*i.e.* 10^{4} ohm-cm) hafnium nitride films have been produced at 3.0×10^{-2} Torr by d-c reactive sputtering onto substrates heated to 350°C. Table I shows that increases in resistivity by more than a factor of 10^{7} are possible as the nitrogen content of the films increases.

Key words: sputtering, thin films, hafnium nitride, tantalum nitride.

Our initial measurements on hafnium nitride films, produced at 7.0×10^{-2} Torr by rf + d-c reactive sputtering onto water-cooled substrates, revealed that the films have a resistivity greater than 10^{10} ohm-cm. Tantalum nitride films produced under the latter conditions show no change from the previously observed value of 10^{4} ohm-cm. These results suggest the possibility of depositing stable thin films with a resistivity that can be controlled over many orders of magnitude by simply varying the tantalum to hafnium ratio. The method to prepare these alloy nitrides in a reproducible manner, and the measurement of their properties are reported below.

Experimental

Film deposition was done by rf + d-c reactive sputtering (6) in an oil diffusion pumped system, with a liquid nitrogen baffle, routinely capable of a pressure of

Table I. Properties of tantalum and hafnium nitrides formed by d-c reactive sputtering

Chemical formula	Nitrogen pressure (Torr)	Resistivity (ohm-cm)	Crystal structure	Density (g/cm³)	Reference

2×10^{-6} Torr prior to the start of each experiment. The simultaneous application of rf and d-c power to the cathode is an advantage in reactive sputtering. The rf increases the degree of ionization in the plasma, and prevents the accumulation of an insulating layer on the cathode. The d-c component is the major source of the negative field at the cathode that extracts ions from the plasma. The combined rf + d-c produces higher deposition rates, and enables a wider range of sputtering parameters to be investigated.

The cathode potential was −3.5 kV d-c with rf power supplied at approximately 3W/in.² of cathode area. The 6 in. × 6 in. sputtering cathode and the substrates were held vertically at a separation of 3 in., as shown schematically in Fig. 1. The sputtering system accommodated square cathodes most easily. No difficulties were encountered due to power loss at the corners. In addition to the rf matching network, a filter consisting basically of an inductor and capacitor separates the rf from the d-c component.

A tantalum wire grid was placed approximately 1 in. from the substrates and held at ground potential. The functions of the grid are to improve the uniformity of electric fields near the substrate, and to reduce the bombardment of the substrate surface by ions and electrons generated in the glow discharge. In the experiments reported here at nitrogen pressures of up to 7.0×10^{-2} Torr the use of the grid improves the uniformity of the films. When the grid becomes coated with a resistive film it is no longer at ground potential, but charges toward the potential of a floating probe. The pattern of such a coated grid has often been observed in the film deposited on the substrate. Thus, frequent cleaning of the grid is required, or for small area substrates a hole may be cut in the grid without loss of uniformity in the film.

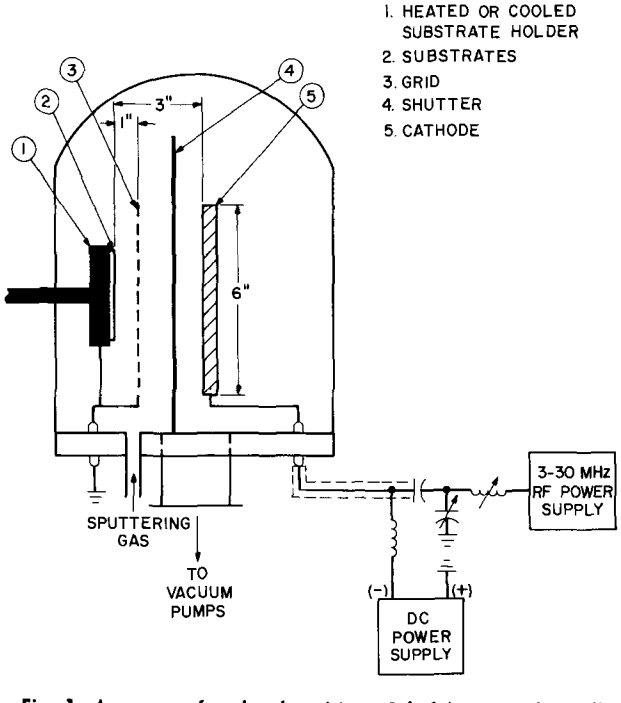

Fig. 1. Apparatus for the deposition of hafnium-tantalum alloy nitrides by rf + d-c reactive sputtering.

Table II lists the types of substrates that were used during the course of the experiments, the quantities measured on each substrate, and the technique that was used. The substrate temperature was regulated by either a water-cooled or resistance-heated substrate holder. Temperature measurements were made with a platinum/platinum-10% rhodium thin-film thermocouple on a sapphire substrate mounted in the center of the substrate holder. Since the presence of the nitrogen discharge affected the thin-film thermocouple emf, both the d-c and rf power were turned off for a short interval while the readings were taken. The thin-film thermocouple measurements were not affected by the nitride film that was being deposited over it.

Preparation of Hf-Ta sputtering sources.—An important factor in the deposition of uniform hafnium-tantalum nitride films with reproducible properties is the preparation of the sputtering cathodes. In previous investigations multicomponent films have been prepared by simultaneous sputtering of the constituents from independent sources, from bulk alloys, with composites formed by inlaying or overlaying ribbons or wires of one component on a plate of the other, or with small particles made self-supporting by powder metallurgical techniques. The first two methods have the advantage that separate sources are not needed for each change in film composition. In all previous reports d-c diode sputtering or pressures much lower than 7.0×10^{-2} Torr have been used. Therefore, previous results do not necessarily apply to rf + d-c reactive sputtering. Preferential sputtering of one component, preferential accommodation on the substrate, or selective formation of a reaction product on the cathode, may lead to poor reproducibility and poor uniformity in reactive sputtering, but may be no problem for d-c sputtering in argon.

Table II. Experimental measurements

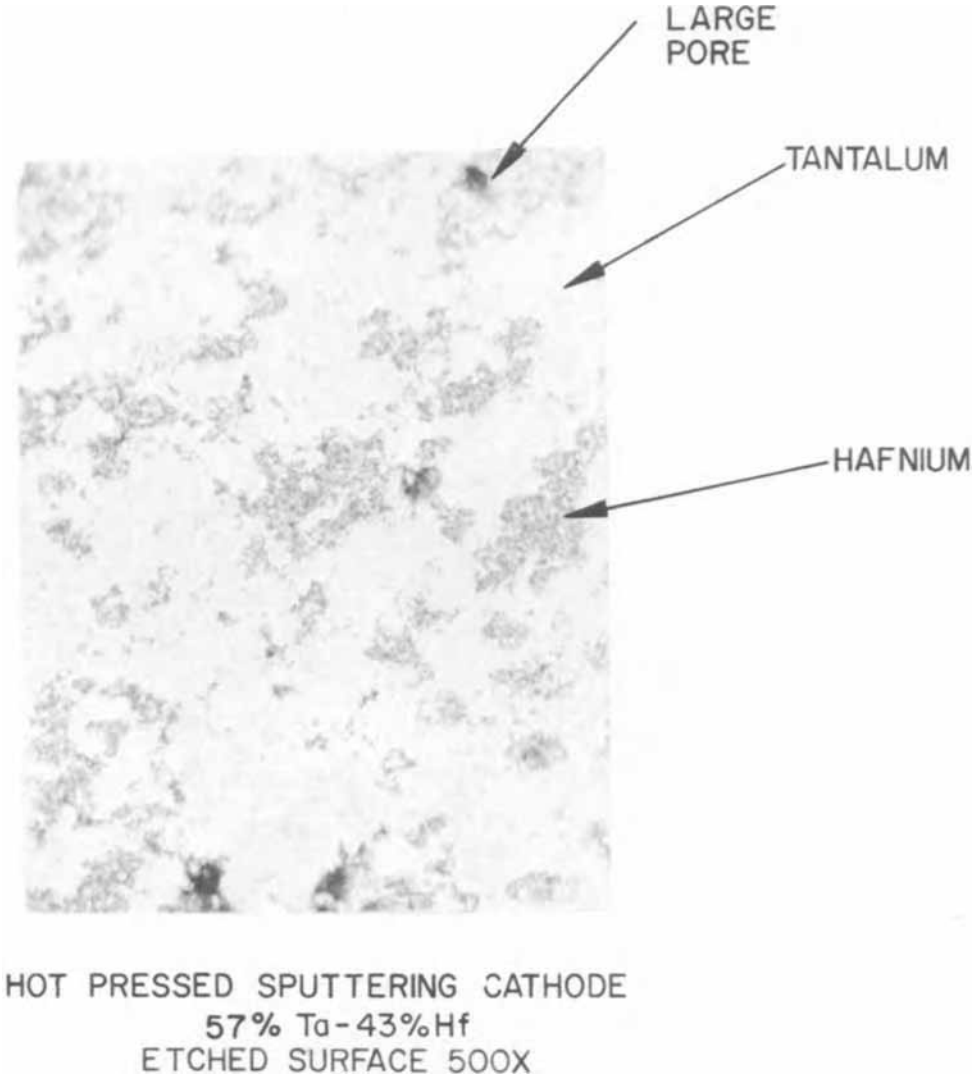

Fig. 2. Optical micrograph of hot-pressed sputtering cathode 500 X. Composition: 57% Ta-43% Hf.

For example, overlays have been used successfully for the deposition of Hf-Ta metal alloys in argon at 2.0×10^{-2} Torr. The compositions of the films are proportional to the relative area of each component exposed to the discharge. However, deviations from the relative area ratio, and lack of reproducibility are characteristics of the same Hf-Ta cathode when it is used in nitrogen at 7.0×10^{-2} Torr. In the latter case a nitride film deposits on both the strips and on the plate. The composition of the layer deposited on the substrate changes with time. The requirement for reproducible composition is rather critical in the hafnium-tantalum nitride system, since the results presented below show that a change of 5% in the relative metal content can change the resistivity by one order of magnitude in the range between 30-65% Hf.

Hot-pressed sputtering sources fabricated from Ta and Hf (2.5% Zr) powders require a new cathode for each composition, but provide reproducibility at least to within the limits of the experimental measurements of the resistivity and composition. The 0.2 in. thick as-pressed disks are cut into 6 in. $\times$ 6 in. squares, and thinned by 0.05 in. by surface grinding with a diamond abrasive. The cathodes have approximately 75% of the theoretical density. A metallograph of the surface of a typical Hf-Ta cathode after etching in an HCl-HNO_3-HF solution is shown in Fig. 2. The distribution of hafnium (dark) and tantalum (light) is evident. Regions of high porosity are also shown in Fig 2. Due to this topography it was necessary to sputter a new target in argon in order to outgas it sufficiently to pump the chamber to 2×10^{-6} Torr. Subsequent experiments could be done without this argon presputter, but a short sputtering period was adopted as standard procedure in all experiments. In addition, a minimum presputter period of 60 min in nitrogen under the actual conditions of each experiment was used before opening the shutter between the cathode and the substrate.

Hot-pressed cathodes have been used to obtain all of the results described below, except of course for pure Ta and Hf. The reproducibility for two sets of consecutive experiments with the substrate at 250° or 400°C, respectively, is shown in Fig. 3 for the source composition 60% Hf-40% Ta. The data show that for rf + d-c reactive sputtering at a nitrogen pressure of 7.0×10^{-2} Torr the resistivity can be reproduced to one-half an order of magnitude, with a confidence limit of 90%. Above approximately 65 weight per cent (w/o) hafnium in the Hf-Ta mixture the pressed plates are extremely brittle, and 6 in. $\times$ 6 in. cathodes have not been successfully fabricated by this method. Plasma spraying techniques are being evaluated and will be reported on in the future.

Results

In all of the experiments the power input to the target has been intentionally kept constant, and the film properties measured as a function of target composition, gas mixture, pressure, and substrate temperature. The temperature is shown below to be extremely important in the deposition process. Since power input has a large affect on substrate temperature (7) the power was fixed.

Resistivity Measurements

Effects of composition.—The resistivity of the hafnium-tantalum nitride films is shown in Fig. 4 as a function of the hafnium content. These results are obtained using a water-cooled substrate holder, with a measured substrate temperature of 250°C. The shape of the resistivity *vs.* composition curve is similar with heated substrates, although the values are lower for corresponding compositions. Changes that occur with increasing amounts of hafnium are further emphasized by the increase in optical energy gap from 2.1 eV (100% Ta) to 3.8 eV (100% Hf). These values were obtained by the same method used previously for highly nitrided tantalum films. (2)

Effects of nitrogen pressure.—Figure 5 shows the effect of nitrogen pressure on the resistivity of the films. The figure consists of three parts; two with nitrogen-argon mixtures and the third with pure nitrogen. In pure nitrogen the resistivity decreases as the pressure increases. However, in the argon-nitrogen mixtures the resistivity increases as the nitrogen partial pressure increases.

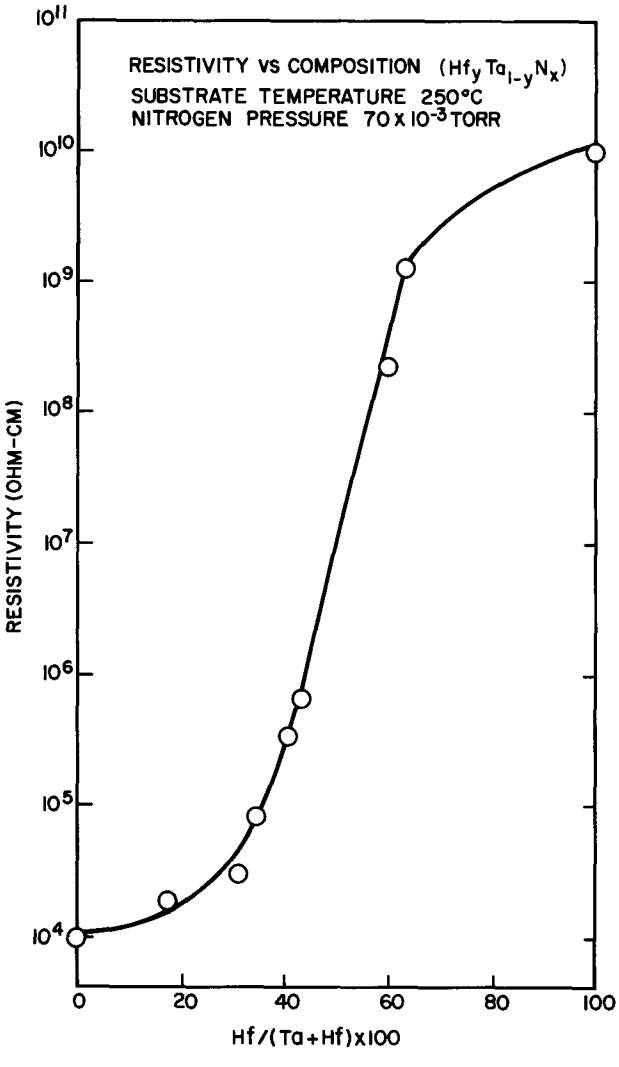

Fig. 4. Changes in resistivity with hafnium content

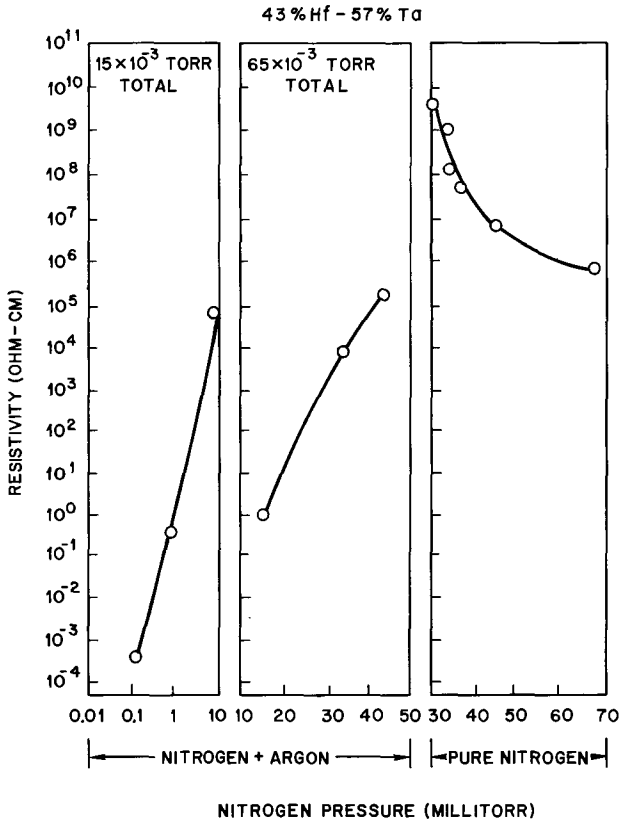

Fig. 5. Resistivity *vs.* nitrogen pressure 43% Hf-57% Ta. Substrate temperature 250°C.

At a total pressure of 1.5×10^{-2} Torr the increase in resistivity with increasing nitrogen partial pressure is in contrast to the plateau of constant resistivity (approx. 1.2×10^{-3} ohm-cm) for reactively sputtered tantalum in the corresponding partial pressure range. For pure tantalum cathodes the product is TaN. For pure hafnium cathodes sputtered in this pressure range there is a change from metallic Hf to HfN. At 1×10^{-4} Torr the hafnium-tantalum alloy nitride films have a metallic appearance. At 10×10^{-3} Torr the films are green and transparent. The resistivity of the films is higher than the values for either TaN or HfN.

At a total pressure of 6.5×10^{-2} Torr and a nitrogen partial pressure of 1.5×10^{-2} Torr the film has the same appearance as the latter one described above, but the resistivity is lower. This resistivity decrease may be attributed to the higher substrate temperature at 6.5×10^{-2} Torr than at a total pressure of 1.5×10^{-2} Torr. The partial pressure range between 1.5×10^{-2}-4.5×10^{-2} Torr is marked by a color change in the film from green to gold. Also, the dissolution rate in hydrofluoric acid is reduced sufficiently, relative to the material prepared at lower pressures, that the films can be removed from glass substrates by etching the glass away in hydrofluoric-nitric acid mixtures.

In pure nitrogen between 3.0×10^{-2}-7.0×10^{-2} Torr the resistivity decreases as the pressure is increased. Again, a pertinent factor is that as the nitrogen pressure is increased, the substrate temperature also increases, undoubtedly due to increased current in the discharge. At 3.5×10^{-2} Torr the substrate temperature is 150°C, and increases by approximately 100°C when the nitrogen pressure is increased to 7.0×10^{-2} Torr.

Effects of substrate temperature.—When the pressure is fixed at 7.0×10^{-2} Torr and the substrate temperature is varied, the resistivity decreases with increasing temperature. The reproducibility of the results shown in Fig. 6 is poorer for the temperature of 125°C than for the higher temperatures, since with a

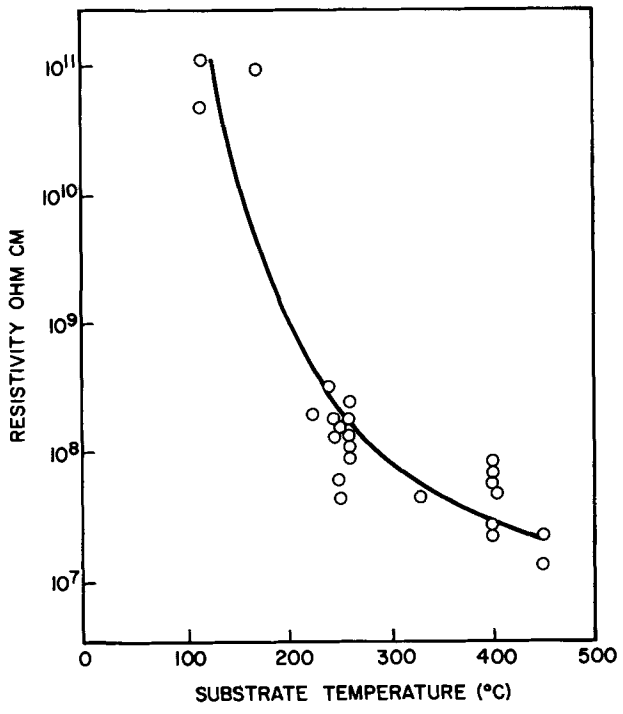

Fig. 6. Resistivity vs. substrate temperature. 60% Hf-40% Ta. Nitrogen pressure 70×10^{-3} Torr.

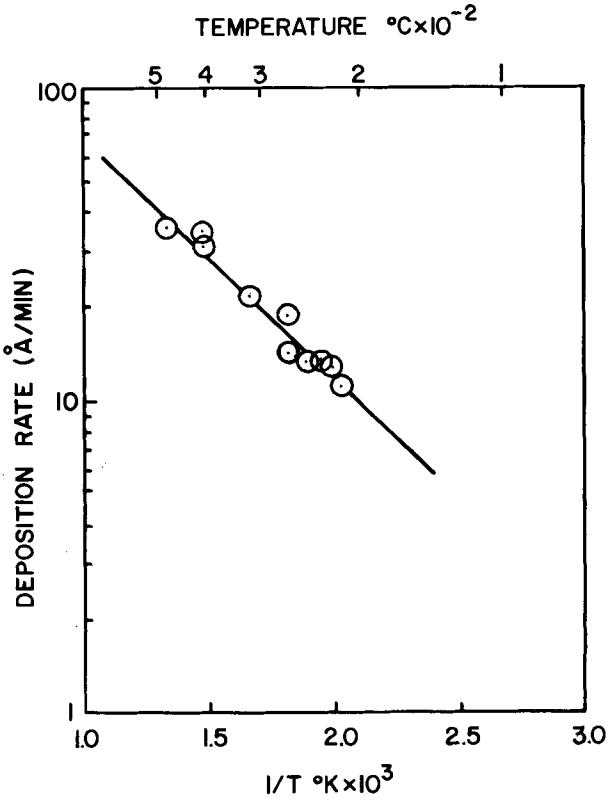

Fig. 7. Effect of substrate temperature on deposition rate. 60% Hf-40% Ta. Nitrogen pressure: 70×10^{-3} Torr.

water-cooled substrate holder it is difficult to control the substrate temperature at 125°C during sputtering. On several samples resistivities of up to 10^{11} ohm-cm have been measured by the electron beam method (8) for films containing 60% Hf, sputtered onto substrates at 125°C.

Deposition Rate vs. Substrate Temperature

The deposition rate increases as the substrate temperature increases from 125° to 450°C. In this temperature range the density decreases by approximately 15%, and the cathode current is constant to within 10%. This is an indication that the films are not porous, and that the plasma density and cathode sputtering rate are not changed by increasing the substrate temperature. If the rate of deposition (Å/min) is plotted in the form of the Arrhenius equation, as in Fig. 7, the slope gives an apparent activation energy of approximately 2 kcal/mole (0.09 eV/molecule). The increase in deposition rate with substrate temperature suggests that the nitride formation occurs at the substrate surface. The relatively low activation energy may be associated with a sequence of reaction processes that affect the over-all deposition rate. This is considered in more detail in the Discussion.

Structure and Chemical Composition

The results given in Table III may be compared to those summarized in Table I for the unalloyed nitrides prepared in previous studies by d-c reactive sputtering.

Unalloyed Hf and Ta nitrides.—Tantalum nitride films containing no hafnium, prepared at 7.0×10^{-2} Torr have a Ta:N atom ratio of 1:2. This TaN_2 phase has the fcc structure reported previously (2, 4) and listed in Table I. Hafnium nitride films, containing no tantalum, have the same fcc diffraction pattern, with a lattice parameter slightly larger than the tantalum dinitride. In the hafnium nitride case the x-ray diffraction pattern contains additional features attributed to the HfN rocksalt structure. It has not been possible to produce a reactively sputtered hafnium dinitride with the experimental conditions used thus far.

Hf-Ta alloy nitrides.—At a nitrogen partial pressure of 1×10^{-4} Torr the alloy nitride is metallic, but the unit cell dimension is larger than for bcc tantalum. At 1×10^{-3} Torr an fcc structure is obtained, which is similar to the TaN and HfN shown in Table I. Above 1×10^{-2} Torr there is no crystalline x-ray diffraction pattern. The metal to nitrogen atom ratio is still 1:1.

Transmission electron diffraction patterns have been obtained from samples deposited in pure nitrogen. The diffraction results show differences between the Hf-Ta nitride ($Hf_yTa_{1-y}N_x$ [$1 < x \leq 2$]), and the unalloyed nitrides. However, there are no significant changes for compositions between 43% Hf-60% Hf when the substrate temperature is varied between 225°-400°C, and the pressure is varied between 3.5×10^{-2}-7.0×10^{-2} Torr.

The diffraction data are summarized in Table III. The lattice spacings cannot be indexed by the single fcc lattice used for the unalloyed nitrides. Extra lines appear at several positions of primary extinctions. It is

interesting that the extra lines can be indexed as HfN. However, until additional experiments are completed no definite conclusions can be made about the structure.

The density of films containing 60% Hf, deposited at 7.0×10^{-2} Torr onto substrates at 225°C is 6.5 ± 0.9 g/cm³. The theoretical density of the fcc TaN_2 ($a \cong 5.0$Å) lattice, with all of the tetrahedral voids filled with nitrogen atoms is 6.66 g/cm³.

The alloy nitride films prepared with the substrate at 225°C contain 8.2 ± 1.4 w/o nitrogen, and approximately 1 w/o oxygen. This corresponds to $x = 1.2 \pm 0.2$ in a compound with the formula $Hf_yTa_{1-y}N_x$. As the substrate temperature is increased, the Hf:Ta ratio remains unchanged, but the nitrogen content of the films increases. At 400°C the films contain approximately 10 w/o N, corresponding to $x = 1.4$. Thus, the alloy dinitride has not been produced.

Discussion

The wide range of properties, structures, and compositions obtained by sputtering hafnium-tantalum cathodes in nitrogen is one example of the general usefulness of reactive sputtering of alloys. For some systems it may be difficult to obtain sputtering sources that produce films with the same metal composition as the starting material. Assuming that suitable sources can be fabricated by one of the methods described previously, some general conclusions can be made from the results obtained in this study in regard to chemical processes in reactive sputtering and the factors that most significantly affect the ability to control the film properties.

Substrate temperature and film quality.—The deposition rate (Fig. 7), chemical composition, and resistivity (Fig. 6) of the hafnium-tantalum alloy nitride films are functions of substrate temperature. Other variables in the sputtering process, such as power input and nitrogen pressure are not independent variables since they affect the substrate temperature. Thus, reproducibility of film properties requires adequate surface temperature control. In addition, thickness uniformity requires uniform thermal contact between the substrate and the heat sink.

The minimum reproducibility of one-half an order of magnitude in the resistivity (Fig. 3) is attributed primarily to the precision of the substrate temperature control. The thin-film thermocouple measurements indicate that with conventional substrate cooling the substrate temperature cannot be satisfactorily maintained below approximately 200°C, under the conditions of nitrogen pressure (7.0×10^{-2} Torr) and rf + d-c power used. Local temperatures may be even higher. The minimum temperature is limited by the thermal contact to the heat sink. Even when the silicon substrates are held with gallium-indium paste, the measured temperature of 125°C plotted in Fig. 6 is at best a low estimate of the local surface temperature. At 125°C the film thickness uniformity is poor.

Until improved methods are designed to control substrate temperature during sputtering, the values reported in published literature must be viewed critically.

Rate processes in reactive sputtering.—At a nitrogen pressure of 7.0×10^{-2} Torr a nitride film forms on the sputtering cathode. However, to interpret the increase in film growth rate with increasing temperature, found in the hafnium-tantalum-nitrogen system and also in other studies of reactive sputtering (9, 10), it must be concluded that the transfer of a nitride through the glow discharge and direct nucleation and growth of the compound on the substrate does not occur. Rather, a sequence of steps including diffusion to the substrate, adsorption, dissociation, and surface reaction on the substrate are the important processes that control the deposition rate. Although low activation energies are characteristic of diffusion-controlled processes, a rate-limiting surface reaction could also explain the observed value of 2 kcal/mole.

For example, if the surface reaction is

$$(Hf, Ta)_s + yN_s \rightarrow (Hf, Ta)N_y \quad [1]$$

where $(Hf, Ta)_s$ represents the hafnium and tantalum on the surface considered here in combination, N_s is the reactive nitrogen species on the surface, and $(Hf, Ta)N_y$ is the hafnium-tantalum nitride product containing y atoms of nitrogen per metal atom, then the deposition rate can be represented by the equation

$$R = k[N]_s[Ta, Hf]_s \quad [2]$$

where s signifies a surface concentration, and k is the reaction rate constant. A first order process is assumed for simplicity.

If the steps such as adsorption and dissociation, which precede the surface reaction, occur rapidly then the surface species are in equilibrium with the vapor phase (g).

$$\frac{[N]_s}{[N]_g} = K_I \quad [3]$$

$$\frac{[Hf, Ta]_s}{[Hf, Ta]_g} = K_{II} \quad [4]$$

A form of Eq. [2] suitable for evaluation of the activation energy of reaction [1] from the Arrhenius plot (Fig. 7) is

$$R = k(T)[N]_g[Hf, Ta]_g K_I(T) K_{II}(T) \quad [5]$$

and

$$\frac{\partial \ln R}{\partial(1/T)} = \frac{\partial \ln k}{\partial(1/T)} + \frac{\partial \ln K_I}{\partial(1/T)} + \frac{\partial \ln K_{II}}{\partial(1/T)} \quad [6]$$

Therefore, the measured activation energy E is related to the activation energy for the surface reaction (E_s), and to the heats of adsorption (H_I and H_{II}) of the reactant species

$$\frac{E}{R} = \frac{E_s + H_I + H_{II}}{R} \quad [7]$$

Since the chemisorption reaction is exothermic the measured value of $E = 2$ kcal/mole is less than E_s. Values of H_I and H_{II} are difficult to estimate since they depend on the surface coverage, $[N]_s$ and $[Hf, Ta]_s$. As the surface temperature increases, the concentration of the reactants decreases. The relative changes in $[N]_s$ and $[Hf, Ta]_s$ may account for the fact that y increases with temperature. This is found experimentally but neglected in the formulation of the rate equations. Alternatively, the adsorption of one of the reactants may be the rate limiting step, and reaction [1] may be rapid. This also could explain the observed value of E and the temperature dependency of y. In either case a more detailed mechanism would require a calculation of the concentration of reactants on the surface. However, the data do verify that it is a process at the substrate surface that is important in reactive sputtering.

Conclusions

Reactive sputtering of hafnium-tantalum alloys in nitrogen can produce nitride films with a resistivity between 10^4-10^{10} ohm-cm. The control of the properties of these films depends on control of the variables (gas mixture, pressure, substrate temperature, *etc.*) in the sputtering process. Reproducibility of the resistivity to within one-half an order of magnitude between 10^4-10^{10} ohm-cm is easily obtained.

The substrate temperature is especially important in reactive sputtering but is difficult to control below 200°C. The effect of substrate temperature on the composition of the films and on the deposition rate is evidence that the substrate surface is the location of the rate determining processes in thin film deposition by reactive sputtering.

Technical Notes

Cathodoluminescence of Alkaline Earth Thiosilicate Phosphors

Frank J. Avella*

Bayside Research Center, GTE Laboratories, Incorporated, Bayside, New York 11360

In 1967 Kaldis *et al.* (1) reported that cadmium thiosilicate Cd_4SiS_6 was capable of intrinsic and sensitized host luminescence but it was not an effective host for activation by Eu. This paper deals with a group of thiosilicates which are effective as hosts for luminescent Eu^{2+} and, in part, for Ce^{3+}. These are the alkaline earth orthothiosilicates having the formula M_2SiS_4, where M = Mg, Ca, Sr, and Ba. Information is presented on the synthesis and some of the physical, chemical, and cathodoluminescence properties of these phosphors.

Experimental

Synthesis.—The alkaline earth thiosilicate phosphors were synthesized by firing powder blends of the alkaline earth sulfide, lanthanide sulfide, silicon, and sulfur in evacuated fused silica capsules. The blends were heated at 50°C/hr to a maximum temperature between 800°-1000°C and were held at such temperatures for 24 hr. Inertial cooling proceeded (approximately 100°C in the first hour, then 50°C/hr) to 300°C or lower before the capsules were removed from the furnace. In some cases improved reactions resulted if the fired charge was mortared, re-encapsulated and refired using the same procedure. Compound formation was verified by comparison of x-ray derived lattice parameters with published values (2-4).

The starting materials were luminescent or reagent grade and were reacted in amounts calculated to yield the formula $M_{2-x}Ln_xSiS_4$, where x = 0.005 or 0.01. Ordinarily no charge compensator was included with Ce^{3+}. Considerable difficulty was encountered with synthesis reproducibility and good chemical reactions were no guarantee of good phosphor performance. After experiments with the firing program, various formulations, capsule pressures, alkali fluoride fluxes, use of an iodine transport agent, pelletizing, argon backfill, and inclusion or exclusion of water vapor, the only significant improvement resulted when certain lots of alkaline earth sulfides were used as starting materials. The cause of their efficacy could not be attributed to their chemical purity and has not yet been determined. Samples of the Mg, Sr, and Ba compounds were prepared without crystalline secondary phases, but Ca_2SiS_4 was always accompanied by a small amount of CaS.

Measurements.—Cathodoluminescence measurements were made with a demountable CRT operated at 12 kV with a beam current of 1 mA on a standard TV raster compressed to 4 x 4 in. The phosphors were coated on 1 x 1 in. conductive glass slides using normal settling techniques; however, water sensitive phosphors were settled in a nonaqueous medium. Each coated slide was baked in air at 400°C for 20 min. The emission spectra were recorded in terms of relative energy *vs.* wavelength by known methods. A 0.30 μsec square pulse was used in measuring the decay times.

Results and Discussion

Physical and chemical properties.—Mg_2SiS_4 and Ca_2SiS_4 were reported by Rocktaschel *et al.* (2) to have the orthorhombic olivine type crystal structure with space group D_{2h}^{16}-Pnma. Ribes *et al.* (3) assign the same space group to Ba_2SiS_4 and compare its structure to that of β-K_2SO_4. Dumail *et al.* (4) place Sr_2SiS_4 in the monoclinic system with space group C_{2h}^2-$P2_1/m$. Unlike their oxygen-dominated homologs the Mg, Ca, and Sr orthothiosilicates are hygroscopic; in moist air Mg_2SiS_4 is the least stable and Sr_2SiS_4 the most stable. On the other hand, Ba_2SiS_4 is not hygroscopic nor does it appear to hydrolyze in water. X-ray examination of the phosphor-coated cathode ray test slides after the 400°C heat treatment showed no evidence of decomposition of the Sr and Ba thiosilicates, although Dumail *et al.* (2) had observed that Ba_2SiS_4 begins to oxidize at 280°C. However, it was found that the bake-out did partially decompose the Mg and Ca compounds so that some MgS and additional CaS were present on their respective test slides. When activated with Eu^{2+}, the phosphors have the following body colors: Mg, orange; Ca, grayish yellow; Sr, greenish yellow; and Ba, light brown. With Ce^{3+} as the activator the Sr and Ba phosphors are gray and tan respectively.

Luminescence.—All four thiosilicates were activated by Eu^{2+}, but activation with Ce^{3+} was confirmed only for the Sr and Ba compounds. All six phosphors respond to excitation by ultraviolet and cathode rays. The cathodoluminescence spectra for the Eu-activated phosphors are reproduced in Fig. 1, and the data are

* Electrochemical Society Active Member.

Key words: cathodoluminescence, luminescence, phosphor, alkaline earth thiosilicate, cerium, europium.

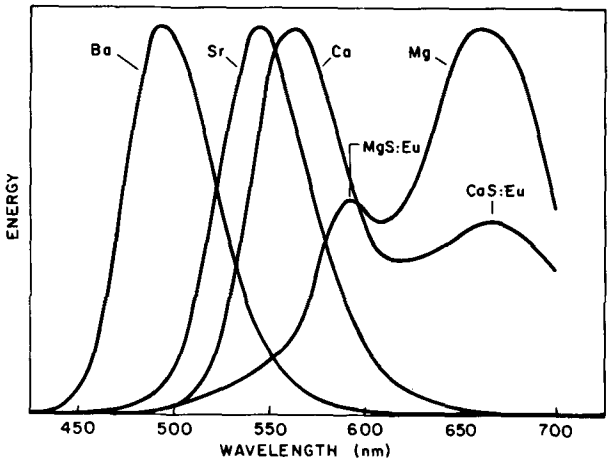

Fig. 1. Cathodoluminescence spectra from M_2SiS_4:Eu (intensities not comparable).

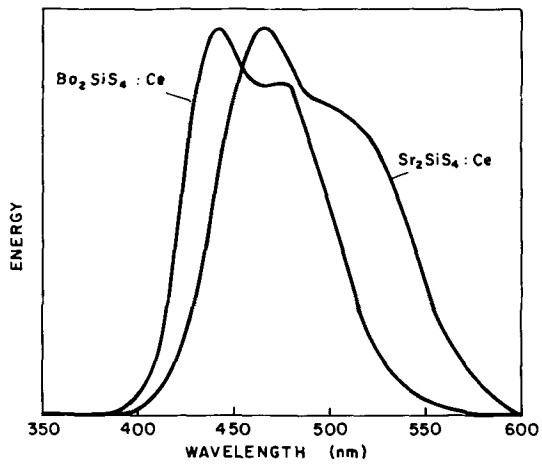

Fig. 2. Cathodoluminescence spectra from M_2SiS_4:Ce (intensities not comparable).

summarized in Table I. The emission bands are characteristic of 5d → 4f Eu^{2+} transitions. Their shift toward shorter wavelength with increasing cation size would be consistent with expansion of the crystal lattice in an homologous isostructural series, but since only the Mg and Ca compounds form such a series, the correlation between spectral band position and cation size cannot be extended to the Sr and Ba compounds. The weaker bands peaking at 592 and 668 nm correspond to Eu^{2+} emissions from the MgS and CaS impurity phases respectively as reported by Jaffe and Banks (5). The Sr and Ba thiosilicates are fairly effective hosts for Eu^{2+}. The emissions from the Mg and Ca compounds are much weaker and, since they also have impurity components, their intensities are not given.

Ce^{3+} activation of the Sr and Ba thiosilicates produces greenish blue and blue cathodoluminescence, respectively, having the spectra shown in Fig. 2. Both emissions have the two overlapping bands attributed to 5d → 4f transitions in the Ce^{3+} ion. The secondary band peaks at about 476 nm in Ba_2SiS_4:Ce, but it is not easily resolvable in Sr_2SiS_4:Ce. In Table II the cathodoluminescence performance of these two phosphors is compared with that of $Ca_2Al_2SiO_7$:Ce, a P-16 type phosphor used as the blue component in some flying-spot scanner tubes. The Sr_2SiS_4:Ce emission is very weak. The emissions from Ba_2SiS_4:Ce and $Ca_2Al_2SiO_7$:Ce have similar values of luminance; the latter is actually more efficient but it emits in a region of lower eye sensitivity. The Sr and Ba thiosilicates have similar nonexponential decay characteristics. The decay times are longer than those recorded for $Ca_2Al_2SiO_7$:Ce by a factor of 2 at $e^{-1}I_0$ and of 5 at 0.1 I_0. This indicates not only a slower initial decay process but also a longer low-level persistence in the thiosilicates; 0.01 I_0 is reached in tens of microseconds. This is not unlike the situation with CaS:Ce where Lehmann and Ryan (6) attribute the relatively slow Ce^{3+} decay to host trapping levels.

In summary, M_2SiS_4 compounds are particularly effective as hosts for Eu^{2+} when M^{II} = Sr and Ba and for Ce^{3+} where M = Ba. The Ce^{3+} decay was found to be slow relative to a P-16 phosphor.

Table I. Cathodoluminescence data for M_2SiS_4:Eu^{2+}

M^{II}	Emission band λ_{max}(nm)	Width at half height (nm)	Chromaticity coordinates (x,y)	Luminance relative to P-1 (%)

The Use of Metalorganics in the Preparation of Semiconductor Materials

IV. The Nitrides of Aluminum and Gallium

H. M. Manasevit, F. M. Erdmann, and W. I. Simpson*

Autonetics Division of North American Rockwell Corporation, Anaheim, California 92803

The use of metalorganic compounds in the preparation of III-V (1-7) and II-VI (8) semiconductor compounds has prompted additional studies in our laboratories to extend the scope of the process to include nitrides of aluminum and gallium, wide bandgap materials in which considerable interest has been generated recently. As wide-bandgap semiconductors, the nitrides can be considered, for example, for the fabrication of semiconductor devices that display high-temperature stability; and in combination with other piezoelectric materials and insulators they are acoustically useful in wide-band high-capacity signal and data processing (9). Aluminum nitride (AlN) is also a refractory electrically insulating material that can be used as both insulating layer and diffusion mask for other semiconductor materials and devices. Gallium nitride (GaN) is transparent to visible radiation; and because of its bandgap, it has potential use for optical devices which will operate in the visible region.

Various methods have been reported for preparing single-crystal films of these nitride materials. These include reactive sputtering (10), gaseous discharge (11-13), and chemical vapor deposition (CVD) (14-19). The latter method has been used more extensively for film preparation and has produced single-crystal AlN films on a number of single-crystal substrates such as Si (14), α-SiC (16, 17), and α-Al_2O_3 (13). Single-crystal GaN growth has also been reported on α-Al_2O_3 substrates (12, 15, 18), (111)-oriented GaAs (12), and (0001)α-SiC (18, 19).

Most CVD processes for the formation of single-crystal nitrides use a hydrogen halide to provide transport of reactants (15) and/or the halide is a major byproduct of the reaction that produces the particular nitride (14, 16, 18, 19). The presence of a halide may set a definite limitation on the purity of the film, for the substrate on which the film is formed may be chemically reactive with the hydrogen halides. This could introduce impurities into the gaseous atmosphere which may be incorporated into the growing film.

Ideally, therefore, one would prefer a process for nitride formation that (*a*) is free of any halide; (*b*) uses an apparatus for growth that is compatible with existing commercial-type apparatus for elemental semiconductor formation; and (c) requires only one hot temperature zone for deposition. The apparatus and techniques meeting these criteria and used for the nitride film formation described here are similar to those which have been previously described (2, 8).

GaN and AlN were formed by mixing the appropriate methyl derivatives of the elements, namely trimethylgallium (TMG) and trimethylaluminum (TMA), respectively, with excess ammonia (NH_3) and decomposing the mixture or the addition product at the substrate which was heated to a sufficiently high temperature to form the corresponding nitride. Pd-purified H_2 was used as the carrier gas in both instances.

Temperature readings, obtained using an optical pyrometer, were made directly on the SiC-covered C pedestal, and are uncorrected for emissivity. The α-Al_2O_3 and Czochralski spinel ($MgAl_2O_4$) substrates were mechanically polished to provide a relatively scratch-free surface as viewed with an optical microscope at 400X magnification, and were treated in H_2 (~1150°C for $MgAl_2O_4$ or ~1250°C for α-Al_2O_3) for about 15 min before film growth. Mechanically polished Si was given a light etch in a mixture of 2 parts of HF, 9 parts of HNO_3, and 4 parts of HAc, rinsed with deionized H_2O and methanol, and heated for 15 min in H_2 at 1250°C to remove surface oxides. The α-SiC substrate used was a flux-grown basal-plane platelet.

Back-reflection Laue x-ray patterns, reflection electron diffraction techniques, and/or full-circle x-ray diffraction analysis were used to establish the reported orientation relationships between the epitaxial film and the substrate.

AlN growth.—Stoichiometric amounts of trimethylaluminum (TMA) and NH_3 react at room temperature (r.t.) to form the solid addition compound $(CH_3)_3Al{:}NH_3$. The reaction has been studied by Wiberg and Bolz (20). Our studies demonstrate that at high temperatures complete dealkylation of the addition compound occurs to form AlN. The over-all reactions may be expressed as in Eq. [1] and [2]

$$(CH_3)_6Al_{2(g)} + 2NH_{3(g)} \xrightarrow[\text{r.t.}]{} 2(CH_3)_3Al{:}NH_{3(s)} \quad [1]$$

$$(CH_3)_3Al{:}NH_{3(s)} \xrightarrow[\sim 1200°C]{} AlN_{(s)} + 3CH_{4(g)} \quad [2]$$

However, the formation of AlN occurs by a stepwise process, with a mole of CH_4 being released at about 60°C, a second mole at ~160°C (20), and the final mole of CH_4 at some higher temperature. Because thermal radiation from the rf heated pedestal at the deposition temperature could cause the formation of AlN powder at a finite distance from the substrate, experimental conditions must be carefully controlled to avoid such formation; otherwise, the powder could impede epitaxy and/or contaminate the film. Therefore, it was found preferable to use a vertical reactor containing a coaxial center tube, mixing the reactants in the upper neck of the center tube, and then directing the addition compound plus NH_3 to the heated substrate with a relatively high total H_2-carrier flow rate.

After a 15 min high-temperature H_2 etch of the substrate surface, the substrate temperature was stabilized for epitaxial growth (~1200°C) and NH_3 flow (~1750 ccpm) was started. A few minutes later TMA vapor was transported to the reactor by bubbling H_2 at 25-100 ccpm through the liquid TMA (stored at ~30°C), and an additional 6-8 lpm of H_2 were then added to "push" the addition compound to the substrate. Growth rates were typically 1-7 μm/hr. These conditions were found sufficient for the growth of epitaxial films on Si, α-SiC, α-Al_2O_3, and $MgAl_2O_4$. The growth of AlN on $MgAl_2O_4[(11\bar{2}0)AlN//(110)MgAl_2O_4]$ was not as reproducible as growth on α-Al_2O_3, probably due to the instability of $MgAl_2O_4$ to H_2 at the growth temperature employed. Crystallographic orientation relationships for growth on α-Al_2O_3 are summarized in Table I.

Film thickness uniformity and growth rate were directly related to reactor geometry; a center tube resulted in films with a concentric ring configuration, with thicker growth occurring at the center of the

* Electrochemical Society Active Member.

Key words: crystal growth, heteroepitaxy, films, insulating substrates, chemical vapor deposition.

Table I. AlN/Al_2O_3 crystallographic orientation relationships

$(11\bar{2}0)AlN//(01\bar{1}2)Al_2O_3$; $[0001]AlN//[0\bar{1}11]Al_2O_3$
$(0001)AlN//(11\bar{2}0)Al_2O_3$; $[\bar{1}2\bar{1}0]AlN//[\bar{1}100]Al_2O_3$
$(0001)AlN//(111)Si$; $[\bar{1}2\bar{1}0]AlN//[\bar{1}10]Si$

ring. Crazing of the AlN film was observed to begin at about the third fringe of growth (*i.e.* at a thickness of ~0.4 μm) on Si and to extend into the thicker areas of growth. A typical "crazing pattern" structure is depicted in Fig. 1.

In the thinner growth areas it was sometimes possible to find evidence of the early stages of AlN growth. The triangular structure depicted in Fig. 2 was obtained on (111)Si.

The as-grown AlN films have invariably demonstrated insulating properties. Resistivities appear to be on the order of 10^5 ohm-cm or above. Reflection electron diffraction patterns for the single crystal film have been very well defined. The film quality was further substantiated by the excellent results obtained during surface acoustic wave studies using some of the films on α-Al_2O_3 (21).

GaN growth.—By substituting trimethylgallium (TMG) for TMA and pyrolyzing TMG-NH_3 mixtures on wafers of α-Al_2O_3 and α-SiC heated to 925°-975°C, single-crystal films of GaN were formed. The surface structures of (0001)GaN obtained on basal-plane α-SiC and α-Al_2O_3 are depicted in Fig. 3. The orientation relationships which have been determined for α-Al_2O_3 are indicated in Table II. Growth rates approaching 0.1 μm/min were adequate for the growth of epitaxial films. Total flow rates of ~3 lpm were used in these experiments.

An undoped 6 μm-thick white film grown at 930°C was n-type with a carrier concentration above 10^{19} cm^{-3} and a mobility ~60 cm^2/V-sec, as measured with the Van der Pauw technique (22). Further studies are necessary to determine if the low mobility is a characteristic of the process.

Films grown at 910°C possessed a yellow cast; and at 700°C, reddish-brown high-resistivity films were obtained. These films were extremely resistant to acids and bases but could be destroyed by heating in H_2 to 1050°C and above, which left a residue of what seemed to be Ga metal droplets on the surface of the substrate. The films formed at 700°C presumably contained intermediate unpyrolyzed [C-H-Ga-N] polymers, formed in the reaction between TMG and NH_3.

Some rather interesting crystallographic structures have been observed during these studies of GaN growth

Fig. 1. AlN growth features on (111)silicon

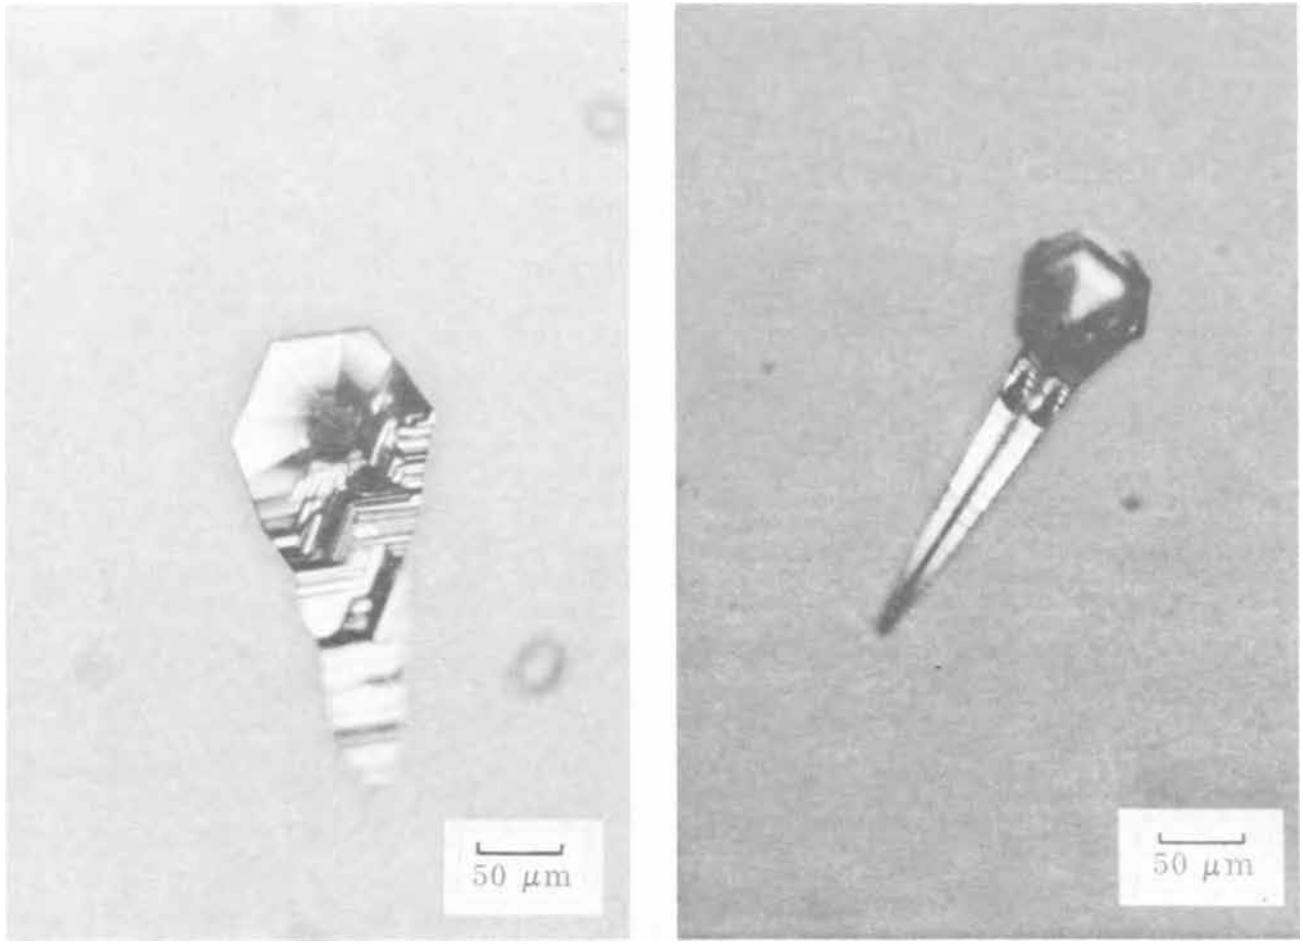

Fig. 5. Two kinds of needle growth of GaN observed during studies

on insulators. GaN displayed a strong tendency to grow at the edges of substrate wafers and to produce well-defined crystallographic growth steps. The growths at the edges of (0001) Al_2O_3 and (111) $MgAl_2O_4$ are recorded in Fig. 4. A slight break in the step-like growth morphology of the crystal can be observed at the edge (center black line) of the $MgAl_2O_4$ wafer.

Step-wise growth could also be observed in random needle-type crystals which sometimes grew very rapidly at the insulator surfaces. Two such structures are shown in Fig. 5. Such crystal growth may have occurred at a Ga droplet which acted as a nucleation site for vapor-liquid-solid (VLS) growth.

In summary, these feasibility experiments have indicated that the scope of the metal-organic process for semiconductor film formation can be extended to include the nitrides of Al and Ga. The relative ease with which these compounds can be formed indicates that further experimentation could produce additional important results in these and related cases.

Acknowledgments

The authors wish to thank Dr. A. C. Thorsen for the electrical measurements, L. A. Moudy for her analysis of the x-ray data, and Dr. R. P. Ruth for his most helpful review of this paper.

Brief Communication

Revelation of Dislocations in (Hg, Cd)Te by an Etch Technique

Sidney G. Parker* and Jack E. Pinnell

Texas Instruments, Incorporated, Dallas, Texas 75222

Etch techniques are frequently used to show the presence of dislocations and their number (1). The (111) planes of material such as (Hg,Cd)Te, which crystallizes in the cubic structure, readily reveal the presence of dislocations as triangular pits or hillocks when etched with a suitable solution (2). Such an etch for $Hg_xCd_{1-x}Te$ has been discovered for values of x ranging from 0.85 to 0.60.

The etch solution consisted of 15 parts of concentrated HNO_3, 15 parts of H_2O, 1 part of concentrated HCl and 1 part of a 5% solution of Br_2 in methanol. The surface to be etched was lapped to a moderately smooth finish with 3200 grit although more polished surfaces were also used. The etching was performed at 25°C for 5-10 min with a dark film forming on the surface. This film was removed by a 1-2 sec treatment with a 5% Br_2-methanol solution followed by a methanol rinse.

Typical etch patterns are shown in Fig. 1 for opposite (111) planes. Because of the difficulty in obtaining large single crystals of $Hg_xCd_{1-x}Te$ we were unable to determine which of the faces was the "A" or metal rich face. However, it can be seen that upon etching, one face developed triangular hillocks or pits while the opposite face gave an irregular pattern. Pits or hillocks denoting dislocations were found for orientations up to 30° off the {111}, although the greater the deviation from the (111) the less regular was the shape of the etch pits. The number of dislocations in $Hg_{0.80}Cd_{0.20}Te$ grown by various techniques varied from 1×10^4 to 5×10^6 per cm^2.

As the Cd content increased it was necessary to dilute the etch solution with H_2O to obtain well defined etch patterns. Longer etch periods were also required

with increasing Cd concentrations. The etch was not evaluated for compositions other than for the range stated above. Care was necessary not to etch too long with Br_2-methanol or else the etch figures developed by the HNO_3-HCl-Br_2 etch would be obliterated. If the amount of HCl in the etch solution was too great only irregular, over-all etching occurred.

Manuscript submitted June 24, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

ECM Study in a Closed-Cell System

I. $NaClO_3$

Kao-Wen Mao*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The electrode reactions involved in electrochemical machining (ECM) of mild steel in $NaClO_3$ were studied in a closed cell system at constant current. The cathodic reaction is found to be essentially hydrogen evolution. At the anode, in addition to the metal removal, significant amounts of oxygen are produced and the total anodic current efficiency for Fe^{++} plus O_2 formation is about 100%. Reduction of $NaClO_3$ to NaCl during ECM is caused by the chemical reaction between $NaClO_3$ and Fe^{++}. The experimental results concerning the anodic process are qualitatively explained by the presence of porous anodic oxide films.

Because of its unique method of removing metal, electrochemical machining (ECM) has found increasing industrial application in the last decade (1). For simplicity, ECM may be described as a controlled rapid anodic corrosion process. In the process, metal is removed anodically at current densities of the order of 10 to 100 A/cm^2, and the reaction products precipitate in the electrolyte as sludge. The sludge is carried away by a rapidly flowing stream of electrolyte. The electrolyte gap between the two electrodes often is very small (usually less than 1 mm) to reduce both wild cutting and ohmic heating.

Recently a considerable amount of effort has been expended in studying this process; however, many basic questions concerning ECM electrode mechanisms remain unanswered. Perhaps this can be attributed to (1) the lack of general basic knowledge concerning high current density processes in the field of electrochemistry and (2) the experimental difficulty in measuring *IR*-free potentials of a high current density process in which the electrolyte, mixed with sludge and gas, flows through a very narrow gap.

In the present work, ECM experiments were carried out in a closed-cell system in order to obtain some general knowledge concerning the anodic and cathodic reactions of this high current density process. The possible reactions were determined by studying the changes of compositions of the electrolyte and the amounts of hydrogen and oxygen generated and metal removed. The first system investigated was ECM of mild steel in $NaClO_3$ solutions because of the excellent ECM properties provided by $NaClO_3$ (2). Further, it was hoped that this study could provide information about the reduction of $NaClO_3$ to NaCl during ECM (3). All experiments were conducted at current densities up to 47 A/cm^2 (or 300 A/in.^{2}), because it is this range of current density in which we are mainly interested.

Experimental Procedure

Closed ECM Cell

Figure 1 shows the arrangement of the closed-cell unit. The cell was made mainly of glass. A 25 cm mild steel (1020) tube (0.645 cm OD and 0.462 cm ID) was used as the anode (workpiece) with one end facing a brass or platinum disk (0.953 cm diameter) which served as the cathode (tool). The steel tube passed through the wall of the cell through a hydraulically sealing rubber O-ring. Outside the cell, the tube was attached to a threaded collet driving system actuated by a revolving nut in a sprocket. This arrangement provided different constant feed rates controlled by means of a constant speed motor and sprockets of different sizes.

The electrolyte was circulated by a polyethylene centrifugal pump at a flow rate of about 2 liters/min. After flowing through the steel tube, the electrolyte directly impinged upon the cathode and then drained to the electrolyte reservoir through two channels. The electrolyte reservoir had a capacity of 800 cm^3. The temperature of the electrolyte in the reservoir was maintained at 27° ± 2°C by a water jacket.

Experiments were conducted at different constant currents. The apparent current densities given in this report were based on the cross-sectional area of the tube wall (0.159 cm^2). The gap between the two electrodes was maintained approximately constant at 0.08 cm by using a proper feed rate which was determined by trial and error. The change of the electrolyte gap was followed by the variation of the applied cell voltage. The electrical current, controlled manually, was drawn from a Mallory, Model VA400, power supply. The current and the applied potential were measured by a Weston ammeter (Model 901) and a Sensitive voltmeter (Model C), respectively. A General Motors Research-made coulometer was used to measure the total applied charge. The electrical circuit of the cell, the anode driving system, and an electrical timer were all controlled by one switch. Experiments were terminated when the total charge reached 2500 or 7000 coulombs.

Preparation and Sampling

For each experiment, the steel tube was degreased with detergent, polished with a 600-grit wet grinding paper, rinsed with distilled water, and dried with acetone. After the experiment, the tube was washed in distilled water and dried. The loss in weight of the tube

due to ECM was measured to determine the amount of metal removed. The cathode was also washed in distilled water for each run. The original surface was polished with a 600-grit wet grinding paper.

The electrolyte for each run was freshly prepared. Distilled water was used for making the solution. The $NaClO_3$ used analyzed 99.5% with NaCl content about 0.02%. All other chemicals employed were of reagent grade. A sample of each new electrolyte was taken for chemical analysis. After a run, the mixture of sludge and electrolyte was collected and filtered through Whatman No. 50 filter paper. The sludge was further washed with distilled water (about 900 cc) which had been previously used to wash the cell. The volumes of the electrolyte filtrate and the washing solution were measured before the chemical analyses were made. The concentrations of iron and sodium in the sludge were determined after the sludge was dried overnight in an oven at 100°C. Since the average amount of sodium in the sludge was found to be less than 1%, the washing process used in this work is believed to be adequate. All chemical analyses were carried out by the Chemistry Department of General Motors Research.

Cell Atmospheres and Gaseous Products

Experiments were conducted in two different cell atmospheres: air or nitrogen. The reason for using a nitrogen atmosphere is the capability of detecting, in addition to hydrogen, any possible oxygen generated at the anode during ECM. The inlet flow rate of air or nitrogen to the cell system was about 4 liters/hr. Before entering the cell, the gas was at least partially saturated with water vapor by bubbling through a distilled water column. The pressure of the cell atmosphere was maintained at about 25 cm H_2O below 1 atm for air[1] and 25 cm H_2O above 1 atm for nitrogen. After leaving the cell, the gas was bubbled through a column of 500 g/liter KI solution to remove any chlorine.[2] The gas then further passed through columns of concentrated H_2SO_4 solution, CO_2 absorbent, anhydrous $CaSO_4$ and anhydrous $Ba(ClO_4)_2$ for removing any H_2O and CO_2 before it entered the apparatus for quantitative determination of hydrogen and oxygen.

For experiments in air atmospheres, only the hydrogen was determined. A Sargent-Welch gas purifying furnace, operated at 450°C, was used to collect the hydrogen by reacting with copper oxide (CuO) turnings in a Vycor high silica glass tube. The water produced by the reaction was then collected by anhydrous $Ba(ClO_4)_2$, and the amount of the hydrogen formed during ECM was determined by the weight change of the anhydrous $Ba(ClO_4)_2$.

When using a nitrogen atmosphere, two Sargent-Welch gas purifying furnaces at 450°C were employed. The first was filled with pure copper turnings,[3] and the second, with copper oxide turnings. In the first furnace, oxygen oxidized copper to copper oxide, which was then immediately reduced by the hydrogen

[1] Because air was introduced into the cell by connecting the outlet of the gas analysis system to a vacuum line.

[2] The amount of chlorine in the gas stream was determined by the change of I_2 concentration in the KI solution.

[3] The pure copper turnings were obtained by passing hydrogen through the furnace at 450°C for about 30 min before the ECM experiment.

present. The remaining hydrogen in the gas stream was removed in the second furnace by copper oxide. The water formed in the two furnaces was collected by two different anhydrous $Ba(ClO_4)_2$ columns. The water collected from the first furnace was used to calculate the amount of oxygen generated at the anode, and the total water from the two furnaces was used to determine the amount of hydrogen formed. Before an experiment was started, the cell system was purged with nitrogen for about 3 to 4 hr, with electrolyte circulating, to remove any possible oxygen in the system.

After ECM, the cell system was always purged with the appropriate gas for about 2 to 3 hr to collect any gaseous products dissolved in the electrolyte.

The accuracy of the above method for the determination of oxygen was checked by electrolyzing water in a 15% NaOH solution in the closed-cell system. A platinum disk was used as the cathode, and the anode was made of a palladium tube. Experiments were conducted at a current density of less than 0.3 A/cm^2 for a total applied charge of 350 coulombs. For experiments in a nitrogen atmosphere (the inlet flow rate also at 4 liters/hr), only about 92% of the oxygen was recovered. This may be due to incomplete mixing between oxygen and hydrogen in the gas stream since, after experiments, a small amount of copper oxide (gray color) was found in the glass tube. However, when a small additional amount of hydrogen (less than 10%) was added to the nitrogen stream, such a phenomenon was not observed and almost 100% of the oxygen was accounted for. Since an excess amount of hydrogen was always present in the gas stream during ECM in $NaClO_3$ solutions (see Tables I and II) and also since no copper oxide was observed after the ECM experiments, it is believed that the method used in this work for determining oxygen should be quite accurate.

Results

The results of studying ECM of mild steel in $NaClO_3$ are shown in Tables I and II for experiments in air and nitrogen, respectively. The amount of iron removal was determined by the weight loss of the anode assuming 100% iron in the 1020 mild steel. The amount of iron in the sludge was about 5% lower than the anode weight loss since there was a loss of sludge during the process of collection. The current efficiency for iron removal was calculated on the basis of the reaction

$$Fe \rightarrow Fe^{++} + 2e^- \qquad [1]$$

Because of low concentrations of sodium chloride, the average error for the values of sodium chloride formation, shown in Tables I and II, was estimated to be about 5%. The error was larger when the value was 0.002 mole or less. The amount of $NaClO_3$ reduced after ECM could not be determined due to the limitation of accuracy in chemical analysis (impossible to determine accurately a small difference between two large numbers).

$NaClO_4$ was not observed in the electrolyte after ECM (infrared spectrophotometry). No experiment in 2M $NaClO_3$ at 26 A/cm^2 was performed because no comparable feed rate could be achieved.

For convenience in discussion, the relationship between the current efficiency for iron removal and current density at different $NaClO_3$ concentrations is given

Discussion

ECM Reactions in $NaClO_3$

By comparing the data in Tables I and II (some of them are plotted in Fig. 2), no apparent difference is observed between the results obtained in air and nitrogen atmospheres. Also, it is seen that the cathodic reaction of ECM in $NaClO_3$ solutions is essentially hydrogen evolution. The amount of hydrogen formed, as shown in Table I, is not altered by using different metals such as brass and platinum as the cathode. The results given in Table II indicate that, in addition to the metal dissolution, oxygen is also produced at the anode during ECM in $NaClO_3$. Since the total anodic current efficiency for O_2 and Fe^{++} formations is so close to 100%, it seems that iron is mainly dissolved as ferrous ion at the anode.

The formation of NaCl (or the reduction of $NaClO_3$) during ECM is probably caused by the following chemical reaction

$$6Fe^{++} + NaClO_3 + 3H_2O \rightarrow 6Fe^{+++} + NaCl + 6OH^- \quad [2]$$

A small portion of chlorate is also reduced to chlorine but the amount is very small compared to chloride.

Having in mind the error in determination of the chloride concentration, the results of the present work may not show any definite influence of various operating conditions on the value of the molar ratio of iron removed to NaCl formed. However, the average value of 5.5 given in Table II is certainly lower than the value of 6 according to Eq. [2]. At present no satisfactory explanation can be given. Nevertheless, based on the average current efficiencies given in Table II, one might speculate about the following "possible" reasons for the excess chloride generation. The average efficiency of 98.9% for hydrogen generation in $NaClO_3$ is slightly lower than the 100.2% efficiency for both the

NaCl and $NaClO_4$ systems (4). It is possible that a very small amount of chlorate is reduced at the cathode. On the other hand, the average total current efficiency for O_2 and Fe^{++} formations is slightly higher than 100%. Some iron may be chemically oxidized by chlorate. Since both current efficiencies mentioned above are very close to 100%, a solid conclusion cannot be drawn.

Tables I and II show that the pH of the electrolyte decreases to a neutral value after ECM. This should result from a saturated $Fe(OH)_3$ solution. During ECM in $NaClO_3$ a red-brown sludge was always observed even when the cell was operated in a nitrogen atmosphere. The sludge in solution was nonmagnetic.

Effect of Passivity on ECM

Before discussing the results further one may take a look at the typical tube end finishes obtained with NaCl and $NaClO_3$ solutions in Fig. 3a and 3b. The difference between the finishes obtained with NaCl and $NaClO_3$ is apparent. $NaClO_3$ gives not only better dimensional control (less wild cutting which is indicated by the distance from the tube end over which a reduction of the tube OD has occurred) but also a brighter surface at the tip of the tube. For the sake of convenience, names are given to the various regions of the finishes in Fig. 3a and 3b. The active-cutting region is represented by A, and P represents the film[4]-protected (from wild cutting) region in which P_1 and P_2 stand for the well- and the less-film-protected regions, respectively. [It should be noted that region P_2 sometimes becomes less apparent at a certain site of the finish (see Fig. 4a for example). This is believed to be caused by the nonuniform electrolyte flow and the presence of gases in the solution.]

Hoare and his co-workers (3, 5, 6) have suggested that the good dimensional control obtained with ECM is associated with the presence of a protective and relatively thick iron oxide film at the outside of the active-cutting region. In the case of $NaClO_3$, an even better control is obtained because of the sharp change of the polarization curve from the passive to the transpassive state. In NaCl, since no such film is present (6), the active-cutting region is considerably larger than that in $NaClO_3$ (see Fig. 3a and 3b). The main constituent of the iron oxide film is probably a cubic oxide which is either γ-Fe_2O_3 or Fe_3O_4 or both (3, 7, 8). In a recent study of current transient on a rotating electrode, Chin (9) suggested that the iron oxide film in $NaClO_3$ is porous and its thickness at the passive state is of the order of 1000Å.

Recently, Hoare, Mao, and Wallace (10) reported that the bright surface finish at the active-cutting region in $NaClO_3$ is related to the effect of electropolishing. A thin, uniform, and porous oxide film is present even in the active-cutting region, and the polishing effect is achieved because ferrous ions have to pass through the randomly distributed pores. The thickness of the film for polishing is of the order of 10 to 100Å (11).

The phenomena of the passivity of copper in KNO_3 and K_2SO_4 have been observed by Landolt, Muller, and Tobias (13) at actual ECM conditions. They found that the onset of passivation occurs at the maximum possible mass transfer rate (convective diffusion) of dissolution products, so it depends on electrolyte flow rate and current density. As for conventional low current density processes, they also report that etched surfaces result from active dissolution and pitted or bright surfaces from transpassive dissolution.

Porous Film Model

In this report, the results concerning the anodic process for ECM of steel in $NaClO_3$ will be qualitatively explained by the presence of oxide films. The film is assumed to be porous. The pores are relatively small and randomly distributed. The oxide film is considered as a barrier layer for the transport of the reaction product, ferrous ion, thus slowing down the rate of iron dissolution. The degree of the slowing-down (or polarization) depends on the thickness of the film.[5]

Perhaps it should be noted that the concept of small "pores" mentioned above is somewhat parallel to that of "contaminated oxides" proposed by Hoar and his co-workers (12). In that work the thin, compact films for polishing are suggested to be not pure oxides but oxides contaminated with significant amounts of the anions from the solution, because oxides themselves have very low ionic conductivity at room temperature. During ECM, iron is dissolved at a very high rate, hence the film has to be porous (or highly "contaminated" with not only the anions of the electrolyte but also water molecules) in order to allow the cations to pass through it rapidly.

During ECM of steel in $NaClO_3$ solutions, because of the slowing-down of the metal dissolution by the presence of the film, a part of the current is used for oxygen generation instead of for metal removal (Table II). The reaction of oxygen generation may be written as

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \qquad [3]$$

In the case of NaCl, since the protective film is not present during ECM, oxygen generation is not observed and the current efficiency for iron removal is significantly higher (about 94 to 99%) (4).

In Table II, it is seen that the current used for oxygen generation increases as the current density decreases. At 12 A/cm^2, the major anodic reaction becomes oxygen generation. From these results it is reasonable to suggest that at the beginning of the transpassive state the current is mainly consumed in oxygen evolution. According to reported data (6, 9), the transition from the passive to the transpassive state in $NaClO_3$ occurs at a current density of the order of 1 mA/cm^2 and at a potential of about 1.4 to 1.6V *vs.* NHE (which is also the potential range where it is possible for Eq. [3] to take place). Hoare (6) also found by using a constant current stripping pulse technique that a large amount of anodic oxide is removed when the potential is increased to the transpassive state. If this film removal is assumed to be mainly caused by the oxygen generation (because films are pushed away by the oxygen gas), then the oxygen should not all be formed at the exterior surface of the film. Therefore, the oxide films in $NaClO_3$ are likely to be porous and not very electronically conductive.

Effect of Potential on Passivity

The results in Fig. 2 show that current efficiency for iron removal increases with current density. This implies that the oxide films are reduced in thickness as the potential increases, since the degree of the slowing-down of iron dissolution is assumed to depend on the film thickness. The effect of potential on the reduction or breakdown of anodic film has been discussed in the literature (12, 14) although the reason for such an effect is still not clear. Hoar (15) recently proposed, in addition to the anion penetration model,[6] a new "mechanical" mechanism wherein the film breakdown is caused by the repulsive forces between the adsorbed anions at the film/solution interface. According to this model, the film could be more easily dissolved as the potential increases because more ClO_3^- ions are adsorbed. Perhaps, at actual ECM conditions, the influence of pH should also be considered. From a thermodynamic viewpoint, Pourbaix (16) has shown that the passivation properties strongly depend on pH and potential. Iron oxide generally becomes more soluble at low pH. During ECM in $NaClO_3$, be-

[4] The anodic oxide film will be discussed later.

[5] For simplicity, the effect of changing film structure by the influence of potential is not discussed in this report.

[6] The breakdown of passivity is caused by anion penetration which makes the film highly "contaminated" and ionically conductive (12).

cause of the rapid formation of oxygen (and ferrous or ferric hydroxide) at (and near) the anode, the pH of the solution near the anode should be lower than that of the bulk solution. The pH further decreases as the current increases if the electrolyte flow rate is not changed. Hence, the film could be more easily dissolved at a higher current density. The reduction of film thickness may also be attributed to the force exerted on the film by the rapid metal removal and by the formation of gaseous oxygen as well.

The effect of potential on the film thickness may become more evident by comparing the finishes shown in Fig. 3b and 3c. It is clear that the degrees of both brightness of the cutting surface and wild cutting for 12 A/cm^2 are less than those for 47 A/cm^2. This is believed to be caused by the presence of relatively thicker films at a lower potential. The films are gradually reduced in thickness when the potential increases. Therefore, a brighter active-cutting surface and larger wild cutting are observed at a higher potential. Such phenomena have previously been observed at General Motors Research (17).

Since the surface finish of the less-film-protected region (P_2) in Fig. 3b is very similar to that of the cutting region in Fig. 3c, the P_2 region should also be in the transpassive state. The well-film-protected region (P_1) is in the passive state due to the further decrease of potential caused by a longer solution path to the cathode. (5, 6). Because of the sharp change from the passive to the transpassive state in $NaClO_3$, the passivity of iron at the boundary between the two states is very sensitive to the flow pattern of the electrolyte; especially when significant amounts of gases are present in the solution. Relatively small changes in the *IR* of the solution path by any nonuniform flow can lead to an uneven metal removal at the boundary (see Fig. 3b, 3c, and 3d).

It should be noted that the current efficiencies for oxygen generation as well as for iron removal given in this report represent only the average values; the actual current efficiency for oxygen generation (or iron removal) should be higher (or lower) in the less-film-protected region because the film there is supposed to be thicker than at the active-cutting region. One also should recognize that the true average current density in this work is lower than the apparent current density due to the wild cutting.

Effect of Electrolyte on Passivity

The ECM properties of various oxidizing electrolytes have been discussed in the literature (5, 6, 10). In the case of $NaClO_3$, Chin (9) and LaBoda and Hoare (18) found that passivity of iron increases with the concentration of $NaClO_3$. In order to study the effect of the $NaClO_3$ concentration on ECM, experiments were carried out in 3M $NaClO_3$ solution with various additional amounts of $NaClO_4$ (0 to 0.5M). The purpose of introducing $NaClO_4$, a relatively stable compound, is to reduce the effective concentration of $NaClO_3$ (or the oxidizing power of $NaClO_3$), although ClO_4^- has also been found to possess certain film-rupturing power (19). If the film-rupturing power of ClO_4^- is assumed to be negligible at low concentrations of $NaClO_4$ (say less than 0.25M),[7] then the results shown in Fig. 4 indicate that the oxide films are indeed affected by the effective concentration of $NaClO_3$. Because of the decrease of passivity, the current efficiency, wild cutting, and brightness increase with the $NaClO_4$ concentration. However, when the $NaClO_4$ concentration further increases (higher than 0.25M), pitted surfaces in both film-protected and active-cutting regions are observed. Apparently, this is caused by nonuniform oxide films resulting from the "mechanical" film breakdown by ClO_4^- ions (15). Severe grain boundary attacks at high concentration of $NaClO_4$ at point (c) lead to the current efficiency for iron removal higher than 100%.

According to the above argument, the passivity of iron during ECM in $NaClO_3$ would be expected to be proportional to the concentration of the electrolyte. However, the results summarized in Fig. 2 show just the opposite effect, where the current efficiency for iron removal increases with the $NaClO_3$ concentration. This may be attributed to the following reasons:

1. The reaction $2H_2O \rightarrow 4H^+ + O_2 + 4e^-$ (Eq. [3]) has to be preceded by the adsorption of water molecules on the anode surface. The increase in electrolyte concentration is expected to hinder the process of oxygen evolution due to the replacement of adsorbed water by adsorbed anions.[8]

2. Because of the increase of $NaClO_3$ concentration, more ClO_3^- is present in the film. Hence, the film is more ionically conductive at a higher concentration of $NaClO_3$ (12).

At low concentrations of $NaClO_3$, since the current is mainly consumed in oxygen evolution, bright surface finishes and large wild cutting are generally not obtained (17) (see Fig. 3d).

As shown in Table I, the current efficiencies for iron removal are not affected by the amount of the applied charge at 4.5M $NaClO_3$ (although there is a slight difference at 26 A/cm^2), but there is quite a difference between the efficiencies for 2500 and 7000 coulombs at 2M $NaClO_3$. This may be caused by the increase in Cl^- ion concentration. The effect of Cl^- ion on the oxide film breakdown (12, 15) is more apparent at low concentrations of $NaClO_3$.

Conclusions

In view of the results of the present work, it is apparent that the anodic process of ECM of steel in $NaClO_3$ is very complicated due to the presence of porous oxide films. Unlike the copper system (13), the iron oxide film is present on the anode over a wide range of operating conditions and the film is probably reduced in thickness as the potential increases. Significant amounts of oxygen are observed during ECM. The oxygen formation increases with the decreases of potential and electrolyte concentration, and it finally becomes the main anodic reaction when the current density is lower than 12 A/cm^2. The cathodic reaction is essentially hydrogen generation. Reduction of $NaClO_3$ to NaCl during ECM is due to the chemical reaction between $NaClO_3$ and Fe^{++}, the anodic product of iron removal.

Acknowledgment

The author wishes to thank Dr. J. L. Griffin of the Electrochemistry Department, General Motors Research Laboratories, for his initiation of this project and his construction of the initial cell system. Thanks are also due to Drs. J. P. Hoare, D. T. Chin, and W. S. Wong, also of the Electrochemistry Department, for their valuable discussions. The efforts made by R. B. Loranger, H. E. Vergosen, Dr. J. L. Johnson, and other members of the Chemistry Department to carry out the chemical analyses are especially appreciated.

Manuscript submitted April 5, 1971; revised manuscript received *ca.* June 28, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

ECM Study in a Closed-Cell System

II. NaCl, $NaClO_4$, and $NaNO_3$

Kao-Wen Mao*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Electrochemical machining (ECM) of mild steel in NaCl, $NaClO_4$, and $NaNO_3$ solutions was studied in a closed-cell system. The anodic processes are found to be different in the various solutions. In NaCl, the anodic reaction is essentially iron dissolution. In $NaNO_3$, however, most of the current is expended for oxygen generation due to the presence of an electronically conductive oxide film. A small amount of oxygen (less than approximately 10% of the current) is observed in the $NaClO_4$ system. The cathodic reaction in both NaCl and $NaClO_4$ solutions is hydrogen evolution. In the case of $NaNO_3$, little or no hydrogen is observed—the current is mainly consumed in reducing NO_3^- ions.

In previous work, the electrochemical machining (ECM) of mild steel in $NaClO_3$ has been studied in a closed-cell system (1). From the results of that work, it is believed that more general knowledge concerning ECM electrode mechanisms can be obtained by extending the study to other electrolyte systems with different oxidizing powers. Hence, NaCl, $NaClO_4$, and $NaNO_3$ were selected for this work. It was expected that the results would provide a better understanding of the effect of the electrolyte on the ECM process.

Experimental Procedure

The closed-cell system, experimental procedures and conditions, and sampling techniques are identical to those described in the previous paper (1). Reagent grade chemicals were used for all experiments. Chemical analyses were carried out by the Chemistry Department of General Motors Research.

The methods of collecting hydrogen and oxygen for the NaCl and $NaClO_4$ systems are the same as those used for $NaClO_3$ (1). Minor changes were made in the case of $NaNO_3$ since little or no hydrogen was formed during ECM in $NaNO_3$.

The experiments using $NaNO_3$ were conducted in a nitrogen atmosphere only in order to concentrate on the study of oxygen generation. However, the procedure of collecting any hydrogen present was still carried out for each run. Thus, the gas, after leaving the ECM cell unit, was first bubbled through a 20% sulfuric acid solution for removing any ammonia as well as water vapor from the gas stream. Then the gas was further dried by passing it through anhydrous $CaSO_4$ and anhydrous $Ba(ClO_4)_2$ before entering two serially connected Sargent-Welch gas purifying furnaces. The Vycor glass tubes used in these furnaces were filled with pure copper and copper oxide (CuO) turnings, respectively. Any water collected by anhydrous $Ba(ClO_4)_2$ as effluent from the two furnaces was used in the determination of the amount of hydrogen formed.[1] Then, after the experiment, hydrogen was introduced into the first furnace to reduce the copper oxide which was formed by the reaction between the oxygen and the copper turnings. The amount of oxygen generation was then determined by the sum of the water collected after the first furnace (including the water used in determining the amount of hydrogen formed).

Results

The experimental results obtained by ECM of mild steel in NaCl, $NaClO_4$, and $NaNO_3$ are summarized in Tables I, II, and III, respectively. Figure 1 shows the tube end finish obtained with 4.5M $NaNO_3$ at 47 A/cm^2.

The amount of iron removed was determined by the weight loss of the mild steel tube, which was used as the anode, assuming 100% iron in 1020 mild steel, and the current efficiency for iron removal was calculated by the assumption that iron was dissolved as ferrous ion at the anode. The apparent current densities were based on the cross-sectional area (0.159 cm^2) of the tube wall.

In the $NaNO_3$ system, little or no hydrogen was collected. However, significant amounts of ammonia, hydroxylamine, and nitrite were found in the $NaNO_3$ solutions after ECM. At present, the concentration of these reaction products cannot be determined accurately due to the complicated interactions among the various species present. Hence, no quantitative result is given in this report concerning the cathodic reaction species formed in $NaNO_3$.

Discussion

ECM in NaCl Electrolytes

The results in Table I show that during ECM in NaCl solutions the current is mainly consumed in iron dissolution. Further, the current efficiency for iron removal is not affected greatly by the applied current density or the electrolyte concentration. These results certainly indicate that the anodic process in NaCl is much simpler than in oxidizing electrolytes such as $NaClO_3$ (1) for example. Because the protective oxide film is not present in NaCl solutions during ECM (2), the current is not consumed in oxygen generation at relatively low current densities, and good dimensional control and bright surface finish are not able to be

ECM Study in a Closed-Cell System

II. NaCl, $NaClO_4$, and $NaNO_3$

Kao-Wen Mao*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Electrochemical machining (ECM) of mild steel in NaCl, $NaClO_4$, and $NaNO_3$ solutions was studied in a closed-cell system. The anodic processes are found to be different in the various solutions. In NaCl, the anodic reaction is essentially iron dissolution. In $NaNO_3$, however, most of the current is expended for oxygen generation due to the presence of an electronically conductive oxide film. A small amount of oxygen (less than approximately 10% of the current) is observed in the $NaClO_4$ system. The cathodic reaction in both NaCl and $NaClO_4$ solutions is hydrogen evolution. In the case of $NaNO_3$, little or no hydrogen is observed—the current is mainly consumed in reducing NO_3^- ions.

In previous work, the electrochemical machining (ECM) of mild steel in $NaClO_3$ has been studied in a closed-cell system (1). From the results of that work, it is believed that more general knowledge concerning ECM electrode mechanisms can be obtained by extending the study to other electrolyte systems with different oxidizing powers. Hence, NaCl, $NaClO_4$, and $NaNO_3$ were selected for this work. It was expected that the results would provide a better understanding of the effect of the electrolyte on the ECM process.

Experimental Procedure

The closed-cell system, experimental procedures and conditions, and sampling techniques are identical to those described in the previous paper (1). Reagent grade chemicals were used for all experiments. Chemical analyses were carried out by the Chemistry Department of General Motors Research.

The methods of collecting hydrogen and oxygen for the NaCl and $NaClO_4$ systems are the same as those used for $NaClO_3$ (1). Minor changes were made in the case of $NaNO_3$ since little or no hydrogen was formed during ECM in $NaNO_3$.

The experiments using $NaNO_3$ were conducted in a nitrogen atmosphere only in order to concentrate on the study of oxygen generation. However, the procedure of collecting any hydrogen present was still carried out for each run. Thus, the gas, after leaving the ECM cell unit, was first bubbled through a 20% sulfuric acid solution for removing any ammonia as well as water vapor from the gas stream. Then the gas was further dried by passing it through anhydrous $CaSO_4$ and anhydrous $Ba(ClO_4)_2$ before entering two serially connected Sargent-Welch gas purifying furnaces. The Vycor glass tubes used in these furnaces were filled with pure copper and copper oxide (CuO) turnings, respectively. Any water collected by anhydrous $Ba(ClO_4)_2$ as effluent from the two furnaces was used in the determination of the amount of hydrogen formed.[1] Then, after the experiment, hydrogen was introduced into the first furnace to reduce the copper oxide which was formed by the reaction between the oxygen and the copper turnings. The amount of oxygen generation was then determined by the sum of the water collected after the first furnace (including the water used in determining the amount of hydrogen formed).

Results

The experimental results obtained by ECM of mild steel in NaCl, $NaClO_4$, and $NaNO_3$ are summarized in Tables I, II, and III, respectively. Figure 1 shows the tube end finish obtained with 4.5M $NaNO_3$ at 47 A/cm^2.

The amount of iron removed was determined by the weight loss of the mild steel tube, which was used as the anode, assuming 100% iron in 1020 mild steel, and the current efficiency for iron removal was calculated by the assumption that iron was dissolved as ferrous ion at the anode. The apparent current densities were based on the cross-sectional area (0.159 cm^2) of the tube wall.

In the $NaNO_3$ system, little or no hydrogen was collected. However, significant amounts of ammonia, hydroxylamine, and nitrite were found in the $NaNO_3$ solutions after ECM. At present, the concentration of these reaction products cannot be determined accurately due to the complicated interactions among the various species present. Hence, no quantitative result is given in this report concerning the cathodic reaction species formed in $NaNO_3$.

Discussion

ECM in NaCl Electrolytes

The results in Table I show that during ECM in NaCl solutions the current is mainly consumed in iron dissolution. Further, the current efficiency for iron removal is not affected greatly by the applied current density or the electrolyte concentration. These results certainly indicate that the anodic process in NaCl is much simpler than in oxidizing electrolytes such as $NaClO_3$ (1) for example. Because the protective oxide film is not present in NaCl solutions during ECM (2), the current is not consumed in oxygen generation at relatively low current densities, and good dimensional control and bright surface finish are not able to be

* Ammonia, nitrite, and relatively small amount of hydroxylamine were observed after ECM.
** Ammonia, hydroxylamine, and nitrite were observed after ECM.

obtained [see Fig. 3 of Ref. (1)]. In order to have proper dimensional control with NaCl, ECM has to be conducted in a dilute solution at quite a low current density (4).

The slight decrease in the current efficiency for iron removal with the increase in current density (Table I) may result from the generation of oxygen due to the increase of polarization of the metal dissolution process. In this study oxygen was not observed, but it might have been consumed in oxidizing some of the ferrous product.

Although the current efficiency for iron removal in 2M NaCl is slightly higher than that in 4.5M NaCl,[2] the results certainly indicate that the current efficiency is not seriously affected by the concentration of chloride ion.

At the cathode, hydrogen evolution is likely to be the only reaction taking place during ECM since the average current efficiency for hydrogen generation is so close to 100%.

[2] This may be due to the effect of polarization caused by the adsorption of anions (5).

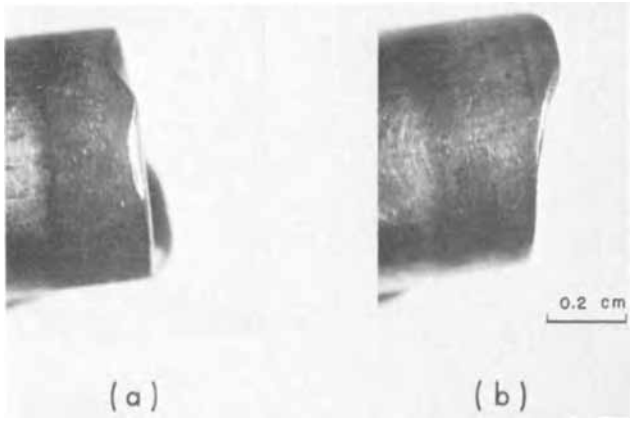

Fig. 1. The tube end finish obtained with 4.5M $NaNO_3$ at 47 A/cm². (a) and (b) are opposite sides of the same tube end.

The final pH of 10 of the NaCl solutions indicates that the solutions are saturated with $Fe(OH)_2$ after ECM. The color of the sludge was greenish-black. The wet sludge from a cell operated in an air atmosphere was found to be partly magnetic, while the sludge obtained under a nitrogen atmosphere appeared to be nonmagnetic. Apparently, in the former system a significant amount of Fe_3O_4 was formed by the reaction between the ferrous hydroxide and dissolved oxygen from the air.

ECM in $NaClO_4$ Electrolytes

Since the average current efficiencies for hydrogen generation in $NaClO_4$ and NaCl solutions are the same (see Tables I and II), it is likely that hydrogen evolution is also the only cathodic reaction for ECM in $NaClO_4$.

According to the results in Table II, some ClO_4^- ions are reduced to chloride, but the amount of chloride formed is significantly lower than that in $NaClO_3$ (1). The chloride formation is probably due to the reaction between ferrous hydroxide and perchlorate. However, since the color of the sludge was always found to be greenish-black and, furthermore, since the final pH of the electrolytes remained in the range for a saturated solution of $Fe(OH)_2$, it is not likely that ferric hydroxide is formed. Because the wet sludge for both air and nitrogen atmospheres was found to be magnetic, it is believed that Fe_3O_4 is the product of the reaction.

From the above discussion, $NaClO_4$ apparently is a more stable species than $NaClO_3$. Because the perchlorate ion is relatively stable and also possesses certain film-rupturing powers (6), one would expect that the oxide film in $NaClO_4$ should be weaker and less uniform than that in $NaClO_3$. Indeed, this was shown by Hoare, Mao and Wallace (3). They found that in $NaClO_4$ the oxide film is almost completely removed at the beginning of the transpassive state. Hence, a bright, polished surface is not observed in the cutting-region, and, furthermore, the surface of the film-protected area is pitted due to the nonuniformity of the films. However, because of the sharp transition from the passive to the transpassive state, the dimensional control obtained with $NaClO_4$ is found to be similar to that observed in $NaClO_3$.

In Table II, it is also seen that a small amount of oxygen is produced during ECM in $NaClO_4$. This may indicate that some residual oxide films are still present in the transpassive state. Perhaps because of these residual films the surface finish with $NaClO_4$ is significantly different from that with NaCl [see Fig. 4 of Ref. (3)]. The presence of such films apparently is not affected by the potential and the $NaClO_4$ concentration since the current efficiency for iron removal is almost constant (about 90%) in the range used in this study.

That the total anodic current efficiency for Fe^{++} and O_2 formations is lower than 100% may indicate that some oxygen is used in oxidizing the ferrous product.

ECM in $NaNO_3$ Electrolytes

In Table III it is seen that hydrogen is not formed at a brass cathode during ECM in $NaNO_3$. The small amount of hydrogen formed at platinum in the same electrolyte is attributed to the relatively low hydrogen overvoltage on platinum. The hydrogen evolution at a copper cathode in KNO_3 has been studied by Landolt and his co-workers (7) at higher current densities (in the range of 50 to 150 A/cm²),[3] and the amount of hydrogen evolved was found to be much less than in KCl. Since, in this work, ammonia, hydroxylamine, and nitrite were detected in $NaNO_3$ electrolytes after ECM, nitrate is apparently reduced at the cathode. The current efficiency for the reduction of nitrate is likely to be affected not only by the cathode material but by the potential as well. (The electrolytic reduction of nitrate at various metals has been investigated by Tafel and others (8) at conventional low current densities.) Because of the formation of ammonia, the final pH of the electrolyte is significantly higher than it is in other systems.

In comparison with $NaClO_3$ (1), the current efficiency for iron removal in $NaNO_3$ is significantly low. This may indicate that the oxide film in $NaNO_3$ is less porous than in $NaClO_3$. During ECM in $NaNO_3$ most of the current is actually consumed in oxygen generation. The current efficiency for oxygen generation is nearly 100% at current densities below 12 A/cm². According to Hoare's study (2), only a relatively small amount of oxide film is removed at the beginning of the transpassive state (at 1.5V *vs.* NHE and 10 mA/cm²). Since the film is not removed to any considerable extent by the oxygen evolution, it is likely that the oxide film in $NaNO_3$ is electronically conductive—thus, oxygen can be formed at the film/solution interface. The electronic resistance of the iron oxide film formed in HNO_3 has been studied by Vetter (9) and was found to be very low.

Figure 1 shows that the tube end is not uniformly machined with 4.5M $NaNO_3$ at 47 A/cm². This nonuniform cutting is believed to be caused by the massive oxygen generation which could lead to a nonuniform coverage of the anode surface with the oxygen gas if the electrolyte flow is not sufficiently fast and uniform. More uniform cutting was observed as current decreased. Because of the low metal removal rate in $NaNO_3$ solutions, it is not possible to give any meaningful comparison about the dimensional control between $NaNO_3$ and $NaClO_3$. The surface finishes obtained with $NaNO_3$ generally are less bright than those machined in $NaClO_3$.

The results in Table III show that the current efficiency for iron removal in $NaNO_3$ increases with the electrolyte concentration and with the current density[4] similar to the results found for the $NaClO_3$ system. Probably these phenomena also can be explained by the arguments given in the previous report (1).

The total anodic current efficiency for Fe^{++} and O_2 formations given in Table III is lower than 100% (especially at high current densities). This may indicate that either some iron is dissolved as ferric ion or that some oxygen is consumed in oxidizing the ferrous product. During ECM, a red-brown sludge of ferric hydroxide was always observed and the wet sludge was nonmagnetic.[5]

Conclusions

From the results of this work [including the previous study of ECM in $NaClO_3$ (1)], it is apparent that the ECM anodic process varies with the electrolyte. In oxidizing electrolytes, the ECM performance is closely

[3] It should be noted that in this work the apparent cathodic current densities are actually lower than the values given in Tables I, II, or III due to the larger cathode area (0.713 cm² compared with 0.159 cm² for anode).

[4] The slight decrease of the efficiency in 4.5M $NaNO_3$ solutions when current density varies from 26 to 47 A/cm² presumably is caused by the nonuniform cutting due to a higher rate of oxygen evolution.

[5] It should be noted that nitrate also can oxidize ferrous hydroxide but the product is Fe_3O_4 (10).

related to the structure of the oxide film formed on the anode. For good ECM performance, the oxide film probably has to be compact, uniform, porous, and preferably thin at the cutting surface; *i.e.*, the film in $NaClO_3$ solutions. Oxygen formation is generally observed when the oxide film is present. In $NaNO_3$ most of the current is consumed in oxygen generation instead of iron removal. This seems to be caused by the presence of an electronically conductive film. The anodic reaction in NaCl is mainly iron dissolution due to the absence of the oxide film.

The cathodic reaction in NaCl, $NaClO_4$ as well as $NaClO_3$ (1) is essentially hydrogen evolution. In $NaNO_3$, however, nitrate is reduced to ammonia, hydroxylamine, and nitrite at the cathode, and little or no hydrogen is formed.

The Effect of Liquid Configuration in Porous Gas Electrodes

T. Katan* and E. A. Grens II*,[1]

Lockheed Palo Alto Research Laboratory, Palo Alto, California 94304

ABSTRACT

The influence of differential pressure on electrode activity was measured for oxygen cathodes made up of beds of uniform silver spheres (156 μm diameter). The extent and nature of this dependence could be explained through use of the concept of pendular and funicular liquid configuration in the pore space of the electrode.

The performance of a porous gas electrode is dependent not only on its pore structure but also on the configuration of the gas-liquid interfaces within the pores. Thus the differential pressure established across an electrode has been found by many investigations to be an important influence (1-7). Explanations presented for differential pressure effects have been based almost entirely on the distribution between gas and liquid filled pores that is found in electrodes with wide ranges of pore size distribution (2, 8, 9). Such theories cannot explain the behavior of electrodes whose pores are all much the same size, although very significant differential pressure effects are also observed for these electrodes.

In gas electrodes with a narrow pore size range (single porosity electrode) the electrochemical reaction must occur primarily under a thin film of electrolyte on the pore walls, the so-called supermeniscus film (10-13). In addition ionic current transport must proceed along electrolyte paths on these walls. For conditions where little or no electrolyte is present in the gas electrode except in the form of thin films it has been found that the performance is scarcely affected by changes in differential pressure and that predictions of overpotential behavior based on a simple film mechanism are quite adequate (6, 14). However, when considerable additional electrolyte is present in the pores, performance deviates considerably from such predictions, and the influence of liquid configuration assumes great importance.

Several investigators have reported strong dependence in the performance of single porosity gas electrodes on differential pressure. Some of the electrodes used by Burshtein *et al.* (their electrode numbers 13-15) in their early studies of structural effects in porous gas electrodes had essentially a uniform pore size (2). The current density produced by these electrodes at constant overpotential showed a distinct maximum at differential pressures on the order of 100 mm Hg for pores with effective radii in the range of 5-10 μm. Ksenzhek later reported additional observations of such behavior for electrodes with apparently narrow pore size distributions (4).

In 1968 Lindstrom made a revealing study of single porosity gas electrodes in which he not only observed maxima in electrochemical activity at particular differential pressures but also correlated this effect with measured changes in the resistance of the electrolyte "film network" in the pores of the electrode (5). He further related this behavior to independent measurements of effective[2] electrode parameters including mean pore diameter, film thickness, and pore and film tortuosity factors. Lindstrom also noted, and qualitatively explained, marked hysteresis effects in the response of electrode activity, liquid penetration, and film network resistance to changes in differential pressure. The work elucidated many aspects of the influence of differential pressure on electrode activity for single porosity electrodes, in terms of measured response of "film network" resistance to differential pressure changes.

Lindholm and Edwardsson also observed drastic changes in "film" conductivity in the region of differential pressure coinciding approximately to maximum electrode activity in a porous oxygen electrode composed of silver electrocatalyst particles (16). The mechanism by which changes in differential pressure across a porous body affect the conductivity of liquid electrolyte paths in the pore space is thus of considerable interest; it can serve as a basis for the understanding of many features in the behavior of single porosity gas electrodes. Earlier work on other porous systems can provide valuable insight into this mechanism.

Over forty years ago Haines observed a variation of the conductivity in damp soils with moisture content very similar to that found in porous electrodes with differential pressure (17). The soils he studied were porous materials quite similar to many electrodes with a single scale of porosity. Therefore the models that he used relating liquid content, liquid configuration in the pores, conductivity, and gas-liquid differential pressure can be considered for the interpretation of gas electrode behavior.

Haines, and other investigators in his field, based their theories upon an "ideal" soil composed of a regular packing of uniform spherical particles (17-21). They discussed two essentially different states of liquid configuration in these porous beds: a "pendular" state at low moisture contents in which the liquid exists as isolated annular rings, or "disks," around the contact points between spheres; and a "funicular" state at higher moisture contents in which these disks have reached such size that they contact each other and form continuous paths through the bed. Haines an-

[2] Determined from exterior measurements.

alyzed the relation between gas-liquid differential pressure and moisture content of the bed, at least in the pendular state, and calculated pressures at which liquid content should be sufficient for transition to the funicular state in regular beds of uniform spheres (21). More recently Harris and Morrow have shown that the pendular moisture contents of random packings of uniform spheres are close to those expected in regular packings at the same gas-liquid differential pressures (22).

These concepts are potentially very useful in description of the functioning of all single porosity gas electrodes. However, their validity in this use can only be confirmed on the basis of situations where they yield quantitative predictions that can be compared with experimental observations. The logical choice for such comparison is the porous gas electrode composed of a bed of uniform spherical particles. We have studied the performance of well-characterized oxygen cathodes of this type over ranges of differential pressure including the expected pendular-funicular state transition.

Experimental

In these studies oxygen was reduced at porous silver cathodes in 13.5M KOH at 95.0°C. The arrangement of the test electrode and the reference cell in the electrolyte resembles that employed in a previous investigation (14). It is shown in Fig. 1 and is described in more detail elsewhere (15). The test electrode, 1.3 cm in diameter, consists of a bed of silver spheres of uniform size which rests on a relatively thin silver mesh (4.2 μm thick) sealed across the end of a Pyrex tube. This silver mesh at the lower side of the bed is in contact with the electrolyte while the upper surface of the bed is exposed to the gas phase. Electrical contact to the spheres is established through the mesh. The bed of spheres has uniform thickness and acts as the cathode for electrochemical reduction of oxygen. A differential pressure of oxygen is applied across the electrode at preselected values to change the extent of electrolyte infiltration into the bed.

Three sizes of silver spheres were used, having average diameters of 156, 54, and 14 μm. Before use, these spheres were thoroughly washed in concentrated aqueous ammonia to remove traces of silver oxides. The spheres were then washed with water and with methanol before drying in air at 110°C for 1 hr. This treatment assured reproducible electrode kinetics and minimized electrical resistance at contacts between spheres. Specific resistivity was always less than 0.74 ohm-cm in electrodes composed of loosely packed sphere beds that were treated in this manner.

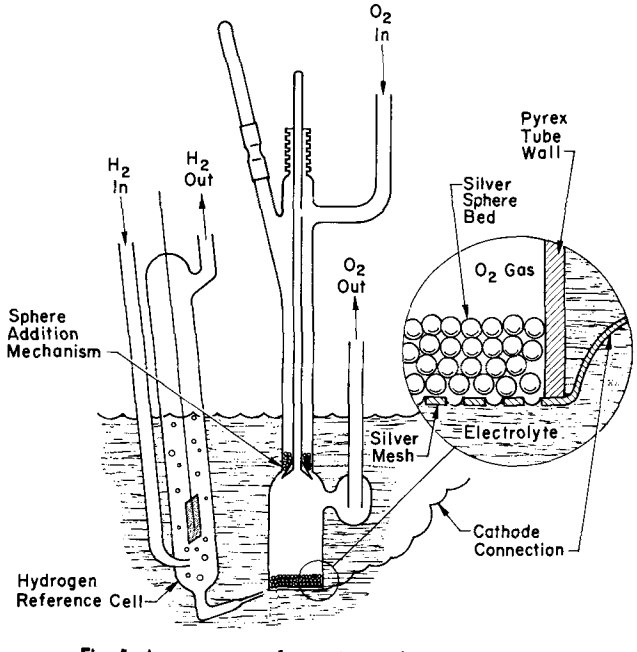

Fig. 1. Arrangement of experimental oxygen cathode

The test electrodes were built up to their final thickness by repeated addition of spheres. The spheres were brought to the temperature of the electrode and then were added to the top of the bed. Thickness of the electrodes was determined from the known density of the sphere packing, the cross sectional area of the bed, and the mass of the spheres added. In a few cases direct observations could be made of the thickness with a microscope; these showed that the actual thickness was within 10% of that calculated and that thickness was quite uniform across the electrode, deviating by less than ±2% from the average value.

Studies of the test electrodes were conducted under galvanostatic conditions. These electrodes were connected, by means of the silver mesh, as cathodes, and current was supplied from a constant current source, an Electronics Measurement, Inc., Model C612 power supply. The circuit was completed through a counter-electrode of smooth platinum foil placed below the test electrode. Electrode current was measured by a Greibach Model 500 ammeter placed in series with the cathode. Electrode potential was determined with respect to a hydrogen (on platinized platinum) electrode operating in cell electrolyte. This reference electrode was located in a separate cell with a Luggin capillary tube leading from this reference cell to a point about 1.5 mm from the edge of the silver mesh of the test electrode. Potential of the test electrode *vs.* this reference cell was recorded with a Sargent MR potentiometer. All electrode potentials in this paper are referred to this hydrogen reference electrode (HRE).

Electrodes were formed under a differential oxygen pressure of 25 cm of water by successive additions of spheres. After each incremental addition of spheres, the current-potential relationships were determined over the cathodic range from the open-circuit potential of about 1035 mV down to 600 mV (*vs.* HRE). The system was allowed to reach steady state at each of the several current values before potential measurements were recorded. When an electrode thickness of 1700 μm had been obtained, the differential oxygen pressure was lowered by increments of approximately 2.5 cm of water to 5 cm of water and then similarly raised to about 80 cm of water; at none of these differential pressures did gas bubbling through the electrode occur. After each differential pressure change, a current-potential curve was again determined. The series of current-potential curves obtained in this manner constituted the basic data used in this study.

Results and Discussion

For this investigation the effect of differential pressure across the electrode on the activity of the electrode has been of primary concern. Thus, it was desirable that other effects on electrode performance be minimized so that those attributable to differential pressure variation could be studied. The effect of temperature was eliminated by careful thermostating and that of oxygen flow past the electrode by maintaining a constant flow of 15 $cm^3\ min^{-1}$. However, no effect caused by changes in oxygen flow rate was observed when the rate was varied from 2 to 50 $cm^3\ min^{-1}$. Electrode thickness was also held constant, and moreover was established at a large enough value so that any further increases in thickness had very little effect on electrode performance. The observable effects of differential pressure variations are enhanced by use of an electrode thickness somewhat greater than the maximum for which the whole electrode can effectively contribute to the electrochemical reaction.

The attainment of sufficient electrode thickness was assessed by comparisons of electrode performances after incremental increases in the thickness of an electrode with spheres having a 156 μm diameter, at a differential pressure of 25 cm of water. Typically, it was found that beyond a thickness of 1000 μm relatively little or no change resulted for further increases up to 4000 μm, as indicated in Fig. 2. This ob-

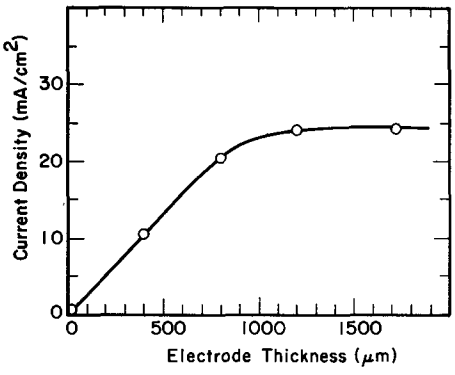

Fig. 2. Effect of electrode thickness on activity of oxygen cathode (156 μm silver spheres). Potential 500 mV (vs. HRE). Differential pressure 25 cm of water.

servation, similar to results reported earlier (14), indicated that the selected constant electrode thickness of 1700 μm for this study was sufficiently large to allow meaningful observations of the effects of differential pressure variation.

Under the conditions described above it was possible to isolate the effects of differential pressure variation on electrode performance. The effects were investigated for an electrode composed of 156 μm silver spheres in a bed 1700 μm thick. The activity of this electrode, expressed as current density at several fixed potentials *vs.* the HRE, is shown as a function of differential pressure in Fig. 3 The upper curves (Fig. 3a) represent the performance at decreasing differential pressure while the lower curves (Fig. 3b) are for increasing differential pressure. A pronounced hysteresis effect is present, as is shown more clearly for the case of 500 mV in Fig. 4. This curve would be retraced, except for some change in the decreasing pressure branch above 15 cm of water, on repeated cycling of differential pressure. For either increasing or decreasing differential pressure electrode activity

attains a pronounced maximum at a certain characteristic differential pressure that is independent of electrode potential. No matter which way the pressure is being changed, the drop in activity after passing the maximum is steeper than the rise in activity on approach to the maximum. This type of behavior has been previously reported for porous hydrogen electrodes (2), and, more recently, for porous oxygen electrodes (5, 6, 16).

The nature of the response of electrode activity to changes in differential pressure clearly indicates that it is associated with the penetration of liquid into pores and its expulsion from them. Characteristically, as differential pressure decreases liquid enters the pores, and as differential pressure increases it is displaced. However, not all of the infiltrated liquid can be expelled; there is a certain amount retained because of the configuration of the pore space. A meaningful description of the mechanism of this liquid infiltration and expulsion is not possible with the complex porous media usually employed as fuel cell electrodes. However considerable simplification in configuration results with these sphere-bed electrodes. An analysis of the liquid penetration cycle for the relatively simple geometry represented by sphere packings can be made on the basis of the concept of pendular and funicular liquid configurations cited earlier.

When an electrode is initially formed at a relatively high differential pressure, the only liquid that can be present in the bed is in thin supermeniscus films, which have been previously observed and described (10-13), and in the isolated bodies or disks of liquid that collect at the sphere-to-sphere contacts as shown in Fig. 5a. This is the pendular state described by Haines. For this state electrochemical reaction beneath the film on the metal is limited to regions near the bulk electrolyte side of the electrode, because ionic transport must occur through the thin film, which presents a very high resistance.

As differential pressure is decreased more liquid enters the bed by capillary action. Then the liquid disks, which were initially isolated from each other, are enlarged by the entering liquid and eventually come into contact with each other so that paths of liquid much thicker than the previously existing film paths are formed throughout the sphere bed. This is the funicular state. It is characterized by an interconnected network of liquid "filaments" formed by coalescence of the liquid disks at sphere-to-sphere contacts. When liquid disks first come into contact considerable areas of thin film on the spheres still remain. The system of liquid filaments provides low resistance paths for ionic current to these areas of supermeniscus film still covering a large part of each sphere Since these films are in contact with a connected gas phase this is a situation where large regions within the

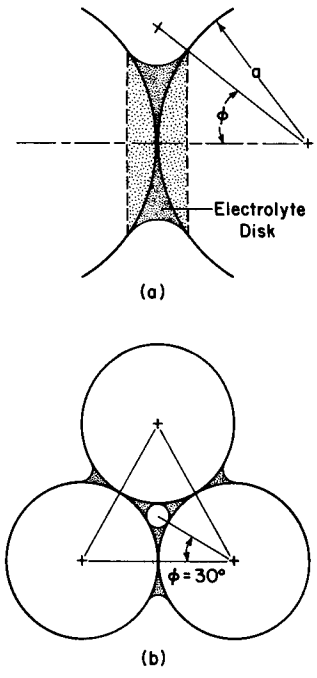

Fig. 5. (a) Configuration of electrolyte disk at the contact of two spheres. (b) Triad sphere arrangement with electrolyte disks at the condition of pendular to funicular transition.

porous electrode are subject to conditions favorable to the electrochemical reaction. Decreasing differential pressure thus leads to increasing electrode activity as the network of liquid filaments is formed. This can be observed down to 16 cm of water in Fig. 3a.

With further reduction in differential pressure more liquid enters the electrode and the areas of sphere surface that are covered only with thin film become reduced in size. Diffusion of oxygen gas to reaction sites on the sphere surfaces must then be through increasingly thicker electrolyte layers, and this process eventually becomes rate limiting. Performance then decreases as seen for lower differential pressures in Fig. 3a. With still further reductions in differential pressure, the pores of the sphere bed would become completely flooded, supermeniscus film areas would be lost, and, eventually, the continuous network of gas channels in the sphere bed would be disrupted and replaced by bubbles of gas entrapped by liquid. A saturation state would be formed (19, 21). This state would result in a drastic suppression of electrode activity.

When differential pressure is increased from the saturation state a continuous interconnected network of gas channels is again established. Improvement in electrode activity occurs as areas on the spheres become again covered only with films and thus readily accessible to the gas phase Further increases in differential pressure cause more liquid to be expelled from the porous structure until the continuous funicular liquid network is ruptured, whereupon ionic transport through thin film to sites of electrochemical reaction inside and throughout the sphere bed is severely restricted, and performance decreases as shown in Fig. 3b. After rupture of the funicular liquid paths, isolated pendular bodies of liquid remain as enlarged disks of liquid around sphere-to-sphere contacts in varying amounts depending on the differential pressure. It would appear that such pendular liquid may be expelled at sufficiently high differential pressures via bulk liquid transport through the supermeniscus film. Once the funicular paths are severed, however, further increases in pressure do not appreciably affect the thickness or the ionic resistance of the supermeniscus film, and the increasing supermeniscus film area cannot be effectively utilized since gas transport is no longer limiting. Performance then remains relatively unchanged, leveling off as shown in Fig. 3 and 4 for the highest pressures.

This interpretation of electrolyte configuration based on the pendular-funicular models leads to an explanation of the observed effects of differential pressure in electrodes with a single scale of porosity. For too high a differential presure, funicular paths are not formed and ionic transport within the supermeniscus film is limiting. For too low a differential pressure insufficient film area remains and diffusive transport of dissolved gas to the site of electrochemical reaction at the solid surface limits electrode activity. These observations are in agreement with experimental results obtained in this study. It can be concluded that the most favorable liquid configuration for obtaining high electrochemical performance for any electrode similar to the sphere bed electrodes considered here is the funicular state that exists just before a funicular to pendular transition or just after a pendular to funicular transition, that is, at a differential pressure which sustains a funicular state but which is not far removed from that for the pendular state. In this condition the supermeniscus film area, and its boundary with meniscus regions, are at a maximum consistent with the existence of low resistance paths for ionic transport, and a connected gas phase system exists throughout the electrode.

When the nature of the hysteresis effect in electrode activity is examined, it is found that the peak in electrode performance, shown in Fig. 3 and 4, is higher and displaced toward higher pressures for the case of increasing differential pressure. This effect is attributed to the typical differences in liquid holdup that occur for decreasing and increasing differential pressure in these systems (21). The liquid disks at sphere-to-sphere contacts can grow, on decreasing differential pressure, only by liquid transport through the supermeniscus film (or through the gas phase) until filaments are formed. This liquid transport is difficult, and what would be stable or equilibrium liquid configurations may not be obtained in any reasonable time. In effect a metastable liquid configuration, containing less liquid than the stable configuration, is established at any differential pressure, and the pressure for transition to the funicular state is shifted to a lower value. Moreover, the funicular configuration that is achieved may be expected to be deficient in connections to some film areas and thus have a relatively low activity maximum. Once liquid paths in the bed are established at low differential pressures, increasing the differential pressure encounters difficulty in reducing all liquid regions to their equilibrium state. Again a metastable condition exists which now shifts the transition to the pendular state to higher differential pressures. In addition a more extensive network of filaments will exist than did for decreasing pressure, and a higher peak is observed in accord with the preceding discussion. The differential pressure for obtaining maximum performance is thus different for decreasing and increasing differential pressure, being shifted to higher values for increasing pressure, as shown in Fig. 4.

The pendular-funicular interpretation just described yields a quantitative prediction for the differential pressure at which a maximum in activity occurs, as in Fig. 3b, when liquid is being displaced from a sphere bed electrode (increasing differential pressure). In the pendular state, a local pressure difference exists across the gas-liquid surface of the liquid disks at the points of contact of the spheres because of the two radii of curvature which define the surface of the liquid. These disks have a well-defined geometry that is simple enough to allow a determination of the local pressure difference across the gas-liquid interface. The liquid disks are just large enough to touch each other at the pendular to funicular state transition. Then the liquid in all disks is connected to the bulk liquid electrolyte at the electrolyte side of the bed and will be at liquid side pressure. The local pressure difference across the

surface of the liquid disks must then be very nearly equal to the gross pressure difference across the bed at pendular to funicular transition. According to the preceding discussions, this differential pressure should correspond to that which yields a maximum in electrode performance on increasing differential pressures.

From the treatments of Haines and Fisher (19-21) the differential pressure for funicular-pendular transition in a sphere bed from which liquid is being expelled can be found in terms of the surface tension of the liquid and the radius of the spheres. Essentially, it is assumed that liquid films exist on the spheres. The pressure difference across the meniscus of liquid held at the contact between two spheres has an equilibrium value which depends on the angle, ϕ, subtended at the sphere center by the radii to the point of contact between spheres and to the (ideal) contact point of the meniscus with the sphere. An expression for this dependence can be derived from the equation of Laplace and Young and the given geometry (18).

$$P = \frac{\sigma}{a} \frac{(1 + \tan \phi/2)(1 - 2\tan \phi/2)}{2 \tan^2 \phi/2} \qquad [1]$$

Here, σ is the surface tension of the liquid and a is the sphere radius. For a sphere bed containing a large fraction of spheres that are in contact with at least two other spheres that are also in mutual contact, that is, forming a triad of three spheres as shown in Fig. 5b, a pendular to funicular transition takes place when $\phi = 30°$. Then local pressure difference across the meniscus is

$$P = 4.1 \frac{\sigma}{a} \qquad [2]$$

Each sphere has approximately eight nearest neighbors in contact in the randomly packed sphere bed of this study, as estimated from the measured fractional void volume of 0.41 with a correspondence method suggested by Smith (23). For such a packing arrangement most spheres must be involved in several "triad" arrangements, which in turn form a network of touching triads throughout the sphere bed; this network serves as the basis for the paths of filaments of liquid in the funicular state. Thus, the differential pressure for a pendular to funicular or a funicular to pendular transition can be calculated for the bed of 156 μm spheres. This requires a value for the surface tension of the electrolyte, which was determined by comparisons of the bubble pressure for a fritted glass disk in water at 25.0°C and in 13.5M KOH at 95.0°C; the surface tension of the 13.5M KOH at 95.0°C was found to be 90 $\pm$1 dyne cm^{-1}.

For a 156 μm sphere bed, Eq. [2] gives a funicular to pendular differential pressure of 48 cm of water. This can be compared with the differential pressures of 40 to 43 cm of water that were observed for maximum electrode activity on increasing differential pressure in Fig. 3 and 4. The increasing pressure branch is the proper one for comparison because electrolyte transport is not inhibited on this branch until after the transition. In view of the imperfections in the packing model for the sphere bed, this is a good agreement indeed. The result not only serves to support the validity of a theory for electrode performance based on the concept of pendular and funicular configurations, but it also substantiates the interpretations we have offered above for the observed dependence of electrode activity on differential pressure. Furthermore, from Eq. [1] it can be seen that a change of only 5° in the angle ϕ causes a change in the calculated differential pressure for pendular-funicular transition by almost a factor of two. This indicates that the liquid configuration at sphere contacts and the arrangement in "triads" must be very close to what we supposed. This quantitative agreement thus confirms both the existence and nature of the pendular and funicular states and the continuous network of triads of spheres in mutual contact which maintains the latter state. It further confirms that peak electrochemical activity in a porous electrode with pores in a single size range occurs at the pendular-funicular transition of liquid configuration in the pores.

A further verification of this interpretation was obtained from additional experiments conducted with electrodes composed of silver spheres 54 μm in diameter. In these electrodes a thin layer of spheres 14 μm in diameter was first placed on the mesh to allow the attainment of significantly higher gas pressures without bubbling through the electrode. The fine and coarse layers were 400 and 1300 μm thick, respectively. The effect of differential pressure on the performance of this 54 μm sphere bed electrode is shown in Fig. 6. As differential pressure is increased, little improvement in performance occurs until 60 cm of water is attained. Then a sharp improvement is noted, with the performance eventually attaining 125 mA cm^{-2} for 0.5V *vs.* HRE at 90 cm of water. Higher differential pressures could not be examined because of limitations of the apparatus. No peak was observed in the pressure range studied; it clearly lies at a higher differential pressure than 90 cm of water. Equation [2] would indicate that the funicular to pendular transition should be expected at 139 cm of water. These results are very limited in scope but they nevertheless demonstrate the shift of the electrode activity maximum to higher differential pressures for the smaller spheres that would be expected from the interpretation offered here, as well as the improved activity associated with the higher specific surface area of the smaller spheres.

Indirect evidence for the importance of the pendular to funicular transition in fuel cell electrodes can also be obtained by comparison of the work of Lindholm and Edwardsson (16) with that of Haines (17), with respect to the effective conductivity of liquid paths in porous media under partially flooded conditions. Haines studied the relationship of conductivity changes to the transition between the pendular and funicular regimes, while Lindholm and Edwardsson related the conductivity to electrode performance. In both cases examination of the conductivity as a function of differential pressure reveals a near linear decrease in conductivity with increasing differential pressure (or decreasing liquid content) until a fairly pronounced change (decrease) in the slope of the relationship is encountered; Haines ascribes this change in slope to the transition between the funicular and pendular regimes. From Lindholm and Edwardsson's work it

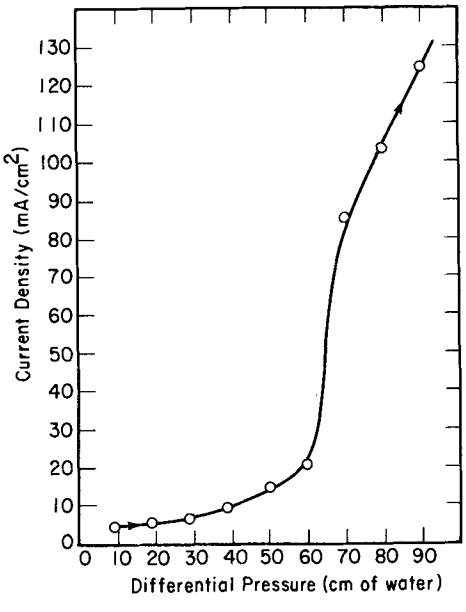

Fig. 6. Effect of increasing differential pressure on activity of oxygen cathode (54 μm silver spheres). Potential 500 mV (*vs.* HRE). Electrode thickness 1700 μm.

can be seen that the same slope change corresponds very nearly to the differential pressure at which maximum electrode activity (current density) is observed.

Local maxima in electrode activity were also seen in the work of Golovkin *et al.* for electrodes composed of spherical particles at differential pressures consistent with the pendular-funicular transition for the sphere sizes involved (7). However these workers found further increases in activity at much higher differential pressures (perhaps because of the activity of a significant "sealing layer" of much finer particles); they offer a theory based on liquid hold-up in systematic distortions of regular packing configurations.

Additional evidence for the pendular and funicular type of liquid configuration may be found in the data reported by Lindstrom (5). Although his electrodes were from particles of irregular shape, at least these particles had a reasonably uniform size. A comparison of Lindstrom's liquid path resistance and electrode activity curves given as functions of differential pressure again shows a maximum in activity closely associated with a change in slope in the resistance (and thus conductivity) relationship. These results also demonstrate a marked hysteresis in both the electrode activity and resistance behavior with increase and subsequent decrease in the differential pressure. These results of Lindstrom not only corroborate the interpretation offered here but also indicate a possibly more general application of the pendular-funicular model to sintered electrode structures of particles of irregular shape.

Conclusions

The present studies have shown that the concept of pendular and funicular liquid configurations in simple porous media can be very useful in explaining the behavior of gas electrodes with a narrow range of pore size. This concept was developed much earlier in the studies of properties of soils, but has not been heretofore applied to electrode systems. The existence of these two states, and the transition between them, accounts for the dependence of electrode activity on differential pressure across the electrode for oxygen cathodes composed of beds of uniform small spheres. Thus this concept can provide an improved understanding of the transport phenomena operative in these electrodes, which can be of value in development of more effective structures.

Energy and Kinetics Department, School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The feasibility of a room-temperature, nonaqueous organic solvent, electrochemical cell that can deliver 10 mA/cm^2 at 4V has been demonstrated. The cell consists of a lithium negative, a graphite compound positive electrode, and a lithium perchlorate-dimethyl sulfite electrolyte solution. The cell develops an open-circuit potential of approximately 4.5V. Apparently the lithium perchlorate-dimethyl sulfite electrolyte undergoes no or least slow oxidation or reduction within a 4.5V range.

To date, the maximum charge storage has been 90 coulombs/g of graphite. Cycles of 1 hr charge and 1 hr discharge at about 3 mA/cm^2 have been repeated up to 33 times. Failure was apparently due to overcharging and graphite disintegration. On wet stand, from 25 to 50% of the cell capacity is lost over one day.

Dimethyl sulfite, $(CH_3O)_2SO$, has been shown to be a potentially useful solvent for application to batteries (1). While using graphite as a positive electrode in lithium trifluoromethanesulfonate-dimethyl sulfite solutions, a 4.3-4.8V open-circuit potential *vs.* lithium metal was repeatedly observed (2). Brenner (3) has recently reported similar observations and suggests a fluorine-containing compound as the active oxidizing agent. Observations on cells of the type Li/$(CH_3O)_2SO$,

Key words: batteries, nonaqueous solvents, lithium perchlorate, dimethyl sulfite, graphite, lamellar compounds of graphite.

$LiClO_4$/graphite are reported here and observed changes in performance after substituting different salts, solvent, and graphites are described.

Experimental

Materials.—Dimethyl sulfite was purchased from Eastman Kodak Company. It was further purified by agitation with Linde A molecular sieves and subsequent vacuum distillation in a packed column at 53°C and 5.7 mm Hg pressure. The water content was 50 ± 10 ppm as determined by Karl Fischer titration.

Anhydrous $LiClO_4$ was purchased from G. F. Smith Chemical Company. It was heated in a vacuum at 105°C or used without further treatment. Performance of the experiments seemed independent of the heating step. Karl Fischer titration of solutions of dimethyl sulfite and $LiClO_4$ indicated the as-received "anhydrous" $LiClO_4$ contained 1 H_2O per 10 $LiClO_4$ molecules. The heating step, as performed on as-received material, only reduced the water by a factor of one-half to one-third.

The $LiCF_3SO_3$ salt was prepared by reacting $BaCF_3SO_3$ (provided by 3M Company) with H_2SO_4 and by neutralizing the resulting aqueous solution with LiOH. The $LiCF_3SO_3$ was twice recrystallized from acetone and vacuum dried at 110°C for 48 hr. Resulting solutions with dimethyl sulfite did not show appreciable increase in water content above 50 ppm.

The $LiBF_4$ was purchased from Foote Mineral Company. It was vacuum dried at 110°C for 48 hr. Resulting solutions with dimethyl sulfite showed high (order of 1000 ppm) water content.

Lithium ribbon packed in argon was purchased from Foote Mineral Company and used as received.

Five types of graphite were used: Great Lakes Carbon Company grade R-1 nuclear reactor grade graphite of density 1.68 g/cm^3, Union Carbide pyrolytic graphite carbon paper (PGCP) of density 0.471 g/cm^3, Union Carbide graphite foil (GRAFOIL) of density 0.836 g/cm^3, Super Temp Company (Santa Fe Springs, California) reinforced pyrolytic graphite (RPG) of density 1.62 g/cm^3, and Super Temp Company annealed pyrolytic graphite of density 2.24 g/cm^3. The RPG was most extensively tested. It is a porous, carbon matrix throughout on which small crystallites of pyrolytic graphite are deposited. The Super Temp Handbook (4) indicates that 80% of the pores are 18-35μ in diameter. The available internal surface area is estimated as 500 cm^{-1}. The weight of the material is about 94% pyrolytic graphite. Further information is available in the Super Temp Engineering Handbook (4).

Apparatus.—Experiments were performed in an argon-filled Vacuum Atmosphere Corporation glove box Model HE-243-2 DRI-LAB equipped with an HE-493 DRI-TRAIN containing molecular sieves for water removal and Dow Q1 (supported copper) for oxygen removal and an HE-593 titanium sponge furnace operating at 800°C for nitrogen removal. Impurity levels of O_2, N_2, and H_2O were between 1 and 10 ppm as estimated from observation of a tungsten light bulb filament life of one day or more and the rate of formation of an oxide or nitride film on molten sodium or lithium. The temperature in the glove box was maintained at 30° ± 1°C.

The test cell is shown in Fig. 1. The lower, test section of the cell is 3.5 x 4.0 x 0.3 cm. The separator was nonwoven polypropylene cloth (The Kendall Company). Contact to the graphite electrode was by a platinum wire wrapped tightly through a hole in the graphite.

Galvanostatic charging and discharging was accomplished by means of a Heathkit Model IP-32 Regulated Power Supply in series with a Clarostat Model 240-C power decade resistance box. Cell voltages were measured by a Keithley 610B electrometer coupled with a Sargent Model SR chart recorder. Cell current was measured with a Simpson Model 267 volt-ohm-milliammeter.

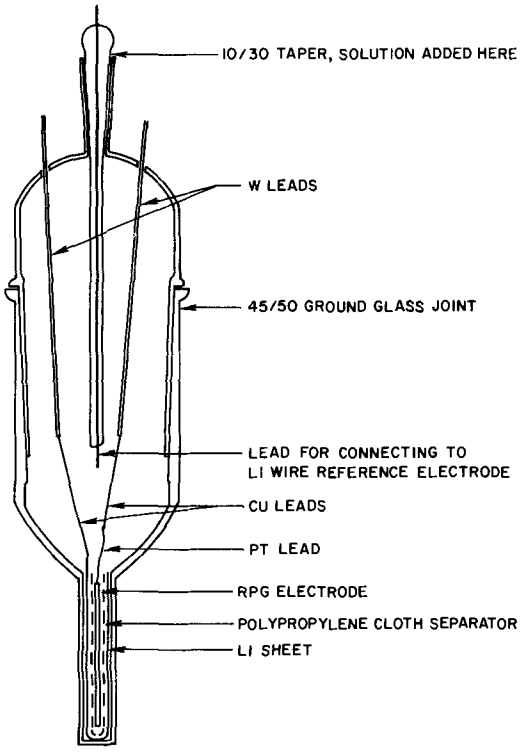

Fig. 1. Test cell

The cells were assembled in the dry box in the discharged state. The electrolyte solution was dimethyl sulfite saturated with lithium perchlorate. The saturation concentration of lithium perchlorate in dimethyl sulfite has not yet been precisely determined. However, a tentative value of 1.73 mole/kg of solution at 23°C was measured. Excess lithium perchlorate was in the bottom of the cell. Constant current was passed through the cell with the graphite electrode attached to the positive terminal of the power supply. Various time periods and rates of charging were used. The open-circuit potential was observed, and the cell potential *vs.* time was recorded during discharge with the electrodes connected across various size resistances. Once the approximate coulombic capacity was established, a timing circuit was used which switched the cell automatically from the charging circuit to the discharging circuit at fixed intervals, generally 1 or 2 hr charge followed by 1 or 2 hr discharge through constant resistance at 2 or 3 mA/cm^2. The cell potential was recorded during the cycling. Cycling was terminated when shorting across the cell electrodes began to occur. Generally the substrate for lithium deposition was a sheet of lithium metal. However, copper, aluminum, and RPG were also tested as possible negative electrode substrates. The solvent was generally dimethyl sulfite, but propylenecarbonate and dimethyl sulfoxide were also tested. Lithium perchlorate was generally used as the electrolyte, but lithium trifluoromethanesulfonate, lithium tetrafluoroborate, lithium nitrate, and lithium thiocyanate were substituted for the lithium perchlorate in a series of tests. Various graphites as mentioned above were used as positive electrodes in addition to some amorphous carbons.

Results

Cell tests.—Using an RPG positive electrode of 5 cm^2 geometric area, a series of 20 min galvanostatic charge-discharge runs were made. Cell voltage was recorded as a function of time for currents of 2 mA/cm^2. A typical result is shown in Fig. 2. Both charge and discharge curves are quite flat. A sharp break downward in the discharge curve occurs at 3.8V. Open-circuit potential is approximately 4.4V with the majority of the discharge above 4.0V. Coulombic efficiencies

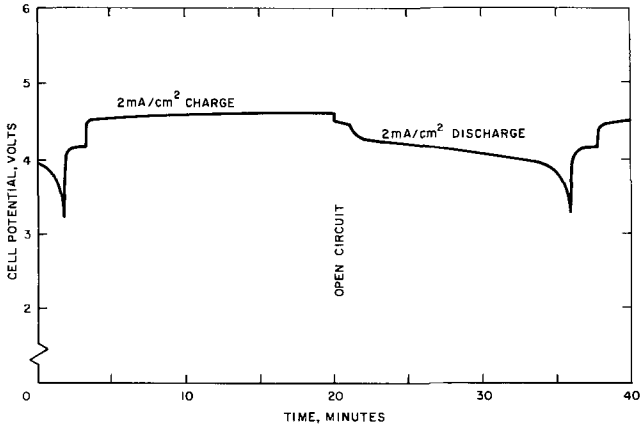

Fig. 2. Typical charge-discharge cycle Li/DMSU, $LiClO_4$/RPG

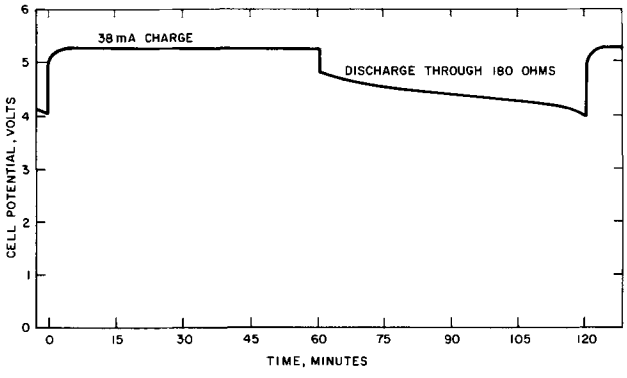

Fig. 3. Typical charge-discharge cycle, Li/DMSU, $LiClO_4$/RPG 23rd cycle. Geometric area ≈ 17 cm² (~62 coulombs/g of RPG).

increased during the first seven cycles as follows: 56%, 73%, 87%, 87%, 89%, 95%, and 90%.

After a 17.5 hr charge at 1 mA/cm², the open-circuit potential was 4.55V and stable during a waiting period of about an hour. A discharge of 2 mA/cm² was carried out for 10 min. Then a 10 mA/cm² (based on geometric area of RPG electrode) discharge was carried out for 30 min to a cutoff potential of 2.5V. Open-circuit cell potential quickly (within a second or so) returned to 4.3V and remained stable for 3 hr. This was followed by a 30 min discharge at 2 mA/cm² with cell potential above 3.5V. A brief short circuit through the ammeter gave 70 mA/cm² for 1 or 2 sec.

The electrolyte solution remained clear during this test. No bubbling was observed at the graphite electrode. A few small bubbles were observed at the lithium electrode.

The RPG electrode had swollen about 30% during charging. The swelling did not diminish on discharge.

In a later charge-discharge cycle (after 26 days of storage out of the electrolyte solution) the RPG electrode was charged for 11 hr at 5 mA (~ 1 mA/cm²). A short circuit through the ammeter gave 620 mA (~ 120 mA/cm²) for 2 or 3 sec. It was next discharged for 4 hr at 10 mA (~ 2 mA/cm²) to a 3.5V cutoff potential. Following this test, a long plateau (several hours) was observed at 2.5-2.0V cell potential at about 2 mA/cm². This low voltage plateau was not investigated further.

Using a lithium wire reference electrode it was determined that the decrease in cell potential at the end of a discharge (see Fig. 2) occurs almost entirely at the graphite electrode. This is expected since there is excess lithium at the negative electrode.

No lithium dendrites were observed except when the lithium perchlorate concentration was below saturation.

Cycle tests.—Two long-term cycle tests were run, each lasting several days. For the first test, an RPG electrode 4.67 x 1.82 x 0.106 cm weighing 1.4535g was used. The cycles were a 1 hr charge followed by 1 hr discharge. A typical cycle is shown in Fig. 3. The size of resistance in the discharge circuit was such as to prevent a rapid fall in the cell potential at the end of an hour. An arbitrary cutoff potential of 4.0V was used. As shown in Fig. 2, very little additional capacity is realized by using a 3.2V cutoff potential. For the first 12 cycles, charging took place at about 0.6 mA/cm² followed by discharge at approximately 0.48 mA/cm². Cycles 13-16 were at about 1.2 mA/cm² on charge and discharge. Cycles 17-26 were at about 2.2 mA/cm² charge and 1.5 mA/cm² discharge. The 27th cycle was increased to a 2 hr charge followed by a 2 hr discharge. However, on the 24th cycle minor jumps in potential began to occur, apparently caused by temporary or intermittent shorts. After 30 min of discharge on the 27th cycle the "shorting" became so severe that the test was terminated. Coulombic efficiency, coulombs in divided by coulombs out, generally varied between 0.66 and 0.9 for these cycles. No charge seemed to be building up on the positive electrode as shown by rapid decrease in cell potential if discharge time was lengthened.

At the end of the run it was observed that the electrolyte solution was a cloudy green color caused by a jellylike suspension. About half of the solid lithium perchlorate initially at the bottom of the cell was still there. On top of the lithium perchlorate was a thick (~ 1 cm) layer of carbon powder which apparently caused the shorting. The RPG electrode was "intact" but had a leached appearance. The lithium reference electrode was discolored black, particularly near the solution-argon interface. A few bubbles were trapped in the cell. There were no salt crystals on or near the graphite electrode. The lithium electrode was still pliable but black in color on the side facing the RPG electrode. The lithium was covered with what appeared to be salt crystals as was the nonwoven polypropylene cloth separator on the side toward the lithium. No lithium dendrites were observed. The polypropylene separator showed no degradation.

A second, similar cycle test yielded 33 cycles and was generally run at about 3 mA/cm². No significant performance differences were noted.

Coulombic capacity.—Various graphite positives were tested and effective charge storage capacity evaluated. The results are shown in Fig. 4. In these tests the discharge took place immediately after the charge. For the three types of graphite tested, the amount of charge recovered was independent of the amount of charge inserted after the charging passes about 90 coulombs/g.

If a cell is charged and then allowed to stand wet for one day, 25-50% of the charge originally inserted can no longer be recovered on discharge.

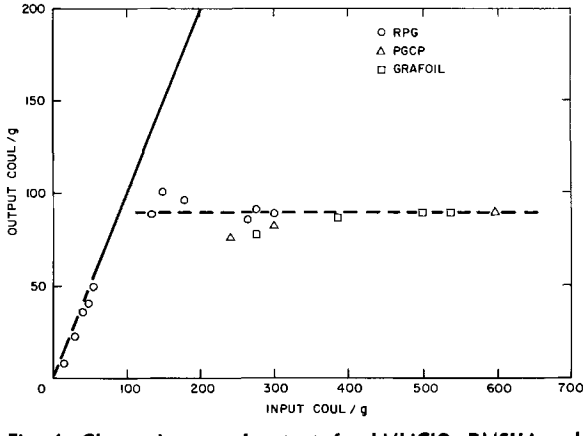

Fig. 4. Charge input and output for Li/$LiClO_4$:DMSU/graphite cell.

Swelling direction.—Tests on pyrolytic graphite chips have shown that swelling takes place along the "c" direction of the graphite. This swelling was not reversible on discharge.

Substitution of materials.—Lithium trifluoromethane sulfonate gave approximately the same performance as lithium perchlorate. Lithium tetrafluoroborate gave a stable open-circuit potential, about 4.6V, but the capacity of the RPG electrode using this salt was only about 10-15 coulombs/g. The charging potential when using lithium tetrafluoroborate was about 0.1-0.2V higher than when using lithium perchlorate as the electrolyte. Tests using lithium nitrate and lithium thiocyanate did not show stable, high open-circuit potentials and no significant coulombic capacity was observed when discharge was attempted. The following salts were too insoluble in dimethyl sulfite to yield any meaningful results: $LiBO_2$, Li_2CO_3, LiCl, Li_2SiO_3, $LiPO_3$, Li_2SO_4, Li_2O, and Li_2O_2.

In addition to the graphites already described, Great Lakes nuclear reactor grade R-1 graphite was tested. These were essentially blocks of material about the same size as the RPG electrodes. The R-1 gave stable cell potentials of about 4.5V. However, the graphite tended to slough off at the surface and crack if charged for more than 1 hr at 10 mA/cm^2. Various types of carbons were also tested, for example, Union Carbide gas fuel cell electrodes. None of the amorphous carbons gave stable open-circuit potentials or appreciable discharge capacities.

Various substrates were used for lithium deposition at the negative electrode. In general, the graphite electrodes were being studied. Thus, using lithium as the negative electrode substrate provided excess lithium capacity and insured that the lithium electrode was not capacity limiting. However, copper seems to work well as a substrate. Aluminum forms an alloy or compound with lithium and lowers the cell potential about 0.3V. Initial rates of charge and discharge using aluminum substrates indicated that the negative electrode overpotentials were small compared with the positive electrode. However, the negative electrode became capacity limiting and the aluminum became brittle, warped, and broke up after a few cycles. When RPG was used as the negative electrode substrate, it performed as a lithium electrode. There was no appreciable under- or overpotential on charging as determined using a lithium wire reference electrode. The cell was capacity limited on discharge by the negative electrode. The RPG did not change dimension. Based on these rather simple tests it did not appear that any lithium intercalation compound was being formed with the graphite.

Wood fiber paper battery separators and nylon cloth were tried as separator materials. They both disintegrated after a day or so in the dimethyl sulfite solutions. The nylon was very poor.

Propylene carbonate was substituted for dimethyl sulfite in a test and essentially the same results were achieved with regard to charge and discharge curves and open-circuit potential. When dimethyl sulfoxide was tried, however, the cell performance was not good. A stable open-circuit potential was not established and no appreciable discharge capacity was realized. Similarly, n-nitrosodimethylamine was not a successful solvent.

Lithium electrolyte solution stability.—Only preliminary tests of the stability of lithium in dimethyl sulfite have been made to date. A white precipitate is observed to form on lithium when immersed in lithium perchlorate-dimethyl sulfoxide solutions. The amount of precipitate produced is proportional to the amount of water in the solution. The reaction apparently ceases when water content is below 5 ppm. The precipitate, when washed and dissolved in water, gives a near neutral pH.

Discussion

The phenomenon of an expanding graphite anode has been known since 1841 (5). This has been explained as the formation of an electrochemical lamellar compound of graphite. That is, anions are incorporated into the interplanar spaces in the graphite structure to provide electroneutrality as the graphite is oxidized to a "macrocation" by the application of an anodic current. Such compounds have been studied in some depth since the mid-1930's (6-9). The similarities in the formation procedure and dimensional changes suggest that a lamellar compound of graphite may be involved in the positive electrode reaction in the Li/$(CH_3O)_2SO$, $LiClO_4$/graphite system. However, there are some differences between the behavior of the nonaqueous, aprotic system reported here and the acid systems. They are:

I) Absence of color change. Graphite compounds prepared in this laboratory by electrochemical oxidation of pyrolytic graphite in $HClO_4$ and H_2SO_4 have a metallic blue color, as reported by other investigators (9). The lithium perchlorate-dimethyl sulfite solutions do not yield a blue-colored graphite product. The graphite remains black.

II) Unlimited expansion of graphite. Lamellar compounds of graphite prepared from pure acid media expand along the "c" direction to an extent limited by the formation of the final stage (most concentrated in anionic species). The tests conducted in lithium perchlorate-dimethyl sulfite show unlimited expansion as the charging process proceeds. No clearly observable final stage was found.

III) Absence of detectable stage formation. Previous workers in acid media have observed stepwise changes in the potential of a graphite anode at constant current (10). Presumably, these correspond to various stages of compound formation as different combinations of interplaner spaces in the graphite are occupied. No such changes in the potential of a graphite anode in nonaqueous media *vs.* either a lithium electrode or a silver-silver perchlorate reference electrode have been observed.

If a simple lamellar compound of graphite is formed in the dimethyl sulfite-lithium perchlorate solutions, one possible reaction characterization would be

$$nC + ClO_4^- = C_nClO_4 + e^-$$

The results shown in Fig. 4 indicate a maximum charge storage capacity of about 90 coulombs/g of graphite. This corresponds to 89 carbon atoms, on the average, per anion using the above relationship. Ratios as low as 6-24 carbon atoms per anion have been observed for some acid media (9). The possible specific energy for such a system is critically dependent upon the value of n in the above relationship. Present results project to a specific energy of 20-45 Whr/kg of battery with n equal to 89.

Using nongraphitic carbons, the cell characterized by a 4.5V stable open-circuit potential does not form. Other workers have found (10, 11) that well-ordered graphites (characterized by negative temperature coefficients of electrical conductivity) are necessary for proper compound formation. The graphites used in this study were not of such perfect crystalline nature but were commercial grades.

The similar performances for the three anions—perchlorate, trifluoromethanesulfonate, and tetrafluoroborate—in addition to similar performances between dimethyl sulfite and propylenecarbonate solvents suggest that the positive electrode reaction is not specific to the particular anion or solvent. This suggests that the simple lamellar compound of graphite formation or a similar reaction gives the correct over-all stoichiometry. Comparing anions that work with those that do not work suggests that the lithium salt of the anion must be soluble in the solvent to be used and the acid of the anion should be a very strong acid. The fact that stable open-circuit potentials of 4.5V, loss of only

50% capacity on storage for one day, and cycle life of up to 33 2-hr cycles are observed suggests that the dimethyl sulfite-lithium perchlorate solution is at least marginally stable to oxidation and reduction over a 4.5V range relative to lithium.

Overpotential Behavior of Stabilized Zirconia Solid Electrolyte Fuel Cells

T. H. Etsell*,[1] and S. N. Flengas**

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The nature and characteristics of the overpotential in cells of the type

$Ar\text{-}O_2$, $H_2\text{-}H_2O$, or $CO\text{-}CO_2/ZrO_2\text{-}CaO/O_2$

were determined from 700° to 1100°C over a wide range of oxygen pressures. Porous Pt black electrodes were deposited on impervious ZrO_2 + 10 m/o (mole per cent) CaO tubes. Almost pure resistance polarization is observed when $Ar\text{-}O_2$ or $H_2\text{-}H_2O$ mixtures are present at the anode. However, for $Ar\text{-}O_2$ mixtures dilute in O_2 at the cathode, diffusion overpotential readily appears and limiting currents are eventually reached. Limiting currents, proportional to P_{O_2}, are controlled by the diffusion of gaseous oxygen in the pores of the Pt electrode. Based on the present results and adsorption data, a mechanism is proposed for the cathode reaction. For $CO\text{-}CO_2$ mixtures, transition overpotential associated with the reaction $CO_2 + 2e \rightleftharpoons CO + O^=$ is observed. The transition factor is about 0.5 and exchange current densities are in the vicinity of 1 mA/cm^2. Equations relating exchange current density to P_{CO}, P_{CO_2}, and the amount of CO adsorbed on the electrolyte are derived and compared with the experimental results. It is concluded that either gaseous or adsorbed CO and gaseous CO_2 are directly involved in the electrochemical step of the reaction.

Solid oxide electrolytes can be used in the construction of high-temperature fuel cells. Only ZrO_2-based electrolytes are suitable since they possess relatively high ionic conductivities and exhibit virtually pure oxygen-ion conduction between oxygen pressures of 1 and 10^{-20} atm at 1000°C (1).

The overpotential behavior of such cells is of interest from both theoretical and practical viewpoints. Nevertheless, only a limited amount of research has been done in this area and there is considerable disagreement among the available results on the overpotential at metal or oxide electrodes in contact with ZrO_2-based electrolytes and either O_2-inert gas (2-11), $H_2\text{-}H_2O$ (12-19), or $CO\text{-}CO_2$ (2, 6, 13, 14, 17, 20-23) mixtures.

Diffusion overpotential is generally observed with O_2-inert gas mixtures at the cathode, but the rate-determining step of the over-all cathode reaction has been concluded to be the diffusion of oxygen atoms in the adsorbed phase at 810°C (3) and through the Pt electrode at 560°C (9, 10), mass transport in the gas phase at 1000°C (6, 7), and either the dissociation of oxygen molecules or the electron transfer step at 400°-800°C (8). At high applied potentials, either oxygen transfer into the electrolyte (9, 10) or electronic conduction in the electrolyte (10) can be rate-limiting. Unspecified overpotential has been reported at the anode (3-5).

Even in atmospheres of oxygen (6, 8, 18, 24-26) and air (4, 6, 9), overpotential has been detected at the electrodes and attributed to slow diffusion processes at 560°-1000°C (4, 6, 9), Pt-O interactions at 600°-1000°C (24), a slow electrochemical step at 900°-1000°C (25), and a constriction resistance at 650°-800°C (26). In the latter case, the Ag cathode was only active at discrete spots which necessitated regions of high current density in the electrolyte. However, in other investigations, significant overpotential at high oxygen pressures has not been observed (2, 5, 11, 15). Impedance measurements have both supported (8, 25, 27, 28) and refuted (29) the existence of overpotential in oxygen and air. Likewise, for $H_2\text{-}H_2O$ mixtures, the possibility of overpotential at the anode from 600°-1100°C has been both confirmed (15, 18, 19) and denied (12-14, 16, 17).

In the case of $CO\text{-}CO_2$ mixtures, diffusion overpotential (6, 13, 20, 21, 23), transition overpotential (20, 21),

[1] Present address: Max-Planck-Institut für Chemie, 65 Mainz, Saarstrasse 23, West Germany.

Key words: zirconia, solid electrolyte, oxide, overpotential, fuel cell.

and reaction overpotential (20) at 800°-1000°C have all been reported. Tafel behavior is often followed (2, 6, 14, 20, 21) although, except in two studies (20, 22), mechanisms have not been given to account for the results. There is serious disagreement concerning the value of the transition factor (2, 14, 20) and the influence of gas composition on overpotential (13, 14, 20, 21). Nickel anodes complicate the analysis due to the formation of NiO (30-32).

The above inconsistencies reflect, in part, the important influence of the electrode on overpotential when gas mixtures are in contact with solid electrolytes. Its composition, structure, and porosity must often be carefully controlled to obtain reproducible results. Electrode structure has recently been shown to be a highly significant variable (10).

To help resolve these discrepancies, current-potential characteristics of porous Pt electrodes in contact with ZrO_2-CaO electrolytes were determined at 700°-1100°C over a wide range of oxygen pressures which were controlled by Ar-O_2 (1 to 10^{-6} atm), CO-CO_2 (10^{-5} to 10^{-21} atm), and H_2-H_2O (10^{-20} to 10^{-23} atm) mixtures. The curves were analyzed to separate the contributions from various types of overpotential. Mechanisms are proposed for the electrode reactions in Ar-O_2 and CO-CO_2 mixtures.

Experimental

The solid electrolytes were impervious ZrO_2 + 10 m/o CaO tubes, closed flat at one end. They exhibited excellent stability when cycled between 700° and 1100°C for two months since their resistances remained unchanged. The closed ends of the tubes were platinized on both sides by applying drops of a 1:1 mixture of a 3-5% chloroplatinic acid solution and formaldehyde solution to the faces which were then heated to 600°-700°C. This procedure, repeated twice for each face, resulted in adherent, porous, fine-grained Pt black deposits.

As illustrated in Fig. 1, a 24-in. long electrolyte tube with an ID of 9.5 mm and OD of 13.5 mm was placed inside a quartz tube with an ID of 15.5 mm and OD of 19 mm which had been made as flat as possible on the bottom. The 6.5-mm alumina rod inside the electrolyte tube contained two 1.5-mm holes which served to hold a 20-mil Pt lead wire and transport gas into the cell. Small slits were cut into the bottom of this rod to facilitate the gas flow. To minimize contact resistance, three springs located at 120° intervals around the top of the cell held the circles of 45-mesh Pt gauze (18 mils thick) firmly against the platinized surfaces of the electrolyte. Irregularities in these surfaces and the inside of the bottom of the quartz tube rendered complete elimination of contact resistance difficult. The lower two Tygon tubing seals kept the pressure approximately constant despite expansion and contraction of the ceramic components during temperature cycling.

Generally, the purified and preanalyzed gas mixtures were passed into the outer compartment. The 6-in. long quartz preheating chamber with an ID of 10 mm, which contained pieces of 1-mil Pt foil, enabled high flow rates to be used without cooling the cell. The constriction at the top of the preheating chamber was made to give the quartz tube added mechanical strength. Oxygen flowed through the inner Pt gauze to form the reference electrode. All of the gases were passed at 1 atm total pressure. Temperature measurements were taken with a Pt-Pt+13% Rh thermocouple welded to the outer Pt gauze.

Potentials were applied to the cell using a circuit consisting of a rectifier and several variable resistors. Potential and current readings were taken with a Weston d-c voltmeter and milliammeter. Upon interrupting the circuit, the cell potential could be recorded quickly and accurately with a Radiometer Universal pH meter. Alternating-current resistance measurements were made with a conductivity bridge equipped with an oscilloscope detector which was supplied by Industrial Instruments (Model RC-18).

Initially, the cells were heated to 1100°C for several hours to reduce contact resistance and partially sinter the Pt black deposits. Reproducible overpotential and resistance results upon temperature cycling could then be obtained.

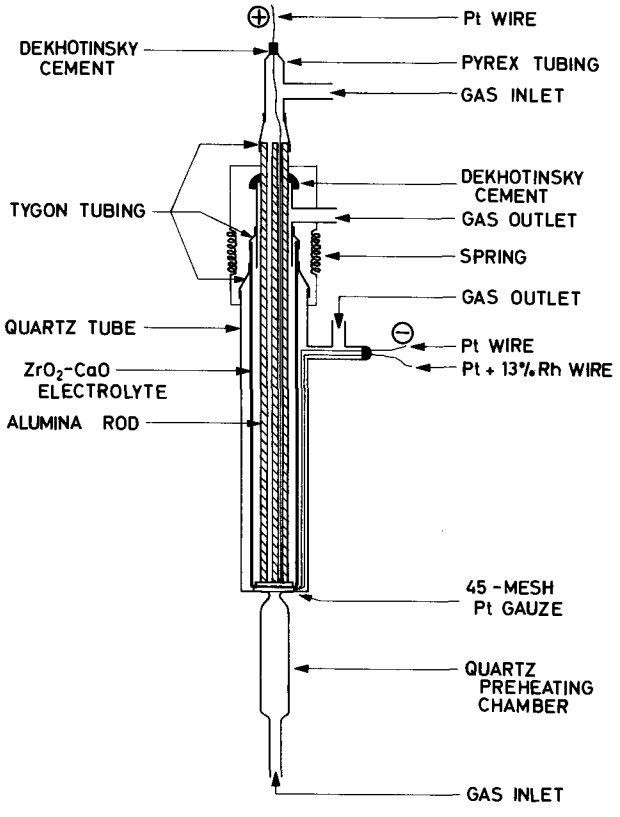

Fig. 1. Cell design for overpotential measurements

Results and Discussion

Close agreement between measured and theoretical emf values (±0.5%) verified the pure ionic conductivity of the electrolyte tubes and the reversibility of the electrodes. Usually, the electrolytes had a-c resistances measured at 3000 Hz of about 1000, 180, 40, and 20 ohms at 700°, 850°, 1000°, and 1100°C, respectively. Occasionally, values which were 15-20% lower than these were found.

Gas flow rates are reported as room-temperature linear speeds based on an approximate area of 0.5 cm^2 for the inlet tube immediately below the outer Pt electrode. High flow rates were used to minimize both concentration effects and the influence of oxygen reaching the outer electrode from the reference electrode because of slight porosity and electronic conductivity in the solid electrolyte. Current densities are based on the geometric area of the outer electrode (1.0 cm^2).

Overpotential measurements were not influenced by the previous history of the cell. The electrodes were sufficiently porous to resist any significant changes in their structure even when treated anodically at high current densities.

Ar-O_2 mixtures.—Current-potential characteristics for O_2 and Ar-O_2 mixtures at 1000°C are shown in Fig. 2. For the Ar-O_2 mixtures, each curve was shifted to pass through the origin by subtracting the appropriate emf from the applied potential.

An important feature of Fig. 2 is that, when pure oxygen is present at both electrodes, only resistance polarization is observed. The slope of the O_2 line, corresponding to the d-c resistance, is virtually identical to the a-c resistance of the electrolyte. This agreement was checked to 250 mA/cm^2 at 1000°C and to 400 mA/

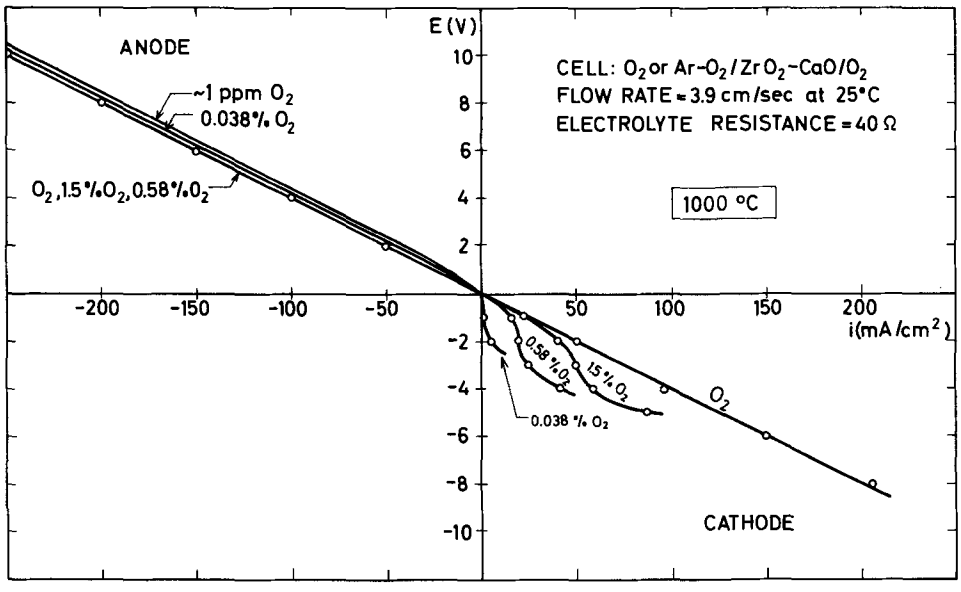

Fig. 2. Anode and cathode characteristics for O_2 and Ar-O_2 mixtures at 1000°C.

cm^2 at 1100°C. Therefore, the reference Pt,O_2 electrode is nonpolarizable and any overpotential can be attributed to the gas mixtures at the outer Pt electrode.

Anodic overpotenial is quite low even for Ar-O_2 mixtures dilute in O_2. At high current densities, the slopes of the lines approximate the a-c resistance of the electrolyte since resistance polarization predominates.

However, cathodic overpotential in the presence of Ar-O_2 mixtures is very high and increases markedly as the oxygen concentration decreases. A tendency towards limiting currents followed by breakdown of the oxide electrolyte at high applied potentials is apparent in Fig. 2. These features are also evident at 700° and 850°C from the curves in Fig. 3 which again have been shifted, when necessary, to pass through the origin. Only resistance polarization was detected with pure oxygen at the cathode. In the breakdown region, the currents increased slowly with time and were recorded after the applied potential had been held constant for 5 min. If sufficient time was allowed, these currents became constant. Breakdown generally occurred when the overpotential exceeded 1.9, 1.7, 1.6, and 1.5V at 700°, 850°, 1000°, and 1100°C, respectively. It did not

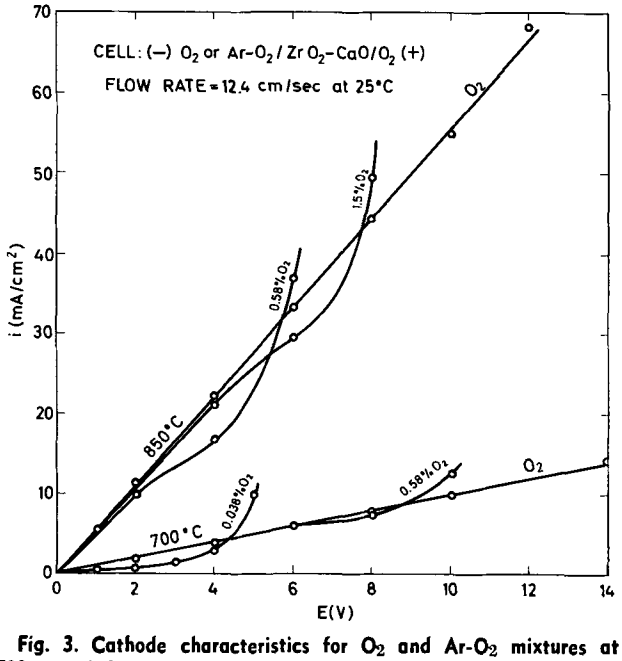

Fig. 3. Cathode characteristics for O_2 and Ar-O_2 mixtures at 700° and 850°C.

lead to any irreversible changes in the electrolyte tubes. Larger currents can cause destabilization of cubic zirconia leading to cracking (11, 33) and an increase in the resistance of the ceramic electrolytes (33).

The over-all cathode reaction which involves three phases is

$$O_{2,g} + 4e \rightarrow 2\,O^{=} \qquad [1]$$

whereby oxygen gas combines with electrons in the electrode to form oxygen ions in the electrolyte. If insufficient oxygen is available due to slow diffusion, adsorption, or dissociation processes near the electrode-electrolyte interface, concentration overpotential will be observed and limiting currents should be realized when the oxygen activity at the surface of the electrolyte becomes negligible with respect to the oxygen activity in the bulk of the gas phase. At high applied potentials, the surface oxygen activity becomes low enough to partially reduce the electrolyte resulting in n-type conductivity. The current increases since a direct electron exchange between the electrode and electrolyte can now occur (3, 9, 10, 34). While the reduced zone slowly spreads towards the anode (34, 35) during which time more $O^{=}$ ions migrate from the cathode side of the electrolyte than are produced via reaction [1], the current continues to increase. Accordingly, the apparent breakdown voltage will be somewhat dependent upon the loading rate, particularly when the electrolyte resistance is high. Conditions favoring breakdown of an oxide electrolyte are low oxygen pressures at the cathode, high current densities, and high temperatures.

A more detailed study of the limiting currents was carried out (smaller applied potential increments) as indicated by the results in Fig. 4. The combination of limiting currents and electrolyte breakdown makes the curves similar in appearance to polarographic waves. Plateaus were not reached when applied potentials exceeding 2V were required, *i.e.*, at low temperatures because of the high resistance of the electrolyte. This is, perhaps, an indication of the inhomogeneous nature of the cathode-electrolyte interface. In regions where the Pt black deposit is very porous, the oxygen activity at the surface of the electrolyte could still be appreciable whereas, in regions where dense Pt particles shield the electrolyte from oxygen, it could be low enough to cause some reduction of the electrolyte.

Regarding the nature of the overpotential, it should be noted that the initial slopes of the curves in Fig. 2-4 for Ar-O_2 mixtures $[(dE/di)_{i=0}]$ were higher than the corresponding a-c resistance, *e.g.*, about 5 and 50% higher at 1000°C for 0.58% and 0.038% O_2, respectively. This difference can be explained by an analysis of Fig.

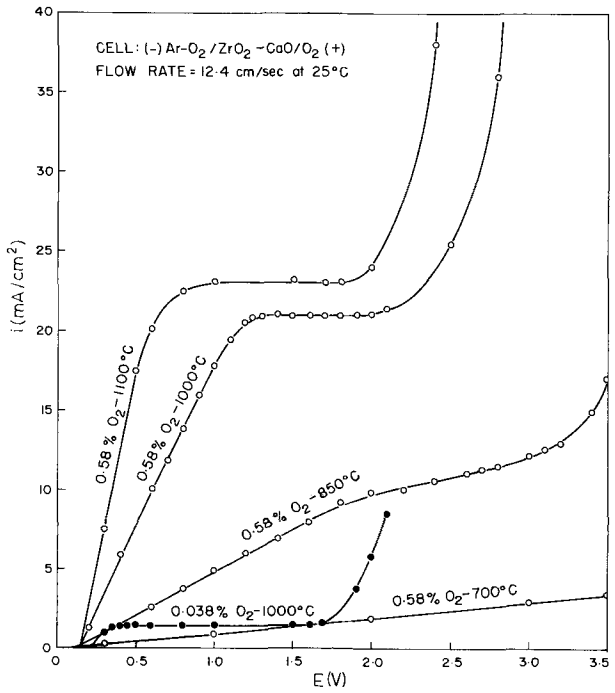

Fig. 4. Current density vs. applied potential with Ar-O_2 mixtures dilute in O_2 at the cathode.

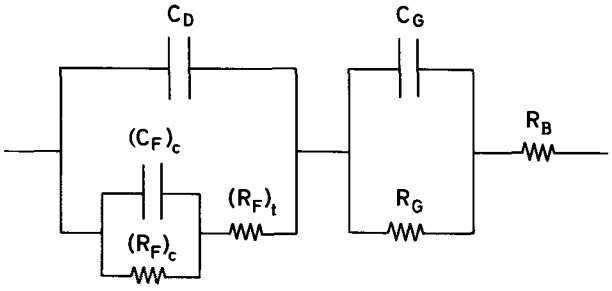
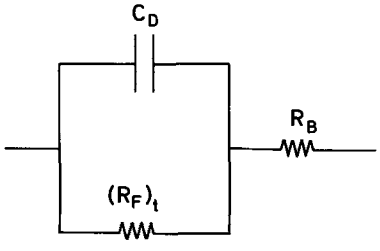
5 which is considered to represent the equivalent circuit for a polycrystalline ionic conductor in either a conductivity or electrochemical cell (see the caption



(a) at low frequencies



(b) at high frequencies

Fig. 5. Equivalent circuit diagram for a polycrystalline ionic conductor in a conductivity or electrochemical cell. Only one electrode-electrolyte interface is shown: C_D, double-layer capacitance; $(C_F)_c$ and $(R_F)_c$, Faraday capacitance and resistance, respectively, resulting from concentration overpotential (slow mass transport or chemical reaction); $(R_F)_t$, Faraday resistance resulting from transition overpotential (slow electrochemical reaction); C_G and R_G, grain boundary capacitance and resistance, respectively, due to grain boundaries, inter-particle contacts, and free surfaces within the sintered polycrystalline electrolyte; R_B, bulk electrolyte resistance (includes contact resistance between the electrode and electrolyte).

for meaning of symbols). Both $(C_F)_c$ and $(R_F)_c$ decrease as the frequency increases whereas $(R_F)_t$ is independent of frequency. At high frequencies, $(R_F)_c$ is "shorted-out" by $(C_F)_c$ which, in turn, has a negligible reactance compared to the resistance of $(R_F)_t$. A similar situation exists for C_G, R_G, and R_B. The value of $(R_F)_t$ can be determined by extrapolating a plot of the total Faraday resistance *vs.* $f^{-1/2}$ where f is the measuring frequency to $f^{-1/2} = 0$ (29). At very high frequencies, the current through $(R_F)_t$ is shunted through C_D. Hence, three possibilities for the total resistance, R_T, can be distinguished:

1. $R_T = (R_F)_c + (R_F)_t + R_G + R_B$ $(f \geqq 0)$
2. $R_T = (R_F)_t + R_B$ $(f >> 0)$
3. $R_T = R_B$ $(f \to \infty)$

From the present results, $R_{d\text{-}c} = R_{a\text{-}c}$ in pure oxygen where $R_{d\text{-}c}$ is the d-c resistance (R_T at $f = 0$ and $i = 0$) and $R_{a\text{-}c}$ is the a-c resistance (R_T at $f = 3000$ Hz). The measuring frequency of 3000 Hz was high enough for case 3 to apply because $R_{a\text{-}c}$ was independent of oxygen pressure contrary to the expected behavior of $(R_F)_c$ and $(R_F)_t$, $R_{a\text{-}c}$ was unaffected by increasing the frequency to 10,000 Hz, and, assuming $C_D = 100$ μF/cm² (8), its reactance at 3000 Hz is only 0.5 ohm meaning that C_D would serve as an effective current shunt for $(R_F)_t$ if $(R_F)_t$ were appreciable. Therefore, in pure oxygen, $(R_F)_c$, $(R_F)_t$, and $R_G \sim 0$.

As mentioned, however, $R_{d\text{-}c} > R_{a\text{-}c}$ in Ar-O_2 mixtures. Since R_G is independent of oxygen pressure, $R_G \sim 0$. Consider $(R_F)_t$. For an electrochemical reaction involving only oxygen species

$$i_o \propto \theta_O^{1-\alpha} (1 - \theta_O)^{\alpha} \qquad [2]$$

where i_o is the exchange current density, α is the transition factor or transfer coefficient, and θ_O and $1 - \theta_O$ are the fractions of electrochemically active sites which are occupied by adsorbed oxygen atoms and which are free, respectively (see Eq. [19]). Consequently, for $\alpha = 0.5$, i_o is a maximum at $\theta_O = 0.5$. Oxygen atoms are strongly chemisorbed on Pt and ZrO_2. For the reaction

$$O_{2,g} \to 2\ O_{ad} \qquad [3]$$

at 25°C, $\Delta H°_{ad}$ on Pt black $= -60$ kcal/mole (36) where the standard states are $O_{2,g}$ at 1 atm and O_{ad} at $\theta_O = 0.5$. Chemisorption ceases after one monolayer is formed (36, 37) and the adsorbed atoms are mobile (36). Desorption was not observed when Pt was heated to 840°C at $P_{O_2} = 10^{-10}$ atm (38). At 400°-900°C, ΔH_{ad} (integral heat) on ZrO_2 powder ~ -80 kcal/mole (39). It was not determined whether the adsorbed atoms are mobile or localized. Adsorption proceeds with activation energies of zero for Pt (38, 40) and 58 kcal/mole for ZrO_2 (39). To estimate the amount of adsorption at high temperatures, consider $\Delta G°_{ad}$ at 1000°C for reaction [3]. At 1000°C, $S°_{O_{2,g}} = 60.2$ cal/mole-°K (41). If the adsorbed species is very mobile, it can be roughly approximated to be a two-dimensional gas. Since the adsorbed oxygen concentration $\sim 5 \times 10^{14}$ atoms/cm² ($\theta_O = 0.5$), an expression for the translational entropy of a two-dimensional ideal gas (42) gives $S°_{O_{ad}} = 18.3$ cal/g atom-°K at 1000°C. The vibrational contribution, which is small (42), and any change in the entropy of the adsorbent will be neglected. Thus, $\Delta S°_{ad} = -23.6$ cal/mole-°K for reaction [3]. Assuming $\Delta H°_{ad} = -60$ kcal/mole yields $\Delta G°_{ad} = -30$ kcal/mole at 1000°C. Therefore, $\theta_O \sim 1$ at $P_{O_2} = 1$ atm and $\theta_O = 0.5$ at $P_{O_2} \sim 10^{-5}$ atm. Referring to Eq. [2], it is now evident that i_o will increase and, therefore, $(R_F)_t$ will decrease as the oxygen pressure decreases at high oxygen pressures. Accordingly, in Ar-O_2 mixtures, $(R_F)_t \sim 0$ and

$$R_{d\text{-}c} = (R_F)_c + R_{a\text{-}c} \qquad [4]$$

Low transition overpotential in stabilized zirconia cells is supported by investigators who have reported

that, at 1000°C, i_0 = 100 to >1000 mA/cm² at solid electrodes (43) and 600 mA/cm² at liquid electrodes (44). Bauerle (8) recently suggested the possibility of a slow electron transfer step at 400°-800°C. As the resistance to the electrode reaction had a high activation energy (2-2.5 eV), it could be negligible at high temperatures. The activation energy for the resistance of the electrolytes used here was determined to be 1.1 eV.

From Eq. [4], concentration overpotential is solely responsible for the deviations from ideal behavior ($R_{d\text{-}c} = R_{a\text{-}c}$) in Fig. 2-4. Assuming for the moment that this overpotential arises from a slow diffusion process, the diffusion overpotential, η_d, can be simply calculated from the relationship

$$\eta_d = E - E_{rev} - IR_{a\text{-}c} \quad [5]$$

where E is the applied potential, E_{rev} is the reversible potential ($I = 0$), and I is the current. Equation [5] was verified by noting that, upon opening the circuit, the overpotential did not decay rapidly and was initially equal to the total overpotential. Based on Fick's first law, diffusion overpotential can be expressed as

$$\eta_d = \frac{RT}{nF} \ln \frac{i_l}{i_l - 1} \quad [6]$$

where n is the number of electrons associated with the slow diffusing species that are involved in the electrode reaction and i_l is the limiting current density. The plot in Fig. 6, based on the data in Fig. 4 at 1000°C, indicates that $n = 4$. The points are less accurate when $\eta_d > 0.1$V (the theoretical slope for $n = 4$ is 0.063V). Thus oxygen molecules, rather than atoms, are involved in the rate-determining step. Further verification comes from Fig. 7 which shows that the limiting current density is directly proportional to the oxygen pressure. These results support the possibility of a "polarographic-like" technique to analyze gas mixtures for oxygen (45). However, limiting currents were not very reproducible from run to run since they are quite sensitive to the porosity and structure of the cathode. They increased somewhat with increasing flow rate.

Since $i_l \propto P_{O_2}$, substituting Eq. [6] into Eq. [5] gives

$$R_{d\text{-}c} = \left(\frac{\partial E}{\partial I}\right)_{I=0} = kP_{O_2}{}^{-1} + R_{a\text{-}c} \quad [7]$$

where k is a constant. Comparing Eq. [4] and [7] results in

$$(R_F)_c = kP_{O_2}{}^{-1} \quad [8]$$

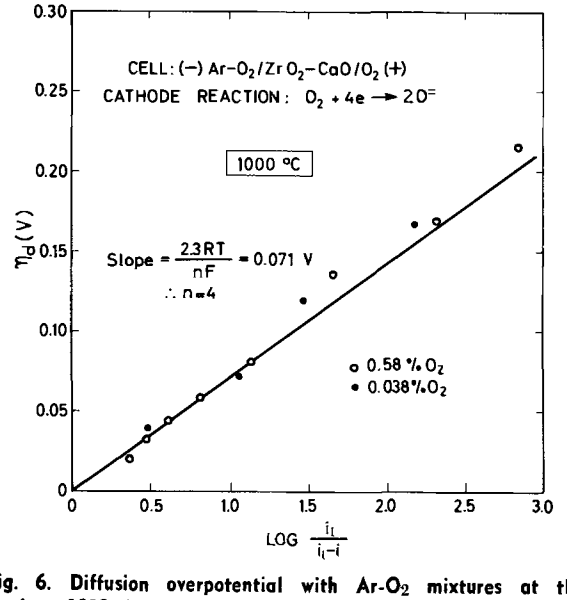


Fig. 6. Diffusion overpotential with Ar-O_2 mixtures at the cathode at 1000°C.

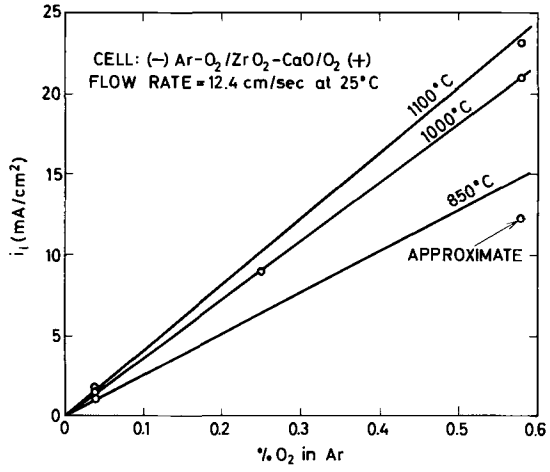

Fig. 7. Limiting current densities with Ar-O_2 mixtures at the cathode.

The quantity $(R_F)_c$ obeyed Eq. [8] and decreased slightly with increasing temperature.

Steps in the cathode reaction involving oxygen molecules include gas diffusion in the electrode pores and surface diffusion along the electrode and electrolyte. Also, the possibility of either slow adsorption or dissociation of oxygen molecules leading to reaction overpotential has not been eliminated. The fact that the limiting currents depended on the gas flow rate supports diffusion and convection in the gas phase as the slow step. Limiting currents increase with temperature (Fig. 7) in accordance with faster diffusion of oxygen molecules.

An earlier study on electrode processes in stabilized zirconia cells indicated that $i_l \propto P_{O_2}{}^{1/2}$ at 810°C (3). Such behavior could be attributed to slow diffusion of oxygen atoms through the electrode or along the electrode and electrolyte. The advantage of porous electrodes in providing oxygen with easier access to the electrolyte is apparent. Contrary to the present results, the plot did not pass through the origin (3). This was attributed to a competing direct electron exchange reaction, necessitating n-type conductivity in the electrolyte. However, the limiting currents appeared at $E <$ 1V corresponding to $P_{O_2} > 10^{-19}$ atm at 810°C. Even at $P_{O_2} = 10^{-19}$ atm, $t_e < 10^{-4}$ where t_e is the electronic transport number (1).

In conclusion, reaction [1] is considered to occur via the following mechanism:

$$O_{2,g}(\text{in bulk}) \rightarrow O_{2,g}(\text{in Pt pores}) \quad [1a]$$

$$O_{2,g}(\text{in Pt pores}) \rightleftharpoons O_{2,ad}(\text{on Pt}) \quad [1b]$$

$$O_{2,ad}(\text{on Pt}) \rightleftharpoons O_{2,ad}(\text{near tpb}) \quad [1c]$$

$$O_{2,ad}(\text{near tpb}) \rightleftharpoons 2\,O_{ad}(\text{near tpb}) \quad [1d]$$

$$2\,O_{ad}(\text{near tpb}) \rightleftharpoons 2\,O_{ad}(\text{at ers}) \quad [1e]$$

$$2\,O_{ad}(\text{at ers}) + 2V_O{}^{\cdot\cdot} \rightleftharpoons 2\,O_O + 4h^{\cdot} \quad [1f]$$

$$4h^{\cdot} + 4e' \rightleftharpoons 0 \quad [1g]$$

In this sequence, tpb means three-phase boundary (lines of contact where the electrode, electrolyte, and gas phases meet), ers means electrochemical reaction site, $V_O{}^{\cdot\cdot}$ is a doubly-ionized oxygen vacancy, O_O is an oxygen ion on a normal lattice site, $h^{\cdot}$ is an electron hole in the electrolyte, and e' is an excess electron in the electrode. Step [1a] is rate-controlling and involves the interdiffusion of oxygen and argon in the pores of the electrode deposited on the solid electrolyte. If simply the collision rate of oxygen gas with the electrode was rate-limiting, kinetic theory predicts that $i_l \sim 10^5$ mA/cm² at $P_{O_2} = 10^{-3}$ atm and 1000°C for an adsorption efficiency of unity. Also, the gas flow rate would have a negligible effect.

Oxygen molecules are then physically adsorbed onto a layer of chemisorbed oxygen atoms covering the electrode (step [1b]). Some direct access of the gas to the electrolyte via Pt channels is certainly possible in which case it reversibly adsorbs as mobile O_2^- ions which can later dissociate to atomic oxygen (46). Since oxygen molecules are not as strongly adsorbed as oxygen atoms [ΔH_{ad} of O_2 on Pt ~ -17 kcal/mole at 200°-400°C (40)], surface diffusion of oxygen molecules to the vicinity of a three-phase boundary (step [1c]) undoubtedly precedes dissociation (step [1d]). Subsequently, oxygen atoms diffuse relatively short distances along the surface of the electrode and electrolyte and through the electrode to electrochemical reaction sites at the surface of the electrolyte (step [1e]). Adsorbed atoms must enter the electrolyte (step [1f]) near a Pt particle so that electron holes can be neutralized quickly (step [1g]). Stabilized zirconia electrolytes will not support high concentrations of electron holes, even at oxygen pressures near 1 atm (1). Consequently, three-phase boundaries are required to minimize diffusion path lengths for oxygen atoms and to maximize the electrochemically active area at the electrolyte surface. The electrochemical step could also occur as follows:

$$2V_O^{\cdot\cdot} + 4e' \rightleftharpoons 2V_O \qquad [1f']$$

$$2\,O_{ad}(\text{at ers}) + 2V_O \rightleftharpoons 2\,O_O \qquad [1g']$$

Electrons are transferred across the electrode-electrolyte interface (step [1f']). If step [1g'] occurs at the gas-electrolyte interface, neutral oxygen vacancies, V_O, are obliged to migrate through the electrolyte. Since ionic migration is relatively slow, the importance of three-phase boundaries is again evident. Several authors have emphasized the necessity of maintaining as much three-phase contact as possible in cells with solid electrodes and oxide electrolytes (3, 4, 9, 47).

Overpotential at the anode (Fig. 2) was most likely observed because either step [1d] or [1a] is slow going to the left resulting in reaction or diffusion overpotential, respectively. An activation energy of about 90 kcal/mole is required to combine oxygen atoms adsorbed on ZrO_2 (39).

Some open-circuit irreversibility of the electrode was noted for Ar-O_2 mixtures very dilute in O_2 (~1 ppm), *i.e.*, the thermodynamic emf was established very slowly upon passing such mixtures into the system. At low oxygen contents, equilibrium between the gas and strongly adsorbed oxygen atoms (<1 monolayer) must be achieved. Step [1d] is probably slow to the left and the gas has a low capacity to chemically remove previously adsorbed species. Overpotential might be expected since the concentration of adsorbed oxygen molecules is very low (8). Accordingly, more oxygen atom diffusion (step [1e]) will be required.

H_2-H_2O mixtures.—Included in the discharge curves presented in Fig. 8 are results for two H_2-H_2O mixtures at the anode at 1000°C. The more dilute mixture contained less than 50 ppm H_2O, but emf measurements indicated that this was the concentration at the electrode-electrolyte interface. Oxygen arrives from the reference electrode compartment due to slight permeability of the electrolyte caused by electronic conductivity. Its influence was minimized by using a high flow rate at the anode. Also, as the cell potential decreases, electronic current in the electrolyte decreases (48). With H_2 as fuel, the cell discharges reversibly. The slopes of the curves ($E < 1.0$V) approximate the a-c resistance of the electrolyte. Overpotential decay characteristics revealed the presence of a small amount of concentration overpotential which was especially significant at low current densities and arose because of a buildup of H_2O at the anode.

CO-CO_2 mixtures.—Marked overpotential is evident in Fig. 8 with CO-CO_2 mixtures at the anode. It was particularly significant (with respect to resistance polarization) at low current densities and limiting currents were not approached, even when 200 mA/cm² at 1000°C and 300 mA/cm² at 1100°C were passed through the cell with the fuel electrode positive—characteristics of transition overpotential. Diffusion overpotential complicates the behavior of the 0.016% and 0.77% CO compositions. Enough CO was not available to maintain the anode reaction. For these gases, a weak dependence of current on flow rate was noted.

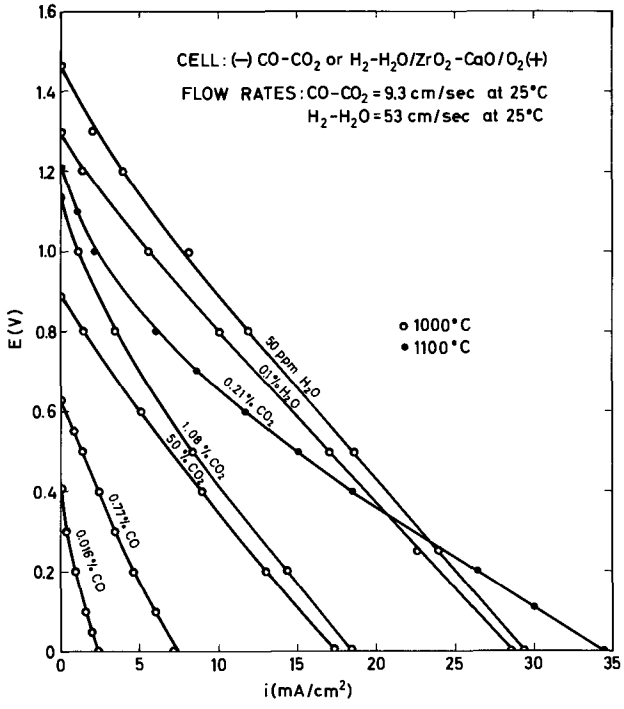

Fig. 8. Fuel cell discharge curves at 1000° and 1100°C

Transition or charge-transfer overpotential, η_t, was calculated from the equation

$$\eta_t = E_{rev} - E - IR_{a\text{-}c} - \eta_d \qquad [9]$$

where E is the cell potential. Small η_d contributions (<0.05V) were determined from cell potential measurements immediately after interrupting the current (η_d decayed much slower than η_t).

Transition overpotential can be expressed by the Tafel equation

$$\eta_t = -\frac{RT}{\alpha n\mathbf{F}} \ln i_o + \frac{RT}{\alpha n\mathbf{F}} \ln i \qquad [10]$$

where n is the number of electrons involved in the slow transition step. This equation applies when the rate of the reverse reaction is negligible compared to that of the forward reaction. A Tafel plot for the 0.21% CO_2 mixture at 1100°C is shown in Fig. 9. No carbon deposition at the anode was observed with this mixture [carbon is thermodynamically stable below 1112°C (41)]. From the slope, $\alpha n \sim 1$, *i.e.*, $\alpha \sim 0.5$ and $n = 2$ (the theoretical slope for $\alpha n = 1$ at 1100°C is 0.272V). From an extrapolation to $\eta_t = 0$, $i_o = 0.6$ mA/cm².

To study the cathode reaction and enable the behavior of CO-CO_2 mixtures dilute in CO to be more readily analyzed, the curves in Fig. 10 were obtained. Reversible potentials have been subtracted from applied potentials so that all the curves pass through the origin. Points below 3V at 700°C have been omitted. Breakdown of the electrolyte is evident at 700° and 850°C and appears at lower applied potentials as the CO_2 concentration decreases. Transition overpotential was determined with an expression similar to Eq. [5]. Again, small η_d contributions (<0.1V) were subtracted. Tafel plots for six curves in Fig. 10 are presented in Fig. 11. When $\eta_t < 0.2$V, the points deviate to the left of the lines since the rate of the reverse reaction cannot be neglected. In every case, $\alpha n \sim 1$

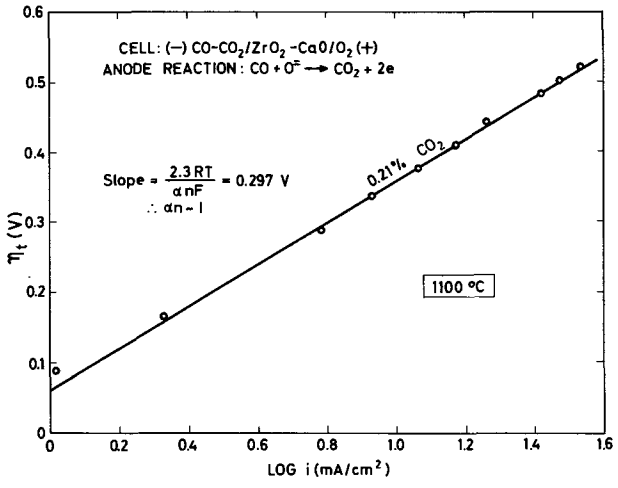

Fig. 9. Tafel plot for a CO + 0.21% CO_2 mixture at the anode at 1100°C.

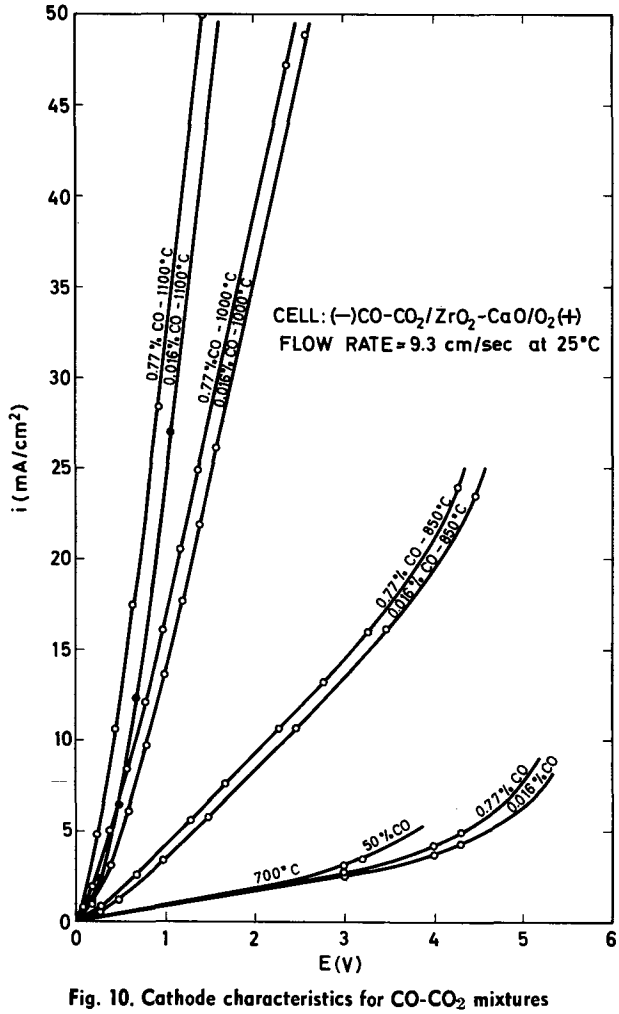

Fig. 10. Cathode characteristics for CO-CO_2 mixtures

(α = 0.46-0.52). Exchange current densities range between 0.1 and 1.6 mA/cm^2. They increase as either temperature or the CO concentration increases. Because of the large $IR_{a\text{-}c}$ drop at 700°C, accurate determination of η_t was difficult. Tafel plots indicated that $i_o \sim 0.05$ and 0.15 mA/cm^2 for the 0.016% and 0.77% CO compositions, respectively. Nevertheless, the a-c resistance of the electrolyte did not influence the Tafel parameters, *e.g.*, values for i_o at 1000°C of 1.1 mA/cm^2 for 0.77% CO and 1.3 mA/cm^2 for 0.89% CO were determined with a-c resistances of 40 and 95 ohms, respectively.

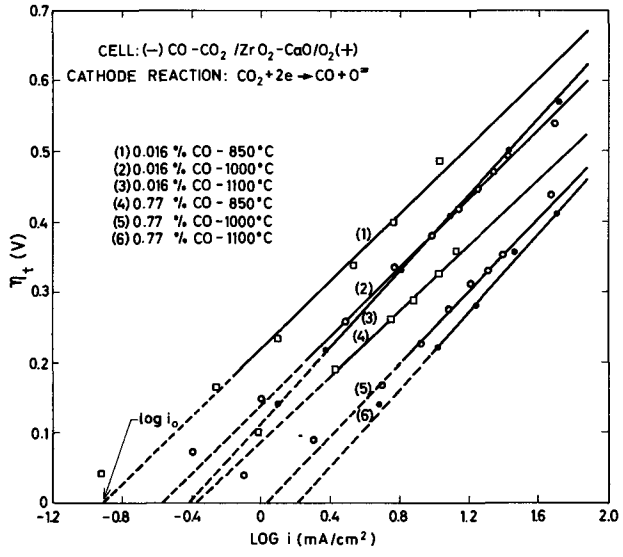

Fig. 11. Tafel plots for CO-CO_2 mixtures dilute in CO at the cathode.

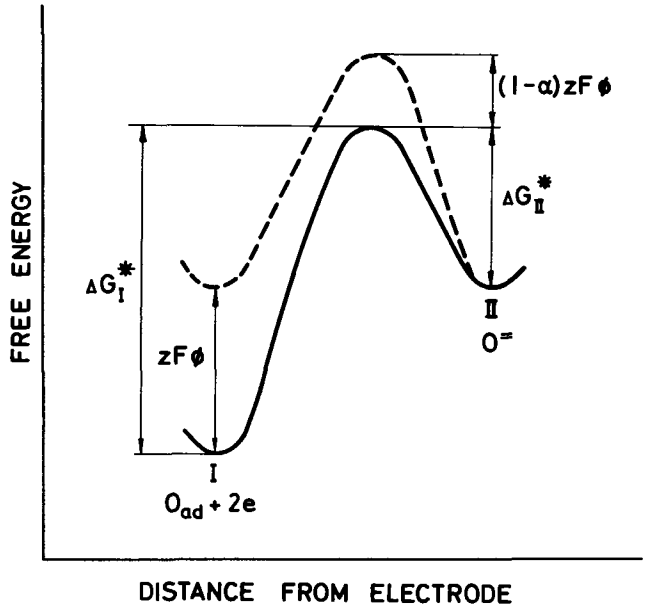

Fig. 12. Free energy profiles at the surface of an oxide electrolyte: ——— chemical free energy before any charge is transferred across the energy barrier, - - - - - electrochemical free energy at equilibrium; α, transition factor, *i.e.*, the fraction of the distance across the Helmholtz double layer where the transition state is located; z, valence of the ions crossing the barrier; ϕ, electrode potential with respect to the bulk of the oxide electrolyte; ΔG_I^* and ΔG_{II}^*, chemical free energies of activation from the initial state (I) and the final state (II) to the transition state, respectively. The pre-electrode state and state II (ϕ = 0) are often equivalent if the potential drop in the diffuse double layer can be neglected—a reasonable assumption for solid ionic conductors.

Regarding the mechanism of the electrode reaction in CO-CO_2 mixtures, the electrochemical equilibria in an oxide electrolyte cell involve the transfer of oxygen across the gas-electrolyte or electrode-electrolyte interface according to

$$O_{ad} + 2e \rightleftharpoons O^= \qquad [11]$$

Oxygen passes through an energy barrier or transition state as schematically drawn in Fig. 12 (symbols are explained in the caption). In this example, electrochemical equilibrium is established after a sufficient number of $O^=$ ions have left the electrolyte to equalize

the free energies of states I and II. Consequently, the double layer consists of electrons in the electrode facing doubly ionized oxygen vacancies at the surface of the electrolyte, ϕ is negative, and $z = -2$. Naturally, for the thermodynamic electrode potential to be established, adsorbed oxygen atoms must be in equilibrium with the gas phase.

The equilibrium given by Eq. [11] and depicted in Fig. 12 (dashed curve) is more fully expressed as

$$O_{ad} + V_O^{\cdot\cdot} + 2e' \rightleftharpoons O_O \qquad [12]$$

which represents the over-all electrochemical equilibrium when only oxygen species participate. The reversible electrode potential, ϕ_{rev}, is

$$\phi_{rev} = \phi^o + \frac{RT}{2F} \ln \frac{\theta_O[V_O^{\cdot\cdot}]}{[O_O](1 - \theta_O)} \qquad [13]$$

where ϕ^o is the standard electrode potential. It includes activity coefficients which are assumed to be constant, *i.e.*, adsorption is assumed to follow a Langmuir isotherm. Adsorbed species other than oxygen atoms occupying electrochemically active sites would simply make the fraction of free sites $1 - \theta_O - \theta_t$ where θ_t is the total fraction of the sites occupied by the additional species. Based on absolute reaction-rate theory, the current in the forward (cathodic) direction, $\vec{i}$, is

$$\vec{i} = k_1\theta_O[V_O^{\cdot\cdot}] \exp [-(\Delta G_I^{o*} - \alpha z\mathbf{F}\phi)/RT] \qquad [14]$$

where k_1 includes $n\mathbf{F}$, a transmission coefficient, and the vibration frequency of the activated species (kT/h), and ΔG_I^{o*} is the standard chemical free energy of activation from state I to the transition state. Similarly

$$\overleftarrow{i} = k_2[O_O](1 - \theta_O) \exp [-(\Delta G_{II}^{o*} + (1 - \alpha)z\mathbf{F}\phi)/RT] \qquad [15]$$

When the reversible potential is established ($\phi = \phi_{rev}$)

$$\vec{i} = \overleftarrow{i} = i_o \qquad [16]$$

Substituting Eq. [13] and [16] into Eq. [14] and recalling that $z = -2$ gives

$$i_o = k_1\theta_O[V_O^{\cdot\cdot}] \exp [-(\Delta G_I^{o*} - \alpha z\mathbf{F}\phi^o)/RT] \left(\frac{[O_O]^\alpha(1 - \theta_O)^\alpha}{\theta_O{}^\alpha[V_O^{\cdot\cdot}]^\alpha}\right) \qquad [17]$$

Therefore

$$i_o = k_3[V_O^{\cdot\cdot}]^{1-\alpha}[O_O]^\alpha\theta_O{}^{1-\alpha}(1 - \theta_O)^\alpha \qquad [18]$$

An identical equation is derived upon substituting Eq. [13] and [16] into Eq. [15]. For $\alpha \sim 0.5$, i_o increases as the electrolyte vacancy concentration increases (the fraction of vacant sites is always less than 0.5). For a given electrolyte composition

$$i_o = k_4\theta_O{}^{1-\alpha}(1 - \theta_O)^\alpha \qquad [19]$$

Equation [19] semiquantitatively describes the relationship between i_o and θ_O. Because of the simplifying assumption that adsorption obeys a Langmuir isotherm, k_4 cannot be regarded as constant over the entire range $0 < \theta_O < 1$, but may be approximately constant if $\theta_O < 0.1$ or $\theta_O > 0.9$.

At the Pt,CO-CO_2 electrode, the over-all equilibrium is

$$CO_{2,g} + 2e \rightleftharpoons CO_g + O^= \qquad [20]$$

Excluding diffusion processes which were found to be relatively rapid, a possible mechanism for the electrode reaction is

$$CO_{2,g} \rightleftharpoons CO_g + O_{ad} \qquad [20a]$$

$$O_{ad} + 2e \rightleftharpoons O^= \qquad [20b]$$

whereby atomic oxygen is adsorbed on either the electrode or electrolyte in step [20a] and diffuses, if necessary, to electrochemically active sites to participate in step [20b]. Nevertheless, step [20a] must occur near three-phase boundaries since the flux of adsorbed oxygen will be very low at the low oxygen pressures under consideration. Studies of the oxidation of CO on Pt (40, 49, 50) have shown that step [20a] is quite rapid. A similar reaction involving CO_{ad} on Pt (50) or ThO_2 (51), a fluorite-type oxide similar to stabilized ZrO_2, is less probable since CO is strongly chemisorbed. For the reaction

$$CO_g \rightarrow CO_{ad} \qquad [21]$$

at 25°C, ΔH_{ad} on Pt $= -48$ kcal/mole (38, 52) and on $ThO_2 = -17$ kcal/mole (51) at low coverage. On both Pt (38, 50) and ThO_2 (51), the process is virtually nonactivated. Consequently, chemisorbed CO might only serve to block reaction sites. This argument does not preclude the possibility of CO physically adsorbing onto chemisorbed oxygen atoms. Carbon dioxide is not adsorbed on Pt at 25°-1400°C (53, 54) or on ThO_2 above 600°C (55).

In the preceding sequence, if step [20b] is slow, transition overpotential will be observed and the discussion based on Fig. 12 will apply. Equation [19] simply becomes

$$i_o = k_4\theta_O{}^{1-\alpha}(1 - \theta_{CO})^\alpha \qquad [22]$$

In CO-CO_2 mixtures, $\theta_{CO} >> \theta_O$ and, therefore, the fraction of free sites $\sim 1 - \theta_{CO}$. Step [20a] will be in equilibrium and its equilibrium constant is

$$K = \frac{P_{CO}\theta_O}{P_{CO_2}(1 - \theta_{CO})} \qquad [23]$$

Rearranging Eq. [23] and substituting into Eq. [22] yields

$$i_o = k_5(1 - \theta_{CO}) \left(\frac{P_{CO_2}}{P_{CO}}\right)^{1-\alpha} \qquad [24]$$

Contrary to the results of this investigation and two other studies (14, 21), Eq. [24] predicts that i_o continuously decreases as the CO/CO_2 ratio increases. From Fig. 9 and 11, $i_o \sim 0.5$ mA/cm^2 for 0.02% and 99.79% CO at 1100°C.

Step [20a] has been suggested as the rate-determining process (20). Reaction overpotential, η_r, would appear due to an accumulation or depletion of adsorbed oxygen at the electrolyte surface. Since step [20b] will be in equilibrium, then, from Eq. [13]

$$\eta_r = \frac{RT}{2F} \ln \frac{\theta_O(1 - \theta_{O,rev})}{\theta_{O,rev}(1 - \theta_O)} \qquad [25]$$

where $\theta_{O,rev}$ and $1 - \theta_{O,rev}$ are the fractions of available active sites occupied by adsorbed oxygen atoms and free, respectively, at the reversible potential ($i = 0$) and θ_O and $1 - \theta_O$ are the corresponding fractions at current density i. A relationship between η_r and i for a given CO-CO_2 mixture is required and, therefore, θ_{CO} is constant (reaction [21] is in equilibrium). Any dependence of adsorption on potential is assumed to be negligible. Adsorbed CO serves only to block a constant number of chemically active sites and, consequently, θ_O is based here on the number of available active sites, rather than the total number of active sites.

The net current density resulting from step [20a] is

$$i = k_6(1 - \theta_O) - k_7\theta_O \qquad [26]$$

In Eq. [26], $i = 2\mathbf{F}v$ where v is the net velocity of reaction [20a]. Cathodic current is positive. Conditions are chosen so that P_{CO} and P_{CO_2} are unaffected by current. At equilibrium, $i = 0$ meaning that

$$i_o = k_6(1 - \theta_{O,rev}) = k_7\theta_{O,rev} \qquad [27]$$

In this sense, $i_o = 2\mathbf{F}v_o$ where v_o is the reaction exchange velocity. Inserting Eq. [27] into Eq. [26] gives

$$i = i_o \left(\frac{1 - \theta_O}{1 - \theta_{O,rev}}\right) - i_o \left(\frac{\theta_O}{\theta_{O,rev}}\right) \qquad [28]$$

Rearranging Eq. [28] and substituting into Eq. [25] leads to

$$\eta_r = \frac{RT}{2F} \ln \left[1 - \frac{i}{i_o \left(\frac{1-\theta_O}{1-\theta_{O,rev}} \right)} \right] \quad [29]$$

or, alternatively

$$\eta_r = -\frac{RT}{2F} \ln \left[1 + \frac{i}{i_o \left(\frac{\theta_O}{\theta_{O,rev}} \right)} \right] \quad [30]$$

Regarding anodic overpotential, if oxygen atoms are weakly adsorbed ($\theta_{O,rev} << 1$), Eq. [29] predicts that, at current densities low enough so that $\theta_O << 1$ but high enough so that $|i| >> i_o$

$$\eta_r = \frac{RT}{2F} \ln \left(-\frac{i}{i_o} \right) \quad [31]$$

That is, Tafel behavior will be observed. The reaction overpotential will be characterized by the appearance of a limiting current when $\theta_O = 1$. From Eq. [26] and [27]

$$i_l = -\frac{i_o}{\theta_{O,rev}} \quad [32]$$

For strong adsorption ($\theta_O, \theta_{O,rev} \sim 1$), Eq. [30] and [32] give

$$\eta_r = \frac{RT}{2F} \ln \frac{i_l}{i_l - i} \quad [33]$$

Cathodic overpotential and weak adsorption ($\theta_O, \theta_{O,rev} << 1$) lead to an expression opposite in sign to Eq. [33] from a consideration of Eq. [26], [27], and [29]. According to Eq. [30], conditions of strong adsorption ($\theta_{O,rev} \sim 1$) and current densities such that $\theta_O \sim 1$ but $i >> i_o$ produce

$$\eta_r = -\frac{RT}{2F} \ln \frac{i}{i_o} \quad [34]$$

From Eq. [26] and [27], a limiting current density given by

$$i_l = \frac{i_o}{1 - \theta_{O,rev}} \quad [35]$$

will be observed when $\theta_O = 0$.

Consequently, reaction overpotential resulting from step [20a] being slow (20) exhibits Tafel behavior for anodic currents if oxygen adsorption is weak and for cathodic currents if oxygen adsorption is strong. Nevertheless, the present results rule out this possibility. In the first place, Eq. [31] and [34] indicate that the Tafel slopes would be half those observed (Fig. 9 and 11). Secondly, as already mentioned, no evidence of limiting currents could be advanced.

Both reactions [20a] and [20b] have now been eliminated as rate-limiting steps and, necessarily, the mechanism they represent must be discarded.

Consider reaction [20] to occur as a single step, *i.e.*, [20a] and [20b] are not independent. It can be fully expressed as

$$CO_{2,g} + V_O^{\cdot\cdot} + 2e' \rightleftharpoons CO_g + O_O \quad [36]$$

In this mechanism, CO and CO_2 participate directly in the electrochemical step of the reaction at the gas-electrolyte interface. Naturally, free active sites at the electrolyte surface are required to effect this reaction. As three phases are involved, reaction [36] must actually occur as follows

$$V_O^{\cdot\cdot} + 2e' \rightleftharpoons V_O \quad [36a]$$

$$CO_{2,g} + V_O \rightleftharpoons CO_g + O_o \quad [36b]$$

At the low oxygen pressures imposed by CO-CO_2 mixtures, excess electrons could migrate through the electrolyte from the electrode-electrolyte interface to the gas-electrolyte interface prior to step [36a]. Alternatively, step [36a] could take place at the electrode-electrolyte interface making neutral oxygen vacancies the migrating species. Since the excess electron concentration in the electrolyte is low ($t_e < 10^{-3}$ at $P_{O_2} = 10^{-16}$ atm and 1000°C) and the ionic conductivity is also low (3.8×10^{-2} ohm^{-1} cm^{-1} at 1000°C), it is advantageous for the steps to proceed near three-phase boundaries.

For reaction [36]

$$\phi_{rev} = \phi^\circ + \frac{RT}{2F} \ln \frac{P_{CO_2}}{P_{CO}} \quad [37]$$

where $[V_O^{\cdot\cdot}]$ and $[O_O]$, which are virtually constant, have been included in ϕ°. Consideration of Fig. 12 and rate theory gives

$$\vec{i} = k_8 P_{CO_2} (1 - \theta_{CO}) \exp [-(\Delta G_1^{o*} - \alpha z F \phi)/RT] \quad [38]$$

A similar expression can be written for $\overleftarrow{i}$. At equilibrium, $\vec{i} = i_o$ and $\phi = \phi_{rev}$. Substituting Eq. [37] into Eq. [38] yields

$$i_o = k_9 (1 - \theta_{CO}) P_{CO_2}^{1-\alpha} P_{CO}^{\alpha} \quad [39]$$

This relationship successfully explains the overpotential behavior in CO-CO_2 mixtures. Since θ_{CO} is undoubtedly quite large (except when P_{CO} is very low) and, therefore, relatively insensitive to gas composition, the $P_{CO_2}^{1-\alpha} P_{CO}^{\alpha}$ factor will predominate. Accordingly, because $\alpha \sim 0.5$, i_o should be a maximum near 50% CO. From the data in Fig. 8 and 11 at 1000°C, i_o is 0.25, 1.1, ~3, and ~0.6 mA/cm^2 for 0.016%, 0.77%, 50%, and 98.9% CO, respectively. In partial support of these data, minimum overpotential was recently observed at 50-70% CO (21), while Zahradnik (22) has shown that earlier results (14) exhibited a trend towards maximum exchange current densities at 50% CO. However, Eq. [39] indicates that the maximum should occur below 50% CO. This is consistent with the finding that exchange current densities are somewhat higher for mixtures dilute in CO than for those dilute in CO_2, *e.g.*, by using Eq. [39] when necessary to interpolate the data in Fig. 8, 9, and 11 (assuming $\theta_{CO} \sim$ constant over narrow gas composition ranges), $i_o = 1.2$ mA/cm^2 for 1% CO and 0.6 mA/cm^2 for 1% CO_2 at 1000°C, and $i_o = 1.0$ mA/cm^2 for 0.2% CO and 0.6 mA/cm^2 for 0.2% CO_2 at 1100°C.

Physically, the mechanism described by reaction [20] or [36] involves direct impingement of gas molecules on the surface of the oxide electrolyte (any CO_{ad} will undoubtedly block the otherwise most active sites). Porous electrodes permitting a considerable amount of gas-electrolyte contact are desirable. For instance, in the anode reaction, carbon atoms in CO collide with $O^=$ ions at the electrolyte surface to form gaseous CO_2 and neutral oxygen vacancies in the electrolyte. In ZrO_2, $O^=$ ions are about one and a half times as large (1) and twice as numerous as Zr^{4+} ions and, therefore, occupy most of the surface area.

The possibility of direct involvement of CO_{ad} in the electrochemical reaction cannot be overlooked, *i.e.*, reactions [20] and [21] could occur in series rather than in parallel. Accordingly

$$CO_{2,g} + 2e \rightleftharpoons CO_{ad} + O^= \quad [40]$$

Since an expression for i_o identical to Eq. [39] can be derived for reaction [40], a distinction cannot be made as to whether CO_g or CO_{ad} participates in the electrochemical step. If ZrO_2 adsorbs CO via carbon atoms linking to $O^=$ ions as reported for ThO_2 (55), CO_{ad} will be favorably located to effect reaction [40].

Equation [39] indicates that the exchange current density depends on the number of free sites. One reason for lower exchange current densities (higher overpotential) in CO-CO_2 mixtures than in H_2-H_2O mixtures (Fig. 8) is that, generally, $\theta_{CO} > \theta_H$. For example, at low coverage and 25°C, ΔH_{ad} of H atoms on Pt ~ −15 kcal/mole H_2 (36, 56) compared to −48 kcal/mole for CO (38, 52) and Pt preferentially adsorbs CO from CO-H_2 mixtures (57). Another reason is the presence of higher energy barriers (Fig. 12) to impede the electrochemical reaction.

Conclusions

To study overpotential in oxide electrolyte fuel cells, the Pt,O_2 electrode serves as an excellent reference electrode over a wide range of temperature and current density. Sufficiently porous electrodes enable the cathode reaction in $Ar-O_2$ mixtures to be solely limited by the diffusion of gaseous oxygen in the electrode pores from 850° to 1100°C. Limiting current densities are directly proportional to oxygen pressure. Although overpotential is essentially absent for H_2-H_2O mixtures, $CO-CO_2$ mixtures cause the appearance of marked transition overpotential at 700° to 1100°C. The transition factor is about 0.5 and exchange current densities, which increase with increasing temperature, vary between about 0.05 and 3 mA/cm². The maximum exchange current density is expected for a gas mixture containing somewhat less than 50% CO. Gaseous or adsorbed CO and gaseous CO_2 participate directly in the electrochemical step of the electrode reaction.

The authors wish to thank the National Research Council of Canada for financial support of this investigation.

Manuscript received April 21, 1971. This was Paper 329 presented at the Los Angeles Meeting of the Society, May 10-15, 1970.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

LIST OF SYMBOLS

C_D	double-layer capacitance
$(C_F)_c$	Faraday capacitance resulting from concentration overpotential
C_G	grain boundary capacitance
CO_{ad}	chemisorbed CO molecule
E	applied potential or cell potential
E_{rev}	reversible potential (emf)
e'	excess electron
f	frequency
ΔG^*	chemical free energy of activation
ΔG_{ad}	free energy of adsorption
ΔH_{ad}	enthalpy of adsorption
$h^{\cdot}$	electron hole
I	current
i	current density
i_l	limiting current density
i_o	exchange current density
k	constant
n	number of electrons associated with the rate-limiting step of an electrode reaction
O_O	$O^=$ ion on a normal lattice site
O_{ad}	chemisorbed oxygen atom
$O_{2,ad}$	physically adsorbed oxygen molecule
R_B	bulk electrolyte resistance
$(R_F)_c$	Faraday resistance resulting from concentration overpotential
$(R_F)_t$	Faraday resistance resulting from transition overpotential
R_G	grain boundary resistance
R_T	total resistance
R_{a-c}	a-c resistance at 3000 Hz
R_{d-c}	d-c resistance at zero current
ΔS_{ad}	entropy of adsorption
t_e	electronic transport number
V_O	neutral oxygen vacancy
$V_O^{\cdot\cdot}$	doubly-ionized oxygen vacancy
z	valence
α	transition factor or transfer coefficient
η_d	diffusion overpotential
η_r	reaction overpotential
η_t	transition overpotential
θ_j	fraction of active sites occupied by adsorbed species j
$\theta_{j,rev}$	fraction of active sites occupied by adsorbed species j at the reversible potential
ϕ	electrode potential with respect to the bulk of the oxide electrolyte
ϕ_{rev}	reversible electrode potential
ϕ^o	standard electrode potential

A Practical Assessment of Recent Transition-State Theories for the Electrical Conductance of Molten Salts

F. W. Dampier*,[1] and G. J. Janz*

Rensselaer Polytechnic Institute, Department of Chemistry, Troy, New York 12181

ABSTRACT

The modification of the Cohen-Turnbull and Adams-Gibbs theories by Angell for equivalent conductance in molten salts is briefly reviewed. The equivalent conductance data for some halide and nitrate melts is examined to determine the degree to which the non-Arrhenius behavior predicted by the Cohen-Turnbull theory occurs. The application of these transition-state theories for the description of the transport properties of molten salts is evaluated. The possibility of using the glass transition temperature as the basis for a corresponding temperature scale for crystallizing salts appears remote.

The present discussion is limited to pure stoichiometric ionic compounds in the molten state. Since a molten salt may be regarded as a highly disordered lattice, with a large number of temperature-independent defects, it has been proposed by various investigators, notably Bloom and Heyman (1), that the variation of electrical conductance with T is governed entirely by an activation energy, E, much as for these compounds in the crystalline state where the ionic conductance is attributed to lattice defects and the migration of ions via vacant sites in the crystal lattice. In another approach, Bockris, Crook, Bloom, and Richards (2) derive an expression for the electrical conductance using the hole model for ionic salts in the molten state and the transition-state theory of reaction rates; the expression shows reasonable accord with experimental results, especially from the Group IA compounds. More recently two additional expressions have been advanced by Angell (3, 4), both based on transition-state models, one starting with the liquid-state theory of Cohen and Turnbull (5), and the other, with that of Adams and Gibbs (6). The approaches by Bloom (1), Bockris (3), Stillinger (7), and others are adequately considered elsewhere (8-10); in this communication the results of an evaluation of the two more recent transition-state based expressions, as advanced by Angell, are reported.

The Free-Volume (Cohen-Turnbull) Model

Angell (3) had interpreted transport properties in ionic liquids using a model based on the concepts of the free-volume theory for transport in liquids, as derived by Cohen and Turnbull (4). Although diffusion was the transport property considered by Cohen and Turnbull, the model can be generalized to include electrical conductance or viscosity.

According to this model a particle of a liquid may undergo diffusive displacement when a void above a certain critical size appears adjacent to it. The voids are considered to arise from the random thermal redistribution of free volume in the liquid structure. The probability of occurrence of such a void adjacent to a given particle was shown to be an exponential function of the ratio of the critical void volume to the total free volume, and an expression for the diffusion coefficient was derived.

$$D = gau\,(-\gamma v^*/v_f) \qquad [1]$$

where g is a geometric factor given the value of 1/6; a, the jump distance; u, the gas kinetic velocity of the particle; γ, an overlap factor for free volume; v^*, the critical void volume; and v_f, the total free volume.

This expression, using known molecular constants and assumptions regarding the free volume and its relation to T_0, reduces to

$$D = AT^{1/2} \exp\,(-k/T - T_0) \qquad [2]$$

where A and k are constants. Differentiating, one obtains

$$\frac{d \ln D}{d(1/T)} = -T/2 - k(T/T - T_0)^2 \qquad [3]$$

The conventional Arrhenius activation energy for diffusion is given by

$$D = A \exp\,(-E_D/RT) \qquad [4]$$

Key words: molten electrolytes, glass transition temperature, electrical conductance, Cohen-Turnbull theory, Adams-Gibbs theory.

A similar differentiation with respect to $1/T$ gives

$$\frac{d \ln D}{d(1/T)} = -E_D/R \quad [5]$$

Combining Eq. [3] and [5], one obtains

$$\frac{d \ln D}{d(1/T)} = -E_D/R = -\tfrac{1}{2}T - k\,(T/T - T_0)^2 \quad [6]$$

Equation [6] predicts that if the Cohen and Turnbull model is valid, $(E_D - \frac{1}{2}RT)$ should be a linear function of $(T/T - T_0)^2$, which passes through the origin. A test could also be made of the linearity of a plot of $\ln D/T^{1/2}$ *vs.* $1/(T - T_0)$; this, however, is a less stringent test of the temperature dependence.

In order to test the temperature dependence using Eq. [6], accurate diffusion data are needed. Since electrical conductance can be measured more accurately than diffusion, the temperature dependence of conductance was corrected to correspond to that for a diffusion process by the relation $E_D = E_A + RT$. The latter expression follows from the Nernst-Einstein relation, if one assumes very nearly equal or markedly differing values for the conductance activation energies of the anionic and cationic species in the melt. Thus, according to the free-volume (Cohen-Turnbull) model the corrected activation energy for equivalent conductance $(E_A + \frac{1}{2}RT)$ should be a linear function of $(T/T - T_0)^2$.

The Configurational-Entropy (Adams-Gibbs) Theory

The Adams-Gibbs theory (6) has been developed from a successful statistical mechanical theory of chain polymer liquids at high particle densities (11), which has been generalized to include nonpolymeric liquids. According to this theory, the translational motion of a given molecule occurs by a mechanism in which the cooperative rearrangement of a group of molecules need not be specified. Rather it is the minimum size of the cooperatively rearranging groups which determines the temperature dependence of the translational process. The minimum size of the cooperatively rearranging group can be obtained in terms of the macroscopic configurational entropy if the assumption is made that the cooperatively rearranging groups do not interact significantly. On this basis Angell (4) has shown that the electrical conductance is proportional to the transition probability

$$\Lambda T \propto \omega(T) = A \exp\left[\frac{-C}{\Delta C_p (T - T_0)}\right] = A \exp\left(-\frac{k}{T - T_0}\right) \quad [7]$$

where

$$C = \frac{\Delta\mu s_0^*}{R/N} \quad [8]$$

and ΔC_p is the difference in glassy and liquid state specific heats; $\Delta\mu$, the potential energy hindering the cooperative rearrangement; s_0^*, the configurational entropy of the critical-size cooperative region; and R/N the Boltzmann constant.

A comparison of the expressions for the temperature dependence of diffusion from the Cohen and Turnbull (Eq. [2]) and Adams-Gibbs (Eq. [7]) theories shows the same exponential temperature dependence on $(1/T - T_0)$. But in the development of the Adams-Gibbs theory (6) the frequency factor A was assumed to be negligibly dependent on the temperature and was not completely evaluated. Since the temperature dependence of the Adams-Gibbs expression has not been completely developed it is customary (4) to test the validity of the temperature dependence of this theory using the technique developed for the free-volume model, that is, from a test of the linearity of a plot of $(E + \frac{1}{2}RT)$ as a function of $(T/T - T_0)^2$.

The Physical Significance of the Temperature T_0

According to the Cohen and Turnbull theory, the temperature T_0 (Eq. [2]) is the temperature at which "free volume" begins to appear. Some evidence has been advanced for using values of the glass transition temperature for T_0. Thus, Angell (3) has reported a value of T_0 of 316°K for the 38.1% $Ca(NO_3)_2$ composition of the mixture of $(Ca(NO_3)_2, KNO_3)$ and this compares favorably with the value of 329°K, found by Dietzel and Poegel (12) for the glass transition temperature.

The Adams-Gibbs theory considers T_0 as the temperature at which the configurational entropy of the liquid becomes zero. This interpretation of T_0 derives from the statistical mechanical analysis rather than as the assumption introduced by Cohen and Turnbull. Regardless of the differing interpretations of the physical meaning of T_0, it is numericaly evaluated by an empirical approach, namely it is the value which gives a linear slope when $(E + \frac{1}{2}RT)$ is plotted as a function of $(T/T - T_0)^2$.

The frequent designation of T_0 as the glass transition temperature tends to imply that theories employing this parameter can only be applied to noncrystallizing liquids. This is not the case since the Adams-Gibbs theory is quite general; also the success of Eq. [2] for a variety of ionic liquids (*e.g.* KNO_3; LiCl-KCl, eut.; $PbCl_2$-AgCl) is further support for the general nature of the equations based on this approach.

The Temperature Dependence of Equivalent Conductance

The degree to which the Adams-Gibbs theory can be applied to molten salts will depend on the size of the deviations of equivalent conductance from classical "Arrhenius behavior." The deviations from a linear dependence of $\ln \Lambda$ *vs.* $1/T$ are dependent on how far the experimental temperature range is removed from T_0. For example, if the temperatures are in the range of $3T_0$ to $4T_0$ (*i.e.* 650°-950°K, if T_0 is about room temperature) the apparent Arrhenius activation energy would change only by 15%, whereas for temperatures in the range $1.5T_0$ to $2.0T_0$, the variation would be 130%.

Angell has successfully applied the Cohen-Turnbull theory to a number of glass-forming nitrate melts (3); for these melts the experimental temperature range is sufficiently close to T_0 so that the deviations from Arrhenius temperature dependence are large enough for T_0 to be calculated with reasonable precision. But for melts which crystallize [*e.g.* the majority of the 174 single-salt melts considered in the NSRDS critical compilation (13)], Angell predicted (3) that T_0 cannot be established precisely due to the present experimental uncertainty. Since the application of the Cohen-Turnbull and Adams-Gibbs concepts to crystallizing melts is of considerable interest, it was decided to test the precision of the Arrhenius equation for electrical conductance for a number of halide and nitrate single-salt melts. For this purpose, the NSRDS critical compilation of equivalent conductance data (13) provided a unique source of experimental values and statistical information. The calculations and results of this study are as follows.

Calculations and results.—One measure of the deviation of equivalent conductance from Arrhenius behavior is the precision of the exponential least squares equation. The precisions for a limited selection of halides and nitrates obtained from the NSRDS compilation (13) are in Table I. From a comparison of these precisions with the estimated accuracies for the conductance of these salts (KCl, 0.6%; RbCl, 3.5%) it could be concluded that the equivalent conductance is adequately and precisely represented by the Arrhenius relation. However, a more detailed consideration of the conductance data reveals that the precision of the experimental measurements as a function of temperature

Table I. Precisions for the recommended* exponential equations for equivalent conductance

Salt	% Precision	Salt	% Precision
LiCl	0.048	LiI	0.68

CsBr	0.42	$TlNO_3$	0.35

* Table 177 (Ref. 13).

is considerably smaller than the estimated accuracy; further, systematic deviations from exponential behavior exist for most molten salts. Although several studies of the same salt [cf. KCl, Ref. (13)] often differ in the absolute amount of the values found for the specific conductance, the temperature dependence of the various investigations often tend to agree more closely.

An inspection of the residuals ($\Lambda_{calc} - \Lambda_{exp}$), gives a better indication of the nature of the deviations from Arrhenius behavior than the precision. Partial lists of the residuals for CsCl and $NaNO_3$ are given in Table II. It should be noted that the residuals are not of random size and sign as would be expected if an adequate fit to an exponential equation had been obtained; the residuals are large and positive near the melting point, and as the temperature increases, the residuals decrease and become negative, pass through a negative maxima, then increase and become positive again. Such systematic behavior of the residuals is characteristic of the exponential least squares equations for the majority of some 174 single-salt melts (13). This uniform departure from exponential behavior also indicates that some function other than the customary Arrhenius equation would probably give a more exact fit for equivalent conductance. There is, thus, good evidence to suggest that the temperature dependence of equivalent conductance can be expressed as a function of $(T/T - T_0)^2$ as has been suggested by Angell.

In a number of cases the experimental data selected as the basis for the NSRDS equivalent conductance equation is not entirely satisfactory for an analysis of the deviations from Arrhenius behavior. Often the specific conductance data from two investigators has been combined (*e.g.* as for salts such as LiCl, $NaNO_3$, and KNO_3) in order to have an equation which is valid over as large a temperature range as possible. For some salts the specific conductance has only been measured at temperatures far above the melting point (*e.g.* $LiNO_3$ mp 527°K; the lowest conductance measurement is 558°K). In other cases (*e.g.* CsCl) the specific conductance has only been measured every 20 or 30 degrees, and this makes a precise study of temperature dependence difficult. Conductance measurements near the melting point are frequently erratic (*e.g.* LiCl) and owing to a variety of experimental problems, it is frequently difficult to distinguish genuine irregularities in conductance behavior and "experimental" irregularities.

* Λ value is an extrapolated value.

To obtain an estimate of the degree to which the deviations from Arrhenius behavior affect the activation energy for equivalent conductance, an exponential least squares analysis of the first three tabulated values near the melting point was carried out. A comparison of these activation energies (low temperature region) with those for the complete temperature range is in Table III. The values of equivalent conductance used for the least squares calculations in both cases were the values tabulated in the NSRDS compilation (13). Inspection of Table III shows that not only does the activation energy change the greatest amount for the heavier alkali metal chlorides but the activation energies for lithium and sodium chloride decrease near the melting point rather than increase as is the case for the other chlorides, KNO_3 and $AgNO_3$ (Tables IV and V). This decrease in the activation energy raises a further problem; a positive value for T_0, the glass transition temperature, can be obtained only if the activation energy increases as the melting point is approached.

The activation energies in Table III should be accepted with some reservations; slight variations of the activation energy are likely to result when limited temperature ranges are considered due to the experimental scatter of the points. The difference between the activation energies for the two temperature ranges is also influenced by the nearness of the lowest experimental conductance value to the melting point, and the over-all span of the complete range of the measurements (LiCl, 140°; NaCl, 310°).

An alternate approach to gain the change of the activation energy with temperature is the solution of two simultaneous exponential equations, using the values of adjacent points. The equivalent conductance values, for this purpose, were calculated from the specific conductance values at the experimental temperatures without employing the least squares equations for specific conductance.[2] The density values employed in these calculations were obtained from the linear temperature density equations (13). The values of the activation energy obtained from the solution of the simultaneous equations, the exponential least squares equation for the tabulated equivalent conductance values and the residuals for LiCl, CsCl, KNO_3, and $AgNO_3$ are in Tables IV and V.

The activation energies for LiCl, in Table IV, are seen to increase; this is in contrast to Table III where a

[2] The direct calculation of equivalent conductance from the experimental specific conductance values is necessary in order to avoid the averaging effect of the least squares equation.

decrease of −2.3% was observed near the melting point. The increase of the activation energy for the lowest equivalent conductance value for LiCl (896.0°K) is quite dramatic (80%) and most certainly is the result of an experimental error. The largest deviations from Arrhenius temperature dependence are those noted for silver nitrate (Table V). The deviations for silver nitrate are more than double the deviations for potassium nitrate and cesium chloride.

The Glass Transition Temperature for Molten Salts

An assessment of the theoretical value of the glass transition temperature, T_0, for crystallizing molten salts requires a quantative evaluation of the precision of the calculation of T_0 from experimental equivalent conductance data. Precise values of T_0 are especially necessary if T_0 is to be considered as the basis of a Corresponding Temperature Scale for molten salts. Since the glass transition temperature can be determined most accurately for systems where the deviations from Arrhenius behavior for equivalent conductance are large, silver nitrate and potassium nitrate were selected for further consideration.

In Table VI the linearity of the corrected activation energy ($E_{corr} = E_A + \frac{1}{2}RT$) as a function of $(T/T - T_0)^2$ has been evaluated using a linear least squares analysis. The precisions of the linear equations are given for various values of T_0 for KNO_3 and $AgNO_3$. The values of the activation energy in these calculations are from Tables IV and V. The temperature given in the first column of Table VI is the average temperature of the two equivalent conductance values used to calculate the activation energy.

The equivalent conductance data employed for the KNO_3 calculations are from the measurements by Angell (14). Using this data Angell (3) computed a glass transition temperature $T_0 = 237$°K. In order to test the effect of a change in T_0 on the linearity of the relationship, the value $T_0 = 250$°K was selected for KNO_3 and the precision of the best fit was found to change from 0.81 to 0.85%.

A value for the glass transition temperature for $AgNO_3$ was selected by initially testing the values at 220°, 250°, 270°, and 300°K, in order to determine the best linear relationship between the E_{corr} and $(T/T - T_0)^2$. The value of 300°K (the best fit), thus, could not be found without such a least squares calculation. A visual inspection of the graphs of E_{corr} as a function of $(T/T - T_0)^2$ for 220° 250°, and 300°K reveals very little difference in linearity among the three temperatures. It appears that the actual value of T_0 is not a critical consideration for $AgNO_3$; a variation of about 30 degrees in the value of T_0 is possible without significantly affecting the graphical analysis.

In order to determine values of T_0 to within ±1°, a computer program for an iterative procedure together with a linear least squares analysis would be one approach for the selection of T_0. Although a value of T_0 could be found which would minimize the precision, the selection of such a glass transition temperature would be the result of an arbitrary interpolation since the convergence is rather gradual (*e.g.* $AgNO_3$).

In Fig. 1 and 2, the variation of E_{corr} as a function of $(T/T - T_0)^2$ is illustrated for KNO_3 ($T_0 = 237$°K) and $AgNO_3$ ($T_0 = 300$°K). The deviations for KNO_3 seem relatively greater than for $AgNO_3$ (even though the precisions indicate otherwise) as a result of the smaller total change in the activation energy.

An Evaluation of the Cohen-Turnbull and Adams-Gibbs Based Transition-State Theories

The major achievement of the Cohen-Turnbull theory is the precise description it gives for the temperature dependence of equivalent conductance. Whereas the Arrhenius expression is in error by about 8% for the activation energy of $AgNO_3$, the Cohen-Turnbull theory predicts the variation of the activation energy with a precision of about 0.5%. The glass transition temperature, although difficult to determine exactly, is physically more meaningful than a fitting parameter. The T_0 parameter gained theoretical support through the Adams-Gibbs theory, and this model has been substantiated by experimental results for glass-forming melts.

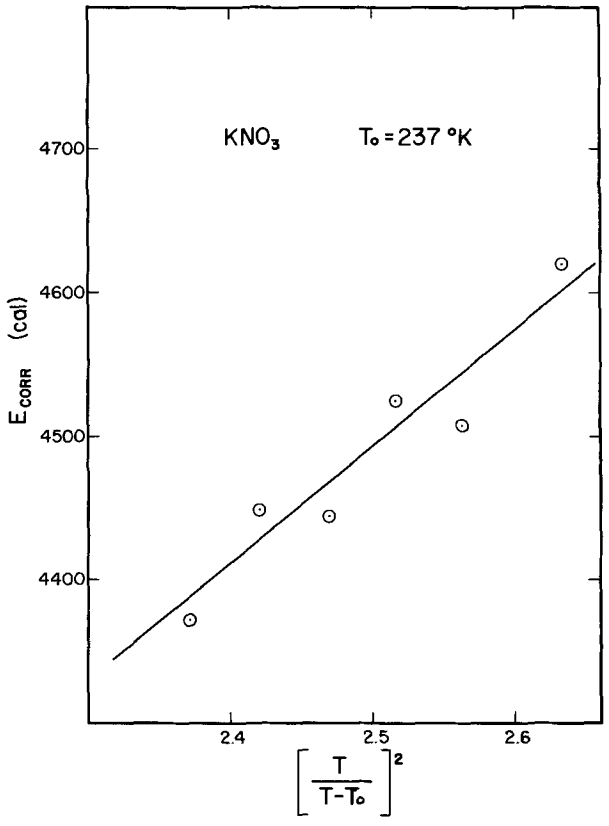

Fig. 1. The temperature dependence of E_{corr} of KNO_3. (The value of 273°K was used for T_o.)

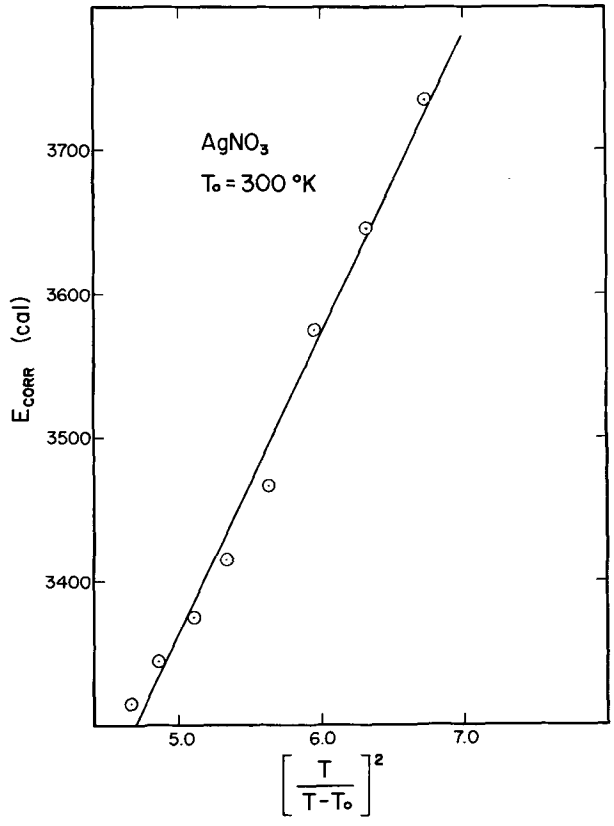

Fig. 2. The temperature dependence of E_{corr} of $AgNO_3$. (The value of 300°K was used for T_o.)

Considering the difficulties encountered in the calculation of precise values of T_o for $AgNO_3$ and KNO_3 the possibilities of using the glass transition temperature as the basis for a Corresponding Temperature Scale for crystallizing molten salts appear to be remote. It will be much more difficult to obtain precise values of T_o for the alkali halides than for $AgNO_3$ and KNO_3 because the halides exhibit significantly smaller departures from Arrhenius behavior than do the nitrates. There seems to be little possibility that an improvement in the accuracy and the precision of the measurement of equivalent conductance by several orders of magnitude would produce any improvement.

Although values of the activation energy, E, and the frequency factor, A, can be calculated (3) from known molecular constants for molten salts by the Cohen-Turnbull theory, close agreement between the theoretical and experimental values has not been obtained. Further developments of transition-state models can be expected to give more precise values for the absolute magnitude of the activation energy for equivalent conductance. It is evident that additional measurements of the transport properties for glassy molten salt systems and binary molten salt systems exhibiting deep eutectics are needed to advance the transition-state models. Accurate equivalent conductance measurements in the molten state but near the melting points of a variety of ionic compounds is another area in need of much attention for this purpose.

MoO_3: A New Electrode Material for Nonaqueous Secondary Battery Applications

Luigi Campanella

Istituto di Chimica Analitica,[1] Università di Roma, Rome, Italy

and Gianfranco Pistoia

Istituto di Chimica Fisica, Università di Roma, Rome, Italy

ABSTRACT

The behavior of MoO_3 as positive electrode material in organic solvent batteries has been investigated. This oxide in $LiAlCl_4$-BL solutions shows low solubility and satisfactory polarization behavior. Micropolarization tests showed the reversibility of the redox process of MoO_3 in the considered electrolyte. From the voltage sweep curve a charge-discharge efficiency of about 100% could be deduced. Discharges at 0.5, 1.0, and 2.0 mA/cm^2 of cells Li/$LiAlCl_4$-BL/MoO_3,C indicated a good cathodic efficiency if a two-electron process is hypothesized. MoO_3 positive electrodes, showing a lower polarization and supplying more practical specific energy, behave better than analogous AgO electrodes in $LiAlCl_4$-BL.

The latest researches in the field of high-energy nonaqueous batteries have been mainly directed to the study of electrochemically active cathode materials characterized by redox reversibility and low solubility. Some new electrode materials have been recently proposed in place of the ones used most so far, *i.e.* the Cu, Ni, and Ag halides. A number of these materials, the performances of which are often not well known, have been reported in a series of patents. These patents have been recently reviewed by Jasinski (1), with attention mainly focused on some oxides (Bi_2O_3, CuO, CrO_3, and AgO) which have been claimed to be useful for the development of secondary cells.

The use of oxides as positive electrodes could be particularly convenient because of their generally low solubility. According to Braeuer (2), however, only AgO seems to behave satisfactorily as a cathode in organic electrolytes. The good behavior of AgO for secondary battery applications has been confirmed by the studies performed by Shaw on several electrode-nonaqueous electrolyte systems (3). In particular, this author recommended the system AgO in butyrolactone (BL) – LiCl + $AlCl_3$.

On the other hand, AgO is not characterized by high values of the utilization coefficient (2) and is quite an expensive substance. In this work, the electrochemical behavior of MoO_3, a naturally occurring and inexpensive oxide, has been considered with the aim of finding a positive material of better electrochemical and practical characteristics than AgO. It has to be noted that so far MoO_3 has never been studied electrochemically in nonaqueous electrolytes; it has only been investigated as a cathode material in KOH aqueous solutions (4).

The low solubility of MoO_3 in organic solvents and its ability to be electrochemically reduced at the usual current densities employed in nonaqueous batteries were first ascertained. The results encouraged a detailed study of the electrochemical properties of MoO_3 in organic solvents and of its use as an electrode in a nonaqueous battery. Considering that AgO behaves reversibly in $LiAlCl_4$-BL (3), this organic electrolyte was also chosen for the present investigation.

Experimental

Materials.—High purity BL (Merck LAB product) was shaken and stored in the presence of Li in order to eliminate hydroxilate impurities. After this treatment, the water content in BL, determined by dead stop end point titration with the Karl Fischer solution, was less than 20 ppm.

$LiAlCl_4$ was prepared by melting equimolar amounts of anhydrous LiCl and $AlCl_3$ at 200°C under dry N_2, according to the method described by Rao (5). Solutions in BL of the salt prepared with this method are completely stable in the absence of moisture showing no change of their pale yellow color with time. When left in the air, these solutions tend instead slowly to gel.

MoO_3 (Carlo Erba RP product), AgO (BDH product) and graphite (Southwestern 1651) were used as received (after drying).

The Li ribbon used for the negative electrodes (99.9%, 15 mil, Alfa Inorganics product) was used as received.

All the chemical manipulations were performed in a dry box under argon atmosphere, the only exception being the preparation of the positive electrode.

Apparatus and technique and specific conductivity.—The specific conductivity, χ, of $LiAlCl_4$-BL solutions was measured, at 25°±0.02°C with a PR 9501 Philips bridge employing a conductivity cell having a constant of 0.5027 cm^{-1}. A starting solution of 25g of $LiAlCl_4$ in 100g of BL was progressively diluted and the corresponding specific conductivities were measured after thermal equilibration. The χ values are reported in Table I.

Solubilities.—MoO_3 was equilibrated at 18°C for six days in a stirred solution of $LiAlCl_1$ in BL (0.92*M*). An aliquot of the supernatant solution was then collected and the MoO_3 solubility calculated by determining the Mo^{VI} content spectrophotometrically with a Bausch-Lomb apparatus, operating at 475 mμ. The color was previously developed by reaction of Mo^{VI} with NH_4CNS and $SnCl_2$. The solubility in the same solution of a MoO_3-graphite electrode, submitted to six charge-discharge cycles, was determined with the same technique.

Table I. Specific conductivity at 25°C of $LiAlCl_4$ in BL

c (g/100g solvent)	$\chi \cdot 10^3$ (ohm^{-1} cm^{-1})
4.31	5.40
7.50	7.70
11.2	9.82
12.8	10.1
16.8	10.6
25.6	9.92

Key words: nonaqueous batteries, MoO_3, lithium.

Preparation of the positive electrode.—Because of the nonconductive nature of MoO_3, a sufficient amount of graphite was added to the cathodic mixture in order to avoid excessive polarization and low values of the cathodic efficiency. As the amount of graphite was increased from 10 to 30% a corresponding improvement of the cell performance was observed. For content higher than 30%, no further variation was observed. The electrode performance was negatively influenced by the addition of a binder (such as polyethylene) and by the dissolution of the cathodic mixture in toluene and successive spreading of it on the metal support.

The dry cathodic mixture (70% MoO_3 and 30% graphite) was pressed on a Cu net at 3000 kg/cm^2 in order to obtain satisfactory adherence. After discharge (1-2 days) the above-described electrodes showed a good appearance. Nevertheless, after an activated storage of 40 days (cycling test) the electrodes revealed some deterioration.

The AgO electrode was prepared in a similar way, employing a Cu net, electrolytically silver-plated, as support.

X-ray analysis.—The x-ray powder patterns were obtained using CuKα radiation filtered by nickel. The samples were analyzed under vacuum for 5 hr with the Debye-Scherrer method.

Macro- and micropolarizations.—These experiments were performed in a Type 494 AMEL cell, uisng a Li sheet as counterelectrode and a Li rod as reference electrode, the latter being separated from the working electrode by a Luggin capillary. The oxide working electrode, prepared as described above, and the Li counterelectrode had the same dimensions (1.8 x 2.3 cm). Macropolarization tests were also performed on the AgO electrode for comparison purposes.

Cyclic voltammetry.—The same cell and electrodes employed for the polarization measurements were also used for cyclic voltammetry, which was carried out by the Electroscan Beckman 30, at a potential scanning rate of 20 mV/sec.

Cell assembly and discharge curves.—The positive electrode, consisting of about 0.4g of the MoO_3-graphite mixture (46 mg/cm^2), was sandwiched between two lithium electrodes. Anodes and cathode had the same dimensions (4.3 cm^2 for each side). A double layer of 0.38 mm thick glass fiber [type Paper-Hurlbult 934 AH, described by Boden (6)] was used as electrode separators. An excess of $LiAlCl_4$-BL solution (12-14% by weight, that is 0.9-1.0*M*) was employed.

The discharge curves at current densities 0.5, 1.0, and 2.0 mA/cm^2, respectively, were performed at 25°C, usually without interruption, to 1.0V cutoff (90% discharge depth). No appreciable change in the performances was detected even when the discharge was interrupted overnight.

Cycling test.—It was performed on the cell that had been previously submitted to an initial discharge at 2.0 mA/cm^2 (see Fig. 4). Thirty cycles over 40 days were carried out at 25°C; the charge current density varied between 0.5 and 2.0 mA/cm^2; the discharge current density was 1 mA/cm^2. The voltage varied between 1.0V at the end of the discharge and 3.6V at the end of the charge.

Potentiometric titration of Cl^-.—Variations in the Cl^- content of the solutions were determined by potentiometric titrations. The apparatus employed was the Electroscan Beckman 30 and the electrodes were silver as indicator and saturated calomel as reference. Direct and analytical (derivative) methods for locating the end point of the titration were employed.

Results and Discussion

MoO_3 preliminary test.—The maximum in the specific conductivity for $LiAlCl_4$-BL solutions was 10.6×10^{-3} ohm^{-1} cm^{-1} (see Table I). This value is greater than that observed for solutions of the same salt in propylene carbonate which is 6.6×10^{-3} ohm^{-1} cm^{-1} (7).

The capability of MoO_3 to be electrochemically reduced in a $LiAlCl_4$-BL solution, without excessive polarization, is shown in Fig. 1. The comparison with the AgO behavior shows the better performances of MoO_3.

The solubility of MoO_3 in $LiAlCl_4$-BL (0.92*M*) was 5×10^{-4}*M*, a value which should ensure a satisfactory shelf-life to batteries using MoO_3 as the positive electrode.

On the basis of these promising results, the reversibility of MoO_3 electrodes was then investigated by the micropolarization test (Fig. 2). The cathodic straight line lies on the prolongation of the anodic one, and no appreciable hysteresis can be observed, showing that the electrode can be considered to be reversible. The possibility of cycling the copper grid was excluded by replacing it with a gold grid and observing that the micropolarization curve remained unchanged.

Further investigation by cyclic voltammetry evidenced a cathodic and an anodic peak in the potential range from 1.0 to 3.8V, as shown in Fig. 3. This result seems to indicate a unistep nature for the redox process of MoO_3. A comparison between the anodic and cathodic peak areas shows that the charge-discharge efficiency can be postulated to be nearly 100% in optimum operating conditions.

Discharge behavior.—Since the above-described results indicated MoO_3 as a feasible electrode material in nonaqueous solvents, it formed the cell

$$Li/LiAlCl_4\text{-BL}/MoO_3,C \qquad [1]$$

The open circuit voltage (OCV) of cell [1] is initially 2.8-2.9V and slowly stabilizes at about 2.7V. This is probably due to the deactivation of certain impurities and/or to the reaction between the copper grid and the cathodic mixture. Using a gold grid, the OCV tended to be more stable.

The background activity of the graphite employed in the preparation of the cathode was evaluated separately in a cell containing only graphite as the cathode material and discharged at 1 mA/cm^2. Its results were quite low, being only the 2% of the total delivered capacity.

The discharge curves for cell [1] are reported at various current densities in Fig. 4.

The discharge process of cell [1] is not completely clear, and it seems to be more complicated than the simple formation of lower Mo oxides (MoO_2, Mo_2O_5)

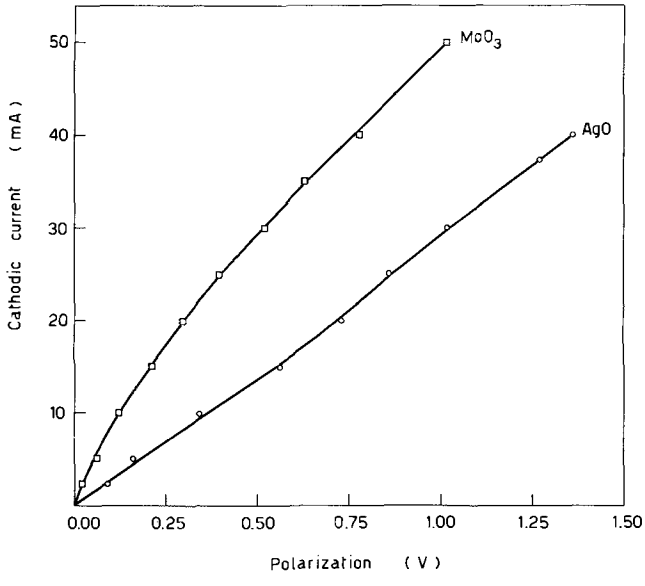

Fig. 1. MoO_3 and AgO polarization in 0.9M $LiAlCl_4$-BL. Electrode surface, 1.8 cm × 2.3 cm.

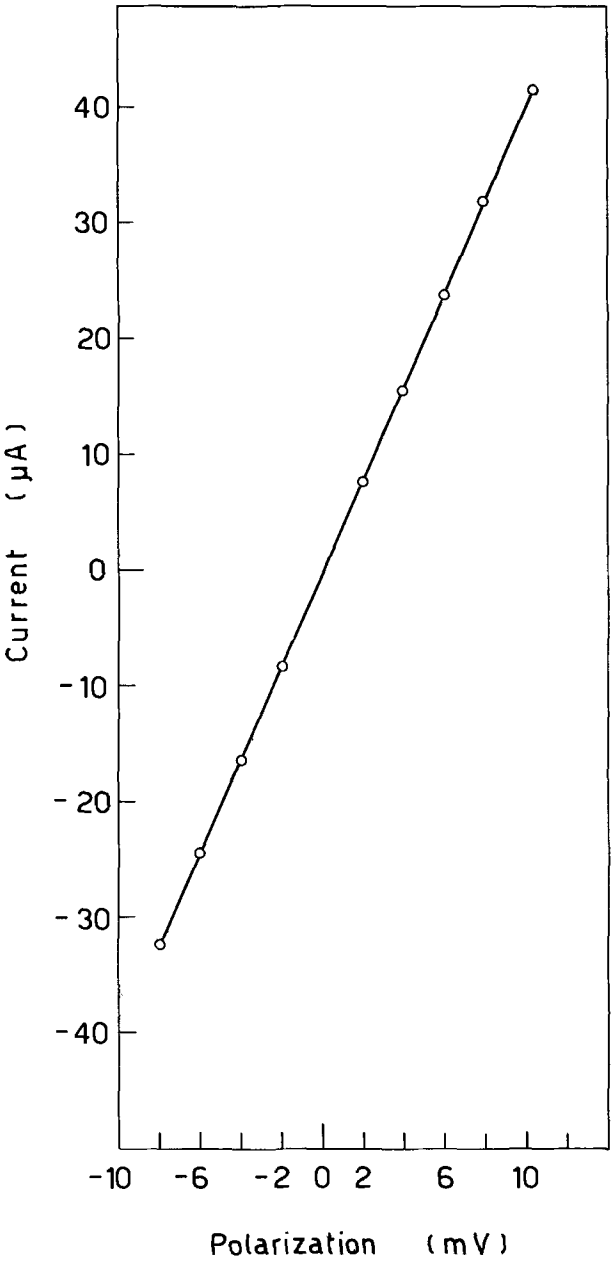

Fig. 2. Micropolarization of a MoO_3 electrode in $LiAlCl_4$-BL 0.9M. Electrode surface, 1.8 cm × 2.3 cm.

and Li_2O. In fact, from the known values of ΔG for Li_2O (−133.8 kcal/mol), MoO_2 (−121.6 kcal/mol), and MoO_3 (−161.9 kcal/mol) and that one estimated

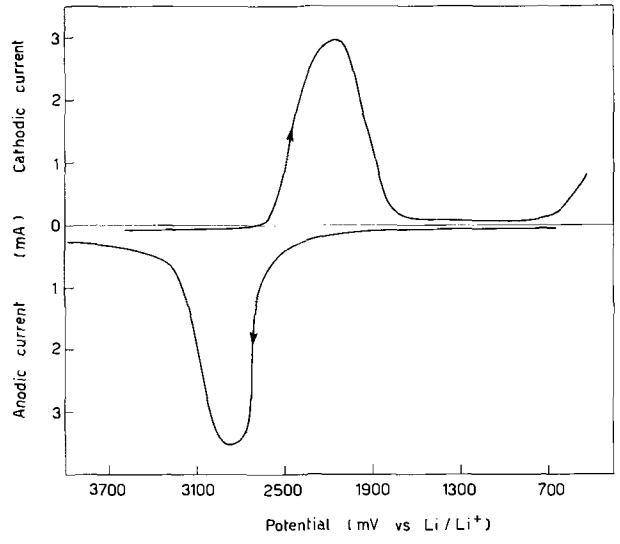

Fig 3. Cyclic voltammetry of a MoO_3 electrode in $LiAlCl_4$-BL 0.9M. Electrode surface 1.8 cm × 2.3 cm. Scanning rate 20 mV/sec.

for Mo_2O_5 (−284 kcal/mol) (8), it is possible to obtain for the formation of these lower Mo oxides E_0 values of about 2.0V. These values are definitely lower than those experimentally observed for cell [1], and the difference can be ascribed only to a minimum extent to impurities contained in the positive electrode mixtures. In fact, the load voltage remains above the value corresponding to the formation of Mo^{IV} or Mo^{V} oxides for a long time, and a large percentage of the total cell capacity is furnished during this time.

It is worthwhile to note that similar behavior has been shown by other oxides in organic electrolytes. In fact, batteries having as cathode: (*a*) AgO in $KAsF_6$-propylencarbonate (PC) (9), $LiClO_4$-methyl formate and $LiClO_4$-PC (2); (*b*) MnO_2 in $KAsF_6$-PC (9); (c) CuO in $LiClO_4$-tetrahydrofurane and $LiClO_4$-PC (10), show both OCV and load voltages higher than those obtainable from thermodynamic data. Therefore, careful study of the mechanism of the oxides' reduction is necessary.

The participation of the electrolyte in positive electrode processes seems to be possible, especially for electrolytes containing PF_6^- or $AlCl_4^-$ or BF_4^- anions, for which the acceptance and release of halide ions has been hypothesized (3, 7). For instance, the cycling behavior of AgO in $LiAlCl_4$-BL (3) is probably due to the reduction of the starting material to Ag, followed by anodic oxidation of Ag to AgCl which is then cycled.

The participation of chloride ions in the processes occurring at the MoO_3 electrode in $LiAlCl_4$-BL has also been investigated. An attempt to identify by x-ray

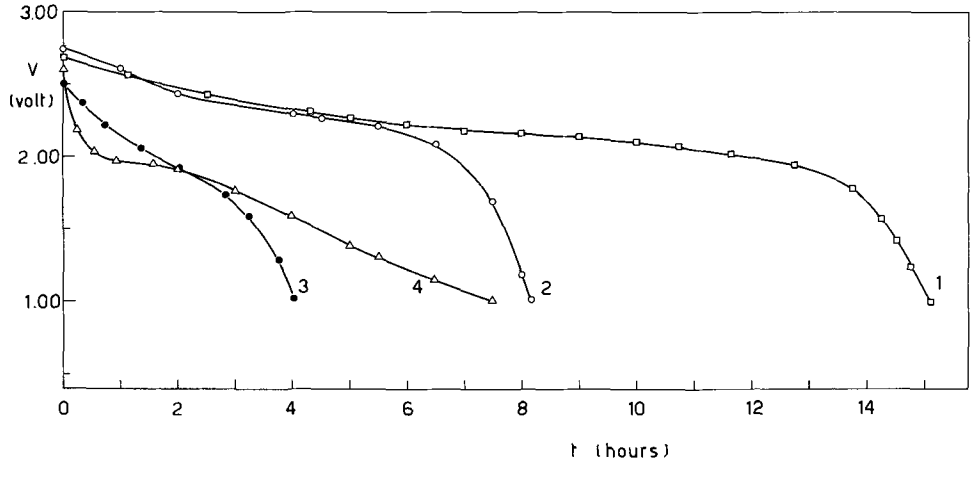

Fig. 4. Discharge curves at 25°C and at various current densities. For curves 1, 2, and 3 (MoO_3) C.D. are 0.5, 1.0 and 2.0 mA/cm^2 respectively; for curve 4 (AgO) C.D. is 1.0 mA/cm^2. Cells of curves 1, 2, and 3 contain 0.27, 0.28, and 0.32g MoO_3 respectively. Cell of curve 4 contains 0.26g AgO.

analysis the formation of compounds involving Cl^- ions on the electrode has not been successful, since the difference between the spectra of a blank formed by MoO_3 + graphite and those of the electrode material after discharge and cycling was not so marked as to make a reliable identification of formed compounds possible.

On the other hand, a variation in the Cl^- content of the solution after discharge was detected. This variation (~5%) was of the order expected on the basis of the amount of current passed through the cell. Thus, the participation of Cl^- ions in the electrode discharge reaction, probably through the formation of Mo oxychlorides, seems to be possible. No further Cl^- decrease was detected, however, in the solution of a charged cell which had been submitted to six cycles. Furthermore, the solubility of the positive electrode in $LiAlCl_4$-BL (0.92*M*), checked after six cycles (with the cell in the charged state), was equal to that of the MoO_3 powder. These results seem to prove the restoration, on charging, of the oxide on the positive electrode.

Whatever the reaction mechanism is, a monoelectron cell reaction has to be excluded, because it would lead to MoO_3 coulombic efficiency higher than 100%. A two-electron total process, to which a theoretical capacity of 0.37 Ahr/g corresponds, seems to be more probable. On the basis of this assumption the cathodic efficiency is quite satisfactory for the different discharge rates (see Table II).

The cell containing MoO_3 is characterized by higher values of voltage and of energy for weight of the cathode material than the cell operating with AgO under the same discharge conditions as expected by the trend of the polarization curves.

The AgO discharge also seems to occur in one step as indicated by the discharge curve of Fig. 4. The single step reduction of AgO has been also observed, for example, in $KAsF_6$-PC (9) and in aqueous KOH at a similar current density (11).

Cycling behavior.—A cell submitted to an initial discharge at 2 mA/cm² was charged and discharged for 30 cycles, during which the cycling efficiency was almost constant with time at the mean value of 61% (C/14 rate, 1.0V cutoff, 90% depth of discharge). During this test a continuous increase of the internal resistance of the cell was observed, probably due to a certain deterioration of the cathode. Consequently the ampere-hours accepted by the cell up to the maximum voltage (3.6V) and then supplied during the discharge were decreasing accordingly.

When a cell was left charged overnight, its charge-discharge efficiency was somewhat reduced due to the lowering of both OCV and voltage on load. In very few cases, however, was the efficiency lower than 50%.

By visual examination of the cell after the cycling test, an appreciable decomposition of the electrolyte could be excluded, while the expected formation of dendrites on the Li electrode and a certain physical deterioration of the MoO_3 electrode were noticed. Using gold instead of copper as the grid, the electrode showed a better appearance after cycling. Furthermore, the charge-discharge efficiency was higher, especially after overnight standing. This confirms the evidence of a certain reactivity of the copper grid with the cathode material.

The term of 40 days adopted for the cycling test is the first evidence of the activated storage capability of the cells containing MoO_3 as cathode. However, one cannot exclude the possibility that a solubility value of $5 \times 10^{-4}M$ can create some problems on longer activated stand periods.

Table II. Cell characteristics

Current density (mA/cm²)	Whr/g oxide	Rate[a]	Cathodic efficiency[a]
0.5	0.52	C/23	66
1.0	0.55	C/12	66
2.0	0.38	C/7	55
1.0 (AgO)	0.40	C/12	56

[a] Based on a two-electron reduction.

Conclusions

The relatively low value of solubility and of polarization make MoO_3 suitable as cathode material for high-energy nonaqueous batteries. Furthermore, since the MoO_3 reduction process is reversible, the construction of secondary cells is possible. Satisfactory charge-discharge efficiency and storage capability are other favorable features of these cells.

The electrochemical properties of MoO_3 are better in comparison with those of AgO considered so far the most efficient oxide for nonaqueous batteries. This stimulates a detailed research on the performances of other insoluble oxides suitable for high-energy nonaqueous batteries.

The Anodic Dissolution of Tungsten

J. W. Johnson* and C. L. Wu

Department of Chemical Engineering and Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

The anodic dissolution of tungsten was studied in H_2SO_4-K_2SO_4 solutions ($pH = -2$ to 2.5) and K_2SO_4-K_2CO_3-KOH solutions ($pH = 11.5$ to 14.5) at 25°C. Faradaic efficiency studies in basic solutions showed the metal to be oxidized to the +6 state. In acid solutions, a thick protective film of yellow WO_3 was formed. Polarization curves possessed linear Tafel regions (slope $\simeq 2.3\ RT/F$) at potentials slightly more positive than the rest potentials. An anodic dissolution mechanism is proposed which involves a surface film of W_2O_5 that is further oxidized to WO_3 and dissolves by hydrolyzation.

Tungsten (1) is one of the so-called "valve metals" which are distinguished by their ability to form highly protective oxide films upon anodic polarization in many aqueous media. Studies of its electrochemical behavior have appeared infrequently in the literature for over 100 years. A bibliography and brief review of much of the early work appears in a paper by Koerner (2). Koerner also reported extensive open-circuit potential measurements of the W electrode and observations of its anodic behavior in various acids and bases. The potentials were dependent on the type of W used, the electrolyte pH, and also showed some variation with the nature of the electrolyte. The former dependence was attributed to the presence of appreciable oxides in the metal and the latter to the effect of specific ions on the solubility of the dissolved W species, primarily $W(OH)_6$. This compound was believed to break down to tungstic cations in acidic electrolytes and anions in basic. Upon commencing polarization in acid electrolytes, films were formed on the W surface whose color changed through a definite sequence. These colors were associated with tungsten oxides of progressively higher oxygen content, *i.e.*

$$W \rightarrow \underset{\text{(brown)}}{WO_2} \rightarrow \underset{\text{(blue)}}{W_2O_5} \rightarrow \underset{\text{(blue)}}{W_4O_{11}} \rightarrow \underset{\text{(green)}}{W_5O_{14}} \rightarrow \cdots \rightarrow \underset{\text{(yellow)}}{WO_3} \quad [1]$$

The passiveness of W in acids was attributed to low solubilities of the oxides in this media and the activeness in bases to high solubilities. A valence of +6 was determined for W dissolving in NH_4OH-NH_4Cl solutions.

Pitman and Hamby (3) noted intense interference colors on W resulting from anodic polishing. They subsequently studied the growth of the oxide, and among other properties, reported it to have a density and dielectric constant of 6.8 g/cm² and 41.7, respectively. A steady-state growth relation between current and thickness was given for 0.1*N* H_2SO_4 at 25°C. It is interesting to note the sequence of colors reported by Koerner for the formation of the various oxides (Eq. [1]) is similar to the sequence of interference colors caused by thickening of transparent oxide films (4).

Thompson and Rice (5) studied the anodic and cathodic behavior of W in KOH solutions. During anodic dissolution, near 100% current efficiencies were found for the oxidation to the W-VI state, even though extremely high polarization (20-100V) occurred in many cases. The break in the polarization curves where the overvoltage rapidly increased was dependent on both C.D. and C_{OH^-}.

El Wakkad *et al.* (6), studied the behavior of W in various buffer solutions. They found the potentials of massive W and powdered W-WO_3 electrodes to correspond closely. A discontinuity in the *E*-pH relation was noted at pH's 4-6. It was proposed that the potentials in neutral and basic solutions were controlled by the reaction

$$W_2O_5 + 2H_2O = WO_3 + WO_4^{-2} + 4H^+ + 2e \quad [2]$$

The discontinuity was attributed to an incompleteness of the reduction portion of the reaction (Eq. [2]) in acid solution with tungsten blue (W_3O_8 or W_4O_{11}) being the product rather than W_2O_5. The effect of pH on potential ($\partial E/\partial pH$) as shown in various plots was *ca.* 50 mV. It was proposed that W dissolves as WO_4^{-2} in strong bases and WO_2^{+2} in strong acids.

Besson and Drautzburg (7) have also reported a study of the anodic dissolution of W in various electrolytes. The oxidation of W was found to proceed quantitatively to the +6 state. Agitation of the electrolyte displaced the Tafel curves. Tafel slopes were reported for both acidic and basic electrolytes that ranged from 55 to 150 mV.

The present study was undertaken in an attempt to establish a more detailed anodic dissolution mechanism for W. It was also of interest to see if a mechanism recently proposed for Mo[8], a chemically similar metal, would be applicable.

Experimental

The tungsten anodes were prepared from cylindrical specimens cut from a rod of 0.75 in. diameter.[1] They were polished on grinding paper down to 600 grit, cleaned in distilled water with ultrasonic agitation, rinsed with distilled water and acetone, dried, and then mounted in a Teflon holder. All solutions employed analytical grade chemicals and distilled water. The electrolyses were carried out in an H-cell containing approximately 300 ml of electrolyte at 25.0° ± 0.1°C. Prepurified nitrogen was bubbled through the electrolyte to purge air from the system and for stirring. The reference electrodes were Hg/Hg_2SO_4 (1*N* H_2SO_4) for acidic and Hg/Hg_2Cl_2 (1*N* KCl) for basic electrolytes. A salt bridge of the same electrolyte as in the electrolysis cell was used to prevent contamination by the reference electrode. All potentials are reported *vs.* the standard hydrogen electrode (SHE) at 25°C.

Results

Self-dissolution experiments were carried out initially with the W anodes kept in the cell at open-circuit for 24 hr. No detectable weight gains or losses were noted except for 1*N* and 3*N* KOH. In these latter electrolytes, an anode with an exposed area of 2.84 cm² lost approximately 5 mg during the 24-hr period.

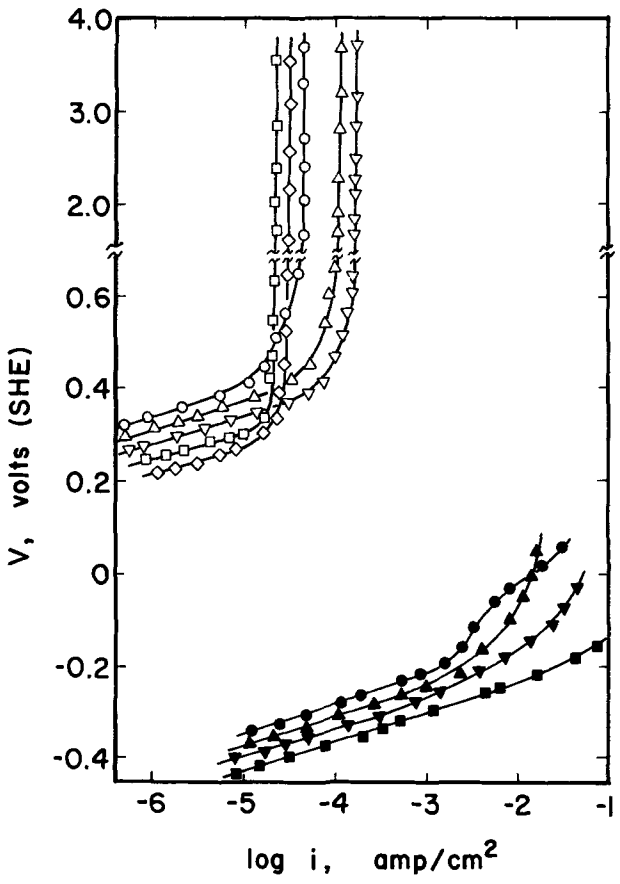

Fig. 1. Anodic polarization of tungsten in aqueous solutions at 25°C. ○, pH = −2.0; △, pH = −0.5; ▽, pH = 0.38; □, pH = 1.5; ◇, pH = 2.5; ●, pH = 11.5; ▲, pH = 12.7; ▼, pH = 13.6, ■, pH = 14.5.

Polarization measurements.—The anodic polarization behavior (steady state) for W was determined potentiostatically in acidic and basic electrolytes and is illustrated in Fig. 1. The curves contain linear (Tafel) sections in the potential region just above the rest potentials. Both the Tafel slopes and the rest potentials are tabulated in Table I. In the acid electrolytes, the active dissolution regions were quite small and limiting currents of 10^{-5}-10^{-4} A·cm² were reached at relatively low overpotentials. Visible oxygen evolution commenced from the anode at potentials of 1.3-2.0V. A lemon-yellow film was formed on the electrode during polarization and was identified by x-ray analysis as WO_3. A high-voltage power supply in a galvanostatic arrangement was used to polarize the W anode in 3*N* H_2SO_4 at C.D.'s greater than the limiting values mentioned above. The results are shown in Fig. 2. The yellow surface film thickened visibly and oxygen was evolved vigorously. At the higher C.D.'s, the potential continually fluctuated by 5-10V.

Table I. Rest potentials and Tafel slopes for the anodic dissolution of tungsten at 25°C

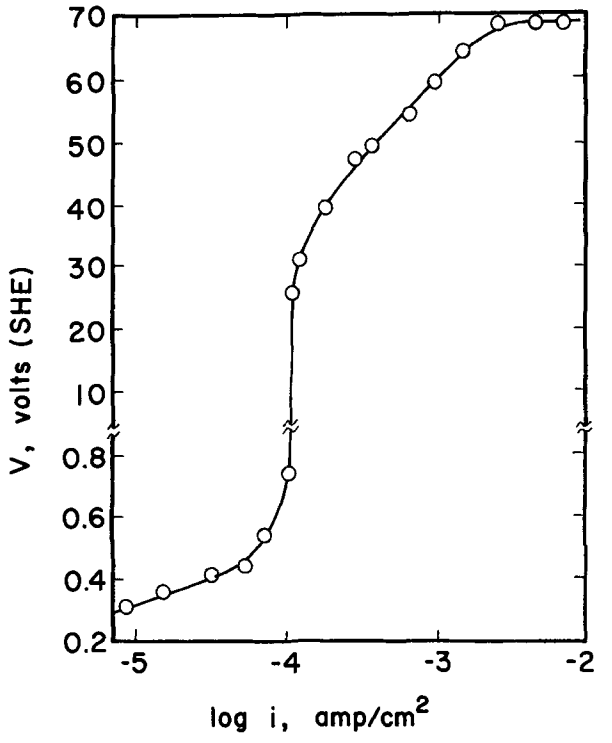

Fig. 2. Anodic polarization (galvanostatic) of tungsten in 3*N* H_2SO_4 at 25°C.

Valence measurements.—The results of the valence determinations in both acidic and basic media are shown in Table II. In the acidic media, oxygen could be seen evolving at all but the lowest current densities. The smallness of the limiting currents precluded an accurate determination of the oxidation state of the dissolving W ions in the active dissolution region. The weight loss for a C.D. of 10^{-4} A·cm² (which occurred over a period of several days) corresponded to a W valence (oxidation state) of 22. Apparently oxygen was also being produced at this C.D., but at such a low rate that it dissolved without bubble formation. It should be noted, though, that significant weight losses of the metal occurred even during visible oxygen evolution at high C.D.'s. (For example, at 0.050 A·cm^{-2}, Table II shows that *ca.* 14% of the anodic current is accounted for by W dissolution.) This and the absence of a decrease in C.D. with increasing potential above the active dissolution region indicates the absence of true anodic passivation.

† Coulombic efficiency based on W-VI oxidation state.

The oxidation state of W species entering into solution in basic electrolytes is very close to +6 within experimental error. It appears to be independent of both *p*H and C.D., and is in agreement with values reported by other investigators.

Discussion

In alkaline media, the apparent valence data indicate that tungsten goes into solution according to the overall reaction

$$W \rightarrow W\text{-}VI + 6e \qquad [3]$$

Qualitative tests of the anolytes showed the presence of WO_4^{-2} as expected from the absence of color and in accord with thermodynamic data indicating it to be a stable ion at these conditions (9-11). In acid media, the yellow film formed on the electrode surface and identified as WO_3 also indicated that oxidation resulted in the +6 state. The formation of this oxide, which is both relatively insoluble and nonconductive, explains the small potential-independent currents that were observed. The fact that W dissolved over the entire potential region (Tafel, limiting current, and oxygen evolution) is evidence of a slight solubility of the oxide. Also, the absence of pitting indicated the film to be nonporous. Thus, the dissolution is probably accomplished through a hydration reaction to form $WO_3 \cdot H_2O$ (or tungstic acid H_2WO_4). These observations (as well as the simultaneous o.e. at relatively low overpotentials) would appear to preclude interpreting the behavior of W in this media simply in terms of valve-action. In the rigorous sense, valve-action "is the tendency to form a protective high-resistance oxide film on anodic polarization to the exclusion of all other electrode processes" (1).

The open-circuit "rest" potentials of the W electrode (shown in Fig. 3) are a function of *p*H. The value $\partial V_{rest}/\partial pH \simeq 0.059V = 2.3\ RT/F$, indicates a 1:1 ratio of H^+ to electrons in the electrochemical step that is controlling the rest potential. As also seen in Fig. 3, the measured values do not correspond to any of the relations for various W-H_2O equilibria that are available from the literature (12, 13). They agree reasonably well with the values reported by El Wakkad *et al.* (6), but not with the *p*H effect from his proposed reaction (Eq. [2]). The slight solubility of WO_3 as well as previous findings regarding Mo[8], a chemically similar metal, suggest an equilibrium between W_2O_5 and $WO_3 \cdot H_2O$ as a possibility, *i.e.*

$$W_2O_5(s) + 3H_2O(aq) \rightarrow 2WO_3 \cdot H_2O(s) + 2H^+(aq) + 2e \qquad [4]$$

Data are not available pertaining to the standard free energy of formation of $WO_3 \cdot H_2O$, but an approximate value can be obtained by estimating the free energy change, *i.e.* ΔG°_{hyd}, for the following reaction

$$WO_3(s) + H_2O(aq) \rightarrow WO_3 \cdot H_2O(s) \qquad [5]$$

An examination of the data for a large number of monohydrated compounds of compositions $MO_x \cdot H_2O$, H_2MO_y, and $M(OH)_2$ shows that the free energy changes for the reactions of the oxides with water are usually within the limits of ± 10 kcal. For compounds normally found in the hydrated form (*e.g.* CrO_3, MgO, MnO), $-10 < \Delta G^\circ_{hyd} < 0$ kcal, while for compounds normally found in the anhydrous form (*e.g.* TeO_2, GeO_2, SiO_2), $0 < \Delta G^\circ_{hyd} < 10$ kcal. Since anhydrous WO_3 is reported to be the normally stable form, its free energy of hydration should be positive and can be estimated to be 5-10 kcal. For the following calculations, 7.5 ± 2.5 kcal will be used. Thus

$$\begin{aligned}\Delta G^\circ_{f,WO_3 \cdot H_2O} &= \Delta G^\circ_{f,WO_3} + \Delta G^\circ_{f,H_2O} + \Delta G^\circ_{hyd} \qquad [6]\\ &= -182{,}740 + (-56{,}690) + (7{,}500 \pm 2{,}500)\\ &= -231{,}930 \pm 2{,}500 \text{ cal}\end{aligned}$$

The corresponding ΔG° for Eq. [4] is

$$\begin{aligned}\Delta G^\circ &= 2\,\Delta G^\circ_{f,WO_3 \cdot H_2O} - \Delta G^\circ_{f,W_2O_5} - 3\,\Delta G^\circ_{f,H_2O} \qquad [7]\\ &= 2(-231{,}930 \pm 2{,}500) - (-306{,}900) - 3\,(-56{,}690)\\ &= 13{,}100 \pm 5{,}000 \text{ cal}\end{aligned}$$

The Nernst relationship for this reaction is[2]

$$\begin{aligned}E &= (0.3 \pm 0.1) - (2.3\ RT/F) \log (1/a_{H^+}) \qquad [8]\\ &= (0.3 \pm 0.1) - 0.059\ pH\end{aligned}$$

The band (area between long dashed lines) representing Eq. [8] on Fig. 3 includes all the experimental rest potentials. A best-fit line through the points yields a free energy change for Eq. [5] of +8 kcal.

With the above information, the anodic dissolution of W can be described qualitatively as follows:

(*A*) When placed in solution, the W electrode very rapidly forms a film of approximate composition W_2O_5 that completely covers the metal surface. Further spontaneous reaction (corrosion or self-dissolution) ceases except at relatively high *p*H's where W_2O_5 is soluble.

(*B*) Upon polarization, the appreciable conductivity of W_2O_5 allows further electrochemical oxidation to WO_3.

(*C*) The solvation of WO_3 is accomplished by hydration to $WO_3 \cdot H_2O$ (or H_2WO_4) which has a very low conductivity, is only slightly soluble in acids, and is appreciably soluble in bases.

(*D*) The limiting (potential independent) curves in acidic electrolytes can be attributed to an insulating layer of WO_3 which accumulates due to its low solubility. The absence of a limiting current in basic electrolytes is due to the solubility of WO_3 in these media.

(*E*) The rapid complete coverage of the metal surface by W_2O_5 indicates the experimental kinetic parameters are associated with its further oxidation (8). The Tafel slope of ~60 mV is thus associated with a chemi-

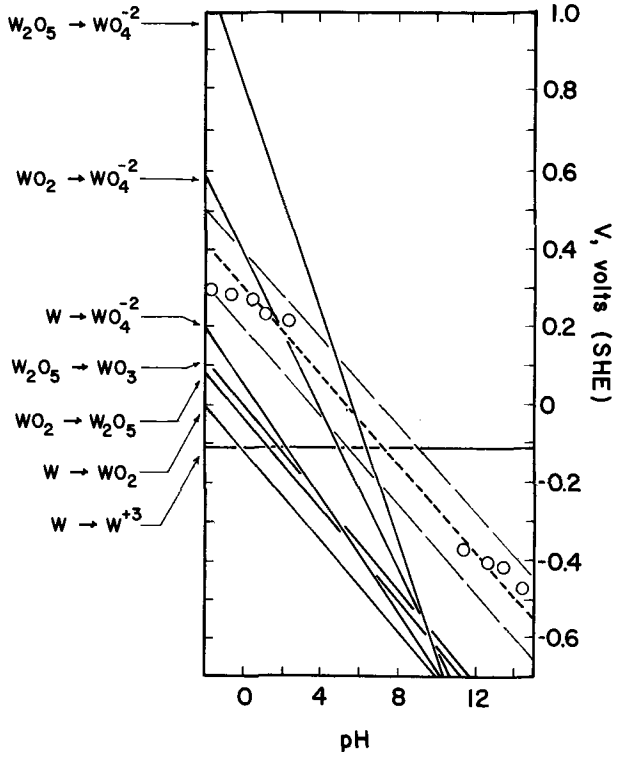

Fig. 3. Comparison of the measured "open-circuit" potentials of the tungsten electrode with the thermodynamic values for various tungsten-water reactions at 25°C. (○, experimental data; ——, Eq. [8]).

[2] For reduction potential.

cal rate-determining step subsequent to the first electron transfer from W_2O_5. The pH effect indicates the production of hydrogen ions (or their equivalent) prior to the r.d.s.

Expressing the above in equation form gives

$$2\,W(s) + 5\,H_2O(aq) \rightarrow W_2O_5(s) + 10\,H^+(aq) + 10e \quad [9]$$

$$W_2O_5(s) + H_2O(aq) = W_2O_5OH(s) + H^+(aq) + e \quad [10a]$$

and/or

$$W_2O_5(s) + OH^-(aq) = W_2O_5OH(s) + e \quad [10b]$$

$$W_2O_5OH(s) + W_2O_5(s) \xrightarrow{\text{r.d.s.}} W_2O_5\text{-}OH\text{-}W_2O_5(s) \quad [11]$$

$$W_2O_5\text{-}OH\text{-}W_2O_5(s) \rightarrow W_2O_5\text{-}O\text{-}W_2O_5(s) + H^+(aq) + e \quad [12]$$

$$W_2O_5\text{-}O\text{-}W_2O_5(s) \rightarrow \cdots \rightarrow 2\,WO_3(s) + W_2O_5(s) \quad [13]$$

$$WO_3(s) + H_2O(aq) \rightarrow H_2WO_4(s) \quad [14]$$

$$H_2WO_4(s) \rightarrow H^+(aq) + HWO_4^-(aq) \quad [15a]^3$$

and/or

$$H_2WO_4(s) + 2\,OH^-(aq) \rightarrow 2\,H_2O(aq) + WO_4^{-2}(aq) \quad [15b]$$

This scheme is similar to the one proposed previously for Mo[8] which also incorporated oxygen-bridged compounds. Such W compounds (W_2O_5, W_4O_{11}, etc.) are known to exist (11). It thus appears that the chemically similar metals Mo and W dissolve anodically in a similar manner.

Acknowledgments

The authors wish to thank Dr. Gary L. Bertrand, Associate Professor of Chemistry, for helpful discussions. This paper is based on a thesis submitted by one of us (C.L.W.) for the M.S. degree in Chemical Engineering at the University of Missouri-Rolla. It is contribution No. 126 from the Graduate Center for Materials Research, University of Missouri-Rolla.

Manuscript submitted June 18, 1971; revised manuscript received ca. Aug. 20, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

The Anodic Oxidation of Titanium Carbide

R. D. Cowling and H. E. Hintermann*

Laboratoire Suisse de Recherches Horlogères, Neuchâtel, Switzerland

ABSTRACT

The anodic dissolution of titanium carbide in 2*N* H_2SO_4 has been examined by coulometric experiments and by the application of a rotating ring-disk electrode. The latter technique has shown that the dissolution proceeds through the intermediate formation of Ti(III) ions, which undergo immediate oxidation to Ti(IV) at the electrode surface.

The anodic behavior of titanium carbide in sulfuric acid solution has been described in a previous paper (1). Dissolution begins at about 0.8V(SHE),[1] and produces Ti(IV) ions, CO, and CO_2. Unsuccessful attempts were made to detect trivalent titanium in the nitrogen-saturated solution. The formation of Ti(III) in the dissolution reaction cannot be ruled out, however, since once formed it would be rapidly oxidized to Ti(IV) at the potential of the corroding electrode. The aim of the present study was to investigate the anodic oxidation of TiC more fully than had been previously possible. Pure, single crystal carbide was used instead of the vapor-deposited material on which earlier work (1) had been based. In particular, the occurrence of Ti(III) was examined. Two techniques were employed. First, the dissolution was studied coulometrically.

Assuming that the net reaction is one of the following

$$TiC + H_2O = Ti^{3+} + CO + 2H^+ + 5e^- \quad [1]$$

$$TiC + 2H_2O = Ti^{3+} + CO_2 + 4H^+ + 7e^- \quad [2]$$

$$TiC + 2H_2O = TiO^{2+} + CO + 4H^+ + 6e^- \quad [3]$$

$$TiC + 3H_2O = TiO^{2+} + CO_2 + 6H^+ + 8e^- \quad [4]$$

which account for the fact that both CO and CO_2, but no other gases, are produced during anodic dissolution, the number of electrons, z, associated with the stoichiometric equation is then $5 \leq z \leq 8$, and is unique for each equation. The value of z may be obtained

* Electrochemical Society Active Member.

Key words: corrosion, dissolution, coulometry, rotating ring-disk electrode.

[1] All potentials reported in this paper are referred to the standard hydrogen electrode.

experimentally. Assuming 100% anodic current efficiency, and that the carbide is stoichiometric, z is given by

$$z = \frac{47.9}{F} \cdot \frac{q}{\omega} \qquad [5]$$

where q coulombs results in ω grams of titanium passing into the solution.

The second technique was to construct a rotating ring-disk electrode whose disk was a single crystal of TiC. A platinum ring was used to detect any Ti^{3+} produced during anodic dissolution of the disk.

Experimental

Small single crystals of titanium carbide were kindly donated by Dr. G. E. Hollox, Brown Boveri Research Center, Baden, Switzerland. These were chips from larger crystals which had been grown from sintered carbide, and whose stoichiometry was given as $TiC_{0.97\pm0.01}$. They contained no free carbon.

In making an electrode from such a crystal, the solderability problem was first overcome by vacuum depositing a layer of chromium onto the surface, followed by a layer of copper, each about 1000Å thick. The copper was then built up galvanically to form a solderable contact to a copper wire, and the area comprising the joint was then embedded in a hard setting resin, stable in dilute acid solutions. An electrode thus produced had roughly the same form as a conventional wire electrode fused in glass, *i.e.* the solution was in contact with different crystal surfaces of the carbide at the same time. This was a simpler arrangement than mounting an electrode such that only a given plane contacted the solution, and was justified by the observation that the [100] and [110] faces of titanium carbide showed the same dissolution kinetics. Before use, the electrode was cleaned of any copper and chromium on the surface by anodic stripping in sulfuric acid.

For certain potentiostatic experiments, the quantity of electricity passed was measured directly with an electronic coulometer. This was designed to integrate small currents, of the order of 100 μA, where the conventional silver coulometer is time consuming and can function with less than 100% current efficiency. The voltage drop across a 100 ohm resistance, placed in the counterelectrode lead of the potentiostat, was amplified and then converted into a pulse signal whose frequency was proportional to the current which was being measured. The pulses were then summed with a frequency counter over any desired period of time, and the total count, with the introduction of a single calibration factor, gave a direct value for the number of coulombs which had passed. The instrument was calibrated to give 1000 Hz at 500 μA. At this current, a precision of about 0.1% was obtained, falling to 1% ($\pm$1 count) at 50 μA. A second range gave a precision of about 0.1% at 1.5 mA. Between 50 μA and 1.5 mA, the precision was better than 1%.

Because of the impossibility of machining single crystals of TiC, the construction of the RRDE posed some problems. Eventually it was made in three separate parts, the ring, disk, and body sections (Fig. 1), which were then press-fitted together as shown in the figure. The disk section was constructed by first grinding a crystal into the form of a regular cylinder, diameter 6.7 mm and thickness about 2 mm. A stainless steel cylinder, diameter 6.7 mm and thickness 5 mm, was then stuck onto the back of this, using Araldite resin. The piece was then mounted in Plexiglas, using a standard metallurgical press, and the outside diameter turned to 7.4 mm. A hole of diameter 3 mm was then drilled through to the back surface of the carbide, and the Araldite at the bottom of the hole scraped away. For the ring section, a cylinder of brass was machined to an external diameter of 8.4 mm and an internal diameter of 7.4 mm. To this was brazed a disk of

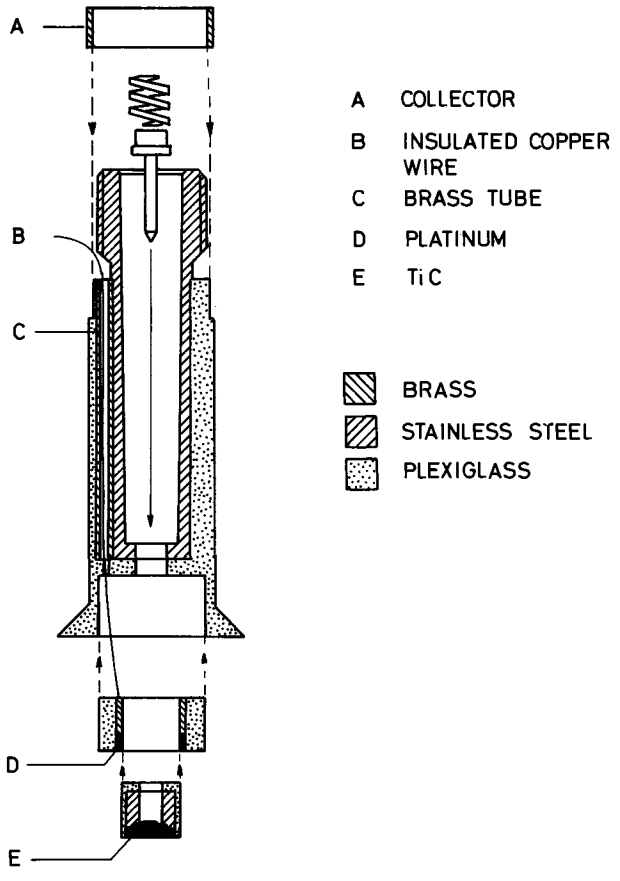

Fig. 1. Rotating ring-disk electrode

platinum, which was then machined to the same internal and external diameter as the cylinder. The brass tube was then cut to a length of 7 mm, and the piece mounted in Plexiglas and the OD turned to 13.5 mm. A fine insulated copper wire, soldered to the top edge of the cylinder, served as the eventual contact for the ring electrode. This passed through a small brass tube attached to, but insulated from, the main body of the electrode, and was fixed to a stainless steel collector ring. The steel body of the electrode was also mounted in Plexiglas, and the three sections were fitted together as shown. Contact to the disk was made by a pin, pressed against the back surface by a spring which was in turn connected through the drive shaft to the potentiostat. The disk diameter was 6.70 mm and the internal and external diameters of the ring were 7.40 and 8.40 mm respectively. The complete rotating disk assembly has been described elsewhere (2). Other experimental details have been described in an earlier paper (1).

Results

Coulometric experiments.—In order to determine whether the dissolution of titanium carbide can be represented by any one of Eq. [1]-[4], a known anodic charge was passed through the electrode, under both galvanostatic and potentiostatic conditions, and the solution subsequently analyzed for titanium by spectrophotometry. z was then calculated by Eq. [5].

A constant anodic current of 1 mA was passed through an electrode of area approximately 0.5 cm^2 in 2N H_2SO_4 saturated with nitrogen During dissolution, the potential of the electrode was 1.01V. The mean value of z, obtained from several experiments on the same electrode, was 6.5 $\pm$ 0.1. However, other electrodes gave different results, suggesting that z varied with current density or, more precisely, with the potential of the corroding electrode. This was investigated by repeating the experiments under

potentiostatic conditions. The current was then integrated with the electronic coulometer described above. At the end of each experiment the solution was analyzed for titanium. By repeating at different potentials, the value of z was obtained as a function of E. The results are shown in Fig. 3A. Below 0.97V, $z \approx 7$ but above this potential, z steadily decreases.

During dissolution of TiC both CO and CO_2 are produced. Potentiostatic experiments showed that as E increases the corrosion produces progressively more CO and less CO_2.

The spectrophotometric analysis of titanium is based on the yellow complex which is formed between titanium ions and H_2O_2. When titanium carbide undergoes anodic dissolution in $2N$ H_2SO_4 containing H_2O_2, the solution becomes progressively more yellow as the concentration of titanium increases. By monitoring the absorbance of the solution, z can be calculated coulometrically. This provides a convenient method for checking the values of z reported above. A constant anodic current was passed through a TiC electrode in a solution containing 50 ml of $2N$ H_2SO_4 and 10 ml of 3% H_2O_2. The absorbance of the solution was measured at half-hourly intervals and plotted as a function of time. A linear relationship was obtained, from the slope of which z was calculated. This was repeated at different currents. The results are shown in Fig. 2. From seven such experiments a value of $z = 4.98 \pm 0.05$ was obtained, which suggests that in the presence of H_2O_2 the anodic dissolution of TiC proceeds by Eq. [1] only. However, analysis of the gaseous corrosion products showed that both CO and CO_2 are formed. An explanation of this, and of the constancy of z in this solution, is proposed below.

As a confirmation of the effect of H_2O_2, the dissolution of TiC was studied in a solution of the same composition under potentiostatic conditions; z was measured as a function of potential. The results shown in Fig. 3B confirm the value of $z = 5$ for potentials less than about 1V. Above this, simultaneous oxidation of the H_2O_2 begins, with a consequent lowering of the current efficiency for carbide dissolution. Calculated values of z therefore become greater.

Rotating ring-disk electrode.—The electrode described above was used to determine whether Ti^{3+} is produced as an unstable intermediate in the anodic oxidation of TiC. The electrode was rotated at 50 rpm in $2N$ H_2SO_4 saturated with nitrogen. A constant potential of 1.15V was applied to the ring, and the ring current i_R was recorded while the disk current i_D was zero. When i_R was steady, a constant anodic current of 200 μA was passed through the disk, which adopted a potential of about 1V. The instant that the disk current was switched on, the ring current rose. When i_D was switched off, i_R fell back to its original value. The absolute value of i_R was very small, less than 0.1 μA (corresponding to 1 $\mu A\ cm^{-2}$). A potential of 1.10V was then applied to the ring with i_D still zero, to establish a new residual ring current. When this was stable, the disk current was switched on and i_R immediately rose. This sequence was repeated at several potentials. Figure 4 shows the effect of i_D on i_R at three ring potentials. Values of i_R were so small that it was not possible to correlate them with values of i_D and with the rotation speed of the electrode. When the residual ring current and the increase, δi_R, which occurred when the disk was switched on were plotted against ring potential, the relationships shown in Fig. 5 were found. These two figures are discussed below.

Tafel curves for the dissolution reaction.—Figure 6 shows Tafel curves obtained in various concentrations of H_2SO_4. A high degree of reproducibility was obtained, and the slope of 0.073V/decade was the same in each solution.

Discussion

The results obtained with the RRDE clearly show (Fig. 4) that dissolution of the TiC disk produces a species which is then oxidized at the ring. When these results are plotted in the form shown in Fig. 5, two interesting features appear. First, the residual ring current (i_R when $i_D = 0$) plotted against ring potential passes through zero at 0.89V. This potential is in close agreement with the equilibrium potential for the Pt/PtO system reported by Hoare (3), who gave a value of 0.88V in the same solution as that used in the present work. When $i_D \neq 0$, the total ring current therefore contains a contribution due to platinum oxidation, plus an additional part due to an oxidizable species produced by the dissolution of the disk. The second feature is that values of δi_R are independent of potential. Absolute values are only about 0.01 μA. This is, however, precisely the order of magnitude which would be expected for the oxidation of an unstable Ti(III) intermediate. From Pourbaix (4), the equilibrium potential for the redox couple Ti^{3+}/TiO^{2+} at pH = 0 and at $TiO^{2+}/Ti^{3+} = 1$ is about 0.16V. Since the potential of the TiC disk is above 0.8V during its dissolution, Ti(III) would undergo immediate oxidation at the disk, and only a very small fraction would be expected to reach the ring. This can be evaluated from the present results. The collection efficiency for the electrode used here is 0.27, from the tabulated values of Albery and Bruckenstein (5). If the dissolution of the disk initially produces Ti^{3+}, for which the stoichiometric reaction may involve 5 electrons (which will be discussed below), a current of 200 μA at the disk should give rise to a ring current of 10.8 μA. Since the observed values of δi_R were about 0.01 μA, only about 0.1% of the Ti(III) produced at the disk was able to leave the surface before being oxidized to Ti(IV). The Ti(III) which reaches the ring is oxidized at the limiting current. This is in good agreement with recent work on the corrosion of titanium (6), in which a similar limiting current was found for the oxidation of Ti^{3+} to Ti^{4+}.

The results of the coulometric experiments can be explained as follows. In the absence of H_2O_2, the effect of which will be discussed below, $z \approx 7$ at potentials below 0.97V (Fig. 3A). Both CO and CO_2 are produced in approximately equal quantities. The reaction therefore clearly follows two paths simultaneously, those represented by Eq. [3] and [4], with Ti(III) occurring as an unstable intermediate. The mean value of z for these two reactions is thus about 7, as observed. At higher potentials, z decreases and a progressive increase in the amount of CO produced was observed. That is, the reaction favors Eq. [3]. It would appear to be contradictory, that as the potential is made more anodic the lower oxide of carbon is favored. This can only be so if CO_2 is formed by the oxidation of CO adsorbed on the electrode surface, and which undergoes progressive desorption above 0.97V. The work of Gilman (7) in fact shows that this is quite possible. He studied the adsorption of CO on a platinum electrode in 1*N* $HClO_4$, and observed that it was adsorbed up to 0.90V (against a hydrogen electrode in the same solution) but that above this potential the surface coverage of CO decreased rapidly. Therefore the dissolution of TiC produces Ti^{3+} and CO as initial products, the Ti^{3+} undergoing immediate oxidation at the electrode surface while the CO may either desorb or be oxidized to CO_2. As the potential increases, the desorption reaction is favored.

This explanation for the potential dependence of z also accounts for the fact that constant current experiments gave values of z which were generally noninteger and which apparently depended on the current density. Thus there is good agreement between the observed potential (1.01V) during the galvanostatic experiment reported above, and that expected from Fig. 3A for $z = 6.5$ (1.02V).

In the presence of H_2O_2 the dissolution of TiC produces both CO and CO_2, but z is constant at 5. This in fact affords further evidence for the intermediate formation of Ti(III). The initial reaction may be represented by Eq. [1], for which $z = 5$, producing Ti(III) and CO as discussed above. The oxidation potential of H_2O_2 is, however, higher than the electrode potential. Therefore oxidation of Ti(III), and of adsorbed CO to CO_2, by H_2O_2 in the double layer occurs at a greater rate than electrochemical oxidation. This may be represented by

$$TiC + H_2O = Ti^{3+} + CO_{ads} + 2H^+ + 5e^-$$

$$CO_{ads} = CO$$

$$CO_{ads} + H_2O_2 = CO_2 + H_2O$$

$$Ti^{3+} + H_2O_2 = \text{yellow complex.}$$

Thus both CO and CO_2 are formed while z remains constant at 5.

The Tafel slope of 0.073V/decade gives $n\beta = 0.81$, where n is the number of electrons involved in the rate-determining step and β is the anodic transfer coefficient. Since the dissolution is a completely irreversible reaction, the absolute value of the overvoltage, η, is not known and the lines of Fig. 6 cannot be extrapolated to $\eta = 0$ to obtain an exchange current density. Whether the R.D. step is a one-electron reaction with $\beta = 0.81$, or a two-electron transfer with $\beta = 0.40$, cannot be determined from the present work, and consequently this step cannot be identified.

Electrodeposition of Resins at Soluble Metal Anodes

Sidney L. Phillips*,[1] and Eugene P. Damm, Jr.

Systems Development Division, International Business Machines Corporation, Poughkeepsie, New York 12602

ABSTRACT

The electrodeposition of dispersed organic polymers onto soluble metal anodes is treated in terms of the diffusion of metal ions through the film as the rate-determining step. Diffusion control of the current was shown by the linearity of plots of current *vs.* $t^{-1/2}$. Equations were derived which relate the instantaneous film thickness and rate of film growth as functions of time. Experiments carried out in an aqueous dispersion gave results in agreement with theoretical predictions. The experimental results do not support the ohmic equation which has been proposed to account for the falloff in current with time.

Electrodeposition of resins from aqueous dispersions has application to coating of metallic objects by organic films (1-6). The deposition process consists of a number of steps, which may include diffusion and migration of cations, anions, and water, flocculation and compaction of the dispersed resin onto the anode, and oxidation of a functional group on the resin. It is generally agreed that flocculation of the resin is caused by metallic ions generated at the anode (2, 5).

In the present work, we report the results of a study focused primarily on deriving equations which can be used to predict deposition rates and the dependence of film thickness on plating time. Included also is a study of the effect of applied voltage on the current and film thickness, and an alternate explanation for the fall off in plating current with time, which has been observed by others (8-10).

Theory

In agreement with other workers, we assume that deposition of resins at soluble metal anodes proceeds via a mechanism involving electrochemical flocculation. After formation of the initial film (5), metal ions formed at the electrode-film interface must pass through the growing organic layer to the film-dispersion interface so that flocculation may continue. One mode of mass transfer of metal ions from the anode through the film is by diffusion.

If the mode of mass transfer of metal ions through the film is by Fickian diffusion, current-time curves will show a typical shape such that a plot of faradaic current *vs.* the reciprocal of the square root of time yields a straight line (14). Plots were constructed according to this relationship using published data for three different dispersion-electrode systems (8-10), and are shown in Fig. 1. As can be seen, straight lines are obtained in each case, showing diffusion control over these time ranges. On this basis, we will assume that the limiting step in the deposition of a concentrated suspension at soluble metal anodes is diffusion of the metal ion through the organic film to derive an equation relating the film thickness as a function of time.

Film thickness controlled by metal diffusion.—The organic film initially formed is assumed free of metal ions (5) so that at the start of the experiment we write

$$t = 0, \quad 0 > x \geqq l: \quad C_O = 0 \qquad [1]$$

Here, t is the time, x is the linear distance within the film, l is the film thickness, and C_O is the concentration of metal ion within the film.

As boundary conditions, we prescribe

$$t > 0, \quad x = 0: \quad C_O = C^*_O \qquad [2]$$

$$x = l: \quad C_O = 0 \qquad [3]$$

$$D_O \left(\frac{\partial C_O}{\partial x} \right) = M \frac{dl}{dt} \qquad [4]$$

Key words: electrophoretic deposition, electroplating, dispersions, diffusion, growing films.

In Eq. [2], C^*_O is the concentration of metal ion at the electrode-film interface, with the value of C^*_O determined by the solubility of the metal ion in the medium (7). In Eq. [3], the concentration of metal ions at the film-dispersion interface is set equal to zero (4, 8), while in Eq. [4], the flux of metal ions at this interface is equated to the rate of growth of the film. In this last equation, M represents the concentration of metal within the film, and D_O is the diffusion coefficient of the metal ion within the wet film. Deposition occurs as metal ions arrive at the film-dispersion interface by a diffusional process, so that Fick's second law may be applied. For a planar electrode

$$\frac{\partial C_O}{\partial t} = D_O \frac{\partial^2 C_O}{\partial x^2} \qquad [5]$$

Equations [1]-[5], representing diffusion with a moving boundary, may be solved by methods analogous to those used in the comparable cases of the freezing of water (11) or metal-tarnishing reaction (12, 13).

In terms of the measured parameters, the solution is

$$C^*_O/M = \sqrt{\pi}\ \alpha\ \exp(\alpha^2)\ \mathrm{erf}(\alpha) \qquad [6]$$

where

$$\alpha = \frac{l}{2\sqrt{D_O t}} \quad \text{and} \quad \mathrm{erf}(\alpha) = \frac{2}{\sqrt{\pi}} \int_0^{\alpha} e^{-y^2}\, dy \qquad [7]$$

For small values of the argument, $\mathrm{erf}(\alpha)$ is expanded in the series

$$\frac{2}{\sqrt{\pi}} \left[\alpha - \frac{\alpha^3}{3} + \frac{\alpha^5}{5.2!} - \frac{\alpha^7}{7.3!} + \cdots \right]$$

so that for thin films or long times, $C^*_O/M = 2\alpha^2$. In this case, the relation between film thickness and coating time may be written in the form

$$l = \sqrt{2\, D_O\, C^*_O\, t/M} \qquad [8]$$

and the film thickness increases as the square root of time.

The comparable expression for the rate of increase in film thickness with time is

$$\frac{dl}{dt} = \frac{2\, C^*_O\, D_O}{M\sqrt{\pi l}} \left\{ \frac{\alpha \exp(-\alpha^2)}{\mathrm{erf}(\alpha)} \right\} \qquad [9]$$

For small α

$$\frac{dl}{dt} = \frac{C^*_O\, D_O}{Ml} \qquad [10]$$

where integration of Eq. [10] yields Eq. [8]. As can be seen in Eq. [9] or [10], the rate of film growth falls off with increasing film thickness.

In the present work, Eq. [8] was applied to deposition of mixtures of polytetrafluoroethylene and acrylonitrile/butadiene copolymer at copper anodes (3).

Experiment

A programmable transistor power supply[2] was used as the voltage source. In practice, the voltage output was applied directly to the two electrodes so that the experiments were conducted under conditions of constant applied voltage. The cathode was a 250 ml capacity stainless steel beaker, while the anodes were prepared from 1 × 2 in. copper strips. Prior to use, the strips were covered with an insoluble polymeric coating using photoengraving techniques so that only a 0.218 × 0.312 in. rectangle of copper was exposed. For experiments where the current was monitored, a decade-box load resistor was placed in the current-carrying loop and the resulting voltage drop was followed using a Sargent Model SR recorder.[3]

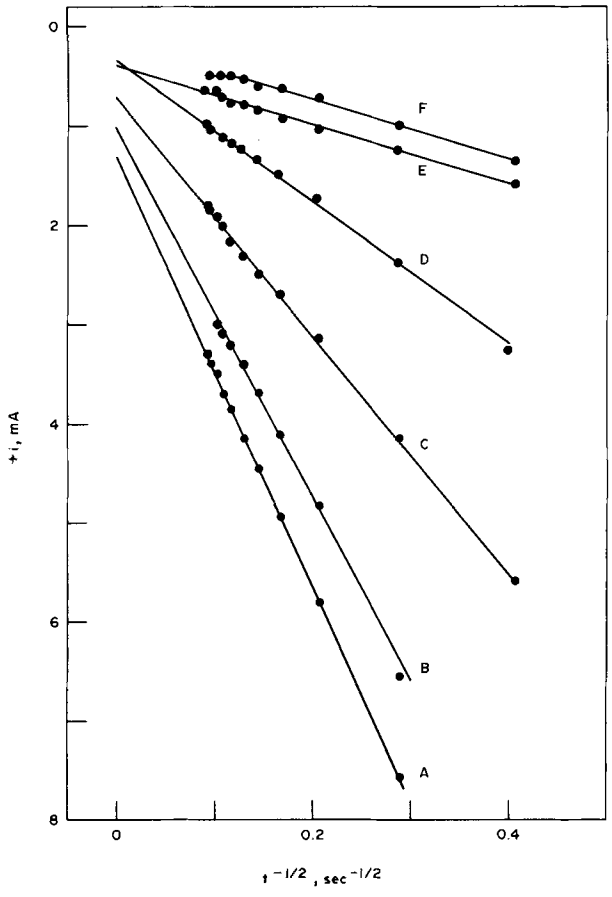

Fig. 2. Plots of faradaic current obtained on anodic dissolution of copper vs. $t^{-1/2}$. Electrode area 0.37 cm². Weight per cent ratio of polytetrafluoroethylene to acrylonitrile/butadiene copolymer: A, 51.1/0; B, 36.6/16.4; C, 24.4/24.6; D, 18.3/28.0; E, 12.2/32.0; F, 0/41.1.

Both of the dispersions were proprietary and were used as received. The polytetrafluoroethylene was E. I. du Pont Teflon 30B containing 61.1 weight per cent (w/o) solids; the acrylonitrile/butadiene copolymer was B. F. Goodrich Hycar 1561, containing 41.1 w/o solids. The dispersions were not stirred during the deposition process.

The electrodes were cleaned with trichloroethylene, followed by detergent and water rinsing before immersion in the dispersion. The two electrodes were then connected to the power supply, and the desired voltage applied for a specific length of time. Usually, the time was measured with a stop watch, but for experiments of less than ten seconds duration a repeat cycle timer[4] was used to apply the voltage.

After completion of deposition, the coated anode was removed from the dispersion and rinsed in distilled water to remove any material which clung to the organic film. The coated anode was then dried under ambient conditions for 2 hr and placed in a forced-flow air oven at 105°C for 10-15 hr. Measurements of the film thickness were made with either a micrometer or under magnification using a Nikon Model C Shadowgraph.

Results and Discussion

Typical plots of the faradaic current *vs.* $t^{-1/2}$ for various weight ratios of the two dispersed substances are shown in Fig. 2. As can be seen, the expected linear plots are obtained in all the experiments where polytetrafluoroethylene is present.

For the acrylonitrile/butadiene copolymer, the current fell rapidly to a constant value, and this behavior is reflected by a change in slope of the linear plot. The

[4] G. C. Wilson & Company, Chatham, New Jersey.

plots shown in Fig. 2 have not been corrected for charging current or residual current effects such as evolution of oxygen (2, 8). Assuming that evolution of oxygen contributes a constant faradaic component to the over-all current at a soluble electrode such as copper, plots such as those shown in Fig. 2 should be obtained; that is, the plots should be linear, but with a positive intercept.

On the basis of these plots, we conclude that passage of copper ions through the polymer film is primarily controlled by a diffusional process describable in terms of Eq. [6] and [8]. Superposed on the anodic copper dissolution current is a contribution from oxidation of the medium, as well as a smaller flow of nonfaradaic charging current caused by a change in the capacitance of the growing organic film.

Variation in film thickness with time.—According to Eq. [8], the instantaneous film thickness is proportional to the square root of time. This relationship was tested for several dispersions, and a typical linear plot obtained from a mixture of polytetrafluoroethylene and acrylonitrile/butadiene is shown in Fig. 3. The data for the plot shown in Fig. 3 were obtained at an applied voltage of 20V, but, as discussed below, higher or lower voltages did not necessarily affect the film thickness significantly.

Effect of applied voltage.—Other workers (4, 8) have accounted for the fall off in faradaic current during an electrophoretic deposition process by noting that the resistance of the growing organic film increases, and therefore the current must decrease according to the ohmic relation, $I = V/(R_F + R)$. In this equation, I is the current, V is the applied voltage, R_F is the time-dependent film resistance, and R is the constant resistance of the dispersed phase. Note that this relation also predicts an increase in current with increasing applied voltage.

In the present work, the applicability of the ohmic equation was tested by depositing Teflon-Hycar organic films onto planar copper electrodes at various applied voltages. The current-time behavior was recorded for those experiments, and typical curves are shown in Fig.

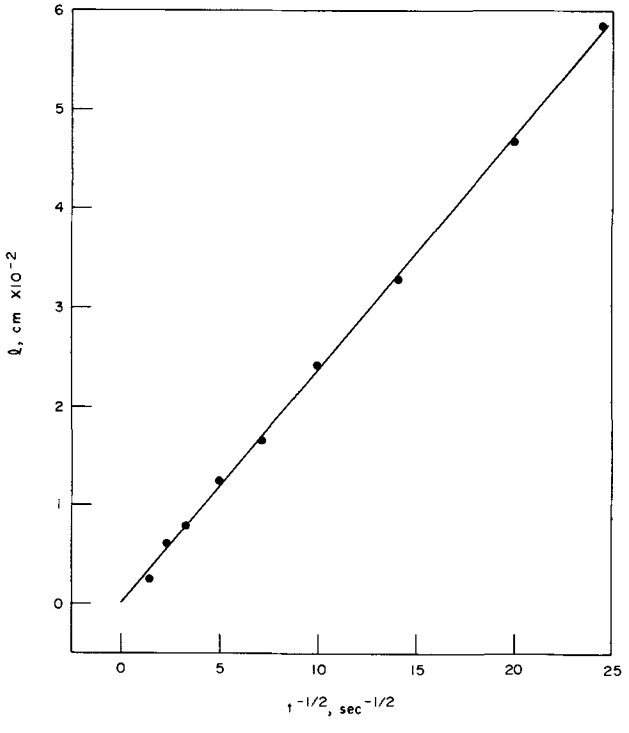

Fig. 3. Plot of film thickness vs. square root of time. Dispersion composed of 36.6 w/o polytetrafluoroethylene and 16.4 w/o acrylonitrile/butadiene copolymer.

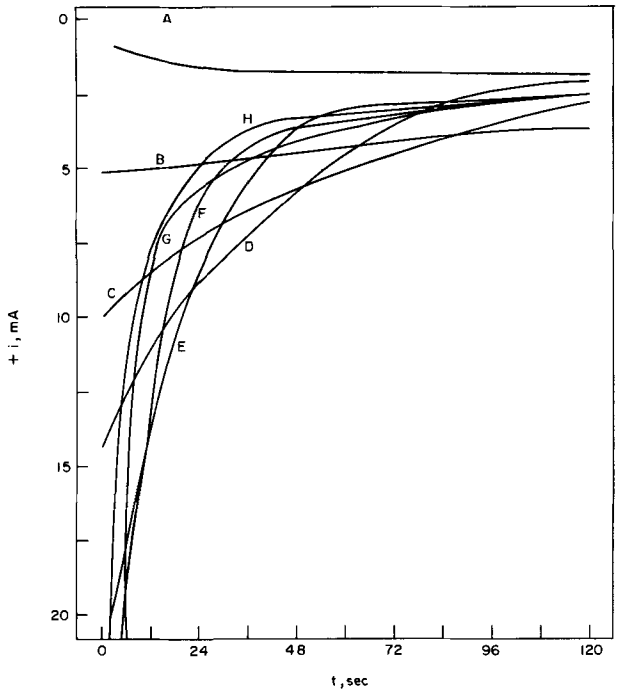

Fig. 4. Current-time curves obtained at various applied voltages for same dispersion composition as in Fig. 2. Applied voltages: A, 1.5; B, 2.0; C, 2.5; D, 3.0; E, 3.5; F, 4.0; G, 5.0; H, 10-100V.

4. Only curves obtained at applied voltages in the range 10-100V gave straight lines over the entire time interval when the current was plotted as a function of $t^{-1/2}$, so that the dissolution of copper is diffusion-limited at all times only over this range. However, the faradaic currents for curves C-G are higher at long times than the corresponding curves obtained at voltages exceeding 10V, indicating that thick films may still be obtained. This is because the film thickness depends on the quantity of metal ions which flowed through the film, so that the important factor to consider is the integral of the current over the time of the experiment which yields the number of coulombs.

Data relating film thickness to the applied voltage are given in Table I and, as can be seen, there is no appreciable change in film thickness over the range 3-100V. Thus, the data in this table and the identical current-time curves obtained at voltages between 10 and 100V do not support the ohmic relation for this dispersion system.

Conclusion

We conclude that the rate-determining step in the deposition of the polymers investigated here is satis-

factorily described by Eq. [6] and [8]. However, these equations apply when the metal ion is free to diffuse through the organic film. When the dispersion has a high resistance, as in the case of a nonaqueous medium, Eq. [6] and [8] do not hold and the film buildup may follow the relationships derived by Hamaker (12), and Hill, Lovering, and Rees (13). The important characteristic which deposited resins must have to follow Fick's law is probably inclusion of a substantial amount of water in the deposit, so that metal ions can diffuse through the film.

Correlations between the Kinetics of Electrolytic Dissolution and Deposition of Iron

I. The Anodic Dissolution of Iron

F. Hilbert,[1] Y. Miyoshi,[2] G. Eichkorn, and W. J. Lorenz[†]

Department of Electrochemistry, University of Karlsruhe, Karlsruhe, Germany

ABSTRACT

A synopsis of experimental results on the anodic dissolution of iron is given. From these data the existence of two different reaction mechanisms is proved, of the noncatalyzed (Bockris) mechanism and of the catalyzed (Heusler) mechanism. The current density-potential relations under steady-state and nonsteady-state conditions are given. An atomistic model of the two dissolution mechanisms is confirmed by electron micrography. It is shown that a change between reaction mechanisms can be brought about at will. Which one of the two mechanisms is predominant depends on the surface activity of the iron sample, which is determined by the crystallographic substructure. This is shown by x-ray measurements, electrochemical experiments, and electron micrographs. The exchange current densities of the Fe/Fe^{++} electrode are calculated and discussed.

With regard to the industrial use the importance of a detailed knowledge about the electrochemical and corrosion behavior of the metals of the iron group is obvious. However, investigations of the mechanisms of these metal/metal-ion electrodes are difficult, due to the great number of parameters determining the electrochemical behavior: charge transfer overvoltage, crystallization overvoltage, adsorption and desorption of gases and other surface active substances, the formation of intermediate reaction compounds, complexation of the metal ions with components of the solution, passivation phenomena, the occurrence of two or more electrode reactions at the same time (on corroding metals), etc.

For solid metals an important influence of the surface activity on the phase boundary reaction itself is to be expected. However, until now the experimental results regarding this dependence are rather scarce. For thermodynamic equilibria the activity of pure condensed phases is equal to one by definition. For kinetic phenomena this approximation is not valid. This has been known for a long time from investigations of catalytic reactions. Especially in the case of heterogeneous reactions of the catalytic active metals of the iron group an influence of the surface activity should be evident.

Thorough investigations into the mechanisms of complicated metal/metal ion electrodes are possible only if a great number of determining parameters can be eliminated or held constant. For this reason, in many experiments the following model system was used:

High purity metal[3]/acid solution; free of oxygen, surface active substances, and complex forming compounds.

[3] In our experiments the purity was better than 99.95% (1).

Key words: corrosion; charge transfer mechanism of iron; crystallographic substructure, influence on charge transfer; iron electrode, exchange current density of.

By using high-purity metal, one eliminates the influence of atomic disorder caused by impurity atoms and the absorption of hydrogen into the metal is made negligible. The kinetics of cathodic hydrogen evolution are relatively well known. Other reactions, *e.g.*, cathodic reduction of oxygen or the formation of surface covering compounds, cannot occur in this medium. The necessary purity grade of all reagents, including water, is very high, owing to the sensitivity of the transition metals to surface active substances. To maintain a high enough electrical conductance of the solution and to simplify somewhat the structure of the electrical double layer a relatively high concentration of an inert electrolyte is necessary. It has been shown (1, 2), that sulfate and perchlorate ions are not surface active on metals of the iron group; for this reason most of the experiments are done in acid solutions of the sodium salts of these anions.

Part I represents mainly a review of the present knowledge about the anodic dissolution of iron, although some as yet unpublished results and interpretations are included. For the first time in print appear the experimental data of the section on Cold working of inactive samples and some of the theoretical interpretations in the sections on Reaction Mechanisms of Anodic Dissolution, Kinetic Equations, Atomistic Model, and Exchange Current Density of the Fe/Fe^{++} Electrode.

General Results

Many papers dealing with the anodic dissolution of iron have been published in the last few years (1-58). All authors agree that the over-all dissolution reaction

$$Fe \rightleftharpoons Fe^{++} + 2e^-$$

shows no dependence on the ferrous iron concentration, but that the reaction is stimulated by hydroxyl ions, even in highly acidic solutions. This is shown by a positive electrochemical reaction order relating to the pH of the solution. At first, a catalytic effect of the hydroxyl ions in acid solutions seems very unlikely. Because at pH = 1 the OH^- concentration is about 10^{-13} moles/liter and one finds one OH^- ion/cm^2, calculated for a distance of 50Å. This concentration is evidently too low to influence the reaction. However, there is the possibility of generation of OH^- ions from water molecules by deprotonation. A positive surface charge and the tendency of the transition metals to form complexes is assumed to be the cause of this reaction. A water dipole will adsorb on the surface with the negative oxygen directed against the positive metal. The energy for deprotonation is supplied by the resulting electrical energy and by the energy of the specific adsorption bond between metal and hydroxyl ions.

The great number of experimental results led mainly to two theories about the anodic dissolution mechanism of pure iron, worked out by Heusler (17-22) and Bockris (24-26). Both authors also investigated the cathodic deposition reaction in order to prove their theories. For some time it seemed impossible to find an explanation for the different results. So the workers seemed to fall into two groups proving either the one or the other theory. Recently it could be shown that both the proposed mechanisms can occur (1, 28, 49-52). They depend on the substructure of the solid. This means that different surface activities lead to different reaction paths for the electrolytic dissolution of iron. The influence of crystal imperfections on the reaction kinetics was quantitatively measured in the model system described above.

Kinetic Parameters of Anodic Dissolution

High-purity iron with very low surface activity is dissolved by a noncatalyzed mechanism, which agrees with the results of Bockris (24-26), Kelly (27), and others. Such a material is produced by zone melting or recrystallization under high vacuum. Evidently single crystals follow the same mechanism.

Highly active material, that is iron with a high density of multidimensional crystal imperfections, dissolves by a catalyzed mechanism, which agrees with results of Heusler (17-22) and others. Such a material with high density of crystal dislocations and strong deformations of the crystal lattice can be produced by cold-working processes.

The two different sets of experimental data obtained in dissolution experiments with these two materials are shown in Table I (1, 28, 49-52). The reproducibility is very good. The density of crystal imperfections was determined by x-ray measurements (1, 28, 49-52). The theoretical values are found from the kinetic equations for the two reaction paths (see below, section on Kinetic Equations). The terminus nonsteady-state means that the results are obtained by galvanostatic or potentiostatic pulse measurements. As can be seen, the agreement between experimental and theoretical results is rather good. The two mechanisms give different Tafel slopes under steady-state conditions and different reaction orders related to the pH. Under steady-state conditions the difference of 10 mV between Tafel slopes is rather small. But precision measurements show this difference beyond doubt. The difference between the reaction orders is big enough and can be exactly determined.

Reaction Mechanisms of Anodic Dissolution

Table II shows the two proposed mechanisms of the anodic iron dissolution (1, 17-28, 49-52). The main difference is in the rate-determining charge transfer reaction. These mechanisms and their dependence on the metal-substructure are discussed in the following section. At the beginning in both cases a potential dependent reaction sequence leads to the formation of adsorbed $(FeOH)_{ads}$. It is assumed, that this sequence is at equilibrium (Eq. [1]).

In the case of the noncatalyzed mechanism this sequence is followed by the charge transfer step. In this rate-determining part of the reaction $FeOH^+$ ions are

Noncatalyzed mechanism

$$(FeOH)_{ads} \not\rightleftharpoons FeOH^+ + e^- \quad [2]$$

Catalyzed mechanism

$$Fe + (FeOH)_{ads} \rightleftharpoons [Fe(FeOH)] \quad [3]$$

$$[Fe(FeOH)] + OH^- \not\rightleftharpoons FeOH^+ + (FeOH)_{ads} + 2e^- \quad [4]$$

$$FeOH^+ + H^+ \rightleftharpoons Fe^{++}\text{-aq} + H_2O \quad [5]$$

formed and pass the electrochemical double layer (Eq. [2]).

In the case of the catalyzed mechanism the first sequence is followed by a second surface reaction (Eq. [3]). In this step a catalytic active surface compound is formed. We believe that the formula [Fe(FeOH)] is a possible schematic hypothesis for this compound. The formation of this surface catalyst is dependent on the surface activity of the metal. Plausibly the formation will take place at kinks of the metal crystal or at adatoms in their vicinity. From these surface complexes the reaction products of the charge transfer step (Eq. [4]) are formed. In this rate-determining step Fe^{++} ions pass the electrochemical double layer and form $FeOH^+$ complexes with OH^- ions. In the course of this mechanism, the sequence Eq. [1] is a parallel electrochemical reaction. The over-all reaction after the start consists only of the steps Eq. [3], Eq. [4], and Eq. [5].

The noncatalyzed mechanism takes place if the equilibrium of Eq. [3] is shifted to the left by a very low surface activity of the metal. If the surface activity is high, this equilibrium is shifted to the right. Large amounts of the surface catalyst are formed and the reaction follows the catalyzed mechanism.

The succeeding reaction is the fast hydrolysis step (Eq. [5]), which is the same for both mechanisms.

The noncatalyzed mechanism shows two consecutive charge transfer reactions of one elementary charge unit. On the other hand, the catalyzed mechanism has only one charge transfer reaction, in which two elementary charge units are transported across the double layer. A reaction of this last type is energetically rather improbable. However, the experimental results of the second type cannot be explained in any other way. Another explanation of the different Tafel slopes could be the superposition of crystallization overvoltage. But in this case there exists no explanation for the large difference in reaction orders. For this reason we beleive that the catalyzed mechanism is possible under certain conditions: (*i*) a high density of crystal imperfections and therefore a high catalytic activity of the metal, and (*ii*) dissolution within a limited range of the anodic polarization curve (compare with section on Exchange Current Density of the Fe/Fe^{++} Electrode).

Two things have to be pointed out at this stage: For the first, the scheme of the catalyzed mechanism is only hypothetical. However, the reaction sequence corresponds to the experimental results. For the second, we think, the terms "catalyzed mechanism" and "noncatalyzed mechanism" are not very suitable, although their use is common in the literature. It would be better to term the charge transfer reaction "catalyzed" and "noncatalyzed."

Kinetic Equations

Steady-state conditions.—For the mechanism with noncatalyzed charge transfer one obtains from Eq. [1], [2], and [5] of Table II the following current-potential relations (the zeta-potential is assumed negligible)

$$i_1 = k_1 \cdot a_{Fe} \cdot a_{H_2O} \cdot \exp\left(\frac{\alpha_1 F \epsilon}{RT}\right) - k_{-1} \cdot a_{(FeOH)_{ads}} \cdot a_{H^+} \cdot \exp\left(-\frac{(1-\alpha_1) F \epsilon}{RT}\right) \quad [6]$$

$$i_{o,1} = k_1 \cdot \bar{a}_{Fe} \cdot \bar{a}_{H_2O} \cdot \exp\left(\frac{\alpha_1 F \epsilon_o}{RT}\right) = k_{-1} \cdot \bar{a}_{(FeOH)_{ads}} \cdot \bar{a}_{H^+} \cdot \exp\left(-\frac{(1-\alpha_1) F \epsilon_o}{RT}\right) \quad [7]$$

$$i_1 = i_{o,1}\left[A \cdot \exp\left(\frac{\alpha_1 F \eta}{RT}\right) - B \cdot \frac{a_{(FeOH)_{ads}}}{\bar{a}_{(FeOH)_{ads}}} \cdot \exp\left(-\frac{(1-\alpha_1) F \eta}{RT}\right)\right] \quad [8]$$

with

$$A = \frac{a_{Fe}}{\bar{a}_{Fe}} \cdot \frac{a_{H_2O}}{\bar{a}_{H_2O}}, \quad B = \frac{a_{H^+}}{\bar{a}_{H^+}}, \quad \eta = \epsilon - \epsilon_o$$

$\bar{a}_i$ = equilibrium activity of the species i at $\epsilon = \epsilon_o$

and

$$i_2 = i_{o,2}\left[\frac{a_{(FeOH)_{ads}}}{\bar{a}_{(FeOH)_{ads}}} \cdot \exp\left(\frac{\alpha_2 F \eta}{RT}\right) - C \cdot \exp\left(-\frac{(1-\alpha_2) F \eta}{RT}\right)\right] \quad [9]$$

with

$$C = \frac{a_{FeOH^+}}{\bar{a}_{FeOH^+}}$$

For a consecutive charge transfer mechanism

$$i = i_1 + i_2 \quad [10]$$

is always valid. Herewith one gets from [8], [9], and [10]

$$\frac{a_{(FeOH)_{ads}}}{\bar{a}_{(FeOH)_{ads}}} = \frac{i - i_{o,1} \cdot A \cdot \exp\left(\frac{\alpha_1 F \eta}{RT}\right) + i_{o,2} \cdot C \cdot \exp\left(-\frac{(1-\alpha_2) F \eta}{RT}\right)}{i_{o,2} \cdot \exp\left(\frac{\alpha_2 F \eta}{RT}\right) - i_{o,1} \cdot B \cdot \exp\left(-\frac{(1-\alpha_1) F \eta}{RT}\right)} \quad [11]$$

Under steady-state conditions

$$\frac{d\, a_{(FeOH)_{ads}}}{d\, t} = \frac{i_1}{z_1 F} - \frac{i_2}{z_2 F} = 0 \quad [12]$$

That means $i_1 = i_2$ and $i = 2\, i_2$ for $z_1 = z_2 = 1$. Therefore [8] = [9] and using [11] it follows that

$$i = 2 \cdot i_{o,1} \cdot i_{o,2} \frac{A \cdot \exp\left(\frac{(\alpha_1+\alpha_2) F \eta}{RT}\right) - B \cdot C \cdot \exp\left(-\frac{(2-\alpha_1-\alpha_2) F \eta}{RT}\right)}{i_{o,2} \cdot \exp\left(\frac{\alpha_2 F \eta}{RT}\right) + i_{o,1} \cdot B \cdot \exp\left(-\frac{(1-\alpha_1) F \eta}{RT}\right)} \quad [13]$$

As shown above, sequence [1] is assumed to be fast, while reaction [2] is rate determining. That means that

$$i_{o,1} >> i_{o,2}$$

and simplifying [13]

$$i = 2 \cdot i_{o,2} \left[\frac{A}{B} \cdot \exp\left(\frac{(1+\alpha_2)\mathbf{F}\eta}{RT} \right) - C \cdot \exp\left(-\frac{(1-\alpha_2)\mathbf{F}\eta}{RT} \right) \right] \quad [14]$$

Equation [14] represents the current density-overvoltage relation for the mechanism with noncatalyzed charge transfer. From [14] the following kinetic data can be obtained under anodic polarization ($\eta >> 0$)

$$b_{+,\mathrm{Fe}} = \left(\frac{\partial \eta}{\partial \log i_+} \right)_{a_i, \bar{a}_i} = \frac{2.303\,RT}{(1+\alpha_2)\mathbf{F}} = +39.4 \text{ mV} \quad [15]$$

(with $\alpha_2 = 0.5$; $T = 298°\mathrm{K}$).

$$n_{+,\mathrm{pH}} = \left(\frac{\partial \log i_+}{\partial \mathrm{pH}} \right)_{a_j, \epsilon} = +1 \quad [16]$$

In the case of the mechanism with catalyzed charge transfer from [1], [3], [4], and [5] one gets the following current density-overvoltage relationships using the symbol K for [Fe(FeOH)]

$$i = k_4 \cdot a_{\mathrm{K}} \cdot a_{\mathrm{OH}^-} \cdot \exp\left(\frac{2\alpha_4 \mathbf{F}\epsilon}{RT} \right) - k_{-4} \cdot a_{(\mathrm{FeOH})_{\mathrm{ads}}} \cdot a_{\mathrm{FeOH}^+} \cdot \exp\left(-\frac{2(1-\alpha_4)\mathbf{F}\epsilon}{RT} \right) \quad [17]$$

$$i_{o,4} = k_4 \cdot \bar{a}_{\mathrm{K}} \cdot \bar{a}_{\mathrm{OH}^-} \cdot \exp\left(\frac{2\alpha_4 \mathbf{F}\epsilon_o}{RT} \right) = k_{-4} \cdot \bar{a}_{(\mathrm{FeOH})_{\mathrm{ads}}} \cdot \bar{a}_{\mathrm{FeOH}^+} \cdot \exp\left(-\frac{2(1-\alpha_4)\mathbf{F}\epsilon_o}{RT} \right) \quad [18]$$

$$i = i_{o,4} \left[\frac{a_{\mathrm{K}}}{\bar{a}_{\mathrm{K}}} \cdot \frac{a_{\mathrm{OH}^-}}{\bar{a}_{\mathrm{OH}^-}} \cdot \exp\left(\frac{2\alpha_4 \mathbf{F}\eta}{RT} \right) - C \cdot \frac{a_{(\mathrm{FeOH})_{\mathrm{ads}}}}{\bar{a}_{(\mathrm{FeOH})_{\mathrm{ads}}}} \cdot \exp\left(-\frac{2(1-\alpha_4)\mathbf{F}\eta}{RT} \right) \right] \quad [19]$$

$$i_+ \simeq i_{o,4} \cdot \frac{a_{\mathrm{K}} \cdot a_{\mathrm{OH}^-}}{\bar{a}_{\mathrm{K}} \cdot \bar{a}_{\mathrm{OH}^-}} \cdot \exp\left(\frac{2\alpha_4 \mathbf{F}\eta}{RT} \right) \quad [20]$$

The activities of the catalytic surface complex are given from Eq. [3]

$$\frac{a_{\mathrm{K}}}{\bar{a}_{\mathrm{K}}} = \frac{a_{\mathrm{Fe}}}{\bar{a}_{\mathrm{Fe}}} \cdot \frac{a_{(\mathrm{FeOH})_{\mathrm{ads}}}}{\bar{a}_{(\mathrm{FeOH})_{\mathrm{ads}}}} \quad [21]$$

In this case under steady-state conditions it follows that

$$\frac{d\, a_{(\mathrm{FeOH})_{\mathrm{ads}}}}{d\, t} = \frac{i_1}{z_1 \mathbf{F}} = 0, \quad z_1 = 1 \quad [22]$$

The combination of [22] and [8] leads to

$$\frac{a_{(\mathrm{FeOH})_{\mathrm{ads}}}}{\bar{a}_{(\mathrm{FeOH})_{\mathrm{ads}}}} = \frac{A}{B} \cdot \exp\left(\frac{\mathbf{F}\eta}{RT} \right) \quad [23]$$

The steady-state current density-overvoltage relation for the mechanism with catalyzed charge transfer reaction is written, using [20], [21], and [23] and $K_w \cdot a_{\mathrm{H_2O}} = a_{\mathrm{H}^+} \cdot a_{\mathrm{OH}^-}$

$$i_+ \simeq i_{o,4} \cdot \left(\frac{A}{B} \right)^2 \cdot \exp\left(\frac{(1+2\alpha_4)\mathbf{F}\eta}{RT} \right) \quad [24]$$

From Eq. [24] one obtains the kinetic data

$$b_{+,\mathrm{Fe}} = \left(\frac{\partial \eta}{\partial \log i_+} \right)_{a_i, \bar{a}_i} = \frac{2.303\,RT}{(1+2\alpha_4)\mathbf{F}} = +29.6 \text{ mV} \quad [25]$$

(with $\alpha_4 = 0.5$ and $T = 298°\mathrm{K}$).

$$n_{+,\mathrm{pH}} = \left(\frac{\partial \log i_+}{\partial \mathrm{pH}} \right)_{a_j, \epsilon} = +2 \quad [26]$$

Nonsteady-state conditions.—Under nonsteady-state conditions the anodic pulse measurements show a decrease of the overvoltage or an increase of the current density with time. The oscillographic curves are illustrated schematically in Fig. 1. The values after charging of the double layer give a Tafel slope of about $b'_+ = +60 \pm 7$ mV at 25°C for both dissolution mechanisms.

These anodic transients and the nonsteady-state Tafel slopes can be explained by an increase of the intermediate ion concentration $(\mathrm{FeOH})_{\mathrm{ads}}$ in the case of the uncatalyzed mechanism or by an increase of the catalyst [Fe(FeOH)] in the case of the catalyzed mechanism. In other words, after the charging of the double layer the steady state of Eq. [12] or [22] is not immediately reached.

The quantitative explanation of the nonsteady-state results is difficult in the case of a consecutive charge transfer mechanism (noncatalyzed charge transfer). Plonski (59-61) has studied the galvanostatic transients by a mathematical treatment. The theoretical results, obtained by computer calculations for a model system, indicate the appearance of "superpolarization" under certain conditions. But the experimental steady-state and nonsteady-state Tafel slopes in a wide overpotential range are not predicted by Plonski's model. Losev (62) has measured the intermediate ion concentration at steady state and found a good agreement between theory of consecutive charge transfer mechanism and experimental results. Recently we have given a very raw mathematical approximation to explain the nonsteady-state Tafel slope (63). But it is evident, that computer calculations based on the theory of Plonski should be studied more exactly.

The measurable electrochemical reaction order in the case of the uncatalyzed mechanism

$$n'_{+,\mathrm{pH}} = \left(\frac{\partial \log i_+}{\partial \mathrm{pH}} \right)_{a(\mathrm{FeOH})_{\mathrm{ads}}, a_i, \epsilon} = +0.5 \quad [27]$$

is only a virtual value. It is dependent on the chosen

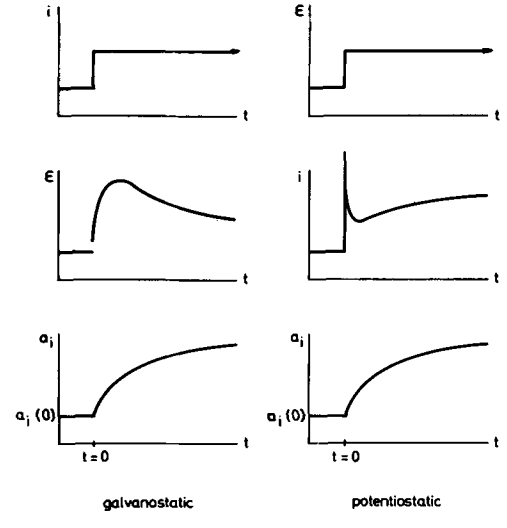

Fig. 1. Pulse measurements (schematic), a_i = intermediate ion activity.

stationary starting conditions, which determine the activity of $(FeOH)_{ads}$ (1, 50).

Now considering the mechanism with catalyzed charge transfer under nonsteady-state conditions, one gets from Eq. [19] with $a_K = \bar{a}_K = \text{const.}$

$$i_+ \simeq i_{0,4} \cdot \frac{a_{OH^-}}{\bar{a}_{OH^-}} \cdot \exp\left(\frac{2\alpha_4 F\eta}{RT}\right) \qquad [28]$$

The current density-overvoltage relation yields the kinetic data

$$b'_{+,Fe} = \left(\frac{\partial\eta}{\partial \log i_+}\right)_{a_{OH^-},\bar{a}_{OH^-}} = \frac{2.303\,RT}{2\,\alpha_4 F} = + 59.2 \text{ mV} \qquad [29]$$

(with $\alpha_4 = 0.5$; $T = 298°K$).

$$n'_{+,pH} = \left(\frac{\partial \log i_+}{\partial \text{ pH}}\right)_{a_k,\epsilon} = +1 \qquad [30]$$

Atomistic Model

It was shown by x-ray investigations of the materials, that the catalyzed mechanism only takes place in the case of high density of multidimensional crystal imperfections (1, 28, 49-52). Owing to the strong deformations of the crystal lattice, the concentration of active centers on the surface is high, as well as the degree of their activity.

If the density of multidimensional disorder is low, the dissolution takes place by the noncatalyzed mechanism. The surface of crystal grains consists of planes of different orientation. These planes are separated by subgrain boundaries that are built up by crystal dislocations. Those dislocations are active centers for the interesting phase boundary reaction. The activation energy for the formation of dissolution nuclei on the nondisturbed crystal planes is relatively high. Therefore the rate of dissolution due to nucleation from crystal planes will be low compared with the over-all dissolution rate, which is preferentially given by successive dissolution of whole monolayers of the subgrains. On account of the high separation energy of metal atoms from the lattice the concentration of adatoms will be low. All this means that the formation of the surface catalyst complex, which needs adatoms or kinks, will be very slow, and the catalyzed charge transfer reaction will supply only a very small part of the current. Substantial proof for this atomistic model was found by electron microscopy of electrolytically etched iron surfaces (51).

The catalyzed mechanism should produce a very rough surface, on account of a high dissolution rate at a great number of active centers. This model for the dissolution of high active metal is shown in Fig. 2. The electron micrograph of Fig. 3 shows the experimental result in good agreement with the model.

The surface produced by the noncatalyzed mechanism should be smooth, because on the slightly disordered planes one can expect the dissolution of more or less a whole monolayer before the next nucleus is formed. This is schematically displayed in Fig. 4.

The micrograph of a recrystallized, anodically etched iron sample is shown in Fig. 5. It seems to prove the theory.

The mean diameter of coherent regions was estimated from electron micrographs and compared with x-ray measurements. For high active material it is less than 1000Å, whereas for low activity metal it is more than 10,000Å.

Changing the Dissolution Mechanism

There are several ways to change the anodic dissolution mechanism by changing the surface activity of the sample (1, 28, 49-52).

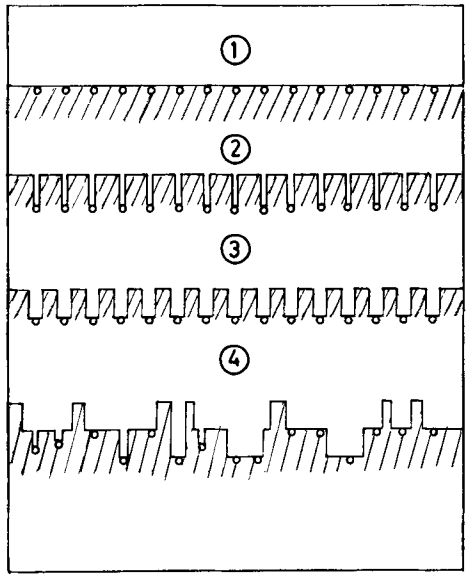

Fig. 2. Development of the surface profile during anodic dissolution of a highly active iron (starting from an electropolished sample). ○ = dislocations; 1,2,3,4 = dependence on time.

Fig. 3. Electron micrograph of an anodically etched iron with high surface activity, $i_+ = 50 \cdot 10^{-3}$ A · cm^{-2}, $t \triangleq 300$ sec, $V = 9600$ (9.6 mm $\triangleq 1\mu$).

Recrystallization of active samples.—The density of crystal imperfections decreases by recrystallization under high vacuum. Table III shows the dependence of the lattice deformations of a highly active sample on the annealing temperature. The data are calculated from the line broadening of x-ray measurements. Above a temperature of about 700°C the lattice deformations practically disappear, and the density of coherent lattice regions is diminished more than two orders of magnitude. This means that the number of subgrains and the density of subgrain boundaries decreases.

Table IV shows the change of the electrochemical kinetic data that is caused by recrystallization of the iron sample at different temperatures. The highly active starting sample gives the data of the catalyzed mechanism. At higher annealing temperatures recrystallized samples give the data of the noncatalyzed mechanism. If the samples are recrystallized at middle temperatures, there is a superposition of both reaction mechanisms.

Cold working of inactive samples.—Unpublished results show that a change from the noncatalyzed to the

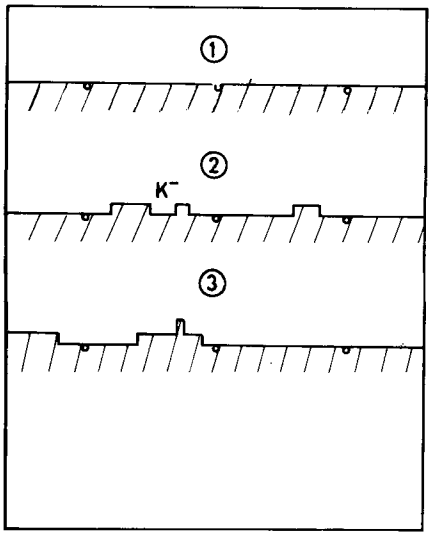

Fig. 4. Development of the surface profile during anodic dissolution of a low activity iron (starting from an electropolished sample). ○ = dislocations; k^- = negative nuclei; 1,2,3 = dependence on time.

Fig. 5. Electron micrograph of an anodically etched iron with low surface activity. $i_+ = 50 \cdot 10^{-3}$ A · cm^{-2}, $t = 300$ sec, $V = 9600$ (9.6 mm ≙ 1μ).

catalyzed mechanism can be brought about by heavy cold working (64). Figure 6 shows current density-potential curves of recrystallized material and of the same iron after heavy mechanical deformation. The change of mechanism is shown by different slopes of the Tafel lines under steady-state conditions, and by the correspondingly different electrochemical reaction orders related to the pH.

Blocking of active surfaces by inhibitors.—In principle it should be possible to change the catalyzed to the uncatalyzed mechanism in this way. Practically, this possibility cannot be realized. A blocking effect is only possible if relatively small inhibitor particles are used that geometrically fit into the semicrystal sites, steps,

900	+40	+63	+0.93 ... 1.08	+0.45

etc. Organic inhibitors have too large molecular sizes, but the surface active halogenide ions would be suitable. Unfortunately, halogenides change both dissolution mechanisms to a third mechanism (1, 20-22, 37, 42, 47, 48, 51). Experimentally it is impossible to decide if the catalyzed mechanism is first changed to the non-catalyzed and only after that to the halogenide-inhibited mechanism, or if the inhibited mechanism is directly reached.

Blocking of low-activity surfaces by inhibitors.—The noncatalyzed mechanism is changed to the catalyzed mechanism if slightly disordered crystal planes are covered with inhibitors (51). In these areas large inhibitor particles fit in much better than at the crystal imperfections (dislocations, semicrystal sites). The blocking causes the dissolution to take place preferentially at the relatively few regions of heavy disarray, following the reaction path of catalyzed charge transfer, while the noncatalyzed mechanism is suppressed.

The experimental results with the inhibitors β-naphthochinoline and o-phenanthroline are shown in Fig. 7. The change of mechanism causes a change of the Tafel slopes under steady-state conditions.

Further proof for the theory is found by electron microscopy (51). The atomistic model leads to the dissolution scheme of Fig. 8, which is in agreement with the real surface profile after anodic etching, as can be seen in Fig. 9. The micrograph shows the dissolution to take place at the relatively few grain boundaries and dislocations.

Exchange Current Density of the Fe/Fe^{++} Electrode

In the present paper we have tried to calculate exchange current densities for the Fe/Fe$^{++}{}_{aq.}$ electrode from literature data and our own results. In order to make comparisons possible, all data were standardized

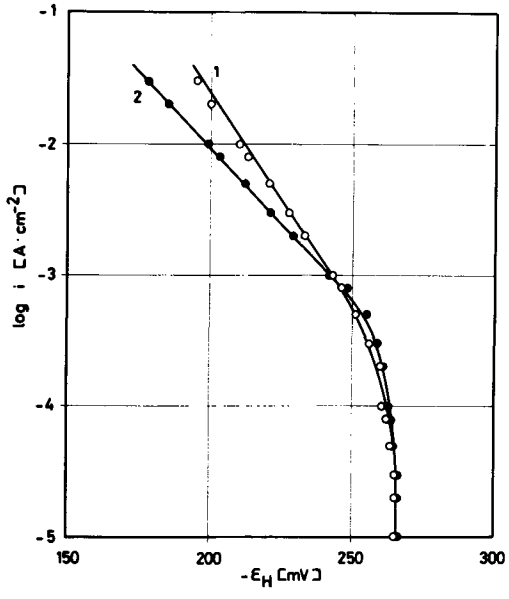

Fig. 6. Steady-state current density-potential curves of recrystallized (2) and cold-worked (1) iron.

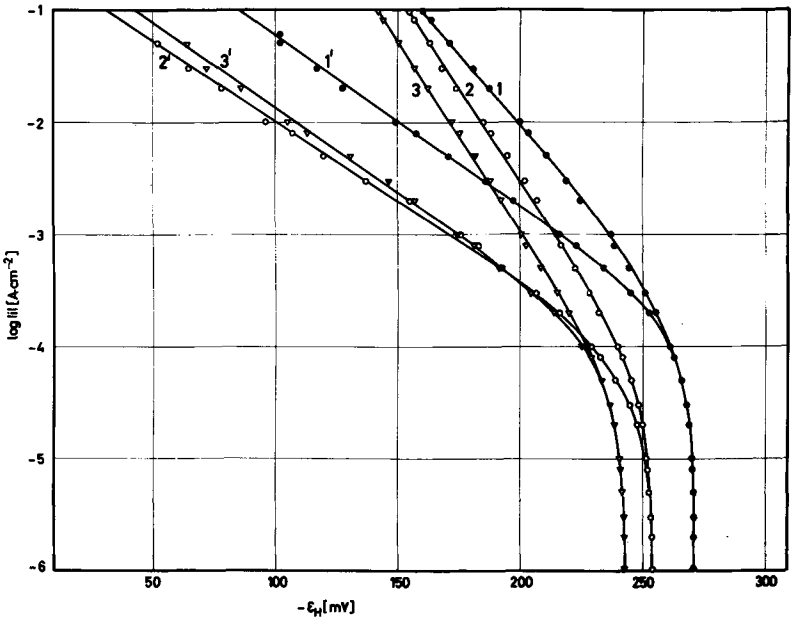

Fig. 7. Steady-state and nonsteady-state current density-potential curves. Electrode: Ommet-iron, annealed at 900°C. Electrolytes: 1 (●), 0.5M H_2SO_4; 2 (○), 0.5M H_2SO_4 + 10^{-2}M o-phenanthroline; 3 (▽), 0.5M H_2SO_4 + 10^{-2}M β-naphthochinoline. Nonsteady-state measurements are marked by primes.

to the conditions: pH = 0, $a_{Fe^{++}} = 1$. The second condition relates all exchange current densities to the standard potential of the iron electrode ($E_{o,H} = -441$ mV). The calculated data are given in Table V. The agreement for each mechanism is good. However, it seems remarkable that the exchange current densities for catalyzed charge transfer are lower than those for noncatalyzed charge transfer. Our explanation is the following one: the noncatalyzed mechanism is energetically favored. Only at elevated anodic potentials and at highly active surfaces the catalyzed charge transfer will be predominant. The activation energy of this process depends much more on the potential. Therefore it becomes predominant at high anodic polarization. The over-all current density is always the sum of two terms

$$i = i_{\text{noncatalyzed}} + i_{\text{catalyzed}} \qquad [31]$$

The polarization curve consists of two regions: at negative potentials the noncatalyzed charge transfer has

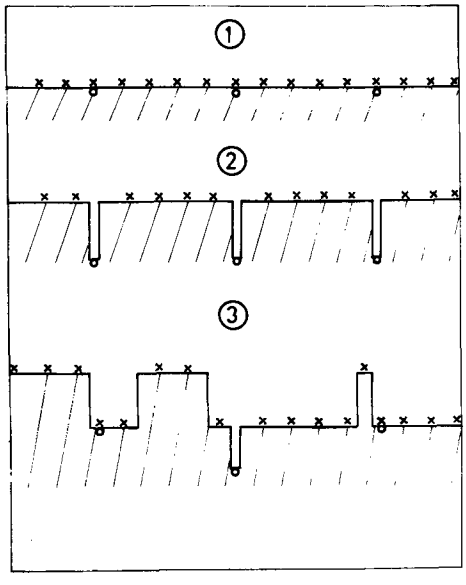

Fig. 8. Development of the surface profile during anodic dissolution of a low activity metal, covered with adsorbed inhibitor molecules. ○ = dislocations; × = adsorbed inhibitor molecules; 1,2,3 = dependence on time.

Fig. 9. Electron micrograph of an anodically etched iron with low surface activity, covered by β-naphthochinoline molecules. $i_+ = 50 \cdot 10^{-3}$ A · cm^{-2}, $t = 300$ sec, $V = 9600$ (9.6 mm ≙ 1μ).

the greater reaction rate and the curve is determined by this process. At more positive potentials the rate of the catalyzed charge transfer is greater and the curve is determined by it. The intersection point of the two parts of the curve depends on the surface activity of the material. The higher the activity, the greater the shifting of this potential to the negative side. In the case of highly active material, we only observe the second part of the curve, because the intersection potential is on the negative side of the corrosion potential.

Conclusions

The experimental results show that the kinetics of anodic phase boundary reactions depend on the surface activity of the solid. For the iron electrode we hope to have proved, beyond doubt, that the anodic dissolution in aqueous solutions can follow two different mechanisms.

In the meantime our results about the iron electrode (1, 28, 49-52, 63, 64) have been confirmed by measurements of Nobe (65). Moreover, the same two mechanisms seem to be valid for the anodic dissolution of cobalt and nickel (22, 39, 40, 66-70).

Manuscript submitted March 19, 1971; revised manuscript received July 27, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Correlations between the Kinetics of Electrolytic Dissolution and Deposition of Iron

II. The Cathodic Deposition of Iron

F. Hilbert,[1] Y. Miyoshi,[2] G. Eichkorn, and W. J. Lorenz[†]

Department of Electrochemistry, University of Karlsruhe, Karlsruhe, Germany

ABSTRACT

The cathodic iron deposition reaction from acid solutions was studied. The partial current density-potential curves of the iron deposition were calculated by current efficiency measurements. The experiments were carried out under steady-state and nonsteady-state conditions at 25°C under hydrogen atmosphere. Under steady-state conditions a rotating gold disk electrode was used in order to eliminate the rise of pH in the vicinity of the electrode surface. The results show two different reaction mechanisms depending on the pH at the electrode surface. At pH < 2.8 the kinetic data correspond to a noncatalyzed mechanism, while at pH > 2.8 a catalyzed mechanism takes place. The influence of the surface pH on the mechanism is due to the different electrochemical reaction orders related to the pH and the formation of hydrolysis products, which may be incorporated in the deposit. The calculated exchange current densities of the Fe/Fe^{++} electrode show that the noncatalyzed mechanism is the normal one.

In Part I we have shown that results of iron dissolution experiments lead to the hypothesis of two different reaction mechanisms.

It is to be expected that a correlation exists between the mechanisms of anodic dissolution and cathodic deposition of iron. The probable form of such a correlation is a reversal of the reaction sequences while the rate-determining step for each mechanism remains the same. This being the case, we have a more pronounced difference between the electrochemical kinetic data of the two reaction mechanisms. We investigated the kinetics of the cathodic iron deposition in order to confirm this hypothesis.

The cathodic deposition of metals with negative standard potentials from aqueous solutions is relatively difficult. This is due to the fact that the reaction rate of the reduction of hydrogen ions as well as that of oxygen is higher than that of the metal ion reduction.

Under such condition a nonnoble metal dissolves with hydrogen evolution, if the electrolyte is an acidic, oxygen-free, and nonoxidizing one. In this case the reversible equilibrium potential of the metal/metal-ion electrode cannot be adjusted without external current. The corrosion potential will then be obtained and lies between the equilibrium potential of hydrogen and that of the metal/metal-ion electrode.

The value of the corrosion potential is determined by the partial current density-potential curves of the cathodic and the anodic processes. The reaction rate and sometimes the type of mechanism depend on the surface activity of the metal, which will then consequently influence the corrosion potential.

Further complications are caused by mass transport phenomena. For example, with increasing pH of the electrolyte the limiting diffusion current density of hydrogen evolution is reached at relatively low values.

The cathodic polarization of such a mixed electrode in acidic, oxygen-free, and nonoxidizing solution leads at first only to hydrogen evolution. The cathodic metal deposition takes place at potentials that are more negative than the equilibrium potential of the metal/metal-ion electrode. Now the total cathodic current is the sum of the metal deposition current and of the hydrogen evolution current

$$i_{-,\text{total}} = i_{-,H^+} + i_{-,Me^{z+}} \qquad [1]$$

In this potential range it is possible to study the kinetics of metal deposition.

Sometimes the complication due to mixed potentials can be avoided. This can be done by increasing the pH of the solution and thereby shifting the equilibrium potential of the hydrogen electrode in the negative direction. Under the conditions

$$\epsilon_{o,H_2/H^+} \leq \epsilon_{o,Me/Me^{z+}}$$

and

$$i_{o,H_2/H^+} < i_{o,Me/Me^{z+}}$$

the hydrogen evolution reaction may be neglected and the system can be considered practically as a simple metal/metal-ion electrode. However, for a number of mixed electrodes these conditions cannot be fulfilled, because (*i*) the equilibrium potentials are too different, (*ii*) the exchange current density of the metal/metal-ion electrode is too low, or (*iii*) the metal ions hydrolyze or precipitate before the necessary pH is reached. In the case of the Fe/Fe^{++} electrode all these points are valid.

The simultaneous evolution of hydrogen has a pronounced influence on the properties of the deposited metal. Such a metal shows higher hardness and brittleness (1, 2). If the limiting diffusion current density of the hydrogen ions is reached, the pH of the cathode film rises. This rise may lead to the formation of hydrolysis products or even precipitates of the metal hydroxides, which can be incorporated in the metal deposit.

To carry out accurate measurements on iron deposition the following requirements should be taken into consideration.

(*I*) The current efficiency of metal deposition has to be known.

(*II*) The hydrogen ion concentration in the cathode film has to be the same as in the bulk of the solution.

(*III*) The metal ion must not hydrolyze neither in solution nor in the cathode film, forming precipitates.

These requirements were not fully taken into account in the previous literature concerning the iron

deposition (3-13). Therefore the given results are not comparable. Especially the investigations of Dahms *et al.* (13) show that precipitation of hydrolysis products of Fe^{2+} ions at the electrode surface has a pronounced influence on the charge transfer process of iron deposition. Such a precipitation takes place, if the surface pH increases up to a value of about pH $\simeq$ 5. Consequently, we examined the kinetics of iron deposition from acid solutions under more exact conditions.

Experimental

Steady-state measurements.—For kinetic studies an exact knowledge of diffusion phenomena is necessary. This was taken into account by using a rotating disk electrode for the steady-state measurements. With increasing rotation rate the limiting diffusion current for hydrogen evolution will rise. This leads to a larger potential range, in which the cathodic hydrogen evolution is controlled by charge transfer. In this Tafel range, the pH is the same both in the double layer as well as in the bulk of the electrolyte. Therefore, exact measurements of cathodic iron deposition are only possible in this potential range.

Experiments dealing with hydrogen evolution under steady-state conditions were carried out in system I

$$\text{rotating gold disk/1M } Na_2SO_4 + x \cdot H_2SO_4$$

at pH values from 1.8 to 4.3. The results of these experiments enabled us to make some statements about mass transport of protons in solutions of this type (14).

The simultaneous cathodic hydrogen evolution and iron deposition was studied in system II

$$\text{rotating gold disk/0.875M } Na_2SO_4 + \text{0.1M } FeSO_4 + x \cdot H_2SO_4$$

at pH values from 1.8 to 3.8.

The ionic strength is the same in both systems. For the determination of the electrochemical reaction order

$$(\partial \log | i_{-,Fe^{++}} | / \partial \log a_{Fe^{++}})_{pH,\epsilon} = n_{-,Fe^{++}}$$

the concentration of both $FeSO_4$ and Na_2SO_4 was varied in such a way that the ionic strength was held constant (at constant pH of the solution).

The limiting diffusion current densities for the hydrogen evolution reaction were assumed to be the same for both systems, because the ionic strength is constant and the supporting electrolyte concentration is only slightly different. This assumption was proved experimentally as is shown later.

The steady-state total current density-potential curves were measured potentiostatically. The measured curves correspond to the simultaneous reduction of Fe^{++} and H^+. Using current efficiency measurements it was possible to calculate the partial current density-potential curves for iron deposition. The current efficiency for iron deposition was determined by potentiostatic anodic stripping (Fig. 1). At time $t = 0$ the potential of the rotating gold disk was stepped up from the basis potential (no hydrogen evolution, no iron deposition) to the wanted cathodic one. After the charging of the electrochemical double layer (the sharp current peak in Fig. 1) the reduction of ferrous ions and protons sets in. The decrease of the current to a minimum at time t_{min} and the increase up to time t_1 is believed to be due to the following facts: (*i*) the gold electrode will be covered gradually with iron, (*ii*) the exchange current density of the hydrogen electrode is higher on gold than on iron, and (*iii*) crystallization overvoltage.

The current efficiency is therefore not constant in the range $t = 0$ to t_1. The steady state is then reached at time t_1. At time t_2 the potential is changed to the stripping potential, which is 100-150 mV more positive than the corrosion potential. In this range practically the whole current is used for the anodic dissolution

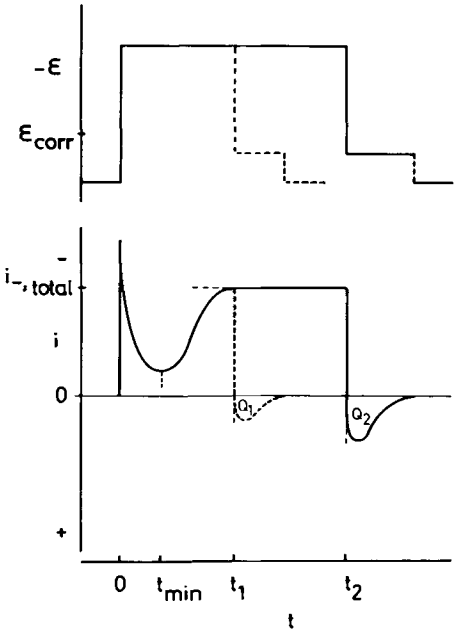

Fig. 1. Electrode potential ϵ and the total current density $i_{-,total}$ as a function of time t (schematic).

of iron. Integration of the current-time curves from t_2 up to t, when the anodic current falls to zero, gives the number of coulombs Q_2 corresponding to the amount of iron deposited. Under the same experimental conditions the amount of iron deposited between $t = 0$ and t_1 was measured and is denoted as Q_1 (dashed lines in Fig. 1). This allows the elimination of the nonsteady-state at the beginning of the pulse.

The partial current density for steady-state cathodic iron deposition is given by

$$| i_{-,Fe^{++}} | = \frac{Q_2 - Q_1}{t_2 - t_1} \qquad [2]$$

The partial current density for hydrogen evolution, i_{-,H^+}, can be calculated using [1]. At time t_1 the rotating disk is already covered with iron, and so the steady-state data refer to iron deposition on an iron substrate. The thickness of the iron deposits did not exceed 1 μm. This ensured undisturbed hydrodynamic conditions at the rotating disk.

Nonsteady-state measurements.—For nonsteady-state experiments a stationary Armco-iron electrode was used. The electrolyte solutions were identical. In these experiments galvanostatic pulse technique was applied. The potential-time curves were recorded by oscilloscope.

In solutions of pH > 2.8 a diffusion overvoltage is superimposed on the charge transfer overvoltage of hydrogen evolution (Fig. 2). The first plateau (curve 1, Fig. 2) relates to charge transfer overvoltage of hydrogen ion reduction on Armco iron. The second plateau (curve 2, Fig. 2) corresponds to simultaneous reduction of hydrogen and ferrous ions with relatively high current efficiency. Evaluation of cathodic transients was done in the following way: for total current density-potential curves the potential values of the second plateau were taken. Current efficiency was calculated from the $i \cdot t$ value of the whole cathodic pulse without correction for the first plateau. Separate measurement of current efficiency for the first plateau is not possible, because the flowing charge is too small. The coulomb value of the first plateau was relatively small compared to the total coulomb value and was neglected. In most cases the calculated current efficiency values were independent of the pulse

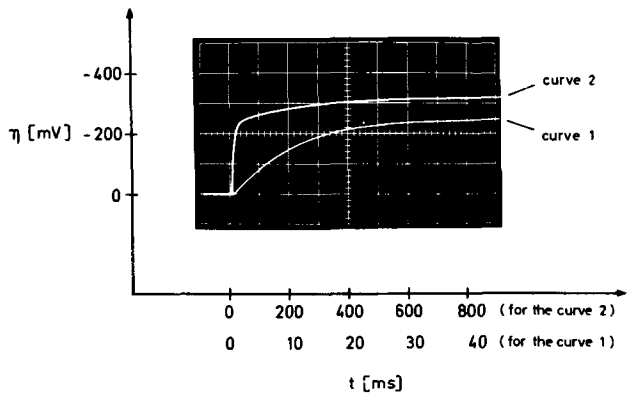

Fig. 2. Electrode potential-time curve under nonsteady-state galvanostatic conditions at pH > 2.8. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4, pH = 3.80 (T = 298°K). $i_{-,total}$ = − 1 mA · cm^{-2}. Curve 1 = the first plateau, curve 2 = the first and the second plateau.

duration except for very short pulses. It was assumed that the pH values in the cathode film were constant after reaching the second plateau.

In solutions of pH < 2.8 no superimposed diffusion overvoltage was detected.

The potentiostatic stripping method is not suitable for determination of the current efficiency of iron under nonsteady-state conditions. Therefore a galvanostatic method was developed (15).

Apparatus.—The electrolytic cell was made from Pyrex glass and contained about 300 cm^3 solution. All solutions were prepared from A.R. grade chemicals, conductance water, and high-purity sulfuric acid. The solutions were deaerated by the bubbling of high purity hydrogen gas for several hours. They were pre-electrolyzed at a platinum cathode kept at potentials not sufficiently negative to reduce ferrous ions. The bubbling of hydrogen was continued during the experiment.

The counterelectrode was separated from the bulk of the solution by a glass frit (Schott, G4). The counterelectrode compartment was bubbled during the experiment with high-purity hydrogen gas to remove anodically formed oxygen.

Ag/AgCl, KCl (saturated) or Hg/Hg_2Cl_2, KCl (saturated) electrodes were used as reference electrodes. The measured potentials were transformed afterward to the standard hydrogen scale.

The rotating disk electrode used for steady-state measurements consisted of gold and had a diameter of 0.80 cm. The rotating speed was always 145 rps. Before each experiment the gold disk was mechanically polished, electrolytically degreased, treated with concentrated acid, and carefully washed with conductance water. The stationary Armco-iron electrodes used for nonsteady-state measurements were electrolytically polished and cleaned, following the procedure described elsewhere (16).

For potentiostatic experiments two Wenking potentiostats 61 RS were used. Galvanostatic pulses were produced by a multichannel pulse generator (17). This instrument was used together with a Tektronix oscilloscope 549 with Type W plug-in unit. Stationary potentials and pH were measured with a Knick-pH-mV-voltmeter 34/1. Glass electrodes for pH determination were of the Type 9255/12 from Schott, Mainz. Calibration of the glass electrodes was done with buffer solutions according to NBS data. Exact adjustment of pH was made with sulfuric acid immediately before beginning the measurements. Current-time curves of the steady-state experiments were recorded with a Beckman 10-in. recorder.

All given potential values are corrected for ohmic overvoltage. Measurement of ohmic drop was made by the galvanostatic pulse technique.

Results and Discussion

Steady-state experiments.—The total current density-potential curves and the current efficiency of iron deposition were measured potentiostatically.

The partial current density-potential curves were calculated according to Eq. [1] and [2] for cathodic iron deposition ($i_{-,Fe++}$) and for hydrogen evolution ($i_{-,H+}$). The results are shown in Fig. 3 and 4 as a function of the pH of the solution. At pH < 2.8 one gets a steady-state Tafel line for iron deposition with a slope of $b_{-,Fe++} = -115 \pm 5$ mV (Fig. 3), while the slope at pH > 2.8 is $b_{-,Fe++} = -39 \pm 5$ mV (Fig. 4).

The horizontal lines ($i_{d,H+}$) in Fig. 3 and 4 represent limiting diffusion current densities of the hydrogen evolution reaction, measured in system I (iron-free, see above). The curves of $i_{-,H+}$, measured in system II, become identical to these lines at high cathodic overvoltages. This shows that the diffusion limiting current density $i_{d,H+}$ for the hydrogen evolution reaction is the same in both systems.

The curves for iron deposition $i_{-,Fe++}$ deviate from the Tafel lines at high cathodic overvoltage as $i_{-,H+}$

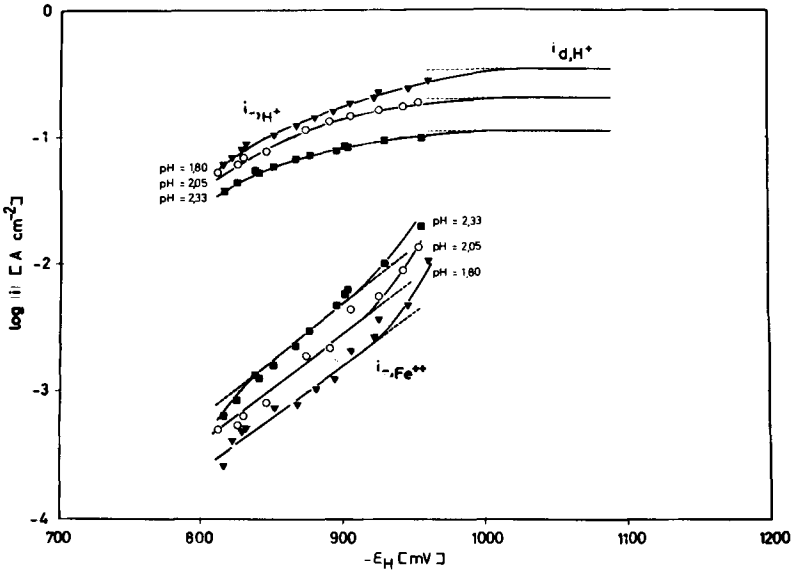

Fig. 3. Partial current density-potential curves under potentiostatic steady-state conditions depending on the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4, pH = 1.80, 2.05, 2.33 (T = 298°K).

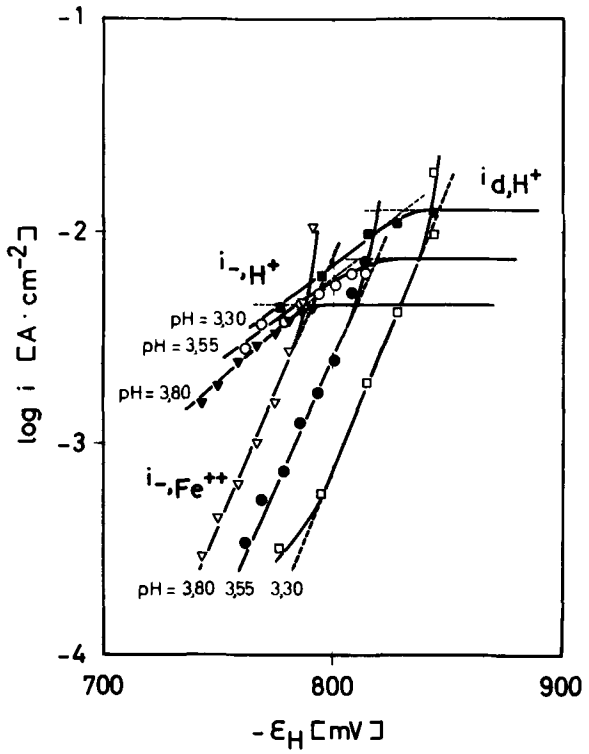

Fig. 4. Partial current density-potential curves under potentiostatic steady-state conditions depending on the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4; pH = 3.30, 3.55, 3.80 (T = 298°K).

→ i_{d,H^+}. This can be seen in Fig. 3 and 4. Here the pH of the cathode film is no longer the same as in the bulk of the solution. A rise of pH causes a rise of $i_{-,Fe^{++}}$ on account of its pH dependence.

Electrochemical reaction orders, relating to the pH of the solution, are shown in Fig. 5. In solutions of pH < 2.8 one gets $n_{-,pH} = +0.9 \pm 0.1$, whereas in solutions of pH > 2.8 the value $n_{-,pH} = +2.0 \pm 0.1$ is found.

The partial current density-potential curves of hydrogen evolution and iron deposition at different ferrous ion concentrations are shown in Fig. 6 and 7. Comparison to the curves of Fig. 3 and 4 shows that the Tafel slopes of iron deposition are independent of the ferrous ion concentration. In the range where i_{-,H^+} becomes of the same magnitude as i_{d,H^+}, the curve of iron deposition again deviates from the Tafel line.

Electrochemical reaction orders, relating to the ferrous ion concentration, are shown in Fig. 8 and 9 for solutions of pH 2.33 and pH 3.80. At pH < 2.8 the reaction order is $n_{-,Fe^{++}} = 1.0 \pm 0.1$, whereas at pH > 2.8 the value is $n_{-,Fe^{++}} = 1.6 \pm 0.2$.

From the curves of Fig. 3, 4, 6, and 7 one can see that the hydrogen evolution reaction is not independent of the iron deposition. First, the electrochemical reaction order of the hydrogen evolution reaction is higher than −1, which is the theoretical value at constant zeta-potential. And second, the partial current density i_{-,H^+} depends on the iron concentration.

Nonsteady-state experiments.—The total current density-potential curves and the current efficiency of iron deposition were measured by the galvanostatic pulse technique. Partial current density-potential curves of iron deposition were calculated from these data.

The experimental results at pH = 1.80 and pH = 2.33 are shown in Fig. 10. The Tafel slope for iron deposition is $b'_{-,Fe^{++}} = -120 \pm 10$ mV. The electrochemical reaction order $n'_{-,pH} = 0.85 \pm 0.1$ is determined from the relation between pH and $i_{-,Fe^{++}}$.

Figure 11 demonstrates the data from measurements in solutions of pH = 3.30 and pH = 3.80. In this pH range the slope of the nonsteady-state Tafel lines is $b'_{-,Fe^{++}} = -65 \pm 5$ mV, in spite of the difference of pH between the cathodic film and the bulk of the solution (cf. section on Nonsteady-state measurements). The constant slope of the Tafel line shows that the pH at the electrode surface is more or less independent of current density over a certain range for a given electrolyte. The value of this surface pH seems to be influenced by the pH of the bulk solution, as can be seen from the different partial current density-potential curves $i_{-,Fe^{++}}$. Therefore an accurate determination of the electrochemical reaction order $n'_{-,pH}$ in this pH range is not possible.

Polarization curves at different ferrous ion concentrations and at pH = 2.33 are presented in Fig. 12. From these data one can estimate the electrochemical reaction order $n'_{-,Fe^{++}} = 0.7 \pm 0.1$. For solutions of pH > 2.8 the determination of $n'_{-,Fe^{++}}$ is not possible for the reasons given above.

Kinetic Data of Iron Deposition

The experimental results show the existence of two different mechanisms. Which kind of mechanism takes place depends on the pH value at the electrode sur-

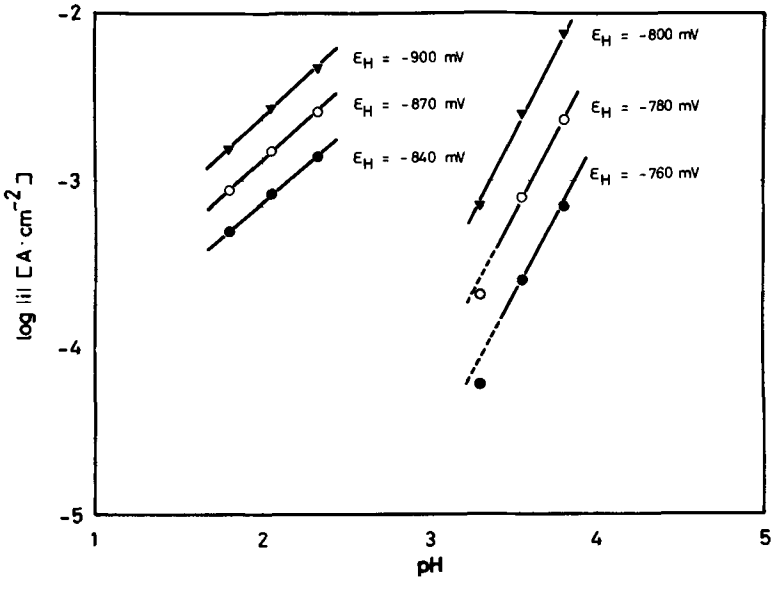

Fig. 5. Electrochemical reaction orders of iron deposition related to the pH. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4 (T = 298°K).

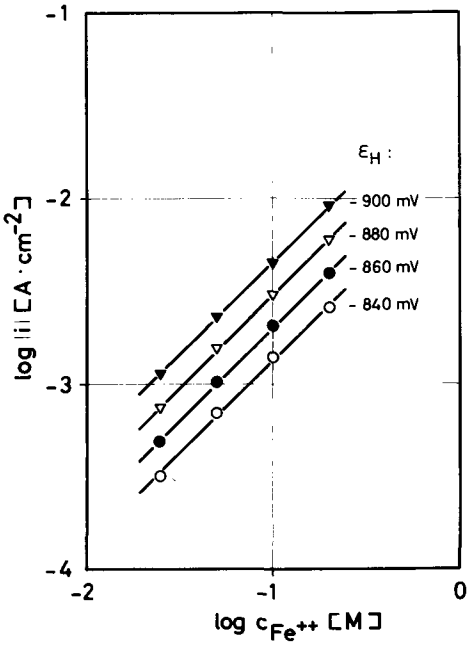

Fig. 8. Electrochemical reaction order of iron deposition related to $c_{Fe}++$ at pH = 2.33 (T = 298°K).

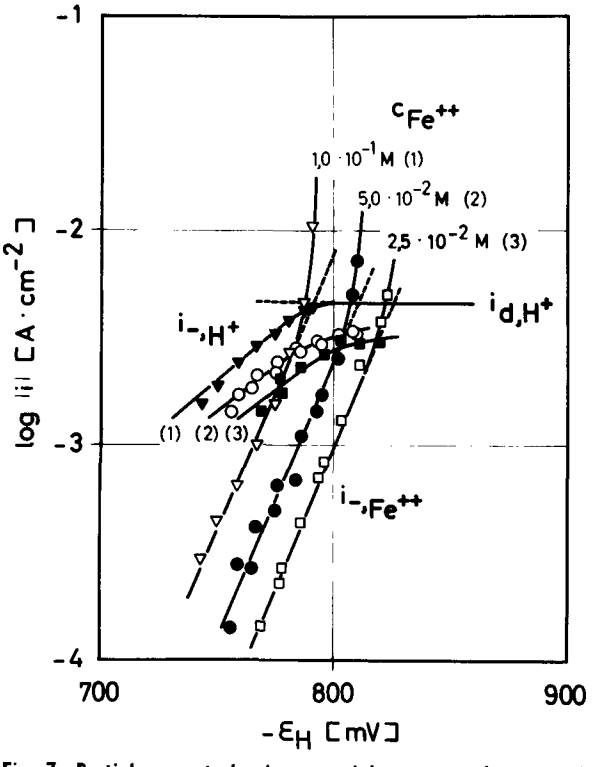

Fig. 7. Partial current density-potential curves under potentiostatic steady-state conditions depending on $c_{Fe}++$. Electrolyte: 0.025M . . . 0.1M $FeSO_4$ + x · Na_2SO_4 (constant ionic strength), pH = 3.80 (T = 298°K).

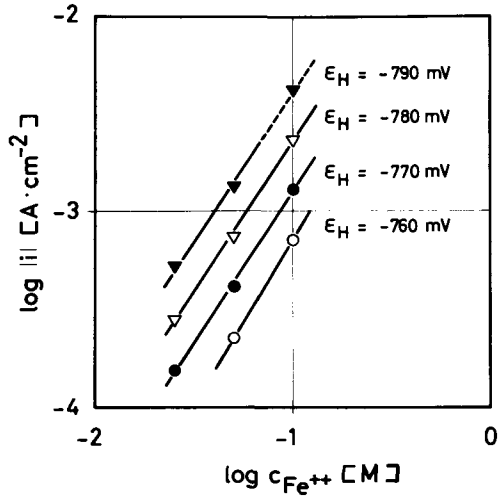

Fig. 9. Electrochemical reaction order of iron deposition related to $c_{Fe}++$ at pH = 3.80 (T = 298°K).

faces. Calculated and experimental values of the kinetic data are shown in Table I. The calculated values are deduced from kinetic relations as will be shown below (*cf.* section on Kinetic Equations).

At pH < 2.8 the experimental data fit to a simple reversal of the noncatalyzed mechanism of the anodic reaction (18). At pH > 2.8 a different mechanism is dominating, which is very probably a reversal of the catalyzed mechanism (18).

In the case of cathodic iron deposition there is a considerable difference between the kinetic data of the two reaction mechanisms. The influence of the surface pH on the type of mechanism is related to the different electrochemical reaction orders. Furthermore, hydrolysis products of $Fe^{++}{}_{aq}$ are formed and incorporated in the deposit at higher pH values of the cathode film. Consequently, the number of multidimensional crystal imperfections and lattice deformations increase. Therefore the surface activity increases too, and the catalyzed mechanism is favored over the noncatalyzed one.

Dahms *et al.* have shown that precipitation of insoluble hydrolysis products on the electrode surface (surface coverage near 1) leads to a sharp change of the deposition process (13). Such precipitation cannot take place under our experimental conditions, because we have evaluated the data of the steady-state measurements only up to current density values: $/ i_{-,total} / < / i_{d,H+} /$. Under this condition the surface pH is practically the same as in the bulk of the solution. Furthermore the formation of insoluble hydrolysis products in solution does not occur at the highest pH value (pH = 3.8) in this study. The con-

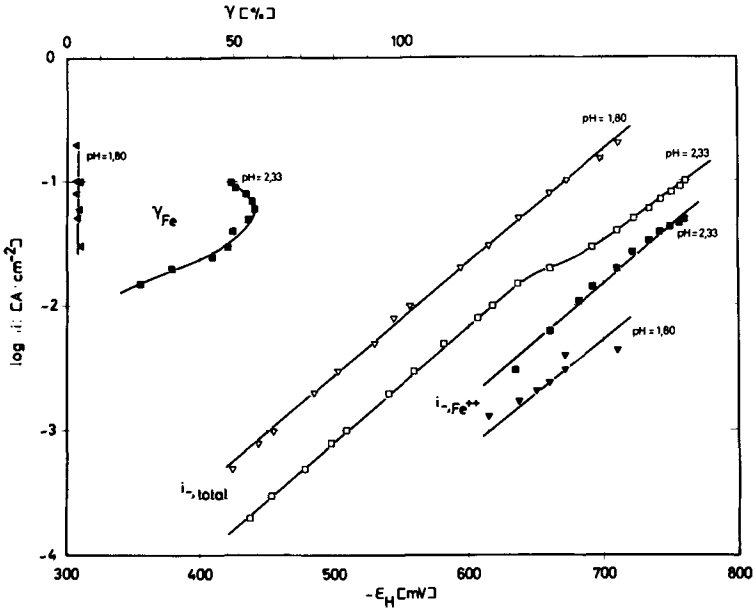

Fig. 10. Total current density-potential curves of simultaneous deposition of iron and hydrogen and partial curves of iron deposition depending on the pH. On the upper left side current efficiency curves of iron deposition. Galvanostatic nonsteady-state conditions. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4; pH = 1.80, 2.33 (T = 298°K).

centration of soluble hydrolysis products (*e.g.* $FeOH^+$) at the electrode surface is at equilibrium with the bulk concentration. This was taken into account in the following kinetic considerations.

The crystallographic substructure of the metal deposits is under investigation.

Mechanisms of the Cathodic Iron Deposition[3]

The noncatalyzed mechanism is a simple reversal of the corresponding anodic process, whereby the rate-determining step (*i.e.*, Eq. [4]) is the same

$$Fe^{++}_{aq} + H_2O \rightleftharpoons FeOH^+ + H^+ \qquad [3]$$

$$FeOH^+ + e^- \rightleftharpoons (FeOH)_{ads} \qquad [4]$$

$$(FeOH)_{ads} + H^+ + e^- \rightleftharpoons Fe + H_2O \qquad [5]$$

Equation [3] is a fast chemical equilibrium reaction,

[3] *Cf.* Part I (18), Table I.

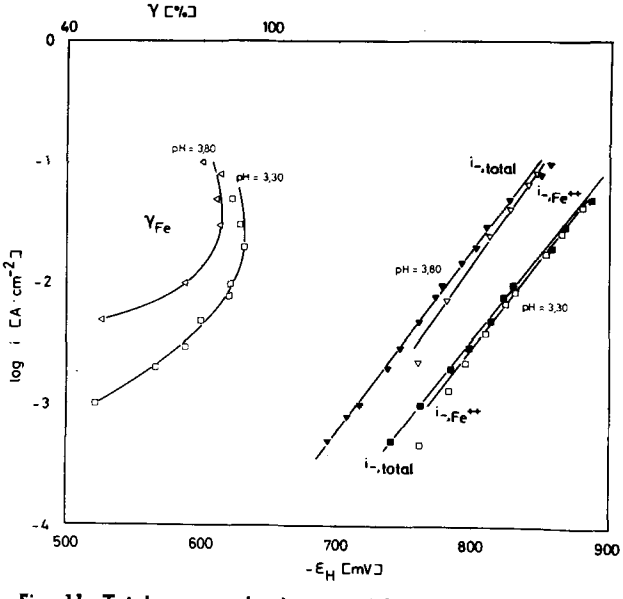

Fig. 11. Total current density-potential curves of simultaneous deposition of iron and hydrogen and partial curves of iron deposition depending on the pH. On the upper left side current efficiency curves of iron deposition. Galvanostatic nonsteady-state conditions. Electrolyte: 0.1M $FeSO_4$ + 0.875M Na_2SO_4; pH = 3.30, 3.80 (T = 298°K).

preceding the rate-determining charge transfer, Eq. [4]. The following electrochemical reaction step, Eq. [5], is also fast compared to [4].

The catalyzed mechanism seems also to be a reversal of the corresponding anodic process. However, the formulation of the kinetics is only hypothetical, as we have pointed out earlier (18). The formation of the catalytic surface complex (possible formula [Fe(FeOH)]) is believed to take place in a parallel reaction according Eq. [7]. The whole sequence may be written as follows

$$Fe^{++}_{aq} + H_2O \rightleftharpoons FeOH^+ + H^+ \qquad [3]$$

$$[Fe(FeOH)] + FeOH^+ + 2e^- \rightleftharpoons [Fe(FeOH)] + Fe + OH^- \qquad [6]$$

Parallel reaction

$$Fe + FeOH^+ + e^- \rightleftharpoons [Fe(FeOH)] \qquad [7]$$

The first step, Eq. [3], is the same as in the noncatalyzed mechanism. The rate-determining charge transfer is described by Eq. [6]. The formation of the catalytic surface complex Eq. [7], goes on parallel to the other steps and is considered to be relatively fast compared to [6].

Kinetic Equations

Steady-state conditions.—The noncatalyzed mechanism according to Eq. [3], [4], and [5] has the following current density-overvoltage relation

$$i = 2i_{o,4}\left[\frac{A}{B}\cdot\exp\left(\frac{(1+\alpha_4)F\eta}{RT}\right) - C\cdot\exp\left(-\frac{(1-\alpha_4)F\eta}{RT}\right)\right] \qquad [8]$$

Equation [8] already has been derived in Part I, (18), Eq. [14], under the condition $i_{o,4} << i_{o,5}$. The expressions for A, B, and C are

$$A = \frac{a_{Fe}}{\bar{a}_{Fe}}\cdot\frac{a_{H_2O}}{\bar{a}_{H_2O}},\quad B = \frac{a_{H^+}}{\bar{a}_{H^+}},\quad C = \frac{a_{FeOH^+}}{\bar{a}_{FeOH^+}}$$

The expression C can be replaced by the following terms according to the chemical equilibrium [3]

$$C = \frac{a_{Fe^{++}}}{\bar{a}_{Fe^{++}}}\cdot\frac{a_{H_2O}}{\bar{a}_{H_2O}}\cdot\frac{\bar{a}_{H^+}}{a_{H^+}} = D\cdot\frac{1}{B} \qquad [9]$$

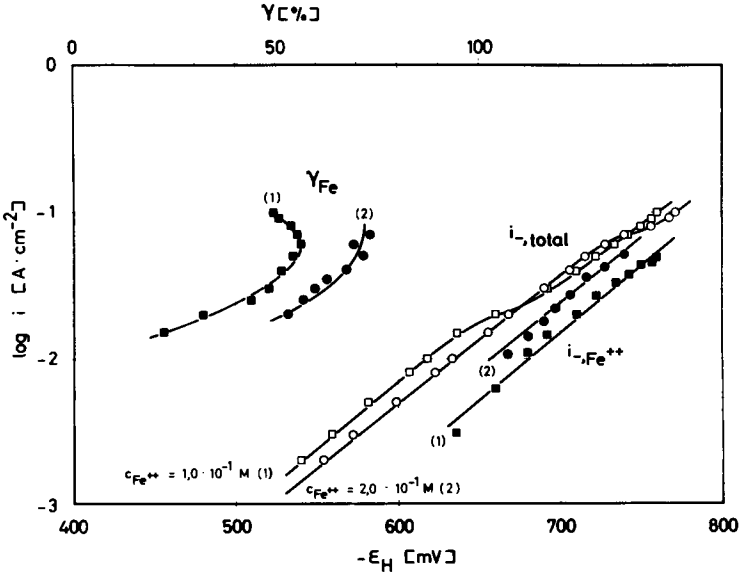

Fig. 12. Total current density-potential curves of simultaneous deposition of iron and hydrogen and partial curves of iron deposition depending on c_{Fe++}. On the upper left side current efficiency curves of iron deposition. Galvanostatic nonsteady-state conditions. Electrolyte: 0.1M $FeSO_4$ and 0.2M $FeSO_4$ + x · M · Na_2SO_4 (constant ionic strength), pH = 2.33 (T = 298°K).

From Eq. [8] and [9] the following kinetic data for the cathodic process ($\eta << 0$) are obtained

$$b_{-,Fe++} = \left(\frac{\partial \eta}{\partial \log |i_{-,Fe++}|}\right)_{a_{FeOH+},\bar{a}_{FeOH+}} = \frac{2.303\,RT}{(1-\alpha_4)\mathbf{F}} = -118.3 \text{ mV} \quad [10]$$

with $\alpha_4 = 0.5$ and $T = 298°K$.

$$n_{-,pH} = \left(\frac{\partial \log |i_{-,Fe++}|}{\partial pH}\right)_{a_i,\epsilon} = +1 \quad [11]$$

$$n_{-,Fe++} = \left(\frac{\partial \log |i_{-,Fe++}|}{\partial \log a_{Fe++}}\right)_{a_i,\epsilon} = +1 \quad [12]$$

For the catalyzed mechanism according to Eq. [3], [6], and [7] the following current density-overvoltage relation is derived (K = [Fe(FeOH)])

$$i = k_6 \cdot a_K \cdot a_{Fe} \cdot a_{OH^-} \cdot \exp\left(\frac{2\alpha_6 \mathbf{F}\epsilon}{RT}\right) - k_{-6} \cdot a_K \cdot a_{FeOH+} \cdot \exp\left(-\frac{2(1-\alpha_6)\mathbf{F}\epsilon}{RT}\right) \quad [13]$$

$$i = i_{o,6}\left[\frac{a_K}{\bar{a}_K}\cdot\frac{A}{B}\cdot\exp\left(\frac{2\alpha_6\mathbf{F}\eta}{RT}\right) - \frac{a_K}{\bar{a}_K}\cdot C\cdot\exp\left(-\frac{2(1-\alpha_6)\mathbf{F}\eta}{RT}\right)\right] \quad [14]$$

For $\eta << 0$ one can write

$$i_{-,Fe++} \cong -i_{o,6}\cdot\frac{a_K}{\bar{a}_K}\cdot C\cdot\exp\left(-\frac{2(1-\alpha_6)\mathbf{F}\eta}{RT}\right) \quad [15]$$

Equation [14] is similar to Eq. [19] in Part I (18). The difference is due to the formulation of the catalytic action of the surface complex [Fe(FeOH)]. Anodically the complex breaks up during the rate-determining charge transfer step and is formed again by a relatively fast topochemical reaction (Part I (18), Eq. [3] and [4]). By summation of these two reaction steps one gets the cathodic charge transfer step, Eq. [6] of this paper.

For the catalyzed mechanism one has under steady-state conditions

$$\frac{d\,a_K}{dt} = -\frac{i_7}{z_7\cdot\mathbf{F}} = 0 \quad [16]$$

The expression for i_7 is

$$i_7 = i_{o,7}\left[\frac{a_K}{\bar{a}_K}\cdot\exp\left(\frac{\alpha_7\mathbf{F}\eta}{RT}\right) - \frac{a_{Fe}}{\bar{a}_{Fe}}\cdot C\cdot\exp\left(-\frac{(1-\alpha_7)\mathbf{F}\eta}{RT}\right)\right] \quad [17]$$

From Eq. [16] and [17] using [9] one can write

$$\frac{a_K}{\bar{a}_K} = \frac{D}{B}\cdot\frac{a_{Fe}}{\bar{a}_{Fe}}\cdot\exp\left(-\frac{\mathbf{F}\eta}{RT}\right) \quad [18]$$

Table I. Kinetic data of the iron deposition at T = 298°K

$b_{-,Fe++}$ = cathodic Tafel slope for the iron deposition reaction
$n_{-,pH}$ = electrochemical reaction order related to pH
$n_{-,Fe++}$ = electrochemical reaction order related to c_{Fe++}

	Steady-state			Nonsteady-state	
	Calculated	Experimental		Calculated	Experimental
		Noncatalyzed mechanism			
$b_{-,Fe++}$	−118.3 mV	−115 ± 5 mV	$b'_{-,Fe++}$	−118.3 mV	−120 ± 10 mV
$n_{-,pH}$	+1	0.9 ± 0.1	$n'_{-,pH}$	+1	+0.85 ± 0.1
$n_{-,Fe++}$	+1	1.0 ± 0.1	$n'_{-,Fe++}$	+1	+0.7 ± 0.1
		Catalyzed mechanism			
$b_{-,Fe++}$	−29.6 mV	−39 ± 5 mV	$b'_{-,Fe++}$	−59.2 mV	−65 ± 5 mV
$n_{-,pH}$	+2	2.0 ± 0.1	$n'_{-,pH}$	+1	?
$n_{-,Fe++}$	+2	1.6 ± 0.2	$n'_{-,Fe++}$	+1	?

By substituting [18] into [15] one gets

$$i_{-,Fe^{++}} \cong -i_{o,6} \cdot \frac{a_{Fe}}{\bar{a}_{Fe}} \cdot \left(\frac{D}{B}\right)^2 \cdot \exp\left(-\frac{[1+2(1-\alpha_6)]F\eta}{RT}\right) \quad [19]$$

Equation [19] is the cathodic steady-state current density-overvoltage relation of the catalyzed mechanism. From [19] one derives the following kinetic data

$$b_{-,Fe^{++}} = \left(\frac{\partial\eta}{\partial \log |i_{-,Fe^{++}}|}\right)_{a_i,\bar{a}_i} = \frac{2.303\,RT}{[1+2\,(1-\alpha_6)]\,F} = -29.6\ \text{mV} \quad [20]$$

with $\alpha_6 = 0.5$ and $T = 298°K$.

$$n_{-,pH} = \left(\frac{\partial \log |i_{-,Fe^{++}}|}{\partial\, pH}\right)_{a_i,\epsilon} = +2 \quad [21]$$

$$n_{-,Fe^{++}} = \left(\frac{\partial \log |i_{-,Fe^{++}}|}{\partial \log a_{Fe^{++}}}\right)_{a_i,\epsilon} = +2 \quad [22]$$

Nonsteady-state conditions.—The noncatalyzed mechanism has identical current density-overvoltage relations and kinetic data under steady-state and under nonsteady-state conditions. The fast reaction step, Eq. [5], is at equilibrium.

For the catalyzed mechanism one derives from Eq. [15] with $a_K = \bar{a}_K = \text{const.}$ and $\eta << 0$

$$i_{-,Fe^{++}} \cong -i_{o,6} \cdot C \cdot \exp\left(-\frac{2(1-\alpha_6)\,F\eta}{RT}\right) \quad [23]$$

The nonsteady-state current density-overvoltage relation, Eq. [23], gives the following kinetic data

$$b_{-,Fe^{++}} = \left(\frac{\partial\eta}{\partial \log |i_{-,Fe^{++}}|}\right)_{a_i,\bar{a}_i} = -\frac{2.303\,RT}{2(1-\alpha_6)\,F} = -59.2\ \text{mV} \quad [24]$$

with $\alpha_6 = 0.5$ and $T = 298°K$.

$$n'_{-,pH} = \left(\frac{\partial \log |i_{-,Fe^{++}}|}{\partial\, pH}\right)_{a_i,\epsilon} = +1 \quad [25]$$

$$n'_{-,Fe^{++}} = \left(\frac{\partial \log |i_{-,Fe^{++}}|}{\partial \log a_{Fe^{++}}}\right)_{a_i,\epsilon} = +1 \quad [26]$$

Exchange Current Density of the $Fe/Fe^{++}{}_{aq}$ Electrode

Exchange current densities were calculated using steady-state experimental data. As in Part I (18) it was necessary to standardize to the following conditions

$pH = 0$

$a_{Fe^{++}} = 1$, which is equivalent to $\epsilon_o = E_o$ (standard potential).

The standardized exchange current density is written as i_o^o.

The cathodic current density of iron deposition $i_{-,Fe^{++}}$ depends on the activity of ferrous ions $a_{Fe^{++}}$. Therefore the exchange current density i_o is also dependent on $a_{Fe^{++}}$.

The exchange current density is found graphically or numerically using the following equation

$$\log i_o = \frac{\epsilon_o - \epsilon}{b_{-,Fe^{++}}} + \log |i_{-,Fe^{++}}| \quad [27]$$

The equilibrium potential ϵ_o is expressed by the Nernst equation

$$\epsilon_o = E_o + \frac{RT}{2F} \ln \bar{a}_{Fe^{++}} \quad [28]$$

The relations between i_o and pH, respectively i_o and $\bar{a}_{Fe^{++}}$, are derived from the kinetic relations.

In the case of the noncatalyzed mechanism Eq. [8] and [9] lead to

$$i_o = 2\,k_{-,4} \cdot \bar{a}_{Fe^{++}} \cdot \bar{a}_{H_2O} \cdot \bar{a}_{H^+}{}^{-1} \cdot \exp\left(-\frac{(1-\alpha_4)\,F\,\epsilon_o}{RT}\right) \quad [29]$$

Using Eq. [28] one gets

$$\left(\frac{\partial \log i_o}{\partial\, pH}\right)_{a_i,\epsilon_o} = +1 \quad [30]$$

and

$$\left(\frac{\partial \log i_o}{\partial \log \bar{a}_{Fe^{++}}}\right)_{a_i} = +0.75 \quad [31]$$

The resulting exchange current density relation of the noncatalyzed mechanism is

$$\log i_o = \log i_o^o + pH + 0.75 \log \bar{a}_{Fe^{++}} \quad [32]$$

The identical derivation gives for the catalyzed mechanism

$$\log i_o = \log i_o^o + 2\,pH + \log \bar{a}_{Fe^{++}} \quad [33]$$

Calculation of ϵ_o, i_o, and i_o^o requires knowledge of $\bar{a}_{Fe^{++}}$. Single ion activity coefficients of Fe^{++} are not available in the literature. Therefore the following calculations are rather doubtful. Nevertheless, following Bockris *et al.* (6) we set

$$f_{Fe^{++}} = f_{Ni^{++}} = f_{\pm,NiSO_4}$$

Tabulated values of $f_{\pm,NiSO_4}$ give a mean activity coefficient of Fe^{++} in 0.875M Na_2SO_4 + 0.1M $FeSO_4$ solution of 0.05.

Using the above value, $\log i_o^o$ was calculated as -6.2 ± 0.5 for the noncatalyzed mechanism and -14 ± 2 for the catalyzed mechanism, respectively. The agreement with data from the anodic dissolution process is not satisfactory [*cf.* Part I (18)]. One of the reasons is probably the assumption $a_{Fe} = 1$ in Eq. [28], which is only a rough approximation in the case of cathodically deposited metal. Nevertheless, it can be seen that the exchange current density of the noncatalyzed mechanism is several orders of magnitude higher than that of the catalyzed mechanism. This conclusion is not influenced by the approximation for $f_{Fe^{++}}$. A detailed discussion was given in Part I (18).

As in the anodic process the current density of the iron deposition reaction consists of two parts

$$i_{-,Fe^{++}} = i_{\text{noncatalyzed}} + i_{\text{catalyzed}} \quad [34]$$

In the vicinity of the equilibrium potential the first term will always dominate. Only at high pH of the cathode film and at high overvoltage the second term may become dominating.

Conclusions

From the experimental data it is shown that the cathodic iron deposition takes place by two different reaction mechanisms, depending on the experimental conditions. These two mechanisms are shown to be most probably a simple reversal of the two mechanisms of the anodic iron dissolution.

Acknowledgments

The authors feel obliged to thank Mrs. Rosswag and Mrs. Burger for helping in the experimental work.

They also acknowledge gratefully the discussions of Prof. Dr. Dr.h.c. H. Fischer. Substantial financial support was granted by the Deutsche Foschungsgemeinschaft and the Bundeswirtschaftsministerium, BRD, for which the authors express their gratitude.

Manuscript submitted March 19, 1971; revised manuscript received July 27, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Transient Behavior during Electrodeposition onto a Metal Strip of High Ohmic Resistance

Richard Alkire*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Electrochemical deposition onto a thin metal strip of high resistance can result in a deposit of varying thickness along the strip if the electrode resistance is sufficiently large to cause a nonuniform reaction rate distribution. As deposition proceeds, the ohmic resistance of the strip decreases and thus transient behavior is observed. The transient thickening process is modeled by a one-dimensional pseudo steady-state method. The results illustrate how transient behavior during deposit growth depends upon the mass transfer, charge transfer, ohmic resistance, and geometric characteristics of the system. Conditions are discussed under which nonuniform deposits may be anticipated.

In the fabrication of printed circuit boards, the deposition of the metal circuit onto an insulating substrate is accomplished by electroless deposition of a thin metal coating which is subsequently thickened by cathodic electrodeposition. The final deposit is usually not of uniform thickness, being somewhat thicker near the region of electrical contact employed during the cathodic thickening operation. In many cases the nonuniform reaction rate distribution which evidently prevails during growth may be primarily attributed to the high ohmic resistance of the thin electroless deposit. As the metal film becomes thicker, its ohmic resistance decreases; eventually the deposition reaction takes place along the electrode surface at a rate which is essentially independent of the electrode thickness. The transient behavior of high resistance electrodes observed during thickening can be quite complicated since several competing effects come into play. Owing to the industrial importance of the problem, the present study has been conducted in order to demonstrate some of the features which are characteristic of the process. The method of solution is not specifically restricted to the circuit board example; the results may be applied to other situations where the thickness of a resistive metal strip is altered by electrochemical deposition or dissolution.

Several previous investigations have evaluated the current distribution along electrodes of high resistance under specific cases of operation, all in the steady state (1-7). These analyses have shown that the current and potential distributions along a resistive electrode can depend on ohmic resistance of the electrolytic solution and on the rate of sluggish charge-transfer reaction. Calculations were carried out by treating the electrode as a one-dimensional region along which electrochemical reaction takes place. To date, no theoretical analyses are known to be reported either on the effect of mass transport restrictions on the current distribution, or on transient behavior observed during thickening of deposits on electrodes of high resistance. In the present study, conditions are ascertained under which a high electrode resistance may be anticipated to affect the reaction rate distribution along its surface. The theoretical model permits calculation of the transient current, potential, and surface concentration distributions along the electrode, from which the deposit thickness distribution may be determined as a function of the extent of reaction. The study illustrates how the deposit thickness distribution depends on mass transfer, charge transfer, and ohmic effects.

Before proceeding, consideration should be given to the events which take place upon application of a cathodic potential to an electrode. Essentially three

* Electrochemical Society Active Member.
Key words: deposit, growth, nonuniform, distribution.

electrochemical phenomena take place on time scales which are distinctly different. First, the electrical double layer will become charged very rapidly so that Faradaic current will pass through the electrode. Second, concentration gradients will become established in the electrolytic solution near the cathodic surface. Finally, cathodic reaction will cause gradual thickening which will reduce the ohmic resistance of the electrode and thus cause the reaction rate distribution to become more uniform. In principle, the entire system will not achieve a steady state until the cathode becomes sufficiently thick that its ohmic resistance is negligible and the current distribution is uniform. In view of the different time constants that characterize the three processes, however, it is a very good approximation to claim that the double layer and the diffusion layer attain a pseudo steady state rapidly with respect to the time during which thickening takes place. In the theory that follows, it will be assumed that the current distribution changes during deposition at a rate that is determined solely by the rate at which the thickening process occurs.

Typically, electrodeposition will involve a number of effects which are not taken into account in the treatment that follows. For example, the primary current distribution may not be uniform, the mass transfer process may be nonuniform, the deposit roughness may vary during growth, or the ohmic resistance of the electrolytic solution may be appreciable. The predictions made below may thus be applicable in some systems, but certainly not in all. The principal point, however, is that the model presented below contains the essential features of many practical problems and thus serves to refine one's intuition as well as provide the foundation for a detailed pursuit of more complicated situations.

Formulation of the Mathematical Model

Prior to the thickening treatment, the electrode consists of a thin metal strip of uniform thickness and of length l. Electrical contact is made to the thin strip along one edge ($z = l$) while the far edge ($z = 0$) is insulated. A reference electrode is placed in the solution near the edge of the strip at which electrical contact is made. A constant potential power supply provides electrons to the thin cathode at such a rate that the potential difference between the electrical contact point and the reference electrode is maintained at a constant value during electrolysis.

Owing to the simple geometry and uniform stirring conditions which characterize the model electrolysis cell, the deposition reaction will proceed at different rates along the electrode surface only if the potential within the thin metal cathode varies along its length because of ohmic resistance. As deposition proceeds, the ohmic resistance of the electrode decreases, owing to thickening, and the current distribution eventually becomes uniform.

Because rigorous calculations are not necessary for a useful analysis of the system, several simplifying assumptions have been introduced: (I) The resistive electrode is a straight strip of unit width, having length l and an initially uniform thickness a_0. The counterelectrode configuration is such that the primary current distribution along the cathode strip is uniform. (II) The electrical double layer and the mass transfer diffusion layer attain steady-state conditions rapidly with respect to the rate at which the electrode thickness increases. (III) During the growth process, the cathode remains thin with respect to distances over which significant variation in potential takes place in the metal phase, so that a one-dimensional specification of the potential in the electrode is sufficient. (IV) Only one electrode reaction occurs and the (reversible) reaction rate expression has the form given by Eq [3]. (V) The surface of the cathode deposit remains smooth during the course of thickening. (VI) The ohmic resistance of the electrolytic solution is negligible with respect to other resistances within the cell. That is, the inequality

$$\frac{J\beta}{\Phi_a}\frac{a_0\sigma y}{l^2\kappa} << 1$$

must be satisfied, where the symbols are as defined at the end of the text. (VII) The reactive cations arrive at the electrode surface by diffusion but not by migration. The solution is sufficiently dilute that concentrations may be used. (VIII) The electrolytic solution is stirred in such a way that the cations are uniformly accessible to the surface at all points; the mass transfer rate is characterized by a mass transfer coefficient.

The resistance to passage of electrons through the electrode is governed by Ohm's law

$$i(z,t) = -\sigma\frac{d\phi_m(z,t)}{dz} \qquad [1]$$

The electronic current in the metal phase, $i(z,t)$, varies with position owing to the electrode reaction which acts as a sink for the electrons in the electrode

$$\frac{di(z,t)}{dz} = -\frac{1}{a(z,t)}j(z,t) \qquad [2]$$

The deposition reaction rate, $j(z,t)$, varies along the electrode and is related to the metal ion concentration at the surface and to the potentials in both electrode and solution phases by the kinetic expression which characterizes the deposition reaction, assumed here to be of the Volmer form

$$j(z,t) = i_o\left\{e^{\frac{\alpha nF}{RT}\eta(z,t)} - \frac{c^s(z,t)}{c^b}e^{\frac{(\alpha-1)nF}{RT}\eta(z,t)}\right\} \qquad [3]$$

For cathodic reactions, both $\eta(z,t)$ and $j(z,t)$ are negative. The exchange current density in Eq. [3] corresponds to the bulk concentration of reactant cation. The overpotential $\eta(z,t)$ is the difference in potential between the electrode and the solution, outside the diffusion layer, during reaction, minus the difference in potential which exists under equilibrium conditions (8). Therefore the overpotential $\eta(z,t)$ is the sum of charge transfer overpotential plus concentration overpotential. Since resistance effects in the solution phase are negligible by assumption (VI), the potential in the solution outside the diffusion layer is uniform and is denoted $\phi_s{}^\bullet$. Thus the overpotential $\eta(z,t)$ is defined as

$$\eta(z,t) = [\phi_m(z,t) - \phi_s{}^\bullet] - [\phi_m{}^e - \phi_s{}^e] \qquad [4]$$

where the equilibrium condition is denoted by superscript e. It is seen that the overpotential $\eta(z,t)$ varies with position along the electrode strip because the potential in the metal phase is not uniform. At this point it is convenient to introduce the potential at the current-feeder end of the strip, $\phi_m{}^\bullet$. Provided that the reference electrode is positioned in the bulk electrolyte, that is, beyond the diffusion layer, the applied potential which is held constant during electrolysis may be related to the overpotential $\eta(z,t)$ by

$$[(\phi_m{}^\bullet - \phi_s{}^\bullet) - (\phi_m{}^e - \phi_s{}^e)] = [\phi_m{}^\bullet - \phi_m(z,t)] + [\phi_s{}^s(z,t) - \phi_s{}^\bullet] + \{[\phi_m(z,t) - \phi_s{}^s(z,t)] - [\phi_m{}^e - \phi_s{}^e]\} \qquad [5]$$

where $\phi_s{}^s(z,t)$ is the potential in the solution "just outside" the electrical double layer. The quantity on the left side of Eq. [5] is the applied potential which is held constant during electrolysis. The right side of Eq. [5] illustrates that the applied potential is counterbalanced by several overpotentials which develop within the electrolysis cell owing to (a) ohmic losses (η_Ω) in the electrode, $[\phi_m{}^\bullet - \phi_m(z,t)]$; (b) concentration overpotential (η_c) in the solution $[\phi_s{}^s(z,t) - \phi_s{}^\bullet]$; (c) charge transfer overpotential (η_s) at the elec-

trode-solution interface, $\{[\phi_m(z,t) - \phi_s{}^s(z,t)] - [\phi_m{}^e - \phi_s{}^e]\}$. The concentration overpotential is related to the concentration difference across the diffusion layer by

$$\phi_s{}^s(z,t) - \phi_s{}^\bullet = \frac{RT}{n\mathbf{F}} \ln \frac{c^s(z,t)}{c^b} \qquad [6]$$

It may be recognized that the concentration dependence of the exchange current density has been extracted and placed in the exponential terms within the brackets of Eq. [3]. Thus, as noted previously, the exchange current density has the value which corresponds to the bulk concentration of reactant, and the overpotential $\eta(z,t)$ includes both charge-transfer and concentration overpotentials. It may be seen that the ohmic, concentration, and charge transfer overpotentials all vary with distance along the electrode and with time during deposition. The sum of the three overpotentials, however, is constant in accord with Eq. [5].

The local deposition rate, $j(z,t)$, is also related to the concentration difference across the diffusion layer through the mass transfer coefficient which has a uniform value along the entire electrode

$$j(z,t) = -n\mathbf{F}k[c^b - c^s(z,t)] \qquad [7]$$

Equations [1] through [7] may be combined in order to eliminate all variables except $\phi_m(z,t)$ and $a(z,t)$. Before reporting the result, it is convenient to rewrite the problem in terms of dimensionless quantities based on the following definitions:

$$Z = \frac{z}{l}$$

$$\tau = \frac{M\sigma RT}{\rho l^2 n^2 \mathbf{F}^2} t$$

$$C^s(Z,\tau) = \frac{c^s(z,t)}{c^b}$$

$$\Phi_m(Z,\tau) = \frac{n\mathbf{F}}{RT}[\phi_m(z,t) - \phi_m{}^\bullet] \qquad [8]$$

$$\Phi_a = \frac{n\mathbf{F}}{RT}[(\phi_m{}^\bullet - \phi_s{}^\bullet) - (\phi_m{}^e - \phi_s{}^e)]$$

$$J(Z,\tau) = \frac{j(z,t)l}{a^\bullet i^\bullet}$$

$$A(Z,\tau) = \frac{a(z,t)}{a_o}$$

When the variables defined in Eq. [8] are introduced into the set of equations which describes the model, several dimensionless groupings of the system parameters arise

$$\xi = \frac{i_o l^2 n\mathbf{F}}{a_o \sigma RT}$$

$$\Gamma = \frac{kc_b l^2 n^2 \mathbf{F}^2}{a_o \sigma RT} \qquad [9]$$

$$\beta(\tau) = \frac{a^\bullet i^\bullet l n\mathbf{F}}{a_o \sigma RT}$$

The parameter ξ corresponds to the ratio of ohmic resistance to charge-transfer resistance insofar as it contains the ratio of exchange current density to electrode conductivity. Similarly, the dimensionless parameter Γ denotes the ratio of ohmic resistance to mass transfer resistance.

Equations [1] through [7], which describe the model, may now be combined and written in dimensionless form; the result has the somewhat compact form

$$(A\Phi'_m)' = \xi \left\{ e^{\alpha(\Phi_m + \Phi_a)} - \left[\frac{1 + \frac{\xi}{\Gamma} e^{\alpha(\Phi_m + \Phi_a)}}{1 + \frac{\xi}{\Gamma} e^{(\alpha-1)(\Phi_m + \Phi_a)}} \right] e^{(\alpha-1)(\Phi_m + \Phi_a)} \right\} \qquad [10]$$

The symbol prime (') is used to denote differentiation with respect to the spatial variable Z. The left side of Eq. [10] represents the divergence of the potential gradient in the electrode phase. The right side is a net species generation term which is given by the pseudohomogeneous electrochemical reaction rate. The rate expression has both anodic and cathodic terms, the concentration dependence of the cathodic term having been reformulated by combination of Eq. [3] and [7] in view of Eq. [4]-[6]. The Appendix provides details.

Equation [10] has two unknown quantities, $\Phi_m(Z,\tau)$ and $A(Z,\tau)$, and four independent parameters (Φ_a, ξ, Γ, and α). Provided that the deposit thickness distribution is known, Eq. [10] may be integrated with use of two boundary conditions. The conditions that correspond to the present model are (A) Current does not pass through the insulated end of the electrode

$$\Phi'_m(0,\tau) = 0 \qquad [11]$$

(B) The potential at the contact end of the electrode, in the metal, is constant during electrolysis

$$\Phi_m(1,\tau) = 0 \qquad [12]$$

Once the potential and concentration distributions along the wire surface are known, the current distribution may be calculated by

$$J(Z,\tau) = \frac{\xi}{\beta}[e^{\alpha(\Phi_m + \Phi_a)} - C^s e^{(\alpha-1)(\Phi_m + \Phi_a)}] \qquad [13]$$

The deposit thickness distribution may be obtained by integration of the prevailing current distribution over the period of electrolysis

$$A(Z,\tau) = 1 + \int_0^\tau J\beta d\tau \qquad [14]$$

The mathematical model described above has extended previously available treatments by accounting simultaneously for both mass transfer and charge transfer overpotentials in addition to the ohmic losses associated with deposition onto electrodes of high resistance. Further, the model includes transient effects owing to pseudo steady-state thickening of the electrode.

Method of Solution

The solution of Eq. [10] was carried out on a digital computer with use of finite difference numerical methods. The timewise variation of the current distribution was determined by alternate solution of Eq. [10] and [14] at specified time steps. First Eq. [10] was integrated with the deposit thickness distribution set equal to the initial value ($A = 1.0$). Calculations were then carried out at specified time intervals during the pseudo steady-state thickening process. After one time interval the "initial" current distribution, already in hand, was used to evaluate the thickness distribution via Eq. [14]. With use of these results, Eq. [10] was solved again and the sequence was repeated for as many time intervals as required. For the calculations reported in this study it was found that time intervals that were less than the value ($0.05/\beta$) yielded results which were essentially independent of the choice of time step.

The numerical integration of Eq. [10], which is nonlinear and of second order, was accomplished by

first linearizing the equation and placing the results into finite difference form. The tridiagonal matrix was inverted (9) on an IBM 360 computer. The solution of the nonlinear equation was obtained by iteration on the approximate linear solution.

Results and Discussion

Calculations based on the preceding theoretical model have been conducted in order to illuminate several salient features of the process. All calculations have been carried out for cathodic deposition (negative applied potentials) with use of a symmetric transfer coefficient ($\alpha = 0.5$). The dimensionless parameters used in the following presentation should permit evaluation of a wide variety of actual systems.

Consider first the situation which is attained shortly after application of potential. Both the double layer and the diffusion layer have developed to a pseudo steady-state condition, but the deposit thickness has not changed appreciably from its initially uniform value. This state is termed the "initial state" in the subsequent discussion. Figure 1 illustrates the values of the three overpotentials along the length of the electrode for a typical choice of parameters. It is seen that, at any point along the surface, the total of values of the three overpotentials equals the applied potential. At the electrical contact end of the electrode, ohmic losses in the metal phase are zero and the applied potential is "partitioned" between concentration and charge-transfer effects. Further along the electrode, the ohmic resistance consumes an increased fraction of the total applied potential so that both charge-transfer and concentration overpotentials are thereby reduced. Clearly the surface concentration of reactants is lowest near the electrical contact, where concentration overpotential is greatest, and increases along the electrode. In addition, the variation of charge-transfer overpotential clearly indicates that the reaction rate will be greatest near the electrical contact and will decrease along the electrode. Figure 2 shows some typical reaction rate distributions along the cathode for several values of the parameter Γ. It may be seen that when the mass transfer coefficient is large (large Γ), the reaction distribution depends on the parameter ξ: a small value of ξ indicates high electrode conductivity and thus a uniform current distribution, whereas large values of ξ correspond to a nonuniform current distribution. As the mass transfer coefficient is reduced (decreased Γ), the concentration overpotential will be increased relative to the other overpotentials and the reaction rate distribution will be forced to become more uniform along the electrode. For a sufficiently small mass transfer coefficient, the reaction distribution is seen to be essentially uniform even though ξ has a large value. Thus the effect of mass transport limitations is to suppress the large reaction rate near the electrical contact point and thereby render the reaction distribution more uniform.

The variation of total current with applied potential is depicted in Fig. 3 for several values of ξ and Γ. In the absence of mass transfer resistance (large Γ), the "polarization" curves assume a Tafel-like shape. The effect of lowering Γ (increasing the mass transfer resistance) is to reduce the upper value of current which may be passed through the electrode. It may be seen that at sufficiently small values of Γ, the curves in Fig. 3 exhibit a current plateau which corresponds to the limiting current.

Continuing with discussion of the "initial state" (before appreciable thickening occurs), consider how the overpotential distributions depend on the parameters ξ and Γ. Since the total of the three overpotentials equals the applied potential, which is held constant during electrolysis, the relative magnitude of each may be illustrated on an equilateral-triangle graph as shown in Fig. 4. Each different point within the triangle, designated as a partition point, corresponds to a different partitioning of the applied potential among concentration, charge-transfer, and ohmic overpotentials. For example, the partition point which corresponds to the insulated end of the electrode already depicted

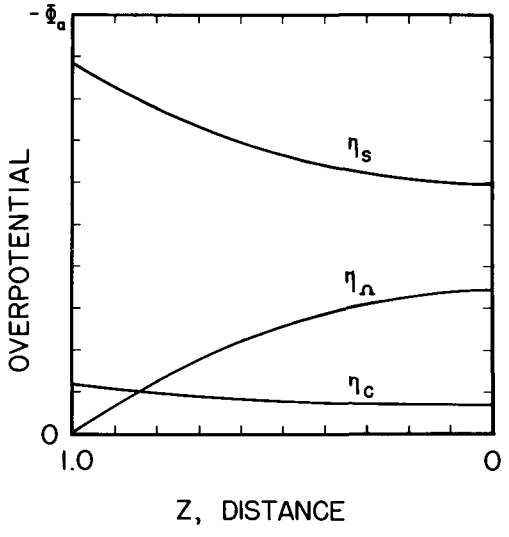

Fig. 1. Overpotential partition distribution along a typical resistive electrode of uniform thickness ($\xi = 1$, $\Gamma = 10$, $\Phi_a = -3.0$).

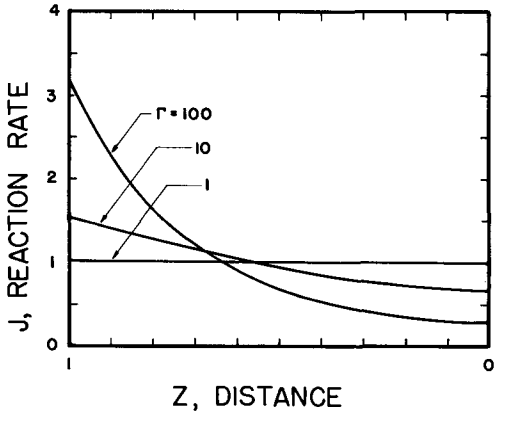

Fig. 2. The effect of mass transport limitations on the current density distribution along a resistive electrode of uniform thickness ($\xi = 10$, $\Phi_a = -3.0$).

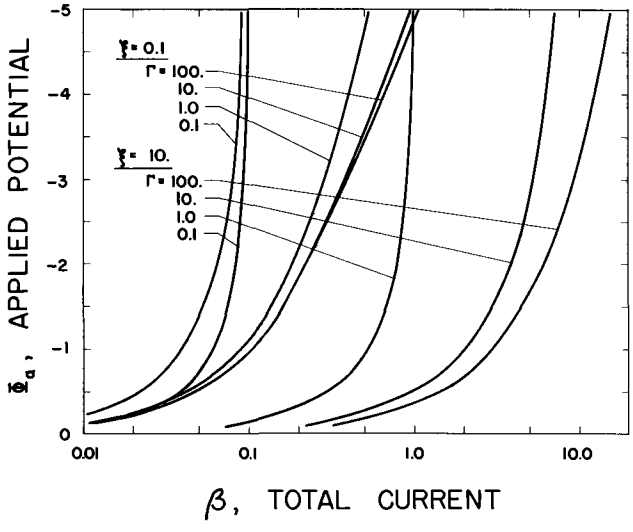

Fig. 3. Current-voltage curves for resistive electrodes of uniform thickness under various conditions of charge- and mass-transport restrictions.

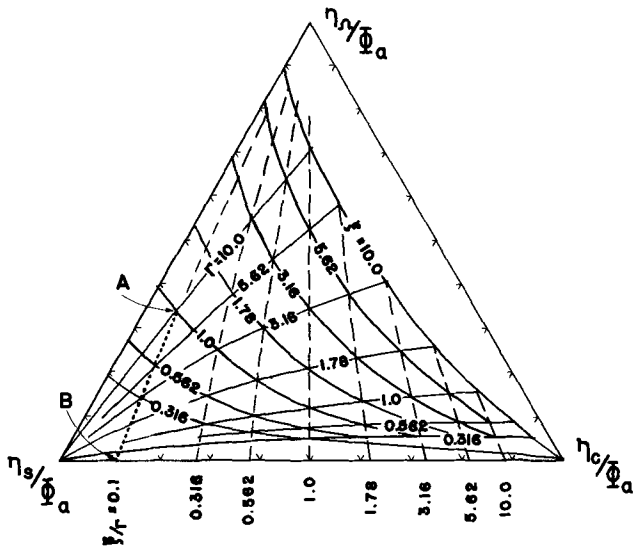

Fig. 4. Overpotential partition at insulated end of a resistive electrode of uniform thickness under various operating conditions ($\Phi_a = -3.0$).

in Fig. 1 ($\xi = 1$, $\Gamma = 10$) is located at point A in Fig. 4. The "partition points" at the insulated end of other systems may also be found in Fig. 4 from the solid grid lines which are drawn at various values of ξ and Γ. Similarly, the partition point in Fig. 4 which corresponds to the electrical contact end of the electrode of Fig. 1 is shown at point B. It may be realized that ohmic effects are always absent at the current feeder so that the partition point falls on the charge transfer-mass transfer "binary" base line at a position which is determined solely by the value of the ratio ξ/Γ. The overpotential partition distribution given in Fig. 1 corresponds to the heavy dotted line which connects points A and B in Fig. 4. By comparing the dotted line with the corresponding intersection of grid points it is seen that the dotted line passes through the locus of points for which the ratio ξ/Γ is constant. That is, the applied potential at any point along an electrode surface is partitioned between charge-transfer and concentration overpotentials in accord with the value of ξ/Γ, independent of ohmic effects. The dashed lines in Fig. 4 correspond to various lines of constant ξ/Γ, as noted beneath the triangle. In accord with the above observations, the overpotential partition distribution along an electrode, prior to significant thickening, may be obtained by locating the end point at the grid location which corresponds to the values of ξ and Γ, and then by following the dashed line of constant ξ/Γ to the $\eta_s - \eta_c$ base line. Although spatial distributions cannot be obtained, the method provides sufficient information to estimate both the extent to which ohmic effects will be appreciable during thickening and the extent to which concentration polarization will become significant once the ohmic resistance is relieved by thickening. Alternatively, Fig. 4 may be used to choose deposition conditions under which deposits of acceptable uniformity and appearance may be obtained. Although the axes of Fig. 4 are normalized by the applied potential, the location of the grid lines depends on the value chosen for the applied potential; an increase in applied potential will usually enhance partitioning into ohmic and concentration overpotentials at the expense of charge transfer overpotential.

At this point, a numerical example should be helpful in establishing some feeling for the matter. Consider copper deposition from an acidified sulfate bath for which approximate values of system parameters would be $n = 2$, $i_o = 10^{-3}$ A/cm^2, $c_b = 5 \times 10^{-4}$ mole/cm^3, $\sigma = 5 \times 10^5$ (ohm-cm)$^{-1}$, and $T = 300$°K. A typical electroless deposit thickness is $a_o = 5 \times 10^{-5}$ cm, and a typical circuit board dimension is $l = 15$ cm. The parameter ξ thus has the value 0.7. In the absence of mass transfer effects, Fig. 4 indicates that for $\Phi_a = -3$ (42 mV applied potential), up to 32% of the applied potential will be consumed by ohmic losses in the electrode phase, so that the current distribution may be expected to be moderately nonuniform. For this system, the diffusion coefficient is about 7×10^{-6} cm^2/sec; if the diffusion layer is of thickness 5×10^{-2} cm, the mass transfer coefficient would be on the order of $k = 7 \times 10^{-6}/5 \times 10^{-2} = 1.4 \times 10^{-4}$, so that Γ would have the value of ten. Referring once again to Fig. 4, it is seen that for $\Gamma = 10$, concentration overpotential consumes only a small portion of the applied potential. As a counterexample, consider a circuit board of length $l = 1$ cm but with the same system parameters as above, so that $\xi = 3 \times 10^{-3}$ and $\Gamma = 4 \times 10^{-2}$. One concludes that ohmic resistance effects in the electrode phase are negligible and will not contribute to a nonuniform deposit.

Now consider the transient behavior which occurs during the thickening process. Figure 5 illustrates, for one set of parameters, how cathodic deposition reduces the ohmic resistance of the electrode and thus renders the reaction rate distribution more uniform during the course of electrolysis. Current distributions are shown for various average deposit thicknesses (A.D.T.) during a tenfold thickening treatment. The initial current distribution (A.D.T. = 1.0) indicates that the deposition rate at the contact end of the electrode is 2.2 times greater than that at the far end of the electrode. After tenfold thickening, however, the current distribution is essentially uniform for the conditions indicated. As the ohmic restriction is thus relieved by thickening, both the concentration and charge transfer overpotentials increase, in relative proportion to the ratio ξ/Γ. Thus, during thickening, the partition point which characterizes the insulated end of the electrode (such as Point A in Fig. 4) moves along a line of constant ξ/Γ toward the $\eta_c - \eta_s$ base line. At a given applied potential, the period of electrolysis during which the current distribution remains nonuniform clearly depends on the initial current distribution, *i.e.*, on the values of ξ and Γ.

During deposition the thickness of the cathodic deposit increases at different rates along the electrode when the "initial" current distribution is not uniform. Figure 6 illustrates several specific cases of transient behavior which are observed during a tenfold thickening operation (that is, the final average deposit thickness is ten times the initial thickness). The ordinate is the deposit thickness distribution which has been normalized by the average prevailing deposit thickness

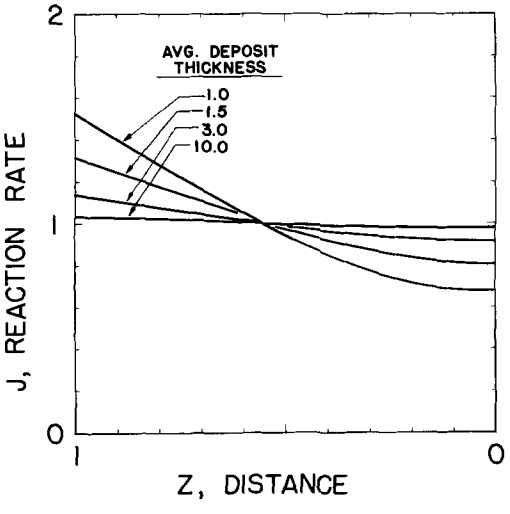

Fig. 5. Current density distributions along a resistive electrode during tenfold thickening by cathodic deposition ($\xi = 10$, $\Gamma = 10$, $\Phi_a = -3.0$).

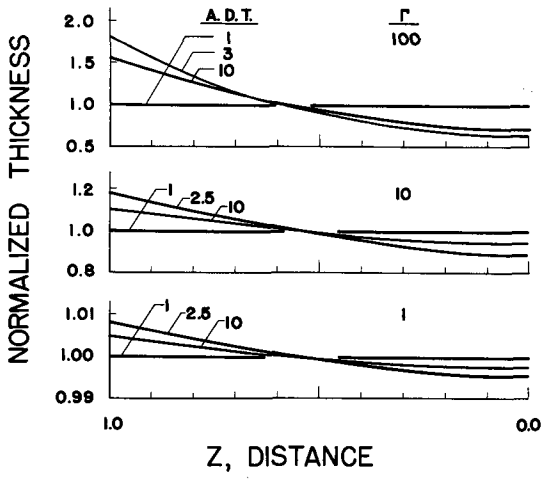

Fig. 6. The effect of mass transport limitations on the deposit thickness distribution during tenfold thickening ($\xi = 10$, $\Phi_a = -3.0$).

$$\frac{1 + \int_0^\tau J\beta d\tau}{1 + \int_0^\tau \beta d\tau} \qquad [15]$$

Normalized distributions are shown at several intermediate stages during the over-all process. As a general observation, the calculations illustrate that the initial deposit thickness distribution (A.D.T. = 1) is uniform and that the thickness becomes more or less nonuniform during the first moments of deposition. Eventually, in accord with Fig. 5, the current distribution becomes uniform so that thickening takes place uniformly along the electrode. Thus the normalized deposit thickness distribution attains a maximum degree of nonuniformity; additional electrolysis renders the deposit more uniform. As shown in Fig. 6, the details of the deposit thickness distributions and the times at which the maximum nonuniformity is attained depend on the value of Γ. When concentration overpotential prevails along the entire electrode (ξ/Γ large), then the current distribution is essentially uniform at the onset of electrolysis and remains so during deposition. The bottom graph of Fig. 6 ($\xi = 10$, $\Gamma = 1$, $\Phi_a = -3$) indicates that a deposit ten times the original layer will be of uniform thickness within ±0.5%. On the other hand, if the ohmic resistance effect is large and not masked by severe mass transport limitations, then the deposit thickness distribution will pass through a highly nonuniform configuration during deposition. The middle graph of Fig. 6 ($\Gamma = 10$) shows that the final deposit thickness will vary by about ±10%. For $\Gamma = 100$ (upper graph of Fig. 6), the final deposit at the contact end will be over twice as thick as at the far end.

Conclusions

The theoretical model presented above is based on assumptions that naturally affect the applicability of the calculated results. Thus while the foregoing predictions may be applicable to many deposition systems, they cannot be expected to apply to all such systems. For example, if a given system is characterized by a value of ξ that is small with respect to unity, one may conclude that ohmic resistance effects in the electrode phase are negligible. However, it would be unwise to claim that it thus follows that the current distribution is therefore uniform for every system having a low value of ξ. The theoretical model focuses on the role of electrode resistance effects and is not intended to provide detailed information in the absence of such effects. On the other hand, it may be recognized that several of the assumptions, such as (I), (IV), (VI), and (VIII), may be altered to suit special circumstances without appreciable complication of the general calculational procedures.

The results presented above find application in the thickening of deposits on insulating substrates as, for example, during the manufacture of printed circuit boards. Although reversible plating baths permit high current densities and rapid device throughput, deposits will be nonuniform if the electroless undercoat is not sufficiently thick. Since the electroless deposition process is slow, an optimum production rate may be anticipated which counterbalances the electroless deposition rate against the uniformity of the cathodically thickened product. If the concentration of reacting ions is low, or if the bath is stirred but slowly, mass transport limitations may set in which render the current density distribution uniform regardless of kinetic or ohmic effects. However, deposition under severe mass transfer limitations can lead to "burned" deposits which are powdery and loosely adherent. If ohmic resistance effects are appreciable and are not masked by mass transport limitations, highly nonuniform deposits may be obtained during the initial period of deposition. In all cases of operation, essentially uniform deposits will be obtained upon extended deposition after the ohmic resistance of the electrode is relieved by thickening. The common usage of a high current density "strike" plating on the electroless deposit may not necessarily achieve the intended goal of coating the basis metal with the plating metal and, indeed, may involve a highly nonuniform deposition. The interplay of the various phenomena that determine the over-all transient thickening process thus provides insight which is useful toward improvement of the over-all production process.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

APPENDIX

Combination of Eq. [1], [2], and [3] gives

$$\sigma \frac{d}{dz}\left(a \frac{d\phi_m}{dz}\right) = i_o \left\{ e^{\frac{\alpha n F}{RT}\eta} - \frac{c^s}{c^b} e^{\frac{(\alpha-1)nF}{RT}\eta} \right\} \qquad [16]$$

In view of Eq. [4] and [5], and the definitions in Eq. [8], one may rearrange Eq. [16] to the form

$$(A\Phi'_m)' = \xi\{e^{\alpha(\Phi_m+\Phi_a)} - C^s e^{(\alpha-1)(\Phi_m+\Phi_a)}\} \qquad [17]$$

The dimensionless surface concentration, C^s, may be found by eliminating J from Eq. [7] and [13]

$$J = \frac{\Gamma}{\beta}(C^s - 1) = \frac{\xi}{\beta}\{e^{\alpha(\Phi_m+\Phi_a)} - C^s e^{(\alpha-1)(\Phi_m+\Phi_a)}\} \qquad [18]$$

whence

$$C^s = \frac{1 + \frac{\xi}{\Gamma} e^{\alpha(\Phi_m+\Phi_a)}}{1 + \frac{\xi}{\Gamma} e^{(\alpha-1)(\Phi_m+\Phi_a)}} \qquad [19]$$

Substitution of Eq. [19] into Eq. [17] yields Eq. [10].

Phase Equilibria in Lithium-Chalcogen Systems

I. Lithium-Selenium

P. T. Cunningham, S. A. Johnson, and E. J. Cairns*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The equilibrium phase diagram of the lithium-selenium system has been investigated. A miscibility gap extends from 0.5 to 30.5 a/o (atom per cent) lithium above a monotectic temperature of 350.1°C; the critical temperature is greater than 800°C. The only intermediate phase found is Li_2Se which melts at 1302°C.

During the last several years there has been an increasing interest in the development of high-specific-power, high-specific-energy secondary cells based on alkali metal-chalcogen couples (1, 2). To optimize the cell design (especially the cathode configuration) and to evaluate cell performance, it is necessary to understand the phase equilibria involved in these systems. The work reported here was undertaken to determine the phase diagram for the condensed lithium-selenium system.

The study of the phase equilibria in lithium-chalcogen systems has heretofore been very limited. The lithium-selenium phase diagram has not been previously reported. The only information available is that lithium monoselenide, Li_2Se, has been prepared both in liquid ammonia (3, 4) and by the reaction of selenium vapor with molten lithium (5). It has been reported to have an antifluorite structure (4, 5) with a lattice parameter of 6.002Å (5).

* Electrochemical Society Active Member.

Key words: lithium, selenium, lithium selenide, cathode, phase equilibria.

Experimental

Materials.—The selenium used was a special high-purity (99.999 + %) grade obtained from American Smelting and Refining Company, South Plainfield, New Jersey. The lithium was high-purity reactor grade (99.98%) obtained from the Foote Mineral Company, Philadelphia, Pennsylvania. Both elements were used without further purification. The Li_2Se was prepared in 5-10g batches by the reaction of selenium vapor with molten lithium in an apparatus similar to that described by Johnston and Heikes (5). Lithium was contained in a molybdenum boat which was placed in an evacuated quartz vessel together with excess selenium and heated at 300°C for two days. The Li_2Se thus prepared had a light salmon color and produced very sharp x-ray powder patterns corresponding to an antifluorite structure with a lattice parameter of

[a] The methods used were heating or cooling curves (TA), where reported temperatures are those of thermal arrests, and differential thermal analysis (DTA), where reported temperatures are those of the intersection.
[b] Sealed container.
[c] Temperature taken from a cooling curve that had clearly undercooled.

6.0014 ± 0.0004Å, which is in good agreement with the value previously reported (5). There was no indication of unreacted lithium. Chemical analysis of portions of several Li_2Se batches indicated an empirical formula of $Li_{2.05\pm0.1}Se$. Li_2Se was mixed with the appropriate terminal phase in a purified-helium-atmosphere glove box (6) to obtain the desired over-all composition for subsequent experiments. The samples were contained in quartz, aluminum, niobium, tantalum, and Type 347 stainless steel, depending on the sample composition and the temperature range covered.

Apparatus and procedures.—The methods used included thermal analysis (heating and cooling curves), differential thermal analysis (DTA), chemical analysis, microscopy, and x-ray diffraction. The DTA samples weighed about 80 mg and were contained in aluminum or niobium capsules with press-fit caps of the same material. Data were obtained with a du Pont Model 900 Differential Thermal Analyzer using a 5°C/min rate of temperature change with powdered alumina as a reference material and a dynamic helium atmosphere. The over-all accuracy of the apparatus, which was checked with NBS standard quartz and KNO_3,[1] was found to be ± 1°C.

Heating and cooling curves were obtained for samples weighing from 10 to 20g using a furnace well which was attached to the floor of a helium-atmosphere glove box (7). Lithium-rich samples were contained in either tantalum or Type 347 stainless steel, whereas selenium-rich samples were contained in quartz. Variation of sample composition because of selenium vaporization was negligible. The selenium-rich samples required vigorous stirring to prevent severe undercooling. Temperatures were measured with platinum *vs.* platinum-10% rhodium thermocouples for both types of thermal analysis. The thermocouples were all fabricated of wire which had been calibrated against NBS pure tin (mp 231.88°C), zinc (mp 419.58°C), and aluminum (mp 660.0°C).

A molybdenum-wound resistance furnace was employed to observe the fusion of Li_2Se. The samples, each about 0.2g, were placed in a niobium crucible, which contained a black-body cavity, and were heated in an argon atmosphere. Temperature was measured with a calibrated optical pyrometer, and the occurrence of fusion was visually determined.

[1] The quartz and KNO_3 are SRM 755 and SRM 756, respectively. They are available from the Office of Standard Reference Materials, National Bureau of Standards, Washington, D. C. 20234.

The samples used for microscopic examination or chemical analysis were placed in quartz ampules, evacuated, and sealed. The ampules were heated to 600-800°C for about 1 hr and cooled to the desired temperature and held at that temperature for periods varying from several hours to several weeks. The samples were then quenched in liquid nitrogen and returned to the helium-atmosphere glove box where the ampules were carefully broken open and the samples examined. Because Li_2Se reacts rapidly with moisture in the air, care was necessary in polishing samples for microscopic examination outside the glove box. The samples were mounted in Polylite (or in some cases Wood's metal) and polished under silicone oil. The polished surface was flooded with silicone oil and a cover glass was placed over the sample. The polished surface could then be examined and photographed at leisure since the surface showed no sign of deterioration for several hours. Information on the number of phases present, their distribution within the sample, and their relative amounts is obtained by microscopy. Chemical analysis was performed on samples that were mechanically separated in the glove box. In most cases, lithium was analyzed by flame photometry, and selenium was obtained by difference. Several checks in which selenium was also determined by the standard potassium iodide method (8) confirmed the accuracy of this procedure (± 5% of the lithium weight).

X-ray diffraction powder photographs were obtained for a large number of samples of various composition and thermal history using a 114.6 mm Debye-Scherrer camera with CuKα radiation.

Results and Discussion

All experimental results are summarized in Fig. 1. The thermal analysis results are listed in Table I. Four thermal effects were observed. On the lithium-rich side of Li_2Se, the only effect noted below 1000°C (the highest temperature attained for this composition range) was at 180.5° ± 0.1°C, which is also the melting point of lithium. The presence of Li_2Se did not affect the lithium melting point within the accuracy of these measurements. The melting point of Li_2Se was observed to be 1302° ± 2°C using DTA and 1303° ± 5°C in the resistance furnace with optical observation. The excellent agreement between these values is considered to be fortuitous considering the difficulty of accurate high-temperature measurements. The melting point of Li_2Se is taken to be 1302° ± 5°C.

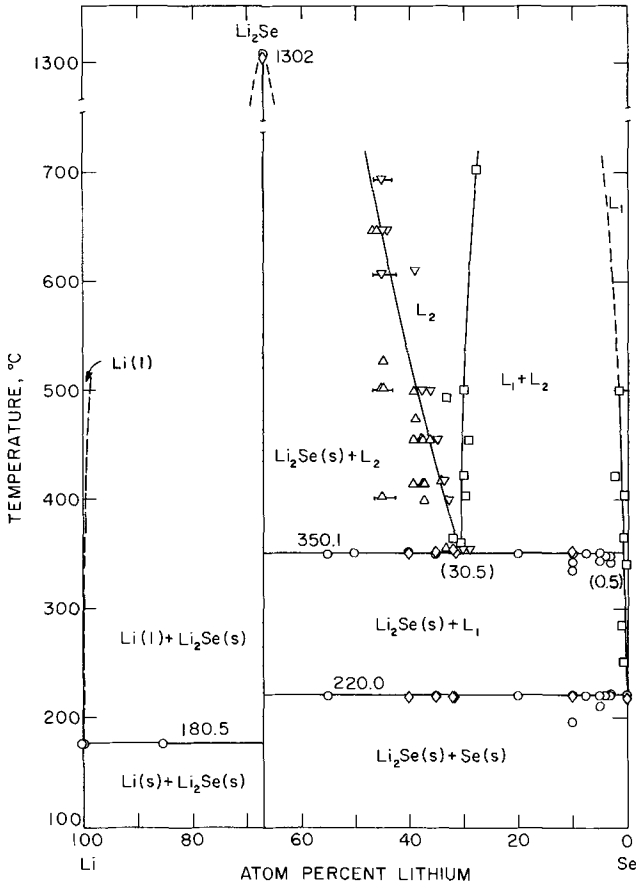

Fig. 1. Partial phase diagram of the lithium-selenium system. ○, Thermal analysis; ◇, differential thermal analysis; □, chemical analysis; ▽, microscopic analysis: sample quenched from above the liquidus; △, microscopic analysis: sample quenched from below the liquidus.

Thermal effects in samples with over-all compositions on the selenium-rich side of Li_2Se were observed at 220.0° ± 0.4°C and 350.1° ± 2.0°C. These temperatures are weighted averages where the weighting used is somewhat subjective. The indicated uncertainties show the variance of the data. The strong tendency for samples containing less than 20 a/o (atom per cent) lithium to undercool led to considerable scatter in the data. The 220°C effect is presumably associated with the eutectic reaction $L_1 \rightarrow Li_2Se(s)$ + selenium. The melting point of selenium is frequently reported to be 217°C, a value which appears to be in error. Our measured value of 220.2° for the selenium melting point is slightly higher than the average eutectic temperature but agrees within experimental uncertainty. The 350.1°C effect is associated with a monotectic type of reaction [$L_2 \rightarrow L_1 + Li_2Se(s)$, see Fig. 1].

The existence of a miscibility gap was confirmed by quenching samples having an over-all composition in the range from 5 to 25 a/o lithium from temperatures above 350.1°C. The quenched samples contained two easily distinguishable zones. One of these was indistinguishable from selenium, whereas the other was black, dull, and granular, distinctly salt-like. These two zones are associated with the separated liquid phases L_1 and L_2, respectively (see Fig. 1). Samples quenched from 800°C still clearly contained these two zones. At temperatures up to about 500°C, the two liquid phases separated easily under gravity within a few hours, with the selenium-like phase being more dense. Separation of the phases was also rapid above 650°C, but the salt-like phase was more dense. Between 550° and 650°C, satisfactory separation was not achieved, even after many days. The extent of the miscibility gap was determined by chemical analysis of the two zones. Results of the analyses are presented in Table II. Considerable care was taken in separating the two zones to prevent cross-contamination which would have led to an apparent narrowing of the miscibility gap. The results certainly represent a lower limit on the extent of immiscibility and are probably accurate to 1 a/o. Chemical analysis of the selenium-like zone in quenched samples was also used to determine the lower liquidus (see Table II and Fig. 1).

Table II. Summary of chemical analyses

Temperature prior to quenching (°C)	Component analyzed	Sample weight (g)	Lithium weight (g)[a]	Lithium (a/o)
700.0	L_2	0.4006	1.30×10^{-2}	27.6

249.8	L_1	0.4785	3.40×10^{-4}	0.80

[a] Analytical uncertainty is ±5% of the lithium weight.

Thermal effects associated with liquidus crossings could not be observed. The upper liquidus was therefore determined by microscopic examination of quenched samples. Several samples, each differing in over-all composition by about 1 a/o lithium, were prepared and equilibrated at the same temperature prior to quenching (see preceding section). The uncertainty in the absolute composition of these samples was 1 a/o lithium. Examination of samples held at temperature for various time periods indicated that equilibration was complete after about 12 hr. In those samples for which the composition was below the liquidus at the equilibration temperature, there were dendritic crystals as well as large, well-developed primary crystals of Li_2Se, whereas samples above the liquidus prior to quenching contained only fine dendritic crystals. In this way the upper liquidus composition was closely bracketed at a number of temperatures. The results are shown by the triangular symbols in Fig. 1, with the apex-up orientation indicating that the sample was below the liquidus prior to quenching and the apex-down orientation indicating that it was above the liquidus prior to quenching.

X-ray powder patterns were taken on a large number of samples of different over-all composition and thermal history. In all cases, the observed lines were accounted for by the terminal phases and Li_2Se. The lattice constant for Li_2Se was 6.0014 ± 0.0004Å if selenium was in excess and 6.0001 ± 0.0004Å if lithium was in excess. This difference suggests a narrow range of solid solution for the Li_2Se intermediate phase.

The simple monotectic phase diagram which we have found for the region between Li_2Se and selenium indicates a positive deviation from Raoult's law. This can be contrasted with other known alkali metal-selenium systems (9) (Na-Se and K-Se), in which several other selenium-rich intermediate phases have been reported. Indeed, in the sodium-selenium system, in which the most selenium-rich phase is Na_2Se_6, there is no miscibility gap. In the potassium-selenium system a miscibility gap does appear between K_2Se_5 (the most selenium-rich intermediate phase) and selenium. It is of interest to note that the lithium-selenium system bears strong resemblance to the copper-selenium (10) and silver-selenium (9) systems.

Several aspects of the lithium-selenium phase diagram bear directly on the design and operation of lithium-selenium secondary cells. It is clear that for

practical operating temperatures the cell product will be Li_2Se and that complete conversion of the cathode material (selenium) to this phase represents the maximum cell capacity. At temperatures below the monotectic (350.1°C), solid Li_2Se will form in the cathode after only slight discharge and its presence must be carefully considered in cells designed to operate in this temperature region. At temperatures above the monotectic, solid Li_2Se will not form (under equilibrium conditions) until the cathode contains at least 30.5 a/o lithium, and cell potential will be constant throughout most of the discharge up to this point. In actual cell operation, consideration must of course be given to nonequilibrium phenomena, reaction kinetics, and possible interaction with the electrolyte (11). Further study of these areas is in progress.

Additional investigation of the lithium-selenium system is needed, particularly at higher temperatures, to determine the critical temperature of the miscibility gap, and at high lithium contents to determine the liquidus in the region between Li_2Se and lithium.

Acknowledgments

The authors wish to thank Dr. R. C. Vogel and Dr. A. D. Tevebaugh for their encouragement and support, Mr. R. Schablaske for his assistance with x-ray analyses, and Mr. Z. Tomczuk and Mrs. R. Hanna for assistance with chemical analyses. This work was performed under the auspices of the United States Atomic Energy Commission.

Laboratoire de Physique Générale, Tour 12, Faculte des Sciences, 9 Quai St Bernard, Paris Vè, France

ABSTRACT

A brief historical account of the Hall effect in very dilute solutions is given in which the interest in Hall effect measurements for the knowledge of electrolytes is shown. Then a systematic examination is presented of the different parasitic voltages which are likely to appear in a Hall cell. The criteria to which the experimental setup must conform to allow detection of the Hall voltage are defined. (This voltage is from 0.1 to 1 μV in our experiments.) Results of measurements in hydrochloric and nitric acid solutions are given confirming the theoretical predictions.

When an electric field is applied in the X direction of a conductor and in the Z direction of a magnetic field, an electric current I_y flows in the Y direction of the Cartesian system of coordinates. The galvanomagnetic measurements are commonly carried out under the condition that $I_y = 0$. To satisfy this, a transverse field E_H must exist. This Hall field takes a value such that the force on charge carriers having a certain "average" velocity is zero in the crossed electric and magnetic fields. Let J_X be the control current density, B the magnetic field, and E_H the Hall field. The Hall coefficient R_H is then defined by the relation

$$E_H = R_H \cdot J_X \cdot B \qquad [1]$$

It is usually most convenient to use parallelepiped-shaped specimens as shown in Fig. 1. If the length of the specimen is 1, the width b, and the thickness e, the Hall voltage produced by the carriers between the two sides perpendicular to OY is simply

$$V_H = E_H \cdot b \qquad [2]$$

Since 1879, when Hall discovered the effect, many scientists have tried to observe it in electrolytes. The attempts were unsuccessful (1) until 1896 when Bagard (2) reported a Hall effect of about 10^{-3}V in SO_4Cu solutions. Bagard's work was strongly criticized by Florio (3), Chiavassa (4), Moretto (5), Heilbrun (6), Delvalez (7), and Voigt (8), who explained the difference between the measured value of the voltage and the theoretical values calculated by Donnan (9), Wind (10), and Larmor (11) by deformation and corrosion of the electrodes, their lack of parallelism, convective motion of the fluid, and by a concentration emf. These two last factors are strongly dependent on

Key words: Hall effect, alternative current, alternative field, very dilute electrolyte solutions, HCl, HNO_3.

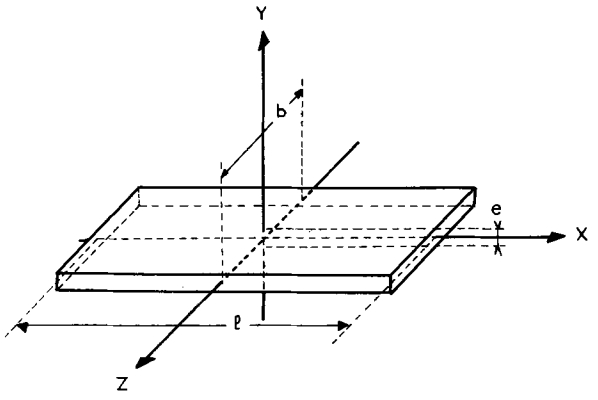

Fig. 1. Hall effect in a parallelepiped-shaped sample

the width of the cell placed in an insufficiently homogeneous magnetic field.

Measurements taking these factors into account gave no reproducible results (12), as the signal was too weak (from 10^{-1} to 1 μV) to be detected by the measuring devices available at that time, and the experimental work on the Hall effect in electrolytes was abandoned until 1950. With better experimental means Evseev (13), Laforgue-Kantzer (14), Muller (15), and Mergault Pages-Nelson (16), working with d.c. found Hall voltages in the tens of millivolt range. However, Trancong Khan (17), Wendhausen (18), and Holzapfel (19) showed that these values are 10^4 to 10^5 times greater than the expected Hall effect. Picard (20) and Naiditch *et al.* (21), using an a-c technique, were able to obtain very encouraging results.

The theoretical work of Friedman and his collaborators renewed interest in measuring the Hall effect. As a matter of fact, by comparing Hall effect measurements with those of electrical conductance in dilute solutions, Friedman (22-24) proposes that it is possible to determine whether the fluctuating motions of the carriers intervene in the transport properties on the macroscopic scale (such as electrical and Hall mobilities and conductances). Friedman (22) calculated first the electrical Hall mobilities of a carrier, whose dynamics obey the Langevin equation. Such a carrier is called a brownon and is characterized by a friction coefficient ζ_i and a mass m_i. Later, in collaboration with Ben-Naim (23) and Harris (24), he tried to describe the nonbrownon case. In view of the difficulty in describing the dynamics of a carrier not obeying Langevin's equation, Friedman and Ben-Naim supposed that the motion still obeyed the Langevin law for short intervals, but that the friction coefficient ζ_i and the mass m_i change in a random way between two sets of values, for instance, due to two different hydration states of the brownon. With this model, they obtained relative values of electrical and Hall mobilities different than those in the first case. This seems to prove that the Hall effect can be used to study fluctuations in the motion of the carrier. Pages-Nelson (25) reached the same conclusion by studying a model in which the cross-section of the ion-solvent collisions takes two well-defined values corresponding to two different hydration states of the ion.

In the present paper we present measurements, with improved a-c technique, of the Hall effect in very dilute solutions.

Calculation of R_H and V_H

Several authors (26, 21, 19) used simplified theories of the Hall effect applied to dilute electrolytes: all led to similar expressions of R_H and V_H, *i.e.*

$$R_H = (1/n_1 e z_1) \cdot [(\mu_1 - \mu_2)/(\mu_1 + \mu_2)] \qquad [3]$$

and

$$V_H = (\mu_1 - \mu_2)\, E\, B\, b$$

where n_1 is the number of ions of the carrier per cubic meter; e is the charge (1,6 · 10^{-19} A-sec); μ_1 is the mobility of the carrier i expressed in m^2-sec^{-1} · V^{-1}; E the electric field in V · m^{-1}; B the magnetic field in Weber · m^{-2}; and b the width of the cell in m. R_H is thus expressed in m^3-sec^{-1} · A^{-1} and V_H in volts.

Holtzapfel (19) showed that when using d-c current, R_H must be corrected by two terms, one from diffusion and the other from polarization voltages due to volume charge and chemical reactions in the neighborhood of the electrodes. This last term is difficult to evaluate. Therefore a-c techniques are preferable. The values of R_H and V_H are very small (about 10^{-1} to 1 μV) in the case of dilute electrolytes, as the carrier mobilities are small. However, it is important to note that the effect is greater if the difference between the mobilities is greater. This is why we began to work with HCl and HNO_3. The experimental device used to detect such a small voltage must satisfy several criteria. We show that the use of an alternating current of frequency ω_1 and of a magnetic field of frequency ω_2 eliminates several problems due to stray voltages.

Stray EMF's

EMF's due to temperature gradients.—Such a gradient gives rise to three galvanomagnetic and thermodynamic effects:

a. The Ettinghausen effect: $V_E = P\, I\, B\, \epsilon/e$

where P is the Ettinghausen coefficient, and ϵ the thermoelectrical power of the couple connecting the Hall probes to a galvanometer.

b. The Nernst effect: $V_N = Q\, B\, b\, (dT/dl)$

where Q is the Nernst coefficient and (dT/dl) the temperature gradient of the specimen.

c. The Righi-Leduc effect: $V_{RL} = S\epsilon\, B\, b\, (dT/dl)$

where S is the Righi-Leduc coefficient.

The Nernst and Righi-Leduc emf depend only on ω_2, the frequency of the magnetic field, whereas the Hall and Ettinghausen emf depend on $(\omega_1 + \omega_2)$ and $(\omega_1 - \omega_2)$. One can thus eliminate the Nernst and Righi-Leduc effects by using frequency filtering making the measurements at $(\omega_1 + \omega_2)$ and $(\omega_1 - \omega_2)$.

Lindbergh (27) calculated the Ettinghausen emf as

$$V_E = \{PI_0H_0/2b\}\{\exp[-(\omega_1 - \omega_2)/\omega_0]\cos(\omega_1 - \omega_2)t - \exp[-(\omega_1 + \omega_2)/\omega_0]\cos(\omega_1 + \omega_2)t\}$$

ω_0 being a constant inversely proportional to the specific heat of the specimen. In order to render the Ettinghausen effect negligible, it is sufficient to use frequencies ω_1 and ω_2 such that $(\omega_1 + \omega_2)$ and $(\omega_1 - \omega_2) >> \omega_0$. In fact, the effect is negligible for frequencies above 5 Hz.

EMF's due to permanent and convective motions in the specimen.—At every point of the specimen, the mechanical force per unit volume in the case of two charge carriers is

$$F = (n_1\, e\, z_1\, v_1 + n_2\, e\, z_2\, v_2) \times B = J \times B$$

Any inhomogeneity of magnetic field or of current density, or of both, gives rise at each point to different densities of force which are not, as it is in solid specimens, balanced by internal stress. The fluid is set into motion. The boundary conditions imposed by the walls give rise to permanent or convection motions. The energy per unit volume and time dissipated in the fluid is equal to the product of F and the local fluid velocity v, *i.e.*, $v \cdot (J \times B)$. Even if the current density is not strictly uniform in the cell, one can suppose that, at each point, it is proportional to the total current passing through the cell, so that v at each point is proportional to I.

a. v has a constant direction (permanent motion). The power dissipated in the cell is proportional to I. These potential differences vary, in this case, linearly with I and B.

b. v varies from one point to another (convective motion). Williams (28) showed that the stray potential differences follow a law which is no longer linear, but a related one.

It is not easy to separate the Hall effect from the stray phenomena due to the liquid motions. Thus it becomes important to minimize these motions. In order to do so, one has to have the current density and magnetic field uniform across the whole cell and reduce the cell thickness to tens or, at most, hundreds of microns. Finally, using alternating current methods, one can reduce considerably the effects of the remaining causes of inhomogeneity.

EMF's due to the Hall probes.—When a current I_X passes through a sample and when there is no magnetic field, a potential difference appears due to the actual impossibility of placing the two probes on the same equipotential. For the cell in Fig. 1, the nonalignment voltage is

$$V_{NA} = I_X \, dl/\sigma \, b \, e$$

where dl is the lateral displacement of the probes, and σ the conductance of the cell. This voltage may be quite important (ranging about 1V in the less favorable cases) with regard to V_H; it is thus necessary to eliminate it. The method of the two frequencies eliminates this parasitic voltage, which depends only on ω_1. One must point out that, using alternating current and field, we can determine the sign of the Hall voltage by comparing its phase to that of a well-known sample. The method of the two frequencies eliminates the stray emf's that we have mentioned. However it produces at least two parasitic effects:

a. The voltage due to the existence of eddy currents in the cell. This is reduced by using a cell 10-100μ thick.

b. The voltage induced by the magnetic induction in the Hall probes

$$V_I = n \, (d\phi/dt)$$

where n is the number of loops (equal to one in this case), and

$$\phi = S \, B_0 \sin \omega_2 t$$

so that

$$V_1 = S \, B_0 \omega_2 \cos \omega_2 t$$

(S is the area of the wires in the direction of B). This voltage is great, as it may be equal to 1.2 volts, when $B = 1$ tesla, $S = 1$ cm^2, and $F = 74$ Hz. It can be considerably reduced by the introduction of another loop in which the flux creates a voltage opposite in phase to that of the probe loop. Residual voltage is compensated by a filtering device that is described later.

Hall Cell

The Hall cell should be parallelepiped-shaped so that the effect is theoretically interpretable and, as was shown by Isenberg, Russel, and Greene (29), five to six times longer than wide. As a matter of fact, let us suppose that the distribution of the electric current density is uniform in the X direction. If the sample is homogeneous, and if the magnetic induction is constant, the Hall field is uniform. But if the length cannot be regarded as great, the current distribution depends on the relative dimensions of the three sides, and on those of the electrodes, with regard to those of the parallelepiped. If the electrode has almost the same direction as the side, it short-circuits the Hall effect. This disadvantage can be reduced by using a sample four, five, or six times longer than wide or thick, and placing the Hall electrodes in the middle of the sample (see Fig. 2). On the other hand, in order to eliminate eddy currents, one must use a cell ten to hundreds microns thick.

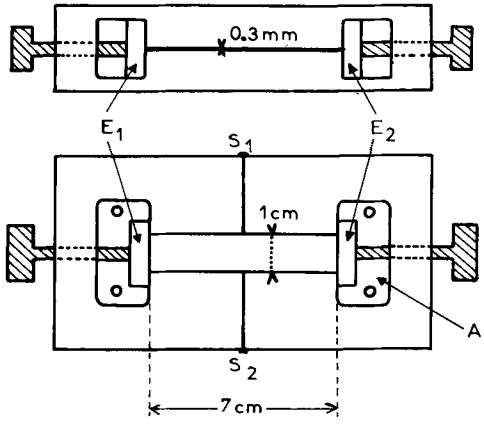

Fig. 2. Hall cell. S_1 and S_2 are Hall probes, E_1 and E_2 are current input electrodes, and A is the filling vessel.

Experimental Device

Measurement circuit.—The measurement circuit shown in Fig. 3 is made of four devices: (*a*) current generating device, (*b*) magnetic induction generating device, (c) device for separation and detection of the Hall voltage, and (*d*) device for measurement and exploitation of the various parameters.

Let us briefly recall the criteria they must obey:

(*i*) Current and magnetic induction are both alternating, with different frequencies, higher than 5 Hz, in order to eliminate the Nernst, Ettinghausen, Righi-Leduc, and nonalignment parasitic emf's.

(*ii*) Magnetic induction must be rigorously homogeneous, and the dimension of the air gap must be great with regard to those of the cell in order to avoid permanent and convective motions of the liquid.

(*iii*) The measurement must be made as quickly as possible in order to prevent the creation of concentration gradients and convective motions of the liquid.

(*iv*) Any vibrations must be carefully avoided.

(*v*) The installation should be placed in a room air conditioned at 20°C.

Current generating device.—The current sent into the cell is emitted by a function generator, as an undamped sine-wave or as a sine-wave-train, parallel or not to the magnetic induction. The characteristics of this device are:

band width ± 1% from 1 to 10,000 Hz
± 3% from 10 to 100 kHz
stability ± 0.5% of p-p amplitude
distortion: less than 0.02 for 1 kHz
amplifier gain: varying from 0 to 10
amplifier output: 40V p-p
0.05A for $0 \leq Z_s \leq 38$ ohms

Magnetic induction generating device.—The magnetic induction is produced by an alternating electromagnet whose poles are 14 cm long. The length of the air gap varies from 0.5 to 2.5 cm. It is placed in a resonant series circuit made of a power supply and a battery of condensers, and produces a maximum field of 12,000 gauss at 74.8 Hz and 17,000 gauss at 50 Hz, when the air gap is 2.5 cm long. More details about the design are to be found in Pich's thesis (30). The field is homogeneous to 10^{-4} on a surface greater than 100 cm^2 and in the whole air gap so that the electrolyte blade is entirely located in a homogeneous field.

Separation and detection device.—The problem is the extraction of a very small signal (about 10^{-7}V) of well-defined frequency drowned in a background noise and mixed with a set of parasitic signals of 10^7 times greater amplitude and of different frequencies. The filtering device is made of four different filters: rejection filter, band filter, high-pass filter, and low-pass

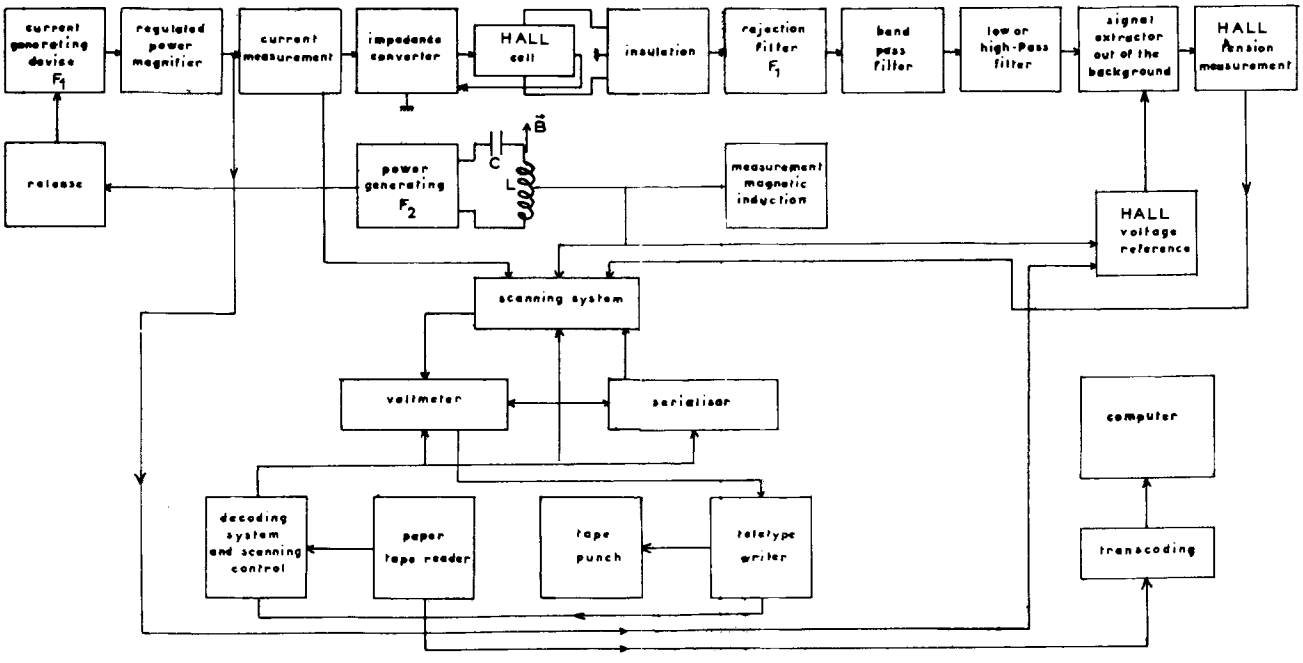

Fig. 3. General organizational chart

filter. This device has an almost instantaneous response time (31). The signal is amplified by a straight band amplifier whose gain varies from 10 to 10^4 with increments of 10. It is then sent to a waveform analyzer which uses an efficient sampling and averaging technique to extract repetitive waveforms from noise. The analyzer has a gain of 10, a time constant varying from 1 to 100 sec, and a band width at 1 db, varying from 1 to 12 Hz. The reference voltage controlling the analyzer is the same as the Hall voltage. The extracted signal is converted and entered into a data acquisition system in order to have a computer (IBM 1620) do the necessary computations. For a more detailed theory of the waveform analyzer, see Longevialle's thesis (32). To control the analyzer, one has to apply a reference voltage with the same frequency as the Hall voltage, the phase and amplitude having any values. It is produced by a Hall effect in a semiconductor submitted to the same magnetic induction and to the same current as the sample. This voltage is much greater than that in the electrolytes, and it is detected merely by a selective amplifier.

Device for measurement and evaluation of the various parameters.—Parameters to measure are: (*a*) electric current, (*b*) magnetic induction, (*c*) gain of the measurement circuit and (*d*) Hall voltage. A first measuring device supplies a constant reading of these values, while a second device records them in the computer.

Measuring device.—(*a*) Current.—As there is no ground in the circuit, measurement is made through an adaptation transformer with unity ratio whose secondary is closed by a resistance R.

$$I = U_R/R$$

U_R is the voltage at the terminals.

(*b*) Magnetic field.—It is measured in the vicinity of the cell with an extra flat coil of very small dimensions

$$B = 10^2\, U/f_2$$

where U is the voltage at the terminals of the coil, and f_2 is the magnetic induction frequency.

(*c*) Gain of the measuring circuit.—The reference voltage mentioned in the section on Separation and detection device is used for this measurement. This voltage is sent into a band filter and measured as U_E. Then it passes through a voltage divider reducing it to value U_S close to that of the Hall voltage. The gain is

$$G = U_S/U_E$$

(*d*) Hall tension.—The Hall signal from the detector is recorded by the first beam of a dual beam oscilloscope. The waveform analyzer ramp is represented by the second beam and both are synchronized by the reference frequency. The voltage is measured by a digital voltmeter after stopping the signal scanning and reading the value recorded in the detector memory.

Data input system.—It is performed with: (*a*) an analogue detector which scans the different beams; (*b*) a digital voltmeter which sequences the beams; (*c*) a serial recorder, which converts the digital voltmeter data in ASCII serial data; and (*d*) a teletypewriter, which includes a typewriter, a tape-reader, and a tape-punch. The reader controls data recording by means of a program tape. They appear in a format which is compatible with the computer.

Operating Technique and Experimental Results

Let us briefly describe the Hall cell.

Cell.—The cells are made of epoxy that can be tooled or moulded with very great precision. Measurement electrodes are platinum wires moulded in the epoxy so that only a small part of the wire is in contact with the electrolyte. The current input electrodes are plates of stainless steel; they cover the whole section of the measurement vessel (in order to assure a uniform current distribution); they can be moved and immersed in the vessel. They are connected to the opening so that the parallelepiped is perfectly defined. Another advantage of the vessel is that losses are prevented and that the electrolyte is isolated (Fig. 2).

Operation.—Choice of frequencies.—We used a current frequency of 303.4 Hz, which is high enough to avoid electrolysis and low enough to produce, together with the magnetic induction frequency of 74.4 Hz, a Hall voltage of 229 and 377.8 Hz which are the values of the Hall voltage frequency that make detection easier.

As a matter of fact, in the detection circuit, right after the impedance adapter, the Hall signal enters several active and passive filters. It is then necessary to have a maximum difference between the frequency of the Hall voltage and that of the nonalignment voltage (which is the same as the current's) in order to weaken as much as possible this parasitic voltage which is the most important one. Besides, by searching this maximum weakening, one eliminates the voltage induced by the induction in the Hall probes loop, as the induction frequency is more than two octaves higher than that of the current.

Electrolytes.—We used hydrochloric and nitric acid solutions whose concentrations c vary from 10^{-3} to 10^{-4} moles · liter^{-1}. The reproducibility of the results depends on the careful preparation of the solutions and on the filling of the cell. The solutions are prepared in a dust-free enclosure, air conditioned at 20°C, by volumetric titration from pure products dissolved in demineralized water whose resistivity is higher than 20 megohms/cm. The cells are cleaned by usual methods, carefully rinsed, and filled very slowly with a polyethylene syringe in order to avoid bubbles.

Adjustments on the measurement circuit.—Measurements are made at the 229 Hz frequency as the rejection rate of parasites is higher. One must set the rejection rate (remaining nonalignment tension must be higher than 100 mV), the magnetic induction (adjusting the no-load current conditions of the output tubes and various parameters of the power supply during the experiment in order to prevent any oscillation of the a-c electronic source), and the Hall frequency (by checking and, if necessary, adjusting the Hall frequency with respect to the reference frequency).

Experimental procedure.—For a given concentration, it is the following: the rinsed and filled cell is put on its stand and the gain is measured. Then the stand is put in the electromagnet air gap so that the cell is in the central area of magnetic induction. When the current and the induction are set to the desired value, the values of each of the parameters are recorded on tape.

Error calculations.—As $R_H = V_H \cdot d/IB$, the relative error is

$$\Delta R_H/R_H = \Delta V_H/V_H + \Delta d/d + \Delta I/I + \Delta B/B$$

The relative errors on V_H and I are of two kinds: errors of reading and of testing. For V_H both are equal to $2 \cdot 10^{-3}$. For I the testing error is negligible with respect to reading error (10^{-2}). The relative error of B is less than 10^{-2}, and that of d is 4/60, so that $\Delta R_H/R_H$ 13.10^{-2} for a given concentration.

Results

The analysis is made by two programs: one puts the experimental values in the requested format and units, and computes R_H for each measurement; the other calculates mean values and root mean squares for a given concentration, current, and induction.

The results are represented in Fig. 4 to 10 giving values of R_H (or V_H) as functions of B, I, c, and e after

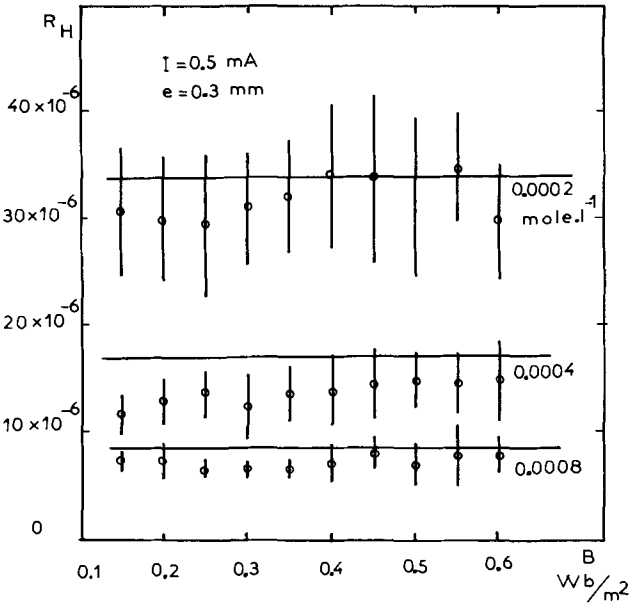

Fig. 5. Variation of R_H as a function of the magnetic field in HNO_3 solutions of various concentrations. Each point represents the mean value of R_H (obtained with 15 measurements). Each vertical bar is the root mean square. The horizontal line is obtained by Eq. [1], [2], and [3].

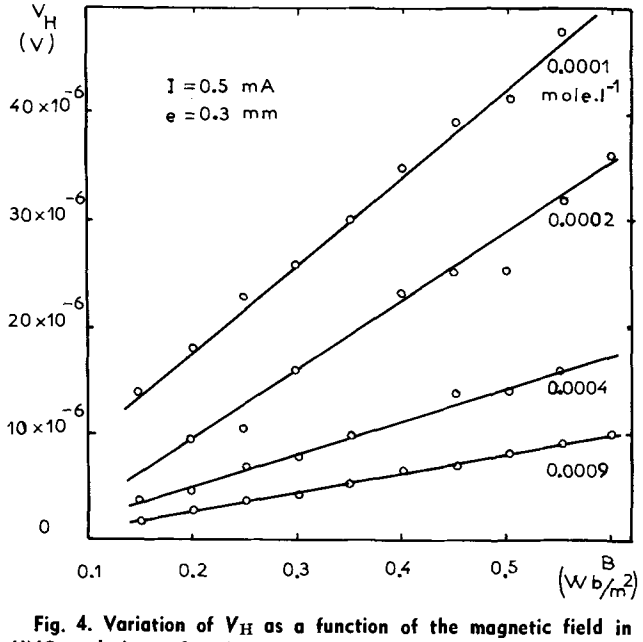

Fig. 4. Variation of V_H as a function of the magnetic field in HNO_3 solutions of various concentrations. Each point is a mean value. The line is best fit for the experimental results.

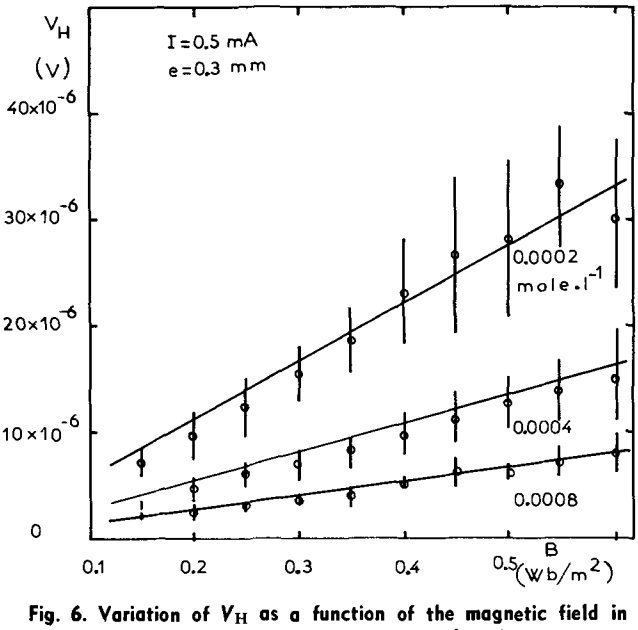

Fig. 6. Variation of V_H as a function of the magnetic field in HNO_3 solutions of various concentrations. Each point represents the mean value of V_H (obtained with 15 measurements). Each vertical bar is the root mean square. The lines are obtained from Eq. [1], [2], and [3].

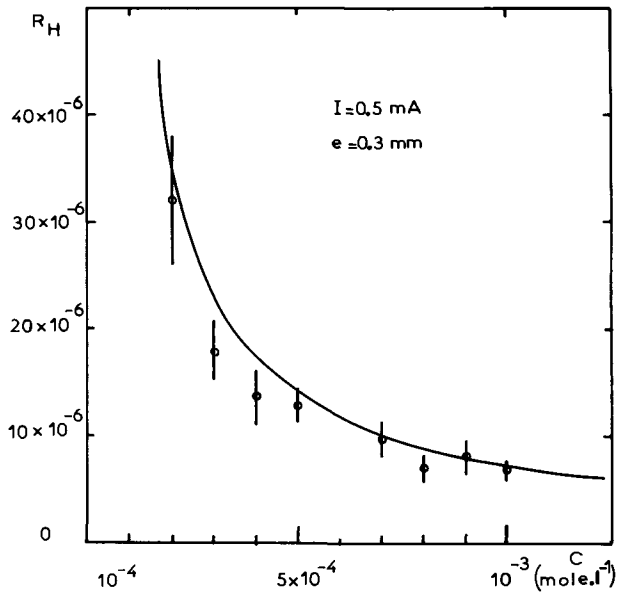

Fig. 7. Variation of R_H as a function of concentration in HNO_3 solutions, for a given d-c current intensity. Each point represents the mean value of R_H (obtained with 15 measurements). Each vertical bar is the root mean square. The curve is drawn according to Eq. [3].

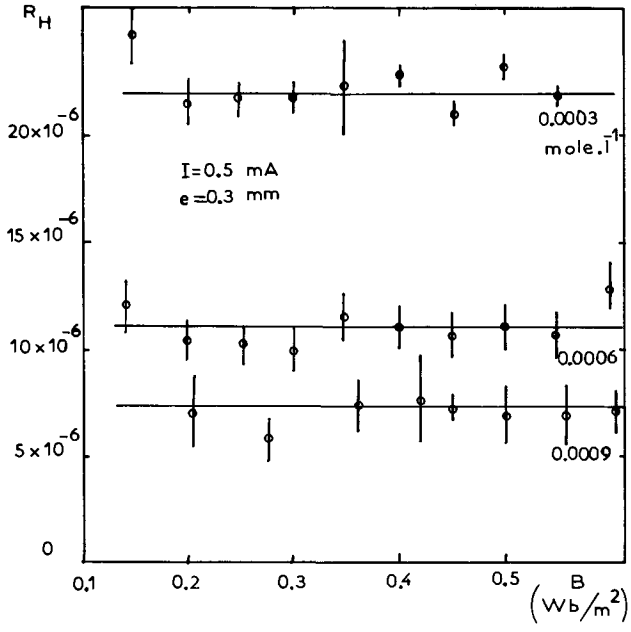

Fig. 9. Variation of R_H as a function of the magnetic field in HCl solutions of various concentrations. Each point represents the mean value of R_H (obtained with 15 measurements). Each vertical bar is the root mean square. The horizontal line is obtained from the relations [1], [2], and [3].

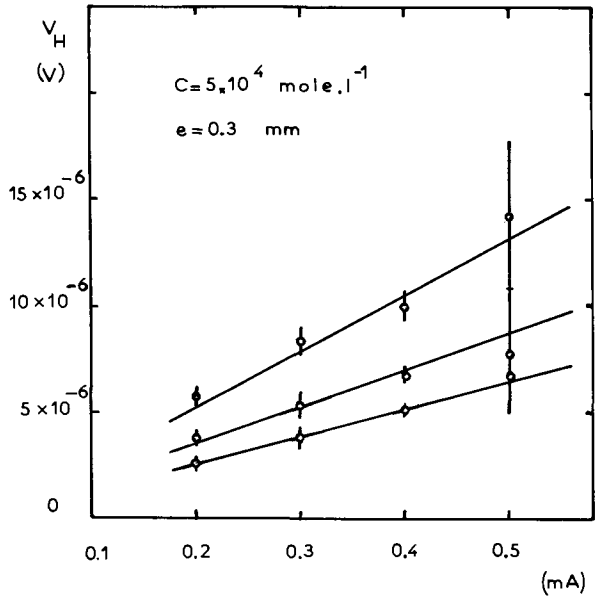

Fig. 8. Variation of V_H in terms of d-c current in HNO_3 solutions of constant concentration; magnetic field has different values. Each point represents the mean value of V_H. Each bar is the root mean square. Measurements were very difficult when the current was less than 0.5 mA, as it proved difficult to keep it constant. That is the reason why the measurements are less numerous than for $I = 0.5$ mA.

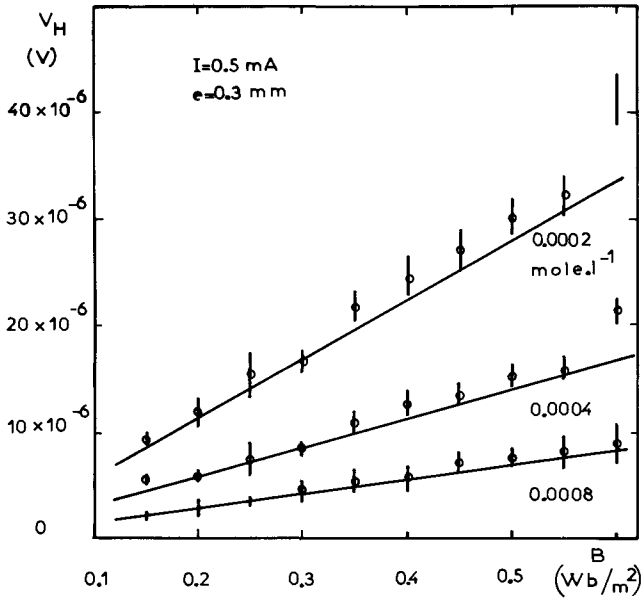

Fig. 10. Variation of V_H as a function of the magnetic field in HCl solutions of various concentrations. Each point represents the mean value of V_H (obtained with 15 measurements). Each vertical bar is the root mean square. The lines are drawn according to Eq. [1], [2], and [3].

about 3000 measurements. One can notice that, on the one hand, V_H is proportional to B and I to $1/c$. On the other hand, R_H has a constant value, as B varies, for fixed I and c. Despite the experimental difficulties, these results confirm that the device does measure the Hall effect in dilute electrolytic solutions, since as shown in Fig. 4-10, the theoretical lines are within the error limits calculated from experimental results.

We are now improving the device by increasing the gain and by using more sophisticated cells and a better filling system. We cannot yet interpret the results obtained because of the restricted concentration range of the limited number of electrolytes. However, the measurements that we are carrying out in acid, base, and neutral solutions, with concentrations between 10^{-4} and 10^{-2} mole · liter^{-1}, should allow us to increase our knowledge of the transport properties of dilute electrolytic solutions.

Technical Notes

Quinones as Rechargeable and Regenerable Battery Cathode Materials

H. Alt,[1] H. Binder, A. Köhling, and G. Sandstede

Battelle-Institut e.V., Frankfurt (Main), Germany

Organic cathode materials investigated in the past as depolarizers in batteries are reduced irreversibly and, therefore, can only be used in primary cells (1). Quinones and hydroquinones are, however, known to act as completely reversible redox couples, but most of the quinones are slightly soluble and partly unstable in electrolyte solutions (2). In order to test their stability electrochemically, we mixed the quinones with graphitized carbon in a weight ratio of 1:1. The powder was put between two graphite felt disks 1 cm^2 in surface area held together by two tantalum gauze strips in a Plexiglas holder. The open-circuit voltages measured in 2*N* H_2SO_4 are very close to the values of the redox potentials measured in alcoholic solutions. Diphenoquinones, which have a potential of about 950 mV (*vs.* NHE) do not have the required stability in aqueous electrolyte. Only tetrachloro-p-benzoquinone (Chloranil) and tetramethyl-p-benzochinone (Duroquinone) have been found to be sufficiently insoluble and completely stable. In 2*N* H_2SO_4 we measured open circuit potentials of 668 mV and 478 mV, respectively, whereas in 50% aqueous alcoholic solution equilibrium potentials of 664 mV and 480 mV have been found (2).[2]

In order to investigate the reversibility of the electrochemical reduction and oxidation a cyclic potentiodynamic current voltage curve was measured (Fig. 1), using chloranil as test substance. As the voltage decreases, the quinone is reduced to hydroquinone, and if the voltage increases the hydroquinone is oxidized. The two curves are symmetrical with respect to the open-circuit potential. The oxidation peak and the reduction peak are both very narrow, indicating that polarization is low. In addition the areas enclosed by the two curves and consequently the charges are equal, indicating that the reaction is completely reversible. The amount of charge transferred is consistent with that calculated from the quinone content, which points to a 100% utilization of the quinone. The cyclic potentiodynamic curve can be reproduced periodically; this suggests that there is no decrease in capacity, at least up to the, say, 50 cycles measured.

The galvanostatic discharge curve (Fig. 2) at a current density of 60 mA/cm^2 is almost horizontal up to a discharge depth of 80%, the polarization being as low as 40 mV. Even at a current density of 600 mA/cm^2 which corresponds to the extremely unusual discharge rate of 10C[3] there is no breakdown of the voltage. The chloranil cathode can also be heavily loaded at low temperatures (Fig. 3) without polarization increasing drastically.

High currents can also be drained in salt solutions. The open-circuit potential in zinc chloride solution is about 400 mV (*vs.* NHE) according to the pH of 4.8. In the case of ammonium chloride solution it is only 340 mV and thus is about 100 mV lower than the redox

[1] Present address: Farbwerke Hoechst, Frankfurt/Main-Höchst, Germany.

[2] The measured open circuit potentials are the equilibrium redox potentials of solid electrodes and do not change when the ratio quinone/hydroquinone changes as long as a small amount of the second phase is present.

Key words: cyclic voltammetry, rechargeable cathodes, regenerable cathodes, air cathodes, hydrogen peroxide cathodes, quinones.

[3] 1C corresponds to a 1 hr discharge rate (galvanostatic discharge of the theoretical Ahr-capacity in 1 hr). The unit of C is reciprocal with time so that 10C corresponds to 1/10 hr discharge rate.

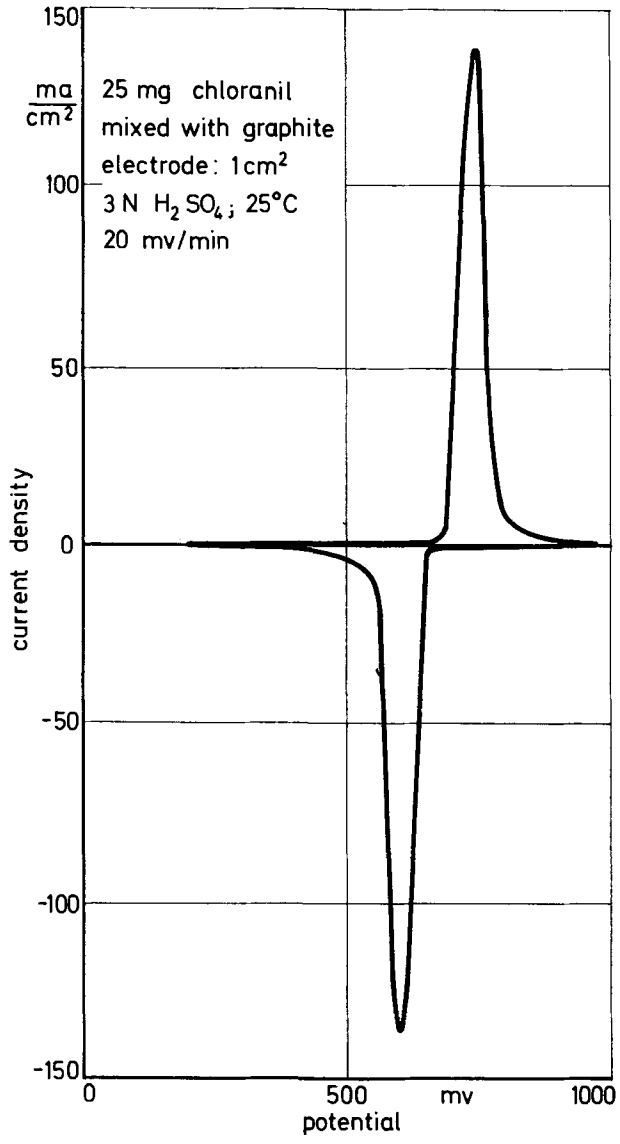

Fig. 1. Cyclic potentiodynamic curve of a chloranil electrode in dilute sulfuric acid.

potential (3) expected from the theoretical pH dependence.

Chloranil cannot only be recharged electrically but also regenerated chemically by means of hydrogen peroxide. Figure 4 shows the discharge curves of chloranil in dilute sulfuric acid after different regeneration times. After 5 min more than half of the capacity is regained. Regeneration with oxygen (air) may even be of greater importance. Normally, hydroquinone is not oxidized by oxygen, but if in contact with a catalytically active material it should be possible to oxidize hydroquinone to quinone with air or oxygen because the oxidation potential of oxygen is higher than that of benzoquinones. As active carbon is known to be capable of activating oxygen, we mixed chloranil and—in another investigation, duroquinone—with Norit BRX active carbon which is electrically conductive.

A hydrophobic electrode has to be produced from a mixture of this type because otherwise the air does not reach the hydroquinone. In order to carry out a simple test we used a hydrophobic fuel cell cathode as a support for the active mass. This cathode is made of BRX carbon and PTFE with a PTFE backing. The quinone/active carbon mixture was put on the electrolyte side of the electrode, which was then covered with a graphite felt disk. The discharge curve is as close to horizontal as for chloranil, polarization being very low (Fig. 5). The capacity is somewhat higher than expected from the amount of duroquinone used. This is due to the fact that the active carbon has a certain capacity because its surface can be partly oxidized. Of course, during the discharge measurements air was replaced by nitrogen.

With chloranil the recovery time was greater than in the case of duroquinone. These results suggest that the regeneration is governed by an electrochemical mechanism. As the active mass was not hydrophobic, the hydroquinone was oxidized anodically, the electrons flowing to the carbon of the supporting electrode where oxygen was cathodically reduced.[4] It seems possible to decrease the recovery time for air regeneration by developing suitable electrodes. Regeneration with air is also possible in salt solutions.

Besides their use as redox material in air cathodes for intermittent operation, quinones can also be used as active mass in secondary batteries. The theoretical energy density of two duroquinone/zinc couples (pH = 3) has been calculated:

duroquinone/SO_4^{2-}/Zn	175 Wh/kg
duroquinone/Cl^-/Zn	190 Wh/kg

These values compare favorably with the theoretical value of 165 Wh/kg for the lead battery. Moreover, relatively light materials can be selected for the construction of the organic active mass.

[4] According to the lower oxidation potential of duroquinone the potential difference between the "oxygen electrode" and the "quinone electrode" is higher than in the case of chloranil; therefore, the current flowing from the durohydroquinone to the carbon of the supporting electrode is higher and the recovery time is shorter than with chloranil.

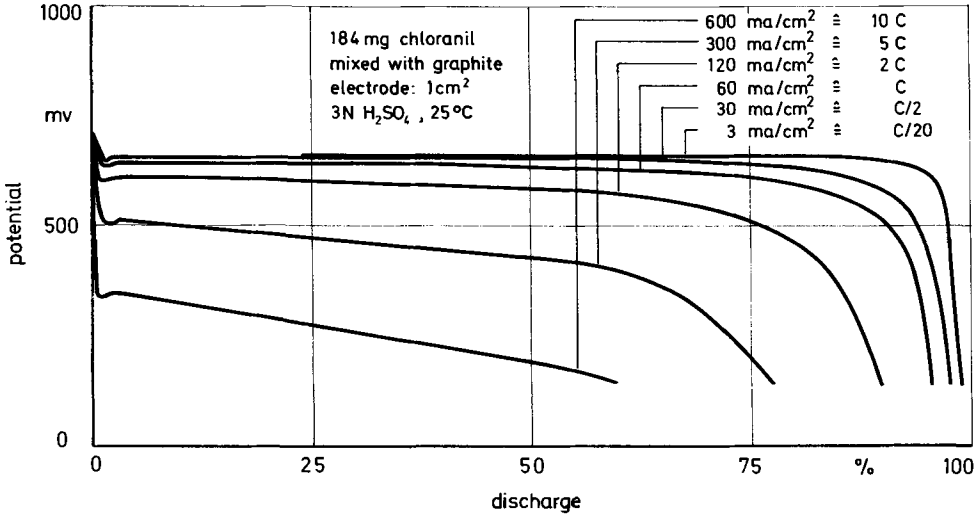

Fig. 2. Discharge curves of a chloranil cathode at different rates in dilute sulfuric acid.

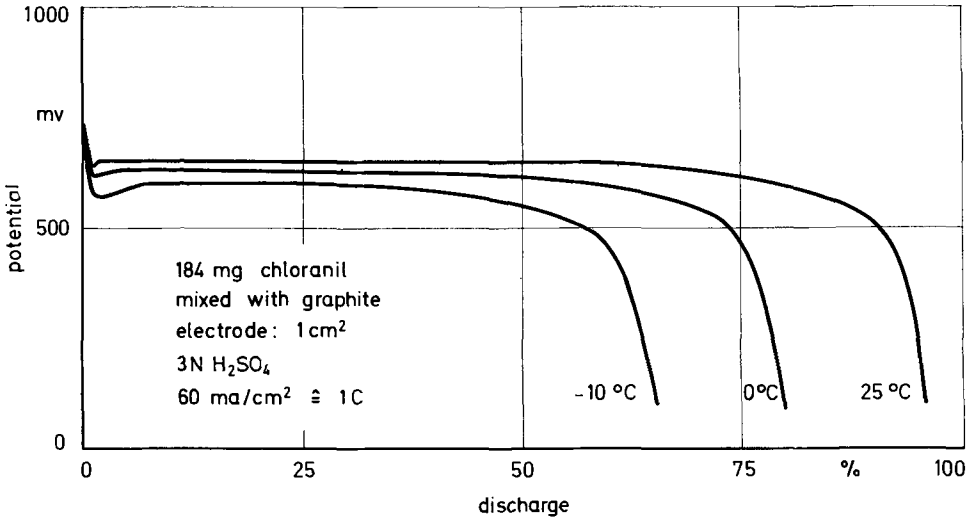

Fig. 3. Discharge curves of a chloranil cathode at different temperatures in dilute sulfuric acid.

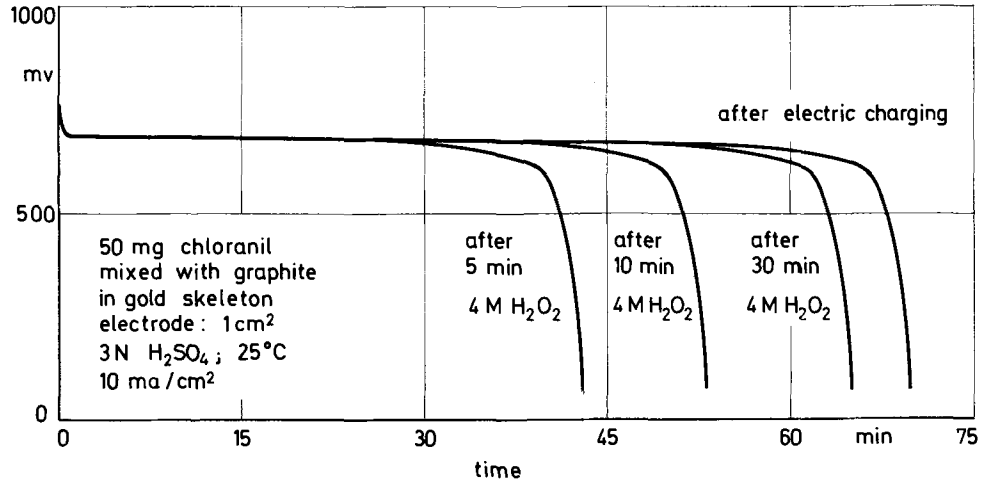

Fig. 4. Discharge curves of a chloranil cathode in dilute sulfuric acid after regeneration with H_2O_2.

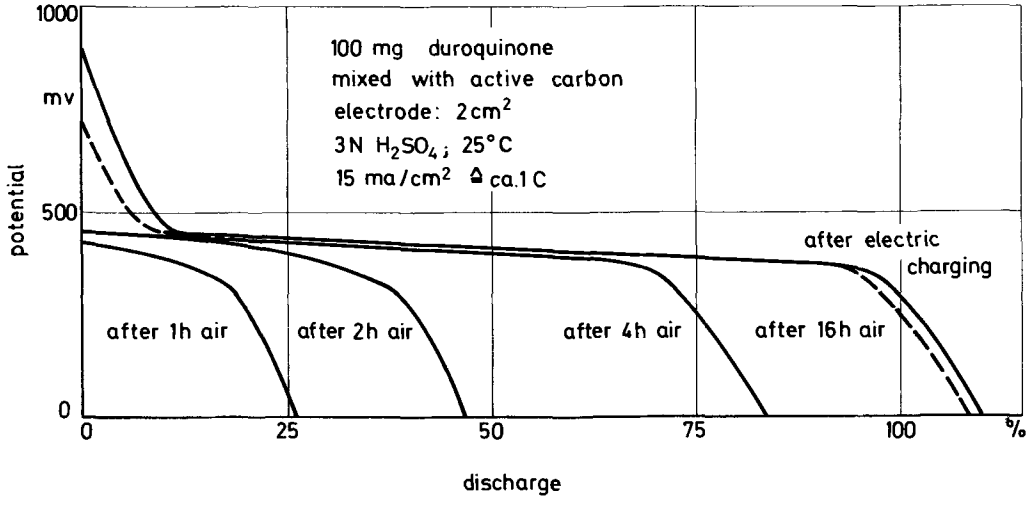

Fig. 5. Discharge curves of a duroquinone cathode in dilute sulfuric acid after regeneration with air.

It should also be noted that quinones are suitable materials for use as cathodes in high energy secondary batteries with organic electrolytes. Their performance is at least the same as that of heavy metal halides; some representatives are still superior because of their insolubility. With the lithium/chloranil couple in propylen carbonate we measured an open-circuit voltage of 3.3V which dropped to 2.6V after 85% discharge. Complete recharge was possible (3). Polymeric quinones should even be better suited because of their higher capacity and complete insolubility.

Adsorption of Cadmium Ions from KOH Solution at a Platinum Electrode[1]

S. Gilman*

Power Sources Division, Electronic Components Laboratory, U. S. Army Electronics Command, Fort Monmouth, New Jersey 07703

and L. D. Sangermano

General Electric Company, Schenectady, New York 12300

Wagner (1) noted the degradation of the platinum-catalyzed oxygen electrode in an experimental cadmium-air battery cell and suggested that the effect might be due to the adsorption of cadmium ions. In this study we verified the degradation effect and made some evaluation of the nature and extent of the adsorption process responsible for the degradation.

Experimental

Voltammetric measurements were made using the electronic equipment described previously (2). Measurements were made in either Cell I or II. Cell I was fabricated of Pyrex glass and was preferred for convenience of use and provision for controlled mechanical stirring. It comprised a main compartment holding 200 cc of solution in which was immersed electrode A or B, and a glass stirrer. The main compartment was separated from the counterelectrode compartment by means of a porous glass disk and from the reference electrode compartment by means of a Luggin capillary and a closed glass stopcock. The counter and reference electrodes were platinized platinum foils and a stream of pure hydrogen gas was allowed to impinge upon the reference electrode surface. Test electrodes A and B were prepared by annealing lengths of 0.030 in. diameter C.P. grade platinum wire and sealing into glass tubing. The geometric areas of electrodes A and B were 0.43 and 0.16 cm^2, respectively.

Cell II was designed so that the electrolyte would not be contacted by any material other than platinum (and less than 0.1 cm^2 of PTFE insulation for the test electrode). A small smooth platinum crucible served as both the counterelectrode and the container for the electrolyte. The test electrode was a length of 0.030 in. C.P. grade platinum wire annealed in a hydrogen flame and encased in heat-shrinkable PTFE tubing, exposing 0.21 cm^2 of geometric area. The reference electrode was a length of 0.1 in. ID platinum tubing platinized at the end immersed in the electrolyte and through which was passed a slow stream of a 1% hydrogen, 99% argon gas mixture. Gas flow was discontinued before making a measurement if a quiescent solution was desired, or continued if stirring was desired. The reference electrode potential (as measured against a conventional hydrogen electrode was found to be highly reproducible and stable. Calculations revealed that the charge associated with the oxidation of hydrogen from the approximately 10^{-5}M solution of hydrogen gas (resulting from use of the dilute hydrogen reference electrode) was negligible and could contribute no significant error to the measured adsorption charges. The platinum crucible was enclosed in a gas-tight quartz vessel provided with a tapered ground quartz cap which served as the electrode support. A second interchangeable cap held a reference electrode and a large platinized gettering electrode (2). For cleanup purposes, the getter electrode was alternatively driven to oxygen evolution, hydrogen evolution and back to oxygen evolution potentials in a portion of electrolyte, and then quickly transferred to the test vessel with the protection of the anodic film (2). The potential was then adjusted to 0.06V and stirring was provided by the reference gas jet.

The 1*N* KOH electrolyte was prepared using A.R. grade KOH pellets and triply-distilled water degassed by sparging with a steam of pure helium for over an hour. The solution was prepared in a platinum evaporating dish under a helium atmosphere in a glove box. Cell II was opened (for electrolyte transfers and gettering) only in the glove box. When required, cadmium ions were added to the KOH solutions by introducing sufficient 0.01M cadmium perchlorate to make the solution 10^{-4}M and then allowing at least several hours for excess cadmium perchlorate to precipitate out.

Both Cells I and II were thermostated at 30°C in an air bath. All potentials are referenced to that of a reversible hydrogen electrode in equilibrium with 1 atm of hydrogen in 1*N* KOH.

Results and Discussion

Polarization curves for oxygen reduction.—These experiments were performed in Cell I using electrode A. The electrode potential was programmed as previously (2) to regenerate a clean and reproducible surface. In the experiment of Fig. 1, after the anodic pretreatment at 1.8 and 1.2V, the surface was reduced and exposed to possible adsorption of cadmium ions at potential U for a time τ. The polarization curves were measured by applying a positive-going potential sweep (speed, 0.1 V/sec) and measuring the resulting current. Pure oxygen was kept bubbling through the electrolyte with additional vigorous stirring by means of the glass stirrer.

In the absence of dissolved cadmium, a single polarization curve was obtained for values of U between 0.1 and 0.5V and for values of τ between 0.1 and 1000 sec (*viz.*, 10 sec trace on rhs of Fig. 1a). That curve exhibits strong dependence of current upon potential in the fractional milliampere current density range. A diffusional influence (curvature toward the voltage axis) is apparent at higher current densities. An oscillatory limiting current dependent on the rotational speed of the stirrer (the average limiting current for the conditions of Fig. 1 is given by the horizontal dashed lines) is assumed to be diffusion-limited. In the presence of

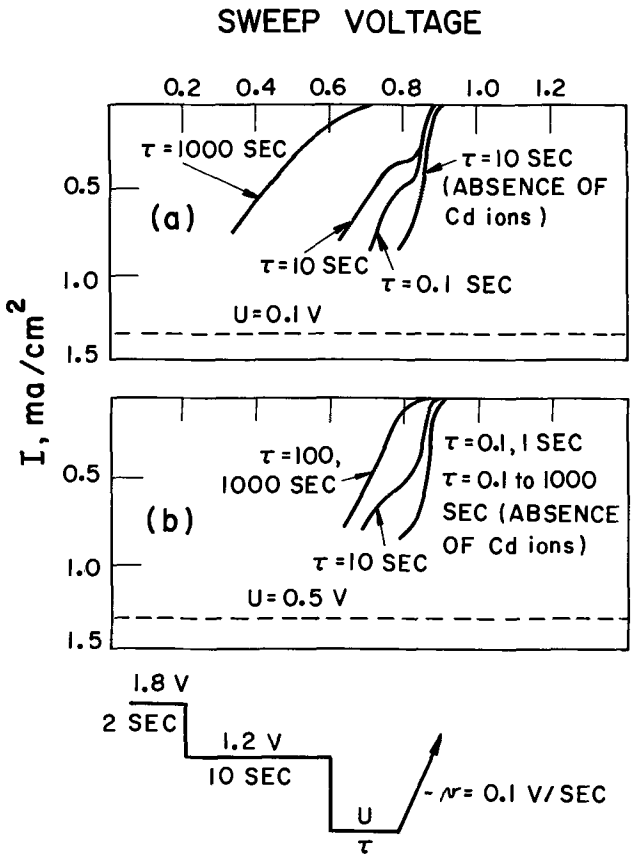

Fig. 1. Polarization curves for electroreduction of oxygen in 1N KOH solution. The polarization curves were measured by applying a linear-potential-time sweep after the indicated electrode pretreatment. The dashed curve was obtained in the absence of cadmium ions for $U = 0.1$ to 0.5V and $\tau = 0.1$ to 1000 sec. The solid curves were obtained after the solution was saturated with cadmium ions. Electrode A was used in Cell 1. The oxygen-saturated solution was mechanically stirred.

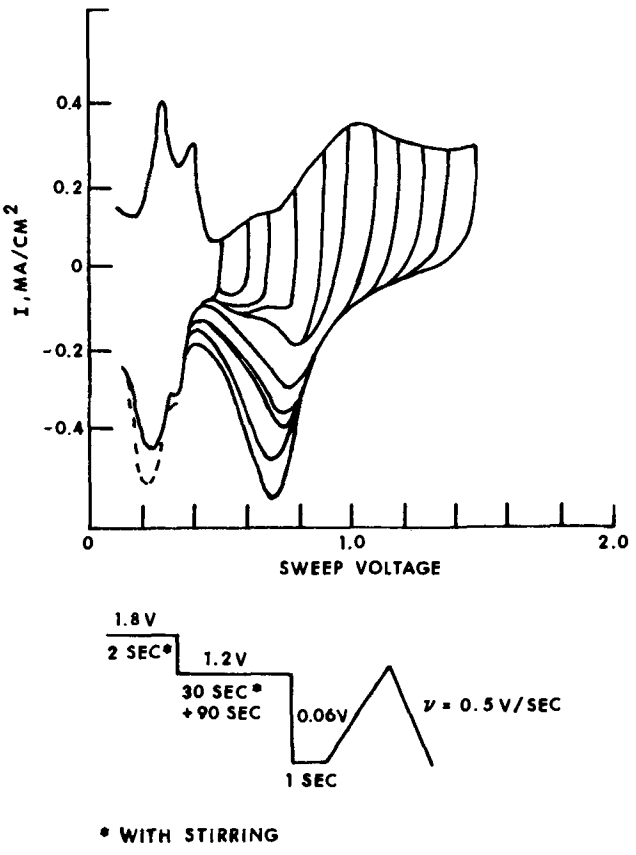

Fig. 2. Current-voltage curves measured during application of a linear potential-time sweep. The 1N KOH solution was degassed with argon and the traces measured by applying triangular sweeps (different amplitudes) after the indicated pretreatment.

dissolved cadmium, polarization increased with decreasing U and increasing τ. Intermediate curves exhibit an inflection at current densities well below the diffusion limit. The inflection may mark a transition between reduction of oxygen to peroxide and to water, as observed on some catalysts other than Pt [*e.g.*, Au, Ref. (3)]. Retardation of oxygen reduction kinetics by metal ions, notably the alkaline ions in acid solution, has been observed by several investigators (4-6).

Reference surface state of a platinum electrode.—The surface state of a Pt electrode in KOH solution may be probed conveniently through application of a linear potential-time sweep. In the experiment of Fig. 2, the potential sweep was applied after anodic treatment of the electrode followed by reduction for 1 sec at 0.06V. Stirring was discontinued during the latter part of the pretreatment to minimize convective diffusion of impurities to the electrode. A complete discussion of the pretreatment scheme appears in Ref. (2). The trace obtained during the sweep of 1.5V is rather similar to that obtained in acid electrolytes (7). Two closely spaced maxima appear during the anodic sweep to approximately 0.4V. Virtually the mirror image of this portion of the trace was obtained during the cathodic sweep to complete the similarity to the hydrogen adsorption region observed in acid electrolytes (7). Above approximately 0.8V, as in acid solutions, there is a very broad oxidation wave terminating in oxygen gas evolution above approximately 1.6V. The corresponding reduction process occurs at markedly lower potentials (peak at 0.7V) and by analogy to the acid electrolyte system, may be assigned to reduction of a film (adsorbed oxygen or oxide precursor) formed during the anodic sweep. Unlike the situation in acid electrolytes, there is no double layer region at potentials intermediate between hydrogen and oxygen adsorption during the positive going sweep. Approximately symmetrical cathodic currents (above the hydrogen adsorption region) may be obtained if the sweep is interrupted at potentials below 0.8V. These currents may correspond to those occurring to a much smaller extent (between approximately 0.6 and 0.8V) in acid solutions and ascribed by Böld and Breiter (8) to hydroxyl radical adsorption.

The effect of electrode pretreatment on the anodic sweep trace, was explored in the experiments of Fig. 3. The potential sequence used was based on the principles previously (2) formulated for acid electrolytes. Employing that sequence, it was found that any particular trace usually could be reproduced to better than 1% on the current axis. From Fig. 3 it is evident that the traces stabilize sometime between 10 and 100 sec. Two mechanisms could account for the time variations: adsorption of impurities from solution; and slow reduction of the surface. To test for the first possibility, the experiments were repeated with stirring and no effect was observed. This would seem to rule out a transport-limited impurity adsorption. In a second test, an attempt was made to getter impurities on a large area platinized platinum gauze electrode held at 0.06V overnight. No effect of gettering was observed, arguing against the possibility of activation-controlled adsorption of impurities.

In support of the second possibility for time-dependence of the electrode surface state, an exponentially decaying reduction current could be measured, where the current remained greater than 0.01 mA/cm² for several seconds. Additional evidence that the variations of Fig. 3 correspond to slow reduction of the sur-

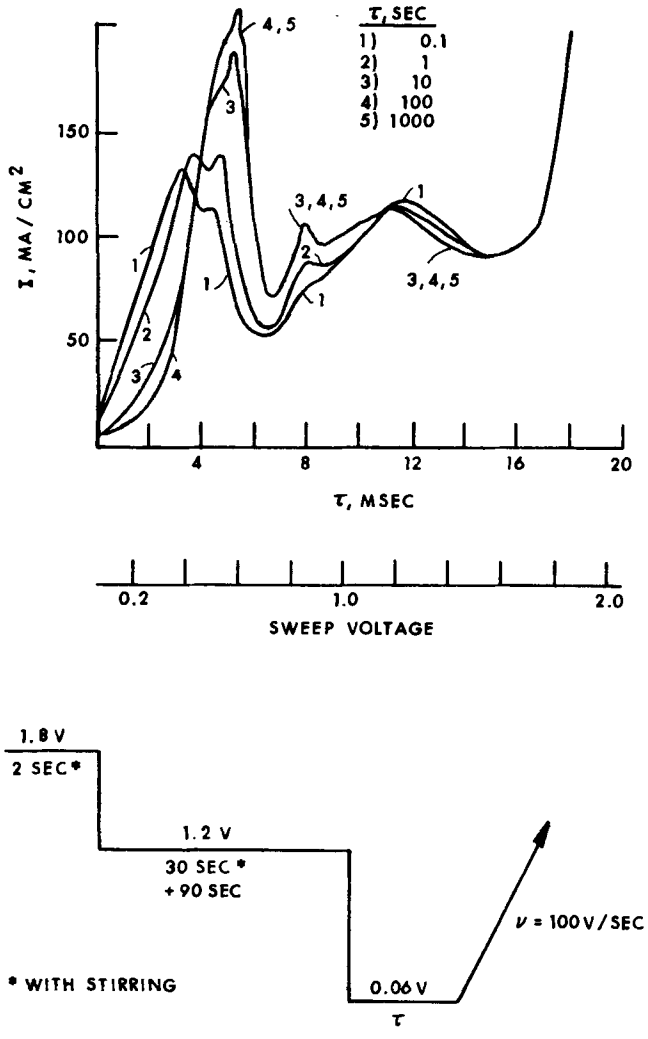

Fig. 3. Time-dependence of the trace obtained during application of a linear anodic sweep. The experiment was performed in Cell II with the solution degassed with an argon-H_2 mixture.

face, was obtained through measurement of the anodic and cathodic charges in the hydrogen adsorption region. The traces were measured as in Fig. 2 with the potential sweep extending from 0.06 to 0.5V. The time, τ, at 0.06V was the variable and the charges, Q, were obtained by integrating the total area under the traces, using a planimeter. The anodic and cathodic charges (corresponding mainly to hydrogen dissolution and deposition, respectively) are plotted against τ in Fig. 4. It can be seen that after approximately 10 sec, Q reaches a value that is (within a few per cent average deviation) independent of the direction of the potential sweep and of stirring. At shorter times, the anodic charge decreases and the cathodic charge increases, as would be expected if there were a concomitant reduction (of the surface) process during τ. If the time effect were due instead to adsorption of an impurity, it would be expected that both the anodic and cathodic values of Q would decrease with increasing τ. It may be noted that the time effects of Fig. 3 are most striking in the hydrogen region where there is a tendency for the waves to shift to more anodic potentials with increasing τ. The effect is less marked at lower values of the sweep speed, indicating that the effect on hydrogen adsorption is partly a kinetic one.

Although impurity effects are not indicated by the experiments of Fig. 3, such effects were encountered in some of our other experiments. Stirring-dependent decreases of currents in the hydrogen region and increases of currents in the oxygen region similar to those encountered in unpurified acid solutions (2) were observed when experiments were performed with some exposure of the electrolyte to the atmosphere. If carbon dioxide (or carbonate) does not adsorb from alkaline solutions as reported by Podlovchenko *et al.* (9) then it appears likely that other organic substances in the air may be troublesome.

The effect of glass as a contaminant was tested by adding crushed Pyrex glass to the Pt crucible of Cell II. A small but noticeable effect of glass was evident after only 10 sec.

Hydrogen adsorption:—Assuming that the anodic and cathodic waves (Fig. 2) obtained below 0.5V correspond to dissolution and deposition of hydrogen atoms, we may estimate the charge ${}_sQ_H$, corresponding to monolayer coverage of the surface with hydrogen atoms, as in acid electrolytes (2), from the cathodic sweep trace. For electrode B, ${}_sQ_H = 0.28$ millicoulomb/cm² suggesting a roughness factor of 1.3 if we assume (2) ${}_sQ_H = 0.21$ millicoulomb/cm² corresponds to R.F. = 1.

Adsorption of cadmium ions:—Our solutions of cadmium ions were obtained by allowing the hydrolysis of an excess of neutral cadmium perchlorate solution to come to equilibrium in 1N KOH at 30°C. Under

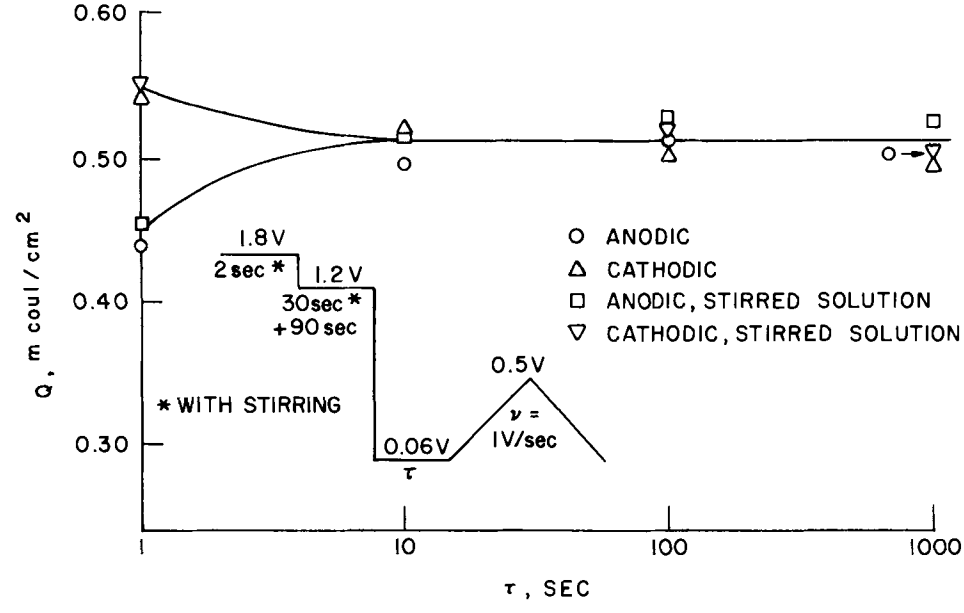

Fig. 4. Dependence of the anodic and cathodic charges in the hydrogen adsorption region upon the reduction time interval.

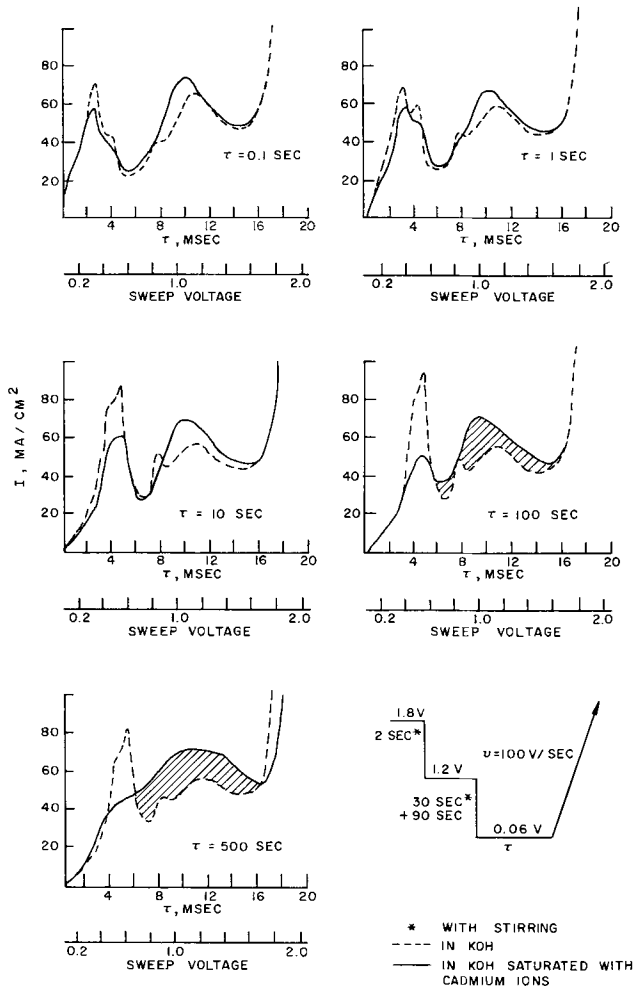

Fig. 5. Time-dependence of the trace obtained during application of a linear anodic sweep in the presence and absence of dissolved cadmium ions.

these conditions (but 5° lower in temperature) the total concentration of bivalent cadmium should be 8 x 10^{-6}M according to Visco and Sonner (10) or 5 x 10^{-6}M according to Ryan *et al.* (11).

The potential sequence of Fig. 5 was selected to determine the effect of cadmium ions on the anodic sweep trace. As shown above, a highly reproducible surface is generated during reduction of the surface at 0.06V, although complete reduction of the surface is not accomplished for $\tau > \sim 10$ sec. Adsorption of cadmium occurs on the freshly (or partially) reduced surface before application of the potential sweep. A high (v = 100 V/sec) value of the sweep speed was chosen so that the adsorption of cadmium ions during the sweep was negligible. The dashed traces were obtained in 1*N* KOH in the absence of cadmium and the solid traces were obtained after addition of cadmium. It is apparent that cadmium ions cause a decrease in hydrogen adsorption and an increase in the charge flowing in the "oxygen adsorption" region. Similar observations were made by Breiter (12) and by Bowles (13) for acid solutions containing copper and thallium ions, respectively. The decrease in hydrogen adsorption may be attributed to blockage of hydrogen adsorption sites by adsorbed cadmium. The increase, Q_{Cd}, of charge at more anodic potentials must correspond to the oxidation of zero (adsorbed cadmium atoms) or monovalent (adsorbed cadmous ions) cadmium to dissolved bivalent cadmium. The present experiments cannot distinguish between these two possibilities, but there is evidence in support of the corresponding adatom adsorption for copper (12) and thallium (13). For adsorption at 0.06V, it is apparent from Fig. 5 that separation of Q_H (charge corresponding to hydrogen adsorption) from Q_{Cd} becomes difficult at large values of τ. This introduces uncertainty only for adsorption potentials $< \sim$ 0.4V where hydrogen coverages are appreciable. Values of Q_{Cd} were approximated at the lower adsorption potentials by integrating from the point at which the traces intersected for the cadmium-containing and cadmium-free solutions (shaded area in Fig. 5).

Values of Q_{Cd} obtained over a wide range of adsorption potentials and apparent steady state at τ = 1000 sec, appear in Fig. 6. For $U > 0.45$V, it was necessary to prereduce the surface briefly at 0.3V as shown. If we make the tentative assumption that cadmium adsorbs as the adatom and that one cadmium adatom occupies one hydrogen adsorption site, then a monolayer of cadmium adatoms would correspond to $Q_{Cd} = 2\ sQ_H$ or 2 x 0.28 = 0.56 millicoulomb/cm². By that criterion, fractional surface coverage, θ_{Cd}, ranges from 0.25 to 0.2 over the range U = 0.1 to 0.7. At the low potential end, the coverage rises steeply as we approach the reversible potential [approximately —0.05V, according to Ref. (14)] for cadmium metal deposition. At the high potential end, θ_{Cd} drops gradually to 0 as we approach 1.2V.

Interpretation of the Q_{Cd} *vs.* U plot of Fig. 6 is difficult because of the complexity of the equilibria between the dissolved ions and because of the interactions of the Pt electrode with the electrolyte in the absence of cadmium ions. Bivalent cadmium might be present as $Cd(OH)_2$, $Cd(OH)_{3-}$, and $Cd(OH)_{4--}$ in alkaline solutions. Ryan *et al.* (11) have suggested that

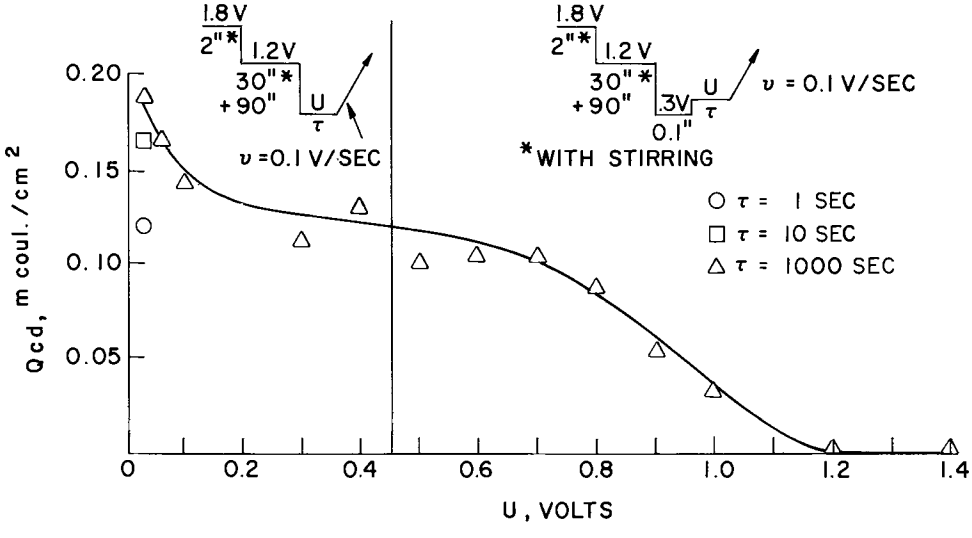

Fig. 6. Dependence of the charge equivalent of adsorbed cadmium upon the potential.

$Cd(OH)_3^-$ and $Cd(OH)_4^{--}$ predominate for OH^- concentrations greater than 0.5*N* while Visco and Sonner (10) argue that $Cd(OH)_4^{--}$ is not encountered even in 15*N* KOH. Adsorption of either negative ion at the original valence would be expected to start near the zpc (zero point of charge) here estimated at 0.72V [based on zpc = −0.11 *vs.* N.H.E. at pH 11.2, Ref. (15)] and to increase with increasing potential. The reverse dependence of Q_{Cd} upon U was actually found. Adsorption as the neutral atom might be expected to yield a semilogarithmic or linear (if heat of adsorption decreases with coverage) dependence of Q_{Cd} upon U. This may be reflected at the low and high potential ends of Fig. 6. The arrest at intermediate potentials may be due to a tendency to form a surface alloy of fixed composition. The decline of Q_{Cd} at high potentials may alternatively reflect a competition with anodic film formation.

Cadmium ion adsorption and electroreduction of oxygen.—From Fig. 6 we see that $Q_{Cd} = 0$ for $U > 1.2$V and hence Cd ion adsorption ought not to affect a platinum-catalyzed oxygen electrode operating near the reversible potential (1.23V). However, practical oxygen electrodes tend to operate at 0.9V or less, as in Wagner's experiment (1). Beginning at 0.9V, in the presence of dissolved cadmium, θ_{Cd} would tend to rise toward the intermediate value reflected by Q_{Cd} in Fig. 6. That coverage would cause a drop in voltage (increase in oxygen overvoltage) and an increased tendency to adsorb cadmium ions until the highest values of Q_{Cd} and the potential of the counterelectrode is reached. This was actually observed in a laboratory cadmium-oxygen battery cell (1).

Mass Transfer to a Rough Rotating Cylinder

R. Kappesser, I. Cornet,* and R. Greif

Department of Mechanical Engineering, University of California, Berkeley, California 94720

There have been numerous studies of mass transfer to rotating cylinders. In particular, Eisenberg, Tobias, and Wilke (1, 2) reported that the experimental results for mass transfer in turbulent flow may be correlated by

$$Sh = 0.079\,Re^{0.70}\,Sc^{0.356} \qquad [1]$$

This result is in agreement with other studies of heat and mass transfer to rotating cylinders (3-12). Note that the mass transfer to smooth rotating cylinders is proportional to the angular velocity raised to the 0.7 power.

Theodorsen and Regier determined the friction factor for a smooth rotating cylinder in turbulent flow and the results were given by (13)

$$1/\sqrt{f/2} = -17.5 + 5.75\log_{10}(Re\sqrt{f/2}) \qquad [2]$$

This may be accurately approximated over a range of Reynolds numbers between 200 and 200,000 by the relation (1, 2)

$$f/2 = 0.079\,Re^{-0.30} \qquad [3]$$

which, when used with Eq. [1], results in a modified Chilton-Colburn relation of the form

$$Sh = (f/2)\,Re\,Sc^{0.356} \qquad [4]$$

Makrides, Hackerman, King, and others (14-16) report that the mass transfer varies linearly with the angular velocity in certain cases of cylinder dissolution. Makrides and Hackerman (14) consider this result to be due to the cylinders becoming rough during dissolution. This results in a friction factor which is independent of the angular velocity for values of the Reynolds number greater than a "critical Reynolds number," Re_{crit} (13). This value is obtained from the following approximate relation

$$Re_{crit} = (11.8\,d/\epsilon)^{1.18} \qquad [5]$$

where d is the cylinder diameter and ϵ is the characteristic roughness dimension. For Reynolds numbers greater than this Re_{crit}, the friction factor was estimated to be given by

$$f/2 = (1.25 + 5.76\log_{10} d/\epsilon)^{-2} \qquad [6]$$

Thus, from Eq. [4] and [6], Makrides and Hackerman obtained (14), for the case of dissolving cylinders at Reynolds numbers greater than Re_{crit}

$$Sh/Re\,Sc^{0.356} = f/2 = (1.25 + 5.76\log_{10} d/\epsilon)^{-2} \qquad [7]$$

Their experimental data was in agreement with Eq. [7].

Makrides and Hackerman (14) were the first to recognize and explain the important phenomena discussed above. However, we note that their use of a dissolving surface does introduce time variations in the surface roughness. This, coupled with the nonuniformity of the surface, makes it difficult to characterize the scale of the surface roughness.

Because of these considerations as well as the desire to extend the applicability of their results to a wide range of Reynolds numbers and roughnesses, we utilized another mass transfer system to study this prob-

Key words: friction factor, surface roughness, oxygen reduction, turbulent flow.

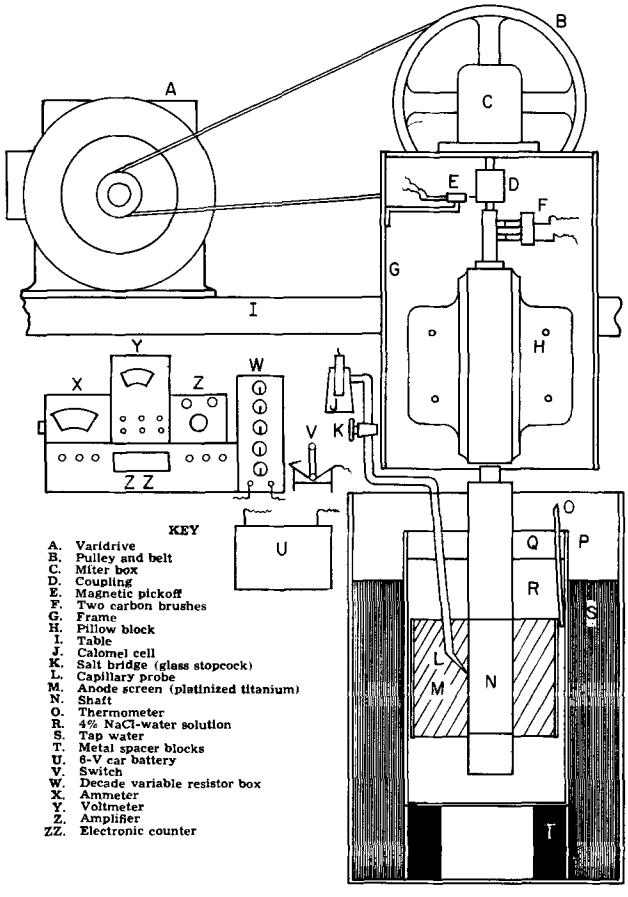

Fig. 1. Apparatus schematic

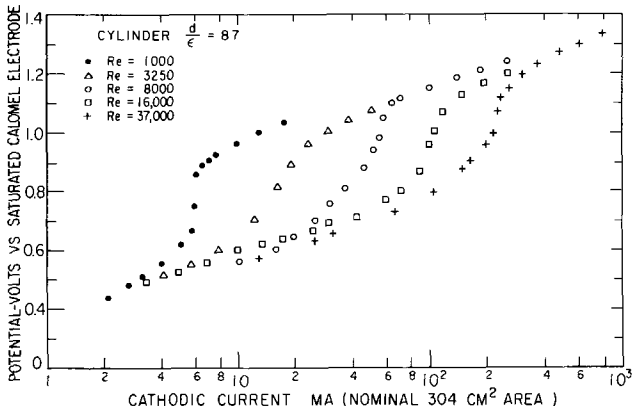

Fig. 2. Representative polarization curves

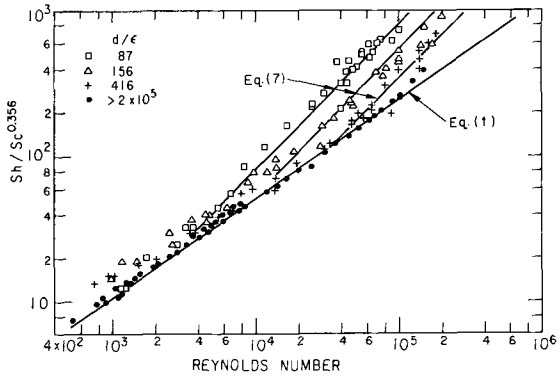

Fig. 3. Mass transfer vs. Re

lem. Briefly, the apparatus (Fig. 1) consisted of an instrumented vertically mounted nondissolving cylinder that was rotated in an oxygenated 4% NaCl-H_2O solution. The mass flux of the oxygen to the cathodic cylinder surface was obtained from the mass transfer limiting current for the reaction

$$O_2 + 2\,H_2O + 4e^- \rightarrow 4\,OH^- \qquad [8]$$

The anode was a platinized titanium cylindrical screen 20 cm in diameter and 15 cm tall, concentric with the rotating cylinder and at the same elevation as the metal portion of the cylinder. Potentials were measured with respect to a saturated calomel cell by means of a capillary probe and a high impedance voltmeter. Cathodic currents were measured by means of a milliammeter. Rotational speeds were measured by a magnetic pickup and electronic counter. The oxygen content was measured by Winkler analysis. Additional information is available in Ref. (11) and (12).

The test cylinders were made of Monel with plastic end pieces. The cylinders were 6.35 cm in diameter, 35 cm long, with a central Monel portion 15.3 cm long. This resulted in a nominal mass transfer surface area of 304 cm², based on the 6.35 cm diameter for a smooth cylinder. Four cylinders were made. The first was a highly polished cylinder with a surface roughness less than 3×10^{-5} cm rms height. The remaining cylinders had staggered diamond knurls machined on their surfaces.[1] The knurls had peak to valley heights, ϵ, of 7.3×10^{-2} cm (cylinder 2), 4.1×10^{-2} cm (cylinder 3) and 1.52×10^{-2} cm (cylinder 4) giving d/ϵ ratios of 87, 156, and 416, respectively.

Cathodic polarization curves were obtained at several rotational speeds for the different cylinders. A typical set of these is shown in Fig. 2. No major difference was observed in the shapes of these curves in comparison with those resulting for the smooth cylinders.

The resulting mass transfer data is presented in Fig. 3. The temperature of the system was 25° ± 1°C. Values of the mass diffusivity, D, and the kinematic viscosity, ν, were obtained by interpolation from the International Critical Tables (17). The values were $D = 2.33 \times 10^{-5}$ cm²/sec and $\nu = 9.3 \times 10^{-3}$ cm²/sec giving a Schmidt number of 400. Operating conditions are shown in Table I.

To check the system a series of runs was carried out on a smooth cylinder and the resulting data is seen to be in excellent agreement with the theoretical expression, Eq. [1], (*cf.* Fig. 3). For the rough cylinders the area used to evaluate current density is based on a diameter of 6.35 cm, as previously noted. This is consistent with Makrides and Hackerman (14), and with Theodorsen and Regier (13) in the presentation of their friction factor data.

From Fig. 3, it is seen that for rough cylinders the mass transfer varies linearly with Reynolds numbers for $Re > Re_{crit}$. Furthermore, there is very good agreement between the data and Eq. [7] for the different roughnesses tested. It should be noted that the friction experiments of Theodorsen and Regier (13) were carried out for sand-roughened surfaces while for the present mass transfer system the surface of the cyl-

Table I. Operating conditions

Cylinder	d/ϵ	Period, sec	RPM	O_2 content, ppm
Smooth	$>2 \times 10^5$	0.08 to 26	750 to 2.3	5 to 6
Fine knurl	416	0.08 to 18.5	750 to 3.23	4 to 6.16
Medium knurl	156	0.071 to 13.4	844 to 4.5	3.68 to 6.64
Coarse knurl	87	0.086 to 12.9	698 to 4.65	2.25 to 6.2

[1] Monel cylinders, 6.35 cm diameter, were knurled with Diamond Pattern Knurls of pitch: coarse, 14; medium, 21; fine, 33 lines per inch. Depth of knurl was regulated by pressure on the tool holder. Depth was measured by averaging several peak top to valley depth diameters.

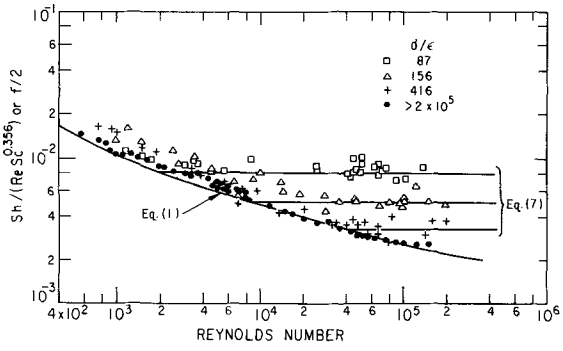

Fig. 4. Mass transfer or friction factor vs. Re

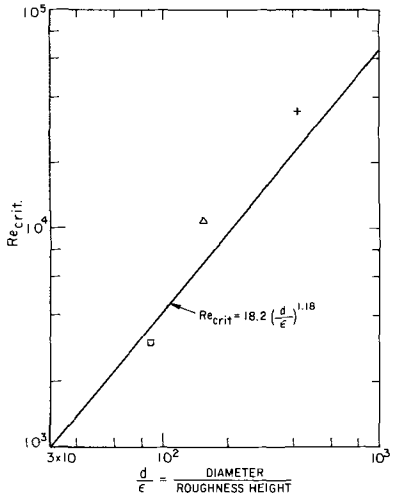

Fig. 5. $Re_{critical}$ vs. relative roughness d/ϵ

inder was covered with diamond-shaped knurls corresponding to a saturated sand roughness condition. Makrides and Hackerman state that the saturated condition also exists for surfaces undergoing dissolution.

For completeness, the experimental results have also been presented in Fig. 4 with an ordinate of $Sh/(Re\ Sc^{0.356})$ or $f/2$ and the results are again compared with Eq. [7]. Note that in this form the results for $Re > Re_{crit}$ are independent of the Reynolds number. Values of Re_{crit} may be obtained from the experimental data for the three roughnesses tested. The three points are presented in Fig. 5 along with the approximate relation, Eq. [5].

In conclusion, the mass transfer to rotating cylinders has been measured over a range of Reynolds numbers from 600 to 250,000 for surface roughnesses varying from d/ϵ equal to 87 to a smooth surface. The results were correlated with

$$Sh = (f/2)\ Re\ Sc^{0.356}$$

where f is the friction factor for the appropriate smooth or rough cylinder.

Acknowledgments

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 118, No. 1, 2, 3, 4, and 6; January, February, March, April, and June 1971.

Electrochemical Studies in Liquid and Solid AgBr

D. O. Raleigh and H. R. Crowe
(pp. 79-86, Vol. 118, No. 1)

R. D. Armstrong and T. Dickinson[1]: It is difficult to understand why Raleigh and Crowe attribute the measured capacitance of the interface Pt/AgBr to an inner layer effect whilst continuing to attribute the capacitance of the C/AgBr interface to a diffuse layer effect. The inner layer capacitance, which arises from the finite size of ions, is always in series with the diffuse layer, so that it is the smallest capacitance of the combination which is dominant. Thus, if a diffuse layer capacity is important in one case (C/AgBr), it is also likely to be important in another (Pt/AgBr). Our own opinion is that in both cases the capacitance arises from an inner layer effect, the differences in magnitude reflecting different true contact areas; and we think that in fitting the measured C-E curve to the theoretical one for C/AgBr, Raleigh[2] is unjustified in placing the theoretical C-E curve at a particular point on the E axis since this point was determined by a calculation of the absolute (*sic*) potential difference between Ag and AgBr.

D. O. Raleigh: We did not attribute the measured Pt/AgBr interface capacitance to an ideal inner layer, but to a layer of adsorbed Ag^+ and/or Br^- ions (depending on potential) on the Pt surface. In this instance, the simple series model for the diffuse and compact layer capacitances is invalid and large over-all capacitances may result[3]. Armstrong and Dickinson are of course entitled to their own interpretation of such data, and the simplicity of a purely inner layer model is admittedly attractive. It seems necessary, however, to deal with diffuse layer capacitance in some manner, and the Grimley-Mott model[4,5] seems reasonable. I have discussed this model for ionic solids at some length in a recent publication[6].

To be sure, the Grimley-Mott estimate of the Ag/AgBr absolute electrode potential may be considerably in error, but the C/AgBr capacitance data[7] match the theoretical curve both in general magnitude and in relative invariance to the potential. Dominance by an ideal inner layer capacitance would require the diffuse layer capacitance to be comparatively large. The theory does not predict this large a diffuse layer capacitance anywhere in the voltage range, regardless of the assignment of the absolute electrode potential. Our way out of the dilemma has been to suggest specific ion adsorption in the Pt/AgBr case.

At this point, it seems useful to state that we are indeed open to alternative explanations and also to point out the dangers in carrying over interface concepts developed for aqueous systems (a practice in which we share some guilt). The solid electrode-solid electrolyte interface is physically unique in a number of respects. Interface models based on a detailed consideration of the microscopic situation would seem to be needed in developing appropriate theoretical treatments.

Anodic Dissolution of Beryllium in Anhydrous Media

H. Aida, I. Epelboin, and M. Garreau
(pp. 243-248, Vol. 118, No. 2)

W. J. James and M. E. Straumanis[8]: The recent article regarding the anodic dissolution of Be in anhydrous media by Aida *et al.*, is most interesting in that it appears to provide further proof that the two concepts of "anomalous" dissolution, namely the presence of transitory species of uncommon valence or the "chunk effect" (film and/or metal spalling) are not incompatible.

The authors approach in attributing greater stability to Be^+ in a water solvent-poor interface as opposed to the greater stability of Be^{+2} in a water solvent-rich, appears to us to be a reasonable one. Our disagreements with proponents of unusual transitory ionic states as being responsible for the anomalous dissolution behavior of metals have been based on the fact that these studies were carried out in dilute aqueous media. Thermodynamic considerations of the stability of ions such as Be^+, Al^+, Zn^+, Mg^+, *etc.* in aqueous solutions virtually rules out the possibility of their existence at any measurable distance from the anodic surface. This is not to say, of course, that the anodic expulsion of, *e.g.* Be, does not occur in two consecutive electron discharges to form Be^{2+}.

Consequently, it is not surprising that the attempts by several investigators to detect directly the existence of such unstable species at considerable distances from the electrodes were doomed to failure.

Furthermore, the undisputable detection of such comparatively stable ions (for references see the article under discussion here) as Cu^+ and In^+ can hardly be considered as verification that anomalous dissolution of considerably more active metals occurs as a consequence of formation of uncommon transitory species.

In their discussion of the nature of the Be surfaces, the authors state that the appearance of a gray coloration on the surface or actual identification of metallic particles in the anode region cannot be taken as indisputable evidence of the chunk effect because the formation of metallic particles may always be attributed to the reaction $2\,Be^+ \rightarrow Be^{++} + Be\downarrow$

Whereas the concept of such a disproportionate reaction is supported by knowledge of other more noble metals which undergo this reaction, *e.g.* Cu, there is absolutely no evidence of direct nature that Be undergoes this reaction either in aqueous or anhydrous media.

On the contrary, experimental evidence suggests that this reaction is very unlikely, taking into account the failure to detect Be^+ in aqueous solutions, the inability to plate Be out of such solutions, the presence of deformation twins on the comparatively large Be-chunks and on the etched Be surfaces, indicating that the former initially belonged to the solid Be piece. In fact, the process of detachment of Be platelets from the Be substrate, dissolving in acids, could be observed optically[9].

[8] Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401.
[9] M. E. Straumanis and D. L. Mathis, *J. Less-Common Metals*, 4, 213 (1962).

Similar behavior has been observed for Al, Mg, Zn, Cd, and Sn in acidic or aqueous salt solutions[10-17]. If the same reasoning were applied to Zn to explain the presence of the gray to black coloration on its surface and the x-ray evidence of metallic particles in the anolyte, how can one explain why, when the Zn surface is amalgamated, no gray coloration is observed together with no metallic particles, and that a valence state of two is obtained in the same electrolytes[18]? Clearly, whereas in the first case Zn particles were detached from the bulk during the dissolution, which resulted in a calculated ionic state less than two, no such process could occur when the metal was amalgamated, since the Zn particles could not penetrate the Hg-surface layer and a valence of two, therefore, resulted.

Furthermore, we have also examined recently by SEM techniques Zn and Mg electrodes exhibiting surface films after anodic dissolution in aqueous media and can state that in all cases the microscopy confirms the source of the metal-like particles as arising from the electrode surface.

The foregoing discussion is not meant to detract from this excellent paper by Aida *et al.* The authors have presented strong evidence for the existence of Be^+ in anhydrous media. Further studies of this nature should go far in accounting on a more quantitative and general basis for the apparently anomalous behavior of many metals in both aqueous and anhydrous media.

H. Aida, I. Epelboin, and M. Garreau: We are pleased to see that W. J. James and M. E. Straumanis agree that anomalous anodic dissolution can be interpreted in terms of the two different basic concepts which have long been opposed in the literature. The protracted discussion on this topic, in which the editors of this Journal allowed us to take part (Discussion Section of June 1957 and June 1959), has been fruitful since it led to a better though still partial understanding of this difficult problem.

We think it necessary, however, to give further information about certain points of our paper that seemed disputable to W. J. James and M. E. Straumanis.

1.—First, we do not think that the transitory species of uncommon valency can only exist in anhydrous solutions. In our experiments, the absence of water in the electrolyte (O, 1 g/liter) highly favors the formation, near the anode, of a layer which is permeable to monovalent ions and almost impermeable to electrons. However, in certain cases, this layer can be partially formed in solutions richer in water. Thus, aluminum dissolves with an apparent valency of about two in an alcoholic solution of $LiClO_4$ containing 100g of water per liter, and this at anodic potentials sufficiently high to cause electrolytic polishing, which is incompatible with the "chunk effect."

2.—Concerning the chunk effect more particularly, the main point seems no longer to be whether the different methods, either those cited by Straumanis and James or ours, may reveal unambiguously its existence. We agree with Straumanis and James and admit that this effect can occur under various conditions; and we think that efforts should henceforth focus on its interpretation rather than on its identification. This is what we are doing at the present time, using the following new approaches: (a) study of the influence of changes in the crystal structure of the dissolved sample, caused either by various thermal treatments or by replacement of polycrystals by very pure single crystals; (b) kinetic study by modern electrochemical methods.

(a) The first results on crystal structure effects show that the disintegration of the metal occurs at the level of the subgrains of the lattice. This might be due to a phenomenon which would start under the influence of the very small differences in the reticular energy which exist between the sites constituting the boundaries of dislocation of the crystal substructure and the unperturbed parts of this crystal.

(b) By improving the analysis of the polarization curves (which have been roughly described in our paper) using a current interruption method completed by electrochemical impedance measurements, we recently showed that the anodic potential necessary to create the layer in which Be^+ is stable was actually much lower than the one predicted by curve c' in Fig. 2. The current-potential curve, corrected for ohmic drop, shows a marked change in the slope at an anodic potential of 1V as measured relative to an Ag/Ag^+ (0.2M) reference electrode. This change corresponds to the border separating the potential range within which Ne equals unity, and the surface is bright, from the range within which Ne differs from unity, and the dissolution is heterogeneous. Consequently, the electric energy actually available at the anode within the field where the chunk effect is observed is not very high. Dissolution can occur rapidly only at the weakest parts of the metallic lattice constituted by the boundaries of dislocation. The surface of the anode is thus divided in two zones: the first one has a small area (emergence of the dislocation boundaries) where the current density is high; the second has a larger area but scarcely contributes to dissolution. The relative importance of the contributions of these zones depends on the potential. Faradaic impedance diagrams obtained at these low potentials provide support for this interpretation since they show, at very low frequencies, more than one time constant.

3.—The fact that beryllium cannot be plated out from the solutions we used is not in disagreement with the formation of stable Be^+ ions moving sufficiently far from the electrode to modify the faradaic yield of the dissolution. In fact, this formation needs a minimal anodic potential which is incompatible with the cathodic reaction $Be^+ + e \rightarrow Be\downarrow$ in the cases considered here.

4.—As for the results obtained with amalgams, we think that the canceling of the anomaly may be related to an easier adsorption of anions on solid surfaces than on liquid surfaces. This might be the reason why the quasi-crystalline anhydrous layer cannot be formed. This interpretation is strongly supported by our results on the anodic dissolution of gallium in $LiClO_4$ solutions in ethanol: with solid Ga ($t = 25°C$) Ne = 1, whereas with liquid Ga ($t = 35°C$) Ne = 3[19].

Crystal Structures of the Elements of the Periodic Table and the Mechanisms of Electrolytic Hydrogen Evolution Reaction

A. K. Vijh (pp. 263-264, Vol. 118, No. 2)

S. Trasatti[20]: Some points of Vijh's reasoning seem to be questionable. First of all, Vijh divides the metals into two main classes according to whether or not the hydrogen evolution reaction (h.e.r.) proceeds with significant steady-state chemisorption of hydrogen. However, copper, silver, and gold are included by Vijh into the class of metals adsorbing hydrogen (Vijh's class II), and in fact, this does not seem to be the case.

This is what we are doing at the present time, using the following new approaches: (a) study of the influence of changes in the crystal structure of the dissolved sample, caused either by various thermal treatments or by replacement of polycrystals by very pure single crystals; (b) kinetic study by modern electrochemical methods.

(a) The first results on crystal structure effects show that the disintegration of the metal occurs at the level of the subgrains of the lattice. This might be due to a phenomenon which would start under the influence of the very small differences in the reticular energy which exist between the sites constituting the boundaries of dislocation of the crystal substructure and the unperturbed parts of this crystal.

(b) By improving the analysis of the polarization curves (which have been roughly described in our paper) using a current interruption method completed by electrochemical impedance measurements, we recently showed that the anodic potential necessary to create the layer in which Be^+ is stable was actually much lower than the one predicted by curve c' in Fig. 2. The current-potential curve, corrected for ohmic drop, shows a marked change in the slope at an anodic potential of 1V as measured relative to an Ag/Ag^+ (0.2M) reference electrode. This change corresponds to the border separating the potential range within which Ne equals unity, and the surface is bright, from the range within which Ne differs from unity, and the dissolution is heterogeneous. Consequently, the electric energy actually available at the anode within the field where the chunk effect is observed is not very high. Dissolution can occur rapidly only at the weakest parts of the metallic lattice constituted by the boundaries of dislocation. The surface of the anode is thus divided in two zones: the first one has a small area (emergence of the dislocation boundaries) where the current density is high; the second has a larger area but scarcely contributes to dissolution. The relative importance of the contributions of these zones depends on the potential. Faradaic impedance diagrams obtained at these low potentials provide support for this interpretation since they show, at very low frequencies, more than one time constant.

3.—The fact that beryllium cannot be plated out from the solutions we used is not in disagreement with the formation of stable Be^+ ions moving sufficiently far from the electrode to modify the faradaic yield of the dissolution. In fact, this formation needs a minimal anodic potential which is incompatible with the cathodic reaction $Be^+ + e \rightarrow Be\downarrow$ in the cases considered here.

4.—As for the results obtained with amalgams, we think that the canceling of the anomaly may be related to an easier adsorption of anions on solid surfaces than on liquid surfaces. This might be the reason why the quasi-crystalline anhydrous layer cannot be formed. This interpretation is strongly supported by our results on the anodic dissolution of gallium in $LiClO_4$ solutions in ethanol: with solid Ga ($t = 25°C$) Ne = 1, whereas with liquid Ga ($t = 35°C$) Ne = 3[19].

Crystal Structures of the Elements of the Periodic Table and the Mechanisms of Electrolytic Hydrogen Evolution Reaction

A. K. Vijh (pp. 263-264, Vol. 118, No. 2)

S. Trasatti[20]: Some points of Vijh's reasoning seem to be questionable. First of all, Vijh divides the metals into two main classes according to whether or not the hydrogen evolution reaction (h.e.r.) proceeds with significant steady-state chemisorption of hydrogen. However, copper, silver, and gold are included by Vijh into the class of metals adsorbing hydrogen (Vijh's class II), and in fact, this does not seem to be the case.

[19] See M. Garreau, *Métaux*, 544, 425 (1970).
[20] Laboratory of Electrochemistry, University of Milan, Milan, Italy.

It is well known[21] that Cu adsorbs hydrogen from the gas phase only if its purity is unsatisfactory. No adsorption of hydrogen from the gas phase is known to occur also on Ag and Au. Electrochemically, copper[22], silver[23], and gold[24] do not present detectable amounts of hydrogen adsorbed on the surface during the h.e.r. However, if the metals are not especially pure, or are subjected to anodic-cathodic treatments[22,24] (particularly Ag and Au) the exchange current for h.e.r. may become even two orders of magnitude higher, and atomic hydrogen usually appears on the metal surface. Thus, Cu, Ag, and Au belong, in fact, to the group of metals not adsorbing hydrogen (Vijh's class I).

Manganese has been included by Vijh into class I. This metal is atypical in many respects, but not in respect to liability to adsorb hydrogen. Mn chemisorbs hydrogen from the gas phase, though the experimental heat of the process seems to be comparatively low[21]. This fact probably makes the detection of steady-state coverage during h.e.r. very difficult. On the other hand, data on h.e.r. are very scanty for Mn, so that an accurate location of this metal may appear difficult; but other data[25] show that manganese chemisorbs gases like all other transition metals. Thus, I would suggest that Mn be included in class II, though additional evidence may be needed for that. At any rate, this point is not as determinant as that regarding Cu, Ag, and Au.

If we now examine the new situation, we can realize that the analysis of the mechanism of the h.e.r. on the basis of the crystalline structure of metals does not seem to be relevant. In fact, typical metals cannot be separated from atypical metals (in Vijh's sense). On the other hand, the crystalline structure is a consequence of the intimate electronic structure of elements. If we pay attention to the electronic structure, we see that the division of metals into two groups is now clear. Metals in class I are sp metals, while metals adsorbing hydrogen (class II) are transition metals. No exception to this rule does exist. I would like to stress again that the starting point for the understanding of the h.e.r. on metals is not the analysis of the crystalline structure, but rather the electronic theory of metals. It is surprising that Vijh does not make any specific reference to this point. He, for example, explains a high strength for the M-H bond with a high sublimation heat of the metal in question. This is an observation but not an explanation. In fact, a high sublimation heat is a consequence of a strong cohesion which in turn can be explained on the basis of the electronic theory[26].

The lack of any attention to the band theory of metals is apparently due somewhat to Vijh's complicated reasoning about the origin of the hydrogen chemisorption heat. I agree that the adsorption of atomic hydrogen can occur also on sp metals. In fact, from the band theory of metals[26] it is shown that chemisorption is possible whenever the solid possesses unfilled bands and when the atom to be adsorbed has electrons to shear, or *vice versa*; but for the extent of adsorption to be detectable, factors are needed which undoubtedly only transition metals possess. Thus, gold and copper adsorb CO but not hydrogen, though in any case the surface bond is weak[21] simply because in hydrogen adsorption there is a parallel path (atomic recombination) which does not exist in the adsorption of CO. At any rate, the heat of adsorption of CO on Cu and Au is 9 kcal/mole, while on transition metals it goes from 153 on Ti to 42 on Ni[21].

Using band-theory concepts, we can attempt to understand, at least qualitatively, the scale of M-H interaction strength. From the discussion above, the outstanding factor is presumably to be sought in the density of electronic states in the energy bands of the solid near the Fermi level. Almost all properties of transition metals are governed by this factor, *i.e.* conductivity, electronic specific heat, para- and ferromagnetism, *etc.* The average density of states is of the order of twenty times greater in the d-band than in the s-band[27]. In principle, every process involving exchange interaction of electrons should thus be easier on d than sp metals. This is a quantum-mechanical problem, and calculations by Horiuti and Toya[28] seem to corroborate this fact. Qualitatively, we can easily correlate the M-H energy to the density of states. In transition metals the density is high and the strength of the M-H bond is high. In Cu, Ag, and Au, the d-bands are completely filled while the s-band is half-filled. The density of states is here lower than in d-bands, but still rather high because the Fermi surface is presumably just below the limit of the Brillouin zone, in a position of maximum density of states for this type of band. For these metals the strength of the M-H bond is thus relatively high, but no chemisorption can occur from H_2 molecules because the energy of M-H is below 50 kcal/mole, half the energy of dissociation of hydrogen molecules. Some trace of chemisorbed hydrogen can presumably appear on these metals at very high current density during h.e.r. due to kinetic reasons, but this fact is of secondary importance and does not alter the terms of the problem. It is readily realized that these metals can be very sensitive to impurities which can introduce holes in the d-bands so modifying deeply the electronic properties of the solid. In fact, the top of the d-band is not too far from the Fermi level.

With one more electron added to the s-band we go to Zn, Cd, and Hg. In these metals the s-bands are completely filled and they are metallic conductors only because of an overlap of s and p-bands. However, the Fermi level is here presumably close to both the top of the s-band and the bottom of the p-band. Thus, the density of states is in this case very low, and the M-H bond is expected to be very weak, as is in fact the case. If we go on to fill the p-band, we expect the strength of the M-H bond to increase with increasing number of electrons until the band is half filled. However, in this case it is difficult to apply the simple concepts of the band theory of metals for p-elements are not typical metals probably because of the strong orientation of their atomic orbitals. Calculated adsorption heats strongly differ from experimental values of interaction energy but, at any rate, the strength of the M-H bond appears to increase in the series Tl < Pb < Bi, and In < Sn < Sb[22].

Many simple correlations between electronic and electrochemical properties[29] indicate that the scale of general chemical reactivity is the same as in electrochemistry and catalysis, so that in any case the electronic structure is the outstanding factor which determines the behavior of a solid. For the h.e.r. the present author has recently found[29] that all metals fall closely on a same straight line in a log i_o *vs.* work function plot, provided the i_o, exchange currents for sp metals be that relative to the positively charged surface. The i_o values for a negatively charged surface fall on another straight line parallel to the former. Since the M-H strength changes almost linearly with work function, this indicates that the ultimate effect is a "volcano" curve, for the dependence of log i_o on the heat of adsorption of hydrogen as predicted by Parsons[30] and found by Krishtalik[22]. It seems to me that the picture for the h.e.r. would be clearly depicted by this result. A higher strength of the M-H bond de-

creases the activation energy for discharge and increases that for the removal of atomic hydrogen. This fact is readily understood if use is made of the potential energy curves[31,32]. Since the M-H energy depends on the electronic structure, this ultimately governs the mechanism of h.e.r. The crystalline structure, as such, does not appear to have a primary effect. I would like to emphasize the fact that volcano-shaped curves have been obtained also in the field of catalysis[33], and the rationale behind them is well known as Sabatier's principle[34].

It is of interest to note that the writer has also found[29] that different relationships between potential of zero charge and work function exist for sp and transition metals, and the difference is to be sought in a restricted possibility of rotation of water on the latter due to chemisorption phenomena. The electronic structure is again the outstanding factor. Close relationships can be also found[29] between electronegativity in Pauling's scale and work function, so that if proper attention is paid to the electronic structure of metals, the picture of their electrochemical properties is less obscure than would appear at first sight, though much still needs to be known. At any rate, it must be stressed that progress in electrochemistry is at this point possible only if the electronic structure of the electrode material is correctly and relevantly taken into account.

A. K. Vijh: We appreciate Dr. Trasatti's keen interest in our paper. The various points he raises are, of course, very pertinent to the fundamental understanding of the mechanisms of the hydrogen evolution reaction (h.e.r.) on metals, a subject which constitutes the very foundations of modern electrode kinetic theory and electrocatalysis, in addition to its involvement in all sorts of applied electrochemical problems. Professor Trasatti has presented a rather detailed dissection of our paper and raised many points which need much further discussion since the arguments formulated in his analysis are not entirely sustained by a further study of the issues he touches upon. For the sake of a systematic treatment of the various matters contained in his critique, it is best to classify them in some logical sequence first. Towards this goal, it is perhaps convenient to classify his points into two broad classes, namely, (A), and (B).

(A) Facts, Pseudo-Facts, Experimental Observations—Direct or Deduced

This category mainly concerns deduced or direct experimental observations with regard to the mechanisms of h.e.r. on Cu, Ag, Au, and Mn and the related vital problem of steady-state coverage by adsorbed hydrogen on these metals during the h.e.r. The three of these metals, namely, Cu, Ag, and Au are no doubt borderline cases as regards the strength of the M-H binding, as determined (or estimated) from the gas phase experimental data. The critically evaluated estimates of this M-H interaction energy, as given by Ehrlich[35] are: Cu-H, 56 kcal/mole^{-1}; Ag, 53 kcal/mole^{-1}; Au-H, ~50 kcal/mole^{-1}. It is clear, therefore, that chemisorption of hydrogen from the gas phase on these metals, at least on Cu and Ag, can give rise to a reckonable steady-state coverage although these metals can by no means be regarded as good adsorbents of hydrogen from the gas phase. However, during the electrochemical evolution of hydrogen, a crucial factor is the presence of overpotential which can give rise to a situation comparable to the presence of astronomically high gas pressures with the result that direct application of the gas phase adsorption data (obtained under ordinary pressures) is misleading. For example, as pointed out by Kita[36] in response to objections raised by Breiter[37] on lines similar to those contained in Trasatti's criticism, a cathodic overpotential of 0.4V corresponds to a very high pressure of *ca.* 10^{15} mm Hg. Under such conditions of applied overvoltage (which are equivalent to enormously high pressures), borderline cases like Cu, Ag, Au, *etc.*, are undoubtedly bound to be covered significantly by adsorbed hydrogen—hence their inclusion in our class II is justified. That moderate values of overvoltage can indeed be equivalent to enormously high gas pressures, with the resultant formation of surface phases on electrode surfaces which cannot be ordinarily formed or predicted thermodynamically, has been plausibly argued in detail by Vermilyea[38] in connection with the oxygen evolution reaction. Other previous calculations on these lines but for the case of hydrogen evolution reaction have been given by Van Rysselberghe[39].

As regards the case of Mn, Ehrlich claims, in agreement with Trasatti, that it chemisorbs molecular hydrogen from the gas phase. Some recent preliminary electrochemical work in our laboratory involving transient studies such as potentiodynamic profiles, open circuit decays and charging curves, *etc.*, gives no evidence, however, to support steady-state coverage on Mn during the h.e.r. This electrochemical evidence, yet to be corroborated, by itself would not appear to be sufficient, however, to justify inclusion of Mn along with "soft" metals in our class I. This is because we have concluded the presence of gold in class II (*i.e.* with the transition metals and with radical-ion or atomic recombination as the mechanism), despite the fact that Schmid's[40] work indicates an absence of significant surface coverage by adsorbed hydrogen on gold during h.e.r. It is fair to add that no exact measurements, on the surface coverage on gold during h.e.r., covering an extended potential range, exist, as has been pointed out by Kuhn and Byrne[41]. Even Schmid's work, which covered only the potential range,—0.3 to 0.4V (h.e.) indicated *ca.* 8% coverage (20 μC cm^{-2}). Furthermore, Will and Knorr[42] reported 3% coverage at the reversible potential. One is perhaps safe in concluding that at high cathodic potentials, gold is covered appreciably by adsorbed hydrogen.

The foregoing evidence and comments show that Trasatti's criticism was derived, unfortunately, from the convenient choice of data and from faulty reasoning, especially, with regard to the effect of overpotential. It is conceded, however, that the case of Mn, Cu, Ag, and Au is not completely clear-cut, as far as direct experimental evidence is concerned, with regard to coverage by chemisorbed hydrogen during steady-state h.e.r.

There is a wide spectrum of indirect evidence, however, which is based on the mechanistic analysis of a large variety of experimentally obtained electrochemical criteria diagnostic of electrode reaction mechanisms, which tends to support our original classification, *i.e.*, Mn with the soft metals (class I) and sustaining h.e.r. by an initial discharge mechanism; Au, Cu, and Ag with the transition metals (class II) on which either a radical-ion or an atomic recombination mechanism is involved. This deduced evidence on these metals is summarized as follows:

1. Copper—A complete consideration of the available experimental evidence has led Matthews[43] and Kita[36] to conclude that the h.e.r. proceeds on copper with a radical-ion mechanism. The electrocatalytic plots reported by the workers[36,43] place copper with the medium overpotential metals. A radical-ion

mechanism means, of course, a significant steady-state coverage by adsorbed hydrogen during the h.e.r. Recent work of Bockris and Srinivasan[44] involving H/D and H/T isotope effects supports our contentions conclusively.

Dr. Trasatti quotes Krishtalik[45] on this point in order to deduce mechanism for copper. Well, this is somewhat dangerous because Krishtalik failed to quote and discuss several key papers on the subject in his review, as we have pointed out elsewhere[46]. If one is trying to deduce mechanism on the basis of all the significant and relevant information, Krishtalik's review (which is outstanding in several other aspects) is not very helpful since the coverage of literature and viewpoints is quite incomplete in that review.

2. *Gold*—The most recent work[41] and the critical analysis of the previous literature therein indicates that h.e.r. proceeds on gold with atomic recombination as the rate-determining step (r.d.s.) at low overpotentials and radical-ion as the r.d.s. at high overpotentials. Thus significant steady-state coverage by adsorbed hydrogen during the h.e.r. must again be inevitably deduced, although it must be conceded, in all fairness to the viewpoint of Professor Trasatti, that direct evidence on the chemisorption of hydrogen on Au during the h.e.r. was not presented. Various electrocatalytic plots[36,43] again place gold with medium overpotential metals thus indicating a radical-ion mechanism.

3. *Silver*—The electrocatalytic plots of Matthews[43] and Kita[36], based on the review of a lot of previous work, especially of Bockris, Conway, Delahay, Horiuti, and their co-workers, assign a radical-ion mechanism to silver indicating thereby that significant steady-state coverage by chemisorbed hydrogen during steady-state h.e.r. on Ag is most likely. Also, clearly detectable amounts of hydrogen coverage, although far from appreciable, have been reported in several electrochemical studies[45]. This metal would thus again be a borderline and a vexing case.

4. *Manganese*—In the electrocatalytic plots of Matthews[43], Mn is grouped with the soft metals which would be consistent with the placement of this metal in our class I. Some preliminary work, yet to be corroborated, in our laboratory[47] indicates that the h.e.r. proceeds on Mn with initial discharge as the r.d.s. This would again indicate that h.e.r. occurs on this metal without a significant coverage by chemisorbed hydrogen in the steady state, as deduced previously[48] in the paper under discussion.

We have made no attempt to present all the available experimental evidence on Mn, Ag, Au, and Cu in support of our opinions expressed here since that would make the present note unnecessarily lengthy. We have quoted, however, some of the key references on the subject in which all the relevant information is cited and discussed.

One may therefore conclude that the original placement[48] of Cu, Ag, and Au in our class II and of Mn in our class I does not merit a revision at this time. It is conceded, however, that these cases are not completely clear-cut. It is further stressed that our classification of atypical (class I) and typical (class II) metals, in addition to involving some tentative aspects as regards the actual placement of some metals, is also only empirical in nature at present.

(B) Theoretical Interpretations

The second aspect of Dr. Trasatti's criticism involves several matters of a theoretical nature which pertain to the following broad points:

1. *Electronic Effects in Chemisorption*—Dr. Trasatti states that we have not considered electronic effects in chemisorption. In fact, a major point of our paper[48] was to stress, after Ehrlich's analysis[35], that the preeminent position of d-bands in chemisorption originally suggested by Dowden[49], and Dilke, Maxted, and Eley[50] and uncritically accepted by many workers in the field of heterogeneous catalysis[51] and electrocatalysis[52], is not always justified. The main point of these workers[49-59] was that since transition metals readily adsorb gases in general whereas sp metals do not, the chemisorption requires specific interactions involving holes in the d-band. This main thesis is easily demolished when one considers that this viewpoint was based on experimental evidence on the adsorption of molecular gases and that we now know that sp metals do not readily adsorb H_2 from the gas phase because of thermodynamic reasons: the chemical potential of hydrogen atoms bound as molecules in the gas phase is less than that of atoms bound to the solid surface of a sp metal. Chemisorption directly from the atomic gas can occur on nontransition metals as pointed out previously[35, 48] showing thereby that holes in d-bands are not necessarily needed for atoms to be chemisorbed on metals, for which one has only to create conditions in which the metals are not required to break the H—H bond in the H_2.

As regards the second point of Professor Trasatti in this context, one needs to know whether there is any correlation between % d-band character of metals (*i.e.*, in those metals, of course, which show any d-band character at all because of sp hybridization) and the experimentally evaluated best possible estimates of M—H binding energy. As Ehrlich[35] has indicated, there is no particularly strong dependence of M—H interaction energy on % d-band character. The detailed results and related calculations on this matter in relation to the mechanism of the h.e.r. cannot be presented here since they constitute the subject of a thesis[53] and a publication[47] which will not be ready for submission for some time yet. In general, our results support Ehrlich's viewpoint, as was also mentioned in a previous publication.

2. *Electrode Processes in Relation to Band Theory of Solids*—As has been pointed out by Boddy[54], a detailed analysis of electrode reaction experimental data on metals in terms of band theory of solids, as is frequently done for the case of electrode processes on semiconductors and insulators, does not appear to be possible because of two fundamental reasons. As a result of rapid interband transitions in metals, features characteristic of an electrode reaction involving exchange of charge carriers with only one of the bands will not be observed on a given metal. Secondly, there is always a fairly high density of states near the Fermi level in metals so that the rate of the electrode reaction can never be limited by the sluggish or insufficient availability of charge carriers from the solid side of the interface, as is observed in case of semiconductors where saturation effects can be observed. Although detailed, quantitative discussion of electrode processes in terms of band theory of solids cannot be carried out for the aforementioned reasons, some interesting qualitative effects can, however, be pointed out as has been done by Dr. Trasatti. He is right, of course, in stating that in general, a high density of states, as in transition metals will herald higher rates of (or easier) exchange of charge carriers in all processes including chemisorption and electrode reactions. This is an obvious point

and is frequently discussed in connection with exchange of charge carriers across solid surfaces in general. For example, this is the reason why exchange current densities, for a given electrode reaction, are generally higher on metals than on semiconductors (the case of injection-type electrode reactions on nonmetallic surfaces, which can attain exchange current densities comparable to those of metals under certain suitable conditions are excluded from this argument) or metals covered by semiconducting films, *e.g.* oxides. This point has been discussed by Boddy and will be further elaborated upon in our forthcoming book[55]. The aspect of these matters which is relevant here is whether such generalizations are applicable to the particular case at hand, *i.e.* the h.e.r. To explore this matter further, we note that in terms of Gerischer's formulation[56, 57] of Gurney's quantum mechanical treatment of electrode reactions, the rate of a cathodic reaction may be written as[53-58]

$$i^- = e \int_{-\infty}^{+\infty} \nu^- (E) \cdot D_{el} (E) \cdot f (E - E_{F,el}) \cdot D_{\text{redox}} f (E_{F\text{redox}} - E) dE \quad [1]$$

where i^- is the cathodic rate (*i.e.* the current) of a reduction of, *e.g.* a redox-type reaction; e is the electronic charge; D_{el} and D_{redox} are the density of state functions for the electrode and the electrolyte, respectively; and, $f(E - E_{F,el})$ and $f(E_{F\text{redox}} - E)$ are the Fermi distribution functions for the electrode and the electrolyte, respectively; the term $\nu^-(E)$ is the proportionality factor which contains two terms: the frequency with which electrons arrive at the electrode/solution interface and the probability of tunneling through the potential barrier at the interface. Now when the metal electrode is covered by adsorbed intermediates, as during the h.e.r. on class II metals[48], D_{el} assumes smaller magnitudes and the magnitude of this diminution cannot be readily evaluated. The presence of chemisorbed films can also lead to a decrease in the magnitude of $\nu^-(E)$ again in a manner which is not readily evaluated. It is clear, therefore, that a simple qualitative picture in terms of density of states, as mentioned by Dr. Trasatti, is not very helpful for the case of bonding reactions such as the h.e.r. Even for the nonbonding electrode reactions, problems associated with the solvent adsorption can complicate the picture. That this approach in terms of density of states in metals does not lead one very far is also emphasized by the fact that a calculation of exchange current densities for the h.e.r. for various metals, from a consideration of basic parameters such as in Eq. [1], has not been attempted, not to our knowledge in any case since we have never encountered a table of exchange current densities thus calculated. It is clear therefore that Professor Trasatti's repeated reference to the quantum mechanical treatment in terms of band theory of metals as being preferable for the basic interpretations of the h.e.r., does not help the reader unless he can come forward with a table of exchange current densities calculated from an equation such as Eq. [1].

In this context, it is vital to point out that the approximate quantum mechanical calculations for the estimation of M—H binding energies, as have been done by Eyring *et al.*[59], give results which are hopelessly out of agreement with the experimental values. For a further elaboration of this matter, the reader is referred to Bond[60]. It appears to be a waste of time to attempt exact quantum mechanical calculations of M—H interaction energies since, as has been concluded by Ehrlich[61], such a calculation "from first principles is out of the question."

3. Analogies Between Chemical Heterogeneous Catalysis and Electrocatalysis—Such analogies, which Dr. Trasatti seems to emphasize rather strongly have been well recognized for several years and no doubt are helpful aids to interpretations. If one must refer to these analogies, however, one must also immediately point out the dangers and limitations involved in the loose and unqualified use of these analogies. Some of the serious qualifications which must accompany such analogies and, again, are well known are briefly as follows: direct transfer of information from chemical catalysis to electrocatalysis must take into account an additional factor, namely, the stability of the electrode surface under conditions of electrochemical charge transfer[62]; high fields correspond to extremely high pressures of gases—hence any discussion of chemisorption must be considered in this context as pointed out earlier; what is the relevance of "clean" surface in the gas phase to electrode surface in solution?

4. Relationship Between P.Z.C. and Work Functions of Metals—The correlation given by Professor Trasatti between potentials of zero charge of metals and their work functions which suggests different behavior for sp and d-metals and which he attributes to different orientation of the water molecule on these two types of metals, does not appear to be consistent with previous work of Frumkin, Antropov, Parsons and Bockris. Bockris and Argarde[64] have derived a linear correlation between work functions and p.z.c. for all metals[62, 65]. Previously a similar relationship was noted by Parsons[66] following earlier suggestion by Frumkin[67] that the orientation of water molecules is similar on a number of metals. Detailed discussions of the qualitative aspects of these matters have been recently given by Bockris and Reddy[68]. Although we are not aware of the current unpublished opinions of the various leading workers on this subject, it does appear that Dr. Trasatti's views are not consistent with the published work of the most authoritative investigators in this area of electrochemistry.

It may be added parenthetically that this particular point raised by Professor Trasatti is not really central to the contents of our paper under discussion here. As regards his plea in his closing remarks that more attention should be devoted to the role of properties of the solid in electrode reactions, we are in complete agreement with him. In fact the point made by him is the main theme and thesis of our forthcoming publication[55].

In closing, it may be stated that the points raised by Dr. Trasatti and discussed here need much further investigation and discussion in order to resolve some important issues on which only tentative conclusions can be made at present. There is no doubt about one question, however: the further understanding of electrode processes must involve application of solid-state science in the interpretation of electrochemical reactions. This has been frequently stressed by Bockris[62, 68] and others[55].

Electrochemical Behavior of the Aluminum Electrode in Molten Salt Electrolytes

B. S. Del Duca
(pp. 405-411, Vol. 118, No. 3)

R. Piontelli and U. Ducati[69]: The suitability of the solid Al electrodes as "sacrificial anodes" in the molten halides appeared already evident from previous work[70]. The practical want of "electrode" contributions[71] to the measurable overvoltages on carefully prepared electrodes was also stated[72].

A confirmation of the last result is given also by Trémillon and Letisse[73]; in molten $NaAlCl_4$ (even mixed with NaCl or $AlCl_3$) the currents at rotating Al microelectrodes are controlled only by the diffusion of the reacting species in the bath.

Del Duca denounces, on the contrary, considerable contributions ascribed to the surface diffusion of adatoms and to the charge transfer[74], and seems to underestimate the importance of the concentration-polarization effects[75] and the difficulty in eliminating them radically.

As a matter of fact, in the molten salt electrochemistry the concentration-polarization is often responsible for a much more significant contribution to the measurable overvoltages than what is usually granted. It is important particularly in those melts, such as the Al halides, in which the source of the ions exchanged with the electrodes are complexes[76].

These effects are quite analogous for solid (active) or liquid electrodes and their dependence laws *vs.* temperature, convection, and other influences are peculiar[77].

Considering now the experimental technique followed by Del Duca, it does not appear suitable for improving the knowledge actually existing in this field. The relevant points upholding this opinion are the following:

(a.) The surface preparation system is quite inadequate. Under these conditions the unavoidable permanence of oxide layers on the electrode surface[78], also when porous and by consequence not involving passivity, leads to substantial increments of the concentration-polarization.

Moreover this occurs much sooner and it becomes important at a much lower apparent c.d., simulating an electrode overvoltage and an apparent electrode capacitance.

(b.) Under these conditions the stirring system adopted by Del Duca, and which can be considered just a palliative even if the electrode surfaces are active, becomes inefficient. Therefore the potentiostatic currents are insensitive with respect to this kind of stirring.

The above conclusions are upheld also by the quite exceptional rise-times to the steady condition, observed by Del Duca in the so called "transients." They could also explain the data collected in the Table III, whose interpretation, given by Del Duca, appears to be hardly acceptable when the influence of temperature, bath composition, and electrode polarity on the so-called exchange current density is considered.

(c.) The hanging electrode arrangement does not grant the required distribution uniformity of the c.d. on the electrode surface, in spite of the spiral shape of the counterelectrode. This distribution varies, moreover, according to the values of the circulating current intensity and also to the time.

(d.) To fully exploit the galvanostatic current-pulse technique, also the overvoltage *vs.* the time data, after the current break, constitutes an essential source of information and control, apparently ignored in this research.

(e.) The utilization of the solid Al as the reference electrode, although in practice it is admissible, would appear rather questionable if accepting the conclusions of the discussed research.

In conclusion, more recent or modern systems do not necessarily mean more reliable systems and we suspect the description of the Al electrode behavior in molten halides, given by previous works, is much more convincing than the one arising from the paper under discussion here.

Engineering Applications of Current and Potential Distributions in Disk Electrode Systems

L. Nanis and W. Kesselman
(pp. 454-461, Vol. 118, No. 3)

J. Newman[79]: Nanis and Kesselman have recently raised the question of the definition of the resistance in electrode configurations where the primary potential distribution does not prevail and where, instead, surface and concentration overpotentials must exist. They have given a valid justification for defining the resistance as an average potential over the surface of the disk, divided by the total current to the disk.

As Wagner[80] has stated, the term "electrical resistance" is confusing in situations where the potential varies along the boundary of the electrolytic solution. The potential of the electrode is uniform. The ohmic potential drop, the surface overpotential, and the concentration overpotential vary with position on the electrode in such a way that their sum is uniform. There should be no ambiguity if these variations are described in detail.

In such a situation, Newman[81] emphasized the ohmic potential drop and the current density to the center of a disk electrode. Thus, the current-potential curve was calculated by adding the ohmic potential drop, and concentration and surface overpotentials at this point. The same over-all curve would be obtained by performing the addition at the edge of the disk or at any point between the center and the edge. Emphasis was placed on the center of the disk in part because the concentration and surface overpotentials at that point are easily computed from the local current density.

This ohmic potential drop is not, of course, directly comparable to the average resistance. In order to use the average resistance, one would first need to know at what point on the electrode the ohmic potential drop is given by the average resistance. At this point, he would then need to know the local current density and the local surface concentration in order to calculate the concentration and surface overpotentials.

Newman[82] has used a simple equivalent circuit to describe the impedance of a disk electrode system in

[79] Inorganic Materials Research Division, Lawrence Radiation Laboratory and the Department of Chemical Engineering, University of California, Berkeley, California.

[80] C. Wagner, *This Journal*, 99, 1-12 (1952). See especially p. 8.

[81] J. Newman, *This Journal*, 113, 1235-1241 (1966).

[82] J. Newman, *This Journal*, 117, 198-203 (1970).

frequency dispersion in capacity measurements. The low-frequency limit, when the interfacial impedance is purely capacitive, coincides with Nanis and Kesselman's result for uniform current density, $4r_0\kappa R_{eff} = 1.08076$. When faradaic reactions are involved, the value of the effective resistance in the equivalent circuit is different because it includes the impedance of the interface. Thus, the entire electrode system is used to define the effective impedance in this case.

In a later paper[83], Newman points out that, for the secondary distribution on a disk electrode, one can estimate the ohmic potential drop from the total current and the resistance for the primary potential distribution. The surface overpotential obtained by subtracting this ohmic potential from the electrode potential can be associated, with little error, with the average current density.

L. Nanis and W. Kesselman: Newman's comments are helpful in clearing the way for the resolution of electrochemical concepts derived from field theory where confusion has unfortunately arisen. Rather than further compound already prevailing misconceptions, some fundamental concepts require restatement. The Laplace equation

$$\nabla^2\phi = 0 \qquad [1]$$

is more properly stated as (for one dimension)

$$\frac{\partial}{\partial x}\left(\kappa\frac{\partial\phi}{\partial x}\right) = 0 \qquad [2]$$

which emphasizes that the smoothly varying functions which satisfy Eq. [1] possess no discontinuities. In particular, Eq. [1] is intended to apply within a domain. It is customary to assume that conductivity, κ, is independent of position, thus considerably simplifying the mathematical treatment. In view of the confusion generated by the (proper) omission of κ in going from Eq. [2] to the more specialized version in Eq. [1], it is worth re-emphasizing the fact that Eq. [1] applies only within a domain and up to its boundaries. Thus, it is correct to speak of an average potential over the layer of electrolyte immediately adjacent to the metal electrode. Once Eq. [1] is solved, the current density may be determined for any cross-section but the layer next to the metal electrode is particularly convenient for evaluating the total current.

The considerations by Wagner[80] of the definition of electrolyte resistance are at best incomplete. To be precise, he indicated that definition of resistance required terminal faces to have uniform electrical potential, since otherwise the concept of voltage across a conductor (electrolyte) is "meaningless." From this statement and subsequent discussion, it is clear that Wagner was considering a boundary condition outside the domain (electrolyte). As Newman correctly indicates above, the potential may vary along the boundary of the electrolyte while the electrode is at uniform potential. As more attention has been devoted to field problems of electrochemical interest, the analytic difficulties have become more apparent, particularly since so-called "boundary conditions of the third kind" of an unusual nature are involved. In retrospect, however, it seems reasonable that a finite cell resistance associated with a constant potential boundary must remain finite when constant current density conditions are achieved. The concept of domain of applicability is stressed in our paper (p. 456) and the Appendix which deals with the resistance of the non-isopotential disk.

In view of the complexity of analytic methods for the solution of field problems, machine computation methods have proved useful. The relative magnitude of ohmic drop compared with overpotential is a concept basic to electrochemical engineering. When combined as a comparative ratio, the importance of each type of potential drop in determining cell current is readily estimated. This ratio or dimensionless group is the familiar "throwing-power" parameter derived from electroplating methods. For a disk electrode of radius a, the ohmic resistance associated with primary current distribution is given in our Eq. [27] as

$$R_{ohm} = \frac{1}{4\kappa a}$$

Considered as a circuit element, the possibly non-ohmic character of the electrode kinetics at the electrode-electrolyte interface may be represented by the variation of overpotential with respect to current density, $|\partial\eta/\partial J|$. The differential notation is, in fact, a more general definition of resistance. For the area of the disk, a virtual interfacial resistance, R_{int}, may be determined in ohm units as $|\partial\eta/\partial J|\,\frac{1}{\pi a^2}$. The ratio of interface resistance

$$\frac{R_{int}}{R_{ohm}} = \left|\frac{\partial\eta}{\partial J}\right|\frac{4\kappa a}{\pi a^2} = \frac{\kappa}{a}\left|\frac{\partial\eta}{\partial J}\right|\frac{4}{\pi} \qquad [3]$$

to electrolyte ohmic resistance contains the familiar terms with a multiplicative constant close to unity, *i.e.* $4/\pi$. In balancing the various potential drops in point-by-point computation, the relative magnitude of each type may be anticipated by the magnitude of the group in Eq. [3]. (The shift to higher resistance for constant current density conditions may be ignored for the purposes of order of magnitude estimation.) In order to prevent further misunderstanding, the following considerations are in order. When secondary current distribution prevails, the electrode is considered to have a uniform current density. However, there is, likewise, a uniform overpotential as a boundary condition. This condition (actually external to the electrolyte domain) closely resembles the constant potential case. At this point, the true meaning of the comparison of ohmic effects in Eq. [3] is of importance. The sum of the individual potential terms is indeed constant, as indicated above by Newman, but as nearly constant current density conditions are approached, the slight differences in the nearly similar but large overpotentials represents the radial variation of the ohmic potential term. This variation is quite mild and is given in the paper as Eq. [30a] and is shown in Fig. 1 for $0 < r/a < 1$. The entire deviation of local ohmic potential from the average value is totally overshadowed by the overpotential associated with the constant J condition. In going from primary distribution, with its theoretical infinity of J near the edge of the disk, to uniform J, the ohmic drop may be considered to be rearranged slightly as a function of position. Our paper has treated these extreme limiting cases and has bounded the variation which occurs. The combination of mixed features of true electrode resistance and local ohmic potential drop (*i.e.* center of disk) can serve no useful purpose since they are not directly comparable, as pointed out above. When used in conjunction with the recommendation of our paper, *i.e.* large remote reversible counterelectrode rather than remote probe, the average resistance is directly measurable and does not require knowledge of local parameters. The association of the notion of resistance with a point is unfortunate. Clearly from Eq. [27] or [34], the resistance becomes infinite as radius decreases. Resistance has meaning only for a finite size current aperture in the conducting domain. One does not need to know the point on the electrode where the drop matches the average, nor is the local concentration and J neces-

[83] J. Newman, *This Journal*, 117, 507-508 (1970).

sary. One simply no longer needs the temporary concept of local ohmic potential drop. One simply measures the resistance as a matter of course, *i.e.* as the rapid drop (oscilloscope) of the voltage-time trace following current interruption.

The agreement with our result found by Newman[82] in his impedance calculations is gratifying. The low-frequency limit for so-called capacitive impedance corresponds to a large value for the group in Eq. [3]. Since the charging of the double layer is just the establishment of overpotential, the interface potential drop predominates.

In his subsequent paper, Newman[83] has approximated the total disk resistance by the lower resistance limit for primary current density. However, Eq. [5] of that paper may equally well be represented within the limits bounded by our Eq. [27] and the upper limit in Eq. [34]. The maximum error caused by following Newman's procedure is to underestimate the true ohmic resistance drop by 8%. Of course, the error, while possibly small, is at variance with statements in Newman's approach which maintain that, independent of the J distribution prevailing before interruption, the ohmic drop measured by interruption corresponds to the primary distribution. In terms of experimental practice, since overpotential requires some finite time to be established, the ohmic drop at the switching on of constant current should be given by the primary current distribution value. As the overpotential builds, the same constant current exists in the circuit, but the J distribution adjusts to some steady value between the primary limit and the uniform secondary distribution limit. The finally large overpotential is greater than the ohmic drop, in accord with Eq. [3]. However, the rearrangement of the field affects the average domain potential in the electrode plane and the corresponding resistance increases. Thus, the interruption IR drop may be as much as 8% greater than the initial switch-on IR drop. The reshaping of the field, particularly close to the electrode, drastically affects the local current density, which varies as $\infty > \frac{J}{J_{avg}} > 1$ at the edge $r = a$ and as $\frac{1}{2} < \frac{J}{J_{avg}} < 1$ at the center, $r = 0$. Finally, it should be mentioned that there is an aspect of practical importance which deserves attention. The concept of "transient current distribution" may be introduced for electrode systems where nonsteady-state boundary conditions prevail. For a simple constant current circuit, at switch-on, current is used principally for double layer charging, with redistribution to the faradaic process as time elapses. The important point is that current distribution computed on the basis of the steady-state overpotential-current relation is inappropriate at the start of the current passage. It is thus implicit that all systems respond initially with a primary current distribution, although the distribution may smooth to be more uniform in a matter of, *e.g.* milliseconds. The importance of this concept to areas such as pulse charging of batteries and reverse cycle plating is clear but requires both further theoretical and experimental effort.

The Thermodynamics and Electrode Kinetic Behavior of Nickel in Acid Solution in the Temperature Range 25° to 300°C

R. L. Cowan and R. W. Staehle

(pp. 557-568, Vol. 118, No. 4)

D. Lewis[84]: Cowan and Staehle, in the paper under discussion, have referred to some of my early work on the thermodynamics of corrosion processes in aqueous systems at elevated temperatures, and have attributed to me some very inaccurate data on the hydrogen-silver chloride, silver cell. However, nowhere in the report they cite is this cell mentioned, let alone any calculated or experimental values given for its emf; and I have not obtained the results they give in their Table I.

Table I. Errors in estimates of the equilibrium constants of typical reactions due to neglecting heat capacity terms

Number of "uncompensated" ions	Reaction	$\log {}_T k$ Estimate 1	$\log {}_T k$ Estimate 2
0	$\frac{1}{2}O_2(g) + H_2(g) = H_2O(l)$	0.17	0.0
0	$NH_4^+ = H^+ + NH_3(aq)$	0.34	0.0
1	$AgCl(s) + e^- = Ag(s) + Cl^-$	1.50	3.21
2	$H_2O = H^+ + OH^-$	2.40	1.48

In later work, described in a report[85] communicated to Staehle shortly after its publication, I have taken results for the reduction of silver chloride (and for some other reactions) to illustrate observations on methods that might be used for estimating equilibrium constants (or electrical parameters) for reactions in aqueous systems up to 374°C. It may be useful to summarize these observations here.

Figure 1 shows values for the equilibrium constant of the reaction

$$AgCl(s) + \frac{1}{2}H_2(g) \rightleftharpoons Ag(s) + H^+ + Cl^- \quad (Ag\ 1)$$

calculated using: (a) the Van't Hoff isobar, *i.e.* neglecting all heat capacities; (b) the assumption that the heat capacities of the aqueous ions are negligible; (c) estimates of the heat capacities of the aqueous ions obtained on the basis of the correspondence relations discovered by Criss and Cobble[86,87]. It is seen that the somewhat modified form of the correspondence relations used in my work leads to results that are in excellent agreement with the corresponding values obtained from the experimental study reported

[85] D. Lewis, Studies of Redox Equilibria at Elevated Temperatures. 1. The Estimation of Equilibrium Constants and Standard Potentials for Aqueous Systems up to 374°C, AB Atomenergi, Studsvik, Sweden. AE-377 (1969).

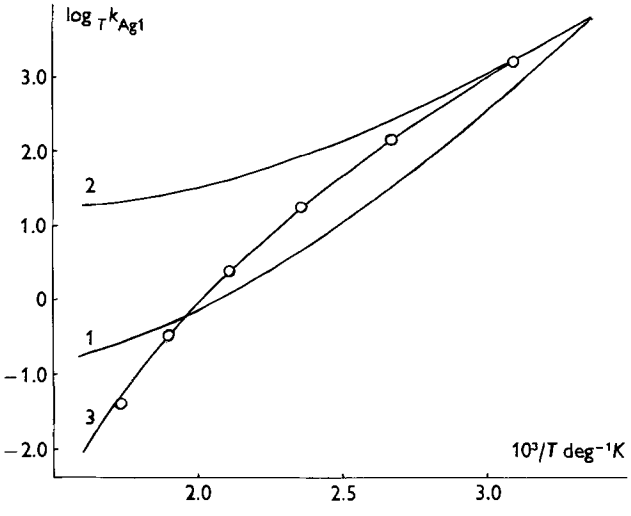

Fig. 1. The variation with temperature of the equilibrium constant for the electrochemical reduction of silver chloride. Values obtained from the experimental study by Greeley *et al.*[88] are indicated by open circles.

by Greeley, Smith, Stoughton, and Lietzke[88]. On the other hand, at the highest temperatures assumption (b) leads to very inaccurate results, like those calculated by Cowan and Staehle, while the Van't Hoff isobar leads to estimates that would be more useful.

Although several other approaches to the problem[89,90] have been shown to give good results in specific cases, I, like many others working in the field, am convinced that at present the Criss and Cobble correspondence relations lead to the most widely useful method for estimating the equilibrium constants for reactions in aqueous systems at elevated temperatures. However, in some cases it may still not be possible to estimate the ionic contributions to the heat capacity of reaction and it is useful to consider the errors that may arise from neglecting them.

Table I of this discussion gives some examples of the errors (log units) that can be expected in estimates of the equilibrium constants for some typical reactions at 350°C, obtained in two ways. First, Estimate 1, $\log_T k$ has been calculated using the Van't Hoff isobar. Secondly, Estimate 2, $\log_T k$ has been calculated with only the heat capacities of ionic constituents set equal to zero. The results obtained on the basis of the Criss and Cobble relations have been taken to be the correct values of the constants and the errors shown in the table are the differences from these results.

Generally, the error introduced by neglecting the heat capacities of ions can be expected to increase with the number of "uncompensated" ions, *i.e.* when there are more cations or anions among the reactants than among the products, or conversely. The error will, of course, be considerable when an electrode (half-cell) reaction is being considered, as illustrated by the results for the silver chloride, silver electrode: thermodynamic parameters for the electron being assimilated into those for the hydrogen-ion. However, when data for conjugate electrode reactions are combined in the estimation of equilibrium constants for complete cell reactions there will be some cancellation of errors.

The errors due to neglecting the heat capacities of cations are opposite in sign to those due to anions and so there will also be some cancellation of errors in the case of reactions like the acid-base dissociation of water. However, in many such cases the resultant may still be large because the errors due to cations may differ considerably in magnitude from those due to anions. Very large errors can be expected when highly charged cations or sulfate-, carbonate- or phosphate-ions are involved.

Finally, without in any way detracting from the work of Townsend[91], one may note that Cowan and Staehle are also mistaken in attributing to him priority in the adoption of the Criss and Cobble method in connection with potential-pH diagrams. In fact, Garrels and Christ[92] drew attention to the method in this connection and Robins and his co-workers were the first to publish equilibrium diagrams based on it[93,94], although there have probably long been many who have independently used it in similar work[95,96].

R. L. Cowan and R. W. Staehle: D. Lewis is mistaken in assuming that we have attributed to him inaccurate data on the H_2-Ag/AgCl cell in Table I of our paper. In fact, we have attributed to him an inaccurate method for calculating the standard electrode potential of half-cell reactions on the standard hydrogen scale at temperatures other than 25°C. As the general heading on our Table I clearly states, the values for the cell reaction were calculated by the method reported in the Lewis reference[97]; *i.e.* by applying Eq. [2] in our paper to the H_2-Ag/AgCl cell reaction with the assumption that the heat capacities of the ionic species (H^+ and Cl^-) are zero. The second column heading in this table might imply that the data were calculated by Lewis because the word "method" was left off immediately after "Lewis." That this is a proof reading or typographical error can be ascertained by noting Table II in R. L. Cowan's dissertation[98]. As a matter of record, R. L. Cowan wrote to D. Lewis[101] in October, 1967 pointing out that the method referred to in Footnote No. 85 did not accurately predict the experimental results of Greeley *et al.*[99,100] for the H_2-Ag/AgCl cell and that any potential-pH diagrams calculated for elevated temperatures by that method (such as those reported in Footnote No. 85 for the Fe-H_2O system) were probably in error. Lewis, in a return letter[102] acknowledged this point.

In regard to the discussion's initial comments concerning his Footnote No. 88, he has reiterated precisely the point we make in our Table I. (We had not received this reference until R. L. Cowan's dissertation[98] was complete and the first draft of our JOURNAL manuscript was complete.)

It should be noted that in Criss and Cobble's original papers[104-106] dealing with ionic entropies and heat capacities above 200°C, the values assigned to the parameters *a* and *b* (Eq. [5] is in our manuscript) used to calculate the entropy and the heat capacity of ions are based on the linear extrapolation of the 25°-200°C values. In fact they do not even give parameters for 350°C. Thus, one should be very careful in assuming that calculated free energy values based on the Criss and Cobble method are absolutely correct, as Lewis implies, at temperatures above 200°C. This is especially true for the 350°C case. As more experimental data are generated in the area of thermodynamic properties of aqueous electrolytes at temperatures above 200°C, the Criss and Cobble parameters should become more well known.

Finally, when we attributed to Townsend[107] the first use of the Criss and Cobble method for calculating *E*-pH diagrams, we did so on the basis that we had a preprint of his article in early 1968, although its eventual publication was delayed to 1970.

A New Technique for Investigating the Electrochemical Behavior of Electroless Plating Baths and the Mechanism of Electroless Nickel Plating

oxidation of hypophosphite and the cathodic partial processes are: the nickel deposition; the phosphorus deposition; and the hydrogen evolution. This concept has been verified experimentally for the copper-formaldehyde system[109]. Each process may involve several steps among which one, at least, is a charge transfer reaction. Coupled chemical reactions may precede or follow the charge transfer step.

If each of the partial cathodic current densities (or deposition rates) can be calculated from experimental data, the steady-state potential measured, which is the algebraic sum of each partial process, cannot be derived from the data presented in the paper under discussion. If a significant interpretation is to be extracted from Fig. 5 and 6 in Feldstein and Lancsek's paper, the correct relationship between potential and current densities should be used.

For a simplified system with only two distinct partial processes under pure activation control, each process having one rate-determining charge transfer step, the measurable mixed potential in the absence of externally applied current is given by[110]

$$V_m = \frac{RT}{(\alpha_a n_a + \alpha_c n_c)\,\mathbf{F}} \left\{ \ln\left(\frac{Q_c}{Q_a}\right) + \ln\left(\frac{I_c}{I_a}\right) \right\} \qquad [1]$$

where:

V_m = mixed potential measured
α_a, α_c = symmetry factors of anodic and cathodic charge transfer step
n_a, n_c = number of charges transferred across the interphase during the anodic or cathodic charge transfer step
Q_a, Q_c = factor containing decomposition frequency of activated complexes, concentrations of reactants, *etc.* as defined in Footnote No. 110
I_a, I_c = exponential integrals containing chemical potentials, as defined in Footnote No. 110.

The general case can be simplified by neglecting reverse reactions in comparison with forward reactions, which are the oxidation of the reducing agent and reduction of the metallic ion. By noting that the anodic and cathodic partial current densities are equal at the mixed potential, and assuming a Tafel relation for both partial reactions, one obtains

$$\ln\left(\frac{i_{o,c}}{i_{o,a}}\right) \cong \frac{\alpha_a n_a \mathbf{F}}{RT}(V_m - V_{e,a}) + \frac{\alpha_c n_c \mathbf{F}}{RT}(V_m - V_{e,c}) \qquad [2]$$

where:

$i_{o,a}; i_{o,c}$ = anodic and cathodic exchange current densities
$V_{e,a}; V_{e,c}$ = equilibrium potential for the anodic and cathodic reactions.

To simplify further Eq. [2], it may be assumed that one of the partial reactions, for example the anodic oxidation of hypophosphite, determines predominantly the rate of deposition (for example, nickel); this means that the anodic Tafel line for this reaction has a much higher slope than the conjugate cathodic Tafel line. In this particular case, the following relation should be observed

$$V_m \cong \frac{RT}{\alpha_c n_c \mathbf{F}} \ln\left(\frac{i_{o,c}}{i_{o,a}}\right) + V_{e,c} \qquad [3]$$

For a given concentration of oxidizing agent (nickel ion), $V_{e,c}$ and $RT/\alpha_c n_c \mathbf{F}$ are constant, so that Eq. [3] may be written as

$$V_m \cong K_1 \ln\left(\frac{i_{o,c}}{i_{o,a}}\right) + K_2 \qquad [4]$$

where K_1 and K_2 are constants. It is worthwhile to note that Eq. [4], describing an approximation for a particular case for two partial processes, is not a usual Tafel-like relation. To rigorously treat the process of chemical deposition of nickel, which includes several partial cathodic processes of comparable rates, a more general relationship should be used.

Consequently, the interpretation of results contained in Fig. 5 and 6 of the paper under discussion does not seem adequate and the complete treatment of the polyelectrode system should be taken into account to reach significant conclusions. The literature gives several treatments of polyelectrode systems[110-113]. Stern[113] describes ideal systems with two and three oxidation-reduction reactions occurring simultaneously. The analysis, while containing several simplifying assumptions, shows the complexity of polarization measurements and indicates the care which must be taken if such measurements are to be interpreted quantitatively. The chemistry of the system must be understood, and the number and magnitude of the rates of each individual oxidation or reduction occurring during polarization should be known. Stern's treatment shows that even ideal polyelectrode systems can produce polarization data which may be difficult to interpret. Complicating factors such as heterogeneity of the electrode surface, changes of electrode area with time-film formation giving rise to a time effect, *etc.* would result in a system which is beyond quantitative description with the present knowledge of the electroless nickel process.

Wagner's treatment[114] predicts experimental methods that are promising for deciding whether a chemical or an electrochemical mechanism prevails for a particular process.

Furthermore, no mention is made in the paper under discussion of an eventual diffusion controlled process which was claimed to occur by several authors[115-117]. Moreover, if any Tafel relation applies to the study under discussion, the correct equation (for example for a cathodic process)

$$\frac{dE}{d(\ln i)} = \frac{-RT}{\alpha n \mathbf{F}} \qquad [5]$$

has to be used and not that reported by the authors. The symbols in Eq. [5] have the same meaning as those used by Feldstein and Lancsek.

The above discussion shows that Fig. 5 and 6 of the paper under discussion cannot be interpreted correctly by using the usual Tafel relation. A relation taking into account the complexity of the system under investigation should be used.

The following discussion will not take into account the restrictions concerning the interpretation of the deposition rate *vs.* the steady-state potentials described above. The disadvantages or advantages of the mechanism proposed by the authors with respect to other mechanisms will not be discussed either.

The modified hydride transfer mechanism proposed by Feldstein and Lancsek for the electroless nickel plating predicts that the oxidation of hypophosphite produces an hydride intermediate reacting with nickel (II) ion to give metallic nickel; with metaphosphite ion to give elementary phosphorus; and with a water molecule (or a proton in acidic media) to give molecular hydrogen. The three reactions are competitive, the first two give rise to the useful metallic deposit,

whereas the third one corresponds to the oxidation of hypophosphite without simultaneous reduction of any useful element. The main characteristics of the process do not belong only to the mechanism proposed by Feldstein and Lancsek, but also stand for the other mechanisms previously advanced, namely the atomic hydrogen mechanism[118,119], the electrochemical mechanism[119], the hydride transfer mechanism[120], the mechanism involving hydrolyzed nickel with hydroxyl ions[121], and others. By not taking into account reactions [1], [2], and [5] together (see Fig. 7), the authors neglect one of the three competitive reactions, *i.e.* the hydrogen evolution accompanying the oxidation of hypophosphite without simultaneous reduction of any useful element.

The authors state that the relation

$$\frac{d}{dt}[H_2] = \frac{d}{dt}[Ni] + 1.5\frac{d}{dt}[P] \qquad [6]$$

was found to be in "excellent agreement between the hydrogen measured and that expected, based on the composition of the deposit." Equation [6] is valid only if all the hypophosphite oxidized is used to reduce either Ni^{2+} or metaphosphite ion and none is lost through reactions [1], [2], and [5] together (see Fig. 7), which is very unlikely to be found with ordinary bath compositions.

Experimental data reported by Feldstein and Lancsek in Fig. 3 and Table III for nickel deposition were used to calculate the efficiency defined as the molar ratio of the useful product formed to the hypophosphite oxidized =

$$\frac{2\,Ni + 3\,P}{Ni + 1.5\,P + H_{2\ total}},$$

for the modified hydride transfer mechanism, which was found to be between 0.89 and 0.94. Data in Fig. 4 and Table IV (of the paper under discussion) for the cobalt deposition give ratio between 0.63 and 0.79. Thus, reaction [5] in Fig. 7 can hardly be neglected since in the above examples taken from Feldstein and Lancsek's data it represents between 6% and 37% of the hypophosphite consumed. (As the hypophosphite consumed has not been determined, it has been calculated from the mechanism described in Fig. 7. It can be seen that: $H_2PO_2^-$ oxidized = 2 Ni + 3 P + H_2 from reaction [5] (Fig. 7) and H_2 from reaction [5] = H_2 total − Ni − 1.5 P; hence, $H_2PO_2^-$ oxidized = Ni + 1.5 P + H_2 total, where Ni, P and H_2 represent the molar amounts).

Typical hypophosphite utilization reported for a normal industrial plant gives molar ratio of Ni plated to $H_2PO_2^-$ consumed of 0.33[122], which corresponds to a ratio of useful products formed to oxidized hypophosphite of 0.82, assuming a phosphorus content of 8% and also for the modified hydride transfer mechanism. Laboratory experiments usually also fall into the same range of efficiencies, *i.e.* 0.76 to 0.92 in Footnote No. 122.

Reaction [5] in Fig. 7 is valid only in alkaline media. The corresponding reaction in the acidic media becomes

$$(X.....H)^- + H^+ \rightarrow H_2 + X \qquad [7]$$

The proton concentration increases as the pH decreases and, therefore, causes the hydride-proton combination reaction to occur more readily, which leaves a smaller portion of hydride ion to participate in the nickel (reaction [3], Fig. 7) or metaphosphite (reaction [6], Fig. 7) reduction reactions. This assumption has been verified experimentally[123]. Results taken from Footnote No. 123 and calculated according to the modified hydride transfer mechanism are summarized in Table I of this discussion.

Table I. Effect of pH on the hypophosphite efficiency (from Footnote No. 123).

Average pH	$H_2PO_2^-$ efficiency $= \frac{2\,Ni + 3P}{H_2PO_2^-}$
5.6	0.94
5.0	0.78
4.4	0.62
3.9	0.57
2.9	0.15

Modified hydride transfer mechanism proposed by Feldstein and Lancsek gives higher efficiencies than the other mechanisms since the molar ratio $H_2PO_2^-/P$ for the reaction giving rise to phosphorus is three for the modified hydride mechanism as compared to two for either the hydride transfer mechanism[120] or the mechanism involving hydrolyzed nickel[121], and 1.5 for the atomic hydrogen and the electrochemical mechanisms[118,119]. In hydride transfer mechanisms and in the mechanism involving hydrolyzed nickel, every mole of nickel reduced corresponds to two moles of hypophosphite oxidized whereas the ratio $Ni/H_2PO_2^-$ is one for both the atomic hydrogen and electrochemical mechanisms. It follows that the modified hydride transfer mechanism is the one which gives the higher hypophosphite efficiencies and, consequently, the lower ratio of hypophosphite oxidized according to reaction [5] (Fig. 7), *i.e.* without simultaneous reduction of any useful element.

Nevertheless, the aforementioned hypophosphite efficiencies of which some have been calculated from Feldstein and Lancsek's results, prove that the hydride-proton combination reaction cannot be neglected as proposed by the authors since it has been shown that this reaction can be the most important in this system. Consequently, Eq. [6] is incorrect and should be replaced by

$$\frac{d}{dt}[H_{2\ total}] = \frac{d}{dt}[Ni] + 1.5\frac{d}{dt}[P] + \frac{d}{dt}[H_{2\ from\ reaction\ [5]}] \qquad [8]$$

Equation [6] proposed by Feldstein and Lancsek is very unfortunate since it could lead to misinterpretations of the mechanism and to a false estimation of the efficiency of the process.

Acknowledgment

The author thanks Dr. A. K. Vijh and G. Bélanger for valuable discussions.

N. Feldstein and T. S. Lancsek: We wish to thank Dr. J. P. Randin for his interest and comments on our paper. In the paper under discussion, it has been demonstrated that a Tafel-like behavior is obeyed for nickel (or cobalt) and phosphorus deposited from electroless plating baths. In most of the cases, identical slopes have resulted in the log *i vs. E* plots. The latter results were especially of significance and practical use since an *a priori* knowledge of such behavior provides a quick way for the estimation of the deposit composition under varied conditions. As demonstrated in Fig. 7 of the text, and as referred to by Randin, the deposition of nickel from hypophosphite-based solutions may be considered as a mixed polyelectrode process. In such a process, the anodic process is the oxidation of hypophosphite (Fig. 7, reaction [1]) and

the cathodic processes yield the nickel and phosphorus deposited and hydrogen evolved (Fig. 7, reactions [3], [5], and [6], respectively). The authors are not aware of any existing publications to date in which the Ni-P deposition was completely treated as a polyelectrode system; probably due to the complex nature of the reaction. Randin has suggested and outlined in his discussion that a complete treatment of a polyelectrode system is in order to further interpret Fig. 5 and 6. The authors are in agreement with Randin's suggestion; such an investigation is in order since it may provide a better correlation between the reported results (Fig. 5 and 6) and a fundamental model. However, caution should be exercised in the final interpretation since the analysis proposed by Randin is not rigorous and is generally simplified with several assumptions made.

As mentioned in the text, for the various nickel baths used in the study (and not for cobalt), a simplified expression was found correlating the hydrogen to the compositional makeup of the deposit (Ni and P). Specifically, the following correlation was found to apply

$$\frac{d}{dt}[H_2] = \frac{d}{dt}[Ni] + 1.5\frac{d}{dt}[P] \qquad [1]$$

and this result leads to the suggestion that reaction [5] (Fig. 7) does not play a major role for the nickel baths examined. In testing the above correlation it should be emphasized that for the case of the glycine bath, analysis of the deposit was carried out in this laboratory; however, the hydrogen evolution data was taken from the work of Holbrook and Twist. In this case, excellent agreement in demonstrating the above correlation was achieved. In the case of electroless Co-P deposition, as indicated in the text, the molar ratio of hydrogen evolved to deposited cobalt was found to be about 3:1; this ratio is considerably greater than corresponding values found for Ni-P-type systems. Due to this trend, our Eq. [1] was specified by the author to apply only in the nickel cases. The attempt by Randin to extend the meaning of this correlation beyond its initial intent shows that great care must be exercised in comparing baths employing different metals. Nevertheless, it is believed that the basic reactions described in Fig. 7 do apply for cobalt as well as for nickel (despite the obviously different rate ratios).

From the modified hydride mechanism proposed by the authors (Fig. 7) the authors and Randin realized that the following correlation may apply

$$-\frac{d[H_2PO_2^-]}{dt} = 2\frac{d[Ni]}{dt} + 3\frac{d[P]}{dt} + \frac{d[H_2]^*}{dt} \qquad [2a]$$

where $\frac{d[H_2]^*}{dt}$ refers to the hydrogen evolved from reaction [5]. If indeed the contribution of reaction [5] is minor, the following simplified expression will result

Table II

Molar concentration of glycine	Weight reclaimed[a] (mg)		Hypophosphite consumed (mmole)	
	Ni	P	Experimental[b]	Predicted[c]
0	15.61	0.66	0.6	0.6
0.01	34.02	2.55	1.5	1.4
0.04	55.27	2.29	2.4	2.1
0.10	42.55	0.54	1.5	1.5
0.30	33.65	0.52	1.4	1.2

[a] Data taken from the text.
[b] Determined from fresh baths of identical compositions to those used in text.
[c] Based upon Eq. [2b].

$$-\frac{d[H_2PO_2^-]}{dt} = 2\frac{d[Ni]}{dt} + 3\frac{d[P]}{dt} \qquad [2b]$$

In order to test the applicability of Eq. [2a] *vs.* [2b], plating solutions were analyzed for the hypophosphite consumption. This work is in progress and details will be published at a later date. However, Table II is provided showing some preliminary results.

Examination of these results shows that Eq. [2b] does apply and thus the contributions of reaction [5] (Fig. 7) may be considered negligible to a first approximation for the nickel bath examined. This trend is consistent with the simplified form of our Eq. [1] and thus further supports the mechanism proposed in Fig. 7.

The plating solutions chosen for the present investigation were, in most cases, taken from the literature. Whether the results of the published paper are unique to these solutions or not, is not obvious and will require further investigation. However, some of the conditions suggested by Randin (Table I) with bath's pH below 4, are not conditions commonly used in commercial practice. It should be pointed out that it is the interfacial pH which is the important parameter rather than bulk pH. In all cases, the interfacial pH values are below bulk values. Furthermore, operating at bulk pH values below 4, it is reasonable to anticipate the occurrence of a new reaction which etches some of the deposited nickel, thereby decreasing the apparent efficiency of plating and increasing the phosphorus content in the deposit. Thus, the efficiency results in Randin's Table I may be misleading with respect to the basic mechanism taking place.

With respect to the choice of reaction [6] (Fig. 7), it should be noted that several other reactions for the phosphorus formation were proposed, in the literature, some of which require more than one mole of hypophosphite oxidized per mole of phosphorus deposited. In this respect it may be helpful to establish the mechanism and stoichiometry for the phosphorus formation in electrolytic plating. The knowledge of phosphorus codeposition in electrolytic plating may provide a better insight to assist in the screening of the various proposed reactions for the phosphorus deposition in electroless plating.

Mechanism of the Oxidation of Titanium Disilicide

F. N. Schwettmann,*,[1] R. A. Graff, and M. Kolodney*

Chemical Engineering Department, The City College of the City University of New York, New York, New York 10031

ABSTRACT

The oxidation of $TiSi_2$ was studied at temperatures of 300°-1300°C. Wafers prepared using the techniques of powder metallurgy had densities of 95 to 98% of the theoretical value. On oxidation at temperatures up to 600°C, the polished wafers formed a protective, titania-silica glass. The rate data indicate a complex surface and diffusion-limited mechanism. Above 600°C, the oxide consisted of an amorphous SiO_2 film with crystalline islands of TiO_2 (rutile). From 1000°-1300°C, parabolic kinetics with an activation energy of 21.3 kcal/mole were observed. These data are consistent with a model in which the rate-determining step is the diffusion of oxygen through the silica film with the simultaneous diffusion of titanium from the substrate to the islands of rutile growing on top of the amorphous silica. The protective nature of the oxide appears to be due in part to the ability of titanium to assume fourfold coordination and replace silicon in the growing silica film without disrupting the tetrahedral network.

In recent years, there has been an increasing demand for structural materials which can be used at temperatures as high as 1300°C. At the present time, tantalum or columbium with a mixed silicide coating provide suitable structural and oxidation resistance for certain applications (1, 2). It has been found that a simple coating of $TaSi_2$ or $CbSi_2$ does not provide sufficient oxidation protection (3). In order to obtain a satisfactory coating, it is necessary to incorporate modifiers such as chromium, titanium, molybdenum, or vanadium silicides into the coating layer (4). In some of the more promising systems, the resulting protective layer consists mainly of $TiSi_2$ (5).

Little work has been done on the oxidation behavior of bulk $TiSi_2$. Samsonov (6) describes the results of an experiment in which $TiSi_2$ was heated to 1200°C over a 4 hr period. An adherent oxide film was formed with a weight gain of only 0.3 mg/cm^2. The author speculates that the protective nature of this film is due to the formation of an eutectic mixture of titanium silicates. No indication was given of the sample quality. The present study was undertaken to provide data and a mechanism for the oxidation of bulk $TiSi_2$.

Experimental

The $TiSi_2$ wafers used in this study were prepared using the techniques of powder metallurgy. The disilicide was formed by the reaction of titanium (99.9%) powder or sponge and silicon (99.99%) powder at 1000°C at a pressure of 10^{-4} Torr. The reaction is quite exothermic and careful control is required to prevent melting of the reaction mass. Microscopic examination and x-ray diffraction showed that no oxide is formed during this process. The spongy product was ground in a hardened steel vial, screened, and the −325 mesh material removed, washed with dilute HCl, and dried. Binder was added and 1 in. diam wafers pressed in a hardened steel die at 5-10 tsi. Sample thickness was approximately 0.1 in. (0.25 cm).

Densification of the compacted wafer was carried out in two stages. In the presinter, the binder was removed by heating slowly to 900°C in vacuum. Final sintering was carried out in a separate furnace at 1375°-1400°C and 5 x 10^{-5} Torr for 15 min. The faces of the sintered disks were ground successively on diamond disks of medium, 30μ, and 6μ coarseness. The ground wafers were lapped with 6μ and then 3μ diamond paste followed by a brief polish with 0.25μ alumina. Prior to oxidation, the lapped wafers were cleaned in boiling organic solvents and water, followed by a quick dip in 10% HF in water.

The oxidation experiments were carried out in a vertical tube furnace. Temperature variation over a 4 in. region in the center of the tube was less than 5°C. The oxidizing atmosphere was a mixture of oxygen and argon flowing at 100 cc/min. The $TiSi_2$ samples were supported on a fused quartz holder and suspended from the top of the furnace.

Oxidation rate data were obtained by periodically removing the sample from the furnace and weighing on a microbalance with a sensitivity of ±2 μg. The structure of the growing oxide film was studied using scanning electron microscopy (SEM), x-ray diffraction, and infrared spectroscopy. A Cambridge Stereoscan Mark II was used in the emissive mode for the SEM work. X-ray diffraction scans were made of the initial silicide surface and of the growing oxide film. The diffraction patterns were obtained with a Norelco Geiger counter x-ray spectrometer using CuKα radiation. The surface of the wafer was usually scanned by inserting it directly in the sample holder, although a number of powder patterns were also prepared by

Key words: oxidation, titanium silicides, silica, titanium dioxide, diffusion.

grinding the finished wafer. Several powder patterns were also obtained on the oxide film.

A more detailed analysis of the amorphous region of the oxide film was performed by infrared spectroscopy using a Perkin-Elmer Micro Specular Reflectance Accessory in conjunction with a Perkin-Elmer 621 Spectrophotometer. The spectrum obtained was a 2X absorption spectrum which can be compared with literature data on amorphous silica and glasses.

Results

Sample quality.—The theoretical density of $TiSi_2$ as determined by x-ray diffraction is 4.13 g/cm^3 (7). Typical values obtained in the present study were 95-98% of the theoretical value. The surface quality of a polished and lightly etched wafer is indicated in Fig. 1. In addition to the $TiSi_2$, a small amount of a second phase identified as silicon was present at the grain boundaries. A few small pits are also present, the majority of them occurring in the silicon phase.

Kinetic data.—The major variable that was considered in the kinetic study was temperature. Unless otherwise indicated, the oxygen partial pressure of the gas phase was 0.2 atm although a limited number of experiments used pure oxygen as the ambient. In the initial phase of the study, alteration of the gas flow from 0 to 200 cc/min produced no change in oxidation rate.

Several $TiSi_2$ wafers were oxidized at 300°C in order to establish the lower level of observable oxidation. After 20 hr at temperature, a total weight gain of 25 μg was observed. After 320 hr, the weight increase was still only 112 μg.

Typical weight gain data obtained at 600°C are shown in Fig. 2 where the square of the weight gain

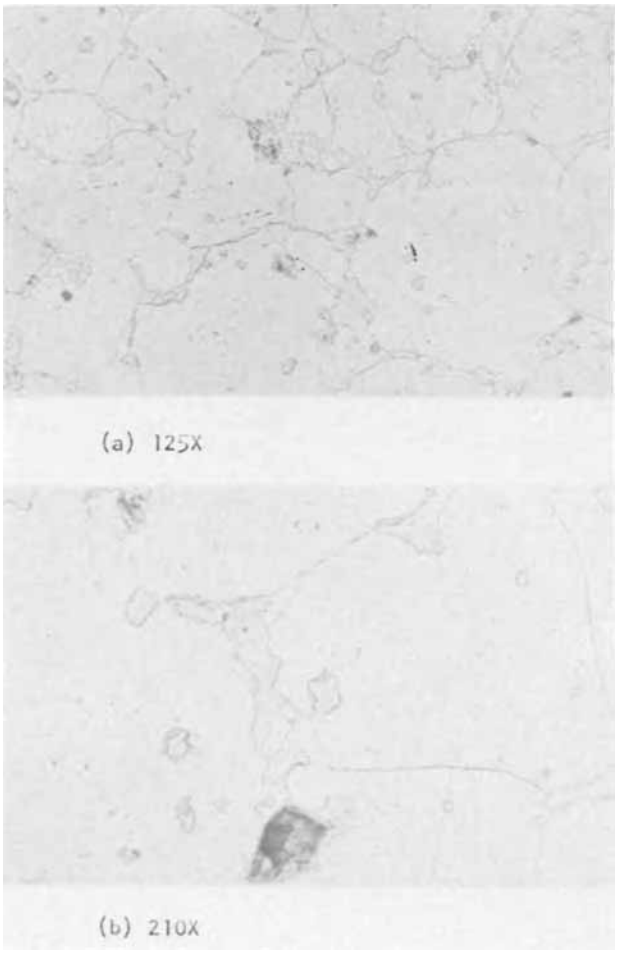

Fig. 1. Surface of polished and etched $TiSi_2$ wafer

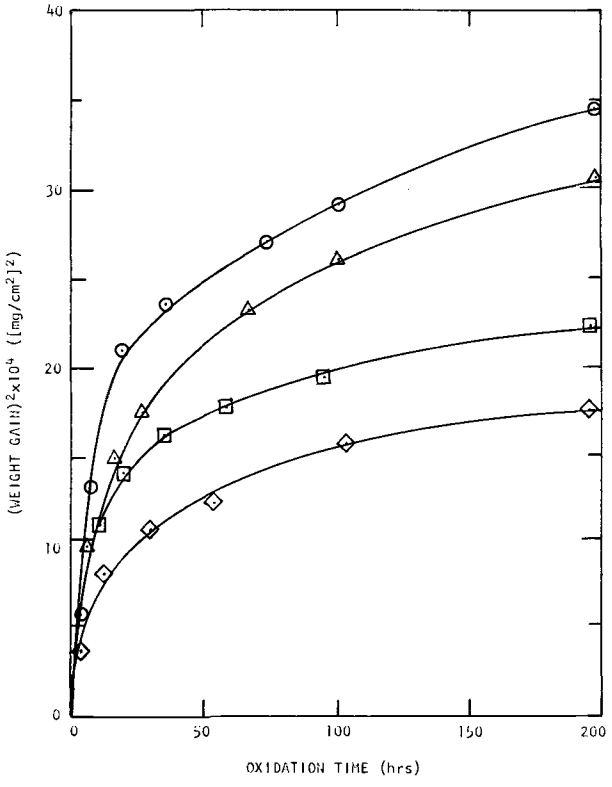

Fig. 2. Rate data for $TiSi_2$ oxidized at 600°C

is plotted against time of oxidation. The considerable variation in the data is caused by differences in surface quality. The greater the number of pits and size of the silicon phase, the higher the oxidation rate. The lower curve is typical of the best quality wafers. When the samples were oxidized in pure oxygen, within experimental error, no difference in rate was found. At 800°C, results similar to those obtained at 600°C were observed. Within experimental error, the magnitude of the observed weight gain for the first 50 hr was the same as that observed at 600°C. Beyond 50 hr, the weight gain at 800°C became greater.

Typical rate data obtained at 1000°C are shown in Fig. 3. Again, variation due to surface quality is evident. In this case, however, straight lines are obtained when the square of the weight gain is plotted against time. Similar straight lines were obtained at 1200° and 1300°C. Parabolic rate constants were determined at oxygen pressures of 0.2 atm and 1 atm. The constants for each run were obtained by the method of least squares and averaged over all runs at identical conditions. Only two short runs were made at 1300°C. The results are given in Table I.

A summary of the best data for intrinsic $TiSi_2$ is shown in Fig. 4. From the parabolic rate constants obtained at 1000°-1300°C an activation energy of 21.3 kcal/mole was obtained.

Character of the oxide film.—At 300°C, no visible continuous oxide film was observed after 300 hr at temperature. A few, very small, isolated, multicolored crystalline areas were visible under a light microscope. X-ray analysis indicated only the $TiSi_2$ substrate which remained unchanged during the oxidation pe-

Table I. Parabolic rate constant (mg/cm^2)^2/hr

riod. It is likely that the observed weight increase is due to the oxidation of small amounts of impurities such as iron and the formation of a thin, continuous silica layer. This is typically observed with single crystal silicon using ellipsometry (8), where, for example, 30Å of SiO_2 form on silicon standing at room temperature for several hours.

At 600°C, a transparent oxide film, exhibiting interference colors, was formed after one hour of oxidation. By incident light microscopy, it was found that the over-all color was a blend of several color regions. Each of the different colors corresponded roughly in size and shape to the $TiSi_2$ grain structure. The oxide formed over the separate silicon phase showed the same interference color throughout the specimen and from specimen to specimen. As the time of oxidation increased, the interference colors changed gradually until about 30 hr after which little change occurred. The color of the oxide on the silicon phase remained a tan to pale brown through the course of a run. Light microscopy of the oxide film revealed no crystalline regions after 300 hr of oxidation, but after 800 hr, a number of small, yellow crystalline islands were found near the holes originally observed in the surface. X-ray analysis showed only the $TiSi_2$ with parameters constant throughout the oxidation period.

Comparison of the infrared spectrum of the oxide with that obtained for silicon dioxide thermally grown on silicon provides considerable insight into the structure of the film. An extensive transmission infrared study of SiO_2 on silicon has been reported by Pliskin and Lehman (9). They found that a dense, thermally grown SiO_2 film with a thickness of 1 μm had absorption peaks at 1093, 805, and 455 cm^{-1}. The 1093 cm^{-1} peak is attributed to Si-O bond stretching and the 455 cm^{-1} peak to Si-O-Si bond bending. The exact nature of the other absorptions in unclear. The position and half-width of these absorptions, particularly the Si-O vibration at 1100 cm^{-1}, is strongly influenced by the structure of the SiO_2. A decrease in the oxide density causes a shift to lower absorption frequencies and an increase in the peak half-width.

The infrared spectrum of the oxide formed on $TiSi_2$ at 600°C has the characteristic absorption peaks of amorphous SiO_2. However, the major 1100 cm^{-1} Si-O peak was shifted to a lower frequency as was the Si-O-Si bond bending at 435 cm^{-1}. The 800 cm^{-1} peak appears to be in the same position as when found in dense, pure SiO_2 films. Based on the work of Zeitler and Brown (10), the observed absorption at 930 cm^{-1} is probably due to a Ti-O-Si vibration [Zeitler and Brown (10), studying the infrared spectra of organic-titanium-silicon compounds, reported an absorption at 920-925 cm^{-1} which they attributed to a Ti-O-Si bond]. These data, plus the observed shift in the Si-O vibration to a lower frequency indicates that the oxide film at 600°C is not pure SiO_2 but a titania-silica glass.

If a stoichiometric reaction occurred between the $TiSi_2$ and oxygen, the oxide should contain two atoms of silicon to each atom of titanium or 40 weight per cent (w/o) titanium. The phase diagram for the SiO_2-TiO_2 system (11) indicates a maximum solid solubility of about 10 w/o in SiO_2 at the eutectic temperature of 1540°C. The concentration of titanium in the glass formed on $TiSi_2$ at 600°C was not determined, but the mobility of the titanium in the oxide at 600°C is sufficiently low that a supersaturated solution of titanium in SiO_2 could be formed. Another possibility is that the oxide film contains approximately the 10 w/o TiO_2 solid solubility limit, with the remaining titanium having reacted to form a lower silicide. Typical reactions would be

$$2\,TiSi_2 + 4\,O_2 = TiO_2 + 3\,SiO_2 + TiSi$$

$$6\,TiSi_2 + 10\,O_2 = TiO_2 + 9\,SiO_2 + Ti_5Si_3$$

where the TiO_2 is in the form of a silica glass. The amount of Ti_5Si_3 could be too small to be observed by the x-ray.

Oxidation at 800°C produced a significant change in the structure of the growing oxide film. In the initial stage of oxidation, an amorphous film similar to that obtained at 600°C was produced, but the interference color was more uniform over the surface. However, after 3 hr, small clumps of crystalline islands were observed situated on top of the amorphous

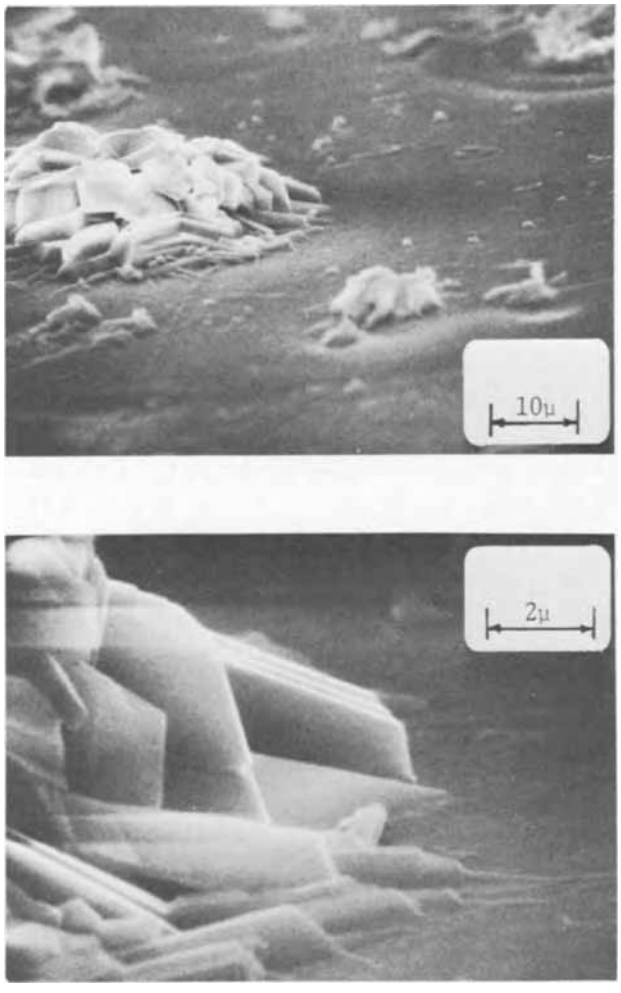

Fig. 5. Scanning electron micrographs of surface after oxidation at 800°C for 100 hr.

phase. A scanning electron micrograph of the surface after oxidation for 100 hr is shown in Fig. 5. Examination of a cleaved specimen in cross section showed that the crystalline region in most cases is separated from the substrate by the amorphous layer. In addition, as shown in Fig. 5, the outer region of the TiO_2 appears to have made intimate contact with the amorphous phase. X-ray diffraction identified TiO_2 in the rutile form. The crystalline islands were generally found at the phase boundary of the $TiSi_2$ and silicon phases, in particular where pits were present. As the oxidation time increased, more islands were formed while those formed earlier increased in size.

The oxide film formed at 1000°C was similar to that obtained at 800°C. X-ray and metallographic studies indicated an amorphous matrix with crystalline islands of TiO_2 (rutile). The crystallization occurred after only about 1 hr at reaction temperature as compared to the 3-7 hr required at 800°C. Most of the crystallization again occurred at the silicide grain boundaries. The TiO_2 clumps were more numerous and larger in size than those formed at 800°C for comparable oxidation times. The infrared spectrum of the oxide is more typical of the spectra observed when silicon is oxidized. The absorption at 930 cm^{-1} caused by titanium in the oxide is no longer present because TiO_2 has crystallized out. The frequency of the Si-O band is now 1060 cm^{-1}. This value is still not as high as the 1090-1100 cm^{-1} obtained for SiO_2 on silicon, indicating a less pure or lower density oxide.

At 1200°C, crystallization of the TiO_2 occurred within 0.5 hr at temperature. The major difference at this temperature was that α-cristobalite was also identified by x-ray after 0.5 hr. After 30 hr, the crystalline α-cristobalite regions could be observed with a light microscope in the amorphous SiO_2 matrix. The infrared spectrum obtained at 1200°C shows amorphous SiO_2 with additional vibrations at 1190, 950, and 535 cm^{-1}. The peaks are very much sharper than at lower temperatures, indicating a denser structure, but the major Si-O vibration is found at 1060 cm^{-1} indicating that the oxide is not as pure or dense as SiO_2 grown on silicon.

At 1350°C, the character of the oxide film was considerably changed. No interference colors were observed; the sample was a dark, dull gray covered with a glassy oxide which was thicker in the center of the sample. The wafer was distorted slightly.

At each of the temperatures studied, changing the oxygen partial pressure from 0.2 to 1.0 atm had no observable effect on the structure of the oxide film.

To explore the possible titanium content of the oxide grown on $TiSi_2$, a brief study was made of the x-ray and infrared characteristics of the TiO_2-SiO_2 system at elevated temperatures. Pellets formed from TiO_2 (rutile) and amorphous silica powders were fired at 1550°C for 15 min at 10^{-4} Torr. Cooling to below red heat was achieved in less than 2 min. When 10 w/o TiO_2 was used, x-ray analysis of the glassy-blue surface indicated that the material was amorphous. The infrared spectrum obtained using the KBr pellet technique was the same as that of the SiO_2 charged, with the exception of a broad absorption at 940 cm^{-1}. When the concentration of TiO_2 was increased to 20 w/o, TiO_2 was found in the x-ray analysis. The infrared spectrum was similar to that found for the 10 w/o TiO_2 sample. The existence of a true glass in this system up to 10.8 w/o titania has recently been confirmed by Evans (12).

Discussion

Effect of surface quality.—In order to obtain reliable oxidation rate data, it is necessary that the sample surface be both chemically and physically clean. However, it is difficult to prepare wafers that contain only a single compound and are free of macroscopic defects because there are three contiguous compounds (Ti_5Si_3, TiSi, $TiSi_2$) in the titanium-silicon system (13). When preparing $TiSi_2$, a small amount of a second phase is likely to be present. In this study, a slight excess of the stoichiometric amount of silicon was used in the preparation to offset any loss of silicon during vacuum sintering and also to insure that the second phase formed was silicon and not a lower silicide. In general, the lower silicides oxidize much more rapidly and it was felt that this would mask the $TiSi_2$ oxidation rate. Several wafers of TiSi and Ti_5Si_3 were fabricated and did show an oxidation rate which was an order of magnitude greater than $TiSi_2$.

On the other hand, the presence of more than 3% silicon causes a large increase in the oxidation rate. This appears to be due to an increase in the number of pits on the surface, most of which are in the silicon phase. During oxidation, these holes act as nucleation sites resulting in rapid localized oxidation. Nevertheless, it is significant that the physical and chemical defects do not prevent the formation of a protective oxide layer.

Kinetics of oxide growth.—Since the oxidation rate was independent of gas velocity and since it was highly dependent on film thickness, especially at low temperatures, it appears that some form of transport of one or both of the reacting species through the oxide film is the rate-controlling step.

The mechanism for the growth of the oxide film on $TiSi_2$ at 1000°-1300°C appears to be similar to that observed for silicon. In a detailed study on the oxidation of silicon, Deal and Grove (14) report parabolic

kinetics for the temperature range 1000°-1200°C. Earlier studies (15) had shown that the rate-controlling step was the diffusion of oxygen through the oxide film. The precise atomistic mechanism is not known although the rupture of Si-O bond appears to be required. The activation energy was measured at 28.5 kcal/mole (14) as compared with the value of 21.3 kcal/mole observed here for the oxidation of $TiSi_2$. The weight gained by $TiSi_2$ at 1000°C is approximately 1.6 to 2.0 times greater than that observed for silicon oxidized a comparable time. If diffusion of oxygen through the SiO_2 matrix is the rate-controlling step for $TiSi_2$ oxidation, the expected weight gain would be 1.5 times greater than for silicon because, assuming stoichiometric oxidation, 1 atom of titanium is oxidized in addition to the 2 atoms of silicon. As oxidation of the silicon occurs at the oxide-silicide interface, the titanium diffuses through the silica to the gas-oxide interface where TiO_2 clumps are formed.

A number of samples with many pits in the surface did not exhibit parabolic behavior in the initial few hours of oxidation at 1000°C. Instead, there was initial rapid oxidation at the pits because of their higher interfacial energy. As the oxidation proceeds, a barrier layer of amorphous SiO_2 forms slowing down the oxidation rate. It is likely that the rate in the localized region goes from surface-controlled to diffusion-controlled. It is difficult to formulate this result mathematically since the area involved in the changing kinetics is difficult to estimate as is the time required for the barrier layer to form.

The kinetic data at 600°C are characterized by a rapid initial oxidation rate followed by an extremely low rate. The variation of the interference color with orientation of the underlying $TiSi_2$ grains indicates that the rate of oxidation is a function of crystal orientation. This implies that in the initial period, bulk diffusion through the oxide is not the rate-controlling step. However, the data cannot be fitted to a linear or combination linear-parabolic mechanism. A possible controlling mechanism would be combination of surface reaction and diffusion with a variable diffusivity. In the initial phase, diffusion through short circuit paths in the oxide is rapid. As the time of oxidation increases, these paths become gradually blocked and bulk diffusion becomes rate controlling. Since the diffusion rate through a silica film at 600°C is small, the weight increase should drop off dramatically. This is what is observed. The mechanism that could account for a decrease in the diffusivity may be a pore closure model as described by Evans (16). While there is no evidence indicating pores in the oxide, the study of Ing *et al.* (17), on the structure of the oxide film formed on silicon indicates the presence of microchannels. This type of defect would be more likely to occur in the impure silica films formed on $TiSi_2$ at low temperatures where the mobilities of the atoms are quite low. The kinetic data for oxidation at 800°C show characteristics similar to those observed at 600°C.

Protective mechanism.—Polycrystalline $MoSi_2$ is highly oxidation-resistant at high temperatures (18), but deteriorates rapidly in the 300°-600°C range (19). This "pest" phenomenon has been attributed to the presence of MoO_3 in this range and its volatilization above 600°C. Microcracks in the substrate are also held to be responsible. Since TiO_2 is not volatile at any temperatures studied, the present work on $TiSi_2$ indicates that a protective film can be formed even when both oxides are present and when the surface has considerable imperfections. These results suggest that while the presence of cracks in the sample present high energy nucleation sites which increase the reaction rate, the compatibility of the oxides is a more fundamental requirement for the formation of a protective oxide. The fact that TiO_2 is partially soluble in SiO_2 appears to be quite significant. The ability of titanium to assume fourfold coordination and replace silicon in the SiO_2 network allows a protective titania-silica glass to be formed at low temperatures and increases the compatibility of the crystalline TiO_2 and amorphous SiO_2 at high temperatures. In the latter case, a dense, continuous transition region is most likely present between the two oxides. By contrast, the incompatibility of MoO_3 and SiO_2 may be due in part to the excess charge of the molybdenum ion. Considerably more work is required to present a clearer picture of oxidation protection by silicides.

The Kinetics and Morphological Development of the Oxide Scale on Nickel-Iron Alloys (0-25 w/o Fe) at 1000°C

A. D. Dalvi*,[1] and W. W. Smeltzer**

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The oxidation kinetics were determined for nickel alloys containing 0-25 w/o (weight per cent) iron in oxygen at 1000°C. The kinetics, which were obtained for periods up to 100 hr, followed a parabolic relationship at long times. The parabolic rate constant was obtained as a function of alloy composition; it increased in magnitude with addition of iron up to 5 w/o and subsequently decreased to a value approximately equal to that for pure nickel. The external scale on alloys containing up to 2 w/o iron was virtually single-phase nickel oxide. All other alloys exhibited scales consisting of an inner nickel oxide layer and an outer two-phase nickel oxide-spinel layer. All alloys oxidized internally, the internal oxide being an iron-nickel spinel, $Ni_xFe_{3-x}O_4$. Iron preferentially concentrated in the oxide phases. There was a large degree of iron depletion in the alloy towards the alloy/oxide interface where the iron concentration was less than 1 w/o. A schematic model based on thermodynamic and diffusion properties is advanced to account for the observed variation of the parabolic constant with alloy composition.

A survey of the high-temperature oxidation properties of Fe-Ni alloys has been presented by Foley (1). Recently, Wulf *et al.* (2) conducted an extensive investigation into the oxidation characteristics of these alloys over the entire composition range in pure oxygen at 1000°C. According to these authors Fe-Ni alloys can be divided into four major types: alloys containing up to 2 w/o Ni which exhibit scales similar to those found on iron; alloys containing approximately 2-30 w/o Ni which form scales devoid of wustite due to a large degree of nickel enrichment at the alloy/scale interface; alloys containing 30-75 w/o Ni which show formation of nickel oxide in the scales, the oxidation kinetics being governed primarily by the growth of a nickel containing spinel; and, alloys containing 75-100 w/o Ni which exhibit scales consisting of nickel oxide and spinel. All alloys show nickel enrichment at the alloy/scale interface and, in addition, exhibit subscale formation. Considerable recent information is also available on the oxidation properties of iron-rich alloys in pure oxygen and controlled atmospheres containing carbon dioxide and water as oxidizing reactants (3-14).

Information on the oxidation properties of nickel-rich alloys is not extensive and the results of kinetic studies have been neither reproducible nor of continuous pattern (15). Accordingly, we have carried out a detailed investigation of the oxidation kinetics of these alloys (0-25 w/o Fe) at 1000°C in conjunction with examination of the composition, structure, and the morphological development of the oxide scales.

Experimental

Electrolytic iron and nickel were used in preparation of the alloys. The compositions of the metals used are given in Table I. Portions of each material were accurately weighed to yield alloys nominally containing 2,4,5,6,8,10,15,20, and 25 w/o Fe. The actual alloy compositions are given in Table II. The melting operation was carried out in a nonconsumable arc furnace with a tungsten electrode and in an argon atmosphere. The samples were remelted to avoid long range segregation of the alloying elements. The buttons thus obtained were alternately cold rolled and vacuum annealed for 10 hr to obtain sheets approximately 1 mm thick. The surfaces of each sheet were cleaned by abrasion. Specimens for oxidation tests were plates, 1 cm × 2 cm. These were batch annealed in vacuum at 1000°C for 5 hr and then furnace-cooled to room temperature. This eliminated any stress and short range segregation in the samples and allowed them to attain an equilibrium grain size. The average grain diameter was in the range 100-300μ which corresponds to ASTM standard grain size No. 2.

Prior to oxidation, the specimens were metallographically polished by abrasion. This type of surface preparation was found to give the most reproducible oxidation kinetics and the scales were more adherent to the metal substrate as compared to electrochemical polishing. The plates were mounted flat in bakelite and polished through 240, 300, 400, and 600 grit silicon carbide papers using water as lubricant, followed by polishing on a wax lap impregnated with 15μ alumina to obtain a flat surface. The final polishing was done with 6μ and 1μ diamond abrasive on wheels with kerosene as lubricant. The samples were cleaned with petroleum ether and stored under acetone until re-

Key words: nickel, nickel-iron alloys, high-temperature oxidation, nickel oxide, spinel.

quired. Immediately before an experimental test a specimen was dried, weighed to ±2 μg, and its surface area computed by measuring the specimen dimensions with a micrometer. The specimen was then cleaned in dilute sulfuric acid, rinsed in distilled water, and dried in acetone.

The kinetics of the oxidation reaction were determined by means of a volumetric apparatus (16). A specimen was brought to the reaction temperature under a vacuum of 10^{-5} Torr. The reaction was initiated by admitting oxygen to the reaction cell and measuring the time thereon. Precision of measurement corresponded to ±0.3 mg. High purity research grade oxygen was used as the reacting gas, the total impurity content being less than 25 ppm. The oxidation reaction was carried out at 1000°C and 400 Torr pressure of oxygen. The temperature of the quartz reaction cell was controlled within ±2.5°C. After reacting a specimen for the desired interval, the reaction was discontinued by evacuating the reaction chamber and allowing the specimens to cool by removal of the furnace from around the reaction cell.

Metallographic examination, x-ray diffraction, and electron microprobe techniques were used in investigating morphology, structure, and compositions of a scale and the alloy substrate. The oxidized plates were cut into two pieces by a jeweller's saw: one-half of the plate was used in x-ray diffraction and the other half mounted for metallographic and electron probe studies. Specimens were mounted in room setting resin and kerosene was used as the lubricant throughout the polishing operations. Specimens were polished on silicon carbide papers 200 through 600 grit, then polished on a wax lap impregnated with 15μ alumina. This procedure resulted in the best retention of oxide grains and in obtaining a flat surface. The final polishing was done with 6μ and 1μ diamond as abrasive on wheels with napless cloths. It was necessary to etch the oxidized samples to reveal their grain structure. An aqueous etchant containing 16.7 v/o (volume per cent) of acetic acid and of hydrofluoric acid was used. Etching was done electrolytically at 300 mA under 10-15V with stainless steel as the cathode for a period of 1 min at 25°C. The techniques for oxide phase identification by x-rays and oxide and alloy compositions by the electron microprobe technique have been described in an earlier paper (17).

Results

Oxidation kinetics.—Typical oxidation curves for alloys containing 0-25% Fe are illustrated by the parabolic plots in Fig. 1 and 2, (weight gain per unit area)^2 *vs.* time. Although the period of oxidation was generally 50 hr, several specimens were exposed up to 100 hr. In each case more than one sample was oxidized to check the reproducibility of the kinetic curves, which was found to be within ±10%.

Oxidation of pure nickel was used as the basis of comparison for the kinetics. It was observed that continuous long time kinetics could be obtained for the alloys if careful metallographic preparation was followed. Parabolic kinetics were observed for pure nickel through the entire oxidation period. In the case of the alloys containing up to 20 w/o Fe an initial nonparabolic transient period of up to 15 hr was observed before onset of parabolic kinetics. The Ni-25 w/o Fe alloy showed two stage kinetics, the initial stage extending up to 45 hr (Fig. 2). The parabolic rate constants are given in Fig. 3. The oxidation rate of the alloys increases initially upon addition of iron and subsequently decreases to a nearly constant value. Composition of the alloy which yields the maximum oxidation rate corresponds to Ni-5 w/o Fe.

Oxide morphology and composition.—Only two oxide phases were identified. These were nickel oxide with dissolved iron, $Fe_xNi_{1-x}O$, and a spinel phase, $Ni_xFe_{3-x}O_4$, of variable compositions. The external scale formed on the 2 w/o Fe alloy consisted of nickel oxide with iron in solid solution. As illustrated by

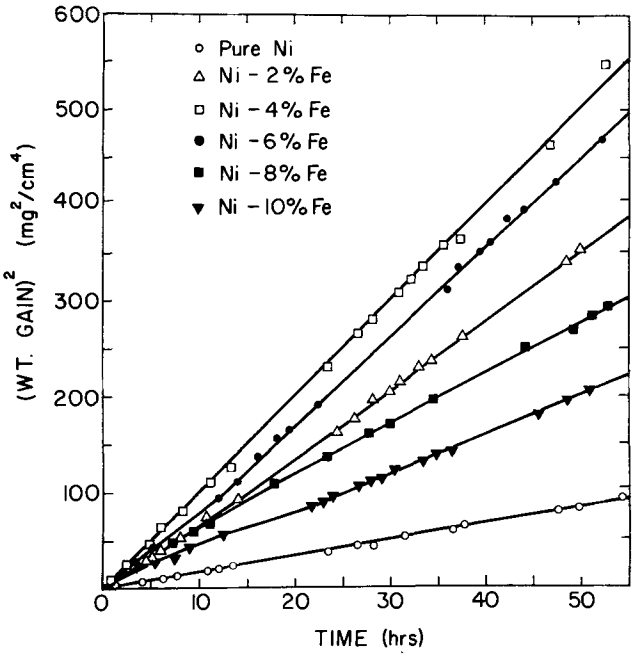

Fig. 1. Oxidation curves in parabolic form, $\left(\frac{\Delta m}{A}\right)^2$ *vs.* t, for nickel and nickel alloys containing up to 10 w/o Fe at 1000°C and 400 Torr oxygen pressure.

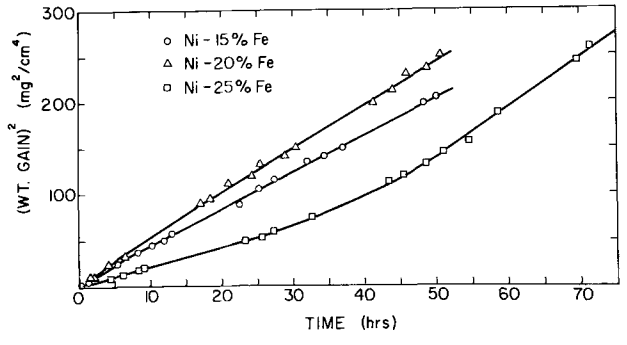

Fig. 2. Oxidation curves in parabolic form, $\left(\frac{\Delta m}{A}\right)^2$ *vs.* t, for Ni-Fe alloys containing 15-25 w/o Fe at 1000°C and 400 Torr oxygen pressure.

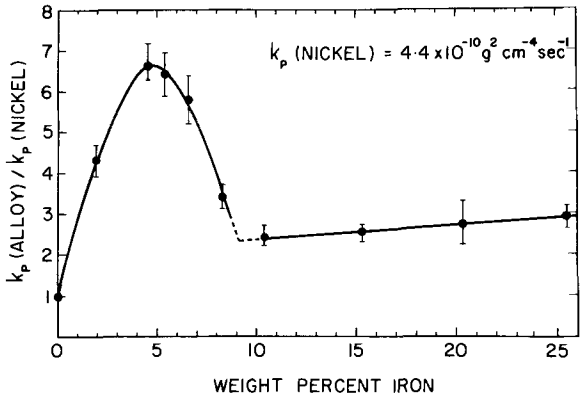

Fig. 3. Variation of the relative parabolic oxidation constant [k_p(alloy)/k_p(nickel)] with bulk alloy composition.

the micrograph in Fig. 4a no spinel growth could be detected in the scale. External scales formed on the remaining alloys consisted of two layers: an inner

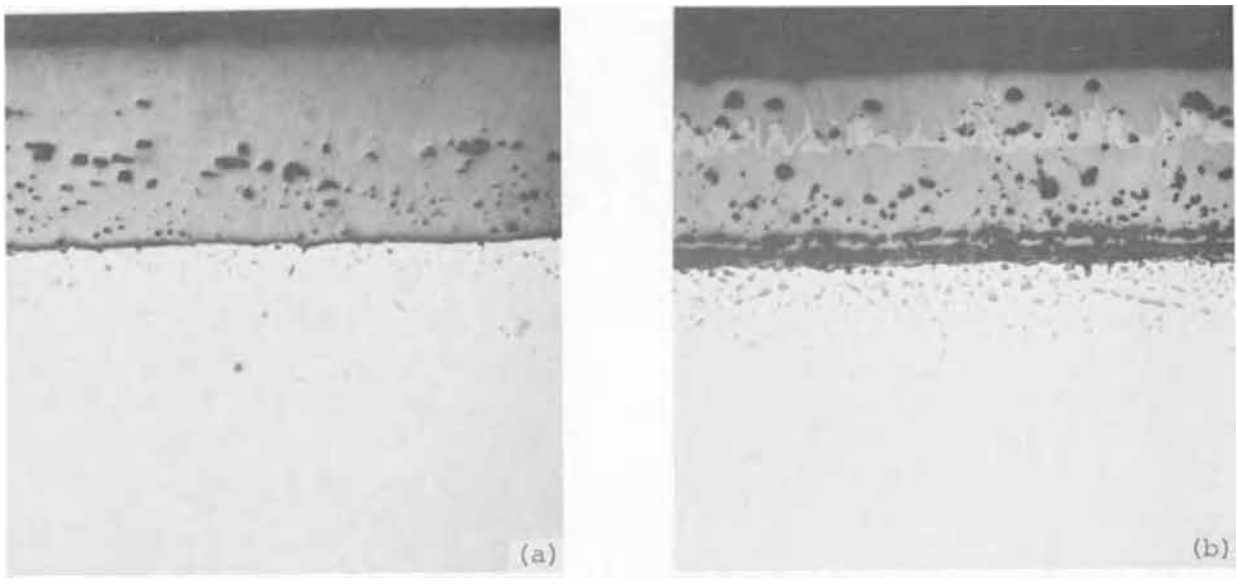

Fig. 4. Scale and internal oxidation zone in Ni-Fe alloys: (a) shows a nickel oxide scale and spinal internal precipitate for a Ni-2 w/o Fe alloy oxidized for 51.5 hr, (200×); (b) shows duplex scale and internal oxidation zone for a Ni-8 w/o Fe alloy oxidized for 48.5 hr, (200×). The external scale consists of an inner single-phase nickel oxide layer and an outer two-phase nickel oxide-spinel layer, the light precipitate phase in this latter layer being the spinel phase. The internal oxidation zone consists of spinel particles.

nickel oxide layer and an outer two-phase layer containing nickel oxide and spinel. The commencement of spinel growth and the consequent formation of the outer two-phase layer was observed in the scale on the alloy containing 4 w/o Fe. The spatial density of spinel phase in the scale increased with increasing iron content of the alloy. The composition of this spinel was found to correspond approximately to that of nickel ferrite, $NiFe_2O_4$. Figure 4b shows the duplex scale formed on an alloy containing 8 w/o Fe oxidized for 48.5 hr. The relative position of the spinel precipitation zone shifted inwards with increasing iron content of the bulk alloy. Grains of spinel started forming in the scale on the 10 w/o Fe alloy while the scale on the 25 w/o Fe alloy consisted of an inner nickel oxide layer which shaded into a predominantly spinel layer (Fig. 5). A continuous spinel layer, however, did not form since nickel oxide formed channels around the boundaries of the spinel grains. This structure agrees with the observations of Kennedy *et al.* (15).

Electrolytic etching of the scales revealed that the grain structure of the oxide formed on the Ni-2 w/o Fe alloy was columnar with small equiaxed grains at the alloy/oxide interface (Fig. 6a). The scales on alloys containing 4 to 8 w/o Fe structurally consisted of three zones (Fig. 6b). A zone containing small equiaxed grains, which exhibited a remarkably sharp boundary, existed at the alloy/oxide interface. Beyond this boundary a zone of medium sized elongated grains was observed up to the spinel precipitates in the scale. Beyond the spinel precipitates a zone of larger columnar grains extending up to the oxide/gas interface was observed (Fig. 6b). The spinel growths mainly occurred at the boundary between the outer zone of columnar grains and the middle zone of medium sized grains.

Internal oxidation.—Internal oxidation occurred in all the alloys and the oxide was identified as a nickel containing spinel, $Ni_xFe_{3-x}O_4$. The nickel content of the spinel appeared to increase from the bulk alloy towards the alloy/oxide interface. Only a qualitative analysis of the oxide composition could be done with the electron probe due to the very small spinel particle size which ranged from a fraction of a micron to about 10μ. The particle size appeared to depend on variables such as alloy composition, oxidation time, and the distance of the precipitate from the alloy/scale interface. The alloy grain boundaries appeared to provide preferential sites for the nucleation of the spinel (Fig. 7a); however, preferential penetration of oxide along the grain boundaries was not observed (Fig. 7b).

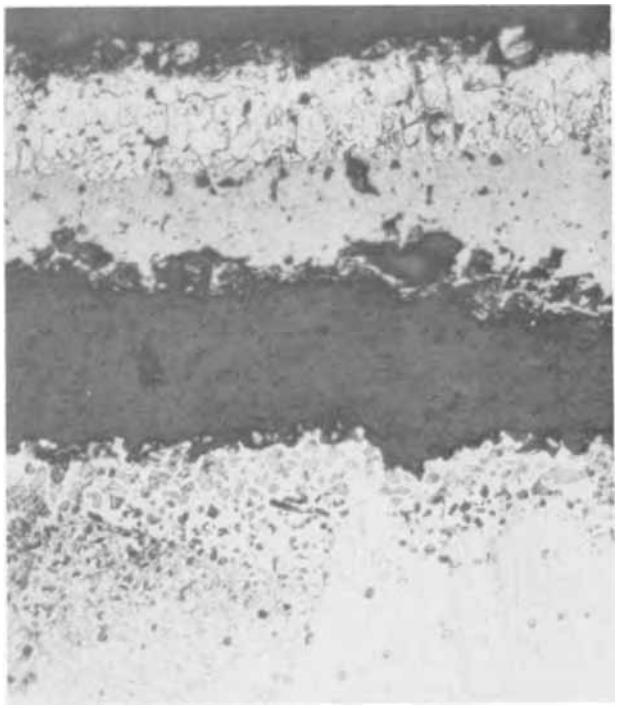

Fig. 5. Scale and internal oxidation zone in Ni-25 w/o Fe alloy oxidized for 61 hr (272×). The scale is of duplex structure consisting of an inner nickel oxide layer and an outer nickel oxide-spinel layer. The gap in the center of the micrograph separating the external scale from the alloy substrate is filled with the mounting plastic. Nickel oxide appears gray and the spinel white in the external scale.

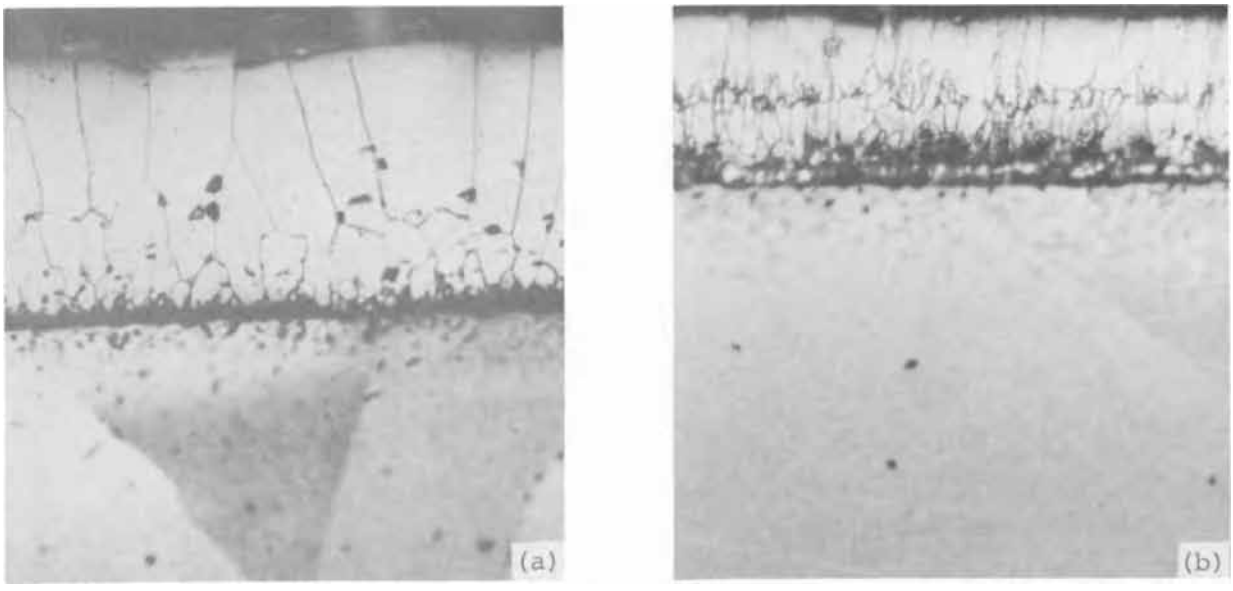

Fig. 6. Scale and internal oxidation zone in Ni-Fe alloys: (a) shows the typical grain structure of nickel oxide scales on alloys containing up to 2 w/o Fe (280×); (b) shows the typical grain structure for nickel oxide and spinel in scales formed on alloys containing between 4-8 w/o Fe (320×).

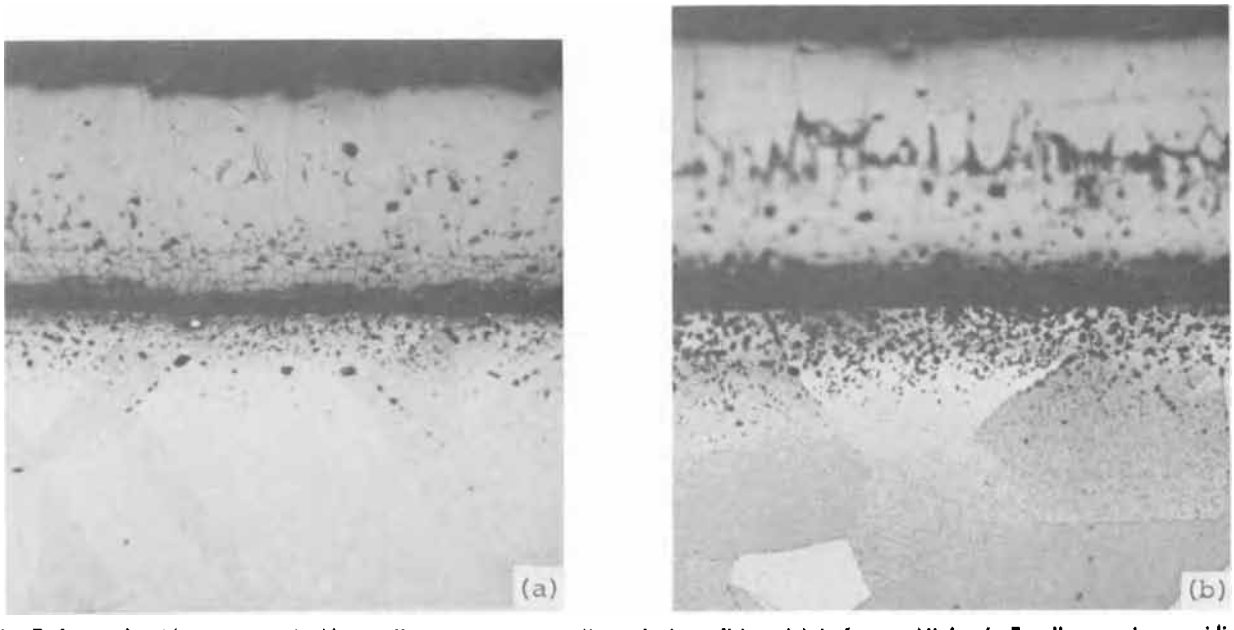

Fig. 7. Internal oxidation zones in Ni-Fe alloys in electrolytically etched condition: (a) is from a Ni-4 w/o Fe alloy specimen oxidized for 25.2 hr (200×); (b) is from a Ni-6 w/o Fe alloy specimen oxidized for 47.5 hr (200×).

Penetration of the internal oxidation zone and the size of the internal oxide particles increased with time. Figure 8 shows a photomicrograph of the internal oxidation zone in an alloy containing 6 w/o Fe oxidized for 47.5 hr which is typical of this zone in all alloys. Since the solubility product for the spinel phase is large, there is no discontinuity in either the concentration or its gradient at the interface between the zone of internal oxidation, and the unoxidized alloy (18). Accordingly, a sharp boundary defining this zone does not exist. Its approximate penetration as a function of time illustrated in Fig. 9 for various alloys shows that the penetration rate follows a parabolic dependence and that it is independent of the bulk alloy composition. However, since the particle density and size increased with increasing iron content of the bulk alloy, the amount of oxygen consumed in this zone also correspondingly increased. The rate constant for the internal oxidation zone as obtained from Fig. 8 is 3.7×10^{-10} cm²/sec.

Surface topography and the crystallographic orientation of the oxide scales.—The topographies of the specimens at various oxidation stages indicated that the grain boundaries and defect sites on the alloy substrate act as preferential growth sites for the external oxide scale during the initial stages (Fig. 10a). The small crystallites initially formed tended to coalesce and grow, forming bigger grains with a terraced structure (Fig. 10b). The preferred orientation as shown by the x-ray diffraction measurements was such that <110> directions are parallel to the oxide surface, The surface plane of the oxide scale was preferentially {111}.

It was observed for slow growing nickel oxide on pure nickel that its surface was smooth. As the oxidation rate increased with increasing iron content, a terraced structure appeared and was pronounced for the fastest growing oxide on the 5 w/o Fe alloy. As the oxidation rate decreased with addition of iron beyond 5 w/o, the terraced structure became less pronounced.

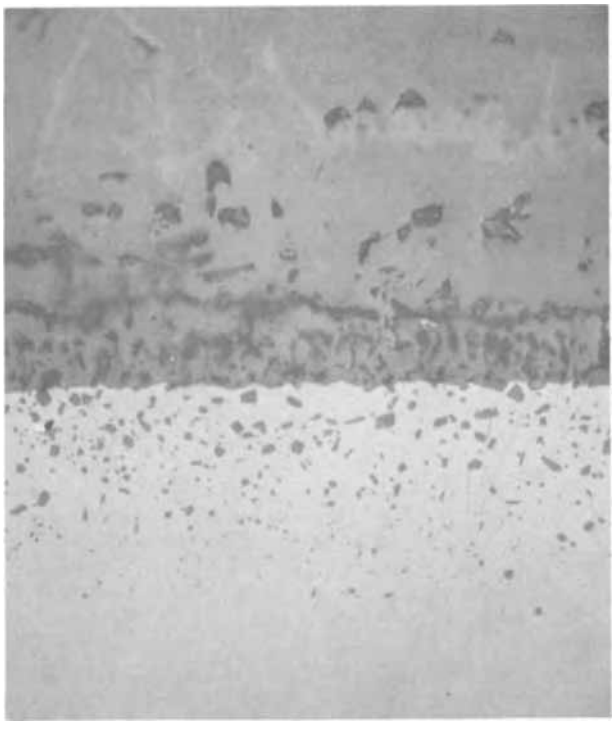

Fig. 8. Internal oxidation zone in a Ni-6 w/o Fe alloy oxidized for 47.5 hr, unetched (400×).

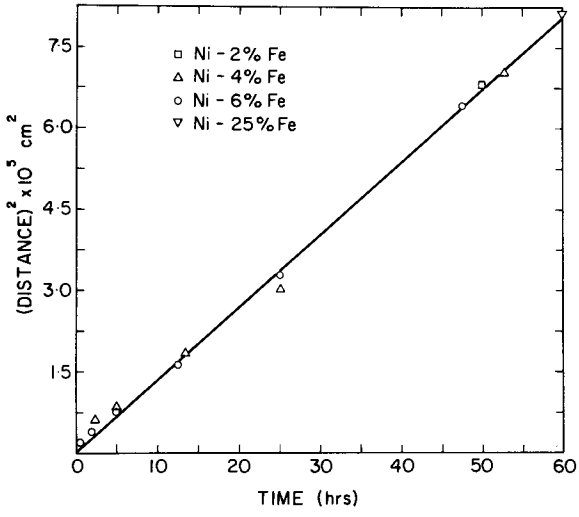

Fig. 9. Penetration of internal oxidation zone in Ni-Fe alloys containing 2-25 w/o Fe exposed at 1000°C to oxygen at 400 Torr pressure.

For slow growing nickel oxide on high iron content alloys, the surface was devoid of terraces as in the case of pure nickel.

Physical properties of the scales.—None of the scales on the oxidized specimens showed any tendency of breakaway during oxidation. The scales showed excellent adherence and the oxidation kinetics followed continuous curves. Scales formed on some alloys, however, showed a tendency to spall during quenching; the extent of spalling depended on the alloy composition and also on the time of oxidation. The tendency to spall appeared to decrease with increasing scale thickness.

The oxide scales formed on the alloys containing 2-6 w/o Fe showed excellent thermal shock resistance. Thus these scales were adherent even after quenching. Scales formed on the alloys containing 8 and 10 w/o Fe adhered to the alloy substrate fairly well after quenching. The scales formed on the 15 and 20 w/o Fe alloys, showed considerable tendency to spall whereas the scale on the Ni-25 w/o Fe alloy showed good adherence and spalling resistance.

The color of the nickel oxide scale was black at the oxide/gas interface and green at the alloy/oxide interface. The oxide scale surface on alloys containing up to 6 w/o Fe appeared black, glazy and with an orange peel texture. The surface of the oxide formed on alloys containing 8 and 10 w/o Fe showed dull and glazy areas. The appearance of the alloys containing 15 and 20 w/o Fe was dull. The 25 w/o Fe alloy showed a pronounced orange peel texture.

Scales formed on alloys containing up to 6 w/o Fe were relatively compact. Porosity was mainly observed at the alloy/oxide interface and it appeared to increase with increasing iron content of the alloy. Data were obtained on the rate of the external scale thickening by metallographic examination of specimens oxidized for different periods. Figures 11a and 11b show these curves for the alloys containing 2 and 4 w/o Fe. In the case of the first alloy, the thickening curve corresponds to the growth of a nickel oxide layer. The scale on the alloy containing 4 w/o Fe was of duplex structure consisting of an inner layer of nickel oxide and an

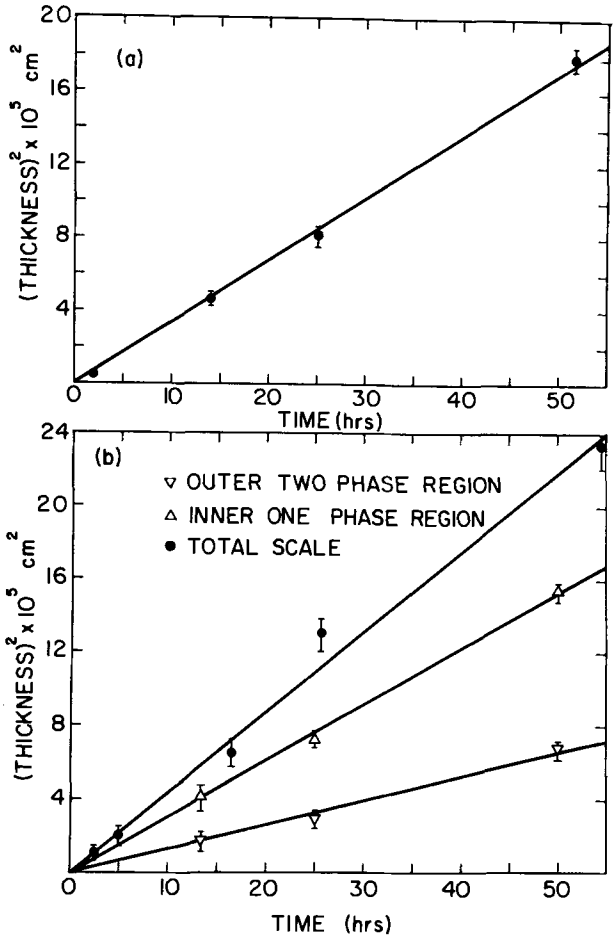

Fig. 11. Parabolic plots for scale growth: (a) the nickel oxide scale on a Ni-2 w/o Fe alloy; (b) the individual layers of nickel oxide, nickel oxide-spinel and the total duplex scale formed on a Ni-4 w/o Fe alloy.

outer layer composed of spinel growths in the nickel oxide matrix. Figure 11b gives the thickening of the individual layers as well as that of the total scale. It should be noted that the relative thicknesses of the two layers remain constant with time.

Iron and nickel distributions.—Several line scans were made for iron and nickel in the alloy and oxide phases in order to qualitatively determine their distributions. A line scan for iron and nickel in a Ni-8 w/o Fe alloy oxidized for 53 hr. is shown in Fig. 12. These metal profiles are typical for the alloys investigated, except that the alloy containing 2 w/o Fe did not show spinel formation in the external scale. It was observed from these profiles that iron tends to preferentially concentrate in the oxide phases. Thus there was a large degree of iron depletion in the alloy towards the alloy/oxide interface with a corresponding enrichment of nickel. The iron content of the alloy at the interface was sufficiently small for stabilization of nickel oxide in the external scale. Moreover, iron concentration in the inner single phase layer of the scale increased towards the oxide/gas interface.

Discussion

To the authors' knowledge, it has not been previously established that continuous and reproducible long time kinetic curves could be obtained for high-nickel alloys in dry oxygen. The present investigation shows that reproducible and continuous curves can be obtained. These findings should lead to a theoretical analysis for the oxidation properties of Ni-Fe alloys, and subsequent formulation of a mechanism for their oxidation kinetics based upon diffusional properties.

The results obtained in the present investigation demonstrated that nickel alloys containing up to 25 w/o Fe follow parabolic oxidation kinetics at 1000°C indicating that diffusion is probably the rate controlling mechanism. It is reasonable to assume that conditions of ambipolar diffusion and local equilibrium at interfaces would occur at this high temperature. The condition of local equilibrium is not satisfied, however, until constancy of composition at interfaces is attained. Thus, parabolic oxidation behavior was not found at short times, and it was only approached at long times.

Porosity in the oxide scales occurred mainly at the oxide/alloy interface, increasing with increasing iron content of the bulk alloy. However, the porosity was small and the oxide scales were essentially compact. Accordingly, one may postulate a mechanism based on diffusion through the different phases since the over-all reaction kinetics and growth of the individual reaction product layers followed a parabolic time dependence (Fig. 1, 2, 9, and 11).

As noted earlier, an iron-nickel spinel is formed both internally and externally during oxidation. A spinel, rich in iron, which has a comparatively low solubility product is precipitated within the alloy matrix. This precipitation is inferred to be brought about by oxygen supersaturation created within the alloy due to its high diffusivity (19, 20). Previous studies on the

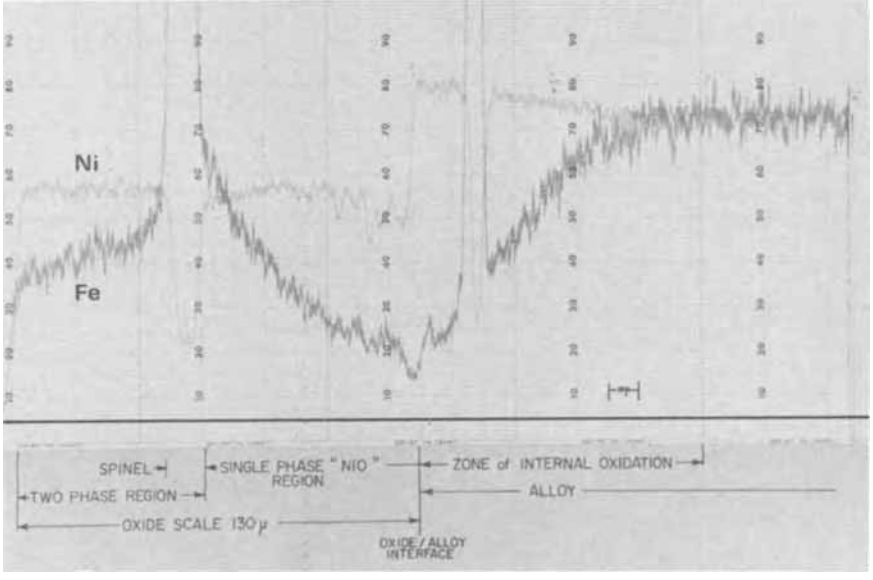

Fig. 12. Electron microprobe line scan for the distribution of iron and nickel in the alloy and oxide scale for a Ni-8 w/o Fe alloy oxidized for 53 hr at 1000°C and 400 Torr oxygen pressure. The datum for the x-ray intensities is indicated by the solid line at the bottom of the scale. Note that the scale for iron is approximately 10× that for nickel. The iron content of the alloy at the interface is less than 1 w/o.

Fe-Ni-O phase diagram at 1000°C have shown that a nickel oxide phase containing iron is stabilized for alloys containing greater than 99 w/o Ni (17). The electron probe results (Fig. 12) have shown that iron is intensively depleted in the alloy adjacent to the external scale. This depletion resulted from formation of iron containing spinel precipitates in the internal oxidation zone and dissolution of iron into the external scale. The occurrence of nickel oxide in the scale adjacent to the alloy/oxide interface is therefore consistent with the phase diagram.

The oxygen activity for these types of spinels increases with increasing nickel content. In fact, a spinel near the composition $NiFe_2O_4$ can coexist with oxygen near 1 atm pressure (17, 21). The spinel growths that occur within nickel oxide of the external oxide layer are high in nickel although quantitative analysis could not be carried out due to the small size of the particles. It is suggested that these particles coexisting with nickel oxide have not been merely carried into the external oxide layer from the zone of internal oxidation. Several observations may be advanced to support this viewpoint. Firstly, spinel particles could be detected almost up to the alloy/oxide interface within the alloy matrix; however, no spinel particles were detected within the scale at the alloy/oxide interface. Also, no inhomogeneities to be associated with the presence of spinel growths at any time were observed within the inner layer of the external scale. These findings indicate that spinel was dissolved rapidly at the nickel oxide/alloy interface. On the other hand, the spinel precipitates in the outer layer of the scale were remarkably stable. Since they did not show any tendency to dissolve in the oxide matrix, spinel would appear to exist in local equilibrium with nickel oxide. Secondly, the relative position of the two-phase outer layer containing spinel was fixed with time in the external scale and the relative thickness of this layer to the total scale thickness was constant (Fig. 11). This is not expected if spinel precipitates are left behind in the oxide layer as the alloy interface recedes inwards.

A schematic model for the oxidation of the alloys may be advanced based on the experimental results and the above discussion. This model is illustrated in Fig. 13 and is summarized as follows:

1. Iron tends to preferentially concentrate in the oxide phases resulting in its depletion in the alloy. In all the alloys containing up to 25 w/o Fe the shift in the alloy composition at the alloy/oxide interface is beyond the value where nickel oxide can coexist with the alloy phase (>99 w/o Ni). Thus nickel oxide is only stabilized externally to the alloy/oxide interface. For low iron alloys (*e.g.* Ni-2 w/o Fe), the external scale is virtually single-phase nickel oxide.

2. Spinel occurs as a second phase in an outer layer of the external scale for alloys with iron contents larger than 2 w/o. The relative thickness of the two-phase outer layer containing spinel and nickel oxide increases with increasing iron content of the bulk alloy.

3. The oxidation rates increase with increasing iron content of the bulk alloy until the spinel phase begins to precipitate in the external scale in substantial proportion. Spinel forms a high resistance diffusion barrier since the diffusion rates of cations in this phase are lower than in iron doped nickel oxide (22, 23). Spinel in a scale becomes copious as the iron content of the bulk alloy is increased. This results in blocking the diffusion of cations and hence effective reduction in the cross section for diffusion.

4. The amount of internal oxide increases with increasing iron content of the bulk alloy. Spinel precipitates in the zone of internal oxidation may block oxygen and metal diffusion in the alloy (22).

5. The double blocking effect of spinel in the external scale and the internal oxidation zone effectively reduces the oxidation rates for these alloys. The diffusion fluxes in the external scale and the alloy are coupled at the alloy/oxide interface and a resistance to diffusion in any one phase would reduce the over-all flux and result in reduction of the oxidation rate. This coupled blocking effect to diffusion of reactants does not change significantly over the alloy composition range 10-25 w/o Fe.

The particular shape of the curve for the parabolic constant *vs.* the bulk alloy composition (Fig. 3) is therefore due to the combined effect of increasing diffusivities of cations in nickel oxide with increasing iron concentration and the increasing blocking effect of spinel growths in the external scale and internal oxidation zone with increasing iron content of the bulk alloy.

Infrared Absorption of Chemical Vapor Deposited Borosilicate Glass Films

E. A. Taft

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

Diffusion sources of high-purity borosilicate films on silicon have been studied by infrared absorption over the full range of glass compositions. The relative strengths of the B-O and Si-O bands in the mixed glasses can be used as a monitor of the boron content of the films. The B-O absorption bands for glasses of high boron content show aging effects in moist air.

Infrared absorption will be shown to be a rapid, nondestructive test for boron concentration in deposited films of borosilicate glass. These films appear to be finding increasing use as diffusion sources for silicon processing (1-5). Older data on boron oxide glasses (6, 7) show the difficulty in removing water from the usual boric acid starting material, but different methods of preparation have shown infrared spectra to be characteristic of B_2O_3 (8). The spectra of the fully hydrated oxide, $B(OH)_3$, has been reasonably well established (9, 10). This paper shows the strengths of infrared absorption bands for pure borosilicate glass films of all compositions. Strong absorption due to the boron oxide in the film can be readily followed as the composition of the glass is changed.

The ratio of the strongest bands of B-O and of Si-O is used to monitor the concentration of boron oxide in the film. The effect of water absorption in the films is discussed.

Experimental Procedure

The reaction tube was made of 2¼ in. Pyrex and gases flowed downward over substrates sitting on a resistively heated substrate holder. The substrates were 1 in. wafers of 2 ohm-cm silicon. The holder temperature was 320°C, with argon carrier gas flowing at 4 CFH. One per cent silane in argon was normally used at 140 cm^3/min for deposition of SiO_2 films while oxygen was supplied at 20 cm^3/min. An adjustable flow of 1 per cent diborane in argon furnished the boron for the mixed oxide films. Growth rates depended on the gas ratios (5), but typical rates were on the order of 500 Å/min.

The infrared absorption of 0.5-1μ thick films was measured in transmission on a Perkin-Elmer 457 Grating Spectrophotometer. A clean silicon wafer was used in the reference beam. Thicknesses were observed by interference colors in reflection with occasional checks by ellipsometer measurements. The index of refraction of the glasses did not vary much from the value for silica of 1.47.

Key words: water, boron diffusion source, film stability.

Boron determinations were made on an Instrumentation Labs 153 Atomic Absorption Spectrophotometer; a Cahn Electrobalance was used for weighing the films.

Changes with time in the infrared absorption of films were observed under various constant humidity conditions.

Results

Infrared absorption.—The experimentally observed absorption coefficients of the principal bands in pure silicon oxide and in pure amorphous boron oxide films formed at these low temperatures are given in Fig. 1. The strongest band peak in SiO_2 at 1070 cm^{-1} (9.4μ) is about one-third smaller than that found in a thermally formed oxide, but it is slightly wider. Occasionally a small amount of hydrogen is seen in some films as is indicated by a broad weak absorption with absorption constant, $\alpha < 0.1 \times 10^4$ cm^{-1} at 3000-3640 cm^{-1} (3.3-2.75μ) and a sharper weak band at 880

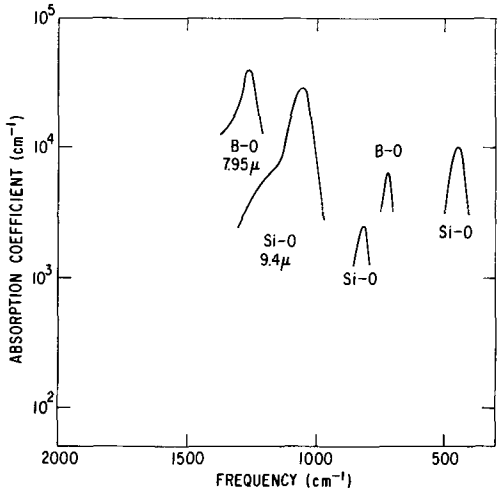

Fig. 1. The absorption coefficient of the major infrared bands in pure SiO_2 and in pure B_2O_3 pyrolytic films.

cm^{-1} (10.4μ) also with $\alpha < 0.1 \times 10^4$ cm^{-1}. The strongest band in B_2O_3 is the asymmetric mode at 1260 cm^{-1} (11) (7.95μ) with a peak absorption coefficient of 3.7 $\times$ 10^4 cm^{-1} making it about 1½ times as strong as the nearby SiO_2 band. The smaller symmetric band at 720 cm^{-1} (13.9μ) (11) has an absorption coefficient of 5 $\times$ 10^3 cm^{-1}. Several thicknesses of the same glass composition were employed to determine the background absorption.

In the mixed glasses there is some interaction of the boron and the silicon bonds within the oxygen lattice, but the two oxide networks do not greatly influence each other (12). Starting from pure SiO_2, as one adds small amounts of diborane to the gas mixture in making a glass film, weak bands of B-O begin to appear in addition to the normal Si-O absorptions. These bands first appear at 1390 cm^{-1}, 920 cm^{-1}, and 670 cm^{-1} (7.2μ, 10.9μ, and 15.4μ). With higher boron concentrations, the stronger Si-O bands clearly broaden and shift slightly in peak position. Figure 2 shows the shape and intensity of the infrared absorption regions in a glass containing approximately 15 (mole per cent) m/o of boron oxide. The arrows show the direction of the shifts in position and changes in intensity of the bands with increasing boron content. The Si-O peaks, of course, all decrease with decreasing silica content. The 720 cm^{-1} (13.9μ) symmetric vibrational mode of B-O does not initially appear at low boron concentrations. Instead it seems to be replaced by bands at 920 cm^{-1} (10.9μ) and 670 cm^{-1} (15.0μ). These bands increase to a maximum intensity as indicated in Fig. 2, then decrease as the boron content of the film continues to increase. As these two bands disappear the 720 cm^{-1} (13.9μ) absorption band appears at very high boron compositions. To further illustrate the behavior of the infrared absorption in the mixed glasses, the approximate absorption coefficients of the six major bands in this boron-silicate glass system are plotted in Fig. 3. The abscissa has been chosen as the ratio of the amount of diborane gas to the amount of diborane plus silane gas flowing through the reactor. The 15 m/o glass of Fig. 2 is found near a gas ratio of 25%.

Boron calibration.—As the B-O and Si-O absorptions remain separate, although slightly interacting, the boron content can be measured as a fraction of the silicon content in the oxide lattice. Using the ratio of the 1340 cm^{-1} (7.45μ) B-O peak absorption to the 1070 cm^{-1} (9.4μ) Si-O peak absorption, the sample thickness need not be determined in arriving at the glass composition. This ratio has been used by other

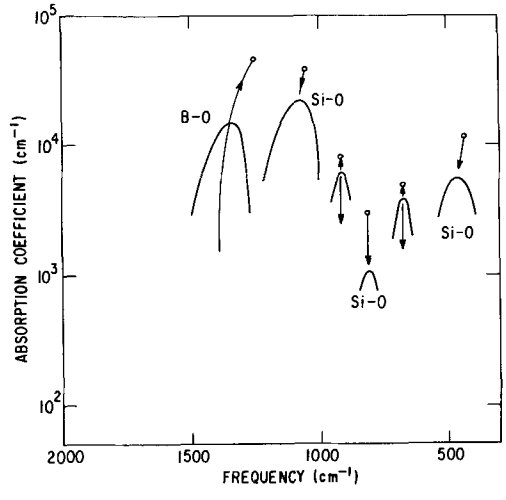

Fig. 2. Infrared bands appearing in a silicon oxide base glass containing approximately 15 m/o of boron oxide. The arrows indicate the direction of shift of the peaks with increasing boron oxide.

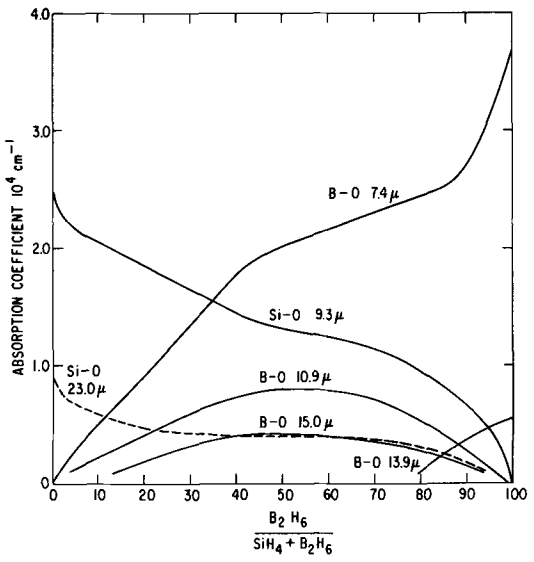

Fig. 3. Absorption coefficient of the major infrared bands in borosilicate glasses. The abscissa is the per cent of diborane gas to diborane plus silane gas flowing to the reactor.

workers with thin films (13-16). Films of from 1/2 to 1μ thickness and 300 μg weight were prepared; the film weight was determined by difference weighings on the 200 mg silicon wafers. The films were dissolved in a 10% HF solution and a 10 ml sample was aspirated in the flame spectrometer. The calibration of the boron content was obtained from standard solutions of boric acid. The mole per cent of B_2O_3 in the mixed glasses as a function of the infrared peak ratios is given in Fig. 4. The scatter in the data comes mostly from the boron determinations by the flame spectrometer. The glass of Fig. 2 while having a preparation gas ratio of nearly 25% B_2H_6 has about 15 m/o B_2O_3 in the finished film.

Water absorption.—Little change was noted in the glass of Fig. 2 after three days' exposure to room atmosphere. However, a pure boron oxide film even when covered with 2500Å of SiO_2 glass takes up a considerable amount of water during this same time. Without a cover, the pure boron oxide glass will show water absorption from the air within minutes after exposure.

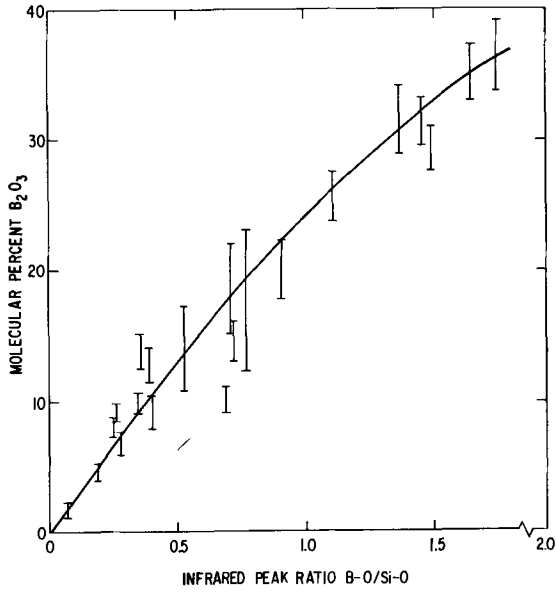

Fig. 4. A calibration of the m/o B_2O_3 in a borosilicate film against the infrared absorption peak ratio for the strongest B-O and Si-O bands at 1340 cm^{-1} and 1070 cm^{-1}.

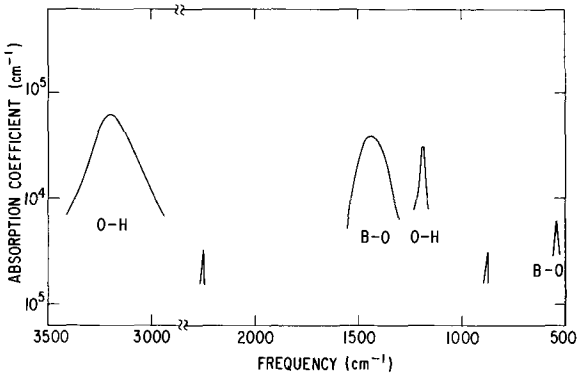

Fig. 5. Absorption coefficient of the infrared bands appearing in a highly hydrated B_2O_3 film.

This change in the film is observed in infrared absorption through the appearance of a number of B-O and O-H bands.

These new bands are identified with $B(OH)_3$ (9, 10); the approximate absorption coefficients of a hydrated boron oxide film are given in Fig. 5. The progress in the hydration of a pure B_2O_3 film can be observed through the infrared absorption changes. First to appear are the strong O-H band at 3220 cm^{-1} and a new B-O band at 1450 cm^{-1}. These bands of $B(OH)_3$ grow at the expense of the B-O bands of B_2O_3 which retain their wavelength positions. Also the new bands appear and increase in strength with no change in wavelength. These facts suggest that the film is two-layered with $B(OH)_3$ overlying the B_2O_3. Further hydration adds the sharp band at 1325 cm^{-1}, and the smaller sharp bands at 2250 and 540 cm^{-1} develop last.

In mixed B_2O_3-SiO_2 glasses the changes that take place in the film are slower. Observations of the stability of the films in controlled humidity tests indicate that water is taken from the air and incorporated in the film. In all deposited borosilicate glasses only a small absorption at 3570 cm^{-1} is originally observed—presumably caused by Si-O-H. Upon exposure of the glass to water vapor this absorption increases and absorption near 3340 cm^{-1} appears. Eventually the film exhibits a broad absorption beginning at 3640 cm^{-1} and tailing out beyond 2900 cm^{-1}. This band can be removed by heating the film for an hour at 400°C.

The main B-O absorption band near 1340 cm^{-1} decreases in amplitude upon exposure to water vapor. Heating the film at 400°C has no effect on this decreased value. The decrease with time in the B-O absorption band at two boron concentrations and at several relative humidities is shown in Fig. 6 and 7.

From Fig. 6, for films containing about 30 m/o B_2O_3, the infrared absorption ratio drops about 50% in two days at 50% relative humidity. From Fig. 7, 25% B_2O_3 films show a decrease of only 10% in two days at 50% relative humidity. The water sensitivity of the films is thus strongly dependent on the B_2O_3 content. The drop in the infrared ratios at 0% humidity is, no doubt, primarily caused by the short time exposures of the wafers to room air while measurements were made. A film containing 20% B_2O_3 has been exposed to normal laboratory atmosphere with relative humidities varying from 30 to 60%. As seen in Fig. 8, the infrared ratio is still dropping after more than a year's time. Also in Fig. 8 is a 10% B_2O_3 film which changes little with time even under 80% relative humidity.

A very rapid pickup of water occurs in borosilicate films of > 25% B_2O_3 content when they are exposed to relative humidities of > 50%. Within minutes after exposure the O-H band of $B(OH)_3$ appears at 3200 cm^{-1}. Often a visible haze appears on the wafer as the $B(OH)_3$ is formed in the borosilicate glass. The

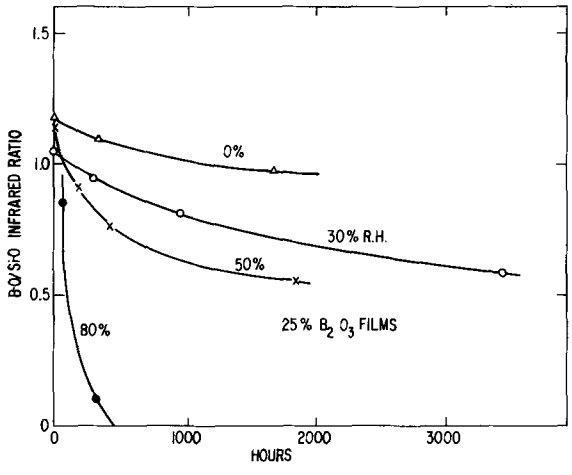

Fig. 7. The decrease with time of the B-O/Si-O infrared peak ratio for 25 m/o B_2O_3 in a borosilicate film exposed to various relative humidities in air.

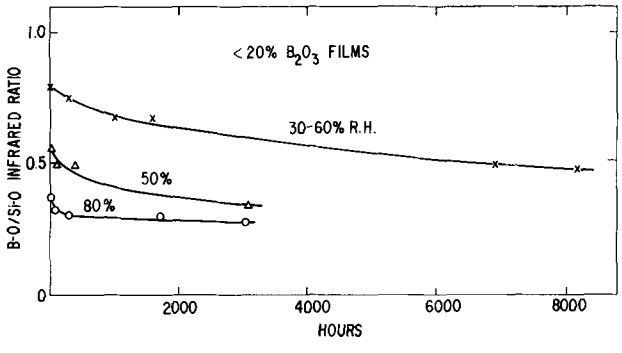

Fig. 8. The decrease with time of the B-O/Si-O infrared peak ratio of 20%, 14%, and 10% B_2O_3 borosilicate glass films exposed to various relative humidities in air.

1450 cm^{-1} band of $B(OH)_3$ also appears, usually as a shoulder on the nearby B_2O_3 absorption peak. The sharper band at 1180 cm^{-1} will also develop with time. Interestingly enough, these $B(OH)_3$ bands after maximum development with time will decrease in amplitude and essentially disappear. A film with this history is then not distinguishable from another film that has not shown the transient $B(OH)_3$ absorptions

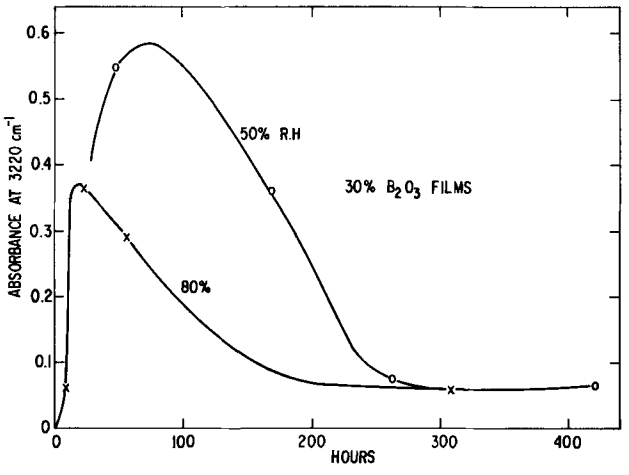

Fig. 9. The change with time in the B-O-H absorbance of a 30 m/o B_2O_3 borosilicate exposed to high relative humidity air.

but has, over a much longer period of time, also degraded insofar as the infrared absorption of B-O is concerned. The rise and decay of the 3200 cm^{-1} B-O-H band in high boron content films as a function of time is shown in Fig. 9 for two films exposed to different relative humidities. Heating of the films will remove the very broad residual absorption at 3640-3000 cm^{-1}, whereupon boron is no longer detected as either B-O or B-O-H. However, a diffusion step readily shows that much of the boron remains in the film presumably in a form which is not infrared active.

Densified films (those which have received a 10 min bake in argon at 800°C) are characterized by a decrease in the peak amplitude of the B-O absorption and an increase in the Si-O peak. The ratio of the peaks, for the same boron content of the film, drops some 30% depending on composition and the degree of heat treatment. The B_2O_3 calibration curve of Fig. 4, therefore, cannot be used for densified layers. However, the hydration in air of the densified films appears to be little different from that of the as-deposited glasses of the same boron content. Valletta *et al.* (14) also observed the water sensitivity.

The borosilicate films of Fisher (2) were covered by 3000Å of SiO_2. The densified films of Kern and Heim (15) were considered stable although the B_2O_3 content was stated to be 17%. Over long periods of time, water effects would no doubt be observed through infrared absorption in these films. For short periods, the water uptake will be delayed by SiO_2 glass overlayers. This modification is especially important for borosilicate glasses containing > 25% B_2O_3 (17).[1]

[1] J. W. Sprague uses thin SiO_2 covers to get short-term stabilization of high boron content films.

Conclusions

Borosilicate films on silicon wafers are readily identified as to boron content using infrared absorption characteristics. Once a calibration has been made, the ratio of the B-O to the Si-O absorption peak gives the molecular percentage of B_2O_3 in the film (18).[2] Water absorption at high humidities in films containing > 25 m/o B_2O_3 is rapid, but the pickup rate can be controlled in normal usage by the use of thin SiO_2 glass cover layers.

Acknowledgments

The help of P. R. Kennicott with the boron calibration and stimulating discussions with D. M. Brown are gratefully acknowledged. G. J. Charney prepared the glass films; R. F. Reihl measured the boron content of the films.

Manuscript submitted April 8, 1971; revised manuscript received June 30, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

[2] The boron content of similar glass films has been checked by another method by A. S. Tenney. He has done intensive work on deposition of films and the boron analysis.

Electrical Properties of Anodic Oxide Films of Ta, Nb, Zr, Ti, W, and V Formed by the Ion-Cathode Method

D. Husted, L. Gruss, and T. Mackus

Pitman-Dunn Laboratories, Frankford Arsenal, Philadelphia, Pennsylvania 19137

ABSTRACT

Amorphous oxide films have been grown on Zr, Ti, W, Ta, Nb, and V by ionized gas anodization using the ion cathode as a source of negative ions. Films were grown on each metal at constant current to 175V followed by constant voltage for about 4 hr. Several electrical and optical properties were measured for the anodic films produced on these refractory metals. Resistivities of the anodic oxide films on Zr, Ti, W, Ta, Nb, and V ranged from 10^{14} to 10^{17} ohm-cm. Breakdown voltages with the refractory metal positive (gold contact negative) were of the order of 31V to 111V. Film capacitances for these metals varied between 0.031 and 0.050 μf/cm^2, and the dissipation factors averaged 0.015 for all the oxides except V which was 0.062. Thicknesses and refractive indices were obtained by ellipsometry for anodic films on Ta and Nb. Film thicknesses were respectively 0.61μ and 0.57μ for Ta and Nb whereas the refractive indices were 2.1 and 2.0. Dielectric constants calculated from capacitance measurements for these anodic films were 22 and 28, respectively. The properties of films prepared by the ion cathode method are compared with those produced by plasma and solution methods reported by others.

The technique for ionized gas anodization utilizing an ion cathode as the source of negative charge carriers was first devised and used at this laboratory for tantalum (1). O'Hanlon (2) re-emphasized the basic differences between our apparatus and those of others. In this method, anodization occurs outside of the concentrated ion plasma region so that the electron and positive ion density in the gaseous electrolyte near the anode is limited while the relative negative ion concentration is increased, with the advantages that anode temperatures out of the main discharge region are lower and film growth may be directly observed without the masking effects of a general discharge.

This paper reports an extension of the earlier work on tantalum (1) in which we attempted to optimize the film growth cycle and to improve film properties such as breakdown potential for thin film applications in electronics. In addition, ionized gas anodization using the ion cathode as a source of negative ions has been extended to Zr, Ti, W, Nb, and V metals. Plasma anodizations of some of these metals have been reported previously by others (2-5). Vratny (6) compared the properties of tantalum films obtained by vacuum techniques with those prepared in solution concluding that the latter films were superior with respect to growth rate and dielectric strength, but that in other respects such as uniformity of thickness and nonshort yield, the gas phase films were very promising. Plasma anodization results on tantalum and niobium by Lee *et al.* (4) stressed the analogy between gas and solution grown films, especially that two layers form in plasma grown films just as during ordinary solution anodization. They infer from this that both metal and oxygen ions are mobile in the solid phase during gas phase anodizations. Some other metals, for example V and Be, cannot be anodized in aqueous electrolytes because their oxidation products rapidly undergo dissolution. It follows that an alternative way to grow an anodic film on these metals would be in a nonaqueous media or by a plasma technique. In 1957, the growth of anodic oxide films on a series of metals including V in an aqueous boric acid-ammonia solution was studied by Johansen *et al.* (7). They concluded for V that either an extremely porous film forms or that the oxidation product is rapidly undergoing dissolution. Young (8) has suggested that anodic oxide films on V would probably best be studied in partly nonaqueous solutions. Keil and Salomon (9) found that uniform anodic V_2O_4 films can be grown on V in acetic acid-tetraborate solutions which contain small quantities of water and when the current densities exceed 450 μA/cm^2. To the best of our knowledge no previous work has been reported in the literature on the vapor phase or plasma anodization of V, nor for Ti and W except for some unpublished data referred to by O'Hanlon for these latter two elements (2). Successful preliminary results for Ti have been mentioned (10). We undertook this work in order to obtain films by the ion-cathode method with which to compare films obtained by other methods. Using techniques previously acquired with Ta (1), our hope was to apply the ion-cathode technique to obtain oxide films possessing high-breakdown voltages, electrical resistances and capacitances with low dissipation factors on other Group 5 and some Group 4 and 6 metals.

Key words: thin films, gas phase anodization, resistance, breakdown voltage, capacitance.

Experimental

The metal anodes were 99.5-99.8% pure except for Zr (98.0%). All of the metals, purchased in rod form with diameters of 2.4 cm, were cut to a length of 1.27 cm for use as anodes. Only one face of the metal disk was used in the anodization process. This surface was mechanically polished to a bright mirror-like finish, washed in warm tap water, rinsed with distilled water and spectrographic grade methanol, and then dried with a stream of dry nitrogen. The metal disk was then mounted in the anodization apparatus. The method of mounting and masking the anodes (Fig. 1) was described previously (11). The anodizations were carried out in an all metal, double base plate, ultra high vacuum system. Oxygen pressure was controlled by a variable leak. Details of the ion cathode have been described previously (1).

Prior to anodization the system was evacuated to 3 $\times$ 10^{-6} Torr and then backfilled with oxygen and held at a pressure of 85 milliTorr during the anodization process. The ion cathode current was maintained at 80 mA by the application of approximately -800V. Anode temperature was monitored using the thermocouple arrangement shown in Fig. 1. Since it is some

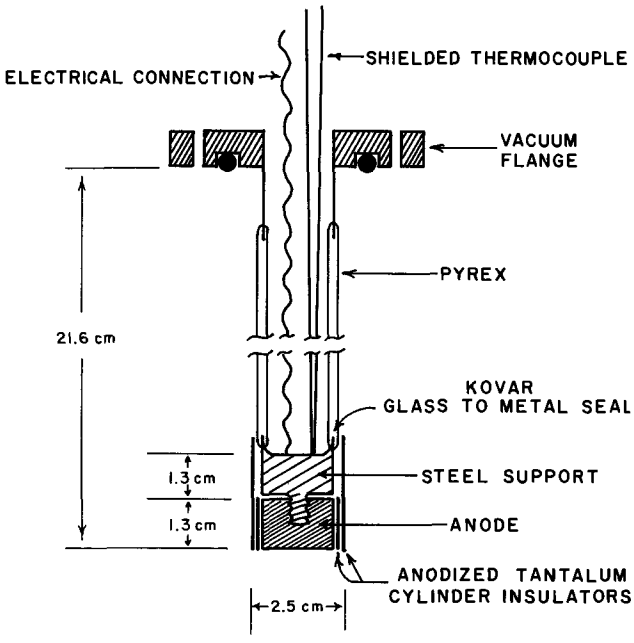

Fig. 1. Method of mounting and masking the metal anode

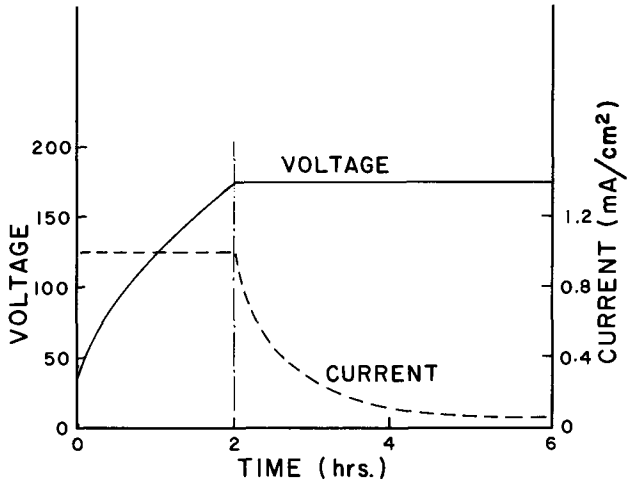

Fig. 2. Typical voltage, current, time relationships during the film growth cycle; current is held constant at 1.10 mA/cm² until the voltage reaches 175V, voltage is then held constant while the current decreases to a minimum value.

distance from the actual anode surface, the temperature measured by this thermocouple was checked against that of a thermocouple actually embedded in a hole drilled into the back of an anode to within 2 mm of the anode surface. The temperatures measured at both points were the same. Anode temperatures never exceeded 105°C.

In our earlier procedures (1) films were grown by anodizing at a constant anode current density to a preselected voltage at which point the anodization was stopped. This process produced films that were clear and uniform but with low breakdown voltages. In order to improve breakdown voltages, we experimented with extended film growth cycles. Being guided by our previous experiences in liquid phase anodization, we used the following cycle: the film growth potential was increased to its maximum value (max. = 175V due to leakage around the anode mask) maintaining a constant current density as the film grew. This operation was followed by a period of four hours during which the maximum potential was maintained while the leakage current fell to values of 0.08, 0.03, 0.08, 0.02, 0.09, and 0.15 mA for Zr, Ti, W, Ta, Nb, and V, respectively. Figure 2 shows an example of the growth cycle. This procedure resulted in improved breakdown voltages but at the expense of poor film uniformity. Anode current densities over the range 0.06-2.20 mA/cm² were investigated to determine the best growth conditions for attainment of uniform films. At 1.10 mA/cm² acceptable uniformity of oxide thicknesses resulted. Film uniformity was monitored by observation of interference colors. The typical film appears uniform in color indicating a uniform thickness across most of the surface of the specimen except for within approximately 3 mm of the anode edge.

Using the above procedure, films grown on Ta, Ti, Zr, Nb, W, and V exhibited strong interference colors, and were firmly adherent. Anodic films were grown on duplicate samples of each metal under identical conditions, and film resistance, capacitance, dissipation factor and breakdown voltage were measured. All measurements were in air, at room temperature, with the relative humidity limited to a maximum of 30%. After removal and exposure to air, gold contacts were vapor deposited onto the film surface using a suitable mask. Silver contact paint was then used to attach a copper wire to the gold contact. The contacts were circular, 0.021 cm² in area and arranged in a 3 row by 6 column array. Electrical properties of the anodic films could be measured through these contacts. The thickness and refractive index of the oxide films on Ta and Nb were measured using a Rudolph Ellipsometer. The dielectric constants of these films were calculated from capacitance measurements. Film resistance was measured using a Keithley Model 610B electrometer. Three contacts per sample were measured, using a potential of 4.0V, with the metal anode at a positive potential and the gold contact negative. Long polarization times were encountered during which the resistance increased with time. The mean final resistances are listed in Table I. The values reported are those

V	31 ± 15	12-57	22 ± 13	6-35	(5.4 ± 5.0) × 10^{11}	0.10-1.5 × 10^{12}	0.050 ± 0.002 (19)	0.062 ± 0.016 (19)

recorded 210 min after the voltage was applied, by which time the resistance had stabilized. No attempt was made to determine whether or not this polarization was reversible by heating or by annealing. It would be necessary to heat tantalum oxide, for example to greater than 500°C (12) for effective annealing in order to determine whether the potentials were due to solid-state transitions or to a resistance polarization caused by semiconductor effects such as a lowering of acceptor density. A General Radio 716 C capacitance bridge was used to measure capacitance and dissipation factor at 1 kHz. Approximately ten contacts per sample were measured and the mean capacitance and dissipation factor for each film is shown in Table I.

Film breakdown voltage was determined by application of a d-c potential to the sample and monitoring the current. The procedure was to raise the voltage to a specific value while monitoring the current. If no current could be observed after 30 sec, the circuit was disconnected, the voltage raised by about 3-6V then the circuit was closed again and the procedure repeated. Breakdown was usually sharp and catastrophic, but in some measurements a significant leakage current would begin to occur before breakdown. In these cases the voltage at which current leakage reached 0.01 μA is reported as the breakdown voltage. This latter procedure is similar to that used by Schwartz and Gresh (13) and Vromen and Klerer (14). Self-healing breakdown would not be observed under our experimental conditions because the RC time constant of our circuit (the measuring circuit incorporated a one megohm resistor) was of the order of a millisecond while the characteristic time for self-healing is of the order of 1 μsec.

Results and Discussion

Using the results of earlier workers (2-6), we presumed that the films reported here are oxides and amorphous. Nevertheless we searched for evidence of crystallinity in the films by normal x-ray diffraction procedures and back-reflection techniques and by electron diffraction methods. These efforts failed to indicate any crystalline oxide. Low angle x-ray diffraction patterns were broad and diffuse. Electron diffraction results were confusing due to space charge effects. Efforts to minimize these effects by depositing a thin carbon film on the anodized film surface were helpful, but no pattern could be observed in any case. In addition, infrared absorption spectra in the range from 4000 to 250 cm^{-1} by the Attenuated Total Reflectance method proved only that the Nb films absorb at near 800 cm^{-1} as did both pure Nb_2O_5 and NbO_2 used as standards. Thus we can conclude only that the films are either amorphous oxides or composed of very small crystallites. The space charge effects observed in the electron diffraction study and their poor conductivity indicate that the surfaces of the anodized films were of higher oxides of the metal. Lower oxides, *e.g.* TaO_2, would possess extra "d" electrons, and hence they would be the more conductive oxides. This is not to say that the anodic films are purely higher oxides. Probably, anodic oxide films of a metal, for example Ta, are a mixture of Ta_2O_5 and TaO_2 as well as nonstoichiometric oxides.

Breakdown voltages (Table I) were measured on two films, each having 6 contacts with the metal side of the anode disk held at a positive potential and 2 contacts with the metal side negative. Breakdown voltage was higher for the metal positively charged for all the oxides (Table I). Several possible causes for this polarity have been suggested such as differing work functions of the contact metal (15), local inhomogeneities in the oxide, or the effects of moisture on conductivity in the anodic direction (13). The data in Table I show that high values of breakdown voltage and film resistance (corresponding to resistivities of the order of 10^{17} ohm-cm, if film thicknesses are about 0.6μ) may be obtained by the ion-cathode method. The large scatter of breakdown voltage measurements was to be expected based upon the experiences of others (16). The follow-up current in breakdown as measured in this work probably augments the initial melting and evaporation damage. Catastrophic breakdown was to be expected in view of the geometry and thickness of the electrodes, and the probable weak spots in the film aid in breakdown and contribute to the scatter in the data. Breakdown strengths of the order of 1×10^6 V-cm^{-1} for ion-cathode grown films on Ta may be compared with the breakdown strengths of tantalum oxide films obtained by aqueous methods (14) and by usual plasma techniques (6, 13, 14). The breakdown strengths of vapor-anodized niobium oxide films are also comparable (17). The breakdown voltages in a forward (metal positive) direction for oxide films grown on Zr, Ti, W, and V metals are 111, 83, 66, and 31V, respectively. If we assume that the thickness for each of these oxide films to be about 0.6μ then their breakdown strengths can be estimated accordingly. Breakdown strengths for plasma grown Zr oxide (5) and for vapor reaction Ti dioxide (18) are comparable to ours.

Breakdown voltages and film resistances for tantalum and niobium oxides appear to be greater than those obtained on vanadium oxide, while film capacitance and dissipation factor for vanadium oxide were greater. Higher resistances appear to be consistent with the bandgap energies obtained by spectroscopic means. Bandgap energies corresponding to the onset of electrical conduction are 3.72 eV for Ta_2O_5 (12), 3.03 eV for Nb_2O_5 (12) (19) compared to about 2.15 eV for V_2O_5 (19). For ZrO_2 (12) and TiO_2 (19) (20) the optical bandgap energies are 5.03 eV and 3.00 eV, respectively. However, because the films are probably a mixture of oxides, these data for higher oxides serve only to indicate the relative resistances of the films studied. For example, the anodic film of Ti may be a mixture of oxides including TiO_2 since its resistivity and breakdown voltage is higher than what would be expected on the basis of its optical bandgap. Similar data for W is unavailable. The dissipation factor of vanadium oxide was not only higher initially, but increased with time on standing. One V sample increased from 0.49 to 0.92 after standing at a relative humidity of $\leq$30% for 168 hr at room temperature. This could be due to absorption of water vapor by the oxide films. The other oxides increase in dissipation factors and capacitances with increasing relative humidity possibly also due to the adsorption of water into pores or flaws in the film. The changes are reversible. For example, in a sample of titanium oxide a large increase in relative humidity (from approximately 13% to 60%) caused the film capacitance to increase by 12% and the film dissipation factor to increase from 0.013 to 0.041 and decrease the same amount in dry atmosphere. Another indication of higher porosity may be the limiting current densities of the films, *i.e.* lower limiting current densities should correspond to a lower porosity. It is to be noted that V had the highest limiting current indicating that the film might possess a high porosity which may account for the higher dissipation factor and low resistance of the V film.

The ellipsometric thickness and refractive index measurements of the anodic films for Ta and Nb are given in Table II. Computations were performed using a program obtained from the National Bureau of Standards (21). In order to measure film thickness by ellipsometry it is necessary to know the optical constants of the film free substrate. However most metals, Au being the only exception (22), are thermodynamically unstable in the presence of oxygen at room temperature, and it is difficult to have a film free surface at the outset. For example, Ta in air, is typically covered by an oxide film about 70Å thick which leads to

Table II. Film thickness and refractive index as determined by ellipsometry

Dielectric constant calculated from capacitance measurement. Values are the mean for two films formed under identical conditions on ion cathode anodized metals.

	Film thickness (μ)	Refractive index at 5461Å at 25°C	Dielectric constant at 1 kHz
Tantalum	0.61	2.1	22
Niobium	0.57	2.0	28

large errors in the determination of the refractive index and extinction coefficient of the Ta metal base (23). The thickness and refractive index results for the films on Ta and Nb given in Table II are based upon the literature values of the optical constants obtained by the curve fitting technique for Ta and Nb metals (23, 24). The values of refractive index, 2.1 for tantalum oxide and 2.0 for niobium oxide, are somewhat lower than the values found in the literature for similar films prepared in an aqueous electrolyte. Kumagai and Young report 2.26 for tantalum oxide (23) and Young and Zobel report 2.37 for niobium oxide (24), both values being determined by ellipsometry. Lee *et al.* (4) found that oxides of Ta and Nb formed by gas anodization and ordinary anodization consisted of two layers with the layer closest to the metal surface being richer in metal atoms. The refractive indices obtained by Lee *et al.* for Ta were 2.22 for the inner layer and 1.89 for the outer layer. For Nb a value of 2.37 is found for the inner and 2.15 for the outer layer. Our data are consistent with Lee and co-workers if we assume that our films are like his outer films but that more time for migration of the ions has been allowed. The ionized gas oxide layer is probably richer in oxygen than inner oxide layers.

Anode glow was visible adjacent to the entire surface of each metal during anodization. The intensity of the glow seemed to remain constant up to the maximum voltage, but noticeably decreased during constant voltage anodization at 175V until at the limiting current, glow was either absent or at most barely visible. Glow is associated with the rate of oxide formation (1, 25). Although anode glow was visible over the wafer during anodization there was no evidence to indicate that film sputtering had occurred. However, Jennings and McNeill (11), working with the very same apparatus reported here, have observed Au film sputtering when the Au was biased positively with respect to the anode. They measured the sputtering rate of the Au to a maximum bias of 200V and showed that the Au sputtering is due to negative oxygen ion bombardment. This observation with Au serves to indicate that the metals studied here may also sputter but not by a significant amount.

Finally, the electrical properties of the anodic films formed in the ion cathode apparatus are consistent with those formed by other methods.

Resistance measurements given in Table I correspond to resistivities of the order of 1.40×10^{17}, 5.95×10^{17}, 4.90×10^{16}, 1.86×10^{16}, 9.1×10^{15}, and 1.89×10^{14} ohm-cm for Zr, Ti, W, Ta, Nb, and V respectively, again assuming thicknesses to be 0.6μ. These may be compared to resistivities of plasma anodized Ta (4, 6) and Nb (4, 24), vapor deposited Ti (18) and liquid phase oxide films of Ti (26), Ta (4), Nb (4), and oxides of vanadium (27). Capacitances and dissipation factors of the ion-cathode anodized metal films may be compared to the data obtained with films of Zr (28, 29), Ti (18, 26), Ta (30), Nb (31) anodized in solution, and with vapor anodized films on Ta (6) by reactive sputtering. The data for anodized films by various methods show inconsistencies but we can conclude with certainty that films deposited by the ion-cathode method are at least comparable in desirable electrical properties to those of solution and normal plasma anodization.

Conduction in Al_2O_3 Films and Charge Storage in MAOS Structures

C. A. T. Salama*

Department of Electrical Engineering, University of Toronto, Toronto 181, Ontario, Canada

ABSTRACT

The conduction characteristics of aluminum oxide films deposited by rf sputtering on silicon substrates and ranging from 400-600Å in thickness were measured over a range of temperatures. It was found that the current transport is essentially bulk limited and independent of the film thickness, the electrode material, and the polarity of the electrode. The three processes which affect the conduction through these films were found to be: Poole-Frenkel emission, field ionization, and trap hopping. The various parameters such as temperature and gate electrode affecting the charge storage in MAOS memory elements, were investigated using an automatic measurement set up and were related to the conduction characteristics of the two insulating layers. The memory elements consisted of 400-600Å thick Al_2O_3 films deposited by rf sputtering on thermally grown SiO_2 layers 50Å thick. The charging and memory retention characteristics of the MAOS structure were also investigated. The effect of charge transport across the silicon dioxide on the surface state density at the $Si-SiO_2$ interface was also observed.

The possibility of using charge storage in a dielectric, which forms the gate insulator of a field-effect transistor, in memory applications has attracted considerable interest and led to an intensive investigation of these structures. Most of the attention has been focused on charge storage in MNOS (metal-silicon nitride-thermally grown silicon dioxide-silicon) structures (1-11). The memory effect is characterized by a shift in the flat-band voltage of the MNOS capacitor under application of a stress field above a certain threshold. This threshold field is typically $1\text{-}3 \times 10^6$ Vcm^{-1} and causes sizable tunneling (3) or conduction (6), across the thin (20-300Å) silicon dioxide layer. The shift in the flat-band voltage is due to accumulation of charge in trapping centers at the interface between the two dielectrics or in the silicon nitride (3-5). The charge accumulation is semipermanent, and charge retention is limited only by current leakage across the dielectrics. The stable charge storage at the silicon nitride-silicon dioxide interface has led to the application of MNOS structures in alterable read-only semiconductor memories and digital circuits with nonvolatile storage capabilities.

The use of other dielectrics, like aluminum oxide instead of silicon nitride, has received relatively little attention. Nakanuma (12) reported the fabrication of a read-only memory consisting of MAS (metal-aluminum oxide-silicon) FET's (field effect transistors) which exhibited threshold voltages alterable both electrically and by radiation. The aluminum oxide films in these devices were deposited by hydrolysis of $AlCl_3$ at 850°C. The charge storage was characterized by positive shifts in the threshold voltage which occurred independently of the polarity of the applied stress bias, provided this bias was higher than a critical value. This phenomenon was explained by Tsujide (13) as being due to electron injection and trapping in the aluminum oxide. The trapped electrons have an extremely long lifetime, hence the good memory retention characteristics.

MAOS (metal-aluminum oxide-thermally grown silicon dioxide-silicon) structures using aluminum oxide films prepared by oxidation of trimethyl aluminum in an oxygen atmosphere at 450°C, as well as aluminum oxide prepared by plasma oxidation of an aluminum film, exhibited a memory behavior which was characterized by positive and negative shifts in the flat-band voltage for positive and negative applied stress bias respectively. The devices, however, exhibited poor reproducibility and high incidence of breakdown (4).

MAOS structures, in which the Al_2O_3 films were prepared from an $Al\,Br_3\text{-}NO\text{-}H_2$ mixture, exhibited positive flat-band voltage shifts for positive applied stress bias; while for negative bias, the flat-band voltage shift was positive at low voltages and became negative as the stress bias increased (14).

The object of this paper is to investigate the charge-storage properties of MAOS structures consisting of rf sputtered aluminum oxide films (15) deposited on a thin (50Å) layer of thermally grown silicon dioxide. The macroscopic model of the memory element, based on the differential conduction properties of the two insulators (6), is briefly reviewed here. The conduction characteristics of rf sputtered Al_2O_3 films are then investigated and related to the charge storage properties of the MAOS structures.

Theory

Macroscopic model of the memory effect.—A macroscopic model which predicts the charging and discharging behavior of the MNOS capacitor structure in terms of the field-dependent conduction characteristics and geometry of the two insulators was developed by Frohman-Bentchkowsky (6). This model has been used to verify the experimental characteristics of MNOS memory devices. The generality of the model makes it useful for any two insulators of arbitrary thickness on an arbitrary semiconductor, and it will be applied here to the MAOS structure.

Qualitatively the memory behavior can be understood as follows. When a stress voltage, V_c, is applied across two insulating layers having different field-dependant conductivities, particle currents will flow in both insulators. Charge accumulation at the insulators' interface will occur when the particle currents in the two layers differ in magnitude. The polarity of the charge depends on the relative magnitude of the two currents. As charge builds up at the interface, the field in each layer will change such that particle current in the layer of high conductivity will decrease while particle current in the layer of lower conductivity will increase. Charge accumulation will stop when the currents become equal. When the applied voltage, V_c, is removed, the field due to the stored charge sheet will cause the charge to leak off by a conduction mechanism appropriate to the individual insulating layer.

* Electrochemical Society Active Member.
Key words: dielectric, thin film, memory.

The value of the two insulator layer structure as a memory device lies in the highly nonlinear conductivity with applied voltage of one of the two layers (in this case aluminum oxide). Because of this, charging (writing) can be accomplished rapidly with relatively high applied voltages while the loss of the charge occurs very slowly at lower biases (during interrogation) or at zero bias (during storage).

The equations describing the memory behavior of the MAOS structure are

$$K_o E_o - K_a E_a = Q_i/\epsilon_o \quad [1]$$

$$X_o E_o + X_a E_a = V_c \quad [2]$$

$$J_o(V_c,t) - J_a(V_c,t) = \frac{\partial}{\partial t} Q_i(V_c,t) \quad [3]$$

where K_o, E_o, J_o, X_o and K_a, E_a, J_a, X_a are the relative dielectric constants, electric fields, current densities, and thicknesses of the silicon dioxide and the aluminum oxide layers respectively. ϵ_o is the permittivity of free space. Q_i is the charge stored at the two insulator interface and can be related to the flat-band voltage V_{fb} of the MAOS structure by the equation[1]

$$V_{fb} = \phi_{MS} - \frac{Q_{ss}}{C_t} - \frac{Q_i}{C_a} \quad [4]$$

in which

$$C_a^{-1} = \frac{X_a}{K_a\epsilon_o}, \quad C_o^{-1} = \frac{X_o}{K_o\epsilon_o}, \quad C_t^{-1} = C_o^{-1} + C_a^{-1} \quad [5]$$

and where C_a, C_o are the Al_2O_3, SiO_2 capacitances per unit area respectively, ϕ_{MS} is the metal-semiconductor work function, and Q_{ss} is the fixed oxide charge at the Si-SiO_2 interface. The data required to solve these equations are the dielectric constants and thicknesses of the two insulating layers as well as relationships describing the conduction mechanisms in each individual layer.

For thermally grown SiO_2 films, 50Å or thicker, the conduction mechanism was shown to be electrode limited due to Fowler-Nordheim emission (16). This mechanism leads to an exponential dependence of the current density J_o on the electric field across the oxide E_o according to the following expression

$$J_o = B_o E_o^2 \frac{\pi b k T/E_o}{\sin(\pi b k T/E_o)} \exp(-E_1/E_o) \quad [6]$$

where T is the temperature in °K, k is Boltzmann's constant, and E_1, B_o, b are characteristic constants depending on the barrier height of the interface, *i.e.* depending on whether injection occurs, in the particular case under consideration, from the silicon or the aluminum oxide. When the silicon dioxide thickness is reduced (below 50Å), to a value at which direct tunneling can occur, the following empirical relation between the oxide current density and the applied field has been shown to apply (17)

$$J_o = B_o' E_o^2 \exp -(E_1'/E_o) \quad [7]$$

where B_o' and E_1' are constants.

Aluminum oxide films prepared by hydrolysis of $AlCl_3$ (13) and decomposition of an aluminum trimethyl-nitrous oxide mixture (18) exhibited bulk-limited conduction characteristics due to field-enhanced thermal excitation of carriers from traps (Poole-Frenkel effect). Duffy (19) reported that the conduction in aluminum oxide films prepared by thermal decomposition of aluminum isopropoxide was controlled by the interfaces. Relatively little information is available on the conduction characteristics of rf sputtered aluminum oxide films. These characteristics are investigated here in order to apply the macroscopic model described above and explain charge storage effects in the specific MAOS structures under investigation.

[1] This equation neglects any possible contact potential at the interface between the two dielectrics (15).

Experimental Techniques

All of the electrical measurements were carried out on MAS or MAOS capacitor structures fabricated on silicon substrates. The silicon used in this work was in the form of polished circular slices (Monsanto), 2.5 cm in diameter, prepared by the Czochralski method. The slices used were n-type (phosphorus doped), (111) orientation of approximately 10 and 0.01 ohm-cm resistivities. The high resistivity slices were used for charge storage studies and the low resistivity ones were used for investigations of the conduction characteristics of the aluminum oxide films. The polished silicon wafers were degreased and cleaned thoroughly (20) prior to aluminum oxide deposition or silicon dioxide growth. The silicon dioxide was grown at 900°C in dry oxygen in a horizontal resistively-heated furnace provided with a quartz tube and alumina liner. The silicon dioxide was then annealed at the same temperature in nitrogen for 10 min. Both the oxygen and nitrogen gases were obtained from liquid sources. The silicon dioxide films were grown, as thin as reproducibly possible, approximately 50Å thick to reduce charging times and voltages in the MAOS memory elements (11). The thickness of the SiO_2 layer was measured using a spectrophotometric technique developed by Rand (21).

The apparatus used for the deposition of aluminum oxide films by rf sputtering has been described previously (15). The films were sputtered from a sintered aluminum oxide (99.97%) target 12.5 cm in diam and 1 cm thick. Ultrahigh purity argon (99.999%) was used as the sputtering gas. The argon pressure was kept at 5-7 $\times$ 10^{-3} Torr during the run. At this sputtering pressure a 3 cm target-to-substrate distance was found to be compatible with a self-sustained uniform discharge and satisfactory deposition rates. The sputtering power density used was approximately 1.5 W/cm^2 resulting in a deposition rate of 30Å/sec. The substrate temperature did not exceed 200°C. After deposition, the aluminum oxide films were annealed in nitrogen for 30 min at 300°C. The heat treatments were restricted to a temperature below 320°C because of the possible occurrence of the γ' phase of aluminum oxide above this temperature (22). The Al_2O_3 film thickness was measured using a Talystep capable of $\pm$ 20Å accuracy and ranged from 400 to 600Å.

The capacitor structures were completed by evaporating aluminum or gold (99.999%) field plates, 1000Å thick, 500 μm in diameter over the dielectric through a mask. Aluminum was also evaporated on the bare back-side of the silicon for contact. The aluminum evaporations were carried out from a resistively heated tungsten filament, and the gold was evaporated from a molybdenum boat. The vacuum during evaporation was kept below 10^{-6} Torr.

The conduction currents through the Al_2O_3 films were measured with a Keithley 602 electrometer or a Keithley 413 A micro-microammeter. All the electrical measurements were carried out in vacuum (<0.1 Torr) and the temperature was monitored using a copper-constantan thermocouple attached to the sample holder. Special care was taken to ensure that conduction measurements were made under equilibrium conditions.

Characterization of charge storage effects involve measurements of the shift in flat-band voltage after each stress voltage is applied. In order to speed-up the characterization of the MAOS structures, a system which stresses the capacitor, samples, and records the flat-band voltage *vs.* stress voltage automatically was used and has been described in detail previously (23).

The operation of the system is based on the fact that the flat-band capacitance remains constant for the MAOS structure at any flat-band voltage. The apparatus is shown in block diagram form in Fig. 1. It consists of a feedback system which can be operated in

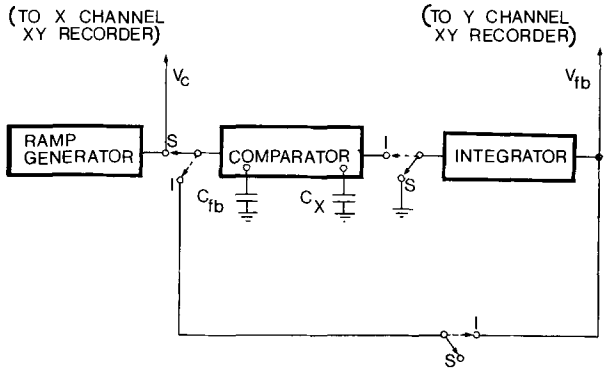

Fig. 1. Block diagram of automatic flat-band vs. stress voltage measurement system.

an open loop or stress (S) mode and a closed loop or integrating (I) mode. During the stress mode, a variable speed ramp generator applies a stress voltage to both the MAOS capacitor C_x and a fixed capacitor set at the appropriate flat-band capacitance value C_{fb}. A differential capacitance comparator (Boonton 71 A) is used to measure the difference between C_x and C_{fb} and produces a signal proportional to that difference. In the integrating mode, the ramp generator is disconnected and the loop is closed. The output of the comparator is applied to the integrator, whose output is in turn applied as a bias voltage to the two capacitors. When the output of the integrator reaches the flat-band voltage required to generate the correct flat-band capacitance, the output of the comparator is reduced to zero. Both the stress and the flat-band voltages are then recorded on an XY plotter. By replacing the ramp generator by a pulse generator, the system can be used to determine the flat-band voltage after application of a single stress pulse. It can also be used to monitor the flat-band voltage decay as a function of time.

The surface state density at the $Si-SiO_2$ interface was obtained from low-frequency C-V curves measured using the quasi-static technique as implemented by Kuhn (24). The method involves measurement of the MAOS capacitor displacement current density J_c in response to a linear gate voltage ramp $V_G = at$ where a is the ramp speed. The low frequency capacitance C_{LF} is related to the displacement current density by $J_c = a\,C_{LF}$.

Results and Discussion

Conduction in Al_2O_3 films.—Figure 2 shows the typical current density *vs.* square root of field for an $Al-Al_2O_3-Si$ structure at room temperature. The Al(+) and Al(−) curves refer to positive and negative aluminum electrodes. The two curves are almost identical and the slight difference in current density can be attributed to the presence of a thin layer of SiO_2 underneath the Al_2O_3 film (25).[2] Two regions can be distinguished on the curves. At high electric fields, the current varies exponentially with the square root of the field and at low fields the characteristic is ohmic. Similar results were obtained with Au electrodes deposited on the Al_2O_3 films. In general, the conduction characteristics were found to be independent of film thickness (for thicknesses in the range 400-600Å), electrode material and polarity of the electrodes. These results strongly suggest that the current is bulk controlled rather than electrode controlled.

Figure 3 shows plots of the current density *vs.* $1/T$ for two different fields for positive Al electrode. At low temperatures the current density becomes nearly independent of temperature.[3] At higher temperatures,

[2] In samples used for conduction measurements, special care was taken to minimize the thickness of the SiO_2 layer present on the silicon substrate prior to sputtering of the Al_2O_3 layer.

[3] At these low temperatures, log J_a exhibited a linear dependence on $1/E_a$.

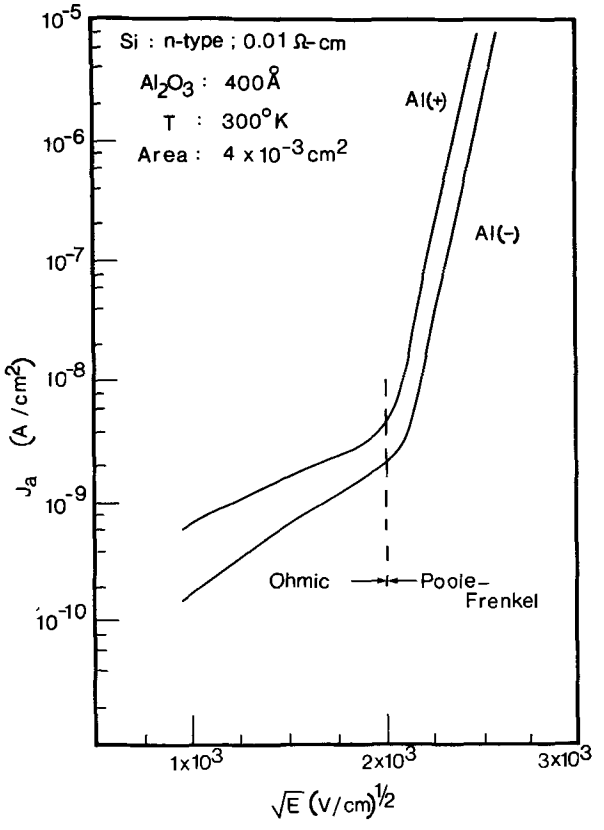

Fig. 2. Current density vs. square root of applied field for a MAS structure.

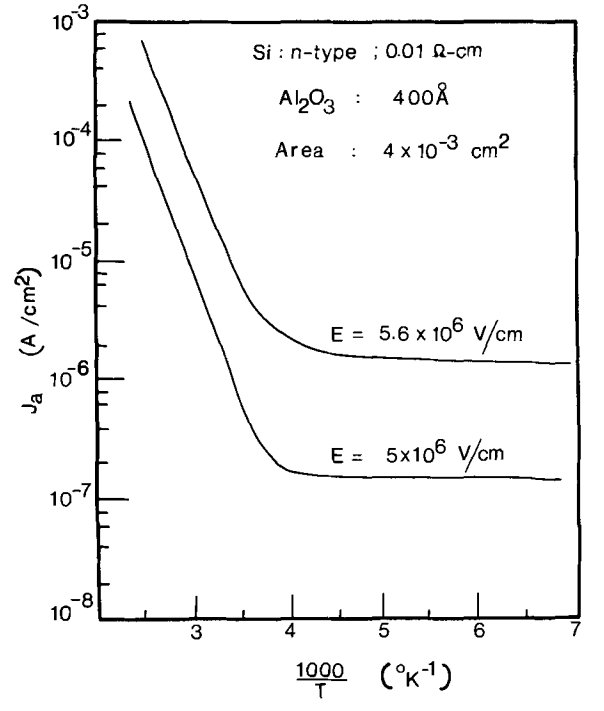

Fig. 3. Current density vs. 1000/T at two values of applied field for the same sample as in Fig. 2.

the current density exhibits a rapid increase. Based on these results and on the work of Mead (26) and Sze (27), the conduction current density J_a in the aluminum oxide films can be attributed to the sum of three contributions all bulk controlled

$$J_a = J_{a1} + J_{a2} + J_{a3} \qquad [8]$$

where

$$J_{a1} = C_1\,E_a \exp(-q\,\phi_a/kT) \exp q/kT\,(\beta E_a)^{1/2} \qquad [9]$$

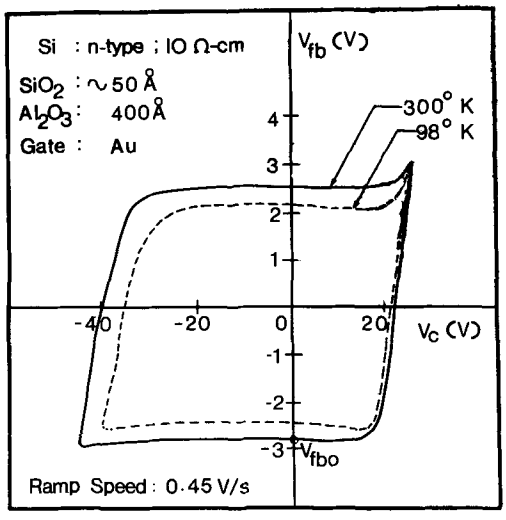

Fig. 4. Flat-band voltage *vs.* stress voltage hysteresis at two different temperatures for a MAOS structure.

$$J_{a2} = C_2 E_a^2 \exp(-E_2/E_a) \quad [10]$$

$$J_{a3} = C_3 E_a \exp(-q\phi_3/kT) \quad [11]$$

Current density J_{a1} is due to field enhanced thermal excitation of trapped electrons into the conduction band. This process is known as the Poole-Frenkel effect (26). In Eq. [9] C_1 is a constant, q is the electronic charge, ϕ_a is the barrier height, and $\beta = q/\pi K_a \epsilon_o$. Current density J_{a2} is due to field ionization of trapped electrons, this is a tunneling process essentially independent of temperature. Both C_2 and E_2 in Eq. [10] are constants (26). Current density J_{a3} is due to the hopping of thermally excited electrons from one isolated state to another (26). This process results in ohmic characteristics. In Eq. [11], C_3 and ϕ_3 are constants.

For the particular case illustrated in Fig. 2 and 3 for Al(+), the values of the constant terms in the current density equations were found to be as follows

$C_1 = 1.2 \times 10^{-6}$ A/V cm $\quad E_2 = 1 \times 10^8$ V/cm

$C_2 = 3 \times 10^{-13}$ A/V^2 $\quad \phi_3 = 0.15$ V

$C_3 = 3 \times 10^{-13}$ A/V cm $\quad \beta = 1.67 \times 10^{-7}$ V cm

$\phi_a = 1.35$ V

The value of β yields a self-consistent dynamic dielectric constant $K_a = 4.1$ for aluminum oxide. This value lies between the static value for the dielectric constant[4] 8 and the optical dielectric constant 2.89 (28) for aluminum oxide, as expected for Poole-Frenkel conduction (26).

The values of the constants were found to vary within a range of ± 10% for the various samples investigated. The magnitude of ϕ_a measured for the rf sputtered films is close to the value of 1.3V reported by Tsujide (13) but is much larger than the value of 0.5V reported by Hall (18).

In general, the results, reported above, are similar to those obtained on Si_3N_4 films except that the conduction current densities in the Al_2O_3 films are an order or two lower than those observed in pyrolitic Si_3N_4 (27). It follows that the charge storage characteristics of MAOS structures should be, qualitatively at least, similar to those of MNOS structures. These characteristics are discussed in the next section.

Charge storage in MAOS structures.—A typical flat-band voltage *vs.* stress voltage hysteresis loop, measured at room temperature (300°K), for a MAOS capacitor with gold gate electrode is shown in Fig. 4. The initial flat-band voltage is $V_{fbo} = -2.85$V. Knowing the value of $Q_{ss} \simeq 4 \times 10^{11}$ q/cm^2 (15), and $\phi_{MS} = -0.35$V (20) as well as the insulator capacitances, Eq. [4] can be used to estimate the initial charge $Q_i(0)$ stored at the Al_2O_3-SiO_2 interface. For the particular sample under investigation $Q_i(0)$ was found to be 3.3 $\times 10^{12}$ q/cm^2. This charge was positive for all the samples investigated and ranged from 3 $\times 10^{12}$ to 3.5 $\times 10^{12}$ q/cm^2. An asymmetry in the characteristics is observed in the figure. A larger negative than positive stress voltage is required to produce a fixed shift in V_{fb}. This asymmetry can be explained by the fact that the barrier height for injection from the Si into the SiO_2 under positive stress voltage, is smaller than the barrier height for injection from the Al_2O_3 into the SiO_2 under negative stress bias (6). Also shown in Fig. 4 is the hysteresis loop obtained on the same sample at 98°K under the same conditions. As expected, the flat-band voltage at 98°K is lower than that at 300°K, since some of the impurities in the substrate are not ionized at low temperatures thus reducing the fixed charge in the silicon depletion region. Under positive stress, the V_{fb} *vs.* V_c characteristics are almost identical at the two temperatures. This is due to the fact that most of the charging occurs through the thin silicon dioxide layer and that the conduction through this layer is almost independent of temperature[5] (see Eq. [6]). The area of the high temperature loop is larger than that of the low temperature one; this is an indication that Q_i increases with increasing temperature, as predicted by the theory, since the conductivity of the aluminum oxide film increases much faster than that of the silicon dioxide (6).

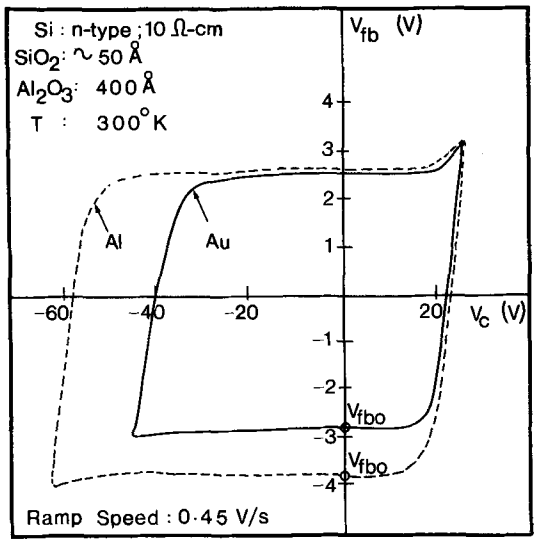

Fig. 5. Flat-band voltage *vs.* stress voltage hysteresis for a MAOS structure illustrating the effect of the gate electrode.

The effect of the gate electrode on the hysteresis characteristics is illustrated in Fig. 5 for Au and Al electrodes. The magnitude of the initial flat-band voltage is smaller for Au than for Al because of the difference in metal-semiconductor work function ϕ_{MS}. The V_{fb} *vs.* V_c curves under positive stress voltage are almost identical since the charging depends mostly on injection from the Si into the SiO_2. The flat-band voltage characteristics under negative stress are, however, different for Au and Al electrodes and this difference cannot be explained by the macroscopic theory, since it predicts that the characteristics should be independent of the gate electrode provided the conduction through the aluminum oxide is bulk controlled. This difference can, however, be attributed to electrode injection. At the very high fields encountered, injection from the aluminum electrode is quite plausible. In

[4] Measured at 1 MHz using a Boonton 71 A capacitance meter.

[5] The term $(\pi bkT/E_o)/\sin \frac{\pi bkT}{E_o}$ in Eq. [6] results in negligible temperature dependence.

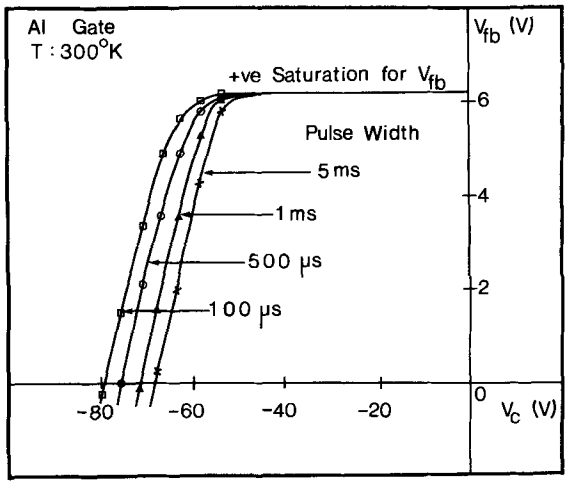

Fig. 7. Charging characteristics of a MAOS structure for various negative pulse widths.

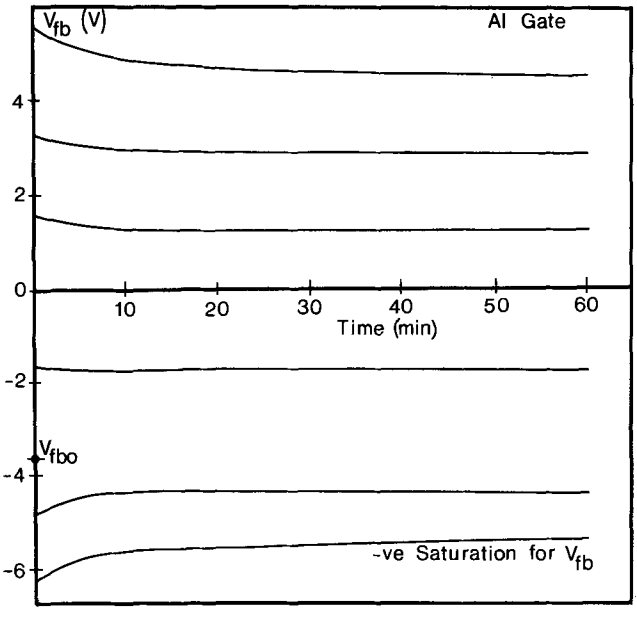

Fig. 8. Flat-band voltage *vs.* time illustrating charge retention characteristics of a MAOS structure.

the case of gold, this injection is transposed to much higher fields, due to the higher work function of gold (as compared to aluminum) (3), and is, therefore, ineffective.

The MAOS structures exhibited positive and negative saturation flat-band voltages at which increasing the magnitude of the stress voltage caused no further increase in the amount of stored charge. This maximum charge is of primary importance in the operation of the memory elements. For typical samples with a 400Å Al_2O_3 layer, a 50Å SiO_2 layer and an Al gate the maximum values of the stored charge as estimated from Eq. [4] are approximately $\pm$ 6.5 $\times$ 10^{12} q/cm^2.

In order to investigate the effect of pulse width and pulse amplitude on the charge transfer characteristics, the MAOS capacitor was first subjected to a large negative voltage typically -40V for 1 min. This voltage was sufficient to cause saturation of the flat-band voltage in the negative direction. A positive pulse of known amplitude and duration was then applied and the corresponding flat-band voltage was measured.[6] After each positive pulse, the flat-band voltage was returned to its saturation value and the procedure repeated. The resulting V_{fb} *vs.* V_c characteristics are shown in Fig. 6. The same procedure was repeated for negative pulses. The flat-band voltage in this case was first saturated in the positive direction prior to the application of the stress pulses. The V_{fb} *vs.* V_c characteristics for negative pulses are shown in Fig. 7. As seen from these curves, the flat-band voltage and therefore the charge stored Q_i depend on both the applied pulse voltage amplitude and its duration. As the pulses become shorter, their amplitude must be increased to shift the flat-band voltage by a given amount. Furthermore, the switching is asymmetric in that negative pulses must be larger than positive pulses for the same shift. Similar observations have been reported on MNOS structures by Frohman-Bentchkowsky (6) and Wallmark (4) and are predicted by the macroscopic theory.

[6] The flat-band voltage was measured 10 min after application of the pulse to avoid the fast initial discharge.

Of great importance to the practical application of MAOS memory structures is the long-term retention of the stored charge. This retention was measured in the following manner. The flat-band voltage was first saturated in the negative direction and positive pulses of various amplitude and 50 μsec duration were applied. The flat-band voltage was then monitored as a function of time in each case. Typical results are shown in Fig. 8. For this sample the initial flat-band voltage was $V_{fbo} = -3.80$V. A rapid rise in V_{fb} was observed whenever V_{fb} was smaller than V_{fbo}, while a rapid decay occurred whenever V_{fb} was larger than V_{fbo}. Most of the change occurred within the first 10 min and the flat-band voltage then reached an equilibrium value over the next 60 min. Any further change in V_{fb}, over a period of 72 hr, was observed to be less than 1%.[7] Similar results have been observed in MNOS structures (3, 11), and the dominant mechanism responsible for the initial loss of charge can be attributed to conduction through the thin SiO_2 layer.

The charge transfer across the silicon dioxide and aluminum oxide was found to affect the surface state density at the Si-SiO_2 interface. This effect was ob-

[7] Charge retention measurements were carried out under a vacuum of less than 0.1 Torr.

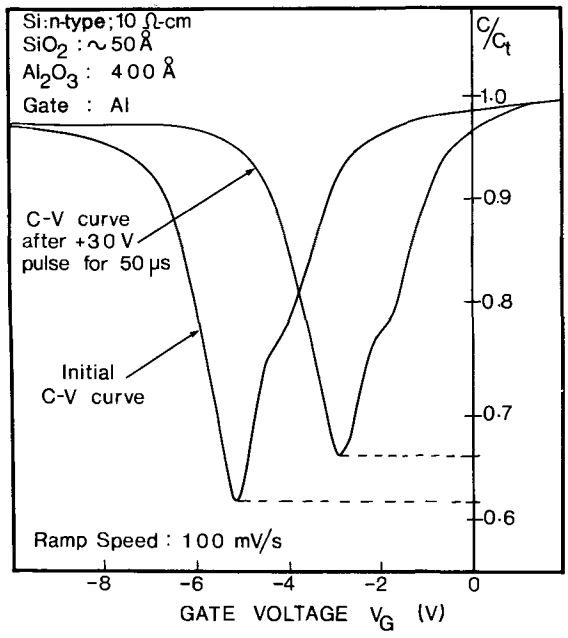

Fig. 9. Low-frequency C-V characteristic of a MAOS structure prior to and after a shift in flat-band voltage.

served by measuring the low-frequency C-V characteristics of the MAOS capacitors after application of a stress voltage large enough to cause a change in the flat-band voltage. The measurements were carried out using the quasi-static technique which has the advantage of allowing the direct determination of the surface state density independently of the charge stored in the dielectrics.

In order to obtain a quick estimate of the approximate surface state density N'_{st} near midgap, the minimum value of the experimental low frequency capacitance C'_{LF} per unit area can be related to N'_{st} by the expression (30)

$$qN'_{st} = \frac{C_t - C'_{FL}}{C_t - C'_{LF}} \left[C'_{LF} - \frac{C_t \; C'_{sc}}{C_t + C'_{sc}} \right] \quad [12]$$

where C'_{sc} is the minimum theoretical space charge capacitance (31) per unit area, C_t is the total capacitance per unit area of the MAOS structure, and the second term in the brackets in Eq. [12] is the minimum theoretical low frequency capacitance per unit area.

Figure 9 shows the typical experimental low-frequency C-V characteristics before and after application of a stress voltage. As observed in the figure the minimum value of the low-frequency capacitance and therefore the surface state density at the Si-SiO_2 interface increase with a change in the flat-band voltage. In the case under consideration, the surface state density N'_{st}, as obtained from Eq. [12], increased from 2.25×10^{12} cm^{-2} to 2.7×10^{12} cm^{-2} after application of a 50 μsec stress pulse with an amplitude + 30V which shifted the flat-band voltage by approximately 2V. The change in surface state density was permanent and was found to increase with increasing stress voltage.[8] This increase in surface-state density was observed in all the samples investigated and may affect the long term reliability of the MAOS memory elements.

Summary

The conduction in rf sputtered Al_2O_3 films deposited on silicon is bulk controlled and consists of three components as in the case of pyrolytic Si_3N_4. At high temperatures and high fields, the current is mainly due to field enhanced thermal excitation of carriers into the conduction band (Poole-Frenkel effect). At low temperatures and high fields, the current is mainly due to field ionization of carriers into the conduction band and at low fields and moderate temperatures the current is due to trap hopping.

The MAOS structures investigated exhibit charge storage and retention characteristics which are very similar to those observed in MNOS memory elements. Most of these characteristics can be explained in terms of the macroscopic theory developed by Frohman-Bentchkowsky (6). Two of the observed characteristics which cannot be explained using this theory, are the dependence of the flat-band voltage *vs.* stress voltage hysteresis on the gate electrode and the increase in the surface state density after a change in flat-band voltage.

The use of Al_2O_3 instead of Si_3N_4 in memory elements is expected to have certain advantages. The dielectric constant of Al_2O_3 ($K_a \sim 8$) is larger than that of Si_3N_4 ($K_N \sim 6.5$), this causes a higher proportion of the applied field to appear initially across the SiO_2 layer resulting in a large current flow, which causes rapid accumulation of charge at the Al_2O_3-SiO_2 interface. Furthermore, the lower conductivity of Al_2O_3 films at low fields as compared to Si_3N_4 films under similar conditions is expected to increase the memory retention time.

Random Substitution of Eu^{3+} for Y^{3+} in Y_2O_3:Eu^{3+}

H. Forest and G. Ban

Zenith Radio Corporation, Chicago, Illinois 60639

ABSTRACT

This paper is an investigation of whether trivalent europium occupies the two inequivalent yttrium sites (C_2 and S_6) in Y_2O_3 (C-form) randomly or preferentially. The distribution is found to be approximately random for concentrations greater than 1 atom per cent by comparing the $^7F_0 \rightarrow {}^5D_1$ reflection spectra of Y_2O_3:Eu^{3+} and C-form Eu_2O_3 powders. From the uncertainty of the measurements, an estimate is made for the ordering energy ($\sim$250 cm^{-1}) which is the maximum difference in the energy of Eu^{3+} located at the two sites.

The crystal structure of C-form Y_2O_3 contains two inequivalent yttrium sites with symmetries C_2 and S_6 which are in the ratio of three-to-one, respectively (see Fig. 1). In a previous paper (1), it has been shown that the narrow line emission and absorption spectra of Y_2O_3:Eu^{3+}, a well-known red emitting television phosphor, are due to Eu^{3+} situated at both sites. The different symmetry of each site results in two spectrally inequivalent and distinguishable Eu^{3+} centers. Table I lists the site assignments of the important Eu^{3+} transitions.

One interesting question is whether there is significant difference in the europium energy for either site (ordering energy) to produce a preferential substitution. For a random distribution the europium energies would be degenerate and, consequently, the substitution would occur for each site with the same probability. In some related studies on Y_2O_3:Eu^{3+} prepared by the oxalate procedure, it was found that the distribution was unaffected by annealing at temperatures between 1000°-1400°C for several hours. Commercially prepared Y_2O_3:Eu^{3+}, obtained from Sylvania, was found to have the same distribution as our phosphors. It seems at these firing temperatures that the ordering energy is small and the europium substitution is random, but this is only suggestive without actual knowledge of the distribution.

The present study was initiated in order to determine the distribution of Eu^{3+} between the two yttrium sites in Y_2O_3:Eu^{3+}. Our results indicate that the distribution can be determined from the relative intensities of the $^7F_0 \rightarrow {}^5D_1$ absorption spectrum which consists of C_2 and S_6 Eu^{3+} lines. From reflection measurements on powders, the relative intensities of the C_2 spectrum (see Table I, lines 2, 4, 5) to the S_6 spectrum (lines 1, 3) were found to be about the same as C-form from Eu_2O_3, where the ratio must be three-to-one, indicating a random distribution.

Key words: distribution, symmetry sites, ordering.

Experimental

The Y_2O_3:Eu^{3+} phosphors were prepared by firing stoichiometric mixtures of the respective oxalates for 2 hr at 600°C followed by 2 hr at 1400°C under an O_2 atmosphere. C-form Eu_2O_3 was also prepared from the oxalates, but the firing temperature was selected so that no conversion to the higher temperature B-form occurred. The sample of Eu_2O_3 was analyzed by x-ray to insure that it was pure C-form with no trace of the high temperature B-form. From reflection spectra, it was found that commercially available Eu_2O_3 is a mixture of the C and B forms, in which the C-form is the major constituent.

Reflection measurements were made on loosely packed powders in planchettes with a 1-meter Jarrell Ash grating monochromator and a ribbon filament in-

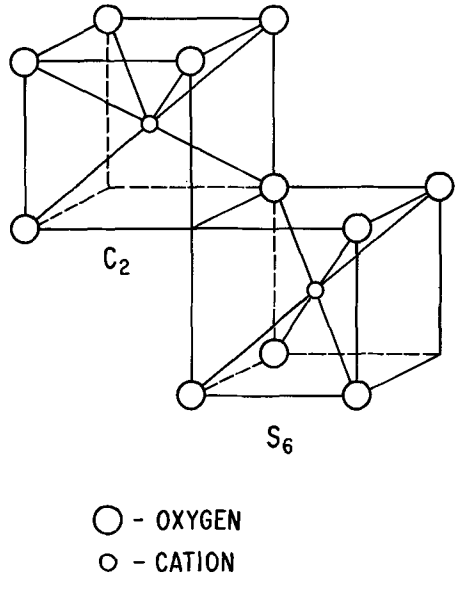

Fig. 1. C_2 and S_6 cation sites in C-form Y_2O_3. The major difference being the direction of the oxygen vacancies; it is along a body diagonal in S_6 and a face diagonal in C_2.

candescent lamp as the light source. The monochromator slit bandpass was set at 0.4Å which is 20% of the half-width of the narrowest line in the spectrum so that there was no significant broadening introduced by the instrument. An RCA 7265 photomultiplier was used as the detector. The reflection spectra reported in this paper are direct single beam measurements of the photomultiplier current *vs.* wavelength. No corrections were made for the response of the photomultiplier or the spectral distribution of the lamp since these were found to be minor for the narrow wavelength range of the $^7F_0 \rightarrow {}^5D_1$ transition. In order to maximize the absorption relative to the scattered light, the optics were arranged so that the focused image of the monochromator slit and light source did not superimpose on the phosphor, but were displaced slightly in a direction perpendicular to the optical axis of the monochromator. In this way the light entering the monochromator would undergo several reflections through the phosphor powder, thereby increasing the effective path length.

Absorption spectra were also taken on a single crystal of Y_2O_3:Eu^{3+} at room temperature with a Cary 14R spectrophotometer. The single crystal was prepared by a flame fusion technique at the Lockheed Palo Alto Research Laboratory.

Results

The five-line $^7F_0 \rightarrow {}^5D_1$ absorption spectrum of Y_2O_3:5% (atom per cent) Eu^{3+} single crystal is shown in Fig. 2. The number above each line corresponds to the symmetry assignment obtained from Table I. Figure 3 shows powder reflection spectra (absorptions appear as stalagtites) over the same wavelength range for Y_2O_3 with several practical Eu^{3+} concentrations, plus C-form Eu_2O_3. Although it is not obvious from the spectra, the amount of absorption does increase with europium concentration. The absorption due to Eu_2O_3 is shown to be less than the 5% sample due to a scale change, but actually it is much greater. No attempt was made to make the reflection spectra quantitative, since only the ratio of the C_2 to S_6 line intensities of each spectrum is important and will be compared. The lack of reproducible quantitative data is due to variations in the packing of the powders, which is of no consequence when taking ratios.

A relative absorption spectrum was obtained for the 5% powder by a point-by-point inversion of the reflection spectrum. The resulting spectrum has essentially the same relative line intensities as the single-crystal spectrum (Fig. 2), which indicates that the spectral corrections of the apparatus are minor. The other reflection spectra in Fig. 3 are also expected to be similar to absorption spectra measured on single crystals.

Discussion

Before proceeding to the comparison of the reflection spectra, a brief discussion of diffuse reflection theory will be necessary. Melamed (2) has calculated the diffuse reflectance of a powder[1] (for various indices of refraction) as a function of the unitless quantity kl, where k is the absorption coefficient in cm^{-1} and l is the particle diameter in cm. A family of curves is very nicely shown in ref. (3). The curves show that for a fixed particle diameter the diffuse reflectance does not vary linearly with absorption coefficient but tends to saturate beyond $kl = 0.50$. The saturation is more pronounced for higher values of the index of refraction. Therefore, when comparing line intensities of reflection spectra over a large concentration range, as we are doing in this paper (k will vary by a factor of 100), it is important to consider to what degree the reflectance nonlinearity will affect the spectra.

From Melamed's curves the nonlinearity of the reflectance spectra over a fixed range of k depends on the

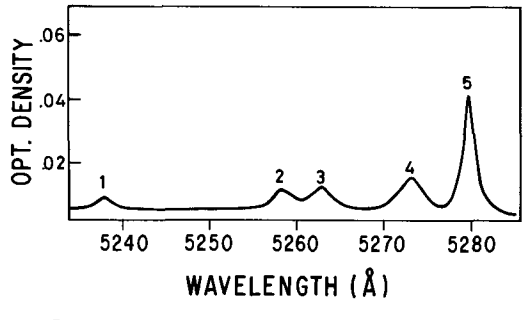

Fig. 2. $^7F_0 \rightarrow {}^5D_1$ absorption spectrum measured on a single crystal (Y_2O_3:Eu^{3+} 5%). The number above each line indicates the site assignment listed in Table I.

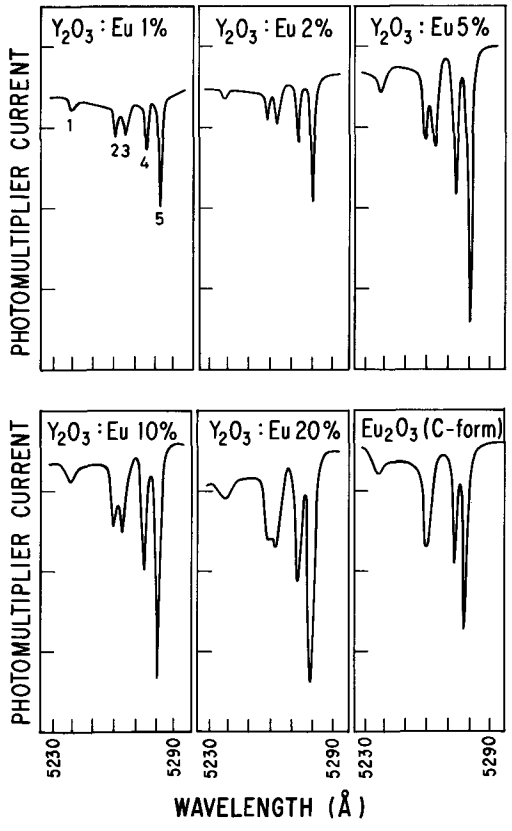

Fig. 3. $^7F_0 \rightarrow {}^5D_1$ reflection spectra for several concentrations of Y_2O_3:Eu^{3+}, including Eu_2O_3.

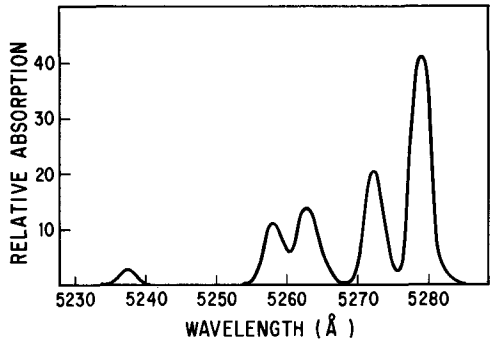

Fig. 4. Relative absorption spectrum obtained by a point-by-point inversion of the reflection spectrum for Y_2O_3:Eu^{3+} 5%. The ordinate is completely arbitrary and is labeled relative absorption only to qualitatively identify the spectrum.

[1] Melamed's model is for spherical particles.

Table II. Absorption coefficients (cm^{-1}) of $^7F_0 \rightarrow {}^5D_1$ transition

Line No.	Y_2O_3:Eu^{3+} 5%	Y_2O_3:Eu^{3+} 1%	Eu_2O_3
1	0.033	0.0067	0.67
2	0.064	0.013	1.3
3	0.076	0.015	1.5
4	0.092	0.018	1.8
5	0.38	0.076	7.6

magnitude of k and is less for low values of k. This means that lines 1 and 5 in Fig. 3 will be affected least and most, respectively, by the nonlinearity. Table II lists the range of the absorption coefficients of the five lines (columns 3 and 4) which were obtained from the single-crystal spectrum (column 2). The phosphor particle size is about 5μ so that kl for the strongest line, 5, varies from 3.8×10^{-5} — 3.8×10^{-3} which places the data on a section of Malamed's curve where the nonlinearity is low. However, examining Fig. 3, the relative intensity of line 5 does decrease slightly over the concentration range indicating some nonlinearity and therefore this line cannot be used to determine the ratio. Lines 2 and 3 have about the same absorption coefficient, but, unfortunately, they superimpose in the Eu_2O_3 spectrum. This leaves lines 1 and 4 for the comparison of the spectra and it will be assumed that their intensities are linear over the concentration range.

All of the spectra in Fig. 3 are similar and have essentially the same C_2 to S_6 line intensity ratio (*i.e.*, the ratio of line 4 to line 1 is 5.2 ± 1.0) indicating that the distribution of europium in Y_2O_3:Eu^{3+} is the same as in Eu_2O_3. This means that the substitution of europium for yttrium at either symmetry site proceeds with approximately equal probability and is independent of the europium concentration.

The major contribution to the uncertainty of the ratio (about 20%) is the determination of the baseline which is somewhat arbitrary and depends on the sample. There is no trend for the ratio to decrease with increasing europium concentration resulting from the nonlinearity of line 4 so that the assumption that the peak heights are linear with concentration appears to be valid.

However, there is a trend for the ratios to follow a trapezoidal dependence on europium concentration, *i.e.*, the ratio goes through a broad maximum at about 20% Eu^{3+} and is the same for 1% Eu^{3+} and Eu_2O_3. This is probably due to the broadening of the spectra which, as is discussed below, follows a similar dependence on europium concentration. The broadening of the spectra contributes to the uncertainty of the ratio, since taking peak heights as a measure of the line intensity implicitly assumes that the width of the C_2 and S_6 lines have the same europium concentration dependence, which may not be true.

The above result is semiquantitative at best, however, since the spectra are not identical and do show some gradual variations with europium concentration. As the europium concentration increases, the lines appear broader and shift by approximately 2Å to shorter wavelengths. As a result of the line shifts and broadening, the doublet at 5260Å formed by lines 2 and 3 is not resolved above 10% europium. We believe these minor variations in the spectra are due to crystal field effects rather than changes in the europium distribution for the following reason: since the atomic radius of Eu^{3+} is 0.95Å compared to 0.88Å for Y^{3+}, it is reasonable to expect some distortion of the crystal field by the substitution of europium into the lattice. Recently, it has been shown that the emissions from Eu^{3+} and Pr^{3+} in several oxysulfides shift to shorter wavelengths as the ionic radius of the host cation increases (4). In effect, the situation is the same for Eu_2O_3 relative to Y_2O_3:Eu^{3+}, since the ionic radius of europium is slightly larger than that of yttrium. For Gd_2O_3:Eu^{3+} where the ionic radius of the europium and gadolinium are very similar, the reflection spectrum, while not shown, is found to be closer to Eu_2O_3 than any of the Y_2O_3:Eu^{3+} spectra in Fig. 3.

The variation of the spectrum with ionic radius of the cation is also responsible for the Eu_2O_3 spectrum being narrower than the Y_2O_3:Eu^{3+} spectra above 5% Eu. The line broadening in the Y_2O_3:Eu^{3+} spectra results from variations of the local crystal field about each europium due to the presence of europium in one or more of the nearest neighbor yttrium positions. Only for Y_2O_3:Eu^{3+} at low europium concentrations, where each europium is surrounded only by yttrium, and for Eu_2O_3 are the europium symmetries unique and the spectra narrow. For intermediate concentrations, the spectra are composites of slightly different spectra and, consequently, appear broadened. Therefore, since the reflection spectra of Y_2O_3:Eu^{3+} are similar to Eu_2O_3 except for minor variations in the crystal field, it is concluded that the europium distribution between the two symmetry sites is random and the C_2 to S_6 ratio is 3.0 ± 0.6.

From the uncertainty of the distribution, the maximum energy difference between europium located at C_2 and S_6 sites can be calculated. The distribution between the two sites $(C_2)/(S_6)$ is given by

$$\frac{(C_2)}{(S_6)} = 3e^{-\Delta E/kT} \qquad [1]$$

where ΔE is the ordering energy and kT is the thermal energy. The factor 3 enters because there are three times as many C_2 sites as S_6 sites. If $(C_2)/(S_6)$ is taken as 2.4 and 3.6, which represents the uncertainty extremes of the distribution, then ΔE is $\sim \pm 250$ cm^{-1} for the 1400°C firing temperature used to prepare the phosphors. In Eq. [1], ΔE can be positive or negative depending on the relative stabilities of europium in the C_2 or S_6 yttrium sites, but at high firing temperatures (>1000°C) it is not possible to determine from the data which configuration is more stable. The ordering energy, which probably results from the distortion of the yttrium site by the presence of europium, is small enough to be insignificant when compared to the thermal energy. At temperatures about 500°C, however, some ordering may be detected and indicate the relative stability of each site.

Conclusion

It has been shown that europium is distributed randomly between the C_2 and S_6 yttrium sites in Y_2O_3 by comparing the reflection spectra with C-form Eu_2O_3. This is only true for the high temperatures (>1000°C) used to prepare the phosphors. At lower temperatures, however, some preferential substitution may be possible.

Characterization of Surface States at the Si-SiO_2 Interface Using the Quasi-Static Technique

E. A. Fogels and C. A. T. Salama*

Department of Electrical Engineering, University of Toronto, Toronto 5, Ontario, Canada

ABSTRACT

The quasi-static technique is used to investigate the effect of processing parameters on the surface-state density at the silicon-thermally grown silicon dioxide interface. The determination of the constant required for the evaluation of surface potential from equilibrium C-V data is discussed. A rapid method of estimating the midgap density of surface states is also described. The dependence of surface-state density on substrate orientation, type of oxide growth, high-temperature annealing in nitrogen, low-temperature heat treatment in forming gas, and temperature of oxide growth are discussed. The interdependence between the fixed oxide charge and the surface-state density is also investigated.

Several methods (1-4) have been developed for the extraction of surface-state properties at the Si-SiO_2 interface from measurements of the electrical characteristics of MOS (metal-oxide-semiconductor) capacitors. Among these is the integration method (3) which can be used in conjunction with low-frequency, thermal equilibrium MOS capacitance-voltage data to obtain the surface-state density distribution in energy. A particular advantage of this method is that the surface potential can be determined directly by a simple integration of the experimental results. Hence, the errors in surface-state densities arising from inaccuracies in doping or surface potential, or relating back to ideal curves, are greatly reduced. While not as accurate as the conductance method (4), the integration method results in the determination of surface-state densities over a wider region of the bandgap energy without the need for complex conductance measurements. Errors are also minimized because no graphical differentiation of experimental results is required as in the differential (1) and temperature (2) methods.

The successful implementation of any low-frequency, thermal equilibrium method is directly dependent on whether or not the bias and signal voltages are capable of creating and maintaining the semiconductor inversion layer and the interface surface-state charges in complete thermal equilibrium at all times. Deviations from thermal equilibrium, which are commonly observed at low temperatures or at high frequencies, would completely invalidate any results based on the integration method.

The original implementation of the integration method (3) used a phase-lock, low-frequency a-c technique. The difficulty with this implementation is due to the presence of drift in the phase sensitive detection system of the lock-in amplifier which introduces large errors in the output signal and therefore in the calculated surface-state density. Furthermore, the low-frequency cutoff of the lock-in amplifier restricts the measurement frequency used in this method to above 1.5 Hz. Such a frequency is often not sufficiently low to overcome the nonequilibrium effects that are apparent in samples having typical inversion layer response times of the order of a second or more.

A more desirable approach is to eliminate the instabilities associated with the lock-in amplifier and reduce the effective measuring frequency ω to such a point that $1/\omega$ is much greater than the time constants of the inversion layer and the surface-state charges, thus ensuring that thermal equilibrium conditions are satisfied. This has been achieved using the quasi-static technique. This technique was first suggested by Castagne (5, 6) and further investigated by Kuhn (7). It involves the measurement of the C-V characteristics of MOS capacitors under application of a very slow ramp bias voltage. This technique is ideally suited for surface-state measurements on thermally oxidized silicon structures possessing moderate surface-state densities. With a minimum amount of implementation and data processing, the method leads to the determination of the density of states over a considerable range of surface potentials extending from heavy inversion to heavy accumulation, with a sensitivity of about 10^{10} states/cm^2-eV for energies within 0.25 eV of midgap.

The basic equations used in conjunction with the quasi-static technique are briefly reviewed in this paper and particular emphasis is placed on the determination of the integration constant required for the evaluation of the surface potential from equilibrium C-V data. A rapid method of obtaining the approximate surface-state density near midgap is also described. The quasi-static technique is then used to investigate the effect of processing parameters on the surface-state density at the Si-SiO_2 interface. The effects of some of the processing parameters investigated here have been previously reported using other techniques of surface-state measurement which were restricted as to the energy range covered and the frequency of the measurement. Both of these limitations are minimized in the quasi-static technique. A correlation of the fixed oxide charge and the surface-state charge has been included, wherever possible, in order to investigate any common origin for these two charges. The advantage of the quasi-static technique in such an investigation is that it determines directly the surface-state density independently of the fixed oxide charge (7).

Analysis

The following analysis, due to Berglund (3), can be used to extract the surface potential and the surface-state density from the experimentally determined low-frequency (LF) C-V data obtained under thermal equilibrium conditions. The experimental variation of surface potential ψ_s with respect to the oxide voltage V_o is given by[1]

$$\left(\frac{d\psi_s}{dV_o}\right)_E = \frac{C_o}{C_{sc} + qN_{st}} = \frac{C_o}{C_{LF}} - 1 \qquad [1]$$

where C_o is the oxide capacitance for unit area, C_{sc} is the space charge capacitance per unit area, N_{st} is the density of surface states in cm^{-2}-eV^{-1}, q is the electronic charge, and C_{LF} is the low-frequency, equilibrium MOS capacitance per unit area. For an ideal capacitor with no surface states, Eq. [1] reduces to

* Electrochemical Society Active Member.

Key words: silicon, passivation, silicon dioxide, semiconductors.

[1] The surface potential ψ_s is given by $(E_F - E_i)/q$ where E_F and E_i are the Fermi and intrinsic energy levels respectively.

$$\left(\frac{d\psi_s}{dV_o}\right)_T = \frac{C_o}{C_{sc}} \quad [2]$$

For a known substrate doping and oxide capacitance, Eq. [2] can be evaluated theoretically for any ψ_s. The surface-state density can then be determined from the following equation

$$N_{st} = \frac{1}{q}\left[\frac{\left(\frac{d\psi_s}{dV_o}\right)_T}{\left(\frac{d\psi_s}{dV_o}\right)_E} - 1\right] C_{sc} \quad [3]$$

The surface potential $\psi_s(V_{g2})$ at any gate voltage V_{g2} can be determined within an additive constant $\psi_s(V_{g1})$ from the integral (3)[2]

$$\psi_s(V_{g2}) = \int_{V_{g1}}^{V_{g2}}\left(1 - \frac{C_{LF}}{C_o}\right) dV_g + \psi_s(V_{g1}) \quad [4]$$

The method of evaluating the constant, suggested by Berglund (3), is to match the experimental and theoretical $d\psi_s/dV_o$ curves in the accumulation region where the effect of surface states can be neglected. The matching points must be judiciously chosen to give accurate results. If the matching is attempted in a region of heavy accumulation where C_{sc} is very large, then $C_{LF} \simeq C_o$ and the value of $(d\psi_s/dV_o)_E$ becomes immeasurably small and is obscured by any error ΔC_{LF} in the measured value of C_{LF}. On the other hand, if matching is attempted in the region of light accumulation (near flat band), C_{sc} may be comparable to qN_{st} and again error in $\psi_s(V_{g1})$ may result. Assuming that the error in determining $\psi_s(V_{g1})$ is to be limited to $\Delta\psi_s$, then the optimum range of ψ_s useful for matching can be obtained by first solving the following equations for limits on C_{sc}

$$C_{sc}(\text{upper limit}) = \frac{C_{ox}\,\beta\,\Delta\psi_s}{2(\Delta C_{LF}/C_{LF})} \quad [5]$$

$$C_{sc}(\text{lower limit}) = \frac{2qN_{st}}{\beta\,\Delta\psi_s} \quad [6]$$

where $\beta = q/kT$.[3] Once the limits on C_{sc} are determined from Eq. [5] and [6], the corresponding values of ψ_s can be determined for an n-type semiconductor (in the heavy accumulation region) from (8)

$$C_{sc} \simeq \frac{\epsilon_s}{L_{De}} \exp\left(\frac{\beta(\psi_s - \psi_b)}{2}\right) \quad [7]$$

where L_{De} is the extrinsic Debye length and ϵ_s is the semiconductor dielectric constant. The bulk potential ψ_b is given by

$$\psi_b = \frac{1}{\beta}\ln\frac{N}{n_i} \quad [8]$$

where N is the bulk donor doping density and n_i is the intrinsic density.

The surface-state distribution in energy in our investigation is determined by a computer program[4] whose input consists of the substrate doping density N, the oxide capacitance C_o, and a point-by-point evaluation of the experimental LF capacitance-voltage characteristics. The program solves Eq. [1] and [2] for the experimental and theoretical values of $d\psi_s/dV_o$, matches these two curves over the range of surface potentials obtained from Eq. [5], [6], and [7], and determines an average value for the additive constant ψ_s (V_{g1}). The surface state density N_{st}, as a function of ψ_s, is then obtained from Eq. [3].

[2] Ideally, if Eq. [4] is evaluated from heavy accumulation to heavy inversion, the integral should give a value for $\psi_s(V_{g2}) - \psi_s(V_{g1})$ equal to, or slightly less than, the bandgap energy. A value greater than the energy gap indicates that gross nonuniformities are present either in the oxide or at the oxide-semiconductor interface and the analysis can no longer be applied (3).

[3] In Eq. [5], $(\Delta C_{LF}/C_{LF})$ is the effective accuracy in the measurement of C_{LF}. In Eq. [6], the value of N_{st} is set at $10N'_{st}$, where N'_{st} is the approximate density of states near midgap as determined from Eq. [10]. The value $10N'_{st}$ represents a worst case condition.

[4] Available on request.

Approximate Surface-State Density Near Midgap

For quality control purposes, it is often sufficient to obtain a single value of the surface-state density, N_{st}, at some point such as the minimum of the *LF* C-V characteristic and assume that this value is representative of the effective density.

Assuming a uniform surface-state density, the minima of the ideal (theoretical) and experimental low-frequency $C - \psi_s$ characteristics [curves (a) and (b) respectively in Fig. 1] occur at the same value, ψ'_s, of surface potential in the light inversion region near midgap.[5] The difference in the minimum capacitance between the two curves can be directly related to the surface-state density, N'_{st}. This observation allows the density of states near midgap (where they are most effective as recombination centers) to be evaluated using the following equations:

The minimum space charge capacitance C'_{sc} is given by Eq. [9]

$$C'_{sc} = \frac{\epsilon_s}{L_{Di}} \frac{[\cosh(\beta\psi_b)]^{1/2}}{1 + 0.542(\beta\psi_b) - 0.0115(\beta\psi_b)^2} \quad \text{for } (\beta\psi_b) < 21 \quad [9]$$

where L_{Di} is the intrinsic Debye length. From Eq. [1], the surface-state density N'_{st} at the minimum of the $C - \psi_s$ characteristic is then given by

$$qN'_{st} = \frac{C_o + C'_{sc}}{C_o - C'_{LF}}\left[C'_{LF} - \frac{C_o C'_{sc}}{C_o + C'_{sc}}\right] \quad [10]$$

where C'_{LF} is the minimum low-frequency capacitance obtained from the experimental C-V or $C - \psi_s$ characteristic. The second term in the brackets in Eq. [10] is the minimum theoretical low-frequency capacitance.

In general, the surface-state density is not uniform over the whole energy gap and the minima of the ideal and experimental $C - \psi_s$ curves will not coincide, as shown in Fig. 1. The value of surface-state density obtained from Eq. [10] then will be in error. However, for typical MOS devices, the surface-state distribution is fairly constant near midgap and good accuracy

[5] $\psi'_s = 1/\beta \cosh^{-1}\left(\frac{L_{Di} - C'_{sc}}{\epsilon_s}\right)^2$.

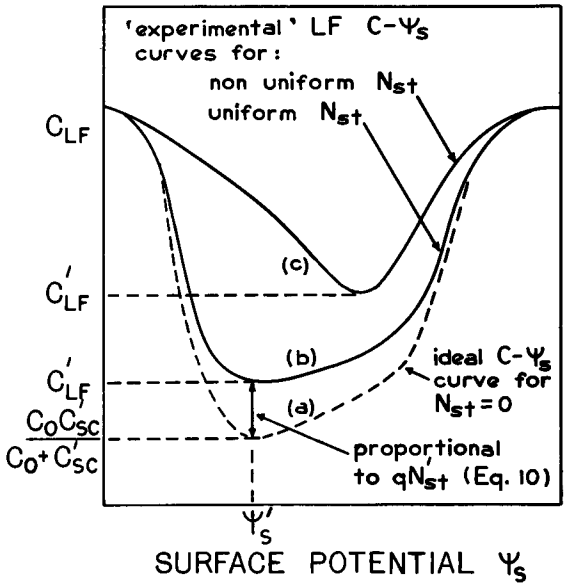

Fig. 1. Effect of uniform and nonuniform density of states on the C-ψ_s characteristics.

(within ± 10%) can be obtained. The validity of this method is illustrated in the following sections.

Experimental Techniques

The implementation of the quasi-static technique used in this investigation is similar to the one described by Kuhn (7). It involves the measurement of the MOS capacitor displacement current density, J_c, in response to a linear gate-voltage ramp, $V_g = at$. The low-frequency capacitance, C_{LF}, is related to the displacement current density by $J_c = aC_{LF}$.

Measurements of surface-state densities at the Si-SiO_2 interface were carried out on suitably prepared MOS capacitors. The silicon used in this work was in the form of polished circular slices (Monsanto), 2.5 cm in diameter, prepared by the Czochralski method. The dislocation count was specified to be less than 10^3 cm^{-2}. The slices used were n-type (phosphorus doped), of both (100) and (111) orientation, having resistivities ranging from 3 to 10 ohm-cm. The polished silicon wafers were degreased and carefully cleaned (10) prior to oxidation.

Oxidation was generally carried out immediately after cleaning. Dry or wet (95°C water) oxides were grown in a resistively heated furnace provided with a quartz tube and an alumina liner. Both the nitrogen and oxygen gases were derived from liquid sources. After oxidation and high-temperature annealing (if necessary), the slices were rapidly (< 3 sec) quenched to room temperature. Annealing was carried out either at the oxidation temperature, in the case of N_2, or at 450°C, in the case of forming gas. The thickness of the films was measured using a Talystep capable of ± 20Å accuracy. Typical oxide thicknesses used in this investigation ranged from 800 to 1500Å.

The MOS structures were completed by evaporating aluminum (99.999%) field plates, 1000Å thick, 500 μm in diameter, over the oxide through a metal mask. Aluminum was also evaporated on the bare back side of the silicon to produce an ohmic contact. The evaporations were carried out from a resistively heated, prefired, tungsten filament in a vacuum of 3×10^{-7} Torr.

After metallization, the over-all oxide quality was assessed by measuring the fixed oxide charge, Q_{ss}, and the mobile ionic charge, Q_o, using high-frequency (HF) C-V measurements and bias temperature (BT) stress techniques. All of the samples investigated exhibited minimal shift under BT stress at 150°C, + 10V for 10 min indicating no ionic contamination. The typical values of Q_{ss} observed ranged from 0.6×10^{11} to 4×10^{11} cm^{-2}, depending on the oxide growth and annealing temperatures. The HF C-V characteristics were also used to determine the effective substrate doping and the oxide capacitance.

After assessing the densities of extraneous charges, the surface-state density was determined. Figure 2 shows a typical C-V characteristic obtained at a bias sweep rate of 50 mV/sec. A factor of ten increase in the bias sweep rate resulted in negligible change in the C-V characteristics, indicating that the required equilibrium was obtained. For this particular sample, the matching of the experimental and theoretical $d\psi_s/dV_o$ was done for ψ_s between 0.375 and 0.430V, assuming $\Delta\psi_s < kT/2q$ and $\Delta C_{LF}/C_{LF} = 0.01$. The corresponding surface-state density is shown in Fig. 3.

The usefulness of the approximate method of determining near midgap surface-state densities was verified for this sample. The value of N'_{st} was 5.4×10^{10} states/cm^2-eV, which is within 10% of the midgap value of 6×10^{10} states/cm^2-eV obtained from computer calculations. For comparison purposes, some of the surface-state density plots in the next section show the estimated N_{st} as obtained from Eq. [10]. In most cases, good agreement between N'_{st} and the actual density of states was obtained.

Experimental Results and Discussion

A large number of MOS samples were prepared and the dependence of surface-state densities on the following processing parameters was investigated: (a) substrate orientation and type of oxide growth, (b) high-temperature annealing in nitrogen, (c) low-temperature heat treatment in forming gas, (d) temperature of oxide growth and fixed oxide charge, Q_{ss}.

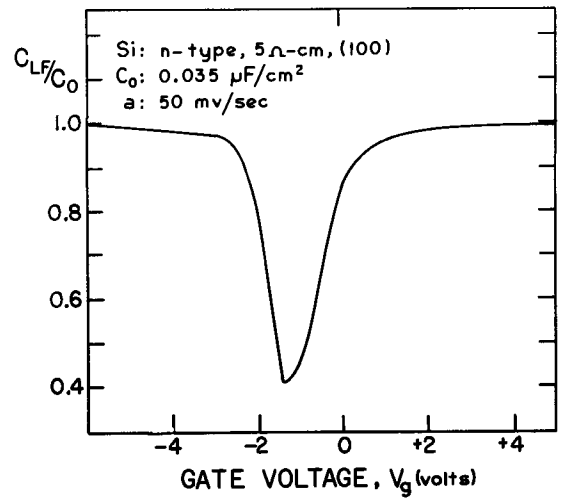

Fig. 2. LF thermal equilibrium C-V characteristics (oxide growth, dry; growth temperature, 1100°C; N_2 anneal, 1110°C for 30 min; H_2 anneal, 450°C for 30 min after metallization).

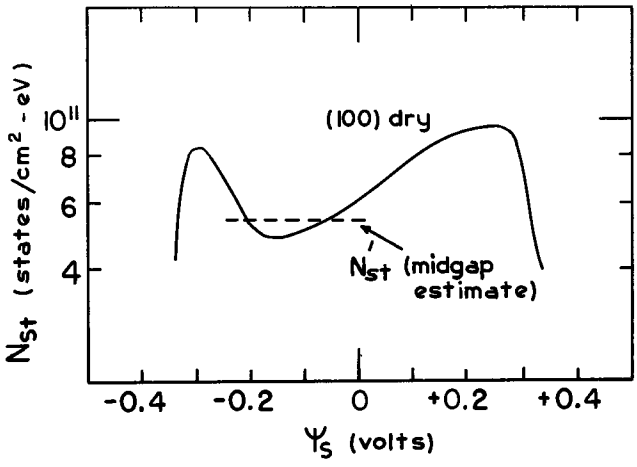

Fig. 3. Surface-state density vs. surface potential for the sample shown in Fig. 2.

The dependence of surface-state densities on orientation of the silicon substrate was evaluated using both dry and wet oxides. The typical surface-state densities obtained using dry oxides grown at 1100°C on (111) and (100) oriented slices are shown in Fig. 4 [curves (a) and (b)]. As expected, the (100) plane shows the lowest over-all density of states. Similar results were obtained using wet oxides, as shown in Fig. 4 [curves (c) and (d)]; however, in general the density of states was lower for wet than for dry oxides. The lower density of states in wet oxides is attributed to the annihilation of states by rapidly migrating and highly active hydrogen species originating from the water vapor. These results are in general agreement with those obtained by Brown (2), Nicollian (4), and Arnold (11).

The effect of nitrogen annealing at 1100°C on dry-grown oxides was investigated for both (100) and (111) oriented slices. Whereas previous to annealing the densities of surface states were quite different on (100) and (111) slices, as shown in Fig. 4, after annealing the densities were not only reduced considerably for both orientations but also approached approximately the same value near midgap, as shown in Fig. 5 [curves (a), (b)]. Furthermore, the midgap

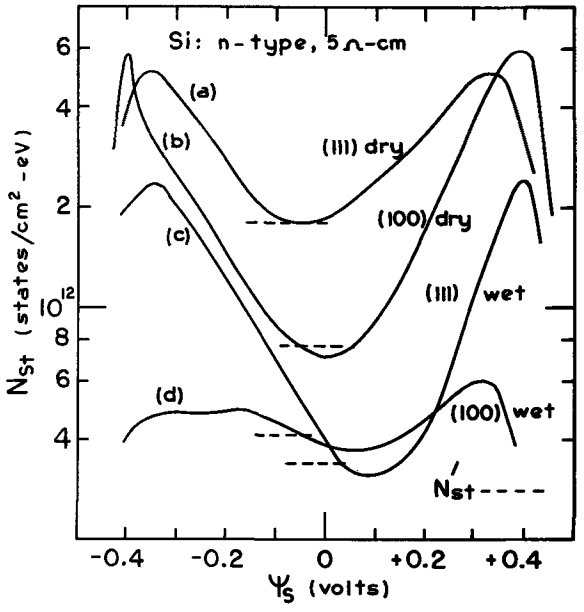

Fig. 4. Dependence of surface-state density vs. surface potential on orientation and type of oxide growth. (Oxide growth temperature, 1100°C; oxide thickness ≃ 1000Å; no annealing).

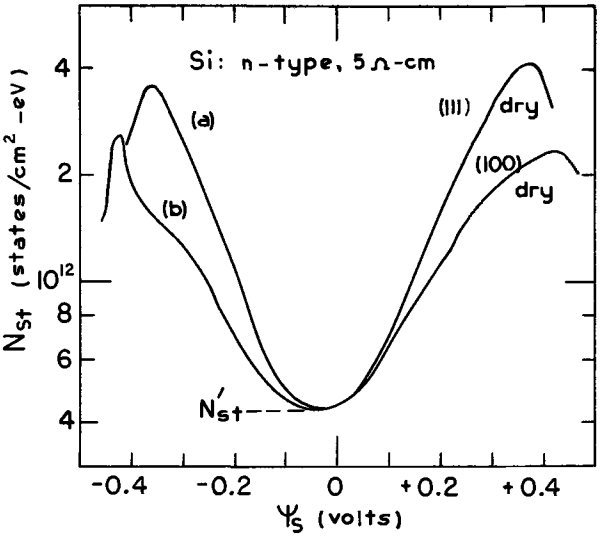

Fig. 5. Effect of N_2 annealing on surface-state density in dry grown oxides (oxide growth temperature, 1100°C; N_2 anneal at 1100°C for 30 min; oxide thickness ≃ 1000Å).

densities observed were close to those obtained on unannealed wet oxides of either orientation. However, the total density of states integrated over the bandgap was still lowest for wet, unannealed oxides on (100) orientation slices.

Nitrogen annealing was also observed to reduce the fixed oxide charge Q_{ss} (12) at the Si-SiO_2 interface. This reduction is the result of traps, induced by annealing (13, 14), competing with the oxide-silicon interface for electrons donated by the ionic silicon.[6] Trapped electrons effectively decrease the net fixed oxide charge Q_{ss} measured by the HF C-V technique.

The effect of low-temperature heat treatment of oxides in forming gas (5% H_2, 95% N_2) at 450°C was also investigated by comparing the surface-state densities observed on (100) oriented substrates under the

[6] These traps are also able to interact with sodium donor sites by trapping the sodium electrons and hence localizing any mobile sodium ions. This explains the experimentally observed improvement in stability of sodium-contaminated samples after nitrogen annealing, although the total sodium concentration in the sample remained fixed.

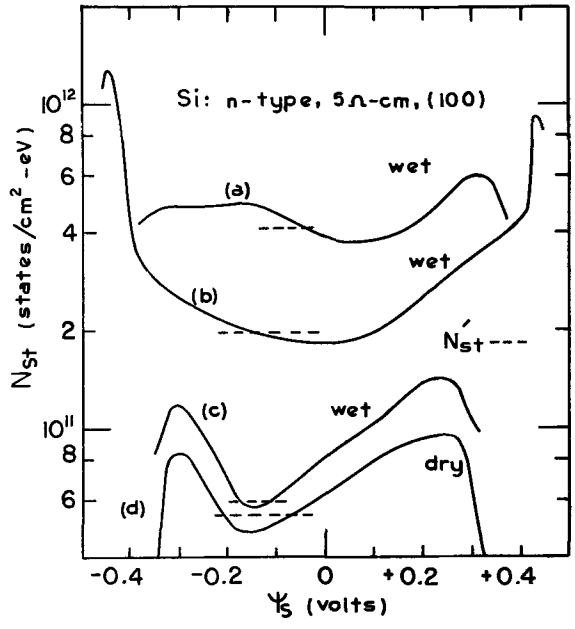

Fig. 6. Effect of annealing in forming gas (oxide growth temperature, 1100°C; oxide thickness ≃ 1000Å). (a) no anneal; (b) H_2 anneal, 450°C for 30 min prior to metallization, (c) H_2 anneal, 450°C for 30 min after metallization; (d) N_2 anneal, 1100°C for 30 min followed by H_2 anneal, 450°C for 30 min after metallization).

following conditions: (*a*) wet grown oxide + aluminum metallization, (*b*) wet grown oxide + forming gas heat treatment + aluminum metallization, (*c*) wet grown oxide + aluminum metallization + forming gas heat treatment.

Curves (a), (b) and (c) in Fig. 6 show that heat treatment of wet oxides in forming gas in the presence of a reactive metal such as aluminum is the most effective in reducing the surface-state density. The reduction in surface-state densities after forming-gas heat treatment is attributed to adsorption of active hydrogen at the Si-SiO_2 interface. The aluminum (15-17) causes a further reduction in surface-state density by reacting with water adsorbed at the oxide surface during the heat treatment. Hydrogen is released and migrates to the Si-SiO_2 interface. This hydrogen (atomic or ionic) is thus available for bonding to any uncompensated bonds which are believed to be a possible origin of fast states at that interface. As the dangling bonds are saturated, the density of fast states is reduced. It has been postulated (18) that ionic Si centers acting either as acceptor or donor states may be reduced according to the reaction

$$\mathrm{Si} + \mathrm{H} \rightleftarrows \mathrm{Si} - \mathrm{H}$$

However, Si—H bonds are not stable at elevated temperatures. This explains why low-temperature heat-treatments reduce the surface-state density even in wet-grown oxides where hydrogen is expected to be plentiful.

Also shown in Fig. 6, curve (d), is the surface-state density for a dry oxide grown at 1100°C and subjected to a nitrogen anneal at the growth temperature and then to a forming-gas anneal at 450°C after aluminum metallization. This combination of anneals resulted in the lowest midgap surface-state density (6×10^{10} cm^{-2}-eV^{-1}) as well as the lowest fixed oxide charge (6×10^{10} cm^{-2}) observed in this investigation and appears to be the optimum processing method of obtaining both low oxide charge and low surface-state density.

The effect of temperature of oxidation on the surface-state density was also investigated using dry oxides grown at 900°, 1000°, and 1100°C on (100) orien-

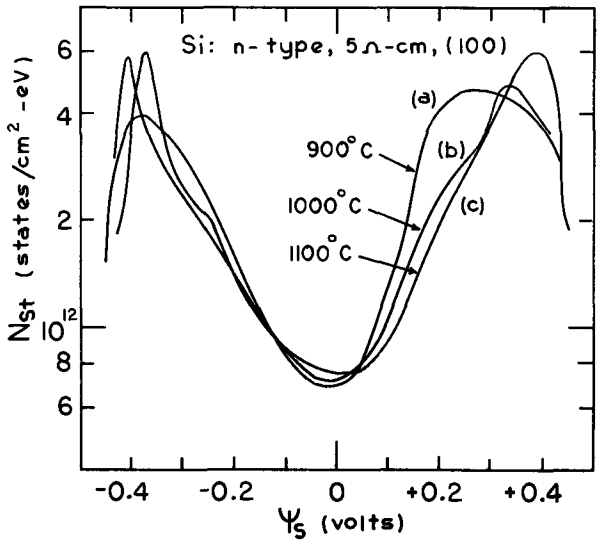

Fig. 7. Effect of dry oxide growth temperature on the surface state density (oxide thickness ≃ 1000Å; no anneal).

tated slices. The results, shown in Fig. 7, indicate no appreciable dependence of surface states on growth temperature. On the other hand, the fixed oxide charge, Q_{ss}, was observed to decrease with increasing temperature of oxidation in agreement with the results of Deal *et al.* (12).

Goetzberger *et al.* (19) have postulated a common origin for the fixed oxide charge and the surface-state charge. Evidence in favor of this postulate include:

(*a*) the fact that the surface-state density and the surface charge have the same crystallographic dependence as demonstrated by Arnold *et al.* (11), and
(*b*) the results obtained in this investigation with high-temperature nitrogen annealing which reduces both Q_{ss} and N_{st}.

However, hydrogen annealing, as shown, reduces the surface-state density without affecting the oxide charge. Similarly, the oxide growth temperature appears to have little affect on the surface-state density while reducing the oxide charge. Hence, it is evident that some processing parameters affect one charge without affecting the other. The lack of a more explicit correlation between the two charges suggests that they may not have a single common origin. It is perhaps possible that two or more discrete mechanisms contribute to the surface-state density, only one of which correlates with the fixed oxide charge (11).

Characterization of Multilevel Interconnection Defects

R. H. Cox* and H. Hentzschel*,[1]

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Scanning electron microscopy and metallurgical sectioning were combined to detect defects and potential reliability problems at crossovers and feedthroughs in multilevel circuits. The extremely large depth of field of the scanning electron microscope permitted "on-edge" examination of the sample surface topography, while metallurgical cross-sectioning allowed examination of buried layers. This method is a very powerful tool for characterizing multilevel integrated circuits.

The advent of large scale integration (LSI) has resulted in electronic components which have considerably greater functional capability than the basic integrated circuit. Conventional integrated circuits are the unit cells of an LSI array, and they are interconnected utilizing a multilevel system formed by interleaving layers of metal and insulation over the basic integrated circuit. Medium scale integration (MSI) lies in between integrated circuits and LSI in complexity. In some cases, MSI can be achieved with one level of interconnection, but frequently, a two-level interconnection system is employed. In order to achieve

* Electrochemical Society Active Member.

Key words: multilevel interconnection defects, LSI (large scale integration), scanning electron microscopy, optical microscopy, metallography.

LSI, a multilevel interconnection system is required. At the present time, both two- and three-level systems are employed. The demands on this technology are more severe than on conventional integrated circuit passivation and metallization technology, for multilevel interconnection requires both that leads cross one another and that they feed through from one level to another. Crossovers are subject to both electrical shorts and opens, and interlevel feedthroughs are subject to electrical opens. Furthermore, the added processing problems of working with a multilevel construction can introduce multilevel defects which are potential reliability problems.

The purpose of this paper is to present two of the methods employed in this investigation and to discuss the defects which were identified and characterized using these techniques. Scanning electron microscopy of sample surfaces and optical microscopy of metallurgical sections were the two above-mentioned techniques. As is shown below, these two methods complement one another and, when they are used together, give a thorough characterization of the multilevel structure.

Experimental

Scanning electron microscopy possesses distinct advantages which can yield information quickly and accurately. A major advantage is that direct examination of the sample surface is possible, and the depth perception and magnification are much greater than that possible with the optical microscope.

Patterned multilevel structures are quite easy to examine in the scanning electron microscope. A particular advantage is the ability to study a slice "on edge," which gives an excellent perspective when searching for multilevel defects. This view is obtained by inclining the slice at a very shallow angle (10° to 30°) to the primary beam. Correspondingly, the secondary electron detector is located normal to the beam and at an 80°-60° angle to the sample. Although features parallel to the slice surface are greatly foreshortened in one direction, features normal to the slice surface are seen at nearly true size. Hence, the edges of patterned metal and the side walls of feedthroughs are seen clearly. These structural features cannot be examined at high magnifications using conventional optical microscopy. In this study, the SEM's emissive mode of operation was employed, utilizing a CRT display of secondary electrons produced by a 25 kV primary electron beam. Image contrast is produced by differences in secondary electron emission from the sample. The resultant image has a remarkable three-dimensional quality, especially when the sample is inclined at an angle to the electron beam.

The metallographic studies required considerable skill in sample preparation, but the results were equally rewarding. Although the depth perception and resolution (0.1-0.2 μm) of the optical microscope are less than the SEM, a major advantage is gained by an optical examination of a cross-sectioned sample. Because the different layers of thin films possessed distinct color and reflectivity differences, an optical examination of the metallographic section often yielded more information than an SEM examination of the same cross-sectioned sample.

The main problem in sectioning multilayer devices deposited on silicon is the rather low mechanical stability of the different layers, which may be as thin as 1000Å or less. Also the extreme difference in the hardness of the various materials involved causes the formation of steps during polishing. The optical microscope with its low depth of field cannot give clear pictures of the layers when steps exist between them. Yet, the goal of a flat, highly polished surface with no mechanical damage of the layers can be reached by the following technique: The sample is glued with the side carrying the devices to a glass plate; preferably, a thermosetting epoxy with a low viscosity in the uncured state is used. It is important to avoid the entrapment of bubbles during mixing. The curing is done at elevated temperatures to make a hard joint. This assembly is mounted in a plastic block in such a way that the multilayers are cut in the desired direction and plane. In the grinding, lapping, and polishing process, extreme care is taken to avoid a mechanical destruction of the various layers. Most of the different layers are visible in the optical microscope after polishing, without etching. It is well known that the etch rate of oxides deposited in different ways varies widely. So, a very slight oxide-etch can differentiate between different kinds of quartz. Now, the reflectivity of SiO_2 is quite low, especially at an oxide-oil interface when an oil-immersion objective is used. Therefore, an extremely thin film of evaporated metal is used to increase the reflectivity of the oxide and make it visible.

The majority of the multilevel structures presented in this paper employed Mo-Au metallization. A few examples of filament-evaporated Al metallization are presented as well. The insulating oxides were produced by RF sputtering and silane vapor-phase deposition.

Results and Discussion

The following photomicrographs were selected to illustrate the strength of the method of combining scanning electron microscopy and optical metallography for multilevel characterization. Both defective and good crossover and feedthrough structures are presented. The examples given represent neither the frequency of defect occurrence nor do they show all types of defects, but rather, they were selected because they were interesting photomicrographs and verified the usefulness of these two characterization tools when used together.

A schematic drawing of a multilevel crossover is given in Fig. 1. The first-level metals (Mo-Au-Mo) are deposited over the thermal oxide (SiO_2) which is grown on the Si substrate. After this first-level metallization is patterned by etching, insulating oxides (RF-sputtered and silane vapor-deposition oxides) are deposited over the entire wafer. Feedthrough holes to first-level metal are etched in the insulating oxide at appropriate locations. Finally, second-level metallization (Mo-Au) is deposited over the insulating oxide and through the feedthrough holes, and the second-level metal is patterned. One defect sometimes observed is an electrical open in the second-level metal.

Figure 2 presents SEM micrographs of defective crossovers with very thin, nearly open metal at the vertical edge of the step. Figure 2a represents Al metallization, and Fig. 2b represents Mo-Au metallization. The oxide-coated step runs from the upper-left to the lower-right part of each picture. The metallurgical cross section, Fig. 3, clearly shows the thin metal at the vertical edge of the step, and it confirms the existence of the defect suggested by the SEM inspection. The insulating oxides appear dark in the photomicrograph because of their low optical reflectivity. The top

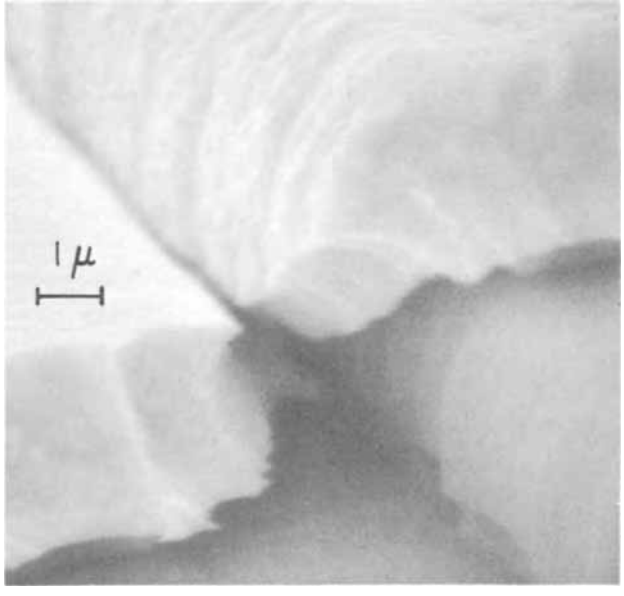

Fig. 2b. SEM micrograph of a defective Mo-Au crossover

Mo layer is very thin, and it is difficult to resolve in most of the figures. The bottom Mo layer shows much more clearly. A possible cause of the thin crossover metal is suggested by the vertical appearance of the edge of the first-level metal. Figures 4 and 5 illustrate the steps taken to produce a greatly improved crossover structure. Tapered Mo-Au-Mo coated with an insulating oxide layer is shown in Fig. 4. Note that the insulating oxide is clearly seen in this figure, as compared to the dark appearing, transparent oxide in Fig. 3. This improvement was achieved by coating the cross section with a very thin layer of evaporated Ge to increase the oxide reflectivity. Figure 5 shows a final Mo-Au crossover produced by tapering first-level metal. Note the second-level metal crosses over the step with no reduction in thickness. Figures 6a and 6b are SEM micrographs of good Mo-Au and Al crossovers, respectively. The slight darkening seen at the edge of the metal-oxide interface is caused by the charging of the oxide by the electron beam. As the beam sweeps over the oxide immediately adjacent to the highly conductive metal, a region of decreased secondary electron emission results. This effect can be troublesome where thick oxides are employed. However, excellent image quality can be gained easily by coating the entire sample with a thin layer of evaporated Au (< 250Å).

A schematic drawing of a multilevel feedthrough is given in Fig. 7; the first-level metallization and insulating oxide are produced in the same manner as explained in Fig. 1 (the multilevel crossover). Holes

are etched in the oxide to produce the feedthrough interconnection, and the final metal is deposited and patterned. Causes of electrical open circuits are shown in the next photomicrographs. Figure 8 is a metallurgical cross section through a feedthrough. The failure to etch completely through the oxide is the obvious cause of the open circuit. In this case, scanning electron microscopy would not have indicated the defect. Figure 9 illustrates a second type of feedthrough defect. Figure 9a is a SEM photomicrograph showing an apparent

hairline crack at the base of the vertical step of the Mo-Au feedthrough. Figure 9b is a cross section which confirms the presence of the hairline crack. The vertical sidewall of the oxide is likely to be the cause of the thin metal. Figure 10 is a cross section of a Mo-Au feedthrough produced by proper processing steps. The third-level metal connects to the second-level metal through a via hole etched in the oxide. The two slopes seen in the oxide wall are due to the difference in etch rates of the two oxides which compose the insulating layer. The top layer, made by silane deposition, etches more rapidly than the lower RF sputtered oxide layer. This feedthrough is excellent in quality, showing no reduction in metal thickness at the step. Figure 11 is a SEM photomicrograph of the same type feedthrough, showing the Mo-Au crossing the tapered oxide wall and connecting to the bottom of the feedthrough. The sharp silane-deposited oxide step runs from the upper center to the lower right-hand portion of the micrograph. The shallow RF deposited oxide step is the left-hand portion of the micrograph.

Conclusion

The combination of scanning electron microscopy and metallographic sectioning provided an excellent method of characterizing multilevel defects. The "on-edge" examination of multilevel crossovers was particularly revealing, and the exact location of metal opens were readily determined. Likewise, defects on the vertical walls of feedthroughs were quickly found. Optical microscopic data obtained from metallographic sections complemented the scanning electron microscope data. Defects in both crossover and feedthrough structures were shown with equal clarity when examined in cross section. The locations of both shorts and opens have been observed by optical microscopy. This investigation has resulted in an enhanced understanding of multilevel defects. Once this knowledge has been gained, it is an easier job to build higher reliability multilevel structures.

Pseudo-Brewster Angle Determination of Carrier Concentration

W. A. Keenan and P. A. Schumann, Jr.*

IBM Component Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

The Brewster angle has long been used to determine the index of refraction of nonabsorbing material. Semiconductors and other absorbing materials exhibit a nonzero minimum at a "pseudo-Brewster" angle which depends on the wavelength of incident light and the optical constants of the materials. Since semiconductor infrared optical constants are strongly dependent on the carrier density, the pseudo-Brewster angle is an indication of this density. An infrared, optical constant model for semiconductors has been used to calculate calibration curves relating carrier concentration in silicon to the pseudo-Brewster angle for several wavelengths, the range of carrier concentrations being limited by the wavelength employed. Experimental results for silicon are presented for a wavelength of 3.391 μm.

Optical techniques are very attractive for characterizing semiconductor materials, because they are both contactless and nondestructive. Infrared interference and plasma resonance are two very good examples of techniques used to measure the properties of processed semiconductors. Infrared interference is used to determine the thickness of epitaxial films. Plasma resonance is used to determine the carrier concentration of semiconductors.

For plasma resonance, a spectrophotometer is used to measure the reflectivity at a fixed angle of incidence on the semiconductor sample while the wavelength of the reflected light is scanned. The wavelength of minimum reflectivity is related to semiconductor carrier concentration by means of a calibration curve (1). In this technique no absolute quantities need be measured since only relative reflectivity is observed and

* Electrochemical Society Active Member.

Key words: semiconductor carrier concentration, polarized infrared light, silicon, Brewster angle, plasma resonance.

the wavelength corresponding to the reflectivity minimum determined.

In the above two techniques, a reflectivity minimum is observed by scanning the wavelength for a fixed angle of incidence. If, on the other hand, the polarized reflectivity is measured as a function of the angle of incidence for one wavelength, a minimum will again be observed. The angle at which this minimum is observed, the pseudo-Brewster angle, is related through the semiconductor optical constants to the carrier concentration of the material. Figure 1 shows calculated reflectivity curves for n-type silicon with an impurity concentration of 1×10^{19} cm^{-3} at a wavelength of 3.391 μm. This wavelength is put out by a He-Ne laser with special resonator windows used in the experimental work presented. R_s, the reflectivity for light polarized with its electric vector perpendicular to the plane of incidence, increases monotonically as the angle of incidence increases from 0 to 90 degrees. The parallel component of reflectivity (R_p), exhibits a minimum at an angle related to the optical constants of the semiconductor.

The approximate expressions (2) for the parallel, Eq. [1], and perpendicular, Eq. [2], components of linearly polarized, reflected light as a function of the angle of incidence are

$$R_p(\theta) = \frac{(n^2 + k^2)\cos^2\theta - 2n\cos\theta + 1}{(n^2 + k^2)\cos^2\theta + 2n\cos\theta + 1} \quad [1]$$

and

$$R_s(\theta) = \frac{(n^2 + k^2) - 2n\cos\theta + \cos^2\theta}{(n^2 + k^2) + 2n\cos\theta + \cos^2\theta} \quad [2]$$

where θ = angle of incidence, n = index of refraction, and k = extinction coefficient.

These approximations are valid for $(n^2 + k^2) >> 1$, which is the case for semiconductors in the infrared region of the spectrum. Setting the derivative of $R_p(\theta)$ with respect to cos θ equal to zero, the minimum in the parallel component of reflectivity is found to occur at

$$\cos\theta_B = \frac{1}{(n^2 + k^2)^{1/2}}$$

or

$$\theta_B = \cos^{-1}\frac{1}{(n^2 + k^2)^{1/2}} \quad [3]$$

where θ_B is defined as the pseudo-Brewster angle.

The Brewster angle for nonabsorbing material (3) (with a zero extinction coefficient) is defined as the angle at which the parallel reflectivity $R_p(\theta)$ goes to zero. For an absorbing material such as a semiconductor, with nonzero k, $R_p(\theta)$ attains a nonzero minimum at θ_B, the pseudo-Brewster angle. This angle is directly related to the optical constants of the material as shown in Eq. [3].

The free-carrier optical constant theory for a semiconductor derived by Schumann and Phillips (4) can be used to relate the index of refraction n and the extinction coefficient k at any wavelength to the impurity concentration of the material. The results are

$$n = \frac{1}{\sqrt{2}}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^{1/2} \left\{1 \pm \left[1 + \frac{e^8\lambda^6 N^4\rho_0^2 g^2 [L(D)]^2}{64\pi^6\epsilon_0^2 C^6 m^{*4}\left[K - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^2}\right]^{1/2}\right\}^{1/2} \quad [4]$$

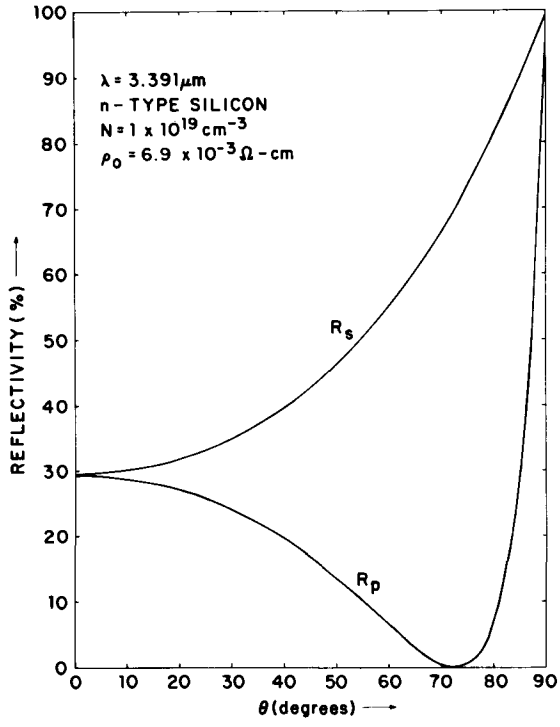

Fig. 1. Parallel and perpendicular reflectivity as a function of the angle of incidence at $\lambda = 3.391$ μm for n-type silicon; impurity concentration $N = 1 \times 10^{19}$ cm^{-3}.

where

$$J(D) = \frac{1}{\Gamma(5/2)}\int_0^\infty \frac{x^{9/2}e^{-x}\,dx}{x^3 + D}$$

$$L(D) = \int_0^\infty \frac{x^3 e^{-x}\,dx}{x^3 + D}$$

$$D = \frac{N^2 e^4 \lambda^2 \rho_0^2 \Gamma(4)\, g}{4\pi^2 C^2 m^{*2}}$$

$$g = \frac{\Gamma(4)}{[\Gamma(5/2)]^2} = 3.39$$

and

$$K_L = \frac{\epsilon_L}{\epsilon_0}$$

In the above equations ϵ_L = lattice dielectric constant, ϵ_0 = free space dielectric constant, $\Gamma(x)$ = gamma function of x, C = speed of light, m^* = effective mass, N = doping impurity concentration, e = electronic charge, λ = wavelength of light, and ρ_0 = d-c resistivity.

Since these equations relate n and k to N and ρ_0 and since θ_B is a function of n and k, θ_B can be used to determine the impurity concentration or resistivity of the semiconductor. In the theoretical curves presented in Fig. 1 through 8 for silicon, the calculations were made using Irvin's (5) curves to relate ρ_0 to N, an assumed value of 0.26 for the effective mass ratio for n-type silicon, and a relative lattice dielectric constant $K_L = 11.7$ (6).

In Fig. 1 the value of $R_p(\theta)$ appears to go to zero on the 100% scale used in the plot. Figure 2, a logarithmic plot of the same $R_p(\theta)$ curve, shows that the reflectivity attains a minimum of 3.63×10^{-4}% at a pseudo-Brewster angle of $\theta_B = 72.73°$. The angular width of

$$k = \frac{1}{\sqrt{2}}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^{1/2} \left\{-1 \pm \left[1 + \frac{e^8\lambda^6 N^4\rho_0^2 g^2 [L(D)]^2}{64\pi^6\epsilon_0^2 C^6 m^{*4}\left[K_L - \frac{e^2\lambda^2 NJ(D)}{4\pi^2\epsilon_0 C^2 m^*}\right]^2}\right]^{1/2}\right\}^{1/2} \quad [5]$$

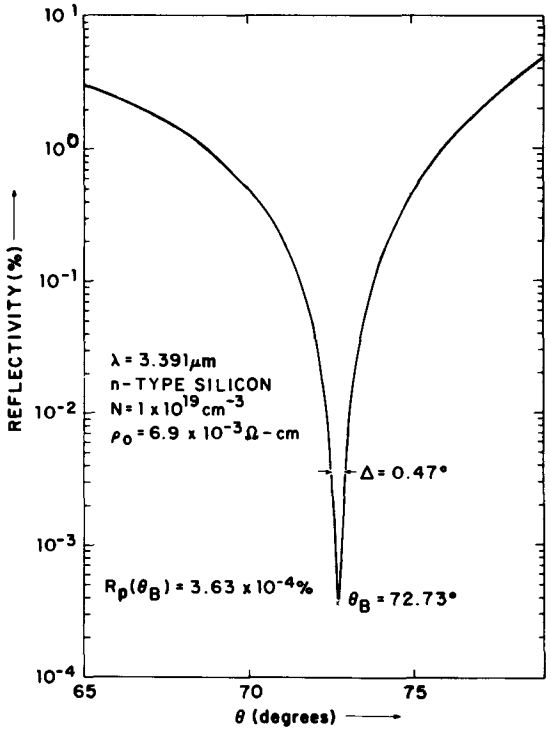

Fig. 2. Logarithm of parallel component of polarized reflectivity as a function of the angle of incidence at $\lambda = 3.391$ μm for n-type silicon; impurity concentration $N = 1 \times 10^{19}$ cm^{-3}.

this minimum is $\Delta = 0.47°$ at a value of R_p one order of magnitude greater than $R_p(\theta_B)$.

Figure 3 shows a logarithmic plot of $R_p(\theta)$ for n-type silicon with $N = 4 \times 10^{19}$ cm^{-3} using $\lambda = 3.391$ μm. Figure 2 is superimposed for comparison. Note that all three parameters [θ_B, $R_p(\theta_B)$, and Δ] that characterize the minimum change as concentration changes.

Calibration curves relating the impurity concentration N and the pseudo-Brewster angle θ_B, have been

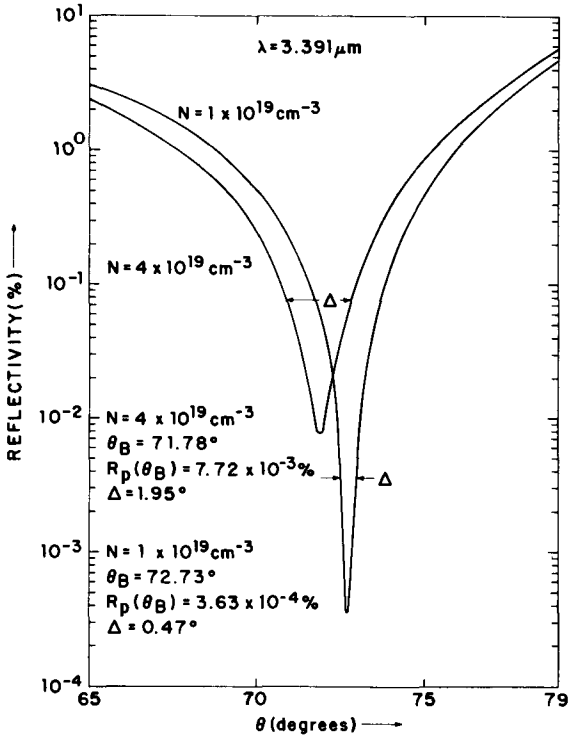

Fig. 3. Logarithmic plot of $R_p(\theta)$ at $\lambda = 3.391$ μm for impurity concentrations of $N = 4 \times 10^{19}$ cm^{-3} and $N = 1 \times 10^{19}$ cm^{-3}.

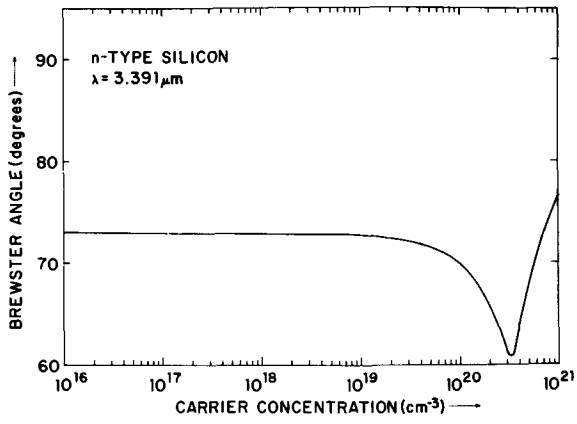

Fig. 4. Pseudo-Brewster angle calibration curve (θ_B vs. N) for n-type silicon at $\lambda = 3.391$ μm.

calculated using Eq. [3], [4], and [5]. Figure 4 shows the θ_B *vs.* N calibration curve for n-type silicon, and a wavelength $\lambda = 3.391$ μm. As the concentration decreases, θ_B approaches 73°, the value for intrinsic silicon. At higher concentrations θ_B is very sensitive to changes in concentration; unfortunately, for any angle less than 73° concentration is not a single-valued function of θ_B. For example, in Fig. 4, a pseudo-Brewster angle of 68.0 could correspond to a concentration of either $N = 1.45 \times 10^{20}$ cm^{-3} or $N = 5.0 \times 10^{20}$ cm^{-3}.

Since the semiconductor infrared optical constants, expressed in Eq. [4] and [5], are strongly dependent on the wavelength of light, the θ_B *vs.* N calibration curves are also strongly dependent on wavelength. A family of calibration curves for n-type silicon is shown in Fig. 5. Note that for short wavelengths, the sensitivity of θ_B to changes in concentration is great, but the range over which it is single valued is small. As wavelength is increased, the sensitivity of this angle to changes in concentration decreases, but the range over which it is single valued in concentration increases.

The fact that θ_B is not single valued in N for angles less than 73° can be resolved by measuring θ_B at two wavelengths. Alternately, if the magnitude of R_p is measured as the angle of incidence is varied around θ_B, then observing either $R_p(\theta_B)$ or the width Δ can resolve which N value is the correct one. Figure 6, showing calculated values of $R_p(\theta_B)$, indicates that it is a strong function of N; hence an order of magnitude measurement of $R_p(\theta_B)$ would suffice. Figure 7 shows that $\Delta = \theta_2 - \theta_1$ where $R_p(\theta_1) = R_p(\theta_2) \equiv 10R_p(\theta_B)$ is also a strong function of N.

Another technique for determining the correct value of N where θ_B is double valued is to measure the mag-

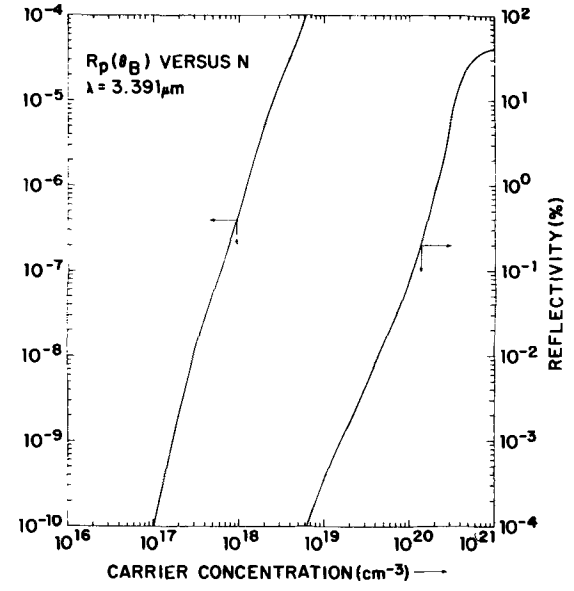

Fig. 6. Parallel component of polarized reflectivity at an angle of incidence equal to θ_B as a function of N for n-type silicon at $\lambda = 3.391$ μm.

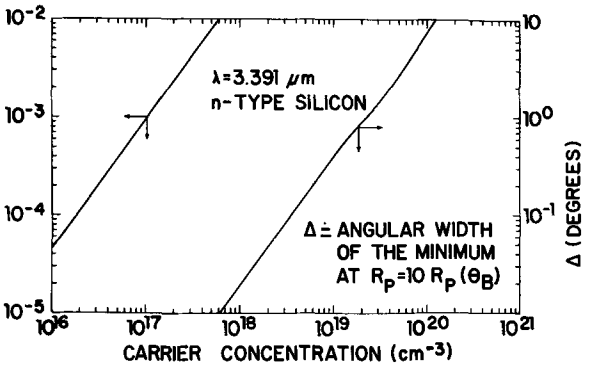

Fig. 7. Angular width of the parallel reflectivity minimum at $R_p = 10\ R_p(\theta_B)$ vs. N for n-type silicon at $\lambda = 3.391$ μm.

nitude of reflectivity of light incident at the pseudo-Brewster angle, but polarized perpendicular to the plane of incidence. This is done by rotating the plane of polarization while at the pseudo-Brewster angle. Figure 8 illustrates which of the double values of θ_B is correct for the sample concentration (N), using the perpendicular reflectivity $R_s(\theta_B)$. $R_s(\theta_B)$, calculated from the model and the calibration curve of θ_B is plot-

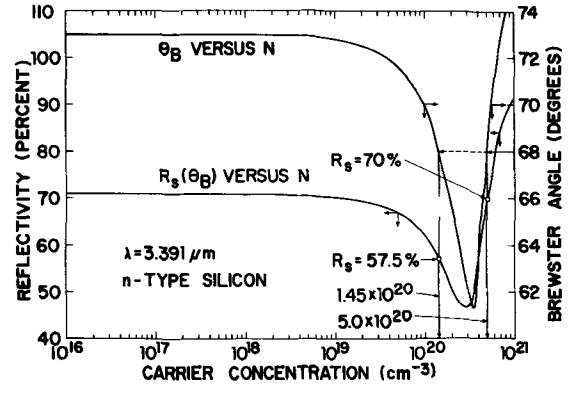

Fig. 8. Perpendicular reflectivity at θ_B vs. concentration and θ_B vs. N for n-type silicon at $\lambda = 3.391$ μm.

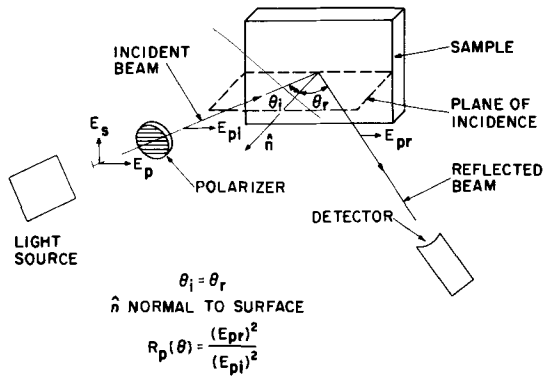

Fig. 9. Schematic of experimental setup to determine θ_B

ted *vs.* N for an assumed $\lambda = 3.391$ μm. As an example a specimen with θ_B measured at 68° would, from Fig. 8, correspond to $N = 1.45 \times 10^{20}$ cm^{-3} or $N = 5.0 \times 10^{20}$ cm^{-3}. Measurement would determine which of the corresponding values of $R_s(\theta_B)$, that is, 57.5% or 70%, obtains for this specimen, thus determining N.

An experimental setup to measure the polarized reflectivity and determine the pseudo-Brewster angle is shown schematically in Fig. 9. A Spectra-Physics He-Ne laser with 3.391 μm wavelength plane-polarized output served as the light source. The reflectivity was measured with a Golay infrared detector while a Siemens diffractometer simultaneously varied the angles of incidence and reflectance. An X-Y recorder (not indicated in Fig. 9) was used to plot R_p *vs.* the angle of incidence.

After orienting the laser for output polarized parallel to the plane of incidence of a test wafer, the angle was scanned to locate the reflectivity minimum. The polarization was adjusted to minimize the reflectivity and the angle was again scanned. This procedure was iterated until the reflectivity could no longer be reduced. The test wafer at its PBA served as an analyzer for adjusting the polarization of the laser.

Experimentally determined θ_B for several n-type silicon samples, both bulk and diffused wafers, are shown in Table I; the carrier concentration was determined from plasma resonance. The carrier concentration implied by the measured θ_B (shown in Table I) was determined using the theoretical calibration curve of Fig. 4. Figure 10 is a plot of the carrier concentrations determined by the two techniques. A least-square linear regression analysis yielded the straight line shown and a correlation coefficient of 0.992.

The concentrations derived from the PBA theoretical calibration curve fall below the plasma resonance concentrations. The excellent correlation implies that with the correct calibration curve, measurement of PBA could be used to determine N. The theoretical model (4) used to calculate the calibration curve assumes the

Conwell-Weisskopf scattering and Maxwell-Boltzmann statistics. Recent work (7) has shown that while the model accurately predicts trends in the optical constants as a function of concentration and wavelength, the actual values are in error. A constant value of effective mass ratio was used in calculating the calibration curve although effective mass is known to vary with concentration. For application of the PBA technique at a particular wavelength an experimental calibration curve would have to be constructed.

The PBA technique for determination of carrier concentration offers several advantages over plasma resonance. It requires scanning the angle of incidence rather than wavelength. It has a sharp minimum which is easy to read, and which becomes sharper as concentration decreases (cf. Fig. 3). The lower limit to the concentration that can be measured with PBA depends only on the wavelength employed, the longer the wavelength the lower the detectable concentration limit. The availability of long wavelength infrared lasers as polarized light sources makes PBA attractive as an automated process monitoring technique.

Partial Pressures in the Cd-Te and Zn-Te Systems

R. F. Brebrick*[1]

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

Partial pressures of Te_2, Cd, and Zn have been determined to within 10% for a number of compositions in the Cd-Te and Zn-Te systems by measuring the optical density of the vapor phase between 1990 and 7000A. For Te-saturated CdTe(c), the partial pressure of Te_2, p_2, reaches a maximum value of 0.188 atm near 915°C. For Cd-saturated CdTe(c), p_{Cd} is within a few per cent of that for pure Cd up to 840°C. At the 1092°C melting point, $p_2 = 5.5(10^{-3})$ and $p_{Cd} = 0.65$ atm. At 900°C the homogeneity range for CdTe(c) is shown to lie within outer limits of 49.0 and 50.5 a/o (atom per cent) Te and ΔG_f varies by less than 150 cal/g-atom between either Cd-saturated or Te-saturated and congruently subliming CdTe(c). Liquidus temperatures and the partial gram-atomic enthalpy and entropy are obtained for 55.0, 60.0, and 65.0 a/o Te melts. The liquidus points confirm the presence of an inflection point in the Te-rich liquidus and it is shown that this behavior is due primarily to the nonideal behavior of the Cd activity coefficient. Similarly, p_{Zn} for Zn-saturated ZnTe(c) has been determined to 900°C and p_2 for the Te-saturated ZnTe(c) to 1080°C. The homogeneity range at 900°C is bracketed between outer limits of 49.5 and 50.5 a/o Te corresponding to a maximum variation of ΔG_f of 190 cal/g-atom between either Zn-saturated or Te-saturated and congruently subliming ZnTe(c).

The liquidus line for CdTe has been determined by de Nobel (1), Kulwicki (2), Lorenz (3), and recently by Steininger *et al.* (4). The last three sets of data agree to within 10°C on the Cd-rich side of 50 a/o (atom per cent). The last two agree to within 20°C on the Te-rich side but are 10°C below the data of de Nobel and as much as 40°C below those of Kulwicki near 60 a/o Te. According to the last two determinations, the Te-rich liquidus temperature drops rapidly with increasing Te-content, being slightly concave out

[1] Present address: Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233.
Key words: phase diagram Cd-Te; thermodynamic properties Cd-Te, Zn-Te.

to 60-65 a/o where an inflection point occurs. The liquidus line is far removed from one calculated by assuming an ideal liquid phase in equilibrium with a compound CdTe(c) that melts at 1092°C with a heat of fusion of 12.01 kcal/mole. Partial pressures along the three-phase loop have been measured by de Nobel (1) and more extensively by Lorenz (3). Although the two determinations are in fair agreement on the partial pressure of Cd, p_{Cd}, along the Cd-rich leg of the loop, they are in poor agreement for that of Te_2, p_2, along the Te-rich leg. Recently Hall and conductivity measurements (5) on single crystal CdTe as a function of temperature and either p_{Cd} or p_2 indicate, on the basis of a simple point-defect model, that the homogeneity range for CdTe(c) includes, or is close to, the stoichiometric composition and is of the order of 10^{-5} a/o wide near 900°C. However, no direct measurements in terms of atom per cent have been made for the outer limits within which the homogeneity range must fall. Therefore, no upper bound has been placed on the variation of the Gibbs free energy of formation of CdTe(c) across its homogeneity range.

In this paper we report the results of optical density measurements which (*i*) give p_2 along the Te-rich leg of the three-phase loop up to the maximum melting point of 1092°C, (*ii*) give p_{Cd} along the Cd-rich leg up to 900°C, (*iii*) place outer limits of 49.0 and 50.5 a/o Te on the homogeneity range, and (*iv*) give liquidus temperatures for 55.0, 60.0, and 65.0 a/o Te. We also report similar measurements on ZnTe(c) that extend our earlier study (6).

Experimental

The experimental details of the optical density measurements between 1990 and 7000Å have been extensively described in an earlier study (6) on ZnTe(c). Essentially the experiment consists of measuring the optical density, $D = \log I_0/I$, of the vapor in a silica optical cell at a fixed temperature while a reservoir of a condensed phase, located at the end of a sidearm to the optical cell, is held at one of a series of lower temperatures. Since it was desired to determine pressures for reservoir temperatures approaching 1100°C, the optical cell was held fixed at 1100°C in some experiments, as well as at 1000°C in others, and calibration runs with pure Te and with pure Cd had to be made at 1100°C. For reservoir temperatures above 920°C, the Ag-liner used to help establish a uniform temperature over the reservoir zone was replaced by one of stainless steel. The temperature difference along the 5 cm reservoir zone was 2°-3°C or less in all measurements. The reservoir temperature was taken as that near the middle of the condensed phase in the reservoir zone and at the surface of the silica sidearm. It was measured using a Pt, 13% Rh thermocouple and an ice junction. The precision of measurement was ±0.1°C and, judging from calibrations at the melting point of Zn and Ag, the accuracy was better than ±0.5°C. The temperature difference across a 2 cm long optical cell at 1100°C was under 10°C. Both temperature differences were constant with time to within 0.5°C.

Spectroscopically pure elements (nominal 99.999% pure from Cominco American Inc., Spokane, Washington) were used to synthesize the samples by fusion. Generally, the Cd and Zn were first individually melted under 10^{-6} Torr vacuum, subjected to 600 Torr of H_2 for 5-10 min while molten, subjected to vacuum, and then quenched. In synthesizing the Cd-Te and Zn-Te samples, the elements were individually weighed to the nearest 0.1 mg to make a total near 3g, loaded into a silica test-tube, and outgassed for 4 hr at 140°C and pressures below 10^{-7} Torr. The sample was then sealed-off under vacuum, reacted with a hand torch, annealed 40 hr at 900°C, then 40 hr at 530°C, and quenched. The sample was removed from the silica test-tube, ground to pass a 1 mm opening, stainless steel sieve, and loaded into the carbon-coated sidearm of an optical cell. For five samples, 49.5 a/o Te Zn-Te, 49.0, 55.0, 60.0, and 65.0 a/o Te Cd-Te, the elements were loaded directly into the carbon-coated sidearm of an optical cell without pre-reaction. After outgassing the loaded cell for 4 hr at 140°C and 10^{-7} Torr, it was sealed-off. Optical cells used in an earlier study and containing 40.0 and 55.0 a/o Te Zn-Te were used again here. The optical cells were generally near 21 or 47 mm in optical path length (total length minus the thickness of two plane parallel windows). Windows that were 0.75 mm thick did not noticeably deform at 1100°C and total vapor pressures under 1 atm while 0.50 mm thick windows did deform over a period of 8-16 hr.

Results

Tellurium.—The qualitative features of the spectrum of $Te_2(g)$ at 1100°C are the same as at lower temperatures. [The optical density for a 1000°C optical cell is shown between 3100 and 4500Å in Fig. 2 of ref. (7) and between 2300 and 4000Å in Fig. 1 of ref. (8).] Since in the present study p_2 was in the 10^{-3} to 1 atm range, it was determined from the relatively weak absorption in the visible. A Te_2 band system extends from a minimum optical density near 3150Å through a maximum near 4100-5500Å and beyond, depending on the value of p_2. Vibronic bands are seen from 3870 to about 4500Å, the upper limit moving toward longer wavelengths with increasing partial pressure. The optical density at a number of wavelengths and for a 22.1 mm optical path length at 1100°C is plotted in Fig. 1 on a logarithmic scale against the reciprocal absolute temperature of the Te(l) reservoir. The line without points and near the middle of the figure gives the vapor pressure (9-11) of Te(l). The optical densities at 4357Å, an absorption band maximum, and at 5000 and 5500Å, in apparently structureless regions of the band system, have close to the same slope as the vapor pressure for optical densities greater than 0.1. When $D_{4357} \geq 0.1$, the relation between optical density and partial pressure is

$$p_2 = 0.320\, D_{4357}/L \qquad [1]$$

where L is the optical path length in millimeters. The optical densities at 2400 and 2800Å shown in Fig. 1 are at wavelengths where Cd(g) also absorbs. Except for two or three points, the straight lines in Fig. 1 fit the experimental points to better than 5% in optical density.

Cadmium.—Cd(g) has two prominent absorption peaks, the stronger at 2287Å, the weaker at 3257Å.

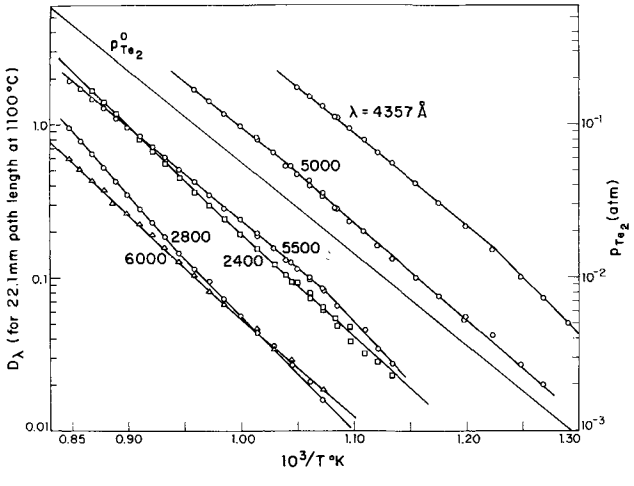

Fig. 1. The optical density of $Te_2(g)$, $D = \log (I^\circ_\lambda/I_\lambda)$, at a number of wavelengths for a 22.1 mm optical path at 1100°C plotted on a logarithmic scale against the reciprocal absolute temperature of a pure Te(l) reservoir. The solid line without points gives the vapor pressure of Te(l) as read with the right hand ordinate.

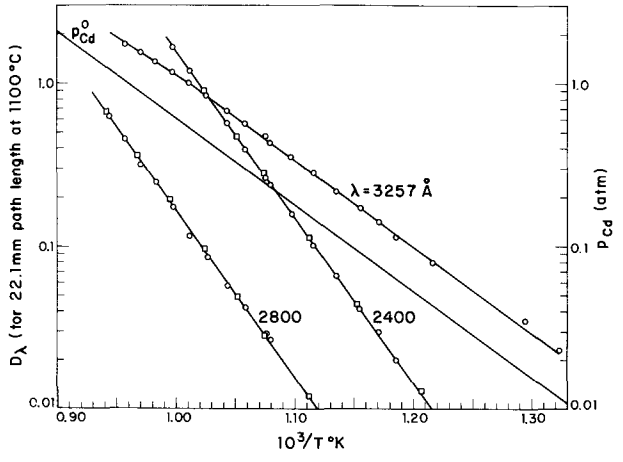

Fig. 2. Optical density of Cd(g) at a number of wavelengths for a 22.1 mm optical path at 1100°C plotted on a logarithmic scale against the reciprocal absolute temperature of a pure Cd(l) reservoir. The squares are normalized values obtained from a 47.5 mm optical-path cell. The line without points gives the vapor pressure of Cd(l) as read with the right hand ordinate.

With increasing pressure the 2287Å peak broadens extensively toward the red, as do the strongest peaks of Hg(g) (12, 13) and Zn(g) (6, 14). Figure 2 shows D_λ for a 22.1 mm path at 1100°C plotted against the reciprocal absolute temperature of the Cd(l) reservoir for a number of wavelengths. The line without points shows the vapor pressure of Cd(l) (15, 16). For the 10^{-2} to 1 atm range of pressure shown, D_{2287} is much greater than the upper limit of measurement, $D = 2$. In the long wavelength tail of this peak D_λ, shown in Fig. 2 for $\lambda = 2400$ and 2800Å, has a slope close to twice that of the vapor pressure, consistent with the statistical theory of self-broadening (17). For these two wavelengths, the plot also includes data obtained using an optical cell with a 47.5 mm path length and then normalized by multiplying by the factor (22.1/47.5). The two sets of points are in good agreement, showing that D depends linearly on the path length. Only the optical densities from the 22.1 mm cell are shown for the 3257Å peak. These are systematically larger than those obtained with a 47.5 mm cell after the latter are multiplied by (22.1/47.5). Thus D_{3257} depends on a fractional power of the path length rather than the first power. A similar behavior was noted (6) for the strong 2138Å Zn-line. Such behavior is to be expected (18) when the optical density at the peak of a narrow absorption line is measured, as is done here, using a spectral band-pass greater than the true half-width of the line.

The values of D at the 3257 and 2138Å peaks for Cd(g) and Zn(g), respectively, are sensitive to the spectrometer slit-width used and care was taken to hold these constant at a given wavelength for each spectral scan. Although D_{3257} has approximately the same temperature dependence as the vapor pressure of Cd(l), Fig. 2 itself was used to obtain p_{Cd} from the partial optical density of Cd(g), as is explained in the next section. Absorption of Cd(g) at 4357, 5000, and 5500Å is below 0.01 and negligible even at the highest values for p_{Cd} in Fig. 2. [The optical density at the strongest, 2287Å peak was used to determine p_{Cd} in a lower pressure range in an earlier study (19) on congruently subliming CdTe(c) using a 1000°C optical cell. The fact that the measured values of p_{Cd} and p_2 were in the ratio 2.00:1.00 attests to the accuracy attainable with this type of measurement as well as to the accuracy of the vapor pressures of Cd(l) and Te(l).]

Cadmium telluride.—For samples containing more than 50 a/o Te, the values of D_λ, $\lambda = 4357$, 5000, 5500Å, had the same relative magnitudes as observed with pure tellurium. As mentioned in the last section, the optical density due to Cd(g) is negligible at these wavelengths. Therefore, the observed value of D was multiplied by the factor, $22.1/L$, where L was the path length in millimeters, and Fig. 1 was used to determine p_2. Next the Te_2 contribution to the optical density at 2400 and 2800Å, where Cd(g) absorbs, was read from Fig. 1. The partial optical density of Cd(g) at each of these wavelengths was taken as the difference between the observed density and the Te_2 contribution. (The partial optical density of Cd(g) at 3257Å was taken as the difference between the observed optical density at 3257Å and an extrapolated value for the background at 3257Å that was obtained by drawing a straight line tangent to both sides of the peak on an optical density-wavelength trace.) The value of p_{Cd} corresponding to each of these partial optical densities was then read from Fig. 2.

The values of p_2 for samples containing more than 50 a/o Te are plotted on a logarithmic scale against the reciprocal absolute temperature in Fig. 3. The upper line without points gives the vapor pressure of Te(l), p^o_2 the vapor being essentially all Te_2(g). The lower line without points gives p_2 for congruently subliming CdTe(c) from an earlier study (19). Values of p_2 along the Te-rich leg of the three-phase loop fall along a parabola-like curve that approaches p^o_2 at low temperatures, reaches a maximum of 0.195 atm between 918° and 946°C, and then falls rapidly with increasing temperature. Near 946°C measurements were taken with both 1100° and 1000°C optical cells. The values obtained with the 1100°C cell are about 10% lower than those with the 1000°C cell, reaching a plateau of 0.180 atm at 940°C. Such a discrepancy could result from a relative error of 4° between the reservoir temperatures measured in the present calibration with a 1100°C cell and those measured in the calibration with a 1000°C cell (7, 8). At any rate, it introduces an uncertainty of 10% in the values reported here for the tellurium partial pressure. Since the values of p_2 agree for 50.5 and 55.0 a/o Te for $10^3/T \geqq 0.764$ and since p_2 for 50.5 a/o

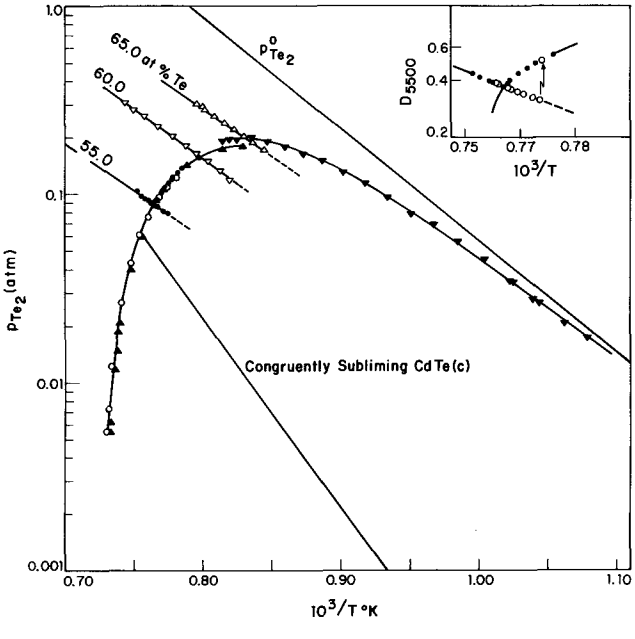

Fig. 3. Partial pressure of Te_2(g) in the Cd-Te system is plotted on a logarithmic scale against reciprocal absolute temperature. The vapor pressure of pure tellurium is given by the uppermost line without points. The lowest line without points gives $p_{Te_2} = p_2$ for congruently subliming CdTe(c) from ref. (19). ▼ 55.0 a/o Te, 1000°C cell; ● 55.0 a/o Te; ○, ▲ 50.5 a/o Te all with 1100°C cell. The inset in the upper right corner for a 55.0 a/o Te sample is described in the text.

Te drops rapidly with increasing temperature for $10^3/T < 0.764$, it appears that 50.5 a/o Te lies in the Te-rich three-phase field and outside the homogeneity range of CdTe(c). Smoothed values of p_2 along the Te-rich leg are given in Table I as a function of temperature. The smoothed values agree with those actually measured to within ±5%.

The three, short line segments cutting the three-phase curve in the upper left-hand portion of Fig. 3 give the p_2-$10^3/T$ relationship for liquids with the labeled compositions. The portions of these lines lying within the three-phase curve are for supercooled liquids. The intersection of these lines with the three-phase curve gives liquidus temperatures for the corresponding compositions, which are listed in Table II. (The 65.0 a/o Te sample was run with a 1000°C optical cell and the liquidus temperature is therefore taken at the intersection with the 1000°C data for the three-phase curve.) The lines are well enough defined that the relative, partial gram-atomic enthalpy and entropy of Te can be evaluated. These are also given in Table II.

Measurements on the 60.0 and 65.0 a/o Te samples were made only with decreasing temperatures and were not carried far enough to observe the termination of supercooling. Such a termination was observed with the 55.0 a/o Te sample as shown in the inset in Fig. 3, where D_{5500} (which is proportional to p_2 with good accuracy) is plotted on a logarithmic scale against $10^3/T$ on an expanded scale. The solid circles indicate points taken with increasing temperature and show that p_2 decreases with increasing temperature along the three-phase curve to the liquidus temperature, after which it increases along a straight line. The open circles indicate points taken with decreasing temperature. They show that the melt supercooled about 22° before crystallization of CdTe(c) commenced. At this time p_2 rose abruptly to a value on the three-phase curve (as indicated by the arrow) and there was a transient increase in temperature. Prior to crystallization, p_2 and T had been steady.

At the highest temperatures, p_{Cd} was obtained along the Te-rich leg of the three-phase curve as well as p_2. The pressure product, $p_{Cd}p_2^{1/2}$, is plotted on a logarithmic scale against the reciprocal absolute temperature in Fig. 4. The points near the upper end of the straight line are from the present study. The circles indicate that p_{Cd} was obtained from the partial optical density of Cd at its 3257Å peak, while the triangles indicate it was obtained from the partial optical density at 2400Å. These two determinations agree to within 15%. The squares at low temperatures along the lowest line are from an earlier study (19). The present results at the highest temperatures agree well with an extrapolation of the earlier results. The values of p_{Cd} in this range

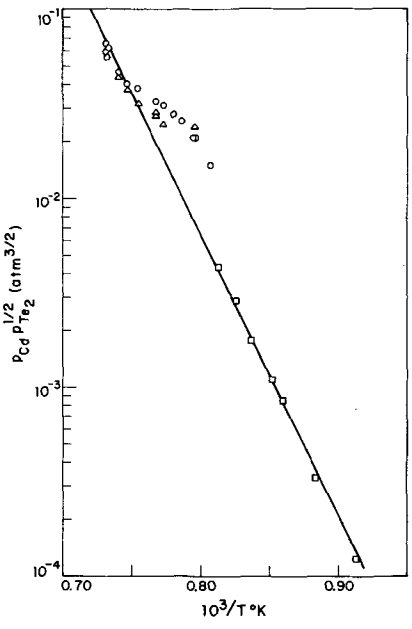

Fig. 4. Pressure product, $p_{Cd}p_2^{1/2}$, for CdTe(c) plotted on a logarithmic scale against the reciprocal absolute temperature. ○, p_{Cd} determined from the partial optical density of Cd(g) at 3257Å; △, p_{Cd} determined from the partial optical density at 2400Å; □, ref. (19).

are given in Table I. [At the melting point of 1092°C, $p_{Cd} = 0.65$ atm and $p_2 = 5.5(10^{-3})$ atm.] However, at the lowest temperature, $10^3/T = 0.81$, the pressure product obtained from the present measurements is high by a factor of three. It can be shown (20) thermodynamically, assuming only that the vapor is ideal, that at a given temperature, $p_{Cd}p_2^{1/2}$ is a maximum over a 50.00 a/o Te condensed phase. Since the present results near $10^3/T = 0.81$ give the pressure product not only for Te-saturated CdTe(c), but also for the 60 a/o Te melt in equilibrium with it (Fig. 3), the pressure product should not be higher than observed for congruently subliming CdTe(c). We, therefore, conclude that the present results at the lower temperatures are thermodynamically inconsistent with those obtained earlier and we believe them to be incorrect. Most likely the error lies in the measurement of p_{Cd} when p_2 is as much as five times larger. In particular, we speculate that under these circumstances our basic assumption is in error; namely, the total optical density is a linear superposition of contributions from Cd and Te_2 and does not depend on any terms of the form, $(p_{Cd})^m(p_2)^n$.

For 49.0 a/o Te, the only Cd-Te composition investigated with less than 50 a/o Te, the optical densities at 2500, 2800, and 2900Å are plotted on a logarithmic scale against $10^3/T$ along the upper three lines in Fig. 5. Also shown by the closed circles are data obtained with pure Cd. At each wavelength the points for these two compositions agree up to $10^3/T = 0.90$ (838°C) within an experimental error of about ±3%. Therefore, at least up to this temperature, 49.0 a/o Te lies outside the CdTe(c) homogeneity range. At higher temperatures, D_{2900} for the 49.0 a/o sample falls a little below that for pure Cd(l). Most likely, this means the Cd-rich liquidus composition is departing enough from pure Cd to cause a detectable decrease in the value of p_{Cd}. The line without points and near the bottom of Fig. 5 gives the vapor pressure of Cd(l) and, up to $10^3/T = 0.90$, also p_{Cd} for Cd-saturated CdTe(c). The points along the straight line branching away from the vapor pressure line at high temperatures give p_{Cd} for Cd-saturated CdTe(c) and were obtained from D_{2900}. At $10^3/T = 0.85$, $p_{Cd} = 3.24$ atm. At $10^3/T = 0.902$, $p_{Cd} = 2.0$ atm.

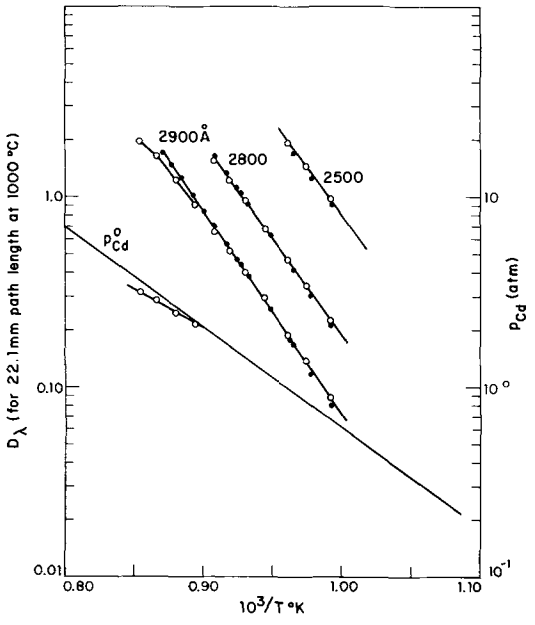

Fig. 5. Partial optical density of Cd(g) at the labeled wavelengths plotted on a logarithmic scale against reciprocal absolute temperature along the upper four lines. Open circles are for 49.0 a/o Te Cd-Te, closed circles for pure Cd(l). The line without points in the lower portion of the figures gives the vapor pressure of Cd(l). Points are shown for p_{Cd} of the 49.0 a/o sample only where they differ by at least 3% from the vapor pressure line of Cd(l).

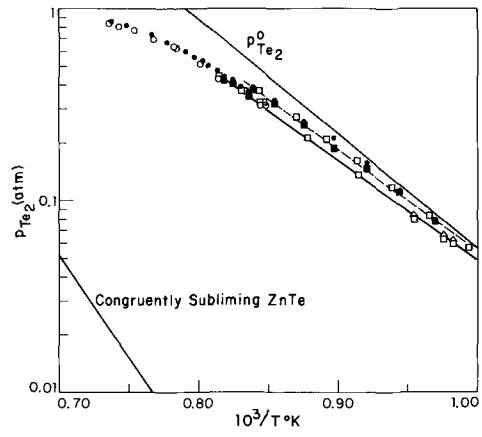

Fig. 6. Partial pressures of $Te_2(g)$ for Zn-Te samples with 50.5 a/o Te (open symbols) and 55.0 a/o Te (closed symbols) are plotted on a logarithmic scale against the reciprocal absolute temperature. Circles, squares, and triangles indicate p_2 was obtained from the optical density at 6000, 5500, and 5000Å, respectively. The lower line without points gives p_2 for congruently subliming ZnTe(c) from ref. (6).

Our first 49.0 a/o Te samples were prepared with as-received Cd and were pre-reacted and annealed before being loaded into the optical cell as described in the Experimental section. Optical density measurements indicated that although these samples were in the Cd-rich three-phase field at low temperatures as expected, they entered the CdTe(c) homogeneity range at 600°-700°C. It seemed likely that Cd had been lost either through reaction with oxygen or perhaps as an unrecovered film on the synthesis tubes. (A 40 mg loss of Cd would change an initially 3g, 49.0 a/o Te sample to a 50.0 a/o sample.) Therefore, the sample on which the results of Fig. 5 are based was prepared from hydrogen-reduced Cd, and the weighed elements were loaded directly into the optical cell without pre-reaction. The optical cell was mounted in the furnace and the Cd-Te heated to 833°C over a 4 hr period. At 680° and 833°C, p_2 (as indicated by D_{5500}) was on the Te-rich leg of the three-phase loop, *i.e.*, was appropriate for Te-saturated rather than Cd-saturated CdTe. When the reservoir temperature was increased to 898°C, the value of p_2 initially increased, then started to decrease. After 16 hr at 898°C the value of p_2 was too low to measure while p_{Cd} was nearly equal to the vapor pressure of pure Cd. The runs giving the data of Fig. 5 were then begun. The above observations show the kinetics of at least the last stages of the Cd-Te reaction are relatively slow, presumably because unreacted liquid Cd is effectively protected by a CdTe(c) film. They also indicate that the surface portion of the sample, which establishes the partial pressures, was eventually equilibrated, since it entered the Cd-rich field spontaneously after initially being in the Te-rich field. As discussed later, similar observations were made with the 49.5 a/o Te Zn-Te sample.

Zinc telluride.—The values of p_2 for Te-saturated ZnTe(c), obtained from the optical density data for samples with 50.5 and 55.0 a/o Te, are plotted on a logarithmic scale against $10^3/T$ in Fig. 6. The value of p_{Zn} was below our detectivity of about 10^{-5} atm. The upper line in Fig. 6 without points gives the vapor pressure of Te(l). The lowest line gives p_2 for ZnTe(c) in equilibrium with a stoichiometric vapor (50 a/o) and is taken from an earlier study (6). In the Discussion we argue that this can be considered to be p_2 for congruently subliming ZnTe(c). The experimental points along the Te-rich leg of the three-phase curve fall along two curves, the pressures obtained with a 1000°C optical cell being about 10-15% higher than those obtained with a 1100°C cell. (See the discussion on the similar discrepancy observed here with CdTe.) With increasing temperature the three-phase curve starts to flatten out and lies increasingly below the vapor pressure line for pure Te. The points for the 50.5 a/o Te sample (closed circles) are in close agreement with those for 55.0 a/o Te (open circles). Thus up to the highest temperature measured, 1086°C, the 50.5 a/o sample lies outside the homogeneity range of ZnTe(c). Smoothed values of p_2 from the 1100°C cell data are given in Table III. Straight line segments drawn through these smoothed values are within ±5% in p_2 of the actual experimental points.

The values of p_{Zn} for samples with 49.5, 40.0, and 0.00 a/o Te are plotted on a logarithmic scale against $10^3/T$ in Fig. 7. (The value of p_2 was below our level of detection of 10^{-6} atm.) Up to the highest temperature of measurement, 909°C, the value of p_{Zn} agrees for all three sample compositions within an experimental error of ±3%. Thus up to this temperature 49.5 a/o Te lies outside the homogeneity range of ZnTe(c). It is emphasized that the coincidence of p_{Zn} for the 49.5, 40.0, and 0.00 a/o Te depends on the coincidence of the optical densities observed and does not depend on the accuracy of the vapor pressure values for pure Zn(l).

Analogous to our observations with 49.0 a/o Te Cd-Te, 49.5 a/o Te Zn-Te samples which had been pre-reacted and annealed before being placed in the optical cell appeared Zn-saturated at the lowest temperatures as expected, but entered the ZnTe(c) homogeneity range between 600° and 700°C. The behavior was different for a 49.5 a/o Te sample prepared by using H_2-reduced Zn and by loading the weighed elements directly into the optical cell. When this sample was first heated, the optical density of the vapor phase indicated the surface layers were Te-saturated even after 40 hr at 899°C and also after 2 hr at 985°C. The temperature was then raised to 1066°C. After 20 min the tellurium pressure started to drop slowly. After 16

Table III. Partial pressure of $Te_2(g)$ over Te-saturated ZnTe(c)

$10^3/T$(°K^{-1})	0.95	0.90	0.85	0.80	0.78	0.76	0.74	0.735
p_2 (atm)	0.089	0.160	0.26	0.53	0.64	0.73	0.82	0.85

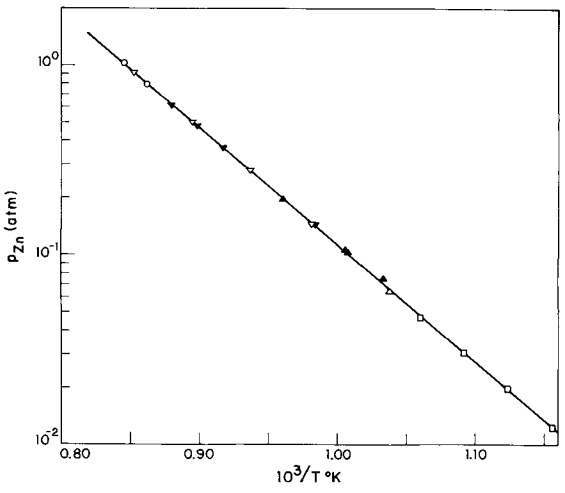

Fig. 7. Partial pressure of Zn(g) for Zn-Te samples with 49.5 a/o Te (open symbols), 40.0 a/o Te (closed symbols), and pure liquid Zn (straight line). Circles indicate p_{Zn} was obtained from D_λ at 2400 and 2500Å, the two values agreeing within ± 2%. Inverted triangles give the common value (to within ± 2%) of p_{Zn} obtained from D_λ at 2300, 2400, and 2500Å. Triangles and squares give p_{Zn} as obtained from D_λ at 2200 and 2150Å, respectively.

hr, p_2 was too low to measure. The reservoir temperature was then lowered to 970°C, the optical cell temperature was lowered to 1000°C, and measurements were taken with decreasing temperature and are shown in Fig. 7. Analogous to the case for CdTe, it appears that liquid Zn is protected from complete reaction with Te by an adhering layer of ZnTe, even when the value of p_{Zn} is well over 1 atm. The spontaneous transition of the surface layers of the sample from a composition in the Te-rich three-phase field to one in the Zn-rich field shows the latter condition to be characteristic of equilibrium for the 49.5 a/o Te sample.

Comparison with Other Work and Further Discussion

Cadmium telluride.—The values of p_2 shown in Fig. 3 for Te-saturated CdTe(c) are considerably below those reported by Lorenz (3), which range from 0.138 atm at 1092°C to 1.2 atm at 1079°C ($10^3/T = 0.740$). The three values reported by de Nobel for $0.786 \leq 10^3/T \leq 0.862$ reach a maximum of 0.168 atm at the lowest temperature but are below ours by 9-50%.

The three liquidus points obtained here for CdTe are close to those of Lorenz and those of Steininger *et al.* (4) as can be seen in Table II. Thus the liquidus temperatures given by Kulwicki (2) for this range of composition appear to be too high and the existence of an inflection point in the Te-rich liquidus is given support.

The activity coefficient for Te was calculated along the Te-rich liquidus using the values of p_2 in Table I and a smooth liquidus curve through the combined points from the present study, from the work of Lorenz, and from that of Steininger *et al.* The activity coefficient is already 0.80 at 60 a/o Te and is close to 1.0 between 80 and 100 a/o Te. The activity coefficient for Cd along the Te-rich liquidus can be obtained from the measured values of p_2 by taking $p_{Cd}p_2^{1/2} = K(T)$ as given by Eq. 8 of ref. (19) and shown here by the line in Fig. 4. This activity coefficient is 10^{-2} at 57 a/o Te, 10^{-3} at 78 a/o, and $2.4(10^{-4})$ at 91 a/o. Thus the behavior of Te in the melt is very nearly ideal between 80 and 100 a/o Te while that of Cd is far removed. Inspection of the "heat-of-fusion" liquidus equation (21) shows that it must be this nonideal behavior of Cd that is primarily responsible for the unusual Te-rich liquidus. As can be calculated from the values in Table II, the excess enthalpy and entropy of Te are about comparable in their contributions toward reducing the chemical potential of Te in melts in the 55-65 a/o Te range. At the maximum melting point of 1092°C both activity coefficients are 0.10.

Medvedev *et al.* (22) have determined p_2 over single crystals of CdTe by measuring the optical density at 4357Å using an optical cell at 815°C. From calibration experiments on pure Te they obtained the relation, $p_2 = 0.304\ D_{4357}/L(\text{mm})$. [For this same proportionality constant we had obtained values of 0.254 for a 755°C optical cell (11) and 0.320 for a 1000°C optical cell (8). Using our numbers the product of the proportionality constant and the reciprocal of the absolute optical cell temperature times 10^3 is 0.247 for a 755°C cell and 0.251 for a 1000°C cell, *i.e.*, the product is constant within experimental error. Thus in this temperature range the dependence of the proportionality constant on optical cell temperature is essentially through the reciprocal dependence of $Te_2(g)$ concentration on optical cell temperature, the product of the probability for the 4357Å transition and the fraction of $Te_2(g)$ molecules in the initial state for the 4357Å transition remaining constant. Taking an average value of 0.249 for the product, we calculate the proportionality constant is 0.271 for a 815°C optical cell. The value found by Medvedev *et al.* is only 12% higher.] Their values of p_2 for a high resistivity, near intrinsic crystal and for a strongly n-type crystal are parallel to our value of p_2 for congruently subliming CdTe(c) as shown in Fig. 3, but are higher by factors of 2.4 and 4.6, respectively. They believe a discrepancy exists and attribute it to our use of a coarse powder and/or inhomogeneities in a powder whose physicochemical properties are ill-defined. In disagreement, we see no obvious reason to conclude that the two sets of data are necessarily inconsistent. They merely show that the composition of our sample was more Cd-rich than that of either of the samples used by Medvedev *et al.* Further, the thermodynamic state of our sample was well defined at the temperatures of measurement since it was shown experimentally that the relation $p_{Cd} = 2p_2$ held. That is, the sample was shown to possess the congruently subliming composition, a unique composition at each temperature even if unknown in terms of atomic per cent or net electron concentration.

The present measurements allow upper limits to be placed on the change in the Gibbs free energy of CdTe(c), ΔG_f, in going from the congruently subliming composition to either that for Cd-saturation or that for Te-saturation at a given temperature. For any composition within the homogeneity range

$$\Delta G_f = (1 - x)RT \ln p_{Cd} + (x/2)RT \ln p_2 \qquad [2]$$

The ratio of p_2 for any two compositions can be related to that for p_{Cd} by an integration of the Gibbs-Duhem relation. Without knowing the detailed dependence of either partial pressure on x, the integration cannot be performed exactly. However, using the fact established here that $0.49 \leq x \leq 0.505$, for all compositions within the CdTe(c) homogeneity range, upper and lower limits can be obtained for the integral involved (7), giving the following inequalities

$$1.041 \ln (p'_{Cd}/p''_{Cd}) \geqq \tfrac{1}{2} \ln (p'_2/p''_2) \geqq 0.9801 \ln (p'_{Cd}/p''_{Cd}) \qquad [3]$$

Thus, if the prime refers to Cd-saturation and the double prime to the congruently subliming composition, then the one unmeasured partial pressure, p'_2, can be bracketed by using Eq. [3]. Upper limits for the difference in ΔG_f for these two compositions can then be calculated by taking $x' = 0.490$ and $x'' = 0.505$. A similar procedure can be followed in comparing Te-saturated and congruently subliming CdTe(c), in which case p''_{Cd} for Te-saturated CdTe is the unknown partial pressure and is bracketed by using Eq. [3]. A maximum value for the difference in ΔG_f for congruently subliming and Te-saturated CdTe is then ob-

tained by taking $x' = 0.490$ for the former and $x'' = 0.505$ for the latter. The result of both calculations is that at 900°C, ΔG_f for both Cd-saturated CdTe and for Te-saturated CdTe are within 150 cal/g-atom of that for congruently subliming CdTe(c). Since the value of p_{Cd} drops by a factor of 20 in going from the Cd-saturated to the congruently subliming composition, this demonstrates the very large curvature in the dependence of ΔG_f on x that is customarily assumed for compounds with a narrow homogeneity range.

Zinc telluride.—The lower line without points in Fig. 6 has been identified here as p_2 for congruently subliming ZnTe(c). Although it was shown (6) that this line gave p_2 for the ZnTe(c) composition in equilibrium with a stoichiometric vapor (50 a/o), the steady state achieved on progressive sublimation with increasing temperature was characterized by a value of 1.8 for the ratio, $R = p_{Zn}/p_2$, rather than the value of 2.0 expected for congruent sublimation. The value for R was based on optical density calibrations with the pure elements which used published values for the vapor pressure of Te (9, 10) and those tabulated by Hultgren *et al.* (23) for Zn just above its melting point. Recently, precision measurements (24) of the vapor pressure of Zn just below its melting point have given values for $p°_{Zn}$ that are higher than those tabulated by Hultgren *et al.* At the melting point the discrepancy is 20% in $p°_{Zn}$. If it is assumed that the tabulated values of $p°_{Zn}$ are also low by 10-20% in the 420°-520°C temperature range, then the corrected value for R is in the range 1.98-2.16. Within the experimental error of ± 0.1 in R, the steady state observed earlier with ZnTe(c) then corresponds to congruent sublimation.

Since we have established that the homogeneity range for ZnTe(c) must be within the 49.5 to 50.5 a/o Te range, outer limits for the change in ΔG_f with composition can be calculated from the present partial pressure measurements in the manner analogous to that used for CdTe(c) and discussed above. It is found that at 900°C the ΔG_f values for both Zn-saturated and Te-saturated ZnTe are within 190 cal/g-atom of that for congruently subliming ZnTe(c). In contrast, based on the measurements reported here, the chemical potential of Zn increases by 13,700 cal/g-atom in going from congruently subliming to Zn-saturated ZnTe(c) and the chemical potential of Te increases by 6300 cal/g-atom in going from congruently subliming to Te-saturated ZnTe(c). We, therefore, have experimental verification for an extremely strong curvature of the Gibbs free energy isotherm for ZnTe(c) as well as CdTe(c). Finally, with the above outer limits for the ZnTe(c) homogeneity range, the standard Gibbs free energy for formation of ZnTe(c) given by Eq. 8 of ref. (19) is changed by less than 1% if the composition dependent term, C, is set equal to zero.

Acknowledgment

The author takes pleasure in acknowledging the capable experimental assistance of Mr. R. N. Capes. He also wishes to express his thanks to Marquette University for providing the facilities to complete this paper. The work reported in this paper was sponsored by the Department of the Air Force.

Manuscript submitted April 7, 1971; revised manuscript received *ca.* July 30, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Some Stability Considerations in Levitation Melting

Edward S. Bocian, Jr.,[1] and Frederick J. Young[2]

Department of Electrical Engineering, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

ABSTRACT

Two types of instabilities are considered. First a circuit model for a levitation system is used to form linearized equations for the vertical motions of suspended metal samples. The basic inductive-resistive circuit model is dynamically stable, but capacitance in the circuit of the supporting coil can account for the self-oscillations of some practical levitation setups. Next, for an idealized coil arrangement, and in the case of negligible skin depth within a suspended molten sample, an upper bound on the mass of the sample is deduced. This result is a simple function of the metal density and surface tension, and of the order of 10g in favorable instances. Since the purely static considerations in this calculation yield an upper mass limit below what some investigators have tried to melt in levitation experiments, this model explains the rupture of such drops without resort to dynamic models of surface oscillations.

Levitation melting was first proposed in 1923 by Muck (1). The basic apparatus, derived from a simple transformer, uses a primary coil but substitutes a conducting sample for the secondary. An a-c coil current induces currents within the sample; there is a corresponding ohmic dissipation and, if the geometry is asymmetric, a net force between coil and sample. Combining these effects a levitation melting system can supply enough heat to melt a metallic sample, while the resultant electromagnetic force exactly balances its weight, and no mechanical support is necessary.

The coil arrangement used to suspend a sample may be a simple toroid, shaped like a nozzle (2), or in a case analogous to a magnetic mirror machine in plasma physics, it may consist of two coils—one below, a smaller one above, the unequal mmf's being necessary to balance the weight of the sample (3). Okress and Wroughton (4, 5), in particular, have experimented with a number of coil designs. Figure 1 shows some of the possibilities.

Levitation melting has been found suitable for casting metal buttons for hardness and corrosion tests, and for metallographic examination (2). An important advantage is that metals with high melting points may be melted out of contact with a crucible, preventing contamination by a refractory (2, 3). To further isolate a sample, a protective atmosphere can be used around reactive specimens (2, 4, 5). The system permits the addition of alloying ingredients while a sample is suspended, and then provides continuous agitation of the melt, insuring a homogeneous ingot (2, 3).

In actual practice, however, levitation is easier to achieve for solid than for molten samples, and instabilities can occur in either case. These unstable situations can be grouped roughly into three classes, though combinations of these mechanisms are certainly possible:

(*A*) A lateral drift of a sample, which continues until it is out of the influence of the coils and falling (3-5).

(*B*) A second gross instability of the suspension, in which the entire sample commences a growing vertical oscillation, leading to its eventual ejection, most likely straight down through the supporting coil (3, 6).

(*C*) A phenomenon limited to the liquid state, or perhaps to semimolten samples, in which surface ripples develop and culminate in a rupture of the suspended drop. The liquid pours down through the coil,

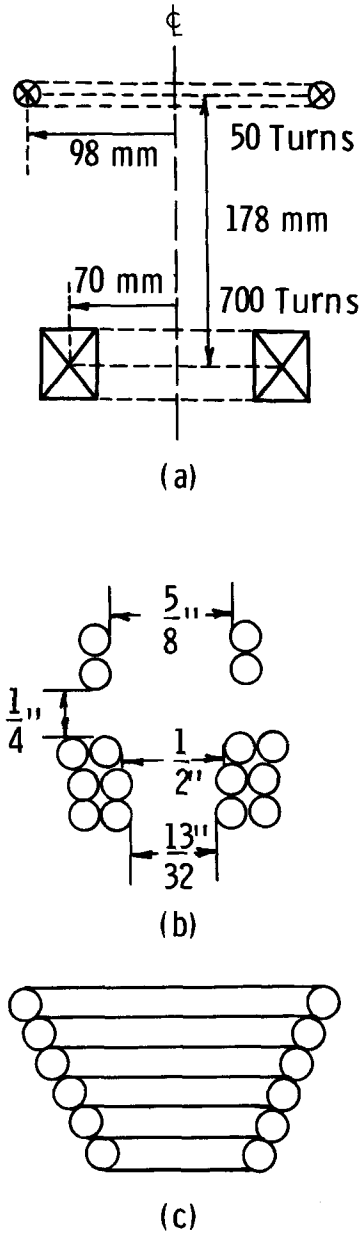

Fig. 1. Some experimental levitation coils; (a) used at 50 Hz by Mikel'son (3,6); (b) at 0.5 MHz by Weisberg (9); and (c) near 10 KHz by Okress (4), (5). The latter two employ ¼ in. OD copper tubing for the coils.

[2] Present address: Westinghouse Research Laboratory, Pittsburgh, Pennsylvania 15230.

Key words: electromagnetic levitations, surface stability.

usually near the axis where the induced current in the sample vanishes (3, 4).

The introduction of a restoring force towards the coil axis can prevent lateral drift. Several investigators (3, 6, 7) have found that a small stabilizing coil positioned above a suspended sample, and carrying current opposite in direction to that in the main coil, effectively solves this problem.

Remedies for the remaining instabilities, and the failure mechanisms themselves, are not so well understood. Kirko and Mikel'son (6) who have proposed a circuit model to explain vertical oscillation, conclude that operation of a levitation system above a certain frequency of excitation leads to instability, but later (3) successfully pass this limit with a high-frequency coil setup.

There are qualitative theories for the rupture of suspended liquid drops (3), but no means of predicting quantitatively how large a mass may be suspended in stable equilibrium. Most experimenters (3-5, 8) have noted such limitations in mass for their particular apparatuses, and both Polonis (2) and Weisberg (9) have recorded the suspicion that this limitation should be implicit in the system, and some function of mass density and surface tension.

This paper is concerned with supplying models for both unstable vertical oscillations of a suspended sample, and for the maximum mass of a molten specimen in stable suspension.

Vertical Stability of a Suspension

Like Kirko and Mikel'son (6) consider two coaxial inductors, one supported electromagnetically by the other, as a simple model for a levitation system (see Fig. 2). The lower coil is stationary; the upper restricted, by the coil form, to vertical motion. Reference directions are indicated. L_1, L_2, and M are self and mutual inductances, R_1 and R_2 coil resistances, V the applied voltage, and z_o the equilibrium co-ordinate of L_2. Write the circuit equation

$$L_1 \frac{dI_1}{dt} + R_1 I_1 + \frac{d}{dt}(MI_2) = V(t) \qquad [1]$$

$$L_2 \frac{dI_2}{dt} + R_2 I_2 + \frac{d}{dt}(MI_1) = 0 \qquad [2]$$

$$M = M_o - \beta(z - z_o) \qquad [3]$$

where M_o is the mutual inductance of the two coils at their equilibrium separation z_o, and the geometric parameter β specifies, to a linear approximation, the change of M with z. β is positive.

Next the equation of motion for the upper coil may be written

$$m\frac{d^2z}{dt^2} + r\frac{dz}{dt} = F_{sus}\left(z, \frac{dz}{dt}\right) - mg \qquad [4]$$

in terms of its mass m, some damping r, the gravitational constant g, and the electromagnetic force F_{sus}. Assuming oscillations of the sample occur at frequencies much lower than that of the excitation voltage, consider z and dz/dt as constants in the electrical equations. Using phasors $V(t) = Re\{\underset{\sim}{V}\, e^{j\omega t}\}$, these may be solved for the currents

$$\underset{\sim}{I}_1 = \frac{\underset{\sim}{V}(R_2 + L_2 j\omega)}{\left[(R_1 + L_1 j\omega)(R_2 + Lj\omega) - \left(Mj\omega - \beta\frac{dz}{dt}\right)^2\right]} \qquad [5]$$

$$\underset{\sim}{I}_2 = \frac{-\underset{\sim}{V}\left(Mj\omega - \beta\frac{dz}{dt}\right)}{\left[(R_1 + Lj\omega)(R_2 + Lj\omega) - \left(Mj\omega - \beta\frac{dz}{dt}\right)^2\right]} \qquad [6]$$

Now represent the electromagnetic force of suspension

$$F_{sus}\left(z, \frac{dz}{dt}\right) = \frac{k}{2} Re\{\underset{\sim}{I}_1 \underset{\sim}{I}_2{}^*\} \qquad [7]$$

with k a second geometric parameter. The asterisk denotes a complex conjugate. In static equilibrium

$$F_{sus}(z_o, 0) = mg = -\frac{k}{2}\frac{V^2\omega^2 L_2 M_o}{[R_1R_2 - \omega^2 L_1L_2 + \omega^2 M_o{}^2]^2 + [R_1L_2\omega + R_2L_1\omega]^2} \qquad [8]$$

and k is obviously negative for this equality to hold. Equation [8] shows the expected behavior at frequency extremes: $F_{sus} \to 0$ as $\omega \to 0$ and as $\omega \to \infty$ unless there is perfect coupling, $L_1L_2 = M_o{}^2$, in which case F_{sus} remains finite in the limit as $\omega \to \infty$.

In the more general dynamic case, the force expression is

$$F_{sus}\left(z, \frac{dz}{dt}\right) = \frac{-\frac{k}{2}V^2\left(\omega^2 L_2 M - R_2\beta\frac{dz}{dt}\right)}{\left[R_1R_2 - \omega^2L_1L_2 + \omega^2M^2 - \beta^2\left(\frac{dz^2}{dt}\right)\right]^2 + \left(R_1L_2\omega + R_2L_1\omega + 2M\omega\beta\frac{dz}{dt}\right)^2} \qquad [9]$$

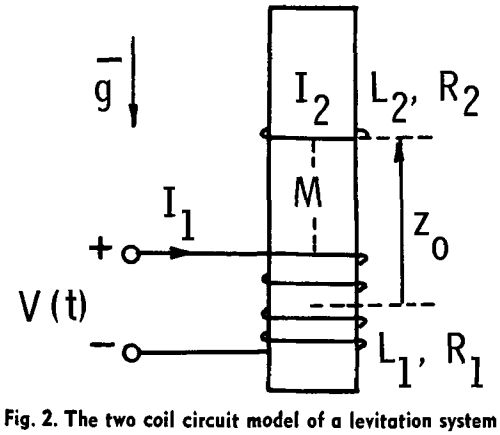

Fig. 2. The two coil circuit model of a levitation system

Since this formulation is valid, and principally of interest, for small departures from equilibrium, expand F_{sus} in a two-parameter Taylor series about the point $\left(z, \frac{dz}{dt}\right) = (z_o, 0)$, and truncate the result to exclude products of perturbations.

$$F_{sus}\left(z, \frac{dz}{dt}\right) \cong F_{sus}(z_o, 0) + (z - z_o)\left.\frac{\partial F_{sus}}{\partial z}\right|_{z_o} + \frac{dz}{dt}\left.\frac{\partial F_{sus}}{\partial \frac{dz}{dt}}\right|_{(z_o,0)} \qquad [10]$$

Use Eq. [9] to evaluate

$$\left.\frac{\partial F_{sus}}{\partial \frac{dz}{dt}}\right|_{(z_o,0)} = \frac{\frac{k}{2}\beta V^2}{\left\{(R_1R_2 - \omega^2L_1L_2 + \omega^2M_o^2)^2 + (R_1L_2\omega + R_2L_1\omega)^2\right\}} \left\{R_2 + \frac{4M_o^2\omega^4L_2(R_1L_2 + R_2L_1)}{(R_1R_2 - \omega^2L_1L_2 + \omega^2M_o^2)^2 + (R_1L_2\omega + R_2L_1\omega)^2}\right\} \quad [11]$$

Since $k < 0$, this entire expression is negative. In general, k is a function of z so $\partial F_{sus}/\partial z|_{(z_o,0)}$ is not available explicitly here. It must be obtained from a measured or calculated force curve, such as that in Fig. 3, obtained for a spherical sample and a simple toroid of N turns, modeled as a loop of vanishing cross section. Coil radius r_c, and the separation distance z_o of the sphere and coil centers are conveniently normalized with division by the sphere radius R_s.

Substituting Eq. [10] into the equation of motion [4] yields

$$m\frac{d^2(z-z_o)}{dt^2} + \frac{d(z-z_o)}{dt}\left\{r - \left.\frac{\partial F_{sus}}{\partial\left(\frac{dz}{dt}\right)}\right|_{(z_o,0)}\right\} + (z-z_o)\left\{-\left.\frac{\partial F_{sus}}{\partial z}\right|_{(z_o,0)}\right\} = 0 \quad [12]$$

Because of the sign associated with $\left.\frac{\partial F_{sus}}{\partial \frac{dz}{dt}}\right|_{(z_o,0)}$ in Eq. [11], the coefficient of velocity is always positive. If $\left.\frac{\partial F_{sus}}{\partial z}\right|_{(z_o,0)} < 0$ as it is for z_o/R_s beyond the peaks of the force curves in Fig. 3, the equilibrium at $z = z_o$ is stable; otherwise it is unstable. The coefficient of velocity in Eq. [12] does not change sign with increasing frequency, so this resistive-inductive model does not predict unstable motions where $\left.\frac{\partial F_{sus}}{\partial z}\right|_{(z_o,0)} < 0$ (10).

The introduction of a series capacitor C_1 into the primary modifies Eq. [5], [6], [9] and [11] as follows

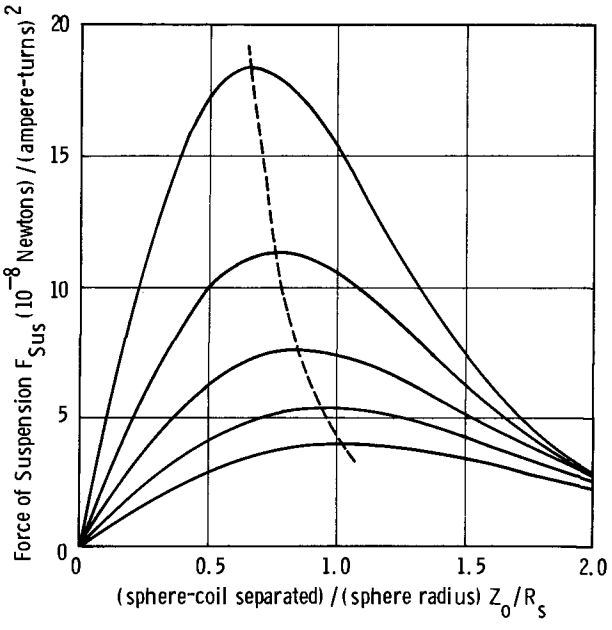

Fig. 3. Force of suspension is plotted vs. the separation of sphere and coil centers for a skin depth $R_s/32$, and in descending order of force magnitudes for r_c/R_s = 1.50, 1.75, 2.00, 2.25, 2.50. The dotted line denotes the limit of stable suspension.

$$\underset{\sim}{I_1} = \frac{\underset{\sim}{V}(R_2 + L_2j\omega)}{\left((R_1R_2 - \omega^2L_1L_2 + \omega^2M^2 + L_2/C_1 - \beta^2\left(\frac{dz}{dt}\right)^2\right) + \left(R_1L_2j\omega + R_2L_1j\omega + 2j\omega M\beta\frac{dz}{dt} + R_2/C_1j\omega\right)} \quad [13]$$

$$\underset{\sim}{I_2} = \frac{-\underset{\sim}{V}\left(j\omega M - \beta\frac{dz}{dt}\right)}{\left(R_1R_2 - \omega^2L_1L_2 + \omega^2M^2 + L_2/C_1 - \beta^2\left(\frac{dz}{dt}\right)^2\right) + \left(R_1L_2j\omega + R_2L_1j\omega + 2j\omega M\beta\frac{dz}{dt} + R_2/C_1j\omega\right)} \quad [14]$$

$$F_{sus}\left(z, \frac{dz}{dt}\right) = \frac{-\frac{k}{2}V^2\left(\omega^2L_2M - R_2\beta\frac{dz}{dt}\right)}{\left(R_1R_2 - \omega^2L_1L_2 + \omega^2M^2 - \beta^2\left(\frac{dz}{dt}\right)^2 + L_2/C_1\right)^2 + \left(R_1L_2\omega + R_2L_1\omega + 2\omega M\beta\frac{dz}{dt} - \frac{R_2}{C_1\omega}\right)^2} \quad [15]$$

$$\frac{\partial F_{sus}}{\partial\left(\frac{dz}{dt}\right)_{(z_o,0)}} = \frac{k}{2}\beta V^2 \frac{\left\{R_2 + \frac{4\omega^3L_2M_o^2(R_1L_2\omega + R_2L_1\omega - R_2/C_1\omega)}{[(R_1R_2 - \omega^2L_1L_2 + \omega^2M_o^2 + L_2/C_1)^2 + (R_2L_1\omega + R_1L_2\omega - R_2/C_1\omega)^2]}\right\}}{[(R_1R_2 - \omega^2L_1L_2 + \omega^2M_o^2 + L_2/C_1)^2 + (R_1L_2\omega + R_2L_1\omega - R_2/C_1\omega)^2]} \quad [16]$$

and, if C_1 is too small, the second term in the numerator may be negative. If the entire expression $\left.\frac{\partial F_{sus}}{\partial\left(\frac{dz}{dt}\right)}\right|_{(z_o,0)}$ is positive, self-oscillations occur and the suspension is unstable. This certainly cannot happen for $\omega^2 > \frac{R_2}{C_1(R_1L_2 + R_2L_1)}$, but the details of the frequency dependence of the damping coefficient are a function of the particular levitation circuit parameters.

Note that Eq. [12] specifies the undamped natural frequency of these oscillations as

$$\omega_{Mech} = \sqrt{-\frac{1}{m}\left.\frac{\partial F_{sus}}{\partial Z}\right|_{(Z_o,0)}}$$

which should be considerably less than ω for these equations to be valid. ω_{Mech} is, of course, a function of

the choice of equilibrium coordinate Z_o—again refer to Fig. 3 for an example.

Levitation of a Molten Sample

In practical applications of levitation melting, perhaps the most significant remaining unknown is the maximum size of a melt for which stable suspension is possible. The literature contains qualitative dynamic theories based on instabilities of a conducting surface in a magnetic field, and subject to perturbations in shape (3, 6). This section shows that an upper mass limit can be derived from purely static considerations, under certain restrictions, and that this mass limit is a function of the ratio ρ/σ_s of liquid metal mass density to surface tension.

First assume that the skin depth in a suspended metal sample is sufficiently small—the frequency of excitation is sufficiently large—so that the electromagnetic force of suspension is concentrated at the surface of the drop. This is certainly valid for experiments performed near 0.5 MHz (8, 9), and is a good approximation over a considerable range of lower frequencies. Then the electromagnetic force is the resultant of a magnetic pressure distribution, exerted on the surface of the drop, and directed normal to the surface at each point. The equation

$$\sigma_s\left\{\frac{-\frac{d^2r}{dh^2}}{\left[1+\left(\frac{dr}{dh}\right)^2\right]^{3/2}}+\frac{1}{r\left[1+\left(\frac{dr}{dh}\right)^2\right]^{1/2}}\right\}+\frac{B^2_{rms}}{2\mu_o}=\frac{2\sigma_s}{b}+\rho gh \quad [17]$$

describes the surface of such a drop in the coordinate system of Fig. 4. b is the radius of curvature at the top of the drop, B_{rms} the local magnetic field, and g the gravitational acceleration. In equilibrium, the drop has an axis of symmetry in common with the supporting coil system. Equation [17] is essentially a pressure balance: the pressure rise through the liquid surface at any height is equated to this same pressure rise through the top of the drop—where the magnetic field is zero with any axisymmetric coil system—plus the additional pressure of the standing liquid. The expressions in the large brackets are inverse principal radii of curvature of the liquid surface (11).

Equilibrium requires

$$F_{sus}=mg=2\pi\int_0^{h_{bot}}\frac{B^2_{rms}}{2\mu_o}\left(\frac{-dr}{dh}\right)dh \quad [18]$$

since the surface tension integrated over the surface of the drop contributes no net vertical force.

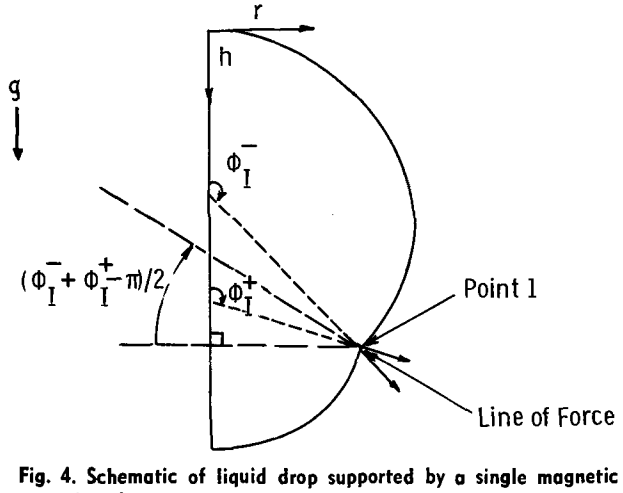

Fig. 4. Schematic of liquid drop supported by a single magnetic pressure impulse.

No analytic solution is known to Eq. [17] without the magnetic pressure term. Bashforth and Adams (11) considered numerical solutions to this simplified version in 1883. The complexity of simultaneous electromagnetic field and surface equation solutions may be circumvented by a second approximation. Model a coil system like the one in Fig. 1(a) with a single wire loop, of negligible cross section, and position it arbitrarily close to the surface of the drop. Then the electromagnetic force of suspension may be modeled as a delta function of force per unit length at a single cross-sectional point—the point of closest approach of coil to drop—and the situation is completely analagous to the purely mechanical problem of supporting a liquid drop with a fine wire ringstand (see Fig. 4).

With F the force per unit length due to the ring—a linear pressure—the surface Eq. [17] may be written

$$\frac{d\phi}{dS}+\frac{\sin\phi}{r}=\frac{2}{b}+\frac{\rho gh}{\sigma_S}-\frac{F}{\sigma_S}\delta(S-S_I);F>0 \quad [19]$$

where S is arc length along the surface from the top of the drop, ϕ the angle from the vertical to the outward surface normal ($\phi = 0$ at the top of the drop), and the subscript I denotes the point at which the idealized coil is located. Then the solution for $S \leq S_I$ is identical to that for a sessile drop (11). Integrating Eq. [19] through the ring of force yields

$$\phi(S_I^+)=\phi(S_I^-)-F/\sigma_S \quad [20]$$

The effect of the support is to introduce a discontinuous derivative to the surface curve, and to bend the surface about the supporting loop. On the average, the linear pressure is exerted along a line inclined at an angle midway between $\phi(S_I^+)$ and $\phi(S_I^-)$ since it must balance the surface tension forces at the point of discontinuity. If $\sigma_S \to \infty$, there is no discontinunity.

In an actual drop, waiving the assumption of infinite pressure also eliminates the discontinuity in ϕ, but the surface should undergo a rapid curvature very near the coil. One conclusion remains the same: a magnetic pressure push on the surface of a suspended drop requires the surface to curve outwards from the axis of symmetry.

From geometric considerations in Fig. 4

$$F_{sus}(S_I,F)=-2\pi r_I F\cos\left(\phi_{I-}-\frac{F}{2\sigma_S}\right) \quad [21]$$

and

$$\pi \geq \phi_{I-} > (\pi/2+F/2\sigma_S) \quad [22]$$

The upper limit is imposed by the set of sessile drop solutions, the lower by a requirement that $F_{sus} > 0$.

Now consider extrema of $F_{sus}(S_I,F)$ with respect to F. At $F = F_{MAX}$, and

$$\phi_{I-}=\pi+\frac{F_{MAX}}{2\sigma_S}-\sin^{-1}\left\{\frac{1}{\sqrt{1+\left(\frac{F_{MAX}}{2\sigma_S}\right)^2}}\right\} \quad [23]$$

the vertical force attains the maximum value

$$F_{sus}(S_I,F_{MAX})=\frac{4\pi\sigma_S r_I\left(\frac{F_{MAX}}{2\sigma_S}\right)^2}{\sqrt{1+(F_{MAX}/2\sigma_S)^2}} \quad [24]$$

If the vertical force of the ring is to support such a drop

$$mg=F_{sus}(S_I,F)\leq F_{sus}(S_I,F_{MAX}) \quad [25]$$

The nature of this force maximum is evident from Fig. 4. At $F = 0$, there is no vertical force; as F is increased, so is F_{sus}, but for larger and larger F, the net force on the drop is applied progressively nearer the horizontal, because of the discontinuity it induces in the surface direction; consequently F_{sus} decreases towards zero.

Next note that the weight of the entire drop must exceed that of the portion of the drop above the ring

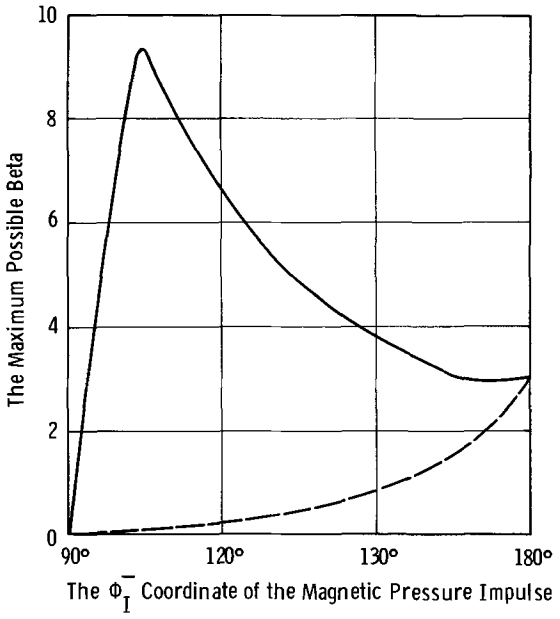

Fig. 5. The maximum β for static equilibrium: The solid line is the result for an infinite series of magnetic pressure impulses, the dotted line for a single magnetic pressure ring.

of magnetic pressure—a quantity available from sessile drop solutions which may be expressed parametrically as

$$\rho g V(\beta, b, \phi_I-) < mg \qquad [26]$$

where $\beta = \rho g b^2/\sigma_s$ is the parameter specifying the shape of a sessile drop (11). Combining this restriction with Eq. [24], [25], and sessile drop solutions produces a restriction $\beta < \beta_{max}(\phi_I-)$. This result is plotted as a dotted line in Fig. 5. The larger ϕ_I- permits the larger β, and the extremum occurs at $\phi_I- = 180°$, where the maximum permissible β is about 3. For any given liquid metal, a restriction on β is also a restriction on b.

The two bounds on the weight of liquid drop Eq. [25] and [26], in combination with the information $\beta_{max}(\phi_I-)$ in Fig. 5 yield numerical results

$$mg < 6.5\sqrt{\frac{\sigma_s^3}{\rho g}} \quad \text{or Volume} < 6.5\left(\frac{\sigma_s}{\rho g}\right)^{3/2} \qquad [27]$$

considered over the set of allowable sessile drop solutions.

The results, Eq. [25], are derived for a situation in which the magnetic pressure distribution is distinctly localized on the surface of the suspended drop.

To account for the distributed magnetic pressure expected in many small scale practical experiments, where the sample is small compared to the spatial extent of the supporting coil, some changes in this model are necessary.

One expedient is to model the magnetic pressure distribution with a sum of pressure impulses of the sort already described. Using an infinite sequence of such impulses, each applied at the same angle ϕ_I- (available after the drop surface has "recovered" from the previous impulse) leaves F_{MAX} unchanged. Under these conditions, the weight of a suspended drop may again be bounded

$$mg < 11.2\left(\frac{\sigma_s^3}{\rho g}\right); \quad \text{Volume} < 11.2\left(\frac{\sigma_s}{\rho g}\right)^{3/2} \qquad [28]$$

These are of the same form as Eq. [27] and again are extrema over the set of permissible combinations of β and ϕ_I-. The upper curve in Fig. 5 is the modified value $\beta_{max}(\phi_I-)$.

Table I summarizes the results of Eq. [28] for some metal elements and compares these calculations with some experimental data on small drops successfully melted in levitation. The largest entry of the calculated masses is some 13g for vanadium. It should be noted that the limitations, Eq. [27] and [28], can be temperature sensitive, and do not apply to only partially molten samples, or to samples with surface crusts due to oxidation or cooling by radiation.

Conclusions

Instabilities resulting from vertical motions of a suspended metal sample should be attributed to the presence of impedance-matching capacitors in the coil circuit, or to capacitance in the output circuit of the power supply, rather than to the resistive and inductive circuit elements contributed by the coil arrangement and sample. Kirko and Mikel'son (6) reach the contrary conclusion only after several sign inversions and ignoring portions of the derivatives, Eq. [11] and [16].

The twin assumptions that: (*A*) a surface magnetic pressure distribution adequately accounts for the electromagnetic field distributions near a suspended drop, and (*B*) the supporting coil is reasonably modeled as a loop of negligible cross section placed very near the suspended sample require, for mechanical equilibrium, that a suspended liquid drop weigh less than an amount specified by its particular surface tension and density. A simple extension of this model, waiving the second assumption, leads to a similar formulation for this upper bound on the mass of a sample. The two versions are within a factor of two of one another, and predict a mass limit of the order of 10g or less for most metals considered. Further, there is enough accord with experimental data to conclude that requirements of static equilibrium are indeed responsible for the rupture, during melting, of larger specimens.

Technical Notes

Sensitivity of Cholesteric Films to Ultraviolet Exposure

James Adams and Werner Haas*

Xerox Research Laboratories, Webster, New York 14580

The pitch of a mixture of two or more cholesterics can be expressed in terms of an intrinsic property of each. The first insight into this relationship was provided by Friedel (1), who demonstrated that in binary mixtures of one right-handed and one left-handed constituent, there was one ingredient ratio for which the mixture exhibited nematic properties. Furthermore, for other ratios the cholesteric possessed the chirality of the dominant component. Much later, Cano (2, 3) demonstrated that in mixtures of certain cholesterics and nematics, the nematic acted as a passive element, and the influence of the cholesteric was essentially linear in proportion to its concentration.

Recently (4), it was shown that the pitch of two or more cholesterics can be expressed in terms of the linear influence of constituents. Thus, the functional form of pitch *vs.* composition is known for a wide variety of systems. In another recent observation (5), it was found that there is a strong connection between the sensitivity of pitch to certain stimuli, such as temperature, and the sensitivity of pitch to small compositional changes. In fact, it is possible to treat a variety of perturbations as if their effect were to change composition.

In those cases where the functional dependence of pitch on composition is known, it is possible to calculate the functional form for sensitivity to stimulus. We present here an experimental example of this principle. In this case the stimulus actually changes the composition of the cholesteric. The effect studied involves the change in pitch of a cholesteric film resulting from exposure to ultraviolet light (6-9).

Theory

In many mixed systems it has been shown that the pitch of the mixture, p, can be written as[1]

$$p = \left| \frac{1}{\Sigma \alpha_i \theta_i} \right| \qquad [1]$$

where α_i is the weight per cent of the i^{th} ingredient and θ_i is the effective rotary power (ERP) of the i^{th} ingredient (10). An example of a system which follows Eq. [1] over a wide compositional range is shown in Fig. 1. If the individual constituents have opposite chirality, the algebraic signs of the ERP's must be appropriately chosen. In general, the total differential change in pitch, dp, resulting from a change in composition and, simultaneously, a change in ERP caused by a differential stimulus, ds, is

$$\left| \frac{dp}{ds} \right| = \left| \Sigma \left(\frac{\partial p}{\partial \alpha_i} \frac{\partial \alpha_i}{\partial s} + \frac{\partial p}{\partial \theta_i} \frac{\partial \theta_i}{\partial s} \right) \right| \qquad [2]$$

or

$$\left| \frac{dp}{ds} \right| = p^2 \left| \Sigma \left(\theta_i \frac{\partial \alpha_i}{\partial s} + \alpha_i \frac{\partial \theta_i}{\partial s} \right) \right| \qquad [3]$$

subject to the constraint

$$\Sigma \alpha_i = 1 \qquad [4]$$

An example of a perturbation which changes composition is exposure to ultraviolet radiation or chemical vapor (8). In this case, the $\partial \theta_i / \partial s = 0$.

An example of a perturbation which changes only ERP's is heat; in which case, the $\partial \alpha_i / \partial s = 0$.

It is also possible to express the result of, for example, a stimulus which changes only ERP's in terms of an "effective" change in composition. Assume some differential stimulus, ds, actually changes only ERP.

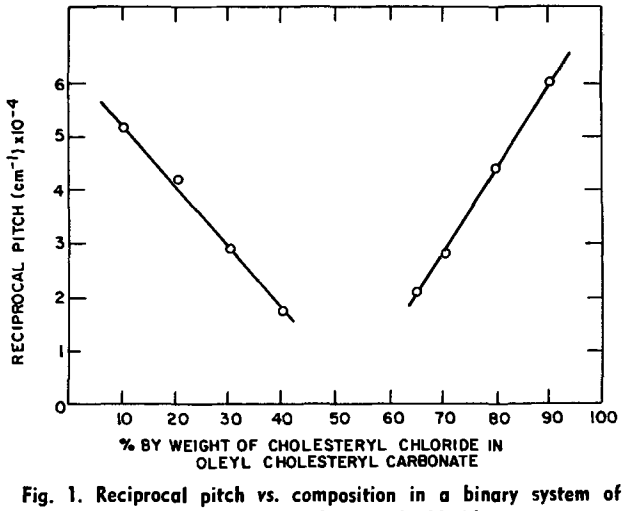

Fig. 1. Reciprocal pitch *vs.* composition in a binary system of oleyl cholesteryl carbonate and cholesteryl chloride.

* Electrochemical Society Active Member.

Key words: liquid crystals, pitch, effective rotary power.

[1] In this discussion we treat pitch as an intrinsically positive quantity and do not attempt to preserve the algebraic sign in derivatives. All calculations, therefore, predict only the magnitude of the system response to stimulus and not the direction. This is indicated by the absolute value signs. It is possible to solve this problem formally; however, the algebra is cumbersome and would obscure the main thrust of this paper.

Then

$$\left|\frac{dp}{ds}\right| = p^2 \left|\Sigma\alpha_i \frac{\partial\theta_i}{\partial s}\right| \qquad [5]$$

If this is treated as a change in composition instead, then

$$\left|\frac{dp}{ds}\right| = p^2 \left|\Sigma\theta_i \left(\frac{\partial\alpha_i}{\partial s}\right)_{\text{eff}}\right| \qquad [6]$$

Evidently,

$$\Sigma\alpha_i \left(\frac{\partial\theta_i}{\partial s}\right) = \Sigma\theta_i \left(\frac{\partial\alpha_i}{\partial s}\right)_{\text{eff}} \qquad [7]$$

In the case of a two-component system Eq. [7] has a unique solution (since $\alpha_2 = 1 - \alpha_1$) given by

$$\left(\frac{\partial\alpha}{\partial s}\right)_{\text{eff}} = \frac{\alpha}{(\theta_1 - \theta_2)}\left(\frac{\partial\theta_1}{\partial s}\right) + \frac{(1-\alpha)}{(\theta_1 - \theta_2)}\left(\frac{\partial\theta_2}{\partial s}\right) \qquad [8]$$

Let us turn now to the specific case of ultraviolet exposure, in which it is known that the actual composition is altered. Assuming that the light-sensitive molecule is the j^{th} species, whenever one of these molecules interacts with the light, it is destroyed and a new species [for example, the $(j + 1)$ species] is created. Evidently,

$$\frac{\partial\alpha_i}{\partial s} = k\alpha_i\left[-\delta_{i,j} + \delta_{i,j+1}\right] \qquad]9]$$

where

$$\delta_{a,b} = 0 \text{ for } a \neq b$$
$$= 1 \text{ for } a = b$$

and k is proportional to the probability of a conversion event.

Substituting into Eq. [3] with the condition that $\partial\theta_i/\partial s = 0$ yields

$$\left|\frac{dp}{ds}\right| = \left|kp^2\alpha_j\,(\theta_{j+1} - \theta_j)\right| \qquad [10]$$

The significance of the terms in Eq. [10] is clear: α_j determines the number of sensitive molecules; $(\theta_{j+1} - \theta_j)$ gives the relative influences of old and new molecules; and p^2 results from the form of Eq. [1]. If more than one species is created by the ultraviolet, it is still possible to characterize the collective role of all new molecules by a single ERP following arguments in Ref. (10). We now present experimental results which show close agreement with Eq. [10].

Experimental

The system chosen for study consisted of binary mixtures of cholesteryl nonanoate (CN) and cholesteryl iodide (CI). Chemicals were obtained from Eastman Kodak and used as received. All measurements were performed at room temperature. The compositional range varied from $\alpha = 25$ to $\alpha = 74$ where α is the per cent by weight of CI in a mixture of CI and CN. Pitch determinations were accomplished by dispersive reflection measurements (11) using a relationship derived by Fergason (12). Pitch *vs.* composition in unexposed films is shown in Fig. 2. In the region of $\alpha \geq 40$ this system is well described by Eq. [1], whereas for $\alpha < 40$ there is a deviation which becomes very strong as α decreases. We believe this relates to the tendency toward smectic of the nonanoate-rich films. This particular system is quite appropriate to our study since it offers a branch where Eq. [9] can be tested quantitatively and also a very anomalous branch which produces both highly sensitive regions ($\alpha \approx 26$) and highly insensitive regions ($\alpha \approx 30$).

The constituents were heated together in a crucible to the isotropic point and thoroughly mixed. An elliptical hole was cut in a two-mil Mylar spacer. The spacer was placed on a glass substrate and an amount of liquid crystal sufficient to fill the elliptical well was deposited in the center of the well. A cover slip was then dragged across the top of the Mylar several times producing a layer of approximately uniform thickness. These films were sufficiently thin to suppress the effect of thickness variation. Detailed absorption coefficient data were not taken; however, the effective coefficient was such that films over about 4 mils in thickness began to show thickness effects, resulting in less total shift for a given exposure, and in addition, the pitch band was broadened.

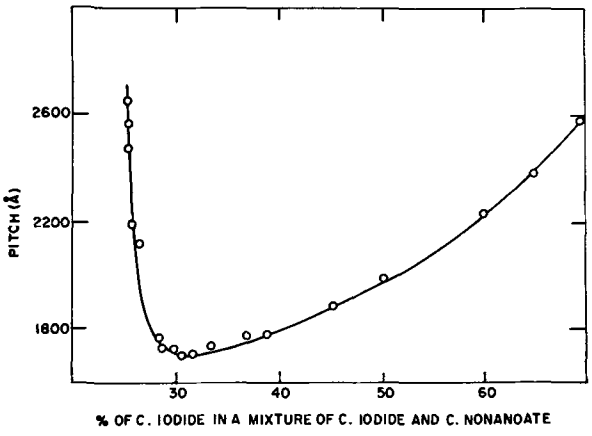

Fig. 2. Pitch *vs.* composition in a binary system of cholesteryl iodide and cholesteryl nonanoate.

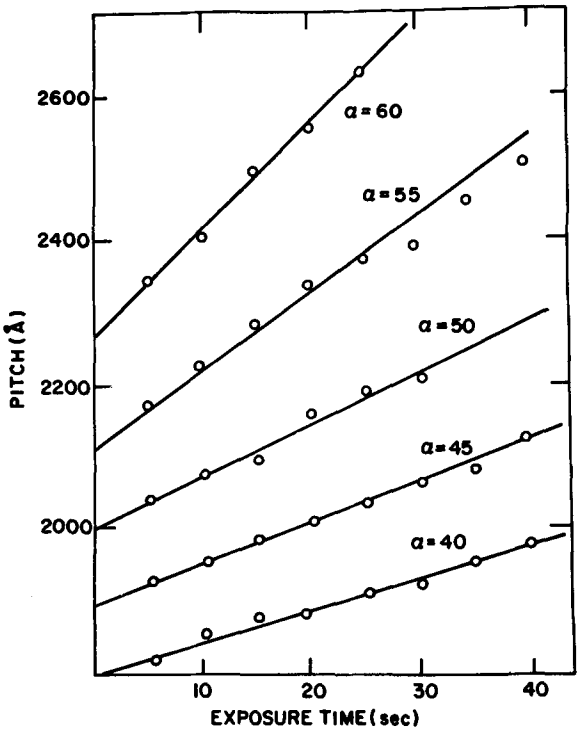

Fig. 3. Pitch *vs.* ultraviolet exposure in the region $dp/d\alpha > 0$

The two-mil films accorded a reproducibility of the order of $\epsilon = 0.1$ where $\epsilon = \delta\lambda/\Delta\lambda$; $\Delta\lambda$ was the pitch shift for a given exposure and $\delta\lambda$, the variation. Films were exposed to ultraviolet light produced by a BH-6 high-pressure, short-arc mercury lamp. Exposure was controlled by a shutter.

The results for several different starting ratios are shown in Fig. 3. The sensitivity is clearly a strong function of composition. A comparison between experimental results and the prediction of Eq. [10] is shown in Fig. 4. The agreement is well within experimental error. Small depletion effects were observed, principally in the region $dp/d\alpha < 0$. The results are shown in Fig. 5. In this case exposure tends to reduce the

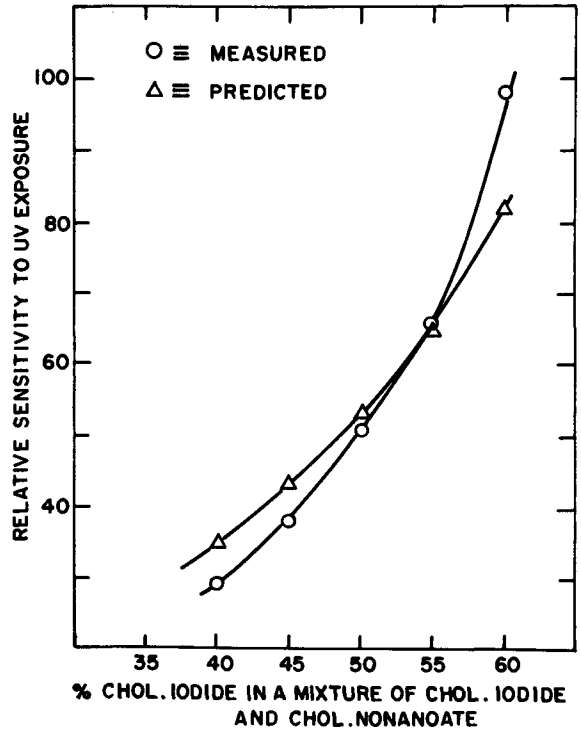

Fig. 4. Comparison of predicted and observed sensitivity

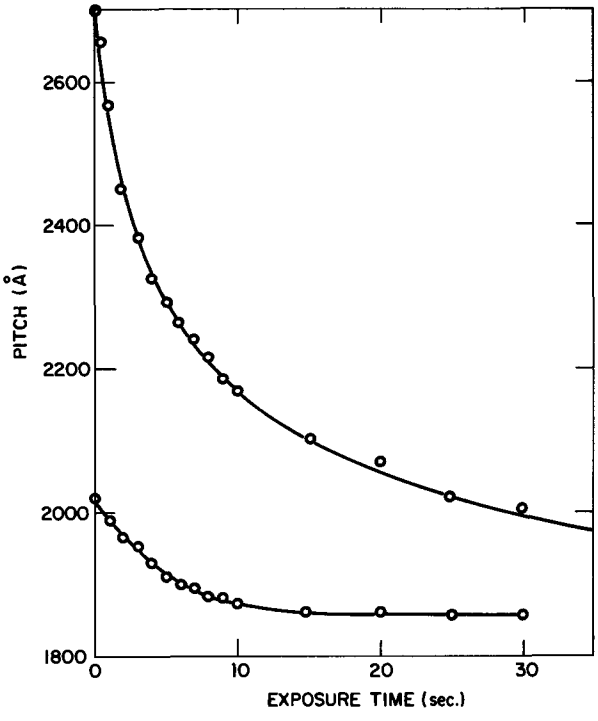

Fig. 5. Pitch vs. ultraviolet exposure in the region $dp/d\alpha < 0$

cholesteryl iodide content of a film and simultaneously shift the film into a region in which it is less sensitive to subsequent exposure. This is due to the shape of the curve in Fig. 3, *i.e.* where $dp/d\alpha < 0$ and $d^2p/d\alpha^2 > 0$. These two effects both decrease sensitivity. However, in the region $dp/d\alpha > 0$, although exposure does deplete cholesteryl iodide content, the film is shifted into a more sensitive composition area and the two effects tend to compensate.

Summary

The response of pitch to a wide variety of stimuli in mixed cholesteric systems can be predicted from compositional data. If the functional form of pitch *vs.* composition for a particular system is known, then it is possible to quantitatively calculate sensitivity. If the functional form is not known, it is still possible to gain qualitative information from the shape of the compositional curves.

Characterization of CVD Molybdenum Thin Films

A.H. El-Hoshy[1]

General Electric Corporate Research and Development, Schenectady, New York 12301

Presently use is being made of CVD molybdenum thin films as an essential element of wafer processing in the manufacture of semiconductor field effect devices (1). In particular, the amount of boron diffused in the channel region of a field effect transistor may be largely determined by the thickness of the molybdenum film. For the purpose of process reproducibility it is necessary to characterize the physical properties of chemically vapor deposited molybdenum films. Previ-

[1] Present address: Integrated Circuits Project, General Electric Company, Electronics Park, Syracuse, New York 13201.

Key words: thin film, CVD molybdenum on silicon dioxide, grain size and orientation, resistance ratio.

ous work on the subject has not fully explored the influence of deposition parameters on film properties (2, 3).

Spark mass spectrometry and flame spectrophotometry have been used to trace certain elements in CVD Mo films (2, 4). The sensitivity of both methods is in the ppm range. These quantitative techniques are vital in detecting the presence of specific elements such as sodium as well as potential dopant impurities in silicon. However, they are not suited for qualitative estimates of the over-all impurity content, and they do not render information about the structure of the films.

In the present work, three techniques for characterizing CVD Mo films are described. Transmission electron microscopy and x-ray diffraction reveal details about the structure of the deposited metal while resistance ratio measurements give a relative estimate of the over-all purity.

Experiment

Polished silicon wafers of n-type 4 ohm-cm resistivity with a 900Å thermally grown oxide served as substrates for Mo deposition. The vapor deposition system used was supplied by Applied Materials Technology Inc. with a rotating graphite rf susceptor. Gaseous hydrogen acts as a carrier for $MoCl_5$; it also reaches the reaction chamber through a line that bypasses the $MoCl_5$ source. It then reduces $MoCl_5$ according to the following reaction (2)

$$MoCl_5 + H_2 \rightarrow HCl + Mo$$

Deposition conditions were varied in the following manner. Substrate temperature was controlled by the amount of rf power fed into the graphite susceptor, while the deposition rate at a fixed temperature was determined by the amount of carrier hydrogen passed over the $MoCl_5$ source. Since the deposition temperature and the deposition rate are interdependent, the first set of samples had the substrate temperature varied while the deposition rates were allowed to change accordingly. The second set of samples had a fixed deposition temperature and a deposition rate controlled by the amount of bleeder hydrogen over the $MoCl_5$ source. Table I lists the different samples tested and their corresponding deposition conditions. Three wafers were coated in each run. Film thickness was measured by a Tallysurf instrument while resistivities were determined by a four-point resistance probe.

Table I. Deposition parameters and resistivities for the molybdenum films

Run No.	Substrate temperature, °C	Molybdenum thickness, Å	Growth rate, Å/min	Resistivity, ohm-cm

244	700	2800	350	7.2×10^{-6}

Transmission Electron Microscopy

The as-deposited Mo films were etched by immersion in a solution of 95 lactic acid, 5 nitric acid, and 1 hydrofluoric acid for times up to 90 sec. The films were then stripped from the wafers and mounted for direct electron transmission microscopy. Figures 1(a) and (b) are the micrographs obtained for samples 229 and 241 at 75,000 magnification. Using the intercept method on the micrographs, the grain surface area per unit volume was determined for each sample (5). Figure 2(a) shows the change in grain surface area per unit volume as a function of the deposition temperature. Except for the sample deposited at 500°C which has smaller grains, the grain size remained constant as the temperature was increased from 600° to 800°C. The variation in grain size with deposition rate at 700°C is shown in Fig. 2(b). The grain size was not affected by the increase in deposition rate from 87 to 226 Å/min; however, at a deposition rate of 350 Å/min the grain size was smaller. The influence of sample thickness on grain size is given in Fig. 3 where four samples of different thicknesses were deposited at 640°C. The variation in grain size is rather small for the thickness range of 2300-5100Å indicating that the observed changes in grain size as a function of deposition temperature and rate do not reflect a sample thickness effect.

Grain size expressed in surface area per unit volume is important for determining the area available for grain boundary diffusion. Since the maximum variation in grain boundary area was approximately a factor of two, the area available for grain boundary diffusion could not change by more than the ratios of the perim-

eters for a given volume, *i.e.* the flux of diffusants through grain boundaries would not increase by more than a factor of two. This seems rather small and should not influence appreciably the amount of diffusant through Mo films.

Resistance Measurements

Through a photoresist procedure, resistance patterns of 220 aspect ratio were created in the Mo films on the oxidized silicon wafers. The wafers were then scribed to obtain separate resistor pellets. These in turn were mounted on transistor headers and aluminum wires were ultrasonically bonded to join four pads on each resistor with corresponding posts on the header. Two wires served as current leads while the remaining two served as voltage leads. The headers were then hermetically sealed and resistance measurements were made using a stabilized current source and a digital voltmeter.

Figures 2(a) and (b) show the resistance measured at 373K divided by that at 77.2K as a function of the deposition parameters. Since previous measurements

Table II. Effect of deposition conditions on grain orientation

Run No.	Substrate Temperature, °C	Growth rate, Å/min	(110)	(200)	(211)	(220)	(310)
ASTM			100	21	39	11	17
1st Set							
229	500	187	100	42.7	—	2.9	11.8
240	600	247	100	25.4	—	4.1	6.1
228	700	226	100	53.0	—	3.8	15.1
241	800	125	69.5	100	—	—	27.8
2nd Set							
243	700	87	61.5	100	13.8	17	7.7
228	700	226	100	53.0	—	3.8	15.1
244	700	350	27.5	100	—	—	12.1

(2, 6) indicate that the contribution of surface scattering to resistivity is quite small for Mo films of several thousand angstrom thickness at 77.2K, the resistance ratio $R_{373K}/R_{77.2K}$ can therefore be directly compared with bulk material. The most recently reported value for $R_{373K}/R_{77.2K}$ for single crystal zone-refined Mo of 99.999% purity is 15.2 (7). The difference between a maximum value of 5.85 obtained for CVD Mo films and 15.2 for bulk material can be attributed to the combined contribution of internal structural defects and the presence of impurities. Although resistance ratio measurement does not render specific details about either composition or structure; it can still serve as a means for detecting gross changes in the CVD Mo films. The resistance ratio can therefore provide a figure of merit for the over-all quality of the metal film, where the higher the resistance ratio the less structural defects and impurities present in the film.

X-Ray Diffraction

An x-ray diffractometer was used to examine the texture of the CVD Mo films. The effect of deposition conditions on grain orientation is shown in Table II. The intensities are normalized to the strongest reflection which is assigned a value of 100. When the relative intensities of reflections from the different crystallographic planes of CVD Mo films are compared with the ASTM (8) reference, a pronounced preferential orientation of the (200) planes is quite apparent. The relative intensities of the (110) and (200) reflections suggest that the amount of preferential orientation decreases as the deposition temperature is increased from 500° to 600°C. It then seems to increase with temperature for the range between 600° and 800°C. The dependence of grain orientation on deposition rate suggests a decrease in preferential orientation for the intermediate deposition rate of 226 Å/min.

Summary

Transmission electron micrographs, resistance ratios, and x-ray diffraction measurements have been used to characterize CVD Mo films for a deposition temperature range from 500° to 800°C and a deposition rate at 700°C that varies between 87 and 350 Å/min.

Brief Communication

Growth and Crystallographic Identification of MAg_4I_5 Single Crystals

M. R. Manning,* C. J. Venuto,* and D. P. Boden*

ESB Incorporated, Research Center, Yardley, Pennsylvania 19067

Compounds of the type MAg_4I_5 (M = K, NH_4, or Rb) have recently aroused considerable interest due to their unusually high ionic conductivities (1-3). It is very desirable to possess large single crystals of these compounds for fundamental physical studies. Previously, these materials have been produced by diffusing the powdered compounds MI and AgI together at a temperature between 100°C and 200°C in the correct molar ratio (4). Material produced by this method was mostly of the form MAg_4I_5, but it did contain small amounts of the compounds MI, AgI, and M_2AgI_3. Attempts at growing large single crystals by diffusion were unsuccessful, probably because of the disruptive effects of the presence of these impurities on the orderly rearrangement of atoms in a crystal structure. Fusion at a temperature above the eutectic points of the compounds MAg_4I_5 (5, 6) also failed to produce single large crystals in our labs for similar reasons.

Finally, a method involving crystallization from hydroiodic acid was successfully developed for growing large single crystals of these compounds. Octahedral crystals have been produced ranging in size from ⅜ to ½ in. in diameter. The technique described herein overcomes the two main obstacles to their successful growth from solution. These are (*a*) main-

tenance of the correct relative concentrations of the cations incorporated into the structure of the desired compound and (b) retention of the degree of supersaturation necessary for a reasonable growth rate while keeping to a minimum the generation of extra seed crystals through spontaneous nucleation. It is believed that this is the first time that single crystals of any of the compounds $MAgI_5$ have been successfully isolated from solution.

Crystal Growth

During a series of attempts to produce suitable samples of the solid electrolytes MAg_4I_5 for electrochemical and physical investigations, it was found that appreciable quantities of both AgI and MI (M = K, NH_4, or Rb) were soluble in concentrated hydroiodic acid and that each of these could be crystallized from the HI solution. On this basis, it was decided to utilize aqueous HI as the solvent in an attempt to produce large single crystals of MAg_4I_5.

Preparation of the large single crystals included several steps. First, 57% hydroiodic acid was heated to 50°C, and to each gram of the warm acid, 0.805g AgI was added. Depending on the solid electrolyte desired, 0.166g RbI, 0.124g KI, or 0.108g NH_4I was added to the warm HI-AgI solution. The final solution was then allowed to cool to 30°C, 39°C, or 35°C (for M = Rb, K, or NH_4 respectively). During the cooling, dendritic orthorhombic crystals of the formula M_2AgI_3 appeared (7). The solution was then allowed to evaporate slowly at a temperature about 1 deg above the lowest temperature at which the compound MAg_4I_5 is stable, *i.e.* 27°, 36°, or 32° for M = Rb, K, or NH_4 respectively (3). During evaporation, the orthorhombic crystals continued to propagate until octahedral crystals began to appear, whereupon the solution was ready for production of the desired solid electrolyte crystals. At this point, most of the orthorhombic crystals were removed by coarse filtration, and the remainder dissolved by warming the solution 3°. The resulting solution will be referred to as growing solution.

The growing solution was then cooled at the rate of 1° every 12 hr. Octahedral seed crystals generally began to form within the first few hours. At the end of 36 hr, these seed crystals had attained a size of 1/8 to 3/16 in. They could then be separated from solution with the aid of Kel-F type plastic tweezers or by simple filtration through spun Fiberglas matting.

To minimize decomposition, the MAg_4I_5 crystals were quickly dried between two layers of asbestos cloth and stored over Drierite at 40°-50°C in an evacuated desiccator.

An individual crystal prepared as described above could be mounted on a glass filament for further growth if desired, as shown in Fig. 1. A glass "T" was suspended over the edges of a vial, 1 in. in diameter and 3 in. high, with the tip of the drawn glass filament heated to form a small bead for mounting. G. E. adhesive RTV-108 was used to hold the seed crystal to the glass bead. A Teflon disk was affixed to the filament as shown, to shield the growing crystal from falling seeds which may form at the surface of the solution. A piece of Fiberglas matting served as cover and evaporation shield.

The vial was then filled with freshly prepared growing solution, and the filament with attached crystal was lowered into it. The crystals grew to a diameter of ⅜ to ½ in. within 2-3 weeks. The temperature was held constant during this period to within half a degree. Figure 2 shows a crystal of $RbAg_4I_5$ grown by the described procedure.

It should also be noted that crystals of the form MAg_4I_5 could only be grown when the concentration of the M^+ ions was between 17.5 and 18.5% of the total cationic concentration, at the temperatures used (27°-40°C). Below this composition range only AgI crystals would appear; above it crystals of M_2AgI_3 or MI would grow. It was also found that below the temperatures of 27°, 36°, or 32°C, for M = Rb, K, or NH_4 respectively,

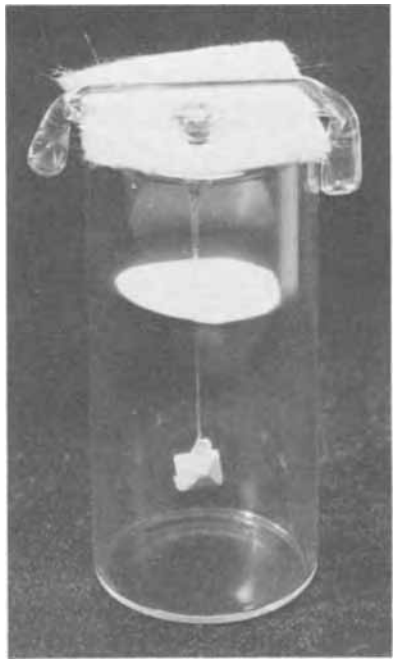

Fig. 1. Photograph showing a single crystal of $RbAg_4I_5$ mounted on glass filament.

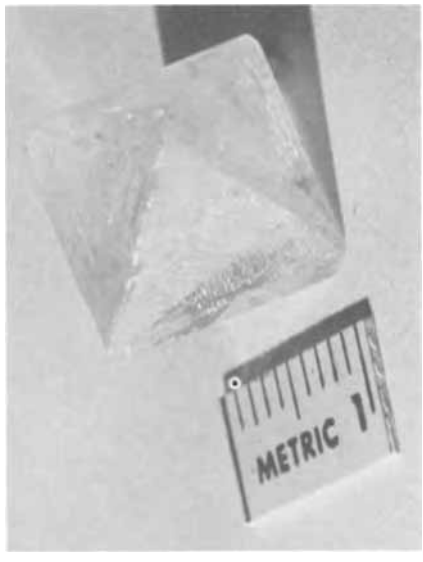

Fig. 2. Photograph of a single crystal of $RbAg_4I_5$. Size of crystal can be seen by reference to the one centimeter scale placed alongside.

no crystals of the type MAg_4I_5 could be formed. Indeed, when previously prepared ⅜ in. diam crystals of these solid electrolytes were inserted in the appropriate growing solutions at temperatures as little as one degree below those specified, they would be transformed within a few hours via the reaction

$$MAg_4I_{5(s)} \rightarrow 1/2\ M_2AgI_{3(s)} + 7/2\ AgI_{(aq)}$$

It was also found that when solutions containing reagent grade HI without the addition of H_3PO_4 as a preservative were used, molecular iodine became entrapped in the growing crystal. This free iodine, which colored the MAg_4I_5 crystals brown, could be removed, in the case of the Rb or K salt, by holding these crystals under vacuum at 100°C for about one week.

As an alternate method, the growing solution could be prepared by utilizing HI acid as sold commercially with 0.5 to 1.5% H_3PO_4 in it as a preservative. During preparation of the growing solution, it would turn brown with freed iodine but this could be removed

by holding the solution at 96°C for 1-3 hr. The resulting straw-yellow solution could then be used as before without impairing crystal quality. Crystals so produced are semitransparent and do not exhibit the brownish tinge characteristic of free iodine. Transparency of the growing solution also aids in monitoring of the growth process.

Crystallographic Examination

A number of small single crystals of $RbAg_4I_5$ were chosen as representative specimens for crystallographic identification. These were ground to a powder for comparison with another powdered sample prepared by fusing RbI with AgI and subsequent cooling. Both samples were observed under the polarizing microscope and determined to be optically isotropic and without impurities.

Table II. Unit cell dimension for $RbAg_4I_5$

Author	Method	Unit cell
Bradley and Greene	Film (powder)	11.15Å
ESB	Film (powder)	11.16Å
ESB	Diffractometer (powder)	11.23Å
Bradley and Greene	Single crystal	11.22Å
Geller	Single crystal	11.24Å

X-ray diffraction powder data for the two samples of $RbAg_4I_5$ are presented in Table I. They agree well with the x-ray diffraction data published by Bradley and Greene (2). The 3.00, 2.57, 2.50, and 1.888 reflections were not observed by those authors. Their equivalents, however, were calculated by Bradley and Greene and are listed in the last column of Table I. All the lines in the ESB powder pattern using the Debye-Scherer method were indexed (column 1). The structure was determined to be cubic with a unit cell dimension of $a_o = 11.16$Å. A slightly larger unit cell of $a_o = 11.23$Å was obtained with the diffractometer method. The former unit cell size agrees with that obtained from powder data by Bradley and Greene, whereas the slightly larger cell agrees with single crystal data obtained by Bradley and Greene and by Geller (6) (Table II). The slight discrepancy is probably due to differences in x-ray method.

Manuscript received June 24, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 117, No. 12 and Vol. 118, No. 4, December 1970 and April 1971.

On the Redistribution of Boron in the Diffused Layer During Thermal Oxidization

J. S. T. Huang and L. C. Welliver (pp. 1577-1580, Vol. 117, No. 12)

M. G. Buehler[1]: The purpose of this note is to indicate that Huang and Welliver have failed to solve the problem they posed. The solution fails because the boundary condition imposed on the diffusive flow at the $Si-SiO_2$ boundary, Eq. [6], has been applied to just solution C_2. This condition should be applied to the total solution $C = C_1 + C_2$. An example of its failure can be seen by examining the special case, $k = m$. For this case, consider an infinitesimal growth of the oxide. Impurity atoms from the Si just converted to SiO_2 satisfy the impurity demands of the oxide with the result that there should be no diffusive flow at the $Si-SiO_2$ boundary. The solution for the impurity distribution in the Si, Eq. [11], does not satisfy the condition of no diffusive flow at the $Si-SiO_2$ boundary for $k = m$.

An additional observation is that the solution, Eq. [11], does not satisfy the diffusion equation because the constant A contains a "square root of time" term. To date, this problem has only been solved numerically,[2] and a closed-form solution is still being sought.

[1] Texas Instruments, Inc., Dallas, Texas.

J. S. T. Huang and L. C. Welliver: We would like to thank Dr. Buehler for his comment on our paper. It should have been pointed out that the model we proposed for boron redistribution is an approximation. The boundary condition, Eq. [6], is equivalent to the so-called radiation boundary condition encountered in heat conduction[3], *i.e.*

[2] T. Kato and Y. Nishi, *J. Appl. Phys. (Japan)*, **3**, 377 (1964).
[3] H. S. Carslaw and J. C. Jaeger, "Conduction of Heat in Solids," Clarendon Press, Oxford, England (1947).

$$D \frac{\partial C}{\partial X} \Big]_o = K\, C(o,t)$$

for which K is a constant. But in our case, K is a function of time due to the parabolic growth rate of thermal oxides. This fact makes the solution of the diffusion equation quite intractable. Even Kato and Nishi[4] in their numerical calculation had to resort to the approximation of K being a constant within a finite time interval. Essentially, our approximation lies in the solution of the second part, Eq. [7], which does not satisfy the diffusion equation but does satisfy the initial and boundary conditions.

The condition, Eq. [6], does apply to the total solution $C_1 + C_2$, since C_1 is approximately a Gaussian distribution, the term $D \frac{\partial C_1}{\partial X}$ evaluated at $X = 0$ vanishes for all times. In the special case for which $k = m$, Eq. [11] approaches a pure Gaussian distribution indicating an impermeable surface with no net diffusive flow across the Si-SiO_2 interface.

We believe that our approximate model is a good one, because it has been validated by extensive experimental results. Furthermore, this model gives considerable physical insight into the redistribution problem. We agree, however, with Dr. Buehler that a rigorous closed-form solution, if it exists, is still being sought.

Gas Phase Etching of Silicon with Chlorine

J. P. Dismukes and R. Ulmer (pp. 634-635, Vol. 118, No. 4)

S. E. Craig, Jr.[5]: Dismukes and Ulmer, in their paper, discussed a new and interesting technique for etching silicon with chlorine in a helium atmosphere. Their data are sufficient to prove that the rate limiting step is the rate of diffusion of reaction products from the surface, or that the reaction rate is mass transfer controlled.

For a mass transfer controlled reaction, the gas phase concentration at the gas-solid interface approaches the equilibrium value. These equilibrium concentrations can be calculated from the thermodynamic data in the JANAF tables[6]. At equilibrium, the concentration of Cl_2 is essentially zero. The only important equilibrium species are $SiCl_2$, $SiCl_4$, and He. The concentrations of these species at the interface are related by the equilibrium for the chemical reaction

$$Si(c) + SiCl_4 \rightleftarrows 2\ SiCl_2 \qquad [1]$$

A diffusion flux, J, for each of the species can be written in terms of a mass transport coefficient, k, and the difference between the inlet mole fraction and equilibrium mole fraction of the species[7]

$$J_{Cl_2} = k\ ([Cl_2] - 0) \qquad [2]$$

$$J_{SiCl_4} = k\ (0 - [SiCl_4]^*) \qquad [3]$$

$$J_{SiCl_2} = k\ (0 - [SiCl_2]^*) \qquad [4]$$

where bracketed quantities represent mole fractions of the indicated species,* indicates equilibrium values, while unstarred quantities represent feed values.

The total diffusion flux of silicon containing species away from the gas-solid interface is related to the etching rate, r, by the mass balance equation

$$\frac{r\rho_c}{M} = -\ (J_{SiCl_2} + J_{SiCl_4}) \qquad [5]$$

where ρ_c = density of solid Si = 2.33 g/cm^3 and M = molecular weight of Si = 28 g/mole. A combination of Eq. [3], [4], and [5] yields the complete rate expression[8].

$$= \frac{M}{\rho_c} k\ [Si]^* \qquad [6]$$

where $[Si]^* = [SiCl_4]^* + [SiCl_2]^*$.

Both k and $[Si]^*$ are functions of temperature. To facilitate comparison of the data with the theory, both sides of Eq. [6] are multiplied by k_o/k where k_o is the mass transfer coefficient computed at a standard reference temperature, T_o.

Graetz type solutions to the combined diffusion and flow problem usually give the Sherwood number, $kd/\mathcal{D}\rho$, as a function of a modified Graetz number, $W/\mathcal{D}\rho L$, where d and L are dimensions characteristic of the channel width and length, W is the molar flow rate of gas, $\mathcal{D}$ is the gas phase diffusivity and $\rho = P/RT$ is the molar density of the gas. These Graetz solutions show that the Sherwood number is proportional to the cube root of the Graetz number in the range of flows normally encountered. Since $\mathcal{D}$ is proportional to the 3/2 power of temperature, and ρ is inversely proportional to temperature, $k_o/k = (T_o/T)^{1/3}$.

Equation [6] becomes

$$r\,(T_o/T)^{1/3} = \frac{Mk_o}{\rho_c} [Si]^* \qquad [7]$$

[Si]* was calculated for the various feed compositions and reaction temperatures used by Dismukes and Ulmer. T_o was taken as 900°C (1173°K). A log-log plot of $r\,(T_o/T)^{1/3}$ *vs.* [Si]* is presented in Fig. 1. The data fit a straight line with a slope of 1 as the theory predicts.

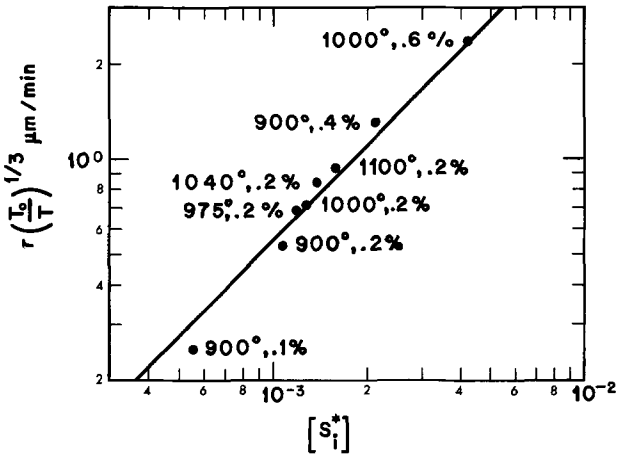

Fig. 1. Etch rate as a function of equilibrium gas phase mole fraction of silicon containing species. The reaction temperature in degrees C and the feed mole per cent (m/o) Cl_2 are shown for each data point. Solid line represents the theory for a mass transfer controlled reaction.

From Fig. 1, Mk_o/ρ_c is found to be 550 μm/min. This yields $k_o = 7.65 \times 10^{-5}$ moles/sec-cm^2. If we take $\mathcal{D} = 3.24$ cm^2/sec, $\rho = 1.04\ (10^{-5})$ moles/cm^3 and $d = 2$ cm, the Sherwood number, $k_o d/\mathcal{D}\rho = 4.6$. This value is typical of what one expects to find in a reactor of this type.

Activation Energy: The apparent activation energy, $\Delta E^\dagger_a$, is obtained by taking logarithms of Eq. [7] and differentiating with respect to $1/T$.

$$\Delta E^\dagger_a \equiv -R \frac{d \ln r}{d\left(\frac{1}{T}\right)} = \frac{RT}{3} - \frac{R\, d \ln [Si]^*}{d\left(\frac{1}{T}\right)} \qquad [8]$$

The first term on the right of Eq. [8] is the apparent activation energy due to the temperature dependence

[4] T. Kato and Y. Nishi, *J. Appl. Phys. (Japan)*, 3, 377 (1964).
[5] Arizona State University, Tempe, Arizona 85281.
[6] D. R. Stull *et al.*, JANAF Thermochemical Tables, Dow Chemical Co., Clearing House for Federal Scientific and Technical Information (1965).
[7] Because all active species are present in dilute concentrations, the increase in gas phase moles is neglected.
[8] For simplification, it is assumed that the mass transport coefficients are the same for all species.

of diffusion. This represents a small contribution and has a value of approximately 0.8 kcal/mole.

The second term on the right of Eq. [8] is the apparent activation energy due to the shift in equilibrium with temperature. For dilute solution this term becomes

$$\frac{-R\,d\ln[\mathrm{Si}]^*}{d(1/T)} = \frac{-R}{[\mathrm{Si}]^*\left(\frac{4}{2[\mathrm{Si}]^*-[\mathrm{Cl_2}]}+\frac{1}{[\mathrm{Cl_2}]-[\mathrm{Si}]^*}\right)}\,\frac{d\ln K}{d\left(\frac{1}{T}\right)} = \frac{\Delta H^o}{[\mathrm{Si}]^*\left(\frac{4}{2[\mathrm{Si}]^*-[\mathrm{Cl_2}]}+\frac{1}{[\mathrm{Cl_2}]-[\mathrm{Si}]^*}\right)} \quad [9]$$

where K and ΔH^o are the equilibrium constant and the heat of reaction for reaction Eq. [1].

At very low temperatures ($T < 900$°C), $SiCl_4$ is the dominant species at equilibrium and $[Si]^* \cong [SiCl_4] \cong [Cl_2]/2$. At these low temperatures, the equilibrium apparent activation energy is zero. The equilibrium apparent activation energy is also zero at very high temperatures ($T >$ melting point) where $SiCl_2$ is the dominant species and $[Si]^* \cong [SiCl_2]^* \cong [Cl_2]$.

The maximum value of the equilibrium apparent activation energy is obtained in the mid-range temperatures (1000°C $< T <$ 1100°C) where half the Cl_2 is in $SiCl_2$ and half is in $SiCl_4$. Under these conditions $[Si]^* = \frac{3}{4}\,[Cl_2]$ and the equilibrium apparent activation is $\Delta H^o/9 = 8.7$ kcal/mole[6]. When this is added to the apparent activation energy for diffusion, the total apparent activation energy of 9.5 kcal/mole is obtained. This is very close to the value of 10 kcal/mole reported in the paper under discussion.

This apparent activation energy is not a "true" activation energy but rather represents a shift in equilibrium with temperature. The rate is faster at high temperatures where $SiCl_2$ is the favored species than at low temperatures where $SiCl_4$ is the favored species because $SiCl_2$ is a more efficient transporter of silicon than is $SiCl_4$ (per atom of Cl).

Conclusion: Since the mass transport assumption correctly predicts all the trends in the kinetic behavior and also predicts the value of the etching rate, we conclude that the gross kinetics of etching Si with Cl_2 in He is indeed mass transfer controlled.

J. P. Dismukes[9] and F. W. Dittman[10]: We concur with Craig's conclusion that, in the etching of Si with Cl_2 in He atmosphere[11], mass transfer of Cl_2 to and of a mixture of $SiCl_2$ and $SiCl_4$ from the Si surface controls the rate of etching at a given temperature. Craig also correctly points out that the temperature dependence of the etch rate is related to a shift to the right of the equilibrium at the interface

$$\mathrm{Si(s)} + \mathrm{SiCl_4(g)} \leftrightarrow 2\mathrm{SiCl_2(g)} \quad [1]$$

rather than to a temperature dependent chemical kinetic process at the interface[11]. However, two additional comments are appropriate, the one with regard to the etching efficiency, which Craig did not discuss, and the other with regard to the preferred use of a Pohlhausen solution[12] rather than a Graetz solution[13] in the mass transfer analysis.

If mass transfer is indeed the rate limiting step, it has to account for the small observed efficiencies (2-4%) for reaction of Cl_2 with Si[11]. Since the mass transfer coefficient k can be more accurately calculated for Cl_2 than for a mixture of $SiCl_4$ and $SiCl_2$, we have estimated the mass transfer limited rate of etching of Si by Cl_2 using the relation

$$R = kAx_{\mathrm{Cl_2}}\frac{(1+\alpha)}{2} \quad [2]$$

where R = etch rate in gram moles Si/sec, A = area of Si in cm^2, x_{Cl_2} = mean unreacted mole fraction Cl_2, and α, calculated from thermochemical data, is the fraction of $SiCl_4$ converted to $SiCl_2$ in the reaction in Eq. [1] at equilibrium. For laminar flow across a plate, the Pohlhausen relation[12], which relates the Sherwood number to the product of the square root of the Reynolds number and the cube root of the Schmidt number

$$\frac{kL}{\rho D} = 0.664\left(\frac{Lv\rho}{\eta}\right)^{1/2}\left(\frac{\eta}{\rho D}\right)^{1/3} \quad [3]$$

was used to calculate k, where L = the length of the susceptor, v = the linear gas velocity, η = the gas viscosity, ρ = the molal density, and D = the diffusion coefficient. For 0.2%Cl_2, the calculated k values are 7.0×10^{-5} at 900°C and 6.5×10^{-5} at 1100°C, and the calculated R values are 4.0×10^{-7} at 900°C and 5.6×10^{-7} at 1100°C. The experimental R values[11], 3.7×10^{-7} at 900°C and 6.9×10^{-7} at 1100°C, show sufficient agreement with the calculated values to indicate that the etching of Si by Cl_2 is indeed mass transfer controlled.

A laminar flow mass transfer analysis using the Pohlhausen solution[12] for a flat plate, rather than the Graetz solution[13] for a tube, employed by Craig, is more meaningful for the actual geometry of the silicon wafer, susceptor, and reactor, as was previously pointed out for epitaxial growth[15] of Si by hydrogen reduction of $SiCl_4$. For the Pohlhausen case, and taking a more accurate temperature dependence of η and D[16], Craig's Eq. [7] becomes

$$r\,(T_o/T)^{0.447} = \frac{Mk_o}{\rho_c}[\mathrm{Si}]^* \quad [4]$$

A plot of this equation similar to Craig's Fig. 1 yields $k_o = 6.7 \times 10^{-5}$ for the mean mass transfer coefficient of the mixture of $SiCl_2$ and $SiCl_4$ at 900°C, compared to Craig's value of $k_o = 7.6 \times 10^{-5}$. For the present data, the difference between the Pohlhausen and Graetz solutions is not large, because the flow velocity was constant and the parameters of temperature and Cl_2 concentration did not vary widely. However, the Pohlhausen solution is the correct one for this type of reactor geometry.

Effect of Sulfur on the Corrosion Characteristics of Iron in Carbonated Beverage

Hideya Okada, Yuzo Hosoi, and Kazuo Yamamoto

Fundamental Research Laboratories, Nippon Steel Corporation, Kawasaki, Japan

ABSTRACT

The anodic polarization curve of sulfur-bearing iron was independent of pH in both sulfuric and phosphoric acids, whereas that of pure iron was influenced by pH. This pH-dependence of the polarization of pure iron was suppressed when SH^- or $S^=$ ions were added to the acid. By the addition of a small amount of cola beverage or "blue dye" (which plays a role similar to the organic substance in the cola beverage in the corrosion of iron) to the acid, anodic polarization of sulfur-bearing iron shifted in the more noble direction. A corrosion mechanism of sulfur-bearing iron in sulfuric acid and the inhibiting action of cola beverage on sulfur-bearing iron are discussed.

It is known that addition of sulfur to steel accelerates the corrosion rate in sulfuric acid (1) and hydrochloric acid (2). Recently, however, the corrosion resistance of steel in cola beverages was improved by alloying with sulfur (3). These two results imply that sulfur in steel plays a different role in corrosion reactions in mineral acids and cola beverages.

In this study, the effect of sulfur on the pH dependence of iron corrosion in both sulfuric acid and a cola beverage has been investigated and the role of sulfur in the corrosion of steel in the cola beverage is discussed.

Experimental

The polarization curve was obtained with the rapid galvanostatic method (4) which makes it possible to obtain a polarization curve within a few seconds (*ca.* 10^{-1} sec for each current density) without changing the surface state of the specimens in a corrosion system. Figure 1 shows the circuit diagram and the electrolytic cell used.

Acid solutions were prepared from analytical grade sulfuric acid and phosphoric acid. Coca Cola was used as the cola beverage. The blue dye test served as a corrosion testing method for estimating the corrosion behavior of steel in cola beverages. In this test, Brilliant Blue FCF (C. I. No. 42090) is used because it is expected to play a role similar to the organic substance contained in cola beverage (5). These solutions were saturated with purified nitrogen gas for more than one day, and kept at 25°C during the test.

Specimens were prepared as follows: (*i*) high frequency vacuum furnace melting, (*ii*) hot rolling or forging, (*iii*) machining, (*iv*) degreasing and chemical polishing [H_3PO_4-H_2O_2], (*v*) heat treatment 700°C, 1 hr], (*vi*) abrading with metallographic papers [0/2-0/4], (*vii*) chemical polishing [H_3PO_4-H_2O_2], (*viii*) acid pickling [1*N* HCl], and (*ix*) water rinse and drying with filter papers.

Chemical composition of materials used is listed in Table I. Electrolytic iron was used in an immersion corrosion test, and Puron was used for polarization measurement in order to avoid the effect of small amount of impurities on the polarization characteristic of iron.

Key words: inhibition, polarization, cola.

Results

Effect of sulfur on the pH-dependence of polarization of iron.—Table II indicates weight loss experiments of

* S = 0.05%.

the electrolytic iron and that of the sulfur-bearing iron in sulfuric acid and the cola beverage. It is noted that the corrosion rate of iron was markedly accelerated by addition of sulfur to iron in sulfuric acid; on the other hand, it was significantly decreased in the cola beverage.

Figure 2 shows the rapid polarization curves of Puron in sulfuric acid. The *p*H values were adjusted to 1.0, 1.9, and 2.7 by addition of sodium sulfate. As clearly shown in Fig. 2, both anodic and cathodic polarization curves were dependent on the *p*H values in this region. On the other hand, in the case of the sulfur-bearing iron, it is shown that anodic polarization curves were independent of the *p*H values. Both anodic and cathodic polarization were decreased as shown in Fig. 3. Similar results were also obtained by the steady-state polarization method (stationary-state method).

Since cola contains phosphoric acid, the anodic behavior of iron in an aqueous solution of phosphoric acid must be considered. Polarization of iron in phosphoric acid also indicated the same behavior as in sulfuric acid.

Effect of Brilliant Blue dye on polarization characteristics of iron in sulfuric acid.—In the case of Puron, there was no appreciable effect of the dye on anodic polarization. While in the case of the sulfur-bearing iron, anodic polarization increased by addition of Brilliant Blue dye (compare curves 1 and 2 with curves 1' and 2' in Fig. 4, respectively), and the *p*H-dependence appeared (see curves 1' and 2' in Fig. 4). Comparing curves 1' and 2' in Fig. 4 with the curves for *p*H 1.0 and for *p*H 2.7, respectively, it is noted that anodic polarization of sulfur-bearing iron is greater than that of Puron. Curve 3 in Fig. 4 shows the polarization of the sulfur-bearing iron in sulfuric acid (*p*H 2.7) to which 20 ml/liter of cola beverage was added.

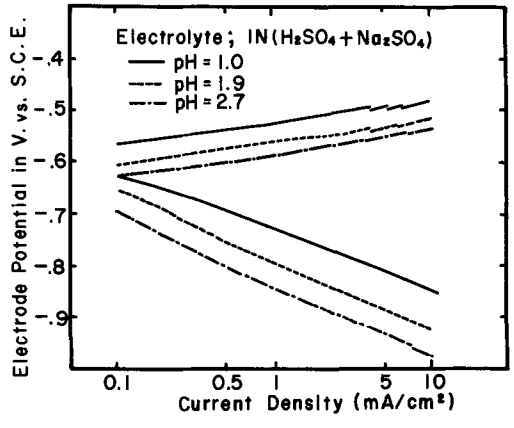

Fig. 2. Rapid polarization curves of Puron in sulfuric acid (N_2 saturated, 25°C).

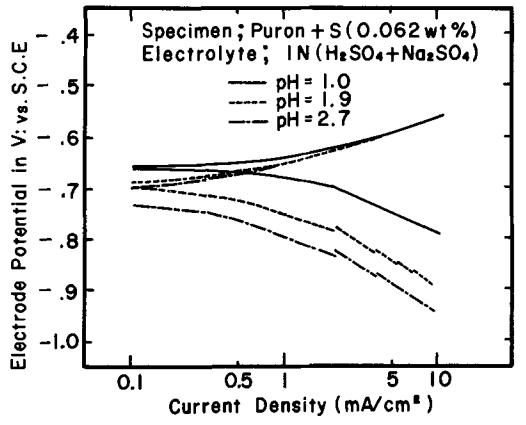

Fig. 3. Rapid polarization curves of sulfur-bearing iron in sulfuric acid (N_2 saturated, 25°C).

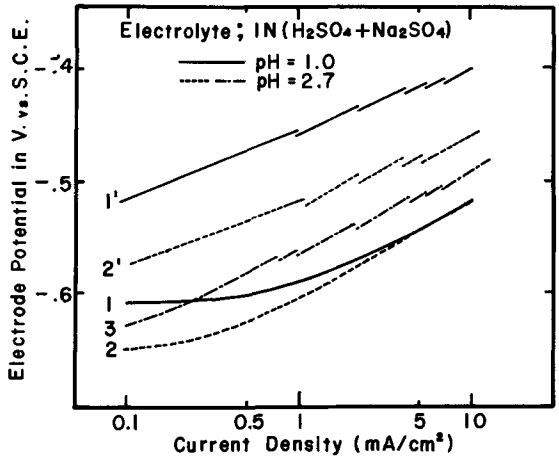

Fig. 4. Effect of Brilliant Blue FCF on anodic polarization of sulfur-bearing iron (N_2 saturated, 25°C). Lines 1,2; $SO_4^=$ solution. Lines 1', 2'; $SO_4^=$ solution containing FCF (1.44 g/liter). Line 3: $SO_4^=$ solution (180 ml) containing cola beverage (20 ml).

These results suggest that some interaction between sulfur and the dyestuff occurs during corrosion of iron.

Effect of SH^- ions on polarization characteristics of iron.—The results mentioned above suggest that the mechanism of the dissolution of the sulfur-bearing iron is somewhat different from that of the sulfur-free iron. It may be assumed that the corrosion of iron was probably affected by the formation of SH^- ions during the dissolution of sulfur-bearing iron. If this assumption is correct, the same behavior as the sulfur-bearing iron should be observed in a solution containing a small amount of sodium sulfide (5 ppm), even for the Puron. As expected, Puron tended to behave in the same manner as the sulfur-bearing iron in the above solution (Fig. 3) showing no detectable *p*H dependence in anodic polarization as shown in Fig. 5.

Discussion

It is well known that the corrosion of iron in acid solution is accelerated by addition of sulfur (1, 2, 6). Concerning the role of sulfur, several investigators (1, 7-9) have suggested that hydrogen sulfide produced by the dissolution of sulfur-bearing steel decreased anodic polarization and others (2) pointed out that sulfur in steel decreased cathodic polarization.

However, none investigated the effect of sulfur on the *p*H dependence of iron dissolution. It is emphasized in this study that the anodic polarization of iron becomes independent of the *p*H of the solution when sulfur is added to iron (Fig. 3).

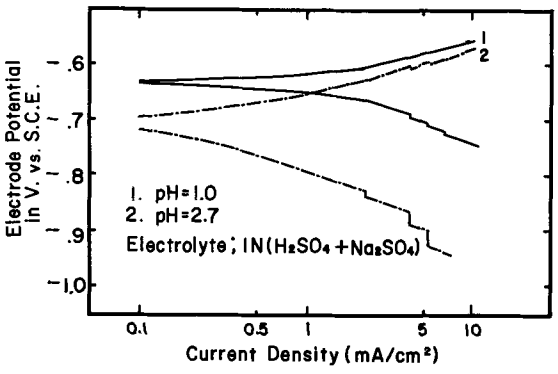

Fig. 5. Effect of the addition of Na_2S (5 ppm) on the rapid polarization curves of Puron in sulfuric acid (N_2 saturated, 25°C).

This fact implies that corrosion mechanism of sulfur-bearing iron is different than that of iron which exhibits pH dependence.

Reaction mechanisms of iron dissolution in acid solution have been presented by several investigators (10-16). Typically

$$Fe + OH^- \rightleftarrows (FeOH)_{ads} + e^- \quad [1]$$

$$Fe + OH^- + (FeOH)_{ads} \rightarrow (FeOH)^+ + (FeOH)_{ads} + 2e^- \quad [2]$$

$$(FeOH)^+ + H^+ \rightleftarrows Fe^{++} + H_2O \quad [3]$$

However, the dissolution reaction of sulfur-bearing iron is difficult to explain by the above reaction mechanism in which the adsorption of OH^- ions are involved, because anodic polarization of sulfur-bearing iron does not show the pH dependence. If SH^- ions exist in the solution, they are expected to be more easily adsorbed than OH^- ions. Thus, a reaction process in which SH^- ions (instead of OH^- ions) take part is introduced in the dissolution mechanism of sulfur-bearing iron.

Accordingly, the following reaction process may be presented

$$Fe + SH^- \rightleftarrows (FeSH)_{ads} + e^- \quad [4]$$

$$Fe + SH^- + (FeSH)_{ads} \rightarrow (FeSH)^+ + (FeSH)_{ads} + 2e^- \quad [5]$$

$$(FeSH)^+ + H^+ \rightleftarrows Fe^{++} + H_2S \quad [6]$$

Since the kinetic data are insufficient in this work, it is not clear whether the dissolution mechanism mentioned above is correct. However, this dissolution mechanism of sulfur-bearing iron is possible because the pH dependence does not appear in this mechanism.

Another important result is that the anodic reaction of sulfur-bearing iron is inhibited by addition of blue dye to the solution (Fig. 4, curves 1' and 2'), and the pH dependence of anodic polarization was observed. These facts suggest that there are some interactions between the dyestuff and the SH^- ions.

The role of dyestuff can be explained as follows: As mentioned above, SH^- ions are probably more easily adsorbed on the iron surface than OH^- ions. When the Brilliant Blue dye is added to the solution, it interacts with SH^- ions and forms a complex compound. Thus, the dissolution of sulfur-bearing iron is inhibited due to the adsorbed Brilliant Blue dye-SH^- complex, as schematically represented in Fig. 6. Under such conditions, OH^- ions contribute to the anodic dissolution of iron. Accordingly, the pH dependence of anodic polarization appears in sulfur-bearing iron when dyestuff is added to the solution (Fig. 4, curves 1' and 2').

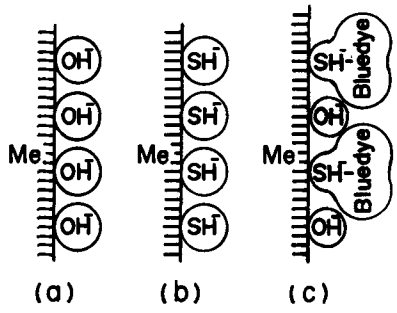

Fig. 6. Schematic representation of inhibition action of blue dyestuff (Brilliant Blue FCF) to SH^- ions. (a) Adsorption of OH^- ions in the dissolution process of pure iron, (b) adsorption of SH^- ions in the dissolution process of sulfur-bearing iron, (c) inhibition action due to SH^--blue dyestuff complex compound.

Conclusion

The corrosion rate of iron in cola beverage is decreased by the addition of sulfur to iron.

Polarization characteristics of iron and sulfur-bearing iron were measured in sulfuric acid, phosphoric acid, and the cola beverage to determine the effect of sulfur on the corrosion behavior of iron. Results were summarized as follows:

1. Polarization curves of sulfur-free iron in sulfuric or phosphoric acid, at pH values ranging from 1.0 to 2.7, depended on the pH, while for sulfur-bearing iron, polarization curves were independent of pH.
2. When SH^- or $S^=$ ions were added to the acid, the polarization curves of iron were independent of pH.
3. Anodic polarization curves of the sulfur-bearing iron shifted in the more noble direction, when Brilliant Blue dye was added to the acid. This effect also appeared when cola was added to the acid.
4. A corrosion mechanism for sulfur-bearing iron in acid is proposed which includes adsorption of SH^- ions.
5. Inhibition action of cola on sulfur-bearing iron was considered to be due to adsorption of a SH^--blue dye complex.

Dielectric Breakdown in Electrolytic Capacitors

F. J. Burger* and J. C. Wu

Sprague Electric of Canada Ltd., Toronto 337, Ontario, Canada

ABSTRACT

Starting with the known but unexplained fact that high-voltage electrolytic capacitors need operating electrolytes of high resistivity, breakdown (sparking) voltages of aluminum and tantalum anodes have been examined. If interfering side reactions are eliminated, breakdown voltage increases linearly with the logarithm of electrolyte resistivity and is insensitive to variations in electrolyte composition and to changes in temperature between 65°C and 95°C.

Guntherschulze and Betz, in their classic on electrolytic capacitors (1), considered ionic concentration of electrolytes to be the controlling factor of sparking voltage. They noted the linear dependence of sparking voltage on the logarithm of resistivity of the electrolyte. However, their experiments were limited to aqueous electrolytes and were done at or below room temperature which perhaps was not a good choice because anomalies in the formation process, *e.g.* etching, porous oxide formation and corrosion, are often experienced under those conditions. Some of their quantitative findings are open to doubt (2). Perhaps the phenomenon of sparking in electrolytic capacitors is still not well understood because side reactions may intervene during the formation process, and thus obscure whatever relationships may exist between sparking voltage and other relevant parameters. The reactions on aluminum in the ethylene glycol/borate system are characterized by electrochemical oxidation of the solvent (3), by metal corrosion and the appearance of a rust-colored solid corrosion product that adheres to the aluminum substrate. However, as will be shown, special measures can be taken to suppress these side reactions, particularly in the case of aluminum, with the result that a clear-cut relationship of wide applicability emerges, linking sparking voltages with the logarithm of electrolyte resistivity.

Experimental Technique

Constant current formations of foil specimens were carried out in a temperature-controlled, closed, reaction vessel, watching the rate of voltage rise and noting the voltage at which the sound of sparking could be clearly heard for the first time (at which point there occurs also an abrupt slowdown in the rate of voltage rise). All foil specimens, except when otherwise stated, were 3 cm wide and 5 cm long, the lead being formed by an integral central tab, 0.4 cm wide and 5 cm long which emerged from one of the 3 cm edges of the foil. The aluminum specimens were cut from 99.99% pure foil, either plain (0.0090 cm thick) or etched (0.0070 cm thick). Before anodization, the samples were given a pretreatment by immersing them first, at room temperature, in 1*N* NaOH solution, for 2 min in the case of plain, and for 30 sec in the case of etched foil. This was followed by rinsing in deionized water and then in absolute methanol before drying the specimens at 110°C for about 5 min. In the case of tantalum, plain capacitor grade, 0.0021 cm thick foil was used. The pretreatment here consisted of degreasing by boiling in trichloroethylene then air drying the specimens, and after rinsing them with deionized water, immersing them in 6*N* HNO_3 at 75°C for 1 min. This was followed by another rinse in deionized water, then absolute methanol, and, finally, drying them at 110°C for 5 min. The apparatus in which the formations were carried out was a three-necked 250-ml Pyrex distillation flask with a magnetic stirrer immersed in a temperature-controlled stirred bath of glycerine. One of the two side necks of the flask held a thermometer, the other held the cathode assembly. The cathode consisted of a piece of platinum foil 2 cm wide by 5 cm long by 0.005 cm thick to which was welded the lead, a platinum wire of 0.08 cm diam. The wire was sealed into the glass stopper of the flask and brought out to form the cathode terminal. The anode was suspended from its own tab which was held in a clip made from platinum wire, the other end of the wire passed through a glass tube and a Teflon seal to the outside to make contact with the anode terminal. The glass tube could be rotated and adjusted through a Teflon stopper sitting concentrically in, and closing off, the glass stopper of the large central neck of the flask. Care was taken to see that the specimen/platinum junction was always well above the electrolyte level and was kept dry during the progress of an experiment.

Details of the anodizing and measuring procedures follows. After bringing the electrolyte to the required temperature, the anodization was carried out at constant current densities of 0.5 mA/cm² in the case of plain foil (a total current of 15 mA) and 1.0 mA/cm² for the etched foil. By means of a VTVM connected across the cell terminals, the rise of voltage with time was followed and the voltage noted at which there was no further increase. The rate of rise for plain aluminum foil and the current densities as stated was mostly about 12.5 V/min; with tantalum, it was about 8.6 V/min. With the electrolytes employed, two kinds of voltage limitations were observed. One kind was due to a side reaction taking over from the formation proper and resulting in the appearance of corrosion spots on the foil surface. The other kind was due to the breakdown of the barrier film and characterized by sparking and a sound that was readily noted, especially if the thermometer bearing stopper was raised to facilitate listening. The voltage at which a side reaction or breakdown occurred could be determined with an accuracy of about 5V. Attempts were also made to detect the sparking voltage by counting breakdown pulses electronically, but this was abandoned since it did not result in any worthwhile improvement.

In order to determine the *IR* drop through the electrolyte, the cell constant of the anodization assembly was determined. This was done by substituting for the usual anode specimen a platinum foil electrode of the same shape and size and determining the impedance by an a-c (2.5 kHz) measurement, with electrolytes of known resistivity. The cell constant was thus found to be 7 cm. Hence, for an electrolyte resistivity of 1000 ohm-cm and using a total current of 0.015A the *IR* drop amounted to about 2.1V. The sparking voltage as referred to throughout this paper is defined as the voltage, corrected for the *IR* drop in the electrolyte, at which the sound of sparking is first heard in a formation experiment, the voltage being read by means of

* Electrochemical Society Active Member.

Key words: anodic oxidation, dielectric breakdown, electrolytic capacitors, sparking voltage.

a VTVM connected across the formation cell while the current is maintained at the initial value, *e.g.* 0.015A.

Results and Discussion

Before discussing sparking voltage, some detailed results are given concerning side reactions. When a plain aluminum foil anode was anodized at 85°C at 0.5 mA/cm² in an electrolyte consisting of a 32% by weight solution of ammonium pentaborate in ethylene glycol (ρ 85°C = 110 ohm-cm), a corrosion product formed on the surface of the foil at 280V and became plainly visible on maintaining the current at its initial value for about 15 min. The point of onset of the corrosion reaction was revealed by a sudden reduction to almost zero in the rate of voltage rise from its former value of about 12.5 V/min. The corrosion product was found to be distributed over the foil surface in plugs associated with the rolling marks of the foil.

When etched foil was substituted for plain aluminum foil, no corrosion occurred. Our belief is that the corrosion originates with metallic impurities picked up and rolled into plain foil during manufacture. Thus it is possible to produce this kind of corrosion at will by deliberately contaminating either a plain or etched foil. For instance, if the foil is struck with a hardened steel punch so as to produce a well-defined impression, corrosion will occur in the struck portion of the foil. If the foil is insulated against direct impact by the interposition of another thin Al foil between punch and specimen, no corrosion is observed. If a definite pattern is scratched onto the foil surface with a sharp piece of glass, no corrosion is observed. But, if the scratches are contaminated by exposing them to CrO_3 or $KMnO_4$ solution and heating them briefly to 100°C, then rinsing away the surplus after several minutes' contact, corrosion becomes evident very soon after formation has reached a certain voltage. Both chromium and manganese compounds show a specific ability to cause corrosion. Surprisingly, no effect was observed following contamination with iron or copper. However, attempts to make a positive identification of the contaminants normally present on the surface of plain foil have not been successful.

We have found that the corrosion causing side reactions can be suppressed by small additions of salicylic acid to the electrolyte, presumably because the acid is instrumental in removing corrosion centers by anodic etching during the formation process. The efficacy of salicylic acid addition in thus restoring proper formation conditions for aluminum can be demonstrated in organic solvent as well as in water-based electrolytes. If additions of salicylic acid are made in amounts insufficient to give complete suppression of side reactions, then tree-like etch patterns are seen to be formed on the foil surface as the result of the corrosion reaction. Two typical patterns are shown in Fig. 1 and 2. Figure 1 is a photomicrograph of a portion of a plain Al foil specimen (the actual field diameter is 1.2 mm) that had been formed at 85°C at a current density of 0.5 mA/cm² to the limit possible (400V) and kept at that voltage for 37 min during which time the tree pattern developed. In this case, the electrolyte was composed, in parts by weight, of 12 boric acid, 3.4 tributylamine, 88 ethylene glycol, and less than 0.1 salicylic acid. When the salicylic acid content was increased by a small amount, formation proceeded to 465V at which point sparking occurred, but neither corrosion nor tree formation. Figure 2 is a photograph taken of a 7 cm by 7 cm plain Al foil specimen formed because of its larger size in a 500 ml resin reaction jar at 85°C and 0.5 mA/cm² to the limiting voltage of 390V and kept at that voltage for about 33 min during which time the tree pattern developed. The electrolyte contained, in parts by weight, 12 boric acid, 2.5 ammonium pentaborate, 88 ethylene glycol, and less than 0.05 salicylic acid. Again, after the salicylic acid content was raised slightly, formation proceeded to 485V, where sparking was observed to take place, but

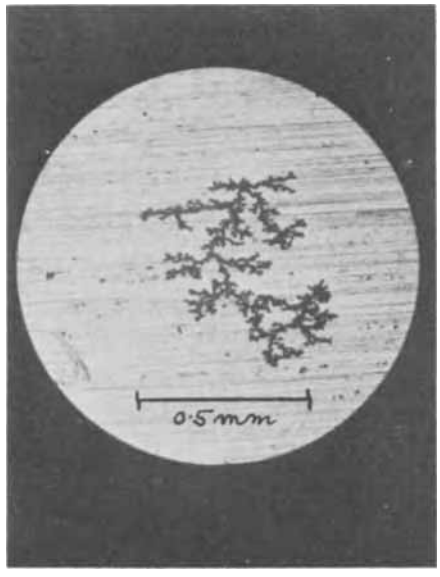

Fig. 1. Photomicrograph of "tree" corrosion pattern on aluminum anode; field diameter: 1.2 mm.

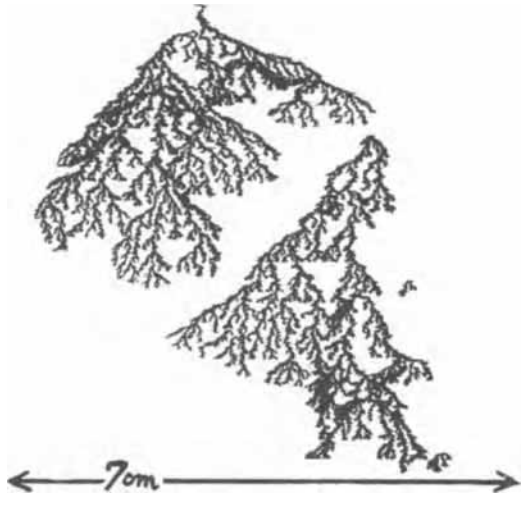

Fig. 2. Large "tree" corrosion pattern developed on aluminum anode specimen measuring 7 cm by 7 cm.

no corrosion or tree formation. The characteristic tree pattern as well as its association with the rolling marks in the foil is clearly evident from both illustrations. Somewhat similar, though possibly not as strikingly characteristic, structures have been reported as occurring in similar circumstances as a result of dielectric breakdown, in both aluminum and tantalum systems (3, 5).

If side reactions are suppressed, formations can proceed right up to the sparking voltage. Sparking voltages obtained by forming aluminum anodes with electrolytes A through I are recorded in Table I.[1] The sparking voltages listed have been corrected for *IR* drop. A plot of sparking voltages *vs.* log of resistivities is shown in Fig. 3. The experiments were done at three different temperatures, and the results are grouped accordingly. As will be seen, the sparking voltage depends linearly on the logarithm of resistivity. The dependence can be represented by a single line obeying the empirical equation

$$V_{Sp} = 123 \log_{10} \rho + 147$$

[1] pH values are as measured with a glass electrode.

V_{Sp}	410	410	439	458	468	506	544

where V_{Sp} = sparking voltage, in volts

and ρ = resistivity, in ohm-cm

Slight deviations from the rule involving aqueous and some organic electrolytes may occur at or near room temperature owing to anomalies in the formation process, but in all other cases experimental results follow the above equation irrespective of variations in electrolyte composition or temperature within the range of 65°C to 95°C. For example, it will be noted that of the aluminum electrolytes those bearing letters B, C, E, F, H, and I are based on ethylene glycol as the solvent, A on a mixture of ethylene glycol and water, D on water, and G on a mixture containing a major portion of dimethyl formamide and a minor portion of ethylene glycol. These electrolytes are typical of a much larger group that were found to confirm the validity of the rule stated above. From the examples listed in Table I and from Figure 3, the range of validity of the straight line relationship is seen to be from 77 to 3000 ohm-cm, corresponding to a voltage range from about 380 to about 580V, respectively. With resistivities greater than 5000 ohm-cm, the sound of sparking is less distinct than with the lower values and hence the measurement of V_{Sp} is somewhat more difficult and less accurate. However, the straight line relationship has been confirmed up to resistivities of 50,000 ohm-cm, the corresponding V_{Sp} being 720V. The results suggest that the sparking voltage/resistivity relationship is of quite fundamental nature. Consequently, the exceptional location of points below or above the straight line whenever it occurs should be taken to indicate an anomaly, either in respect to the anodizing process or to the composition or structure of the anodic oxide.

To test the effect of a pre-existing oxide layer, experiments were carried out with foils that had been preformed. These were first anodized to 600V at 85°C and of 0.5 mA/cm². The formation was continued at the constant voltage of 600V for 2 hr in an electrolyte of suitable resistivity (*e.g.* one very similar to but containing less ammonium pentaborate than electrolyte I of Table I) before determining their sparking voltages in the electrolyte (A, B, E, or F). The results of these experiments are included in Fig. 3 for comparison with those from aluminum anodes not so preformed. As can be seen, the sparking voltage of Al foil preformed to 600V again follows a semilog relationship with electrolyte resistivity. It runs at an angle to and above the standard line, merging into it at and near the 600V range.

Finally, results are given of anodization experiments done at 85°C with tantalum foil. Electrolyte particulars are shown in Table II[1] and the plot of sparking voltages *vs.* log of electrolyte resistivities is shown in Fig. 3 for comparison with the aluminum results. Thus the tantalum results also follow a semilogarithmic relationship. The tantalum line is parallel to that of aluminum, but displaced downward from it by about 40V. Hence, the voltage to which tantalum can be formed in a given electrolyte is always 40V below that of aluminum.

Attempts were also made to compare the behavior of other anodic metal oxides such as niobium and zirconium with that of aluminum and tantalum, but while generally confirming the findings of Alwitt and Vijh

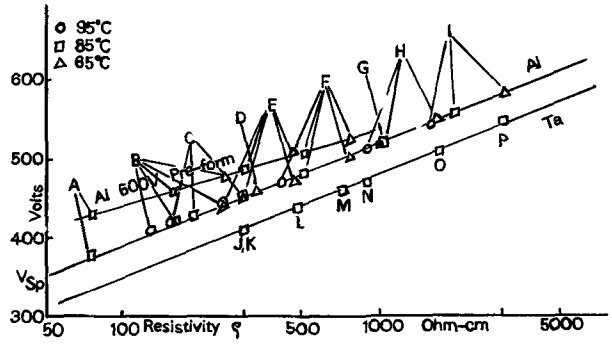

Fig. 3. Sparking voltages (V_{Sp}) *vs.* logarithm of electrolyte resistivities (log ρ): Al foil; Al foil preformed to 600V; Ta foil.

(4) as to the relative order of sparking voltages, namely V_{Sp} of Al > Zr > Ta > Nb, the results were inconclusive because of the scarcity of suitable electrolyte systems for Zr and Nb which permit flawless anodic oxides to be formed over an adequate voltage range.

The interpretation of the empirical semilogarithmic relationship between sparking voltage and electrolyte resistivity which is characterized by an unexpected insensitivity toward temperature changes presents difficulty. Guntherschulze (1) tried to link the phenomenon with the electrochemical potential which is a function of the logarithm of ion concentration, but this explanation is not acceptable today. Young's assumption (2) that the breakdown may not be a bulk phenomenon but may be taking place in electrolyte-filled fissures and flaws of the oxide is probably correct. However, it must be admitted that more work is needed before an adequate theory can be formulated.

ABSTRACT

Mössbauer spectroscopy has been used to study tin(II) sensitizer deposits formed on Kapton films (du Pont polyimide) for use in the recently reported photoselective metal deposition (PSMD) process. Combined with previous results, this work shows that the sensitizer is present as a colloid in the sensitizing bath and is adsorbed on the substrate when it is dipped. This activation mechanism would be expected to apply to other insulating substrates as well. The photosensitive substance contains more tetravalent tin than divalent. The divalent tin is oxidized by exposure either to air or to the Pd activation bath. The photosensitive compound is not any well recognized tin oxychloride or hydroxide.

This paper presents the results of Mössbauer measurements on "tin oxide" sensitizer films as currently prepared and used in the Western Electric Engineering Research Center, Princeton, New Jersey, (ERC) photoselective metal deposition (PSMD) process (1-4). Mössbauer spectroscopy (MS) is a relatively new and powerful technique which can be used to study chemical structure and related properties. The results presented here were obtained using typical PSMD sensitizer deposits formed on Kapton (du Pont polyimide) substrates and supplement other sensitizer film research already in progress at ERC 4,5).

This paper is divided into two parts: The first part briefly discusses the applications of MS to the study of tin compounds and tin chemistry, and also gives, in a highly abbreviated fashion, the techniques and details of the PSMD process. The second section describes the results of the Mössbauer measurements on typical photosensitive layers on Kapton films and discusses the chemical intermediates involved in the sensitization and imaging. In addition, the material deposited on the Kapton film is shown to be similar to that present as a colloid in the solution before dipping.

We make no attempt here to develop a comprehensive discussion and introduction to MS principles and techniques, since a large number of books (6), journal articles, and reviews (7) are already available. However, we show some examples to illustrate the application of MS to already well-characterized tin compounds to give an idea of the possibilities and limitations of the technique. The over-all approach used here, of identifying compounds by distinctive spectral patterns, is a well-established one in many other forms of spectroscopy. For this investigation, the fact that MS is a relatively insensitive technique (in that only the immediate surroundings of the atom being studied affect the observed spectrum) is a definite advantage as it makes it possible to characterize compounds which have only very poorly maintained long-range order. Even highly nonstoichiometric and completely "amorphous" material such as tin atoms frozen into solutions can be studied conveniently.

The data are presented here in the format which has become standard for MS, that is, with "velocity" or

Key words: Mössbauer spectroscopy, electroless plating, sensitization, photochemistry.

Doppler energy shift along a horizontal scale and "counts transmitted" on the vertical scale, so that resonance absorption appears as a dip or a peak pointing downward. The observed lines have two significant parameters, namely their intensities and their positions relative to the zero of velocity. In all of the experiments shown, a source of tetravalent tin (Sn^{119m} in $BaSnO_3$) was used and all experiments were performed with source and absorber at 78°K. Standard MS techniques described in the literature were used. Since a tetravalent tin source was used, the isomer shift between the source and tetravalent tin in the absorber is relatively small, so that lines due to tetravalent tin in the absorber appear near zero velocity. The isomer shift between divalent tin and tetravalent tin is approximately 3-4 mm/sec (8). Thus, lines in the regions near 4 mm/sec can be identified as arising from divalent tin compounds. In both di- and tetravalent compounds, the absorption line can be split into two components of roughly equal intensity by the quadrupole splitting of the nuclear excited state level. This splitting tends to be much more pronounced for divalent tin than for tetravalent tin, because the hybridization of 5s electrons into 5p orbitals in the divalent ion produces a relatively large field gradient at the Sn^{119} nucleus. Variations in the isomer shift are generally attributed to the effects of covalency or of sp hybridization in the bonding of the tin atom.

Figure 1 shows spectra taken by us for a number of stannous compounds which can be considered "well characterized." These compounds are closely related to those used in the PSMD process and their spectra are shown primarily to demonstrate some of the possibilities and limitations of MS as applied to tin chemistry. For all three compounds shown the presence of divalent and tetravalent tin is readily observed and relatively small amounts of tetravalent tin can be seen by this technique (note the trace of tetravalent impurity in the figure). Since the spectrometer repeatability, resolution, and linearity are substantially better than 0.01 mm/sec, it is meaningful to determine line positions to this order of accuracy even though the linewidths are much broader. Figure 1 also shows the expected line positions [taken from a recent publication (9)] for a number of compounds relevant to the PSMD process chemistry. It can be seen that with proper data, the combination of isomer shift and quadrupole splitting provides a reasonably good basis for determining whether two compounds are identical. Thus the unknown may be identified if its spectrum corresponds to that of an already known compound. The compounds for which line positions are shown are all rather similar, being oxychlorides, hydroxides, and hydrated oxides, yet the spectra are obviously distinct.

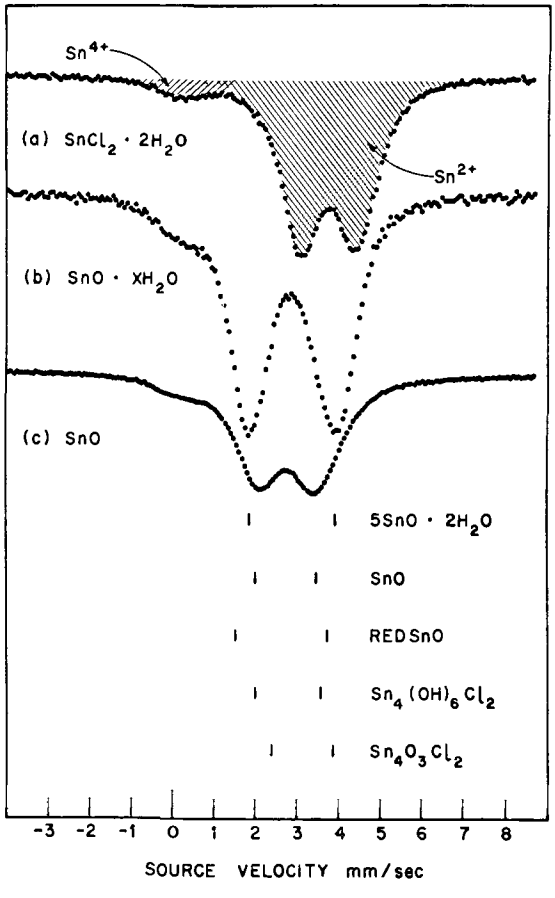

Fig. 1. Observed spectra of three stannous compounds. The $SnCl_2 \cdot 2H_2O$ was Baker, reagent grade; the other two were made in our laboratory by standard preparative techniques. Note the existence of a line due to Sn^{4+} in all samples. Line positions reported in ref. (9) for various well-characterized tin compounds are shown below the spectra.

The chemistry of the electroless metallization used in PSMD is similar to that used throughout the printed circuit industry. When one considers this chemistry in detail, the interest in studying the tin oxides, hydroxides, and hydroxychlorides is obvious. The substrate is dipped into a solution of tin chloride in water and HCl, then rinsed in water and partly dried. The sample is then placed in a dilute solution of palladium chloride in water and HCl, and is subsequently able to catalyze the deposition of copper from a electroless copper plating bath. Thus, it is a quite general technique for metallizing surfaces. The ability to selectively deposit comes from the fact that the sensitizer effectiveness for initiating electroless copper deposition can be destroyed by exposing the sample to ultraviolet light before it is placed in the palladium bath. By the use of appropriate masking it is possible to metallize in selected areas of the substrate and thus to make printed wiring boards and printed cables. Figure 2 shows the process as implemented for the continuous production of printed wiring on flexible substrates. This technique has a number of very obvious advantages for making wiring and cable.

At the initiation of our Mössbauer work, some important aspects of the sensitization process were rather speculative: *e.g.*, the chemical structure of the deposit on the substrate, its changes at various stages in the process chemistry, and the relation, if any, between the deposit and the contents of the sensitizer solution. In addition, it was not known exactly how the uv exposure altered the sensitizer, though it was clear from earlier work (1-5) that the imaging was in fact a light-induced tin oxidation. The use of Mössbauer spectroscopy on this problem offered the possibility of reaching many of these problems, providing a more positive identification of the photosensitive

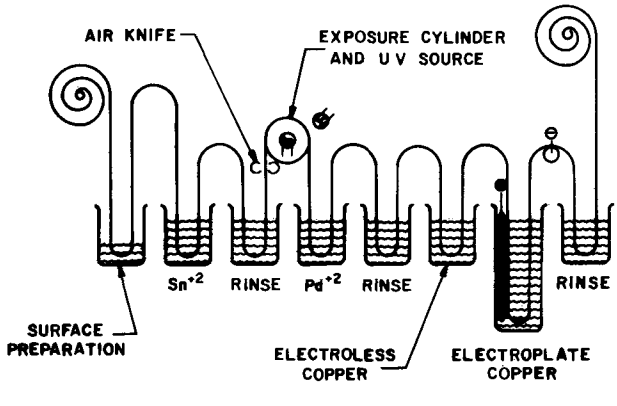

Fig. 2. Outline of the various steps in the PSMD production process [from ref. (4)].

species, and clarifying the results of the earlier ERC experiments.

The tin bath and rinse shown in Fig. 2 deposit on the substrate a thin layer of nominally divalent tin compound. This compound, when immersed in the palladium chloride, reduces palladium ions to their metallic state. The Pd layer on the substrate serves as the catalytic site for deposition of electroless copper. Where the substrate has been exposed to uv light, however, the divalent tin is converted to a tetravalent compound which is unable to reduce the palladium ions. Thus, at sites that have been exposed, no palladium metal is deposited and no copper plating occurs.

In the MS studies reported here, we have examined the sensitizer deposit at various stages in the imaging and metallization process to study the basic chemical processes.

Experimental

Deposits on Kapton.—Specimens were prepared by sensitizing 2 mil Kapton substrates using a solution containing 10g $SnCl_2 \cdot 2H_2O$ and 10 ml conc HCl per liter of deionized water.

Previous work (10) had shown that the amount of tin deposited and remaining on the substrate after the rinse operation was only on the order of a few micrograms per square centimeter. This is about 10,000 times less material than that desirable for an absorber in a tin MS experiment; typically layers containing from 10-50 mg of tin per square centimeter are desirable. This problem was alleviated somewhat by making absorbers from as many as 100 layers of Kapton foil. Each piece of Kapton was "sensitized" on both sides so that there was an increase by 200X in the effective absorber thickness. This increase to the range of 0.1 to 1 mg of tin per square centimeter made it possible to obtain reasonable spectra in about one or two days measuring time. (In contrast, satisfactory spectra of compounds available in bulk, *e.g.*, the spectra in Fig. 1, can be obtained in times from a few minutes to an hour.) Thus, the small amount of tin deposited was not a severe limitation in doing these experiments. The absorbers were prepared by punching ½ in. diameter disks out of the Kapton specimens with a small hand operated punch press and stacking these in a specially prepared absorber well.

To prevent possible sensitizer dehydration under vacuum, specimens were first cooled to ~120°K before pumpdown to 10^{-5} Torr, the pressure at which our MS measurements were made. Those specimens designated as freshly prepared and unexposed were, after sensitization, cooled, pumped down, and measured immediately to avoid air oxidation. The other specimens were stored under nitrogen during the time between their preparation and measurement.

Results

The spectra of the tin-sensitized Kapton foils at various stages of processing are given in Fig. 3 and 4. Figure 3 shows the Kapton foil under normal processing procedures. An inspection of the figure shows immediately that the layer deposited by the sensitization process contains roughly[1] two stannic ions for each stannous ion. We consider this deposit to consist of one substance, probably amorphous, containing both di- and tetravalent tin ions rather than a mixture of a stannous compound with a stannic compound. This is not established here.[2]

A careful examination of the divalent tin line positions shows that the divalent lines do not correspond exactly with line positions expected for any of the oxychloride or hydroxide phases shown in Fig. 1. We have also been able to make two other distinct crystalline phases of oxychloride and hydroxide materials

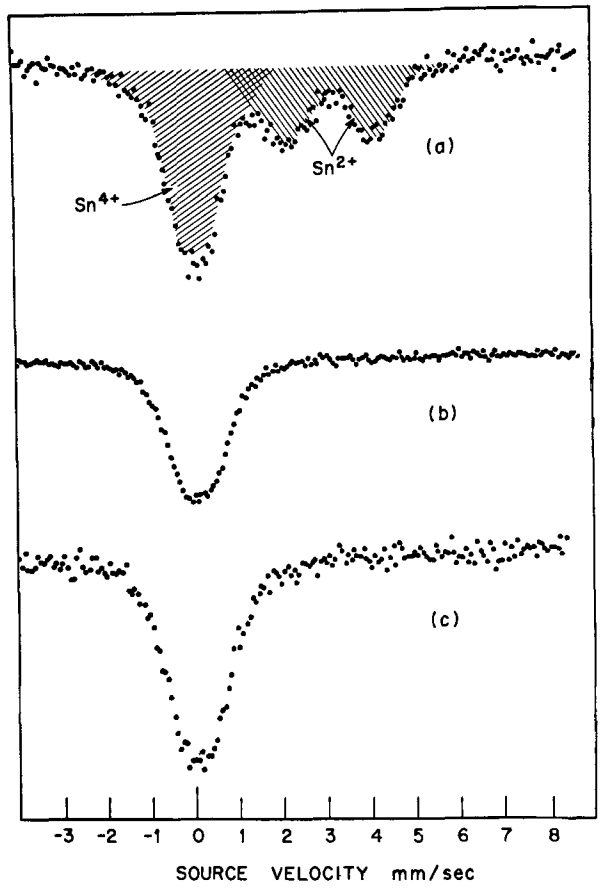

Fig. 3. Spectra of the tin layers on Kapton foil: (a), sensitized by tin bath and unexposed; (b), sensitized by tin bath and uv exposed; (c), sensitized by tin bath and then dipped in Pd solution. The relative amounts of di- and tetravalent tin can be estimated (see footnote 1) from the relative areas in the corresponding spectral lines.

of divalent tin by precipitation from HCl baths under slightly different conditions of *p*H. In no case did the positions of the divalent tin lines in these well-defined compounds correspond to the positions of the divalent tin lines observed in the material deposited on the Kapton. This lends support to the idea that the material deposited on the Kapton is not simply a microscopic mixture of already identified divalent and tetravalent tin compounds. The identification of the sensitizing material is discussed further in the next section and in ref. (11).

The second fact that is immediately clear from the spectra in Fig. 3 is that exposure to uv light oxidizes essentially all of the divalent tin to tetravalent tin. We can estimate roughly (from the lack of noticeable absorption in the region from 2-4 mm/sec) that no more than 10% of the divalent tin remains after uv exposure.

A third result which is evident from inspection of the spectra is that when the sensitized tin layer is placed in the palladium bath, once again essentially all the divalent tin is eliminated. Measurements[3] of tin and palladium on Kapton prepared and processed as we describe here show that (*a*) the amount of tin on the substrate is the same (~10 $\mu g/cm^2$) before and after the palladium treatment, and (*b*) the atomic ratio of tin to palladium on the substrate after the palladium step (plus a water rinse) is approximately 3.8:1. Within the accuracy of the Mössbauer measurements, this shows that the amount of palladium picked up corresponds to the amount of tin oxidized. This supports the picture of a redox reaction $Sn^{2+} + Pd^{2+} \rightarrow$

[1] We assume throughout that the "f value" (recoil-free fraction, related to the strength of the Mössbauer effect) is the same for both the di- and tetravalent tin ions. It is difficult to determine this ratio, and not very significant for the interpretation of the data, which is dependent primarily on the relative proportion of divalent tin under various conditions, rather than the absolute 2+/4+ ratio.

[2] A more extended discussion of the colloid and solution chemistry is given in ref. (11).

[3] Unpublished x-ray fluorescence measurements for palladium and tin on Kapton were made by D. A. Green, J. F. D'Amico, and M. A. De Angelo. Standardization was done by atomic absorption spectroscopy.

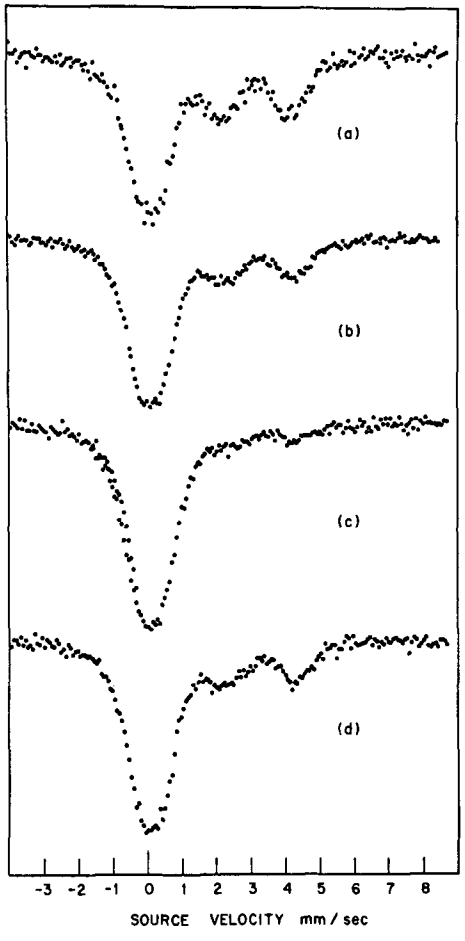

Fig. 4. Spectra of tin layers on Kapton after processing delays: (a), freshly sensitized layer; (b), after exposure to room light (1.5 hr each side, then kept in air for one week); (c), as in (b), but exposed to uv light just before the measurement; (d), as in (b), but after dipping in Pd solution.

Sn^{4+} + Pd, and excludes the possibility[4] that the Pd is picked up by adsorption.

Figure 3 shows the characteristics of the deposited layer at three critical points in the process: the sensitized layer, the exposed sensitized layer, and the layer treated with palladium solution. These samples were made under essentially ideal conditions of processing: fresh bath, careful handling, and negligible time between sensitization and the ultraviolet and palladium treatments.

Figure 4, in contrast, shows the effect on the photosensitive tin layer of such factors as a delay in processing, exposure to room light, or air oxidation. Such factors are known to alter the sensitizer's effectiveness for metallization. At the top of Fig. 4, the spectrum of the freshly sensitized Kapton foil is shown for reference. The second spectrum in Fig. 4 shows a substantial but far from complete oxidation of the divalent tin as a result of 1½ hr exposure to room light on each side plus an additional one week period kept in the dark but in ordinary laboratory air. It can be seen that this exposure substantially decreases, but does not completely remove, the divalent tin present in the sensitized layer. The result of exposure to uv light after this air aging is shown in the third spectrum in Fig. 4. It can be seen that the exposure to uv light after this air aging further decreases, but does not completely eliminate the remaining divalent tin.[5] Figure 4d shows that the spectrum of material dipped in the palladium solution after being exposed to air for one week does not change noticeably suggesting that little or no palladium is deposited. This observation is in accord with the known reduction in the palladium deposit as the photosensitive layer ages in air.[3] A reasonable explanation for this might be that the oxidation forms an impermeable skin of some oxide or hydroxide on the surface of the sensitizer and prevents access of the palladium ions to the remaining divalent tin.

Comparison of sensitizer vs. colloid spectra.—While the line positions for the sensitizer deposit do not match those of the identified compounds, they do closely match those obtained from MS measurements on colloid particles centrifuged from the sensitizer solutions. This result suggests that the deposit on the Kapton is in fact produced by adhesion of the colloid to the substrate at the time of immersion.

The presence of the colloid in sensitizer solutions has already been noted (5), and accordingly, the model used to describe sensitization included a colloid contribution to the total deposit. [The other contribution has been attributed (1-4) to the water rinse and hydrolysis of the soluble in species.] However, it was not possible to determine in the earlier results whether or not the substrate deposit was identical to, similar to, or perhaps quite different from the colloid species in the solution. In Fig. 5(a) we have replotted our results for a fresh tin deposit on Kapton and in Fig. 5(b) we present the Mössbauer results for colloid particles which were centrifuged from a fresh (*i.e.*, 2 hr old) standard tin solution. This separation was made using a field of 110,000G for 2 hr. (If the density of the colloid particles is 2 g/cc, particles > 60Å diameter are separated by this treatment.) Sard (13) has observed by electron microscopy the presence of particles of roughly this size range for deposits on evaporated carbon films from similar solutions. In Fig. 5(c) we show the spectrum obtained from measurements on the products of precipitation filtered from the solution after very long times (~600 hr). The line positions in both Fig. 5(b) and (c) are identical to those found for

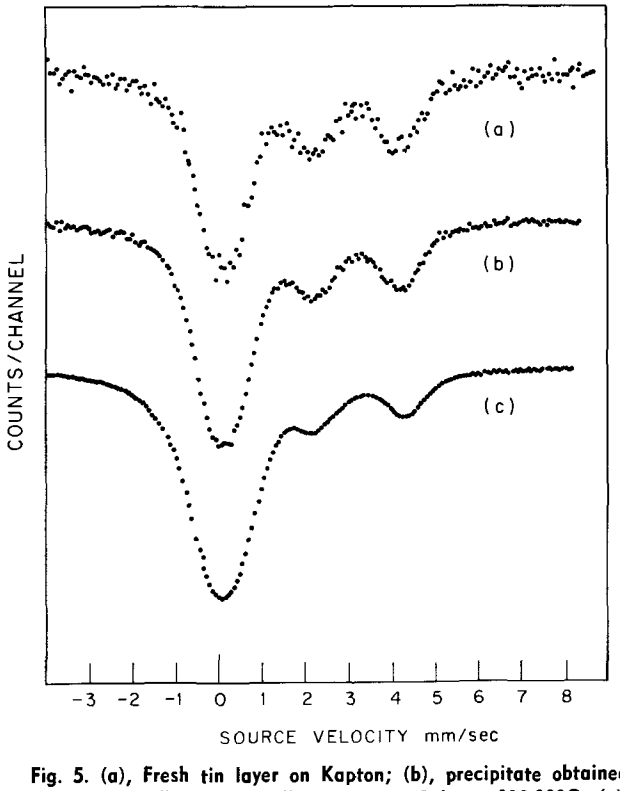

Fig. 5. (a), Fresh tin layer on Kapton; (b), precipitate obtained by centrifuging "standard tin" solution for 2 hr at 110,000G; (c), precipitate produced by aging solution 600 hr in contact with air.

[4] This alternative has been proposed, for example, by Goldie (12).
[5] This conclusion applies when light exposures sufficient to react freshly sensitized specimens are used. In aged specimens large overexposures are required for complete reaction.

the fresh Kapton deposits in (a), although the stannous component in (c), as expected, is greatly reduced.

The data of Fig. 5 suggest that the substrate deposit is in fact chemically identical to the colloid species in the solution at the time of substrate immersion. As the solution ages, the stannous component in solution diminishes.

If the solubility products[6] for the stannous and stannic hydroxides are used to estimate the respective equilibrium tin concentrations in solution, one finds that at $pH = 1$ the stannous solubility is at least 5M, while that of the stannic compound is only 10^{-4}M. Thus it would be reasonable to expect that the colloid is predominantly due to the stannic species, with the stannous ions incorporated by coprecipitation or adsorption onto the colloid (11). This analysis is compatible with the results reported here and in ref. (5).

Summary

Sensitizer deposits formed on Kapton from fresh tin chloride solutions contain roughly twice as much tetravalent tin as divalent. The Mössbauer spectrum of the deposited layer was distinctively different from that of any reported oxide, hydroxide, or oxychloride, and could not have arisen from a simple mixture of such compounds.

Specimens freshly sensitized with fresh solutions when exposed to uv light, or immersed in an acid palladium chloride solution, showed essentially quantitative conversion of the divalent tin component to the tetravalent form. On the other hand, similar specimens aged in laboratory light and air showed only a partial oxidation of divalent tin under these treatments. A possible explanation is that an impermeable barrier layer, which can inhibit the photo-oxidation or the deposition of palladium ions, is formed on standing.

The sensitizer deposit appears identical to the colloid species present in solution at the time of substrate immersion. Thus the adhesion of the colloid to the substrate appears to be a significant source of sensitization. This conclusion agrees with models previously proposed (2-5). In addition, any deposit due to water rinse and hydrolysis of the tin in the liquid layer appears to have the same chemical form. The sensitization mechanism described here would be expected to work for other insulating substrates as well, although no direct verification of this has been done.

[6] These estimates represent lower limits because they neglect the chloride complexing. Solubility products used were taken from Latimer and Hildebrand (14).

Acknowledgments

The authors gratefully acknowledge the technical assistance of M. A. DeAngelo for preparation and sensitization of the specimens. We also thank R. Sard for helpful discussions of the problem and M. W. Sagal for general encouragement. The colloid work was greatly aided by the use of the Biophysics Research Department's ultracentrifuge.

Manuscript submitted June 8, 1971; revised manuscript received Aug. 9, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

Calculations of Profitability in Electrolysis Installations

Alfred Schmidt[1]

Chemische Werke Hüls AG, Marl, Kreis Recklinghausen, Germany

ABSTRACT

Simple mathematical relationships, which can be used for all kinds of electrolysis installations, were derived by the methods of investment calculations. It is possible to calculate rapidly with these relations by means of a few characteristic numbers, the most economical current load of electrolysis cells, bus-bars, and electrodes, and to investigate the influence of the various cost factors on the optimum load, such as price of electric current, cell potential, cost of installation, lifetime, rate of interest on capital, and taxes on profits. The determination of the characteristic numbers and the use of the formulas are explained by means of examples of electrolytic chlorine production in mercury cells.

Optimum Load of Electrolysis Cells

In planning nonelectrochemical installations as a rule we use the smallest possible number of reactors of the largest possible size to keep the installation costs low. In order not to have too great a loss of production when a reactor breaks down, the economic and operating optimum ought to be at about 2-4 reactors. These considerations do not prove to be correct in the construction of electrolysis installations, because a minimum number of production units which is far larger than the numbers mentioned above is needed for tech-

[1] After retirement active as consulting engineer. Present address: 6241 Eppenhain/Ts, Im Birkenfeld 12, West Germany.

Key words: economics, optimization, mercury cell.

nical reasons (*e.g.* current rectification, limitation on the construction of larger electrolysis cells).

The modern development of the silicon and germanium rectifiers today permit an economic rectification of current, even at potentials down to 100V. Even at these potentials a minimum number of 10-25 cells is still necessary in electrolytic processes which normally operate with cell potentials in the range of about 4-10V.

In electrolytic processes the level of production of an electrolysis cell depends only upon the magnitude of the current, according to Faraday's law. Therefore, it must be decided in planning whether it is more economical to produce the desired capacity with a smaller number of cells at higher circuit currents or with a larger number at lower circuit currents. In the first case the installation costs of the cells are indeed smaller, but the costs of specific current consumption is higher. On the other hand in the second case we attain lower specific current consumption with higher installation costs. Thus for a given level of production two alternatives are possible:

Alternative 1. Equal current densities and thus equal potentials and equal specific energy consumption with the supposition of equal current efficiency. The installation is equipped with a few larger cells at a higher circuit current or with a larger number of smaller cells at lower circuit current. In Alternative 1, (see Fig. 1), the installation comprises a fewer number of larger cells, as compared to the base case with equal current density. The investment costs of the cells will be less, but the costs of the rectifier unit will be higher.

The most economical combination will be found by minimizing total costs of cells and rectifier installations. Above a certain minimum plant capacity, this generally leads to a choice of the fewest possible cells of the largest possible type.

Alternative 2. Different current densities and thus different cell potentials and different specific energy consumption at the same current efficiency. We use a smaller number of cells at higher current density or a larger number at lower current density. In Alternative 2 (see Fig. 1), the installation comprises a fewer number of cells of the same size, operating at a higher current density as compared to the base case. In this alternative, total installation cost is indeed lower, but the continuous operating costs increase considerably at higher current densities.

The object of this paper is to find, for a desired capacity, the optimum circuit current for a certain cell type and with it the number of cells required. The object is not to derive the optimal physical size of the cell type, which is dependent upon the desired production capacity and the limit of economic current rectification.

Chemical process reactors can be brought to higher capacity within the permissible limits with a relatively small additional consumption of energy (higher gas or liquid pressure, larger heat-exchanger surfaces, etc.). These installations as a rule operate more economically, the higher they are loaded, *i.e.* the more we produce with the installed capital. On the other hand, the higher load on electrolytic cells requires a higher cell potential in electrolysis processes and thus a quite important increase in the specific current costs, so that the question concerning the economical optimum of circuit current is here very much more difficult to determine.

In planning electrolysis installations the tendency today is to maximize the current density in order to produce as much as possible with minimum investment costs. In these attempts, the economic point of view should not be disregarded. The designer is faced with the question where the optimum current load for the cells lies. Whether, for example, it is more economical to attain the desired production capacity with a smaller number of cells at higher current density, or with a larger number of cells at lower current density. In addition to this, the load for the bus-bars, switches and for the electrodes must be optimized.

As a rule the profitability of an investment is judged by the level of interest on the invested capital or by the period of time in which the investment is returned. In the present problem we are dealing with only a relative comparison of alternatives for the same manufactured products at the same level of production and thus also with same proceeds for the products so that the proceeds could be disregarded here. In the same way, all of the costs that do not change for the various alternatives can remain outside of consideration. These are all of the costs, which arise from the manufacturing before and after electrolysis, and the costs within the electrolysis stage which are independent of the number of cells.

Several authors have already concerned themselves with the problem of the optimum design of electrolysis installations (1-7). In the following, simple mathematical relationships are developed. They shall help the designer to picture the optimal conditions of an electrolysis installation rapidly to himself by means of a few characteristic numbers (number and load of the cells, cross section of the bus-bars and the electrodes, etc.). These methods, like all investment calculations, could only be evaluated as approximations, since it is impossible to predict price and technical developments for years ahead. However, the results give a valuable reference point for deciding how the installation should be designed under the conditions which exist at the time of planning.

In the present method the optimal circuit current is determined, where for a given period of the investment return, and for a fixed rate of interest, the sum of investments including interests corresponds to the return of the yearly savings including interests (cash flow). The use of these methods remains limited to the planning of a uniform installation. Thus, for example, the question of whether it is more economical to load an existing installation higher or to establish a second new installation for a desired increased production, can be settled only from case to case on the basis of the existing situation. It is also not possible to consider with this method the intention to increase the capacity at a later date because the resulting factors are unknown and can therefore not be taken into consideration in the mathematical derivations. In this case the owner of the plant has to decide to what extent he will probably increase the capacity. If the probability is high, he has to decide if he will calculate the optimum for the intended end-capacity. If the probability is not high, he could decide to calculate the optimum for the first capacity or for a certain higher per cent of the possible end-capacity.

Example:	Fixed planned capacity	100,000 tons/year
	Possible demand in future	200,000 tons/year
	Calculations for the optimum load could be made for:	
		100,000 tons/year
		150,000 tons/year
		200,000 tons/year

The final decision is only in the hands of the owner and is his own risk. It depends upon the probability, the time, and to what extent the increase of the capacity will occur.

In order to design an installation for the desired capacity, we must first establish the size of cell (electrode surface). In this example a size of cell is chosen [see Fig. 1, Alternative 1] which permits operation in the lower potential region where the current rectification is still economical at the desired production capacity, *i.e.* the fewest possible number of cells of the largest possible size and used. The optimum current density is then calculated for this type of cell. The result of this calculation determines the number of

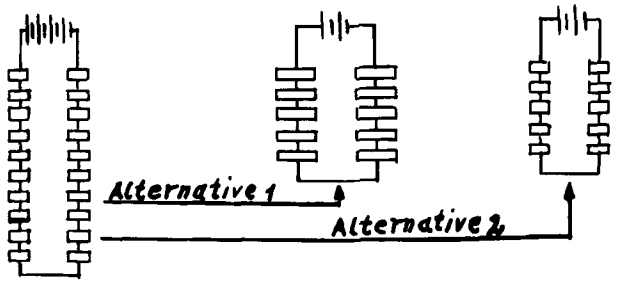

Fig. 1. Distribution of production by number of cells and current load.

Number: 2N cells	N cells	N cells
Load: I_T amperes	2 I_T amperes	2 I_T amperes
Electrode surface: S m²/cell	2 S m²/cell	S m²/cell

cells for the desired production capacity. In the following derivation a few simplifying assumptions have been made which however, do not significantly influence the result:

(a) Cell resistance does not change with the load (presuppositions: the same electrolyte temperature, the same electrolyte concentration, the same electrode distance, the same resistance of the current conductors, etc.).

(b) The current efficiency remains unchanged.

(c) Within the range of loading the current density and cell potential are linearly related.

(d) The life time of the cells shall be independent of the current density.

Not only the specific current costs change at a given level of production with the number of cells, but also the repair and operation costs. It should further be considered that the savings in current costs attained by higher investment costs are additional profits for the manufacturer and as such are subjected to taxation. Finally the investment costs of the rectifier plant are higher at the same electrical capacity if the available current intensity shall be higher.

For these various alternatives corresponding derivations are developed in stages as follows: (a) Only savings in electric current are considered. (b) Savings in electric current, repair and operation costs are considered. (c) Savings in electric current, repair and operation costs, and taxes on profits are considered. (d) The influence of the rectifier costs upon the optimum current load is examined.

Derivation of the optimum load under consideration of savings in current.—The equation for the current costs of an electrolysis installation (C_I) at a current load, I_T, polarization potential, V_p, the average specific resistance of the cells including the supply lines from the rectifier, R_r, time, t, current price, P_I, and the number of cells, N, is

$$C_I = (V_p + I_T \cdot R_r) \cdot I_T \cdot t \cdot P_I \cdot N \cdot 10^{-5} \quad [1]$$

At a constant-level of production the cell amps are constant

$$I_T \cdot N = \text{constant} = K, \quad \text{or } N = K/I_T \quad [2]$$

accordingly

$$C_I = (V_p + I_T \cdot R_r) \cdot t \cdot K \cdot P_I \cdot 10^{-5} \quad [3]$$

If the fixed amount of current cost is

$$F_I = V_p \cdot t \cdot K \cdot P_I \cdot 10^{-5} \quad [4]$$

and the factor of the varying part of cost is

$$b_I = R_r \cdot t \cdot K \cdot P_I \cdot 10^{-5} \quad [5]$$

then

$$C_I = F_I + b_I \cdot I_T \quad [6]$$

In this equation the fixed current cost F_I, is given by the polarization potential, V_p. b_I is defined by the slope of this line (increasing current costs with increasing current load). In case of investment costs, y_I, per cell the total investment costs of an electrolysis are

$$Y_i = y_T \cdot N \quad [7]$$

According to Eq. [2], it follows

$$Y_i = \frac{y_T \cdot K}{I_T} \quad [8]$$

If the electrochemical equivalent of the electrolysis product in g/A-hr is called e and the current efficiency, U, the constant, K, for a production of M_T tons/year product is calculated as follows

$$M_T = I_T \cdot t \cdot e \cdot \frac{U}{100} \cdot N \cdot 10^{-6} \quad [9]$$

From Eq. [2]

$$N = K/I_T \quad [10]$$

and

$$K = \frac{M_T \cdot 10^{-8}}{t \cdot e \cdot U} \quad [11]$$

follows.

To determine the optimum load, we calculate on one side the sum of the incremental change in current costs, when changing the circuit current; and on the other side the sum of the incremental change in investment costs, when changing the number of cells. All these costs include interest in full measure for a time of n years. We can calculate the optimum load, if these two sums have attained the same amount, as follows.

Between two current loads I_T and $I_T + \Delta I_T$:

1. the change in the current costs C_I, upon changing the current load I_T by ΔI_T is

$$\frac{\Delta C_I}{\Delta I_T} = \frac{F_I + b_I(I_T + \Delta I_T) - (F_I + b_I \cdot I_T)}{\Delta I_T} = b_I \quad [12]$$

and

2. the change in the expenditure for investment Y_i, with change of the current load I_T by ΔI_T is

$$\frac{\Delta Y_i}{\Delta I_T} = \frac{1}{\Delta I_T}\left(\frac{y_T \cdot K}{I_T} - \frac{y_T \cdot K}{I_T + \Delta I_T}\right) = \frac{y_T \cdot K}{I_T \cdot (I_T + \Delta I_T)} \quad [13]$$

The ratio in the change of the current costs to the change in the investment costs is then

$$\frac{\Delta C_I}{\Delta Y_i} = \frac{b_I}{y_T \cdot K} \cdot I_T(I_T + \Delta I_T) \quad [14]$$

The increased investment (Eq. [13]) is to be paid before the installation[2] is set into operation and interest is paid in full measure for this time. After $n + 1$ yr its sum is

$$\sum_0^n \frac{\Delta Y_i}{\Delta I_T} = \frac{\Delta Y_i}{\Delta I_T} \cdot Z^{(n+1)} \quad [15]$$

The savings in current (Eq. [12]) occurs annually[3] and it is likewise charged with interest correspondingly. After n years it amounts to

$$\sum_1^n \frac{\Delta C_I}{\Delta I_T} = \frac{\Delta C_I}{\Delta I_T} \cdot \frac{Z^n - 1}{Z - 1} \quad [16]$$

The capital is returned when the two sums have attained the same amount

$$\frac{\Delta C_I}{\Delta I_T} \cdot \frac{Z^n - 1}{Z - 1} = \frac{\Delta Y_i}{\Delta I_T} \cdot Z^{(n+1)}$$

The result is

[2] Since the investments are made before the savings occur, interest is paid on them for a full year previously in the following calculations. This corresponds to a construction time of about 2 yr.

[3] It is required that the level of savings remains constant. According to this, changes in costs are not taken into consideration.

Table I. W-Values for various interest factors, Z and years, n

n	Z = 1.050	Z = 1.060	Z = 1.070	Z = 1.075	Z = 1.080	Z = 1.090	Z = 1.100
5	0.243	0.252	0.261	0.266	0.270	0.280	0.290
10	0.136	0.144	0.152	0.157	0.161	0.170	0.179
15	0.101	0.109	0.117	0.122	0.126	0.135	0.145
20	0.084	0.092	0.101	0.105	0.110	0.119	0.129
25	0.075	0.083	0.092	0.096	0.101	0.111	0.121
30	0.068	0.077	0.086	0.091	0.096	0.106	0.117

$$\frac{\Delta C_I}{\Delta Y_i} = \frac{Z^{(n+1)}\,(Z-1)}{Z^n - 1} = W \qquad [17]$$

Equation [17] cannot be simplified any further mathematically, and we must therefore take the values for $W = C_I/Y_i$ for various values from n and Z from tables or curves. Values of W for various rates of interest are gives in Table I.

By combination of Eq. [14] and [17] we obtain

$$\frac{b_I}{y_T \cdot K} \cdot I_T(I_T + \Delta I_T) = W \qquad [18]$$

For a small value of I_T we obtain for the product $I_T \cdot (I_T + \Delta I_T) = I_T^2$ and with it the following relationship for the current intensity I_T

$$I_T = \sqrt{\frac{W \cdot y_T \cdot K}{b_I}} \qquad [19]$$

In this derivation the factor b_I, as the slope of the current cost line, takes into consideration only the savings in current costs with increasing investment, or the increased costs of current with decreasing investment. The personnel and repair costs, c_T, have not previously been taken into account. They change with the investment (number of cells). The influence of taxes on profit shall also be considered in the next sections.

Derivation of the optimum current intensity under consideration of savings in current, repair and operation costs.—The savings in current obtained with a larger number of cells are decreased by higher personnel and repair costs. The changes in these costs with the circuit current depend upon the number of cells, N, and are given by a hyperbolic function, like the investments.

Corresponding to Eq. [8] is

$$C_T = \frac{c_T \cdot K}{I_T} \qquad [20]$$

and according to Eq. [13] for the change of C_T with I_T

$$\frac{\Delta C_T}{\Delta I_T} = \frac{c_T \cdot K}{I_T(I_T + \Delta I_T)}$$

In Fig. 2 the installation costs, Y_i, the current costs, C_I, the personnel and repair costs, C_T, as well as the current costs minus the personnel and repair costs $(C_I - C_T)$ are plotted against the current intensity for the calculation example given later. The shape of the curves show that the factor b_T for the current costs modified by the personnel and repair costs is no longer constant like b_I but depends upon the current load, I_T

$$b_T = b_I - \frac{c_T \cdot K}{I_T(I_T + \Delta I_T)} \qquad [21]$$

Only at higher current intensities ($I_T > 150{,}000$A) the function, C_T, (curve ▲) again approaches a straight line, so that b_T is again approximately constant.

If we insert the equation for b_T in place of b_I in Eq. [19] we obtain

$$I_T = \sqrt{\frac{K(W \cdot y_T + c_T)}{b_I}} \qquad [22]$$

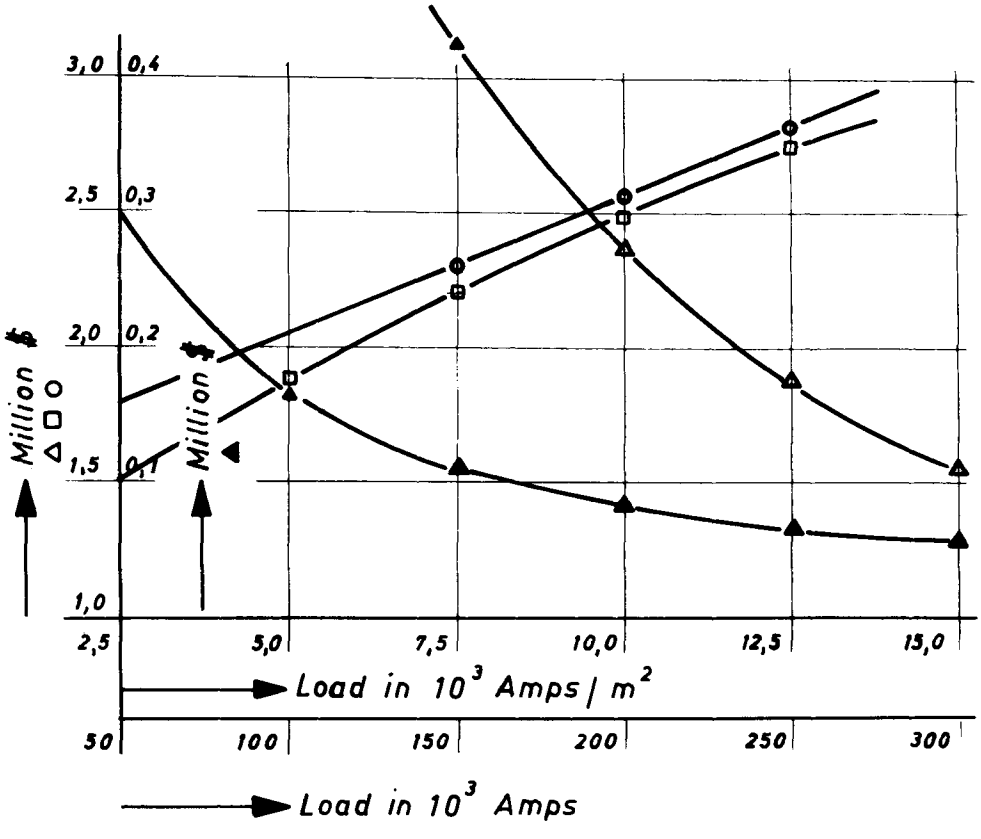

Fig. 2. The costs as function of current load. Curve ○, current costs $C_I = F_I + b_I \cdot I_T$; curve □, current costs minus personnel and repair costs $C_I - C_T$; curve △, investment costs Y_i (including mercury); curve ▲, personnel and repair costs C_T.

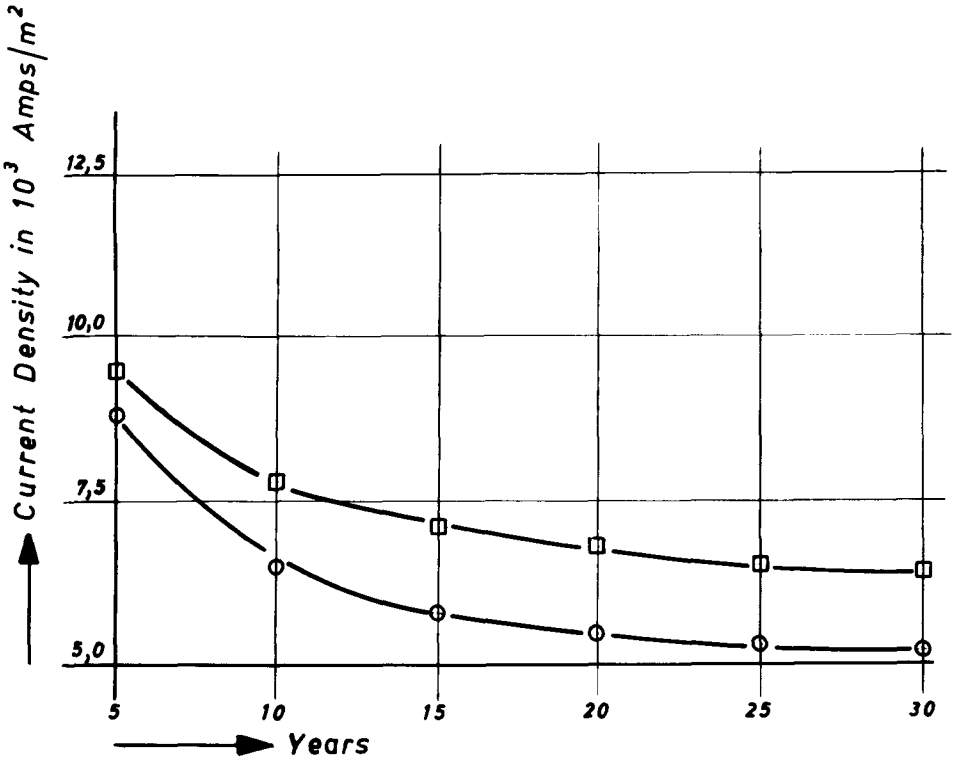

Fig. 3. Change in the optimum current load I_T with the operating time n Curve □ I_T calculated by Eq. [22] for a 20 m² cell. Curve ○ I_T calculated by Eq. [26] for a 20 m² cell.

From this simple relation we can calculate the optimum current load with a few characteristic numbers. As a rule in this type of calculation all of the dimensions (K,y_T,b_I,Z,c_T)[4] will be fixed so that only I_T and n remain as variables. The times in which the invested capital is returned may be fixed by the choice of n. The current density is plotted against the operation time in Fig. 3, for the calculated values of examples on page 2051. The smaller n is chosen the higher is the current load, I_T (fewer cells with a smaller installation cost).

Derivation of the optimum current density under consideration of savings in current, repair, and operation costs and taxes on profit.—In the derivation of Eq. [19] and [22], it has not been taken into consideration that the savings of current costs obtained with higher investment costs must in general be taxed by the company as additional profit. In this way the effective savings in current costs are reduced by the amount of taxes on profit. The slope b_p of the resulting cost curve is calculated from b_I with depreciation λ_i and a tax rate of P per cent[5]

$$b_p = \frac{(b_T - \lambda_i)(100 - P)}{100} + \lambda_i = b_T \cdot \frac{100 - P}{100} + \lambda_i \frac{P}{100} \quad [23]$$

According to Eq. [13] the depreciation λ_i of the incremental investment for a depreciation rate of i % is[6]

$$\frac{\Delta\lambda_i}{\Delta I_T} = \frac{y_T \cdot K \cdot i}{I_T(I_T + \Delta I_T) \cdot 10^2}$$

$$\lambda_i = \frac{y_T \cdot K \cdot i}{I_T^2 \cdot 10^2} \quad [24]$$

[4] Z and n are contained in W (see Eq. [17]).

[5] According to the "cash flow" method of calculation, only the amount of b_T decreased by the depreciation λ_i is taxed, so that the amount remaining after the subtraction of the taxes must again be increased by the depreciation λ_i.

[6] Here a linear depreciation is used to simplify the calculation.

If we introduce into Eq. [23] the term for

$$b_T = b_I - \frac{c_T \cdot K}{I_T^2} \quad [21] \text{ and for } \lambda_i = \frac{y_T \cdot K \cdot i}{I_T^2 \cdot 10^2} \quad [24]$$

we obtain

$$b_p = \frac{1}{100 \cdot I_T^2}(I_T^2 \cdot b_I(100 - P) - c_T \cdot K(100 - P) + y_T \cdot K \cdot P \cdot i \cdot 10^{-2})$$

According to the relation corresponding with Eq. [19], we obtain

$$b_p = \frac{W \cdot y_T \cdot K}{I_T^2}$$

From these two equations results for

$$I_T = \sqrt{\frac{K}{b_I(100 - P)}(100 \cdot W \cdot y_T + (100 - P)\, c_T - P \cdot y_T \cdot i \cdot 10^{-2})} \quad [25]$$

At a tax rate of $P = 50\%$ the equation simplifies to

$$I_T = \sqrt{\frac{2K}{b_I}[(W \cdot y_T + 0.5\,(c_T - y_T \cdot i \cdot 10^{-2})]} \quad [26]$$

In Eq. [25] and [26] the term, $y_T \cdot W$, stands for the interest on the whole investment capital, the term, $y_T \cdot i$, for the depreciation of the investment capital. If parts of the investment shall not be depreciated as for example mercury in a mercury cell chlorine plant, then y_T in the term, $y_T \cdot i$, must be decreased by this part of the investment.

Influence of the installation costs of the rectifier plant.—The costs of a rectifier installation are higher, the higher the circuit current. Figure 4 shows, for a rectifier installation of 50 MW, how much these costs depend on the circuit current, I_T. The plotted relation is a straight line, from which the equation for the installation costs, Y_E, may be deducted as

$$Y_E = F_E + b_E \cdot I_T \quad [27]$$

The optimum current load with consideration of the rectifier costs and the savings in current corresponding to Eq. [19] is then

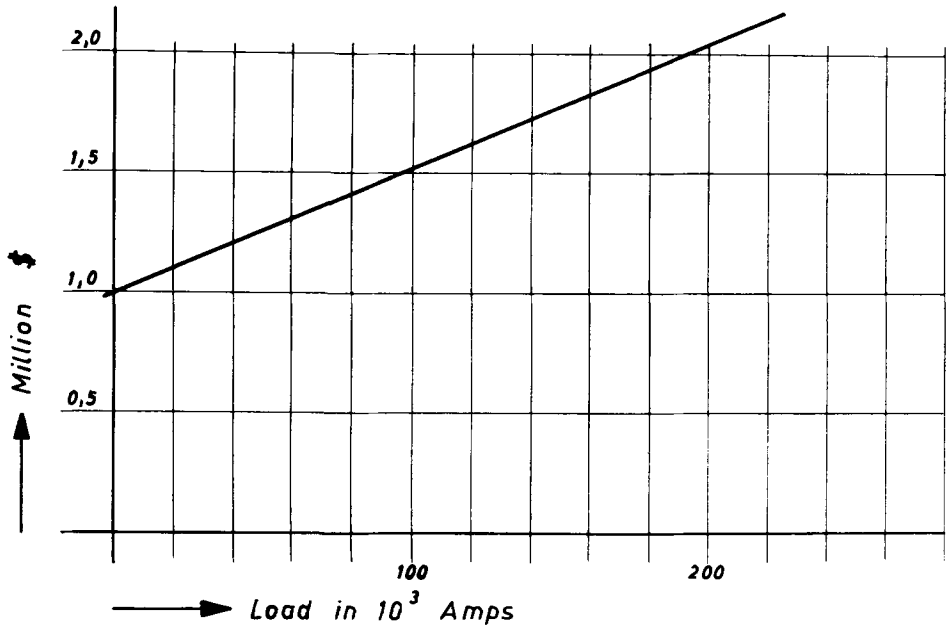

Fig. 4. Rectifier installation costs as function of current intensity for an installation of 50 MW.

$$I_T = \sqrt{\frac{W \cdot y_T \cdot K}{b_I + W \cdot b_E}} \qquad [28]$$

in which case $W \cdot b_E$ is the part of the variable installation costs for the rectifier per year. Figure 4 indicates a value of 5.37 for b_E.

Use in practice and calculation examples.—Using these relations in practice one proceeds as follows: (*a*) Look at the largest cell type, which can be used for the intended capacity, for the largest type will normally be the cheapest, related to its capacity. Thereby consider the lowest direct current voltage of the rectifier plant. (*b*) Determine all items, needed for Eq. [25] and [26] (compare the following examples) and calculate I_T. (*c*) I_T gives the production capacity of one cell, so that one can calculate the number of cells required for the desired production. (*d*) If the calculated optimum current intensity should be too low or too high for the chosen cell equipment (cell bottom, bus-bars, etc.) one may change y_T (cell type, equipment, etc.) and repeat the calculation.

The practical use shall be shown on the example of a chlorine electrolysis with amalgam-cells. The optimum current on circuit of an installation with a capacity of 60,000 tons chlorine/yr shall be determined.

The pretesting of this project shall have shown that the lowest limit of the rectifier voltage is 150V. At this potential an installation of 30-60 cells is needed to reach the desired production at current intensities of 90,000-150,000A. The suitable cell type for the current range is the 20 m² cell. Its average electrical resistance under operating conditions including all bus-bar losses beginning from the rectifiers shall be 11.0 x 10^{-6} ohm for each cell.

Moreover, the following numbers are used for the calculation:

t	= 1 year	8750 hours
U	= current efficiency	= 95%
R_r	= ohmic resistance of the cell	= $11.0 \cdot 10^{-6}$ ohm
c_T	= operation and repair costs per cell	= $3 \cdot 10^3$ \$/year
P_I	= electrical power price	= 1 \$/100 kWh
K		= $5.45 \cdot 10^6$ (Eq. [11])
b_I		= 5.28 \$ (Eq. [5])
Z_i	= rate of interest	= 7.5%
Z	= factor of interest $= \frac{100 + Z_i}{100}$	= 1.075
P	= tax on profits	= 50%
i	= depreciation/year	= 5%
n	= years after the startup of the plant	= 20
W	= for Z = 1.075 and n = 20	= 0.105

Example to 1: According to Eq. [19], we obtain

$$I_T = \sqrt{\frac{W \cdot y_T \cdot K}{b_I}} = \sqrt{\frac{0.105 \cdot 0.085 \cdot 10^6 \cdot 5.45 \cdot 10^6}{5.28}}$$

$$= I_T = \sqrt{92 \cdot 10^8} = 96.000\text{A}$$

Example to 2: According to Eq. [22], we obtain

$$I_T = \sqrt{\frac{K(W \cdot y_T + B)}{b_I}}$$

$$= \sqrt{\frac{5.45 \cdot 10^6 (0.085 \cdot 10^6 \cdot W + 3 \cdot 10^3)}{5.28}}$$

$$= \sqrt{1.23 \cdot 10^{10}} = 111.000\text{A}$$

Example to 3: According to Eq. [26], we obtain

$$I_T = \sqrt{\frac{2K}{b_I}[(W \cdot y_T + 0.5\ (c_T - y_c \cdot i \cdot 10^{-2})]}$$

$$= \sqrt{\frac{10.9 \cdot 10^6}{5.28}(W \cdot 0.085 \cdot 10^6 + 0.5\ (3 \cdot 10^3 - 0.065 \cdot 10^6 \cdot i \cdot 10^{-2})} = \sqrt{1.795 \cdot 10^{10}} = 135.000\text{A}$$

y_c	= costs per cell	= $0.065 \cdot 10^6$ \$[7]
y_m	= mercury costs per cell	= $0.020 \cdot 10^6$ \$
y_T	= total costs per cell	= $0.085 \cdot 10^6$ \$

[7] These costs proportionately cover all costs depending directly on the number of cells such as bus-bars, pipe lines, building of the cell room, etc.

In Table II the optimum current load I_T of the 20 m²-cell has been calculated for some other values of n, accordingly for i and W too.

These optimum current loads are the basis of the calculation for the three examples of Table II for a chlorine production of 60,000 tons/yr covering the values assembled in Table III for the number of the

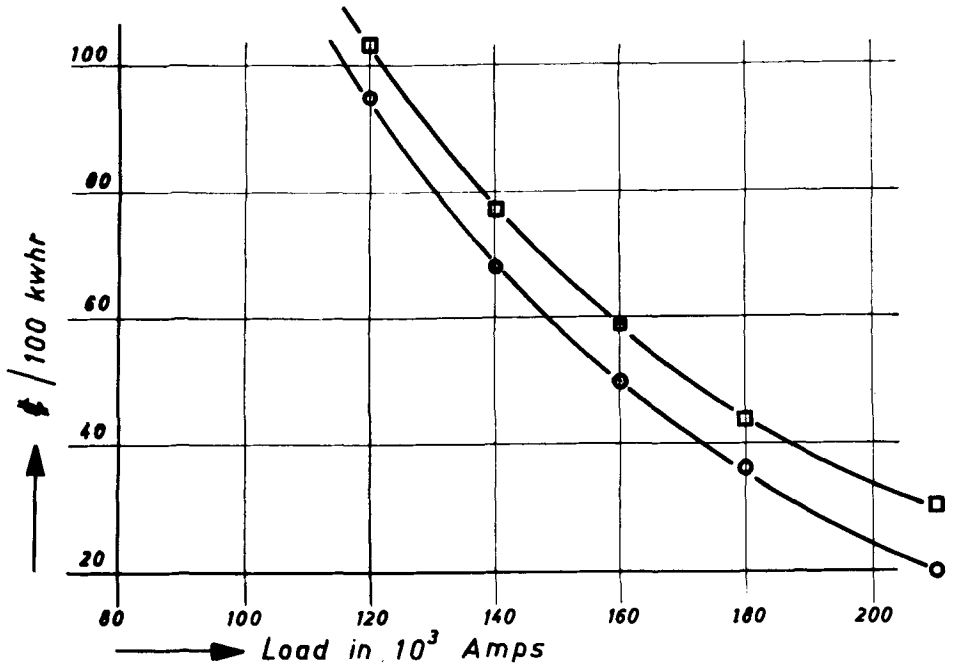

Fig. 5. Optimum load as function of current price. Curve ○, with rectifier costs; curve □, without rectifier costs.

cells N required (columns 2, 7, and 12), their production in tons/month chlorine (columns 3, 8, and 13), their average cell potential V (columns 4, 9, and 14), the direct current total potential (columns 5, 10, and 15) and the specific current consumption/100 kg chlorine (columns 6, 11, and 16).

Figure 5 represents the optimum current load for the values of the calculation Example 1 as a function of the current price with and without consideration of the installation costs of the rectifier. The course of both curves shows that these costs have no big influence unless the current prices are low.

Discussion of the Results

When examining the influence of the various parameters such as installation costs, mercury price, cell resistance, operating lifetime, installation costs for the rectifier on the optimum load by means of the derivations, it can be said that it fluctuates within comparatively narrow limits in the technical and economic fields in question.

Table II. The optimum current load I_T as a function of the operating years n

1	2	3	4	5	6
n	i	W	I_T	I_T	I_T
years	%	—	(Example 1) KA	(Example 2) KA	(Example 3) KA
5	20	0.266	153	162	191
10	10	0.157	117.5	130	154.5
20	5	0.105	96	111	135
30	3.3	0.091	89.5	103.5	131

The optimum current load is influenced considerably if we take into consideration the taxes on profit in the case of saved current costs. The comparison of the course of the curves □ and ○ in Fig. 3, shows that for the chosen example the optimum current load rises by about 25,000A, corresponding to a rise of current density from 1200 to 1300 A/m². For a lifeteime of 20 yr for the installation, we equal 6800 A/m², still considerably under the load of 10,000 A/m². At a current price of 75¢/100 kWhr, this load increases to 7500 A/m² and only at a price of 40¢/100 kWhr would we reach a specific load of 10,000 A/m².

In Eq. [19], [22], and [26] we can have at our disposal the two variables I_T and n (n is contained in W). The other items y_T, i, K, c_T, b_I, and Z are to be regarded as constant for a given installation. It is up to the company to define the time in which invested capital should be returned by the choice of n. In this case it should be taken into account that a short return time is purchased at the expense of a higher current load I_T, and with it higher specific costs. Also these higher current costs occur throughout the entire life time of the installation. Therefore n should be chosen corresponding to the entire life time of the installation, and n = 10-15 yr should come rather close to the practical situation.

The values of Table II and Fig. 3 show that with a return time $n > 15$ yr the optimum current load I_T changes only slightly with n.

Optimum Load of Bus-bars

The optimum load of bus-bars is calculated by the somewhat simpler method of cost comparison since the

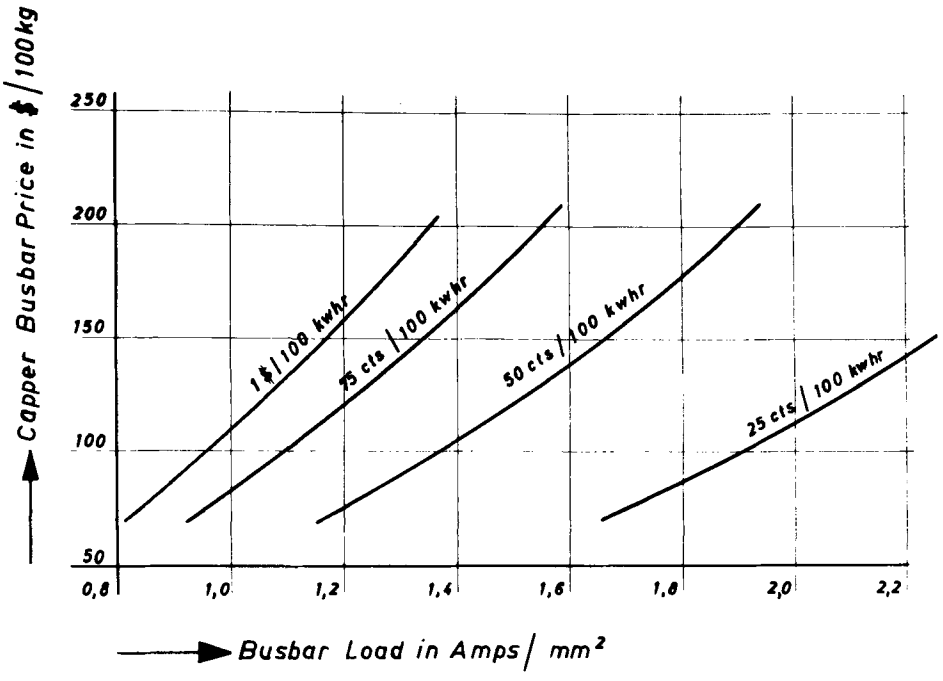

Fig. 6. Specific bus-bar load as function of copper price at different current prices.

influence of taxes on profits is insignificant on the result. The optimum lies where the sum of the costs for the current losses by ohmic resistance on the one hand, and the capital costs of the investment for the bus-bars on the other hand, reach a minimum.

This minimum is found by calculation if we represent the costs for the current losses $f_1(S_B)$ and for the capital costs $f_2(S_B)$ as functions of the bus-bars cross section S_B differentiate both functions with respect to S_B and set the sum of the differential quotients equal to 0

$$\frac{d f_1(S_B)}{d S_B} + \frac{d f_2(S_B)}{d S_B} = 0 \qquad [29]$$

The costs for the current losses are

$$C_B = f_1(S_B) = I_B^2 \cdot R_B \cdot \frac{L}{S_B} \cdot t \cdot 10^{-3} \cdot P_I \cdot 10^{-2} \qquad [30]$$

The part of the capital costs to be annually purchased for the bus-bars (depreciation and interest) depends on the depreciation period, (n), and the interest factor, Z. It corresponds to the value W (Table I).

The capital costs are

$$Y_B = f_2(S_B) = S_B \cdot L \cdot 10^{-3} \cdot \omega \cdot P_B \cdot W \qquad [31]$$

Differentiating Eq. [30] and [31] and setting the sum of the results = 0, we find for the specific load

$$\frac{I_B}{S_B} = \sqrt{\frac{\omega \cdot P_B \cdot W}{R_B \cdot t \cdot P_I}} \text{ A/mm}^2 \qquad [32][8]$$

Figure 6 shows the optimum specific load for copper bus-bars as a function of bus-bars-prices for various current prices.

Optimum Operating Time of Electrodes

This calculation principle for the solution of optimization problems in the electrolysis is also used to calculate the most favorable operating time of vertically arranged electrodes consumed during the electrolysis. As a consequence of the decrease in the cross section of the electrodes, higher potential losses occur. A condition for the following derivation is that the gap between anode and cathode is held nearly constant by continuous adjustment. The consumption of graphite anodes in a vertical mercury chlorine cell with rotating cathodes serves as an example for these calculations.

In this cell the graphite anodes are placed facing the two sides of the vertical rotating amalgamated iron cathode, as shown in cross section in Fig. 7. In this cell type the anodes are arranged as shown in the upper part of the cell, in which the brine is electrolyzed. The graphite anodes are adjusted every 2-3 days, to realize a nearly constant anode-cathode gap. Figure 7 shows the arrangement with new anodes and partly consumed anodes wherein the cross section is decreased and the voltage drop in the anodes increased.

The longer the anodes are in operation, the smaller are the specific graphite costs and the higher the specific current costs. From the economic point of view the most favorable time for renewing the anodes comes when the sum of the specific graphite costs and the specific current costs reaches a minimum. Other influences on the cell with increasing operating time, such as the change in the current efficiency etc. are not considered here.

We find this cost minimum by calculation when the specific current costs/100 kg chlorine, $f_1(t_c)$, and the specific graphite costs/100 kg chlorine, $f_2(t_c)$ are represented as a function of the operating time, t_c, of the anodes. Both functions are differentiated with respect to t_c and the sum of the differential quotients is set equal to 0

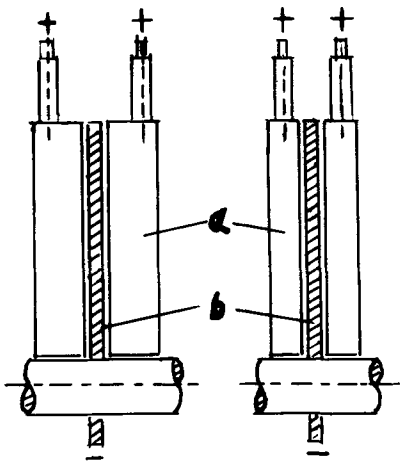

Fig. 7. Electrodes in a vertical chlorine cell; left, with new anodes, right, with anodes which are partly consumed. a, Fixed graphite anode; b, rotating iron cathode.

[8] As W refers to one year according to the definition, the number of hr/yr = 8750 must be inserted for t.

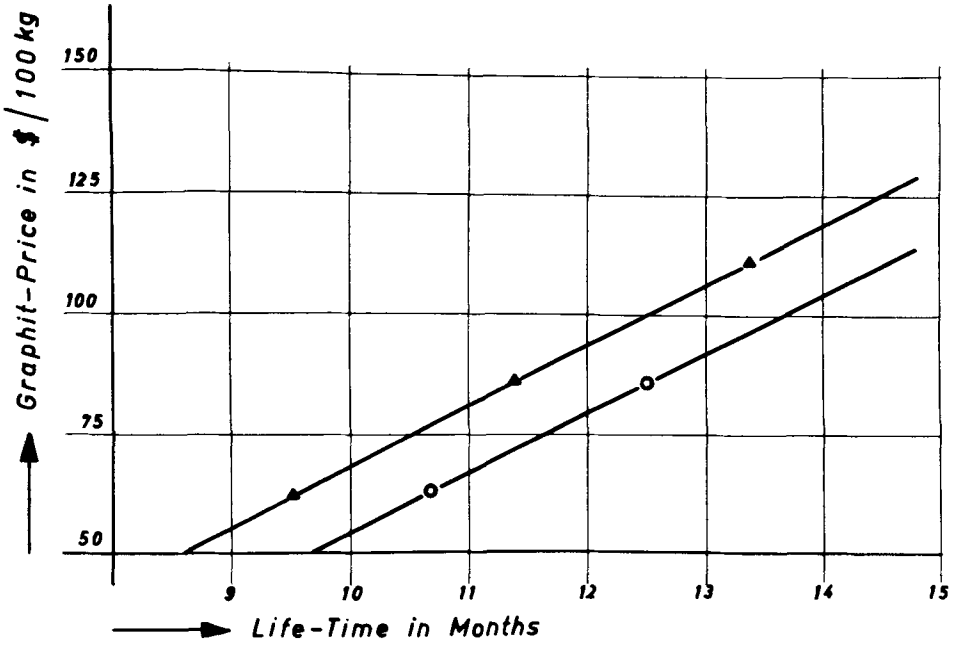

Fig. 8. Optimum operating time of graphite anodes as function of the price of graphite and current. Curve ○, 100¢/100 kWhr; curve △, 125¢/100 kWhr.

$$\frac{d f_1(t_c)}{d t_c} + \frac{d f_2(t_c)}{d t_c} = 0 \qquad [33]$$

The specific current costs for 100 kg chlorine during the operating time t_c are

$$c_I = f_1(t_c) = \frac{I_B \cdot P_I \cdot 720}{10^6 \cdot m \cdot t_c} [V_c + (V_c + v) + (V_c + 2v) + \ldots\ldots (V_c + t_c \cdot v)]$$

$$= \frac{I_B \cdot P_I \cdot 360}{10^6 \cdot m} (2V_c + v \cdot t_c) \quad \$/100\ \text{kg Cl}_2 \qquad [34]$$

The specific graphite costs are

$$c_G = f_2(t_c) = \frac{g \cdot P_G \cdot 10}{m \cdot t_c \cdot 10} \quad \$/100\ \text{kg Cl}_2 \qquad [35]$$

Differentiating these two equations with respect to t_c we obtain the most favorable operating time in months

$$t_c = \sqrt{\frac{g \cdot P_G \cdot 10^5}{I_B \cdot P_S \cdot 36 \cdot v}} \qquad [36]$$

In Fig. 8 there is graphically represented the optimum operating time, t_c, as a function of the graphite costs at various current prices for the example

m = 40 tons chlorine/month
g = 1.5 tons graphite
V_c = 4.5V
I_B = 45,000A
v = 0.05V
P_I = 1 and 1.25 $/100 kWhr

From the point of view of mechanical stability, the operating time of anodes of this type is about 9 to 10 months. At current prices below $1.25/100 kWhr, the price of graphite must be below $60/100 kg to justify removal before this time. At higher graphite prices or lower current costs, the optimum operating time is greater than the operating time which is technically possible, so that the anodes can be consumed as far as it is technically possible.

Manuscript submitted May 16, 1969; revised manuscript received ca. March 11, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1972 JOURNAL.

TECHNICAL SYMBOLS

Optimum Load of Electrolysis Cells

I_T (A) = Circuit current of the electrolysis
t (hr) = Time
V_p (V) = Polarization potential
R_r (ohm) = Average specific resistance of one cell (including its share of the total bus-bar resistance beginning from the rectifier)
e (g/Ahr) = Electrochemical equivalent
U (%) = Current efficiency
K = Production constant (cell amperes)
M_T (mtons) = Quantity produced
N = Number of cells

Optimum Load of Bus-bars

S_B (mm²) = Bus-bar cross section
I_B (A) = Current intensity of the bus-bars or electrodes
R_B (ohm · mm² · m^{-1}) = Specific resistance of the bus-bar metal
L (m) = Length of the bus-bars
ω (g/cm³) = Specific weight of the bus-bar metal

Optimum Operating Time of Electrodes

t_c (months) = Operating time of the cell
V_c (V) = Total potential of the cell
v (V) = Average potential increase per cell and month
m (mtons) = Quantity produced per cell and month
g (mtons) = Weight of graphite anodes per cell

COST SYMBOLS

Optimum Load of Electrolysis Cells

y_T ($) = Investment cost per cell
c_T ($) = Personnel and repair costs per cell/year as well as all of the other operating costs which depend upon number of cells
F_I ($) = Fixed current costs (see Eq. [4])
Y_i ($) = Total investment costs ($y_T \cdot N$)[9]
C_I ($) = Total current costs/year
C_T ($) = Personnel and repair costs/year
Y_E ($) = Investment costs for rectifier
F_E ($) = Fixed share of costs for rectifier
b_I ($) = Factor for the variable cost of current (see Eq. [5])

[9] Including its share of the total installed investment costs of the complete cell house as building, cells, piping, bus-bars, switches, instrumentation, auxiliaries (*e.g.* mercury in mercury chlorine plants etc.), but without rectifier investment costs (Y_E).

b_T (\$) = Factor for the variable current costs, including the personnel and repair costs, as well as all of the other operating costs which depend upon the cell
b_p (\$) = Factor for the variable current costs including the personnel and repair costs + taxes on profits
b_E (\$) = Factor of the variable capital costs of the rectifier plant
Z_i (%) = Rate of interest
Z = Interest factor
n Years = Period of time after the installation has been put into operation
$W = \frac{Z^{(n+1)} \cdot (Z-1)}{Z^n - 1}$
i (%) = Rate of depreciation
λ_i (\$) = Depreciation/year
P (%) = Taxes on profits
P_I (\$/100 kWhr) = Direct current price

Optimum Load of Bus-bars

C_B (\$) = Current costs for bus-bar losses
Y_B (\$) = Capital costs for bus-bars
P_B (\$/100 kg) = Price for bus-bars

Optimum Operating Time of Electrodes

c_I (\$) = Specific current costs for 100 kg product
c_G (\$) = Specific graphite anode costs for 100 kg product
P_G (\$/100 kg) = Graphite price

Technical Note

Sodium Borohydride ($NaBH_4$) Initiation of Electroless Plating

Donald G. McBride and Gary P. Vlasak

International Business Machines Corporation, Systems Development Division, Endicott, New York 13760

The most widely used method for activating nonconductive materials prior to electroless plating consists of an acid solution of $SnCl_2$ as a sensitizer and an acid solution of $PdCl_2$ as an activator (1). This reaction is an oxidation-reduction as follows

$$Sn^{++} + Pd^{++} \rightarrow Sn^{+4} + Pd^{o}$$

The thin layer of deposited Pd acts as a catalyst and initiates electroless plating. A method of activation using a phosphorus system which forms an effective bond to the substrate has been reported (2). The reasons for investigating new methods of initiation were to obtain more complete metallic coverage, to improve adhesion of the metal to the substrate, and to eliminate permanent activation of the substrate with Pd. If a substrate on which a circuit has been provided is permanently activated, it is difficult to selectively electroless plate the circuitry without plating the total substrate.

A system has been developed using $NaBH_4$ (a strong reducing agent) which initiates metal plating on nonconductors but does not permanently activate the substrate. The primary criterion used for evaluation of the electroless metal deposits was adhesion. Electroless Cu, Ni, and Co on ceramic were evaluated. A sintering process was used to improve adhesion of Cu to ceramic. In addition, a comparison was made between Cu to ceramic using the $NaBH_4$ and sintering process *vs.* Cu to epoxy glass (laminated, and plated using both the $NaBH_4$ and $SnCl_2$-$PdCl_2$ methods of initiation).

Experimental Procedure

Materials.—The substrates were ceramic—American lava (96% alumina, ~ 20 μin. surface finish) and G-10 epoxy glass. The initiation solutions were stannous chloride, $SnCl_2$ 40 g/liter and HCl 40 cc/liter at room temperature; palladium chloride, $PdCl_2$ 0.15 g/liter and HCl 10 cc/liter at room temperature; and $NaBH_4$ = 19 g/liter. The plating solutions used were electroless Cu: copper sulfate, formaldehyde (37%), sodium potassium tartrate, NaOH, sodium carbonate, at room temperature, pH 11-12; electroless Ni: $NiCl_2$ 30 g/liter, sodium hypophosphite 10 g/liter, ammonium citrate 65 g/liter, ammonium chloride 50 g/liter, at boiling temperature, pH 3.0; electroless Co: cobalt chloride 75 g/liter, sodium hypophosphite 25 g/liter, ammonium citrate 163 g/liter, ammonium chloride 125 g/liter, 0.1M sodium borohydride 125 g/liter, ammonium hydroxide 125 g/liter, at boiling temperature, pH ~ 9-10.

Key words: electroless plating, nonconductor plating, initiation by $NaBH_4$.

Metallization.—The procedure for nonconductor metallization using $NaBH_4$ is (*a*) clean the substrate in an alkaline cleaner, (*b*) use deionized water rinse, (*c*) 30% (vol) HCl (37% wt), and (*d*) repeat deionized water rinse. Dip-coat the substrates in 0.5M $NaBH_4$. Electroless plate first in a "sludge pot" and then in a fresh solution. Finally, electrolytic plate 0.003 in Cu-Cu pyrophosphate.

The sludge pot is a separate electroless plating solution which decomposes because of the dragged in $NaBH_4$.

A thin layer of metal should be plated onto the substrate in the sludge pot; then further plating should be done in a fresh solution. The more difficult a substrate is to plate, the greater the concentration of $NaBH_4$ required, but the faster the sludge pot decomposes. An alternate method has been developed that eliminates the sludge pot technique. Substrates are dip coated in 0.5M $NaBH_4$ and subsequently sprayed with the electroless plating solution or a 10% solution of $NiCl_2$ or $AuCl_3$. Then they are placed in a standard electroless plating solution.

The $NaBH_4$ technique is not an activation of the substrate. It is just an adsorption of a reducing agent onto the substrate which reduces metal ions in solution at the substrate/plating solution interface. The metal then deposits onto the nearby substrate. If the $NaBH_4$ is rinsed off, the substrate remains unchanged

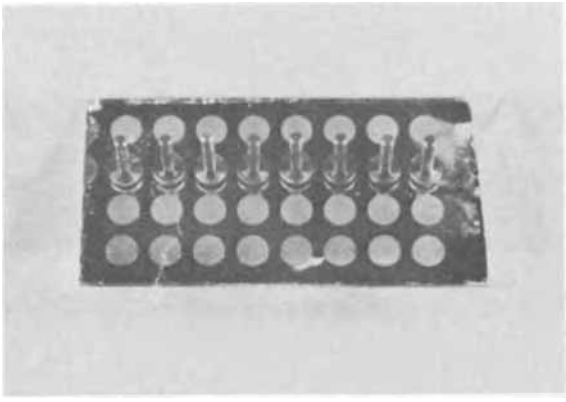

Fig. 1. Copper studs (150 mil diam)

and electroless plating will not occur—thus, no permanent activation occurs.

The procedure for nonconductor metallization using the $SnCl_2$-$PdCl_2$ system is (*i*) clean the substrates in an alkaline cleaner—deionized water, 30% HCl, deionized water; (*ii*) soak in $SnCl_2$ for 5 min, and rinse well with deionized water; (*iii*) soak in $PdCl_2$ for 2 min, and rinse well with deionized water; (*iv*) electroless plate; (*v*) electrolytic plate 0.003 in. Cu.

Sintering to improve adhesion.—Copper metallized ceramic substrates prepared by using both the $NaBH_4$ and $SnCl_2$-$PdCl_2$ processes were sintered for 45 min in an argon atmosphere in an attempt to improve adhesion. The sintering temperature was varied from 480°C to 1000°C to define the temperature which yielded the optimum adhesion.

Electroless Ni and Co metallized ceramic substrates using the $NaBH_4$ process were sintered at 800°C for 45 min in argon to compare their adhesion with that obtained with Cu.

Table I. Comparison of adhesion of Cu,* Ni, and Co to ceramic

Activation	Metal deposited	Avg. pull strength (lb/in.²)	Sintering temp (°C)
$SnCl_2$-$PdCl_2$	Cu	2060	None
$SnCl_2$-$PdCl_2$	Cu	2411	800
$NaBH_4$	Cu	1471	None
$NaBH_4$	Cu	2994	480
$NaBH_4$	Cu	>4244	600
$NaBH_4$	Cu	>4244	800
$NaBH_4$	Cu	>4244	1000
$NaBH_4$	Ni	198	800
$NaBH_4$	Co	170	800

* Accurate adhesion data of Cu to ceramics was not obtained for temperatures above 600°C because the ceramic broke in the fixture. Therefore, a small area was tested.

Table II. Optimization of sintering temperature

Sintering temperature (°C)	Avg. pull test (grams)
None	49
500	78
800	116
1000	43

Adhesion test.—The adhesion of the metals to the substrates was measured by three tests: 0.150 in. diam stud pull test (Fig. 1), 0.005 in. wire pull test, and 0.020 in. line peel test.

Using photolithographic and etching techniques, 0.150 in. diam pads, 0.005 in. lines, and 0.020 in. lines were etched on the metallized substrates. Then, a 0.150 in. stud, a 0.005 in. wire, or 0.020 in. wire was soldered to the Cu pad or line using 60/40 Sn/Pd solder. Pull testing was done on an Instron[1] tester at 90° to the substrate.

[1] Instron Corporation.

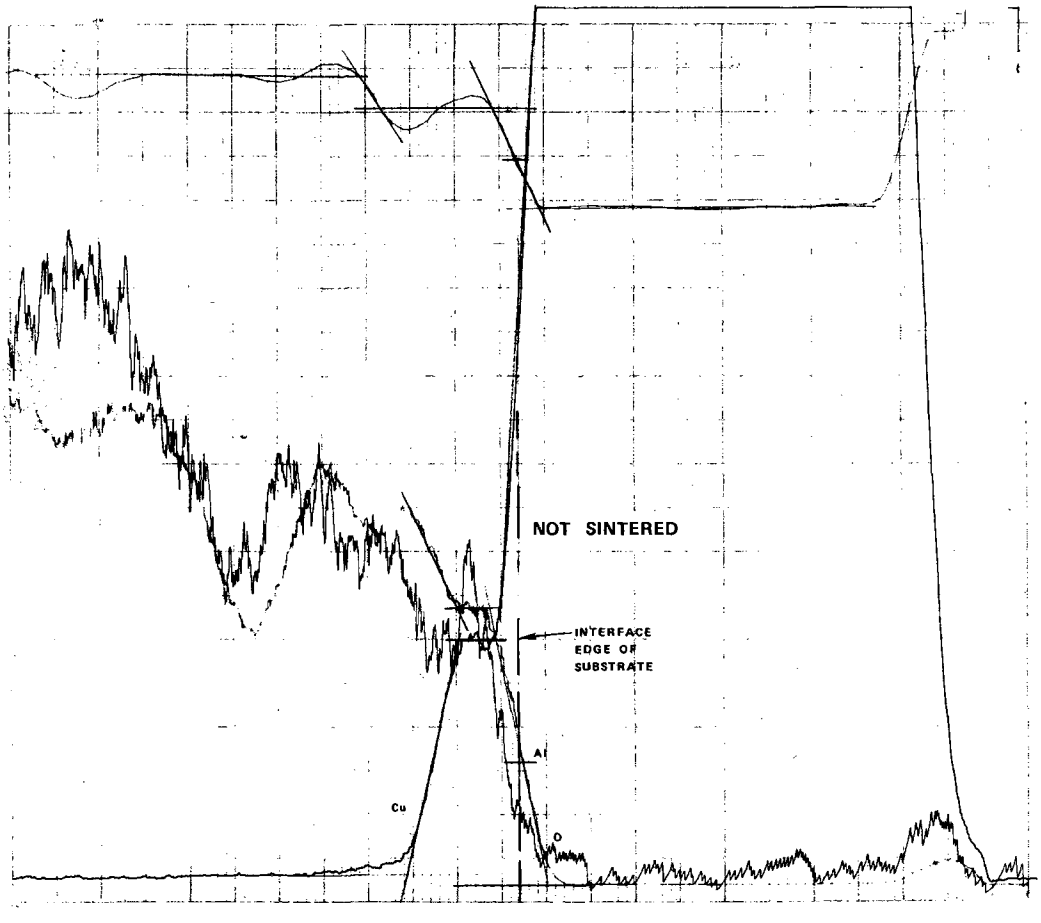

Fig. 2a. Cu plated plus CuO plus substrate (not sintered).

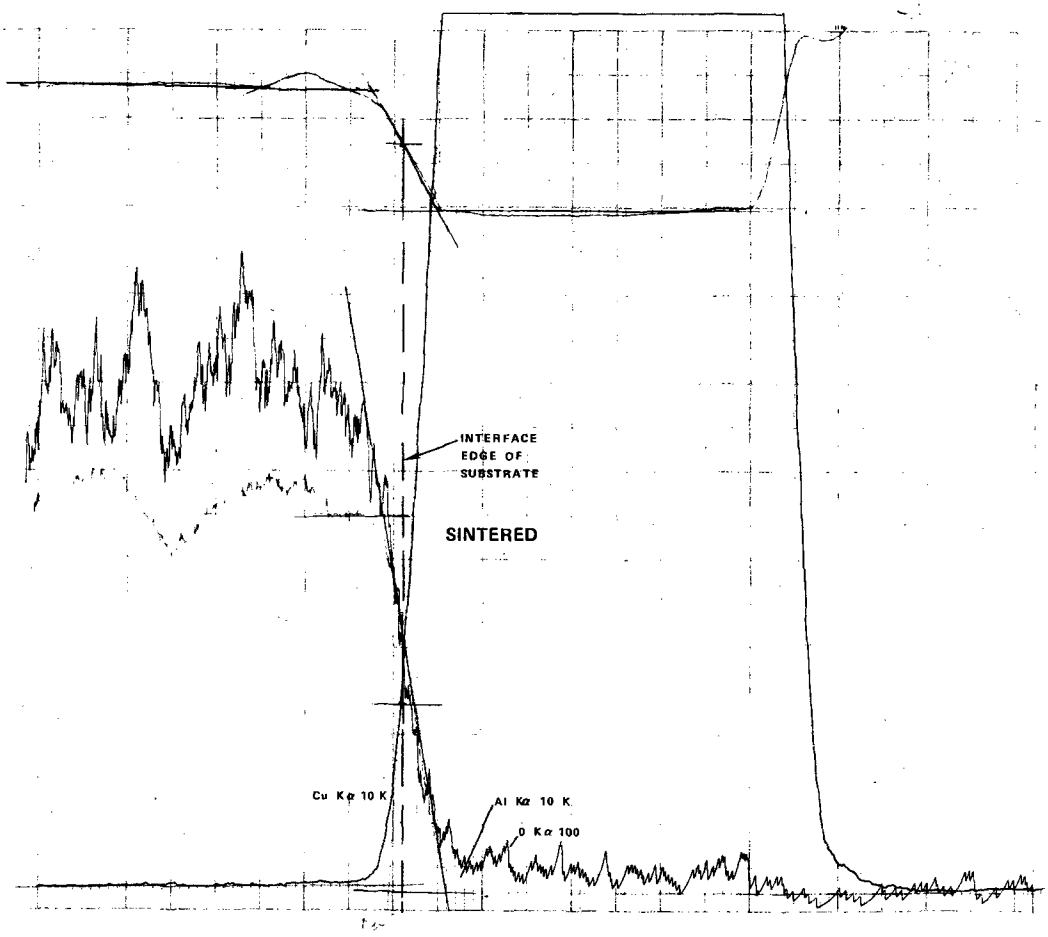

Fig. 2b. Cu plated plus CuO plus substrate (sintered).

Metallurgical evaluation.—X-ray and electron probe analysis was performed on substrates metallized using the $NaBH_4$ and sintering (800°C) process in an attempt to determine the mechanism of improved adhesion.

Results

Table I is a comparison of the adhesion of Cu, Ni, and Co to ceramic as determined by a 0.150 in. diam dot pull test.

Table II displays the pull test data obtained for a 0.005 in. wire soldered to a 0.005 in. Cu line, prepared using the $NaBH_4$ method of plating initiation and sintering at temperatures 500°-1000°C.

Electron probe analysis (Fig. 2a) indicates that prior to sintering Cu is approximately 4μ into the ceramic, at the left of the interface. The oxygen curve is on an expanded scale (100K) as opposed to Cu (10K). Thus, the Cu and O coincidence does not prove or disprove the presence of CuO. The slight peak (increased Cu) as the probe moves into the interior of the ceramic is probably an indication of irregular Cu because of the porous nature of the ceramic. Figure 2b indicates that after sintering the Cu has diffused away from the interior of the ceramic, to the right of the interface. This more abrupt junction obtained after sintering is probably the result of physical forces such as surface tension and stress relief, which are in operation at the sintering temperature (800°C).

A comparison was made between the adhesion of Cu to ceramic using the $NaBH_4$ and sintering at 800°C method and Cu to epoxy glass (laminated, and plated using both the $NaBH_4$ and $SnCl_2$-$PdCl_2$ methods of initiation). See Table III. Adhesion was measured using a 0.020 in. line peel test.

Table III. Adhesion of copper to ceramic vs. copper to epoxy glass

Substrate	Activation	Avg. peel strength (g)
Ceramic	$NaBH_4$	30-60
Epoxy glass	$NaBH_4$	20-30
Epoxy glass	$SnCl_2$-$PdCl_2$	50-70
Epoxy glass	Laminated	80-100

Qualitatively it has been observed that for difficult to metallize substrates, such as glazed ceramic, more complete coverage is obtained with the $NaBH_4$ initiation than with the $SnCl_2$-$PdCl_2$ method of activation. Also, $NaBH_4$ initiation does not permanently activate the surface as does $SnCl_2$-$PdCl_2$. This point is of considerable importance when one desires to selectively electroless plate circuitry on a substrate that has previously been activated.

Discussion

The initial Cu plate onto ceramics using $NaBH_4$ initiation appears to be Cu which immediately oxidizes into CuO from x-ray analysis. During sintering, Cu appears to diffuse into the ceramics. See Fig. 3. It is known (3) that several per cent of CuO wil diffuse into various glasses.

The improved adhesion may be the result of some shallow diffusion of CuO and Cu into the glass and ceramic. Also, a more homogeneous junction results (microprobe analysis) which may cause better interlocking of the Cu around the alumina. Reduced stress in the system should also lead to improved adhesion.

More recent work indicates that the adhesion obtained with the $NaBH_4$ and sintering method is substrate dependent. The difference obtained is probably the result of the different impurities (glass, etc.) used as a binder. Further investigation will be necessary to understand the observed phenomenon.

Conclusion

A new method of electroless plating initiation has been developed using $NaBH_4$. This method yields more complete coverage on difficult to metallize substrates, does not permanently activate the substrate, and leads

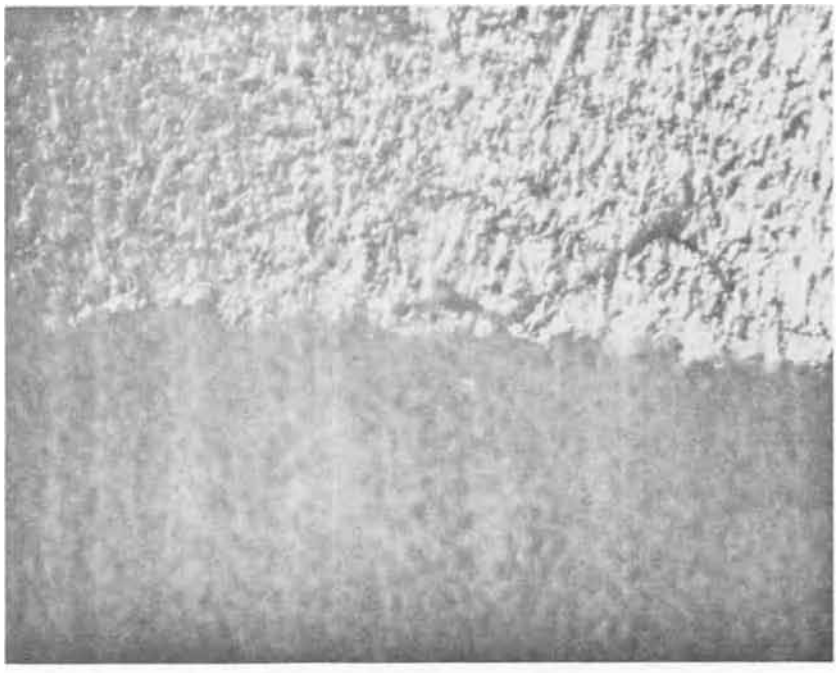

Fig. 3a. Ceramic (not sintered) (magnification: 1000X).

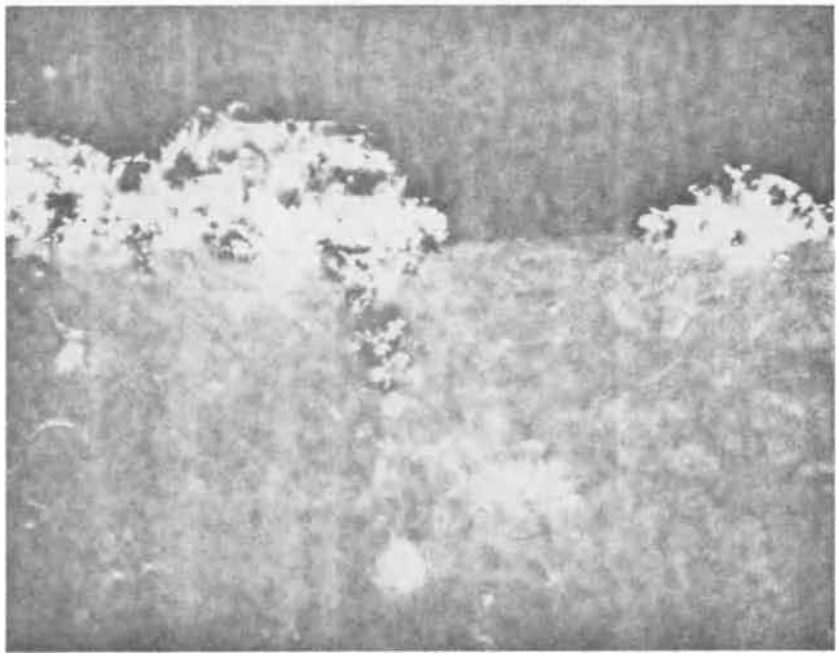

Fig. 3b. Ceramic (sintered) (magnification: 1000X).

to improved Cu to ceramic adhesion if the Cu is sintered into the ceramic at 800°C.

DISCUSSION SECTION

This Discussion Section includes discussion of the paper appearing in the *Journal of The Electrochemical Society*, Vol. 117, No. 11, November 1970.

Electrophoretic Deposition of Luminescent Materials

P. F. Grosso, R. E. Rutherford, and D. E. Sargent
(pp. 1456-1459, Vol. 117, No. 11)

E. I. Szabo and S. L. Gertsman: In the paper under discussion, the authors advocate the use of a multivalent ion to charge suspended particulates, since milling is claimed to have a deleterious effect on the light output efficiency of the phosphors.

While the authors acknowledge that the introduction of an ionic component results in a conductive suspension, and hence, gassing, they attempt to overcome the latter by including an organic depolarizer in the liquid vehicle.

We would comment, that while milling does indeed induce electrophoretic mobility in practically any solid/liquid combination, this is incidental, and is the result of the fresh, unoccupied sites generated. The deterioration in light output efficiency is the result of lattice distortion

Since the sole requirement to induce electrophoretic mobility in any suspended solid appears to be that of offering the atmosphere (preferably a polar liquid) an unoccupied site, this is easily accomplished by removing the adsorbates from the surface.

In practice, heating the powders to 400°C at a modest vacuum of 10^{-2} to 5 x 10^{-3} mm mercury, and holding there for 24-48 hr, was found sufficient. If the powders are to be stored for a time, backfilling with an inert gas, or maintaining the contents in a sealed container can retain the mobility of the powders.

Chlorine-Caustic Soda

I. Production.—Another record high was set last year with the production of chlorine reaching 9,710,000 tons in the United States, a 3.0% increase over production in 1969. Canadian production was 852,500 tons, down approximately 4.1% from the preceding year. During the last ten years the growth rate in the U. S. has been about 8% and 11.5% in Canada (1).

From December 1, 1969, to December 1, 1970, U. S. daily chlorine capacity increased 800 tons to 29,002 tons while Canadian capacity remained constant at 2,631 tons. In 1970, U. S. producers operated at 92.6% of capacity, while Canadian facilities operated at 90.4%.

A summary of U. S. caustic soda capacity by producer is shown below (2):

Producer	Capacity, T/D
Alcoa	529
Allied	1,760
Diamond Shamrock	2,100
Dow	10,000
FMC	850
GAF	510
Goodrich	330
Hooker	1,820
Kaiser	500
Olin	1,630
Pennwalt	990
PPG Industries	3,330
Shell	275
Stauffer	810
Vulcan	470
Wyandotte	1,780
Paper Companies	715
Other	980
Total	29,620

Reflecting the short supply of caustic soda, price increases were announced on four separate occasions during the past few months (3-6). List prices for 50% and 73% now stand at $71/ton and $73/ton with dry flake and beads at $7/cwt. Anhydrous caustic is now available from PPG and Dow in the form of free-flowing beads. These dust-free prills have been well received.

A summary of Canadian chlor-alkali capacity by producer is shown below (7):

Producer	Capacity 1,000 tons/yr Chlorine	Caustic
Aluminum Co. of Canada	29	34
Canadian Industries Ltd.	135	156
Canso Chemicals	18	21
Domtar Group	35	41
Dow Chemical	394	455
Dryden Chemical	47	54
FMC Canada, Ltd.	36	40
Hooker Chemical	123	145
E. B. Eddy	8	9
Interprovincial Co-op.	35	40
Marathon Paper Co.	13	14
Standard Chemical, Ltd.	61	71
Totals	935	1,080

II. Expansions. (8-10)—

Company and Location	Type of cell	Capacity tons/day	Completion date
A. Shutdown			
Oxford Paper Div. Ethyl Corp. Rumford, Maine	Sorensen Mercury	13	August 1970
Dow Chemical Co. Plaquemine, La.	Solvay V-200 Mercury		December 1970
B. Production started			
Standard Chemical Ltd. Beauharnois, Quebec	Uhde Mercury	220	February 1971
Stauffer Chemical St. Gabriel, La.	Uhde 30m² Mercury	500	December 1970
C. Building or planned			
Dow Chemical Co. Dallesport, Wash.	Dow (Magnesium)	24,000 T/yr Magnesium, 40,000 T/yr Cl_2	Early 1972
Dow Chemical Co. Freeport, Texas	Dow Diaphragm	Expansion Bldg.	1971
Dow Chemical Co. Midland, Mich.	Dow Diaphragm	Moderniza-tion Planned	1971-1972
Hooker Chemical Corp. Taft, La.	Hooker S-4	120	1st Quarter 1971
Mobay Chemical Co. Cedar Bayou, Texas	HCl Electrolysis, Uhde	200	Late 1971
National Lead Co. Grantsville, Utah	BASF	45,000 T/yr Magnesium	Late 1971
PPG Industries, Inc. Guayanilla, Puerto Rico	DeNora Mercury	500	3rd Quarter 1971
PPG Industries, Inc. Lake Charles, La.	PPG-DeNora Bipolar	1,500	Not Announced

III. New developments.—A. Metal anodes.—Metal Anode Associates, a joint venture of Union Carbide Corporation and Engelhard Minerals and Chemicals Corporation, was formed in March, 1970, to produce and market metal anodes. The company combines Engelhard's years of experience producing and processing precious metals with those of Union Carbide in anode design and electrolytic operations. Engelhard is supplying the production facilities and Union Car-

[1] This report is sponsored by the Industrial Electrolytic Division of The Electrochemical Society. While it is primarily a summary of production and developments in the chlor-alkali industry, reports of other electrolytic industries are included.

The material presented herein has been gathered from many sources, as noted in the references, and does not necessarily represent the opinions of the authors.

* Electrochemical Society Active Member.

bide is serving as the marketing and technical service arm (11, 12).

As of this report, a number of chlor-alkali producers, both domestic and foreign, have been supplied with metal anodes by MAA.

Electrode Corporation, a joint venture of DeNora and Diamond Shamrock, continues as a leading supplier of the DSA for use in mercury cells. Titanium based anodes are now being used in many different types of mercury cells employing current densities from 4 to 14 kA/m^2.

Hooker Chemical Company signed an agreement with Electrode Corporation covering use of the DSA in Hooker cells. A new base assembly adapts this cell type to use of the DSA, eliminating the need of lead and asphalt (13, 14).

B. New cell designs.—A new diaphragm cell is being developed jointly between PPG Industries and Oronzio DeNora using a bipolar configuration and metal anode. The low investment per daily ton produced and lower operating cost will make the new cell attractive for large chlorine plants and installations where older cell technology has reduced profit margins. Electrode elements can be assembled into individual cell units that will produce up to 36 tons per day, more than double the capacity of most large mercury cells now in operations (15). PPG will market the cell in the U. S. and Canada, while deNora will market throughout the rest of the world.

C. Mercury.—Consumption, production, and imports of mercury were down in 1970. Decline in usage was due in part to the slowed pace of the U. S. economy and the problem of mercury pollution. Imports were down 20% and mine production was down slightly to 28,000 flasks (76 lbs each). California supplied 66% and Nevada 22% of domestic production with the balance split between Alaska, Arizona, Idaho, Oregon, and Texas. The value of primary production was estimated at 11 million dollars (16).

Canada furnished 80% of the imported mercury; Italy, 7%; and Spain, 7%, down significantly because of lower demand. The U. S. rate of duty on mercury imports dropped to $12.92/flask on January 1, 1970. The price per flask was $410 in 1970 compared to a $505 average in 1969. GSA reported that only 703 flasks were sold of 14,000 offered in January and Congressional hearings were cancelled on the bill to authorize release of 73,000 flasks from stockpile surplus. Several factors have contributed to the mercury price drop (17):

1. Controversy over mercury being a health hazard
2. State of U. S. economy
3. Massive new Canadian production

Several years ago mercury production was near zero. As world prices for mercury increased, Canadian companies, notably Cominco Ltd., were encouraged to develop their own plants. Within two years production has zoomed to between 20,000 and 25,000 flasks a year. To guarantee their markets, they signed long-term contracts guaranteeing 2-3% lower prices than U. S. quotes. This discounting clearly helped pull down the mercury prices.

The following is a breakdown of mercury consumption (18, 19):

76 lb. flasks	1969	1970	Estimated 1974-75
Agriculture	2,689	2,700	2,660
Catalysts	2,958	2,400	2,342
Dental preparations	3,053	2,000	3,795
Electrical apparatus	18,650	18,000	22,700
Chlorine and caustic*	20,720	16,000	22,840
General laboratory use	2,041	3,000	2,080
Industrial and control instruments	6,981	7,300	9,250
Mildew-proofing paint	9,486	9,000	10,700
Paper and pulp	558	725	237
Pharmaceuticals	724	650	658
Other	11,144	7,625	6,187
Total	79,104	70,000	83,500

* Quantities for chlorine cell startup included under "Other" uses.

Source: Bureau of Mines, CW estimates.

No attempt will be made in the limited space available here to discuss the mercury discharge problem faced by chlor-alkali producers; however, it is a safe guess to say that approximately $1,000-$1,500/daily ton of chlorine produced has been spent to reduce the amount previously discharged to essentially zero. Both in-plant recycling and effluent treatment have been used extensively.

Other Alkalis and Electrolytic Processes

Caustic potash.—Caustic potash facilities currently operable in the U. S. are shown below (20):

Producer	Capacity (short tons/yr)
Allied Chemical Co. Syracuse, N. Y.	30,000*
Diamond Shamrock Corp. Delaware City, Del.	16,000
Diamond Shamrock Corp. Muscle Shoals, Ala.	40,000
Hooker Chemical Corp. Niagara Falls, N. Y.	36,000*
International Minerals and Chemical Corp. Niagara Falls, N. Y.	23,000*
Monsanto Co. Sauget, Ill.	45,000
Pennwalt Corp. Calvert City, Ky.	25,000
PPG Industries, Inc. Corpus Christi, Texas	7,000*
PPG Industries, Inc. New Martinsville, W. Va.	8,000

* Includes solid or flake production.

Preliminary production figures for caustic potash total approximately 17,000 tons for 1970 (21).

Dow Chemical announced plans to dismantle its 10,000 ton/yr plant at Pittsburg, California, the only caustic potash plant on the West Coast (22). PPG announced a price increase on bulk 45% grade of $4/ton to $4/cwt. effective July 1, 1970. No changes were made in drummed liquid and dry caustic potash (23).

Soda ash.—National soda ash production in 1970 was 2.6 million tons valued at $53.3 million, an increase of 4% in quantity and 5% in value over 1969. The mines in Wyoming supplied the bulk of the total national output, the remaining amount came from dry lake beds in California (24). The production of synthetic soda ash, light, was 1,786,873 tons and synthetic, dense, was 2,477,490 tons (25).

Domestic alkali demand (25).—

Year	(1,000 Tons as Na_2O) NaOH	Na_2CO_3	Total
1960	4,734	5,196	9,930
1965	6,420	6,143	12,563
1969	8,845	6,674	15,519
1970	9,075	6,626	15,701
1975	12,450	7,300	19,750

With curtailed operations in 1970 in Aluminum and Pulp and Paper Industries, increased utilization of caustic soda was gained at the expense of soda ash which was down by 0.7% from 1969.

The growth rate of soda ash over the past five years has averaged 1.5% annually. In 1970, synthetic soda ash plants experienced problems with the government crackdown on pollution. Consequent reductions in synthetic soda ash and the over-all growth is forecasted at about 2%/yr.

Year end prices were quoted at $2.35 per 100 lb for light and $2.40 for dense, and $1.65 and $1.80 respectively in carload lots, f.o.b. production facility.

Sodium chlorate.—Facilities for the production of sodium chlorate in the U. S. are listed below (26):

Producer	Capacity (short tons/yr)
American Potash and Chemical Corp. Hamilton, Miss.	23,500
American Potash and Chemical Corp. Henderson, Nev.	30,000
Brunswick Pulp and Paper Co. Brunswick, Ga.	7,000
Georgia-Pacific Corp. Bellingham, Wash.	5,000
Hooker Chemical Corp. Columbus, Miss.	55,000
Hooker Chemical Corp. Niagara Falls, N. Y.	15,500
Reigel Paper Corp. Butler, Ala.	4,000
Reigel Paper Corp. Reigelwood, N. C.	7,000
Pacific Engineering and Production Co. Henderson, Nev.	6,000
Penn-Olin Chemical Co. Calvert City, Ky.	31,000
Pennwalt Corp. Portland, Oreg.	15,000
PPG Industries, Inc. Lake Charles, La.	15,000
	214,000

Hooker Chemical is building a 45,000 TPY sodium chlorate plant at Taft, Louisiana, with startup scheduled in 1972. An entirely new cell design will be employed (27).

The United States' production of sodium chlorate in 1970 was approximately 201,000 tons (28). The majority of production is consumed by the pulp and paper industry for the generation of chlorine dioxide for paper bleaching. Cotton defoliation and railroad rights-of-way cleaning account for most of the herbicide use while the production of perchlorates accounts for most of the balance.

Olin raised the price of sodium chlorate $20/ton to $150/ton while PPG raised the published price $10/ton (29).

Sodium.—The production of sodium metal set a new all-time high in 1970 of 171,220 tons (30, 31). This exceeded 1969 production of 164,588 tons by 4% and the previous high of 165,000 tons set in 1966 by 3.7%.

A dock strike in 1969 depressed sodium production resulting in a depletion of stocks. This in turn tended to increase 1970 production to replace stocks. Production was 10-12% higher during the first six months of 1970 than in the last half of the year when general economic conditions curtailed the purchase of gasoline.

Of the sodium produced, approximately 83% went to the manufacture of lead alkyls for gasoline additives, 6% to the production of titanium sponge, and 11% for miscellaneous uses (peroxide, sodium hydride, descaling of metals, chemical and drug intermediates, and as a coolant for nuclear power stations).

Publicity concerning air pollution resulting from lead additives in gasoline was of major interest in 1970. A number of articles discussed the problems (32-39). Considerable research is being done to find replacement additives. The only real problem for its removal is that it is not compatible with catalytic mufflers which the auto industry wants to put on the motor vehicles.

It appears that the oil industry is resigned to the fact that lead must come out of gasoline. This means that the 2.9% per year growth rate for lead additives (1960-1970) will decline about 17%/yr through 1975. Exports, which account for 9.7% of the gasoline additives, are expected to hold steady (31). Over-all, it appears the sodium producers will be forced to reduce production or find new uses for the metal in the next few years.

Aluminum.—Output of primary metal was estimated at 3,950,000 tons and inventories at reduction plants were said to have increased (40). The U. S. was a net exporter of aluminum products for the second consecutive year.

For the past 15 years, return on investment for the three major aluminum companies—Alcoa, Reynolds, and Kaiser—has rarely gotten above 6%, Even so, companies have continued to expand to increase their per cent of the market and have built a long-term debt equaling 40-50% of total capitalization (41). This trend was reversed somewhat in 1970 as some expansions were deferred, planned shutdowns brought forward, and unscheduled outages by Hurricane Celia (Reynolds, Corpus Christi) and strikes (Alcoa, Kitimat, B.C.) were lengthened, all combining to restrict production.

The price of primary ingot was raised 1¢/lb, bringing it to 29¢ and making a 3¢ total increase since January 1969 (42). Mill products, plate sheet, and extruded shapes average between 40-52¢/lb. Justification for these price increases was explained by the over-all aluminum situation. Consumption in the free world outside the U. S. was up 21%. In Japan consumption was up 33% over the 1968 level; in Germany 28%; in the European Economic Community as a whole, 24% (43). The use of aluminum in the U. S. is not declining; it just seems that way when compared to the rapid growth rate of foreign markets.

Approximately 66% of U. S. output is used by four industries: housing and mobile homes, 22%; transportation, 20%; electrical goods, 13.2%; and packaging, 10.2% (44).

Primary aluminum producers in the U.S. (45)

* First potline onstream Oct. 1970; second potline expected to be built by 1974.

Magnesium.—Production of primary magnesium in 1970 totaled 112,007 tons, up 12.2% over 1969. Shipments in 1970 were 118,693 tons, up only slightly from 1969. Imports for consumption in 1970 totaled 3,294 tons. Exports of magnesium metal and alloys in crude form and scrap, and in semi-fabricated forms were 35,731 tons, 31% higher than in 1969 (46).

Recovery of secondary magnesium was approximately 15,000 tons. Magnesite, brucite, and olivine production continued at about the same level as in 1969 (47).

On March 4, 1970, the Office of Emergency Preparedness abolished the stockpile objective for magnesium, which totaled 114,722 tons on March 31, 1970. Under authorization of Public Law 91-321, passed on July 10, 1970, the G.S.A. was authorized to sell 12,000 tons of magnesium (47).

Imports of refractory magnesium during the first ten months were 78,755 tons valued at $6,055,920. For the same period, imports of dead-burned and grain magnesium and periclase totaled 30,887 tons valued at $1,537,687 (47).

Manganese.—Domestic consumption of ore containing 35% or more manganese was estimated at 2.2 million short tons, approximately equal to the level of consumption of the two preceding years. The only mine in the U. S. (Nancy-Tower mine in Sacono County, N. M.) producing manganese ore containing 35% or more manganese, closed in October. Shipments continued to be made from inventory (48).

Approximately 1.8 million tons of manganese ore was imported from suppliers in Gabon and Brazil. Ferromanganese was imported at a slightly lower rate than in 1969, primarily from the Republic of South Africa and France. An increase in ocean freight rates was reflected in a price increase of ore containing 46 to 48% manganese from 49 to 53¢/ton to 56 to 59¢/ton.

Deepsea Ventures, Inc., a subsidiary of Tenneco, Inc., began pulling manganese ore from the floor of the ocean, 150 miles off the coast of Florida, in 3,000 ft of water (49). The presence of manganese-rich lumps or "nodules" scattered about on the ocean floor waiting to be gathered may be a new, competitive source of manganese. Nickel, cobalt, and copper also occur with the manganese in these nodules. Two, as yet unanswered, questions are: who owns rights to the ocean bottom and will a method that works in 3,000 ft of water be feasible at depths of two to three miles of water where some of the richest deposits lie?

Beryllium.—Beryl (a beryllium-aluminum-silicate) consumption leveled off in 1970 according to the Bureau of Mines and was about equal to the 6,000 tons reported for 1969. Actual figures remain classified due to the limited number of producers.

Production was reported from Colorado, Maine, New Mexico, South Dakota, and Utah. Successful operation of the Spur Mountain, Utah bertrandite (another beryllium-aluminum-silicate) mine will furnish a domestic source for beryllium, assure a more stable supply, and encourage use of the metal (50).

Imports in 1970 declined from 1969 with 3,575 tons valued at $1.4 million for 9 months. Midyear government stockpile inventories contained 22,990 tons of beryl (11% BeO equivalent), 7,387 tons of beryllium-copper master alloy, and 229 tons of beryllium metal. Through June the government disposed of 1,481 short tons of beryl. In September, 545 tons of beryl (5,500 short tons of BeO) sold for $207,625.

Kawecki Berylco Industries, Inc. installed one of the world's largest isostatic presses for use in powdered beryllium and other metals at Hazelton, Pennsylvania. The press has a 24-inch diameter by 96-inch long chamber capable of 80,000 psi and is expected to decrease the cost of finished beryllium parts because less machining is required with resultant less scrap.

Uses of beryllium in 1970 were the electronics industry—35%, transmission switchgear—25%, nuclear and space applications—20%, welding—10%, and other —10%.

Chromium.—Chemical-grade chromite sales for the first three quarters of the year totaled 184,000 tons while metallurgical-grade chromite shipments totaled 126,000 tons. Domestic consumption was about the same as in 1969, with a 2% increase in the metallurgical industry offset by a 6% decrease in use in the refractory industry (51).

Imports of chromite totaled nearly 1.2 million tons during the first 10 months, a 20% increase compared to the same period in 1969. GSA announced that no acceptable offers were received in response to its bid invitation for 803,000 tons of metallurgical-grade chromite stored at Nye, Montana.

Metallurgical-grade chromite prices rose for the fourth successive year as the United Nations economic sanctions against Southern Rhodesia remained in effect. Rhodesia was one of the principal suppliers of domestic requirements prior to 1967. Domestic production of chromite was last reported in 1961. Published prices for Turkish chromite ore/long ton, 3-1 ratio, 48% Cr_2O_3, delivered Atlantic ports, increased from $47.50-$48.50 in 1970 to $55-$57 for 1971 delivery. Quoted prices for Russian chromite, 54-56% Cr_2O_3, 4-1 ratio, was $55.10-$59.60/long ton.

Titanium.—In 1970, a total of 535,000 tons of titanium were consumed in the U.S. Ilmenite (Fe-Ti ore) was the source for 416,000 tons while 119,000 tons were from rutile (94-95% TiO_2 ore). Over 95% of the total went to nonmetal uses, primarily pigment. Approximately 27,000 tons of titanium from rutile went to titanium metal (52).

Metal production (short tons) (53, 54)				Consumption		
Type	1969 Classified	1970	% Change	1969	1970	% Change
Sponge	est. 19,500	est. 15,000	−23	20,124	16,413	−19.2
Ingot	28,490	24,728	−13.2			
Scrap				7,242		−4.3

Imports of titanium sponge totaled 6,565 tons. Of this, 6,240 was for consumption, 72% from Japan, 17% from Russia, and 11% from the United Kingdom. Exports of the metal sponge and scrap were expected to reach 3,100 tons (55). Sponge producers include: Titanium Metals Corp. of America, Henderson, Nevada; Reactive Metals, Inc., Astabula, Ohio; and Oregon Metallurgical Corp., Albany, Oregon. There are nine users of sponge, 14 of titanium scrap and 15 of ingot.

The demand for titanium metal was strong in the first three months of 1970, but decreased due to cutbacks in the space and aircraft industries.

The General Services Administration purchased 3,100 tons of titanium sponge during the first six months, increasing their stockpile to 33,859 tons, 25% of which is substandard grade.

Developments of interest are as follows:

1. Schlienger nonconsumable electrode arc furnace
2. Reactive Metals' new 60 in. wide alloy and pure titanium sheet
3. TMCA's stress free—completely flat alloy plate in sizes to 10 x 35 ft
4. Production of a 700 lb ball for a valve by Ti-Line

Domestic prices for titanium sponge (99.3% pure) remained at $1.32/lb. Prices of the same grade from Japan and the United Kingdom were quoted at $1.20-$1.25/lb.

Lithium.—As a result of trade sanctions, domestic imports from Southern Rhodesia were nil for the second consecutive year, and production of lithium minerals and lithium carbonate continued at a high rate. Processors of lithium raw materials to lithium primary products were: Foote Mineral Co., Sunbright, Virginia, and Silver Peak, Nevada; American Potash and Chemical Corp., Trona, California; and Lithium Corp. of America, Bessemer City, North Carolina.

Important new uses of lithium in increasing amounts were the use of lithium carbonate by the aluminum industry and the increased use of lithium hypochlorite for bleaches and as a sanitizing agent for swimming pools. Other domestic uses include ceramics and glass, greases, welding and brazing fluxes, air conditioning equipment, rubber, and pharmaceuticals (56).

Lithium metal was quoted at $8.18/lb in 1000 lb lots, which includes a 25¢/lb increase announced by Foote Mineral on April 1, 1970 (57). Lithium carbonate in carload lots was priced at $0.52/lb and lithium chloride $0.87/lb.

Copper.—The U. S. domestic copper industry set new production records in 1970. Mine production was 1.715 million tons, up 11% over 1969. Smelter output from domestic ores set a record at 1.606 million tons, up 3.8%. Refinery production was 1.514 MM tons from domestic ores, 0.238 MM from foreign ores to total 1.752 MM tons from primary plants. Secondary material production was 510,000 tons (58).

There was a dramatic reversal in copper markets from a short supply to a surplus situation. Consumption of primary refined copper was down from 1.683 MM tons in 1969 to 1.597 MM tons in 1970, down 5.1%. Total refined consumption was off 4% to 2.06 MM tons. The price reflected the market change. There was an increase in price in April followed by price reductions in October and December. The changed supply

situation led to the removal in September of export controls imposed in 1965. Consumption in the second half of 1970 was affected by the general slowdown in business activity and by the General Motors strike (58, 59).

Copper stocks (refined) increased 151% to 98,000 tons by year end. Imports were down slightly (465,893 tons-11 months 1970) and exports increased slightly (451,633 tons-11 months 1970). Fabricators' stocks of copper in all forms increased from 502,000 to 522,000 tons from the start of the year through October (58, 59).

The Duval Sierrita mine in Arizona, owned by Pennzoil United Corporation, was dedicated in June and achieved capacity production of 65,000 tons of ore/day in October (58).

Hydrometallurgical processing (leaching, reduction) of sulfide ores may soon compete with the conventional roasting, smelting reduction and electro-refining. Economics appear competitive or possibly better and the sulfur dioxide air pollution problem is eliminated. Several smelter operators are under fire by anti-pollution crusades. At least two processes for leaching and reduction are being tested. Anaconda is building a multi-million dollar pilot plant in Tucson, Arizona, based on a patent owned by Treadmill Corporation. Sheritt Gordon Mines, Ltd. (Toronto, Ontario) is working on another process (60).

The two-tier pricing for copper may be gone. A cabinet sub-committee appointed by President Nixon in January, decided the system was not justified and recommended steps to end it. Subsequently, congressional hearings were held. In the meantime, the surplus copper situation forced cuts in the world price determined by the London Metal Exchange. The two-tier system originated in 1964 when the LME, as high as 90¢/lb at one point, forced U. S. producers to set a lower price to prevent substitution of other metals. Copper was allocated under the system and some fabricators were unhappy. With the present surplus situation, political-economic problems are reduced. U. S. copper prices were at 53¢/lb with world prices just under 50¢/lb (61).

Nickel.—Nickel consumption, excluding secondary nickel, was approximately 320 million lb. Nickel imports were about 300 million lb with domestic mine production estimated at 18,000 tons of nickel from laterite ore. The year was marked by exceptionally rapid recovery of the industry from the severe shortage caused by the labor strike in Canadian mines in 1969 (62).

The four-year shortage of nickel is ending even though demand is expected to grow 7-8%/yr through 1975. World production of nickel totals about 1 billion lb, slightly under the estimated demand of 1.05 billion lb. Stainless steel consumes approximately 40% of the world's nickel production (63).

The nickel industry is virtually unique today in that the major economies of the West are uncomfortably dependent on the output of one company, International Nickel. INCO produces about 475 million lb annually, more than half of that consumed in the non-Communist world. Falconbridge, also based in Sudbury, has a capacity of about 90 million lb and Societe' Le Nickel produces 88 million lb annually from the Island of New Caledonia in the Western Pacific (64). When prices went from 77¾¢/lb in 1965 to $1.28 in 1969, the lower grade laterite ores became economical (65).

Falconbridge is investing $195 million in a new plant in the Dominican Republic where it is developing new sources of ferronickel, a combination of nickel and iron, especially suited for making stainless steel (66).

Russia will not be a major factor in the world's nickel supply, but through Greg-Gary International Corporation, the U. S. will import about 5,000 tons annually. By itself this represents a 50% increase in Soviet exports to the U. S. which amounted to only $52 million last year (67).

The development by United Aircraft Research Laboratories of a high-strength nickel based alloy was announced with a strength three times that of the widely used superalloys. The eutectic, a mixture of trinickel aluminide and trinickel columbium, was said to have tensile strength of 140 thousand psi at 2,000°F.

Zinc.—United States mine output of zinc in 1970 decreased slightly over 1969, 546,772 tons *vs.* 553,124 tons, down 1.1% (68). Of 21 states reporting production, 12 registered decreases and 9 showed increases relative to 1969. Tennessee continued to be the largest producer (69).

Smelter production of zinc slab dropped by 150,000 tons, from 1,111,150 tons in 1969 to 961,153 tons in 1970, off 13.4%, reflecting the general downward trend in industrial activity. Imports of ores and concentrates dropped from 602,120 tons in 1969 to 525,757 tons in 1970, off 12.3%. Imports of slab zinc dropped from 329,008 to 272,577 tons, down 17%. Exports of zinc slab dropped from 9,298 tons to 289 tons while exports of zinc scrap increased 1,989 tons to 3,113 tons.

Consumption of zinc was as indicated below:

Base-recoverable zinc content	(Tons) 1969	1970	Change—%
Zinc slab	1,368,323	1,164,622	−14.8
Ores	126,712	118,400	−6.6
Zinc base scrap	100,636	86,400	−14.2
Copper base scrap	194,356	134,400	−30.8
Al-Mg base scrap	7,083	6,000	−15.3
Total	1,797,110	1,509,822	−16.0

The automobile industry, which normally accounts for one-third of the total U. S. consumption of zinc for die castings, galvanized steel, brass and bronze, and zinc oxide, had its worst year since 1962. Appliance manufacturers, the second largest consumers of zinc die castings, and the construction industry which uses most of the galvanized steel, suffered sharp losses in demand and used substantially less zinc. Comparing broad use categories for 1970 with 1969, galvanizing was down 5%, brass and bronze 26%, zinc-base alloys 18%, rolled zinc 17%, other uses 17% and zinc oxide was up 12%. Consumers operated principally on a current delivery basis as their stocks were reduced approximately 15,000 tons during the year.

General Services Administration sales of zinc continued through the year but amounted to only 25 tons, leaving 22,583 tons in the existing disposal authorization. Sales to government agencies amounted to 20,049 tons. The Commodity Exchange suspended trading in zinc effective December 4, 1970, as a result of lack of activity. When buying and selling interest is revived, trading will be reinstituted.

Prime western zinc price was reduced ½¢ in August and was quoted at 15¢/lb at year end. The London Metal Exchange price fluctuated throughout the year and was 13½¢/lb at year end. Foreign producers established a price of 13.93¢/lb on January 2, 1970, which continued throughout the year.

Electrical Energy

U. S. generation.—The reported power consumption for the United States reached 1,638,000,000 kilowatt hours (kWhr) in 1970. The nation's electric utilities produced 1,530,000,000 kWhr, up 6.1% over 1969. Private industrial, self-generated power totaled 108,000,000 kWhr in 1970 (70).

Production by electric utilities (71)
(Million-kWhr)

Type	1969	1970	% Increase
Coal fired plants	706.0	709.1	0.4
Gas fired plants	333.0	369.5	11.0
Oil fired plants	137.0	180.9	32.0
Nuclear plants	13.9	21.8	56.8
Total—Fuel burning	1,192.0	1,282.3	7.6
Hydroelectric	250.2	247.3	−1.1
Total	1,442.2	1,529.6	6.1

Installed capacity—electrical utilities, kW (71)

Type plant	1969	1970	% Increase
Steam—electric[a]	246,297,381	265,493,023	7.8
Hydroelectric	52,753,126	55,059,406	4.4
Internal combustion	4,205,114	4,320,661	2.6
Gas turbine	10,093,724	15,480,183	43.9
Total	313,349,345	340,353,273	8.6

[a] Includes nuclear capacity of 3,979,975 in 1969 and 6,493,206 in 1970.

Fuel consumed for power production (71).—

	1970 Preliminary	1969
Coal—millions of tons	322.36	310.64
Oil—millions of Bbl	332.10	251.03
Gas—billions of cu ft	3,894.0	3,487.6
Coal and equivalent of oil and gas millions of tons	583.14	524.48
lb/kWhr	0.909	0.880

Peak demands for electric utilities in the United States will rise to 1,056,000,000 kW by 1990 and annual energy consumption will exceed 5.8 trillion kWhr according to FPC forecasts. The forecast covers all 50 states and are higher than comparative estimates issued in 1964. The annual rate of growth is expected to vary from a low of 6.2% in the northeast region to a high of 8.4% in the south central region. Industrial use is the largest category, accounting for 41% of the total national requirement in 1965 and is expected to grow at an annual rate of 7%. The new forecast takes into account the expanding national income with greater purchasing power and includes greater allowances for growth in air conditioning and space heating requirements. The following table shows the forecasts (72):

Forecast of electric utility power requirements by categories of use 1965-1990 (million kWhr)

Category of use	Actual 1965	Estimated 1970	1980	1990
Farm	26,974	36,718	60,471	96,790
Irrigation and drainage pumping	10,917	14,946	22,762	34,779
Residential (non farm)	255,281	381,262	758,849	1,416,623
Commercial	190,916	279,149	578,378	1,141,697
Industrial	436,434	613,550	1,260,145	2,392,820
Street and highway lighting	9,159	12,841	23,355	40,388
Electrified transportation	4,885	5,418	6,995	8,435
Other uses	33,004	48,280	106,350	216,242
Losses and unaccounted for	92,009	135,155	268,995	504,406
Total	1,059,579	1,527,319	3,086,300	5,852,180

Tight fuel supplies are being strained by an environment-conscious public. Electric utilities are being strained to meet a demand growing by 12%/yr. Low sulfur oil consumption increased by 35.7% in the last year. The industry burned 7.8 million more tons of coal than was excavated in 1969, the difference made up from stockpiles. The coal industry is reluctant to put money into new mines which could be pre-empted by nuclear energy in a few years. New technological advances are needed to meet sulfur and thermal pollution regulations. Yet, research and development has a low priority in electrical utility budgeting, accounting for 0.226% of operating revenues in 1969 (73).

Gas turbines may be an answer to the power crisis. Chlorine, magnesium, and aluminum producers are considering ways to switch out of the public utility systems which lack reserve capacities (74). The Dow Chemical Company at Freeport, Texas, will have a portion of its power supplied by a 300,000 mW power plant to be built on adjacent property by Salt Grass Power, Inc. and will incorporate the world's largest and most efficient gas turbines (75). The new Westinghouse turbines are about 96 ft long and provides 43,000 kW plus feedwater heat for boilers. The unit incorporates gas and steam turbines. Using the exhaust gas heat to help make steam to drive the steam turbines increases the over-all efficiency of the turbine-generator from 25.5% to 79.3%. The installation costs roughly $95/kW. Allis-Chalmers has announced it is getting back into the gas and steam turbine business to compete with Westinghouse and General Electric. North American Turbine Corporation was organized in April 1970, to manufacture and market industrial gas turbines, and turbine powered generator, pump, and compressor packages for industrial applications in the 1100-3000 hp range (76).

Nuclear power.—Nuclear power generating capacity in 1970 increased to 6,493,206 kW (up from 3,979,975 in 1969) or 1.8% of the national electrical energy total (77). These facilities produced 21,800,000,000 kWhr of electricity in 1970. By 1980 nuclear generating capacity is expected to be 150,000 Mwe. or nearly 25% of the national total capacity (78).

The growth rate of the atomic power segment of the nuclear industry showed a sharp rebound in 1970 and all indicators point to a strong and viable future (78). Nuclear plant orders to date are as follows:

Year	Units ordered	Installed capacity Mwe.
1970	14	14,336
1969	7	7,225
1968	16	14,791
1967	31	25,941
1966	20	16,306
Thru 1965	27*	8,435
Total	115*	87,064

* Includes 7 small plants no longer in operation or used for experimental work.

1. Twelve of the 1970 ordered plants will be located adjacent to previously ordered plants.
2. Of the 108 plants in operation, under construction or planned, there are 67 plant sites in 28 states; 33 of the sites will involve multiple units.
3. Assume six years to build a nuclear plant (79).

The Atomic Industrial Forum cited rising fossil fuel costs as a prime reason for the good showing of nuclear power in 1970. The cost of a nuclear plant was about $40/kW more than fossil-fueled plant. However, the cost of low sulfur coal has increased from 28¢ to 45¢/million BTUs in recent years compared to a stable 20¢/million BTUs for uranium fuels. The industry still faces problems with radioactive and thermal discharges and protracted licensing proceedings. The first delay in start-up, due to contested license hearings which affected two plants, occurred in 1970 (79).

The AEC is carrying out over 50 separate projects in the field of environmental and health related research. They have also entered into 40 agreements with other agencies for related studies. A thermal effects facility is being built at the Savannah River plant. The AEC claims an unprecedented safety record that there has not been a single radiation injury to the general public or any plant employee. While biological risks and many other environmental factors may be largely unknown, useful information on radiation is growing daily.

There are 155,000 people in the U. S. who depend on atomic energy for their *livelihood*. Government facilities employ 100,000 and private industry employs about 55,000. Most of these people are engaged in the manufacture, design and engineering of nuclear facilities. Approximately 3,000 utility employees are assigned to the operation, maintenance, and technical support of power reactors.

Allied Chemical and Gulf Oil formed a partnership for the recovery of nuclear fuel. Allied-Gulf Nuclear Services purchased 1,500 acres of land at Barnwell, S.C., to build the recovery plant (80). This plant was licensed to recover "spent" nuclear fuel on December 18, 1970, and is the nation's third such plant.

A science team at Princeton University claims they will bridge the technical gap between today's fission and tomorrow's fusion reactors. Today's reactors are based on fission reaction whereby the nuclei of atoms are split. They consume fuel such as uranium U-235 and create unwanted radioactive by-products. Fusion reactors would use energy released when atomic nuclei (derived from a virtually limitless supply of deuterium) are joined together. The process leaves no radioactive residue, but would require heating the nuclei to millions of degrees. Within a year the researchers hope to have answers to the basic questions with fusion reactors producing electricity forecasted by 1980 (81).

Manuscript received May 24, 1971. This report was presented at the Industrial Electrolytic Division Luncheon at the Washington, D.C., Meeting of the Society, May 9-13, 1971.

Any discussion of this report will appear in a Discussion Section to be published in the June 1972 JOURNAL.
